Kinetic Characterization of 4-Hexylresorcinol as Tyrosinase Substrate. After confirmation that HR is an alternative substrate of tyrosinase, a kinetic characterization of the same was made, for which it was necessary to calculate the molar absorptivity coefficient of the *p*-quinone generated at the working pH and wavelength. The action of the enzyme on HR was measured at 490 nm, in the presence of catalytic concentrations of TBC and NADH as reductant. Low concentrations of HR were used, and the substrate was exhausted in relatively short times (Figure 8). TBC and NADH as reductant could be used in these assays due to the capacity of NADH to reduce the *o*-*tert*-butylquinone produced by the oxidation of TBC and its inability to reduce the *p*-quinone generated from the HR, at these concentrations. This made it possible to measure the absorbance of the *p*-quinone alone and to regenerate the catalytic *o*-diphenol necessary to generate the enzymatic form E_{ox} in the medium, which continued acting on HR until its exhaustion. Figure 9 proposes a kinetic scheme for this mechanism.

To use this methodology to calculate the molar absorptivity coefficient of the *p*-quinone generated, it is essential that the reductant (NADH) in the system does not become exhausted because, in this case, the product would cease to be generated before the substrate is exhausted. To confirm that the NADH added to the reaction medium was sufficient to keep the system working until the exhaustion of HR, the disappearance of the NADH was measured at 380 nm (Figure 10, inset). It can be seen how at 550 s (maximum recorded time) NADH was still

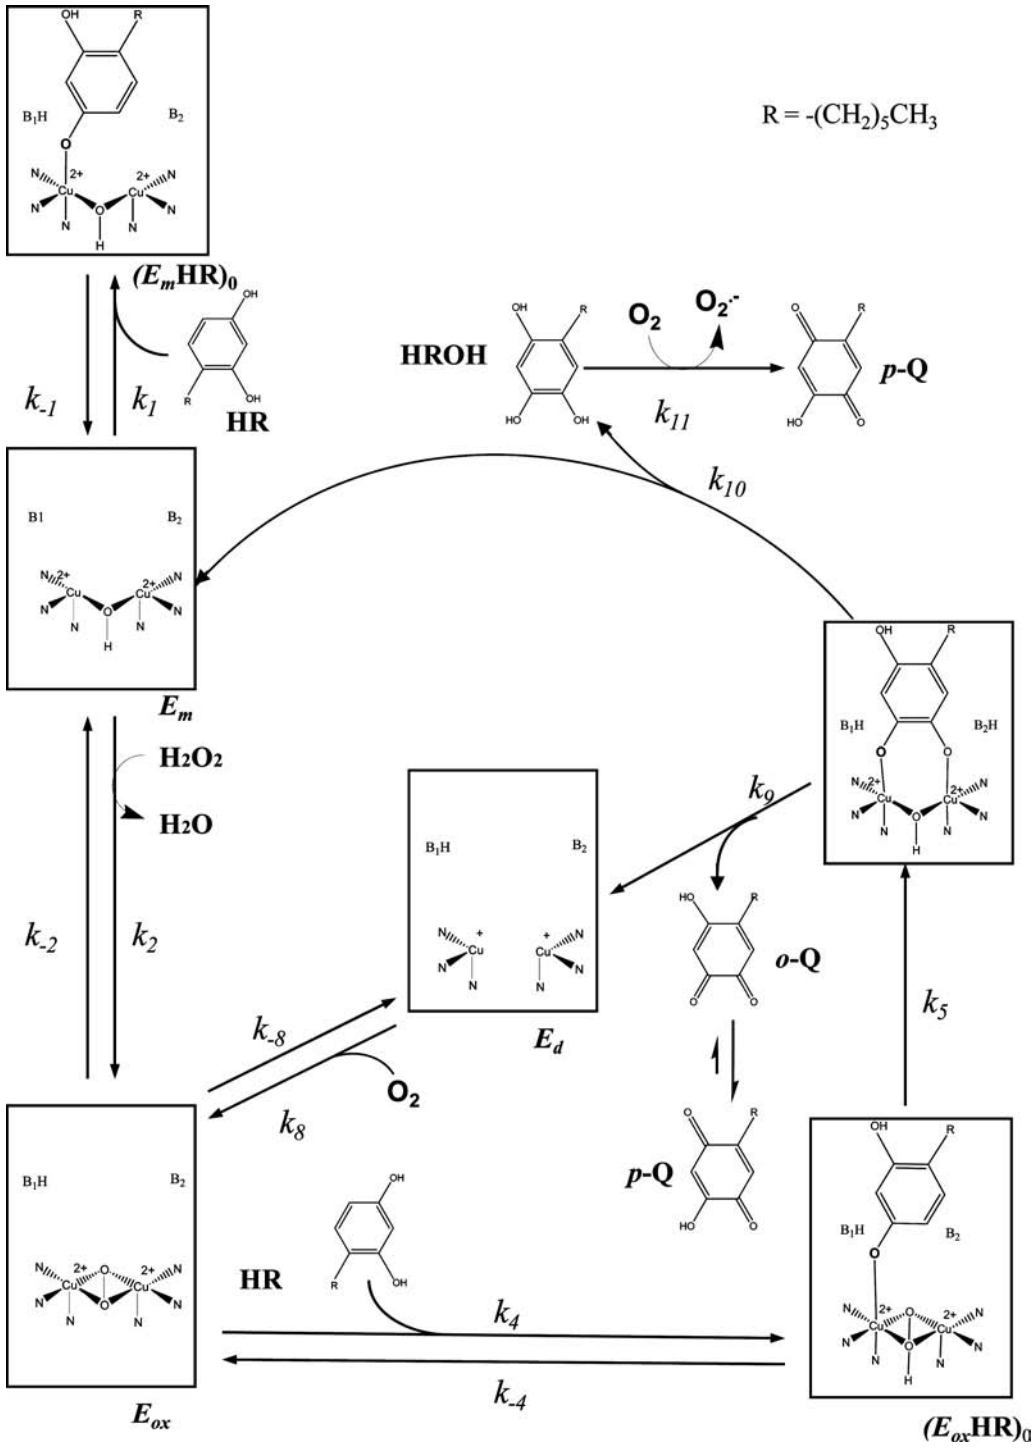

Figure 5. Structural mechanism of the action of tyrosinase on HR in the presence of hydrogen peroxide. E_m = met-tyrosinase, E_d = deoxy- tyrosinase, E_{ox} = oxy-tyrosinase, HR = 4-hexylresorcinol, E_mHR = met-tyrosinase/4-hexylresorcinol complex, E_{ox}HR = oxy-tyrosinase/4-hexylresorcinol complex, HROH = 5-hexylbenzene-1,2,4-triol, *o*-Q = *o*-quinone from 4-hexylresorcinol, and *p*-Q = *p*-quinone from 4-hexylresorcinol.

available in the medium, confirming that the HR was exhausted in these assays.

The experiment was repeated at several concentrations of HR (Figure 8), and the final absorbance values obtained were represented versus the concentration of substrate (Figure 10). The molar absorptivity coefficient was calculated by linear regression using the Sigma Plot 9.0 program for Windows.[50] The final value obtained was 2081 ± 37 M^{-1} cm^{-1}.

The next step was the kinetic characterization of HR by measuring the initial rate values ($V_0^{p\text{-}Q}$) at different substrate concentrations (Figure 11, inset). Hydrogen peroxide was chosen as cosubstrate to simplify the rate equation to eq 1 (equivalent to eq A12), working at saturating conditions of both H_2O_2 and oxygen (see the Appendix).[44−46] In this way, the action rate was expressed as a function of HR concentration (by measuring the formation of *p*-quinone).

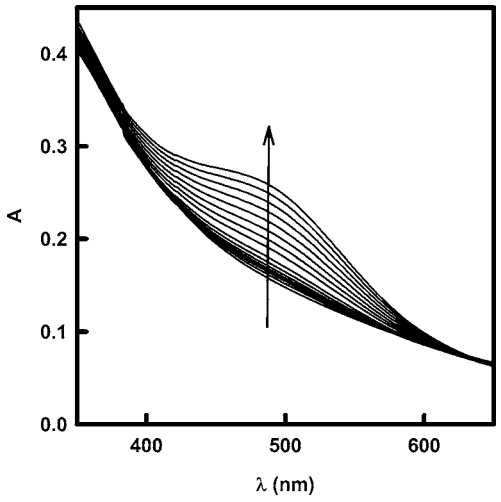

Figure 6. Scan spectra of the action of tyrosinase on HR in the presence of ascorbic acid. The experimental conditions were $[HR]_0$ = 100 μM, $[AH_2]_0$ = 200 μM, and $[E]_0$ = 415 nM. Recordings were made every 2 min.

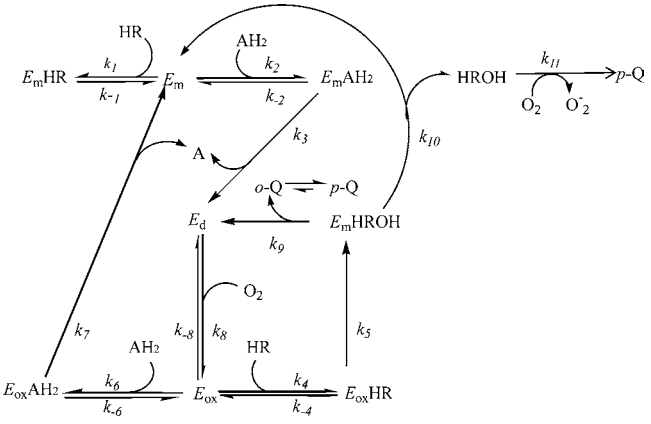

Figure 7. Kinetic mechanism of the action of tyrosinase on HR in the presence of ascorbic acid. E_m = met-tyrosinase, E_d = deoxy-tyrosinase, E_{ox} = oxy-tyrosinase, HR = 4-hexylresorcinol, HROH = 5-hexylbenzene-1,2,4-triol, *o*-Q = *o*-quinone from 4-hexylresorcinol, *p*-Q = *p*-quinone from 4-hexylresorcinol, AH_2 = ascorbic acid, and A = dehydroascorbic acid.

$$V_0^{p\text{-}Q} = \frac{V_{max}^{p\text{-}Q}[HR]_0}{K_M^{HR} + [HR]_0} \quad (1)$$

In these experimental conditions and in the measurement times used for determining the initial rate, the enzymatic activity was not affected. The values of $V_0^{p\text{-}Q}$ were represented versus $[HR]_0$ and fitted by nonlinear regression to eq 1 (equivalent to eq A12) using the Sigma Plot 9.0 program for Windows (Figure 11),[50] providing the values of K_M^{HR} and $V_{max}^{p\text{-}Q}$.

In view of the obtained results, it can be said that HR acts as a substrate of tyrosinase, alternative to L-dopa and L-tyrosine, with a low Michaelis constant and therefore high affinity (K_M^{HR} = 60.31 ± 6.73 μM) and a low catalytic constant (k_{cat}^{HR} = 0.85 ± 0.04 s^{-1}). Tyrosinase hydroxylates the HR and then oxidizes it to an *o*-quinone, which finally isomerizes to *p*-quinone (Figures 5, 7, and 9).[56−59]

Comparison of the Kinetic Constants Obtained for 4-Hexylresorcinol and Those Described for Classic Tyrosinase Substrates. When the catalytic (k_{cat}) and

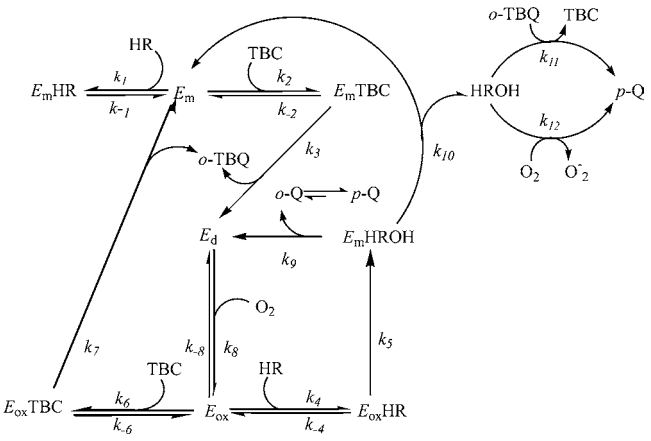

Figure 9. Kinetic mechanism of the action of tyrosinase on HR in the presence of TBC and NADH. E_m = met-tyrosinase, E_d = deoxy-tyrosinase, E_{ox} = oxy-tyrosinase, HR = 4-hexylresorcinol, HROH = 5-hexylbenzene-1,2,4-triol, *o*-Q = *o*-quinone from 4-hexylresorcinol, *p*-Q = *p*-quinone from 4-hexylresorcinol, TBC = 4-*tert*-butylcatechol, *o*-TBC = *o*-*tert*-butylquinone, NADH = reduced β-nicotinamide adenine dinucleotide, and NAD^+ = oxidized β-nicotinamide adenine dinucleotide.

Michaelis (K_M) constants obtained for HR are compared with those of monophenols, their low value is particularly notable (see Table 1).[51]

The dependence of chemical shift values (δ) in ^{13}C for a carbon atom on its electron density has been described.[60,61] The electron-donating capacity of the oxygen atom from phenolic compounds (nucleophilic power) is correlated with experimental δ values in ^{13}C for the carbon atom that supports the hydroxyl group.[51] With regard to k_{cat}, according to the chemical shift values shown in Table 2, the nucleophilic attack of the oxygen in the hydroxyl group in C-1 (Figure 1) on the copper atom in E_{ox} would be favored in the case of HR by the presence of an electron donor group (hexyl group) in the C-4 position (intermediate position in Table 2). Moreover, with

[a]This value corresponds to the ^{13}C NMR chemical shift of the carbon atom in position 6, the equivalent position 2 in monophenols.

regard to the electrophilic attack, it must be noted that HR displays low values of δ_2 and δ_6 compared with those of the monophenols from Tables 1 and 2 and, therefore, we expected that this compound should behave as a moderate substrate, but it is really a weak substrate. This is due to the fact that the monophenols could be attacked in the C-2 and C-6 positions (double possibility of attack), whereas HR could be attacked only in the C-6 position because of the steric interference of the hydroxyl group in the C-3 position. Furthermore, the intermediate generated during the action of E_{ox} on HR, E_mHROH, has axial and equatorial bonds between the *o*-diphenol and copper atoms of the active site. Because the orbitals are not coplanar, the concerted oxidation−reduction reaction cannot occur. Instead, a bond, probably that of C-1, is broken to achieve coplanarity, producing a more labile intermediate that will then release the *o*-diphenol to the medium or reunite it diaxially, involving oxidation to *o*-quinone.[32] We suggest that this step also suffers certain steric hindrance due to the effective size of the substituent determined by the C−C bond rotation of the hexyl group, indirectly affecting the catalysis.

With regard to the K_M values, it should be emphasized that the presence of a large hydrophobic group, such as hexyl, contributes to the value being the lowest of those described in Table 1. This agrees with the increased inhibition provoked by a homologous series of alkylbenzaldehyde inhibitors, in which the substituent hydrophobic radical group varies.[62]

From these values of k_{cat} and K_M it is deduced that the catalytic efficiency of tyrosinase acting on HR is low but of the same order of magnitude as those of other physiological substrates of the enzyme (Table 1).[51]

In conclusion, HR has been characterized as a substrate of tyrosinase. The long hydrophobic chain in the C-4 position increases the affinity of the enzyme (small K_M). In turn, this

long chain and the fact that its rotation around C-4 produces unfavorable interactions in the enzymatic pocket would be a reasonable cause of the obtained low catalytic constant. Whatever the case, the most important thing is that this compound, which is used as an antibrowning and depigmenting agent, may produce *p*-quinones, which may react with nucleophilic reagents such as cysteine and glutathione, diminishing the antioxidant capacity of the cell in which tyrosinase acts.[63−65]

APPENDIX

Applying the steady-state approximation to the mechanism shown in Figure 5 provides the following expression for the *p*-quinone (*p*-Q) formation rate:[47−49]

$$V_0^{p\text{-Q}} = (\alpha_1[H_2O_2]_0[O_2]_0[HR]_0[E]_0) / (\beta_1[O_2]_0 + \beta_2[H_2O_2]_0 + \beta_3[O_2]_0[HR]_0 + \beta_4[H_2O_2]_0[HR]_0 + \beta_5[H_2O_2]_0[O_2]_0 + \beta_6[O_2]_0[HR]_0^2 + \beta_7[H_2O_2]_0[O_2]_0[HR]_0) \quad (A1)$$

Expressions of α_1 and $\beta_1-\beta_7$ are given by eqs A2−A9:

$$\alpha_1 = K_1k_2k_4k_5k_8(k_9 + k_{10}) \quad (A2)$$

$$\beta_1 = K_1k_{-2}k_8(k_{-4} + k_5)(k_9 + k_{10}) \quad (A3)$$

$$\beta_2 = K_1k_2k_{-8}(k_{-4} + k_5)(k_9 + k_{10}) \quad (A4)$$

$$\beta_3 = k_{-2}k_8(k_9 + k_{10})(k_{-4} + k_5) + K_1k_4k_5k_{10}k_8 \quad (A5)$$

$$\beta_4 = K_1k_2k_4k_5k_9k_8 \quad (A6)$$

$$\beta_5 = K_1k_2k_8(k_9 + k_{10})(k_{-4} + k_5) \quad (A7)$$

$$\beta_6 = k_4k_5k_{10}k_8 \quad (A8)$$

$$\beta_7 = K_1k_2k_4k_8(k_5 + k_9 + k_{10}) \quad (A9)$$

The oxygen concentration is saturating,[44,45] and so from eq A1 we obtain

$$V_0^{p\text{-Q}} = (\alpha_1[H_2O_2]_0[HR]_0[E]_0) / (\beta_1 + \beta_3[HR]_0 + \beta_5[H_2O_2]_0 + \beta_6[HR]_0^2 + \beta_7[H_2O_2]_0[HR]_0) \quad (A10)$$

With $[H_2O_2]_0 \to \infty$,[46] eq A10 gives

$$V_0^{p\text{-Q}} = \frac{\alpha_1[HR]_0[E]_0}{\beta_5 + \beta_7[HR]_0} \quad (A11)$$

Considering that the hydroxylation step is limiting, $k_5 \ll k_9, k_{10}$, we obtain

$$V_0^{p\text{-Q}} = \frac{k_5[HR]_0[E]_0}{\frac{k_5}{k_4} + [HR]_0} = \frac{k_{cat}^{HR}[HR]_0[E]_0}{K_M^{HR} + [HR]_0} = \frac{V_{max}^{p\text{-Q}}[HR]_0}{K_M^{HR} + [HR]_0} \quad (A12)$$

where

$$k_{cat}^{HR} = k_5 \quad (A13)$$

and

$$K_M^{HR} = \frac{k_5}{k_4} \quad (A14)$$

From the analysis of $V_0^{p\text{-Q}}$ versus $[HR]_0$ by nonlineal regression, we obtain the catalytic constant eq A13) and the Michaelis constant (eq A14).

authors found that Stev content was not affected by the presence or absence of nitrogen fertilizer,[17] and no effect of P and K on this SG was shown.[18] Similarly, rebaudioside A was not affected by supply of different concentrations of N, P, and K.[19,20] Thus, according to the importance of phytochemicals and antioxidant power for functional aspect of Stevia, the aim of this study was to evaluate the effects of N supply on SG content and total phenol and flavonoid compositions, as well as on total antioxidant capacity in Stevia leaves. At the same time, the effects of harvest time, as well as of N supply × harvest time interaction, were also investigated, with the aim to define the best conditions to maximize the levels of beneficial bioactive compounds in Stevia leaves.

MATERIALS AND METHODS

Chemicals. Ethanol, methanol, and ferrous sulfate were purchased from Carlo Erba SpA (Milan, Italy). Water and acetonitrile were obtained from J. T. Baker (Phillipsburg, NJ, USA). Pure Stev (99.9% purity) and pure RebA (97.4% purity) were purchased from Extrasynthese (Genay, France). 2,2-Diphenyl-1-picrylhydrazyl (DPPH), gallic acid monohydrate (3,4,5-trihydroxybenzoic acid), 2,4,6-tri(2-pyridyl)-s-triazine (TPTZ), Trizma acetate, Folin−Ciocalteu reagent, sodium carbonate, and ferric chloride were obtained from Sigma-Aldrich Chemical Co. (Milan, Italy). The standards luteolin-7-*O*-glucoside, rutin, myricetin, apigenin-7-*O*-glucoside, quercitrin, and kaempferol were purchased from Extrasynthèse (Genay, France). All reagents and solvents used were of analytical or high-performance liquid chromatography (HPLC) grade. All solvents and water were accurately degassed before being used in the analyses.

Plant Material and Experimental Conditions. A pot trial was carried out at the Experimental Centre of the Department of Agriculture, Food and Environment (DAFE) of the University of Pisa, located in San Piero a Grado, Pisa, Italy (43°40′ N; 10°19′ E, 5 m above sea level), during the 2010 growing season. A selected clone (RG) of *S. rebaudiana*, belonging to the DAFE germplasm collection, was used. The plants were obtained by stem cuttings taken from 3-year-old parental plants grown in the open field at the DAFE experimental center. The stem cuttings, 4−5 cm long, were placed into 20 L pots to allow the maximum development of the roots, which were then filled with sandy-loam and low-fertility soil (68.5% sand; 25.9% silt; 5.6% clay; pH 7.74; organic matter = 0.83%; total N = 0.32 g kg^{-1}; available P = 11.49 mg kg^{-1}; exchangeable K = 44.84 g kg^{-1}; 1.65 g cm^{-3} bulk density). The trial was conducted in open air from May to September. The area has a Mediterranean climate, with rainfall mainly concentrated in the autumn and spring (mean = 948 mm $year^{-1}$). Mean maximum and minimum temperatures in the growing season were 26.9 and 13.1 °C, respectively.

Stevia plants were grown under different rates of nitrogen: N0 (without N fertilization); N50 (50 kg N ha^{-1} equal to 0.4 g N per pot as ammonium nitrate); N150 (150 kg N ha^{-1}, equal to 1.2 g N per pot as ammonium nitrate), N300 (300 kg N ha^{-1}, equal to 2.4 g N per pot as ammonium nitrate), and Norg (150 kg N ha^{-1}, equal to 1.2 g N per pot as organic nitrogen from Nutex N7 based on wool wastes, poultry manure, blood, and pomace with 7% organic N and 35% organic carbon).

The pots were arranged in a randomized block design with five replications (one pot per replicate) for each treatment. Starting from the middle part of May, during the vegetative growth, the nitrogen was split in four applications every 30 days. In addition, a mix of macro (Mg) and microelements (Bo, Cu, Fe, Mn, Mo, Zn) was supplied, at the dose of 0.1 g L^{-1} per pot. A constant source of phosphorus and potassium was distributed to all treatments at the rate of 100 kg ha^{-1} of P and K, respectively (equal to 0.80 g P per pot as triple superphosphate and 0.80 g K per pot as potassium sulfate), before the plants were transplanted. Water (20 m^3 ha^{-1}) was supplied to all pots to facilitate transplanting recovery. During the trial, the plants were maintained under optimal water supply through a drip irrigation system to maintain soil moisture to 75−80% of field capacity. No pests and diseases were observed during the trial.

Crop Sampling. Three different samplings of the leaves were carried out to evaluate the dynamics of accumulation of bioactive compounds in Stevia leaves. Leaf samplings were accomplished at the beginning and end of July, during vegetative growth (H1 = July 9, H2 = July 21) and at the beginning of September, when the plants started flowering (H3 = September 10). After each sampling, the leaves were air-dried in a ventilated oven at 40 °C until constant weight (8% residual water content) and ground to a fine powder using a laboratory mill. Samples were used to determine SG content, total phenols, flavonoid composition, and antioxidant capacity.

Preparation of Extracts. Samples (0.5 g of powder) were randomly chosen from each plant treatment and placed in 250 mL Erlenmeyer flasks. Extracts were sonicated for 30 min at 60 °C with 50 mL of 70% (v/v) ethanol. Before analysis, extracts were passed through a 0.45 μm nylon filter attached to a syringe to remove any suspended material.

Steviol Glycoside Content. The procedure was performed following the method described by Hearn and Subedi[21] and Kolb et al.[22] Briefly, 20 μL of filtered extract was injected into a HPLC system (Jasco PU980) coupled with a UV−visible wavelength detector. A LiChrospher NH2 column, 5 μm, 250 mm × 4.6 mm (Alltech Italia), in conjunction with a LiChrospher Amino All-Guard and All-Guard Cartridge Holder (Alltech Italia) was used. The following HPLC operating conditions were used: an isocratic mobile phase, acetonitrile/water (80:20), pH 5 adjusted with acetic acid, a flow rate of 1.0 mL/min, and a run time of 20 min. Detection was at 210 nm at ambient temperature. Chromatograms were acquired online, and data were collected via a Jasco interface (Hercules 2000 interface chromatography). The identity of SG was confirmed by chromatography on HPLC with authentic standards, and quantification was performed using a standard curve in the range of 0.25−1 g/L of standard mixtures containing Stev and RebA.

Total Phenolic Content. Determination of total phenolic compounds was performed on ethanolic extracts by the Folin−Ciocalteu method according to the procedure of Dewanto et al.[23] This procedure involves the reduction of Folin−Ciocalteu reagent by phenolic compounds, with concomitant formation of a blue complex determined at 765 nm by UV−visible spectrophotometer (Varian Cary 1E, Palo Alto, CA, USA). Calculations were performed using a calibration curve prepared with gallic acid as standard, and results were expressed as milligrams of gallic acid equivalents (GAE) per gram of dry weight (DW).

Ferric-Reducing Antioxidant Power (FRAP) Assay. The FRAP method, based on the reduction of the ferric tripyridyltriazine complex (Fe^{3+}−TPTZ) by antioxidants, was carried out according to Benzie and Strain[24] with slight modifications. Briefly, 2 mL of freshly prepared FRAP reagent, containing 300 mM acetate buffer (pH 3.6), 10 mM TPTZ solution (in 40 mM HCl), and 20 mM ferric chloride in a 10:1:1 (v/v/v) ratio, was added to a known aliquot of Stevia leaf ethanolic extract. After incubation at 37 °C for 10 min, absorbance at 593 nm was recorded. Ferrous sulfate was used as a standard (0−1500 μM). Total antioxidant capacity was expressed as micromoles of Fe^{2+} per gram of DW.

DPPH Radical-Scavenging Assay. The free radical-scavenging activity of Stevia leaf extracts was evaluated by the DPPH free radical method according to Tadhani et al.[25] Briefly, 200 μL of ethanolic extract was placed in a test tube, and the volume was made up to 1 mL with methanol. Then 3 mL of freshly prepared DPPH solution (200 μmol L^{-1} in methanol) was added, and the tube contents were mixed vigorously. The tube was subsequently kept in a water bath at 37 °C for 20 min, after which the absorbance of the sample was measured at 517 nm using a UV−visible spectrophotometer (Varian Cary 1E). The decrease in absorbance at 517 nm was measured against a blank of pure methanol to estimate the radical-scavenging capacity of the samples. Radical-scavenging activity was calculated as the inhibition of the free radical by the sample using the formula

$$\%\ \text{inhibition}\ (\%\text{I}) = [(A_0 - A_t)/A_0] \times 100$$

where A_0 is the absorbance of the control DPPH solution at 0 min and A_t is the absorbance in the presence of the extract after t = 20 min. The extract concentration providing 50% of radical-scavenging activity

[a]N0, without N fertilization; N50, 50 kg N ha^{-1}; N150, 150 kg N ha^{-1}; N300, 300 kg N ha^{-1}; Norg, 150 kg N ha^{-1} as organic nitrogen. [b]H1, July 9; H2, July 21; H3, September 10. [c]Results are the means ± SD of five replicates that were each analyzed in triplicate. A two-way ANOVA was used to evaluate the effect of nitrogen fertilization (N), harvest time (H), and the interaction between nitrogen and harvest time (N × H). Significance was as follows: ***, significant at $P < 0.001$ level. Upper-case letters indicate effect of nitrogen rate (N) and harvest time (H); lower case letters indicate N × H interaction.

(IC_{50}) was calculated from the graph of inhibition percentage against extract concentration. The results were also expressed as ascorbic acid equivalent.

Flavonoid Determination. Qualitative and quantitative analyses were performed by RP-HPLC. Twenty microliters of extract was injected into a Waters model 515 HPLC system (Waters, Milford, MA, USA) fitted with a 4.6 mm × 250 mm Prodigy ODS column (Phenomenex, Bologna, Italy). Detection was carried out at 360 nm, using a Waters 2487 dual λ UV−visible detector. Mobile phase A contained water acidified with formic acid (pH 2.7), and mobile phase B contained methanol. A linear gradient of 10−90% mobile phase B was run for 26 min at 1 mL/min. The identity of the free flavonoids was confirmed by cochromatography with authentic standards. Quantification was performed using standard curves in the range of 10−500 ng of a standard mixture containing luteolin-7-*O*-glucoside, rutin, myricetin, apigenin-7-*O*-glucoside, quercitrin, quercetin, luteolin, and kaempferol. Chromatogram analysis was performed by the software Millennium 32 (Waters).

Statistical Analysis. All data were subjected to analysis of variance (ANOVA) using CoStat version 6.2 (CoHort Software, Monterey, CA, USA). Two-way completely randomized ANOVA was carried out to estimate the variance components of N supply (N), harvest time (H), and their interaction (N × H). Means were separated on the basis of least significant difference (LSD) only when the ANOVA *F* test showed significance at the 0.05 or 0.01 probability level. Finally, linear regression analyses using GraphPad PRISM version 4.0 (GraphPad Software, Inc., La Jolla, CA, USA) were performed to evaluate the relationships between antioxidant capacity, total phenols, total flavonoids, and SG. For inhibition percentage data, obtained by the DPPH assay, an arcsine transformation was applied before statistical analysis was performed.

RESULTS

Nitrogen fertilization (N), harvest time (H), and their mutual interaction (N × H) significantly affected the Stev and RebA contents, although the individual compounds showed different behaviors (Table 1). The results indicated that the Stev content in the leaf changed with the stage of plant development. Results showed that the Stev content was higher in the vegetative stage (H1) and decreased until the beginning of flowering time (H3). In fact, the maximum Stev content was reached in the leaves collected at the beginning of July (H1) during maximum vegetative development, and it decreased thereafter (Table 1). With regard to N, the maximum Stev content was observed in plants grown without N (N0), followed by Norg. Taking into consideration the N × H effect, the highest Stev contents were recorded in plants grown at N0 and Norg and harvested in H1.

In contrast to Stev, the RebA content increased significantly from the beginning to the end of July, reaching its highest value in the second harvest (Table 1). Considering mean values, the N rate also significantly affected RebA content, with the maximum values in leaves of Stevia plants grown with 150 and 300 kg N ha^{-1}. In contrast, considering the N × H interaction, at H2 the Norg-treated plants showed the lowest level of this compound, whereas no significant differences were observed among the mineral N doses (Table 1).

Due to the changes in the two main SG, the RebA/Stev ratio significantly varied depending on N rates, harvest time, and N × H interaction. The maximum ratio was recorded in plants harvested at H2 and H3 and in plants grown with 150 and 300 kg N ha^{-1}. In particular, the leaves of plants grown with 150 kg N ha^{-1} and harvested in H2 showed the highest ratio, whereas the lowest ratio was found in plants grown without N and harvested at H1.

Similarly to SG, total phenols and total flavonoids were significantly affected by N rate, harvest time, and N × H interaction (Figure 1). With regard to total phenols, the highest values were recovered at H1 in leaves of plants grown with 50 and 150 kg N ha^{-1} (105.50 and 110.41 mg g^{-1} DW, respectively). At the same harvest time, the N150-treated plants showed the highest level of total flavonoids (104.03 mg g^{-1} DW). As a general trend, by averaging over N treatments, both phenols and flavonoids were significantly higher in H1 (83.4 and 68.9 mg g^{-1} DW for phenols and flavonoids, respectively) than in H2 (60.8

J. Agric. Food Chem. 2015, 63, 7041−7050

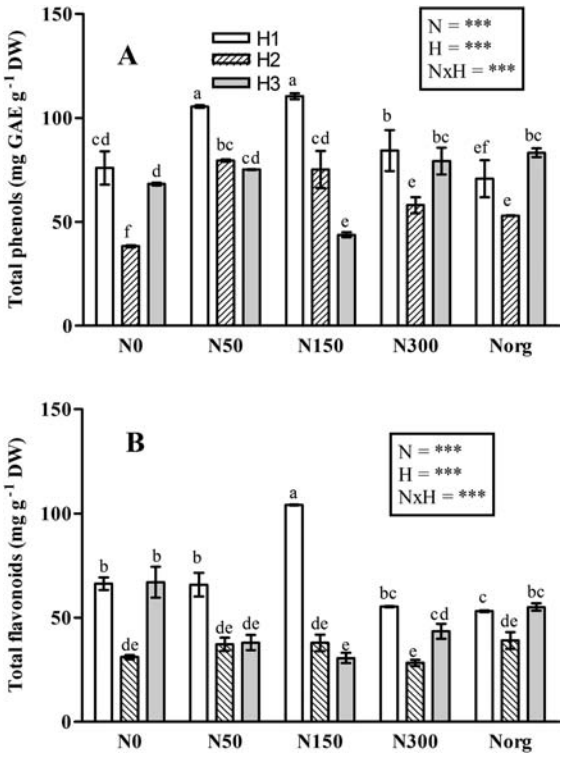

Figure 1. Effect of nitrogen rate and harvest time on total phenolic content (A) and total flavonoids (B) in leaves of *Stevia rebaudiana* plants. Data are means of five replicates ± SDs; bars represent standard deviation. Means with the same letters are not significantly different for $P = 0.05$ following two-way ANOVA test with nitrogen rate and harvest time as variability factors. Asterisks indicate significant differences according to two-way ANOVA test (***, significant at $P < 0.001$ probability level).

and 34.7 mg g^{-1} DW for phenols and flavonoids, respectively) and H3 (69.9 and 46.9 mg g^{-1} DW for phenols and flavonoids, respectively). With regard to the N effect, as an average over harvest times, the N50-treated plants showed the highest phenolic content (86.7 mg g^{-1} DW), followed by N150 and N300 treatments (76.5 and 73.9 mg g^{-1} DW, respectively). Otherwise, the N150-treated plants were characterized by the highest flavonoids (58.0 mg g^{-1} DW), followed by the N0-treated plants (54.5 mg g^{-1} DW).

Among the flavonoids, rutin, myricetin, apigenin-7-*O*-glucoside, quercitrin, kaempferol, and luteolin-7-*O*-glucoside have been identified (Table 2). All of the flavonoids were significantly affected by the N rate, harvest time, and N × H interaction with the exception of myricetin, for which H was not significant. Luteolin-7-*O*-glucoside was the main flavonoid in Stevia leaf extracts, ranging from 43 to 74% of the total flavonoids (Table 2), depending on nitrogen rate and harvest time. In particular, it was recovered at higher amounts in H1 compared to the other harvests, reaching the highest content in plants grown with 150 kg N ha^{-1} (74%). In contrast, in H2, luteolin-7-*O*-glucoside content was 2−4 times lower than the one recorded in H1. In H3, the amount of this compound increased in each N treatment in comparison with H2, with the exception of the N150 treatment, whereas under N0 and Norg treatments, it approached again values recorded in H1 (Table 2).

Among the identified flavonoids, kaempferol appeared to be present in minor amount, representing 0.1−2% of the total flavonoid pool (Table 2). Myricetin and quercitrin showed values around 2−3 mg g^{-1} DW, representing 3−9% of the total flavonoid amount. Rutin and apigenin-7-*O*-glucoside values were about 4−5 and 7−10 mg g^{-1} DW, respectively. Apigenin-7-*O*-glucoside showed a value 2-fold higher than rutin, representing 14% of the total flavonoid pool (Table 2). As observed for luteolin-7-*O*-glucoside, both rutin and apigenin-7-*O*-glucoside showed the highest value at H1 under N150 treatment, contributing to determine also the highest value of total flavonoid in these conditions (Figure 1; Table 2). In contrast to what was observed for luteolin-7-*O*-glucoside and apigenin-7-*O*-glucoside, rutin and quercitrin showed no increase from H2 to H3, and the lowest values were recorded in the last harvest.

To evaluate the total antioxidant capacity, both FRAP and DPPH assays have been performed (Figure 2). N, H, and the N × H interaction significantly affected also the antioxidant activity, measured with both FRAP and DPPH assays. According both methods, the higher antioxidant capacities, and consequently the higher presence of bioactive molecules, have been observed in H1 (589 mmol $FeSO_4$ g^{-1} DW and 83 mmol ASA g^{-1} DW, for FRAP and DPPH, respectively) and H3 (475 mmol $FeSO_4$ g^{-1} DW and 80 mmol ASA g^{-1} DW for FRAP and DPPH, respectively) in comparison with H2 (354 mmol $FeSO_4$ g^{-1} DW and 78 mmol ASA g^{-1} DW for FRAP and DPPH, respectively). The only exception to this trend was observed for Norg treatment, where the values recorded in H1 did not differ significantly from those obtained in H2, whereas at H3 they reached the highest values (Figure 2). With regard to the effect of N rate, the on-average highest values, measured by FRAP method, were recorded under N50 and Norg treatments (545 and 536 mmol $FeSO_4$ g^{-1} DW, respectively), whereas considering the N× H interaction, the highest FRAP values were recorded for N50- and N150-treated plants when harvested at H1 (Figure 2A).

DPPH radical scavenging has been used widely to test the antioxidant activities of plant extracts and foods. Figure 3 shows the IC_{50} value (the antioxidant concentration necessary to decrease the initial concentration of DPPH by 50%) calculated, for each N dose, by pooling data from the three harvest times, and for ascorbic acid, luteolin, and BHT, used as positive controls (Figure 3). In the DPPH assay, the lower is the IC_{50} value, the higher is its ability to scavenge radicals, particularly peroxy radicals, which are the propagators of the autoxidation of lipid molecules and thereby break the free radical chain reaction.[26] Our results showed that the Stevia leaf extracts were potent radical scavengers. In fact, notwithstanding their IC_{50} values were higher than those of ascorbic acid and luteolin, they were lower than that of BHT (Figure 3).

Significant high correlations between secondary metabolites of Stevia leaves and antioxidant capacities were found by both antioxidant measuring methods (Table 3). In particular, positive correlations were found among antioxidant activity and total phenols and flavonoids for N50, N150, and N300 treatments (Table 3). In addition, it was demonstrated that the antioxidant activity, measured by both assays, was negatively correlated with the amount of RebA for N0 treatment and positively correlated with the Stev content under N150 treatment. In the plants grown under Norg treatment, total flavonoid, Stev, and RebA contents did not correlate with the antioxidant activities. In addition, interesting positive statistic correlations have been found in N150-treated plants between Stev and total flavonoids, rutin, myricetin, apigenin-7-*O*-glucoside, quercitrin, and luteolin-7-*O*-glucoside (Table 4). In contrast, no significant correlation was observed in N150-treated plants either between RebA and total

[a]N0, without N fertilization; N50, 50 kg N ha^{-1}; N150, 150 kg N ha^{-1}; N300, 300 kg N ha^{-1}; Norg, 150 kg N ha^{-1} as organic nitrogen. [b]H1 = July 9; H2 = July 21; H3 = September 10. [c]Results are the means ± SD of five replicates that were each analyzed in triplicate. A two-way ANOVA was used to evaluate the effect of nitrogen fertilization (N), harvest time (H), and the interaction between nitrogen and harvest time (N × H). Significance was as follows: ***, significant at $P < 0.001$ level; **, significant at $P < 0.01$ level; *, significant at $P < 0.05$ level; ns, not significant. Upper case letters indicate effect of nitrogen rate (N) and harvest time (H); lower case letters indicate N × H interaction.

flavonoids or between RebA and individual flavonoids (Table 4). Moreover, RebA was negatively correlated at N0 and N50 with total flavonoid contents, apigenin-7-*O*-glucoside, and luteolin-7-*O*-glucoside (Table 4). Notably, the two latter N doses did not in general correlate with either total or individual flavonoids.

DISCUSSION

The achieved results showed that most of the phytochemical contents, as well as the antioxidant capacity, were significantly affected by N rate, harvest time, and the N × H interaction, emphasizing the importance of these preharvest factors in the biosynthesis of Stevia secondary metabolites and, consequently, in determining the Stevia leaf extract quality. Considering the mean N values, our findings point out that 150 kg N ha^{-1} appeared to be the optimal dose giving an improvement of the quality, because, for this N rate, the highest contents of RebA, RebA/Stev ratio, total phenol and flavonoid, apigenin-7-*O*-glucoside, luteolin-7-*O*-glucoside, and antioxidant activity have been recorded.

Our study demonstrates that, using an adequate N rate and choosing an appropriate harvest time, it is possible to increase significantly the content of RebA and, consequently the ratio between RebA/Stev, considered to be a good qualitative measure of sweetness.[27] The maximum Stev content was recorded in N deficiency conditions (N0), whereas, in the presence of higher N supply, Stev decreased and RebA significantly increased (N150 and N300). Because Stev is the substrate for the synthesis of RebA,[28] our findings indicated that N supply could modulate the composition of SG, promoting the transformation of Stev in RebA. At the same time, the harvest time was found to be an extremely important factor in affecting the SG content and, consequently, RebA/Stev ratio, that increased in the Stevia leaves from July to September.

These findings are extremely important because RebA represents the preferred SG for sweetening purposes. Due to

Data are means of three replicates ± SDs; bars represent standard deviation. Means with the same letters are not significantly different for $P = 0.05$ following one-way ANOVA test, with scavenger/leaf extract as variability factor.

the commercialization of RebA, intensive selection and cultivation practices have yielded cultivars with markedly altered SG compositions in their leaves.[29,30] One parameter to evaluate cultivars/genotypes for the commercial extraction of RebA is the ratio of its concentration against that of Stev within the leaves.[31] Some studies have been carried out to investigate this ratio as a function of different parameters, but no evidence is reported about the effect of N status on the RebA/Stev ratio. For example, it was reported that, within the same cultivar, this ratio appeared to be relatively stable during vegetative growth, but a 35% increase occurred in the lower leaves during reproductive development.[31] Similarly to the individual SG pools, this pattern was also influenced by photoperiod and genotype.[32,33] Consequently, our study gives new information for better understanding the complex interactions underlying the accumulation of SG within the Stevia leaves. The SG accumulation has emerged as a dynamic process, strongly influenced not only by the genetic variability[31] but also by the nutrient conditions and their temporal availability.

Similarly to that observed for SG, total phenols and flavonoids, as well as the antioxidant activity and flavonoid composition, changed markedly in response to different N rates. Such variability may be due to the regulation of individual enzymes involved in the biosynthesis of these compounds, such as phenylalanine ammonia-lyase (PAL, EC 4.3.1.5).[34,35] Our findings showed an increase in total phenols and flavonoids from N0 to N150 treatments. At high supply rates, N may inhibit the synthesis of phenols and flavonoids via enhancing the channeling of L-phenylalanine toward proteins.[36] Because polyphenols contribute mostly to the antioxidant activity of plant extract,[37] also the antioxidant activity of Stevia may be reduced at high N supply.

There are conflicting reports regarding the effects of N fertilization on the plant antioxidant concentrations and capacities[16] and, generally, it was found that high nitrogen supply has a negative effect on the biosynthesis of soluble phenolics, condensed tannins, and flavonoids in plant tissues.[38,39] The lack of plant nutrients may cause alterations in phenolic content and composition for several crops, although most studies conclude that its effect is difficult to prove.[40] Besides the effects of other potential covariables (e.g., weather conditions, UV radiation, pest incidence), the variable effect of nutrient shortage on phenolic content might also be due to the complexity of plant response to nutrient availability. According to the growth/differentiation balance theory, plants always optimize the resources available by exploiting them in growth or differentiation processes (primary or secondary metabolism), even taking into account the particular needs of each crop stage.

In the case of Stevia, our findings demonstrate that the bioactive compounds and their related antioxidant activity increased by optimizing the N supply and decreased with increasing or decreasing N rates compared to the optimal N dose (150 kg N ha^{-1}). The lower values recorded in Norg, compared with N150, could be related to the slow N release pattern of organic N sources, attributable to the dependence of organic manure on microbial decomposition and subsequent mineralization of N, a process largely affected by climate as well as by manure quality, such as the C:N ratio and polyphenolic content.[41−43]

With regard to flavonoid composition, the flavonoids detected in Stevia leaves, under the different N rates, belong to the subgroups of flavonols and flavones, as already observed in previous studies.[9,11,44] All flavonoids, except myricetin, have already been described.[9,11,44,45] Myricetin has a unique chemical structure and, recently, the health benefits of this flavonoid have been demonstrated; in particular, its therapeutic potential in diabetes mellitus has been investigated.[46] This finding adds to the Stevia extract's particular importance, confirming the beneficial role of Stevia and its metabolites on health-promoting properties. Particular attention should be paid to its insulinotropic activity, which could make Stevia's role most promising.[47]

[a]Significance was as follows: ***, significant at $P < 0.001$ level; **, significant at $P < 0.01$ level; *, significant at $P < 0.05$ level; ns, not significant. N0, without N fertilization; N50, 50 kg N ha^{-1}; N150, 150 kg N ha^{-1}; N300, 300 kg N ha^{-1}; Norg, 150 kg N ha^{-1} as organic nitrogen.

The most abundant flavonoid appears to be luteolin-7-*O*-glucoside, which was strongly affected by the harvest time, with a 2-fold higher value in the first sampling than in the other two harvests. Furthermore, the choice of the optimal harvest time can contribute to enhance the phytochemical quality of Stevia leaf extracts. The great differences in the bioactive compounds and antioxidant activity of Stevia leaves harvested at different times may be a consequence of some physiological changes. Samples collected at H1 (beginning of July) generally showed higher phenolic and flavonoid contents, antioxidant activity and Stev levels, compared to samples collected in H2 and, with the exception of a few cases, in H3. Environmental factors such as photoperiod, water availability, temperature, and pest and disease incidence, as well as physiological status of the plant, have a direct impact on biochemical pathways, thus affecting the metabolism of secondary products.[48] Our results point out that time of harvest, being related with the physiological stage of the plant, is an important factor in influencing the secondary metabolites of Stevia leaf extracts. Stevia is an obligate short-day plant with a critical day length of about 12−13 h.[32,33] Under long-day condition, the vegetative growth phase of short-day plants is retained for a long time by prohibiting precocious flowering. It was reported that the long-day conditions significantly increased leaf biomass and Stev content in Stevia leaves.[49] Similarly, it was reported that, in leaves of sweet potato plants, photoperiod regimes influenced the accumulation of phenolic acids, anthocyanins, and other flavonoids by increasing the total contents of these compounds under long-day conditions, suggesting a role for these compounds in protection against enhanced light exposure.[48]

Antioxidant capacity depends on the type of antioxidant that prevails in the extract and, thus, on the type of plant extract, which can be essentially distinguished on the basis of its hydrophobic/hydrophilic nature. At present, none of the antioxidant capacity assays truly reflect the "total antioxidant capacity", because this measure needs to reflect both lipophilic and hydrophilic capacity and to differentiate between hydrogen atom transfer (radical quenching) and electron transfer (radical reduction). Consequently, to comprehensively evaluate a sample's ROS scavenging capacity, more than one assay measuring individual ROS scavenging capacity is needed. For this reason, both FRAP and DPPH assays have been performed. The difference found here by applying the two assays on Stevia extracts (Figure 2) lies in the chemistry of the reaction involved, namely, the biomolecule acting as reductant (type and number of functional groups involved) as well as the detection radical and the solvent used.[50] However, with both FRAP and DPPH assays, the high correlations found between secondary metabolites of Stevia leaves and antioxidant capacities confirm that the high antioxidant capacity characterizing Stevia leaves is mainly attributable to the presence of both phenolic compounds, such as flavonoids, and SG. In particular, the high and positive correlations found between Stev and FRAP and between Stev and DPPH in the N150-treated plants (Table 3) confirm that SG are potent ROS scavengers and that Stev is a stronger scavenger than RebA for superoxide radicals, as reported by Geuns et al.[51]

Interestingly, in leaves of plants grown under N150 treatment, Stev positively correlated with both the content of total and individual flavonoids, with the exception of kaempferol (Table 4). In contrast, for the N150 dose, RebA did not significantly correlate with either total or individual flavonoids, whereas significant and negative correlations have been found between this compound and total flavonoid content and luteolin-7-*O*-glucoside and apigenin-7-*O*-glucoside, in N0- and N50-treated plants (Table 4).

Further investigations are needed to elucidate a possible interrelationship of flavonoids with the metabolic pathway of Stev synthesis. In fact, key functions of flavonoids as developmental regulators—signaling molecules in plants and humans have been reported.[52] This could shed light on a possible

additional role of flavonoids, besides those well-known of being potent antioxidants.

All together, the results obtained in this study provide useful information on Stevia response to different N regimes and harvest date, emphasizing the possibility to increase, from a phytochemical point of view, Stevia quality. Moreover, this work succeeded in improving the knowledge about the changing SG, flavonoid composition, and antioxidant capacity of Stevia in response to different N rates and harvest dates. In fact, our results indicate that the manipulation of N fertilization might be an effective tool to increase the accumulation of bioactive compounds in Stevia. In fact, higher RebA/Stev ratio, total phenolic content, total flavonoids, luteolin-7-*O*-glucoside levels, and antioxidant capacity were observed in Stevia when nitrogen supply was equal to 150 kg ha^{-1}. Moreover, at the highest nitrogen treatment level, Stevia exhibited significantly lower bioactive compounds and antioxidant activity than under N150 treatment. The lower phytochemical content and antioxidant capacity observed in Norg-treated plants in comparison with N150-treated plants may be attributable to a distinct temporal N availability that characterized organic and inorganic N sources. In addition to nitrogen fertilization, harvest time or more precise plant developmental stage was also found to have a significant influence on bioactive compounds and antioxidant activity in Stevia.

mashing and brewing quality.[35,36] In finger millet [*Eleucine coracana* (L.) Gaertn.], Siwela et al. (2010)[37] found that phenolics are positively correlated with diastatic power and amylase, whereas Chethan et al. (2008)[38] reported an opposing result that phenolic compounds are detrimental to malt quality due to their inhibitory effect on malt amylase. However, there has been no report on the relationships between phenolics and these parameters in barley malt.

The genetic control of polyphenol has been intensively investigated in pear,[39] cider apple,[40] tomato,[41] sorghum,[42] rice,[43] and barley.[44] Most studies were limited to determining the total polyphenol content and did not consider individual phenolic compounds. Phenolic acids represent only a small portion of total polyphenols. Thus, any identified quantitative trait loci (QTLs) associated with total polyphenol could not be linked to an individual phenolic acid, which may potentially be the key ingredient for the brewing industry and functional foods. Modification of the biosynthesis pathway and breeding barley for high accumulation of economically important phenolic acids will only be possible after the identification of QTLs or genes for individual phenolic acids and by understanding the links between phenolic acids and malt quality.

Accordingly, the aims of this study were (1) to determine the relationship between barley grain and corresponding malt in their content of individual phenolic acids in 68 barley genotypes, (2) to investigate the potential relationship between individual phenolic acids and malt quality, and (3) to identify QTLs associated with content of the key phenolic acids in barley grain and malt.

MATERIALS AND METHODS

Plant Materials. Sixty-eight barley genotypes (Supplementary Table 1, Supporting Information) were planted in the field of the experimental farm at Zhejiang University, Huajiachi campus, Hangzhou, China (Hangzhou, 120.2°E, 30.5°N). All of these genotypes are hulled barley with only one genotype, Xindengmenggumai, being a hulless barley. Each genotype was sown in a 2 m row with 0.25 m between rows with three replications. Field management, including fertilization, weed, and disease control, were the same as that applied locally. At maturity, barley grains were harvested and stored in a cool room at 4 °C.[45,46]

Grain samples (150 g) were micromalted in a Phoenix System Micromalting Apparatus (John & White, Adelaide, Australia) according to the method described by Dai et al. (2007)[45] and Dvořáková et al. (2008b)[28] with some modifications. The procedure for the malting process was as follows: (1, steeping stage) 5 h of wet stage at 17 °C, 8 h of air-rest stage at 17 °C, 8 h of wet stage at 16 °C, 12 h of air-rest stage at 16 °C, 4 h of wet stage at 15 °C, 5 h of air-rest stage at 15 °C, and 2 h of wet stage at 15 °C; (2, germination stage) 48 h of germination at 16 °C and 48 h of germination at 15 °C; (3, Kilning stage) 2 h at 50 °C, 4 h at 55 °C, 6 h at 60 °C, 4 h at 65 °C, 1 h at 70 °C, 1 h at 75 °C, 1 h at 80 °C, and 2 h at 82 °C. The malt was stored at 4 °C for further analysis. The barley grains and malt were finely ground and fitted with a 0.5 mm screen.

Extraction of Phenolic Acids. The procedure for extraction of phenolic acids was based on that described by Zhao et al. (2006)[47] with some modification. Two hundred milligrams of ground sample was sonicated (40 kHz, 120 W) for 40 min with 4 mL of 80% methanol (v/v) at 70 °C. After centrifugation (5,000 *g* for 15 min), the supernatant was collected and freeze-dried in a vacuum freezing dryer. The residue was redissolved in 250 μL of 70% methanol (v/v) and filtered through a 0.45 μm membrane. The filtrate was transferred to 2 mL autosampler vials (Agilent, Santa Clara, USA) equipped with 200 μL glass inserts.

Determination of Phenolic Acids by High-Performance Liquid Chromatography. Measurement of phenolic acid content was carried out by high-performance liquid chromatography (HPLC) analysis with an Agilent 1260 Liquid Chromatograph (Agilent, Santa Clara, USA). Separation was performed with a Diamonsil 5u C18 (250 × 4.6 mm) column (Dikma, China) at 40 °C. Elution was performed using a gradient procedure with a mobile phase containing Solvent A (0.1% formic acid in water) and Solvent B (methanol) through the following steps: 0 min, 30% B; 10 min, 45% B; 20 min, 50% B; 25 min, 80% B; 32 min, 30% B; 37 min, 30% B. The total run time was 37 min at a solvent flow rate of 0.8 mL min^{-1} and with a 15 μL injection volume. The content of the individual phenolic compound in the extracts was calculated using a standard curve.

Association Mapping of Individual Phenolic Acids. Association analysis between 758 DArT markers and phenolic acids was performed using TASSEL v3.0 (http://www.maizegenetics.net). Three different models were employed in the association analysis according to a previous study with some modifications.[48−50] The structure matrix and kinship were included as a covariate to correct the population structure in the model $y = X\beta + Q\nu + Z\mu + e$, where X is the DArT marker matrix, Q is the structure matrix, Z is the kinship matrix, β and ν are coefficient vectors for DArT marker and population structure, respectively, μ is a vector of random genetic effects [$\mu \sim N(0, 2K)$], and e is the random error vector. Other models including only the structure matrix or kinship were also applied in the association analysis. These models are as follows: $y = X\beta + Z\mu + e$, and $y = X\beta + Q\nu + e$. For the fitness and efficiency of different models to be evaluated, the quantile-quantile (Q-Q) plot was displayed using TASSEL v3.0. The Benjamini−Hochberg false discovery rate (BHFDR) of $P < 0.01$ was applied in association with a significance test.

Statistical Analysis. Person correlation index among grain and malt phenolic acids and between malt phenolic acids and malt quality parameters were calculated using SPSS 19.0 (SPSS Inc., Chicago, USA). One-way ANOVA with the Tukey method was employed in a significance test using SPSS 19.0.

RESULTS

Genotypic Diversity of Phenolic Acid Content in the Grain and Malt of Barley. Two types of phenolic acids, FA and *p*-CA, were identified in all of the genotypes (Supplementary Table 1, Supporting Information), except for *p*-CA in Xindengmenggumai, a hulless barley. The mean content of FA and *p*-CA in the grains were 2.15 μg g^{-1} (ranging from 1.13 to 4.04 μg g^{-1}) and 1.10 μg g^{-1} (ranging from 0.19 to 3.53 μg g^{-1}), respectively (Table 1, Figure 1). The mean content of *p*-CA in malt was 1.44 μg g^{-1}, ranging from 0.65 to 3.56 μg g^{-1}, which was similar to those in grains (Table 1, Figure 1). However, the average content of FA at 4.07 μg g^{-1} in malt was nearly double that in the grains, including the highest FA content at 11.27 μg g^{-1} found in the malt of genotype, Belae (Table 1, Figure 1). The coefficient of variation (CV) for FA and *p*-CA content was 0.48 and 0.33, respectively (Table 1).

Table 1. Descriptive Statistics of Phenolic Acids in Grain and Malt[a]

	p-CA in grain	FA in grain	*p*-CA in malt	FA in malt
min	0.19	1.13	0.65	1.64
median	0.97	1.94	1.36	3.99
max	3.53	4.04	3.56	11.27
mean	1.10	2.15	1.44	4.07
CV	0.48	0.33	0.40	0.40

[a] *p*-CA: *p*-coumaric acid. FA: ferulic acid. CV: coefficient of variation. The units for the phenolic acids are μg g^{-1}.

J. Agric. Food Chem. 2015, 63, 7051−7057

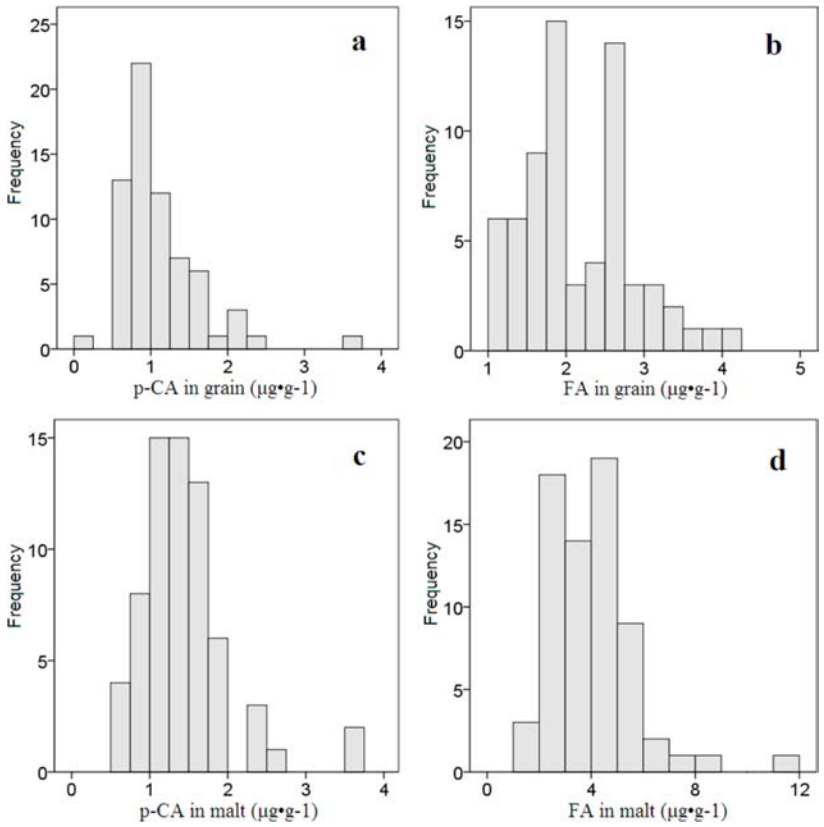

Figure 1. Distribution of phenolic acids in grain and malt among 68 genotypes for (a) *p*-CA in grain, (b) FA in grain, (c) *p*-CA in malt, and (d) FA in malt.

Correlation of FA and *p*-CA Content in Barley Grain and Malt. There were significant and positive correlations between FA and *p*-CA in grains (r = 0.758, P < 0.01, n = 67) and in malt (r = 0.745, P < 0.01, n = 68) (Table 2). However, no significant correlation of FA or *p*-CA was found between grain and malt of barley. For determining the effect of malting on phenolic acid content, the difference of phenolic acid content between grains and malt was evaluated by one way ANOVA analysis. After malting, *p*-CA increased significantly in 37 genotypes and was reduced in 14 genotypes (Figure 2; Supplementary Table 1, Supporting Information). Fifty-five genotypes exhibited a remarkable increase in FA content after malting, whereas the FA content of two genotypes was reduced (Figure 2; Supplementary Table 1, Supporting Information). The ratios of grains to malt ranged from 0.39 to 8.65 for *p*-CA among all genotypes and from 0.68 to 6.28 for FA (Figure 2; Supplementary Table 1, Supporting Information), indicating that the effect of malting on phenolic acid is highly genotype independent.

Table 2. Correlation Analysis of Phenolic Acids in Barley Grains and Malt

	p-CA in grain	FA in grain	*p*-CA in malt
FA in grain	0.758[a]		
p-CA in malt	0.092	−0.002	
FA in malt	0.044	0.043	0.745[a]

[a]Significant correlation at the P < 0.01 level.

Phenolic Acids Are Associated with Malt Quality. Correlation analysis was conducted between phenolic acids in malt and six malt quality parameters, including diastatic power, malt extract, Kolbach index, viscosity, and soluble and total N content.[51] The two phenolic acids were positively correlated with Kolbach index (r = 0.496 and r = 0.393 for *p*-CA and FA, respectively) and soluble N (r = 0.539 and r = 0.307, respectively). Negative correlations between *p*-CA and FA with malt extract (r = −0.283 and r = −0.271, respectively) and viscosity (r = −0.299 and r = −0.408, respectively) were also observed (Table 3).

Association Analysis of DArT Markers and Phenolic Acids in Grains and Malt. The content of phenolic acids in grains and malt and 758 DArT markers were used to perform association mapping. Q-Q plots showed that the k model has the best fit to the association analysis (Supplementary Figure 1, Supporting Information). A total of 13 markers were identified to be significantly associated with phenolic acids (Table 4). Twelve molecular markers were found in grain, but only one was identified in malt. Eight markers on Chromosomes 1H, 2H, 4H, and 7H were associated with *p*-CA in grain, and 4 markers on Chromosomes 3H and 7H were associated with FA in grain. Marker bpb-3484 on Chromosome 7H was found to be associated with both FA and *p*-CA in grain. Additionally, a marker on Chromosome 3H was associated with FA in malt. Each of these markers could account for 15.7−22.7% of the phenotypic variation. Moreover, the marker associated with FA in malt, bpb-9583, was located at 6.0 cM of 3H, independent of any locus linked to FA in grains (Table 4), suggesting a large impact of malting on the content of phenolic acids.

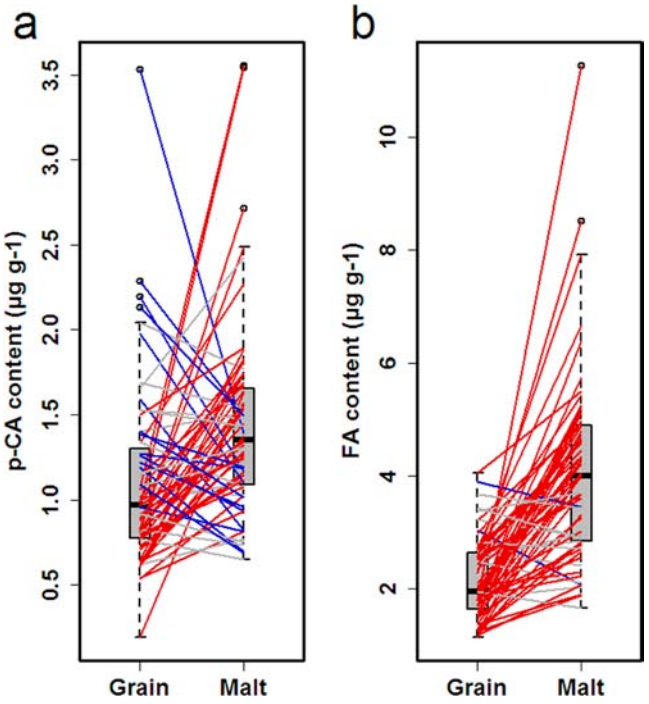

Figure 2. Changes of phenolic acids in grain and their corresponding malt for each genotype for (a) *p*-CA and (b) FA. The left and right point of each line (between two boxplots) represents the content of phenolic acid in grain and the corresponding malt, respectively. Red and blue lines represent a significant increase and decrease in the phenolic acid after the malting process, respectively. Gray lines represent no significant difference between the content of phenolic acid in grain and that in malt.

Table 3. Correlation Analysis of Malt Phenolic Acids and Malt Quality Parameters

	p-CA	FA
diastatic power	0.236	0.060
Kolbach index	0.496[b]	0.393[b]
malt extract	−0.283[a]	−0.271[a]
viscosity	−0.299[a]	−0.408[b]
soluble N	0.539[b]	0.307[a]
total N	0.230	0.097

[a]Significant correlation at $P < 0.05$ level. [b]Significant correlation at $P < 0.01$ level.

DISCUSSION

Barley and malt contain a large number of antioxidant compounds, such as phenolics, ascorbic acid, phytic acid, and melanoidins, which can impact beer stability.[52] Of these, polyphenol and melanoidins are the main sources of natural antioxidants, which originate from either raw barley or malting processes.[53] Malting processes, including steeping, germination, and kilning, have a huge effect on the fate of endogenous phenolic compounds.[25] It was found that malt always has a higher total polyphenol content as well as higher antioxidant activity than corresponding barley grains, suggesting that the malting process results in an increase in the antioxidant activity and total polyphenols.[24,25] However, controversial results were documented regarding the changes of individual phenolic compounds during the malting process.[26−28]

In this study, we determined the contents of two main phenolic acids, FA and *p*-CA, in 68 barley genotypes and corresponding malts to investigate the genotypic difference of the effect of the malting process on individual phenolic acids. Most of the genotypes exhibited a notable increase in the contents of FA and *p*-CA after malting. The increase may be attributed to the effect of the Maillard reaction during the early stage of the kilning process, which leads to enzymatic release of extractable bound phenolics in the matrix.[52,54−56] For example, ferulic acid esterase is released during the germination and early kilning steps of the malting process, thus facilitating the release of bound FA associated with lignin and arabinoxylans.[57,58] Similar results have been reported on the effect of the germination process on phenolic acid in rice.[59,60] Shibuya (1984)[59] reported that free phenolics increased in germinated brown rice due to dismantling of the cell wall. Tian et al. (2004)[60] found that bound phenolic compounds were released during the germination of rice due to carbohydrase enzymes hydrolyzing the endosperm.

However, a decrease in the content of malt phenolic acid was observed in a few genotypes (2 and 14 genotypes for FA and *p*-CA, respectively) in this study, as well as in some previous reports.[27,28] The reason for this decrease could be due to leaching of phenolic compounds into the steeping water[61] or due to formation of insoluble complexes with proteins.[62] High kilning temperature in the late stage of the kilning process may also lead to degradation of phenolic compounds.[56]

Phenolic acids exhibited a complex change during the malting process.[25] However, it remains unknown whether these compounds have an impact on barley malt qualities, such as diastatic power, malt extract, viscosity, Kolbach index, and soluble and total N. To our knowledge, this study is the first attempt to investigate the causal relationships between individual phenolic acids and these malt quality indicators. The current experiment employed 68 genotypes (Supplementary Table 1, Supporting Information) to ensure the representativeness and reliability of the results. The phenolic acids showed significant and positive correlations with soluble N and Kolbach index (Table 3). Obviously, the malt extract with high soluble N is rich in hydrolytic enzymes (i.e., esterase),

Table 4. DArT Markers with a Significant Marker-Trait Association[a]

trait	marker	chromosome	genetic position (cM)	*P* value	R^2 (marker)
p-CA in grain	bPb-4909	1H	72.9	0.0086	0.157
	bPb-0631	1H	128.5	0.0071	0.165
	bPb-1959	1H	133.1	0.0056	0.175
	bPb-6822	2H	114.4	0.0018	0.227
	bPb-8949	2H	122.3	0.0034	0.204
	bPb-1469	4H	14.6	0.0039	0.198
	bPb-0027	7H	111.7	0.0056	0.176
	bPb-3484	7H	133.4	0.0026	0.210
FA in grain	bPb-9746	3H	54.8	0.0074	0.163
	bPb-6347	3H	55.6	0.0053	0.197
	bPb-7156	7H	27.2	0.0083	0.158
	bPb-3484	7H	133.4	0.0061	0.172
FA in malt	bPb-9583	3H	6.0	0.0054	0.178

[a]These markers were identified using the *k* model. The significance test for association analysis is $P < 0.01$. R^2 (marker) denotes the contribution of the marker for phenotypic variation.

facilitating the release of phenolic acids.[57,58] These hydrolytic enzymes can modify the endosperm to liberate some of the bound phenolic compounds during germination.[63] Conversely, the phenolic acids were significantly and negatively correlated with malt extract and viscosity. It is well-known that phenolic acids are mainly located in the husk and aleurone layer.[13,14] Thus, we proposed that the genotypes with more husk and/or aleurone (in another words, fewer endosperm) might contain a higher content of phenolic acids, and fewer endosperm will obviously lead to a lower malt extract. An extreme example is that the *p*-CA content of a hulless genotype, Xindengmenggumai, was below the detection limit of HPLC analysis. This result was in agreement with the observation that hulled barley has a higher content of phenolic acid than dehulled barley.[17]

Identifying QTLs and genes controlling phenolic acids in barley grain and malt could improve the understanding of the molecular genetic basis of phenolic acid metabolism. The results of association mapping indicated that phenolic acids in barley grain are polygenic traits. Although QTLs associated with total polyphenol content have been identified in barley,[44] none of them are colocated with the QTLs detected in the present study. This could be due to the fact that QTLs of total polyphenol content are not likely to be responsible for the genetic variation in the individual phenolic acids. As phenolic acids only represent a small portion of total polyphenols, which also include flavonoids, tannins, and anthocyanins. Interestingly, *p*-CA associated marker bpb-8949 (122.3 cM, 2H) colocalized with the major QTL (119−125 cM, 2H) controlling polyphenol oxidase (PPO) activity.[44,64,65] PPO enzyme functions to catalyze the oxidation of phenolic substrates to quinines; therefore, its activity could influence the content of the phenolic compound.[66,67] This may explain the colocalization of QTLs for *p*-CA and PPO.

The barley genomic information facilitates the identification of probable candidate genes based on QTL results.[68] The sequences of DArT markers were obtained from the Web site of Diversity Array Technology Pty Ltd. (http://www.diversityarrays.com). These sequences were used to search the corresponding contigs in the IPK barley genome database, some of which contain genes with annotations (http://webblast.ipk-gatersleben.de/barley). Interestingly, the sequence of marker bpb-0027 was found to match contig_137941, which contains the cytochrome P450 (CYP73 encoding cinnamate 4-hydroxylase) gene. It has been well-established that cytochrome P450 catalyzes cinnamic acid to *p*-CA in the phenylpropanoid pathway, leading to the biosynthesis of lignin and numerous other phenolic compounds in plants.[69,70] Another search for the sequence of marker bpb-7156 was found to match contig_51262, which contains the oxidoreductase gene. Oxidoreductases, such as PPO and peroxidase (PDX), play vital roles in the regulation of the phenolic content of virgin olive oil.[71] These identified genes may participate in phenolic acid metabolism; however, the functions of these genes need to be studied thoroughly using transgenic approach in the future.

It is worth noting that marker bpb-3484 is associated with both FA and *p*-CA, indicating that the two phenolic acids could be tightly linked or even likely be controlled by the same group of genes. This hypothesis was partially supported by the highly positive correlations between the contents of the two phenolic acids. Conversely, the results provide some insights into understanding of the molecular mechanisms controlling the two traits. The lack of any common marker between grain and malt phenolic acids is consistent with the finding that there is no correlation between grain and malt for this trait. Moreover, our results may provide some preliminary genetic evidence for the significant effect of the malting process on phenolic acid metabolism.

creating affinity sites for divalent cations to "lock" the junctions. It is hypothesized that in this way the ability to dissipate energy will be affected. For that purpose gelatins are chemically modified on the available lysine residues using succinic anhydride with various degrees of substitution, converting positive charges into negative ones. Using calcium ions, the strands, bearing now a higher negative charge density, could become stabilized at their interstrand junction zones. The materials are chemically and physically characterized and tested for helix propensity and thermal behavior, and the impact of the modification on the mechanical behavior is studied using small and large deformation rheology.

MATERIALS AND METHODS

Gelatin Modification by Succinylation. Gelatin type A (PGS from pork skin, Bloom 150, and an average molecular weight of ∼124 kDa) was kindly provided from Rousselot (Gent, Belgium). The material was succinylated according to a protocol described elsewhere.[8] To this end, 1% w/v gelatin was dispersed in 0.02 M phosphate buffer (pH 8), stirred for 1 h at 60 °C, and cooled to 40 °C to dissolve all material. Succinic anhydride (239690-250G, Sigma-Aldrich) was gradually added in small aliquots (∼10 mg portions) to the gelatin solutions under continuous stirring at 40 °C up to fixed amounts between 5 and 35 mg/g of gelatin (see Table 1), to obtain batches with different degrees of modification. The pH was continuously adjusted to 8.0 using a pH-stat by titration with 1 M NaOH. After addition of the succinic anhydride, the solutions were stirred for another 30 min. The solutions were extensively dialyzed (Thermo Scientific 10 kDa cutoff, 22 mm diameter) against deionized water (at room temperature; pH 6.8) in four repetitions with equilibration times of 6 h each and subsequently lyophilized. A reference sample was subjected to the same procedure without addition of succinic anhydride.

Table 1. Characterization of Gelatin Materials Subjected to Different Degrees of Succinylation (DS), As Determined from the Chromogenic OPA Assay, and the Apparent Isoelectric Point, As Established from Zetasizer Measurements As Described under Materials and Methods[a]

material (code)	mg of succinic anhydride added per g of gelatin	DS (%)	apparent IEP
reference	0	0	7.5
A	5	12	4.9
B	10	26	4.7
C	20	43	4.5
D	30	65	4.5
E	35	82	4.4

[a]Estimated error in determination of DS as determined by the OPA assay is ±3%.

Chromogenic OPA Assay. To quantify the degree of succinylation (DS), the availability of lysine residues was determined using the specific reaction between *o*-phthaldialdehyde (OPA) and free primary amino groups in the proteins in the presence of 2-(dimethylamino)ethanethiol hydrochloride (DMA) as described previously.[9] The measured absorbance was corrected with that of a sample containing nonreacted reagent. A calibration curve was obtained by diluting the OPA reagent with a series of L-leucine (1 mM stock). All assays were done in triplicate. The DS is expressed as 100% minus the percentage of nonreacted primary amines relative to the reference material.

Apparent Isoelectric Point. To determine the apparent isoelectric point, freeze-dried gelatin (reference and modified) was dissolved in Milli-Q water at a concentration of 0.5% (w/v). Zeta potential (ζ) values were determined as a function of pH at 20 °C using a Zetasizer Nano ZS (Malvern Instruments, UK). Automatic titration was performed with 0.1 M HNO_3 and 0.1 M NaOH solutions under continuous stirring. The isoelectric point was evaluated as the pH at which the detected zeta potential value of the material (mV) was zero. For each sample five runs were performed. All experiments were performed at least in duplicate.

Calcium-Binding Measurements. A 0.1 M $CaCl_2$ stock solution was prepared by dissolving calcium chloride dihydrate (Sigma-Aldrich, Germany) in the appropriate acetate buffer (pH 6.5). The concentration of free Ca^{2+} ions was measured using a calcium ion selective electrode device (Ca ISE, connected to an Orion Star A214 ISE meter). The potentiometric readings (mV) of the electrode were calibrated using standard $CaCl_2$ solutions (0.5−30 mM) with the addition of ISA solution to match the ionic strength in all solutions. Gelatin samples (0.9% w/v; pH 6.5) were titrated with $CaCl_2$, and the corresponding amount of moles of calcium bound per mole of protein (assuming an average molecular weight of 124 kDa) was established using a Scatchard analysis (see elsewhere for details[10]). This higher protein concentration was chosen to increase the sensitivity in the experiment by providing a higher absolute number of calcium-binding sites, but to refrain from too viscous solutions. The contribution of the potassium acetate buffer with gelatin was neglected in the determination of calcium activity, and all samples were adjusted to a similar ionic strength as described previously.[11] All experiments were performed in triplicate at 20 °C.

Calorimetric Analysis. The enthalpic transition of succinylated solution samples 3% (w/v) in 20 mM acetate buffer (pH 6.5) in the absence or presence of calcium (0−20 mM) during heating−cooling ramps (60−5 °C and vice versa) was measured by differential scanning calorimetry (TA Instrument Q1000 Tzero DSC) under ambient conditions. Gelatin solutions (20 μL) were placed in aluminum pans and sealed followed by heating−cooling ramps The heat flow was recorded at 2 °C/min speed rate in duplicate for each modified and reference sample relative to a protein-free sample. Temperature and enthalpy transition values were obtained by integration of melting and cooling thermograms using Universal Analysis V1.7F software (TA Instruments).

Optical Rotation Measurements. The triple-helix propensity in gelatin in the absence or presence of calcium was monitored by optical rotation at 436 nm using a PerkinElmer 341 polarimeter equipped with a thermostated water bath (HAAKE Phoexix II C25P model). Solutions were prepared by pre-equilibration at 60 °C for 1 h and subsequent cooling from 50 to 5 °C at 0.5 °C/min. Samples (0.5% w/v; 20 mM acetate buffer, pH 6.5) were incubated in a cell with a path length of 10 mm. The specific rotation, $(\alpha)\lambda = \alpha/cl$, where α is the optical rotation angle in degrees at λ = 436 nm, c is gelatin concentration (g/mL), and l is the length of optical path (dm), was continuously measured. The helix content (h) at a given concentration is determined by means of eq 1.

$$h = ((\alpha)\lambda - (\alpha_{coil})\lambda)/((\alpha_{collagen})\lambda - (\alpha_{coil})\lambda) \quad (1)$$

Representative values for $(\alpha_{coil})\lambda$ and $(\alpha_{collagen})\lambda$ at 436 nm of −256° and −800° are used, respectively.[12]

Mechanical Deformation. The evolution of the storage and viscous moduli (G' and G'', respectively) is monitored during temperature ramps for (modified) gelatin solutions in 20 mM acetate buffer (pH 6.5) (3% w/v) in the presence of 0−20 mM calcium. Strain-controlled dynamic oscillatory measurements were carried out in an Anton Paar MCR 502 rheometer (Anton Paar, Graz, Austria) using a concentric cylinder geometry. A scan rate of 0.5 °C/min was used during cooling and heating ramps from 5 to 50 °C and vice versa.

For large deformation studies, preformed 3% w/v gelatin gels were used, prepared as described above, cooled to room temperature (20 ± 1 °C), and equilibrated for 24 h. Uniaxial compression to fracture experiments were performed using an Instron universal testing machine (model 5543, Instron International LDT, Edegem, Belgium) equipped with plate−plate geometry. A uniaxial (de)compression speed of 1 mm/s was used. Cylindrical gelatin gels were prepared in 50 mL (diameter = 21.7 mm) syringes prelubricated with paraffin oil and cut with a wire in self-supported specimens of 20 mm height. To

DOI: 10.1021/acs.jafc.5b01962
J. Agric. Food Chem. 2015, 63, 7058−7065

determine the fracture properties, the gels were compressed for 90% of the original height and the stress response was monitored as a function of applied strain.

Determination of the recoverable energy (RE) was established by applying a compression−decompression cycle to a strain of 20% at a deformation speed of 1 mm/s. The work necessary to compress the samples to this strain (W_c) was calculated from the area below the stress−strain curve. After reaching the maximal strain, the samples were decompressed immediately at the same speed and the work (W_s) released by the gel specimen was determined accordingly. The results were expressed as RE (%) = 100% × W_s/W_c. All gels were analyzed at least in triplicate.

In a similar setup as described above stress relaxation was evaluated for specimens prepared in the same way. The gels were compressed up to a set strain of 20% at a compression speed of 1 mm/s and held at the maximal loading strain for 5 min. During this time interval the stress was recorded with a step resolution of 60 ms. Every sample was analyzed at least in duplicate. Analysis of the time intervals was performed using a two-exponential decay nonlinear regression curve-fitting procedure (normalized stress = $A_1 \times \exp(-\tau_1/t) + A_2 \times \exp(-\tau_2/t) + A_0$), as described in detail elsewhere.[13] This provided two relaxation times, τ_1 and τ_2, with corresponding proportions A_1 and A_2. A_0 reflects in this analysis the stress contribution that does not dissipate in the experimental time regime of 5 min. Typically, in all cases R^2 values >0.995 were obtained. A higher order of exponents did not give fits with higher R^2 values. For this study, with an experimental time scale for the RE measurements of ∼8 s, only the fast-relaxing contribution is reported.

RESULTS AND DISCUSSION

Characterization of the Material. The conceptual idea behind this study is to enable a fortification of the strand−strand interaction points by affinity binding with calcium. For that purpose different degrees of succinylation of the protein were performed. Table 1 presents the different materials obtained when gelatin is subjected to different degrees of succinylation (DS) as described under Materials and Methods. The DS shows a linear relationship with the amount of succinic anhydride added, indicating that the number of lysine groups available for chemical modification is not limiting and/or hampered by steric or electrostatic constraints. It can also be observed that, where the reference material has an isoelectric point (IEP) of around 7.5, the lowest DS already yields an apparent IEP just below 5. The IEP gradually decreases further with increasing DS to 4.4 when ∼82% of all lysine residues are modified with negative succinate groups. From its amino acid composition this gelatin contains about 27 lysines per 1000 residues with an average molecular weight of 124 kDa, which implies that for the highest DS about 26 succinate groups have been introduced per molecule. All experiments described in this work have been carried out at a pH of 6.5, above the isoelectric point of all succinylated variants but below that of the reference material.

Figure 1 shows the triple-helix content as obtained from optical rotation measurements during a cooling ramp to 5 °C for aqueous solutions of reference and succinylated gelatins with different DS. It can be observed that even a high DS does not affect the onset temperature for helix formation. Moreover, a DS of 43% does not impair the extent of helix induction, whereas this is marginally affected at a DS of 65%. Only for a DS of 82% is a significant reduction of the helix content found of about 20−25%. Recent work showed that the ability of gelatin to form helices decreased when the availability of lysine decreased.[14] Prolonged incubation at low temperature did not

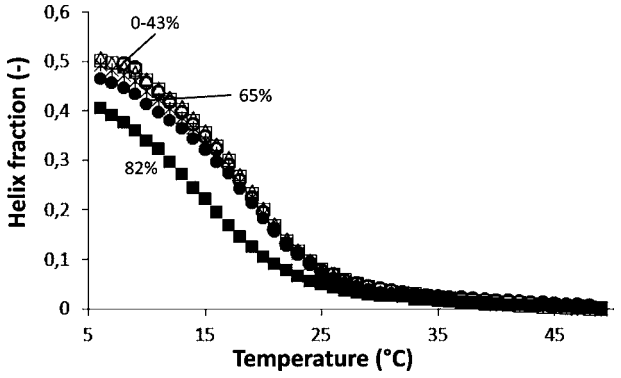

Figure 1. Helicity as established from optical rotation measurements as described in the text for aqueous solutions of reference and succinylated gelatin with different DS. The materials with a DS of 82 (solid squares) and 65% (solid circles) are indicated separately from the other DS and reference (open crosses, triangles, squares, and circles).

increase the helicity of this latter sample, illustrating that the observed reduction is not the result of a slower kinetic process.

Overall, it can be concluded that a series of succinylated gelatins can be prepared that, when studied above their isoelectric point, all exhibit the ability to adopt a triple-helical configuration essential for developing a spatial network.

Gelling Behavior in the Absence of Calcium. The gelling properties of the various materials have been studied using small deformation rheology at concentrations well above the critical gel concentration (3% w/v). The subsequent cooling and heating traces are shown in Figure 2. It can be

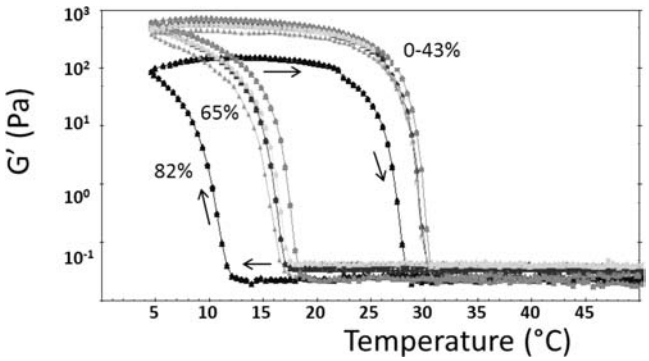

Figure 2. Storage modulus (G') as a function of cooling/heating temperatures at 0.5 °C/min scan rate for reference and gelatin solutions with different DS (3% w/v). Only the traces with a DS of 82 and 65% are indicated separately. The small arrows in the figure illustrate the applied temperature ramp of cooling and subsequent heating of the sample.

observed that up to a DS of 65% the introduced succinate groups have only very limited impact on both gelling/melting temperatures as well as on the gel strength developed. Only at a DS of 82% was a significant loss in gel strength (factor of 5−6) observed, and the gelling temperature shifted from 17 to 11 °C. Also, the helix melting temperature was lowered. Lowering the cooling rate from 0.5 to 0.2 °C/min had a marginal effect on the transition temperature and no significant impact on G' (results not shown).

The gelling temperatures observed with small deformation rheology are confirmed by those obtained from thermal calorimetric analysis (Table 2). The corresponding transition

Table 2. Calorimetric Analysis of Reference and Succinylated Gelatin

material (% DS)	transition temperature gelling (°C)	transition enthalpy gelling (J/g)	transition enthalpy melting (J/g)
reference	20.3 ± 0.9	15.0 ± 1.8	40.2 ± 1.6
12	17.8 ± 0.8	13.2 ± 0.9	39.2 ± 1.4
26	18.2 ± 0.7	9.2 ± 0.8	37.4 ± 1.6
43	17.9 ± 0.7	7.2 ± 0.5	35.9 ± 2.1
65	17.3 ± 0.6	6.3 ± 1.1	34.4 ± 1.2
82	11.8 ± 0.9	0.8 ± 0.4	28.5 ± 0.9

enthalpy (related to cooperative thermal processes) decreases with increasing DS and shows a strong reduction for the highest DS of 82%. A lower transition enthalpy was suggested to result from a less cooperative assembly of the triple helices as found by Dardelle and co-workers[15] using different cross-linkers that distorted the gelatin strand formation locally. Alternatively, the energy content related to the melting process (Table 2, last column) shows much higher values compared to those found for the gelling and a smaller dependence on the DS. This suggests that during the gel assembly the kinetics of strand−strand interactions is strongly hindered by the electrostatic repulsions, making the process of network formation less cooperative.

Calcium Binding. Figure 3 shows the calcium-binding curves for reference and succinylated gelatin at concentrations

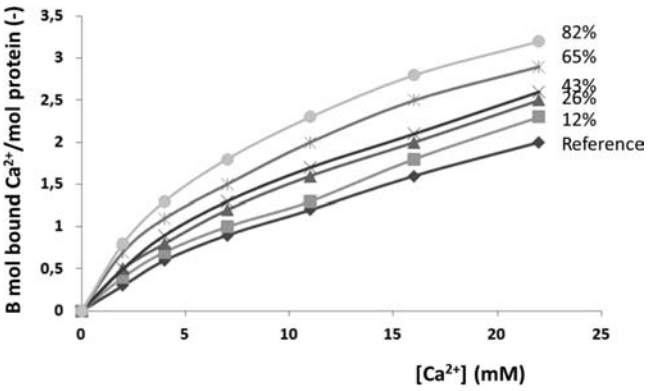

Figure 3. Calcium binding curves for 0.5% w/v solutions of reference succinylated gelatin with different DS as indicated in the graph. An ensemble-averaged molecular weight of 124 kDa is used to calculate *B*.

below the critical gel concentration (0.5% w/v). It can be observed that reference gelatin (net negatively charged under the conditions) shows a moderate calcium binding, and with increasing succinate content (all positively charged) the number of calcium ions that are bound to the protein steadily increases. The fact that no plateau value is reached for any of the samples indicates that the binding affinity to molecular gelatin is relatively weak and there is a continuous equilibrium between bound and nonbound calcium that is shifted toward the bound state by increasing the bulk calcium concentration.

The macroscopic impact of the presence of calcium on gel formation is evaluated by assessment of the physical state of protein solutions (pre-equilibrated at 60 °C), after cooling to 20 °C, qualitatively in terms of whether the sample appears liquid (free flow), viscous (a lumpy cohesive flow), or gelled (immobilized) at room temperature. In all cases visually transparent samples (liquids/gels) were obtained. It can be observed in Figure 4A that in the absence of calcium for reference gelatin a concentration >0.8% (w/v) is needed to

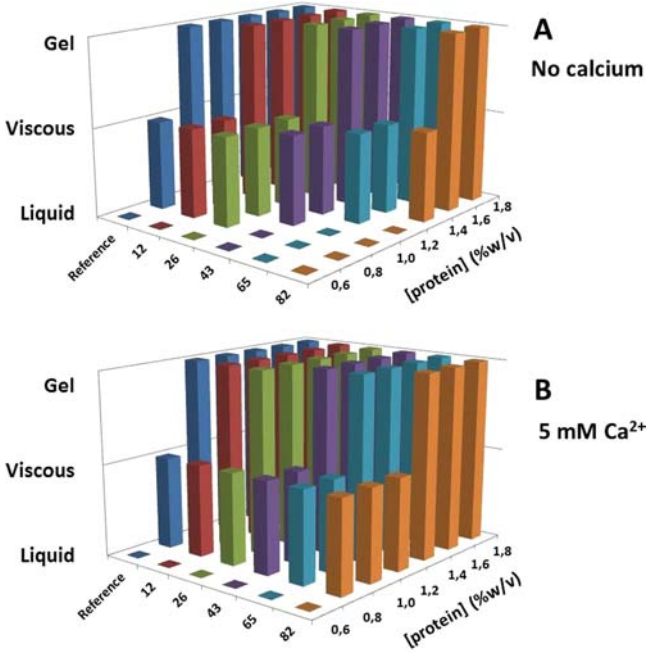

Figure 4. Qualitative assessment of gelatin solutions (reference and with various DS) at different protein concentrations in terms of liquid, viscous, or gel (definitions see text) in the (A) absence or (B) presence of 5 mM calcium. Protein solutions are preheated for 30 min at 60 °C, subsequently cooled to 20 °C, and assessed after 1 h of equilibration at this temperature.

obtain a viscous solution and >1.0% to obtain a gel. In the absence of added calcium it can also be observed that with increasing DS the protein concentration required to obtain a viscous or a gel state shifts to higher protein concentrations. This can be explained by the increased intermolecular electrostatic repulsions with increasing DS. Figure 4B shows the same samples in the same concentration range but cooled to room temperature in the presence of 5 mM calcium. Whereas for reference gelatin no effect of added calcium is present, for all succinylated samples a fortification of the protein network can be observed and most effectively at higher DS. For example, gelatin with a DS of 26% behaves in the presence of 5 mM calcium physically like reference gelatin. A 1.2% (w/v) gelatin with a DS of 82% behaves like a liquid in the absence of calcium, but is gelled in the presence of 5 mM calcium.

To elaborate on this effect, the impact of calcium on the gel properties has been studied for all materials. To illustrate this, the gel properties of reference gelatin and that with a DS of 82% are presented in more detail below.

Calcium Sensitivity in Gel Formation. Figure 5 shows the small deformation rheology of 3% (w/v) gelatin solutions (reference and DS 82%) when a cooling ramp is applied to pre-equilibrated samples from 50 to 4 °C and subsequently a heating ramp to 50 °C in the presence of different calcium concentrations. For reference gelatin (Figure 5A) there is no detectable impact of the presence of added calcium up to a concentration of 20 mM, nor in gelling or melting temperature, nor in the maximal gel strength developed. For the succinylated gelatin it was already shown in Figure 2 that in the absence of

DOI: 10.1021/acs.jafc.5b01962
J. Agric. Food Chem. 2015, 63, 7058−7065

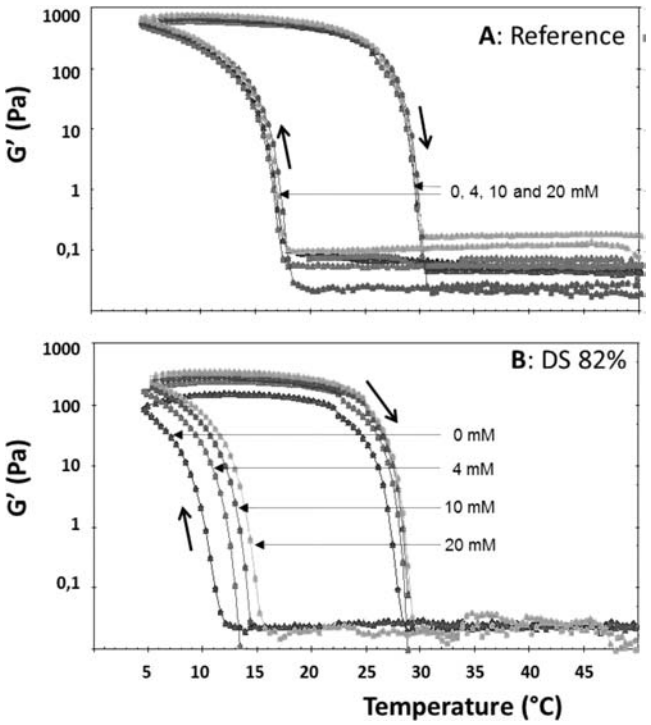

Figure 5. Small deformation rheology on 3% (w/v) (A) reference and (B) succinylated (DS = 82%) gelatin during a cooling and subsequent heating ramp between 50 and 5 °C in the presence of different calcium concentrations (0−20 mM) as indicated in the graphs. The arrows indicate the cooling−heating cycle.

calcium both the gelling temperature and the gel strength were significantly reduced. Figure 5B shows that addition of calcium "restores" both the gelling temperature and gel strength to those observed for reference gelatin. For DS 65% it has been found that whereas in the absence of calcium (see Figure 2) a slightly reduced G' was observed at 5 °C, in the presence of 4 mM calcium no differences with the reference gelatin were observed any longer (results not shown).

This behavior was confirmed when these systems were analyzed calorimetrically, as illustrated in Figure 6. Whereas for reference gelatin no impact is observed of the presence of calcium either on the gelling temperature or on the concomitant enthalpy change, for the 82% succinylated sample the gelling temperature steadily increases from 11 to 17 °C. Moreover, the concomitant enthalpy change increases from almost negligible in the absence of calcium to about 10 J/g in the presence of 10 mM calcium. This is still considerably lower (∼30−40%) compared to that observed for reference gelatin. For the 65% DS sample the transition temperature and enthalpy were fully restored by the addition of 10 mM calcium.

To evaluate whether the calcium acts at the level of strand−strand interactions or at the level of helix assembly, the optical rotation of these samples is followed. Figure 7 shows the optical rotation as monitored during cooling for reference (panel A) and 82% succinylated gelatins (panel B) at concentrations below the critical gelling concentration in the presence of different calcium concentrations. In line with the above results calcium does not have an impact on the helix formation of reference gelatin. As was already shown in Figure 1, in the absence of calcium highly succinylated gelatin has a lower helix propensity. This can, as shown in Figure 7B, be partly (for about half of the loss of helicity in the absence of calcium) restored by the presence of 20 mM calcium. The increased helicity as induced by the presence of calcium does not, however, fully explain the enhancement of the gel mechanical properties as shown in Figure 5, suggesting that the effect of calcium is not limited to the ability to adopt a triple helix only.

To study this in more detail, the effects of 20 mM calcium on the helix content and maximal gel strength are determined and presented in Table 3 for the different succinylated materials. It can be observed that the helicity steadily declines with increasing DS in the presence of 20 mM calcium. The storage modulus, on the other hand, shows a maximum at a DS of 43%,

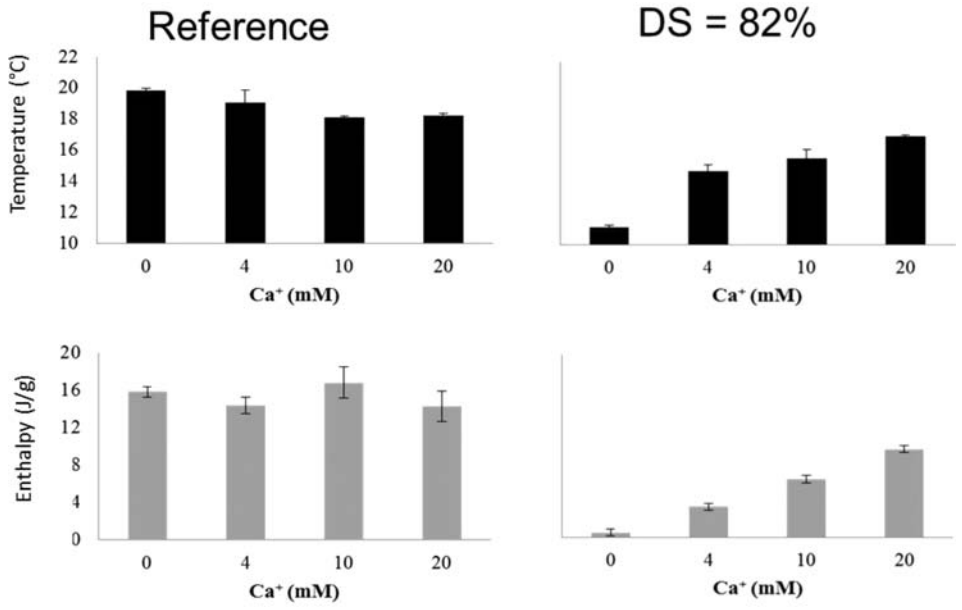

Figure 6. Calorimetric analysis of the cooling ramp from 50 to 5 °C of a 3% w/v reference (left panels) and an 82% succinylated (right panels) gelatin in the presence of different concentrations of calcium. The upper panels present the onset of the gelling temperature, and the lower panels show the concomitant change in enthalpy.

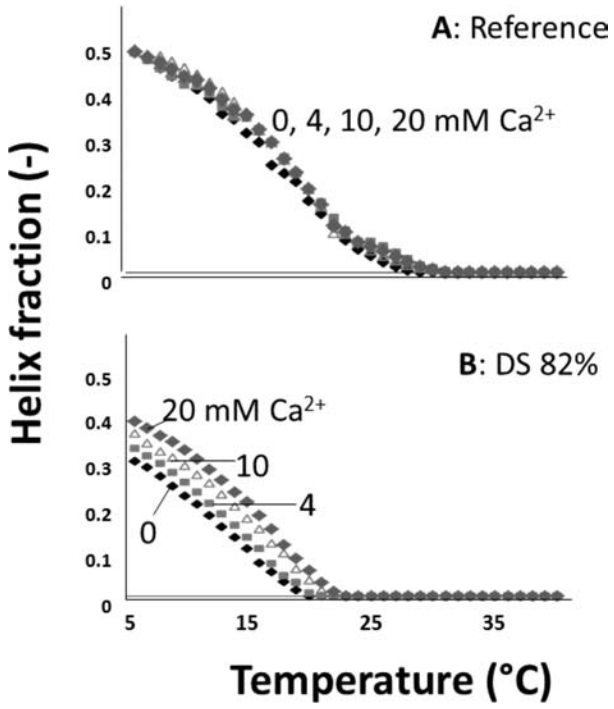

Figure 7. Helix fraction as established from optical rotation measurements for reference (top panel) and 82% succinylated (lower panel) gelatin in the presence of various calcium concentrations (0−20 mM) as indicated in the panels during cooling from 50 to 5 °C.

Table 3. Helix Propensity (Optical Rotation) and Maximal Gel Strength (Small Deformation Rheology of Reference and Various Succinylated Gelatins in the Presence of 20 mM Calcium)

material (% DS)	helicity (fraction) at 5 °C	maximal G' (Pa)
reference	0.45 ± 0.02	760 ± 20
12	0.44 ± 0.03	780 ± 30
26	0.42 ± 0.02	830 ± 40
43	0.40 ± 0.02	930 ± 50
65	0.37 ± 0.03	550 ± 40
82	0.34 ± 0.03	280 ± 30

where an enhancement of the gel strength of ∼20% is found, and the helicity is reduced compared to the reference. At higher DS G' decreases again rather drastically, despite the fact that under these conditions the helicity is not concomitantly reduced.

Responses to Large Mechanical Deformation. The above-presented results show that extensive succinylation of gelatin does not prohibit gel formation. At high DS helix formation is hampered, but still profound, and the gel strength is reduced only slightly. The presence of calcium restores the material properties to those of unmodified gelatin to some extent. There are two opposing aspects introduced by succinylation of the protein. Increasing DS gradually reduces the helix propensity (Figure 1), the cooperativity in network assembly (Table 2), and the storage modulus of the gel (Figure 2) due to increased electrostatic repulsions. Alternatively, succinylation also increases calcium binding with moderate affinity (Figure 3), which leads to at a DS of 43% even to a significant fortification of the gel elasticity (Table 3). Obviously, calcium binding not only affects the molecular interactions but also acts as a fortifier of strand−strand interactions.

For technological impact it is most relevant to study the gel responses to large deformation from a product storage, handling, and oral processing perspective. In the evaluation of the strain required to create sufficient stress in the gel to result in fracture events (Table 4), it can be observed that for reference gelatin the addition of calcium has no effect but that the stress evoked by the applied strain leading to fracture diminishes 10−15% with increasing calcium concentration. This situation is different for the gelatin with a DS of 82% (Table 4), where in the absence of calcium almost half the strain is sufficient to initiate fracture compared to the reference material. Calcium restores this property and even to strains beyond that observed for the reference material. Interestingly the fracture stress remains, independent of the calcium concentration, approximately 30% lower than that of the reference material.

The picture that emerges is that increased electrostatics increases the structural heterogeneity in the gel, thereby lowering the fracture strain. The addition of calcium "glues" the strands together, smooths the heterogeneities, and thereby reduces the brittleness of the material. As the fracture stress is the result of unzipping of the triple helices and dissociation of the strands, this is less affected by electrostatics or the presence of calcium.

Gelatins are renowned for their high recoverable energy and elastic nature.[13] As these rheological properties have been related to texture perception of food products,[16,17] it is essential to evaluate how these varied electrostatics in the network assembly and calcium-induced network stabilization affect these mechanical responses. Table 4 presents the recoverable energies (from a compression−decompression cycle up to a 20% compressive strain, so below the observed fracture strains) for reference gelatin and for a gelatin with a DS of 82% as the two extreme cases. It can be observed that rheological response is not affected at all by increased electrostatic repulsions between the individual network strands. Moreover, also the addition of calcium has no impact. For the gelatins with the other DS values comparable RE values between 93 and 95% were obtained, and none of the samples showed a sensitivity toward calcium (results not shown). These results emphasize that the RE is not related to the elastic modulus or gel stiffness or a network characteristic, but set by the energy dissipation modes as suggested in the literature.[13]

As gelatin networks have a fine coarseness with typical mesh sizes on the order 30−100 nm,[18] their water-holding capacity is consequently close to 100%.[19] This indicates that the enclosed liquid phase in the gel deforms along with the protein network, not giving rise to significant energy dissipation by friction caused by serum flow through the protein network.[13] Also, the occurrence of (micro)fractures during deformation is not likely as the fracture stress is only marginally affected by succinylation or by the addition of calcium. As stress relaxation, related to spontaneous rearrangements of the microstructure upon deformation of the material, was shown to be a dominant energy dissipation mode for these gels,[13] the relevant stress relaxation times and their corresponding fraction of the total applied stress have been determined. The results are presented in the last two columns of Table 4. It can be observed that both the relaxation times and the corresponding fractions are not affected by either succinylation or the addition of calcium. A relaxation time around 8 s for 6% of the total stress (the average numbers from Table 4) implies that this dissipation mode, acting from the very start of the deformation applied (total cycle for compression−decompression takes 8 s), accounts for about 2% of the energy loss during the RE measurement. Apparently, stress relaxation is set by the inherent molecule and maybe to a limited extent by the ability to adopt triple helices, rather than strand−strand interactions, of the network. This explains why the RE is not affected by the succinylation or the restored storage modulus by the addition of calcium.

In summary, in this work it is shown that extensive succinylation of gelatin does not prohibit gel formation. Properties such as helix propensity, gelling/melting temperatures, and concomitant transition enthalpy changes and gel strength are shown to become calcium sensitive by high degrees of succinylation. The presence of relatively low concentrations of calcium restores these material properties mostly to those of nonmodified gelatin. However, although succinylation has a major impact on the brittleness of the gels formed and the addition of calcium makes the material even less brittle compared to the nonmodified gelatin, the modification has no impact on the energy balance in the gel, where all of the energy applied is stored in the material. This insight allows food industries to tailor gelatins for texture attributes.

Table 1. Molecular Structures of the Cyanidin Compounds That Comprise the Black Carrot Anthocyanin Mixture and Proton-Numbering Schemes Used in the Assignment of NMR Spectra

Name	Anthocyanin Structure	Sugar Structure	Retention Time (min)	m/z [M^+]
1 Cyanidin-3-xy-glc-galactoside			15.4	743.2
2 Cy-3-xy-galactoside			16.3	581.2
3 Cy-3-sin-xy-glc-galactoside			17.1	949.2
4 Cy-3-fer-xy-glc-galactoside			17.6	919.2
5 Cy-3-coum-xy-glc-galactoside			18.2	889.2

also suggested that coumarin 3,5-diglycosides are common degradation products for anthocyanin 3,5-diglycosides.[4,17]

During heat exposure, the stability of anthocyanins depends upon the composition and the characteristics of the medium, with pH playing an important role. Anthocyanins adopt different chemical structures, which exist in pH-dependent equilibrium.[18−20]

Some studies indicate that acylated anthocyanins, mainly those with planar aromatic substituents, exhibit greater stability, especially when kept in aqueous solutions, and play an important role in increasing the thermal stability of the dye compared to the non-acylated counterparts. It is believed that the aromatic residues of the acyl groups stack with the pyrylium ring of the flavylium cation, which reduces the likelihood of the hydration reaction in the vulnerable C-2 and C-4 positions.[21−25]

Black carrot consists of a high ratio of monoacylated anthocyanins.[10−13] The question that arises is are black carrot acylated anthocyanins more stable compared to the non-acylated anthocyanins? In other words, does the structure of anthocyanins affect the stability?

Previous studies of black carrot have typically used HPLC and ultraviolet/visible (UV/vis) analysis for quantification of the compounds, but there are some weaknesses to these techniques. For HPLC, there are concerns about pH-dependent variation in the wavelengths of absorption maxima and the values of absorption coefficients, leading to unreliable quantification. Using UV/vis spectroscopy alone, it is impossible to resolve and quantify the separate compounds; only the total anthocyanin concentration can be approximated.

In the present study, proton nuclear magnetic resonance (^{1}H NMR) spectroscopy and signal integration was used to investigate the thermal degradation of the individual anthocyanin compounds of a commercial black carrot concentrate and the effect of pH on this degradation. Complementary UV/vis spectroscopy and CIE color space measurements[26] were used to follow color degradation. Separation of the mixture into individual compounds and assignment of each compound followed by integration of ^{1}H NMR signals in spectra of the mixtures were the steps used. The resulting understanding of the relative stabilities of the different compounds, in particular, the role of structure (acylation) on the stability, should be valuable in developing future strategies to enhance the stability of this commercially available natural colorant.

MATERIALS AND METHODS

Plant Materials. Commercial concentrate of black carrot (*Daucus carota* L.) was supplied by Naturex, Ltd. (manufacturer's code, COPG4167; sample code, G00017). The concentrate was stored at −18 °C.

Solvents and Reagents. Deuterated NMR solvents were purchased as follows: methanol-d_4 from Sigma-Aldrich (St. Louis,

DOI: 10.1021/acs.jafc.5b02543
J. Agric. Food Chem. 2015, 63, 7066−7073

MO), trifluoroacetic acid-*d* from Sigma-Aldrich (St. Louis, MO) or Cambridge Isotope Laboratories (CIL) (Tewksbury, MA). Hydrochloric acid with specific gravity (SG) of 1.18 (≈37%), sodium hydroxide (97%), and sodium dihydrogen orthophosphate dihydrate were purchased from Fisher Scientific (U.K.). Disodium hydrogen phosphate dihydrate and citric acid monohydrate were obtained from Sigma-Aldrich (St. Louis, MO). Acetonitrile and water for HPLC were purchased from VWR International. All of the HPLC solvents were of analytical grade. C-18 cartridges with a vacuum of 35 cm^3 (10 g) (WAT043345) were purchased from Waters (Ireland).

Sample Preparation. A two-step extraction process was applied to the black carrot sample to remove non-anthocyanin compounds. A total of 100 g of black carrot concentrate was mixed with 150 mL of chloroform in a separating funnel and left overnight. The aqueous phase was collected and further purified by solid-phase extraction,[27] using mini columns [C-18 cartridges with a vacuum of 35 cm^3 (10 g) (WAT043345)] purchased from Waters (Ireland). The eluent of the extraction (methanolic mobile phase) was concentrated in a rotary evaporator (IKA RV 10 basic) at 25 °C and further dried under vacuum, using liquid nitrogen, yielding 5 g of powder.

HPLC. A total of 100 mg of the extracted black carrot powder (see the Sample Preparation) was dissolved in 1 mL of distilled water. Semi-preparative reverse-phase (RP)-HPLC was performed on a HP1100 system equipped with a semi-preparative C_{18} Agilent column Eclipse XDB-C18 (9.4 × 250 mm inner diameter, 5 μm) at a constant temperature of 20 °C and a flow rate of 2 mL/min. A mobile-phase gradient was used for elution; eluent A consisted of water with 0.1 mL of formic acid, and eluent B consisted of acetonitrile (ACN) and water with 0.1% formic acid (1:1). The elution profile was 10% B at 0 min, 35% B at 10 min, 50% B at 35 min, 80% B at 40 min, and 10% B at 45 min. The injection volume was 20 μL, and the detector was set at 520 nm. The fractions were transferred into vials, and mass spectrometric analysis was performed on an Agilent Series 1100 HPLC system fitted with an electrospray ionization (ESI) source. Repeated injections were performed, and the isolated fractions were combined until a mass of 2−5 mg per fraction was obtained. The purified fractions were frozen using dry ice and acetone and then dried under vacuum on a freeze drier.

Heating Experiments. A domestic oven (Dēlonghi E012001W) was used to heat treat aqueous solutions with pH values of 3.6, 6.8, and 8.0. Citric acid/phosphate and phosphate buffers were used to adjust the pH. Hydrochloric acid and sodium hydroxide were also used where necessary for adjusting the pH, to avoid salts that interfere with the HPLC column. The samples were heated in an oven at around 180 °C, to maintain the aqueous sample temperature at 100 °C, for periods up to 100 min. A 60 min heat treatment was also applied to samples for which the pH ranged between 3.4 and 8.2.

Powder samples of black carrot were prepared by dissolving black carrot in aqueous solutions, adjusting the pH to 3.6 and 6.8, followed by freeze drying. The powders were then exposed to heat in a high-performance furnace [Carbolite (U.K.) at 180 °C].

NMR Spectroscopy. A mixed solvent consisting of 10 g of MeOH-d_4/0.5 mL of trifluoacetic acid-*d* (TFA-*d*) was used for all NMR measurements. The structures of the compounds isolated by RP-HPLC were determined using one-dimensional (1D) ^{1}H NMR analysis on a Bruker 500 MHz spectrometer (10 mg in 0.8 mL of MeOH/TFA) in combination with two-dimensional (2D) correlation spectroscopy (COSY) NMR to assign aromatic peaks. High-resolution ^{1}H NMR spectra of the purified (unseparated) black carrot (10 mg in 0.8 mL of MeOH/TFA) were acquired on a Bruker 800 MHz spectrometer. In addition, ^{1}H NMR spectra (800 MHz) used for integration of the samples exposed to heat were also acquired (10 mg in 0.8 mL of MeOH/TFA).

UV/vis Spectroscopy. Absorption spectra in the visible region (300−800 nm) were recorded using a Jasco V-670 series spectrophotometer. Solutions (40 μL of sample solution in 3 mL of citric acid/phosphate buffer) were contained in a quartz cell (d = 1 cm), and the data were collected using Spectra Manager II software.

Color Measurements. The Spectra Manager II software was used to calculate the CIE lab coordinates using the Jasco V-670 series spectrophotometer (Tokyo, Japan). Chroma value C^* [$C^* = (a^{*2} + b^{*2})^{1/2}$] and hue angle $h°$ [$h° = \arctan(b^*/a^*)$] were calculated from parameters a^* (from green to red) and b^* (from blue to yellow) values. The hue angles were expressed on a 360° color wheel, in which 0° and 360° represent red, 90° represents yellow, 180° represents green, and 270° represents blue. The illuminant was D65, and the observer angle was 10°. The change in color produced by heat treatment was calculated using the $\Delta E^* = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$ equation at pH 3.6, 6.8, and 8 for several time intervals.[26]

RESULTS AND DISCUSSION

Isolation and Structure Characterization: NMR Studies. As shown in Figure 1, even after purification by solid-phase extraction, the NMR spectrum of the black carrot mixture contains many overlapping peaks, preventing the assignment of individual compounds. The extraction process has simplified the aromatic region (6.2−9 ppm), as shown by comparison to Figures S1 and S2 of the Supporting Information, but further information on the individual compounds is needed to enable assignment of the aromatic protons.

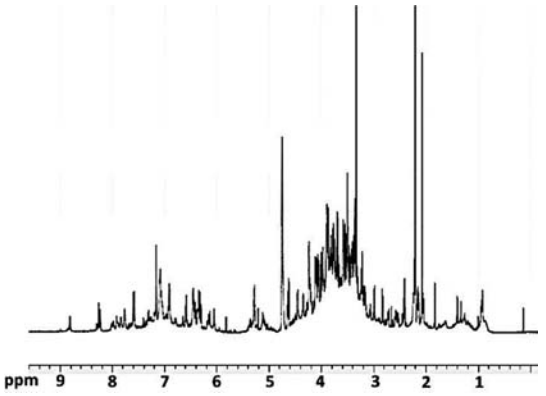

Figure 1. ^{1}H NMR spectrum (800 MHz) of black carrot mixture following purification by solid-phase extraction.

Montilla et al. describe that, for different black carrot species, the composition of anthocyanins can vary.[11] Using RP-HPLC, five major anthocyanin compounds of black carrot were isolated, as shown in the chromatogram in Figure 2. Mass spectrometric analysis indicated that each fraction corresponds to a particular anthocyanin molecule (identifiable as the molecular ion), as summarized in Table 1 (see Figures S3−S7 of the Supporting Information). These results are consistent with previous studies of the composition of black carrot.[10−13]

[a]See Table 1 for the proton-numbering scheme.

chemical shifts are consistent with the chemical shifts assigned for the anthocyanins from cell suspension culture of *D. carota* L. in the study by Gläßgen et al.[28] The NMR results from the present study (Table 2) show that compounds **1** and **2** are the non-acylated compounds and compounds **3**–**5** are the acylated anthocyanin compounds, confirming results from previous studies. It can also be seen that the presence of sinapic, ferulic, and coumaric acids on the glucose moiety has an effect on the chemical shift of the cyanidin protons. For example, the chemical shifts of H-4 in the non-acylated compounds are in the range of δ = 9.016–9.010, while those for the acylated compounds appear at δ close to 8.540. The same effect is seen on the chemical shifts of the H-6 and H-8 protons. In the study by Gläßgen et al., a low-frequency shift of H-4 protons of black carrot anthocyanins acylated with sinapic, ferulic, and coumaric acids compared to the non-acylated counterparts was also noted.[28] Also, Dougall et al. described a marked effect of cinnamic or benzoic acids on the chemical shifts of the cyanidin H-4, H-6, and H-8 protons in the acylated compounds, providing evidence for NMR shifting caused by acylation.[29]

The aromatic region of the black carrot mixture could be assigned completely with reference to the NMR spectra of the five separated compounds. Each signal in the spectrum of the mixture can be identified with a single signal or with overlapping signals from the spectra of the five compounds, as illustrated in Figure 3. In the region between δ = 6.0 and 7.5 ppm, there is considerable overlap between peaks of the individual compounds in the spectrum of the mixture. On the other hand, in the region between δ = 7.8 and 9 ppm, the individual compound peaks are generally well-resolved. The small intensity doublets in the region δ = 7.55, highlighted in red, and δ = 6.25 (overlapped), are attributed to minor impurities and also appeared in the spectrum for compound **5**.

Thermal Degradation Studies. The clear assignment of the NMR peaks in the black carrot mixture enables the fractional concentration of compounds **1**–**5** to be unambiguously determined and to be followed during thermal degradation. The well-resolved region between δ = 8.4 and 9 ppm was used for integration to determine the composition of the mixture and to quantify the degradation of each compound. Specifically, the integrals were determined for the combined H-4 proton signals of compounds **1** and **2** at δ = 9 ppm and the individual H-4 proton signals of the other three compounds in the region around 8.5 ppm. Overall, the expected general trend was noticed; the longer the exposure to heat, the more the integrated NMR signals of the compounds were reduced. However, it was also apparent that the integrals of the individual compounds were decreasing at different rates, resulting in variation in the composition of the mixture during thermal degradation.

Before examining the NMR results in detail, we first describe the general degradation behavior observed in the UV/vis spectra of the anthocyanin mixture in solution and as a solid powder.

UV/vis Spectroscopy and Color Measurements: Black Carrot in Solution. Exposure to heat at pH 3.6 for 100 min resulted in an increase in lightness, L^*, by 7.99 units, insignificant change in the hue angle h°, and a decrease in the chroma, C^*, by 16.13 units (see Table S1 of the Supporting Information). This indicated that the color of the anthocyanins was fading with a slight change of the hue. The UV/vis spectra (Figure 4a) showed a decrease in absorbance, but λ_{max} was not notably shifted. Heat treatment at pH 6.8 for 100 min also resulted in an increase in lightness (8.65 units) and a decrease in chroma (22.26 units), but there was also an increase in the hue angle by 18.12 units (see Table S1 of the Supporting Information). Therefore, in neutral conditions, the color not only faded but the hue also changed from red to a more orange

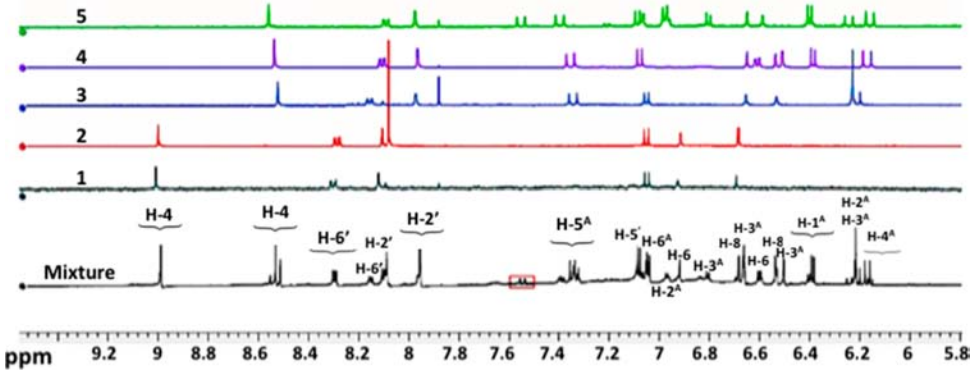

Figure 3. NMR spectra of black carrot mixture (bottom, black) and the HPLC compounds **1**–**5**. The singlet at δ = 8.08 ppm of compound **2** and δ = 7.9 ppm of compounds **3**–**5** are solvent residual signals.

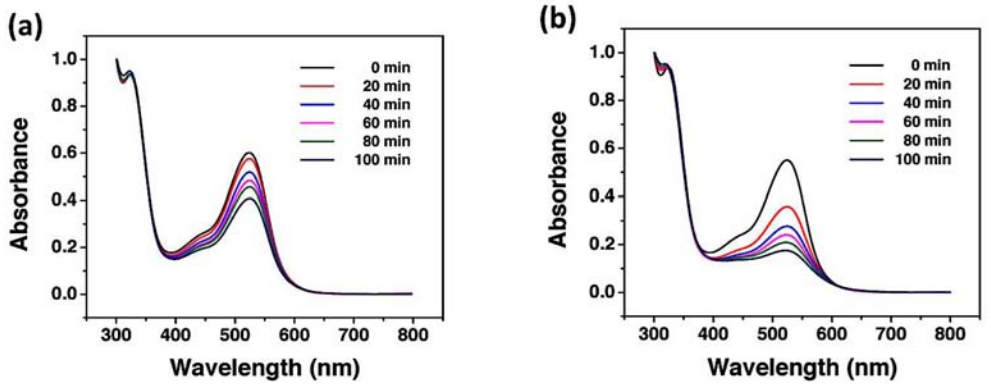

Figure 4. UV/vis spectra as a function of time for heat treatment of black carrot solution at (a) pH 3.6 and (b) pH 6.8.

shade. The UV/vis spectra (Figure 4b) showed both a decrease in absorbance and a slight bathochromic shift in λ_{max}. To explore the pH dependence of these effects, the UV/vis spectra of the black carrot heat treated for 60 min at a range of pH values, from 3.4 to 8.2, were recorded. As shown in Figure 5,

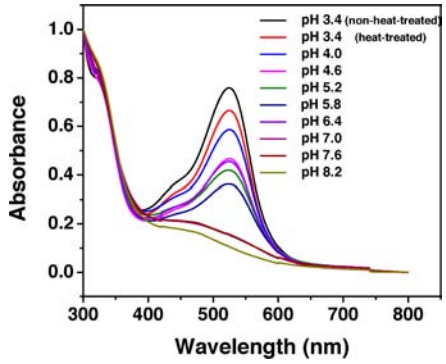

Figure 5. UV/vis spectra as a function of pH for heat treatment of black carrot solution for 60 min.

with increasing pH, λ_{max} shifted bathochromically and the absorbance maximum was noticeably decreased. Observing the CIE lab parameters, the lightness gradually enhanced by 25.89 units, h° increased dramatically to 70.43 units, and the color of neutral and more basic solutions decolorized and gradually turned brown. The color saturation decreased 40.52 units (see Table S2 of the Supporting Information). It is clear from the UV/vis spectra that there is more rapid degradation of the anthocyanins at higher pH values. This can be related to the different forms of the anthocyanins present as a function of pH; in the case of the acidic solution, more of the stable flavilium cationic form of anthocyanin is present, whereas in neutral conditions, the percentage of less stable chalcone, carbinol, and quinonoidal forms will be increased.

Black Carrot Powders. To assess the effect of pH on solid-state samples, the pH was adjusted to 3.6 and 6.8 before freeze drying. After 60 min of heat treatment, the colors showed a slight increase in lightness (L^*) by 2.73 and 5.03 units, respectively. The hue value change was negligible for both cases, and the chroma (C^*) value decreased by 7.92 and 12.47 units, respectively (see Table S1 of the Supporting Information). The difference in the absolute absorbance between the two samples is also negligible in λ_{max} of the UV−vis spectra (panels a and b of Figure 6). The UV/vis spectra show that, at pH 3.6, the thermal stabilities of the solution and powder samples are similar; however, at pH 6.8, the powder shows much higher stability than the solution. In comparison of the two powder samples, it is evident that the pH prior to freeze drying has little effect on the stability.

NMR Spectroscopy. Integration of the H-4 proton peaks in the aromatic region of NMR spectrum (δ = 8.4−9), as indicated in Figure 3, enabled the percentage of each compound in the anthocyanin mixture to be quantified as a function of the heating time, over a range of pH. The results are presented in Figures 7−11. As shown in the insets of the figures, the overall degradation of the total anthocyanin content determined from the NMR integrals follows a similar trend to

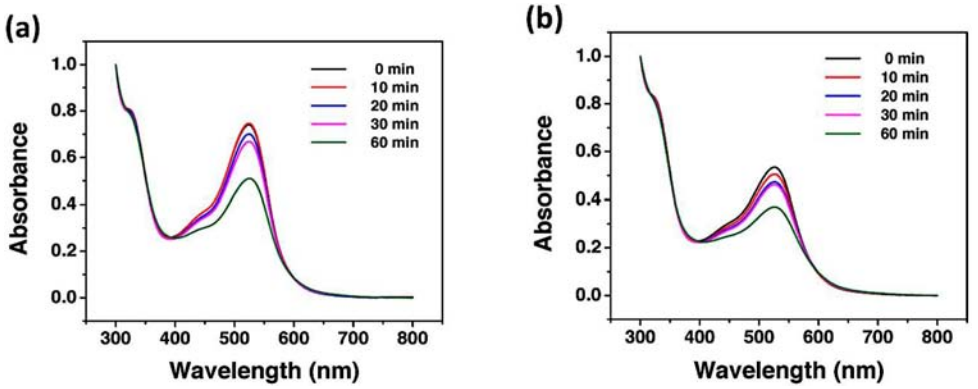

Figure 6. UV/vis spectra as a function of time for heat treatment of black carrot powder prepared by freeze drying of solution at (a) pH 3.6 and (b) pH 6.8.

DOI: 10.1021/acs.jafc.5b02543
J. Agric. Food Chem. 2015, 63, 7066−7073

that derived from the UV/vis absorbance. Notably, however, the absorbance measurements imply a lesser extent of degradation than that quantified by the NMR data. This can be attributed to residual absorbance, in this spectral region, by the decomposition products, which persist after degradation of the primary anthocyanin compounds. Thus, the NMR data are able to give a better quantitative measurement of degradation than the commonly used UV/vis data.

Black Carrot in Solution. As shown in Figure 7, at pH 3.6, all compounds showed substantial degradation after heating for

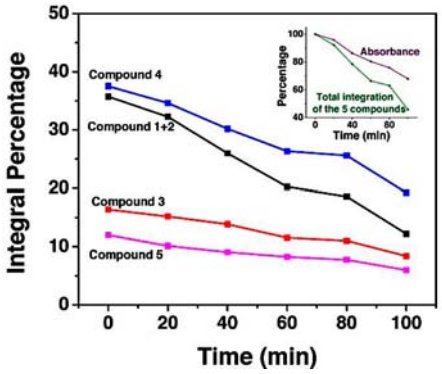

Figure 7. Percentage of each compound (determined from NMR integrals) in black carrot solution as a function of the heating time, at pH 3.6. The inset compares the heating time dependence of the total anthocyanin content derived from NMR data (green) to that derived from UV/vis data (purple). The lines are a guide to the eye.

100 min but there was not complete destruction; the total anthocyanin concentration was decreased by about 60%. In contrast, at pH 6.8, there was almost complete thermal degradation after 100 min, with only about 10% of the total anthocyanin content remaining. These observations are consistent with the expectation that the anthocyanins are more stable in acidic conditions.[18] In basic conditions (pH 8), we found complete degradation of black carrot solution after 48 h of storage at room temperature in the dark (see Figure S10 of the Supporting Information).

The rate of degradation of the anthocyanin compounds can be assessed by considering the percentage decrease in the concentration after 60 min of heating. At pH 3.6, the non-acylated compounds, **1** + **2**, showed the greatest rate of decomposition, resulting in a 43% decrease in the concentration in 60 min, compared to a decrease of about 30% for each of the acylated compounds (Figure 7). At pH 6.8, the rate of decomposition of all of the compounds was accelerated. However, the non-acylated compounds (**1** + **2**) decomposed more slowly than the acylated compounds; the former showed a 66% drop in concentration after 60 min compared to a 75% drop for the latter (Figure 8).

The effect of pH on the composition of the thermally degraded anthocyanin mixture after heating for 1 h is illustrated in Figure 9. It is evident that the stability of all compounds decreases significantly with increasing pH in the range of pH 3.4−5.8. There is little pH dependence between pH 5.8 and 6.4 (a slight increase in stability is seen). An abrupt drop-off in stability occurs as neutral pH is approached, with complete decomposition at pH 7 and above.

To summarize, the thermal stability of all of the anthocyanin compounds is greater under acidic conditions, but the relative stability of acylated and non-acylated compounds is pH-

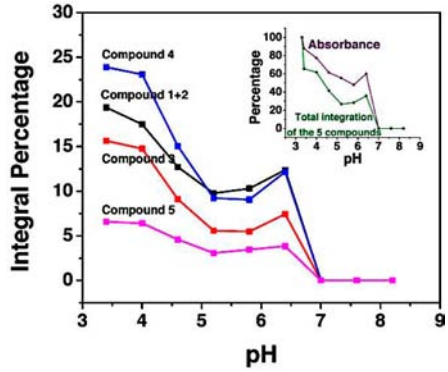

Figure 9. Percentage of each compound (determined from NMR integrals) in black carrot solution heated for 60 min, as a function of pH. The inset compares the pH dependence of the total anthocyanin content derived from NMR data (green) to that derived from UV/vis data (purple). The lines are a guide to the eye.

dependent. At low pH, the acylated compounds are more stable than the non-acylated compounds but become less stable at higher pH. This is contrary to the general consensus in the literature that acylation enhances the stability of anthocyanins at higher pH by protecting the flavilium cation from nucleophilic attack by water molecules at C-2 and C-3 positions.[21−24,30] However, previous studies have been based on the comparison of the color stabilities of anthocyanin pigments with different degrees of acylation rather than direct quantitation of individual acylated and non-acylated compounds.[21−24,30]

Black Carrot Powders. To investigate the thermal degradation of black carrot in the solid state, powder samples were prepared by freeze drying solution samples of pH 3.6 and 6.8. After heating, the solid samples were dissolved and NMR spectra were recorded.

The thermal degradation of powder and solution samples, after 1 h of heating, is compared in Figures 10 and 11 (note that the solids were effectively heated at a higher temperature because no evaporation was occurring). For the samples at pH 3.6 (Figure 10), the degradation properties of the powder are similar to those of the solution. At pH 6.8, there is only a small overall increase in degradation in the powder compared to pH 3.6. In solution at pH 6.8, however, the powder is significantly more stable than in solution. With regard to the individual

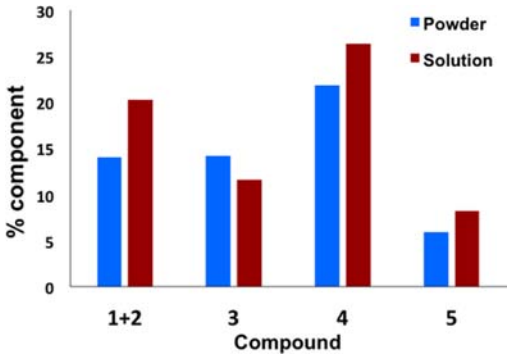

Figure 10. Comparison of the effect of heating on a solution sample (red) at pH 3.6 and a powder sample (blue) freeze dried at pH 3.6. The percentage of each compound (determined from NMR integrals) in each sample after 1 h of heating is shown (the solution sample was heated in a domestic oven at around 180 °C, and the solid sample was accurately heated in a furnace at 180 °C).

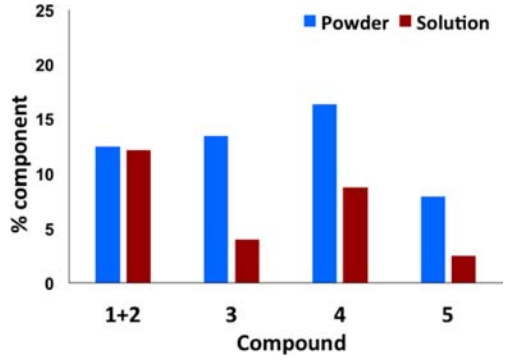

Figure 11. Comparison of the effect of heating on a solution sample (red) at pH 6.8 and a powder sample (blue) freeze dried at pH 6.8. The percentage of each compound (determined from NMR integrals) in each sample after 1 h of heating is shown (the solution sample was heated in a domestic oven at around 180 °C, and the solid sample was accurately heated in a furnace at 180 °C).

anthocyanins, it appears that changing the pH from acidic to neutral prior to freeze drying has little effect on the relative stability of the acylated and non-acylated compounds in the resulting solid sample. This is consistent with the UV/vis results (*vide supra*). It is also notable that, at pH 6.8, the stability of the acylated compounds is markedly higher in the powder than in the solution. These observations imply differences in the degradation mechanism between solid and aqueous conditions.

To conclude, the anthocyanin compounds in a black carrot concentrate were successfully isolated using HPLC, and their chemical shifts were fully assigned using 1D ^{1}H NMR and 2D COSY NMR. The UV/vis and the CIE lab color measurements showed an increased degradation with increasing the pH and heating time. NMR measurements confirmed these general trends. The summed NMR integrals of the five anthocyanin compounds followed a similar trend to the UV/vis absorbance. However, the UV/vis data underestimate the extent of degradation, as a result of the residual absorbance of decomposition species, making the NMR method more accurate. Furthermore, integration of the H-4 proton peaks between the region δ = 8.4 and 9 enabled percentage degradation of the individual compounds of the mixture to be quantified.

The NMR results show that, in acidic aqueous solution, there is enhanced stability of the monoacylated compounds, whereas in neutral conditions, their stability is lower compared to the non-acylated compounds. The thermal stability of powder samples, produced by freeze drying solutions at pH 3.6 and 6.8, was similar, and the heat stability of the powders at pH 6.8 was superior to that of the solutions.

It is important to emphasize the benefits of NMR for studying individual anthocyanin compounds, avoiding factors such as the pH dependence of the absorption, interfering absorbing compounds, and only approximate knowledge of molar absorption coefficients at different pH values, which are severe disadvantages using the common methods of HPLC and UV/vis. Although there are some limitations, such as overlapping chemical shifts for the compounds **1** and **2**, reliable information can be gleaned on the relative stability of the different anthocyanins. The observation of an unexpected effect of pH on the relative stability of monoacylated and non-acylated anthocyanins emphasizes the utility of NMR in providing insight into the degradation of multi-compound natural colorants, such as black carrot.

sone, aldosterone, progesterone, testosterone, estradiol, diethylstilbestrol, tributyltin chloride (TBTC), tributyltin bromide (TBTB), tributyltin iodide (TBTI), tributyltin hydroxide (TBTOH), triphenyltin chloride (TPTC), triphenyltin hydride (TPTH), and triphenyltin hydroxide (TPTOH) were purchased from Sigma-Aldrich (Prague, Czech Republic). All other chemicals were of the highest commercially available quality.

Human Cell Lines. The A-172 (ECACC no. 88062428), A549 (ECACC no. 86012804), HEK293T (ECACC no. 85120602), HeLa (ECACC no. 93021013), HepG2 (ECACC no. 85011430), HOS (ECACC no. 87070202), MCF-7 (ECACC no. 86012803), MIA-Pa-Ca-2 (ECACC no. 85062806), OACP4C (ECACC no. 11012005), SK-HEP-1 (ECACC no. 91091816), and U2OS (ECACC no. 92022711) cell lines were cultivated in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, 4 mM L-glutamine, 1% nonessential amino acids, and 1 mM sodium pyruvate. The A2780 (ECACC no. 93112519) and LNCaP (ECACC no. 89110211) cell lines were cultivated in RPMI-1640 medium supplemented with 10% fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, and 4 mM L-glutamine. The G-361(ECACC no. 88030401) cell line was cultivated in McCoy's 5A medium supplemented with 10% fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, 4 mM L-glutamine, and 1 mM HEPES. The FTC-133 (ECACC no. 94060901) cell line was cultivated in DMEM/F-12 nutrient mixture (DMEM/F-12) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, 4 mM L-glutamine, and 1% nonessential amino acids. All cells were cultivated at 37 °C and 5% CO_2 in a humidified incubator.

Electrophoretic Separation of Proteins and Western Blot Analyses. The total protein extracts were prepared as previously described.[12] The proteins were separated on an 8% SDS-PAGE gel using the Mini-PROTEAN Tetra System (Bio-Rad, Hercules, CA, USA) according to the manufacturer's instructions, followed by transfer onto a PVDF membrane. The blots were probed with primary antibodies against TRα1/α2, TRα1/β1, and RXRα. As a positive control, human recombinant TR-α1, TR-β1, and in vitro translated RXRα proteins were used. Chemiluminescent detection was performed using horseradish peroxidase-conjugated secondary antibodies against mouse and rabbit IgG and the Western blotting luminol reagent kit.

Quantitative Reverse Transcriptase PCR (qRT-PCR). The total RNA was isolated using TRI reagent, and, after treatment with DNase I, the cDNA was synthesized using M-MuLV reverse transcriptase, according to the manufacturer's instructions. qRT-PCR was performed in a LightCycler 480 II instrument (Roche Diagnostic Corp., Prague, Czech Republic), and the levels of Spot14 and GAPDH mRNAs were determined. The gene expression levels of *Spot14* were normalized to the housekeeping gene *glyceraldehyde-3-phosphate dehydrogenase* (*GAPDH*). The measurements were performed in triplicate, and the data were processed using the delta−delta method.

Reporter Plasmid. The luciferase reporter plasmid that is responsive to transcriptionally active TR pGL4.14-TRE was prepared by cloning the synthesized fragment containing two copies of tandem TREs oriented as direct repeats separated by four nucleotides (DR4) with the sequence TA**AGGTCA**TTTA**AGGTCA**TTTA**AGGTCA**-TTTA**AGGTCA**A into the multiple cloning region of the promoterless pGL4.14[*luc2*/Hygro] vector (catalog no. E6691) from Promega. As a control for luciferase gene expression, the basic SV40 promoter

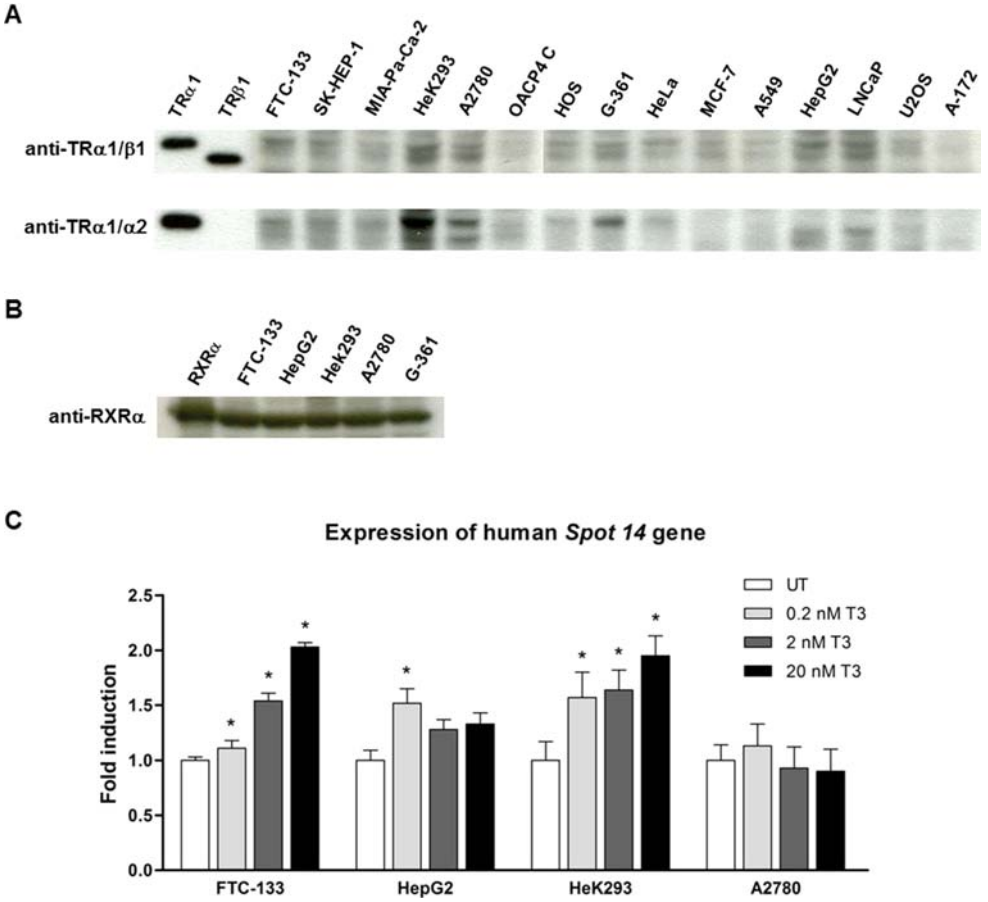

Figure 2. Characterization of the human cell lines suitable for stable transfection with the pGL4.14-TRE luciferase reporter plasmid. (A) Western blot of endogenous TRα and TRβ in protein lysates from 15 different human cell lines. As positive controls, commercial recombinant TRα1 and TRβ1 were used. (B) Western blot of the five selected cell lines for the detection of endogenous RXRα using in vitro translated RXRα as a positive control. (C) Quantitative real-time PCR analysis of the human *Spot 14* mRNA following T3 treatment in four selected cell lines. The analyses were performed after treatment of the cells with vehicle (UT; 0.1% DMSO v/v), 0.2, 2, or 20 nM T3 for 24 h, and the data were normalized to the GAPDH mRNA levels. The data are the means ± SD of triplicate measurements from three independent experiments and are expressed as the fold induction over the DMSO-treated cells. (∗) Values are significantly different from the vehicle-treated cells ($p < 0.05$) as determined by Student's *t* test.

with a deleted 5′ enhancer region was attached upstream of the TREs, and the entire insert was cloned between the *Kpn*I and *Hin*dIII restriction sites (Figure 1).

Stable Transfection of HepG2 Cells and the Selection Process. Human hepatocarcinoma HepG2 cells were seeded into 60 mm cell culture dishes at a density of 1.5×10^6 cells in 5 mL of DMEM culture medium. After 16 h of stabilization, the cells were transfected with 2 μg of the pGL4.14-TRE reporter plasmid using the FuGENE HD transfection reagent according to the manufacturer's standard protocol. After 48 h, the culture medium was replaced by selection medium supplemented with hygromycin B (500 μg/mL). The medium was changed every 4−5 days for a period of 8 weeks, until a polyclonal population of transfected cells was selected. The cells were subsequently transferred into 10 mm cell culture dishes at a density of 100−500 cells in 10 mL of selection medium supplemented with hygromycin B (500 μg/mL) and were cultivated for an additional 5 weeks, until small colonies appeared. Thereafter, 21 colonies were isolated and transferred into 24-well tissue culture plates to obtain monoclonal populations of cells (PZ-TR cells). The stably transfected, hygromycin B-resistant clones were tested for their responsiveness to T3. The use of GMO at the Faculty of Science, Palacky University Olomouc, was approved by the Ministry of the Environment of the Czech Republic (Ref. 91997/ENV/10).

Luciferase Gene Reporter Assay. The PZ-TR cells were seeded into 24-well tissue culture plates at a density of 0.15×10^6 cells in 0.5 mL of DMEM culture medium supplemented with 10% charcoal-stripped fetal bovine serum instead of normal fetal bovine serum. After 16 h of stabilization, the cells were treated with the compounds under investigation or vehicle (0.1% DMSO or ethanol v/v) as described in the figure captions for the indicated period of time. After the treatments, the cells were lysed in reporter lysis buffer and the luciferase activity was measured using a Tecan Infinite M200 reader (Tecan, Männedorf, Switzerland).

Data and Statistical Analyses. The results represent two or three independent experiments (indicated in the figure captions). The data correspond to the means ± standard deviation (SD) of triplicate measurements. Standard error of the mean (SEM) was used in the analysis of variance. Statistical significance was tested by Student's *t* test or one-way analysis of variance (ANOVA) followed by Tukey's test. Differences were considered significant at $p < 0.05$. The dose−response curve fits and EC_{50} values were determined using GraphPad Prism 5 software (GraphPad Software, San Diego, CA, USA).

RESULTS

Selection of Human Cell Lines. Fifteen human cell lines were examined for the presence of endogenously expressed TRs. The Trα1 and TRβ1 isoforms were detected in the total protein extracts by Western blot analyses using primary antibodies against TRα1/α2 and TRα1/β1 and a secondary polyclonal goat anti-mouse IgG−HRP antibody. We preselected A2780, FTC-133, G-361, HEK293, and HepG2 cells,

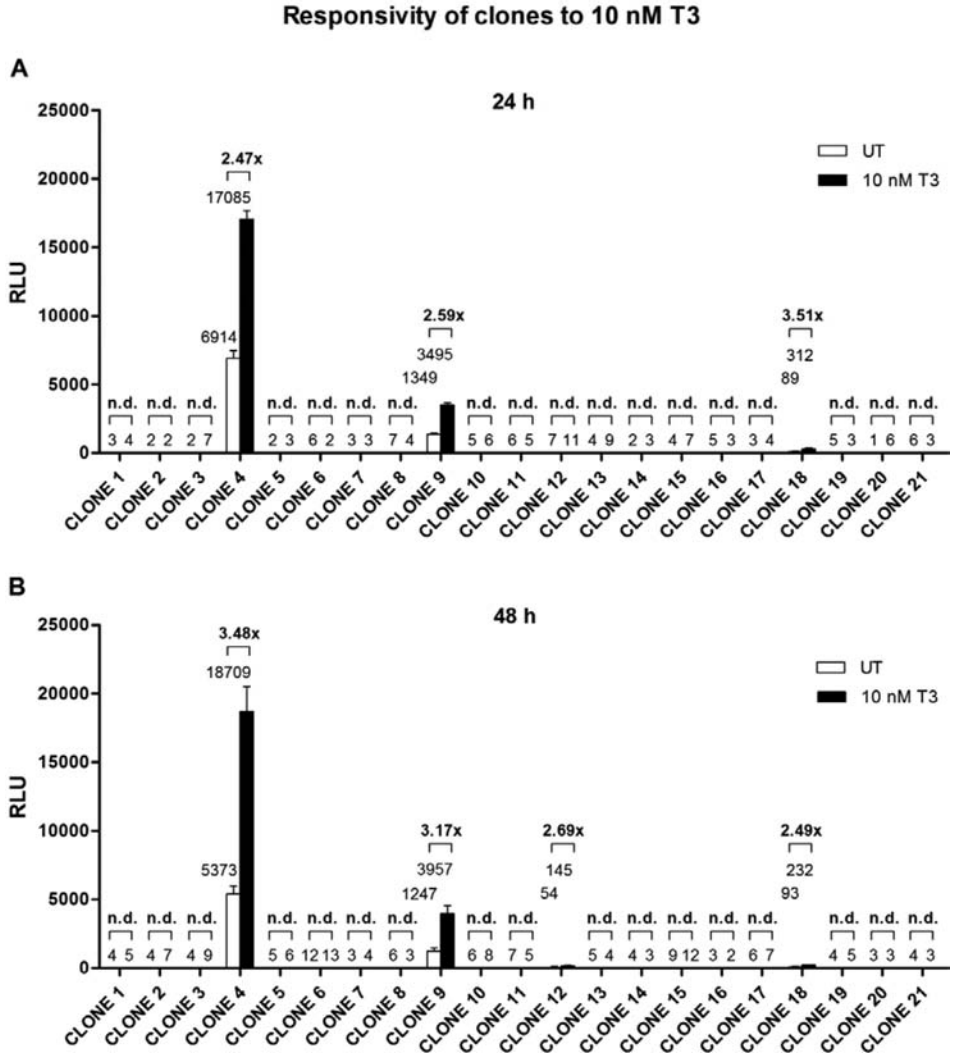

Figure 3. Response of stably transfected clones to T3. Cells seeded into 24-well plates were stabilized for 16 h and treated with vehicle (UT; 0.1% DMSO v/v) or 10 nM T3. After 24 h (A) and 48 h (B), the cells were lysed and the luciferase activity was measured. The data correspond to the means ± SD of triplicate measurements from two independent experiments and are expressed as the relative luciferase units (RLU). The fold induction for T3 over the DMSO-treated cells is indicated above the UT-T3 pair in the bar graph.

which were identified as the cell lines with the highest levels of endogenously expressed TRs (Figure 2A). Consequently, we confirmed the presence of the main TR heterodimer partner RXRα in all five lines using a primary antibody against RXRα and a goat anti-rabbit IgG−HRP antibody (Figure 2B). Because the presence of TRs in cells does not solely provide the functionality of the mechanism responsible for TR-dependent regulation of gene expression, qRT-PCR studies were performed in preselected cell lines. The changes in levels of the human *Spot 14* mRNA were measured after treatment of the cells with 0.2, 2, and 20 nM T3. We found that among the five preselected lines, the most prominent induction of *Spot 14* mRNA expression was in the FTC-133 and HEK293 cells, and the level of expression was T3 dose-dependent (Figure 2C). T3-induced *Spot 14* mRNA expression was observed also in HepG2 cells, but its intensity was lower (Figure 2C). According to these results, we designated the FTC-133, HEK293, and HepG2 cell lines to be suitable candidates that met the criteria for successful transfection with prepared reporter plasmid.

Transfection and Selection of Clones. Before stable transfection, the susceptibility of the selected cell lines to transfection with the pGL4.14-TRE reporter plasmid was tested. The results of the luciferase reporter assays from the transient transfections showed that luciferase activity was induced only in the transiently transfected HepG2 cells following the 10 nM T3 treatment, but not in the FTC-133 or HEK293 cells (data not shown). Therefore, the HepG2 human hepatocellular carcinoma cells were used to construct the stably transfected reporter cell line for the assessment of thyroid receptor transcriptional activity. After transfecting the HepG2 cells with the pGL4.14-TRE reporter plasmid and cultivating them under the selection pressure of hygromycin B, we obtained 21 hygromycin B-resistant, stably transfected clones. All isolated clones were tested for their responsivity to T3. We found that after 24 and 48 h of treatment with 10 nM T3, luciferase activity was significantly induced in only three clones, ranging from 2.5- to 3.5-fold induction (Figure 3). However, the relative luciferase units (RLU) in clones 9 and 18 were too low for their practical use in the experiments; thus, clone 4 (termed PZ-TR) was selected as the most reliable candidate and was further characterized.

DOI: 10.1021/acs.jafc.5b01519
J. Agric. Food Chem. 2015, 63, 7074−7083

Characterization of PZ-TR Cell Line. In the first step, we characterized the dose-dependent response of the PZ-TR cell line to T3. PZ-TR cells were treated with increasing concentrations of T3 (0.1−1000 nM), which yielded typical sigmoid logarithmic dose−response curves (Figure 4).

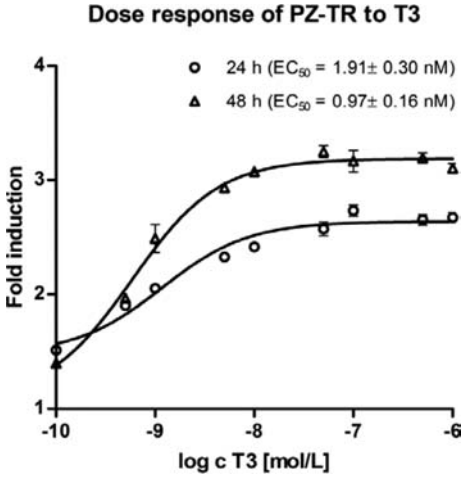

Figure 4. Dose−response of the PZ-TR cell line to T3. Cells seeded into 24-well plates were stabilized for 16 h and treated with vehicle (0.1% DMSO v/v) or T3 (0.1−1000 nM) for 24 and 48 h. After the treatments, the cells were lysed and the luciferase activity was measured. The data represent the means ± SD of triplicate measurements from three independent experiments and are expressed as the fold induction of T3 over the DMSO-treated cells.

Prolonged exposure of the cells to T3 (48 h) resulted in a higher maximum induction of luciferase activity (3.25-fold) compared to cells treated for 24 h (2.73-fold). The T3-induced luciferase activity started to reach its maximum at concentrations of 10−50 nM, and the calculated EC_{50} values corresponded to 1.91 ± 0.30 nM for the 24 h treatment and 0.97 ± 0.16 nM for the 48 h treatment.

As a second parameter, the PZ-TR cell line was cryopreserved to test the effects of this treatment of cellular functionality. The cells were frozen in fetal bovine serum and the cryoprotectant DMSO using a standard procedure and were stored for 1 week in liquid nitrogen. The thawed cells were treated with 10 nM T3 for 24 h, and the luciferase activity was measured. We found that after the freeze−thaw cycle, the RLU values in the cryopreserved cells decreased slightly, but the luciferase activity was induced to the same level as in the fresh cells (Figure 5).

The maintenance of luciferase inducibility is another important feature of the newly prepared reporter cell line that is required for its practical use. Therefore, we studied the ability of PZ-TR cell line to respond to T3 over a long period. The cells were treated with 10 nM T3 for 24 h every third passage, and the luciferase activity was measured. The induction of luciferase activity was stable for 54 days (corresponding to 12 passages), and there was no substantial decrease in the T3-induced luciferase activity in both the absolute RLU values and the fold induction (Table 1).

Finally, we compared the morphology of the stably transfected PZ-TR cells and parental HepG2 cells. We did not observe any significant differences in the morphology of the PZ-TR and HepG2 cells, even after maintaining the cells in culture for 10 passages (Figure 6).

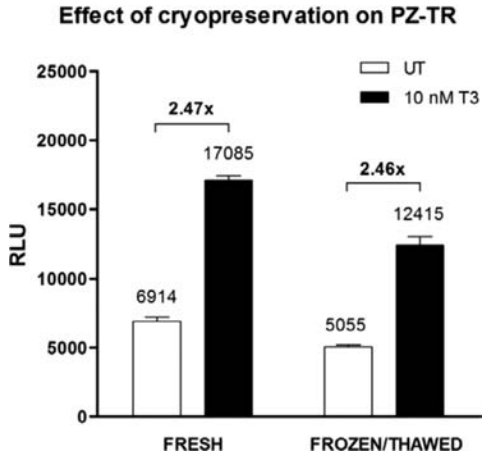

Figure 5. Effect of cryopreservation on functionality of the PZ-TR cell line. Fresh cells and frozen−thawed cells were grown on 24-well plates, stabilized for 16 h, and treated with vehicle (UT; 0.1% DMSO v/v) or 10 nM T3. After the treatments, the cells were lysed and the luciferase activity was measured. The data correspond to the means ± SD of triplicate measurements from two independent experiments and are expressed as relative luciferase units (RLU). The fold induction for T3 over the DMSO-treated cells was calculated, and the value is indicated above the UT-T3 pair in the bar graph.

Table 1. Maintenance of Luciferase Inducibility by 10 nM T3

passage no.	days in culture	RLU ± SD	fold
0	4	12415 ± 1109	2.46
3	16	9205 ± 68	2.57
6	29	11344 ± 954	2.73
9	41	8944 ± 520	2.42
12	54	8954 ± 276	2.45

Responsiveness of the PZ-TR Cell Line to Diverse Hormonal Treatments. Thyroid receptors belong to the subfamily of nuclear receptors, and their activity is regulated by thyroid hormone ligand binding. Therefore, it was necessary to demonstrate the ability of PZ-TR cells to be specifically induced by TH and exclude the possibility of luciferase activity induction by other hormones. The PZ-TR cells were treated with steroid hormones and ligands for nuclear receptors in concentrations ranging from 0.1 to 10 μM for 24 h. We did not observe any substantial changes in the luciferase activity after the application of corticosteroids (corticosterone, cortisol, betamethasone, and aldosterone), sex steroid hormones (progesterone, testosterone, estradiol, and diethylstilbestrol), and VDR ligands (25-hydroxyvitamin D3 and vitamin D3) (Figure 7). The application of 9-*cis*-retinoic acid (cisRA) induced a significant increase of luciferase activity in the PZ-TR cells. The luciferase activity was dose-dependently induced and ranged from 1.61-fold at 1 μM to 2.27-fold at 10 μM (Figure 7). These values corresponded to 56% (1 μM) and 83% (10 μM) of the level of induction obtained after treatment with 10 nM T3. These findings were in accord with our expectation that cisRA, a ligand of RXR (the main heterodimer partner of TR), might partially induce luciferase activity in the PZ-TR cells. Surprisingly, increased luciferase activity was detected also after treatment with all-*trans*-retinoic acid (transRA). The luciferase activity was again dose-dependently induced, but the intensity was lower than that of cisRA, ranging from 1.26-fold at 1 μM to 1.82-fold at 10 μM (Figure 7). These values corresponded to

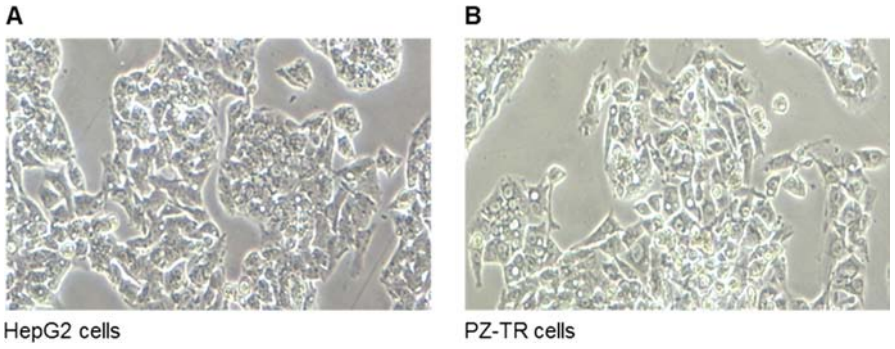

Figure 6. Morphology of the HepG2 and PZ-TR cell lines. Phase contrast micrographs of the parental HepG2 cells at the eighth passage (A) and the PZ-TR reporter cells at the 10th passage (B).

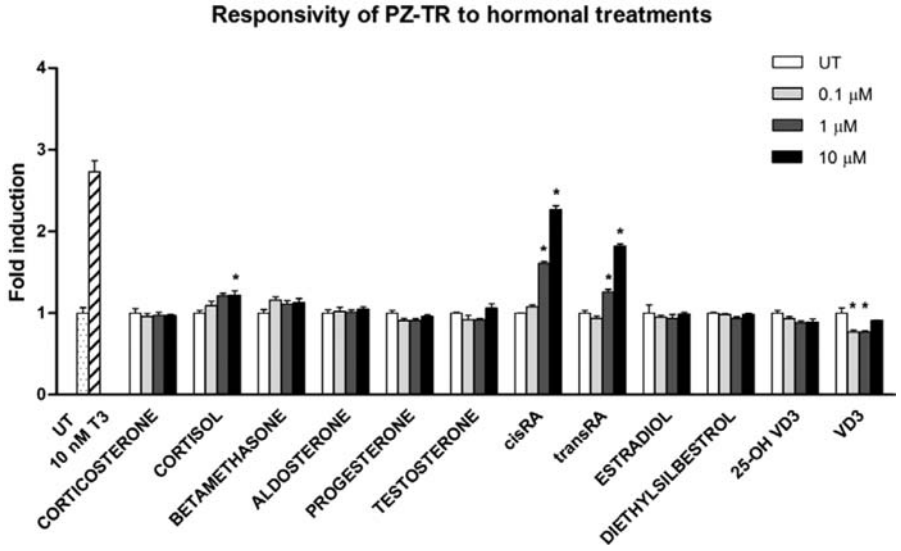

Figure 7. Response of the PZ-TR cell line to hormones. Cells seeded into 24-well plates were stabilized for 16 h and treated with vehicle (UT; 0.1% DMSO v/v) or the different hormones for 24 h. After the treatments, the cells were lysed and the luciferase activity was measured. The data represent the means ± SEM of triplicate measurements from three independent experiments and are expressed as the fold induction of the hormone-treated cells over the DMSO-treated cells. (∗) Values are significantly different from the vehicle-treated cells ($p < 0.05$) as determined by ANOVA followed by Tukey's test.

46% (1 μM) and 67% (10 μM) of the levels of induction obtained after treatment with 10 nM T3.

Responsivity of the PZ-TR Cell Line to Retinoic Acids. To explain the luciferase activity that was induced in the PZ-TR cell line after RA application, we studied the effect of RAs in more detail. PZ-TR cells were treated with cisRA and transRA in concentrations of 0.1, 1, and 10 μM, alone and in combination with 10 nM T3. After 24 h of treatment, both cisRA and transRA induced a significant increase in luciferase activity in the PZ-TR cells at 1 and 10 μM (Figure 8), similar to previous experiments (see Responsiveness of the PZ-TR Cell Line to Diverse Hormonal Treatments.). The luciferase activity was dose-dependently induced, with the highest intensities of 2.27-fold at 10 μM cisRA and 2.03-fold at 10 μM transRA. These values corresponded to 93% (10 μM cisRA) and 83% (10 μM transRA) of the level of induction obtained after treatment with 10 nM T3. The luciferase activity was induced 2.45-fold in the PZ-TR control cells treated with 10 nM T3 (Figure 8).

In cells treated for 24 h with combinations of RAs and 10 nM T3, we observed a slight inhibition of luciferase activity by 0.1 μM cisRA and 0.1 μM transRA compared to the control cells treated with 10 nM T3 (Figure 8). However, the differences were statistically significant only in the case of cisRA. The 2.11-fold (0.1 μM cisRA + 10 nM T3) and 2.35-fold inductions (0.1 μM transRA + 10 nM T3) corresponded to 86 and 96% of the level of induction obtained after treatment with 10 nM T3, respectively. In contrast, 10 μM cisRA and 10 μM transRA enhanced the effect of 10 nM T3, with 3.15-fold (10 μM cisRA + 10 nM T3) and 2.79-fold (10 μM transRA + 10 nM T3) inductions, representing 129 and 114% of the level of induction of the control cells treated with 10 nM T3, respectively (Figure 8). Application of 1 μM cisRA and 1 μM transRA in combination with 10 nM T3 did not significantly affect the induction of luciferase activity compared to the 10 nM T3-treated PZ-TR cells (Figure 8).

To determine whether RAs are able to trigger the expression of TR-inducible genes or if this phenomenon is specific only for the induction of luciferase activity in the novel PZ-TR cell line, qRT-PCR studies were performed to monitor the changes in the expression of human *Spot 14* gene. The levels of the *Spot 14* mRNA were measured 24 h after treatment of the cells with 0.1, 1, and 10 μM T3. We found that both cisRA and transRA induced the expression of the *Spot 14* gene in the PZ-TR cells (Figure 9). Whereas significant increases of the mRNA levels were observed only in the cisRA-treated cells at the 1 and 10

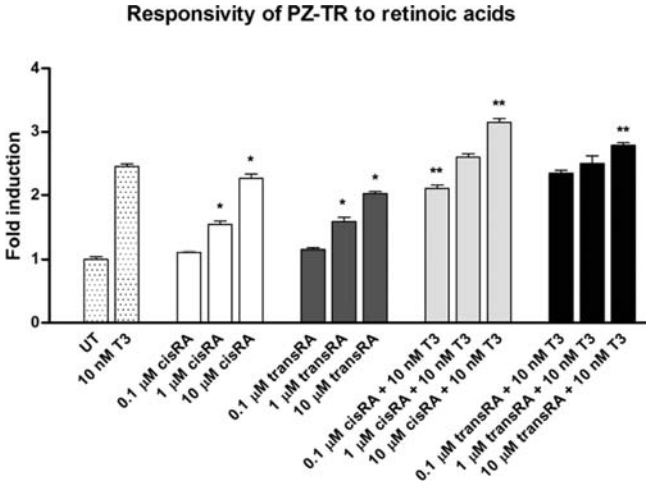

Figure 8. Response of the PZ-TR cell line to retinoic acids. Cells seeded into 24-well plates were stabilized for 16 h and treated for 24 h with vehicle (UT; 0.1% DMSO v/v), 9-*cis*-retinoic acid, or all-*trans*-retinoic acid, alone and in combination with 10 nM T3. The cells were lysed, and the luciferase activity was measured. The data represent the means ± SEM of triplicate measurements from three independent experiments and are expressed as the fold induction over the DMSO-treated cells. (∗) Values are significantly different from the vehicle-treated cells ($p < 0.05$) as determined by ANOVA followed by Tukey's test. (∗∗) Values are significantly different from the 10 nM T3-treated cells ($p < 0.05$) as determined by ANOVA followed by Tukey's test.

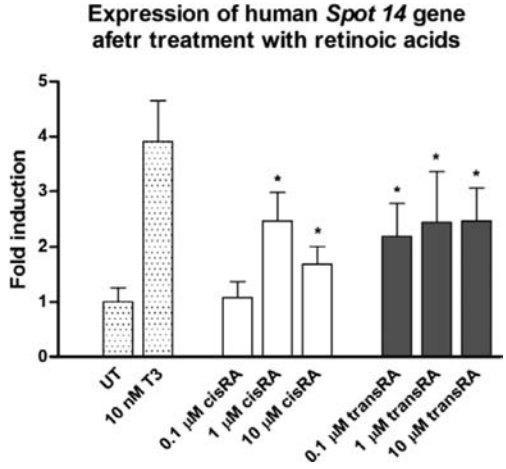

Figure 9. Quantitative real-time PCR analysis of the human *Spot 14* mRNA levels following retinoic acid treatment in the PZ-TR cell line. Cells were treated with vehicle (UT; 0.1% DMSO v/v), 9-*cis*-retinoic acid, or all-*trans*-retinoic acid for 24 h. The measurements were normalized to the GAPDH mRNA levels. The data are the means ± SD of triplicate measurements from three independent experiments and are expressed as the fold induction over the DMSO-treated cells. (∗) Values are significantly different from the vehicle-treated cells ($p < 0.05$) as determined by Student's t test.

μM concentrations (2.46- and 1.69-fold, respectively), transRA induced a significant increase of the mRNA levels at all tested concentrations. The transRA-induced expression of the *Spot 14* mRNA was dose-dependent, with 2.18-fold (0.1 mM), 2.44-fold (1 mM), and 2.46-fold (10 mM) inductions. Although the increased mRNA levels reached a maximum of 62−63% (1 μM cisRA, 1 μM transRA, and 10 μM transRA) of the mRNA level detected after treatment of the PZ-TR cells with 10 nM T3, we provide clear evidence that the expression of human *Spot 14* (TH-regulated gene) can be activated by both cisRA and transRA.

Effect of Organic Tin Compounds on the Transcriptional Activity of TR. We studied the effect of two groups of organic tin compounds on the transcriptional activity of TR using the novel PZ-TR reporter cell line. The first group was represented by the tributyltin derivatives TBTC, TBTB, TBTI, and TBTOH. PZ-TR cells were treated with the studied compounds at concentrations of 1, 10, and 100 nM (higher concentrations had a strong cytotoxic effect, data not shown) for 24 h. After application of all four tested tributyltin derivatives, we observed a significant increase of luciferase activity at the 10 and 100 nM concentrations (Figure 10A). The luciferase activity was dose-dependently induced and ranged from 1.60- to 1.90-fold for TBTC, from 1.29- to 1.30-fold for TBTB, from 1.33- to 1.48-fold for TBTI, and from 1.37- to 1.53-fold for TBTOH. These values corresponded to 36−54% (TBTC), 17−18% (TBTB), 20−29% (TBTI), and 22−32% (TBTOH) of the level of induction attained after treatment with 10 nM T3.

In parallel experiments, we studied the possible effects of the tributyltin derivatives on the transcriptional activity of TR in the presence of T3, the natural ligand of TR. PZ-TR cells were treated with the examined compounds at concentrations of 1, 10, and 100 nM in combination with 10 nM T3 for 24 h. After the treatments, we observed only slight and statistically insignificant changes in luciferase activity compared to the control cells treated with 10 nM T3, in which the luciferase activity was induced by approximately 2.68-fold (Figure 10B). The luciferase activity was induced from 2.58- to 2.84-fold for TBTC, from 2.82- to 2.91-fold for TBTB, from 2.87- to 2.91-fold for TBTI, and from 2.98- to 3.07-fold for TBTOH, and these inductions corresponded to 94−110% (TBTC), 108−114% (TBTB), 111−114% (TBTI), and 118−123% (TBTOH) of the level of induction attained after treatment with 10 nM T3 alone.

The second group of examined compounds contained three triphenyltin derivatives, TPTC, TPTH, and TPTOH. The PZ-TR cells were similarly treated with the studied compounds in concentrations of 1, 10, and 100 nM (higher concentrations had a strong cytotoxic effect, data not shown) for 24 h. We observed an increase in luciferase activity after application of all three tested compounds (Figure 10C). The luciferase activity was dose-dependently induced and reached highest statistically significant values at the 100 nM concentration. The luciferase activity was induced 1.57-fold for TPTC, 1.68-fold for TPTH, and 1.70-fold for TPTOH. These values corresponded to 33% (TPTC), 39% (TPTH), and 40% (TPTOH) of the level of induction attained after treatment with 10 nM T3.

In parallel experiments, the PZ-TR cells were treated with the tested compounds in concentrations of 1, 10, and 100 nM in combination with 10 nM T3 for 24 h. After the treatments, we observed an increase of luciferase activity compared to the control cells treated with 10 nM T3, in which the luciferase activity was induced by approximately 2.74-fold (Figure 10D). The differences were more prominent than in the cells treated with the tributyltin derivatives. The luciferase activity was significantly induced by 3.26−3.36-fold for TPTC, 3.29−3.54-fold for TPTH, and 3.40−3.47-fold for TPTOH, and these values corresponded to 130−136% (TPTC), 132−146% (TPTH), and 138−142% (TPTOH) of the level of induction attained after treatment with 10 nM T3 only.

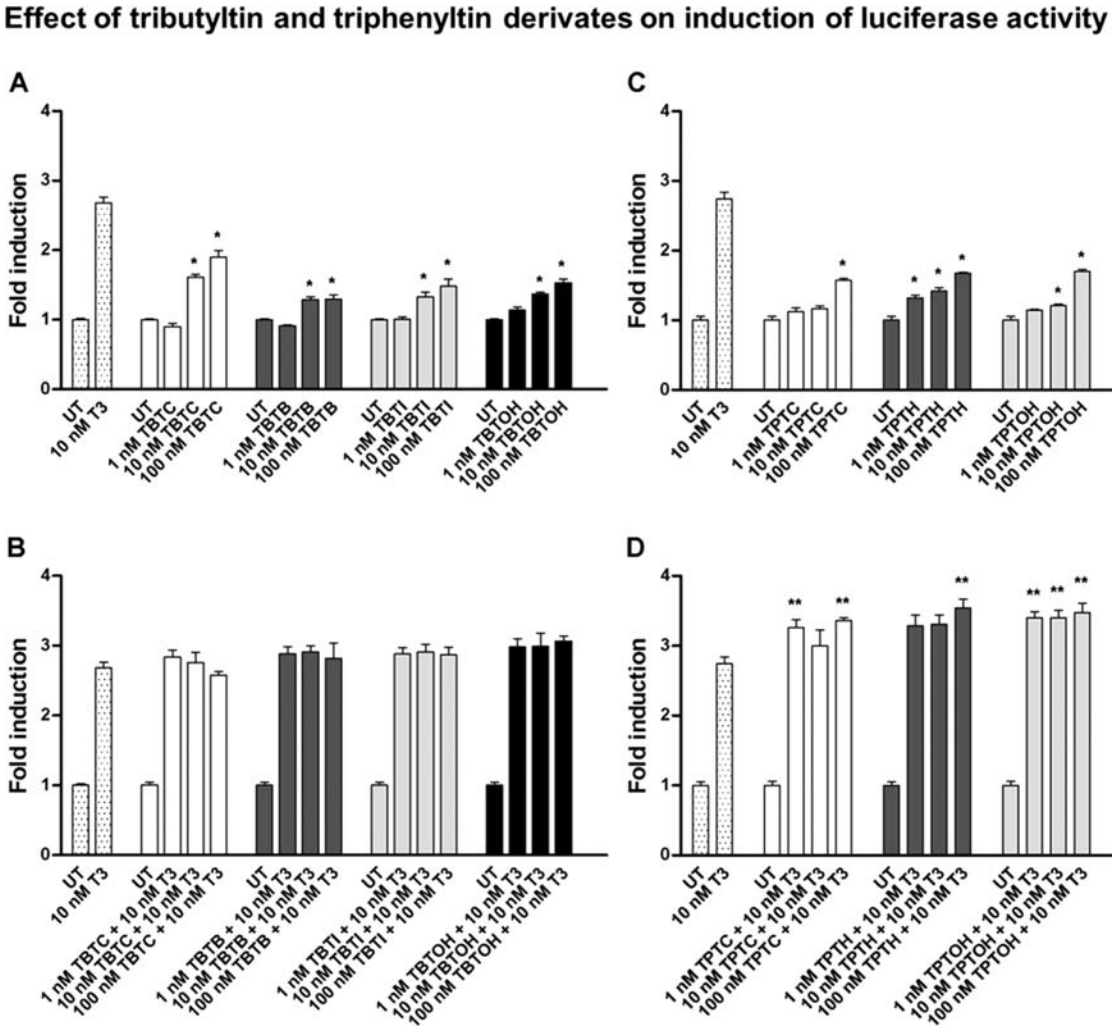

Figure 10. Effects of organic tin compounds on the transcriptional activity of TR in the PZ-TR reporter cell line. Cells seeded into 24-well plates were stabilized for 16 h and treated with vehicle (UT; 0.1% DMSO or ethanol v/v), tributyltin derivatives (TBTC, TBTB, TBTI, TBTOH) (A), or triphenyltin derivatives (TPTC, TPTH, TPTOH) (C), alone and in combination with 10 nM T3 (B, D). After 24 h, the cells were lysed and the luciferase activity was measured. The data represent the means ± SEM of triplicate measurements from three independent experiments and are expressed as the fold induction over the vehicle-treated cells. (∗) Values are significantly different from the vehicle-treated cells ($p < 0.05$) as determined by ANOVA followed by Tukey's test. (∗∗) Values are significantly different from the 10 nM T3-treated cells ($p < 0.05$) as determined by ANOVA followed by Tukey's test.

DISCUSSION

It is known that a large group of natural and synthetic compounds, generally termed endocrine disruptors, can interfere with the endocrine system and disrupt the homeostasis of the processes that regulate hormones in humans. Several in vitro models have been developed to screen for substances that may potentially disrupt the hormone system.[13] Among them, reporter gene-based assays have been widely used as reliable tools to detect various biologically active compounds in many environmental and biological applications. The construction of reporter gene systems is based on transient or stable transfection of cells with a reporter plasmid that contains a domain that binds a hormonal receptor (response element) and a reporter gene located downstream. Different genes, such as those coding for proteins such as luciferase,[14] galactosidase,[15] chloramphenicol acetyl transferase,[16] and green fluorescent protein,[17] are usually used as reporter genes because their activities can easily be measured. There is also a large diversity in the selection of cells or cell lines used for transfection. There are many paper describing the development of gene reporter systems derived from yeast,[15,18,19] amphibian,[6] mammalian,[7−10,20,21] or human[14,21−23] cell lines for screening endocrine disruptors. Because gene reporter systems play such a crucial role, the presence of a functional receptor and the high variability and natural characteristics of the parental cell lines used for construction of such systems often result in the necessity of additional cotransfections. In particular, the introduction of an expression plasmid encoding the receptor of interest is required in yeast-derived reporter systems.[15,17,19] However, cotransfection with the appropriate receptor construct is also essential in animal[9,20,21] and human[16,22,23] cell line-derived gene reporter systems when the parental cells lack adequate endogenous expression of the receptor. These manipulations may lead to changes in the stoichiometric ratio between the introduced receptor protein, which is usually overexpressed, and other transcriptional regulators, and does not reflect the natural situation.

Although the construction of a stable gene reporter cell line is time- and material-consuming process, the prospective long-

term advantages of this type of system are indisputable. Stable gene reporter systems are characterized by highly sensitive assays, good reproducibility of the results, homogeneity of the data, and no need for additional normalization, which permits high-throughput and low-cost experimentation. Large-scale stable reporter cell lines have been constructed for the detection of potential hormonal disruptors using mainly corticosteroids and sex steroid hormones. In an effort to expand the field of research of endocrine disruptors to the thyroid axis, several stable luciferase reporter systems have been developed over the past decade. The thyroid hormone-responsive gene reporter cell line XL58-TRE-Luc was constructed by introducing LV-TRE-Luc, a self-inactivating lentivirus vector containing the luciferase reporter gene downstream of the *Xenopus laevis* TRE, into *Xenopus laevis* XL58 cells.[6] XL58-TRE-Luc was used by the authors to study the effects of chlorinated derivatives of bisphenol A on the TR transcriptional activity, revealing their possible influence on TR-regulated gene expression. Soon after, Jugan and co-workers developed a new stable reporter cell line, PC-DR-LUC, which allowed them to measure the effects of putative thyroid-disrupting chemicals on the modulation of TRα1 transcriptional activity.[7] The reporter cell line was derived from rat PC12 cells expressing TRα1 of avian origin by transfecting the cells with a pGL3-DR4 reporter plasmid carrying four TRE half-sites separated by four nucleotides located upstream of the luciferase gene. Using the PC-DR-LUC cell line, the authors determined the influence of several halogenated phenolic and phenol compounds on the transcriptional activity of TRα1. Later, the PC-DR-LUC cell line was successfully used to evaluate the thyroid-disrupting potential of water from wastewater treatment plants, rivers, and drinking water supplies.[24] Recently, a novel reporter cell line, GH3-TRE.Luc, has been developed to detect TR disruptors.[8] The rat GH3 cell line constitutively expressing both isoforms of TR was stably transfected with the pGL4CP-SV40-2xtaDR4 construct containing two TREs upstream of the firefly luciferase gene. The authors used the GH3-TRE reporter cell line to test hydroxylated polybrominated diphenyl ethers, hydroxylated polychlorinated biphenyls, and halogenated derivatives of bisphenol A as chemicals with potential thyroid-disrupting effects.

Because TH-mediated signaling in amphibian and rodent cells can be substantially different from signaling in human cells,[25] it is of great interest to establish a reporter cell line to assess the thyroid receptor transcriptional activity based on the human system. We developed and described a new stably transfected gene reporter cell line, PZ-TR. The PZ-TR cell line presented here is an exclusively human system derived from HepG2 human hepatocellular carcinoma cells, which endogenously expresses both isoforms of TR (Figure 2). The stable transfection with a reporter gene driven by TRE from the human gene needs no additional cotransfections with a TR expression vector, guarantees the preservation of the stoichiometric ratio between the TR receptor and other transcriptional regulators, and reflects natural situations. These characteristics demonstrate significant advancements for the PZ-TR cell line compared to as yet developed cell lines.

and Leydig cells in the male offspring, leading to disorganization in seminiferous tubules and reductions in daily sperm production, sperm motility, and Sertoli cell number in mice,[37] and male mice exposed to TiO_2 NPs by intraperitoneal injection showed significant decreases in sperm numbers and motility, and elevated abnormal sperm and germ cell apoptosis in the testes.[38] Gao et al. reported that TiO_2 NPs can be translocated to the ovary and testis, leading to injuries of both organs, lower fertility, sperm concentration, and sperm motility, higher malformation rates of sperm, and alter gene expression profile in the damaged mouse ovary and testes.[39,40] The reproductive system of male mammals mainly consists of the testis, epididymis, and ductus deferens. The testis produces spermatozoa, and the epididymis stores the spermatozoa and completes sperm maturation. While spermatogenesis is a complex process of multi phase, activities of testicular marked enzymes, including lactate dehydrogenase (LDH), sorbitol dehydrogenase (SODH), succinate dehydrogenase (SDH), glucose-6-phosphate dehydrogenase (G-6PD), acid phosphatase (ACP), alkaline phosphatase (AKP), nitric oxide synthase (NOS), are related to this process in the testes.[41−46] In addition, the ion channels are suggested to associate with various sperm functions such as spermatogenesis, sperm activation, and sperm−egg interaction. As important enzymes to keep energy utilization of spermatogenesis, ATPases (including Ca^{2+}-ATPase, Ca^{2+}/Mg^{2+}-ATPase, and Na^+/K^+-ATPase) are key ion pumps on the plasma membrane to maintain cell membrane structure and keep physiological and biochemical activities in the testes.[47] We hypothesize that the lowered sperm numbers and sperm motility and the increased percentage of abnormal sperm caused by exposure to TiO_2 NPs may be associated with testicular biochemical dysfunctions. To date, no studies have examined whether TiO_2 NPs induce testicular biochemical dysfunction by assessing the activities of LDH, SODH, SDH, G-6PD, ACP, AKP, NOS, Ca^{2+}-ATPase, Ca^{2+}/Mg^{2+}-ATPase, and Na^+/K^+-ATPase in the damaged testes in male mice. In addition, many conditions or events associated with male infertility can induce oxidative stress and germ cell apoptosis. Given that spermatozoa are rich in polyunsaturated fatty acids, they are very susceptible to attack by reactive oxygen species (ROS).[48,49] Thus, the aims of the current study were to test the hypothesis that TiO_2 NPs induce biochemical dysfunction and oxidative stress in the damaged testes of mice by causing alterations in the enzymatic activities and ROS production. In addition, the mechanisms of TiO_2 NP-inhibited spermatogenesis in mouse testes were evaluated.

MATERIALS AND METHODS

Chemicals. The preparation of TiO_2 NPs was described and fully characterized in Yang's study[50] and our previous studies, suggesting anatase for phase, 5−6 nm for particle size, 174.8 m^2/g for surface area, mainly 294 nm for mean hydrodynamic diameter, and 9.28 mV for zeta potential, respectively.[50,51]

Animals and Treatment. 160 ICR (Imprinting Control Region) male mice, aged 5 weeks with a mean body mass of 22 ± 2 g, were purchased from the Animal Center of Soochow University (Jiangsu, China). All procedures performed on the animals were approved by the Institutional Animal Care and Use Committee of Soochow University, and thus within the guidelines for human care of laboratory animals for scientific purposes. Both water and food were provided ad lib.

Hydroxypropylmethylcellulose (HPMC) K4M (Sigma-Aldrich, St. Louis, MO, USA) of concentration 0.5% was used as a suspending agent. TiO_2 NP powder was dispersed onto the surface of 0.5% w/v HPMC solution, and then the suspending solutions containing TiO_2 NPs were treated ultrasonically for 30 min and mechanically vibrated for 5 min. During the experiment, the mice were randomly divided into four groups (n = 40 each), including a control group (treated with 0.5% w/v HPMC) and three experimental groups (2.5, 5, or 10 mg/kg BW of TiO_2 NPs). For dose selection, we consulted a report of the World Health Organization from 1969. According to the report, the LD 50 of TiO_2 for rats is >12 g/kg body weight after oral administration. In addition, the quantity of TiO_2 NPs does not exceed 1% by weight of the food according to U.S. federal regulations. In the present study, we selected 2.5, 5, and 10 mg/kg TiO_2 NPs, which were given to mice by intragastric administration every day. They were equal to about 0.15−0.7 g of TiO_2 NPs for humans with 60−70 kg body weight with such exposure, which are relatively safe doses. All mice were weighed, and the TiO_2 NP suspensions of different doses were administered to mice by intragastric feeding every day for 60 days. Food and water intake were carefully recorded at the last week in the second month. Food and water intake were calculated according to the Drozdz method.[52]

Testicular and Epididymis Collection. After the 60-day study period, all mice were weighed and lightly anesthetized with ether, and the testes and epididymis were quickly removed and placed on ice. After the body and testes were weighed, the relative testicular weight was calculated as the ratio of testis (wet weight, mg) to body weight (g). Fresh testes and epididymis from 5 mice in each group were quickly soaked in 10% formaldehyde solution for histopathological examination. The remaining fresh testes were quickly stored in liquid nitrogen and subsequently assayed for enzymatic activity and oxidative stress.

Semen Evaluation. Each left cauda epididymis was dissected and incised using a pin in 1.5 mL of Dulbecco's modified Eagle's medium with 10 mg/mL bovine serum albumin and then incubated for several minutes to release the sperm. Measurements of total sperm concentrations, sperm motility, and percentage of abnormal sperm were described in Gao's study.[40]

Histopathological Evaluation. After fixation in 10% neutral formalin and being embedded in paraffin, testes and epididymis from 5 mice in each group were sliced at a thickness of 5 μm, and placed on separate glass slides. After hematoxylin and eosin staining, the testis and epididymis simples were routinely evaluated by a histopathologist unaware of the treatments for light microscopy (U-III Multipoint Sensor System; Nikon, Tokyo, Japan).

Assay of Enzyme Activities. For enzymatic activity determinations, the testes were homogenized in 10 volumes of 0.15 M NaCl with a certain quantity of the homogenate. The activities of LDH, SODH, SDH, G-6PD, ACP, AKP, total nitric oxide synthase (TNOS), Ca^{2+}-ATPase, Ca^{2+}/Mg^{2+}-ATPase, and Na^+/K^+-ATPase in the testes were spectrophotometrically measured with a commercially available apparatus (Nanjing Jiancheng Bioengineering Institute, Jiangsu, China).

Oxidative Stress Assay. Reactive oxygen species (ROS) ($O_2^{\bullet-}$ and H_2O_2) production and levels of malondialdehyde (MDA), protein carbonyl (PC), and 8-hydroxydeoxyguanosine (8-OHdG) in the testicular tissues (n = 5 in each group) were assayed using commercial enzyme-linked immunosorbent assay kits (Nanjing Jiancheng Bioengineering Institute, Jiangsu, China) according to the manufacturer's instructions.

Statistical Analysis. All data are expressed as the mean ± standard deviation (SD). Statistical analysis was performed using SPSS 19 software (SPSS, Inc., Chicago, IL, USA), and statistical comparisons were analyzed using one way ANOVA followed by Tukey's HSD post hoc test. Differences with P values of less than 0.05 were considered significant.

RESULTS

Daily Food and Water Intake. The daily food and water intake of male mice after intragastric feeding with TiO_2 NPs at the last week in the second month is exhibited in Figure 1, suggesting that the daily food intake and water intake due to

DOI: 10.1021/acs.jafc.5b02652
J. Agric. Food Chem. 2015, 63, 7084−7092

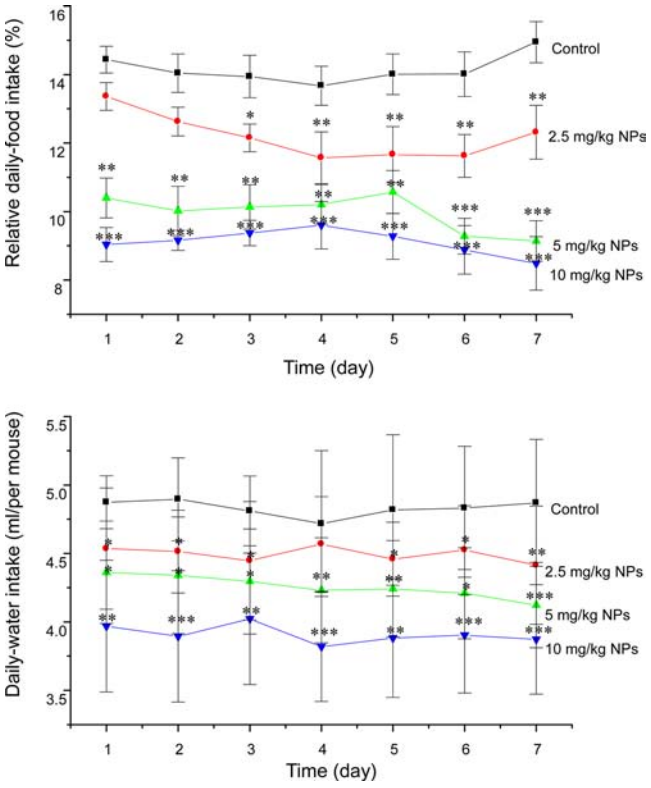

Figure 1. Daily food intake and water intake of male mice after intragastric feeding with TiO_2 NPs at the last week in the second month. *, $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$. Values represent means ± SD ($n = 10$).

TiO_2 NP exposure (2.5, 5, or 10 mg/kgbw) were decreased by 7.44% to 43.24% for daily food intake ($P < 0.05$), and by 3.82% to 16.41% for daily water intake ($P < 0.05$), respectively.

Body Weight and Testis Indices. The mice were weighed and sacrificed, and testis was also collected and weighed following the 60-day treatment with TiO_2 NPs. As shown in Table 1, with increasing TiO_2 NP dose, significant reductions in final body weight, testicular weight, and relative testicular weight were observed, e.g., final body weight, testicular weight, and relative testicular weight were reduced by 5.92%, 15.29%, and 19.6%, by 12.9%, 32.26%, and 41.94%, and by 7.41%, 20.0%, and 27.81% ($P < 0.05$), respectively. It suggested that decreases of testicular weight and relative testicular weight caused by TiO_2 NPs were higher than that of final body weight.

Semen Assay. Sperms from the cauda epididymis were collected, and the total sperm concentrations, sperm motility, and percentage of abnormal sperm were evaluated. With increasing TiO_2 NP dose (2.5, 5, or 10 mg/kgbw), sperm numbers and sperm motility were remarkably reduced by 29.73%, 40.54%, and 48.65% and by 7.45%, 27.65%, and 41.49%, respectively; whereas abnormal sperm was significantly elevated by 3.78-, 5.59-, and 11.64-fold in the TiO_2 NP-exposed groups (Figure 2, $P < 0.05$), respectively. In addition, we

Histopathological Evaluation. Testis and epididymis histopathological images are shown in Figures 4 and 5.

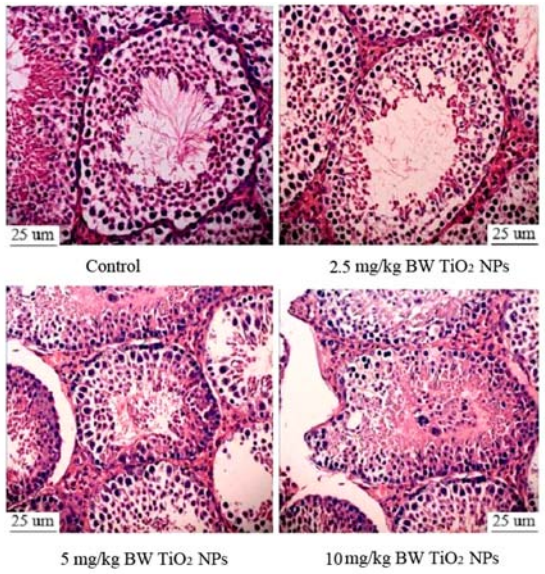

Figure 4. Histopathological observation of testis of male mice following exposure to TiO_2 NPs for 60 consecutive days. 2.5 mg/kg BW TiO_2 NPs: fragmentary seminiferous tubule and immature sperm. 5 mg/kg BW TiO_2 NPs: decreased seminiferous tubule epithelium layer and degeneration, sperm breakages, and spano-sperm within the lumen. 10 mg/kg BW TiO_2 NPs: decreased seminiferous tubule epithelium layer and degeneration, androgone fusion and pycnosis, and spano-sperm within the lumen.

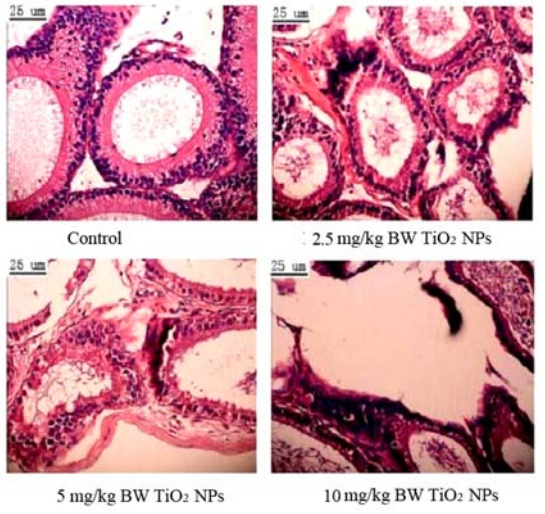

Figure 5. Histopathological observation of epididymis of male mice following exposure to TiO_2 NPs for 60 consecutive days. 5 mg/kg BW TiO_2 NPs: cell pycnosis, necrosis and abscission, spano-sperm within the lumen. 5 mg/kg BW TiO_2 NPs: cell pycnosis, necrosis and abscission, and spano-sperm within the lumen. 10 mg/kg BW TiO_2 NPs: severe destruction of tissue structure, and spano-sperm within the lumen.

Unexposed testis and epididymis samples presented intact architecture and regularly arranged cells, while those from the mice exposed to increasing concentrations of TiO_2 NPs exhibited severe pathological changes, including lowered seminiferous tubule epithelium layer and degeneration, reductions of Leydig cells and mature sperm within the lumen, immature sperm, sperm breakages, androgone fusion and/or pycnosis, and spermatolysis (Figure 4), cell pycnosis, necrosis and abscission, severe disorganization of tissue, and spano-sperm within the lumen (Figure 5).

Activity Testicular Marked Enzyme. The activities of testicular marked enzymes in mouse testis after intragastric administration with TiO_2 NPs for 60 consecutive days are presented in Table 2 and Figure 6. As suggested, with

OHdG levels were examined. As shown in Table 3, $O_2^{\bullet-}$, H_2O_2, MDA, and PC levels were significantly elevated, with increases of 16.15%, 96.02%, and 110.52% for $O_2^{\bullet-}$, 35.87%, 47.0%, and 104.11% for H_2O_2, 38.96%, 84.34%, and 118.07% for MDA, and 20.98%, 46.74%, and 108.1% for PC ($P < 0.05$) with increasing TiO_2 NPs dose, respectively. A marked increase in testicular 8-OHdG level was observed, with increases of 89.81%, 108.33%, and 183.33%, in the TiO_2 NP-treated groups ($P < 0.05$), respectively, indicating that excessive ROS production led to DNA damage in the testis due to TiO_2 NP-induced toxicity.

