diffusion have been reported for a range of applications.[11,22,25−27] Furthermore, a number of researchers have studied the interactions between various solutes in systems based on casein micelles: small polyphenol compounds,[28−31] positively charged proteins such as lactoferrin and lysozyme,[32,33] and polysaccharides in mixed systems.[34,35] However, the specific interactions between casein micelles, which are negatively charged at neutral pH, and other macromolecules, in particular, negatively charged proteins, have not been studied in detail. Moreover, the influence of these interactions on the diffusion of solutes as a function of their physicochemical characteristics has rarely been explored in casein systems.[18] In a previous work, we have shown that the diffusion of rigid and negatively charged proteins (α-lactalbumin (α-LA), β-lactoglobulin (β-LG), and bovine serum albumin (BSA)) was hindered more than that of flexible and neutral dextrans with similar hydrodynamic radius when diffusing through a model cheese; in this case, the cheese had a casein concentration below close-packing (estimated as 178 g/L).[18] It was concluded that solute−matrix interactions had hindered the diffusing proteins. However, the nature of these interactions was not clearly identified and was related to the molecule flexibility and/or its charge.

The question thus arises of how the diffusion of solutes is specifically affected by their physicochemical characteristics in casein systems. The study carried out considered the effect of the flexibility and charge of solutes on diffusion and subsequently evaluated the nature of the solute−matrix interactions implied. Diffusion coefficients of a selected group of solutes were measured in casein systems. The solutes studied were dextrans (neutral or charged, flexible solutes), proteins (charged, rigid solutes), and peptides (charged, flexible solutes). The casein systems presented different microstructures (suspension versus gel), but their casein concentration and water activity were kept constant. A casein concentration lower than that for the close-packing of the micelles was chosen to specifically highlight solute−matrix interactions. The casein gels had different pH values (5.2 and 6.6), which enabled a modification in the net charge of the diffusing proteins to explore the effect of the solute charge on diffusion. The technique of fluorescence recovery after photobleaching (FRAP) was chosen because it allows a nondestructive and fast measurement of the solute diffusion coefficient. This technique has been recently successfully applied to study diffusion properties of solutes in casein systems.[17,18] Furthermore, it enables an estimation of the proportion of the solute present that is immobile (i.e., the fraction of molecules that are locked in place and prevented from diffusing), which can provide relevant information about solute−matrix interactions.[36−38]

MATERIALS AND METHODS

FITC-Labeled Solutes. *Dextrans and Poly-L-lysines.* Neutral fluorescein isothiocyanate (FITC)-dextrans of five different average molecular weights (M_w = 4, 10, 20, 40, and 70 kDa, denoted FITC-D4, FITC-D10, FITC-D20, FITC-D40, and FITC-D70, respectively) were used in this study (Sigma-Aldrich, St. Louis, MO, USA). Product specification declared that all of the FITC-dextrans contained between 0.003 and 0.02 mol of FITC per glucose unit. One anionic FITC-dextran with an average molecular weight of 70 kDa was purchased from Molecular Probes (Eugene, OR, USA). Product specification in this case stipulated that the anionic FITC-dextran contained from 0.01 to 0.02 mol of FITC per glucose unit. Two FITC-labeled poly-L-lysines (FITC-PLLs) with molecular weight ranges of 15−30 and 30−70 kDa were purchased from Sigma-Aldrich. According to the supplier, the average molecular weights of the FITC-PLLs of 15−30 and 30−70 kDa were 23 and 32 kDa, respectively, and will be denoted FITC-PLL23 and FITC-PLL32. Both FITC-PLLs contained between 0.003 and 0.1 mol of FITC per lysine monomer.

Globular Proteins. The studied set of solutes was completed with three globular proteins. The first was FITC-labeled bovine serum albumin (denoted FITC-BSA) (Sigma-Aldrich). The second and third globular proteins were α-LA and hen egg white lysozyme (LYS) (Liot, Pleumartin, France), which were labeled separately using FITC (Sigma-Aldrich) as previously reported.[18] The procedure was as follows. Proteins were first dissolved at a concentration of 0.27 mM in a 10 mM phosphate buffer solution (pH 8.0). They were covalently labeled with FITC by mixing 1.8 mL of a FITC solution (38 mM FITC) with 100 mL of the protein solution for 90 min at room temperature and protected from light. The solutions of FITC-α-LA and FITC-LYS were then dialyzed with cellulose membranes with a nominal cutoff of 6−8 kDa (Spectrum Laboratories, Canada) against 10 mM Tris/0.6 M NaCl buffer (pH 7.33) for 2 days to eliminate any remaining free FITC. A final dialysis was made by using deionized water. The two solutions from the α-LA and LYS proteins were lyophilized, and labeling efficiencies were determined by mass spectrometry analyses. Following this procedure, the α-LA and LYS proteins were mainly monolabeled (10 and 43%, respectively) with FITC. The mass spectrometry analyses were carried out on a hybrid quadrupole time-of-flight (Q-TOF) mass spectrometer QStar XL (MDS Sciex, Toronto, ON, Canada). Measurements were performed by direct infusion electrospray ionization mass spectrometry (ESI-MS) using a nano ESI sample source. Data were collected in the selected mass range of m/z 1000−3000 for MS spectra and processed using Analyst QS 1.1 Sciex software. The deconvolution of spectra was carried out using Bioanalyst 1.1.5.

Preparation of FITC-Labeled Solutes. All of the FITC-dextrans and FITC-α-LA were dissolved in a 0.1 M BisTris buffer at pH 6.8 (called buffered water hereafter) to a concentration of 50 g/L, FITC-BSA and FITC-LYS to 25 g/L, and FITC-PLLs to 5 g/L. For the FRAP measurements, all of the FITC-labeled solutes were diluted to 1/100 (v/v) in the different media (i.e., buffered water, permeate, and casein systems). These solute concentrations were chosen because they fell in the concentration range where fluorescence intensity and solute concentration are related linearly. The diffusion coefficients of the FITC-labeled solutes were measured by using trace amounts, thus approaching the condition of infinite dilution with respect to the FITC-labeled solute concentration to avoid solute−solute interactions.

Physicochemical Characteristics of FITC-Labeled Solutes. The physicochemical characteristics of the described set of FITC-labeled solutes such as size (molecular weight and hydrodynamic radius), flexibility, and charge are summarized in Table 1. The hydrodynamic

Table 1. Physicochemical Characteristics of FITC-Labeled Solutes

FITC-labeled solute	M_w (kDa)	R_h (nm)	flexibility	net charge at neutral pH
FITC-D4[a]	4	1.4	flexible	neutral
FITC-D10[a]	10	2.3	flexible	neutral
FITC-D20[a]	20	3.3	flexible	neutral
FITC-D40[a]	40	4.5	flexible	neutral
FITC-D70[a]	70	6.0	flexible	neutral
anionic FITC-D70[a]	70	6.0	flexible	negative
FITC-PLL23[a]	23		flexible	positive
FITC-PLL32[a]	32		flexible	positive
FITC-α-LA[b]	14.2	2.1	rigid	negative
FITC-BSA[b]	66.3	3.6	rigid	negative
FITC-LYS[c]	14.3	2.5	rigid	positive

[a]Supplier information. [b]Bouhallab and Croguennec[39] and Johnson et al.[10] [c]Bouhallab and Croguennec[39] and Parmar and Muschol.[40]

DOI: 10.1021/acs.jafc.5b02401
J. Agric. Food Chem. 2015, 63, 6624−6632

radii given were taken from the literature. The molecular weights of the globular proteins are well-known and were taken from literature. The molecular weights of the FITC-dextrans and of the FITC-PLLs come from the supplier and correspond to average values from a distribution of molecular weights. On the basis of information from the supplier, the mole proportion of FITC per glucose and lysine (for FITC-dextrans and FITC-PLLs, respectively) was very low, and the negative charge contribution of the FITC for these solutes was not taken into account. The net charge of each FITC-labeled protein at the pH of the casein systems studied in the present work (pH 6.6 and 5.2) was calculated by using simulated titration curves for the unlabeled proteins, which took their 3D structure and the dosage of the label into account to adjust the contribution of the carboxyl group of the FITC.[41−44] These values are presented in Table 2.

Table 2. Simulated Net Charge of FITC-Labeled Proteins at pH 6.6 and 5.2

		net charge at pH 6.6[a]			net charge at pH 5.2[a]		
solute	p*I*	protein	FITC	FITC-protein	protein	FITC	FITC-protein
α-LA	5.0	−4.6	−0.06	−4.7	−0.7	−0.005	−0.7
BSA	5.8	−9.5	−7.2	−16.7	+11.3	−0.6	+10.7
LYS	10.9	+8.8	−0.2	+8.6	+10.1	−0.02	+10.1

[a]The given net charge values were calculated by using simulated titration curves obtained from PROPKA[41−44] for the unlabeled proteins and the dosage of labeled protein to adjust the contribution of the carboxyl group of the FITC.

Preparation of Casein Systems. A casein concentrate was prepared following a previously described procedure.[45] The process allowed the concentration of the total proteins of milk by a factor of 4.3. Neither NaCl nor cream was added, leaving a salt-free and fat-free concentrate. The final composition of the casein concentrate was as follows: dry matter, 196.4 g/kg; casein, 130.3 g/kg; whey proteins, 4.4 g/kg; lactose and minerals, 60.1 g/kg; and 1.6 g/kg of all other components. Sodium azide was added (0.05% w/w) to prevent bacteria growth.

Prior to the FRAP measurements, each FITC-labeled solute was added to the casein concentrate (1:100 v/v) to obtain the casein suspensions. For the casein gels, the coagulant agent Maxiren 180 (DSM Food Specialties, France) was added to the casein concentrate (at a dosage of 0.03% v/v) after the FITC-labeled solute addition. To obtain the acid casein gels, glucono-δ-lactone (GdL) (Merck, Darmstadt, Germany) was added simultaneously with the coagulant agent Maxiren 180 at a dosage of 24 g/L.

The use of gel cassette systems[46,47] (IFR, Norwich, UK) enabled nondestructive and microscopic examinations as discussed previously.[17,18] The gel cassette systems were filled with 1 mL of the previously prepared mixture and then incubated at 30 °C for 1 h before being held at 19 °C for 2 h to obtain both casein suspension or gel. The final pH for these two systems was 6.6 ± 0.05. The "gel time" of the casein gel, that is, the time at which the storage modulus (G') and the loss modulus (G'') are equal, was about 16 min (determined using an AR2000 rheometer (TA Instruments, Guyancourt, France) equipped with a coaxial cylindrical geometry using the oscillatory mode at a frequency of 1 Hz and 0.1% strain; data not shown). Therefore, the time of 2 h after coagulation was chosen for FRAP experiments because both G' and G'' values had by then reached a plateau. Beyond this time, the gel microstructure was not expected to develop further, and measurements could thus be performed under stable conditions. For the acid casein gel, the gel cassette systems were also incubated at 30 °C for 1 h, but this time held at 19 °C for 4 h to obtain the stable pH of 5.2. The final pH of the acid casein gel was 5.2 ± 0.05. No gel shrinkage was observed during the experiments for both gels (casein gel or acid casein gel).

The water activity of casein systems was determined using a water activity meter (FA-st lab, GBX Instrumentation Scientific, Bourg de Peage, France), which involved placing about 5 mL of sample in a small cylinder container. This apparatus uses chilled dew point technology to measure water activity. Condensation occurred on a gold mirror cooled by the Peltier effect. This technique involved the measurement of the relative humidity in an enclosed chamber containing the sample being studied. The measurement was done in triplicate on each sample. The water activity values did not differ significantly between the three casein systems studied ($a_w \sim 0.979 \pm 0.003$).

Fluorescence Recovery after Photobleaching. Diffusion coefficients of FITC-labeled solutes in the casein systems were measured using the FRAP protocol described by Floury et al.[17] and adapted by Silva et al.[18] Measurements were carried out using an inverted confocal laser scanning microscope (CLSM) (Nikon, Champigny-sur-Marne, France). Samples were observed using a 40× objective lens (oil immersion) with a numerical aperture of 1.30. The FITC-labeled solutes were excited using a 50 mW sapphire laser system with a wavelength of 488 nm and detected on the 500−530 nm spectral bandwidth. All diffusion measurements were performed at 19 °C in an air-conditioned room to avoid any temperature effects on the diffusion coefficient values. The procedure used is summarized as follows: three prebleach images were taken at 0.1% of the maximum laser intensity. Five images were then scanned at 100% laser intensity to bleach a small circular region of interest (ROI) of 5.2 μm radius. A series of 100−150 single-section images (depending on the solute) were then collected to follow the recovery process at 0.1% of the maximum laser intensity. The FRAP measurements were also carried out in the same way in buffered water (0.1 M, pH 6.8) and in the permeate (∼0.1 M, according to the methods of Jenness and Koops[48] and Bouchoux et al.,[49] and pH 6.8). The permeate is mainly made up by water, lactose, minerals, and free amino acids and corresponds to the aqueous phase filling the voids of the structure of the casein systems. Measured diffusion coefficients of the FITC-labeled solutes in both the buffered water and the permeate were used to calculate the hydrodynamic radii of the solute molecules. About 100 μL of the fluorescent buffered water or permeate was used for the measurement, being placed between a glass slide and a coverslip sealed with an adhesive frame (Gene Frame, ABgene House, UK). About 10 repetitions of the FRAP measurements were done on each sample. Results were separately modeled to obtain an average diffusion coefficient for the FITC-labeled solutes in each of the media and to test the repeatability of the method. Two different sets of casein systems (i.e., suspension, gel or acid gel) were prepared for the FRAP measurements of the charged solutes to test the reproducibility of the method.

FRAP Data Analysis. Diffusion coefficients of FITC-labeled solutes in the different systems were calculated according to the method of Silva et al.[18] By assuming a homogeneous medium and considering that the diffusion is the only relevant transport process, the system behaves according to the classical diffusion equation after photobleaching as follows:

$$\frac{\partial}{\partial t}C(\vec{r},t) = D\nabla^2 C(\vec{r},t) \quad (1)$$

$C(\vec{r},t)$ is the solute concentration at position $\vec{r}$ at time t.

The effective diffusion coefficient (D_{eff}) of the diffusing fluorescent solute was calculated using eq 2:

$$D_{eff} = \frac{w_M^2}{4\tau_D} \quad (2)$$

Data analysis was performed by the EZ-C1 FreeViewer software, Gold Version 3.2, Nikon Corp.

It has been proposed that only a fraction of the solutes is mobile (f_m) and that the rest ($1 - f_m$) remains immobile and does not diffuse during the diffusion measurements.[36−38] The mobile fraction is related to the measured fluorescence before (F_i) and immediately after photobleaching (F_0) and at "infinite" time after recovery (F_∞) by the following expression:

DOI: 10.1021/acs.jafc.5b02401
J. Agric. Food Chem. 2015, 63, 6624−6632

$$f_m = \frac{F_\infty - F_0}{F_i - F_0} \quad (3)$$

Statistical Analysis. One-way analysis of variance (ANOVA) and Tukey's paired comparison test were applied to the diffusion coefficient data of the three casein systems (i.e., casein suspension, casein gel, and acid casein gel) to determine which mean values were significantly different from one another at the 95% confidence level. Results are presented with the mean value and standard deviation. The mean values of diffusion coefficients obtained were statistically compared using R software (version R i386 3.0.2) (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

Diffusion of FITC-Labeled Solutes in the Permeate. It was important to first check if there were interactions between the solutes and the components present in the permeate. This was tested by comparing diffusion behavior of solutes in the permeate with that in a buffered water with a similar ionic strength and pH.

Diffusion coefficient values of FITC-labeled solutes in the buffered water (D_∞) and in the permeate (D_{aq}) at 19 °C are given in Table 3. The hydrodynamic radii of the FITC-labeled solutes (Table 3) were calculated from diffusion coefficient values using the Stokes−Einstein equation

$$R_h = \frac{k_B T}{6\pi\eta D} \quad (4)$$

where k_B is the Boltzmann constant (1.38×10^{-23} J/K), T is the absolute temperature (K), and η is the viscosity of water (1×10^{-3} Pa s) or of the permeate (1.2×10^{-3} Pa s, according to Bouchoux et al.[49]).

The hydrodynamic radii of FITC-labeled solutes calculated from experimental diffusion coefficient values (Table 3) in buffered water were found to be in very good agreement with those found in the literature (Table 1). Moreover, the calculated hydrodynamic radii whether in the permeate or in the buffered water were very similar in all cases. These results showed that interactions between FITC-labeled solutes and the components present in the permeate (i.e., lactose, minerals, and free amino acids) can be considered as negligible, as previously reported for neutral FITC-dextrans and negatively charged FITC-labeled proteins.[17,18]

Table 3. Diffusion Coefficients of the Studied FITC-Labeled Solutes (Obtained by Using the FRAP Technique at 19 °C) and Their Hydrodynamic Radii in the Buffered Water and in the Permeate

FITC-labeled solute	D_∞[a] (μm^2/s)	D_{aq}[a] (μm^2/s)	R_h in water[b] (nm)	R_h in permeate[b] (nm)
FITC-D4	102 ± 5	94 ± 8	2.1 ± 0.1	1.9 ± 0.2

[a]Diffusion coefficients of FITC-labeled solutes in the buffered water (D_∞) and in the permeate (D_{aq}) determined by FRAP at 19 °C. The diffusion coefficient values of neutral FITC-dextrans, FITC-α-LA, and FITC-BSA were taken from a previous study.[18] Diffusion coefficients are given as the mean ± one standard deviation for 10 measurements. [b]Hydrodynamic radii of solutes calculated from the Stokes−Einstein eq (eq 4) and given as the mean value ± one standard deviation for 10 diffusion coefficient measurements.

Diffusion of FITC-Labeled Solutes in Casein Systems at pH 6.6. *FITC-Labeled Globular Proteins Are More Hindered than FITC-Dextrans.* Figure 1 shows the diffusion coefficients of (i) flexible and neutral FITC-dextrans (results from Silva et al.[50]), (ii) two rigid and negatively charged FITC-labeled proteins (FITC-α-LA and FITC-BSA), and (iii) one rigid and positively charged FITC-labeled protein (FITC-LYS) in both casein suspension and gel at pH 6.6. All values are presented as a function of the hydrodynamic radius of the FITC-labeled solutes. The net charge of each protein at the same pH (Table 2) is also given.

A key finding emerging from Figure 1 is that the FITC-labeled proteins were much more hindered in both casein suspension and gel than FITC-dextrans of a similar hydrodynamic radius. More specifically, the FITC-α-LA was 3 and 2 times more hindered (than the dextran of similar size) in the casein suspension and gel, respectively. For the FITC-BSA, diffusion was retarded by factors of 10 and 3 times in casein suspension and gel, respectively. The FITC-LYS was also more hindered (than the dextran of similar size) in both casein systems, being even more hindered than the FITC-α-LA and FITC-BSA proteins. These results show that the diffusion of rigid and charged proteins was more hindered than that of flexible and neutral dextrans in the casein suspension or gel.

Figure 1 also shows that the FITC-dextrans (FITC-D4, FITC-D10, and FITC-D20) as a group presented similar diffusion behaviors whether in the casein suspension or in the gel. Diffusion coefficients for both FITC-D4 and FITC-D10 are superposed in casein suspension and gel, and thus results are not distinguishable. On the other hand, the FITC-labeled proteins (FITC-α-LA, FITC-LYS, and FITC-BSA) were more hindered (by factors of 1.4, 3.4, and 2.5, respectively) in the casein suspension than in gel.

Cationic FITC-Poly-L-lysines and Anionic FITC-Dextrans Present the Same Diffusion Behavior as Neutral FITC-Dextrans. To study the influence of the charge of flexible solutes on their diffusion in casein systems, the diffusion coefficients of both neutral and charged flexible solutes were compared in the casein suspension and in the gel.

Table 4 sets out the diffusion coefficients in both casein suspension and gel (pH 6.6) of the charged flexible solutes (cationic FITC-PLL23, cationic FITC-PLL32, and anionic FITC-D70) and the neutral FITC-dextrans with a similar hydrodynamic radius.

The diffusion coefficients of both FITC-PLLs (FITC-PLL23 and FITC-PLL32) presented higher standard deviation values than for the other solutes. This fact could be related to the distribution of molecular weights of the FITC-PLLs.

Despite the variability, Table 4 shows that the diffusion coefficients of the positively charged solutes (FITC-PLL23 and FITC-PLL32) and that of the negatively charged one (anionic FITC-D70) are very similar when compared with those of neutral FITC-dextrans of similar hydrodynamic radius in both casein suspension and gel (Table 4).

Charged FITC-Labeled Solutes Present Higher Immobile Fractions than the Neutral Ones. Figure 2 shows that the

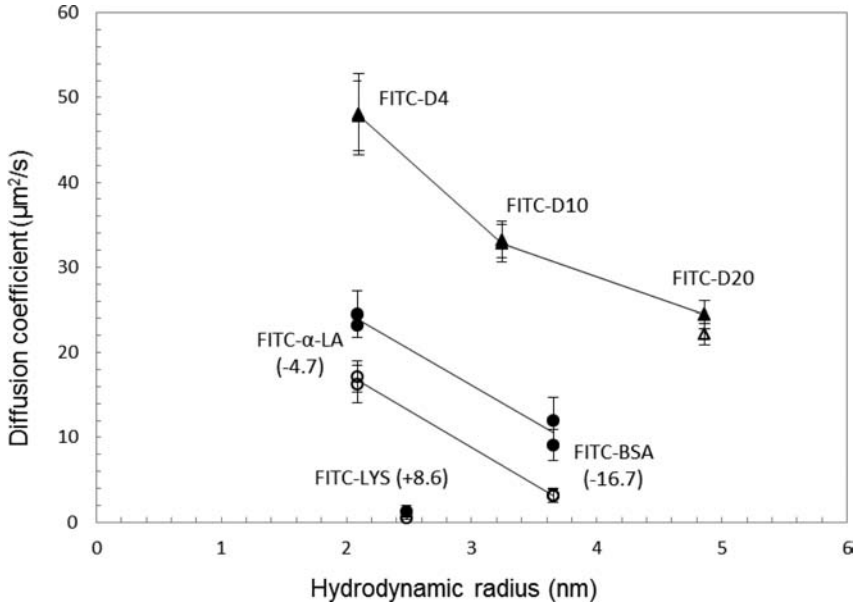

Figure 1. Diffusion coefficients of FITC-dextrans (△ in casein suspension and ▲ in casein gel) and FITC-labeled proteins (FITC-α-LA, FITC-LYS, and FITC-BSA) (○ in casein suspension and ● in casein gel) plotted as a function of their hydrodynamic radii. The diffusion coefficients of FITC-dextrans in these casein systems were taken from a previous work.[50] The net charge values at pH 6.6 were taken from Table 2. The solid lines are only guides to the eyes.

Table 4. Diffusion Coefficients of the Flexible FITC-Labeled Solutes in Casein Suspension and Gel (pH 6.6)

solute	R_h in water (nm)	D (μm^2/s) in casein suspension	D (μm^2/s) in casein gel
neutral solutes[a]			
FITC-D20	4.9 ± 0.3	22 ± 1	24 ± 2
FITC-D40	5.0 ± 0.2	13 ± 1	17 ± 1
FITC-D70	6.5 ± 0.2	9 ± 1	12 ± 1
charged solutes			
FITC-PLL23	4.7 ± 0.8	22 ± 8	22 ± 7
FITC-PLL32	5.6 ± 0.8	12 ± 8	13 ± 4
anionic FITC-D70	7.1 ± 0.1	9 ± 1	11 ± 1

[a]The diffusion coefficients of the neutral FITC-dextrans were taken from a previous study.[50] For the charged solutes, the diffusion measurements were carried out on two different samples of each casein system. Diffusion coefficients are given as the mean ± one standard deviation for 10 measurements.

immobile fractions of neutral FITC-dextrans are close to zero, irrespective of their molecular weight (over a range of 4−70 kDa). This observation was expected because neutral FITC-dextrans are not supposed to bind to the casein matrix in dairy systems.[17,18] However, the immobile fraction of all the charged solutes was >10% (except for the anionic FITC-dextran). Moreover, all of the positively charged solutes (FITC-PLL23, FITC-PLL32, and FITC-LYS) presented much higher immobile fraction values when compared with the negatively charged ones for diffusion in both casein suspension and gel.

Diffusion of FITC-Labeled Solutes in an Acid Casein Gel (pH 5.2). *FITC-Labeled Globular Proteins Are More Hindered than FITC-Dextrans.* To explore the charge effect of rigid solutes on diffusion in casein systems, the diffusion of the FITC-labeled proteins was also studied in an acid gel system at pH 5.2.

Table 2 lists the variation of the net charge of the FITC-labeled proteins as a function of the pH of the system. FITC-α-LA is less negatively charged at pH 5.2 than at pH 6.6. FITC-BSA is negatively charged at pH 6.6 and positively charged at pH 5.2. FITC-LYS is less positively charged at pH 6.6 than at pH 5.2.

Figure 3a shows that, in the acid casein gel, the diffusion of the FITC-labeled proteins was much more hindered (2.5 times for both FITC-α-LA and FITC-BSA and 14 times for FITC-LYS) than that of the FITC-dextrans of a similar hydrodynamic radius. These results are in agreement with findings in the casein suspension and gel (both at pH 6.6) discussed above and also with findings for a model cheese discussed in ref 18.

The diffusion coefficient of FITC-α-LA did not differ significantly in the casein gel (Figure 1) from that in the acid casein gel (Figure 3a), whereas the net charge of this protein was changed from −4.7 to −0.7. On the other hand, a slight increase of the diffusion coefficients values of FITC-BSA in the acid casein gel (protein charge = +10.7) compared with those in the casein gel (protein charge = −16.7) was observed. Furthermore, in the case of the positively charged FITC-LYS, an increase of the diffusion coefficient was observed in the acid casein gel.

Figure 3b shows that, as for the casein systems at pH 6.6 (Figure 2), FITC-labeled proteins present higher immobile fractions than FITC-dextrans of similar size in the acid casein gel. The immobile fractions of both FITC-α-LA and FITC-BSA were higher in the acid casein gel than in the casein gel at pH 6.6. On the other hand, the immobile fraction of FITC-LYS was lower in the acid casein gel.

■ DISCUSSION

Dextrans Diffuse More Rapidly than Proteins in Casein Suspensions and Gels. The present results highlighted that the diffusion of rigid and charged solutes (FITC-labeled proteins) was more hindered than that of flexible and neutral solutes (FITC-dextrans) in both casein suspension and gel at pH 6.6. This fact suggests that interactions between the

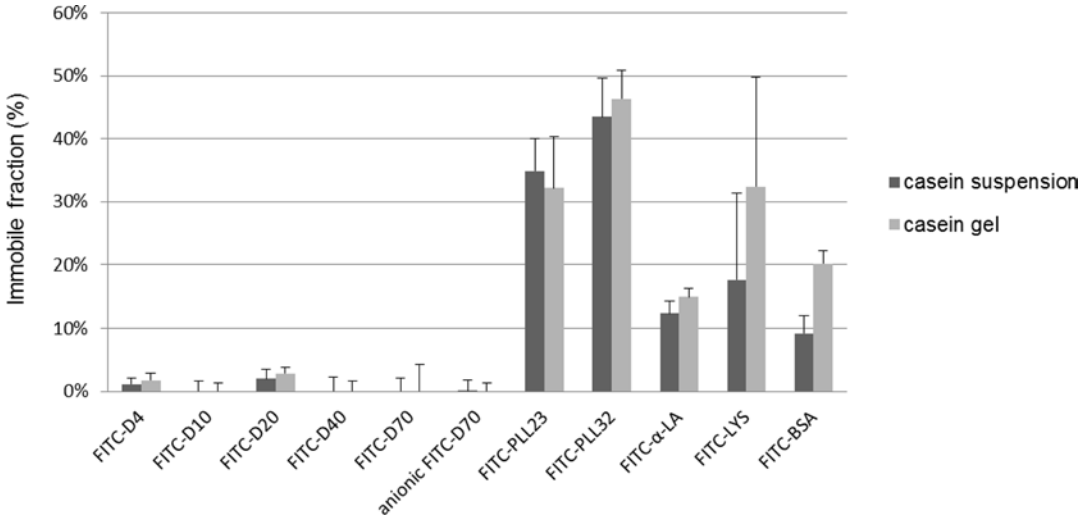

Figure 2. Calculated immobile fractions $(1 - f_m)$ of the diffusing FITC-labeled solutes in both casein suspension and gel (pH 6.6).

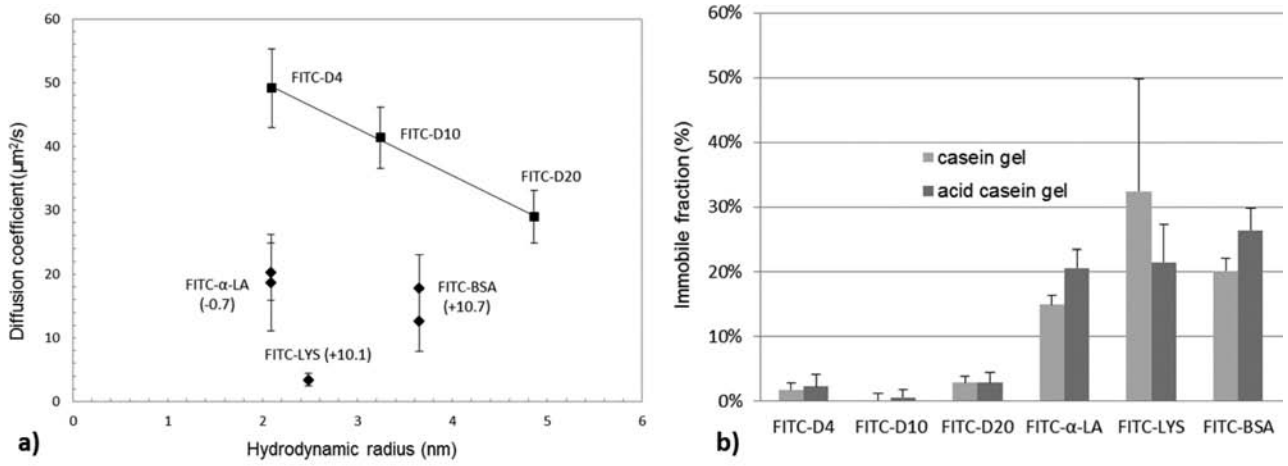

Figure 3. (a) Diffusion coefficients of FITC-labeled proteins (FITC-α-LA, FITC-LYS, and FITC-BSA) (◆) and FITC-dextrans (■) of similar hydrodynamic radius (FITC-D4, FITC-D10, and FITC-D20) in acid casein gel (pH 5.2). The solid line is only a guide to the eyes. (b) Immobile fractions $(1 - f_m)$ of FITC-labeled proteins and FITC-dextrans of similar size calculated from eq 3 in both casein gel (pH 6.6) and acid casein gel (pH 5.2).

diffusing proteins and the casein matrix exist. We will now discuss the possible nature of these interactions.

First, it is important to point out that any molecular interaction of hydrophobic origin was excluded by comparing the diffusion behavior of three different FITC-labeled proteins in two kinds of milk protein suspensions (see Figure SI-1 in the Supporting Information (SI)). The first suspension corresponds to the native casein suspension described under Material and Methods. The second suspension (UF-suspension in SI) corresponds to a heat-treated protein concentrate where whey proteins were also present. At temperatures >60 °C, whey proteins are known to denature and interact with themselves and with casein micelles, forming aggregates via hydrophobic interactions and disulfide bridging.[30] Consequently, these interactions can modify the surface hydrophobicity of the casein micelles in the heat-treated protein concentrate and should affect hydrophobic interactions between the matrix and the diffusing proteins. However, as shown in Figure SI-1, diffusion coefficients of the three FITC-labeled proteins did not differ significantly ($p < 0.05$) in both suspensions presenting casein micelles with different surface hydrophobicities. Moreover, it is unlikely that other types of forces such as van der Waals and London forces are involved because they are very short ranged.

Therefore, in the present study, we will discuss the different diffusion behaviors between dextrans and proteins on the basis of their specific physicochemical characteristics, such as the molecule charge (which could be responsible to electrostatic interactions) and/or molecule flexibility.

Immobile Fractions Are Related to Attractive Electrostatic Interactions between the Charged Solutes and the Casein Matrix. Higher immobile fractions were associated with electrostatic interactions between charged solutes and the casein matrix. The casein matrix is overall negatively charged in both casein suspension and gel at pH 6.6. In both systems, the immobile fraction of the charged solutes was higher compared with that of the neutral solutes, except for the anionic FITC-dextran. The anionic FITC-dextran, the only charged solute that has no positively charged groups in its structure, had an immobile fraction close to zero, as the neutral FITC-dextrans. The other charged solutes, even if their net charge is negative at pH 6.6 (such as FITC-α-LA and FITC-BSA), have positively

DOI: 10.1021/acs.jafc.5b02401
J. Agric. Food Chem. 2015, 63, 6624−6632

charged groups in their structure, which can then interact with the negatively charged casein matrix by electrostatic forces.

Moreover, the increase of the immobile fraction values for both FITC-α-LA and FITC-BSA in the acid casein gel compared with the casein gel strengthens the hypothesis of the existence of attractive electrostatic interactions between these diffusing proteins and the matrix. Electrostatic attractions were higher in the acid casein gel because these diffusing proteins are respectively less negatively charged and positively charged at pH 5.2 than at pH 6.6.

The higher immobile fractions of charged FITC-labeled proteins compared with neutral FITC-dextrans showed the existence of attractive forces due to electrostatic interactions between the positive charges of the diffusing proteins and the negative charges of the casein matrix. It is now important to investigate if this higher immobile fraction of the FITC-labeled proteins also accounts for the diffusion hindrance of these diffusing proteins (compared with dextrans) in both casein suspension and gel.

Electrostatic Interactions Are Not the Main Factor Hindering the Diffusion of Charged Solutes in Casein Systems. The initial hypothesis was that the diffusion of FITC-labeled proteins was more hindered in casein systems than that of FITC-dextrans because of electrostatic interactions between these charged diffusing proteins and the casein matrix, rather than because of the solute flexibility. This hypothesis was supported by recent results of Salami et al.,[51] who concluded that the solute flexibility did not influence their diffusion behavior in casein suspensions below the close-packing of casein micelles (estimated as 178 g/L).[49] They measured, using pulsed field gradient-NMR (PFG-NMR), that flexible PEGs and rigid dendrimers (both neutral) of similar size (R_h) presented similar diffusion behaviors in such suspensions.

The casein concentration of the casein systems studied here was also below the close-packing limit. This fact was confirmed in a previous work[45] in which we determined by image analysis of TEM observations that the mean pore sizes were around 120 and 150 nm in the casein suspension and gel, respectively. Thus, the spaces in which diffusion takes place are much larger than the diameter of the FITC-labeled solutes (largest solute ~14 nm of diameter).

We observed that the charge of flexible solutes did not modify their diffusion behavior either in the casein suspension or in the gel. We have shown that electrostatic interactions between these flexible charged solutes and the casein matrix exist, because a non-negligible fraction of FITC-PLLs solutes was shown to be immobile. However, even if a certain proportion of these solutes could not diffuse in the casein systems because of these interactions, their global diffusion rates were no more affected than those of the neutral solutes. This can be explained by the high ionic strength of the casein systems, which screened the electrostatic interactions between the charged solutes and the charged matrix.[25,26] Indeed, due to their mineral contents, the ionic strength of the aqueous phase of the casein systems is relatively high, around 0.1 M. At this ionic strength, the Debye screening length (κ^{-1}) is around 1 nm, which reflects the short-range of electrostatic interactions under these conditions.

If solute charge determined diffusion rate, it might be expected that FITC-α-LA, which is almost neutral (−0.7) at pH 5.2, has the same or similar diffusion behavior as the neutral FITC-dextran of similar size (FITC-D4) in the acid casein gel. FITC-α-LA was, however, 2.5 times more hindered compared with the FITC-D4 in this system.

To confirm this, we also compared the diffusion behaviors of solutes in both casein gel and acid casein gel, acidified to modify the net charge of the diffusing proteins. The microstructure of both gels, and not only the net charge of the diffusing proteins, is expected to be different, which could also influence the diffusion behavior of solutes.[50] Nevertheless, in the present study, the diffusion coefficient of FITC-D4 did not differ between these two casein systems, and the diffusion coefficients of both FITC-D10 and FITC-D20 were only 1.2 times greater in the acid casein gel when compared with the casein gel. Moreover, the diffusion coefficients of much larger FITC-dextrans ranging from 40 to 2000 kDa did not differ significantly ($p < 0.05$) between the casein gel and the acid casein gel (see Figure SI-2 in the SI). Therefore, the physicochemical characteristics of solutes influenced more the diffusion than the microstructure of the casein system itself.

The diffusion behavior of FITC-α-LA did not differ significantly between the casein gel and the acid casein gel. If diffusion were predominantly influenced by the solute charge, greater differences in the diffusion coefficients should be observed for FITC-α-LA when its charge changed from −4.7 (at pH 6.6) to −0.7 (at pH 5.2). Furthermore, at pH 5.2 the casein matrix itself is also less negatively charged than at pH 6.6. We expected that the FITC-α-LA was less hindered in the acid casein gel when compared with the casein gel because of the reduced interactions of electrostatic nature. The high ionic strength of the aqueous phase screened electrostatic interactions (see above), so this kind of interaction (due to the solute and matrix charge) is insufficient to explain diffusion behavior. Thus, the solute charge seems to influence less the diffusion than the solute flexibility in these casein systems.

The solute charge had no major influence on the diffusion in a high ionic strength. However, this effect can be pronounced when a rigid solute undergoes a major change on its charge or when specific electrostatic interactions are present. Indeed, in contrast to FITC-α-LA, which was negatively charged at both pH values, the effect of the pH change on the FITC-BSA charge was substantial, its net charge changing from −16.7 to +10.7. The slight increase of the diffusion coefficient values of FITC-BSA in the acid casein system (compared with the casein gel) was due to this major variation of its net charge. Similar results were found when diffusion coefficients of myoglobin (pI 6.8) were measured in agarose (neutral) and κ-carrageenan (negatively charged) at three pH values (2.0, 6.8, and 9.0).[25] These authors proposed that when the matrix repels the diffusing protein, the effective accessible space for the protein in the medium voids decreases.

Moreover, we observed that the diffusion of the positively charged FITC-LYS was much more hindered when compared with that of the negatively charged proteins in the casein systems. This fact is explained by the existence of specific interactions between the lysozyme and casein micelles as reported.[32,33] In a recent study, Anema and de Kruif[33] showed that in skim milk lysozyme penetrates the casein micelles (similar ionic strength compared with the casein systems in the current study) and binds to the more charged α_s-casein and β-casein. They showed that because lysozyme is a small protein (with a radius of about 2 nm), it diffuses into the casein micelle and effectively replaces counterions inside the micelles. This hypothesis was established by knowing the average mesh size of micelles, calculated to be 4.5 nm, which is comparable to the

DOI: 10.1021/acs.jafc.5b02401
J. Agric. Food Chem. 2015, 63, 6624−6632

diameter of the lysozyme. In the present study, the FITC-LYS diffused significantly more quickly in the acid casein gel (3.4 ± 1.0 $\mu m^2/s$) than in the casein suspension (0.5 ± 0.3 $\mu m^2/s$) and casein gel (1.2 ± 0.6 $\mu m^2/s$). It has been shown that the binding between the lysozyme and the casein micelles is less pronounced in acid conditions as a consequence of a reduced electrostatic interaction between the NH_3 group of lysines in the lysozyme and the ionized phosphate groups of the caseins in the casein micelles at low pH.[52]

Solute Flexibility Facilitates the Diffusion in Casein Systems. We showed that rigid solutes were more hindered than flexible solutes in casein systems. In agreement with our results, different diffusion behaviors were found for flexible and rigid solutes in other polymer systems even when the solute size was smaller than the pore size of the system.[24] This fact has been related by Seiffert and Oppermann[24] to solute dynamics; that is, flexible solutes present a high internal flexibility and dynamics compared with the rigid ones. When comparing the diffusion of solutes in casein suspension versus gel, we showed that flexible solutes had the same diffusion behavior, whereas the rigid ones were more hindered in the suspension compared to the gel. This fact is explained by the inherent dynamics of the casein system itself that influenced the diffusion of rigid solutes. The friction to diffusion caused by the motionless or immobile structure of the gel is less than the friction caused by the mobile structure of the suspension, as previously observed for larger FITC-dextrans ranging from 40 to 2000 kDa in casein systems,[50] in κ-carrageenan,[9] and in heat-set globular protein systems.[53] Seiffert and Opperman[24] suggest that the mobility of rigid solutes is solely determined by the structure and dynamics of the surrounding matrix, whereas for flexible solutes, their internal flexibility and dynamics will have a major and decisive influence. Therefore, the flexibility of solutes facilitates their diffusion in casein systems and represents the limiting factor of the solute diffusion in these systems. This factor was more important than electrostatic interactions between charged proteins and the casein matrix.

J. Agric. Food Chem. 2015, 63, 6624−6632

by more than one mycotoxin, mostly by AFs, T-2, and ZEN together.[10] An extensive study investigating the content of 35 mycotoxins in traditional Chinese medicines found 83% of the 60 tested, commercially available supplements to be positive and contain mainly AFs, trichothecenes, and ochratoxins (OTs), usually at levels of units or tens of micrograms per kilogram.[11] Different types of botanical-based dietary supplements were investigated by Di Mavungu et al., who analyzed set of samples containing mainly garlic, soy, radish, and maca.[12] From the 23 investigated mycotoxins, only FBs and OTA were detected in 10% of samples. Mycotoxin contamination has been also evaluated in dietary supplements made from green coffee, red rice, and ginkgo biloba. The following mycotoxin concentration ranges were determined in a study testing 34 mycotoxins in 50 commercially available green coffee supplement products: OTA, 2.7−136.9 μg/kg; ochratoxin B (OTB), 3.5−20.2 μg/kg; fumonisin B1 (FB1), 110.0−415.0 μg/kg; and mycophenolic acid (MPA), 43.1−395.0 μg/kg.[13] As concerns the red rice, Li et al. investigated the content of CIT in 109 samples, where 31 were positive, with CIT ranging from 16.6 to 5 253 μg/kg.[14] A study by Martinez-Dominguez et al. focused on gikgo biloba-based dietary supplements and investigated a set of 9 samples for 10 mycotoxins.[15] Six samples were contaminated with mycotoxins as follows: aflatoxin B1 (AFB1), 5−54 μg/kg; aflatoxin B2 (AFB2), 4−300 μg/kg; and T-2, 18−20 μg/kg. The details about all of the mentioned studies are summarized in the Supporting Information

Various conditions influencing the final quality of botanical-based dietary supplements are thoroughly discussed in a study of Sanzini et al.[16] In addition to potential contamination by mycotoxins, pesticide residues, and other environmental contaminants, other issues, such as addition of pharmacologically/psychotropically active compounds or adulteration with plants of different species, could potential threaten health of various herbal dietary supplements.

The aim of this study was to assess mycotoxin contamination in a unique set of botanical-based dietary supplements using ultrahigh performance liquid chromatography coupled to tandem mass spectrometry (U-HPLC-MS/MS) for the analysis of 57 mycotoxins. The evaluated products included dietary supplements supporting liver function (based on milk thistle); reducing menopause effects (red clover, flax seed, and soya); and supporting health in general (green barley, nettle, goji berries, yucca, etc.).

This pilot study provides interesting results about the co-occurrence of multiple toxins in these preparations and discusses the health risk associated with this phenomenon. Moreover, important questions related to the quality of the botanicals used in dietary supplements have been raised in this study, which could help to increase the quality requirements for the raw materials entering the dietary supplements production chain.

MATERIALS AND METHODS

Analytical Standards and Chemicals. Analytical standards of mycotoxins 3- and 15-acetyldeoxynivalenol (3- and 15-ADON); beauvericin (BEA); DON, deoxynivalenol-3-glucoside (DON-3-Glc); diacetoxyscirpenol (DAS); enniatins A, A1, B, B1 (ENN-A, ENN-A1, ENN-B, ENN-B1); fumonisins B1, B2, B3 (FB1, FB2, FB3); fusarenon X (FUS-X); T-2; HT-2; neosolaniol (NEO); nivalenol (NIV); ZEN; α- and β-zearalenol (α-ZEL, β-ZEL); tentoxin (TEN); agroclavine (A-clavine); ergocornine (E-cornine); ergocorninine (E-corninine); ergocristine (E-cristine); ergocristinine (E-cristinine); ergocryptine (E-cryptine); ergocryptinine (E-cryptinine); ergometrine (E-metrine); ergosine (E-sine); ergosinine (E-sinine); ergotamine (E-amine); ergotaminine (E-aminine); aflatoxins B1, B2, G1, G2 (AFB1, AFB2, AFG1, AFG2); altenuene (ATE); gliotoxin (GLIO); sterigmatocystin (STER); cyclopiazonic acid (CPA); CIT; meleagrin (MEL); MPA; OTA; patulin (PAT); paxilline (PAX); penicillic acid (PEN-Ac); penitrem A (PEN-A); roquefortine C (ROQ-C); verruculogen (Verruc); and stachybotrylactam (STACH) were purchased from Romer Labs (Austria). Analytical standards of mycotoxins alternariol (AOH), alternariol-methyl ether (AME), tenuazonic acid (TeA), and verrucarol (VER) were purchased from Sigma-Aldrich (United States). All the used analytical standards were certified by the manufacturers with defined purity (95.0−99.8%).

HPLC grade acetonitrile, ammonium acetate (≥99.0%), ammonium formate (≥99.0%), sodium chloride (>99.5%), and magnesium sulfate (>99.5%) were obtained from Sigma-Aldrich (United States). HPLC grade methanol and hexane were purchased from Merck (Germany), formic acid from Penta Chrudim (Czech Republic), and Bondesil-C18 sorbent from Varian (United States). Water was purified by a Milli-Q water system (Millipore, Germany).

Samples. Samples of dietary supplements based on various herbs or plants were collected from Czech and US retail markets. The detailed description of the preparations (matrix characterization, application form, recommended dosage, and the country of origin) is provided in the Supporting Information. Generally, the samples can be divided into three main groups: (i) 32 samples based on milk thistle, containing silymarin, intended to treat and maintain the health of liver; (ii) 9 samples based on red clover, soy, flax, and black cohosh, containing phytoestrogens and intended for reduction of menopausal effects; (iii) 28 samples based on other herbs and plants, e.g., green barley/wheat, nettle, goji, yucca, acerola, magnolia, guarana, orange peel, turmeric, black cohosh, bacopa monnieri, Chinese jujube, green tea leaf, boswellia serrate, containing various antioxidants and intended for general health improvement (immunity, vitality, cardiovascular system, brain functions, etc.).

Sample Preparation. Prior to the extraction procedure, the tested samples were properly homogenized. Seeds, dried leaves, and uncoated tablets were homogenized directly using a mill Grindomix GM200 (Retsch, Germany). In the case of wrapped capsules, only the inside part containing the herbal extract was used for the analysis (the empty capsule was removed and weighed for the purposes of follow-up results recalculation). Samples were processed by the QuEChERS-based (quick, easy, cheap, effective, rugged, safe) method published by Dzuman et al.[17] Representative sample (1.00 ± 0.01 g) was weighed into a 50 mL polytetrafluorethylene (PTFE) centrifuge tube (Merci, Czech Republic) and mixed with 10.0 mL of 1% aqueous formic acid. Matrix was allowed to soak for 30 min, followed by a 30 min extraction by shaking with 10.0 mL of acetonitrile using an automatic shaker HS 250 basic (IKA Labortechnik, Germany). After that, 1.00 g of sodium chloride and 4.00 g of magnesium sulfate were added and the tube was shaken again for 1 min by hand. After centrifugation (5 min at 15 800*g* using ROTINA 35R, Hettich, Germany), a 2.00 mL aliquot of the upper acetonitrile layer was taken for dispersive solid phase extraction (d-SPE) cleanup in a smaller PTFE centrifuge tube (15 mL) containing 100 mg of Bondesil-C18 sorbent and 300 mg of magnesium sulfate. The d-SPE tube was shaken by hand for 1 min and then centrifuged for 5 min (15 800g). An aliquot of the upper acetonitrile layer was microfiltered (0.2 μm PTFE microfilter, Alltech, United States) and transferred into a 2 mL PTFE autosampler vial (MicroSolv, United States).

For solid samples with high amount of fat (preparations formed as encapsulated oily paste), the sample (1.00 g) was first shaken for 5 min with 3.00 mL of hexane to solubilize the samples. After this step, the procedure described above was followed (i.e., addition of 1% aqueous formic acid and acetonitrile, shaking, addition of inorganic salts, shaking again, and d-SPE cleanup with Bondesil-C18).

Separation and Detection. Analyte separation and detection were performed using an U-HPLC-MS/MS system consisting of an ultrahigh performance liquid chromatograph (Acquity UPLC System, Waters, United States) coupled to a highly sensitive tandem mass spectrometer QTRAP 5500 (AB SCIEX, Canada). The chromato-

[a]Analysis of spiked samples at 500 μg/kg was performed in 7 replicates.

DOI: 10.1021/acs.jafc.5b02105
J. Agric. Food Chem. 2015, 63, 6633−6643

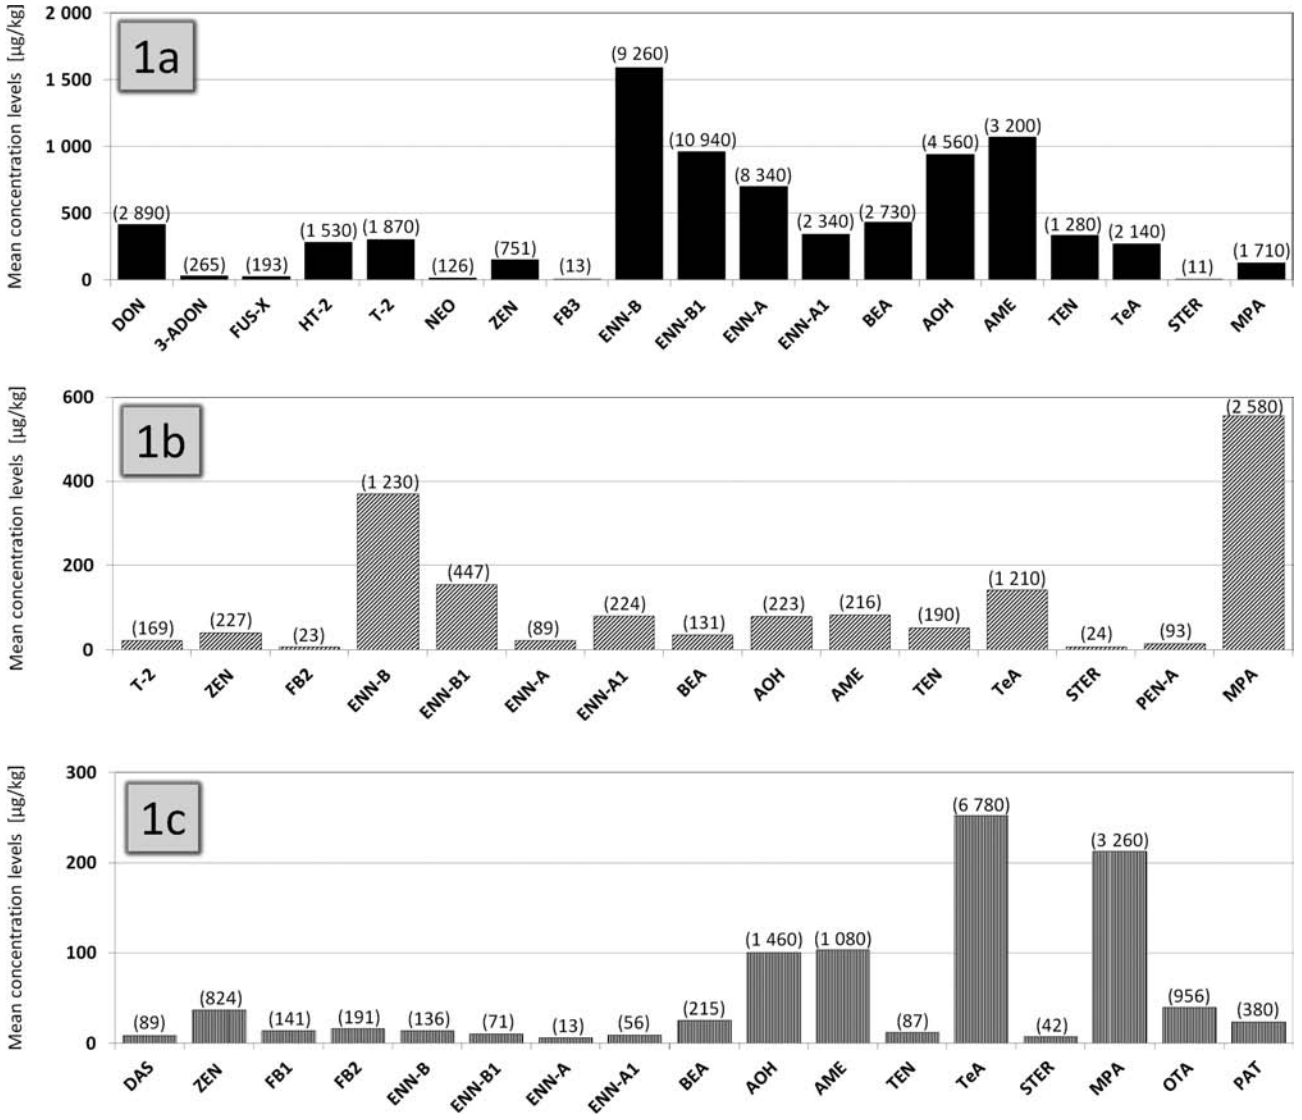

Figure 1. Mean concentrations of mycotoxins (µg/kg) determined in the tested dietary supplements: (a) milk thistle-based supplements, $n = 32$; (b) supplements for menopause effects treatment, $n = 9$; (c) supplements for the general health improvement, $n = 28$. Maximum concentrations are noted in brackets. 1/2LOQ of analytes was used for samples without findings. Abbreviations used: 3-ADON, 3-acetyldeoxynivalenol; AME, alternariol-methyl ether; AOH, alternariol; BEA, beauvericin; DAS, diacetoxyscirpenol; DON, deoxynivalenol; ENN-A, enniatin A; ENN-A1, enniatin A1; ENN-B, enniatin B; ENN-B1, enniatin B1; FB1, fumonisin B1; FB2, fumonisin B2; FB3, fumonisin B3; FUS-X, fusarenon X; HT-2, HT-2 toxin; MPA, mycophenolic acid; NEO, neosolaniol; OTA, ochratoxin A; PAT, patulin; PEN-A, penitrem A; STER, sterigmatocystin; T-2, T-2 toxin; TeA, tenuazonic acid; TEN, tentoxin; ZEN, zearalenone.

graphic separation was carried out with an Acquity UPLC HSS T3 column (100 × 2.1 mm i.d., 1.8 µm; Waters, United States). The working parameters of the separation−detection method were set according to Dzuman et al.:[17] column temperature, 40 °C; injection volume, 2.0 µL; and autosampler temperature, 10 °C. The mobile phases were different for ESI(+) and ESI(−) analyses. ESI(+) employed 5 mM ammonium formate and 0.2% (v/v) formic acid in Milli-Q water and in MeOH as mobile phases A1 and B1, respectively. In ESI(−), 5 mM ammonium acetate in Milli-Q water was used as the mobile phase A2 and pure MeOH as B2. The gradient was different in ESI(−) and ESI(+). In ESI(+), the initial composition of mobile phases was 10% (v/v) of B1 at 0.35 mL/min followed by a linear change to 50% B1 in 1 min, a slower linear gradient from to 100% of B1 in 8.5 min followed, simultaneously with flow change to 0.55 mL/min. The column was then washed for 2 min at 0.7 mL/min with 100% organic solvent and reconditioned for 2 min with 10% of B1 (0.35 mL/min). In ESI(−), the initial mobile phase composition was 10% of B2 at 0.35 mL/min followed by a linear change to 50% of B2 in 1 min. A linear gradient to 100% of B2 with linear increase of the flow rate to 0.5 mL/min in 6.5 min was followed by a column wash with 100% of B2 for 2 min at 0.7 mL/min. The column was then reconditioned for 2 min using the starting composition of the mobile phases at 0.35 mL/min.

The mass spectrometric detection was performed by QTRAP 5500 tandem mass spectrometer equipped with an electrospray (ESI) ion source operated in both positive and negative modes. The ESI(+) ion source parameters were as follows: needle voltage 4 500 V and turbo gas temperature, 500 °C. In ESI(−): needle voltage −4 500 V and turbo gas temperature 450 °C. Gas pressures were the same for both ESI(+) and ESI(−): curtain gas 241 kPa (35 psi), nebulizer and turbo gases 379 kPa (55 psi). Scheduled multiple reaction monitoring (MRM) methods were used in both ESI(+) and ESI(−) with the cycle time 0.6 and 1 s, respectively. Declustering potential (DP), collision energy (CE), collision cell exit potential (CXP), and particular MRM transitions of mycotoxins and all analyte-dependent parameters are summarized in the Supporting Information.

Method Validation. For validation of the method performance characteristics (recoveries, repeatabilities, and limits of quantitation,

DOI: 10.1021/acs.jafc.5b02105
J. Agric. Food Chem. 2015, 63, 6633−6643

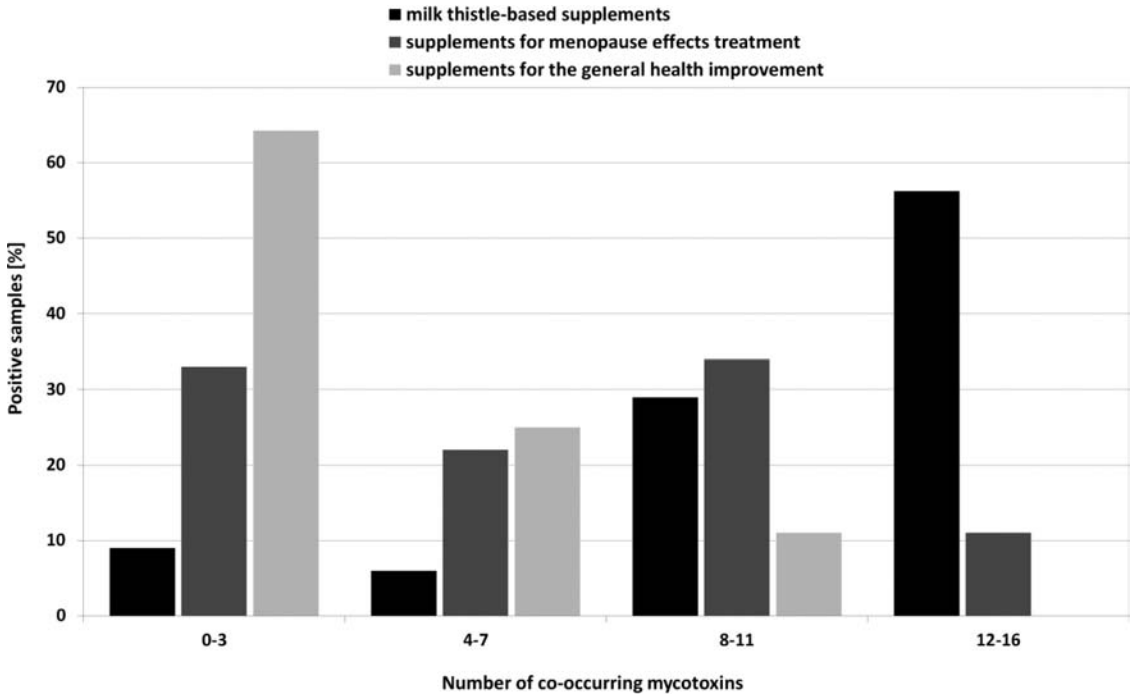

Figure 2. Histogram showing co-occurrence of mycotoxins in analyzed samples (black, milk thistle-based supplements, n = 32; dark gray, supplements for menopause effects treatment, n = 9; light gray, supplements for general health improvement, n = 28).

LOQs) we selected "blank" matrices with very low or no mycotoxin content, which also represented matrices with different chemical composition to verify the method rugedness. Based on these considerations, powdered milk thistle extract (sample 16), oil-based milk thistle preparation (sample 9), and dry nettle tea (sample 10) were used. The external matrix-matched calibration standards at levels 0.5, 1, 2, 5, 10, 25, 50, 100, and 200 μg/L (corresponding to 5−2 000 μg/kg in the sample) were prepared. The repeatability of the method expressed as a relative standard deviation (RSD) was assessed by analysis of spiked samples (mixed standard was added to the "blank" matrix before extraction at 500 μg/kg in seven replicates). LOQs were estimated as the lowest matrix-matched calibration standard levels which provided signal-to-noise ratio (S/N) higher than 10 at the quantifier and 3 at the qualifier ion transitions. For calculation of SSE (signal suppression/enhancement), matrix-matched calibration standards and solvent standards (acetonitrile) at 100 μg/L were used. Validation results are summarized in Table 1.

Quantitation of Mycotoxins in Real Samples. Because medical plant-based extracts used for dietary supplements production represent very diverse matrices, also the matrix induced ionization suppression/enhancement can be different for various mycotoxin/matrix combinations. To minimize potential bias in calculated results, the standard addition approach was chosen for quantitation, to compensate for matrix effects. The practical realization of the standard addition method was as follows. First, the set of samples was preliminarily screened and detected mycotoxins quantitated using generic matrix-matched standards (prepared using the "blank" matrix employed in the method validation). Then, the standard addition was performed by spiking the sample after extraction at three different concentration levels (referring to approximately 1 times, 3 times, and 5 times of the estimated concentration).

A calibration curve was created by plotting the added concentrations (x-axis) against the peak areas measured in samples with standard addition after extraction (y-axis). The native extract (without any standard addition) was included in the regression using a concentration of zero. The analyte concentration in the sample was calculated from the linear regression formula according to eq 1, where the "k" is the calibration curve slope.

$$c\ (\mu g/kg) = \mathrm{Area(sample)}/k \quad (1)$$

All the results were corrected for recovery calculated based on the standard added before and after the extraction procedure.

Arithmetic means of mycotoxins concentrations (presented in Figure 1 and the Supporting Information) were calculated using determined mycotoxin concentrations and, in the case of no detection, 1/2 of LOQ value (micrograms per kilogram) for a given mycotoxin (LOQs derived from the milk thistle powder matrix were used for capsules with dried powder and for tablets; LOQs derived from nettle tea matrix were employed for herbal teas; and LOQs derived from the oil-based milk thistle matrix were utilized for capsules with oil-based content).

Dietary Intake Calculation. Tolerable daily intake (TDI) values are set by the Health and Consumer Protection Directorate General of the European Commission for the following mycotoxins: 1 μg/kg body weight (bw) for DON, 0.1 μg/kg bw for the sum of HT-2 and T-2, 0.25 μg/kg bw for ZEN, 2 μg/kg bw for sum of FB1 and FB2, 0.12 μg/kg bw for OTA, and 0.4 μg/kg bw for PAT.[18] Overview of the above-mentioned TDIs is stated in Commission Regulation 1881/2006. For these mycotoxins, the percentage of TDI obtained by consumption of the tested dietary supplements was calculated. For the mycotoxin exposure calculation (in micrograms of the mycotoxin per kilogram of human bw), the average adult body weight (70 kg) and the recommended dosage of the particular dietary supplement declared by the manufacturer were considered.

RESULTS AND DISCUSSION

As dicussed in the Introduction, beside health-promoting biologically active components, also various contaminants, such as mycotoxins, may occur in botanical-based dietary supplements. Until now, only limitted information has been available on their presence. To get more comprehensive information on the mycotoxins pattern in this commodity, multianalyte method targeting altogether 57 toxic secondary fungal metabolites was employed for analysis of 69 samples obtained in the Czech and US market. Rather unexpectedly, almost 96% of all samples (66 of the 69) contained detectable mycotoxins. As shown in Figure 1 and the Supporting Information, 25 of 57 mycotoxins involved in the method scope were quantitated.

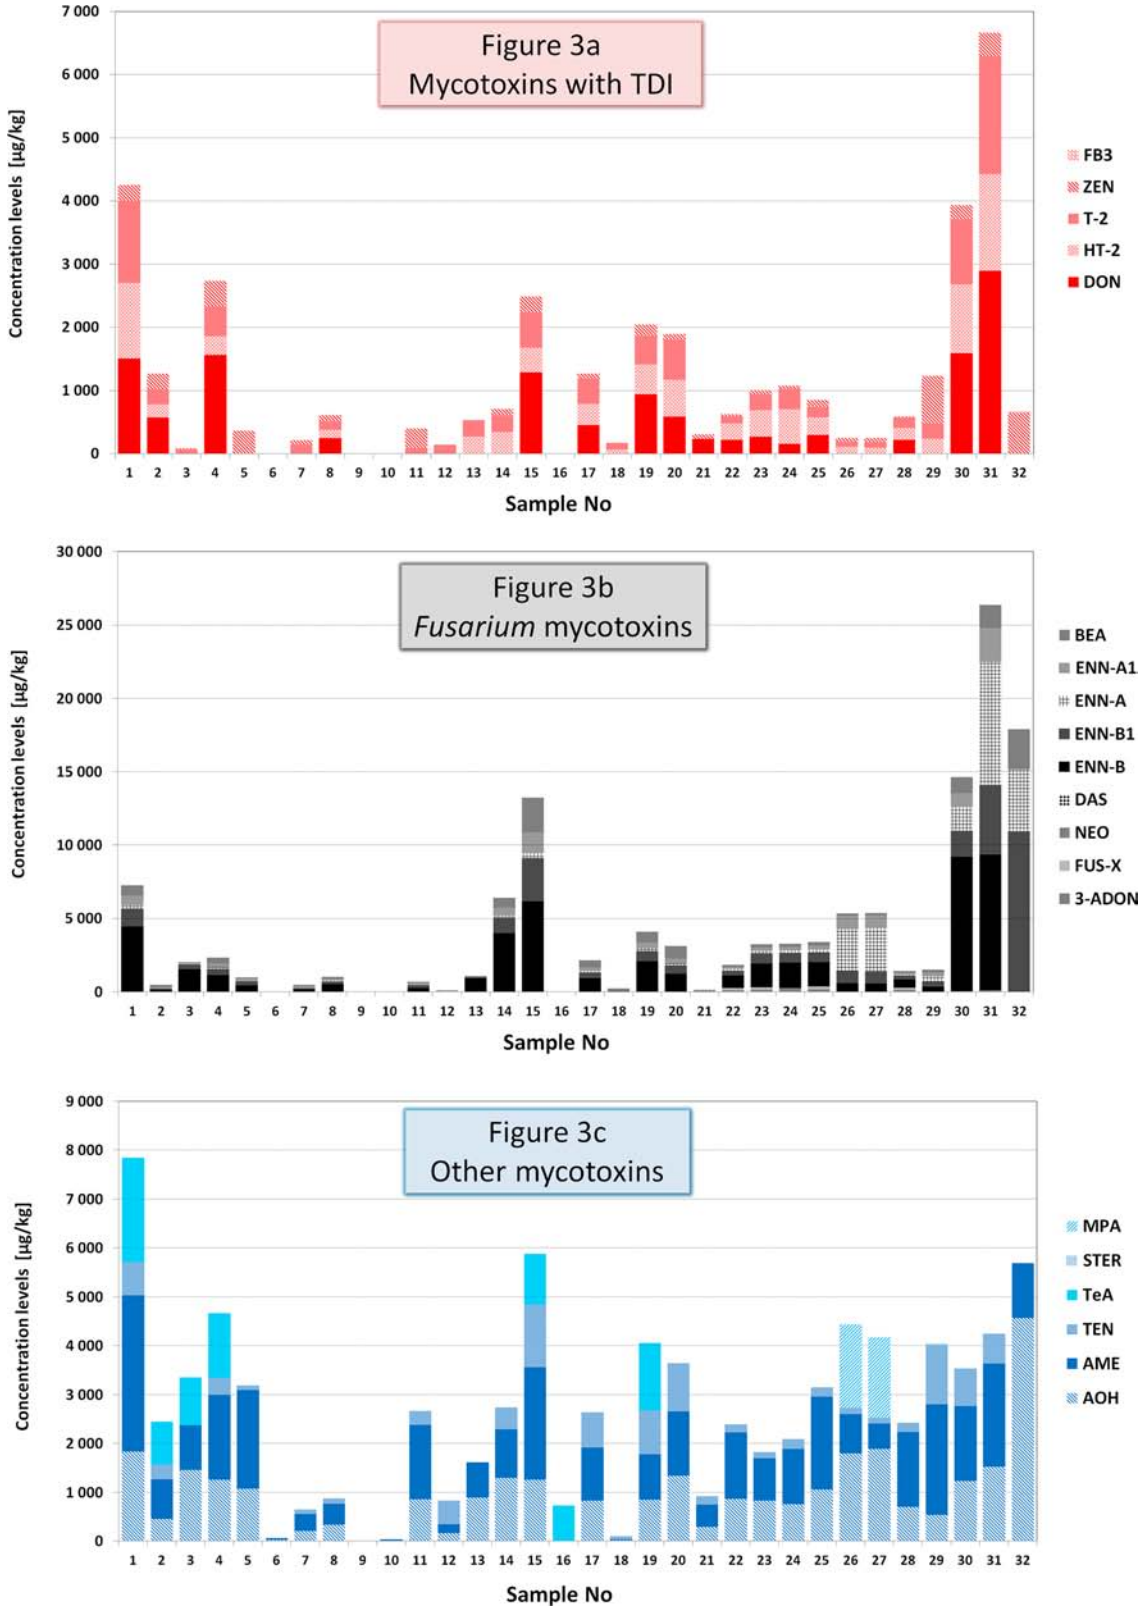

Figure 3. Concentration of mycotoxins (micrograms per kilogram) found in dietary supplements made from milk thistle: *Fusarium* mycotoxins for which the TDI has been established (a); other *Fusarium* mycotoxins (b); other *Alternaria*, *Aspergillus*, and *Penicillium* mycotoxins (c). Abbreviations used: 3-ADON, 3-acetyldeoxynivalenol; AME, alternariol-methyl ether; AOH, alternariol; BEA, beauvericin; DAS, diacetoxyscirpenol; DON, deoxynivalenol; ENN-A, enniatin A; ENN-A1, enniatin A1; ENN-B, enniatin B; ENN-B1, enniatin B1; FB3, fumonisin B3; FUS-X, fusarenon X; HT-2, HT-2 toxin; MPA, mycophenolic acid; NEO, neosolaniol; STER, sterigmatocystin; T-2, T-2 toxin; TDI, tolerable daily intake; TeA, tenuazonic acid; TEN, tentoxin; ZEN, zearalenone.

DOI: 10.1021/acs.jafc.5b02105
J. Agric. Food Chem. 2015, 63, 6633−6643

The highest incidence and concentrations were observed for *Fusarium* mycotoxins (DON, HT-2/T-2, ZEN, and enniatins, ENNs); *Alternaria* mycotoxins (AOH, AME, TEN); and MPA. The comments on the contamination of particular sample groups are discussed in detail below.

Milk Thistle-Based Dietary Supplements. Dietary supplements derived from the milk thistle were clearly the most contaminated samples from all three sample groups. As shown in Figure 1a and in the Supporting Information, in all of 32 tested samples at least one mycotoxin was present, and also the co-occurrence of more than one mycotoxin was very frequent as shown in Figure 2. The majority of the samples contained mycotoxins DON, ZEN, HT-2, and T-2. Moreover, a wide range of the newly emerging mycotoxins (other *Fusarium* mycotoxins such as 3-ADON, FUS-X, DAS; and NEO, ENNs, BEA; *Alternaria* mycotoxins such as AOH, AME, TEN; TeA; and several *Penicillium* and *Aspergillus* mycotoxins, from which the MPA was the most concentrated) were present. The frequency of occurrence of the highly abundant mycotoxins was 13−78% for trichothecenes, 78% for ZEN, 84−91% for ENNs, and 22−97% for *Alternaria* toxins. The average concentrations of trichothecene mycotoxins, ENNs, and *Alternaria* toxins were occurring typically in order of units of milligrams per kilogram (see Figure 3a−c and the Supporting Information). The highest concentration levels were observed for ENNs (2 340−10 900 μg/kg in samples 31 and 32), DON (2 890 μg/kg in sample 31), and AOH (4 560 μg/kg in sample 32).