DISCUSSION

As an integral part of the nanotoxicology, the reproductive and developmental toxicity due to exposure to TiO_2 NPs has been demonstrated.[32,39,40,53−56] As suggested, testis is highly sensitive to toxic and hazardous nanomaterials; even when extremely low amounts of the substances are in the testis, they will still cause severe damage.[55] In testicular injuries, suppression of spermatogenesis and/or decreased sperm production have been suggested to be a significant state[56] and nanoparticles could affect spermatogenesis.[32,40,53] Our findings indicated that exposure to TiO_2 NPs for 60 consecutive days decreased daily food and water intake (Figure 1), final body weight testicular weight, relative testicular weight (Table 1), sperm concentrations and motility, increased the percentage of abnormal sperm (Figure 2), and caused sperm lesions in the cauda epididymis (Figure 3), impaired testis and epididymis architecture, and presented severe histopathological changes (Figures 4, 5); this is consistent with our previous reports.[40,53] Importantly, the present study observed that reductions of final body weight were lower than those of testicular weight, and relative testicular weight under TiO_2 NPs, indicating that exposure to TiO_2 NPs resulted in testicular toxicity, thus suppressed spermatogenesis in male mice. Decreased body weight may be related to appetite loss. Reduced food intake is closely involved in excessive ROS,[57] and TiO_2 NP exposure could result in the overproduction of ROS in mouse testis.[53] In our study, alterations of spermatogenesis-related factors of testicular marked enzymes and oxidative stress in the testis are examined, suggesting that exposure to TiO_2 NPs significantly inhibited the activities of LDH, SDH, SODH, G-6PD, Na^+/K^+-ATPase, Ca^{2+}-ATPase, and Ca^{2+}/Mg^{2+}-ATPase (Table 2, Figure 6) and increased the activities of ACP, AKP, and NOS (Table 2), promoted production of ROS, lipid and protein peroxidation and DNA injury (Table 3), which may be associated with reductions of both sperm concentrations and motility, and sperm lesions. The main results are discussed below.

As suggested, male fertility is associated with the successful perpetuation of spermatogenesis, the multistep process of male germ cell expansion and development in the seminiferous tubules of the testes.[58] In this process, a spermatogonium that yields a primary spermatocyte by mitosis divides into two secondary spermatocytes, then completes meiosis as it divides into two spermatids, which finally develop into mature sperm cells. However, hazardous substances could produce toxic effects (such as ROS overproduction) on the growth and development of male germ cells, leading to spermatogenesis disorder.[59] Importantly, spermatogenesis is considered to be a high-energy-demanding process, and the activities of energy metabolism-related enzymes, including LDH, SDH, and SODH, play key roles for the growth and development of testicular cells, while the energy metabolism disequilibrium in the spermatogenesis process may damage testicular cells.[41−43] As an important glycolytic enzyme, LDH catalyzes the conversion of pyruvate to lactate and is related to the maturation of the germinal epithelial layer of seminiferous tubule.[60] Due to spermatogenic cells locating behind the tight junction of Sertoli cells in the convoluted tubules of the testis, it is difficult for them to obtain nutrition from the testicular interstitium, and glycolysis is the pathway of dominating energy metabolism in the testis.[42] SDH is part of both the citric acid cycle and respiratory electron transfer chain and is a vital enzyme for aerobic respiration that is mainly located in spermatogenic cells and on sperm mitochondrial membrane,[61] and it could be a marker of maturity and perfect form of sperm function.[62] Because spermatozoa contain only a small amount of cytosol, the energy obtained is dependent upon SDH that is quicker than glucose in energy production.[41] SODH is considered to provide energy to sperm cells by converting sorbitol to fructose, and its activity elevates during the maturation of germ cells and reduces during the depletion of germ cells.[63,64] In our study, the decreased daily food intake (Figure 1) and activities of LDH, SODH, and SDH caused by TiO_2 NP exposure in the testis (Table 1) may be associated with disturbance to energy metabolism in germ cells, deterioration of germinal epithelium, and spermatogenic cell damage, further resulting in attenuation of both spermatogenesis and motility, and sperm lesions.

It has been demonstrated that testicular G-6PD is associated with androgen biogenesis.[43,65] The reduced testosterone (T) production from cholesterol is mainly ascribed to the lower supply of decreased NADPH that may be related to the reduced activity of G-6PD.[66] While G-6PD largely presents in the Leydig cells of seminiferous tubules, it is an important source of NADPH and a signal of Leydig cell function whether it promotes spermatogenesis or maintains sperm function.[67] It implies that reduction of G-6PD activity caused by TiO_2 NPs could influence the function of Leydig cells, thereby affecting

DOI: 10.1021/acs.jafc.5b02652
J. Agric. Food Chem. 2015, 63, 7084−7092

androgen secretion and spermatogenesis. Our previous study has suggested that TiO_2 NP exposure could lower T, follicle stimulating hormone (FSH), and luteinizing hormone (LH) levels in male mice,[40] showing that the growth and development of germ cells and Leydig cells in male mice treated by TiO_2 NPs could be inhibited, thus leading to spermatogenesis suppression, which is confirmed by the histopathological evaluation of testis (Figure 4).

To further determine whether testicular function is normal or not, activities of other testis-marker enzymes related with Sertoli (ACP) and germinal epithelium (AKP) were measured (Table 2). ACP is largely located in the cytoplasm of Sertoli cells, and its activity is directly associated with the degeneration of the seminiferous epithelium. The AKP activity in the testis is related to the division activity of testicular germ cell and the transport from glucose to spermatogenic cells.[45] Therefore, activities of ACP and AKP could be used as markers whether spermatogenesis was impaired. The increased activities of ACP and AKP due to TiO_2 NP exposure in mouse testis may reflect testicular degeneration, which may likely be a consequence of suppressed T and indicative of lytic activity,[68] and increase permeability of the cell membrane or cell degeneration and necrosis,[69] which is consistent with the histopathological evaluation of testis (Figure 4).

As suggested, NO signaling is involved in fertilization and in development in vertebrates, NOS is an important enzyme in the production of NO, and NO produced by NOS can decrease oxidative stress in reproductive system. A study found that the NOS expression of Sertoli cells depends on the presence of sperm cells, and is closely associated with the degree of development of sperm cells in the testis of infertile male.[46] Furthermore, the NO concentration in the testis also influences spermatogenesis, and reasonable NO concentration can maintain sperm motility, whereas excessive NO would damage the spermatogenesis and inhibit the sperm motility.[62] Due to significant elevations in NOS activity may be the most important determinant of increasing NO levels, and over NO production can quickly react with ROS resulting in the formation of the peroxynitrite anion ($ONOO^-$),[70] which can cause the testicular damage, as found in the pathological observations (Figure 4). Therefore, over higher NOS activity in mouse testis (Table 2) is related to impairment of sperm cell development and spermatogenesis under TiO_2 NP exposure. In addition, the changes of three important membrane ATP enzymes including Na^+/K^+-ATPase, Ca^{2+}/Mg^{2+}-ATPase, and Ca^{2+}-ATPase following exposure to TiO_2 NPs in the testis were examined. Na^+/K^+-ATPase and Ca^{2+}/Mg^{2+}-ATPase are demonstrated to keep intracellular gradients of ions that are essential for signal transduction. Na^+/K^+-ATPase plays the most important role in regulating of ion transport and generating of membrane potential in the male reproductive system.[71] Vignini et al. indicated that the decreased sperm motility and the lower sperm concentration are due to reductions of Na^+/K^+-ATPase and Ca^{2+}-ATPase activities.[72] In an in vitro study about testis Sertoli cells, the activities of Ca^{2+}-ATPase, Ca^{2+}/Mg^{2+}-ATPase, and Na^+/K^+-ATPase were increased shortly to help the outward transport of positive ions and finally reduced due to the disturbance of the membrane structure.[73] It is well-known that, in the front of sperm DNA, there is a top body containing calcium, and progesterone (P4) could greatly induce stimulation of Ca^{2+} channel on the sperm flagella.[74] According to the serum level of P_4, P_4-mediated intracellular Ca^{2+} could be evaluated, to judge the viability of sperm in male.[75] Ca^{2+} in cells is an essential element for cellular activities that are closely related with mitotic activity and development of cells. Its homeostasis in germ cells is dependent upon the function of Ca^{2+}-ATPase that transport cytosolic free Ca^{2+} into intracellular storage compartments.[76] It is also reported that Ca^{2+}-ATPase plays a key role in regulating spermatogenesis processes,[77] for instance, in the transition of spermatogenic cell to sperm cell, Ca^{2+} gradients across the plasma membrane and establish Ca^{2+} homeostasis and signaling are both maintained in part by plasma membrane Ca^{2+}-ATPase activity.[78] Our previous findings suggested that, with increased P_4 level following TiO_2 NP exposure, the intracellular calcium may be disordered, and resulted in spermatogenesis suppression.[40] In the present study, the significant reductions of Na^+/K^+-ATPase, Ca^{2+}/Mg^{2+}-ATPase, and Ca^{2+}-ATPase activities (Figure 6) were observed following TiO_2 NP induced toxicity in the testis, which may be associated with spermatogenesis disorder in male mice (Figures 2−5). These results give rise to a hypothesis: the lowered enzyme levels in the testis raise the possibility of imbalance in intracellular ion concentrations as a promoter of spermatogenesis dysfunction.

Oxidative damage can affect many classes of molecules including lipids, proteins, nucleic acids, and sugars. Thus, the cell nucleus, mitochondrial membranes, structural and cytoplasmic proteins, complex carbohydrates, RNA, and DNA may all potentially be affected by oxidative stress.[79] In the testis with high rates of metabolism and cell replication, oxidative stress can be especially produced. To further confirm oxidative damage in the testis, reactive oxygen specifics (such as $O_2^{\bullet-}$, H_2O_2), lipid peroxidative product (such as MDA), protein oxidative product (such as PC), and DNA damaged marker (such as 8-OHdG) levels were detected. Our data showed that increased MDA was concurrent with significant oxidative damage to testicular protein ((increased carbonyl level) and DNA (increased 8-OHdG level), which resulted from the overproduction of ROS due to TiO_2 NPs during the spermatogenesis process (Table 3), which is consistent with our previous reports.[53] Rajesh Kumar et al. showed that oxidative stress associated DNA damage in mouse testis could induce abnormal sperm and adverse effect on fertility.[80] When the oxidative stress in the male germ line is high level, normal fertilization could not occur successfully with peroxidation of unsaturated fatty acids in the sperm plasma membrane.[81] This excessive ROS production has been suggested to be closely connected with the imbalance of oxidative/antioxidative system in the testis.[82] The results indicated that testis underwent severe oxidative stress by exposure to TiO_2 NPs, leading to testicular dysfunctions and sperm lesions.

In conclusion, the current study indicated that dose-dependent exposure to TiO_2 NPs caused testicular toxicity, reduced sperm production, and induced sperm lesions in mouse testes, which were closely related to reductions of daily food and water intake, biochemical dysfunctions, and oxidative stress. Especially, LDH, SODH, SDH, G-6PD, AKP, ACP, NOS, and ATPases may be the biomarkers of spermatogenesis suppression caused by TiO_2 NP exposure. Therefore, in the application of TiO_2 NPs in different kinds of areas, more attention should be paid to the workers and consumers. Especially, potential epidemiological connections between nano TiO_2 consumption and reproductive health for male consumers or exposed male workers in nano workshop should be investigated in the future.

Correction to MALDI-TOF-MS Platform for Integrated Proteomic and Peptidomic Profiling of Milk Samples Allows Rapid Detection of Food Adulterations

Mauro Sassi, Simona Arena, and Andrea Scaloni*

J. Agric. Food Chem. **2015**, *63* (27), 6157−6171. DOI: 10.1021/acs.jafc.5b02384

Table 3 was missing two subheadings in the original publication.
The corrected table appears below.

Table 3. Marker Species Recognized during MALDI-TOF-MS Protein Profiling for Milk Speciation[a]

DAve	description	exptl MH^+	theor MH^+ (UniProt Code)
	Bovine Milk		
36.26	α-lactalbumin	14181	14179 (P00711)
29.46	γ2-casein/β-casein f(106−209)	11827	11825 (P02666)
17.55	γ3-casein/β-casein f(108−209)	11560	11560 (P02666)
15.97	unknown	12006	
10.29	proteoso peptone p.p.8.I/β-casein f(29−105)	8640	8638 (P02666)
	Buffalo Milk		
33.66	β-casein f(69−209)	15749	15750 (Q9TSI0)
30.90	unknown	11991	
30.39	γ3-casein/β-casein f(108−209)	11521	11520 (Q9TSI0)
27.62	β-casein f(1−68)P_5	8251	8252 (Q9TSI0)
20.56	γ2-casein/β-casein f(106−209)	11786	11785 (Q9TSI0)
16.63	α-lactalbumin variant B	14236	14236
	Goat Milk		
36.26	α-lactalbumin variant A	14186	14187 (P00712)
29.02	unknown	11882	
21.33	γ3-casein/β-casein f(108−207)	11288	11287 (Q95L76)
16.48	unknown	11922	
15.17	unknown	5891	
14.06	γ2-casein/β-casein f(106−207)	11554	11553 (Q95L76)
9.48	β-casein f(98−207)	12466	12466 (Q95L76)
8.66	β-lactoglobulin	18185	18187 (P02756)
	Ovine Milk		
36.25	γ2-casein/β-casein f(106−207)	11536	11535 (P11839)
31.26	γ3-casein/β-casein f(108−207)	11271	11270 (P11839)
22.59	unknown	8573	
14.40	β-casein f(98−207)	12449	12448 (P11839)
9.48	unknown	9712	

[a]MS experiments were performed in linear mode as reported under Experimental Procedures. Difference value between the maximal and the minimal average peak/area intensity of all classes (DAve) (see ClinProt Tools software for details), protein/polypeptide name, and experimental/theoretical MH^+ (average) value are reported. Theoretical MH^+ values were calculated according to the amino acid sequence entries present in the UniProt Knowledge Database and the corresponding post-translational modifications. P, phosphate; f, fragment. α-Lactalbumin variant B mass value was calculated according to dedicated studies.[35]

Vanishing Boundaries between Chemistry and Biology: Reflections on Our Journal

Six months after taking over the position of the Editor-in-Chief of the *Journal of Agricultural and Food Chemistry* (JAFC), it is time to draw a first summary. First of all, I would like to thank the authors for consistently submitting the best of their scientific work to our journal during this transition time, our international team of Associate Editors for their unbroken passion to further increase the quality of papers published, and Matt Hotze for his continuous efforts as the Managing Editor of JAFC. My transition into the role of EIC would never have been successful without Matt being highly committed to pursuing the everyday tasks of dealing with papers and reviewers, growing experiences that are pivotal for us. As you might have noticed that the journal has been changing within the past months, I would like to take this opportunity to share changes in personnel with you, define the scope of the journal, and clarify our current thinking on the standard for papers we wish to publish.

Since March 2015, the team of 12 Associate Editors has been expanded by a new member: Holger Zorn, Director of the Institute of Food Chemistry and Food Biotechnology, Justus Liebig University Giessen, Germany. Holger is a trained food chemist focusing on the enzymology of basidiomycetous fungi and insects. He is building a bridge from the discovery of biochemical phenomena to novel biocatalysts tailored to industrial applications (e.g., flavor biotechnology and enzymatic utilization of renewable resources including the final downstream processing). Besides knowledge on enzymology and protein chemistry, he brings new expertise on molecular biotechnology and modern bioanalytics to the team. Holger, cordial welcome to our team!

The changes in the Editorial Team have mirrored adjustments to the scope of JAFC. Founded in 1953, the journal has been the home of significant advances in agricultural and food chemistry, while reflecting the broad interest of those who practice it. The journal's scope had grown organically over the decades to include the related fields of bioactive molecules, molecular nutrition, and chemosensory research, to name a few. This has resulted in our citations increasing to over 82000 in 2014. In the future, the journal will continue to publish original and high-quality chemical research advancing the molecular understanding of renewable resources, product attributes, processes, and technologies, as well as health aspects encompassing the agriculture–food–nutrition continuum. However, the boundaries between chemistry and biology are vanishing. With this in mind we will now also consider manuscripts that have a fundamental component of biochemistry and/or molecular biology. This can be combined with novel aspects of process engineering and food technology, authenticity and origin aspects of food, or the biological evaluation of agricultural and/or food systems. The latter may include microbial, nutritional, physiological, sensory, or toxicological properties; however, data must accompany sufficient discussion to demonstrate their relevance to food and nutrition. Concurrent with these changes to our scope, we have also reconsidered the sections the journal is divided into. Current specific categories within the scope of the journal include the following:

(i) *Agricultural and Environmental Chemistry*: to advance molecular knowledge (e.g., crop protection chemistry, nanotechnology, natural toxins, fate and biotransformation of residues) and understanding of mechanisms of action of agrochemicals and to promote innovative solutions for increased agricultural productivity, a sustainable supply of food and fiber, and protection of public health and the environment including water quality/treatment, agricultural waste, and energy-related issues.

(ii) *Bioactive Constituents, Metabolites, and Functions*: to increase knowledge of chemical structures of bioactive constituents, phytonutrients, and nutraceuticals in foods, their human metabolism, and their mechanisms of biological function to affect human health status, including various aspects of molecular nutrition such as nutritional biochemistry, nutrigenomics, and metabolomics.

(iii) *Biofuels and Biobased Materials*: to advance knowledge of the chemistry, biology, and processing of biobased products and biofuels including all of the related areas of biodiesel, bioethanol, biogas, biotransformations, and bioprocesses (plants, algae, etc.), waste utilization, biorefinery and bioresource technologies associated with the conversion or production of biobased materials, and sustainability and environmental emissions and effects associated with these processes.

(iv) *Biotechnology and Biological Transformations*: to foster technological advances in plant/agricultural biotechnology (e.g., crop improvement, nutraceuticals, bioenergy, transgenic plants, phytoremediation), microbial and insect biotechnology (metabolic engineering and synthetic/systems biology of bacteria, fungi, insects, yeasts, and algae in the context of fermentation/bioproduction, biocatalysis, bioremediation, biodegradation), food and flavor biotechnology (biotransformations and metabolic aspects of food/beverage systems), and protein and enzyme technology (recombinant proteins/enzymes, cell-free protein expression systems, and biocatalysis using immobilized enzymes).

(v) *Chemistry and Biology of Odor and Taste*: to advance molecular knowledge of the instrumental analysis (e.g., bioelectronics sensors), chemical structures, formation pathways of aroma and taste molecules of plant- and animal-derived foods and beverages, chemosensory receptors mediating flavor object recognition (in vitro cell assays etc.), human in vivo psychophysics (including multisensory integration), and neurological processing of flavor stimuli (imaging technologies etc.).

(vi) *Food and Beverage Chemistry/Biochemistry*: to deepen the fundamental understanding of chemical structures, structural modifications, interactions, and (bio)chemical

transformations of major and minor components in foods and beverages, potentially in combination with novel aspects of process engineering, food technology, nanotechnology, packaging and storing, authenticity and origin aspects of food, or the biological evaluation of food and beverage systems.

(vii) *Food Safety and Toxicology*: to advance our knowledge of detrimental health effects and the mechanisms of adverse physiological or pathological changes induced by natural or synthetic chemicals occurring in the human environment with particular emphasis on foods, crop protection chemicals, contaminants, and related chemicals (e.g., nanomaterials, biotechologically derived products), including agricultural safety and consumer product safety, and the design and action of chemically related processes that enhance food safety.

(viii) *Functional Structure/Activity Relationships*: to increase the knowledge of the relationship between chemical structure and biological (microorganisms, insects, animals, human) or technofunctional activity (e.g., emulsifying, foaming, gelation) of agricultural and food components; the category comprises (a) organic synthetic studies and structural biological studies (X-ray, NMR, etc.) of relevant ligands and targets with the aim of investigating molecular recognition processes in the action of biologically active compounds, (b) molecular biological studies (e.g., site-directed mutagenesis) of macromolecular targets that lead to an improved understanding of molecular recognition, and (c) computational studies that analyze the SAR of compound series of general interest and lead to experimental studies or analysis of other available chemical and/or biological data that substantially advance the knowledge in agricultural and food chemistry.

(ix) *New Analytical Methods*: to expand the repertoire of analytical methods in agricultural and food research by new analytical method development using chemical, physical, and biological principles.

(x) *Omics Technologies Applied to Agriculture and Food*: to promote a more integrative understanding of complex systems in agriculture, food, and nutrition by the application of metabolomics, proteomics, and transcriptomics/genomics technologies combined with but not limited to bioinformatics and computational biology.

This scope makes JAFC a broad and large journal; we currently publish about 120 articles per month. In a sense, JAFC could be considered many journals in one. We embrace participation by scientists across traditionally defined fields and international boundaries. JAFC is the place to publish when you want the attention of scientists not just in your specialty area, and it is the place to publish when you want those same scientists to know your manuscript cleared a high standard for publication. Today the pressure to publish may be surpassing the pace of major scientific progress. In this atmosphere, I believe that JAFC has a responsibility to the scientific community to maintain a large signal-to-noise ratio. Therefore, JAFC's publication criteria require papers to present significant new and important molecular knowledge on key topics encompassing the agriculture–food–nutrition nexus. Correctness of data alone is not sufficient for publication in JAFC, and premature publication of the latest increment of what could be further developed to become a more comprehensive and stronger paper does not serve the scientific community. For example, manuscripts presenting omics data should go beyond a sheer holistic fingerprinting of samples; that is, metabolic changes need to be identified on a molecular level and validated by means of targeted analysis of the key metabolites. Similarly, incremental extensions of existing compound series without a better understanding of the structure–activity relationships or without any novel chemical/biological approaches only consume reviewer and editor time better spent on other studies. In particular in an era when biological evaluations of extracts and fractions, as well as the mechanistic understanding of biological activities of compounds, are en vogue, it is mandatory that manuscripts reporting biological properties of crude extracts include detailed information on the chemical composition of the extracts responsible for the described properties. Moreover, discussion of data on nutritional or physiological relevance and conclusions drawn about human health benefits should be formulated carefully considering the experimental design used (appropriate cell-based or other in vitro assays, animal models, clinical human trials, significance of test/trail, relevant dose levels, etc.) and the robustness of the data obtained. Although new findings on food product health benefits attract media attention, it is our responsibility as scientists to treat our data with care; we should not allow ourselves to overestimate findings and present specific solutions to cure life-threatening diseases without a solid scientific basis. "Overselling of certainty" will undermine the credibility of science and will lead to more confusion than progress.

Although these criteria are not new and to a certain extent subjective, authors should expect a stricter application. I wish to emphasize that for a manuscript to be suitable for JAFC, it should conform to the highest standards of chemical/biological research, be comprehensive in content, make a significant contribution to one of the journal's categories (i–x above), and also present interesting science for our broad group of international readers. We look forward to your participation in our endeavor to continue improving JAFC so it can best serve the needs of our community.

Thomas F. Hofmann, Editor in Chief

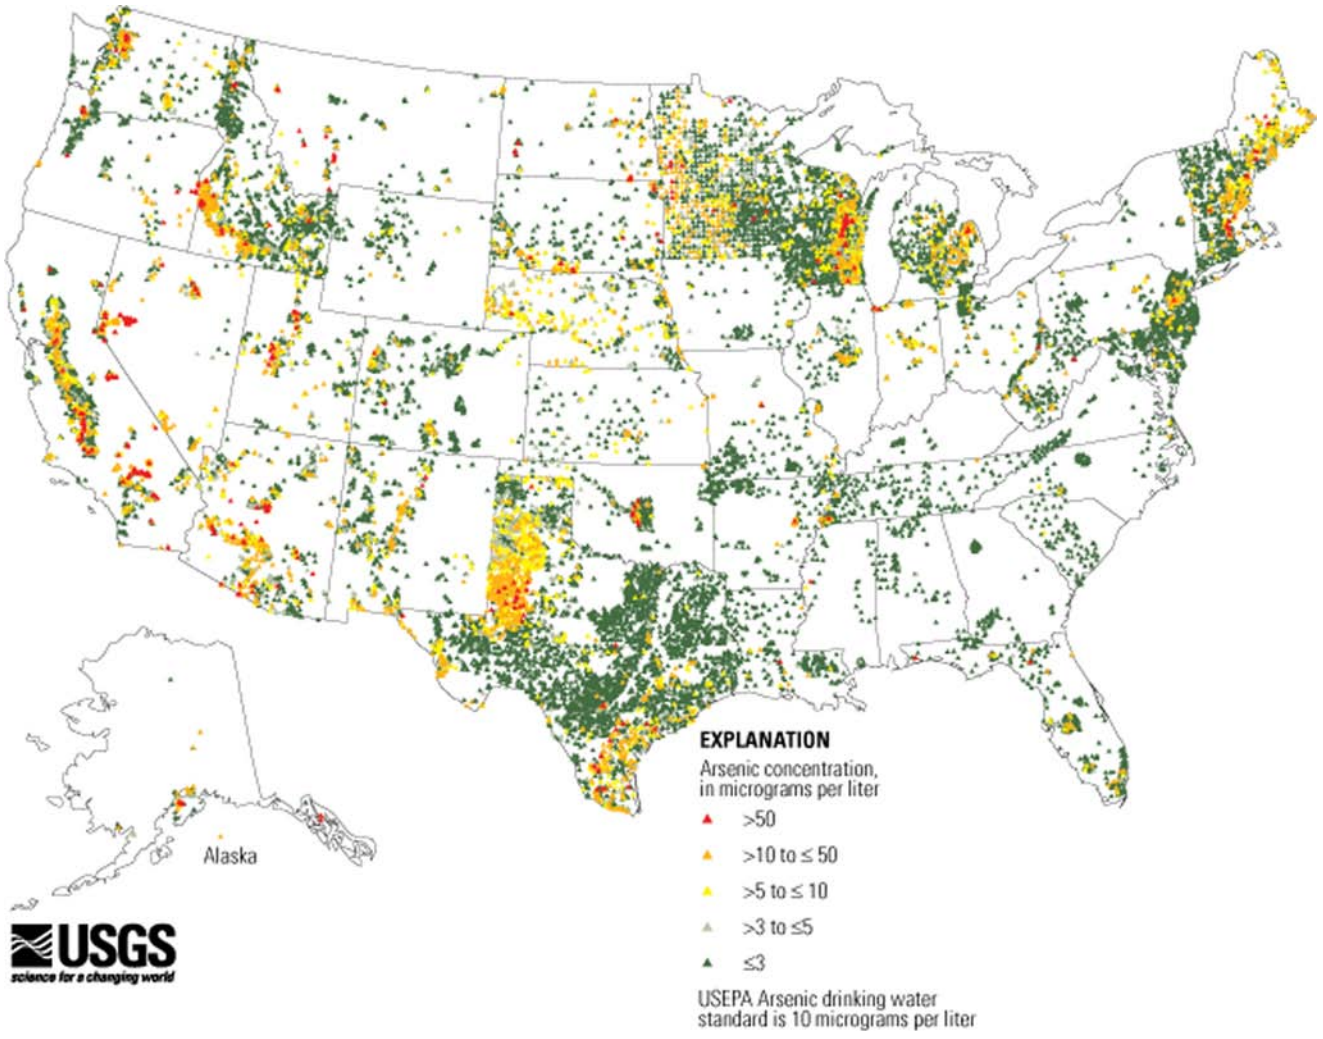

Figure 1. Arsenic levels in groundwater in the United States (data found by U.S. Geological Survey; chart source http://water.usgs.gov/nawqa/trace/arsenic/).

H_3AsO_3) are even more toxic.[4,14] Distinguishing between species is important due to the differences in properties and mechanisms of toxicity.[15] An example of a property that influences arsenic stability differently for separate species is pH. One study employed the agricultural residue rice polish to sorb inorganic arsenic. Rice polish is a byproduct of the milling process composed of a starchy material and inner coating of the rice hull, and this study found that the maximum sorption for AsO_4^{3-}/H_3AsO_4 on rice polish occurs at neutral pH, whereas AsO_3^{3-}/H_3AsO_3 has maximum sorption at a pH of 4.[2,16] The relatively higher stability of AsO_4^{3-}/H_3AsO_4 at neutral pH makes it more readily removed than AsO_3^{3-}/H_3AsO_3.

A third factor to consider in toxicity is the route of exposure. According to the WHO, most human diseases can be attributed to water pollution.[17] Uptake through drinking water is the most important source of arsenic in humans.[18] Inhalation is another relevant mode of exposure and is known to contribute to respiratory system problems including lung cancer.[10] Another route known for causing deleterious effects in humans is dermal exposure. The susceptibility of the skin to arsenic can lead to lesions and aggressive, non-melanoma skin cancers.[19] Another less direct route that has come to public attention in recent years is the uptake of arsenic via contaminated fruits and vegetables.

Arsenic Interaction in Plants and Soil. Clearly, arsenic contamination is not limited to water sources. The contamination of soil has emerged as a serious environmental hazard, especially in agricultural areas of the world.[20] The health of the soil can be compromised by chemical contaminants including arsenic.[21] Arsenic can cause problems with microbial activities in the soil, which in turn affects the microbes' interaction with other life.[22] Soil can act as a sink for arsenic and other hazardous metals with the capacity to transfer these pollutants to plant roots.[23] High concentrations of arsenic can cause deleterious effects to the plant including cell necrosis, chlorosis, inhibition of growth, and even death.[24] Human consumption of arsenic-contaminated food products may also provide a hazardous amount of the element. Food chain transport of arsenic and trace metals is thus a threat to human health.[23] Because research has yielded inconclusive evidence on the health effects of consuming contaminated crops,[5] more studies are needed in this area. It is worth noting that different species of plants have unique methods of reaction to arsenic exposure.[25] For example, data suggest that tomatoes do not efficiently accumulate arsenic,[9] yet rice is so efficient an accumulator that millions of tons of grain are rendered unsafe for consumption on a yearly basis.[26] The behavior of each plant in response to chemical contamination is important both in

DOI: 10.1021/acs.jafc.5b02487
J. Agric. Food Chem. 2015, 63, 7097−7107

terms of consumption and for the plant's ability to take up and tolerate contaminants.

With regard to the health risks of consuming contaminated plants, it is helpful to consider the capacity of plants for remediation. Phytoremediation is the process of plants extracting arsenic and other contaminants from soil via their roots.[27] Although there is ongoing experimental research concerning direct remediation of water,[28] phytoremediation has emerged as the most promising potential technique for reducing arsenic and heavy metals from contaminated areas due to its eco-friendly methods. However, the process has a few important drawbacks. One problem is that phytoremediation tends to be time-consuming. Another is that if the remediating crops are not properly disposed of or treated, these contaminants can still enter the food chain through fodder or other means of animal consumption.[18] A recent study has investigated the possibility of effluxing arsenic from plants,[29] but the efficiency of these experimental technologies needs further study. Although phytoremediation is not yet an ideal solution to the problem of arsenic contamination, it is a promising technology that could evolve over time into the most effective method of arsenic cleanup. An improved understanding of this technique will pave the way for greater insight into the worldwide problem of contaminated crops.

Purpose of Review. The purpose of this review is to consider the chemical and physical properties of arsenic in the broad context of human toxicity and phytoremediation. The behavior of arsenic is key to its interaction with plants and humans. Therefore, attention will be brought to the results of recent studies concerning arsenic and its mechanisms of toxicity and transport. The connection of arsenic to human health will be evaluated in relation to its toxicological properties. Although some ailments such as cancer have been attributed to arsenic exposure for many years, new studies are being conducted to determine other deleterious effects for which arsenic may be responsible. Effects of exposure proposed by recent experimentation will also be evaluated and compared.

Another area of interest to be addressed will be the interaction of plants with arsenic and other contaminants such as heavy metals. This review will cover mechanisms and interactions commonly seen between plants and metals including arsenic. Details of specific plants that are well-suited for remediation will be noted, as will a few species that are resistant to the process. This process will be covered in depth with an emphasis on arsenic cleanup. Finally, the commonly employed methods of arsenic determination, alongside a few newly proposed techniques, will be described. It is important to understand the potential health risks posed by arsenic and heavy-metal accumulation as well as the possible environmental utility of phytoremediation. Compiling this research will create a greater understanding of arsenic toxicity and provide insight on where further research may be needed.

PHYSICOCHEMICAL AND MECHANISTIC PROPERTIES OF ARSENIC AND IMPLICATIONS ON HUMAN HEALTH

Origin and Behavior. Arsenic is an important element because it is ubiquitous in the environment.[30] It is a naturally occurring element in rock formations containing copper and lead. The metalloid is known to persist in soil, water, and air as well as their rock structures of origin.[31] Arsenic in groundwater ranges from 0.5 to 5000 μg/L in more than 70 countries worldwide.[32] It makes up only 0.0001% of the Earth's crust and is far from the earth's most abundant element.[33] Water and soil near arsenic-enriched formations tend to have high concentrations of the element.[1] Areas with soils of high organic carbon content are generally more susceptible to accumulating arsenic than sandy soils.[34] Arsenic is a member of group 15 on the periodic table of elements and is classified as a heavy metalloid.[35] It has been compared to other elements including phosphorus, antimony, chromium, and selenium[22,36,37] to help assess its physicochemical properties and toxicity. These comparisons are particularly helpful when arsenic accumulation in plants is evaluated.

The inorganic arsenic-containing compounds are considered a much more important threat to environmental health than the organic forms. AsO_4^{3-}/H_3AsO_4 and AsO_3^{3-}/H_3AsO_3 are often separated and speciated because they have different mechanistic properties and interact differently with biological systems.[38] In aerobic environments of moderate, near-neutral pH, most AsO_4^{3-}/H_3AsO_4 is present as anions $H_2AsO_4^-$ and $HAsO_4^{-2}$. In anoxic settings, AsO_3^{3-}/H_3AsO_3 occurs as H_3AsO_3.[33] Studies of the different species of arsenic show trivalent species are generally more toxic than pentavalent ones,[3] although one review suggests that the species' potencies are ultimately dependent on the biological system in question.[18] Research has determined that different species may target different parts of biological systems. One study suggests that AsO_3^{3-}/H_3AsO_3 targets human prostate stem cells and gives them an aggressive, malignant phenotype, whereas other research has revealed that AsO_4^{3-}/H_3AsO_4 is an analogue for inorganic phosphate that can potentially replace the phosphate nutrient in essential reactions and disrupt normal processes.[18,39] The subtle differences in the species of arsenic are key to defining the mechanisms of remediation.

Common Effects on Human Health. The effects of arsenic on human health are well-known, and both chronic and acute toxicities have been connected with exposure to the metalloid. Symptoms widely attributed to the element such as skin lesions, liver fibrosis, and cancer have been reported in more than 30 countries worldwide.[40] Cases of "black-foot" disease have been reported in areas of extreme contamination such as Bangladesh.[1] Black-foot is a peripheral vascular disease that can result in severe pain in the extremities and eventually the mummification and falling off of affected areas.[41] More common lesions caused by arsenic on the skin are less debilitating, but are unique from other dermal damage such as that caused by UV light because they can affect multiple sites.[19] Damage to skin by the toxicant can result in hyperpigmentation and hyperkeratosis, which can act as a precursor to cancer.[42] Chronic exposure to arsenic is connected to non-cirrhotic portal fibrosis (NCPF).[43] This disease can manifest even at an early age. One study found a statistical correlation between arsenic-affected areas and NCPF in children in Kolkata, India.[44]

The skin, lungs, and bladder are considered to be the main target areas of arsenic carcinogenesis.[42] Arsenic-related skin lesions can progress to malignancies including squamous cell carcinoma, Bowen's disease, and basal-cell carcinoma. This process may be potentiated by other carcinogens such as those in tobacco products.[1] There is a higher risk of developing lung cancer as a result of arsenic exposure. Studies show that the element is both cytotoxic and genotoxic to human lung cells.[45] Although it is primarily connected to contaminated drinking water,[1] there is research speculating that arsenic inhalation also plays a significant role in inducing lung cancer.[46] In the bladder, cytokines can be inflamed by the metalloid, leading to potential

DOI: 10.1021/acs.jafc.5b02487
J. Agric. Food Chem. 2015, 63, 7097−7107

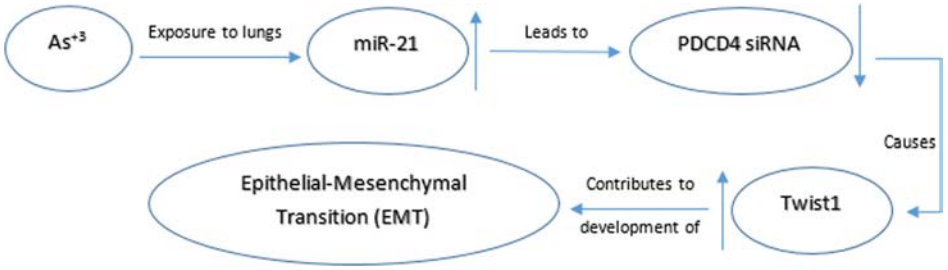

Figure 2. Flowchart of the development mechanism of EMT as a result of arsenite toxicity. Mechanism proposed in ref 62.

malignancies.[47] Bladder cancer follows mechanisms of carcinogenesis similar to those of lung cancer.[48] Evidence suggests a synergistic relationship of the toxicant with tobacco.[1] This may promote cancer development in both organs for smokers.[49] The study of these common forms of cancer resulting from arsenic exposure will be instrumental in determining future cancer treatment options as well as understanding the nature of the element and its role in carcinogenesis.

Other Target Organs and Cancer. Although arsenic is most commonly associated with malignancies in the skin, bladder, and lungs, there is evidence that strongly suggests that the toxicant may contribute to cancer development in other organs as well. Organs that have been experimentally associated with arsenic carcinogenesis include the kidneys, liver, and prostate.[42] Although these may not be as prevalent as cancers of the skin and lungs, there has been research to strongly suggest the connection. One study in Bangladesh reported that the statistical relationship between arsenic concentration and renal cancer cells indicates that it is a causal factor even in nonsmokers.[50] Because the liver is the body's primary organ for detoxification, it is expected that the liver would be a target of this toxic element. A previous thorough review of the literature found that chronic exposure from drinking water increases liver cancer mortality.[51] Another study suggests that the metalloid causes androgen independence of the prostate, promoting cancer progression.[52] Even though it is not yet widely connected to the toxicant, one study suggests a tie between arsenic methylation and breast cancer.[14] The broad spectrum of target sites for arsenic carcinogenesis illustrates the versatility of the metalloid and its threat to human health.

Cancer has historically been the focus of worldwide study of chronic arsenic exposure. However, new studies have reported that the metalloid may be responsible for other deleterious effects as well.[13] An interesting characteristic of arsenic is its ability to adversely affect entire multiorgan body systems via chronic toxicity called arsenicosis.[40] This effect has been linked to the element's mutagenic and carcinogenic potential.[53] Arsenicosis is pronounced during periods of development, where the toxicant can potentially leave the patient immunocompromised and at higher risk for other diseases.[12] Thus, the toxicant can affect almost the entire body in some way. Experimental studies have revealed potential links to a variety of problems. Patients experiencing arsenicosis have shown cognitive impairment and other neuropathic issues.[40] Some evidence suggests that children are especially vulnerable to these cognitive effects due to their continuing development.[54] One study determined a connection between arsenic exposure and the dilation of the pulmonary artery in response to chronic lung disease.[55] Another study reported low levels of chronic arsenic exposure might contribute to the development of diabetes.[56] Cardiovascular diseases such as ischemic heart disease have also been found to be related to inorganic arsenic exposure.[40] Toxicant accumulation of heavy metals and arsenic is largely individualized and can be influenced by genetics and environmental surroundings.[57] This list of potential effects is therefore not complete or universally applicable. Nevertheless, it is clear that the scope of arsenic toxicity is broad, and research will almost certainly discover new disease connections in the future.

Possible Mechanisms of Action. The scientific understanding of the arsenic mechanism of action in biological systems is far from complete. Unlike some xenobiotics, arsenic can affect several biological mechanisms and result in a wide range of effects.[12] It has the potential for both genetic and epigenetic changes, meaning it can have mutagenic effects at the DNA sequence level.[58] Short-term exposure is connected to the increased production of reactive oxygen species (ROS),[59] which are apoptosis-inducing agents that are capable of disrupting a number of key processes.[59] One human mechanism ROS may interrupt is mRNA deadenylation. In this case, AsO_3^{3-}/H_3AsO_3 selectively induces proteolytic degradation of two enzymes, Tob and Pan3, which results in disruptive oxidative stress.[60] Oxidative stress has also been connected with cancer as well as other benign diseases.[61]

Research suggests that one of the most sensitive sites for arsenic exposure is the lungs.[55] The methylation of arsenic species to organic acids is considered to be connected to cancer in the lungs and the bladder.[48] This sensitivity may also be in part because of the miRNA-21 molecules in the lungs. One study has indicated that AsO_3^{3-}/H_3AsO_3 up-regulates miR-21, which in turn represses the expression of the PDCD4 siRNA. The up-regulation of the oncogene Twist1 caused by a decrease in the neoplastic transformation inhibitor programmed cell death 4 (PDCD4) small interfering RNA (siRNA) contributes to epithelial−mesenchymal transition (EMT).[62] This effect is more clearly illustrated in the flowchart in Figure 2.

Human prostate epithelial cells are another target of arsenic and ROS. One study showed that the expression of DNA repair genes ERCC6, XPC, and OGG1 are influenced by arsenic.[63] The study concluded that chronic exposure causes DNA damage while increasing cell survivability, promoting the possibility of neoplastic transformation. The sensitivity of the skin to the toxicant may be partially due to the inhibition of SIRT1 activity.[19] The number of potential targets for arsenic is daunting, but it means that there are many proteins that can be used to detect the effects of arsenic exposure. A study on urinary tract epithelial cells identified one example where three cytokines were found that can potentially be monitored as arsenic biomarkers.[47] Establishing these biomarkers and analyzing the related mechanisms are among the most promising leads available in controlling and eliminating arsenic-related ailments as a worldwide threat.

DOI: 10.1021/acs.jafc.5b02487
J. Agric. Food Chem. 2015, 63, 7097−7107

Therapeutic Applications. Whereas arsenic has long been associated with cancer and other health problems, it has also been shown to have therapeutic effects in blood and solid cancers.[64] Arsenic trioxide is a chemotherapeutic that has been adopted for the treatment of leukemia.[65] Studies demonstrate that it can be an effective countermeasure for cancers such as mesothelioma, breast cancer, and cervical cancer.[64,66,67] This is possible because of arsenic's capacity to induce apoptosis. Arsenic trioxide is specifically used due to its ability to cause autophagic cell death.[68] It induces the mitochondrial pathway via oxidative stress, DNA damage, change of mitochondrial membrane potential, and translocation/up-regulation of apoptotic protein.[65] Experiments with arsenic sulfide have shown promise that it could be an effective anticancer drug.[69] This new compound has not yet been as widely adapted as arsenic trioxide. Despite its success in combating cancer, the use of arsenic and autophagy is still somewhat controversial.[68] This is due to the bidirectional nature of the element and its capacity to harm as well as help.[61]

Worldwide Exposure and Study. Arsenic contamination worldwide is a problem of epidemic proportions. This is particularly true in terms of polluted water sources. Surveys from organizations such as the EPA and the British Geological Survey predict that millions of people have been exposed to arsenic via contaminated drinking water.[70] Recent research has investigated the role of accumulation in edible plants as a potential source of heavy metals and arsenic. Studies in places such as (Sargohda) Pakistan, (Delhi) India, Bangladesh, and the Xinjiang province in China are all in agreement that metal and arsenic contamination in produce poses a threat to human health.[5,20,71,72] There is research in (San Luis Potosi) Mexico, (Gejiu) China, and the Bengal Delta Plain[5,24,26,73] that has focused on the effects of arsenic contamination on the plants themselves as well as in soil biota. All of these studies have contributed to a better understanding of the interaction of plants with arsenic and heavy metals.

INTERACTIONS OF PLANTS WITH ARSENIC AND HEAVY METALS

Plants and Arsenic Uptake. There are several key factors to consider in the interaction of plants with arsenic and other pollutants. A very thorough review of arsenic's interaction and metabolism in plants was conducted in Meharg and Hartley-Whitaker's paper.[74] Due to the broader scope of the present review, these processes will be only summarized and expanded for subsequent experimental evidence. The most important thing to note is the nature of the mechanisms activated within plants in response to the contamination. Plants grown in areas of high arsenic contamination have been shown to exhibit slightly reduced biomass,[25] but the problem of contamination is broader than just the size of the plant. Most of the arsenic and heavy metals present in plants come from the cultivation soil,[9] which in most cases is initially contaminated via irrigation water and tainted fertilizers.[73]

Hazards and Risks of Accumulation. The safety of consuming produce irrigated by arsenic- or metal-contaminated water is a worldwide health concern. Even plants that contain only trace levels of a contaminant can still contribute to the total risk of exposure.[71] Some research states that vegetables with higher water retention accumulate more arsenic.[20] This has led to studies of plants such as lettuce, which showed a high concentration of arsenic in the roots.[7] Produce that has shown potential for dangerous arsenic accumulation include maize, tobacco, lotus roots, spinach, bitter gourd, Chinese jujubes, arum, radish, and most grains.[3,13,19,21,70−73] One grain of particular interest in the research community is rice. This plant is an inherently efficient accumulator of arsenic and constitutes a major exposure route for arsenic's inorganic species.[75] The high sensitivity of rice to contamination is attributed to its nodulin 26-like intrinsic aquaporin channels, which allow arsenic to interfere with amino acid mechanisms and compromise the nutritional value of the grain.[76] This makes growing rice problematic worldwide. It becomes especially difficult in flooded paddy fields, which facilitates the mobilization of AsO_3^{3-}/H_3AsO_3 and enhances its bioavailability in the soil.[73] Although research states that brown rice tends to accumulate more arsenic than white rice,[75] all types of rice are potentially significant sources of contamination. Rice is so efficient an accumulator that one study even incorporated rice in experimental phytoremediation techniques.[25]

Whereas many studies have been conducted on phytoremediation of polluted areas, other research has sought to identify plants naturally resistant to contamination. One such plant that has shown promise is the tomato. Analysis of tomato roots grown in contaminated soil showed a high concentration of arsenic uptake,[20] but another study found very little accumulation of arsenic or any metals in the fruit portion of the plant.[9] This means that tomato roots serve as an effective protection mechanism and might make it an effective crop for areas where contamination is a concern. Extreme arsenic concentrations have still been found to decrease root length and fruit size in tomatoes.[31] The prevalent emphasis of research is therefore still on phytoremediation of the soil.

Environmental Effects and Interactions. Arsenic and heavy metals in soil can present problems for soil biota as well as plants and animals. Research suggests that polluted soil, particularly sites that suffer repeated contamination, suffers a decrease in enzyme activity, bacterial life, and fungal growth.[77] Because of the major role the biota play in soil function, the resulting environmental stress can have far-reaching effects.[22] Xenobiotics enter the plants alongside other nutrients in the rhizosphere through the roots and enter the shoots. These parts have a unique relationship of translocation, which varies from plant to plant.[78] Generally, metal accumulation is higher in the roots than in the shoots, forming a natural barrier to protect the sensitive fruits from potential toxicity.[20] There are several plants that are exceptions to this general rule, however, and accumulate metals in their shoots.[79] Studies suggest that this protective mechanism has various degrees of success depending on the contaminant.[6] For example, one study reported that arsenic is more bioaccessible for edible parts of plants than the similar group 15 element antimony.[36] Vegetables are also capable of absorbing metals out of the air in their exposed parts,[5] although this is not the most efficient mechanism.

Effects of Arsenic Speciation on Plant. Another important factor in the interaction between plants and arsenic is speciation. Research has determined that the species of arsenic present makes a noticeable impact on uptake and translocation.[30] AsO_4^{3-}/H_3AsO_4 is generally more easily absorbed through roots than other inorganic species.[76] This property, along with the affinity of AsO_4^{3-}/H_3AsO_4 to replace phosphate in reactions, has translated into the use of phosphate fertilizers to prevent arsenic accumulation in crops such as tobacco.[80] Once it is inside the plant it has been determined that AsO_4^{3-}/H_3AsO_4 is readily reduced to AsO_3^{3-}/H_3AsO_3.[18] The concentrations of AsO_4^{3-}/H_3AsO_4 and AsO_3^{3-}/H_3AsO_3

DOI: 10.1021/acs.jafc.5b02487
J. Agric. Food Chem. 2015, 63, 7097−7107

tend to fluctuate in plant systems but maintain a stable ratio over time.[15]

Areas of Potential Further Study. The unique interactions of arsenic with each plant system make it an area in need of further research. A more complete understanding of these relationships will be vital in the effort to better control human exposure. It may also provide new insight into the safe removal of arsenic from contaminated areas. The natural accumulation of nutrients and contaminants by plants has already given rise to phytoremediation and similar bioremediation methods as highly promising mechanisms of cost-effective environmental cleanup.[35] These methods have already been the topic of thorough research, and studies are ongoing to improve worldwide practices of remediation.

TECHNIQUES FOR THE REMEDIATION OF ARSENIC AND OTHER METALS FROM WATER AND SOIL

Commonly Accepted Methods of Remediation. Remediation techniques are broad in scale and scope. They are often large-scale undertakings that are both laborious and costly.[34] Remediation can be used to remove metals such as arsenic and organic contaminants such as pesticides from water and soil, both of which employ unique methods. Water remediation methods have been the topic of particularly intense study. Two well-established methods include oxidation and forward osmosis.[32] Experimental methods also continue to be developed for the removal of arsenic from water. One such method is electrocoagulation, which aims to remove the toxicant using iron electrolysis with locally available materials.[81] Titanium dioxide-based technology is another method that uses granular columns to adsorb AsO_3^{3-}/H_3AsO_3 and cadmium from highly concentrated areas such as smelting wastewater.[82] There are also hybrid technologies that combine different methods to create a potentiating effect.[28] Improved water remediation could have widespread effects on biological systems. Improving soil conditions is equally important for plant life. There are fewer techniques used to remediate contaminants in soil. Two that are commonly used include thermal treatment to volatize molecules or simple soil washing to try to pull away soluble ions.[83] These methods are useful for removing arsenic, but can also be used effectively for mercury.

Experimental Methods and Appropriate Application. Experimental work in remediation has yielded potential techniques such as nanoscale iron particles, which react with particles in soil or water when injected.[84] Another study investigated biosurfactants that use anionic agents to mobilize contaminants including arsenic.[85] A third process focused on phosphate fixation, which transforms many contaminants including arsenic into insoluble or barely soluble species and can be used in extremely cold environments.[86] Chemical coagulation is a particularly effective method for removing arsenic from water but can potentially leave undesired anions behind and is therefore not very environmentally efficient.[81]

Remediation techniques vary based on conditions, and the most efficient application method for remediation is highly situational based on chemical circumstances.[87] Therefore, the most experimentally proven bioremediation techniques such as phytoremediation are widely used due to their environmental consciousness and versatility.[34] Bioremediation is the use of microorganisms and plants for the purpose of remediating soil.[88] These methods are unique from older methods of environmental cleanup in that they exploit natural biological processes to help certain microorganisms better remediate soil and groundwater.[32] They are particularly effective when it comes to the treatment of heavy metals. Two examples of this are the use of bacteria such as hay bacillus (*Bacillus subtilis*), which employs chemical reduction of Cr(VI) to the less toxic Cr(III), and the organic material biochar, which is charcoal used to improve soil productability, to raise soil pH to make hazardous metals less bioavailable for plant uptake.[88] In terms of arsenic, both AsO_3^{3-}/H_3AsO_3 and AsO_4^{3-}/H_3AsO_4 can be treated with bacteria for remediation, although AsO_3^{3-}/H_3AsO_3 can also be aerobically oxidized via arsenite oxidase enzymes.[33] One microbial agent that is particularly adept at detoxifying AsO_4^{3-}/H_3AsO_4 is *Chrysiogenes arsenatis*, which uses nitrate and nitrite as electron acceptors.[33]

Some research has attempted to develop new, advanced techniques to improve remediation efforts. Biosorbents such as iron oxide-coated biomass (IOCB) have increased in popularity due to their eco-friendly nature. The capacity of IOCB to remove aqueous arsenic makes it an effective alternative to more conventional treatments.[2] A recent study developed an in situ method involving the injection of iron-containing reagents into an aquifer, causing the arsenic to participate in the iron oxidation process and be trapped in crystalline structures. A simulation of this technique involving added arsenic yielded promising results, with all of the aqueous arsenic being removed.[89] Another approach to establishing new techniques is to combine bioremediation techniques with phytoremediation to reduce the level of a target contaminant. Called phytobial remediation, these hybrid methods are designed to utilize both types of technique in a way that they complement each other's limitations.[35] Although they are not yet widely adopted over more traditional approaches such as phytoremediation, these advanced methods could represent the future of environmental arsenic cleanup.

Phytoremediation and Environmental Fate. Phytoremediation of contaminants such as arsenic can occur through at least five mechanisms, including phytoextraction, phytostabilization, phytovolatization, phytofiltration, and phytostimulation.[35] The downside to this technique is that regardless of the mechanism, contaminants can potentially interfere with growth and essential metabolic processes.[18] Some evidence suggests that contaminants accumulate more readily in the roots of plants than in their shoots. This may be a mechanism to protect the plant's other more susceptible parts.[7] This effect is dependent on the plant. For arsenic, speciation is key to how the contaminant interacts with plant uptake and translocation.[30] For example, AsO_4^{3-}/H_3AsO_4 is reportedly more prone to being absorbed by roots than AsO_3^{3-}/H_3AsO_3.[76] Once inside the plant, however, AsO_4^{3-}/H_3AsO_4 is readily reduced to AsO_3^{3-}/H_3AsO_3.[18] AsO_3^{3-}/H_3AsO_3 is considered in most cases to have more deleterious effects on plants, such as shorter root systems and decreased fruit size, than AsO_4^{3-}/H_3AsO_4. This may be because it inhibits enzymes that need free sulfhydryl groups to function properly or because AsO_3^{3-}/H_3AsO_3 is the more soluble of the two inorganic species.[31]

Although speciation of contaminants is important, bioaccumulation, bioavailability, and bioaccessibility are the most important properties of phytoremediation and environmental fate.[87] Whether one is considering metal uptake in edible plants or environmental restoration, the capacity of each metal's bioaccumulation, bioavailability, and bioaccessibility must not be overlooked. These properties are closely related, but each serves a different purpose in the phytoremediation process. Studies in toxicology and human health are particularly

Instrumentation	Detection Limit	Strengths	Weaknesses
GFAAS Thermo Elemental AAS, GFAAS, ICP or ICP-MS? Which technique should I use? 2001	Sub-ppb range	• Small sample size • Compact • Few spectral interferences	• Slower • Chemical interferences • 1 – 6 elements / determination • No screening ability • Limited range
ICP-OES Thermo Elemental AAS, GFAAS, ICP or ICP-MS? Which technique should I use? 2001	1 – 10 ppb range	• Multi-element (73) • High productivity • Few chemical interferences • Robust • Excellent screening abilities • High total dissolved solids • Solid or organic samples	• Moderate to low detection limits • Spectral interferences • Some element limitations
ICP-MS Thermo Elemental AAS, GFAAS, ICP or ICP-MS? Which technique should I use? 2001	ppt range	• Multi-element (82) • High productivity • Wide dynamic range • Isotopic measurements • Fast semi-quant screening • Hybrid techniques (LA, LC) • Easily interpreted data	• Method development skill required • Higher initial capital cost • Some spectral interferences (well defined) • <0.2% dissolved solids
XRF http://serc.carleton.edu/research_education/geochemsheets/techniques/XRF.html	Ppm range	• Well-suited for bulk analysis in rock/sediment • Field applications (FPXRF)	• Not as precise or accurate with elements Z<11 • Cannot distinguish isotopes • Large sample sizes
Mercury CVAA http://www.labcompare.com/10-Featured-Articles/133134-Mercury-Analyzers-in-the-Laboratory/	ppt range	• Short analysis time (1-3 min)	• Only analyzes for mercury

Figure 3. Strengths and weaknesses of several common techniques of analysis. Inductively coupled plasma optical emission spectrometry (ICP-OES) is also called inductively coupled plasma atomic emission spectroscopy (ICP-AES). Graphite furnace atomic absorption spectrometry (GFAAS), inductively coupled plasma mass spectrometry (ICP-MS), and ICP-OES are all useful for determining arsenic concentration. Sources: Labcompare, Thermo Scientific, and Science Education Resource Center at Carleton College.

interested in bioaccumulation. Bioaccumulation is the process of contaminants moving up the food chain, and it is important to take into account intake, biotransformation, and elimination of each species on the food chain, which all affect the ultimate human toxicity of the contaminant.[90]

The difference in bioaccessibility and bioavailability is that the former refers to the total amount of a contaminant in an environment, whereas the latter is only the amount that can enter living beings.[87] Bioaccessibility can be affected by environmental conditions. Thiols can cause an increase of bioaccessible arsenic in the form of methylarsenicals including monomethyl monothio arsenic acid ($MMMTA^{5+}$) and dimethyl monothio arsenic acid ($DMMTA^{5+}$).[91] Bioavailability has been reported to be the most vital of the three when it comes to remediation.[87] One environmental assessment states that this is due to the fact that bioavailability is closely tied to risk characterization.[92] Determining the phytoremediation abilities of individual plants provides more information not only about how to clean up environmental contaminants but also which consumable crops pose a risk to human health.

Hyperaccumulators. Phytoremediation is based on a group of plants called hyperaccumulators. In these plants arsenic is naturally stored in the shoots instead of in the roots, as is the case in most plants.[34] In hyperaccumulators, organic acids serve as chelating agents, which allow the plant to store more metals and arsenic than other plants without suffering deleterious effects to their growth and metabolism.[93] This removal of contaminants from the soil system can help make the system safer for future crops. One study recommends multiple phytoremediation cycles to further optimize the soil.[27]

The first plant established as a hyperaccumulator was the Chinese brake fern (*Pteris vitatta*), and today the species is used for its tolerance of up to 1500 ppm of arsenic in soil.[94] The fern can increase arsenic bioavailability by exuding dissolved organic carbon to change rhizospheric pH.[30] Other plants considered to be hyperaccumulators of arsenic include barnyard grass, curly endives, and most other ferns.[25,31,73] It is important to note that different plant species hyperaccumulate different contaminants. For example, fire phoenix (*Festuca arundinacea*) and alfalfa (*Medicago sativa*) are highly efficient in extracting polycyclic aromatic hydrocarbons (PAHs),[95] whereas Alpine penny-cress (*Noccaea caerulescens*) can tolerate large amounts of zinc and cadmium.[93] Choosing the proper phytoremediation technique and hyperaccumulating species is essential to effective environmental remediation. Understanding the properties of individual plants has important implications for human consumption and health.

Controlling the Contamination Problem. Although phytoremediation and other techniques have helped improve conditions in arsenic-contaminated areas, the effects of arsenic toxicity are still spread throughout the world, although the removal of environmental arsenic is extremely important, understanding the nature of its toxicity is key to minimizing its influence on society. This is especially true in places where exposure has reached epidemic proportions such as Bangladesh and India.[20,23] Determining all possible targets of arsenic toxicity will greatly support future efforts to fight the symptoms

DOI: 10.1021/acs.jafc.5b02487
J. Agric. Food Chem. 2015, 63, 7097−7107

and even identify methods of early detection. To further aid in the understanding of arsenic, research is constantly being conducted on better ways to analyze contaminants. One such experiment combined traditional methods to help better track its inorganic species in water.[38] The continued study of these new methods will lead to better phytoremediation in the future.

METHODS OF ARSENIC AND METAL QUANTIFICATION

Commonly Accepted Methods of Metal Determination. There are several accepted methods used to determine metal concentrations. Figure 3 contains brief descriptions of a few commonly used techniques. The appropriate technique is dependent on factors such as sample size and necessary detection limit. One method that is commonly employed due to its capacity to test for multiple metal concentrations is inductively coupled plasma mass spectroscopy (ICP-MS).[57] Some experiments have conducted arsenic speciation using high-performance liquid chromatography (HPLC).[30] One method uses HPLC to separate different species of arsenic in blood plasma and then find the concentration of each using ICP-MS with a detection limit of 2.5 ppb.[10] When a study is primarily interested in the total concentration, atomic absorption spectrometry can assess a digested solution via graphite furnace (GFAAS).[27] This technique can employ digestion of soft tissue samples from a plant to determine the total arsenic present with a detection limit of 200 ppb.[10] It is useful for assessing accumulation and has been used experimentally to evaluate vegetable uptake.[72] Other analytical methods that are proficient for finding even low arsenic concentrations include hydride generation atomic fluorescence spectrometry (HG-AFS), which has arsenic detection limits as low as 100 ppb, and inductively coupled plasma optical emission spectroscopy (ICP-OES), which can detect as little as 8 ppb in an acid solution.[7,10,38,96]

Emerging and Experimental Methods. Several emerging studies propose that developing hybrid techniques, such as coupling HPLC and HG-AFS, may result in simple, reliable methods for routine laboratory procedures.[97] One study aims to find a viable method of direct water determination by combining dispersive liquid−liquid microextraction with solid-phase extraction to prepare samples for the graphite furnace.[38] Another method sometimes used for its uniquely non-destructive testing is magnetic resonance imaging (MRI) alongside high-resolution magic angle spinning nuclear magnetic resonance (HR-MAS NMR) to observe changes in metabolites of polluted samples.[98] All established and experimental methods should be considered in future studies and could serve a role in solving the problem of arsenic worldwide.

DISCUSSION

On the basis of this assessment of the literature, arsenic toxicity is clearly a topic of widespread importance. Even with the foundation of knowledge established by years of research, the scientific understanding of the metalloid is continuously evolving. Arsenic has unique physical and chemical properties that facilitate dozens of interactions with biological systems, and each year more mechanisms in various plants and animals are proposed through new studies. Some of these involve human health, and the effects of the element on different organs and systems in the body can be dangerous and even fatal. Continuing to study the interactions between arsenic and human systems is important, as it will help guide not only options of toxicity treatment but also methods of safe cleanup and exposure prevention all the way down to the trophic level of plants.

Accumulation of the toxicant in plants has ramifications across the entire food chain. Several methods of remediation have been investigated for the cleanup of this contaminant. However, the most important problem at present is the tainting of food crops for millions of people in over a dozen countries. Although there is some ongoing research into human arsenic uptake via consumable plants, more is needed to assess the risk of eating specific products. More studies would yield new information concerning which plants are resistant to arsenic accumulation, which ones to avoid planting in contaminated areas, and which are contributing a significant amount of arsenic to the human diet. This research would be instrumental in controlling arsenic exposure and make major progress in permanently solving the problem on a worldwide scale.

subclade is mainly composed of representatives from East Asia. Because new *Hericium* species continue to be discovered,[13] it would be of interest to compare the compositions and bioactivities of taxonomically and phylogenetically related and different *Hericium* species to those of *H. erinaceus*, the subject of the present study.

COMPOSITION

H. erinaceus fruit bodies and mycelia contain an exceptionally large amount of structurally different bioactive and potentially bioactive components. Figure 1 shows a photograph of an *H. erinaceus* mushroom with its mane-like surface. Figures 2–6 depict structures arbitrarily subdivided into five classes of organic compounds (erinacines, aromatic compounds, steroids, alkaloids, and lactones) isolated from the fruit bodies and mycelia. It seems to be a unique event in nature for a single mushroom species to biosynthesize about 70 different secondary metabolites. Here, the chemical nature of some of the compounds that might be responsible for the observed health-promoting properties is described below. The reader is referred to the cited references for details about structural and stereochemical characterization and nomenclature.

Figure 1. Photograph of Lion's Mane mushroom (from Congaree National Park, South Carolina, USA, courtesy of the National Park Service).

Hericerins. Hericerins—aromatic compounds with medicinal properties—have been isolated and identified from *H. erinaceus*. In a recent publication, Li et al. describe the isolation and structural characterization of two new aromatic compounds (hericerin A and isohericenone J) along with five known compounds (isoericerin, hericerin, *N*-dephenylethyl isohericerin, hericenone J, and 4-(3′,7′-dimethyl-2′,6′-octadienyl)-2-formyl-3-hydroxy-5-methoxybenzylalcohol) from a chloroform extract of the *H. erinaceus* fruiting bodies.[14] In related studies, Li et al.[15] describe the isolation of a new aromatic compound, erinacene D, from *H. erinaceus*. Miyazawa et al.[16] reported on the isolation of two new aromatic compounds, including a new D-arabinol ester, and two known compounds from *H. erinaceus*, and Zhang et al.[17] identified a new diterpene from *H. erinaceus* mycelia. The anticancer properties of some of these compounds are mentioned below.

Kobayashi et al.[18] achieved the total synthesis of bioactive resorcinols, erinacerins, and hericenols, isolated from the fruiting bodies of *H. erinaceus*. The structure of hericenone B was revised as the carbonyl regioisomer at the lactam moiety.

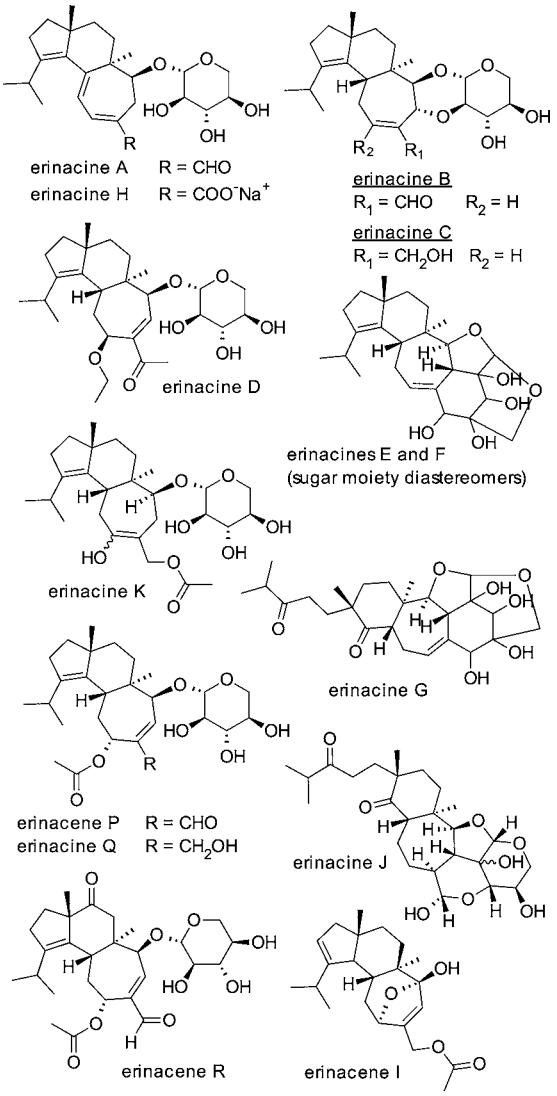

Figure 2. Structures of erinacines isolated from *Hericium erinaceus* fruit bodies and mycelia. Researchers at Shizuoka University first identified erinacines A–I;[80,103,132–134] Kenmoku et al.[135,136] characterized erinacines P and Q; and Ma et al.[137] characterized erinacine R.

Erinacines. The erinacines are a group of cyathane-type diterpenoids, including 20 members of 24 diterpenoids in *H. erinaceus* described by Tang et al.,[19] that have potential neuroprotective properties. Lee et al.[20] isolated erinacine A from an ethanol extract *H. erinaceus* mycelia. The compound contains the usual seven-member ring with two conjugated double bonds, which enables analysis by HPLC with UV detection at 340 nm.

Erinacerins—Isoindolin-1-ones. The isoindoline-1-ones are another group of secondary metabolites produced by *H. erinaceus*. Wang et al.[21] isolated 10 new isoindoline-1-ones, named erinacerins C–L, from a solid *H. erinaceus* culture. The structures of the compounds were established using spectroscopic methods, and the absolute configurations of some of these were assigned by comparing the specific rotations with those of related phthalimidines. The authors suggest that the described solid-state fermentation technique seems to be a useful method to stimulate the biosynthesis of secondary metabolites in edible and medicinal mushrooms and offer a hypothetical biogenesis pathway for the formation of the

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108–7123

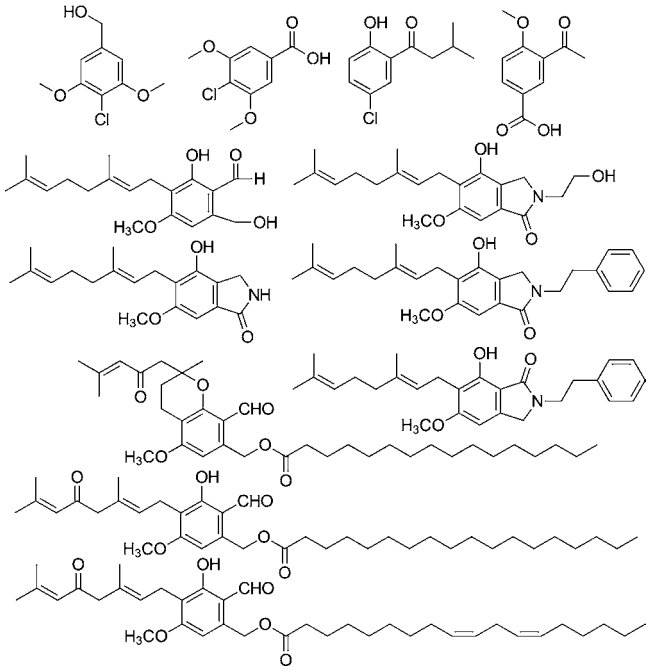

Figure 3. Structures of aromatic compounds isolated from *Hericium erinaceus* fruit bodies and mycelia. Adapted from Li et al.,[14] Noh et al.,[109] Zhang et al.,[17] and Miyazawa et al.[16]

erinacerins. Some of the compounds inhibited the growth of cancer cells, as described below.

Erinaceolactones. A recent study describes the isolation and characterization by spectroscopic methods of three novel erinaceolactones from the culture broth of *H. erinaceus*.[22] The absolute configuration of one of the compounds was determined by X-ray crystallography. A bioassay of plant-growth regulatory activity revealed that the new and structurally related *Hericium* compounds inhibited hypocotyl and root growth of lettuce at nanomolar concentrations.

Glycoprotein. Cui et al. isolated a novel glycoprotein (HEG-5) from cultures of *H. erinaceus* mycelia. The compound has a molecular weight of 14.4 kDa and has been shown to have hemagglutinating activity.[23] The protein/polysaccharide ratio of HEG-5 is 10:1 (%/%), and it contains D-glucose, L-rhamnose, D-galactose, and D-mannose in a molar ratio of 1.00:1.09:2.45:7.14 in the polysaccharide fraction. Analysis using FT-IR and NMR showed that HEG-5 contains the protein and carbohydrate parts with (1→4)-linked β-galactose and β-glucose residues, and circular dichroism showed that the HEG-5 is a predominantly β-sheet glycoprotein. The complete three-dimensional structure was obtained by protein sequencing and modeling using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS), NCBI blast search, and online SWISS-MODEL Workplace service. The glycoprotein inhibited the growth of human gastric carcinoma cells in the MTT cell viability assay and exhibited hemagglutinating, but not hemolytic, activity in rat erythrocytes, as described below.

Polysaccharides. Polysaccharides from *H. erinaceus* have been of particular interest because of the bioactivities that have been attributed to them. There are therefore a number of studies on their isolation and analysis. For example, a Russian study[24] describes the isolation of two polysaccharides from *H. erinaceus* mycelia that differ in solubility in aqueous ethanol. Both products contained the following sugars in different ratios: fucose, galactose, glucose, rhamnose, and xylose.

Wu et al. used colorimetry with iodine and KI, high-performance size exclusion chromatography coupled with multiangle laser light scattering and refractive index detection (HPSEC-MALLS-rid analysis), gas chromatography−mass spectrometry (GC-MS) analysis, and saccharide mapping based on carbohydrate gel electrophoresis (PACE) analysis to identify polysaccharides isolated from *H. erinaceus* fruiting

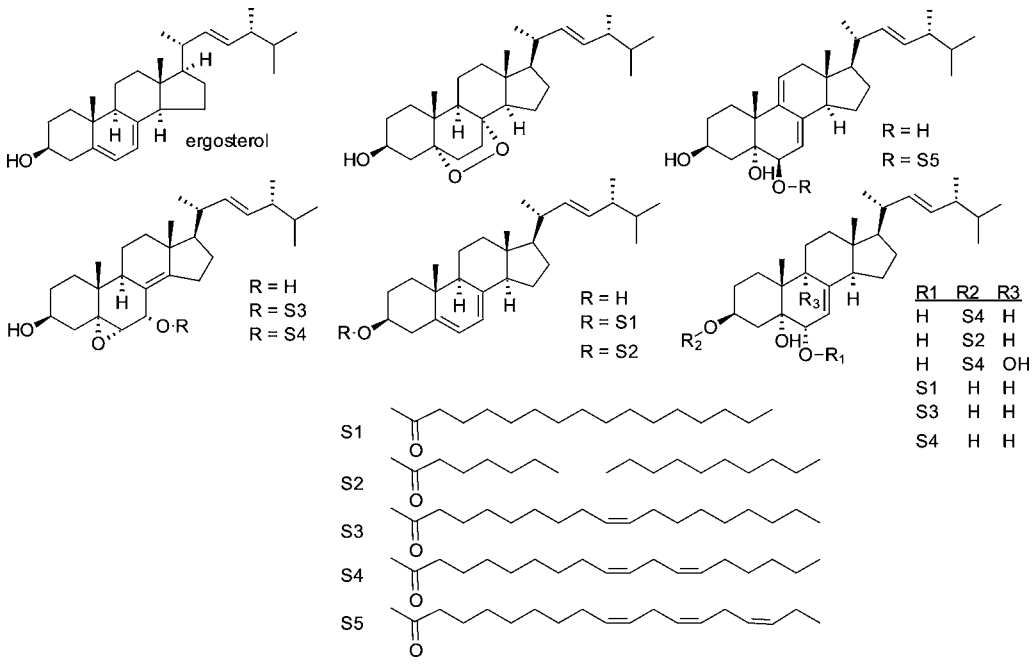

Figure 4. Structures of steroid compounds isolated from *Hericium erinaceus* fruit bodies and mycelia. Adapted from Avtonomova et al.,[24] Zan et al.,[32] and Li et al.[44]

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108−7123

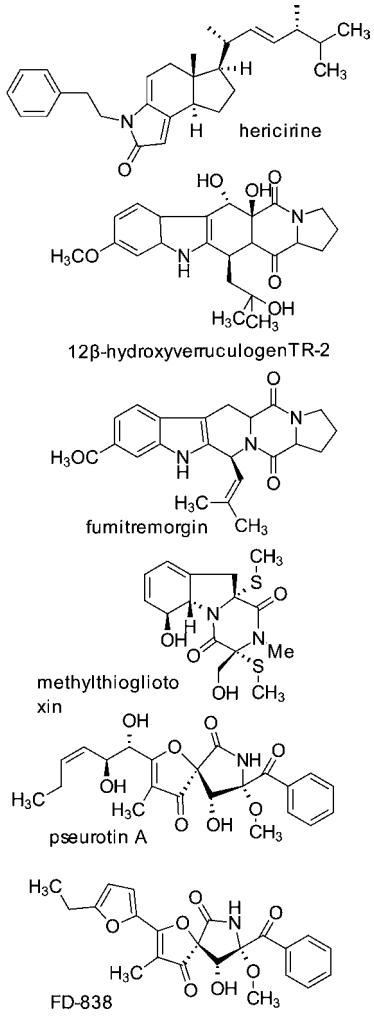

Figure 5. Structures of alkaloids isolated from *Hericium erinaceus* fruit bodies and mycelia. Adapted from Li et al.[138] and Lu et al.[139]

bodies collected from different parts of China.[25] The results show similarity in their profiles, including molecular weights, the composition of monosaccharides, and the glycosidic linkages in the polysaccharides, suggesting that the described experimental approach could be used for quality control of polysaccharides in edible and medicinal mushrooms as well as in commercial mushroom products. In addition, Hou et al.[26] isolated a water-soluble oligosaccharide from *H. erinaceus* with antioxidative properties. Other studies on the identification and characterization of *H. erinaceus* polysaccharides (*β*-D-glucans) are also reported by Kim et al.,[7] Bhandari et al.,[27] Li et al.,[28] Malinowska et al.,[29] Semedo et al.,[30] Shang et al.,[31] Wu et al.,[25] Zan et al.,[32] Zhang et al.,[33,34] and Zhu et al.,[35] some of which we elaborate here.

Using HPSEC to establish the degree of homogeneity and molecular weights, Malinowska et al.[29] evaluated several factors that govern the mycelial growth in a submerged culture of *H. erinaceus* and production of intracellular polysaccharides (IPS) and exopolysaccharides (EPS). They found that the kinetics of EPS biosynthesis in a bioreactor proceeded until depletion of the carbon source in the medium on day 14 of cultivation, suggesting the value of the method for large-scale production of bioactive polysaccharides from *H. erinaceus*.

An enzyme mixture (cellulase, pectinase, and tryptinase) facilitated extraction of polysaccharides from the fruits of *H.*

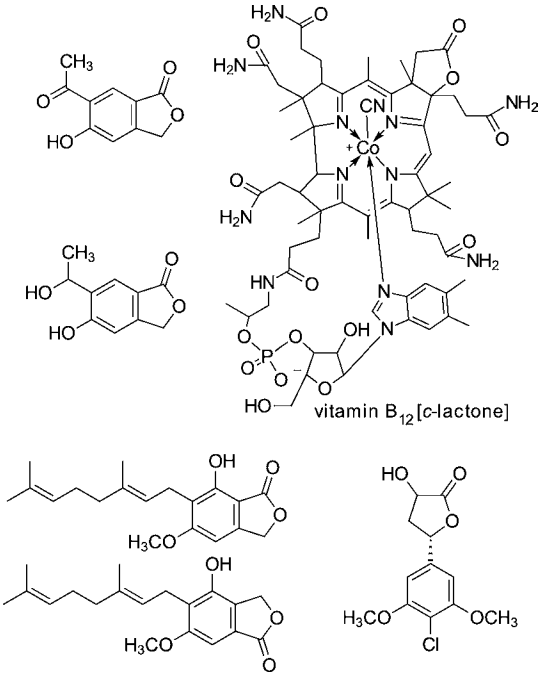

Figure 6. Structures of lactones isolated from *Hericium erinaceus* fruit bodies and mycelia. Adapted from Wu et al.[22] and Teng et al.[47]

erinaceus mushrooms using response surface methodology and the Box−Behnken design based on single-factor and orthogonal experiments to optimize the extraction conditions (pH 5.7, 52.0 °C, and 33.8 min).[35] The optimal extraction produces a high yield (13.5%) corresponding to an increase of 67.7% compared to hot water extraction. The functional groups of the two extracted polysaccharides seemed to be identical but differed in conformations. The authors suggest that the method might be useful for extracting polysaccharides from other mushroom species. Related studies describe the isolation and structural characterization of a rhamnoglucoagalactan[36] and a *β*-D-glucan[37] from *H. erinaceus* fruiting bodies.

H. erinaceus and other mushroom varieties are reported to be a useful source of lignocellulose-degrading (ligninolytic) carboxymethyl cellulase and laccase enzymes, suggesting that mushrooms can provide enzymes for use in the development of bioenergy.[38] Mushroom spent straw, an important lignocellulosic biomass, might serve as a potential substrate for an ethanol-based biorefinery.[39]

Sterols. The identification of various sterols from *H. erinaceus* has also been reported. For example, Avtonomova et al.[24] detected the presence of ergosterol in the *H. erinaceus* mycelia biomass. Because exposure of ergosterol to UV(B) light transforms ergosterol in mushrooms to vitamin D,[40,41] a process used to commercially market vitamin D-containing mushrooms, it would be of interest to find out whether such exposure would also induce an analogous transformation of *H. erinaceus* fruiting bodies and mycelia, thus further enhancing the health-promoting potential of this mushroom.

Because the amounts of such bioactive sterols, including ergosterol, are fairly low in *H. erinaceus*, Dai et al. evaluated the biomass and ergosterol content of *H. erinaceus* mycelium following supplementation of the liquid culture with the plant-derived compounds salicylic acid and methyl jasmonate.[42] The highest ergosterol content of 2.33 mg/g was obtained following 6 days of cultivation with 100 *μ*mol/L salicylic acid. With 50

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108−7123

μm/L methyl jasmonate, the highest ergosterol content was 2.0 mg/g. Both values were significantly higher than ergosterol production without the additives. Because methyl jasmonate induced significant increases in both mycelium biomass and ergosterol content during the logarithmic growth phase, whereas salicylic acid enhanced only the production of ergosterol but not biomass, the authors conclude that the use of added jasmonate might be preferable over methyl salicylate.

In other examples of sterol identification, Li et al.[43] compared the nature of sterols present in *H. erinaceus* in ethanol and water extracts, finding them mainly in the ethanol extract and identifying new sterols. Related studies describe the isolation and structural characterization of 6 new (erinarols A−F) and 5 known ergostane-type sterol fatty acid esters and 10 known ergostane-type sterols and erinarols G−J from methanol extracts of the dried fruiting bodies of *H. erinaceum* as well as anti-inflammatory and antiproliferative properties of some of these compounds in cell assays.[32,44]

Vitamin B_{12} Lactone. Some mushrooms, not including *H. erinaceus*, are reported to contain vitamin B_{12},[45] which is of particular interest to vegetarians,[46] because animal-derived foods are the usual dietary sources of vitamin B_{12}. *H. erinaceus* is, however, reported to contain the biologically inactive vitamin B_{12}[c-lactone],[47] and it may be possible to generate the active vitamin from this compound by chemically opening the lactone ring.

Volatile Compounds. Analysis of dried fruiting bodies of *H. erinaceus* by GC and GC-MS identified 77 components, representing 87.6% of the total volatile oil.[48] The main components of the oil were hexadecanoic acid (26.0%), linoleic acid (13.1%), phenylacetaldehyde (8.9%), and benzaldehyde (2.5%). Aroma evaluation of the oil using GC-MS−olfactometry and aroma extract dilution analysis showed that 2-methyl-3-furanthiol, 2-ethylpyrazine, and 2,6-diethylpyrazine seem to be the major contributors to the mushroom aroma. Because plant essential oils and aromatic aldehydes inactivate pathogenic bacteria,[49,50] will the mushroom oil and components also be active against pathogenic microorganisms? (See also Antibiotic Properties.)

NUTRIENTS, NUTRITION, AND FOOD USE

Here, we will first mention some general aspects associated with mushroom production, composition, and nutrition followed by a discussion of the limited studies on the nutrition of *H. erinaceus*.

Nutritional Composition. In describing culinary aspects of mushrooms, McGee notes that mushrooms are fungi that have no chlorophyll and thus they cannot harvest energy from the sun.[51] Instead, they live off plants and plant remains. They are therefore distinct from biologically derived foods such as cereals, fruits, and vegetables, and meat and dairy products.[1] The distinctive flavor of mushrooms is associated with a high content of free amino acids, especially glutamic acid, and numerous volatile compounds. Many mushrooms contain enzymes such as polyphenol oxidase that catalyze rapid enzymatic browning reactions[52] and, therefore, darken rapidly when cut or crushed.

A comprehensive review by Sawant et al.[53] provides information on mushroom cultivation and production methods including solid state and submerged culture; diseases caused by pathogenic fungi, bacteria, viruses, and pests; harvesting, grading, and packaging; storage; and processing (canning, dehydration, freezing and freeze-drying, and pickling). The reader is referred to the above-mentioned chapter by Savant for specific details on growing, harvesting, and processing of mushrooms.

An earlier review by Kurtzman,[54] reports that (a) the proximate composition of five mushroom species (not including *Hericium*) ranged as follows: water, from 73 to 91%; crude protein (N × 4.38), from 10.5 to 28.5%; fat, from 1.6 to 8.0%; carbohydrate, from 57.4 to 81.8 g/100 g dry wt; fiber, from 7.5 to 17.4 g/100 g dry wt; ash, from 6.1 to 12.0 g/100 g dry wt; and energy, from 271 to 387 kcal/100 g dry weight; and (b) the total essential amino acid composition ranged from 38.4 to 50.1 g amino acid/100 g of crude protein compared to 51.3 g amino acid/100 g for high-quality egg protein, suggesting that the nutritional quality of these mushrooms is quite high and that the content of essential amino acids approaches that of egg protein.

Ulziijargal and Mau summarize the results of proximate composition studies of 38 fruiting bodies and 19 mycelia of 32 species of culinary−medicinal mushrooms, including *Hericium*.[55] Most fruiting bodies and mycelia are low in fat and rich in protein and dietary fiber; some are rich in polysaccharides and others in crude fiber, suggesting that proximate composition and energy for fruiting bodies and mycelia should be taken into account for proposed uses as culinary and health food and as food additives.

In another study, Rodrigues et al. determined the composition and nutritive values of five mushroom species, including *H. erinaceus*.[56] Protein, sugar, and fat contents were in the ranges of 16.22−26.6, 52.7−64.9, and 2.3−3.5 g/100 g dry mushrooms, respectively. These mushroom are also good sources of phenolic compounds and contain more monounsaturated and polyunsaturated fatty acids than saturated fatty acids, with a high concentration of linoleic acid (>30 g/100 g fat), and they are good sources of magnesium, phosphorus, and especially potassium (2.6−3.7 g/kg dry mushroom). The mushrooms also contain significant amounts of copper, iron, and zinc, suggesting their dietary nutritional potential as a source of multiple macro- and micronutrients.

A comprehensive quantitative study by Cohen at al. of the composition of 15 Basidiomycetes medicinal mushroom strains belonging to 12 species, including *H. erinaceus* fruiting body (FB) and mycelia biomass (MB), found that almost all investigated mushrooms are a good source of proteins and carbohydrates, the levels of which are 8.6−42.5 and 42.9−83.6%, respectively, and that different species exhibited distinct free amino acid profiles.[2] The following information is limited to their reported findings with *H. erinaceus*. The analyses were performed on mushrooms dried at 50 °C and then ground into a powder. The dried powder of *H. erinaceus* FB contained 20.8% protein, 61.1% total carbohydrate, 5.1% fat, 6.8% ash, 6.2% water, and 374 kcal/100 g energy, whereas the MB contained 42.5% protein, 42.9% total carbohydrate 6.3% fat, 4.4% ash, 3.9% water, and 398 kcal/100 energy. The corresponding values for the total free amino acid content are 14.3 and 30.6 mg/g dry weight basis for the FB and MB, respectively. The total fatty acid content consisted of 11 individual unsaturated and saturated forms for FB and 7 for MB. Both FB and MB also contained various amounts of nutritional macro- and microelements (calcium, chromium, cobalt, copper, iron, magnesium, manganese, molybdenum, phosphorus, selenium, sodium, sulfur, and zinc) as well as low amounts potentially toxic elements (aluminum, arsenic, barium, boron, cadmium, nickel, silver, strontium, tin, titanium, and

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108−7123

vanadium). The content of amino-acid-derived bioactive compounds (in μg/g dry weight) in FB and MB, respectively, was as follows: γ-aminobutyric acid (GABA), 42.9 and 56.0; ergothioneine, 630.0 and 149.2; and lovostatin, 14.4 (FB). A levostatin value for MB was not reported.

It seems that both FB and MB contained useful nutrients and bioactive compounds and can as well serve as a resource for their use in food and pharmaceuticals (neutraceuticals); because of differences in composition among the MB and FB of the same species and among different species, combination of different species could be used to optimize their nutritional and health-promoting potential.

Because the use of mushrooms in main entrées in plant-based diets is growing, Feeney et al.[1,3] suggest that the nutritional and health benefits of mushrooms in terms of their nutrient, culinary, and health-promoting characteristics should be re-evaluated in the context of three separate food kingdoms: plants/botany, animals/zoology, and fungi/mycology. Because of the increasing availability of complete compositional data for different mushroom species, Feeney et al.[1,3] suggest the need for mathematical modeling designed to optimize the nutritional and health potential of combinations of different fruiting bodies and mycelia followed by animal and human feeding studies to confirm the predicted benefits. It may be possible to help meet this need by applying a mathematical modeling method to the relationship of composition to nutritional and health properties of mushrooms developed by Finotti et al.[57,58] for other food categories as well as principal component analysis of the bioactive *H. erinaceus* compounds as described for other mushroom species.[59,60] Moreover, the composition of the mushrooms also seems to depend on whether they are cultivated or grown in the wild.[61]

There is also a need to confirm the calculated nutritional values (scores) of mushrooms based on the content of essential amino acids,[62] by nutritional evaluation using feeding studies with mice, rats, and humans (as described elsewhere for free amino acids and other food proteins).[63−66] Unlike the in vitro results, the in vivo results are influenced by the digestibility of the proteins, absorption of the digested amino acids into the circulation, and their utilization for the synthesis of essential proteins.

Food Uses. The following three studies suggest the potential of *H. erinaceus* as a source of bioactive compounds and antioxidants in bread and in fermented mushroom wine, vinegar, and nonalcoholic beverages. Possible ways to inhibit enzymatic browning in mushrooms are also mentioned.

Bread Additive. Bread baked with 5% of *H. erinaceus* and other mushroom mycelia contained significant amounts of γ-aminobutyric acid (0.23−86 and 0.79−2.1 mg/g dry matter, respectively), reported to affect brain function,[67] and ergothioneine, reported to impact heart function,[68,69] suggesting that adding mushroom mycelia to bread might provide health benefits.[70]

Mushroom Wine and Vinegar. Another food application might be the reported use of *H. erinaceus* as a fermentation substrate for the production of wine and vinegar.[71] After 9 days of fermentation of 5% *H. erinaceus* powder, the alcohol content of the resulting mushroom wine reached 16%. A sensory evaluation by a human panel expressed overall acceptance of the organoleptic properties of the new wine. The wine was then treated with *Acidophilus aceti* bacteria to produce vinegar with an acidity of 4.09% due to presence of acetic, malic, and succinic acids. The new vinegar showed antioxidant activity possibly associated with its phenolic content comparable to those of known vinegars, suggesting the possibility that the *H. erinaceus* vinegar might represent a new food product with antioxidant capacity.

Fermented Mushroom Beverages. Because non-alcoholic fermented plant beverages are produced by fermentation of plant sources with different lactic acid bacteria, Woraharn et al.[72] evaluated the production of L-glutamic and γ-aminobutyric acid in a fermented *H. erinaceus* beverage by two *Lactobacilli* starter cultures. Glutamic acid production was significantly influenced by K_2HPO_4, pH, and temperature, whereas γ-aminobutyric acid production was significantly influenced by pH and temperature, suggesting that the mushrooms can be used to prepare high-quality fermented beverages at low cost.

Inhibition of Browning. Because heat used in cooking and baking is reported to adversely and beneficially affect the composition of mushrooms,[73,74] it would be of interest to find out to what extent food processing (canning, cooking, baking, frying, grilling, microwaving, sautéing) might affect the composition of *H. erinaceus* fruit bodies and mycelia. For example, the enzymatic browning reaction (formation of brown spots) that occurs on storage and heat drying of mushrooms, catalyzed by the enzyme tyrosinase, is a problem that has been addressed by Li et al.[75] for the culinary mushroom *Lentinus edodes* (Shiitake). They pretreated the mushrooms with the amino acid L-cysteine and other inhibitors of the enzyme tyrosinase to inhibit the browning process. L-Cysteine is reported to also inhibit enzymatic browning in potatoes[76] and nonenzymatic (Maillard) browning that can produce the potentially toxic acrylamide.[77,78]

MEDICINAL PROPERTIES

As mentioned, *H. erinaceus* has long been used for its beneficial health properties, which are reported to be wide ranging, as outlined in the sections below. Many of the activities reported for *H. erinaceus* can have crossover (overlapping) effects on different medical conditions as indicated in some of the sections below.

ANTIBIOTIC PROPERTIES

The following observations indicate that *H. erinaceus* extracts and bioactive erinacines and polysaccharides have been shown to have antimicrobial activities against both antibiotic-resistant and nonresistant (susceptible) pathogenic bacteria.

Methicillin-Resistant *Staphylococcus aureus* (MRSA). The prevalence of antibiotic-resistant pathogenic bacteria, especially MRSA, is a major unsolved problem in microbial food safety and human health, as reviewed by Friedman.[79] The identification of new compounds to treat antibiotic-resistant bacteria is therefore welcome. To contribute to this aim, using a Petri dish agar and microplate assays, Kawagishi et al. found that several erinacines isolated from cultured *H. erinaceus* mycelia showed potent anti-MRSA activity, with minimum inhibitory concentrations (MIC) values ranging from 62.5 to 500 μM.[80] An examination of the structure−antimicrobial activity relationship showed that the ring skeleton of the aglycone in the active compounds was indispensable to the anti-MSRA activity. It would be of interest to confirm this useful finding against MRSA-containing food and MRSA-infected animals and humans.[81]

***Salmonella* Typhimurium.** *Salmonella* Typhimurium is a pathogen that contaminates numerous foods, including leafy

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108−7123

greens, meat, and poultry. Kim et al.[82] discovered that although *H. erinaceus* extracts were inactive against this pathogen in vitro, they protected mice against lethal infection through the activation of innate macrophage immune cells. Two of the four extracts evaluated stimulated the activity of macrophage cells in vitro and protected infected mice against mortality and liver damage. Because systemic salmonellosis induces liver necrosis, liver injury was used as a biomarker for the incidence for in vivo salmonellosis in the mice. It seems that the protection of the liver by the mushroom extracts might be the result of stimulation of the innate immune cells, which then kill the *Salmonella* bacteria that induced the liver injury, analogous to that observed with the cultured macrophage cells. This first report on the inhibition of adverse effects of *Salmonella* in mice via stimulation of the immune system by mushroom extracts suggests that *H. erinaceus* mushrooms or extracts could be used to improve microbial food safety and infectious diseases. It would be of interest to find out whether the *H. erinaceus* extracts and/or pure compounds would also protect mice and humans against adverse effects caused by other foodborne pathogenic bacteria, including *Bacillus cereus*, *Escherichia coli*, *Listeria monocytogenes*, and *Vibrio cholerae*.

In a related study Kim et al.[83] also reported that a polysaccharide isolated from the liquid culture of *L. edodes* mushroom mycelia containing black rice bran protected mice against salmonellosis-induced liver injury and mortality through stimulation of the immune system. The same polysaccharide–black rice bran formulation also protected mice against *Salmonella* lipopolysaccharide-induced endotoxemia.[84] It would be interesting to investigate whether a similar *H. erinaceus* formulation might also protect mice against *Salmonella*-induced lethal infections and often fatal endotoxemia.

Helicobacter pylori. *H. pylori* is a human gastrointestinal pathogen that may contribute to the cause of adverse effects, possibly including ulcers. Shang et al.[85] determined the minimum inhibitory concentration (MIC) values of extracts prepared from the fruiting bodies of 14 mushroom species including *H. erinaceus* against *H. pylori* clinical strains using a microplate agar diffusion assay. MIC values of ethyl acetate fractions of *H. erinaceus* against nine clinical isolates of *H. pylori* ranged between 62.5 and 250 μg/mL. Ethanol extracts were less effective. The extracts of *H. erinaceus* also inhibited *Staphylococcus aureus* (MIC = 10 mg/mL) but had no effect on the growth of two *Escherichia coli* test strains (MIC > 10 mg/mL). The in vitro inhibitory effect of *H. erinaceus* extracts against *H. pylori* suggests antimicrobial mechanisms that do not seem to involve the immunomodulating effects observed with polysaccharides.[82]

Anti-*H. pylori* activities in vitro were evaluated using an agar dilution assay of two novel polysaccharides isolated from *H. erinaceus* with molecular weights of 197 and 20 kDa.[86] Although the polysaccharides alone inhibited the bacteria, complexes with bismuth exhibited stronger inhibition effects (MIC = 20 μg/mL), suggesting the need to evaluate these novel *H. erinaceus*-derived compounds against *H. pylori* infections in humans. It would be of interest to determine whether *H. erinaceus* and bioactive compounds would also inhibit the biological activity of microbial and plant toxins.[87]

Multiple Pathogens. A study by Wong et al.[88] using the well diffusion method that measures inhibition zones on Petri plates found that various *H. erinaceus* extracts inhibited the growth of multiple Gram-positive and Gram-negative pathogenic bacteria. The inhibition depended on the type of extract tested. Oven-dried fruit body extract was inactive.

■ ANTICARCINOGENIC PROPERTIES

Carcinogenesis is a sequential multistage cellular process consisting of tumor initiation, tumor promotion, and tumor progression. Plant compounds in some foods are a potential source of bioactive safe compounds for cancer chemoprevention and suppression of tumor initiation, promotion, and metastasis.[89] Dietary components can protect against cell proliferation and induce cell death (apoptosis) by a variety of mechanisms, including destruction of reactive oxygen species (ROS) that damage DNA and essential proteins, suppression of signaling pathways, and expression of proteins involved in carcinogenesis, inhibition of angiogenesis (blood flow to cancer cells), cancer cell metastasis (migration of cells from the origin to other organs), and stimulation of the immune system that helps eliminate carcinogens.[82,83,90,91] Here, we will briefly mention selected reported studies on the antioxidative, antimutagenic, antitumor-promoting, and anticarcinogenic activities of *H. erinaceus* and bioactive components in mammalian cells and rodents (mice, rats).

Inhibition of Cancer Cells. The recently isolated newly discovered diterpene mentioned under Nutritional Composition above both exhibited anti-*H. pylori* activity and inhibited the growth of human leukemia (K562) and human prostate cancer (LANCAP) cells.[17] The isolated hericerin A and hericerin also significantly reduced the proliferation of leukemia cells with IC_{50} values of 3.06 and 5.47 μM.[14]

A study by Lee and Hong[92] on the mechanism of *H. erinaceus* inhibition of human liver (HepG2) cancer cells showed that (a) hot-water *H. erinaceus* extract enhances the apoptosis induced by the clinical cancer drug doxorubicin and (b) the *H. erinaceus* extract acts as an enhancer to sensitize doxorubicin-mediated apoptotic signaling by reducing C-FLIP expression via JNK activation and enhancing intracellular doxorubicin accumulation via inhibition of NF-κB activity. The mushroom extract seems to have the potential to provide therapeutic effects against drug-resistant human liver carcinoma.

Li et al. isolated a lectin (agglutinin) from dried fruiting bodies of *H. erinaceus* with a molecular mass estimated at 51 kDa, a hemagglutinating activity of 12.5 mM by the inulin assay, and high heat and pH stability.[93] The lectin showed antiproliferative activity toward hepatoma (HepG2) and breast cancer (MCF7) cells with IC_{50} values of 56.1 and 76.5 μM, respectively, HIV-1 reverse transcriptase inhibitory activity with an IC_{50} of 31.7 μM, and mitogen activity toward mouse splenocytes. Because lectins are non-immunglobulin proteins that can agglutinate cells through sugar-specific binding sites, their mechanism of anticancer and antimicrobial action differs from that of other mushroom components, reviewed by Hassan et al.[94]

Kim et al.[8] also evaluated hot water (HWE), microwaved 50% ethanol (MWE), acidic (ACE), and alkaline (AKE) extracts of the fruit body (sporocarp) of *H. erinaceus* for their ability to induce apoptosis (programmed cell death) in U937 human monocytic leukemia cells. Cell culture, cell viability, cytotoxicity, flow cytometry, chromosomal DNA integrity, mitochondrial membrane potential, expression of pro- and anti-apoptotic proteins, and activation and inhibition of caspase assays were carried out to help define the mechanism of observed apoptosis. The aqueous and aqueous/ethanol extracts were active in all assays, whereas the acidic and alkaline extracts

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108−7123

with similar proximate compositions were both inactive. The results of the bioassays with the active extracts are consistent with an apoptosis mechanism governing suppression of the cell proliferation pathway that involves activation of mitochondria-mediated caspase-3 and caspase-9 but not caspase-8. Proximate analysis of the freeze-dried mushroom powder showed that it contains high amounts of proteins, carbohydrates, and minerals. The described observations indicate that aqueous and aqueous/ethanol extracts of *H. erinaceus* that induced NO production in macrophage cells strongly suppressed the proliferation of U937 leukemia but not normal cells, by induction of apoptosis, suggesting that *H. erinaceus* may have therapeutic potential against human leukemia.

The novel HEG-5 polysaccharide-protein isolated from fermented *H. erinaceus* mycelia inhibited human gastric SGC-7901 cancer cells by promoting apoptosis and cell cycle arrest at the S-phase.[32] RT-PCR and Western blot analysis showed that HEG-5 decreased the expressions of Bcl2, PI3K, and AKT1 proteins and increased the expressions of caspase-3, caspase-8, p53, CDK4, Bax, and Bad, suggesting that caspase- and p53-dependent mitochondrial-mediated signaling pathways participate in the molecular events of apoptosis. The results imply that the novel polysaccharide might be a candidate for treating gastric cancer. The use of HEG-5 against human gastric cancer is expected to be successful in light of the fact that *H. erinaceus* mushrooms are reported to prevent gastric ulcers, chronic gastritis, and other digestive tract-related diseases.[95,96]

Chen et al.[97] isolated polysaccharides from eight mushroom species by water extraction and alcohol precipitation. The *H. erinaceus* polysaccharide exhibited the highest antioxidant capacity and strongly inhibited MCF-7 breast cancer cells.

Inhibition of Tumor Growth. Kim et al.[7] investigated antitumor effects of the four extracts of freeze-dried *H. erinaceus* in Balb/c mice intracutaneously transplanted on their backs with CT-26 colon cancer cells; HWE and MWE, with a higher content of β-glucans than ACE and MKE and determined using an assay kit, were active in all bioassays. GC-MS analyses showed the presence of 40, 27, 16, and 13 compounds, respectively, in the four extracts. Daily intraperitoneal (ip) injections of HWE and MWE for 2 weeks significantly reduced tumor weights by 38 and 41%. Tumor regressions were associated with changes in the following cancer biomarkers as compared to phosphate buffer (PBS)-treated control mice: 2.7- and 2.4-fold increases in cytolytic activity of splenic natural killer (NK) cells; restored nitric oxide production and phagocytosis (engulfing and destruction of cancer cells by phagocyte cells) in peritoneal macrophages to 95−98% of normal levels; 2-fold increase in released pro-inflammatory cytokines tumor necrosis factor-α, interleukin-1β, and interleukin-6 from macrophages; and 56 and 60% reductions in the number of blood vessels inside the tumor. The pro-angiogenic factors vascular endothelial growth factor (VEGF), cyclooxygenase 2 (COX-2), and 5-lipoxygenase (5-LOX) were also significantly reduced in mRNA and protein expression by tumor genes. Enzyme-linked immunosorbent assay of tumor cells confirmed reduced expression of COX-2 and 5-LOX (32 and 31%). Reduced COX-2 and 5-LOX expression down-regulated VEGF expression, resulting in the inhibition of neo-angiogenesis inside the tumors. It seems that induction of NK activity, activation of macrophages, and inhibition of angiogenesis all contribute to the mechanism of reducing tumor size.

Another study by Kim et al. investigated the antimetastatic activity of four *H. erinaceus* mushroom extracts using CT-26 murine colon carcinoma cells as an indicator of inhibition of cell migration to the lung.[6] The HWE and MWE extracts strongly elicited cancer cell death through apoptosis and inhibited metastasis of cancer cells to the lungs by 66 and 69%, respectively. The same extracts reduced the expression of matrix metalloproteinases MMP-2 and MMP-9 in cells and their activities in culture media. Urokinase-type plasminogen activator (u-PA), another extracellular matrix (ECM)-degrading proteinase, also showed decreased protein expression. In CT-26 cells, HWE and MWE down-regulated extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and p38 mitogen-activated protein kinase (MAPK) phosphorylations. The reduced phosphorylations seem to cause reduction of activity of the MMPs, thereby blocking migration and invasion of cells. Dietary administration of HWE and MWE reduced the formation of tumor nodules in the lung by about 50 and 55%, respectively, and prevented increases in lung weight caused by cancer cell metastasis.

It seems that HWE and MWE behaved as antimetastatic agents, targeting their upstream signaling molecules for mediating the expression of the ECM-degrading proteinases. Acidic and alkaline extracts were not bioactive. This study elucidated the mechanism of the observed inhibition of metastasis of cancer cells from one organ to another in terms of biomarkers known to be associated with prevention of metastasis, suggesting that inhibition of metastasis seems to be related to the composition of *H. erinaceus*.

Daily oral administration of three amounts (50, 100, and 200 mg/kg/day for 10 days) of *H. erinaceus* polysaccharides to 50 mice with S180 solid tumors reduced the increase in tumor weight from 100% for the control group to 68.5, 32.1, and 43.2% in treated groups, respectively, as compared to 18.5% for treatment with the cancer drug cyclophosphamide.[98] The reduced tumor weight gains were accompanied by increased serum levels of antigen-specific-γ (IFN-γ) and interleukin-2 (IL-2), suggesting that the antitumor effect might be associated with immunostimulation. A related study on the antitumor and immunoenhancing effects of polysaccharides is mentioned under Stimulation of the Immune System.

The cited studies suggest that *H. erinaceus* polysaccharides merit further study to determine if their anticarcinogenic activities in mice also occur in humans.

An interesting finding was that the replacement of aspartic acid/glutamic acid with asparagine/glutamine residues in ribonuclease from *H. erinaceus* resulted in a modified enzyme that inhibited the proliferation of a human leukemia cell line.[99] The authors suggest that the modified ribonuclease, which was expressed by recombinant methods in *E. coli* bacteria, might be of general importance for the production of anticancer biologics that are based on ribonuclease activity.

NEUROPROTECTION AGAINST NEURODEGENERATION

Cell and Mice Studies. A review by Wong et al. on the treatment of peripheral nerve injury by *H. erinaceus* concludes that the neuroprotective effects of *H. erinaceus* and other mushrooms in rodents need to be confirmed in human studies.[100] Here, we will be briefly examine selected studies on the neuroprotective effects of *H. erinaceus* in cells and animals and their potential impact on cognitive abilities in humans, which suggest that such mushrooms may help improve brain and nerve diseases in humans.[20,101,102]

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108−7123

A systematic screening of 19 commercial *Hericium* strains revealed that the administration of fruiting bodies of *H. erinaceus* could attenuate (protect against) Aβ25-35-triggered damage in rat pheochromocytoma (PC12) cells, which are widely used to study neuritogenesis in vitro.[11] The observed effects were an increase in cell viability and a decrease in the release of lactate dehydrogenase; the described method could therefore be used to screen for the neuroprotective effects of mushrooms.

Nerve growth factor (NGF) is involved maintaining and organizing the function of cholinergic neurons of the basal forebrain complex (BFC) of the central nervous system, the neurons of which degenerate during the progression of Alzheimer's disease (dementia). Kawagishi et al. discovered and named the bioactive diterpenoids erinacine A, B, and C from *H. erinaceus* mycelia that stimulated NGF synthesis.[103] Phan et al.[104] cultured *H. erinaceus* mycelia and screened pure compounds isolated from the basidiocarps for neurite outgrowth activity using PC12 cells.

The use of HPLC, LC-MS, and ^{1}NMR facilitated the elucidation of the structures of six compounds from the basidiocarps: hericenones B−E, erinacerin A, and isohericerin. Hericenone E stimulated NGF secretion to a level that was 2 times higher than that of the positive control, by potentiating outgrowth in the PC12 cells, possibly mediated by ERK1/2 (extracellular signal-regulating kinases) and P12Akt (protein kinase) signaling pathways to induce neuronal differentiation and neuritogenesis.

A related study by Mori et al. examined the effect of four edible mushroom fruiting bodies including *H. erinaceus* on NGF gene expression in 1321N1 human astrocytoma cells (astrocytes).[105] The results show that *H. erinaceus* fruiting bodies, but not the isolated hericenones C, D, and E, promoted NGF mRNA expression in a concentration-dependent manner and enhanced the secretion of the NGF protein from the cells. Additional studies showed that the extract also enhanced the neurite outgrowth of PC12 cells in vitro and increased NGF mRNA expression in the hippocampus, but not in the cortex, of mice fed a 5% dry *H. erinaceus* powder for 7 days and that the stimulation of NGF production occurs via activation of the JNK pathway.

Another study by Mori et al. examined the effect of oral administration of *H. erinaceus* powder added to the mouse diet over a 23 day experimental period on the amyloid β(25−35) peptide-induced learning and memory deficits (cognitive dysfunctions) in mice.[106] Evaluation of the learning function of the mice by behavioral pharmacological methods (Y-maze and novel-object recognition tests) indicates that the mushroom powder improves the cognitive deficits induced by the amyloid peptide, suggesting that the powder might be a promising treatment for cognitive dysfunction. Additional HPLC studies showed that the powder contained the following three hericenones: C, 4.12 mg/g; D, 0.21 mg/g; and E, 0.49 mg/g.

The cited cell and mice feeding studies imply that because NGF levels decrease in the basal forebrain of Alzheimer's patients and in the frontal cortices of people with senile plaques, the results of the cell and mice feeding studies showing increased secretion of NGF indicated that hericenone E and the *H. erinaceus* powder merit further studies for their potential to prevent progress of dementia and senile plaques in humans.

Antifatigue Effects. A study by Li et al. examined the antifatigue activity of a polysaccharide extracted from *H. erinaceus* in a mouse model using the following criteria.[107] A control group and three test groups of mice were treated with the polysaccharide (50, 100, and 200 mg/kg for 28 days). The results of a force swimming test, a measure of fatigue, decreased blood lactic acid (BLA), serum urea nitrogen (SUN), and malondialdehyde (MDA) content, and increased tissue glycogen content and antioxidant enzyme activity suggest that an *H. erinaceus* component induced significant antifatigue activity and might, therefore, be of value in the field of sport nutrition.

Acceleration of Wound Healing in Rats. A Malaysian study found that the topical application of an *H. erinaceus* aqueous extract (0.2 mL of 20, 30, and 40 mg/mL) accelerated the rate of wound healing in rats.[108] The healed wounds contain fewer macrophages and more collagen, suggesting that the healing effect might be associated with the up-regulation of collagen formation and an increase in the tensile strength of the wounds. Because the livers and kidneys of the rats were not affected by the treatment, hematology and clinical biochemistry were within the range of control animals tested, and the highest dose of the extract (5 g/kg body weight) did not cause any toxicity, it seems that the mushroom extract is relatively nontoxic. The authors suggest the need to identify the bioactive component in the extract that has possible immunostimulatory potential.

Inhibition of Cell Senescence. Noh et al. evaluated the inhibitory effects of six compounds isolated from *H. erinaceus* on adriamycin-induced cellular senescence in human dermal fibroblasts (HDFs) and human umbilical vein endothelial cells (HUVECs).[109] One of the compounds—ergosterol peroxide—reduced senescence-associated β-galactosidase (SA-β-gal) activity that is increased in HUVECs treated with adriamycin, suggesting that one or more of the pure compounds might have the potential to treat/prevent age-related diseases in humans.

HUMAN STUDIES

Beneficial Effects on Depression and Anxiety. Nagano et al. investigated the effect of *H. erinaceus* on depression, menopause, and sleep quality using epidemiological-based questionaires.[110] In a randomized, double-blind, placebo-control trial conducted over 4 weeks, 30 females aged 41.3 ± 5.6 years were randomly assigned to either *H. erinaceus* or placebo groups and fed *H. erinaceus* cookies containing 0.5 g of the powdered fruiting body 4 times a day for 4 weeks or placebo cookies for the same regimen. The mean standard scores at the end of the test were lower for the *H. erinaceus* than for the placebo group, suggesting that orally consumed *H. erinaceus* has the potential to reduce depression and anxiety in women but this is by a different, and as yet unknown, mechanism from the NGF-enhancing effect by the mushroom extracts and hericenones mentioned above.

Improvement in Cognitive Impairment. Mori et al. examined the efficacy of oral administration of 250 mg tablets containing *H. erinaceus* mushrooms (prepared by air-drying harvested fruiting bodies at 60 °C overnight and powdering) to patients diagnosed with mild cognitive impairments.[111] A double-blind, parallel-group, placebo-controlled trial was used on two 15-person groups of 50−80-year-old Japanese men and women for 4 weeks. At weeks 8, 12, and 16 of the trial, the mushroom group significantly increased scores on the cognitive function scale compared with the placebo group. Following treatment, a comparison of 21 medical laboratory tests of the two groups showed no significant differences, suggesting that

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108−7123

the mushroom tablets were safe and that their consumption improved mild cognitive impairment without serious adverse effects.

ANTIOXIDANT AND ANTIDIABETIC PROPERTIES

The antioxidant activity of *H. erinaceus* has been associated with the proposed treatment of several conditions. For example, the reduction of alloxan-induced diabetic neuropathic pain in rats following oral administration of an ethanol *H. erinaceus* extract was associated with a significant increase in the total in vivo antioxidant status (TAOS) in *Hericium*-treated groups, suggesting that the mushrooms might relieve diabetic neuropathic pain in humans.[112] The results of a related study on the antidiabetic and in vitro antioxidant activities of eight medicinal mushroom species seem to support the apparent relationship between antioxidant and antidiabetic effects.[113]

Indeed, it has also been shown that the ip administration of an aqueous extract of *H. erinaceus* (100 and 200 mg/kg body weight) to diabetic rats for 28 days resulted in a significant decrease in the serum glucose level and a significant increase in the insulin level and attenuated serum lipid profiles (disorders) as compared to control rats.[114] These findings were accompanied by increased activities in the antioxidative enzymes catalase (CAT), superoxide dismutase (SOD), and glutathione peroxidase (GSH-Px) and increased GSH (glutathione) and reduced malondialdehyde (MDA) levels in the liver, suggesting that the mechanism of the health-promoting effects seems to be the result of inhibition of ROS (oxidative stress parameters) known to damage the liver function. The specific compounds in the extract that may be responsible for the described effects are not known.

BENEFICIAL EFFECTS ON ISCHEMIA

Because ischemia (deficient supply of blood to organs) followed by reperfusion is a frequent clinical problem in cardiovascular surgery, Han et al. evaluated the effect of the preadministration of an *H. erinaceus* polysaccharide to mice by gavage at a dose of 300 mg/kg for 15 days on induced ischemia.[115] The results show that the treated mice had a significant decline in levels of blood urea nitrogen and serum creatinine and an increase in creatinine clearance levels compared to a renal ischemia−reperfusion control group. Additional studies with associated biomarkers (glutathione, malondialdehyde, antioxidative enzymes) showed that the polysaccharide pretreatment significantly decreased the lipid peroxidation level and increased antioxidant enzyme activities compared to the renal ischemia reperfusion group, suggesting that the polysaccharide prevented oxidative injury in the kidneys of the experimental animals and that it might help prevent acute kidney failure in humans.

ANTIOXIDATIVE AND HEPATOPROTECTIVE EFFECTS

As mentioned briefly above, *H. erinaceus* has been reported to have hepatoprotective effects, and these can be linked to its antioxidative activity. For example, a study by Zhang et al. of antioxidant and hepatoprotective effects of endo(intracellular)-polysaccharides from three fractions of *H. erinaceus* grown on the soybean processed product tofu whey found that the polysaccharide isolated from one of the fractions had strong in vitro antioxidant activity and protected mice against liver damage (assessed by observed changes in liver enzyme levels) induced by carbon tetrachloride (300 mg/kg body weight).[116] The beneficial effect on the liver is presumably the result of the potent antioxidant capacity of the polysaccharide, as determined by several different methods. The polysaccharides from the other two fractions were less effective. The most active polysaccharide could be used as a dietary supplement to prevent hepatic disease.

ANTIOXIDATIVE, ANTIHYPOLIPIDEMIC, AND ANTIHYPERTENSIVE EFFECTS

Feeding rats an exobiopolymer (molecular mass ∼ 40 kDa; protein and sugar contents of 8.8 and 91.2%, respectively) isolated from a submerged mycelia culture of *H. erinaceus* at a dose of 200 mg/kg body weight significantly reduced in a concentration-depended manner plasma total cholesterol (32.9%), bad low-density lipoprotein (LDL) cholesterol (45.4%), triglyceride level (34.3%), and the atherogenic index (58.7%) and increased good plasma high-density lipoprotein (HDL) cholesterol level (31.1%) as compared to the control diet.[117] The authors suggest the need to define the mechanism of the striking hypolipidemic effect.

Because oxidation of LDL might be a key factor in the pathogenesis of atherosclerosis, Rahman et al. investigated the in vitro inhibitory effect of *H. erinaceus* fractions extracted with different solvents on LDL oxidation and the activity of the cholesterol biosynthetic enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMG Co-A) reductase.[118] Of the solvent extractions, the hexane fraction showed the highest inhibition of oxidation and strongly inhibited the activity of the enzyme by up to 59.9% at 10 mg/mL. GC-MS analysis revealed that this fraction contained ergosterol and linoleic (9,12-octadecadienoic) and octadecanoic acids, suggesting that these components and possibly also a polysaccharide (not evaluated) might be responsible for the observed antioxidative properties of the mushroom extract and that the hexane extract might help to prevent oxidative stress-induced pathogenesis of atherosclerosis.

Because platelet aggregation in blood vessels causes vascular disease such as arterial thrombosis (formation of a blood clot) that may be accompanied by the formation of atherosclerotic lesions associated with myocardial infraction and stroke, Mori et al. evaluated the compound hericenone B isolated from *H. erinaceus* on collagen-induced platelet activity in rabbit and human platelets.[119] The results show that hericenone B exhibited strong antiplatelet aggregation activity by a mechanism that blocks collagen-induced platelet aggregation through the inhibition of arachidonic acid release in integrin $\alpha 2/\beta 1$ signaling, suggesting that it has potential to be used in antiplatelet therapy to prevent cardiovascular disease and stroke.

An in vitro study was conducted by Abdullah et al. on the inhibition of lipid peroxidation of buffered egg yolk and angiotensin converting enzyme inhibitory effects, an indicator of in vivo hypertensive activity, by water extracts of 10 culinary−medicinal mushrooms, including *H. erinaceus*. They found that *Ganoderma lucidum* mushrooms, with the highest phenolic content (63.5 GAE/g extract), exhibited the highest angiotensin converting enzyme inhibitory activity (IC_{50} = 0.05 mg/mL),[120] whereas the corresponding values for *H. erinaceus* were much lower: 10.2 GAE/g and IC_{50} = 0.58 mg/mL. There seems to be a good correlation between total phenolic content of the 10 mushroom varieties and their antioxidant capacities as determined by different methods. To determine whether

J. Agric. Food Chem. 2015, 63, 7108−7123

mushroom extracts can serve as protective agents against hypertension, however, the in vitro results need to be reproduced in vivo, in particular in humans, as is the case for many of these studies.

STIMULATION OF THE IMMUNE SYSTEM

Here, we will briefly describe reported studies on the stimulation of the immunes system in various animals and also the effect on dendritic cells by *H. erinaceus* mushrooms and associated polysaccharides.

Wang et al. compared the antitumor and immunoenhancing effects of polysaccharides with molecular weight > 1×10^5 kDa isolated from *H. erinaceus* and *H. laciniatum* mushrooms cultivated in a shaker at 25 °C for 25 days.[121] The results showed that both polysaccharides had significant antiartificial pulmonary metastatic tumor effects in mice, with the polysaccharide from *H. erinaceus* being more effective than that from *H. laciniatum* and that both enhanced the increase of T cells in the mouse model at the same rate, indicated by higher numbers of $CD4^+$ cells and macrophages in the test than in the control group. The results suggest that the antitumor effects might be associated with the immunoenhancing activities of the polysaccharides.

Supplementation of the diet of the olive flounder fish (*Paralichthys olivaceus*) with 0.1 and 1.0% *H. erinaceus* mushroom protected the fish that were infected with the parasite *Philasterides dicentrarchi* against mortality via enhancement of the innate immune response, as indicated by cumulative mortalities during the 4 weeks of 45 and 30%, respectively, compared to 90% in the control group, suggesting that the mushrooms modulated the nonspecific defense mechanisms against the pathogen.[122] The protection was associated with an increase in scuticocidal activity, enhanced respiratory burst activity of phagocyte cells, phagocytosis, and lysozyme activities in plasma. The authors suggest that, because of their biodegradability, mushroom diets merit further study for their beneficial effects in aquaculture.

A related study evaluated the effect of particle size (100−150, 74−100, and <74 μm) of dried *H. erinaceus* powder on the immune response and disease resistance against the pathogen *Vibrio alginolyticus* in white shrimp (*Litopenaeus vannamei*).[123] The results show that shrimp mortality was particle size dependent, with particles of <74 μm inducing a significantly greater effect on the disease resistance than those >74 μm, as indicated by a significantly lower mortality of the shrimp during the 28 day test period with a diet containing the mushroom powder at a concentration of 0.2 μg/g shrimp. The protective effect was accompanied by an increase in phenol oxidase activity, respiratory bursts, superoxide dismutase activity, and glutathione peroxidase activity, parameters usually associated with destruction of ROS. It seems that the smaller particle size improves the bioavailability of the dietary mushroom powder.

Dendritic cells are antigen-presenting cells that act as mediators of peripheral immune tolerance and help maintain immune homeostasis.[124,125] An evaluation of several biomarkers associated with the immunostimulatory effects of polysaccharides isolated from *H. erinaceus* mushrooms on murine dendritic cells showed that treatment with 50 μg/L of a 20% β-glucan-containing polysaccharide extract induced activation and promoted morphological changes, reduced endocytosis (incorporation of the polysaccharide into the cells by phagocytosis), increased the expression of surface molecules that are important for antigen presentation, and stimulated the secretion of cytokines that promote immune responses,[126] suggesting the potential value of the polysaccharides as an immunostimulatory food additive and adjuvant to enhance the immunogenicity of vaccines.

OUTLOOK

This overview covers an area of food medical science of current importance to mushroom growers, consumers, and food and biomedical scientists. Although the described results of the extensive, worldwide studies on multifunctional health properties of *H. erinaceus* in cells and in rodents, and to some extent in humans, need to be further confirmed in human nutritional, clinical, and epidemiological studies, a number of suggested research needs on the chemistry and numerous health-promoting aspects have been mentioned in the text. Because *H. erinaceus* species seems to lack toxicity in rodents and humans, nutritionists, pharmacists, and physicians should consider recommending these mushrooms to their clients and patients. The apparent exceptional beneficial properties will, hopefully, induce mushroom growers in the United States and elsewhere to produce *H. erinaceus* mushrooms for sale in stores. Because a large number of other *Hericium* species exist in nature, it would also be of interest to compare the described results on the composition, nutrition, and health benefits of *H. erinaceus* to phylogenetically related species. The suggested studies might lead to the discovery of new, highly bioactive *Hericium* species with high health-promoting potential. We anticipate that these efforts will contribute to the improvement of human nutrition and health.

It is also relevant to note that a meal consisting of *H. erinaceus* and other foods such as tomatoes that contain bioactive lycopene and tomatine[90] or pigmented rice that contains bioactive γ-oryzanol[127] will contribute multiple types of health-promoting properties to the diet that might induce additive or synergistic beneficial effects after consumption. This aspect also merits study. Finally, we expect readers to also benefit from our earlier related reviews on the health benefits of other food categories and their bioactive compounds that complement the present review.[77,79,87,91,127−131]

ABBREVIATIONS USED

ACE, AKE, HWE, MWE: acid, alkaline, hot water, and microwave *H. erinaceus* extracts
CD-4: helper T cells that promote adhesion to antigen-presenting cells in response to infection
Bad, Bax: pro-apoptotic proteins
Bcl2,: apoptotic protein
BFC: basal forebrain complex
BUN: blood urea nitrogen
COX-2: cyclooxygenase-2
BLA: blood lactic acid

DOI: 10.1021/acs.jafc.5b02914
J. Agric. Food Chem. 2015, 63, 7108−7123

ECM: extracellular matrix
DC: dendritic cells
EPS: exopolysaccharides
ERK: extracellular signal-regulating kinase
FB: fruit body
FT-IR: Fourier transform infrared spectroscopy
GABA: γ-aminobutyric acid
GAE: gallic acid equivalents
HDFs: human dermal fibroblasts
HEG-5: *H erinaceus* glycoprotein
HUVECs: human umbilical vein endothelial cells
HPSEC-MALLS-RID: high-performance size exclusion chromatography with multiangle laser light scattering and refractive index detection
IC_{50}: concentration of test compound that inhibits 50% of cancer cells
IFN-γ: antigen-specific-γ
IL: interleukin-2
IPS: intracellular polysaccharides
ITS: rDNA internal transcribed tracer
JNK: c-Jun N-terminal kinase
5-LOX: 5-lipoxygenase
MAPK: mitogen-activated protein kinase
MIC: minimum inhibitory concentration
MDA: malondialdehyde
MMP: metalloproteinase
MRSA: methicillin-resistant *Staphylococcus aureus*
MTT: methyl tetrazolium cell viability assay
NF-κB: nuclear factor kappa-light-chain-enhancer of activated B cells
NK: killer cells
NGF: nerve growth factor
P12Aκt: protein kinase
RT-PCR: reverse transcription polymerase chain reaction
ROS: reactive oxygen species
TAOS: total in vivo antioxidant status
u-PA: urokinase-type plasminogen activator
VGEF: endothelial growth factor

there is very limited information available on the inhibitors of SA signaling.

Recently, we screened a chemical library for inhibitors of SA signaling and found that 4-phenyl-2-{[3-(trifluoromethyl)-aniline]methylidene}cyclohexane-1,3-dione (PAMD, **1**) suppresses the expression of SA-related genes in *Arabidopsis* and increases its susceptibility to pathogens.[22] In addition to the suppressive effects of PAMD on the expression of *PR* genes, PAMD also inhibits the growth of *Arabidopsis*, including its root growth, seedling establishment, and fresh weight. These side effects limit the utility of PAMD in studies of the SA signaling pathway. Structure−activity relationship studies of PAMD derivatives predicted that a 2-substituted enamine moiety conjugated with 1,3-cyclohexadione is essential for the inhibition of the SA signal. On the basis of this structure−activity relationship analysis, a number of derivatives of PAMD were synthesized in the present study to develop better candidate SA signaling inhibitors. We ultimately selected a compound that strongly suppresses the expression of the *PR* genes with fewer adverse effects on the growth of *Arabidopsis* than PAMD. We also found that the retardation effect of these new compounds on plant growth partly depends on the stabilization of the DELLA proteins, negative regulators of GA signaling, which are also involved in the pathogen defense responses.

MATERIALS AND METHODS

Plant Materials and Growth Conditions. Most of the experiments were carried out with *Arabidopsis thaliana* Col-0. Landsberg *erecta* (L*er*) was used as the genetic background of 5Δ*della*, a mutant with loss-of-function mutations in all five DELLA proteins. *RGA*:*GFP-RGA*, a line that expresses GFP-RGA driven by the *RGA* promoter, was used to detect GA-induced DELLA degradation. The seeds were surface-sterilized with 70% ethanol for 20 min, rinsed with 99% ethanol, dried on sterilized filter paper, and then placed onto culture medium containing half-strength Murashige and Skoog ($^1/_2$ MS) Plant Salt Mixture (Wako, Osaka, Japan), 1% sucrose, 0.8% agar, vitamin mixture, and 0.01% myo-inositol (Wako). After stratification under dark conditions at 4 °C for 2 days, the seeds were germinated under constant light (18.2−46.5 μmol/m^2/s) at 22.5 °C. For the dark treatment in the hypocotyl experiment, the seeds were light-pulsed (18.2−46.5 μmol/m^2/s) for 6 h before they were kept under constant dark at 22.5 °C.

SA Treatment. Seedlings grown on plates with or without the test compound, as indicated, were foliar sprayed with a 2 mM SA aqueous solution (0.5% DMSO), cultured for a further 3 days under the same conditions, and then frozen in liquid nitrogen.

RT-PCR Analyses. Total RNA was extracted from seedlings treated with or without SA, purified with the Total RNA Extraction Mini Kit (RBC Bioscience, Taipei, Taiwan), and then converted to cDNA with the PrimeScript RT Reagent Kit (Takara Bio, Shiga, Japan) according to the manufacturers' protocols. Quantitative PCR was carried out with Thermal Cycler Dice Real Time System TP800 (Takara Bio) and the SYBR Premix Ex Taq (Takara Bio). The transcript levels of *PR* genes were normalized against those of *Actin7* (encoding actin 7), using primers specific for *PR1* (5′-CGTCTTTGTAGCTCTTGT-AGGTGC-3′ and 5′-TGCCTGGTTGTGAACCCTTAG-3′), *PR2* (5′-CGTCTTTGTAGCTCTTGTAGGTGC-3′ and 5′-TGCCTG-GTTGTGAACCCTTAG-3′), *PR5* (5′-CGTCTTTGTAGC-TCTTGTAGGTGC-3′ and 5′-TGCCTGGTTGTGAACCCTTAG-3′), and *Actin7* (5′-GATATTCAGCCACTTGTCTGTGAC-3′ and 5′-CATGTTCGATTGGATACTTCAGAG-3′).

Phenotypic Observations. *Germination Rate.* After sterilization (as described in the Plant Materials and Growth Conditions section), more than 30 seeds for each treatment were placed on $^1/_2$ MS medium with or without the test compound. Germination was defined as the emergence of the radicle.

Hypocotyl Growth. To determine hypocotyl growth during the constant dark treatment, the seeds were germinated on $^1/_2$ MS medium with or without the test compound. After stratification at 4 °C for 2 days, the seeds were light-pulsed for 6 h to improve their germination and then kept in the dark for 5 days at 22.5 °C. The 5 day old seedlings were raised in the dark, and the lengths of the hypocotyls were measured with ImageJ software (National Institutes of Health, Bethesda, MD). For hypocotyl growth under constant light, seedlings of L*er* and the 5Δ*della* mutants were grown on $^1/_2$ MS medium under constant light (18.2−46.5 μmol/m^2/s) at 22.5 °C, transferred 3 days after germination (3 DAG) to $^1/_2$ MS medium containing GA_4 (10 μM), PAMD (25 μM), **4** (25 μM), or combinations of them, and monitored during culture for 9 days under constant light at 22.5 °C. The lengths of the hypocotyls were measured with ImageJ software.

Fresh Weight. The seeds were germinated on $^1/_2$ MS medium with or without the test compound under constant light at 22.5 °C. The seedlings were sampled at 10 DAG or 12 DAG and their weights measured.

Colletotrichum higginsianum Infection Assay. Seedlings (5 DAG) germinated and grown on $^1/_2$ MS medium at constant light were transferred to treatment medium $^1/_2$ MS (no sucrose) and further cultivated for 8 days. Seedlings (8 day-after-treatment (DAT)) were sprayed with *Colletotrichum higginsianum* (*C. higginsianum*) and further cultivated for 4 days. The leaves of 4 day-after-infection (DAI) seedlings were sampled by liquid nitrogen. The RNA samples were extracted and converted to the cDNA as described above. The *actin* mRNA of *C. higginsianum* (*Ch-Actin*) was quantified by qRT-PCR using primers specific for *Ch-Actin* (5′- CCGCAGACCGCAATCTT-3′ and 5′- AATGGAGGCTGAGAGCTGGTT-3′). The transcript levels of *Ch-ACT* were normalized against those of *Arabidopsis Actin7*.

Quantification of Endogenous SA and ABA. *Chemicals.* Deuterium-labeled SA (SA-d_4) and deuterium-labeled ABA (ABA-$^{13}C_2$) were purchased from Wako Pure Chemical Industries, Ltd. (Japan).

Growth Condition. Seedlings (5 DAG) grown on $^1/_2$ MS medium under constant light at 22.5 °C were transferred to $^1/_2$ MS medium with or without the 25 μM compounds (PAMD or **4**) for further cultivation for 8 days under constant light at 22.5 °C. The plants were frozen by liquid nitrogen.

Extraction and Purification. The frozen plant tissues were homogenized and purified by using solid-phase extraction (SPE) as described by Miyazaki et al.,[23] with the exception that SA or ABA was eluted with 0.2 M formic acid (FA) in acetonitrile (AcCN) in this paper.

LC-MS/MS Analysis. LC-MS/MS was equipped as described Miyazaki et al.[23] The dried samples were reconstituted in 50 μL of 10 mM FA in 10% (v/v) methanol (MeOH), and 10 μL of each sample was then injected onto a reversed-phase UPLC column (Acquity UPLC BEH C18, 2.1 mm × 50 mm, 1.7 μm, Waters) with a guard column (Acquity UPLC BEH C18 VanGuardTM Precolumn, 1.7 μm, 2.1 mm × 5 mm, Waters) coupled to the ESI-MS/MS system. SA and ABA were analyzed in the negative ion mode as $[M - H]^-$. MS/MS analysis conditions for SA were as follows: cone energy, 24 eV; collision energy, 17 V; and MRM, 137.0 > 93.0 for unlabeled SA and 141.0 > 97.0 for labeled SA. The cone energy and collision energy for ABA and ABA-$^{13}C_2$ were 22 and 24 eV, and 14 and 12 eV, respectively, and those of MRM were 263.2 > 153.0 and 165.2 > 153.0, respectively. SA and ABA were analyzed by a linear gradient of 1% (v/v) FA in water (A) and 1% FA in MeOH (B) at a flow rate of 0.20 mL/min, from 80:20 A/B (v/v) (0 min), 55:45 A/B (v/v) (1 min), 25:75 A/B (v/v) (8 min), and 0:100 A/B (v/v) (9 min), maintaining this composition until 1 min and equilibrated to initial conditions.

Chemicals. PAMD (**1**, ID: KM05261) was purchased from MayBridge (Cornwall, UK), as described previously.[22] The PAMD derivatives were synthesized as follows.

2, *2-((3-(Trifluoromethyl)phenylamino)methylene)cyclohexane-1,3-dione.* 1,3-Cyclohexanedione (10 mmol), orthoacetic acid triethyl ester (13 mmol), and 10 mmol trifluoromethylaniline were combined and stirred for 5 min at 130 °C. Ethanol (3 mL) was added, and the mixture was stirred for 3 min at 130 °C. The mixture was then cooled

to room temperature, and 10 mL of distilled water was added to quench the reaction. Suction filtration was carried out with distilled water, then twice with 60% ethanol, and once with hexane. The compound was purified by recrystallization with ethyl acetate and hexane. The crystal was collected by suction filtration. ^{1}H NMR (500 MHz, $CDCl_3$): δ 2.03 (2 H, quin, J = 6.9), 2.55 (2 H, t, J = 6.3), 2.60 (2 H, t, J = 6.9), 7.43 (1 H, d, J = 7.4), 7.48−7.50 (2 H, m), 7.53 (1 H, d, J = 8.6), 8.61 (1 H, d, J = 13.2).

***3**, 2-((Phenylamino)methylene)cyclohexane-1,3-dione.* 1,3-Cyclohexanedione (10 mmol), orthoacetic acid triethyl ester (13 mmol), and aniline (10 mmol) were combined and stirred for 5 min at 130 °C. Ethanol (3 mL) was added, and the mixture stirred for 3 min at 130 °C. The mixture was then cooled to room temperature, and 10 mL of distilled water was added to quench the reaction. Suction filtration was carried out with distilled water, then twice with 60% ethanol and once with hexane. The compound was purified by recrystallization with ethyl acetate and hexane. The crystal was collected by suction filtration. ^{1}H NMR (500 MHz, $CDCl_3$): δ 2.02 (2 H, quin, J = 6.9), 2.54 (2 H, t, J = 6.9), 2.58 (2 H, t, J = 6.9), 7.20−7.25 (3 H, m), 7.40 (2 H, t, J = 8.0), 8.60 (1 H, d, J = 13.7).

***4**, 5,5-Dimethyl-2-((phenylamino)methylene)cyclohexane-1,3-dione.* 5,5-Dimethyl-1,3-cyclohexanedione (10 mmol), orthoacetic acid triethyl ester (13 mmol), and aniline (10 mmol) were combined and stirred for 5 min at 130 °C. Ethanol (3 mL) was added, and the mixture stirred for 3 min at 130 °C. The mixture was then cooled to room temperature, and 10 mL of distilled water was added to quench the reaction. Suction filtration was carried out with distilled water, then twice with 60% ethanol and once with hexane. The compound was purified by recrystallization with ethyl acetate and hexane. The crystal was collected by suction filtration. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.08 (6 H, s), 2.41 (2 H, s), 2.45 (2 H, s), 7.22−7.26 (3 H, m), 7.40 (2 H, t, J = 8.6), 8.60 (1 H, d, J = 13.7).

***5**, 2-((2,4-Dichlorophenylamino)methylene)-5,5-dimethylcyclohexane-1,3-dione.* 5,5-Dimethyl-1,3-cyclohexanedione (10 mmol), orthoacetic acid triethyl ester (13 mmol), and 2,4-dichloroaniline (10 mmol) were combined and stirred for 5 min at 130 °C. Ethanol (3 mL) was added, and the mixture was stirred for 3 min at 130 °C. The mixture was then cooled to room temperature, and 10 mL of distilled water was added to quench the reaction. Suction filtration was carried out with distilled water, then twice with 60% ethanol and hexane. The compound was purified by recrystallization with ethyl acetate and once with hexane. The crystal was collected by suction filtration. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.09 (6 H, s), 2.43 (2 H, s), 2.49 (2 H, s), 7.32 (1 H, d, J = 11.5), 7.40 (1 H, d, J = 8.6), 7.47 (1 H, s), 8.54 (1 H, d, J = 13.2).

***6**, 2-((3-Chlorophenylamino)methylene)-5,5-dimethylcyclohexane-1,3-dione.* 5,5-Dimethyl-1,3-cyclohexanedione (10 mmol), orthoacetic acid triethyl ester (13 mmol), and 3-chloroaniline (10 mmol) were combined and stirred for 5 min at 130 °C. Ethanol (3 mL) was added, and the mixture was stirred for 3 min at 130 °C. The mixture was then cooled to room temperature, and 10 mL of distilled water was added to quench the reaction. Suction filtration was carried out with distilled water, then twice with 60% ethanol and once with hexane. The compound was purified by recrystallization with ethyl acetate and hexane. The crystal was collected by suction filtration. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.08 (6 H, s), 2.41 (2 H, s), 2.46 (2 H, s), 7.14 (1 H, d, J = 18.9), 7.21−7.27 (2 H, m), 7.31−7.34 (1 H, m), 8.53 (1 H, d, J = 13.2).

***7**, 2-((3-Chloro-2-methylphenylamino)methylene)-5,5-dimethylcyclohexane-1,3-dione.* 5,5-Dimethyl-1,3-cyclohexanedione (10 mmol), orthoacetic acid triethyl ester (13 mmol), and 3-chrolo-2-methylaniline (10 mmol) were combined and stirred for 5 min at 130 °C. Ethanol (3 mL) was added, and the mixture was stirred for 3 min at 130 °C. The mixture was then cooled to room temperature, and 10 mL of distilled water was added to quench the reaction. Suction filtration was carried out with distilled water, then twice with 60% ethanol and once with hexane. The compound was purified by recrystallization with ethyl acetate and hexane. The crystal was collected by suction filtration. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.09 (6 H, s), 2.37 (3 H, s), 2.42 (2 H, s), 2.47 (2 H, s), 7.09−7.11 (1 H, m), 7.15−7.17 (1 H, m), 7.37 (1 H, d, J = 1.7), 8.56 (1H, d, J = 13.2).

***8**, 2-((4-Hydroxyphenylamino)methylene)-5,5-dimethylcyclohexane-1,3-dione.* 5,5-Dimethyl-1,3-cyclohexanedione (10 mmol), orthoacetic acid triethyl ester (13 mmol), and 4-hydroxyaniline (10 mmol) were combined and stirred for 5 min at 130 °C. Ethanol (3 mL) was added, and the mixture was stirred for 3 min at 130 °C. The mixture was then cooled to room temperature, and 10 mL of distilled water was added to quench the reaction. Suction filtration was carried out with distilled water, then twice with 60% ethanol and once with hexane. The compound was purified by recrystallization with ethyl acetate and hexane. The crystal was collected by suction filtration. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.08 (6 H, s), 2.42 (2 H, s), 2.45 (2 H, s), 6.91 (2 H, d, J = 9.2), 7.12 (1 H, d, J = 8.6), 8.50 (1 H, d, J = 13.7).

***9**, 5,5-Dimethyl-2-((3-(trifluoromethyl)phenylamino)methylene)-cyclohexane-1,3-dione.* 5,5-Dimethyl-1,3-cyclohexanedione (10 mmol), orthoacetic acid triethyl ester (13 mmol), and trifluoromethylaniline (10 mmol) were combined and stirred for 5 min at 130 °C. Ethanol (3 mL) was added, and the mixture was stirred for 3 min at 130 °C. The mixture was then cooled to room temperature, and 10 mL of distilled water was added to quench the reaction. Figure 1. Effects of PAMD on *Arabidopsis* growth. (A) At 12 days after germination (12 DAG), *Arabidopsis thaliana* Col-0 was grown on $^1/_2$ MS medium with or without PAMD (as indicated) under constant light at 22.5 °C. Scale = 5 mm. (B) Seeds were germinated on $^1/_2$ MS medium with or without PAMD and grown under constant light at 22.5 °C. Error bars indicate the means ± SE of three independent replicates, $n > 30$. (C) Fresh weights of 10 DAG Col-0 plants grown on $^1/_2$ MS medium with or without PAMD under constant light at 22.5 °C. Error bars indicate means ± SE of three independent replicates, $n > 10$. Student's t test was used to determine the significance of differences relative to the mock treatment; *, $P < 0.05$. (D) After stratification for 2 days at 4 °C, Col-0 seeds were light-pulsed for 6 h and were germinated and grown on $^1/_2$ MS medium with or without the test compound under constant dark at 22.5 °C. Hypocotyl length was measured at 5 DAG. Error bars indicate the means ± SE of three independent replicates, $n = 10$. Student's t test was used to determine the significance of differences relative to the mock treatment; **, $P < 0.01$.

washed with 5 mM FA and MeOH successively. Anthocyanins were eluted with MeOH (1% NH_4OH) and water/MeOH (40:60 in volume ration, 1% NH_4OH) successively. The two successive elutions were combined together and quantified by reading the absorbance at 530 nm (A_{530}) and 657 nm (A_{657}) using GeneQuant (GE Healthcare Life Science). The relative level of anthocyanin was calculated as $(A_{530} - 0.25 \times A_{657})$ g^{-1} FW.

GA-induced DELLA Degradation. The *RGA:GFP-RGA* line of *Arabidopsis* was used to observe the GA-induced degradation of DELLA. After stratification for 2 days at 4 °C in the dark, the *RGA:GFP-RGA* line was germinated on $^1/_2$ MS medium under constant light at 22.5 °C. The primary roots of the seedlings (2 DAG) were placed on a microscope slide with a drop of liquid-phase $^1/_2$ MS containing GA_4 (10 μM) or GA_4 combined with PAMD (25 μM) or **4** (25 μM). The green fluorescence of green fluorescent protein (GFP) was observed under a confocal-laser scanning microscope (LSM700, Zeiss, Oberkochen, Germany), and the degradation of GFP-RGA was recorded with time-lapse photography.

RESULTS

PAMD Inhibits the Growth of *A. thaliana*. PAMD was isolated from a chemical library of 9600 randomly synthesized compounds using SA-induced β-glucuronidase (GUS)-expressing plants (*PR1::GUS* line) and was determined to be an effective inhibitor of SA signaling.[22] However, the *Arabidopsis* seedlings treated with PAMD were smaller than the untreated seedlings, indicating that PAMD suppresses plant growth (Figure 1A). Further studies showed that PAMD had no obvious suppressive effect on the seed germination time or germination rate (Figure 1B). We then investigated the dose-dependence of the phenotype of the seedlings treated with PAMD and found a positive correlation between the PAMD concentration and *Arabidopsis* growth suppression, including rosette size, fresh weight, and hypocotyl growth (Figure 1A,C,D). However, it was unclear whether the plant-growth-suppressing effects of PAMD were relevant to its inhibitory effect on SA signaling.

Synthesis of PAMD Derivatives. To investigate the relationship between the chemical structure and SA-signal-inhibiting activity of PAMD (**1**) and to reduce its inhibitory effects on plant growth without affecting its SA-signal-inhibiting activity, several PAMD derivatives with deletions or changes to various groups were synthesized (Figure 2). The PAMD derivatives were synthesized with one-step reactions, which are much simpler than the reaction used to synthesize PAMD (Figure 2A).

SA-Signal-Inhibiting Activities of PAMD Derivatives. The effects of the derivatives described above on the suppression of *PR1* expression were determined with real-time PCR (Figure 3). Compound **2**, in which the 2-phenyl group is deleted, and compound **3**, in which both the 2-phenyl group and the trifluoromethyl group on the phenyl group attached to the N atom are deleted, did not suppress *PR1* expression, suggesting that the phenyl group on the cyclohexadione group contributes to this activity. The substitution of **3** with a dimethyl group at the 5-position of the cyclohexadione group generated compound **4**, which recovered its capacity to suppress *PR1* expression, although this activity was weaker than that of PAMD. This suggests that in addition to the phenyl group the dimethyl group on the cyclohexane ring also contributes to the suppression of *PR1* expression, perhaps as an electron-donating group. On the basis of the structure of **4**, various derivatives with several substituents on the N-attached phenyl group of **4** were synthesized, and their activities were determined. Compound **5**, with 2,4-dichloro groups on the N-attached phenyl group, showed more potent activity in suppressing *PR1* expression than did **4**. Compound **6**, with a 3-chloro group, compound **7**, with 3-chloro and 2-methyl groups, and compound **8**, with a 4-hydroxyl group, each

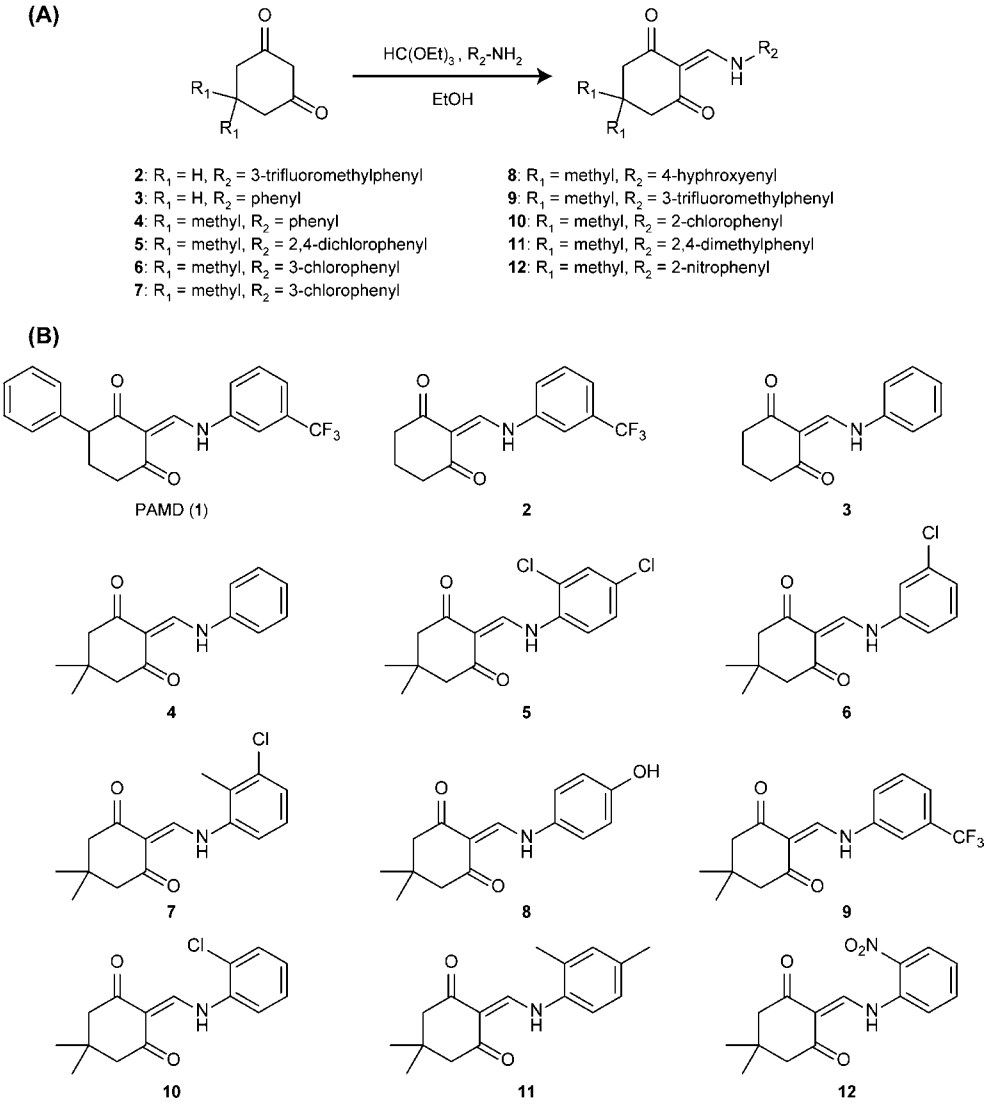

Figure 2. Synthesis of PAMD derivatives. (A) Scheme of the synthesis of derivatives with one-step methods. (B) Chemical structure of PAMD (**1**) and its derivatives newly synthesized in this paper.

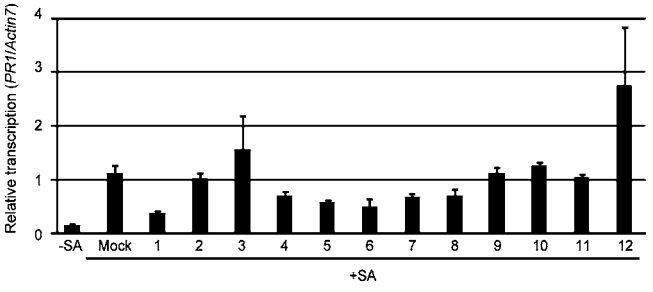

Figure 3. Determination of SA signal inhibition by PAMD derivatives. Seedlings grown for 5 DAG on $^1/_2$ MS medium under constant light at 22.5 °C were transferred to $^1/_2$ MS medium containing the indicated compounds (25 μM) for further cultivation for 8 days under constant light at 22.5 °C, followed by foliar-sprayed SA treatment. *PR1* expression was determined relative to *Actin7*. Error bars indicate the means ± SD of three replicates.

showed activity almost equal to that of **4**. However, some other derivatives, such as compound **9**, with a 3-trifluoromethyl group, compound **10**, with a 2-chloro group, and compound **11**, with 2,4-dimethyl groups on the N-attached phenyl group, lost the capacity to suppress *PR1* gene expression. Unexpectedly, compounds **3** and **12** increased *PR1* gene expression. It is noteworthy that although substituted with the same atom(s) the activities of compounds **5** and **6** differed significantly from that of compound **10** in suppressing *PR1* gene expression suggesting the importance of the positions and the combinations of the substituents on the N-attached phenyl group. Various groups on the N-attached phenyl group also played important roles in suppressing *PR1* expression and further study of the structure−activity relationships of the substituents on the N-attached phenyl group should reveal important factors that increase or reduce *PR1* expression.

Effects of Treatment with PAMD Derivatives on Plant Growth. The side effects of the PAMD derivatives on *Arabidopsis* growth were investigated (Figure 4). At a concentration of 10 μM, **2** reduced the fresh weight of *Arabidopsis* less than did PAMD, which indicates that the inhibitory effect may be partly induced by the 2-phenyl group. Compound **3** did not differ significantly from PAMD in reducing the fresh weight of *Arabidopsis*. However, **4** showed clearly less inhibitory effect on growth than did PAMD. These results indicate that the growth-inhibitory effect may result

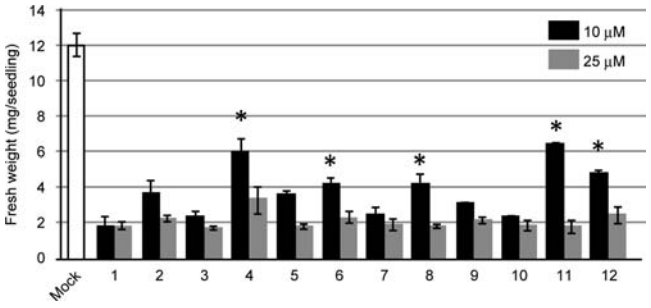

Figure 4. Estimation of the inhibitory effects of PAMD and its derivatives. Seedlings (5 DAG) grown on $^1/_2$ MS medium under constant light at 22.5 °C were transferred to $^1/_2$ MS medium with or without the test compound and further cultivated for 11 days under constant light at 22.5 °C. Fresh weight was determined as an estimate of growth. Error bars indicate the means ± SE of three independent replicate measurements of the average weights of 10 seedlings. Student's *t* test was used to determine the significance of differences relative to the PAMD (**1**) treatment; *, $P < 0.05$.

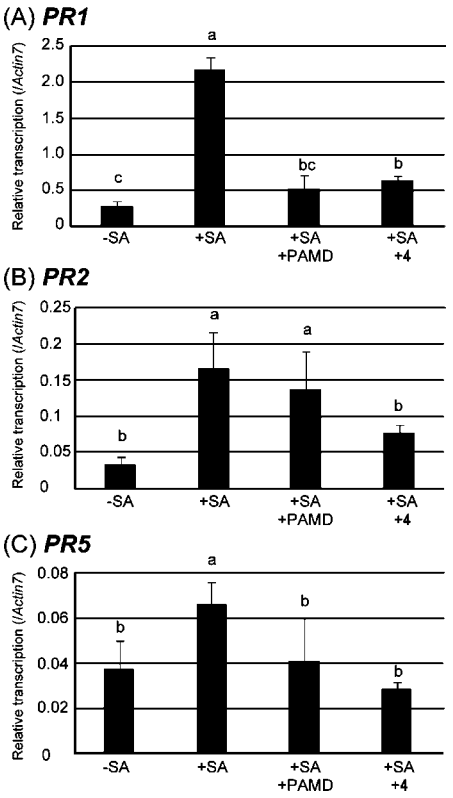

Figure 5. Suppressive effect of PAMD (**1**) and **4** on the expression of *PR2* and *PR5*. Seedlings (5 DAG) grown on $^1/_2$ MS medium under constant light at 22.5 °C were transferred to $^1/_2$ MS medium containing 25 μM of the test compound, as indicated, for further cultivation for 8 days under constant light at 22.5 °C, followed by foliar-sprayed SA treatment. *PR1* expression was determined relative to *Actin7*. Error bars indicate the means ± SD of three replicates. Statistical differences between the groups were calculated with ANOVA analysis (Posthoc: Duncan). Bars with different letters are significantly different, with $P < 0.01$.

from the basic structure of **3** and that the 5,5-dimethyl groups reduce the inhibitory effect on growth. The result for **9** showed that the trifluoro group has a negative effect on plant growth when it exists in combination with the 3,3-dimethyl groups. Except for **11**, which showed similar levels of growth inhibition as **4**, all the derivatives based on the structure of **4**, including **5**−**8**, **10**, and **12**, inhibited growth more strongly than **4**, but most of them, including **5**, **8**, **10**, and **12**, inhibited growth less strongly than PAMD.

However, at a concentration of 25 μM, all the PAMD derivatives suppressed the growth of *Arabidopsis* (Figure 4). The growth-inhibitory effect of **4** was smallest of all the PAMD derivatives tested, even though it did not differ significantly from that of PAMD (Figure 4). Compound **4** also suppressed the expression of the *PR2* and *PR5* genes even more strongly than PAMD (Figure 5), indicating that **4** is not a specific inhibitor of *PR1* expression. The *Collectotrichum higginsianum* (*C. higginsianum*) infection assay indicated that **4** likely increased the susceptibility of *Arabidopsis* to *C. higginsianum* (Figure 6). Because some of the PAMD derivatives showed less growth-inhibitory activity than PAMD when applied at 10 μM, we tested whether a lower concentration of **4** suppressed the induction of *PR1* gene expression by SA and found that **4** inhibited SA-induced *PR1* expression in a concentration-dependent manner (Figure 7A). This result clearly shows that **4** suppresses SA-induced *PR1* expression as strongly as PAMD (**1**) at 10 μM (Figure 7B) at which concentration **4** affects plant growth less than it does at 25 μM (Figure 4).

Compound **4** showed less adverse effects on plant growth than PAMD, including on seed germination, fresh weight, seedling establishment, and root growth under constant light (Figure 8A−E). Remarkably, hypocotyl growth in the dark was only slightly inhibited by **4**, even when 25 μM of **4** was applied (Figure 8F). On the basis of these results, **4** could be considered a better inhibitor of SA signaling than PAMD because it suppresses *PR* gene expression to a similar or greater extent than PAMD but with a less adverse effect on growth.

Quantification of Endogenous Salicylic Acid and Abscisic Acid in *Arabidopsis* using LC-MS/MS. Although the inhibitory effects of PAMD and its derivatives on *PR1* expression were determined under exogenous SA treatment, it is still an open question whether PAMD and its derivatives impact SA biosynthesis, which may also contribute to the final effects of the compound. To answer this question, the endogenous level of SA in the *Arabidopsis* treated by PAMD or **4** was quantified. The results showed that treatment by PAMD or **4** increased the SA level compared to mock treatment (Figure 9A). Meanwhile, we also quantified the endogenous level of ABA, which is well-known for its accumulation in plants under stresses and its negative roles in regulating plant growth. The plant treated with PAMD or **4** accumulated a higher level of ABA compared to the mock treatment (Figure 9B). In accordance with the increasing level of ABA, the anthocyanin level was also higher in the plants treated by PAMD (Supporting Information Figure 1). The increasing levels of ABA and anthocyanin by PAMD treatment are considered to be the side effects of the compounds, which caused stresses to the plant. Treatment by **4** induced a moderate increase in the ABA level and no change in anthocyanin level compared to that effected by the treatment with PAMD (Figure 9B, Supporting Information Figure 1). These results further indicate that **4** is a better candidate than PAMD with less adverse effects on plants.

Inhibitory Effects of PAMD and Its Derivatives Depend Partly on DELLA. Although **4** is a better SA signal inhibitor than PAMD, it still inhibits plant growth to some extent (Figure 8). The positive regulatory roles of GA in plant growth are well-known, and the binding of GA to its receptor

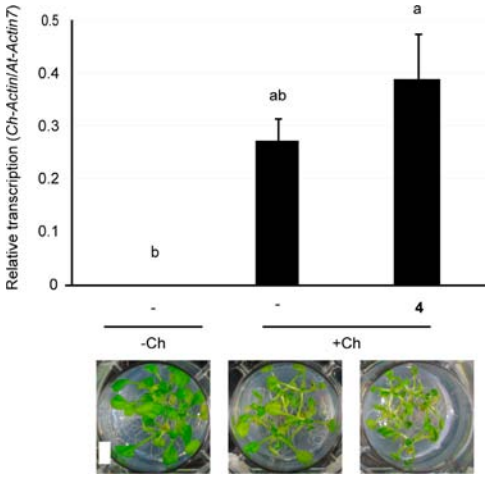

Figure 6. *Collectotrichum higginsianum* (*C. higginsianum*) infection assay. Seedlings (5 DAG) were transferred to treatment medium containing compounds as indicated or not and further cultivated for 8 days. The 8 day-after-treatment (DAT) seedlings were sprayed by 1×10^7 spores/ml of *C. higginsianum* and followed by 4 days' cultivation. *Ch-Actin* expression was determined relative to *Arabidopsis Actin7* (*At-Actin7*). Error bars indicate the means ± SD of three replicates. Statistical differences between the groups were calculated with ANOVA analysis (Posthoc: Duncan). Bars with different letters are significantly different, with $P < 0.01$. Scale = 5 mm.

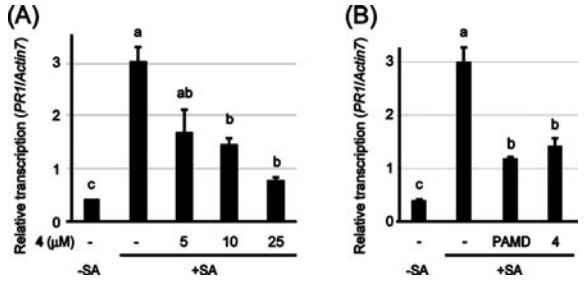

Figure 7. Suppressive effects of PAMD or **4** on the expression of the *PR1* gene. (A) Dose-dependent inhibition of SA-induced *PR1* expression by **4**. (B) Suppressive effect of PAMD (**1**) or **4** at the concentration of 10 μM. Seedlings (5 DAG) grown on $^1/_2$ MS medium under constant light at 22.5 °C were transferred to $^1/_2$ MS medium containing a serial concentration of test compound, as indicated, for further cultivation for 8 days under constant light at 22.5 °C, followed by foliar-sprayed SA treatment. After treatment with SA for 3 days, the seedlings were frozen in liquid nitrogen. *PR1* expression was determined relative to *Actin7*. Error bars indicate the means ± SD of three replicates. Statistical differences between the groups were calculated with ANOVA analysis (Posthoc: Duncan). Bars with different letters are significantly different with $P < 0.01$.

GID1 triggers the degradation of the DELLA proteins, negative regulators of GA signaling, by 26S proteasomes.[24] The defective GA biosynthesis in the *ga1-3* mutant or the loss of DELLA degradation in the *gai-1* and *rga-Δ17* mutants, in which the DELLA domain is deleted, cause a severe dwarf phenotype in *Arabidopsis*.[25,26] Therefore, suspecting that PAMD and **4** might inhibit plant growth by compromising GA signaling, we tested whether the growth suppression effects of **1** and **4** were restored by treatment with GA (Figure 10A). Both PAMD and **4** suppressed hypocotyl growth under constant light, and GA treatment partly restored this growth-suppression effect in wild-type plants (L*er*). To further investigate whether this restorative effect of GA on hypocotyl growth is related to the DELLA proteins, we applied GA_4 with PAMD or **4** to the *5Δdella* mutant line of *Arabidopsis*, which is insensitive to GA biosynthesis inhibitors or GA antagonists because it carries loss-of-function mutations in all five DELLA proteins.[27] The results showed that the hypocotyl growth of the *5Δdella* line was less inhibited by PAMD or **4** than was the wild-type line (L*er*), although there was still a significant difference between the effects of the mock treatment and test compound treatments in the *5Δdella* line (Figure 10A). The restorative effect of GA on the hypocotyl growth suppressed by PAMD or **4** was observed in L*er* plants but not in *5Δdella* plants (Figure 10A). We then analyzed the effects of treatment with PAMD or **4** on the accumulation of the DELLA proteins using the *RGA:GFP-RGA* line. Treatment with either of the two compounds delayed the GA-mediated degradation of the GFP-RGA fusion protein (Figure 10B). These results indicate that PAMD and its derivative **4** alleviate the DELLA degradation induced by GA treatment and GA signaling. Therefore, their effects on plant growth partly depend on the function of the DELLA proteins.

DISCUSSION

Not only plant hormone mimics, but also chemical inhibitors such as paclobutrazole, an inhibitor of GA biosynthesis, brassinazole, an inhibitor of brassinosteroids biosynthesis,[28] and naphthylphthalamic acid, an inhibitor of auxin transport,[29] are useful in studies on plant hormone signaling. Until recently, there has been limited information about inhibitors of SA signaling. In a previous paper, we reported that PAMD (**1**) inhibits SA signaling in *Arabidopsis* and increases the susceptibility of the plants to pathogens,[22] suggesting that PAMD is an inhibitor of SA signaling and may be a useful tool for determining the SAR mechanism. However, besides its effects on SA signaling, PAMD adversely affected plant growth. In the present study, we prepared several derivatives of PAMD and found that one of them compound **4** suppressed the expression of the SA-response-marker *PR* genes with a smaller adverse effect on growth than PAMD. Therefore, we selected **4** as a better SA-signaling inhibitor than PAMD. LC-MS/MS analysis confirmed that PAMD and **4** increased the endogenous level of SA, which should have induced the expression of *PR* gene. This inconsistency between the increasing SA level and the decreasing *PR* gene expression level in the *Arabidopsis* treated by PAMD or **4** indicated that these compounds affect the SA signaling pathway and resistance to *C. higginsianum* by impairing the *PR* gene expression but not through an impact on the biosynthesis of SA. The induction of SA level could be considered negative feedback resulting from the inhibitory effects of PAMD and **4** on the SA signaling pathway. Our study of the structure−activity relationships of the PAMD derivatives demonstrated that the suppression of *PR1* expression by the PAMD derivatives is not directly related to their inhibition of plant growth and that structural modification of the PAMD derivatives dramatically altered their effects on *PR1* expression. These results suggest that further chemical modification of the PAMD derivatives may identify more specific inhibitors of SA signaling.

The side effects of PAMD on growth have also been investigated here. PAMD severely impacted seedling establishment and root growth and induced an accumulation of a higher level of ABA and anthocyanin compared to mock treatment. These limitations were overcome to some extent by structure−activity relationship modification, and compound **4** was

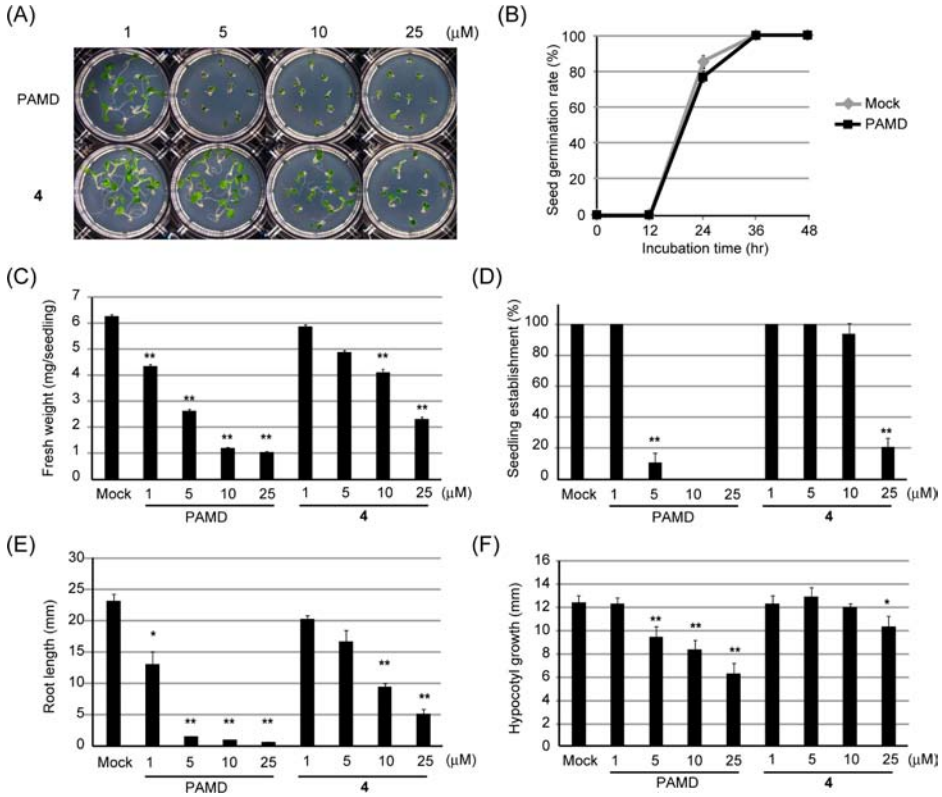

Figure 8. Inhibitory effects of PAMD and **4** on *Arabidopsis* growth. (A) Seedlings (5 DAG) of *Arabidopsis* grown on $^1/_2$ MS medium containing PAMD or **4** under constant light at 22.5 °C. (B) Seeds were germinated on $^1/_2$ MS medium with or without **4** under constant light at 22.5 °C. Error bars indicate the means ± SE of three independent replicates, $n > 30$. (C) Fresh weight of seedlings (12 DAG) grown on $^1/_2$ MS medium with or without the test compound under constant light at 22.5 °C. Error bars indicate the means ± SE of three independent replicates, $n > 30$. Student's t test was used to determine the significance of difference relative to the mock treatment; **, $P < 0.01$. (D) Seeds were germinated on $^1/_2$ MS medium with or without the test compound under constant light at 22.5 °C. Seedling establishment was determined as the appearance of the first pair of true leaves at 5 DAG. Error bars indicate the means ± SE of three independent replicates, $n = 10$. (E) Primary root lengths of seedlings (6 DAG) that were germinated on $^1/_2$ MS medium with or without the test compound under constant light at 22.5 °C. Error bars indicate the means ± SE of three independent replicates, $n = 10$. Student's t test was used to determine the significance of differences relative to the mock treatment: *, $P < 0.05$; **, $P < 0.01$. (F) After stratification at 4 °C for 2 days, seeds were light-pulsed for 6 h and germinated and grown on $^1/_2$ MS medium with or without the test compound under constant dark at 22.5 °C. Hypocotyl length was measured at 5 DAG. Error bars indicate the means ± SE of three independent replicates, $n = 10$. Student's t test was used to determine the significance of differences relative to the mock treatment: *, $P < 0.05$; **, $P < 0.01$.

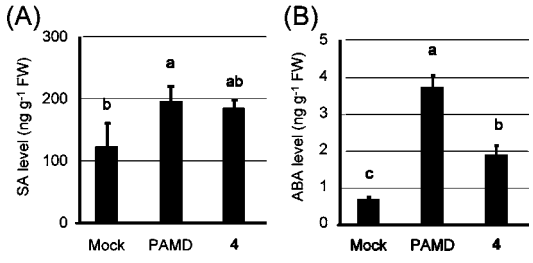

Figure 9. Quantification of salicylic acid and abscisic acid in *Arabidopsis*. Seedlings (5 DAG) were transferred to $^1/_2$ MS medium containing 25 μM of the test compound, as indicated, for further cultivation for 8 days, followed by being sampled and analyzed by LC-MS/MS. Error bars indicate the means ± SD of three replicates. Statistical differences between the groups were calculated with ANOVA analysis (Posthoc: Duncan). Bars with different letters are significantly different: $P < 0.05$ (SA) or $P < 0.01$ (ABA).

selected as a better candidate for SAR studies. However, at present, no derivative has yet been found that suppresses *PR* gene expression but does not inhibit plant growth. The new PAMD derivatives, such as **4**, are more selective inhibitors of SA signaling but still inhibit *Arabidopsis* growth. Here, we have demonstrated that the inhibitory effects of PAMD and its derivative **4** are partly dependent on their effects on GA signaling by interrupting GA-induced DELLA degradation (Figure 10).

Recently, many studies of plant immunity to pathogens have indicated a cross talk between SA and other plant hormones.[30] Tan et al. showed that the effector protein of the pathogenic bacterium *Xanthomonas campestris*, $XopD_{Xcc8004}$, initiates the disease defense mechanisms of plants by interacting with RGA and delaying its degradation.[31] This confirms that the stabilization of the DELLA proteins affects the plant's disease responses. It has been shown that DELLA increases the plant's resistance to necrotrophs but reduces its resistance to biotrophs, thus demonstrating that the DELLA proteins control plant immune responses by modulating the balance between SA and JA signaling.[13] This supports our results that PAMD and **4** suppress the expression of SA-responsive genes and also stabilize the DELLA proteins. We suggest that the activity of PAMD and its derivatives in repressing *PR* gene expression is partly dependent on the DELLA proteins, although further study is required to confirm this.

It is noteworthy that the growth of the 5Δ*della* mutant line was still suppressed by both PAMD and compound **4** (Figure 10A), indicating that DELLA and DELLA-induced signaling are

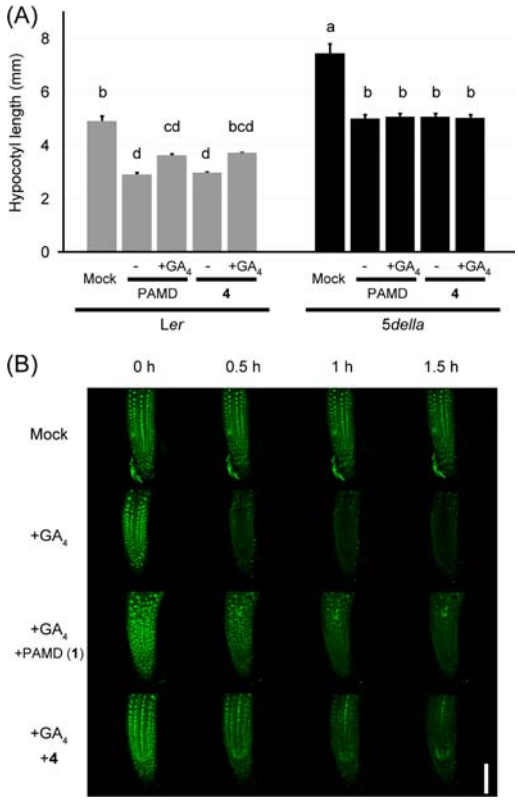

Figure 10. Effects of PAMD and **4** on GA signaling. (A) Seedlings (3 DAG) of L*er* and 5Δ*della* grown on $^1/_2$ MS medium under constant light at 22.5 °C were transferred to $^1/_2$ MS medium containing GA_4 (10 μM), PAMD (25 μM), **4** (25 μM), or combinations of them as indicated, followed by several days' cultivation under constant light at 22.5 °C. Hypocotyl length was measured 9 days after treatment. Error bars indicate the means ± SE of three independent replicates (n = 6). Statistical differences between the groups were calculated with ANOVA analysis (Posthoc: Duncan). Bars with different letters are significantly different with $P < 0.01$. (B) The primary roots of 2 DAG *RGA:GFP-RGA* seedlings grown on $^1/_2$ MS medium under constant light at 22.5 °C were placed onto slides and immersed in $^1/_2$ MS medium with or without GA_4 (10 μM) combined with PAMD (25 μM) or **4** (25 μM), as indicated. Green fluorescence was observed with a confocal-laser scanning microscope and time-lapse photography. Scale = 100 μm.

not the only points at which these compounds function. Although the exact target(s) of PAMD and its derivatives is (are) still unclear, investigation of these targets and their modes of function will extend our understanding of SA signaling and/or its cross talk with other plant hormones.

identification of different variants or 2DGEs (2DGE protein spots produced either from a single gene or from paralogous genes as per the classification given previously)[11] of β-conglycinin and glycinin proteins.[12] In addition to their high abundance in seed, recent proteomic studies revealed their presence in soybean seed coat.[13,14] Methods have been developed to deplete these major soybean SSPs using isopropanol,[15] calcium,[16] and protamine sulfate (PS).[17] However, these methods have not been fully utilized for the comparative soybean proteome analysis to get a better insight into the nutritional values of the seeds.

Because soybean seeds are rich source of proteins and oils, one of the major goals of plant breeders worldwide is to enhance the nutritional properties of soybean seeds by increasing either their oil content or their protein content. However, for successful breeding programs, it is highly essential to understand the biochemical pathways underlying the accumulation of proteins and oils in soybean seeds. In this direction, we have carried out a comparative biochemical and proteomic profiling of protein- versus oil-rich-seed cultivars of *G. max* and *G. soja*. In this study, a combination of the PS and 2DGE methods was used to establish the proteomes of two cultivars each of *G. max* (Daewon and Saedanbaek) and *G. soja* (WS15 and WS22), differing in protein and oil reserve contents in order to get a better understanding of why soybean seeds differ in their protein and oil content.

2. MATERIALS AND METHODS

Plant Materials. Seeds of *G. max* (Daewon and Saedanbaek) and *G. soja* (WS22 and WS15) cultivars were grown in silt loam soil in the experimental fields of the National Institute of Crop Science, Rural Development Administration (RDA) at Miryang, South Korea, in the month of June. The soil was supplemented with a standard RDA N−P−K fertilizer (N−P−K = 3−3−3.3 kg/10 acre). Seeds were harvested in October (average temperature = 23.5 ± 3.5 °C, average day length = 12 h 17 min).[13]

Analysis of Total Protein and Amino Acid Contents. Total protein content in the soybean seeds was measured using a protein analyzer (rapid N cube, Hanau, Germany). Using a high-speed vibrating sample mill (CMT T1−100, CMT Company Ltd., Tokyo, Japan), seeds were powdered, and 50 mg of each sample was then wrapped in nitrogen-free paper and pressed to pellets. All the parameters were set to default. Glutamic acid (9.52% N) was used as test standard, and a protein factor of 6.25 was used. Each sample was analyzed in duplicate.

Amino acids were analyzed using an amino acid analyzer (Biochrom 30, Biochrom Ltd., Cambridge, UK). Briefly, the samples were hydrolyzed with 6 N HCl in sealed glass tubes filled with nitrogen at 110 °C for 24 h. The HCl was removed from the hydrolyzed sample on a rotary evaporator and brought to 10 mL with 0.2 M sodium citrated buffer, pH 2.2. Amino acids were analyzed by Biochrom 30 amino acid analyzer using nihydrin as color reactant on a cation-exchange resin column. Obtained data were analyzed using Ezchrom E software, and the quantity of amino acids was calculated by comparison with a known concentration of amino acid standard.[14]

Fatty Acid Composition Analysis. Fatty acid (FA) analysis was carried out as described previously.[18] Fatty acid methyl esters (FAMEs) were prepared by Soxhlet extraction, saponification, acid-catalyzed transesterification, and finally extraction of FAMEs in hexane. FAMEs were subsequently analyzed by capillary gas chromatography (column: 30 m × 0.25 μm I.D., 0.5 μm; flame ionization detected temperature, 210 °C; carrier gas, N_2 at 1.0 mL/min; injector temperature, 210 °C; and oven temperature, programmed from 180 to 210 °C) using an Agilent 1100 capillary gas chromatograph. Quantitative data were calculated using the peak area ratio (% total FAs).

Protein Extraction and Enrichment of Low-Abundance Proteins. Total seed proteins were extracted as described previously.[17] Briefly, soybean seeds (cv. Daewon, Saedanbaek, WS22, and WS15) were powdered in liquid nitrogen using pestle and mortar. Powdered samples (1 g) were homogenized in 10 mL of Mg/NP-40 protein extraction buffer (0.5 M Tris-HCl (pH 8.3), 2% (v/v) NP-40, 20 mM $MgCl_2$), followed by centrifugation at 12 000 g for 10 min at 4 °C. Supernatant thus obtained was incubated with 0.1% PS in ice for 30 min after which the extract was again centrifuged at 12 000 g for 10 min at 4 °C to separate the PS supernatant (PSS) and PS pellet (PSP) fractions, as described earlier.[17] PSP fraction was dissolved in an equal volume of Mg/NP40 buffer, and then proteins were extracted from the PSS and PSP fractions using a TCA/acetone precipitation method. At the final step, proteins were stored in 80% acetone until analysis.

2D Gel Electrophoresis. 2DGE was carried out as described previously.[17] Briefly, proteins from the 80% acetone solution were precipitated by centrifugation at 12 000 g for 5 min, and the pellet obtained was dissolved in the rehydration buffer containing 7 M urea, 2 M thiourea, 4% v/v CHAPS, 2 M DTT, and 0.5% v/v IPG buffer, pH 4−7 (GE Healthcare, Waukesha, WI, USA). Protein concentrations in each fraction were determined by 2D-Quant kit (GE Healthcare). Proteins (600 μg) of each sample were loaded on 24 cm IPG strips (pH 4−7) by rehydration loading overnight at 20 °C, and isoelectric focusing was carried out using following protocol: 50 V for 4 h, 100 V for 1 h, 500 V for 1 h, 1000 V for 1 h, 2000 V for 1 h, 4000 V for 2 h, 8000 V for 5 h, 8000 V for 9 h, and 50 V for 6 h on the IPGphor II platform (GE Healthcare). The second-dimensional separation was carried out on 12% SDS-PAGE, after sequential equilibration of the strips in in equilibration buffer (6 M urea, 30% v/v glycerol, 2% v/v SDS, 50 mM Tris-HCl (pH 6.8), and 0.1 mg/mL bromophenol blue) containing 100 mM DTT and 55 mM iodoacetamide. Gels were stained with colloidal Coomassie Brilliant Blue (CBB). A total of three biological replicates were carried out for each data set.

Image Acquisition and Data Analysis. Images of all the CBB-stained gels were acquired using a transmissive scanner (PowerLook 1129, UMAX) at 32 bit pixel depth and 300 dpi resolution and saved as a TIFF file. The gel spots were detected using ImageMaster2DPlatinum software 6.0 (GE Healthcare). For analyzing the differential expression of proteins, spot volumes were normalized in the percentage volume mode, and spots showing a ≥1.5-fold change in spot volume were considered as differentially expressed spots. Student's *t* test ($p < 0.05$) was carried out to check the significance of differential expression.

Mass Spectrometry. Differentially expressed spots were excised from the gel, destained, and subjected to in-gel digestion.[19] In brief, first, spots were subjected to in-gel reduction using 10 mM DTT in 100 mM ammonium bicarbonate at 56 °C for 30 min and then alkylated using 50 mM iodoacetamide in 100 mM ammonium bicarbonate for 30 min in the dark. Gel pieces were washed with 1:1 ammonium bicarbonate/acetonitrile (ACN) solution and dehydrated using 100% ACN for 5 min. Gel pieces were digested with 5 μL of trypsin solution (20 ng/μL, gold mass-spectroscopy-grade, Promega, Madison, USA) in 50 mM ammonium bicarbonate, pH 7.8, for 16 h at 37 °C. Trypsin-digested peptides were extracted twice with 0.1% trifluoroacetic acid (TFA). Each sample was mixed with same volume of matrix (10 mg/mL α-cynohydroxycinnamic acid, 0.1% TFA, 50% ACN), loaded on a MALDI target plate and allowed to dry at 25 °C. Prepared samples of trypsin-digested peptides were subjected to MALDI-TOF/TOF MS analysis using ABI 4800 Plus TOF-TOF Mass Spectrometer (Applied Biosystems, Framingham, MA, USA).[14] Spectra were calibrated with the peptide calibration standard (Mass Standard Kit for the 4700 Proteomics Analyzer, Calibration Mixture 1) prepared in the same way. The 10 most and least intense ions per MALDI spot with signal/noise ratios >25 were selected for subsequent MS/MS analysis in 1 kV mode using 800−1000 consecutive laser shots.[13,17] MS/MS spectra were searched against the Uniprot/Swiss-Prot database (14 926 175 sequences, 5 299 740 401 residues) and soybean peptide database obtained from the soybean genome database (Phytozome ver. 8.0, http://www.phytozome.net/soybean) by Protein

J. Agric. Food Chem. 2015, 63, 7134−7142

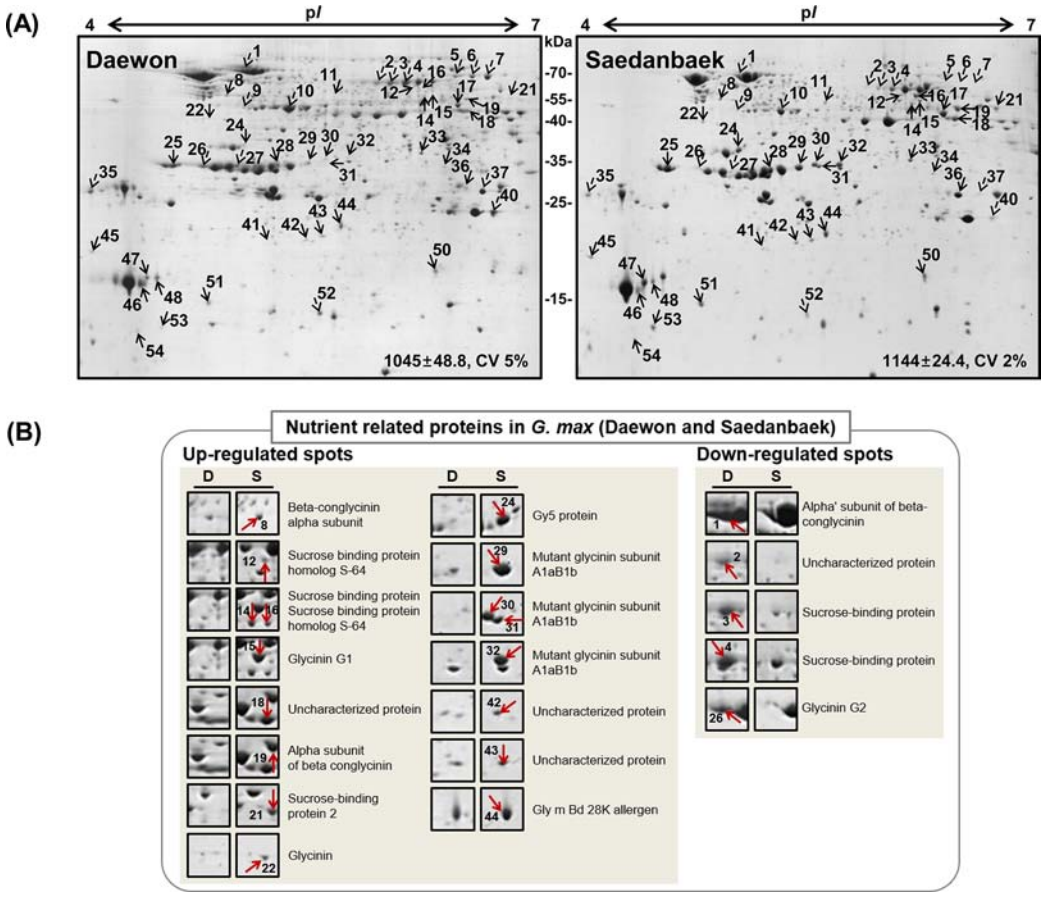

Figure 1. (A) Representative 2D gels of PSS fractions of Daewon and Saedanbaek cultivars of *G. max*. First-dimension separation was carried out on 24 cm IPG strips, pH 4−7, and second-dimension separation was carried out on 12% SDS-PAGE. Gels were stained with colloidal CBB stain. Differentially expressed spots in supernatant fractions are marked by arrows. (B) Enlarged view of 2D gel areas showing differentially expressed protein spots in PSS fractions of Daewon and Saedanbaek.

Pilot v.3.0 software (AB Sciex, Framingham, MA, USA) using MASCOT as search engine (ver. 2.3.0, Matrix Science, London, UK). The search parameters used for the protein identification were as follows: fixed modifications, carbamidomethylation of cysteine; variable modification, methionine oxidation; peptide and fragment-ion mass tolerances, 50 ppm; maximum trypsin missed cleavage, 1; and instrument type, MALDI-TOF/TOF. Only high-confidence identifications with statistically significant search scores (greater than 95% confidence, $p < 0.05$) were used for further analyses.

Data Processing and Statistical Analysis. Functional categories and statistical analyses were carried out on differential protein spots. Gene ontology (GO) terms analysis was carried out using an UFO web server (http://ufo.gobics.de/). Spot volumes of all the differentially expressed proteins were subsequently $\log_2$-transformed to equalize the scale of expression. The $\log_2$-transformed values of each spot were then used for hierarchical clustering analysis (HCL) using MultiExperimental viewer (MeV) software to generate the heat map. Principal component analysis (PCA) of the differentially expressed protein spots was carried out using the statistical tool of the Microsoft Excel program (XLSTAT).

Tofu Production. For production of tofu, a previously published protocol based on $MgSO_4$ precipitation was used.[20,21] In brief, seeds were soaked in water and incubated at 4 °C for 24 h. After incubation, soaked seeds were ground with water for 5 min at high speed in a blender (Koco-4800, Koco Silver Co., Incheon, Korea). Soybean slurry thus obtained was filtered using a cheese cloth and squeezed manually to obtain the filtrate. The residue was mixed with water and the slurry was filtered again to obtain the soymilk. After adding 3% $MgSO_4$, the soymilk was boiled in a tofu maker. The bean curd thus obtained was pressed smoothly. After pressing, the tofu was stored at 4 °C until analysis.

Antibody Generation and Western Blot Analysis. For production of antibodies, spots corresponding to the different subunits of SSPs were excised from the 2D gels, and the proteins were identified by MS/MS. Protein sequences thus obtained were used for designing the primers, and the genes for respective proteins were cloned in a pQE30 expression vector. Recombinant proteins were purified according to the manufacturer's protocol (Qiagen, Valencia, CA, USA) and used for generation of polyclonal antibodies by immunizing rabbits. Antibodies were then purified from rabbit's blood as described previously.[22] For immunoblotting experiments, the total, PSS, PSP, tofu, and whey protein samples (25 μg) were resolved on SDS-PAGE and transferred to a PVDF membrane.[17] Transfer of proteins to the membrane was confirmed by Ponceau-S staining. Membrane was incubated in blocking solution for 2 h in 5% nonfat dry milk in TTBS (50 mM Tris-HCl, pH 8.2, 0.1% (v/v) Tween-20, and 150 mM NaCl), after which the membrane was incubated overnight with antibodies against the SSPs (β-conglycinin α subunit, α' subunit, β subunit, glycinin acidic chain; 1:10 000). After three washings of the membrane in TTBS for 15 min, it was incubated with secondary anti-rabbit-IgG antibody (1:6500) conjugated with horseradish peroxidase. Finally, the immunoblot signals were detected using SuperSignal West pico Chemiluminescent Substrate Kit (Thermo Scientific, Waltham, MA, USA).

3. RESULTS

Protein, Oil, and Fatty Acid Analysis. The protein content in seeds of Daewon, Saedanbaek, WS22 and WS15, was

DOI: 10.1021/acs.jafc.5b03196
J. Agric. Food Chem. 2015, 63, 7134−7142

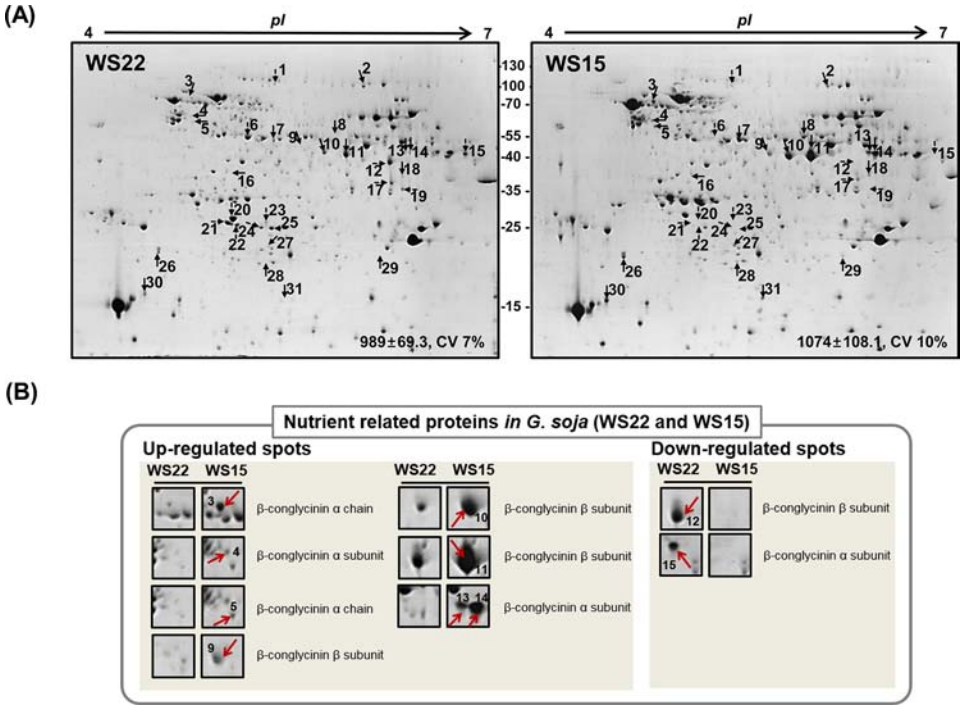

Figure 2. (A) Representative 2D gels of PSS fractions of WS22 and WS15. (B) Enlarged view of the differentially expressed protein spots.

39.2, 47.9, 46.9, and 56.5%, respectively, whereas the oil content was 19.7, 16.3, 10.9, and 6.9%, respectively (Figure S1A). Out of the total 17 amino acids analyzed, only glutamate and arginine showed significant differences between Daewon and Saedanbaek (Table S1).

A total of five FA content levels were analyzed in seed cultivars of *G. max* and *G. soja* including palmitic acid (C16:0), stearic acid (C18:0), oleic acid (C18:1), linoleic acid (C18:2), and linolenic acid (C18:3). The content of linoleic acid was highest among all FAs analyzed, constituting 50.3, 57.9, 56.7, and 56.6% in Saedanbaek, Daewon, WS22, and WS15, respectively (Figure S1B). Contents of palmitic acid and stearic acid were almost similar in *G. max* and *G. soja*. In the case of the *G. max* seeds, significant differences in the contents of oleic acid and linolenic acid were observed, whereas *G. soja* seeds contained an almost similar concentration of these two FAs. The contents of oleic acid and linolenic acid were 24.6 and 10.6% in Saedanbaek, respectively, whereas they were 18.7 and 9.3% in Daewon. In case of *G. soja* cultivars, these were 10.5 and 10.4% in WS22 and 18.1 and 18.5% in WS15, respectively (Figure S1B).

SDS-PAGE Analysis of Daewon and Saedanbaek Seed Proteins. Following the observation that there are significant differences in the protein and oil contents, total seed proteins were isolated from Daewon and Saedanbaek and resolved on SDS-PAGE. In each cultivar, approximately 30 bands were observed, ranging from 12−130 kDa, of which two polypeptides of ∼19 and 35 kDa were the most abundant, representing the major SSPs in soybean. Addition of 0.1% PS precipitated major SSPs in the pellet fractions, thus allowing the enrichment of rare or low-abundance proteins (LAPs) in the PSS fraction (lanes 3 and 6, Figure S2A).[17]

Comparative 2DGE Proteome Analysis of Two *G. max* Cultivars. Using ImageMaster2DPlatinum software, a total of 1045 ± 48.8 (coefficient of variation, CV = 5%) and 1144 ± 24.4 (CV = 2%) spots were detected in the 2D gels of Daewon and Saedanbaek, respectively (Figures 1A and S3). Of these spots, a total of 71 differential spots were identified, wherein 39 and 32 spots showed increased and decreased abundance, respectively, in Saedanbaek compared to Daewon (Figure 1A). MALDI-TOF/TOF MS analysis of the 71 differential spots resulted in confident assignment of 48 spots (Tables S2 and S3). Gene ontology (GO) analysis of the differentially expressed protein spots showed that up-regulated proteins in protein-rich Saedanbaek were associated with nutrient reservoir activity and majorly included SSPs (53%; spots 8, 12, 14−16, 18, 19, 21, 22, 24, 29−32, and 42−44), seed maturation proteins (spots 33, 36, 45, and 51), and trypsin inhibitors (spots 41, 47, and 48). Out of the total 53% nutrient-related proteins, nine were identified as different 2DGEs of glycinin and three as β-conglycinin. Except for the α' subunit of β-conglycinin (spot 1) and glycinin G2 (spot 26), the rest of the 2DGEs of β-conglycinin and glycinin were increased in abundance in Saedanbaek. GO functional annotation of the identified proteins showed two major categories: nutrient-related (42.6%) and metabolism-related (14.8%) proteins in Saedanbaek. In contrast, the up-regulated proteins in oil-rich Daewon were mainly associated with the proteasome core complex and ubiquitin-dependent protein catabolic processes such as proteasome subunit alpha type (spot 27) and UDP-glucose pyrophosphorylase 2 (spot 9) (Figure 1B and Table S3).