As mentioned in the Introduction, high levels of mycotoxins in dietary supplements can be associated with the use of low-quality raw materials for their production. The low quality of the raw material could relate to nonoptimal or unsuitable conditions during plant growing, harvesting, and storage. On the basis of the results of mycotoxins in milk thistle-based dietary supplements determined in our study, we contacted several Czech and European milk thistle producers to communicate the potential health risk and possible reasons for such high contamination of milk thistle-based products. As we have learned, the critical point influencing the spreading of fungi on the milk thistle heads and seeds is the humidity during harvesting. Wet and humid weather is needed during the harvest because, under these conditions, the milk thistle heads are closed, and losses of achens (seeds) are thereby prevented. After the harvest, the proper drying to 12% humidity should be performed. The weather during the harvest and the postharvest drying were assessed as the critical parameters in several studies.[4,19,20] The truth is that only a small percentage of milk thistle intended for dietary supplements production is grown in Europe; the majority of the current commercial milk thistle production comes from Argentina and China. The European pharmaceutical companies or dietary supplements producers often purchase the "ready-to-use", dried ethanolic extracts.

Phytoestrogenic Dietary Supplements. Regarding the dietary supplements based on soy, red clover, flax seed, and black cohosh intended for menopause effects treatment, all of the nine examined samples were contaminated with at least one mycotoxin. The most frequently found mycotoxins included ENNs, *Alternaria* toxins, and MPA. Their incidence was 67−78% for ENNs, 11−67% for *Alternaria* toxins, 67% for MPA. However, the average concentrations of *Fusarium* and *Alternaria* mycotoxins in these preparations were approximately one or two orders of magnitude lower than those found in milk thistle-based preparations. The average concentrations of T-2, ENNs, AOH, AME, and TEN were in order of tens to hundreds of micrograms per kilogram. The mean concentration of TeA (143 μg/kg) exceeded the mean concentrations of other *Alternaria* mycotoxins 2-fold. Also, the *Penicillium* mycotoxins, PEN-A and MPA, were determined in the discussed supplements at average concentrations of 15 and 557 μg/kg, respectively. The highest concentration were detected for MPA (2 580 μg/kg, sample 6), ENN-B (1 230 μg/kg, sample 6), and TeA (1 200 μg/kg, sample 9). For detailed information about the sample contamination, see the Supporting Information.

As in the case of other plants and agricultural commodities, also the soy, red clover, flax seed, and black cohosh can be affected by fungi in the field, as well as during the storage, when the appropriate agricultural and manufacturing practices are not followed. The most important factors probably include application of fungicides, air humidity, and temperature during the harvest and water activity during the storage.

Other Dietary Supplements Intended for General Health Improvement. The last group of investigated samples included dietary supplements containing various antioxidants, based on a large number of different herbs and plants (green barley/wheat, nettle (*Urtica dioica* L.), goji (*Lycium barbarum* Mill.), yucca (*Yucca spp*. L.), boswellia (*Boswellia serrata* Roxb. ex Colebr.), acerola (*Malpighia glabra* L.), magnolia (*Magnolia* L.), guarana (*Paullinia cupana* Kunth ex H.B.K.), orange peel, turmeric root, black cohosh (*Actaea racemosa* L.), bacopa monnieri (*Bacopa monnieri* L.), Chinese jujube, and green tea leaves). From a total number of 28 samples, 25 of them were positive for at least one mycotoxin. Dietary supplements with a very low or no mycotoxin contamination were made of green wheat, green barley, acerola, and boswellia. Preparations based on nettle contained predominantly ENNs, BEA, AOH, TEN, and MPA at concentrations of tens up to hundreds of micrograms per kilogram (with the exception of nettle tea, sample 9, which was almost mycotoxin free). One sample of dried goji berry tea contained an extremely high concentration of TeA (6 780 μg/kg, sample 12), whereas no mycotoxins were detected in another sample of goji berry tea (sample 11). Regarding yucca-based preparations, only one sample from four investigated (sample 16) contained mycotoxins, ENNs (5−37 μg/kg) and *Alternaria* toxins (191−261 μg/kg). In the black cohosh sample (sample 18), rather high concentrations of FBs (110 and 101 μg/kg for FB1 and FB2, respectively), ZEN (45 μg/kg), and *Alternaria* toxins (123 and 129 μg/kg for AOH and AME, respectively) were determined. The main mycotoxins in an orange peel extract sample (sample 20) were FBs (141 and 191 μg/kg for FB1 and FB2, respectively). Turmeric powder samples (samples 24 and 25) contained mainly BEA (up to 215 μg/kg), FB2 (29 μg/kg), AME (27 μg/kg), ENN-B (5 μg/kg), NEO (8 μg/kg), and STE (11 μg/kg). In guarana bark powder (sample 26), BEA (21 μg/kg) and *Alternaria* toxins were found (169 and 106 μg/kg for AOH and AME, respectively). In the sample of Chinese jujube, magnolia bark, and green tea (samples No 23, 27, and 28, respectively), high concentrations of MPA were present (3 260, 1 380, and 304 μg/kg, respectively), and also very high levels of *Alternaria* toxins in the first two samples (samples 23 and 27). Magnolia bark (sample 27) contained 1 460 and 1 080 μg/kg of AOH and AME, and in Chinese jujube (sample 23), these two mycotoxins reached the concentration of 692 and 889 μg/kg, respectively. In bacopa monnieri-based sample (sample 21), 824 μg/kg of ZEN, 218 μg/kg of AME, and 956 μg/kg of OTA were determined.

[a]Values are calculated for a 70 kg person. [b]Provisional maximum TDI. [c]Tolerable weekly intake.

There are probably similar reasons for the mycotoxin contamination of raw materials used for production of these dietary supplements as in the previously described cases (i.e., weather conditions in the field and agricultural and storage management). The recommendation on keeping the good agricultural and manufacturing practices should be commonly applied.

Co-occurrence of Mycotoxins. We would like to emphasize that most of the samples were contaminated with multiple mycotoxins, i.e., more than one mycotoxin occurred in one sample. Figure 2 shows a histogram of multiply contaminated samples and demonstrates the relationship between the number of co-occurring mycotoxins and the dietary supplement type. For example, approximately 58% of milk thistle-based samples contained a "cocktail" of more than 12 mycotoxins together. On the other hand, a low number of co-occurring mycotoxins was determined for supplements made from green barley/wheat, nettle, goji, yucca, acerola, magnolia, guarana, orange peel, turmeric, black cohosh, bacopa monnieri, Chinese jujube, green tea leaf, and boswellia. Quite a high number of co-occurring mycotoxins was observed for supplements made from red clover, soy, flax, and black cohosh (preparations containing phytoestrogens); 22% of samples contained 4−7 mycotoxins, 33% of samples contained 8−11 mycotoxins, and 10.5% of samples contained more than 12 mycotoxins together in one sample. Interestingly, co-occurrence of mycotoxins representing various toxin classes was very common. The most frequent combination was *Fusarium* mycotoxins ENNs, HT-2/T-2, and *Alternaria* toxins (AOH, AME, TEN). The next very frequent combination was ENNs and *Alternaria* toxins (AOH, AME, TEN) and MPA. As discussed in several previous studies, the toxic effects resulting from the co-occurrence of multiple mycotoxins can be both additive and even synergistic, i.e., the overall toxicity might be even higher than the sum of individual toxicities.[21−23] From this point of view, the co-occurrence of mycotoxins may pose an underestimated toxicological hazard because the impact of mycotoxin "cocktails" on human health is currently unknown.

Mycotoxins and Legislation. As regards mycotoxins included in the EU legislation, OTA, PAT, DON, ZEA, FBs, HT-2, and T-2 were found in many samples in various combinations (for details see the discussion above).[18,24−27] AFs were not detected in the investigated samples. There are no maximum limits established for mycotoxins in dietary supplements in the EU. Nevertheless, when considering the concentrations determined in our study, we can point out that they often dramatically exceeded even the highest maximum limits established for other food commodities. For example, in the bacopa-based tablets, 956 μg/kg of OTA was found (see the Supporting Information). The highest maximum regulatory limit for OTA, which is set for the liquorice extract, is 80 μg/kg.[25] Therefore, the bacopa-based sample exceeded this level more than 10-fold. The other example can be given for the sum of HT-2 and T-2. The legislatively recommended maximum concentration level in cereals intended for human consumption is 200 μg/kg.[27] As shown in the Supporting Information, the sum of HT-2 and T-2 in 56% of the investigated milk thistle-based preparations exceeded this value up to 17-times. Of course, this comparison of the mycotoxin concentrations determined in dietary supplements with the maximum limits set for other food commodities is meant as approximate only because the maximum limits consider not only the toxicity but also the quantities of the food which is usually consumed. The best way to express the risk associated with the mycotoxins occurrence in this commodity is to calculate the daily exposure based on the recommended dosage of the particular dietary supplement and compare the calculated value with the tolerable daily intake (TDI) given by the regulations.[18] This exposure assessment is discussed in detail in the paragraph below.

Exposure Assessment. To assess possible health risk associated with mycotoxins occurrence, the mycotoxin daily intake, calculated based on the recommended dosage of the respective dietary supplement, should be considered. Table 2 provides the information about fulfilling the TDI (in %) for mycotoxins, for which the TDI level (in micrograms per kilogram of body weight) have been set.[18] The highest consumer exposure to mycotoxins occurs through the milk thistle-based preparations. Administration of the dose recommended by the manufacturers (usually, two capsules or tablets can cause fulfilling of up to approximately 50% of the TDI for the sum of HT-2 and T-2 (e.g., samples 1, 15, 18, 23, and 24 fulfilled the TDI of HT-2 and T-2 from 39, 52, 45, 57, and 75%, respectively). Considering the fact that the milk thistle preparations are mainly used by people who suffer from a liver disease, such high intake of immunotoxic, genotoxic, and hepatotoxic mycotoxins from the "health beneficial" preparations are of concern. Moreover, when taking into account high concentrations of mycotoxins co-occurring in cocktails, the toxicological impact might be even more serious.

On the basis of the results obtained from the analysis of mycotoxins in the set of botanical-based dietary supplements,

DOI: 10.1021/acs.jafc.5b02105
J. Agric. Food Chem. 2015, 63, 6633−6643

we can conclude that the preparations made from milk thistle were of the highest contamination; mycotoxin concentrations in the sum reached up to milligrams per kilogram. Effective communication of this topic with dietary supplement manufacturers and increased requirements on the quality of botanical-based raw material would be very helpful. The toxicological impact of many emerging mycotoxins is still unknown (especially when present in cocktails), and research focused on this topic should be performed. Nevertheless, considering the 75% fulfillment of the TDI for HT-2 and T-2 toxins at the recommended dosage of milk thistle preparations, it is obvious that the health risk problem should not be marginalized (especially for people who suffer from a liver disease).

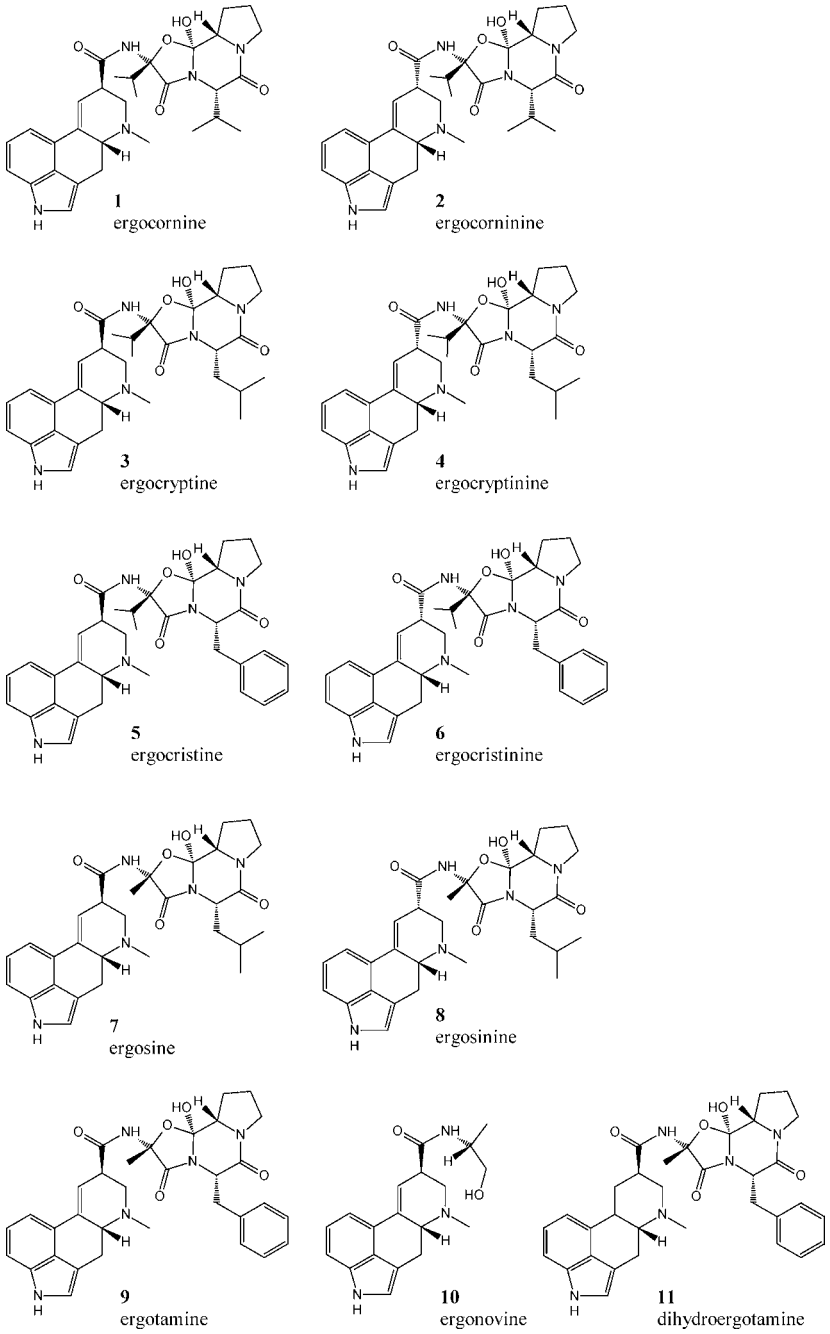

Figure 1. Structures of ergot alkaloid analytes and internal standard.

fine enough that ≥85% of mass passed through a U.S. 50 sieve (nominal sieve openings of 300 μm).

In addition, samples from shipments of western Canadian cereals were provided by CGC Industry Services inspectors. Grains sampled included wheat (n = 117), durum (n = 46), barley (n = 25), and rye (n = 1). These samples represented randomly selected export shipments of cereal grains that occurred between August 1, 2010, and July 31, 2012. It should be noted that the year of transport does not necessarily correspond to the year in which grain was grown and harvested. During the loading of the shipments, moving grain was sampled according to standardized procedures at a constant interval using CGC-approved automated cross-stream sample diverters and dividers.[12] The increments obtained during loading of a lot were combined into a composite sample that was considered to be representative of the entire lot. A Boerner divider (Seedburo Equipment Co.) was used to divide the composite sample into 10 kg laboratory samples. The 10 kg laboratory samples were stored at room temperature in canvas bags for up to 5 weeks until further preparation.

Test portions of the shipment samples were prepared from the 10 kg laboratory sample of whole grain according to the process described previously.[13] The 10 kg laboratory sample of whole grain was comminuted using a Retsch SR 300 rotor beater mill fitted with a 750 μm screen and coupled with a Retsch DR 100 vibratory feeder. After comminution, the entire mass of ground grain was homogenized and divided into 10 × 1 kg portions on a rotary sample divider (Materials Sampling Solutions, Southport, Australia). After the first division into 10 × 1 kg, all 10 portions were recombined in the RSD hopper and divided into 10 × 1 kg again. One 1 kg portion of ground grain was randomly selected and further divided on another RSD into 10 subsamples of 100 g of ground grain. Subsamples of 100 g were stored at room temperature in closed high-density polyethylene or polypropylene containers. The containers were not airtight, but were sealed to prevent the possibility of insects entering the samples.

Analysis of Ergot Alkaloids. Ten ergot alkaloids were included in the analytical method (Figure 1). Standards of individual analytes were obtained as crystals (Sigma-Aldrich, Oakville, Canada; Novartis, Dorval, Canada; Biopure, Tulln, Austria); purities ranged from 97 to 99%. Four of the alkaloids were *S* epimers of *R* enantiomers. The two epimers that were not included in the method were not easily obtained at the time of analysis. Dihydroergotamine (**11**, Fluka, analytical standard grade) was used as an internal standard for the analytical method.

A method based on that of Krska et al.[4] was developed for the extraction and ultrahigh-pressure liquid chromatographic−tandem mass spectrometric (UPLC-MS/MS) analysis of the 10 ergot alkaloids. Ground sample (10 g) was extracted with 50 mL of a 84:16 (v/v) acetonitrile/3.03 mM aqueous ammonium carbonate in 250 mL polyethylene centrifuge bottles. This mixture was shaken on a flatbed shaker for 30 min and then centrifuged at 2450*g* for 10 min at room temperature. A 464 μL aliquot of the supernatant was transferred to a glass test tube and mixed with 20 μL of internal standard solution (4 ng/μL dihydroergotamine in acetonitrile) and 1536 μL of 3.03 mM aqueous ammonium carbonate. Samples were vortexed to mix well and filtered using a disposable plastic syringe and PTFE syringe filter prior to injection.

Final extracts were autoinjected, with the autosampler tray held at 15 °C, and chromatographed on a 2.1 × 100 mm i.d., 1.7 μm, BEH C_{18} column (Waters) held at 30 °C on a Waters Acquity I-class UPLC. A gradient of two solutions (A = 3.03 mM ammonium carbonate and B = acetonitrile) was used to resolve the analytes. The mobile phase began at 80% A, changed to 20% A over 5 min, and returned to 80% A after a further 1 min. Analysis was performed using a Waters Xevo MS/MS in the positive electrospray ionization mode using multiple reaction monitoring. The source and desolvation temperatures were held at 150 and 500 °C, respectively, with the capillary at 0.50 kV and the extractor at 3.0 V. The cone, desolvation, and collision gas flows were 100 L/h, 700 L/h, and 0.15 mL/min, respectively.

To avoid epimerization of analytes, diluted standard mixes were dried down and kept in a freezer until needed. The dried mixes were reconstituted in acetonitrile just prior to instrumental analysis. Exposure to light was minimized, and samples and extracts were kept covered during processing and were placed in the UPLC sample manager with the illumination option turned off once diluted.

Analytes were considered to be positively identified and quantitated if their retention times were within 0.1 min of the average retention time of the corresponding analyte in the external calibration standards; the peak had a signal-to-noise ratio >9:1, and the ratio of qualification to quantitation ions was within acceptable tolerances.[14] The analyte responses were normalized to the dihydroergotamine responses during calculation of concentrations.

Blank samples fortified with a solution of standards and an in-house reference material were analyzed with each batch of samples and were used to monitor the performance of the analytical method.

RESULTS AND DISCUSSION

Validation and Method Performance. Validation of the analytical method was performed using fortified wheat and rye. Blank wheat and rye were created by hand-cleaning grain samples to remove ergot sclerotia. Even with this extra cleaning, some ergot alkaloids were still present in the blanks; therefore, during method validation concentrations of ergot alkaloids in the fortified samples were corrected by subtracting the concentration of analyte in the blanks prior to calculation of recoveries. Blank samples were fortified at three different concentrations and extracted and analyzed on multiple days. Seven replicates were fortified and extracted for each day/concentration combination: low (2 μg/kg ergonovine and 10 μg/kg other analytes), medium (41 μg/kg ergonovine and 200 μg/kg other analytes), and high (407 μg/kg ergonovine and 2000 μg/kg other analytes). To conserve standards, the *S* ergot alkaloid analytes were fortified only at the medium concentration.

During validation, separate sets of blanks were fortified with *R* and *S* ergot alkaloid analytes because a low amount of *S* enantiomers was found in the *R* enantiomer standard solutions. Ergosinine, ergocorninine, ergocryptinine, and ergocristinine were present at approximately 6% of the concentration of their analogues in the *R* enantiomer standard mix. Ergosine, ergocornine, ergocryptine, and ergocristine were also present in the *S* enantiomer standard mix, although at only about 2% of the concentration of their analogues. It was not clear if this was due to impurities in the analytical standards or due to epimerization during handling and use of the standard solutions over time. Both of these possibilities have been noted in the literature.[15] Because of this apparent "contamination", separate calibration standards were made for *R* and *S* enantiomers, and these were used in the validation and in all subsequent samples analyses.

The method produced good results with recoveries from individual ergot alkaloids in individual fortified samples ranging from 60 to 132%. The overall mean recovery ± standard deviation for all ergot alkaloids over all fortification concentrations and days was 83 ± 12% for wheat and 88 ± 15% for rye.

A comparison of individual ergot alkaloid peak areas from standard solutions prepared in solvent to postextraction fortified wheat and rye matrix matched standards indicated some enhancement of ergocorninine, ergocryptinine, and ergocristinine occurred due to matrix effects. The enhancement was somewhat higher for the rye matrix as compared to the wheat matrix (Table 1). The average ratio of ergot alkaloid peak area in matrix to solvent was 1.13 for wheat and 1.22 for rye. These averages are very close to the ratios observed for the internal standard dihydroergotamine in wheat (1.12) and rye (1.23). This similarity indicates that normalization of individual ergot alkaloid responses to the dihydroergotamine internal standard would mitigate matrix effects on the measurement of the sum total concentration of all 10 ergot alkaloids analyzed.

Table 1. Ratios of Responses for Ergot Alkaloids and Internal Standard in Wheat and Rye Matrix Extract As Compared to Solvent

	wheat	rye
ergonovine	1.05	1.05
ergosine	0.94	0.82
ergotamine	1.09	1.10
ergocornine	0.99	1.07
ergocryptine	1.05	1.12
ergocristine	1.07	1.19
dihydroergotamine	1.12	1.23
ergosinine	1.05	1.08
ergocorninine	1.28	1.40
ergocryptinine	1.34	1.55
ergocristinine	1.43	1.83

Limits of quantitation (LOQs) were 2 μg/kg for ergonovine and 10 μg/kg for the nine other ergot alkaloids. The LOQs were estimated as the lowest concentration to produce a chromatographic peak with a signal-to-noise ratio of at least 9:1 having an area that could be measured with good precision (i.e., a relative standard deviation of ≤20% for seven replicate injections).

Stability of Ergot Alkaloids during Sample Storage. An additional Canadian western rye sample was provided by CGC grain inspectors for use as an in-house reference material. This sample was ground and homogenized following the procedure used for the shipment samples described above.

The ground and homogenized sample was stored, and test portions were weighed prior to each run and analyzed to monitor for changes in ergot alkaloid concentrations during storage.

Portions of the in-house reference material were analyzed 27 times over a 10 month period. There was variation in the sum total ergot alkaloid concentrations over this period, but no overall decreasing or increasing tendency in sum total ergot alkaloid concentration was apparent. There were also no visible trends in individual ergot alkaloid concentrations or as fractions of the sum total ergot alkaloid concentrations over the storage period. The absence of trends in ergot alkaloid concentrations supports the appropriateness of storage at room temperature for ergot alkaloids in ground cereals.

Ergot Alkaloids in Harvest Samples and Grain Shipments. The amounts of ergot sclerotia determined in all 2011 CWAD and CWRS submitted to the CGC Harvest Sample Program are shown in Figure 2, along with results from other harvests between 2002 and 2013 for context. The number of samples inspected for the presence of ergot sclerotia each year ranged from approximately 3200 to 5000 for CWRS and from 820 to 2000 for CWAD. Figure 2 shows that the occurrence and severity of ergot infection (as shown by the percentage of samples downgraded due to ergot and the mean percentage of ergot in submitted samples, respectively) vary from year to year in both CWRS and CWAD. The mean percentages of ergot in 2011 were 0.030 and 0.026 for CWAD and CWRS, respectively. These means were both lower than in 2010; however, for CWRS the percentage of samples submitted to the CGC Harvest Sample Program that were downgraded due to the presence of ergot in 2011 was the highest between 2002 and 2013; for CWAD the second highest percentage of samples was downgraded in 2011. These data indicate that ergot was more widespread in 2011, even though the levels of infection in CGC Harvest Sample Program submitted grain were not the most serious that had been observed between 2002 and 2013.

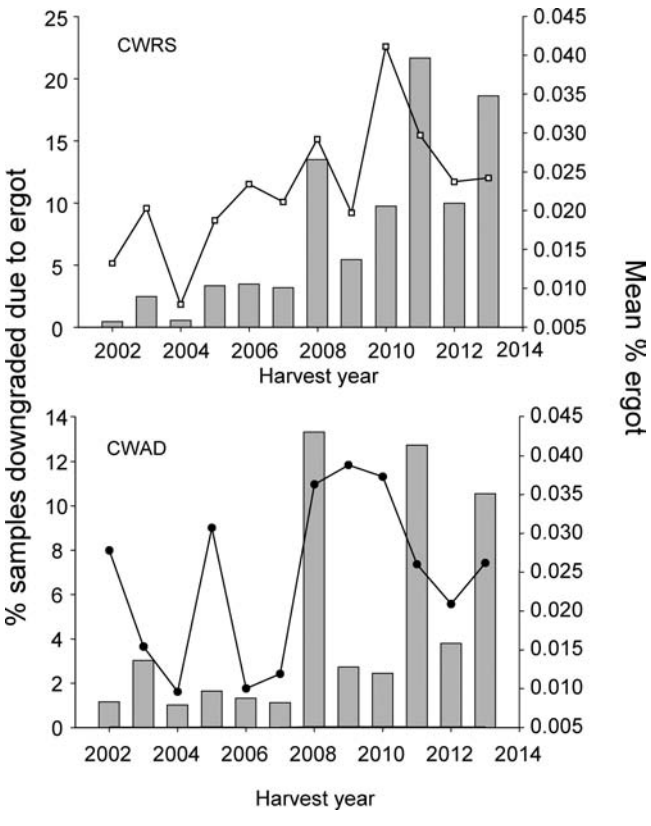

Figure 2. Occurrence of ergot in wheat (CWRS) and durum (CWAD) samples submitted to the Canadian Grain Commission Harvest Sample Program. The percentage of samples downgraded due to ergot is provided by the vertical bars, and the mean percent ergot observed in the samples is indicated by the line graph. Samples with no ergot sclerotia were set to 0 for the calculation of the annual mean percent ergot.

Overall, the data illustrated in Figure 2 suggest that the occurrence and severity of ergot infection in CWRS and CWAD have increased over the time period from 2002 to 2013. The incidence of ergot in the United Kingdom also increased during the mid-2000s.[16]

Changes in agronomical practices, such as the use of grass field margins and zero-tillage treatment of fields, have been implicated as factors contributing to the increase of ergot. Because burying ergot sclerotia prevents the release of ascopores and subsequent infection of flowering cereal plants,[17] zero-tillage practices result in more inoculum on the field. The adoption of zero tillage in the Canadian Prairie provinces grew during the 2000s. From 2002 to 2008, the percentage of area in zero tillage increased from about 35% to 55%.[18] Field margins act not only as a reservoir for *C. purpurea* inoculum but as a local source of secondary inoculum as well. Bayles et al.[16] reported a higher risk of ergot infection to wheat mainly at the edges of wheat fields due to secondary inoculum from infected grasses in field margins. These practices would affect the presence of ergot in addition to environmental factors such as precipitation, temperature, and soil conditions,[19] which have also been implicated as affecting ergot in cereals.

Total concentrations of ergot alkaloids in CWAD and CWRS harvest samples from 2011 are shown in Figure 3. Concentrations of sum total ergot alkaloids in the harvest

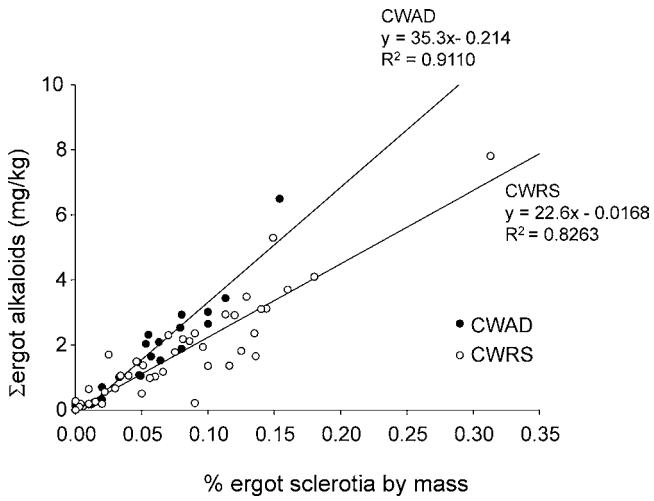

Figure 3. Relationship between the amount of ergot sclerotia and ergot alkaloids in Canada Western Amber Durum (CWAD) and Canada Western Red Spring (CWRS) samples from the 2011 harvest.

DOI: 10.1021/acs.jafc.5b02977

Table 2. Total Concentration of 10 Ergot Alkaloids Quantitated in Cereals Shipped between August 1, 2010, and July 31, 2012

grain	n	n > LOQ[a]	mean ΣEA (mg/kg)	median ΣEA (mg/kg)	range ΣEA (mg/kg)	90th percentile ΣEA (mg/kg)
wheat	117	117	0.229	0.195	0.012−0.666	0.399
durum	46	46	0.225	0.193	0.040−0.584	0.406
barley	25	21	0.065	0.047	<0.002−0.149	0.149
rye	1	1	1.138			

[a]Limit of quantitation of most sensitive analyte ergonovine, 2 μg/kg.

samples ranged from < LOQ to 7.81 mg/kg and were generally higher than the sum total ergot alkaloids observed in cereal shipments (Table 2). The maximum sum total ergot alkaloids in cereal shipments was in the rye sample at 1.14 mg/kg. The higher concentration in rye is not unexpected because it is particularly susceptible to infection by *C. purpurea* as it is a cross-pollinator with large open florets.[5]

The lowest mean sum total ergot alkaloid concentration was in barley shipments, which mainly represented grain selected for malting. It is not clear from these results if the low sum total ergot alkaloid concentrations observed are due to less ergot infection in barley or to a more thorough cleaning of barley prior to export for use as malt. There were no significant differences between the sum total ergot alkaloid concentrations measured in wheat and durum.

The wider range of sum total ergot alkaloid concentrations in the harvest samples is not unexpected, due to the nature of the samples and the design of the research. The 2011 harvest samples were not cleaned to remove contaminants such as ergot sclerotia prior to analysis. They were also selected to include grain with high levels of ergot infection to examine the relationship between sum total ergot alkaloid concentrations and percent ergot sclerotia, whereas the cereal shipments analyzed represent grain that had been graded and cleaned. The use of color sorters or mechanical methods including sieving[5] in grain-handling facilities can remove contaminants such as ergot sclerotia.

There are few studies in the literature regarding ergot alkaloids in raw grain. Two studies that do present data on the occurrence of ergot alkaloids in unprocessed cereal grains did not analyze the same 10 analytes that were included in this study; therefore, an in-depth comparison of results is not possible. Martos et al.[20] reported the presence of ergocornine and ergotamine in only 10% of eastern Canadian wheat samples analyzed. However, total concentrations of these two ergot alkaloids ranged from 0.076 to 0.638 mg/kg. Considering that the analysis did not include the predominant alkaloids ergocristine and ergocristinine, and assuming the pattern of occurrence of individual ergot alkaloids is consistent, the eastern wheat samples appear to contain higher levels of ergot alkaloids than in the western grain shipments, but the levels are consistent with the harvest samples analyzed in the current study. Uhlig et al.[21] reported lower average concentrations of 0.058 and 0.049 mg/kg for the sum of eight ergot alkaloids in Norwegian wheat and barley delivered to mills.

Ergot Alkaloid Patterns in Grain. The relative amounts of individual ergot alkaloids present in the wheat and durum shipments, as well as the harvest samples, are shown in Figure 4. The relative amounts were calculated as the fraction of an individual alkaloid concentration as compared to the sum total ergot alkaloid concentration. For the shipments, ergocristinine was the predominant alkaloid at a fraction of 0.39, followed by ergocristine (0.28) and ergotamine (0.10). The ergocristine/inine and ergotamine/inine pairs were the most abundant

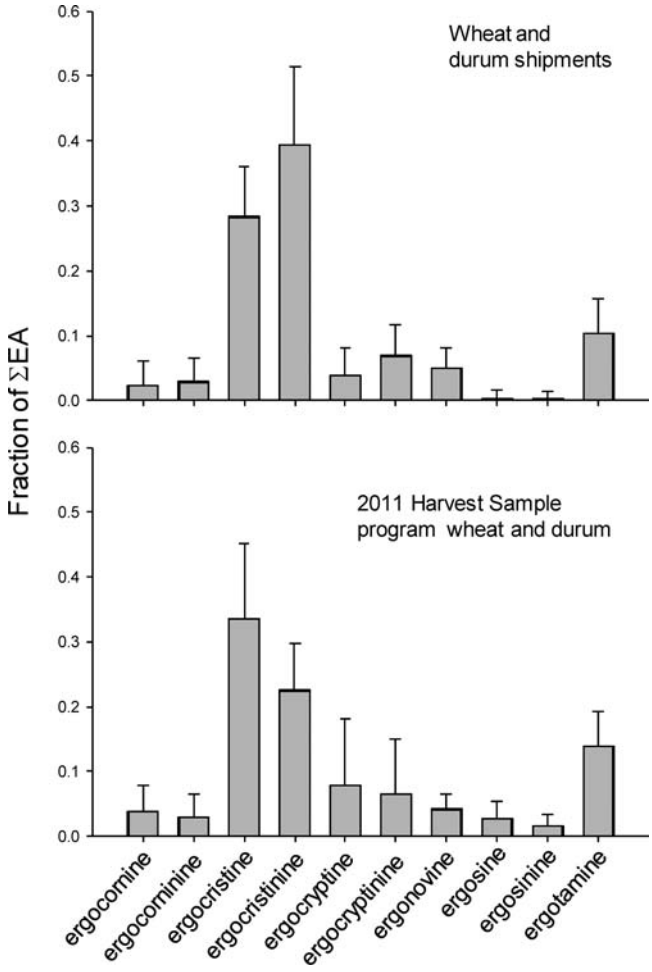

Figure 4. Ergot alkaloid patterns observed in shipments (n = 163) and harvest samples (n = 65) of wheat and durum. Bars represent the mean of each alkaloid as a fraction of the total concentration of ergot alkaloids (ΣEA); error bars indicate the standard deviation. Results less than the limit of quantitation were set to 0 for calculations.

alkaloids observed in sclerotia from Canadian wheat.[22] The pattern observed for the wheat and durum shipments was also very similar to those for barley and rye shipments (data not shown). Young and Chen[23] also noted a similarity in ergot alkaloid patterns among rye, wheat, and barley ergot sclerotia from grains grown in western Canada.

The pattern observed in the harvest samples differed slightly from the grain shipments. In the harvest samples for all *R* and *S* enantiomeric pairs, the *R* enantiomers were present at higher mean fractions of total ergot alkaloid than their epimers. Most noticeably, ergocristine rather than ergocristinine was the predominant alkaloid at a fraction of 0.32. The second most abundant alkaloid was ergocristinine (0.23). In the grain shipment samples, ergocornine, ergocristinine, and ergocrypti-

DOI: 10.1021/acs.jafc.5b02977
J. Agric. Food Chem. 2015, 63, 6644−6650

nine were all at higher mean fractions than their corresponding enantiomers.

The harvest samples can be considered to be "fresher" samples, as they were not stored as long prior to analysis as compared to the shipment samples. The shipment samples were stored for at least a year prior to analysis. In addition, the grain in the shipment samples would have been stored for an additional period on the farm and in grain-handling facilities prior to shipment. Potentially, a number of years could have passed between harvest and analysis of the grain in the shipment samples. During this time, epimerization could have occurred, thereby transforming the *R* enantiomers into *S* enantiomers. Such a change has been observed for sclerotia stored for several years; older sclerotia contained a higher percentage of *S* enantiomers as compared to sclerotia stored for a few months (36 vs 20%).[24]

The predominance of ergocristine/inine in the Canadian cereal samples and the consistency of the predominance across the various cereal grains differ from reports of ergot alkaloid patterns observed in other studies. In cereal-based food and feed in Europe, ergocryptine was reported as the predominant ergot alkaloid in rye and wheat-based food and rye feed, whereas ergosine was the most abundant compound in wheat feed.[25] Ergotamine was predominant in rye sclerotia from Australia,[24] and ergocornine and ergosine were predominant in wheat sclerotia from England.[16] The differences observed in ergot alkaloid patterns likely reflect variation in production by *C. purpurea* strains among host plants,[5,16] epimerization, and other transformations under field, storage, and processing conditions.

Relationship between the Presence of Ergot Sclerotia and Ergot Alkaloids in Grain. Figure 3 illustrates the relationship observed between the percentage of ergot sclerotia and sum total ergot alkaloid concentration in CWAD and CWRS samples from one growing season. The sum total ergot alkaloid concentrations increase with an increase in the percentage of ergot sclerotia present in a sample, with the relationship for CWRS significantly different from CWAD (parallel lines analysis; $p = 0.005$). The steeper slope of the CWAD relationship may indicate that durum is more susceptible to infection or production of ergot alkaloids when infected or that it is grown in areas with more virulent and/or toxigenic strains of *C. purpurea* as compared to CWRS. Differences in host resistance to ergot sclerotia production, as well as differences in the ability of various *C. purpurea* strains to elicit production of sclerotia, have been reported for wheat.[5,16] Variation in total ergot alkaloid concentrations in wheat sclerotia are also seen among fields and broader geographic regions.[22,26]

Even though studies have reported variation in sum total ergot alkaloid concentrations in sclerotia, the relationships observed between percentage of ergot sclerotia and sum total ergot alkaloid in CWAD and CWRS are strong. The relationships support the use of ergot sclerotia percentage as a tool to manage the presence of ergot alkaloids in wheat and durum. Figure 5 illustrates a comparison of sum total ergot alkaloid concentrations among wheat and durum shipments of various grades. Even though these grades were based on a number of grading factors and not just the presence of ergot sclerotia, the median sum total ergot alkaloid concentration of the lowest quality shipments (feed) was significantly higher than that of the highest quality grades (1 and 2). Changes to the Canadian grading tolerances for ergot are not expected to result in sizable changes to ergot alkaloid concentrations in future shipments, as the new grading tolerances are the same as those recently used for CWAD and CWRS grades 3 and 4.

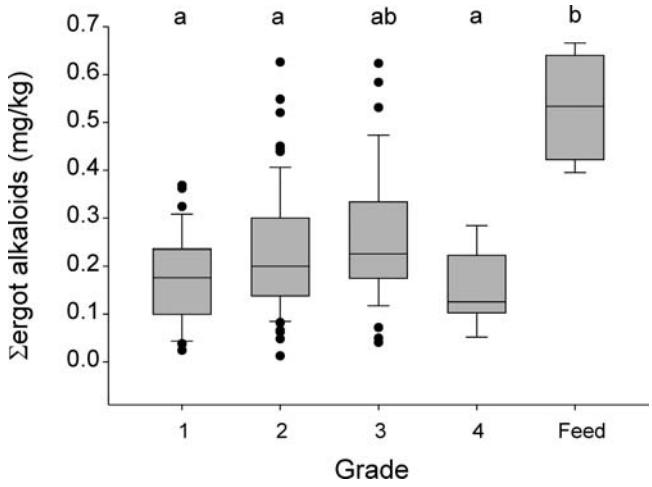

Figure 5. Sum of 10 ergot alkaloids in various grades of wheat and durum shipments. Median concentrations are indicated by horizontal lines in the boxes encompassing the 25th−75th percentiles. Whiskers indicate the 90th and 10th percentiles. Outliers in the 95th and 5th percentiles are indicated by dots. Unique letters indicate that median concentrations are significantly different among grades (Kruskal−Wallis one-way analysis of variance on ranks).

Correction to Neutral Pectin Side Chains of Amaranth (*Amaranthus hypochondriacus*) Contain Long, Partially Branched Arabinans and Short Galactans, Both with Terminal Arabinopyranoses

Daniel Wefers, Catrin E. Tyl, and Mirko Bunzel*

J. Agric. Food Chem. **2015** (2), 707−715. DOI: 10.1021/jf505283x

From our previous experiments, we assigned α-L-arabinopyranose as the terminal sugar unit of disaccharide **A-II2**. However, further purification of compound **A-II2** for its use as an analytical standard compound, followed by HPAEC monosaccharide analysis, yielded xylose and arabinose in equal amounts. Determination of the D/L configuration confirmed the presence of D-xylose. Because the NMR data are in good agreement with values obtained for terminal β-D-xylose, we now conclude that compound **A-II2** contains β-D-xylopyranose and not α-L-arabinopyranose. However, because this oligosaccharide was released due to *endo*-arabinanase treatment, it may be a new structural element of arabinans with similar impact as the originally published structure.

A more appropriate title for this publication would be "Neutral Pectin Side Chains of Amaranth (*Amaranthus hypochondriacus*) Contain Long, Partially Branched Arabinans and Short Galactans with Terminal Arabinopyranoses".

Most of the sections referring to substitution of arabinans by arabinopyranoses are also correct for xylopyranoses; the more specific discussions about the arabinopyranoses are irrelevant now.

A revised version of Figure 1 is provided below.

dual effect of GME (i.e., antimicrobial and PDI) could be involved in tobacco plant protection against *Ppn*.

MATERIALS AND METHODS

Biological Compounds and Chemicals. The GME is a *Vitis vinifera* L. extract provided by Grap'Sud (Cruviers-Lascours, France). Its pesticide (<1 ppm), heavy metal (<3 ppm), and bacterial (*Escherichia coli*-free, *Salmonella*-free, and total coliform-free) contents were certified by the manufacturer. Lot LPb123281703 used in our experiments was produced by water extraction containing SO_2 followed by concentration. The aqueous end-product contains 23.6% DW with <1000 ppm of SO_2. GME is produced from the postharvest grape marc of several red wine varieties (e.g., Merlot, Syrah, Carignan, Grenache, Cabernet, and Alicante) cultivated in southern France. The partial characterization of GME indicated that the winery byproducts from red grapes consist mainly of polyphenols (PP) including anthocyanins, a low amount of soluble sugars, and no detectable salicylic acid, jasmonic acid, or *trans*-resveratrol.[11,14] The GME used here came from the 2012 grape harvest, and the water-extracted product contains 35% PP of the dry matter with 2% anthocyanins (as specified by Grap'Sud). GME diluted in ultrapure water to reach 0.19% PP concentration is an acidic solution at pH 3.2. Salicylic acid (SA) was purchased from Sigma (St-Quentin-Fallavier, France).

Plant Material and Treatments. The biological activity of GME was assayed on 8-week-old wild-type tobacco plants (*N. tabacum* L. var. Samsun NN) and NahG transgenic plants (NahG8 line[16]) carrying the *NahG* gene, which encodes a bacterial salicylate hydroxylase. NahG seeds were generously provided by M. Ponchet (INRA, Sophia Antipolis, France). Plants were grown in a growth chamber at 22 °± 5 °C with a 16 h photoperiod. GME was infiltrated as an aqueous solution on foliar tissue using a plastic syringe. As routine protocol, 50 μL was infiltrated until the solution was spread across a 1−2 cm^2 leaf area. Three leaves per tobacco plant were infiltrated with GME at 0.19% PP, and GME was serially diluted prior to use for dose-dependent experiments. Leaves were infiltrated with 2 mM SA for the positive control and with acidic water (pH adjusted to 3.5 with acetic acid) for the negative control. Macroscopic symptoms were examined under bright-field (white light from 60 W bulb) or UV light (at 312 nm). Fluorescent areas were measured using Optimas 6.1 software.

Quantitative Real-Time RT-PCR. Leaf tissue was collected from whole limb infiltrated in 20 areas covering the whole limb of the three most basal leaves without chlorotic symptoms. Total RNA was extracted from 200 mg of leaves using CTAB extraction buffer as described by Chang et al.[17] The purified total RNAs were treated with 1 U of DNase I solution (Euromedex, France) containing 40 U of RNase inhibitor (Euromedex, France) to remove DNA contamination. RNA purity and concentration were measured at 260/280 nm using a NanoDrop-1000 spectrophotometer (Thermo Scientific, Villebon-sur-Yvette, France). RNA integrity was verified on a 1% agarose gel by detecting rRNAs. First-strand cDNA was synthesized from 1 μg of total RNA using Euroscript Reverse Transcriptase (Eurogentec, France) according to the manufacturer's instructions. PCR reactions were prepared using the qPCR Mastermix kit for SYBR green (Eurogentec, France) following the manufacturer's protocol. Reaction mix consisted of SYBR green-containing buffer (7.5 μL), forward primer (1 μL, 100 nM), reverse primer (1 μL, 100 nM), and template (2.5 μL, 0.1 ng). The three-step protocol PCR conditions were as follows: initial denaturing at 94 °C for 5 min, followed by 40 cycles of denaturing at 94 °C for 20 s, annealing at 55/59 °C for 20 s and polymerization at 72 °C for 20 s. Quantitative assessment of mRNA levels was performed using an iCycler iQ5 (Bio-Rad, France). The cDNA concentration used yielded a threshold cycle value (C_T) between 15 and 30 cycles. Amplification specificity was checked by melting-curve analysis. Elongation factor EF-1α was used as internal control.[18] The relative quantity of transcripts was calculated with the delta−delta method mathematical model developed by Pfaffl.[19] For every experiment, the abundance of targeted gene transcripts was set relative to control plants (no GME exposure). The relative quantities of targeted gene transcripts in controls take then always the value of 1. We analyzed transcript accumulation on three infiltrated leaves per plant and at least two independent experiments. Every run was carried out in triplicate. Primers and amplicon sizes are given in Table 1. Efficiencies of all primer sets were routinely checked (data not shown). Bars give means ± standard error (SEM).

Oomycete Material and Culture Conditions. The model pathosystem *Phytophthora*/tobacco was used for the pathogenesis experiments. *Ppn* isolate 329 was obtained from the INRA (Sophia-Antipolis, France) *Phytophthora* collection[20] and cultivated on V8 juice agar (V8A) plates (1 L of V8A contains 200 mL of commercial V-8, 2 g of $CaCO_3$, 17 g of agar, and 800 mL of distilled water) at 24 °C in the dark and then transferred to fresh medium every week. GME was used at concentrations of 0.95% PP, 0.19% PP, 0.038% PP, and 0.0076% PP.

In Vitro Antifungal Activity Assays. *Mycelial Growth.* Individual agar disks (6 mm in diameter) were removed from the edge of an actively growing culture of *Ppn* and placed at the middle of a fresh V8A plate (90 mm in diameter) amended or not with GME. GME was added to the prewarmed V8A to adjust the required final PP concentrations. GME was replaced by acidic water (pH 3.5) for the control. After a 5-day incubation period at 24 °C in darkness, radial growth of mycelia was measured by using ImageJ 1.48 software.

Sporangium Formation. Sporangia were produced by growing *Ppn* on V8A plates as above. Four agar disks (6 mm in diameter) and attached mycelia were removed from the edge of an actively growing culture and placed in a series of plastic Petri dishes (60 mm in diameter) containing 7 mL of sterile water supplemented or not (negative control) with GME. Following a 4-day incubation period at 24 °C in darkness, the liquid was decanted from the Petri dishes, and the agar disks were stained and fixed with acid fuchsin in 85% lactic acid. The number of sporangia along the margins of each agar disk was counted under a microscope (Olympus CX41, Japan).

Zoospore Motility and Cyst Germination. Zoospores were released from *Ppn* sporangia. *Ppn* mycelia were used, macerated and incubated for 4 days on agar plates (2% agar in water) to produce sporangia. Zoospores were released by heat shock treatment with chilling first at 4 °C for 20 min and then heating by adding 10 mL of prewarmed water (37 °C) followed by incubation at 37 °C for 30 min. Aqueous mixtures of GME were added to equal volumes of the zoospore suspensions, leading to final concentrations of 0.95, 0.19, 0.038, and 0.0076% PP. Control zoospore suspensions received an equal volume

DOI: 10.1021/acs.jafc.5b01740
J. Agric. Food Chem. 2015, 63, 6653−6659

of water only. Zoospore suspensions were held at 25 °C and observed microscopically at 10× magnification to determine the maximum elapsed time for complete cessation of motility. Observations were made at 1 min intervals for the first 15 min, then at 15-min intervals for the next 45 min, and finally at 1-h intervals until there was no detectable zoospore movement. To determine cyst germination, equal volumes of the encysted zoospore suspensions were deposited on Petri dishes containing V8A amended with GME. The encysted zoospores were incubated at 24 °C for 6 h and examined for mycelial growth arising from germinating cysts. Every cyst with a germ tube was counted as germinated.

In Vivo Protection Test. Experiments were performed on 8-week-old tobacco leaves from wild-type and NahG transgenic plants. Nonsenescent leaves were first sprayed with GME containing 0.19% PP or 2 mM SA (positive control) or acidic water (negative control) onto the adaxial face using a fine atomizer (2 mL per leaf). Sprayed leaves were detached from the plant at 0, 2, and 4 days after treatment (dpt), and two leaf disks (8-cm diameter) were punched out from every sprayed leaf. *Ppn* was then inoculated into distinct areas with 100 μL of zoospore suspension containing 200 zoospores. Leaf disks were placed on agar plates (17 g of agar in water) and incubated at 24 °C in the dark. Level of protection was evaluated 3 days after inoculation by measuring the *Ppn*-infected areas. The infection areas were measured by using Optimas 6.1 software. In each experiment at least four consecutive mature leaves received *Ppn* inoculations. All experiments were performed at least with duplicates of plants.

Statistical Analysis. All experiments were performed in biological and technical triplicates. Results were expressed as means ± standard error of the mean (SEM). Letters above bars indicate statistically significant differences between samples, according to one-way ANOVA followed by LSD significant test ($p \leq 0.05$) using JMP 11.2.0 software. Significant changes in gene expression were determined using Fisher's least significant differences (**, $0.001 < P < 0.01$; ***, $P < 0.001$).

RESULTS

GME-Induced Macroscopic Symptoms. To investigate the involvement of SA in the GME-induced HR-like response, we first looked at the deployment of macroscopic symptoms on tobacco plants. Wild-type and NahG transgenic tobacco plants were infiltrated with 5 GME concentrations ranging from 0.19% PP (dilution 1) to the 4-, 8-, 16-, and 32- fold diluted GME concentrations (Figure 1). The 0.19% PP concentration produced a high level of defense in tobacco.[11] At 4 days postinfiltration (dpi), the 0.19% GME concentration generated microlesions on leaf tissues in both tobacco lines (Figure 1A–C,E) in a dose-dependent manner. The wild-type leaves developed topical lesions with large and marked chlorotic zones when GME was infiltrated at the 0.19% or 4-fold diluted level. The NahG leaves were less sensitive to GME, and lesions appeared when the concentrated GME (0.19% PP) was applied. The diluted GME failed to generate tissue injury in the tobacco mutant. Examination of the macroscopic changes under UV light ($\lambda_{312\ nm}$) revealed the expected sharp fluorescence surrounding the necrotic zone, with an estimated area value near 8.5 cm^2 indicative of high phenolic compound accumulation on wild-type leaves (Figure 1D). Transgenic leaves were less affected by GME, with only weak production of autofluorescent compounds (estimated area value near 0.5 cm^2) (Figure 1F).

GME-Induced PR Transcript Accumulation. The ability of GME to induce defense-related gene expression was investigated in tobacco plants. Transcript accumulation of four *PR* genes in response to GME treatment was assayed by quantitative real-time PCR. Figure 2A shows the ratio of transcript levels in treated leaf tissues versus negative control (acidic water-infiltrated tissues) of the antimicrobial *PR1*, β-1,3-glucanase *PR2*, endochitinase *PR3*, and osmotin-like *PR5* target genes in wild-type and NahG transgenic plants. Total RNA was extracted at 4 dpi from leaves infiltrated with GME containing 0.19% PP.

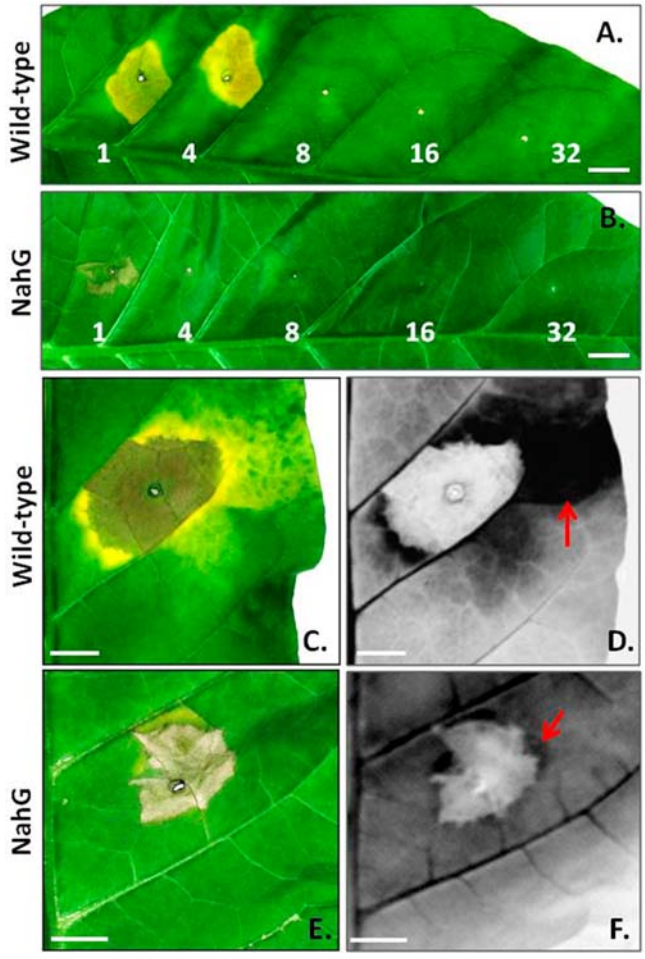

Figure 1. Macroscopic symptoms induced on tobacco leaves of wild-type plants (A, C, D) and NahG transgenic plants (B, E, F) by GME infiltration observed at 4 dpi under bright light (A, B, C, E) and UV light (D, F). GME was infiltrated at 0.19% PP in panels C–F and serially diluted: no dilution (1), 4-fold (4), 8-fold (8), 16-fold (16), and 32-fold (32) in panels A and B. Bars, 1 cm. Arrows point to fluorescent areas.

The transcripts for the four defense genes were over-accumulated in wild-type GME-treated tobacco plants, with 12-, 127-, 55-, and 186-fold inductions for *PR1*, *PR2*, *PR3*, and *PR5*, respectively, compared to water treatment. The accumulation profile of the defense markers was dramatically lower in NahG transgenic plants. *PR1* transcript accumulation was impaired (ratio below 1) and *PR2*, *PR3*, and *PR5* transcripts accumulated to ratios reaching 6–16-fold the water control. These data showing reduced sensitivity of the NahG transgenic plants carrying the salicylate hydroxylase gene point to the involvement of SA pathways in GME-induced defense marker gene expression. To validate the experimental plant system, *PR1* transcripts were quantified in wild-type and NahG tansgenic plants treated with exogeneous SA (Figure 2B). As expected, treatment with 2 mM SA induced strong *PR1* transcript accumulation in wild-type tobacco leaves (60-fold the water treatment). In contrast, application of SA on NahG leaves induced lower *PR1* transcript accumulation than wild-type

DOI: 10.1021/acs.jafc.5b01740
J. Agric. Food Chem. 2015, 63, 6653–6659

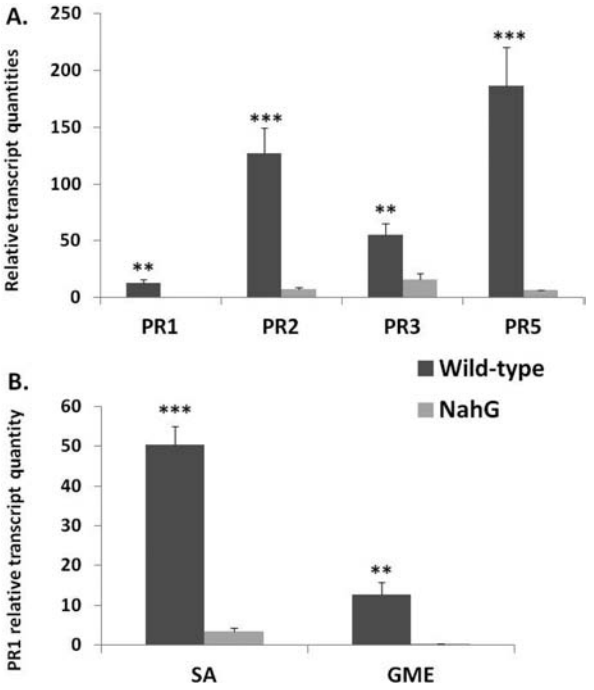

Figure 2. *PR* transcript accumulation in wild-type and NahG transgenic tobacco plant leaves infiltrated with 0.19% PP of GME or SA (2 mM). Transcripts encoding the *PR1*, *PR2*, *PR3*, and *PR5* (A) and *PR1* (B) genes were quantified by real-time RT-PCR in the infiltrated leaves. Values are expressed relative to control (acidic water treatment) values. Three leaves per plant were treated for each experiment. Statistics were generated from at least two independent experiments. Bars represent means ± SEM. Asterisks indicate significant differences compared with the wild-type: (**) $0.001 < P < 0.01$; (***) $P < 0.001$.

leaves with nevertheless residual expression level (3.5-fold the water treatment) (Figure 2B).

Antimicrobial Effect of GME on *Ppn*. The potential antimicrobial properties of GME were investigated on *Ppn* via a series of in vitro tests studying mycelia growth, sporangium formation, zoospore motility, and cyst germination of the oomycete. GME effect was assayed at different PP concentrations ranging from 0.0076 to 0.95%. Figure 3, panels A and B, shows the in vitro impact of GME on mycelial growth and germ hyphae elongation of *Ppn* on V8A medium. GME inhibited both developmental stages of *Ppn* in a dose-dependent manner. The radial surface of the *Ppn* mycelium was inversely proportional to GME concentration. The length of cyst germ tubes observed under microscope 24 h after treatments was highly affected proportionally to GME concentration.

Figure 3C shows the quantified inhibitory effects of GME over the water control. GME dramatically affected both sporangium formation and zoospore motility, with marked inhibition (82%) at 0.0076% PP. The complete inhibitory effect was achieved at 0.038% PP. Cyst germination was less affected by the lowest concentrations of GME (19% inhibition at 0.0076% PP and 44% inhibition at 0.038% PP), and full inhibition was reached at 0.19% PP. Higher GME concentrations were required to inhibit mycelial growth of *Ppn*. GME at 0.19% PP induced a 60% inhibition of mycelial growth, and only GME 0.95% PP was able to generate full inhibition.

Taken together, all of the GME concentrations tested were found to have inhibitory effects with various degrees of sensitivity according to asexual developmental stage of *Ppn*. The GME concentrations with inhibitory activity in spore experiments did not significantly affect the mycelial growth of *Ppn*. The GME at 0.038% PP, which had fully inhibited sporangium formation and zoospore motility, led to only an 8% inhibition of radial growth. These results indicate that spores are likely more sensitive than mycelium to the antimicrobial effect of GME.

GME-Induced Protection against *Ppn* Infection. We further determined how far the GME-induced protection of tobacco plants against *Ppn* was SA-dependent. Both wild-type and NahG transgenic plants were sprayed with GME, and then leaves were detached from the plant at 0, 2, and 4 days for zoospore inoculation. Figure 4 shows the lesion areas measured 3 days after *Ppn* inoculation relative to water treatment. SA-induced protection was also measured on leaves treated with 2 mM exogenous SA.

In wild-type tobacco plants, GME induced a significant reduction of infected areas translating to a high level of protection against *Ppn*. The local lesion areas induced by *Ppn* were reduced in size by 33, 45, and 46% at 0, 2, and 4 dpt, respectively. The 33% protection level was the result of GME biocide action because GME treatment was applied right before inoculation (0 dpt). Lesion areas of the NahG leaves were reduced to similar extents as in wild-type tobacco plants at 0 dpt. Protection level decreased radically in the NahG leaves when GME had been sprayed previously (at 2 and 4 dpt), with local lesion sizes mirroring those measured in control leaves infiltrated with water. This demonstrates that NahG transgenic plants lacking endogenous SA accumulation had lost GME-induced protection against *Ppn* at 2 or 4 dpt. The data clearly demonstrate that GME induced efficient protection against *Ppn* in wild-type leaves and suggest that endogenous SA may well be involved in GME-induced protection.

Exogenously supplied SA could protect tobacco leaves from *Ppn* with the reduction in size of infected areas in the wild-type (Figure 4). The SA treatment also induced a degree of protection at 0 dpt (32%), 2 dpt (20%), and 4 dpt (36%). Either SA might act as biocide agent or the NahG plants were still sensitive to SA in our experimental conditions.

DISCUSSION

The elicitor activity of GME has been largely demonstrated in previous work. This PP-rich extract activates a cascade of chemical defenses in tomato, *Arabidopsis*, and tobacco with local tissue injury, biochemical changes, and systemic molecular responses.[11,13] We predicted that SA may be involved in the plant defense reactions deployed after GME application to tobacco tissues. GME elicited molecular responses leading to up-regulation of the acidic *PR1*, *PR2*, *PR3*, and *PR5* genes in treated tobacco tissues. The expression of this array of PR protein genes occurs via an SA-dependent signaling pathway during elicitor-induced LAR and SAR in tobacco.[21] Here, the use of NahG transgenic plants expressing the salicylate hydroxylase gene allowed us to dissect the role of SA in GME-induced PDI events.

NahG transgenic plants expressing the bacterial salicylate hydroxylase gene did not exhibit the full spectrum of defense responses. The necrotic lesion was dramatically abolished, and the surrounding fluorescent zone in the NahG tissue was reduced by about 95% compared to the wild-type tissue at the HR-dose of GME containing 0.19% PP. Necrosis is the result of topical cell death together with the surrounding phytoalexin

DOI: 10.1021/acs.jafc.5b01740
J. Agric. Food Chem. 2015, 63, 6653−6659

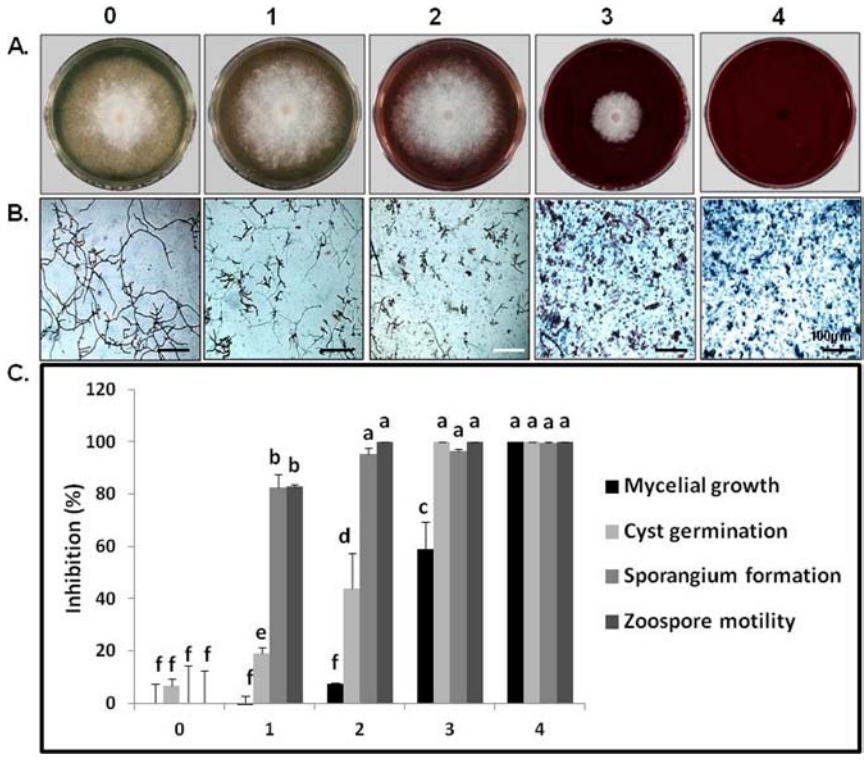

Figure 3. Antipathogenic activity of GME against *Ppn*. GME was serially diluted and used at different concentrations: no GME (0); 0.0076% PP (1); 0.038% PP (2); 0.19% PP (3); 0.95% PP (4). The impact of GME on (A) mycelial radial growth and (B) germ hyphae elongation of *Ppn* was observed in V8 medium amended with GME. The germ elongation and radial growth of *Ppn* were observed 24 h and 5 days postculture, respectively. (C) Quantification of the inhibitory effect of GME on several asexual developmental stages of *Ppn*. The in vitro antifungal assays were repeated in triplicate. Statistics were generated from at least two independent experiments. Results are expressed as means ± SEM. Letters next to bars indicate significant differences between treated and control samples according to one-way ANOVA followed by LSD test ($p \leq 0.05$).

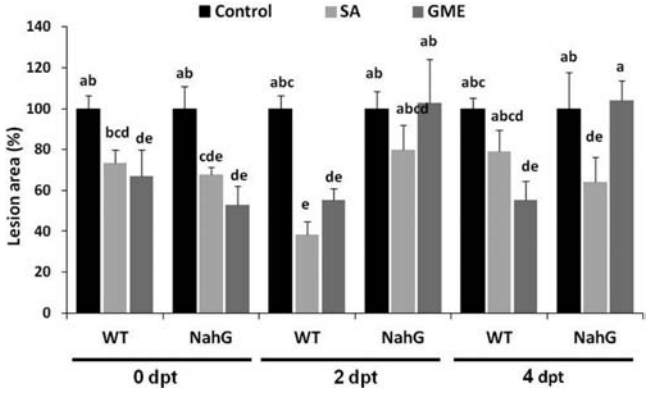

Figure 4. Induction of protection against *Ppn* in tobacco leaves. Leaves from 8-week-old wild-type (WT) and NahG transgenic plants were sprayed with water (control), 0.19% PP GME, or 2 mM SA and detached from the plant. At 0, 2, or 4 days post-treatment (dpt), *Ppn* zoospores were inoculated on the treated leaves. The pathogen-invaded areas were measured 3 days after *Ppn* inoculation. Bars represent standard error of four replicates from two independent experiments. Letters next to bars indicate statistically significant differences between treated and control samples according to one-way ANOVA followed by LSD test ($p \leq 0.05$).

production. SA has been previously demonstrated to be involved in phenomena modulating both HR cell death and phytoalexin accumulation.[22] Cell death is believed to occur before SA accumulation, but feedback mechanisms may mediate the regulation of cell death by an SA-dependent pathway.[23,24] In our GME/tobacco system, NahG transgenic plants showed dramatically compromised signs of GME-induced HR. These data serve as evidence that SA is required to mount the GME-induced HR in tobacco plants.

Treatment of NahG transgenic plants with the HR dose of GME also demonstrated the involvement of SA in later molecular defense events. The whole treated leaves were taken into account for molecular analysis, meaning that both LAR and SAR zones were indifferently pooled.[21] The LAR/SAR reactions were largely affected, with a dramatic down-regulation of *PR* genes in the NahG transgenic plants. This suggests that SA likely orchestrates *PR* transcript accumulation. Interestingly, a coordinated regulation was observed in the NahG plants with down-regulation of all four *PR* transcript accumulations. Nevertheless, the amount of acidic *PR1* transcripts was clearly suppressed and the amounts of *PR2*, *PR3*, and *PR5* transcripts were partially reduced in GME-treated NahG transgenic plants. As posited by Friedrich et al.,[25] residual SA levels might occur in NahG plants. The accumulation profile of the acidic isoforms would reflect their differential sensitivity to SA in the GME-treated plants.

Here we demonstrated the antifungal activity of GME against the oomycete *Ppn*. Polyphenols are groups of compounds serving as plant defense mechanisms against pathogenic microorganisms.[7] The many defensive functions of these bioactive phytochemicals enable cell strengthening and repair (lignin and suberin), antimicrobial activity (isoflavonoid phytoalexins), and signaling (SA). The largest and best studied polyphenols are extracted from grapes. Their direct antimicrobial activity has been demonstrated for bacteria and fungi (reviewed by Yu and Ahmedna[26]), although with various

J. Agric. Food Chem. 2015, 63, 6653−6659

sensitivities according to microbe species.[27] The relationship between compound structure and antimicrobial activity has been established.[28] Position(s) and numbers of hydroxyl groups and the degree of polymerization might be pivotal to the antimicrobial activity of phenolics. The different parts of grapes are rich sources of potentially bioactive polyphenols that vary in content between grape varieties.[29,30] The *V. vinefera* extract used here is produced from the marc of grapes harvested from various red wine varieties and showed potential antifungal activity in vitro with an inhibitory effect on the four asexual developmental stages of *Ppn*. The 0.19% PP concentration fully suppressed sporangium formation, cyst germination, and motility and partially suppressed mycelial growth.

The antipathogenic activity of GME could also induce in vivo protection against *Ppn* in tobacco leaves. Indeed, the GME treatment right before *Ppn* inoculation (at 0 dpt) in the wild-type and NahG transgenic plants led to 30−45% reduction in infection area. The involvement of PDI activity in GME-induced protection level was demonstrated by experiments led on NahG plants at 2 and 4 dpt. GME-induced accumulation of *PR1*−5 transcripts was highly reduced in the NahG tissues 4 days after infiltration, and the SA-depleted tissues did not show any GME-induced protection effect at 2 and 4 dpt compared to wild-type tissues. These results suggest that the in situ PR antimicrobial action might not have been high enough to provide protection against *Ppn* at 2 and 4 dpt. They also demonstrate that SA-dependent defense reactions play a primary role in GME-induced protection level. Interestingly, the *Ppn* infection areas at 2 and 4 dpt were significantly identical in control and GME-sprayed NahG tissues (100% infection areas), suggesting that the direct antimicrobial impact of GME was nonfunctional from day 2 postspraying. In the wild-type tobacco plants, PDI activity would play a preponderant role at 2 and 4 dpt, leading to 45% protection against *Ppn*. This suggests that the GME-induced *PR1*−5 transcript accumulation was high enough to provide the protection.

The impact of SA was concomitantly analyzed in our *Ppn*/tobacco pathosystem to rule out the possibility that NahG transgenic plants could respond to SA. Exogenous application of SA provided significant antifungal effect against *Ppn* at 0 dpt, leading to an average 30% protection level in both wild-type and NahG transgenic tissues. Treatment of wild-type plants with 2 mM SA provided clear protection against *Ppn* (62%) at 2 dpt, whereas exogenous SA treatment of SA-depleted NahG tissues led to at least partial loss of the high protection level. The phytohormone SA plays a central role in regulating defense response in plants, and its accumulation leads to resistance against pathogens.[5] At the dose tested (2 mM), the phytohormone was able to induce an accumulation of *PR* transcripts in wild-type tobacco plants and potentiate their resistance against the oomycete *Ppn*. The phenolic compound sprayed on tobacco leaves also led to a direct antifungal effect against *Ppn* that could match its antipathogenicity properties evidenced for plant pathogens.[31,32]

Taken together, our data provide key insights into the mode of action of GME. The dual antifungal and PDI activities of GME could induce high levels of protection against *Ppn*. This natural grape extract is geared to meet current plant protection product criteria and can be regarded as a promising biocontrol agent appropriate for more environmentally friendly crop protection schemes. We have so far investigated GME-induced disease resistance under controlled laboratory conditions, but the critical factor that will decide the real-world value of GME will be its potential effectiveness on crops in open fields. Field trials are currently in progress.

germination was not significantly affected by biochars made from a range of organic sources. Solaiman et al.[17] showed that biochars generally increased germination at low application rates (10−50 t/ha), whereas higher application rates of 100 t/ha had no effect or decreased germination rate. Alburquerque et al.[27] observed that different biochars exerted a positive effect on seed germination also at high application rates.

Recent studies have also suggested different methods for reducing the toxicity of biochar.[28,29] Washing biochar with water or an organic solvent has been successfully tested to reduce the phytotoxicity of biochar.[21,28,30] Meanwhile, Kołtowski and Oleszczuk[31] demonstrated significant reduction in the toxicity of biochars by drying them at various temperatures (100−300 °C) for 24 h.

Although the published and ongoing investigations are providing increasing data helpful to understanding the relationships between biochar characteristics and seed germination,[28,31] further studies are needed to better clarify the role played by the chemical properties in determining the toxicity effect on plants in order to forecast strategies in biochar synthesis or post-treatments. Biochars from different feedstock and process conditions may exhibit a wide range of plant response, from growth inhibition to stimulation. The relatively simple seed germination test is a valid and fast tool to compare several biochars obtained from different starting materials and under different pyrolysis conditions. Because the test is performed in a short time and without the buffering effect of soil, it could be considered a kind of precautionary procedure that highlights the intrinsic phytotoxicity of the tested materials.