Validation of the Results in Two *G. soja* Cultivars. To validate the above findings in *G. max* cultivars, the same approach was applied to *G. soja* cultivars: WS22 and WS15. SDS-PAGE of WS22 and WS15 proteins showed significant depletion of SSPs in the pellet fractions (lanes 4 and 7, Figure S2B). 2DGE analysis of the PSS fractions of WS22 and WS15 revealed a total of 989 ± 69.3 (CV = 7%) and 1074 ± 108.1 (CV = 10%) protein spots, respectively (Figures 2A and S3). A comparison of the 2D gels of WS22 and WS15 proteins identified a total of 53 differentially expressed spots, wherein 38

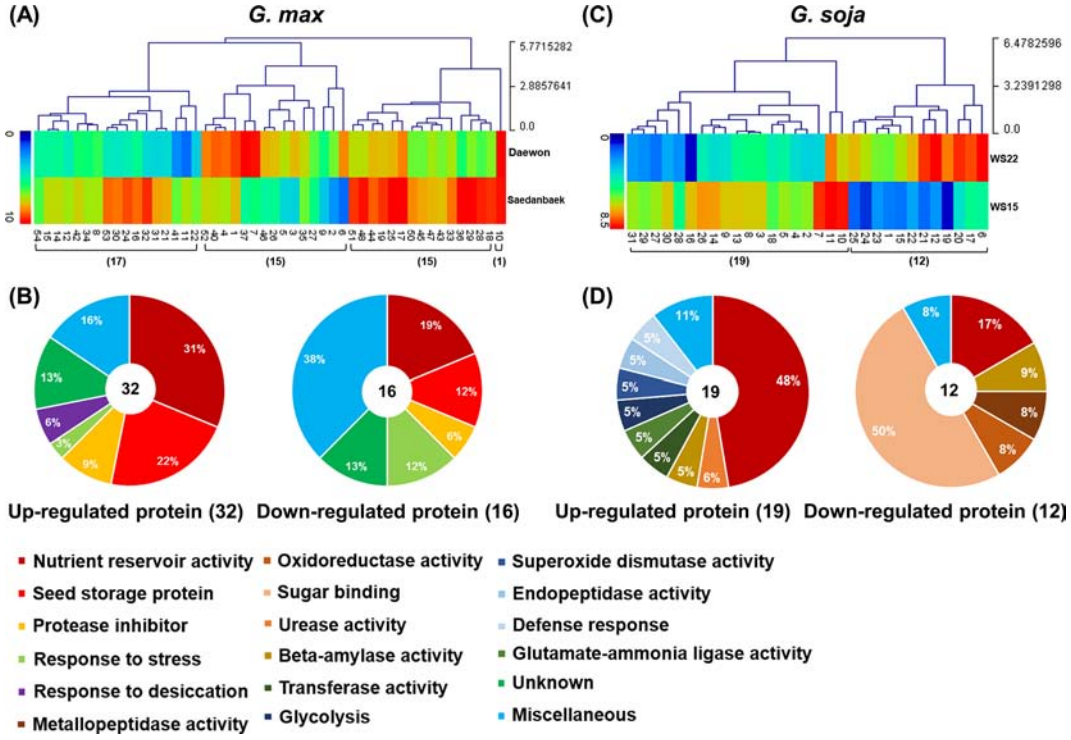

Figure 3. (A) Hierarchical clustering (HCL) analysis of the differentially expressed proteins of *G. max* (Daewon and Saedanbaek) and *G. soja* (WS15 and WS22). For HCL, percentage spot volumes for each spot were calculated using ImageMaster 2D Platinum software and subsequently log-transformed to base 2. Clustering was carried out using MultiExperiment Viewer (MeV) software. (B) GO enrichment analysis of the identified differentially expressed proteins.

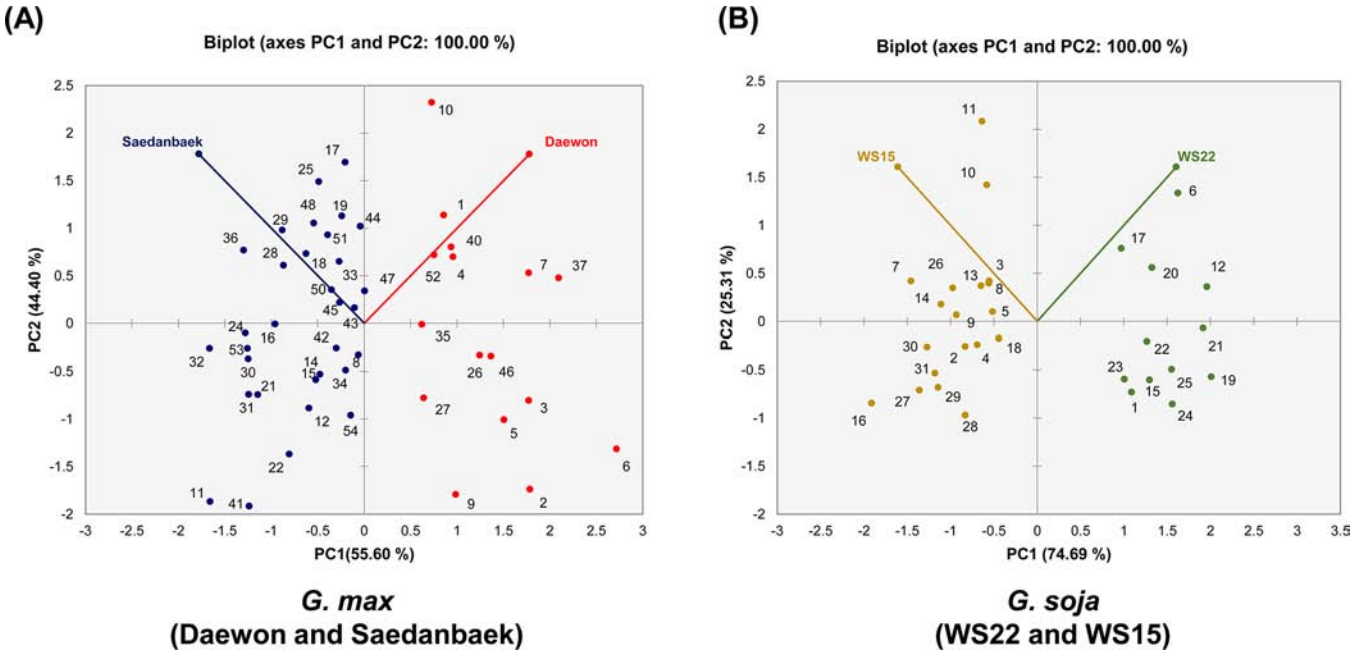

Figure 4. Principal component analysis of the differentially expressed proteins of (A) Daewon and Saedanbaek and (B) WS22 and WS15. Two principal components formed accounted for 100% cumulative variance in both the data sets.

and 15 had increased and decreased abundance, respectively, in WS15 compared to WS22 (Figure 2A). Protein assignment by MALDI-TOF/TOF MS and their GO annotation revealed a similar trend as observed in the *G. max* cultivars (Tables S4 and S5). Protein spots showing increased abundance in protein-rich WS15 cultivar were mainly SSPs with nutrient reservoir activity (spots 3−5, 9−14, and 26), beta-amylase activity (spot 7), and urease activity (spot 2), whereas in oil-rich WS22 cultivar, proteins having increased abundance were mainly involved in the sugar binding activity (spots 20−25, Figure 2B and Table S5).

Hierarchical Clustering and PCA Analysis. To analyze the expression pattern of differential protein spots in protein- versus oil-rich cultivars of *G. max* and *G. soja*, normalized spot

DOI: 10.1021/acs.jafc.5b03196
J. Agric. Food Chem. 2015, 63, 7134−7142

volumes of identified differentially expressed spots were calculated using the ImageMaster software. The obtained values for each spot were subsequently transformed to its base 2 logarithm and finally the obtained $\log_2$ values of spots were used for hierarchical clustering using MeV software (ver. 4.9.0). A total of four and two clusters were formed on the basis of the similar expression pattern in *G. max* and *G. soja*, respectively (Figures 3A and 3C). Functional groups, associated with the up- and down-regulated proteins in *G. max* and *G. soja* are depicted Figure 3B,D, respectively. To identify the protein groups responsible for correlated variations, the differential data set was subjected to PCA. Two principal components, PC1 and PC2, contained 55.6 and 44.4% cumulative variance in *G. max* (Figure 4A) and 74.69 and 25.31% in *G. soja*, respectively (Figure 4B). The distribution of spots in two PCs was highly pronounced, suggesting significant differences in the spot volumes of the differential protein spots between protein- versus oil-rich soybean seed cultivars.

Western Blots Confirmed Differential Regulation of SSPs in Protein- versus Oil-Rich Seed Cultivars. Western blotting was carried out to confirm the differential modulation of SSPs in Daewon and Saedanbaek seeds using antibodies against β-conglycinin α subunit, β-conglycinin α' subunit, β-conglycinin β subunit, and glycinin acidic chain. As expected, very strong signals of β-conglycinin α subunit, β-conglycinin α' subunit, and glycinin acidic chain were seen in the total and PSP fractions, and no differences could be observed, which might be due to the saturation of the signal even though only 25 μg of proteins were loaded into each lane (Figure S4). Even in the PSS fraction, no significant modulation of SSPs was observed in Daewon and Saedanbaek (Figure 5A). At first, use of a high concentration of primary antibody might be expected to be one of the possible causes of these strong signals observed in the Western blots. Therefore, to check the effect of primary antibodies, different dilutions of primary antibodies ranging from 1:10 000−1:80 000 were tried; however, even at the lowest concentration used (1:80 000), no differential expression of these SSPs were observed in the Western blots of total, PSS, and PSP fractions (Figure S5). Therefore, to further detect the differential expression, soybean proteins were fractionated as tofu and whey fractions. Surprisingly, even in the tofu fraction, no differences in the expression pattern of the glycinin and β-conglycinin were observed (Figure 5B). However, when the whey fractions of Daewon and Saedanbaek seeds were analyzed, differences in all the subunits of β-conglycinin were observed (Figure 5C). All the subunits of β-conglycinin including α subunit, α' subunit, and β subunit showed higher expression in the Saedanbaek in comparison with Daewon (Figure 5C). The fold change of expression between Daewon and Saedanbaek was highest for the α' subunit of β-conglycinin and lowest for the β subunit of β-conglycinin (Figure 5C). In the case of glycinin acidic chain, no differences were observed even in the whey fraction, suggesting that it does not contribute to the increased protein content in soybean cultivars.

4. DISCUSSION

The commercial importance of soybean seeds is primarily due to their high protein and oil content. Therefore, our first study objective was to investigate the total protein and oil content in the seed cultivars of *G. max* (cv. Daewon and Saedanbaek) and *G. soja* (cv. WS22 and WS15). Our results showed that of *G. max* cultivars, Saedanbaek is rich in protein, whereas Daewon is rich in oil content. In the case of *G. soja*, WS15 contained more

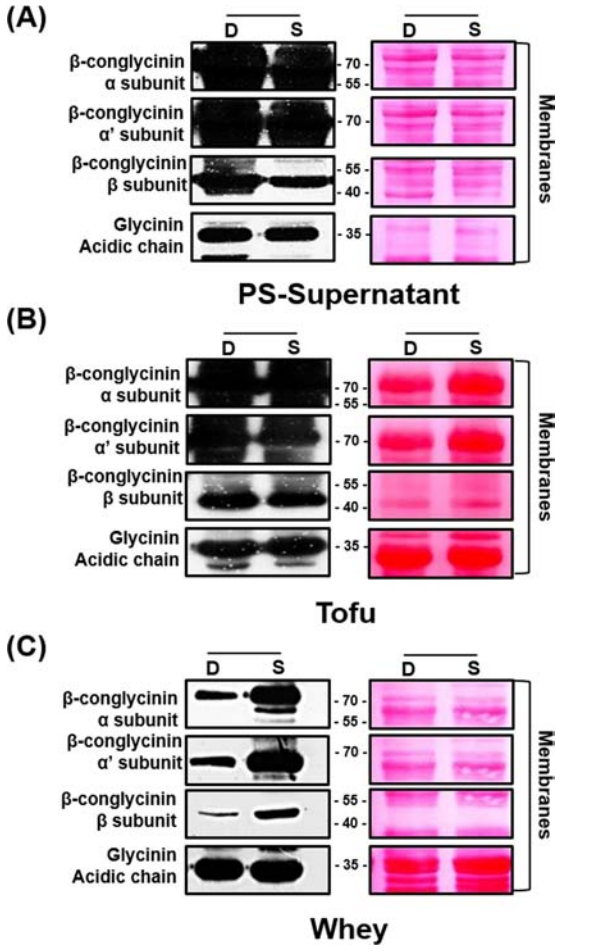

Figure 5. Immunoblotting of the Daewon and Saedanbaek proteins in different protein fractions using β-conglycinin and glycinin antibodies. A total of 25 μg of protein was loaded in each lane of 14% SDS-PAGE, and then the proteins were transferred to a PVDF membrane. After blocking in 5% skim milk, membrane was incubated first with 1:10 000 dilutions of primary antibody and second with 1:10 000 dilutions of secondary antibody. Blot was developed using Super signal Westpico chemiluminescent substrate kit (Thermo Scientific).

protein than did WS22. These results suggested that the selected cultivars of *G. max* and *G. soja* differ in the total protein and oil content significantly and hence can be used for analyzing their proteome as high-protein and high-oil cultivars. FAs are important constituents of the oil, determining the quality of the oil for human consumption. The commercial application of the soybean oil is due to its unique FAs composition. Linoleic acid and linolenic acids are polyunsaturated FAs (PUFA), and both are essential FAs because human beings are not able to synthesize these FAs.

PS Precipitation Leads to Enrichment of LAPs in the PSS Fraction. Soybean seeds are rich in SSPs including different subunits of glycinin and β-conglycinin.[1] These SSPs are major HAPs of the seeds that inhibit the detection and identification of LAPs. It has been shown that without incorporation of any depletion method identification of SSPs can reach up to 80% resulting in loss of time, efforts, and resources. Because LAPs are crucial components of the signaling and regulation machinery in cells, their identification might provide a better picture of the seed physiology. In the past few years, several methods have been developed to reduce or completely deplete these HAPs from the total seed proteins

DOI: 10.1021/acs.jafc.5b03196
J. Agric. Food Chem. 2015, 63, 7134−7142

with an aim to enhance the detection and identification of LAPs.[15−17] These methods are based on the specific depletion of SSPs using 40% isopropanol,[15] 10 mM calcium,[16] or 0.1% PS.[17] Here, we used the PS method for the depletion of SSPs and concurrently enrichment of the LAPs. After PS treatment, proteins were resolved by high-resolution 2DGE to enhance the detection of LAPs. Percent CV for different replicates of 2DGE of each sample were calculated as 5 and 2%, respectively, for Daewon and Saedanbaek, representing high reproducibility of the used PS method. 2DGE followed by MS identification of PSS fractions of *G. max* and *G. soja* showed that out of the total 79 identified proteins (48 from *G. max* and 31 from *G. soja*), only 30% (24 spots) were identified as SSPs (i.e., different 2DGEs/subunits of glycinin and β-conglycinin), validating the efficacy of PS precipitation method in the enrichment of LAPs. Enrichment of LAPs by isopropanol or calcium-based depletion methods has also been shown previously. Using 10 mM calcium, 541 LAPs were detected, of which 197 showed more than 2.5-fold enrichment after isopropanol treatment.[15] In this study, identified LAPs in *G. max* and *G. soja* included different 2DGEs of sucrose-binding proteins, trypsin inhibitors, seed maturation proteins, seed biotin-containing proteins, seed-biotinylated proteins, urease, beta-amylase, glutamine synthetase, phosphoglycerate kinase, superoxide dismutase, proteasome subunit beta type, stress-induced protein SAM22, and lectins (Tables S3 and S5). In addition to these proteins, 15 spots were identified as uncharacterized proteins. As the annotation suggest, these proteins are not yet characterized most probably because of their masking by HAPs that hinders their identification and characterization. Moreover, a few novel proteins including Ran-binding protein 1 homologue a (spot 25, *G. max*), and tau-class glutathione S-transferase (spot 29, *G. soja*) were also identified, and these have not been reported previously in the matured-seed proteome. A more comprehensive identification of PSS proteins in a future study is likely to identify many more novel proteins, which can increase our understanding of the seed physiology.

Up-Regulated Proteins in High Protein Cultivars Were Mainly SSPs. 2DGE analysis followed by MS identification of the differentially expressed proteins showed a similar trend on accumulation of SSPs in the high-protein cultivars of *G. max* and *G. soja*. Although a similar trend of SSPs accumulation was observed in the high-protein cultivars, a contrasting pattern of accumulation of SSPs was observed in WS15 and Saedanbaek. In *G. soja*, only different subunits of β-conglycinin were identified with no identification of glycinin subunits, whereas in the case of *G. max*, the total number of glycinin subunits was three times higher than that of β-conglycinin. It has been shown that the ratio of glycinin and β-conglycinin is important for the texture of the tofu.[23] Similar results were also observed in a comparative study of *G. max* and *G. soja* seed where less 2DGEs of glycinin were observed in *G. soja*.[11] In *G. max*, 32 2DGEs of glycinin were observed, whereas in *G. soja*, only 23 2DGEs could be detected. These results suggest that the protein-rich Saedanbaek cultivar accumulates a higher amount of SSPs than do oil-rich Daewon seeds. This finding is in line with a previous observation that the amount of either β-conglycinin or/and glycinin is associated with protein-rich seeds.[24]

Recently, Xu and co-workers compared the protein profiles of four soybean cultivars.[8] A comparison of the results of this study with their study showed 15 common proteins identified in both studies, with 25 and 39 unique proteins in the previous and current study, respectively (Figure S6). Common proteins were divergent in nature and included glycinin A1aBx subunit, dehydrin, sucrose-binding protein-like, glycinin G4 allergen Gly m Bd 28 K, and beta-conglycinin alpha subunit. Unique proteins identified in this study were mainly stress related, whereas the unique proteins identified in the previous study were associated with sugar metabolism. These differences might be cultivar specific and were probably due to the use of different cultivars in this and the previous study. In this study, we used Saedanbaek and Daewon cultivars whereas Jiyu-73 and Zhonghuang-13 cultivars were used in the previous study.[8]

Western Blotting Confirmed the Association of SSPs with the Enhanced Protein Amount. Our findings showed significant changes in the abundance of glycinin and β-conglycinin between high- and low-protein cultivars of *G. max* and *G. soja*. A previous proteomic study also found higher accumulation of SSPs in the protein-rich cultivars. However, because there is high variability in MS results, it is always advisible to have some confirmatory experiments. Therefore, here we used Western blotting to confirm the association of SSPs with enhanced protein amount. Although PS precipitation led to significant depletion of the SSPs from the PSS fraction, we could not visualize any differential expression of these SSPs in the PSS fraction of Daewon and Saedanbaek using Western blotting approach (Figure 5A). Therefore, to further analyze the differential modulation of the SSPs, a novel approach was employed. Soybean seeds are being largely used for the production of tofu. The precipitated proteins are used for tofu production, whereas rest of the proteins is washed away as whey. Therefore, we used both Daewon and Saedanbaek seeds for the production of tofu, and both tofu and whey protein samples were analyzed by Western blotting. Even though the total protein and SSP amount were higher in the Saedanbaek as compared with those in Daewon, no differences in the amount of SSPs in the tofu fractions were observed. One of the possible explanations of this could lie in the tofu-making procedure. Tofu production involves precipitation of proteins using $MgSO_4$, and because the same amount of $MgSO_4$ (3%, unsaturated concentrations) was used for precipitation of seed proteins, it is expected that an equal amount of seed proteins are precipitated from both Daewon and Saedanbaek seeds. Thus, the rest of the proteins come out in the whey fraction. Using this methodology, we found the differential expression of the SSPs, suggesting the efficacy of the used approach. Taken together, our results confirm that the high protein content in some of soybean cultivars is due to the accumulation of SSPs.

Established Differential Protein Profiles Provide a Possible Explanation for Soybean Cultivars Differing in Protein- versus Oil-Rich Seeds. Urease enzymes are involved in the degradation of urea to form ammonia and carbon dioxide.[25,26] The ammonia thus formed is converted into glutamine by the action of glutamine synthetase.[25] Surprisingly, both urease and glutamine synthetase proteins showed increased abundance in seeds of the protein-rich cultivars Saedanbaek and WS15 (Tables S3 and S5), including one urease-activating protein, namely, Ni-binding urease accessory protein UreG found in Saedanbaek. Urease accessory proteins are involved in the activation of urease by incorporating nickel ions to the active site of urease, which is critical for urease activity.[26] Up-regulation of glutamine synthetase in a high-protein cultivar of soybean was also observed previously.[8] Taken together, increased accumulation

DOI: 10.1021/acs.jafc.5b03196
J. Agric. Food Chem. 2015, 63, 7134−7142

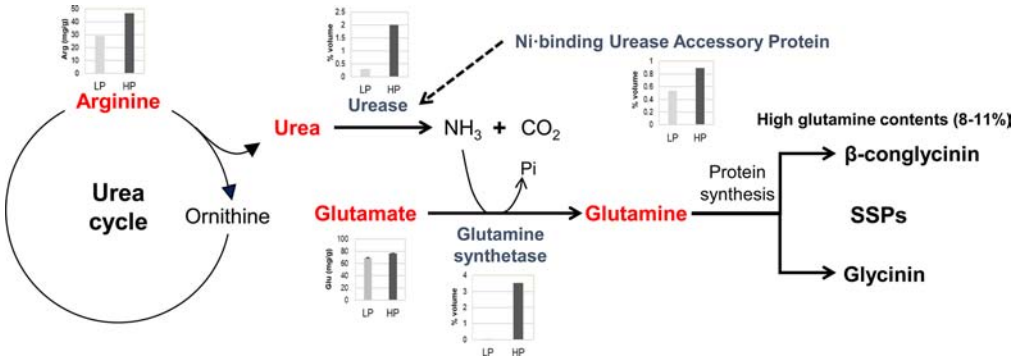

Figure 6. A hypothetical model explaining why some soybean seeds are rich in proteins. Up-regulation of urease, Ni-binding urease accessory protein, and glutamine synthetase suggest higher production of urea and thus glutamine in the high-protein cultivar. This was further confirmed by the amino acid analysis, which showed the higher concentration of glutamate and arginine, precursors of urea and glutamine, in high-protein cultivars. Glutamine thus formed is used for the synthesis of SSPs that are rich in glutamine (8−11%). On the basis of these results, it can be concluded that glutamine concentration can be the determining factor of total protein contents in soybean seeds.

of these proteins indicates the production of a higher amount of glutamine in the protein-rich cultivars (Saedanbaek and WS15) in comparison with that in the Daewon and WS22. Interestingly, soybean SSPs, which govern the total protein content of soybean seeds, are rich (8−11%) in the amino acid glutamine, whereas the glutamine content of other proteins is less than 2−5%. On the basis of these results, it could be proposed that glutamine content is likely to be one of the factors involved in determining the total amount of SSPs accumulation in soybean seeds. Because the amount of SSPs is directly associated with the increased protein amount, restriction of the glutamine concentration could be one of the limiting factors determining the amount of protein accumulation in seeds. Moreover, analysis of amino acid contents in the Daewon and Saedanbaek seeds also revealed higher concentrations of glutamate and arginine in Saedanbaek. Because both of these amino acids are the precursors of urea and glutamine, their higher concentrations in Saedanbaek further suggest the increased production of urea and thus glutamine in high-protein cultivar Saedanbaek (Figure 6). Overall, it can be speculated the high protein content in the protein-rich cultivars is potentially due to a higher amount of glutamine, which is the result of the higher activities of urease, its accessory proteins, and glutamine synthetase.

In the case of the high-oil cultivar Daewon, increased accumulation of many biotinylated proteins (spots 5−7) including seed biotin-containing protein SBP65 and seed biotinylated protein 68 kDa isoform was observed. The exact role/functions of these SBPs remain largely unclear in plants; however, the majority of the biotinylated enzymes of plants like acetyl-CoA carboxylase, 3-methylcrotonoyl-CoA carboxylase, propionyl CoA carboxylase, and pyruvate carboxylase are involved in the FA biosynthesis, suggesting similar functions of SBPs in plants.[27,28] Observed increased abundance of these biotinylated proteins in the oil-rich cultivars may partially explain the high accumulation of oil in Daewon and WS22 seeds in comparison with that in Saedanbaek and WS15.

Taken together, our results confirmed that the protein-rich cultivars Saedanbaek and WS15 accumulate higher amounts of SSPs including various subunits of glycinin and β-conglycinin. Moreover, our results also indicate that the levels of glutamine might be one of the potential factors for SSPs synthesis, which determines the total protein content in soybean seeds.

their biodegradation. Biosurfactants possess different chemical structures consisting of glycopeptides, lipopeptides, glycolipids, neutral lipids, and fatty acids and in comparison with chemical surfactants they are less toxic, more biodegradable, and effective at extreme operational conditions.[10]

Some biosurfactants also are able to stabilize emulsions between hydrophilic and hydrophobic solutions. For instance, biosurfactants produced by *Lactobacillus pentosus* exhibited a strong emulsion capacity when added to kerosene/water emulsions,[11] gasoline/water emulsions,[12] octane/water emulsions,[13] rosemary oil/water emulsions,[14] and fluorene/water emulsions.[15]

In the literature have been reported several works about the utilization of chemical surfactants for the bioremediation of contaminated soils[16,17] because these are cheaper and more available to the consumer than biosurfactants produced biotechnologically. Therefore, few works deal with the utilization of biosurfactants for the biocorrection of contaminated soils or sludge.[18] Shin et al.[19] have used a rhamnolipid biosurfactant produced by the genus *Pseudomonas* to remediate phenanthrene-contaminated soil by the combination of solubilization and biodegradation processes, whereas Das and Mukherjee[20] studied the utilization of pyrene as the sole source of carbon by *Bacillus subtilis* and *Pseudomonas aeruginosa* strains as well as the role of biosurfactants in enhancing the bioavailability of this organic contaminant, although most works focus on studying the solubilization of PAHs in aqueous solutions in the presence of biosurfactants.[21,22]

This work aims to study the bioremediation of sewage sludge provided by a municipal wastewater treatment plant and contaminated with high doses of PAHs. The bioremediation processes will be performed using a low-cost biosurfactant extracted form corn steep liquor, and the biodegradation of the persistent organic pollutants will be studied by applying different kinetic models.

MATERIALS AND METHODS

Reagents. Anthracene (99%) and pyrene (98%) were purchased from Acros Organics (Morris Plains, NJ, USA).

Naphthalene, acetonitrile (supergradient HPLC grade), and acetone (synthesis grade for contamination of sewage sludge) were supplied by Scharlau (Barcelona, Spain).

Chloroform (stabilized with 50 ppm of amylene as preservative, 99.8%) was purchased from Panreac (Barcelona, Spain).

Corn steep liquor, hexane (Chromasolv, HPLC, ≥97.0%), and acetone (puriss. p.a., ACS reagent, reag. ISO, reag. Ph. Eur., ≥99.5% for ASE extraction) were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Nitrogen (Extrapure 3× (high purity, >99.998%)) was supplied by Praxair (Spain).

Characteristics of the Sewage Sludge. *Composition of Sewage Sludge.* For the determination of inorganic carbon (IC) 0.5 g of sewage sludge was introduced in a muffle at 400 °C during 3 h to eliminate the organic matter contained in the sewage sludge samples, whereas for the determination of organic carbon (OC) and total nitrogen (TN) samples did not undergo this process. An Elemental Analyzer (LECO, CN-2000) was used for carbon and nitrogen determination using infrared (IR) detection and thermal conductivity detection (TCD), respectively.

Scanning Electron Microscope (SEM) Images of Sewage Sludge. Samples were dried, covered with gold, and then observed using a scanning electron microscope (JEOL JSM-6700F FEG), operating at an acceleration voltage of 5.0 kV for secondary-electron imaging (SEI).

Optical Images of Sewage Sludge. The macroviews of sewage sludge samples treated with water, acetonitrile, or biosurfactant

DOI: 10.1021/acs.jafc.5b02346
J. Agric. Food Chem. 2015, 63, 7143−7150

solution were obtained with a regular digital camera (Sony optical SteadyShot) using an Optical Zoom 4× with 26 mm wide-angle lens and 14.1 megapixels.

Contamination of Sewage Sludge. Sewage sludge used in this work was obtained after a secondary wastewater treatment in a local water treatment plant in Galicia (Spain), which was contaminated with a mixture of naphthalene, anthracene, and pyrene. Hence, 250 g of sewage sludge was contacted with different PAHs solubilized in acetone and stirred vigorously for 30 min to promote the homogeneous distribution of persistent organic pollutants. Before mobilization and biodegradation of PAHs was begun, the sewage sludge samples were left to rest for 48 h at 28 °C, to eliminate all of the acetone, in a shaker at 150 rpm. Table 1 includes the initial concentration of PAHs achieved in the sewage sludge after the acetone evaporation.

Characteristics of the Biosurfactant Solution. The biosurfactant used in this work was obtained from a liquid stream of the corn milling industry usually called corn steep liquor (CSL). Prior to the preparation of washing solution, biosurfactant was extracted from CSL, with chloroform, using the methodology proposed by Vecino et al.[23] The efficiency of a biosurfactant is determined by its critical micelle concentration (CMC), which is the point at which micelles start to form; hence, biosurfactant washing solution was formulated with concentration over 2.5 times the CMC (998.5 mg/L).

Mobilization and Biodegradation of PAHs Contained in Sewage Sludge. Sewage sludge (10 g) samples contaminated with PAHs were placed in 250 mL Erlenmeyer flasks together with 100 mL of an aqueous solution containing the lipopeptide biosurfactant. The experiments were conducted in a shaker at 150 rpm, for 27 days at 30 °C. Moreover, acetonitrile (AcN) was used as solvent control extractant under the same conditions.

Analysis of PAHs in the Sewage Sludge by Accelerated Solvent Extraction Process. Sewage sludge samples (around 5 g) were submitted to an extraction process using an accelerated solvent extraction system (Dionex-ASE 200). The empty spaces of extraction tubes were filled with diatomaceous earth. The cell contents (11 mL extraction cell) were extracted during four cycles of 5 min, at 100 °C and 1500 psi, with a hexane/acetone 1:1 (v/v) flush volume of 6 mL (60% of ASE cell capacity) and purged with nitrogen (60 s). The extracts were evaporated to dryness under a gentle stream of nitrogen gas in a TurboVap station (at 35 °C and 12 psi). Subsequently, samples were transferred by adding acetonitrile to reach a final volume of 5 mL, filtered through a 0.45 μm syringe filter, and injected into the HPLC-DAD-FLD system.

Quantification of PAHs in the Liquid Phase by HPLC-DAD-FLD. To analyze the PAHs mobilized to the liquid phase, sewage sludge samples were removed from the washing solution consisting of acetonitrile or biosurfactant, by filtration (PTFE syringe filter). Subsequently, PAHs solubilized in the liquid phase were identified and quantified by high-performance liquid chromatography (HPLC) with diode array detection (DAD) and fluorescence detection (FLD) (Agilent Technologies 1200 series, Germany) using an Envirosep PP column (125 × 4.60 mm) (Phenomenex, Torrance, CA, USA) with the column oven kept at 35 °C. The mobile phase consisted of Milli-Q water/acetonitrile (1:1), the injection volume was 20 μL, and the flow rate was 2 mL/min.

RESULTS AND DISCUSSION

Physicochemical Characterization of Treated Sewage Sludge. In this work, sewage sludge was submitted to a bioremediation process in the presence of lipopeptide biosurfactant, extracted from corn steep liquor, for the removal of naphthalene, anthracene, and pyrene. Table 2 shows the elemental analysis of sewage sludge under different conditions. It was observed that contaminated samples treated with acetonitrile gave the highest percentages of organic and inorganic carbon, whereas the contaminated sewage sludge samples treated with biosurfactant reduced the concentration of organic and inorganic carbon at levels lower than those achieved in the untreated sewage sludge. The same behavior was observed regarding the nitrogen percentage.

Table 2. Elemental Analysis of Sewage Sludge at the Beginning of the Bioremediation Process and after Treatment with Acetonitrile (AcN) or Biosurfactant (BS)

sample	total N (%)	inorganic C (%)	organic C (%)
sewage sludge contaminated	5.39 ± 0.38	3.15 ± 0.22	29.75 ± 2.08
sewage sludge treated with AcN	5.90 ± 0.47	3.19 ± 0.26	32.02 ± 2.56
sewage sludge treated with BS	4.51 ± 0.27	1.80 ± 0.11	28.39 ± 1.70

Figure 1 shows the FTIR spectra of sewage sludge before and after treatment with acetonitrile or biosurfactant, showing a decrease in the main bands for treated samples in comparison with untreated sewage sludge. In addition Figure 2 shows SEM images of untreated and treated sewage sludge; samples containing biosurfactant gave a more homogeneous aspect, with less roughness in comparison with untreated sewage sludge or samples treated with acetonitrile.

On the other hand, Figure 3 shows the macroview aspect of sewage sludge when it was introduced in water, acetonitrile, or biosurfactant solution. It was observed that biosurfactant allowed the homogenization of sewage sludge in water and stabilized the emulsion of the aqueous phase with the sewage sludge. This aspect is consistent with the pictures shown in Figure 2. Otherwise, when the sewage sludge was dissolved in acetonitrile, a clear separation between solid samples and the organic phase was observed (Figure 3b); similar behavior was detected when sewage sludge was dissolved in water in the absence of biosurfactant (Figure 3a).

Bioremediation of Sewage Sludge Contaminated with PAHs. A bioremediation experiment for the decontamination of sewage sludge containing PAHs was developed during 27 days in the presence of a lipopeptide biosurfactant extracted from CSL. During the experiments, solid (sewage sludge) and liquid samples were obtained at several intervals of time to follow the solubilization and the kinetic biodegradation of PAHs. A control consisting of contaminated sewage sludge treated with acetonitrile was included in the study to compare the efficiency of treatment, using biosurfactant, with classical and less ecofriendly washing methodologies.

Table 1 includes data about the amount of PAHs solubilized and biodegraded from sewage sludge as well as the amount of PAHs that remain in the sewage sludge at the end of the treatment (27 days), in comparison with the initial concentration of PAHs contained in the sewage sludge. The amount of PAHs mobilized from sewage sludge was calculated as the difference between the amount of PAHs contained in the sewage sludge at the beginning of the experiment and the amount of PAHs at specific interval of times that remained in the sewage sludge. In Table 1 are included the maximum amounts of PAHs mobilized after 27 days of treatment with acetonitrile and biosurfactant.

Furthermore, Table 1 shows the maximum concentrations of PAHs that could be achieved in the washing solution. These values were calculated by taking into account the amount of PAHs in the sewage sludge before the bioremediation experiments and the liquid−solid ratio used during the bioremediation experiments.

Figure 3. Optical images of sewage sludge (a) in water, (b) in acetonitrile, or (c) in biosurfactant solution.

In addition, Figures 4 and 5 show the variation in PAH percentages contained in the sewage sludge or in the washing solution, as well as the biodegraded PAH percentages in experiments carried out with acetonitrile or biosurfactant, respectively, at different intervals of time. At the end of the bioremediation experiments the concentration of PAHs in the sewage sludge, in the presence of biosurfactant, was reduced about 98.3, 48.3, and 30.6% for naphthalene, anthracene, and pyrene, respectively, after 27 days of treatment. Probably PAHs were removed from sewage sludge by combining desorption mechanisms induced by the ambiphilic nature of the biosurfactant and the biodegradative processes carried out by the microbial biomass contained in the sewage sludge. Biosurfactants reduce the surface tension between the aqueous phase of sewage sludge and the hydrophobic contaminants through the formation of micelles favoring the sequential solubilization and biodegradation of PAHs contained in the sewage sludge. Thus, the biosurfactant, extracted from CSL, not only promoted the solubilization of PAHs from sewage sludge but also induced the biodegradation of these organic contaminants. For instance, from the 48.3% of anthracene removed from sewage sludge, 19.7% remained in the aqueous phase and 28.6% was biodegraded, whereas 100% of the solubilized naphthalene was biodegraded.

In the current work, it was observed that acetonitrile was able to remove all anthracene and pyrene from sewage sludge, although they remained undigested in the aqueous phase, whereas acetonitrile was able to extract only 43.5% of naphthalene, probably due to the stronger adsorption ability of sewage sludge for naphthalene rather than anthracene and pyrene. Oluseyi et al.[24] also observed that methanol and acetonitrile gave lower extraction yields for naphthalene in comparison with anthracene and pyrene.

Remediation methods relying on the immobilization of contamination or its removal may be carried out in place of its formation (in situ) or out of the place of its original location (ex situ).[18] Organic solvents were the first agents used for extracting PAHs from soil, both in laboratory-scale studies and in field scale remediation projects.[25] Some authors have proposed the utilization of physical−chemical methods to remove polycyclic aromatic hydrocarbons from sewage sludge,[26] but in comparison with the utilization of biosurfactants[13] or fermentation process,[27,28] these methods are less ecofriendly. Bacteria able to form biosurfactants are of increasing interest as biosurfactants, have low toxicity, and are easily biodegraded.[18] Moreover, it has been reported that some species, such as white rot fungi (e.g., *Pleurotus ostreatus*), allow high efficiency in the cleanup of soil contaminated with PAHs.[29]

There are few works in the literature dealing with the direct biodegradation of PAHs in soil or sewage sludge; thus, to discuss the results obtained in the current work, references related with the biodegradation of PAHs in aqueous streams will be introduced. Once the PAHs contained in sewage sludge achieve the aqueous phase, the biodegradation of these pollutants could follow a behavior similar to that observed in aqueous streams, obviously with lower biodegradation kinetic rates. Thus, Lima et al.[30] performed consecutive washings of soil contaminated with 200 mg/kg of phenanthrene using different lipopeptide biosurfactants, observing that 80−88% of phenanthrene from soil can be removed using lipopeptide biosurfactant as washing solution.

The results obtained in the current study also are consistent with those achieved by other authors.[31,32] Thus, Jacques et al.[31] reported biodegradation values for pyrene between 24.8 and 36.8%, for phenanthrene between 31.4 and 48.2%, and for anthracene between 24.4 and 71.1% in the presence of *Pseudomoma* species isolated from a petrochemical sludge land farming site, which produced biosurfactants. Additionally, Obayori et al.[32] found that pyrene degradation rates were increased when media were supplemented with CSL, probably not only because the presence of nutrients in CSL can induce the growth rate of *Pseudomona* but also due to the presence in

J. Agric. Food Chem. 2015, 63, 7143−7150

CSL of biosurfactants that increased the solubilization and biodegradation of pyrene, achieving pyrene biodegradation percentages about 55.5% after 21 days of treatment.

Biodegradation of PAHs: Kinetic Study. Microbial degradation of organic compounds can be defined following kinetic models, typically used to describe the consumption of reagents during a chemical reaction.[33−36]

Usually, microbial degradation of different carbon sources tends to be hyperbolic saturation functions and can be expressed by eq 1:

$$r_p = r_{pmax}\frac{C}{K} + C \quad (1)$$

where r_p is the biodegradation rate, r_{pmax} is the maximum specific biodegradation rate, C is the pollutant concentration, and K is the half-saturation coefficient.

Assuming that the pollutant concentration is much lower than the half-saturation coefficient ($C \ll K$), eq 1 can be converted to eq 2:

$$r_p = r_{pmax}\frac{C}{K} \quad (2)$$

Furthermore, if $K_1 = r_p/K$, a linearized first-order kinetic reaction can be shown, eq 3:

$$\ln C = C_0 + K_1 t \quad (3)$$

Hence, following the first-order kinetic reaction, the biodegradation half-life can be calculated according to eq 4:

$$t_{1/2} = \frac{\ln 2}{K_1} \quad (4)$$

On the other hand, taking into consideration eq 1, if it is assumed that the amount of PAHs contained in the sewage sludge is much higher than the half-saturation constants ($C \gg K$), the biodegradation of PAHs could be described following eq 5, where the biodegradation rate is independent of the concentration of PAHs ($r_p = r_{pmax}$). Thus, increasing the concentration of PAHs will not increase the biodegradation rate of these pollutants; hence, the amount of PAHs biodegraded will be proportional to the time. If the biodegradation rate is constant, $K_0 = r_p$ approaching a zero-order kinetic model is described by eq 5:

$$C = C_0 + K_0 t \quad (5)$$

where C_0 is the initial concentration of PAHs and K_0 is the zero-order kinetic constant. For a zero-order reaction the half-life is given by eq 6:

$$t_{1/2} = \frac{C_0}{2K_0} \quad (6)$$

Figure 6 shows the description of naphthalene, anthracene, and pyrene biodegradation by first-order kinetic model, observing a good agreement between the experimental data and the theoretical results predicted by the model with relative high correlation coefficient values. Moreover, Table 3 includes the kinetic parameters (C_0, K_0, K_1, and $t_{1/2}$) predicted by the equation as well as the relative coefficients (R^2). Otherwise, when the biodegradation of PAHs was adjusted to a zero-order kinetic model, a good concordance was not observed between experimental and theoretical data as can be deduced by the correlation coefficients included in Table 3. Thus, the biodegradation of PAHs in sewage sludge will be directly

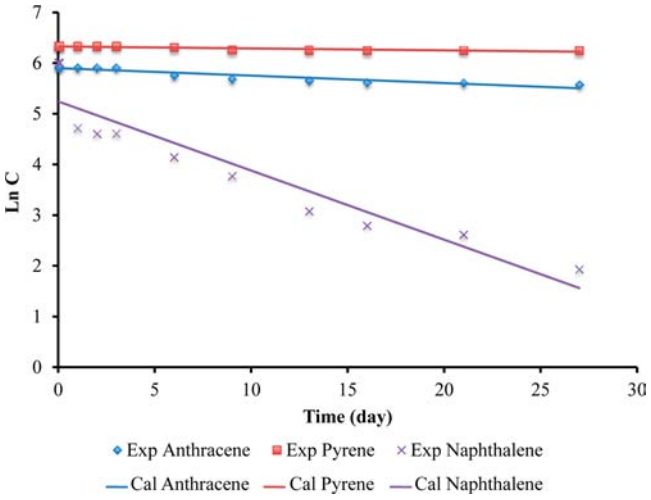

Figure 6. Kinetic plots achieved for the biodegradation of different PAHs, contained in sewage sludge, in the presence of biosurfactant extracted from corn steep liquor.

related with the initial concentration of PAHs in the solid matrix. It was observed that naphthalene gave the lowest half-life value (around 5 days), whereas the half-life for biodegrading anthracene and pyrene was 47 and 182 days, respectively. Half-life values obtained in this work are higher than those achieved by other authors who studied the biodegradation of phenanthrene and pyrene contained in aqueous solutions in the presence of surfactants such as Tween 80 or Tween 20.[36] However, it is necessary to take into consideration that in the current work the biodegradation occurs from a solid substrate (sewage sludge); thus, PAHs have to be first mobilized from sewage, solubilized, and then biodegraded and, therefore, it is obvious that the biodegradation of PAHs adsorbed in a solid matrix has to be slower than the biodegradation of any carbon source contained in an aqueous stream. Jianlong et al.[33] also described the microbial biodegradation of phthalic acid esters, contained in mixed anaerobic digested sludge collected from a local wastewater treatment plant, by a first-order kinetic model. They observed that the biodegradation rate and biodegradability of three phthalates under anaerobic conditions appeared to be related to the length of the alkyl side chains. Thus, >90% of dimethyl and di-*n*-butyl phthalate were biodegraded, whereas the biodegradation of dinoctyl phtalate was limited, with a half-life value of 21 days.

Some authors have reported that the half-life of hydrocarbons in biotic conditions was 17−126 days, whereas in abiotic conditions this ranged increased to 32−2048 days.[3]

In other work, Jianlong et al.[37] studied the biodegradation of four phthalic acid esters (dimethyl phthalate, diethyl phthalate, di-*n*-butyl phthalate, and di-*n*-octyl phthalate) in soil supplemented with acclimated sludge, observing that those phthalic acid esters with a shorter alkyl chain were biodegraded more quickly than phthalic acid esters with higher alkyl chains. These results are consistent with the data achieved in the current work during the biodegradation of PAHs contained in sewage sludge, in the presence of biosurfactant, observing that those more complex PAHs were biodegraded more slowly. In the present work it was also observed that PAHs with a lower carbon chain length (naphthalene) gave higher biodegradation rates than anthracene and pyrene.

Jianlong et al.[37] also observed that the biodegradation of phthalic acid esters followed a first-order reaction kinetic

pyrene	559.81	−2.05	136.62	0.82	6.33	−0.004	182.43	0.82

equation with a biodegradation half-life that decreased significantly with increasing carbon number of the alcohol moiety and correlated with the alkyl chain length and their octanol−water partition coefficients.

Other authors[36] proposed these models to explain the biodegradation of phenanthrene and pyrene in the presence of nonionic surfactants produced by chemical synthesis. These authors observed low correlation coefficient values when trying to describe the biodegradation of phenanthrene and pyrene in the presence of Tween 20 and Tween 80 at different concentrations applying zero-order kinetic model; however, they found relatively high correlation coefficient values when applying the first-order kinetic model to describe the biodegradation of both PAHs, and the same behavior was observed in the current work.

Furthermore, related with the kinetic description of PAH biodegradation, Lu et al.[35] found that the biodegradation of two- and three-ring PAHs can be described by a first-order kinetic model, whereas the biodegradation of four-ring PAHs followed a zero-order kinetic model.

Biosurfactants have the ability to increase apparent aqueous solubility and bioavailability of PAHs, and they can be used to stimulate the biodegradation of these persistent contaminants contained in sewage sludge. The utilization of biosurfactants as washing agent not only has the advantage of allowing the solubilization of hydrophobic contaminants but also can promote their simultaneous biodegradation. Therefore, the elimination of PAHs from sewage sludge using biosurfactants could allow the safe use of this sewage sludge as fertilizer or as organic soil improver in agriculture.

province), and yellow paddy soil (H, GB/T-A2111511, Jingzhou, Hubei province), respectively. The soil samples were taken from the surface zone (0−15 cm depth) in rice fields in Fujian, Jiangsu, Zhejiang, and Hubei provinces, China. Their basic physicochemical characteristics were determined according to methods previously reported by Gee et al. and are listed in Table 1.[20]

Degradation Experiments in Soils. To study the behavior and degradation of IPP in anaerobic soils, IPP was sprayed into the test soils to give a final concentration of 20 mg kg^{-1} of soil and thoroughly mixed. The soil moisture content was adjusted to about 60% of the maximum water-holding capacity by adding Milli-Q (MQ) water. The incubation temperature was controlled at 25 ± 1 °C in an anaerobic incubator. Ten grams of soil was sampled from the flask at different time intervals (0, 5, 10, 20, 30, 45, 60, 75, and 100 days after treatment, DAT) for determining the concentration of IPP and its metabolites. All experiments were carried out in triplicate.

IPP Extraction. IPP in soils was extracted according to the reported methods.[21,22] The extraction procedure was employed with each subsequent solvent being less polar. The extraction system was performed as follows in three steps: 0.01 M $CaCl_2$, dichloromethane, and acetonitrile/water (9:1, v/v). Fifty milliliters of each successive solvent was added and shaken for 1 h. After the first step, the $CaCl_2$ extract was

DOI: 10.1021/acs.jafc.5b02645

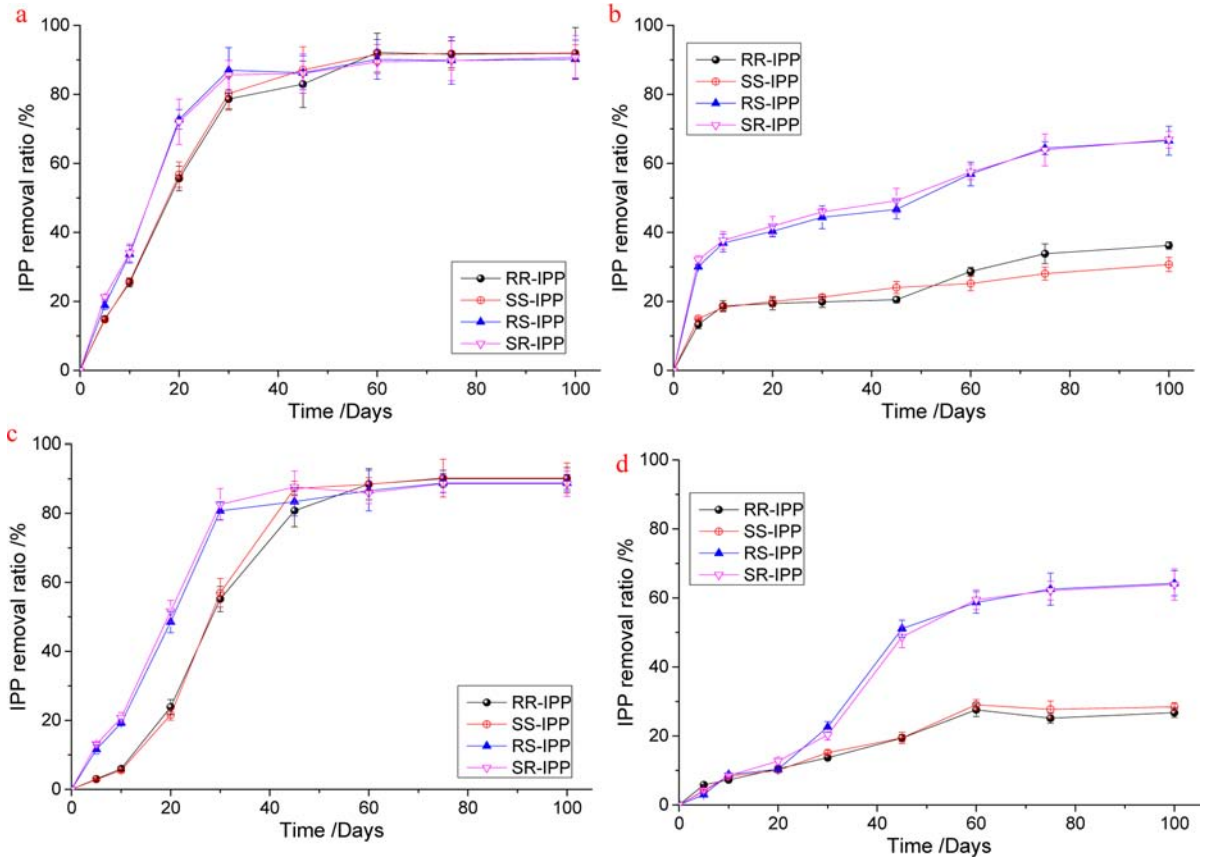

Figure 2. Degradation of RR-IPP, SS-IPP, SR-IPP, and RS-IPP in anaerobic soil: (a) yellow loam soil (F); (b) Huangshi soil (J); (c) paddy field on desalting muddy polder (C); (d) yellow paddy soil (H).

adjusted to pH 3.0 and then extracted with dichloromethane (1:1, v/v) three times. The dichloromethane extract was combined with the other two extracts obtained from the last three extraction steps and concentrated on a vacuum rotary evaporator at 40 °C until dry, and the residue was dissolved in 1 mL of methanol. The overall average recovery of IPP in soils varied from approximately 89.32 to 96.15% in the final extract solution. The relative standard deviations (RSDs) for IPP extraction within each run of soil samples ranged from 2 to 5%, which indicated that the variation between the soil samples was relatively small and within control. These results showed that the method used for IPP extraction and analysis in this study was reproducible and reliable.

Statistical Analysis and Calculation. The aerobic degradation of IPP in soils followed a first-order exponential decay model. The rate constant from the first-order model was used to determine the DT_{50} (half-life value). DT_{50} was calculated by

$$-\ln \frac{c_t}{c_0} = kt \text{ or } c_t = c_0\, e^{-kt} \quad (1)$$

where C_0 is the initial concentration of IPP (mg kg^{-1} soil), C_t is the concentration of insecticide at time t, t is the incubation time (days), and k is the degradation rate constant of the insecticide (day^{-1}). DT_{50} and DT_{90} were calculated as ln 2/k and ln 10/k, respectively.

Analytical Procedures. IPP was determined with high-performance liquid chromatography (HPLC, Agilent 1260, Agilent Technologies, USA); the photodiode array (PDA) detector was operated at 354 nm, with a Daicel Chiralpak IC (5 μm, 4.6 × 250 mm), and the column temperature was 30 °C. The mobile phase was ethanol and pure water (90:10, v/v), and the flow rate was 1.0 mL min^{-1}.

IPP biodegradation intermediates were monitored and analyzed with HPLC (Agilent 1260), 268 nm, C_{18} column (3.5 μm, 4.6 × 250 mm) and 30 °C according to the methods reported by Fu et al.[5−7] Acetonitrile with 0.1% (v/v) acetic acid (HPLC grade) and a mixture of 0.1% (v/v) acetic acid in water (HPLC grade) was at a linear gradient program (minutes/% acetonitrile: 0/15; 7/15; 20/35; 40/100; 45/100; 50/15; 60/15). The flow rate was 1.0 mL min^{-1}.

LC-MS/MS analysis was conducted using a Dionex U3000 HPLC system coupled with a Bruker maXis 4G ion trap mass spectrometer with electrospray ionization source (ESI). LC separation conditions were accordance with those used for HPLC analysis. The ion source

temperature was controlled at 250 °C, and the capillary voltage was −4.5 kV. The analysis mode of ionization was electrospray ionization (ESI, positive). The operation conditions were as follows: collision energy, 10.0 eV; ISCID energy and ion energy, 5.0 eV; dry gas, 6 L min^{-1}; dry temperature, 180 °C; gas pressure, 1.5 bar. The continuous full scanning from m/z 50 to 500 Da was performed in positive ion mode.

PCR Amplification of 16S rRNA and Pyrosequencing. The primers 515F (5′-GTGCCAGCMGCCGCGG-3′) and 907R

DOI: 10.1021/acs.jafc.5b02645
J. Agric. Food Chem. 2015, 63, 7151−7160

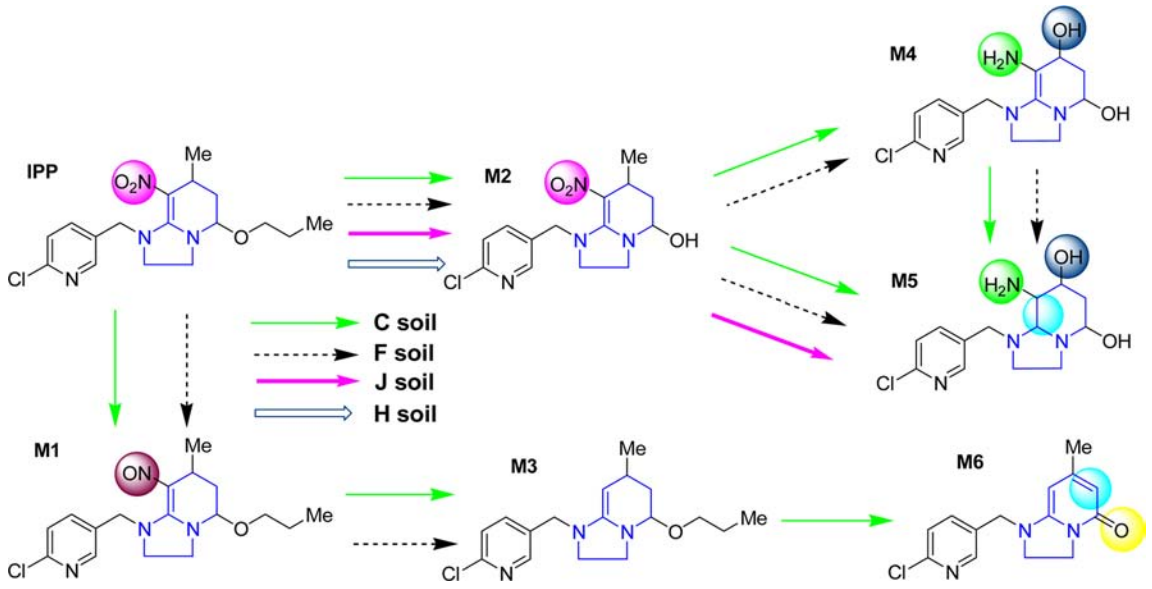

Figure 4. Proposed pathways of IPP degradation in anaerobic soils.

(5′-CCGTCAATTCMTTTRAGTTT-3′) were used for amplifying the fragment of the 16S rRNA gene. The PCR reaction program was as follows: 0.2 μM of each primer and 0.2 mM dNTP, 1.5 mM $MgCl_2$, and 0.2 unit of Taq polymerase. The cycling conditions were 98 °C for 30 s, followed by 30 cycles of 98 °C for 10 s, 55 °C for 20 s, and 72 °C for 30 s, with a final extension step at 72 °C for 5 min (GeneAmp 9700, ABI, USA). PCR products were purified with the DNA gel recovery kit (Axygen BioScience) and were sent for sequencing service using Miseq sequencing technique (Majorbio Co., Shanghai, China).

Bioinformatic and Statistical Analysis. Totally 240,414 16S rRNA sequence reads were filtered; Trimmomatic was used for denoising and processing. Trimmomatic is a fast, multithreaded command line tool that can be used to trim and crop Illumina (FASTQ) data as well as to remove adapters. The resulting sequences after quality control were analyzed through QIIME. The reads were clustered into operational taxonomic units (OTUs) at 97% sequence similarity using Usearch (version 7.1, http://drive5.com/uparse/). OTU representative sequences were aligned against the Greengenes (release 13.5, http://greengenes.secondgenome.com/), and chimeric sequences were identified using Mothur (version 1.26). OTU sequences were classified by RDP classifier and QIIME by BLASTING, and the obtained data were used in the subsequent analyses. Community richness was assessed with Chao 1 estimator (http://www.mothur.org/wiki/Chao) and ACE estimator (http://www.mothur.org/wiki/Ace). Community diversity was estimated with the Shannon index (http://www.mothur.org/wiki/Shannon) and the Simpson index (http://www.mothur.org/wiki/Simpson).

Statistical analysis was performed in R 2.15.2, using vegan (redundancy analysis (RDA) with significance testing by permutation—ANOVA) and Hmisc packages.

RESULTS AND DISCUSSION

Degradation of IPP in Anaerobic Soils. The results of IPP anaerobic degradation in soils is shown in Figure 2. The removal ratio of all IPP stereoisomers (RR-IPP, SS-IPP, RS-IPP, and SR-IPP) reached >90% at 60 DAT in F and C soils, whereas the RR-IPP and SS-IPP only were <30% in J and H soils. In J and H soils, the removal of RS-IPP and SR-IPP was greater than that of RR-IPP and SS-IPP, and RR-IPP and SS-IPP were hard to degrade in these two soils. The results showed that IPP enantiomer degradation rate differed in different soilsand that the IPP degradation rate was higher in F and C soils. IPP, especially RR-IPP and SS-IPP, were relatively hard to degrade in J and H soils. Degradation of IPP in anaerobic soils followed a first-order exponential decay model. The first-order exponential equation, k, DT_{50}, and DT_{90} are listed in Table 2. The IPP degradation rate was the same in F and C soils, and a similar degradation rate was observed in J and H soils. DT_{50} values of RR-IPP, SS-IPP, RS-IPP, and SR-IPP in F soil were 24, 24, 28, and 28 days, respectively.

It has been reported that greater total carbon (TC) contributes to a larger organic chemical biodegradation rate because the increased carbon content can enhance microorganisms that are responsible for degrading organic pollutants.[23] In this study, the TC content in F and C soils was higher than that in J and H soils. Moreover, the pH value of soil also affects the soil microbial and enzyme activity, which acted as the key important role during IPP degradation process. The IPP degradation rate in F and C soils was higher than that in J and H soils, the reason being that the pH value in F and C soil was appropriate for microbial growth and activity. The lower pH value in J and H soils lead to the slower degradation rate. These results illustrate that the soils with rich OM and neutral pH lead to a greater IPP degradation rate, because these provide suitable conditions for IPP-degrading bacterial growth and biodegradation.

Identification of Metabolites of IPP. During the degradation of IPP in anaerobic soils, six degradation metabolites were detected by HPLC analysis with retention times of 16.9 min (M1), 4.1 min (M2), 14.6 min (M3), 17.6 min (M4), 19.7 min (M5), and 21.3 min (M6). These intermediates occurred with the decrease of IPP. All six intermediates were determined in C soil, and M1, M2, M3, M4, and M5 appeared during IPP anaerobic degradation in F soil. M2 and M5 were determined in J soil, whereas M2 was found in H soil. Six degradation intermediates of IPP were analyzed and identified by high-performance chromatography-time-of flight mass spectrometry (LC-MS) and LC-MS/MS.

The ion fragments of IPP were at m/z 367.1500 ($C_{17}H_{23}ClN_4O_3$) $[M + H]^+$ and m/z 321.1578, and the ion fragment of m/z 367.1500 includes daughter ions of 306.1368 (100), 308.4442 (15), and 137.1069 (62), which were in accordance with the structure of standard IPP.[5−7,14]

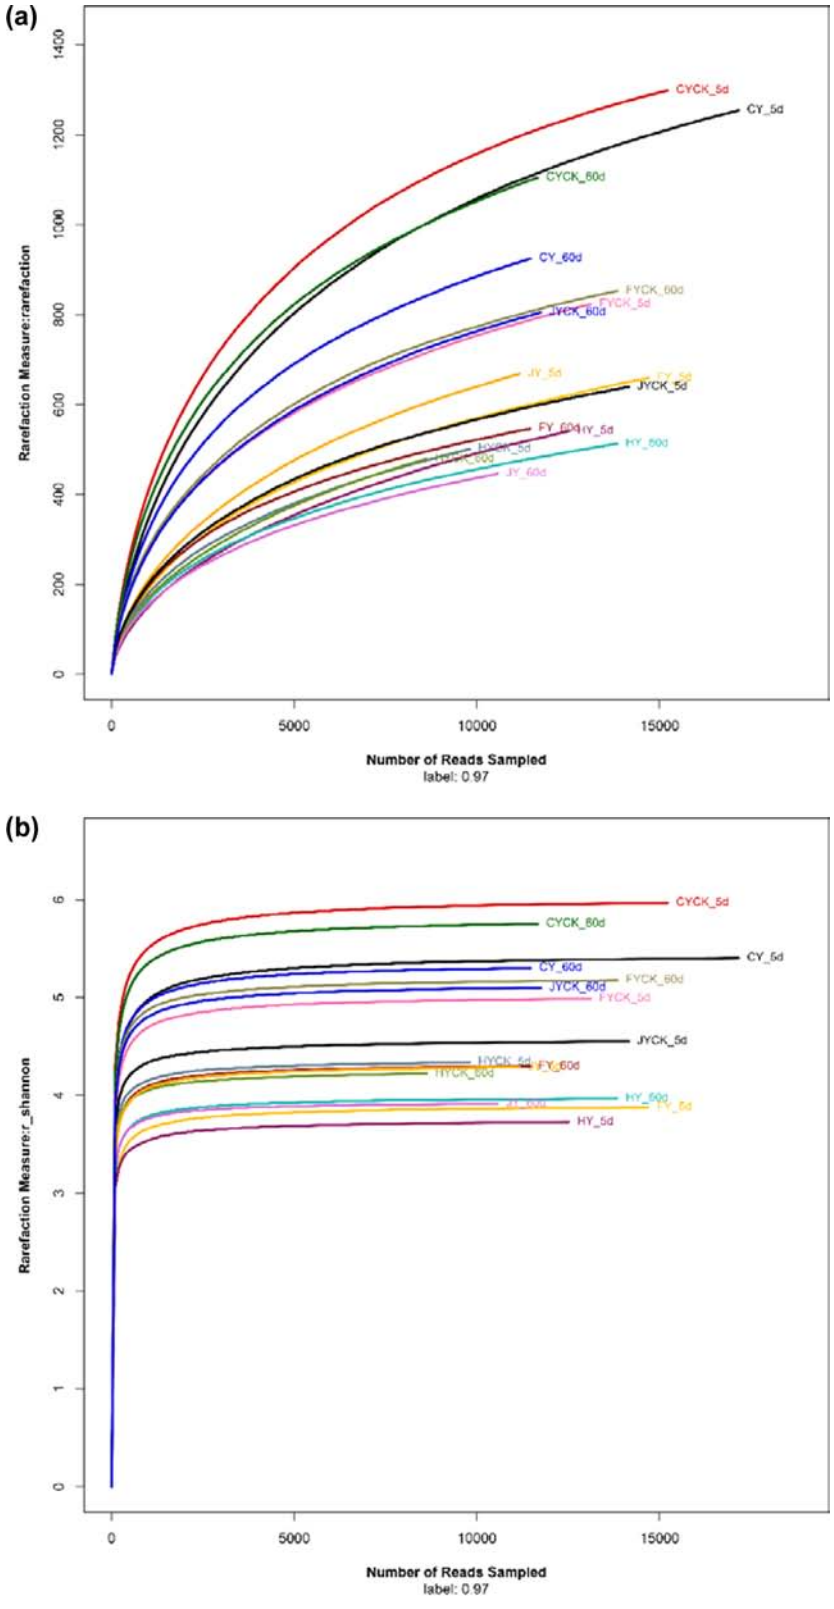

Figure 5. Bacterial diversity comparison with rarefaction curves (a) and Shannon−Wiener curves (b) in different soils at 5 and 60 DA: (CK_5d and CK_60d) control experiment without IPP spray at 5 and 60 DAT; (CY_5d and CY_60d) C soil with IPP spray at 5 and 60 DAT; (JY_5d and JY_60d) J soil with IPP spray at 5 and 60 DAT; (HY_5d and HY_60d) H soil with IPP spray at 5 and 60 DAT; (JY_5d and JY_60d) J soil with IPP spray at 5 and 60 DAT.

M1 showed m/z 351.1583, and the daughter ion showed m/z 278.1039; the daughter ion should be formed by the loss of a propoxyl group from the parent compound IPP. M1 was attributed to loss of oxygen from the nitro group and was identified as 1-(6-chloropyridin-3-ylmethyl)-7-methyl-8-nitroso-5-propoxy-1,2,3,5,6,7-hexahydroimidazo[1,2-α]pyridine

J. Agric. Food Chem. 2015, 63, 7151−7160

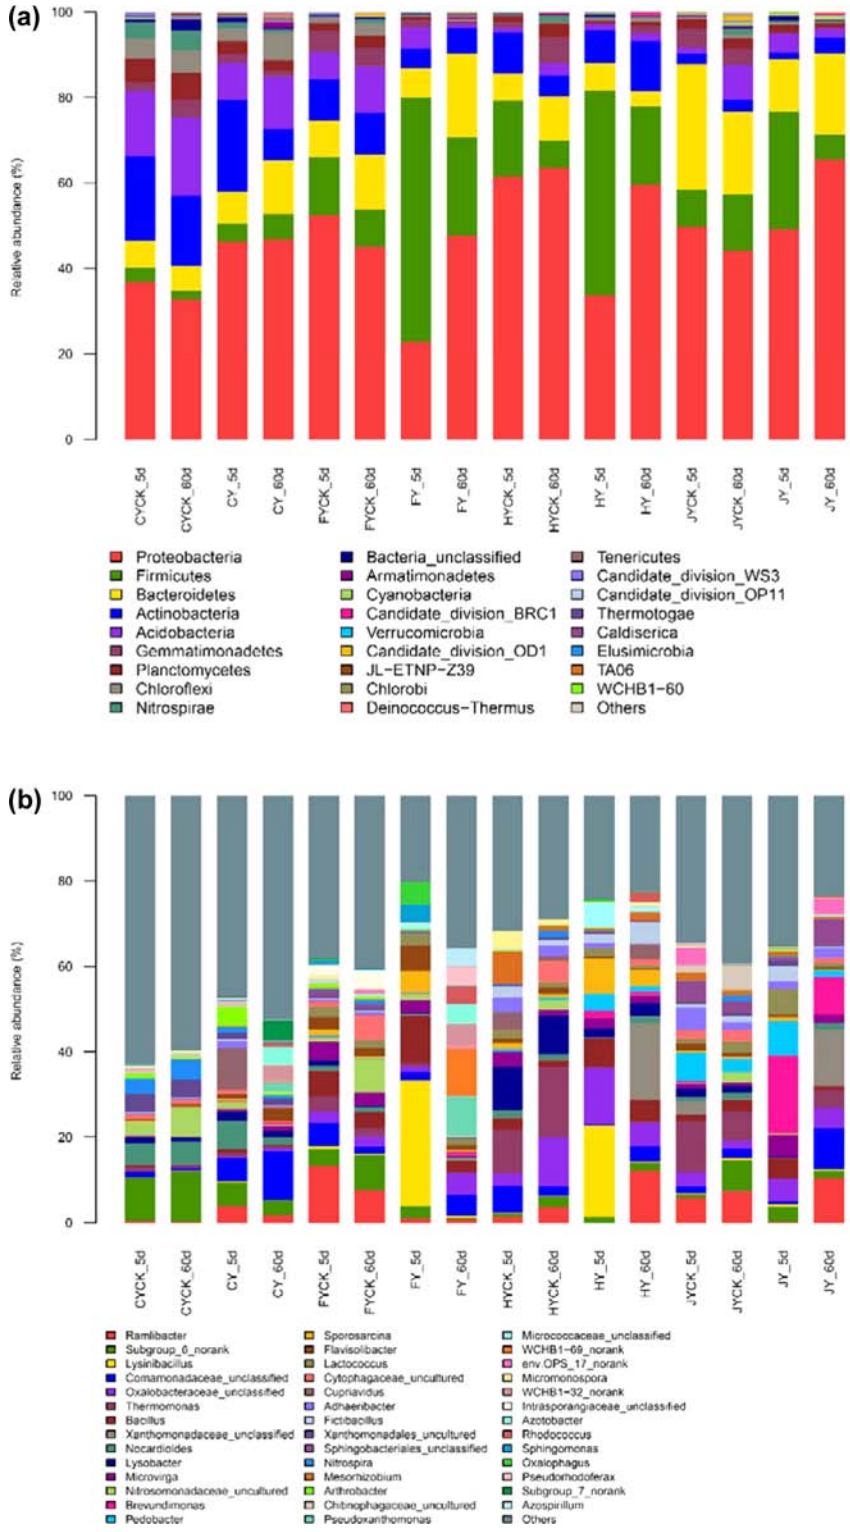

Figure 6. Bacterial composition of the different communities in anaerobic soils: (a) % of relative read abundance of bacterial phyla within each community; (b) % of relative read abundance of bacterial genus within each community.

(Figure 3a). Metabolite M2 was identified as 1-((6-chloropyridin-3-yl)methyl)-7-methyl-8-nitro-5-hydroxy-1,2,3,5,6,7-hexahydroimidazo[1,2-α-]pyridine according to its LC-MS/MS and MS^2 spectra (Figure 3b). The ion fragment of M2 was at m/z 325.1072 $[M + H]^+$, which indicated that M2 was generated through hydrolysis of the propoxyl group of IPP.

The intermediate M3 was at m/z 322.1687 ($C_{17}H_{24}ClN_3O$) $[M + H]^+$, and its daughter ions were m/z 322.1687 and 324.1672. M3 likely corresponded to the loss of the group of 8-nitroso on M1 and was identified as 1-(6-chloropyridin-3-ylmethyl)-7-methyl-5-propoxy-1,2,3,5,6,7-hexahydroimidazo-[1,2-α]pyridine, which was in accordance with previous reports (Figure 3c).[7,14] Figure 3d shows that the m/z of metabolite M4

J. Agric. Food Chem. 2015, 63, 7151−7160

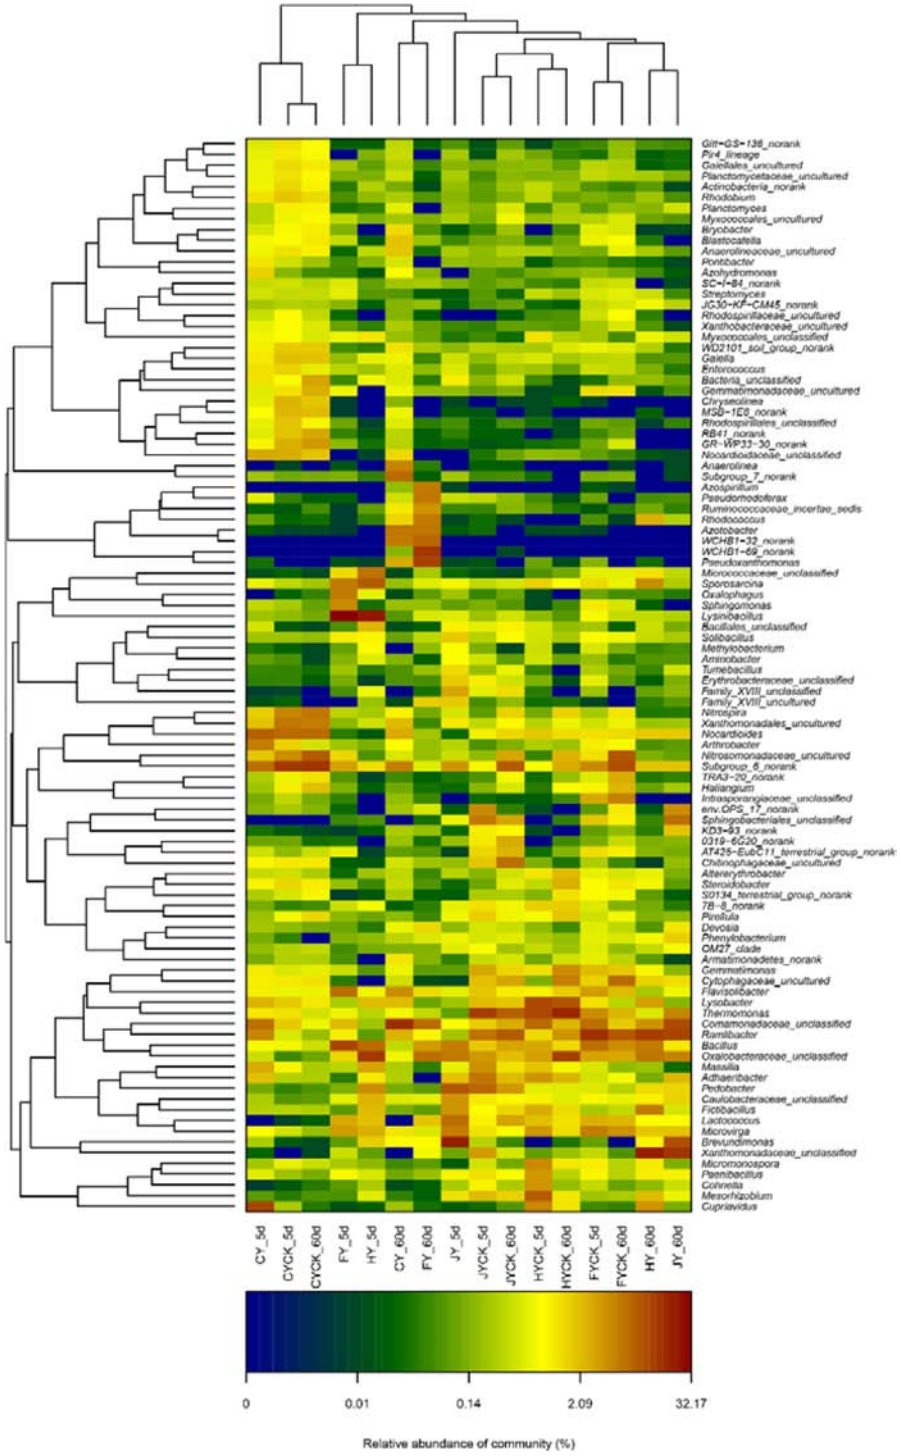

Figure 7. Distribution heatmap of microbial genus arranged by hierarchical clustering of S1 and S2 soils with different treatments.

was 297.1144, which should be the transformation of the group of 8-nitroso on M2 to the 8-amino group, and the nitroso group on M1 transformed to hydroxyl. On the basis of these characteristics, M4 was preliminarily identified as 1-((6-chloropyridin-3-yl)methyl)-5,7-diol-8-amino-1,2,3,5,6,7-hexahydroimidazo[1,2-α]pyridine.

The intermediate M5, with m/z 299.1284 (M + H, Figure 3e), was determined as a derivative of M4 on the basis of the elemental formula fit, adding a mass unit of 2 corresponding to hydrogenation of the C═C double bond. The M5 ions matched the formula $C_{13}H_{18}ClN_3O_3$, Thus, M5 was identified as 1-((6-chloropyridin-3-yl)methyl)-5,7-diol-8-amino-octahydroimidazo[1,2-α]pyridine. M6 appeared after M3 and its m/z was 276.0887 (M + H, Figure 3f); the M6 ions matched the formula $C_{14}H_{14}ClN_3O$, and M6 was identified as 1-((6-chloropyridin-3-yl)methyl)-2,3-dihydro-5-one-7-methylimidazo[1,2-α]pyridine.

IPP Anaerobic Degradation Pathway in Soils. In J soil, only two metabolites, M2 and M5, were determined, M2 appearing first and then M5 forming from M2; in H soil, only M2 appeared. Therefore, an anaerobic degradation pathway in J and H soils was proposed (Figure 4). The propyl group of IPP was de-esterified and hydrolyzed to form M2, which was in

DOI: 10.1021/acs.jafc.5b02645
J. Agric. Food Chem. 2015, 63, 7151−7160

accordance with the previous study.[5−7] The nitro group of M2 could be aminated to form amino, and methyl was hydrolyzed to a hydroxyl group. Thus, M5 was generated through these biocatalyzed reactions.

Therefore, the biodegradation pattern can be described as follows: M1 and M2 are first produced and then increased, and this was then followed by M3, M4, and M5, which appeared at almost the same time. M6 was generated in C soil, and M6 was formed from M3 by the loss of a propyl group on M3. On the basis of the identified metabolites during degradation and their patterns of appearance, the proposed degradation pathway of IPP in soils is as follows (Figure 4): In anaerobic F soil, the nitro group of IPP was reduced to a nitroso group and then formed M1. The nitroso group was eliminated during IPP biodegradation, resulting in the denitration product M3. M2 was determined and generated by the loss of a propyl group from the IPP parent. Subsequently, the nitro group on M2 was aminated to form an amino group, and 7-methyl was transformed to a hydroxyl group; thus, M4 was generated. Both M2 and M4 could be transformed to M5. M6 was generated from M3 only in C soil. On the basis of the identified metabolites during degradation and their patterns of appearance, the proposed degradation pathway of IPP in soils is shown in Figure 4. The metabolites M1, M2, and M3 were in accordance with previous reports.[5−7] M4 and M5 were first observed and identified during IPP anaerobic degradation in soils. In anaerobic soils, a hydroxyl group appeared during M2 transformation to M4, and the reaction should be catalyzed by methyltransferase from microorganism.

Bacterial Diversity and Community Structure in Anaerobic Soils. The community species diversity is shown in Figure 5a. It can be concluded that the bacterial communities in the CK soils (soils without IPP application) were more diverse than in soils with IPP-spraying, which indicated that IPP can affect soil microbial species diversity and IPP could inhibit some bacteria growth and their activity in soils. Under the same conditions, bacteria in the C and F soils were more diverse than in the J and H soils. The sequence of high-to-low order of organic matter (OM) content was C and F > H and J. OM content affects bacterial growth and activity; this was in accordance with the community diversity. The results of rarefaction analysis (Figure 5a) were also similar to the comparison of Shannon's H′ (Figure 5b). Evenness in all samples was close to 0.97 for the 0.03 clustering level, and the highest values were observed in C soil. All of the reads in the microbial community were assigned to bacteria. Proteobacteria was the most abundant phylum in all samples (20.5−62.4%, Figure 6a), Firmicutes was the most abundant in F and H soils with IPP-spraying after 5 DAT (56.2 and 48.3%, respectively). Other major phyla were Bacteroidetes, Actinobacteria, Acidobacteria, Gemmatimonadetes, Planctomycetes, Chloroflexi, and Nitrospirae. The most abundant genera were *Ramlibacter*, *Lysinibacillus*, *Comamonadaceae*, *Oxalobacteraceae*, *Thermomonas*, *Bacillus*, *Nitrosomonadaceae*, and *Sporasarcina* (Figure 6b). The community composition was affected by IPP in anaerobic soils. The relative abundance of *Ramlibacter*, *Thermomonas*, *Nitrosomonadaceae*, and *Nocardioides* was higher in C soil with IPP spraying than in CK soil, whereas in F soil, the genera *Lysinibacillus*, *Thermomonas*, *Cytophagaceae*, *Sporosarcina*, and *Nitrospira* were stimulated to increase after IPP application. RS-IPP and SR-IPP were quickly degraded in the first 10 days in J soil, whereas in H soil, the two insecticides were quickly degraded between 20 and 40 days (Figure 2b,d). Figure 6 shows that phylum relative abundance of Acidobacteria, Planctomycetes, Cyanobacteria, and Chlorobi in J soil was higher than in H soil, and *Deinococcus-Thermus* was determined only in J soil. Several studies showed that despite similar microbial composition at the initial stage, microbial response to insecticide application was remarkably different.[24−27] Insecticide-degrading bacteria rapidly increased in the soils after insecticide application. Itoh et al. reported that *O*,*O*-dimethyl *O*-(3-methyl-*p*-nitrophenyl) phosphorothioate (MEP) degrading microbes increased rapidly after MEP application. Microbial response to MEP application was different, and MEP-degrading *Burkholderia* bacteria are predominant in soils.[24] Formesafen and its residues also affect soil microbial activity and soil microbial communities.[27] The clustered heatmap analysis based on the bacterial community profiles at the genus level disclosed that the bacterial communities in anaerobic soils after spray IPP shared higher similarity (Figure 7). The bacterial profile in anaerobic soils was distant from that of anaerobic soils after IPP-spraying.

Conclusions. The results in this study show that IPP anaerobic degradation rate is different in four different kinds of soil. Soils' physical−chemical characteristics strongly influenced IPP degradation rate. The metabolites of IPP degradation in soils were identified, and anaerobic degradation pathways were proposed, which presents novel biodegradation pathway of IPP in soils. The determination of new metabolites is very important for better understanding of the mechanism and pathway of IPP biodegradation in anaerobic soils. The bacterial communities in the CK soils were more diverse than in soils with IPP-spraying. Both the rarefaction curves and Shannon−Wiener diversity index in anaerobic soils showed significant difference after IPP application, and the community composition also differed at both phyla and genus levels. The results suggest that application of IPP may change the soil microbial community; IPP-degrading bacteria increased quickly after IPP application in soils.

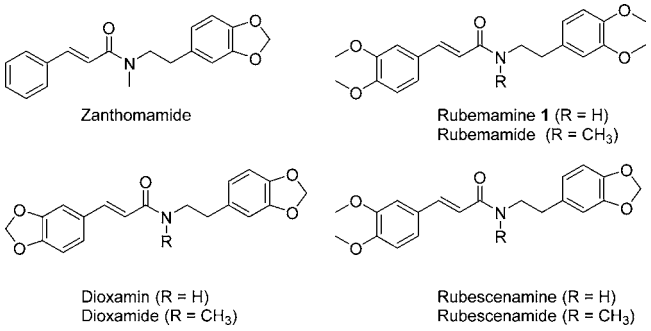

Figure 2. Amides from *Zanthoxylum rubescens*.[13]

The subject of this work includes the synthesis of many cinnamic acid related amides, their sensory evaluation for umami taste, the necessary structural features for umami taste,[19] and the subsequent analysis of *Zanthoxylum piperitum* to show the natural occurrence of these umami amides.

MATERIALS AND METHODS

General. Unless otherwise specified, commercially available reagents and solvents were purchased from Fluka-Sigma-Aldrich, Buchs, Switzerland; Acros Organics, Geel, Belgium; and Carlo-Erba, Val de Reuil, France.

NMR Spectra. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a DPX 400 spectrometer (Bruker, Rheinstetten, Germany) at 25 °C operated at 400 MHz (^{1}H) or 100 MHz (^{13}C), with tetramethylsilane as the internal standard. The ^{13}C signal assignments were obtained from standard gradient-selected correlated spectroscopy, heteronuclear single-quantum coherence, and heteronuclear multiple bond correlation experiments performed on a Bruker Avance 500 spectrometer. NMR spectra were processed with Bruker TopSpin 2.0 software (s, singlet; d, doublet; t, triplet; m, multiplet).

UPLC-MS Method. Analyses of samples were performed on a Acquity I-Class UPLC system (Waters, Milford, USA) coupled with a Q-Exactive Plus mass spectrometer (Thermo, San Jose, CA, USA). The column was an Acquity HSS-T3, 100 mm × 2.1 mm i.d. (Waters) operated at 30 °C. Solvent A was UPLC/MS-grade water (BioSolve, Valkenswaard, The Netherlands) containing 0.1% MS-grade formic acid (Sigma-Aldrich, Steinheim, Germany). Solvent B was acetonitrile (Biosolve) containing 0.1% formic acid at 0.3 mL/mL. The gradient elution was as follows: 40% B, 1 min; 40−80% B for 9 min; 80% B, 1 min; and re-equilibration at 40% B for 1 min.

The mass spectrometer was equipped with an H-ESI II electrospray source operated in the positive mode: spray 3500 V, probe heater 400 °C, heated capillary 300 °C, sheath gas 50 arb units, auxiliary gas 10. The mass calibration was performed each week. The full scan/ddMS^2 mode combined with the targeted MS^2 (tMS^2) acquisition mode were used. The full scan/ddMS^2 triggered the recording of the MS^2 spectra for the three most intense ions. The tMS^2 mode recorded the MS^2 spectra of 15 amides (Results and Discussion) on the basis of an inclusion list containing their molecular formulas. The full-scan spectra were acquired with a resolution of 70 000 from 100 to 1000 Da, and the MS^2 spectra were acquired with a resolution of 17 500 and a higher energy collisional dissociation cell energy of 30 V. Automated gain control was targeted to 3×10^6 and 1×10^5 ions with a maximum injection time of 100 ms for full scan and 50 ms for ddMS^2.

Synthesis of Amides with Ethyl Chloroformate, General Procedure. The acid component (typically 33 mmol) and diisopropyl ethyl amine (2 equiv) were diluted in 200 mL of EtOAc and 50 mL of dichloromethane. The solution was cooled to 15 °C, and ethyl chloroformate (1 molar equiv) was added dropwise. The reaction was stirred for 1 h before the primary amine component (1 molar equiv, diluted 2−3× in EtOAc) was added. The reaction was stirred overnight at room temperature. It was washed with aqueous 5% $KHSO_4$, brine, aqueous 5% $NaHCO_3$, and brine and then dried over Na_2SO_4 and evaporated under high vacuum for 3 h. The crude product was purified by flash chromatography (silica gel; cyclohexane/EtOAc, e.g., 2:8). Yields were between 50 and 80% of the purified product. MS and UV data only are given below. The description of ^{1}H and ^{13}C NMR spectra can be found in the Supporting Information.

*Amide **1**, Rubemamine, (E)-N-(3,4-Dimethoxyphenethyl)-3-(3,4-dimethoxyphenyl)acrylamide.* ESI (+): 372.1798 ($C_{21}H_{26}O_5N$, −2.1 ppm). UV max (nm): 316, 287, 222.

*Amide **2**, (E)-N-(3,4-Dimethoxyphenethyl)-3-(4-methoxyphenyl)-acrylamide.* ESI (+): 342.1690 ($C_{20}H_{24}O_4N$, −2.8 ppm). UV max (nm): 310, 288, 224.

*Amide **3**, (E)-3-(Benzo[d][1,3]dioxol-5-yl)-N-(3,4-dimethoxyphenethyl)acrylamide.* ESI (+): 356.1483 ($C_{20}H_{22}O_5N$, −4.2 ppm). UV max (nm): 322, 286, 228, 219.

*Amide **4**, (E)-3-(3,4-Dimethoxyphenyl)-N-(4-methoxyphenethyl)-acrylamide.* ESI (+): 342.1693 ($C_{20}H_{24}O_4N$, −2.0 ppm). UV max (nm): 316, 291, 223.

*Amide **5**, (Z)-3-(3,4-Dimethoxyphenyl)-N-(4-methoxyphenethyl)-acrylamide.* Amide **4** (500 mg) in 50 mL of ethanol was irradiated for 16 h by using a water-cooled 125 W Hg lamp. UPLC analysis showed that the crude product contained 50% of the (*Z*) isomer. The product was chromatographed over a Puriflash 50 C18 cartridge (Interchim Montluçon, France) eluted with a water/ethanol mixture (60:40). A mixture of amides **5** and **4** (90:10) was obtained (96 mg). ESI (+): 342.1693 ($C_{20}H_{24}O_4N$, −2.1 ppm). UV max (nm): 310, 276, 224.

*Amide **6**, 3-(3,4-Dimethoxyphenyl)-N-(4-methoxyphenethyl)-propanamide.* ESI (+): 344.1849 ($C_{20}H_{26}O_4N$, −2.0 ppm). UV max (nm): 277, 225.

*Amide **7**, N-(4-Methoxyphenethyl)cinnamamide.* ESI (+): 282.1481 ($C_{18}H_{20}O_2N$, −2.8 ppm). UV max (nm): 275, 222.

*Amide **8**, N-(3-Methoxyphenethyl)cinnamamide.* ESI (+): 282.1491 ($C_{18}H_{20}O_2N$, −2.6 ppm). UV max (nm): 274, 223.

*Amide **9**, (E)-N-(4-Methoxyphenethyl)-3-(4-methoxyphenyl)-acrylamide.* ESI (+): 312.1585 ($C_{19}H_{22}O_3N$, −2.9 ppm). UV max (nm): 310, 290, 224.

*Amide **10**, (E)-N-(4-Methoxyphenethyl)-3-(2-methoxyphenyl)-acrylamide.* ESI (+): 312.1586 ($C_{19}H_{22}O_3N$, −2.7 ppm). UV max (nm): 317, 274, 225.

*Amide **11**, (E)-N-(4-Methoxyphenethyl)-3-(3-methoxyphenyl)-acrylamide.* ESI (+): 312.1587 ($C_{19}H_{22}O_3N$, −2.4 ppm). UV max (nm): 310, 277, 224.

*Amide **12**, (E)-3-(2,5-Dimethoxyphenyl)-N-(4-methoxyphenethyl)acrylamide.* ESI (+): 342.1690 ($C_{20}H_{24}O_4N$, −2.8 ppm). UV max (nm): 342, 276, 223.

*Amide **13**, (E)-N-(4-Methoxyphenethyl)-3-(3,4,5-trimethoxyphenyl)acrylamide.* ESI (+): 372.1797 ($C_{21}H_{26}O_5N$, −2.4 ppm). UV max (nm): 299, 228.

*Amide **14**, (E)-2-Methoxy-4-(3-((4-methoxyphenethyl)amino)-3-oxoprop-1-en-1-yl)phenyl Acetate.* ESI (+): 370.1639 ($C_{21}H_{24}O_5N$, −2.6 ppm). UV max (nm): 310, 277, 224.

*Amide **15**, (E)-3-(4-Hydroxy-3-methoxyphenyl)-N-(4-methoxyphenethyl)acrylamide.* Amide **14** was deprotected in MeOH/Na_2CO_3. The reaction was acidified and extracted from EtOAc. The product was recrystallized from EtOAc (yield 75%). ESI (+): 328.1535 ($C_{19}H_{22}O_4N$, −2.5 ppm). UV max (nm): 317, 293, 222.

*Amide **16**, (E)-3-(Benzo[d][1,3]dioxol-5-yl)-N-(4-methoxyphenethyl)acrylamide.* ESI (+): 326.1379 ($C_{19}H_{20}O_4N$, −2.4 ppm). UV max (nm): 322, 284, 219.

*Amide **17**, (E)-3-(3,4-Dimethylphenyl)-N-(4-methoxyphenethyl)-acrylamide.* ESI (+): 310.1794 ($C_{20}H_{24}O_2N$, −2.6 ppm). UV max (nm): 285, 224.

Amide ***27****, (E)-3-(3,4-Dimethoxyphenyl)-N-(3,4-dimethylphenethyl)acrylamide.* ESI (+): 340.1899 ($C_{21}H_{26}O_3N$, −2.6 ppm). UV max (nm): 316, 292, 218.

Amide ***28****, (E)-3-(3,4-Dimethoxyphenyl)-N-(4-methoxybenzyl)-acrylamide.* ESI (+): 328.1537 ($C_{19}H_{22}O_4N$, −2.6 ppm). UV max (nm): 317, 292, 223.

Amide ***29****, (E)-N-(Benzo[d][1,3]dioxol-5-ylmethyl)-3-(3,4-dimethoxyphenyl)acrylamide.* ESI (+): 342.1327 ($C_{19}H_{20}O_5N$, −2.7 ppm). UV max (nm): 317, 292, 235, 218.

Amide ***30****, Beecheyamide, (E)-3-(3,4-Dimethoxyphenyl)-N-(4-methoxyphenethyl)-N-methylacrylamide.* A solution of amide **4** (478 mg, 1.4 mmol) in 14 mL of tetrahydrofuran (THF) was added to a suspension of sodium hydride (120 mg, 5.0 mmol) in 9 mL of THF at 0 °C under argon atmosphere. The reaction was stirred for 30 min at 0 °C before 240 mg of methyl iodide was added. The reaction was stirred at room temperature overnight, the mixture poured into 50 mL of cold water, and the pH adjusted to 7 with 5% $KHSO_4$. Extraction from EtOAc, followed by flash chromatography (pure EtOAc), gave 402 mg of **20** (yield 81%). The product was fully in agreement with the NMR data (showing two rotamers of the amide bond) described by Cheng et al.[20] ESI (+): 356.1847 ($C_{21}H_{26}O_4N$, −2.6 ppm). UV max (nm): 320, 285, 224.

Amide ***31****, Podocarpamide, (E)-N-(2-(Benzo[d][1,3]dioxol-5-yl)-ethyl)-3-(3,4-dimethoxyphenyl)-N-methylacrylamide.* Amide **16** (1.70 g, 5.2 mmol) in 50 mL of THF was added dropwise to a suspension of sodium hydride (150 mg, 1.2 equiv) in 34 mL of THF at 0 °C under argon atmosphere. The reaction was stirred for 30 min at 0

[a]This work. [b]Evaluated in large panel only (Table 2). [c]Not evaluated.

°C. Iodomethane (390 μL, 1.2 equiv) was added, and the reaction was stirred overnight at room temperature. After workup and flash chromatography (cyclohexane/EtOAc, 60:40), 1.37 g was obtained (77% yield). NMR data (showing two rotamers of the amide bond) were compliant with those reported by Delle Monache et al.[21] ESI (+): 340.1535 ($C_{20}H_{22}O_4N$, −2.4 ppm). UV max (nm): 321, 285, 232.

Amide ***32****, (E)-3-(4-Hydroxy-3-methoxyphenyl)-N-(4-methoxyphenethyl)-N-methylacrylamide.* 4-Acetoxy-3-methoxycinnamic acid (360 mg, 1.5 mmol, Alfa Aesar) was condensed on [2-(4-methoxyphenyl)-ethyl]methylamine (1 equiv, Aldrich) as described above. The product was purified by flash chromatography (cyclohexane/EtOAc, 50:50) and subsequently deprotected (MeOH/1 M KOH, 1/1 v:v). The reaction was neutralized by addition of 5% $KHSO_4$, and the product was extracted 3 times with EtOAc, then with CH_2Cl_2. After drying over Na_2SO_4 and evaporation, 132 mg of pale-yellow oil was obtained (26%). NMR showed the presence of two rotamers (as described for amide **30**)[20] in a 55:45 ratio. ESI (+): 342.1691 ($C_{20}H_{24}O_4N$, −2.6 ppm). UV max (nm): 321, 285, 232.

Preparation of the Extracts from *Z. piperitum* (L.) DC. The stems and roots were separately cut from the fresh plants, and 207.15 g of stems and 110.44 g of roots were obtained. The stems were ground into a fine powder, poured into 4 L of dichloromethane, stirred for 6 h, and left standing over the weekend. The suspension was filtered, and the solvent was evaporated to yield 1.06 g of brownish oil (0.51% w/w). Similarly, the roots gave 1.6 g of extract (1.45% w/w). The botanical identification of the species was confirmed by a professional botanist (Y.-M. Yuan). Voucher specimens were prepared and kept in the herbarium of the company.

Sensory Evaluation. All of the compounds were assessed by a toxicologist, and many of them were classified as Cramer class III. Therefore, a daily intake of 90 μg/day was allowed. Only one compound of the cinnamic amides family was tasted per session using the "sip and spit" method for 20 mL of solution at 20 ppm, therefore minimizing the amount of ingested product. All panelists had signed a consent form informing them about the risk associated with such tasting of new compounds.

Umami Score (Small Panel). Most of the amides were evaluated by a panel of 4−9 trained people. Each amide was evaluated at 20 ppm in Henniez water against 0.05% monosodium glutamate (MSG) in a blind pair test. The panelists were asked to score the umami taste on a scale of 0−10 for the sample in each cup. The relative umami score was calculated as follows: relative umami score = (amide score/MSG score) × 10

Umami Score (Large Panel). To assess the sensory performance of the selected amides with a larger panel, we asked 15 panelists to evaluate them at 20 or 100 ppm in water (Henniez mineral water) alone and in a 0.05% MSG solution. They were asked to taste the sample while using nose clips in order to focus on taste and trigeminal sensations in the mouth and then without nose clips in order to describe the olfactive notes. The panelists evaluated the samples (20 mL served in a black cup) blind by sipping and spitting the sample out after 5 s before answering the questions. For the pure water system, the panelists had to select the most appropriate attributes from lists of attributes (see below) when they were and were not using nose clips. The attributes were ranked by decreasing order as a function of attribute number cited by the panelists. In the MSG model system, all solutions tasted contained 0.05% MSG and the panelists had to evaluate the perceived umami intensity in the reference solution and in the samples by using a linear scale score ranging from 0 (not intense) to 10 (very intense). The potential umami-enhancing effect of the amide was then evaluated by comparing the perceived intensity of the samples "amide in MSG" versus "MSG alone" (i.e., Δ score corresponding to the intensities of "amide in MSG" minus "MSG alone"). Student's test (paired test, one-tailed) was performed to evaluate the significance of the observed umami difference. The following is the list of attributes: with nose clips: astringent, bitter, cooling, fatty, hot, licorice taste, metallic, mouthfeel, pungent, salivating, salty, sour, sweet, tingling, and umami; without nose clips: earthy, fruity, green, herbal, mushroom, nutty, tea, and woody.

RESULTS AND DISCUSSION

Structure Taste Relationship Study of Nature-Inspired Amides. Most of the amides occurring in *Z. rubescens* consist of amides of substituted cinnamic acid and phenethylamine.[13] Throughout this study, 29 such amides (**1**−**29**) bearing different substituents were synthesized (Figure 3 and Table 1). A few amides shown in Table 1 were already identified in plants[13,22,23] or microorganisms.[24] We limited the study to amides formed from acids and amines whose structural scaffolds were close to those already known to occur in nature. We thought it might increase the chances of showing the natural occurrence of these amides afterward by targeted analysis. Thus, for example, 4-methoxyphenethylamine clearly derives from the amino acid tyrosine, but 3-methoxyphenethylamine could also form from the uncommon but naturally occurring *meta*-tyrosine.[25] The amide bond was formed from the mixed carbonic anhydride generated by reaction of the acid with ethyl chloroformate, followed by addition of the amine. The synthetic amides were subsequently evaluated for their umami taste by a panel of 4−9 trained people. A relative umami score was calculated as follows: (amide score/MSG score) ×

[a]Above the highest point of calibration.

10. For a umami score of 10, the umami taste intensity of the amide at 20 ppm was perceived as being equal to that of 0.05% MSG. Thus, rubemamine (**1**), which was perceived as umami with a score of 3.3, was used as a lead compound in this study. The structural optimization was performed step by step by varying the substituents independently.

The comparison of the relative umami score for the amides shown in Table 1 led to the following conclusions. The double bond of (*E*) configuration in the acid part was needed because compound **5** with the (*Z*) configuration and the saturated compound **6** did not have a umami taste. Two methoxy groups were the most favorable (**4** vs **7**, **9**−**11**, and **13**), and they should be in the meta and para positions (i.e., **4** was better than **12**). With substituents other than methoxy groups (**14**−**17**), the umami taste intensity decreased significantly. Thus, it appeared that 3,4-dimethoxycinnamic acid was needed as the acid part of the amide. The phenethylamine part (n = 1) tolerated much more variation on the aromatic ring. Thus, compounds **18** and **19** and **20**−**27**, bearing different R_5 and R_6 groups, were perceived as umami-tasting, either moderately (**18**, **21**, and **22**) or strongly (**19** and **22**−**27**). In particular, compounds having one alkoxy or one alkyl group in meta position were all very strong (**19** > **4** > **20**). Benzylamides (n = 0) **29** and **30** were only very weakly umami-tasting.

In the large panel study, all but two of the evaluated amides significantly enhanced the umami taste (Table 2). The delta scores represent the average difference between the perceived umami intensity of the model solution (MSG) and that with the amide added. A positive value denotes an increase of umami taste intensity when the amide was present. Student's test

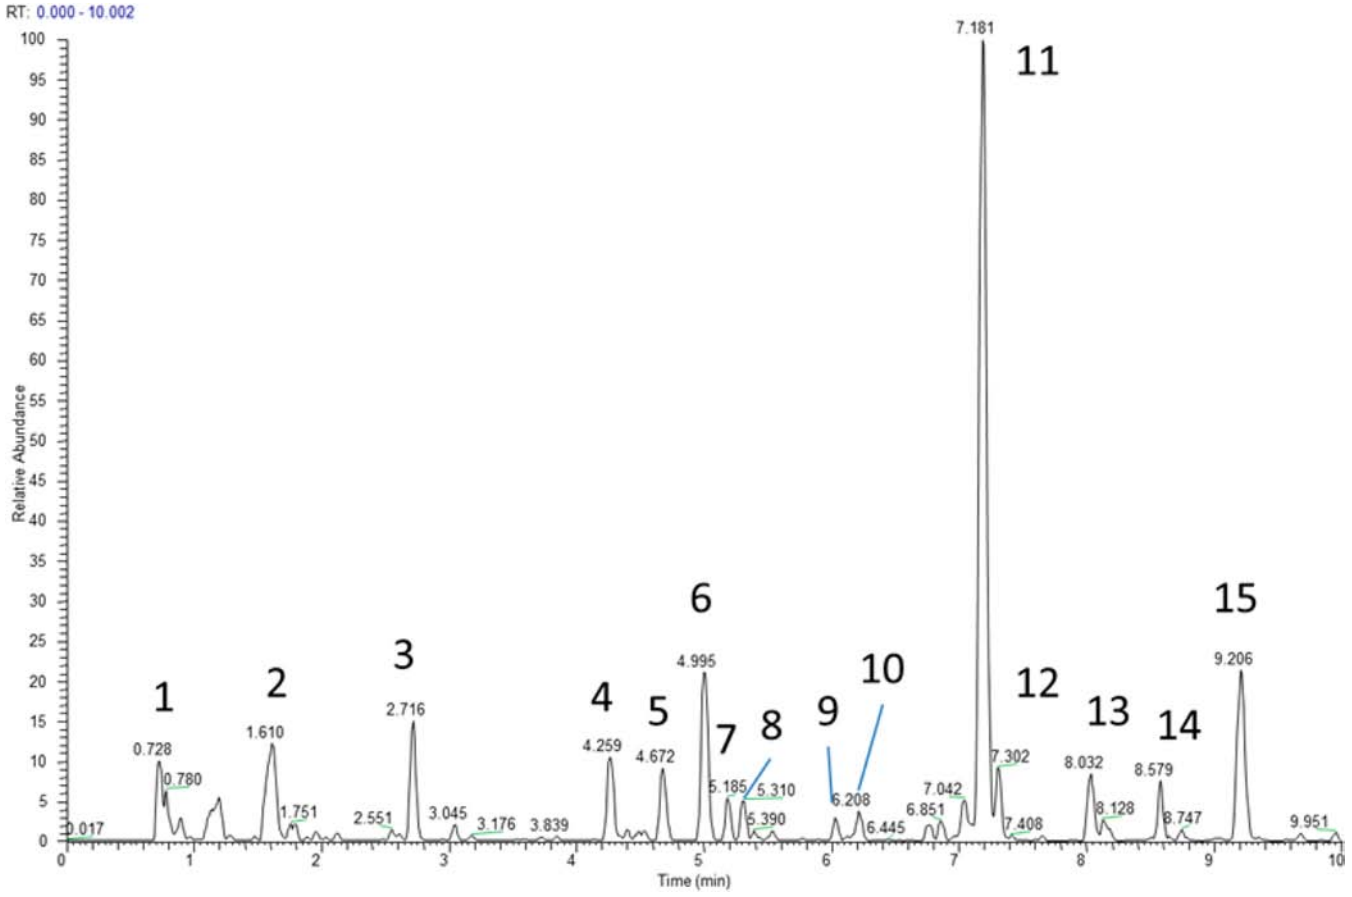

Figure 4. UPLC/MS chromatogram (Full scan mode) of *Z. piperitum* root extract.

(paired test, one-tailed) indicates whether this difference is significant at different levels of confidence between these two samples (*, **, and ***, at 95, 99, and 99.9%, respectively). The best performing amides were **1**, **4**, **19**, and **23**−**27**. One of the most interesting compounds was **4**, which increased the perceived intensity of umami by 1.3, with a significance level of 99.9% with and without the nose clip. Furthermore, the comments regarding the water system with the nose clips were quite positive, except for the astringency; there was no olfactive off-note (no comment without the nose clips).

Targeted UPLC/MS/MS Analysis and Occurrence of Amides 1, 4, 15, 16, and 30−**32 in *Z. piperitum*.** There are more than 500 species in the genus *Zanthoxylum* (Rutaceae),[15] which often used as medicinal plants, as ornamentals, or in culinary applications. Cheng et al. analyzed *Z. beecheyanum* K. Koch, which K. Koch purchased in Taiwan, and it contained many aromatic amides.[20] The description of this plant as an evergreen shrub originating from Japan introduced as an ornamental plant in Taiwan is very similar to that of *Z. piperitum*. The latter plant is used as ornamental plant in China and as bonsai in Japan, whereas the pericarp of the species is commonly used as a spice in Japan.[15] We decided to focus our study on this plant. Dichloromethane was selected as the solvent for the extraction because the synthetic amides described earlier were all very soluble in it. The stems and the roots were extracted separately and analyzed by UPLC/MS operated in positive electrospray ionization mode. For this study, we used a high-resolution hybrid quadrupole-Orbitrap mass spectrometer in full scan/data-dependent MS^2 experiment mode followed by a targeted MS^2 experiment (t-MS^2) within the same run. The t-MS^2 mode used an inclusion list comprising the molecular formulas of the 15 selected amides (Table 3) to record the corresponding product ion spectra. Figure 4 shows the UPLC/MS profile of the root extract of *Z. piperitum*. It was not the aim of this study to fully characterize the extract, but some major products already known to occur in *Zanthoxylum* species could be tentatively identified on the basis of their accurate masses. The major products identified in Figure 4 were amides such as α-sanshool (peak 11), beecheyamide (**30**, peak 4), podocarpamide (**31**, peak 6), alkaloids such as skimmianine (peak 3) and zanthoxyline (peak 2), and probably lignan-related products (peaks 9−10). Amides **30**−**32** (Figure 5) were synthesized to be used in the study.

According to the International Organization of the Flavor Industry guidelines for the positive identification of chemicals

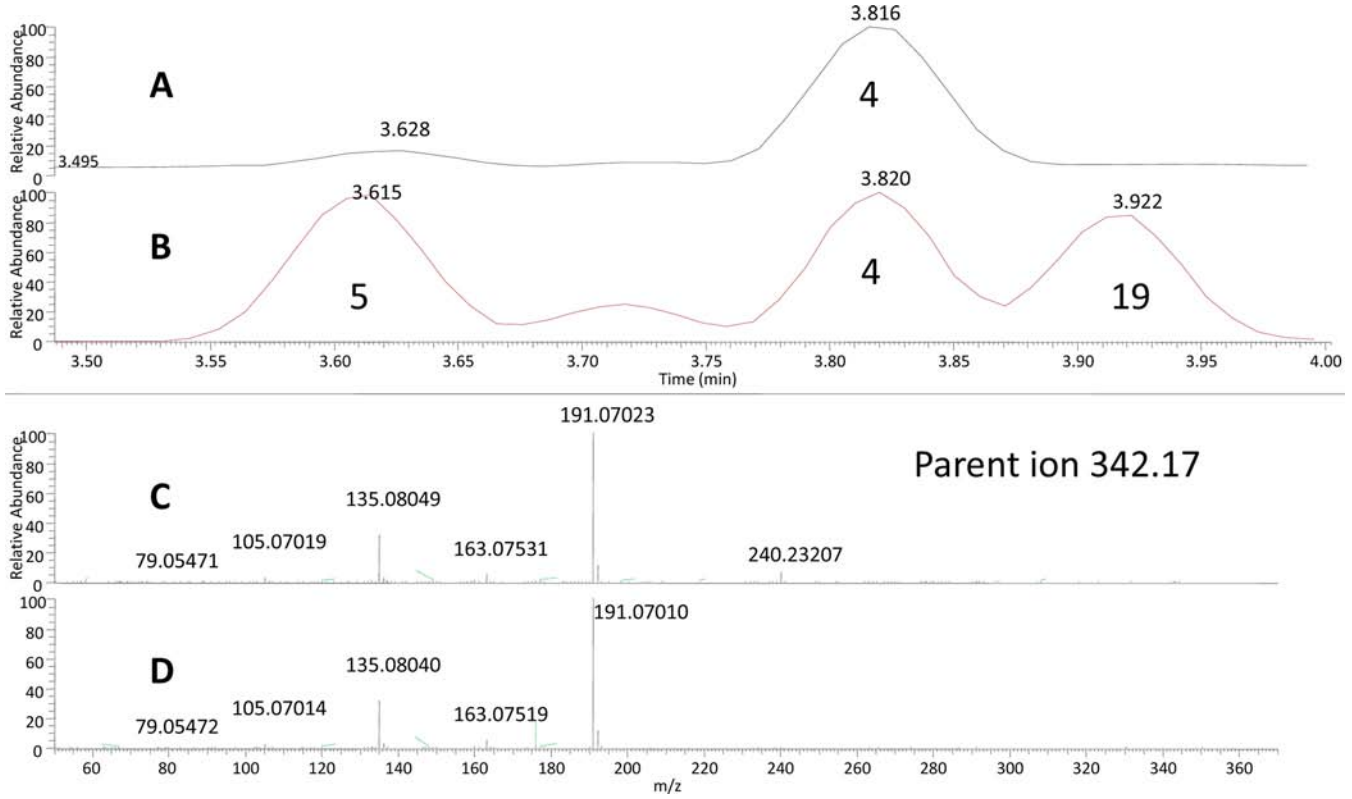

Figure 6. UPLC/MS trace in targeted-MS^2 mode (Materials and Methods) of ion 342.17 in (A) *Z. piperitum* root extract and (B) a mixture of synthetic products. MS/MS spectra of (C) peak at 3.827 min in *Z. piperitum* and (D) peak at 3.820 min in the synthetic mixture, showing the natural occurrence of amide **4**.

by high-resolution LC/MS/MS,[26] an undisputed identification of new compounds in plants requires six points of identification when comparing the reference synthetic material with the analyte in the plant: 1 precursor in low resolution + 2 product ions in high resolution + 1 ratio → 6 identification points (IPs). A mixture of 15 amides (Table 3) was injected at concentrations ranging from 0.1 to 1000 ppb. The t-MS^2 data were then compared with those obtained from the injection of the extract at 1000 ppm after blank runs were performed. The comparison of the chromatographic and mass spectral data (Table 3 and the Supporting Information) between the synthetic compounds and the natural extract showed the unambiguous occurrence of amides **1**, **4**, **15**, **16**, and **30**−**32** in *Z. piperitum* root extract. Quantitative results presented below should be considered with care because we did not check for ion suppression effects. Also, the most abundant amides were present at concentrations higher than the highest concentration of the calibration curves.

Amides **1** (rubemamine), **16**, **20** (beecheyamide), and **31** (podocarpamide) were already reported to occur in *Zanthoxylum* species (Table 1). Amides **30** and **31** were abundant compounds in our extract, accounting for 0.57 and 1.87% w/w, respectively. Figure 6 shows the t-MS^2 trace of ion 342.17. The peak at 3.816 min in the plant extract (Figure 6A) and the synthetic amide **4** eluting at 3.820 min in the reference mixture (Figure 6B) injected separately showed identical MS/MS spectra (Figure 6C,D; same fragments, same ratio). Because amide **4** was well-separated from its isomers **5** and **19**, its occurrence is thus unambiguously supported. The comparisons between the UPLC/MS/MS data of the synthetic products and the natural products for the other amides are available in the Supporting Information.

This work illustrates how compounds already known to occur in plants served as a starting point for umami taste relationship studies to find more intense ingredients. Targeted UPLC/MS/MS analyses then unambiguously supported the natural occurrence of a few of these molecules in a plant extract. The combination of plant knowledge, chemical synthesis, and modern LC/MS techniques thus provided an efficient way to discover new taste-active and naturally occurring ingredients. A similar approach was used by Süss et al., who synthesized a series of kitchenlike amides by reaction of lactones and amines, evaluated them for their umami taste and finally showed the natural occurrence of one of them in blue cheese.[27]

Present Address

N.N.: Schwarzkopf Professional, 161 rue de Silly, 92 642 Boulogne, Billancourt, France.

Notes

The authors declare no competing financial interest.

■ ACKNOWLEDGMENTS

We thank Mr. Alain Bagnoud for his help in chemical synthesis, Mrs. Esmeralda Cicchetti for preliminary LC/MS analyses, Mrs. Aurore Planchais and Christine Saint-Léger for the organization of the large panel evaluations, Dr. Sylvain Etter for toxicology assessment, and Mrs. Kasia Aeberhardt for stimulating discussions. The reviewers for their constructive suggestions to improve the manuscript are also acknowledged.

■ ABBREVIATIONS USED

MSG, monosodium glutamate; THF, tetrahydrofuran; UPLC/MS, ultraperformance liquid chromatography mass spectrometry; ESI, electrospray ionization

compounds. Thus, tree marker compounds were isolated and characterized via MS, 1D- and 2D-NMR, and CD spectroscopy and evaluated for their antioxidative properties via H_2O_2 scavenging, hydrophilic and lipophilic oxygen radical absorbance capacity (H-/L-ORAC), and Trolox equivalent antioxidant capacity (H-/L-TEAC) assays.

MATERIALS AND METHODS

Chemicals. The following reagents were obtained commercially: H_2O_2 (Merck, Hohenbrunn, Germany); 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), peroxidase from horseradish (HRP), *rac*-6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid (Trolox), fluorescein sodium salt (FL), 2,2′-azobis(2-methylpropinamidine) (AAPH), quercetin, and ascorbic acid (Sigma-Aldrich, Steinheim, Germany). H_2O for chromatographic separations was purified with a Milli-Q Gradient A10 system (Millipore, Schwalbach, Germany), and solvents used were of HPLC grade (Merck, Darmstadt, Germany). Deuterated solvents were obtained from Euriso-Top (Saarbrücken, Germany).

General Experimental Procedure. 1D- and 2D-NMR spectroscopy ^{1}H, ^{1}H−^{1}H COSY, HSQC, HMBC, and ^{13}C were performed on an Avance III 500 MHz spectrometer with a CTCI probe (Bruker, Rheinstetten, Germany). Mass spectra of the compounds were measured on a Waters Synapt G2-S HDMS mass spectrometer (Waters, Manchester, UK) coupled to an Acquity UPLC core system (Waters, Milford, MA, USA). For ECD spectroscopy, methanolic solutions of the samples were analyzed by means of a Jasco J-810 spectropolarimeter (Hachioji, Japan). HPLC separations were performed using a preparative HPLC system (PrepStar, Varian, Darmstadt, Germany). Medium-pressure liquid chromatography (MPLC) separations were performed on a Büchi Sepacore (Flawil, Switzerland) system using a YMC (YMC Europe, Dinslaken, Germany) DispoPackAT ODS-25 flash cartridge (120 g, i.d. = 40 mm, l = 150 mm).

Plant Material. Leaves, stem bark, and roots from *G. buchananii* were collected from trees in their natural habitats in Karagwe, Tanzania, dried, and ground to powder.[2] A voucher specimen of the powders was deposited at the University of Idaho Stillinger herbarium (voucher 159918).

Extraction and Isolation. Extraction of *G. buchananii* leaf powder and MPLC separation were performed as described for root and bark powder.[9,10,12,27] Ten fractions were collected, concentrated under reduced pressure, and freeze-dried. (2*R*,3*S*)-Morelloflavone (**12**, Figure 1) was obtained from MPLC fraction 8: yellow amorphous powder (yield, 9% from extract); UV (MeOH) λ_{max} (log ε) 227 (4.85), 288 (4.58), 339 (4.32) nm; ECD (c 4.2 × 10^{-4} M, MeOH) λ_{max} nm ($\Delta\varepsilon$) 348 (+4.6), 316 (+1.4), 286 (+10.4), 250 (−1.9), 224 (−13.1); ^{1}H and ^{13}C NMR (DMSO-d_6, 22 °C, 500, 125 MHz) data (Supporting Information, Tables S1 and S2); HRESIMS m/z 555.0921 $[M - H]^-$ (calcd for $C_{30}H_{19}O_{11}$, 555.0927).

HPLC Isolation of (2*R*,3*S*)-Volkensiflavone (13) from Leaf Extract. Chromatography of MPLC fraction 9 was performed using a RP column (10 × 250 mm, phenylhexyl, 5 μm; Phenomenex, Aschaffenburg, Germany) as the stationary phase. The effluent (4.2 mL/min) was monitored at 300 nm. The separation started with a mixture (65:35, v/v) of aqueous HCO_2H (0.1% in H_2O) and MeCN, and the MeCN content was linearly increased to 45% within 20 min. Collected fractions were concentrated under reduced pressure and freeze-dried twice, affording (2*R*,3*S*)-volkensiflavone (**13**, Figure 1): slight yellow amorphous powder (yield, 1% from extract); UV (MeOH) λ_{max} (log ε) 227 (4.94), 289 (4.67), 339 (4.40) nm; ECD (c 2.9 × 10^{-4} M, MeOH) λ_{max} nm ($\Delta\varepsilon$) 347 (+4.9), 316 (−0.2), 287 (+10.7), 250 (−1.8), 223 (−12.5); ^{1}H and ^{13}C NMR (DMSO-d_6, 22 °C, 500, 125 MHz) data (Supporting Information, Tables S3 and S4); HRESIMS m/z 539.0978 $[M - H]^-$ (calcd for $C_{30}H_{19}O_{10}$, 539.0978).

HPLC Isolation of Garcicowin C (21) from Bark Extract. Preparative HPLC separation of MPLC fraction 8 was performed as described.[10] Collected fractions were concentrated under reduced pressure and freeze-dried twice, affording 18 fractions, M8-1−M8-19. Garcicowin C was obtained from M8-14 by semipreparative HPLC (4.2 mL/min, 278 nm) using ThermoHypersil ODS (10 × 250 mm, 5 μm; Kleinostheim, Germany) as the stationary phase and a mixture (28:72, v/v) of aqueous HCO_2H (0.1% in H_2O) and MeCN. Collected fractions were concentrated under reduced pressure and freeze-dried twice, affording garcicowin C (**21**, Figure 1): slight yellow amorphous powder (yield, 0.3% from extract); UV (MeOH) λ_{max} (log ε) 231 (4.37), 273 (4.24), 319 (3.94) nm; ECD (c 8.3 × 10^{-4} M, MeOH) λ_{max} nm ($\Delta\varepsilon$) 313 (+2.3), 267 (−9.6), 220 (+5.5); ^{1}H and ^{13}C NMR (MeOD-d_3, 27 °C, 500, 125 MHz) data (Supporting Information, Tables S5 and S6); HRESIMS m/z 599.3380 $[M - H]^-$ (calcd for $C_{38}H_{47}O_6$, 599.3373).

Antioxidant Assays. *H_2O_2 Scavenging Assay.* The H_2O_2 scavenging assay was performed in accordance with the method of Ichikawa et al.[21] Sample solutions at appropriate concentration were prepared using phosphate buffer (100 mM, pH 6.0). Sample solution

[a]Each sample was analyzed by means of ORAC and ABTS assays by quadruplicate studies. [b]Values represents the mean ± SD. [c]Each sample was analyzed by means of H_2O_2 assay by triplicate studies. [d]Range in parentheses represents 95% confidence interval. [e]Values comparable to those of Stark et al.[9,10,12] [f]L-TEAC values from Re et al.[55] [g]L-ORAC values from Mercader-Ros et al.[56]

(100 μL), phosphate buffer (30 μL, 100 mM, pH 6.0), and H_2O_2 solution (10 μL, 500 μM) were mixed in a transparent 96-well microplate (VWR, Ismaning, Germany). Then peroxidase (40 μL, 150 U/mL) and ABTS (40 μL, 0.1%) were added. The microplate was incubated at 37 °C for 15 min. The absorbance (A) of each well was measured at 414 nm with FLUOstar OPTIMA (BMG LABTECH, Offenburg, Germany). The scavenging effect (E) was calculated as shown using the formula below (blank stands for solution without hydrogen peroxide, and control did not include a test compound), and EC_{50} was calculated by the probit analysis.

$$E = [(A - A_{blank})_{control} - (A - A_{blank})_{test}]/(A - A_{blank})_{control} \times 100$$

Hydrophilic Oxygen Radical Absorbance Capacity (H-ORAC) Assay. The ORAC assay was carried out according to the method of Ou et al.[22] with some modifications. Trolox and FL were used as standard and fluorescent probe, respectively. Free radicals were produced by AAPH to oxidize FL. Different dilutions of Trolox (200, 100, 50, 25, and 12.5 μM) and appropriate dilutions of tested sample were prepared with phosphate buffer (10 mM, pH 7.4). Trolox dilution (25 μL) or sample solution was pipetted into a black 96-well microplate (VWR), and then FL (150 μL, 10 nM) was added. The reaction mixture was incubated at 37 °C for 30 min. Afterward, fluorescence was measured every 90 s at the excitation of 485 nm and the emission of 520 nm using FLUOstar OPTIMA. After three cycles, AAPH (25 μL, 240 mM) was added quickly, and then the measurement was resumed and continued up to 90 min (60 cycles in total). The background signal was determined using the first three cycles. The ORAC values were calculated according to the method of Cao et al.[23] and expressed as Trolox equivalent (μmol TE/μmol).

Lipophilic Oxygen Radical Absorbance Capacity (L-ORAC) Assay. The lipophilic ORAC assay was adapted from the Madrona procedure with some modifications.[24] Trolox standards (200, 100, 50, 25, and 12.5 μM) as well as dilutions of each sample solution were prepared using 7% (w/v) randomly methylated methyl-β-cyclodextrin (RMCD) in acetone/H_2O (1:1 v/v). FL and AAPH solutions were prepared in the same way as the H-ORAC method using phosphate buffer (10 mM, pH 7.4). After FL solution (150 μL) was added in a black 96-well microplate, Trolox standards, the diluted samples, and the 7% RMCD solution as blank, 25 μL each, were applied with mixing. Incubation of the microplate was done as described for the H-ORAC assay, and an AAPH solution (25 μL) was immediately added to all wells. All conditions of the measurement as well as data handling and export were the same as for the H-ORAC assay.

Hydrophilic Trolox Equivalent Antioxidant Capacity (H-TEAC) Assay with ABTS. The ABTS radical scavenging activity was measured employing ABTS assay as previously described by Floegel et al.[25] with some modifications. Briefly, ABTS (2.5 mM) solution was prepared with phosphate-buffered saline (PBS, 10 mM, pH 7.4), and AAPH (1 mM) was added in the solution. The mixture was heated in a water bath at 68 °C for 40 min. The blue-green ABTS radical solution was cooled to room temperature, filtered through a syringe membrane (0.45 μm), and diluted with PBS buffer until an absorbance of 0.325 ± 0.01 at 730 nm. Then Trolox standards (1000, 500, 250, 125, and 62.5 μM, 4 μL each) or samples were mixed with the diluted ABTS radical solution (196 μL) in a transparent 96-well microplate. The microplate was incubated at 37 °C for 10 min. The absorbance of each well was measured at 730 nm with FLUOstar OPTIMA. ABTS radical scavenging activity was calculated employing standard curves and expressed as Trolox equivalent (mmol TE/mmol).

Lypophilic Trolox Equivalent Antioxidant Capacity Assay with ABTS (L-TEAC). To measure TEAC of lypophilic compounds, the H-TEAC method was modified.[26] In brief, Trolox was dissolved in aqueous DMSO (50%, v/v) for standard solutions (1000, 500, 250, 125, and 62.5 μM), and the dilution of sample solutions was also performed with aqueous DMSO (50%, v/v). Neat DMSO (20 μL) was added in a transparent 96-well microplate, and subsequently all of the wells (final DMSO concentration, 10%) were processed in the same way as described for the H-TEAC method. Finally, all conditions of the measurement as well as data handling and export were the same as for the H-TEAC assay.

Ultraperformance Liquid Chromatography−Electrospray Ionization−Time-of-Flight Mass Spectrometry (UPLC-ESI-TOF MS). Aliquots (3 μL) of the extracts (10 mg/10 mL, 50% MeCN, each) were analyzed in five replicates by means of UPLC-ESI-TOF MS on a Waters Synapt G2-S HDMS mass spectrometer (Waters, Manchester, UK) coupled to an Acquity UPLC core system (Waters, Milford, MA, USA) equipped with a 2 × 150 mm, 1.7 μm, BEH C18 column (Waters, Manchester, UK) consisting of a binary solvent manager, sample manager, and column oven. Operated with a flow rate of 0.4 mL/min at 50 °C, the following gradient was used for chromatography: starting with a mixture (1:99, v/v) of aqueous HCO_2H (0.1% in H_2O) and MeCN (0.1% HCO_2H), the MeCN content was increased to 50% within 6 min, to 98% within 1 min, kept constant for 1 min, decreased to 1% within 0.2 min, and finally kept constant for 0.8 min at 1%. Scan time for the MS^e method (centroid) was set to 0.1 s. Analyses were performed with negative ESI in high-resolution mode using the following ion source parameters: capillary voltage, −2.0 kV; sampling cone, 50 V; source offset, 30 V; source temperature, 120 °C; desolvation temperature, 450 °C; cone gas flow, 2 L/h; nebulizer, 6.5 bar; and desolvation gas, 800 L/h. Data processing was performed by using MassLynx 4.1 SCN 9.16 (Waters, Manchester, UK) and the elemental composition tool for determining the accurate mass. All data were lock mass corrected on the pentapeptide leucine enkephaline (Tyr-Gly-Gly-Phe-Leu, m/z 554.2615, $[M - H]^-$) in a solution (1 ng/μL) of MeCN/0.1% HCO_2H (1:1, v/v). Scan time for the lock mass was set to 0.3 s, at intervals of 15 and 3 scans to average with a mass window of ±0.3 Da. Calibration of the Synapt G2-S in the range from m/z 50 to 1200 was performed using a solution of HCO_2Na (5 mmol/L) in 2-propanol/H_2O (9:1, v/v). The UPLC and Synapt G2-S systems were operated with MassLynx software (Waters). The collision energy ramp for MS^e was set from 20 to 40 eV.

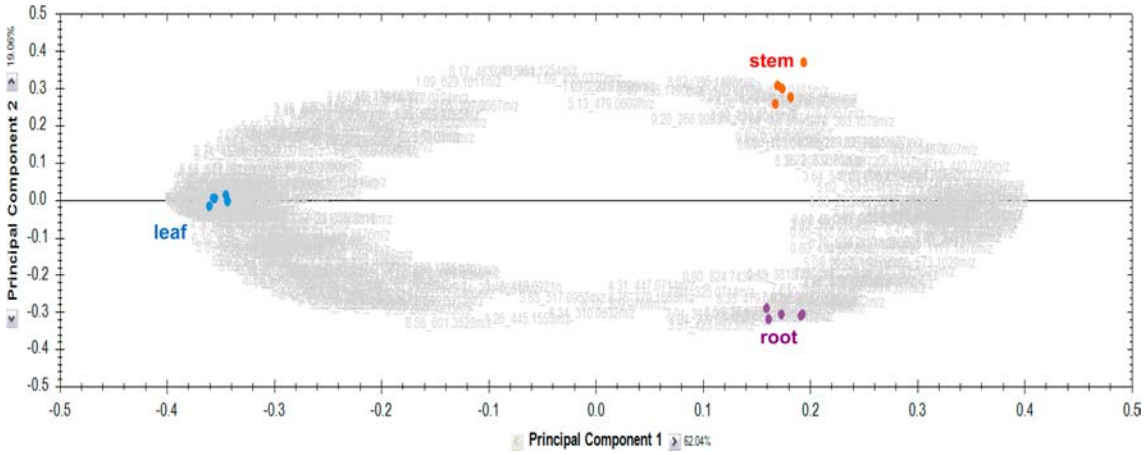

Figure 2. Score plot (comp 1 vs comp 2]) of UPLC-ESI-TOF MS full scan analysis (50−1200 Da, ESI^-, high-resolution mode) of *G. buchananii* tree (five replicates per sample).

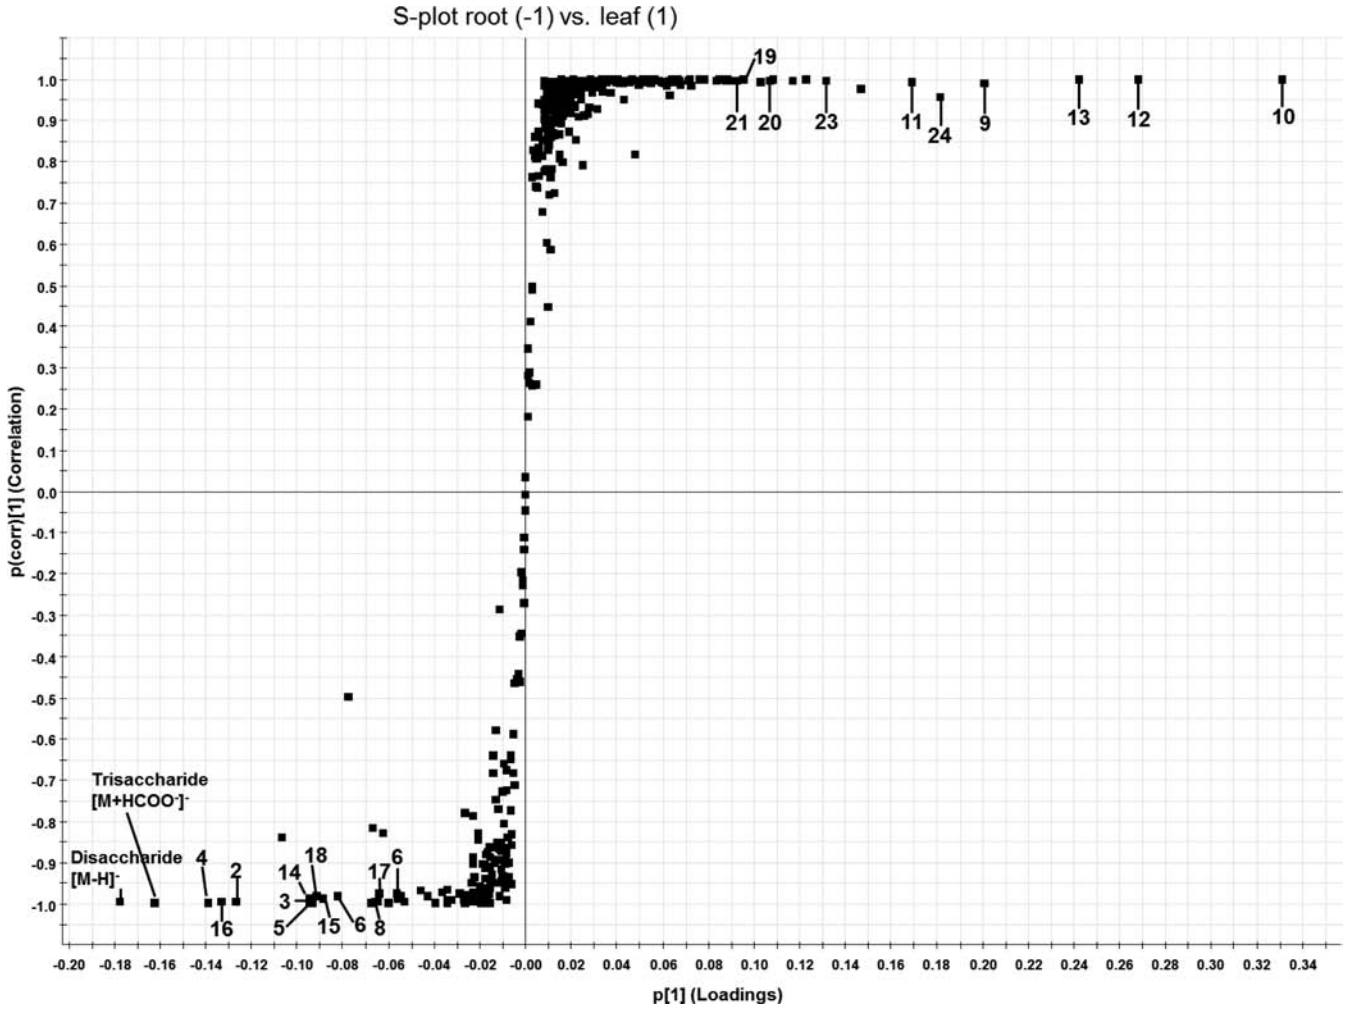

Figure 3. S-plot of root versus leaf extract.

The raw data of all organs and replicates obtained from UPLC-ESI-TOF MS analysis were processed with Progensis QI using the following peak picking conditions: all runs, limits automatic, sensitivity 3, and retention time limits 0.5−9.25 min. Compounds used for principal component analysis (PCA) were filtered by means of ANOVA p value ≤0.05 and a fold change of ≥2. The processed data were exported to EZinfo, where the matrix was analyzed by PCA with pareto scaling. Group differences were calculated using orthogonal partial least-squares discriminant analysis (OPLS-DA) highlighted as S-plots.

RESULTS AND DISCUSSION

As the aqueous ethanolic stem bark extract of *G. buchananii* showed high antioxidative activity comparable to that of grape seed extract,[9,22] the question arose as to whether other organs

[a]Compound numbering relates to the retention time. [b]The sum formula of all fragments is given in the Supporting Information. [c]Identified via accurate mass, fragments, and database searching focused on *Garcinia* species.

of this tree might be an alternative source for antioxidative extracts or for strong antioxidative and bioactive purified compounds. Also, the idea of a faster or more efficient isolation procedure from other parts of this tree for already known lead compounds from stem bark arose. Comparative antioxidative analysis of aqueous ethanolic leaf, root, and stem bark extract revealed high capacities for all three tree organs; however, the antioxidative activity of leaf extract was slightly lower in four of five assays (Table 1).

To investigate the metabolite composition of the different parts of *G. buchananii*, we conducted an untargeted metabolomics approach using UPLC-ESI-TOF MS with simultaneous acquisition of low- and high-collision energy mass spectra (MS^e). Using the Progensis QI workflow consisting of import data, review alignment, experiment design setup, peak picking, review deconvolution, review compounds, and compound statistics, unsupervised statistics were performed to evaluate if any differences in the metabolomes of the organs were detectable. Compounds used for PCA were filtered by means of ANOVA p value ≤ 0.05 and fold change of ≥ 2, resulting in a reduction from 1008 to 450 compounds and the PCA displayed in Figure 2. Analysis of each organ in five replicates showed a rather good clustering of each replicate in close proximity, thus confirming the reproducibility of the UPLC-ESI-TOF MS profiling method. Inspection of the PCA output illustrated that the largest differences were observed between leaf and stem bark as well as root extracts along PC1, whereas root and stem bark extracts could be clearly separated along PC2 (Figure 2).

As the root extract showed higher antioxidative activity than leaf extract, at first, these two organs were compared by means of OPLS-DA. To visualize similarities and differences between root and leaf extracts, S-plots of data pairs of accurate mass and retention time of each metabolite were calculated (Figure 3).

As the y-axis of the S-plot denotes confidence of a metabolite's contribution to the group difference and the x-axis denotes the contribution of a particular metabolite to the group difference, the S-plot indicates the ion m/z 557.1083 (**10**) showing by far the highest difference for both organs (Figure 3; Supporting Information). In addition, the ions m/z 555.0924 (**12**), 539.0979 (**13**), 573.1030 (**9**), 601.3527 (**24**), and 557.1079 (**11**) for leaf and m/z 341.1082, 549.1665, 735.1560 (**4**), 341.1027 (**16**), and 449.1082 (**2**) for root were found to clearly contribute to the differences between both tree tissue extracts. On the basis of the accurate mass data, the sum formulas of **2**, **4**, **9**−**13**, **16**, **24** were determined (Table 2), and the ions m/z 341.1082 and 549.1665 were calculated to be $C_{12}H_{21}O_{11}$ and $C_{19}H_{33}O_{18}$, respectively. The ion m/z 341.1082 could be proposed as a disaccharide such as sucrose, cellobiose, or maltose and ion m/z 549.1665 as the formic acid adduct of a trisaccharide such as raffinose, maltotriose, or cellotriose. Chromatography of authentic samples as well as cochromatography with the pooled sample of all *G. buchananii* tree organs confirmed the compounds (2*R*,3*R*)-aromadendrin-6-*C*-*β*-D-glucopyranoside (**2**), (2*R*,3*S*,2″*R*,3″*R*)-GB-2 7″-*O*-*β*-D-glucopyranoside (**4**), (2*R*,3*S*,2″*S*)-buchananiflavanone (**9**), (2*R*,3*S*,2″*R*,3″*R*)-GB-1 (**10**), (2*R*,3*S*,2″*S*)-GB-2a (**11**), and garcinol (**24**).[9,10,12,27,28] The marker compounds m/z 555.0924 (**12**) and 539.0979 (**13**) were isolated from leaf extract by means of MPLC and HPLC and unequivocally identified via MS analysis, 1D- and 2D-NMR, and CD spectroscopy (Supporting Information) as (2*R*,3*S*)-morello-

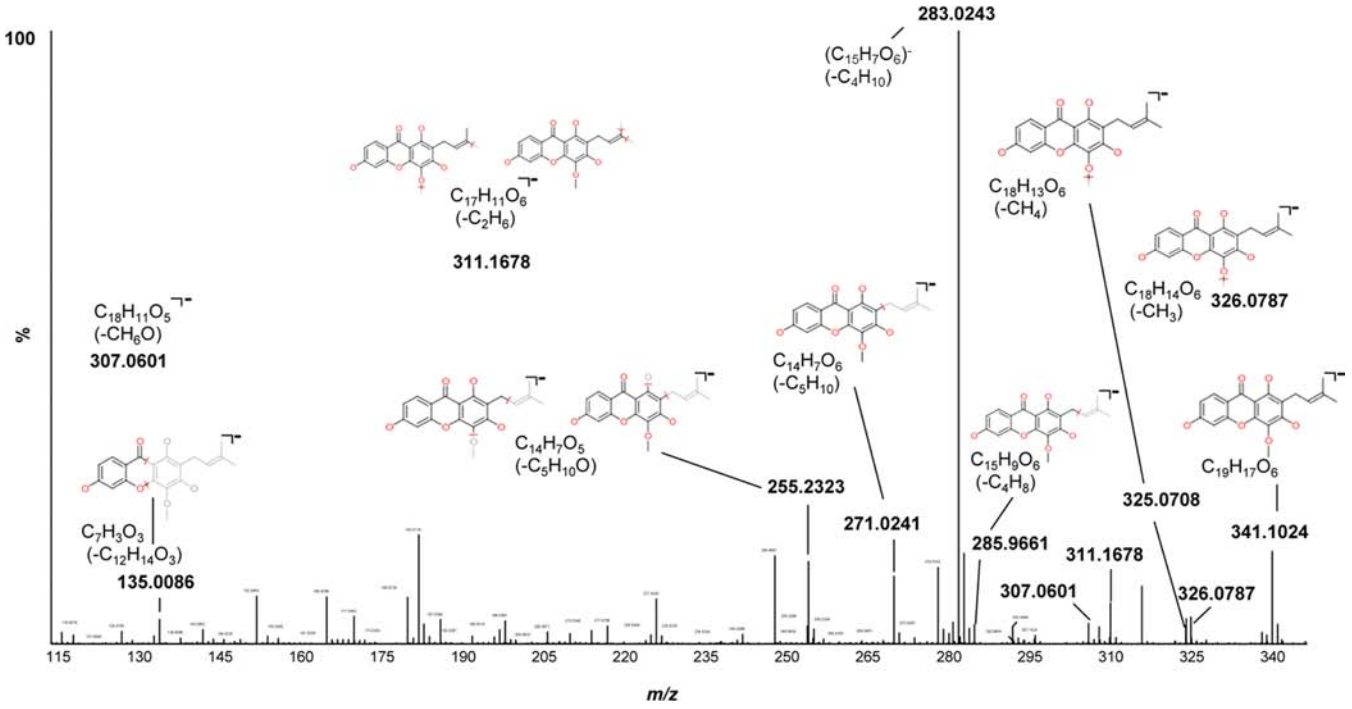

Figure 4. High-collision energy (MS^e) mass spectrum of **16** exemplified with **16e**.

flavone (**12**) and (2*R*,3*S*)-volkensiflavone (**13**) and are in very good agreement with the literature.[29−32] Additional compounds identified in the S-plot by means of chromatography of authentic samples as well as cochromatography are (2*R*,3*S*,2″*R*,3″*R*)-manniflavanone-7″-*O*-*β*-D-glucopyranoside (**3**), (2*R*,3*S*,2″*S*,3″*S*)-manniflavanone (**5**), (2*R*,3*S*,2″*R*,3″*R*)-manniflavanone (**6**), and (2*R*,3*S*,2″*S*,3″*S*)-isomanniflavanone (**8**).[9,10,12,27,28] Compound *m*/*z* 599.3364 (**21**) was isolated from stem bark and identified via MS, NMR, and CD spectroscopy as garcicowin C (**21**).[33] For the ions *m*/*z* 309.0765 (**14**), 311.0919 (**15**), 341.1030 (**16**), 393.1342 (**17**), 379.1544 (**18**), 533.2899 (**19**), 633.3423 (**20**), and 531.2744 (**23**), the corresponding sum formulas were calculated (Table 2), and compounds annotated by database searching focused on compounds that have only been isolated from *Garcinia* species. 6-Deoxyjacareubin or 6-deoxyisojacareubin and 1,3,5-trihydroxy-2-prenylxanthone could be proposed for **14** and **15**,[34−38] which were further strengthened by their fragments in the high-collision energy mass spectra (Table 2; Supporting Information). The calculated elemental composition of $C_{19}H_{18}O_6$ for **16** revealed eight possible structures (**16a**−**16h**) identified in *Garcinia* species so far (Figure 1).[35,39−45] Several fragment ions such as *m*/*z* 255.2323, 271.0241, 285.9661, and 325.0712 supported their identification in *G. buchananii* (Figure 4). The fingerprint fragments of *m*/*z* 91.0186 ($C_6H_3O^-$) and 135.0085 ($C_7H_3O_3^-$) as well as the absence of *m*/*z* 108.0186 ($C_6H_4O_2^-$) indicated isocaledonixanthone D (**16b**) or garcinenone X (**16e**) with a higher probability (Figure 4). Staudiixanthones B (**17a**) and C (**17b**),[46] or garcinone B (**17c**),[47] or 1,6,7-trihydroxy-6′,6′-dimethyl-2*H*-pyrano(2′,3′:3,2)-4-(3-methylbut-2-enyl)-xanthone (**17d**) and 1,5,6-trihydroxy-6′,6′-dimethyl-2*H*-pyrano(2′,3′:3,4)-2-(3-methylbut-2-enyl)xanthone (**17e**),[36] or garciesculenxanthone A (**17f**)[36] could be putatively identified as compound **17** by means of the elemental composition of $C_{23}H_{22}O_6$ and accurate mass fragment. From the determined sum formula for compound **18** of $C_{23}H_{24}O_6$ and fragments, four compounds could be proposed: garcinone A (**18a**),[47] or 8-deoxygartanin (**18b**),[34,37] or 1,3,7-trihydroxy-2,4-di(3-methylbut-2-enyl)xanthone (**18c**),[48] or mangostinone (**18d**).[49] The fact that we detected the diagnostic fragment of *m*/*z* 91.0186 ($C_6H_3O^-$) for compound **16** but not for **18** displayed a more reliable identification of 8-deoxygartanin (**18b**). Aristophenone A or B (**19a**,**b**) could be proposed as compound **19**,[50−52] which additionally showed the corresponding key fragment of *m*/*z* 109.0293 ($C_6H_5O_2$) (Table 2; Supporting Information). Paucinone C and hanburin could be tentatively identified as compounds **20** and **23**, respectively[53,54]

Comparing leaf and stem bark extract by means of OPLS-DA yielded an S-plot (Figure S2 in the Supporting Information) highlighting similar marker compound distribution as described above for leaf versus root extract. Compounds **10**, **12**, **13**, **24**, **11**, **9**, **23**, **19**, **20**, and **22** for leaf extract and disaccharide(s) as well as trisaccharide(s) for stem bark extract were the most important *m*/*z* for the differentiation. This is not surprising as leaf could be separated from stem bark as well as root extracts along PC1 (Figure 2).

S-plotting root versus stem bark extract revealed (2*R*,3*S*,2″*S*)-buchananiflavanone (**9**) as the decisive marker compound for stem bark, whereas (2*R*,3*S*,2″*R*,3″*R*)-GB-1 (**10**), garcinol (**24**), **16**, isogarcinol (**22**), (2*R*,3*S*,2″*R*,3″*R*)-GB-2 7″-*O*-*β*-D-glucopyranoside (**4**), (2*R*,3*R*)-aromadendrin-6-*C*-*β*-D-glucopyranoside (**2**), **14**, **18**, **15**, and (2*R*,3*S*,2″*R*,3″*R*)-manniflavanone 7″-*O*-*β*-D-glucopyranoside (**3**) could be identified as markers for root extract (Figure S3 in the Supporting Information).

In summary, (2*R*,3*S*,2″*R*,3″*R*)-GB-1 (**10**), (2*R*,3*S*)-morelloflavone (**12**), and (2*R*,3*S*)-volkensiflavone (**13**) were identified as the most decisive marker compounds discriminating leaf from root and stem extract. The normalized abundance (ArcSinh) of all five replicates, the mean, and SD as well as trend plots of all three organs are summarized in Figure 5 and

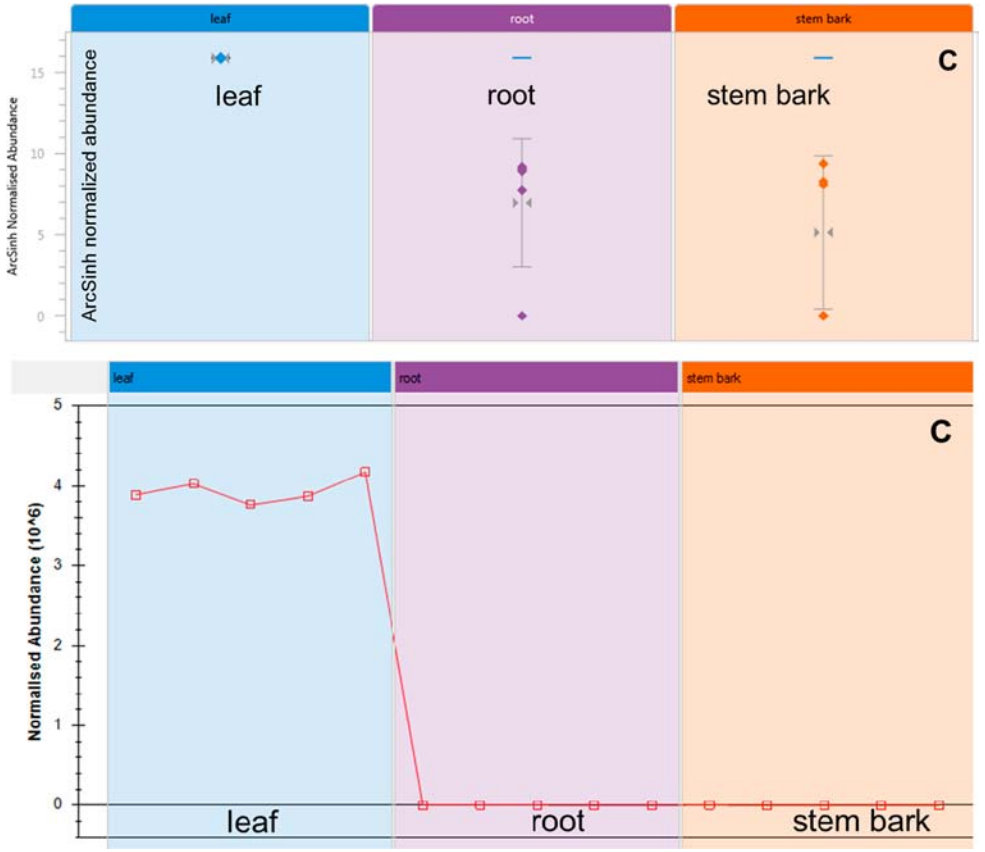

Figure 5. ArcSinh normalized compound abundance and chemometric trend plot illustrating normalized abundance (area) of (A) (2*R*,3*S*,2″*R*,3″*R*)-GB-1 (**10**), (B) (2*R*,3*S*)-morelloflavone (**12**), and (C) (2*R*,3*S*)-volkensiflavone (**13**).

in the Supporting Information for all other compounds (Figures S4−S25). On the basis of the relative abundance of the compounds, leaves represent the best organ to isolate **10**, **12**, and **13**. In fact, **12** and **13** were not detectable in root and stem bark extract (Figure 5). In contrast, the glycosides **2**, **3**, and **4** as well as isomanniflavanone (**8**) were isolated in higher yields from root extract, whereas the biflavanone-7″-*O*-glucosides **3** and **4** and **8** were not observed in leaves (Supporting Information). In general, root extract was the best organ of *G. buchananii* to isolate the described xanthones (**14**−**18**), which are hardly or not detectable in the other two organs (Supporting Information). Stem bark extract was the best source to isolate (2*R*,3*S*,2″*R*,3″*R*)-manniflavanone (**6**), and the identified or annotated polyisoprenylated benzophenones (**19**−**22** and **24**) are characteristic compounds for the leaf organ, which were hardly or not detectable in root and stem bark extracts (Supporting Information). The putatively identified polyisoprenylated xanthone hanburin (**23**), described earlier in *G. hanburyi*,[54] represents an exception compared to xanthones **14**−**18**, as the highest abundance was observable in leaves and was not detectable in the other two organs (Supporting Information).

Compounds **12**, **13**, and **21** were evaluated for their in vitro antioxidative activities using H_2O_2 scavenging, H/L-TEAC, and the H/L-ORAC assays, respectively. When compared to reference compounds ascorbic acid and quercetin, compounds **12** and **13** exhibited especially strong antioxidative capacity in both ORAC assays (Table 1). The activities of **12** and **13** in both TEAC assays (0.47/2.22 and 0.79/1.34 mmol TE/mmol) were in the range of those of ascorbic acid. (2*R*,3*S*)-Morelloflavone (**12**) showed a strong and comparable activity to quercetin in the H_2O_2 scavenging assay (12.4 μM, EC_{50}), whereas (2*R*,3*S*)-volkensiflavone (**13**) displayed almost 3-fold lower activity. The antioxidative capacity of the flavanone−flavone biflavanoids **12** and **13** is clearly lower than those of the biflavanone marker compounds **9** and **10**,[9,12] indicating a strong structure−activity relationship. Garcicowin C (**21**) revealed moderate activities comparable to those of isogarcinol (**22**) and garcinol (**24**) in all assays.[10]

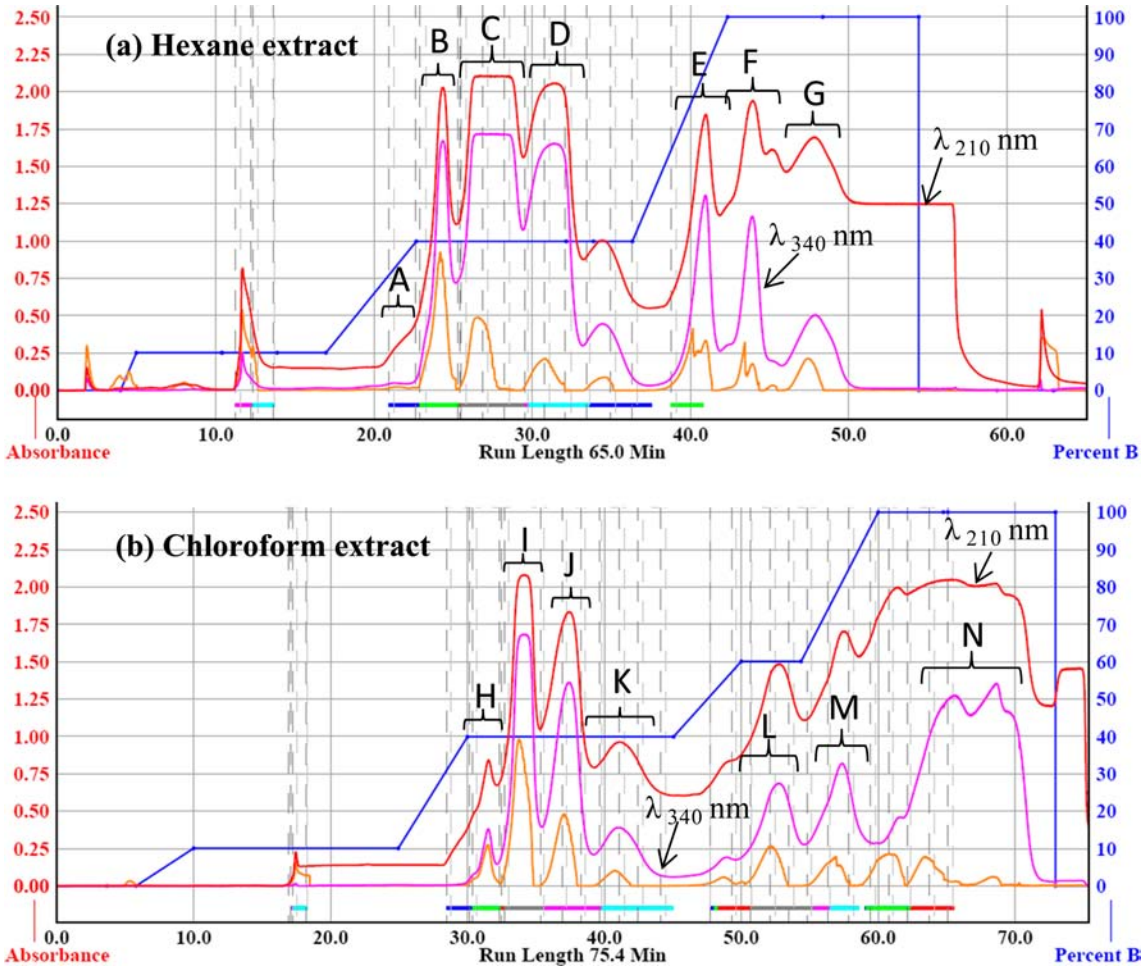

Figure 1. Flash chromatograms obtained by the separation of extracts of Miaray mandarin peel using silica gel columns. The individual peaks A–G yielded compounds **1**–**7**, and H–N yielded compounds **1**, **3**, **4**, and **7**–**10**.

including large sample volumes, a wide range of solvents, automated detection, and inline ultraviolet–visible spectral scanning (UV–vis). This improved technique enables medium-pressure liquid chromatographic separations as well as real-time monitoring of the compounds by their unique UV–vis spectral characteristics. Flash chromatography has been successfully applied for the separation and isolation of several bioactive compounds such as curcuminoids, flavonoids, and coumarins from a wide range of plant extracts and industrial by-products.[17,23,24]

The antimicrobial activity of citrus peel extracts has been intensively investigated,[25,26] but only a few studies have evaluated the effect of pure polymethoxyflavones, primarily due to commercial unavailability. Furthermore, polymethoxyflavones do not demonstrate potent bactericidal or bacteriostatic effects. For example, a recent study showed that polymethoxyflavones nobiletin and tangeretin exhibit low antimicrobial activities against six strains of microorganisms, including *Escherichia coli*, *Staphylococcus* sp., and *Salmonella typhi*.[26] An alternative mechanism to attenuate bacterial pathogenicity is interference with bacterial cell–cell communication pathways. We have previously demonstrated that several citrus limonoids and flavonoids interfere with bacterial signaling cascades, leading to attenuation of various virulence mechanisms including biofilm formation.[27−29] Our prior study showed that 3′,4′,5,6,7-pentamethoxyflavone (sinensitin) exerts biofilm inhibitory activity in a dose-dependent manner. Citrus has approximately 28 structurally distinct reported polymethoxyflavones, with variation in the number and position of the methoxyls attached to the flavone backbone.[30] These structural variants may potentially demonstrate a wide range of inhibitory activities on bacterial biofilms and help in the identification of novel antimicrobial agents.

In the present study, nine polymethoxyflavones and one limonoid were isolated for the first time from Miaray mandarins using rapid flash chromatography along with 3,5,7,3′,4′-pentamethoxyflavone (pentamethylquercetin). These compounds were characterized by spectral analysis using high-performance liquid chromatography (HPLC), matrix-assisted laser desorption/ionization-time-of-flight-mass spectrometry (MALDI-TOF), and 1D and 2D nuclear magnetic spectroscopy (NMR). All identified compounds were evaluated for their biofilm inhibitory activity using *Vibrio harveyi*.

MATERIALS AND METHODS

Plant Material. Mature *Citrus miaray* mandarin fruits (Figure S1) were harvested in December 2010 from the Texas A&M University–Kingsville Citrus Center orchard (Weslaco, TX, USA). A voucher specimen (249960) has been submitted to the S. M. Tracy Herbarium, Texas A&M University (College Station, TX, USA). The peels were separated and dried to ≤5% moisture. The peels were blended to obtain 40–60 mesh size powder in a Vita-prep blender (Vita-Mix Corp., Cleveland, OH, USA) and used for extraction.

DOI: 10.1021/acs.jafc.5b02445
J. Agric. Food Chem. 2015, 63, 7180−7189

Reagents and Instrumentation. Solvents used for analysis were of HPLC grade and obtained from Fisher Scientific (Pittsburgh, PA, USA). Nanopure water (NANOpure, Barnstead/Thermolyne, Dubuque, IA, USA) was used for HPLC analysis. The solvents used for flash chromatography were of analytical grade and purchased from Fisher Scientific. The separation of polymethoxyflavones was carried out on a flash chromatography system (Combiflash Rf, Teledyne ISCO, Lincoln, NE, USA). Silica gel (particle size 35−60 μm) columns (220 g) were purchased from ISCO Inc. (RediSep Rf ISCO Inc.).

Soxhlet Extraction of Peels. Eight hundred grams of dried peel powder was loaded into a Soxhlet-type apparatus and extracted with hexane and chloroform sequentially for 16 h each. The extracts were concentrated to obtain 31 and 23 g of hexane and chloroform extracts, respectively.

Sample Preparation and Chromatographic Separation. The hexane extract (31 g) was dissolved in 50 mL of hexane, impregnated with 20 g of silica gel, and dried at room temperature in a hood. A similar procedure was followed for the chloroform extract and used for purification. The chromatography system Teledyne ISCO CombiFlash Rf 4x system equipped with a fiber optic spectrometer, a UV−vis ($\lambda_{200\ nm}$−$\lambda_{700\ nm}$) detector, and a 220 g silica gel flash column was used for the separation. This detector can detect and monitor UV spectra of the eluent after separation from the flash column using PeakTrak 2.0.0 software.

Hexane Extract. The silica gel impregnated hexane extract of Miaray mandarin was subjected to flash chromatography on a silica gel column. The column was equilibrated with hexane for 3 column volumes prior to separations. Polymethoxyflavones were separated with a 65 min gradient program of solvent A (hexane) and solvent B (chloroform): 100% A held for 4 min, linearly increased to 10% B over 1 min, held for 12 min, linearly increased to 40% B over 6 min, held for 14 min, linearly increased to 100% B over 6 min, held for 12 min, and then finally returned to the initial conditions and held for 10 min. The flow rate was maintained at 150 mL/min, and individual fractions were collected by monitoring the eluting analytes at $\lambda_{210\ nm}$ and $\lambda_{340\ nm}$. The eluent from the column was also monitored using an inline UV−vis detector for monitoring the absorption spectra of the separating compounds. Individual peaks were tentatively identified on the basis of the distinct absorption spectrum of each fraction. Seven major peaks (A−G) were observed and collected in individual fractions (Figure 1A). The retention times of the separated peaks were as follows: peak A, 22.5−25 min; peak B, 25−29.5 min; peak C, 29.5−34 min; peak D, 34−37.5 min; peak E, 39−42 min; peak F, 42−45 min; peak G, 45−50 min. The individual peak fractions were further analyzed by HPLC and pooled on the basis of their similarity in retention time and matching UV spectral data. Evaporation of the solvent from the pooled fractions of peaks A−G yielded crystallization of compounds **1**−**5**, **8**, and **9**, respectively.

Chloroform Extract. The silica gel impregnated chloroform extract was subjected to flash chromatography on a silica gel column (220 g). The column was equilibrated with hexane for 3 column volumes prior to separations. Polymethoxyflavones were separated with a 75 min gradient program of solvent A and solvent B: 100% A held for 6 min, linearly increased to 10% B over 4 min, held for 15 min, linearly increased to 40% B over 5 min, held for 15.5 min, linearly increased to 60% B over 5 min, held for 4.5 min, linearly increased to 100% B over 6 min, held for 12 min, and then finally returned to the initial conditions and held for 2 min. The flow rate was maintained at 150 mL/min, and individual fractions were collected by monitoring the eluting analytes at $\lambda_{210\ nm}$ and $\lambda_{340\ nm}$. The eluent from the column was also monitored using an inline UV−vis detector for monitoring the absorption spectra of the separating compounds. Individual peaks were tentatively identified on the basis of the distinct absorption spectrum of each fraction. Seven major peaks (H−N) were observed and collected (Figure 1B). The retention times of the separated peaks were as follows: peak H, 30−32.5 min; peak I, 32.5−35 min; peak J, 35−39 min; peak K, 39−44 min; peak L, 51−55 min; peak M, 55−59 min; peak N, 62−70 min. Twenty microliters of each fraction was diluted with 500 μL of acetone and analyzed by HPLC for detection of polymethoxyflavones and further pooling of fractions with similar compounds. Evaporation of the solvent from the pooled fractions of peaks H−N yielded crystallized compounds **1**, **3** **4**, **5**, **6**, **7**, and **10**.

Liquid Chromatography. The HPLC system consisted of a Waters 1525 HPLC series (Milford, MA, USA) connected to a photodiode array detector. A Gemini C_{18} column (3 μm, 250 × 4.6 mm) (Phenomenex, Torrance, CA, USA) was used for the separations. A gradient mobile phase of 3 mM phosphoric acid (A) and acetonitrile (B) was used for the separations at a flow rate of 1 mL/min. Initially, elution was started with a gradient of 5% B followed by a linear increase to 50% in 20 min and then returned to 5% in 5 min. The injection volume was set at 10 μL, and the polymethoxyflavones were detected at $\lambda_{280\ nm}$ and $\lambda_{340\ nm}$. Chromatographic data were collected and processed using Empower2 software (Waters).

Matrix-Assisted Laser Desorption/Ionization-Time of Flight-Mass Spectrometry (MALDI-TOF-MS) Analysis. The samples for MS analysis were prepared by dissolving the isolated compounds (**1**−**10**) in acetonitrile and mixed with 2′,4′,6′-trihydroxyacetophenone (THAP) matrix. Half a microliter of the matrix mixture was spotted on a MALDI sample plate and air-dried. MALDI-TOF mass spectra were acquired using a Voyager DE-Pro (Applied Biosystems, Carlsbad, CA, USA) mass spectrometer in positive reflector ion mode. After time-delayed extraction of 275 ns, the ions were accelerated to 20 kV for TOF mass spectrometric analysis. A total of 100 laser shots were acquired with the signal averaged per mass spectrum.

NMR Analysis. ^{1}H and ^{13}C NMR attached proton test (APT) spectra were recorded at 400 and 100 MHz, respectively, by FT NMR (JEOL USA, Inc., Peabody, MA, USA). The isolated compounds were dissolved in chloroform ($CDCl_3$) except compound **8**, which was dissolved in deuterated dimethyl sufoxide (DMSO-d_6). Compounds **1**, **5**, **6**, **8**, and **10**) were identified by using 1D and 2D NMR data including heteronuclear single-quantum correlation spectroscopy (HSQC); heteronuclear multiple-bond correlation spectroscopy (HMBC), double quantum filter correlation spectroscopy (DQF-COSY), and nuclear Overhauser effect spectroscopy (NOSEY).

Bacterial Strains and Media. *V. harveyi* strains BB170 (luxN::Tn5), BB886 (luxPQ::Tn5), BB120 (wild-type), JAF483 (luxO D47A), and BNL258 (hfq::Tn5lacZ) were kindly provided by B. L. Bassler (Princeton University, Princeton, NJ, USA).[31−34] *E. coli* 5, an environmental isolate, was used as a positive control for autoinducer-2 (AI-2) activity.[35] Autoinducer bioassay (AB) or Luria Marine (LM) media were used to culture the *V. harveyi* strains.[36]

Growth Assay. Overnight cultures of *V. harveyi* BB120 were diluted 100-fold in AB media and treated with polymethoxyflavones (50 μM) or an equivalent volume of DMSO. The cultures were grown for 16 h, and OD_{570} was measured every 15 min by using a Synergy HT multimode microplate reader (BioTek Instruments, Winooski, VT, USA). The instrument was set to maintain a temperature of 30 °C, and plates were constantly shaken at medium speed between readings. The data are presented as the mean of three biological replicates.

Bioluminescence Assay. The bioluminescence was measured using the method described previously from our laboratory.[27] In brief, *E. coli* 5 and *V. harveyi* BB120 were cultured overnight in Luria−Bertani (LB) and LM media, respectively, to obtain high concentrations of autoinducer activity. The overnight cultures were centrifuged at 10000 rpm for 10 min in a microcentrifuge and filtered using a 0.2 μm cellulose acetate membrane filter to obtain clear cell-free supernatant (CFS). The CFSs were stored at −20 °C until use. Inhibition of autoinducer [harveyi autoinducer (HAI) and AI-2]-mediated bioluminescence was measured in a 96-well plate assay.[27] The final concentrations of polymethoxyflavones tested were 12.5, 25, and 50 μM. Diluted (2500-fold) overnight cultures (900 μL) of reporter strains BB886 (for HAI) and BB170 (for AI-2) were incubated with 5 μL of CFS, 0.5 μL of polymethoxyflavones or DMSO, and 4.5 μL of sterile Autoinducer Bioassay (AB) medium at 30 °C with shaking at 100 rpm. Light production was measured by a Victor2 1420 multilabel counter (Beckman Coulter) in luminescence mode. The values were recorded as relative light units and used for calculations. The relative activity was calculated as the ratio of luminescence of the test sample to the control (DMSO) sample.[36]

J. Agric. Food Chem. 2015, 63, 7180−7189

Biofilm Assay. The biofilm assay was conducted using the method described previously from our laboratory.[29] Briefly, an overnight culture of *V. harveyi* BB120 was diluted 1:50 in LM medium, and 190 μL of this fresh culture was incubated with 7 μL of sterile medium and 0.5 μL of DMSO or polymethoxyflavones (12.5, 25, 50 μM) dissolved in DMSO. The biofilm mass was quantified by washing with phosphate buffer (0.1 M, pH 7.4), followed by staining with 0.3% Crystal Violet (Fisher) for 20 min. The dye associated with biofilm was dissolved with 200 μL of 33% acetic acid, and A_{570} was measured. The mean ± standard deviation of three biological replicates is presented.

RESULTS AND DISCUSSION

Extraction. Successive extractions of mandarin peels using nonpolar hexane and medium-polar chloroform in a Soxhlet type apparatus yielded 3.9 and 2.9% of concentrated crude extract, respectively. HPLC analysis of the extracts (Figure S2) suggested that the extracts contain high levels of polymethoxyflavones. Additionally, the chromatograms suggested that the successive extractions with hexane and chloroform enabled fractionation of low-polar and medium-polar molecules, respectively. The individual polymethoxyflavones were purified by flash chromatography.

Purification of Polymethoxyflavones. *Hexane Extract.* The step gradient elution using hexane and acetone enabled clear separation of individual polymethoxyflavones (Figure 1a). The eluent from the column was monitored using an inline UV−vis detector to show the absorption spectra of the compounds, which were subsequently collected in fractions. The initial isocratic elution using 10% acetone separated the oil from the crude extract. After separation of the oils, the linear change in gradient elution to 60:40 hexane/acetone resulted in good separation of the low-polarity polymethoxyflavones, whereas medium-polar polymethoxyflavones were separated by the gradual increase in the solvent polarity to 100% acetone. On the basis of HPLC analysis, fractions showing similar peak profiles were pooled and concentrated under vacuum. The concentrated peak (A−G) fractions yielded crystallized compounds, which were collected, their purity was analyzed by HPLC, and they were identified by spectroscopic data.

Chloroform Extract. The impregnated chloroform extract was subjected to flash chromatographic separation using a step gradient of hexane and acetone solvents with a total run time of 75 min. To enable good separation of medium- and low-polar polymethoxyflavones, an additional step gradient of 40:60 hexane/acetone was used, followed by a linear increase to 100% acetone (Figure 1b). The step gradient elution resulted in separation of peaks H−N. Similar to the chromatographic separation of the hexane extract, the eluent from the column was monitored using an inline UV−vis detector. Individual peaks with distinct absorption spectra were collected in individual fractions. The fractions collected for individual peaks were analyzed by HPLC and concentrated to obtain crystallized compounds. These were further subjected to spectral analysis using MS and NMR to identify the compounds.

Altogether, 10 purified compounds were isolated from hexane and chloroform extracts. The yields of the isolated compounds were as follows: **1**, 18 mg; **2**, 76 mg; **3**, 8628 mg; **4**, 2012 mg; **5**, 210 mg; **6**, 121 mg; **7**, 1077 mg; **8**, 79 mg; **9**, 810 mg; and **10**, 820 mg.

Identification. The identification and structural elucidation of the isolated compounds from Miaray mandarin were conducted using spectral analysis by HPLC, MS, and NMR. The chromatograms of the HPLC analysis of the isolated compounds are presented in Figure 2. The absence of other peaks demonstrates the purity of the isolated compounds. The purity of the isolated compounds ranged between ≥95 and ≤98%. The absorption spectra of the compounds were obtained using a photodiode array detector. All of the isolated

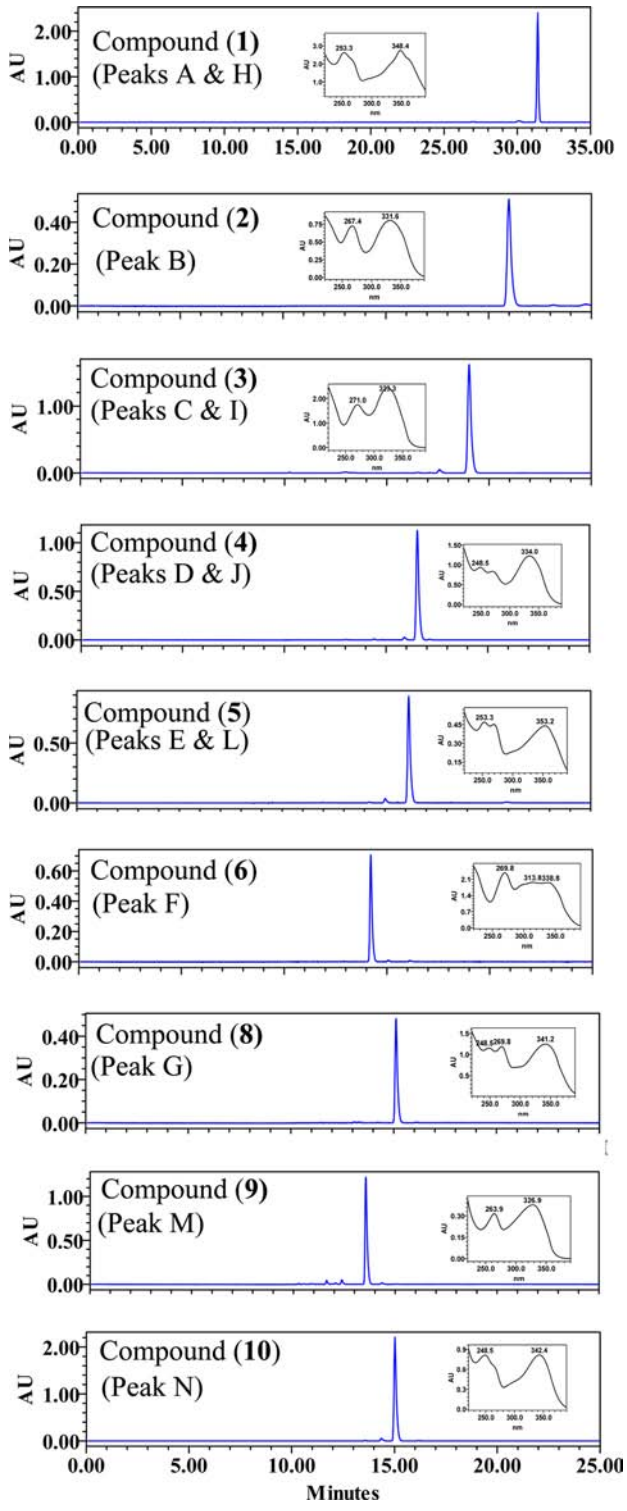

Figure 2. HPLC chromatograms of isolated compounds (**1**−**10**) along with their UV spectra. The separation was conducted on a Gemini C_{18} column using gradient mobile phase.

J. Agric. Food Chem. 2015, 63, 7180−7189

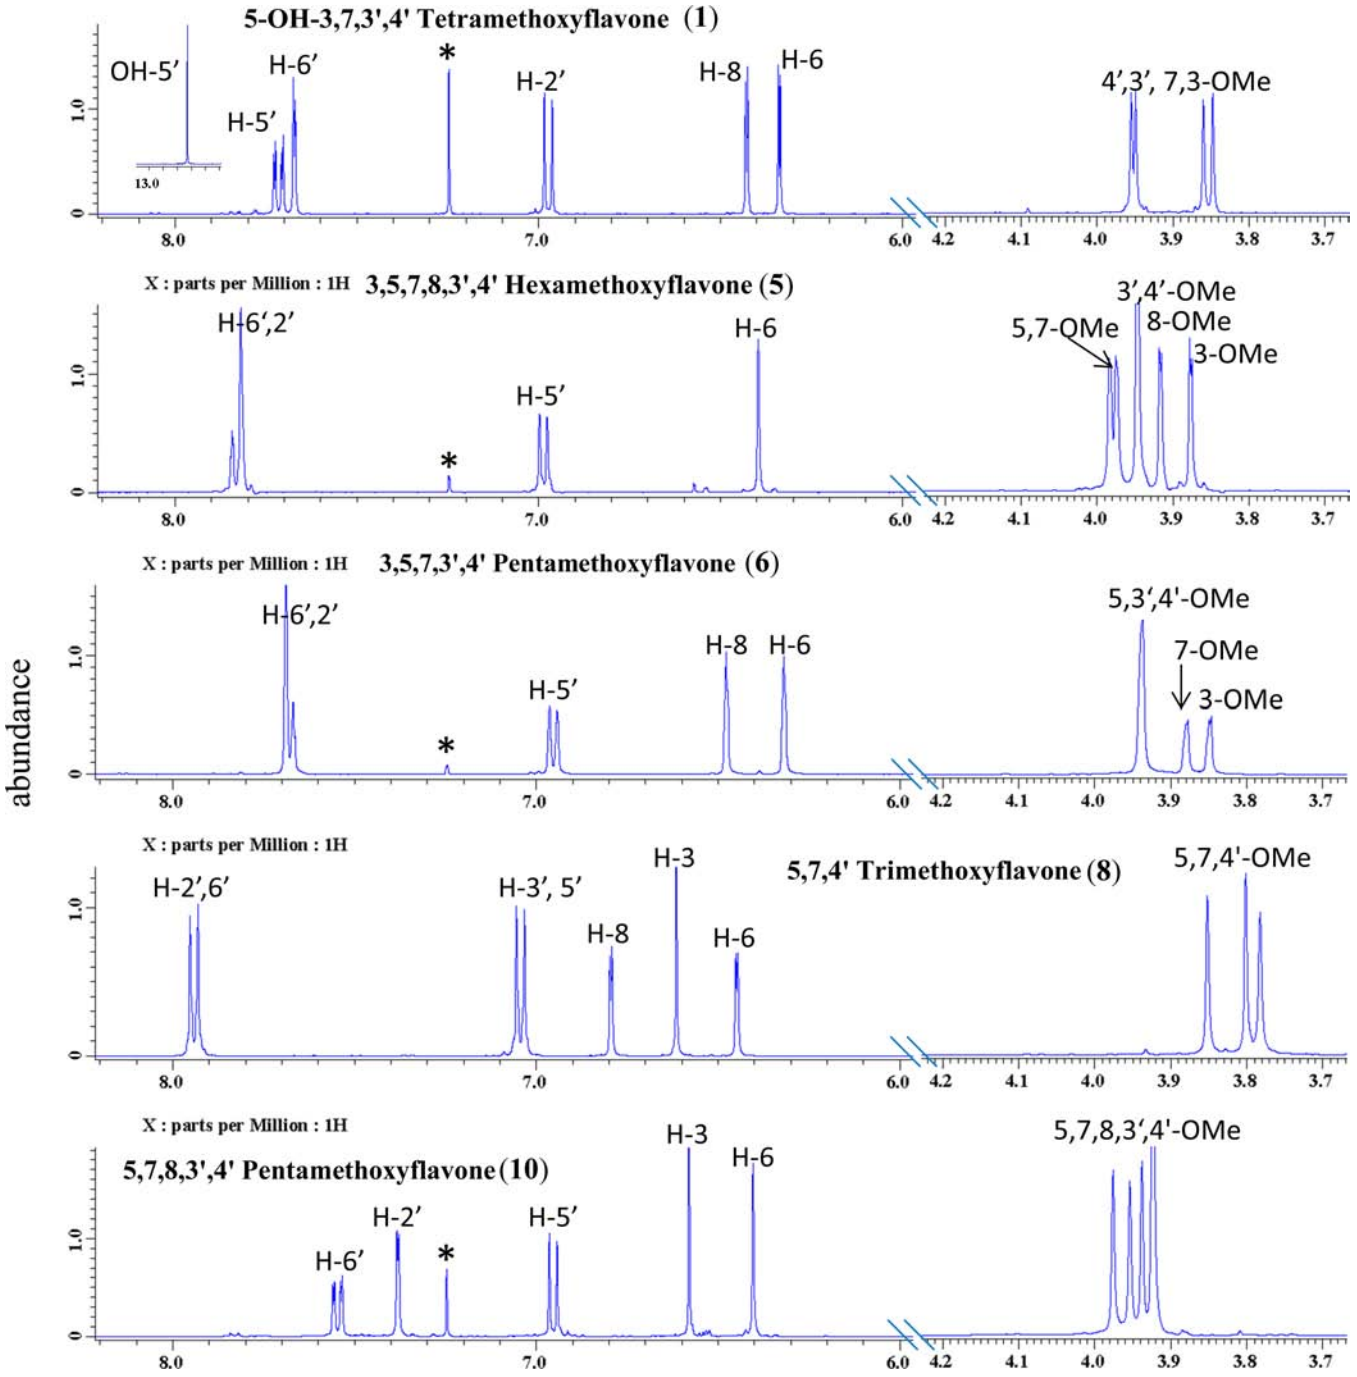

Figure 3. [1] H NMR spectra of purified compounds (**1**, **5**, **6**, **8**, and **10**) recorded on a JEOL ECS NMR spectrometer at 400 MHz. All compounds were dissolved in $CDCl_3$ except **8**, which was dissolved in DMSO-d_6. The solvent peak is denoted by an asterisk (*).

compounds had distinct UV maxima in the range of $\lambda_{325\ nm}$–$\lambda_{353\ nm}$, which is characteristic of polymethoxyflavones. The results are consistent with earlier studies.[16,37,38] The MALDI-TOF mass spectral data for compounds **2**, **3**, **4**, **7**, and **9** were found to be 373.04, 433.16, 403.31, 470.21, and 343.26, respectively (Figure S3). The NMR chemical shifts (not shown) of these compounds were matched to reported values.[16,39] Using these data, the structures of compounds **2**, **3**, **4**, **7**, and **9** were confirmed and identified as 5,6,7,8,4′-pentamethoxyflavone (tangeretin), 3,5,6,7,8,3′,4′-heptamethoxyflavone, 5,6,7,8,3′,4′-hexamethoxyflavone (nobiletin), limonin, and 5,7,8,4′-tetramethoxyflavone, respectively. The structure of tangeretin was also confirmed by 2D NMR spectral assignments (Figure S4). These data were helpful when assigning the chemical shifts of another three pentamethoxyflavones of compounds **6** and **10**.

Compounds **4** and **5** are hexamethoxyflavones, whereas compound **2**, **6**, and **10** are pentamethoxyflavones with $[M + 1]^+$ of 403 and 373, respectively. The structural confirmation is not very accurate using only mass spectral data. Therefore, we have used 1D and 2D NMR spectral data to validate the findings (Figures 3 and 4 and Figures S4–S9). ^{1}H NMR signals (Figure 3) of compounds **1**, **5**, **6**, **8**, and **10** showed at δ 3.5–4.0 and 6.3–8.0, indicating that all compounds had structures typical of polymethoxyflavones. Their characteristics and assignments were made using ^{13}C APT NMR (Figure 4) and

DOI: 10.1021/acs.jafc.5b02445
J. Agric. Food Chem. 2015, 63, 7180–7189

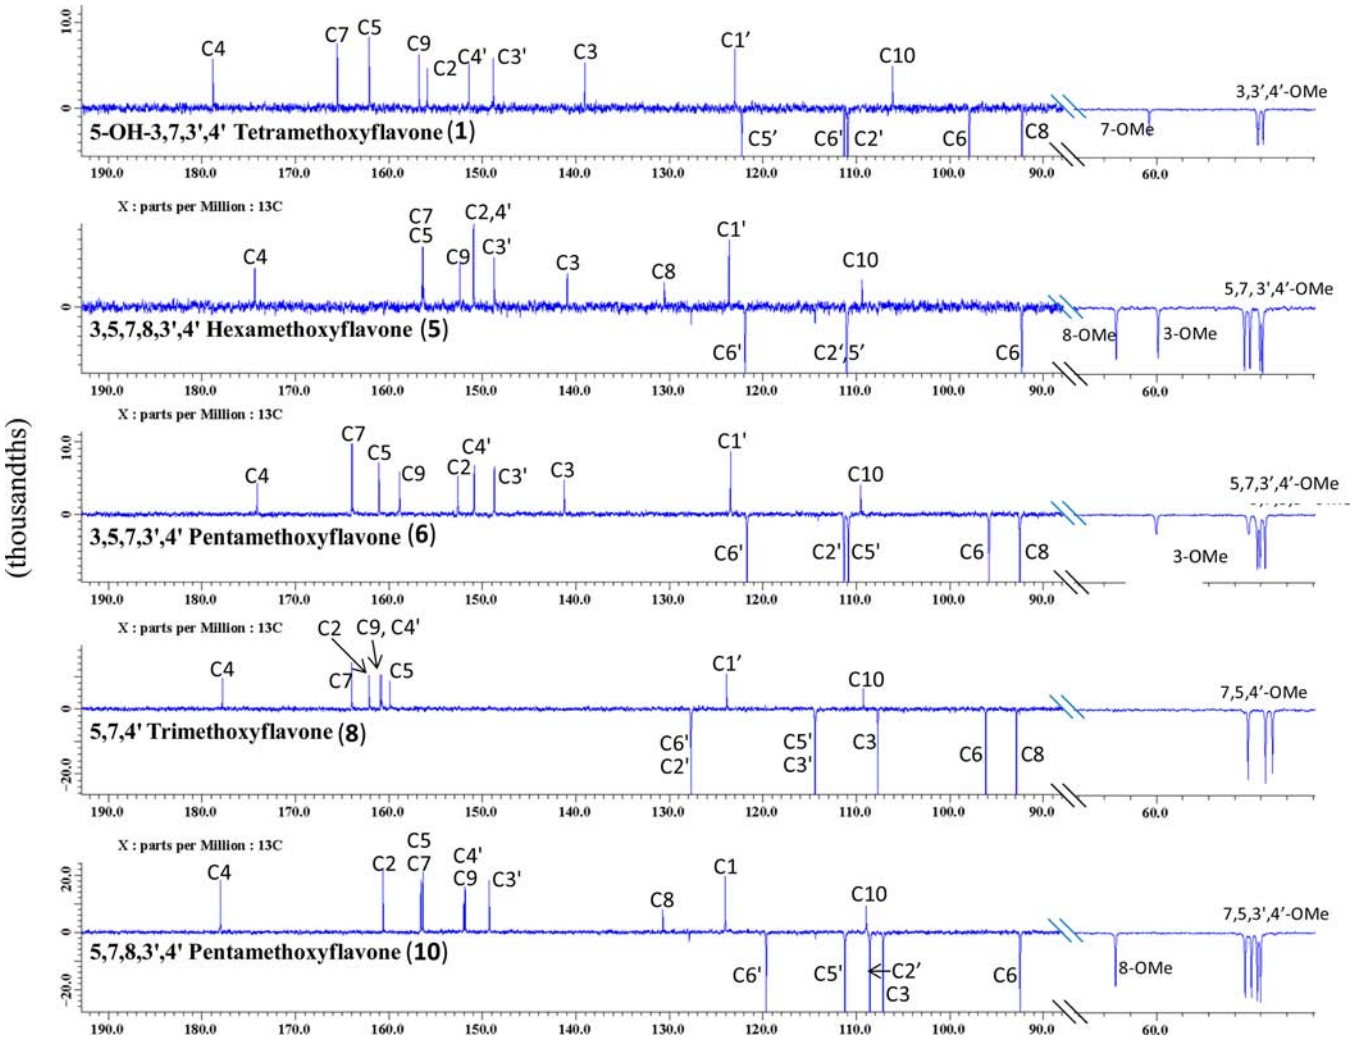

Figure 4. ^{13}C NMR attached proton test (APT) spectra of the isolated compounds (**1**, **5**, **6**, **8**, and **10**) recorded on a JEOL ECS spectrometer at 100 MHz. All compounds were dissolved in $CDCl_3$ except **8**, which was dissolved in DMSO-d_6.

2D experiments including HMBC, HMQC, DQFCOSY, and NOSEY.

Compound **1**: The presence of a downfield proton resonance at 12.5 ppm on ^{1}H NMR is a characteristic indicator of a chelated hydroxyl group at the fifth position of the flavone skeleton. Due to the presence of the hydroxyl group at C-5, the carbonyl signal at the fourth position in ^{13}C NMR showed at δ 178.5. Moreover, the lack of a resonance at δ 6.6 for the olefinic proton in ^{1}H NMR indicated that there is a substituent at the 3-position. The ^{1}H NMR spectrum showed the ABX-type aromatic proton signals indicating the existence of 1′,3′,4′-trisubstituted flavones. ^{13}C NMR showed the presence of three methyl groups at around δ 56 and one distinct signal at δ 60.2 for the 7-methoxyl group. The MALDI-TOF-MS spectrum showed the $[M + 1]^+$ at m/z 359.3011. Using these spectral data identified compound **1** as 5-hydroxyl-3,7,3′,4′-tetramethoxyflavone. The chemical shifts show good agreement with the earlier papers by Li et al.[40]

Compound **5**: The ^{1}H NMR spectrum showed the presence of six methoxyl groups at δ 3.88−3.98, and those were tentatively assigned to the 3-, 5-, 7-, 8-, 3′-, and 4′-positions. These assignments were further confirmed from ^{13}C NMR APT chemical shifts with two signals observed at low field (δ 59.9 and 61.5) for two typical methoxyl groups at 3- and 8-substitution. A sharp singlet at δ 6.4 was assigned to the sixth position, which was evidenced from the δ 92.32 signal. The B-ring proton signals showed a pattern similar to ABX coupling for three protons at H-2′, H-5′, and H-6′ (Figure S5). However, the H-2′ displayed a broad singlet due to NOE effect caused by methoxyl substitution at the C-3 position. Using these spectral data and MALDI-TOF-MS (m/z at 403.3491), compound **5** was identified as 3,5,7,8,3′,4′-hexamethoxyflavone and signals were matched to reported values.[45]

Compound **6**: The ^{1}H NMR spectrum showed the presence of five methoxyl groups, and those were shown from the ^{13}CNMR APT spectrum to be similar to compound **5**, with substitutions at 3-, 5-, 7-, 3′-, and 4′-positions. These data suggested that compound **6** is a pentamethoxylated flavonoid. In ^{1}H NMR two aromatic broad singlets at δ 6.34 and 6.48 well correlated in DQFCOSY to two different neighboring methoxy groups at δ 3.88 and 3.93, which indicates meta substitution in the A-ring (Figure S6). On the other hand, in the proton NMR spectrum, the δ 6.34 proton had a meta coupling to δ 6.48 (J = 1.8 Hz), which was assigned to H-6 and H-8. Spectra in the B-ring had ABX type aromatic proton signals, which confirms the presence of three protons, and it was confirmed by integrated area of three protons. The size of the coupling constant (J = 1.1 and 8.4 Hz) is characteristic of meta and ortho coupling as found in

DOI: 10.1021/acs.jafc.5b02445
J. Agric. Food Chem. 2015, 63, 7180−7189

3′,4′-methoxylated flavonoids, whereas such correction were not found in tangeretin due to the absence of ABX coupling (Figure S7). Moreover, proton signals for H-2′ displayed downfield at δ 7.9 as compared to PMF (**10**) due to the presence of methoxyl substitution at the C-3-position, which will cause NOE effect. A similar trend was observed for hexamethoxyflavone (**5**). Using this NMR and mass spectral data ($[M + 1]^+ - 373.3003$), we confirmed compound **6** as 3,5,7,3′,4′-pentamethoxyflavone (pentamethylquercetin). These chemical shifts were identical to those from the scientific literature.[42] This compound was previously identified in the bark extract of *Melicope subunifoliolata*.[43]

Compound **8**: The TOF-MS spectrum showed a molecular ion peak at m/z 313.2550. The ^{1}H NMR (DMSO-d_6) spectral analysis showed the presence of three methoxyl signals at δ 3.78, 3.8, and 3.86, which were confirmed in the ^{13}C NMR APT spectrum at δ 55.5, 55.9, and 56.5. Two broad singlets for one proton in the aromatic region showed the presence of two meta-coupled doublets at δ 6.38 (J = 2 Hz) and δ 6.55 (J = 2 Hz) in the A-ring for H-6 and H-8 protons. Another two ortho-coupled doublets at δ 7.05 (J = 9 Hz, 2H) and δ 7.92 (J = 9 Hz, 2H) were assigned to the B-ring (H-3′, H-5′, H-2′, H-6′) (Figure 3). This compound had one proton singlet at δ 6.61, which was assigned to the olefinic proton at H-3.[44] Thus, compound **8** was determined to be 5,7,4′-trimethoxyflavone, and the spectral data were consistent with data from the literature.[30,41]

Compound **10** had a TOF-MS m/z 373.2725 $[M + 1]^+$, which indicates the compound is a pentamethoxyflavone. The ^{1}H NMR spectrum showed the presence of five methoxyls at δ 3.91−3.99 and two proton singlets at δ 6.4 and 6.6 (Figure 3). In the APT spectrum (Figure 4), the A-ring carbon signals coincided well with those of compound **9** (tetramethoxyflavone).[17] The ^{1}H NMR spectrum revealed the presence of an ABX system for the three aromatic protons in the B-ring at H-2′, H-5′, and H-6′ as demonstrated by coupling constant signals at δ 7.39 (d, 1H, J = 1.8 Hz), δ 6.95 (d, 1H, J = 8.2 Hz), and δ 7.6 (d, 1H, J = 8.2 Hz), respectively (Figure 3 and Figure S8). These results indicate the presence of methoxyls at the 3′- and 4′-positions in the B-ring. The singlets at δ 6.58 and 6.4 were assigned to the H-3 and H-6 protons, respectively, using DQFCOSY data in Figure S8. ^{1}HNMR spectra of four pentamethoxyflavones for understanding the chemical shifts and structural assignments of all signals are presented in Figure S9. Although sinensetin is not isolated from Miaray mandarins, the spectrum was given for comparison purposes from our earlier study. Using these spectral data, compound **10** was determined to be 5,7,8,3′,4′-pentamethoxyflavone, and the chemical shifts were compared to reported data.[33,45]

In summary, results from the spectral analysis of the isolated compounds confirm the identity of the isolated compounds as 5-hydroxy-3,7,3′,4′-tetramethoxyflavone (**1**), 5,6,7,8,4′-pentamethoxyflavone (tangeretin) (**2**), 3,5,6,7,8,3′,4′-heptamethoxyflavone (**3**), 5,6,7,8,3′,4′-hexamethoxyflavone (nobiletin) (**4**), 3,5,7,8,3′,4′-hexamethoxyflavone (**5**), 3,5,7,3′,4′-pentamethoxyflavone (pentamethylquercetin) (**6**), limonin (**7**), 5,7,4′-trimethoxyflavone (**8**), 5,7,8,4′-tetramethoxyflavone (**9**), and 5,7,8,3′,4′-pentamethoxyflavone (**10**), respectively (Figure 5). The results are consistent with the reported values.[38,45,46] To the best of our knowledge, this is the first report of the isolation of 3,5,7,3′,4′-pentamethylquercetin from the genus *Citrus*. It is worth noting that this compound was previously reported in a review describing the various compounds present in citrus species by Manthey et al.[47]

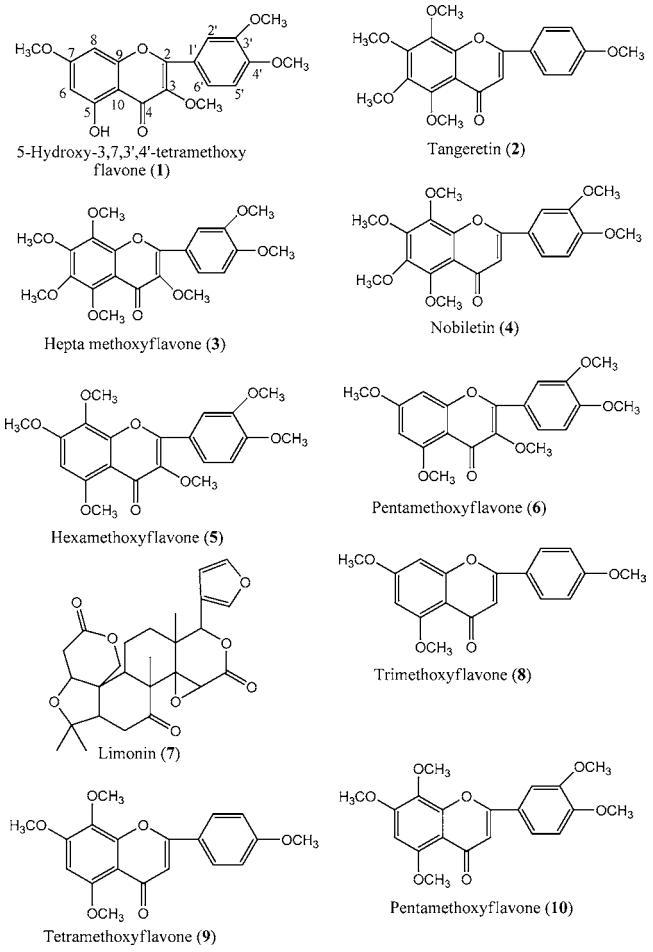

Figure 5. Structures of isolated compounds (**1**−**10**) from Miaray mandarins. Compounds **1**, **5**, **6**, **8**, and **10** were identified by NMR and mass spectral analysis as 5-hydroxy-3,7,3′,4′-tetramethoxyflavone, 3,5,7,8,3′,4′-hexamethoxyflavone, 3,5,7,3′,4′-pentamethoxyflavone (pentamethylquercetin), 5,7,4′-trimethoxyflavone, and 5,7,8,3′,4′-pentamethoxyflavone, respectively. Compounds **2**, **3**, **4**, **7**, and **9** were identified by mass spectral analysis as tangeretin, heptamethoxyflavone, nobiletin, limonin, and tetramethoxyflavone, respectively.