The aim of this study was to evaluate the phytotoxicity of biochar from poultry litter by means of standard germination tests and to identify possible relationships with its chemical characteristics. To this purpose, germination tests with cress (*Lepidium sativum* L.) were conducted with poultry litter biochars synthesized under different pyrolysis conditions. Besides manure, poultry litter typically contains bedding such as sawdust, wood shavings, rice hulls, and straw.[8,12] Therefore, a comparison was made with biochars produced from a lignocellulosic material, prepared under the same conditions, to better discriminate the contributions of lipids/proteins and (hemi)cellulose/lignin. The effect of solvent extraction and biological conditioning on seed germination was tested on a selected poultry litter biochar prepared upon pyrolysis at 400 °C (PL400). The chemical composition of mobile constituents in this sample capable of being potentially released in water and air compartments was investigated by solvent extraction and solid-phase microextraction (SPME).

MATERIALS AND METHODS

Biochar Synthesis. Cornstalk was described in a previous study.[32] Granular poultry litter was a marketed organic fertilizer obtained after processing raw poultry litter collected from local broiler farms by pasteurizing at 80−110 °C, milling, and pelletizing. Biomass was air-dried at 60 °C, milled, and sieved at 2 mm before pyrolysis.

Batch pyrolysis experiments were conducted under nitrogen flow with a fixed bed tubular quartz reactor placed into a refractory furnace (see Conti et al.[33] for details) with about 20 g of cornstalk or 35 g of poultry litter exactly weighed and uniformly placed onto a sliding quartz boat; nitrogen flow was set at 1500 cm^3/min, and when the temperature inside the reactor, measured with a thermocouple, reached the selected value, the boat was pushed into the oven and left for a given residence time before it was pulled back into the unheated part of the reactor. Pyrolysis was performed under three different conditions based on a previous study[33] of temperature/residence time: 400 °C/20 min, 500 °C/10 min, and 600 °C/5 min. In accordance with the original biomass (cornstalk, CS; poultry litter, PL) and pyrolysis temperature, the obtained biochar samples were named CS400, CS500, CS600, PL400, PL500, and PL600. Chemicals were purchased from Sigma-Aldrich. SPME Carboxen-PDMS fibers and the fiber holder were purchased from Supelco.

Biochar Characterization. Elemental composition (HCNS) was determined by combustion using a Thermo Scientific Flash 2000 series analyzer. Ash was determined as the residual mass left after exposure at 600 °C for 5 h. The oxygen content was calculated from the mass balance, O% = 100 − (C + H + N + ash)%.

Analytical pyrolysis (Py-GC-MS) was conducted at 900 °C for 100 s with a CDS 5250 pyroprobe interfaced to a Varian 3400 GC-Saturn 2000 MS. GC-MS conditions and the determination of indicators of carbonization percent charred and the toluene/naphthalene ratio were described in Conti et al.[33]

The content of the 16 EPA priority PAHs was measured in triplicate as described in Fabbri et al.[34] Briefly, about 0.5 g of biochar was spiked with 0.1 mL of surrogate PAH mix (Supelco for EPA 525 containing acenaphthene-d_{10}, phenanthrene-d_{10}, and chrysene-d_{12}, 5 μg/mL each in acetonitrile) and Soxhlet extracted with acetone/cyclohexane (1:1, v/v) for 36 h. The solution was filtered, added to 1 mL of *n*-nonane (keeper), carefully evaporated by rotatory vacuum evaporation at 40 °C, and cleaned up by solid phase extraction onto a silica gel cartridge before analysis with an Agilent HP 6850 GC coupled to an Agilent HP 5975 quadrupole mass spectrometer; GC-MS conditions were those detailed in Fabbri et al.[34] Recovery of surrogate PAHs was determined with respect to the internal standard tri-*tert*-butylbenzene added prior to GC-MS analysis.

Volatile fatty acids (VFAs) were determined by the single-drop extraction procedure as described in Torri et al.[35] About 200 mg of biochar exactly weighed was added to 0.1 mL of internal standard solution (1 g/L 2-ethylbutyrate in deionized water) and thoroughly mixed with 0.2 mL of saturated aqueous $KHSO_4$. After centrifugation, a drop of dimethyl carbonate (1.2 μL) from a 10 μL chromatography microsyringe was exposed into the supernatant aqueous solution. After 20 min of exposure, the drop was retracted and injected into a GC-FID (injection temperature = 250 °C) equipped with a polar GC column (Agilent Q7221J&W nitroterephthalic acid-modified polyethylene glycol DB-FFAP 222 30 m, 0.25 mm, 0.2 μm) with the following thermal program: 80 °C for 5 min, then 10 °C/min to 250 °C. Calibration was performed by applying the same procedure to standard solutions containing known concentrations of each VFA (namely, acetic, propionic, isobutyric, butyric, isovaleric, and valeric acids).

For the determination of N-NH_4^+, about 10 g of biochar was placed in an end-to-end shaker for 2 h with 1 N KCl (1:10 dw/v) followed by centrifuging at 4500*g* for 20 min and passing through a 0.45 μm paper filter.

SPME of Mobile Compounds. An aliquot (1 mL) of the aqueous extract solution was introduced into a vial mixed with 0.5 mL of KH_2PO_4/Na_2HPO_4 phosphate buffer 2 M at pH 5.3 and then spiked with 1 μg/mL *o*-eugenol and 5 μg/mL 2-ethylbutyric acid as internal standards. SPME analyses were performed by directly exposing the Carboxen-PDMS fiber into the test solution under magnetic stirring. After 30 min of exposure, the fiber was inserted into the injector of an Agilent 5977 gas chromatograph, and analytes were thermally desorbed at 250 °C for 10 min and analyzed as described for VFAs with a DB-FFAP polar column (30 m length, 0.25 mm i.d, 0.25 μm film thickness). Detection was made with a quadrupole mass spectrometer Agilent 7820A operating under electron ionization at 70 eV with acquisition at 1 scan/s in the m/z 35 and 450 range. Mass spectra were acquired in full scan mode with a gain factor of 5. Prior to sample analysis, blanks were performed first with a thermal desorption of the fiber alone and then after a 30 min exposure to a solution of deionized water with 0.67 M phosphate buffer.

Headspace (HS) analysis was performed following the procedure described by Spokas et al.[36] (150 °C, 30 min) but using SPME instead of syringe sampling. Poultry litter biochar was weighed (0.5 g) into 20 mL headspace vials. The vials were spiked with 1 μg of *o*-eugenol

(1000 μg/mL solution in methanol) and then sealed. HS-SPME was carried out by placing the fiber holder at the top of the vial and exposing the Carboxen-PDMS fiber to the headspace close to the cap (30 min) while the bottom of the vial was put on a heating plate at 150 °C. GC-MS analysis was carried out as described above but with the GC oven starting from 36 °C held for 5 min. Prior to sample analysis, blanks were carried out first with a thermal desorption of the fiber alone and a sealed vial with empty headspace.

Biochar Post-treatments. *Aqueous Extraction.* About 2 g of PL400 was extracted with 50 mL of deionized water in a 100 mL flask at room temperature for 12 h with mechanical shaking. The aqueous phase was separated by filtration through a 0.22 μm paper filter and used as such for the germination test, whereas an aliquot was kept at −20 °C for SPME-GC-MS analysis (see above). The solid biochar residue left after water extraction was further extracted with 50 mL of methanol under reflux for 12 h. The methanol was separated by filtration, and an aliquot corresponding to the 40 g/L suspension of biochar was poured into Petri dishes and dried overnight at 70 °C under vacuum to remove all of the methanol. Thereafter, deionized water was added to perform germination tests. The final solid biochar residue left after water and methanol extraction was dried overnight at 100 °C under vacuum and utilized for germination tests.

Biological Treatment. Microbial treatment of PL400 was conducted with an activated sludge obtained from a municipal wastewater treatment plant located in Ravenna after centrifugation at 6000 rpm (20% w/w volatile suspended solids). A suspension containing 0.5 g of the concentrated sludge and 250 mL of 40 g/L PL400 in deionized water was thoroughly mixed under laminar shaking at 120 rpm overnight. An aliquot of 10 mL of this suspension was added in Petri dishes and stored for 14 days at 25 °C as shown above before germination tests were performed.

Germination Tests. The germination tests were conducted in four replicates by incubating 50 seeds of cress (*L. sativum* L.) with 5 g of a mixture containing biochar and deionized water onto sterilized cellulose filter paper (Whatman no. 1) placed in a Petri dish sealed with paraffin film. Three levels of biochar concentration were tested, 2, 5, and 40 g/L. These rates were equivalent to 2, 5, and 40 t/ha on an area basis of 10 cm soil depth and a dry bulk density of 1.5 kg/m^3. Germination tests were also performed on the fractions obtained from the chemical and biological post-treatments of PL400 described above. The quantity of these fractions was adjusted to correspond to the concentration level of 40 g/L of the original biochar. Before incubation, the samples were shaken at 150 rpm on a platform shaker at room temperature for 24 h. pH and electrical conductivity (EC) were both determined. The pH was directly measured by placing the glass electrode into the suspension with a Mettler Toledo SG 2-ELK pH-meter. The EC was measured with a Delta OHM HD 8706 conductimeter in the supernatant obtained by centrifuging the suspension and filtered at 0.45 μm.

Phytotoxicity tests were performed on biochar/deionized water mixtures (wetted biochar) according to the procedure described in UNI 11357:2010. The experiments were conducted with 50 seeds of cress, which were incubated with 10 g of biochar saturated with deionized water according to value of the water-holding capacity (Table 1) on sterilized cellulose filter paper placed in a Petri dish. All Petri dishes were covered and incubated at room temperature, 25 ± 2 °C, for 72 ± 0.5 h in the dark. Similarly, a control was prepared with deionized water.

After 72 h of exposure, visible root development was used as the operational definition of seed germination. Data were reported as relative seed germination (RSG) percentage with respect to the control (deionized water):

$$\text{RSG} = (\text{no. of germinated seeds in the sample}/\text{no. of germinated seeds in control}) \times 100$$

Statistical Analysis. All of the experiments were conducted at least in duplicate. Results of germination tests were evaluated statistically using analysis of variance (ANOVA) performed with R software version 3.1.2 (http://www.r-project.org) followed by Student−Newman−Keuls post hoc tests. The difference between the treated groups and the control group was evaluated with Dunnett's t test ($p < 0.05$).

RESULTS AND DISCUSSION

Characterization of Biochar. *Bulk Analysis.* The yields and characteristics of biochars obtained from the pyrolysis of poultry litter (PL400, PL500, PL600) under three different pyrolysis conditions are reported in Table 1 and compared with those of biochar from corn stalk (CS400, CS500, CS600). As expected, the chemical characteristics of the biochars were dependent on the original biomass and the pyrolysis conditions. In particular, the H/C and O/C ratios decreased with increasing pyrolysis temperature, whereas the content of ash increased as observed with the same pyrolysis unit under the same conditions.[33] Biochar from poultry litter contained higher levels of nitrogen, sulfur, and ash, derived from the manure fraction, as demonstrated by comparative studies on manure and lignocellulosic biochars.[9] In general, the elemental composition, ash content, and the trends with pyrolysis conditions of the investigated poultry litter chars were comparable to those reported in the literature.[7,8,37]

Extractable Compounds. The concentrations of specific potentially toxic extractable compounds, namely PAHs, VFAs, and ammonium, are reported in Table 2. Solvent-extractable PAHs occurred within the range of 0.7−1.7 mg/kg, values that were typical of biochars from different origins.[34,38,39] PAH concentration can be considered negligible for acute effect and comparable to typical values in soils.[40] Generally, naphthalene was the most abundant PAH followed by phenanthrene and fluorene; the level of benzo[a]pyrene was in the 5−65 ng/g range.

PL600	0.79 ± 0.01	6.8 ± 1.8	14	88 ± 3	11 ± 2

[a]T/N, toluene/naphthalene ratio.

The concentration of VFAs was significantly higher in poultry litter biochars (4−9 mg/g) in comparison to those from cornstalk (1−4 mg/g). Acetic acid was always the most abundant VFA and could be derived from the thermal degradation of hemicellulose.[41] VFAs could also be derived from the thermal degradation of triacylglycerols[42] and free fatty acids.[43]

Ammonium was not detected in cornstalk biochar, whereas it was abundant in biochars from poultry litter with higher concentrations in the less carbonized biochars.

Py-GC-MS. Thermolabile Fraction. The molecular composition of the thermally labile fraction could be inferred from the structural identification of the compounds identified in the pyrolysates.[33,34,44] The pyrolysate of CS400 was characterized by a complex pattern of compounds dominated by phenols and methoxyphenols associated with the presence of partially charred lignin, whereas the pyrolysate of CS600 contained few peaks due to the hydrocarbons associated with more heavily charred fraction (Figure 1). Proxies of the degree of carbonization established in previous studies[33] for lignocellulosic biomass were confirmed in this study for corn stalk biochar: the toluene/naphthalene ratio and the relative abundance of compounds representative of the charred fraction (% charred) exhibited a clear trend with H/C ratios (Table 2). However, biochar samples from poultry litter did not exhibit significant changes with the H/C ratios, and the variability was higher. This finding would suggest that the pyrolysis proxies developed for lignocellulosic biochar could not be valid for biochar containing charred proteins and lipids.

The occurrence of partially charred components from proteins and lipids was clearly evidenced in the pyrolysates of biochar. Phenols and methoxyphenols were detected in PL400 as well as in CS400 in accordance with the fact that the original substrates contained a lignocellulosic component. The distinctive signature of PL pyrolysate was the occurrence of nitrogen-containing compounds (NCCs) from proteins and a pattern of *n*-alkanes/*n*-alk-1-enes assigned to the thermal cracking of bound or free fatty acids (Figure 1). The occurrence of saturated alkyl domains was confirmed by ^{13}C NMR studies on poultry manure biochars that disappear after carbonization and may play a role in the availability of sorbed compounds.[37] Among the tentatively identified NCCs, pyrrole, pyridine, (iso)quinoline, and carbazole along with their alkyl derivatives are indicative of partially charred proteinaceous matter. It is worth noting that NCCs were also identified in the volatile fraction by SPME as described in the next section.

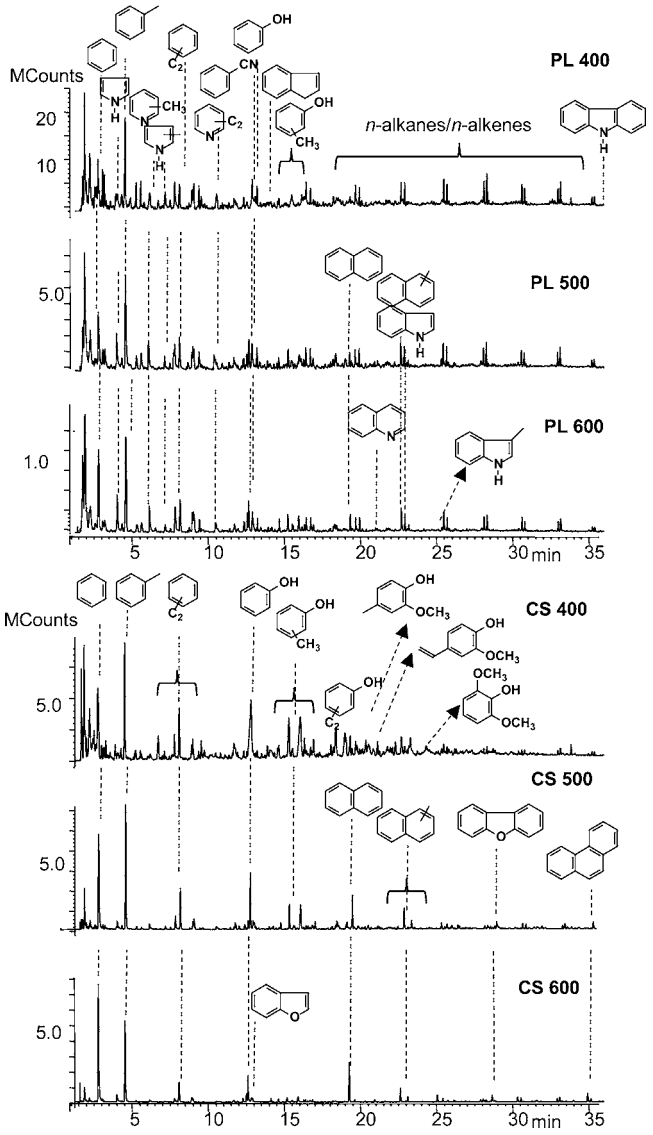

Figure 1. Total ion chromatograms from Py-GC-MS of poultry litter (PL) and cornstalk (CS) biochars.

SPME-GC-MS. Volatile and Water-Soluble Compounds. Information on the molecular characteristics of the mobile fraction was gathered by HS-SPME (volatile) and DI-SPME (water-soluble). Poultry litter contains heavy metals that may end up in the resulting biochar.[45] However, our attention was specifically focused on organic compounds, it having been reported that heavy metals are generally present below the limits causing adverse effects and loosely bioavailable.[46] Moreover, Bastos et al.[16] argued that in aqueous extracts PAHs and metals might occur at concentrations below the level to pose detrimental effects, at least for woody biochar up to 80 t/ha; however, it has to be remarked that the biological response depends on the organisms selected in the bioassay,[16] and the content of metals depends on pyrolysis conditions;[45] thus, the influence of inorganic constituents cannot be always excluded.

SPME was applied to sample PL400 that was utilized in post-treatment studies. The results are shown in Figure 2 for the analysis of volatile organic compounds (VOCs) by HS-SPME (Figure 2A) and DI-SPME of aqueous extracts (Figure 2B), respectively. The VOCs were characterized by the presence of a

J. Agric. Food Chem. 2015, 63, 6660−6667

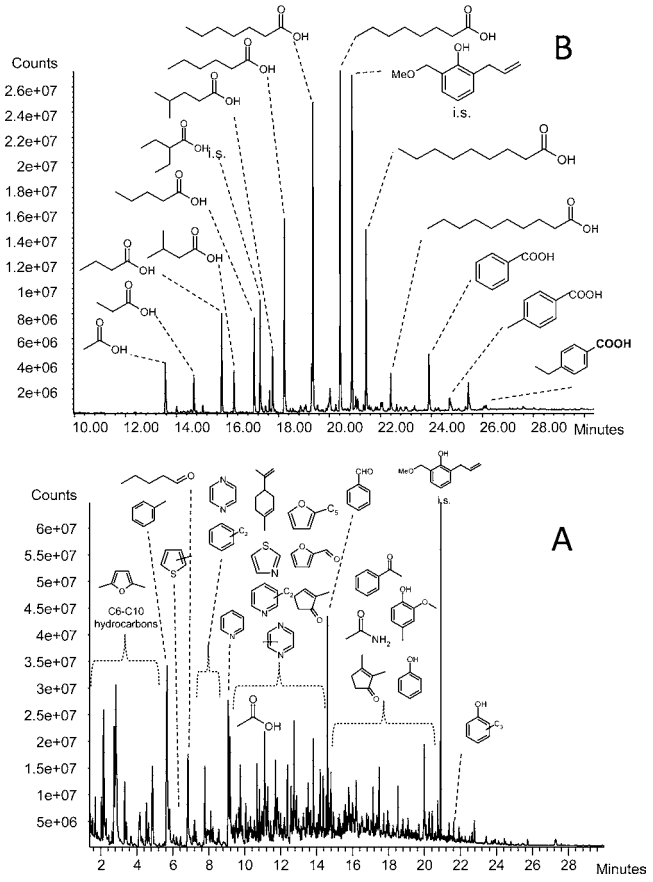

Figure 2. Total ion chromatograms obtained after (A) HS-SPME of volatile organic compounds and (B) DI-SPME of water extract of poultry litter biochar (PL400).

wide array of compounds deriving from the thermal degradation of polysaccharides (e.g., cyclopentenones, furans), lignin (e.g., 4-vinylphenol, guaiacol), proteins (e.g., pyrroles, pyridines, indole), lipids (e.g., VFAs; acetic acid is also derived from hemicellulose). Alkylated pyrazines and acetamide were probably derived from Maillard reactions between carbohydrates and proteins.

Notably, a suite of short-chain *n*-alkanes/alkenes were identified, supporting Py-GC-MS results and literature data about the occurrence of aliphatic components in poultry litter biochar.[37] It is expected that the polar fraction of VOCs will be preferentially distributed into the aqueous phase in comparison to nonpolar constituents. In fact, the SPME-GC-MS analysis of the PL400 water extract showed a predominance of organic acids, including C_2-C_{10} aliphatic and C_7-C_9 aromatic acids (Figure 2B).

Effect of Biochar on Seed Germination. The pH and EC of the biochar/water suspensions utilized in germination tests are reported in Table 3. The pH values were higher for the suspensions, from the same feedstock, with the more carbonized biochars and increased, for each biochar type, with increasing concentration. Under the same conditions, the pH was higher in the suspensions with poultry litter biochar, in accordance with previous studies.[9]

The EC values of the suspensions increased with increasing biochar concentration and, at the same concentrations, the biochar from poultry litter had much higher (from 4 to 40 times for the same condition) EC values than the CS suspensions. Salinity can have a detrimental effect on seed germination and plant growth, especially in the seedling stage, although the response of various plant species to salinity differs considerably.[47] In general, salinity effects are mostly negligible in extracts with EC readings of ≤2000 μS/cm.[48] This critical level was exceeded in poultry litter biochar at 40 g/L. The toxicity of inorganic nitrogen results mainly from ammonia (NH_3), which affects plant growth and metabolism at low concentration levels at which NH_4^+ is not harmful.[47] At concentrations of 0.15−0.20 mM, which are comparable to those calculated in the 40 g/L biochar/water mixtures, NH_3 could be toxic.[49]

Table 3. Results from Chemical Analysis of Biochar Water Suspensions

	pH			electrical conductivity (μS/cm)		
biochar	2 g/L	5 g/L	40 g/L	2 g/L	5 g/L	40 g/L
CS400	7.6	8.0	8.5	16	75	1.8×10^3
CS500	8.2	8.5	9.3	72	76	1.9×10^3
CS600	8.4	8.9	10.1	1.9×10^2	3.5×10^2	1.9×10^3
PL400	8.0	9.0	9.7	7.1×10^2	1.3×10^3	7.3×10^3
PL500	8.4	9.3	10.2	8.7×10^2	1.5×10^3	7.7×10^3
PL600	9.4	9.8	10.3	9.3×10^2	2.0×10^3	8.1×10^3

The effect of the biochar suspensions on seed germination of cress (*L. sativum* L.) is presented in Table 4 in terms of relative seed germination percentage with respect to control (deionized water only).

Table 4. Relative Seed Germination (% of Control) of Cress (*Lepidium sativum* L.) in Biochar/Deionized Water Suspensions (2, 5, and 40 g/L) and Phytotoxicity Tests (% Seed Germination with Respect to Control) according to UNI 11357:2010 (Mean Values and SD from Four Replicates)[a]

	germination (%)			
biochar ID	2 g/L	5 g/L	40 g/L	UNI
control	96 ± 2	97 ± 2	98 ± 2	94 ± 2
CS400	98 ± 2	93 ± 1*	96 ± 4	81 ± 3*
CS500	97 ± 5	98 ± 1	96 ± 2	41 ± 3*
CS600	95 ± 4	95 ± 2	96 ± 1	14 ± 4*
control	92 ± 2	92 ± 2	92 ± 2	94 ± 1
PL400	83 ± 4*	74 ± 3*	52 ± 19*	no germination
PL500	77 ± 2*	73 ± 2*	47 ± 10*	no germination
PL600	77 ± 3*	74 ± 3*	53 ± 7*	no germination

[a]The percent seed germination in pure deionized water (control) is also reported. * indicates differences at the 0.05 level compared with the control by Dunnett's tests.

The assay results in this work suggested that all of the cornstalk biochar suspensions had little impact on seed germination as one-way ANOVA showed no significant difference between control group and test groups ($p > 0.05$). Notably, CS400 was almost nontoxic to germination even if used as the growth substrate (UNI test, Table 4).

On the contrary, all of the biochar samples from poultry litter significantly inhibited seed germination at the highest level of 40 g/L in water suspensions. At the harsh conditions of the UNI test the germination was totally suppressed.

J. Agric. Food Chem. 2015, 63, 6660−6667

The comparison with cornstalk suggested that the toxicity of biochar from poultry litter could be explained by some distinctive chemical components originated from this feedstock. Compounds derived from lignin and cellulose/hemicellulose could be excluded on the grounds that biochar samples from corn stalk did not suppress seed germination in water suspensions. The biochar suspensions from both substrates presented similar pH values; thus, this parameter is not involved in toxicity. This is in accordance with the findings of Gell et al.,[50] who found no evidence of clear trends of pH and short-term phytotoxicity in biochars of different origins, at least under neutral/basic conditions. Similarly, the solvent-extractable PAH concentrations were similar in PL and CS biochars; thus, PAHs cannot be responsible for the observed toxicity. The calculated concentrations of VFAs in biochar suspensions (from data of Table 2) are at levels that may cause detrimental effects; for instance, the calculated PL400 VFAs at 40 g/L (374 μg/g) was higher than 252 μg/g EC_{50} values for plant growth.[46] However, different factors govern the physiological response of VFAs, including pH and bioavailability.[51,52] Acetic acid was present in all of the biochars, partly due to the decomposition of cellulose/hemicellulose. In addition, the occurrence of benzoic acid and other aromatic acids was identified by DI-SPME along with VFAs. Benzoic acid is reported to inhibit hydraulic conductivity and nutrient uptake by plant roots, thus resulting in growth inhibition.[53] However, no significant effect of benzoic acid on *Orobanche crenata* seed germination was observed by Fernández-Aparicio et al.[54]

The suite of alkanes/alkenes characterizing the Py-GC-MS pyrolysates of poultry litter biochar samples would suggest the presence of a lipid fraction producing shorter chain fatty acids by thermal degradation as confirmed by SPME-GC-MS on PL400.

The main differences between the CS and PL biochars were the higher content of elemental nitrogen (Table 1) and ammonium (Table 2) and the presence of a thermally labile fraction derived from proteins and lipids (Py-GC-MS data).

Germination Tests after Biochar Post-treatment. A selected sample of poultry litter biochar (PL400) was extracted with water followed by methanol extraction; the extracts and the residue were utilized in germination tests. Germination tests were also performed on PL400 after treatment with sewage sludge to assess the effect of biodegradation. The quantity of extracts and the residues corresponded to the biochar loading level of 40 g/L. The results are presented in Figure 3. The cress germination rate in the water extracts was similar to that of the original biochar suspensions, indicating inhibition due to some components in the water extracts. The germination rates increased significantly to values similar to the control when the suspension was made with the biochar left after solvent extraction. These observations are supported by the results of Rogovska et al.,[21] who showed that growth inhibition no longer occurred when biochars were washed prior to germination.

Biochar suspensions treated with an active sludge for almost 2 weeks displayed a germination rate similar to that of the extracted biochar (Figure 3). The reduced toxicity could be ascribed to microbial degradation of some noxious components as suggested by Bargmann et al.[28]

The results shown in Figure 3 indicated that the relative seed germination of water extracts is low and comparable to that of the original biochar, strongly supporting the hypothesis that the polar/ionic constituents ending up in water are responsible for the observed biochar toxicity. Similarly, Bargmann et al.,[28] applying germination tests to hydrochars from various origins, demonstrated that the inhibiting effects were caused by some water-soluble substances. These authors hypothesized that organic acids could be possibly responsible for the water-extractable fractions' toxicity. The potential of microbial detoxification was evidenced by Busch et al.,[26] who observed that the genotoxicity of hydrochar mixed with compost became lower than that of pure hydrochar.

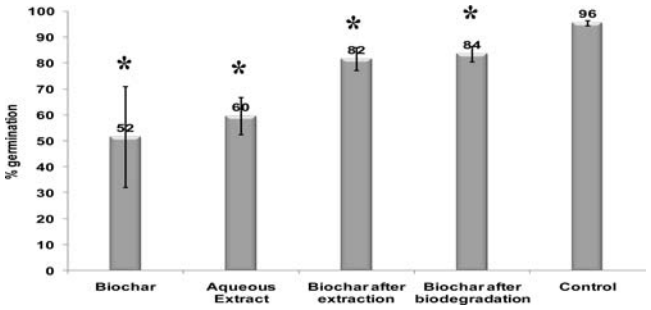

Figure 3. Seed germination rates relative to control of original poultry litter biochar (PL400), water extracts, and PL400 after post-treatments (solvent extraction and treatment with active sludge). Germination tests referred to a biochar load of 40 g/L. The germination rate of control (water only) is reported for comparison. * indicates differences at the 0.05 level compared with the control by Dunnett's tests.

Gell et al.[50] showed that the short-term phytotoxicity of biochar is dependent on the feedstock and is probably associated with ionic water-soluble constituents rather than the less polar organic compounds' composing tars. Accordingly, the methanolic extract of biochar after water extraction exhibited a seed germination rate of 93% (not reported in Figure 3), higher than that measured in the water extracts. Interestingly, among the various biochars investigated by Gell et al.,[50] those obtained from poultry biochar exhibited positive effects (radish root elongation) and acted to decrease the phytotoxicity of digestates.

The results of this study suggested that toxic compounds responsible for the toxicity of PL400 were water extractable and biodegradable. The SPME analysis of the water extracts (Figure 2) evidenced that aliphatic and aromatic carboxylic acids were the dominant compounds. Py-GC-MS and HS-SPME analyses evidenced the presence of NCCs that seemingly were not partitioned into the water phase.

Biochar has potential as a soil amendment for improving soil quality, decreasing fertilizer losses, and storing carbon in the soil. Nevertheless, as a soil additive, the absence of phytotoxicity is the minimal requirement. Biochar from poultry litter may exert a negative effect at least at the relatively high level of soil amendment (40 t/ha) due to the presence of water-soluble and biodegradable components, probably derived from the thermal decomposition of proteins and lipids. However, the toxicity can be drastically reduced by means of washing with water or mixing with biologically active material. Whereas leaching (accompanied by wastewater generation) would be not an applicable option, biological treatment (e.g., composting or mixing with activated sludge) of phytotoxic biochars could be a simple and economic solution for increasing the agronomic performance of biochar characterized by toxicity issues. The results obtained show that biochars are not an "intrinsically safe" material, and every biochar (from different processes and/or feedstocks) has to be evaluated, checked, and eventually treated before agronomic application.

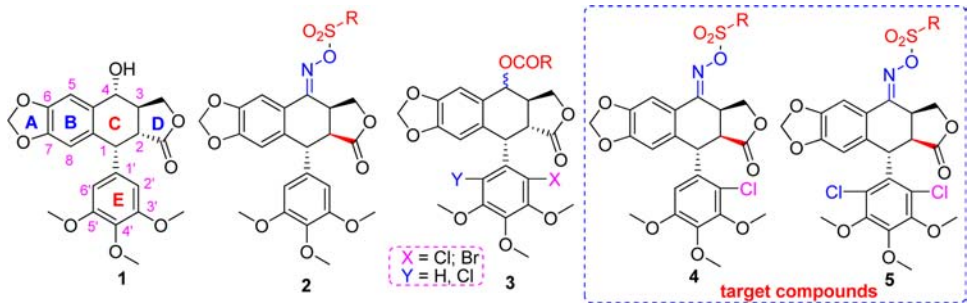

Figure 1. Chemical structures of podophyllotoxin (**1**) and its derivatives (**2**−**5**).

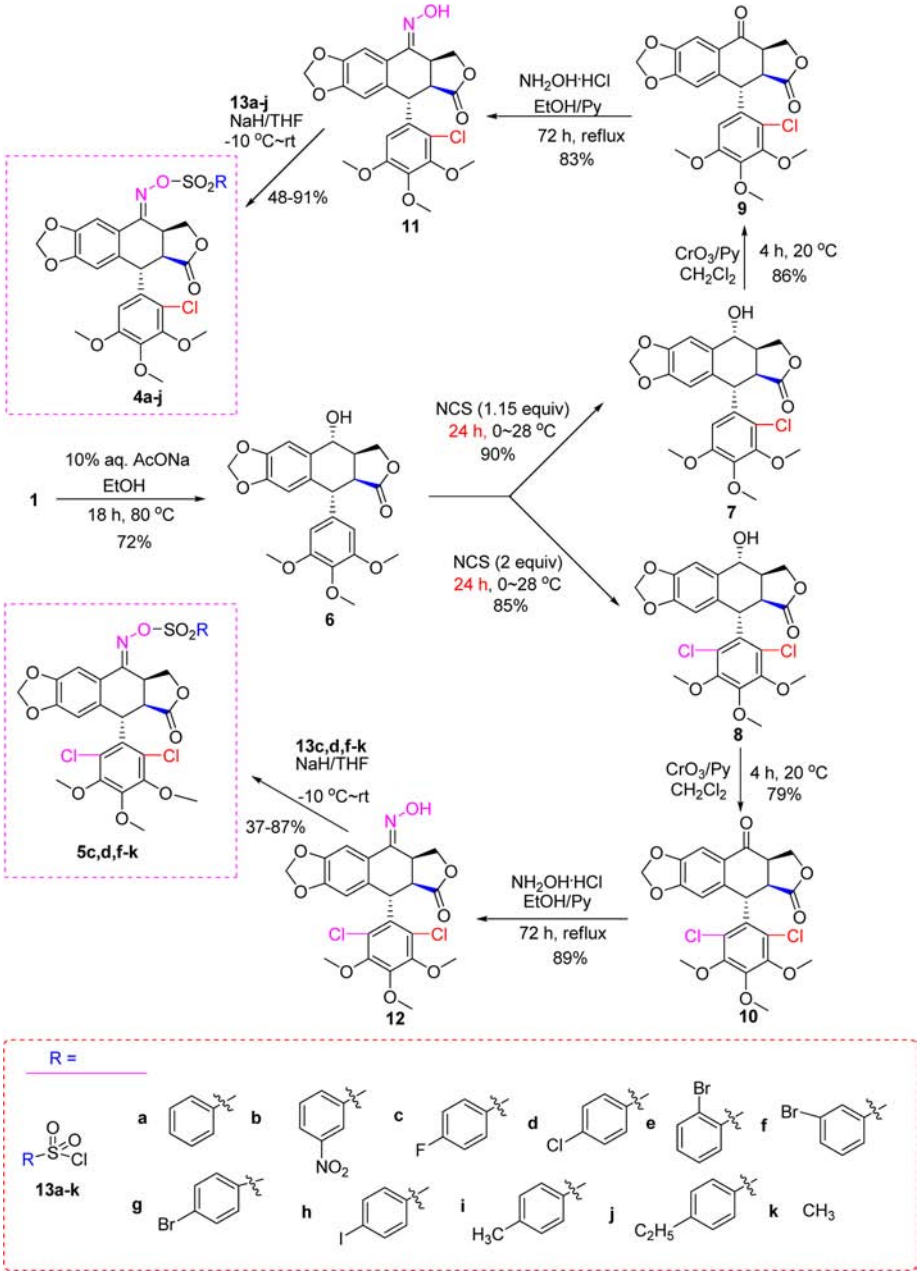
Scheme 1. Synthesis of Oxime Sulfonate Derivatives of 2′(2′,6′)-(Di)chloropicropodophyllotoxins (4a−4j, 5c, 5d, and 5f−5k)



Instrumentation. Melting points (mp) were determined on a XT-4 digital melting point apparatus (Beijing Tech Instrument Co., Ltd., Beijing, China) and were uncorrected. Optical rotation was measured on a Rudolph Research Analytical Autopol III automatic polarimeter. Proton nuclear magnetic resonance spectra (^{1}H NMR) were recorded in $CDCl_3$ on a Bruker Avance III 500 MHz instrument using tetramethylsilane (TMS) as the internal standard. High-resolution mass spectrometry (HRMS) was carried out with an IonSpec 4.7 T FTMS instrument.

General Procedure for Synthesis of 2′-Chloropicropodophyllotoxin (7) and 2′,6′-Dichloropicropodophyllotoxin (8). To a solution of compound **6** (2 mmol) in dry DMF (5 mL) at 0 °C, a solution of NCS (1.15 or 2.0 equiv) in dry DMF (4 mL) was added dropwise for 10 min. During 1 h, the solution was allowed to warm slowly from 0 to 28 °C. When the reaction was complete checked by TLC analysis, the reaction mixture was diluted with water (15 mL) and extracted with ethyl acetate (30 mL × 3). Subsequently, the combined organic phase was washed by saturated aqueous Na_2CO_3 (30 mL × 3) and brine (30 mL), dried over anhydrous Na_2SO_4, concentrated *in vacuo*, and purified by silica gel column chromatography eluting with petroleum ether/ethyl acetate (1:1, v/v) to afford compound **7** (747 mg, 90% yield) or compound **8** (705 mg, 85% yield).

*Data for Compound **7**.* CAS Registry Number: 1458601-21-2. Yield: 90%, white solid. mp: 115−117 °C (literature value of 116−117 °C).[21] $[\alpha]_D^{20}$ = 5 (*c* 3.2 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.09 (s, 1H, H-5), 6.61 (s, 1H, H-8), 6.18 (s, 1H, H-6′), 5.94 (s, 2H, OCH_2O), 4.66 (d, *J* = 9.5 Hz, 1H, H-11), 4.47 (d, *J* = 9.5 Hz, 1H, H-4), 4.40−4.43 (m, 1H, H-11), 4.38 (d, *J* = 5.0 Hz, 1H, H-1), 3.92 (s, 3H, 3′-OCH_3), 3.91 (s, 3H, 5′-OCH_3), 3.80 (s, 3H, 4′-OCH_3), 3.27−3.30 (m, 1H, H-2), 2.90 (s, 1H, 4-OH), 2.60−2.65 (m, 1H, H-3). HRMS (ESI): calcd for $C_{22}H_{25}ClNO_8$ ($[M + NH_4]^+$), 466.1263; found, 466.1271.

*Data for Compound **8**.* CAS Registry Number: 1458601-23-4. Yield: 85%, pale yellow solid. mp: 155−157 °C (literature value of 159−160 °C).[21] $[\alpha]_D^{20}$ = 29 (*c* 3.8 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.15 (s, 1H, H-5), 6.05 (s, 1H, H-8), 5.93 (s, 2H, OCH_2O), 5.01 (d, *J* = 6.5 Hz, 1H, H-1), 4.77 (d, *J* = 10.0 Hz, 1H, H-4), 4.44−4.46 (m, 2H, H-11), 3.99 (s, 3H, 3′-OCH_3), 3.96 (s, 3H, 5′-OCH_3), 3.89 (s, 3H, 4′-OCH_3), 3.49 (dd, *J* = 9.0 and 6.5 Hz, 1H, H-2), 2.59−2.64 (m, 1H, H-3). HRMS (ESI): calcd for $C_{22}H_{24}Cl_2NO_8$ ($[M + NH_4]^+$), 500.0873; found, 500.0876.

General Procedure for Synthesis of 2′-Chloropicropodophyllone (9) and 2′,6′-Dichloropicropodophyllone (10). A mixture of compound **7** or **8** (1 mmol), chromium trioxide (CrO_3, 5 mmol), and pyridine (10 mmol) in dry dichloromethane (20 mL) was stirred at room temperature. When the reaction was complete after 4 h and checked by TLC analysis, the mixture was diluted by dichloromethane (60 mL), washed by saturated aqueous $NaHSO_3$ (30 mL) and brine (30 mL), dried over anhydrous Na_2SO_4, concentrated under reduced pressure, and purified by silica gel column chromatography eluting with petroleum ether/ethyl acetate (1:1, v/v) to afford compound **9** (386 mg, 86% yield) or compound **10** (383 mg, 79% yield).

*Data for Compound **9**.* Yield: 86%, yellow solid. mp: 105−107 °C. $[\alpha]_D^{20}$ = −30 (*c* 3.4 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.51 (s, 1H, H-5), 6.68 (s, 1H, H-8), 6.07 (d, *J* = 1.0 Hz, 2H, OCH_2O), 5.85 (s, 1H, H-6′), 5.21 (d, *J* = 1.5 Hz, 1H, H-1), 4.75 (d, *J* = 9.0 Hz, 1H, H-11), 4.32−4.35 (m, 1H, H-11), 3.95 (s, 3H, 3′-OCH_3), 3,85 (s, 3H, 5′-OCH_3), 3.54 (s, 3H, 4′-OCH_3), 3.42 (dd, *J* = 8.0 and 2.0 Hz, 1H, H-2), 3.15−3.18 (m, 1H, H-3). HRMS (ESI): calcd for $C_{22}H_{20}O_8Cl$ ($[M + H]^+$), 447.0841; found, 447.0835.

*Data for Compound **10**.* Yield: 79%, yellow solid. mp: 90−92 °C. $[\alpha]_D^{20}$ = −67 (*c* 3.3 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.48 (s, 1H, H-5), 6.32 (s, 1H, H-8), 6.01 (s, 2H, OCH_2O), 5.68 (d, *J* = 4.5 Hz, 1H, H-1), 4.91 (dd, *J* = 9.0 and 3.5 Hz, 1H, H-11), 4.50 (dd, *J* = 9.5 and 7.0 Hz, 1H, H-11), 3.97 (s, 3H, 3′-OCH_3), 3.96 (s, 3H, 5′-OCH_3), 3.86 (s, 3H, 4′-OCH_3), 3.65−3.69 (m, 1H, H-2), 3.43−3.45 (m, 1H, H-3). HRMS (ESI): calcd for $C_{22}H_{19}O_8Cl_2$ ($[M + H]^+$), 481.0451; found, 481.0455.

General Procedure for Synthesis of Oximes of 2′-Chloropicropodophyllone and 2′,6′-Dichloropicropodophyllone (11 and 12). A mixture of compound **9** or **10** (0.5 mmol), hydroxylamine hydrochloride (0.75 mmol), and pyridine (2 mmol) in absolute ethanol (20 mL) was refluxed. When the reaction was complete after 72 h and checked by TLC analysis, the solvent was removed under reduced pressure and saturated aqueous $NaHCO_3$ (15 mL) was added to the residue, which was extracted with ethyl acetate (3 × 30 mL). The combined organic phase was dried over anhydrous Na_2SO_4, filtered, concentrated under reduced pressure, and purified by silica gel column chromatography eluting with petroleum ether/ethyl acetate (1:1, v/v) to afford compound **11** (193 mg, 83% yield) or compound **12** (214 mg, 89% yield).

*Data for Compound **11**.* Yield: 83%, pale yellow solid. mp: 106−107 °C. $[\alpha]_D^{20}$ = −27 (*c* 3.4 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.27 (s, 1H, H-5), 6.70 (s, 1H, H-8), 5.99 (s, 2H, OCH_2O), 5.95 (s, 1H, H-6′), 5.07 (d, *J* = 2.0 Hz, 1H, H-1), 4.47−4.53 (m, 2H, H-11), 3.93 (s, 3H, 3′-OCH_3), 3.83−3.86 (m, 4H, H-3, 5′-OCH_3), 3.52 (s, 3H, 4′-OCH_3), 3.43 (dd, *J* = 8.5, 2.5 Hz, 1H, H-2). HRMS (ESI): calcd for $C_{22}H_{21}O_8NCl$ ($[M + H]^+$), 462.0950; found, 462.0949.

*Data for Compound **12**.* Yield: 89%, white solid. mp: 118−120 °C. $[\alpha]_D^{20}$ = 54 (*c* 5.3 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.63 (s, 1H, OH), 7.41 (s, 1H, H-5), 6.21 (s, 1H, H-8), 5.93 (s, 2H, OCH_2O), 5.24 (d, *J* = 10.5 Hz, 1H, H-1), 5.02−5.08 (m, 1H, H-11), 4.28−4.33 (m, 2H, H-11, H-3), 3.99 (s, 3H, 4′-OCH_3), 3.93 (s, 3H, 3′-OCH_3), 3.90 (s, 3H, 5′-OCH_3), 3.59 (dd, *J* = 10.5 and 6.5 Hz, 1H, H-2). HRMS (ESI): calcd for $C_{22}H_{20}O_8NCl_2$ ($[M + H]^+$), 496.0560; found, 496.0555.

General Procedure for Synthesis of Oxime Sulfonate Derivatives of 2′(2′,6′)-(Di)chloropicropodophyllotoxins (4a−4j, 5c, 5d, and 5f−5k). To a stirred solution of NaH (1.4 mmol) in dry THF (8 mL) at −10 °C was slowly added compound **11** or **12** (0.2 mmol). After the completion of addition, the reaction mixture was stirred at −10 °C for 0.5 h. Then, the corresponding sulfonyl chlorides RSO_2Cl (**13**, 0.8 mmol) were added to the above mixture. The reaction process was checked by TLC analysis. When the reaction mixture was stirred for 3 h at −10 °C (for methanesulfonyl chloride, the reaction mixture was stirred at room temperature for 48 h), saturated aqueous $NaHCO_3$ (15 mL) was added to the mixture, which was extracted with dichloromethane (3 × 30 mL). The combined organic phase was dried over anhydrous Na_2SO_4, filtered, concentrated under reduced pressure, and purified by preparative thin-layer chromatography (PTLC) to give target products compounds **4a−4j**, **5c**, **5d**, and **5f−5k** in 37−91% yields. The example data of compounds **4a−4e**, **5c**, and **5d** are described as follows, whereas the data of compounds **4f−4j** and **5f−5k** are shown in the Supporting Information.

*Data for Compound **4a**.* Yield: 82%, white solid. mp: 102−104 °C. $[\alpha]_D^{20}$ = 4 (*c* 4.2 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.02−8.04 (m, 2H, H-2″, H-6″), 7.73 (t, *J* = 7.5 Hz, 1H, H-4″), 7.59−7.62 (m, 2H, H-3″, H-5″), 7.14 (s, 1H, H-5), 6.71 (s, 1H, H-8), 6.02 (s, 2H, OCH_2O), 5.77 (s, 1H, H-6′), 5.08 (d, *J* = 2.0 Hz, 1H, H-1), 4.54 (dd, *J* = 10.0 and 7.0 Hz, 1H, H-11), 4.31 (d, *J* = 10.0 Hz, 1H, H-11), 3.92 (s, 3H, 3′-OCH_3), 3.89−3.91 (m, 1H, H-3), 3.84 (s, 3H, 5′-OCH_3), 3.40 (dd, *J* = 8.5 and 2.5 Hz, 1H, H-2), 3.36 (s, 3H, 4′-OCH_3). HRMS (ESI): calcd for $C_{28}H_{25}O_{10}NClS$ ($[M + H]^+$), 602.0882; found, 602.0885.

*Data for Compound **4b**.* Yield: 48%, yellow solid. mp: 112−114 °C. $[\alpha]_D^{20}$ = 6 (*c* 4.0 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.90 (s, 1H, H-2″), 8.59 (d, *J* = 7.5 Hz, 1H, H-6″), 8.36 (d, *J* = 7.5 Hz, 1H, H-4″), 7.87 (t, *J* = 7.5 Hz, 1H, H-5″), 7.09 (s, 1H, H-5), 6.73 (s, 1H, H-8), 6.03 (s, 2H, OCH_2O), 5.77 (s, 1H, H-6′), 5.09 (s, 1H, H-1), 4.54−4.57 (m, 1H, H-11), 4.31 (d, *J* = 10.0 Hz, 1H, H-11), 3.93 (s, 3H, 3′-OCH_3), 3.89−3.90 (m, 1H, H-3), 3.85 (s, 3H, 5′-OCH_3), 3.42−3.46 (m, 4H, 4′-OCH_3, H-2). HRMS (ESI): calcd for $C_{28}H_{24}O_{12}N_2ClS$ ($[M + H]^+$), 647.07; found, 647.07.

*Data for Compound **4c**.* Yield: 75%, yellow solid. mp: 106−108 °C. $[\alpha]_D^{20}$ = 10 (*c* 3.6 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.04−8.07 (m, 2H, H-2″, H-6″), 7.27−7.30 (m, 2H, H-3″, H-5″), 7.12 (s, 1H, H-5), 6.72 (s, 1H, H-8), 6.03 (s, 2H, OCH_2O), 5.77 (s, 1H, H-6′), 5.08 (d, *J* = 2.0 Hz, 1H, H-1), 4.55 (dd, *J* = 10.0 and 7.0 Hz, 1H, H-11), 4.32 (d, *J* = 9.5 Hz, 1H, H-11), 3.92 (s, 3H, 3′-OCH_3), 3.90 (m, 1H, H-3), 3.84 (s, 3H, 5′-OCH_3), 3.39−3.41 (m, 4H, 4′-OCH_3, H-2). HRMS (ESI): calcd for $C_{28}H_{24}O_{10}NClFS$ ($[M + H]^+$), 620.0788; found, 620.0784.

*Data for Compound **4d**.* Yield: 82%, white solid. mp: 88−90 °C. $[\alpha]_D^{20}$ = 15 (*c* 4.0 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.96 (d, *J* = 7.0 Hz, 2H, H-2″, H-6″), 7.59 (dd, *J* = 6.5 and 2.0 Hz, 2H, H-3″, H-5″), 7.13 (s, 1H, H-5), 6.72 (s, 1H, H-8), 6.03 (s, 2H, OCH_2O), 5.75 (s, 1H, H-6′), 5.08 (d, *J* = 2.5 Hz, 1H, H-1), 4.55 (dd, *J* = 9.5 and 7.0 Hz, 1H, H-11), 4.30−4.32 (m, 1H, H-11), 3.92 (s, 3H, 3′-OCH_3), 3.87−3.90 (m, 1H, H-3), 3.84 (s, 3H, 5′-OCH_3), 3.41 (dd, *J* = 8.5 and 2.5 Hz, 1H, H-2), 3.38 (s, 3H, 4′-OCH_3). HRMS (ESI): calcd for $C_{28}H_{24}O_{10}NCl_2S$ ($[M + H]^+$), 636.0492; found, 636.0498.

*Data for Compound **4e**.* Yield: 57%, yellow solid. mp: 116−118 °C. $[\alpha]_D^{20}$ = 21 (*c* 3.0 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$)

HRMS (ESI): calcd for $C_{28}H_{23}O_{10}NCl_2FS$ ([M + H]$^+$), 654.0398; found, 654.0407.

Data for Compound ***5d***. Yield: 44%, yellow solid. mp: 96−98 °C. $[\alpha]_D^{20}$ = 20 (c 3.8 mg/mL, acetone). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.98−8.00 (m, 2H, H-2″, H-6″), 7.58−7.59 (m, 2H, H-3″, H-5″), 7.30 (s, 1H, H-5), 6.22 (s, 1H, H-8), 5.99 (d, J = 9.5 Hz, 2H, OCH_2O), 5.25 (d, J = 10.0 Hz, 1H, H-1), 4.91−4.97 (m, 1H, H-11), 4.24−4.27 (m, 2H, H-11, H-3), 3.97 (s, 3H, 4′-OCH_3), 3.92 (s, 3H, 3′-OCH_3), 3.87 (s, 3H, 5′-OCH_3), 3.48−3.51 (m, 1H, H-2). HRMS (ESI): calcd for $C_{28}H_{23}O_{10}NCl_3S$ ([M + H]$^+$), 670.0103; found, 670.0100.

Biological Assay. The insecticidal activity of compounds **1**, **4a**−**4j**, **5c**, **5d**, **5f**−**5k**, and **6**−**12** was evaluated as the mortality rate values by the leaf-dipping method, as described previously,[19] against the pre-third-instar larvae of oriental armyworm (*M. separata* Walker). For each compound, 30 pre-third-instar larvae (10 larvae per group) were used. Acetone solutions of compounds **1**, **4a**−**4j**, **5c**, **5d**, **5f**−**5k**, and **6**−**12** and toosendanin (a positive control) were prepared at 1 mg/mL. Fresh wheat leaf discs (1 × 1 cm) were dipped into the corresponding solution for 3 s, then taken out, and dried. Leaf discs treated with acetone alone were used as a blank control group. Several pieces of treated leaf discs were kept in each dish (10 larvae were raised in each dish), which was then placed in a conditioned room [25 ± 2 °C, 65−80% relative humidity (RH), and 12/12 h (light/dark) photoperiod]. If the treated leaf discs were consumed, additional treated leaf discs were added to the dish. After 48 h, compound-soaked leaves were removed and the larvae were fed with untreated fresh wheat leaves thereafter until adult emergence. The corrected mortality rate values were obtained by the formula

$$\text{corrected mortality rate } (\%) = (T - C) \times 100/(100\% - C)$$

where T is the mortality rate in the tested compound group and C is the mortality rate in the blank control group (T and C were expressed as percentages).

RESULTS AND DISCUSSION

Synthesis. As described in Scheme 1, 2′-chloropicropodophyllotoxin (**7**) and 2′,6′-dichloropicropodophyllotoxin (**8**) were smoothly prepared by reaction of compound **6** with different amounts of NCS. Further oxidation of the hydroxy group at the C-4 position of compound **7** or **8** in the presence of CrO_3 and pyridine gave 2′-chloropicropodophyllone (**9**) and 2′,6′-dichloropicropodophyllone (**10**), respectively. Subsequently, oximes of 2′-chloropicropodophyllone and 2′,6′-dichloropicropodophyllone (**11** and **12**) were obtained by reaction of hydroxylamine hydrochloride with compounds **9** and **10**, respectively. Finally, oxime sulfonate derivatives of 2′(2′,6′)-(Di)chloropicropodophyllotoxins (**4a**−**4j**, **5c**, **5d**, and **5f**−**5k**) were afforded by reaction of sulfonyl chlorides with compounds **11** and **12**, respectively. The structures of all target compounds were well-characterized by ^{1}H NMR, HRMS, optical rotation, and melting point. Moreover, the single-crystal structure of compound **5f** was further confirmed by X-ray crystallography (Figure 2). It clearly demonstrated that the substituents on the C═N double bond of compound **5f** were present in *trans* configuration; two hydrogen atoms at the C-2 and C-3 positions all adopted α configuration (that is, the configuration of lactone (D ring) of compound **5f** was *cis*), and two chlorine atoms were at the C-2′ and C-6′ positions of compound **5f**. Crystallographic data (excluding structure factors) for the structure of compound **5f** have been deposited with the Cambridge Crystallographic Data Centre (CCDC) as supplementary publication number CCDC 1055791. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (fax, +44-0-1223-336033; e-mail, deposit@ccdc.cam.ac.uk).

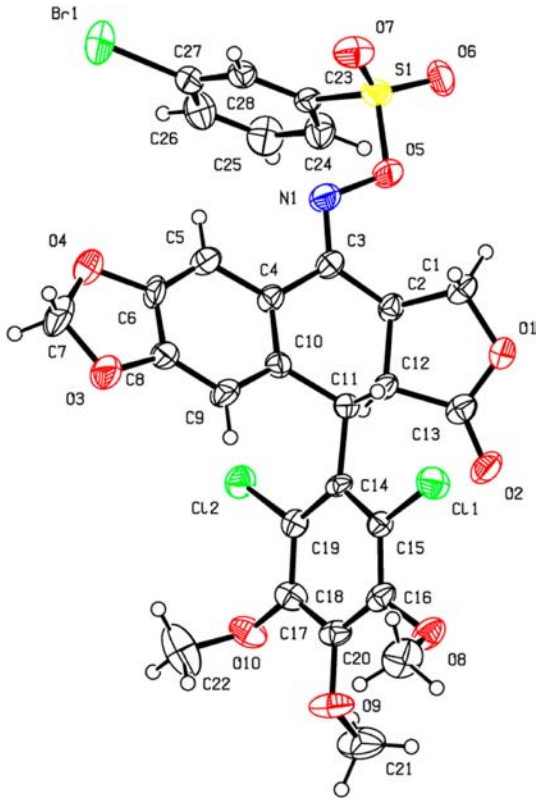

Figure 2. X-ray crystal structure of compound **5f**.

Insecticidal Activity. As shown in Table 1, the insecticidal activity of compounds **1**, **4a**−**4j**, **5c**, **5d**, **5f**−**5k**, and **6**−**12** against the pre-third-instar larvae of *M. separata in vivo* was evaluated as the mortality rates at 1 mg/mL. Toosendanin was used as a positive control at 1 mg/mL, and leaves treated with acetone alone were used as a blank control group. The corresponding mortality rates of the treated groups after 35 days were higher than those after 5, 10, 15, 20, and 25 days, as we reported in our previous papers.[19−21] As described in Figure 3, the lethal times for 50% mortality of compounds **8**, **4c**−**4g**, **5c**, **5d**, **5f**, and **5g** were 32, 23, 26, 31, 29, 29, 24, 25, 27, and 28 days, respectively. In addition, the symptoms of *M. separata* in the treated groups were characterized as follows: some larvae with the slim and wrinkled bodies died at the larval stage because of feeding too much treated leaves during the first 48 h (Figure 4); some larvae molted to malformed pupae or died during the pupation period (Figure 5), and it was noteworthy that more than half of the final mortality rates were generally occupied by the mortality rates at this stage; malformed moths also appeared with imperfect wings (Figure 6). It suggested that the podophyllotoxin derivatives possibly exhibited the anti-molting hormone effect. Among all derivatives, compounds **7**, **8**, **4c**−**4g**, **5c**, **5d**, **5f**, and **5g** exhibited insecticidal activity equal to or higher than that of the positive control

toosendanin. Especially compounds **4c**, **5c**, and **5d** exhibited more promising insecticidal activity, with the final mortality rates greater than 60%. For example, the final mortality rates of compounds **4c**, **5c** and **5d** were 62.1, 65.5, and 62.1%, respectively, whereas the final mortality rates of the precursor **1** and toosendanin were 37.9 and 48.3%, respectively. Introduction of the chlorine atom at the C-2′ or C-2′,6′ position on the E ring of compound **6** afforded the potent compounds **7** and **8** (48.3% for compound **7** and 51.7% for compound **8**, while 34.5% for compound **6**). Similarly, introduction of the chlorine atom at the

Figure 4. Representative abnormal larvae pictures of compounds **4g** (WR-015), **4d** (WR-026), **4c** (WR-039), **5g** (WR-022), **5j** (WR-043), **5d** (WR-038), and **5c** (WR-041) during the larval period (CK = blank control group).

Figure 5. Representative malformed pupae pictures of compounds **4g** (WR-015), **4d** (WR-026), **4f** (WR-046), **5j** (WR-043), **5g** (WR-022), **5d** (WR-038), and **5c** (WR-041) during the pupation period (CK = blank control group).

C-2′ or C-2′,6′ position on the E ring of oxime sulfonate derivatives of picropodophyllotoxin (**2**) could also produce more potent compounds compared to compound **2**.[19] For example, the final mortality rates of compounds **4a**, **4b**, **4d**, **4g**, **4i**, and **4j** were 37.9, 41.4, 58.6, 55.2, 41.4, and 37.9%, respectively, whereas the final mortality rates of the corresponding oxime sulfonate derivatives of picropodophyllotoxin were 24.1, 13.8, 55.2, 27.6, 44.8, and 27.6%, respectively.[19] To oxime sulfonate derivatives of 2′-chloropicropodophyllotoxins (**4a**−**4j**), introduction of a halogen atom (such as a fluorine, chlorine, or bromine atom) on the phenylsulfonyl group of compound **4a** resulted in more promising compounds **4c**−**4g**. The final mortality rates of compounds **4c**−**4g** were 62.1, 58.6, 51.7, 55.2, and 55.2%, respectively, whereas the final mortality rate of compound **4a** was only 37.9%. Interestingly, to oxime sulfonate derivatives of

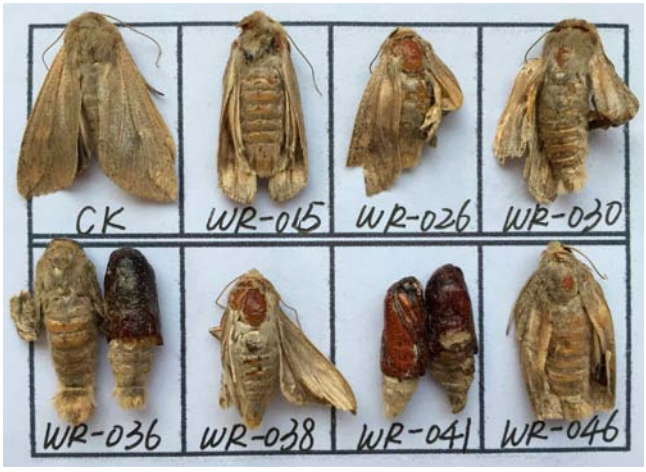

Figure 6. Representative malformed moth pictures of compounds **4g** (WR-015), **4d** (WR-026), **4a** (WR-030), **5k** (WR-036), **5d** (WR-038), **5c** (WR-041), and **4f** (WR-046) during the stage of adult emergence (CK = blank control group).

2′,6′-dichloropicropodophyllotoxins (**5c**, **5d**, and **5f**–**5k**), introduction of a fluorine, chlorine, or bromine atom on the phenylsulfonyl group could also give potent compounds **5c**, **5d**, **5f**, and **5g**, the final mortality rates of which were 65.5, 62.1, 58.6, and 58.6%, respectively. On the contrary, compounds **4a**–**4j**, **5c**, **5d**, and **5f**–**5k**, whether introduction of a nitro group (electron-withdrawing group) or methyl/ethyl group (electron-donating group) on the phenylsulfonyl fragment, all afforded less potent compounds **4b**, **4i**, **4j**, **5i**, and **5j**. When the methylsulfonyl group was introduced at the oxime fragment of compound **12**, the corresponding compound **5k** showed less potent insecticidal activity compared to compound **5c** (44.8% for compound **5k** and 65.5% for compound **5c**).

In conclusion, a series of oxime sulfonate derivatives of 2′(2′,6′)-(Di)chloropicropodophyllotoxins were prepared by structural modification of podophyllotoxin. Their insecticidal activity was evaluated at 1 mg/mL against the pre-third-instar larvae of *M. separata*. The key steric structure of compound **5f** was unambiguously determined by single-crystal X-ray diffraction. Among all derivatives, compounds **4c**, **5c**, and **5d** exhibited more potent insecticidal activity, with the final mortality rates greater than 60%. It demonstrated that introduction of the chlorine atom at the C-2′ or C-2′,6′ position on the E ring of picropodophyllotoxin or oxime sulfonate derivatives of picropodophyllotoxin was necessary for the insecticidal activity and introduction of a halogen (e.g., fluorine, chlorine, or bromine) atom-substituted phenylsulfonyl group on the oxime fragment of 2′(2′,6′)-(di)chloropicropodophyllones led to more promising compounds. It will pave the way for further design and chemical modification of podophyllotoxin as botanical insecticidal agents.

The spring onion (*Allium fistulosum*) is widely used throughout southeast Asia as well as in the north in China, Korea, and Japan. It is used raw as a herb to give flavor and a touch of bright green color to many soups, noodles, and other dishes. Dried spring onion is used for seasonings or condiments to improve the flavor and pungency of food, which have some potential benefits for human health.[7,8]

Because pesticides are a toxic compound used to kill pests in crops, when it remains on treated crops, the presence of harmful pesticide residues in food has caused a great concern among consumers. Food safety is an area of growing worldwide concern on account of its direct bearing on human health. Food processing treatment such as washing, peeling, canning, or cooking leads to a significant reduction of pesticide residues.[9]

There are no publications on the dissipation of etofenprox in spring onion and residue removal during processing. In this paper, we report residue decline in green onion after treatment of etofenprox with two different application rates and reduction of residual etofenprox on spring onion by various washing and drying processes with a heating oven or a freeze dryer.

MATERIALS AND METHODS

Chemicals and Reagents. The analytical standard of etofenprox (97.7%) was purchased from Fluka (Switzerland). The etofenprox formulation with 20% emulsifiable concentrate (EC) (Kyung Nong Co., Ltd., Korea) was purchased from a local market. Acetonitrile, dichloromethane, ethyl acetate, *n*-hexane, and methanol were high-performance liquid chromatography (HPLC)-grade (Burdick and Jackson, Ulsan, Korea). Sodium chloride [Extra Pure (EP) grade] and sodium sulfate (EP grade) were from Samchun Pure Chemical Co., Ltd. (Pyeongtaek, Korea). Florisil (0.15−0.250 mm) was purchased from Merck KGaA (Germany) and activated by drying at 130 °C for over 5 h. Filter papers (GF/A) were from Whatman International, Ltd. (Maidstone, U.K.). The vacuum rotary evaporator was from Heidolph (Germany). The Waring blender was from Zymark (Germany). A FO-600M drying oven was from Jeio Tech, Korea. The PVTFD20R freeze dryer was from ilShin Biobase, Korea.

Field Experiment. The field trial on spring onion (Jeju Island variety) was carried out in a greenhouse located in Cheong-ju, Republic of Korea. Treatment (control, single application, and double application) was made in triplicate of 30 m^2 plot size with a total of 90 m^2 for each treatment. Each randomized plot was separated by a buffering area of 5 m^2 to avoid cross-contamination by drift, etc. The first application was sprayed to onions 20 days after germination, and the second application was performed after 7 days. The planting density of spring onion was 15 × 15 cm, and over 1300 bunches of onions were evenly distributed for each test plot (30 m^2). The temperature and relative humidity in the greenhouse were continuously measured during the spring onion cultivation period using an electric data logger (Lascar, China).

Pesticide Application and Sample Collection. Etofenprox with 20% EC with the product name of "Severo" (Gyung Nong Co., Ltd., Korea) was sprayed at a standard rate (20 mL/20 L) 1 time or 2 times with a 7 day interval using a pressurized hand-held sprayer. The total volume of spray solution applied to each 30 m^2 plot was 10 L, which is equivalent to 200 mg of etofenprox per plot. To study the dissipation pattern, 2 kg of spring onion samples was collected randomly from each treated plot as well as from the untreated plot at 0, 1, 4, 6, 8, 10, 12, and 14 days after final treatment (DAT). Immediately after picking, the samples were put into polyethylene bags and transported with ice to the laboratory, where the samples were homogenized. The homogenate of each sample was then placed into polyethylene bottles and frozen at −20 °C until analysis. For the processing experiment, 12 DAT samples were collected and processed with washing or drying.

Growth Condition during Cultivation. During spring onion cultivation, the greenhouse air temperature range was 12.5−20.8 °C and humidity was 63.6−90.5%. The weights of collected spring onion were gradually increased from 25.5 g at 0 DAT to 45.5 g at 14 DAT (Figure 1).

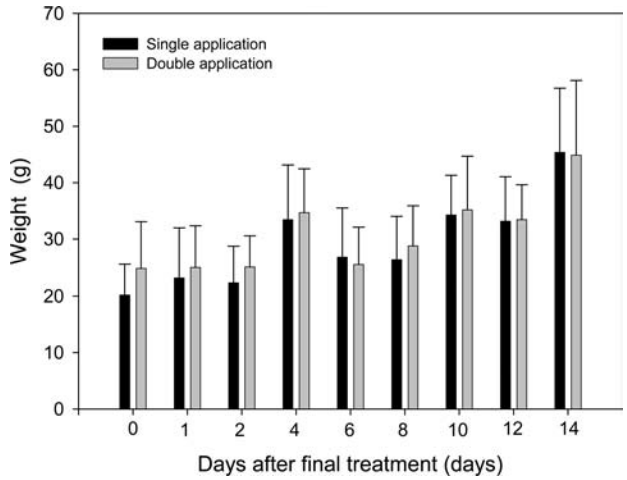

Figure 1. Growth rate of spring onion during cultivation [means ± standard deviation (SD); n = 10].

Measurement of Instrumental Sensitivity and Calibration Curve Linearity. The etofenprox analytical standard (97.7%, 10.24 mg) was dissolved in 100 mL of acetonirile to make stock 100 mg/L solution. From this stock solution, a working standard solution (50 mg/L) was prepared by dilution with acetonirile and then serially diluted to obtain a standard solution of 10, 5, 2.5, 1.0, 0.5, and 0.25 mg/L. An aliquot of 10 μL was analyzed using HPLC, and a standard calibration curve was prepared on the basis of the peak area.

HPLC Analysis Condition. HPLC was performed using a HP1200 system (Hewlett-Packard, Palo Alto, CA) with a Phenomenex Gemini-NX C_{18} (4.6 × 150 mm, 3 μm, Phenomenex, Torrance, CA) column. Mobile phases consisted of water (A) and acetonitrile (B) acidified with 0.1% acetic acid. The gradient condition used was from 70:30 (A/B, at 0−3 min) to 15:85 (at 12−17 min) and 70:30 (at 18−20 min). The flow rate was 0.8 mL/min. The injected sample (10 μL) was monitored at the wavelength of 235 nm.

Recovery Test of Etofenprox from Samples. To a sample (20 g) of homogenized spring onion, a standard solution of etofenprox was spiked at 0.5, 1.0, and 10 mg/kg. Then, the sample was extracted with 100 mL of acetone by homogenation in a Waring blender for 2 min, followed by filtering into a round-bottom flask of 500 mL capacity under vacuum through a Whatman filter paper no. 2. The container and filter cakes were washed twice with 50 mL of acetone, and the combined extracts were collected in a 500 mL flask. The filtrate was redissolved in 100 mL of dichloromethane (DCM). Then, 10 mL of saturated NaCl solution and 90 mL of water were added in the separatory funnel, and the funnel was shaken. After shaking, the lower DCM layer was drained into a 500 mL flask through anhydrous sodium sulfate supported on a prewashed glass wool in the conical funnel. This procedure was repeated with 100 mL of DCM. Then, extracts were collected, pooled, and concentrated to dryness using a vacuum evaporator at 40 °C. Then, the residue was redissolved in 10 mL of hexane. The concentrated extract was transferred to a chromatographic glass column, which was packed with 10 g of florisil in the bottom and 3 g of sodium sulfate in the top, with hexane as the packing solvent. The packed column was washed with 50 mL of hexane prior to use, and the concentrated extract was loaded on the top of the column and washed with 100 mL of hexane. Then, etofenprox was eluted with 100 mL of 5% ethyl acetate in hexane. Eluate was concentrated using a rotary vacuum evaporator, and the residue was redissolve in 4 mL of acetonitrile for analysis. Spring onion samples collected from the treated field were prepared with the method described above and analyzed using HPLC.

J. Agric. Food Chem. 2015, 63, 6675−6680

Dissipation and Biological Half-Life on Spring Onion. Dissipation of pesticide on spring onion was determined by first-order kinetic regression analysis with the following model:

$$C_t = C_0 e^{-kt}$$

where C_t is the concentration of pesticide at any time t, C_0 is the initial concentration, and k is the rate of constant in day^{-1}.

The biological half-life (DT_{50}), which is the time at which the concentration of initial deposits reaches the 50% level, was determined by the following equation:

$$DT_{50} = \ln 2k^{-1} = 0.693/k$$

Washing Process with Running Tap Water. The spring onion samples (1 kg) at 12 DAT were washed with running tap water for 1 min. The flow rate of the running tap water was regulated to 1 L/10 s. Then, the spring onion was air-dried under room temperature.

Tap Water Bath. The spring onions (1 kg) at 12 DAT were rinsed in a 6 L of tap water for 1 min, after which the onions were removed, the water was allowed to drain, and the onions were allowed to dry at room temperature for approximately 30 min.

Neutral Detergent Solution. The spring onion samples (1 kg) at 12 DAT were dipped at stagnant tap water containing 1% neutral detergent for 1 min. Afterward, they were washed with running tap water (the flow rate of the water was 1 L/10 s) for 30 s 2 times. Then, the spring onion was air-dried under room conditions.

Drying Process. Spring onion samples from a treated field were dried in the oven at 80 °C for 24 h or freeze-dried in the freeze dryer for 3 days. The compensated residue level (CRL) was expressed as fresh sample weight based on using the weight loss during the dry process. Weight reduction ratio (WRR) was calculated by dividing the weight before dry by the weight after dry. The CRL and removal rate was derived from the following formulation:

$$\text{WRR} = \frac{\text{weight before dry (g)}}{\text{weight after dry (g)}}$$

$$\text{CRL (mg/kg)} = \frac{\text{residue after dry (mg/kg)}}{\text{WRR}}$$

$$\text{removal rate (\%)} = \left(1 - \frac{\text{CRL}}{\text{residue before dry}}\right) \times 100$$

RESULTS AND DISCUSSION

Validation of the Analytical Method. Method validation is a set of procedures to evaluate the performance characteristics, such as recovery, reproducibility, linearity, range of calibration, limit of detection (LOD), and quantitation of a method for specific analyte and sample types.[10]

Quantification was accomplished by preparation of an external standard calibration curve after the dilution of the stock standard solution with acetonitrile. The calibration curve of etofenprox was linear from 0.25 to 50 mg/kg, covering the whole range of concentrations in the samples. The regression equation was $y = 20.60396x + 9.97170$, with the correlation coefficient (R^2) of 0.9995.

Instrumental LOD and limit of quantitation (LOQ) express the sensitivity of analytical instruments.[11,12] On the basis of the analysis of several concentrations, 1.0 and 2.5 ng were determined as the LOD and LOQ, respectively, which were satisfactory for sensitive analysis of etofenprox residue.