Antimicrobial Activity of Polymethoxyflavones. We next examined whether these compounds affect bacterial growth by treating *V. harveyi* with polymethoxyflavones. The kinetic growth curve was calculated by recording the OD_{570} for 16 h of growth at optimal temperature. Figure 6 illustrates the growth kinetics of *V. harveyi* BB120 after treatment with 50 μM of the eight polymethoxyflavones. The sigmoid bacterial growth curve observed indicates the polymethoxyflavones do not inhibit the bacterial growth at 50 μM concentration. Similar results were also observed in other studies evaluating the antimicrobial activity of polymethoxyflavones (nobiletin and tangeretin), which had minimum inhibitory concentration (MIC) of ≥1600 μg/mL,[26] suggesting that these compounds are not bactericidal.

Inhibition of Biofilm Formation and Bioluminescence. Biofilms are surface adherent colonies of bacteria that form an extracellular polymeric matrix to protect themselves. Control of biofilm formation remains a concern among medical personnel, primarily related to medical devices and implants. The bacterial biofilms in medical devices and implants are difficult to control

DOI: 10.1021/acs.jafc.5b02445
J. Agric. Food Chem. 2015, 63, 7180−7189

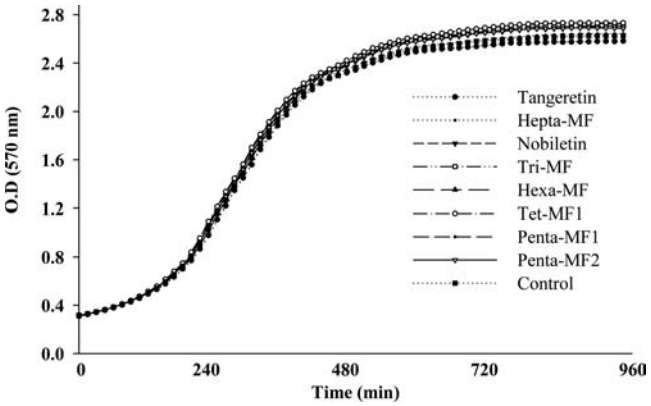

Figure 6. Growth curve of *V. harveyi* BB120 in the presence of polymethoxyflavones. The evaluated polymethoxyflavones were tangeretin, 3,5,6,7,8,3′,4′-heptamethoxyflavone (Hepta-MF), nobiletin, 5,7,4′-trimethoxyflavone (Tri-MF), 3,5,7,8,3′,4′-hexamethoxyflavone (Hexa-MF), 5,7,8,4′-tetramethoxyflavone (Tet-MF), 3,5,7,3′,4′-pentamethoxyflavone (Penta-MF1), and 5,7,8,3′,4′-pentamethoxyflavone (Penta-MF2).

due to increased antimicrobial resistance of biofilms.[48] As biofilm formation is regulated by several factors including quorum sensing, interference with the quorum sensing pathway is currently thought to be a viable strategy to control biofilms.

Quorum sensing is a population-dependent phenomenon that is mediated through the concentration of autoinducers, signaling molecules synthesized by bacteria.[49] Quorum sensing regulated bioluminescence production in *V. harveyi* and its signal transduction pathway has been well studied. The autoinducers are detected by three coincidence detectors, LuxN, LuxPQ, and CqsS, that phosphorylate LuxU, a phosphorelay protein. LuxU then phosphorylates the response regulator LuxO that in turn regulates the expression of downstream genes including bioluminescence genes.[31−34] Furthermore, interference with *V. harveyi* bioluminescence has been widely used as a model to study and identify quorum sensing inhibitors.[27−29] Panels A and B of Figure 7 illustrate the results obtained from the analysis of bioluminescence in BB886 and BB170 strains of *V. harveyi*, respectively. Among the evaluated polymethoxyflavones, only 3,5,6,7,8,3′,4′-heptamethoxyflavone and 3,5,7,8,3′,4′-hexamethoxyflavone seem to interfere with AI-2-mediated bioluminescence in BB170. The treatment of BB886 strain with polymethoxyflavones demonstrated <40% inhibition over control (DMSO).

The inhibition of bioluminescence suggests that certain polymethoxyflavones may interfere with biofilm formation. Consistent with the bioluminescence interference results, only 3,5,6,7,8,3′,4′-heptamethoxyflavone and 3,5,7,8,3′,4′-hexamethoxyflavone inhibited biofilm formation in a dose-dependent manner (Figure 8). Approximately 61% (with respect to control−DMSO treatment) of biofilm formation was inhibited by 3,5,7,8,3′,4′-hexamethoxyflavone at a concentration of 50 μM. The IC_{50} value of 3,5,7,8,3′,4′-hexamethoxyflavone was calculated to be 37.38 μM. Although 3,5,6,7,8,3′,4′-heptamethoxyflavone inhibited biofilm, the percent inhibition was approximately 35% at the maximum evaluated concentration of 50 μM. Other polymethoxyflavones did not have >35% inhibition of biofilm with respect to control.

Analyzing the bioluminescence in specific mutant strains after treatment with polymethoxyflavones may enable us to understand the possible pathway through which these

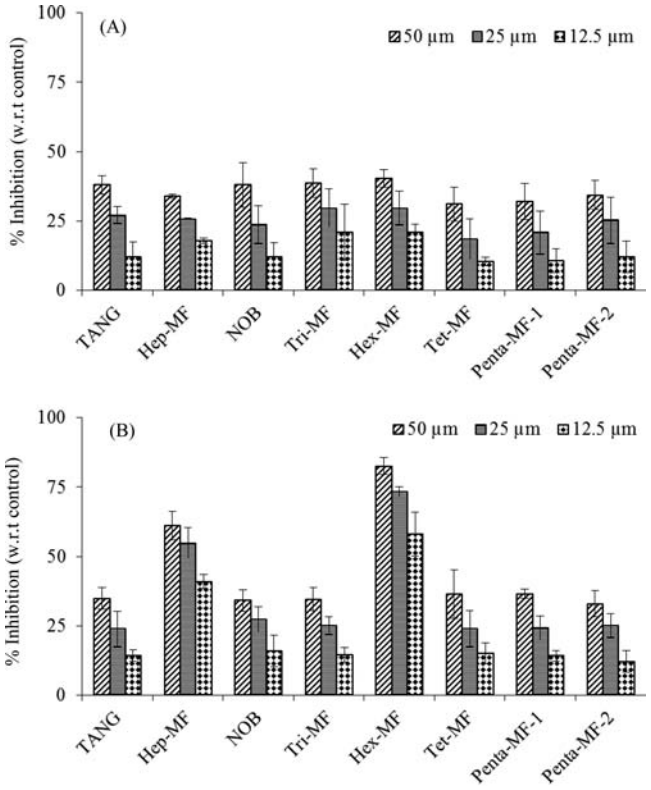

Figure 7. HAI-1 and AI-2 induced bioluminescence inhibition in *V. harveyi* BB886 (A) and BB170 in the presence of polymethoxyflavones (B). The evaluated polymethoxyflavones were tangeretin (TANG), 3,5,6,7,8,3′,4′-heptamethoxyflavone (Hep-MF), nobiletin (NOB), 5,7,4′-trimethoxyflavone (Tri-MF), 3,5,7,8,3′,4′-hexamethoxyflavone (Hex-MF), 5,7,8,4′-tetramethoxyflavone (Tet-MF), 3,5,7,3′,4′-pentamethoxyflavone (Penta-MF-1), and 5,7,8,3′,4′-pentamethoxyflavone (Penta-MF-2).

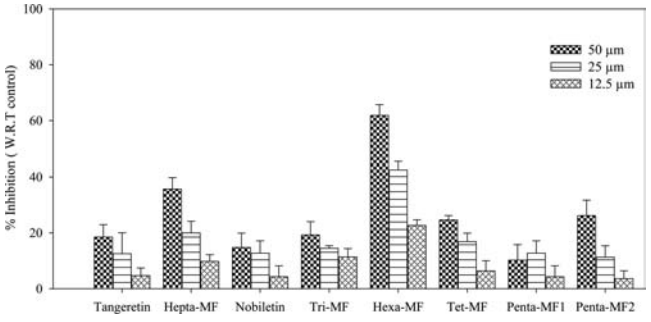

Figure 8. Inhibition of *V. harveyi* BB120 biofilm after treatment with polymethoxyflavones. The evaluated polymethoxyflavones were tangeretin, 3,5,6,7,8,3′,4′-heptamethoxyflavone (Hepta-MF), nobiletin, 5,7,4′-trimethoxyflavone (Tri-MF), 3,5,7,8,3′,4′-hexamethoxyflavone (Hexa-MF), 5,7,8,4′-tetramethoxyflavone (Tet-MF), 3,5,7,3′,4′-pentamethoxyflavone (Penta-MF1), and 5,7,8,3′,4′-pentamethoxyflavone (Penta-MF2).

compounds might inhibit biofilm formation. Therefore, constitutively luminescent *V. harveyi* mutants were investigated after treatment with 50 μM 3,5,7,8,3′,4′-hexamethoxyflavone (Figure 9). The results demonstrated an increase in bioluminescence in the *luxO* mutant strain (JAF483), but showed no change in the *hfq* mutant (BNL258), suggesting an effect on LuxO. However, further studies are needed to validate the effect on LuxO. The results indicate that 3,5,7,8,3′,4′-hexamethoxy-

DOI: 10.1021/acs.jafc.5b02445
J. Agric. Food Chem. 2015, 63, 7180−7189

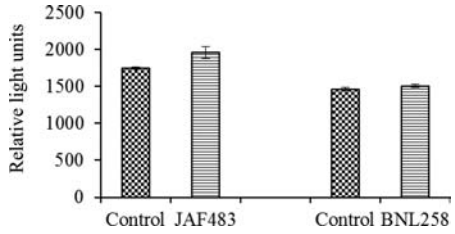

Figure 9. Bioluminescence inhibition in *V. harveyi* mutants JAF483 (*luxO*) and BNL258 (*hfq*) by 3,5,7,8,3′,4′-hexamethoxyflavone (50 μm).

flavone is a potent inhibitor of *V. harveyi* quorum sensing and appears to have larger effect on the AI-2 system. The effect on *luxO* mutants seems to suggest that 3,5,7,8,3′,4′-hexamethoxyflavone may be a nonspecific inhibitor. Further studies are required to evaluate the ability of polymethoxyflavones to interfere with quorum sensing-mediated biofilm formation in human pathogens.

In summary, 10 bioactive compounds were successfully isolated from Miaray mandarin using flash chromatography, and their structural identification was confirmed by spectral analysis using MALDI-TOF and NMR. Among the isolated compounds, 3,5,7,3′,4′-pentamethoxyflavone is reported here for the first time from *Citrus spp.*. Among the evaluated polymethoxyflavones, 3,5,7,8,3′,4′-hexamethoxyflavone demonstrated inhibitory activity on autoinducer-mediated cell−cell signaling and biofilm formation in *V. harveyi*. Further research is required to understand the role of polymethoxyflavones in the inhibition of biofilm in pathogenic bacteria. Results from this study could enable the development of strategies using polymethoxyflavones for preventing bacterial pathogenicity. Moreover, identification of potent antimicrobials from citrus species will provide added economic benefits to both producers and the citrus-processing industry.

analyze the key pathways and subcategories of the proteins that were shown to have differential expression. Our results provide fundamental information regarding the mechanism of action of the antimicrobial peptide F1.

MATERIALS AND METHODS

Bacterial Strain and Antimicrobial Peptide. The pathogenic *E. coli* ATCC 25922 was stored at the microbial culture laboratory in the College of Food Science, South China Agricultural University (Guangzhou, China). The antimicrobial peptide F1 was isolated as previously described.[24] The minimal inhibition concentration (MIC) against *E. coli* ATCC 25922 was 62.5 μg/mL.[24]

Examination of Morphological Changes of *E. coli* Caused by Antimicrobial Peptide F1. Antimicrobial peptide F1 was incubated with *E. coli* ATCC 25922 (10^8 CFU/mL) during the exponential growth phase at a final concentration of 5 MIC in Luria−Bertani (LB) broth for 2 h at 37 °C. Cells were harvested and pelleted at different time points during the incubation, including 0, 0.5, 1, and 2 h, using centrifugation at 3000*g* for 10 min. The cells were then processed as previously described, and a transmission electron microscope (Hitachi H-7000, Japan) at a magnification of 11000× was used to examine the ultrastructural changes of *E. coli* cells.[25]

Determination of Growth Rate of *E. coli*. Cultures of *E. coli* were incubated in LB broth at 37 °C on an orbital shaker set at 150 rpm. Overnight cultures were diluted to an optical density of 0.075 in LB broth and allowed to grow to an optical density of 0.25 at 600 nm, as determined using an ultraviolet spectrophotometer (Shimadzu UV-1201). The bacterial cultures, at an optical density of 0.25 at 600 nm, were then incubated either with or without antimicrobial peptide F1 at 0.8 MIC. The growth rate was determined by measuring the optical density at 600 nm every 5 min.

Extraction, Quantification and Digestion of Cellular Proteins. Cultures of *E. coli*, at an optical density of 0.25 at 600 nm, were incubated either with or without peptide F1 at 0.8 MIC for 30 min and then harvested using centrifugation at 5000*g* for 10 min at 4 °C. Total cellular protein was extracted as previously described.[26] The protein concentration was quantified using the Bradford method.[27] One hundred micrograms of total cellular protein from each treatment group was digested with Trypsin Gold (Promega, Madison, WI, USA) at a 30:1 weight ratio of trypsin to extract protein and was incubated at 37 °C for 16 h. Following the digestion with trypsin, vacuum centrifugation was done to dry the peptides.

iTRAQ Labeling and SCX Fractionation. The iTRAQ labeling method was performed as previously reported with slight modifications.[28] The dried peptide samples were dissolved in 0.5 M triethylammonium bicarbonate (TEAB). iTRAQ reagents 114 and 116 were used to label the peptide samples from the treated and control bacterial cultures, respectively. The labeled peptides were incubated at room temperature for 2 h and then pooled and dried using vacuum centrifugation. The iTRAQ-labeled peptide mixture was dissolved in 4 mL of buffer A (25 mM NaH_2PO_4 in 25% ACN, pH 2.7) and separated using an LC-20AB HPLC pump system (Shimadzu, Kyoto, Japan) with an Ultremex SCX column (4.6 × 250 mm, 5 μm, Phenomenex, Torrance, CA, USA). Elution was carried out using a linear gradient of buffer A for 10 min, 50−60% buffer B (25 mM NaH_2PO_4 and 1 M KCl in 25% ACN, pH 2.7) for 27 min, and 60−100% buffer B for 1 min. The flow rate was set at 1 mL/min, and the absorbance wavelength was 214 nm. The eluted peptides were collected every minute, pooled into 20 fractions, desalted using a Strata X C18 column (Phenomenex), and dried using vacuum centrifugation.

LC-ESI-MS/MS Analysis Based on Triple TOF 5600. The analytical separation was performed using an LC-20AD nanoHPLC (Shimadzu) coupled to a triple TOF 5600 system (AB SCIEX, Concord, ON, Canada) fitted with a Nanospray III source (AB SCIEX) and a pulled quartz tip as the emitter (New Objectives, Woburn, MA, USA). The system was equipped with a C18 trap column (5 μm, 180 μm × 20 mm) for online trapping and desalting, and a C18 column (1.7 μm, 100 μm × 100 mm) for analytical separation. During experimentation, a 10 μL (0.5 μg/μL) sample was loaded along with mobile phase A (5% acetonitrile in double-distilled water with 0.1% formic acid). Separation was achieved using a gradient of 2% mobile phase B (95% acetonitrile in double-distilled water with 0.1% formic acid) at a flow rate of 300 μL/min for 1 min, followed by a 2−35% gradient of mobile phase B for 40 min, a 35−60% gradient of mobile phase B for 5 min, a 60−80% gradient of mobile phase B for 2 min, 80% mobile phase B for 4 min, and finally 5% mobile phase B for 1 min. Data were acquired using an ion spray voltage of 2.5 kV, curtain gas of 30 psi, nebulizer gas of 15 psi, and an interface heater temperature of 150 °C.

Data Analysis. MS/MS data were matched using the Mascot search engine (Matrix Science, London, UK; version 2.3.02) against the *Ecol* 3493 (5108 sequences) database to both identify and quantify the proteins. The search parameters were set as follows: enzyme specificity was set to trypsin with one missed cleavage; potential variable modifications were Gln- > pyro-Glu (N-term Q), oxidation (M), and deamidated (NQ); fixed modifications were carbamidomethyl (C), iTRAQ8plex (N-term), and iTRAQ8plex (K); peptide mass tolerance was set to ±0.05 Da; fragment mass tolerance was set to ±0.1 Da; charge states of peptides were set to +2 and +3; and monoisotopic mass was used.

Protein identification was based on Mascot probability analysis. Peptides with significant scores ≥20 and a 99% confidence interval, indicative that matches were greater than "homology", were counted as identified.[21] Each successful protein identification involved at least one unique peptide. Only proteins that had at least two unique peptides were used for protein quantification. The quantitative protein ratios were weighted and normalized using the median ratio in Mascot. Results were considered statistically significant only if there was a 1.2-fold increase or decrease in protein expression levels ($P < 0.05$).

The Blast2GO program against the nonredundant protein database (NR; NCBI) was used in the functional annotation of the proteins. Gene Ontology (GO) annotation (http://www.geneontology.org/) and the Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway (http://www.genome.jp/kegg/) enrichment analysis were both used to determine the functional subcategories and the metabolic pathways for the differentially expressed proteins.[29,30]

Real-Time PCR. RNA was prepared from both the *E. coli* cell cultures that had been treated with peptide F1 at 0.8 MIC for 30 min and the control *E. coli* cell cultures that had been used for iTRAQ analysis. Total RNA was extracted using the E.Z.N.A. Total RNA kit II (Omega, USA) and was subsequently analyzed for both purity and total RNA content. Total RNA was reverse-transcribed into cDNA using the ReverTra Ace qPCR RT Kit (TOYOBO, Japan). The forward (F) and reverse (R) primer sequences were designed (see Supporting Information file 3 for more information), and the efficiency was confirmed using the standard curve method. Real-time PCR reactions were carried out using a Bio-Rad CFX96 Real-Time System in a total volume of 20 mL volume with 10 μL of SYBR qPCR Mix (TOYOBO), 1.0 μL of template cDNA, 1 μL (final concentration of 0.2 mM) of each primer, and PCR grade water to a final volume of 20 μL. The following procedure was used: initial denaturation at 95 °C for 1 min; followed by 40 cycles of amplification (95 °C for 15 s and 60 °C for 30 s). The fold change of selected genes was normalized to the fold change of the reference gene (16S rRNA gene). The formula $2^{-\Delta\Delta Ct}$ was used to determine the relative expression.[31] Three technical replicates and two biological replicates were done for all PCR experiments. Significant differences in the data were determined using one-way ANOVA ($P < 0.05$).

RESULTS AND DISCUSSION

Peptide F1, with a molecular weight of 2113.8 Da, was identified in our previous study as a potent bacteriocin produced by a lactic acid bacterium that was isolated from Tibetan kefir.[24] Peptide F1 was shown to potently inhibit not only Gram-negative bacteria (*E. coli*, *S. enterica*, and *S. dysenteriae*) but also Gram-positive bacteria (*S. aureus* and *B. thuringiensis*) and fungi (*A. flavus*, *A. niger*, *R. nigricans*, and *P. glaucum*), which is rarely seen among bacteriocins produced by lactic acid bacteria.[24]

DOI: 10.1021/acs.jafc.5b00678
J. Agric. Food Chem. 2015, 63, 7190−7197

Additionally, the antimicrobial activities of peptide F1 were over a wide range of stressful conditions, including a pH range between 3 and 9 for 2 h, 121 °C for 20 min, and treatments with proteases (e.g., pepsin and trypsin). To gain mechanistic insights on peptide F1 modes of action, we investigated the alterations in the morphology and global protein expression of *E. coli* induced by peptide F1.

Alteration in the Morphology of *E. coli* Induced by Antimicrobial Peptide F1. The effects of peptide F1 on the morphology of the bacterial cells were determined after treatment of the bacteria with peptide F1 at 5 MIC (MIC was previously determined[24]). Morphological alterations induced by peptide F1 treatment were visualized using transmission electron microscopy (Figure 1). The morphology of the untreated

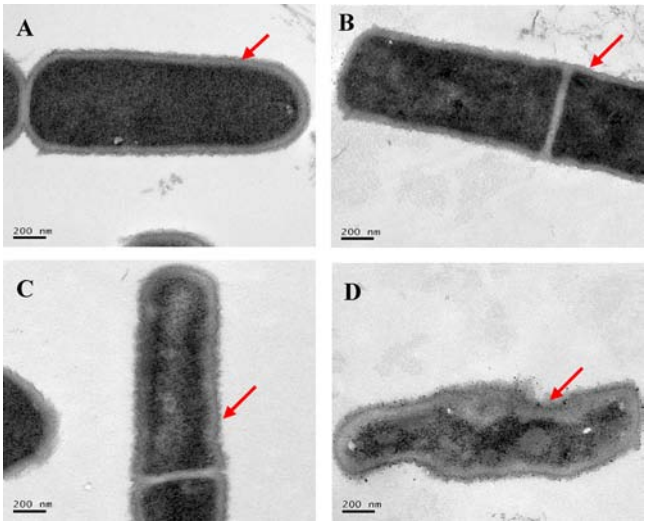

Figure 1. Transmission electron microscopic analysis of *Escherichia coli* treated with 5 MIC of peptide F1 for 0 h (A), 0.5 h (B), 1 h (C), and 2 h (D), respectively. Twenty pictures were taken for each treatment, and representative pictures are shown here.

bacteria (Figure 1A) appeared smooth with a uniform cytoplasmic region and a well-defined cell membrane. Following peptide F1 treatment for 0.5 h (Figure 1B) and 1 h (Figure 1C), the well-defined outline of the cell membrane was lost, especially at the 1 h post-treatment time point. The bacteria also became gradually smaller in size during the course of the treatment. These results were indicative of a potential cytoplasmic leakage through the damaged cell membrane, resulting in the shrinkage of the bacterial cells. Two hours of peptide F1 treatment resulted in severely deformed and partially lysed bacterial cells, with an unidentifiable cellular morphology (Figure 1D). The effects of peptide F1 on the morphology of *E. coli* were different from those previously reported for other antimicrobial peptides. For example, lactoferrin was shown to cause membrane blistering and clumping of cytoplasmic elements.[32] Peptide HLP2 resulted in a marked accumulation of electron-dense material in the periplasmic space and the outer membranes of *E. coli* cells.[7] Additionally, the HLP 2-treated *E. coli* cells showed a separation of the outer membranes at the ends of the cells or at the junction of dividing cells and blisters on the outer membrane.[33] The specific mechanism underlying the different effects of these antimicrobial peptides on *E. coli* cells warrants further investigations.

Inhibition on the Growth of *E. coli* by Antimicrobial Peptide F1. The inhibitory effects of peptide F1 on *E. coli* were investigated to determine the appropriate conditions to induce alterations in the global expression of cellular proteins. The bacteria were incubated with peptide F1 at 0.8 MIC (50 μg/mL). This lower level of the MIC, which is 62.5 μg/mL, was used to minimize bacterial cell death caused by the peptide to observe meaningful protein expression level information. As shown in Figure 2, peptide F1 caused static effects on the

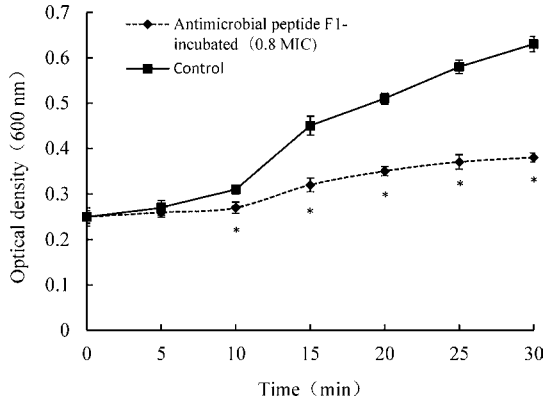

Figure 2. Growth rate of *E. coli* in the absence (control) or presence of antimicrobial peptide F1 at 0.8 MIC. (*) Statistical significance ($p < 0.01$, $n = 8$).

bacteria. After only 5 min of being treated with peptide F1, the optical density of the treated bacteria was lower in comparison to the control bacteria. After about 30 min, the optical density of treated bacteria became relatively stable. At this time point, examination of cell morphology by transmission electron microscopy revealed that there was no difference in the cellular morphology between treated and control cells. Thus, bacterial cells used to isolate cellular proteins for proteomic analysis were treated with peptide F1 at 0.8 MIC for 30 min.

Identification and GO Analysis of Proteins with Altered Expression Induced by Peptide F1. The isolated proteins were processed as described under Materials and Methods and subjected to MS/MS analysis. The MS/MS spectra of the total proteins in *E. coli* cells were processed using the Mascot software and resulted in the identification of 280 proteins (Supporting Information file 1). The expression levels of 31 proteins were shown to be significantly different (>1.2-fold change, $p < 0.05$) between treated and untreated cells. Among these proteins, 21 were up-regulated and 10 were down-regulated in the treated cells as compared to the untreated cells (Table 1). GO enrichment analysis was done to classify the cellular components, molecular functions, and biological processes that these proteins are involved in, and the results of this analysis are presented in Figure 3 (see Supporting Information file 2 for more information). The cellular component analysis revealed that most of the proteins with altered expression belong to the nitrate reductase complex, the macromolecular complex, the protein complex, the ribosomal subunit, the cytoplasmic and organelle parts, the cytosol, or the ribosome. Among the 31 differentially expressed proteins, 29 proteins have distinct molecular functions, mainly involving the binding of different factors (such as cofactors, molybdenum, and pyridoxal phosphate), enzymatic activity (such as 3′−5′ exonuclease, transaminase, nitrate reductase, oxidoreductase, transferase, and peptidase activities), catalytic activity, and act on nitrogenous compounds as donors or transfer nitrogenous groups. The biological process analysis indicated that 28 of the 31 proteins play a role in 132

different biological processes, with a high concentration of them acting in a variety of metabolic and proteolytic processes.

KEGG Pathway Analysis of the Differentially Expressed Cellular Proteins. KEGG pathway analysis was done to determine the biological pathways that the 31 differentially expressed proteins are involved in, and the results of the analysis are shown in Table 2. The results indicate that the 31 differentially expressed proteins are mainly involved in metabolic pathways, degradative pathways, and biosynthesis pathways. Additionally, these proteins were also found to be related to the two-component system, cell cycle—caulobacter, tricarboxylic acid cycle, carbon fixation, oxidative phosphorylation, homologous recombination, bacterial chemotaxis, DNA replication, ribosomes, pentose phosphate pathway, and mismatch repair. The following sections will focus on the involvement of these proteins in the four major pathways, including the tricarboxylic acid cycle, oxidative phosphorylation, glycerophospholipid metabolism, and cell cycle—caulobacter.

Roles of the Down-regulated Proteins. Among the 10 proteins that were shown to be down-regulated upon peptide F1 treatment, several of them are involved in the energy and metabolism pathways, including fumarate hydratase FumB (gi|407056449|gb|AFS76500.1|), ATP synthase F0F1 subunit α (gi|407056823|gb|AFS76874.1|), *N*-acetylglutamate synthase (gi|407052948|gb|AFS72999.1|), L-threonine aldolase (gi|407055221|gb|AFS75272.1|), nitrate reductase 2 (NRZ), β subunit (gi|407054468|gb|AFS74519.1|), and nitrate reductase 2 α subunit (gi|407054467|gb|AFS74518.1|).

Fumarate hydratase FumB is an important enzyme in *E. coli*, playing important roles in multiple metabolic pathways. One of the most important metabolic pathways related to fumarate hydratase FumB is the tricarboxylic acid cycle, which is the major cellular process involved in the generation of energy and is a common metabolic pathway in the complete oxidation of proteins, carbohydrates, and lipids (pathway ID ko00020) (Table 2). Fumarate hydratase FumB catalyzes the reaction that converts fumarate into malic acid in the seventh step of tricarboxylic acid cycle. Down-regulation of fumarate hydratase FumB inhibits the tricarboxylic acid cycle and negatively affects cellular functions. Treatment of *E. coli* with peptide F1 resulted in the down-regulation of fumarate hydratase FumB, which partly explains the inhibited cell growth observed above (Figure 2).

The ATP synthase F0F1 subunit α is an ATP synthase that has many functions, including catalytic activity, ATPase activity, hydrolase activity, pyrophosphatase activity, and transporter activity (see Supporting Information file 2 for more information). This enzyme plays an important role in the oxidative phosphorylation pathway (pathway ID ko00190). Oxidative phosphorylation serves as the main source of ATP production in the cells, during which ATP synthesis is completed by ATP synthase. ATP synthase is composed of two units, the F_O unit and F_1 unit. The spherical F1 unit is composed of five different polypeptides (α, β, γ, δ, and ε) and is an ATP multienzyme complex. The ATP synthase FOF1 subunit α is one of the ATP synthases in the multienzyme complex (α, β, γ, δ, and ε).

J. Agric. Food Chem. 2015, 63, 7190−7197

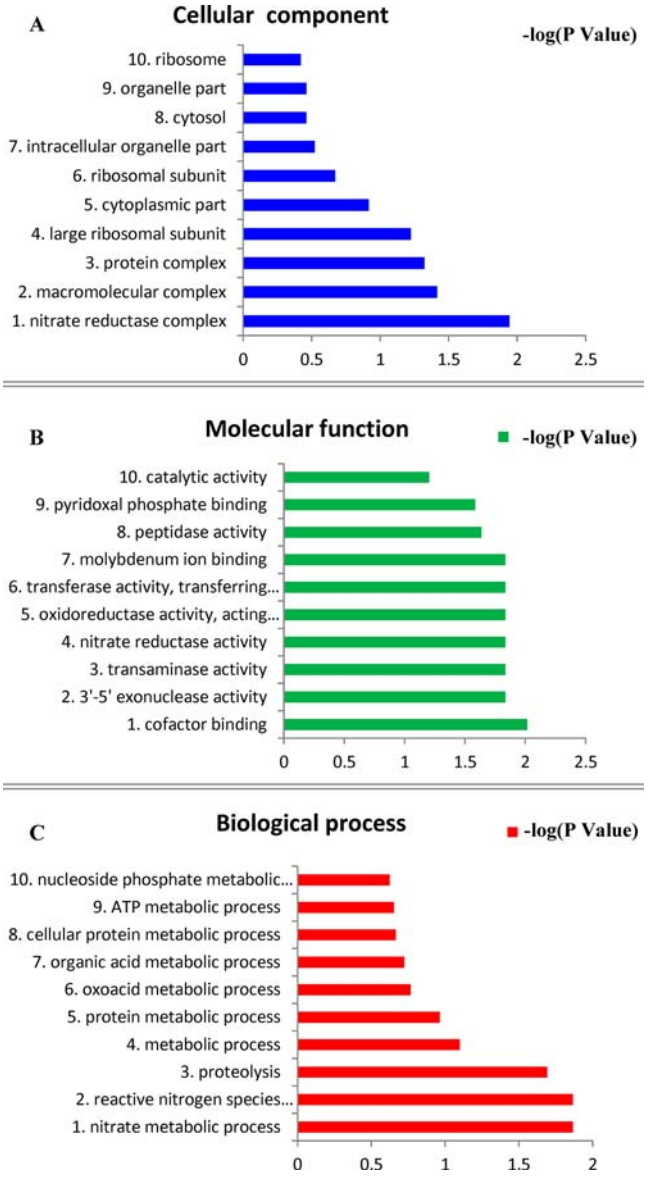

Figure 3. GO enrichment analysis of the differentially expressed proteins. The top 10 components for cellular component (A), molecular function (B), and biological process (C) of the differentially expressed proteins are presented along with their enrichment score represented as a *P* value.

Treatment with peptide F1 resulted in the down-regulation of the ATP synthase FOF1 subunit α, suggesting that treatment of peptide F1 may negatively affect oxidative phosphorylation and decrease ATP production.

Roles of Up-regulated Proteins. Among the 21 differentially expressed proteins shown to be up-regulated, several, including the putative inner membrane diguanylate cyclase (gil 407053138|gb|AFS73189.1|), DNA polymerase III subunit β (gil407051886|gb|AFS71937.1|), putative acyltransferase (gil 407056709|gb|AFS76760.1|), and ATP-dependent protease ATP-binding subunit ClpX (gil407055679|gb|AFS75730.1|), have been shown to have macromolecular degradation activity or hydrolase activity. The putative inner membrane diguanylate cyclase protein is present in both the cell membrane and the cytoplasm. This protein has been observed to have catalytic activity, signal transducer activity, molecular transducer activity, and lyase activity (see Supporting Information file 2 for more information). The primary pathways in which this protein is involved include the two-component system, cell cycle, and bacterial chemotaxis (Table 2). DNA polymerase III subunit β is a protein complex with 3′−5′ exonuclease activity, catalytic activity, nuclease activity, transferase activity, and hydrolase activity (Supporting Information file 2). The pathways this protein is primarily involved in include microbial metabolism in diverse environments; glycine, serine, and threonine metabolism; lysine biosynthesis; selenocompound metabolism; cysteine and methionine metabolism; biosynthesis of secondary metabolites; homologous recombination; DNA replication; purine metabolism; mismatch repair; metabolic pathways; and pyrimidine metabolism.

The putative acyltransferase possesses catalytic activity, transferase activity, and hydrolase activity and is capable of transferring acyl groups. Additionally, it has also been shown to be involved in pathways relating to microbial metabolism in diverse environments, benzoate degradation, ethylbenzene degradation, glycerolipid metabolism, aminobenzoate degradation, limonene and pinene degradation, glycerophospholipid metabolism, tyrosine metabolism, and metabolic pathways (Table 2). Among these pathways, the putative acyltransferase is primarily involved in the glycerophospholipid metabolism (pathway ID ko00564). Up-regulation of putative acyltransferase accelerates the catalytic conversion process of lyso-phosphatidic acid (1-acyl-*sn*-glycerol 3-phosphate) to phosphatidic acid (1,2-diacyl-*sn*-glycerol 3-phosphate) using acyl-CoA as the acyl donor. Acyl-CoA is an important enzyme that catalyzes the synthesis of cholesteryl esters from free cholesterol and long-chain fatty acids, which is closely associated with the microstructure and function of the cell membrane. Phosphatidic acid is a component of the cell membrane, as well as a predecessor of phosphatidylcholine, phosphatidylethanolamine, and other macromolecules. Phosphatidic acid or one of its metabolites may recruit or activate downstream effectors, directly inducing membrane bending and/or destabilization.[34] Up-regulation of putative acyltransferase leads to a disruption in the normal glycerophospholipid metabolic pathway, which results in changes in the lipid composition of the membrane and microstructures, affecting the normal biophysical properties of the cellular membrane. This is consistent with our finding that treatment of peptide F1 results in extensive morphological changes in *E. coli* as described above (Figure 1).

The ATP-dependent protease ATP-binding subunit ClpX, which is a heat shock protein, is also a protein disaggregation chaperone.[35,36] It has been shown to have peptidase activity, catalytic activity, and hydrolase activity. On the basis of the KEGG pathway analysis, ClpX appears to be involved only in the cell cycle-caulobacter pathway (pathway ID ko04112) (Table 2). In *E. coli*, there are two types of Clp proteases, including the ClpP proteolytic subunit and the ClpQ (or HslV) proteolytic subunit. Among them, the ClpP proteolytic subunit, along with ClpP that serves as the proteolytic core, is capable of interacting with either ClpX or ClpA.[35,37,38] In the cell cycle−caulobacter pathway, the ClpP proteolytic subunit associates with ClpX, referred to as the ClpP−ClpX protease system, which is an autolyzed system that governs normal cell division and proliferation. Up-regulation of CLpX leads to an increased ability to depredate proteins, and it also enhances the effectiveness of the ClpP proteolytic core. An autolysis system in bacterial cells has been reported that, under normal circumstances, is involved in the regulation of cell division and the elimination of unwanted cell wall components and governs the

regeneration process after damage occurs from external factors. The autolysis system consists of enzymes with muramidase activity, *N*-acetylglucosaminidase activity, amidase activity, and peptidase activity.[39] Under normal conditions, these autolytic enzymes are inhibited by the endogenous lipids, such as phospholipids and lipoteichoic acid. When an external stimuli disrupts the balance between these autolytic enzymes and the inhibitory lipids, the autolytic enzymes are activated, resulting in autolysis of the cell.[40] Our results suggested that the ClpP−ClpX protease system, acting within the cell cycle−caulobacter pathway, was activated by antimicrobial peptide F1, which subsequently resulted in the autolysis and death of *E. coli* cells. The morphological changes observed for the *E. coli* cells that had been treated by peptide F1 confirmed the process of autolysis and cell death (Figure 1).

Real-Time PCR Analysis of the Differentially Expressed Proteins. To validate the iTRAQ results, real-time PCR was used to analyze the transcripts of the proteins found to be differentially expressed (Figure 4). The mRNA transcription

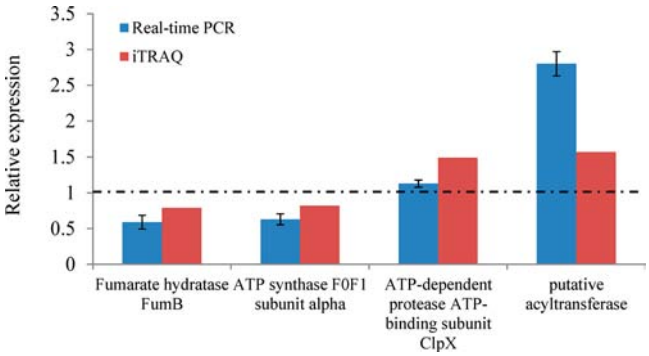

Figure 4. Comparative analysis of RNA and protein levels of specific differentially expressed proteins revealed by real-time PCR and iTRAQ.

levels were measured for four of the differentially expressed proteins, including the genes encoding for two proteins that were found to be up-regulated (ATP-dependent protease ATP-binding subunit ClpX and putative acyltransferase) and the genes encoding for two proteins that were found to be down-regulated (fumarate hydratase FumB and ATP synthase F0F1 subunit α), which include the important proteins functioning in the cell cycle−caulobacter pathway (pathway ID ko04112), glycerophospholipid metabolism (pathway ID ko00564), tricarboxylic acid cycle (pathway ID ko00020), and oxidative phosphorylation pathway (pathway ID ko00190). The expression levels of the transcripts for the two proteins found to be down-regulated were in agreement with the iTRAQ data, which indicated that the two genes displayed both similar protein and mRNA expression patterns and similar overall quantitative values. The mRNA level for the gene of the ATP-dependent protease ATP-binding subunit ClpX, in which the protein level had been found to be increased, was also increased by 1.13-fold, which is similar to the 1.486-fold increase in the protein expression level as determined from the iTRAQ analysis. The mRNA level of the putative acyltransferase was significantly increased by 2.81-fold, which is higher than the 1.572-fold increase in the protein expression level as determined from the iTRAQ analysis. The real-time PCR results demonstrated that these genes displayed similar protein and mRNA expression patterns with similar or slightly divergent overall quantitative values.

In conclusion, our findings revealed that upon treatment of *E. coli* with the antimicrobial peptide F1, there is a comprehensive global protein response characterized by the down-regulation of major catalytic enzymes involved in energy metabolism and the up-regulation of proteins with peptidase activity, catalytic activity, and hydrolase activity. The inhibitions of the tricarboxylic acid cycle pathway and the oxidative phosphorylation pathway were potentially associated with the observed decrease in cell growth and cell death. The promotion of the glycerophospholipid metabolic pathway and the cell cycle−caulobacter pathway potentially increased the permeability of the cellular membrane, resulting in the autolysis of the cellular structures, which may result in cell death. Overall, our study provides novel insights into the mechanisms underlying the mode of action of the antimicrobial peptide F1.

Soybean, *Glycine max*, is a source of dietary protein and oil and contains various phenolic compounds with biological activity. Although soybeans are used as a food source, soy leaves are also consumed in some parts of Asia. In the Gyungsang-do province of Korea, soy leaves are used to prepare traditional dishes, including *jangachi* and *kimchi*. Many studies have reported the

DOI: 10.1021/acs.jafc.5b01639
J. Agric. Food Chem. 2015, 63, 7198−7210

health benefits of soybeans; however, evidence of health benefits from soy leaves is limited, although they can exert effects on serum lipid profile,[8,9] carotid arteries,[10] in vitro α-glucosidase activity,[11,12] and diabetes.[13−16] Soy leaves contain isoflavonols (kaempferol and its glycosides), isoflavones (daidzin, genistin, and malonyl-genistin),[10] pterocarpans (glyceofurans, coumestrol, isotrifoliol, and phaseol),[11,12] and pheophorbides, products of chlorophyll breakdown. We previously demonstrated that pterocarpan-enriched soy leaf extract improved glucose homeostasis by enhancing insulin sensitivity and pancreatic β-cell proliferation in high-fat diet (HFD)-induced type 2 diabetic mice.[16] A kaempferol glycoside (KG)-rich fraction from unripe soy leaves decreased fasting blood glucose and glycated hemoglobin (HbA1c) levels and regulated lipid metabolism in KK-A^y and HFD-fed mice.[14,15] A recent study reported that soy leaf extracts have beneficial effects on fasting blood glucose, HbA1c, and homeostasis model assessment of insulin resistance (HOMA-IR) levels, as well as adiposity and dyslipidemia, in prediabetic patients.[13] However, these studies did not fully investigate the mechanisms or active components. In this study, we used obese diabetic *db*/*db* mice to verify the antidiabetic effect of ethanol extract of soy leaves (ESL) containing KGs and pheophorbides and to study the mechanisms focusing on these effects in enhancing IRS-mediated β-cell insulin signaling and suppressing hepatic lipid accumulation. Furthermore, we investigated the active components of ESL and their mechanisms in MIN6 pancreatic β-cells.

MATERIALS AND METHODS

Chemicals and Reagents. Glucose, kaempferol, and pheophorbide *a* (PA) were obtained from Sigma-Aldrich (St. Louis, MO, USA). Anti-fatty acid synthase (FAS), anti-phospho-Akt, anti-Akt, anti-phospho-FoxO1, and anti-FoxO1 antibodies were purchased from Cell Signaling Technology (Danvers, MA, USA), and anti-insulin, anti-sterol regulatory element-binding protein (SREBP)-1, anti-phospho-protein kinase A (PKA), anti-PKA, and anti-β-actin antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA).

Diaion HP-20 resin (250−850 μm Mitsubishi Chemical Corp., Tokyo, Japan), flash octadecyl SiO_2 (ODS) (Biotage SNAP Cartridge KP-C18-HS, 9.5 × 15 cm; Biotage, Charlottesville, VA, USA), RP-18 silica gel (ODS-A, 12 nm, S-150 μm; Merck, Darmstadt, Germany), and Sephadex LH-20 (25−100 μm; GE Healthcare Biosciences, Uppsala, Sweden), Sep-Pak C18 (Waters, MA, USA), and ODS prep-HPLC columns (Cosmosil 5C18-MS-II column, 10 × 150 mm or 10 × 250 mm, 5 μm; Nacalai Tesque, Inc., Kyoto, Japan) were used for column chromatography. All solvents used for extraction and isolation were of analytical grade. All purifications were monitored on commercially available glass-backed Merck precoated TLC plates and visualized under UV at 254 and 365 nm or stained with *p*-anisaldehyde solution.

Preparation and HPLC Analysis of ESL. Soybeans, *G. max* (L.) Merr., were cultured in JeungPyeong county (Chungcheongbuk-do, Korea) for 80 days. The air-dried leaves (500 g) were chopped and extracted twice with 70% ethanol (5 L) at room temperature for 48 h. The extract was filtered and evaporated to dryness under reduced pressure at a temperature below 40 °C to afford ESL (112 g).

The main components present in ESL were analyzed and confirmed using a Shimadzu HPLC system equipped with a binary pump delivery system, a diode array detector (DAD), and an autosampler (Shimadzu Corp., Tokyo, Japan) and a Brownlee SPP C18 column (4.6 × 100 mm, 2.7 μm; PerkinElmer, Inc., Waltham, MA, USA). The injection volume was 5 μL, and the mobile phase was 0.1% acetic acid in water (solvent A) and acetonitrile (solvent B). The linear gradient elution program was as follows: 5−40% B for 0−40 min, 40−100% B for 40−50 min, 100% B for 50−55 min, and 5% B for 55−60 min. The flow rate was 1.4 mL/min, and the absorbance was 345 nm. KGs **1**−**5**, which were isolated from ESL, and PA, which was obtained from Sigma-Aldrich, were used as external standards for the HPLC analysis.

Isolation and Identification of KGs and Phoephorbides. The 70% EtOH extract of air-dried leaves (500 g) was concentrated under reduced pressure, and the ESL, as an aqueous suspension, was subjected to Diaion HP-20 absorption column chromatography (CC) (9.5 × 20 cm). The column was washed with H_2O to remove unabsorbed materials and subsequently eluted with 30, 50, 70, and 100% aqueous MeOH (v/v) to yield four fractions (A−D). Fractions that were rich in KGs (A and B), as evidenced by HPLC DAD monitoring, were combined (23.2 g) and separated using ODS flash CC (Biotage SNAP cartridge KP-C18-HS, 9.5 × 15 cm) by eluting with aqueous MeOH (10, 20, 30, 40, 50, and 70% MeOH, v/v). Six fractions (AB-1−AB-6) were produced. The KG-rich fractions AB-1 and AB-2 were combined (9.0 g) and further purified using Sephadex LH-20 CC (5.0 × 90 cm) and eluted with 50% MeOH to yield five subfractions (S-1−S-5). Subfraction S-3 was subjected to CC on Sep-Pak C18 and eluted with 20% MeOH, followed by separation by reversed-phase (RP) preparative HPLC (Cosmosil 5C18-MS-II column, 10 × 150 mm, 5 μm; 254 nm; 11% aqueous acetonitrile; 4 mL/min) to afford compounds **1** (17.5 mg) and **2** (19.2 mg). Subfraction S-4 was also separated by RP preparative HPLC and eluted with 12% aqueous acetonitrile to afford compound **3** (14.9 mg). Subfraction S-5 was subjected to CC on Sep-Pak C18, eluted with 20−25% aqueous MeOH, and then separated by RP preparative HPLC and eluted with 11% aqueous acetonitrile to afford compounds **4** (15.6 mg) and **5** (8.0 mg). Isolated KGs were identified using the UV spectra gathered during HPLC DAD monitoring (Figure 1A−C), ^{1}H and ^{13}C NMR data (Supporting Information, Tables S1 and S2), and ESI-MS data and were consistent with previously reported data.[14,17,18] For chemical structure elucidation of KGs **1**−**5**, see the Supporting Information.

Pheophorbide-rich fraction D (10.6 g) was identified using HPLC DAD monitoring and applied to RP-18 silica gel (5.0 × 29 cm); it was eluted with 80 and 100% MeOH and $CHCl_3$/MeOH (1:9, v/v) to produce 15 fractions (D-1−D-13). Subfraction D-5 (1.35 g) was eluted with 100% MeOH and was further separated using RP preparative HPLC (Cosmosil 5C18-MS-II column, 10 × 250 mm, 5 μm; 410 nm; mobile phase A, 0.1% acetic acid in water; mobile phase B, acetonitrile) to afford compounds **7** (T_R = 37.3 min, 20.9 mg) and **7′** (T_R = 39.1 min, 6.1 mg). The linear gradient elution program was as follows: 5−80% B for 0−15 min, 80−95% B for 15−30 min, 95−100% B for 30−40 min, 100% B for 40−50 min, and 100−5% B for 50−60 min; the flow rate was 3 mL/min. PA was identified on the basis of the spectroscopic data (Supporting Information, Figure S1), which were consistent with those previously reported.[19−21] For chemical structure elucidation of PA, see the Supporting Information.

Animals and Diets. Five-week-old male C57BLKS/J lar-Lepr^{db}/Lepr^{db} (*db*/*db*) and C57BLKS/J lar-m$^+$/Lepr^{db} (*db*/+) mice purchased from Japan SLC (Shizuoka, Japan) were kept at a constant temperature (25 ± 2 °C), humidity (50 ± 5%), and lighting (12 h light/dark cycle) at the Korean Research Institute of Bioscience and Biotechnology (KRIBB, Daejeon, Korea). After 2 weeks of acclimation, the *db*/*db* mice were randomly divided into two groups (n = 8 per group). The *db*/+ and *db*/*db* control groups were fed a standard diet (AIN-76A diet, Research Diets, Inc., New Brunswick, NJ, USA) with no supplement, and the *db*/*db*-ESL group was fed a standard diet with 1% (wt/wt diet) ESL for 8 weeks. Animal study protocols were approved by the Animal Care Committee of KRIBB (KRIBB-AEC-11101).

Oral Glucose Tolerance Test (OGTT). The OGTT was performed 7 weeks after initiation of the animal experiments. Mice were fasted for 6 h and then orally administered glucose (1 g/kg body weight).[22] The blood glucose level was measured in tail vein blood at 0, 15, 30, 60, and 90 min postglucose injection using a glucometer (Accu-Check Active; Roche, Mannheim, Germany).

Measurement of Metabolic Parameters. For analyses of all metabolic parameters, see previous papers.[16,23] Hepatic TG contents were determined using the methods described by Folch et al.[24] Plasma tumor necrosis factor α (TNFα) levels were measured by mouse ELISA kits (Enzo Life Sciences, Inc., Farmingdale, NY, USA).

Histological Analysis of the Pancreas and Liver. Freshly isolated pancreas and liver tissues were fixed for histopathological

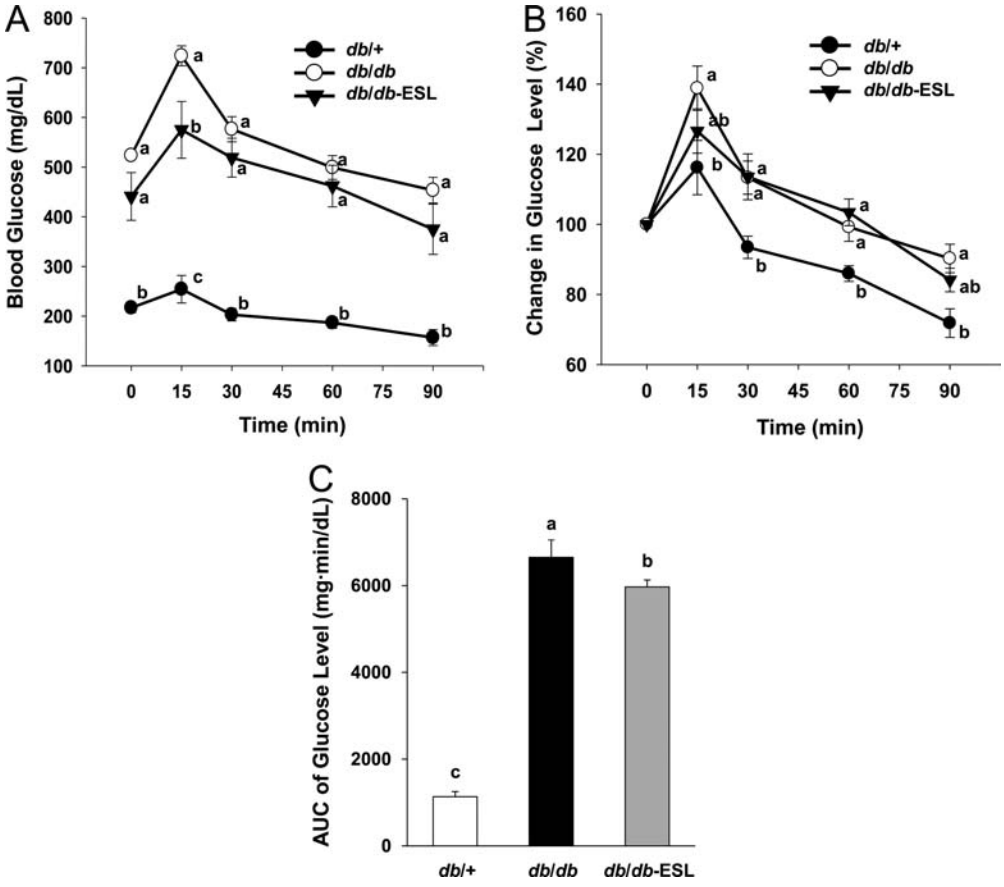

Figure 2. Effect of ESL supplementation on OGTT in *db*/*db* mice. The OGTT was performed in the seventh week after the start of the animal experiments. (A) Changes in glucose levels after glucose (1 g/kg body weight) administration. Blood glucose level was measured in tail vein blood at 0, 15, 30, 60, and 90 min. (B) Percentage of changed glucose levels during the OGTT. The glucose levels were expressed in percentage change in glucose level at 0 min. (C) Area under the curve (AUC) of plasma glucose during OGTT. Values are presented as the mean ± SE. Different letters (a−c) within a variable are significantly different at $p < 0.05$.

analysis.[16,23] Stained section images per each sample were obtained using an Olympus BX61 with an Olympus DP71 digital camera (Tokyo, Japan) and Metamorph imaging software (Molecular Devices, Sunnyvale, CA, USA).

Pancreatic Insulin Content. Pancreases were cut in half and weighed; insulin was then extracted using 70% EtOH solution containing 1.5% HCl.[16] Insulin content was determined by ELISA kit (Alpco Diagnostics, Salem, NH, USA) and calculated by tissue weight.

Real-Time Quantitative RT-PCR (qRT-PCR). For detection of gene expression, see previous papers.[16,23] Results were normalized using glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) as a reference gene. The primer sequences used in the experiments are shown in Table 1.

Western Blot Analysis. For detection of protein expression, see previous papers.[23] Mouse pancreas, liver, and total cell extracts were subjected to immunoblot analysis with antibodies against phospho-FoxO1, FoxO1, FAS, SREBP-1, phospho-Akt, Akt, phospho-PKA, and PKA.

MIN6 Cell Culture and Insulin Secretion Test. MIN6 pancreatic β-cells were cultured in Dulbecco's modified Eagle's medium (DMEM), containing 25 mM glucose, 15% fetal bovine serum, 100 U/mL penicillin, and 100 U/mL streptomycin at 37 °C in a 5% CO_2 atmosphere. To measure glucose-stimulated insulin secretion, MIN6 cells were seeded into a 24-well plate and grown for 48 h. Medium was removed from the cells, and the cells were washed twice and pre-incubated for 1 h. Cells were then treated with medium containing low (3 mM) and high (30 mM) glucose levels, with or without compounds, and incubated for 1 h. After incubation, the medium was stored at −20 °C until insulin measurement.

Statistical Analyses. Data from tissue and plasma are presented as the mean ± SE. Significant differences among the groups were assessed by one-way ANOVA with Tukey's post hoc test by using JMP software (SAS Institute Inc., Cary, NC, USA). Data from MIN6 cell experiments are expressed as the mean ± SD and analyzed by using Student's *t* test. A p value <0.05 was considered significant.

RESULTS AND DISCUSSION

HPLC Analysis of KGs and Pheophorbides in ESL. ESL and standard compounds were analyzed using HPLC DAD at 345 nm (Figure 1A,B). ESL primarily contained KGs and pheophorbides; the total peak area percentages of KGs **1**−**5** and pheophorbides **6**−**8** were 50.4 ± 2.8 and 23.2 ± 1.2%, respectively. The five KGs were identified as kaempferol 3-*O*-β-D-glucopyranosyl(1→2)-*O*-[α-L-rhamnopyranosyl(1→6)]-β-D-galactopyranoside (**1**), kaempferol 3-*O*-β-D-glucopyranosyl-(1→2)-*O*-[α-L-rhamnopyranosyl(1 → 6)]-β-D-glucopyranoside (**2**), kaempferol 3-*O*-(2-*O*-β-D-glucopyranosyl)-β-D-galactopyranoside (**3**), 3-*O*-(2,6-di-*O*-α-L-rhamnopyranosyl]-β-D-glucopyranoside (**4**), and kaempferol 3-*O*-β-D-glucopyranosyl-(1→2)-β-D-glucopyranoside (**5**). The chlorophyll derivatives were identified as pheophorbide *a* (PA, **7**), pheophorbide *a*′ (**7**′) and other pheophorbides (**6**, **8**). Figure 1 shows that compounds **1** and **2** were most abundant KGs in ESL on the basis of the peak area of standard compounds (Figure 1A,B). The contents of KGs **1** and **2** and PA in ESL were measured using HPLC DAD with their own standard curves. The contents of KG1, KG2, and PA were 30.60 ± 1.26, 16.41 ± 0.03, and 14.54 ± 0.57 μg/mg ESL, respectively (Supporting Information, Table S3 and Figure S2).

ESL Improved Glucose Tolerance. The OGTT was used to evaluate pancreatic β-cell insulin secretion and tissue insulin sensitivity. The *db*/*db* group showed impaired glucose tolerance, as compared to age-matched *db*/+ group (Figure 2). In human and rodent physiology, insulin secretion reaches a peak in the first phase (approximately 5−10 min), followed by a sustained second phase of release, during which insulin pulses are secreted over 3−8 min.[25] The 6 h fasting glucose levels at week 7 were lower in the *db*/*db*-ESL group (15.8%) than in the *db*/*db* group (Figure 2A). In the OGTT, the glucose levels of all groups reached individual peaks at 15 min and then declined gradually. ESL supplementation markedly reduced early-phase blood glucose levels. The glucose levels at 15 min were significantly lower in the *db*/*db*-ESL group (20.6%) than in the *db*/*db* group (Figure 2A), and the change in glucose level at 15 min, as compared to 0 min, was also decreased in the *db*/*db*-ESL group (15.8%, Figure 2B). Finally, the area under the curve (AUC) of the blood glucose levels revealed that ESL significantly improved glucose tolerance (Figure 2C).

ESL Improved Plasma Profiles. At the end of the experiment, *db*/*db* mice showed hallmark characteristics of T2DM models. The body weight, food intake, organ weight (liver, pancreas, muscle, abdominal adipose, and inguinal adipose), and all plasma levels (glucose, HbA1c, insulin, FFA, TC, TG, GOT, and GPT) were significantly higher in the *db*/*db* group, as compared to the *db*/+ group. ESL had no effect on body weight gain, food intake, and the organ weights of the liver, muscle, and WAT (abdominal and inguinal adipose tissues). However, ESL supplementation increased pancreatic tissue weight 25% versus the *db*/*db* group, although this change was not significant (Table 2). The plasma glucose and HbA1c levels were significantly lower in the *db*/*db*-ESL group (23.1 and 21.2%, respectively) than in the *db*/*db* group (Table 3). These results indicate that ESL improved glucose tolerance. Fasting plasma insulin concentrations in *db*/*db* mice are significantly increased, indicating insulin resistance.[26] Plasma insulin levels in ESL-treated mice were slightly decreased. The HOMA-IR index of the *db*/*db* group was dramatically higher than that of the *db*/+ group. ESL supplementation also significantly decreased the HOMA-IR index, although the value was still high. Therefore, the *db*/*db*-ESL group still exhibited hyperinsulinemia to compensate for the sustained severe hyperglycemia. Additionally, plasma TG levels

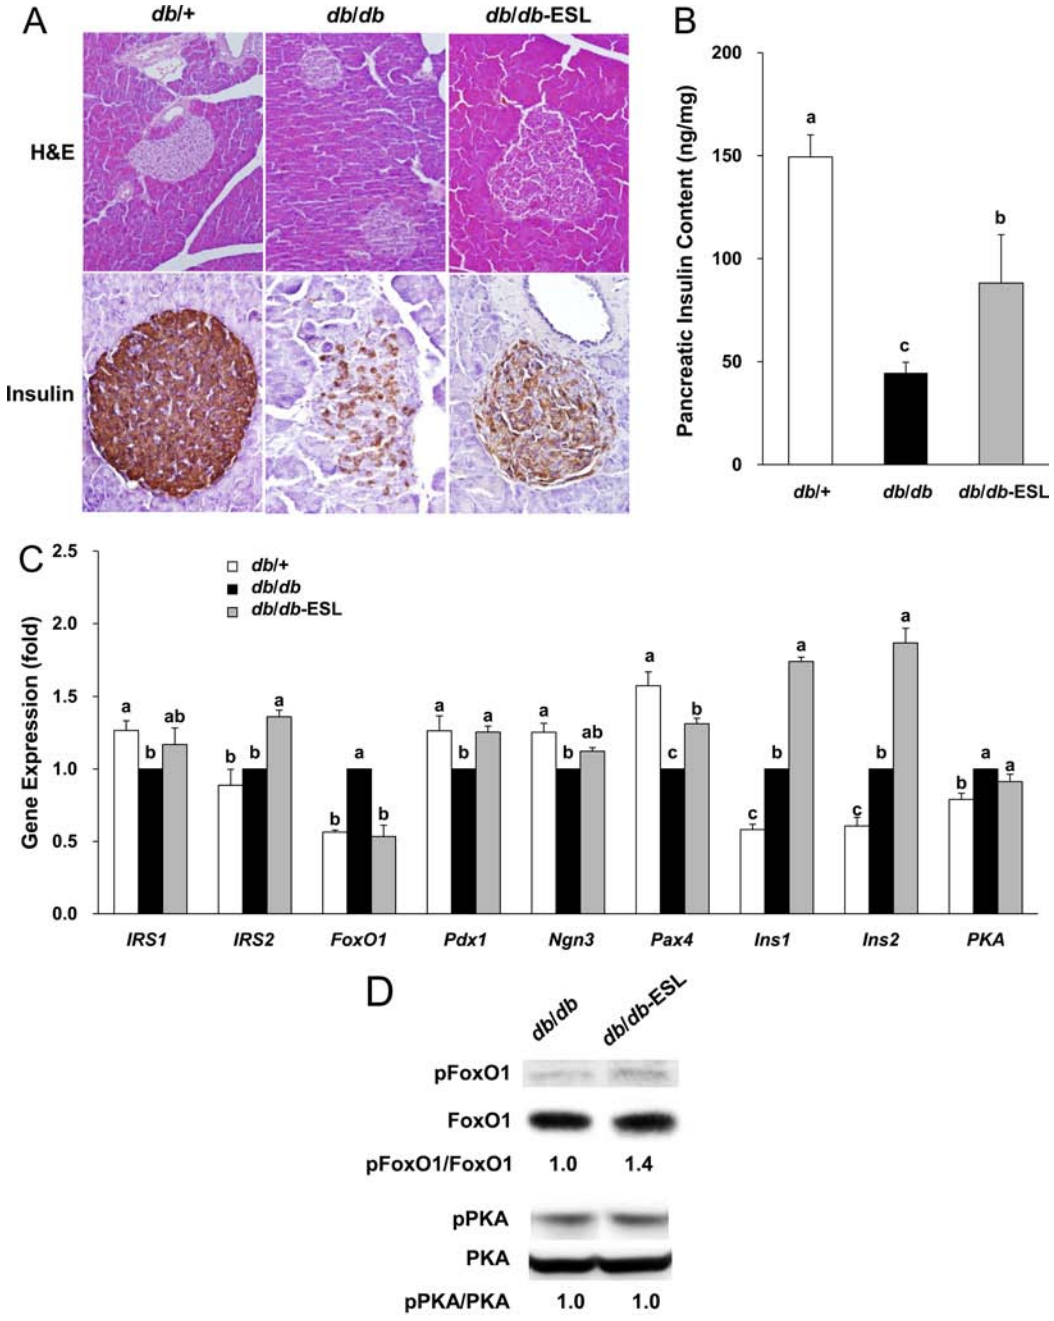

Figure 3. Effects of ESL supplementation on pancreatic dysfunction and insulin content in *db*/*db* mice. (A) Sections from pancreas stained with H&E and insulin IHC. (B) Insulin content in the pancreas. (C) mRNA levels measured by real-time qRT-PCR in pancreas and normalized using *GAPDH* as a reference gene. Values are presented as the mean ± SE. Different letters (a−c) within a variable are significantly different at $p < 0.05$. (D) Protein levels measured in the pancreas. Protein expressions of FoxO1, PKA, and their phosphorylated forms were analyzed by Western blot.

were markedly decreased in the *db*/*db*-ESL group (33.8%, $p < 0.05$). ESL showed a tendency to decrease TC and FFA levels, although this change was not significant. The liver function parameters, GOT and GPT, were decreased in the *db*/*db*-ESL group (18.1 and 10.9%, respectively), with GOT showing a significant difference versus the *db*/*db* group (Table 3).

Our results indicate that ESL effectively regulates hyperglycemia in diabetic mice. Recent studies also agree with our results, as KGs regulate glucose homeostasis and lipid profiles in KK-Ay and high-fat diet-fed mice.[14,15] In KK-Ay mice, KGs significantly decreased blood HbA1c level and slightly lowered fasting glucose and glucose tolerance, although these changes were not significant.[14] In high-fat diet-fed mice, KGs decreased fasting blood glucose, HbA1c, and insulin levels, as well as the AUC on the OGTT. In this study, ESL significantly decreased glucose and HbA1c levels and the HOMA-IR index. Furthermore, it improved glucose tolerance in *db*/*db* mice with severe hyperglycemia. Both KK-Ay and *db*/*db* mice are T2DM models, displaying hyperglycemia, hyperinsulinemia, and obesity. These characteristics revert to normal in KK-Ay mice older than 40 weeks of age; in contrast, hyperglycemia in *db*/*db* mice is sustained over the entire life span.[26] In the pancreas, KK-Ay mice display pancreatic β-cell hypertrophy, whereas *db*/*db* mice showed pancreatic β-cell necrosis and islet atrophy. Next, we investigated whether ESL affected β-cell dysfunction in pancreatic islets.

Values are presented as the mean ± SE. Different letters (a−c) within a variable are significantly different at $p < 0.05$.

ESL Improved Impared Pancreatic Function. ESL improved glucose tolerance, as indicated by plasma glucose, HbA1c, and insulin levels. This may occur by improving pancreatic or liver function. In T2DM, β-cell numbers and function are decreased, underlying much of the disease pathology.[27] Therefore, identifying ways to preserve or expand pancreatic β-cell number and function may be an effective therapeutic approach for T2DM. We investigated the histology of the pancreas. H&E staining revealed that the size of the pancreatic islet was markedly decreased in *db*/*db* mice, as compared to *db*/+ mice; however, ESL treatment recovered the islet size (Figure 3A). Furthermore, the pancreatic insulin

content was significantly increased in the *db*/*db*-ESL group, as compared to the *db*/*db* group (Figure 3A,B).

β-Cells can be generated from pancreatic α-cells, ductal cells, and exocrine cells in mice by overexpressing the transcription factors *MafA*, *Ngn3*, and *Pax4* and pancreatic and duodenal homeobox 1 (*Pdx1*).[28−30] These transcription factors are closely regulated during β-cell reprogramming and differentiation. *Pdx1* drives *Ngn3* expression, and *Pax4* is directly downstream of *Ngn3*.[31] In pancreatic β-cells, the IRS plays an important role in β-cell survival, proliferation, and insulin secretion via PI3K/Akt signaling.[5] Activated Akt inhibits FoxO1 and its transcriptional activity. Phosphorylation of FoxO1 sequesters this protein in the cytoplasm, leading to ubiquitin−proteasome degradation. Nuclear import of FoxO1 directly contributes to the suppression of *Ins2* and *Pdx1*, but not *Ins1*, gene expression in pancreatic β-cells.[32] FoxO1 also inhibits β-cell differentiation by repressing *Ngn3* gene expression.[33] In contrast, activation of the PI3K/Akt pathway leads to increased expression of *MafA*, *Ngn3*, *Pax4*, and *Pdx1*, thereby enhancing insulin gene expression in insulin-producing cells.[34,35] Therefore, we investigated ESL-induced changes in the expression of pancreatic genes associated with reprogramming and differentiation of β-cell using real-time qRT-PCR analyses.

The mRNA levels of *IRS1* and transcription factors, including *Pdx1*, *Ngn3*, and *Pax4*, were down-regulated in the *db*/*db* group, as compared to the *db*/+ group (Figure 3C). Additionally, *FoxO1* gene expression was up-regulated in the *db*/*db* group. ESL supplementation increased the gene expression of *IRS1*, *IRS2*, *Pdx1*, *Ngn3*, and *Pax4* and decreased that of *FoxO1* (Figure 3C). Interestingly, insulin I (*Ins1*) and insulin II (*Ins2*) gene expression were higher in the *db*/*db* group than in the *db*/+ group. This discrepancy in insulin gene expression could be due to a compensatory response for enhanced insulin demands in diabetics or other factors that also regulate insulin gene expression. Nevertheless, the mRNA levels of *Ins1* and *Ins2* in the *db*/*db*-ESL group were higher than those of the *db*/*db* group (Figure 3C). Additionally, phosphorylation of FoxO1 was increased by ESL supplementation, although there were no changes in PKA mRNA or protein expression (Figure 3C,D). These results indicate that ESL treatment improved pancreatic function though regulation of *IRS1*, *IRS2*, and their downstream effectors, *FoxO1*, *Pdx1*, *Ngn3*, and *Pax4*.

ESL Suppressed Hepatic Lipogenesis. The liver plays a key role in glucose and lipid metabolism. The liver stores excess energy through glycogen synthesis and lipogenesis. Hepatic lipogenesis is induced by excess carbohydrate ingestion, leading to TG formation for long-time energy storage. During feeding or overnutrition, the liver enhances lipogenesis, converting the surplus nutrients to TGs, stored in lipid droplets. In this study, hepatic lipid accumulation in the *db*/*db* group was markedly enhanced, as compared to the *db*/+ group. Although there were no differences in liver weight between the *db*/*db* and *db*/*db*-ESL groups (Table 2), the *db*/*db*-ESL group accumulated many fewer hepatic lipid droplets than the *db*/*db* group (Figure 4A). To clarify the histology of livers, the hepatic TG contents were measured: the hepatic TG contents in the *db*/*db*-ESL group were significantly reduced, compared to the contents in the *db*/*db* group (Figure 4B).

SREBP-1 is a master regulator of the lipogenic pathway. SREBP-1 also plays a critical role in potentiating the effects of hyperinsulinemia by regulating insulin sensitivity during hepatic lipid accumulation.[36] Insulin drastically increases *SREBP-1c* mRNA levels in diabetic livers, and overexpression of *SREBP-1c* in the mouse liver markedly enhances the expression of lipogenic genes and causes massive hepatosteatosis.[37] Fatty liver and insulin sensitivity can be markedly improved by decreasing SREBP-1c activation and lipogenesis while inhibiting endoplasmic reticulum stress in obese rodents.[38] Additionally, hepatic activation of SREBP-1 suppresses IRS2 expression via negative feedback.[39] Fatty acid transport protein 4 (FATP4) mediates fatty acid influx from plasma in hepatocyte membranes, and the recruitment of fatty acids can contribute to the development of fatty liver. Our data revealed that the expression levels of *SREBP-1*, *FAS*, acetyl-CoA carboxylase (*ACC1*), and *FATP4* were significantly decreased in ESL-treated mice, as compared to *db*/*db* control mice (Figure 4C). Furthermore, SREBP-1 and FAS protein expression were markedly decreased by ESL supplementation (Figure 4D). Therefore, ESL improved insulin sensitivity in the liver by suppressing SREBP-1 expression and lipogenesis.

Zang et al. reported that KGs decrease liver lipid levels, including TC, TG, nonesterified fatty acids (NEFA), and phospholipids, by decreasing *peroxisome proliferator-activated receptor gamma* (PPARγ) and *SREBP-1c* in HFD-fed obese mice.[15] In our recent study, ESL containing primarily KGs suppressed body weight gain and reduced WAT weight and plasma TG via down-regulation of adipogenesis-related genes including PPARγ, c/EBPα, SREBP-1, aP2, and FAS, and up-regulation of fat oxidation-related genes including HSL, CPT-1, and UCP2 in the WAT of HFD-induced obese mice.[23] Kwon et al. suggest that luteolin, a natural flavone, improves IRS2-mediated insulin resistance by suppressing SREBP-1 through the

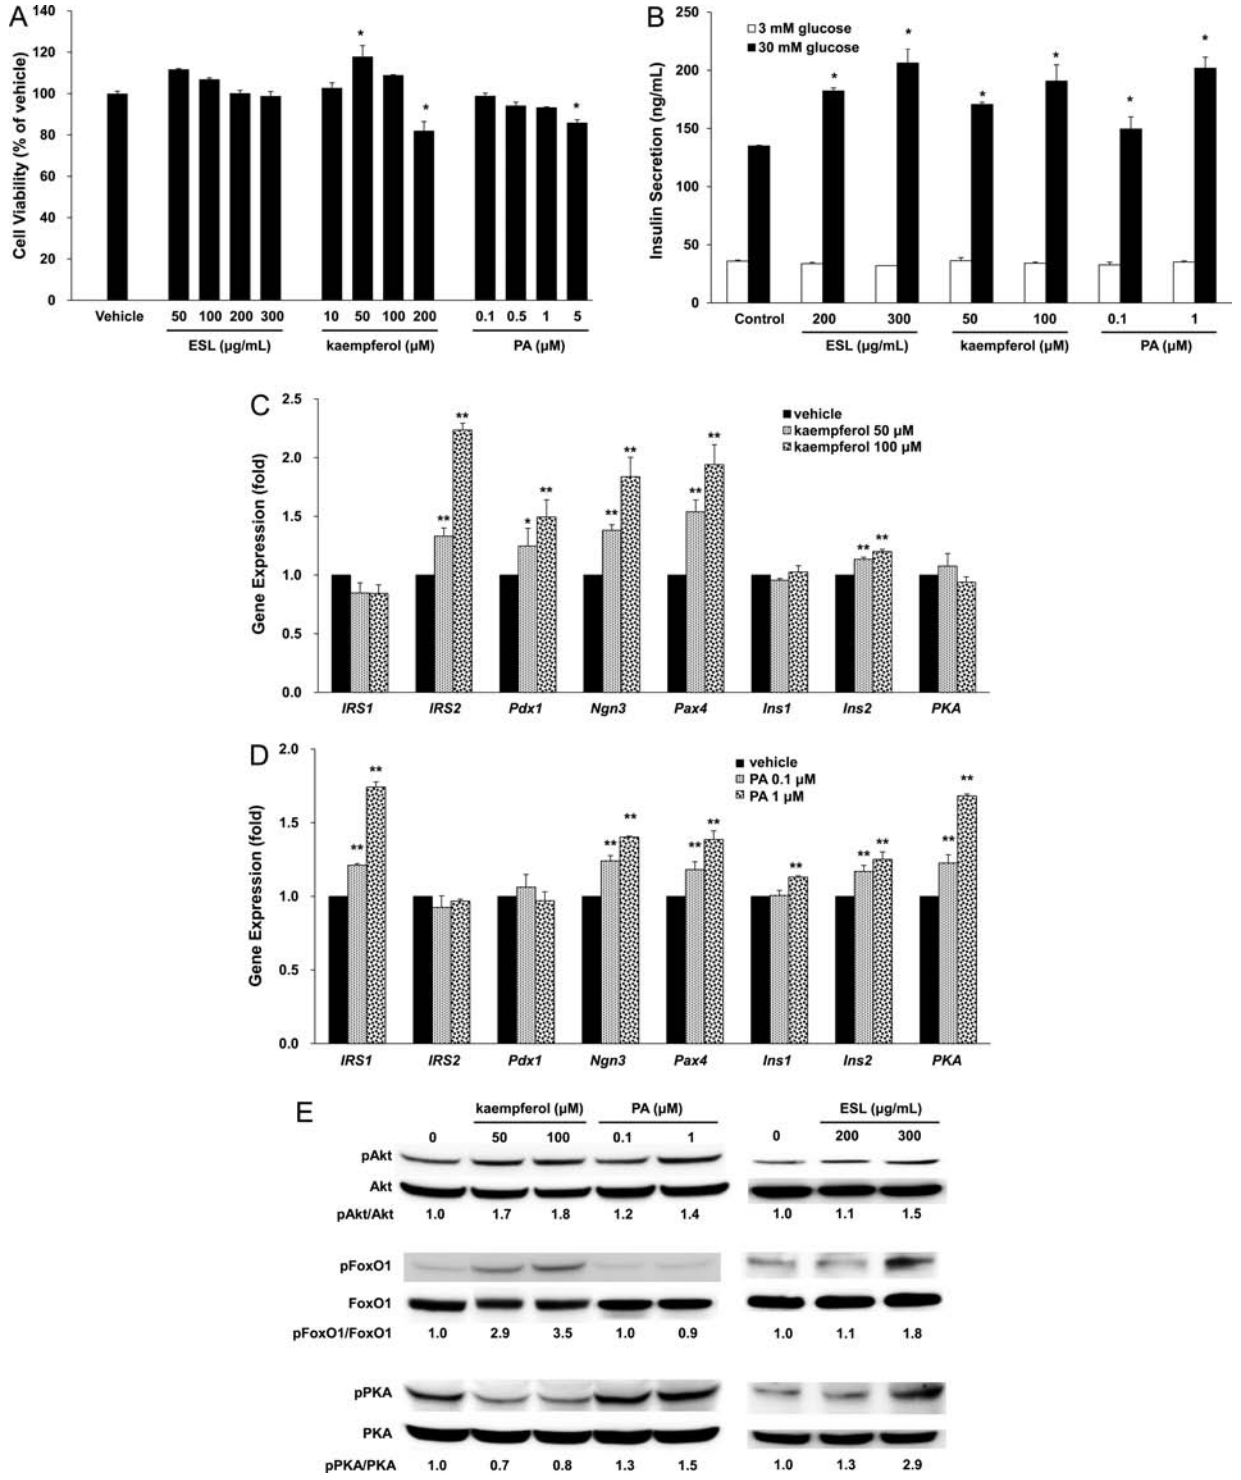

Figure 6. Effects of kaempferol and PA in pancreatic MIN6 cells. (A) Cytotoxicity of ESL, kaempferol, and PA in MIN6 cells. (∗) $p < 0.05$ versus the media alone treated group. Kaempferol 100 μM = 28.6 μg/mL; PA 5 μM = 2.97 μg/mL. (B) Effects of ESL, kaempferol, and PA on glucose-induced insulin secretion in MIN6 cells. (∗) $p < 0.05$ versus the glucose alone treated group. (C, D) Effects of kaempferol and PA on relative mRNA levels of insulin secretion-related genes in MIN6 cells. MIN6 cells were incubated with or without compounds for 48 h. The mRNA levels were measured by real-time qRT-PCR and normalized using *GAPDH* as a reference gene. Data from MIN6 cells are expressed as mean ± SD values of three independent experiments performed in duplicate. (∗) $p < 0.05$ and (∗∗) $p < 0.01$ versus vehicle. (E) Effects of kaempferol, PA, and ESL on protein expression of Akt, FoxO1, PKA, and their phosphorylated forms in MIN6 cells. PA, pheophorbide *a*.

interplay between the liver and adipose tissue in HFD-induced obese mice.[40] From these results, we found that the action mechanism of ESL in the liver and adipose tissue is similar to that of luteolin. In the same vein, we speculate that the improvement of glucose homeostasis by KGs in ESL-treated *db*/*db* mice may be associated with IRS-mediated insulin signaling and lipid accumulation in liver via inhibition of adipogenesis and stimulation of fat oxidation in WAT.

Next, we investigated the activity and gene expression of hepatic glucose-regulating enzymes, glucokinase (GK),

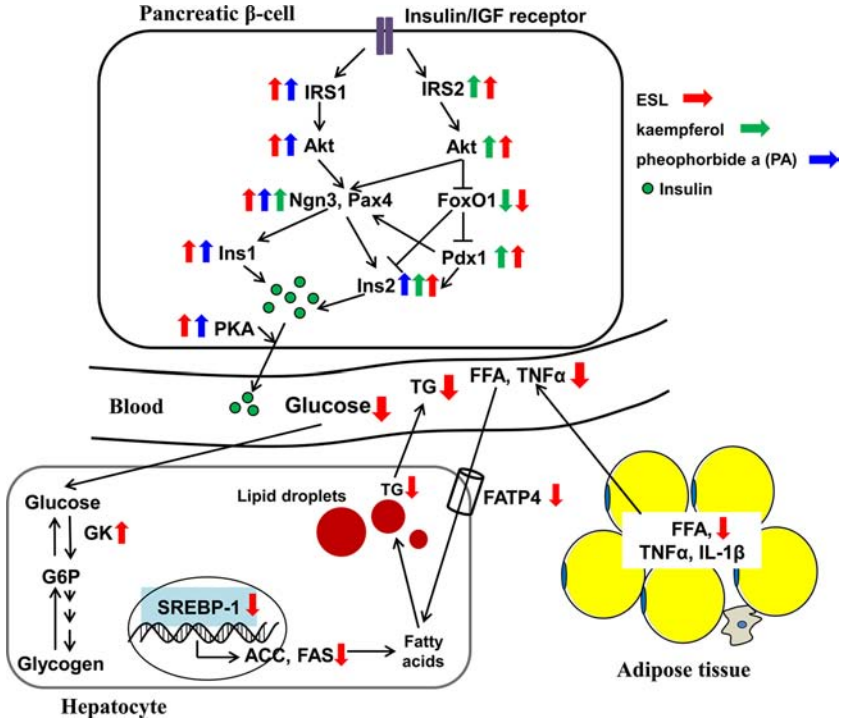

Figure 7. Possible molecular mechanisms of antidiabetic effect by ESL, kaempferol, and pheophorbide *a* (PA). ESL improved glucose homeostasis in diabetic *db*/*db* mice by enhancing *β*-cell survival and insulin secretion via IRS-mediated insulin signaling, suppressing SREBP-1-mediated lipogenesis in the liver, and decreasing inflammatory cytokines and FFA to improve insulin sensitivity.

glucose-6-phosphatase (G6Pase), and phosphoenolpyruvate carboxykinase (PEPCK). The hepatic enzyme activity and mRNA level of GK decreased in the *db*/*db* group, compared to the *db*/+ group (Figure 4E,F). The decreased enzyme activity and mRNA level of GK were significantly restored by ESL treatment (Figure 4E,F); however, ESL did not alter G6Pase and PEPCK activity and gene expression levels (Figure 4E,F). Hepatic GK plays a major role in controlling glucose utilization.[41] Low hepatic GK activity in diabetic mice leads to impaired insulin secretion in response to glucose.[42] Thus, the activation of glucose via increased hepatic GK activity is associated with improved hepatic insulin sensitivity in ESL-treated *db*/*db* mice.

ESL Inhibited Inflammation in WAT. Inflammation contributes to the pathogenesis of T2DM and its associated complications. Chronic inflammation is associated with visceral obesity and insulin resistance, which is characterized by the production of adipocytokines, including tumor necrosis factor *α* (TNF*α*), interleukin (IL)-1, IL-6, leptin, and adiponectin.[43] TNF*α* is overexpressed and mediates insulin resistance in obese animal models.[43] Secretion of inflammatory cytokines, such as IL-1*β* and TNF*α*, by adipose tissue macrophages impairs insulin secretion[44] and inhibits insulin action in adipocytes.[45] In this study, the gene expressions of *TNFα*, *IL-1β*, and *IL-6* in WAT of the *db*/*db* group were markedly higher than those of the *db*/+ group; however, the mRNA levels of *TNFα* and *IL-1β* but not *IL-6* were significantly decreased in the *db*/*db*-ESL group (Figure 5A). Plasma TNF*α* levels were also decreased by ESL supplementation (Figure 5B). This anti-inflammatory action of ESL in WAT may improve insulin secretion and sensitivity.

Kaempferol and PA Improved Insulin Secretion in MIN6 Cells. ESL primarily contained KGs and pheophorbides (Figure 1A). Kaempferol (3,4′,5,7-tetrahydroxyflavone) is an aglycone of KGs, and PA is a main component among pheophorbides, which are the products of chlorophyll. Deglycosylation of flavone glycosides increases absorption of the dietary flavone, aglycone, in vivo. The anti-inflammatory activity of dietary flavones is higher than that of their glycosides in vitro.[46] To clarify the mechanisms of ESL-induced improvement in insulin sensitivity and suppression of lipid accumulation in *db*/*db* mice, we investigated the antidiabetic effects of the major components, kaempferol and PA, and their mechanisms in MIN6 pancreatic *β*-cells.

ESL and kaempferol did not exert cytotoxicity up to 300 *μ*g/mL and 100 *μ*M (28.6 *μ*g/mL), respectively, in MIN6 cells; however, PA was cytotoxic at the relatively low concentration of 5 *μ*M (2.97 *μ*g/mL) (Figure 6A). Treatment with 200 and 300 *μ*g/mL of ESL significantly increased high glucose (30 mM)-induced insulin secretion in MIN6 cells (Figure 6B). Treatment with kaempferol (50 and 100 *μ*M) and PA (0.1 and 1 *μ*M) did not exert cytotoxicity and also increased insulin secretion in a dose-dependent manner (Figure 6B).

Next, we investigated whether kaempferol and PA influenced the expression of genes associated with pancreatic function in MIN6 cells. Treatment with 50 or 100 *μ*M kaempferol enhanced the mRNA levels of *IRS2*, but not *IRS1* (Figure 6C). Disruption of IRS2 impairs both peripheral insulin signaling and pancreatic *β*-cell function and causes T2DM.[47] IRS2 mediates PI3K/Akt signaling, and Akt-mediated FoxO1 phosphorylation promotes *β*-cell survival via the expression of Ngn3, Pax4, and Pdx1. Kaempferol was previously reported to improve pancreatic *β*-cell viability and insulin secretion through the modulation of Pdx1 protein expression.[48] Additionally, FoxO1-silenced MIN6 cells displayed increased basal *Ins2* gene expression.[33] This study demonstrated that the effects of kaempferol are initiated by IRS2 induction. Kaempferol also increased Akt and FoxO1 phosphorylation (Figure 6E). Kaempferol treatment induced the gene expression of *Pdx1*, *Ngn3*, *Pax4*, and *Ins2*, but not *Ins1* (Figure 6C). This may be related to the degradation of phosphorylated FoxO1.

DOI: 10.1021/acs.jafc.5b01639
J. Agric. Food Chem. 2015, 63, 7198−7210

Thus, kaempferol improved β-cell survival and proliferation through IRS2-related signaling via FoxO1.

PA, a product of chlorophyll breakdown, has anticancer, antioxidant, and virucidal activities.[20,29] In contrast to the effect of *IRS1* and *IRS2* gene expression by kaempferol, treatment with 0.1 or 1 μM PA induced *IRS1* expression, but not that of *IRS2* (Figure 6D). PA also increased *Ngn3*, *Pax4*, *Ins1*, *Ins2*, and *PKA* gene expression (Figure 6D) and induced Akt and PKA but not FoxO1 phosphorylation (Figure 6E). PKA, a mediator of the second-messenger cAMP, plays an important role in β-cell function. These results suggest that PKA is involved in the up-regulation of pro-insulin processing by PA in MIN6 cells. Therefore, PA increased the β-cell survival-related gene expression, including *Ngn3* and *Pax4*, via enhancing Akt phosphorylation. To conclude, PA improved both β-cell proliferation and insulin secretion through IRS1-mediated signaling. Above all, this is the first report describing the antidiabetic effects of PA in pancreatic β-cells.

Taken together, kaempferol and PA were induced insulin secretion via different pathways; kaempferol improved β-cell survival and proliferation through IRS2-related PI3K/Akt signaling via FoxO1, whereas PA improved both β-cell proliferation and insulin secretion through up-regulation of the IRS1-mediated PI3K/Akt pathway with PKA. Furthermore, ESL containing KGs and pheophorbides also enhanced phosphorylation of Akt, FoxO1, and PKA (Figure 7). Thus, both kaempferol and PA could contribute to the antidiabetic effects of ESL.

In summary, this study established the mechanisms of the antidiabetic effects and active components of soy leaf ethanol extracts. ESL improved diabetes-associated phenotypes, including glucose tolerance, glucose, HbA1c, and HOMA-IR. These effects may be induced by improved β-cell function in the pancreas and reduced lipid accumulation in the liver. ESL increased pancreatic *IRS1*, *IRS2*, *Pdx1*, *Ngn3*, and *Pax4* gene expression. Additionally, ESL decreased *FoxO1* gene expression and increased FoxO1 phosphorylation. Finally, ESL increased *Ins1* and *Ins2* gene expression. Importantly, KGs and PA were identified as the active components of ESL. Kaempferol improved β-cell survival and proliferation via IRS2 signaling through FoxO1, whereas PA increased insulin secretion through IRS1-related signaling and PKA in MIN6 cells. ESL decreased lipogenesis-related gene expression in the liver, including *SREBP-1*, *ACC1*, *FAS*, and *FATP4*. Furthermore, SREBP-1 and FAS protein expression was also decreased by ESL supplementation. Additionally, inflammatory cytokine gene expression, including *TNFα* and *IL-1β*, was suppressed following ESL treatment. Plasma TNFα levels were also decreased by ESL. The suppression of lipogenesis and cytokines by ESL supplementation could contribute to improved insulin sensitivity. Taken together, soy leaves may be a good component for the development of antidiabetic health foods.

■ ABBREVIATIONS USED

ACC1: acetyl-CoA carboxylase
CREB: cAMP-response element-binding protein
ESL: ethanol extract of soy leaves
FAS: fatty acid synthase
FATP4: fatty acid transport protein 4
FFA: free fatty acid
FoxO1: forkhead box protein O1
GK: glucokinase
G6Pase: glucose-6-phosphatase
GOT: glutamate oxaloacetate transaminase
GPT: glutamate pyruvate transaminase
H&E: hematoxylin and eosin
HbA1c: glycated hemoglobin
IHC: immunohistochemistry
IL: interleukin
Ins1: insulin I
Ins2: insulin II
IRS: insulin receptor substrate
KGs: kaempferol glycosides
MafA: V-maf musculoaponeurotic fibrosarcoma oncogene homologue A
Ngn3: neurogenin 3
OGTT: oral glucose tolerance test
PA: pheophorbide a
Pax4: paired box 4
Pdx1: pancreatic and duodenal homeobox 1
PEPCK: phosphoenolpyruvate carboxykinase
PI3K: phosphatidyl inositol-3 kinase
PKA: protein kinase A
SREBP-1: sterol regulatory element-biding transcription factor 1
TC: total cholesterol
TG: triglyceride
TNFα: tumor necrosis factor α
WAT: white adipose tissue

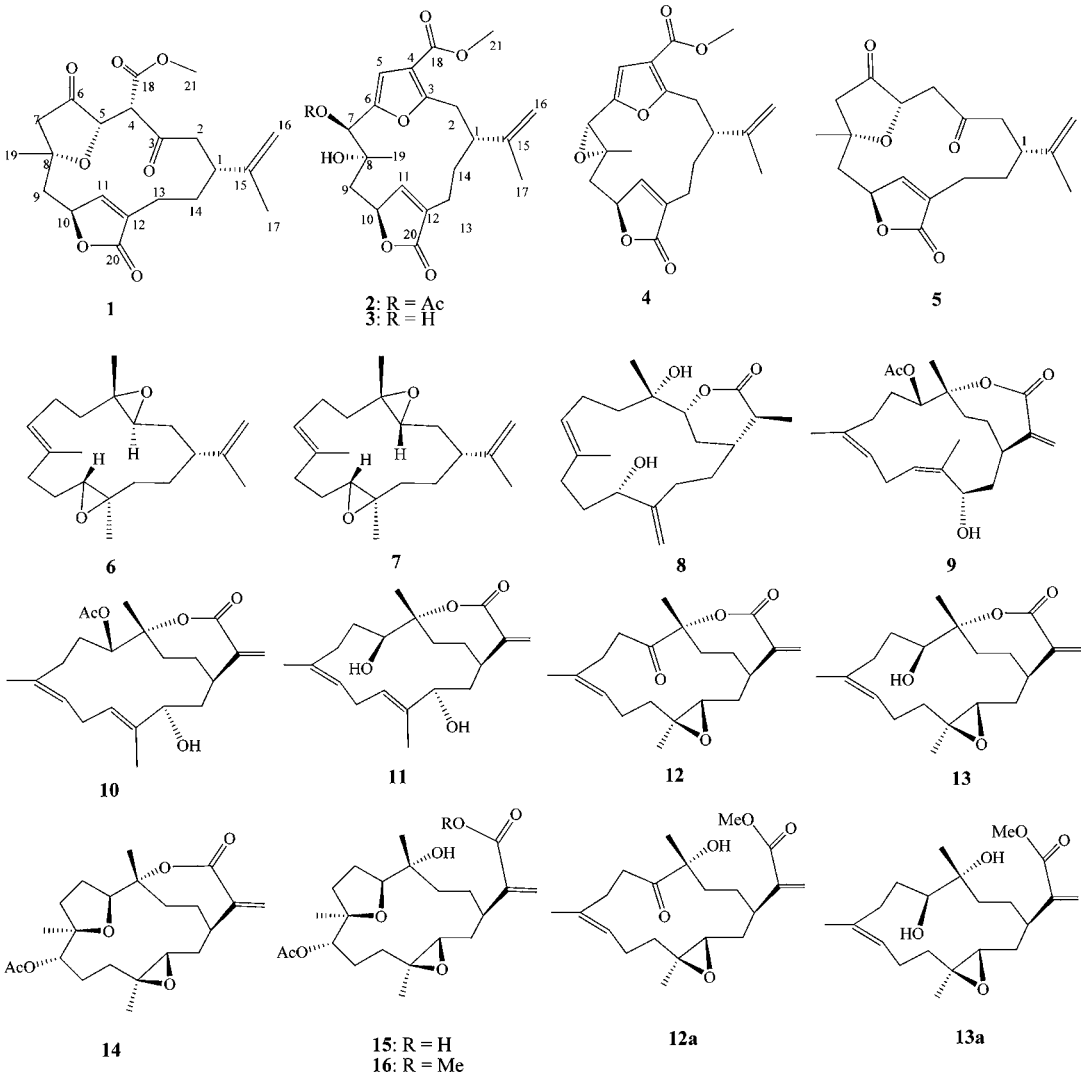

Figure 1. Structures of metabolites **1**−**16**, **12a**, and **13a**.

(Figure 1) were tested for anti-inflammatory activity to inhibit the protein expressions of inducible nitric oxide synthetase (iNOS) and cyclooxygenase-2 (COX-2). The structural determination and anti-inflammatory activities, in addition to the structure−activity relationships, of the isolates are reported herein.

MATERIALS AND METHODS

General Method. Infrared (IR) spectra were obtained on a Fourier-transform IR spectrophotometer (Varian Digilab FTS 1000). ^{1}H and ^{13}C NMR spectra were recorded on a Varian Unity INOVA 500 FT-NMR instrument at 500 and 125 MHz, respectively. Optical rotations were determined by a digital polarimeter (Jasco P-1010). Electrospray ionization mass spectrometry (ESIMS) analyses were performed on an APEX II Instrument (Bruker). Single-crystal X-ray analyses were performed on a Bruker APEX DUO diffractometer. Gravity column chromatography was performed with 230−400 mesh silica gel (Merck). TLC analyses were conducted on 0.2 mm thick precoated Kieselgel 60 F254 plates (Merck), and visualization of TLC spots was conducted by spraying the plate with a 10% aqueous H_2SO_4 solution followed by heating. High-performance liquid chromatography (HPLC) was performed using a system consisting of a Hitachi L-7100 pump and a Rheodyne 7725 injection port. A preparative normal phase column (φ 21.2 mm × 25 cm, silica gel 60, 5 μm) and a Supelco C_{18} column (φ 21.2 mm × 25 cm, 5 μm) were used for HPLC.

Animal Material. The two light yellow cultured soft corals *S. sandensis* and *S. flexibilis* were initially collected from the wild and subsequently grown for 8 years in an 80 ton cultivation tank located in the National Museum of Marine Biology & Aquarium. The tank was a flow-through seawater system, and deliberate feeding was not required. This was the first successful system that has been reported for the farming of *S. sandensis*. The specimens were collected by hand in January 2013, frozen immediately, and kept frozen until extraction. Two soft corals were identified by one of the authors (C.-F.D.). Voucher specimens were deposited in the National Museum of Marine Biology & Aquarium (Specimens 2013CSC-1 and 2013CSC-2).

Extraction and Isolation. The frozen *S. sandensis* material (2.8 kg, wet weight) was freeze-dried, and the resulting material (320 g) was then minced and extracted exhaustively with EtOAc (6 × 1.5 L). The EtOAc extract was evaporated under reduced pressure to afford a residue (20.5 g), and the residue was subjected to column chromatography on silica gel, using *n*-hexane, an *n*-hexane/EtOAc mixture of increasing polarity, and finally pure acetone to yield 12 fractions: Fr-1 (eluted with *n*-hexane/EtOAc, 100:1), Fr-2 (eluted with *n*-hexane/EtOAc, 50:1), Fr-3 (eluted with *n*-hexane/EtOAc, 30:1), Fr-4 (eluted with *n*-hexane/EtOAc, 20:1), Fr-5 (eluted with *n*-hexane/EtOAc, 10:1), Fr-6 (eluted with *n*-hexane/EtOAc, 8:1), Fr-7 (eluted with *n*-hexane/EtOAc, 5:1), Fr-8 (eluted with *n*-hexane/EtOAc, 3:1), Fr-9 (eluted with *n*-hexane/EtOAc, 1:1), Fr-10 (eluted with *n*-hexane/

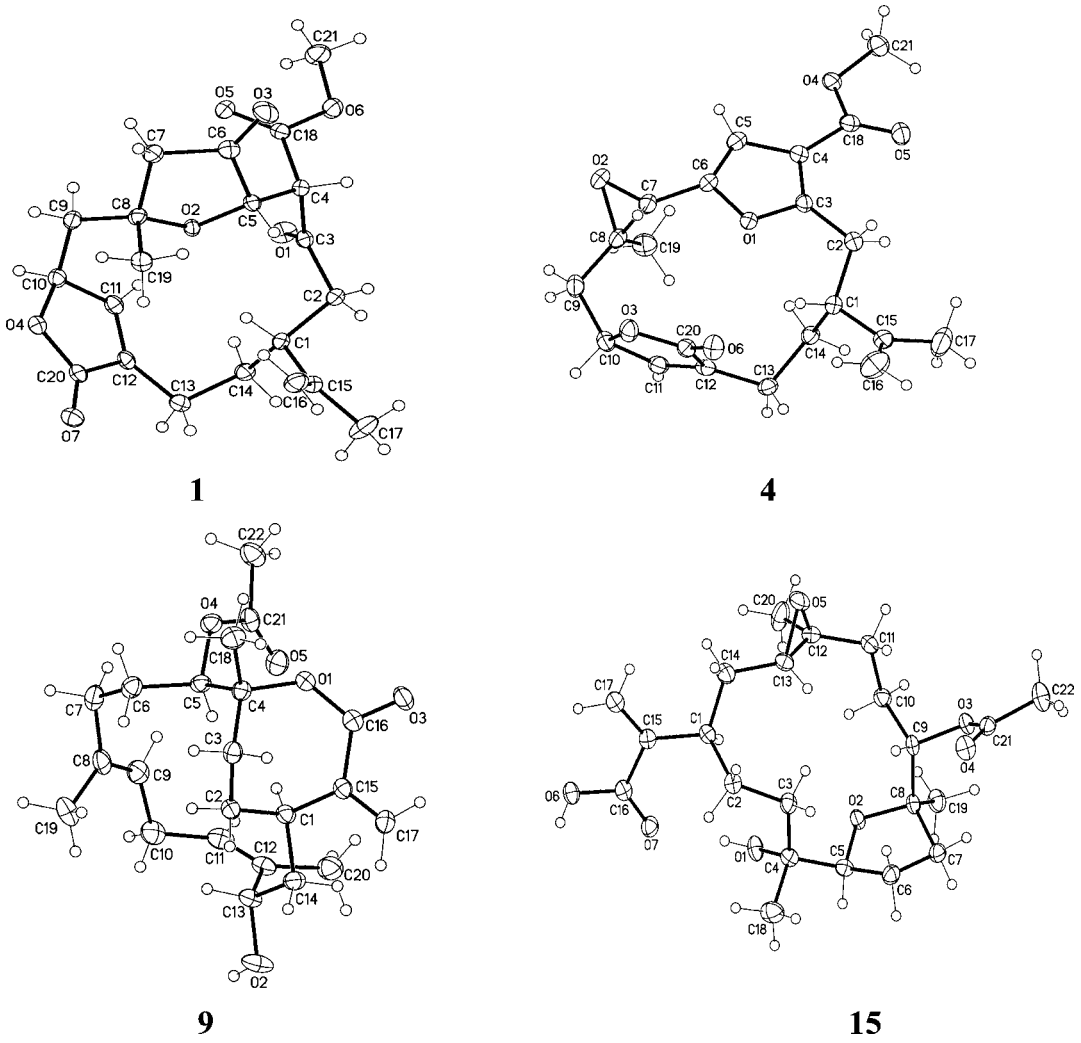

Figure 2. Molecular plots of **1**, **4**, **9**, and **15** with confirmed absolute configurations.

EtOAc, 1:2), Fr-11 (eluted with EtOAc), and Fr-12 (eluted with acetone). Fr-9 was further purified with silica gel (*n*-hexane/acetone, 3:1 to 2:1) to afford 10 subfractions (9A–9J). Subfraction 9E was then separated by normal-phase HPLC (*n*-hexane/acetone, 3:1) to obtain **4** (560 mg). Subfraction 9G was separated by normal-phase HPLC (*n*-hexane/EtOAc, 1:1) to afford **5** (1.2 mg) and **1** (10.2 mg). Fraction 10 was separated by normal-phase HPLC with gradient elution (*n*-hexane/acetone, 3:1 to 2:1) to yield five subfractions (10A–10E). Subfraction 10C was separated by reverse-phase HPLC (CH_3CN/H_2O, 7:3) to afford **2** (4.5 mg). Compound **3** (9.4 mg) was obtained from subfraction 10E using normal-phase HPLC (*n*-hexane/acetone, 1:1).

The frozen *S. flexibilis* (4.2 kg, wet weight) was freeze-dried, and the resulting material (450 g) was minced and extracted exhaustively with EtOAc (6 × 2 L). The EtOAc extract was evaporated under reduced pressure to afford a residue (30.5 g), and the residue was subjected to column chromatography on silica gel using *n*-hexane (H), an *n*-hexane/EtOAc (E) mixture of increasing polarity, and finally pure acetone to yield 13 fractions: Fr-1 (eluted with H/E, 100:1), Fr-2 (eluted with H/E, 50:1), Fr-3 (eluted with H/E, 30:1), Fr-4 (eluted with H/E, 20:1), Fr-5 (eluted with H/E, 10:1), Fr-6 (eluted with H/E, 8:1), Fr-7 (eluted with H/E, 5:1), Fr-8 (eluted with H/E, 3:1), Fr-9 (eluted with H/E, 2:1), Fr-10 (eluted with H/E, 1:1), Fr-11 (eluted with H/E, 1:2), Fr-12 (eluted with EtOAc), and Fr-13 (eluted with acetone). By using acetone as the mobile phase, Fr-7 was purified by passage over a Sephadex LH-20 column to afford five subfractions (7A–7E). Subfraction 7C was separated by normal-phase HPLC (CH_2Cl_2/*n*-hexane/EtOAc, 2:2:0.5) to obtain **6** (3.0 mg) and **7** (10.2 mg). Fr-9 was separated by normal-phase HPLC (*n*-hexane/EtOAc, 2:3) to yield **12** (71.5 mg) and **14** (55.2 mg). Fr-10 was separated by normal-phase HPLC (*n*-hexane/acetone, 4:1) to afford **8** (3.2 mg), **13** (2150 mg), and **16** (105.3 mg). Fr-11 was separated by normal-phase HPLC with gradient elution (*n*-hexane/EtOAc, 1:2 to 1:3) to yield four subfractions (11A–11D). Subfraction 11A was separated by normal-phase HPLC (*n*-hexane/EtOAc, 2:3) to afford **9** (4.5 mg) and **10** (4.1 mg). Compound **11** (25.6 mg) was obtained from subfraction 11C using normal-phase HPLC (*n*-hexane/EtOAc, 1:1). Compound **15** (19.9 mg) was obtained from subfraction 11D using normal-phase HPLC (*n*-hexane/acetone, 2:1).

*4-Carbomethoxyl-10-epigyrosanoldie E (**1**).* Colorless needles: UV (MeOH) λ_{max} (log ε) 213 (3.87) nm; $[\alpha]^{25}_D$ −28.0 (*c* 0.5, $CHCl_3$); IR (neat) ν_{max} 2935, 1755, 1715, 1642, 1443, 1383, 1280 cm^{-1}; ^{13}C and ^1H NMR data in Table 1; ESIMS *m*/*z* 413 $[M + Na]^+$; HRESIMS *m*/*z* 413.1571 $[M + Na]^+$ (calcd for $C_{21}H_{26}O_7Na$, *m*/*z* 413.1570).

*Single-Crystal X-ray Analysis of **1**.*[11] The ethyl acetate solution was allowed to slowly evaporate to generate a suitable colorless crystal. Diffraction intensity data were obtained on a Bruker APEX DUO X-ray diffractometer using graphite-monochromated Cu Kα radiation (λ = 1.54178 Å). Crystal data for this compound: $C_{21}H_{26}O_7$ (formula weight 390.42), approximate crystal size of 0.40 mm × 0.40 mm × 0.40 mm, monoclinic, space group $P2_1$ (No. 4), T = 100(2) K, a = 9.1141(2) Å, b = 8.9035(2) Å, c = 12.2954(3) Å, V = 962.98(4) Å,^{3} Z = 2, D_{calcd} = 1.346 mg/m^3, F(000) = 416, and $\mu_{(MoK\alpha)}$ = 0.838 mm^{-1}. A total of 6772 reflections were collected in the θ range of 5.420–66.673°, with 2603 independent reflections [R(int) = 0.0210], and completeness to θ_{max} was 96.2%; semiempirical from equivalents of absorption correction was applied. The refinement method was full-matrix least-squares on F^2; the data, restraints, and parameters were 2603, 1, and 256, respectively. The goodness of fit on F^2 = 1.080. Final R indices [$I > 2\sigma(I)$] R_1 = 0.0266 and wR_2 = 0.0707. R indices (all data) R_1 = 0.0267 and wR_2 = 0.0707. The largest difference peak and hole were 0.185 and −0.190 e/Å^3, respectively; the absolute structure parameter was 0.04(5).

*Single-Crystal X-ray Analysis of **4**.*[11] The ethyl acetate solution was allowed to slowly evaporate to generate a suitable colorless crystal. Diffraction intensity data were obtained on a Bruker APEX DUO X-ray diffractometer using graphite-monochromated Cu Kα radiation (λ = 1.54178 Å). Crystal data for this compound: $C_{21}H_{24}O_6$ (formula weight of 372.40), approximate crystal size of 0.30 mm × 0.20 mm × 0.15 mm, monoclinic, space group $P2_1$ (No. 4), T = 100(2) K, a = 8.862(3) Å, b = 12.539(4) Å, c = 16.776(5) Å, V = 1864.1(10) Å,^{3} Z = 4, D_{calcd} = 1.327 mg/m^3, F(000) = 792, and $\mu_{(MoK\alpha)}$ = 0.800 mm^{-1}. A total of 6658 reflections were collected in the θ range of 5.646–66.464°, with 3026 independent reflections [R(int) = 0.0225], and completeness to θ_{max} was 94.7%; semiempirical from equivalents of absorption correction was applied. The refinement method was full-matrix least squares on F^2; the data, restraints, and parameters were 3026, 0, and 247, respectively. The goodness of fit on F^2 = 1.175. Final R indices [$I > 2\sigma(I)$] R_1 = 0.0330 and wR_2 = 0.0960. R indices (all data) R_1 = 0.0332 and wR_2 = 0.0963. The largest difference peak and hole were 0.347 and −0.261 e/Å^3, respectively; the absolute structure parameter was 0.12(5).

*Single-Crystal X-ray Analysis of **9**.*[11] The ethyl acetate solution was allowed to slowly evaporate to generate a suitable colorless crystal. Diffraction intensity data were obtained on a Bruker APEX DUO X-ray diffractometer using graphite-monochromated Cu Kα radiation (λ = 1.54178 Å). Crystal data for this compound: $C_{22}H_{32}O_5$ (formula weight of 376.47), approximate crystal size of 0.60 mm × 0.35 mm × 0.30 mm, monoclinic, space group $P2_1$ (No. 4), T = 100(2) K, a = 8.0404(2) Å, b = 14.3426(4) Å, c = 17.9352(6) Å, V = 2068.29(10) Å,^{3} Z = 4, D_{calcd} = 1.209 mg/m^3, F(000) = 816, and $\mu_{(MoK\alpha)}$ = 0.681 mm^{-1}. A total of 14442 reflections were collected in the θ range of 3.946–66.656°, with 3651 independent reflections [R(int) = 0.0225], and completeness to θ_{max} was 97.7%. Semiempirical from equivalents of absorption correction was applied. The refinement method was full-matrix least squares on F^2; the data, restraints, and parameters were 3651, 0, and 249, respectively. The goodness of fit on F^2 = 1.046. Final R indices [$I > 2\sigma(I)$] R_1 = 0.0263 and wR_2 = 0.0677. R indices (all data) R_1 = 0.0264 and wR_2 = 0.0678. The largest difference peak and hole were 0.164 and −0.128 e/Å^3, respectively; the absolute structure parameter was 0.09(3).

*Single-Crystal X-ray Analysis of **15**.*[11] The ethyl acetate solution was allowed to slowly evaporate to generate a suitable colorless crystal. Diffraction intensity data were obtained on a Bruker APEX DUO X-ray diffractometer using graphite-monochromated Cu Kα radiation (λ = 1.54178 Å). Crystal data for this compound: $C_{44}H_{68}O_{14}$ (formula weight of 820.98), approximate crystal size of 0.40 mm × 0.30 mm × 0.30 mm, monoclinic, space group $P2_1$ (No. 4), T = 100(2) K, a = 9.7079(6) Å, b = 23.0869(14) Å, c = 9.72692(6) Å, V = 2172.1(2) Å,^{3} Z = 2, D_{calcd} = 1.255 mg/m^3, F(000) = 888, and $\mu_{(MoK\alpha)}$ = 0.760 mm^{-1}. A total of 3825 reflections were collected in the θ range of 3.829–66.665°, with 3825 independent reflections [R(int) = 0.0334], and completeness to θ_{max} was 95.7%. Semiempirical from equivalents of absorption correction was applied. The refinement method was full-matrix least squares on F^2; the data, restraints, and parameters were 3825, 1, and 536, respectively. The goodness of fit on F^2 = 1.032. Final R indices [$I > 2\sigma(I)$] R_1 = 0.0289 and wR_2 = 0.0751. R indices (all data) R_1 = 0.0291 and wR_2 = 0.0752. The largest difference peak and hole were 0.180 and −0.227 e/Å^3, respectively; the absolute structure parameter was 0.14(8).

*Acetylation of **3**.* Ac_2O (0.1 mL) was added to a solution of **3** (4.0 mg) in pyridine (0.2 mL), and the mixture was stirred at room temperature. After 24 h, pyridine and excess Ac_2O were evaporated by adding EtOAc, and the residue was subjected to column chromatography over Si gel (*n*-hexane/EtOAc, 1:1) to yield acetyl derivative **2** (3.9 mg, 8%). The specific rotation [$[\alpha]^{25}_D$ −50.0 (*c* 0.05, $CHCl_3$)] and ^{1}H NMR spectrum were in full agreement with those of natural product **2**.

*Hydrolysis of **12**.* A solution of **12** (16.0 mg) was dissolved in a 5% methanolic NaOH solution (1.0 mL). After being stirred at room temperature for 12 h, the mixture was neutralized with diluted HCl (0.1 M) and evaporated. The resulting residue was extracted with $CHCl_3$. The $CHCl_3$ soluble layers were dried over anhydrous $NaSO_4$

and evaporated. The dried residue was purified by silica gel column chromatography (*n*-hexane/acetone, 6:1) to yield **12a** (8.2 mg, 46.9%).

Hydrolysis of ***13***. Using the same preparation method that was used for **12**, the reaction of **13** (10.0 mg) with 1 mL of a 5% methanolic NaOH solution yielded a crude product, which was further separated by normal-phase HPLC (*n*-hexane/EtOAc, 1:2) to afford **13a** (3.8 mg, 34.4%).

***In Vitro* Anti-Inflammatory Assay.** A macrophage-like mouse cell line, RAW 264.7, was purchased from ATCC. Using Western blot analysis,[12,13] the *in vitro* anti-inflammatory activities of compounds **1**–**4** and **6**–**16**, and two derivatives **12a** and **13a**, were assessed by measuring their suppression effects on lipopolysaccharide (LPS)-stimulated iNOS and COX-2 protein overexpression in RAW 264.7 cells.

RESULTS AND DISCUSSION

4-Carbomethoxyl-10-epigyrosanoldie E (**1**) was isolated as colorless needles. Its infrared (IR) absorptions showed the presence of both lactone (1755 cm^{-1}) and ketone (1715 cm^{-1}) functionalities. The molecular formula of **1** was determined to be $C_{21}H_{26}O_7$ by HRESIMS (m/z 413.1571 $[M + Na]^+$) and ^{13}C NMR data (Table 1), requiring nine degrees of unsaturation. Resonances due to two ketones (δ 212.3 and 202.5), two ester carbonyl carbons (δ 174.4 and 167.8), and two olefinic carbons (δ 151.9, CH; 145.8, C; 130.4, C; 113.0, CH_2) in the ^{13}C NMR and DEPT spectral data accounted for six double-bond equivalents, which indicated that **1** was a tricyclic compound. The ^{1}H NMR spectrum of **1** (Table 1) revealed the presence of resonances of one olefinic methine proton (δ 7.16, s), two olefinic methylene protons (δ 4.79 and 4.61, each s), two oxygenated methines (δ 5.19, s, and δ 4.26, d, J = 3.5 Hz), and one oxymethyl group (δ 3.74, s). By comparison of the NMR data of **1** with those of **5**,[14−16] it was found that **1** differed from **5** only in the presence of a carbomethoxyl group instead of a proton at C-4. Moreover, single-crystal X-ray crystallographic analysis using Cu Kα irradiation at 100 K (Figure 2) confirmed the stereostructures of **1**. The Flack parameter [0.04(5)] (CCDC 1028007) allowed the assignment of the absolute configuration of **1** as (1*R*,4*S*,5*S*,8*S*,10*S*)-5(8)-epoxy-4-carbomethoxyl-1-isopropenyl-8-methyl-3,6-dioxocyclotetradec-11(12)-en-10,12-carbolactone.

The HRESIMS spectrum of 7-acetylsinumaximol B (**2**) exhibited an ion peak at m/z 455.1675 $[M + Na]^+$, which matched the formula $C_{23}H_{28}O_8$. The ^{1}H and ^{13}C NMR spectral data (Table 1) of **2** were similar to those of **3**,[17] the difference being that the hydroxy group attached at C-7 in **3** was replaced with an acetoxy group in **2**. Acetylation of **3** gave an acetyl derivative, whose ^{1}H and ^{13}C NMR spectral data were identical to those of the 7-acetyl derivative (**2**) derived from **3**. Hence, **2** was the 7-acetyl derivative of **3**. Therefore, **2** was established as (1*R*,7*R*,8*R*,10*S*,11*Z*)-3(6)-epoxy-7-acetoxy-4-carbomethoxyl-8-hydroxy-1-isopropenyl-8-methyl-3(4),5(6),11(12)-trien-10,12-carbolactone

Diepoxycembrene B (**6**) had the same molecular formula ($C_{20}H_{32}O_2$) as **7**, as indicated by HRESIMS and NMR spectra (Table 2). The gross structure of **6** was established by interpretation of two-dimensional (2D) NMR data, especially by analysis of $^{1}H-^{1}H$ COSY and HMBC correlations (Figure 3). The $^{1}H-^{1}H$ COSY spectral data assigned three isolated consecutive proton spin systems. The aforementioned results indicated that **6** had the same molecular framework as known compounds diepoxycembrene A (**7**) [(1*R**,3*R**,4*S**,11*R**,12*R**)-3,4,11,12-diepoxycembra-7,15-diene][18] and diepoxycembrane A [(1*R**,3*S**,4*S**,11*S**,12*S**-3,4,11,12-diepoxycembra-7,15-diene],[19] which were isolated previously from soft corals *Sinularia* sp. and *S. flexibilis*, respectively. NOE correlations observed in the NOESY spectrum were used to determine the relative configuration of **6** (Figure 4). The NOE correlations observed between H_2-6 and H_3-19 reflected the *E* configuration of the double bond

Figure 3. Selected ^{1}H−^{1}H COSY (—) and HMBC (→) correlations of **6** and **8**.

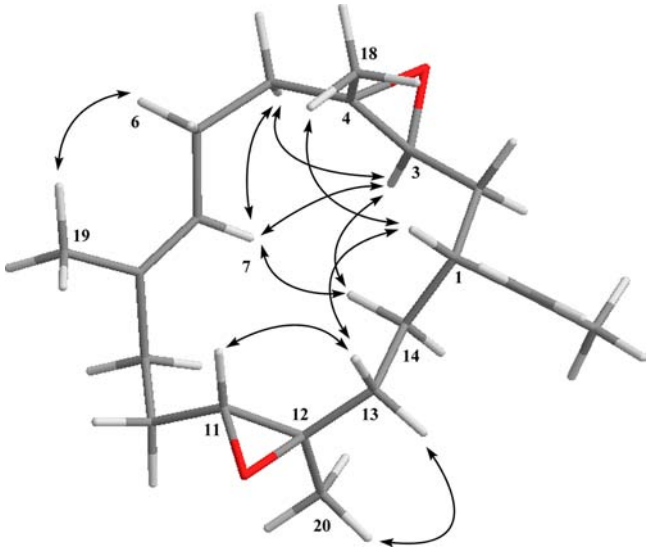

Figure 4. Selected NOE correlations of **6**.

between C-7 and C-8. In addition, it was found that H-1 showed NOE interactions with one proton of the C-13 methylene (δ 0.85) and H_3-18. Thus, assuming a β-orientation of H-1, H_3-18 should be positioned on the β face. Moreover, H-13β was found to exhibit correlations with H-11 (δ 2.61, dd, J = 10.3, 3.5 Hz), indicating that H-11 was situated on the β face; H-11 was assigned as a β proton, as the C-20 methyl was α-oriented at C-12, which was verified by a correlation between H_3-20 and H-13α (δ 1.90 m). This result shows that the epoxide at C-11/C-12 was of a *trans* geometry of the trisubstituted epoxide. Furthermore, the epoxide at C-3/C-4 was also of a *trans* geometry of the trisubstituted epoxide from the NOE correlations displayed by H-3 with the one proton of the C-5 methylene (δ 1.36), but not with H_3-18. In light of these results and other detailed analyses of NOE correlations, **6** was unambiguously identified as (1*R**,3*S**,4*S**,11*R**,12*R**)-3,4,11,12-diepoxycembra-7,15-diene.

Dihydromanaarenolide I (**8**) was isolated as a colorless amorphous powder. The HRESIMS (m/z 359.2200, [M + Na]$^+$) and NMR data of **8** indicated the molecular formula $C_{20}H_{32}O_4$. Both the ^{1}H and ^{13}C NMR signals of **8** (Table 2) were found to be very closely related to those of known compound manaarenolide I, which was isolated previously from the soft coral *Sinularia manaarensis*.[20] NMR comparison of **8** with manaarenolide I demonstrated that the two exomethylene proton signals in manaarenolide I were replaced by a methyl proton signal (δ_H 1.39, d, J = 7.0 Hz) in **8**. Additionally, 2D NMR data (^{1}H−^{1}H COSY and HMBC) further revealed that **8** possesses one methyl group at C-15 (Figure 3). The relative configurations of all stereocenters except C-15 of **8** were determined to be the same as those of manaarenolide I by comparisons of the coupling constants and proton shifts. Because of the NOE correlation between H_3-17 and H-1, the methyl at C-15 was assigned a β-configuration primarily. Moreover, by comparison of the NMR data of **8** with those of similar known compounds, it was confirmed that all compounds have the same relative stereochemical configuration at C-15.[20] According to the aforementioned results, the structure of **8** was established as (1*R**,3*R**,4*S**,11*S**,15*S**,7*E*)-4,11-dihydroxy-cembr-7(8),12-(20)-dien-16,3-olide.

Isosinulaflexiolide K (**9**) was found to have the [M + Na]$^+$ ion at m/z 399 in its ESIMS spectrum. The molecular formula was deduced to be $C_{22}H_{32}O_5$ from HRESIMS and NMR data (Table 2). The structure and absolute stereochemistry of **9** were also confirmed by single-crystal X-ray diffraction (Figure 2) with Cu Kα irradiation [Flack parameter of 0.09(3)] (CCDC 1044093). On the basis of the results presented above, compound **9** was established as (1*R*,4*R*,5*R*,13*S*,8*E*,11*Z*)-5-acetoxy-13-hydroxy-cembr-8(9),11(12),15(17)-trien-16,4-olide

In addition, the 11 known compounds obtained were identified as sinumaximol B (**3**),[17] pukalide (**4**),[21] 10-epigyrosanoldie E (**5**),[14,15] diepoxycembrene A (**7**),[17] sinulaflexiolide K (**10**),[22] (−)-sandensolide (**11**),[23] 11-dehydrosinulariolide (**12**),[24] sinulariolide (**13**),[25] 3,4:8,11-bisepoxy-7-acetoxycembra-15(17)-en-1,12-olide (**14**),[26] dendronpholide F (**15**),[27] and dendronpholide G (**16**)[24] by comparison of spectroscopic data with published values. The absolute configurations of **4** and **15** were confirmed by single-crystal X-ray diffraction analysis with Cu Kα radiation [Flack parameters of 0.12(5) and 0.14(8), respectively] for the first time (Figure 2). In the previous report, compound **4** was obtained from Gorgonacean coral *Leptogorgia rigida*, and the absolute configuration of **4** was fully determined by CD spectroscopic data analysis.[21] One hypothesis suggested that all cembranes of the known absolute configuration of an isopropyl group at C-1 obtained from Alcyonacean soft corals belong to the α series, whereas analogues isolated from Gorgonacean corals belong to the β series.[28,29] However, compounds **9** and **15** isolated from an Alcyonacean soft coral have a β conformation, with the isopropyl group pointing upward at position C1, and **4** was obtained from Gorgonacean and Alcyonacean corals. Thus, this result showed that this hypothesis is not applicable for a small number of cembranoids.

Using Western blotting, the effects of **1**−**4** and **6**−**16** on the inhibition of the accumulation of pro-inflammatory iNOS and COX-2 in LPS-stimulated RAW 264.7 cells were studied. The results presented in Figure 5 show that compounds **9**−**14** were found to significantly reduce the levels of iNOS to 30.9 ± 4.1, 37.4 ± 5.9, 61 ± 3.4, 31.9 ± 5.1, 47.7 ± 6.3, and 25.7 ± 5.2%, respectively, and the levels of COX-2 to 47.1 ± 3.8, 51.4 ± 5.6, 51.9 ± 7.2, 49 ± 5.6, 52.2 ± 5.1, and 55.3 ± 8.2%, respectively. Preliminary structure−activity relationships in diterpenes of the cembrane type may be deduced from anti-inflammatory bioassays. In the bioassays, the presence of one seven-membered lactone functional group is critical for the anti-inflammatory action of this class of compounds. Moreover, to confirm the active moiety, base-catalyzed hydrolysis of both **12** and **13** was performed, and the reactions were found to afford **12a** and **13a**. The two derivatives were inactive against the

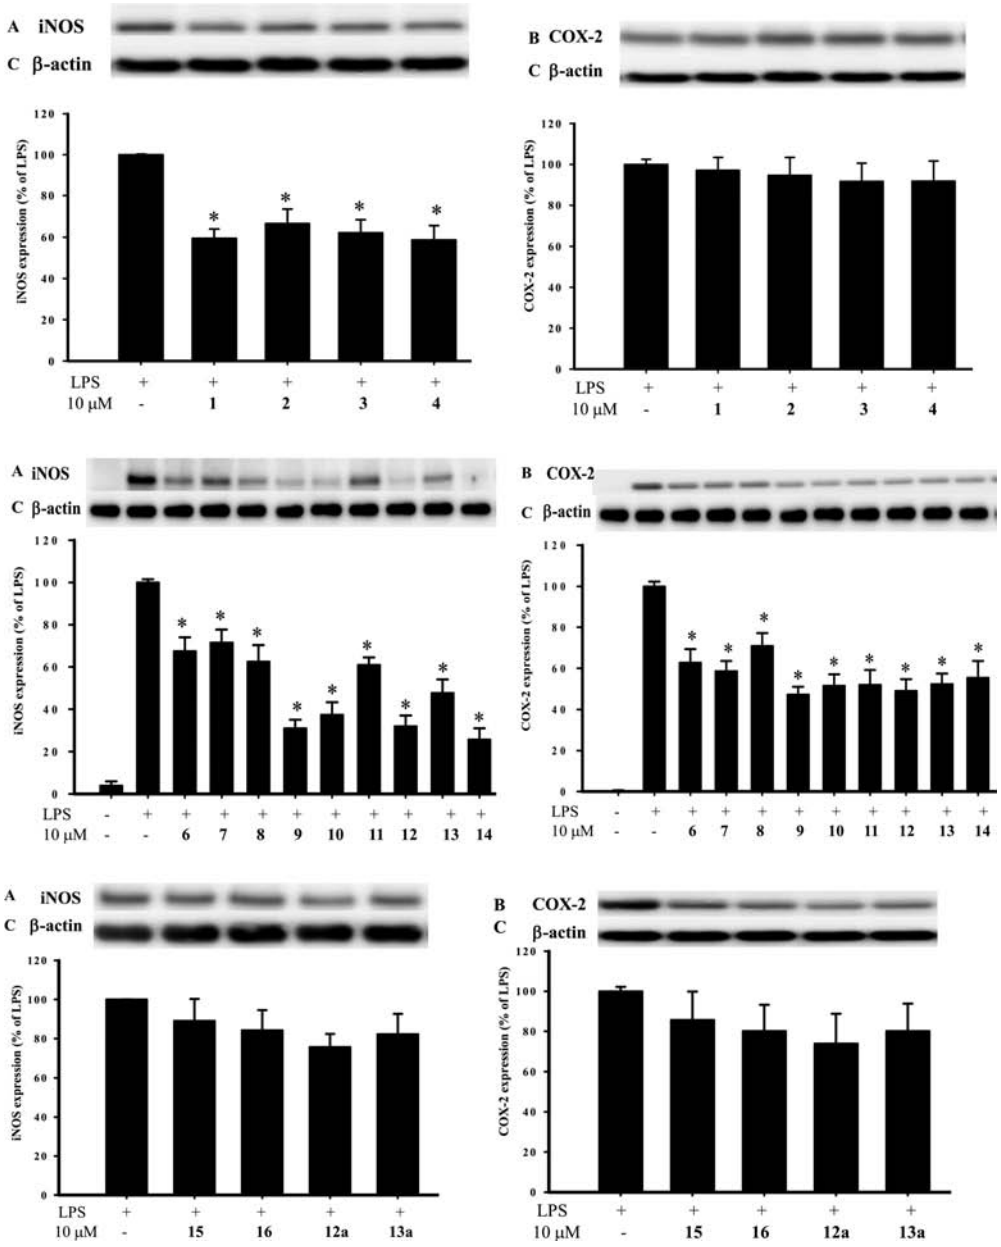

Figure 5. Effects of compounds **1**−**4**, **6**−**16**, **12a**, and **13a** at 10 μM on pro-inflammatory iNOS and COX-2 protein expression in LPS-induced RAW 264.7 macrophage cells by Western blot analysis: (A) quantification of iNOS expression, (B) quantification of COX-2 expression, and (C) quantification of β-actin expression. Band intensities were quantified by densitometry and normalized to that of the group treated with LPS only (set to 100%). At a concentration of 10 μM, positive control, dexamethasone was found to significantly reduce the levels of iNOS to 30.8 ± 9.6 and 6.9 ± 3.4%, respectively, relative to that of the control cells stimulated with LPS only in this study. This experiment was repeated three times. *$p < 0.05$ as compared with the LPS-stimulated group.

expressions of both iNOS and COX-2 proteins (Figure 5). These results showed that the anti-inflammatory activity depended on the seven-membered lactone functional group at position C1.

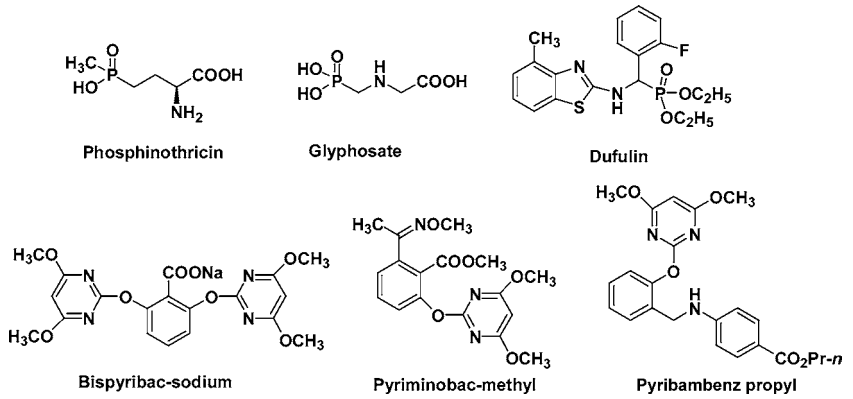

Figure 1. Structures of commercial α-amino phosphonic acid and pyrimidine pesticides.

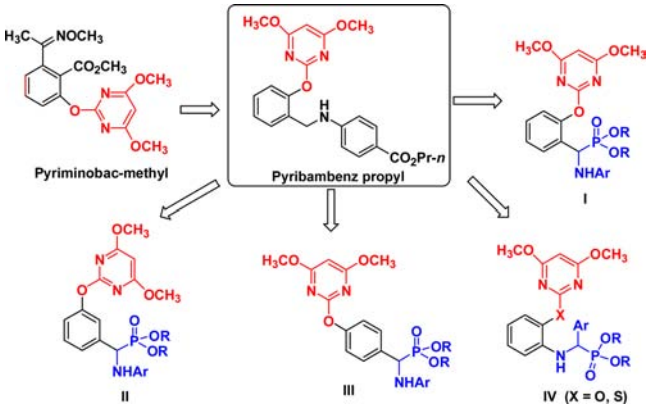
four series of novel α-amino alkyl phosphonate derivatives containing a pyrimidinyl moiety via a Lewis acid (magnesium perchlorate) catalyzed Mannich-type reaction of aldehydes, amines, and phosphites (Schemes 1 and 2). The target compounds were evaluated for herbicidal activities in vitro and in vivo, and their preliminary herbicidal mode of action and structure−activity relationship were also studied.

Scheme 1. Molecular Design of Title Compounds I−IV



MATERIALS AND METHODS

Instruments. ^{1}H and ^{31}P NMR spectra were performed on a Varian Mercury-PLUS400 (400 MHz) or Varian Mercury Plus-600 (600 MHz) spectrometer at room temperature in $CDCl_3$ with TMS and 85% H_3PO_4 as the internal and external standards, respectively; chemical shift values (δ) are given in parts per million. Elemental analyses were taken on a Vario EL III elemental analysis instrument. Mass spectra were measured on a Finnigan TraceMS 2000 spectrometer at 70 eV using EI method or an Applied Biosystems API 2000 LC/MS/MS (ESI-MS) spectrometer. The IR spectra were recorded on a Nicolet NEXUS470 spectrometer as KBr pellets with absorption given in cm^{-1}. The melting points were determined on an X-4 binocular microscope melting point apparatus (Beijing Tech Instruments Co., Beijing, China) and were uncorrected. Analytical TLC was performed on silica gel GF254. Column chromatographic purification was carried out using silica gel. Yields were not optimized. Unless otherwise noted, all materials were commercially available and were used directly without further purification. All solvents were dried and redistilled before use.

General Procedure for the Preparation of *O,O*′-Dialkyl (Diphenyl) N-Substituted Phenyl-1-amino-[2 or 3 or 4-(4,6-dimethoxypyrimidin-2-yloxy)phenyl]methyl Phosphonates I−III. The mixture of aldehyde **1a−1c** (3 mmol), dialkyl phosphite, or diphenyl phosphite (3 mmol), substituted aniline (3.3 mmol), and anhydrous $Mg(ClO_4)_2$ (0.033 g, 0.15 mmol) in anhydrous acetonitrile (5 mL) was stirred at 50−60 °C until the reaction finished (monitored by TLC). The solid was filtered off, the solvent was removed under reduced pressure, and the crude product was purified by column chromatography on silica gel using a mixture of petroleum ether and acetone (v/v, 2:1) as eluent to give the target compounds **I**, **II**, and **III** as a white solid or light yellow oil. The detailed procedures and spectral data for intermediates **1a−1c** and **2a−2b** and the target compounds **I−IV** are available in the Supporting Information. **Ia−Ir** are known compounds, and their spectra data can also be found in the literature.[32]

Data for compound **Is** (R = Et, Ar = 4-FC_6H_4): white solid; yield, 71%; mp, 125.3−126.5 °C; IR (KBr) ν 3316 (NH), 2981 (Ar—H), 1600, 1572, 1502, 1468 (Ar), 1362 (P═O), 1216, 1193 (P—O—C), 1066, 1025 (C—O—C) cm^{-1}; ^{1}H NMR ($CDCl_3$, 600 MHz) δ 1.06 (t, J = 7.8 Hz, 3H, CH_3), 1.30 (t, J = 7.2 Hz, 3H, CH_3), 3.70−3.74 (m, 1H, CH_2), 3.79 (s, 6H, $2CH_3O$), 3.88−3.94 (m, 1H, CH_2), 4.17−4.22 (m, 2H, CH_2), 4.65 (t, J = 8.4 Hz, 1H, NH), 5.15 (dd, J = 8.4 Hz, J = 24.0 Hz, 1H, PCH), 5.79 (s, 1H, pyrimidine-H), 6.49−6.51 (m, 2H, ArH), 6.71 (t, J = 8.4 Hz, 2H, ArH), 7.20 (d, J = 7.2 Hz, 2H, ArH), 7.28 (t, J = 7.8 Hz, 1H, ArH), 7.63 (d, J = 7.2 Hz, 1H, ArH); ^{31}P NMR ($CDCl_3$, 162 MHz) δ 21.90; EI-MS (70 eV) m/z (%) 491.4 (M^+, 2.7), 355 (23.7), 354 (100), 214 (12.8). Anal. Calcd for $C_{23}H_{27}FN_3O_6P$: C, 56.21; H, 5.54; N, 8.55. Found: C, 56.07; H, 5.39; N, 8.31.

anhydrous $Mg(ClO_4)_2$ (0.033 g, 0.15 mmol) in anhydrous acetonitrile (5 mL) was stirred at 50−60 °C until the reaction completed (monitored by TLC). The solid was filtered off, the solvent was removed under reduced pressure, and the crude product was purified by column chromatography on silica gel using a mixture of petroleum ether and acetone (v/v, 2:1) as eluent to yield the target compound **IV** (Scheme 3) as white solid or light yellow oil.

Data for compound **IVa** (R = Et, X = S, Ar = C_6H_5): white solid; yield, 68%; mp, 120.3−122.2 °C; IR (KBr) ν 3345 (NH), 2985 (Ar—H), 1586, 1552, 1504 (Ar), 1370 (P═O), 1278, 1190 (P—O—C), 1042, 1015 (C—O—C) cm^{-1}; ^1H NMR ($CDCl_3$, 600 MHz) δ 1.10 (t, J = 7.2 Hz, 3H, CH_3), 1.18 (t, J = 7.2 Hz, 3H, CH_3), 3.64 (s, 6H, $2CH_3O$), 3.70−3.74 (m, 1H, CH_2), 3.89−3.95 (m, 2H, CH_2), 3.99−4.02 (m, 1H, CH_2), 4.78 (dd, J = 7.8 Hz, J = 24.0 Hz, 1H, PCH), 5.72 (s, 1H, pyrimidine-H), 5.91 (t, J = 8.4 Hz, 1H, NH), 6.48 (d, J = 8.4 Hz, 1H, ArH), 6.68 (t, J = 7.2 Hz, 1H, ArH), 7.15 (t, J = 7.8 Hz, 1H, ArH), 7.23−7.28 (m, 3H, ArH), 7.35 (d, J = 7.8 Hz, 2H, ArH), 7.46 (d, J = 7.2 Hz, 1H, ArH); ^{31}P NMR ($CDCl_3$, 162 MHz) δ 20.96; EI-MS (70 eV) m/z (%) 489.4 (M^+, 5.0), 354 (7.0), 353 (22.9), 352 (100), 212 (14.8), 180 (6.1), 136 (3.5), 109 (4.9). [a]Scores are given as percent phytotoxicity score. The higher the score (% phytotoxicity), the greater the efficacy of the compound. Herbicide symptomologies are given as a phytotoxicity type: NC, necrosis; ST, stunting; GI, germination inhibition; CL, chlorosis; DG, darker green; BL, bleaching. [b]Compounds **II–IV** displayed no herbicidal activity in the GH1 bioassay screening.

422 (70.4), 421 (21.6), 420 (100), 384 (5.8). Anal. Calcd for $C_{23}H_{26}Cl_2N_3O_5PS$: C, 49.47; H, 4.69; N, 7.52. Found: C, 49.33; H, 4.40; N, 7.73.

Herbicidal Activity Assays. All of the herbicidal activity assays (in vitro and in vivo) were performed in the bioactive activity evaluation platform at Syngenta Jealott's Hill International Research Centre.

Herbicidal Plate Assays (in Vitro). The compounds were tested for herbicidal activity against *Arabidopsis thaliana* at 10 mg/L and

indoxacarb	0	0	0	0	99	99	99	99	99	99	99	99

against *Poa annua* at 32 mg/L. Test plates were stored for 7 days in a controlled environment cabinet. They were scored as 0 or 99, where 99 means significant herbicidal effect and 0 means no effect. The herbicidal activity is summarized in Table 1.

Herbicide Glasshouse Screening (in Vivo, GH1). The substances were dissolved in dimethyl sulfoxide (DMSO) for storage. Subsamples to be tested were dried down and formulated into spray solution for application. The compounds were tested for pre- and postemergence activity against four weed species, with the compounds applied at 1000 g/ha. The plants were then stored in the glasshouse for 12 days. The weeds tested were *Amaranthus retroflexus*, *Stellaria media*, *Lolium perenne*, and *Digitaria sanguinalis*. Assessments were made of pecent phytotoxicity and converted to a banded score between 0 and 100, where complete control of the target is 100 and 0 is no control. Acetochlor, atrazine, mesotrione, and glyphosate were used as positive controls for the test. The herbicidal activity is summarized in Table 2.

Herbicide Glasshouse Screening (in Vivo, GH2). The substances were dissolved in DMSO for storage. Subsamples to be tested were dried down and formulated into spray solution for application. The compounds were tested for pre- and postemergence activity against a range of weed species (dicotolydon plant weeds *Chenopodium album*, *Abutalon theophrasti*, *Koschia scoparia*, and *Bidens pilosa*; monocotolydon plant weeds *Echinochloa crus-galli*, *Setaria fabari*, *Eleusine indica*, and *Sorghum halapense*), with the compounds applied at 1000 g/ha. The plants were then stored in the glasshouse for 12 days. Assessments were made of percent phytotoxicity and converted to a banded score between 0 and 100, where complete control of the target is 100 and 0 is no control. Acetochlor, atrazine, mesotrione, and glyphosate were used as positive controls for the test. The herbicidal activity is summarized in Table 3.

Insecticide Assays. All of the insecticidal assays were carried out in the bioactive activity evaluation platform at Syngenta Jealott's Hill International Research Centre. The compounds were tested for activity against an aphid species at 1000 mg/L on a leaf-piece-based assay and against *Plutella xylostella* and *Diabrotica balteata* at 500 mg/L in artificial diet assays. Chemicals were applied to feeding aphids or prior to infestation with *P. xylostella* and *D. balteata* larvae. Mortality was assessed relative to control wells using a two-band system (0 or 99 where 99 = significant mortality and 0 = no effect), 3−6 days after the treatments depending on the assay. In addition to the test compounds, thiamethoxam and indoxacarb as the positive control compounds were included in each insecticide assays. For all screens, data were recorded for replicates and averaged. The insecticidal activity is summarized in Table 4.

Mode of Action Investigation. *Methodology.* The mode of action screen (MOA1) comprises a series of biochemical, cell-based, and whole plant assays that enable scientists at Syngenta to determine if test compounds have any of the major herbicide modes of action. Compounds are tested only once in MOA1 (i.e., there is no duplicate or replicate), so the IC_{50} values are just an approximation.

Compounds **Ib**, **Ic**, **Ig**, and **Ii** did not give any specific MOA in MOA1 as it was inactive in all of the assays; for example, compounds **Ib** and **Ig** did not give any specific MOA in MOA1 as it was inactive in all of the assays apart from some activity on tobacco cells (EC_{50} = 1 mg/L, 0.4 mg/L, respectively) and some weak injury on *Arabidospsis* seedlings (EC_{50} = 36 mg/L, 1 mg/L respectively) and tobacco seedlings (EC_{50} = 36 mg/L, 18 mg/L, respectively), so it suggested that these compounds perhaps have novel herbicidal modes of action. Further herbicidal mode of action determination is underway at Syngenta Jealott's Hill International Research Centre.

RESULTS AND DISCUSSION

Synthesis. Series of novel α-amino phosphonate derivatives containing a pyrimidinyl moiety, **I**, **II**, **III**, and **IV**, were designed and synthesized by Lewis acid (magnesium perchlorate) catalyzed Mannich-type reaction of benzoaldehyde containing a pyrimidinyl group, substituted benzylamine, and phosphites. It was found that Lewis acid (magnesium perchlorate) has a large effect on the rate of the reaction and yields of products; without the use of the catalyst, the rates of the reaction were remarkably slowed and the yields were very low, too (about 20%). The structures of target compounds **I**−**IV** were determined by their spectral data (IR, ^{1}H NMR, ^{31}P NMR, EI-MS, or ESI-MS) and elemental analyses.

Herbicidal Activities and Structure−Activity Relationships. The results of herbicidal activities, in vitro and in vivo (GH1, GH2), of these compounds are listed in Tables 1, 2, and 3, respectively. To our delight, most compounds **I** exhibited good herbicidal activities in vivo (Tables 2 and 3). However, their meta-position and para-position pyrimidin-2-oxy-substituted structural isomers **II** and **III** and their analogues **IV** did not display any herbicidal activities in vivo (GH1; data not listed), although some of them displayed good selectivity inhibitory activity against *Arabidopsis thaliana* at a concentration of 10 mg/L in vitro (Table 1).

For the in vivo (GH1) herbicidal activity, it was found that compounds **Ib**, **Ic**, **Ig**, **Ii**, **Is**, and **Iv** displayed 100% inhibition against *Amaranthus retroflexus* at the dose of 1000 g/ha in postemergence treatment. Moreover, both compounds **Is** and **It** showed 100% inhibition against *Lolium perenne* at the dose of 1000 g/ha in postemergence treatment. Furthermore, all compounds **I** exhibited better inhibition against the four plants tested in postemergence treatment than in pre-emergence one. Finally, compounds **Ib**, **Ic**, **Ig**, **Is**, and **It** displayed good broad-spectrum herbicidal activities against the four plants in both post- and pre-emergence treatments. As for the preliminary structure−activity relationships, it was shown that the different phosphonic acid esters affected the herbicidal activity significantly; phosphonic acid methyl and ethyl esters were universally advantageous for the herbicidal activities compared with the butyl and phenyl esters. However, the electronic effects of substituent on the benzene ring have no remarkable effect on the herbicidal activity. Both electron-donating (**Ig**, 4-methoxy-substituted) and electron-withdrawing compounds (**Ic**, 4-nitro-substituted; **Is** and **It**, 4-fluoro-substituted) displayed as good herbicidal activity; even nonsubstituted compound **Ib** also exhibited good herbicidal activity.

As for the in vivo (GH2) herbicidal activity of **I**, as shown in Table 3, all of the tested compounds (**Ib**, **Ic**, **Ig**, **Ii**, **Ik**, and **In**)

DOI: 10.1021/acs.jafc.5b02335
J. Agric. Food Chem. 2015, 63, 7219−7229

showed better inhibition activity against *Chenopodium album* and *Kochia scoparia* than against the other six plants (*Abutilon theophrasti*, *Bidens pilosa*, *Echinochloa crus galli*, *Setaria faberi*, *Eleusine indica*, and *Sorghum halepense*) at the dose of 1000 g/ha in both post- and pre-emergence treatments; for instance, both compounds **Ig** and **Ik** displayed 100% inhibition against *Chenopodium album* in the postemergence treatment. However, these test compounds exhibited weak herbicidal activity against *Bidens pilosa* relative to the other seven plants in both post- and pre-emergence treatments, except for compound **Ig**, which displayed 50% inhibition in the pre-emergence treatment. Further herbicidal activity evaluation in a lower dose and mode of action investigation are underway at Syngenta Jealott's Hill International Research Centre.

Insecticidal Activities. It is worth noting that some of the analogues **IV** showed selective insecticidal activities (Table 4), although compounds **IV** did not display any herbicidal activities in vivo. For example, compounds **IVs** and **IVt** exhibited insecticidal activity against *Aphis* species to some extent at the concentration of 1000 mg/L. Moreover, the sulfur analogue **IVl** showed insecticidal activity against *Plutella xylostella* at the concentration of 500 mg/L. Further insecticidal activity study will be performed and will be reported in due course.

In summary, α-amino phosphonic acids and their ester derivatives, as bioisosteres of natural amino acids, exhibited versatile biological activities. To find novel high-activity and low-toxicity herbicide lead compounds with novel herbicidal modes of action, four series of novel α-amino phosphonate derivatives containing a pyrimidinyl moiety **I**, **II**, **III**, and **IV** were designed and synthesized by Lewis acid (magnesium perchlorate) catalyzed Mannich-type reaction of aldehydes, amines, and phosphites. The bioassay (in vivo, GH1 and GH2) showed that most compounds **I** exhibited good selective herbicidal activities. However, their structural isomers **II** and **III** and analogues **IV** did not display any herbicidal activities in vivo, although some of them displayed selectivity inhibitory activity against *Arabidopsis thaliana* in vitro. Interestingly, compounds **IVs**, **IVt**, and **IVl** possessed selective insecticidal activities against *Aphis* species or *Plutella xylostella*, respectively. Their preliminary herbicidal mode of action and structure–activity relationships were also investigated.

some progress has been made in elucidating growth-promoting effects of AHX and AOH in plants, the effects of AHX and AOH on the accumulation of carotenoids are completely unknown. In the present study, to elucidate the roles of AHX and AOH in carotenoid metabolism in plants, the effects of AHX and AOH on carotenoid content and composition and the expression of carotenoid metabolic genes were investigated using the culture system. These results presented herein will contribute to a better understanding of the roles of AHX and AOH in plants and provide insights into elucidating the mechanism of AHX and AOH regulation of plant growth.

MATERIALS AND METHODS

Plant Materials. Satsuma mandarin (*Citrus unshiu* Marc.) harvested in October at the Fujieda Farm of Shizuoka University was used as materials.

***In Vitro* Culture System and Treatments.** The fruits were surface-sterilized by a 10 min soak in 70% ethanol and a 30 min soak in 1% (w/v) NaOCl and rinsed in sterile water. Juice sacs excised from the equatorial region of the fruit were placed on 10 mL of agar medium in culture tubes (22 × 120 mm^2) and incubated in the dark at 25 °C. The explants were placed with the endocarp side up, so that the juice sacs were not in contact with the Murashige and Skoog (MS) medium supplemented with 10% (w/v) sucrose and 1% (w/v) agar. The pH of the MS medium was adjusted to 5.7 and autoclaved.[19] AHX and AOH were added into the MS medium, and the final concentration was 100 μM. The juice sacs were treated with AHX or AOH for 4 weeks. Juice sacs cultured on the MS medium without AHX and AOH were used as the control. At each sampling point, 50 juice sacs from 5 fruits were used for each treatment. After each treatment, the juice sacs were immediately frozen in liquid nitrogen, ground into granules, and kept at −80 °C until used.

Extraction and Determination of Carotenoids. The identification, extraction, and quantification of carotenoids in citrus fruits have been described previously.[15] The contents of β-carotene, β-cryptoxanthin, all-*trans*-violaxanthin, 9-*cis*-violaxanthin, and lutein in the juice sacs were examined every 2 weeks during the experiment periods. The content of carotenoid was expressed as $\mu g\ g^{-1}$ fresh weight. Carotenoid quantification was performed in three replicates.

Total RNA Extraction and Real-Time Quantitative RT-PCR. Total RNA was extracted from the juice sacs of Satsuma mandarin according to a previously reported method.[15] The total RNA was cleaned up with the RNeasy Mini Kit (Qiagen, Hilden, Germany) with on-column DNase digestion. The reactions of reverse transcription (RT) were performed with 2 μg of purified RNA and a random hexamer at 37 °C for 60 min using TaqMan reverse transcription reagents (Applied Biosystems).

TaqMan MGB probes and sets of primers for *CitPSY*, *CitPDS*, *CitZDS*, *CitLCYb1*, *CitLCYb2*, *CitLCYe*, *CitHYb*, *CitZEP*, *CitNCED2*, and *CitNCED3* were designed according to Ma et al.[20] For endogenous control, the TaqMan Ribosomal RNA Control Reagents VIC Probe (Applied Biosystems) was used. TaqMan real-time PCR was carried out with the TaqMan Universal PCR Master Mix (Applied Biosystems) using StepOnePlus Real-Time PCR system (Applied Biosystems) according to the manufacturer's instructions. Each reaction mixture contained 900 nM primers, a 250 nM TaqMan MGB Probe, and template cDNA. The thermal cycling conditions were 95 °C for 10 min followed by 40 cycles of 95 °C for 15 s and 60 °C for 60 s. The levels of gene expression were analyzed with StepOnePlus Real-Time PCR system software (Applied Biosystems) and normalized with the results of 18S rRNA. Real-time quantitative RT-PCR was performed in three replicates for each sample.

Statistical Analysis. All values are shown as the mean ± SE for three replicates. The data were analyzed, and Tukey's HSD test (at $P < 0.05$) was used to compare the treatment means.

RESULTS

Effect of AHX and AOH on Carotenoid Content and Composition. In the present study, the juice sacs of Satsuma mandarin were treated with AHX or AOH for 4 weeks, and the changes in carotenoid contents were examined every 2 weeks. Under treatment with AHX, the contents of β-carotene, β-cryptoxanthin, and total carotenoid were increased in the second week. In the fourth week, the content of β-carotene was slightly decreased, while the contents of β-cryptoxanthin, all-*trans*-violaxanthin, 9-*cis*-violaxanthin, lutein, and total carotenoid were not significantly affected by the AHX treatment. Under treatment with AOH, the contents of all the carotenoids examined in the present study were similar to those of the control in the second week. In the fourth week, however, the accumulation of carotenoid was clearly induced by AOH. Under treatment with AOH, the contents of β-cryptoxanthin, all-*trans*-violaxanthin, 9-*cis*-violaxanthin, lutein, and total carotenoid were significantly increased in the fourth week (Figure 2).

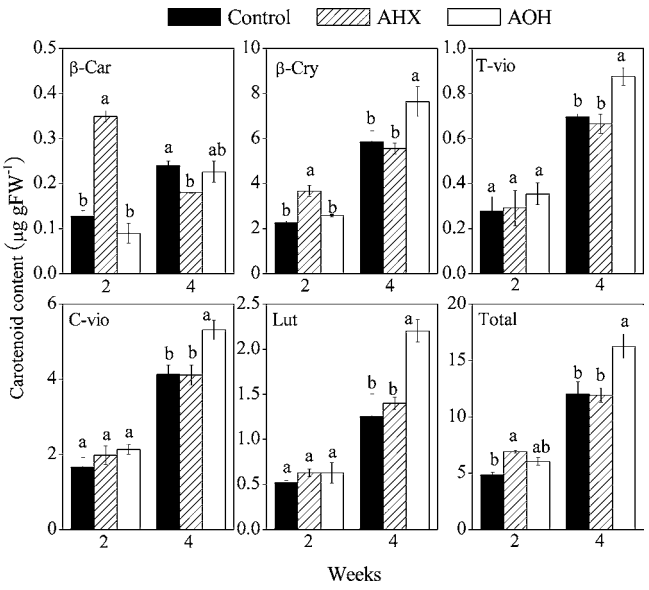

Figure 2. Effect of AHX and AOH on the carotenoid content in citrus juice sacs *in vitro*. β-Car, β-carotene; β-Cry, β-cryptoxanthin; T-vio, all-*trans*-violaxanthin; C-vio, 9-*cis*-violaxanthin; Lut, lutein; Total, total carotenoids. The value for total carotenoids was the sum of identified carotenoids. Columns and bars represent the means and SE (n = 3), respectively. Different letters indicate significant differences at the 5% level by Tukey's HSD test.

Effect of AHX and AOH on the Expression of Genes Related to Carotenoid Metabolism. In citrus fruits, transcriptional regulation of carotenoid metabolic genes is a major mechanism by which carotenoid accumulation is regulated during the ripening process.[15,16,18−20,22] As shown in Figure 3, gene expression of *CitPDS*, *CitZDS*, and *CitLCYb2* was up-regulated, while gene expression of *CitLCYb1*, *CitHYb*, and *CitZEP* was down-regulated by AHX treatment in the second week. In the fourth week, the expression of genes related to β,β-xanthophyll biosynthesis (*CitPSY*, *CitPDS*, *CitZDS*, *CitLCYb1*, *CitHYb*, and *CitZEP*) and genes related to carotenoid catabolism (*CitNCED2* and *CitNCED3*) was simultaneously up-regulated by the AHX treatment. With AOH treatment, the expression of genes investigated in the present study was not significantly affected in the second week, except for *CitHYb* and *CitZEP*. In the fourth week, gene expression of *CitPSY*, *CitPDS*, *CitZDS*, *CitLCYb1*, *CitLCYb2*, *CitHYb*, and *CitZEP* was up-regulated by the treatment with AOH, while the gene expression of *CitNCED2* and *CitNCED3* was not significantly affected. The up-regulation of the expression of β,β-xanthophyll biosynthetic genes was in parallel with the increase in carotenoid contents in AOH treatment in the fourth week.

DISCUSSION

AHX and AOH are novel plant-growth promoting compounds isolated from one fairy forming fungus, *Lepista sordida*. Recently, the presence of endogenous AHX and AOH has been confirmed in various plants, such as rice, tomato, potato, and *Arabidopsis*. In bentgrass seedings, the shoots and roots were elongated by different concentrations of AHX (from 0.05 to 1 mM).[2] Choi et al. reported that treatments with AHX and AOH stimulated the growth of all the plants tested regardless of their families, and the growth-promoting effect of AHX was independent of cytokinin (6-benzylaminopurine) and auxin (naphthalene acetic acid).[2,4] To date, the molecular mechanisms by which AHX and AOH regulate plant growth have not been completely elucidated, and their effects on carotenoid metabolism in plants are still unknown. Citrus fruits are useful materials for studying carotenoid metabolism in plants, due to their high carotenoid contents and complex carotenoid compositions. In recent years, extensive efforts have been made to elucidate the mechanisms of carotenoid accumulation in different citrus varieties, and some key factors that affected carotenoid metabolism have been identified.[15−22,24−26] Rodrigo et al. found that high temperature (37 °C) dramatically decreased the contents of carotenoids, especially β-citraurin, while low temperature (12 °C) increased carotenoid contents in citrus fruits.[21,27] In addition, carotenoid accumulation in citrus fruits was induced by ethylene and abscission agents, while it was suppressed by ABA and GA.[19,20,28] In the present study, the results showed that the carotenoid accumulation was temporally induced by AHX. The total carotenoid content was increased by AHX in the second week, while not significantly affected in the fourth week (Figure 2). In the second week, the contents of β-carotene and β-cryptoxanthin in AHX treatment were 2.7 times and 1.6 times of those in the control, respectively. Gene expression results showed that the up-regulation of the gene expression of *CitPDS*, *CitZDS*, and *CitLCYb2* was consistent with the accumulation of β-carotene and β-cryptoxanthin in the AHX treatment in the second week (Figure 3). In the fourth week, the expression of carotenoid biosynthetic and catabolic genes was simultaneously increased, and as a result, the total carotenoid content was not significantly affected by the treatment with AHX (Figure 3). With AOH treatment, the induction of carotenoid accumulation and the expression of carotenoid biosynthetic genes occurred in the fourth week, which was later than that in the AHX treatment, indicating that the juice sacs might be less sensitive to AOH compared with AHX (Figures 2 and 3). In the fourth week, the up-regulation of the expression of β,β-xanthophyll biosynthetic genes was in parallel with the increase in the contents of β-cryptoxanthin, all-*trans*-violaxanthin, and 9-*cis*-violaxanthin in the treatment of AOH. The results from this study suggest that the two "fairy chemicals", AHX and AOH, regulate carotenoid metabolism in citrus juice sacs. Because carotenoid metabolism is closely related to the biosynthesis of

J. Agric. Food Chem. 2015, 63, 7230−7235

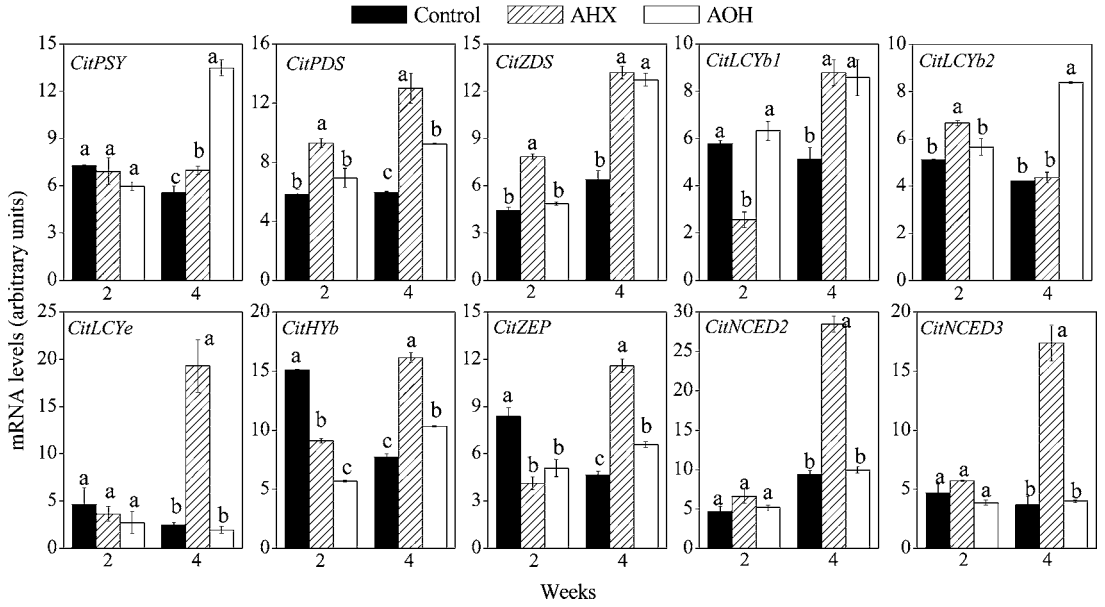

Figure 3. Effect of AHX and AOH on the expression of carotenoid metabolism related genes in citrus juice sacs *in vitro*. The mRNA levels were analyzed by TaqMan real-time quantitative RT-PCR. Real-time RT-PCR amplification of 18S rRNA was used to normalize the expression of the genes under identical conditions. Columns and bars represent the means and SE ($n = 3$), respectively. Different letters indicate significant differences at the 5% level by Tukey's HSD test.

the plant hormones, GA, ABA and strigolactone, we deduced that treatment with AHX and AOH might affect the levels of GA, ABA, and strigolactone through regulating carotenoid metabolism in plants. Moreover, the regulation of GA, ABA, and strigolactone biosynthesis might be a mechanism by which AHX and AOH stimulate plant growth. Further research is needed to confirm this.

β-Cryptoxanthin, the major carotenoid in Satsuma mandarin, is a precursor of vitamin A and beneficial to human health. Some epidemiological studies have shown that serum *β*-cryptoxanthin inversely associated with the risks for cancers, diabetes, rheumatism atherosclerosis, liver dysfunction, metabolic syndrome, and low bone mineral density, as well as oxidative stress.[29−34] In recent years, several efforts have been devoted to enhancing the content of *β*-cryptoxanthin in Satsuma mandarin.[19,35] Rodrigo et al. reported that postharvest storage of citrus fruit at 12 °C promoted the accumulation of *β*-cryptoxanthin in both pulp and juice.[27] Previously, we found that the accumulation of *β*-cryptoxanthin in juice sacs was induced significantly by blue LED light irradiation.[19] In the present study, the results showed that the content of *β*-cryptoxanthin was increased by 60% and 30% by AHX treatment in the second week and AOH treatment in the fourth week, respectively. This suggested that the application of AHX and AOH might be a new strategy for improving nutritional value of Satsuma mandarin.

Previously, it has been found that plants developed tolerance to environmental stress by increasing gene expression of glutathione-*S*-transferases and Bowman-Birk-type proteinase inhibitor after AHX treatment.[2] In rice and wheat, the increase of the yields was due to AHX-induced tolerance to environmental stress.[5] NCEDs, the rate-limiting enzymes for ABA biosynthesis, are also tolerance-related in plants. In *Arabidopsis*, overexpression of *AtNCED3* led to an improvement in drought tolerance.[36] In the present study, the results showed that the expression of *CitNCED2* and *CitNCED3* was simultaneously up-regulated by the AHX treatment in the fourth week. The up-regulation of NCED contributed to enhancing tolerance of juice sacs treated with AHX. Additionally, these results suggested that the regulation of ABA level might be a mechanism by which AHX treatment induced tolerance in plants.

In conclusion, the effects of two "fairy chemicals", AHX and AOH, on carotenoid metabolism of citrus juices sacs were investigated in the present study. The results showed AHX and AOH treatments were effective for enhancing carotenoid content in juice sacs *in vitro*. Meanwhile, the modification of carotenoid accumulation by AHX and AOH treatments was highly regulated at the transcriptional level. This study provides new information on the functions of AHX and AOH in plants, which will contribute to elucidating the mechanisms by which AHX and AOH stimulate plant growth.

lead compounds for the synthesis of new potent PPO inhibitors that are suitable for biotechnological applications.[13−15]

MATERIALS AND METHODS

Mushroom Tyrosinase and Enzymatic Assay. MT (5771 U/mg) was purchased from Sigma-Aldrich (Milan, Italy). A stock solution of the enzyme contained 1 mg/mL. Before use, the enzyme solution was accurately inspected by means of syringaldazine, a typical and sensitive laccase substrate, which allowed us to exclude any laccase contamination. This was necessary because some lots of commercial tyrosinase contain laccase activity.[16,17] This could lead to measurements with ambiguous results as contaminant laccases could share the same substrates with tyrosinase (i.e., *o*-diphenols). A tyrosinase unit was defined according to the manufacturer's definition and calculated such that 1 unit will cause an increase in A_{280} of 0.001 per minute at pH 6.5 and 25 °C in a 3 mL reaction mix containing L-tyrosine. All experiments were performed in 100 mM potassium phosphate buffer, pH 6.5, at 25 °C.

The monophenolase activity using L-tyrosine as its substrate was measured at 468 nm by following the formation of dopachrome with an Ultrospec 2100 Pro UV−vis (Amersham Biosciences) spectrophotometer in the presence of various putative substrates or inhibitors. A control reaction was also conducted. Diphenolase activity was monitored spectrophotometrically by tracking the adduct formation between 4-*tert*-butyl-1,2-benzoquinone and 4-amino-*N*,*N*-diethylaniline at 625 nm (ε_{625} = 11120 M^{-1} cm^{-1}).[18,19] The percentage of inhibition (I %) of the enzyme activity was also calculated according to the equation $I\% = (\Delta A - \Delta B)/\Delta A \times 100$, where ΔA is the difference in the absorbance of the control sample between two incubation times when the absorbance increased linearly and ΔB is the difference in the absorbance of the test sample calculated in the same range of time.[20] The results were the average of at least three readings. Other details are given in the text and in the figure captions.

HPLC Analysis and Sample Preparation. Identification of the products was performed by HPLC analysis using a Beckman System Gold apparatus that was equipped with an UV−vis detector module. An RPC18 column (Phenomenex, Luna, 250 mm × 3 mm i.d., 5 μm), purchased from Chemtek Analytica (Bologna, Italy), was equilibrated with 0.085% phosphoric acid and 5% methanol in water, v/v (solvent A). Solvent B was 0.085% phosphoric acid and 95% methanol in water, v/v. After an initial isocratic elution (10% B for 10 min), a gradient phase of 10−90%, using solvent B, was applied for 10 min (1 mL/min flow rate).

Before the HPLC run was performed, aliquots of the samples were withdrawn at a fixed time, deproteinized by adding phosphoric acid up to 0.085% v/v, and centrifuged at 8000*g* for 10 min. The supernatants were then filtered using a 0.22 μm pore size membrane.

Molecular Docking. *Protein Modeling.* The X-ray crystal structures of MT (PDB entries 2Y9X and 2Y9W)[3] were used as templates for molecular docking studies of the enzyme in complex with our compounds. Note that the crystal structure denoted with the PDB entry 2Y9X contained tropolone, a well-known inhibitor that binds to the active site of the enzyme.

The protein structures were prepared using the Amber tool Xleap,[21] which included all hydrogen atoms. The orientation of polar hydrogen atoms was optimized, the protein protonation state was adjusted, and each structure was minimized with harmonic restraints on the heavy atoms. Successively, all hetero groups and water molecules were deleted. The structures of the enzyme were compared through root-mean-square distance (RMSD) analysis by superimposing the 2Y9W and 2Y9X structures. The RMSD for Cα is low (~0.3 Å), which indicates that the structures are similar (Figure 1C). Because no significant difference was observed in the protein structures, particularly in the binding site, the prepared cocrystal structure (after removal of tropolone) was used for docking studies.

Ligand Modeling. The lead molecules were first drawn with ACD Chem Sketch 11.0 (http://www.acdlabs.com/resources/freeware/chemsketch/). The resulting molecular geometry was then optimized at the B3 LYP/6-31G (d, p) level until a convergence, in energy, of 10^{-5} au using the Gaussian 03 package.[22]

Docking Protocol. Because no explicit information concerning the interaction between MT and the compounds under investigation has been reported previously, we searched for putative binding sites on the enzyme using two different protocols. These protocols were modified from our previous works.[23,24] First, we exploited the available empirical data from the guided docking runs concerning the binding of tropolone to the enzyme.[3] To assess the validity of our results, we performed blind docking calculations. More details about the docking steps and binding site detection programs are provided in the next sections.

From the ligand clusters that were obtained from blind docking on the protein surface, the top five clusters were chosen for further analysis. We then compared these poses with those obtained from guided docking. Once consensus sites were identified, we performed focused docking ("redocking") calculations that centered the docking grid on the center of mass of our compounds in the top pose. All docking runs were performed with AutoDock version 4.2.[25] This program uses a semiempirical, free energy force field to evaluate

DOI: 10.1021/acs.jafc.5b02636
J. Agric. Food Chem. 2015, 63, 7236−7244

conformations during docking simulations. More details about the formulation of the scoring function and its testing can be found in the manual for the program (http://autodock.scripps.edu/faqs-help/manual/autodock-4-2-user-guide/AutoDock4.2_UserGuide.pdf, pp 8−11). The binding site is composed of two copper ions that are coordinated by three histidine residues (for CuA, H61, H85, and H94; and for CuB, H259, H263, and H296). The other residues involved in the stability of compound bonding are as follows: C83, F90, E256, N260, H263, M280, G281, S282, and F292 (see Figure 1B). Therefore, in all docking runs, we modeled the flexibility of these residues.

In an additional protocol for defining the binding sites, we defined the center of the binding site as the center of mass of the residues surrounding the tropolone (Figure 1B), that is, H61, H85, H259, N260, H263, P264, M280, S282, V283, and A286.

Guided Docking. Guided docking is a biased docking procedure, for which we used previously acquired information about the binding of the substrate on the target protein (MT). The availability of the cocrystal structure of MT with tropolone allows us to perform this guided docking. Thus, to check the reproducibility of our docking protocol, we first performed the docking with the tropolone molecule [the complexed structure (PDB-ID 2Y9X)]. In step 1, the tropolone molecule was removed and then redocked. In step 2, the modeled and optimized structure of tropolone (drawn by Chemsketch and optimized through the Gaussian 03 package) was used to perform the docking. The binding pocket of the tropolone was chosen as the grid center in both steps.

Grids with dimensions of 68 × 80 × 80 and a spacing of 0.375 Å were used. The Lamarckian genetic algorithm was used for conformational sampling of the compound. For each docking simulation, 200 runs were carried out with 300 random individuals in the first population and 2.5×10^6 energy evaluations. For a local search, the so-called pseudo-Solis and Wets algorithms[25] were applied using the default parameter. The low RMSD difference (0.6 Å) between the complex docked-pose of tropolone obtained from the above-described steps 1 and 2 (data not shown) confirmed the reliability of the docking protocol. Furthermore, the optimized structures of our compounds were docked in the same binding site by using the same input parameters. The binding poses of compounds were ranked and clustered on the basis of their energy scores and populations.

Blind Docking. This docking protocol is an unbiased docking approach, whereby a grid covers the whole surface of the protein to locate the most likely binding site of lead molecules. AutoGrid 4.0 was employed to build a 126 × 126 × 126 grid map covering the whole RdRp, with grid spacing of 0.586 Å and a center on the center of mass of the whole MT. The Lamarckian genetic algorithm was used for conformational sampling of the compounds. For each docking simulation, 200 runs were carried out with 300 random individuals in the first population, 2.5×10^7 energy evaluations, and 2.7×10^7 generation numbers. For each run, the lowest energy conformation of the compounds was chosen for clustering according to an RMSD cutoff of 2 Å. Clusters were then ranked and clustered on the basis of the AutoDock energy scores and populations. The goal of conducting blind docking was to validate the guided docking outcome: whether the lead substrate candidate sat only in the tropolone-binding site or in some other binding location. Indeed, the top cluster representatives obtained from the blind docking (i.e., the clusters having the lowest docking energy and maximum number of confirmations/population) confirmed that each lead occupied the same binding site.

RESULTS AND DISCUSSION

In this study, we explored the effects of four hydroxycoumarins (3-, 4-, 6- and 7 isomers, see Scheme 1) on the activity of MT under different conditions. This will ultimately provide us with mechanistic insights from kinetic data.

Hydroxycoumarins with a Hydroxy Substituent on the Aromatic Ring. Two of the four hydroxy-substituted coumarins studied in this work (6- and 7-isomers) are hydroxylated on the aromatic ring. Of these, only one has a reported interaction with PPOs.[26−28] In particular, the inhibitory action of 7-hydroxycoumarin (7-HC, also known as umbelliferone) toward L-tyrosine hydroxylation was noted.[27] The MT-catalyzed transformation of L-tyrosine was monitored through the detection of dopachrome formation. As shown in Figure 2, dopachrome is strongly inhibited by 7-HC in a

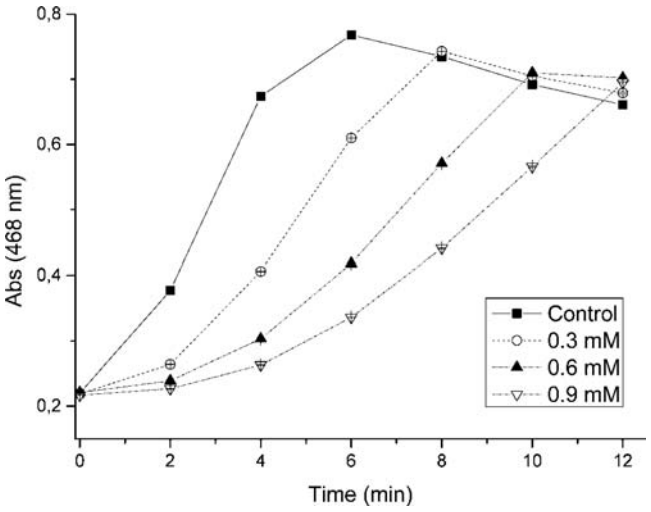

Figure 2. Tyrosinase-catalyzed oxidation of L-tyrosine in the presence of 7-hydroxycoumarin (7-HC). The reaction mixture contained 3 mM L-tyrosine, 95 enzyme units, and 7-HC substrate at a concentration that ranged from 0.3 to 0.9 mM. Other experimental conditions were 100 mM potassium phosphate buffer, pH 6.5, in a 1 mL final volume and 25 °C temperature.

concentration range of 0.3−0.9 mM. At the maximum 7-HC concentration, the inhibition reached 88%. This phenomenon is due to the specific inhibition of L-tyrosine conversion, which is confirmed by HPLC analysis of the reaction products (see the Supporting Information, Figure SM1) and not due to any interference by a putative quinone arising from 7-HC hydroxylation and oxidation, as previously suggested.[26] A further confirmation of the reduced conversion of L-tyrosine can be observed in the decreased appearance of L-3,4-dihyroxyphenylalanine (DOPA), which is the product of the reaction (see the Supporting Information, Figure SM2).

Moreover, the hydroxylation of 7-HC by MT, which yielded 6,7-dihydroxycoumarin (also known as esculetin), has been observed; however, this occurred only under particular experimental conditions and with a very low k_{cat}.[26] Although these observations appear contradictory, they are not surprising. A substantial reduction of the conversion speed of a certain substrate is normally observed in the presence of another substrate, the affinity of which is much higher and having a k_{cat} much smaller than those observed for the first substrate. The second substrate then behaves as a "competitive substrate", as its enzymatic transformation is too slow to be observed during the planned reaction time for the first enzymatic reaction. However, if the favorable substrate is absent from the reaction mixture, then even the less favorable substrate can be converted by the enzyme. Recently, a method to discriminate between alternative substrates and inhibitors of tyrosinase has been proposed.[29]

Unlike 7-HC, 6-hydroxycoumarin (6-HC) is rare in nature and has been found in only a few plants[30] and as a secondary

DOI: 10.1021/acs.jafc.5b02636
J. Agric. Food Chem. 2015, 63, 7236−7244

metabolite of an unsubstituted coumarin in certain animals. Yet, like 7-HC, it bears its hydroxyl substituent on the aromatic ring; for this reason, it could be considered a true monophenol derivative. Therefore, given the monophenolase/hydroxylase activity of the enzyme, this compound could behave as a substrate. This was confirmed by the experimental results, with the consumption of 6-HC in the presence of the enzyme. Therefore, 6-HC was found to be a substrate for MT (Figure 3A, line a). 6-HC behaved as a monophenol substrate and was

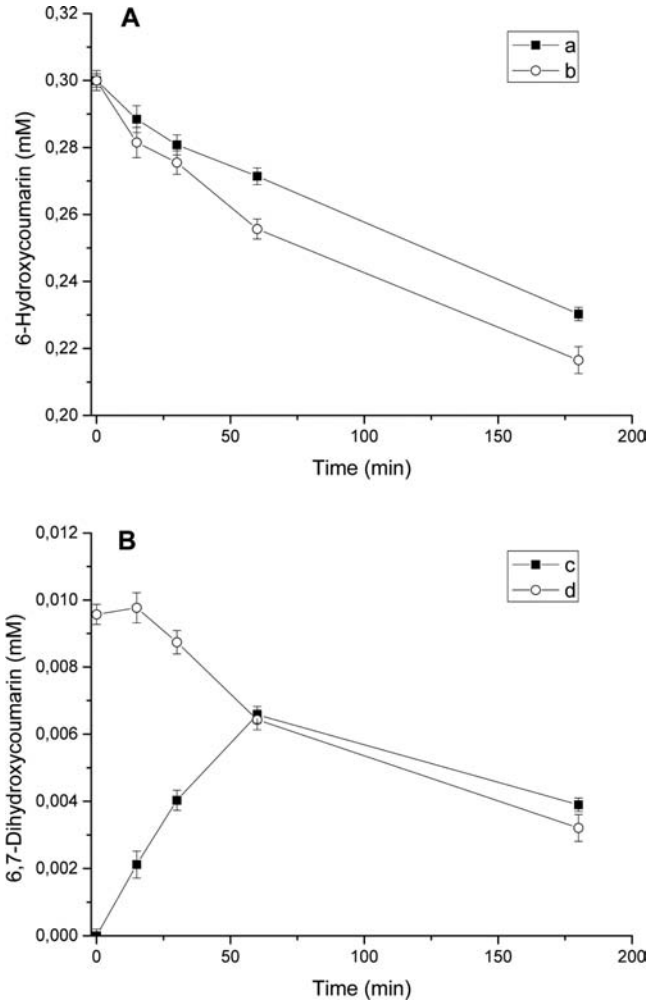

Figure 3. Tyrosinase-catalyzed oxidation of 6-hydroxycoumarin (6-HC) and 6,7-dihydroxycoumarin (esculetin). HPLC measurement was performed in a time course of 6-HC (A) and esculetin (B) concentration in a reaction mixture containing mushroom tyrosinase (95 enzyme units), 0.3 M 6-HC (lines a, c), and 0.3 mM 6-HC plus 10 μM esculetin (lines b, d) as the initial concentrations. Other experimental conditions were 100 mM potassium phosphate buffer, pH 6.5, in a 1 mL final volume and 25 °C temperature.

therefore *o*-hydroxylated to yield the corresponding *o*-diphenol. Two different compounds could be the products of 6-HC *o*-hydroxylation: esculetin and 5,6-dihydroxycoumarin. From our experiments, this latter unnatural compound was not detected at all, indicating that 6-HC exclusively was converted into esculetin, (Figure 3B, line c), which is a substrate for the enzyme.[27] Indeed, after 60 min, the esculetin concentration decreased as it was enzymatically converted to the corresponding *o*-quinone. It is already known that low concentrations of diphenols can operate by activating the monophenolase activity of tyrosinase.[31] Indeed, when the reaction was conducted in the presence of sufficient concentrations of esculetin (Figure 3B, line b), the disappearance of 6-HC and the formation/disappearance of esculetin (Figure 3B, line d) accelerated. This confirmed the ability of this compound to play the dual role of both a substrate and an activator of tyrosinase.

Hydroxycoumarins with an Unsubstituted Aromatic Ring. 3-Hydroxycoumarin (3-HC) is also rare in nature, but is sometimes found in plants.[32] Interestingly, 3-HC was recently demonstrated to protect sea urchin reproductive cells against ultraviolet B damage.[33] It has been chosen for the present study because MT should not hydroxylate it. This is because the hydroxyl-bearing ring is not aromatic and the aromatic ring of the compound is unsubstituted. MT is only able to ortho-hydroxylate phenols and aromatic amines.[31,34,35] Furthermore, the close proximity of the carbonyl moiety in 3-HC renders the putative hydroxylation site, the 4-position, relatively electrophilic and therefore not suitable for hydroxylation by MT,[36] which performs ortho-hydroxylation through an electrophilic mechanism that requires relatively high electron density on the target carbon atom.[37] The HPLC analysis of the products of the reaction of tyrosinase with 3-HC as a possible substrate shows that there was no consumption of 3-HC (see the Supporting Information, Figure SM3). Finally, 3-HC shows the same structural motif (i.e., an enol−ketone) that is typical of some well-known PPO inhibitors, such as tropolone, kojic acid, and mimosine.[38] On the basis of these considerations, we tested 3-HC as a possible inhibitor of MT and compared its effectiveness with that of tropolone.

Figure 4 shows the trend of catalytic consumption of L-tyrosine by MT in the presence of 3-HC or tropolone in comparison to a control. Figure 4A shows that the consumption of L-tyrosine is negligible when the reaction is carried out in the presence of tropolone, whereas in the presence of 3-HC, only approximately 3% of the substrate is consumed after 30 min of incubation. This behavior of the two inhibitors was confirmed by the concentration of L-DOPA in the same samples (Figure 4B), which is below the limit of measurement in the presence of 3-HC and tropolone.

This sharp inhibitory behavior of 3-HC on MT follows from the general trend of the structure−activity relationship between MT and phenolics (and phenolic analogs).

In contrast, nonsubstituted coumarin (1,2-benzopyrone) was reported to inhibit apple PPO.[39] Docking studies performed with this enzyme revealed that the compound is able to enter the enzyme active site, where it is anchored to a specific L-tyrosine residue by a hydrogen bond.[39] The alleged complexing ability of coumarin toward Cu^{2+} is not presently well evidenced and, therefore, should not be considered as a driving force for the observed PPO and coumarin interaction(s). However, we could not find any interaction between the MT and the unsubstituted coumarin. This observation highlights the importance of the hydroxy substituent(s) for a specific interaction with the enzyme active site to occur.

We can conclude that the chelating ability of tropolone toward the cupric ions of the dicopper cluster is not important to explain its inhibitory properties: the molecule lays too far from the metal center and is most likely connected to one cupric ion by means of a hydrogen-bond-engaged water molecule. The kinetics of the inhibition of MT by tropolone has been already studied,[40] and a specific interaction with the oxy form of the enzyme was proposed to explain the particular behavior of the inhibitor. To establish the true mechanism of

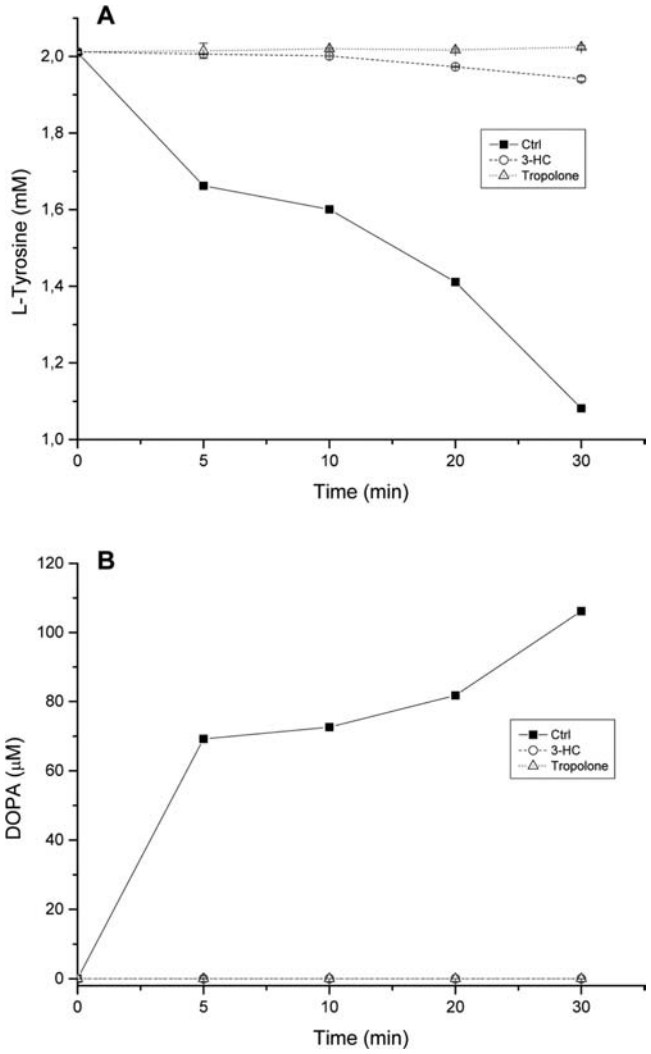

Figure 4. Tyrosinase-catalyzed oxidation of L-tyrosine in the presence of 3-hydroxycoumarin (3-HC) and tropolone. HPLC measurements of L-tyrosine (A) and L-DOPA (B) concentrations were performed over time in the presence of 0.5 mM 3-HC and 0.5 mM tropolone and in their absence (Ctrl). Other experimental conditions were 2 mM L-tyrosine, 100 mM potassium phosphate buffer, pH 6.5, in a 1 mL final volume and 25 °C temperature.

MT inhibition by 3-HC, we conducted spectrophotometric experiments to compare the kinetics of tropolone and 3-HC as inhibitors of MT under identical experimental conditions. Whereas tropolone behaved as a slow-binding inhibitor, which confirmed the findings of Espin and Wichers,[40] 3-HC behaved as a "normal" inhibitor (data not shown). This finding suggests that the two molecules are accommodated differently within the enzyme active site. More specifically, 3-HC most likely interacts with the most abundant form of MT, namely, the met form.[1] Remarkably, even the addition of 0.2 mM $CuSO_4$ was not able to remove the inhibition.[40]

Due to the bonding pattern described above, 4-hydroxycoumarin (4-HC) also should not behave as a substrate for MT. HPLC analysis confirmed that 4-HC did not behave as a substrate for MT (see the Supporting Information, Figure SM4).

In Figure 5, the reaction of MT with L-tyrosine in the presence of increasing concentrations of 4-HC is reported. Note that in the first minutes, the formation of dopachrome is

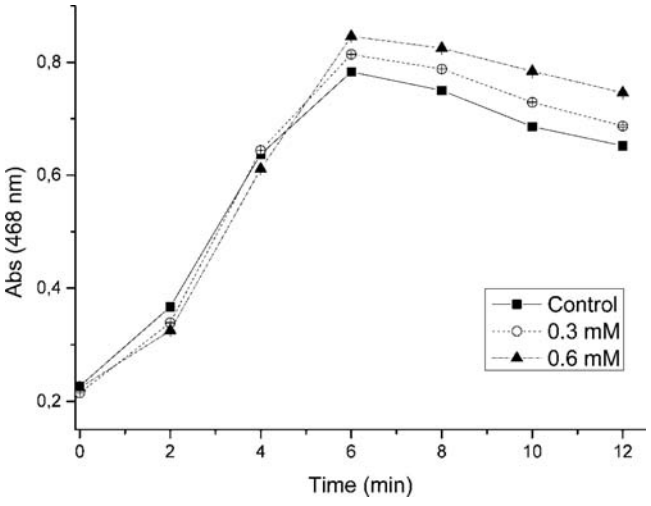

Figure 5. Tyrosinase-catalyzed oxidation of L-tyrosine in the presence of 4-hydroxycoumarin (4-HC). The reaction mixture contained 3 mM L-tyrosine and 95 enzyme units. The 4-HC concentration ranged from 0.3 to 0.6 mM. Other experimental conditions were 100 mM potassium phosphate buffer, pH 6.5, in a 1 mL final volume and 25 °C temperature.

not substantially affected by the presence of 4-HC. In its presence, the formation of dopachrome appears to be slightly increased between the fourth and sixth minutes and then persists for a longer period before it decreases because of nonenzymatic reactions that lead to the formation of melanin. The origin of this behavior is still unknown, but we can assume that, at concentrations much higher than the amount of dopachrome, 4-HC can create an effect of crowding at the catalytic site of the enzyme, thereby slowing the release of the product of the reaction. Yet, a reaction between 4-HC and nonenzymatic transformation products of dopachrome is also possible.

A comparison of the overall effect of the examined hydroxycoumarins can be observed in Figure 6. The four compounds, 3-, 4-, 6-, and 7-hydroxycoumarin, were incubated in the presence of MT. We then used L-tyrosine as a substrate and measured the formation of melanin over time. Both 4-HC and 6-HC had no inhibitory effect on enzymatic activity, as the formation of melanin did not decrease. The presence of 7-HC, however, slowed the formation of dopachrome in the early stages of the reaction but failed to prevent melanin formation after an adequate period of time. In contrast, only 3-HC persisted in its inhibitory activity, as the formation of melanin was not observed in the 2 h following the start of the experiment. Moreover, the inhibitory activity of 3-HC is strictly dose-dependent (see the Supporting Information, Figure SM5).

Molecular Docking Study. Prompted by these findings, we searched for the putative positions of three compounds within the active site of the enzyme (3-HC, 6-HC, and 7-HC) via in silico molecular docking (4-HC was not considered in the molecular docking investigation, being neither a substrate nor an inhibitor). The results of the docking runs are summarized in Table 1.

Concerning the comparatively bulky 3-HC, the molecular modeling investigation resulted in two clusters, of which the representative Ori1 and Ori2 clusters are shown in Figures 7A,B. The two clusters have very different populations (46% of the configurations are in Ori1, whereas 14% of the configurations are in Ori2; see Table 1), and Ori1 has a

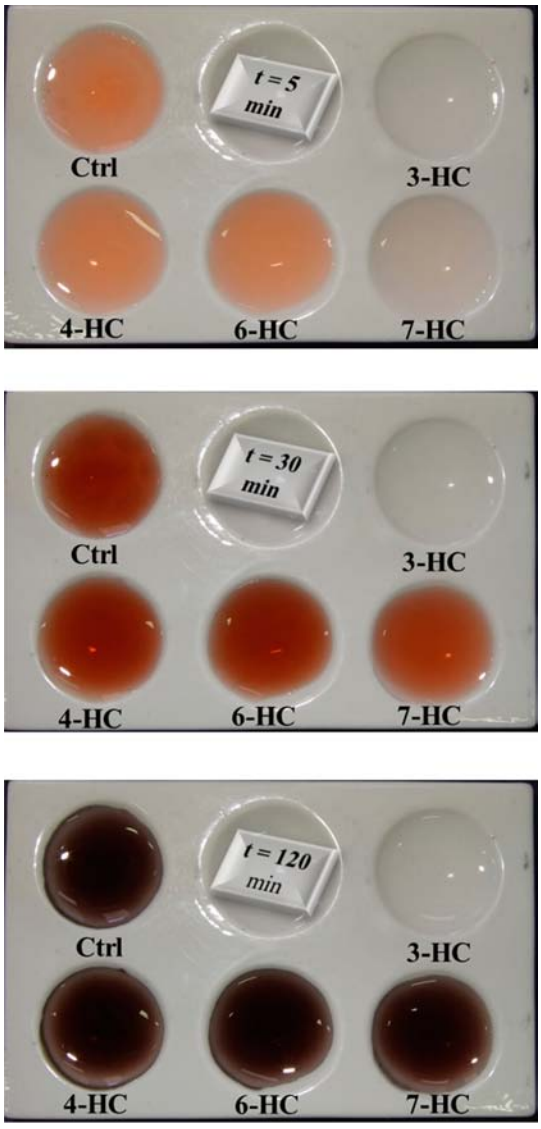

Figure 6. Effect of the four studied hydroxycoumarins on the formation of melanin via mushroom tyrosinase in the presence of L-tyrosine as the substrate. The following enzymatic reactions have been performed on a porcelain spot plate: Ctrl, incubation of tyrosinase (46 EU) and L-tyrosine (2 mM) as the control; 3-HC, 4-HC, 6-HC, and 7HC, incubation of tyrosinase (46 EU) and L-tyrosine (2 mM) in the presence of 0.6 mM of each hydroxycoumarin. The enzymatic reaction was buffered with 0.1 M potassium phosphate, pH 6.5. Pictures were taken over the reported time.

Table 1. Results of Molecular Docking[a]

compound	orientation	scoring function (kcal/mol)	population (%)
3-HC	Ori1	−7.88	46.0
	Ori2	−7.36	14.0
6-HC	Ori1	−8.29	29.5
	Ori2	−8.15	38.0
7-HC	Ori1	−6.52	17.5
	Ori2	−6.28	21.5

[a]The population is given over the total population of the run associated with each compound.

slightly better scoring function. The two configurations are rotated with respect to one another by an angle of approximately 180° around the major axis of the molecule (flip orientation). In Figure 7C, the two orientations are superimposed upon one another. The H atoms of the hydroxyl groups of the two conformations are directed in an opposing manner, whereas, in both conformations, the oxygen atom of the OH group occupies a position along the location of the oxygen atom of a crystallographic water molecule. Therefore, 3-HC accommodates within the MT active site in a manner quite similar to that proposed for mimosine[41] and kojic acid.[42] With these inhibitors, which are transition state analogues, the oxygen of the hydroxyl group acted as a bridge between the two cupric ions, thus displacing the pre-existing water (or hydroxide) already present in the met form. As a consequence, a stable adduct between the dicupric cluster and the inhibitor molecule is formed, preventing the approach of the substrate to the catalytic site. In principle, both Ori1 and Ori2 poses fit well with such an inhibitory mechanism.

However, the distances of the O atom of the OH group from the Cu ions differ in the two poses. The O atom of Ori1 is roughly at the same distance from both Cu ions (2.4 vs 2.6 Å), whereas the O atom of Ori2 is located 2.0 and 3.0 Å away from CuA and CuB, respectively. Ori1 is characterized by the position of the O atom of the OH group, which is more symmetric with respect to the two Cu ions when compared with Ori2. The different population of the two clusters associated with Ori1 and Ori2 suggests that the hydroxyl group interacts with the two Cu ions, thus confirming the bridging role of the oxygen atom of the hydroxyl group as depicted above. Both kinetic and docking data confirm the strict analogy between the inhibitory behavior of mimosine and kojic acid and that of 3-HC. However, despite the structural analogy, tropolone behaves differently, due to its peculiar positioning within the active MT site that follows from the water molecule bridging the inhibitor to the oxy form of the enzyme.[40] The Ori2 pose is less symmetrical than the Ori1 and could be less effective as an inhibitor; however, due to the above-described structural and mechanistic reasons, the potential substrate role for this pose is not possible.

For the 6-HC substrate, two clusters have been identified that have the lowest docking scoring functions. Interestingly, the highest affinity site obtained from the blind docking protocol is similar to the site obtained from the guided docking protocol (i.e., Ori1 and Ori2 are representatives of the two clusters that are reported in Figure 7D,E, respectively, with Figure 7F displaying both poses). The difference in the scoring function of the two orientations was small, and also the populations of the two clusters did not differ remarkably (29.5 and 38.0% over the total population, respectively, as reported in Table 1). The two poses are characterized by the opposite orientation of the hydroxyl group. In Ori1, the pose that belonged to the cluster with a better scoring function but a slightly lower population, the hydroxyl group is close to the two Cu ions with the OH group at distances of 1.9 and 2.8 Å from CuA and CuB, respectively. The asymmetrical positioning of the hydroxyl group in Ori1 is in agreement with the substrate nature of 6-HC, which can be ortho-hydroxylated to esculetin by the oxy-MT. The hydroxyl group of Ori2 points toward the opening of the active site, and the distances between the CuA and CuB and the closest oxygen atom of Ori2 are 2.1 and 2.9 Å, respectively. It is readily apparent that this pose is unproductive as a MT substrate; however, it could act, in principle, as a slight inhibitor by obstructing the active site. Interestingly, the stability of the poses of this compound appears to be unaffected

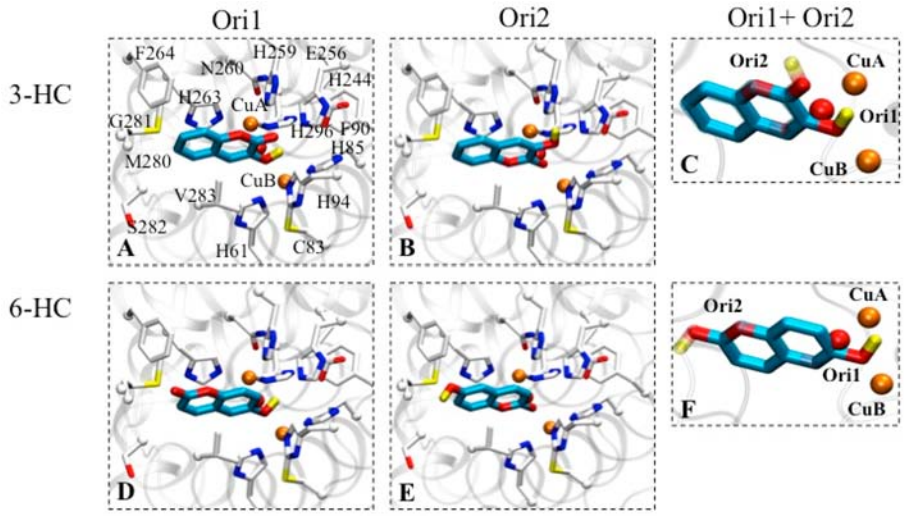

Figure 7. Characterization of the binding site and of representatives of the most populated clusters of the lead molecules (3-HC, upper panels; 6-HC, lower panels). Panels A and B show the two representatives (Ori1 and Ori2) of 3-HC (in thick licorice), and panel C shows the combination of the two poses (in solid Ori1, in transparence Ori2). In panel A, the residues of the binding site are shown in licorice and are labeled. In all panels, the Cu ions are colored dark orange and the residues of the binding site are rendered in an atom type manner, such that C is white, O is red, N is blue, and S is yellow. Panels D and E contain the two representatives of the most populated clusters of 6-HC, and panel F collects both poses. The binding site residue's name and their positions are the same in all of the panels as well as the color and rendering codes.

by the position of the hydroxyl group relative to the active site groups.

The docking runs for the 7-HC substrate also yielded two main clusters with populations that were not dissimilar (17.5 and 21.5% for Ori1 and Ori2, respectively, over the total population; Table 1). The two clusters were characterized by the worst scoring functions among the three compounds. This might suggest a poor affinity of the compound for the enzyme. Yet, the 7-HC substrate behaves as an effective "competitive substrate" during MT-catalyzed L-tyrosine conversion to melanin, even though its affinity for the MT active site appears from the docking calculations to be comparatively low in comparison with that of 6-HC. Additionally, the 6-HC substrate is a distinctly more effective MT substrate than the 7-HC substrate (see the Supporting Information, Figure SM6). Moreover, it is unable to reduce the L-tyrosine conversion into melanin (Figure 6). The answer could be that the two top poses found for the 7-HC substrate account for <40% of the whole population, whereas the remaining 60% of the population is distributed over several configurations that are poorly populated.

However, the ranking of the poses might be affected by the intrinsic limitations of the docking procedure, such as the absence of the solvent or the limited description of the flexibility of the enzyme and compounds. The apparent contradiction between kinetic and docking data indicates that a variety of factors affect the complicated MT and substrate interactions. Thus, a more complete picture requires a molecular dynamics study in which the solvent, temperature, and dynamical effects are considered. This might be a future direction of investigation.

In conclusion, our study, which was based on the structure–activity relationship of four hydroxycoumarins and MT, allowed us to identify anti-tyrosinase properties for use in developing molecules that are derived from coumarin. In particular, the positioning of the hydroxyl group of the hydroxycoumarin on the aromatic ring determines the substrates' behavior. For example, the hydroxyl group at positions 6 or 7 results in the molecule behaving as a weak substrate for the enzyme. This follows from the direct interaction of the hydroxyl group with the two Cu ions of the enzyme active site. However, if the hydroxyl group is located on the pyrone ring of coumarin, the interaction with the enzyme is only possible if the molecule enters the active site with a rotation of 180°. Because the pyrone ring cannot be hydroxylated by tyrosinase, the presence of a pre-existing hydroxyl group makes this molecule unreactive with the enzyme (e.g., the 4-HC substrate) or a potent inhibitor (e.g., the 3-HC substrate).

The results obtained from both the kinetics experiments and molecular docking approach studies demonstrate that the structure of 3-hydroxycoumarin may represent a lead compound for the development of a new class of inhibitors.

Table 1. Main Ingredients Relative to Protein and Fat Fractions of Infant Formulas (IFs) Analyzed, Fat Content Determined, and Reconstitution Factors (RF)[a]

IFs	country	ingredients	fat (% w/w)	RF (% w/v)
1	Spain	milk lipids, skimmed milk, vegetable oils (rapeseed, sunflower, oleic sunflower), whey protein, fish oil (DHA), *Mortierella alpina* oil (ARA), emulsifier (soya lecithin)	22.0 ± 2.1	13.5
2		demineralized whey protein, skimmed milk, vegetable oils (palm, rapeseed, coconut, sunflower), mortierella alpine oil (ARA), fish oil, soya lecithin, milk proteins	25.5 ± 1.0	12.9
3		skimmed milk, vegetable oils (palm, palm kernel, rapeseed, sunflower, sunflower high oleic, arachidonic acid), whey protein enriched with α-lactoalbumin, emulsifier (soya lecithin), fish oil (source of DHA)	23.7 ± 0.3	13.5
4		vegetable oils (palm, coconut, rapeseed, high oleic sunflower, sunflower), skimmed milk, whey protein concentrate, fungi and seedweed oils	25.3 ± 0.8	12.9
5		skimmed milk, milk fat, whey enriched in MFGM, whey enriched in α-lactoalbumin, soya lecithin, fish oil, vegetable oils (sunflower, rapeseed, palm, coconut, single cell oil)	27.2 ± 0.6	13.0
6		vegetable oils (sunflower, rapeseed, palm, coconut, single cell oil), skimmed milk, milk fat, whey protein rich in MFGM, whey protein rich in α-lactoalbumin, milk protein, fish oil, emulsifier (soya lecithin)	34.8 ± 0.7	11.4
7	Sweden	whey powder, vegetable oil (palm, canola, coconut, sunflower), skimmed milk powder, fish oil, oil from *Mortierella alpina*, emulsifier (soy lecithin)	25.8 ± 0.1	12.9
8		organic skimmed milk, organic demineralized whey powder, organic vegetable oils (palm, rapeseed, sunflower), polyunsaturated oils (fish, vegetable)	23.2 ± 0.6	13.0
9		skimmed milk, milk fat, whey enriched in MFGM, whey enriched in α-lactoalbumin, soya lecithin, fish oil, vegetable oils (sunflower, rapeseed, palm, coconut, single cell oil)	27.7 ± 2.2	13.0
10	Czech Republic	demineralized whey powder, vegetable oils, whole milk powder, skimmed milk powder, emulsifier (lecithin)	22.4 ± 2.0	12.9
11		demineralized whey, skimmed milk powder, vegetable oils (palm, rapeseed, sunflower, coconut, microbiologic (ARA)), soya lecithin, fish oil	22.3 ± 2.6	13.5
12		demineralized whey (from milk), vegetable oil, dried skimmed milk, whey protein concentrate (from milk), fish oil, soya lecithin	24.3 ± 0.4	13.5
13		demineralized whey, vegetable oils (palm, rape, coconut, sunflower, oils from microbial resource (ARA)), dried skim milk, concentrated whey milk, soya lecithin	21.4 ± 0.5	13.8

[a]DHA: docosahexaenoic acid. ARA: arachidonic acid. MFGM: milk fat globule membrane.

MATERIALS AND METHODS

Reagents. *Standards.* For sterol determination, the standards used were 5β-cholestan-3α-ol (epicoprostanol) (purity ≥95%) as internal standard (IS), 5-cholesten-3β-ol (cholesterol) (purity 99%), 5,24-cholestadien-3β-ol, (desmosterol) (purity 84%), stigmasta-5,22-dien-3β-ol (stigmasterol) (purity 95%), stigmast-5-en-3-ol (β-sitosterol) (purity 98%), and 24α-ethyl-5α-cholestan-3β-ol (stigmastanol) (purity 97.4%) from Sigma Chemical Co. (St. Louis, MO, USA) and 5,22-cholestadien-24β-methyl-3β-ol (brassicasterol) (purity 98.6%) and 5-cholesten-24α-methyl-3β-ol (campesterol) (purity 98.6%) purchased from Steraloids (Newport, RI, USA).

Reagents. Chloroform, diethyl ether, ethanol, methanol, potassium chloride, sodium chloride, anhydrous sodium sulfate, acetone, and 2-propanol were purchased from Merck & Co., Inc. (Whitehouse Station, NJ, USA). Potassium hydroxide, butylated hydroxytoluene (BHT), and *N*,*O*-bis(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane (silylating reagent) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Anhydrous pyridine (silylating reagent) was from Fluka (Buchs, Switzerland), and *n*-hexane (purity 96%, HPLC grade) was from Scharlau Chemie, S.A. (Sentmenat, Barcelona, Spain). All reagents were of analytical grade. Ultrapure water was obtained by means of a Millipore Q water purification system (Milford, MA, USA).

Preparation of Solutions. Internal standard (IS) solution of epicoprostanol in ethanol was prepared at a concentration of 1 mg/mL. Standard solutions of sterols were prepared by dissolving the standards in an *n*-hexane:2-propanol (3:2, v/v) mixture at the following concentrations: 1 mg/mL (β-sitosterol), 100 μg/mL (brassicasterol), 1 mg/mL (campesterol), 1 mg/mL (cholesterol), 100 μg/mL (desmosterol), 2.5 μg/mL and 100 μg/mL (stigmastanol), and 100 μg/mL (stigmasterol). All solutions were aliquoted (1 mL) and stored at −20 °C under a nitrogen atmosphere (purity >99%, nitrogen generator Zefiro 40 F-DBS, Courtaboeuf-Cedex, France). To prevent falsely elevated values of IS and standard solutions, immediately prior to analysis the solvents of the stock solutions were completely evaporated with a stream of nitrogen and dissolved with 1 mL of solvent.

A mixture of pyridine:*N*,*O*-bis(trimethylsilyl)trifluoroacetamide (with 1% trimethylchlorosilane) (3:10, v/v) was prepared weekly and stored at 4 °C in an amber glass flask for derivatization. Glass material used for this preparation was rinsed with acetone immediately before use to remove moisture.

Samples. Thirteen powdered IFs marketed in three European countries (Sweden, the Czech Republic, and Spain), for infants between 0 and 6 months of age, were selected for sterol analysis. The label-stated compositions referring to compounds of the protein and fat fractions as a source of sterols are summarized in Table 1. It should be mentioned that, in addition to vegetable oils and fish oils commonly added to these products, some formulas (1, 5, and 9) contain milk fat and whey enriched with MFGM.

Determination of Plant Sterols. Samples were reconstituted as indicated on the labeling (reconstitution factor between 11.4 and 13.8% w/v), and a volume of sample (2 mL) providing approximately 70 mg of fat. Three independent assays of the same batch were analyzed. Lipids were extracted applying the method described by Alemany-Costa et al.,[15] though filtration was made with Whatman no. 2V, 125 mm, (Buckinghamshire, U.K.), and 20 mL of 1 M KCl solution was added to the filtrate instead of 10 mL. The lipid fraction obtained (approximately 70 mg) was processed using the method described by González-Larena et al.,[16] with minor modifications. Briefly, IS (20 μg of epicoprostanol) was added to the lipid fraction, and hot saponification (2.5 mL of 2 N KOH in 90% ethanol at 65 °C during 1 h) was performed. The unsaponifiable material was then extracted with diethyl ether and subjected to derivatization with BSTFA-1%TMCS:pyridine (10:3). The trimethylsilyl ether (TMSE) derivatives obtained were dissolved in *n*-hexane, filtered (syringe-driven Millex-FH filter unit, 1 mL, 0.45 μm Millipore, Milford, MA, USA), and evaporated with nitrogen. The TMSE derivatives were dissolved in 100 μL of *n*-hexane, and 1 μL was injected into a gas chromatograph with flame ionization detector (GC-FID) (AutoSystem XL, PerkinElmer, Norwalk, CT, USA) equipped with a CP-Sil 8 low bleed/MS (50 m × 0.25 mm × 0.25 μm film thickness) capillary column (Chromopack-Varian, Middelburg, The Netherlands), with application of the chromatographic conditions previously proposed for serum sterol determination,[11] with a split ratio of 1:10.

p[c]	*[d]	*[d]		*[d]

[a]Values are expressed as mean ± standard deviation of three replicates. Different letters in the same column indicate significant differences between infant formulas (IFs). Tukey's HSD test. [b]Not detectable. [c]ANOVA results for each sterol and total animal sterols among IFs. [d]*$p < 0.001$.

All glassware (tubes and vials) was scrupulously cleaned, rinsed with distilled water, and introduced in a Heraeus Thermicon K1253A oven at 450 °C during 8 h to remove contamination according to García-Llatas et al.[17] The Pyrex glass tubes with a conical bottom, employed for derivatization, were previously silanized with derivatization solution in order to avoid the adsorption of TMSE derivatives.[18]

Sterols were identified by comparing standards derivatized by the same procedure as the samples. For quantification, sterol calibration curves of brassicasterol (1−6 μg), β-sitosterol (25−78 μg), campesterol (10−39 μg), cholesterol (20−317 μg), desmosterol (1.7−227 μg), stigmasterol (2−15 μg), and sitostanol (stigmastanol) (0.24−6 μg) containing 20 μg of IS (epicoprostanol) were performed. The correlation coefficients (r) obtained for the different sterols were >0.99.

Estimation of Intake. To calculate intake during the first months of life, the average intake (mL/day) obtained from the literature and corresponding to a total of 1113 healthy infants born at term was used.[19−26] The mean volumes of the IFs (mL/day) ingested by these newborn infants were evaluated at 7 concrete moments of lactation: 0.5 months, 607 ± 31 (n = 307); 1 month, 754 ± 112 (n = 1093); 2 months, 877 ± 158 (n = 937); 3 months, 895 ± 160 (n = 937); 4 months, 933 ± 157 (n = 875); 5 months, 990 ± 31 (n = 645); and 6 moths 873 ± 125 (n = 665).

Statistical Analysis. Analysis of variance (ANOVA) and Tukey's HSD test ($p < 0.001$) were applied to total sterols and individual sterol contents to evaluate possible differences according to the type of sample involved.

In estimating intake, two-tailed (sample and lactation stage) ANOVA was applied to the mean values, followed by Tukey's HSD test. A significance level of $p < 0.001$ was adopted for all comparisons.

The Statgraphics Plus version 5.1 statistical package (Rockville, MD, USA) was used throughout.

RESULTS AND DISCUSSION

Animal Sterols. The total and individual contents of the main animal sterols (cholesterol and desmosterol) are summarized in Table 2. Total animal sterols ranged from 1.71 to 5.46 mg/100 mL sample, cholesterol being the main animal sterol (1.46−5.1 mg/100 mL). The cholesterol concentrations found in our study were comparable to those reported by other authors (Table 3). It has been shown that the amount of cholesterol in IFs is lower than the levels found in HM (4.3−29.2 mg/100 mL) (Table 3).

In our study, IFs 5 and 6 (marketed in Spain) and 9 (marketed in Sweden) showed the highest cholesterol contents (≥4.0 mg/100 mL). It should be underscored that whey protein enriched with MFGM and milk fat is included in these formulations, and MFGM is a good source of cholesterol.[30] The small differences in cholesterol content between IFs 5 and 9 (involving the same formula manufactured in different countries) could be due to different origins of the milk fat used, and even to the different technological treatments applied during the cream separation process.[31]

Table 3. Cholesterol and Desmosterol Content in Infant Formulas (IFs) and Human Milk Indicated in Bibliography

cholesterol (mg/100 mL)		desmosterol (mg/100 mL)	
IFs	human milk	human milk	ref
	9.7−11.0	0.6−1.3	Clark et al.[27]
	15.6−18.9	1.2−1.5	Kallio et al.[28]
	10.0−20.0		Jensen[29]
1.16−4.64	12.0−16.6		Huisman et al.[12]
0.3−25.8	6.5−18.4		Scopesi et al.[13]
	9.0−15.0		Koletzko et al.[7]
7.5−12.8	9.5−29.2	0.5−3.1	Ramalho et al.[14]
0.93−5.45	4.3−21.8[a]		Kamelska et al.[9]

[a]Determined by ATR-FTIR (attenuated total reflectance Fourier transform infrared) spectroscopy.

Infant formula 1 (marketed in Spain) presented an intermediate cholesterol content (2.6 mg/100 mL) that may be related to the use of milk fat. The lowest IF cholesterol content ranged from 1.46 to 2.22 mg/100 mL. All these formulas contain vegetable oils as the main source of fat.

From a compositional point of view, the amount of cholesterol in IFs seems to be positively related to the dairy ingredient used in the formulation (whole milk/milk fat and MFGM). This observation is also supported by the study published by Scopesi et al.,[13] in which the cholesterol content was also related to the source of fat: lower cholesterol contents corresponding to formulas in which the fat source was vegetable oil, intermediate contents corresponding to formulas containing milk fat with the addition of vegetable oil, and the highest contents (approximately 22−26 mg/100 mL) corresponding to samples containing animal fat and eggs, in addition to vegetable oils.[13]

On the other hand, Maduko and Park[10] determined cholesterol in 5 formulations based on skimmed goat milk with different blends of coconut, safflower, and soybean oils.

p[b]	*[c]	*[c]	*[c]	*[c]	*[c]	*[c]

[a]Values are expressed as mean ± standard deviation of three replicates. Relative percentage to total plant sterols content is indicated in parentheses. Different letters in the same column indicate significant differences between infant formulas (IFs). Tukey's HSD test. [b]ANOVA results for each sterol and total plant sterols among IFs. [c]*$p < 0.001$.

Cholesterol contents of these caprine IFs ranged from 9.7 to 9.9 mg/100 g of formula and were higher than in the formulas analyzed in our study (1.41−4.81 mg/100 g of reconstituted formula or 1.46−5.10 mg/100 mL). This may be due to the greater quantity of whole goat milk added to infant milk formulas analyzed by Maduko and Park.[10]

The cholesterol contents in our study are in line with those reported by Wong et al.[11] (2.2 ± 1.1 mg/100 g of reconstituted formula). Only our formulas with dairy fats showed higher cholesterol contents than those indicated by these authors.

The cholesterol concentrations in IF analyzed by Huisman et al.[12] were 3−35 times lower compared with the levels in HM. In our study, the cholesterol concentration in IFs was 2.7−10 times lower compared with the mean HM data described by Huisman[12] (14 mg/100 mL). Interestingly, only the formulas with dairy lipid ingredients (IFs 5, 6, and 9) showed a concentration between 2.7 and 3.5 times lower versus HM. The dairy lipid enriched formulas come closer to the lowest cholesterol contents found in HM in previous studies (6.5 mg/100 mL described by Scopesi et al.[13]).

Albeit to a lesser degree, desmosterol was quantified in all the formulas (0.25−0.43 mg/100 mL) except IF 10 (showing only detectable traces) (Table 2). This is the first time that desmosterol is quantified in IFs. In the study conducted by Ramalho et al.,[14] desmosterol was not detected in IF. Desmosterol is a precursor of cholesterol that is present both in human milk fat globule and in cow's milk.[3]

In IFs, desmosterol expressed as a percentage of total animal sterols is higher than in HM. A significant correlation ($y = 0.0152x + 0.053$; $R^2 = 0.8449$) was observed between desmosterol content and the label stated values of docosahexaenoic acid (DHA) and arachidonic acid (AA). Fish, fungi, and algae oils are frequently used as DHA and AA sources (see Table 1), which could explain these results.

Lathosterol was not detected in the IFs analyzed in our study, and has not been detected in IFs in other studies to date. However, in human milk, Kallio et al.[28] found lathosterol values ranging from 2.7 to 4.9 μg/mg cholesterol. Benoit et al.[3] in turn found lathosterol in HM to range from nondetectable levels to 4.40 μg/mg cholesterol (with a mean value of 0.44 μg/mg cholesterol).

Cholesterol/Desmosterol Ratio: Infant Formulas vs Human Milk. In general, cholesterol and desmosterol contents in the analyzed IFs were lower than the HM values indicated by other authors (Table 3). Although a significant correlation to total cholesterol in HM has not always been observed, most authors report desmosterol contents below or close to 10% of the cholesterol content. The desmosterol content in the analyzed IFs was less variable than the cholesterol content, and represented ≤10% of the total sterols in the formulas with the highest cholesterol content (IFs 1, 5, 6, and 9). The IFs with the highest desmosterol percentages (>10%) with respect to the animal sterol contents contained algae and/or fungi and/or fish oils (see ingredients, Table 1). It is now well-known that cholesterol and desmosterol (two C_{27} sterols) are the major sterols in crabs, mussels, and crustaceans in general. In snow crab hepatopancreas, desmosterol was found to be the second most predominant sterol (>15%), after cholesterol (67−76%).

J. Agric. Food Chem. 2015, 63, 7245−7251

Furthermore, desmosterol is abundant in many red algae,[32] and may be absorbed in large quantities from the crab diet, though it may also have an endogenous origin.[33]

Some Zygomycetes synthesize primarily C28 sterols (ergosterol), while others synthesize primarily C27 sterol. These fungi include members of the family Mortierellaceae, in which desmosterol (approximately 86% of total sterol) has been reported as the most abundant sterol.[34] *Mortierella alpina* is an oleaginous fungus which can produce lipids accounting for up to 50% of its dry weight in the form of triacylglycerols. It is commercially used for the production of arachidonic acid employed in the formulation of IFs. This fungus produces only two major sterol lipids, desmosterol and 24(28)-methylenecholesterol.[35]

Plant Sterols. In the IFs studied we identified plant sterols such as brassicasterol, campesterol, stigmasterol, β-sitosterol, and sitostanol. Total plant sterol contents ranged from 3.1 to 5.0 mg/100 mL sample, and β-sitosterol (ranging from 1.82 to 3.01 mg/100 mL) was found to be the most abundant phytosterol, followed by campesterol (0.72−1.15 mg/100 mL), stigmasterol (0.27−0.53 mg/100 mL), and brassicasterol (0.14−0.28 mg/100 mL) (Table 4). Sitostanol was detected in amounts (0.031−0.142 mg/100 mL) always lower than those of the respective plant sterols (Table 4).

Few studies have evaluated the plant sterol contents in IFs. Huisman et al.[12] analyzed the sterols in 10 types of cow's milk-based IFs, and reported total plant sterol contents ranging from 5.345 to 11.936 mg/100 mL. These total plant sterols and individual plant sterol (β-sitosterol, campesterol, stigmasterol, and fucosterol) contents were higher than those determined in our study, and β-sitosterol showed the highest content in both studies.

Maduko and Park[10] found higher plant sterol levels (7.2−13.5 mg/100 g) in ready to drink milk blends (goat milk and vegetal oils) than in our study (2.98−4.72 mg/100 g of reconstituted formula or 3.11−5.0 mg/100 mL). Regarding the content of plant sterols, the 13 IFs had quantities markedly higher (Table 4) than human milk, as reported Laitinen et al.[36] (0.108 mg/100 mL) and Benoit et al.[3] (0.16 μg/mg cholesterol). This could be because the IFs were formulated with a combination of vegetable oils (coconut, soy, canola, high oleic safflower, high oleic sunflower, and palm oleic oils), in order to more closely simulate the fatty acid profile of HM.[37]

The total plant sterol contents in the analyzed IFs were higher than in HM. From a functional point of view, no data are available in the literature describing a possible beneficial role of plant sterols in infants. In this sense, in hypercholesterolemic children and adolescents, an emulsified combination of plant sterols, fish oil (with EPA + DHA), and B vitamins decreased LDL-cholesterol, and thus exerts beneficial effects upon cardiovascular risk factors.[38]

Total Sterol Content and Sterol Ratio. As far as we know, the total sterol contents obtained in our study (5.20−10.47 mg/100 mL or 5.01−9.87 mg/100 g of reconstituted IF) can only be compared with those reported by Huisman et al.[12] (7.69−13.37 mg/100 mL) and Maduko and Park[10] (21.3−27.00 mg/100 g of reconstituted IF). These latter data are very surprising, because the authors indicated that the IFs were prepared using skimmed goat milk (0.17 g residual fat/100 g) with very high cholesterol contents.

Except in the formulas with dairy lipids (IFs 5, 6, and 9), the total vegetable sterol levels were higher than those of the animal sterols (see Figure 1a). Although the physiological meaning of this has not been studied, the higher proportion of plant sterols in IFs is one more difference to add to the list when IFs and HM are compared.

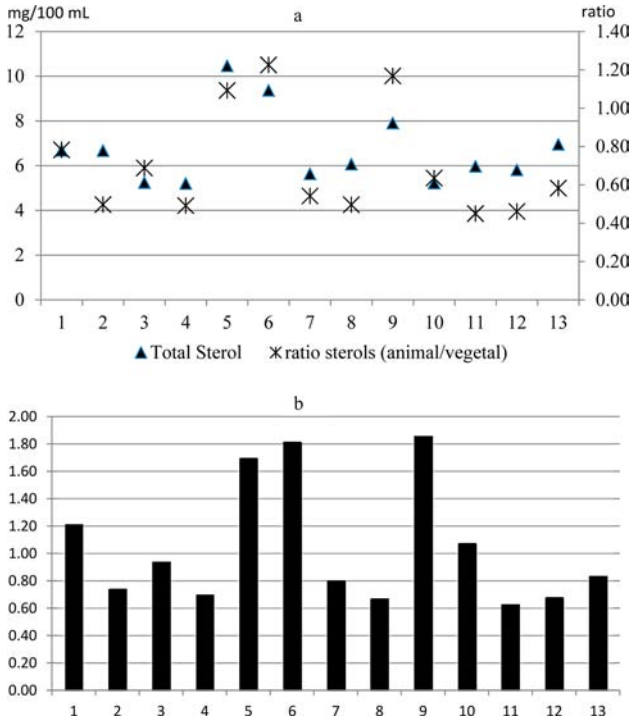

Figure 1. Sterol contents: (a) total sterol contents and ratio of animal and vegetal sterols; (b) ratio cholesterol and β-sitosterol.

The same tendency can be observed in relation to the cholesterol/β-sitosterol ratio (see Figure 1b). The four formulas that included dairy lipids (IFs 1, 5, 6, and 9) were the only ones with significantly higher levels of cholesterol than β-sitosterol. Surprisingly, only Maduko and Park[10] found plant sterol and total sterol contents closely simulating those of HM, despite their use of skimmed caprine milk and vegetable oils (coconut, sunflower, and soybean).

Estimation of Intake. Cholesterol intake (mg/day) ranged from a minimum of 9 mg/day (0.5 month old infant IF 4) to 51 mg/day (5 month old infant IF 5). Cholesterol is the sterol contributing most to animal sterol intake. Variability in cholesterol in animal sterol intake was attributable to the high cholesterol variability seen in the IFs (Figure 1a,b). Independently of the IF for the calculation, the average cholesterol and total animal sterol intake ranged from 15 to 25 mg/day and from 17 to 28 mg/day, respectively, at 0.5 and 6 months (Figure 2a,b). Wong et al.[11] determined cholesterol intakes at 5 months (24.14 mg/day) for formula-fed infants, and the values were in line with our own results. Daily cholesterol intake in breastfed infants has been estimated to range from 75 to 150 mg/day[39] or 131 ± 38 mg/day[40] or 116 mg/day.[11] These values are twice the intake in formula-fed infants. Therefore, the cholesterol intakes in formula-fed infants are still too far from the cholesterol intakes corresponding to HM. Although there is still controversy about the effects of early cholesterol intake upon long-term cardiovascular health,[7] the addition of dairy lipids, and therefore an increase in the cholesterol content, may be a good approach to close the gap in intake between breastfed and formula-fed infants.

Plant sterol intake (mg/day) ranged from a minimum of 19 mg/day (0.5 month old infant IF 3) to 50 mg/day (5 months

DOI: 10.1021/acs.jafc.5b02647
J. Agric. Food Chem. 2015, 63, 7245−7251

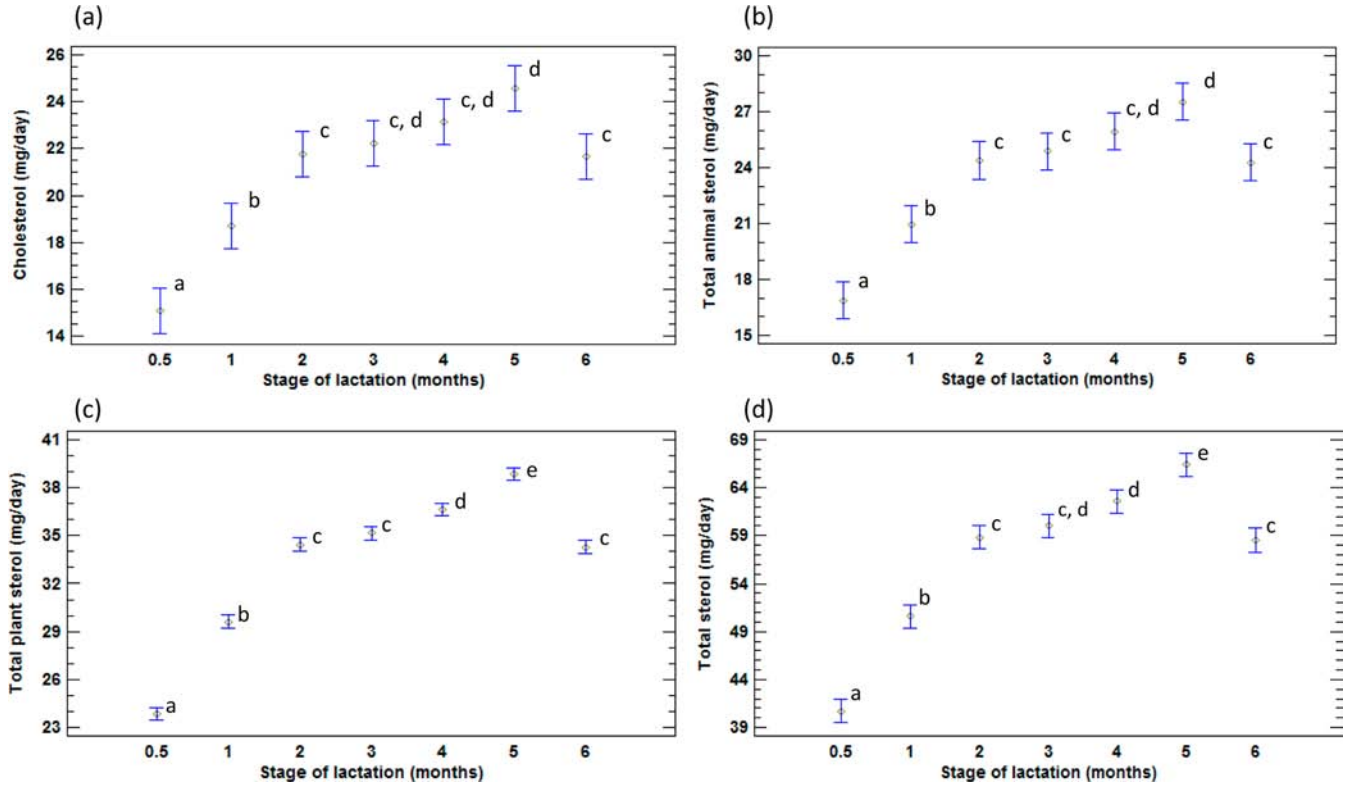

Figure 2. Average intakes of cholesterol (a), animal sterol (b), plant sterol (c) and total sterol (d). Different superscript letters denote significant differences ($p < 0.001$) between lactation stages. Tukey's HSD test.

old infant IF 5) contributing significantly to total sterol intake (see Figure 2d). Independently of the IF, average plant sterol intake ranged from 24 to 39 mg/day at 0.5 and 6 months (see Figure 2c). To the best of our knowledge, no data on plant sterol intake in infant have been published to date.

In summary, mean total sterol intake estimated was 41−66 mg/day (see Figure 2d). Taking into account the formula milk volume intake from the literature, sterol intake increased during first 5 months (see Figure 2), when the values were highest ($p < 0.001$). The introduction of complementary food, and therefore less infant formula, in the sixth month could explain the significant decrease ($p < 0.001$) in animal sterol intake in this month.

The sterol profile of IFs is highly dependent upon the type and quantity of oils and fats used in their formulation. The use of bovine milk fat and whey protein rich in MFGM in the IF formulations can approximate the profile of animal sterols to those found in HM, though cholesterol intakes in breastfed infants are still higher than in formula-fed infants. Furthermore, in order for the sterol composition of IFs to resemble that of HM, it would be necessary to decrease the desmosterol content to less than 10% and reduce plant sterols in order to obtain an animal/plant sterol ratio closer to that of HM. Further research is needed to characterize the sterol contents of ingredients to improve the formulations of IFs, that allow mimicking the composition and functionality of HM. Such requires technological advances in different areas such as analytical research, food and ingredient technology, and nutritional and clinical science. The main starting point for innovation in IFs is research on the nutritional and functional properties of HM and to assess whether the differences in sterol contents between IFs and human milk are related to health outcomes.

seeds and help in the use of this byproduct generated in food processing to improve human health.

MATERIALS AND METHODS

Chemicals and Reagents. Minocycline, silybin, 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), 6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid (trolox), lipopolysaccharide (LPS), and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma-Aldrich. Cell culture medium [Dulbecco's modified Eagle's medium (DMEM)], fetal bovine serum (FBS), penicillin, streptomycin, and all other materials required for culturing cells were purchased from Gibco BRL, Life Technologies.

Apparatus. Optical rotations were determined using a JASCO P-1020 polarimeter. The UV spectra were recorded on a Shimadzu UV-1700 spectrometer, and the CD spectra were obtained using an MOS 450 detector from BioLogic. The FT-IR spectra were measured using a Bruker IFS-55 spectrometer. NMR spectra were performed on a Bruker AV-600 spectrometer. HRESIMS experiments were measured using an Agilent G6520 Q-TOF spectrometer. Preparative and semipreparative RP-HPLC isolation was achieved with Agilent 1100 and 1200 instruments using an Acchrom XAqua C18 column (5 μm, 250 mm × 20 mm) and a YMC C18 column (5 μm, 250 mm × 10 mm). Peaks were identified using a refractive index detector (RID). The absorbances in bioassays were measured using a varioskan flash multimode reader (Thermo Scientific). Column chromatography (CC) was performed using silica gel (200−300 mesh; Qingdao Marine Chemical Inc.), macroporous adsorption resin D101 (Cangzhou Bon Adsorber Technology Co., Ltd.), and ODS (50 μm, YMC Co. Ltd.). TLC was conducted on precoated glass plates (SiO_2 GF254; Qingdao Marine Chemical Inc.).

Plant Material. The seeds of *C. pinnatifida* were collected in Hebei province, China, in June 2011 and were identified by Professor Jin-Cai Lu (School of Traditional Chinese Materia Medica, Shenyang Pharmaceutical University). A voucher specimen (no. 20110701) has been deposited in the Herbarium of Shenyang Pharmaceutical University, Liaoning, China.

Extraction and Isolation. The air-dried seeds of *C. pinnatifida* (30 kg) were crushed and refluxed with 70% EtOH (3 × 30 L) for 4 h. The solvent was filtered, concentrated under vacuum and, then, the extract (1500 g) was suspended in H_2O and partitioned sequentially with ethyl acetate and *n*-BuOH. The ethyl acetate and *n*-butyl alcohol fractions were tested in antioxidant (scavenging activities for DPPH and $ABTS^{\bullet+}$) and anti-inflammatory assays, and the ethyl acetate extract was found to exhibit stronger activities. The ethyl acetate extract (420 g) was suspended in H_2O and then chromatographed on a D101 macroporous resin column using H_2O/EtOH (from 100:0 to 5:95) as eluents, yielding four fractions (fractions A−D). The four fractions were also tested in antioxidant and anti-inflammatory assays, and fraction B (H_2O:EtOH = 70:30; 128.0 g) was found to exhibit more potent activities.

Fraction B was subjected to silica gel CC and eluted with CH_2Cl_2/CH_3OH to yield eight fractions (B_1−B_8). Among them, B_3 (20.2 g) was further purified by ODS CC using H_2O/MeOH as a mobile phase gradient (from 95:5 to 50:50) to afford five fractions ($B_{3\text{-}1}$−$B_{3\text{-}5}$) on the basis of HPLC analysis. $B_{3\text{-}3}$ (3.4 g) was subjected to further silica gel column chromatography and eluted with CH_2Cl_2/CH_3OH (from 95:5 to 80:20) to yield eight fractions ($B_{3\text{-}3\text{-}1}$−$B_{3\text{-}3\text{-}8}$) on the basis of silica gel TLC analysis. $B_{3\text{-}3\text{-}5}$ was subjected to preparative HPLC and

DOI: 10.1021/acs.jafc.5b02835
J. Agric. Food Chem. 2015, 63, 7252−7260

eluted with CH_3OH/H_2O (40:60) to yield two fractions ($B_{3\text{-}3\text{-}5\text{-}1}$ and $B_{3\text{-}3\text{-}5\text{-}2}$). $B_{3\text{-}3\text{-}5\text{-}1}$ was subjected to semipreparative HPLC and eluted with CH_3CN/H_2O (23:77) to yield **1** (18 mg, t_R 31 min, 4 mL/min) and **3** (8 mg, t_R 36 min, 4 mL/min). $B_{3\text{-}3\text{-}5\text{-}2}$ was subjected to semipreparative HPLC and with CH_3CN/H_2O (23:77) as eluents to afford **2** (8 mg, t_R 29 min, 4 mL/min) and **4** (6 mg, t_R 39 min, 4 mL/min). $B_{3\text{-}4}$ was also subjected to silica gel column chromatography and eluted with CH_2Cl_2/CH_3OH (from 95:5 to 80:20) to afford nine fractions ($B_{3\text{-}4\text{-}1}$–$B_{3\text{-}4\text{-}9}$) on the basis of silica gel TLC analysis. $B_{3\text{-}4\text{-}4}$ was subjected to semipreparative HPLC and eluted with CH_3CN/H_2O (30:70) to yield **5** (4 mg, t_R 27 min, 4 mL/min) and **6** (15 mg, t_R 28 min, 4 mL/min). $B_{3\text{-}2}$ was separated by silica gel column and eluted with CH_2Cl_2/CH_3OH to afford seven fractions ($B_{3\text{-}2\text{-}1}$–$B_{3\text{-}2\text{-}7}$). $B_{3\text{-}2\text{-}3}$ was subjected to semipreparative HPLC and with CH_3CN/H_2O (22:78) as eluent to give **13** (16 mg, t_R 40 min, 4 mL/min), **14** (20 mg, t_R 29 min, 4 mL/min), **15** (11 mg, t_R 21 min, 4 mL/min), and **7** (8 mg, t_R 33 min, 4 mL/min). $B_{3\text{-}2\text{-}5}$ was subjected to semipreparative HPLC with CH_3OH/H_2O (19:81) as eluent to yield **8** (4 mg, t_R 52 min, 4 mL/min). $B_{3\text{-}2\text{-}5}$ was subjected to semipreparative HPLC and eluted with CH_3CN/H_2O (9:91) to give **9** (42 mg, t_R 18 min, 4 mL/min), **10** (40 mg, t_R 19 min, 4 mL/min), **11** (66 mg, t_R 23 min, 4 mL/min), and **12** (68 mg, t_R 24 min, 4 mL/min).

Hawthornnin A (**1**): yellow oil; $[\alpha]_D^{20}$ −7.0 (*c* 0.10, MeOH); UV (MeOH) λ_{max} (log ε) 233 (0.63), 283 (0.31); CD [*c* 0.20 mg/mL, MeOH, nm (ε)] 234 nm (9.02), 256 nm (−7.72), 283 nm (−9.97); IR (KBr) ν_{max} 3384, 2938, 1605, 1516, 1463, 1141, 1032, 822, and 760 cm^{-1}; HRESIMS *m*/*z* 535.1902 $[M + Na]^+$ (calcd for $C_{28}H_{32}O_9Na$, 535.1939). For ^1H and ^{13}C NMR, see Tables 1 and 2.

Hawthornnin B (**2**): yellow oil; $[\alpha]_D^{20}$ +3.5 (*c* 0.13, MeOH); UV (MeOH) λ_{max} (log ε) 227 (0.66), 281 (0.32); CD [*c* 0.20 mg/mL, MeOH, nm (ε)] 226 nm (3.52), 233 nm (0.86), 284 nm (1.52); IR (KBr) ν_{max} 3407, 2928, 1610, 1510, 1453, 1243, 1112, 821, and 753 cm^{-1}; HRESIMS *m*/*z* 535.1937 $[M + Na]^+$ (calcd for $C_{28}H_{32}O_9Na$, 535.1939). For ^1H and ^{13}C NMR, see Tables 1 and 2.

Hawthornnin C (**3**): yellow oil; $[\alpha]_D^{20}$ −4.5 (*c* 0.12, MeOH); UV (MeOH) λ_{max} (log ε) 227 (0.73), 281 (0.33); CD [*c* 0.15 mg/mL, MeOH, nm ($\Delta\varepsilon$)] 237 nm (3.45), 267 nm (−10.26), 279 nm (−11.02), 286 nm (−7.01); IR (KBr) ν_{max} 3357, 2938, 1604, 1517, 1464, 1276, 1217, 822, and 765 cm^{-1}; HRESIMS *m*/*z* 535.1941 $[M + Na]^+$ (calcd for $C_{28}H_{32}O_9Na$, 535.1939). For ^1H and ^{13}C NMR, see Tables 1 and 2.

Hawthornnin D (**4**): yellow oil; $[\alpha]_D^{20}$ +7.2 (*c* 0.10, MeOH); UV (MeOH) λ_{max} (log ε) 228 (0.53), 282 (0.37); CD [c 0.15 mg/mL, MeOH, nm (ε)] 231 nm (4.46), 245 nm (2.02), 278 nm (3.44); IR (KBr) ν_{max} 3406, 2936, 1605, 1498, 1452, 1274, 1029, 822, and 765 cm^{-1}; HRESIMS *m*/*z* 535.1944 $[M + Na]^+$ (calcd for $C_{28}H_{32}O_9Na$, 535.1939). For ^1H and ^{13}C NMR, see Tables 1 and 2.

Hawthornnin E (**5**): yellow oil; $[\alpha]_D^{20}$ +4.2 (*c* 0.16, MeOH); UV (MeOH) λ_{max} (log ε) 228 (0.63), 285 (0.32); CD [*c* 0.10 mg/mL, MeOH, nm (ε)] 219 nm (3.86), 242 nm (2.58), 281 nm (1.26); IR (KBr) ν_{max} 3382, 2940, 1603, 1518, 1432, 1274, 1030, 819, and 769 cm^{-1}; HRESIMS *m*/*z* 549.2064 $[M + Na]^+$ (calcd for $C_{29}H_{34}O_9Na$, 549.2095). For ^1H and ^{13}C NMR, see Tables 1 and 2.

Hawthornnin F (**6**): yellow oil; $[\alpha]_D^{20}$ −8.7 (*c* 0.13, MeOH); UV (MeOH) λ_{max} (log ε) 226 (0.73), 281 (0.38); CD [*c* 0.15 mg/mL, MeOH, nm (ε)] 234 nm (−7.52), 283 nm (−4.87); IR (KBr) ν_{max} 3405, 2969, 1603, 1518, 1274, 1124, 1031, 819, and 769 cm^{-1}; HRESIMS *m*/*z* 549.2057 $[M + Na]^+$ (calcd for $C_{29}H_{34}O_9Na$, 549.2095). For ^1H and ^{13}C NMR, see Tables 1 and 2.

Hawthornnin G (**7**): yellow oil; $[\alpha]_D^{20}$ −5.8 (*c* 0.11, MeOH); UV (MeOH) λ_{max} (log ε) 230 (0.72), 280 (0.41); CD [*c* 0.10 mg/mL, MeOH, nm (ε)] 222 nm (5.26), 261 nm (3.78), 282 nm (−0.91); IR (KBr) ν_{max} 3357, 2940, 1667, 1599, 1512, 1133, 1031, 819, and 594 cm^{-1}; HRESIMS *m*/*z* 395.1469 $[M + Na]^+$ (calcd for $C_{21}H_{24}O_6Na$, 395.1465). For ^1H and ^{13}C NMR, see Tables 1 and 2.

Hawthornnin H (**8**): yellow oil; $[\alpha]_D^{20}$ −6.5 (*c* 0.10, MeOH); UV (MeOH) λ_{max} (log ε) 230 (0.63), 280 (0.28); CD [*c* 0.10 mg/mL, MeOH, nm (ε)] 236 nm (−5.72), 281 nm (−0.84); IR (KBr) ν_{max} 3381, 2904, 1604, 1514, 1422, 1267, 1135, 1030, 817, and 751 cm^{-1}; HRESIMS *m*/*z* 445.1458 $[M + Na]^+$ (calcd for $C_{21}H_{26}O_9Na$, 445.1469). For ^1H and ^{13}C NMR, see Tables 1 and 2.

Assay for DPPH Radical-Scavenging Activity. The DPPH scavenging activity assay was adopted from a previous paper.[20] The 0.1 mM solution of DPPH in ethanol was prepared first, and then 100 μL of this solution was mixed with 100 μL of sample solution in a 96-well microplate. After 30 min of incubation in the dark at 37 °C, the absorbance was measured using a varioskan flash multimode reader at 517 nm. The percentage of scavenged DPPH was calculated using the following equation: DPPH scavenging activity (%) = $[1 - (S - S_b)/(C - C_b)] \times 100\%$, where S, S_b, C, and C_b are the absorbances of the sample, blank sample, control, and blank control, respectively. All experiments were performed in triplicate, and trolox was used as a positive control.

Assay for ABTS Radical-Scavenging Activity. The ABTS radical-scavenging activity of isolates was determined as in a previous study with some modifications.[20] ABTS radical cations ($ABTS^{\bullet+}$) were produced by reacting a 7 mM stock solution of ABTS with 2.45 mM potassium persulfate and allowing the mixture to stand in the dark at room temperature for 12 h before use. The $ABTS^{\bullet+}$ solution was then diluted with ethanol to the absorbance of 0.7 ± 0.05 at 734 nm. Different concentrations of test samples (100 μL) and $ABTS^{\bullet+}$ solution (150 μL) were added to each well of the 96-well plates. After 30 min of incubation at 37 °C, the absorbance at 734 nm was recorded, and the percentage of ABTS free radical scavenging activity was calculated using the same formula as for the DPPH assay.

Cell Culture and Cell Viability Assay. Mouse macrophage RAW264.7 cells were cultured in DMEM, 100 mg/mL streptomycin, and 100 U/mL penicillin. Cells were plated at a density of 5×10^5/mL and then cultured in a 96-well plate containing DMEM, which was supplemented with 10% FBS for 24 h until almost confluent. Cell viability was evaluated by MTT assay. Cells were treated with test samples (100 μM) for 1 h and stimulated with LPS (100 ng/mL) for 24 h, and then the cells were incubated with MTT (0.25 mg/mL) followed by incubation for 4 h at 5% CO_2 and 37 °C. The formation of formazan was recorded at 540 nm using a varioskan flash instrument.[21,22]

NO Assay in RAW264.7 Cells. NO produced by the cells was determined by assaying the levels of NO^{2-} using the Griess reagent.[22] RAW264.7 cells were plated at a density of 5×10^5/mL in a 96-well plate and pretreated with test samples at concentrations of 100, 50, 10, and 1 μM, respectively. After the cells were incubated with samples and stimulated with LPS (100 ng/mL) for 24 h, the cell culture media were collected to determinate NO. Briefly, a 100 μL aliquot of each sample was added to an equal volume of Griess reagent (1% sulfanilamide in 5% H_3PO_4 and 0.1% *N*-naphthylethylenediamine dihydrochloride) in a 96-well plate and then incubated at 37 °C for 10 min. After incubation, the absorbance was recorded at 540 nm on a varioskan flash instrument. The amount of NO in the sample was calculated using $NaNO_2$ standard curve, and minocycline was used as a positive control.

TNF-α Assay in RAW264.7 Cells. The levels of TNF-α were determined using an ELISA kit (R&D Co.) according to the manufacturer's instructions. TNF-α was determined from a standard curve, and silybin was used as positive control.[23]

Statistical Analysis. Results were expressed as the mean ± standard error of means (SEM) of three determinations. The IC_{50} values were calculated using Microsoft Excel software. One-way analysis of variance (ANOVA) followed by Dunnett's test was used for statistical analysis.

RESULTS AND DISCUSSION

The HRESIMS of **1** revealed the molecular formula of $C_{28}H_{32}O_9$ from the pseudomolecular ion at *m*/*z* 535.1902 $[M + Na]^+$. The UV spectrum showed the absorbances at λ_{max} 233 and 283 nm, and the IR spectral data indicated the presence of OH (3384 cm^{-1}) and an aromatic ring (1605, 1516, and 1463 cm^{-1}). Eight aryl proton signals [δ_H 6.89 (d, J = 1.6 Hz, H-2), 6.75 (d, J = 8.1 Hz, H-5), 6.77 (dd, J = 8.1, 1.6 Hz, H-6), 6.51

DOI: 10.1021/acs.jafc.5b02835
J. Agric. Food Chem. 2015, 63, 7252−7260

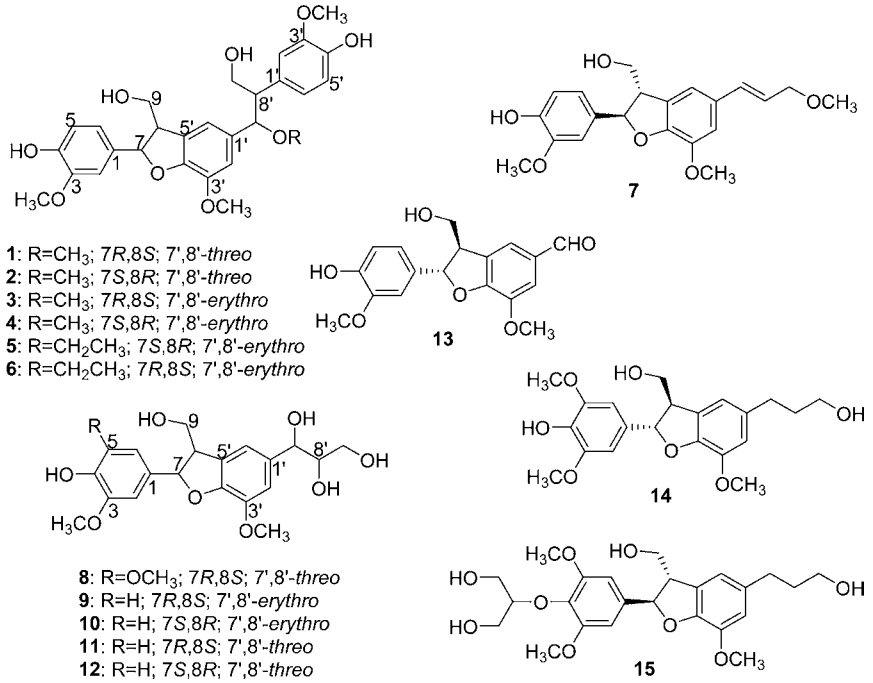

Figure 1. Structures of compounds **1**−**15**.

(br s, H-2′), 6.54 (br s, H-6′), 6.43 (d, J = 1.8 Hz, H-2″), 6.61 (d, J = 8.1 Hz, H-5″), 6.50 (d, J = 8.1, 1.8 Hz, H-6″)] found in the ^{1}H NMR spectrum of **1** (Table 1) were attributed to two 1,3,4-trisubstituted (ABX system) moieties and one 1,3,4,5-tetrasubstituted (AX system) phenyl moiety. In addition, signals for four aliphatic methine protons [δ_H 5.49 (d, J = 5.5 Hz, H-7), 3.40 (m, H-8), 4.32 (d, J = 8.6 Hz, H-7′), 2.96 (m, H-8′)], four methoxy protons [δ_H 3.79 (3H, s, OCH_3-3), 3.72 (3H, s, OCH_3-3′), 3.64 (3H, s, OCH_3-3″), 3.24 (3H, s, OCH_3-7′)], and two sets of oxygenated methylene protons [δ_H 3.67 (dd, J = 11.0, 5.1 Hz, H-9a), 3.48 (dd, J = 11.0, 8.3 Hz, H-9b), 4.07 (dd, J = 10.9, 5.0 Hz, H-9′a), 3.92 (dd, J = 10.9, 7.1 Hz, H-9′b)] were observed. The ^{13}C NMR spectrum (Table 2) showed 28 signals, characteristic of 4 methoxy carbons, 18 phenyl carbons, and 6 aliphatic carbons. In addition to the above spectroscopic findings, the HMBC spectrum of **1** showed cross-peaks between H-7/C-1, C-2, C-6, C-9, C-4′, C-5′ and H-7′/C-1′, C-2′, C-6′, C-9′, C-1″. Moreover, other long-range correlations, including H-8/C-4′, C-5′ and H-8′/C-1″, C-2″, C-6″, were also found (Figure 2). Thus, the postulated structure of **1** contains two phenylpropanoid moieties and one benzene moiety. Subtracting 9 double bonds from the 13 degrees of unsaturation suggested that 4 rings remained in **1**. Together with the above findings, **1** was proposed to have a dihydrobenzo[*b*]furan neolignan skeleton, which is similar to that of the dehydrodiconiferyl alcohol. Furthermore, long-range correlations between H-7′/C-1″, H-9′/C-1″, and H-8′/C-2″, 6″, as well as the other correlated cross-peaks found in the HMBC spectrum, supported the presence of a C−C linkage between the dehydrodiconiferyl moiety and a 3-methoxy-4-hydroxybenzene moiety (Figure 2).[24] In addition, the coupling constant between H-7 and H-8 was 5.5 Hz (in CD_3OD) in the ^{1}H NMR spectrum and cross-peaks of H-7/H-9, H-8/H-2, and H-8/H-6 were observed in the NOESY spectrum in **1**, suggested the relative conformation of H-7 and H-8 as *trans*. The CD spectrum showed a negative Cotton effect (ε_{283} −9.97), so it was found that **1** had the 7*R*,8*S*-configuration.[25,26]

The *threo* relative configuration at the C-7′/C-8′ in **1** was suggested by comparing the ^{13}C NMR spectra with those of *threo* and *erythro* isomers.[27,28] Thus, the structure of **1** was established, and it was named hawthornnin A.

Compound **2** was assigned as $C_{28}H_{32}O_9$ from its HRESIMS data, and its UV, IR, ^{1}H NMR, and ^{13}C NMR spectroscopic data were identical with those of compound **1**, which suggested the planar structure of **2** was the same as for **1**. The *trans* relative configuration at C-7 and C-8 was confirmed by the $J_{7,8}$ value of 6.0 Hz in the ^{1}H NMR spectrum and the existence of cross-peaks (H-7/H-9, H-8/H-2, and H-8/H-6) in the NOESY spectrum. Furthermore, the CD cotton curve (ε_{284} 1.52) of **2** was opposite to that of **1**, indicating the configuration of the dihydrofuran ring was 7*S*,8*R*.[25,26] In addition, the chemical shifts of C-7′ and C-8′ indicated compound **2** also had a 7′,8′-*threo*-configuration.[27,28] Thus, compound **2** was identified as an optical isomer of **1** and given the trivial name hawthornnin B.

Compound **3** was also identified as $C_{28}H_{32}O_9$ by HRESIMS at m/z 535.1941 $[M + Na]^+$. Its ^{13}C NMR data were very similar to those of **1** except for a small difference in the chemical shift of C-7′ ($\Delta\delta$ 2.7), and a small coupling constant of H-7′ (J = 5.2 Hz) was observed in the ^{1}H NMR spectrum, which was different from that of **1** and indicated that **3** had a 7′,8′-*erythro*-configuration.[27,28] In addition, the 7,8-*trans* configuration of **3** was obtained from the $J_{7,8}$ value (5.8 Hz) and the NOESY spectrum. The positive Cotton effect at 278 nm in the CD spectrum supported the 7*S*,8*R*-configuration.[25,26] Therefore, the structure of **3** was identified as shown in Figure 1 and accorded the trivial name hawthornnin C.

The UV, IR, and NMR spectra of **4** were identical to those of **3**, suggesting that the planar structure of **4** was the same as that of **3**. The chemical shifts of C-7′ and C-8′ suggested a 7′,8′-*erythro* relative configuration.[27,28] In addition, the relative configuration of C-7/C-8 was suggested to be relative-*trans* according to the $J_{7,8}$ value of 6.3 Hz. This was also verified by NOE correlations of H-7/H_2-9 and H-8/H-6 and H-8/H-2 in the NOESY spectrum. The positive CD effect at 278 nm of **4**

DOI: 10.1021/acs.jafc.5b02835
J. Agric. Food Chem. 2015, 63, 7252−7260

supported the 7*R*,8*S*-configuration,[25,26] and compound **4** was named hawthornnin D.

Compound **5** was obtained as a yellow oil, with $C_{29}H_{34}O_9$ as its molecular formula, as indicated by HRESIMS at *m*/*z* 549.2064 $[M + Na]^+$. The IR spectrum displayed absorption bands for OH (3382 cm^{-1}) and an aromatic ring (1603 and 1518 cm^{-1}) groups. The ^1H and ^{13}C NMR spectra of **5** showed similarities to those of **1**, except for the presence of the OCH_3-7′ (δ_H 3.24; δ_C 57.0), which was replaced by an ethoxy group (δ_H 3.30, 1.08; δ_C 65.2, 15.7) in compound **5**. These minor structural changes were further supported by HMQC and HMBC correlations (Figure 2). The *erythro* configuration

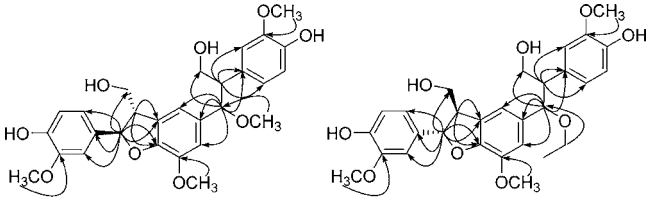

Figure 2. Key HMBC correlations of **1** and **5**.

between the two chiral centers at C-7′ and C-8′ was determined by comparing the NMR spectra with those of the *erythro* and *threo* isomers.[27,28] The *trans* relationship between H-7 and H-8 was inferred from their coupling constant ($J_{7,8}$ = 6.1 Hz), which was also further verified by the NOE correlations between H-7 and H_2-9 and between H-8 and H-2, 6. The positive CD effect at 281 nm of **5** supported the 7*S*,8*R*-configuration,[25,26] and it was named hawthornnin E.

The molecular formula of **6** was determined as $C_{29}H_{34}O_9$ by the $[M + Na]^+$ ion peak at *m*/*z* 549.2057 in the HRESIMS. Its IR and NMR spectroscopic data were in good agreement with those of **5** (Tables 1 and 2), suggesting that the planar structure and relative configuration of **6** were the same as those of compound **5**. The CD spectrum showed a negative Cotton effect (ε_{283} −4.87), which indicated that the absolute configuration of the dihydrofuran ring was 7*R*,8*S*.[25,26] Consequently, the structure of **6** was fully identified, and it was named hawthornnin F.

Compound **7** gave a positive HRESIMS *m*/*z* 395.1469 $[M + Na]^+$ (calcd for $C_{21}H_{24}O_6Na$, 395.1465), consistent with the molecular formula $C_{21}H_{24}O_6$. The IR spectrum of **7** showed absorption for hydroxyl (3357 cm^{-1}) and aromatic (1599 and 1512 cm^{-1}) functions. The NMR data of **7** (Tables 1 and 2) were in good agreement with those of 2-(4-hydroxy-3-methoxyphenyl)-3-hydroxymethyl-5-(3-methoxyallyl)-7-methoxycoumaran.[29] The relative configuration of compound **7** was suggested to be relative-*trans* according to the $J_{7,8}$ value of 6.6 Hz. In addition, the CD spectrum of **7** showed a negative Cotton effect at 282 nm, indicating that the absolute configuration of **7** was (7*R*,8*S*).[25,26] Therefore, the structure of **7** was assigned as 7*R*,8*S*-2-(4-hydroxy-3-methoxyphenyl)-3-hydroxymethyl-5-(3-methoxyallyl)-7-methoxycoumaran, and it was named hawthornnin G.

In its HRESIMS, compound **8** exhibited a pseudomolecular ion peak at *m*/*z* 445.1458 $[M + Na]^+$ (calcd for $C_{21}H_{26}O_9Na$, 445.1469), which is compatible with the molecular formula $C_{21}H_{26}O_9$. The UV spectrum showed absorbances at λ_{max} 230 and 280 nm, and the IR spectrum of **8** showed the presence of an aromatic moiety (1604 and 1514 cm^{-1}). Inspection of the NMR data (Tables 1 and 2) of **8** showed signals for two substituted aromatic rings, a characteristic doublet at δ_H 5.56 (1H, d, *J* = 6.2 Hz, H-7) for a dihydrobenzofuran-type lignan, and three OMe groups. A detailed NMR data analysis revealed the similarity between **8** and the known compound bennettin, previously isolated from *Flacourtia ramontch*,[30] suggesting that they shared the same structural skeleton. The *trans*-relative configuration of C-7 and C-8 was determined by comparison of the coupling constant of H-7 and H-8 (6.2 Hz) with that in the literature.[25] The absolute configurations at C-7 and C-8 of **8** were assigned to be *R* and *S* on the basis of the negative CD Cotton effects at 281 nm.[25,26] Furthermore, according to the literature,[31] the chemical shifts of C-8′ and C-7′ and the value of $\Delta\delta_{C8'-C7'}$ were different due to the *threo* and *erythro* isomers. The relative configuration of C-7′ and C-8′ was determined to be *threo* by its ^{13}C NMR data at δ_C 75.4 (C-7′) and 77.5 (C-8′) and the value of $\Delta\delta_{C8'-C7'}$ > 1.0 ppm. Consequently, the full structure of **8** was deduced, and it was named hawthornnin H.

The known compounds from the seeds of *C. pinnatifida* were identified by comparing their physical and spectroscopic data with values reported in the literature. They are 7*R*,8*S*-*erythro*-dihydroxydehydrodiconiferyl alcohol (**9**),[32] 7*S*,8*R*-*erythro*-dihydroxydehydrodiconiferyl alcohol (**10**),[31] 7*R*,8*S*-*threo*-dihydroxydehydrodiconiferyl alcohol (**11**),[32] 7*S*,8*R*-*threo*-dihydroxydehydrodiconiferyl alcohol (**12**),[31] 7*S*,8*R*-ficusal (**13**),[33] 7*S*,8*R*-5-methoxydihydrodehydroconiferyl alcohol (**14**),[34] and 7*R*,8*S*-sakuraresinol (**15**).[35]

Various lignans are distributed in significant concentrations in edible plants, especially in flax seed, sesame seed, and other oil seeds.[36−38] Most lignans possess a phenolic hydroxyl group in their structures and, therefore, they should exhibit high antioxidant ability.

The DPPH and $ABTS^{\bullet+}$ radical-scavenging assays are usually used to evaluate the antioxidant abilities of extracts or pure compounds.[39] The radical-scavenging activities of all isolates are summarized in Table 3. In the DPPH assay, compounds **1**−**6** and **8** showed more potent activity in the DPPH assay, although they are slightly weaker than trolox, and the other compounds exhibited only weak antioxidant activity. In the ABTS assay, most of the isolated compounds exhibited

Table 3. Antioxidant Activities of Compounds 1−15

[a]Each value represents the means ± SEM of three parallel measurements. Significantly different from the control: *, $p < 0.05$; **, $p < 0.01$.

significant antioxidant activity, with compounds **1**−**6** being the most potent (IC_{50} = 10.6−14.3 μM), whereas compounds **7**−**15** exhibited moderate ABTS radical-scavenging activities (IC_{50} = 18.7−49.8 μM), comparable with that of the standard compound trolox, with an IC_{50} value of 23.7 μM. A comparison of the structures of **1**−**6** with those of **7**−**15** indicated that the additional 3-methoxy-4-hydroxybenzene moiety groups at C-8′ appeared to increase the antioxidant activity of the dihydrobenzofuran neolignans. This fact indicated that the free phenolic hydroxyl was crucial for the antioxidant activity, which was consistent with previous observations.[40]

Pro-inflammatory cytokines (such as TNF-α, IL-1β, IL-6, IFN-γ) and NO are the key mediators for the pathogenesis of osteoarthritis, inflammatory bowel diseases, psoriasis, ulcerative colitis, and rheumatoid arthritis. Hence, the inhibition of pro-inflammatory cytokines and NO will be an important strategy for the treatment of these inflammatory conditions.[23,41,42] In this investigation, we further evaluated the anti-inflammatory activities of the isolated compounds **1**−**15** using exposure to LPS-induced NO and TNF-α production in the mouse macrophage RAW264.7 cell line. At a concentration of 100 μM, the MTT assay results showed that **1**−**15** did not affect cell viability (data not shown). Thus, the effects of compounds **1**−**15** on LPS-induced production of the inflammatory mediators NO and TNF-α in RAW 264.7 cells were evaluated at concentrations lower than 100 μM.

As shown in Tables 4 and 5, compounds **1**−**7**, **13**, and **14** showed potent inhibition of NO and TNF-α production. In particular, the activities of **7**, **13**, and **14** were more potent than that of the positive control. The observed NO and TNF-α inhibitory activities appear to be correlated with their structures. For example, with regard to the results for **14** and **15**, it appeared that the 4-OH might be important for higher activities. In addition, comparing the structures and inhibitory activities of **7** and **14** with those of **8**−**12**, it appeared that the two hydroxyl groups at C-7′, 8′ may cause a reduction in the inhibition of NO and TNF-α production. Interestingly, consideration of the structures of **1**−**6** versus **8**−**12** suggested

DOI: 10.1021/acs.jafc.5b02835
J. Agric. Food Chem. 2015, 63, 7252−7260

that 8′-OH was replaced by a 3-methoxy-4-hydroxybenzoic group, resulting in an increase in the NO and TNF-α inhibitory activities of those dihydrobenzofuran neolignans that have the 7, 8-OH moiety in their side chain. A structure−activity relationship study of the related diverse derivatives might be needed to identify the key moiety in dihydrobenzofuran neolignans responsible for inhibiting NO and TNF-α production.

In conclusion, 15 dihydrobenzofuran neolignans were isolated from the active fraction of *C. pinnatifida* seeds and evaluated for inhibition of NO and TNF-α along with antioxidant activities. The results of the present investigations indicate the importance of these neolignans as potential anti-inflammatory and antioxidant agents. From the activity results of the tested compounds, **1**−**6** showed promising activity against NO and TNF-α with less cytotoxicity and considerable antioxidant activity. The results of **7**, **13**, and **14** as inhibitors of NO and TNF-α are certainly encouraging, but the antioxidant activity of these compounds possibly limits their therapeutic applications. The structure−activity relationship of isolated lignans was also discussed. It is notable that the additional 3-methoxy-4-hydroxybenzene moiety at position C-8′ appeared to increase the antioxidant and anti-inflammatory activities of the dihydrobenzofuran neolignans. The results obtained in our study provide a potential justification for the use of the seeds from *C. pinnatifida* industrial byproducts as a valuable source of raw material for new antioxidant and anti-inflammatory agents.

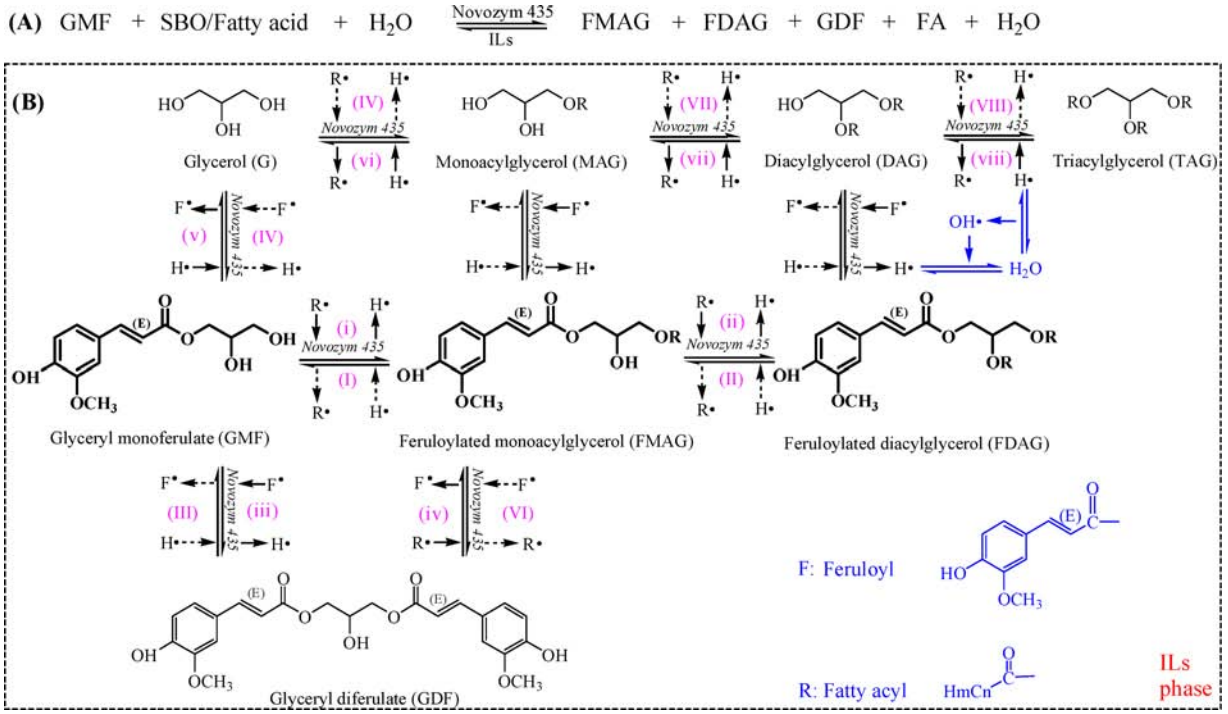

Figure 1. (A) Reaction scheme of enzymatic transesterification of glyceryl monoferulate (GMF) with soybean oil (SBO) and the mixed fatty acid (MFA). (B) Reaction mechanism for enzymatic synthesis of feruloylated monoacylglycerols (FMAG) + feruloylated diacylglycerols (FDAG) in ILs.

Sigma (Shanghai, China). Linoleic acid ($C_{18:2}$, purity >95%) was purchased from Anqing Zhong Chuang Bioengineering Co., Ltd. (Anqing, China). The mixed fatty acids (MFA, in which lauric acid ($C_{12:0}$) 2.1%, palmitic acid ($C_{16:0}$) 3.5%, stearic acid ($C_{18:0}$) 2.5%, oleic acid ($C_{18:1}$) 78.6%, and linoleic acid ($C_{18:2}$) 12.5% were contained) was purchased from Aladdin (Shanghai, China).

Ionic liquids, 1-ethyl-3-methylimidazolium hexafluorophosphate ([Emim][PF_6]), 1-butyl-3-methylimidazolium hexafluorophosphate ([Bmim][PF_6]), 1-octyl-3-methylimidazolium hexafluorophosphate ([Omim][PF_6]), 1-decyl-3-methylimidazolium hexafluorophosphate ([C_{10}mim][PF_6]), 1-dodecyl-3-methylimidazolium hexafluorophosphate ([C_{12}mim][PF_6]), 1-tetradecyl-3-methylimidazolium hexafluorophosphate ([C_{14}mim][PF_6]), 1-octadecyl-3-methylimidazolium hexafluorophosphate ([C_{18}mim][PF_6]), 1,3-dimethylimidazolium bis[(trifluoromethyl)-sulfonyl]imide ([Mmim][TF_2N]), 1-ethyl-3-methylimidazolium bis-[(trifluoromethyl)sulfonyl]imide ([Emim][TF_2N]), 1-butyl-3-methyl-imidazolium bis[(trifluoromethyl)sulfonyl]imide ([Bmim][TF_2N]), 1-ethyl-3-methylimidazolium tetrafluoroborate ([Emim][BF_4]), 1-butyl-3-methylimidazolium tetrafluoroborate ([Bmim][BF_4]), and 1-hexyl-3-methylimidazolium tetrafluoroborate ([Hmim][BF_4]), were purchased from Shanghai Cheng Jie Chemical Co., Ltd. (Shanghai, China). Methanol (HPLC grade) and glacial acetic acid (HPLC grade) were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). All other reagents were of analytical grade.

Methods. *GMF Preparation by the Enzymatic Transesterification of EF with Glycerol in Room Temperature Ionic Liquid (RTIL).* RTILs are salts that are composed entirely of ions with melting points below room temperature, for example, [Emim]TF_2N (mp 15 °C). GMF was prepared in 100 mL round-bottom flasks with a vacuum evaporator. EF was mixed with glycerol (molar ratio, 1:1.4), which was catalyzed by Novozym 435 (60 mg/mL) at 80 °C in [Emim]TF_2N. The reaction mixture was stirred with a magnetic stirrer at 300 rpm for 5.0 h under 90 kPa. Then, the RTIL solutions of the transesterification mixture were obtained by filtration to remove the immobilized Novozym 435. Then, GMF was separated and purified according to previous report.[38]

Enzymatic Transesterification of GMF with SBO or the Esterification of GMF with Fatty Acids. The reactions of GMF (1.50 mmol/mL) with SBO (or fatty acids) (molar ratio of GMF and SBO (or fatty acids), 1:2) were carried out in 25 mL round-bottom flasks. ILs (1 mL) were used as reaction media. The reaction mixtures (reactants and ILs) were incubated at various temperatures using an oil bath with a magnetic stirrer at 200 rpm under 90 kPa, and then Novozym 435 (45 mg/mL) was added to the reaction mixtures. Meanwhile, control experiments without lipase or IL were carried out. Samples (5 μL) were withdrawn at specified time intervals.

Experimental Design for RSM. A three-level-four-factor Box–Behnken design was employed to investigate the effect of reaction variables on the transesterification of GMF with SBO or the esterification of GMF with fatty acids, respectively. The factors and levels selected were as follows: reaction time (2, 8, 14 h for SBO and 0.5, 6, 11.5 h for fatty acids), reaction temperature (60, 90, 120 °C for SBO and 60, 80, 100 °C for fatty acids), molar ratio (1.0, 3.0, 5.0 for SBO/GMF and 1.0, 2.5, 4 for fatty acids/GMF), enzyme load (10, 35, 60 mg/mL for SBO and 10, 30, 50 mg/mL for fatty acids).

Analytical Techniques. Reactants and products were analyzed and identified as in previous reports.[23] HPLC and internal standard method (ISTD) were used to determine the purity of GMF in the product.

Reaction selectivity for FAGs formation can be defined as follows:

$$\text{FAG selectivity} = \frac{\text{FAG yield (\%)}}{\text{GMF conversion (\%)}}$$

Statistical Analysis. The experiments were carried out for analysis using a three-level-four-factor Box–Behnken design. The mathematical relationship relating the variables to the responses can be calculated by the quadratic polynomial equation (from Box–Behnken design):

$$Y = \beta_0 + \sum_{4}^{i=1} \beta_i X_i + \sum_{4}^{i=1} \beta_{ii} X_i^2 + \sum_{3}^{i=1} \sum_{4}^{j=i+1} \beta_{ij} X_i X_j$$

where Y is one of the responses (GMF conversion or FAG yields); X_i and X_j represent the represent the independent variables; and β_0, β_i, β_{ii}, and β_{ij} are the constant coefficients.

All experiments were performed at least in triplicate. Results were expressed as average ± SEM. A two-way analysis of variance (ANOVA) was used. Statistical significance was considered at $p < 0.05$.

Reaction conditions: GMF/SBO (or MFA) = 1:2 (mol/mol), Novozym 435 concentration 45 mg/mL, GMF 1.50 mmol/mL, ILs 1 mL, 80 °C, 90 kPa.

RESULTS AND DISCUSSION

Effect of Different Fatty Acids as Acyl Donors. Different fatty acids as GMF acceptors showed a clear effect on FAG selectivity (Table 1). However, the effect of different fatty acids on GMF conversions was not significant. GMF conversions rapidly increased up to >80% (1 h), and then maintained at high levels (>95.7 ± 1.5%) after 4 h, which indicated that GMF was completely bonded with fatty acyl (or another feruloyl) donors. Using $C_{18:0}$ as acyl donor, feruloylated diacylglycerols (FDAG) were not found in the products, and the byproduct glyceryl diferulate (GDF) yield was up to 23.2 ± 0.2% after 12 h (Table 1), which was higher than those of other fatty acids (<15.0%). Low FAG selectivity (0.74) was found using $C_{18:0}$ as acyl donor. These results can be explained by the fact that the primary product feruloylated monoacylglycerols (FMAG) (contain feruloyl and stearoyl in 1,3-position) were difficult to bind with another stearoyl in sn-2 of glycerol to form FDAG, and excess water formed by the esterification of GMF with fatty acids can favor GDF formation (Figure 1B). However, maximum FDAG yield (69.6 ± 0.6%) and minimum byproduct GDF yield (6.0 ± 0.3%) were obtained using mixed fatty acids (MFA) as acyl donor, and the maximum GMF conversion (99.2 ± 0.5%) and FAG selectivity (0.92) were achieved. Therefore, the MFA was used as GMF acceptors in the subsequent work.

Effect of Soybean Oil (SBO) and MFA as Acyl Donors in ILs. Figure 2A shows the effect of different ILs on the

enzymatic transesterification of GMF with SBO. Using $[Emim]BF_4$, $[Bmim]BF_4$, and $[Hmim]BF_4$ as reaction media, GMF conversions were all <40% after 16 h; and using $[Mmim]TF_2N$, $[Emim]TF_2N$, and $[Bmim]TF_2N$ as reaction media, GMF conversions were ~60% at 16 h. These low reaction rates were attributed to shorter alkyl chains of $[Emim]BF_4$,

$[Bmim]BF_4$, $[Hmim]BF_4$, $[Mmim]TF_2N$, $[Emim]TF_2N$, and $[Bmim]TF_2N$ than that of $[C_{10}$-$C_{18}mim]PF_6$, which resulted in the loss of bound water of the enzyme in these hydrophilic ILs. Similar results that hydrophilic ILs decreased enzyme activity were also found in previous reports.[39,40] However, when the

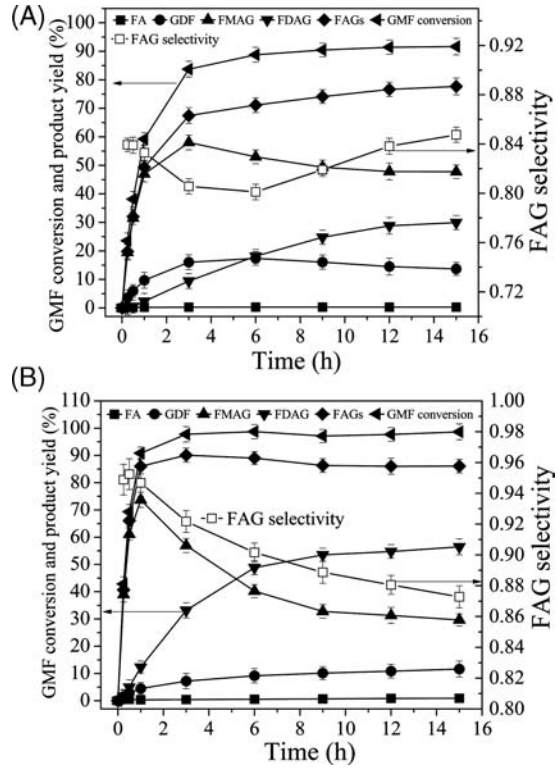

Figure 6. (A) Effect of reaction time on the transesterification of GMF with SBO in $[C_{12}mim]PF_6$. (B) Effect of reaction time on the esterification of GMF with MFA in $[C_{10}mim]PF_6$. Reaction conditions: GMF/SBO (or MFA) = 1:2 (mol/mol), Novozym 435 concentration 45 mg/mL, 80 °C, GMF 1.50 mmol/mL, ILs 1 mL, 90 kPa.

MFA was used as GMF acceptor in $[Emim]BF_4$, $[Bmim]BF_4$, $[Hmim]BF_4$, $[Mmim]TF_2N$, $[Emim]TF_2N$, and $[Bmim]TF_2N$ (Figure 2B), higher GMF conversions (97.0 ± 0.8%, 50.2 ± 2.2%, 83.8 ± 1.3%, 99.7 ± 0.2%, 97.4 ± 1.6%, and 99.5 ± 0.3%) were achieved at 16 h. These results can be explained by the fact that MFA has good compatibility with ILs and low steric hindrance of MFA can enhance the transfer rate of MFA to the glycerol of GMF (or FMAG) to form FMAG and FDAG.

Using PF_6^- based ILs as reaction media for the transesterification of GMF with SBO, GMF conversions increased with the increase of carbon chain number of ILs (Figure 2A). These results can be explained by the fact that, for those ILs with PF_6^-, with the increase of carbon chain number of ILs, the hydrophobicity of ILs increased, which resulted in better compatibility of SBO with ILs. However, when the carbon chain number of ILs increased up to >14, great mass transfer limitations between ILs and SBO were found, which may be ascribed to the great viscosity and high melting point of ILs. Similar results were also found in the reaction using the MFA as GMF acceptor, and the maximum GMF conversions (99.3 ± 0.5% after 16 h) were found in the esterification of GMF with MFA using $[C_{10}mim]PF_6$ as reaction medium. FAG selectivity showed similar change with GMF conversion using SBO (Figure 2C) and MFA (Figure 2D) as acyl donors. Compared with solvent-free system about FAG preparation, ILs can accelerate reaction rates, favor the FAG formation in the esterification of GMF with MFA, and show protective effect on the inactivation of enzyme at high temperature. ILs as reaction media instead of soybean oil[22] can make the transformation of the substrate molecule more economical and efficient. The control experiments, without lipase or IL, showed that GMF

[a]Numbers were run randomly.

conversions were all lower than 2%, which were mainly ascribed to the thermal decomposition of GMF.

Effect of Reaction Temperature. Figure 3A shows the effect of temperature (60−130 °C) on the transesterification of GMF with SBO in $[C_{12}mim]PF_6$. Reaction temperatures in the range of 70−110 °C resulted in high GMF conversion (91.7 ± 1.1% after 15 h, 90 °C), which could be attributed to high enzyme activity and low viscosity of reaction system. Similar effect of temperature on the viscosity of ILs can also be found in some previous reports.[32,41] However, when reaction temperature increased up to 130 °C, GMF conversion decreased to 83.5 ± 2.2% after 15 h, which may be ascribed to the inactivation of Novozym 435 at higher temperatures (≥110 °C). It is an interesting fact that immobilized Novozym 435 has activity at higher temperatures (90−130 °C), which may be attributed to the remarkably protective effect of ILs on the inactivation of enzyme at high temperature. Similar protective effect of ILs on the enzyme activity at high temperature can also be found in other previous reports.[42,43] When the MFA was used as acyl donor, the time to reach equilibrium was shortened to 3 h (≥80 °C), and high GMF conversions (98.7 ± 1.5% at 90 °C, 98.9 ± 1.0% at 105 °C after 15 h) were obtained (Figure 3B) in $[C_{10}mim]PF_6$, respectively, which could be attributed to the lower steric hindrance of MFA than that of SBO.

Figure 3C shows the effect of reaction temperature on GMF conversion, product yields (curve), and FAG selectivity (column) of the transesterification of GMF with SBO in $[C_{12}mim]PF_6$ or MFA in $[C_{10}mim]PF_6$. When SBO was used, the main product FMAG yield initially decreased to 47.8 ± 2.2% at 110 °C, and then increased to 65.0 ± 2.7% at 130 °C. However, FDAG yield initially increased to 29.7 ± 2.1% at 110 °C, and then decreased sharply to 7.9 ± 1.5% at 130 °C. These results indicated that high temperatures (<110 °C) can favor the FDAG formation (Figure 1B-ii).

When MFA was used as acyl donor, the FMAG yields initially decreased to 30.6 ± 2.2% at 105 °C, and then increased to 50.1 ± 2.7% at 120 °C. However, FDAG yields initially increased to 59.4 ± 2.3% at 105 °C, and then sharply decreased to 40.8 ± 1.9% at 120 °C (Figure 3C). FDAG yields using MFA as acyl donor were significantly higher than those of SBO, which could be ascribed to the lower steric hindrance of MFA than that of SBO.

To obtain good reaction rates and equilibrium yields without thermally deactivating the lipase in reuses, the temperature of the transesterification (or esterification) of GMF with SBO (or MFA) should be kept around 90 °C.

Effect of Enzyme Load. Figure 4A,B shows the effect of enzyme concentration on the transesterification of GMF with SBO in $[C_{12}mim]PF_6$ or MFA in $[C_{10}mim]PF_6$. The increase of the enzyme concentration can enhance reaction rate and shorten the time to reach equilibrium. However, GMF conversions almost maintained the same levels (~90% for SBO and ~98% for MFA) after 15 h among all tested enzyme concentrations. These results can be explained by the fact that the increase of enzyme concentration provides more active site of enzyme, however, excessive immobilized enzyme can result

DOI: 10.1021/acs.jafc.5b03479
J. Agric. Food Chem. 2015, 63, 7261−7269

in the aggregation of enzyme, which can lead to the low catalytic efficiency of enzyme. The maximum GMF conversion (91.7 ± 2.2%), using SBO as acyl donor, was obtained at 35 mg/mL, and using MFA as acyl donor, the maximum GMF conversion (98.1 ± 1.2%) was achieved at 30 mg/mL.

Figure 4C shows the effect of enzyme concentration on product yields (curve) and FAG selectivity (column) of the transesterification of GMF with SBO in $[C_{12}mim]PF_6$ and the esterification of GMF with MFA in $[C_{10}mim]PF_6$. When SBO was used as acyl donor, with the increase of enzyme concentration from 10 mg/mL to 60 mg/mL, FMAG yield decreased to ~50%; however, FDAG yield increased to ~30%. At different enzyme concentrations, when MFA was used as acyl donor, FDAG yields were almost higher than those of FMAG, and FAG selectivity decreased linearly with the increase of enzyme concentration, which were different from that of SBO as acyl donor (Figure 4C).

Effect of Substrate Ratio and Reaction Time. Figure 5A,B shows the effect of substrate ratio (GMF/SBO (or MFA), mol/mol) on the transesterification of GMF with SBO (or MFA) in $[C_{12}mim]PF_6$ (or $[C_{10}mim]PF_6$). The increase of acyl donor (SBO or MFA) concentration can enhance reaction rates and GMF conversions and shorten the time to reach equilibrium (Figure 5A,B). With the increase of acyl donor concentration, main product FAG yields and FAG selectivity all increased significantly (Figure 5C).

When SBO was used as acyl donor, FMAG yield initially increased and then decreased with the reaction progress; however, FDAG yield increased during the reaction (Figure 6A). These results indicated that FMAG as intermediate product were initially formed and then more acyl donors reacted with FMAG to form FDAG. Therefore, the transesterification mechanism of SBO with GMF can be explained as follows (Figure 1): GMF is initially bonded with a fatty acyl from SBO to form FMAG (Figure 1B-i); and then FMAG as an intermediate reacts with another fatty acyl to form FDAG (Figure 1B-ii). Meanwhile, feruloyl from GMF and FMAG can react with another GMF to form GDF (Figure 1B-iii); and then GDF reacts with fatty acyl to form FMAG (Figure 1B-iv). Figure 6B shows the esterification process of GMF with MFA. Similar reaction mechanism of the esterification of GMF with MFA can also be explained in Figure 1. Similar other reaction mechanisms can also be found in previous reports.[16,23]

Model Fitting. Models of factors and responses were performed by RSM to predict the highest possible GMF conversion and FAG yields. The results obtained for the models are listed in Table 2. The data were analyzed employing a multiple regression technique to evaluate the true relationship between the factors and responses. The analysis of variance (ANOVA) indicated that the quadratic regression models were all extremely significant ($P < 0.0001$) (Table 3), which suggested that these models were prominent and adequate to explain the actual relationship between the response and the significant variables, with satisfactory coefficients of determination ($R_1^2 = 0.9500$, $R_2^2 = 0.9482$, $R_3^2 = 0.9802$, $R_4^2 = 0.9461$). The values of *R*-squared indicated that these models are suitable to represent the relationships among the selected factors. As a result, the models for GMF conversions and FAG yields were successfully established. The following second-order models satisfactorily explained GMF conversion and FAG yields, and X_1, X_2, X_3, and X_4 are the coded variables as described in Table 2. Four quadratic regression models are given as follows:

Table 3. Analysis of Variance (ANOVA) for Quadratic Model for the GMF Conversions and FAG Yields

Optimum Conditions and Model Verification. Reaction conditions were optimized using RSM as follows: (1) for the transesterification of GMF with SBO in $[C_{12}mim]PF_6$, enzyme concentration 45 mg/mL, 90 °C, GMF/SBO 1:2.5 (mol/mol), and 11 h. Under these optimal conditions, GMF conversion and FAG yield were 94.3 ± 0.7% and 83.8 ± 1.0%, respectively; (2) for the esterification of GMF with MFA in $[C_{10}mim]PF_6$, enzyme concentration 20 mg/mL, 90 °C, GMF/MFA 1:2 (mol/mol), and 8 h. Under these optimal conditions, high GMF conversion (98.9 ± 0.9%) and FAG yield (88.9 ± 0.6%) were achieved, which are both higher than that of using SBO and the previous reports of using GMF to synthesize FAGs.[44] Furthermore, either SBO or MFA as acyl donor can remarkably improve the lipophilic FAG yields compared to previous reactions that using EF/FA/VF in shorter reaction time.[15−22]

In conclusion, FAGs, the lipophilic feruloyl structure lipids, were successfully synthesized by the enzymatic reaction of GMF with different acyl donors (SBO and MFA) in IL systems. For the esterification of GMF with MFA, higher FAG selectivity (0.90) was obtained; and for the transesterification of GMF with SBO, relative high FAG selectivity (0.89) was also obtained. The low reaction rate, using SBO as acyl donor, was attributed to the steric hindrance of SBO. Although, using MFA as acyl donor, GMF conversion (98.9 ± 0.9%) and FAG yield (88.9 ± 0.6%) were both higher than those (94.3 ± 0.7% and 83.8 ± 1.0%) of SBO, SBO is still a good choice for FAG preparation considering the price of raw materials and the more convenient use of SBO.

verified by high-performance liquid chromatography (HPLC) analysis (Figure 1A).

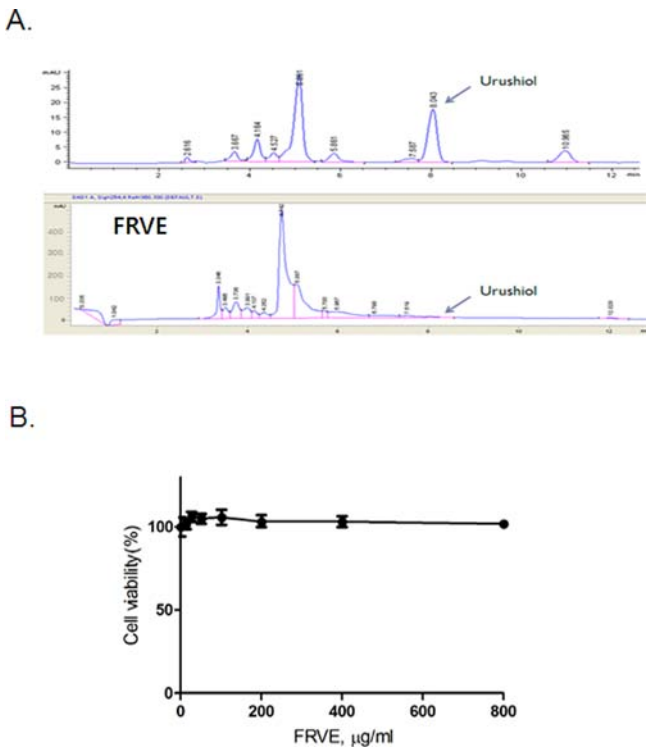

Figure 1. Determination of allergen-free FRVE by HPLC analysis. (A) Urushiol standard and FRVE. The solvent flow rate was 0.8 mL/min, and the ambient temperature was set at 30 °C. UV detection was at wavelengths of 280 nm. (B) Cytotoxicity of FRVE against HepG2 cells was determined by the MTT assay. Cells were treated with various concentrations of FRVE (0, 12.5, 25, 50, 100, 200, 400, and 800 μg/mL) for 24 h.

Cell Culture Assay. The human hepatoma cell line HepG2 was cultured in Dulbecco's modified Eagle's medium (DMEM) (Welgene, Korea) that contained 10% fetal bovine serum (FBS), 2 mM L-glutamine, and 100 units/mL penicillin and streptomycin. The cells were maintained at 37 °C in an incubator under 5% CO_2.

Cell Viability Assay. The cell viability assay was measured by a colorimetric 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay (Sigma, St, Louis, MO). Cells (1×10^4 cells/well) were exposed to various concentrations (0, 12.5, 25, 50, 100, 200, 400, and 800 μg/mL) of FRVE in 96-well sterile plastic plates (SPL Life Science, Korea). After 24 h of incubation, 50 μL of the MTT reagent (1 mg/mL) was added. After 1 h of incubation, cell counts were determined by an enzyme-linked immunosorbent assay (ELISA) reader (Tecan, Switzerland) at a wavelength of 570 nm. The final sample of cells included less than 0.1% dimethyl sulfoxide (DMSO).

HPLC Analysis (for Compounds of FRVE). To analyze the compounds of FRVE, compound standards were run on Hichrom HPLC columns (5 μm, 250 × 4.6 mm, Hichrom, Ltd.) using a high HPLC system (Agilent Technologies, Santa Clara, CA). The binary mobile phase consisted of 80% methanol/tetrahydrofuran solvent (99.8:0.2, v/v). The solvent flow rate was 0.3 mL/min, and the ambient temperature was set at 30 °C. Ultraviolet (UV) detection was at wavelengths of 254 and 280 nm (see Supplementary Figure 1 of the Supporting Information).

Oil-Red-O (ORO) Staining. Cells were cultured in 6-well plates at 1×10^5 cells/well in medium supplemented with 10% fetal bovine serum (FBS) and 1% antibiotics (penicillin and streptomycin, 100 units/mL). The cells were incubated in the absence of serum for 24 h and treated with FRVE (400 μg/mL) or fustin, fisetin, gallic acid, quercetin, and 1-hexacosanol individually (20 μM) with OA (200 μM, Sigma-Aldrich) for 24 h. The AMPK inhibitor compound C (10 μM, Sigma-Aldrich) was added to the HepG2 cell culture media.

The HepG2 cells were then washed twice with phosphate-buffered saline (PBS) buffer followed by 10 min of incubation with 0.3% ORO working solution. After the HepG2 cells were washed twice with PBS buffer, they were then dried. The plate was examined using a camera connected to an Axio observer a1 inverted microscope (Zeiss, Germany) at 200× magnification.

Western Blot Analysis. Cell lysates were prepared by adding 20 μL of RIPA lysis buffer (Cell Signaling) to the cell cultures. Proteins were separated on sodium dodecyl sulfate (SDS)−polyacrylamide gels and were electrotransferred to nitrocellulose blotting membranes (GE Healthcare Life Sciences, U.K.). The membranes were blocked in 3% nonfat dry milk and probed with primary antibodies for p-AMPK (Cell Signaling), AMPK (Cell Signaling), low-density lipoprotein receptor (LDLR, Abcam), PPARα (Cell Signaling), CPT-1 (Cell Signaling), fatty acid synthase (FAS, Cell Signaling), SREBP-1 (Santa Cruz), glycerol 3-phosphate acyltransferase (GPAT, Cell Signaling), and β-actin (Sigma). Detection of specific proteins was carried out using an enhanced chemiluminescence (ECL) assay (GE Healthcare Life Sciences, U.K.).

Reverse Transcriptase Polymerase Chain Reaction (RT-PCR). The total RNA of cells was isolated using Qiazol lysis reagent (Qiagen Sciences, Germantown, MD), according to the instructions of the manufacturer, and cDNA was synthesized from 1 μg of total RNA and subjected to PCR by the SuperScript One-Step RT-PCR kit (Invitrogen, Carlsbad, CA). The PCR conditions were 30 cycles of 95 °C for 30 s, the annealing temperature of the primer for 30 s, and 72 °C for 30 s. Primer sequences used were synthesized by Bioneer (Daejeon, Korea) with the following sequences: LDLR (forward, 5′-CAA TGT CTC ACC AAG CTC TG-3′; reverse, 5′-TCT GTC TCG AGG GGT AGC TG-3′), 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCR) (forward, 5′-A GG TTC CAA TGG CAA CAA CAG AAG-3′; reverse, 5′-ATG CTC CTT GAA CAC CTA GCA TCT-3′), SREBP-1 (forward, 5′-GGA TTG CAC TTT CGA AGA CAT-3′; reverse, 5′-AGG ATG CTC AGT GGC ACT G-3′), GPAT (forward, 5′-GCC GCT TCT GTT TCT ACC AG-3′; reverse, 5′-ACA CCG GTT TCT GAC TTT GG-3′), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (forward, 5′-TCA CCA TCT TCC AGG AGC GA-3′; reverse, 5′-CAC AAT GCC GAA GTG GTC GT-3′). RT-PCR products were run with loading star (DyneBio, South Korea) on a 1% agarose gel. Stained bands were visualized under UV light and photographed.

Measurement of Cellular Triglyceride (TG) and Total Cholesterol (TC). Cells were collected (less than 6×10^6 cells) and mixed with 1 mL of chloroform/methanol (2:1, v/v). The resulting mixture was shaken at room temperature (RT) for 20 min and then centrifuged (500*g*) for 10 min. The bottom layer was collected and resuspended for analysis of TG and TC. TGs were measured using an enzymatic method kit from Asan Pharm (AM157S-K, South Korea) in accordance with the instructions of the manufacturer. TC was measured using an enzymatic method kit from Asan Pharm (AM 202-K, South Korea) in accordance with the instructions of the manufacturer.

Statistical Analysis. The data were expressed as means ± standard deviation (SD) of three replications per experiment. Analysis of variance (ANOVA) was conducted to determine the significance of differences between groups. $p < 0.05$ was considered significant.

RESULTS

Confirmation for Detoxified FRVE. To confirm FRVE detoxification, HPLC analysis was performed. As shown in Figure 1A, urushiol (the standard urushiol peak was found at 5.091 min) was not detected in FRVE (Figure 1A).

FRVE Inhibits OA-Induced Cellular Lipid Accumulation in HepG2 Cells. The effect of FRVE on the viability of HepG2 cells is presented in Figure 1B. The cytotoxicity of FRVE was determined by the MTT assay. Cells were treated

DOI: 10.1021/acs.jafc.5b01954
J. Agric. Food Chem. 2015, 63, 7270−7276

with various concentrations of FRVE for 24 h. FRVE did not significantly affect HepG2 cell viability. OA reduced cell viability at concentrations of 0.5 mM and higher (data not shown). In this study, both OA (0.2 mM) and FRVE (200 and 400 μg/mL) were used at non-cytotoxic concentrations. To investigate whether FRVE could affect OA-induced cellular steatosis, ORO staining, a simple qualitative method to analyze the amount of lipid-droplet-stored TG in cells,[18] was performed in OA-induced HepG2 cells with FRVE. As shown in Figure 2A, OA increased the intracellular lipid content. The number and size of lipid droplets significantly reduced after FRVE and OA treatment in HepG2 cells compared to the OA group. Additionally, fat deposits decreased by 24.6 and 48.8% with 200 and 400 μg/mL FRVE treatments, respectively, compared to OA treatment alone (Figure 2A).

FRVE Inhibits OA-Induced Lipogenesis in HepG2 Cells. To assess the regulation of lipogenesis-related key factors by FRVE, the expression of AMPK, SREBP, FAS, GPAT, LDLR, and HMGCR in HepG2 cells was determined. The OA-treated group displayed increased protein expression levels of SREBP-1, FAS, and GPAT and increased mRNA levels of SREBP-1, GPAT, and HMGCR (panels B and C of Figure 2). In the presence of OA, FRVE treatment prevented the increased protein and mRNA expression levels of SREBP-1, FAS, GPAT, and HMGCR (panels B and C of Figure 2). LDLR and AMPK phosphorylation significantly increased after FRVE treatment in the presence of OA (panels B and C of Figure 2).

FRVE Promotes Hepatic Lipolysis in HepG2 Cells. To assess whether FRVE regulates fatty-acid-oxidation-related factors, the levels of PPARα and its target gene, CPT-1, in OA-treated HepG2 cells were determined by western blotting. As shown in Figure 2B, FRVE increased the expression of PPARα and CPT-1.

FRVE Inhibits OA-Induced Intracellular TG and TC Amounts. To evaluate the effect of OA treatment on TG accumulation in HepG2 cells, cellular TG and TC from cell lysates were measured. As shown in panels D and E of Figure 2, OA treatment in HepG2 cells increased the TG and TC contents compared to the control. The amount of TG decreased by 36.7 and 46.1% following 200 and 400 μg/mL FRVE treatment, respectively, compared to OA treatment alone (Figure 2D). The amount of TC decreased by 32.7 and 35.3% following 200 and 400 μg/mL FRVE treatment, respectively, compared to OA treatment alone (Figure 2E).

FRVE Inhibits OA-Induced Steatosis in the Liver through AMPK Activation. AMPK is a key sensor of hepatic lipid metabolism. As shown in Figure 2B, FRVE significantly increased the levels of phosphorylated AMPK as well as fatty-acid-oxidation-related factors and inhibited hepatic lipogenic factors. To assess the underlying mechanism of FRVE, the AMPK antagonist compound C was used in OA-induced HepG2 cells. AMPK activation was blocked by compound C; thus, FRVE-induced AMPK activation was suppressed by compound C (Figure 3B). In addition, compound C prevented FRVE-mediated inhibition of SREBP-1. ORO staining indicated the effect of compound C on lipid accumulation. As shown in Figure 3A, FRVE-mediated inhibition of lipid accumulation was blocked by compound C. Consistently, compound C blocked FRVE-mediated inhibition of intracellular TG and TC contents (panels C and D of Figure 3).

FRVE Contains Phenolics and Cosanols. To determine the active compounds in FRVE, the phenolic and cosanol

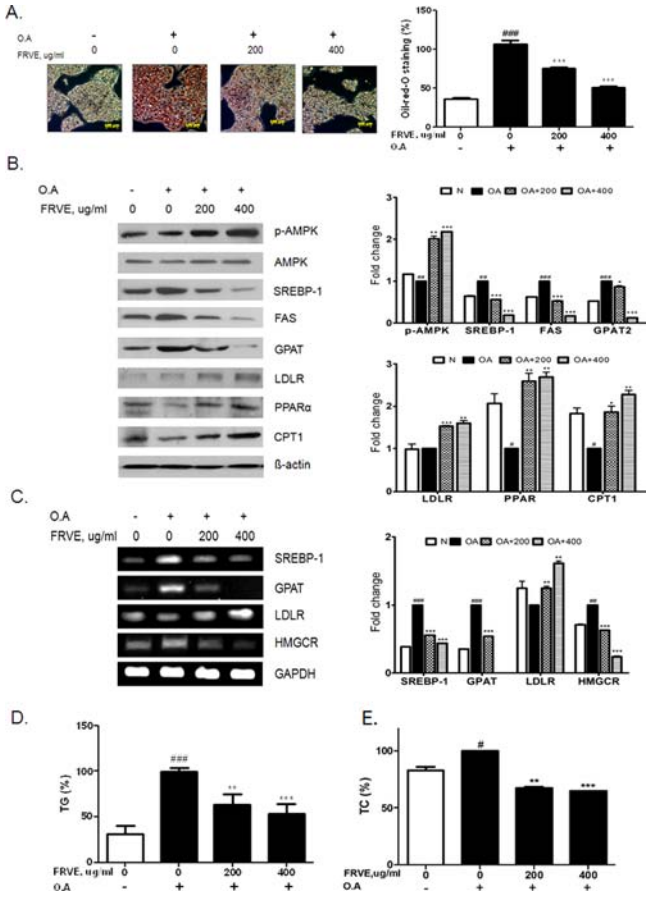

Figure 2. Effects of FRVE on cellular lipid accumulation and lipogenesis in OA-induced HepG2 cells. Cells were co-treated with OA (0.2 mM) and indicated concentrations of FRVE for 24 h. (#) $p < 0.05$ (in comparison to the non-OA-treated control). (*) $p < 0.05$ and (***) $p < 0.001$ (in comparison to the OA-treated control).

respectively. FRVE comprised 55.0 ± 0.2 mg/g of fustin, 15.0 ± 2.8 mg/g of gallic acid, 0.33 ± 0.2 mg/g of fisetin, 5.0 ± 2.5 mg/g of 1-hexacosanol, and 1.7 ± 0.3 mg/g of quercetin (Table 1).

Table 1. Single Compounds in FRVE Organ Extracts

compound	mg/g
fustin	55.0 ± 0.2
gallic acid	15.0 ± 2.8
1-hexacosanol	5.0 ± 2.5
quercetin	1.7 ± 0.3
fisetin	0.33 ± 0.2

FRVE Components Fustin, Gallic Acid, Fisetin, Quercetin, and 1-Hexacosanol Activate AMPK. To identify the active compounds in FRVE, we tested the effects of 20 μM fustin, fisetin, gallic acid, quercetin, and 1-hexacosanol individually on p-AMPK and SREBP-1 expression, lipid accumulation, and TG content. All of these compounds (20 μM) reduced lipid accumulation in OA-induced HepG2 cells without affecting cell viability (Figure 5A). Consistently, all of these compounds also reduced the TG levels in OA-induced HepG2 cells (Figure 5C), and they increased the levels of phosphorylated AMPK and decreased SREBP-1 expression compared to the OA treatment group (Figure 5B).

DISCUSSION

In this study, we evaluated whether FRVE inhibits cellular lipid accumulation and promotes lipolysis through AMPK activation. AMPK activation induces fatty acid oxidation and inhibits lipogenesis in the liver through SREBP-1.[19] As a transcription factor, SREBP-1 directly activates the expression of more than 30 genes, such as FAS and GPAT. In addition, SREBP-1 is responsible for the synthesis and uptake of fatty acids, cholesterol, and TG.[20−22] The loss of SREBP-1 mediates fatty acid oxidation, thereby activating PPARα.[23,24] PPARα activation increases fatty acid oxidation and reduces cellular lipids.[25] Many extracts from various natural sources act as AMPK activators, including mulberry extract, which can inhibit hepatic steatosis by activating AMPK and inhibiting SREBP-

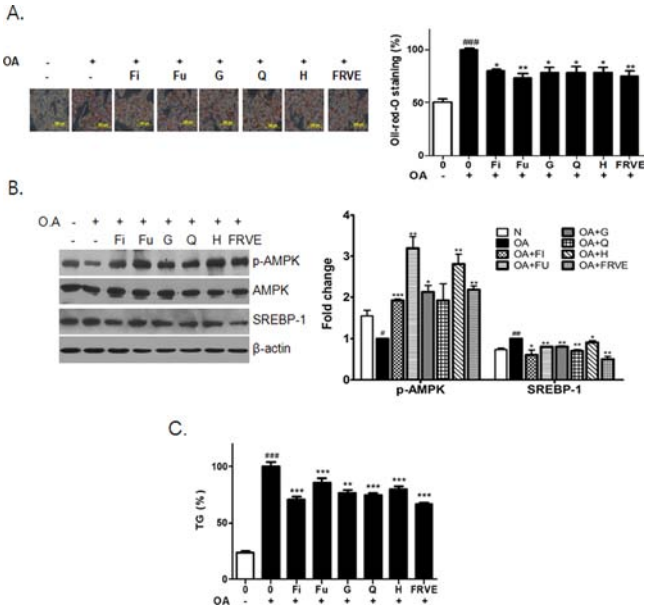

Figure 5. Effect of fustin, gallic acid, fisetin, quercetin, and 1-hexacosanol on AMPK activity. Cells were co-treated with OA and fustin, fisetin, gallic acid, quercetin, and 1-hexacosanol (each at 20 μM) for 24 h. (A) Cells were stained with ORO and analyzed using a spectrophotometer. Quantitative data of ORO staining is shown. (###) $p < 0.001$ (in comparison to the non-OA-treated control). (*) $p < 0.05$ and (**) $p < 0.01$ (in comparison to the OA-treated control). (B) Cell lysates were prepared and subjected to western blotting using p-AMPK, AMPK, and SREBP-1 antibodies. Quantitative western blotting data are shown. (#) $p < 0.05$ (in comparison to the non-OA-treated control). (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ (in comparison to the OA-treated control). (C) Intracellular TG. (###) $p < 0.001$ (in comparison to the non-OA-treated control). (**) $p < 0.01$ and (***) $p < 0.001$ (in comparison to the OA-treated control).

1.[26] Hepatic expression of LDLR is important for low-density lipoprotein (LDL) cholesterol homeostasis regulation, because LDLR is a membrane-spanning glycoprotein that plays a role in removing LDL from the blood.[27,28] Here, FRVE upregulated LDLR mRNA and protein levels in OA-induced HepG2 cells (panels B and C of Figure 2).

HMGCR catalyzes the rate-limiting step in cholesterol biosynthesis and modulates cholesterol levels.[29] HMGCR inhibitors reduce TG levels, and HMGCR knockdown reduces plasma LDL cholesterol levels.[30] Our results show that FRVE treatment decreases both TG (Figure 2D) and HMGCR levels (Figure 2C).

The HPLC data show that FRVE contains fustin, gallic acid, fisetin, quercetin, and 1-hexacosanol (Figure 4 and Table 1). In previous studies with *R. verniciflua* extracts, phenolic compounds, such as 2,4-dihydroxybenzoic acid, protocatechuic acid, caffeic acid, chlorogenic acid, *p*-coumaric acid, phloretin-20-*O*-glucoside, kaempferol-3-*O*-glucoside, quercetin, butein, and kaempferol, in addition to gallic acid, 2,6,30,40-tetrahydroxy-2-benzylcoumaran-3-one, fustin, fisetin, and sulfuretin have been reported.[31,32] Additionally, according to another previous report,[33] the phenolic compounds gallic acid, compound R, fustin, and fisetin were reported as the main components present in RV water extract (similar to FRVE).[33] Recently, it was reported that fisetin protects against hepatosteatosis in mice by inhibiting miR-378. However, fustin has never been reported to be associated with AMPK or NAFLD.

Gallic acid is a naturally abundant plant phenolic compound in vegetables and fruits.[34] It has been recently reported to ameliorate impaired glucose and lipid homeostasis in high-fat-diet-induced NAFLD mice.[35] Quercetin is a dietary flavonoid found in various fruits, teas, red wines, and many medicinal herbs.[36] Much is known about the role of quercetin in NAFLD. Quercetin upregulates the expression of PPARα and CPT-1, two regulators of fatty acid oxidation, and downregulates the expression of SREBP-1 in the liver.[37]

Hexacosanol is a major constituent of policosanol and occurs naturally in the epicuticular wax and plant cuticle of many plant species.[38] Policosanol is known to inhibit cholesterol synthesis through AMPK.[39] Hexacosanol from barley sprouts has recently been reported to activate AMPK in HepG2 cells.[40] From these data, we surmised that fustin, fisetin, quercetin, gallic acid, and 1-hexacosanol are the major contributors to the beneficial effects of FRVE. Therefore, these compounds were assessed for their effect on the phosphorylation of AMPK and SREBP-1 by western blotting and lipid accumulation using ORO staining. Five compounds were shown to increase AMPK phosphorylation and reduce fat accumulation in OA-induced HepG2 cells. Fustin, fisetin, gallic acid, quercetin, and 1-hexacosanol displayed decreased expression of SREBP-1. The fustin content was enriched in FRVE (5.5%), whereas quercetin (0.17%) or fisetin (0.33%) content was decreased in FRVE. A total of 400 μg of FRVE tested in this study contained 22 μg of fustin, 6 μg of gallic acid, 2 μg of 1-hexacosanol, 0.68 μg of quercetin, and 0.132 μg of fisetin. Tested 20 μM fustin (5.76 μg/mL) had a much lower content than the fustin content in FRVE, whereas tested 20 μM 1-hexacosanol (3 times higher content), quercetin (9 times higher content) and fisetin (43 times higher content) were much higher than the content of individual compounds in FRVE. Furthermore, fustin increased AMPK phosphorylation more than others. The fustin content correlated and predicted the potency of FRVE in an antihepatic lipogenic effect via AMPK upregulation.

There was no report on the antilipogenic activity of fustin in NAFLD. This study is the first to demonstrate the activity of fustin in NAFLD. Therefore, an improved study is required to further verify the antilipogenic effect of fustin in NAFLD in the near future.

2.0 mg/mL) and packed coil structures (>2.0 mg/mL).[13] Such conformational change of chitosan molecules suggested that they could adopt various interaction mechanisms with liposomal membrane, besides the flat adsorption, which seemed of interest to further investigate.

On the other hand, it is important to point out that most of the suggestions aforementioned were based on a simple model membrane system composed of synthesized phospholipids. From a food industry perspective, egg yolk phosphatidylcholine (EYPC) is the commonly used lipid for the preparation of liposomes as it is a generally recognized as safe (GRAS) food ingredient. Previously, we explored a new type of liposome composed of mixed lipids including EYPC and a nonionic surfactant (Tween 80) as carriers for coenzyme Q_{10},[14,15] carotenoids,[16−19] and vitamin E.[20] The appropriate amount of Tween 80 in the formulation was demonstrated to impart high rigidity to the liposomal membrane, thus favoring the encapsulation efficiency and stability of liposomes. To the best of our knowledge, however, there is little information regarding the interaction of chitosan with mixed lipids-based liposomes.

Taken together, further detailed knowledge of such chitosan−lipid bilayer composite structure is required with special attention to the role of polymer conformation. Herein, the effect of chitosan conformation on the physical characterization of liposomes is thoroughly investigated including membrane dynamics, structure, hydrophobicity, surface morphology, and size. Several analysis techniques are introduced, including fluorescence anisotropy, electron paramagnetic resonance (EPR), transmission electron microscopy (TEM), atomic force microscopy (AFM), and dynamic light scattering (DLS). The aggregation and fusion behaviors of decorated liposomes as well as membrane permeability against surfactant are also evaluated.

MATERIALS AND METHODS

Materials. Egg yolk phospholipid (EYPC, composed of approximately 80% phosphatidylcholine, 5% lysophosphatidylcholine, and phosphatidic acid, and 15% fatty acids) was purchased from Chemical Reagent Plant of East China Normal University (Shanghai, China). Polyoxyethylene sorbitan monooleate (Tween 80) was obtained from China Medicine (Group) Shanghai Chemical Reagent Co. (Shanghai, China). Partially deacetylated chitosan (85%) with an average molecular weight of 200,000 was purchased from Ao Xing Biotechnology Co., Ltd. (Zhejiang, China). The fluorescent probe, 5(6)-carboxyfluorescein (CF), 1-[4-(trimethylammonio)phenyl]-6-phenyl-1,3,5-hexatriene (TMA-DPH, 98% purity), 8-anilino-1-naphthalenesulfonic acid (ANS, 98% purity), and the spin labels 5-doxyl-stearic acid (5-DSA) and 16-doxyl-stearic acid (16-DSA) were all purchased from Sigma Chemical Co. (St. Louis, MO, USA). All other reagents were of analytical grade.

Preparation of Chitosan-Decorated Liposomes. Bare liposomes were prepared according to our earlier method.[14] Briefly, phospholipid (6 g) and Tween 80 (4.32 g) were dissolved in 12 mL of warm ethanol at 55 °C. The ethanol solution was rapidly injected using a syringe as a pump into 120 mL of buffer solution (0.1 M acetic acid/0.01 M phosphate, 75 mM NaCl, pH 4.0) at 55 °C in a water bath under stirring at 700 rpm using an IKA RW 20 digital overhead stirrer (IKA Works Guangzhou). After agitation for 30 min, the liposomal system was transferred to a round-bottom flask attached to a rotary evaporator at 55 °C under reduced pressure to remove ethanol. The obtained liposomal suspension was then submitted to a probing sonication process in an ice bath for 10 min at 240 W with a sequence of 1 s of sonication and 1 s of rest using a sonicator (Sonics & Materials, Inc., 20 kHz). The final samples were filled into vials (the headspace of the vials was blanketed with nitrogen) and kept in a refrigerator (4 °C in the dark). The CF-entrapped liposomes were prepared in the same way expect for using 20 mM CF solution (0.1 M acetic acid/0.01 M phosphate, 75 mM NaCl, pH 4.0) instead of buffer solution. Unencapsulated CF was removed from the liposomal suspension by gel filtration through a Sephadex G-25 column.

The chitosan-decorated liposomes were prepared as follows: the chitosan was dissolved in the same buffer solution for bare liposomes and then added dropwise to bare liposomal suspension at equal volume at 1000 rpm for 30 min using an overhead stirrer at room temperature. The final concentration of chitosan was adjusted from 0.5 to 4 mg/mL. The phospholipid concentration was kept at 25 mg/mL. The final samples were filled into vials and stored at the same conditions as bare liposomes.

Liposomal Membrane Fluidity. A weighed amount of ANS probe was dissolved in ethanol solution, and the final concentration was 6×10^{-3} mol/L. The TMA-DPH stock solution was prepared by dissolving the TMA-DPH powder in tetrahydrofuran/water (1:1, v/v) and adjusting the concentration to 10^{-2} mol/L. The final TMA-DPH concentration was adjusted to 10^{-4} mol/L by PBS dilution before use. When the liposomal fluidity was determined, aliquots of probe solution were first mixed with bare liposomes in a 10 mL tube and incubated at 37 °C for 30 min. Then, different concentrations of chitosan in the same buffer were added dropwise to the incubated sample under stirring at 1000 rpm for 30 min. Note that before being mixed with liposomal samples, the ANS solution should be dried by

DOI: 10.1021/acs.jafc.5b01422
J. Agric. Food Chem. 2015, 63, 7277−7285

nitrogen to avoid the destructive effect of ethanol on liposomal membrane.

Microviscosity of liposomal membrane was measured at 25 °C using a fluorescence spectrometer (Hitachi F-7000, Japan) equipped with excitation and emission polarization filters. The excitation and emission wavelengths were, respectively, for ANS, λ_{ex} = 337 nm and λ_{em} = 480 nm and for TMA-DPH, λ_{ex} = 365 nm and λ_{em} = 430. The slit widths for both excitation and emission were 5 nm. The fluorescence intensities were measured according to our previous study.[19] The microviscosity (η) was calculated by fluorescence polarization (P) according to the equation[21]

$$\eta = 2P/(0.46 - P)$$

$$P = (I_{0,0} - GI_{0,90})/(I_{0,0} + GI_{0,90}),\ G = I_{90,0}/I_{90,90}$$

where $I_{0,0}$ and $I_{0,90}$ are the fluorescence intensities of the emitted light polarized parallel and vertical to the exciting light, respectively, and G is the grating correction coefficient.[22]

Electron Paramagnetic Resonance. The EPR technique was applied to monitor the molecular dynamics of lipids by observing the changes in the spin tropic movement of an unpaired electron. EPR measurements were performed using a Bruker EMX spectrometer (Bruker, Rheinstetten, Germany) at the X-band (9 GHz). The spectra were recorded at a microwave power of 20 mW with sweep width 120 G, center field 3511 G, and 20 s sweep time. All measurements were performed in triplicate at room temperature. In the present study, 5-DSA and 16-DSA were used as spin markers. These compounds consist of a radical group and a hydrocarbonated chain (stearic acid), which acts as a radical support (Figure 1). The radical in the 5- or 16-position of the alkyl chain will determine local motional profiles in the two main regions of the lipid bilayer, near the polar headgroup (5-DSA) or at the end of the hydrophobic chain (16-DSA). A weighed amount of 5-DSA or 16-DSA was dissolved in ethanol solution, with the final concentration adjusted to 1.0 or 0.9 mol/L, respectively. One milliliter of spin probe solution was added into a 10 mL tube followed by nitrogen dryness to remove the ethanol solution. An aliquot of 2.5 mL of bare liposomes was added into the tube and incubated at 25 °C for 30 min. Then, the chitosan solution was added dropwise to the incubated sample under stirring for 30 min.

Line widths $2A_{max}$, $2A_{min}$, and ΔH, in gauss (G), and heights of the high-field and midfield lines, h_{-1} and h_0, respectively, were obtained from the first derivative of each absorption spectrum. Spectral parameters used to study the location of spin labels in liposomal membrane are shown in Figure 1.

The order parameter (S) reflects the segmental order parameter of the segment to which the nitroxide fragment is attached.[23] It can be obtained from the conventional EPR spectra and calculated as $S = 0.5407 \times (A_{max} - A_{min})/a_0$, where $a_0 = (A_{max} + 2A_{min})/3$. The order parameter S is equal to zero for the membrane in total disorder. When it equals 1, the membrane has a crystal structure.[24]

The EPR spectrum of 16-DSA incorporated into the lipid bilayer reflects an isotropic motion of the acyl chain. In this case, rotational correlation time (τ, ns), assuming isotropic rotational diffusion of 16-DSA, can be used to measure the motion of the phospholipid acyl chains near the hydrophobic end.[25] An increase in τ indicates a decrease of membrane fluidity. It can be calculated from the following equation:

$$\tau = 6.5 \times 10^{-10} \times \Delta H \times \left(\sqrt{\frac{h_0}{h - 1}} - 1 \right)$$

Transmission Electron Microscopy. TEM micrographs were performed on a Hitachi-7650 at an accelerating voltage of 200 kV. The samples (bare liposomes and chitosan-decorated liposomes) were prepared as described above. An aqueous suspension of the samples was deposited upon a carbon-coated copper grid, followed by air-drying for 1 min. Then, the sample was instantly stained with 2 wt % phosphotungstic acid for 15 s.

Atomic Force Microscopy. AFM imaging was carried out using a commercial AFM (Dimension Icon, Bruker Co., Santa Barbara, CA, USA). The ScanAsyst mode was applied using silicon tip (TESP, Bruker, nominal frequency of 320 kHz, nominal spring constant of 42 N/m) with a scan resolution of 512 samples per line. Mica sheets were freshly cleaved to obtain a flat and uniform surface and were used as the substrate for AFM observations. Just before the analysis, the liposomal samples were diluted in water to obtain a less sticky fluid. An aliquot of 1 μL of liposome suspension was deposited on the mica surface and incubated for 30 min at room temperature. Afterward, samples were carefully washed with ultrapure water to eliminate salts and nonadsorbed vesicles and dried for 24 h at room temperature. Height mode images are acquired simultaneously at a fixed scan rate (0.997 Hz) with a resolution of 512 × 512 pixels in the dimension of 5 μm × 5 μm. Processing of images and analysis was carried out using NanoScope software (Digital Instruments, version V614r1). All height images are presented after the zero-order two-dimensional flattening.

Particle Size Distribution. Size measurements were performed at 25 ± 0.1 °C using a commercial zeta-sizer (Nano-ZS90, Malvern Instruments Ltd., Worcestershire, UK) with a He/Ne laser (λ = 633 nm) and scattering angle of 90°. To evaluate the aggregation and fusion of particles, the liposomal sample was heated at 37 °C for 5 h. After heat treatment, 2 mL of liposomal dispersion was transferred into the polystyrene cuvette for size determination, and then the particle size distribution was recorded by DLS. The measurements were repeated three times.

5(6)-Carboxyfluorescein Release Study. It is generally assumed that the fluorescence emission of CF is quenched to a high extent when the molecules are encapsulated in the interior aqueous compartments of liposomes at high concentration.[26] Upon release of CF from liposomes to the bulk aqueous phase, the fluorescence intensity would increase greatly. Therefore, the release of CF was taken as a measure of the membrane permeability after the incubation of liposomes with chitosan. Briefly, an aliquot of chitosan solution (1 mL) at different concentrations was added into 1 mL of liposomal suspension. At proper time intervals, 10 μL of sample was withdrawn and diluted with 2 mL of tris buffer (50 mM, pH 7.5). The fluorescence intensity of the samples was then measured at 25 °C with a spectrofluorimeter (Hitachi F-7000, Japan) with excitation at 488 nm and emission at 520 nm. The percentage of CF release from liposomes was calculated from the equation % release = $100 \times (F_t - F_0)/(F_\infty - F_0)$, where F_0 and F_t are the fluorescence intensities of the liposome samples before and after incubation with chitosan for the time period t and F_∞ is the total flurescence intensity after liposome lysis with 10% Triton X-100. To evaluate the stability of decorated liposomes against surfactant Triton X-100, 100 μL of 10% Triton X-100 solution was added to the liposomal sample (1 mL). The CF fluorescence was immediately monitored every second by spectrofluorimeter.

Statistical Analysis. Data are presented as a mean value with its standard deviation indicated (mean ± SD). All experiments were carried out in triplicate using freshly prepared samples.

RESULTS AND DISCUSSION

Fluidity of Liposomal Membrane. The fluidity of a liposomal membrane quantitatively characterizes the mobility and molecular rotation rate of lipid.[27] Lower membrane fluidity represents a higher structural order. It is well-known that ANS and TMA-DPH serve as markers for the molecular movement on the exterior membrane surface[28] and superficial region including the surface and glycerol side-chain region,[29] respectively. The relative microviscosity η/η_0 as a function of chitosan shows that the influence of chitosan binding was more pronounced on the fluidity in membrane surface than in the glycerol side-chain region (Figure 2). As the chitosan concentration increased from 0.25 to 1.5 mg/mL, microviscosity in membrane surface region was considerably increased, but remained virtually unchanged in the superficial region. Apparently, chitosan chains mainly adsorbed to the membrane surface and restricted the motion of the polar headgroup. Notably, restriction was stronger in the case of

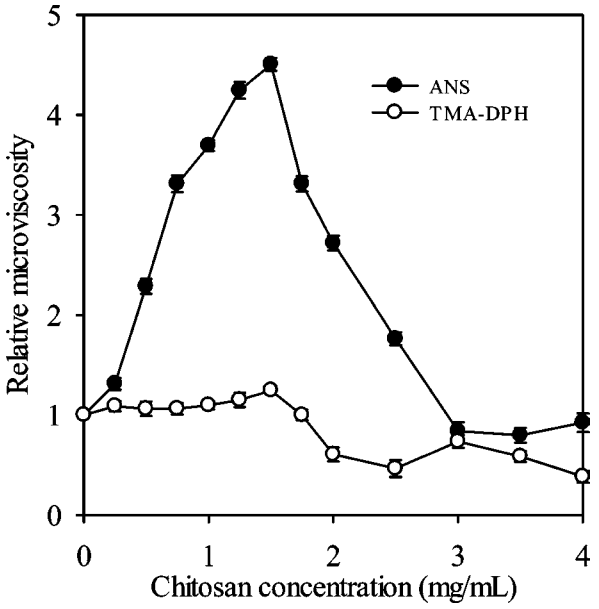

Figure 2. Relative microviscosity η/η_0 in liposomes for ANS and TMA-DPH as a function of decorated chitosan concentration. η_0 refers to the calculated microviscosity in bare liposomes, and η refers to the microviscosity in chitosan-decorated liposomes. Each point represents the mean value ± standard deviation (n = 3).

crimped chains. Considering the appearance of hydrophobic interaction accompanied by crimped chains, we speculated that besides electrostatic attraction, a weak hydrophobic force also contributed to the stabilizing effect on liposomal membrane. This hypothesis was supported by earlier research which concluded that the involvement of hydrophobic interaction could promote the physical adsorption and deposition of chitosan on membranes.[11] However, when the concentration was >1.5 mg/mL, η/η_0 values were decreased greatly surrounding ANS but only slightly surrounding TMA-DPH. This indicated that the presence of coils not only increased the fluidity of membrane surface but also somewhat disturbed the superficial region. The destabilization of chitosan coils might be correlated with the enhancement of hydrophobic interaction and, consequently, different adsorption patterns are expected instead of flat adsorption.

Motion of Alkyl Chains. EPR is a useful technique for determining the fluidity and structural changes of the lipid bilayers of liposomes. Figure 3 reveals that decoration of chitosan chains (<1.5 mg/mL) enhanced the order in the polar headgroup (at the 5-DSA position) and in the center of the bilayer (16-DSA position). This result was consistent with the Raman spectra analysis in relation to the *gauche* conformation change in the choline groups and lateral packing enhancement of the lipid chains.[19] However, the presence of chitosan coils (2.0−4.0 mg/mL) reduced the order of both regions. Combined with the high fluidizing properties, it was believed that the chitosan coils exerted a disturbing effect across the liposomal membrane. As evidenced previously, the zeta potential values were practically constant above the decorated concentration of 2 mg/mL.[13] Besides, the hydrophobic character along the chitosan chains became stronger, accompanied by the formation of chitosan coils. Therefore, it was concluded that the hydrophobic interaction prevailed in the formation of chitosan coil−liposome composites. Wydro's group[30] has also demonstrated that strong hydrophobic

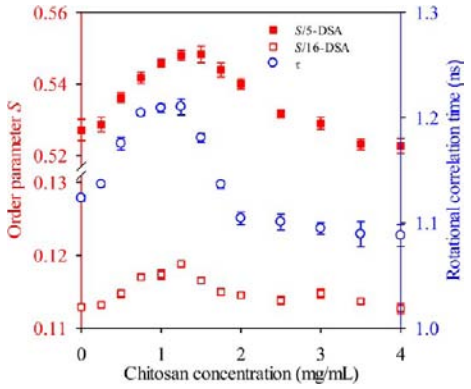

Figure 3. Order parameter S of spin probes and rotational correlation time of 16-DSA measured as a function of decorated chitosan concentration. Each point represents the mean value ± standard deviation (n = 3).

interaction between the phospholipid tails and chitosan allowed chitosan to come up to the monolayer and fill in the empty space. With these points taken into consideration, it was very likely that chitosan coils penetrated into the lipid hydrophobic core by hydrophobic interaction. On the other hand, it was noted that the disturbing effect of chitosan on the bilayer center was less pronounced than on membrane surface. This indicated that chitosan coils shallowly embedded into the one leaflet of the membrane.

Figure 3 also shows that the correlation time of 16-DSA free radical moiety increased from 0.25 to 1.5 mg/mL, whereas beyond this range, it was considerably decreased. This indicated that the segmental motion of the alkyl chains was restricted by the binding of chitosan chains, whereas chitosan coils failed to restrict the motion of the alkyl chains. The fluidizing property of chitosan deduced from correlation time was well in accordance with the results of membrane fluidity. On the basis of the analysis of membrane fluidity and structure, it was believed that besides providing a physical barrier, chitosan chains also exerted a rigidifying effect on the lipid membrane. Through modifying the membrane fluidity and ordering state, chitosan could mediate the permeation of foreign molecules into the membrane, thereby exhibiting a stabilizing role in liposome. These advantages of chitosan contribute to the development of composite phospholipid−chitosan vesicles (chitosomes) as new structures for the encapsulation of drugs and nutraceuticals.

Membrane Hydrophobicity. The isotropic hyperfine coupling constant a_0 of 5-DSA and 16-DSA was measured to determine the hydrophobicity of the polar headgroup region of the membrane and hydrophobic core, respectively. A decrease of the a value indicates an increase of hydrophobicity at the spin label position.[31] The hydrophobicity of the membrane headgroup region did not vary when the chitosan concentration was <0.5 mg/mL, whereas it was greatly increased in the range of 0.75−1.5 mg/mL (Figure 4). Apparently, the coated layer of chitosan chains can effectively increase the activation energy for polar small molecules to get across the membrane. Furthermore, the thicker the coated layer formed by the crimped chains, the higher was the physical barrier against the penetration of polar molecules. Another reason for the high hydrophobicity was that the decoration of crimped chains rigidified the organization of phospholipids at the polar headgroup and decreased the membrane permeability. These

J. Agric. Food Chem. 2015, 63, 7277−7285

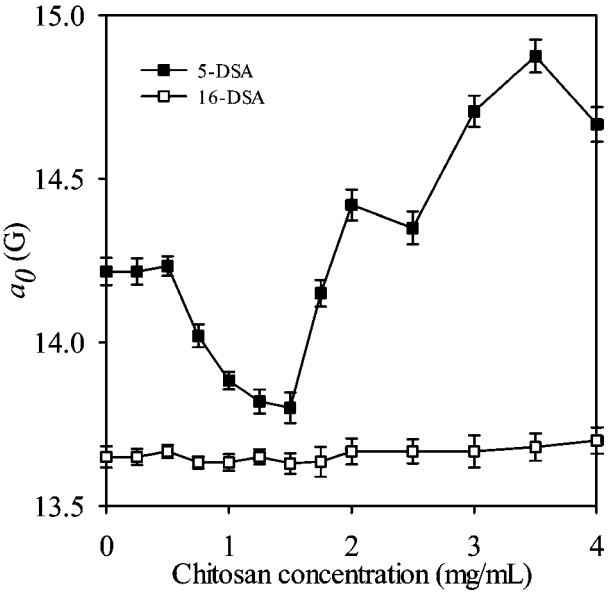

Figure 4. Isotropic hyperfine coupling constant a_0 of 5-DSA and 16-DSA in chitosan-decorated liposomes as a function of concentration. Each point represents the mean value ± standard deviation (n = 3).

mechanisms may contribute to the controlled release of encapsulated compounds in vehicles by decreasing water penetration.[32,33] However, a sudden increase in the a_0 values of 5-DSA was observed as the concentration was increased to 1.5 mg/mL. This phenomenon was understandable because the chitosan coils tended to penetrate into the liposomal membrane, rather than flat adsorption. Consequently, the polar region of the membrane was loosened, and more additional space was available for water penetration. By contrast, the effect of chitosan decoration on the hydrophobicity of membrane bilayer core was not pronounced, with a slight increase in a_0 values of 16-DSA from 1.75 mg/mL. In combination with the small influence of chitosan decoration on the fluidity of bilayer centre, this observation further confirmed the shallow insertion of chitosan coils, thus practically preserving the hydrophobic barrier of bilayer core.

Liposome Morphology. Alteration of adsorption behavior is always accompanied by a change in mechanisms of membrane deformation.[34] The morphological characterization of bare liposomes and chitosan-decorated liposomes was visualized by TEM after negative staining (Figure 5). It can be seen that bare particles were spherical. After decoration by chitosan, a different trend in morphological change was observed. At chitosan concentrations of 1.0, 1.5, and 2.0 mg/mL, the composite particles seemed to exhibit rectangular shape but maintained relatively monodispersion. The particle size was roughly in the range of 70−150 nm. The size observed from the microscopic images was somewhat greater than that determined using DLS technique.[13] This difference may have been related to the artifact effect of the analytical methods. For instance, the light-scattering instrument requires the high dilution of samples prior to analysis, which may have changed the particle size of the samples.[35] On the other hand, a very thin

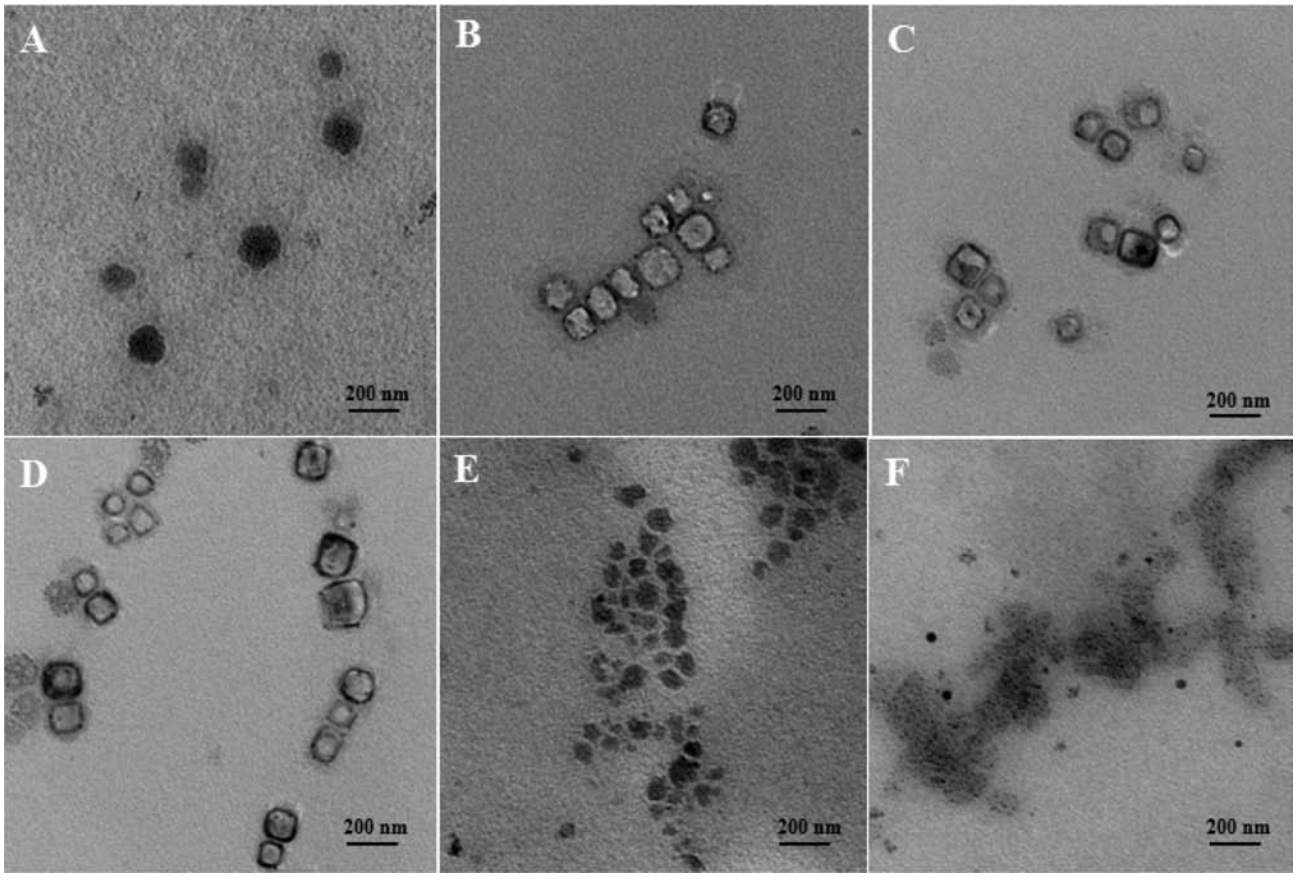

Figure 5. Transmission electron micrographs of bare liposomes (A) and liposomes decorated by chitosan at 1.0 mg/mL (B), 1.5 mg/mL (C), 2.0 mg/mL (D), 3.0 mg/mL (E), and 4.0 mg/mL (F).

J. Agric. Food Chem. 2015, 63, 7277−7285

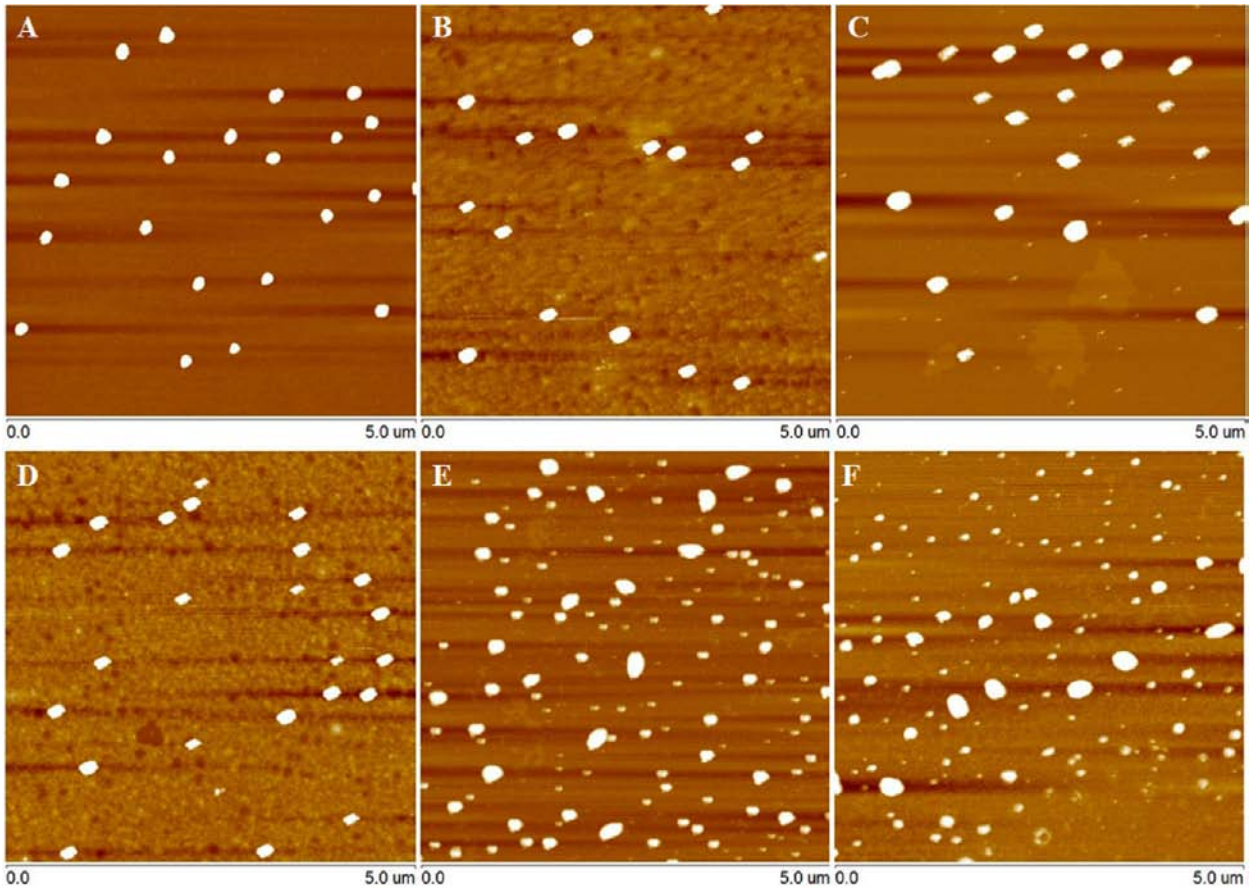

Figure 6. Scan Asyst mode AFM images of bare liposomes and liposomes decorated by chitosan at concentrations of 1.0, 1.5, 2.0, 3.0, and 4.0 mg/mL. The study was performed immediately after the preparation. Scan size = 5 μm × 5 μm.

coated layer (~10 nm) around the liposomal particles can be observed, demonstrating the interaction of chitosan with liposomes as well as the flat adsorption of chitosan chains.[13] The dimension and charged property of the system also revealed an electrostatic interaction that, after titration with chitosan to attain a concentration of 0.5 mg/mL, increased the average diameter of liposomes from 82.9 to 90 nm, with a charge inversion from −17.9 (bare liposomes) to 10.6 (decorated liposomes).[13] However, with further increase of chitosan concentration (from 3.0 to 4.0 mg/mL), the suspension became very heterogeneous and the shape of the particles was completely distorted (Figure 5E,F). Many small particles (<50 nm) were found in the field of vision. Diameter distribution analysis provided a complementary picture of a strong volume peak of liposomes located in the range of 10−50 nm in the presence of chitosan coils.[13]

AFM images of bare liposomes and chitosan-decorated liposomes are shown in Figure 6. The majority of bare liposomes maintained a spherical and well-defined shape. The presence of chitosan led to a change in the shape of liposomes, depending upon the chitosan concentration. The shape of liposomes appeared rectangular at concentrations of 1.0, 1.5, and 2.0 mg/mL, but was more irregular at 3.0 and 4.0 mg/mL. This observation supported the results obtained by TEM analysis. Deformation of particles observed from AFM images could be attributed to different factors, such as particle collapse during evaporation[36] and interactions of adsorbed polymer with supported surface.[10] In our case, it appeared that the original morphology of liposome was not significantly influenced by the spontaneous collapse, as evidenced from the fairly spherical shape of bare liposomes (Figure 6A).

In combination with TEM observation, the morphological alteration of liposomes has to be related to the modification of chitosan on the lipid headgroup. Upon binding of chitosan to the surface of small vesicles, the chitosan chain would bend to adapt to the large curvature of the sphere. This process probably, in turn, builds tension in the membrane and increases the spontaneous curvature of the bilayer. This phenomenon brought about the change in morphology. Moreover, if the binding of polyelectrolyte becomes stronger, the membrane would be subjected to a higher degree of bending.[34] Thus, the deformation of liposomes was more apparent in the presence of crimped chains (at 1.5 and 2.0 mg/mL). It was also possible that the hydrophobic residues of crimped chains incorporated into the membrane interior and occupied the position of phospholipid molecules. As a result, a portion of lipid acyl chains orientated toward higher curvature, leading particles to be elongated.[37] At higher chitosan concentrations (3.0 and 4.0 mg/mL), a number of very heterogeneous particles were visible, which may be generated probably due to the reorganization of particles subsequent to collapse. This observation can be explained by the fact that chitosan coils progressively penetrated into the lipid bilayer until disrupting it. At this stage, the hydrophobic interaction was intensified, accompanying the formation of chitosan coils. The almost unchanged zeta potential values of the system (>2 mg/mL) also confirmed the existence of hydrophobic interaction.[13] Therefore, it was believed that the main forces involved were

DOI: 10.1021/acs.jafc.5b01422
J. Agric. Food Chem. 2015, 63, 7277−7285

hydrophobic in nature, as demonstrated by the incorporation of surfactant molecules into the phospholipid bilayer.[38] If the main aim of chitosan modification was to stabilize liposome, high concentrations at which chitosan adopted coil conformation should be avoided, considering the lipid bilayer membrane disruption. On the other hand, the "polymeric surfactant" property of chitosan provided us a new perspective to elucidate that the ability of chitosan to disrupt the lipid bilayer membrane for the antimicrobial[39] and biological activity[40] partially related to its coil conformation.

Aggregation and Fusion of Liposomes. The susceptibility of liposome to aggregation or fusion during production, storage, transport, and after administration is highly challenging.[41] Here, we briefly discuss the observations on the aggregation and fusion of the composite chitosan−lipid particles after heat treatment.

Analysis on the particle size using DLS technique showed that there was only a single volume peak observed for the chitosan-decorated liposomes at 1.0, 1.5, and 2.0 mg/mL after 5 h of incubation at 37 °C (Figure 7). This indicated that the

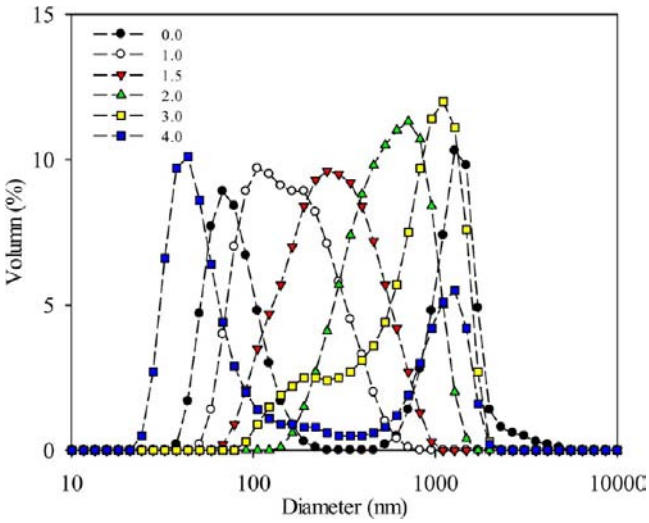

Figure 7. Diameter distribution of bare liposomes and chitosan-decorated liposome after 5 h of incubation at 37 °C.

suspensions can maintain the homogeneous distribution even though they were heated. However, bimodal distribution occurred for uncoated liposomes and liposomes decorated by chitosan of 3.0 and 4.0 mg/mL. It is very likely that the volume peak located at large diameter (around 1100 nm) was caused by the particle aggregation or fusion.

AFM measurement provided direct visualization of the aggregated and fused behavior of particles (Figure 8). In the absence of chitosan, particles adhered to each other after incubation. The diameter of fused particles ranged from 295 to 957 nm. After decoration by chitosan at 1.0 and 1.5 mg/mL, few particles aggregated together and the boundary of the unit particle was clearly observed. It was believed that the combining effect of electrostatic repulsion and steric hindrance by externally adsorbed polymers inhibited particle aggregation. However, decoration of high chitosan concentration induced the aggregation and fusion. We can observe that four or five individual particles adhered to each other, forming bigger aggregates in the whole vision field (Figure 8D). This interesting phenomenon might be associated with the bridging effect of chitosan-bound chains to neighboring vesicles.[11] The aggregated liposomes fused into a single liposome resembling the shape of a distorted rod or an elongated sphere (Figure 8E) or into large irregular clusters (Figure 8F). The lateral segregation of the anionic lipid by polyelectrolyte adsorption and consequently disordered lipid packing could be a possible reason for liposome fusion.[42] In addition, a low level of membrane fluidity was supposed to prevent particle aggregation effectively, whereas it behaved oppositely at high fluidity.[43] Thus, liposome aggregation was also readily understandable when correlated with the analysis on fluorescence anisotropy (Figure 2).

Liposomal Membrane Permeability. To understand whether the interaction of chitosan affected membrane permeability, leakage of CF from liposomes was monitored during the interaction process of chitosan and liposomes. Figure 9A shows that bare liposomes (0.0 mg/mL) spontaneously released very small amounts of encapsulated CF due to instability. After liposomes had been incubated with chitosan in the range of 0.5−1.5 mg/mL, the release profile of CF was not significantly affected. Only when incubation time exceeded 15 min were the leaked amounts of CF from decorated liposomes lower than that from bare liposomes, suggesting the gradual formation of a chitosan layer. This process also implied that although the morphology was modified by chitosan, the permeability of the membrane was not significantly altered. However, once the chitosan concentration increased (2.0−4.0 mg/mL), a progressive and higher leakage of CF appeared. This observation demonstrated that the interaction process of chitosan coils with liposomes was accompanied by the penetration of chitosan coils into the membrane.

The physicochemical barrier of the lipid bilayer against the penetration of foreign elements plays a key role in protecting the incorporated bioactive components. To evaluate the rigidity of liposomal particles, their resistance against surfactant Triton X-100 was carried out. Figure 9B shows that the release of CF from bare liposomes increased dramatically, as around 30% of encapsulated CF molecules leaked after 120 s. It was suggested that a large amount of Triton X-100 penetrated into the bilayer and initiated the solubilization process. Liposomes decorated by chitosan ranging from 0.5 to 1.5 mg/mL possessed higher durability against Triton X-100 penetration and maintained the release rate at a low level. The strong resistance could be due to the dense mesh covering the membrane surface and rigidification of chitosan. Conversely, liposome membrane decorated by a high concentration of chitosan became more permeable to surfactant, as observed from serious leakage of CF. After 120 s of incubation, around 30, 35, and 38% of CF leaked from liposomes decorated by 2.0, 3.0, and 4.0 mg/mL chitosan, respectively, confirming the destabilizing effect of chitosan coils.

Conclusion. In the present study, we have demonstrated the contrasting modulations of chitosan on the dynamics, structure, hydrophobicity, morphology, and permeability of liposomal membrane. The extended and crimped chains of chitosan not only provided a physical barrier to the liposome surface but also rigidified the lipid membrane. Although the morphology was altered by chitosan decoration, the membrane permeability was preserved or decreased. Such characteristics make these composite vesicles potential candidates for an efficient delivery system for drugs and nutraceuticals. However, chitosan coils displayed a "polymer surfactant" nature by penetrating into the interior of lipid bilayer. These destabilizing

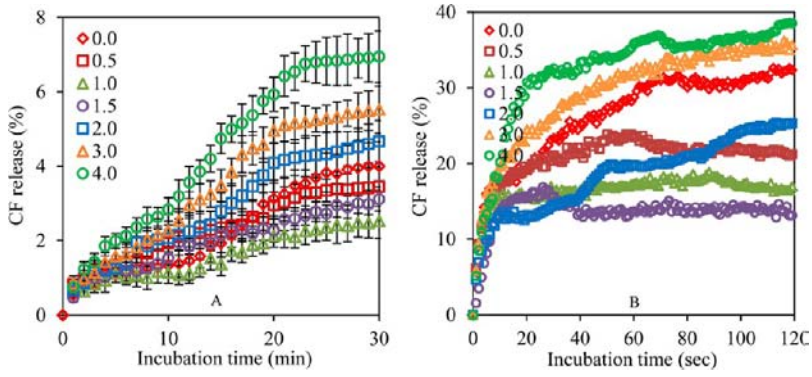

Figure 9. Time course of CF release kinetic from bare liposomes after exposure to chitosan of different concentrations (A) or from chitosan-decorated liposomes after exposure to Triton X-100 (B). When Triton X-100 was added to the suspension, the CF fluorescence was immediately monitored every second by a spectrofluorimeter.

effects of coils implied the ability of chitosan to disrupt cell membranes and the infeasibility in the design of nutraceutical delivery systems.

Figure 1. (A) Brittle, crystalline structure of the native Frost grape arabinogalactan polysaccharide. The piece shown is approximately 1 cm in length. (B) Viscous FGP exuding from a cut, debarked vine stem after 20 h.

DMSO, powdered NaOH), acid hydrolyzed with trifluoroacetic acid (2 M, 120 °C, 1 h), and converted to partially methylated aldononitrile acetates for GC-MS analysis of the glycosidic linkage positions.[18] The permethylation analysis was done in triplicate. Hydroxyproline was determined colorimetrically.[19]

Acetylation under Aqueous Condition. To acetylate the FGP, freeze-dried material (30 mg) was dissolved in 2 mL of 3% aqueous solution of trisodium phosphate. Vinyl acetate (400 μL) was added dropwise, and the reaction was maintained at room temperature for 18 h. Excess vinyl acetate was extracted with ethyl acetate, and the aqueous phase containing the acetated FGP was freeze-dried.

NMR Analysis. All NMR experiments were performed on an Avance spectrometer (Bruker Biospin, Billerica, MA, USA) operating at 500.11 MHz using a standard 5 mm *z*-gradient BBI probe at either 27, 60, or 80 °C. The deuterated solvents used were obtained from Cambridge Isotope Laboratories (Tewksbury, MA, USA). The diffusion-orientated NMR pulse sequence used was ledbpgp2s (standard Bruker ^{1}H DOSY sequence), and the spectra were recorded at 27 °C. The processing was done with the Bruker TOPSPIN software package (v. 1.3), and other pulse sequences used were those supplied by Bruker Biospin.

Preparation of Frost Grape Polysaccharide and Emulsification Assays. Clove oil (>85% eugenol) was obtained from Spectrum Chemical Mfg. Corp. (Gardena, CA, USA). Grapefruit essential oil (>95% terpenoids) was obtained from Eden's Garden (San Clemente, CA, USA). Both of these oils are practically insoluble in water. FGP was isolated from Frost grape (*V. riparia* Michx.) stem sections by cutting the stems into ∼15 cm sections and placing these in a plastic bag for 24 h, after which time the FGP had exuded into nearly clear, tubular crystals. After drying in an oven at 40 °C for 48 h, the crystals were ground in a coffee grinder to a fine powder. Solutions of FGP were prepared at 0.1 and 1.0% (w/v). Subsequently, 0.1 mL of clove oil and 0.1 mL of grapefruit oil were added to 100 mL of the 0.1% FGP solution, and 1.0 mL of the oils was added to the 1.0% FGP solution. The mixtures were then homogenized with a Polytron homogenizer for 30 s at 2000 rpm. Photographs were taken after 48 h with no further agitation.

RESULTS

Extraction and Carbohydrate Compositional Analysis.

An arabinogalactan polysaccharide was found to be exuded from the cut stems of Frost grape and was first noticed from the vine growing around oak trees. Saw-cut stems exuded a colorless, low-viscosity sap, which dried within hours first to a gel and later to a brittle, crystalline solid (Figure 1). About 8 g of the material was recovered from cut sections of vine stem about 30 cm long × 2.5 cm diameter. This brittle solid polysaccharide was recovered by breaking it from the cut ends of the vine, and this material is referred to as the native Frost grape polysaccharide. Larger quantities of material were prepared by debarking the vine stems, cutting them into small sections about 3−5 cm in length, splitting them open lengthways, and extracting the pieces for 15 min with either cold or boiling water. These water extracts were viscous and yellowish in color.

The component monosaccharides in the FGP extracts were determined by GC-MS analysis of aldononitrile acetate (Figure 2; Table 1), as described.[15] In the first extraction, the brittle solid polysaccharide was recovered from the cut ends of the Frost grape vine, and we refer to this as the native polysaccharide. The polysaccharide is composed of approximately 2:1 L-arabinofuranose/D-galactopyranose, with minor components of D-xylose (∼11%) and D-mannose (∼3%). We also tested for hydroxyproline (Hyp) using a colorimetric assay[19] and compared it to commercial gum arabic (Table 1). We conclude that there is <0.02% Hyp in the FGP and probably none since this was below the detection limit. A bicinchoninic acid protein assay was also negative.

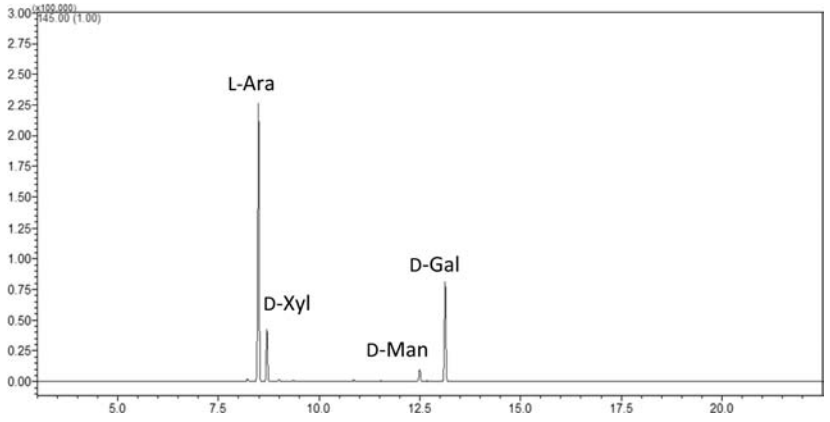

Figure 2. Monosaccharide compositional analysis of the native Frost grape polysaccharide. The FGP was acid hydrolyzed, and component sugars were determined by GC-MS as aldononitrile acetates.

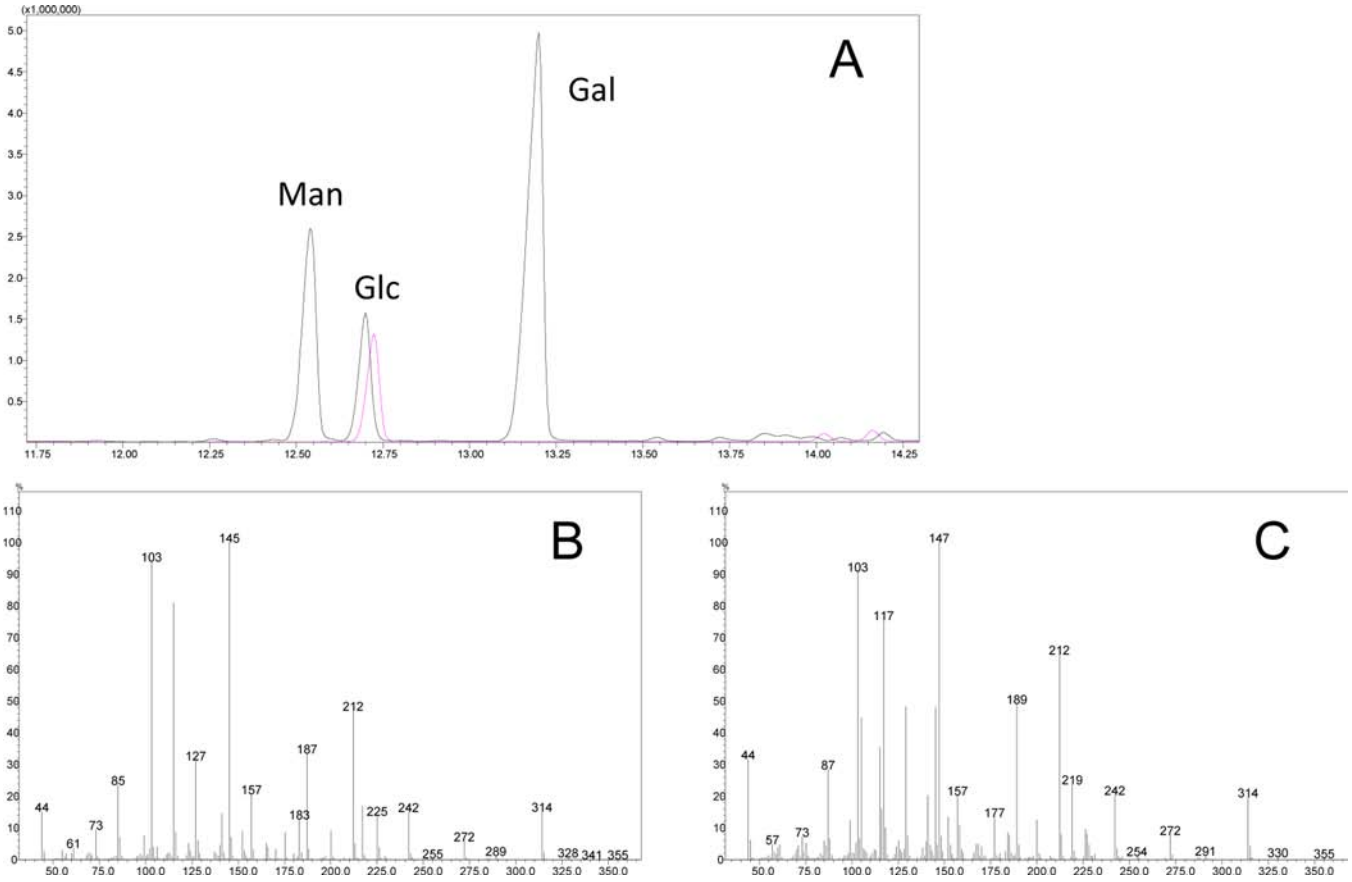

Figure 3. Uronates from FGP after $NaBD_4$ reduction, overlaid with Man, Glc, and Gal aldononitrile acetate standards: (A) composition determined by GC-MS (the deuterated Glc at 12.71 min arising from glucuronic acid (GlcA) is shown in magenta); EI-MS spectra of the GlcA residue from (B) $NaBH_4$-reduced FGP and from (C) $NaBD_4$-reduced FGP.

Frost Grape Uronic Acid Component Analysis. The acidic sugar residues present on the FGP were analyzed by the standard carbazole colorimetric assay for hexuronates,[16] which was inconclusive due to a high dark brown background color. We therefore made hexuronate methyl esters by treating the polysaccharide with methanolic HCl (+ chloroform) and reduced these with either sodium borohydride or borodeuteride. The reduced polysaccharides were acid hydrolyzed (2 M TFA), and PAANs derivatives were prepared for analysis by GC-MS.[15] After the reduction with borohydride, a new GC peak was observed for glucose at 12.7 min (Figure 3A), but only after the reduction step. The evidence that this glucose is derived from glucuronic acid comes from the observed incorporation of two deuterium atoms at carbon-6 following the reduction with borodeuteride and is evident from analysis of the electron impact mass spectrometric (EI-MS) data. Noticeably, the reduction of the glucuronate 6-methyl ester with $NaBD_4$ is evident from the 2 mass unit increase of ions m/z 87, 105, 117, 129, 147, and 189 (Figure 3B,C) and shows that the borodeuteration has occurred at the glucuronic carboxyl group. Hence this relatively small amount (peak integration indicates about 75% relative to the small mannose component) of glucuronic acid is derived from the FGP.

There is also a minor peak arising later in the GC chromatograph at 19.97 min due to a disaccharide peracetate (Supporting Information). The mass spectra arising from this peak also indicate that the disaccharide component is labeled with two deuterium ions. The +2 mass increase at m/z 407, 347, 333, 305, and 171 shows that this is a disaccharide composed of two neutral hexose sugars, one residue of which is derived from the borodeuteride-reduced glucuronic acid. The other residue is not deuterium labeled; otherwise, there would be an increase of +4 deuterium atoms. Moreover, the masses and the fragmentation ions indicate that this unlabeled second residue is a neutral hexose (i.e., probably Gal or possibly Man) rather than an arabinose residue. We conclude that the GlcA residue is attached to the polysaccharide backbone linked via galactosyl residues, but not to an arabinosyl part of the chain.

Permethylation Linkage Analysis of Native Frost Grape Polysaccharide. The GC separated seven peaks between 4 and 10 min giving EI-MS ions characteristic for partially methylated sugars (Table 2). The three fast eluting peaks before 5.5 min were assigned as methylated pentoses arising

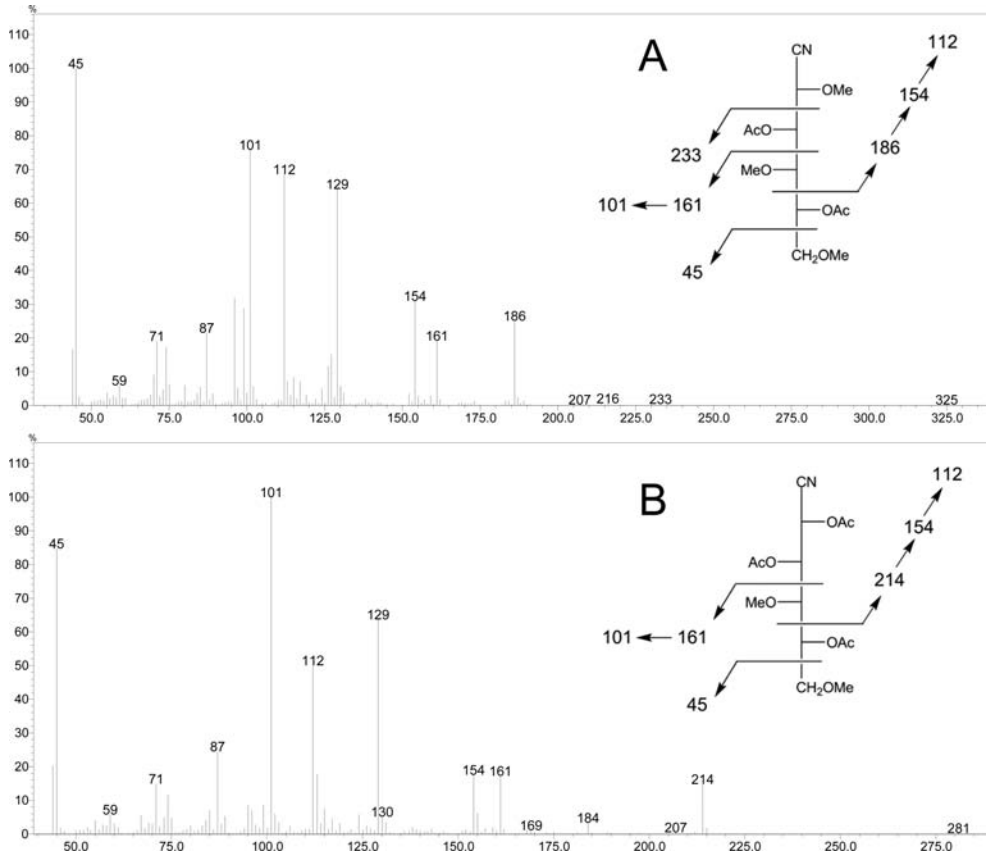

Figure 4. GC-MS permethylation linkage data: GC-MS spectra of (A) 3,5-diacetyl-2,4,6-trimethylgalactose aldononitrile acetate (t_R 8.38 min) and (B) 2,3,5-triacetyl-4,6-dimethyl-galactose aldononitrile acetate (t_R 9.66 min). The major fragmentation pathways are as shown.

from the variously linked arabinosyl and xylosyl residues. The presence of 4-acetyl-2,3,5-methylarabinose indicates that the arabinose residues are in the furanosyl form, as is confirmed by NMR. The peak at 6.38 min corresponds to 2,3,4,6-MeHex*p*, indicating a terminal hexopyranose, either Gal*p* or the small component of Man*p*. The three later peaks correspond to trimethylated (8.38 min) and dimethylated (9.66 and 10.00 min) hexopyranosyl residues and integrate approximately 3:2:1. Importantly, the GC peak at 9.66 min is readily assigned as 4,6-*O*-dimethyl-2,3,5-*O*-triacetylgalactose, arising from 2,3-linked Gal*p*. The EI-MS ion series m/z 214 → 154 → 112 indicates C4−C5 cleavage adjacent to the 4-methoxy group with retention of change at the nitrile end (Figure 4B). Similarly, m/z 161 → 101 is evidence for C3−C4 bond cleavage with charge retention in the other direction. This shows that two *O*-acetyl groups have been introduced into the galactopyranosyl residues at the 2- and 3-positions, indicating a core 1→3-linked galactosyl chain that is 1→2-substituted with Ara*f* residues. Similar analysis indicates that the GC peak at 8.38 min is due to 2,4,6-trimethyl-3,5-diacetylgalactose, arising from 3-linked Gal*p* (Figure 4A). This contains the ion sequences m/z 186 → 154 → 112 (m/z 214 is absent, hence only 3-linked) and m/z 161 → 101, plus a major ion at m/z 45 due to cleavage of a terminal C-6−CH_2OMe group. The smaller GC-MS peak at 10.0 min gave a mass spectrum identical to the 9.66 min peak and is possibly due to 2,3-linked mannosyl residues. Taken together, these data are consistent with a carbohydrate backbone of 1,3-linked Gal*p* residues with a 2-substituted Gal*p* present at a ratio of 3:2. Hence, the most probable linkage arrangement is that the 2-linked substituent is arabinofuranosyl side chains, the structure of which is determined by NMR as described below.

Analysis of the Native Frost Grape by HSQC-NMR, TOCSY-NMR, COSY-NMR, and Diffusion-Orientated (DOSY) NMR. The high viscosity made it difficult to obtain NMR data at room temperature, as is often common with polysaccharides, and this was not improved by switching the solvent to either d_6-DMSO or a 50:50 d_6-DMSO/D_2O mixed solvent. However, better HSQC, COSY, and TOCSY spectra of FGP were obtained at higher temperatures (80 and 60 °C in D_2O). The acquisition at high temperature led to a ∼0.5 ppm downfield shift of the proton signals (Figure 5), but by comparison with the HSQC data it was possible to extrapolate these assignments to room temperature (Table 3). The structural assignments were initially made by reference to published data on gum arabic and other arabinogalactans.[20−24] Three α-linked arabinofuranose anomeric signals, α-Ara-A, -A′, and -A″, were detected at 5.44, 5.38, and 5.19 ppm at room temperature and are coupled to ^{13}C NMR signals at 107.2, 108.3, and 109.4 ppm, respectively (Figure 5; Table 3). The corresponding β-Gal G1 signals are at 4.54/101.4 ppm. Unlike gum arabic there are no NMR signals for rhamnose, confirming the GC-MS compositional analysis (Table 1). Integration of the ^{1}H NMR signals showed that α-Ara-A, -A′, and -A″ are present in a ratio of 1:0.6:1. The α-Ara-A residue is structurally distinct from the other two, and the α-Ara-A H-2 is detected at 4.35 ppm and is coupled to the corresponding C-2 at 87.5 ppm. This carbon shift is ∼6 ppm downfield of the C2 carbons for the Ara-A′ and Ara-A″ residues, showing that the Ara-A is glycosidically linked at this position.

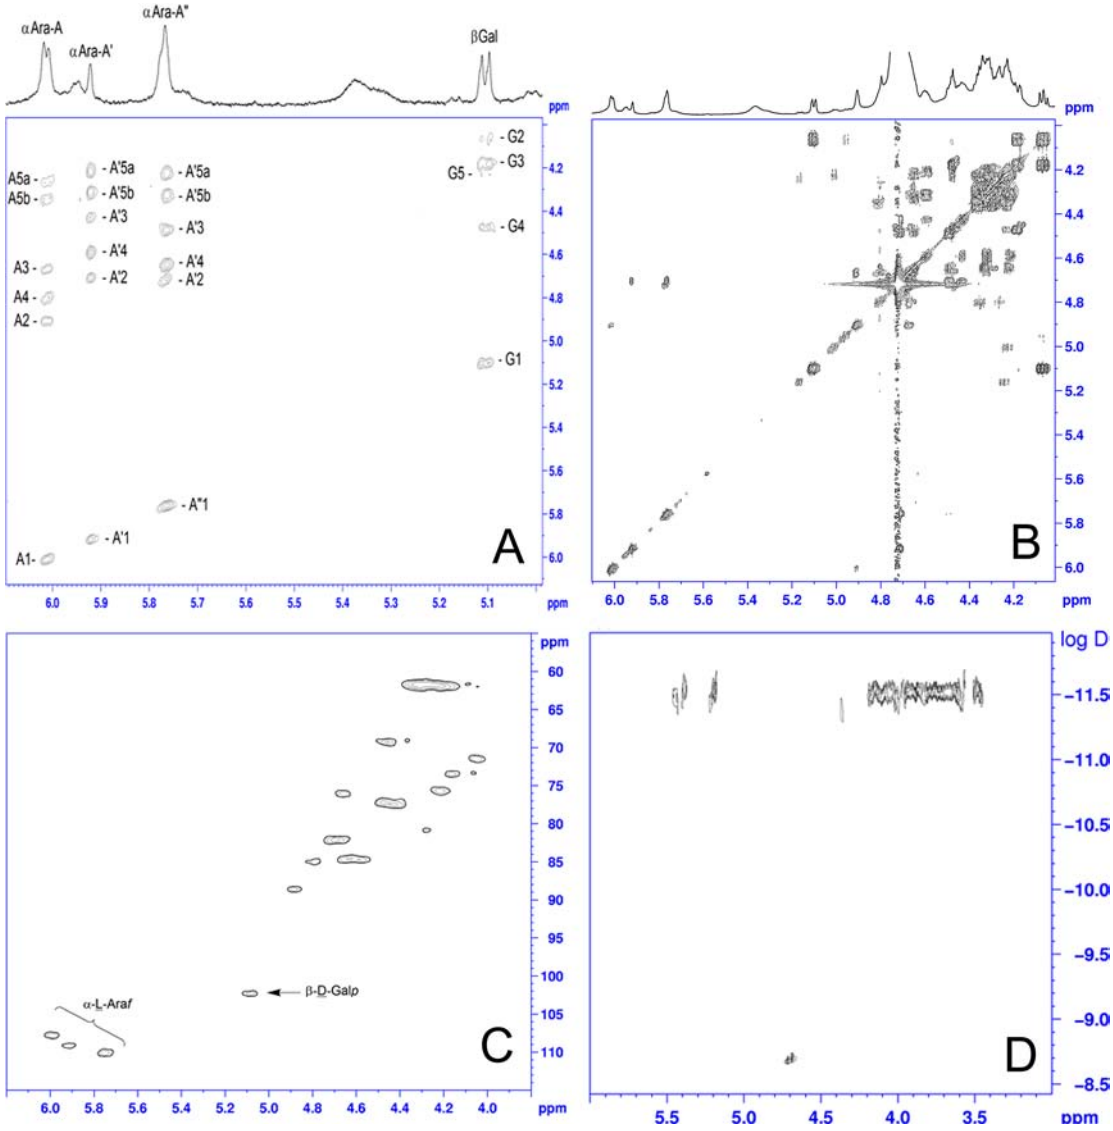

Figure 5. Total (TOCSY, A), $^{1}H-^{1}H$ (COSY, B), and $^{1}H-^{13}C$ correlation (HSQC, C) NMR spectra of D_2O-exchanged native Frost grape polysaccharide at 80 °C. Four spin systems are evident: the α-linked Ara*f* residues (A, A′, and A″) with anomeric proton shifts at 6.01, 5.92, and 5.76 ppm respectively, and a β-linked Gal*p* residue at 5.10 ppm at 80 °C. The corresponding carbohydrate ring protons are at 4.0−5.2 ppm and correlate to ^{13}C signals at 60−90 ppm in the HSQC spectrum. The full assignments are in Table 3, and the deduced FGP structure is shown in Figure 7. (D) Diffusion-ordered NMR spectra (DOSY) obtained at 27 °C in D_2O for Frost grape polysaccharide (−11.5 log D). The *x*-axis is ^{1}H NMR spectra and the *y*-axis is −log diffusion constants. The 4.7 ppm signal is due to the residual HDO signal.

Correlation (COSY) and total correlation (TOCSY) spectra were used to assign the arabinosyl A, A′, and A″ ring protons and the G1−G5 protons for the β-galactosyl residue (Figure 5A,B). Noticeably weak coupling was observed between G4 and G5 protons in the galactosyl ring and is consistent with the H4-equatorial-H5-axial dihedral angle that is characteristic for a galactopyranosyl ring configuration. Also, no coupling was observed between G5 and the geminal G6 CH_2 protons. Generally, the H4 protons of galactose have the lowest field chemical shift, although for FGP the H3 (G3 = 3.60 ppm) and H2 (G2 = 3.47 ppm) shifts are both found at lower field than this. This suggests that the Gal ring is glycosidically linked at both positions 2 and 3, by the β-1,3-Gal backbone and the 1,2-linked arabinosyl side chain, as is confirmed by the permethylation analysis (Figure 4). The corresponding ^{13}C NMR signals were fully assigned by correlations through the HSQC spectrum (Figure 5C; Table 3) and confirmed the positions and anomericity of the glycosidic linkage. The Gal G6 carbon shift is at 61.5 ppm, showing that it is not substituted at this position. If it was, the expected shift would be closer to 67 ppm.[24] The homogeneity, purity, and molecular weight of the FGP were estimated by a diffusion-ordered (DOSY) NMR experiment (Figure 5D). A single polysaccharide chain was observed at −11.5 log *D*, which by comparison with a 1.6 MDa pullulan standard indicated a probable molecular mass of about 1−10 MDa. Furthermore, unlike gum arabic or arabinogalactans from larch, there is no evidence for terpenoids or other small molecule impurities.

Further structural assignments were obtained from comparison of the HSQC data with a NOESY-NMR spectrum (Figure 6 and Supporting Information). A through-space coupling was observed from the αAra-A anomeric H1 proton to the corresponding anomeric proton of the αAra-A″ residue (Figure 6). This assigns these two protons as being close

together and is confirmed by a second NOE signal from the αAra-A″ H1 to the αAra-A H2 (Supporting Information). This is consistent with the αAra-A″ ring being glycosidically linked to the 2-position of the αAra-A ring and with the 6 ppm downfield shift observed for the αAra-A C2 carbon. The smaller NOESY signal observed in the opposite direction, from αAra-A H1 to the αAra-A″ H2 (Supporting Information), is also consistent with this structure. A final NOESY through-space correlation was seen from the αAra-A′ H1 to the αAra-A″ H4 proton, which is consistent with these two residues being connected via an α-1,3-linkage. It is also apparent that the chemical shifts for the αAra-A′ arabinosyl residue are very close to those reported for synthetic α-L-Araf-(1→2)-β-D-Galp-(1→6)-β-D-Galp,[24] confirming that the αAra-A′ is indeed a terminal residue. However, it is also conceivable that the terminal Ara-A′ forms a separate branch from the galactosyl backbone, so that Ara-A′ and Ara-A″ are both terminal residues. This arrangement would explain the absence of a predicted downfield shift for the 3-linked Ara-A′ H3/C3 signals,[20] but it also contradicts the A′-to-A″4 NOESY correlation (Supporting Information) and the data from the permethylation analysis. Indeed, the NMR integral ratios for Ara-A and A″ are 1:1, whereas Ara-A′ is 0.6 of these, suggesting that there is probable structural diversity in the arabinosyl side chains.

Acetyl Modification and Emusifying Properties. The native Frost grape polysaccharide was soluble in water at concentrations <2% w/v. At higher concentrations the FGP formed gels that were difficult to dissolve even at elevated temperatures. Aqueous 1−2% w/v solutions are viscous, but the FGP material was readily pourable at concentrations up to 0.5% w/v. The point at which gels formed was about 12% w/v, whereas less concentrated solutions were viscous liquids (Figure 7A). It was also noted that the FGP was poorly soluble in dimethyl sulfoxide (DMSO) and that it remained as an insoluble gel during attempted acetylation with acetic anhydride. Indeed, attempts to peracetylate the polysaccharide in acetic anhydride catalyzed by either pyridine, DMAP, or even sodium hydroxide were entirely unsuccessful, even when reacted at elevated temperatures. A considerable amount of coloration occurred at reflux temperature in acetic anhydride, and the majority of the FGP remained as a solid mass. To circumvent these problems we acetyl-modified the native FGP in aqueous phosphate buffer using vinyl acetate as the acetyl donor as described by Adeuya and Price.[25] This acetylated FGP was compared with the native FGP and commercial gum arabic for the ability to emulsify oil/water mixtures (Table 4; Figure 7B).

DISCUSSION

In summary, we report the structure of a new arabinogalactan polysaccharide produced from the cut stems of the North American grape species *V. riparia* (Frost grape). The neutral sugars composition of the native FGP, determined by aldononitrile acetate GC-MS analysis, consists of predominantly L-arabinofuranose (L-Araf, 55.2%) and D-galactopyranose (D-Galp 30.1%), with smaller components of D-xylose (11.2%) and D-mannose (3.5%). Permethylation linkage analysis indicates a complex nonlinear structure containing terminal arabosyl and mannosyl residues and β-1,3-linked internal galactosyl residues. Analysis of the uronic acid sugars present identified a minor component of glucuronic acid (GlcA) at about 2% of the total sugars. GC-MS analysis of the borodeuteride-reduced GlcA showed that the GlcA is linked via a galactosyl residue, rather than through the arabinose groups. HSQC, COSY, TOCSY, and DOSY NMR data were obtained on the native polysaccharide by acquiring spectra at high temperature (80 °C) and from the analysis of the anomeric signals showed the presence of at least three distinct α-linked arabinosyl groups and a major β-linked galactosyl residue. Unlike gum arabic and several other arabinogalactans, the FGP did not give a positive colorimetric test for hydroxyproline or a positive Bradford assay, and we conclude that the hydroxyproline-rich protein (AGP) content is low or entirely absent. DOSY NMR indicated a single high-molecular-weight arabinogalactan (molecular mass of about 1−10 MDa) and confirmed that it contains no smaller molecules such as oligosaccharides, terpenoids, free monosaccharides, or hydroxylproline-rich glycoprotein. We therefore conclude that the structure of FGP is as presented in Figure 6.

Gum arabics typically consist of a mixture of arabinogalactan polysaccharide and a hydroxyproline-rich glycoprotein but with significant variability with source, such that the exact molecular structures are uncertain. The glycoprotein is a hydroxyproline-rich arabinogalactan (~2% protein) and is attached to oligo-α-1,3-L-arabinofurans and the galactose residues of oligo-arabinogalactans.[26−28] The polysaccharide component is a β-1,3-D-galactopyran core with 1,6-linked side chains of β-D-uronic acids, β-D-galactose, α-L-arabinose, and α-L-rhamnose and terminal sugars composed of α-L-rhamnopyranose, α-L-arabinofuranose, and β-D-uronic acids via 1,2- and 1,4-linkages.[12−14,20,29]

A related arabinogalactan is tragacanth gum (*Astragalus gummifer*, E413) which is an exudate gum consisting of a mixture of

polysaccharides containing α-L-arabinofuranose and 1,4-linked β-D-galactopyranose, plus an acidic complex poly-1,4-linked α-D-galacturonate.[30] It is used as an acid-resistant thickener and emulsifier in sauces, salad dressings, and confectionery lozenges. Other related commercial gums are Western larch arabinogalactan[31] and mesquite gum, which is an arabinogalactan also with a β-1,3-galactopyran core and L-arabinose side chains.[32] Corn fiber gum is an alternative arabinogalactan replacement for gum arabic but requires an alkaline-peroxide pretreatment to enable its recovery.[33] The present Frost grape arabinogalactan polysaccharide is structurally analogous to gum arabic but gives a superior noncolored product that is readily extractable in large quantities. It differs from these prior mentioned gums, noticeably by rhamnosyl and AGP components, and is readily distinguished by minor unique xylosyl and mannosyl groups. With regard to the function and biosynthesis of the FGP, this is as yet unknown, although a possible role in cold tolerance or a resistance to insects (especially phylloxera aphids) remains a possibility. Because of the attributes the FGP has considerable potential as a replacement or extender for gum arabic in the food and beverage industries.

Table 4. Emulsifying Properties of Frost Grape Polysaccharide

polysaccharide	lipid[a]	emulsion stability (h)
1% native FGP	1% clove oil	++ (72)
0.1% native FGP	1% clove oil	++ (72)
1% native FGP	1% grapefruit oil	++ (72)
0.1% native FGP	1% grapefruit oil	++ (72)
native FGP	15% lemongrass oil	− (<1)
acetyl-modified FGP	15% lemongrass oil	+ (3)
20% gum arabic	15% lemongrass oil	+ (3)

[a]Controls without the emulsifier addition were immiscible.

isolated from commercial products, with the aim to discriminate their cultivar and origin. This approach allowed us not only to describe the chemical changes occurring in hazelnut after roasting but also (and this is the main object our work) to evaluate whether chemical composition permits hazelnut identification and which chemical parameters can be useful "markers" for hazelnut traceability.

MATERIALS AND METHODS

Chemicals. Methanol and acetonitrile (HPLC grade) and formic acid (50%, LC–MS grade) were purchased from Sigma–Aldrich (Milan, Italy). Water (HPLC grade) was obtained by Elga Purelab Ultra system (M-medical, Cornaredo, Milano, Italy). Polyphenol standard molecules (gallic acid, protocatechuic acid, *p*-hydroxybenzoic acid, caffeic acid, catechin, epicatechin, myricetin, quercetin, and kaempferol) were purchased also from Sigma–Aldrich (Milan, Italy). All the other chemicals and solvents were of reagent-grade level and purchased also from Sigma–Aldrich (Milan, Italy).

Samples. Three different lots of "Tonda Gentile Trilobata" hazelnuts (1TGT and 2TGT samples from Piedmont, Italy; 3TGT sample from Chile), one lot of "Tonda di Giffoni" (4TG sample, from Campania, Italy), and one lot of "Tombul" hazelnuts (5T sample, from Turkey) were kindly provided and certified by INOQ (Istituto Nord Ovest Qualità, Moretta, Cuneo, Italy). Hazelnuts were all from the same harvesting year (2007), except the 2TGT hazelnuts, which were harvested in the 2008 season. The hazelnut lots (2000 g) were divided in three subsamples (600 g). From each subsample, a portion (50 g) was analyzed as raw (shelled with perisperm). The other portions (each 200 g) were roasted in a ventilated conventional oven, following two different roasting conditions (160 °C for 25 min and 180 °C for 10 min). These two different roasting protocols were previously selected in order to obtain similar browning degree and optimal organoleptic properties (unpublished data). All the roasted hazelnuts were analyzed after removing perisperm.

Hazelnuts obtained from commercial processed food (whole roasted hazelnuts without perisperm) were also analyzed: hazelnuts in milk chocolate bars (6CL and 11RS samples), white chocolate bars (7CB sample), and gianduja chocolate bars (10CG sample), hazelnuts with a dark chocolate coating (8CF), and hazelnuts contained in pralines (9FR). 7CB and 10CG samples were labeled as Tonda Gentile Trilobata hazelnuts from Piedmont (Italy). Whole hazelnuts were separated by melting chocolate at 40 °C, and any chocolate residue was removed using filter paper. For each commercial product, at least 200 g of hazelnuts was obtained; afterward, the hazelnuts were pooled and subsampled in three portions (each 50 g) that were independently analyzed.

Proximate Composition Analysis. The proximate composition was determined as previously described.[15] Raw, roasted, and commercial hazelnuts were ground in a mortar (particle size <2 mm) and then subjected to the determination of moisture, proteins, ashes, and lipid content. Lipid fraction was extracted using a semiautomatic Soxhlet Büchi extraction system B-811 (Büchi Labortechnik AG, Flawil, Switzerland) for 6 h, employing dichloromethane as solvent. Fatty acid methyl esters (FAMEs) were obtained by transesterification of triacylglycerols and successively analyzed by GC-FID;[15] the semiquantification of individual compounds was done as relative percentage.

Extraction and Characterization of Phenolic Fraction. The extraction and characterization of phenolic fraction were performed as previously described.[15] Polyphenols were extracted from defatted hazelnut powders using methanol; each sample was extracted in triplicate and dry extracts were stored at −20 °C until use. The antioxidant activity of hazelnut extracts was evaluated using the DPPH$^{\bullet}$ scavenging assay and expressed as inhibition percentage (I %).[15] Polyphenol separations were obtained by RP-HPLC/DAD.[15] Phenolic acids and flavonoids were tentatively identified by comparison with retention times and UV spectra of individual standard molecules (gallic acid, protocatechuic acid, *p*-hydroxybenzoic acid, caffeic acid, catechin, epicatechin, myricetin, quercetin, and kaempferol); the quantification was performed on the basis of calibration curves obtained with the corresponding standards.

The total phenol content was determined using the Folin–Ciocalteu method,[16] modified as follows. One hundred microliters of Folin–Ciocalteu reagent and 350 μL of aqueous Na_2CO_3 (5% w/v) were added to 200 μL of sample (methanolic solution of phenolic extract at concentration 3 mg mL^{-1}), and then the solutions were diluted to a final volume of 2900 μL with distilled water. After 1 h, the absorbance was read at 760 nm, using a Kontron UVIKON 930 spectrophotometer (Kontron Instruments, Milan, Italy). Results were expressed as gallic acid equivalents.