The method limit of quantitation (MLOQ) is not an instrumental LOQ but, instead, is a practical LOQ for the total analytical method. It is calculated using LOQ, injection volume, final solution volume, and sample weight in the analytical method.[13]

$$\text{MLOQ (mg/kg)} = (\text{LOQ} \times \text{final solution volume}) / (\text{injection volume} \times \text{sample weight})$$

$$\text{MLOQ (mg/kg)} = (2.5\ \text{ng} \times 4\ \text{mL})/(10\ \mu\text{L} \times 20\ \text{g}) = 0.05\ \text{mg/kg}$$

The MLOQ value for etofenprox calculated using the equation was 0.05 mg/kg. This value satisfied the criteria of the Korea Food and Drug Administration (KFDA), which are below 0.05 mg/kg or half of the maximum residue limit (MRL).[14]

The recovery was validated to estimate the efficiency of extraction and purification procedure before the determination of quantities of pesticides on collected samples. The untreated samples were fortified with etofenprox standard solution at three different levels and were analyzed after pretreatment. Average recovery ranged from 92.0 to 107.7% (Table 2), with the coefficient of variation (CV) less than 7.9%. According to the methods and criterion of pesticide registration tests, a typical recovery range should be from 75 to 120%, and the CV (standard deviation/average × 100) should be below 20%.[14] The HPLC chromatograms of the spring onion sample were shown in Figure 2. The retention time of etofenprox was 17.4 min, and no chromatographic interferences in the untreated sample of spring onion were observed. Thus, the developed method is applicable to analysis of the etofenprox residue in spring onion.

Table 2. Recovery and MLOQ for Etofenprox in Spring Onion

fortified level (mg/kg)	recovery ± CV[a]	MLOQ (mg/kg)[b]
0.5	97.0 ± 7.9	0.05
1	92.0 ± 6.3	
10	107.7 ± 4.3	

[a]Coefficient of variation = standard deviation/average × 100. [b]Method limit of quantification.

Biological Half-Lives of Etofenprox on Spring Onion. Under field conditions, various environmental conditions, such as temperature, moisture, and microbial activity, result in different degradation kinetics during the experimental period.[15] Decline of the pesticide residue during crop cultivation may be attributed primarily to physical chemistry characteristics of the pesticide as well as conditions of the cultivation, weathering, heat decomposition, methods for application, pre-harvest interval, or other complex conditions.[16−18] The etofenprox residue on the spring onion on the day of application under a standard application rate was 9.0 mg/kg and decreased to 3.1 mg/kg after 14 days after final treatment, while the initial concentration of etofenprox with 2 times application with a 7 day interval was 10.6 mg/kg and decreased to 2.7 mg/kg after the same period (Table 3). The MRL of etofenprox was set as 2.0 mg/kg in spring onion in Korea, but the residue at 14 DAT was higher than the MRL. To find the method to reduce the residue below the MRL, we conducted a removal experiment by washing and drying.

The biological half-life of etofenprox at 1 time application determined from the first-order kinetics was 9.5 days, and degradations could be described by following equation $C = 8.8197e^{-0.073t}$, with a correlation coefficient R^2 of 0.8792. At 2 times application, the half-life was 7.9 days and degradations

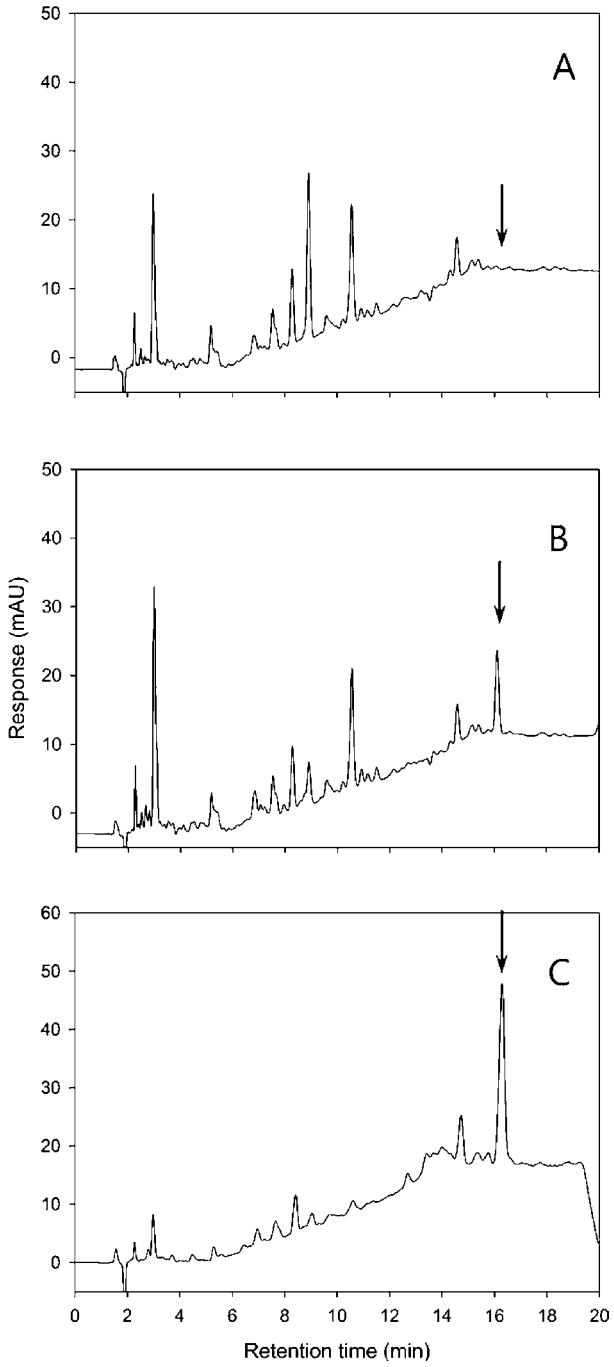

Figure 2. HPLC chromatograms of etofenprox in spring onion extract (A, untreated; B, 1.0 mg/kg level fortified; and C, 12 DAT sample of one time application).

could be described by following equation $C = 10.368e^{-0.088t}$, with $R^2 = 0.9611$ (Table 4).

The biological half-lives of etofenprox in Chinese cabbage under the greenhouse condition were 3.2 and 2.7 days at the recommended rate and the double rate of recommendation, respectively.[19] The half-lives of etofenprox in green onion are longer than in Chinese cabbage. The weight and growth rate of Chinese cabbage were higher than those of spring onion. Spring onion had a more specific surface area per unit weight than Chinese cabbage, which made a higher deposition of pesticide on the surface, and a slow growth rate resulted in slower dissipation of residues. The greenhouse temperature during the experiment with Chinese cabbage ranged from 16.47 to 39.26 °C; this was higher than the greenhouse temperature of spring onion, which was 12.5−20.8 °C. Because a higher temperature accelerates the degradation of etofenprox, the half-lives of Chinese cabbage were less than those of spring onion.[20] Photodegradation half-lives of etofenprox on the flooded soil surface and the air-dried surface under 300 nm ultraviolet (UV) light were 3.0 and 19 days, respectively.[21] Etofenprox degradation occurred relatively quickly on a glass surface with the half-life of 0.23 days compared to both flooded and air-dried soil layers.[21] From the microbial degradation experiment, the overall anaerobic half-lives ranged from 49.1 to 100 days at 22 °C compared to 27 days at 40 °C, whereas they were 27.5 days at 22 °C and 10−26.5 days at 40 °C under aerobic conditions. Etofenprox was stable for 56 days of the incubation period in the sterilized control soil.[22]

Table 3. Decline of Etofenprox Residues (mg/kg) on Spring Onion after 1 and 2 Times Application (n = 3)

		residue level (mg/kg)

application	application dose	equation	R^2	half-life (day)
1	20 mL/20 L	$C = 8.8197e^{-0.073t}$	0.8792	9.5
2	20 mL/20 L × 2	$C = 10.368e^{-0.088t}$	0.9611	7.9

Removal Efficiency of Etofenprox by Washing. Washing is generally the first step in various types of processes of food commodities in combination with cooking, drying, peeling, and juicing, to allow for effective decontamination from pesticide.[9]

The average residue of etofenprox on spring onion at 12 days after treatment was 4.44 mg/kg. The washing of treated spring onion in the water bath, running tap water, and 1% neutral detergent solution reduced the residue level to 3.48, 2.49, and 3.18 mg/kg, respectively, with a corresponding removal percentage of 21.6, 43.9, and 28.5, respectively (Figure 3). The running tap water washing was more effective than tap water bath washing in removal of etofenprox in spring onion. The water solubility of etofenprox is very low and non-

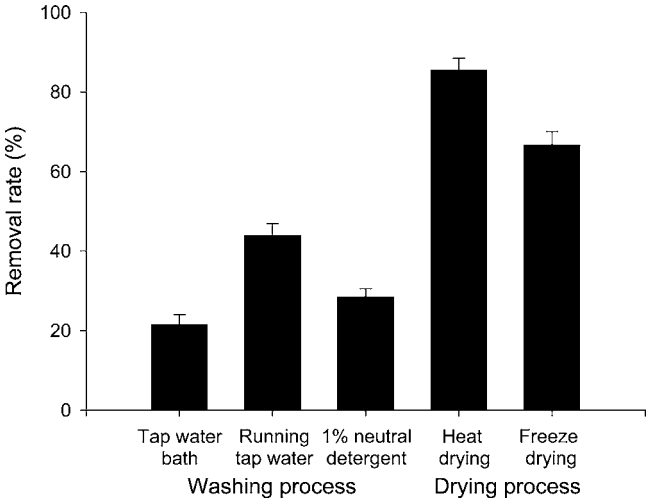

Figure 3. Removal efficiency of etofenprox on spring onion by different washing and drying processes (n = 3).

systemic. Most etofenprox will be deposited on the surface of the crop, and loosely attached residues could be effectively removed by a gentle running stream of water, which also results in a low removal rate of detergent solution in a bath. Running water was effective to remove diazinon and procymidone residues in cucumber and tomatoes, respectively.[23,24]

Washing is the most common process, which is the preliminary step in both household and commercial preparations. Loosely held residues of several pesticides are removed with reasonable efficiency by various types of washing processes in many agricultural commodities, such as green bean, bitter gourd, rice, eggplant, mango, apple, peach, and tomatoes.[25−34] In this study, the running water washing is the most effective to remove etofenpox by 43.9%, but another paper reported that tap water was least effective in reducing the pesticide residues and removed them by only 10−12%.[35] Washing with water and/or detergent solution was necessary to decrease the intake of the pesticide residue. The acidic detergent solution was more effective in the removal of organochlorine under investigation than alkaline and neutral solutions.[35]

Removal Efficiency of Etofenprox by Drying. Drying is the oldest and quite a simple method of preserving food compared to other methods. Several methods of drying by sun or in an oven or a freeze dryer can be used. The residue of etofenprox on spring onion 12 days after treatment was 4.44 mg/kg on average. The residue level increased to 12.04 and 30.29 mg/kg after heat dry and freeze dry, respectively. The residue could be concentrated by mass reduction during the dry process because of water evaporation. The CRL calculated was 0.64 by heat dry, while it was 1.48 mg/kg by freeze dry, corresponding to a removal rate of 85.5 and 66.6%, respectively (Figure 3 and Table 5). The heating drying was more effective than freeze drying in removal of etofenprox in spring onion, because the pesticide degraded by heat.[36] Drying has been reported to reduce the pesticide residues considerably. Sun drying of raisin decreased the dimethoate residue by 81%, while oven drying after washing lead to a 73% decline in the residue. The decrease in dimethoate was attributed to heat, which could cause evaporation and degradation.[36] For sunlight drying in raisin processing, the residue level of vinclozolin and dimethoate was reduced to one-third and one-fifth of the fresh fruits, respectively. While the oven drying after washing caused residue decreases for iprodione and procdymidone of 57 and 47%, respectively. However, oven drying increased the phosalone residue level compared to sunlight drying, which could be attributed to photodegradation.[36] Drying of grape leads to 64.2−71.9% losses of methamidophos possibly because of evaporation of the pesticide during the process.[37]

Table 5. Pesticide Residue and Removal Rate from Spring Onion Dried in an Oven and a Freeze Dryer (n = 3)

		after drying	
	before drying	heat	freeze
residue (mg/kg)	4.4 ± 0.2	12.0 ± 2.5	30.1 ± 3.1
weight reduction ratio		18.7 ± 0.2	20.4 ± 0.1
compensated residue (mg/kg)		0.6 ± 0.1	1.5 ± 0.2
removal rate (%)		85.5 ± 3.0	66.6 ± 3.4

In conclusion, the biological half-lives of etofenprox in spring onion were found to be 9.5 and 7.9 days, at the single or double application rates and most residues of etofenpox in spring onion could be removed by oven drying after washing with running tap water.

J. Agric. Food Chem. 2015, 63, 6681−6688

were from TCI Europe (Zwijndrecht, Belgium). All chemicals were used without further purification.

Nuclear Magnetic Resonance (NMR) Spectra. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ on an Avance 360 spectrometer, 360 MHz, and an Avance 600, 600 MHz (Bruker Biospin, Rheinstetten, Germany) at room temperature operating at 360 or 600 MHz (^{1}H) and 90 or 150 MHz (^{13}C), with tetramethylsilane (TMS) as internal standard.

GC-FID, GC−Olfactrometry (GC-O), and GC−Electron Impact−Mass Spectrometry (GC-EI-MS). GC-FID and GC-O analyses were performed with a Trace GC Ultra (Thermo Fisher Scientific GmbH, Dreieich, Germany) by using the following capillaries: FFAP (30 m × 0.32 mm fused silica capillary, free fatty acid phase, 0.25 μm; Chrompack, Mühlheim, Germany) and DB5 (30 m × 0.32 mm fused silica capillary, 0.25 μm; J&W Scientific, Fisons Instruments). The samples were applied by the cool-on-column injection technique at 40 °C. After 2 min, the temperature of the oven was raised at 10 °C/min to 240 °C, then raised at 40 °C/min to 280 °C (DB5) or at 10 °C/min to 240 °C (FFAP), respectively, and held for 5 min. The flow rate of the carrier gas helium was 2.5 mL/min. At the end of the capillary, the effluent was split in a ratio 1:1 (by volume) into an FID and a sniffing port using two deactivated but uncoated fused silica capillaries (50 cm × 0.32 mm). The FID and the sniffing port were held at 250 °C, respectively. GC-EI-MS analyses were performed with an Agilent MSD 5975C (Agilent Technologies, Waldbronn, Germany) and a Thermo ITQ 900 (Thermo Fisher Scientific, Dreieich, Germany) with the capillaries described above. Mass spectra in the electron impact mode (EI-MS) were generated at 70 eV.

Retention Indices (RI). Retention indices were determined according to the method previously described by Van den Dool and Kratz.[19]

Panelists. Panelists were trained volunteers from the University of Erlangen (Erlangen, Germany), exhibiting no known illness at the time of examination and with audited olfactory function. In preceding weekly training sessions the assessors were trained for at least half a year in recognizing orthonasally about 90 selected known odorants at different concentrations according to their odor qualities and in naming these according to an in-house developed flavor language. Furthermore, the panel was trained every 2 weeks on specific attributes with the help of specifically developed sniffing sticks; in the course of this training, all panelists also had to fill out the same questionnaire (hedonic, intensity) to obtain insights into their specific sensitivities or insensitivities, which were systematically recorded. On the basis of these tests, panelists were tested regularly for compliance with the established flavor language.

Odor Threshold Values. Thresholds in air were determined by GC-O with (*E*)-2-decenal as internal standard.[1,20,21] Of every dilution, 2 μL were applied for injection into the GC system. The thresholds were determined by five panelists (one male, four females), with each experiment being conducted once. GC analyses were performed on capillary FFAP as already described. The purity of all commercially available and synthesized compounds was taken into account in the GC-O experiments. All synthesized compounds were further checked for potential olfactorily active impurities by sniffing each substance on both capillaries of different polarity, to exclude interferences.

Odor Quality Determination. The odor qualities, determined during GC-O evaluation, were related to odor qualities of commercially available reference compounds. Panelists were asked to freely choose the respective odor quality descriptors based on the in-house developed flavor language (cf. Panelists). No additional descriptors were supplied to the panelists. The panelists determined the qualities during sniffing of FD 1 solution (injection of 2 μL). The panelists were instructed to record any changes in odor qualities in all following dilutions.

Syntheses, General Procedures. *(E)-3-Alkenoic Acids (**7** and **8**, Figure 1a).* Malonic acid (1 equiv) was dissolved in triethylamine (1.5 equiv) in a round-bottom flask fitted with a reflux condenser, a dropping funnel, and a nitrogen inlet tube. The corresponding aldehyde (1 equiv) was added slowly over a period of 0.5 h under continuous stirring at room temperature. The contents were then heated to 80 °C and maintained at this temperature for 3 h. The product was then acidified with dilute HCl (1 mL/mmol malonic acid) and extracted with diethyl ether (1 mL/mmol malonic acid) three times. The ether extracts were thoroughly washed with distilled water and dried over anhydrous magnesium sulfate. After evaporation of the solvent, the residue was purified by column chromatography (silica gel; eluent, hexane/EtOAc = 4:1) to give the pure product.[22]

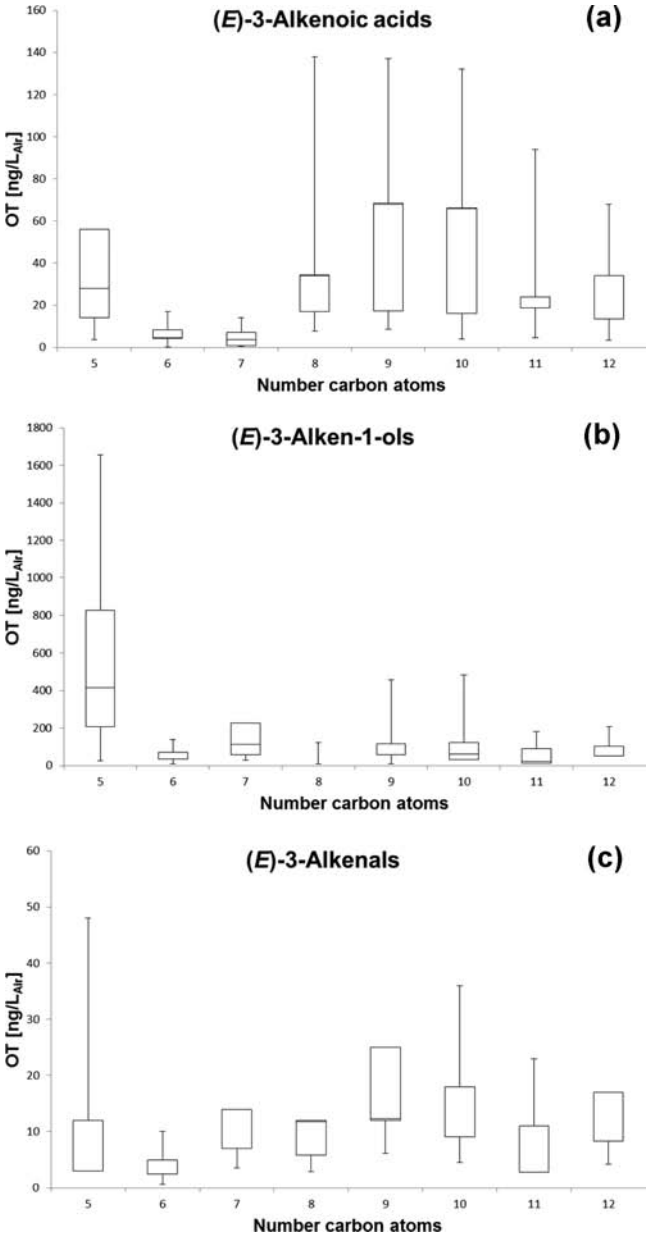

Figure 2. Influence of the chain length on the odor thresholds of (a) (*E*)-3-alkenoic acids, (b) (*E*)-3-alken-1-ols, and (c) (*E*)-3-alkenals (mean value (±SD), markers at minimum and maximum OT, box percentage 25−75%).

The mechanism follows a Linstead modification of the Knoevenagel reaction.[22−26]

*(E)-3-Alken-1-ols (**9** and **11−16**, Figure 1b).* Under a nitrogen atmosphere $LiAlH_4$ (1 equiv, 1 M THF) was added to an ice-cold solution of (*E*)-3-alkenoic acid (1 equiv) in THF (3 mL/mmol acid). The reaction was allowed to warm to room temperature. After 2 h, the reaction mixture was cooled in an ice bath, and water (4 mL/mmol acid) was added slowly. NaOH (3 M) and water (4 mL/mmol acid each) were added, and the resulting mixture was extracted with CH_2Cl_2 (8 mL/mmol acid) three times. The combined organic layer was washed with brine (8 mL/mmol acid) and then dried over $MgSO_4$, filtered, and evaporated to get the corresponding (*E*)-3-alken-1-ol as an oily substance.[27]

(E)-3-Alkenals (17−24, Figure 1c). A solution of (*E*)-3-alken-1-ol (1 equiv) in CH_2Cl_2 (1 mL/mmol alcohol) was added dropwise to a suspension of Dess−Martin periodinane (1.1 equiv) in CH_2Cl_2 (2 mL/mmol Dess−Martin periodinane). After a few minutes, in some cases the reaction mixture started to boil and was allowed to do so for about 5 min. After that, the obtained suspension was stirred for 3 h at room temperature. It was then filtered through a glass frit, and the filtrate was washed with saturated aqueous $NaHCO_3$ solution containing $Na_2S_2O_3$ (25%) (3.5 mL/mmol alcohol). The resulting clear solution was dried over $MgSO_4$ and filtered, and the CH_2Cl_2 was removed by using a rotary evaporator to give the corresponding (*E*)-3-alkenal as a colorless to pale yellow oil.[28]

RESULTS AND DISCUSSION

The median odor threshold values in air, the odor threshold range, and the main odor qualities of the homologues (*E*)-3-alkenoic acids, (*E*)-3-alken-1-ols, and (*E*)-3-alkenals are given in Table 1 and Figure 2. For the interested reader, besides the median odor threshold values, the geometric mean values are given in Table 2. In the following, only the median values are discussed, because they appear to be the more representative ones: In this study, the number of single values is limited, and some of these single values more strongly deviate from those of the other panelists. Such deviations would influence the geometric mean more significantly than the median. Nevertheless, when the geometric mean and the corresponding median values are compared, it becomes evident that both values show the same overall tendencies, and, if compared with each other, the differences are quite low, with only a few exceptions (e.g., (*E*)-3-decenoic or (*E*)-3-dodecenoic acid).

Regarding the median odor thresholds, the lowest can be found for (*E*)-3-pentenal with 3.03 ng/L_{Air}, followed by (*E*)-3-heptenoic acid with 3.6 ng/L_{Air} and (*E*)-3-hexenoic acid with 4.13 ng/L_{Air}. Due to the, at times, quite broad spreading of the individual threshold values, no clear insights about potential minima in the OT values can be deduced. Thereby, clustering or, on the other hand, broad spreading of the OT values of individual panelists is not evenly distributed among substances. As can be seen in Table 1a and Figure 2a, the OT range of (*E*)-3-pentenoic acid is much higher than for the homologously related (*E*)-3-hexenoic acid and (*E*)-3-heptenoic acid. Clustering of the OT values for these six- and seven-carbon atom compounds is also much narrower than that of the OTs of the substances of the same series with longer chain lengths. The widest clustering was observed for (*E*)-3-octenoic acid, followed by (*E*)-3-nonenoic and (*E*)-3-decenoic acid. From 11 and 12 carbon atoms onward, the broadness of the clustering decreases again. A similar pattern was observable in the case of the homologous series of the (*E*)-3-alken-1-ols (Table 1b and Figure 2b). However, despite the wide spreading of the odor threshold for (*E*)-3-penten-1-ol, the clustering range of the alkenols was not as wide as in the case of the (*E*)-3-alkenoic acids. Table 1c and Figure 2c present the values for the (*E*)-3-alkenals. Again, there is a comparable pattern to the (*E*)-3-alkenoic acids and (*E*)-3-alken-1-ols, with a quite wide spreading of the OT ranges for each substance in this homologous series. However, it needs to be kept in mind that a

larger panel number, or an untrained panel, might lead to changes in the order of threshold ranking and might lead to a distinct change of the spreading and clustering.[2,29−33]

When all three homologue series were compared, the series with the lowest median odor thresholds was the series of (*E*)-3-alkenals, followed by the (*E*)-3-alkenoic acids. However, when the single odor thresholds of all five panelists were viewed independently (Table 1, OT range; Table 2) enormous differences between the respective values of the individual panelists can be observed. Especially with regard to the series of (*E*)-3-alkenoic acids, huge variances between individual values can be found. The lowest OT of 0.27 ng/L_{Air} for (*E*)-3-hexenoic acid and the highest of 17 ng/L_{Air} span a threshold range with a factor of 63. An analogously broadly distributed pattern can be found for (*E*)-3-penten-1-ol with a threshold range from 26 to 1655 ng/L_{Air}, which corresponds to a factor of 64, and for (*E*)-3-nonen-1-ol with a range from 7 to 459 ng/L_{Air}, which relates to a factor of 66 between the most extreme values. Nevertheless, despite these huge differences, the ranking of the thresholds of the single panelists of a homologous series was in many cases comparable (cf. Table 2). For instance, for four of five panelists, the lowest individual OT of the (*E*)-3-alkenoic acids was that of (*E*)-3-heptenoic acid. On the other hand, the highest individual OT in the case of the (*E*)-3-alken-1-ols was that of (*E*)-3-penten-1-ol, again for four of the five panelists.

Compared with other studies, such as that of Czerny et al.,[21] in which the odor thresholds range "only" from a factor of 2 to 8, the differences between the odor thresholds of the individual panelists in this study might seem very huge. However, in the case of Czerny et al., it needs to be highlighted that only two panelists participated in the experiments. Furthermore, only aromatic compounds, and, more precisely, phenol derivatives, were investigated, and not open-chained substances as in the present study.[21] Accordingly, a satisfactory comparison would be hard to achieve.

DOI: 10.1021/acs.jafc.5b02169
J. Agric. Food Chem. 2015, 63, 6681−6688

The main odor quality in the series of (*E*)-3-alkenoic acids changes noticeably with increasing chain length from sweaty for (*E*)-3-pentenoic acid and (*E*)-3-hexenoic acid, to plastic-like for (*E*)-3-heptenoic acid to (*E*)-3-decenoic acid, to waxy for (*E*)-3-undecenoic acid and (*E*)-3-dodecenoic acid. (*E*)-3-Penten-1-ol and (*E*)-3-hexen-1-ol of the homologous series of (*E*)-3-alken-1-ols show a green odor, changing with increasing chain length to citrus-like and cleanser-like for (*E*)-3-hepten-1-ol to (*E*)-3-nonen-1-ol, ending in a cleanser-like smell for (*E*)-3-decen-1-ol to (*E*)-3-dodecen-1-ol. The (*E*)-3-alkenals start also with a green odor quality for the short-chain (*E*)-3-pentenal to (*E*)-3-heptenal, shifting to citrus-like for (*E*)-3-octenal, to fatty for (*E*)-3-nonenal, and finally to coriander-like for (*E*)-3-decenal to (*E*)-3-dodecenal. With regard to the individual odor qualities named by each panelist (Table 3), there are similarly broadly distributed patterns in the individual naming of the odor characters as observed for the individual odor thresholds, and they vary enormously. The odor quality descriptions of (*E*)-3-pentenoic acid range from sweet and flowery to sweaty to pungent and plastic-like. (*E*)-3-Dodecen-1-ol is described either as citrus-like, musty from another, or herb-like, depending on the evaluating panelist. Only in the case of the (*E*)-3-alkenals was the variety not that broad, with most panelists having reported the terms green for (*E*)-3-pentenal and (*E*)-3-hexenal, soapy for (*E*)-3-heptenal and (*E*)-3-octenal, soapy and coriander-like for (*E*)-3-nonenal, and coriander-like for (*E*)-3-decenal, (*E*)-3-undecenal, and (*E*)-3-dodecenal.

One explanation for these discrepancies in the odor thresholds and odor qualities between the single panelists could be the interindividual interaction of the respective odorant with the receptors. There are reports on interindividual differences in receptor expression in humans that might be related to the observed differences.[34,35] It also needs to be kept in mind that numerous odorants activate not only one receptor but a number of them and that receptors can also be activated by a range of odorants.[36,37] The interindividual patterns in activation resulting from that coding might also be divergent between different subjects. However, apart from the direct binding of an odorant to the respective receptors in the olfactory system, there might also be interindividually different effects related to the so-called peri-receptor events, meaning that odorants may be biotransformed, for example, by cytochrome P 450 metabolization, prior to interacting with the target receptor sites. This biotransformation of aroma compounds can alter the quality and quantity of the substances and might lead to differences in odor threshold as well as odor quality.[38−43] Accordingly, the investigated compounds, bearing, for example, double-bond moieties, might be prone to metabolic attack as has been previously shown for other unsaturated compounds by Schilling et al.[38,39,43,44]

Here, it might be worth drawing some comparison between the substances investigated within this study and other related substance groups differing in degree of saturation. Table 4 provides a compilation of literature data and our own data of the present study for direct comparison of the impact of the double-bond configuration (either *E* or *Z*) or the impact of saturation of the double bond on the respective OT values. Unfortunately, available data for a straightforward comparison are not comprehensive. Nevertheless, from the few reported (*Z*)-3-compound values it becomes clear that the (*Z*)-3-configuration obviously represents a very favorable moiety in terms of high odor impact. In contrast to this, the (*E*)-3-configuration obviously does not impart the same effect, and is even, in several cases, to be regarded as less odoriferous than even the saturated analogue. Nevertheless, these conclusions would need to be further substantiated by future studies, filling in the missing data of Table 4.

[a]Odor thresholds in air were determined as described by Ullrich and Grosch.[1] [b]In this study determined median odor threshold values. [c]nr, OT (determined as in this study) has not been reported previously, to the best of our knowledge.

To sum up, our study demonstrates that some of the investigated compounds in the series of the (*E*)-3-alkenoic acids, (*E*)-3-alken-1-ols, and (*E*)-3-alkenals show low odor thresholds or high odor potencies and interesting odor qualities. In consideration of the fact that many of the 24 investigated substances have already been identified in food, or generally in nature, some of the currently unreported substances may be also promising candidates to be discovered as natural compounds in future studies. The analytical data compiled in this study, such as retention indices, mass spectra, odor thresholds in air, or odor qualities can aid in their future discovery. Moreover, this study aims at raising future attention to this substance class, not only in

terms of some of the compounds being potentially important odorants in food but also with regard to other biological meaning that has not been investigated comprehensively to date.

In view of this, one needs to keep in mind that chemosensorically active compounds can serve a number of purposes in nature such as communication between and across species, resulting, for example, in chemo-attraction or -repulsion. As an example, another interesting field of research is the potential biological meaning of the target compounds investigated within the present study in relation to entomology. As mentioned in the introduction, some of the investigated compounds have already been shown to function as pheromones, attractants, or repellents in insects. Accordingly, it would be of high interest to have a closer look at such possible functionalities of the compounds of the current study and to also establish the respective structure−response relationships in view of insect behavior. Comprehensive substance libraries as generated in the current study will aid the targeted and systematic discovery of such effects in future investigations.

Additionally, matrix effects, which can significantly interfere with the accuracy of an analytical method,[28] were not studied in the previous literatures.

A liquid chromatography−mass spectrometry (LC-MS) technique has been developed to measure QACs in both environmental media and food products.[25−27,29,30] However, a gas chromatography−mass spectrometry (GC-MS) technique has only been developed to measure QACs in environmental media without food products.[5,9,31,32] GC-MS is available in ordinary laboratories much more commonly than LC-MS because of the cost. Furthermore, GC-MS performs higher chromatographic resolution than LC-MS because it possesses a long capillary column where analytes can be effectively separated, which is beneficial to improve the accuracy of an analytical method.[31,32] Therefore, we believe that the GC-MS technique is more appropriate, cost-effective, and practical to be developed for routine determination of QACs in vegetables.

Dodecyltrimethylammonium chloride (DTAC), cetyltrimethylammonium chloride (CTAC), and didodecyldimethylammonium chloride (DDAC) (Figure 1), the representatives of

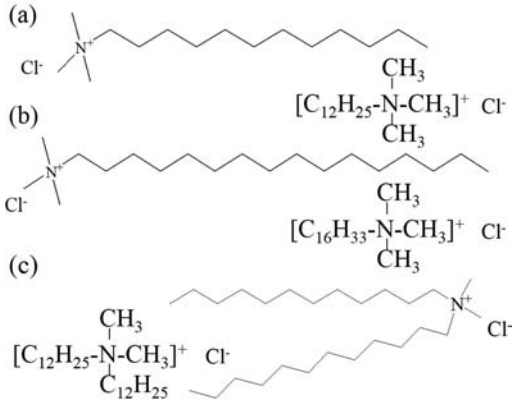

Figure 1. Structure of the three tested QACs: (a) dodecyltrimethylammonium chloride (DTAC), (b) cetyltrimethylammonium chloride (CTAC), and (c) didodecyldimethylammonium chloride (DDAC).

alkyl QACs with shorter alkyl chain lengths [C12−C16] as well as higher mobility and toxicity than other homologues [C18−C22],[11,13,33] have been detected in both agricultural soils and irrigation water as mentioned above.[5,9] Therefore, these QACs are most likely to be taken up by vegetables and consequently exhibit a health risk to humans through the food chain.[26,27,34]

The aim of the present study was to develop a reliable, sensitive, and cost-effective analytical method for routinely determining the three typical QACs (DTAC, CTAC, and DDAC) in various vegetables using ultrasonic-assisted extraction and GC-MS. This method is composed of sample pretreatment procedures optimized and reliable methodologies validated with linearity, matrix effect, precision, and accuracy. Acceptable results were obtained using this method to determine QACs in various real vegetables. To the best of our knowledge, this is the first study for the quantitation of QACs in various vegetables using GC-MS technique, and we believe it will effectively promote further research on QACs in soil−plant systems.

MATERIALS AND METHODS

Reagents. Standards DDAC (99%, purity) and CTAC (99%, purity) were purchased from Adamas (Emeryville, USA), and DTAC (99%, purity) was obtained from Aladdin (Seattle, USA). HPLC-grade solvents (including methanol, methyl trichloride, dichloromethane, and *n*-hexane) were purchased from Sigma-Aldrich (Steinheim, Germany). Neutral silica gel (200 mesh), neutral alumina oxide (200 mesh), and hydrochloric acid bought from Guangzhou Chemical Reagent Co., Ltd. (Guangzhou, China) were all of analytical grade.

Mixture stock solution (100 mg/L) of the three QACs (DTAC, DDAC, and CTAC) was prepared in methanol, which was kept in a refrigerator at 4 °C in the dark and used within one month. Standard working solutions of the three tested compounds at 20, 50, 100, 200, 500, 1000, and 2000 μg/L were prepared by diluting the stock solution with methanol when they would be used. Because matrix components in vegetables can influence detector responses, and the same vegetable species should have similar matrix effects,[28] nine vegetables including leafy vegetables (Chinese flowering cabbage, water spinach, and lettuce), root vegetables (white radish, potato, and carrot), and fruit vegetables (cucumber, pumpkin, and eggplant) were chosen to evaluate the matrix effects on the determination of QACs in vegetables. Correspondingly, matrice-matched standard solutions (20, 50, 100, 200, 500, 1000, and 2000 μg/L) were obtained by adding a blank vegetable sample extract to each diluted standard solution. All of these nine blank vegetables without the target QAC pollution were purchased from an organic vegetable farm where clean water and fertilizer without QAC residues were used.[28]

Sample Treatment. Approximately, 5 kg of each fresh vegetable sample was chopped and homogenized using a crusher (Jiu Yang Co., Ltd., China). An aliquot of about 1000 g of the sample was weighed and then lyophilized in a vacuum freeze drier (Jiangsu Hengfeng Equipment Manufacture Co., Ltd., China). Compared to the fresh vegetable sample, using a lyophilized vegetable sample was beneficial not only to minimize the sample volume and the reagent volume but also to shorten the extraction time.[28] The lyophilized samples were ground to a powder (0.45 mm) in a mill and stored in brown glass bottles. The spiked samples at three concentration levels (50, 200, and 1000 μg/kg) were obtained by adding 1 mL of mixture standard working solutions at 50, 200, and 1000 μg/L in methanol to 1.0 g of lyophilized blank vegetable sample powder, respectively. Afterward, the spiked samples were shaken continually to be homogenized and left for 12 h under a fume hood to evaporate the solvent at room temperature before analysis.

One gram aliquot of each lyophilized vegetable sample powder was weighed into 50 mL of Teflon centrifuge tube. Then, 10 mL of 0.1% acidified methanol (hydrochloric acid/methanol, v/v) was added into each tube. The tubes were shaken vigorously for 10 min with a constant temperature vibrator and then ultrasounicated for 10 min in a 100 W ultrasonic instrument (Kunshan Ultrasonic Instrument, Co., Ltd., China). The supernatant of each sample was collected after centrifugation at 8000 rpm for 5 min. The extraction was repeated twice again. All of the supernatants of each sample were combined and concentrated to almost 2 mL using a rotator vacuum evaporator (Shanghai Optical Instrument Factory, China) with 200 rpm at 40 °C. In order to remove interfering matrix components and other contaminants, neutral alumina oxide sorbent presoaked in methanol overnight was loaded into a glass column (30 cm height, 1 cm diameter) coupled with a flow control valve and filter cartridge until 8 cm height. The extracts were separately passed through the glass columns and eluted with 7 mL of methanol. The resulting elutes were collected and evaporated to near dryness, and then were redissolved with methanol, strained through 0.22 μm nylon filters, and transferred to sampler vials for GC-MS analysis.

Instrument and Apparatus. Analysis of the three QACs was conducted on a Shimadzu-QP2010 Plus series gas chromatograph equipped with a triple quadrupole mass spectrometry (GC-MS). According to the optimized conditions of GC-MS, the three QACs were separated with a DB-5MS fused silica capillary column (30 m length × 0.25 mm diameter, 0.1 μm film thickness). Samples were injected in splitless mode with 1 μL volume. The carrier gas was high purity helium (99.9999%) at a flow rate of 1.0 mL/min. The temperatures of injector, detector, and ion source were set at 280 °C, 250 °C, and 250 °C separately. The column oven temperature program was set as follows: start at 100 °C for 2 min, increase to 200

[a]Peak area produced by the standard QACs in a concentration. [b]Concentration of the standard QACs.

°C at a rate of 30 °C/min, and increase to 280 °C at a rate of 40 °C (held 4 min), in a total run time of 11.33 min. The mass spectrometer was operated using electron-impact (EI) mode (70 eV) in the selective ion monitoring (SIM) mode in order to improve detection limits of the three QACs. The target ions of DTAC, CTAC, and DDAC were 58, 58, and 212 m/z, respectively,[31] and their retention time in this analytical procedure was 5.31, 6.85, and 8.67 min, respectively.

Validation Study. Validation of the developed method was performed in terms of linearity, limit of detection (LOD), limit of quantitation (LOQ), specificity, accuracy, and precision using the nine vegetables (Chinese flowering cabbage, water spinach, lettuce, pumpkin, cucumber, eggplant, potato, white radish, and carrot). The linearity was studied for each of the tested three QACs by spiking their standards in methanol and the nine vegetable matrices, respectively, in triplicate at seven concentration levels (20, 50, 100, 200, 500, 1000, and 2000 μg/L). The calculated parameters of the linear regression equations (slope, determination coefficient (R^2), and intercept) are presented in Table 1. Matrix effects were determined by calculating the slope ratios of matrix-matched calibration curves to solvent one. The matrix dependent LOD and LOQ were determined using the blank and calibration standards of the tested nine vegetable matrixes. The LOD of the each QAC is the concentration that produces a signal-to-noise (S/N) ratio of three, whereas the LOQ is estimated based on the S/N ratio of 10. Specificity of the developed method was analyzed based on the absence of interfering peaks at the retention time of the three QACs in the nine blank sample matrices. Accuracy and precision of the developed method were tested using recovery assays performed on samples spiked at three concentrations (50, 200, 1000 μg/kg). Five replicates for each spiked sample were prepared on three different days. The precision of the developed method was expressed as the intraday (repeatability) and interday (reproducibility) relative standard deviation (RSD^a and RSD^b) for 5 and 15 replicates, respectively.

Statistical Analysis. QAC concentrations from GC-MS analysis were calculated using postrun software of a Shimadzu-QP2010 plus series gas chromatograph. The data were exported to SPSS 21.0 (International Business Machines Co, USA) to determine the means and relative standard deviations (RSDs). Microsoft Excel 2010 was used to draw tables and figures.

RESULTS AND DISCUSSION

GC-MS Condition Optimization. The GC-MS conditions were optimized using the single and the mixture standard solutions of the three typical QACs (DTAC, CTAC, and DDAC) at 1000 μg/L. First, the mass spectral fragmentation pattern of each QAC was evaluated by analyzing the standard working solutions using EI mode at full-scan mode with the mass range of 50−300 m/z and at a rate of 3 scan/s. The three QACs were effectively converted into the corresponding tertiary amines by demethylation in the injection port at 280 °C as previously reported.[31,32] Then the tertiary amines were separated on a capillary column, depending on their alkyl chain lengths.[31] The target ions of DTAC, CTAC, and DDAC under the EI mode were 58, 58, and 212 m/z, respectively (Figure 2). Both the target ions at m/z = 58 ($[CH_2{=}N(CH_3)_2]^+$) and m/z = 212 ($[CH_2{=}N(CH_3)(C_{12}H_{25})]^+$) were derived from the α-cleavage of the carbon−carbon bond with respect to nitrogen.[31] In order to obtain an optimized separation of the tested QACs, three capillary columns (30 m × 0.25 mm × 0.25 μm) with

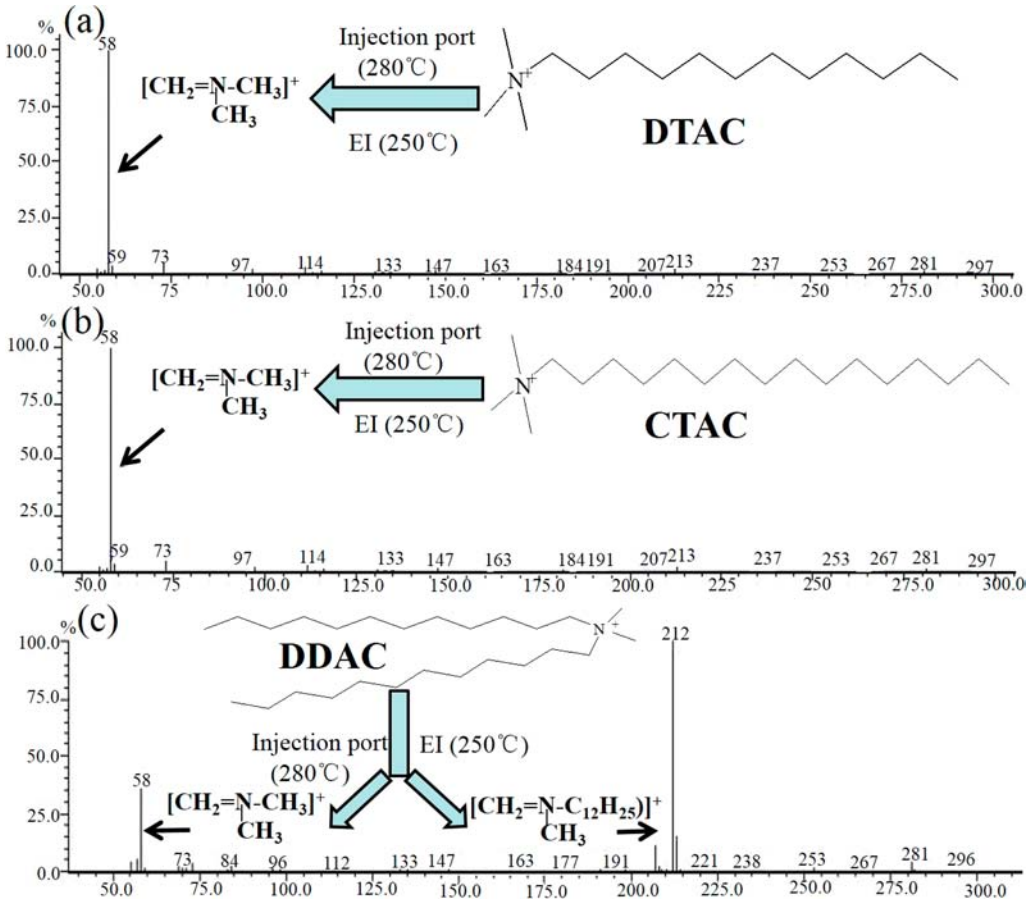

Figure 2. Product ion spectra of the three tested QACs: (a) DTAC, (b), CTAC, and (c) DDAC.

different stationary phases (i.e., DB-5MS consisted of 5% phenyl and 95% dimethylpolysiloxane, HP-1MS consisted of 100% dimethylpolysiloxane, and Rtx-35 consisted of 35% phenyl and 65% dimethylpolysiloxane) were compared. The best separation was obtained at the DB-5MS column with the appropriate proportion of phenyl and dimethylpolysiloxane. So the DB-5MS column was selected for the subsequent analysis. Furthermore, various temperature programs were investigated in order to achieve the best separation in the minimal time. By monitoring the target ions of the three QACs under the optimized GC-MS conditions, high response, remarkable selectivity, and excellent peak shape were obtained in a suitable analytical time (11.33 min), which are presented in Supporting Information, Figure S1.

Sample Extraction Optimization. To obtain an optimized sample extraction procedure, recovery tests for each single-variable (variety and acidity of extraction solvents, extraction times, and cleanup solvent) using QAC-spiked lettuce samples at 1000 μg/kg were carried out. Sequentially, the obtained procedure was evaluated in the other eight vegetable samples. First, four commonly used solvents (methanol, dichloromethane, methyl trichloride, and *n*-hexane) were separately investigated in recovery tests to get a satisfied extraction solvent for the three QACs. As the results exhibit in Figure 3 a, both recoveries (60%−77%) and RSD (<10%) of the three QACs were satisfied when methanol was used as the extraction solvent, while low recoveries of QACs were observed when using methyl trichloride and *n*-hexane as extraction solvent. QACs are cationic compounds tending to be extracted by polar solvents according to the similarity−intermiscibility theory.[9] Therefore, the highest recovery was obtained when using methanol with the strongest polarity among the four tested solvents in the present study.

As reported in the literature, the acidity of the extraction solvent significantly influences the extraction efficiency of QACs in the sample matrix (water and sediment).[29,30] So, recovery experiments using methanol as the extraction solvent with acidity ranging from 0.05% to 0.5% (hydrochloric acid/methanol, v/v) were conducted. Results showed that recoveries of the three QACs increased with increasing acidity of methanol under lower acidity (<0.1%, v/v) (Figure 3b). However, lower recoveries were observed with further increase in acidity from 0.2% (v/v) to 0.5% (v/v). Appropriate increase in acidity of methanol promoted the transfer of QACs from the sample matrix to the methanol phase because this approach not only improved methanol's polarity but also increased the concentration of hydrogen ion (H^+) which competed with the cationic compounds (i.e., QACs) in activated sorption sites of the sample matrix.[9,32] However, excessive increase in the acidity of methanol decreased recoveries of the three QACs because additional water entered the methanol solvent with the addition of hydrochloric acid, which heavily interfered with separation and extraction of the three QACs from the sample matrix.[9] So, methanol acidified with 0.1% of hydrochloric acid (v/v) was selected as the extraction solvent for subsequent experiments.

The influences of extraction times (once to three times) on recoveries of the three QACs were also investigated. As shown in Figure 3c, recoveries of all of the three QACs increased with increasing extraction times, and three times of extraction gained recoveries up to 96%−100%.

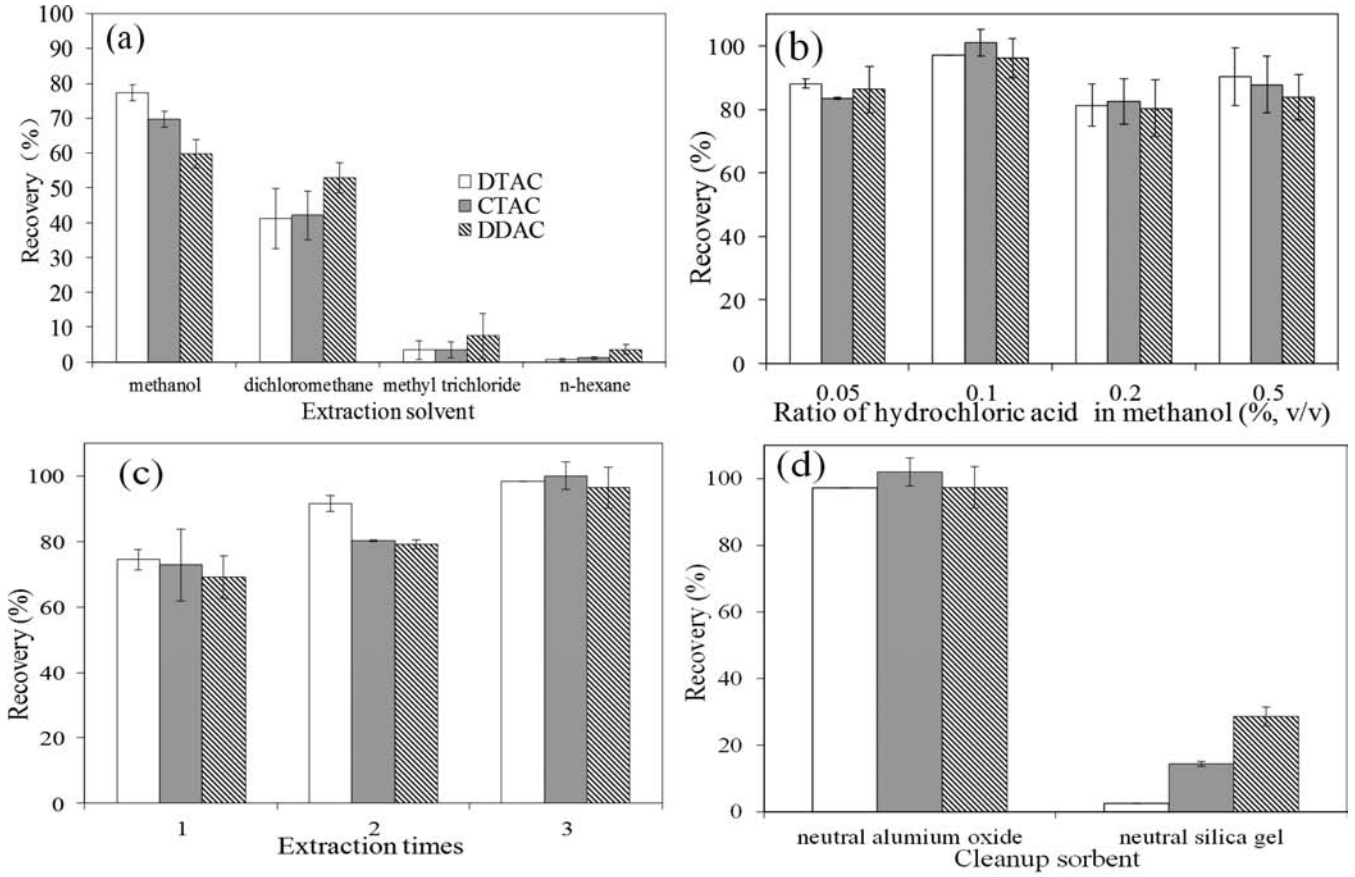

Figure 3. Effects of extractant (a), extractant acidity (b), extraction time (c), and cleanup sorbent (d) on the recovery of QACs in lettuce sample spiked with 1000 μg/kg.

In the cleanup procedure, two commonly used sorbents, neutral silica gel and neutral aluminum oxide filled to 8 cm height in a glass column (30 cm height, 1 cm diameter), were separately tested to obtain a satisfactory cleanup effect for the vegetable matrix. Unfortunately, as shown in Figure 3d, neutral silica gel used as the cleanup sorbent presented low recoveries for the three QACs (<30%). However, when neutral aluminum oxide was used, satisfactory recoveries (97%−102%) of the three QACs were observed. As we know, the negative polar silanol group (Si−OH), which is the main functional group of neutral silica gel, could be strongly bonded to positive polar chemicals especially cationic compounds.[9,35] Furthermore, the positive polarity of the three QACs decreased in the order of DTAC > CTAC > DDAC because increasing length and branch structure of the carbon chain remarkably decreases the polarity of QACs.[11] Thereby, the QACs with positive charges were more difficult to elute from neutral silica gel, and recoveries decreased with increasing polarity of the three QACs when using neutral silica gel as cleanup sorbent. Conversely, neutral aluminum oxide is suitable to separate positive polar chemicals from the sample matrix because the active-sites of aluminum oxide with the positive functional aluminum−oxygen group (Al−O) can hardly retain positive polar chemicals but can remove matrix compounds like lipid and chlorophyll via sorption.[9] Therefore, neutral aluminum oxide was selected as the cleanup sorbent in the present study.

Once the pretreatment procedure of the three QACs in lettuce had been optimized, it was used to determine the analytes in other eight vegetable samples including Chinese flowering cabbage, water spinach, pumpkin, cucumber, eggplant, potato, white radish, and carrot. Satisfactory recoveries between 72% and 108% were obtained in Chinese flowering cabbage, cucumber, potato, white radish, and carrot. However, lower recoveries (52%−70%) in water spinach, pumpkin, and eggplant were observed, but they were still acceptable as to the complex vegetable matrix.[28] Especially, when the eluant volume of the cleanup procedure was adjusted from 6 to 7 mL, satisfactory recoveries were obtained for the three QACs in all of the vegetables.

Method Validation. *Linearity, LOD, and LOQ.* The peak areas of the QACs target ions obtained from MS mode were applied to achieve the linearity, LOD, and LOQ. The linearity was estimated by preparing different calibration curves (methanol, and various vegetable matrixes including Chinese flowering cabbage, water spinach, lettuce, pumpkin, cucumber, eggplant, potato, white radish, and carrot) at seven concentrations ranging from 20 to 2000 μg/L for each compound. The regression equations and coefficients of determinations (R^2) of the standard solution curves and the nine matrix-matched curves are presented in Table 1. Good linearities (R^2 > 0.992) of the three QACs were obtained in all cases. The LODs and LOQs of the three compounds ranged from 0.7 to 6.0 μg/kg (dw) and 2.3 to 20.0 μg/kg (dw), respectively. As for specificity, no responses were observed in the procedure blank and the vegetable blank, indicating a high specificity of MS determination (Supporting Information, Figure S2).

Matrix Effect. The presence of matrix effects in the analysis of trace organic pollutants in complex samples by GC-MS is

[a]Intraday precision (n = 5). [b]Interday precision (n = 15).

well-known, which may exert a strong impact on the precision and accuracy of analyte quantitation.[36,37] As referred to in previous research, the matrix effects can suppress or enhance detector response compared with the standard response in pure solvent.[36−39] Usually, the extent of matrix effect depends on the analytes, type and amount of matrix, and sample preparation procedure, etc.[40] Therefore, in the present study, various matrix effects were evaluated by calculating the slope ratio of the matrix-matched standard calibration curves to the solvent one. An accepted ranking criterion was applied according to Zhu et al., i.e., at the slope ratio value under 0.9, the matrix effect suppressed detector response; at the slope ratio value between 0.9 and 1.1, the matrix effect was negligible; at the slope ratio value above 1.1, the matrix effect enhanced the detector response.[38] Dada in Table 1 indicated that matrix effects on all of the three QACs in two matrices (Chinese flowering cabbage and water spinach) was negligible since the slope ratios of the matrix/methanol ranged from 0.96 to 1.08. However, matrix effects slightly enhanced the detector response of DTAC in lettuce, pumpkin, cucumber, and carrot but slightly suppressed that in eggplant. Matrix effects on CTAC and DDAC were negligible in five matrices (Chinese flowering cabbage, water spinach, lettuce, pumpkin, and cucumber) but enhanced the detector response to various extents in the other four matrices (cucumber, carrot, potato, and white radish). Generally, matrix effects originate from insufficient removal of the interfering constituents such as fatty acids, pigments, and phospholipids in the sample matrix.[40,41] However, the mechanism underlying these matrix-effects are still not completely understood and need to be further investigated.[38] Therefore, in order to obtain more realistic results in various samples in the present study, matrix-matched standard calibrations were applied to eliminate the matrix effects.

Precision and Accuracy. The recovery and RSD of the three QACs were measured to evaluate the precision and accuracy of the proposed method by spiking with the QACs at three different concentrations (50, 200, and 1000 μg/kg) in the blank sample and then analyzing them in quintuplicate (Table 2). The precision of the method expressed as RSD was determined by both repeatability and reproducibility experiments. The repeatability RSD[a] (intraday precision, n = 5) was obtained by calculating the standard deviation of the recoveries for the spiked samples run during the same day. The reproducibility RSD[b] (interday precision n = 5, for three distinct days) was also measured by analyzing the spiked samples. Detailed recovery, RSD[a], and RSD[b] data of the three QACs analyzed in nine vegetable samples are presented in Table 2. The recoveries in various vegetable matrices at three spiked concentrations (50, 200, and 1000 μg/kg) were between 70.5% and 108.0% (n = 15), and the RSD[a] (n = 5) and RSD[b] (n = 15) for the proposed method ranged from 2.1% to 18.0%, and 2.2% to 15.7%, respectively, which meet DG SANCO/12459/2011 guidelines (recovery at the range of 70% to 120%, and RSD lower than 20%).[37] These results indicated that the proposed method achieved satisfactory precision and accuracy.

The determination methods of QACs in food stuffs using LC-MS/MS have been recently developed.[25−27] Compared with these methods (recoveries, 72%−112%; RSDs, 1.4%−

17%; LODs, 0.4−6 μg/kg), the present method for determining QACs in vegetables using GC-MS provided the comparable precision and accuracy as well as the LODs (recoveries, 70.5%−108%; RSDs, 2.1%−18.0%; LODs, 0.7−6 μg/kg). Furthermore, the sample amount used (1 g) and analytical time (11.33 min) in the present method were smaller than those of previous methods (sample amount, 2−10 g; analytical time, 14−16 min). In addition, the GC-MS instrument used in the present study is available more commonly in ordinary laboratories than LC-MS. Therefore, the developed method is more cost-effective and practical for routine determination of the three QACs in vegetables.

Method Application. To estimate its practicality, the developed method was applied to measure the real vegetable samples ($n = 27$; Supporting Information, Figure S3) including Chinese flowering cabbages, water spinaches, lettuces, pumpkins, cucumbers, eggplants, potatoes, white radishes, and carrots. These samples with water contents between 80.1% (potato) and 95.4% (lettuce) were collected from several local markets in Guangzhou, southern China, a metropolitan city with high daily consumption of vegetables. Three quality controls at 50, 200, and 1000 μg/kg were performed for each sample in the analysis procedure.

As shown in Table 3, the three QAC compounds were detected in all of the tested vegetable samples (except carrot) with a concentration of 23−180 μg/kg (dry weight, dw). The detection frequency and concentration range (dw) of the three QACs were 33.3% and ND-30 μg/kg for DTAC, 88.9% and ND-122 μg/kg for CTAC, and 77.8% and ND-28 μg/kg for DDAC, respectively. CTAC was one of the dominant varieties of industrial QAC products and was frequently detected in sludge and agricultural soil,[8,9] which likely explained the highest frequency and concentration in the vegetable samples among the three tested QACs. As for the tested vegetable samples, all of the three QACs were detected in cucumber and white radish at concentrations of 4 to 122 μg/kg (dw). Both CTAC and DDAC were detected in lettuce, pumpkin, eggplant, and potato with concentrations of 5 to 41 μg/kg (dw). Only CTAC was detected in water spinach at concentrations of 23 μg/kg (dw). However, the concentration of all of the three QACs in carrot was lower than LOQs.

In conclusion, a reliable, sensitive, and cost-effective method was developed for routine determination of trace QACs (DTAC, CTAC, and DDAC) in vegetables using ultrasonic-assisted extraction and GC-MS. This method performed an accurate determination of the three QACs in a short time (11.33 min) with excellent specificity. Using a simple procedure consuming only 1 g of lyophilized sample for ultrasonic-assisted extraction, neutral aluminum oxide cleanup, and GC-MS analysis, the method can be applied to simultaneously analyze the three common QACs in various vegetable samples at μg/kg level with recoveries ranging from 70.5% to 108.0% and RSDs below 18.0%. The proposed method was used to successfully determine QACs in real vegetable samples collected from several markets in a metropolitan city of southern China. QACs were detected in almost all of the samples with a concentration of 23−180 μg/kg (dw). More studies are needed to further estimate human health risk of exposure to QACs through edible terrestrial plants, particularly vegetables, in the future.

J. Agric. Food Chem. 2015, 63, 6689−6697

similar to that of solid-phase microextraction (SPME) and allows for extraction and concentration in a single step, followed by thermal desorption of the entire extracted fraction into a GC system. These capabilities greatly simplify the sample preparation process and minimize any risk of contamination. Moreover, the enrichment factor for SBSE, which is determined by the analyte recovery in the extraction phase, is much higher than that of SPME using the same extraction phase, i.e., polydimethylsiloxane (PDMS), because of the 50−250 times larger volume of the extraction phase on the stir bar. SBSE can also be used in combination with a derivatization step similar to SPME. For polar solutes with low octanol−water distribution coefficient (K_{ow}) values, the corresponding derivatives generally have higher K_{ow} values, resulting in higher recovery and sensitivity.[18] Also, higher molecular weights of derivatives provide higher selectivity in GC−MS analysis. In this regard, SBSE with *in situ* derivatization (der−SBSE) using pentafluorobenzylhydroxylamine (PFBHA), followed by thermal desorption (TD)−GC−MS, was demonstrated for the analysis of stale-flavor carbonyl compounds, including *E*-2-nonenal, in beer.[21]

In this study, we developed a simple and solvent-less method for the quantitation of hop-derived thiols (4S4M2Pone, 3SHol, and 3SHA) in the three different sample matrices of beer, hop water extract, and wort at nanogram per liter levels by der−SBSE using ETP, followed by TD−GC−tandem mass spectrometry (MS/MS). Although the ETP derivatives (thioacrylates) of thiols (4S4M2Pone-ETP, 3SHol-ETP, and 3SHA-ETP) increase both log K_{ow} values (from 1.07−2.70 to 1.83−3.45) and molecular weights (from 132−176 to 230−274), the selectivity and sensitivity of conventional GC−single-quadrupole MS in selected ion monitoring (SIM) mode were not sufficient for real samples, which include very complex matrices. Therefore, GC−triple-quadrupole (QQQ) MS with selected reaction monitoring (SRM) mode was used for both increased selectivity and sensitivity.

MATERIALS AND METHODS

Chemicals. 4S4M2Pone, 3SHol, and 3SHA were purchased from Penta Manufacturing Co. (Livingston, NJ). d_{10}-4-Sulfanyl-4-methylpentan-2-one (d_{10}-4S4M2Pone) was purchased from aromaLAB AG (Freising, Germany). d_2-3-Sulfanylhexan-1-ol (d_2-3SHol) was purchased from NARD Institute, Ltd. (Hyogo, Japan). ETP and Tris(hydroxymethyl)-aminomethane hydrochloride (Tris−HCl) solution (1 M, pH 9.0) were purchased from Wako Pure Chemicals (Osaka, Japan). Sodium hydroxide (NaOH) solution (1 N) and ethanol (pesticide residue analysis grade) were purchased from Kanto Kagaku (Tokyo, Japan).

Hops. The hop cultivars investigated were Cascade, Citra, and Nelson Sauvin. Cascade (6.4% α-acid pellets, 2013 crop) was purchased from John I. Haas, Inc. (Yakima, WA). Citra (12.8% α-acid pellets, 2013 crop) was purchased from Yakima Chief (Sunnyside, WA). Nelson Sauvin (11.2% α-acid pellets, 2013 crop) was purchased from New Zealand Hops, Ltd. (Nelson, New Zealand).

Brewing Processes. Pellets of the hop cultivars Cascade, Citra, and Nelson Sauvin were used in the brewing process. For the evaluation of each cultivar, the wort from each hop cultivar was prepared to contain equal amounts of α acid. A 20 L volume of wort without hops was boiled for 60 min in a wort kettle. An amount of the hop pellet with 130 mg of α acid was then added to 1 L of hot wort (85 °C) in a glass vessel, and the wort was cooled promptly to 5 °C. The yeast was pitched at a rate of 20 × 10^6 cells/mL into the wort (12.5 °P), and static fermentations were carried out while stirring at 14.0 °C for 7 days in the 1 L glass vessel. The finished beer was obtained by cooling to −1 °C for 5 days and then centrifuging at 7000 rpm for 30 min.

Hop Water Extract. The water extract of each hop cultivar was prepared to contain the same amount of α acid as the corresponding wort. The amount of each hop pellet containing 130 mg of α acid was added to 1 L of hot water (85 °C) to extract the water-soluble aroma components and then cooled promptly. The hop water extracts were obtained by centrifuging at 7000 rpm for 30 min at −1 °C.

Stir Bar Sorptive Extraction with *in Situ* Derivatization (der−SBSE). Stir bars (Twister) coated with 24 μL of PDMS were obtained from GERSTEL (Mülheim an der Ruhr, Germany). For SBSE, 20 mL headspace vials with a metal screw cap containing polytetrafluoroethylene (PTFE)-coated silicon septa (GERSTEL) and a multiple-position

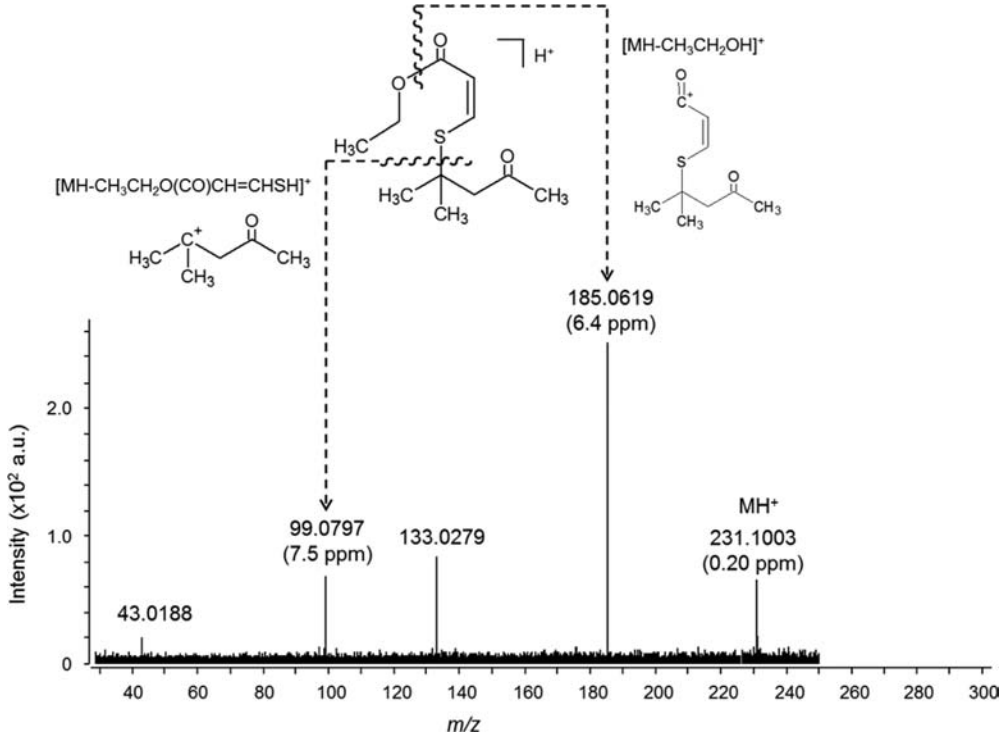

Figure 1. CAD mass spectrum of the *cis*-ETP derivative of 4S4M2Pone obtained from der−SBSE−TD−GC−Q−TOF−MS/SCD of spiked water at 10 ng/L. Mass errors from the theoretical formula are also shown in parentheses.

J. Agric. Food Chem. 2015, 63, 6698−6706

magnetic stirrer (20 positions) from Global Change (Tokyo, Japan) were used. Prior to use, the stir bars were conditioned for 20 min at 250 °C in a flow of helium. Before der−SBSE, beer and wort samples were adjusted to pH 9 using NaOH solution (1 M). Hop water extract was adjusted to pH 9 using 5 mM Tris−HCl to give buffer capacity. A total of 10 mL of sample containing 35 mM ETP, internal standards (20 ng/L d_{10}-4S4M2Pone and 200 ng/L d_2-3SHol), and the PDMS stir bar was transferred to 20 mL headspace vials. The vial was sealed with the metal screw cap, and the PDMS stir bar was first stirred at room temperature (25 °C) for 10 min at 500 rpm for the ETP derivatization step.[17] After 10 min of initial stirring, 30% NaCl was added and the vial was sealed again. To prevent damage to the glass jacket of the stir bar when dissolving NaCl, the PDMS stir bar was first attached to the inside of the metal screw cap with magnetic attraction. Then, the vial was gently shaken for a few minutes (horizontally). Finally, the PDMS stir bar was dropped to the bottom of the vial, and SBSE was performed for 180 min while stirring at 1500 rpm. After extraction, the stir bars were removed with forceps, dipped briefly in ultrapure water, dried with a lint-free tissue, and placed in a glass thermal desorption liner. The glass liner was placed in the thermal desorption unit. No further sample preparation was necessary. No carry-over was observed for concentrations up to 1000 ng/L after analysis. Reconditioning of stir bars was performed after use by soaking each consecutively in ultrapure water and acetonitrile for 1−2 h. Stir bars were then removed from the solvent and dried on a clean surface at room temperature for 1 h. Finally, the stir bars were thermally conditioned for 20 min at 250 °C in a flow of helium. Typically, the same PDMS stir bar could be used more than 50 times.

Thermal Desorption−Gas Chromatography−Quadrupole Time-of-Flight Mass Spectrometry with Parallel Sulfur Chemiluminescence Detection (TD−GC−Q−TOF−MS/SCD). For the identification of the ETP derivatives of thiols, the TD−GC−Q−TOF−MS/SCD analysis was performed with a thermal desorption unit (TDU) equipped with a MPS 2 autosampler and a Peltier-cooled CIS 4 programmed temperature vaporization (PTV) inlet (GERSTEL) installed on an Agilent 7890A gas chromatograph with a 7200 Q−TOF−MS and a SCD (Agilent Technologies, Santa Clara, CA). The GC−Q−TOF−MS/SCD configuration was equipped with an Agilent capillary flow technology (CFT) three-way splitter (with makeup gas line), which was controlled with a pressure control module (PCM).

The stir bars were thermally desorbed by programming the TDU from 30 °C (held for 0.5 min) to 200 °C (held for 3 min) at 720 °C/min with 50 mL/min desorption flow. Desorbed compounds were focused at 10 °C on a liner packed with quartz wool in the Peltier-cooled PTV inlet for subsequent GC−Q−TOF−MS/SCD analysis. After desorption, the PTV inlet was programmed from 10 to 240 °C (held for GC run time) at 720 °C/min to inject trapped compounds onto the analytical column. The injection was performed in the splitless mode, and the split valve was closed for 3 min. Separations were performed on a 30 m × 0.25 mm inner diameter, 0.25 μm film thickness DB-Wax column (Agilent). The column temperature for the DB-Wax was programmed from 40 °C (held for 3 min) to 250 °C (held for 20 min) at 10 °C/min. After the retention time of 33 min, the capillary column was back-flushed. The inlet pressure was 362 kPa, and the pressure of the PCM for the three-way splitter was 25 kPa. The constant pressure mode was used with helium carrier gas. A deactivated fused silica capillary with 1.1 m × 0.25 mm inner diameter was used for connecting from the splitter to the SCD, and a deactivated fused silica capillary with 1.1 m × 0.20 mm inner diameter was used for connecting from the splitter to the Q−TOF−MS. These pressures and transfer-line capillaries allow for parallel MS and SCD with minimum delay time (typically less than 0.1 s) at a constant split ratio of 1:2.

The Q−TOF−MS was operated at a mass range of m/z 29−500 with dual gain mode {resolution was approximately 7000 full width at half maximum [(fwhm)]}. The data acquisition speed was 5 Hz. The electron accelerating voltage of the electron ionization (EI) was 70 eV. Methane was used as a reagent gas at 1.0 mL/min in the positive chemical ionization (PCI) mode. Nitrogen was used as collision gas at 1.5 mL/min, and a collision energy of 2.5−10 V was used for MS/MS

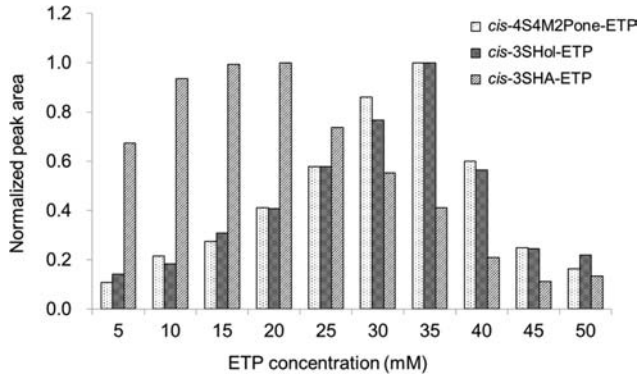

Figure 2. Comparison of the normalized responses of *cis*-ETP derivatives of thiols in spiked beer as a function of the ETP concentrations (5−50 mM).

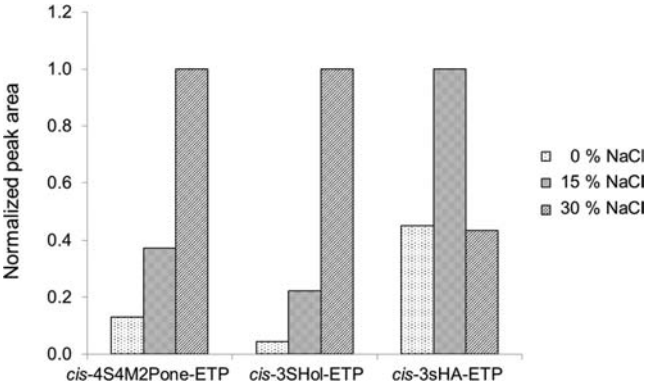

Figure 3. Comparison of the normalized responses of *cis*-ETP derivatives of thiols in spiked beer as a function of the NaCl concentrations (0, 15, and 30%).

experiments. Alternate MS mode was used in the MS/MS measurement for simultaneous TOF−MS and Q−TOF−MS (MS/MS) detection. TOF−MS calibration was performed with perfluorotributylamine (PFTBA) for EI and perfluoro-5,8-dimethyl-3,6,9-decane trioxide (PFDTD) for PCI, respectively, in every sequence.

Thermal Desorption−Gas Chromatography−Triple-Quadrupole Mass Spectrometry (TD−GC−QQQ−MS). For the optimization of the method parameters and the determination of the ETP derivatives of thiols, TD−GC−MS/MS in the SRM mode using the GERSTEL MPS2/TDU/CIS system installed on the Agilent 7890GC combined with a 7000B triple-quadrupole (QQQ) MS was used. GC−QQQ−MS was equipped with the PCM and a purge tee option for back-flush capability.

The same TD condition described in the previous section but with the liquid nitrogen cooling for the PTV inlet (because of the higher GC initial temperature of 100 °C) was used for the TD−GC−QQQ−MS analysis. Separations were performed on a 15 m × 0.25 mm inner diameter, 0.25 μm film thickness DB-Wax column (Agilent). A 0.75 m × 0.15 mm inner diameter uncoated deactivated post-column (Agilent) was used and connected between the purge tee and the QQQ−MS. Column flow was set at a constant helium flow of 1.2 mL/min. The column temperature for the DB-Wax was programmed from 100 °C (held for 3 min) to 250 °C (held for 11 min) at 10 °C/min. After the retention time of 19 min, the capillary column was back-flushed.

The QQQ−MS was operated in three acquisition modes: (1) scan mode at a mass range of m/z 29−500, (2) product ion scan mode at a mass range of m/z 29−500, and (3) SRM mode with the selected transitions (precursor to product ion). Transitions of the analytes are listed in Tables 2 and 3. The electron accelerating voltage of the EI was 70 eV. Methane was used as a reagent gas at 1.0 mL/min in the

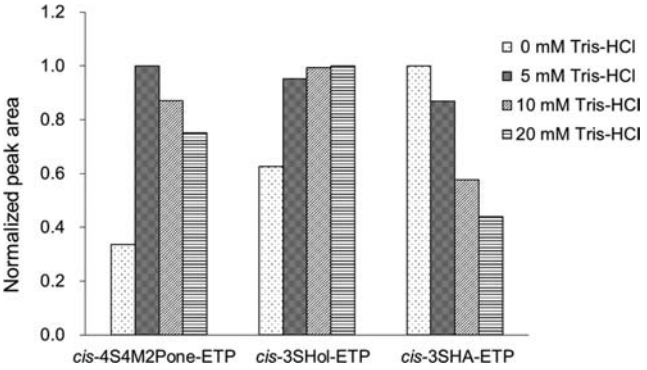

Figure 5. Comparison of the normalized responses of *cis*-ETP derivatives of thiols in spiked hop as a function of the Tris−HCl concentrations (0, 5, 10, and 20 mM).

PCI mode. Nitrogen was used as collision gas at 1.5 mL/min, and a collision energy of 2.5−10 V was used for MS/MS experiments.

Data Analysis. MassHunter qualitative analysis version B.06.00633 (Agilent) and MassHunter Quantitative Analysis version B.06.00388 (Agilent) were used for data analysis. The log K_{ow} values are calculated with a SRC-KOWWIN version 1.68 software package (Syracuse Research, Syracuse, NY).

RESULTS AND DISCUSSION

Identification of ETP Derivatives of Thiols. Because reference compounds of the ETP derivatives of the target thiols are not commercially available, identification of the ETP derivatives was first investigated. der−SBSE of spiked water at 10 ng/mL (adjusted at pH 9 and containing 5% ethanol and 10 mM ETP) was performed for 60 min with the PDMS stir bar. After extraction, the PDMS stir bar was analyzed with TD−GC−Q−TOF−MS/SCD. The peaks in the SCD chromatogram clearly indicate the presence of sulfur compounds. From the corresponding peaks in a total ion chromatogram (TIC), EI mass spectra of ETP derivatives of thiols (4S4M2Pone-ETP, 3SHol-ETP, and 3SHA-ETP) were obtained for both *cis* and *trans* stereoisomers. Previous studies[22] reported that the major isomer is likely to be *cis* form. Although molecular ions were observed for all analytes with mass errors of less than 1.3 mDa (5.4 ppm), the relative abundances of those ions were very small (especially for 3SHol). To determine the molecular mass of these compounds, PCI was also performed. The protonated molecule (MH^+) and adduct ions ($[M + C_2H_5]^+$ and $[M + C_3H_5]^+$) from PCI with methane could be observed for all analytes, with the mass errors in the range of 0.69−2.55 mDa (2.5−9.3 ppm). Finally, structure elucidation was performed with collision-induced dissociation (CID) [also known as collisionally activated

[a]The highest intensity ion as well as having higher m/z than that of the molecular ion of the non-derivative form. [b]The ions shown in bold were used for SRM transitions. [c]The ions shown in underline were used for quantification. [d]Selectivity was shown as follows: ○, targeted peak (*cis* form) was separated from interferences; △, targeted peak was co-eluted with interferences, but the targeted peak in the spiked beer was clearly higher than those in the non-spiked beer; and ×, targeted peak was co-eluted with interferences. [e]Sensitivity was shown by the signal-to-noise ratio of the targeted peak in the spiked beer.

dissociation (CAD)[23]] of the protonated molecule (MH^+ ± 0.5 mDa). It is known that fragmentation of the protonated molecule generally occurs in the protonated part (function) of a compound,[24,25] resulting in a simple bond cleavage process compared to the more extensive EI fragmentation. Therefore, CAD of the protonated molecule in accurate mass measurement can significantly help structure elucidation. Figure 1 demonstrates the CAD mass spectra of the protonated molecule of 4S4M2Pone−ETP using the collision energy of 2.5 V. Also, structures and bond cleavages of the analytes are shown in Figure 1. Considerable information concerning the structures of ETP derivatives of thiols can be derived from the fragment ions in the CAD mass spectra. For 4S4M2Pone−ETP [$CH_3CH_2O(CO)$-$CH{=}CHSC(CH_3)_2CH_2(CO)CH_3 + H]^+$], the mass error of the protonated molecule (m/z 231.1003) was 0.46 mDa (2.0 ppm). The most abundant ion at m/z 185.0619 corresponds to the bond cleavage 1 and [$MH - CH_3CH_2OH]^+$, with a mass error of 1.2 mDa/6.4 ppm, and the ion at m/z 99.0797 corresponds to the bond cleavage 2 and [$MH - CH_3CH_2O(CO)CH{=}CHSH]^+$, with a mass error of 0.74 mDa/7.5 ppm. The neutral loss of $CH_3CH_2O(CO)CH{=}CHSH$ demonstrates the derivatization of the mercapto function of thiols with ETP ($CH_3CH_2O(CO)$-$CH{\equiv}CH$). These ions clearly demonstrate that the structures, such as CH_3CH_2O- and $CH_3CH_2O(CO)CH{=}CHS-$, are involved. The neutral loss of $CH_3CH_2O(CO)CH{=}CHSH$ and CH_3CH_2OH is also observed for 3SHol−ETP (m/z 101.0941, mass error of 2.0 mDa/20 ppm; m/z 187.0762, mass error of 2.4 mDa/13 ppm) and 3SHA−ETP (m/z 143.1056, mass error of 1.1 mDa/7.4 ppm; m/z 229.0881, mass error of 1.2 mDa/5.2 ppm). Consequently, the ETP derivatives of three thiols could be identified with molecular mass determination, formula calculation, and structure elucidation. The mass spectral information used for the identification of the ETP derivatives is summarized in Table 1.

Optimization of der−SBSE Conditions for the Beer Sample. To optimize der−SBSE of thiols with ETP in beer matrices, the influence of varying concentration of ETP was first examined with the spiked beer. The pH of the spiked beer was adjusted to 9, and the spiked concentration of thiols was 10 ng/mL each. The concentration of ETP was varied with the addition of a 50% ethanol solution of ETP. SBSE with 60 min extraction was performed in duplicate for 10 concentrations of ETP between 5 and 50 mM. Figure 2 demonstrates a comparison of normalized responses of the *cis*-ETP derivatives as a function of ETP concentrations. For 3SHA−ETP, which has the highest log K_{ow} of 3.45 (the most hydrophobic of the analytes), the ETP concentrations of 20 mM showed the largest response and the ETP concentrations of 10 and 15 mM also showed a similar large response (94 and 99% of the largest response, respectively). However, the responses decreased with ETP concentrations of more than 25 mM. For 4S4M2Pone−ETP (log K_{ow} of 1.83) and 3SHol−ETP (log K_{ow} of 2.45), the normalized responses gradually increased with increasing ETP concentrations from 5 to 35 mM and the ETP concentration of 35 mM showed the largest response. However, the responses dramatically decreased with the ETP concentrations of more than 40 mM. It was observed that the ETP concentrations of more than 40 mM induced a visible "droplet" of ETP in beer matrices. This "oil effect" might influence the reaction and/or the kinetics between thiols, ETP, ETP derivatives (thioacrylates), beer matrices, and the PDMS coating of the stir bar in der−SBSE, even before the appearance of the visible droplet. This relationship is quite complex, but it is clear that the solubility of ETP in sample matrices is a critical parameter. This parameter should be considered when the method is applied for non-alcoholic sample matrices, such as hop water extract and wort, which might have low ETP solubility without percent levels of ethanol. Because 4S4M2Pone has the lowest odor threshold level in beer at 1.5 ng/L[4] compared to those of 3SHol at 55 ng/L[4] and 3SHA at 5.0 ng/L,[5] the parameters should be optimized for the condition that gives the best sensitivity of 4S4M2Pone. Therefore, the ETP concentration of 35 mM was selected for further study.

Previous studies have shown that salt addition increases the recovery of polar solutes with low log K_{ow} values (e.g., log K_{ow} < 2.5).[19,20] Therefore, the effect of salt addition was examined with the spiked beer at 10 ng/mL containing 35 mM ETP. der−SBSE was performed for 50 min in duplicate. Figure 3 demonstrates a comparison of normalized responses of the *cis*-ETP derivatives as a function of the NaCl concentrations (0, 15, and 30%). As expected, the responses for 4S4M2Pone−ETP (log K_{ow} of 1.83) and 3SHol−ETP (log K_{ow} of 2.45) significantly increased with the salt addition and the 30% salt addition gives the largest responses. However, 3SHA−ETP (log K_{ow} of 3.45)

DOI: 10.1021/acs.jafc.5b02298
J. Agric. Food Chem. 2015, 63, 6698−6706

shows the largest response with the 15% salt addition, and the 30% salt addition results in nearly the same response as with the non-salt addition. It is known that the salt addition decreases the recovery of more hydrophobic solutes (e.g., log K_{ow} > 4.0) in SBSE.[19,20] Although the log K_{ow} value of 3SHA−ETP is lower than 4.0, the oil effect of ETP might be promoted with the 30% salt addition, resulting in the reduced response of 3SHA−ETP (in comparison to the 15% salt addition). To obtain the best sensitivity for 4S4M2Pone, which has the lowest odor threshold level, the 30% salt addition was selected for further study. Finally, the extraction time profile was examined with five extraction times between 30 and 240 min. Duplicate analyses were performed for each extraction time. Figure 4 shows the extraction time profiles of the *cis*-ETP derivatives in the spiked beer. Equilibrium was nearly reached at 120 min for 3SHol−ETP and 180 min for 4S4M2Pone−ETP and 3SHA−ETP. Although it is necessary to have 180 min extraction for the maximum recovery for 4S4M2Pone (and 3SHA), the der−SBSE method can be performed in parallel (up to 20 samples on one stir plate) and does not require any additional manual steps after extraction (before TD−GC analysis). Therefore, the extraction time of 180 min was selected for further study.

Optimization of der−SBSE Conditions for Hop Water Extracts and Wort Samples. The optimized der−SBSE condition with the spiked beer in the previous section was applied to the spiked beer, hop water extract, and wort at 1 ng/mL (except for 3SHol at 10 ng/mL) in duplicate. All samples were adjusted to pH 9 using NaOH solution (1 M). In comparison to the spiked beer, ETP derivatives of all target thiols were, however, much more weakly detected in the hop water extract and were not detected in the wort. This is due to the low ETP solubility of both hop water extract and wort, which do not contain percent level ethanol, resulting in the "oil effect" (visible "droplet") of ETP in the samples. To give a similar ETP solubility with beer, hop water extract and wort were 2-fold diluted with 10% ethanol solution (resulting in 5% ethanol in the diluted sample). Then, the same der−SBSE conditions were applied to the spiked hop water extract and wort again. For the spiked wort, ETP derivatives of all target thiols were detected with nearly the same abundance as the spiked beer. However, for the spiked hop water extract, 4S4M2Pone−ETP and 3SHol−ETP were still lower than those of the spiked beer and wort. This might be due to lack of buffer capacity of hop water extract, which leads to changes in pH during the derivatization. It is known that both beer and wort have relatively similar buffer capacities that resist changes in pH on the addition of acids or bases.[25] To examine the effect of buffer in the hop extract, Tris−HCl (1 M, pH 9) was added to the spiked hop water extract. Figure 5 shows a comparison of normalized responses of *cis*-ETP derivatives as a function of the Tris−HCl concentrations (0, 5, 10, and 20 mM). The response for 4S4M2Pone−ETP notably increased with the buffer addition, and 5 mM gives the largest response. The response for 3SHol−ETP also increased with the buffer addition, and similar responses are seen with all buffered conditions. However, the response for 3SHA−ETP decreased with the buffer addition, especially for 10 and 20 mM. Therefore, the 5 mM Tris−HCl addition was selected for the hop extract sample.

Selectivity and Sensitivity in GC−MS/MS Analysis. To evaluate the selectivity and sensitivity of the method, the spiked water at 1−10 ng/mL and non-spiked and spiked beer at 10−100 pg/mL were analyzed with several GC−MS/MS conditions, including different ionization modes (EI and PCI), collision energies, and SRM transitions. We selected the following

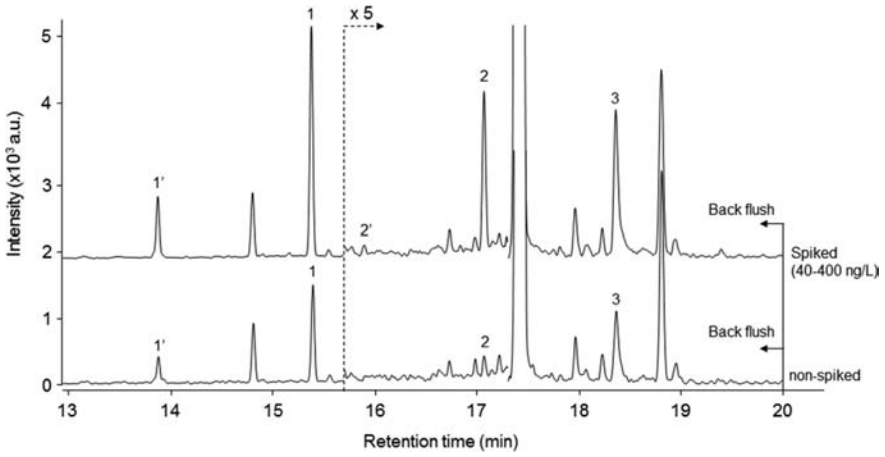

Figure 6. SRM chromatograms obtained by der−SBSE−TD−GC−QQQ−MS of spiked and non-spiked beer hopped with Citra hop: (1′) *trans*-4S4M2Pone−ETP, (1) *cis*-4S4M2Pone−ETP, (2′) *trans*-3SHA−ETP, (2) *cis*-3SHA−ETP, (3′) *trans*-3SHol−ETP, and (3) *cis*-3SHol−ETP. Spiked concentrations are 40 ng/L for 4S4M2Pone and 3SHA and 400 ng/L for 3SHol.

precursor ions for SRM: (1) molecular ion, (2) fragment ion that shows the highest intensity as well as having higher m/z than that of the molecular ion of the non-derivative form (e.g., m/z > 132 for 4S4M2Pone), (3) protonated molecule (PCI), and (4) adduct ion (PCI). Product ion scan with EI and PCI for the precursor ions was first performed with collision energies of 2.5, 5, 10, and 20 V for the spiked water, and the collision energies that give the largest sum of the ion intensities were selected for SRM of each precursor ion. SRM with EI and PCI was then performed with the selected collision energies for non-spiked and spiked beer. The selectivity of SRM conditions was evaluated with the following criteria: (1) the targeted peaks (*cis* form) should be separated from the interferences, and (2) the targeted peaks in the spiked beer should be clearly higher than those in the non-spiked beer (if detected). The sensitivity of SRM conditions was evaluated with a signal-to-noise (S/N) ratio of the targeted thiols in the spiked beer. More than two acceptable transitions could be obtained for all targeted thiols, with SRM using the molecular ion or fragment ion as the precursor ion in the EI. However, no acceptable transitions and only one transition were obtained for 4S4M2Pone−ETP and 3SHol−ETP, respectively, with all SRM conditions in the PCI. Therefore, SRM transitions that give the highest S/N ratio in the EI mode were selected for quantitation. Additionally one or two SRM transitions in the EI were selected as qualifiers. The relative ratios of transition intensities (e.g., 230 > 132/230 > 99 for 4S4M2Pone−ETP) were compared to those in the spiked water, and those were less than 20%. Finally, the selection of SRM transitions for the internal standards (d_{10}-4S4M2Pone and d_2-3SHol) was performed with the same procedure but with the EI only. Tables 2 and 3 summarize the parameters used for the selectivity and sensitivity in GC−MS/MS analysis.

Analytical Performance. We evaluated linearity, limit of detection (LOD), and apparent recovery (the quantity of observed value/reference value, obtained using an analytical procedure that involves a calibration graph[26]) of the method. The standard addition calibration method and the spiked beer sample were used for the evaluation. The peak area of the selected ion from the *cis*-ETP derivative was used for both calibration and determination. Linearity was assessed at six concentration levels between 1 and 100 ng/L for 4S4M2Pone and 3SHA in the beer sample, which contains these compounds at non-detectable levels (below sub-nanogram per liter) with the proposed method. Because detectable levels of 3SHol (>20 ng/L) are present in most beer samples, the linearity between 20 and 1000 ng/L for 3SHol was evaluated. For each level, duplicate analyses were performed. For all compounds, good linearity was achieved with r^2 above 0.9943. The LOD for 4S4M2Pone and 3SHA was estimated using low-concentration spikes (at 1 ng/L) in the same beer samples used for the linearity study and calculating the standard deviation of the determination. The LOD is then defined as 3 times the standard deviation (for six replicates) obtained for the analyte concentration not greater than 10 times the LOD.[27] The LOD for 3SHol was estimated using the blank determination procedure[28] because of the presence of 3SHol at the detectable levels in the beer samples. The LOD for 3SHol is then expressed as the analyte concentration corresponding to the sample blank value plus 3 times the standard deviation.[28] For all analytes, the LODs were below their odor threshold levels in the range of 0.19−27 ng/L. The apparent recovery was assessed by six replicate analyses of the spiked beer samples. The spiked levels were 10 ng/L for 4S4M2Pone and 3SHA and 100 ng/L for 3SHol. The apparent recoveries were good for all analytes in the range of 99−101% [relative standard deviation (RSD) of 1.3−7.2%; n = 6]. The linearity, LOD, and apparent recovery of the method are summarized in Table 4.

Analysis of Beer, Hop Water Extract, and Wort Samples. To demonstrate the applicability of the method, quantitation of the targeted thiols was performed for three kinds of beer hopped with Cascade, Citra, and Nelson Sauvin hop cultivars.

DOI: 10.1021/acs.jafc.5b02298
J. Agric. Food Chem. 2015, 63, 6698−6706

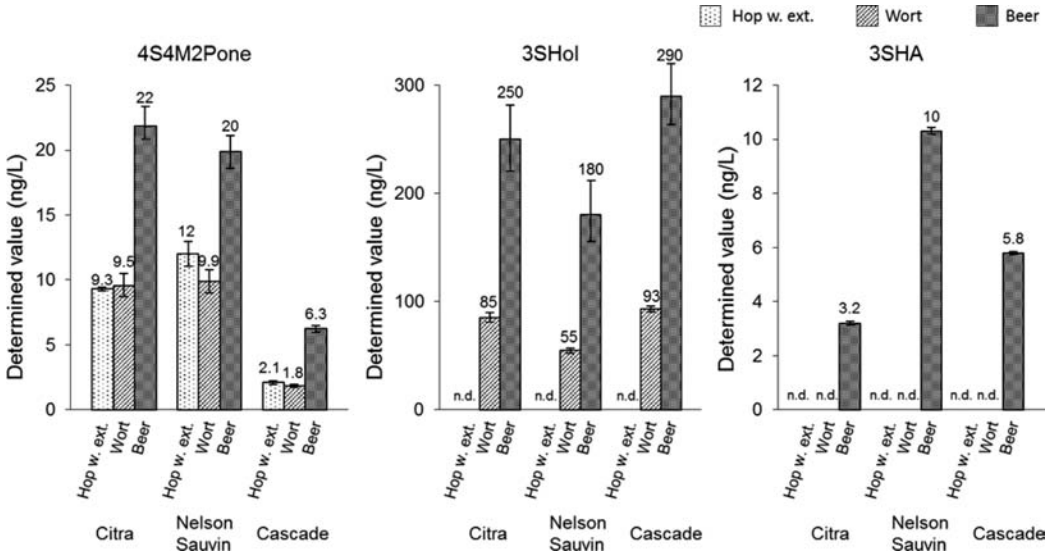

Figure 7. Determined values obtained by der−SBSE−TD−GC−QQQ−MS of beer samples hopped with Cascade, Citra, and Nelson Sauvin hop cultivars and the corresponding hop water extracts and wort sample.

The corresponding hop water extract and (hopped) wort were also analyzed. Triplicate analyses with a three-point standard addition calibration method using internal standards (d_{10}-4S4M2Pone for 4S4M2Pone and 3SHA and d_2-3SHol for 3SHol) were performed for each sample. The peak area of the selected ion from the *cis*-ETP derivative was used for both calibration and determination. Figure 6 illustrates the sum of SRM chromatograms obtained from beer hopped with Citra hop cultivar. The determined values are shown in Figure 7. For 4S4M2Pone, Citra hop and Nelson Sauvin hop show higher values (9.3−12 ng/L; RSD of 3.0−5.2%; n = 3) than that of Cascade hop (2.1 ng/L; RSD of 4.1%; n = 3). The corresponding hopped wort and beer also show a similar trend, and the increased values of all beer samples (6.3−22 ng/L; RSD of 5.1−8.2%; n = 3) indicate the formation of 4S4M2Pone during fermentation from precursors.[6] Although 3SHol was not detected in all hop water extract samples, the determined values of 3SHol in hopped wort and beer are in the range of 55−93 ng/L (RSD of 11−12%; n = 3) and 180−290 ng/L (RSD of 7.5−12%; n = 3), respectively. Again, the increased values of all beer samples illustrate the effect of precursors during fermentation. As a previous study reported,[10] the determined values of 3SHol between hopped wort and beer show a linear correlation with r^2 of 0.9477. 3SHA was not detected in hop water extract and hopped wort and was only detected in beer (3.2−10 ng/L; RSD of 4.6−9.8%; n = 3). It is known that some yeasts have high capability of converting 3SHol into 3SHA during fermentation.[29,30] However, the order of the determined values of 3SHA in beer (Nelson Sauvin > Cascade > Citra) did not reflect those of 3SHol in hopped wort and beer (Cascade > Citra > Nelson Sauvin).

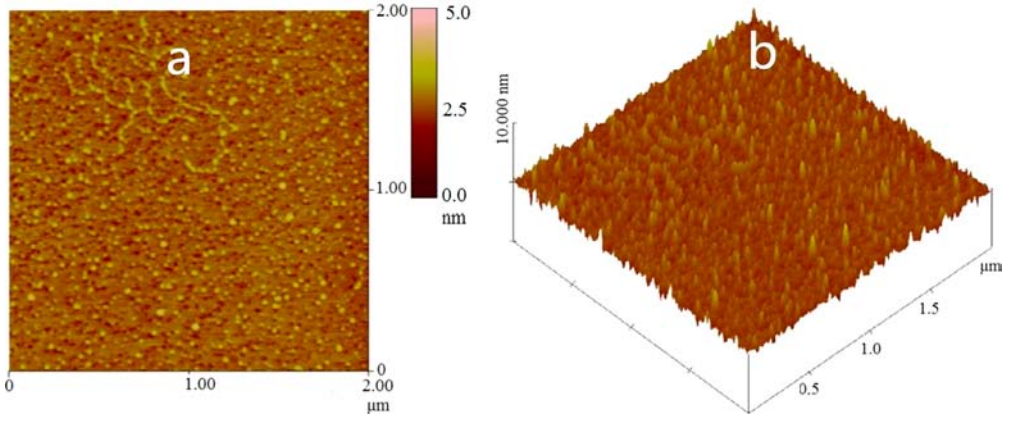

Figure 1. AFM images of the C-dots.

EXPERIMENTAL PROCEDURES

Materials. Aloe was obtained from potted plants in our laboratory and washed with water for further use. Dichloromethane (CH_2Cl_2, 99.5%) was purchased from Aladdin Industrial Corp. (Shanghai, China). Tartrazine ($C_{16}H_9N_4Na_3O_9S_2$, 87%), sunset yellow ($C_{16}H_{10}N_2Na_2O_7S_2$, 85%), erioglaucine disodium salt ($C_{37}H_{34}Na_2N_2O_9S_3$, 85%), and amaranth ($C_{20}H_{11}N_2Na_3O_{10}S_3$, 85%) were received from Aladdin Chemistry Co. Ltd. (Shanghai, China). Sodium dihydrogen phosphate ($NaH_2PO_4{\cdot}H_2O$) and disodium hydrogen phosphate dodecahydrate ($Na_2HPO_4{\cdot}12H_2O$) were obtained from Tianjin Fuchen Chemical Reagents Co., Ltd. (Tianjin, China). All chemicals were of analytical reagent grade and used without further purification. The ultrapure water used throughout the experiments was purified through an UPH-II-20T up water purification system (Chengdu Ultrapure Technology Co. Ltd., Chengdu, China).

Apparatus and Characterization. The AFM analysis was carried out on a Multimode/Nanoscope (Veeco Corp., USA) on a tapping mode with a RTESP-Veeco cantilever on a platinum-coated mica substrate. All absorption spectra were recorded on a Shimadzu UV-2550 UV−vis absorption spectrophotometer (Kyoto, Japan). Fluorescence measurements were conducted with a Cary Eclipse fluorescence spectrophotometer (Varian, Palo Alto, CA, USA). The infrared spectra were obtained on a Nicolet 6700 Fourier transform infrared (FTIR) spectrometer (Thermo Electron Corp., USA) with passed KBr pellet at room temperature.

Synthesis of Fluorescent C-Dots. The C-dots were prepared by hydrothermal treatment of fresh aloe in water. In a typical procedure, 5 g of aloe was added into 25 mL of water, and then the mixture was transferred into a 50 mL Teflon-lined autoclave and was heated at 180 °C for 11 h. After heating, the autoclaves were allowed to naturally cool in a fume hood on a heat-resistant plate and the resulting yellow solution was filtered with a 0.22 μm membrane followed by washing with dichloromethane to remove the unreacted organic moieties. Finally, the upper light yellow aqueous solution containing C-dots was collected and stored at 4 °C for further characterization and use.

Quantum Yield Measurements. The quantum yield of the as-synthesized C-dots was measured on the basis of a procedure described previously.[25] Rhodamine 6G aqueous solution was used as a reference standard, for which the quantum yield was 0.95 at 488 nm reported by the literature. Absolute values of the quantum yield were calculated according to the equation

$$\Phi_x = \Phi_{std}\frac{I_x}{A_x}\frac{A_{std}}{I_{std}}\frac{\eta_x^2}{\eta_{std}^2}$$

where Φ is the quantum yield of the as-prepared C-dots, A is the absorbance, I is the corrected emission intensity at the excitation wavelength, and η is the refractive index of the solvent. The subscripts "std" and "x" refer to reference standard with known quantum yield and the C-dots solution, respectively. For the sake of reducing effects of reabsorption within the sample on the observed emission spectrum, the absorbance values (A) of all solutions in the 10 mm cuvette were always controlled under 0.1.

Sample Pretreatment. Candy, steamed buns made of corn, and honey were selected as test samples because tartrazine may be added as a colorant into them. All samples were obtained from a local supermarket in Nanchong, China. The candy or honey sample (10.0 g) was crushed and subsequently dissolved in hot water (~60 °C). The resulting solution was transferred and diluted to a 50 mL volumetric flask. The diluted solution was filtered through a 0.45 μm filter membrane for subsequent use. Ten grams of steamed buns and a certain amount of water were added into a 100 mL beaker, and then the mixture was blended by electric mixer and extracted with ultrasonic for 15 min, respectively. After extraction, the mixture was centrifuged at 12000 rpm for 10 min followed by transferring the supernatant and diluting to 50 mL. The diluted solution was also filtered through a 0.45 μm filter membrane for subsequent use. The above sample pretreatment method is referenced to the literature with some minor modifications.[26]

Detection of Tartrazine in Food Samples. The tartrazine detection procedure was carried out in phosphate buffer (PB) (30 mM, pH 6.0) at 5 °C. In a typical run, 450 μL of C-dots solution was added into 500 μL of PB, followed by the addition of 1000 μL of sample solution and thorough mixing. The resulting mixture was reconstituted to 4 mL with water. After a reaction time of 5 min at 5 °C, the spectra were recorded under excitation at 441 nm with slit widths setting at 10/10 nm. All of the recoveries were calculated according to the equation below:

$$\text{recovery} = (C_{measured} - C_{initial})/C_{added}$$

RESULTS AND DISCUSSION

Optimization of the Synthesis Conditions. To ensure excellent performance of the synthesized C-dots, we have optimized the time and temperature of the synthesis simply, and results are shown in Figures S1 and S2. From Figure S1 we can see clearly that the fluorescence intensity gradually increased with the reaction time up to 11 h but decreased when the time exceeded 11 h. Therefore, 11 h was chosen as the optimal reaction time. Simultaneously, as displayed in Figure S2, the fluorescence intensity increased with the reaction temperature rise. We finally chose 180 °C as the optimal temperature because when the temperature exceeded 180 °C, the fluorescence intensity increase was not obvious.

Characterization. Figure 1 shows the typical AFM image of the as-synthesized C-dots solution. It reveals that the C-dots are well dispersed in solution with spherical shape and have an average size of 5 nm approximately. Similarly, Figure S3 shows the typical TEM image of the C-dots. It can be seen that the C-

DOI: 10.1021/acs.jafc.5b02319
J. Agric. Food Chem. 2015, 63, 6707−6714

dots are in the monodispersion state and their size is consistent with the results of AFM.

The absorption (black line) and emission spectra (green line) of the as-synthesized C-dots are shown in Figure 2. A peak

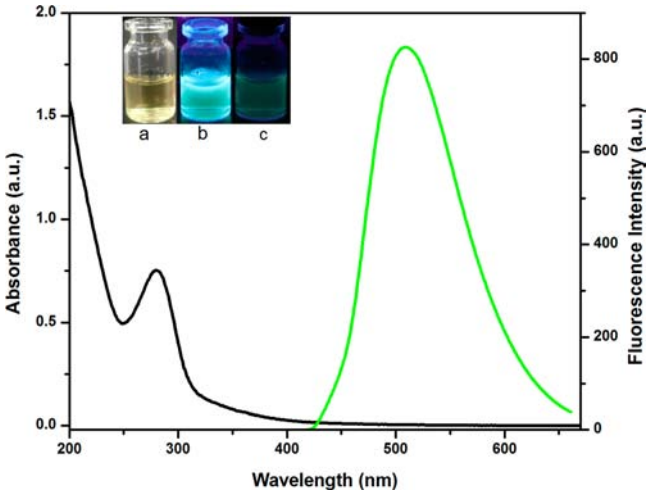

Figure 2. UV−vis absorption (black line) and fluorescence emission (green line) spectra of the C-dots. (Inset) Photographic images of C-dots under (a) visible light, (b) ultraviolet light, and (c) ultraviolet light with tartrazine (22.5 μM).

at 278 nm is exhibited in the UV−vis absorption spectrum, which was attributed to n−π* transition of C═O and π−π* transition of C═C.[27] The photoluminescent (PL) spectrum shows an optimal emission peak at about 503 nm when excited at 441 nm. The inset photograph in Figure 2 indicates the C-dots aqueous solution under visible (a) and UV illumination at 365 nm (b). The bright yellow PL of the C-dots under UV light is strong enough to be seen with the naked eye, but when tartrazine was added, the fluorescence was obviously quenched (c). The full width at half-maximum (fwhm) is 100 nm, suggesting a relatively small size distribution of C-dots, which was consistent with AFM and TEM data and approximately equal to that of most reported C-dots.[28,29] The strong fluorescence can be caused by the surface energy traps in the C-dots that become emissive upon stabilization.[17]

To further investigate the optical properties, the PL emission spectrum of the C-dots was recorded at progressively increasing excitation wavelengths (Figure 3). It can be observed that a red shift was attributed in the emission spectra of C-dots from 443 to 525 nm with increasing excitation wavelengths, accompanied by a decrease of the fluorescence intensity, revealing that the fluorescence of C-dots is strongly dependent on the excitation wavelength. This finding is substantially in agreement with that of Vaibhavkumar.[30,31] To investigate the components, surface groups, and structure of the as-synthesized C-dots, EDS and FT-IR have been carried out. Figure S4 shows the as-prepared C-dots are mainly composed of C, H, O, and N. As shown in Figure 4, characteristic absorption bands of the −OH stretching vibration mode at about 3400 and 1073 cm^{-1} could be observed. The band at 2923 cm^{-1} corresponds to the C−H stretching mode.[32] In addition, the peaks appearing at 1590 and 1400 cm^{-1} may be caused by the asymmetric and symmetric stretching vibration of COO^{-}, respectively. These findings provide evidence that both the hydroxyl and carboxylic groups originated from carbohydrates in the aloe.

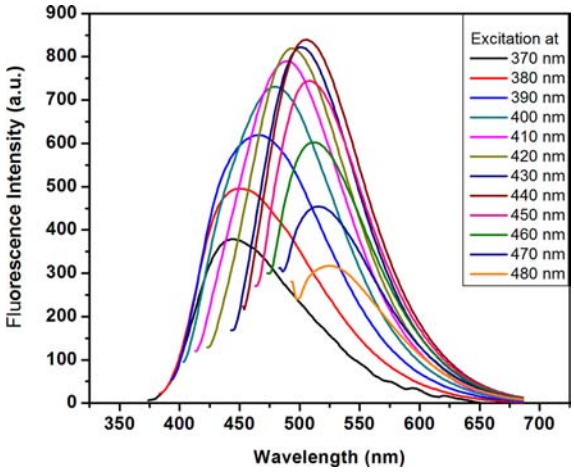

Figure 3. Fluorescence emission spectra of C-dots obtained at different excitation wavelengths progressively increasing from 370 to 480 nm in 10 nm increments.

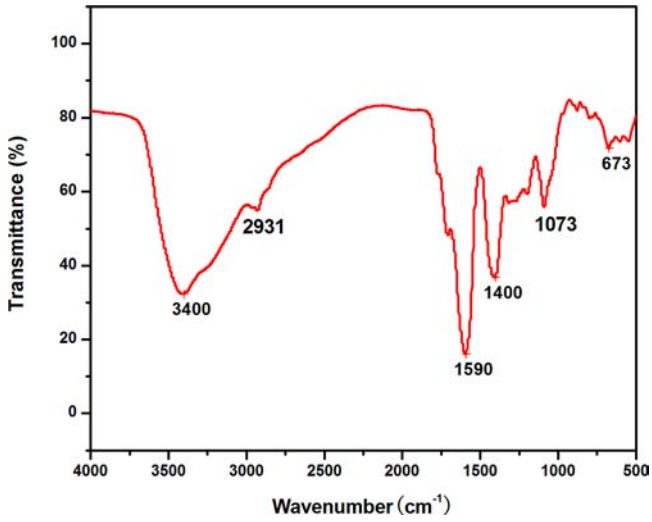

Figure 4. FT-IR spectrum of C-dots.

It is well-known that the photostability of C-dots plays a key role in sensitive fluorescence detection. In this connection, we studied the emission behavior of the C-dots under continuous UV light illumination at 365 nm for 120 min. It was also noted that as shown in Figure S5 the photobleaching of C-dots is not observed and the fluorescence intensity of C-dots remained constant even after 120 min of continuous UV light illumination, indicating the good photostability of C-dots. Using rhodamine 6G as a reference, a PL quantum yield (QY) of 10.37% was measured. Table S1 shows the comparison of the optical properties and applications of the C-dots derived from aloe with the reported methods. It can be seen that the present method is green and simple and has a relatively high quantum yield. At the same time, it is worth mentioning that the as-prepared C-dots emit strong yellow fluorescence, whereas most reported carbon dots are blue, and they can be a sensitive fluorescent probe for colorant detention.

Design Principle of the Sensor. Under the same experimental conditions, the fluorescence spectra of the C-dots alone and the system of C-dots with tartrazine were recorded, respectively. As shown in Figure S6, the C-dots presented strong fluorescence at 503 nm when excited at 441

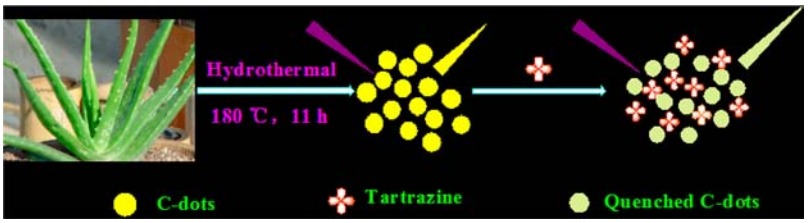
Scheme 1. Scheme of the Synthetic Strategy for C-Dots and the Principle of Tartrazine Sensing



nm. Upon the addition of tartrazine, the fluorescence intensity of the prepared C-dots decreased significantly. On the basis of the fluorescence quenching, we speculated that a facile fluorescence sensor for the determination of tartrazine could be constructed. The synthetic strategy for C-dots and the principle of tartrazine sensing are schematically presented in Scheme 1.

Mechanism of Fluorescence Quenching. Broadly speaking, various kinds of molecular interactions with the quencher molecule can reduce the fluorescence quantum yield, such as electron or energy transfer, collisional quenching, excited-state reaction, and ground-state complex formation The quenching mechanisms are usually divided into dynamic quenching, which results from collision, and static quenching, resulting from the formation of a ground-state complex between the fluorescence material and quencher. On the other hand, they could be distinguished by some additional formations such as the relationship between the quenching and viscosity, temperature, and lifetime measurements.[33] In general, the dynamic fluorescence quenching constants will increase with the rise of the system temperature due to the energy transfer efficiency, and the effective collision times between molecules will also increase. On the contrary, the values of the static fluorescence quenching constants will decrease with the rise of temperature. Let us suppose that the mechanism is dynamic quenching; it can be described by the Stern–Volmer equation[34]

$$F_0/F = 1 + K_{SV}[Q] = 1 + K_q\tau_0[Q]$$

where F_0 and F are the C-dots fluorescence intensities at 503 nm in the absence and presence of tartrazine, respectively; K_{SV} and K_q are the Stern–Volmer quenching constant and the bimolecular quenching constant, respectively; [Q] is the concentration of tartrazine; and τ_0 is the average lifetime of the C-dots without any other fluorescence quencher, with a general value of 10^{-8} s. Figure 5 shows the fluorescence intensities of the C-dots analyzed by plotting F_0/F versus [Q] at 278, 288, 298, and 308 K. Table 1 summarizes the calculated K_{SV} and K_q values for each temperature. As shown, the K_{SV} is inversely correlated with temperature, and the value of K_q is far larger than 2.0×10^{10} L mol^{-1} s^{-1}, which is the maximum scatter collision quenching constant. These findings indicate that the quenching process may be caused by static quenching. Additionally, the UV–vis spectra of the prepared C-dots alone and the system of the C-dots with tartrazine are illustrated in Figure S7. As can be seen from this figure, with the addition of tartrazine, the absorbance intensity of the C-dots at 280 nm increases, with a blue shift. This observation indicates that the formation of ground-state complexes is generated due to the interaction between tartrazine and C-dots.

Optimization of Experimental Conditions. With the purpose of investigating the sensitivity, precision, and selectivity of the analytical method, parameters including the medium pH, dosage of C-dots, reaction temperature, and incubation time were systematically optimized for the system.

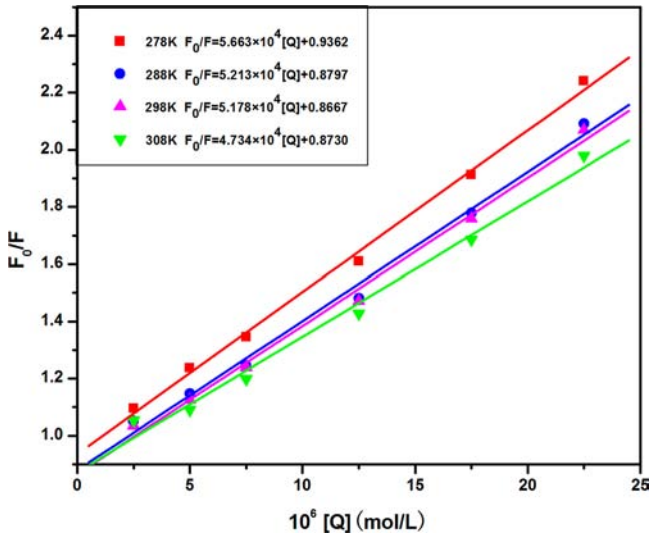


Figure 5. Stern–Volmer plots for the system of C-dots–tartrazine under temperatures of 278, 288, 298, and 308 K, respectively. F_0 and F are the fluorescence intensity of C-dots in the absence and presence of tartrazine, respectively. Conditions: C-dots, 450 μL; PB, 30 mM, pH 6.0.

Table 1. Stern–Volmer Quenching Constants for the Interaction of C-Dots and Tartrazine at Different Temperatures

pH	T (K)	K_{SV} (L mol^{-1})	K_q (L mol^{-1} s^{-1})	R	SD
6.0	278	5.663×10^4	5.663×10^{12}	0.9984	0.0278
6.0	288	5.213×10^4	5.213×10^{12}	0.9960	0.0402
6.0	298	5.178×10^4	5.178×10^{12}	0.9967	0.0361
6.0	308	4.734×10^4	4.734×10^{12}	0.9939	0.0452

The effect of the solution pH on the fluorescence quenching of C-dots in the presence of tartrazine is shown in Figure 6a. An increase in pH from 4.0 to 6.0 results in the increased fluorescence quenching efficiency (represented as F_0/F, where F_0 and F are the fluorescence intensities of the C-dots at 503 nm before and after the addition of tartrazine, respectively.) whereas a further increase in pH from 6 to 7.5 leads to a gradual decrease. Such an observation suggests that the fluorescence intensity of the C-dots strongly depends on the pH value of the system. Our results are consistent with those of C-dots functioned with hydroxyl and carboxylic/carbonyl moieties.[10,19,32] Consequently, we selected 6.0 as the optimal pH for our study.

The effect of the dosage of C-dots on the fluorescence quenching efficiency is presented in Figure 6b. The fluorescence quenching efficiency gradually increased with the dosage of C-dots up to 450 μL. When the dosage of C-dots

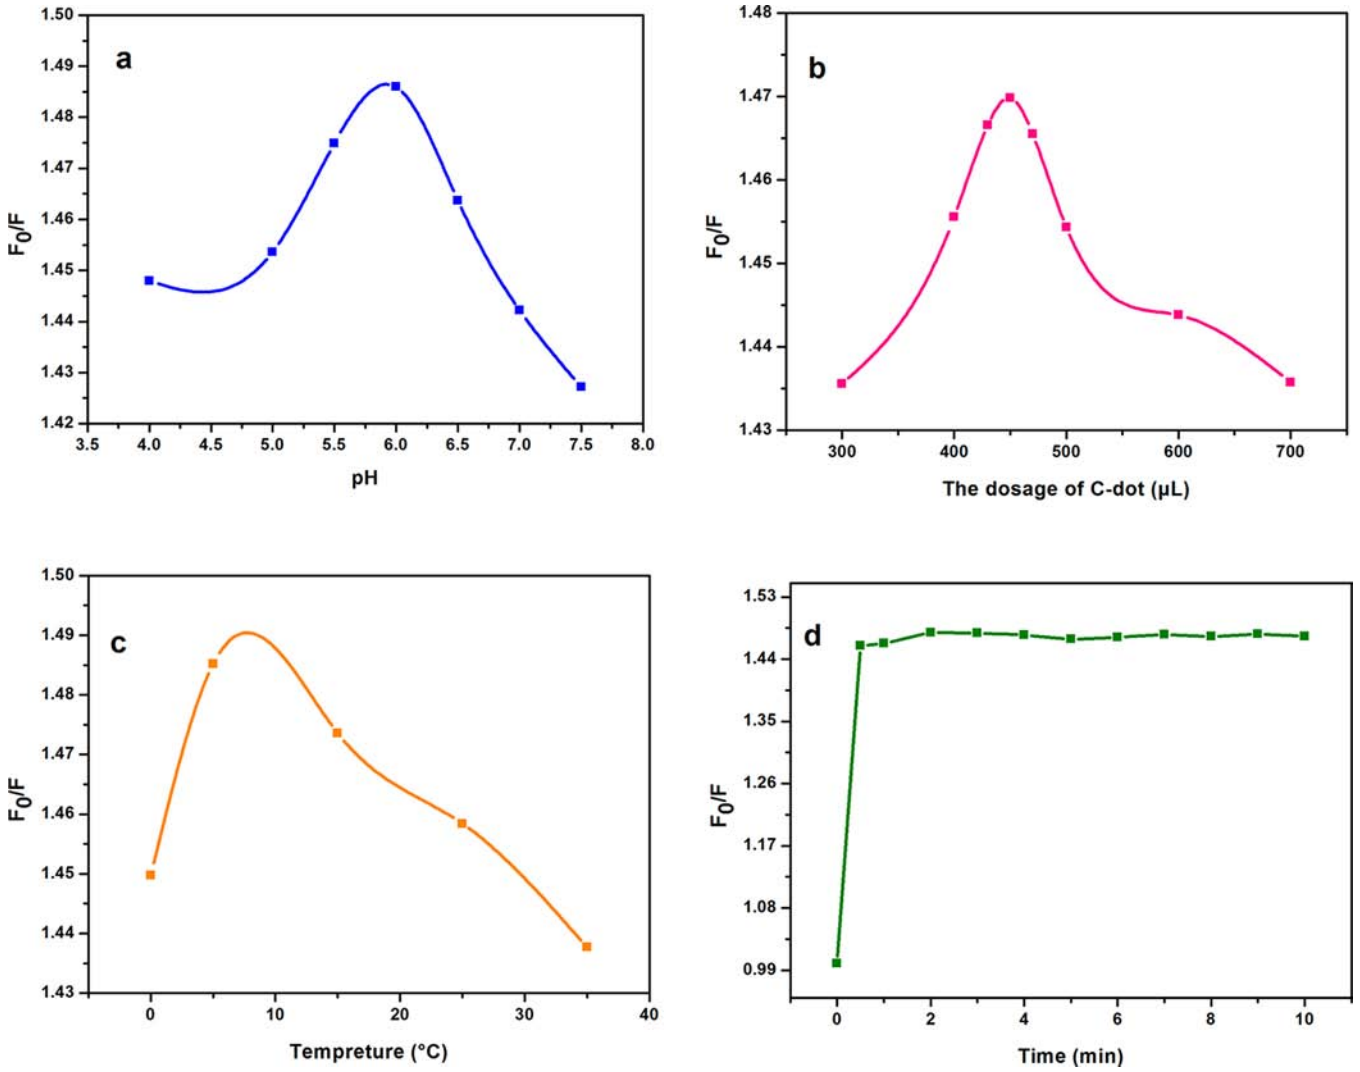

Figure 6. Effect of (a) pH of buffer solution, (b) dosage of C-dots, (c) reaction temperature, and (d) reaction time on fluorescence quenching efficiency of the C-dots−tartrazine system. F_0 and F are the fluorescence intensity of C-dots in the absence and presence of tartrazine, respectively. Conditions: PB, 30 mM; tartrazine, 10 μM.

exceeded 450 μL, the fluorescence quenching efficiency decreased. Therefore, 450 μL was used as the optimal dosage for further performance

Figure 6c shows the fluorescence curves of the system at different temperatures. As the temperature increased from 5 to 35 °C, the fluorescence quenching efficiency decreased gradually. Among the temperatures studied, the maximum fluorescence intensity efficiency was achived at 5 °C. Hence, 5 °C is selected as the optimum reaction temperature.

The effect of incubation time on the fluorescence intensity of the system is shown in Figure 6d. No significant changes in F_0/F were observed after an incubation time of 1 min. To ensure the consistency of the whole experiment, it is important to record the stable fluorescence signal. Thus, 5 min is conservatively chosen as the optimum incubation time.

Analytical Performance for Tartrazine Sensing. *Sensitivity.* The dependence of F_0/F on the different concentrations of tartrazine under the identical conditions is shown in Figure 7. As displayed, the fluorescence quenching efficiency of C-dots gradually decreases with an increase in the concentration of tartrazine. As shown in the upper right inset of Figure 7, the decrease in fluorescence quenching efficiency exhibited a linear response to the tartrazine concentration in the range of 0.25−32.50 μM, which was consistent with the photograph of the solutions under UV light. The calibration curve can be depicted as $F_0/F = 0.9604 + 0.0577X$ (X is the concentration of tartrazine, μM) with a correlation coefficient of 0.9986. The relative standard deviation (RSD) was 0.25% through five parallel determinations ($n = 5$) at a fixed tartrazine concentration of 10.00 μM, indicating the excellent reliability of this sensor. The detection limit is estimated to be 73 nM at a signal-to-noise ratio of 3.

In Table 2, we compare the experimental results with those for reported methods of tartrazine detection. As shown in Table 2, our developed assay exhibits a wider linear range and lower RSD compared to some methods. Our method can be an alternative to others for the determination of tartrazine in samples, although the limit of detection (LOD) our method is not the smallest in Table 2. It is worth mentioning that almost all of the reported sensors need special equipment, a sophisticated technique, or complicated operations. By contrast, the sensor we developed here has its own features, including low instrumentation cost, simplicity of operation, and fast

response, which makes it more applicable for routine analysis of tartrazine in foods.

Selectivity. To evaluate the selectivity of this sensing system, we examined the fluorescence response of the system to tartrazine at a concentration of 5.0 μM with the presence of coexisting foreign substances such as K^+, Ca^{2+}, Zn^{2+}, Fe^{3+}, HCO_3^-, NO_2^-, glutamic acid, glutathione (GSH), citric acid, phenylalanine, starch, tartaric acid, vitamin C, glucose, lactose, sunset yellow, erioglaucine disodium salt, and amaranth under the same conditions. As shown in Figure 8, for the present study, various different substances were added in the test solution at the amount of 100 times tartrazine initially, and the ratio would be gradually reduced when the interference presented. It was found that some of the materials, such as Fe^{3+}, sunset yellow, erioglaucine disodium salt, and amaranth, could be only allowed at relatively lower levels. Nevertheless, the concentrations of these substances were much lower than the allowed levels in food samples. Meanwhile, most of the common excipients in foods could be tolerated at high concentrations up to 100 times. That is to say the established strategy possesses a high selectivity toward tartrazine detection.

Application in Food Samples. The developed approach was employed to detect the trace level of tartrazine in some food samples. The results for the pretreated food samples spiked with known amounts of standard tartrazine are shown in Table 3. The intraday and interday recoveries ranged from 88.6 to 103.4% and from 87.3 to 106.6%, respectively. All of these results indicate that the accuracy and reliability of the proposed method can be applied to the determination of tartrazine in food samples.

In summary, C-dots based on aloe were synthesized via a simple and green method. Without further chemical modification, the synthesized C-dots have been applied to the sensitive and selective detection of tartrazine in some food samples. The new C-dots described here may extend their great potential for cell imaging and drug delivery applications due to

leaves, has several pharmacological activities, including antioxidant, anti-inflammatory, and antimicrobial activities.[16] As oleuropein exhibits potent antioxidant activity *in vitro*,[17] it is speculated to be the main component responsible for the potentially beneficial effects of olive leaves on various diseases.[18] In fact, previous studies have indicated that oleuropein ameliorates hepatic steatosis,[19] cardiovascular diseases,[20] and neurodegenerative diseases.[21] In addition, hyperglycemia in type 1 diabetes model animals[22] and metabolic abnormalities in high-carbohydrate and high-fat diet rats[20] were partially attenuated by feeding oleuropein-rich extracts. However, it is unknown whether an oleuropein-rich diet is efficacious against type 2 diabetic phenotypes, including chronic hyperglycemia and impaired glucose tolerance.

In the present study, we investigated the effect of the oleuropein-containing supplement OPIACE, an olive leaf extract whose oleuropein content exceeds 35% (w/w), on the diabetic phenotypes in type 2 diabetes model TSOD mice. We found that OPIACE attenuated hyperglycemia and impaired glucose tolerance over the long-term but had no effect on obesity in TSOD mice. Furthermore, we demonstrated that OPIACE mildly reduced oxidative stress in TSOD mice when feeding duration was extended. Interestingly, OPIACE also attenuated anxiety-like behavioral abnormality in aged TSOD mice. Our findings suggest that the oleuropein-rich diet has beneficial effects on the progression of type 2 diabetes and behavioral disorder that is likely related to diabetes.

MATERIALS AND METHODS

Chemicals. 13-Hydroxy-9*Z*,11*E*-octadecadienoic acid [13-(*Z*,*E*)-HODE], 9-hydroxy-10*E*,12*Z*-octadecadienoic acid [9-(*Z*,*E*)-HODE], and 13*S*-hydroxy-10*E*,12*Z*-octadecadienoic-9,10,12,13-d_4 acid (13-HODE-d_4) were obtained from Cayman Chemical Company (MI, USA). 9-Hydroxy-10*E*,12*E*-octadecadienoic acid (9-(*E*,*E*)-HODE) and 13-hydroxy-9*E*,11*E*-octadecadienoic acid (13-(*E*,*E*)-HODE) were purchased from Larodan Fine Chemicals AB (Malmo, Sweden). OPIACE was provided by Eisai Food & Chemical Co., Ltd. (Tokyo, Japan). The nutrient composition in OPIACE was measured by high performance liquid chromatography (HPLC). OPIACE was dissolved in methanol/water (60:40, v/v) and subjected to HPLC analysis. Other materials were of the highest grade commercially available.

Animals. Male TSOD mice and male Tsumura Suzuki Non Obesity (TSNO) (control) were obtained from the Institute for Animal Reproduction (Ibaraki, Japan). The animals were housed individually and had free access to food (CE-2; Clea Japan Inc., Tokyo, Japan) and water. The animal room was maintained at 23 ± 2 °C and 50 ± 10% humidity under a 12 h light (8:00−20:00) and dark (20:00−8:00) cycle. The animals were acclimated to the laboratory environment for at least 1 week before the experiment. TSOD mice were divided into two weight-matched groups (n = 12 each), the control diet group and OPIACE-containing diet group. The OPIACE-containing diet was prepared by mixing the control diet (CE-2) with 0.2% (w/w) OPIACE, and began to feed TSOD mice from 4 weeks of age. The experimental protocols were approved by the Institutional Animal Care and Use Committee of the National Institute of Advanced Industrial Science and Technology.

Measurements of Body Weight, Food Intake, and Biochemical Parameters. Body weight, food intake, and nonfasting blood glucose levels were measured once a week. Nonfasting blood glucose level was measured with the same method as that described previously.[4] For the measurement of plasma triglyceride levels, mice at 5, 8, 11, and 13 weeks of age were sacrificed after fasting for 16 h. Blood was collected from the vena cava and gently mixed with heparin. The obtained plasma samples were stored at −30 °C until use. Plasma triglyceride levels were measured with a LabAssay Triglyceride kit (Wako Pure Chemical Industries, Ltd., Osaka, Japan) according to the manufacturer's instructions. The weight of epididymal white adipose tissue (WAT), a type of visceral fat, in mice was measured at 5, 8, 11, and 13 weeks of age.

Oral Glucose Tolerance Test (OGTT). After fasting for 16 h, glucose solution at the dose of 1.5 g/kg body weight was administered orally with a gavage needle to mice at 5, 8, 11, 13, 15, and 24 weeks of age. For the measurement of blood glucose level, mice were placed in a mouse restrainer, and their tail tips were resected with surgical scissors. Glucose level in effused blood (approximately 1 μL) was measured with a glucose meter (Life Check; EIDIA Co., Ltd., Tokyo, Japan). Measurement of blood glucose levels in the tail was performed at 0 (preadministration), 15, 30, 60, and 120 min after glucose administration. The area under the curve (AUC) after OGTT was calculated using the trapezoidal method.

Analysis of Hydroxyoctadecadienoic Acid by Liquid Chromatography−Mass/Mass Spectrometry (LC-MS/MS). Hydroxyoctadecadienoic acids (HODEs) were measured with a previously described method.[23] Briefly, the mouse plasma sample was mixed with the internal standard, 13-HODE-d_4, and then butylated hydroxytoluene and triphenylphosphine were added to reduce hydroperoxides in the sample. The reduced sample was saponified by adding KOH in methanol. The mixture was acidified with 10% (v/v) acetic acid in water and extracted with chloroform/ethyl acetate (4:1, v/v). The chloroform/ethyl acetate layer was concentrated and divided equally into two portions, and each portion was evaporated to dryness under nitrogen. One portion of the derivatized sample was reconstituted with methanol/water (70:30, v/v) and subjected to LC-MS/MS analysis of HODEs. The precursor, the product ions, and the collision energies were determined after the optimization of MS/MS conditions as follows: m/z = 295.0 and 194.6−195.6 at 21 eV for 13-(*E*,*E*)-HODE; m/z = 295.0 and 170.5−171.5 at 24 eV for 9-(*E*,*E*)-HODE; m/z = 295.0 and 182.6−183.6 at 22 eV for both 10-(*Z*,*E*)-HODE and 12-(*Z*,*E*)-HODE; and m/z = 299.0 and 197.6−198.6 at 15 eV for 13-HODE-d_4. Plasma total hydroxyoctadecadienoic acid (tHODE) levels were determined from the total amount of the products of the free-radical-mediated oxidation of the four isomers: 13-(*Z*,*E*)-HODE, 13-(*E*,*E*)-HODE, 9-(*Z*,*E*)-HODE, and 9-(*E*,*E*)-HODE.

Open Field Test. The open field test was performed according to a modified version of the test described previously.[24] The open field apparatus was constructed by a square box with a black wall (35 × 35 × 20 cm^3). The field was divided two areas: the central and peripheral zones. A central square (15 × 15 cm^2) was set in the middle of the open field, and another square was set in the peripheral area. A mouse was placed in one corner of the field and allowed to explore for 10 min. Locomotor activity (movement distance, line crossing, and movement rate) and anxiety-related parameters (freezing, entry into central area, and latency of entry into central area) were measured with the ANY-maze video tracking system (Brain Science Idea Co., Ltd., Osaka, Japan). The field was cleaned before the start of each session.

Statistics. The results were expressed as the means ± standard error. Outliers were omitted by the Smirnov-Grubbs' outlier test. Statistical analysis was performed by using analysis of variance (ANOVA) followed by Tukey's test for multiple comparisons with Ekuseru-Toukei 2012 (Social Survey Research Information Co., Ltd., Tokyo, Japan). Differences with a probability of 5% or less were considered significant.

RESULTS

Effect of OPIACE on Obesity-Related Parameters in the TSOD Mice. We investigated the effect of OPIACE (the nutrient composition indicated in Table 1) on obesity, which is a major risk factor for the development of type 2 diabetes, in TSOD mice. As shown in Figure 2A and B, body weight and food intake of TSOD mice (black circle) were significantly higher than those of control TSNO mice (white circle) throughout the experiments. However, there were no significant differences in body weight and food intake between

J. Agric. Food Chem. 2015, 63, 6715−6722

Table 1. Nutrient Composition of OPIACE[a]

nutrient composition	(%)
oleuropein	35
phenolic compounds	7
saccharides	54
ignition residue	2
moisture	2

[a]Phenolic compounds consist of 0.08% caffeic acid, 0.06% vanillic acid, 0.04% vanillin, 0.26% rutin, 1.89% luteolin-7-glucoside, 1.04% apigenin-7-glucoside, and 3.8% oleuroside.

TSOD and OPIACE-fed TSOD (gray triangle) mice (Figure 2A and B). Whereas plasma triglyceride level and epididymal WAT weight, which are related to obesity, were significantly higher in TSOD mice (black bar) than in TSNO mice (white bar), these parameters were not significantly different between TSOD mice and OPIACE-fed TSOD mice (gray bar) (Figure 2C and D). The results indicate that OPIACE has no effect on obesity in TSOD mice.

Effect of OPIACE on Blood Glucose Level in TSOD Mice. Next, we investigated the effect of OPIACE on the diabetic phenotypes in TSOD mice. As shown in Figure 3, nonfasting blood glucose levels in TSOD mice (black circle) gradually increased with age, and a significant increase was noted from 6 weeks of age compared with that of age-matched TSNO mice (white circle). Whereas nonfasting blood glucose levels in OPIACE-fed TSOD mice (gray triangle) were comparable to those in TSOD mice until 9 weeks of age,

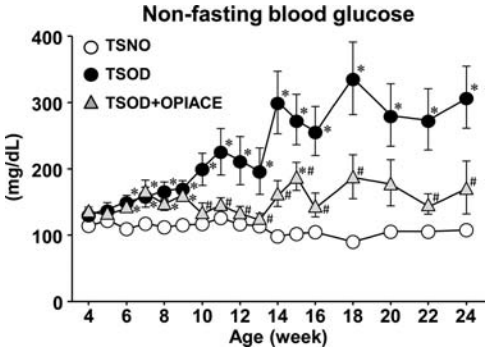

Figure 3. Effect of OPIACE on blood glucose level. Time course of changes in nonfasting blood glucose level in TSNO (white circle), TSOD (black circle), and 0.2% (w/w) OPIACE-fed TSOD (gray triangle) mice. Results are expressed as the means ± standard error (n = 11−12). Statistical analyses were carried out using ANOVA (Tukey's *posthoc* test). *Significant difference from age-matched TSNO mice (p < 0.05). #Significant difference from age-matched TSOD mice (p < 0.05).

glucose levels in the OPIACE-fed TSOD mice were significantly lower than those in the TSOD mice up to 24 weeks of age (Figure 3). The results indicate that OPIACE partially attenuates blood glucose elevation in TSOD mice over the long-term.

Effect of OPIACE on Glucose Tolerance in TSOD Mice. To evaluate the effect of OPIACE on glucose tolerance, we performed OGTT in TSOD mice at 5, 8, 11, 13, 15, and 24

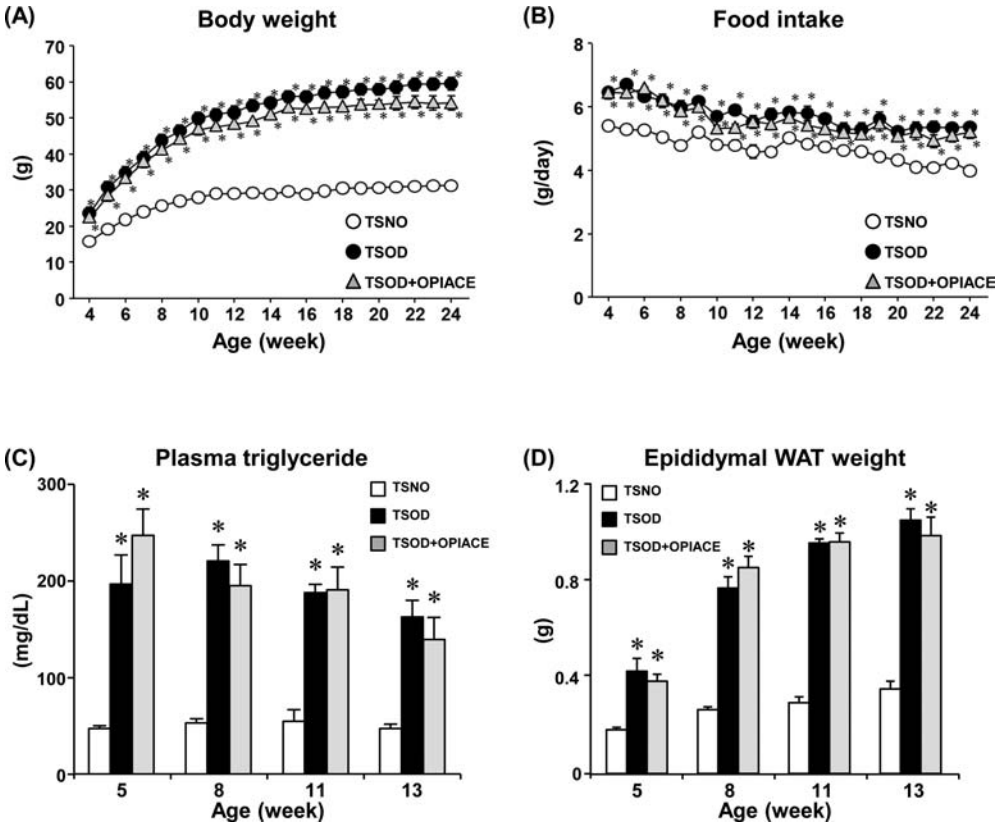

Figure 2. Effects of OPIACE on obesity-related parameters. Time course of changes in body weight (A), food intake (B), plasma triglyceride level (C), and epididymal WAT weight (D) in TSNO (white), TSOD (black), and 0.2% (w/w) OPIACE-fed TSOD (gray) mice. Results are expressed as the means ± standard error (n = 6−12). Statistical analyses were carried out using ANOVA (Tukey's *posthoc* test). *Significant difference from age-matched TSNO mice (p < 0.05).

DOI: 10.1021/acs.jafc.5b00556
J. Agric. Food Chem. 2015, 63, 6715−6722

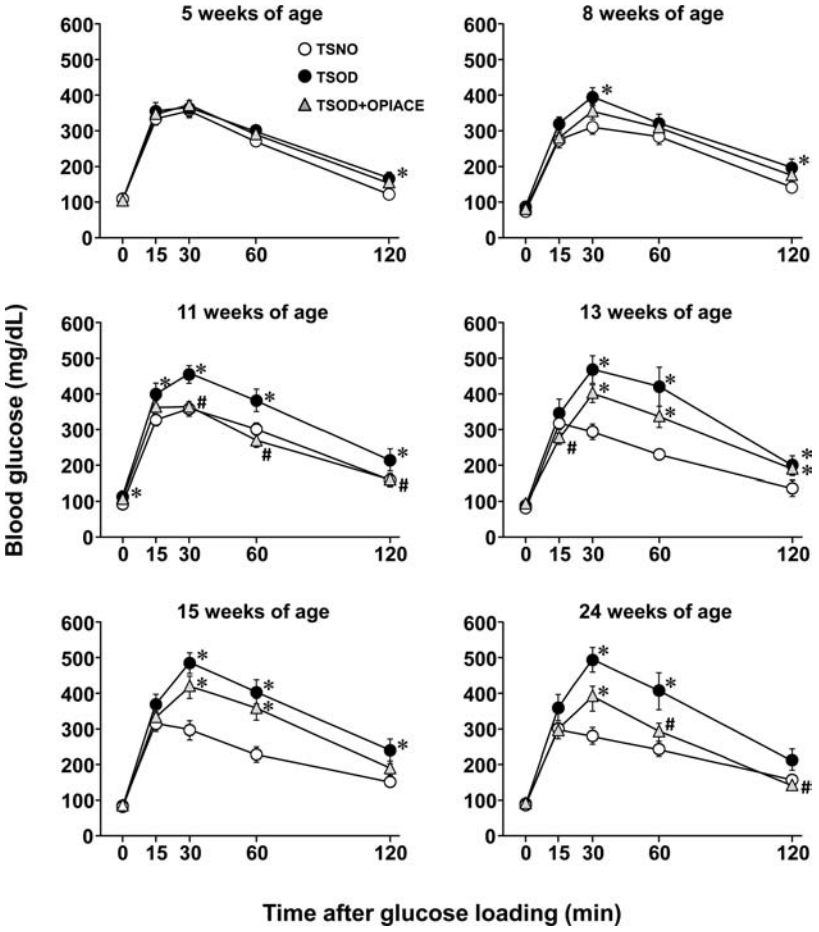

Figure 4. Effect of OPIACE on glucose tolerance. Time course of changes in glucose tolerance in TSNO (white circle), TSOD (black circle), and 0.2% (w/w) OPIACE-fed TSOD (gray triangle) mice at 5, 8, 11, 13, 15, and 24 weeks of age. Results are expressed as the means ± standard error (n = 11−12). Statistical analyses were carried out using ANOVA (Tukey's *posthoc* test). *Significant difference from age-matched TSNO mice (p < 0.05). #Significant difference from age-matched TSOD mice (p < 0.05).

weeks of age. At 5 weeks of age, there was no obvious abnormality in glucose tolerance of TSOD mice (black circle) compared with that of age-matched TSNO mice (white circle) (Figure 4). However, glucose levels after glucose loading in TSOD mice increased with age, and a significant increase was noted from 8 weeks of age compared with that of age-matched TSNO mice (Figure 4), indicating that glucose tolerance in TSOD mice was impaired from around 8 weeks of age, consistent with our previous report.[25] Glucose tolerance in TSOD mice was markedly impaired after 11 weeks of age. However, the impaired glucose tolerance in TSOD mice at 11 and 24 weeks of age was almost completely attenuated by OPIACE (gray triangle). Glucose levels after glucose loading in OPIACE-fed TSOD mice at 13 and 15 weeks of age tended to be lower than those of age-matched TSOD mice, although there were no significant differences between those glucose levels (Figure 4). Those findings indicate that the impaired glucose tolerance in TSOD mice is partially inhibited by OPIACE.

Effect of OPIACE on Oxidative Stress in TSOD Mice. It is known that oxidative stress induces insulin resistance that in turn leads to the progression of type 2 diabetes.[5] To investigate the effect of OPIACE on oxidative stress *in vivo*, we examined plasma levels of tHODE, which has been used as a biomarker for the evaluation of oxidative stress,[23] in TSNO and TSOD mice. tHODE were determined from the total amount of the four isomers: 13-(*Z*,*E*)-HODE, 13-(*E*,*E*)-HODE, 9-(*Z*,*E*)-HODE, and 9-(*E*,*E*)-HODE, which were measured with LC-MS/MS as reported previously[23](Figure 5A; also see Materials and Methods). As shown in Figure 5B, plasma tHODE levels in TSOD mice (black bar) were significantly higher than those in TSNO mice (white bar), consistent with our previous report,[4] and the levels were maintained during the measurements. Plasma tHODE levels in OPIACE-fed TSOD mice (gray bar) tended to decrease with feeding duration and significantly decreased at 13 weeks of age compared with those in TSOD mice. The results indicate that OPIACE mildly attenuates oxidative stress in TSOD mice by long-term feeding.