Determination of Protein Fingerprint (SDS-PAGE). Proteins were extracted from hazelnut powders obtained after removing the polyphenols, using the Laemmli sample buffer, prepared by adding 2 mg of bromophenol blue to 4.2 mL of 0.5 M TRIS-HCl (pH 6.8), 0.8 mL of 80% glycerol, and 1.6 mL of sodium dodecyl sulfate (SDS) 15% (w/v).[17] Each sample (0.5 mg) was suspended in 1.5 mL of sample buffer and then mixed in a Thermomixer apparatus (Thermomixer comfort, Eppendorf, Milan, Italy) at 37 °C and 750 rpm for 2 h. The solid residue was separated by centrifugation at 20800*g* for 20 min, and supernatant (i.e., protein extract) was directy loaded on the gel. Proteins were separated by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE; Mini-PROTEAN 3 Cell, Bio-Rad, Richmond, CA, USA) with 15% acrylamide resolving and 4% acrylamide stacking gel. Following electrophoresis, the gel was stained with 0.1% Coomassie blue R-250 (w/v) in 10% acetic acid (v/v) and 40% methanol (v/v) for 1 h and destained with 10% acetic acid (v/v) and 40% methanol (v/v) overnight.

Fluor-S Multimager and Quantity One software (Bio-Rad) were used for gel analysis. Gel bands were expressed as relative percentage for each sample and used as parameters for statistical analysis.

Statistical Analysis. Results were expressed as mean ± standard deviation (SD) of at least three independent experiments. All statistical analyses were performed using the free statistical software R 2.8.1 version (http://www.R-project.org).[18] Differences were estimated by analysis of variance (ANOVA) and Tukey HSD test (Laercio package). Pearson's correlation analysis was used to determine correlation coefficients and their statistical significance. The statistical significance level was set to 0.05. Multivariate statistical analysis was performed using principal component analysis (PCA) and hierarchical clustering on principal components (HCPC), both implemented on FactoMineR package for R. For details concerning the statisical analysis results, readers are referred to the Supporting Information (Tables 1S−10S; Figures 1S−7S).

RESULTS AND DISCUSSION

Proximate Composition of Hazelnut Samples. The proximate composition of hazelnut samples is reported in Table 1. The values are in agreement with the data previously reported in literature.[8,19]

As expected, moisture values significantly decrease after the roasting process (no significant differences were observed between the two different roasting conditions); thus the other parameters were expressed on a dry weight (dw) basis.

Concerning lipid content, roasting slightly increased the oil extractability, although this increment was not statistically significant. In a general way, the commercial hazelnuts showed significantly higher values (mean value 65.8%) than the other hazelnut samples (mean values of 62.9% and 64.2% for raw and roasted hazelnuts, respectively. Presumably, the impact of the industrial process was stronger than that of experimental laboratory roasting (for example, higher damage of membranes or higher protein denaturation, as suggested by Amaral and coauthors).[8] No differences were observed depending on the hazelnut origin.

In contrast, the protein content was significant for hazelnut discrimination. Tombul (5T) and Tonda di Giffoni (4TG) samples showed significantly higher values than Tonda Gentile Trilobata hazelnuts. In a previous work, we additionally observed that Italian TGT hazelnuts have a higher protein content than that of the same cultivar cultivated in Chile.[15] Also in the present work, the Chilean TGT hazelnuts showed minimal but statistically significant differences from the Italian TGT ones, which showed higher protein content in both raw and roasted samples. Furthermore, the protein content was significantly lower in raw hazelnuts than in the corresponding roasted ones. This difference could be related to detachment and successive removal of perisperm after roasting, because the protein content of hazelnut skin (perisperm) is lower than that of hazelnut kernel.[20,21]

The ash content, which is the expression of the total mineral content, was in the range 1.30−2.75%. Also in this case, for the major part of the samples, the roasting process caused a significant increase of the values. In a general way, the ash content was not so useful for geographic origin identification, excepting for Tonda di Giffoni hazelnuts, which presented significantly higher values than those of TGT hazelnuts. In a previous work, it was demonstrated that the analysis of individual trace metals, especially lanthanides, is able to identify hazelnuts coming from different areas of cultivation, having individuated a link among hazelnuts and soil through lanthanide distribution.[12]

Considering roasted hazelnuts from commercial products, a quite homogeneous composition was observed for lipids and ashes (the only exception was 11RS sample, which presented lower ash content with respect to the other samples). The protein content was more variable, ranging from 12% (7CB sample) to 17% (11RS).

Characterization of Fatty Acid Fraction (FAMEs). The hazelnut oil was characterized by GC-analysis of fatty acid methyl esters (FAMEs). The major fatty acids were identified and quantified in terms of relative percentage: palmitic acid (C16:0), stearic acid (C18:0), oleic acid ($C18:1_{\Delta 9}$) and its isomer vaccenic acid ($C18:1_{\Delta 11}$), and linoleic acid (C18:2) (Table 1).

The relative content of fatty acids in hazelnut oil is in agreement with literature data;[22,23] oleic acid was the predominant fatty acid, ranging from 76.7% to 84.9%. The roasting process did not influenced the relative composition of FAMEs (generally no significant differences were observed between raw and roasted hazelnuts); however, a significantly higher palmitic and, particularly, stearic acid content in commercial samples than in all the other hazelnuts (raw and roasted in laboratory) was observed. In this regard, it is interesting to note that stearic acid is the major fatty acid of cocoa butter (35.8%), followed by oleic (33.6%), palmitic (26.2%), and linoleic (2.68%) acids.[24] Considering that all the commercial hazelnuts were obtained from chocolate-based products, it is presumable that a phenomenon of fat migration, typical of composite confectionery products and thoroughly studied in different model systems, occurred. Fat migration is driven by the concentration gradient between the differing triacylglycerol compositions of the adjacent fat phases and depends on temperature of storage, formulation, and structure of the layers.[25] Thus, the different triacylglycerol compositions of hazelnut and cocoa could be responsible of the higher content of stearic and palmitic acids in the commercial products. Another reason for stearic acid increasing could be the partial degradation of unsaturated fatty acids during technological processing, but no information is known about the treatment of hazelnuts isolated from the commercial products, thus it is difficult to argue this hypothesis.

Fatty acid composition also varied depending on hazelnut cultivar and their geographic origin. Considering roasted hazelnuts, palmitic and vaccenic acids were higher in TGT hazelnuts, while linoleic acid was prevalent in Turkish and TG samples. TGT hazelnuts from Italy and from Chile differ for the relative percentage of oleic acid (higher in Italian TGT) and palmitic acid and vaccenic acid (higher in Chilean TGT). The same results were obtained from analysis of raw and roasted

hazelnuts together, thus confirming that fatty acid composition is related to the hazelnut cultivar and origin.

Determination of Total Phenol Content, Antioxidant Activity and Polyphenolic Profile. The hazelnut phenolic fraction, obtained after removing lipid and using methanol as solvent, was preliminarily characterized for the total phenol content and the antiradical activity (DPPH• method); then some phenolic acids and flavonoids (free phenolic fraction extractable in methanol) were individually identified and quantified.

The total phenol content of raw hazelnuts was in the range 10.21−23.28 mg of gallic acid equivalents (GAE) per gram of hazelnut (dry weight) and was in the order 2TGT > 5T > 3TGT > 1TGT > 4TG (Table 2). After roasting, a strong decrease was observed (from 60% in 4TG-160 to 85% for 2TGT-180). These results are consistent with those reported by Pelvan and coauthors,[9] which observed a loss of total phenols after roasting (140 °C for 30 min) from 42% to 88%, but differ in the absolute values, being about 3.5-fold higher. This difference could be ascribed to the different extraction protocol (80% acetone as solvent) but also to the different cultivars analyzed, their geographical origin, and the harvest season.

The loss of polyphenols after roasting is prevalently due to removal of hazelnut skin (perisperm), which is an important source of phenolic compounds containing about 40-fold higher polyphenols than kernels.[20,26] Furthermore, the high temperatures applied during the process could cause the degradation of thermally sensitive compounds, thus negatively influencing the total phenol content.

The hazelnuts isolated from the commercial products showed values in the range or lower than that obtained for the hazelnuts experimentally roasted in laboratory (from 1.59 to 3.57 mg GAE g^{-1} for 11RS and 9FR samples, respectively). In a general way, commercial samples did not evidence significant differences with respect to the experimentally roasted hazelnuts.

In the same manner, the antioxidant activity drastically decreased as a consequence of roasting. Polyphenolic extracts were evaluated at 200 μg mL^{-1} concentration, and results were expressed as DPPH• inhibition percentage (I%) (Table 2). The major antioxidant activity was observed for 5T hazelnuts (93.6%), followed by 3TGT, 1TGT, 2TGT, and 4TG hazelnuts (90.4%, 90.1%, 86.0%, and 84.9%, respectively). After roasting, the antioxidant activity diminished in different proportions, from about 79% for 1TGT to about 53% for 2TGT hazelnuts; in general, no significant differences were evidenced between the two roasting protocols employed. The amount of loss of antioxidant activity seems to be not dependent on hazelnut variety and only partially related to the loss of polyphenolic compounds, for which a higher decrease was observed (even though the correlation between these two parameters was significant; $r = 0.8932$, $p = 5.07 \times 10^{-8}$). In fact, the overall effect of roasting depends on the balance between the loss of natural hazelnut polyphenols, through both their thermal degradation and the removal of skin from roasted kernels, and the formation of new antioxidant molecules derived from the Maillard reaction (melanoidins). A previous work demonstrated that the antioxidant activity of roasted hazelnuts tends to increase from 10 to 60 min of roasting (at the constant temperature of 150 °C).[11] In the experimental conditions adopted in the present work (180 °C for 10 min and 160 °C for 25 min), no significant differences were observed; presumably the effect of prolonged roasting time was counterbalanced by the reduction of the temperature.

Different from that observed for the total polyphenol content, the antioxidant activity of commercial hazelnuts was significantly lower than that of experimentally roasted ones. Among them, only the 9FR sample (praline) showed an antioxidant activity similar to that of experimentally roasted

hazelnuts (25.4%), presumably because of its higher total phenol content (3.57 mg GAE g^{-1}).

Individual phenolic compounds were tentatively identified and quantified by RP-HPLC/DAD; results, expressed as micrograms per gram of hazelnut (dry weight), are reported in Table 2 (free phenolic acids) and Table 3 (flavonoids).

Considering raw hazelnuts, the major compound was catechin (mean value 7.08 μg g^{-1}), followed by quercetin (6.93 μg g^{-1}), and miricetin (6.78 μg g^{-1}); among phenolic acids, protocatechuic acid (5.66 μg g^{-1}) was prevalent. The highest catechin content was observed in 4TG hazelnuts, while the other compounds were generally present in higher concentration in the other cultivars.

The effect of the roasting process was different depending on both individual compounds and hazelnut cultivar. In a general way, all the phenolic compounds diminished or remained unvaried during roasting, except gallic acid and catechin, which increased. Previously, Schmitzer and coauthors observed a significant positive effect of roasting on gallic acid concentration (up to 9-fold higher in roasted than in raw hazelnuts), suggesting that this could be due to degradation of polymerized polyphenols (hydrolyzable tannins), and hydrolysis of other glycosylated flavonoids.[10] In contrast, Pelvan and coauthors reported a significant decrease of gallic acid in roasted hazelnuts, calculating an average loss of 52.7% and of 75.5% for its free and bound form, respectively.[9] Concerning catechin, this is the first time that an increase after roasting has been observed in hazelnut kernels. Schmitzer and coauthors registered a general decrease of flavan-3-ols, suggesting their thermal degradation. Nevertheless, our results are in agreement with observations in other food matrices, cocoa as an example, in which catechin content increases probably because of epicatechin epimerization.[27] In this regard, a negative significant correlation between catechin and epicatechin content in roasted hazelnuts was observed ($r = -0.5079$; $p = 0.0446$).

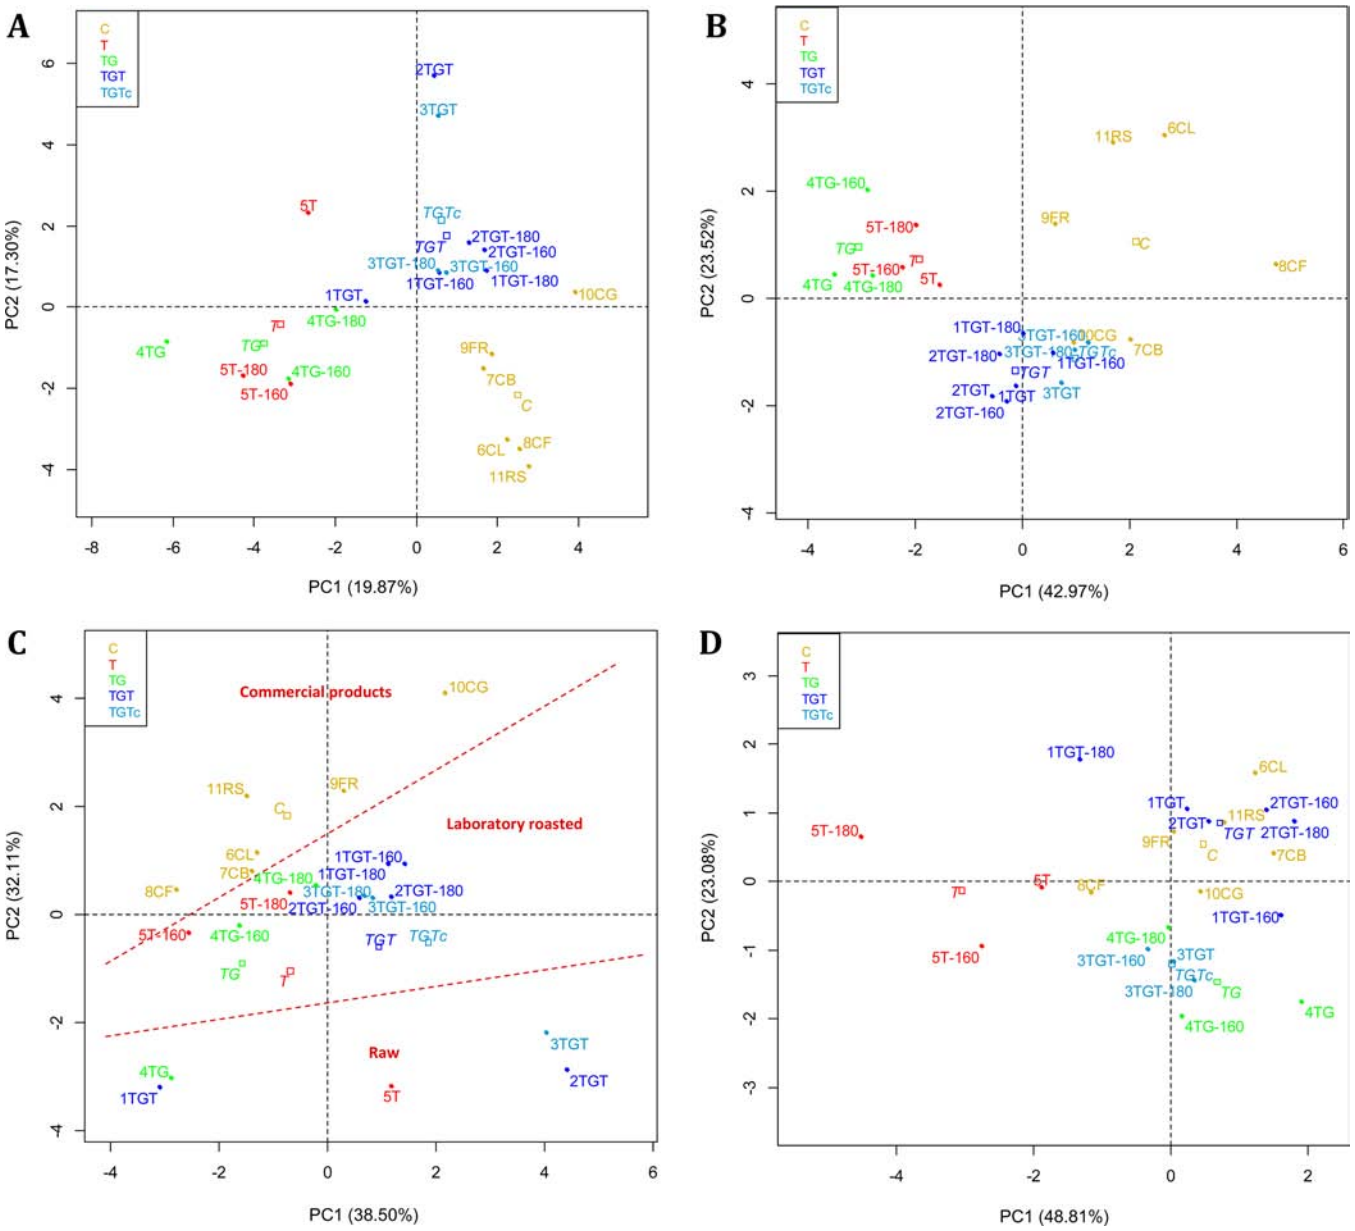

Figure 2. Two-dimensional representation of PCA (raw and roasted hazelnuts) based on complete data set (panel A), proximate composition and fatty acid profile (panel B), phenolic composition and antioxidant activity (panel C), and relative percentage of SDS-PAGE bands at molecular weight 75, 60, 43, 39, and 10 kDa (panel D). C, hazelnuts from commercial products; T, Turkish hazelnuts; TG, Tonda di Giffoni hazelnuts; TGT, Tonda Gentile Trilobata hazelnuts from Piedmont (Italy); TGTc, Tonda Gentile Trilobata hazelnuts from Chile.

Individual polyphenol content of commercial hazelnuts was in the range of experimentally roasted hazelnuts; the only exception was epicatechin, for which significantly lower values were generally observed in industrially roasted products.

Protein Fingerprint. Protein fingerprint was evaluated in nondenaturing conditions by SDS-PAGE; as an example, in Figure 1 is depicted the electrophoretic gel representing the proteins extracted from 5T hazelnuts (both raw and roasted) and commercial samples.

The protein migration profiles obtained for different hazelnut samples are comparable and similar to others previously reported in the literature.[15,28,29] Based on molecular weights and literature data (http://www.uniprot.org), some bands can be referred to well-known hazelnut allergens. Particularly, the 60 kDa band is attributable to 11S globulin (UniProt Q8W1C2), the 50 kDa band to 7S vicilin (UniProt Q8S4P9), and the 18 kDa band to Bet v 1 omologue (UniProt Q9SWR4), the 15 kDa band can contain profilin (UniProt Q9AXH5) and oleosin (UniProt Q84T21), and the 13.5 kDa band is ascribable to a protein group including lipid transfer protein (LTP, UniProt Q9ATH2).

In order to obtain quantitative data for statistical analyses, the relative percentages of individual bands were calculated; 13 common bands were determined. The major bands identified were those at 13.5, 15, and 60 kDa, with mean relative percentages of 23.4%, 18.0%, and 10.5%, respectively. In a general way, no significant variations were observed between raw and roasted samples, while significant differences were determined depending on hazelnut cultivar and origin. Turkish hazelnuts presented the highest values of the 60 kDa band (mean relative percentage 18.0%), followed in the order by Chilean TGT (10.3%), TG (10.09), TGT (10.0%) and

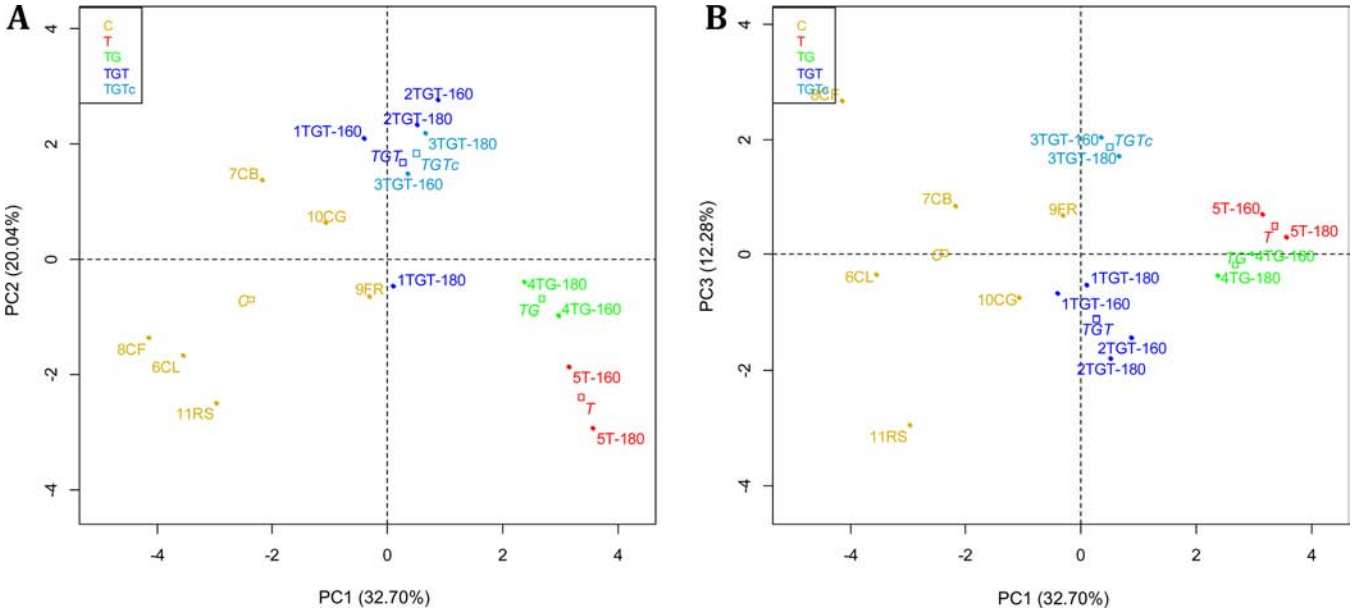

Figure 3. Two-dimensional representation of PCA (roasted hazelnuts) based on proximate composition, fatty acids, total polyphenol content, antioxidant activity, and SDS-PAGE bands at molecular weight 75, 60, 43, 39, and 10 kDa (panel A, PC1 vs PC2; panel B, PC1 vs PC3). C, hazelnuts from commercial products; T, Turkish hazelnuts; TG, Tonda di Giffoni hazelnuts; TGT, Tonda Gentile Trilobata hazelnuts from Piedmont (Italy); TGTc, Tonda Gentile Trilobata hazelnuts from Chile.

commercial (8.0%) hazelnuts. This result is in accord with our previous work on unroasted hazelnuts, in which the band at 58 kDa (presumably including 11S globulin) showed the highest values in Turkish (mean relative percentage 30%) and Chilean TGT (26%) hazelnuts.[15] In contrast, 39 kDa band showed the lowest values in Turkish hazelnuts. This band was putatively associated with 11S globulin acidic subunit, primarily because of the molecular weight but also for the strong negative correlation with the 60 kDa band ($r = -0.7545$, $p = 7.75 \times 10^{-5}$). Other unspecified bands at molecular weight 75, 43, and 10 kDa elicited significant differences among hazelnuts of different origin, while the other bands ascribable to major allergens were not significant for the origin discrimination.

Chemometric Evaluation of the Data. The chemometric characterization of hazelnuts was performed using a complex data set, in which all the chemical data were collected (33 variables). The principal component analysis led to nine principal components (PCs) explaining about 90% of total variance (cumulative variance for PC1−PC9 88.99%). The representation of the first two principal components (percentage of variance 19.87% and 17.30%, respectively) did not permit a clear discrimination of hazelnuts based on their different origin and cultivar. Even if three subgroups related to TGT (Italian and Chilean), Turkish and TG, and commercial hazelnuts can be tentatively identified, it is evident that raw hazelnuts are generally separated from their corresponding roasted samples (Figure 2A). The visualization of the third principal component (12.34% of the total variance) was not useful to improve the hazelnut separation. Among commercial hazelnuts, the 10CG sample presents high similarity with the TGT cluster (Figure 2A); this result is in accord with the fact that it contains Piedmontese TGT hazelnuts, as declared on the product label.

Afterward, chemical variables were grouped in four reduced data sets: proximate composition (moisture, proteins, ashes, lipids), fatty acids (C16:0, C18:0, C18:$1_{\Delta 9}$, C18:$1_{\Delta 11}$, and C18:2), phenolic fraction (total polyphenol content, antiradical activity, individual phenolic compounds identified by HPLC), and protein fingerprint (13 common bands identified by SDS-PAGE). Analyzing the individual reduced data sets by PCA, we observed that general composition and fatty acids included useful variables to identify hazelnut origin; thus they were successively combined and processed together. The individual plot of the first two principal components (42.97% and 23.52% of the total variance for PC1 and PC2, respectively) permitted separation of TG and T from TGT hazelnuts, while 10CG and 7CB samples, declared to contain TGT hazelnuts from Piedmont, clustered with TGT (Figure 2B). Considering also PC3 (percentage of variance 16.30%), TG were separated from Turkish hazelnuts and Chilean TGT from Italian ones; the chemical parameters significantly contributing to discriminate samples on PC3 were ashes and relative percentage of C18:$1_{\Delta 9}$ (correlation coefficient 0.8251 and −0.4498, respectively).

The PCA performed on the variables related to phenolic fraction led to a slightly different result. In fact, the graphical representation of the samples on PC1 and PC2 (total variance 70.61%) shows a less clear clustering based on hazelnut cultivar, but it is possible to note three areas in which raw, laboratory roasted, and commercial hazelnuts are prevalently located. In fact, as previously described, roasting process had a strong impact on phenolic compounds and antioxidant activity and, consequently, the hazelnut clustering was significantly influenced (Figure 2C).

Protein fingerprint did not permit the identification of different cultivar or origin, except in the case of Turkish hazelnuts, which presented lower values of PC2. The most important variables for Turkish hazelnut discrimination were the bands at molecular weight 39, 75, 43, and 28.5 kDa (which were significantly correlated to PC2 by a positive correlation) and the bands at 15 and 60 kDa (significant negative correlation).

In our previous work on raw hazelnuts, we observed that protein fingerprint is useful to differentiate the hazelnut origin.[15] This different result seems to be related to the

DOI: 10.1021/acs.jafc.5b03201
J. Agric. Food Chem. 2015, 63, 7294−7303

roasting process. In fact, even if the overall protein profile of raw and roasted hazelnuts was almost the same, the bands of roasted hazelnuts were generally less resolved and this could have negatively influenced the possibility to discriminate different hazelnuts. Moreover, in order to improve the protein extraction yield, in this work we employed a different extraction solvent (sample buffer instead of NaCl solution), and this change of the analytical protocol could be partially responsible for having obtained different results. However, considering only the bands for which hazelnut samples resulted significant differences (i.e., bands at molecular weight 75, 60, 43, 39, and 10 kDa), the first two principal components permitted separation of Chilean and Piedmontese TGT hazelnuts and Turkish from TG (Figure 2D).

Finally, we decided to omit raw hazelnuts from PCA computations, in order to focus attention on roasted samples and avoid misinterpretation of the results due to the impact of roasting on sensitive parameters. In a general way, hazelnuts can be better separated on the basis of their origin; for example, considering the total data set, Chilean TGT hazelnuts are separated from the Italian TGT. In the case of general composition and fatty acids data set, the exclusion of raw hazelnuts had an uninfluential effect on the capacity to discriminate different samples, because these parameters, expressed on a dry weight basis, are not influenced by roasting. The combination of chemical parameters that permitted us to obtain the best discrimination based on hazelnut cultivar and origin was as follows: general composition, fatty acids, total polyphenol content, antioxidant activity, and SDS-PAGE bands at molecular weight 75, 60, 43, 39, and 10 kDa (overall 16 variables). The two-dimensional representation of PCA (PC1 vs PC2, cumulative variance explained 52.74%) shows the discrimination of TGT hazelnuts from those belonging to the other cultivars; on PC2 also TG are separated from Turkish hazelnuts (Figure 3A). Considering the third principal component (12.27% of the total variance), TGT samples cultivated in Chile are clearly distinguished from Italian ones, gathering in a cluster at higher values of PC3 (Figure 3B). The chemical variable mainly responsible for this clustering is the ash content, being the unique one significantly correlated to the third principal component (r = 0.5464, p = 0.0285).

The results of PCA were further processed by an unsupervised clustering method, that is, HCPC (hierarchical clustering on principal components). HCPC is an unsupervised method, which combines principal component analysis, hierarchical clustering, and partitional clustering (specifically k-means). In HCPC, PCA is a preprocessing step that reduces the number of dimensions in parameter space. In a second step, hierarchical clustering is performed on the PCA axes using Ward's criterion. The number of clusters is chosen on the basis of the increase of inertia. Finally, the clusters obtained from the hierarchical tree cut are used to initialize the k-means algorithm, which consolidates the initial clustering. For this analysis, the minimum number of clusters was set to three, and sample partition was performed by cutting the dendrogram at the higher relative loss of inertia. As reported in Figure 4, the hazelnuts were automatically grouped in three different clusters (the clusters are identified by rectangles). The first cluster includes both TG and Turkish hazelnuts, highlighting major similarities within the same cultivar; the second cluster contains all the TGT hazelnuts and three commercial products (9FR, 7CB, and 10CG samples); in the third cluster are included the remaining commercial hazelnuts, more specifically 11RS, 8CF, and 6CL samples. Concerning the TGT cluster, two subgroups can be further identified, in which hazelnuts are separated depending on their geographic origin (Chile or Italy). Moreover, it is interesting to note that hazelnuts isolated from 7CB and 10CG commercial products, declaring to contain TGT hazelnuts from Piedmont, were correctly inserted in the TGT cluster, showing high similarity with Italian hazelnuts. Also 9FR sample was associated with TGT hazelnuts but highlighting higher homology with Chilean samples.

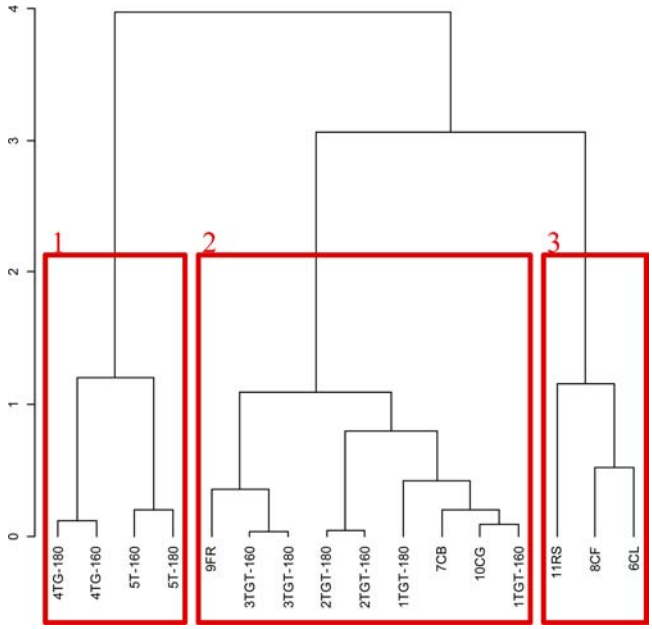

Figure 4. Hierarchical classification of roasted hazelnuts by HCPC analysis.

In conclusion, the chemometric evaluation of chemical parameters selected within proximate composition, fatty acids profile, polyphenols, antioxidant activity, and protein fingerprint, permitted us to recognize hazelnuts belonging to different cultivars and, considering TGT samples, also their different geographic origin (Chile and Italy). Among the parameters considered, phenolic compounds and antioxidant activity were the most influenced by the hazelnut roasting.

The identification of hazelnuts based on their chemical profile is important because it can permit their traceability and, consequently, ensure the quality of their derived products. This is fundamental to certify the quality of high value hazelnuts and, particularly, after the roasting process, which drastically modifies the organoleptic and chemical characteristics of raw hazelnuts, compromising their identification. In this contest, the present study, prevalently based on the identification of Tonda Gentile Trilobata hazelnuts, can be considered as preliminary for the traceability of roasted hazelnuts analyzing their chemical composition. In the future, other research will be necessary to confirm our results, more particularly considering hazelnuts from other geographic origin and cultivars and different harvesting years.

hazelnut samples each other (Table 1S), comparing raw, lab-roasted, and commercial hazelnuts (Table 2S), and comparing laboratory-roasted hazelnuts from different origin and cultivar (Table 3S). Statistical significance for the total polyphenols, the antioxidant activity, the phenolic acid content (Table 4S), and the flavonoid content (Table 5S) obtained comparing hazelnut samples each other; for total polyphenols, antioxidant activity, phenolic acid content (Table 6S), and flavonoid content (Table 7S) obtained comparing raw, lab-roasted, and commercial hazelnuts; for total polyphenols, antioxidant activity, phenolic acid content (Table 8S) and the flavonoid content (Table 9S) obtained comparing laboratory-roasted hazelnuts from different origin and cultivar. Screeplot of the PCA performed on the complete data set (Figure 1S). Loading plots of the PCA performed on both raw and roasted hazelnuts using the complete data set (Figure 2S), the proximate composition and fatty acid profile (Figure 3S), the phenolic composition and the antioxidant activity (Figure 4S), and the relative percentage of SDS-PAGE bands at molecular weight 75, 60, 43, 39, and 10 kDa (Figure 5S). Loading plots of the PCA performed on the proximate composition, fatty acids, total polyphenol content, antioxidant activity and SDS-PAGE bands at molecular weight 75, 60, 43, 39, and 10 kDa of roasted hazelnuts (PC1 vs PC2, Figure 6S; PC1 vs PC3, Figure 7S). Contribution of the variables defining PCs obtained from the analysis of proximate composition, fatty acids, total polyphenol content, antioxidant activity and SDS-PAGE bands (molecular weight 75, 60, 43, 39, and 10 kDa) of roasted hazelnuts (Table 10S) (PDF)

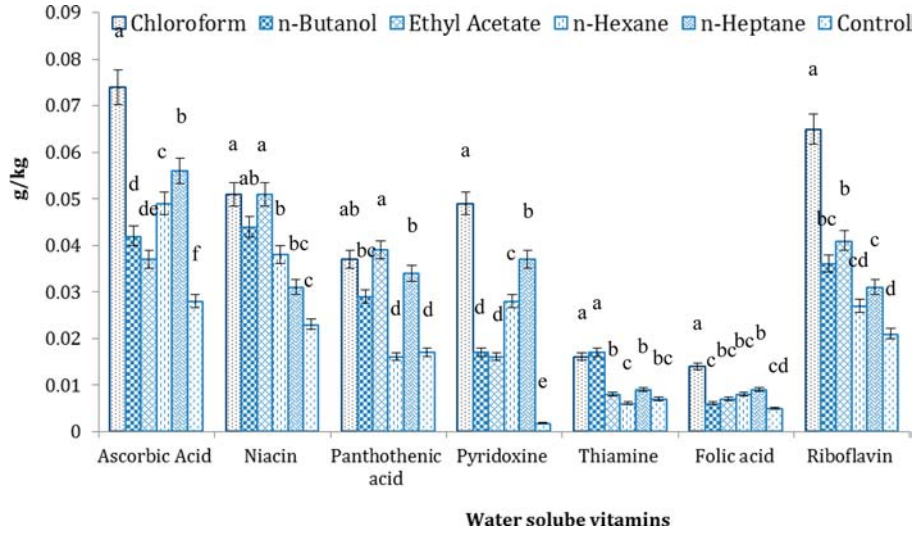

Figure 1. Quantities of vitamin contents in barley treated with organic fractions of *Acetobacter aceti* extracts. Control treatment refers to no application of bacterial extracts. Error bars show the standard error among each treatment, while different alphabetic letters show significant difference between treatments, calculated through Duncan's multiple range test (DMRT) at $p \leq 0.05$. Statistical analysis was performed through DSAASTAT (Onofri, Italy).

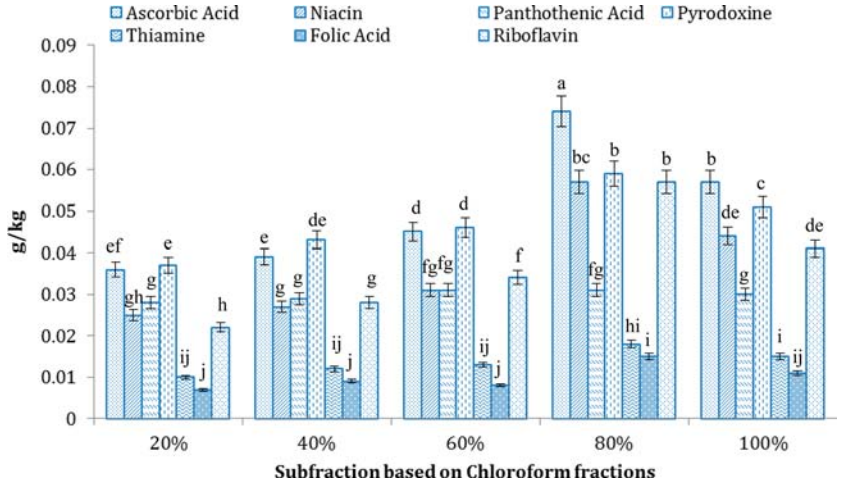

Figure 2. Quantities of water-soluble vitamins in barley obtained from treated plants. Plants had been treated with subfractions of chloroform extracts, prepared in, i.e., 20, 40, 60... 100% concentrations of chloroform in ethyl acetate (plotted on *X*-axis). The quantities of vitamins in g/kg have been presented on the *Y*-axis. Error bars have been plotted to represent the standard error among each data set, whereas changing lowercase letters represent significant difference in data. Data were statistically analyzed through Duncan's multiple range test the (DMRT) at $p \leq 0.05$ and using the MS-Excel add-in statistical package DSAASTAT (Onofri, Italy).

SF01, SF02, SF03, SF04, and SF05. The biochemical profile of each subfraction was estimated through thin layer chromatography, while bioactivity was studied by applying subfractions on barley plants.

Organic subfraction induced maximum quantities in barley were analyzed through chromatographic techniques to identify the specific compound(s) responsible for vitamin induction in the greenhouse assay. Barley plants were grown under 24 ± 2 °C in a greenhouse, and watering was carried out when needed. Vitamin contents of barley were quantified, and the best organic fraction was screened out. The organic fraction was further fractionated into 5 subfractions (i.e., FR01, FR02, FR03, FR04, and FR05) through column chromatography (CC). For this purpose, the concentrate of the previous fraction was mixed with a small quantity of silica gel of Uni-Chem (mesh 60−100) to make its slurry. A two third portion of the column (200 g) was filled with silica gel, and then a thin layer of prepared slurry was uniformly spread over the surface of the silica column. Moreover, the slurry was again overlaid by a uniform thin layer of silica gel. A stepwise elution of samples was performed with a solvent system of ethanol/chloroform, having a constant increment of 20% in concentration of chloroform. All prepared subfractions were studied for vitamin elevation potential, through the bioactivity guided assay. Therefore, all these subfractions were applied to barley plants, and plants were allowed to grow up to seed harvesting stage. These seeds were crushed and tested for water-soluble vitamin quantities (i.e., ascorbic acid, niacin, panthothenic acid, pyridoxine thiamine, folic acid, and riboflavin). These quantities were quantified by measuring peak height and peak area of gas chromatograms of vitamins along with some other contaminants. Moreover, preparative thin layer chromatography (PTLC) was performed to remove the maximum possible contaminants from the fractions. PTLC was performed through glass plates (20 × 20 cm^2) coated with silica. Bioactive compounds were isolated with the minimum possible number of contaminants before performing gas chromatography−mass spectrometery (GCMS).

Gas Chromatography−Mass Spectrometery. GCMS was performed on a gas chromatography unit of Agilent Technologies (7890A), accompanied by a mass spectrometer unit of (5975C) and column HP-5MS. Operation was started from 70 °C temperature with continuous increments of 5 °C/min up to 200 °C temperature.

DOI: 10.1021/acs.jafc.5b01817
J. Agric. Food Chem. 2015, 63, 7304−7310

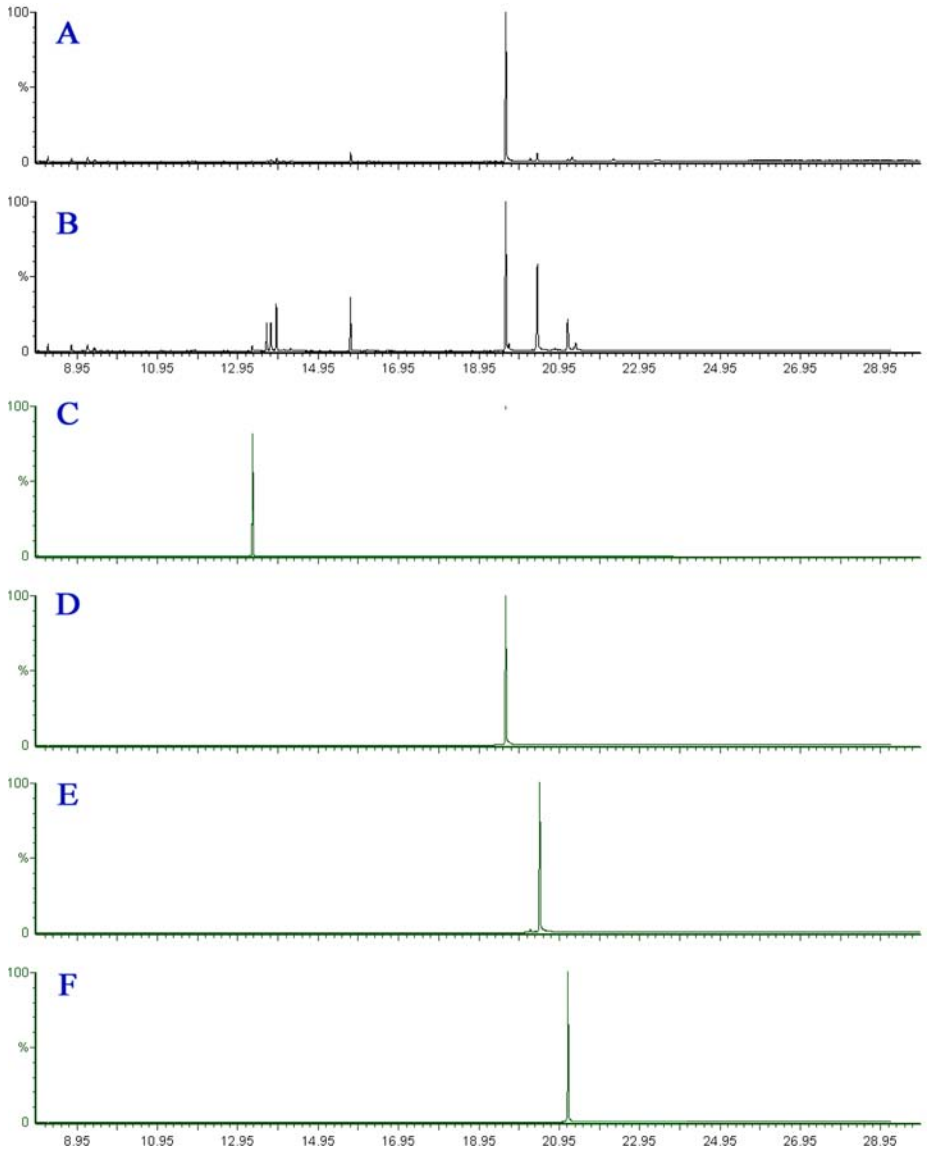

Figure 3. GCMS profiles of the two most active chloroform fractions, i.e., 80% (A) and 100% (B). Standard run of most active compounds were performed providing identical GCMS conditions on the same GCMS apparatus. Quinolinic acid (C), pyridoxic acid (D), *p*-aminobenzoate (E), and *α*-oxobutanoic acid (F). *X*-Axis has been marked with the time elapsed for chemical elution, and the *Y*-axis represents the height of peaks dependent upon chemical quantities.

Operation was further continued up to 240 °C at a continuous increment of 10 °C/min. The flow rate of carrier gas (helium) was maintained 1 mL/min during the entire operation. Mass spectra of compounds were identified using TURBOMASS (Perkinelmer, Shelton, USA) equipped with a mass spectral NIST library.

Data Analysis. Statistical analysis of data was carried out through analysis of variance (ANOVA) and Duncan's multiple range test (DMRT) at $p \leq 0.05$. Statistical operations were performed using the statistical package of MS-Excel based add-in DSAASTAT (Onofri, Italy). Principal component analysis (PCA) was performed to determine the most active bacterial metabolite, and the screened chemical was applied to barley plants to verify the results of the study.

Activity Verification of Identified Compound. Purified chemicals were purchased from Sigma-Aldrich (Lahore) and applied separately to sets of barley plants of 2 weeks of age, treating the control with distilled sterilized water. Seeds of the plants were tested for vitamin contents, and data were compared with the standard GCMS run of purified compounds to test the efficacy of treatment. The whole experiment was independently repeated thrice to ensure the authenticity of the results.

RESULTS

Chloroform fraction provided the maximum levels of most of the tested vitamins. Significantly higher quantities of ascorbic acid, pyridoxine, folic acid and riboflavin were recorded in barley. Niacin and pantothenic acid were recorded in equal quantities in both treatments of chloroform and ethyl acetate, whereas *n*-butanol exhibited nonsignificantly more amounts of thiamine contents than chloroform treatment. *n*-Hexane was recorded with nonsignificantly lower quantities of panthothenic acid and thiamine contents than the respective values of control treatment (Figure 1).

Eighty percent chloroform treatment induced the highest quantities of vitamins in barley. It was most efficient for inducing ascorbic acid content in barley seeds. Moreover, the quantity of riboflavin was also elevated by 80% chloroform in the most efficient way. Pyrodixine was recorded to be significantly elevated after getting 80% chloroform treatment. Similarly, the quantity of niacin was found to be significantly

Table 1. Chemical Compounds in Chloroform Fractions (with Concentrations of 80% and 100%) Were Identified through GCMS Analysis[a]

serial no.	chemical	retention time (min)	total peak area (E)
1	thymol	8.03	4.7
2	eugenol	8.88	4.9
3	globulol	9.17	5.1
4	mevalonic lactone	9.29	4.3
5	quinolinic acid	12.33	4.7
6	*E*-8-octadecacen-1-ol acetate (ODCA)	13.68	5.6
7	pentadenoic acid	13.85	5.8
8	phthalic ester (methyl octyl ester)	14.08	5.9
9	octadecatrienoic acid (ODTA)	15.75	6.1
10	pyridoxic acid	19.67	7.4
11	*p*-aminobenzoate	20.41	6.5
12	α-oxobutanoic acid	21.18	5.3
13	glycine	21.28	4.2

[a]MZmine (Pluskal, Okinawa, Japan) was used to analyze chromatograms and mass spectra. Properties of each compound were recorded and mentioned against it. Retention time is the time taken by chemicals for their individual elution and has been calculated in minutes (min), whereas total peak area has been calculated through MZmine unit of relativity (E).

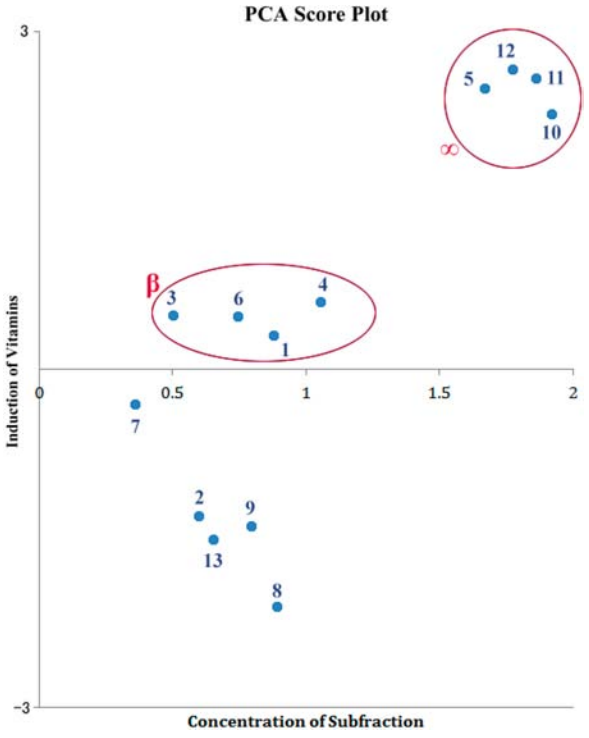

Figure 4. Principal component analysis (PCA) of all detected compounds through GCMS analysis of chloroform subfractions of *A. aceti* extracts. Thirteen chemical componds detected in GCMS analysis were 1, thymol; 2, eugenol; 3, globulol; 4, mevalonic lactone; 5, quinolinic acid; 6, *E*-8-octadecacen-1-ol acetate (ODCA); 7, pentadenoic acid; 8, phthalic ester; 9, octadecatrienoic acid (ODTA); 10, pyridoxic acid; 11, *p*-aminobenzoate; 12, α-oxobutanoic acid; and 13, glycine. Association of all compounds was calculated with the concentration of chloroform in extraction solvent and induction of vitamins. The statistical package DSAASTAT (Onofri, Italy) was used to perform PCA analysis.

higher in 80% chloroform than in all other treatments. The second most efficient treatment in terms of vitamins induction was 100% chloroform. It induced ascorbic acid at significantly higher concentrations than 20, 40, and 60% chloroform treatments. Induction in the quantity of pyrodoxine was also significantly higher in 100% chloroform treatment than 20, 40, and 60%. A similar trend was found in the case of riboflavin, which was detected in significantly higher amounts in 100 chloroform treatments than 20%, 40%, and 60% treatments. Thiamine was the only vitamin, which did not show any significant variation in its quantities among all treatments; however, the quantity folic acid was recorded to be significantly greater in the 80% treatment in comparison to the respective quantities in 20, 40, and 60% treatment (Figure 2). Two fractions (i.e., 80% and 100%) possessed the most efficient vitamin induction activities and were thus analyzed by GCMS to figure out active compounds.

Thirteen chemical compounds were detected in the most active (80%) chloroform fraction. These chemicals were identified as thymol, eugenol, globulol, mevalonic lactone, quinolinic acid, *E*-8-octadecacen-1-ol acetate (ODCA), pentadenoic acid, phthalic ester, octadecatrienoic acid (ODTA), pyridoxic acid, *p*-aminobenzoate, α-oxobutanoic acid, and glycine. The second most active (100%) chloroform fraction was missing in quinolinic acid and ODCA. However, the concentration of most of the compounds (i.e., quinolinic acid, ODCA, pentadenoic acid, phthalic ester, ODTA, *p*-aminobenzoate, and α-oxobutanoic acid) was lower in the 100% chloroform fraction than in the 80% fraction (Figure 3).

Chemical properties of all detected compounds were recorded in order to evaluate the principal compound. All 13 compounds had peaks sufficiently apart with good resolution. Thymol was the first compound detected at 8.03 min of the chromatographic run with a peak area of 4.7E. Eugenol was eluted at 8.88 min and recorded a peak area of 4.9E. Mass spectra of globulol (peak area: 5.1E) and mevalonic lactone (peak area: 4.3E) were recorded after chromatographic runs of 9.17 and 9.29 min, respectively. Quinolinic acid with a peak area of 4.7E was detected at 12.33 min. Pyridoxic acid (19.67 min) exhibited the highest peak area 7.4E. The second highest peak area (6.5E) was recorded in the case of *p*-aminobenzoate, which had the retention time of 20.41 min. α-Oxobutanoic acid and glycine (peak area: 5.3E and 4.2E, respectively) were the last eluting compounds with retention times of 21.18 and 21.28 min, respectively (Table 1).

Pyridoxic acid was a compound having maximum affinity with the concentration of chloroform in the extraction solvent. *p*-Aminobenzoate had a lower affinity with chloroform concentration than pyridoxic acid. However, it exhibited stronger association with vitamin induction than pyridoxic acid. Similarly, α-oxobutanoic acid had the third strongest association with chloroform concentration, but it recorded the strongest correlation with vitamins induction. Quinolinic acid recorded the third strongest relationship with vitamin induction, just after *p*-aminobenzoate; but it was fourth according to its interrelationship with chloroform concentration. All these four compounds (i.e., quinolinic acid, *p*-aminobenzoate, pyridoxic acid, and α-oxobutanoic acid) collectively construct a group (∞) and are closely placed over a PCA plot. Similarly, thymol, globulol, mevalonic lactone, and ODCA were members of a second group (β), and this group had more variable association with chloroform concentration than with vitamin induction. Mevalonic lactone

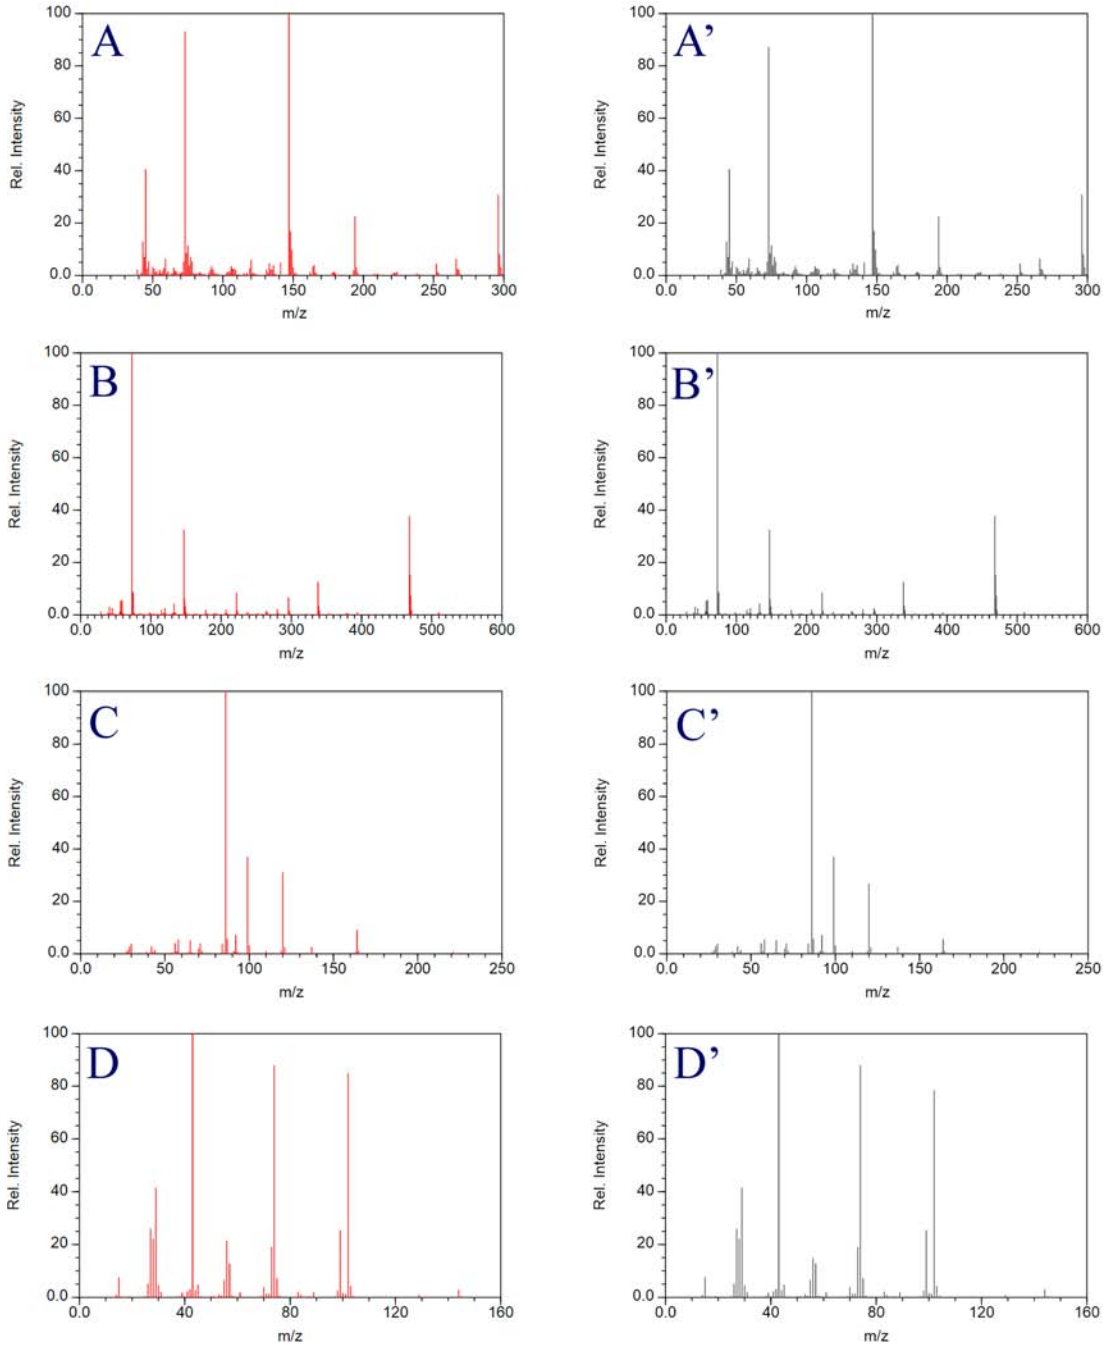

Figure 5. Standard mass spectra of active compounds taken from the NIST library, i.e., quinolinic acid (A), pyridoxic acid (B), *p*-aminobenzoate (C), α-oxobutanoic acid (D). Mass spectrum recorded during an experimental run of *A. aceti* fractions has been tagged with the English alphabet followed by symbol -'-. Compoounds were identified using TURBOMASS (Perkinelmer, Shelton, USA) equipped with the NIST library.

had the strongest association with chloroform concentration as well as vitamin induction among all the members of group β. Thymol was the least associated member of group β with vitamin induction. Eugenol, pentadenoic acid, phthalic ester, ODTA, and glycine were found in inverse relationship with vitamins induction; however, they were positively associated with concentration of chloroform in extraction solvent (Figure 4). All compounds which occupied distinct positions in the correlation matrix plot were purified up to >99% to test their effectiveness for the induction of vitamin contents.

Mass spectra of bioactive compounds were recorded through TURBOMASS (Perkinelmer, Shelton, USA) and their respective compounds in the NIST library compared. More than 800 similarity scores were calculated in the case of all identified compounds (Figure 5).

Activity Verification of Identified Compounds. Maximum quantities of vitamins were induced after the application of *p*-aminobenzoate. It recorded significantly higher quantities of six vitamins, i.e., ascorbic acid, niacin, pathothenic acid, pyridoxine, and thiamine and folic acid (Figure 6). However, the highest quantities of riboflavin were recorded in the case of quinolinic acid and *p*-aminobenzoate. Quinolinic acid was the second best inducer of vitamins in barley seeds. However, pyridoxic acid and α-oxobutanoic acid had a variable behavior

DOI: 10.1021/acs.jafc.5b01817
J. Agric. Food Chem. 2015, 63, 7304−7310

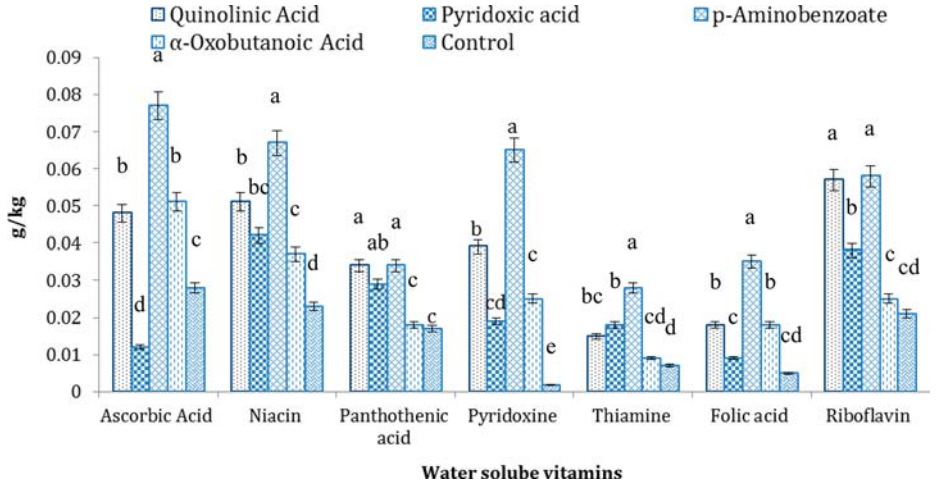

Figure 6. Vitamin contents in barley seeds treated with different biochemicals (i.e., quinolinic acid, pyridoxic acid, *p*-aminobenzoate, and *α*-oxobutanoic acid). Control treatment refers to no chemical application. Data were statistically analyzed through analysis of variance (ANOVA) using DSAASTAT (Onofri, Italy), and error bars show standard error of the data, and each change in lowercase letters represents the significant difference among treatments calculated through Duncan's multiple range test (DMRT) at $p \leq 0.05$.

with respect to each individual vitamin. They could not induce significant quantities of most of the vitamins with respect to the control treatment. However, pyridoxic acid inhibited the production of ascorbic acid in barley seeds (Figure 6).

DISCUSSION

The current investigation describes an array of microbial metabolites which affect plant biochemicals. This study has highlighted the metabolites which more specifically enhanced nutritional quality related biochemicals in barley seeds. Barley is a staple food crop which can be routinely consumed by humans and animals. Therefore, the current investigation is an advancement in the improvement of food quality of large populations. It recommends the microbial application for getting augmented agricultural yields in terms of nutritional contents.

The solubility of different compounds is extremely variable in a single organic solvent.[13] Similarly, different organic solvents dissolve highly variable amounts of a single compound.[14] Thus, the optimization of solvent is necessarily required to isolate a desired compound with minimum number of contaminants; and this optimization is imperative when an active compound is needed to be isolated from a mixture containing thousands of bacterial metabolites.[15] This study suggests a solvent system of 80% chloroform and 20% ethanol to isolate active compounds with a minimum number of impurities from bacterial metabolites. The individual purity index of these metabolites is >99.9%. However, their concentrations in subfractions were recorded as quinolinic acid (1.09%), pyridoxic acid (50.54%), *p*-aminobenzoate (36.26%), and *α*-oxobutanoic acid (12.11%).

Plants respond to external applications of chemicals, while metabolites of *A. aceti* contain a number of chemicals which had unknown effects on plants. Hence, the purification of active compounds becomes very important in order to reduce the number of undesired compounds. Furthermore, the composition solvent system affects the quantity and quality of compounds being extracted.[16,17] The current study approves the two step extraction of *A. aceti* metabolites: first, the extraction with 100% chloroform and subsequent extraction with an 80% chloroform solvent system in ethanol (chloroform/ethanol (4:1) solvent system). Thus, the resulting extracts have more amounts of active compounds and are more specific in action.

GCMS analysis of biologically active fractions identified the compounds present in them; however, PCA analysis determined the activity of each identified biochemical and arranged them in a hierarchal manner on the basis of their ability to induce vitamins. Four compounds were found to be strongly associated with the induction of vitamins; however, the interactions among these chemicals have not been studied. It might be possible that they have a cumulative effect on vitamin biosynthesis or that they have synergistic effects on vitamin metabolism.[18,19]

All the biochemicals identified in this research are either precursors of vitamin biosynthesis pathways (e.g., quinolinic acid and pyridoxic acid)[20,21]or they are facilitators of these pathways (e.g., *p*-aminobenzoate and *α*-oxobutanoic).[22,23] Thus, the increased production of vitamins in barley can be supported with the logic that "providing precursors of vitamins would facilitate plants in their production process."[24,25]

PCA analysis categorized the compounds on the basis of their affinity with induced vitamin quantities and concentration of chloroform in extraction solvent. This revealed mevalonic acid as the most active compound among group *β* of the identified compounds. Mevalonic acid was the compound with the highest concentration in extracted fraction, as compared to the other compounds of group *β*. Moreover, this compound plays a key role in the isoprenoid pathway for the biosynthesis of squalene,[26] which is responsible for the ultimate production of sterols.[27]

GCMS analysis also revealed the presence of glycine in tested fractions. Glycine takes part in the process of folate biosynthesis for the production of glutamic acid. It is a three step former biochemical reaction just equivalent to the production of 5,10-methenyltetrahydrofolate polyglutamate. Logically, glycine would be in positive relationship with vitamin induction; however, it was inversely related with vitamin quantities. These findings indicate some complexities in folate metabolism, which still need to be resolved. Pyridoxic acid treatment on plants results in the decreased sensitivity of plant photosystem II and protects plants against photooxidative stress.[28] However, the decreased sensitivity of the photosystem II reaction center

DOI: 10.1021/acs.jafc.5b01817
J. Agric. Food Chem. 2015, 63, 7304−7310

hampers light acclimation and reduced ascorbate content.[29] Moreover, the quenching of O_2 starts proteolytic degradation of ascorbate and lowers its contents in plant tissues.[30] All these studies support the decreased ascorbic acid contents recorded after treating barley plants with pyridoxic acid.

The study concludes that two biochemicals, i.e., *p*-aminobenzoate and quinolinic acid can induce vitamin contents in barley seeds. However, *p*-aminobezoate is recommended as the best vitamin inducer. All of these two biochemicals can be isolated from the metabolites of *A. aceti* using an organic solvent system (chloroform/ethanol 4:1). This study would be a step toward the cultivation of food crops with improved nutritional values.

[a]Ig, immunoglobulin. [b]Butler, 1974. [c]Butler, 1983.

0.5−2 g/L in human milk.[17,18] These Ig ratios reflect the different events occurring in utero: infants are born with circulating maternal IgG transferred via the placenta,[19,20] whereas calves are born agammaglobulinemic. For this reason, bovine colostrum has very high levels of IgG, derived mainly from serum during the last few weeks of pregnancy. Calves are singularly dependent on ingesting maternal IgG in colostrum to provide them with protection against environmental pathogens until their own immune system matures.[21] After this time, the major function of milk Igs in ruminants is a protective, developmental role in the intestinal lumen, as in humans.[22]

GLYCOSYLATION OF sIgA

The glycans (carbohydrates groups), attached to both the Fc and Fab regions of sIgA, play a key role in its protein structure and stability and ultimately its function.[23−25] In humans (and higher primates) IgA has two isoforms, IgA_1 and IgA_2, which are produced in approximately equal amounts in human milk.[26,27] Most other species, including ruminants, have only one isoform, which is similar to human IgA_2.[28,29] There are differences in the glycosylation of the two isoforms. The hinge region of IgA_1 is longer than that of IgA_2 and has O- and N-glycosylation sites, whereas IgA_2 contains only N-glycosylation sites.[30] Along the Fc portion of IgA_2, there are a greater number of *N*-glycans compared with IgA_1.[30] SC is also heavily glycosylated, constituting between 15 and 24% of its whole molecular mass,[31] with seven N-linked sites. In human milk, the presence and patterns of glycans on Igs vary with stage of lactation, with maternal genotype controlling expression of the glycosyl transferases.[32]

Glycosylation is important in the functional activities of sIgA and FSC. The diverse array of glycan epitopes are targets for lectins and bacterial adhesins.[30] SC glycans can help anchor sIgA to the mucosal lining of the epithelium,[33] where bacteria can be sequestered, thus increasing the bacterial binding capability of IgA.[34] In addition, SC glycans nonspecifically bind to Gram-positive commensal bacteria[24] as well as reduce virulence of *Vibrio cholera* (Gram-negative), thereby preventing pathogenic biofilm formation.[35] FSC derived from milk has been shown to act as a nonspecific microbial scavenger reducing the effects of *Clostridium difficile* toxins[36] and inflammatory cytokine IL-8[37] and preventing adhesion of bacteria[38,39] via interactions with its glycans.[31] A recent study comparing the *N*-glycome of human and bovine milk observed species-specific variations in the glycan repertoire;[40] however, the significance of these differences with regard to function has yet to be determined.

sIgA AND IMMUNE EXCLUSION

Termed immune exclusion, the binding of IgA to microbes and microbial metabolic products and toxins promotes bacterial aggregation, entrapment in mucus, and clearance from the gastrointestinal tract.[41] sIgA purified from human milk has been shown to have a nonspecific "exclusion" function similar to that of intestinal-derived sIgA. In a study using human buccal epithelial cells, sIgA from human colostrum inhibited adhesion of *Escherichia coli*, a major agent of sepsis and meningitis in newborns.[42] Adhesion of *E. coli* is often mediated by bacterial fimbriae, which recognize specific receptors on the epithelial cells. The mechanism of inhibition in this instance was shown to involve specific interactions between sialyloligosaccharides on sIgA and the bacterial adhesins.[43] Similarly, bacterial toxins, such as the plant-derived shiga-like toxin, ricin, have been shown to interact with human colostral sIgA.[44]

Human milk sIgA also protects infants from specific pathogens (reviewed by Liu et al.[45]) via Fab epitopes. The Fab region of sIgA (Figure 1) interacts specifically with enteric

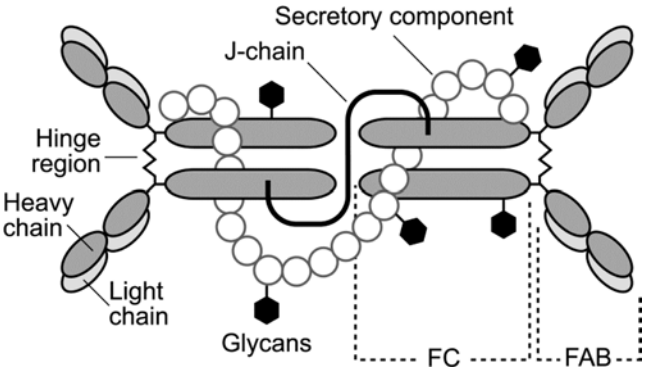

Figure 1. Schematic representation of the structure of sIgA showing the heavy and light chains, the antigen binding sites (Fab), effector (Fc) regions, the hinge region, and glycosylation sites (glycans). Secretory component binds the dimerized IgA molecule, composed of two monomeric IgA molecules, that are joined by the J chain. Diagram adapted from Woof and Russell.[78]

toxins and pathogens that in turn impede the processes of early infection. Protection of infants against infections, including *Vibrio cholera*,[46] *Campylobacter jejuni*,[47] *Shigella* species,[48] *enterotoxigenic E. coli (ETEC)*,[49] and *Giardia lamblia*,[50] relates to the specific sIgA content in human milk. In addition, human and animal studies have demonstrated that delivery of specific sIgA antibodies directly to mucosal surfaces can prevent,

DOI: 10.1021/acs.jafc.5b01836
J. Agric. Food Chem. 2015, 63, 7311−7316

diminish, or cure bacterial infections including *Campylobacter jejuni*[51] and *Clostridium difficile*[52] (reviewed by Corthesy[53]).

sIgA may also have a direct impact on the ability of microbial pathogens to secrete virulence factors required for invasion of intestinal epithelial cells. For example, *Shigella flexneri* usually enters intestinal epithelial cells via a type 3 secretion (T3S) system; however, when sIgA antibodies specific to the *O*-antigen of *Shigella flexneri* are present, entry is prevented.[54] These data suggest milk-derived sIgA may have potential as an antidiarrheal agent for at-risk populations. People with low IgA levels have been shown to have increased risk of inflammatory disorders of the gut.[55] It is possible dietary supplementation with milk-derived sIgA could reduce these inflammatory processes.

BIOFILMS AND sIgA

Bacteria do not always exist singularly, but form complex structures called biofilms. A biofilm is defined as an aggregate of microorganisms that self-produce a matrix of extracellular polymeric substance (EPS), containing polysaccharides, proteins, and DNA.[56] There are two types of biofilms described in the literature: those where the biofilm matrix is produced by the bacteria themselves and those where the colonizing bacteria depend to a lesser or greater extent on the host organism to provide the extracellular matrix. Host-supported biofilms can be utilized by the resident microbes for support and nutrition.[57−59] In turn, the biofilm and its residents provide a barrier against other invading pathogens and provide metabolites, which are of use to the host.[57−59] This is of benefit if the colonizing bacteria are commensals; however, 60−80% of human microbial infections are caused by pathogenic bacteria growing in biofilms. These "protected" bacterial colonies are exceptionally resistant to environmental stresses, especially antibiotics,[60] and this poses a major public health problem.[61] In a recent study, specific IgA antibodies, produced in response to an anti-caries vaccine against *Streptococcus mutans*, were shown to inhibit the formation of pathogenic bacterial biofilm formation in the mouth, by preventing the initial adherence, the first stage of biofilm formation.[62,63] This suggests another application for sIgA-based functional food products.

sIgA AND IMMUNE INCLUSION

Seemingly at odds with the previous section, human sIgA can also facilitate biofilm formation.[64] The hydrophilic glycosylated regions of sIgA allow the molecule to associate with both adhesins and lectin-like receptors expressed by the bacteria as well as the mucus lining on the mucosal surface.[65] Microorganisms bound by sIgA are thereby more readily entrapped by the mucus,[33] and this has been demonstrated in in vitro studies.[66,67] Furthermore, the glycans of sIgA facilitate adhesion of bacteria to both the gut epithelium and mucins.[66,68]

Whereas the length of the human gastrointestinal tract is populated with bacteria, the principal areas of permanent bacterial colonization are in the terminal ileum and the large intestine. This is primarily because of the passing of gastric acid and rapid food transit through the stomach and small intestine.[69] Transit slows in the large bowel, enabling ecosystems to develop,[70] and bacteria can live freely, in microcolonies (biofilms) or on surfaces of particulate matter (food).[71] Milk-derived sIgA could also play a role in promoting commensal biofilm formation. Studies have shown that sIgA from human milk can transit intact through the infant gut and be recovered from infant feces with retained activity.[10] The presence of SC protects sIgA against proteolytic degradation.[7,8] Thus, there is potential for milk-derived sIgA to act in a prebiotic manner, aiding colonization of probiotic bacteria in the gut.

IgA VERSUS IgG

There are a plethora of immune products that are based on the functionality and content of IgG from mammalian milk. IgG antibodies act by fixing complement, opsonizing and agglutinating bacteria, and neutralizing toxins and viruses. All of these functions include inflammatory processes. In contrast, IgA antibodies are less inflammatory acting by agglutinating antigens, neutralizing bacterial toxins and viruses, and preventing the adhesion of enteropathogenic bacteria to mucosal epithelial cells.[72] Compared to IgG, sIgA has several advantageous capabilities. For example, it has greatly increased nonspecific bacterial binding capacity via its glycosylated regions.[34] It has greater stability against proteolytic degradation,[7−9] helping sIgA retain its activity for prolonged periods in hostile environments, such as the gut lumen.[10] The anti-inflammatory profile of sIgA makes it attractive for development as a functional food product that may benefit sufferers of intestinal inflammatory disorders. However, the amount of IgA required to give a health benefit is an important question that has not been adequately answered to date. Data on naturally occurring mucosal IgA titer range are also lacking. These questions will need to be addressed to evaluate the feasibility of IgA-enriched foods.

EFFECTS OF FOOD PROCESSING ON Igs

Milk is processed at industrial scale into a wide range of consumer products, including liquid milks, yogurts, cheeses, ice creams, milk powders. As with all manufactured food products, consumer safety is of paramount importance. For milk products this is assured primarily through the use of heat treatments, with various temperature and time combinations prescribed to inactivate the spoilage and pathogenic bacteria in raw milk.[73] Milk is also subjected to heating during other processing operations, for example, separation, thermal evaporation, and spray-drying, depending on the product being manufactured.

However, immunoglobulins are among the more thermolabile milk proteins. Exposure to processing operations involving heat, pressure, or pH change can affect the conformation of these proteins and ultimately their antibody activity (reviewed in Hurley et al.[74]). Indeed, the exclusion of colostrum from dairy-processing plants as part of regular milk supply is, in part, based on the high proportion of Igs and their different physicochemical properties such as lower stability to heat compared with the major milk proteins. Denaturation of these heat-sensitive proteins during thermal processes can result in aggregation, precipitation, and consequent fouling of equipment, particularly of heat exchangers, limiting processing run times and increasing cleaning frequencies.[75] Using lower temperatures and longer retention times is an effective way of improving the quality of human heat-treated milk,[75] whereas high-pressure processing has been used for human breast milk with apparent minimal effect on IgA.[76] Methods aiming to identify markers of heat damage to milk products have been investigated.[77] Other alternative methods, which retain the bioactivity of milk while meeting product safety requirements,

DOI: 10.1021/acs.jafc.5b01836
J. Agric. Food Chem. 2015, 63, 7311−7316

are being developed. This will create an opportunity for the manufacture of bovine bioactive sIgA-enriched milk.

In summary, the role of IgA in mucosal homeostasis could be exploited using bovine milk-derived sIgA. Glycobiology, an emerging area of immunology, may reveal new opportunities for heavily glycated proteins such as sIgA, for application in novel functional food products. Recent developments in extraction and processing techniques, to retain functionality, will help realize the opportunity for the untapped resource of sIgA in bovine milk. A key question to address is the amount of IgA required to observe functional health benefit. This is not known and needs to be better defined to evaluate the feasibility of sIgA in functional products. Potential applications for sIgA have been illustrated throughout this paper, but understanding how exogenous bovine sIgA could benefit the gastrointestinal environment to provide health benefits to the consumer is an area waiting to be further explored.

protects liver function.[22] Anticancer activities have been observed in various mammalian cancer cell lines.[23−25] Sesamin retards the growth of HepG2 cells and induces apoptosis by inhibiting STAT3 signaling and upregulating p53 and p21, leading to cell cycle arrest in G_2/M.[26] A combination of γ-tocotrienol and sesamin treatment has a synergistic antiproliferative effect on +SA, MCF-7, and MDA-MB-231 mammary cancer cells and induced G_1 cell cycle arrest by decreasing the levels of cyclin D1, CDK2, CDK4, CDK6, and p-Rb, and increasing $p27^{KIP1}$ and $p16^{INK4a}$ expression, in +SA cells.[27] However, the effects of sesamin on VSMCs remain poorly understood. Thus, we explored the inhibitory effects of sesamin on PDGF-induced VSMC proliferation and growth, and the molecular mechanisms of sesamin action.

MATERIALS AND METHODS

Chemicals. Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), phosphate-buffered saline (PBS), penicillin/streptomycin, and trypsin−EDTA were from Gibco BRL (Grand Island, NY). Anti-phospho-ERK 1/2 (Thr^{202}/Tyr^{204}), anti-ERK1/2, anti-phospho-JNK (Thr^{180}/Tyr^{182}), anti-phospho-p38 (Thr^{180}/Tyr^{182}), anti-p38, anti-phospho-PLCγ1 (Tyr^{783}), anti-PLCγ1, anti-phospho-PDGF-Rβ chain (Tyr^{751}), anti-PDGF-Rβ, anti-phospho-STAT3 (Tyr^{705}), anti-STAT3, anti-Akt, anti-cleaved poly-ADP ribose polymerase (PARP), anti-PCNA, and anti-Alexa 555 antibodies were from Cell Signaling Technology, Inc. (Beverly, MA, USA). Anti-phospho-Akt (Ser^{473}), anti-p53, and anti-$p27^{KIP1}$ antibodies were obtained from Millipore Corporation (Billerica, MA, USA). Anti-phospho-pRb (Ser^{807}), anti-CDK2, anti-CDK4, anti-cyclin D1, anti-cyclin E, and anti-β-actin were from Abfrontier (Geumcheon, Seoul, Korea). Anti-$p21^{CIP1}$ was from Calbiochem (Darmstadt, Germany). Anti-FITC was from Sigma (St. Louis, MO, USA). PDGF-BB was obtained from Upstate Biotechnology (Lake Placid, NY, USA). All other chemicals were of the highest available analytical grade.

Cell Culture. Rat aortic VSMCs were isolated via enzymatic dispersion, as previously described.[28] Cells were cultured in DMEM supplemented with 10% (v/v) heat-inactivated FBS, 100 IU/mL penicillin, and 100 μg/mL streptomycin, at 37 °C in a humidified incubator under 95% air and 5% CO_2 (both v/v). VSMC purity was confirmed by immunocytochemical visualization of β-smooth-muscle actin. VSMCs were used at passages 4−8. Sesamin was dissolved in DMSO, but the final concentration of DMSO in any experimental medium did not exceed 0.1% (v/v).

Cell Proliferation Assay. VSMC proliferation was measured using both an indirect colorimetric WST-1 assay (premix WST-1; Takara, Otsu, Japan) and direct cell counting. For the indirect assay, VSMCs were seeded into 96-well culture plates at 4×10^4 cells/mL and incubated in DMEM with 10% (v/v) FBS at 37 °C for 24 h. The medium was then replaced with serum-free DMEM, and incubation continued for 24 h prior to addition of various concentrations of sesamin, followed by a further 24 h of incubation in fresh serum-free medium. Cells were next stimulated by PDGF-BB (50 ng/mL) for another 24 h. After 22 h, WST-1 solution was added, and absorbances at 450 nm were determined 2 h later with the aid of a microplate reader (Tecan Group Ltd., Männedorf, Switzerland). All results were expressed as percentages of the control value (no PDGF stimulation). To obtain direct cell counts, VSMCs were seeded into 12-well culture plates at 1×10^5 cells/mL and treated as described above, with the exception of WST-1 addition. After PDGF-BB treatment for 24 h, cells were suspended by addition of trypsin−EDTA and microscopically counted using a hemocytometer.

Cell Viability Assay. VSMCs were seeded into 96-well culture plates at 4×10^4 cells/mL and incubated in DMEM with 10% (v/v) FBS at 37 °C for 24 h and in serum-free medium for another 24 h, and next they were exposed to 10 μM sesamin or 100 μg/mL digitonin (a cytotoxic control) for various times. WST-1 solution was added, and absorbances at 450 nm were measured 2 h later with the aid of a microplate reader.

DNA Synthesis Assay. [^{3}H]-Thymidine incorporation was measured. The assay conditions were as described above for the cell proliferation assay, to the time of PDGF-BB treatment. After cell stimulation via addition of PDGF-BB (50 ng/mL) in serum-free medium, [^{3}H]-thymidine (2 μCi/mL) was added 4 h prior to harvesting. Each reaction was terminated by aspiration of medium and sequential washing in PBS with 10% (v/v) trichloroacetic acid, and ethanol/ether (1:1, v/v). Acid-insoluble [^{3}H]-thymidine was extracted into 500 μL amounts of 0.5 M NaOH/well, and these solutions mixed with 3 mL amounts of scintillation cocktail (Ultimagold; Packard Bioscience, Waltham, MA, USA). Radioactivity was measured with the aid of a liquid scintillation counter (LS3801; Beckman, Düsseldorf, Germany).

Analysis of Cell Cycle Progression. Cell cycle progression was monitored as described previously.[8] VSMCs were seeded into six-well culture plates and treated as described above (the cell proliferation assay) until the time of PDGF-BB treatment. After stimulation with PDGF-BB (50 ng/mL) for 24 h, cells were harvested by trypsinization and centrifuged at 1,500 rpm for 10 min. The pellets were suspended in 1 mL amounts of 1× PBS, washed twice, fixed in 70% (v/v) ethanol at −20 °C for 24 h, briefly vortexed, and centrifuged at 3,000 rpm for 10 min. The ethanol was discarded and the pellets stained with 500 μL propidium iodide (PI) solution (50 μg/mL PI in sample buffer with 100 μg/mL of DNase-free RNase A). After incubation at 4 °C for 30 min, the level of PI−DNA complex in each nucleus was measured using a FACScalibur (Becton Dickinson Co., Franklin Lakes, NJ, USA). The fluorescence intensity of incorporated PI was used as a measure of nuclear DNA content. The rate of cell cycle progression from the G_0/G_1 to the S and G_2/M phases was determined using the Modfit LT software (Verity Software House, Topsham, ME, USA).

Immunoblotting. Immunoblotting was performed as described previously with slight modifications.[4,5] VSMCs were stimulated with 50 ng/mL PDGF-BB to trigger phosphorylation of JNK (3 min poststimulation [ps]); ERK 1/2 (5 min ps); p38 and PDGF-Rβ (10 min ps); PLCγ1, STAT3, and Akt (15 min ps). Cells were stimulated with 50 ng/mL PDGF-BB for 24 h prior to evaluation of cyclin D1, cyclin E, CDK2, CDK4, PCNA, $p21^{CIP}$, $p27^{KIP}$, and p53 expression levels; the extent of PARP cleavage; and the pRb phosphorylation level. Each reaction was terminated by washing the cells twice in ice-cold PBS followed by addition of Laemmli sample buffer; each lysate was next boiled for 10 min. For each blot, equal amounts of cell lysates were separated via sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE; 7.5−12.5% [w/v] acrylamide gels) and transferred to polyvinylidene fluoride (PVDF) membranes (Atto Corp., Tokyo, Japan) via application of 200 mA for 2 h. Blots were blocked with 5% (w/v) bovine serum albumin (BSA) in TBS-T and incubated with 1:500−1:1,000 dilutions of primary antibodies overnight at 4 °C, and then with 1:2,000 dilutions of secondary antibody. Bands were detected using ECL kits (Atto) and band intensities (normalized to those of β-actin) quantified using the Quantity One software (Bio-Rad, Hercules, CA, USA).

RNA Extraction and Reverse Transcription-Polymerase Chain Reaction (RT-PCR). Prior to RNA extraction, VSMCs were seeded into six-well culture plates and cultured in DMEM with 10% (v/v) FBS at 37 °C for 24 h. The assay conditions were as described above for the cell proliferation assay. RNA was isolated using Total RNA Extraction kits (Real-Biotech Co., Ping-Tung, Taiwan). All preparations were treated with DNaseI (RNase-free; Takara, Japan), and approximately 1 μg amounts of total RNA were reverse-transcribed to cDNA using AccuPower CycleScript RT PreMix (dN12) (Bioneer, Daejeon, Korea). RT-PCR was performed with the aid of HiPi Plus PCR Premix (ELPIS, Daejeon, Korea) and specific primer pairs, on a MyCycler (Bio-Rad). All primers were synthesized by Bioneer, and all primer pairs spanned introns (Supplementary Table 1). The PCR conditions were as follows: 1 cycle of 5 min at 95 °C; followed by 30 cycles of 10 s at 95 °C, 10 s at 58 °C (p27) or 56 °C (p21 and p53), and 10 s at 72 °C; and 1 cycle of 5 min at 72 °C. The products were subjected to 2% (w/v) agarose gel electrophoresis and visualized by ethidium bromide staining.

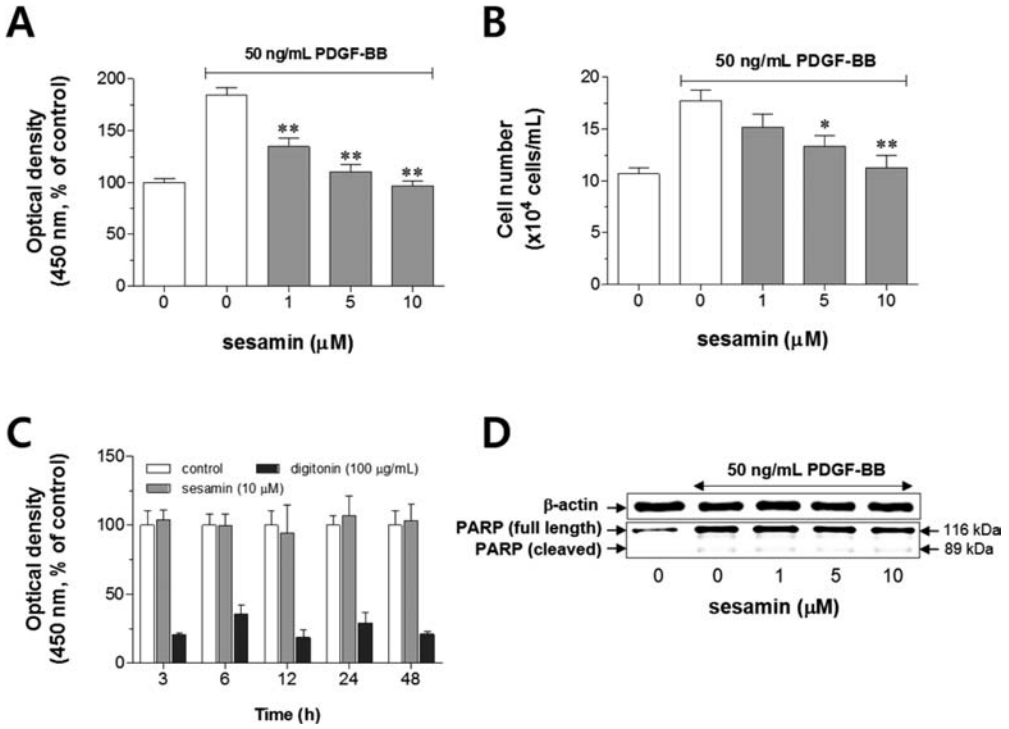

Figure 2. Effects of sesamin on proliferation of PDGF-stimulated VSMCs and cell viability. (A) Serum-deprived VSMCs were treated with sesamin (1−10 μM) for 24 h and next stimulated with 50 ng/mL PDGF-BB for a further 24 h. The WST-1 assay was performed, and the optical densities at 450 nm are shown (n = 3). (B) For direct cell counting, cells were harvested after treatment with 50 ng/mL PDGF-BB and microscopically counted using a hemocytometer (n = 4). (C) Cell viability levels were determined using the WST-1 assay. Serum-deprived VSMCs were incubated with control solution (0.1% [v/v] DMSO), or sesamin (10 μM) or digitonin (100 μg/mL), for various times (3−48 h). The values shown are means ± SEM, and significant differences from PDGF control (PDGF-stimulated, but no sesamin) values are shown by either * ($P < 0.05$) or ** ($P < 0.01$). (D) The extent of VSMC apoptosis was determined by assessment of PARP (a cell apoptosis marker) cleavage levels. The levels of full-length PARP (116 kDa) and the cleaved fragment thereof (89 kDa) were measured by immunoblotting as described in Materials and Methods. Band densities were normalized to those of β-actin. The images shown are representative of those obtained in three similar, independent experiments.

Immunofluorescence. To detect PCNA, p21, and p27 via immunofluorescence, VSMCs were seeded onto glass coverslips in 24-well culture plates. The assay conditions were the same as described above for the cell proliferation assay. After treatment of VSMCs, the cells were washed twice with ice-cold PBS, fixed in 4% (v/v) formaldehyde in PBS for 15 min, and quenched in 100 mM glycine in PBS for 10 min. The cells were next washed twice with PBS; permeabilized with 0.1% (v/v) Triton X-100 for 3 min; blocked in 5% (v/v) goat serum in PBS for 1 h; and incubated with anti-PCNA antibody solution (1:500 dilution in 3% [w/v] BSA in PBS), anti-p21 antibody solution (1:100 dilution in 3% [w/v] BSA in PBS), or anti-p27 antibody solution (1:200 dilution in 3% [w/v] BSA in PBS), for 1.5 h. After washing with PBS, the cells were incubated with secondary antibody (FITC-IgG; 1:200 dilution in 3% [w/v] BSA in PBS) for 1.5 h. Cells were washed with PBS, mounted in Mounting Medium containing DAPI (Vector Laboratories Inc., Burlingame, CA, USA), and observed under a confocal laser microscope (LSM5 live configuration Variotwo VRGB; Zeiss, Jena, Germany).

siRNA Transfection. The $p27^{KIP1}$ siRNA (accession no. NM_031762.3), $p21^{CIP1}$ siRNA (accession no. NM_080782.3), and negative control siRNA (si-con) oligonucleotides were synthesized by Bioneer Corp. (Daejeon, Korea). The target sequences of the siRNA for $p27^{KIP1}$ (si-p27) were sense 5′-AGU ACA CUU GAU CAC UGA A(dTdT)-3′ and antisense 5′-UUC AGU GAU CAA GUG UAC U(dTdT)-3′, and for $p21^{CIP1}$ (si-p21) were sense 5′-UGA CAG UGA AGC AGU CAC A(dTdT)-3′ and antisense 5′-UGU GAC UGC UUC ACU GUC A(dTdT)-3′. Transfection of siRNAs was performed using TransIT-X2 (Mirus BIO LLC, Madison, WI, USA) according to the manufacturer's protocol. Final concentrations of 50 nM si-con, si-p27, and si-p21 oligonucleotides with TransIT-X2 in OptiMEM were incubated with VSMCs for 6 h; then transfection medium was removed and cells were changed to serum free medium. The ability of the siRNA oligonucleotide to knockdown target protein expression was analyzed by immunoblotting of whole cell extracts.

Statistical Analysis. Data are expressed as means ± SEM. One-way ANOVA was used to perform multiple comparisons (GraphPad Software, San Diego, CA, USA). Dunnett's test was applied if a significant difference was evident between treatment groups. A p value less than 0.05 was considered to reflect significance.

RESULTS

Effects of Sesamin on VSMC Proliferation and Viability. To evaluate the effect of sesamin on PDGF-induced VSMC proliferation, we performed both the WST-1 and direct cell counting assays. As shown in Figure 2A, sesamin significantly inhibited PDGF-BB-stimulated VSMC proliferation in a concentration-dependent manner. The levels of inhibition at 1, 5, and 10 μM sesamin were 49.8%, 74.6%, and 87.8%, respectively. Direct cell counting showed that VSMC numbers increased significantly after treatment with 50 ng/mL PDGF-BB (to 17.7 ± 1.5 × 10^4 cells/well) compared to the nonstimulated group (10.7 ± 1.8 × 10^4 cells/well) (Figure 2B). As the sesamin concentration increased to 1, 5, and 10 μM, the cell numbers fell significantly to 15.2 ± 2.4, 13.4 ± 1.8, and 11.2 ± 2.0 × 10^4 cells/well, respectively. We used the WST-1 assay to show that the antiproliferative effect was not attributable to cytotoxicity (Figure 2C). Exposure to the highest tested sesamin concentration (10 μM) for various times was not cytotoxic to VSMCs suspended in serum-free medium. Digitonin (100 μg/mL), which permeabilizes the cell

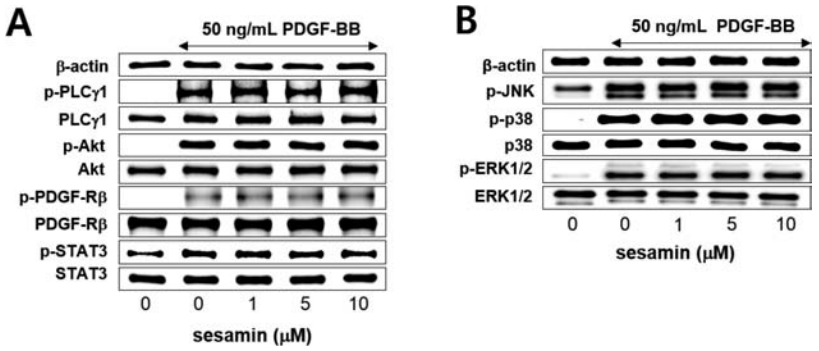

Figure 3. Effects of sesamin on PDGF-Rβ downstream signaling in PDGF-stimulated VSMCs. Serum-deprived VSMCs were treated with sesamin (1−10 μM) for 24 h and next stimulated with 50 ng/mL PDGF-BB to activate PDGF-Rβ downstream signaling. After termination of the reactions, cells were lysed and immunoblotting was performed as described in Materials and Methods (A, B). Regulation by sesamin of the PDGF-induced phosphorylation of PLCγ1, Akt, PDGF-Rβ, STAT3, JNK, p38, and ERK1/2 was assessed. The gel images are representative of those obtained in four similar, independent experiments.

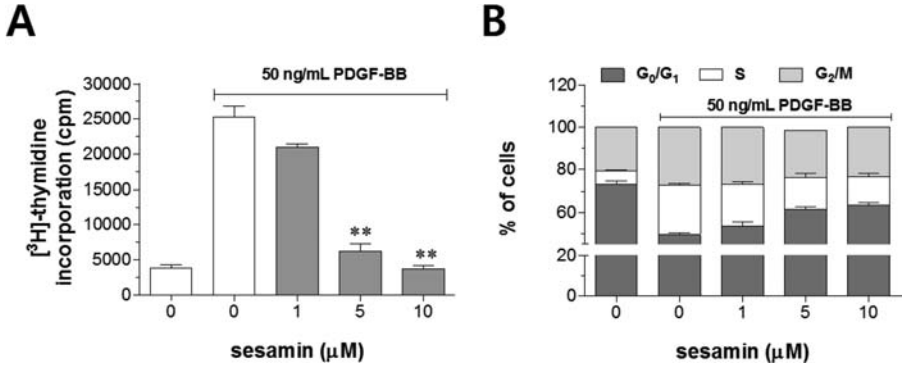

Figure 4. Effects of sesamin on DNA synthesis by and cell cycle progression of PDGF-stimulated VSMCs. (A) Serum-deprived VSMCs were treated with sesamin (1−10 μM) for 24 h and next stimulated with 50 ng/mL PDGF-BB for a further 24 h. To measure DNA synthesis, [^{3}H]-thymidine (2 μCi/mL) was added 4 h prior to harvesting. Radioactivity levels were determined using a liquid scintillation counter (n = 3). All data are expressed as means ± SEM, and significant differences compared to the PDGF control (PDGF-stimulated, but no sesamin) are shown by ** (P < 0.01). (B) Serum-deprived VSMCs were treated with sesamin (1−10 μM) for 24 h and next stimulated with 50 ng/mL PDGF-BB for 24 h. Cells were harvested via trypsinization and the DNA contents of individual nuclei analyzed by flow cytometry. Each value shown was derived by counting at least 10,000 events. The numbers of cells in the G_0/G_1, S, and G_2/M phases are expressed as percentages of total cells. The values shown are averages of data obtained in three similar, independent experiments.

membrane, was used as a positive cytotoxic control.[29] To explore whether sesamin caused apoptosis PARP cleavage, a marker of cell apoptosis, was examined via immunoblotting. As shown in Figure 2D, PARP was not obviously cleaved in the presence of 1−10 μM sesamin, and we thus concluded that sesamin did not cause apoptotic cell death.

Effects of Sesamin on PDGF-Rß Downstream Signaling in PDGF-Stimulated VSMCs. After angioplasty, or in the early stages of atherosclerosis, PDGF-R is overexpressed and PDGF-BB may bind thereto, triggering downstream phosphorylation of PDGF-R, phospholipase Cγ (PLCγ), protein kinase B (Akt/PKB), signal transducer, and activator of transcription 3 (STAT3), members of the mitogen-activated protein kinase (MAPK) family including c-Jun N-terminal kinases (JNK), p38, and extracellular signal-regulated kinase 1/2 (ERK1/2).[30] To explore the molecular basis of the antiproliferative activity of sesamin, we determined whether PDGF-R-activated downstream signaling molecules were induced when PDGF bound to its receptors. Figure 3A shows that stimulation of PLCγ1, Akt, PDGF-Rß, and STAT3 phosphorylation by PDGF-BB (50 ng/mL) was not inhibited by sesamin; also, the total amounts of these proteins were not affected by sesamin. Phosphorylation of JNK, p38, and ERK1/2 was stimulated by addition of PDGF-BB (50 ng/mL), and this was not affected by preincubation with sesamin (Figure 3B). These results indicate that the antiproliferative activity of sesamin did not involve an effect of sesamin on the PDGF-R-induced activation of downstream signaling pathways.

Effects of Sesamin on DNA Synthesis and Cell Cycle Progression in PDGF-Stimulated VSMCs. To assess the effects of sesamin on DNA synthesis, we measured [^{3}H]-thymidine incorporation by VSMCs. As shown in Figure 4A, such incorporation increased significantly after stimulation with 50 ng/mL PDGF-BB (to 25,325.0 ± 3372.5 cpm/well) compared to the nonstimulated control (3,856.2 ± 813.2 cpm/well). [^{3}H]-Thymidine incorporation into DNA of PDGF-stimulated VSMCs was significantly inhibited by sesamin, in a concentration-dependent manner. The counts after addition of 1, 5, and 10 μM sesamin were 21,628, 19,122, and 4,354 cpm/well, respectively.

Flow cytometry showed that sesamin affected cell cycle progression in PDGF-induced VSMCs. As shown in Figure 4B, about 72.8 ± 3.0% and 6.5 ± 1.0% of VSMCs were in the G_0/G_1 and S phases in the absence of PDGF, but these percentages changed to 49.5 ± 1.4% and 23.0 ± 1.6% upon stimulation with PDGF. Sesamin significantly inhibited cell cycle progression, in

J. Agric. Food Chem. 2015, 63, 7317−7325

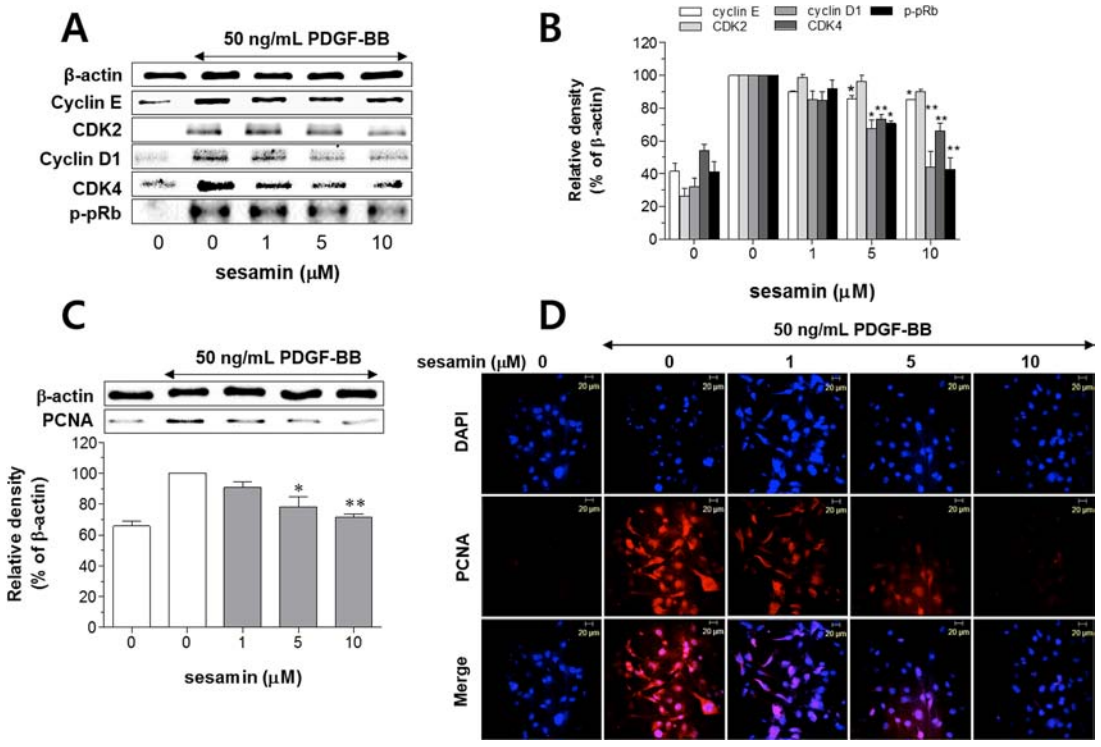

Figure 5. Effects of sesamin on cyclin E, CDK2, cyclin D1, CDK4, and PCNA expression levels, and pRb phosphorylation in PDGF-stimulated VSMCs. (A, B) Serum-deprived VSMCs were treated with sesamin (1−10 μM) for 24 h and next stimulated with 50 ng/mL PDGF-BB for 24 h. After termination of the reactions, immunoblotting was performed as described in Materials and Methods. The expression levels of CDK2, cyclin E, CDK4, and cyclin D1 and the phosphorylation status of pRb were measured via immunoblotting and normalized to the total levels of β-actin. The values shown were derived from three similar, independent experiments. Data are expressed as means ± SEM, and significant differences compared to the PDGF control (PDGF-stimulated, but no sesamin) are shown using either * ($P < 0.05$) or ** ($P < 0.01$). (C) PCNA expression levels were normalized to those of total β-actin. The values shown were derived from three similar, independent experiments. Data are expressed as means ± SEM, and significant differences compared to the PDGF control (PDGF-stimulated, but no sesamin) are shown using either * ($P < 0.05$) or ** ($P < 0.01$). (D) PCNA expression levels were measured by confocal microscopy. Serum-deprived VSMCs were treated with sesamin (1−10 μM) for 24 h and next stimulated with 50 ng/mL PDGF-BB for a further 24 h. Immunofluorescence evaluation was performed using anti-PCNA and anti-Alexa 555 antibodies. The images are representative of those obtained in two similar, independent experiments. Scale bar = 20 μm.

a concentration-dependent manner. The reductions in S-phase cell numbers were 19.3 ± 2.0% ($P < 0.01$), 14.8 ± 3.5% ($P < 0.01$), and 13.2 ± 2.1% ($P < 0.01$) at sesamin concentrations of 1, 5, and 10 μM, respectively. The percentages of cells in the G_0/G_1 phase increased by 53.6 ± 3.0% ($P < 0.01$), 61.3 ± 2.7% ($P < 0.01$), and 63.6 ± 2.1% ($P < 0.01$), at the same sesamin concentrations. These results indicated that sesamin inhibited PDGF-induced VSMC proliferation by triggering cell-cycle arrest in the G_0/G_1 phase, and that this effect was associated with a reduction in DNA synthesis.

Effect of Sesamin on Cell-Cycle-Related Protein Expression and Phosphorylation. Cell-cycle progression is controlled by CDKs and the cyclin proteins that regulate CDK activities. During the G_0/G_1-S transition, the cyclin E−cyclin dependent kinase (CDK)2 complex and the cyclin D1−CDK4 complex hyperphosphorylate pRb, inducing expression of PCNA, E2F release from pRb, and transcription of growth-associated genes.[31] To explore how sesamin induced cell cycle arrest, we measured the expression levels of cyclin E, CDK2, cyclin D1, CDK4, and PCNA and the extent of pRb hyperphosphorylation. The data of Figures 5A and 5B show that sesamin significantly suppressed PDGF-induced cyclin D1 and CDK4 expression, and slightly suppressed that of cyclin E and CDK2, in a dose-dependent manner. Also, sesamin dose-dependently inhibited pRb hyperphosphorylation. Sesamin-induced inhibition of VSMC proliferation and pRb phosphorylation was shown to reduce PCNA expression (Figure 5C), as also revealed by immunofluorescence (Figure 5D). Together, the results indicate that sesamin affects the expression of G_0/G_1 phase- and S phase-associated cell cycle components of VSMCs.

Effect of Sesamin on Expression of CDK Inhibitors. The kinase activities of CDK−cyclin complexes are regulated by CKIs. We explored whether the inhibitory effect of sesamin on VSMC proliferation was mediated by modulation of CKI expression. First, the effect of sesamin alone on the expression of CKIs was measured. The results showed that sesamin enhanced expression of $p27^{KIP1}$, $p21^{CIP1}$, and p53 in a concentration-dependent manner (Figure 6). Since sesamin alone did not cleave PARP at the concentration rage of 1−10 μM, sesamin alone did not induce apoptosis.

In PDGF-stimulated proliferative condition, the mRNA (Figure 7A) and protein (Figure 7B) levels of $p27^{KIP1}$ fell upon addition of PDGF-BB. The level of $p27^{KIP1}$ in PDGF-stimulated VSMCs was about 52.2% that of the control (no PDGF) (Figure 7C). Inhibition of $p27^{KIP1}$ expression was rescued to the extents of 10.8%, 19.6%, and 30.0% upon treatment with 1, 5, and 10 μM sesamin, respectively. The $p21^{CIP1}$ protein level increased by about 36.6% upon addition of PDGF-BB. $p21^{CIP1}$ expression was increased, in a concentration-dependent manner, by sesamin (the increases were 75.5%, 102.1%, and 193.5% upon treatment with 1, 5, and 10

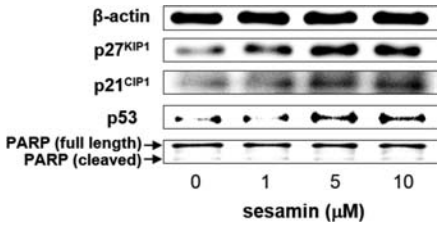

Figure 6. Effects of sesamin alone on $p21^{CIP1}$, $p27^{KIP1}$, and p53 expression levels and PARP cleavage in VSMCs. Serum-deprived VSMCs were treated with sesamin (1−10 μM) for 48 h, and the cell lysates were obtained after reactions terminated. Immunoblotting was performed as described in Materials and Methods using the specific antibodies for $p21^{CIP1}$, $p27^{KIP1}$, p53, and PARP. β-Actin was used for normalization. The images are representative of those obtained in three similar, independent experiments.

μM sesamin, respectively), compared to the no-PDGF group. As expected, the mRNA and protein levels of p53, an upstream regulator of $p21^{CIP1}$, increased in a similar manner. As the concentration of sesamin increased (from 1 to 5 and 10 μM sesamin), the p53 protein expression levels rose by 34.0%, 61.3%, and 92.8%, respectively. The images of cells shown in Figure 7D ($p27^{KIP}$) and Figure 7E ($p21^{CIP1}$) are consistent with the development of sesamin-induced alterations in mRNA and protein expression levels. Together, the results indicate that $p27^{KIP1}$ and $p21^{CIP1}$ are involved in inhibition of VSMC proliferation by sesamin.

Effects of siRNA for $p27^{KIP1}$ and $p21^{CIP1}$ on Sesamin-Induced Inhibition of DNA Synthesis. To determine whether the inhibition of VSMC proliferation by sesamin is mediated via $p27^{KIP1}$ and $p21^{CIP1}$, cells were transfected with specific siRNA for $p27^{KIP1}$ or $p21^{CIP1}$ to knock down these proteins. Since $p27^{KIP1}$ expression is higher in serum-deprived condition than PDGF-treated condition, it was examined only in serum-deprived condition, but $p21^{CIP1}$ expression is increased by PDGF-BB, and it was examined in both conditions. In Figures 8A and 8B, $p27^{KIP1}$ expression and $p21^{CIP1}$ expression were silenced about ~60% in VSMCs. The sesamin-induced inhibition of DNA synthesis was decreased in cells transfected with either siRNA (Figure 8C). Under si-con (negative control siRNA) treatment in VSMCs, 10 μM sesamin inhibited 91% of DNA synthesis. However, the inhibitory effect was alleviated to 50.6% by si-p27 ($p27^{KIP1}$ siRNA) and 25% by si-p21 ($p21^{CIP1}$ siRNA). Together, the results indicate that $p27^{KIP1}$ and $p21^{CIP1}$ may contribute to sesamin-induced inhibition of VSMC proliferation.

DISCUSSION

We present two major findings: (1) sesamin exerts an antiproliferative action on VSMCs by inhibiting cell cycle progression via arrest in G_0/G_1; and (2) sesamin enhances the

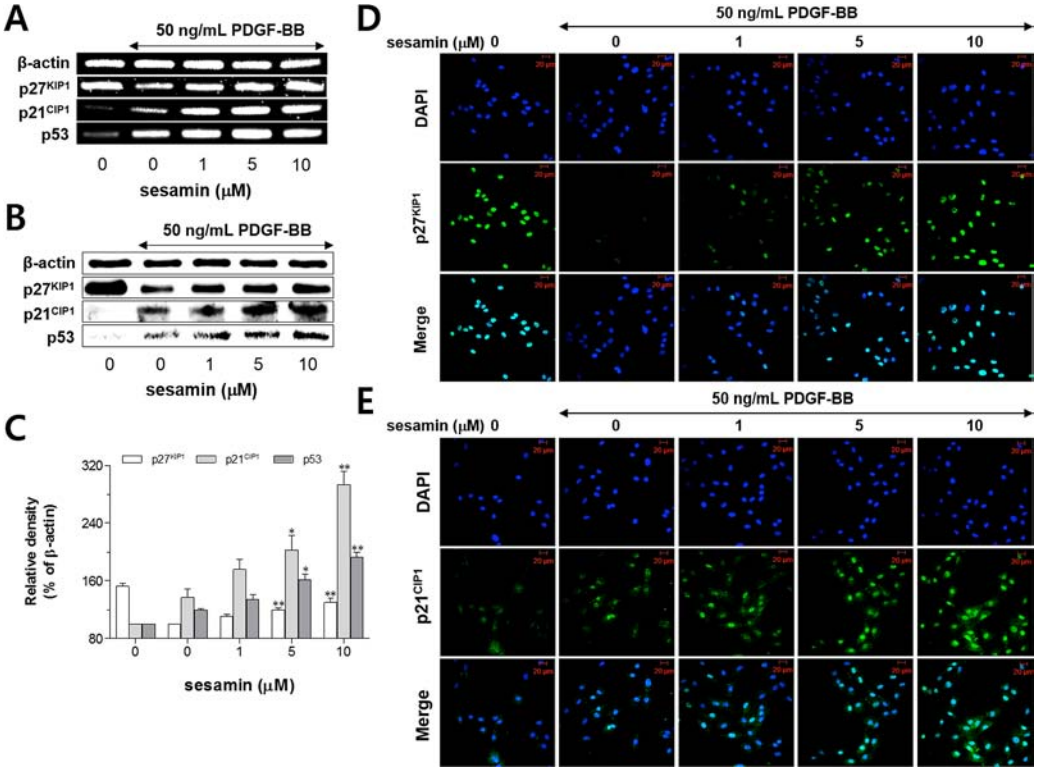

Figure 7. Sesamin upregulation of $p21^{CIP1}$, $p27^{KIP1}$, and p53 in PDGF-stimulated VSMCs. (A) Serum-deprived VSMCs were exposed to sesamin (1−10 μM) for 24 h and then stimulated with 50 ng/mL PDGF-BB for a further 24 h. Total RNA was extracted and RT-PCR analysis performed as described in Materials and Methods. Representative blots from three similar, independent experiments are shown; band intensities were normalized to those of total β-actin. (B) $p21^{CIP1}$, $p27^{KIP1}$, and p53 expression levels were quantified by immunoblotting after normalization of all band intensities to those of total β-actin (C). The values in the bar graphs (means ± SEM) were derived in three similar, independent experiments. Significant differences from the PDGF control (PDGF-stimulated, but no sesamin added) are noted as either * ($P < 0.05$) or ** ($P < 0.01$). (D, E) $p27^{KIP1}$ and $p21^{CIP1}$ were detected via confocal microscopy. Serum-deprived VSMCs were treated with sesamin (1−10 μM) for 24 h and next stimulated with 50 ng/mL PDGF-BB for a further 24 h. Immunofluorescence detection featured the use of anti-$p27^{KIP1}$, anti-$p21^{CIP1}$, and anti-FITC-conjugated IgGs. The images are representative of those obtained in two similar, independent experiments. Scale bar = 20 μm.

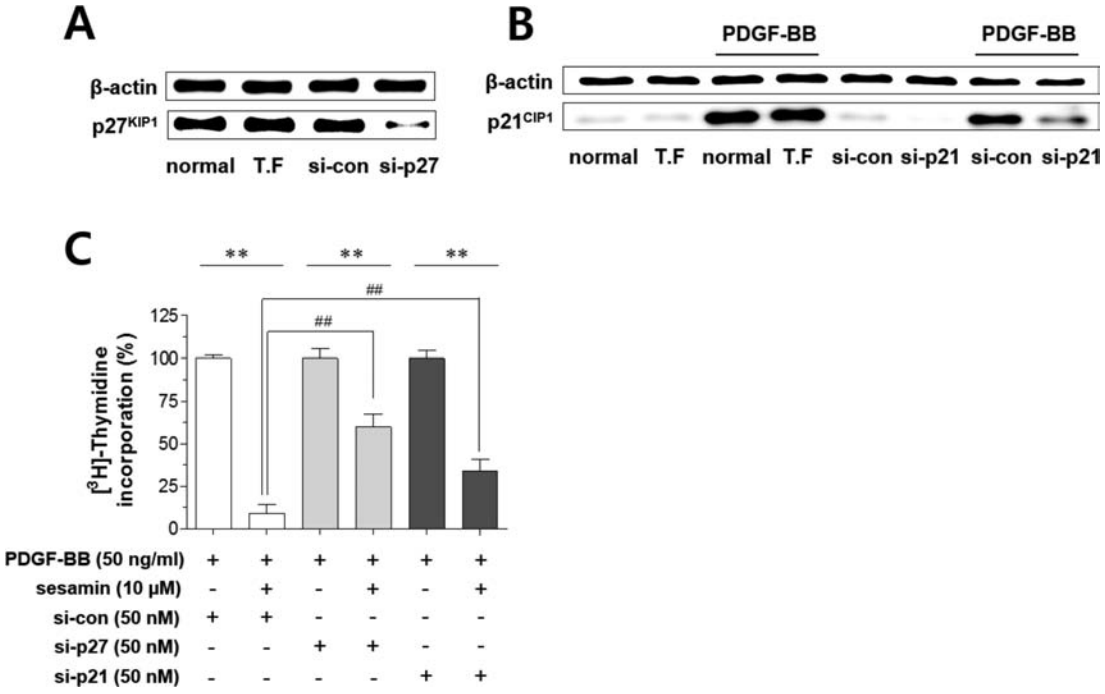

Figure 8. Effects of siRNA for $p27^{KIP1}$ or $p21^{CIP1}$ on sesamin-induced inhibition of VSMC proliferation. The siRNAs for negative control (si-con, 50 nM), $p27^{KIP1}$ (si-p27, 50 nM) or $p21^{CIP1}$ (si-p21, 50 nM) were transfected for 54 h in VSMCs. TransIT-X2 was used as transfection reagent (T.F), and normal means no treatment with T.F and siRNA. Serum-deprived VSMCs were incubated with transfection mixture for 6 h and changed to serum-free medium. After 48 h, cells were lysed, and $p27^{KIP1}$ (A) and $p21^{CIP1}$ (B) expression was detected. (C) After incubated with transfection medium for 6 h, medium was removed and cells in serum-free medium were treated with sesamin (1−10 μM) for 24 h. After 24 h, VSMCs were stimulated with 50 ng/mL PDGF-BB for a further 24 h. To measure DNA synthesis, [^{3}H]-thymidine incorporation was performed as described in Materials and Methods (n = 3). All data are expressed as means ± SEM, and significant differences compared to the PDGF control (PDGF-stimulated, but no sesamin) are shown by ** ($P < 0.01$), and compared to si-con treated group are shown by $^{\#\#}$ ($P < 0.01$).

expression of CKIs including $p27^{KIP1}$, $p21^{CIP1}$, and p53; thus suppressing the binding and activation of CDK−cyclin complexes. The data suggest that sesamin may play a role in suppressing PDGF-induced VSMC proliferation in vitro, and explain the molecular mechanisms in play.

VSMCs are the principal cells of arterial vessels; abnormal proliferation of such cells is associated with progression of atherosclerotic lesions.[32] PDGF released mainly in activated platelet stimulates the growth of VSMCs.[33] Associations between PDGF levels and the extent of VSMC proliferation have been noted in various models; inhibition of PDGF signaling prevented neointimal cellular proliferation.[34] Thus, it seemed worthwhile to screen for compounds that might limit inappropriate VSMC growth under conditions of high-level PDGF expression.

Sesamin is a major lignan constituent of sesame seed oil and has many biological activities, but no study to date has explored the effects of sesamin on signaling pathways associated with PDGF, the principal growth factor regulating VSMC proliferation after angioplasty. We found that sesamin inhibited PDGF-induced VSMC proliferation, but that this was not attributable to cytotoxicity or apoptosis (Figure 2). However, sesamin did not suppress PDGF-induced phosphorylation of PDGF-Rβ or downstream signaling molecules thereof, including PLCγ1, Akt, STAT3, and MAPK kinase family members (Figure 3). Thus, the antiproliferative action of sesamin is not mediated by PDGF-R-induced activation of early signaling pathways. We next explored whether sesamin acted at another level of the cellular machinery.

PDGF-stimulated cell cycle progression of VSMCs requires the binding and activation of CDK−cyclin complexes. Activation of cyclin D1, followed by cyclin E, CDK4, and CDK2, triggers phosphorylation of the Rb protein. Such phosphorylation plays a role in the G_1−S transition by sequestering E2F, and stimulating the expression of PCNA, which promotes DNA synthesis.[35] Sesamin suppressed PDGF-stimulated DNA synthesis and caused VSMCs to arrest in the G_0/G_1 phase (Figure 4), implying that the actions of several cell cycle regulatory proteins may be affected by sesamin. We found that sesamin significantly suppressed cyclin D1 and CDK4 expression, thus inhibiting pRb hyperphosphorylation (Figures 5A and 5B). Although the sesamin-induced inhibition of cyclin E and CDK2 expression was weak, this was nonetheless adequate to prevent pRb hyperphosphorylation, as both cyclin D1 and CDK4 were potently suppressed.[36] Moreover, sesamin inhibited PCNA expression, normally induced by hyperphosphorylated pRb in the early G_0/G_1 and S phases of the cell cycle (Figures 5C and 5D).

CKIs are classified two families. One is Cip/Kip family including $p21^{CIP1}$, $p27^{KIP1}$, and $p57^{KIP2}$, the other is INK4 family including $p15^{INK4b}$, $p16^{INK4a}$, $p18^{INK4c}$, and $p19^{INKd}$. It is known that the Cip/Kip family members bind to both cyclin and CDK subunits, cyclin D−, E−, A−, and B−CDK complexes, and regulate their activities. INK4 family members bind only to CDK4 or CDK6 not to cyclins and, thus, affect cell cycle progression.[37] Since sesamin was shown to decrease cyclin E−CDK2 and cyclin D−CDK4 in Figure 5, $p21^{CIP1}$ and $p27^{KIP1}$, Cip/Kip family members, were focused on in this study. Interestingly, expression of $p21^{CIP1}$, $p27^{KIP1}$, and p53,

DOI: 10.1021/acs.jafc.5b03374
J. Agric. Food Chem. 2015, 63, 7317−7325

upstream of $p21^{CIP1}$, is increased by sesamin alone without influence of PARP cleavage (Figure 6). p53, tumor suppressor protein, regulates $p21^{CIP1}$ activation in G_1−S transition point, thus occurred cell cycle arrest.[38] In another aspect, it is known that p53 leads to DNA damage, senescence, or apoptosis. However, p53-induced apoptotic effect may not occur in every cell line, and other cofactors or modifications are required for dead pathway.[39] Furthermore, it is reported that some substances have antiproliferative effects on VSMCs by upregulation of $p21^{CIP1}$ and p53.[40−43] Thus, these phenomena might be cytostatic, not cytotoxic or apoptotic.

The expression levels of CKIs were upregulated by sesamin in VSMCs treated with PDGF-BB (Figure 7). Upregulated CKIs bind to cyclin−CDK complexes and inhibit the catalytic activity of these complexes, and subsequently Rb phosphorylation was decreased. Sesamin-induced inhibition of DNA synthesis was restored in PDGF transfected with $p27^{KIP1}$ or $p21^{CIP1}$ siRNAs, and recovery rate in cells treated with $p27^{KIP1}$ siRNA is larger than that in $p21^{CIP1}$ siRNA (Figure 8). These results suggest that $p27^{KIP1}$ may be the major factor compared to $p21^{CIP1}$; however, further studies are needed. Thus, our results indicate that the inhibitory effect of sesamin on PDGF-stimulated VSMC proliferation is attributable to upregulation of $p27^{KIP1}$, $p21^{CIP1}$, and p53, in turn triggering G_0/G_1 cell cycle arrest.

In conclusion, we provide the first evidence that sesamin, the most abundant lignan of sesame seed oil, present also in several medicinal herbs including *A. heterotropoides*, inhibits PDGF-induced VSMC proliferation in vitro, attributable to upregulation of $p27^{KIP1}$, $p21^{CIP}$, and p53, in turn downregulating the expression levels of CDK−cyclin complexes. Therefore, sesamin may be valuable to prevent and treat vascular disorders such as restenosis developing after angioplasty, and atherosclerosis.

There is an urgent need for counter-measures against ionizing radiation in fields that run the gamut from medical radiation therapeutics to the nuclear industry to space travel. Apart from external physical shielding, there is little that can be done currently to protect individuals who are exposed to large doses of radiation. However, we have observed,[9] and others have confirmed,[10,11] that the presence of melanin in the intestinal lumen during extra-corporeal irradiation translates into remarkable protection against the deleterious effects of extra-corporeal ionizing radiation in mice. The presumed mechanism of action for this melanin protective effect is shielding of the gut tissue, including the associated lymphatic tissue, which in turn provides cells to replenish radiation-depleted bone marrow. More specifically, melanin involves physical shielding of the cells via Compton scattering of the incoming photons, accompanied by the scavenging of Compton electrons and free radicals by the melanin macromolecules.[9]

Melanin is an insoluble and non-digestible pigment with a complex molecular structure that is generated by polymerization of indolic and phenolic compounds.[12] Melanins are found in all biological kingdoms, but their structure and function remain poorly understood, as these heterogeneous pigments cannot be crystallized for high-resolution structural studies. There are five types of melanin commonly found in nature: eumelanin, pheomelanin, neuromelanin, pyomelanin, and allomelanin.[13] Of the five, eumelanin is the most abundant and is a brown to black pigment.[13−15] The eumelanin polymer is composed 5,6-dihydroxyindole (DHI) and 5,6-dihydroxyindole-2-carboxylic acid (DHICA) units.[9] It can be highly concentrated in the human epidermal, retinal, and auditory systems.[13,14] Structures for both oligomers for eumelanin and pheomelanin have been already proposed.[9] Melanins are readily produced by many fungi, including edible fungi, where their functions could include energy transduction.[16] Consequently, the edible fungi constitute a potential source of nutritional melanin that could find important use as a radiation countermeasure; e.g., the benefits from the *A. auricula* mushroom could be gained by ingesting the raw material. In addition to radiation protection, melanins have semiconductor properties that could be exploited in the design of edible electronic devices.[17] Hence, there is a need for identifying good sources of melanin from edible biomaterials in such diverse areas as radioprotection and electronic design. As mushroom powders are now sold as food supplements, we conducted an essential study of the melanin content and associated molecular characteristics in commercial preparations of powdered *A. auricula*.

MATERIALS AND METHODS

Melanin Sources. *Auricularia auricula* mushroom preparations were obtained from Maypro (New York, NY, http://maypro.com/). As a control for L-DOPA melanin, we isolated melanin from *Cryptococcus neoformans* as described previously.[16] Briefly, melanized cells were obtained by growing *C. neoformans* strain H99 (American Type Culture Collection, Rockville, MD) in defined minimal medium (15 mM glucose, 10 mM $MgSO_4$, 29.4 mM KH_2PO_4, 13 mM glycine, 3 μM vitamin B1 [Sigma Chemical Co., Cleveland, OH]) with 1 mM L-DOPA (Sigma) at 30 °C for 10 days with shaking at 150 rpm.

Melanin Isolation. The same protocols were used to isolate melanin from melanized *C. neoformans* and powdered mushrooms. For *C. neoformans*, melanized cells were harvested by centrifugation at 2000 rpm and washed with phosphate-buffered saline (PBS). Similarly, 20 g samples of *A. auricula* mushroom powders were dissolved in PBS. Fungal cells and powdered mushroom material were each suspended in a 1 M sorbitol/0.1 M pH 5.5 sodium citrate solution and incubated at 30 °C for 24 h with 10 mg/mL of lysing enzymes from *Trichoderma harzianum* (Sigma). The enzyme-digested materials were collected by centrifugation at 3000 rpm for 10 min and washed repeatedly with PBS until the supernatant was nearly clear. Proteinaceous materials were denatured by incubating the pellets with 4 M guanidine thiocyanate in a rocker for 12 h at room temperature. The recovered debris was collected by centrifugation, washed two or three times with ∼20 mL of PBS , and then incubated for 4 h at 65 °C in 10 mL of buffer (10 mM pH 8.0 Tris-HCl, 5 mM $CaCl_2$, 5% SDS) containing 1 mg/mL of proteinase K (Boehringer, Mannheim, Germany). The debris was recovered and washed two or three times with ∼20 mL of PBS, after which lipids were extracted three successive times by the Folch method, maintaining chloroform, methanol, and saline solution in the final mixture at 8:4:3 (v/v/v). The product was suspended in 20 mL of 6 M HCl and boiled for 1 h to hydrolyze cellular contaminants associated with the melanin. The resulting acid-resistant insoluble material was dialyzed against distilled water for 14 d with daily water changes and lyophilized. Elemental analysis (carbon, nitrogen, and hydrogen) was performed by Intertek (Whitehouse, NJ).

Scanning Electron Microscopy (SEM). Mushroom powders and melanin extracts were suspended in PBS, incubated on coverslips coated with 0.01% poly-L-lysine, and fixed with 2.5% glutaraldehyde in 0.1 M sodium phosphate buffer (pH 7.3) for 24 h at 4 °C. Mushroom and melanin extracts were post-fixed with 1% OsO_4, dehydrated progressively in 70%, 90%, 95%, and 100% ethanol, and critical-point-dried in CO_2. The material was sputter-coated with gold using an EMitech K550 sputter coater and viewed in a Zeiss Supra 40 scanning electron microscope operating at a voltage of 10 kV.

Transmission Electron Microscopy (TEM). Samples were fixed with 2% paraformaldehyde−2.5% glutaraldehyde−0.1 M sodium cacodylate buffer, followed by a post-fixation step with 1% osmium tetroxide and 1% uranyl acetate. Samples were then dehydrated by immersion in a graded series of ethanol concentrations and embedded in LX112 resin (LADD Research Industries, Burlington, VT). A Reichert Ultracut UCT instrument was used to cut ultrathin (80 nm thick) sections that were then stained with uranyl acetate followed by lead citrate. TEM was done using a JEOL 1200EX transmission electron microscope operating at 80 kV.

Electron Paramagnetic Resonance (EPR) Spectroscopy. EPR spectra were obtained at 77 K using a Varian E112 X-Band model spectrometer equipped with a TE102 resonator. Approximately 5 mg samples of melanin preparations were loaded into 4 mm quartz EPR tubes (Wilmad LabGlass, Buena, NJ), which were held in place in the resonator using a quartz finger dewar. Typical parameters used to acquire the spectra were as follows: modulation amplitude, 1.6 G; microwave frequency, 9.11 GHz; and microwave power, 0.10 mW. The quartz EPR signal generated as a result of the irradiation was subtracted from the spectra of the irradiated samples. EPR spectra were also obtained after illumination of melanin suspensions with a 150 W fiber optic lamp for 30 min at 77 K or by suspending the melanins in 0.1 M $ZnCl_2$.

Solid-State Nuclear Magnetic Resonance (NMR) spectroscopy. Solid-state ^{13}C NMR measurements were performed using a Varian (Agilent Technologies, Santa Clara, CA) DirectDrive1 (VNMRs) NMR spectrometer operating at a ^1H frequency of 600 MHz (^{13}C frequency of 150 MHz) and a temperature set to 25 °C. The ^{13}C cross-polarization (CP) experiments were conducted at a magic-angle spinning (MAS) frequency of 20 kHz (±20 Hz) using a 1.6 mm HXY fastMAS probe filled with 4−6 mg of powdered sample. Ramped-amplitude ^{13}C CPMAS (RAMP-CP)[18] measurements were conducted to identify the carbon chemical moieties, and ^{13}C multiple-CP experiments[19] were carried out to achieve high-throughput quantification of the carbon-containing pigment functional groups. Detailed experimental parameters for CPMAS measurements on fungal melanins have been reported elsewhere.[20,21] The recycle delay for the ramp CP measurements and at the beginning of the multiple-CP sequence was 3 s, and the duration of the re-polarization period in multiple-CP was 0.8 s for the pigment samples. The CP times were 1.0−1.5 ms for the RAMP-CP[22] and 1.0 ms for the multiple-CP

DOI: 10.1021/acs.jafc.5b02713
J. Agric. Food Chem. 2015, 63, 7326−7332

measurement, each with 10 recursive cycles. The SPINAL method[23] was used to apply high-power heteronuclear ^{1}H decoupling of 170–185 kHz, and 2048–7400 transients were acquired to generate each ^{13}C spectrum. 1D ^{13}C spectral data sets were processed with 100–200 Hz of line broadening; chemical shifts were referenced externally to the ethylene ($-CH_2-$) group of adamantane (Sigma) at δ_C = 38.48 ppm. Reproducibility of the spectroscopic measurements was assessed by obtaining replicate ^{13}C spectra on each sample; biological replicates of these materials and previously reported *C. neoformans* melanins[20] displayed minor variations in their ^{13}C NMR spectra due to differences in cellular media, scale of synthesis, extent of polymerization, and pigment deposition within the cellular matrix.

RESULTS

Microscopic Analysis of Commercial Mushroom Preparations. Commercial edible mushroom preparations are usually available as powders. We studied the ultra-structural features of commercial powders of *A. auricula* edible mushrooms. *A. auricula* mushroom appears as a dark powder (Figure 1A). Analysis of these "raw" preparations by SEM showed that

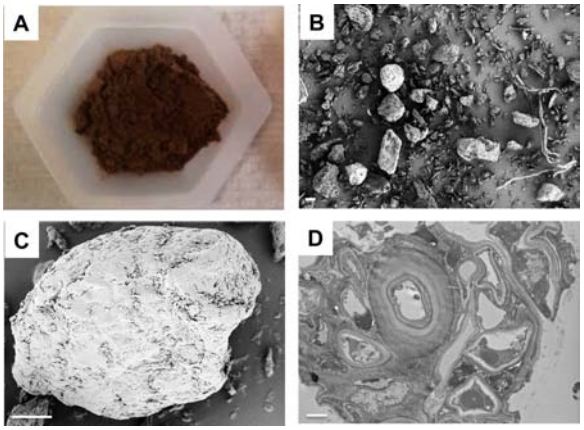

Figure 1. Electron microscopy analysis of the *A. auricula* mushroom powders (A). *A. auricula* mushroom preparations were processed for scanning electron microscopy (SEM, B and C) and transmission electron microscopy (TEM, D). Scale bars in B and D are 10 μm, and scale bar in C is 1 μm.

A. auricula powder was composed of a heterogeneous mixture of amorphous fragments with a size distribution ranging between 1 and 50 μm (Figure 1B). Higher magnifications of some of the mushroom pieces showed that the surface of these fragments appeared to have a rough morphology (Figure 1C).

Melanin is associated with the cell wall in the human pathogen *C. neoformans* and often appears as an electron-dense layer in transmission electron micrographs.[24] We performed TEM on mushroom extracts and found that both mushroom powders have very similar internal structure, including circular units with a dense cell wall made of several concentric layers embedded in a heterogeneous mass of material with different textures (Figure 1D). However, the *A. auricula* mushroom powder had more electron-dense material. The darker areas in this mushroom were associated with material randomly distributed across the section, although we could observe that the inner layers of the circular units were also highly electron dense (Figure 1D), suggesting that melanin might not have a regular distribution pattern in edible mushrooms.

Melanin Content of Commercial Mushroom Preparations. A prior analysis of *A. auricula* mushrooms obtained at a local market revealed that melanin comprises approximately 10% of the dry weight of the fungal mass.[9] To determine the melanin content of commercial mushroom preparations, we used a quantitative melanin isolation protocol adapted from the fungus *C. neoformans*. Twenty grams of powder was processed for melanin isolation, beginning with suspension in PBS (Figure 2A). Of note, we observed a remarkable expansion in

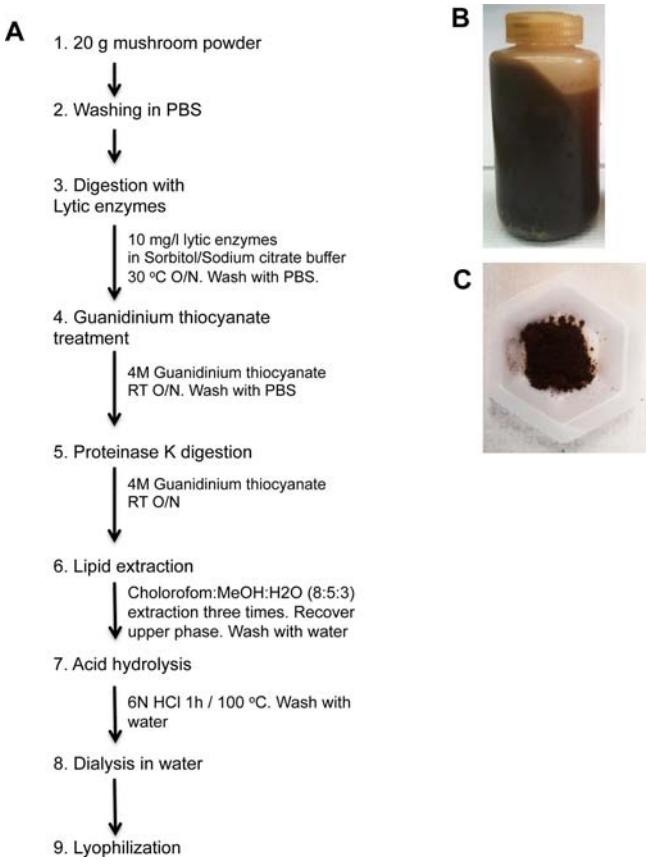

Figure 2. Melanin isolation protocol from commercial mushroom preparations. (A) The protocol was adapted from that for the fungus *C. neoformans* and involved digestion of cell walls, de-proteination, de-lipidation, and acid hydrolysis. (B) Appearance of *A. auricula* commercial mushroom powders after dissolving in PBS and centrifugation (steps 1 and 2 in the melanin isolation protocol). Note that 20 g of *A. auricula* powder expanded when dissolved in PBS. (C) Appearance of the melanin extract from *A. auricula* mushrooms.

the volume of the *A. auricula* powder upon hydration (Figure 2B). Subsequent steps in the melanin isolation from *A. auricula* involved digestion of cell-wall structural components and protein denaturation and digestion. Extraction of lipids by chloroform and methanol treatment revealed that 0.5% of the dry weight was due to lipids. Subsequent acid hydrolysis of the denatured, proteinase-digested and de-lipidated material reduced the wet weight by 50%. After hydrolysis, the product was dialyzed and lyophilized. The color of the extract was significantly darker than the original mushroom powder, which reflects enrichment in the melanin pigment (Figure 2C). Approximately 10% of the dry weight of the mushroom powder corresponded to melanin pigment that is resistant to acid hydrolysis.

Ultrastructural characterization of the final (melanin) product by SEM revealed a very different morphology relative to the original mushroom powder, namely an amorphous material with little structural resemblance to the commercial

DOI: 10.1021/acs.jafc.5b02713
J. Agric. Food Chem. 2015, 63, 7326–7332

powder (Figure 3). The removal of acid-digestible material was apparent as an increase in effective surface area. TEM analysis

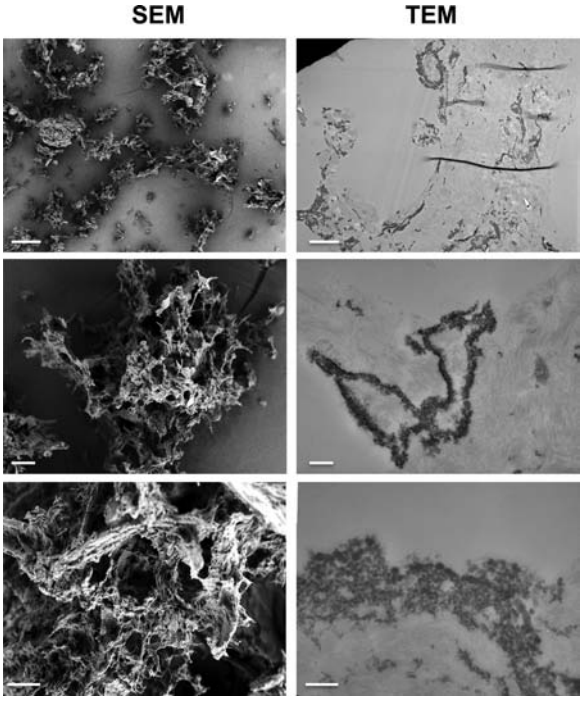

Figure 3. Electron micrographs of isolated melanin from commercial *A. auricula* mushrooms. Note the hollowness of the isolated material. Scale bars are 100 μm (top panel), 20 μm (medium panel), and 10 μm (lower panel).

of the isolated melanin showed that the units observed by SEM were hollow and consisted mainly of a melanin ring with no associated internal material. High-magnification micrographs revealed that mushroom melanin is composed of small spherical units with an estimated diameter of 20−30 nm (Figure 3).

Physicochemical Characterization of Mushroom Melanins. Melanins are complex, amorphous, and incompletely understood polymeric pigments.[12] Demonstration that a compound is melanin by chemical means is difficult, and not all dark pigments in nature are melanins. Fungal melanins include DHI and DHICA monomer units with 6−9% nitrogen or 1,8-dihydroxynaphthalene (DHN) with no nitrogen in its structure.[9] Elemental analysis of *C. neoformans* melanin showed 59% C, 7% H, and 6% N (C/N of 10.6, no S), indicating that *C. neoformans* melanin was primarily a DHI/DHICA eumelanin. In contrast, *A. auricula* melanin contained 41% C, 5% H, and 1.6% N (C/N of 24.8, no significant S), suggesting that it contained a mixture of DHICA/DHI and DHN eumelanin, as previously reported (Table 1).[9] Of note, structural formulas for DHN melanins have been already reported.[9]

Melanin pigments are remarkable in that they contain a stable population of organic free radicals, making EPR spectroscopy a particularly effective method for identifying and classifying them. A set of qualitative EPR criteria were established for melanin identification based on the increase in EPR signal upon (a) illumination with a bright white light or (b) addition of $ZnCl_2$.[9,24,25] As previously reported, irradiation of *C. neoformans* melanin with a bright light or supplementation with 0.1 M $ZnCl_2$ increased the EPR by approximately 200% and 500%, respectively (Figure 4A).[9,24] To assess whether the dark product resulting from the *A. auricula* commercial mushroom preparation was melanin, we performed EPR measurements before and after bright illumination and upon addition of $ZnCl_2$. The EPR spectra of the material isolated from mushroom powder revealed a stable free radical signal like that described for melanin (Figure 4B). Illumination of this material for 30 min with white light from a 150 W fiber optic lamp and suspension in 0.1 M $ZnCl_2$ increased the magnitude of the EPR signal by 150% and 900%, respectively (Figure 4B). Thus, the acid insolubility of the dark residue combined with the EPR results established the material derived from *A. auricula* as a melanin.

Table 1. Elemental Composition of Melanins

NMR Spectroscopy of Commercial and *C. neoformans* Fungal Mushroom Preparations. The heterogeneous and amorphous character of melanin pigments combined with their insolubility in aqueous buffers requires specialized techniques such as solid-state NMR to elucidate the constituent chemical moieties present in the intact pigment. The ^{13}C CPMAS spectrum of *C. neoformans* L-DOPA melanin revealed similar resonances to prior ^{13}C NMR reports for fungal melanin ghosts, exhibiting major indole-based aromatic and/or olefinic

DOI: 10.1021/acs.jafc.5b02713
J. Agric. Food Chem. 2015, 63, 7326−7332

carbons (110−160 ppm) and additional long-chain methylene groups ($(CH_2)_n$, 20−40 ppm), oxygenated aliphatic carbons (CH_nO, 50−105 ppm), and carboxyls or amides (COO or CONH, 170−173 ppm)[20,21] (Figure 5). The resonances at 30, 24, and 15 ppm can be attributed to a typical pattern from $-(CH_2)_n-CH_2CH_3$ alkyl chains.[20] The broad aromatic spectral envelope centered at ∼128 ppm is attributable to overlap of resonances from slightly dissimilar aromatic indole-based constituents, structural heterogeneity of the disordered pigment materials, and/or the presence of paramagnetic species, as demonstrated by the EPR results.

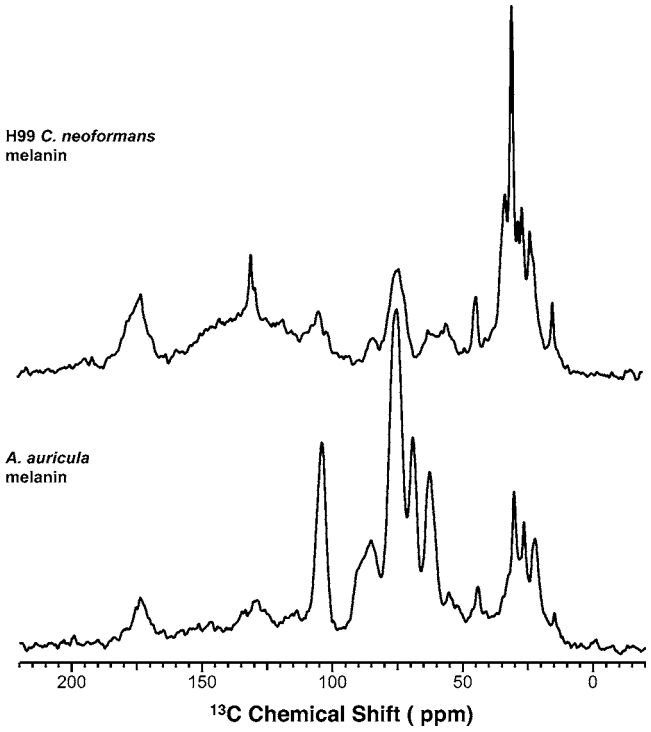

Figure 5. 150 MHz ^{13}C NMR spectra of *C. neoformans* melanin produced with natural abundance L-DOPA (top) and commercial mushroom melanin (bottom), measured at 20 kHz MAS using the quantitatively reliable multiple cross-polarization magic-angle spinning technique. Each spectrum is normalized by setting the largest peak to full scale.

The quantitatively reliable multiple-CPMAS ^{13}C spectra of the purified melanin pigment obtained from commercial *A. auricula* mushroom materials had several features comparable to those of the *C. neoformans* melanin. However, the spectra also manifested several structural differences, including modest signal intensity from aromatic moieties (110−160 ppm), diminished signals from the alkyl chains (20−40 ppm), and significantly enhanced signals from oxygenated carbons (50−105 ppm) (Figure 5). As deduced for the NMR spectra of *C. neoformans* melanin ghosts, key oxygenated aliphatic carbon moieties in the mushroom sample included signals from a range of functional groups, such as CH_3O and CH_2CH_2O (40−60 ppm), CH_2O (62 ppm), and CHO groups (69, 75, 86, and 105 ppm), that could be derived from attached cell-wall polysaccharides. A set of relatively sharper oxygenated carbon resonances for the mushroom-derived material suggests a comparatively ordered cell-wall matrix; the prominence of the oxygenated carbon NMR signals also conforms with elemental analysis results that imply a larger percentage of oxygen. Our NMR spectra supported the presence of chemically recalcitrant aliphatic frameworks associated with melanization in both pigmented samples that underwent exhaustive degradative treatments (Figure 2).

DISCUSSION

The aim of this study was to analyze the nature of the melanin pigment from *A. auricula* commercial mushroom preparations, in the context of exploring the feasibility of using those products as sources of edible protectants for ionizing radiation. SEM revealed significant ultrastructural differences in the morphology of the constituents of these preparations. The yield of the melanin obtained from the *A. auricula* commercial powder was in agreement with that reported previously from intact mushrooms.[9] Scanning electron micrographs of isolated melanin showed a very different product compared to the initial mushroom preparations: isolated melanin consisted of a heterogeneous population of fragments with high specific surface area. This final material was resistant to acid hydrolysis, a property that it shares with *C. neoformans* fungal melanin.

Isolated melanin from *C. neoformans* appears as empty melanin spheres that conserve the fungal cell's shape and were thus named melanin "ghosts". The morphology observed in the TEM images of *A. auricula* commercial mushroom preparations was more heterogeneous than fungal cells, and the dark material appeared to be associated with different areas of the respective materials. However, when the melanin recovered from the mushroom powder was analyzed by TEM, very discrete, closed, and empty dark structures were observed that retained the shape of the inner layer of cell walls. Hence, these *A. auricula* cell-wall ghosts could be viewed as comparable to the *C. neoformans* melanin ghosts that retained the shape of individual yeast cells.[24,26] Electron micrographs at higher magnification showed that the commercial mushroom melanin is composed of small spherical units with an estimated diameter of 20−100 nm, with the smallest particle size estimated as 20−30 nm. An in-depth microscopy analysis of *C. neoformans* melanin showed a similar size distribution,[28] indicating that the ultrastructural morphology of melanin is similar in both microscopic and macroscopic fungi. Similar analysis of the surfaces of isolated melanin from hair melanosomes and *Sepia officinalis* showed substructures in the size range of a few to 30 nm.[29]

To confirm that the black residue recovered from commercial mushroom powder was melanin, we conducted a standardized test based on EPR analysis, which takes advantage of the fact that melanin pigments contain a stable free radical population.[25] The dark material from commercial mushroom had a spectrum similar to that of *C. neoformans* melanin[24] and responded to either illumination with a bright lamp or addition of $ZnCl_2$ with a significant increase in the EPR signal.[24] These results establish that the pigment conforms to spectroscopic criteria assigned to melanins.

The molar C/N ratios of the *C. neoformans* and black mushroom melanin were 10.6 and 24.8, respectively, indicating differences between the melanin structures. No sulfur was found, so both materials could be classified as eumelanins. In agreement with previous studies on *A. auricula* melanin,[9] the low percentage of N revealed by elemental analysis suggested that commercial *A. auricula* mushroom melanin contains some DHN melanin. Nonetheless, oxidative high-performance liquid chromatography of *A. auricula* melanin in the cited study detected the presence of pyrrole-2,3-dicarboxylic acid, an

DOI: 10.1021/acs.jafc.5b02713
J. Agric. Food Chem. 2015, 63, 7326−7332

oxidation product of DHI. Thus, it is possible that *A. auricula* contains a mixture of DHN and DHI/DHICA melanins. Of note, both *C. neoformans* and commercial mushroom melanins showed a higher C/N ratio compared to synthetic and human hair melanins, also suggesting a divergence in structural features and/or an association with denaturant- and proteinase-resistant materials for these latter eumelanins.

Solid-state NMR analysis provided additional evidence for differences in carbon-containing structures between *C. neoformans* and commercial mushroom melanins. Analysis of the ^{13}C CPMAS spectral features associated with carbon-containing moieties showed diminished contributions at chemical shifts corresponding to aromatic and alkyl chain moieties, but significantly enhanced signals from the oxygenated carbons. The larger proportion of oxygenated carbons was also reflected in our elemental analysis results, from which percentage O values can be calculated as 51.60 for *A. auricula* and 28.34 for *C. neoformans*, respectively. Given the comparable colors, EPR intensities, and EPR line widths for *C. neoformans* and *A. auricula* mushroom samples, the weaker mushroom aromatic spectral contributions could reflect broadening associated with closer proximity to the unpaired electrons. Similar to *C. neoformans* melanin, NMR signatures associated with cell-wall polysaccharides were detected in the commercial mushroom preparation.[20,21,26,27] The sharper oxygenated carbon resonances displayed for commercial mushroom melanin suggested a more ordered cell-wall matrix as well as a different type of scaffolding on which the pigment can assemble.

A previous study demonstrated that isolated melanin from *A. auricula* mushrooms protects mice from acute ionizing radiation when administered orally.[9] Although the current study did not test the capacity of the fungal melanin isolated from mushroom powder to protect mice, the near identity of the melanins isolated from *A. auricula* whole mushrooms and commercially available powdered mushroom preparations suggests that the latter can offer a relatively cheap and plentiful source of melanin for future radioprotective studies. The location of melanin at the cell wall, according to our ultrastructural studies, suggests that cells will be protected from ionizing radiation going deeper into the cells.

Given the ongoing necessity of new oral radioprotectors suitable for treatment before acute radiotherapy or to alleviate the effects of radiation during catastrophic events, ingestion of melanin from powdered mushrooms could represent a new inexpensive and safe protective protocol.

In summary, we characterized the pigment derived from a commercial *A. auricula* mushroom as an edible source, established that it was a melanin by spectroscopic criteria, and characterized it using ultrastructural techniques and solid-state NMR as well as EPR. Melanin is insoluble and indigestible, yet it can provide medicinal effects by its presence in the gastrointestinal tract through its ability to mediate local shielding against external radiation. Melanin has the additional distinction of being an edible stable free radical, although the biological effects associated with this characteristic during its residence in the gastrointestinal tract remain to be determined. Melanins have electronic properties and metal-binding capacities that could be exploited for several purposes, making the availability of commercial non-toxic melanin sources promising for future studies to assess their clinical and technological usefulness.

J. Agric. Food Chem. 2015, 63, 7326−7332

published procedure.[13] Preparative silica gel (SiO_2) chromatography was used to fractionate TWK10-fermented soy milk water extract. Sequential elution using ethyl acetate (EA)/methanol (MeOH) (9:1), EA/MeOH/H_2O (7:3:0.5), EA/MeOH/H_2O (7:3:2), EA/MeOH/H_2O (7:3:4), and isopropanol/H_2O (7:3) resulted in five fractions (F1−F5) being obtained. Fractions F2 and F4 were further separated using a RP-HPLC system (Thermo, Waltham, MA, USA) coupled to a variable UV absorbance detector (Thermo) operated at 254 nm. The chromatogram was recorded using an electronic integrator (Thermo). Chromatographic separation was performed using a C18 RP analytical HPLC column [YMC-Pack ODS-AQ (25 μm, 12 nm) 250 × 10 mm i.d.] (YMC Co., Ltd., Kyoto, Japan). The composition of the mobile phase during the gradient elution was increased linearly from 0 min (100% water and 0% acetonitrile) to 30 min (85% water and 15% acetonitrile). The flow rate was held constant at 2 mL/min. Five isolates were collected from each fraction, named F2-1−F2-5 and F4-1−F4-5, and the inhibitory effects of these subfractions on ACE activity were investigated. Moreover, F2-2 and F2-3 were further isolated using TLC [solvent EA/MeOH/H_2O (8:3:1)], and detected at a UV absorbance of 254 nm. Four subfractions were obtained from F2-2 and F2-3, which were named F2-2A, F2-2B, F2-3A, and F2-3B, respectively. The inhibitory effects of these four subfractions on ACE activity were then determined. Finally, the ACE inhibitor, F2-2A, was identified. Time-of-flight mass spectrometry TOF MS data were obtained using a Microflex MALDI-TOF MS (Bruker Daltonics, Billerica, MA, USA). NMR spectra were obtained using Varian NMR spectrometers (Varian Gemini 500 MHz; Varian Inc., Palo Alto, CA, USA) using D_2O as solvent.

Measurement of ACE Inhibition. ACE inhibition was measured according to the method described by Cushman and Cheung with some modifications.[14] Aliquots (50 μL) of buffered substrate solution (12.5 mM HHL in 100 mM borate buffer solution containing 300 mM NaCl; pH 8.3) were mixed with samples (50 μL) at each tested concentration, and then pre-incubated at 37 °C for 5 min. ACE (25 μL; 25 mU/mL) was added to the reaction, which was incubated at 37 °C for 20 min. The enzymatic reaction was stopped by adding 0.5 N HCl (1 mL). The hippuric acid that was released because of ACE activity was extracted with ethyl acetate (1 mL), which was then dried. The sediment was dissolved in deionized water (1 mL), and the absorbance at 228 nm was measured. The inhibitory activity was calculated using the following equation: ACE inhibitory activity (%) = $100 \times [(A - B) - (C - D)]/(A - B)$, where A is the absorbance of a solution containing ACE but no sample, B is the absorbance of a solution containing ACE that had been previously inactivated by the addition of HCl but no sample, C is the absorbance of a solution containing both ACE and the sample, and D is the absorbance of a solution containing HCl-inactivated ACE and the sample.

Lineweaver−Burk Plots. The kinetics parameters were evaluated by Lineweaver−Burk's method. Briefly, 160 μL of FAPGG (dissolved in 50 mM Tris-HCl buffer containing 0.3 M NaCl, pH 7.5) was mixed with 20 μL of ACE (final activity of 20 mU) and 20 μL of CUG. The rate of decrease in absorbance at 345 nm was recorded for 10 min at room temperature. Distilled water was used instead of CUG solution in the blank experiment. The kinetics of ACE inhibition was studied with 0.0625, 0.125, 0.25, and 0.5 mM FAPGG.

In Vivo Assay of Antihypertensive Effect over Short- and Long-Term Intake. A total of 42 SHRs (13 weeks old, 260−300 g) and 6 Wistar Kyoto (WKY) rats (13 weeks old, 260−300 g) were used in this experiment and were obtained from BioLASCO Taiwan Co., Ltd. (Taipei, Taiwan). The animals were maintained at a temperature of 21 ± 2 °C and a relative humidity of 55 ± 10% with 12 h light/dark cycles in the Fu Jen Laboratory Animal Center (Taipei, Taiwan). Rats were fed tap water and a standard diet (5001-Laboratory Rodent Diet; LabDiet, St. Louis, MO, USA).

Each sample was dissolved in distilled water (1 mL) and was administered orally by gastric intubation between 12 and 1 p.m. Distilled water was used as a negative control, and the known antihypertensive agents CAP (50 mg/kg) and GABA (0.76 mg/kg) were used as positive controls.[15] The dose was based on 400 mL/day/person (weight was 65 kg and height of 170 cm), and human doses were converted to animal equivalent doses using the Boyd formula.[16] The dose of TWK10-fermented soy milk water extract powder was 0.51 g/kg.

The dose of combined uracil and glycerol (CUG) was based on the content of TWK10-fermented soy milk water extracts. The 1:1, 1:2, and 1:3 ratios of uracil/glycerol (1.24/1.24 mg/kg, 1.24/2.48 mg/kg, and 1.24/3.72 mg/kg, respectively) were dissolved in distilled water and administrated orally, and their antihypertensive effects in SHRs were evaluated 8 h after treatment. Moreover, low- and high-doses of soy milk extracts (0.51 and 2.55 g/kg, respectively) and low (uracil, 1.24 mg/kg; glycerol, 3.72 mg/kg) and high (uracil, 6.20 mg/kg; glycerol, 18.60 mg/kg) doses of CUG were administered. Systolic blood pressure (SBP) and diastolic blood pressure (DBP) were recorded using the tail-cuff method before administration and at 4, 8, and 24 h postadministration using a BP-2000 Blood Pressure Analysis System (Visitech System, Inc., Apex, NC, USA). Before measurements, the rats were kept at 37 °C for 40 min to detect pulsations in the tail artery. Five readings were taken, and the mean of all measurements was calculated. To minimize stress-induced variations in BP, the same individual made all measurements in the same peaceful environment. A training period of 2 weeks was established before the actual trial time, during which time the rats became accustomed to the procedure, to guarantee the reliability of the measurements.

After the short-term tests, the SHRs continued to receive low and high doses of CUG for 8 weeks, and SBP and DBP were recorded biweekly. Twenty-four hours before sacrifice, all food was removed. Animals were anesthetized by carbon dioxide inhalation and sacrificed. Blood was collected by cardiac puncture, and serum samples were obtained by drawing the blood into a serum separated tube, allowing it to clot, and centrifuging it for 10 min at 3000g to separate serum. In addition, plasma was obtained by collecting blood in heparinized syringes containing 5% heparin and 2% sodium citrate and centrifuging at 3000g for 15 min. The aorta, liver, lung, and kidney tissues were cleaved and divided into two parts; one part was homogenized (2 g in 10 mL of PBS) using a FastPrep System (MP Biomedicals, Santa Ana, CA, USA), and the other was immediately fixed in 10% neutral buffered formalin for further histological analysis. The experiment was reviewed and approved by the Animal Care and Research Ethics Committee of the Fu Jen Catholic University (IACUC approval A10105).

Biochemical and Histological Assessment. The activity of ACE in liver, lung, and kidney tissues was determined as previously described (see Measurement of ACE Inhibition). The serum level of bradykinin in SHRs was determined using a bradykinin enzyme immunoassay kit (Uscn Life Science Inc., Houston, TX, USA). The levels of aldosterone and renin activity in plasma were evaluated using a Wallac 2470 WIZARD^2 gamma counter (PerkinElmer Life and Analytical Sciences, Waltham, MA, USA), and AngII levels were measured using an AngII EIA kit (Phoenix Pharmaceuticals, Inc., Burlingame, CA, USA). The level of nitrite (NO^{2-}) and nitrate (NO^{3-}) anions in plasma was measured using a nitric oxide EIA kit (Cayman Chemical Co., Ann Arbor, MI, USA). The level of lipid peroxide in serum was determined by measuring the thiobarbituric acid reactive substance (TBARS) concentration as an index of lipid peroxidation, according to the Yagi method.[17] In addition, the activity of SOD was measured using an SD125 kit supplied by Randox Laboratories Ltd. (Crumlin, UK).

The aorta samples from each of the rats were divided into two parts. One part was for evaluating the vascular elastin distribution and nitric oxide synthase (eNOS) protein expression. The other part was used to determine the protein expression of calmodulin (CaM). To prepare them for optical microscopy, the aorta samples were embedded in paraffin, and sections were stained with hematoxylin−eosin. Verhoff's stain was used to evaluate the expression and distribution of vascular elastin. eNOS protein expression was quantified with an immunohistochemical assay according to the method of Zhao et al. and examined using an Nikon TS-100 microscope (Tokyo, Japan). Motic Images 2000 software (Xiamen, China) was used for examination of hypertensive tissues changes. In addition, CaM protein levels were

DOI: 10.1021/acs.jafc.5b01649
J. Agric. Food Chem. 2015, 63, 7333−7342

investigated using Western blotting. The aorta samples (0.2 g) were homogenized with Nonidet P-40/SDS lysis buffer (200 μL; 1% Nonidet P-40, 0.01% SDS, 0.1 M Tris-HCl at pH 7.2, 100 mM phenylmethanesulfonyl fluoride, and 1 mg/mL of aprotinin) using a FastPrep System (MP Biomedicals). The lysate was centrifuged at 11000*g* for 20 min at 4 °C, and supernatants were collected. Each gel lane was loaded with total protein from the cell extracts (40 μg). Proteins were resolved by SDS-PAGE using a 7.5% acrylamide gel and then transferred to a nitrocellulose membrane. Blocking was performed in Tris-buffered saline containing 2% nonfat milk powder. Membranes were incubated overnight at 4 °C, in blocking solution containing anti-CaM antibody (Santa Cruz Biotechnology, Inc., Dallas, TX, USA) (1:500) and mouse anti-β-actin monoclonal antibody (Chemicon International, Inc., Temecula, CA, USA) (1:5000). Blots were then incubated in blocking buffer containing the corresponding horseradish peroxidase-conjugated secondary antibodies for 1 h at 25 °C. Protein bands were visualized using an enhanced chemiluminescence kit (Amersham Pharmacia Biotech, Arlington Heights, IL, USA), and a UVP image analysis system (UVP, Upland, CA, USA). Analysis was performed using Gel-Pro Analyzer 4 (Media Cybernetics, Inc., Rockville, MD, USA).

Statistical Analysis. All values represent means and standard deviations of three repeats. Data were then compared using Duncan's multiple-range method using SPSS statistical analysis software.

Table 1. Inhibitory Effect of the Uracil and Glycerol on ACE[a]

group	ACE inhibitory activity (%)
CAP	74.21 ± 0.73 A
uracil, 10 μg/mL	24.31 ± 8.45 B
glycerol, 30 μg/mL	ND
1:1 ratio of uracil/glycerol (10 μg/mL/10 μg/mL)	72.92 ± 3.14 A
1:2 ratio of uracil/glycerol (10 μg/mL/20 μg/mL)	72.58 ± 2.88 A
1:3 ratio of uracil/glycerol (10 μg/mL/30 μg/mL)	70.94 ± 3.83 A

[a]Data are presented as the mean ± SD (N = 3). Values with different letters in the same column are significantly different by Duncan's multiple-range test (p < 0.05). ND, not detected; CAP, captopril at a concentration of 3.4 mM.

RESULTS AND DISCUSSION

ACE-Inhibitory Ingredients in TWK10-Fermented Soy Milk Extract. The half-maximal inhibitory concentration (IC_{50}) value of water extract from TWK10-fermented soy milk for ACE inhibition was 5.61 mg/mL. After extensive fractionation of the TWK10-fermented soy milk water extract, the IC_{50} values of F2, F3, and F4 were 43.44, 100.00, and 36.91 μg/mL, respectively. Fractions F2 and F4 had the higher inhibitory effect on ACE and were further separated using a RP-HPLC system. In addition, subfractions F2-3 and F4-3, derived from F2 and F4, respectively, had the same retention time (13 min) during the separation using the RP-HPLC system. Moreover, the IC_{50} values of F2-2, F2-3, and F4-3 were 7.26, 9.19, and 9.35 μg/mL, respectively. According to our findings, F2-3 and F4-3 had similar retention times and IC_{50} values; there is an empirical basis to support the fact that these two isolates were hypothesized as the same one. Furthermore, F2-2A and F2-3B had better ACE inhibitory effect than others, and the IC_{50} values of F2-2A and F2-3B were 1.35 and 2.37 μg/mL, respectively, after extensive fractionation of F2-2 and F2-3. A component fraction, F2-2A, was isolated as a white amorphous solid and identified as one of the inhibitors having ACE inhibitory activity (68.94 ± 7.47 and 49.3 ± 4.7% at 10 and 1 μg/mL, respectively). The following spectral data allowed the fraction to be identified as a mixture of uracil and glycerol (Supplemental Figure 1): TOF MS, m/z 113.0498 $[M + H]^+$ for uracil and 115.0516 $[M + Na]^+$ for glycerol (Supplemental Figure 2); ^{1}H NMR (D_2O, 500 MHz) δ 3.54 (2H, dd, J = 6.5 and 11.5, H-7 and 9), 3.63 (2H, dd, J = 6.5 and 12.0, H-7 and 9), 3.76 (H, tt, H-8), 5.78 (H, d, J = 8.0, H-5), and 7.51 (H, d, J = 8.0, H-6) (Supplemental Figure 3); ^{13}C NMR (D_2O, 125 MHz) δ 63.46 (C-7 and 9), 79.04 (C-8), 101.38 (C-5), 144.33 (C-6), 153.99 (C-2), and 168.35 (C-4) (Supplemental Figure 4).

Sugar nucleotides act as substrates during the biosynthesis of polysaccharides in higher plants. Uridine diphosphoglucuronic acid donates D-glucuronosyl units for the synthesis of several types of structural polysaccharides. It is also the precursor of other nucleotide sugars, including uridine diphosphate galacturonic acid, uridine diphosphate xylose, uridine diphosphate L-arabinose, and uridine diphosphate D-apiose, which are incorporated into pectin and hemicelluloses in plants.[18] Previous

studies suggested that uracil formation is a consequence of the enzymatic hydrolysis of uridine by microorganisms.[19] In addition, Hidalgo et al. reported that the presence of uracil in tomato products is an index of LAB contamination, suggesting that uracil is a metabolic product that correlates with the growth of LAB in the presence of uridine.[20] In the present study, lipids were present in unfermented soy milk (1.4%, w/w), and lipase activity was observed (data not shown). Taken together, these data suggest that the functional ingredients, uracil and glycerol, were present TWK10-fermented soy milk. In addition, Schanker and Tocco demonstrated that uracil is absorbed across the rat intestinal epithelium via an active transport mechanism.[21] Moreover, the principal transport mechanism for glycerol in the rat small intestine is passive (diffusive) transport via the paracellular route and an Na^+-dependent carrier-mediated transport system. Therefore, these two functional ingredients are theoretically both absorbed in the rat small intestine.

Inhibitory Effects of Uracil and Glycerol on ACE Activity in Vitro. The uracil content in TW10-fermented soy milk water extracts was analyzed using HPLC according to a method described by Deporte et al.[22] and was found to be 2.44 ± 0.07 mg/g in dried powder. In addition, the glycerol content of soy milk extract was 7.31 ± 0.58 mg/g as shown using enzymatic kits (GY105, Randox Laboratories Ltd., Crumlin, UK). The ratio of uracil and glycerol was nearly 1:3. The ACE inhibitory effects of different ratios of pure uracil and glycerol were then evaluated. As shown in Table 1, there were no significant differences between each ratio of uracil/glycerol ($p > 0.05$) and the positive control. Each substance alone had little or no effect on ACE activity.

Glycerol is a water-soluble trivalent alcohol normally present in human tissues as an integral part of both fats and triglycerides. It is readily metabolized, primarily in the liver, and systemic hyperosmolarity may be reduced and dehydration limited. MacDonald and Uden (1982)[23] indicated that intravenous glycerol and mannitol were equally effective in lowering acute elevations of intracranial pressure. Previous studies employing glycerol as a major osmotherapy agent entailed pharmacologically inert substances that increase the osmotic pressure of plasma, promoting movement of water from interstitial spaces to vascular spaces.[24] Osmotic agents include mannitol, urea, sorbitol, glycerol, and hypertonic saline, and they have primarily been applied in the treatment of cerebral infarction, experimental ischemia, traumatic intracranial hypertension, or edema.[25] In the current study, uracil and glycerol had low or no ACEI activity, respectively, and the inhibitory effect rose with an increase in the ratio of uracil/glycerol (from 1:1 to 1:3), indicating that the presence of glycerol increased the inhibitory effects of ACE by increasing the level of uracil to bind to ACE.

The mode of ACE inhibition by CUG was investigated by kinetic studies using Lineweaver–Burk plots. As shown in Figure 1, the double-reciprocal plots of ACE-catalyzed reactions in the absence and presence of a combination of uracil and glycerol indicate mostly uncompetitive inhibition of ACE activity. The result suggests that the combination of uracil and glycerol exhibited activities by binding to only the enzyme–substrate complex. The combination of uracil and glycerol as an uncompetitive inhibitor can bind to the enzyme–substrate complex to prevent catalysis. The K_m value for ACE activity in the absence of the combination of uracil and glycerol was 0.08 mM FAPGG, and V_{max} was 0.005. The presence of the

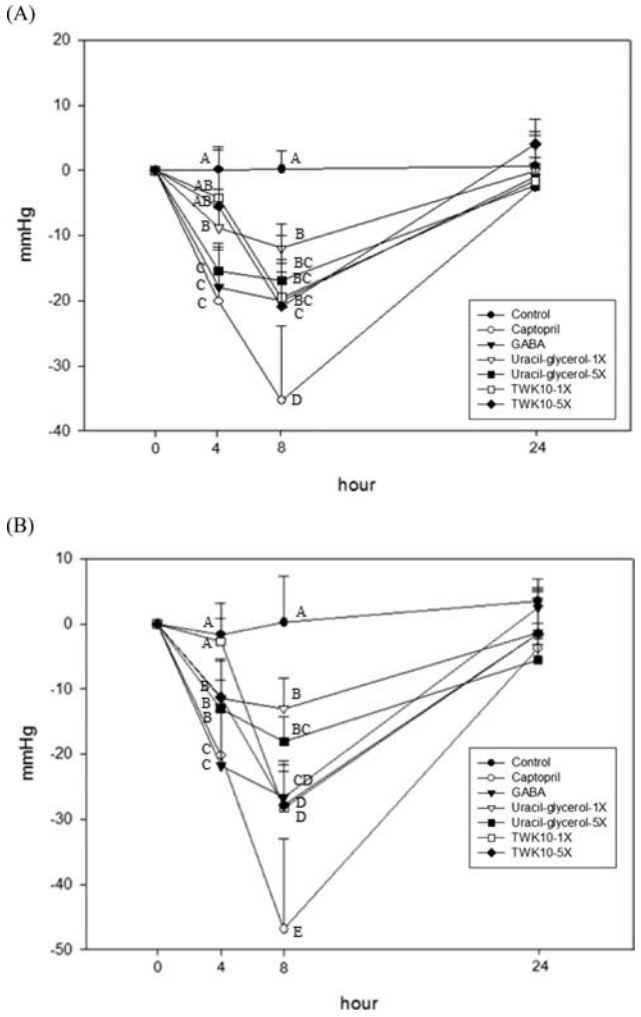

Figure 2. Effect of the single oral administration of TWK10-fermented soy milk water extract and combined uracil and glycerol treatment on (A) systolic and (B) diastolic blood pressure in spontaneously hypertensive rats. Control, administration of H_2O; captopril, administration of captopril at a dose of 50 mg/kg; GABA, administration of γ-aminobutyric acid at a dose of 0.76 mg/kg; uracil-glycerol-1×, administration of combined uracil and glycerol at doses of 1.24 and 3.72 mg/kg bw, respectively, 0.76 mg/kg bw; uracil-glycerol-5×, administration of combined uracil and glycerol at doses of 6.20 and 18.60 mg/kg bw, respectively, 0.76 mg/kg bw; TWK10-1×, administration of soy milk extracts at a dose of 0.51 g/kg bw; TWK10-5×, administration of soy milk extracts at a dose of 2.55 g/kg bw. Data are presented as means ± SD ($n = 6$). Values with different letters were significantly different according to Duncan's multiple-range test ($p < 0.05$).

combination of uracil and glycerol resulted in concentration-dependent decreases in both V_{max} and K_m values.

In the uncompetitive inhibition system, the inhibitor bound only to the enzyme–substrate complex and decreased the maximum enzyme activity, taking longer for the substrate or product to leave the active site. Most ACE inhibitory peptides obtained from the hydrolysis of pea (*Pisum sativum* var. Bajka) globulins,[26] rapeseed protein digest,[27] chickpea,[28] or wakame (*Undaria pinnatifida*)[29] belong to uncompetitive inhibitors. In addition, nonpeptide compounds such as usnic acid from lichen species *Usnea complanata* under submerged fermentation or polyphenols from tea (*Camellia sinensis*) also showed an uncompetitive type of ACE inhibition.[30,31] According to our

findings, based on kinetic studies using Lineweaver−Burk plots, the CUG demonstrated mostly uncompetitive inhibition of ACE activity, and we can hypothesize that a conformational change in ACE occurs upon binding to the substrate, which presents a binding site for CUG. As a result, inhibition occurs because the substrate−enzyme−inhibitor complex cannot form the final product in vitro.

Antihypertensive Effects of Soy Milk Extract and CUG on SHRs in Short-Term Study. The antihypertensive effects of TWK10-fermented soy milk water extracts and CUG were investigated in SHRs. The initial SBP and DBP were measured as reference values before the oral administration of samples. As shown in Figure 2, there was no significant difference in the SBP and DBP of the control group during the 24 h after oral administration of the samples ($p > 0.05$). In the CAP group, SBP and DBP were suppressed by 20.11 ± 8.35 and 20.20 ± 7.84 mmHg, respectively, after 4 h, and by 35.31 ± 11.52 and 46.91 ± 13.92 mmHg after 8 h ($p < 0.05$). GABA was used as an additional positive control and suppressed SBP by 17.90 ± 5.75 and 19.96 ± 6.25 mmHg ($p < 0.05$) after 4 and 8 h, respectively.

The uracil content in the low dose of soy milk extract was 1.24 mg/kg, and this was used to determine the low dose of uracil in CUG. Doses of 1:1, 1:2, and 1:3 ratios of uracil/glycerol (1.24/1.24 mg/kg, 1.24/2.48 mg/kg, and 1.24/3.72 mg/kg, respectively) were administered orally to evaluate their antihypertensive effect 8 h after treatment of SHRs. The SBP and DBP of rats was suppressed most effectively by the 1:3 uracil/glycerol, which induced reductions of 12.18 ± 3.13 and 10.47 ± 3.07 mmHg, respectively ($p < 0.05$). This ratio was used in subsequent experiments.

As shown in Figure 2, there was no significant difference between the SBP and DBP in the negative control group rats and those that received the low dose of soy milk extract (0.51 g/kg) 4 h after treatment ($p > 0.05$). However, 8 h after treatment, the extract decreased SBP and DBP significantly by 19.54 ± 9.54 and 28.19 ± 7.14 mmHg, respectively ($p < 0.05$ versus negative control). A high dose of soy milk extract (2.55 g/kg) significantly suppressed DBP 4 h after treatment and SBP after 4 and 8 h, compared with the negative control group ($p < 0.05$). Moreover, the SBP of rats treated with low and high doses of CUG was decreased by 8.83 ± 4.18 and 15.42 ± 4.21 mmHg, respectively, 4 h after oral administration ($p < 0.05$), compared with the control group. It was also reduced 8 h after oral administration ($p < 0.05$), compared with the low and high doses of soy milk extract. The low and high doses CUG suppressed SBP significantly by 11.97 ± 3.71 and 16.89 ± 2.59 mmHg and DBP by 13.01 ± 4.77 and 18.03 ± 3.74 mmHg, respectively, compared with the control group. The initial DBP and SBP values were restored to the initial levels after 24 h. These data show that CUG was more effective than soy milk extract 4 h after oral administration. However, the TWK10-fermented soy milk water extract suppressed DBP more potently than CUG after 8 h, suggesting that there might be additional functional ingredients in the other fractionated extract.

Antihypertensive Effects of CUG on SHR in Long-Term Study. Tables 2 and 3 show the changes in SBP and DBP during 8 weeks of CUG administration. There was no significant difference in the SBP and DBP of the all groups before oral administration of the samples ($p > 0.05$). During the 8 week period, SBP and DBP of the control group increased. The low and high doses of CUG significantly suppressed SBP and DBP after 4 and 8 weeks of administration ($p < 0.05$) compared to control. In the low-dose CUG group, SBP and DBP both increased significantly between the baseline and after 4 weeks of administration and between 4 and 8 weeks ($p < 0.05$). However, in the high-dose CUG group neither SBP nor DBP had significant changes over the 8 weeks ($p > 0.05$). In summary, although long-term oral administration of a

HDG	7.95 ± 2.96 C	13.20 ± 2.98 E	18.28 ± 3.24 C

[a]Data are presented as means ± SD (N = 6). Values with different letters are significantly different by Duncan's multiple-range test (p < 0.05). N, normal control group; C, hypertension control group; GABA, administration of γ-aminobutyric acid at a dose of 0.76 mg/kg bw; LDG, administration of combined uracil and glycerol at doses of 1.24 and 3.72 mg/kg bw, respectively; HDG, administration of combined uracil and glycerol at doses of 6.20 and 18.60 mg/kg bw, respectively.

low-dose CUG suppresses the increase in SBP and DBP in SHRs, a high dose of CUG is required to prevent an increase in BP entirely. In addition, the difference in effectiveness between low and high doses of CUG after 8 weeks of administration reached significant levels (p < 0.05), indicating a positive correlation between the dose of CUG and its efficacy.

Effect of Long-Term CUG Treatment on Elastin Arrangement in Arcuate Arteries of SHRs. Elastin is a protein that maintains vascular elasticity and gives blood vessels the capacity to stretch and contract. Previous studies have indicated that hypertension causes excessive pressure within blood vessels, leading to an altered distribution of elastic fibers.[32] Figure 3 shows that elastin in untreated SHRs was the most disorganized. After 8 weeks of treatment with higher doses of CUG, fibers were more ordered, indicating a positive correlation between CUG dose and elastin arrangement. This result indicated that CUG can improve the elasticity and tensile strength of blood vessels. In addition, there have been reports that spontaneous hypertension increases levels of elastin and causes inelastic fibrous masses to accumulate within blood vessels.[33] In this study, elastin bands in arteries were counted (Table 4), and significantly fewer were found in the two CUG-treated groups (p < 0.05). In summary, the elastin fibers in the aorta of CUG-treated SHRs were significantly straighter than those of controls, affecting the elasticity of vessels and aiding in the improvement of hypertension.

Regulatory Effects of Long-Term Administration of CUG on the RAS in SHRs. Figure 4A shows the aldosterone levels in plasma of SHRs after 8 weeks of administration of CUG and indicates that administration of low and high doses of CUG caused significant decreases in aldosterone level, compared with the control group (p < 0.05). The results also show that AngII was significantly suppressed by both low and high doses of CUG, compared to the control group (p < 0.05) (Figure 4B). Figure 4C shows that only a high dose of CUG significantly increased the concentration of bradykinin after long-term administration. These results indicate that suppression of aldosterone levels may lead to the inactivation of the upstream catalytic enzyme. Moreover, Table 5 shows the effects of 8 weeks of CUG administration on ACE activity in the kidney, lung, and liver of SHRs. CUG was found to dose-dependently

LDG	2.38 ± 0.22 B	10.00 ± 1.69 B
HDG	2.43 ± 0.18 B	10.75 ± 2.71 B

[a]Data are presented as means ± SD (N = 6). Values with different letters are significantly different by Duncan's multiple-range test (p < 0.05). N, normal control group; C, hypertension control group; GABA, administration of γ-aminobutyric acid at a dose of 0.76 mg/kg bw; LDG, administration of combined uracil and glycerol at doses of 1.24 and 3.72 mg/kg bw, respectively, HDG, administration of combined uracil and glycerol at doses of 6.20 and 18.60 mg/kg bw, respectively.

Table 7. Effect of the Mixture of Uracil and Glycerol on Immunohistochemical of eNOS in the Sections of Aorta and Nitric Oxide Concentration in Plasma in SHRs[a]

group	eNOS density (%)	nitrate + nitrite (μM)
N	4.50 ± 2.84 A	16.73 ± 1.12 A
C	3.87 ± 1.76 A	16.23 ± 3.09 A
GABA	3.39 ± 2.59 A	16.58 ± 4.06 A
LDG	6.75 ± 2.91 A	15.50 ± 2.39 A
HDG	18.23 ± 4.89 B	22.45 ± 5.89 B

[a]Data are presented as means ± SD (N = 6). Values with different letters are significantly different by Duncan's multiple-range test (p < 0.05). N, normal control group; C, hypertension control group; GABA, administration of γ-aminobutyric acid at a dose of 0.76 mg/kg bw; LDG, administration of combined uracil and glycerol at doses of 1.24 and 3.72 mg/kg bw, respectively; HDG, administration of combined uracil and glycerol at doses of 6.20 and 18.60 mg/kg bw, respectively.

suppress ACE activity in the liver, kidneys, and lungs, and the results were significant (p < 0.05). In addition, GABA decreased ACE activity in the lung and liver because GABA suppresses BP through inhibition of sympathetic nerve activation and reduction of binding with α_1-receptors on vascular smooth muscle cells that connect with the RAS.[34,35]

DOI: 10.1021/acs.jafc.5b01649
J. Agric. Food Chem. 2015, 63, 7333−7342

Figure 4D shows that only the high dose of CUG caused a significant decrease in renin activity in SHRs, compared to the control group ($p < 0.05$). Previous studies indicate that blockade of the RAS leads to a feedback increase in renin secretion and synthesis.[36] The inhibitory effect of CUG on renin activity was determined in vitro in this study using a Renin Inhibitor Screening Kit (K799-100, BioVision, Inc., Milpitas, CA, USA). It was found that renin activity was significantly inhibited by 52.94 ± 6.79, 29.41 ± 3.23, 20.59 ± 3.19, 17.65 ± 4.24, and 5.88 ± 1.23% at concentrations of 1000, 100, 50, 10, and 1 μg/mL, respectively. In summary, CUG can decrease BP through AngII and the hormone aldosterone, downstream products of RAS. These downstream factors were regulated by suppressing renin activity and reducing ACE activity.

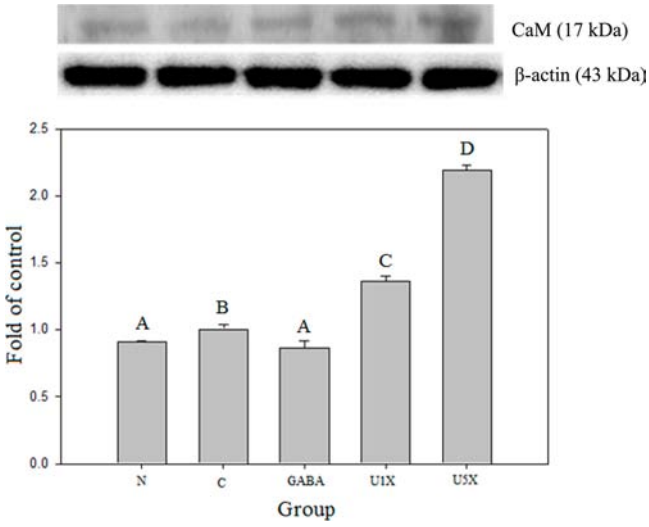

Figure 5. Expression of calmodulin by administration of combination of uracil and glycerol. Data are presented as means ± SD ($n = 3$). Bars with different letters are significantly different by Duncan's multiple-range test ($p < 0.05$).

Effects of Long-Term Administration of CUG on Antioxidant Capacity and Nitric Oxide (NO) Production in SHRs. Free radicals bind with NO, which then is then oxidized into peroxynitrate, reducing NO levels and affecting vasodialation. Additionally, the accumulation of products of lipid overoxidation—such as malondialdehyde (MDA)—in blood vessels causes atherosclerosis, resulting in an increase in BP. The effect of CUG administration on SOD activity and MDA was determined. Table 6 shows that the administration of low and high doses of CUG and GABA significantly increased SOD activity and decreased MDA levels compared to the control group ($p < 0.05$).

Table 7 shows the effect of CUG administration on plasma NO level and eNOS expression in SHRs. Plasma NO levels following a high dose of CUG increased 1.38 times, compared with the control group ($p < 0.05$); however, low-dose CUG administration made no difference ($p > 0.05$). Immunostaining showed that there was no difference in eNOS expression between low-dose CUG-treated and GABA-treated groups, compared to the control group ($p > 0.05$). However, the high-dose CUG administration significantly increased eNOS expression within arcuate arteries, 4.71 times greater than the control group ($p < 0.05$). This result corresponds with the NO level in the treated SHRs. Figure 5 shows that long-term administration of low and high doses of CUG increased CaM protein expression by 1.36 and 2.19 times, respectively, compared to the control group ($p < 0.05$). It can mediate eNOS activity by binding calcium ions to further produce NO.[37] In summary, administration of low and high doses of CUG can increase the SOD activity and decrease the MDA level to prevent NO bound with free radicals. In addition, eNOS and CaM expressions were also improved to increase the NO

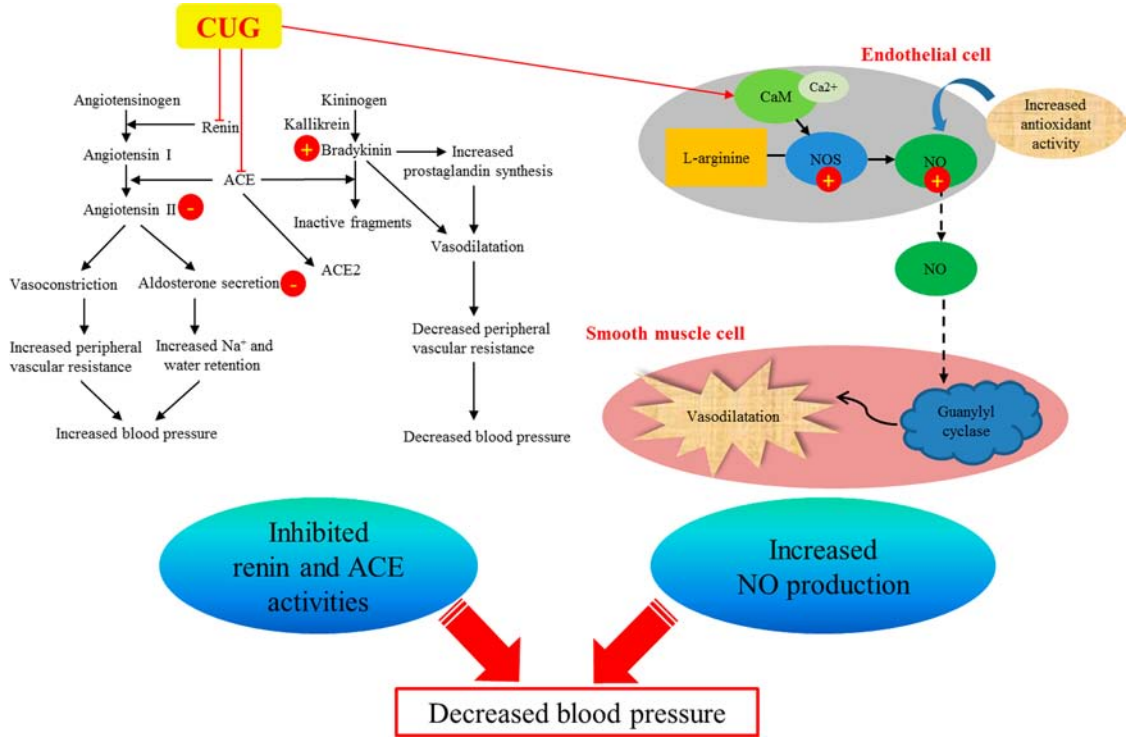

Figure 6. Mechanism of antihypertensive effect of combined uracil and glycerol treatment.

production. These factors can promote vasodilation, resulting in the improvement of hypertension (Figure 6).

BP is controlled by a number of different biochemical pathways. NO levels can be increased indirectly by enhancing the activity of endothelial eNOS. Upon entering smooth muscle cells, NO can activate guanylyl cyclase, increasing the accumulation of cyclic guanosine monophosphate and promoting smooth muscle relaxation.[38−40] Along with NO, ACE is an important factor that exerts a cardiovascular protective effect and regulates BP.[41] Oxidative stress has been implicated as a causal factor in diseases such as hypertension and atherosclerosis.[42,43] Martinez-Villaluenga reported that *Enterococcus faecium*-fermented soy milk inhibited ACE, had antioxidant activity, and had an antihypertensive effect.[10] The regulation of BP involves the RAS, which involves ACE; therefore, inhibiting ACE is a key target for regulating BP. Specifically, ACE inhibitors can lower BP by reducing the production of AngII and inhibiting the degradation of bradykinin.[44] This study indicated that SBP and DBP were suppressed following treatment with the CUG. A previous study indicated that the administration of LAB or related fermentation products suppressed SBP and DBP by 4.4−16 and 3.4−11 mmHg, respectively,[45−47] which was similar to the effect exerted by CUG in this study. In this work, we confirmed that the mechanism by which CUG reduces BP is by inhibiting ACE activity and suppressing the downstream vasoactive peptide AngII and the hormone aldosterone. Additionally, in the case of ACE inhibitors, blockade of the RAS leads to a feedback increase in renin activity,[36] and angiotensin I (AngI) can be observed; however, the renin activity of SHRs administered with CUG was suppressed. Moreover, the results revealed that renin activity was inhibited by CUG in vitro. It has been suggested that the CUG derivative derived from TWK10-fermented soy milk can be effective in lowering BP as either renin or ACE inhibitors and is an important novel finding as a functional foods.

In conclusion, we identified that a combination of uracil and glycerol was one of the ACE inhibitory functional ingredients in TWK10-fermented soy milk and have demonstrated that it works as a renin inhibitor, an ACE inhibitor, and a promotor of NO production and have shown that it is as effective as an existing drug at lowering BP in vivo for the first time. We are currently in the process of confirming another ACE inhibitor, F2-3B. Compared with peptides or other organic compounds described previously, CUG has significant BP-lowering effects, suggesting that they could be novel and potent natural ingredients in antihypertensive functional foods.[48−50]

summarized that the natural compounds may be potential to improve inflammasome-related diseases, including renal injury, diabetes, infection, and liver diseases.[15] However, it remains unclear whether the phenolic compounds exert the inhibitory effects on MSU-induced inflammation. We examined and selected the potential agents in several phenolic compounds, and this study aimed to investigate the effects and underlying mechanisms of these candidate molecules on MSU-induced inflammation and inflammasome activation in vivo and in vitro.

MATERIALS AND METHODS

Chemicals. Cinnamic acid, *o*-coumaric acid, *m*-coumaric acid, ferulic acid, *p*-hydroxybenzoic acid, vanillic acid, syringic acid, protocatechuic acid, gentisic acid, gallic acid, catechin, monosodium urate (MSU), 2′,7′-dichlorofluorescin diacetate (DCFH-DA), xanthine oxidase, phorbol 12-myristate 13-acetate (PMA), 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), colchicine, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), sulforhodamine B (SRB), β-mercaptoethanol, and nitro blue tetrazolium (NBT) were purchased from Sigma-Aldrich (St. Louis, MO, USA). The purity of the phenolic compounds was over 95%. RPMI-1640 medium and fetal bovine serum (FBS) were obtained from Gibco BRL (Grand Island, NY, USA). Penicillin−streptomycin and sodium pyruvate solution were obtained from Hyclone (Logan, UT, USA). Antibodies against caspase-1, β-actin, Bcl-2, DJ-1, and TRX were obtained from Cell Signaling Technology (Beverly, MA, USA). NLRP3 antibody was purchased from Abgent (San Diego, CA, USA). Dihydroethidium (DHE), MitoSOX red mitochondrial superoxide indicator, the TXNIP antibody, and Fluo3-AM were purchased from Life Technologies (Carlsbad, CA, USA). The JC-1 mitochondrial transmembrane potential assay kit was obtained from Cayman Chemical Co. (Ann Arbor, MI, USA).

Scavenging Free Radical Assay. The free radical scavenging assay was performed according to the methods of Orallo et al.[16] Briefly, free radical scavenging was measured as the absorbance at 570 nm using a FLUOstar Omega spectrophotometer (BMG Labtechnologies, Germany) after incubation with 200 μL of working solution (50 mM phosphate buffer, pH 7.4, 100 μM EDTA-2Na, 100 μM xanthine, and 100 μM NBT), 25 μL sample solution (5, 10, or 25 μM), and 25 μL xanthine oxidase (0.066 U) for 10 min. Allopurinol was used as a positive control.

Animal Treatment. The animal experiments were conducted in accordance with the guidelines of the National Institutes of Health and approved by the Institutional Animal Care and Use Committee (IACUC) of National Chung Hsing University (no. 101-81). Male C57BL/6 mice were purchased from the National Laboratory Animal Center (Taipei, Taiwan). The animals were provided a chow diet and water ad libitum under conditions of 22−24 °C, 40−70% relative humidity, and a 12 h light−dark cycle. Acute gout inflammation was induced by intraperitoneal injection with 3 mg of MSU in 0.5 mL of phosphate-buffered saline (PBS), and the mice were subcutaneously treated with or without phenolic compounds at 100 mg/kg body weight (BW) (n = 5). After 6 h, all mice were sacrificed using carbon dioxide (CO_2), and the mice were intraperitoneally injected with 4 mL of PBS.[17] The peritoneal fluid was then collected, and the volume of peritoneal fluid was about 2.5−3.0 mL from each mouse.