Effect of OPIACE on Locomotor Activity and Anxiety-Like Behavior in TSOD Mice. It has been reported that locomotor activity is reduced in type 2 diabetes model animals, including the db/db mouse,[24] Akita mouse,[26] and high-fat fed rat.[27] The behavioral abnormality is more clearly observed in older animals with diabetes than younger animals.[24,27] In addition, repeated hyperglycemia was found to reduce locomotor activity in an open field test,[28] which is used to assess general locomotor activity and as an initial screen for anxiety-related behavior in rodents.[29] To investigate the long-term effects of OPIACE on the behavioral traits of TSOD mice, we performed an open field test in TSOD mice at 36 weeks of age (Figure 6). We found that the differences in body weight and food intake between TSNO and TSOD mice remained

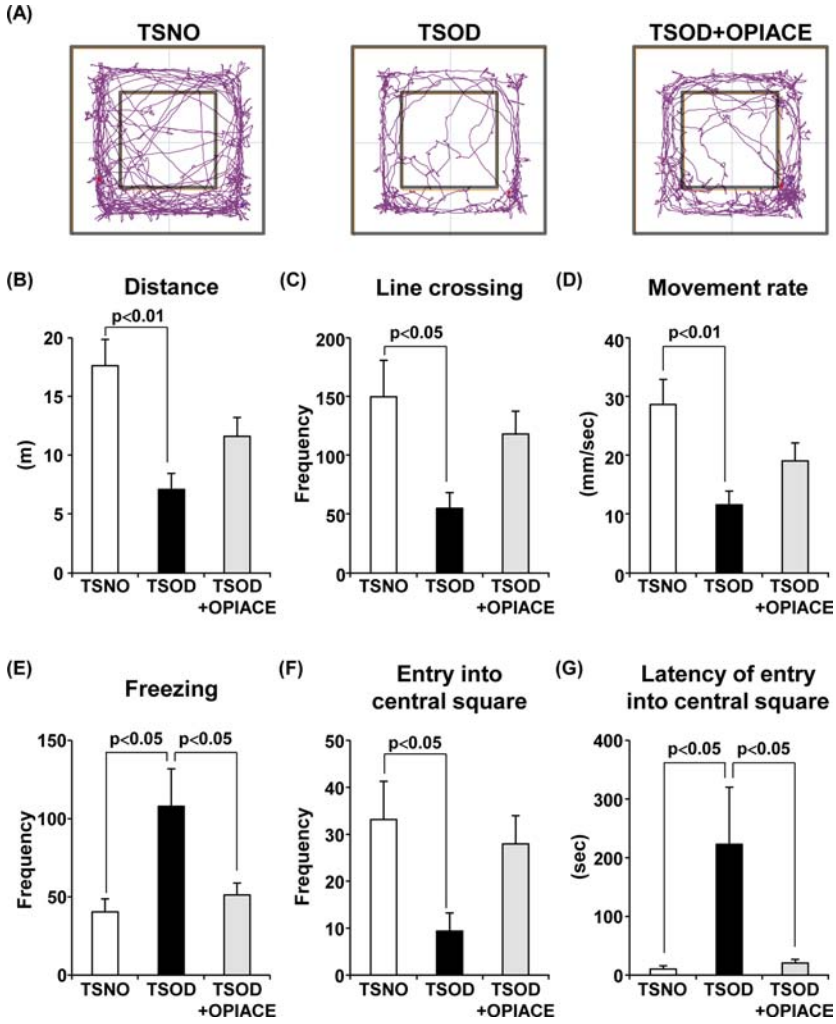

Figure 6. Effect of OPIACE on locomotor activity and anxiety-like behavior. (A) Representative trajectories of TSNO, TSOD, and 0.2% (w/w) OPIACE-fed TSOD mice in the open field test. Movement distance (B), line crossing (C), movement rate (D), freezing (E), entry into the central square (F), and latency of entry into the central square (G) were measured for 10 min. Results are expressed as the means ± standard error (n = 6 each). Statistical analyses were carried out using ANOVA (Tukey's *posthoc* test).

TSNO and TSOD mice were 2.53 ± 0.09 and 3.08 ± 0.71 arbitrary units, respectively) (Table 2), as observed in other diabetic model ob/ob mice of a similar age.[30] Movement distance (Figure 6B), line crossing (Figure 6C), and movement rate (Figure 6D) were significantly decreased in TSOD mice (black bar) compared with those in TSNO mice (white bar), indicating that TSOD mice have low locomotor activity.

Table 2. Body Weight, Food Intake, Nonfasting Blood Glucose Level, and OGTT AUC in TSNO, TSOD, and OPIACE-Fed TSOD Mice at 36 Weeks of Age[a]

	TSNO	TSOD	TSOD + OPIACE
body weight (g)	37.8 ± 0.88	64.6 ± 1.24[b]	65.2 ± 0.68[b]
food intake (g/day)	3.42 ± 0.13	4.64 ± 0.18[b]	5.19 ± 0.20[b]
nonfasting blood glucose (mg/dL)	120 ± 0.85	136 ± 9.45	152 ± 32.5
OGTT AUC (× 10^4, arbitrary unit)	2.53 ± 0.09	3.08 ± 0.71	2.69 ± 0.42

[a]Results are expressed as the means ± standard error (n = 6 each). Statistical analyses were carried out using ANOVA (Tukey's *posthoc* test). [b]Significant difference from age-matched TSNO mice ($p < 0.05$).

OPIACE-fed TSOD mice (gray bar) tended to attenuate the decreases in locomotor activity compared with that of TSOD mice (Figure 6B–D), although there were no significant differences in the results. TSOD mice showed increased freezing (Figure 6E), decreased frequency of entry into the central square (Figure 6F), and longer latency of entry into the central square (Figure 6G) compared with those of TSNO mice, indicating that TSOD mice have anxiety-like phenotypes. Interestingly, the anxiety-like phenotypes in free-fed TSOD mice were significantly attenuated by the feeding of OPIACE (Figure 6E and G). Thus, long-term feeding of OPIACE has a preventive effect on the anxiety-like symptoms in the type 2 diabetes model mouse.

DISCUSSION

Our results indicated that OPIACE attenuated chronic hyperglycemia (Figure 3) and impaired glucose tolerance (Figure 4) in TSOD mice. Those effects are likely to be due to oleuropein because it is the major component in OPIACE (Table 1). It has been demonstrated that an oleuropein-containing diet improved insulin sensitivity in middle-aged overweight men[31] and decreased homeostasis model assessment as an index of insulin resistance (HOMA-IR) in high-fat

DOI: 10.1021/acs.jafc.5b00556
J. Agric. Food Chem. 2015, 63, 6715–6722

diet fed mice.[32] In addition, plasma insulin levels were unchanged between TSOD mice and OPIACE-fed TSOD mice from 5 to 13 weeks of age (data not shown). These findings suggest that the improvement effects of OPIACE on blood glucose level are due to not the acceleration of insulin secretion but the improvement of insulin resistance.

As oleuropein has potent antioxidative activity *in vitro*,[17] we expected that the preventive effects of an oleuropein-rich diet on blood glucose elevation in TSOD mice would be partly due to the antioxidative capacity of oleuropein. However, OPIACE did not clearly reduce plasma tHODE levels in TSOD mice even at 11 weeks of age, which is the age when OPIACE exerted a preventive effect on the diabetic phenotypes (Figure 5B). Furthermore, OPIACE had no effect on obesity in TSOD mice (Figure 2). It was reported that potent antioxidants resveratrol[33] and epigallocatechin-3[34] suppressed high-fat diet induced obesity and hyperglycemia. In addition, in a previous DNA microarray analysis, oleuropein was found to have beneficial effects on nonalcoholic fatty liver disease by exerting multiple effects, including antilipogenesis, anti-inflammation, and anti-insulin resistance,[35] and the multiple effects of oleuropein are likely to contribute to the improvement of the diabetic phenotypes. Therefore, our results suggest that an oleuropein-rich diet exerts not only a mild antioxidant effect but also other effects for the attenuation of the increased glucose levels in TSOD mice.

A recent meta-analysis indicated that diabetes is associated with the increased possibility of having anxiety disorders.[36] In fact, our results indicated that TSOD mice exhibited anxiety-like behavior (Figure 6) consistent with other diabetic models, including the ob/ob mouse,[37] Akita mouse,[26] and high-fat fed mouse.[38] Some reports suggest that this central nervous system disorder is a kind of diabetic complication.[9] It is easily presumed that the comorbidity of diabetes and anxiety disorder may lead to a lower quality of life than the morbidity of those diseases separately.[39] In addition, it was recently suggested that the treatment of anxiety disorder may exacerbate the symptoms of diabetes, as selective serotonin reuptake inhibitors, which are used for the treatment of mood and anxiety disorders, promote insulin resistance and insulin secretion in Min6 cells.[40] Thus, as shown in Figure 6, our results suggested that OPIACE may be a valuable supplement for reducing diabetes-related anxiety, although the mechanism for attenuating the anxiety-like behavior in TSOD mice is unknown. Blood glucose levels in TSOD mice and OPIACE-fed TSOD mice at 36 weeks of age were not significantly increased compared with those in TSNO mice, probably because food intake in TSOD mice tended to decrease with age (Table 2). The improvement of blood glucose levels in TSOD mice over the long-term might contribute to the antianxiety effect of OPIACE.

In conclusion, we demonstrated that OPIACE attenuated chronic hyperglycemia and impaired glucose tolerance in TSOD mice over the long-term. Furthermore, OPIACE attenuated the anxiety-like behavior in aged TSOD mice. Our results suggest that an oleuropein-rich diet has the potential to inhibit the progression of type 2 diabetes and diabetes-related behavioral disorders.

DOI: 10.1021/acs.jafc.5b00556
J. Agric. Food Chem. 2015, 63, 6715−6722

The formation of these lysine derivatives ("lysine blockage") implicates a decrease of the nutritional value of proteins.[12,13] Moreover, the accessibility by intestinal peptidases is impaired; thus, the release also of other proteinogenic amino acids into absorbable units is hampered.[14,15] However, at levels of lysine modification that are relevant in food (8−15%), the digestibility of casein is not significantly lowered.[16,17] Individual Maillard reaction products (MRPs) can be released from glycated proteins as small peptides and free amino acids, similarly to the proteinogenic amino acids,[16,17] but they cannot be transported across the intestinal membrane via amino acid carriers. Bound in small peptides, some MRPs can be translocated into epithelial cells via the di- and tripeptide transporter PEPT1. After intracellular peptidolysis, glycated amino acids with polar or charged side chains (e.g., CML) are "trapped" inside the cells, whereas those with unpolar side chains (e.g., PYR and MAL) can pass the basolateral membrane.[18−20] It has been shown in several human studies that dietary FL can pass into the circulation only to a very small extent, whereas 50−100% of dietary PYR must be absorbed as it appears in the urine after oral administration.[7,21,22]

Unabsorbed amino acids and peptides, as well as intracellularly accumulated amino acids released during desquamation, will pass into the colon. A passage of approximately 13 g per day of protein (endogenous protein from intestinal peptidases and mucins, as well as recalcitrant dietary protein) has been estimated.[23] The distal colonic microbiota can degrade large peptides and proteins, and all proteinogenic amino acids can then be fermented by anaerobic bacteria.[24] The predominant products are ammonia, carbon dioxide, hydrogen, and short-chain fatty acids (SCFA; acetic, propionic, and butyric acids). Branched-chain amino acids are degraded to branched-chain fatty acids (e.g., isobutyrate, isovalerate, and 2-methylbutyrate), which can serve as urinary markers of colonic protein fermentation. Products such as phenol, cresol, indole, and substituted acetic and propionic acids mainly result from the fermentation of aromatic amino acids. Due to the toxicological properties of some of these products, protein fermentation in the colon is often regarded as detrimental.[24,23,25] Glycated proteins passing into the colon can have specific effects on the composition of the colonic microbiota: On incubation with glycated bovine serum albumin, the amount of clostridia, sulfate-reducing bacteria, and *Bacteroides* in the microbiota from humans suffering from ulcerative colitis, but not that from healthy subjects, increased, whereas the amount of eubacteria and bifidobacteria decreased.[26] An inhibitory effect on the growth of lactobacilli was also found in the colonic microbiota of adolescents consuming a diet rich in MRPs (bread with crust, grilled meat), compared to a diet low in MRPs (bread without crust, baked meat).[27] Protein glycated with different sugars (galactose, lactulose, and galacto-oligosaccharides), however, can induce a bifidogenic effect on the human microbiota in vitro.[28,29] The structural basis of these findings remains unclear. In particular, the stability of individual MRPs in the colon has been only poorly investigated.

FL is the only MRP that was found to be unstable in the presence of rat and human intestinal microbiota in vitro and in vivo.[7,21,30] Several enzymatic degradation mechanisms have been described.[31,32] It has also been postulated that CML is degraded by the human colonic microbiota, because the recovery of the substance in urine and feces after oral administration never reaches 100%, either in human or in rat studies.[33,34]

As the human colonic microbiota has the ability to metabolize all proteinogenic amino acids,[24] and because it is continuously exposed to substantial amounts of unabsorbed dietary MRPs, we hypothesized that the human colonic microbiota is able to degrade MRPs. Four individual MRPs were synthesized and incubated in the presence of fecal suspensions from eight human volunteers. The stability of the MRPs was measured by HPLC with UV or MS/MS detection.

MATERIALS AND METHODS

Chemicals. Nonafluoropentanoic acid (NFPA), resazurin sodium salt, and cysteine hydrochloride monohydrate were from Sigma (Steinheim, Germany). Acetic acid for HPLC was obtained from Merck (Darmstadt, Germany). HPLC grade methanol and acetonitrile were from VWR Prolabo (Darmstadt, Germany). [$^2H_2$]CML was obtained from PolyPeptide (Strasbourg, France). The synthesis of the following MRPs was performed according to the literature stated: FL,[35] [$^{13}C_6$,$^{15}N_2$]FL,[36] CML,[20] PYR,[18] and MAL.[19]

Brain−heart infusion (BHI) medium was used for anaerobic cultivation and prepared as follows: 18.5 g of brain−heart infusion broth (Merck) and 0.28 g of cysteine hydrochloride monohydrate were dissolved in distilled water, and 50 μL of an aqueous resazurin solution (1%, w/v) was added. The pH was adjusted to 7.6 with 5 M sodium hydroxide, and water was added to a final volume of 500 mL. The required volume of medium was filled into Hungate tubes. The filled Hungate tubes were subjected to three cycles of first vacuum and then N_2 overpressure application to remove oxygen. The media were autoclaved (121 °C, 15 min). The medium needed for the preparation of fecal suspensions was allowed to equilibrate overnight under oxygen-free conditions in an anaerobic workstation (MG 500, Don Whitley, Shipley, UK).

Incubation of MRPs in the Presence or Absence of Human Fecal Inocula. Feces samples were obtained from eight healthy volunteers (6 males, 2 females) aged between 25 and 55 years who consumed a Western diet (no vegetarians). The volunteers had not taken antibiotics in the previous 3 months. One experiment with a feces sample from one volunteer was performed per week.

The preparation of fecal suspensions was performed as described previously[37] in an anaerobic workstation under an atmosphere consisting of $N_2/CO_2/H_2$ (80:10:10, v/v/v). Feces samples were suspended in BHI medium to a concentration of 25% (w/v). The suspensions were shaken (10 min, 180 rpm) and then centrifuged (10 min, 300*g*). The supernatants were removed carefully and directly utilized for the incubations as the native fecal suspension. In addition, an aliquot (20 mL) of the suspension was autoclaved (121 °C, 20 min).

Aqueous solutions (5 mM) of the MRPs were prepared and sterile-filtered (0.2 μm). The stability of the MRPs in the presence of BHI medium was assessed by adding 0.5 mL of the 5 mM MRP solutions to 9.5 mL of autoclaved oxygen-free BHI medium in a Hungate tube (V = 16 mL). The stability of the MRPs in the presence of an autoclaved feces sample was assessed by adding 0.5 mL of the 5 mM MRP solutions and 1.0 mL of autoclaved fecal suspension to 8.5 mL of autoclaved, oxygen-free BHI medium. These controls were done in a single determination in parallel to each experiment. The stability of the MRPs in the presence of native feces samples was analyzed by adding 0.5 mL of the 5 mM MRP solutions and 1.0 mL of native fecal suspension to 8.5 mL of autoclaved oxygen-free BHI medium. The latter incubation was performed in triplicate for each feces sample. All MRPs were incubated separately. The stability of medium components was analyzed by mixing 1.0 mL of native fecal suspension and 9.0 mL of autoclaved oxygen-free BHI medium.

Samples were withdrawn directly after the addition of the fecal suspension (0 h) and then after 4, 24, 48, and 72 h. A portion of sterilized gas was injected, and 1.0 mL of the suspension was removed. All samples were then frozen and stored at −80 °C.

Preparation of Samples for Analysis. For the analysis of PYR and MAL, 50 μL of the samples was mixed with 950 μL of 0.1% acetic acid in 5% aqueous methanol. The mixture was shaken vigorously and

Table 1. Transitions Recorded during Measurement of FL and CML in the MRM Mode[a]

analyte	transition	fragmentor voltage (V)	collision energy (eV)	Q/q[b]
FL	m/z 309 → m/z 84	125	36	Q
	m/z 309 → m/z 225	125	13	q
[$^{13}C_6$,$^{15}N_2$]FL	m/z 317 → m/z 233	70	13	Q
	m/z 317 → m/z 129	70	15	q
CML	m/z 205 → m/z 130	100	9	Q
	m/z 205 → m/z 142	100	9	q
[$^{2}H_2$]CML	m/z 207 → m/z 130	80	5	Q
	m/z 207 → m/z 144	80	12	q

[a]General conditions: positive mode; dwell time, 120 ms. [b]Q, transition used for quantification; q, transition used to confirm the presence of the analyte.

centrifuged (10 min, 13000 rpm). The supernatant was transferred to an HPLC vial. For the analysis of FL and CML, 50 μL of the samples was mixed first with 50 μL of methanol and shaken vigorously. After 45 min, 900 μL of 0.1% acetic acid was added; the mixture was shaken and frozen. After the mixture had been thawed and centrifuged (10 min, 13000 rpm), 180 μL of the supernatant was mixed with 20 μL of the internal standard solution containing 0.121 mM [$^{2}H_2$]CML and 0.656 mM [$^{13}C_6$,$^{15}N_2$]FL in water.

Pellet extraction followed a protocol employed for the extraction of water-soluble metabolites from *Escherichia coli*.[38] An aliquot of 500 μL of the above samples was centrifuged (10 min, 13000 rpm) and the supernatant removed. A 300 μL aliquot of 5 mM NFPA in 80% aqueous acetonitrile was then added to the pellet. After vigorous shaking, the suspension was stored at −80 °C for 30 min. After the suspension had been thawed and centrifuged (2 min, 13000 rpm), the supernatant was transferred to another tube and the pellet was extracted two more times. The supernatants were combined, and 300 μL of water was added. From these solutions, 200 μL was mixed with 800 μL of a solution of 0.1% acetic acid in 5% aqueous methanol. The mixtures were centrifuged (10 min, 13000 rpm) and the supernatants transferred to HPLC vials.

High-Pressure Liquid Chromatography with UV Detection. HPLC-DAD analyses were performed on a LaChrom Elite system consisting of a pump L-2130, an autosampler L-2200, a column oven L-2300, and a diode array detector L-2450 (all from VWR Hitachi, Darmstadt, Germany). A stainless steel column (150 mm × 4.6 mm, 5 μm) filled with Eurospher 100 C-18 material with an integrated guard column (5 × 4 mm) of the same material (Knauer, Berlin, Germany) was used for the analysis of PYR.[18] For the analysis of MAL, a polymer-based RP-18-column (PLRP-S, 100 Å, 250 mm × 4.6 mm, 8 μm, Polymer Laboratories, Darmstadt, Germany) with a guard column of the same material (5 × 4 mm) was used.[19] Eluent A was a solution of 5 mM NFPA in water; eluent B was a solution of 5 mM NFPA in a mixture of 80% methanol and 20% water. During the analysis of PYR, a linear gradient from 13% B to 100% B in 20 min was applied at a flow rate of 0.8 mL/min, whereas during the analysis of MAL, a linear gradient was mixed from 20 to 80% B in 20 min at a flow rate of 1.0 mL/min. During all analyses, the temperature of the autosampler was maintained at 10 °C, and the temperature of the column oven was set at 35 °C. The injection volume was 50 μL. UV spectra were recorded between 200 and 350 nm, and the quantification was performed with the chromatograms extracted at 280 nm (MAL) and 297 nm (PYR), respectively. External calibration was performed with the isolated MRP standards.

High-Pressure Liquid Chromatography with Mass Spectrometric Detection. Chromatography was performed with the high-pressure gradient system 1200 series (Agilent Technologies, Böblingen, Germany), consisting of a binary pump, an online degasser, a column oven, and an autosampler. A stainless steel column (Zorbax 300 SB-C18, 50 mm × 2.1 mm, 3.5 μm, Agilent Technologies) was used for the analysis of FL and CML. The eluents used were a solution of 10 mM NFPA in bidistilled water (solvent A) and a solution of 10 mM NFPA in acetonitrile (solvent B). A linear gradient from 5 to 29% B in 8 min was applied at a flow rate of 0.25 mL/min. The column temperature was maintained at 35 °C. The injection volume was 10 μL. The chromatographic system was connected to the mass spectrometer 6410 triple-quad (Agilent Technologies), working in the positive mode with a capillary voltage of 4000 V and a source temperature of 350 °C. FL and CML were quantified by MS detection in the multiple reaction monitoring (MRM) mode using the stable isotope dilution technique. The transitions used for the quantification of the analytes (quantifier, Q) and for the confirmation of the presence of the analytes (qualifier, q) are compiled in Table 1. All transitions were recorded between 1 and 9 min after injection. Data acquisition and evaluation were performed with the software MassHunter B.02.00 (Agilent). The same HPLC system was also used during metabolite analysis. Selected samples were measured first in the scan mode (m/z 90−500) and then in the product ion scan mode. For the latter approach, protonated molecular ions ([M + H]$^+$) of possible metabolites (e.g., biogenic amines, oxidized/reduced species) were stabilized in the first quadrupole and fragmented in the second quadrupole (fragmentor voltage, 100 V; collision energy, 20 eV), and spectra (m/z 50−250) were recorded with the third quadrupole.

Statistical Treatment. Comparisons of mean MRP concentrations between inoculated and non-inoculated media were performed using Student's t test. P values ≤0.05 were considered significant using the software PASW Statistics 18.

RESULTS AND DISCUSSION

Incubation Conditions. Significant amounts of protein-bound glycated amino acids are taken up with the daily diet. Unabsorbed glycated amino acids or those positioned at recalcitrant sites of heat-damaged proteins and not released during gastrointestinal digestion can pass into the colon. Although the microbial metabolism of FL has been investigated in vitro and in vivo,[7,13,21,22,30] no knowledge has yet been gained about the stability of other MRPs in the presence of the colonic microbiota, especially the human microbiota. Smith and Macfarlane have performed such investigations with the proteinogenic amino acids.[24] These authors had worked with a minimal medium and a final feces concentration of 20%. In our study, we wanted to conserve the metabolic variability of the gut microbiota as much as possible, and therefore chose brain−heart infusion broth, which is recommended for fastidious microorganisms, as in earlier investigations.[37] Unfortunately, due to the abundance of other amino acids from peptones in the medium, the analysis of SCFA as typical products of microbial amino acid metabolism was not possible.

J. Agric. Food Chem. 2015, 63, 6723−6730

In vitro experiments on the digestion of protein-bound MRPs show that FL and PYR are released during luminal digestion bound in short-chain peptides (<1 kDa) or as the free amino acids, whereas CML remains in longer peptides (1−4 kDa).[16,17] Dipeptides incorporating MRPs can be cleaved by membrane-bound peptidases of intestinal cells. Thus, a major portion of unabsorbed MRPs should enter the colon as the free amino acids. Considering a passage of the whole daily amount of 500−1000 mg of ARPs into the colon and a mean daily feces mass of 124 g,[10,39] an incubation of 250 μM of the free amino acid FL in the presence of a 2.5% (w/v) fecal suspension was chosen. This concentration was also applied to the other MRPs.

Stability of MRPs in the Absence of a Viable Microbiota. The incubation conditions chosen in this study comprised an elevated incubation temperature of 37 °C, a particularly low redox potential, and high concentrations of amino acids and phosphate from the medium, as well as a slightly alkaline pH. Under such conditions, it cannot be excluded that FL is degraded nonenzymatically. The formation of MRPs such as FL and CML from medium components is possible as well.[40] Therefore, the non-inoculated medium was incubated at 37 °C for up to 72 h without MRPs added. Samples were taken regularly up to 72 h of incubation and analyzed by RP-HPLC-MS/MS. The medium itself contained measurable amounts of FL and CML (Figure 2), but the formation of additional FL or CML from medium components could be excluded. PYR and MAL were not detected in the autoclaved medium. The MRPs were then added to non-inoculated BHI medium at a concentration of 250 μM and incubated at 37 °C. The concentrations of FL and MAL decreased slightly during 72 h of incubation, whereas the concentrations of CML and PYR remained constant (Figure 3). To assess a possible influence of the feces matrix on the recovery of MRPs, the compounds were incubated in the presence of autoclaved fecal suspension without a viable microbiota. No loss of compounds that could have been traced back to adsorption to feces matrix components could be measured; there were no significant differences in the time courses of MRP concentrations after the addition to non-inoculated medium or medium with added autoclaved feces matrix, respectively.

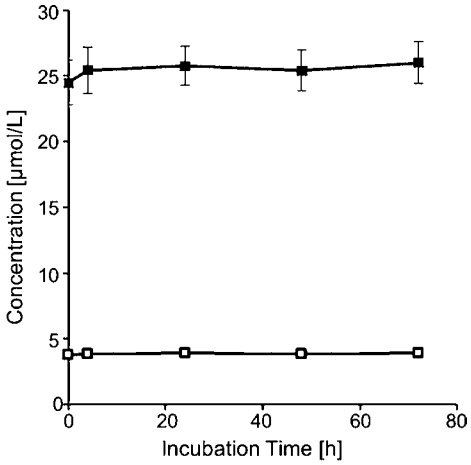

Figure 2. Development of the concentrations of FL (solid squares) and CML (open squares) in the non-inoculated BHI medium during anaerobic incubation at 37 °C for 72 h (no MRPs added). Data are given as means ± SD.

Stability of MRPs in the Presence of a Viable Microbiota. The four MRPs at a concentration of 250 μM were then added to 2.5% (w/v) fecal suspensions obtained from eight healthy volunteers. The analysis of FL by HPLC-MS/MS allowed quantification of at least 0.2 μM in the undiluted samples, equivalent to 0.08% of the initial FL concentration. Likewise, as low as 2.7 μM CML, corresponding to 1.1% of the initial amount, could be quantified in the undiluted samples. The recoveries of FL and CML, respectively, after addition to the non-inoculated medium, were 94.2 ± 5.1 and 92.1 ± 2.7%, respectively. For data evaluation, the MRP concentration measured in the non-inoculated medium was regarded as 100%, and all other values were expressed as percentages of this concentration.

As could be expected from the literature,[7,21,30] the concentration of FL declined very quickly in the presence of the viable microbiota (Figure 3A; Table S1). In some cases, >80% of the initial amount had already disappeared in the sample taken directly after the addition to the fecal suspension. The time between sampling inside the anaerobic chamber and deep-freezing (approximately 30−45 min) must have been sufficient for the degradation of the substance. This short time could probably point to metabolism of the substance by extracellular enzymes, as already proposed by Griffiths and Pridham.[41] After 4 h of incubation, FL was in each case not detectable anymore. The separation by centrifugation of the samples taken from the inocula and the independent analysis of supernatants and pellets after extraction did not lead to a higher recovery of FL; that is, at no time was FL detectable in the cell pellet extract. Our data therefore suggest that the low recovery of orally administered FL in urine and feces[21,22] can at least in part be explained by metabolism of the compound by the intestinal microbiota.

CML was also degraded in the presence of all fecal samples, but to a lesser extent than FL. After 4 and 24 h, average amounts of 84.6% (range of 45−98%) and 36.2% (range of 0−59%) remained, respectively (Figure 3B; Table S2). Only about 1% of the initial CML amount was detectable in the pellet extract for samples taken at different incubation times. The interindividual differences of CML degradation were very pronounced. After 24 h of incubation, CML was degraded to <15% of the initial concentration in the presence of the fecal microbiota of three of the eight volunteers, whereas for the other five, the remaining CML concentration ranged between 53 and 59%. The first group could thus be tentatively classified as "fast CML metabolizers" and the second as "slow CML metabolizers". On average, the relative standard deviation of the CML concentration between the triplicate stability measurements performed for each of the subjects was 3−5%. The differences that appeared between subjects can thus not be explained by insufficient precision. Further studies will have to show the microbiological background of these findings and whether this difference is of any (patho)physiological importance. Because the volunteers during the duration of this study consumed their usual diet, food matrix components might also be causative for the observed differences, and further studies should be performed with volunteers on controlled diets.

For both FL and CML samples, MS/SCAN experiments were performed for m/z 90−500. However, no significant changes in the extracted ion chromatograms became apparent when samples of viable microbiota incubated with or without the MRPs were compared. Owing to the free lysine content of

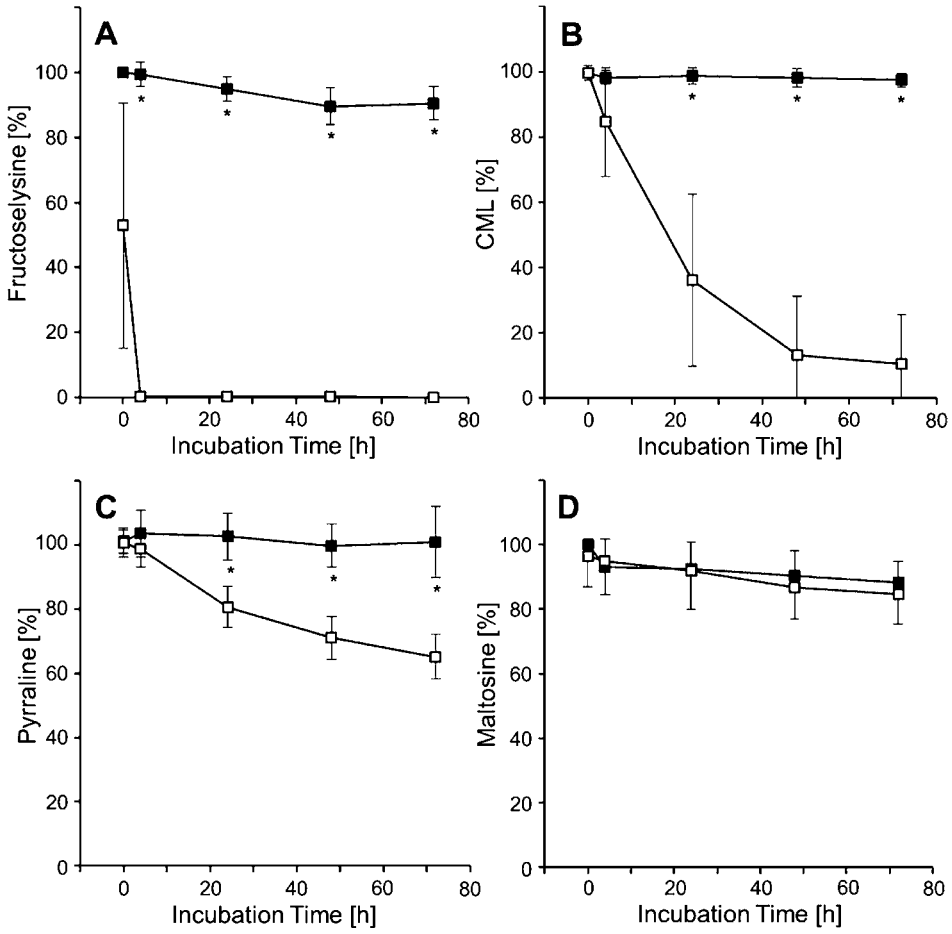

Figure 3. Time course of the concentrations of (A) fructoselysine, (B) carboxymethyllysine, (C) pyrraline, and (D) maltosine in fecal suspensions (2.5%, w/v) in BHI medium (open squares) and in non-inoculated BHI medium (solid squares) at an initial concentration of 250 μM MRP (eight human volunteers, eight separate trials). MRPs were quantified by HPLC with mass spectrometric detection (FL, CML) or UV detection (PYR, MAL) as described under Materials and Methods. Data are given as the percentage of the initial concentration of each MRP in the non-inoculated medium as means ± SD. Significant differences ($P < 0.05$) between means are indicated by asterisks (*).

the medium and the concomitant release from peptides and proteins, it was not possible to assess whether lysine might be a, possibly even an extracellular,[41] metabolite of FL. A qualitative analysis was performed for typical products of the amino acid metabolism, for example, the corresponding biogenic amines[42] or organic acids,[24] by selected ion monitoring and product ion scanning; however, no verification of the presence of these products was possible. We therefore conclude that FL and CML enter microbial amino acid degradation pathways and that the concentration of intermediates is too low to be detected by the mass spectrometric techniques applied.

PYR and MAL were quantified by RP-HPLC with UV detection. As for FL and CML, this technique still allowed quantification of the analytes at concentrations corresponding to 1% of the initial amount. PYR was degraded by the fecal microbiota of all individuals (Figure 3C; Table S3), but again to a lesser extent than CML. Tryptophan could be detected besides PYR with our method (Figure 4). The degradation of tryptophan, which is known from the literature,[24] was corroborated qualitatively in our experiments. A small portion of PYR (3.5% of the initial amount) was detected in the pellet extract in samples taken after 24 h, but this small portion cannot fully explain the decrease of PYR in the course of fermentation. HPLC-DAD allowed generation of extracted wavelength chromatograms between 200 and 400 nm; however,

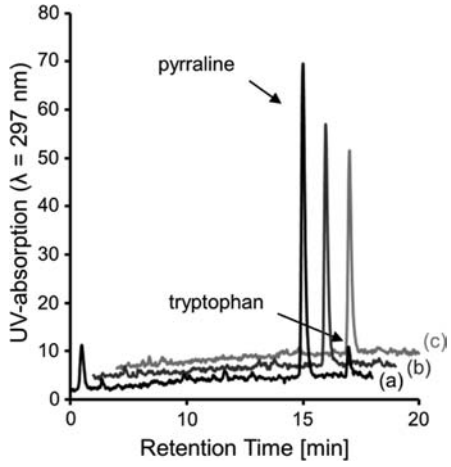

Figure 4. RP-HPLC with UV detection of fecal suspensions (2.5%, w/v) in BHI medium supplemented with 250 μM pyrraline measured after 0 h (a), 24 h (b), and 72 h (c) of incubation.

neither with this approach nor with the MS experiments performed as for FL and CML samples was it possible to detect potential metabolites. It is most probable that the metabolism of PYR starts with a modification of the pyrrole ring, possibly a

J. Agric. Food Chem. 2015, 63, 6723−6730

reduction, leading to a decline in the UV absorbability rendering the metabolite(s) undetectable by UV detection.

The concentration of MAL slightly declined in the presence of the viable microbiota; however, this was not significantly different from the decline in the non-inoculated medium (Figure 3D; Table S4). We thus conclude that MAL is not degraded by the intestinal microbiota.

In conclusion, we have shown that the human fecal microbiota is able to degrade the MRPs FL, CML, and PYR, but not MAL, when cultivated anaerobically in a nutrient-rich medium. Our data, especially those showing strong differences in the extent of degradation of individual substances, provide an experimental basis for some new questions concerning the metabolism of MRPs. First, is the higher degradability of products appearing earlier in the Maillard reaction cascade due to the lower chemical stability compared to the advanced products (secondary amines vs chemically more stable *N*-substituted heterocycles)? The investigation of further Amadori products (*N*-ε-tagatosyllysine, *N*-ε-lactulosyllysine, *N*-ε-maltulosyllysine) should reveal whether the intestinal microbiota is generally able to metabolize such products or whether this is specific only for FL. Moreover, because PYR and MAL can be transported across the small-intestinal membrane whereas FL and CML cannot,[20] a further question to be answered is whether the higher degradability of FL and CML is due to their higher concentrations in the ileal chyme and, thus, whether the human gut microbiota has accommodated to using glycated amino acids as a source of energy, nitrogen, or carbon. With regard to the passage of protein into the colon of 13 g per day,[23] an intake of ca. 500−1000 mg of ARPs represents an important part of the colonic nitrogen supply. Studies on the metabolism of FL in *E. coli* consistently show an induction period needed to induce the necessary enzyme systems.[41,43] In the present study, a similar induction period was not observed, possibly because the enzyme systems are permanently induced in the microbiota of human subjects due to permanent exposure to ARPs such as FL. Recent experiments with tagatosylated proteins reveal the possibility of generating bifidogenic substances from non-bifidogenic precursors.[28] Further studies have to show whether such a bifidogenic effect might also result from dietary ARPs such as FL. Whether degrading FL is a general capability of microorganisms or whether there are "specialists" that even might have had an evolutionary benefit remains to be elucidated. Experiments using *E. coli* indicate a pronounced strain specificity of FL degradation, because some authors report degradation of the compound,[32,41] whereas others do not.[40]

Interestingly, the influence on the amino acid supply to the colonic microbiota by intestinal transport phenomena is not restricted to glycated amino acids. Diets high in protein can generally give rise to increasing amino acid fermentation in the colon and the production of the respective metabolites, some of which are discussed as being toxicologically relevant.[44,45] Moreover, metabolic diseases based on impaired intestinal transporter activity, such as Hartnup disease, lead to significant increases in the concentrations of tryptophan metabolites in the blood.[46] Some of these products, for example, phenylacetic and indoleacetic acids, are classified as uremic toxins for patients suffering from uremia.[47] Links between MRPs and their negative effects in disease states such as uremia[10] and ulcerative colitis[26] can likely be explained by adverse actions not necessarily of glycated amino acids themselves but of their microbial metabolites. Therefore, it would be of high interest to determine whether MRPs can enter into microbial amino acid metabolism. Further studies concerning the identity of microbial metabolites of individual MRPs and the identification of the metabolizing species are urgently needed.

populations, including those derived from the human monocyte cell line THP-1,[17−19] and, furthermore, without need of further oxidation.[20]

The FA composition of CMR influences their uptake and lipid accumulation in macrophages.[12,21] De Pascale et al.[12] studied the effects of CMR-like particles (CRLP) enriched in saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), n-6 polyunsaturated fatty acids (PUFA), and n-3 PUFA, obtained by incorporating TAG from palm, olive, corn, and fish oils, respectively, on THP-1 macrophage foam cell formation. They reported that CRLP enriched in SFA or MUFAs were taken up more rapidly than those enriched in n-6 or n-3 PUFA and that SFA-rich particles showed the greatest lipid accumulation.

Accordingly, the FA composition of CMR may be determinant for the accumulation of cholesterol and TAG in the macrophages, affecting their metabolism and modulating their atherogenicity.[19,22] However, the effect of different FA profiles of monovarietal oils on foam cell formation from macrophages has not been addressed so far. Therefore, in the present study we investigated the effect of the fatty acid composition of EVOO from five olive cultivars on foam cell formation by THP-1 macrophages.

MATERIALS AND METHODS

Chemicals. Cholesterol and cholesteryl esters (CE) were supplied by Larodan Inc. (Malmö, Sweden). Phospholipids (PL) (phosphatidylcholine, lysophosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine, and sphingomyelin), Trypan Blue, albumin (BSA), and Oil Red O were obtained from Sigma-Aldrich (St. Louis, MO, USA). Human serum was supplied by VWR International Eurolab, S.L (Spain). The THP-1 monocyte−macrophage cell line was provided by the European Collection of Cell Cultures (ECACC, UK). RPMI 1640 medium with L-glutamine (L-alanyl-glutamine) and fetal bovine serum (FBS) were purchased from Biowest SAS (France). Penicillin−streptomycin (5000 U/mL) was obtained from Gibco (Paisley, UK). Phorbol 12-myristate 13-acetate (PMA) and phosphate-buffered saline (PBS) were supplied by Fisher Scientific (USA). All other chemicals were of analytical reagent grade.

Plant Material and Virgin Olive Oil Extraction. 'Picual', 'Buidiego', 'Blanqueta', 'Galega', and 'Chetoui' (*Olea europaea* L.) olive cultivars were selected according to differences in their FA composition. The trees were spaced 7 × 7 m and grown in the experimental orchard of Centro IFAPA "Venta Del Llano", Mengibar, Jaen, Spain, using standard growing techniques. The study was carried out during the 2013/2014 crop year. Olives were harvested separately from two olive trees per cultivar.

EVOO extraction was performed using an Abencor laboratory oil mill (Comercial Abengoa, S.A., Seville, Spain) equipped with a hammer mill, a thermobeater, and a paste centrifuge; it simulates at laboratory scale the industrial process of EVOO production. The extraction was carried out for each cultivar and tree separately. The milling of olive fruits was performed using a stainless steel hammer mill operating at 3000 rpm provided with a 5 mm sieve. The olive paste malaxation was carried out at 28 °C with kneading at 50 rpm for 45 min. Centrifugation of the kneaded olive paste was performed in a basket centrifuge at 3500 rpm for 1 min. After centrifugation, the obtained oil was decanted, filtered, and stored in glass bottles at −20 °C in the dark without headspace and under N_2 until analysis.

Fatty Acid Composition of Virgin Olive Oil. Fatty acid methyl esters (FAME) were prepared as described by EU Regulation 2568/91.[23] The chromatographic separation was carried out on a Perkin-Elmer Autosystem gas chromatograph (Perkin-Elmer, Spain) equipped with an autosampler, split/splitless injector, flame ionization detector (FID), and fused silica capillary BPX70 column of 50 m length × 0.25 mm i.d. and 0.25 μm of film thickness (SGE Scientific Pty. Ltd., Australia). Helium was used as carrier gas, and the oven temperature was maintained at 198 °C throughout the analysis. The injector and detector temperatures were 235 and 245 °C, respectively. The results were expressed as relative area percent of the total.

Preparation of Chylomicron Remnant-like Particles (CRLP). TAG were isolated from 'Chetoui', 'Buidiego', 'Galega', 'Blanqueta', and 'Picual' EVOO by solid-phase extraction (SPE) using diol cartridges (Supercleane LC-Diol; Supelco, Bellefonte, PA, USA) and hexane/methylene choride (9:1, v/v) as eluent. The eluate containing TAG was evaporated to dryness under a stream of nitrogen and redissolved in hexane. CRLP were prepared using a lipid mixture containing 70% TAG from EVOO, 2% cholesterol, 3% cholesteryl esters (CE)/ and 25% PL as described previously.[24] The composition of the initial PL moieties was phosphatidylcholine, 70.50%; lysophosphatidylcholine, 6.88%; phosphatidylethanolamine, 11.00%; phosphatidylinositol, 2.58%; phosphatidylserine, 2.58%; and sphingomyelin, 6.54%.

Lipids were sonicated by immersing a clean ultrasonic probe (Bandelin Electronics, Berlin, Germany) directly into the lipid mixture in 0.9% NaCl in tricine buffer (20 mM, pH 7.4) and supplying the probe with 50 W for 20 min (5 min bursts with 5 min rest periods to allow for cooling) at 56 °C. The resulting emulsion was brought to a density of 1.21 g/mL with KBr, layered under a stepwise density gradient (2.5 mL, d = 1.065 g/mL; 2.5 mL, d = 1.020 g/mL; 3 mL, d = 1.006 g/mL) as described previously,[24] and centrifuged at 17000g for 20 min at 20 °C (Beckman Optima L-90K centrifuge; Beckman Coulter, Palo Alto, CA, USA) in a SW41Ti swing-out rotor. The upper layer, which was an uneven emulsion of lipids, was discarded. The removed layer was replaced with an equal volume of NaCl solution (d = 1.006 g/mL), and tubes were centrifuged at 70000g for 1 h (20 °C) in a SW41Ti swing-out rotor. The upper layer was then collected and stored at 4 °C until use (maximum of 2 days).

Apolipoprotein E Transfer to CRLP. The apolipoprotein transfer was achieved by incubation of the lipid emulsion with a fraction of human serum (1:2, vol/vol), prepared by ultracentrifugation and dialyzed before use[24] (5 h, 4 °C). After incubation, the particles were ultracentrifuged (154000g, 16 h, 12 °C) under a NaCl solution (d = 1.006 g/mL). The upper layer was collected and recentrifuged (254000g, 5 h, 12 °C) under a NaCl solution (d = 1.006 g/mL) to isolate the CRLP fraction. CRLP were dialyzed before use (2 h, 4 °C) and stored a 4 °C. All preparations were used within 1 week.

Culture of THP-1 Macrophages. THP-1 monocytes were maintained in suspension at a density of (3−8) × 10^5 cells/mL in RPMI 1640 culture medium containing 10% fetal bovine serum (previously inactivated at 56 °C, 30 min), 2 mM L-alanyl-glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin at 37 °C in 95% air/5% CO_2.

The cells at a 1 × 10^6/mL concentration were induced to differentiate into macrophages by incubation with phorbol myristate acetate (PMA) (200 ng/mL) for 72 h at 37 °C in 95% air/5% CO_2. After this time, the cells adhering to the culture dishes were washed with RPMI 1640 culture medium without FBS (3 × 2 mL) to remove any undifferentiated cells and traces of PMA. The viability of the THP-1 monocytes, as assessed by Trypan Blue exclusion, was >90% in all experiments. The adherent cell was 70−80%, and cell viability was unaffected with incubation with CRLPs.

Lipid Accumulation Studies. Cells adhering to the culture dishes were added to 2 mL of RPMI 1640 culture medium without fetal bovine serum and were incubated with CRLP (0.15 μmol TAG/mL medium) for 24 h at 37 °C in 95% air/5% CO_2. For Oil Red O staining, cells were washed with PBS 1× (3 × 2 mL) and 60% propan-2-ol, and then 1 mL of Oil Red O (0.15% w/v) in 40% propan-2-ol/H_2O v/v was added. After 10 min, the stain was removed and cells were washed with 3 mL of PBS 1× as many times as necessary to remove traces of the solution. Then, 2 mL of glycerol (30%) was added, and images were captured using a microscope-mounted Canon digital camera.

For intracellular lipid analysis, cells were washed with PBS (3 × 3 mL), harvested in 0.7 μL of PBS, and kept on a bed of ice. Cells were then disrupted by sonication for 5 s (× 2, 50 W), and a sample was taken for protein determination (preserved at −70 °C); the rest were

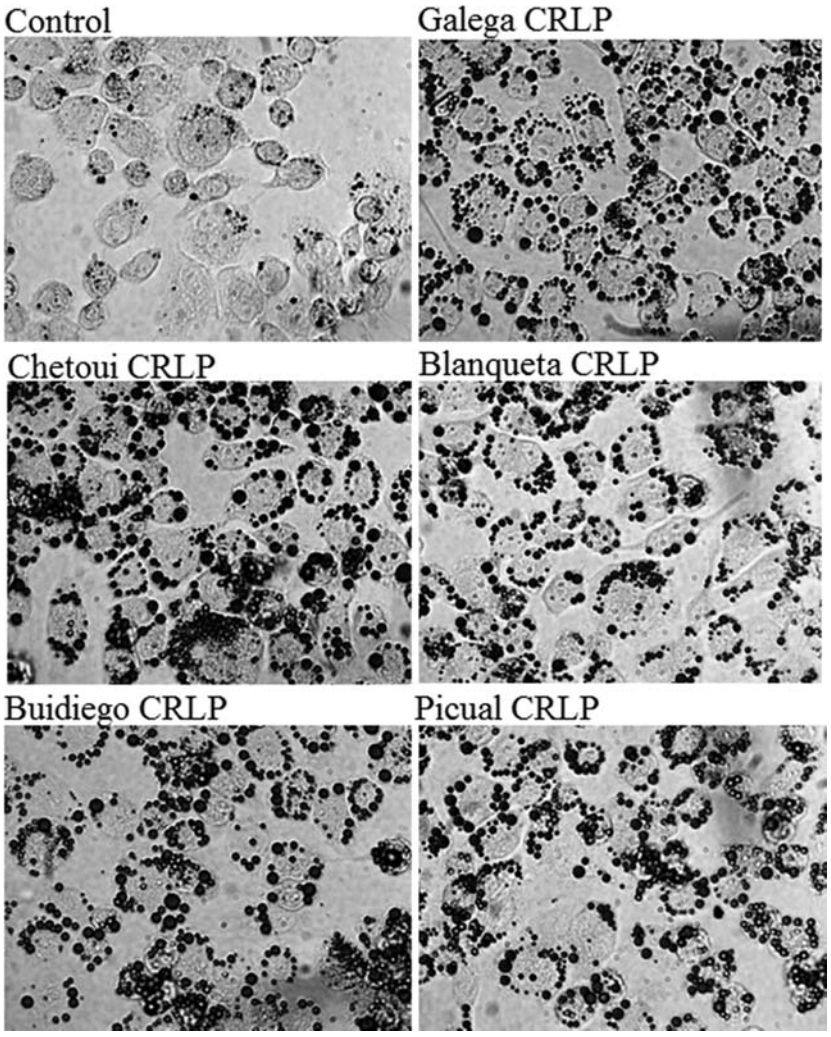

Figure 1. Lipid accumulation in cell THP-1 macrophagues incubated with CRLP containing TAG from 'Chetoui', 'Buidiego', 'Galega', 'Blanqueta', and 'Picual' EVOO cultivars. THP-1 macrophages were incubated with CRLP (final concentration = 0.15 μmol TAG/mL) for 24 h and stained with Oil Red O.

kept at −20 °C for subsequent total TAG determination and FA composition.

Triacylglycerol and Fatty Acid Composition. Total TAG in CRLP and cells were determined by enzymatic analysis using a commercial enzymatic reagent colorimetric/fluorometric kit (BioVision Inc., Milpitas, CA, USA). For the determination of CRLP FA composition, TAG were isolated by SPE diol columns as described above and were transmethylated using sodium metoxide in methanol (0.5%). For the analysis of FA composition in the cells, intracellular TAG were directly transmethylated using a methylation mixture (MeOH/toluene/DMP/H_2SO_4) and heptane. The resulting FAME of CRLP and cells were analyzed by GC, using a model 5890 series II GC (Hewlett-Packard Co, Avondale, AZ, USA) equipped with a flame ionization detector and a capillary silica column Supelcowax 10 (Supelco Co., Bellefonte, PA, USA) of 60 m length and 025 mm internal diameter. FAME were identified by comparison of their retention times against those of standards and quantified by external standard using peak area integration; results were expressed as relative area percentage. CRLP and cell protein content were measured according to the method of Bradford using BSA as standard.

Statistical Analysis. Results are expressed as means ± SD, unless otherwise stated. Statistical analyses were conducted using the GraphPad Prism v.5 statistical package (GraphPad Software, Inc.). Statistical significance was assessed by one- or two-way ANOVA, followed by Bonferroni's multiple-comparison tests. Correlations between variables were assessed using Pearson's correlation coefficients. Differences were considered statistically significant at $p < 0.05$.

RESULTS

CRLP TAG Content and FA Composition. The TAG contents were similar in all five types of CRLP (μmol/mL, n = 3): 'Chetoui' CRLP, 2.38 ± 0.4; 'Buidiego' CRLP, 1.99 ± 0.62; 'Galega' CRLP, 2.76 ± 0.17; 'Blanqueta' CRLP, 1.93 ± 0.10; 'Picual' CRLP, 1.83 ± 0.53.

Overall, the FA profiles CRLP-TAG and EVOO of all cultivars studied were similar (Table 1). However, significant differences were observed among cultivars, which resulted in differences in CRLP-TAG. Oleic acid content was the main FA in all CRLP, accounting for 60−76% of all FA, with significant differences among cultivars. Likewise, linoleic acid ranged from 4 to 18%. 'Picual' CRLP showed the highest oleic acid content (76.6%) and the lowest linoleic acid content (4.1%), whereas 'Chetoui' CRLP had the lowest oleic acid content (60.9%) and the greatest linoleic acid content (18.9%). As a consequence, the MUFA concentration was highest in 'Picual' CRLP and PUFA concentration in 'Chetoui' CRLP. SFA content was higher in 'Blanqueta' CRLP.

Intracellular Lipid Accumulation in THP-1 Macrophages. THP-1 macrophages were treated with 'Chetoui', 'Buidiego', 'Galega', 'Blanqueta', and 'Picual' CRLP (0.15 μmol TAG/mL) for 24 h. Incubation of macrophages with all CRLP resulted in increased intracellular accumulation of lipids as assessed by Oil Red O staining (Figure 1). Images revealed a light staining in control cells and a strong red staining in cells incubated with CRLP, confirming the intracellular lipid incorporation.

Intracellular TAG concentrations differed according to the type of CRLP used. There was a significantly higher accumulation of TAG in cells incubated with 'Chetoui' and 'Blanqueta' CRLP than with 'Buidiego' and 'Picual' CRLP (Figure 2).

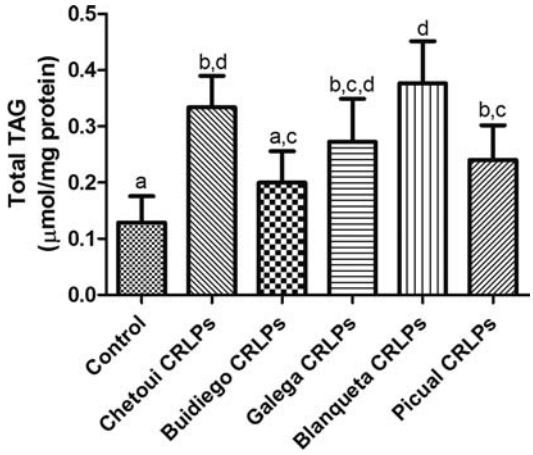

Figure 2. Total TAG accumulated after 24 h in THP-1 macrophages incubated with 'Chetoui', 'Buidiego', 'Galega', 'Blanqueta', and 'Picual' CRLP. Data are the mean from three separate experiments, and error bars show the SD. Different letters indicate significant difference ($p < 0.05$) by one-way ANOVA analysis and Bonferroni's post hoc test.

The TAG fraction of THP-1 macrophages showed significant differences for the main FA, namely, palmitic, palmitoleic, stearic, oleic, linoleic, and arachidonic (20:4 n-6) acids and, therefore, for the SFA, MUFA, and PUFA contents (Table 2). Control cells presented a higher SFA proportion compared with cells incubated with CRLP. Among cells incubated with CRLP, SFA accumulation was enhanced in cells incubated with 'Galega' CRLP (29%), whereas MUFA concentration was higher in those incubated with 'Picual' (62%) and 'Buidiego' (61%) CRLP and lower with 'Chetoui' CRLP (51%). Finally, PUFA content was increased in cells treated with 'Chetoui' CRLP (22%) and decreased with 'Picual' CRLP (11%). As well as in CRLP, palmitic, stearic, oleic, and linoleic acids were found with the highest proportions in the intracellular TAG fraction. It was observed that oils with the greatest oleic and linoleic acid contents led to cells engorged with TAG rich in those FA. Oleic acid was found at higher concentration in cells incubated with 'Picual' CRLP (59%) and at lowest concentrations in those treated with 'Chetoui' (48%) and 'Galega' CRLP (50%). Conversely, linoleic acid was found at greater amounts in cells incubated with 'Chetoui' CRLP (13%) and at lower concentration in cells incubated with 'Picual' CRLP (4%).

The oleic acid to linoleic acid ratio (18:1/18:2 ratio) of the EVOO was plotted against TAG accumulation in cells to determine the relationship between oleic and linoleic acid content in the parent oils and lipid intracellular accumulation (Figure 3A) and the FA composition in intracellular TAG (Figure 3B). A higher 18:1/18:2 ratio was associated with lower TG accumulation in the cells and very strongly with the intracellular 18:1/18:2 ratio.

DISCUSSION

Dietary fats enter the blood as CM that undergo lipolysis in extrahepatic capillary beds. The resulting CMR particles contain about 30% of TAG and most of the cholesterol mass of the parent lipoproteins and are considered atherogenic lipoproteins. CMR are taken by several types of macrophages[13] and give rise to foam cells by inducing accumulation of cholesterol, TAG, or both.[12,13,17,25−27]

A number of epidemiologic studies developed in different countries constitute a firm and reliable experimental base supporting the beneficial effects of the Mediterranean diet, rich in olive oil, with regard to the reduction of cardiovascular disease.[28,29] Although the benefits of EVOO against cardiovascular disease cannot be attributed solely to oleic acid,[30] the protective effects have been ascribed to higher intakes of oleic and α-linolenic acid (18:3 n-3) acids and lower intakes of SFA and linoleic acid (18:2 n-6).[31−34]

The FA composition of EVOO depends on the zone of production, the latitude, the climate, the variety, and the stage of maturity of the fruit.[4−6] For instance, Greek, Italian, and Spanish EVOO are, in general terms, low in linoleic and palmitic acids, and they have a high percentage of oleic acid. In contrast, Tunisian EVOO are high in linoleic and palmitic acids and lower in oleic acid.[4] Given these differences, we evaluated the uptake of CRLP prepared with TAG obtained from five EVOO cultivars and the induction of lipid accumulation in macrophages derived from the human monocyte cell line THP-1. Because it is difficult to obtain CMR uncontaminated with lipoproteins of a similar density, such as CM and very-low-density lipoproteins, from human blood, we used CRLP as an experimental model.[24] CRLP have been used previously by a number authors to study lipid metabolism[12,26,35−38] as their composition can be easily manipulated, providing a suitable and convenient model.

We obtained EVOO from 'Chetoui', 'Buidiego', 'Galega', 'Blanqueta', and 'Picual' cultivars, which presented differences in their FA composition, and we used their TAG to prepare CRLP that did not differ in their TAG content and having FA composition similar to that of the parent oils (Table 1). These findings are consistent with previous works using palm, olive, corn, or fish oils.[37,38]

The exposure of human THP-1 cells to EVOO-CRLP caused intracellular lipid accumulation and thus provided evidence of CRLP uptake by macrophages and foam cell formation. It has been reported that not all CMR are equally taken up by macrophages, and the particle size and lipid composition may have a significant influence on the process of uptake and lipid accumulation.[39] Batt et al.[17] studied the effect of LDL and CRLP on lipid accumulation in human monocyte-derived macrophages (HMDMs) and in THP-1 cells. They found that CRLP, without prior oxidation, caused lipid accumulation in human macrophages to an extent comparable to that caused by oxidized LDL. They also reported a greater proportion lipid accumulation in response to CRLP in the form of TAG and in the form of CE in response to oxidized LDL.

Our experiments showed that 'Blanqueta' and 'Chetoui' CRLP caused the greatest TAG accumulation in THP-1 cells.

[a]Data are expressed as area percent and are the mean ± SD from three separate preparations (n = 3). Different letters within a row are different (p < 0.05) by two-way ANOVA analysis.

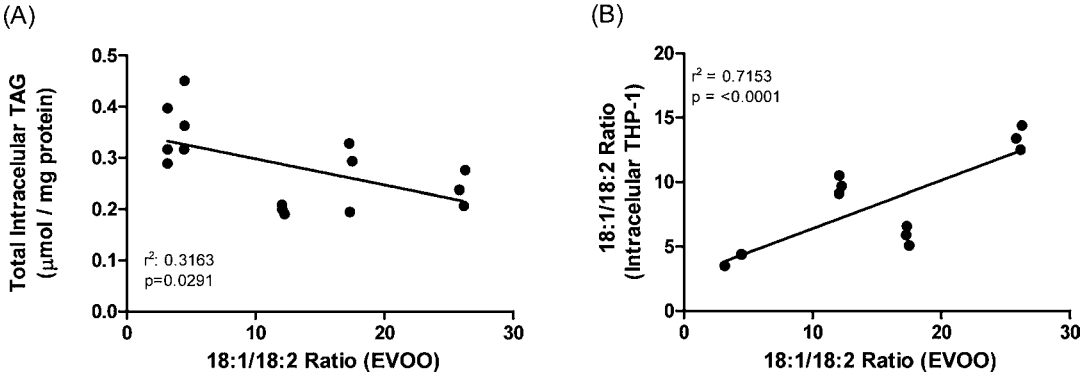

Figure 3. Correlation of oleic acid to linoleic acid ratio (18:1/18:2) of EVOO with (A) TAG accumulated in THP-1 macrophages and (B) oleic acid to linoleic acid ratio (18:1/18:2) in intracellular THP-1 macrophages after incubation with 'Chetoui', 'Buidiego', 'Galega', 'Blanqueta', and 'Picual' CRLPs.

'Blanqueta' CRLP were characterized by higher SFA content and 'Chetoui' CRLP by higher linoleic acid and PUFA content. This result is comparable with previous works by De Pascale et al.[12] and Song et al.,[27] who added SFA, MUFA, and n-6 or n-3 PUFA to THP-1 macrophages in the form of CRLP or nonesterified FA, respectively. Both confirmed that SFA are taken up more rapidly and result in greater lipid accumulation in cells, although they observed that PUFA-rich particles caused the lowest lipid accumulation. In contrast, our results showed the CRLP with greater PUFA content caused more lipid accumulation in cells than MUFA rich-CRLP. In this sense Song et al.[27] described differences between incubation with oleic or linoleic acids only for cholesterol and not for TAG. Likewise, De Pascale et al.[12] employed CRLP, reporting significant differences in intracellular TAG accumulation only between palm-CRLP and corn-CRLP, although differences between corn-CRLP and olive-CRLP were not observed. Interestingly, in that study the 18:1/18:2 ratio in CRLP (7.65) was similar to that obtained when we prepared CRLP from the 'Buidiego' cultivar (9.63), which caused the lowest TAG accumulation in the cells.

When the FA composition of intracellular TAG was compared with that of CRLP, we observed that it was highly preserved; that is, cells treated with CRLP with the highest concentrations of 18:1, 18:2, or 16:0 also exhibited the highest levels of these FA intracellularly. In fact, the 18:1/18:2 ratio in the oils correlated positively and very strongly with the same ratio in cell TAG. Also, we found that the 18:1/18:2 ratio also

DOI: 10.1021/acs.jafc.5b01626
J. Agric. Food Chem. 2015, 63, 6731−6738

correlated with TAG concentration in the cells, although a negative relationship was obtained. Napolitano and Bravo[40] studied the influence of the TAG source (trilinolein or triolein) in CRLP in human macrophages. Their results were in close agreement with ours, finding that particles enriched with both trilinolein and triolein induced a pattern of increase in intracellular TAG synthesis, but which was higher after incubation with trilinolein. However, an important point to consider is that although all of the CRLP employed here were rich in oleic acid, they differed in every other minor FA. Slight differences in the FA can lead to a highly different TAG molecular species composition, which may have important effects in the metabolic fate of lipoproteins, as observed in elderly individuals.[41]

Although the mechanisms by which TRL are taken up by macrophages have not been studied extensively, CMR are believed to be incorporated into macrophages by two main pathways: uptake of whole particles via membrane receptors and hydrolysis by macrophage-secreted LPL.[40] Extracellular lipolysis seems particularly important for internalization of dietary fatty acids.[40] It has been suggested that the V_{max} of LPL in the adipose tissue decreases with increasing chain length and unsaturation degree of monoacid CM-TAG due to decreased fluidity of the particle.[42] However, differences between oleic acid- and linoleic acid-rich seem to be significant only for large CM and not for VLDL.[43] On the other hand, studies carried out in THP-1 cells have proposed that oleic acid-rich dietary fats may prevent excessive lipid accumulation in monocyte/macrophage cells by down-regulating the gene expression of apolipoprotein B48 receptor[44] and that linoleic acid stimulates CD36 receptor, promoting intracellular TAG accumulation.[45]

In conclusion, the results of this study demonstrated that the effect of differences in the FA composition of EVOO is similar to the effect caused by the same FA when forming part of other dietary oils. In fact, linoleic acid-rich EVOO induced higher TAG incorporation into THP-1 macrophages compared to oleic acid-rich EVOO, the 18:1/18:2 ratio being consistently correlated with intracellular TAG accumulation. In this regard, the ratio between 18:1 and 18:2 could be used as a helpful marker to identify EVOO with possible cardioprotective effects. Because EVOO oleic and linoleic acid composition is cultivar dependent, among other agronomical factors, this marker could be independent of these factors.

Although the results presented here may be a starting point to indicate the possibility of selecting VOO cultivars for specific nutritional uses according to their FA composition, it is certainly too early to give recommendations to the population. Apart from the fatty acid composition, there are many other factors to consider that may have direct or indirect influence on health.

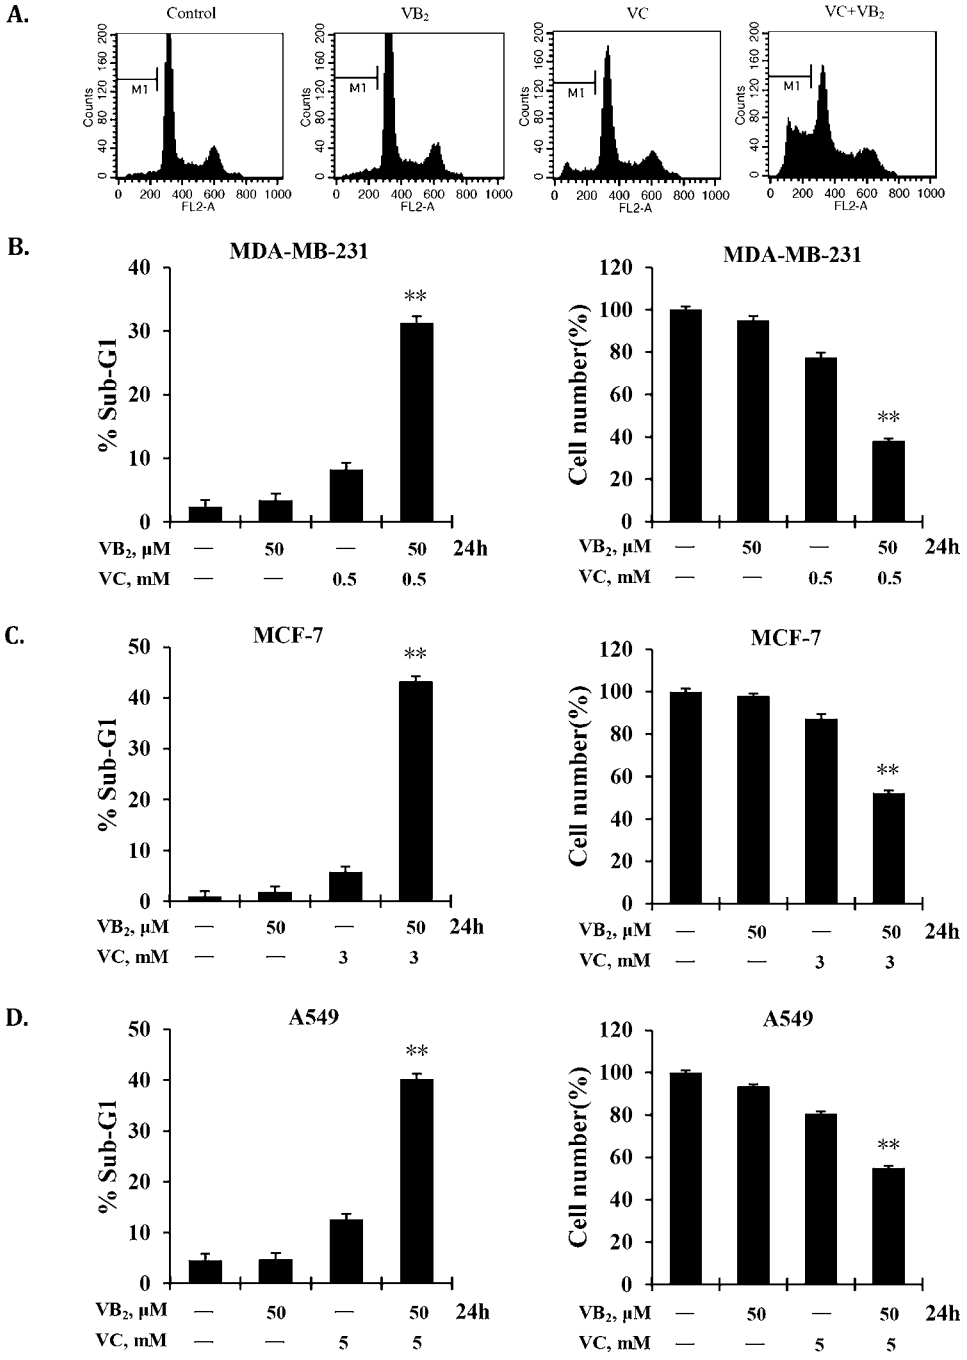

Figure 1. Combining vitamin C with vitamin B_2 resulted in enhanced cytotoxicity in MDA-MB-231 and MCF-7 breast cancer cells and A549 lung cancer cells. The cells were exposed to vitamins C and/or B_2 for 24 h, and apoptosis induction and overall inhibitory effects were measured by sub-G1 analysis and crystal violet staining, respectively: (A and B) MDA-MB-231 cells, (C) MCF-7 cells, and (D) A549 cells (**, $p < 0.01$).

agent alone or the combination on cell proliferation and survival. Briefly, the cells were exposed to vitamins C and/or B_2 for the indicated time, and then 1% glutaraldehyde was used to fix the cells for 15 min. After fixation, 0.02% crystal violet dye was added to stain the cells for 30 min. After staining, 70% ethanol was used to solubilize crystal violet dye bound to the cells. An enzyme-linked immunosorbent assay (ELISA) reader (Thermo, MA) was used to measure the absorbance at a wavelength of 570 nm, with the reference wavelength at 405 nm.

Determination of the Combination Index (*CI*). The nature of the combinatory effects of vitamins C and B_2 was quantitatively evaluated by the Chou−Talalay method.[17,18] The cells were exposed to varying doses of vitamins C and/or B_2. The overall suppressive actions were used to calculate the *CI* using the following formula:

$$CI = \frac{CA, x}{ICx, A} + \frac{CB, x}{ICx, B}$$

where *CA,x* and *CB,x* are the doses of each compound alone used in combination to produce *x*% inhibitory action and *ICx,A* and *ICx,B* are the doses for each compound alone to produce the same action. $CI < 1$ indicates a synergistic effect by the combination, whereas $CI = 1$ means an additive effect. If *CI* is greater than 1, it suggests antagonism produced by the combination.

Immunoblotting Assay. The cell was lysed with radioimmunoprecipitation assay (RIPA) buffer. An equal amount of proteins of the samples was loaded onto the gel. After electrophoretic separation, the proteins were transferred to a nitrocellulose membrane. The membrane was subsequently incubated with primary antibodies,

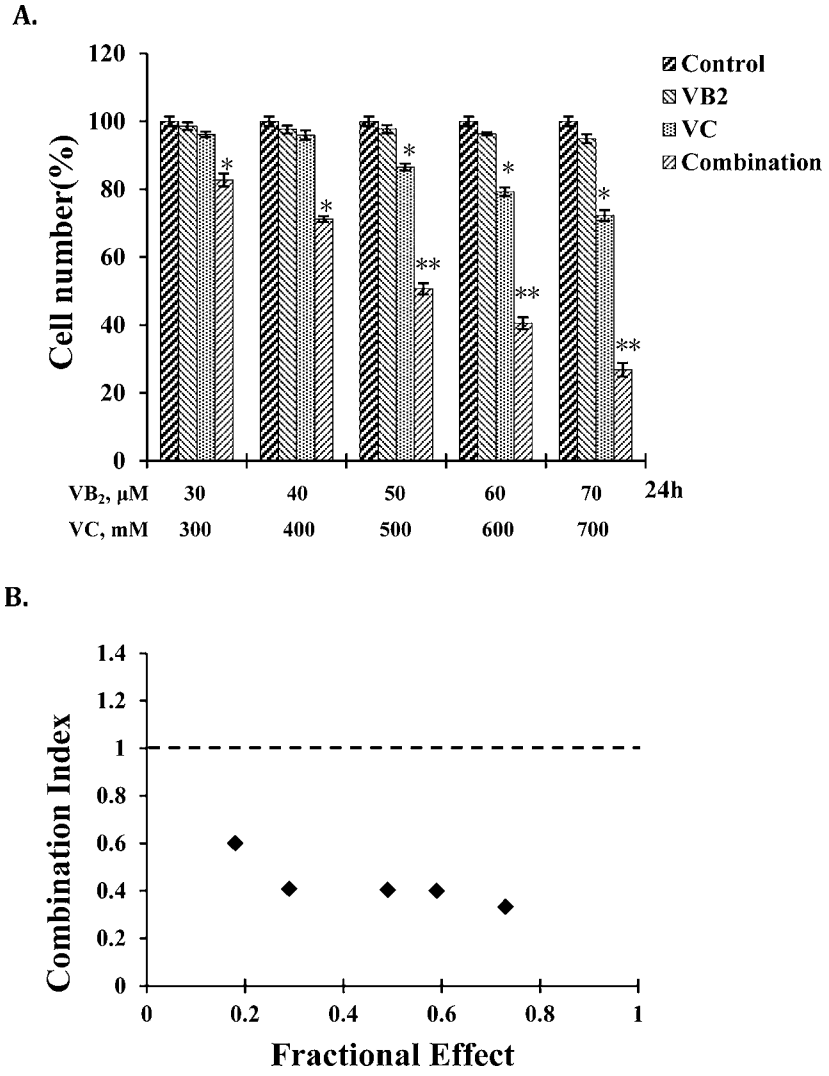

Figure 2. Enhanced inhibitory effect of vitamins C/B_2 combination is a synergistic action. (A) MDA-MB-231 cells were treated with each agent alone and combinations in a fixed ratio of 1:10 (vitamins B_2/C) for 24 h, and overall inhibitory effects of each agent alone or combinations on cell number were determined by crystal violet staining. (B) *CI* charts for the vitamins C/B_2 combination were plotted on the basis of data generated in panel A (∗, $p < 0.01$).

followed by recognition with corresponsive secondary antibody. The immunoreactive bands were detected using enhanced chemiluminescence.

Detection of AIF Translocation. The cells were exposed to vitamins C and/or B_2 for 12 h. After the treatment, the cells were fixed with 4% paraformaldehyde for 15 min, followed by permeabilization with Triton X-100 (0.25%) for 10 min. After blocking with 1% bovine serum albumin (BSA), the cells were probed with the antibody of AIF for 2 h, followed by incubation with fluorescein isothiocyanate (FITC)-conjugated secondary antibody for 1 h. DAPI was employed to counterstain the nuclei. The fluorescence was detected using confocal microscopy.

Preparation of Nuclear Extraction. A nuclear extraction kit (Thermo Scientific, catalog number P78835) was used to isolate nuclear fractions following the instructions of the manufacturer. Briefly, cells were exposed to vitamins C and/or B_2 for the indicated time, harvested with trypsin−ethylenediaminetetraacetic acid (EDTA), and centrifuged at 4 °C and 500*g*. Cells were washed by suspending the cell pellet with PBS and centrifuged to obtain the cell pellet. Three lysis buffers (CER I, CER II, and NER) were used sequentially following the protocol to isolate cytoplasmic and nuclear fractions.

Measurement of Mitochondrial Membrane Potential. The cells were exposed to vitamins C and/or B_2 the indicated time. After treatment, the cells were stained with 5,5′,6,6′-tetrachloro-1,1′,3,3′-tetraethylbenzimidazolocarbocyanine iodide (JC-1 dye) for 20 min. The fluorescence conversion from red to green was measured by flow cytometry.

RNA Interference. Bim siRNA and non-targeting siRNA were synthesized by Ambion (Austin, TX). To knockdown Bim, 50 nm of Bim siRNA was transfected into the cells using siPORT NeoFX. At 24 h post-transfection, the cells were used for subsequent experiments.

Statistical Analysis. The data shown represent the mean ± standard deviation (SD) for triplicates. A one-way analysis of variation (ANOVA) was used determine differences among multiple groups. The difference between two groups was assessed by the Student's *t* test using SPSS 18.0 for Microsoft Windows.

RESULTS

Combination of Vitamin C and B_2 Achieved a Significant Increase of Cell Death Induction in MDA-MB-231 and MCF-7 Breast Cancer Cells and A549 Lung Cancer Cells. To evaluate the combined actions of vitamins C and B_2 on cell death, MDA-MB-231 cells were treated with a mild toxic dose (around 10% cell death) of each single agent (on the basis of dose-finding experiments and literature[15,19,20]) or the combination for the indicated time. Cell death was

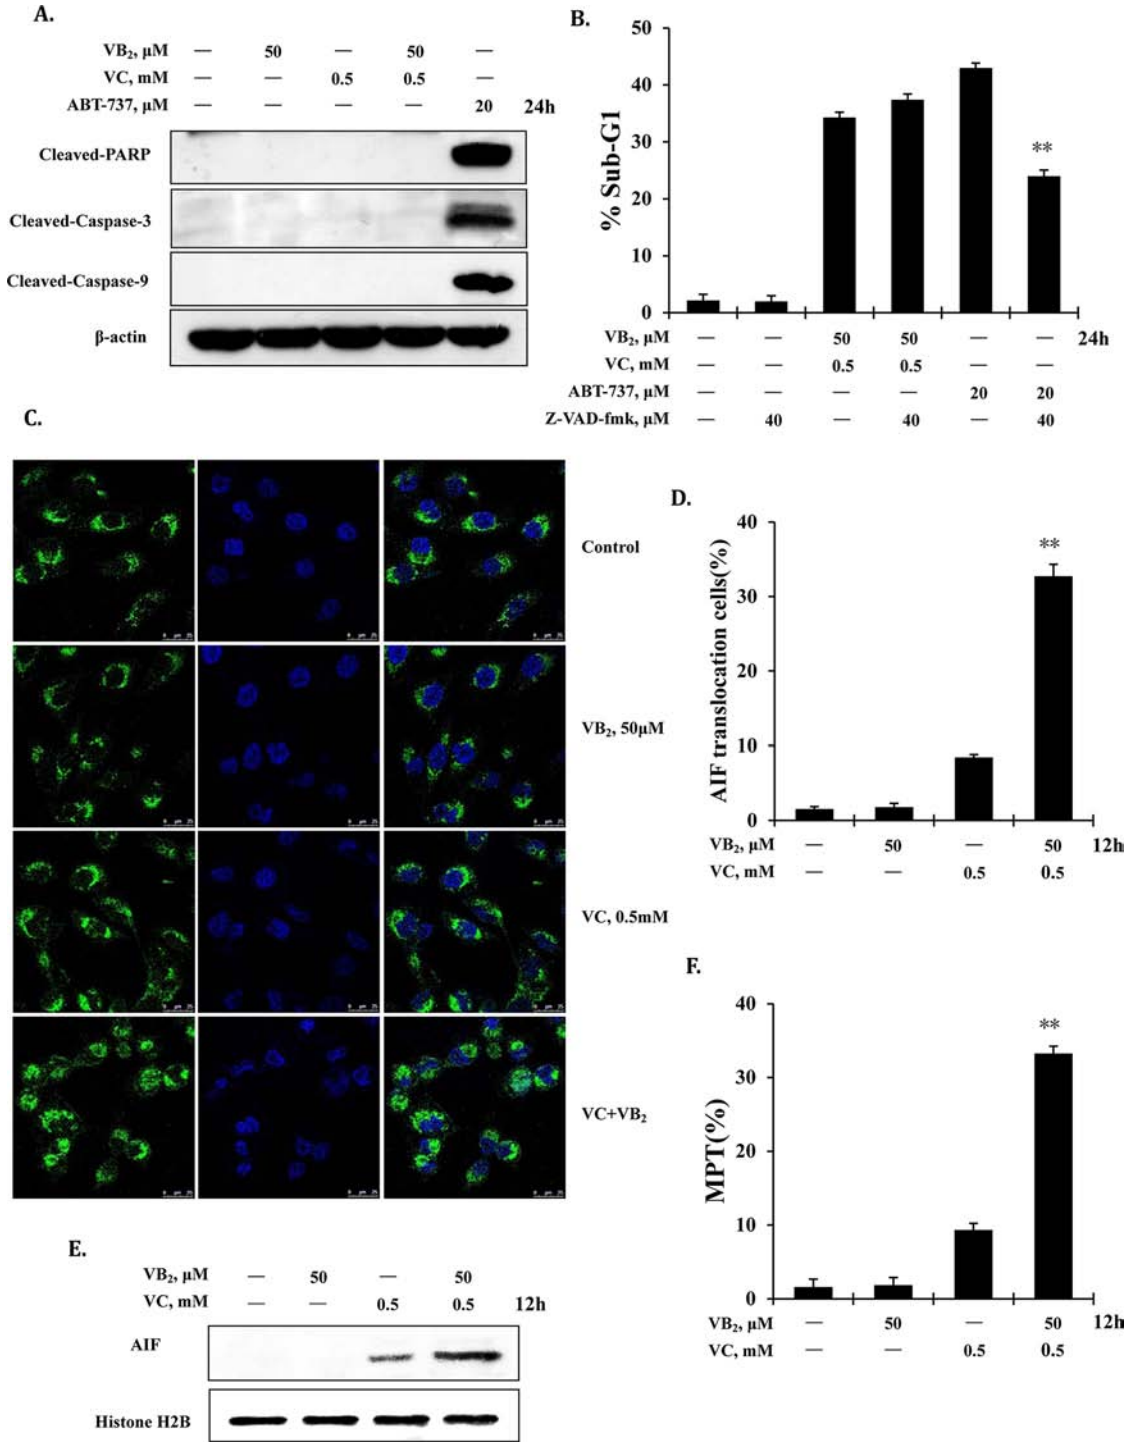

Figure 3. Caspase-independent apoptosis was involved in the combination-induced cytotoxicity in MDA-MB-231 cells. (A) Effects of the combination on caspase activation. The cells were exposed to vitamins C and/or B_2 for 24 h, and cleavages of caspases and PARP were analyzed by western blotting. (B) Effects of a pan-caspase inhibitor on the combination-induced cell death. Cell death was estimated by sub-G1 analysis after 24 h of treatment with vitamins C/B_2 and/or caspase inhibitor. (C) Caspase-independent apoptosis by the combination was associated with an enhanced AIF nuclear translocation. The cells were treated with vitamins C and/or B_2 for 12 h, and localization of AIF was detected using immunofluorescence staining. (D) Quantitative analysis of AIF nuclear translocation. (E) Nuclear content of AIF was detected by western blotting. (F) Vitamins C/B_2 combination induced an enhanced MPT measured by flow cytometry, following JC-1 staining.

assessed using sub-G1 analysis. As shown in panel A and the left panel in panel B of Figure 1, 50 μM vitamin B_2 alone caused 3.44% cell death, whereas 8.27% cell death was induced by 0.5 mM vitamin C alone. In contrast, the combination resulted in significantlly increased cytotoxicity (31.33%; $p < 0.01$). To further validate these enhanced actions, we next measured the overall suppressive action induced by vitamin C, vitamin B_2, or their combination using crystal violet staining, and results are presented in the right panel of Figure 1B. Each agent alone caused a marginally or slightly suppressive effect, but the combination resulted in a much stronger inhibitory action, further supporting the enhanced effects achieved by combining

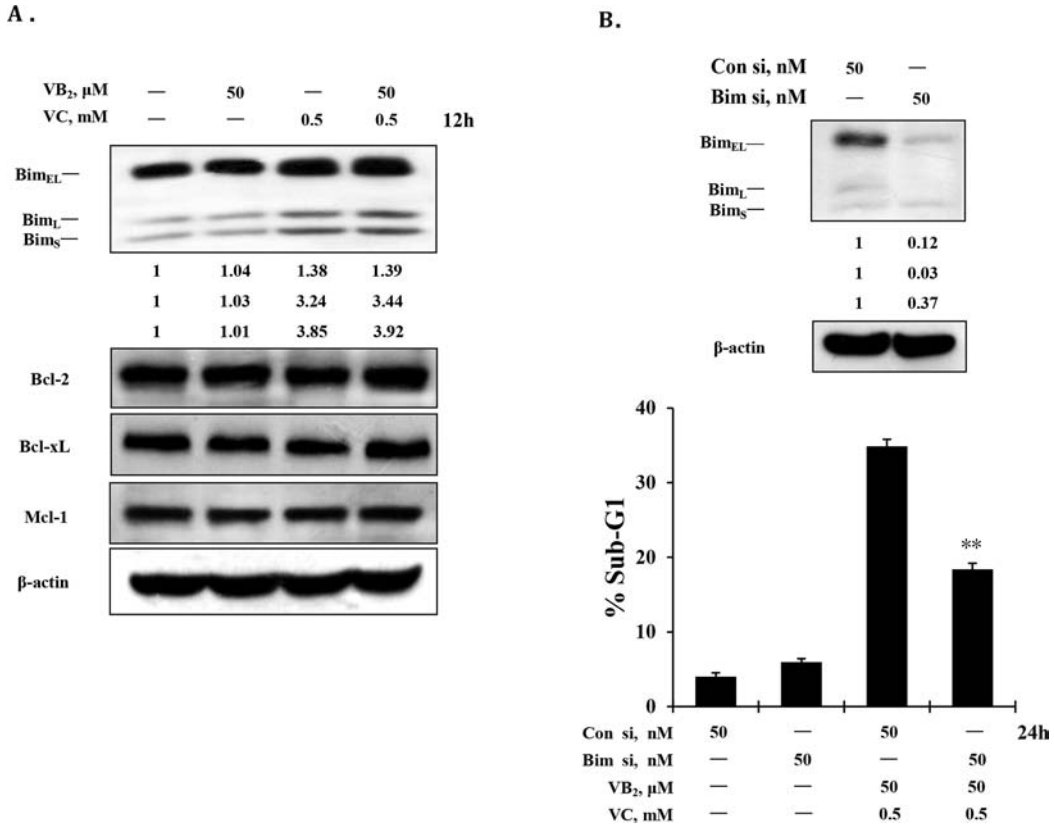

Figure 4. Activation of Bim was required for the combination-induced apoptosis in MDA-MB-231 cells. (A) Effects of vitamins C and/or B_2 on expression of Bcl-2 family proteins. The cells were treated with each agent alone or the combination for 12 h, and expression of Bim, Bcl-2, Bcl-x1, and Mcl-1 was analyzed by western blotting. Relative protein levels were quantitated and indicated below each band. (B) Effects of Bim knockdown on the combination-induced apoptosis. Knockdown efficiency was validated by western blotting, and apoptosis was assessed by sub-G1 analysis.

vitamin C with vitamin B_2. To determine whether the enhanced effect is specific for MDA-MB-231 cells, vitamins C/B_2-induced cell death and overall inhibitory effects in two additional cell lines were investigated by sub-G1 analysis and crystal violet staining, respectively. The data are shown in panels C and D of Figure 1. Similar increased cell death and overall inhibitory effects of the combination were also observed in MCF-7 breast cancer cells (Figure 1C) and A549 lung cancer cells (Figure 1D).

Enhanced Inhibitory Effect of Vitamins C/B_2 Combination Is a Synergistic Action. To evaluate critically whether the enhancement effect by vitamins C/B_2 combination is a synergism, we assessed the combinatory actions of varying combinations in a fixed ratio of 10:1 (vitamins C/B_2) by crystal violet staining. As shown in Figure 2A, vitamin B_2 (30−70 μM) or vitamin C (300−700 μM) induced a dose-dependent suppressive effect, whereas the combinations resulted in significantly further increased suppressive actions. These data were used to calculate the *CI* based on the Chou−Talalay method.[17,18] As shown in Figure 2B, *CI* values were less than 1 at all combinations tested, supporting a synergism achieved by combining vitamin B_2 with vitamin C.

Enhanced Effect by Vitamins B_2/C Combination Was Not Associated with Caspase Activation. To investigate if increased caspase activation contributed to the cell death induction by the combination, we analyzed active forms of caspase-9 and caspase-3 and substrate of caspase PARP cleavage by western blotting, and the results are shown in Figure 3A. Cleavages of caspase-9, caspase-3, and PARP (positive control ABT-737 induced significantly increased cleavages of these three proteins) were not detected with all of the treatments, suggesting that caspase activation might not play a role in this enhanced action. To further confirm this notion, we examined the influence of caspase inhibition on cell death examined using sub-G1 analysis. Caspase inactivation by its inhibitor did not influence the combination-induced cell death (but dramatically decreased apoptosis induction by positive control ABT-737; Figure 3B), further supporting the enhanced cytotoxic effect by the combination not associated with activation of caspases.

AIF plays a critical role in caspase-independent cell death.[21] A previous study has shown that vitamin C causes AIF-triggered caspase-independent cell death in SK-BR3 and Hs578T breast cancer cells.[9] We then questioned if this enhanced caspase-independent cell death by the combination was attributed to promoting nuclear relocation of AIF. The AIF localization was examined using the immunofluorescence assay, and the results are presented in Figure 3C. A clear AIF cytoplasmic distribution was observed in the control cells. Vitamin B_2 did not change AIF cytoplasmic distribution, whereas vitamin C induced a slight increase of AIF nuclear relocation, and the percentage of the cells with AIF nuclear staining was 8.46% (Figure 3D). Vitamins C/B_2 combination led to a significantly further enhanced AIF nuclear relocation (32.72%; $p < 0.01$, as compared to vitamin C treatment alone). The enhanced AIF nuclear translocation was further validated by western blotting analysis of the nuclear content of AIF (Figure 3E). These results clearly indicate that vitamin B_2 facilitated vitamin-C-induced AIF nuclear translocation. The

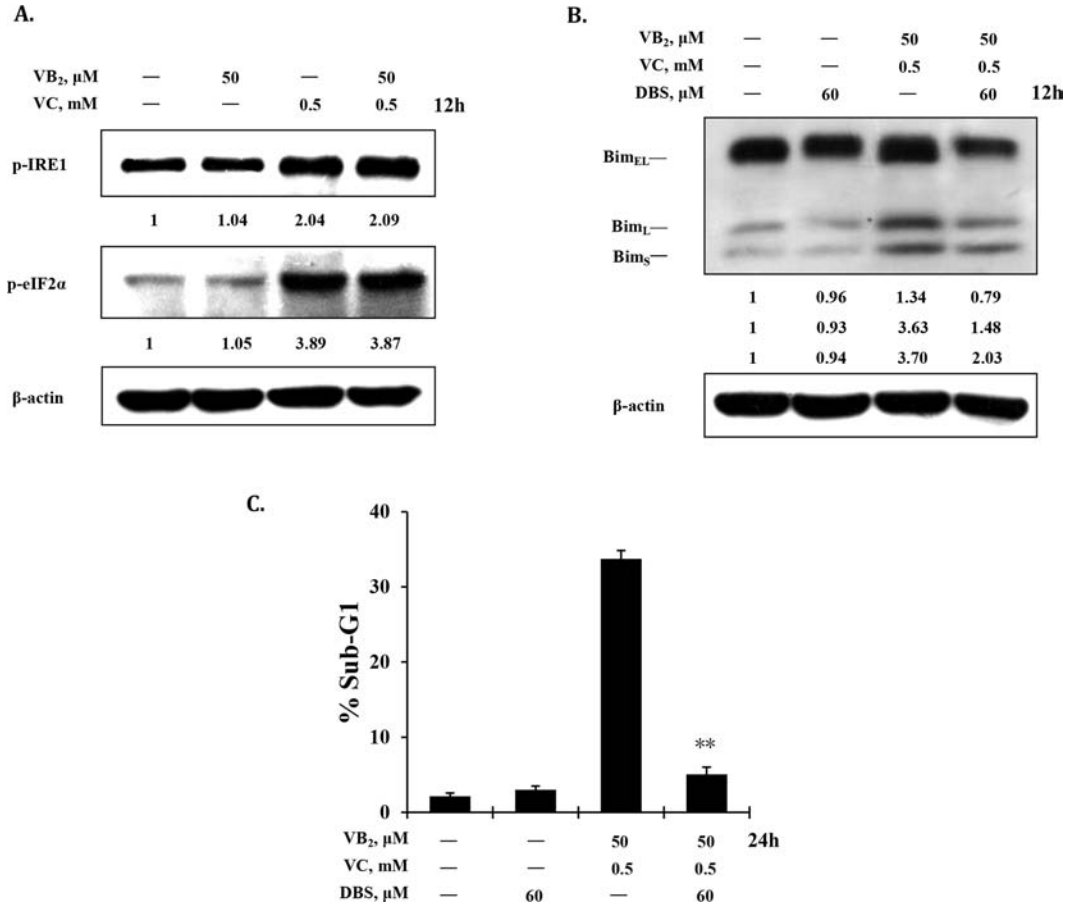

Figure 5. Activation of Bim was attributed to ER stress of MDA-MB-231 cells. (A) Influences of vitamins C and/or B_2 on ER stress. The cells were treated with vitamins C and/or B_2 for 12 h, and changes of ER stress markers were analyzed by western blotting. (b) Effects of IRE1 inhibition by its inhibitor DBS on Bim expression analyzed by western blotting. Relative protein levels were quantitated and indicated below each band. (C) Effects of IRE1 inhibition by its inhibitor on apoptosis induction by the combination measured by sub-G1 analysis.

AIF release from mitochondria suggested that mitochondrial membrane potential was reduced in response to the combination. We next examined the changes of mitochondrial membrane potential by flow cytometry, following JC-1 staining. As expected, the combination treatment caused a significantly enhanced disruption of mitochondrial membrane potential. Together, these results suggested that combining vitamin C with vitamin B_2 induced an enhanced mitochondrial permeability transition (MPT), which, in turn, led to a synergistic AIF-mediated caspase-independent cell death.

Activation of Bim Was Required for the Combination-Induced Cell Death in MDA-MB-231 Cells. Mitochondrial membrane potential is tightly regulated by Bcl-2 family members.[22] Having found the enhancement action of the combination on mitochondria, we next investigated the mechanisms of mitochondrial activation by Bcl-2 family members in response to vitamins C/B_2 exposure. The changes of key Bcl-2 proteins were analyzed by western blotting. As shown in Figure 4A, a significant upregulation of Bim was observed in vitamin-C-treated cells, but the combination failed to induce a further increase of Bim expression. No obvious changes of Bcl-2, Bcl-xl, and Mcl-1 were found in response to either each agent alone or the combination. To assess the role of Bim in cell death induction by vitamins C/B_2, we tested the influence of Bim inactivation by the RNA interference (RNAi) approach on the combination-induced cell death. As shown in Figure 4B, under the condition that Bim was silenced by its siRNA, cell death induction by the combination was significantly reduced in comparison to that found with control siRNA/combination. These data suggested that Bim induction by vitamin C played an important role in vitamins C/B_2-induced cell death, but the synergistic effect of vitamins C/B_2 combination did not happen at the Bim activation level.

Endoplasmic Reticulum (ER) Stress Was Responsible for Bim Upregulation. It has been shown that Bim can be activated by ER stress in a certain model of systems.[23] To decipher the mechanisms involved in the upregulation of Bim, we first evaluated the changes of the key ER stress markers in response to each agent alone or the combination by western blotting. As shown in Figure 5A, phosphorylation of IRE1 and eIF2α was significantly increased in response to vitamin C but not vitamin B_2, whereas the combination caused a comparable level of phosphorylation of these two ER stress markers with vitamin C alone. To determine the role of ER stress activation on the upregulation of Bim, we next tested the effect of IRE1 inhibition by its inhibitor DBS[24] on the combination-induced Bim expression. As shown in Figure 5B, when IRE1 was blocked by its inhibitor, the expression of Bim was significantly decreased. Consistent with Bim reduction, the combination-induced cell death was dramatically attenuated under the condition of IRE1 inactivation (Figure 5C). These results supported a critical role of ER stress, especially IRE1 activation, in the combination-induced Bim upregulation and cell death induction.

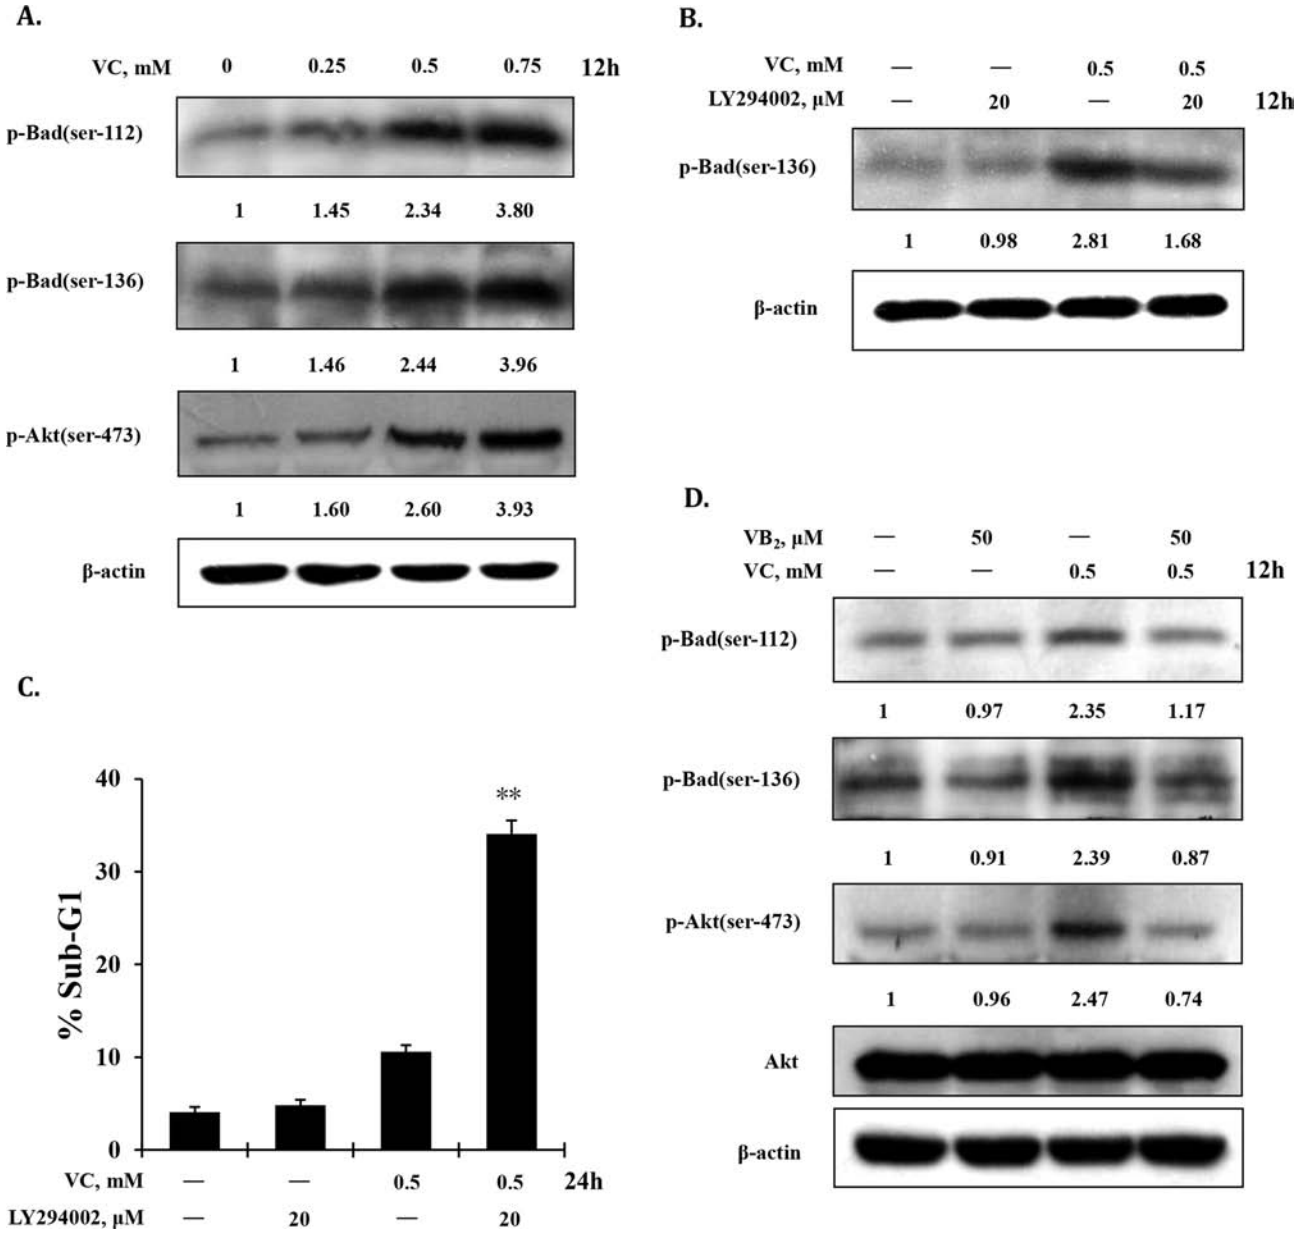

Figure 6. Vitamin B_2 sensitized cancer cells to vitamin-C-induced apoptosis via modulation of Akt activation and Bad inactivation. (A) Vitamin C induced a concentration-dependent increase of Bad and Akt phosphorylation. (B) Effects of Akt inactivation by its inhibitor LY294002 on vitamin-C-induced Bad serine 136 phosphorylation. (C) Effects of Akt inactivation by its inhibitor LY294002 on vitamin-C-induced apoptosis. (D) Influences of vitamin B_2 on phosphorylation of Akt and Bad induced by vitamin C. Relative protein levels were quantitated and indicated below each band.

Vitamin B_2 Sensitized Cancer Cells to Vitamin-C-Induced Cell Death via Modulation of Akt Activation and Bad Inactivation. Bad is a member of BH3-only pro-apoptotic Bcl-2 family proteins. It has been shown that the phosphorylation status of Bad plays a key role in the regulation of its apoptotic activity.[25,26] To further investigate the mechanisms by which vitamin B_2 potentiated cancer cells to vitamin-C-induced cell death, we assessed influences of vitamins C and/or B_2 on Bad phosphotylation by western blotting. As shown in Figure 6A, phosphorylation of Bad at serine 136 and serine 112 was significantly increased in response to vitamin C. Because Akt could phosphorylate Bad at serine 136,[27] we then asked if vitamin-C-induced Bad serine 136 phosphorylation could be due to activation of Akt. As shown in Figure 6A, vitamin C increased phosphorylation of Akt at serine 473, which was consistent with phosphorylation of Bad at serine 136. To determine the relationship between phosphorylation of Akt and Bad and the effect of Akt phosphorylation on cell death induced by vitamin C, we measured influences of Akt inhibition by LY294002 on these events. As shown in Figure 6B, under condition of Akt inactivation, phosphorylation of Bad at serine 136 by vitamin C was dramatically suppressed. Consistent with Bad dephosphorylation, inactivation of Akt resulted in a significant enhanced cell death in response to vitamin C exposure (Figure 6C). These results suggested that Akt activation by vitamin C compromised its cytotoxic activity via phosphorylating Bad at serine 136. We next examined whether vitamin B_2 could prevent phosphorylation of Akt/Bad by vitamin C, and the results are shown in Figure 6D. The combination of vitamins C/B_2 significantly inhibited vitamin-C-induced phosphorylation

DOI: 10.1021/acs.jafc.5b01909
J. Agric. Food Chem. 2015, 63, 6739−6748

of Akt/Bad, which was consistent with the enhanced cell death induction by the combination.

DISCUSSION

Combinatory therapy is considered to be an attractive approach to improve the efficacy of cancer chemotherapy. MDA-MB-231 is a representative of triple-negative breast cancer that lacks effective targeted therapy.[28] The present study demonstrated that combining serum achievable level of vitamins C and B_2 can achieve a synergistic cytotoxic effect on multiple types of cancer cells, including a cell line of triple-negative breast cancer, providing an additional support for combination as a practical approach for improving the chemotherapeutic outcome. Findings of the present study may have important clinical implications for vitamin-C-based combinatorial therapy, especially for the management of triple-negative breast cancer.

As mentioned above, Bad is member of a BH3-only pro-apoptotic Bcl-2 family. A previous study has revealed that phosphorylation of Bad at serine 112 and serine 136 could inhibit its apoptotic function.[25] Indeed, such a mechanism has been reported to contribute cancer cells resistant to several anticancer compounds.[29−32] The findings of the present study, for the first time, demonstrated that Bad was phosphorylated by vitamin C at serine 136 and serine 112 (Figure 6A), which suppressed cytotoxic action of vitamin C. Moreover, we revealed that Bad phosphorylation at serine 136 was attributed to phosphorylation of Akt (Figure 6A), an important anti-apoptotic kinase contributed to drug resistance. Akt inactivation led to a significant dephosphorylation of Bad and increase of cell death (panels B and C of Figure 6). The results supported an important mechanism of cancer cells resistant to vitamin C through activation of Akt and inactivation of Bad. We further revealed that vitamin B_2 was able to significantly suppress Akt and Bad phosphorylation in response to vitamin C exposure. Thus, Akt/Bad axis is a reasonable target for sensitizing cancer cells to vitamin-C-induced cell death. Our data show that vitamin B_2 effectively blocked vitamin-C-induced Akt phosphorylation. Because PI3K/PDK1 are the key upstream kinases that are responsible for Akt phosphorylation,[33] we speculated that inhibition of Akt phosphorylation by vitamin B_2 is probably through regulation of the PI3K/PDK1 axis.

Bim is another BH3-only protein contributing to apoptosis by direct binding and inactivation of pro-survival Bcl-2 family proteins or direct activation of the downstream death mediator Bax and Bak.[34,35] The functional role of Bim in vitamin-C-induced apoptosis has not been established. Our current study showed that vitamin C was able to increase Bim expression and inhibition of Bim expression by the RNAi approach resulted in a significant reduction of cell death by vitamins C/B_2 combination, suggesting that activation of Bim is required for the combination-induced cell death. However, a further enhanced Bim expression by the combination was not observed in comparison to that found in vitamin C treatment alone, suggesting that the synergistic cell death induction by the combination was not due to further increased activation of Bim. With regard to upstream mediator of Bim activation in response to vitamin C exposure, our data revealed that activation of ER stress was responsible for the upregulation of Bim. However, combining vitamin C with vitamin B_2 did not cause further enhanced induction of ER stress compared to vitamin C alone, which was consistent with the changes of Bim expression. Together, these data suggested that activation of ER stress of the Bim axis was only attributed to vitamin C and functioned as an important pro-death signal, contributing to the combination-induced cell death. ER stress is a well-established activator of autophagy.[36] We have tested the role of autophagy in this synergistic action by vitamins C/B_2 and found that autophagy was indeed activated in response to the combination. However, inhibition of autophagy by the genetic approach did not influence the cell death level (data not shown), ruling out the possible involvement of autophagy in the combination-induced cell death.

Several studies have showed that an increased apoptosis or cytotoxicity was observed by a combination of vitamins C and B_{12b}[37] or K3,[38−41] which was associated with augment of oxidative stress. To determine whether this mechanism was also involved in cell death induction by vitamins C/B_2 combination in our current system, we measured the levels of reactive oxygen species (ROS) with flow cytometry, following staining with 2′,7′-dichlorodihydrofluorescein diacetate (H2DCFDA). An enhanced ROS level by combining vitamin C with vitamin B_2 was not detected (data not shown), suggesting that vitamin B_2 sensitized cancer cells to vitamin-C-induced cell death was not due to the boost of ROS.

In summary, vitamin B_2 was capable of sensitizing breast cancer cells to vitamin-C-induced cell death via dephosphorylation of vitamin-C-mediated Akt active and Bad inhibitory phosphorylation. The findings of the present study suggest that vitamin B_2 has great potential as a sensitizer for improving therapeutic efficacy of vitamin C against triple-negative breast cancer.

biological activity. Altogether, three natural compounds, xanthohumol (**14**), isoxanthohumol (**6**), and naringenin (**5**), and 11 synthetic derivatives with various structural modifications were examined for aphid-deterrent activity.

Usually, antifeedants are natural compounds with a lactone ring,[29−31] but they may also belong to terpenes[32,33] or phenolic compounds.[34] Many plants have strong repellent properties, and for this reason they have been used for a long time to repel the wheat weevil, the major pest of stored cereal grains. This group of plants includes field mint (*Mentha arvensis*), common yarrow (*Achillea millefolium*), and several other common plant species.[35] Obtained by extraction, preparations of lavender (*Lavandula luisieri*) and rough cocklebur (*Xanthium sibiricum*) demonstrated insecticidal activity, among others, against the peach-potato aphid (*Myzus persicae*).[36,37] Tropical plants are a very rich source of antifeedants. Among them, Indian neem (*Azadirachta indica*) is one of the best known, because it contains the strongest of known feeding repellents, azadirachtin. Nawrot et al. in 2013 proved the strong deterrent activity of ionic liquids toward wheat weevil beetles (*Sitophilus granarius* L.), confused flour beetle larvae (*Tribolium confusum* Duv.), and khapra beetle larvae (*Trogoderma granarium* Ev.).[38] This activity was equal to or stronger than that of azadirachtin. There is increasing application of microbial agents, so-called bioinsecticides, that contain live bacterial cultures, mostly of the genus *Bacillus* (*Bacillus thuringiensis*).[39] Another large group of biopreparations that inhibit plant pest development is based on viruses and nematodes.[40] Apart from interacting with insect chemoreceptors of taste, preparations of antifeeding activity may inhibit the fertility of insects, prolong their larval development, or inhibit the transmission of some viruses.[41,42]

According to literature data, biological methods constitute only a small fraction of plant protection management. One reason is that there have been no effective biological methods of crop protection developed, especially concerning control of diseases and pests of cereals and plants of the families Fabaceae and Brassicaceae, which are essential for the production of organic food.[43] Gökçe et al. in 2011 proved antifeedant activity of the extract from hop cones (*H. lupulus*) against the Colorado potato beetle (*Leptinotarsa decemlineata*).[44]

In our previously published study, we found that one of the hop extracts examined significantly deterred *M. persicae* settling on treated leaves, and the effect was relatively stable and lasted at least 24 h.[45] However, aphid probing and phloem sap consumption were not impeded. Therefore, we hypothesized that the extract contained a component that could reach sieve elements using the symplastic or apoplastic pathway and produce a delayed, postingestional metabolic detrrent effect without evoking the rejection behavior based on gustatory stimuli. Consequently, we decided that there was a need for a more detailed study to find which components of the hop extract were responsible for the deterrent activity. Exogenously applied hop chemicals, α- and β-hop acids and colupulone, had an antifeedant effect on the grain aphid (*Sitobion avenae*) and bird cherry-oat aphid *Rhopalosiphum padi*.[46] However, to the best of our knowledge, there is no information about the deterrent activity of hop flavonoids toward plant pests, especially aphids. There is also no study on the antifeedant activity of chalcone (**10**) and its structural analogues toward the peach-potato aphid (*M. persicae*).

The aim of our research was to evaluate the deterrent activity of natural flavonoid compounds found in hop (*H. lupulus*): xanthohumol (**14**) and isoxanthohumol (**6**). The settling behavior of the peach-potato aphid (*M. persicae* [Sulz.]) was evaluated. We investigated also the effect of structural modifications of these flavonoid molecules on aphid behavior. We selected compounds of diverse chemical structures, belonging to three flavonoid groups, compounds with 4-chromanone (**1**), chromone (**7**), or *trans*-chalcone (**10**) skeletons.

MATERIALS AND METHODS

Reagents. Chemical reagents were purchased from Sigma-Aldrich, Merck, Chempur, and Alfa Aesar. For the study we used commercially available 4-chromanone (**1**) (Sigma-Aldrich), flavanone (**4**) (Alfa Aesar), naringenin (**5**), chromone (**7**) (Sigma-Aldrich), flavone (**8**) (Sigma-Aldrich), 7-aminoflavone (**9**) (Sigma-Aldrich), *trans*-chalcone (**10**) (Sigma-Aldrich), and 4-methoxychalcone (**12**) (Sigma-Aldrich).

General Procedures. The structures of products obtained were determined by spectroscopic methods (^{1}H NMR, ^{13}C NMR, IR, and HR ESI-MS). The purity of compounds **2**, **3**, **11**, and **13** was established by gas chromatography (GC) using an HP-5 capillary column, whereas, for compounds **6** and **14**, high-performance liquid chromatography (HPLC) was employed, with the help of the reversed-phase C-18 column as described perviously.[19] For the biological tests we used the compounds with the purity >95%.

Synthesis of Compounds. 7-Hydroxy-2,2-dimethylchroman-4-one (**2**) was obtained in the reaction of 1,3-dihydroxybenzene with dimethylacrylic acid (DMAA) in the presence of zinc chloride in phosphorus oxychloride, followed by isomerization of the intermediate product according to a modified method of Alizadeh et al.[47] (80% of isolated yield). The spectroscopic data were consistent with those reported in the literature.[47,48] In the next step the purified product (**2**) was subjected to the Williamson ether synthesis with methyl iodide to give 7-methoxy-2,2-dimethylchroman-4-one (**3**), the spectroscopic data of which matched those reported by An et al.[49] The synthesis of 4-hydroxychalcone (**11**) and 4-ethyl-4′-methoxychalcone (**13**) was carried out according to the literature method[50] under strongly basic conditions (KOH), using methanol as a solvent. Xanthohumol (**14**) was isolated using the earlier described method[51] from spent hops, the residue of supercritical carbon dioxide hop extraction, which was delivered by the Supercritical Extraction Department of the New Chemical Syntheses Institute in Puławy, Poland. The second prenylated hop flavonoid, isoxanthohumol (**6**), was obtained by the alkaline isomerization of xanthohumol (**14**) according to the method of Wilhelm and Wessjohann.[52]

Cultures of Aphids and Plants. Aphids (*M. persicae*) and plants (Chinese cabbage *Brassica pekinensis*) were reared in the laboratory at 20 °C, 65% realtive humidity, and a 16/8 h light/dark photoperiod. All experiments were carried out under the same conditions.

Aphid Settling. This bioassay allows aphid host preferences to be studied under seminatural conditions. In this bioassay, aphids are given free choice between control and treated leaves. The standard leaf-dip method[53] was applied for the evaluation of activities of xanthohumol (**14**), isoxanthohumol (**6**), and their derivatives. The compounds studied were applied by immersing a leaf in 0.1% ethanolic solution of a given compound for 30 s. Control leaves of similar size were immersed in 70% ethanol, which was used as a solvent for the tested compounds. Treated and control leaves were placed in a Petri dish and allowed to air-dry for 1 h before being offered to the insects. Next, aphids were placed in the dish along the line that divided the area into two halves so that aphids could choose between treated (on half of a Petri dish) and control leaves (on the other half of the dish). Aphids that settled, that is, they did not move and the position of their antennae indicated feeding, on each leaf were counted at 1, 2, and 24 h intervals after access to the leaf (8 replicates, 20 viviparous apterous females/replicate). Aphids that were moving or out of any of the leaves were not counted.

The data were analyzed using one-way ANOVA (Statistica 6.1. package). If aphids showed a clear preference for the leaves treated with the tested compound ($P < 0.05$), the compound was described as having **attractant** properties. If aphids settled mainly on the control

[a]Numbers for T, test, and C, control, represent mean number of aphids settled on test or control leaves (choice test); *p*, significance level (ANOVA); significant differences (Student's *t* test, $p < 0.05$) between number of aphids settled on either half of the Petri dish are in bold; DI, indices of deterrence.

half of the Petri dish ($p < 0.05$), the compound tested in the respective choice test was labeled a **deterrent**. From the data thus obtained the indices of deterrence (DI) were calculated (DI_1, DI_2, and DI_{24} corresponding with 1, 2, and 24 h after exposure monitoring, respectively):

$$DI = (C - T/C + T)$$

C is the number of aphids settled on control leaves, and *T* is the number of aphids settled on the leaves treated with the tested compound. The value of DI ranged between 1 (ideal deterrent) and −1 (ideal attractant).

RESULTS AND DISCUSSION

Aphid Settling. On the basis of the bioassay, we found that the natural hop flavanone, isoxanthohumol (**6**), has deterrent properties toward the peach-potato aphid. In comparison, xanthohumol (**14**) did not demonstrate such an activity. In contrast, xanthohumol (**14**) was a weak attractant. However, strong deterrent properties of isoxanthohumol (**6**) were expressed with a delay, that is, at least 2 h after treatment ($DI_{24} = 0.6$, $p = 0.0000$) (Tables 1 and 3).

The compounds with strongly polar groups in the aromatic ring, such as hydroxyl ones, were inactive, as opposed to their methoxy derivatives with a 4-chromanone skeleton (**2** and **3**) and to chalcones (**11** and **12**).

Comparing the activity of ketones (**7**) and (**1**), we observed that hydrogenation of the C_2−C_3 double bond in compound **7** resulted in a switch from attractant to deterrent activity. However, the effect on aphid behavior was of various potencies

[a]Numbers for T, test, and C, control, represent mean number of aphids settled on test or control leaves (choice test); *p*, significance level (ANOVA); significant differences (Student's *t* test, $p < 0.05$) between number of aphids settled on either half of the Petri dish are in bold; DI, indices of deterrence.

and durabilities. For 4-chromanone (**1**), strong deterrent activity was noted until the second hour of the experiment, whereas chromone (**7**) proved to be a weak attractant to the peach-potato aphid. The opposite situation was observed for the derivatives with a phenyl substituent at C-2, where flavone (**8**) ($DI_1 = 0.5$, $p = 0.0006$) was more active than flavanone (**4**), which proved to be inactive: the relative index of deterrence was within the range from $DI_1 = 0.2$ ($p = 0.1597$) to $DI_2 = DI_{24} = 0.3$ ($p = 0.0383$ and $p = 0.0922$, respectively (Tables 1 and 2).

In the case of the derivatives with a chromone system, the presence of a phenyl group at C-2 resulted in an increase in the deterrent activity; during the initial 2 h after treatment later on, the deterrent effect ceased (flavone (**8**): $DI_1 = 0.5$, $p = 0.0006$; $DI_2 = 0.4$, $p = 0.0090$; $DI_{24} = 0.4$, $p = 0.0609$). The introduction of an amine group at C-7 in the flavanone led to a considerable increase of the antifeedant activity, which was observed during the whole time of the experiment. The relative coefficient of deterrence values from DI = 0.7 after 1 h ($p = 0.0002$) to DI = 0.5 after 24 h ($p = 0.0167$) determined for compound **9** proved its high deterrent properties (Table 2).

It was observed that in the case of chalcone derivatives, the compound that caused the strongest reduction of aphid settling on treated leaves was 4-methoxychalcone (**12**). It was proved by the values of the relative coefficient of deterrence ($DI_1 = 0.5$, $p = 0.0086$; $DI_2 = 0.5$, $p = 0.0386$). However, the effect of 4-methoxychalcone (**12**) on inhibition of aphid settling was short-lived. 4′-Methoxy-4-ethylchalcone (**13**) proved to be also an active deterrent, which additionally reduced aphid settling during the whole experiment time (Table 3). The relative index of deterrence value (DI) was within the range from $DI_1 = 0.25$ to $DI_{24} = 0.30$ at $p < 0.05$. The deterrent activity at 2 h after application was also observed for *trans*-chalcone (**10**) ($DI_2 = 0.3$, $p = 0.0406$; $DI_{24} = 0.4$, $p = 0.0216$) (Table 3).

Differences in the durability of deterrent effects of compounds examined in the present study, for example, isoxanthohumol (**6**), and changes in their activity over time may be caused by changing conditions of their action. Presumably, it may be related to altered concentration of a tested substance in the phloem juice and changes in the pH, arising from metabolic transformations in a plant.[45] Additionally, aphids may decompose some substances with the help of their saliva enzymes. The important factors may be also aphid endogenous enzymes and symbiotic microbes, which can perform detoxification of tested compounds.[54] Xanthohumol (**14**), the most important hop prenylated chalcone, in the in vitro study was transformed into isoxanthohumol (**6**) and 8-prenylnaringenin.[55] Biotransformations of isoxanthohumol (**6**) using human liver cells[56] and fungi[57] led to the product of *O*-demethylation, 8-prenylnaringenin, which is the strongest phytoestrogen known so far. An aphid attack may induce synthesis of some organic compounds in *B. pekinensis* as a defense response to feeding. In response to the oxidative stress caused by aphids, a plant may activate a very efficient production of certain enzymes (for example, antioxidative ones, such as superoxide dismutase or catalase), hormones, and signaling molecules, which are part of plant defense against invading insect herbivores (e.g., H_2O_2 and NO).[58] These may also cause transformations of tested compounds into their derivatives.[59]

Structure–Activity Aspects. The current state of the art in antifeedant activity of flavonoid compounds relates to plant extracts, pure compounds, products of their metabolism, and also their synthetic analogues.[60,61] Russel et al.[62] came to the conclusion that the lack of substituents in ring C of flavanone as well as the lack of 3-oxo groups (−OH, $-OCH_3$) at C-3 led to an increase in antifeeding activity of the compounds toward larvae of *Ctenopsteustis obliquana*, which feed on avocado leaf

shoots and young fruitlets. It is an advantage for antifeedant activity to have an ether linkage such as a pyran moiety in the chemical structure. Among the prenyl flavanones isolated from *Tephrosia apollinea* L., the most active antifeedants proved to be compounds with a dihydrofuran ring.[63] According to the literature, good antifeeding activity was also observed for compounds with a naphthalene substituent[64] and chalcones with electron acceptor groups in ring A.[65,66]

The objective of our work was to obtain hop flavonoid compounds and their derivatives of diverse relatively simple chemical structures and to evaluate their antifeedant activity. For the biological tests we have chosen two major prenylated hop flavonoids, xanthohumol (**14**) and isoxanthohumol (**6**), and an isoxanthohumol derivative without the prenyl and methyl groups, naringenin (**5**), a flavonoid that is commonly found in citrus fruits. As model compounds for this study, flavone and flavanone derivatives were used without the phenyl substituent, containing either a chromone or 4-chromanone skeleton obtained by chemical synthesis and also flavones and flavanones, which are structural analogues of natural phytoestrogens and their derivatives. To the group of compounds described in the earlier works[67,68] and also for comparison, we decided to expand our group of tested substrates by adding a flavone derivative with an amino group at C-7 in ring A. The antifeedant activity of synthetic aminoflavones toward plant pests, especially aphids, has not been investigated, so far. We expected that comparing the results of antifeedant activity of chromones, chromanones, and the selected flavanones and chalcones, which are precursors of flavonoids, would allow us to determine which structural elements of the compounds are necessary for subsequent reduced aphid settling.

The antifeedant activity of hop compounds, selected synthetic chalcone derivatives, and chromones against the peach-potato aphid (*M. persicae* [Sulz.]) was evaluated. Synthetic pesticides, which are used against agricultural pests, are highly toxic to humans and the environment. However, these natural compounds were regarded as one of the plant's defensive systems against phytophagous insects along with the peach potato plant surface. Our results showed that deterrent properties changed depending on their structure, cyclic or not. Isoxanthohumol (**6**), obtained by cyclization of xanthohumol (**14**), had strong deterrent activity against the peach-potato aphid, whereas its derivative, xanthohumol (**14**), was inactive. As we have already mentioned, the presence of a 2′-OH group

DOI: 10.1021/acs.jafc.5b02025
J. Agric. Food Chem. 2015, 63, 6749−6756

in chalcones facilitates their cyclization to their isomeric forms, flavones. The second major difference likely to affect the activity is the existence in compound **14** of a strong intramolecular hydrogen bond between the carbonyl group and the hydroxyl group. On the ^{1}H NMR spectrum it is evidenced by the presence of a signal at δ 14.7 for the proton of the 2′-OH group involved in a strong intramolecular hydrogen bond.[18] The carbonyl group of isoxanthohumol (**6**) for obvious reasons is not involved in such binding. According to the literature, the observed differences in activity may also arise from inhibition of the activity of the enzymes involved in the detoxification of xenobiotics, for example, cytochrome P450 enzymes.[69] The compounds selected for the study showed various degrees of feeding detterent activity. In our study, flavanones, chromanones, and chalcones having hydroxyl groups did not show any insect antifeedant activity. The most inactive was a 4-hydroxychalcone (**11**), which was an attractant. An additional substituent of a hydroxyl group at the *para* position in ring B of a chalcone decreased the antifeedant activity, compared to the unsubstituted chalcone (**10**). The structure−activity analysis led to the conclusion that acylation of the hydroxyl group in ring B of chalcone **11** results in an increase of the antifeedant activity, compared to the molecule with the free OH group. The presence of hydroxyl groups in the molecule of naringenin (**5**) had a considerable influence on the antifeedant activity, compared to the unsubstituted flavanone (**4**), which was only weakly active. As in the case of other biological activity, moderate deterrent properties of polyphenolic compounds, including naringenin (**5**), stem from the presence of the reactive hydroxyl groups, which facilitate binding to enzyme active sites as well as formation of hydrogen bonding with enzyme system in aphids. These result in a change of their metabolism. Flavonoids **4**, **8**, and **9**, especially, have no hydroxy substituent on the A-ring. Recent research confirming the antifeedant activity of naringenin (**5**) and its derivatives indicates that generalizations concerning the structure−activity relationships of the mentioned compounds cannot be applied to a wide range of pests[34,70,71] because the above-mentioned compounds stimulated feeding behavior of the insects, whereas another was the best feeding deterrent. As describe in the literature, cleavage of the ether linkage of the pyran ring of flavanoids[67] and the hydrogenation of the α,β-unsaturated bond in chalcones decrease the antifeedant activity.[72] Ohmura et al. reported that a dihydrochalcone, phloretin, has the same structure as naringenin, except for the absence of the pyran ring, and showed less antifeedant activity against the subterranean termite *Coptotermes formosanus* than naringenin (**5**). As was reported by Morimoto et al.,[67] although the decrease in the activity and the number of hydroxyl groups were correlated, it was attributable to the penetrability toward the receptor in the insect taste-sensitive organ. The substitution of the flavonoid ring system with the prenyl unit and a $-OCH_3$ group increases the lipophilicity and confers to the molecule a strong affinity for biological membranes, which play an important role in biomolecule transport, distribution, action, and selectivity. The hop compounds intercalate into the lipid bilayer, influencing its glycerol backbone region, hydrocarbon chain region, and, to a lesser extent, polar headgroup region. The calculation of log *P* values identified xanthohumol (4.38 ± 0.78) as a more lipophilic molecule compared to isoxanthohumol (3.82 ± 0.86).[73] However, looking at the structures of our tested compounds it is difficult to predict whether their interactions with the lipid membrane will exert any impact on the antifeedant activity. Our results indicate that the prenyl group, and flavanones, rather than the flavonols and chalcones, might make predominant contributions to antifeedant inhibition. Therefore, prenylated flavonoids possessing lipophilic moieties may be potent candidates for antifeedants. Our results suggested that the antifeedant activity required not only the important 2-position substituent but also the substituent pattern on the A-ring and the hydrogenation of the C_2-C_3 double bond of these insect antifeedants, flavonoids and chromones. Similar results were reported by Morimoto et al.[67] In our study the introduction of an additional amino group at C-7 to flavone (**9**) caused an increase in antifeedant activity against the peach-potato aphid. This is a first report about the feeding deterrent activity of aminoflavones in the literature. Significant correlations were found between biological activity and molecular size of the derivatives with a chromone system. The presence of a phenyl group at C-2 of chromone (**7**) and the introduction of an amino group at C-7 in the flavone (**8**) resulted in an increase in the deterrent activity, which was observed during the longer time. The relationship between physicochemical properties and insect antifeedant activity of compounds has been reported by Morimoto et al.[74]

Among several pest control strategies (comprising mechanical, agrotechnical, and chemical methods), biological methods of crop protection that employ compounds of plant origin (including flavonoids) are best accepted in organic food production. Therefore, this biological method of plant protection should be recommended, which is confirmed by the results of laboratory tests.

In the next step of the research an optimization of the chemical structure of these compounds is needed. This will involve computational methods such as QSAR models that relate experimentally measured biological activities of compounds to their molecular structure.[67] Natural plant compounds, such as hop flavonoids, may be applied as models or substrates for the synthesis of highly specific substances that inhibit feeding of pests.

Because we observed no improvement in ferritin content in Caco-2 cells after addition of the same CPPs pools (α-CPPs and β-CPPs) as those used in the present study,[29] the latter were designed to complete these studies in hepatic cell lines by evaluating the effect of CPPs isolated from α_s- or β-CN upon iron uptake markers, specifically ferritin and soluble transferrin receptor in HuH7 cells.

MATERIALS AND METHODS

Reagents. *Digestion.* Porcine pepsin, pancreatin, and bile extract were purchased from Sigma Chemical Co. (St. Louis, MO, USA). The working dissolutions of these enzymes were prepared immediately before use. Water of cellular grade (Aqua B Braun, Braun Medical, Barcelona, Spain) or Milli-Q water (18.2 MΩ cm resistivity) was used for the preparation of all reagents.

Trifluoroacetic acid (TFA), absolute ethanol, and acetonitrile were purchased from Merck (Darmstadt, Germany), and all of these reagents were of analytical grade. $CaCl_2$ was purchased from Panreac (Barcelona, Spain).

Iron−calcein complex in 20 mM HEPES buffer (*N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid, pH 7.3) contained 0.1 μM calcein from Molecular Probes (Leiden, The Netherlands) and 1 μM $FeCl_3$ from Analytical Carlo Erba (Barcelona, Spain) .

Preparation of α-CPPs and β-CPPs Pools. Two pools of α-CPPs and β-CPPs were obtained from α_s- and β-CN (Sigma Chemical Co.) and respectively subjected to simulated gastrointestinal digestion according to the method of García-Nebot et al.[11] Briefly, both samples were digested using two demineralized enzymatic solutions (pepsin solution in the gastric stage at pH 2 for 2 h at 37 °C and pancreatin−bile solution in the intestinal stage at pH 6.5 for 2 h at 37 °C). Samples were centrifuged (3500*g*, 60 min at 4 °C) after their pH was adjusted to 7.2. The undigested casein in the supernatants was precipitated at pH 4.6, and then the CPPs were selectively precipitated with $CaCl_2$ and absolute ethanol at pH 8. The preparation was then centrifuged at 12000*g* for 10 min at 10 °C. The precipitate was washed with 50% (v/v) ethanol, lyophilized, and stored at −20 °C.

Analysis of CPPs by Online RP-HPLC-ESI-MS/MS. The analysis of the α-CPPs and β-CPPs pools was carried out according to the method of García-Nebot et al.[11] Solvent A was a mixture of water/TFA (1000:0.37, v/v), and solvent B contained water/acetonitrile/TFA (200:800:0.27, v/v/v). The gradient was 60% of solvent B during 90 min, after which the percentage of solvent B increased to 90% in 5 min and remained constant at 90% for 5 min.

The m/z spectral data were processed and transformed to spectra representing mass values using Data Analysis version 3 (Bruker Daltonik). BioTools version 2.1 (Bruker Daltonik) was used to process the MS(n) spectra and perform peptide sequencing.

Iron Binding to α-CPPs and β-CPPs: Calcein Assay. The cellular labile iron pool (LIP) consists of chelatable and redox-active iron, which plays a key role as a crossroads in cell iron metabolism. The ability of iron chelators to mobilize this temporary iron pool bound to low-molecular-weight and low-iron affinity chelators (citrate, ascorbate, phosphate, and adenosine triphosphate) is an essential factor influencing their biological efficiency. According to previous work, the calcein test can predict the iron-chelating efficiency of chelators.[30−32]

Thus, an acellular calcein test was performed to compare the potential ability of CPPs to chelate this labile iron pool at physiological pH, at concentrations used for the assays with α-CPPs and β-CPPs pools in HuH7 cells. The fluorescence of this metallosensor dye is quenched during its interaction with iron and conversely is restored during removal of iron from the calcein−iron complex by various chelators. The rate and extent of fluorescence recovery depend on the chelator concentration, the kinetics and stoichiometry of iron binding, and the relative binding affinity. The calcein test is qualitative, but the concentration of the chelator for which 50% of the fluorescence is restored is indicative of chelator affinity (RC_{50}).

Twenty microliters of the α-CPPs and β-CPPs pools in HEPES buffer (20 mM HEPES, 150 mM NaCl, pH 7.3), in a final concentration interval between 0 and 74.07 μM, was added in a microplate and mixed with 250 μL of the complex iron−calcein (containing 0.1 μM calcein and 1 μM $FeCl_3$). Then, the microplate was subjected to shaking at room temperature in darkness for 4 h, and the fluorescence (λ_{exc} = 485 nm, λ_{em} = 520 nm) of calcein was measured with a microplate fluorescence reader (Packard, Fusion). Three independent replicates were performed for each experiment, and each experiment was repeated twice.

HuH7 Cells. The human hepatoma cell line HuH7 was a gift from Dr. Ferry (Centre Anticancéreux, Hôpital Ponchaillou, Rennes, France). The cell cultures were maintained in complete culture Dulbecco's Modified Eagle Medium (DMEM+GlutaMAX), containing 10% (v/v) fetal bovine serum, 1% (v/v) nonessential amino acids, 1% (v/v) antibiotic solution, and 1% (v/v) HEPES (Gibco BRL Life Technologies, Scotland) and were used between passages 13 and 16. The cells were seeded at a density of 21000 cells/cm^2 onto 96-well plates for the cytotoxicity assays or onto 6-well plates for iron bioavailability assays.

Cytotoxicity. Before the iron bioavailability assay, we analyzed the potential cytotoxicity of the Fe−CPPs complexes in the CPP concentration range from 0 to 25 μM (Fe:CPPs ratio 4:1). The binding of iron to α-CPPs and β-CPPs pools was performed by mixing them with $FeCl_3$ solution for 30 min at 37 °C. This interval was selected by taking into account the concentration of iron and β-CN(1−25)4P already used in iron bioavailability studies in Caco-2 cells.[16,17,29,33]

Cytotoxicity was evaluated at 4 days postseeding and 24 h of incubation by measuring extracellular lactate dehydrogenase (cytotoxicity detection kit LDH, Roche, Penzberg, Germany), according to the manufacturer, on a 20 μL aliquot of cell-free medium (supernatants) at 485 nm.[28] An LDH standard curve (0−4000 mU/mL) was used to quantify enzyme (L-lactate dehydrogenase, Sigma Chemical Co.). Extracellular LDH was reported as a percentage of the control value.

Ferritin and Soluble Transferrin Receptor Contents. Five samples were analyzed: iron control (50 μM $FeCl_3$), CPPs control (α-CPPs and β-CPPs) at 12.5 μM, and the Fe−CPPs complexes (Fe−α-CPPs and Fe−β-CPPs) obtained by mixing α-CPPs and β-CPPs with $FeCl_3$ solution for 30 min at 37 °C, final pH 7.4.

At 7 days from initial seeding, 2 mL of the sample was added to the cell monolayer, and cell cultures were incubated for 2 h at 37 °C in 5% CO_2 with 95% relative humidity. Cell supernatants containing the sample were then removed and replaced by culture medium. After 22 h of incubation at 37 °C, the cell supernatants were collected and concentrated 10-fold by ultrafiltration on Vivaspin spin columns with a membrane cutoff value of 3000 Da (Vivascience, France) for sTfR measurements. sTfR was quantified by immunonephelometry (BNII analyzer, Dade Behring, Paris) using the "N latex STFR" kit (Siemens Healthcare Diagnostics, Marburg, Germany).[32]

Finally, the cells were washed twice with 50 mM sodium phosphate buffer (PBS), pH 7, and were scraped and collected in 1 mL of PBS and centrifuged for 10 min at 1500*g*. The cell pellets were sonicated for 30 s at 4 °C in 600 μL of a homogenization buffer containing 25 mM Tris-HCl (pH 7.5), dithiothreitol (1 mM), ethylenediaminetetraacetic acid (EDTA) (0.1 mM), and Brij 35 (0.02%). These cell lysates were centrifuged at 10000*g* for 10 min prior to biochemical analysis, including protein levels and ferritin concentration measurements.

The ferritin content was quantified in the cell lysates by immunoturbidimetry (Olympus analyzer AU2700, Olympus Diagnostics GmbH), using commercial Olympus kits (Olympus OSR61138).[34]

Cell protein content was determined using Kit BC Assay, a colorimetric protein assay using bicinchoninic acid[35] for expressing ferritin content and soluble transferrin receptor as micrograms of ferritin per milligram of protein and nanograms of sTfR per milligram of protein and to check reproducibility among cell cultures.

Statistical Analysis. One-way ANOVA and the Tukey test for determining significant differences ($p < 0.05$) were used for calcein and cytotoxicity assays. The results referred to ferritin content and sTfR were analyzed by two-factorial ANOVA (pool of CPPs with three levels (control, α-CPPs, and β-CPPs); iron content with two levels

(with/without iron)), and the Tukey test was used to determine significant differences ($p < 0.05$), with a view to evaluating the influence of the addition of different pools of CPPs and determining whether this effect is greater than when iron is added as chloride (Statgraphics Plus v. 5.1, Warrenton, VA, USA).

RESULTS AND DISCUSSION

CPPs Identified from α-CPPs and β-CPPs Pools. The main CPPs sequences identified in α-CPPs and β-CPPs pools, obtained from α- and β-CN, respectively, subjected to simulated gastrointestinal digestion and selective precipitation, are shown in Figure 1. The CPPs identified in our study contained R, T, S, V, P, K, L, E, Q, D, and F at the C-terminus, which matched with cleavages by the action of pancreatin and/or pepsin used during the simulated gastrointestinal digestion process.[1,36,37]

A total of 16 CPPs were identified in the α-CPPs pool; 9 of them corresponded to α_{s1}-CN and 7 to α_{s2}-CN. It should be noted that four CPPs contain the cluster (SpSpSpEE), which is observed in the sequences α_{s1}-CN(66−70), α_{s2}-CN(8−12), and α_{s2}-CN(55−60) (Figure 1a). From α_{s2}-CN subjected to simulated gastrointestinal digestion similar to that used in this study, Miquel et al.[5] identified peptides including the cluster (SpSpSpEE), such as α_{s2}-CN(14−73)5P and α_{s2}-CN(54−87)4P, which partially coincide with the CPPs identified in this study, that is, α_{s2}-CN(57−73)3P and α_{s2}-CN(54−73)4P. Moreover, α_{s2}-CN(137−154)1P identified by these authors has amino acid sequences common to α_{s2}-CN(138−148)1P, identified in this work.

Different digested substrates (α-CN, a commercial mixture of α_{s1}- and α_{s2}-CN used in this study versus α_{s2}-CN obtained from CN subjected to precipitation used in the above-mentioned study) and/or different experimental conditions during simulated gastrointestinal digestion (intestinal pH of 6.5 used in this study versus 5.2 in the above study) could explain the differences found in the identified product.

The peptides α_{s2}-CN(53−70)4P, α_{s2}-CN(126−137)2P, and α_{s2}-CN(138−149)1P identified by Tauzin et al.[3] from α_{s2}-CN subjected to tryptic hydrolysis partially coincide with the peptides α_{s2}-CN(54−73)4P, α_{s2}-CN(57−73)4P, α_{s2}-CN(124−137)2P, α_{s2}-CN(138−146)4P, and α_{s2}-CN(138−148)1P identified in this work. In the same way, CN subjected to simulated gastrointestinal digestion with two stages, pepsin and trypsin[8] or pepsin and a mixture of trypsin, chymotrypsin, elastase, carboxypeptidase, and intestinal brush border membrane enzymes,[9] released CPPs that totally or partially coincide with the peptides α_{s2}-CN(52−73)5P, α_{s1}-CN(115−119)1P, and α_{s2}-CN(138−146)1P identified in this study. On the other hand, some studies conducted in rats[38] or minipigs[39,40] fed CN have identified CPPs from feces or intestinal content, respectively, fully containing the cluster sequence present in the α_{s1}-CN fraction, α_{s1}-CN(66−70); thus, they partially

coincide with some of the CPPs molecules identified in our work.

A total of 18 CPPs were identified in the β-CPPs pool, and 4 of them contained the same cluster (SpSpSpEE) present in the sequence β-CN(17−21) (Figure 1b). All peptidic fragments of CPPs identified in this sample are contained in peptide β-CN(1−52)5P, a CPP identified from the β-CN subjected to simulated gastrointestinal digestion similar to that used in this study.[7] The peptides β-CN(1−25)4P and β-CN(33−48)1P released from β-CN subjected to tryptic hydrolysis[4,41,42] partially coincide with the peptides found in this study. In this sense, Picariello et al.[9] identified the peptides β-CN(33−40)1P, β-CN(33−43)1P, β-CN(33−51)1P, and β-CN(33−52)1P from CN subjected to simulated gastrointestinal digestion with pepsin and a mixture of trypsin, chymotrypsin, elastase, carboxypeptidase, and intestinal brush border membrane enzymes, which totally coincide with some of the peptides found in this study.

Iron Binding to α-CPPs and β-CPPs: Calcein Assay. The qualitative calcein fluorescence assay was used to compare the iron-binding capacity of the α-CPPs and β-CPPs pools. For the α-CPPs pool, no statistically significant differences were recorded ($p > 0.05$) over concentrations ranging from 0.29 to 1.18 μM, this fluorescence being lower than that obtained over the concentration interval from 9.26 to 74.07 μM. No statistically significant differences were recorded ($p > 0.05$) versus this latter interval (Figure 2).

For the β-CPPs pools, a significantly greater fluorescence recovery ($p < 0.05$) was observed over concentrations ranging from 0.14 to 1.18 μM, but no statistically significant differences were obtained over concentrations from 1.18 to 4.63 μM. The fluorescence intensity obtained for this latter concentration range was lower than the fluorescence obtained over the concentration interval from 9.26 to 74.07 μM.

With these results taken into account, the β-CPPs pool showed greater fluorescence recovery from calcein/iron complexes than the α-CPPs pool over the concentration interval from 9.26 to 74.07 μM (Figure 2), thus suggesting that the β-CPPs pool could show greater iron-binding capacity

J. Agric. Food Chem. 2015, 63, 6757−6763

compared to the α-CPPs pool at the concentration used in the iron bioavailability assays (12.5 μM CPPs).

Cytotoxicity in HuH7 Cells from α-CPPs and β-CPPs Pools. No statistically significant differences were observed ($p > 0.05$) in extracellular LDH, indicating the absence of a cytotoxic effect of the α-CPPs and β-CPPs pools over a CPPs concentration range from 0 to 25 μM (Fe:CPPs ratio 4:1) (Figure 3).

After confirmation of the lack of a cytotoxic effect of the α-CPPs and β-CPPs pools at the assayed concentrations, the concentrations of 12.5 and 50 μM for CPPs and iron, respectively, were chosen for subsequent assays in HuH7 cells.

Ferritin and Soluble Transferrin Receptor Contents. The cell ferritin content and sTfR in supernatants in HuH7 cells are shown in Table 1. Treatment of the HuH7 cells with the pools of α-CPPs and β-CPPs at a concentration of 12.5 μM did not significantly improve ($p > 0.05$) either ferritin or sTfR contents versus control cells, taking into account the pool of CPPs factor (Figure 4a). The results obtained in the calcein assay are unable to justify these latter results, because the β-CPPs pool showed greater iron-binding capacity than the α-CPPs pool over a concentration range from 9.26 to 74.07 μM (Figure 2), a fact that would imply greater ferritin content due to treatment with β-CPPs than with α-CPPs.

Table 1. Ferritin Synthesis and Soluble Receptor Transferrin in HuH7 Cells[a]

sample		ng ferritin/mg protein	ng sTfR/mg protein
without iron	control	0.23 ± 0.03	0.99 ± 0.05
	α-CPPs	0.21 ± 0.02	1.11 ± 0.06
	β-CPPs	0.40 ± 0.13	1.12 ± 0.19
with iron	Fe control	0.66 ± 0.07	0.88 ± 0.18
	Fe-α-CPPs	0.66 ± 0.11	0.97 ± 0.01
	Fe-β-CPPs	0.57 ± 0.11	0.82 ± 0.05

[a]Control Fe, iron as chloride (mean ± standard deviation, $n = 2$ for soluble receptor transferrin (sTfR), and $n = 4$ for ferritin content). α-CPPs and β-CPPs at 12.5 μM and iron at 50 μM.

To our knowledge, no studies have evaluated the influence of CPPs upon iron bioavailability in HuH7 cells. The addition of a pool of CPPs obtained from CN (containing a mixture of both α_s-CN and β-CPPs) to fruit beverages subjected to simulated human gastrointestinal digestion did not increase iron uptake in Caco-2 cells.[19] These results were attributed to a greater proportion of CPPs proceeding from α_s-CN versus the β-CN fraction.[11] Consequently, the efficiency of various CPPs preparations in relation to iron bioavailability depends on their origin and structural properties, as previously reported by other authors. Besides, in Caco-2 cells, iron bound to a mixture of α_s-CN (α_{s1}-CN(59−79)5P and α_{s2}-CN(2−21)4P)[16] or to α_{s1}-CN(59−79)5P[17] decreased iron retention, transport, and uptake versus iron bound to β-CN(1−25)4P and iron gluconate or sulfate. Comparisons between these results and our own observations are difficult to establish, because the above-mentioned studies were performed in Caco-2 cells and the experimental conditions were different. These differences included the iron solution used (gluconate or sulfate versus chloride used in our study), the phosphopeptide concentration (25 versus 12.5 μM), and the use of a specific CPP (β-CN(1−25)4P, α_{s1}-CN(59−79)5P, or a mixture of α_{s1}-CN(59−79)5P and α_{s2}-CN(2−21)4P versus a pool of CPPs obtained from α-

or β-CN, in which 16 or 18 CPPs have been identified, respectively).