Identification of MSU Crystal-Elicited Neutrophils. The collected peritoneal exudate cells were washed and resuspended in PBS. The cells were stained with fluorescent antibodies against the specific surface markers Ly-6G (eBioscience, San Diego, CA, USA) and 7/4 (AbD Serotec, Raleigh, NC, USA) for 20 min at 37 °C in the dark, and the cell populations were sorted using a FACScan flow cytometer (Becton-Dickinson, San Jose, CA).

Cell Culture. The THP-1 cell line was purchased from the Bioresource Collection and Research Center (BCRC 60430, Food Industry Research and Development Institute, Hsinchu, Taiwan) and cultured in RPMI-1640 media with 10% (v/v) FBS, 100 μg/mL streptomycin, 100 U/mL penicillin, 10 mM HEPES, 1 mM sodium pyruvate, 1.5 g/L sodium bicarbonate, and 50 μM β-mercaptoethanol at 37 °C in a humidified atmosphere of 5% CO_2. THP-1 cells were treated with 100 nM PMA for 3 h to initiate the NF-κB pathway. The cells were subsequently treated with 75 μg/mL MSU crystals in the presence or absence of 20 μM phenolic compounds for 6 h as our previous methods.[18]

Cell Viability Assay. Cell viability was examined using MTT and sulforhodamine B (SRB) assays. For the MTT assay, the cells were cultured in 0.5 mg/mL MTT for 2 h at 37 °C, and formazan blue formation in cells was dissolved using dimethyl sulfoxide (DMSO). The optical density (OD) was detected at 570 nm using a FLUOstar Omega spectrophotometer. For the SRB assay, the cells were fixed in cold 10% trichloroacetic acid at 4 °C. A solution of SRB in 1% acetic acid was added to each well and incubated for 30 min. Cell-bound SRB was dissolved in 10 mM Tris base solution, and the absorbance was measured at 510 nm using a FLUOstar Omega spectrophotometer.

Cytokine ELISA Assay. Human IL-1β, mouse IL-1β, and mouse IL-6 cytokine secretions were measured using the ELISA kits (eBioscience, San Diego, CA, USA) according to the manufacturer's instructions.

Immunoprecipitation Assay. Immunoprecipitation was performed using the Catch and Release Reversible Immunoprecipitation System (Millipore, Billerica, MA, USA) according to the manufacturer's instructions. Treated THP-1 cells were washed with PBS and resuspended in lysis buffer containing 1× protease inhibitor cocktail (Sigma-Aldrich, St. Louis, MO, USA). Each cell lysate (500 μg) was incubated with 4 μg of anti-TXNIP antibody and 10 μL of antibody capture affinity ligand for 30 min at room temperature. The immunoprecipitated proteins were washed twice in 1× wash buffer, and the bound proteins were eluted in 70 μL of elution buffer.

Detection of Superoxide Anion and MtROS Production. The levels of superoxide anion and MtROS production were determined after treatment with 8 μM DHE and 2.5 μM MitoSOX red mitochondrial superoxide indicator, respectively, for 20 min at 37 °C using the FL-2 channel (excitation 488 nm and emission 585 nm) of a FACScan flow cytometer.

Detection of Mitochondrial Transmembrane Potential. The mitochondrial transmembrane potential was determined using the Cayman JC-1 assay kit according to the manufacturer's protocol. The mitochondrial transmembrane potential was detected using the FL-2 channel of a FACScan flow cytometer.

Detection of Intracellular Calcium Levels. Intracellular calcium levels were determined using Fluo3-AM stain. The cells were treated with 5 μM Fluo3-AM for 40 min, and the fluorescent intensity was analyzed at 485/530 nm using a FLUOstar Galaxy fluorescence plate reader (BMG Labtechnologies, Offenburg, Germany).

Western Blot. The protein lysates were boiled in 4× protein loading dye [8% SDS, 40% glycerol, 200 mM Tris-HCl (pH 6.8), 0.04% Coomassie blue R-250, and 10% 2-mercaptoethanol], and the samples were subjected to SDS-polyacrylamide gel electrophoresis. The proteins were transferred to nitrocellulose membrane (Sartorius Stedim Biotech, Aubagne Cedex, France) and incubated with specific primary antibodies at 4 °C. The membranes were washed three times with Tris-buffered saline containing 0.05% Tween-20 (TBST) and incubated with horseradish peroxide-conjugated secondary antibody before analysis using a chemiluminescence ECL detection system (Millipore, Billerica, MA, USA). The levels of protein were normalized to the β-actin or TXNIP signals and quantitated using Vision Works LS 6.3.3 (UVP, Cambridge, UK).

Statistical Analysis. All results are expressed as the means ± SD from at least three independent experiments. ANOVA was used to evaluate the differences between multiple groups. Significant differences ($p < 0.05$) between the means were determined using Duncan's multiple range test or Student's t-test. All statistical analyses were performed with SPSS 12.0 software.

RESULTS

Gallic Acid and Catechin Exhibited Potent Free Radical Scavenging. Previous studies have suggested that

J. Agric. Food Chem. 2015, 63, 7343−7352

redox molecules are major signals for MSU-induced inflammation.[8−10] This study investigated potential inflammation inhibitors, including cinnamic acid, *o*-coumaric acid, *m*-coumaric acid, ferulic acid, *p*-hydroxybenzoic acid, vanillic acid, syringic acid, protocatechuic acid, gentisic acid, gallic acid, and catechin. The results showed that gallic acid and catechin exhibited higher free radical scavenging activity than other phenolic compounds (Figure 1). Therefore, the effects of gallic acid and catechin on MSU-induced inflammation were further explored using MSU-challenged models in vivo and in vitro.

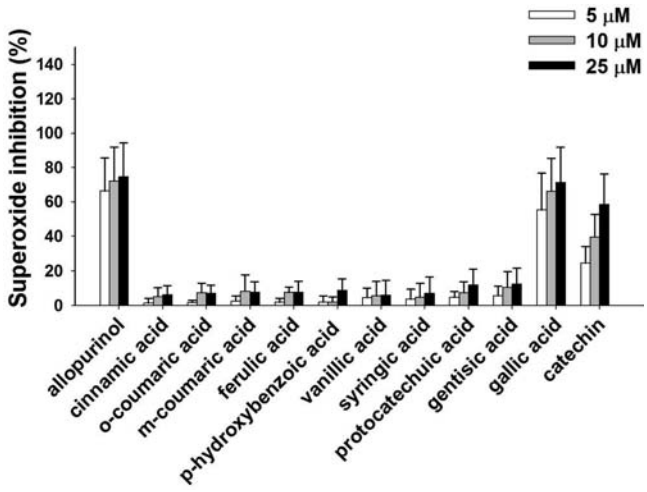

Figure 1. Effects of phenolic compounds on free radical scavenging activity. The values are presented as the means ± SD (n = 3).

Effects of Gallic Acid and Catechin on Murine Peritoneal Inflammation in C57BL/6 Mice. Intraperitoneal injection of MSU (3 mg) significantly (p < 0.05) increased IL-1β (Figure 2A) and IL-6 (Figure 2B) secretion compared with the control group in C57BL/6 mice. The subcutaneous administration of gallic acid (100 mg/kg BW) or catechin (100 mg/kg BW) significantly (p < 0.05) attenuated MSU-induced IL-1β and IL-6 secretions in the murine peritoneal fluid. The positive control colchicine (1 mg/kg BW) also showed the inhibitory effects on IL-1β and IL-6 secretions. MSU also significantly stimulated the population of Ly-6G$^+$ neutrophils (Figure 2C), ROS level (Figure 2D), and superoxide anion production (Figure 2E). However, gallic acid and catechin did not affect the levels of MSU-induced Ly-6G$^+$ neutrophils, ROS, and superoxide anion (Figure 2C−E).

Effects of Gallic Acid and Catechin on the IL-1β Activation in THP-1 Cells. The inhibitory mechanisms of gallic acid and catechin on MSU-induced IL-1β secretion were investigated in vitro. THP-1 cells were cultured in MSU (75 μg/mL) with gallic acid (20 μM) or catechin (20 μM) for 6 h, and THP-1 cells showed no cytotoxicity (cell viability >95%) according to MTT (Figure 3A) and SRB (Figure 3B) assays. Pro-inflammatory cytokine IL-1β secretion was significantly (p < 0.05) induced by MSU compared with control, but MSU-induced IL-1β secretion was significantly (p < 0.05) suppressed by catechin treatment; however, gallic acid had no significant effect on MSU-induced IL-1β secretion (p > 0.05) (Figure 3C).

IL-1β secretion was modulated through two signaling pathways. NF-κB pathway provides pro-IL-1β, and NLRP3 inflammasome promotes the release of IL-1β from pro-IL-1β.[7,8] As shown in Supporting Information Figure S1, MSU treatment showed no significant effect on NF-κB-mediated IL-1β mRNA expression compared with control group, but gallic acid and catechin significantly attenuated IL-1β mRNA expression (Figure S1A). The levels of nuclear NF-κB were down-regulated following treatment with MSU, gallic acid, and catechin (Figure S1B). The levels of inhibitor of κ Bα (IκBα) phosphorylation (Figure S1C) and extracellular signal-regulated kinases (ERK) phosphorylation (Figure S1D) were down-regulated by gallic acid and catechin.

This study further elucidated the effects of gallic acid and catechin on MSU-induced NLRP3 activation. MSU increased the conjugation of TXNIP and NLRP3 complex, but this activity was attenuated from 2.0-fold to 1.3-fold following catechin treatment (Figure 3D). However, NLRP3 and pro-caspase-1 expressions in the cell lysates were not altered following treatments with MSU, gallic acid, and catechin (Figure 3E,F), indicating that catechin inhibited NLRP3 inflammasome activation without reducing NLRP3 and pro-caspase-1 protein levels.

Effects of Gallic Acid and Catechin on the Oxidative Stress in THP-1 Cells. NLRP3 inflammasome activation is initiated through frustrated phagocytosis and lysosomal disruption.[19] The effects of gallic acid and catechin on phagocytosis and lysosomal function were studied, and the results showed that gallic acid and catechin did not decrease phagocytosis index and lysosomal disruption (Supporting Information Figure S2).

To obtain further evidence of the inhibitory mechanisms of catechin on NLRP3 inflammasome activation, we investigated the status of oxidative stress. THP-1 cells treated with MSU significantly increased superoxide anion and ROS productions. Gallic acid and catechin had no significant inhibition on MSU-induced superoxide anion (p > 0.05), but both compounds significantly (p < 0.05) suppressed MSU-triggered ROS generation (Supporting Information Figure S3). In addition, the level of MtROS was significantly (p < 0.05) increased in MSU-challenged THP-1 cells, but MSU-induced MtROS level was significantly (p < 0.05) ameliorated by catechin treatment. However, gallic acid did not affect MSU-triggered MtROS levels (Figure 4A,B).

Previous study indicates that TRX is the redox protein modulating oxidative stress and NLRP3 inflammasome activation,[9,11] and TRX is modulated by DJ-1.[20] The results showed that the expressions of TRX and its modulating protein DJ-1 were up-regulated by catechin but not gallic acid (Figure 4C,D). Glutathione (GSH) level, a kind of redox protein, was significantly decreased by MSU treatment, but MSU-induced consumption of GSH levels was not affected by gallic acid and catechin treatments (Supporting Information Figure S4).

Effects of Gallic Acid and Catechin on the Calcium Levels in THP-1 Cells. Calcium accumulation could lead to MtROS generation and NLRP3 inflammasome activation.[21,22] This study tested calcium level after THP-1 cells were treated with MSU for 1, 3, or 6 h. After treatment with MSU, the calcium levels were significantly (p < 0.05) elevated at 3 and 6 h compared with control (Figure 5A,B). Therefore, THP-1 cells were cultured in MSU with gallic acid or catechin for 3 h. MSU-induced calcium levels were significantly (p < 0.05) ameliorated by catechin compared with MSU (Figure 5C,D); however, gallic acid had no significant effect on MSU-triggered calcium levels (p > 0.05).

Effects of Gallic Acid and Catechin on Mitochondrial Damage in THP-1 Cells. Bcl-2 overexpression significantly

damage.[10,23] To elucidate the level of mitochondrial damage in MSU-treated cells, this study detected the mitochondrial transmembrane potential using the fluorescent probe, JC-1. The level of JC-1 was significantly ($p < 0.05$) reduced by MSU treatment (64%), and this reduction in JC-1 was significantly ($p < 0.05$) reversed through gallic acid (90%) and catechin (84%) in THP-1 cells (Figure 6B,C).

DISCUSSION

Uric acid is a purine metabolite derived from the conversion of xanthine and hypoxanthine.[1] Accumulated uric acid crystallizes into MSU and precipitates in the joint cavity.[1] MSU crystals trigger arthritic inflammation, known as gout, and neutrophil infiltration and IL-1β secretion are the primary clinical manifestations of early MSU attack.[3−5] This study selected two compounds, gallic acid and catechin, to examine their inhibitory effects on MSU-induced inflammation. Consistent

with the results of previous studies,[24−26] we observed that gallic acid and catechin acted as highly effective antioxidants (Figure 1). In animal study, the levels of ROS and superoxide anion were not altered by gallic acid and catechin (Figure 2D,E) because ROS and superoxide anion production were observed to accompany with neutrophil infiltration.[27] In addition, these two compounds suppressed pro-inflammatory cytokines but not neutrophil infiltration, suggesting that the inhibitory effects of gallic acid and catechin on pro-inflammatory cytokine release were not associated with neutrophil infiltration. Our findings demonstrated that catechin suppressed IL-1β release in animal (Figure 2A) and cell (Figure 3C) models; however, gallic acid suppressed the release of IL-1β secretion in vivo but not in vitro. The result of gallic acid on IL-1β secretion in the animal experiment was inconsistent with the cell model. The reason for the discrepancy is the different types of cells. Overall, the cell model was mainly monocytes, but neutrophils were the major reactive cells in the animal model.[27] On the basis of the results of IL-1β in vivo and in vitro, it suggested that gallic acid and catechin differently inhibited at least one of the inflammatory pathways to suppress IL-1β secretion.

During in vitro IL-1β secretion, NF-κB signaling provides pro-IL-1β formation, and NLRP3 inflammasome activation controls IL-1β cleavage from pro-IL-1β.[7,8] Gallic acid and catechin are known to act as inflammation suppressors in the NF-κB-mediated pathway.[12,28,29] These two compounds inhibited IL-1β mRNA, IκB phosphorylation, and ERK phosphorylation in this study. Importantly, NLRP3 inflammasome activation was specifically inhibited by catechin but not gallic acid (Figure 3D). Previous studies indicated that the inhibition of MtROS generation prevented NLRP3 inflammasome activation.[10] However, ROS scavenging by antioxidants was independent to inhibit NLRP3 inflammasome activation.[30] ROS scavengers, such as *N*-acetyl cysteine, exhibited potent anti-inflammatory effects on the specific inhibition of NF-κB pathway but not on NLRP3 inflammasome activation.[30] We observed that catechin inhibited ROS and MtROS levels, but gallic acid only suppressed ROS levels (Figure 4B and Figure S3C). Taken together, these results suggest that catechin inhibits both NF-κB signaling and NLRP3 inflammasome activation, while gallic acid only suppresses NF-κB signaling.

The protective effects of catechin on NLRP3 inflammasome activation involve three mechanisms. First, catechin reversed the mitochondrial transmembrane potential impairment and up-regulated Bcl-2 expression (Figure 6). The maintenance of mitochondrial membrane stabilization is a vital approach to prevent NLRP3 inflammasome activation because the release of mitochondrial DNA from damaged mitochondria could trigger NLRP3 inflammasome activation.[23,31] NLRP3 inflammasome activation was not affected by gallic acid although this compound reversed the mitochondrial transmembrane potential impairment. Because MAPK signaling could mediate the

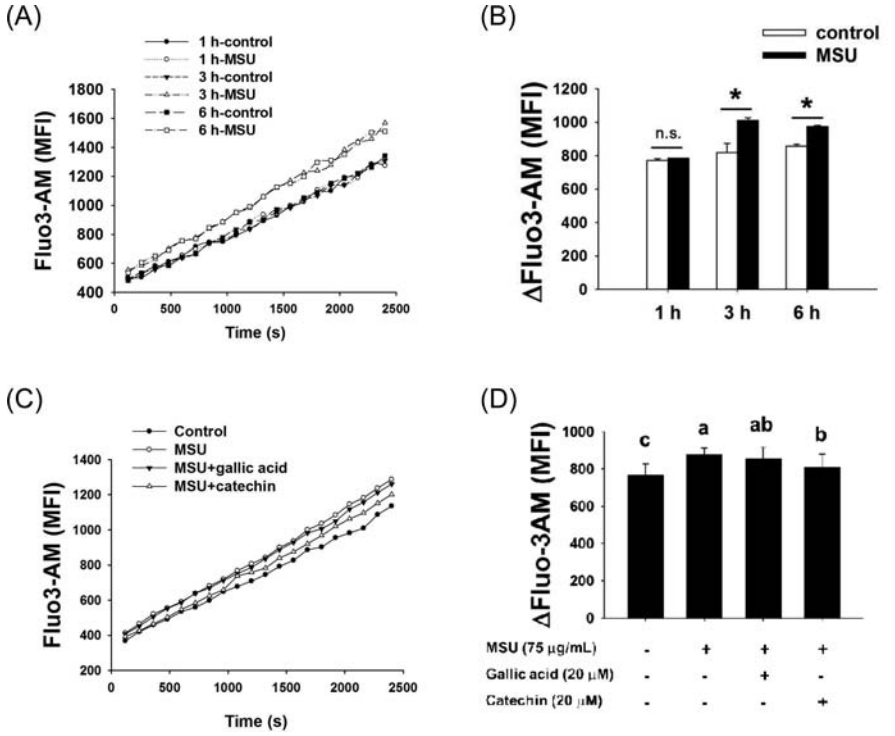

Figure 5. Effects of gallic acid and catechin on MSU-induced calcium accumulation. THP-1 cells were treated with 75 μg/mL MSU for 1, 3, or 6 h. (A) The calcium level was detected using Fluo3-AM, and (B) the fluorescent intensity levels are shown. *p < 0.05 was considered significant compared with the control using student's t-test. After THP-1 cells were treated with 75 μg/mL MSU in the presence or absence of 20 μM gallic acid or catechin for 3 h, (C) the fluorescent intensity of Fluo3-AM was detected and (D) quantified. The mean changes in the fluorescent intensity from 0 to 2400 s are shown. The values are presented as the means ± SD (n = 6). The values denoted with the different letters show significantly at p < 0.05.

mitochondrial transmembrane potential,[32] we speculated that the down-regulation of MAPK signaling by gallic acid indirectly maintained mitochondrial transmembrane potential. On the other hand, it has been suggested that the inhibition of NLRP3 inflammasome activation requires the significant up-regulation of Bcl-2 because the overexpression of Bcl-2 effectively prevents NLRP3 inflammasome activation.[10,23] Second, we observed that catechin inhibited calcium influx (Figure 5D), while calcium accumulation could induce mitochondrial damage and NLRP3 inflammasome activation.[21,22] Furthermore, the results showed that catechin inhibited MSU-stimulated calcium accumulation after 3 h treatment, and catechin reduced NLRP3 inflammasome activation after 6 h exposure, suggesting that catechin suppressed calcium overloading before mitochondrial damages and NLRP3 inflammasome activation. Moreover, catechin up-regulated the expression of redox proteins such as TRX and DJ-1 (Figure 4D). We concluded that the up-regulation of TRX by catechin inhibited the release of TXNIP and impaired IL-1β secretion. In agreement with the studies, the regulation of TRX expression contributes to IL-1β secretion.[9,11] In addition, DJ-1 is the ROS scavenger that degrades DJ-1 at cysteine 106 and prevents oxidative stress through the up-regulation of TRX.[20,33] Therefore, the preventive effect of catechin on NLRP3 inflammasome activation is to mediate the status of oxidative stress in the mitochondria and conferred protection to the mitochondria.

An association between catechin and the NLRP3 inflammasome has been suggested. It has been demonstrated that catechin attenuated *Helicobacter pylori* infection through a decrease in caspase-1 activity.[34] In addition to catechin, EGCG also prevented NLRP3-dependent lupus nephritis development in mice,[13] and EGCG suppressed melanoma growth through the inhibition of the NLRP1 inflammasome and IL-1β secretion.[35] Structurally, EGCG differs from catechin, possessing a third B-ring hydroxyl group at C5′ and a gallic acid residue esterified to the C3 hydroxyl.[36] Taken together, the inhibitory effects of flavan-3-ols (catechin and EGCG) on NLRP3 inflammasome activation reflect catechin monomers. Therefore, catechin derivatives, such as epicatechin, epigallocatechin (EGC), epicatechin gallate (ECG), and catechin-rich green tea extract, should be further determined whether these compounds inhibit NLRP3 inflammasome activation.

Catechin was given using the subcutaneous injection rather than the oral administration because of the low bioavailability of catechin and acute MSU attacks. The pharmacokinetics estimates of tea catechins with oral (5000 mg/kg) and intravenous (50 mg/kg) administration have pointed out the low bioavailability, slow C_{max} and long T_{max} in an animal model.[37] Therefore, subcutaneous injection of catechin is proposed to speed (or to increase) the concentration of catechin in serum. Colchicine was investigated to administrate using subcutaneous or intraperitoneal injection or using oral gavage for 4 h after MSU challenged C57BL/6 mice. Subcutaneous and intraperitoneal administration of colchicine significantly suppressed MSU-induced superoxide production and neutrophil infiltration,[38] but oral colchicine exhibited a delayed inhibitory effect on MSU-induced inflammation.[38] In addition, the natural compounds are commonly treated intraperitoneally to investigate their preventive effects on MSU-challenged animal models because MSU triggers acute inflammatory responses during 24 h.[39−41] On the basis of these findings, mice were treated with an intraperitoneal injection of

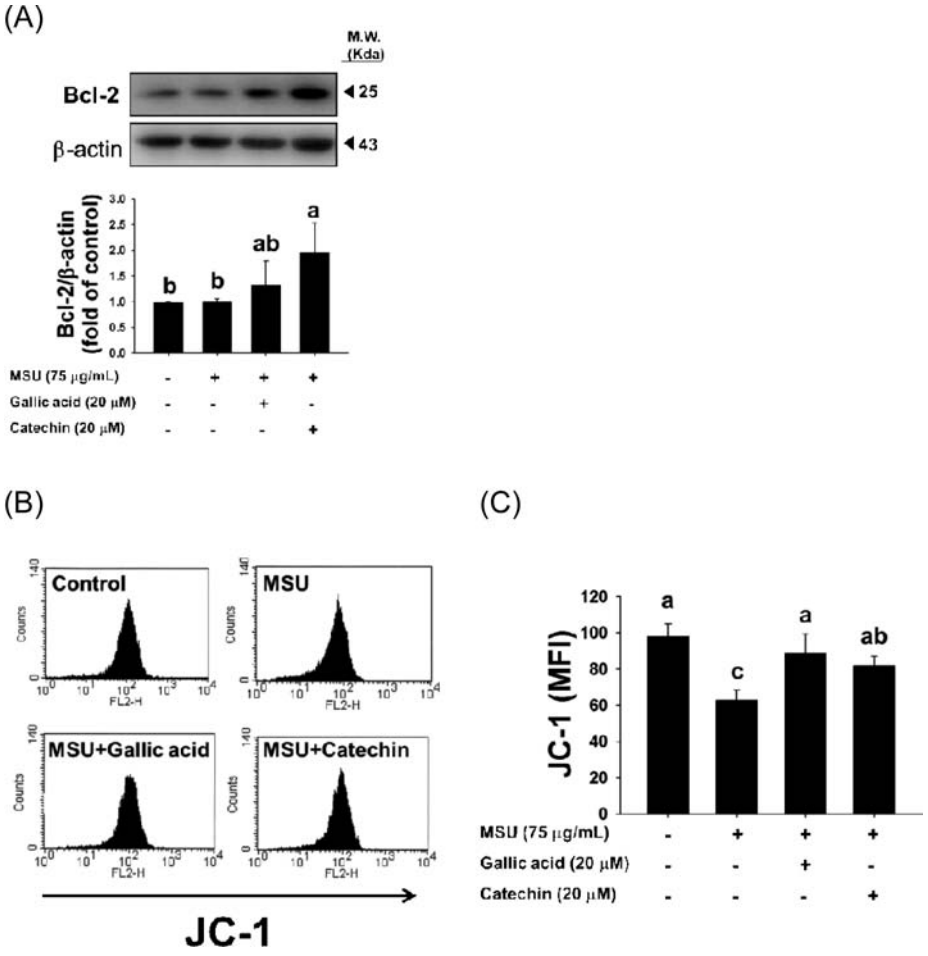

Figure 6. Effects of gallic acid and catechin on (A) Bcl-2 expression and (B) mitochondrial transmembrane potential. THP-1 cells were cultured with 75 μg/mL MSU in the presence or absence of 20 μM gallic acid or catechin for 6 h. (C) The quantitative value of JC-1 stain is shown. The values are presented as the means ± SD (n = 3). The values denoted with the different letters show significantly at $p < 0.05$.

MSU and with a subcutaneous injection of gallic acid or catechin.

It is a weakness of this study that the treatments of gallic acid and catechin are using subcutaneous injection in the animal model. Although subcutaneous injection of catechin might increase the concentration of catechin in plasma, subcutaneous injection is toward to drug system.[42] Catechin has multiple health-promoting properties when catechin is given orally for a long period,[43] but few studies report that subcutaneous injection of catechin could promote health. In addition, the metabolite of catechin is present in serum and urine predominantly as glucuronide, sulfate, or methylated conjugates.[44] Catechin exhibits the anti-inflammatory activity in MSU-challenged THP-1 cells; however, the inhibitory effect of catechin metabolites on MSU-induced inflammation remains unclear. Although the present results cannot determine the realistic dose of catechin as food to prevent MSU-induced inflammation, catechin has potential to protect gout attack by modulation of NLRP3 inflammasome activation.

In conclusion, this study demonstrates that catechin possesses potent superoxide anion scavenging activity greatly to inhibit MSU-induced IL-1β secretion and NLRP3 inflammasome activation. Catechin also regulates the status of oxidative stress in mitochondria via the up-regulation of TRX and DJ-1, and these effects prevent mitochondrial damage from MSU attack. These results suggest that catechin intake has potential to prevent acute gout attack.

plasma at a 7 μM peak concentration, 3 h after the ingestion of four cactus pear fruits containing 28 mg.[7] Moreover, the oral administration of a dose of pure indicaxanthin (2 μmol/kg), equivalent to a dietary amount ingested with cactus pear fruits in humans,[7] generated in rats a plasma peak concentration of 0.2 μM, which appeared to be safe and exhibited a strong anti-inflammatory effect in a carrageenan-induced acute inflammation model.[15]

While consumption of most phytochemicals has been associated with an extended life span,[16] the intake of quite a few has been reported to exert neuroprotective effects,[17] mainly due to the sealing nature of the blood brain barrier (BBB) that shields brain from the majority of xenobiotics.[18] Among all flavonoids, flavanols and anthocyanins are the only ones that have been reported to cross the BBB, accumulate within several regions of the brain, and modulate memory and learning proceses.[17−19] However, because of limited bioavailability, these molecules are poorly absorbed in the brain, especially anthocyanins.[17] On the other hand many studies claimed accumulation of phytochemicals assayed at amounts much higher than those ingested with a normal diet.[20]

Taking into account its bioavailability in rats,[15] this work first researched whether indicaxanthin crossed the BBB and accumulated in the rat brain. In addition, eventual action of the molecule on the neuronal function in the central nervous system (CNS), in particular the hippocampus, was investigated. This study was carried out exploiting recording techniques associated with microiontophoresis, a current-based approach for direct drug delivery, applied to locally investigate the neuromodulatory effects of molecular messengers on the electrophysiological properties of CNS neurons in vivo.[21] Indicaxanthin activity in the framework of glutamatergic synaptic system has been considered on the basis of inhibition studies in the presence of glutamate. The impact of indicaxanthin on the neuronal bioelectric activity in a structure involved in basic physiological processes is discussed.

MATERIALS AND METHODS

Reagents. Unless stated otherwise, all reagents were from Sigma-Aldrich (Milan, Italy) and of the highest grade commercially available.

Extraction and Purification of Indicaxanthin from Cactus Pear Fruits. Indicaxanthin was isolated from cactus pear (*Opuntia ficus-indica*) fruits (yellow cultivar). Briefly, the phytochemical was separated from a methanol extract of the pulp by liquid chromatography on Sephadex G-25 as previously reported.[1] Fractions containing the pigment were submitted to cryodesiccation, purified as described,[1] quantified by HPLC as below reported, and suspended in PBS for the experiments.

Animals and Surgery. Adult male Wistar rats (Morini, Milan, Italy) weighing 220−280 g were used in all experiments. Animals were fed and had access to water ad libitum. The light cycle was automatically controlled (on at 07:00, off at 19:00) and the room temperature was thermostatically regulated at 22° ± 1 °C. Before the experiments, rats were housed and acclimatized under these conditions for 3−4 d. In each experimental step, all efforts were made to minimize the number of animals used and their sufferance. All experiments were performed in strict accordance with the European Directive (2010/63/EU) on animal experimentation and with the National Institutes of Health Guide for the Care and Use of Laboratory Animals (1986).

As for pharmacokinetic studies, the animals were anesthetized on the day of the experiment with urethane at a dose of 1.2 g/kg (ip). One group received indicaxanthin (2 μmol/kg) by oral gavage, while control rats received saline alone. Animals were sacrificed at 1, 2.5, 3, 4, and 5 h after indicaxanthin administration, and brain samples were collected[15] and processed as described below. Each experiment was performed three times with groups of 10 rats. Data from separate experiments were pooled.

With regard to electrophysiological experiments, after having been anesthetized as above reported, rats were positioned in a stereotaxic apparatus (David Kopf Instruments, Tujunga, CA). A 3 mm burr hole was drilled in the skull, 5 mm anterior to the interaural line and 2.4 mm lateral to the midline. Physiological parameters were monitored throughout all experimental sessions.

Quantification of Indicaxanthin in Brain Samples. The amount of indicaxanthin within brain samples was evaluated at selected time intervals after a single oral administration of the pigment, as reported below. Briefly, animals were perfused with normal saline to remove any compounds still circulating in the blood. Brains (10 per time point) were then isolated, carefully washed with saline, pooled, and homogenized in PBS. Indicaxanthin was extracted from samples with chloroform:methanol, 2:1 by volume (1 g of tissue with 3 volumes of extraction mixture). The methanol phase from all samples at each time point was dried under nitrogen, resuspended in 1% acetic acid in water, analyzed on a Varian Microsorb C-18 column (4.6 × 250 mm; Varian, Palo Alto, CA), and eluted with a 20 min linear gradient elution from solvent A (1% acetic acid in water) to 20% solvent B (1% acetic acid in acetonitrile) with a flow rate of 1.5 mL/min. Spectrophotometric revelation was at 482 nm. Under these conditions, indicaxanthin eluted after 8.15 min and was quantified by reference to standard curves constructed with 5−100 ng of purified compounds and by relating its amount to the peak area.

Electrophysiological Recordings. A seven-barrel glass microelectrode was directed stereotaxically to the hippocampus for both recording and drug ejection (4.8−5.8 mm anterior to the interaural line, 1−3 mm lateral to the midline, 2.4−4 mm ventral to the cortical surface).[22] The system was set as previously reported.[23] The center recording barrel (1.1−2.0 MΩ resistance) was filled with 2 M NaCl with 1% Fast Green (Sigma), one side barrel was filled with 2 M NaCl 0.9% buffered saline solution (for automatic current balancing), and the others were filled with 12 mM, 6 mM, and 3 mM indicaxanthin (pH 7.4) and 100 mM L-glutamic acid monosodium salt (GLU, pH 8).

Retaining currents of 8−10 nA (positive for GLU and negative for the indicaxanthin solutions) were applied to drug barrels (20−70 MΩ) (Neurophore BH-2 System, Harvard Apparatus, Hamden, CT). At the beginning of each track (0.5 mm ventral to the cortical surface), maximal ejection currents were applied to each barrel for 30 min, to concentrate the drug at the pipet tip. Electrical signals were amplified, filtered, acquired, and stored on a computer together with their temporal markers (time precision 100 ms) for off-line analysis as previously described.[24] A ratemeter histogram of neuronal activity was continuously displayed and updated every 5 s on the computer screen with a counter window, to detect variations of neuronal firing rate online. All computer operations were performed using the SciWorks package, version 5.0 (Datawave Technologies, Loveland, CO). Neuronal units were not added to the database if marked changes in amplitude or configuration of the spike were observed, or if there was early death of the cell in the course of recording. Baseline activity of each neuron was recorded for 3−5 min before acute vehicle or drug administration.

Indicaxanthin Treatment. Microiontophoretic preliminary procedures were previously described.[24] Drug-test recordings were carried out at increasing ejection currents to identify both the kinetics of phytochemical action and the minimal current exerting an effect on all responsive neurons. For this purpose, 90 s pulses at 40, 60, and 80 nA ejection currents were tested, with a 90 s interpulse interval between pulses to prevent any influence of the previous pulse on the following one. After this step, all recorded neurons underwent the iontophoretic administration of indicaxanthin (in the concentration range reported above) for 5 min at the current of 60 nA in order to outline a correlation between the modifications of neuronal response and the concentration of the drug. Once the application of indicaxanthin was terminated, recording continued until the spontaneous firing rate recovered to baseline. Control tests, applying the same ejection currents used for the treatments, were performed with vehicle solutions; no changes in the neuronal firing were recorded. It is

DOI: 10.1021/acs.jafc.5b02612
J. Agric. Food Chem. 2015, 63, 7353−7360

worth highlighting that ejection times and currents in our microiontophoretic approach were set to result in an actual amount of indicaxanthin interacting with single neurons in a nanogram range compatible with the amount measured in the rat brain after the ingestion of the pigment. Indeed, indicaxanthin interacting with a single neuron was approximately 0.34 ng (for 12 mM), 0.17 ng (for 6 mM), and 0.085 ng (for 3 mM).

When required, the group of neurons that had received 0.34 ng of indicaxanthin per neuron were tested in coadministration with GLU; namely, at the recovering of baseline, GLU was ejected (40 nA ejection current)[25] before and during subsequent administration of the phytochemical, and responses were assessed. For all groups, only data from cells exhibiting recovery at the end of treatments were included in statistical analysis.

At the end of each electrophysiological experiment, the recording sites were marked with Fast Green through the electrode by using a 50 mA ejection current for 15 min. Coronal frozen sections were cut at 50 mm and stained with cresyl violet for histological verification and reconstruction of recording sites.

Preparation of Protein and Ligand. The crystal structure of amino terminal domains of the *N*-methyl-D-aspartate (NMDA) glutamate receptor dimeric GluN1/GluN2B subunit, in complex with antagonist ifenprodil (Pdb: 3QEL),[26] and dimeric GluN1/GluN2A subunit, in complex with either D-(−)-2-amino-5-phosphonopentanoic acid (D-AP5) (Pdb: 4NF5) or 1-(phenanthrene-2-carbonyl)piperazine-2,3-dicarboxylic acid (PPDA) (Pdb: 4NF6),[27] were retrieved from the RCSB Protein Data Bank. The starting coordinates of the crystal complexes were subjected to protein preparation using the protein preparation wizard of Glide software 5.9 (Schrodinger, LLC, New York, NY). The proteins were minimized by applying the OPLS-2005 force field. Water molecules and other nonligand molecules were deleted, and the structures refined by means the optimization of H-bond assignment, and the minimization until the average root-mean-square deviation of the non-hydrogen atoms reached 0.3 Å.

The structures of the ligands were then extracted from the X-ray complexes, and appropriate bond order was assigned using the LigPrep software 2.6 (Schrodinger, LLC, New York, NY). The same treatment was carried out on indicaxanthin, generating all the possible states and tautomers at pH = 7.0 ± 2.0.

Docking Experiments. The ligands were extracted and docked by the Glide XP high performance docking procedure, to evaluate if the docking algorithm fits the crystallized conformation.[28−31]

Binding Free Energy Calculation. Prime/MM-GBSA software 3.2 (Schrodinger, LLC, New York, NY) was used to calculate the free energy of binding between the receptor subunits and either the ligands or indicaxanthin, according to the default parameters for in water estimation.

Computational Mutagenesis. Alanine scanning studies were carried out using the Mutate Residue script from Maestro (Schrodinger, LLC, New York, NY). Computational mutagenesis is an approach used to find out the contribution of specific residues to the protein function by mutating the original residues to alanine[32] to recognize the structural and energetic characteristics of the hotspots. The mutated systems were not minimized, and it was assumed that no local rearrangements occur after the mutation. The interacting residues with indicaxanthin were mutated to alanine, and the binding free energy was recalculated.

Statistical Analysis. Data from electrophysiological study were analyzed using 1-factor ANOVA, followed by a Bonferroni's test. Neuronal firing rate was off-line analyzed before, during, and after drug administration for each recorded unit. Individual rate-meter histograms (5 s bin width) were analyzed by means of a nonparametric Mann−Whitney *U* test to detect any statistically significant treatment-related change in neuronal firing. To analyze the effects induced by treatments, neurons were considered responsive if changes were significant (probability level $P < 0.05$) for at least six consecutive bins for indicaxanthin and two for glutamate, the first of which was respectively labeled as the onset of a response. The intensity of the effect on neuronal firing (changes in the discharge with respect to baseline) was expressed as percentage magnitude, rather than absolute values, in order to normalize the responses of neurons with different baseline discharge frequencies. The dose−effect of indicaxanthin on the mean magnitude of discharge frequencies and on latency and duration of the effect was analyzed by a Mann−Whitney *U* test. For all statistical tests used, the null hypothesis was rejected at a *P* lower than 0.05. If not otherwise indicated, all results are expressed as mean ± SD.

RESULTS AND DISCUSSION

Indicaxanthin Crosses the BBB and Accumulates within the Rat Brain. Pharmacokinetic data from this study fall within the area of research on neuromodulatory effects of dietary phytochemicals.[17−20,33−35] Here we explored the potential for indicaxanthin to cross the BBB and accumulate within the brain. Taking into account previous studies[15] and human bioavailability,[7] rats received a single oral administration of 2 μmol/kg body weight, an amount calculated to be nutritionally relevant that can easily be provided to humans with a single serving of cactus pear fruit.[7,36]

Entry of indicaxanthin in rat brain was investigated kinetically by assessing the amount of the pigment in the whole brain (1.2 ± 0.1 g fresh weight, $n = 15$) between 60 min and 5 h after administration. The pigment was detectable after 60 min, and a peak of 20 ± 2.4 ng/g of fresh brain was reached 2.5 h after administration (Figure 2). Indicaxanthin disappeared from

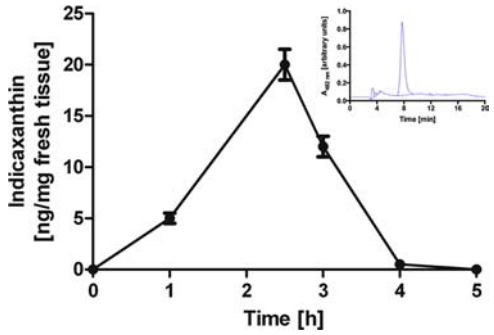

Figure 2. Kinetics of indicaxanthin accumulation in the rat brain after ingestion of 2 μmol/kg. Values are means ± SEMs, $n = 30$ (ten rats in 3 separate experiments). The inset shows a representative chromatographic profile of the indicaxanthin extracted from ten brains.

brain at 4 h, and log transformation of its amount within 2.5−4 h after ingestion indicated that the disposal followed first-order kinetics. The calculated half-life was 0.82 ± 0.07 h (Figure 2). As previously reported,[15] oral administration of 2 μmol/kg resulted in a 0.20 μM indicaxanthin plasma peak at 2.5 h, with total disappearance within 4 h with first-order kinetics. Comparing present and previous data,[15,37] and considering a mean rat blood volume of 16 mL, it can be calculated that the amount of indicaxanthin in the brain at 2.5 h (a time point reflecting an equilibrium of distribution already reached), is approximately 2% of that absorbed.

Brain is highly perfused; the distribution rate of compounds in cells is then determined primarily by permeability. While demonstrating that indicaxanthin crossed the rat BBB, our kinetic data showing parallel disposal kinetics in plasma and brain suggest simple diffusional mechanisms. Similarly, dietary indicaxanthin from cactus pear fruits has been found to distribute in human red blood cells with kinetics that paralleled plasma kinetics.[5]

Indicaxanthin Modulates Bioelectric Activity of Hippocampal Neurons. Taking into account that indicaxanthin

DOI: 10.1021/acs.jafc.5b02612
J. Agric. Food Chem. 2015, 63, 7353−7360

crossed the rat BBB, a putative influence of the molecule on neuronal cell function was explored. We examined the effect of indicaxanthin on the neuronal activity of the hippocampus applying microiontophoresis[38] to classical techniques of extracellular recording in in vivo models. By means of a multibarrel electrode, this methodology allows recording of a well-defined bioelectric activity of single neuronal units in conjunction with the local ejection of molecules of interest. Consequently, every change in the neuronal activity recorded is due to the substance administered, with negligible or null external interference.

Under the applied conditions a spontaneous discharge was evident for all recorded cells. Groups of 10 hippocampal neurons received 0.34 ng, 0.17 ng, or 0.085 ng of indicaxanthin per neuron, and the effect was evaluated as magnitude, latency, and duration of response; these parameters respectively express: (a) the percentage difference between mean values of the discharge frequency in basal condition and during the drug administration, (b) the time from the appearance of the effect, and (c) its timespan (Figure 3). With respect to baseline, treatment with 0.34 ng of indicaxanthin caused a statistically significant ($P < 0.05$) decrease of firing rate in 7 cells (70%). The effect had a mean magnitude of −73.93 ± 11.94%, a mean latency of 7.86 ± 2.67 s, and a mean duration of 260.00 ± 64.81 s. The firing rate of neurons treated with 0.17 ng of indicaxanthin decreased significantly ($P < 0.05$) in 6 cells (60%), with a mean magnitude of −49.71 ± 14.00%, a mean latency of 25.83 ± 13.93 s, and a mean duration of 241.67 ± 58.20 s. Finally, 5 of 10 neurons treated with 0.085 ng of indicaxanthin showed a significant reduction of the rate of discharge ($P < 0.05$). The effect had a mean magnitude of −29.59 ± 7.02%, a mean latency of 69.00 ± 36.64 s, and a mean duration of 65.00 ± 47.57 s.

Statistical analysis revealed that the effect of indicaxanthin was dose-dependent (Figure 3). In detail, considering the magnitude values (Figures 3, 4), the inhibitory effect of 0.34 ng/neuron was higher than the effect of both 0.17 ng ($P = 0.0152$) and 0.085 ng ($P = 0.0045$), and a significant reduction was observed comparing the effect of 0.17 ng with 0.085 ng ($P = 0.0176$). With regard to the latency of the effect (Figure 3), neurons treated with 0.34 ng showed a reduced latency when compared to 0.17 ng ($P = 0.015$) and to 0.085 ng ($P = 0.0045$). In addition, the latency for neurons treated with 0.17 ng was significantly lower than that for neurons treated with 0.085 ng

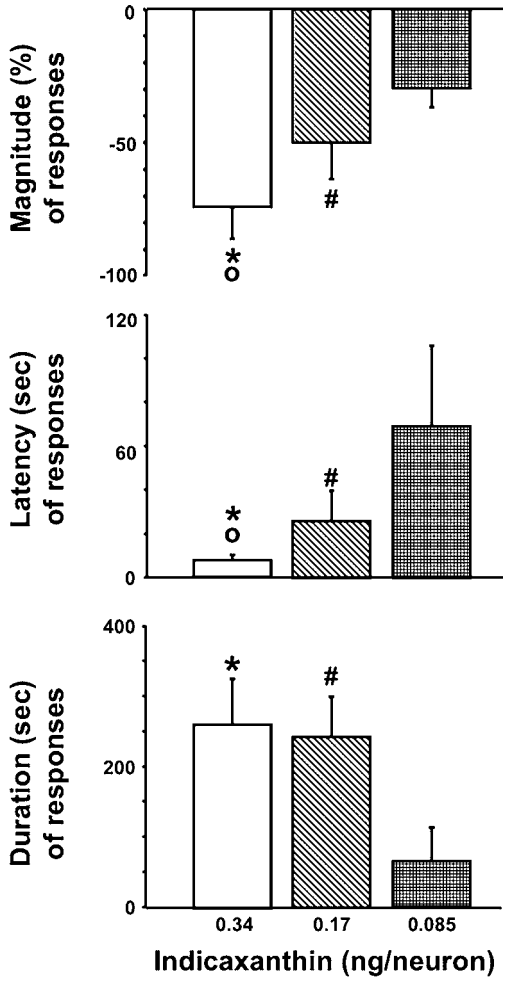

Figure 3. Bar histogram for magnitude, latency, and duration showing the effect of indicaxanthin at different amounts (0.34, 0.17, 0.085 ng/neuron) on hippocampal neuronal responses. Each bar represents mean values (±standard deviation) (○statistically significant effect of indicaxanthin 0.34 versus 0.17 ng/neuron; *statistically significant effect of indicaxanthin 0.34 versus 0.085 ng/neuron; #statistically significant effect of 0.17 versus 0.085 ng/neuron). Statistical significance for $P < 0.05$.

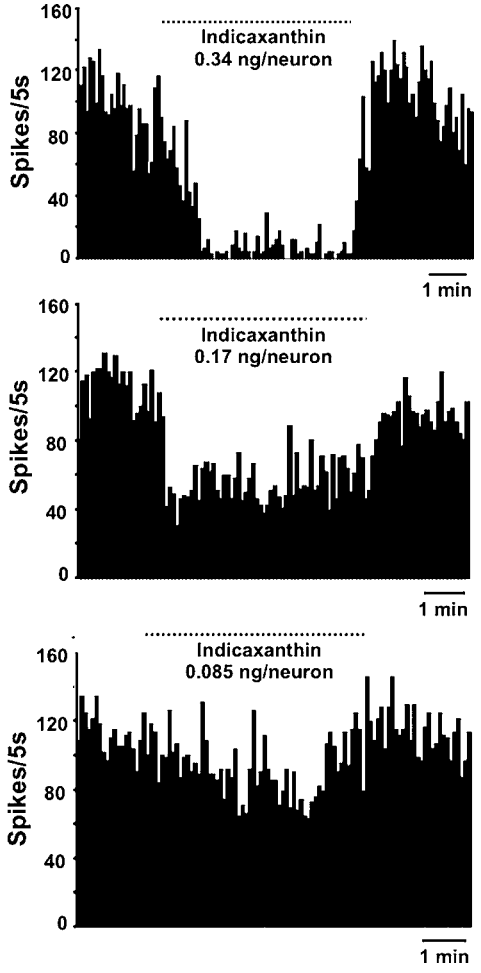

Figure 4. Representative rate-meter histogram (bin width 5 s) showing decreased magnitude of responses following indicaxanthin administration at various amounts (0.34, 0.17, 0.085 ng/neuron) for 5 min.

DOI: 10.1021/acs.jafc.5b02612
J. Agric. Food Chem. 2015, 63, 7353−7360

(P = 0.0446). As for the duration (Figure 3), in the 0.34 ng treated neurons the effect was greater than in 0.17 and 0.085 ng treated ones, though significant only for the latter (P = 0.058); also, there was a greater duration of the effect of 0.17 ng compared to 0.085 treated neurons (P = 0.0062). As a whole, our data revealed the ability of indicaxanthin to remarkably and dose-dependently inhibit the magnitude of spontaneous neuronal discharge of hippocampal cells, with a global modulation of neuronal bioelectric activity.

The hippocampus is involved in a variety of normal brain function and implicated in synaptic processes underlying memory formation, learning, modulation of emotions, regulation of the stress response, and cognition.[39] Cells of this brain region are mainly equipped with glutamatergic synapses, underpinning hippocampal activity.[40] Interestingly, reports reveal that phytochemicals can modulate excitatory glutamate-dependent hippocampal processes.[41]

Our results showing that indicaxanthin interfered with the hippocampal neuronal activity prompted us to investigate potential effects on the hippocampal glutamate-induced excitatory transmission. Therefore, the neurons that had previously reacted to 0.34 ng of indicaxanthin were subsequently submitted to coadministration of GLU and indicaxanthin (Figure 5A,B). This treatment affected the GLU-induced excitation of the neural discharge of 6 neurons (85,71%). In detail, 40 nA GLU pulses were first administered alone; this caused a mean increase in neuronal firing by +62.00 ± 21.34%. When GLU pulses were administered during ejection of indicaxanthin, the excitation was significantly reduced to +29.67 ± 8.08% (percentage difference: −52.14%; P = 0.0039). Latency and duration of GLU action were not significantly altered, due to the rapid kinetics of GLU and to the time-limited pulse ejection. Our results show that that indicaxanthin has the potential to modulate the hippocampal synaptic activity affecting glutamatergic transmission. These effects, observed with amounts of nutritional relevance, suggest the phytochemical as a natural compound with the potential of acting as a functional brake in the context of excitatory circuits, under a physiological condition.

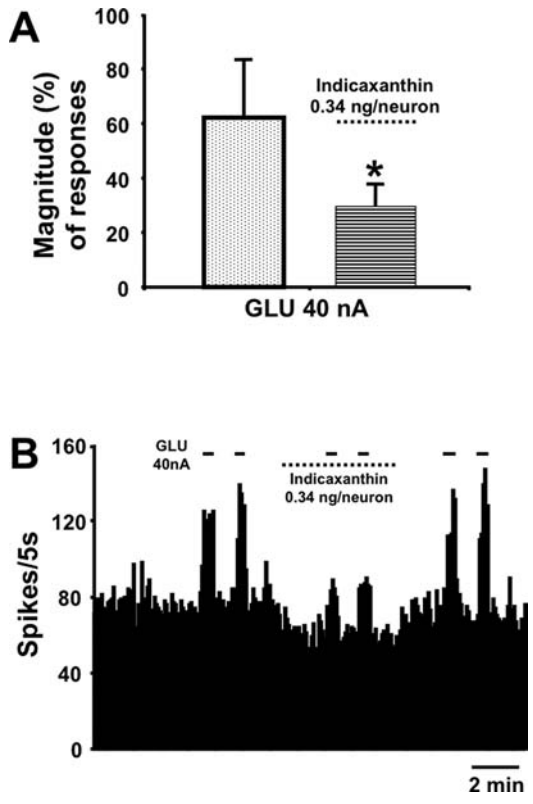

Figure 5. (A) Bar histogram for magnitude showing the effect of indicaxanthin (0.34 ng/neuron, at 60 nA) on GLU-induced responses of hippocampal neuronal. Each bar represents mean values (±standard deviation). *Statistically significant effect of coadministration of indicaxanthin (0.34 ng/neuron, at 60 nA) during GLU pulses (40 nA for 30 s) versus GLU-induced effect. Statistical significance for P < 0.05. (B) Representative rate-meter histogram (bin width 5 s) showing decreased magnitude of neuronal responses to GLU during indicaxanthin administration (0.34 ng/neuron, at 60 nA) for 5 min.

Interactions of Indicaxanthin with Glutamate Receptors. A number of receptors, including NMDAR, 2-amino-3-(3-hydroxy-5-methyl-isoxazol-4-yl)propanoic acid receptor (AMPAR), and metabotropic glutamate receptor (mGluR), are involved with the glutamatergic transmission, NMDAR being the most represented in the hippocampus, playing a central role in controlling synaptic plasticity and metaplasticity.[42,43] In this context, an in silico approach has been used to achieve a preliminary assessment of eventual interactions of indicaxanthin with these receptors.

The NMDA glutamate receptor forms a heterotetramer with two GluN1 and two GluN2 subunits, with various isoforms known to have distinct brain distribution. A number of studies showed that the GluN2A and GluN2B subunits are highly expressed in cortex and hippocampus,[42,43] which prompted us to focus our molecular modeling experiments on these subunits. Several crystallographic structures of GluN2A/B exist in the RCSB Protein Data Bank, free or in complex with natural agonists or antagonists. X-ray data of GluN1/GluN2B amino terminal domain (ATD) in complex with ifenprodil (Pdb: 3QEL), a selective antagonist of GluN2B subunit that interacts with ATD as an allosteric modulator, were selected for our aims. Ifenprodil represents the prototype of a prodil-like antagonist class of ligands.[44,45] In addition, the X-ray data of GluN1−GluN2A in complex with two selective competitive antagonists, the small D-AP5 (Pdb: 4NF5) and the larger PPDA (Pdb: 4NF6), were selected. PPDA has higher degree of GluN2A selectivity than D-AP5 because the core of glutamate binding pocket is highly conserved for these subunits; then small antagonists are generally unable to exert selectivity.[46] Therefore, selection of complexes with a small antagonist and a larger one to be compared with indicaxanthin could provide good information on the binding mode of indicaxanthin with the NMDAR. The modeling study was performed redocking the three antagonists and docking indicaxanthin into the coordinates of the three crystallographic structures of the receptor. The redocking procedure showed a root mean square deviation (RMSD) < 1 Å for ifenprodil, D-AP5, and PPDA with respect to the experimental conformation, confirming the suitability of the docking software to discriminate the correct poses. When compared with PPDA (docking score 5.72), indicaxanthin showed a better docking pose (score 9.63) on the interaction with GluN2A subunit residues. Four H-bonds were formed: oxygen of carboxyl C13 with the $-NH_2$ of Gly89; oxygen of carboxyl C15 with the $-NH_2$ of Arg176; oxygen of carboxyl C2 with Ser173 and Tyr214. In addition, the carboxyl group C2 and C15 form three salt bridges with Arg121, Arg176, and Lys87 (Figure 6). The

DOI: 10.1021/acs.jafc.5b02612
J. Agric. Food Chem. 2015, 63, 7353−7360

docking pose with the GluN2B (score 7.08) was weaker than with GluN2A, quite lower than that of ifenprodil (score 10.98).

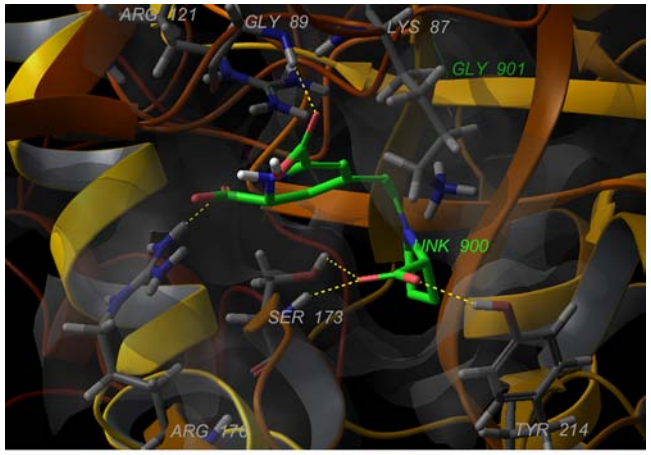

Figure 6. Binding pose of indicaxanthin in GluN2A subunit.

The free energy of binding for the GluN2B and GluN2A subunits in complex with ifenprodil, PPDA, D-AP5, and indicaxanthin was then calculated using the MM/GBSA approach. The free energy was −87.3 kcal/mol for ifenprodil/GluN2B, −92.7 kcal/mol for PPDA/GluN2A, and −57.6 kcal/mol for D-AP5/GluN2A. The binding free energy of indicaxanthin with GluN2B was −41.3 kcal/mol, indicating the ability to bind this subunit, with a quite higher ΔG binding than the selective antagonist ifenprodil. On the other hand, the free energy of binding with GluN2A was −80.7 kcal/mol, much higher than that of D-AP5 and comparable with that of PPDA.

The relevance of the residues in the ligand−GluN2A subunit interaction was explored by computational mutagenesis, replacing each of the aforementioned residues with alanine.[32] The energetic data are reported in Table 1. All mutations applied were unfavorable, with an increase of ΔG_{Bind} in a range between 20 and 40 kcal/mol, indicating that K87, R176, G89, S173, Y214, and R121 were fundamental for the indicaxanthin binding with the receptor subunit.

In conclusion, dietary phytochemicals are now acknowledged to exert positive effects on cell functions and then contribute to maintain health. Only a few of them, however, have been reported to cross the BBB and have activity at the brain level.[17,47,48] This study in rats was aimed at addressing whether indicaxanthin, a highly bioavailable dietary phytochemical from cactus pear fruits, shown to be absorbed in humans without being transformed,[7,9] has the ability to cross the BBB. In our model we clearly demonstrate that orally administered indicaxanthin accumulates within the brain and is released with kinetics consistent with its plasma kinetics. We also show that amounts of the pigment comparable with those recovered in the brain, locally applied in the rat hippocampus, can modulate dose-dependently the bioelectric activity of hippocampal cells, possibly acting at the level of glutamatergic synapses. Molecular modeling studies, carried out to have an insight into eventual interactions of indicaxanthin with Glu receptors, may suggest involvement of the NMDAR. The interaction with other Glu receptors cannot be ruled out at this time and deserves further electrophysiology and molecular modeling studies.

The hippocampal glutamatergic transmission is involved in many processes both physiological and pathological, from learning and memory to excitotoxicity, anxiety, and seizures, and is controlled by inner mechanisms of inhibition finely tuning synaptic transmission, exerting a negative feedback in glutamatergic-activated terminals.[49,50] In this context the neuromodulatory activity of dietary phytochemicals inhibiting the Glu-induced hippocampal synaptic transmission may contribute to a balanced control of neuronal activity and appears of remarkable interest.

Finally, it should be mentioned that present findings in rats have been obtained with amounts of indicaxanthin of the same order as those measured in human plasma after a dietary consumption of cactus pear fruits.[7] While molecular activity and pharmacological effects of indicaxanthin may deserve further studies in specific pathology models, effects on neural function could be expected from foods containing this molecule.

oxidized NAD^+ form.[32,33] Thus, it is of interest to study whether tNOX and the NAD^+/NADH ratio are involved in the differential effect of capsaicin. Here, we present evidence for the first time that the intracellular NAD^+/NADH ratio and SIRT1 deacetylase activity are central to the regulation of capsaicin-induced cell death.

MATERIALS AND METHODS

Cell Culture and Reagents. Capsaicin with purity >95% was purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). Anti-Bax, anti-Bak, anti-PARP, anti-Bcl-2, anti-p53, anti-acetyl-p53, anti-SIRT1, anti-mTOR, anti-phospho-mTOR, anti-phospho-AMPK, anti-phospho-JNK, and anti-acetyl-Lys antibodies were from Cell Signaling Technology, Inc. (Beverly, MA, USA). Anti-beclin-1, anti-Atg5, anti-Atg7, and anti-LC3 antibodies were from Novus Biologicals, Inc. (Littleton, CO, USA). The anti-survivin antibody was purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). Anti-β-actin antibody was from Millipore Corp. (Temecula, CA, USA). Antisera to tNOX were generated as described previously.[34] Other chemicals were from Sigma-Aldrich Corp.

A549 (human lung adenocarcinoma epithelial) cells were grown in DMEM, and MRC-5 (human lung tissue) cells were grown in MEM. All media were supplemented with 10% FBS, 100 U/mL penicillin, and 50 μg/mL streptomycin. Cells were maintained at 37 °C in a 5% CO_2−95% air-humidified incubator. ON-TARGETplus tNOX (ENOX2) siRNA and negative control siRNA were purchased from Thermo Scientific, Inc. (Grand Island, NY, USA), and SignalSilence Sirt1 siRNA I and control siRNA were from Cell Signaling Technology, Inc. Briefly, cells were seeded in 10 cm dishes and allowed to attach overnight. The next day, cells were transfected with tNOX/Sirt1 siRNA and control siRNA using Lipofectamin RNAiMAX reagent (Life Technologies, Grand Island, NY, USA) according to the manufacturer's instructions.[35]

Cell Impedance Measurements. Cell impedance technology was used to continuously monitor changes in cell growth. Cells (10^4 cells/well) were seeded onto E-plates. After 30 min of incubation at room temperature, E-plates were then set down onto the Real-Time Cell Analysis station (Roche, Mannheim, Germany). Cells were grown overnight before exposure to ethanol or different concentrations of capsaicin, and cell impedance was measured every hour, as previously described.[36]

WST-1 Cell Viability Assay. Cells (5×10^3) were seeded in 96-well culture plates and permitted to adhere overnight. Cells were then treated with capsaicin or ethanol for 72 h, and at the end of treatment, cell viability was determined using a WST-1 assay (Roche Applied Science, Mannheim, Germany).

Apoptosis Determination. Annexin V-FITC Apoptosis Detection Kits were used to determine apoptosis (BD Pharmingen, San Jose, CA, USA). Briefly, cells treated with ethanol or different concentrations of capsaicin were harvested by centrifugation after trypsinization. Cell pellet was washed with PBS and resuspended in 1× binding buffer. Next, cell pellet was stained with annexin V-FITC (fluorescein isothiocyanate) and also propidium iodide (PI) according to the manufacturer's protocol. The patterns of cell death (necrosis and apoptosis) were analyzed using a Beckman Coulter FC500 flow cytometer, and results were expressed as a percentage of total cells.

Autophagy Determination. Autophagosomes were visualized by staining with Acridine Orange (AO). After incubation, cells were washed with PBS and stained with 1 mg/mL AO for 15 min at 37 °C. AO-stained cells were then washed, trypsinized, and analyzed using a Beckman Coulter FC500. The results are expressed as a percentage of total cells.

Visualization of Autophagosome Formation Using EGFP-LC3. For autophagy experiments, MRC-5 cells were transiently transfected with a pEGFP-LC3 construct (a generous gift from Dr. Tamotsu Yoshimori, Osaka University, Japan) using Lipotectamine 2000 reagent according to the manufacturer's instructions (Invitrogen, Carlsbad, CA, USA).[37] MRC-5-EGFP-LC3 cells were either starved or exposed to capsaicin or ethanol, and autophagosomes formation was visualized.

Measurement of Intracellular NAD^+/NADH Ratio. Both oxidized and reduced forms of intracellular nicotinamide adenine dinucleotide were determined using an NADH/NAD Quantification Kit (BioVision Inc., Milpitas, CA, USA). Briefly, 2×10^5 cells were washed with cold PBS, pelleted, and extracted with 400 μL of NADH/NAD extraction buffer by two freeze/thaw cycles. Samples were vortexed and centrifuged at 14000 rpm for 5 min. For each sample, a 200 μL aliquot of extracted NADH/NAD supernatant was transferred to a microcentrifuge tube. Samples were first heated to 60 °C for 30 min to allow decomposition of all NAD^+, while retaining NADH intact, and then placed on ice. Samples were rapidly centrifuged and transferred to a multiwall plate. Standards and a NAD cycling mix were prepared according to the manufacturer's protocol. One hundred microliters of the reaction mix was added into each well of NADH standards and samples, and all samples were incubated at room temperature for 5 min to convert NAD^+ to NADH. NADH Developer Solution was added to each well, and plates were incubated at room temperature for 30 min. The reaction was stopped by adding 10 μL of Stop Solution, and absorbance was measured at 450 nm.

Measurement of SIRT1 Deacetylase Activity in Vitro. SIRT1 deacetylase activity was determined using a SIRT1 direct Fluorescent Screening Assay Kit (Cayman Chemical Co., Ann Arbor, MI, USA). Briefly, the substrate solution was first prepared by adding 240 μL of NAD^+ solution and 850 μL of diluted assay buffer to 15 μL of the p53 peptide Arg-His-Lys-Lys(ε-acetyl)-AMC, to yield final concentrations of 125 μM peptide (substrate) and 3 mM NAD^+. Background was determined in wells containing 30 μL of assay buffer and 5 μL of solvent. Maximal initial activity (defined as 100%) was determined in wells containing 5 μL of diluted human recombinant SIRT1, 25 μL of assay buffer, and 5 μL of solvent. For our experiments, 5 μL of capsaicin was added to wells containing 25 μL of assay buffer and 5 μL of diluted human recombinant SIRT1. Reactions were initiated by adding 15 μL of substrate solution to all of the wells. The plate was then covered and incubated on a shaker for 45 min at room temperature. Reactions were stopped by adding 50 μL of Stop/Developing Solution to each well and incubating the plate for 30 min at room temperature. Plates were read in a fluorometer using an excitation wavelength of 350−360 nm and an emission wavelength of 450−465 nm.

Western Blot Analysis. Cell extracts were prepared in lysis buffer containing 20 mM Tris-HCl, pH 7.4, 100 mM NaCl, 5 mM EDTA, 2 mM phenylmethanesulfonyl fluoride (PMSF), 10 ng/mL leupeptin, and 10 μg/mL aprotinin. Volumes of extract containing equal amounts of proteins (40 μg) were applied to SDS-PAGE gels, and resolved proteins were transferred to nitrocellulose membranes (Schleicher & Schuell, Keene, NH, USA). The membranes were blocked with nonfat milk solution for 30 min, then washed, and probed with primary antibody. Membranes were then rinsed with Tris-buffered saline containing 0.1% Tween 20 to remove unbound primary antibody and incubated with horseradish peroxidase-conjugated secondary antibody for 2 h. The membranes were rinsed again and developed using enhanced chemiluminescence (ECL) reagents (Amersham Biosciences, Piscataway, NJ, USA).

Statistics. All data are expressed as the mean ± SE of three or more independent experiments. Comparison between groups was made by one-way analysis of variance (ANOVA) followed by an appropriate post hoc test to analyze the difference. A value of $p < 0.05$ was considered to be statistically significant.

RESULTS

A549 Cells Exhibit Greater Responsiveness to Capsaicin than MRC-5 Cells. Given that transformed and noncancerous cells exhibit differential cytotoxicity to capsaicin, we decided to choose lines from lung tissue, MRC-5 (human lung tissue) and A549 (human lung adenocarcinoma), cells in this study. We continuously monitored the dynamic effects of capsaicin on cell growth, measuring cell impedance and

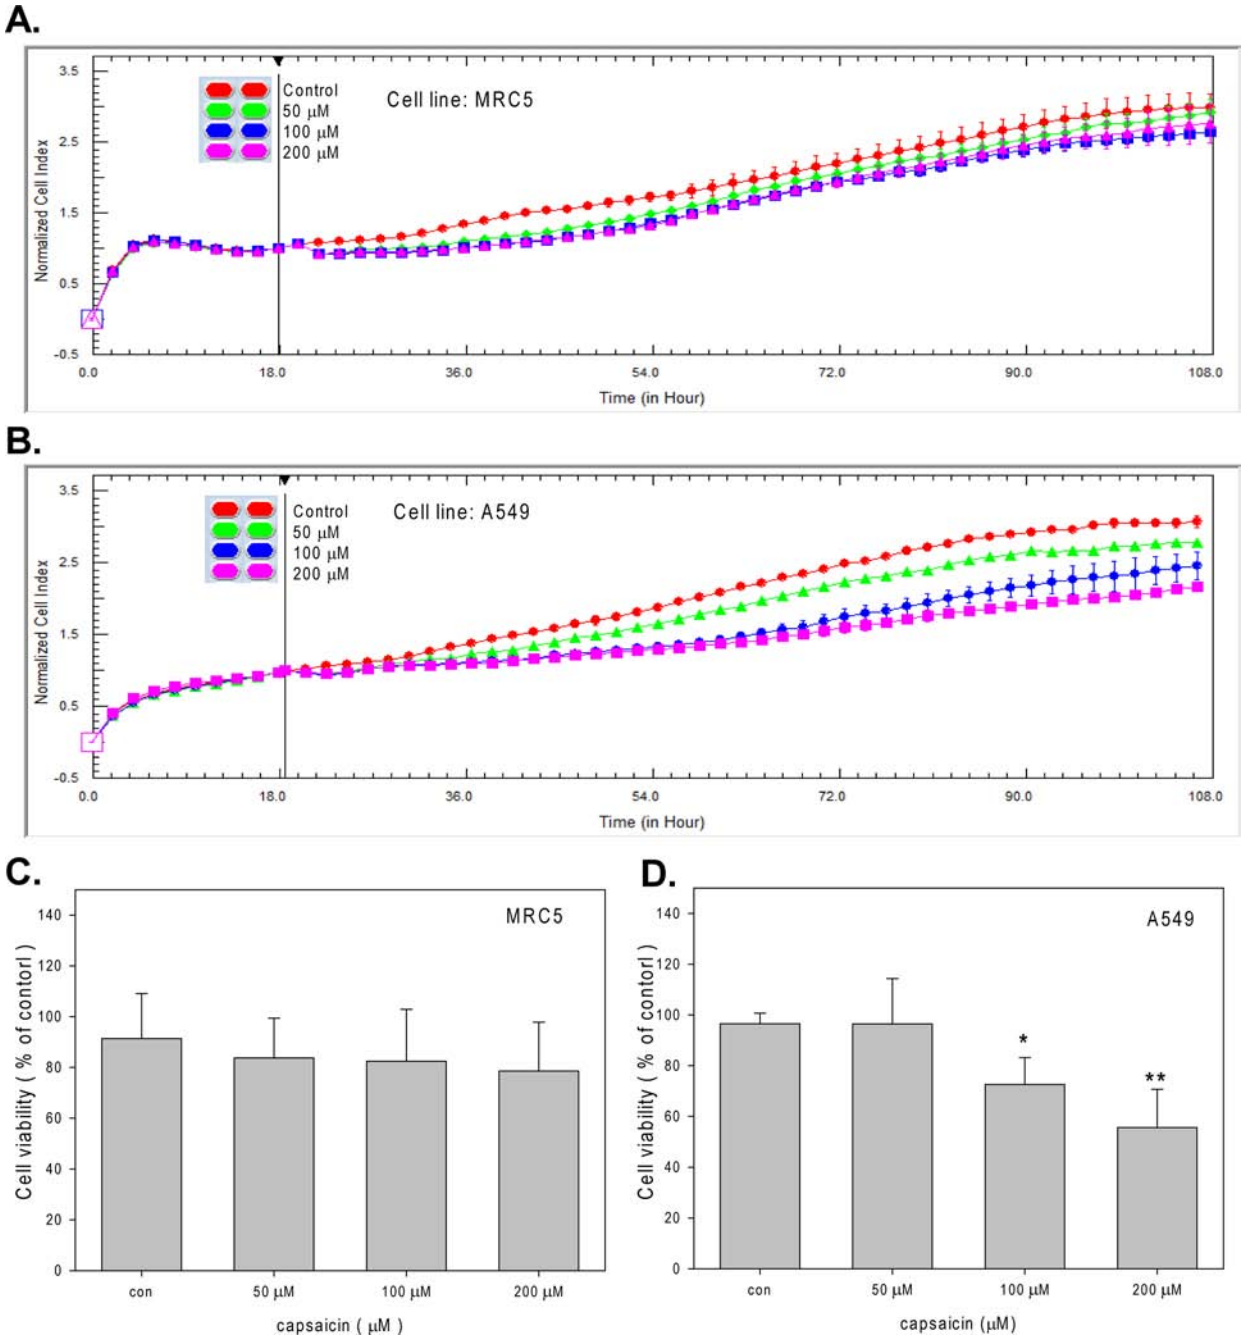

Figure 1. Capsaicin inhibits cell growth in A549 cells but not in MC-5 cells. (A, B) Cell growth with or without capsaicin was dynamically monitored using impedance technology, in MRC-5 cells (A) and in A549 cells (B). Normalized cell index values measured over 108 h are shown. (C, D) Cells were treated with capsaicin for 72 h, and cell viability was determined by WST-1 assay, in MRC-5 cells (C) and in A549 cells (D). Values (mean ± SE) are from three independent experiments performed in at least triplicates: (∗) $p < 0.05$ and (∗∗) $p < 0.01$ for A549 cells treated with capsaicin versis controls.

displaying the results as cell index values.[38] Using this approach, we found that MRC-5 cell growth was decreased by capsaicin at an early stage of exposure; however, cell growth gradually recovered, resulting in little overall inhibition at all concentrations tested (Figure 1A). In contrast, capsaicin induced a significant concentration-dependent decrease in cell growth in A549 cells; this inhibitory effect was much more evident than that in MRC-5 cells (Figure 1B). The greater responsiveness of A549 cells to capsaicin is reflected in IC_{50} values, which was determined to be 33.8 μM for A549 cells but could not be calculated in MRC-5 cells because the degree of inhibition was so low in these cells. We also tested cell viability using WST-1 assays and demonstrated that the viability of MRC-5 cells was not inhibited significantly by capsaicin (Figure 1C), whereas that of A549 cells was decreased considerably (to less than 76 and 60% of control values at 100 and 200 μM, respectively) (Figure 1D). The IC_{50} value for capsaicin in A549 cells determined on the basis of WST-1 assays was 146 μM and could not be calculated for MRC-5 cells due to a low degree of inhibition. These data suggested that capsaicin is cytotoxic in A549 cells but not in MRC-5 cells.

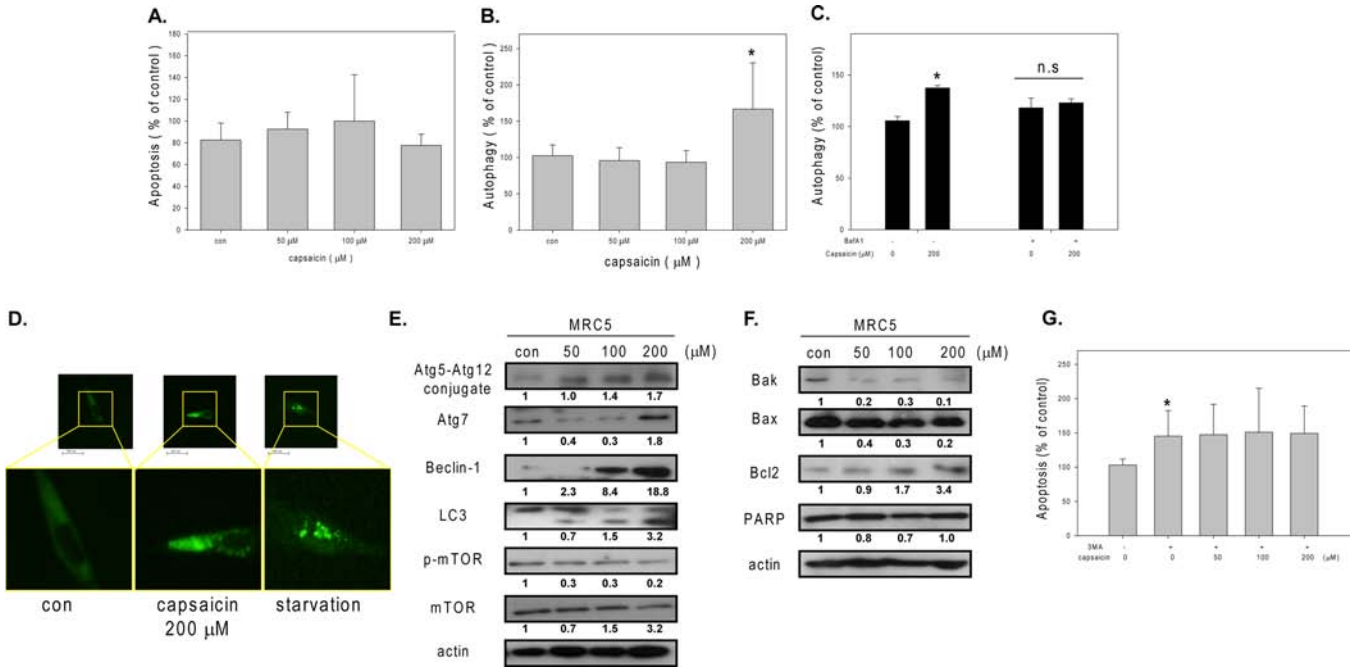

Figure 2. Capsaicin preferentially induces autophagy but not apoptosis in MRC-5 cells. (A) MRC-5 cells were treated with capsaicin or ethanol for 24 h. The percentage of apoptotic cells was determined by flow cytometry, and the results are expressed as a percentage relative to the control group. Values (mean ± SE) are from three independent experiments. No significant differences were observed. (B) Cells were treated with capsaicin or ethanol for 6 h. Autophagy was determined by AO staining using flow cytometry, and the results are expressed as a percentage relative to the control group. Values (mean ± SE) are from four independent experiments: (∗) $p < 0.05$ for MRC-5 cells treated with 200 μM capsaicin versus controls. (C) MRC-5 cells were pretreated with 0.1 μM BafA1 or not for 30 min before exposure to capsaicin for 6 h. The percentage of autophagic cells was assessed by flow cytometry, and the results are expressed as a percentage relative to the control group. Values (mean ± SE) are from three independent experiments: (∗) $p < 0.05$ for MRC-5 cells without BafA1 pretreatment treated with capsaicin versus controls. (D) MRC-5 cells were transiently transfected with EGFP-LC3 for 48 h and serum starved or treated with capsaicin or ethanol for 6 h. EGFP fluorescence was observed under a fluorescence microscopy. (E, F) MRC-5 cells were treated with capsaicin or ethanol for 24 h. Aliquots of cell lysates were separated by SDS-PAGE and analyzed by Western blotting; β-actin was used as internal control. Representative images from three experiments are shown. (G) MRC-5 cells were pretreated with 100 μM 3-MA or not for 1 h before exposure to capsaicin or ethanol for 24 h. The percentage of apoptotic cells was assessed by flow cytometry, and the results are expressed as a percentage relative to the control group. Values (mean ± SE) are from four independent experiments: (∗) $p < 0.05$ for MRC-5 cells without 3-MA pretreatment versus other groups.

Capsaicin Induces Autophagy in MRC5 Cells but Not Apoptosis. To determine whether programmed cell death is involved in the differential cellular responses to capsaicin, we analyzed cells for apoptotic subpopulations. Interestingly, little apoptotic effect was observed in capsaicin-exposed MRC-5 cells, indicating that MRC-5 cells were largely impervious to the apoptotic effect of capsaicin (Figure 2A). We also explored the possibility that capsaicin induces autophagy—a type II programmed cell death-related pathway—in these cells. Using AO staining for detection of acidic vesicular organelles, we found that 200 μM capsaicin significantly increased the population of MRC-5 cells undergoing autophagy at 6 h (Figure 2B). Pretreatment of MRC-5 cells with the autophagy inhibitor bafilomycin A1 (BafA1) has shown to reverse the capsaicin-induced autophagy (Figure 2C). To further explore autophagy in capsaicin-exposed MRC-5 cells, we exogenously expressed a fusion protein of enhanced green fluorescent protein and the autophagy marker microtubule associated light chain 3 protein (EGFP-LC3) and observed the fluorescence. We showed that capsaicin exposure resulted in autophagosomes formation as green punctuate dots, similar to that observed in serum-starved cells (Figure 2D). Moreover, protein analyses verified that important autophagy regulators, such as autophagy-related 7 (Atg7), Atg5−Atg12 conjugate, beclin-1, and cleaved LC3 II, were up-regulated, whereas phosphorylated and total mammalian target of rapamycin (mTOR) were down-regulated by capsaicin (Figure 2E). Expressions of apoptosis-related proteins also indicated a lack of apoptosis in capsaicin-exposed MRC-5 cells, pro-apoptotic Bak protein Bax were decreased, pro-survival Bcl-2 protein was increased, and a caspase-3-mediated poly(ADP-ribose) polymerase (PARP) cleavage was not detected (Figure 2F). Pretreatment of MRC-5 cells with the autophagy inhibitor 3-methyladenine alone indeed significantly enhanced apoptosis; however, it had little impact on capsaicin-induced apoptosis (Figure 2G).

Capsaicin Induces Cytotoxic Apoptosis in A549 Cells. To verify that transformed and noncancerous cells indeed exhibit differential cytotoxicity to capsaicin, lung carcinoma cells were used in this study. In A549 cells, a 24 h capsaicin exposure induced a significant, >2-fold, increase in apoptosis at 200 μM (Figure 3A). Western blot analyses also revealed that capsaicin triggered considerable up-regulation of the Bak and Bax as well as cleaved PARP, with concurrent down-regulation of Bcl-2 and survivin in capsaicin-exposed A549 cells (Figure 3B). However, we found a lack of capsaicin-induced autophagy at 6 h of exposure (Figure 3C). Changes in autophagy protein levels were less marked in A549 cells (Figure 3D). Moreover, pretreatment with z-VAD, a pan-caspase inhibitor, had little effect on capsaicin-induced autophagy (Figure 3E).

Capsaicin Modulates Intracellular NAD^+/NADH Ratio. An association between capsaicin-inhibited tumor-associated NADH oxidase (tNOX) activity and cytotoxic apoptosis has

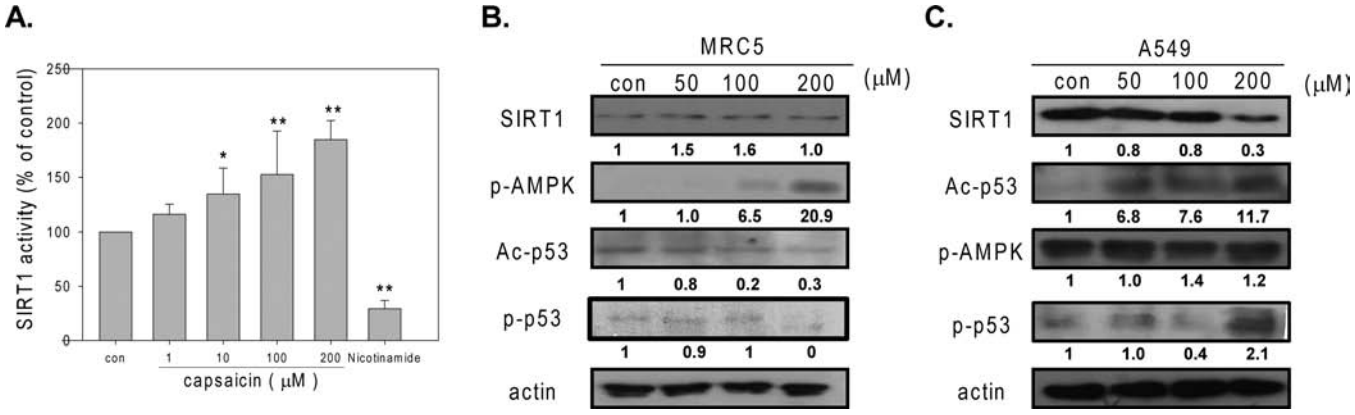

Figure 5. Modulation effects of capsaicin on SIRT1 in vitro activity and protein expression. (A) Samples were incubated with ethanol or capsaicin, and SIRT1 deacetylase activity in vitro was determined using a direct fluorescence assay kit. Nicotinamide was used as a control. Values (mean ± SE) are from three independent experiments performed in at least triplicates: (**) $p < 0.01$ and (*) $p < 0.05$ for samples treated with capsaicin or nicotinamide versus controls. (B, C) Cells were treated with capsaicin or ethanol for 24 h, in MRC-5 cells (B) and in A549 cells (C). Aliquots of cell lysates were separated by SDS-PAGE and analyzed by Western blotting; β-actin was used as internal control. Representative images from three experiments are shown.

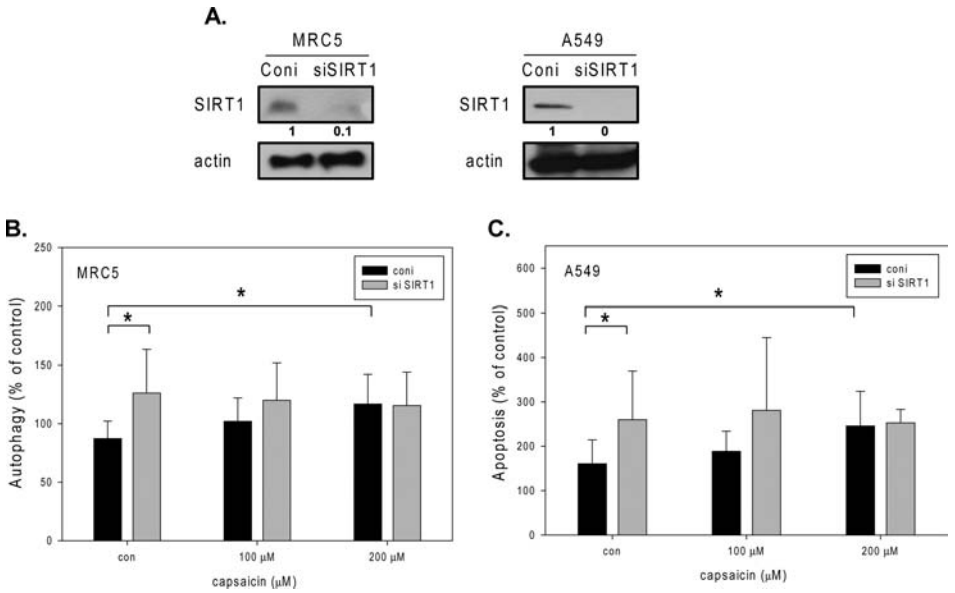

Figure 6. Effect of SIRT1 depletion on capsaicin-induced programmed cell death. (A) SIRT1 was down-regulated by siRNA, and cells were treated with ethanol or capsaicin. Aliquots of cell lysates were separated by SDS-PAGE and analyzed by Western blotting; β-actin was used as internal control. Representative images from three experiments are shown. (B) Control or SIRT1-depleted MRC-5 cells were treated with capsaicin or ethanol for 6 h. Autophagy was determined by AO staining using flow cytometry, and the results are expressed as a percentage relative to the control group. Values (mean ± SE) are from four independent experiments: (*) $p < 0.05$ for siRNA-control cells versus SIRT1-knockdown controls and also for siRNA-control cells treated with 200 μM capsaicin versus untreated controls. (C) Control and SIRT1-depleted A549 cells were treated with capsaicin or ethanol for 24 h. Apoptosis was determined by annexin V staining by flow cytometry, and the results are expressed as a percentage of apoptotic cells. Values (mean ± SE) are from three independent experiments: (*) $p < 0.05$ for siRNA-control cells versus SIRT1-knockdown controls and also for siRNA-control cells treated with 200 μM capsaicin versus untreated controls.

been previously established only in cancer/transformed cells.[1] This observation prompted us to examine whether the capsaicin-induced cytotoxicity in A549 cells involves tNOX and, if so, by what mechanism. NAD^+ is a biological oxidizing agent for many metabolic reactions, and tNOX oxidizes hydroquinones and NADH, converting the latter to the oxidized NAD^+ form.[33] Thus, it is reasonable to presume that a capsaicin-inhibited tNOX could potentially disturb cellular redox homeostasis and, consequently, disrupt cellular responses. In this regard, we found that the basal NAD^+/NADH ratio in A549 cells was much greater than that in MRC-5 cells, possibly reflecting endogenous tNOX activity in A549 cells (Figure 4A). Treatment of A549 cells with 200 μM capsaicin significantly decreased the NAD^+/NADH ratio but increased it in MRC-5 cells, although the change was relatively small compared with that in A549 cells (Figure 4A). These data support that tNOX oxidizes NADH to NAD^+ and capsaicin-inhibited tNOX resulted in a decrease in the intracellular NAD^+/NADH ratio in cancer cells. Moreover, capsaicin (200 μM) down-regulated tNOX expression in A549 cells, whereas tNOX expression was not detected in MRC-5 cells (Figure 4B), confirming tNOX expression in a cancerous, but not a nontransformed, line. We further found that targeting tNOX in A549 cells with siRNA (Figure 4C) decreased the NAD^+/

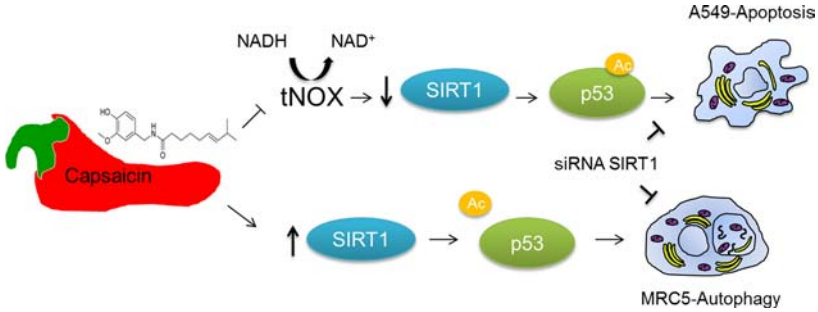

Figure 7. Schematic diagram of the mechanism of capsaicin-induced programmed cell death.

NADH ratio compared to A549 cells expressing control (scrambled) siRNA (Figure 4D). We also noted that tNOX-depleted A549 cells exhibited reduced silent mating type information regulation 1 (SIRT1) expression, whereas p53 acetylation and JNK phosphorylation were increased and cyclin D was attenuated (Figure 4C), confirming a tumor-promoting role of tNOX in cancer cells.

Capsaicin Inhibits SIRT1 Deacetylase Activity in A549 Cells but Enhances It in MRC-5 Cells. Given that NAD^+ is also a cofactor for SIRT1 deacetylase, we were interested in determining whether the opposing effects of capsaicin on the NAD^+/NADH ratio in A549 and MRC-5 cells affected SIRT1 activity. Utilizing an in vitro assay with recombinant SIRT1, we found that capsaicin effectively stimulated its activity at concentrations of 10−200 μM, whereas nicotinamide, a SIRT1 inhibitor, significantly decreased SIRT1 activity in vitro (Figure 5A). We also found that 200 μM capsaicin had little effect on SIRT1 expression in MRC-5 cells (Figure 5B). Thus, in the absence of a change in SIRT1 expression, the higher in vitro SIRT1 activity by capsaicin (Figure 5A) together with the capsaicin-induced increased in intracellular NAD^+/NADH ratio (Figure 4A) led to enhanced SIRT1 deacetylase activity. This interpretation is supported by the decrease in the acetylation level of p53 and enhancement of adenosine monophosphate-activated protein kinase (AMPK) phosphorylation/activation, an activator of SIRT1 (Figure 5B). It is documented that deacetylation of p53 induces autophagy,[39] and we also found that capsaicin reduced p53 acetylation accompanying the up-regulation of Atg5, Atg7, becline-1, cleaved LC3 II, and autophagy (Figure 2). Interestingly, exposure of A549 cells to 200 μM capsaicin reduced SIRT1 protein expression (Figure 5C). Alongside the decrease in intracellular NAD^+/NADH ratio in capsaicin-exposed A549 cells (Figure 4A), we found that the p53 acetylation level was noticeably augmented (Figure 5C), possibly by the decreased SIRT1 acetylase activity. Thus, capsaicin induced acetylated/activated/phosphorylated p53 (Figure 5C), and, in turn, up-regulated apoptotic Bax and Bak; this, together with down-regulation of Bcl-2, resulted in apoptosis in A549 cells (Figure 3). Furthermore, small interfering RNA (siRNA) effectively decreased SIRT1 expression in both lines (Figure 6A). In SIRT1-depleted MRC-5 cells, capsaicin-induced autophagy was diminished (Figure 6B), whereas capsaicin-induced apoptosis was reduced in SIRT1-knockdown A549 cells (Figure 6C), demonstrating a key role for SIRT1 in the regulation of capsaicin-mediated programmed cell death-related pathways.

DISCUSSION

Capsaicin acts on an array of cellular targets, several of which have been identified, and initiates a number of signaling pathways. Transient receptor potential vanilloid type 1 (TRPV1) is the most-often mentioned protein targets of capsaicin that belongs to a member of the TRP family of nonselective cation channels.[40] Several studies have suggested that capsaicin exerts its anticancer actions through interaction with the TRPV1, although capsaicin also acts through TRPV1 as a cocarcinogen.[41,42] Here, we present evidence demonstrating that capsaicin modulates SIRT1 deacetylase activity; in particular, depending on the cellular context, capsaicin decreases the NAD^+/NADH ratio and increases p53 acetylation, resulting in enhanced cytotoxic apoptosis (A549 cells), or increases the NAD^+/NADH ratio and SIRT1 deacetylase activity toward p53, leading to survival autophagy (MRC-5 cells). These pathways are summarized in Figure 7.

One major finding of this study is our clarification of the molecular mechanisms underlying the differential effect of capsaicin on cancer and noncancer cells. Capsaicin has long been considered as a chemopreventive agent by virtue of its inhibitory effect on cancer cell survival and proliferation as well its induction of apoptosis.[15,43,44] Interestingly, noncancerous cells exhibit greater tolerance to capsaicin compared to cancer cells, although the basis for this selective cytotoxicity is uncertain.[15] Consistent with the reports of others, our study provides support for the idea that capsaicin induces different mechanisms leading to distinct outcomes depending on cell type and cellular context.[1,4,14] Our results confirmed that capsaicin preferentially induces cytotoxicity in A549 human lung cancer cells but not in MRC-5 cells normal human lung tissue, as supported by the observed IC_{50} value of 33.5 μM (based on cell impedance measurements) for A549 cells, but unmeasurable IC_{50} value in MRC-5 cells. A similar phenomenon was also reported in H-*ras*-transformed MCF10A and their parental noncancerous MCF10A cells.[14] The current study further demonstrated that capsaicin acts through SIRT1 to selectively induce two types of programmed cell death-like pathways: protective autophagy in noncancerous cells but cytotoxic apoptosis in cancer cells.

Another significant finding of this study is the demonstration of a regulatory role of SIRT1 in capsaicin-induced programmed cell death. SIRT1 belongs to the sirtuin protein family of NAD^+-dependent deacetylases that target histones and nonhistone proteins.[45,46] To our knowledge, Lee et al.[47] is first to focus on the links between SIRT1 and capsaicin. Although these researchers found that capsaicin acted through inhibition of apoptosis to exert a neuroprotective effect against glutamate-induced toxicity, they found no significant effect of capsaicin on SIRT1 mRNA levels. Thus, it remained unclear whether capsaicin affected SIRT1 deacetylase activity and its downstream target proteins. In this study, we found that capsaicin reduced SIRT1 expression in A549 cells (Figure 5B), although

DOI: 10.1021/acs.jafc.5b02876
J. Agric. Food Chem. 2015, 63, 7361−7370

we have not examined whether capsaicin-induced SIRT1 down-regulation is at the translational or transcriptional level at this point. It is suggested that p53 enhances microRNA-34a expression and promotes apoptosis[48] and that SIRT1 is one of the direct target genes of microRNA-34a.[49] Consistent with our results (Figure 5C), it is possible that capsaicin induces p53 activation, leading to microRNA-34a expression and SIRT1 down-regulation in A549 cells. The lack of inhibitory effect of capsaicin on SIRT1 expression in MRC-5 cells was perhaps due to less activation of p53 (Figure 5B); however, it remains unconfirmed at this point.

Interestingly, activation of AMPK, an important activator for SIRT1, was found to be associated with capsaicin-induced apoptosis in cancer cells.[11,50] However, whether capsaicin-induced AMPK activation modulates SIRT1 activity and subsequent apoptosis was not examined further in these previous studies. A most recent report has demonstrated that capsaicin increases FOXO-1 acetylation through the modulation of SIRT deacetylase activity, leading to apoptosis in pancreatic cancer cells.[51] All of this evidence provides a rationale to explore the role of SIRT1 in capsaicin-induced programmed cell death, as shown in our present study; capsaicin modulates SIRT1 deacetylase activity, leading to apoptosis in A549 cancer cells but autophagy in MRC-5 cells. By dissecting the different pathways triggered by capsaicin, we present evidence that the intracellular NAD^+/NADH ratio contributes to the divergent effects of capsaicin in noncancer and cancer cell lines. NAD^+ plays an essential role in many metabolic reactions, and it has recently emerged that NAD^+ acts as a metabolic regulator, in part, through regulation of SIRT family.[52] Given the metabolic centrality of NAD, NAD^+/NADH ratios must be well regulated by several complex systems to maintain redox homeostasis. In this context, we here provide evidence suggesting that tNOX also participates in modulating the cellular NAD^+/NADH ratio in cancer cells. Thus, it is not surprising that tNOX also plays a role in capsaicin-induced apoptosis in this system. In fact, we previously discovered that capsaicin has divergent effects on the growth of gastric cancer cells that parallel its effects on tNOX expression, apoptosis in association with reduced tNOX expression in SNU-1 gastric cancer cells, and little apoptosis accompanied by insignificant changes in tNOX in the TMC-1 metastatic gastric carcinoma line.[4] However, whether the intracellular NAD^+/NADH ratio also contributed to the different cellular responses between these two gastric cancer lines was not examined. Experiments utilizing tNOX-knockdown cells showed that tNOX-depletion decreased the intracellular NAD^+/NADH ratio compared to that in control cells (Figure 5), further confirming a regulatory role of tNOX in maintaining the NAD^+/NADH redox status. Our results thus provide yet another scenario in which capsaicin regulates intracellular NAD^+/NADH ratio and SIRT1 activity in A549 cancer cells, in this case through tNOX protein. In contrast, the lack of tNOX expression in the noncancer MRC-5 line resulted in an attenuated inhibitory effect of capsaicin on the intracellular NAD^+/NADH ratio that acted concurrently with capsaicin-induced SIRT1 activity (measured in vitro) to ultimately deacetylate p53 and induce autophagy.

Notwithstanding being generally considered a chemopreventive agent, capsaicin has demonstrated mutagenic properties[53] and tumor-promoting effect.[42,54−58] Moreover, data from epidemiologic studies suggest that capsaicin may exert dual effects—antitumor or tumor-promoting—depending on the dose.[59] For example, capsaicin functions as a cocarcinogen through EGFR signaling in the TPA-induced skin cancer model.[60] Erin et al. also reported that capsaicin promotes a more aggressive gene expression phenotype and represses expression of pro-apoptotic proteins in breast cancer cells,[61] supporting the idea that capsaicin acts on other targets to activate unanticipated pathways, subsequently leading to tumorigenesis. A study from our own laboratory has shown that low concentrations of capsaicin up-regulate tNOX expression in colon cancer cells in conjunction with enhanced cell proliferation and migration.[62] Consistent with our findings, Waning et al. also present a precedent for the reinforcing effect of capsaicin on cell migration.[63] Much remains to be learned regarding the cellular targets of capsaicin and the molecular mechanisms initiated by capsaicin that mediate its effects, from cell death to sustained cell survival.

We have elucidated the differential effects of capsaicin utilizing cell lines from lung tissues addressing not only the role of tNOX in cancer cells but also the signal pathways leading to two types of programmed cell death. Our results demonstrated, for the first time, that intracellular NAD^+/NADH ratio and SIRT1 deacetylase activity are central to the regulation of capsaicin-induced programmed cell deaths in cancer and noncancerous cell lines, specifically, apoptosis in A549 cancer cells but survival autophagy in MRC-5 cells. The findings of this study assist us in understanding the biological function of capsaicin and should provide a rational framework for the further development of improved chemopreventive strategies.

mechanisms for the observed reduction of total cholesterol levels in serum. Other studies carried out using other mushroom species such as *G. frondosa* mentioned hepatic upregulation of the *Abcg5/8* genes (genes encoding cholesterol transporters, ATP-binding cassette subfamily G proteins, involved in cholesterol excretion from the liver to the bile or in reverse cholesterol transport from the enterocyte to the intestinal lumen).[15] Mushroom DF fractions include mainly by water-insoluble polysaccharides, with β-glucans and chitins being higher in concentrations, whereas the levels of water-soluble polysaccharides are usually lower than 10% (depending on species).[1]

However, the described molecular studies on edible mushroom DF were carried out using cholesterol-free or standard diets; therefore, animals showed no hypercholesterolemia or altered cholesterol-related biochemical parameters. Functional foods with hypocholesterolemic properties (such as products enriched in phytosterols, cereal β-glucans, etc.) are usually recommended by physicians/nutritionists to people with slight to moderate hypercholesterolemia; thus, if a new functional product (based on mushroom DF) is intended to be developed, then the effect of such a fraction should be tested on individuals with certain level of hypercholesterolemia. Moreover, other reports indicated that when hypercholesterolemic animals were regularly fed with whole fruiting bodies, lowering of cholesterol in serum was noticed.[11]

Thus, in order to study whether DF fraction obtained from edible mushrooms can be used as a hypocholesterolemic ingredient to design novel functional foods and study their influence at the molecular level under cholesterol-altered physiological conditions, the modulation of mRNA expression of genes related to cholesterol metabolism was investigated using two models of hypercholesterolemic mice and low-density arrays (LDA). First, a preliminary in vitro study was carried out using Caco-2 cell cultures to select one DF fraction out of the three most consumed mushrooms (*A. bisporus*, *P. ostreatus*, and *L. edodes*) to reduce the number of mice and assays. Then, two different in vivo experiments were carried out in order to compare the effect of a mushroom DF fraction with two hypocholesterolemic drugs.

MATERIALS AND METHODS

Raw Material and Preparation of the Dietary Fiber-Enriched Extracts. Fresh fruiting bodies of *A. bisporus* L. (Imbach) Fungisem H-15, *P. ostreatus* (Jacq. Ex Fr.) Kummer strain Gurelan H-107, and *L. edodes* S. (Berkeley) from Sylvan 4312 from the first flush were harvested, cut in slices, lyophilized, and ground until a dry powder was obtained following the procedure described by Gil-Ramírez et al.[16] Resulting mushroom powders were utilized as starting material to extract the DF. DF-enriched fractions from the three mushroom species were prepared according to the method of Jeurink et al.[17]

Standards and Reagents. Solvents such as hexane (95%), chloroform, and methanol (HPLC-grade) were obtained from LAB-SCAN (Gliwice, Poland). Potassium hydroxide, ascorbic acid, BHT (2,6-di-*tert*-butyl-*p*-cresol), cholesterol, cholic acid, ergosterol, congo red, and hexadecane were purchased from Sigma-Aldrich (Spain). Simvastatin was obtained from Cinfa Laboratories (Spain) and ezetimibe (Ezetrol) from Merck Sharp & Dohme (Spain). Schizophyllan was purchased from Contripo Biotech S.R.O. (Czech Republic). All other reagents and solvents used were of analytical grade.

β-Glucan Content of DF Fractions. The β-glucan content of the obtained DF fractions (50 mg) was evaluated in duplicate by a β-glucan determination kit specific for mushrooms (Megazyme, Spain) as described in Palanisamy et al.[18] The amount of β-(1 → 3)(1 → 6)-glucans was also determined following the method of Nitschke et al.[19] using a red congo concentration of 0.08% (w/v) and schizophyllan as standard curve; chitins concentrations were determined as described in Palanisamy et al.[18]

In Vitro Digestion. Obtained DF fractions were submitted to an in vitro digestion according to Palanisamy et al.[18] Briefly, the extracts were digested in 1 mL of 0.01 M HCl for 1 h at 37 °C with gentle agitation (Orbital incubator S150, Stone, UK). Afterward, the sample pH was adjusted to 6.3 with 0.1 mL of 0.1 M NaOH. Then, 4 mL of bile extract (14.3 mg in Tris-maleate buffer, pH 6.3) and 5 mL of pancreatin (10 mg in tris-maleate buffer, pH 6.3) were added, and the mixture was incubated for 1 h at 37 °C. After digestion, the samples were added to Caco-2 cultures. A control sample was prepared following the same digestion protocol but without the addition of DF fractions.

Caco-2 Cell Cultures. Human colorectal adenocarcinoma cell line Caco-2 (ATCC HTB-37) obtained from the ATCC (Rockville, MD, USA) were maintained in Dulbecco's modified Eagle's medium (DMEM) with high glucose content (4.5 g/L) and supplemented with 10% fetal bovine serum, 1% penicillin−streptomycin, and 1% nonessential amino acids. First, the cytotoxicity was evaluated using 3-(4,5-dimethylthiazol)-2,5-diphenyl tetrazolium bromide (MTT) according the method published by Mosmann et al.[20] Then, cells were seeded at a density of 3.3×10^5 cell/mL and were allowed to generate a monolayer for 21 days before experiments. The digested DF fractions were applied at subtoxic concentrations (4 μL/mL) and left incubating at 37 °C and 5% CO_2 for 1 or 24 h. Afterward, cells were separated from the membranes by incubation at 37 °C during 30 min with Triton 0.1% and submitted to RNA extraction. Four replicates per sample were carried out.

Animals and Diets. Male C57BL/6JRj mice were purchased from Janvier SAS (Le Genest, France). Mice were maintained in temperature-, humidity-, and light-controlled conditions (24 ± 2 °C, 40−60% humidity, 12:12 h light: dark cycle) and had free access to water and food. They were randomly divided into five groups. Normal control group (NC, $n = 6$) was fed a standard diet (Safe Rodent Diet A04, France), and the hypercholesterolemic control group (HC, $n = 8$) was fed a high-cholesterol diet. The treated groups ($n = 8$) were given a high-cholesterol diet supplemented with their corresponding mushroom extract or control drug and were identified as follows: PDF (*Pl. ostreatus* DF fraction), SV (simvastatin, as a positive control for inhibition of cholesterol biosynthesis), and EZ (ezetimibe as a positive control for inhibition of cholesterol absorption). The animal intervention was carried out following two experimental settings in order to evaluate whether PDF might act as a palliative agent (sequential supplementation) or preventive agent (simultaneous supplementation) against diet-induced hypercholesterolemia. In the sequential supplementation, mice were fed high-cholesterol diet for 4 weeks (from 5 to 9 weeks of age), followed by another 4 weeks of high-cholesterol diet plus mushroom extract (from 10 to 13 weeks of age), whereas in the simultaneous supplementation, mice were simultaneously fed a high-cholesterol diet and the mushroom extract for 4 weeks (from 10 to 13 weeks of age). The composition of diets, the dose per day of mushroom extract, drug, or β-glucans as well as the energy that was received by the mice daily is shown in Table 1. Body weight was registered before the experimental feeding period and at the end of the experiments. Wet mass of the liver was also registered. Animal studies were approved by our institution's Animal Welfare and Ethics Committee and were carried out according to Spanish and European legislation (RD 53/2013, 2010/63/EU, respectively).

Feces, Plasma, and Liver Lipid Analyses, Tissue Collection. At the end of the experiments, mice were sacrificed by intracardiac exsanguination under anesthesia with 1.5% isoflurane, and plasma was stored at −80 °C before use. Jejunum, ileum, cecum, and liver samples were removed, immediately frozen in liquid nitrogen, and stored at −80 °C. Feces were collected at the beginning and at the end of the experimental feeding period and maintained at −20 °C until further use. Cholesterol extraction from the stored feces (300 mg) and analysis by GC-MS were carried out as described in Gil-Ramírez et al.[16] Plasma levels of total cholesterol, triglyceride, HDL cholesterol, and LDL cholesterol were measured in duplicate for each sample using

[a]NC, normal control; HC, hypercholesterolemic control; PDF: *Pleurotus ostreatus* DF fraction; SV: simvastatin; EZ: ezetimibe; n.m.: not measured. [b]β-glucans excluded. [c]A04 mineral mixture.

a Covas C311 Auto analyzer (Roche, Spain). Cholesterol and triglyceride were extracted from the liver and analyzed in duplicate according to the manufacturer's protocol by colorimetric kits (BioVision Inc., CA, USA).

Statistical Analysis for Biochemical Data. All values were expressed as mean ± SD. The SPSS v15.0 software (Lead Technologies, IL, USA) was used to determine whether the variables differed among treatment groups. The effects of treatments were assessed by one-way ANOVA followed by Tukey's test when the ANOVA identified significant treatment effects. Differences with $P < 0.05$ were considered statistically significant.

RNA Extraction from Cells and Mice Tissues and Quantitative Real-Time PCR for LDA. Total RNA from cell cultures or mice tissues was extracted by magnetic bead technology using a pureLinkTM Total RNA kit TRIzol Plus RNA Kit (Invitrogen, CA, USA) in an iPrepTM Purification Instrument (Invitrogen) programmed with an iPrepTM total RNA card (Invitrogen) according to manufacturer instructions. The RNA concentration was determined by spectrophotometry at 260 nm, and the purity of the extracted RNA was calculated from ratio of absorbance at 260/280 nm and 260/230 nm in a NanoDrop ND-1000 (NanoDrop Technologies Inc., Wilmington, DE, USA). A 400 ng amount of total RNA from each sample was reverse transcribed using the High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, MA, USA). The obtained cDNA (100 μL per port) were loaded into microfluid cards designed for low-density array (LDA), and the microfluid cards were run in a 7900HT Fast Real-Time PCR system (Applied Biosystems, MA, USA). Amplification conditions were 50 °C for 2 min, 94.5 °C for 10 min, followed by 40 cycles with 97 °C with 30 s and 59.7 °C for 1 min. The microfluid card was constructed using human and mouse commercially available assays for several genes related to the cholesterol metabolism, some internal standards, and housekeeping genes that are described in detail elsewhere.[21] The cholesterol-related genes were ABCA1 (ATP-binding cassette, sub-family A, member 1), ABCG5 and ABCG8 (ATP-binding cassette, subfamily G (WHITE), members 5 and 8), ACAT1 and ACAT2 (acetyl-CoA acetyltransferase 1 and 2), APOB (apolipoprotein B), DGAT1 and DGAT2 (diacylglycerol O-acyltransferase 1 and 2), FDFT1 farnesyl-diphosphate farnesyltransferase 1), HMGCR (3-hydroxy-3-methylglutaryl-CoA reductase), LDLR (low-density lipoprotein receptor), MTTP (microsomal triglyceride transfer protein), NPC1L1 (Niemann-Pick C1-like 1), NR1H3 and NR1H4 (nuclear receptor subfamily 1, group H, member 3 and 4), SOAT1 and SOAT2 (sterol O-acyltransferase 1 and 2), SREBF1 and SREBF2 (sterol regulatory element binding transcription factor 1 and 2). Comparative analysis of each of these genes was performed using specialized computer programs SDS2.3 and RQ 2.1 (Applied Biosystems).

Gene Expression Statistical Data Analysis. The expression of each gene was measured at least in duplicate, and each biological group included a minimum of three replicates. To control for potential outliers, Grubb's test was applied to technical replicates with a threshold of 0.05. Biological replicates were quality controlled using the median absolute deviation test (MAD test). Samples of the same biological group with a MAD score higher than 3 were removed from the analysis. Genorm algorithm[22] was used to identify the most stable reference genes for normalization. Genes GUSB and HPRT1 were found to be the most stably expressed in Caco-2 cell cultures. In the mouse tissue samples, genes *Hprt1* and *Polr2a* were the most stably expressed in cecum and liver tissues; *Gusb* and *Polr2a* were the most stably expressed in jejunum and ileum tissues. Relative gene expression levels were calculated by using the 2-ΔΔCT method;[23] using these, we identified most stable genes as internal control genes in each group. Statistical significance of the results was assessed using a Limma test, and Benjamini–Hochberg false discovery rate procedure was subsequently applied. Adjusted P values lower than 0.05 were considered significant. All these calculations were carried out with Real Time StatMiner 4.5 (Integromics S.L, Spain).

RESULTS

Modulation of the mRNA Expression Pattern in Caco-2 Cell Cultures. First, three mushroom species (*A. bisporus*, *L. edodes*, and *P. ostreatus*) were selected because they showed in vitro bile-acid-binding capacity, and this ability could be related to hypocholesterolemic activities.[18] Then, digestates of the mushroom DF fractions were applied to Caco-2 cells to investigate their influence on cholesterol-related gene expression. Results indicated that 1 h after application only digested DF fraction from *A. bisporus* and *P. ostreatus* were able to induce significant overexpression of NR1H4 (Figure 1a). Moreover, the digestate of the *A. bisporus* DF fraction upregulated the ACAT2 gene and downregulated the MTTP and SOAT2 genes. However, when the treated cells were incubated for 24 h, overexpression of other genes was induced by the digestates obtained from the DF fractions of *L. edodes* and particularly of *P. ostreatus* (Figure 1b), acting differently than those of *A. bisporus* that showed no effect. Both digestates were able to induce significant overexpression of the NPC1L1 gene directly involved in cholesterol absorption. Digestates from the DF fraction of *L. edodes* induced mRNA LDLR expression, whereas those from *P. ostreatus* induced mRNA expression of other cholesterol-related genes such as DGAT1, FDFT1, SOAT1, and SREBF1 and inhibited mRNA expression of SOAT2.

The fractions of the three mushroom species contained similar polysaccharide compositions,[18] including chitin content lower than β-glucans content. However, those β-glucans apparently showed different solubilities (Table 2). The DF fraction of *A. bisporus* contained lower β-(1,3)(1,6)-glucans concentration than the other two DF fractions, and they were not soluble in KOH. β-(1,3)(1,6)-glucans from the *L. edodes* DF fraction were mainly soluble in alkalis, whereas those of the *P. ostreatus* DF fraction were more soluble in KOH than in NaOH.

Effect of Mushroom Extract on Body and Liver Weight and Fecal Cholesterol Excretion. Food intake was approximately 4 g/day per mouse throughout the experimental feeding period in all groups, with no significant difference among groups (data not shown). No differences were noticed in initial body weight (Table 3). The normal control group gained weight over the feeding period in the sequential and simultaneous experiments. As expected, the remaining groups showed a slight tendency to lose weight because diets supplemented with cholate and cholesterol induced even higher

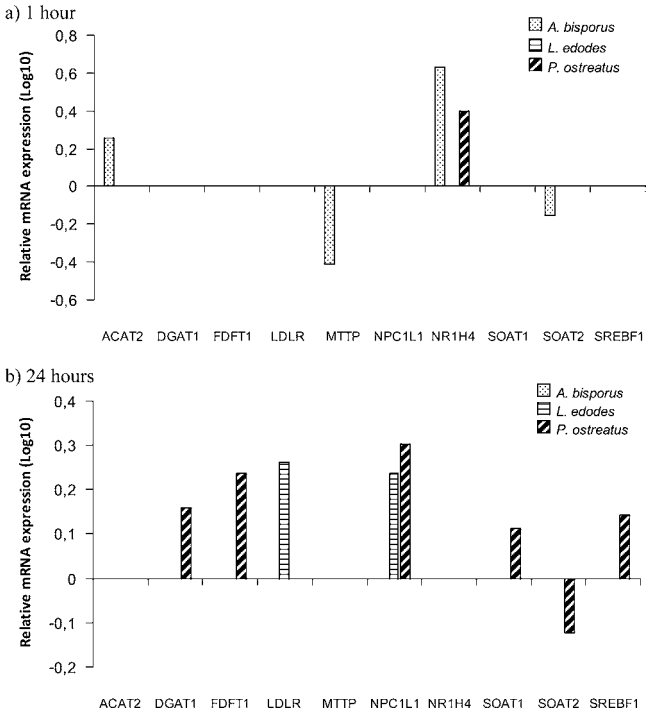

Figure 1. Relative mRNA expression (log 10) of Caco-2 cells' cholesterol-related genes after (a) 1 h and (b) 24 h application of the digested DF fraction obtained from *A. bisporus*, *L. edodes*, or *P. ostreatus*. Indicated genes are only those noted as significant ($P < 0.05$) compared with their controls (addition of the digestion product without DF addition). The expression of each gene was measured at least in duplicate, and each biological group included a minimum of three replicates. A few genes did not pass the quality control either in the target or the control group; therefore, their expression level was omitted in the figure.

weight loss in C57BL/6J mice.[24] No significant differences in final body weight of the treated groups was noticed compared with that of the hypercholesterolemic control group either in the sequential or simultaneous experiment, except for the simvastatin group where a significantly lower final body weight was recorded compared to those of all other groups. In the sequential experiment, liver weight was significantly increased in the hypercholesterolemic controls and the treated groups, except the simvastatin group, compared with that of the normal control group. Similar results for liver-to-body-weight ratio were observed, with a significant increase in all groups compared to that of the normal control group. In the simultaneous experiment, liver weight was also significantly increased in the hypercholesterolemic controls compared with that of the normal control group, and liver-to-body-weight ratio was significantly increased in the hypercholesterolemic controls and PDF group. The simvastatin and ezetimibe groups showed a significantly lower liver weight compared with that of hypercholesterolemic controls. Similar results for liver-to-body-weight ratio were observed, although only the ezetimibe group reached statistical significance.

No cholesterol was detected in feces of normal controls, but hypercholesterolemic controls significantly increased their cholesterol excretion in either the sequential or simultaneous supplementation compared with normal controls. In the sequential experiment, no significant difference in cholesterol excretion was noticed between hypercholesterolemic controls and the treated groups, except for mice fed the PDF extract where a significantly lower cholesterol excretion was observed. In the simultaneous experiment, the slightly higher cholesterol excretion was significant for the ezetimibe group compared with that of hypercholesterolemic controls but not for mice fed with PDF. No differences were noticed in mice treated with simvastatin with respect to hypercholesterolemic controls.

Modulation of the Lipid Profile of Plasma and Liver in the Animal Intervention. *Sequential Supplementation.* Plasma cholesterol levels increased 3.3-fold in hypercholesterolemic controls compared with normal controls (Table 4). In mice fed PDF or treated with simvastatin, plasma cholesterol levels remained unchanged compared with those in hypercholesterolemic controls, whereas a reduction reaching normal levels was observed in the ezetimibe group. There was no significant difference in the plasma HDL levels between normal controls and hypercholesterolemic controls. No significant differences between mice fed the PDF or treated with simvastatin and hypercholesterolemic controls were observed, although interestingly the mushroom DF extract slightly increased HDL levels by 9% compared to that of hypercholesterolemic controls. Ezetimibe induced a significant reduction. The LDL levels were markedly increased by 6.6-fold in hypercholesterolemic controls compared with normal controls but remained unchanged in mice fed PDF or treated with simvastatin with respect to hypercholesterolemic controls. Reduction was noticed with the administration of ezetimibe compared with hypercholesterolemic controls. In addition to the plasma lipid profile, two atherogenic indexes were calculated: total cholesterol/HDL and LDL/HDL ratios. Compared with normal controls, the total cholesterol/HDL and the LDL/HDL ratios were significantly increased in hypercholesterolemic controls by 2.1- and 5.3-fold, respectively. It is noteworthy that a slight and not significant negative balance in both indexes was improved in mice fed PDF compared with hypercholesterolemic controls mainly because of the increase in HDL levels. A significant reduction in both indexes was noticed in the ezetimibe group but not in the simvastatin group. Hypercholesterolemic controls and treated groups showed a reduction in plasma triglyceride levels compared to normal controls. However, when compared to hypercholesterolemic controls, treated groups showed quite similar plasma triglyceride levels.

Liver cholesterol levels were significantly increased by 4.9-fold in hypercholesterolemic controls compared with normal controls. In contrast with the lacking effect of PDF on total plasma cholesterol, a 21% reduction in liver cholesterol levels

Table 2. Total β-Glucan Concentrations of the DF Fractions Obtained from the Three Mushroom Species and Their Distribution as β-(1,3)(1,6)-Glucans or Chitins

[a]NC, normal control; HC, hypercholesterolemic control; PDF: *Pleurotus ostreatus* DF fraction; SV: simvastatin; EZ: ezetimibe. TC, total cholesterol; HDL, high-density lipoprotein cholesterol; LDL, low-density lipoprotein cholesterol; TG, triglyceride. The results are mean ± SD of six (NC group) or eight (remaining groups) mice on each diet and were analyzed by one-way ANOVA and the Tukey's procedure. The assays were performed in duplicate for each sample. [b]$P < 0.05$ vs NC. [c]$P < 0.05$ vs HC. [d]$P < 0.05$ vs SV. [e]$P < 0.05$ vs EZ.

compared to hypercholesterolemic controls was observed, although it did not reach statistical significance. Simvastatin had no effect, whereas ezetimibe produced a significant reduction compared with hypercholesterolemic controls. No significant differences in liver triglyceride levels were detected between hypercholesterolemic and normal controls. Treated groups showed a significant reduction with respect to normal and hypercholesterolemic controls, and mice treated with simvastatin or ezetimibe showed significant lower values compared with those of mice fed PDF.

Simultaneous Supplementation. Plasma cholesterol levels increased 1.9-fold in hypercholesterolemic controls compared to normal controls (Table 5). No significant difference was noticed between PDF and hypercholesterolemic control group. Simvastatin and ezetimibe produced a significant reduction, with ezetimibe being the most effective. Plasma HDL levels were increased in hypercholesterolemic controls compared with normal controls. No significant difference in plasma HDL levels was observed between PDF and hypercholesterolemic control group, whereas treatment with simvastatin or ezetimibe induced a significant reduction. A 16-fold increase in plasma LDL levels was observed in hypercholesterolemic controls compared with normal controls. Mice fed with PDF showed no significant changes compared with hypercholesterolemic controls, whereas simvastatin and ezetimibe groups showed significant reductions. The total cholesterol/HDL ratio was moderately increased ($P = 0.071$) in hypercholesterolemic controls compared with normal controls. No significant differences between hypercholesterolemic controls and treated groups were observed. An 11.3-fold increase in the LDL/HDL ratio was noticed in hypercholesterolemic controls compared with normal controls. Similar values were observed in the treated groups except for the ezetimibe group where a significant reduction compared with hypercholesterolemic controls was recorded. Plasma triglyceride levels were reduced in hypercholesterolemic controls compared to normal controls, and compared to hypercholesterolemic controls, similar plasma triglyceride levels were observed in the treated groups.

There was no significant difference in liver cholesterol levels between normal and hypercholesterolemic controls. Liver cholesterol levels in the simvastatin group were significantly higher than those in the hypercholesterolemic control group, but no significant differences in the PDF or ezetimibe groups were observed compared with hypercholesterolemic controls. No significant differences in liver triglyceride levels were detected between normal and hypercholesterolemic controls or between PDF group and hypercholesterolemic controls. Liver triglyceride levels in mice treated with simvastatin or ezetimibe were significantly lower than those in hypercholesterolemic controls.

Modulation of the mRNA Expression Pattern in the Animal Intervention. *Sequential Supplementation.* In the jejunum, PDF induced overexpression of 10 genes, particularly

The results are mean ± SD of six (NC group) or eight (remaining groups) mice on each diet and were analyzed by one-way ANOVA and the Tukey's procedure. The assays were performed in duplicate for each sample. [b]$P < 0.05$ vs NC. [c]$P < 0.05$ vs HC. [d]$P < 0.05$ vs SV. [e]$P < 0.05$ vs EZ.

Fdft1, *Abca1* and *Npc1l1*. On the contrary, it inhibited the expression of *Nr1h4* and *Srebf2* to a degree similar to that induced by simvastatin and ezetimibe. Treatment with either simvastatin or ezetimibe inhibited the expression of *Srebf1*, and simvastatin further inhibited other genes such as *Fdft1*, *Hmgcr*, *Ldlr*, *Npc1l1*, and *Nr1h3* (Figure 2a). No significant changes induced by PDF or the two drugs were observed in the ileum (data not shown). However, a higher transcriptional regulation was found in the cecum, with PDF being the one that modulated the expression of more genes, whereas simvastatin showed no effect, suggesting a response for the accumulation of the indigestible DF fraction in the large intestine (Figure 2b). PDF induced upregulation of *Abcg5*, *Acat1*, *Dgat1*, *Ldlr*, and *Srebf1*, whereas the expression of *Hmgcr* and *Nr1h4* were slightly decreased. Ezetimibe induced upregulation of *Abcg5* and downregulation of *ApoB* and *Fdft1*. In the liver, PDF inhibited *Dgat1*, *Ldlr*, and *Nr1h4* expression to a degree similar to that induced by simvastatin and induced overexpression of *Acat1*, *Srebf1*, and *Srebf2*. Simvastatin inhibited the expression of *Abcg8*, *Ldlr*, *Nr1h4*, and *Dgat1*/2 (Figure 2c). Ezetimibe inhibited expression of *Abcg8* and *Dgat1*.

Simultaneous Supplementation. In the jejunum, PDF induced *Fdft1* overexpression (Figure 3a) at levels similar to those induced by sequential supplementation (Figure 2a) and *Srebf2* overexpression. Simvastatin induced overexpression of *Abcg8*, whereas ezetimibe did not induce statistically significant changes. In the ileum, PDF did not modify the gene expression profile (Figure 3b). Simvastatin induced upregulation of *Abca1*, *Fdft1*, and *Nr1h3* genes and downregulation of *ApoB*, whereas ezetimibe induced *Dgat1* and *Nr1h3* upregulation. In the cecum, *Dgat1* and *Soat2* expression were upregulated by PDF and simvastatin, respectively (Figure 3c). The hepatic expression profile was largely modulated by PDF and drugs with a clear tendency to downregulate rather than upregulate cholesterol-related genes (Figure 3d). PDF increased *Acat1* and *Srebf2* expression and decreased the expression levels of eight genes. Simvastatin slightly increased expression levels of *ApoB* and decreased expression levels of nine genes, particularly *Fdft1*. Ezetimibe increased and decreased expression levels of, respectively, 3 and 10 genes. *Abcg5*, *Fdft1*, *Ldlr*, *Nr1h3*, and *Nr1h4* were downregulated by PDF, simvastatin, and ezetimibe.

DISCUSSION

To select the more interesting DF fraction regarding its potential hypocholesterolemic effect, in vitro gene expression studies were carried out before in vivo studies. The DF fractions obtained from *A. bisporus*, *P. ostreatus*, and *L. edodes* mushrooms were submitted to in vitro digestion and applied to Caco-2 cultures in order to mimic in vivo conditions. The expression profiles of cholesterol-related genes in Caco-2 cells were different depending on the DF fraction assayed with *P. ostreatus* being the one that showed larger transcriptional changes. DF digestion can induce conformational changes in β-glucans structure, influencing their solubility, or can stimulate partial liberation of more water-soluble oligosaccharides,[18,25] modifying their biological properties.[26] Thus, the different DF fractions' effects at the transcriptional level could be due to the different solubilities and conformations formed in the DF digestates. PDF induced transcriptional changes in the short and longer terms because NR1H4 mRNA was upregulated after 1 h whereas FDFT1 and NPC1L1 genes were upregulated after 24 h. These results might suggest a possible cholesterol-lowering effect because on one hand FXR activation lowers plasma cholesterol in mice[27] and on the other hand the retarded activation of genes that enhance cholesterol biosynthesis (FDFT1) and cholesterol absorption (NPC1L1) suggests a compensatory response to the reduced available cholesterol in the cells 24 h after application of *P. ostreatus* digestate. Taking into account these observations together with the fact that *Pleurotus* is one of the genera that have been target of more studies describing its hypocholesterolemic properties, PDF was selected for in vivo studies.

In the sequential supplementation, PDF administration did not improve plasma and liver cholesterol levels and slightly reduced fecal cholesterol, indicating that the extract was not able of acting as a palliative agent. However, increased plasma and liver cholesterol levels as a consequence of reduced fecal cholesterol excretion were also not observed. In contrast, concomitant overexpression of *Npc1l1*, *Abcg5*, and *Abcg8* in the jejunum makes difficult a clear explanation because *Npc1l1* upregulation could be associated with enhanced intestinal cholesterol absorption and therefore reduction of fecal cholesterol excretion[28] but not upregulation of *Abcg5* and *Abcg8* genes, which can stimulate effect opposite that of *Npc1l1*. Mice fed PDF showed slightly higher (not significant) HDL levels compared with those of hypercholesterolemic controls. Elevation in

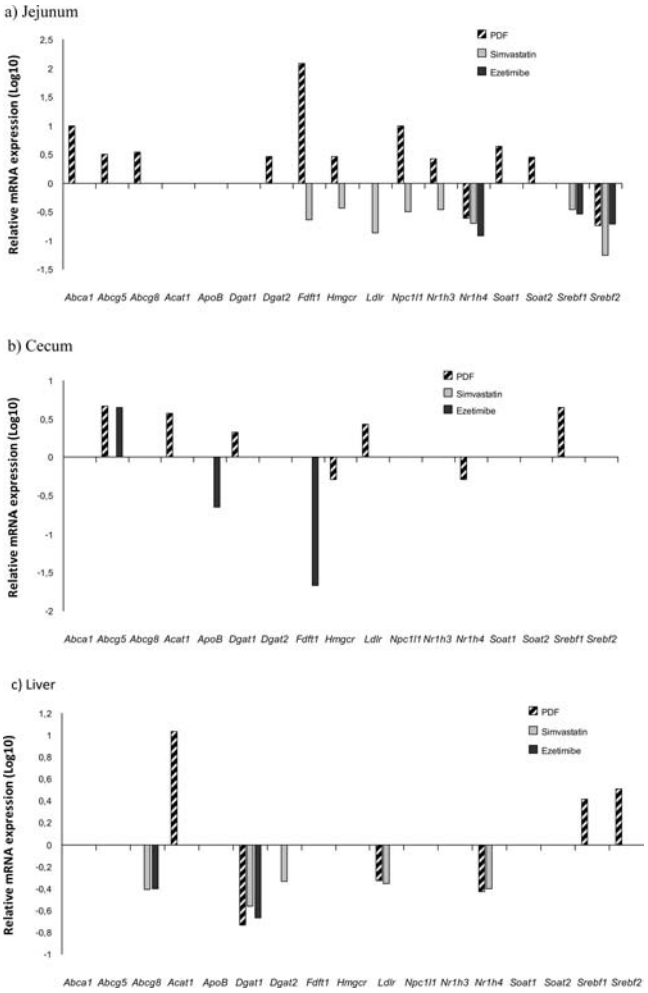

Figure 2. Relative mRNA expression (log 10) of cholesterol-related genes in (a) jejunum, (b) cecum, and (c) liver of mice treated for 4 weeks with PDF, simvastatin, or ezetimibe simultaneously with high-cholesterol diet after 4 weeks of high-cholesterol diet alone (sequential supplementation). Indicated genes are only those noted as significant ($P < 0.05$) compared with hypercholesterolemic mice at 8 weeks as control. The expression of each gene was measured at least in duplicate, and each biological group included a minimum of three replicates. A few genes did not pass the quality control either in the target or the control group; therefore, their expression level was omitted in the figure.

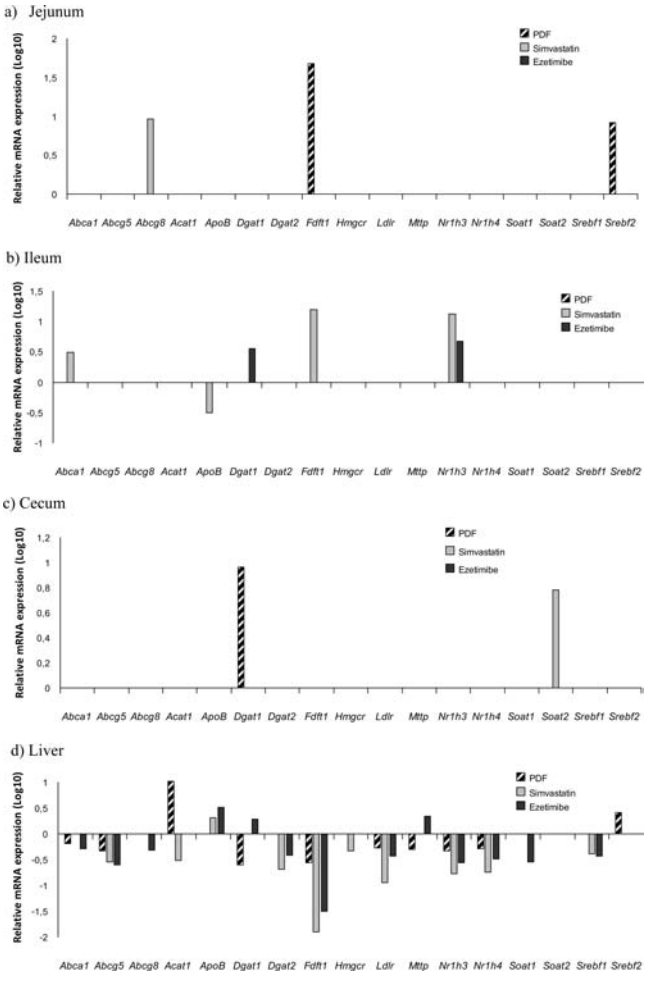

Figure 3. Relative mRNA expression (log 10) of cholesterol-related genes in (a) jejunum, (b) ileum, (c) cecum, and (d) liver of mice treated for 4 weeks with PDF, simvastatin, or ezetimibe simultaneously with high-cholesterol diet (simultaneous supplementation). Indicated genes are only those noted as significant ($P < 0.05$) compared with hypercholesterolemic mice at 4 week as control. The expression of each gene was measured at least in duplicate, and each biological group included a minimum of three replicates. Few genes did not pass the quality control either in the target or the control group; therefore, their expression level was omitted in the figure.

HDL levels occurs through an increase in liver production of *apoAI*,[29] and *Abca1* overexpression in the jejunum was associated with enhanced *apoAI* and HDL plasma levels in mice.[30] Thus, the slight (not significant) increase of HDL levels induced by PDF might be related to the enhanced jejunal *Abca1* expression, and the weakness of that effect might likely be due to the lower HDL production in jejunum compared to liver.

Diet supplementation with PDF and control drugs decreased triglyceride in the liver but not hepatomegaly (measured as liver-to-body-weight ratio) induced by high-cholesterol diet. Parallel to that reduction, hepatic *Dgat1* downregulation in the three experimental groups was observed, suggesting that the reduced hepatic triglyceride accumulation could be induced by inhibition of triglyceride synthesis. Another hepatic triglyceride-lowering pathway is the one induced by cholic acid. In mouse models of hypertriglyceridemia, cholic acid reduces hepatic expression of *Srebp-1c* via *Nr1h4* upregulation.[31] In contrast, *Srebf1* upregulation and *Nr1h4* downregulation were observed in mice fed PDF, which rules out regulation of liver triglyceride via that pathway. Reduction of liver triglyceride by simvastatin or ezetimibe was also not associated with that pathway. Therefore, results suggest a common effect for PDF, simvastatin, and ezetimibe for reducing liver triglyceride by inhibition of triglyceride synthesis mediated via *Dgat1* downregulation. Triglyceride accumulation in the liver caused by lifestyle-related diseases can result in more serious diseases. In this line, administration of *A. bisporus* prevents hepatic steatosis in mice,[32] and *Panellus serotinus* ameliorates nonalcoholic fatty liver disease in obese, diabetic mice.[33,34] Thus, PDF could be of interest to develop new therapeutic approaches preventing hepatic triglyceride accumulation. In addition to that effect, PDF showed a trend to reduce hepatic cholesterol (21%), although it did not reach statistical significance. Cholesterol-lowering effects in the liver can be directly induced by inhibition of synthesis (statins) or indirectly by decreasing enterohepatic circulation of bile acids

DOI: 10.1021/acs.jafc.5b02942
J. Agric. Food Chem. 2015, 63, 7371−7380

(bile acid sequestrants) that in turn results in increased bile acid synthesis and then decreased hepatic cholesterol.[35] Concerning the first case, neither PDF nor control drugs influenced *Fdft1* or *Hmgcr* expression in the liver, suggesting a lack of transcriptional effect on cholesterol synthesis. However, mice fed PDF showed hepatic overexpression of *Srebf-2* (gene encoding *Srebp2* protein), and *Srebp2* overexpression induces upregulation of *Fdft1* and *Hmgcr* in liver of mice fed a high-protein/low-carbohydrate diet.[36] Differences between the diet used by Sakakura et al. and those used in the models of this work could explain that apparent controversy. Regarding the second case, PDF induced downregulation of jejunal *Nr1h4* expression. In this line, the classical mechanism of action for the bile acid sequestrants is mediated by blocking apical bile acid uptake in the ileum, which results in downregulation of *Nr1h4* and its target genes[37], suggesting that the uptake of bile acids in the jejunum could be similarly blocked. Further studies assessing intestinal transport of bile acids are needed to confirm this possibility. The association between reduced liver cholesterol and reduced jejunal *Nr1h4* expression was more clearly noticed for ezetimibe but not for simvastatin where despite reduced jejunal *Nr1h4* a lack of effect on liver cholesterol was noticed.

In contrast with the effect of PDF in the sequential supplementation, no significant changes in fecal cholesterol excretion were noticed in the simultaneous supplementation. Lack of significant influence on cholesterol excretion in feces as compared with the hypercholesterolemic controls was also previously reported in hypercholesterolemic rats given powder of *P. ostreatus* fruiting bodies.[38] Although these slight changes were not directly associated with jejunal regulation of genes involved in cholesterol absorption or reverse cholesterol transport, *Srebf2* and *Fdft1* overexpression induced by PDF in the jejunum might be related, with a possible enhancing of cholesterol synthesis in the small intestine.

The hypocholesterolemic effect of edible mushrooms, particularly *P. ostreatus*, have been evidenced by animal trials,[11,39,40] and some of them pointed out mushroom DF from other mushrooms as having potential responsibility for the observed effects[12,13,41] although not all.[42,43] Rats administrated powdered *P. ostreatus* fruiting bodies (including similar amounts of DF than PDF) under similar experimental setting to the simultaneous supplementation but for a longer period of time did have lowering of plasma and liver cholesterol after 8[44] and 10 weeks.[42] Either the lower experimental time set for this experiment or different extract concentration could be the reason for the lack of significant hypocholesterolemic activity because in the latter reports a higher mushroom fiber dose (5 vs 1.5%) and normocholesterolemic condition instead of diet-induced hypercholesterolemia were utilized. Regarding the tissue-specific transcriptional regulation, no large changes were observed except for the liver. However, it is wise to notice that *Fdft1* upregulation was noticed in the jejunum of both mice models as well as in Caco-2 cells after PDF administration. Overexpression of the genes encoding enzymes might sometimes be related to reduction or insufficient enzyme activity; thus, perhaps PDF administration could inhibit or impair the normal squalene synthase function in enterocytes acting at post-transcriptional levels. However, more studies are needed to confirm this possibility. In liver, the administration of PDF or the two control drugs downregulated most of the genes. Interestingly, the hepatic expression of *Abcg5*, *Fdft1*, *Ldlr*, *Nr1h3*, and *Nr1h4* genes was downregulated by PDF, simvastatin, and ezetimibe. However, these changes do not mirror those observed in hepatic cholesterol or triglyceride levels. Concerning *Abcg5* expression in the liver, the heterodimer conformed by *Abcg5* and *Abcg8* is necessary for cholesterol excretion into bile,[45,46] and their overexpression promotes this phenomena.[47] Therefore, the physiological significance of downregulation of *Abcg5* gene alone is difficult to interpret. Although simvastatin and ezetimibe downregulated hepatic *Srebf1* and its target gene *Fdft1*[36] and PDF downregulated *Fdft1*, no correlation with changes in hepatic cholesterol levels was observed. Similarly, the *Ldlr* downregulation induced by PDF, simvastatin, and ezetimibe was not correlated with changes in plasmatic LDLc. However, the downregulation of *Dgat2* gene by simvastatine or ezetimibe suggests a possible association with the reduction of hepatic triglyceride levels observed.

PDF induced a downregulation of *Dgat1* mRNA similar to that induced by simvastatin or ezetimibe in liver, suggesting a possible relation between their reduced hepatic triglyceride levels and inhibition of triglyceride synthesis in the sequential supplementation. Thus, PDF may be useful in limiting hepatic triglyceride accumulation. The biochemical data recorded in plasma and liver for mice treated with PDF showed no significant changes in the cholesterol metabolism and no relation with the transcriptional changes observed. Once the hypercholesterolemia was induced in mice, administration of PDF or simvastatin was unable to revert that status. Thus, it seems that doses of fungal DF fractions similar to those effective in normocholesterolemic models for lowering cholesterol levels are ineffective in hypercholesterolemic mice. However, a mushroom extract that can modulate the transcription of genes involved in the cholesterol homeostasis in a manner similar to that of hypocholesterolemic drugs promotes further studies in a dose-dependent experimental setting to investigate in more detail its potential as a hypercholesterolemia preventive agent. Studies with higher doses are currently being developed to clarify the effect of mushroom DF fractions on lipid metabolism.

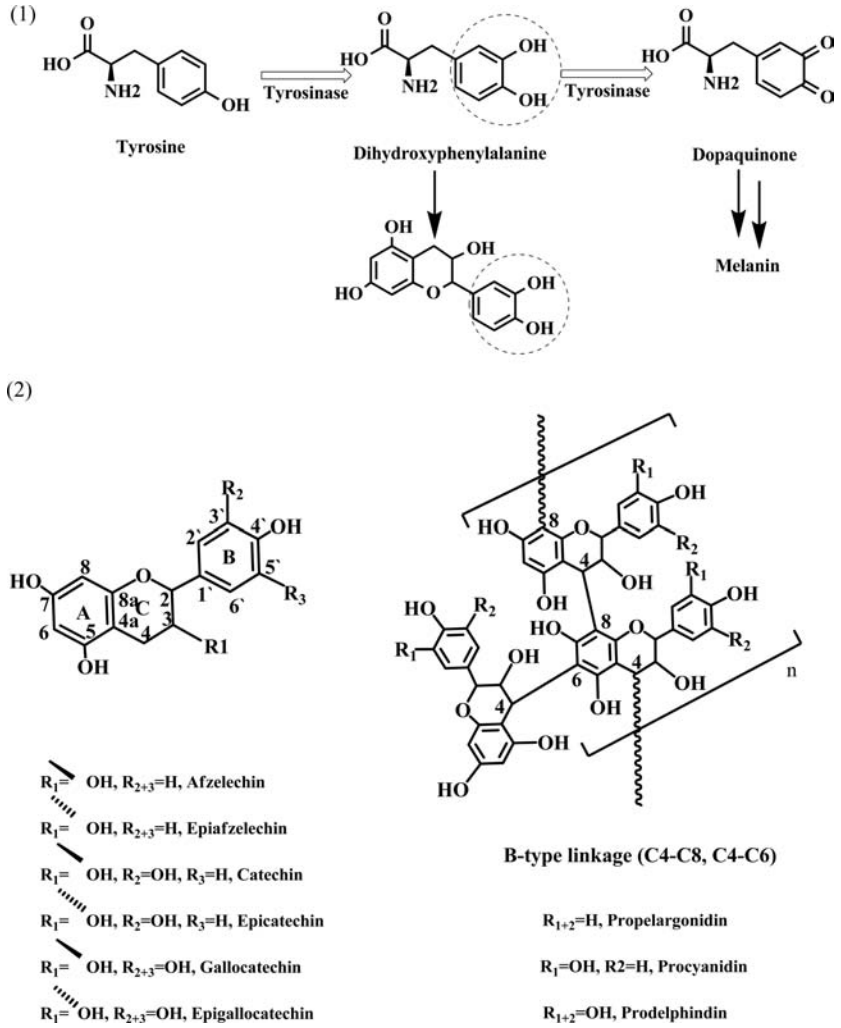

Figure 1. Chemical structures of proanthocyanidins, flavan-3-ol monomer units, and substrates of tyrosinase. (1) Processes of melanogensis and structural similarity between epicatechin/catechin and L-DOPA. (2) Chemical structures of flavan-3-ol monomer units and proanthocyanidins.

Amberlite IRP-64 cation-exchange resin, cesium chloride, 2,5-dihydroxybenzoic acid, and all HPLC standards were purchased from Sigma-Aldrich (St. Louis, MO). Arbutin was obtained from Aladdin (Shanghai, China). The fresh fruits of avocado were picked from the trees growing in Xiamen University (Xiamen, China) in August 2012. They were immediately washed, freeze-dried, ground, and stored at −20 °C before further processes.

Extraction and Purification of Avocado Proanthocyanidins. Powders (10.0 g) of the avocado fruit were ultrasonically extracted 3 times with acetone/water (70:30, v/v, each 200 mL) solution at 25 °C. Simultaneously, 0.1% ascorbic acid was added to prevent the oxidation of proanthocyanidins. Petroleum ether and ethyl acetate were then selected as an extractant to eliminate chlorophyll, lipophilic compounds, and low-molecular-weight phenolics. The remaining aqueous fraction was chromatographed on a Sephadex LH-20 column (50 × 1.5 cm inner diameter), which was eluted successively with 50% methanol/water and 70% acetone/water. The fraction of 70% acetone/water was retained; acetone was eliminated; and then the aqueous fraction freeze-dried to obtain purified proanthocyanidins.

MALDI−TOF MS Analysis. The MALDI−TOF MS spectra were obtained through a Bruker Reflex III (Germany). The experiment was completed according to the conditions and steps previously described.[4] As the irradiation source, a pulsed nitrogen laser (337 nm) would last 3 ns. Cs^+ and 2,5-dihydroxybenzoic acid were selected as the cationization and matrix, respectively. The sample solutions (10 mg/mL), the cesium chloride solution (1.52 mg/mL), and the matrix solution (10 mg/mL) were mixed at a volumetric ratio of 1:1:3.

Reversed-Phase HPLC−ESI−QTRAP MS Analysis after Thiolysis Reaction. Reversed-phase HPLC−ESI−QTRAP MS analysis was completed in the method described by Zhou et al.[7] Proanthocyanidins were thiolysis-degraded in the presence of benzyl mercaptan, and then the degradation products were injected into an Agilent 1200 system (Agilent, Santa Clara, CA) interfaced to a QTRAP 3200 (Applied Biosystems, Foster City, CA) with a 250 × 4.6 mm inner diameter, 5.0 mm Hypersil ODS column (Elite, Dalian, China). The mean degree of polymerization (mDP) was calculated on the basis of the following equation:

$$\text{mDP} = (\text{total area of the extender units}) / (\text{total area of the terminal units}) + 1$$

Enzyme Assay. L-Tyrosine was selected as a substrate of monophenolase, and 3,4-dihydroxyphenylalanine was used as a substrate of diphenolase. The final concentrations of the enzyme were 16.67 and 3.33 mg/mL for the monophenolase and diphenolase analyses, respectively. The experiment was repeated 3 times. Their results were expressed in IC_{50} value (μg/mL). The inhibition type depended upon the Lineweaver−Burk plot. Arbutin was selected as a positive control. The procedure and conditions for the enzyme reaction were carried out as described in our previous study.[4]

Fluorescence Quenching Analysis. The fluorescence test of tyrosinase and proanthocyanidins was performed on a fluorescence spectrophotometer (Varian Cary Eclipse). Sample solution, tyrosinase solution, and sodium phosphate buffer (pH 6.8) were mixed at a

DOI: 10.1021/acs.jafc.5b03099
J. Agric. Food Chem. 2015, 63, 7381−7387

volumetric ratio of 1:2:7 (v/v/v). The final reaction total volume was 3 mL. The analysis was carried out with an excitation wavelength of 290 nm at 25 °C. The Stern–Volmer equation describes fluorescence quenching[13]

$$F_0/F = 1 + K_q\tau_0[Q] = 1 + K_{SV}[Q]$$

where F_0 and F are the fluorescence intensities in the presence and absence of the quencher, respectively, K_q is the bimolecular quenching constant, τ_0 (10^{-8} s) is the lifetime of the fluorophore in the absence of the quencher, [Q] is the concentration of the quencher, and K_{SV} is the Stern–Volmer quenching constant.

There exist two types of fluorescence quenching mechanisms: static and dynamic.[14] When the type was static, the apparent binding constant (K_A) and the binding affinity (n) are estimated by the following equation:[15]

$$\log[(F_0 - F)/F] = \log K_A + n \log[Q]$$

The fluorescence assays of L-tyrosine/3,4-dihydroxyphenylalanine and proanthocyanidins were also performed on a fluorescence spectrophotometer (Varian Cary Eclipse). In brief, L-tyrosine (12 mM) or 3,4-dihydroxyphenylalanine (0.5 mM) solution, sample solution, and sodium phosphate buffer (pH 6.8) were mixed at a volumetric ratio of 1:1:3 (v/v/v) at 25 °C. The mixture was preincubated for 30 s before fluorescence spectra analysis. The excitation wavelength was 290 nm. The experiment was repeated 3 times.

Determination of Cu^{2+} Chelating Activity. A total of 100 μL of copper sulfate solution with different concentrations (25, 50, and 100 μM) and 100 μL of sample (1 mg/mL) solution were added to sodium phosphate buffer (50 mM, pH 6.8). The final volume was 1 mL, and the mixture was then shaken well and kept at 25 °C for 1 min prior to ultraviolet–visible (UV–vis) and fluorescence quenching analyses.

Molecular Docking of Tyrosinase with Ligands. Protein–ligand docking was completed by Molecular Operation Environment (MOE) 2010 software. In present study, we selected the structure of the oxy-tyrosinase of *Streptomyces castaneoglobisporus* as the initial model for docking simulations. ChemBioDraw Utra 12.0 was used to prepare the three-dimensional (3D) structures of the ligands. The structure models of the protein and ligands were energy-minimized before docking. Then, hydrogens were added to the protein and ligands. The refinement module of molecular docking was set to force field and retains scoring set to 10. The docking poses ranged according to the MM/GBVI binding free energy scoring. The binding mode was judged by the docked conformation, which had the lowest energy value.

Statistical Analysis. SPSS 19.0 was applied to the calculations. Results of antityrosinase analyses were indicated as the mean ± standard deviation.

RESULTS AND DISCUSSION

MALDI–TOF MS Analysis. The MALDI–TOF MS technique is an effective method for the characterization of proanthocyanidins in food science.[4,7,16,17] It has the potency to distinguish molecular weight differences because of the hydroxylation pattern in the B ring (Δ 16 Da), 3-*O*-galloylation (Δ 152 Da), or A-type linkage (Δ 2 Da).[16] Figure 2A displayed the MALDI–TOF mass spectra of avocado fruit proanthocyanidins, recorded as Cs^+ adducts in the reflection mode. Peaks increased equably from 999.00 Da (3-mers) to the 6183.42 Da (21-mers) at a distance of 288 Da, which was in accordance with the addition of one (epi)catechin. Therefore, it could be concluded that the main constitute unit is (epi)catechin. For each multiple, masses of 16 Da higher and lower were also detected in spectra when they were enlarged (Figure 2A). These masses were heteropolymers of repeating constitution units, which indicated the presence of (epi)gallocatechin and (epi)afzelechin. These results further demonstrated the coexistence of procyanidins, prodelphinidins, and propelargonidins in avocado fruit proanthocyanidins, which were dominated by procyanidins. However, in comparison to procyanidins, there were few prodelphinidins and propelargonidins. Besides the series of peaks described above, mass signals following the main groups of peaks at a distance of 152 and 132 Da were detected (Figure 2A). The 152 Da mass distance was in accordance with the addition of one galloyl group at the heterocyclic C ring.[18] The 132 Da mass distance may be produced by the substitution of a pentoside[18] or synchronous attachment of two Cs^+ and the absence of a proton $[M + 2Cs^+ - H]^+$.[19] Specifically, mass signals following the main groups of

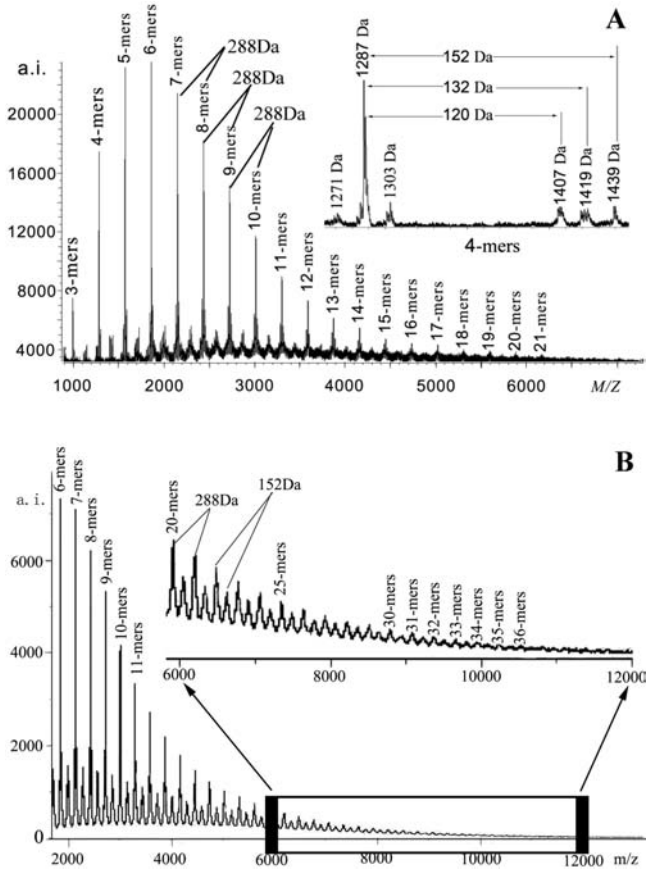

Figure 2. MALDI–TOF positive-ion (Cs^+) mode mass spectra of avocado proanthocyanidins in the (A) reflectron mode and (B) linear mode. The *y* axis represents absolute intensity (ai), that is, the number of ions of each species that reach the detector.

Table 1. Effects of Avocado Proanthocyanidins on the Activity of Mushroom Tyrosinase for the Oxidation of L-Tyr and L-DOPA[a]

	monophenolase	diphenolase		
sample	IC_{50} (μg/mL)	IC_{50} (μg/mL)	inhibition	inhibition type
proanthocyanidins	40 ± 1.2	19.5 ± 0.6 a	reversible	competitive
arbutin	not detected	1442.9 ± 2.77 b	reversible	competitive

[a]Values are expressed as the mean of triplicate determinations ± standard deviation. Different letters in the same column show significant differences from each other at the $p < 0.05$ level.

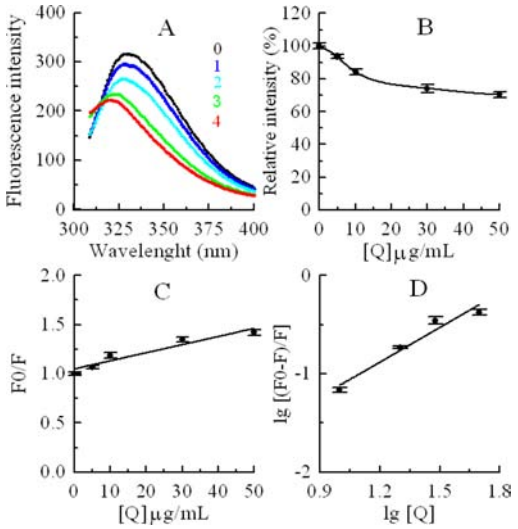

Figure 4. Changes in intrinsic tyrosinase fluorescence at different concentrations of avocado pulp proanthocyanidins. (A) Emission spectra 0, 1, 2, 3, and 4 of tyrosinase in the presence of proanthocyanidins are 0, 5, 10, 30, and 50 μg/mL, respectively. (B) Maximum florescence intensity changes. (C) Stern–Volmer plot describes the tyrosinase quenching caused by association with the quencher. (D) Plot of $\log[(F_0 - F)/F]$ against $\log[Q]$ for tyrosinase and various concentrations of the quencher. F_0 and F are the fluorescence intensities before and after the addition of the quencher.

peaks at a distance of 120 Da were also found in the mass spectrum. Additionally, the degree of polymerization of these compounds varied from 3-mers to 21-mers under the reflection mode, with the most intensity in 6-mers. However, the linear MALDI–TOF MS technique allowed for the test of avocado fruit proanthocyanidins up to 36-mers (Figure 2B). These results revealed structural heterogeneity and complexity of avocado fruit proanthocyanidins. The structures of proanthocyanidins extracted from avocado fruit were therefore successfully analyzed by employing MALDI–TOF MS for the first time.

Analysis of Proanthocyanidins by Reversed-Phase HPLC–ESI–QTRAP MS after Thiolysis Reaction. Avocado fruit proanthocyanidins were depolymerized by thiolysis reaction, which was proven to be a powerful method.[16,17,20] Benzylmercaptan was selected as the nucleophile. The result of the thiolysis reaction showed that terminal units were released as free monomers, but extender units were released as benzylthioether adducts.[21] Figure 3 showed that the dominant peak detected was epicatechin benzylthioether, while the other five smaller peaks were catechin, epicatechin, (epi)gallocatechin benzylthioether, catechin benzylthioether, and (epi)afzelechin benzylthioether. These results indicated that avocado fruit proanthocyanidins were mainly constituted of procyanidins, which were composed of an epicatechin unit. These results agreed well with the findings completed by the MALDI–TOF MS method. Besides, mDP of the proanthocyanidin polymers was calculated to be 12.3 ± 0.8. In fact, depolymerization by phenolysis (phloroglucinol) was also an efficient approach to determine the mDP of proanthocyanidins. Proanthocyanidin oligomers of 15 strawberry cultivars were depolymerized by phenolysis, and their mDP (3.4–5.8) was estimated.[22]

Effects of Avocado Fruit Proanthocyanidins on Monophenolase Activity. Effects of avocado fruit proanthocyanidins on monophenolase activity, where L-tyrosine was catalyzed by monophenolase, were first studied (see Figure 1-I of the Supporting Information). When the monophenolase activity was tested, a lag period (lag time) was observed. After the lag time, the monophenolase activity reached a steady-state rate, which was estimated by extrapolation of the linear portion of the product accumulation curve to the abscissa. Increasing concentrations of the avocado fruit proanthocyanidins not only extended the lag time (see Figure 1-III of the Supporting Information) but also decreased obviously the steady-state rate (see Figure 1-II of the Supporting Information). IC_{50} of proanthocyanidins on monophenolase activity was calculated as 40 ± 1.2 μg/mL (Table 1). Arbutin had little effect on the monophenolase activity (Table 1). The lag time was extended by 36 ± 0.8 s when the concentration of the proanthocyanidins was increased to 80 μg/mL. These results showed that avocado fruit proanthocyanidins were efficient inhibitors of monophenolase.

Effect of Avocado Fruit Proanthocyanidins on Diphenolase Activity. Effects of avocado fruit proanthocyanidins on oxidation of L-3,4-dihydroxyphenylalanine (L-DOPA) catalyzed by diphenolase were investigated. The results showed that diphenolase activity was obviously reduced with increasing the concentration of the inhibitor, but it was not completely suppressed (see Figure 2-I of the Supporting Information). IC_{50} of proanthocyanidins on diphenolase activity was estimated to be 19.5 ± 0.6 μg/mL (Table 1). IC_{50} of arbutin was 1442.9 ± 2.77 μg/mL (Table 1). The molecular weight of proanthocyanidins was markedly larger than that of arbutin, and avocado fruit proanthocyanidins might therefore be considered as excellent tyrosinase inhibitors.

Table 2. Stern–Volmer Equation for the Interaction between Quenchers and Tyrosinase

quencher	type of quenching	K_{SV} $(\mu g/mL)^{-1}$	K_q $(\mu g\ mL^{-1}\ s^{-1})^{-1}$	K_A $(\mu g/mL)^{-1}$	n
proanthocyanidins	static	$(8 \pm 0.2) \times 10^{-3}$	$(8 \pm 0.2) \times 10^{5}$	$(5 \pm 0.4) \times 10^{-3}$	1.17 ± 0.02

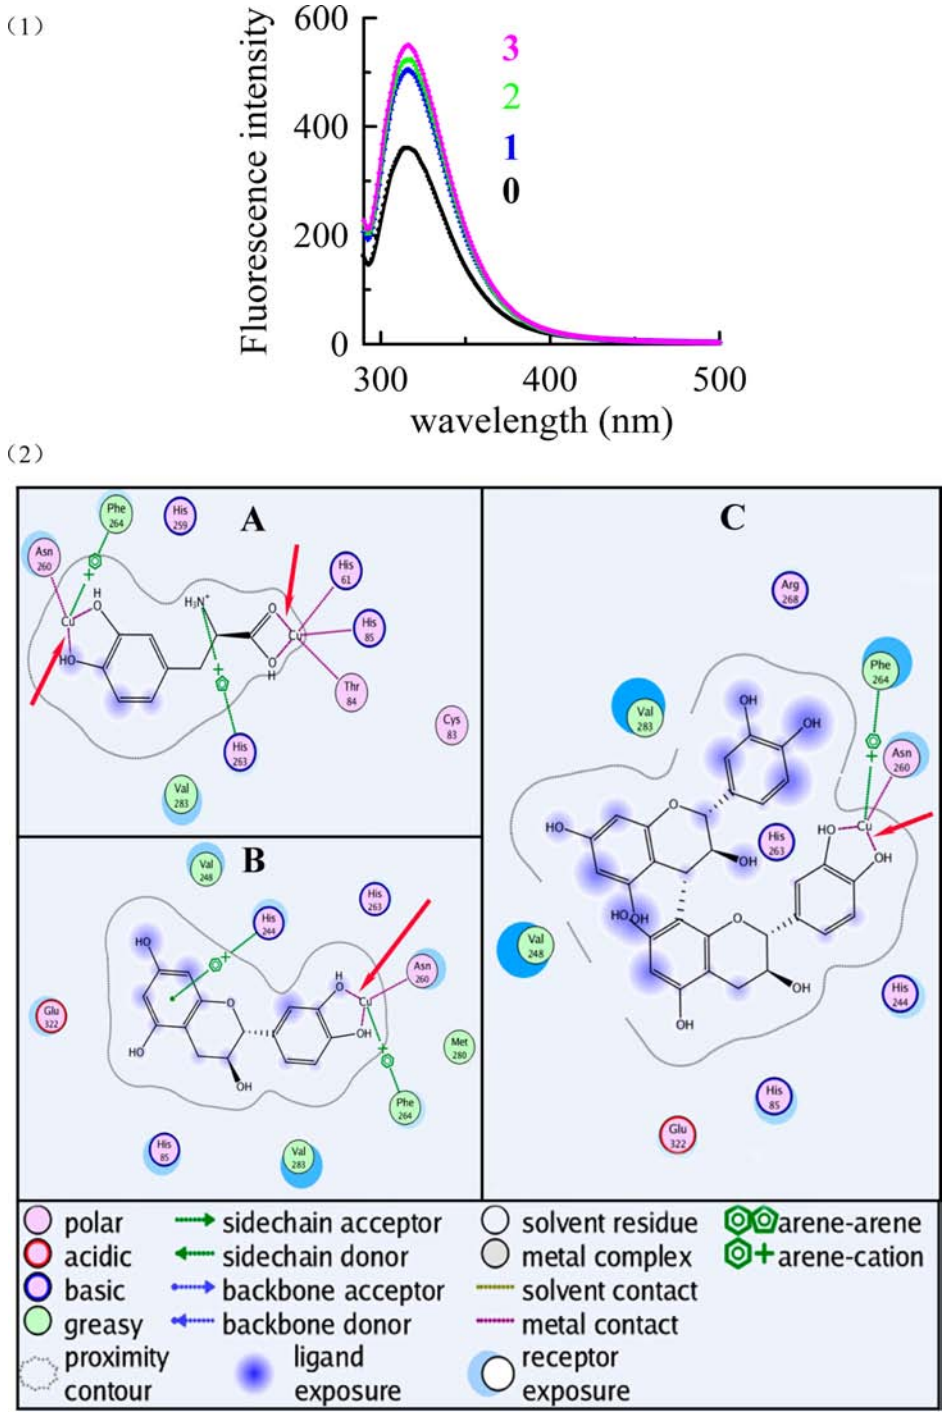

Figure 5. (1) Interaction of Cu^{2+} and proanthocyanidins. (2) Binding mode found from the ligand with tyrosinase residues using the lowest energy docked method. The receptor exposure differences were shown by the size and intensity of the turquoise discs surrounding the residues. The red arrows indicated the interaction of the ligand and the copper iron. Panels A, B, and C represented L-DOPA, epicatechin, and procyanidin dimer, respectively.

The inhibition mechanism of the avocado fruit proanthocyanidins on diphenolase activity was studied. It was revealed in Figure 2-II of the Supporting Information that, with the different concentrations of proanthocyanidins, the enzyme activity relied heavily on its concentration. The plots of the residual enzyme activity versus the concentrations of enzyme at different concentrations of proanthocyanidins gave a family of straight lines, which passed through the origin, indicating that the inhibition of the enzyme by proanthocyanidins was reversible. With the proanthocyanidin concentrations increased gradually, the slopes of the lines were descending.

The kinetic behavior of diphenolase in the process of oxidation of L-DOPA was then studied. The oxidation of L-DOPA catalyzed by diphenolase followed Michaelis–Menten kinetics. Plot of $1/v$ versus $1/[S]$ gave a family of lines with a fixed intercept on the y axis but with different slopes. These lines intersected on the y axis, which indicated that avocado

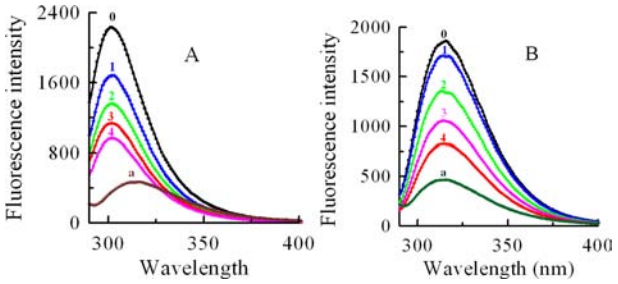

Figure 6. (A) Relative fluorescence intensities of L-tyrosine in solution with different concentrations of proanthocyanidins. The concentrations of proanthocyanidins of curves 0, 1, 2, 3, and 4 were 0, 10, 30, 40, and 80 μg/mL. (B) Relative fluorescence intensities of 3,4-dihydroxyphenylalanine in solution with different concentrations of proanthocyanidins. The concentrations of proanthocyanidins of curves 0, 1, 2, 3, and 4 were 0, 20, 30, 40, and 50 μg/mL, respectively. Curve a was the fluorescence intensity of proanthocyanidins when their concentration was 80 μg/mL.

fruit proanthocyanidins were competitive-type inhibitors (see Figure 2-III of the Supporting Information and Table 1).

Plant extracts have attracted more and more attention because of their potent tyrosinase inhibition activity.[23−25] In comparison to extracts obtained from *Aloe vera* L. gel,[23] red koji,[24] kiwifruit pericarp,[4] and fruit stone of Chinese hawthorn,[17] avocado fruit proanthocyanidins could better inhibit monophenolase and diphenolase activities. It could be speculated that strong inhibition of avocado fruit proanthocyanidins on the enzyme might mainly derive from structural similarity between the proanthocyanidin substrate of tyrosinase. In addition, a high polymer of avocado proanthocyanidins was considered as a important fator for the efficient inhibition. In our previous study, the proanthocyanidins with higher mDP showed better antityrosinase activity.[4] In comparison to synthesized compounds, tyrosinase inhibitors obtained from natural sources have attracted more and more attention because of the food and cosmetic demands.[26] Because of fact that proanthocyanidins are already in use for different medicinal properties, it is apparent that these compounds could well be applied in food, cosmetic, and pharmaceutical industries.

Analysis of Fluorescence Quenching of Tyrosinase with Avocado Fruit Proanthocyanidins. Fluorescence quenching was used to evaluate the interaction of ligand (proanthocyanidins) and tyrosinase by using a Varian Cary Eclipse fluorescence spectrophotometer. Figure 4A showed the fluorescence emission spectra of tyrosinase with different concentrations of avocado fruit proanthocyanidins. The results showed that enzyme gave a strong emission peak at 337 nm and decreased inversely with an increasing concentration of proanthocyanidins (Figure 4B). Figure 4C, the Stern−Volmer plot, was selected to measure the Stern−Volmer quenching constants of the proanthocyanidins. The results showed a good linear Stern−Volmer plot with K_q and K_{SV} values of $(8 \pm 0.2) \times 10^5$ $(\mu g\ mL^{-1}\ s^{-1})^{-1}$ and $(8 \pm 0.2) \times 10^{-3}$ $(\mu g/mL)^{-1}$, respectively (Figure 4C and Table 2). Because of the fact that the K_{SV} for dynamics cannot be larger than 100 L/M,[15] the K_{SV} that we obtained demonstrated that the type of fluorescence quenching mechanism between tyrosinase and avocado fruit proanthocyanidins was static. Figure 4D showed the plot of $\log[(F_0 - F)/F]$ against $\log[Q]$. From the intercept and the slope of this graph, values of K_A and n were calculated to be $(5 \pm 0.4) \times 10^{-3}$ $(\mu g/mL)^{-1}$ and 1.17 ± 0.02, respectively (Table 2).

Interaction of Cu^{2+} and Proanthocyanidins. Interaction between proanthocyanidins and Cu^{2+} were investigated using fluorescence analysis. The intrinsic fluorescence intensity of avocado fruit proanthocyanidins increased with the addition of Cu^{2+} (part 1 of Figure 5). The Cu^{2+} concentrations for curves 0, 1, 2, and 3 were 0, 25, 50, and 100 μM, respectively. The results revealed the binding of Cu^{2+} and proanthocyanidins.

Molecular Docking. To better understand the mechanism of the potent antityrosinase activities of the proanthocyanidins, molecular docking were carried out using MOE. Interactions of the ligands (L-DOPA, epicatechin, and procyanidin dimer) and the virtual enzyme catalytic center were simulated. The results revealed that L-DOPA (panel A in part 2 of Figure 5), (epi)catechin (panel B in part 2 of Figure 5), and proanthocyanidin dimer (panel C in part 2 of Figure 5) could chelate with copper irons of tyrosinase. The results obtained from docking simulations were a good supplement of the interaction experiment between Cu^{2+} and proanthocyanidins. The results revealed that the copper ion chelating ability of proanthocyanidins with an adjacent hydroxyl group on the B ring may be a significant mechanism to explain their inhibitory potency on the tyrosinase.

Fluorescence Quenching Analysis between the Substrate of Tyrosinase and Avocado Fruit Proanthocyanidins. The interaction between the proanthocyanidins and substrate of tyrosinase was investigated using the fluorescence quenching method. The result showed that intrinsic fluorescence intensity of L-tyrosine and 3,4-dihydroxyphenylalanine decreased distinctly with the addition of proanthocyanidins (Figure 6). The fluorescence intensity of L-tyrosine was reduced by 56.8% when the proanthocyanidin concentration reached 80 μg/mL (curve 4 in Figure 6A). Concentrations of curves 0, 1, 2, 3, and 4 were 0, 20, 30, 40, and 80 μg/mL, respectively (Figure 6A). The fluorescence intensity of 3,4-dihydroxyphenylalanine reduced by 74.9% when the proanthocyanidin concentration reached 50 μg/mL (curve 4 in Figure 6B). Concentrations of curves 0, 1, 2, 3, and 4 were 0, 20, 30, 40, and 50 μg/mL, respectively (Figure 6B). However, blue or red shifts were not found in the experiment. This indicated that the conformations of L-tyrosine and 3,4-dihydroxyphenylalanine were unchanged. Curves labeled "a" were fluorescence emission spectra of proanthocyanidins with a concentration at 80 μg/mL.

These results strongly proved that proanthocyanidins were the effective binding agents of L-tyrosine and 3,4-dihydroxyphenylalanine. Because of this, proanthocyanidins could efficiently stop the oxidation of the substrate. This could also make it clear that proanthocyanidins have a strong inhibitory effect on the tyrosinase catalytic reaction.

In conclusion, this study demonstrated that avocado fruit proanthocyanidins were comprised of homo- and heteropolymers of procyanidins, prodelphinidins, propelargonidins, and procyanidin gallate with a degree of polymerization up to 36-mers. They possessed structural heterogeneity in monomer units, substituent, and degree of polymerization. The results obtained from the enzyme assay revealed that these compounds were a potent, reversible, and competitive-type antityrosinase agent. Interactions of proanthocyanidins (particularly high polymer) with a substrate and dicopper catalytic center of tyrosinase were important mechanisms to explain their efficient inhibition. Structural similarity between proanthocyanidins and

DOI: 10.1021/acs.jafc.5b03099
J. Agric. Food Chem. 2015, 63, 7381−7387

the substrate of tyrosinase was the foundation of strong interactions. These findings played a significant role in both screening and designing great potential tyrosinase inhibitors. Our study revealed that proanthocyanidins purified from avocado fruit may have possible applications in agriculture, food, pharmaceutical, and cosmetic industries.

from bovine mammary gland. Later, ficoll and sucrose density gradient centrifugations were proven to obtain a high purification of the PM fraction from lactating bovine mammary gland.[12] Differential velocity centrifugation has been used to isolate the membrane fraction of mammary tissues from Holstein cows.[13] Recently, proteomics technologies have been successfully applied to reveal proteome profiles of lactating bovine mammary tissue,[13−15] milk fat globule membrane,[16] and cultured mammary epithelial cells from humans[17] and *Bos indicus*,[18] but it has not been used to elucidate the proteome profile of PM from lactating bovine mammary gland.

Therefore, this experiment was designed to isolate and identify the PM of bovine mammary gland by discontinuous sucrose density gradient centrifugation and by liquid chromatography−tandem mass spectrometry (LC-MS/MS), respectively. Investigating the composition of PM proteins in the mammary gland of lactating cows, and subsequent identification of regulatory proteins involved in synthesis and secretion pathways of milk components on the subcellular level, would extend our understanding of the milk synthesis and secretion mechanisms of the bovine mammary gland.

MATERIALS AND METHODS

Preparation of Plasma Membranes of the Bovine Mammary Gland. Plasma membranes were isolated from bovine mammary gland homogenates by discontinuous sucrose density gradient centrifugation. Twelve mammary gland tissue blocks were obtained from the right or left fore-quarter of the mammary gland of four female Holstein-Friesian dairy cows (500−530 kg, 6 years old) in their fourth parity and midlactation period. This experiment was conducted according to the animal care guidelines of the Animal Care Committee, Institute of Subtropical Agriculture, The Chinese Academy of Sciences, Changsha city, Hunan province, China (no. KYNEAAM-2013-0009). Three technical replicates per cow were prepared for the isolation of plasma membranes. Approximately 6−8 g of fresh, mixed mammary gland tissue was weighed for each technical replicate and washed in ice-cold 0.9% NaCl, until the blood, milk, and connective tissues were removed. The tissue samples were then minced in 5 volumes of ice-cold homogenization buffer (0.25 M sucrose, 10 mM HEPES, pH 7.5) and homogenized by a Fisher Scientific PowerGen 125 homogenizer (Thermo Fisher Scientific Inc., USA). The homogenate was filtered through one layer of nylon gauze, and the filtrates were centrifuged at $1000g_{max}$ for 20 min in a Himac CR21 centrifuge (Hitachi High Technology, Japan). The resulting pellet was resuspended in 3 mL of buffer A (0.3 M sucrose, 50 mM Tris-HCl, 3 mM $MgCl_2$, pH 7.5) and 9 volumes of buffer B (1.98 M sucrose, 50 mM Tris-HCl, 3 mM $MgCl_2$, pH 7.5) to achieve a concentration of 1.8 M sucrose. Thirty milliliters of suspension liquids was transferred into one each of SW28 rotor tubes and overlaid with buffer C (0.25 M sucrose, 10 mM HEPES, 1 mM EDTA, pH 7.5) to fill the tubes. They were then centrifuged at $70900g_{av}$ for 90 min in a Beckman Optima L-XP100 ultracentrifuge (Beckman Coulter Inc., USA). The band at the interface was collected, resuspended in buffer C, and centrifuged at $20000g_{max}$ for 10 min. The resulting pellet was resuspended in a 1.45 M sucrose solution mixed with buffers C and D (2.4 M sucrose, 10 mM HEPES, pH 7.5), overlaid with enough buffer C to fill the SW28 rotor tubes, and then centrifuged at $68400g_{av}$ for 80 min. The pellicle at the interface was resuspended in buffer C and centrifuged at $17600g_{max}$ for 10 min. Isometric buffer C and buffer D were added into the pellet to bring the final concentration of sucrose to 1.35 M, the solution was transferred into an NVT100 rotor tube, overlaid with enough buffer C, and centrifuged at $231000g_{av}$ for 60 min. The purified plasma membranes were collected from the interface, washed in buffer C and then 10 mM HEPES (pH 7.5), and then centrifuged at $40000g_{max}$ for 10 min. All operations were performed at 4 °C, and a piece of protease inhibitor cocktail tablet (Roche Diagnostics GmbH, Mannheim, Germany) was added into every centrifugation tube in each step. The PM fractions were stored in a final volume of 2 mL at −80 °C.

Electron Microscopy. Fresh PM (0.1 mL) and 3% glutaraldehyde in PBS were mixed, incubated overnight at 4 °C, and centrifuged at 14500*g* for 15 min. The resulting pellets were fixed in 2% OsO_4, dehydrated through a graded series of ethanol (50, 70, 90, and 100% in turn) and acetone (100%), embedded in Epon overnight at 37 °C, and then solidified at 60 °C for 48 h. After cooling, the samples were sliced into thin sections with thickness of 70 nm and observed under a transmission electron microscope (Hitachi JSM-1230; JEOL, Tokyo, Japan) at 100 kV.

Western Blotting. Proteins of the homogenates and PM fractions were solubilized in a lysis buffer (LB1: 5 M urea, 2 M thiourea, 10% glycerol, 50 mM Tris-HCl, 2.0% OG, 2.5% SB3-10, 1 mM PMSF, pH 8.0), incubated at 37 °C for 30 min and room temperature for 1 h, respectively. Then the suspension was centrifuged at 20000*g* for 1 h, and the concentration of protein in the supernatant was determined by RC DC protein assay kit (catalog 500-0120, Bio-Rad, Hercules, CA, USA). The extracted proteins were separated by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) and then transferred to polyvinylidene fluoride membranes (Bio-Rad, USA). The membranes were blocked overnight at 4 °C and then incubated with anti-Na^+/K^+-ATPase α1 subunit (Novus Biologicals, LLC, Littleton, CO, USA), anti-flotillin-1 (Santa Cruz Biotechnology, Inc., Santa Cruz, CA, USA), and anti-prohibitin and anti-actin (Abcam, Hong Kong, China) for 2.5−3 h at room temperature. After being washed three times with PBST (0.1% Tween 20 in PBS), the membranes were incubated with peroxidase-conjugated goat anti-mouse, anti-rabbit, and donkey anti-goat IgG (H + L) for 1.5 h, washed three times with PBST, and detected by WesternBright ECL Western Blotting HRP Substrate (APGBio, Shanghai, China). Densitometric analysis of immunoblots was performed using an AlphaImager 2200 digital imaging system (Digital Imaging System, Kirchheim, Germany). Experiments were performed in triplicate and replicate three times.

Enzyme Activity Determination. The determination of organelle marker enzyme activity of the purified PM fractions was performed according to the standard protocols of the following kits: the 5′-nucleotidase assay kit (A041, Nanjing, China), the bovine Na^+/K^+-ATPase ELISA kit (catalog no. CSB-eq 027407BO, Wuhan, China), the bovine monoamine oxidase, succinodehydrogenase, aryl sulfatase, β1,4-GTase ELISA kits (JRDUN Biotechnology Co. Ltd., Shanghai, China), and the bovine NADPH cytochrome *c* reductase assay kit (BGI, Guangdong, China).

Preparation of PM-Associated Proteins. To compare the solubilization efficiency of PM proteins, two lysis buffers (one is LB1 as previously described; the other is LB2, containing 4% SDS, 10 mM Tris-HCl, 20% glycerol, and 100 mM dithiothreitol, pH 6.8) were used to dissolve the pooled PM fractions isolated from 12 homogenates. The isolation procedure of proteins and determination of protein concentration were the same as that of LB1. The isolated proteins were used for further in-solution digestion and SDS-PAGE separation. The PM proteins were separated by 6% SDS-PAGE and then stained by Coomassie brilliant blue R250 solution (Zomanbio, Beijing, China) overnight. Each protein gel lane was divided into four to five equal parts and removed by a sterilized knife.

In-Gel Digestion of Samples. Protein slices in fresh Coomassie brilliant blue R250-stained gel were excised and destained twice with 200 μL of 50 mM NH_4HCO_3 and 50% acetonitrile (ACN). Then 200 μL of 10 mM dithiothreitol (DTT) in 50 mM NH_4HCO_3 was added for protein reduction at 56 °C. After the removal of supernatant, 40 μL of 55 mM iodoacetamide in 100 mM NH_4HCO_3 was immediately added for protein alkylation in the dark. Finally, protein slices were dried twice with 200 μL of ACN. Afterward, the dried pieces of gels were incubated with ice-cold digestion solution (12.5 ng/μL trypsin and 20 mM NH_4HCO_3) for 20 min and then transferred into a 37 °C incubator for digestion overnight. Finally, peptides in the supernatant were collected after extraction twice with 200 μL of extract solution (5% formic acid in 50% ACN).

Table 1. Enzyme Activities in Homogenates and Isolated Plasma Membranes (PMs) from Bovine Mammary Gland

enzyme	homogenates	PMs	relative specific activity[a]
protein (8) mg/mL	2.10 ± 0.550	1.11 ± 0.370	
5′-nucleotidase, U/mg protein (6)	0.143 ± 0.053	1.58 ± 0.694	11.3 ± 2.49
Na^+/K^+-ATPase, ng/mg protein/h (7)	0.182 ± 0.053	1.64 ± 0.464	9.09 ± 0.920
monoamine oxidase, U/mg protein (8)	0.071 ± 0.019	0.282 ± 0.141	2.37 ± 0.015
NADPH cytochrome *c* reductase, nmol/min (7)	4.14 ± 1.19	47.8 ± 17.1	11.3 ± 1.89
succinodehydrogenase, IU/mg protein (10)	4.11 ± 0.842	6.31 ± 1.07	1.54 ± 0.103
aryl sulfatase	ND[b]	ND	
β1,4-GTase, U/mg protein	ND	ND	

[a]Relative specific activities were calculated as the ratio of the specific activity of the plasma membranes to that of the homogenates. The specific activity of the homogenates was normalized to 1. [b]ND, not detectable.

In-Solution Digestion of Samples. The membrane proteins isolated by LB1 and LB2 were in-solution digested using the method previously described[19] with minor modification. In each experiment, the concentrated proteins were heated at 100 °C for 10 min. After the sample was cooled to room temperature on ice, DTT was introduced into the solution to reach a final concentration of 10 mM, and the sample was incubated at 57 °C for 30 min. To prevent disulfide bond formation, cysteine residues were alkylated by iodoacetamide, which was added to the sample solution at 20 mM final concentration. The 30 min incubation in the dark, and at room temperature, was performed for cysteine derivatization. The reaction was quenched by the addition of DTT at a 10 mM final concentration in solution for 10 min. After iodoacetamide deactivation, the sample solution was diluted 10-fold with 50 mM NH_4HCO_3 buffer. Trypsin was added to the sample at a ratio of (1:50) and incubated overnight at 37 °C. All digested peptide mixtures were passed over a C18 column to remove extra DTT and salt. Tryptic peptides were eluted from the column with 80% ACN in 0.1% trifluoroacetic acid, and the peptide solution was divided equally. Thereafter, each aliquot was dried in a vacuum centrifuge for later use.

Strong Cation Exchange (SCX) Chromatography. The peptide mixtures from in-gel and in-solution digestion were fractionated by SCX chromatography on a 20AD high-performance liquid chromatography (HPLC) system (Shimadzu, Kyoto, Japan) using a polysulfethyl column (2.1 × 100 mm, 5 um, 200 Å; Nest Group, Southborough, MA, USA). The mixed sample was diluted with a loading buffer (10 mM KH_2PO_4 in 25% ACN, pH 2.6) and loaded onto the column. Buffer A was identical in composition to the loading buffer, and buffer B was formatted using buffer A containing 350 mM KCl. Separation was performed using a linear binary gradient of 0−80% buffer B in buffer A at a flow rate of 200 μL/min for 60 min. The absorbance at 214 and 280 nm was monitored, and a total of 40 SCX fractions were collected along the gradient.

Automated Nano-LC-ESI-MS/MS Analysis of Peptides. All of the eluted fractions and extracted solutions mentioned above were dried thoroughly using a vacuum centrifuge and then resuspended with 40 μL of 5% ACN in 0.1% formic acid, separated by Nano-LC, and analyzed by online electrospray tandem mass spectrometry as follows. The experiments were performed on an LC-20AD system (Shimadzu) connected to an LTQ Orbitrap mass spectrometer (Thermo Electron, Bremen, Germany) equipped with an online nanoelectrospray ion source (Michrom Bioresources, Auburn, CA, USA). The separation of the peptides took place in a 15 cm reverse phase column (100 μm i.d., Michrom Bioresources). The peptide mixtures were injected onto the trap column with a flow of 60 μL/min, subsequently eluted with a gradient of 5−45% solvent B (95% ACN in 0.1% formic acid) over 90 min, and then injected into the mass spectrometer at a constant column-tip flow rate of 500 nL/min. Eluted peptides were analyzed by MS and data-dependent MS/MS acquisition, selecting the eight most abundant precursor ions for MS/MS with a dynamic exclusion duration of 1 min.

Database Searching. The .mzXML files in the LTQ Orbitrap mass spectrometer were converted to.mgf files by MassMatrix Mass Spec Data File Conversion Tools and submitted for database sequence searches using ProteinPilot software (version 4.0, Applied Biosystems). The following parameters were set in the searching: trypsin as enzyme, fixed modification of carbamidomethyl-labeled cysteine, no special factors, biological modification, thorough identification search, SwissProt database. Other parameters, such as tryptic cleavage specificity, precursor ion mass accuracy, and fragment ion mass accuracy, were built-in functions of ProteinPilot software, and the Paragon method was adopted. The detected protein threshold was set at 1.3, responding to the minimum identification probability of ≥0.95, and the competitor error margin was 2.00.

Data Analysis and Bioinformatics. Swiss-Prot accession numbers of identified proteins were submitted to the retrieve ID/mapping tool of UniProt (http://www.uniprot.org) to generate FASTA formatted protein sequences. The prediction of transmembrane helices in identified proteins was carried out using the transmembrane hidden Markov model (TMHMM) algorithm, available at http://www.cbs.dtu.dk/servies/TMHMM. The average hydrophobicity for identified proteins was calculated using ProtParam software (http://us.expasy.org) by submitting each protein accession. The proteins exhibiting positive grand average of hydropathicity (GRAVY) values were recognized as hydrophobic, and those with negative values were deemed hydrophilic.[20] The subcellular location and function of all the identified proteins were elucidated by gene ontology (GO) component and function terms respectively, which were online annotated by DAVID Bioinformatics Resources 6.7 (http://david.abcc.ncifcrf.gov) against the background of *Bos taurus*. Functional enrichment analyses of cellular components, molecular functions, and biological processes were also performed via DAVID database. In the enrichment analysis, modified Fisher's exact tests and false-discovery rate were used for statistical analysis. The significantly ($p < 0.05$ and false-discovery rate <5%) enriched GO categories were investigated. The enriched pathways were analyzed by Ingenuity Pathway Analysis (content version: 17199142), choosing Ingenuity Knowledge Base as reference set and mammary gland as tissue.

RESULTS

Purity and Identification of Plasma Membranes. The PM fraction was located at the interface of the 0.25 M/1.35 M sucrose gradient. The protein yield of the plasma membranes was 0.185 mg/g of mammary gland. As shown in Table 1, the activities of various marker enzymes localized to the PM or subcellular organelles suggested that the Na^+/K^+-ATPase and 5′-nucleotidase activities were 9- and 11-fold greater in the plasma membranes than in the homogenates, respectively. Marker enzyme activities for outer mitochondrial membranes (monoamine oxidase), mitochondria (succinodehydrogenase), lysosomes (aryl sulfatase), and Golgi (β1, 4-GTase) were not significantly enriched in the plasma membranes compared to the homogenates. However, NADPH cytochrome *c* reductase activity in the plasma membranes, an endoplasmic reticulum marker, was enriched 11-fold in comparison with the homogenates.

J. Agric. Food Chem. 2015, 63, 7388−7398

The quality of the PM was morphologically evaluated by transmission electron microscopy (Figure 1). The predominant

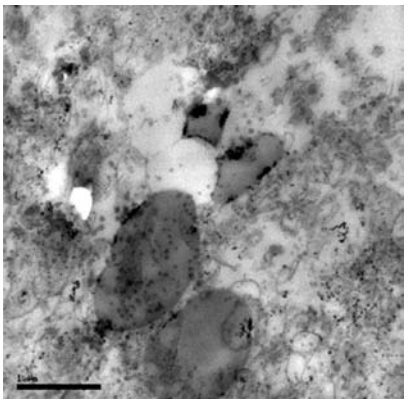

Figure 1. Electron micrographs of isolated plasma membranes from bovine mammary gland. The predominant structures in this fraction were membrane sheets and irregular vesicles. Bar, 1 μm × 30000.

structures in the final PM fraction were small, closed, and irregular membrane vesicles. Occasional mitochondrial membranes and endoplasmic reticulum membranes were also observed.

The purity of the plasma membranes was further examined by Western blotting using antibodies against organelle-specific protein markers (Figure 2). To estimate the degree of

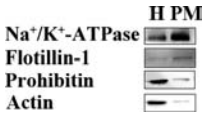

Figure 2. Western blotting analysis of the plasma membranes (PM) isolated by subcellular fractionation. Eighty micrograms of the mammary gland homogenate and plasma membrane proteins were separated by 12% SDS-PAGE and transferred to PVDF membranes. The blots were probed with antibodies against organelle-specific proteins: anti-Na^+/K^+-ATPase and anti-flotillin-1 for plasma membranes (PM); anti-prohibitin for mitochondria; anti-actin for cytoplasm. H represents homogenates.

enrichment of plasma membranes, we detected the PM-specific proteins Na^+/K^+-ATPase and flotillin-1 and found that these proteins were enriched about 4- and 5-fold, respectively, in PM in comparison with mammary gland homogenate. Meanwhile, both mitochondria and cytoplasm-specific proteins prohibitin and actin were about 14-fold less in PM than in mammary gland homogenate.

Separation and Identification of PM Proteins. The overall separation profiles of PM proteins isolated by two different lysis buffers are shown in Figure 3. The staining patterns of the two samples were similar for most bands, but differences in the intensities of a few bands were apparent. Gel slices cut from SDS-PAGE gel and proteins isolated by lysis buffers were digested in gel and in solution, respectively, separated by SCX chromatography, and further analyzed by automated Nano-LC-ESI-MS/MS. As shown in Table 2, PM protein yield of LB1 was 4.5-fold greater than that of LB2. The total number of nonredundant proteins identified from LB1 and LB2 was 872 (Supporting Information Supplementary Table 1). Of these 445 were found in LB1 and 575 were found in LB2; therefore, there were 381 proteins in common. Eight-

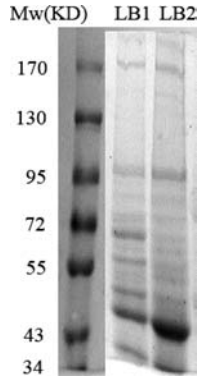

Figure 3. SDS-PAGE analysis of the proteins isolated from LB1 and LB2. Eighty micrograms of isolated proteins were separated by SDS-PAGE.

Table 2. Comparison between LB1 and LB2 and Total Identified Proteins

parameter	LB1[a]	LB2	total
protein yield, mg/g mammary gland	0.156	0.035	
no. of proteins identified	445	575	872
no. of proteins with TM[b] ≥ 1, %	132 (29.7)	182 (31.7)	195 (22.4)
no. of proteins with GRAVY[c] > 0, %	99 (22.2)	124 (21.6)	143(16.4)
no. of proteins with plasma membrane-associated locations, %	135 (30.3)	162 (28.2)	215 (24.7)

hundred and sixty-two of the 872 proteins were recognized by DAVID, and the remaining 10 proteins were not recognized and defined as unknown proteins. The transmembrane domains of the identified proteins were predicted with TMHMM. One-hundred and ninety-five (22.4%) were integral membrane proteins with at least one predicted transmembrane domain, and the percentage of these within LB2 (31.7%) was slightly greater than that of LB1 (29.7%). The GRAVY index represented the hydrophobicity property of proteins. One-hundred and forty-three (16.4%) proteins had positive values, and the percentage of LB1 (22.2%) was greater than that of LB2 (21.6%). Two-hundred and fifteen proteins (24.7%) of 872 identified proteins belonged to the PM proteins according to their GO annotations and the published literature; 30.3 and 28.2% of all identified proteins were from LB1 and LB2, respectively, including a list of known PM marker proteins such as sodium/potassium-transporting ATPase subunit α-1, flotillin-1, vesicle-associated membrane proteins, and 5′-nucleotidase.

Protein Classification and Enrichment Analysis. Among the identified proteins, 215 (30.6%) proteins were classified as PM proteins, with a smaller number classified as proteins in mitochondria (25.2%), endoplasmic reticulum (7.7%), Golgi apparatus (2.4%), nuclei (6.4%), and ribosome (7.6%). There were 20.1% unknown proteins without cellular component terms (Figure 4a).

The PM-associated proteins were further classified according to their molecular functions. As Figure 4b displays, 100 proteins (47.4%) and 41 proteins (19.4%) were binding proteins and transporter molecules, respectively, 32 proteins (15.2%)

DOI: 10.1021/acs.jafc.5b02231
J. Agric. Food Chem. 2015, 63, 7388−7398

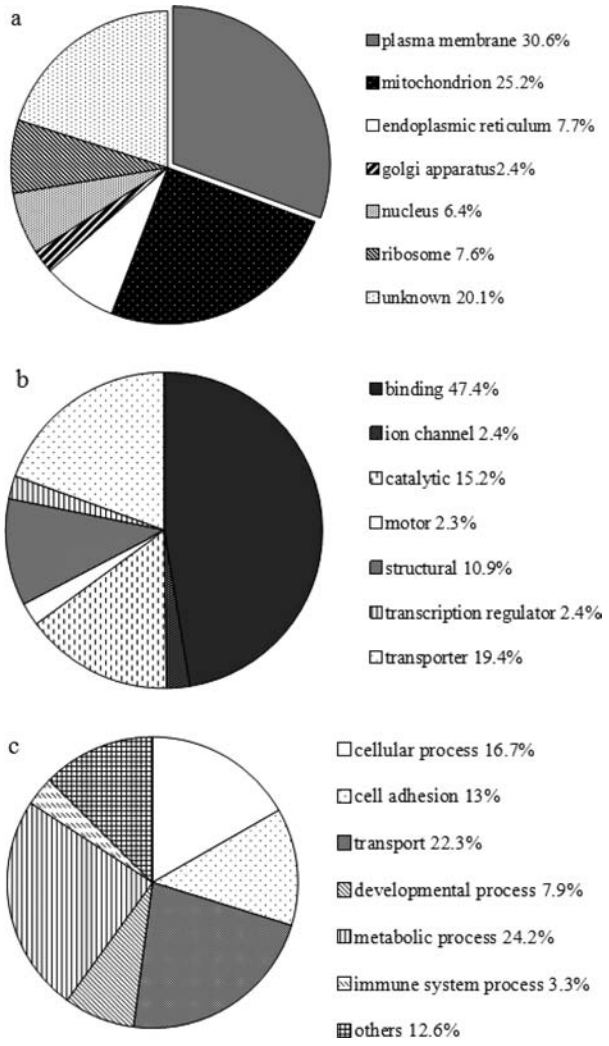

Figure 4. Classification of proteins identified in isolated bovine mammary gland plasma membrane. The subcellular localization of the identified proteins (a), functional characterization of plasma membrane proteins (b), and biological processes of plasma membrane proteins (c) were classified by GO terms annotated by DAVID Bioinformatics Resources 6.7 against the background of *Bos taurus*.

corresponded to catalytic activity, and 23 proteins (10.9%) were associated with structural proteins. Other proteins were involved in ion channel activity (2.4%), motor activity (2.3%), and transcription regulator activity (2.4%).

The PM proteins were also classified into several categories according to their DAVID annotation (Figure 4c): 36 (16.7%) proteins were involved in cellular processes, 28 (13%) in cell adhesion, 48 (22.3%) in transport, 17 (7.9%) in developmental process, 52 (24.2%) in metabolic process, 7 (3.3%) in immune system process, and 27 (12.6%) in apoptosis, cell cycle, generation of precursor metabolites, and response to stimulus. Seventy-five of 215 PM proteins had transmembrane domains and were involved in various processes associated with milk synthesis and secretion (Table 3), such as nutrient (glucose, amino acids, and fatty acids) transport, endocytosis, lactation, and synthesis of steroid and phospholipid.

To access the enrichment degree of plasma membranes and to explore over-represented biological functions associated with the PM proteins, DAVID was used to characterize potential biological functions in the PM proteome of bovine mammary gland. With respect to cellular components, the top 10 cellular component terms were significantly over-represented, including PM, vesicle, melanosome, pigment granule, cytoplasmic membrane-bounded vesicle, cytoplasmic vesicle, membrane-bounded vesicle, PM part, internal side of PM, and cell surface (Figure 5a).

Similar to the cellular components, the top 10 over-represented molecular function terms were typically associated with the PM, including enzyme binding, GTP binding, guanyl ribonucleotide binding, guanyl nucleotide binding, calcium-dependent phospholipid binding, unfolded protein binding, cytoskeletal protein binding, purine nucleotide binding, purine ribonucleotide binding, and ribonucleotide binding (Figure 5b).

In biological processes, the top 10 enriched terms were vesicle-mediated transport, protein localization, protein transport, cell adhesion, cellular protein localization, intracellular transport, small GTPase mediated signal transduction, membrane organization, establishment of protein localization, and biological adhesion (Figure 5c).

The identified PM proteins were involved in 74 pathways according to the pathway analysis. The top 15 pathways that were significantly enriched included caveolae-mediated endocytosis signaling, leukocyte extravasation signaling, clathrin-mediated endocytosis signaling, RhoGDI signaling, ephrin receptor signaling, signaling by Rho family GTPases, ephrin B signaling, virus entry via endocytic pathways, aldosterone signaling in epithelial cells, lipid antigen presentation by CD1, eNOS signaling, remodeling of epithelial adherens junctions, sertoli cell sertoli cell junction signaling, PPARα/RXRα activation, and tight junction signaling (Figure 5d).

DISCUSSION

Discontinuous sucrose gradient centrifugation, with its advantage of a reproducible and wide range of applications, was employed in this study to isolate the plasma membranes from lactating bovine mammary gland. However, this method often encounters difficulties in separating particular domains of PM from other cellular organelles, and from each other,[21] which also appeared in the current study. The sheet-like plasma membranes were low in relative activities of marker enzymes and protein yield (0.185 mg per g wet tissue). This was greater than the yield of 0.032 mg obtained from plasma membranes isolated from lactating cow mammary gland,[12] but less than that of isolated PM from lactating rat mammary gland by two-phase polymer partitioning (0.3 ± 0.1 mg).[5] The marker enzymes used in the present study, 5′-nucleotidase and Na^+/K^+-ATPase, are considered to be reliable as PM markers of lactating mammary cells.[12] Their activities in the PM were only 9 or 11 times greater than in the homogenates; perhaps the contamination of cytoplasmic proteins originating from the outer mitochondrial membranes caused this result. Western blotting results also confirmed that the plasma membranes were relatively enriched as indicated from an increased amount of PM marker proteins Na^+/K^+-ATPase and flotillin-1 and a lower amount of mitochondria and cytoplasm-specific proteins prohibitin and actin. All of these results indicate that plasma membranes isolated from bovine mammary gland and purified by discontinuous sucrose gradient centrifugation can be used for identification of proteins specific to the PM.

In the current investigation, two different detergents were employed to solubilize more PM proteins. LB1 contains zwitterionic detergent SB3-10 and nonionic detergent *n*-octyl-β-D-glucopyranoside (OG), and LB2 contains ionic detergent

[a]TM, transmembrane domain. [b]The predict function of PM proteins was noted by the molecular function or biological process of the Gene Ontology annotation. −, the protein had no Gene Ontology annotation.

SDS and reductive agent DTT. Although the protein yield of LB1 was slightly greater than that of LB2, the number of total identified proteins, PM proteins, transmembrane proteins, and hydrophobic proteins was less than that of LB2 (Table 2). It could be suggested that the solubilization efficiency of LB2 was higher than that of LB1; thus, LB2 was more suitable for the extraction of PM proteins of the mammary gland.

1D-SDS-PAGE was applied in this study because of its high loading capacity and high solubilizing power of hydrophobic membrane proteins.[22] Finally, 215 of the identified 872 proteins were PM proteins. If 20.1% unknown proteins were deducted, the proportion of PM proteins would be greater. Janjanam et al.[18] had identified 111 and 37 PM proteins of mammary epithelial cells by 1D-Gel-LC-MS/MS and 2DE-MS/MS, respectively. It was reported that around 9.1% of 700 protein spots detected by 2DE-MS/MS were localized to PM in the rat mammary gland.[23] Peng et al.[15] and Yang et al.[13] had identified 160 and 183 membrane proteins by 1D-Gel-RPLC-MS/MS and 1D-Gel-LC-MS, respectively. Therefore, 1D-SDS-PAGE combined with LC-MS/MS had its advantage of high-throughput identification for PM-associated proteins.

In the proteomic maps of PM fractions (Supplementary Table 1), many proteins were associated with metabolic pathways and involved in lactation-associated function such as staphylococcal nuclease domain-containing protein 1, annexin A5, and Rab GDP dissociation inhibitor 2. Signorelli et al.[24] reported that in lactating sheep there was an increased expression of these three proteins at the lactation peak, which was in agreement with their basic cellular functions in relationship to higher milk yield. Staphylococcal nuclease domain-containing protein 1 was increased in humans in response to lactogenic hormones.[25] Apolipoprotein A-I observed in this study's PM fractions has been involved in delivering cholesterol to milk fat globules,[26] and the highest expression of this protein occurred at midlactation.[24] The eukaryotic translation elongation factor 2 was also present in the PM fractions. It has been reported that the main limiting factor in the protein synthesis at the end of lactation was the availability of this protein.[24,26] The enzymes of the pentose phosphate pathway (transketolase), the tricarboxylic acid cycle (cytosolic NADP-isocitrate, succinate dehydrogenase, and malate dehydrogenase), and de novo lipogenesis (fatty acid synthase and fatty acid-binding proteins) were also identified in the PM fractions. These proteins provide a substantial fraction of the reducing equivalents of NADPH and long-chain fatty acids taken up from blood, needed for lipid synthesis in the mammary gland.[27−31]

We also detected 5 of 10 enzymes involved in glycolysis, including hexokinase, triosephosphate isomerase, glyceraldehyde-3-phosphate dehydrogenase, ADP-dependent glucokinase, and enolase. This suggests that our lactating bovine mammary glands provide the necessary precursors for the energy-generating pathway required for milk synthesis and secretion. Additionally, we also identified six proteins participating in milk secretion and lactation regulation, including β-casein, κ-casein, lactotransferrin, xanthine dehydrogenase, butyrophilin A1, and fatty acid synthase.

We compared the proteome profile of our PM fractions with the proteome profiles of mammary tissues and cells. Of 215 proteins and 188 PM proteins reported in lactating mammary tissue of Friesian cows,[14,15] 83 proteins (39%) and 48 proteins (26%) matched our data. Seventy-four proteins (25%) of 297 proteins identified in bovine milk fat globule membrane[31] and 138 proteins (28%) of 497 proteins reported in bovine mammary epithelial cells[18] matched our data, respectively. Relatively less coverage of our data with data from other groups can be attributed to the different lactation period of mammary glands and the fact that the mammary tissue may represent a mixed-cell population that constitutes adipose and stromal tissue, epithelial tissue, macrophages, and lymphocytes.[32] It would appear that some newly identified PM-associated proteins of lactating bovine mammary gland have not been reported earlier.

The PM proteins were further classified according to their functional characterization (Figure 4b,c). The main groups identified were binding and transport proteins, including annexin proteins (ANXA2, ANXA6, ANXA7, ANXA9, ANXA11), heat shock proteins, integrin, RAS oncogene family members, S100 calcium binding proteins, and solute carrier (SLC) families and members (SCL1A1, SLC1A5, SLC2A3, SLC16A1, SLC25A1, SLC44A3). Different types of annexins identified in the bovine mammary gland in midlactation have roles in various cellular functions including cell proliferation,[33] secretion of milk components,[34] apoptosis,[35] and other

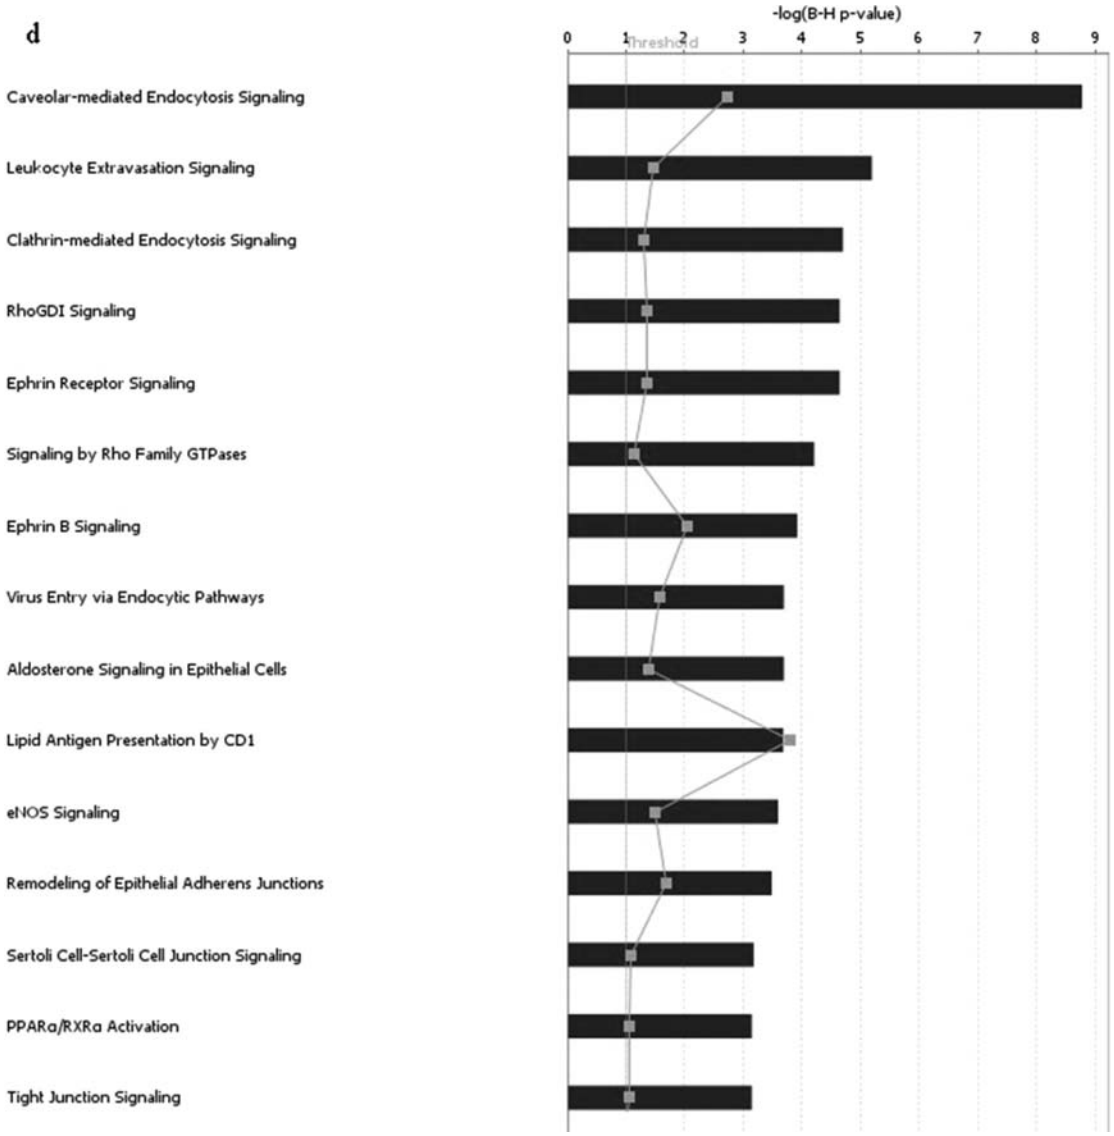

Figure 5. Enriched cellular components, molecular functions, biological processes, and pathways in the plasma membrane proteome. The over-representation of each category is determined by p value ($\leq$0.05). Each general category is organized by GO algorithms, and only top 10 categories are shown: enriched cellular components in plasma membrane proteome (a), enriched molecular functions in plasma membrane proteome (b), enriched biological processes in plasma membrane proteome (c), and enriched pathways in plasma membrane proteome (d). PM, plasma membrane; CMB, cytoplasmic membrane-bound; ARVC, arrhythmogenic right ventricular cardiomyopathy.

essential signaling events during lactation. SLC1A1 (EAAC1) and SLC1A5 (ASCT2) mediated transport of L-Glu, L-Asp, and D-Asp and Na^+-dependent exchange of small neutral amino acids such as Ala, Ser, Cys, and Thr, respectively,[36] implying that SLC1A1 and SLC1A5 play important roles in providing materials for milk protein synthesis. Physiological functions regarding other SLC families and members expressed in mammary gland are not characterized yet and need to be investigated in the future.

DAVID was used to identify enriched cellular component terms such as PM, vesicle, PM part, internal side of PM, and cell surface (Figure 5a). Functions such as binding (Figure 5b) and transport and adhesion (Figure 5c) were typically associated with the PM proteins. We found that six CD antigen proteins (CD9, CD36, CD47, CD166, PECAM1, ICAM1) were included in the cell adhesion terms. These cell surface molecules often act as receptors or ligands, which usually initiate a signal cascade. Yonezawa et al.[37] have demonstrated that CD36 facilitated the movement of fatty acids across the PM in bovine mammary gland. Also, the expression of CD36 mRNA in the bovine mammary gland has been shown to increase during lactation[38] and stimulated by octanoate in the bovine mammary epithelial cells,[37] demonstrating that CD36 expression could be related to physiological variations of lipid transport and metabolism within the cell. The relationship between the expressions of other CD antigen proteins and biological function in mammary gland has not been reported; therefore, there is an area for further investigation.

In the investigation of the significantly enriched pathways (Figure 5d), it was found that integrin β1 was involved in eight signal pathways. Integrins mediate adhesion-induced phosphorylation events that trigger activation of numerous signaling intermediates such as FAK, Src, ILK, p130CAS, PI3K, JNK, and MARK and regulated Rho-family GTPases, which are central for the control of actin cytoskeleton organization, contractility,

DOI: 10.1021/acs.jafc.5b02231
J. Agric. Food Chem. 2015, 63, 7388−7398

and cell shape changes.[27] It was also reported that β1 integrins were critical for the alveolar morphogenesis of a glandular epithelium and for the maintenance of its differentiated function.[27] β1 integrins and activation of FAK were essential for ductal morphogenesis, and Rac and ILK appeared to be major mediators of integrin signaling in the regulation of mammary luminal cell lactogenic differentiation.[27] Myoepithelial cell contractile activity in lactation required α3β1 integrin-mediated activation of Rac, FAK, and PAK1.[39] In the bovine mammary gland, milk accumulation decreased the mRNA expression of integrins (β1, α5, α6) involved in cell−extracellular matrix communication and was associated with the induction of apoptosis.[27] The integrin-induced intracellular signal transduction in bovine mammary gland remains to be further characterized.

In summary, the PM fractions isolated from lactating bovine mammary gland by discontinuous sucrose gradient centrifugation were relatively enriched. Eight hundred and seventy-two nonredundant proteins were identified by 2D-Nano-LC-ESI LTQ-Orbitrap MS/MS, wherein 215 proteins belonged to the PM. Bioinformatic analysis revealed that the main groups of the PM proteins had functions related to binding, transport, and catalysis and were predicted to be involved in caveolae-mediated endocytosis, leukocyte extravasation, aldosterone signaling in epithelial cells, and remodeling of epithelial adherens junctions. The results of this study provide the proteome profile of PM from bovine mammary tissue in vivo. This profile will be helpful to further elucidate the composition and functions of PM proteins and provide more knowledge about the molecular events taking place in the lactating bovine mammary gland.

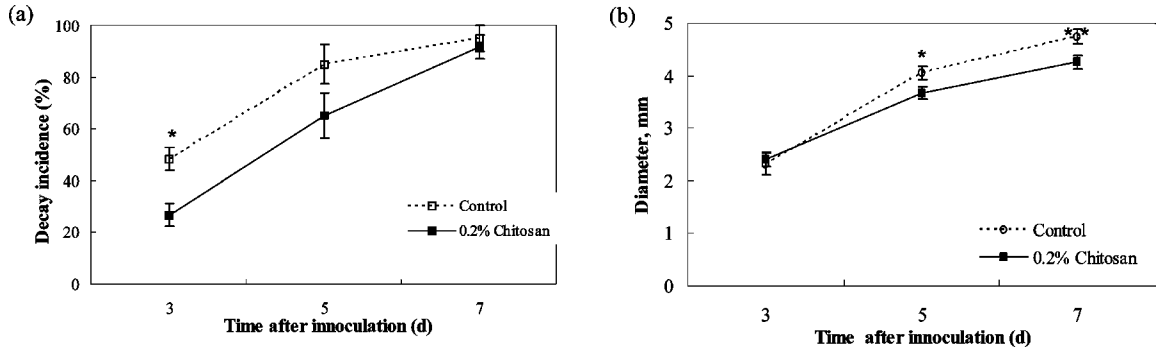

Figure 1. (a) Disease incidence and (b) lesion diameter of cherry tomato fruits inoculated with *B. cinerea*. Cherry tomato fruits treated with 1% acetate solution serviced as the control. Statistical significance of the difference was confirmed according to Duncan's multiple range test at $p < 0.05$ (*, $p < 0.05$; **, $p < 0.01$).

with a sterile nail at the equator on two opposite sides, dipped in 0.2% of chitosan solution for 5 min, and then air-dried on a clean bench. A total of 5 μL of spore suspension of *B. cinerea* was injected into each wound. Because acetate could also attribute to the inhibition of fruit decay,[20] we used the fruit treated with 1% acetate solution (pH was adjusted to 5.0) as the control.

Treated fruits were put in 200 × 130 × 50 mm plastic boxes with tap water to maintain a high relative humidity (about 80%) and stored at 22 °C. Decay incidence of tomato fruit was determined 3, 5, and 7 days after inoculation. After storage, the disease symptoms and severity (lesion diameter) were recorded. Disease incidence (%) was calculated as follows:

$$\text{disease incidence (\%)} = \frac{\text{number of infected wounds}}{\text{total wounds per replicate}} \times 100$$

Each treatment contained three replicates with 10 fruits per replicate, and the experiment was repeated 3 times.

Determination of the Malondialdehyde (MDA) Content and POD Activity in Tomato Fruit Tissue. To determine the MDA content, we conducted two treatments for cherry tomato fruit samples: (i) dipped in 0.2% chitosan solution for 5 min and air-dried, and 1 g of fruit tissue was collected 0, 3, 5, and 7 days after treatment; (ii) immersed in 0.2% chitosan solution for 10 min, 20 min, 30 min, 1 h, 2 h, and 3 h, and 1 g of fruit tissue was collected immediately. Tissue samples were homogenized in 5 mL of 100 mM ice-cold sodium phosphate buffer (pH 6.4) containing 0.1 g of polyvinyl polypyrrolidone (Sigma-Aldrich, St. Louis, MO). The MDA content was determined as the description of Song et al.[21] POD activity was determined according to Liu et al. and expressed as units mg^{-1} of protein, where 1 unit was expressed as the increase rate of absorbency per mass of protein per minute.[11] The protein content was determined using bovine serum albumin (Sigma-Aldrich, St. Louis, MO) as the standard.[22] Fruit treated with 1% acetate solution (pH 5.0) serviced as the control. Each treatment contained three replicates with three fruits per replicate, and the experiment was repeated 3 times.

Detection of Hydrogen Peroxide in Tomato Epidermal Peel. Cherry tomato was immersed in 0.2% chitosan solution for 10 min, 20 min, 30 min, 1 h, 2 h, and 3 h. Then, the tomato epidermal peel was collected immediately for H_2O_2 detection and total mRNA extraction. For H_2O_2 determination, peel samples were stained with 10 μM 2′,7′-dichlorodihydrofluorescein diacetate (H_2DCFDA, Invitrogen) for 30 min in darkness at 30 °C as the description of Liu et al.[23] H_2O_2 accumulation was examined on a laser confocal microscopy (FV1000, Olympus) at 488 nm excitation and 520 nm emission. For total mRNA extraction, peel samples were stored at −80 °C. Relative gene expressions would be detected in the total mRNA sample. Fruit treated with 1% acetate solution (pH 5.0) serviced as the control. Each treatment contained three replicates with three fruits per replicate, and the experiment was repeated 3 times.

RNA Extraction and Real-Time Quantitative Reverse Transcription Polymerase Chain Reaction (qRT-PCR). The tomato peel samples stored at −80 °C were milled using liquid nitrogen, and total mRNA was extracted using Trizol reagent (Invitrogen) according to the instruction of the manufacturer. About 100 ng of mRNA was used for cDNA synthesis. Real-time qRT-PCR was performed using the cDNA, and the gene-specific primers used were presented in Table 1. Real-time qRT-PCR was performed using Transgen Supermix (TransGen Biotech, Beijing, China) in a StepOne Plus real-time PCR system (Applied Biosystems). The PCR conditions were as follows: 95 °C for 30 s, followed by 40 cycles of 95 °C for 5 s and 60 °C for 15 s. Melting curve analyses of amplification products were performed at the end of the PCR reaction. The melting cycle was 95 °C for 15 s, 60 °C for 1 min, and 95 °C for 15 s. The expression level was normalized by the internal control gene UBI3, using the $2^{-\Delta\Delta C_T}$ method.[24]

Statistical Analysis. All statistical analyses were performed using SAS 9.2 (Cary, NC). Data were analyzed by one-way analysis of variation (ANOVA). Mean separations were performed by Duncan's multiple range tests. Least square means (LSMEANS) and standard errors of least-squares means (SEM) were calculated using the LSMEANS. Differences at $p < 0.05$ were considered to be significant.

RESULTS AND DISCUSSION

Effects of Chitosan on Postharvest Diseases of Cherry Tomato Fruit. Results in Figure 1a showed that chitosan at the concentration of 0.2% could control gray mold caused by *B. cinerea* notably 3 days after innoculation ($p < 0.05$). The disease incidence was reduced by 44.7%. However, at 5 days after innoculation, the difference was not significant ($p > 0.05$). A previous study showed that chitosan at the concentration of 0.05% could significantly inhibit the decay of citrus fruit caused by *B. cinerea*.[25] Liu et al. reported that 0.5% of chitosan could significantly decrease decay incidence of tomato fruit after 3 days of storage at 25 °C.[11] It suggested that chitosan inhibits the tomato gray mold depending upon the dosage. The lesion diameter on the fruit was also observed, and it was lower on the chitosan treatment than the control after 5 days of storage (Figure 1b), in accordance with previous studies that chitosan could reduce decay on fruits.[10,26]

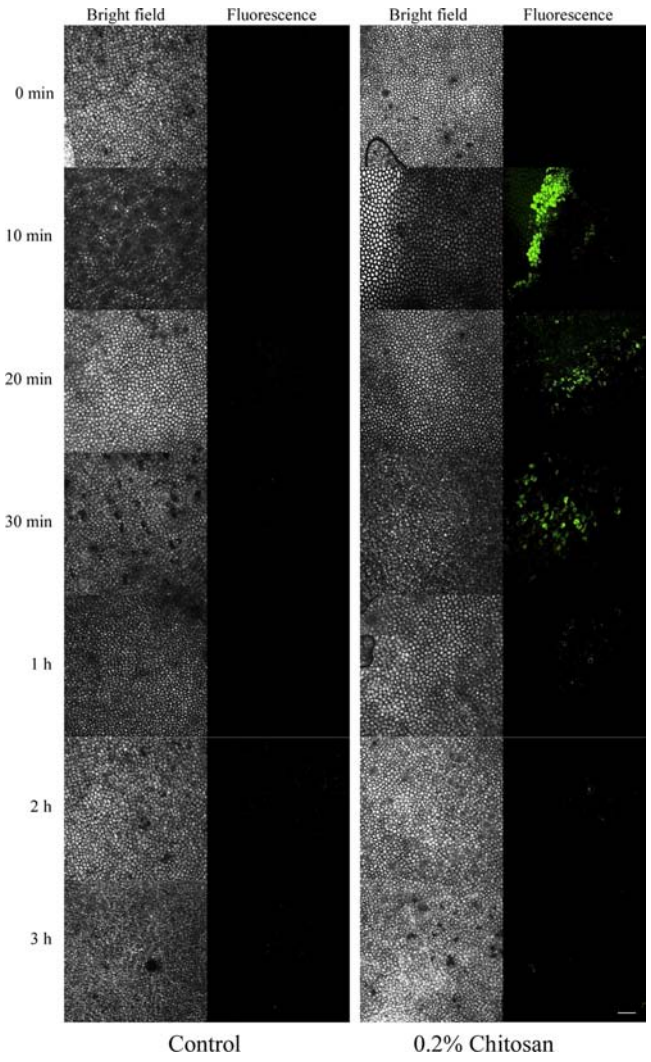

Figure 2. H_2O_2 accumulation in cherry tomato epidermal peel with chitosan. Peels were stained with H_2DCFDA and observed with a laser confocal microscopy at 488 nm excitation and 520 nm emission. Cherry tomato treated with 1% acetate solution serviced as the control. Bar = 150 μm.

Effect of Chitosan on ROS Accumulation in Cherry Tomato Fruit Epidermal Peel. Chitosan was recognized by receptors localized on the cell surface as the attack of fungal pathogens, and then ROS was stimulated.[27,28] This is one of the earliest cellular responses following successful pathogen recognition.[29] ROS include H_2O_2 and other chemical forms, such as superoxide anion, hydroxyl radical, and peroxyl radical; among them, H_2O_2 is most stable, although it lasts for no more than 1 s in fresh tissue.[30]

ROS accumulation has already been observed in *Arabidopsis* treated with chitosan.[31−33] A similar result was observed in sycamore cultured cells.[34] In this study, while cherry tomato was treated with 0.2% chitosan for 10 min, H_2O_2 accumulation in the epidermal peel could be observed; in 20 and 30 min, the fluorescence signal of H_2O_2 remained strong (Figure 2). However, the H_2O_2 level was reduced significantly in the treatments in 1 h; and in 3 h, it could hardly be detected (Figure 2). This result indicated that, in the mature tomato fruit peel, H_2O_2 was stimulated as an early response to chitosan. Zeng et al. reported that, in the navel orange fruit treated with chitosan, the H_2O_2 content significantly increased and, subsequently, inhibited the postharvest decay.[35] The increase

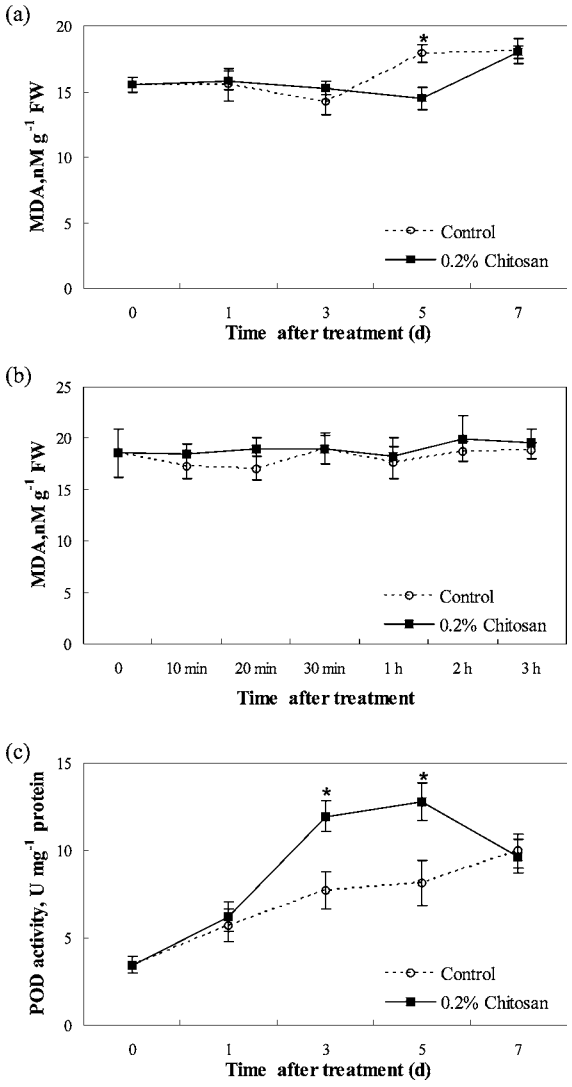

Figure 3. (a and b) MDA production and (c) POD activity in cherry tomato treated with chitosan. Cherry tomato treated with 1% acetate solution serviced as the control. Statistical significance of the difference was confirmed according to Duncan's multiple range test at $p < 0.05$ (*, $p < 0.05$).

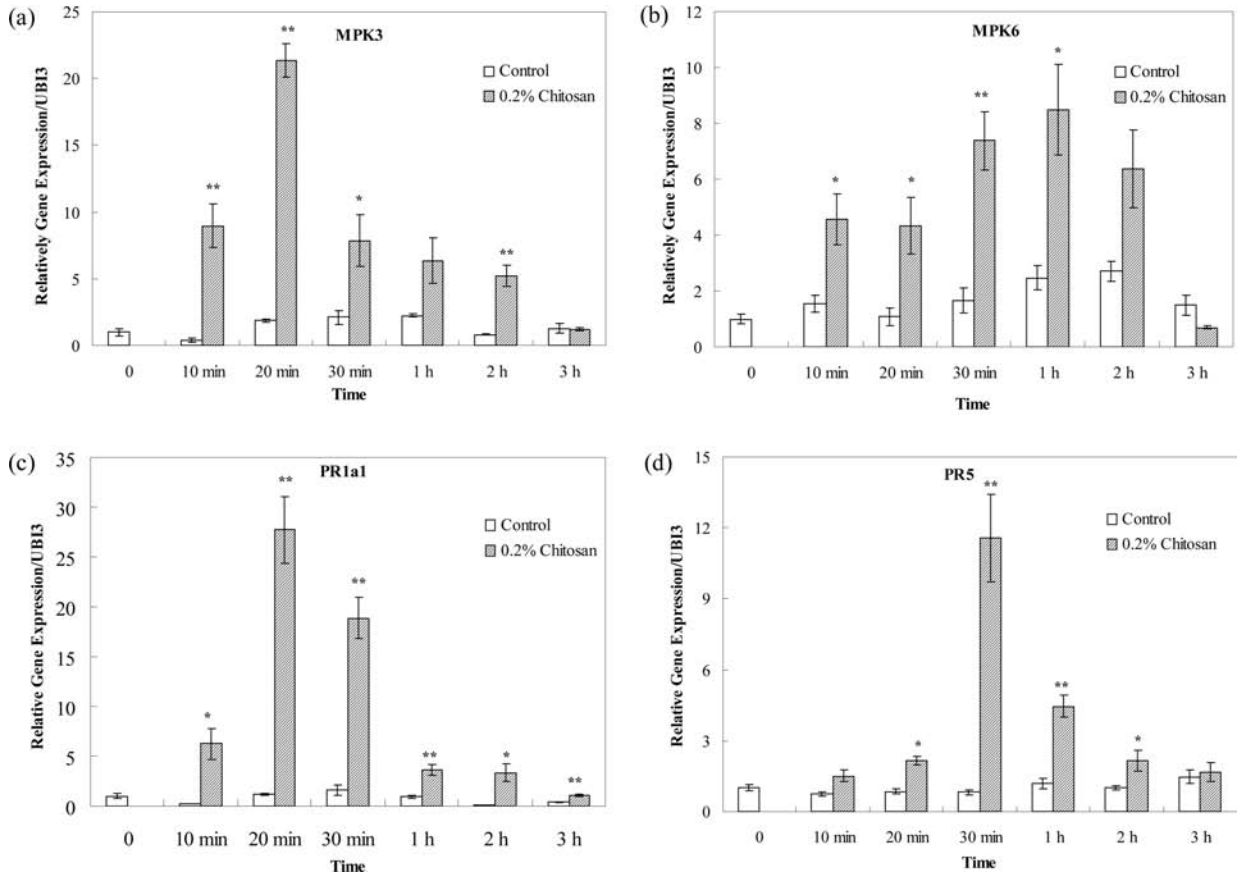

Figure 4. Relative expression of (a) *MPK3*, (b) *MPK6*, (c) *PR1a1*, and (d) *PR5* in cherry tomato epidermal peel treated with chitosan. *UBI3* was used as the internal control gene. Cherry tomato treated with 1% acetate solution serviced as the control. Statistical significance of the difference was confirmed according to Duncan's multiple range test at $p < 0.05$ (*, $p < 0.05$; **, $p < 0.01$).

of the H_2O_2 content was believed to promote resistance of apple fruit to *Penicillium expansum*.[36] Therefore, the improvement of the H_2O_2 level might serve as an important signaling molecule to activate plant defense-related genes in cherry tomato fruit.

Effect of Chitosan on the MDA Content and POD Activity in Cherry Tomato Fruit Tissue. In the past, ROS was always considered to contribute to the senescence of harvested fruit.[37,38] ROS in peach petals induced by *Monilinia fructicola* resulted in oxidative damage in host tissues,[23] which might enhance the infection by necrotrophic pathogen. Therefore, the content of ROS must be maintained at a nontoxic level, and ROS producing/scavenging enzymes were involved in the maintaining of this balance.[39]

MDA, a decomposition product of polyunsaturated fatty acid hydroperoxides, is often used as a marker for monitoring lipid peroxidation caused by oxidative damage.[40] In our study, the MDA content in fruit treated by chitosan was not different with the control (panels a and b of Figure 3; $p > 0.05$), indicating that the instantaneous H_2O_2 accumulated in the epidermal peel had no effect on the oxidation of fruit tissue. After 5 days of storage, the MDA content was even lower than that in the control ($p < 0.05$). This might be ascribed to the increasing activities of catalase and POD, which were crucial for suppressing the toxic ROS level.[30]

Figure 3c showed that the POD activity was enhanced notably with the addition of chitosan ($p < 0.05$), in agreement with the previous studies on tomato, sweet cherry, and peach.[11,41,42] After 3 days, POD activity in chitosan treatment was significantly higher than that in the control ($p < 0.05$); this might explain the decrease of the MDA content 5 days after treatment. However, it was reduced after 7 days and had no difference compared to the control ($p > 0.05$). In the control, the POD activity also increased markedly during storage, in agreement with a previous report that the POD activity was increased dramatically in grape fruit treated with deionized water at pH 5.6.[26]

Effect of Chitosan on *MPK3*/*MPK6* and *PR* Transcripts in Cherry Tomato Fruit Epidermal Peel. MAPK cascades are major components downstream of receptors that can rapidly transduce stress signals into intracellular responses in all eukaryotes.[15] MAPK cascade activation is one of the earliest signaling events while the plant interacts with PAMPs. Many of the known PAMPs were shown to activate MAPKs, e.g., flagellin,[43] peptidoglycan,[44] and chitin.[45,46] PAMPs are recognized by pattern recognition receptors on the plasma membrane, and intracellular immune responses are immediately initiated.[47] Several chitin/chitosan receptors have been identified in *Arabidopsis*.[48−50] The cascades mainly composed of a MAPK kinase kinase, a MAPK kinase, and a MAPK link upstream receptors to downstream targets involved in the regulation of development, growth, and programmed cell death and in responses to a diversity of environmental stimuli.[15]

MPK3 and *MPK6* are key players and make positive effects in the defense response to bacterial and fungal pathogens. They show a high level of functional redundancy.[15] In this experiment, the relative expression level of *MPK3* was induced 10 min after treatment, reached the highest level at 20 min,

DOI: 10.1021/acs.jafc.5b01566
J. Agric. Food Chem. 2015, 63, 7399−7404

which was 11 times higher than that in the control ($p < 0.05$), and reduced to the basal level 3 h after treatment (Figure 4a). The expression of *MPK6* was also induced in 10 min ($p < 0.05$) and reached the highest level at 1 h. At 3 h after treatment, the expression level of *MPK6* was significantly decreased (Figure 4b).

The activated MPK3/MPK6 is followed by a series of modifications of the cell, including the synthesis of pathogen-induced synthesis of PR proteins (e.g., β-1,3-glucanases and chitinases),[15,51] lignin deposition,[52] and phytoalexin (e.g., camalexin) synthesis.[53] *PR* genes play an important role in plant defense responses and have been widely used as a marker of downstream immune signaling.[54] They are classified into 17 families.[55] In our study, *PR1a1* and *PR5* were selected to detect the defense response in tomato fruit peel. The expression of *PR1a1* was also induced in 10 min ($p < 0.05$) and reached the highest level at 20 min, about 24 times higher than the control ($p < 0.01$; Figure 4c), while the expression of *PR5* was induced in 20 min ($p < 0.05$) and reached the highest level at 30 min ($p < 0.01$; Figure 4d). This might be one of the reasons that the disease severity was notably lower on fruits treated by chitosan. Additionally, we had also determined two other *PR* genes, *PR-P2* and *PR-P4*; however, they were not induced (data not shown), indicating that not all *PR* genes were induced in response to the chitosan-triggered defense.

The regulation of the *PR1* gene is considered to depend upon the salicylic acid signaling pathway and correlated with the onset of systemic acquired resistance.[54] It was reported that salicylic acid improved the activities of the main defense-related enzymes, including phenylalanine ammonia-lyase, POD, chitinase, and β-1,3-glucanase in jujube fruit and, consequently, enhanced the fruit resistance.[56]

In conclusion, this study showed that 0.2% of chitosan could induce the accumulation of ROS and the expressions of *MPK3*, *MPK6*, *PR1*, and *PR5* genes in cherry tomato peel. The result suggested that the MAPK signaling pathway was possibly activated in the cherry tomato fruit treated with chitosan. This might be one of the molecular mechanisms that the resistance to fungal pathogens of fruit was enhanced by chitosan. However, the complete cascade stimulated by chitosan on tomato contains the specific MAPK kinase kinase, and MAPK kinase upstream of MPK3/MPK6 should be further identified.

multilayer microcapsules based on TA and synthetic polymers (poly-*N*-vinylpyrrolidone) via hydrogen-bonding interaction, for drug encapsulation, controlled delivery, and long-term storage. TA−protein interactions are essentially physical: hydrophobic and hydrogen bond mediated.[7] The tannin affinities for human salivary proline-rich proteins (PRP) were found to be related to astringency,[12] and tannin−gliadin interactions for haze formation[13] had been investigated extensively. For PRP, including gliadin[13] and kafirin,[14] hydrogen bonds between the hydroxyl groups of tannins and the carbonyl groups of proteins are believed to be involved in the complexation of the proteins and tannins. PRP can also interact with pentagalloyl glucose of TA via hydrophobic interactions with the pyrrolidine ring of proline. Below the tannin critical micelle concentration (CMC), the protein polypeptides surround the tannins; above the tannin CMC, tannins act as bridges to cross-link the polypeptides for forming aggregates or agglomerates of proteins.[15]

Stabilization of the oil−water interface with colloidal particles, which leads to the formation of Pickering emulsions, is known to display long-term stability against coalescence, and the potentials for texture modification, calorie and fat reduction, and bioactive compound delivery have emerged.[16] As compared to conventional emulsifiers, the main benefits of Pickering emulsions are high physical/chemical stabilities. The particle-stabilized interface can be modified after emulsion formation to bring additional functionality; this modification of interfacial properties can be in response to a trigger, and Pickering emulsions can serve as templates for preparing materials that could not be obtained from conventional emulsions.[16] Studies on protein-based particles used as Pickering emulsion stabilizers are still scarce, although they show clearly a growing research field. Zein, a major protein of corn, is capable of forming self-assembled nanoparticles to stabilize Pickering emulsion due to its amphiphilic character. Therefore, zein-based particles possess promising potential to serve as food-grade Pickering emulsion stabilizers in the food industry. de Folter and co-workers have employed unmodified zein colloidal particles to stabilize Pickering emulsion, but it was very unstable to creaming and the aqueous phase was turbid.[17] Fortunately, we have reported the stabilization of oil−water interfaces with zein complex colloidal particles.[18,19] Our findings showed that the complexation of zein particles and the surfactant sodium stearate (SS) was due to nonspecific hydrophobic interaction, which resulted in enhanced adsorption and accumulation of zein particles at the oil−water interface. The resultant Pickering emulsions exhibited superior stability against both coalescence and creaming.[18] More recently, we fabricated dual-functional zein/chitosan complex particles (ZCP), which were loaded with antioxidant curcumin, and further prepared antioxidant Pickering emulsions via manipulation of the interface framework. The combination of steric hindrance from ZCP-based interfacial architecture and interfacial cargo of curcumin gave rise to emulsions with favorable oxidative stability.[19] However, modifiers such as SS and chitosan are either synthetic or have a poor organoleptic acceptation, which limit their application in food formulations. Moreover, emulsions stabilized by zein−SS complexes presented oil droplets in the top phase after a few days of storage. In this work, TA, a natural polyphenol, was used as an efficient tool to control the self-assembly behavior of zein, so as to fabricate stable and edible zein/TA colloidal particles (ZTP) and consequently prepare stable Pickering emulsions. Interestingly, the results indicated that the complexation of zein and TA was due to noncovalent interaction (mainly hydrogen bonding), which was more specific than the hydrophobic interaction in zein−SS complexes. Because of the multiple biological properties of TA, including antioxidant and antibacterial properties, these emulsions might inherently possess excellent chemical stability and some health benefits, and they could be developed as novel functional food ingredients.

MATERIALS AND METHODS

Materials. Zein (purity is around 88−96%), tannic acid, and fluorescent dyes (Nile Red and Nile Blue A) were purchased from Sigma-Aldrich, Inc. (St. Louis, MO, USA). α-Zein is the major component of zein, which has two subtypes, Z19 and Z22, confirmed by SDS-PAGE. Corn oil was obtained in a local supermarket (Guangzhou, China). Other chemicals were of analytical grade.

Colloidal Particle Synthesis. The zein colloidal particles were prepared via an antisolvent precipitation technique,[19] with modification. In brief, an aliquot of 2.5 g of zein powder was dispersed in 100 mL of a 70:30 ethanol/water (v/v) solution and stirred using a magnetic stirrer for 2 h, then stored overnight at 4 °C to allow complete hydration. Zein stock solutions with different TA concentrations (expressed as zein/TA ratios, 1:0−1:0.5 w/w) at different pH values (3.0, 5.0, 7.0; the pH was adjusted with 2 mol/L HCl and 2 mol/L NaOH) were heated in a water bath at 55 °C for 50 min with slow stirring. The preheated zein−TA solutions (10 mL) were quicklyt poured into 25 mL of Millipore water (18.2 MΩ·cm) under continued stirring (1000 rpm). After 15 min of stirring, the ethanol in zein−TA solutions were further removed, and preconcentration of colloidal particle was performed by using an RV 10 digital rotary evaporator (IKA-Works Inc., Germany). Finally, the zein concentration in the solutions (8.3 mL) was 3% (w/v). The obtained solutions were centrifuged at 4000*g* for 10 min to remove insoluble aggregates, and then they were stored at 4 °C for further use. For field emission scanning electron microscope (FE-SEM) observation and contact angle measurement, the resultant ZTP colloidal particles were lyophilized for 24 h (Christ Delta 1-24 LSC, Martin Christ, Germany) and then ground into homogeneous powders.

Particle Size and Zeta (ζ)-Potential Measurements. The ZTP colloidal particles were diluted to 1 mg/mL with Millipore water, and the pH was adjusted to 3.5; then the particle size, ζ-potential, and polydispersity index (PDI) were measured using a Nano ZS Zetasizer instrument (Malvern Instruments, Worcestershire, UK). All measurements were carried out at 25 °C, and the results are reported as averages of three readings.

Morphology Observation. The morphology of the freeze-dried ZTP powders was observed by FE-SEM. The powder samples were loosely glued onto a conductive adhesive mounted on a stainless steel stage, subsequently coated with a thin conductive gold and platinum layer using a sputter coater (Hummer XP, Anatech, Union City, CA, USA). They were observed with a Zeiss Merlin FE-SEM (Zeiss, Oberkochen, Germany).

Contact Angle Measurement. The three-phase contact angle (θ_{ow}) of colloidal particles was measured using an OCA 20 AMP (Dataphysics Instruments GmbH, Germany), which was described in our previous research.[18] The ZTP powders were prepared as pellets of 13 mm in diameter and 2 mm in thickness, and the pellets were placed into an optical glass cuvette containing purified corn oil. Next, a drop of pH 3.5 Milli-Q water (5 μL) was deposited on the surface of the pellets using a high-precision injector. After 4 min for equilibration, the drop image was photographed using a high-speed video camera, and the profile of the droplet was numerically solved and fitted to the Laplace−Young equation. Contact angles were measured on each of four pellets per sample, and three measurements were performed for each pallet.

Circular Dichroism (CD) Spectroscopy. A Chirascan spectropolarimeter (Applied Photophysics Ltd., UK) was used for monitoring the configuration of zein in 70% (v/v) aqueous ethanol after heating with TA. The samples were diluted to 0.1 mg/mL by 70% (v/v)

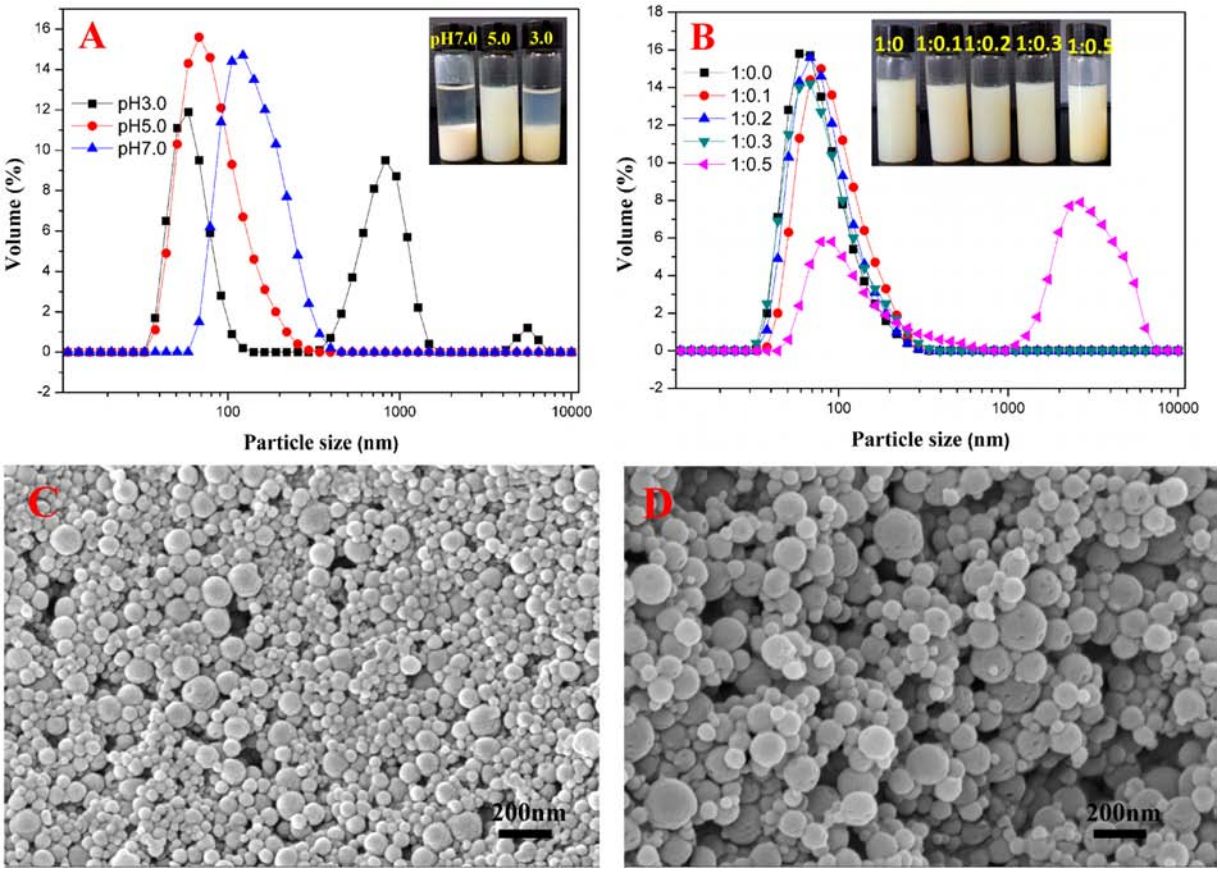

Figure 1. Size distribution and morphology of the zein/TA complex colloidal particle (ZTP) prepared at (A) various pH values (3.0, 5.0, and 7.0) with a zein/TA ratio of 1:0.2 and (B) various zein/TA ratios (from 1:0 to 1:0.5 w/w) at pH 5.0. FE-SEM images showed the ZTP prepared at pH 5.0 (C) and 7.0 (D) with the same zein/TA ratio of 1:0.2.

aqueous ethanol solution with different pH values (3.0, 5.0, 7.0), which was also used as the reference buffer. The CD spectroscopy was recorded from 190 to 260 nm in a 1 mm path length quartz cuvette, expressed as mean residue ellipticity in deg cm^2 $dmol^{-1}$. From the CD spectra, fractional contents of the secondary structure (α-helix, β-sheet, β-turn, and random coil) of the zein−TA complex in 70% (v/v) aqueous ethanol were calculated according to the CONTIN/LL program in CD Pro software.

Small-Angle X-ray Scattering (SAXS). SAXS experiments were performed using a SAXSess camera (Anton-Paar, Graz, Austria) to collect information about the structure parameters and the shape of zein/TA complexes in 70% (v/v) aqueous ethanol solutions. A PW3830 X-ray generator with a long fine-focus sealed glass X-ray tube (PAN Alytical Almelo, The Netherlands) was operated at 40 kV and 50 mA. The samples with a zein concentration of 1.0 wt % were filled into a capillary of 1 mm diameter and 0.01 mm wall thickness. The capillary was placed in a TCS 120 temperature-controlled sample holder unit (Anton Paar) along the line-shaped X-ray beam in the evacuated camera housing. A shot exposure period of 900 s was used to acquire the scattering data. The sample-to-detector distance was 261.2 mm, and the temperature was kept at 25.0 °C. Data analyses were done by Guinier methods. The overall radius of gyration (R_g) calculated from the initial slope of a Guinier plot as $\ln(I(q))$ against q^2, where $I(q)$ is the scattering intensity and $q = (4\pi/\lambda)\sin(\theta/2)$ is the modulus of the scattering vector with θ the scattering angle and λ the wavelength of the X-ray beam. The limit of Guinier plots is usually defined as $qR_g < 1$. The $I(0)$ was evaluated at very small angles, and the intensity is represented as $I(q) = I(0)\exp(-1/3(qR_g)^2)$. If one of the particle dimensions is much larger than other two dimensions, the radius of gyration of the cross-section (R_c) is obtained in a larger q range than that used in the R_g analyses and calculated from the slope of the cross-section plots as $\ln(I(q)q)$ against q^2 ($qR_c < 1$). Moreover, if the observed asymmetric particles are approximated by a rectangular prism with edges of a, b, and c (b and $c \ll a$), knowledge of R_g and R_c gives edge a with the largest length from the equation $a^2 = 12(R_g^2 - R_c^2)$.[21]

Fourier Transform Infrared Spectroscopy (FTIR). The FTIR spectra of ZTP powder were recorded at 400−4000 cm^{-1} using a Bruker VERTEX 70 spectrometer (Germany) equipped with a narrow-band mercury cadmium telluride detector with a resolution of 2 cm^{-1}.

Preparation of Pickering Emulsion. The Pickering emulsions were prepared by resultant zein/TA colloidal particles with different concentrations (0.25−1.5 wt %). All emulsions were prepared by homogenizing the mixture of 50 v % corn oil and 50 v % corresponding concentration particle suspensions. In brief, corn oil (5 mL) was added to the particle suspensions (5 mL) in a glass vial, and the resultant mixtures were sheared using an Ultra-Turrax T10 homogenizer (IKA-Works Inc., Germany) at 23000 rpm for 2 min at room temperature to yield Pickering emulsions.

Droplet Size Distribution of Emulsion. The oil droplet size distribution of emulsions was determined using a Malvern MasterSizer 3000 (Malvern Instruments Ltd., Worcestershire, UK). The samples were diluted with deionized water. The refractive indices of water and corn oil were taken as 1.33 and 1.52, respectively. Droplet size measurements were reported as the volume-average diameter, $d_{4,3} = \Sigma n_i d_i^4 \Sigma n_i d_i^3$, where n_i is the number of particles with diameter d_i. All of the experiments were performed in three replicates.

Confocal Laser Scanning Microscopy (CLSM). The microstructure of emulsions was observed with a Leica TCS SP5 confocal laser scanning microscope (Leica Microsystems Inc., Heidelberg, Germany). The emulsions were dyed with a mixed fluorescent dye solution consisting of 1 mg/mL Nile Red and 1 mg/mL Nile Blue A. The stained emulsions were placed on concave slides and covered with

DOI: 10.1021/acs.jafc.5b03113
J. Agric. Food Chem. 2015, 63, 7405−7414

coverslips. They were observed with a 100× oil immersion lens and an argon krypton laser having an excitation line of 488 nm and a helium neon laser (He/Ne) with excitation at 633 nm.

Rheology of Emulsion Gels. The dynamic oscillatory measurement of Pickering emulsion gels was performed at 25 °C with the frequency ranging from 1 to 10 rad/s (all of the measurements were conducted within the linear viscoelastic region), using a Haake RS600 rheometer (Thermo Electron Co., Waltham, MA, USA) between two parallel plates (d = 35 mm) with a gap of 1.0 mm. The elastic (G') and loss (G'') moduli as a function of the frequency were recorded. All of the experiments were performed in three replicates.

Statistics. Statistical analyses were performed using an analysis of variance (ANOVA) procedure of the SPSS 21.0 statistical analysis program, and the differences between means of the trials were detected by a least significant difference (LSD) test ($P \leq 0.05$).

RESULTS AND DISCUSSION

Preparation of Zein−TA Complex Colloidal Particles (ZTP). Compared with the traditional antisolvent approach that was used to fabricate zein colloidal particles,[18,19] we adopted a modified method to prepare ZTP. In brief, both zein and TA were dissolved in 70% (v/v) aqueous ethanol solution and heated to enhance their interaction, rather than directly diluting the aqueous ethanol solution of zein with TA aqueous solution. Heating can unravel some α-helical chain structures of zein by breaking hydrogen bonds, followed by realignment and reorganization into a β-sheet conformation.[21] It can be hypothesized that hydrogen bonds of α-helical structures and β-sheets may be broken during incubation, leading to the formation of random coils, which may provide complexation sites for TA to interact. The complexation sites are probably the carbonyl groups of the polypeptide, which hydrogen bond with the hydroxyl groups of the TA.[22] Due to the protonation, neutralization, and ionization of TA in solutions under varied pH, TA exhibited the capability to facilitate hydrogen-bonded interaction with macromolecules through pH-dependent regulation.[11,17] Therefore, the colloidal stability of ZTP was explored at pH 3.0, 5.0, and 7.0, respectively. Figure 1 shows the morphology and size distribution of ZTP formed at different pH values and TA concentrations (expressed as zein/TA ratio). Table 1 shows the mean size, polydispersity (PDI), and ζ-potential values of ZTP as a function of pH and zein/TA ratio. Unlike the ZTP prepared at pH 3.0 and 7.0, which showed severe aggregation, greater particle size (~200 nm, determined by FE-SEM), and multiple-modal size distribution (PDI ≈ 0.74, pH 3.0), the ZTP prepared at pH 5.0 with intermediate TA concentration (zein/TA wt/wt = 1:0.2) exhibited colloidal stable, nanosized (~99 nm), and nearly monodisperse size distribution (PDI ≈ 0.11). FE-SEM images (Figure 1C,D) further confirmed that the particles formed at pH 5.0 were relatively small and well dispersed, whereas ZTP particles formed at pH 7.0 were aggregated clusters. The ZTP prepared at pH 5.0 with zein/TA ratios of 1:0.2 actually possessed much higher ζ-potential (about +51 mV), which contributed to the strong electrostatic repulsion among particles. However, when the zein/TA ratio was increased from 1:0.3 to 1:0.5, the ζ-potential of ZTP declined to +35 mV and the particle dispersions became unstable (Figure 1B; Table 1), indicating that the excess TA resulted in the aggregation and complex precipitation of ZTP. Moreover, the ζ-potentials of TA colloidal particles (prepared via an antisolvent precipitation technique stated under Materials and Methods; TA concentration in ethanol aqueous of 5 mg/mL) prepared at pH 3.0, 5.0, and 7.0 and finally adjusted to a pH of 3.5 were +9.32, −2.67, and −4.26 mV (data not shown), respectively.

Zein is positively charged below its isoelectric point (pI 6.2).[23] After the antisolvent and evaporation procedure, the pH of the ZTP dispersion decreased from pH 5.0 to 3.48 (data not shown). The protonation of zein at such a pH resulted in a strong positive surface charge on colloidal particles (about +51 mV); thus, this long-range electrostatic repulsion was able to stabilize zein in water, which was its poor solvent.[17] However, the final pH of ZTP formed at pH 3.0 was much lower (about 2.85; data not shown), and these particles had lower surface charge (+33 mV), leading to colloidal instability and precipitation. Recently, Kharlampieva and co-workers[11,24] studied the TA−poly(*N*-vinylpyrrolidone) (TA−PVPON) multilayer microcapsules formed at pH 5.0 and 7.4, respectively. They found that TA was in its neutral and partially protonated form at pH 5.0, and this facilitated strong hydrogen-bonding interactions between the hydroxyl groups on TA and the carbonyl groups on the pyrrolidone rings in PVPON. This complexation further suppressed the ionization of TA, resulting in the improvement of their drug encapsulation and long-term storage.[11,24] In a similar way, hydrogen-bonding interaction between protonated TA and zein might dominate in the ZTP formed at pH 5.0. At pH 3.0 and 7.0, TA was in partial ionization of hydroxyl groups, leading to the formation of electrostatic complexes with low surface charge and unstable colloidal dispersions.

The interfacial wettability of the particles plays a crucial role for the preparation of emulsions stabilized by particles or Pickering emulsions. The near-neutral wettability (θ_{ow} ~ 90°) can facilitate efficient packing of particles at the oil−water interface and create a steric barrier against the coalescence of oil droplets. The wettability of the zein particles had been successfully modified by ionic surfactant, sodium stearate, via hydrophobic interaction[18] or by a positively charged polysaccharide, chitosan, via weak electrostatic interaction,[19] as we reported previously. In this study we tried to tune the wettability of zein particles via modulating the hydrogen-bonding interaction between TA and zein. Figure 2 shows typical images of water droplets deposited to zein films immersed in corn oil. The wettability of zein particles expressed as oil-in-water three-phase contact angles (θ_{ow}) was calculated,[19] which is shown in the insets of Figure 2. The θ_{ow} of bare zein particles formed at pH 5.0 was around 107.13°, which was consistent with our previous result (θ_{ow} ~ 112.7°).[19] These particles actually did not favor interfacial particle adsorption and formation of oil-in-water Pickering emulsion. The ZTP

formed at pH 3.0 and 7.0 as well as at pH 5.0 with excess TA concentrations (zein/TA ratios of 1:0.3−1:0.5) had much lower θ_{ow} (70−77°) and surface charge (+30 mV) concurrently. These implied that the excess TA and ionization of TA facilitated the formation of electrostatic complexes. In contrast, the ZTP formed at pH 5.0 with a zein/TA ratio of 1:0.2 had near-neutral wettability ($\theta_{ow} \sim 86°$) without decreasing their surface charge significantly, suggesting that this ZTP could be utilized to yield stable Pickering emulsion. These interactions might be dominated by hydrogen bonding between the carbonyl moieties of zein and the hydroxyl groups of the neutral TA at acidic pH and caused an increase in the hydroxyl groups at the surface of zein particles, thereby lessening their hydrophobic characteristics.

Structure Characterization of Zein/TA Complexes and Particles. The structure and conformation of α-zein in various solutions had been extensively studied.[25−27] The consensus is that α-zein in aqueous ethanol solution exists as an extended oblong structure with an axial ratio of 6:1−12:1, which was evidenced by SAXS experiments.[25,27] The extended configuration of zein in protic solvents could provide increased accessibility to the reactive sites of protein for TA, thus modifying their functionality. The secondary structure of zein in 70% (v/v) aqueous ethanol was monitored in the far-ultraviolet (UV) region. The CD profiles of zein with different pH values and TA concentrations are shown in Figure 3. The fractional contents of secondary structure (α-helix, β-sheet, β-turn, and random coil) of zein were calculated, and they are shown in the insets of Figure 3. First, because the CD spectrum of TA was almost the same as that of the buffer (70:30 v/v ethanol/water solutions), TA did not have its own CD pattern to interfere with zein (data not shown). The CD spectra of zein exhibited the characteristics of α-helix with two strong negative ellipticity values at around 208 and 222 nm. CD ellipticity at 222 nm has been widely used to estimate α-helix content in proteins.[27] Compared to the complexes at pH 5.0, a slight

increase of α-helix content and decrease of β-sheet for zein/TA complexes at pH 3.0 and 7.0 were observed, but the difference was not significant (Figure 3A). Cabra et al.[21] found that the secondary structure of zein in aqueous ethanol solutions strongly depended on the pH on the basis of CD measurements. It was also shown that the α-helix and β-sheet contents at pH 5.0 were around 33 and 12%, which were similar to our results. Huang and co-workers[27] compared the dissolution behavior of α-zein in aqueous ethanol with that in acetic acid solutions by SAXS, which indicated that the protonation of acetic acid imposed on zein. The positive surface charges of zein and reduction of hydrophobic interaction with the presence of the acetate solvation layer, which was able to provide long-range electrostatic repulsion, enhanced the solution stability of zein. As a weak acid, TA completely protonates and ionizes at pH 3.0 and 7.0, respectively.[11] Therefore, the increase of α-helix content at pH 3.0 and 7.0 might contribute to the formation of electrostatic complexes between zein and protonated or ionized TA.

Figure 3B clearly shows evidence for a conformational change of zein in aqueous ethanol solution that was induced by TA binding. It can be seen that binding of TA causes an obvious transformation from α-helix to β-sheet configuration of zein at pH 5.0, and the greatest shift generated on the zein−TA complexes with intermediate TA concentration (a zein/TA ratio of 1:0.2). The protein interaction with polyphenol driven by hydrophobic attraction and enhanced with hydrogen-bonding network had been well confirmed.[28] The interaction between milk β-lactoglobulin (β-LG)[29] and tea tannins (epigallocatechin gallate, EGCG) was studied in detail,[27] which indicated that the β-LG conformation was altered in the presence of EGCG with an increase in β-sheet and α-helix, which helped to enhance the structural stabilization of protein. The conformational change of zein due to the TA binding is dependent on the TA concentration. When the zein/TA ratio was increased to 1:0.3−1:0.5, the fractional contents of the secondary structure in zein were close to that of pure zein (Figure 4B), implying that the binding model of zein and TA would be changed. Recent findings indicated that for native unfolded protein, such as β-casein[30] and PRP,[15] interactions with tannin were dependent on the colloidal state and the concentration of tannins. Small tannins below their CMC generate a conformational change of the protein surrounding or "wrapping" the tannins. However, larger tannins with high concentration led to aggregation and complex precipitation by a bridging effect. Zein, which is a proline-rich protein, adopts an extended and flexible conformation in aqueous ethanol solution,[21,27] and its binding with TA might comply with the similar model.

SAXS experiments suggested that α-zein in aqueous ethanol solution existed as an extended oblong structure with an axial ratio of 6:1.[27] In this study, SAXS was used to monitor the possible changes of the contour structure of zein in aqueous ethanol with TA binding. On the basis of Guinier plots for the oblong structure of zein, the structural parameters, including overall gyration radius (R_g), the longest edge in an elongated particle (a), and the extrapolation of intensity to an angle of zero $I(0)$ of zein, were calculated and are shown in Table 2. It was noteworthy that there was a little difference in R_g and $I(0)$ values of zein/TA complexes when compared with those of

DOI: 10.1021/acs.jafc.5b03113
J. Agric. Food Chem. 2015, 63, 7405−7414

pure zein. R_g values of zein in all ethanol solutions at pH 5.0 with different zein/TA ratios are between 2.17 and 3.25 nm, which were equal to or even less than that of pure zein (2.90 nm), indicating that the TA binding at pH 5.0 did not disturb the contour structure of zein in aqueous ethanol, although small changes were recorded in its secondary structure (Figure 3). A similar result was observed for β-casein.[30] Small tannins could increase the number of proteins per micelle without changing their size, leading to compaction of micelles. In the case of pH 7.0, the R_g and a values of zein/TA complexes increased significantly. They were nearly twice greater than those of the ZTP prepared at pH 3.0 and 5.0, indicating the formation of complex aggregates. This might explain why the ZTP formed at pH 7.0 was larger than that formed at pH 5.0 (Figure 1; Table 1).

FTIR spectra of zein colloidal particles, which were used to characterize the noncovalent interaction of zein and TA, are shown in Figure 4. The absorption peak at 3308 cm^{-1} is assigned to the N—H stretching vibration of the amide I from zein, whereas the absorptions at 1657 and 1540 cm^{-1} are attributed to C═O of amide I and C—N—H of amide II of zein, respectively (Figure 4D).[31] Wide bands in the range of 3600−3100 cm^{-1} are attributed to O—H stretching of the phenolic or hydroxyl group of TA (Figure 4C).[32,33] Both C═O and N—H bonds were involved in the hydrogen bonding between different elements contributing to the secondary structure of zein. For ZTP (Figure 4A), the absorption at 1657 cm^{-1} related to the C═O bond (amide I) of zein overlapped the TA band at 1614 cm^{-1} (aromatic C═O bonds). Therefore, only a single band at 1656 cm^{-1} was observed, and the new component at 3356 cm^{-1} appeared. Collectively, the results revealed the hydrogen-bonding interaction in nature for the zein/TA complex colloidal particles. For the zein/TA physical mixture (mixture of the zein and TA powder with a zein/TA ratio of 1:0.2), the absorbance peaks at 1386, 1311, 1237, and 1170 cm^{-1} were almost similar to those of the zein particle and the peaks at 1448 and 869 cm^{-1} were similar to those of TA, but all peaks above were significantly different from those of the ZTP. Moreover, the range below 1500 cm^{-1} is significant for deformation, bending, and ring vibrations, which can be very specific for a substance or for different types of substitution; thus, this range is frequently referred to as the "fingerprint region" of a spectrum.[34]

Pickering Emulsions and Gels Prepared by ZTP. As shown in Figure 5, Pickering emulsions prepared by using bare zein colloidal particle and ZTP (prepared at pH 5.0) as stabilizers were compared in terms of storage stability. The bare zein colloidal particle was actually not a good emulsifier for Pickering emulsions, which showed severe aggregation and oil release on the top phase of fresh emulsions. In contrast, the emulsions stabilized by ZTP showed no sign of oil separation even after 30 days of storage. Actually, these emulsions immediately transformed from the liquid state to the solid state and exhibited arrested dynamics. This further contributed to the long-term stabilization action (Figure 5). Interestingly, it could be seen that the emulsion stabilized by ZTP with relatively low particle volume fractions (0.25−1.0 wt %/v) showed creaming and serum release, but significant increase of the serum in the bottom phase was not observed in the prolonged 30 days of storage, which had been observed in typical Pickering emulsion stabilized by zein/chitosan particles (ZCP).[23] Nevertheless, emulsions prepared with high particle fractions (1.0−1.5 wt %/v) exhibited homogeneous gels

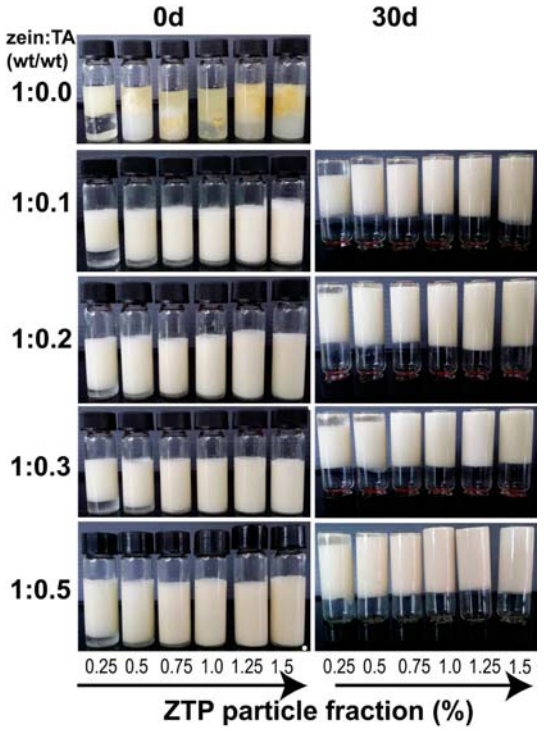

Figure 5. Visual observation of fresh emulsion gels prepared by ZTP with varied zein/TA ratios by different particle concentrations (0.25−1.5%, w/v) for fresh (0 days) and 30 days of storage. ZTP was prepared at pH 5.0.

without creaming and phase separation after 30 days of storage. These homogeneous emulsion gels are remarkable given the formation of protein continuous networks.

CLSM was used to characterize the microstructure of emulsions prepared with ZTP by different particle fractions, and the obtained images are shown in Figure 6. Droplets were rendered visible by the fluorescent protein particles (labeled in red) that covered the oil droplets (labeled in green). For the emulsions stabilized solely by zein particles, few protein molecules were absorbed around the oil droplets. In contrast, the interfacial protein network around the oil droplets was

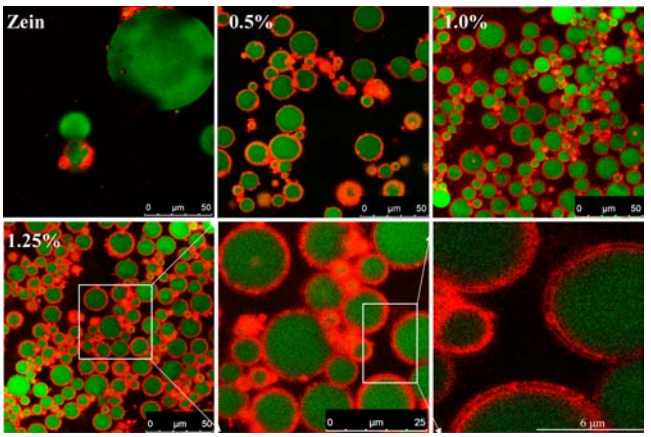

Figure 6. CLSM images of the emulsions stabilized by pure zein colloidal particles (1.5% w/v) and ZTP with different particles contents (0.5, 1.0, and 1.25% w/v). Protein was stained red and the oil phase, green. ZTP was prepared at pH 5.0 with a zein/TA ratio of 1:0.2.

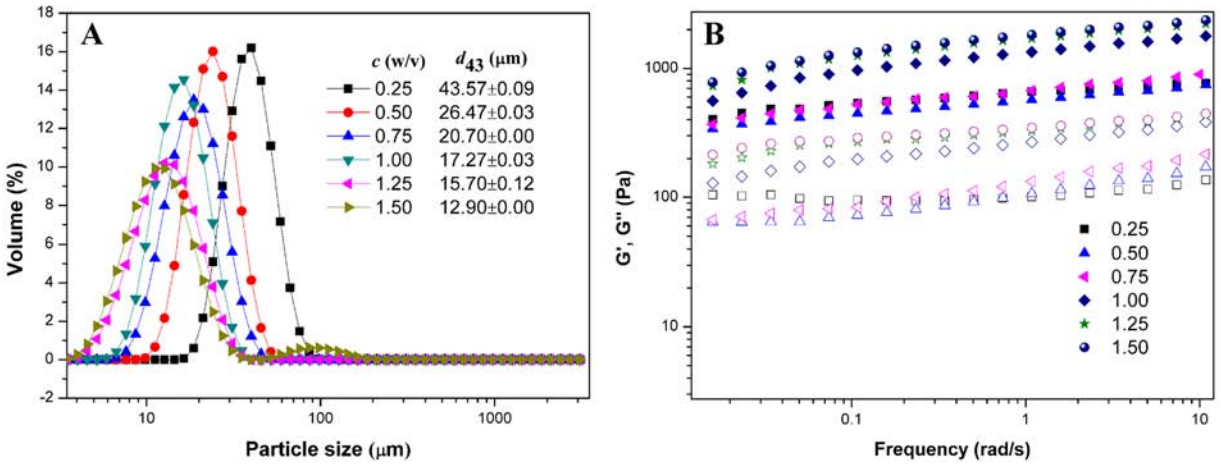

Figure 7. Droplet size distribution profiles (A) and rheological property (B) of Pickering emulsion gels prepared by ZTP with different particle fractions: storage moduli, G' (solid symbols) and loss moduli, G'' (open symbols). ZTP was prepared at pH 5.0 with a zein/TA ratio of 1:0.2.

found in the emulsions stabilized by ZTP, confirming the formation of an oil-in-water (O/W) Pickering emulsion. Furthermore, higher magnification confocal images clearly showed that the multilayer interfacial architecture was formed on the oil−water surface. These microstructures were typically hierarchical, which probably arose from the predominantly LbL assembly behavior of zein particles and TA.[24,35] We previously found that the ZCP could facilitate the formation of particle-based interfacial network architecture, and the ultrastable Pickering emulsions finally formed. However, to the best of our knowledge, this was the first observation of this ordered morphological signature on the oil−water interface, which implied a possibility to fabricate hierarchical interface microstructure via modulation of the noncovalent interaction between hydrophobic protein and natural polyphenol.

The droplet size distributions and the mean droplet diameter (d_{43}) for emulsions stabilized by ZTP were measured to assess the emulsifying ability and physical stability, which are shown in Figure 7A. The oil droplets in fresh emulsions prepared with ZTP had approximately uniform size with a very narrow peak in their distribution, which remained unchanged even after 30 days of storage, confirming their long-term storage stability against coalescence (data not shown). In addition, the mean droplet diameter (d_{43}) showed the particle fraction-dependent behavior. It decreased with increase of the ZTP fraction. This behavior was further supported by the CLSM observation (Figure 6). We believe these results can be attributed to the competition for surface space of oil droplets with more surface-active TA micelles. As a hydrolyzed tannin, TA is actually an amphiphilic polyphenol, which can self-assemble to form micelles when their concentration is above the CMC (about 10 mM for hydrolyzed tannins).[15,36] Accordingly, TA might form micelles with high ZTP fractions, resulting in interfacial particle displacement, and, consequently, decrease the size of oil droplets. Our previous findings showed that the amphiphilic stevioside (STE) micelles, competitively adsorbed on the oil−water interface with soy protein isolate (SPI), formed a mixed interfacial layer, resulting in a decrease in particle size and evident enhancement in the physical stability of SPI-based emulsions.[6] Moreover, the emulsion stabilized with zein alone showed oil release on the top phase, which was not suitable to evaluate the diameter, so we did not show its diameter.

There are two kinds of protein-based emulsion gels. One is emulsion-filled protein gel, in which oil droplets act as filler particles incorporated in the continuous protein network. The other is protein-stabilized emulsion gels or particulate gels in which protein molecules on the surface connect together and form a network. Both of these two types have totally different rheological behaviors.[37] We therefore investigated the rheological properties of the Pickering emulsion gels, which are presented in Figure 7B using frequency sweep tests. In all cases, the storage modulus (G') slightly but progressively increased with the increase of particle fractions, indicating their noncovalent "physical" cross-links in nature.[37] The increased intermolecular noncovalent cross-links among ZTP particles strengthened the gel network. The G' of emulsion gels with low particle fraction (0.25−0.75% w/v) showed less frequency dependence, which was the hallmark of particulate gels,[38] whereas the G' of the emulsion gels with high particle fraction (1.0−1.5% w/v) showed more frequency dependence. Hence, it can be concluded that the shift of gelling model from particulate gels to protein-based emulsion gels occurs with the increase of the colloidal particle loading, which involves cross-linking of the continuous phase. The enhanced reactivity of ZTP was due to the complexation of zein and TA, and it would be a key to explain the formation of Pickering emulsion gels. At high particle fractions, excess ZTP might trigger cross-links via hydrogen-bonded interaction and form a continuous network among and around the well-dispersed oil droplets (as active filler particles), leading to the formation of strong emulsion gels.

DISCUSSION

The novel colloidal structure, which is based on food-grade materials and formed via modulation of noncovalent interactions, has emerged with potential as a functional ingredient for the formulation and delivery of bioactive molecules or enhancement in the functionality of food biopolymers.[1,2] In this study the novel zein/TA complex colloidal particle (ZTP) based on the antisolvent approach and the hydrogen-bonding interaction between zein and TA was successfully generated. These complex colloidal particles with tuned wettability and enhanced interfacial reactivity can be utilized for the preparation of stable Pickering emulsions gels by one-step homogenization. To better understand the underlying mech-

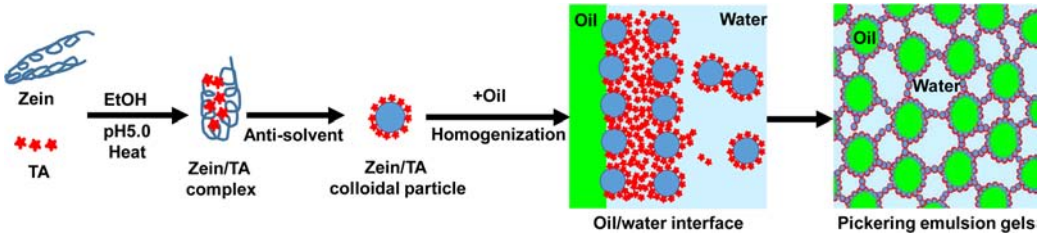

Figure 8. Schematic mechanism for the formation of the Pickering emulsions gels prepared with zein/TA complex colloidal particles.

anism of ZTP-stabilized Pickering emulsion gels, we propose a schematic illustration to explain the formation pathway of Pickering emulsion gels, shown in Figure 8.

The protonation and ionization of TA are both critical to understanding the colloidal behavior with protein,[11,24] which can be modulated efficiently via changing the pH and ionic strength of the solution. Furthermore, the colloidal state of TA affects the nature of their interaction with proteins,[15,39] especially for proline-rich proteins such as zein. Zein adopted an extended configuration in aqueous ethanol solution,[25,27] which exhibited a different tannin binding model compared with compacted protein in aqueous solution. TA in the neutral and partially protonated form at pH 5.0 with intermediate TA concentration facilitated strong hydrogen-bonding interactions between the hydroxyl groups on TA and the carbonyl moieties on the pyrrolidone rings of the proline-rich domain in zein. This specific interaction generated a conformational change of zein without altering their supramolecular structure (Figure 3; Table 2). The TA binding consequently affected the self-assembly behavior of zein during the antisolvent process, leading to the formation of zein colloidal particles that were coated or "wrapped" by TA (Figure 8). This complexation further suppressed the ionization of TA,[11] and it caused an increase in the hydroxyl group on the surface of zein particles at acidic pH (~3.48), thereby lessening their hydrophobic characteristics without decreasing surface charge (+51 mV) significantly (Table 1). The hydrogen-bonded zein/TA complex colloidal particle, evidenced by FTIR, with near-neutral wettability (Figure 2) and enhanced reactivity (due to the neutral TA coating), was capable of facilitating the multilayer interfacial architecture on the oil−water surface of the oil droplets (Figure 6), resulting in the formation of Pickering emulsion. In addition, the hydrogen-bonding interaction further triggered cross-links between the colloidal particles to form a continuous network among and around the oil droplets, leading to the formation of stable Pickering emulsion gels.

In conclusion, stable colloidal particles with near-neutral wettability and high interfacial reactivity, which is fabricated by modulating the noncovalent interactions between small molecules (TA) and macromolecules (zein), can be used as building blocks with reaction activity to form novel edible Pickering emulsion gels with orderly interfacial architecture. This study implies a possibility to fabricate hierarchical interface microstructure via modulation of the noncovalent interaction between hydrophobic protein and natural polyphenol.

ethanol, the reaction between cyanate and ethanol was studied as a model. Therefore, herein we describe the kinetic aspects of this reaction and use density functional theory (DFT) calculations to discuss potential mechanistic pathways.

MATERIALS AND METHODS

Reagents. The reagents and solvents used were of analytical or chromatographic grade and were purchased from Sigma-Aldrich (Steinheim, Germany), Mallinckrodt Baker (Paris, KY, USA), and Carlo Erba (Milano, Italy). The water used was previously distilled and then deionized using a Milli-Q system (Millipore, Bedford, MA, USA).

Reference Cachaça. One commercial, nonaged cachaça sample (200 L), which was provided and certified by a major producer, was used as a model (reference) solution during the experiments. Selected constituents were evaluated in terms of their initial concentrations in this matrix (Table S1, Supporting Information).

Ethyl Carbamate Analysis. The samples were analyzed using a gas chromatograph system equipped with a mass selective detector (GC-MS) using electron impact (70 eV) as an ionization source. The mass spectrometer was operated in selected ion monitoring (SIM) mode (m/z 62), and propyl carbamate was added as an internal standard.[10] The oven temperature program was as follows: 90 °C (2 min), followed by an increase to 150 °C at 10 °C/min (0 min) and then an increase to 230 °C at 40 °C/min (10 min). A HP-FFAP (50 m, 0.2 mm, 0.3 μm, Agilent Technologies, Santa Clara, CA, USA) capillary column was used in the EC separation. The inlet and detector interface temperatures were 250 and 230 °C, respectively. Sample aliquots of 1.0 μL were injected into the gas chromatograph system in the splitless mode.

Copper and Iron Ion Analysis. Copper and iron ions were determined using methodology described in the literature.[9] The analysis was performed using inductively coupled plasma atomic emission spectroscopy (Optima 3000 model dual view, PerkinElmer, Santa Clara, CA, USA). The calibration curves were constructed using an external standard method.

Photochemical Experiments. The irradiation of commercial cachaças and the aqueous ethanolic model solutions was performed in a photochemical bench (model 68805 Universal) equipped with a 200 W xenon lamp with interference filters (Oriel Instruments, Irvine, CA, USA). The intensity of the incident radiation was 1.3×10^{-7} einstein/min, which was calculated using a chemical actinometer (K_3[Fe(C_2O_4)$_3$], tris(oxalato)ferrate(III) of potassium, 0.2 mol/L), as previously described.[20]

Kinetic Experiments. Unless otherwise indicated, the kinetic experiments were carried out using a previously described cachaça model solution. During the kinetic studies, potassium cyanate was added to this solution, and the formation of EC was monitored. These analyses were performed as a function of the following parameters: alcoholic degree; pH; addition of salts of copper, iron, and EDTA; influence of light (photochemical irradiation bench); and temperature. In the experiments, the solution pH was controlled using an acetic acid/sodium acetate buffer system. Half-life ($t_{1/2}$) data were calculated from plots of ethyl carbamate concentration ([EC]) as a function of reaction time. $t_{1/2}$ was defined as the time corresponding to the formation of half of the maximum urethane concentration ($[EC]_\infty$).[21,22]

The experiments were carried out under pseudo-first-order conditions (excess of ethanol), and the rate constant k_{obs} (observed rate constant) was calculated from plots of $\ln([EC]_\infty - [EC]_t)$ versus time.[21,22] These plots were linear for at least 3 half-lives. To calculate the kinetic parameters, the temperature was controlled at ±0.2 °C using a thermostat, and the experiments were run at 15, 25, and 35 °C. The activation parameters ($\Delta G_1^{\ddagger}$, $\Delta H_1^{\ddagger}$, and $\Delta S_1^{\ddagger}$) were determined graphically.[21,22]

Preparation, Storage, and Analysis of Model Solutions Fortified with Potassium Cyanate. All cachaça model solutions were obtained using the reference cachaça (Table S1) and buffered using an acetic acid/sodium acetate buffer system. These solutions were spiked with a stock solution of potassium cyanate and stored in 28 mL glass bottles (vials), sealed with rubber septa and aluminum, and kept in the dark (wrapped in aluminum foil). During the kinetic experiments, the pH, the contents of copper(II) and iron(II), the alcoholic concentration of the cachaça, and the temperature (25 °C) were kept constant, except when the influences of these parameters were evaluated separately. During the experiments, aliquots of the cachaça model solution were collected with the aid of a glass syringe.

Decay of the Cyanate Ion. The cyanate concentration decay was monitored using two different procedures that have been described in the literature.[19,23] Both methods involve the reaction between cyanate ion and 2-aminobenzoic acid in the presence of HCl to form 2,4-(1*H*,3*H*)-quinazolinedione. The choice of method was based on the sensitivity required. One method uses the light absorption,[23] whereas the other uses the fluorescence[19] of the derivatization reaction product. The absorbance measurements were performed at 310 nm (ε = 412 L/mol cm) on a UV−visible spectrophotometer (model U-3501, Hitachi, Tokyo, Japan) with a 10 cm path length cylindrical quartz cell. The fluorescence measurements were carried out on a model F-4500 fluorescence spectrophotometer (Hitachi, Tokyo, Japan); 310 nm was used as the excitation wavelength, and the maximum emission was observed at 410 nm. The emission spectra were recorded over a range of 320−600 nm at a resolution of 240 nm/min using a 5 nm slit and a 1 cm quartz cell.

Cyanate Influence in the Formation of Ethyl Carbamate. Model solutions of cachaça (50 mL) were prepared at final cyanate ion concentrations of $(0.5-4.5) \times 10^{-5}$ mol/L. Subsequently, the influence of the OCN^- ion on the formation and evolution of EC levels was evaluated at 25 °C. On the basis of the analytical results (linearity, reproducibility, and repeatability)[24] obtained for the EC levels in these experiments, a concentration of approximately 2.1×10^{-5} mol/L of KOCN was selected for further experiments.

Influence of pH on the Ethyl Carbamate Formation. The pH measurements were carried out in an Ion Analyzer Radiometer Analytical model PHM250 (MeterLab, Villeurbanne, France). Model solutions of spirits (50 mL) were prepared with the following pH values: 3.0 ± 0.1, 3.9 ± 0.1, 5.3 ± 0.1, and 6.0 ± 0.1. The pH was decreased and increased with hydrochloric acid (1.0×10^{-2} mol/L) and sodium hydroxide (1.0×10^{-2} mol/L) solutions, respectively. These solutions were fortified with approximately 2.1×10^{-5} mol/L of KOCN, and their EC contents were subsequently analyzed at 25 °C.

Influence of Light in the Formation of Ethyl Carbamate. Cachaça model solutions (50 mL) were prepared with approximately 2.1×10^{-5} mol/L KOCN. One of these solutions was protected from light (wrapped in aluminum foil and kept in the dark), whereas the others were exposed to radiation in a photochemical bench with appropriate filters (250−500 nm). Subsequently, these solutions were analyzed for their EC contents at 25 °C.

Influence of Alcohol Content in the Formation of Ethyl Carbamate. Two new standard solutions with alcohol levels of 13.3% v/v (2.3 mol/L ethanol) and 24.4% v/v (4.2 mol/L) were prepared by diluting the reference cachaça, which had an alcohol content of 48% v/v (8.2 mol/L ethanol), with distilled water. These solutions were fortified with approximately 2.1×10^{-5} mol/L KOCN and subsequently analyzed for EC content at 25 °C. Then, aqueous ethanolic solutions were prepared with different alcohol concentrations (1.70−91.5% v/v), fortified with 2.1×10^{-5} mol/L KOCN, and analyzed for their EC contents at 35 °C. The alcoholic strength was decreased and increased using deionized water and ethanol (99.5% v/v), respectively.

Molecular Energies and Structures Calculations. The reaction between cyanate and ethanol was modeled using ab initio DFT[25,26] calculations with a B3LYP[27] exchange correlation function. The all-electron 6-31+G(d,p)[28−30] basis set function was used to describe the electronic structures of the studied systems.

An isomeric equilibrium reaction (Scheme 1, path A) was considered for the corresponding acid species cyanic acid (HOCN) and isocyanic acid (HNCO). Both of these species can react with ethanol (EtOH) according to the mechanism (B, C) in Scheme 1, forming ethyl carbamate (EC). A hydrolysis reaction (D) was also considered.

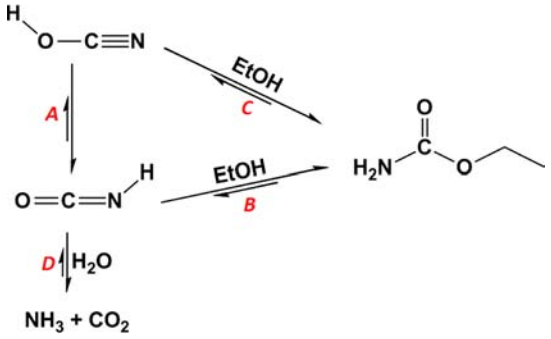
J. Agric. Food Chem. 2015, 63, 7415−7420

Scheme 1. Studied Reactions Using DFT/B3LYP Conformations: (A) Isocyanic to Cyanic Acid Isomerization; EC Formation through Isocyanic Acid (B) and Ethanol Reaction and Cyanic Acid (C) and Ethanol Reaction and Isocyanic Acid Hydrolysis (D) Yielding CO_2 and NH_3



The reaction pathway was proposed on the basis of the potential energy surface (PES) scanning[31] considering a free gas phase system, a solvated model with integral equation formalism to the polarization continuum model[32] (IEFPCM), and explicit solvent effects, with solvent molecule inclusion in the calculation matrix designed to maximize hydrogen bond stabilization. The PES stationary points were confirmed via a vibrational mode calculation.[31] The minimal energy structure does not show imaginary frequencies, and the saddle points were confirmed by a QST3[33] model, revealing a unique imaginary frequency with displacement that corresponds to the atoms shown in the pathway, also confirmed with an intrinsic reaction coordinate[34] (IRC) method.

RESULTS AND DISCUSSION

The addition of cyanate either to an aqueous ethanolic solution or to cachaça leads to the formation of EC. This phenomenon is clearly reproducible if a second addition of cyanate is carried out at the end of the reaction. As can be observed in Figure 1,

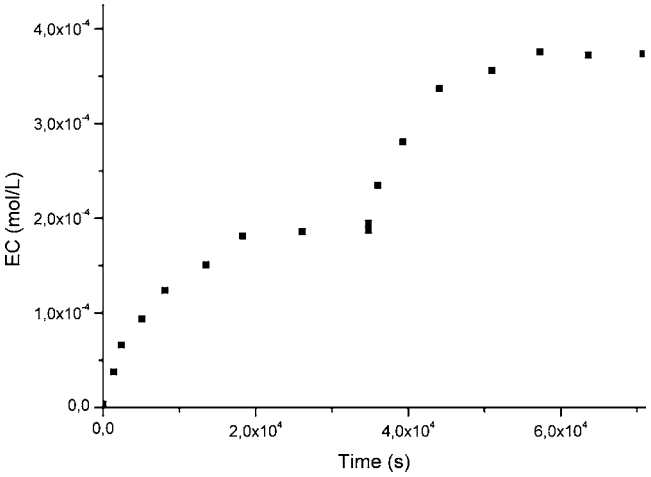


Figure 1. EC formation at 25 °C, as a function of the time in aqueous ethanolic solution (48% v/v, pH 4.5) after successive additions of 5.0 × 10^{-3} mol/L KOCN.

both plots of EC concentration versus time exhibit the same half-life values. However, no significant EC formation was observed when arginine, citrulline, or carbamyl phosphate, which are all possible EC precursors,[1] was added to the same solutions (at concentrations up to 5.0 × 10^{-3} mol/L) instead of cyanate (Figure S1). Only a very small amount of EC is formed as a consequence of the addition of urea or cyanide. This residual EC formation is <0.5% of the EC formed when an equal molar concentration of cyanate is added and was attributed to the presence of traces of cyanate in the urea and cyanide. As depicted in Figure 2, cyanate consumption, which was monitored using UV−vis or fluorescence spectrophotometry, occurs simultaneously with ethyl carbamate formation, which was observed via GC-MS.

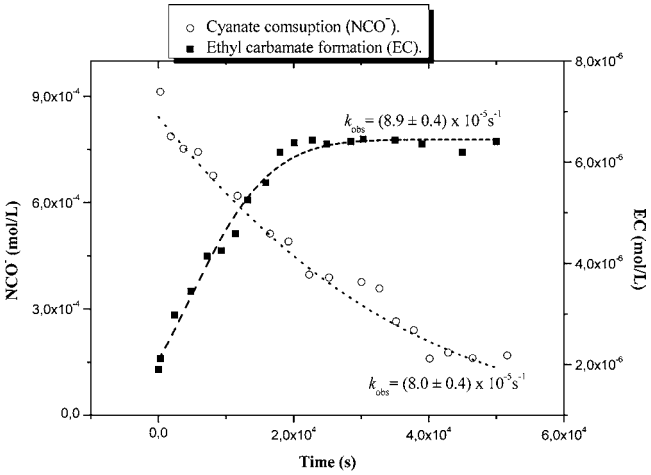

Figure 2. Consumption of the cyanate ion (○) and EC formation (■) as a function of the time in cachaças model solutions fortified with cyanate 4.1 × 10^{-4} mol/L KOCN (○) and 2.1 × 10^{-5} mol/L KOCN (■), at 25 °C and pH 4.5.

Tables 1 and 2 summarize the stoichiometry and kinetic data for the cyanate/ethanol reaction under a wide range of experimental conditions.

Table 1. Effect of Different KOCN Concentrations on Ethyl Carbamate Formation in the Cachaça Model Solution (48% v/v, pH 4.5 at 25 °C)

$[OCN^-]_{added}$ (mol/L)	$[EC]_{formed}$ (mol/L)	k_{obs} (s^{-1})	$t_{1/2}$ (s)
0.5 × 10^{-5}	0.2 × 10^{-5}	8.5 × 10^{-5}	8.4 × 10^3
0.8 × 10^{-5}	0.3 × 10^{-5}	9.3 × 10^{-5}	7.6 × 10^3
2.1 × 10^{-5}	0.6 × 10^{-5}	8.6 × 10^{-5}	8.1 × 10^3
4.5 × 10^{-5}	1.5 × 10^{-5}	9.1 × 10^{-5}	7.8 × 10^3

According to Table 1, the final EC content depends on the cyanate ion concentration that is added to the ethanolic solution (48%) and indicates that around 0.3 mol of EC is formed per mole of added cyanate (≈32%) when all other experimental parameters are kept constant. For whiskey, a "rule of thumb" proposed for use in distilleries is to calculate the potential of EC formation in the beverage as 32% of the total amount of EC precursors.[7] The hydrolysis of HNCO in water can occur in parallel with the formation of EC. Under comparable experimental conditions, this competitive reaction takes place 3.6 times (k_{obs} = 2.9 × 10^{-4} s^{-1} at 25 °C)[35] faster than EC formation, which may account for the above-mentioned EC yield with respect to the available cyanate.

According to Table 2, the EC yield increases as the ethanol concentration ([EtOH]) increases, reaching a maximum value of around 0.3 when [EtOH] is equal to 9.8 mol/L (57.5% v/v) and then remaining constant until [EtOH] = 15.7 mol/L (91.5% v/v). Furthermore, in our experiments, the ethyl

carbamate yield was not sensitive to the solution pH in the range of 3.0−6.0 (Table 2).

Neither the addition of 5.0×10^{-3} mol/L Cu(II), Fe(II), or EDTA nor the irradiation of the solution with 250−500 nm light (Table S2) leads to a noticeable change in the EC yield or the rate of ethyl carbamate formation.

Within the limits of experimental error, the rate constant values (k_{obs}) for cyanate ion decay $(8.0 \pm 0.4) \times 10^{-5}$ s^{-1} and EC formation $(8.9 \pm 0.4) \times 10^{-5}$ s^{-1} were in agreement with the corresponding values reported in the literature,[19,35] which were determined using different techniques and by monitoring cyanate concentration and formed product (EC) (Table 2 and Figure 2).

The observed rate constants are independent of ethanol concentration in the range from 2.9×10^{-2} to 15.7 mol/L but increase as the temperature increases (Table 2). In the pH range of 3.0−6.0, the rates decrease as the solution pH increases (Table 2). When the solution pH exceeds 7, the rate of EC formation was estimated to be $<10^{-7}$ s^{-1}, indicating the relevance of the protonated form of cyanate in this reaction.

The effect of temperature on EC formation was evaluated using kinetic data as a function of temperature (Table 2) to calculate the activation parameters as follows: $\Delta H_1^{\ddagger} = 19.4 \pm 1$ kcal/mol, $\Delta S_1^{\ddagger} = -12.1 \pm 1$ cal/K, and $\Delta G_1^{\ddagger} = 23.0 \pm 1$ kcal/mol.

EC is formed via a reaction between ethanol and cyanate. However, it is interesting to recall that under the experimental conditions described in Table 2, the rate of this reaction is independent of ethanol and cyanate concentrations and is equal to $(8.9 \pm 0.4) \times 10^{-5}$ s^{-1} at 25 °C. These observations would suggest a reaction in which an intermediate is formed, the concentration of which would be dependent on the presence in the medium of a protonated form of cyanate as the rate-determining step. Indeed, four isomers of cyanic acid are described: HNCO, HOCN, HONC, and HCNO. Isocyanic acid (HNCO, $pK_a = 3.7$) and cyanic acid (HOCN, $pK_a < 3.0$) are the most abundant and exist in a tautomeric equilibrium.[36−38] On the basis of infrared spectra of the vapor and liquid, it was inferred that the acid was primarily HNCO, containing <0.2% of HOCN. Furthermore, the formation of HNCO is favored as the temperature increases.[36] According to our DFT calculations, in water or ethanolic solutions, isocyanic acid is more stable than the corresponding HOCN isomer in terms of free energy (ΔG_{eq}) by 23.6 ± 2 kcal/mol. The isomerization barrier is $\Delta G_1^{\ddagger} = 24.9 \pm 1$ kcal/mol when the IEFPCM effect is considered and solvent molecules (three molecules of water or ethanol) are explicitly considered in the matrix.

Considering that the typical pH value found in cachaça is approximately 4.5, both HNCO and HOCN could be considered as potential active precursors for EC formation. However, HNCO is likely the most relevant precursor because of its abundance under the experimental conditions.[36]

EC formation was investigated using reaction modeling between ethanol and both isocyanic (Figure 3) and cyanic acids

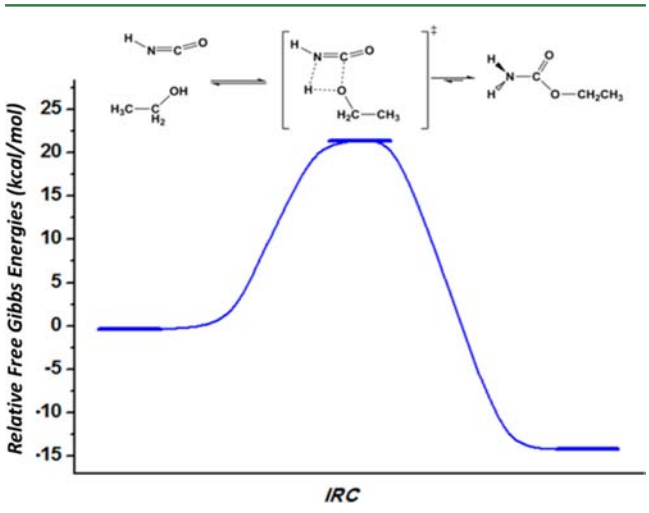

Figure 3. EC formation reaction pathway through isocyanic acid and ethanol: relative free Gibbs energies considering explicit solvent model (−).

(Figure 4). Considering the isocyanic acid pathway, the reaction is straightforward; the activation parameters $\Delta G_1^{\ddagger}$, $\Delta H_1^{\ddagger}$, and $\Delta S_1^{\ddagger}$ were calculated to be 21.5×10^{-3}, 14.6×10^{-3}, and -23.1×10^{-3} kcal/mol, respectively (Table 3), and the ΔG_{eq}, ΔH_{eq}, and ΔS_{eq} are thus -14.1×10^{-3}, 19.0×10^{-3}, and 16.9×10^{-3} kcal/mol, respectively.

When cyanic acid is considered as the active form, the mechanism appears to be more complex, as can be observed in the reaction sequence shown in Figure 4.

For this case, in the first step, one molecule of HOCN associates with one molecule of CH_3CH_2OH, and a proton is transferred from the oxygen atom of the ethanol to the nitrogen atom of HOCN.

In the next step, the proton bonded to the oxygen atom of the cyanic acid migrates to the nitrogen atom, yielding ethyl carbamate. The activation parameters $\Delta G_1^{\ddagger}$, $\Delta H_1^{\ddagger}$, and $\Delta S_1^{\ddagger}$ in this case are 41.8×10^{-3}, 34.4×10^{-3}, and 23.0×10^{-3} kcal/mol, respectively. From Table 3, the reaction between ethanol and isocyanic acid is more favorable than the reaction with cyanic acid by 20.3 kcal/mol. Furthermore, there is very good

agreement between the calculated reaction parameters of the isocyanic acid pathway and the experimental ones determined for EC formation (Table 3).

The formation of EC in freshly distilled sugar cane spirit is not sensitive to light irradiation (250-550 nm) or to the presence of copper and iron salts or EDTA. This reaction reaches completion in <10 days. However, distilled whiskey is reported to be sensitive to light irradiation, and the reaction has been shown to reach completion after 3−4 weeks.[7] Thus, it is unlikely that these differences could be satisfactorily explained on the basis of the experimental conditions (temperature and alcoholic degree) alone. These observations suggest that comparing the chemistry of these beverages is not as straightforward a process as might be initially assumed. Because cachaça and whiskey are produced using different raw materials (sugar cane vs malt and grains) processed in different ways, they are expected to present some differences in their final chemical compositions[39] and, therefore, in their respective carbamate precursor profiles. According to our experimental data, the active precursor in sugar cane spirit is likely cyanate. The presence of cyanate in the spirit can be explained as a consequence of the degradation of urea during the wine distillation process.[1] Urea can also be formed by arginine degradation during fermentation,[1] and cyanate could be transferred to the distillate as acid vapors of HOCN or HNCO. Because the reaction occurs between ethanol and cyanate, although this study was performed in cachaça and water−ethanol model solutions, the findings described here could be extended to other distillates and to ethanol production. Finally, EC can be reduced or eliminated in cachaça and whiskey by a simple redistillation.

acetylvulgarine, and echivulgarine *N*-oxide.[1,14] The full structural elucidation of echivulgarine, including its absolute configuration, is presented herein.

MATERIALS AND METHODS

General. The optical rotation was obtained using an Autopol II polarimeter (Rudolph Research Analytical, Hackettstown, NJ), while the CD spectrum was recorded on a Chirascan CD spectrometer (Applied Photophysics, Surrey, U.K.) using a 1 cm quartz cell. Nuclear magnetic resonance (NMR) spectra were recorded using a DirectDrive 600 NMR spectrometer equipped with a cryogenically cooled probe (Agilent Technologies, Santa Clara, CA) operating at 600, 150, and 60 MHz for ^{1}H, ^{13}C, and ^{15}N nuclei, respectively. Spectra were acquired using standard Agilent pulse sequences (^{1}H, s2pul; ^{13}C, s2pul; COSY, gCOSY; ^{1}H−^{13}C HSQC, HSQCAD; ^{1}H−^{13}C HMBC, gHMBCAD; ^{1}H−^{15}N HMBC, CIGARAD; two-dimensional NOESY, NOESY) and were internally referenced to the residual solvent peak ($CDCl_3$, 7.26 ppm for ^{1}H and 77.0 ppm for ^{13}C). HRESI-MS data were acquired using an Agilent Technologies 6530 Q-TOF instrument in positive and negative ion modes with MS/MS data generated using Ar as a collision gas using energies of 10−50 V. The relative ionization responses of various DHPA analytes were determined with an AB Sciex Triple Quad 6500 instrument (AB Sciex, Framingham, MA) operating in positive electrospray ionization MRM mode. Quantitative proton NMR (qNMR) using 1,4-dinitrobenzene as an internal standard was used to calibrate solutions of echivulgarine for use as reference material in quantitative LC−MS/MS analysis. When monitored by LC−MS/MS in MRM mode, associated *N*-oxides, including echivulgarine *N*-oxide, were detected (sum of impurity peak areas of <1%).

Pollen Material. Bee pollen granules (280 g), containing a high proportion of dark blue granules (estimated level of 50%), were obtained from Central Otago, New Zealand. The blue granules were presumed to originate from *E. vulgare*, which is a common plant found in this region.

Extraction and Isolation. The pollen was extracted with 30% methanol in 0.025 M sulfuric acid (2 × 850 mL) and filtered under vacuum. The acidic filtrate was washed twice by being shaken with hexane. Small aliquots of the acidic methanol (25 mL) were purified using 0.5 g Bond Elute Plexa PCX cation exchange cartridges (Agilent Technologies) based on the method of Boppré.[14] Ammoniated methanol eluates from multiple SPE cartridges were combined and concentrated under reduced pressure. Further purification was achieved via semipreparative HPLC using a 250 mm × 9.4 mm (inside diameter), 5 μm, Zorbax Eclipse XDB-C18 column (Agilent Technologies). Mobile phases were 0.1% formic acid in water (A) and 0.1% formic acid in 95% methanol (B), starting at 50% B with a gradient to 100% B from 8 to 12 min. The column flow rate was 3.0 mL/min. The fraction containing echivulgarine and its *N*-oxide was collected from 6 to 8 min. Fractions collected from multiple runs were combined and evaporated to dryness. These were chemically reduced to the tertiary base using indigo carmine redox resin.[16] Additional cleanup was achieved by dissolving the dry extract in 10 mL of dichloromethane and loading onto a 1 g silica SepPak cartridge (Waters Corp., Milford, MA). The cartridge was washed with dichloromethane (10 mL) and tertiary base alkaloids eluted with 25% methanol in chloroform (10 mL) to give echivulgarine (**2**) (11 mg).

Echivulgarine, ***2****.* White amorphous solid: $[\alpha]_D^{20}$ −75.5 (*c* 0.03, CH_2Cl_2); ^{1}H, ^{13}C, and ^{15}N ($CDCl_3$) (Table 1); HRESIMS *m*/*z* 480.2606 $[M + H]^+$ (calcd for $C_{25}H_{38}NO_8$, *m*/*z* 480.2592), *m*/*z* 502.2421 $[M + Na]^+$ (calcd for $C_{25}H_{37}NO_8Na$, *m*/*z* 502.2411); HRESIMS/MS *m*/*z* 322.1656 (calcd for $C_{17}H_{24}NO_5$, *m*/*z* 322.1649), *m*/*z* 220.1334 (calcd for $C_{13}H_{18}NO_2$, *m*/*z* 220.1338), *m*/*z* 120.0806 (calcd for $C_8H_{10}N$, *m*/*z* 120.0819), *m*/*z* 83.0490 (calcd for C_5H_7O, *m*/*z* 83.0497).

Computational Methods. A conformational analysis of all four possible diastereoisomers of echivulgarine (**2a**−**2d**) was performed with the Boltzmann jump method (SP4, 3000 steps, 300 K, 60° root-mean-square deviation) as implemented in the AMMP package with the Vega ZZ graphical frontend.[17] After duplicate structures had been removed, the obtained conformers were fully optimized using hybrid density functional theory (DFT) with Gaussian 09.[18] The 1996 hybrid functional of Perdew, Burke, and Ernzerhof[19−22] was employed for all calculations in combination with Alrichs' basis set, i.e., PBE0/def2-SVP, and Grimme's empirical D3 correction with Becke−Johnston damping (D3BJ).[23,24] Solvent effects were considered through the polarizable continuum model (PCM) in the integral equation formalism variant (IEFPCM)[25] with Cramer and Truhlar's SMD parameter set.[26] Dichloromethane was used as a solvent in all the calculations. All conformers were confirmed to be minima on the potential energy surface at the PBE0-D3BJ/def2-SVP/SMD_{CCl2H2} level through the calculation of harmonic force constants. NMR calculations were performed using the same level of theory. The DP4 statistical analysis[27] was employed to distinguish between different diastereomers. Theoretical electronic circular dichroism (ECD) spectra were calculated using time-dependent density functional theory (TDDFT) with the same level of theory (24 excited states).[28]

[a]At 150 MHz (^{13}C) or 60 MHz (^{15}N; indirect detection). [b]Operating at 600 MHz.

RESULTS AND DISCUSSION

A protonated molecular ion consistent with the empircal formula $C_{25}H_{38}NO_8$ was detected at *m*/*z* 480.2606 (calcd at *m*/*z* 480.2592) using an accurate mass ESI-Q-TOF-MS instrument. Confirmation of all the carbons and nitrogen was obtained via the ^{13}C and ^{15}N NMR spectra obtained from echivulgarine (Table 1). Of the 37 protons required by the molecular formula, 35 were attached to carbon (Figure 1), based upon the multiplicity-edited ^{1}H−^{13}C HSQC experiment, leaving two exchangeable protons.

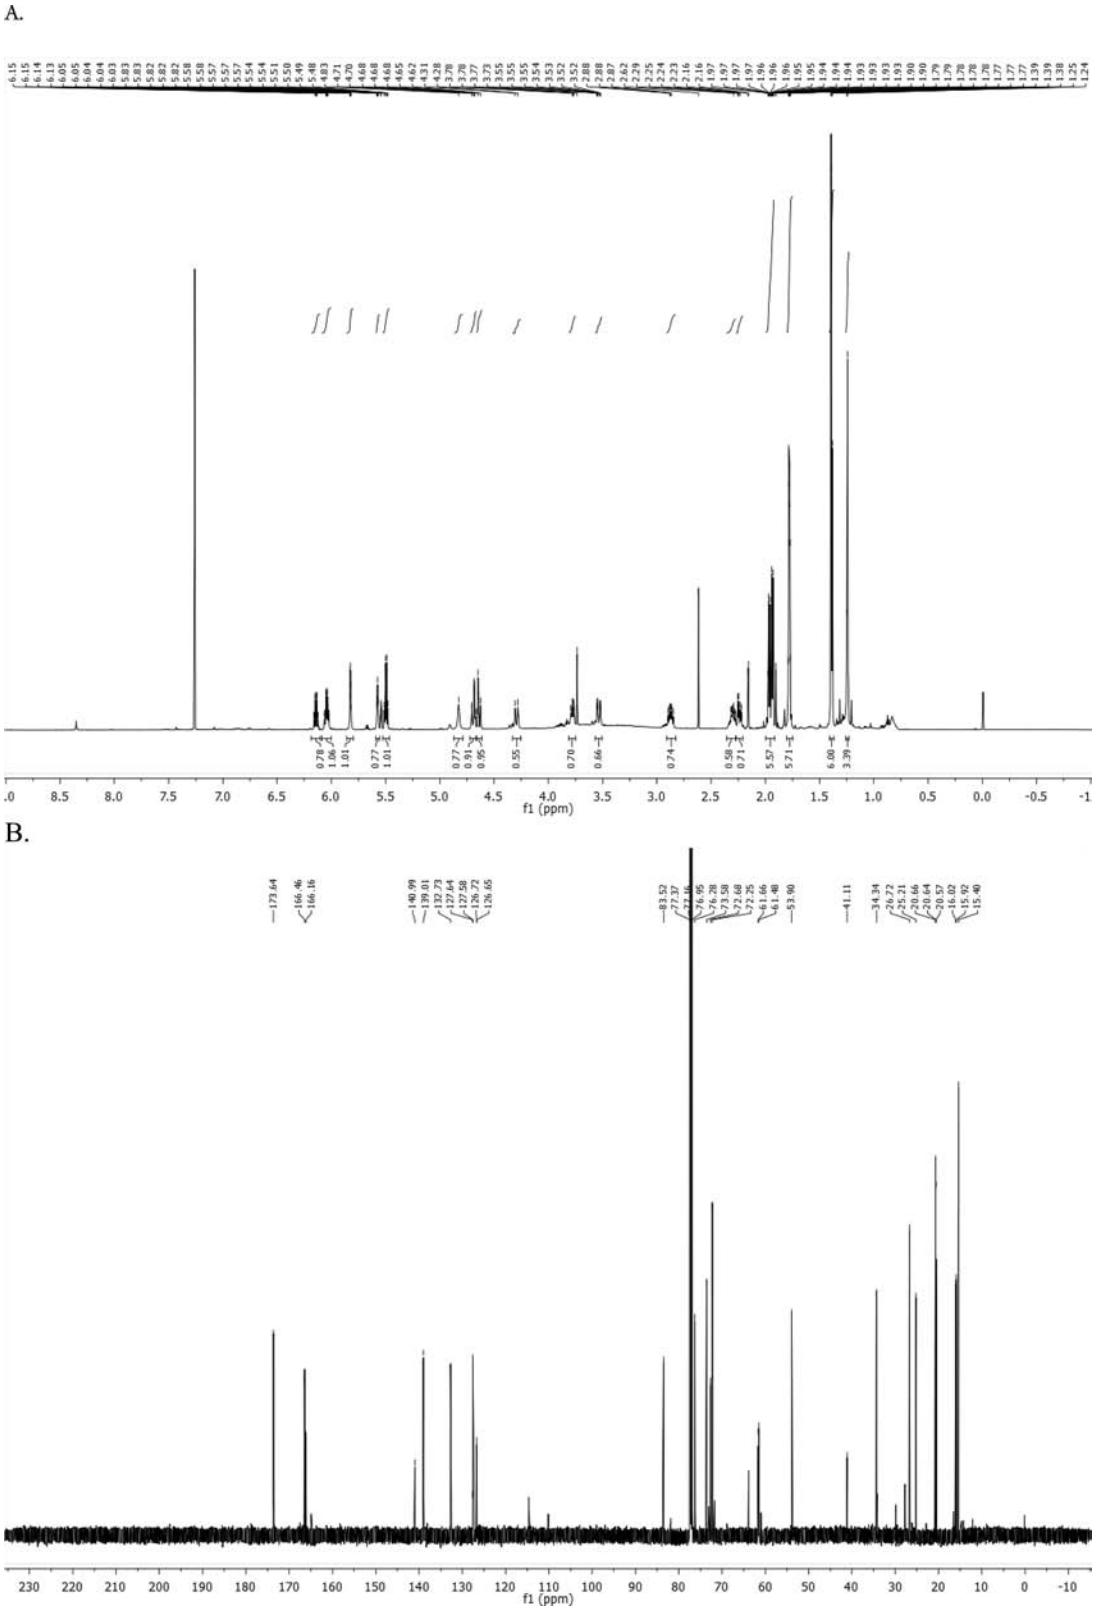

Figure 1. (A) ^{1}H (600 MHz) and (B) ^{13}C (150 MHz) NMR spectra of echivulgarine, **2** ($CDCl_3$).

The core necine base skeleton was rapidly established from a combination of $^{1}H-^{1}H$ COSY and both $^{1}H-^{13}C$ and $^{1}H-^{15}N$ HMBC spectra (Figure 2), in complete agreement with data compiled in reviews of the NMR data of DHPAs.[1,29] COSY and HMBC correlations were also used to establish the presence of one 5-hydroxytrachelanthyl and two angelyl fragments. Key HMBC correlations linked the various side-chain moieties to the necine base core. In particular, H-7 showed an HMBC correlation to C-1‴, while H_2-9 correlated with C-1′, as did quartet methine H-3′. A key and intense HMBC correlation was

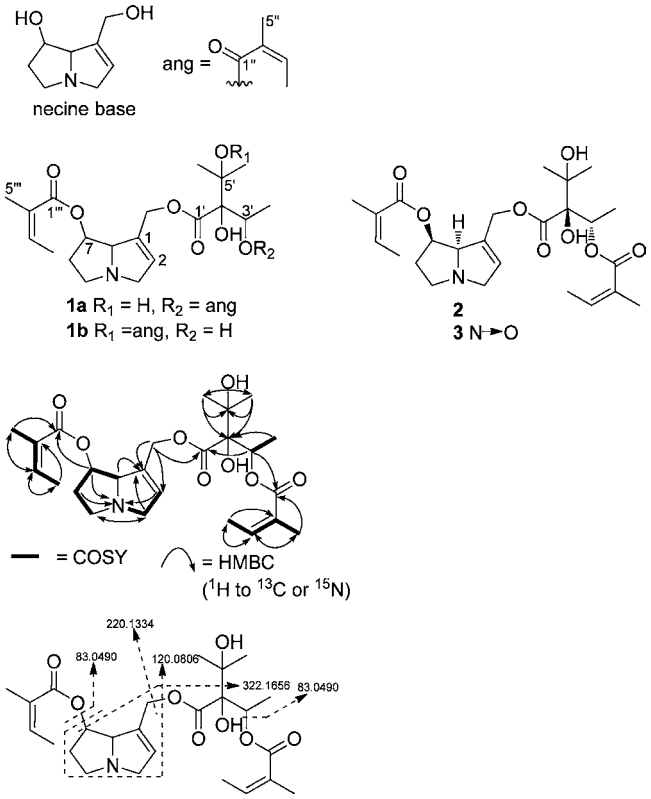

Figure 2. Key two-dimensional NMR correlations and MS/MS fragments confirming the planar structure of echivulgarine, **1a**.

observed between H-3′ and C-1″ of the second angelic acid group, finalizing the planar structure of echivulgarine as **1a** and thereby establishing the placement of this ester functionality that could not be determined during previous MS^n studies.[14] Finally, the planar structure of **1a** (Figure 2) established by NMR was corroborated by high-mass accuracy MS/MS experiments conducted with a Q-TOF instrument. As an ion trap mass spectrometer was not available, the fragments observed by Boppré could not be corroborated,[14,15] but those observed (Figure 2) were consistent with the structure proposed.

The final structural feature of echivulgarine to be established was the overall relative and absolute configurations of the molecule. Colegate et al.[30] have indicated that individual NMR measurements can be unreliable for the assignment of relative configuration within the family of DHPA diesters. Various researchers have obtained conflicting results when trying to use nuclear Overhauser effect (NOE) data alone to relate the configuration of C-7 and C-8, as well as configurations within the side-chain esters. Moreover, scalar couplings between mutually coupled protons can be unreliable for confirming relative configurations around five-membered rings. Chemical shift arguments can therefore be a useful guide for assisting in assigning the relative relationship between substituents at C-7 and C-8. Accordingly, the proton resonances noted for echivulgarine were all consistent with the trends noted[30] for a *syn* relationship between H-7 and H-8, although the signals for H_2-6 to H-8 resonate approximately 0.2 ppm downfield of those reported previously.[30] Such a *syn* relationship would result in the 7*R**, 8*R** relative configuration as previously assumed. This proposed relative configuration was supported by observation of multiple through-space interactions via a two-dimensional NOESY experiment (Figure 3). A key through-space NOE

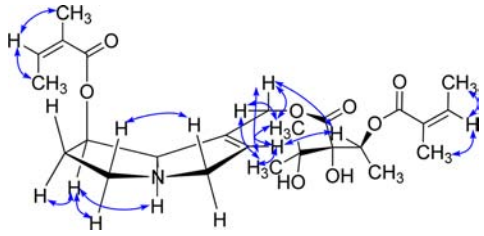

Figure 3. Key NOE correlations establishing the relative configuration of the necine base core of echivulgarine, **2**.

correlation was noted between H-7 and H-8, confirming the expected *cis* fusion of the two five-membered rings within the pyrrolizidine core. Fortuitously, this correlation was corroborated by the cofacial NOE correlations noted between both H-7 and H-8 and the deshielded resonances of methylenes H_2-5 and H_2-6, and also supported by correlations between the shielded proton resonances of methylenes H_2-3 and H_2-5 (Figure 3).

Unfortunately, significant issues for resolving the relative configurations at C-2′ and C-3′ of the 5-hydroxytrachelanthyl side chain precluded the establishment of their spatial relationship using NOE or coupling constant data. Furthermore, no clear trend in the ^1H or ^{13}C chemical shifts could differentiate among the four possible diastereomers of the side chain. We therefore undertook a detailed computational study to elucidate the relative configuration of the side chain, and the absolute configuration of the compound as a whole.

To get insight into the absolute configuration of echivulgarine, **2**, TDDFT ECD calculations were performed and the results compared with the experimental CD spectrum of the compound obtained in dichloromethane. For this purpose, all four possible side-chain diastereomers of **2**, i.e., 2′*R*,3′*R*-echivulgarine (**2a**), 2′*R*,3′*S*-echivulgarine (**2b**), 2′*S*,3′*R*-echivulgarine (**2c**), and 2′*S*,3′*S*-echivulgarine (**2d**), were taken into account. A conformational analysis was applied to each diastereomer using molecular mechanics. Then, after duplicates had been carefully removed, the energetically lowest-lying 40, 49, 48, and 49 conformers for **2a**−**2d**, respectively, were optimized using DFT at the PBE0-D3BJ/def2-SVP/SMD_{CCl2H2} level. The energies obtained at this level of theory were then used to determine their relative contributions (Boltzmann distribution at 298.15 K) to the solution phase mixture. The most strongly contributing conformers (accounting for >99.0%) were selected for ECD calculations. The resulting computed ECD spectra were summed and Boltzmann averaged using SpecDis[31] and compared with the experimental ECD spectra (Figures 4). By careful comparison, the best match of the calculated to the experimental CD spectrum was that of **2b**, with both exhibiting negative Cotton

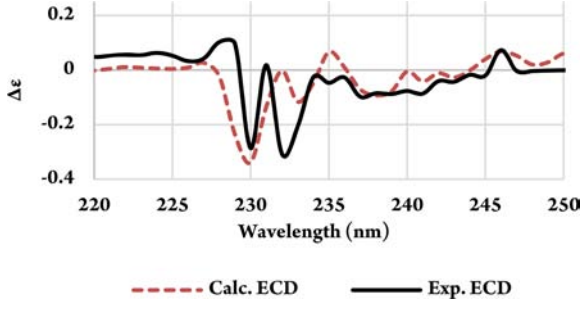

Figure 4. Comparison of the experimental (dichloromethane) and calculated ECD spectra of 2′*R*,3′*S*-echivulgarine, **2**.

effects at 230 nm. The lowest-energy conformer of **2b** (92.74% Boltzmann weight) is shown in Figure 5. This structure has a

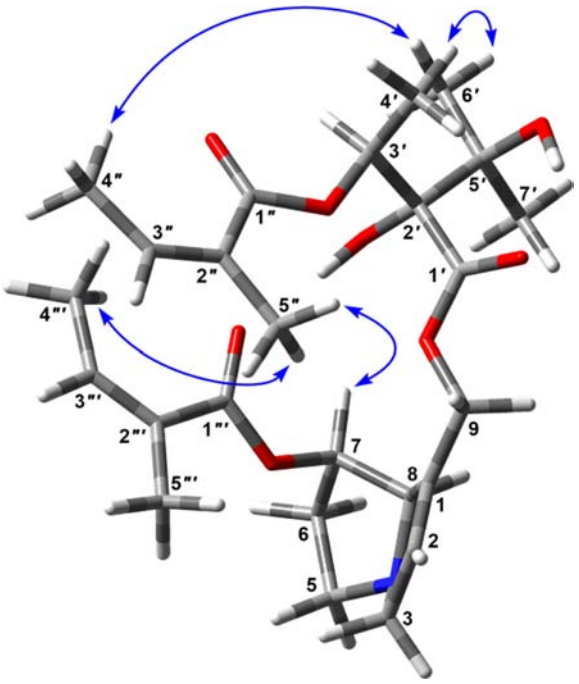

Figure 5. Lowest-energy conformer predicted for 7*R*,8*R*,2′*R*,3′*S*-echivulgarine, **2b**.

twisted geometry with an intramolecular hydrogen bond between the C-2′ hydroxyl group and the C-1‴ oxygen. This geometry is also supported by the key NOE correlations noted between H-4‴ and H-5″, H-7 and H-5″, and H-4‴ and H-6′, all of which were supportive of structure **2b**. Therefore, the absolute configuration of echivulgarine, **2**, was proposed to be 7*R*,8*R*,2′*R*,3′*S*, although this proposal would require further experiments such as X-ray crystallography or total synthesis to confirm this assignment.

To further verify the results, DP4 statistical analysis[27] was also applied to differentiate further among the different possible diastereomers of this highly flexible molecule. For this purpose, the previously selected conformers were subjected to NMR calculations at the PBE0-D3BJ/def2-SVP/SMD_{CCl2H2} level of theory. The Boltzmann-averaged NMR data of all calculated conformers and the experimental data were subjected to DP4 analysis, which also predicted the structure of **2b** to be the most probable candidate when both the ^{13}C and ^{1}H NMR data were used in the analysis. Overall, the combination of experimental and calculated NMR and ECD data all supported the same conclusion, an absolute configuration of 7*R*,8*R*,2′*R*,3′*S* for **2**. We also tentatively suggest that the structure of echivulgarine *N*-oxide, **3**,[14,15] be reassigned to reflect the complete planar and configurational assignments presented here for the parent tertiary amine, although such an inference would need to be confirmed by in-depth spectroscopic investigation of an authentic sample of this compound.

Given that different natural product congeners vary dramatically in ionization response (Table 2), and that this depends upon the type of mass spectrometer ion source, industry reliance upon mass spectrometric detection, identification and subsequent "quantitation" of newly discovered DHPAs may be risky. The toxic contributions of each DHPA to any food product would need to be assessed individually. Unfortunately, a paucity of material prevented the evaluation of the actual toxicity of **2** at this time.

In the future, a potentially better approach to the global assessment of total DHPA concentration within a foodstuff could be the use of quantitative NMR (qNMR).[32] In fact, the use of ^{1}H NMR spectroscopy as a possible tool for pyrrolizidine alkaloid quantitation in *Senecio* plant species was first applied in 1979.[33] Since then, recent advances in NMR technology, specifically higher-field-strength magnets and cryogenically cooled and/or capillary probes, have allowed for significant increases in spectral dispersion and sensitivity, making such an instrumental approach more useful. NMR has the benefit of not varying significantly in response to congener composition, and the dynamic range is insensitive to widely varying concentrations of the metabolite.[32] Several works by the Molinski group[34−36] have shown that complete structural elucidation of complex marine macrolides is possible with as little as 7 μg, equating to concentrations of <30 nM. As an extension of these studies, they have also developed a methodology for qNMR determinations using the ^{13}C satellites detected in coupled ^{1}H NMR spectra to quantitate metabolites in the range of 1−200 nM.[37] Moreover, qNMR has very recently been used to determine the concentrations of azaspiracids, potent dinoflagellate toxins, for subsequent determination of LC−MS/MS ion response factors.[38] Consequently, the integra-

tion of various conserved DHPA resonances within a ^{1}H NMR spectrum and relating those to the area of an internal standard resonance (or resonances) would give an unbiased view of overall DHPA concentration. The overall DHPA content would give a measure of potential toxicity far more reliable than that of LC−MS measures of compounds with widely varying response factors, especially when calculating concentrations for regulatory reasons. We are currently evaluating the use of qNMR in such a fashion as a viable alternative for measuring DHPA content.

addition to these, the other carotenoids that have been identified so far are phytoene, phytofluene, ζ-carotene, γ-carotene, and neurosporene.[12,18,19]

Even if the chromatographic behavior and the UV-vis absorption spectrum offer valuable clues for the identification of carotenoids, the MS detection has recently been combined with DAD to enhance identification power and sensitivity of their LC analysis in complex matrices.[20−27] Besides molecular weight, MS can provide molecular structure information, based on fragmentation patterns, to support the UV−vis identification of structural and geometrical isomers[11,28−30] as well as that of epoxidized forms.[31]

This work has aimed at developing an effective analytical approach, based on the HPLC-DAD-QqQ$_{LIT}$ hyphenation, to profile carotenoids occurring in five of the most known Italian tomato varieties: 'Tangerine', 'Pachino', 'Datterino', 'Camone', and 'San Marzano'. Six carotenoids, whose authentic standards are commercially available and moderately expensive, were used as model compounds to predict the behavior of carotenes and xanthophylls toward the chromatographic retention on a C_{30} stationary phase and the chemical ionization at atmospheric pressure. The product ion scan spectra (PIS) of these six compounds and the enhanced product ion (EPI) spectra of untargeted carotenoids, obtained by planning an adequate IDA experiment, allowed us to select MRM transitions useful (i) to support the LC-DAD identification of major carotenoids, (ii) to screen carotenoids occurring at low concentrations with high sensitivity, and (iii) to discriminate among structural isomers by using, for the first time, the ion ratio. Compared to the previous LC-DAD-MS methods,[11,28−31] the developed approach has made possible the acquisition of a large number of experimental data to realize a large-scale screening by using a minimum number of analytical standards; since the latter ones are very expensive and/or difficult to find, our approach also offers a considerable economical and practical advantage.

All data on the composition of the different varieties of tomatoes will be presented and discussed in this paper along with the results related to the method development.

EXPERIMENTAL SECTION

Chemicals and Materials. *all-trans-β*-Carotene, *all-trans*-lutein, *all-trans*-zeaxanthin, *all-trans-β*-cryptoxanthin, and *all-trans*-lycopene were provided by Aldrich-Fluka-Sigma Chemical (Milan, Italy). *all-trans-γ*-Carotene was acquired from CaroteNature GmbH (Ostermundigen, Switzerland). All standards had a purity grade ≥90% and were used without further purification.

Butylated hydroxytoluene (BHT), provided by Aldrich-Fluka-Sigma Chemical, was used as antioxidant both in standard solutions and during the several steps of extraction procedure. Acetonitrile and methanol were RS-Plus grade (special grade reagents); 2-propanol, hexane, and chloroform were RS grade (elevated purity grade); absolute ethanol was RPE grade (analytical grade). All of these solvents, potassium hydroxide (KOH), magnesium carbonate, and sodium sulfate were purchased from Carlo Erba (Milan, Italy). Distilled water, used in the extraction procedure based on the cold saponification, was further purified by passing it through a Milli-Q Plus apparatus (Millipore, Bedford, MA, USA).

Diatomaceous earth SPE-ED MATRIX 38 was purchased from Applied Separations (Allentown, PA, USA). Syringe-like polypropylene tubes (i.d. 26 mm, 75 mL capacity) and polyethylene frits were from Alltech (Deerfield, IL, USA).

Standard Solutions. After a stability study was performed over a period of 30 days, the individual stock solutions of the six carotenoids were prepared fortnightly by dissolving the weighed amounts (OHAUS DV215CD Discovery Semi-Micro and Analytical Balance 81 g/210 g capacity, 0.01 mg/0.1 mg readability) in chloroform containing 0.1% (w/v) BHT at the following concentrations:

- 1 μg/μL, for *all-trans-β*-carotene and *all-trans*-lycopene
- 0.5 μg/μL, for *all-trans*-lutein (sonicating for 6 min at 30 °C), *all-trans*-zeaxanthin, *all-trans-β*-cryptoxanthin
- 0.2 μg/μL for *all-trans-γ*-carotene

Working multistandard solutions were prepared from the individual stock solutions by diluting in methanol with 0.1% (w/v) BHT to obtain concentrations suitable for the several studies and experiments. When unused, all preparations were degassed with nitrogen and stored in amber glass flasks at −18 °C in the dark. Authentic standards were stored at −80 °C.

Tomato and Passata Samples. The five tomato varieties ('Tangerine', 'Pachino', 'Datterino', 'Camone', 'San Marzano') selected for this study were purchased from some supermarkets and green-groceries of Rome. The passata of 'San Marzano' tomatoes was homemade or bought from local grocery stores.

Tangerine tomato owes its orange color to the prevalence of *cis*-lycopenes that, in its GMO variants, accumulate prevalently as prolycopene; in this work, we have studied the wild type.[32] 'Pachino' is a protected geographical indication (GPI) variety, produced in a restricted area of Sicily; we have considered the cherry type, characterized by small, sweet, and bright red fruits. Also the 'Datterino' variety has small fruits, but they have an elongated form and a superior sweetness. The 'Camone' variety was introduced in the mid-1980s in the south of Sardinia; its fruits are red-green, crispy, and suitable for salads. Finally, the 'San Marzano' tomato is an Italian variety with protected designation of origin (PDO), and it is famous worldwide because its red pulpy fruits are particularly suitable for making passata. The passata preparation provides few fundamental steps: blanching of tomatoes in boiling water for 20 to 30 s, squeezing of the peeled fruits, sieving to separate the juice from the skins and flesh, bottling of the juice, and finally, sterilization at 95−100 °C.

Sample Treatment. A whole fruit was homogenized in an Ultra-Turrax homogenizer (Janke & Kunkle, Staufenim Breisgau, Germany), adding magnesium carbonate (in a ratio of 10:1, w/w) to neutralize the released organic acids and BHT (in a ratio of 10:0.1, w/w), in order to prevent isomerization and degradation of carotenoids. Tomato passata, ready to be used, was only spiked with BHT at the specified ratio.

Two different extraction procedures were used to exclude the potential formation of artifacts: overnight cold saponification and matrix solid phase dispersion (MSPD). In both procedures, the analytes were shielded from UV light by using low actinic glass tubes and plastic tubes wrapped with aluminum foil; for the same reason, all operations were performed in subdued light. Protection from oxygen was ensured by the addition of BHT to the solvents (0.1% (w/v)).

Overnight Cold Saponification. A 4 g aliquot of homogenized tomato was transferred into a 50 mL polypropylene centrifuge tube with a screw-cap (falcon). Six milliliters of absolute ethanol containing BHT and 1 mL of 50% (w/v) aqueous KOH were poured into the centrifuge tube. After flushing with oxygen-free nitrogen, the falcon was promptly closed and placed in a water bath kept at 25 °C, under magnetic stirring overnight (15 h).

At the end of the incubation period, the digest was diluted with 3 mL of Milli-Q water and the analytes were extracted with 4 mL of hexane with 0.1% (w/v) BHT. The extraction was repeated six times. After the addition of each aliquot, the mixture was stirred for 5 min, vortexed for 5 min, and then, centrifuged at 6000 rpm for 10 min to facilitate the separation of the insoluble residue, aqueous phase, and organic phase. Afterward, the combined hexane layers were washed with 8 mL portions of Milli-Q water; two washings were enough to remove alkalis completely (no color was observed on phenolphthalein addition). At this point, the extract was collected into a glass tube with conical bottom (i.d. 2 cm), evaporated up to 100 μL in a water bath kept at 30 °C under a slow nitrogen flow, and diluted to a final volume of 200 μL with 2-propanol:hexane (75:25, v/v) solution containing 0.1% (w/v) BHT. Eventually, after sonication for 10 min at 25 °C, 40 μL was injected into the HPLC-DAD-QqQ$_{LIT}$ system.

J. Agric. Food Chem. 2015, 63, 7428−7439

Matrix Solid Phase Dispersion. Owing to the high water content of tomato fruit and passata, MSPD was performed by using diatomaceous earth, as a dispersing medium, in combination with sodium sulfate, a highly hygroscopic salt.

For each experiment, 4 g of sample, 6 g of diatomaceous earth, and 2 g of Na_2SO_4 were placed into a ceramic mortar and pounded with a pestle until the achievement of an evenly colored powder. At this point, the extraction cartridge was prepared by filling large-diameter syringe-like polypropylene tubes with a layer of C_{18} sorbent (0.4 g) and a layer of the solid mixture, in this order. Polyethylene frits were placed below and above the chromatographic bed.

The analytes were eluted with 15 mL of methanol, 5 mL of 2-propanol, and 20 mL of hexane, with the aid of vacuum. The eluates were collected into a 50 mL falcon and centrifuged at 6000 rpm for 10 min. The supernatant was poured out into a glass tube with conical bottom (i.d. 2 cm) and evaporated up to 200 μL in a water bath kept at 25 °C under a gentle flow of nitrogen. The extract was then sonicated for 2 min, transferred into an Eppendorf tube, and centrifuged (Centric150, Tehtnica, Slovenia) at 4000 rpm for 5 min. Forty microliters was injected into the chromatographic column for the HPLC-DAD-QqQ$_{LIT}$ analysis.

Instrumentation. *Liquid Chromatography.* Liquid chromatography was performed by means of a micro HPLC series 200 (PerkinElmer, Norwalk, CT, USA) equipped with an autosampler, a vacuum degasser, and a column oven.

The analytes were separated on a ProntoSIL C30 column (4.6 mm i.d. × 250 mm, 3 μm particle size) from Bischoff Chromatography (Leonberg Germany) protected by a guard column of the same type (4.0 × 10 mm, 5 μm) under nonaqueous reversed-phase (NARP) conditions and with the column kept at 19 °C. In separating carotenoids, phase A was methanol and phase B a mixture 2-propanol/hexane 50:50 v/v. The elution profile was as follows: after the first minute in isocratic mode at 100% of eluent A, phase B was linearly increased from 0% to 50% in 20 min and then from 50% to 99.5% in 0.1 min; finally, phase B was maintained at 99.5% for 10 min. Flow rate of the mobile phase was 1 mL/min, and it was entirely introduced into the DAD-MS detection system. Phase B was also used to wash the autosampler injection device.

Diode Array Detection. Carotenoids were identified by a series 200 model (PerkinElmer) diode array detector, equipped with a flow Z cell (12 μL volume; optical path of 10 mm), coupled online between the chromatographic column and the mass spectrometer. The LC-DAD chromatograms were acquired by selecting the 450 nm wavelength (λ_{max} of *all-trans-β*-carotene, *all-trans*-zeaxanthin, and *all-trans-β*-cryptoxanthin) and a bandwidth of 10 nm. The UV−vis spectra were recorded in the range of 200−700 nm. The software packages used for running the instrument and acquiring spectral data were Totalchrom Navigator 6.3.1 and Iris (PerkinElmer) respectively.

Mass Spectrometry. The analytes were also identified by means of a 4000 Qtrap (AB SCIEX, Foster City, CA, USA) mass spectrometer. Detection was performed in positive ionization, placing the APCI probe in the Turbo V source and setting a needle current (NC) of 3 μA and a probe temperature of 450 °C. High-purity nitrogen was used as curtain (40 psi) and collision gas (4 mTorr), whereas air was used as nebulizer (55 psi) and makeup gas (30 psi).

A preliminary mass axis calibration of each quadrupole mass-analyzer, Q_1 and Q_3, was carried out by infusion of a polypropylene glycol solution at 10 μL/min. Unit mass resolution was established and kept in the each mass-resolving quadrupole by maintaining a full width at half-maximum (fwhm) of approximately 0.7 ± 0.1 u.

The APCI-Q1-full scan spectrum and the PIS spectra of *all-trans*-lutein, *all-trans*-zeaxanthin, *all-trans-β*-cryptoxanthin, *all-trans-β*-carotene, *all-trans-γ*-carotene, and *all-trans*-lycopene were acquired by working in flow injection analysis (1−10 ng injected; 1 mL/min of flow rate).

Structural information on untargeted carotenoids in the real samples was obtained by acquiring an IDA scan cycle, including an enhanced-mass scan (EMS) as the survey scan, an enhanced-resolution (ER) scan to obtain high resolution m/z values for the precursor ions of interest, and dependent EPI scan. With the threshold of the ion intensity at 10000 counts per second (cps), the IDA criteria were set to allow the most abundant ions in the EMS to trigger EPI scans. The EMS scan was carried out from m/z 500 to m/z 610 at 100 ms of dwell time. The EPI scan was in the range m/z 100−610, scanned at 4000 Da/s, under a collision energy (CE) of 60 eV with a CE spread of 20 eV (60 ± 20 eV).

A sensitive LC-DAD-MRM screening of carotenoids in real samples was performed selecting two MRM transitions per carotenoid on the basis of the fragmentation spectra previously acquired; when such fragmentation spectra were not available, two theoretical MRM transitions were "guessed" by using ChemBioDraw Ultra 12.0.

The software used for running the instrument and acquiring LC-MS data was Analyst 1.5.1 (AB Sciex).

RESULTS AND DISCUSSION

Selection of Nonaqueous Reversed-Phase Chromatographic Conditions as a Compromise between Requirements of Separation and MS Detection. The NARP chromatography has often been used for the separation of carotenoids and fat-soluble vitamins.[30,33] This technique makes use of C_{18} or C_{30} columns and of poorly polar mobile phases. The triacontyl stationary phase is superior to the octadecyl one for shape selectivity, which significantly improves at subambient temperature. A typical nonaqueous mobile phase consists of a polar solvent (for instance, acetonitrile or methanol) and a solvent of lower polarity (for example, dichloromethane) to solubilize the analytes and to adjust the eluting strength of the mobile phase. It is well-known that the APCI ionization process uses the mobile-phase vapor as reactant gas in addition to the nebulizer gas and makeup gas; nevertheless, the composition of a nonaqueous mobile phase is, in general, not completely suitable to support APCI ionization. For this reason, our chromatographic conditions were selected as a compromise between requirements of separation and MS detection. The six model compounds were used to refine the separative conditions which included the use of

- a C_{30} analytical column, kept at 19 °C to enhance shape selectivity and efficiently solve structural and geometrical isomers
- methanol and a mixture 2-propanol:hexane (50:50, v/v) as mobile phase. Hexane is not involved in the acid−base reactions during APCI ionization, but it was indispensable to reduce the retention time of carotenes (especially lycopene) and to avoid peak broadening phenomena due to longitudinal diffusion. Both alcohols participate in the acid−base reactions; in particular, in order to assist the ionization of the analytes with high capacity factors, a percentage of 0.5% methanol was maintained in the final part of the chromatographic run.

The chromatographic selectivity was adjusted by modulating the polarity difference between stationary phase and mobile phase: the smaller was the difference, the higher was the selectivity. Selecting this mobile phase we have achieved good results in terms of resolution.

Identification Criteria of Carotenoids by HPLC-DAD-QqQ$_{LIT}$. The model compounds were also used to study their APCI ionization and fragmentation, and to forecast the chromatographic retention of untargeted carotenoids on the triacontyl-bonded stationary phase. Table 1 shows the parameters applied for their identification in tomato and passata samples (retention time, two MRM transitions for each analyte, ion ratio).

Expected Retention Time. The expected retention time is an important parameter to support the UV−vis/MS identification of a specific carotenoid. In this work, it has been deduced both on

[a]Standard deviation. [b]The ion ratio was calculated as follows: I_r = (intensity$_{(\text{MRM on the first line})}$/intensity$_{(\text{MRM on the second line})}$. [c]Declustering potential. [d]Collision energy.

the basis of the chromatographic behavior of the six model compounds under the NARP conditions, described in the Liquid Chromatography section, and on the basis on data from the literature.[33] The following elution patterns have been considered for the prediction of retention times:

(i) The increase of molecular weight or the conjugation extension corresponds to longer retention time.

(ii) The retention time decreases as the number of hydroxyl and/or epoxy groups increases, because the increase of polarity prevails over the corresponding increase of the chromophore length; therefore, among β,β-type carotenoids, zeaxanthin elutes before β-cryptoxanthin, which, in turn, elutes before β-carotene. This behavior has allowed us to simplify the carotenoid identification, subdividing each LC-DAD-MS chromatogram into three regions: the first one including xanthophylls with two and more than two polar groups (t_r up to 12 min); the second one comprising xanthophylls with only one polar group (t_r between ∼12 and 15 min); finally, the third one encompassing carotenes (t_r between ∼15 and 26 min). Within each of these ranges, further considerations can be made to postulate the retention times. For example:
- Comparing the chromatographic behavior of the pairs lutein/zeaxanthin and α-carotene/β-carotene (mixed carotenes from carrots; purchased Aldrich-Fluka-Sigma Chemical, Milan, Italy), it can be deduced that β,ε-carotenoids have a lower retention time than β,β-carotenoids.
- A bicyclic carotenoid elutes before a monocyclic carotenoid that, in turn, elutes before an acyclic carotenoid; for example, β-carotene (bicyclic β,β) elutes before the γ-carotene (β,ψ-carotene), which in turn elutes before lycopene (ψ,ψ-carotene).

(iii) The molecule shape can affect the retention of carotenoids, sometimes representing an exception to the rule in the point (i). For example:
- 5,8-Epoxycarotenoids (mutatoxanthin) elute later than the 5,6-epoxycarotenoids (antheraxanthin, taraxanthin), although 5,8-epoxycarotenoids have a shorter chromophore. This happens because the 5,8-epoxide group affects the molecule shape and exerts a deep interaction with the stationary phase despite of the less extensive conjugation length.[33]
- A *cis* double bond affects the elution order of equal length chromophores, depending on its location in the system of conjugated double bonds.[33] The 15-*cis*-isomers are the least retained because their molecules are more twisted than the 13-*cis*- and 13,9-di-*cis* isomers. On the other hand, carotenoids with peripheral *cis* double bonds (9-*cis*- and 9,9′-di-*cis*-isomers for bicyclic carotenoids; 5-*cis*-isomers for monocyclic and acyclic carotenoids) are more retained than the *all-trans* isomers which, thus, elute between the next-to-central and the peripheral geometrical isomers.

MS Identification Criteria. On the basis of what was observed in this work and described in previous papers[20,34] and reviews,[30,35,36] it can be stated that both carotenes and xanthophylls show $[M + H]^+$ as base peak on APCI(+)-full scan mass spectra. For *all-trans*-β-carotene, *all-trans*-γ-carotene, and *all-trans*-lycopene, such an ion is observed at m/z 537; when

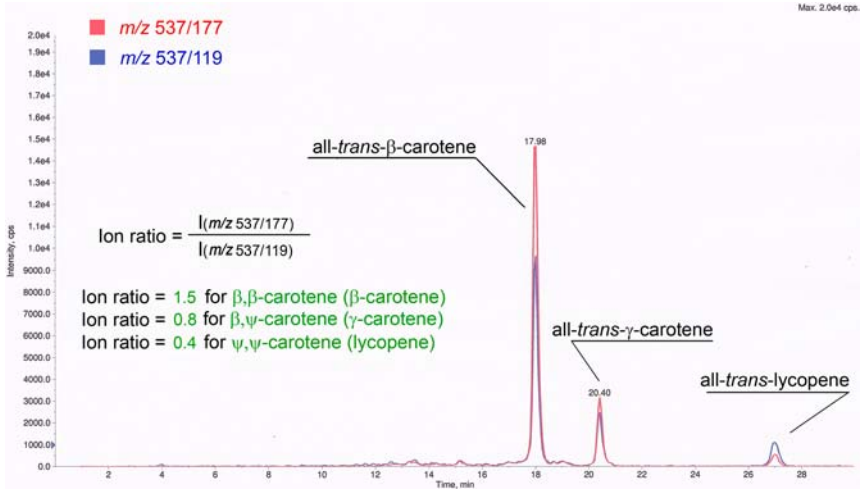

Figure 1. Relative abundance of two MRM transitions, shared by isomeric carotenes, is an effective parameter to distinguish and identify *all-trans*-β-carotene, *all-trans*-γ-carotene, *all-trans*-lycopene, and the related families of geometrical isomers in real samples (see also Figure 4).

DOI: 10.1021/acs.jafc.5b02910
J. Agric. Food Chem. 2015, 63, 7428−7439

selected as precursor ion in MS/MS experiments, it exhibits a similar fragmentation pattern with two series of fragment ions: the first series is originated from breaking the double bonds (C7−C8, C9−C10, C11−C12, C13−C14, and C15−C15′) and generates intense product ions at m/z 137 and m/z 177; the second series is due to the cleavage of single bonds (C6−C7, C10−C11, C12−C13, and C14−C15) and produces an abundant ion at m/z 119. The main distinctions between the PIS spectra of these three structural isomers consist of the different intensities of the common fragment ions.

Besides $[M + H]^+$, xanthophylls also show the dehydrated ion $[MH - H_2O]^+$. Zeaxanthin and β-cryptoxanthin are β,β-carotenols and exhibit $[M + H]^+$ as base peak, while lutein is a β,ε-carotenol and has $[MH - H_2O]^+$ as base peak. In general, all carotenols with a hydroxyl group in an allylic position (for example lutein and α-cryptoxanthin) lose a water molecule, producing an intense fragment ion which is stabilized by mesomeric effects.[35] We have exploited this behavior to distinguish isomeric xanthophylls from each other such as lutein from zeaxanthin or lutein epoxide from antheraxanthin. Product ions common to all xanthophylls are the fragments at m/z 135 and m/z 175, corresponding to a dehydrated terminal ring with cleavage at the C7−C8 bond and the C9−C10 bond, respectively: these ions can be considered diagnostic for this carotenoid class. Like β-carotene, γ-carotene, and lycopene, also lutein and zeaxanthin are structural isomers which share similar fragmentation pattern; nevertheless, unlike carotenes, lutein exhibits two exclusive fragment ions at m/z 495 and m/z 430.[37] However, their intensity is too low to detect lutein (and to distinguish it from zeaxanthin) at the concentrations naturally occurring in tomato samples. To this end, the abundant ion at m/z 119 is more useful despite its lower specificity.

Relying on the PIS spectra, we have selected the two most intense MRM transitions to identify each model compound as well as their isomeric unknowns (sharing the same ion currents). Although there is no unique fragment to differentiate carotenes that are structural isomers, we have found a simple but efficacious solution to this problem: the relative abundance between the two MRM transitions, shared *all-trans*-β-carotene, *all-trans*-γ-carotene, and *all-trans*-lycopene, provides a characteristic ion ratio (see Table 1 and Figure 1) which we have used successfully to distinguish the three carotenes and their families of geometrical isomers in the real samples (see the paragraph entitled Characterization of the Carotenoid Fraction of Some Italian Varieties of Tomatoes).

For carotenoids that are not isomers of the six model compounds, the MRM transitions have been deduced from the EPI spectra acquired by the IDA experiments. When the sensitivity of the IDA analysis was poor, theoretical MRM transitions were inferred by using the Fragmentation Tools, provided by the software ChemBioDraw 12.0.

In general, the MRM scan mode is particularly effective in the identification of low-abundance compounds. Moreover, the partial specificity of MRM ion currents of isomeric carotenoids is advantageous because it allows their screening without having the availability of all the authentic standards, but on the condition that their chromatographic separation is guaranteed. To this aim, we used the model compounds also to verify the complete chromatographic separation of the isomeric groups lycopene/γ-carotene/β-carotene and lutein/zeaxanthin. A good resolution was achieved as a result of the chromatographic selectivity related to the small polarity difference between nonaqueous reversed mobile phase and C_{30} stationary phase.

In this work, the UV−vis data have been correlated with the MS data, considering that the retention times on the LC-MS chromatogram are about 0.8 min later compared to those on the corresponding LC-DAD chromatogram.

UV−Vis Identification Criteria. Carotenoids are characterized by a strong absorption in the UV−vis region of electromagnetic spectrum due to the extensive conjugated double-bond system. The majority of these compounds exhibit a three-peak spectrum[5,7] whose fine structure and absorption maxima allow the chromophore identification. In this work, the experimental UV−vis data have been compared to both the literature data and theoretical data. The latter has been obtained by applying the Fieser rules,[38] which allows foreseeing the wavelength of the central peak (λ_{II} or λ_{max}) on the basis of the hypothesized structure:

$$\lambda_{max} = 114 + 5M + n(48 - 1.7n) - 16.5R_{endo} - 10R_{exo}$$
for carotenes (1)

$$\lambda_{max} = 114 + 5M + n(55.5 - 2.1n) - 16.5R_{endo}$$
for carotenals and carotenic acids (2)

$$\lambda_{max} = 118 + 5M + n(48 - 1.7n) - 23R_{endo}$$
for epoxycarotenoids (3)

where n = number of conjugated double bonds; M = number of alkyl or alkyl-like substituents on the conjugated system; R_{endo} = number of rings with endocyclic double bonds in the conjugated system; R_{exo} = number of rings with exocyclic double bonds.

Such rules are valid only if the polyene moiety contain more than 4 conjugated double bonds.

In all cases, the degree of fine structure has been expressed as the percentage ratio between the heights of the peaks II and III, measured from baseline (i.e., % III/II).

The identification of a *cis* isomer[5] has relied on the comparison between its absorption spectrum and that of the corresponding *all-trans* isomer. The following differences have been evaluated: (i) a decrease of % III/II; (ii) a hypochromic effect; (iii) a hypsochromic shift of about 2−6 nm for mono-*cis* isomers, 10 nm for di-*cis* isomers, and 50 nm for poli-*cis* isomers; (iv) the appearance of a *cis*-peak (peak B) in the UV region. Since the height of the *cis*-peak increases as the *cis*-double bond becomes closer and closer at the center of the conjugated system, the *Q*-ratio has been used as parameter to establish the position of such a bond.[7] This parameter has been calculated as the ratio between the heights of the peaks II and B, measured from the baseline of spectrum; in the literature, it is sometimes calculated also as (B/II).

Extraction of Carotenoids from Tomato Fruits and Passata. In this work, the extraction of carotenoids from the real samples has been achieved by applying two different extraction methodologies: (a) cold saponification and (b) MSPD. The definitive conditions were established after optimizing several parameters including sample amount, type of extractants, and volume of extractants.

In general, hot saponification is one of the most used procedures to extract carotenoids from foods because it allows the effective removal of lipids and chlorophylls. In alkaline media, carotenoids are quite stable, but isomerization and degradation can occur to an extent depending on the applied conditions, especially for xanthophylls.[39] To avoid these processes, we applied milder conditions by digesting the real samples overnight

[a] λ_{max} was calculated by using the Fieser rules as explained in the UV−Vis Identification Criteria paragraph. [b] In this work, the solvents used for the carotenoid separation and, therefore, for the acquisition of the UV-vis spectra were methanol, 2-propanol, and hexane. [c] The majority of the UV−vis data have been taken from ref 5; references different from ref 5 are given explicitly next to the corresponding datum. [d] See ref 44. [e] See ref 45. [f] See ref 46. [g] Reference 47 reports λ_{max}, but does not show the UV−vis spectrum. [h] For polyenes with less than 4 conjugated double-bonds, the Fieser rules cannot be applied. [i] See ref 42. [j] See ref 13. [k] See ref 48.

[a]The retention times on the LC-MS chromatogram appear with a delay of about 0.78 min compared to the corresponding LC-DAD chromatogram. [b]Monoisotopic masses have been calculated by Chem & Bio Draw 12.0. [c]The mass range of the EMS experiment includes m/z values from 500 to 610. [d]Only the most intense or characteristic fragment ions have been listed. [e]For these compounds the MRM transitions are theoretical.

at room temperature with the minimal amount of KOH (established comparing the results obtained with 0.5, 1.0, and 2 mL of KOH). Compared to MSPD, the advantages of this procedure (see the detailed conditions in the corresponding paragraph) are several: (i) a very clean extract; (ii) slightly superior yields; (iii) the achievement of a greater enrichment factor; (iv) simplification of the carotenoid analysis by hydrolyzing esters of carotenols with fatty acids.

MSPD is a valuable technique for a mild and rapid isolation of carotenoids from foods (especially for solid samples). Its extraction efficiency without the formation of artifacts during the sample preparation process has been already verified previously.[20,40]

The comparison of the LC-DAD-MS chromatograms, acquired after applying the two different extraction protocols, is an easy and quick way to deduce the occurrence of esterified carotenols in real matrices. When this comparison was performed for the tomato samples, the matching between the LC-DAD-MS chromatograms has proved the absence of bound carotenols as well as of artifacts during the saponification.

Characterization of the Carotenoid Fraction of Some Italian Varieties of Tomatoes. The developed method was applied to the analysis of the previously mentioned tomato varieties (see Tomato and Passata Samples paragraph). Like a representative example, Figure 2 depicts the LC-DAD chromatogram of a sample of 'Wild Tangerine' tomato, after cold saponification. Figure 3 shows the UV−vis spectra extracted from each chromatographic peak of Figure 2, while Tables 2 and 3 summarize the LC-DAD and LC-MS data used for the identification of carotenoids in the 'Tangerine' tomato as well as in the other tomato varieties.

Most of the assignments comply with the biosynthetic sequence of carotenoids in plants and confirm the supposition that the biosynthetic pathway involves *cis* configurations of the precursor (15-*cis*-phytoene) and the intermediates (*cis* isomers of ζ-carotene and lycopene).[41,42] For almost all the analyzed varieties, we have observed the presence of phytoene only in the 15-*cis* configuration and of phytofluene in the 15-*cis* and *all-trans* forms.

9,15,9′-Tri-*cis*-ζ-carotene is the intermediate that follows 15-*cis*-phytoene in the biosynthetic pathway.[42] In this work, we have

DOI: 10.1021/acs.jafc.5b02910
J. Agric. Food Chem. 2015, 63, 7428−7439

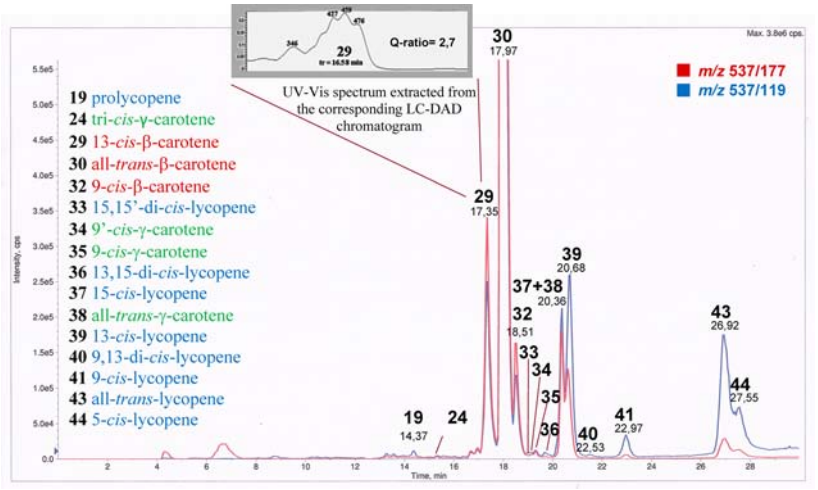

Figure 4. LC-MRM profiles of a saponified extract from 'Wild Tangerine' tomato: the ion currents m/z 537/177 and m/z 537/119 are shared by *all-trans*-lycopene, *all-trans*-β-carotene, *all-trans*-γ-carotene, and their corresponding *cis* isomers; each family of geometrical isomers can easily be distinguished on the basis of the characteristic ion ratio (see Table 1 and Figure 1).

identified 9,15,9′-tri-*cis*-ζ-carotene along with 15-*cis*-ζ-carotene and *all-trans*-ζ carotene in all tomato varieties. The *all-trans* isomer was prevalent only in the passata samples, probably because of the isomerization of 15-*cis*-ζ-carotene to the more stable *all-trans* isomer during the tomato processing. Neurosporene, another intermediate in the synthesis of lycopene,[42] was never detected in any of the analyzed varieties.

Prolycopene is known as the final product of the desaturation reactions that a specific isomerase converts into *all-trans*-lycopene;[41] subsequent cyclizations of *all-trans*-lycopene create a series of carotenes that have one or two rings of β-type and/or of ε-type. Unlike their precursors, lycopene, γ-carotene and β-carotene occur as *all-trans*-carotenes in wild-type tomato fruits; nevertheless, we have also observed their geometrical isomers and epoxidic forms in the 'Wild Tangerine' variety and passata (Tables 2 and 3). Figure 4 depicts the MRM profiles shared by lycopene, β-carotene, and γ-carotene, for a saponified sample of 'Wild Tangerine' tomato. These ion currents, together with the UV−vis data (Table 2; Figure 3), were used to identify 16 carotenes including three geometrical isomers of β-carotene, nine geometrical isomers of lycopene, and four geometrical isomers of γ-carotene. As an example, the peak 29 has been ascribed to 13-*cis*-β-carotene for the following reasons:

- the ion ratio value (ion ratio = $(I_{(m/z\ 537/177)}/I_{(m/z\ 537/119)})$ = 1.5) indicates that it is one of the geometrical isomers of β-carotene (Table 1; Figure 2)
- the retention time suggests that it is a next-to-central *cis*-isomer, because it elutes before the *all-trans* form
- the Q-ratio, calculated as (II/B) = 2.4, is in agreement with the data of the literature (Table 2); the hypsochromic shift of λ_{II} of 6 nm (from 456 nm for *all-trans*-β-carotene to 450 nm for the unknown) and the decrease in the intensity of peak III reinforce the attribution

Similarly, the peaks 37 and 39 have been attributed to 13-*cis* and 15-*cis* isomers of lycopene. The peaks 43 and 44 have been assigned to *all-trans*-lycopene and 5-*cis*-lycopene, respectively; the peak assignment has been based on the retention time of the authentic standard of *all-trans*-lycopene in solvent and on the occurrence of *cis*-peak at 367 nm detected only for the unknown 44. It is interesting to highlight that 5-*cis*-lycopene (peak 44), 13-*cis*-β-carotene (peak 29), and 9-*cis*-β-carotene (peak 32) were detected only in the extracts of 'Wild Tangerine' tomato and passata of 'San Marzano' tomatoes (probably due to the isomerization of *all-trans* forms during tomato processing). In the other tomato varieties, *all-trans*-lycopene and *all-trans*-β-carotene did not accompany the above-mentioned geometrical isomers.

The presence of γ-carotene in tomato and tomato products has previously been reported by Tonucci et al.[18] and Kimura et al.,[19] based on the online acquisition of UV−visible spectra without peak verification using more specific techniques. In this work, the occurrence of *all-trans*-γ-carotene (peak 38 of Figure 4) has been confirmed by using its authentic standard (Table 1; Figure 1); the key element of the identification has been the matching of the retention time, the perfect overlapping of the UV−vis spectra (λ_I, λ_{II}, λ_{III}, and % III/II), and the MS data. Even if *all-trans*-γ-carotene coelutes with 15-*cis*-lycopene (peak 37 + 38), their UV−vis spectra are perfectly distinguishable (see spectra 37 and 38 of Figure 3); moreover, the ion ratio close to 1 (compare Figure 1 and Figure 4) indicates that *all-trans*-γ-carotene is more abundant than 15-*cis*-lycopene.

Apo-lycopenals are hypothesized to be lycopene metabolites in mammals; nevertheless, they have recently been found in raw tomato and processed tomato products,[43] suggesting that these compounds may also be absorbed from food. In this work, the occurrence of apo-10′-lycopenal (peak 14) has been supposed on the basis of the UV−vis spectrum (Figure 2), the correspondence with the λ_{max} calculated according to the Fieser rule modified for aldehydes (eq 2; Table 2), and the LC-MRM profile obtained by acquiring the m/z 377/308 ion current (Table 3). For this compound, the two theoretical MRM transitions, listed in Table 3, have been deduced by hypothesizing an allylic cleavage of the C4−C5 bond.

Finally, among the xanthophylls identified in the 'Wild Tangerine' tomato, relevant for abundance were *all-trans*-lutein and 9-*cis*-antheraxanthin, followed by *cis*-lutein epoxide and *all-trans*-zeaxanthin. A series of *cis* isomers of low intensity were observed in particular for lutein, together with epoxides of zeaxanthin and β-cryptoxanthin (Tables 2 and 3). Traces of valenciaxanthin, a norcarotenoid occurring in some orange varieties, were found in the 'Pachino' tomato along with antheraxanthin and mutatoxanthin, all of them in the 9-*cis*-configuration. Usually, epoxidic forms are difficult to identify

using only the UV−vis detection (UV−Vis Identification Criteria paragraph, eq 3); LC-MS supports their LC-DAD identification since fragments at m/z 352, 221, and 181 indicate the presence of an epoxy group in a ring with a hydroxyl,[30] while fragment ions at m/z 165 and m/z 205 are characteristic of an epoxy group as the only substituent in the β-ring.[30] In passata and raw tomatoes, we also have identified epoxides of some carotenes (Tables 2 and 3).

In conclusion, the approach described in this paper has allowed us to realize a large-scale screening of carotenoids with the support of few authentic standards by exploiting the versatility of the LC-DAD-QqQ_{LIT} hyphenation. The identification power of this hyphenated technique is quite strong when all data (retention time; λ_I, λ_{II}, λ_{III}; % III/II; Q-ratio; m/z of pseudomolecular ion; fragmentation spectrum; relative abundance between the MRM transitions) are available, otherwise the assignment has to be considered tentative. Our methodology has been proved to be time-saving, because it can collect a large number of data with few analytical steps, and money-saving, because it uses a small number of standards commercially available at a reasonable cost. The 'Wild Tangerine' tomato has shown a number of carotenoids significantly larger than those of other analyzed varieties (up to forty-four compounds). In passata from 'San Marzano' fruits, some *cis*-forms of β-carotene and lycopene have been found particularly abundant since they were probably formed during the manufacturing process (isomerization due to the heat treatment and/or the occurrence of the organic acids freed during the squeezing step). The presence of *cis*-isomers in food has recently been revalued due to the superior bioavailability of these carotenoid forms.[9−11]

This study has not examined the effect of geographic area, the season, the ripening grade, and other variability parameters which can potentially affect the concentrations of these micronutrients. In the future, such an analytical approach could be extended to the comprehensive characterization of antioxidants in the genetically engineered varieties of tomato, enriched with anthocyanins to enhance the anticancer power of these fruits that, in the wild types, is only due to the carotenoids.

J. Agric. Food Chem. 2015, 63, 7428−7439

MCs are present in fish tissue in two different forms: (1) the free fraction consisting of the dissolved and reversibly bound MCs to tissues and (2) the covalently bound fraction associated with PP or cysteine-containing peptides within tissues. Extracting the bound fraction has been a challenge for tissue extraction procedures in fish exposed to MCs.[15] Conventional extraction methods involve organic solvents using aqueous or acidified methanol (MeOH). However, solvent extraction yielded poor recovery values because only the free fraction of MCs was recovered and detected.[16] A different approach was explored to analyze the total MCs in fish tissue via Lemieux oxidation (Figure 1) in order to release the oxidative product of Adda, 2-methyl-3-methoxy-4-phenylbutyric acid (MMPB).[15,17,18] Common to all congeners, MMPB makes it possible to quantify the total MCs and has been successfully used for analyses in water by our research group and other laboratories.[19−22] As for fish tissue analysis, a method was proposed using trypsinization followed by Lemieux oxidation and SPE cleanup, and MMPB was detected using liquid chromatography coupled with mass spectrometry (LC-MS).[15,17,18] However, the results from oxidation recoveries, SPE extraction efficiency, and signal recovery from matrix effects gave poor values. Moreover, the global procedures were laborious: up to 20 h of sample preparation was required for the trypsinization step and long LC-MS analysis times with over 40 min runs.[15]

We have developed a new approach to detect total MCs (free and protein-bound) in fish tissues. First, the tissue was digested with sodium hydroxide followed by Lemieux oxidation. A different SPE procedure was proposed to enhance recovery values and decrease the amount of salts in the extracts. Finally, the MMPB moiety was analyzed using a technology known as laser diode thermal desorption (LDTD) coupled with atmospheric pressure chemical ionization (APCI), and the detection was done with a high-resolution mass spectrometer, the Q-Exactive (HRMS). The LDTD has ultrafast analysis times (<15 s/sample), works with small amount of samples (2−10 μL) per analysis, and requires only a small volume of solvents because there is no liquid chromatography. In a previous study, the LDTD was successfully used to analyze MMPB in water samples with a triple-quadrupole mass spectrometer detector (MS/MS).[20] Anatoxin-A was also detected with this technology for its direct determination in water using both MS/MS and HRMS.[23,24] The LDTD was also successfully applied to small molecules in different matrices, including wastewater, sludge, sediment, soil, and biological matrices.[25−30] For this method, the Q-Exactive was chosen for two reasons: the sensitivity is higher than that of a standard triple quadrupole, thus giving better limits of detection and quantification; and the selectivity is better because the mass spectrometer enables precursor fragmentation and exact mass detection. Indeed, this hybrid Orbitrap detector combines a quadrupole precursor selection with a high-energy collisional dissociation cell (HCD), making it possible to fragment selected precursor ions. Also, with a resolving power of up to 140,000 full width at half-maximum (fwhm) at m/z 200, the mass accuracy obtained with the Q-Exactive is between 1 and 3 ppm.[31]

The objective of this study was to develop a new analytical method for the detection of all the MC variants and to improve their extraction in fish tissue to get a more realistic quantification for prudent risk management. By applying this method to samples of fish exposed to cyanotoxins, we aimed to determine the possible undervaluation from their quantification by conventional analytical methods based on the analysis of individual MCs using available standards.

MATERIALS AND METHODS

Chemicals, Reagents, and Stock Solutions. 2-Methyl-3-methoxy-4-phenylbutyric acid sodium salt (MMPB, purity ≥ 94%) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). 4-Phenylbutyric acid (4-PB, purity ≥ 99%) was obtained from Sigma-Aldrich (Oakville, ON, Canada). Ampules of certified standard solutions of microcystin-LR (MC-LR, 10.2 μM aqueous methanol (1:1, v/v)) were obtained from the Certified Reference Materials Program (NRC, Halifax, NS, Canada). Potassium permanganate ($KMnO_4$, purity ≥ 99.0%), sodium (meta)periodate ($NaIO_4$, purity ≥9 9.0%), sodium bisulfite (purity ≥ 95%), sodium hydroxide (NaOH, purity ≥ 98%), hydrochloric acid (HCl, ACS reagent 37%), and sulfuric acid standard solution (1.000 M) were obtained from Sigma-Aldrich. All solvents were of high-performance liquid chromatography (HPLC) grade from Fisher Scientific (Whitby, ON, Canada). Deionized/distilled water (dd-H_2O) was used for recovery evaluation. Individual stock standard solutions were prepared in methanol (MeOH) at a concentration of 100 mg L^{-1} and kept at −20 °C for 12 months for the MMPB standards and a maximum of 6 months for the 4-PB standards, according to compound stability.[20] Compressed air (Ultra Zero Certified grade; ≤2 ppm of water) was used as a carrier gas for the LDTD desorption and obtained from MEGS Specialty Gases, Inc. (St-Laurent, QC, Canada).

Fish Tissue Samples. Environmental samples were provided by the monitoring program of the Ministère du Développement durable, de l'Environnement et de la Lutte aux changements climatiques (MDDELCC), Québec provincial environment ministry (Québec, QC, Canada), as part of an MC project to monitor fish in natural lakes where cyanobacterial blooms occur. Fish were caught on August 20, 2009, and on October 14 and 15, 2009, in three different lakes in the province of Québec, Canada: Lac Vert, Lac Roxton, and Lac Noir. All three lakes were affected by cyanobacterial blooms. Eight different species were caught and kept at −20 °C until homogenization and analysis: rainbow smelt, white sucker, brook trout, yellow perch, walleye, pike, brown bullhead, and lake whitefish. The analysis was first performed by the government monitoring program of the Centre d'expertise en analyze environnementale du Québec (CEAEQ). Fish tissue (muscle and whole fish) was weighed and dried using diatomaceous earth, followed by slow elution with acidified MeOH with formic acid. The solvent was evaporated, and the samples were reconstituted in the mobile phase and filtered using 0.2 μm nylon filters submitted to ultracentrifugation. An aliquot was used for LC-MS/MS analysis. Four microcystins were quantified: MC-LA, MC-LR, MC-RR, and MC-YR.

NaOH Digestion and Lemieux Oxidation. Frozen homogenized fish tissue was used instead of freeze-dried tissue to make direct comparisons with MCs previously found in the samples using the CEAEQ's standard analytical procedure. Thus, 1 g of wet weight and homogenized fish tissue was submitted to a freeze−thaw lysis three times to break the remaining cells and leach the toxins. The tissues were then digested in 5 mL of NaOH solution (50 mM) for 2 h. The pH was adjusted to 9 using an HCl solution (100 mM), and oxidants were added in solution with $KMnO_4$ (50 mM) and $NaIO_4$ (50 mM). The reaction was conducted at room temperature for 2 h in the absence of light. Saturated $NaHSO_3$ solution was added until the purple color turned white to quench the reaction. A 10% sulfuric acid solution was used to acidify the solution (pH ∼2).

Solid Phase Extraction (SPE) Procedures. Before the SPE step, suspensions were transferred in centrifuge tubes and submitted to sonication for 15 min. They were then centrifuged for 15 min at 3000 rpm, and the supernatants were filtered using 0.2 μm nylon filters from Whatman (Florham Park, NJ, USA) prior to extraction. A polymeric hydrophobic sorbent consisting of styrene−divinylbenzene (Strata SDB-L) was used as an SPE cartridge from Phenomenex (Torrance, CA, USA) with a 500 mg bed mass and a volume of 6 mL. The

procedure was carried out using a 12-position manifold from Phenomenex. The SPE was performed with the filtered aliquots of sample supernatants with the pH already adjusted to 2. The SPE cartridges were conditioned with 5 mL of methanol (MeOH) for sorbent activation followed by 5 mL of acidified water with 0.1% formic acid (HPLC grade). The samples were then loaded on the cartridge columns by gravity. The cartridges were washed twice with 5 mL of water with 0.1% formic acid containing 10% MeOH (v/v). Elution was performed with 5 mL of MeOH into glass conical-bottom centrifuge tubes. The eluates were completely dried under a gentle stream of nitrogen at room temperature with a nine-port Reacti-Vap unit (Pierce, Rockford, IL, USA). The dried fractions were then reconstituted in acetonitrile (ACN) and directly submitted to LDTD-APCI-HRMS detection.

LDTD-APCI-HRMS. Compound desorption was achieved with a T-960 LDTD-APCI ionization interface model, and the instrument was controlled using LazSoft 4.0 software (Phytronix Technologies, Québec, QC, Canada) integrated with Excalibur 2.2 software (Thermo Fisher Scientific, Waltham, MA, USA). The LDTD instrument was described in previous work.[20,29,30] In this experiment, 4 μL aliquots from extract samples were spotted into a LazWell 96-well sample metal plate. After complete solvent drying at 40 °C for 5 min, the back of the sample well was heated by an infrared laser (980 nm, 20 W, continuous) in the LDTD instrument. The sample was desorbed, and a carrier gas flow of 2 L min^{-1} was then set at a temperature of 50 °C to avoid temperature variations and transfer the gas phase molecules to negative APCI ionization followed by HRMS detection. Finally, the laser power is expressed as a percentage, and the laser pattern was optimized to the following settings: 2 s at 0%, 2 s ramping from 0 to 40%, 1 s hold at 40%, 0.1 s from 40 to 0%, and 2 s hold at 0%, with a total desorption time of 7 s per sample. APCI in negative mode is within these parameters: ion sweep gas, 0.3; sheath gas, auxiliary gas, and skimmer offset set to 0 (all arbitrary values); vaporizer temperature, 0 °C; and capillary temperature, 350 °C.

The detection was performed using a Q-Exactive mass spectrometer controlled by Excalibur 2.3 software (Thermo Fisher Scientific). Instrument calibration in negative mode was done every 5 days to avoid mass shifts in detection with a direct infusion of a LTQ Velos ESI Negative Ion Calibration Solution (Pierce Biotechnology Inc., Rockford, IL, USA). The Q-Exactive parameters were selected toward mass resolution and accuracy for better quantification, sensitivity, and selectivity. The targeted ion fragmentation (t-MS^2) mode was used for MMPB quantification, and normalized collision energy (NCE) was optimized. Standard solutions of MMPB and 4-PB at a concentration of 100 μg L^{-1} were directly infused with a syringe at a flow rate of 0.01 mL min^{-1}. The fragment ions and their NCE were chosen using Q-Exactive Tune 2.3 software (Thermo Fisher Scientific). The precursor ions were filtered by the quadrupole, which operates at an isolation width of 0.4 amu. The optimized collision energies, precursor ions, and fragment ions are presented in Table 1. A resolving power of 17500 fwhm at m/z 200 was used with an automatic gain control (AGC) target set at 1×10^5 ions for a maximum injection time of 50 ms. For more technical details, please refer to previous studies.[23,32−34]

Method Validation. Data treatment was carried out using Excalibur 2.3 software (Thermo Fisher Scientific). The method validation was done according to the recommendations of the validation protocol for environmental chemistry analysis from the MDDELCC ministry guidelines. The two fragment ions with the highest signal intensity were selected as the quantification and confirmation ions. The quantification ion was used to establish the method limits of detection and quantification. Compound confirmation could be done with the ratio of their relative intensities to avoid false positives. The second most abundant ion from the isotopic pattern and the isotopic ratio with <10% intensity variations were used for confirmation. A mass tolerance window was set to 5 ppm (±2.5 ppm) for the extracted masses from acquisition to get a good selectivity in data analysis. The reaction recovery yield values for fish tissue digestion and oxidation were evaluated using a blank matrix, which consisted of fish that were not in contact with cyanobacterial bloom at three MMPB concentrations: 25, 250, and 1000 μg kg^{-1}. The fish tissue was spiked with MC-LR and the corresponding MMPB concentrations prior to digestion and oxidation. To obtain a relevant matrix with interactions between the fish tissue and the added MC, the blank homogenates were incubated for 3 h prior to the extraction procedure. The mean peak area values were compared with those obtained by spiking the digested and oxidized fish tissue with MMPB before SPE. The recovery values of the SPE method and the matrix effects were also evaluated using blank fish tissue at three concentrations: 25, 250, and 1000 μg kg^{-1}. Extraction recoveries were determined with the mean peak area of MMPB spiked prior to extraction in matrix-containing (blank fish tissue) samples compared to matrix-containing samples spiked postextraction. The matrix effects were evaluated with the mean peak area of MMPB spiked prior to extraction in matrix-containing samples compared to spiked matrix-free (dd-H_2O) samples prior to extraction. All recovery values were evaluated in triplicate, and the results are reported as percentages. A seven-point internal calibration curve was prepared with blank fish tissue by standard addition with concentration levels ranging from 15 to 2500 μg kg^{-1}. The concentration of internal standard (IS) 4-PB was selected at 500 μg kg^{-1} for its capacity for signal correction (data not shown). The method detection limit (MDL) and method quantification limit (MQL) were established by calculating 3 and 10 times the standard deviation of the mean value of six spiked blank fish tissue samples containing approximately 5 times the estimated concentration for detection limit (15 μg kg^{-1}), respectively. Accuracy—expressed as relative error (RE %)—and interday/intraday—expressed as the relative standard deviation (RSD %)—were determined with three different concentrations on the linearity range (25, 250, and 1 000 μg kg^{-1}, $n = 6$) in blank fish tissue samples. Intraday repeatability was estimated over 3 weeks. Statistical comparison was used when needed with the Statistical Package for Social Sciences (SPSS 21.0, Chicago, IL, USA) for Windows. ANOVA and Tukey's post hoc tests were used with statistical significance defined as $P < 0.05$.

RESULTS AND DISCUSSION

Digestion and Oxidation. The extraction of total MCs through MMPB from biological matrices was previously explored with the use of trypsinization and Lemieux oxidation followed by SPE cleanup.[15,18] For higher extraction efficiency, our study first considered the possibility of NaOH as a digestion reagent to break down the tissue and thus allow the free and bound MCs to react to Lemieux oxidation and then be

concn (μg kg^{-1})	accuracy RE (%)	intraday RSD (%)	interday RSD (%)	digestion/oxidation recovery ± SD (%)	SPE recovery ± SD (%)	signal recovery from matrix effects ± SD (%)
25	10	6	7	70 ± 7	91 ± 6	92 ± 7
250	6	4	5	75 ± 9	95 ± 9	90 ± 10
1000	5	5	9	72 ± 6	98 ± 7	93 ± 9

converted to MMPB. MCs are known to be stable in a wide range of pH as well as high temperatures and sunlight.[35] Because MCs can withstand higher alkaline and acidic pH, NaOH was then used as a digestion agent for fish tissue without affecting MC stability. The optimization was developed by spiking MC-LR in blank fish tissue before the digestion and oxidation with the corresponding MMPB concentration (1000 μg kg^{-1}) recovered after SPE cleanup, and this concentration was chosen for its higher signal intensity and therefore easier optimization. Different NaOH concentrations between 10 and 100 mM were studied and submitted to different digestion periods ranging from 30 min to 5 h (n = 3). The results are shown in Figure 2a. The optimal results were 50 mM NaOH used for 2 h, which yielded in higher MMPB signals and less variability. Longer digestion durations did not significantly increase the MMPB signal (P > 0.05), and the faster digestion time was therefore preferred. Finally, higher concentrations enhance salt concentration in solution and can reduce LDTD desorption due to the presence of a salt layer in the wells and may also induce ion suppression during the charge transfer of APCI ionization.[30,36,37]

Lemieux oxidation was previously used in bloom water matrices in a previous work and was optimized according to three parameters: pH, oxidation time, and reagent concentration. The reaction medium was alkaline with a pH of 9 with 100 mM HCl after digestion. This was set as the most efficient pH value used for MC oxidation in previous studies. However, because the oxidation takes place in fish tissue, reagent concentration and oxidation time were reassessed to obtain the best reaction yield. $KMnO_4$ and $NaIO_4$ were tested with concentrations between 10 and 100 mM, and each concentration was tested for an oxidation time between 30 min and 5 h (n = 3). The results are shown in Figure 2b. The optimal values were the use of 50 mM reagents at a reaction time of 2 h. Reaction conditions were similar to those in the previous study, with a reaction time of 2 h instead of 1 h being the only difference. The lower reaction time and reagent concentrations were selected for faster sample preparation and to limit ion suppression from ionization due to the high amount of salts in the matrix. The digestion and oxidation reaction recovery values were determined together, using blank fish tissue spiked before digestion with MC-LR, and the results were compared with blank fish tissue spiked after oxidation with the

corresponding MMPB concentrations (25, 250, and 1000 μg kg^{-1}). Recovery yield values are shown in Table 2 with their respective standard deviations (SD) and values ranging from 70 to 75%. These results represent a significant improvement as compared to previous studies using trypsinization prior to Lemieux oxidation with results ranging from 5 to 40%.[17,18]

Sample Cleanup and Elution. A SPE cleanup was developed to isolate MMPB and 4-PB from the reaction mixtures. Extensive cleanup was necessary because of the fish tissue, which constitutes a highly complex matrix, and the high amounts of salts in the digestion and oxidations steps.[17] Indeed, the presence of proteins, lipids, and salts can induce ion suppression during APCI ionization due to charge transfer limitations and thus affect signal intensity.[37] In the analysis of MMPB in animal tissues, reverse phase or ion-exchange SPE sorbents are generally used for cleanup.[15,17,18] In this study, SDB-L sorbent was tested to enhance MMPB recovery and limit the elution of contaminants from the matrix. The SDB-L SPE targets hydrophobic and aromatic analytes, which is appropriate for MMPB because its structure includes an aromatic cycle. The pK_a of MMPB being 4.63, the molecule is in neutral state in acidic conditions and can be adsorbed on the SDB-L sorbent. As for the procedure, SPE sorbents were washed twice with 5 mL of H_2O with 0.1% formic acid 10% MeOH to eliminate a maximum of interfering compounds and salts from the matrix. The elution step was done with 5 mL of MeOH because the compounds did not need a change of polarity to be released from the sorbent. The recovery values for the SPE procedure were evaluated using blank fish tissues spiked before SPE, and the mean peak area values were compared to blank fish tissue spiked after SPE. The recovery results were deemed satisfactory (ranging from 91 to 98%) and are shown in Table 2 for the three concentration levels (25, 250, and 1000 μg kg^{-1}). The matrix effects were determined by comparing the mean peak area of targeted compounds in matrix-containing samples spiked before extraction as compared to dd-H_2O spiked before extraction. The signal recoveries are shown in Table 2 and ranged from 90 to 93%, illustrating that the MMPB signal is not significantly affected by the matrix.

LDTD-APCI-HRMS. Different parameters were optimized to improve signal intensity for optimal MMPB detection by LDTD-APCI-HRMS. Several parameters from the LDTD desorption had to be reassessed. Indeed, in earlier work, an analytical method was developed and optimized to analyze MMPB by LDTD-APCI-MS/MS in lake water. However, fish tissue is a completely different matrix, and the LDTD desorption may be affected if parameters such as deposition solvent, volume of deposition, laser power, and laser pattern are not optimized. In this case, the carrier gas flow was not studied because changing the parameter did not lead to improvement. The different optimizations were done with postextraction blank fish tissue spiked with 100 μg L^{-1} MMPB (n = 6).

First, the deposition solvent will affect compound desorption by LDTD depending on its solubility and on how the dried solvent will create layers of nanocrystals constituted of the analytes and the matrix.[30] Therefore, deposition solvents were tested as solvents of reconstitution after the SPE cleanup and included ethyl acetate, isopropanol, methanol, hexane, acetone, water, ethanol, and acetonitrile. As the results demonstrate in Figure 3, the optimal deposition solvent was acetonitrile (ACN). Indeed, the use of ACN considerably reduces the amount of proteins and amino acids available in the samples by their precipitation, thus reducing matrix complexity. Second, deposition volumes were evaluated to maximize the amount of analytes submitted to desorption, thus increasing the signal intensity. Figure S1 in the Supporting Information shows the results, and a volume of 4 μL yields a significantly higher signal intensity ($P < 0.05$) with a lower variability. With higher deposition volumes, higher variability is observed followed by a signal decrease. This is explained by the higher mass of analyte, which is concomitant with a higher presence of interfering compounds that can reduce LDTD desorption and also affect APCI ionization with ion suppression. Third, the laser power is the amount of energy transferred to the back of the well of the LDTD plate expressed as a percentage (of maximum) and which influences the analytes' desorption rate. Laser power values were studied between 10 and 60% because higher power can burn the well, thus inducing compound degradation or fragmentation. The results in Figure S2 show that 40% is the optimal laser power for higher MMPB desorption with minimal signal variability.

The laser pattern was studied, including the laser ramp time enhancement followed by the laser plateau time. The laser ramp time influences the shape of the LDTD peak and, by the same token, the number of acquisition data points per peak. Because LDTD desorption is fast, the HRMS detection can often lack data acquisition points for low-variability quantification (the criteria being at least seven points).[34] The laser

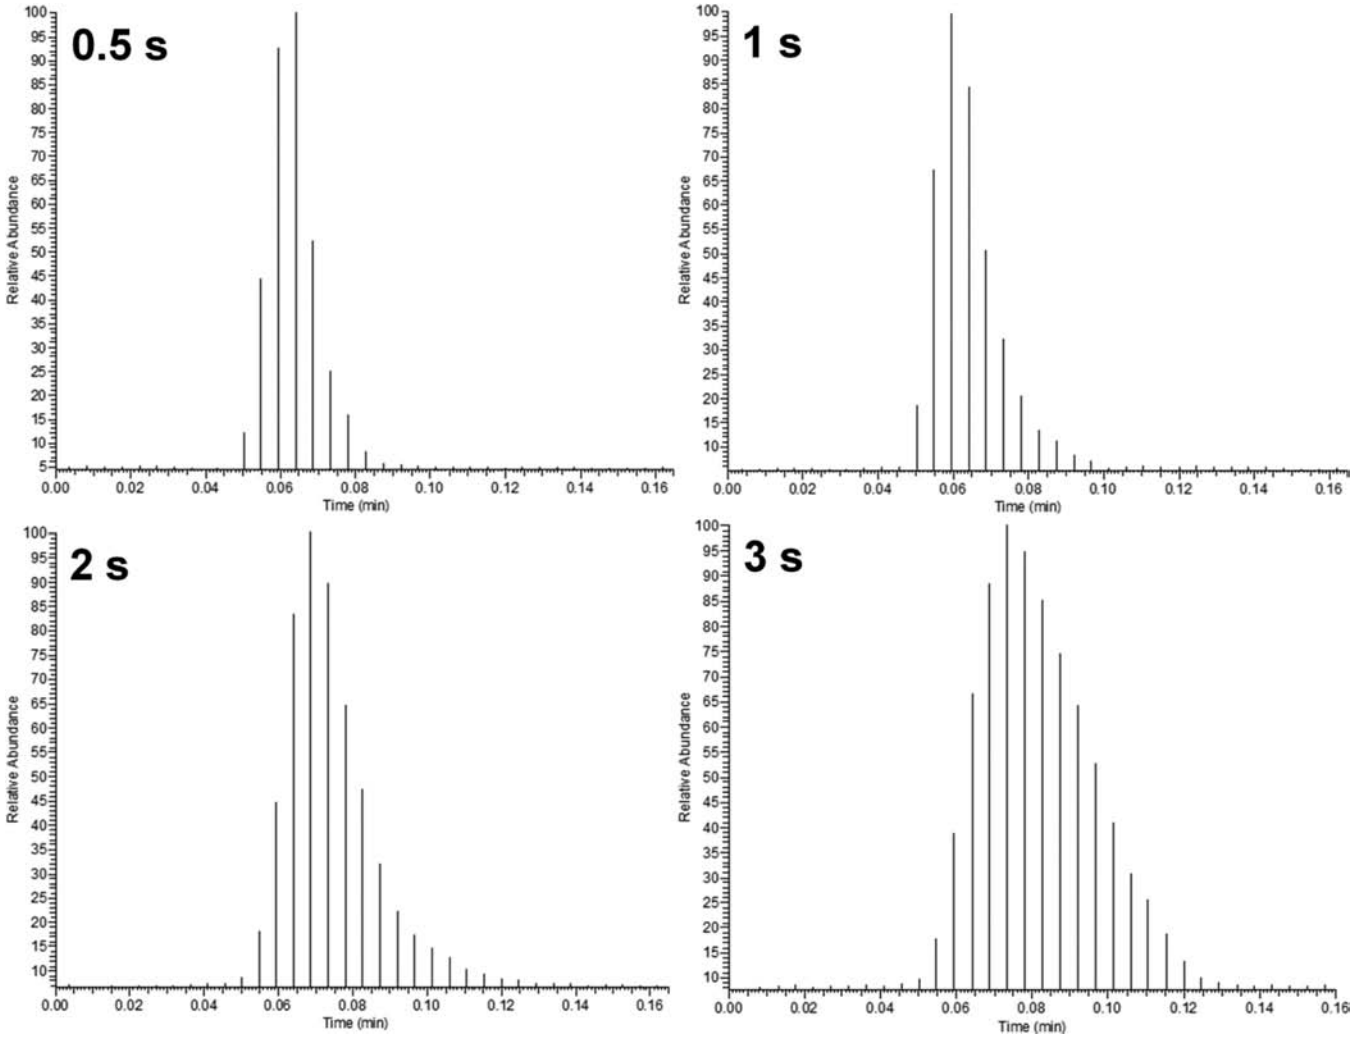

Figure 4. Number of data acquisition points for LDTD peaks of MMPB with different laser ramp times.

plateau time influences the amount of compound that will desorb and the signal stability. The two parameters were evaluated together by varying them between 0.5 and 3 s (Figure S3). The optimal values were a laser ramp time of 2 s with a laser plateau time of 1 s yielding more than 10 data acquisition points in a peak width of about 5 s (Figure 4). Higher laser plateau times caused signal instability and higher variability. The phenomenon also occurred with higher laser ramp time, at >3 s, when the beginning of a peak distortion was observed and caused higher signal variability. With 4 s of laser ramp time, peak distortion is obvious, causing much higher signal variability (Figure S4). No significant enhancement was observed with higher laser plateau and ramp time ($P > 0.05$).

Method Validation. The evaluation of the LDTD-APCI-HRMS method was done according to these parameters: linearity, sensitivity, accuracy, precision, selectivity, and matrix effects, which were previously discussed under Sample Cleanup and Elution. Due to the unavailability of isotopically labeled MMPB, 4-PB was used as the internal standard based on previous studies.[17,20] All validation parameters were evaluated using spiked blank fish tissue to take matrix effects into account. A seven-point standard addition calibration curve spiked prior to the SPE procedure was used with a linear dynamic range between 15 and 2 500 $\mu g\ kg^{-1}$ analyzed in triplicate. The optimal concentration of 4-PB used as signal variation correction was set at 500 $\mu g\ kg^{-1}$ depending on the lowest variability throughout the calibration linearity range (data not shown). Ultimately, correlation coefficients showed a good linearity with $R^2 > 0.999$. The method detection limit and method quantification limit (MDL and MQL) were 2.7 and 8.2 $\mu g\ kg^{-1}$, which are comparable to previous work. Figure S5 shows a sample LDTD peak signal obtained around the MQL (8 $\mu g\ kg^{-1}$).[17] Table 2 summarizes the validation parameters determined at three concentrations from the linearity range (25, 250, and 1000 $\mu g\ kg^{-1}$). Values from the accuracy expressed as the relative errors (RE %) and from intraday and interday precisions expressed as relative standard deviations (RSD %) were ≤10%, which means that the method was both selective and precise.

Fish Tissue Samples. The method was applied to determine the total MCs present in 49 samples of fish tissue caught in three different lakes of the province of Québec, Canada, where cyanobacterial blooms occurred during the growing season. Tables 3 and S1 present the results obtained using three different analytical methods. The results from the method developed in this study are presented first. Then, the same samples were submitted to LDTD-APCI-MS/MS analysis using a previously developed method for total MCs in lake water.[20] The purpose here was to compare the sensitivity and selectivity of MS/MS detection with HRMS detection using