The addition of exogenous iron significantly increased ($p > 0.05$) the ferritin content in HuH7 cells, with the iron content factor (samples with or without iron) taken into account (Figure 4b), this being consistent with the results reported by Trinder and Morgan.[23] These authors showed an increase in iron uptake in HuH7 cells after the addition of iron as ferric citrate for 2 h. This iron uptake was also demonstrated to be a saturable process from 1 to 16 μM iron, thus suggesting that it is mediated by an iron carrier.[23] In this context, in HepaRG cells isolated from a human hepatocellular carcinoma, an increase in ferritin content was reported due to the incubation of the cell line for 72 h with iron at 20 μM as ferric chloride.[32]

Treatment with ferric ammonium citrate (10 μg/mL) for 2 or 16 h resulted in a 1.3- or 5.6-fold increase in ferritin content versus the controls in the human hepatoma cell line HepG2.[26] When the same cell line was exposed to a different concentration of ferric ammonium citrate for 24 h, an increase was observed in iron uptake from 20 to 50 μg/mL iron, whereas a decrease was recorded at higher concentrations.[27] This fact was attributed to the capacity of the HepG2 cells to regulate their iron needs with the ability to limit uptake at concentrations >40 μg/mL of iron. However, no change was detected in the expression of ferritin from 20 to 120 μg/mL of iron in the medium under the same conditions.[27]

Concomitantly to the ferritin increase, the addition of exogenous iron was seen to significantly decrease ($p < 0.05$) sTfR in HuH7 cells, taking into account the iron content factor (samples with/without iron) (Figure 4b). These results indicate an inverse relationship between ferritin content and sTfR, in

J. Agric. Food Chem. 2015, 63, 6757−6763

agreement with the observations of other authors[28] and with Iron Regulatory Protein/Iron-Responsive Element regulation. A decrease in the expression of membrane transferrin receptor (TfR) in HuH7 cells was found to result from ferric ammonium citrate addition at 30 μg/mL for 24 h,[25] and in HepG2 cells over a range from 20 to 120 μg/mL during 24 h.[27] Furthermore, in HepaRG cells exposed to 20 μM ferric chloride for 72 h, a decrease in soluble transferrin receptor (TfR) in proliferating cells (assays performed at 4 days from initial seeding) has been reported, whereas the levels remained unchanged in differentiated cells (21 days from initial seeding).[32] These results have been attributed to the very low sTfR levels observed in the differentiated cells, which reflects the detection limit of this parameter under this condition.

On the basis of the ferritin and soluble transferrin receptor contents, used as markers, the treatment of HuH7 cells with iron complexed to phosphopeptides from either α_s-casein or β-casein did not improve iron bioavailability. Compared to already published works involving various CPPs preparations and different cell models, we confirm that the influence of different CPPs upon iron bioavailability depends on their structural properties and on the conformation which the complex can acquire when iron is bound to CPPs. Further research with CPPs proceeding from α_s- and β-CN fractions and purified CPP sequences, containing the sequence SpSpSpEE, such as the β-CN(1−25)4P, for which the positive influence upon iron bioavailability is known, are needed to evaluate their positive effects and compare their influence upon iron bioavailability, with a view to relating their structural properties to their influence upon iron bioavailability. Because no difference was detected, it will be also interesting to test smaller CPPs−iron complexes obtained after in vitro gastrointestinal digestion of CPPs−Fe complexes used in the present work.

Table 1. Accurate Mass Measurements of Pseudo-molecular and Fragment Ions of Seven Standards

compound	t_R (min)	formula	measured mass (Da)	calculated mass (Da)	error (mDa)	MS/MS fragment ions (Da)
echinacoside	3.02	$C_{35}H_{45}O_{20}$	785.2505	785.2504	0.1	623, 477, 461, 315, 179, 161, 153, 135
acteoside	3.78	$C_{29}H_{35}O_{15}$	623.1971	623.1976	−0.5	461, 315, 179, 161, 135
hydroxytyrosol	1.57	$C_8H_9O_3$	153.0562	153.0552	1.0	123
caffeic acid	2.33	$C_9H_7O_4$	179.0344	179.0344	0.0	135
3,4-dihydroxybenzenepropionic acid	2.26	$C_9H_9O_4$	181.0509	181.0501	0.8	137
3-hydroxyphenylpropionic	3.39	$C_9H_9O_3$	165.0560	165.0552	0.8	121
3-phenylpropionic acid	5.71	$C_9H_9O_2$	149.0612	149.0603	0.9	105

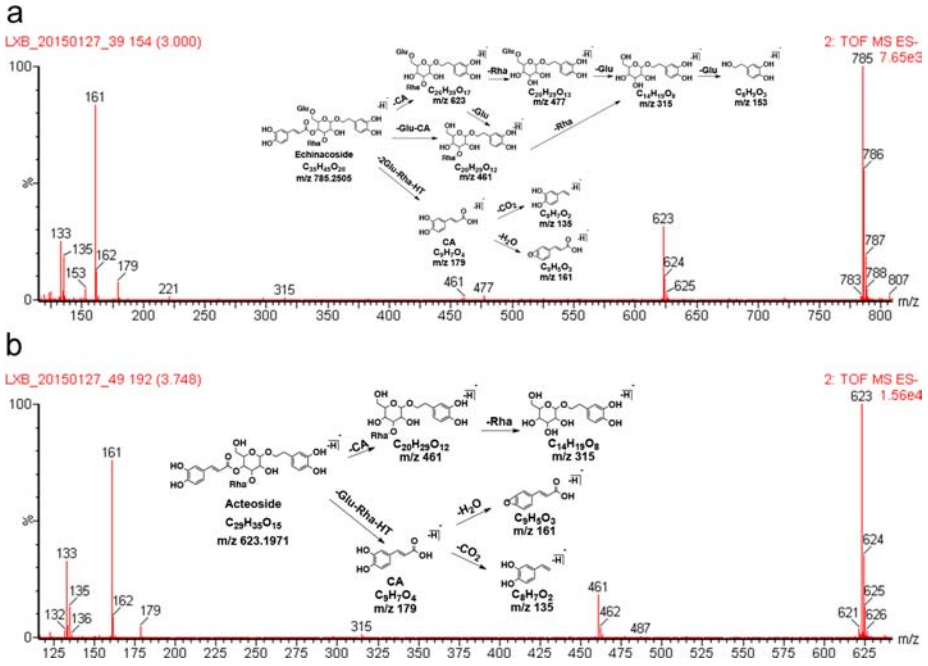

Figure 1. UPLC-MS/MS spectra and proposed fragmentation pathways of echinacoside (a) and acteoside (b).

Echinacoside was kindly provided by Dr. Pengfei Tu's laboratory from Peking University (Beijing, China). Acteoside was purchased from Sichuan Weikeqi Biological Technology Co., Ltd. (Chengdu, China). Hydroxytyrosol (HT), caffeic acid (CA), 3,4-dihydroxybenzenepropionic acid, 3-hydroxyphenylpropionic acid (3-HPP), and 3-phenylpropionic acid were purchased from Aladdin Industrial Inc. (Shanghai, China). The purity of each compound was determined to be >95% by HPLC-UV.

Stability Study of ECH in Simulated Gastric Juice and Intestinal Juice. One milligram of ECH was placed in 10 mL of simulated gastric juice (0.08 M HCl containing 50 mg of pepsin, pH 1.5) and incubated at 37 °C for 0, 1, 2, or 4 h, respectively. The reactions were quenched by water-saturated *n*-butanol immediately. The mixture was centrifuged at 4800 rpm for 20 min, and then the supernatant was evaporated. The residue was dissolved in 0.5 mL of methanol and centrifuged at 12000 rpm for 10 min at 4 °C, and the supernatant was analyzed by HPLC.

One milligram of ECH was placed in 10 mL of simulated intestinal juice (0.05 M KH_2PO_4 containing 50 mg of pancreatin, pH 6.8) and incubated at 37 °C for 0, 2, 4, or 6 h, respectively. The sample processing was the same as that for ECH in simulated gastric juice.

HPLC Analysis. The HPLC system (Agilent 1200, USA) consisted of a multisolvent delivery pump equipped with a quaternary solvent delivery system, an autosampler, and a DAD detector, which was used to analyze the stability of ECH in simulated gastric juice and intestinal juice. A ZORBAX Eclipse XDB-C18 column (250 mm × 4.6 mm i.d., 5 μm, Agilent Ltd., USA) was used. The chromatographic condition was acetonitrile (A) and water (B) with gradient elution, 0−30 min (A, 10−30%) and 30−35 min (A, 30−100%). UV absorption was monitored at 330 nm. The column temperature was set at 35 °C. The flow rate was 1.0 mL/min, and the sample injection volume was 10 μL.

Metabolism Study of ECH by Human Intestinal Bacteria. Fresh human fecal samples were obtained from six healthy volunteers (three males and three females, 22−50 years of age) who had no history of gastrointestinal disorders or antibiotics usage for at least 3 months prior to the study. The fresh fecal samples were mixed and immediately homogenized with 25 times volume of GAM broth. The sediments were removed by filtration through three pieces of gauze. The suspension was incubated at 37 °C in an anaerobic incubator in which the air had been replaced by a gas mixture (H_2 5%, CO_2 10%, N_2 85%). Three milligrams of ECH was placed in 10 mL of human fecal suspension, and the suspension was incubated at 37 °C for 48 h. The cultured mixture was removed and extracted with water-saturated *n*-butanol at time points of 1, 3, 6, 9, 12, 24, and 48 h. The mixture was centrifuged at 4800 rpm for 20 min, and the supernatant was then evaporated. The residue was dissolved in 0.5 mL of methanol and centrifuged at 12000 rpm for 10 min at 4 °C, and the supernatant was analyzed by UPLC-Q-TOF-MS.

UPLC-MS Analysis. UPLC-Q-TOF-MS analysis was performed on a Waters ACQUITY UPLC system (Waters Corp., Milford, MA, USA) using an ACQUITY UPLC BEH C18 column (100 mm × 2.1 mm i.d., 1.7 μm, Waters Corp., USA) by gradient elution using acetonitrile (A) and water (B) at a flow rate of 0.4 mL/min. The gradient profile was 0−3 min (A, 5−20%), 3−6 min (A, 20−30%), 6−9 min (A, 30−70%), and 9−10.5 min (A, 70−99%), then held for 2 min. The gradient was recycled back to 5% in 2.5 min for the next run. The injection volume was 3 μL. The temperature of the column oven was set to 35 °C.

M13	5.72	149.0623	2.0	$C_9H_9O_2$	105	3-phenylpropionic acid

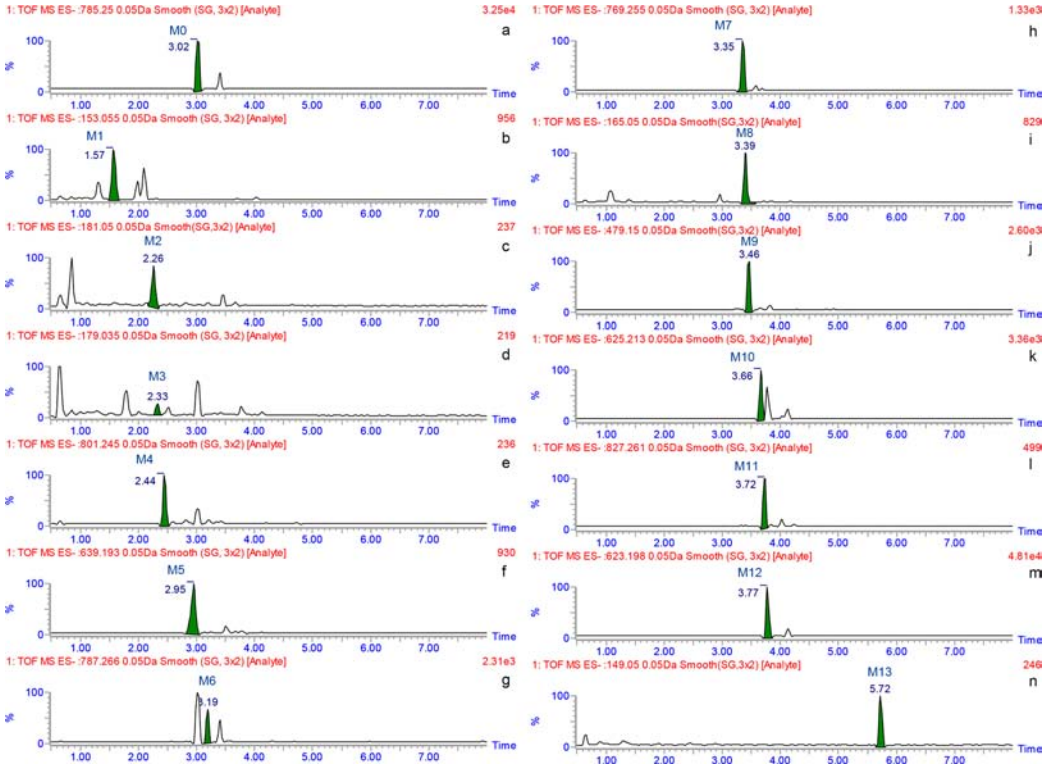

Figure 2. UPLC-MS extracted ion chromatograms (XICs) of echinacoside and its metabolites: (a) **M0**; (b) **M1**; (c) **M2**; (d) **M3**; (e) **M4**; (f) **M5**; (g) **M6**; (h) **M7**; (i) **M8**; (j) **M9**; (k) **M10**; (l) **M11**; (m) **M12**; (n) **M13**.

Mass spectrometry was carried out using a Waters Synapt mass spectrometer (Waters Corp., Milford, MA, USA). Ionization was performed in the negative electrospray (ESI) mode. The MS parameters were as follows: capillary voltage, 2.8 kV; cone voltage, 35 V; source temperature, 115 °C; desolvation temperature, 350 °C; gas flows of cone and desolvation, 50 and 700 L/h, respectively. For accurate mass measurement, leucine-enkephalin was used as the lock mass. The MS^E experiment in two scan functions was carried out as follows: function 1 (low energy), m/z 50−1000, 0.25 s scan time, 0.02 s interscan delay, 4 eV collision energy; function 2 (high energy), m/z 50−1000, 0.25 s scan time, 0.02 s interscan delay, collision energy ramp of 55−70 eV. The data were processed using MassLynx 4.1 software (Waters Corp.).

Data Analysis. Data analysis was performed using MetaboLynx software (Waters Corp.) that employs an expected list of potential biotransformation reactions such as deglycosylation, dehydroxylation, and acetylation. This software automates the detection and identification of metabolites by comparing the sample with the control to eliminate the interfering peaks in the sample that also appear in the control. The mass defect filter was set as 25 mDa. Results were filtered on the basis of the mass fractional deviation from the parent compound and the expected metabolites of the parent compound. The mass window of 0.05 Da was set for both expected and unexpected metabolite mass chromatograms. Apex track peak integration was used for peak detection, and the response threshold of the absolute peak height was set to 20 units.

RESULTS

Stability of ECH in Simulated Gastric Juice and Intestinal Juice. ECH was found to be stable in simulated gastric juice and intestinal juice. After incubation with artificial

DOI: 10.1021/acs.jafc.5b02881
J. Agric. Food Chem. 2015, 63, 6764−6771

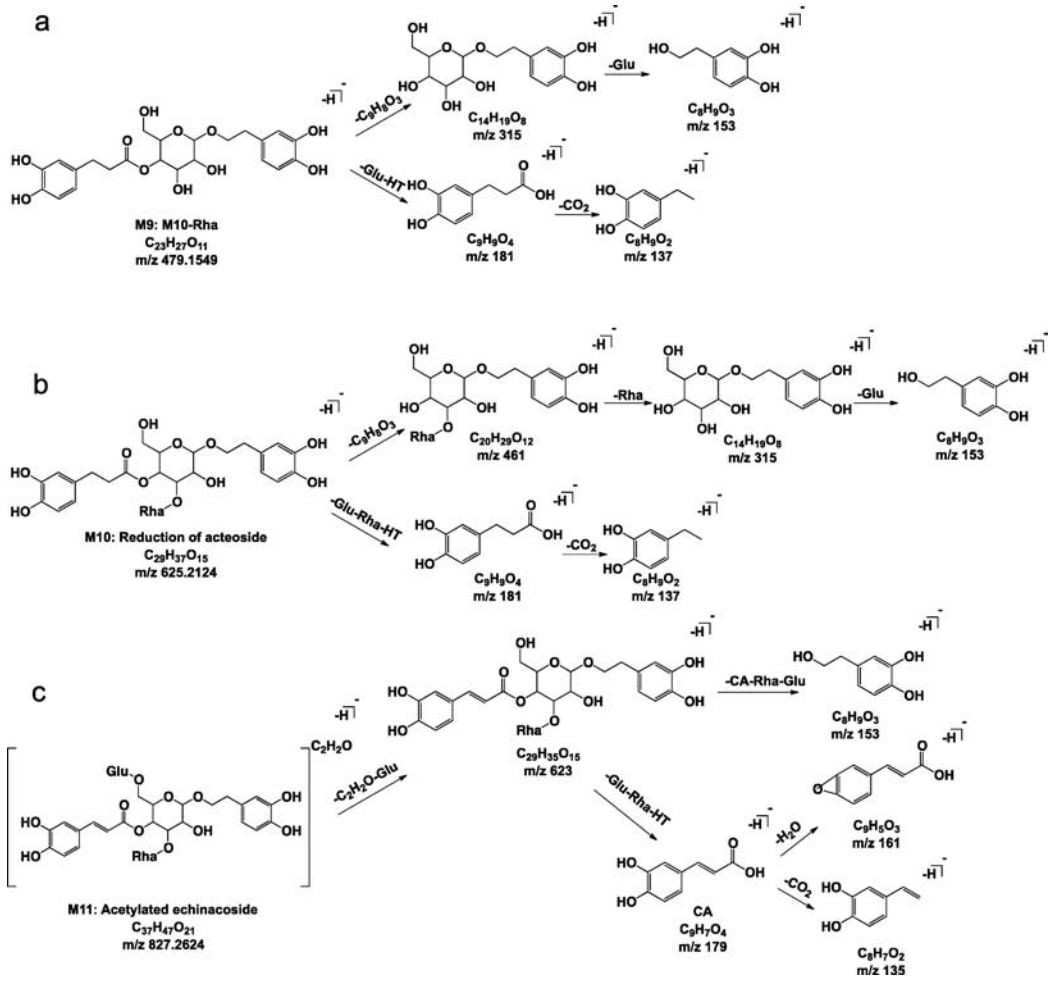

Figure 3. Proposed fragmentation pathways: (a) **M9** (m/z 479); (b) **M10** (m/z 625); (c) **M11** (m/z 827).

juices, the content of ECH did not change significantly over time according to the peak areas during the course of incubation (RSD < 3.0%).

Fragmentation Studies. Solutions of ECH, acteoside, HT, CA, 3,4-dihydroxybenzenepropionic acid, 3-HPP, and 3-phenylpropionic acid prepared in methanol were used for the fragmentation pattern study to support metabolite characterizations. The above seven standard compounds were eluted at 3.02 min (ECH), 3.78 min (acteoside), 1.57 min (HT), 2.33 min (CA), 2.26 min (3,4-dihydroxybenzenepropionic acid), 3.39 min (3-HPP), and 5.71 min (3-phenylpropionic acid), respectively (Table 1).

The fragmentation patterns of ECH and acteoside were described as followed. As shown in Figure 1a, ECH (m/z 785.2505) produced a fragment at m/z 623 by loss of a CA moiety, and then the sequential losses of rhamnose (Rha), glucose (Glu), and Glu moieties yielded the respective fragment ions at m/z 477, 315, and 153. The fragment at m/z 461 was generated through the loss of Glu and CA moieties from the precursor ion. The product ion at m/z 179, which was one of the major fragments, corresponded to the CA moiety and then produced ions at m/z 135 and 161 by the further loss of CO_2 and H_2O, respectively. Acteoside (m/z 623.1971) displayed a similar fragmentation pattern in the spectrum of ECH (Figure 1b). It produced the fragment ion at m/z 461 by losing the CA moiety and then produced the ion at m/z 315 by the further loss of a Rha moiety. The CA moiety was also found at m/z 179 that produced ions at m/z 135 and 161 by the loss of CO_2 and H_2O, respectively. HT (m/z 153.0562) produced a fragment at m/z 123, which was probably through the loss of a CH_2O moiety. Similarly, CA (m/z 179.0344) yielded a product ion at m/z 135 by the loss of CO_2. 3,4-Dihydroxybenzenepropionic acid (m/z 181.0509) produced the ion at m/z 137 by the loss of CO_2. CO_2 was lost from 3-HPP (m/z 165.0560) to form the ion at m/z 121. 3-Phenylpropionic acid (m/z 149.0612) produced m/z 105 by the loss of CO_2 as well.

Identification of ECH Metabolites by Human Intestinal Bacteria. Compared with the blank sample, the parent compound ECH (**M0**) and its 13 metabolites (**M1**−**M13**), including the metabolites of parent compound (**M4**−**M7**, **M9**−**M12**) and degradation products (**M1**−**M3**, **M8**, **M13**), were identified in human intestinal bacteria samples. Detailed information on these metabolites is listed in Table 2. Deglycosylation, dehydroxylation, reduction, hydroxylation, and acetylation were considered as the main metabolic pathways for the parent compound.

The extracted ion chromatograms (XICs) of the parent compound (**M0**) and its metabolites (**M1**−**M13**) from the total UPLC-MS chromatograms are shown in Figure 2. In addition, **M9**, **M10**, and **M11** were selected as the representative metabolites, and their proposed fragmentation pathways are shown in Figure 3.

Parent Compound (M0). ECH (**M0**) was identified by comparing the UPLC retention time (3.02 min), accurate MS

DOI: 10.1021/acs.jafc.5b02881
J. Agric. Food Chem. 2015, 63, 6764−6771

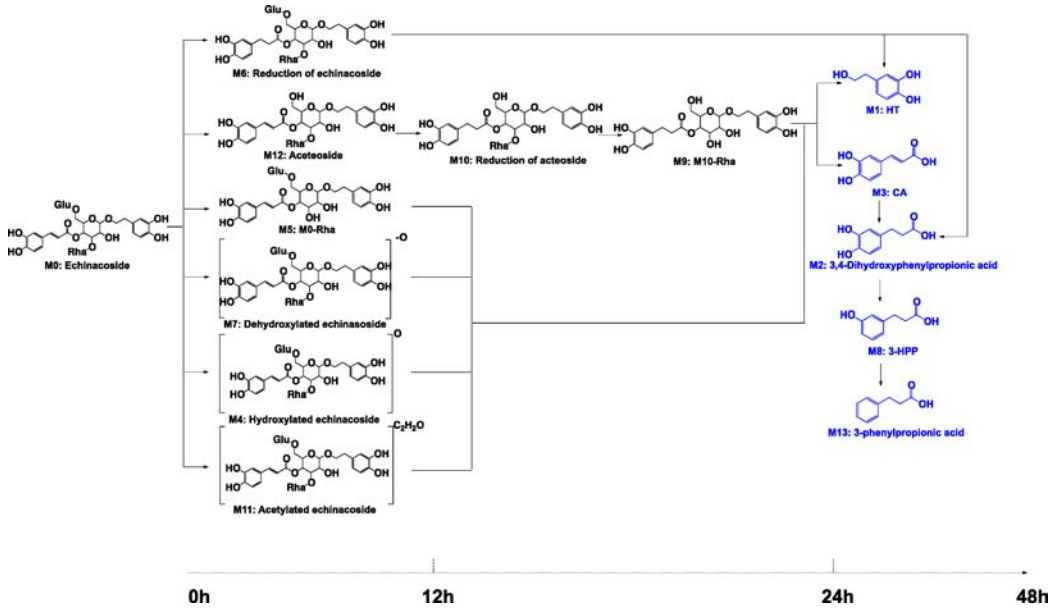

Figure 4. Proposed metabolic pathways of echinacoside by human intestinal bacteria.

at m/z 785.2482, and MS/MS spectra with those of the authentic reference standard. Characteristic product ions at m/z 623, 477, 461, 315, 179, 161, 153, and 135 were also found in the MS^2 fragmentation.

Metabolites of Parent Compound (M4−M7, M9−M12). In this study, the direct metabolites of parent compound were identified by the distinctive fragmentations when compared with the parent compound.

M12 (m/z 623.1945, $C_{29}H_{35}O_{15}$, 3.77 min), a loss of Glu (162 Da) from ECH (**M0**), was identified as acteoside through comparison of the UPLC retention time, accurate MS, and MS/MS spectra with the authentic reference standard. **M10** (m/z 625.2124, $C_{29}H_{37}O_{15}$, 3.66 min) was 2 Da (2H) higher than **M12**, which indicated that **M10** was the reduced product of **M12**. In the MS/MS spectrum of this metabolite, the presence of a diagnostic fragment ion at m/z 181 implied that reduction occurred on the α',β'-double bond of the CA moiety. Additionally, other fragment ions from **M10** were consistent with the product ions of **M12**. The previous study on caffeic acid metabolism by bacteria from the human gastrointestinal tract indicated that CA could be reduced to dihydro-CA by human intestinal bacteria,[19,20] which implied this reduction route might occur in the metabolic process of phenylethanoid glycoside and caffeoyl-containing compound. **M9** (m/z 479.1549, $C_{23}H_{27}O_{11}$, 3.46 min) was 146 Da (Rha) lower than **M10** in molecular weight and was considered as the de-Rha product of **M10**. **M9** produced signals at m/z 315, 181, 153, and 137, which were similar to the generated ions of **M10**. The proposed fragmentation pathways of **M9** and **M10** are shown in Figure 3.

M4 (m/z 801.2433, $C_{35}H_{45}O_{21}$, 2.44 min), a hydroxylated product of ECH, was 16 Da (O) higher than ECH in molecular weight. The characteristic product ion at m/z 783 was generated by a H_2O loss from the quasi-molecular ion. Moreover, caffeic acid related fragment ions were found at m/z 179, 161, and 135, which were the same as the fragment ions of ECH (**M0**), suggesting that the hydroxylation position was not on the CA moiety. A previous study proposed that the hydroxylation is more likely to occur on the HT moiety to form a benzenetriol structure.[21]

M5 (m/z 639.1900, $C_{29}H_{35}O_{16}$, 2.95 min) was 146 Da (Rha) lower than ECH (**M0**) in molecular weight and was identified as the de-Rha product of **M0**. The characteristic product ion at m/z 477 was shaped by the elimination of CA moiety (162 Da). The CA moiety was also found at m/z 179 and produced the ion at m/z 135 through the loss of CO_2.

M6 (m/z 787.2650, $C_{35}H_{47}O_{20}$, 3.19 min) was 2 Da (2H) higher than **M0** in molecular weight, which indicated that **M6** was the reduced product of **M0**. The characteristic fragments produced by **M6** at m/z 623, 181, and 153, were similar to those of **M10**. These results suggested that **M6** was generated by the reduction of ECH, which occurred on the α',β'-double bond of the CA moiety.

M7 (m/z 769.2546, $C_{35}H_{45}O_{19}$, 3.35 min) was 16 Da (O) lower than the protonated ion of ECH, which indicated that it was a metabolite of ECH after the loss of oxygen. In the MS/MS spectrum of **M7**, fragment ions associated with CA were found at m/z 179, 161, and 135. Therefore, the dehydroxylated site of **M7** was not at the CA moiety. However, the exact dehydroxylated site of **M7** could not be confirmed due to the limited information obtained in our study.

M11 (m/z 827.2624, $C_{37}H_{47}O_{21}$, 3.72 min) was 42 Da (C_2H_2O) higher than the protonated ion of ECH, suggesting a possible conjugation of an acetyl group on ECH. In addition, the characteristic MS/MS fragment ions of **M11** at m/z 623, 179, 161, 153, and 135 were observed. The proposed fragmentation pathways of **M11** are shown in Figure 3c. According to the previous research, the C-2′ position might be one of the acetyl conjugation sites of **M11**.[20]

Metabolites of Degradation Products (M1−M3, M8, M13). In this study, five degradation metabolites were identified using the authentic reference standard. ECH first degraded to HT (**M1**) and CA (**M3**), and CA underwent further metabolism to its major microbial metabolite, 3-HPP (**M8**).

M1 (m/z 153.0567, $C_8H_9O_3$, 1.57 min), **M2** (m/z 181.0505, $C_9H_9O_4$, 2.26 min), **M3** (m/z 179.0372, $C_9H_7O_4$, 2.33 min), **M8** (m/z 165.0563, $C_9H_9O_3$, 3.39 min), and **M13** (m/z 149.0623, $C_9H_9O_2$, 5.72 min) were identified as HT, 3,4-dihydroxyphenylpropionic acid, CA, 3-HPP, and 3-phenyl-

propionic acid, respectively, after analysis of the UPLC retention time, accurate MS, and MS/MS spectra of the authentic reference standards.

Analysis of the Metabolic Pathways of ECH by Human Intestinal Bacteria. According to the results of our experiment, the proposed metabolic pathways of ECH by human intestinal bacteria are displayed in Figure 4. After incubation with human intestinal bacteria, ECH was metabolized to **M4**, **M5**, **M6**, **M7**, **M11**, and **M12**. Additionally, **M12** was metabolized to **M10** and **M9** sequentially. After the degradation metabolites **M1** and **M3** emerged, **M3** was further metabolized to **M2**, **M8**, and **M13**.

Analysis of Relative Content of Metabolites by Human Intestinal Bacteria. The relative contents of parent compound ECH (**M0**) and its metabolites (**M1**−**M13**) by human intestinal bacteria were determined at 1, 3, 6, 9, 12, 24, and 48 h, respectively, by the percentage of each metabolite peak area accounted for in the total peak area of the determined metabolites (Table 3). According to our experimental results, ECH (**M0**) was metabolized to 50% in 24 h and was completely metabolized after 48 h. The major metabolites in the first 12 h were **M4**, **M5**, **M6**, **M7**, and **M11**, which decreased significantly from 24 h until the complete disappearance. Metabolites **M9**, **M10**, and **M12** generated the maximum level of their relative contents at 24 h, which then declined significantly afterward. The results above indicated that metabolites **M4**−**M7** and **M9**−**M12** were the intermediates of ECH metabolism by human intestinal bacteria, which were also susceptible to further metabolism. In contrast, the relative contents of metabolites **M1**, **M2**, **M3**, **M8**, and **M13**, especially **M1** and **M8**, were increased remarkably at 48 h. Therefore, these metabolites might be assumed to be the bioactive constituents of ECH that were formed before being absorbed into the blood.

DISCUSSION

In this study, we established an approach to analyze the metabolites of ECH produced by human intestinal bacteria and studied the relevant metabolic pathways. The combination of UPLC-Q-TOF-MS, MS^E technology, and MetaboLynx software was used to determine the metabolic profile and to detect the metabolites of ECH. Both precursor and fragment ions could be simultaneously obtained from a single analytical run through the application of the highly selective MS^E technique,[18] which provides a great advantage for the rapid investigation of multiple structures. MetaboLynx is an automated software[22,23] that can detect trace level of metabolites from biological samples and is a powerful tool for metabolic characterization.

Previous research found that the poor membrane permeability and the extensive presystemic metabolism of ECH might be the cause of its low oral bioavailability in rats.[21,24,25] Therefore, it is not surprising that the presence of bacteria and acidic/alkaline conditions in gastrointestinal ducts could initiate the hydrolysis of ECH. However, these previous studies did not provide detailed information about the metabolism of ECH in gastrointestinal ducts. Thus, we assessed whether gastric juice, intestinal juice, or intestinal microorganisms of gastrointestinal system could metabolize ECH. In our study, ECH was found to be stable in simulated gastric juice and intestinal juice, whereas it could be metabolized to HT and 3-HPP by intestinal bacteria. 3-HPP has been reported as a major microbial metabolite of CA by human intestinal bacteria in vitro,[26,27] which is in agreement with our findings. Additionally, reported evidence has shown that HT and 3-HPP possess bioactivities such as antioxidant,[28,29] neuroprotective,[30,31] and anti-inflammatory functions.[32,33] Therefore, we conclude that ECH acts as a prodrug that is transformed to bioactive compounds (HT and 3-HPP) by intestinal bacteria after oral administration, and the released compounds then exert biological activities.

In conclusion, a highly selective and sensitive approach using MS^E and MetaboLynx combined UPLC-Q-TOF-MS was applied to the screening and identification of ECH metabolites produced by human intestinal bacteria in vitro. Among the 13 metabolites (**M1**−**M13**) identified in this study, **M5**, **M6**, and **M11** have not been previously reported to our knowledge. Deglycosylation, dehydroxylation, reduction, hydroxylation, and acetylation were the five possible metabolic pathways that led to the generation of these metabolites. The observation of human intestinal bacteria produced HT and 3-HPP, which possess biological functions similar to those of ECH, could potentially explain the fact that ECH has prominent bioactivity but poor bioavailability. This study further explored the role of intestinal bacteria in the metabolism of natural products and improved the current understanding of ECH metabolism.

analyzed the expression of genes involved in the biosynthetic pathways of phenolic compounds during different light irradiations and investigated the distribution of the compounds in the various organs of adult plants. Chinese cabbage is an important source of beneficial nutrients, such as carotenoids, fibers, vitamins, minerals, glucosinolates (GSLs), and phenolics, and it is widely consumed in East Asia and, in particular, in Korea, where both the adult and sprouting plant parts are an important ingredient of kimchi and salad. Our results in this study provide useful information for improving the nutritional quality of Chinese cabbage as well as for improving horticultural practice.

MATERIALS AND METHODS

Plant Materials. Chinese cabbage (*B. rapa* ssp. *pekinensis* var. 'Bulam No. 3') was grown under field conditions at the experimental farm of the National Institute of Horticultural and Herbal Science, Rural Development Administration (Suwon, Korea). Different organs (flowers, stems, leaves, and roots) were separately harvested from at least than five 85-day-old field-grown plants. For white, blue, and red LED light irradiation, germinated seeds were sown onto vermiculate and cultivated in a growth chamber at 25 °C under a 16 h photoperiod with different LED light irradiation (380 nm for white, 470 nm for blue, and 660 nm for red) over a 12-day period. Whole seedlings were harvested at 6, 9, and 12 days after irradiation (DAI). All samples were immediately frozen in liquid nitrogen and then stored at −80 °C and/or freeze-dried for RNA isolation and/or high-performance liquid chromatography−ultraviolet (HPLC-UV) analysis. Whole cultivations and irradiations were repeated three times, and the samples from each set of cultures were used for biological repeats.

Identification of Phenylpropanoid Biosynthesis-Related Genes in Chinese Cabbage. Phenylpropanoid biosynthetic genes of *Arabidopsis thaliana* were searched and downloaded from The *Arabidopsis* Information Resource (TAIR) database.[12] The collected genes were subjected to a TBLASTX search against the genome of the *B. rapa* line Chiifu-401,[13] which was downloaded from the *Brassica* database (BRAD) to identify their homologues in the *B. rapa* genome. Only resultant sequences with *e* values <0 and identities >85% were considered as potentially orthologous, and among these we selected for further use only the ones that had the highest identities with each phenylpropanoid biosynthetic gene of *Arabidopsis*. A total of 11 Chinese cabbage phenylpropanoid biosynthetic genes were selected, and gene-specific primers for the 11 genes were designed with GenScript Real-Time PCR (TaqMan) Primer Design (https://www.genscript.com/ssl-bin/app/primer) software and used for quantitative real-time polymerase chain reaction (qRT-PCR) analysis. The accession numbers of the genes and primer sets used in this study are listed in Table 1.

Total RNA Extraction and Quantitative Real Time-PCR. Total RNA was isolated by an Easy BLUE Total RNA Kit (iNtRON, Seongnam, Korea). The quantity of RNA was measured on a NanoVue Plus spectrophotometer (GE Healthcare Life Sciences), and its quality was confirmed by running 1 μg of the RNA on 1.2% formaldehyde RNA agarose gel. Then, 1 μg of total RNA was reverse-transcribed by a ReverTra Ace-α Kit (Toyobo) and oligo $(dT)_{20}$ primers, according to the manufacturer's protocol. The cDNA was diluted 20-fold for qRT-PCR. qRT-PCR was performed in a 20-μL reaction volume containing 0.5 μM primers and 2× Real-Time PCR Smart mix (SolGent; Daejeon, Korea). The qRT-PCR program was as follows: initial denaturation at 95 °C for 15 min followed by 40 cycles of denaturation at 95 °C for 20 s, annealing at 55 °C for 40 s, and extension at 72 °C for 20 s. The qRT-PCR results were obtained as the mean of three replicates. *BrEF-1-α* (GO479260) was used as a reference gene because it was previously determined to be the most suitable reference gene among several Chinese cabbage genes.[14]

Extraction and Analysis of Phenylpropanoids in Chinese Cabbage. HPLC-UV analysis of the phenylpropanoids was carried out according to previously described methods with some modification.[15] Samples were freeze-dried and ground into a fine powder. A total of 100 mg of sample was transferred to 6 mL of 62.5% methanol containing 2 g/L *tert*-butylhydroquinone as an antioxidant. To hydrolyze, 1.5 mL of 6 N HCl was then added and incubated at 90 °C for 2 h. After centrifugation at 1000*g* for 5 min, the supernatant was passed through a 0.22 μm PTFE syringe filter prior to HPLC. External standards were purchased from Extrasynthese (Genay, France). MeOH and HCl were purchased from Wako Pure Chemical Industries (Osaka, Japan) and Sigma-Aldrich Co., Ltd. (St. Louis, MO, USA), respectively. The extract was diluted 2-fold with MeOH prior to HPLC-UV analysis. Samples were identified using a Futecs model NS-4000 HPLC apparatus (Daejeon, Korea) with an UV−vis detector and autosampler. The analysis was monitored at 280 nm and performed using a C18 column (250 × 4.6 mm, 5 μm; RStech; Daejeon, Korea). The mobile phase consisted of a mixture of (A) MeOH/water/acetic acid (5:92.5:2.5, v/v/v) and (B) MeOH/water/acetic acid (95:2.5:2.5, v/v/v), as described previously.[16] The initial mobile phase composition was 0% solvent B, followed by a linear gradient from 0 to 80% of solvent B in 48 min, then holding at 0% solvent B for an additional 10 min; the column was then maintained at 30 °C. The flow rate was set at 1.0 mL min^{-1}, and the injection volume was 20 μL. Quantification of the different compounds was based on peak areas and calculated as the equivalents of representative standard compounds. All contents are expressed as micrograms per milligram DW and were analyzed by ANOVA and Tukey's post hoc test using R software (ver. 3.1.0).

RESULTS AND DISCUSSION

Expression of Phenylpropanoid Biosynthetic Genes in Chinese Cabbage Irradiated with White, Blue, and Red Lights. The biosynthetic pathways for the phenolic compounds and genes responsible for those biosyntheses analyzed in this study are illustrated in Figure 1. The transcripts of the phenylpropanoid biosynthetic genes of *B. rapa* ssp. *pekinensis* were investigated by qRT-PCR in the whole seedlings of Chinese cabbage at 6, 9, and 12 DAI with white, blue, and red LED lights (Figure 2). Under white light, the expression levels of *BrDFR* noticeably increased at 9 DAI, whereas those of

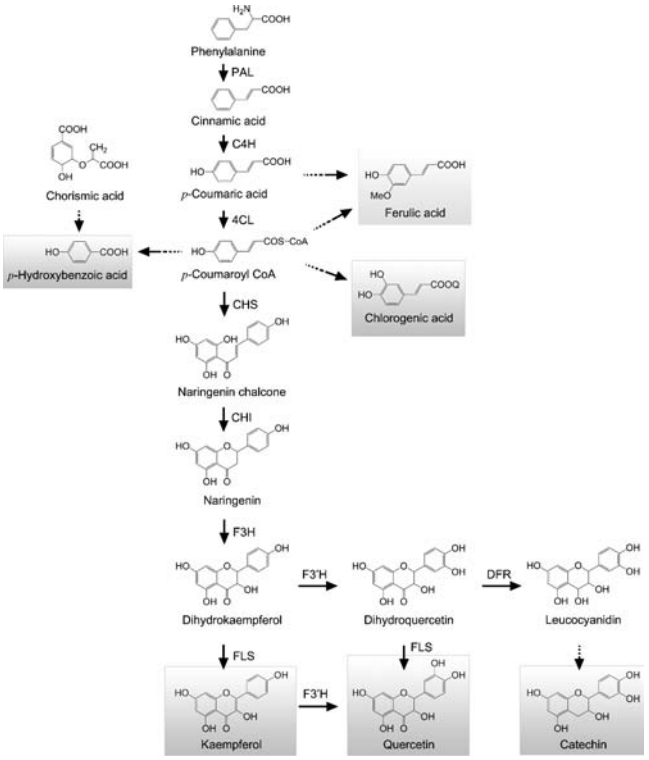

Figure 1. Proposed phenylpropanoid biosynthetic pathway in Chinese cabbage. PAL, phenylalanine ammonia-lyase; C4H, cinnamate 4-hydroxylase; 4CL, 4-coumaroyl CoA ligase; CHS, chalcone synthase; CHI, chalcone isomerase; F3H, flavanone 3-hydroxylase; F3′H, flavonoid 3′-hydroxylase; FLS, flavonol synthase; DFR, dihydroflavonol-4 reductase. The shaded boxes indicate the compounds analyzed in this study. The dashed arrow indicates the process catalyzed by unidentified enzymes in the Brassicaceae family.

BrPAL, *Br4CL1*, *Br4CL3*, *BrCHS*, *BrCHI*, *BrF3H*, *BrF3′H*, and *BrFLS* declined after peaking at 9 DAI. The expressions of *BrC4H* and *Br4CL2* did not significantly change during white light irradiation. Compared to white light, blue light had a more noticeable effect on the change in the expression patterns of phenylpropanoid biosynthetic genes. The transcript levels of *BrF3H*, *BrF3′H*, *BrFLS*, and *BrDFR* dramatically increased at 12 DAI. In particular, the expressions of *BrF3′H* and *BrFLS* peaked when compared with the white and red light treatments. Red light caused the expression of many phenylpropanoid genes to increase, including *Br4CL2*, *Br4CL3*,*BrCHS*, *BrCHI*, *BrF3H*, and *BrFLS* at 6 DAI. However, red light had no effect on the expression of *BrPAL*, *BrC4H*, *BrF3′H*, and *BrDFR* during irradiation. The transcript level of *Br4CL1* was noticeably up-regulated by red light at 12 DAI, unlike other genes, implying that the machinery for the transcription of *Br4CL1* might be regulated differently from other genes. Our results on the expressions of phenylpropanoid biosynthetic genes showed difference with results in similar studies with different crops. For example, similar light irradiation in buckwheat resulted in gradually reduced expression of most orthologous genes after 2 days of all LED light irradiation.[10] Basil leaves grown over yellow and green plastic mulches had higher phenolics content than those grown over white and blue covers.[17] Along with our study, these results indicate crops have diverse responses to light irradiation in terms of phenylpropanoid biosynthesis.

Accumulation of Phenylpropanoids in Chinese Cabbage Irradiated with White, Blue, and Red Lights. Previous studies have reported that abundant flavonol aglycones in Chinese cabbage pak choi (*B. rapa* L. ssp. *chinensis* L. (Hanelt.)) included quercetin, kaempferol, and isorhamnetin, as found for other species in the Brassicaceae family.[18] Studies analyzing hydroxycinnamic acid derivatives in various cultivars of pak choi demonstrated that phenolic

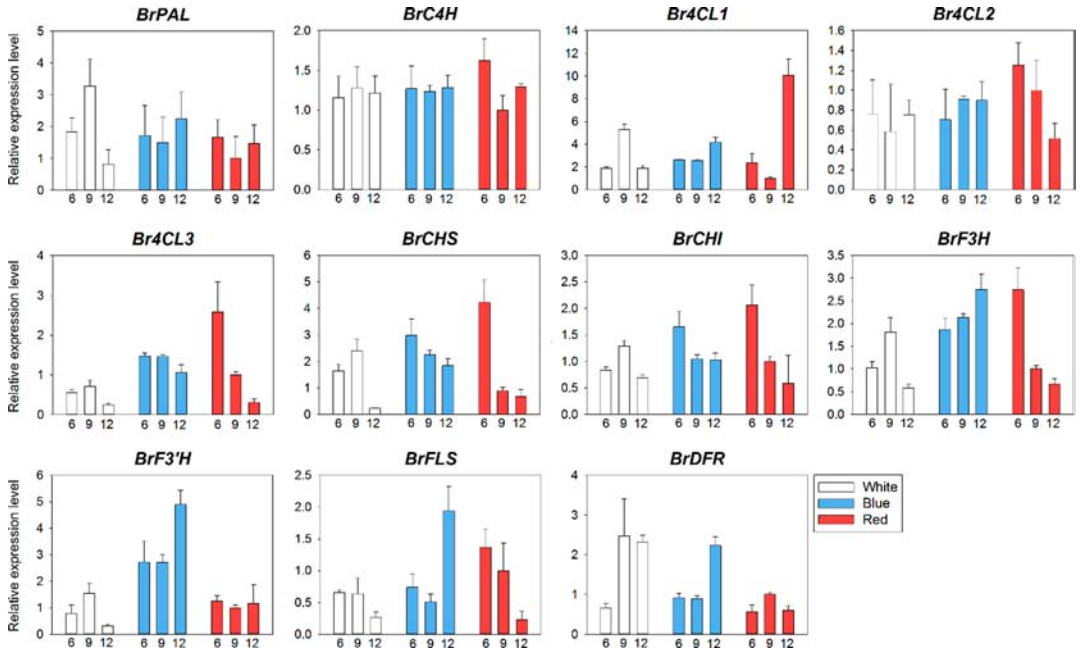

Figure 2. Expression levels of phenylpropanoid biosynthetic genes in the seedlings of Chinese cabbage irradiated with white, blue, and red LED lights. Total RNA was extracted from whole seedlings sampled at 6, 9, and 12 days after irradiation and used for qRT-PCR analysis. The relative expression ratio of transcripts was shown to be calibrated with expression of *BrEF-1-α*. The height of each bar and the error bars indicate the mean and standard error, respectively, from three independent measurements.

[a]Whole seedlings were sampled at 6, 9, and 12 days after irradiation and used for HPLC-UV analysis. The means and standard deviations were obtained from three independent experiments. Letters a–c indicate significant differences ($P < 0.05$).

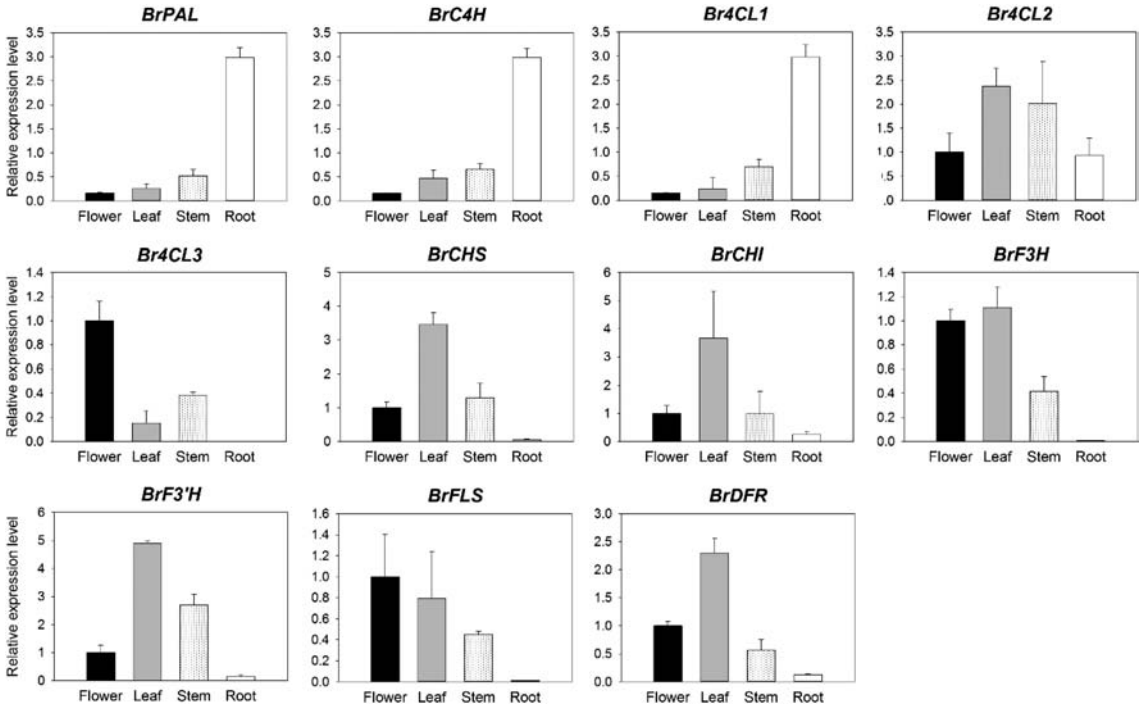

Figure 3. Expression profiles of phenylpropanoid biosynthetic genes in different organs of adult Chinese cabbage plants. Total RNA was extracted from the flowers, leaves, stems, and roots of 85-day-old plants and used for qRT-PCR analysis. The relative expression ratio of the transcripts was shown to be calibrated with expression of *BrEF-1-α*. The height of each bar and the error bars indicate the mean and standard error, respectively, from three independent measurements.

compounds, including chlorogenic acid, are also present in Chinese cabbage.[19] In our HPLC-UV analysis, *p*-hydroxybenzoic acid, ferulic acid, chlorogenic acid, quercetin, and kaempferol were detected in the seedlings of Chinese cabbage (Table 2). The phenolics found at the highest quantities were *p*-hydroxybenzoic acid (up to 49.06 ± 2.15 $\mu g\ g^{-1}$), followed by cholorogenic acid.

The effects of light irradiation on the accumulation of phenolic compounds appeared to differ with different light conditions. White light irradiation led to the accumulation of kaempferol (up to 7.71 ± 1.23 $\mu g\ g^{-1}$) and the reduction of *p*-hydroxybenzoic acid and quercetin content. Chlorogenic acid content remained unchanged during white light irradiation. Blue light led to the accumulation of all detected phenolic compounds at 6 DAI. In particular, *p*-hydroxybenzoic acid content was noticeably raised (up to 49.06 ± 2.15 $\mu g\ g^{-1}$) under blue light irradiation compared to other light conditions. In addition, quercetin and kaempferol content increased by >4-fold (up to 4.8 ± 0.59 and 7.48 ± 0.91 $\mu g\ g^{-1}$, respectively). Ferulic acid content increased by roughly 2-fold (up to 10.6 ± 2.01 $\mu g\ g^{-1}$) during blue light irradiation. The maximum *p*-hydroxybenzoic acid, ferulic acid, and quercetin content was obtained by blue light irradiation at 12 DAI, at which time the chlorogenic acid, benzoic acid, and quercetin contents almost reached their highest levels. This highest accumulation of phenylpropanoids by blue light irradiation coincided with the increased expression of *BrF3H*, *BrF3′H*, *BrFLS*, and *BrDFR* during irradiation. On the other hand, red light irradiation had a noticeable effect on ferulic acid accumulation. Ferulic acid content increased by about 2.7-fold to its highest level (19.52 ± 1.47 $\mu g\ g^{-1}$) under red light irradiation. Quercetin and kaempferol content only slightly increased. *Br4CL2*, *Br4CL3*,

quercetin	339.19 ± 18.87 b	15.13 ± 5.74 a	0 ± 0 a	0 ± 0 a
kaempferol	678.57 ± 3.05 c	0 ± 0 a	0 ± 0 a	26.21 ± 4.53 b
catechin	0 ± 0 d	46.64 ± 0.83 a	18.23 ± 1.18 c	8.67 ± 1.1 b

[a]The flowers, leaves, stems, and roots were collected from more than three 85-day-old plants and used for HPLC-UV analysis. The means and standard deviations were obtained from three independent experiments. Letters a–c indicate significant differences among organs ($P < 0.05$).

BrCHS, *BrCHI*, *BrF3H*, and *BrFLS* were highly expressed at initial stage during red light irradiation, but this did not lead to high accumulation of quercetin and kaempferol. Under all light conditions, chlorogenic acid content remained unchanged.

When combined with the gene expression results of this study, this finding indicates that blue light may induce the phenylpropanoid biosynthetic pathway, leading to an increase of many phenolic compounds in Chinese cabbage seedlings. In previous studies, blue light irradiation was effective in increasing rutin and cyanidin 3-*O*-rutinoside levels in buckwheat and total ploy phenol content in lettuce. Many previous studies have revealed environmental factors that act as abiotic stresses inducing phenylpropanoids in plants, for example, excessive light, UV, pathogen attack, elicitation, wounding, heat and cold stress, nutrient deficiency, and heavy metal stress.[2,20] It may be possible to employ the environmental factors as strategies to enhance phenylpropanoid biosynthesis in Chinese cabbage. However, they have some disadvantages, such as plant growth retardation, quality deterioration, and soil contamination, whereas the short-term LED light irradiation used in this study can be applied as a suitable method to increase phenylpropanoid content in seedlings of Chinese cabbage without negative effects on plant growth and quality and the environment. Although further studies are needed to apply this practice to Chinese cabbage grown in the field, the results in this study might be utilized as useful information to improve the nutritional quality of Chinese cabbage.

Expression Profiles of Phenylpropanoid Biosynthetic Genes in Different Organs. The expression patterns of *BrPAL*, *BrC4H*, *Br4CLs*, *BrCHS*, *BrCHI*, *BrF3H*, *BrF3Ls*, *BrFLS*, *BrDFR*, and *BrANS* were analyzed in the flower, leaf, stem, and root of adult Chinese cabbage plants (Figure 3). *BrPAL*, *BrC4H*, and *Br4CL1* were specifically expressed at the highest levels in the roots. The expression patterns of the three genes were fairly similar, with the highest transcript levels being recorded in the root, followed by the stem and leaf, and finally the flower. *Br4CL1*, *Br4CL2*, and *Br4CL3* are the paralogous genes of 4-coumarate:coenzyme A ligase and showed different expression profiles according to the plant organs. The highest expression was detected in the root, leaf and stem, and flower, respectively. *BrCHS*, *BrCHI*, *BrF3H*, *BrF3′H*, and *BrDFR* displayed the highest transcription levels in the leaf and the lowest transcription levels in the root. High transcript levels of *BrF3H* and *BrFLS* were also detected in the flowers. In summary, the upstream genes of *BrPAL*, *BrC4H*, and *Br4CL1* were highly expressed in the root, whereas all other genes were expressed at relatively abundant levels in the leaf or flower.

Accumulation of Phenylpropanoids in Different Organs of Chinese Cabbage. The phenylpropanoid contents in different organs of adult Chinese cabbage plants were analyzed by HPLC-UV (Table 3). Along with the phenolic compounds detected in seedlings, catechin was found in the leaves, stems, and roots, which is the flavonoid that is highly abundant in fruits and legumes.[21] The highest phenolic compound content was obtained for kaempferol (up to 678.57 ± 3.05 $\mu g\ g^{-1}$), whereas quercetin, ferulic acid, and *p*-hydroxybenzoic acid were also detected in great quantities.

Among detected nonflavonoids, considerable levels of *p*-hydroxybenzoic acid were detected in the leaf (253.25 ± 4.82 $\mu g\ g^{-1}$), whereas lower quantities were detected in the flower (32.79 ± 2.03 $\mu g\ g^{-1}$). *p*-Hydroxybenzoic acid was not detected in the stem and root. The highest ferulic acid content was detected in the leaf (407.27 ± 15.24 $\mu g\ g^{-1}$), followed by the flower (272.52 ± 2.06 $\mu g\ g^{-1}$), stem (95.12 ± 0.40 $\mu g\ g^{-1}$), and root (25.97 ± 0.48 $\mu g\ g^{-1}$). Chlorogenic acid contents were similar among the different organs: root (28.97 ± 0.63 $\mu g\ g^{-1}$), flower (23.51 ± 6.38 $\mu g\ g^{-1}$), leaf (20.48 ± 0.32 $\mu g\ g^{-1}$), and stem (15.79 ± 0.64 $\mu g\ g^{-1}$). Interestingly, there was no significant difference in chlorogenic acid content in the different organs at the adult stages or in seedlings grown under different light conditions.

High amounts of quercetin accumulated in the flower (339.19 ± 18.87 $\mu g\ g^{-1}$), whereas only small amounts were detected in the leaf (15.13 ± 5.74 $\mu g\ g^{-1}$). No quercetin was detected in the stem or root. Of note, high quantities of kaempferol were present in the flower (678.57 ± 3.05 $\mu g\ g^{-1}$), with 25.9 times more kaempferol being present in the flower than in the root. The antioxidant effect of *Brassica* species may be attributed to those phenolic compounds, because phenolics, including quercetin and kaempferol, have higher antioxidant activities than vitamins and carotenoids.[22] In the present study, quercetin and kaempferol specifically accumulated in the flowers of Chinese cabbage, indicating that greater nutritional benefits may be obtained from Chinese cabbage when the flowers are used. Relatively lower catechin content was detected compared to those of other flavonoids. Catechin content in the leaf (46.64 ± 0.38 $\mu g\ g^{-1}$) was 2.5- and 5.4-fold higher than that in the stem (18.23 ± 1.18 $\mu g\ g^{-1}$) and root (8.67 ± 3.05 $\mu g\ g^{-1}$), respectively. Catechin was not detected in the flower.

Many previous studies have revealed that the organ distribution of the phenylpropanoids was correlated with the expression patterns of *PAL*, *C4H*, and *4CL*.[23−25] However, in our results, the accumulation patterns of *p*-hydroxybenzoic acid and ferulic acid did not coincide with the expression patterns of *BrPAL*, *BrC4H*, *Br4CL1*, and *Br4CL3*, which are the genes responsible for their biosynthesis. It is well-known that phenylpropanoid metabolism in plants is an intricate network in which many enzymes are implicated. Multiple isoforms and paralogous genes might have redundant functions, and those synergistic regulations might complicate elucidating phenylpropanoid metabolism.[26−28] In addition, the biosynthesis of nonflavonoids yet unidentified in *Brassica* species might also

DOI: 10.1021/acs.jafc.5b02086
J. Agric. Food Chem. 2015, 63, 6772−6778

affect their accumulation. Further studies can be performed to elucidate the genes corresponding to the organ-specific distribution of phenylpropanoids in Chinese cabbage.

The organ-specific accumulation of quercetin, kaempferol, and catechin could be explained by the expression patterns of *Br4CL3*, *BrF3H*, and *BrFLS*, which were relatively high in the flower. Previous studies have revealed distinct functions and substrate specificities of the *4CL* gene family for phenylpropanoid biosynthesis[28−30] and the major role of FLS, which directs flux into flavonols such as quecertin and kaempferol,[31,32] indicating these genes may be key regulators in flavonoid biosynthesis. Although we did not investigate expression profiles of all of the genes responsible for phenylpropanoids biosynthesis, our results revealed organ-specific distribution of phenylpropanoids and corresponding expression patterns of key biosynthetic genes in Chinese cabbage.

In this study, we aimed to investigate light conditions that lead to accumulation of phenylpropanoids in Chinese cabbage and organ-specific distribution of the phenylpropanoids. The results of this study demonstrate that blue light is an effective light source to lead to enhancement of phenylpropanoid biosynthesis, and leaves and flowers are suitable organs from which to obtain specific phenylpropanoids from Chinese cabbage. Our results are expected to provide useful information for developing a strategy to enhance phenylpropanoid biosynthesis in Chinese cabbage.

Virgin Olive Oil and Oxidation Experiments. Four Tunisian monovarietal extra virgin olive oil samples (Chemlali, Chétoui, Oueslati, and El Hor cultivars) that differed mainly in terms of their natural antioxidant content, phenolic compounds, and tocopherols were collected from quality-assured industrial oil mills in the 2011−2012 crop season. Olive oil samples (100 mL) were stored in 250 mL amber glass bottles. Half the samples were kept in open bottles (OB; internal diameter (i.d.) = 5.5 cm; surface area exposed to the atmosphere = 23.74 cm^2) to avoid oxygen limitation and therefore favor the autoxidation process. To compare the effect of oxygen availability during conservation, the other half of the olive oil samples were stored in closed 250 mL amber glass bottles (CB) with 10% headspace. All samples were stored in the dark, in a refrigerator set at 5 ± 1 °C or one of three other incubators set at 15 ± 1, 25 ± 1, or 50 ± 1 °C. Samples were periodically withdrawn from the incubator for scheduled analyses (0, 3, 6, 9, 12, and 18 months at 5−25 °C and 0, 0.75, 1.5, 3, 4.25, and 6.5 months at 50 °C).

Quality and Oxidation Indices. Free acidity was expressed as percentage of oleic acid; peroxide value (PV) was expressed as milliequivalents of active oxygen per kilogram of oil (mequiv O_2/kg), and K_{232} and K_{270} extinction coefficients, calculated from absorption at 232 and 270 nm, were measured following the analytical methods described in European Commission Regulation EEC 2568/91 (1991) and later amendments (the latest being EU 1348/2013).[18] Initial oxidation rates (for oxidation indices) and initial degradation rates (for phenolic compounds) are used to define the behavior at the beginning of the degradation or oxidation process, because the change in the value of the variable during storage could modify the observed rate. They are calculated by the slope of the tangent to the concentration/value versus time curve at time zero.

Phenolic Compounds. Phenolic compounds were identified and quantified at 280 nm using syringic acid as the internal standard according to the method of Mateos et al.[19] A 2.5 g sample of filtered VOO was weighed, and 250 μL of a solution of the internal standard (15 mg/L of syringic acid in methanol) was added. The solvent was evaporated in a rotary evaporator at 35 °C under vacuum, and then the oil was dissolved in 6 mL of *n*-hexane. A diol-bonded phase cartridge (bed wt = 500 mg, volume = 3 mL; Supelco Co., Bellefonte, PA, USA) was placed in a vacuum elution apparatus and conditioned by the consecutive addition of 6 mL of methanol and 6 mL of *n*-hexane. The vacuum was then released to prevent drying of the column. The oil solution was applied to the column, and the solvent was pulled through, leaving the sample and the standard on the solid phase. The sample container was washed with 6 mL of *n*-hexane (2 × 3 mL), which was run out of the cartridge. The sample container was washed again with 4 mL of *n*-hexane/ethyl acetate (85:15, v/v), which was run out of the cartridge and discarded. The column was eluted with 15 mL of methanol, and the solvent was evaporated in a rotary evaporator at room temperature and low speed under vacuum until dry. The phenolic residue was dissolved in 250 μL of methanol/water (1:1, v/v).[19]

High-performance liquid chromatography (HPLC) analysis was performed using an Agilent Technologies series 1100 system equipped with an automatic injector, a column oven, and a diode array UV detector. A Spherisorb S3 ODS2 column (250 × 4.6 mm i.d., 5 μm particle size) (Waters Co., Milford, MA, USA) was used, maintained at 30 °C, with an injection volume of 20 μL and a flow rate of 1.0 mL/min. The mobile phase was a mixture of water/acetic acid (95:5, v/v) (solvent A), methanol (B), and acetonitrile (C). The elution gradient was from 95% (A), 2.5% (B), 2.5% (C) to 34% (A), 33% (B), 33% (C) over 50 min, followed by 100% (B) for 15 min to clean the column.

Tocopherols. Tocopherols were measured following AOCS Method Ce 8-89.[20] A solution of oil in *n*-hexane was analyzed by HPLC (Agilent Technologies series 1100) on a silica gel Lichrosorb Si-60 column (particle size = 5 μm, 250 × 4.6 mm i.d.; Sugerlabor, Madrid, Spain), which was eluted with *n*-hexane/2-propanol (98.5:1.5, v/v) at a flow rate of 1 mL/min. A fluorescence detector (Thermo-Finnigan FL3000, San Jose, CA, USA) was used with excitation and emission wavelengths set at 290 and 330 nm, respectively.

Statistical Analysis. The experimental data set consisted of two individual batches of samples for each of four cultivars and for each of the two oxidation conditions studied (open and closed bottles). Moreover, duplicate measurements were carried out for each sample taken at scheduled time intervals. The standard deviation of the mean values of the analyzed concentration of phenolic and tocopherol compounds was generally <10%; if a higher value was obtained, a new analysis was performed. Statistical analysis was performed using IBM SPSS 22 statistical software (Chicago, IL, USA). Least-squares linear regression analyses were performed, and the best equations were selected on the basis of statistical parameters of the fit (r, p).

RESULTS AND DISCUSSION

The monovarietal VOOs studied in this assay, Chemlali, Chétoui, El Hor, and Oueslati, represent the most common olive cultivars grown in Tunisia, especially in the northern and central parts of the country. An initial characterization of their properties was reported by Krichene et al.[21]

Evolution of the Oxidation Process. The VOO samples stored at different temperatures (5, 15, 25, and 50 °C) in both CB and OB conditions were studied for their oxidative stability over a storage period of 18 months. The progress of the oxidation

[a]DOA and AOA, hydroxytyrosol secoiridoid derivatives: dialdehydic and aldehydic form of elenolic acid linked to hydroxytyrosol, (also known as 3,4-DHPEA-EDA and 3,4-DHPEA-EA). DLA and ALA, tyrosol secoiridoid derivatives: dialdehydic and aldehydic form of elenolic acid linked to tyrosol (aka p-HPEA-EDA and p-HPEA-EA).

process was monitored by measuring PV, acidity, and UV characteristics (K_{232} and K_{270}), which are indicators of oil stability and its oxidation level.[18−22]

Initial oxidation rates, expressed as the weekly increase in PV, K_{232}, and K_{270}, are reported in Table 1. As expected, the oxidation rate was faster in OB compared to CB due to oxygen limitation.

DOI: 10.1021/acs.jafc.5b02187
J. Agric. Food Chem. 2015, 63, 6779−6786

For example, PV-based rates of 1.073 mequiv O_2/kg/week in OB versus 0.385 mequiv O_2/kg/week in CB were found for El Hor VOO at 25 °C. The storage temperature also greatly affected the oxidation process. For example, the initial oxidation rate increased from 0.313 mequiv O_2/kg/week at 15 °C to 1.542 mequiv O_2/kg/week at 25 °C and up to 11.93 mequiv O_2/kg/week at 50 °C for Chétoui oil in OB conditions. The effect of the oil variety is also noteworthy; however, as previously reported,[21] no clear relationship between composition (mainly fatty acid profile and natural antioxidant content) and initial oxidation rate could be established. Nevertheless, the observed oxidation based on the evolution of K_{232} is very similar for all of the VOO varieties studied (Table 1).

The shelf life of VOO considerably increased at reduced storage temperature. For example, the shelf life of Chétoui olive oil in CB (based on PV = 20, the maximum value for edible VOO as established by EEC 2568/91 and later amendments) increased from 48 weeks at 25 °C to 57 weeks at 15 °C, due to a reduction of 22% in its oxidation rate, from 0.229 to 0.188 mequiv O_2/kg/week (Table 1). The increased shelf life of Oueslati VOO in CB (at PV = 20) was even greater: from 26 weeks at 25 °C to 44 weeks at 15 °C, associated with a reduction of 36% in its oxidation rate, from 0.156 mequiv O_2/kg/week at 25 °C to 0.115 mequiv O_2/kg/week at 15 °C (Table 1). In storage at 5 °C none of the VOOs studied reached PV > 20 during the 72-week experimental period.

Stability of Phenolic Compounds. The two main families of complex phenolic compounds in VOO (secoiridoids) are the derivatives of hydroxytyrosol (dialdehydic and aldehydic forms of elenolic acid linked to hydroxytyrosol, DOA and AOA, respectively) and of tyrosol (dialdehydic and aldehydic forms of elenolic acid linked to tyrosol, DLA and ALA, respectively). DOA and AOA are also known as 3,4-DHPEA-EDA and 3,4-DHPEA-EA, and DLA and ALA are also known as p-HPEA-EDA and p-HPEA-EA. The stability of secoiridoids, expressed as reduction in concentration over 18 months, is depicted in Figure 1.

As expected, the stability of phenolic compounds was higher under closed bottle storage conditions (Figure 1a,b) compared to OB conditions (Figure 1c,d) due to oxygen limitation. However, the observed difference was not great and the general behaviors of these two phenolic families were quite similar. For example, in Chemlali VOO (square symbols in figures) the residual content of hydroxytyrosol secoiridoid derivatives after 6 months of storage at 25 °C was 63% in CB and 52% in OB and the residual contents of tyrosol derivatives were 85 and 67% in CB and OB, respectively. In El Hor olive oil (up triangles in figures) after 12 months at 15 °C the content of hydroxytyrosol derivatives was maintained at 73% in CB and at 62% in OB and tyrosol derivative content remained at 73 and 49% in CB and OB, respectively (Figure 1).

The stability of the tyrosol secoiridoid compounds (Figure 1b,d) appeared to be greater than that of hydroxytyrosol derivatives (Figure 1a,c), especially in CB conditions, in agreement with previous studies.[13,17]

It is remarkable that in all cases the stability of the phenolic compounds in the Chétoui VOO (circles in figures) was considerably lower than in the other three varieties. El Hor, Oueslati, and Chemlali VOOs behaved similarly. Chétoui VOO had much higher phenolic secoiridoid content (DOA, AOA, DLA, and ALA) than the other varieties (Table 2). This may be the cause of the observed difference.

As expected, an increase in storage temperature increased the degradation of phenolic compounds, particularly at 50 °C

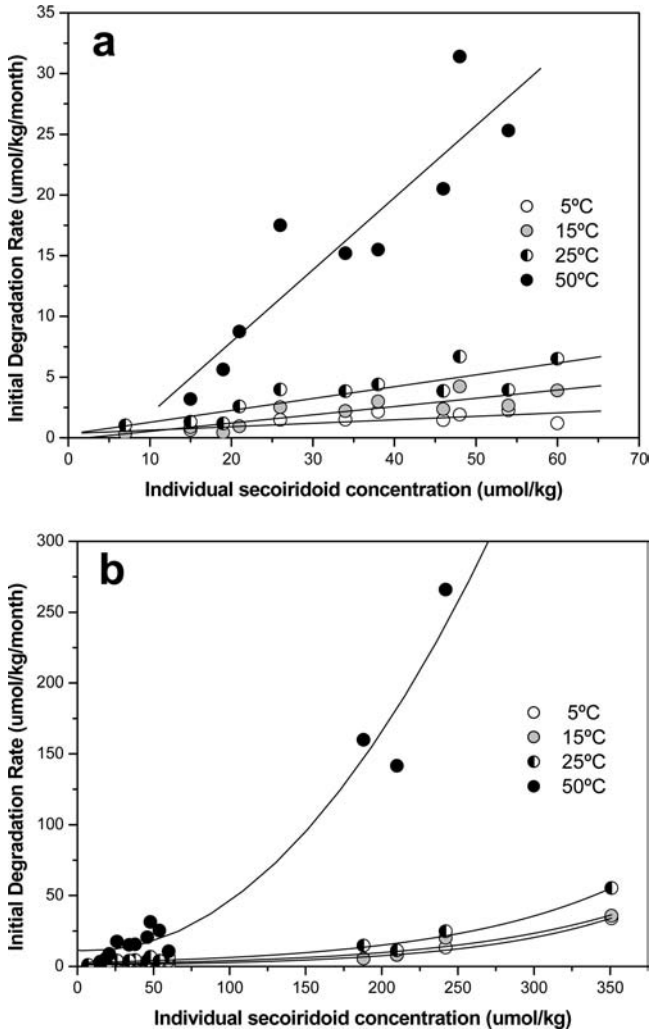

Figure 2. Effect of the concentration of individual secoiridoids (DOA, AOA, DLA, ALA) on their initial degradation rate. Storage temperature: 5 °C (open symbols); 15 °C (gray symbols); 25 °C (half-solid symbols); 50 °C (solid symbols). DOA and AOA, hydroxytyrosol secoiridoid derivatives: dialdehydic and aldehydic form of elenolic acid linked to hydroxytyrosol (also known as 3,4-DHPEA-EDA and 3,4-DHPEA-EA). DLA and ALA, tyrosol secoiridoid derivatives: dialdehydic and aldehydic form of elenolic acid linked to tyrosol (also known as p-HPEA-EDA and p-HPEA-EA).

(Figure 1). For example, in Oueslati oil (down triangle in figures) the residual content of hydroxytyrosol secoiridoid derivatives after 3 months of storage in OB was much lower at higher temperatures: 77% at 25 °C, but 28% at 50 °C. Similarly, the residual content of tyrosol derivatives after 6 months was 51% at 25 °C but 29% at 50 °C (Figure 1).

Only Chétoui VOO contained >250 mg/kg (5 mg/20 g) of the sum of hydroxytyrosol and its derivatives (Table 2), as established by European health claims for olive oil phenolics.[10] This minimum required amount was maintained for 10 months at 25 °C but for up to 18 months in storage at 15 °C. The initial content of total phenolics (hydroxytyrosol and tyrosol and their derivatives) in El Hor oil was 317 mg/kg;[21] this total amount was reduced to 250 mg/kg in just 4.5 months in storage at 25 °C but maintained for up to 7 months at 15 °C. The effect of storage temperature on the stability of phenolic compounds is therefore of great interest in regard to the nutritional and biological value of VOO, because lower storage temperatures considerably increase

J. Agric. Food Chem. 2015, 63, 6779−6786

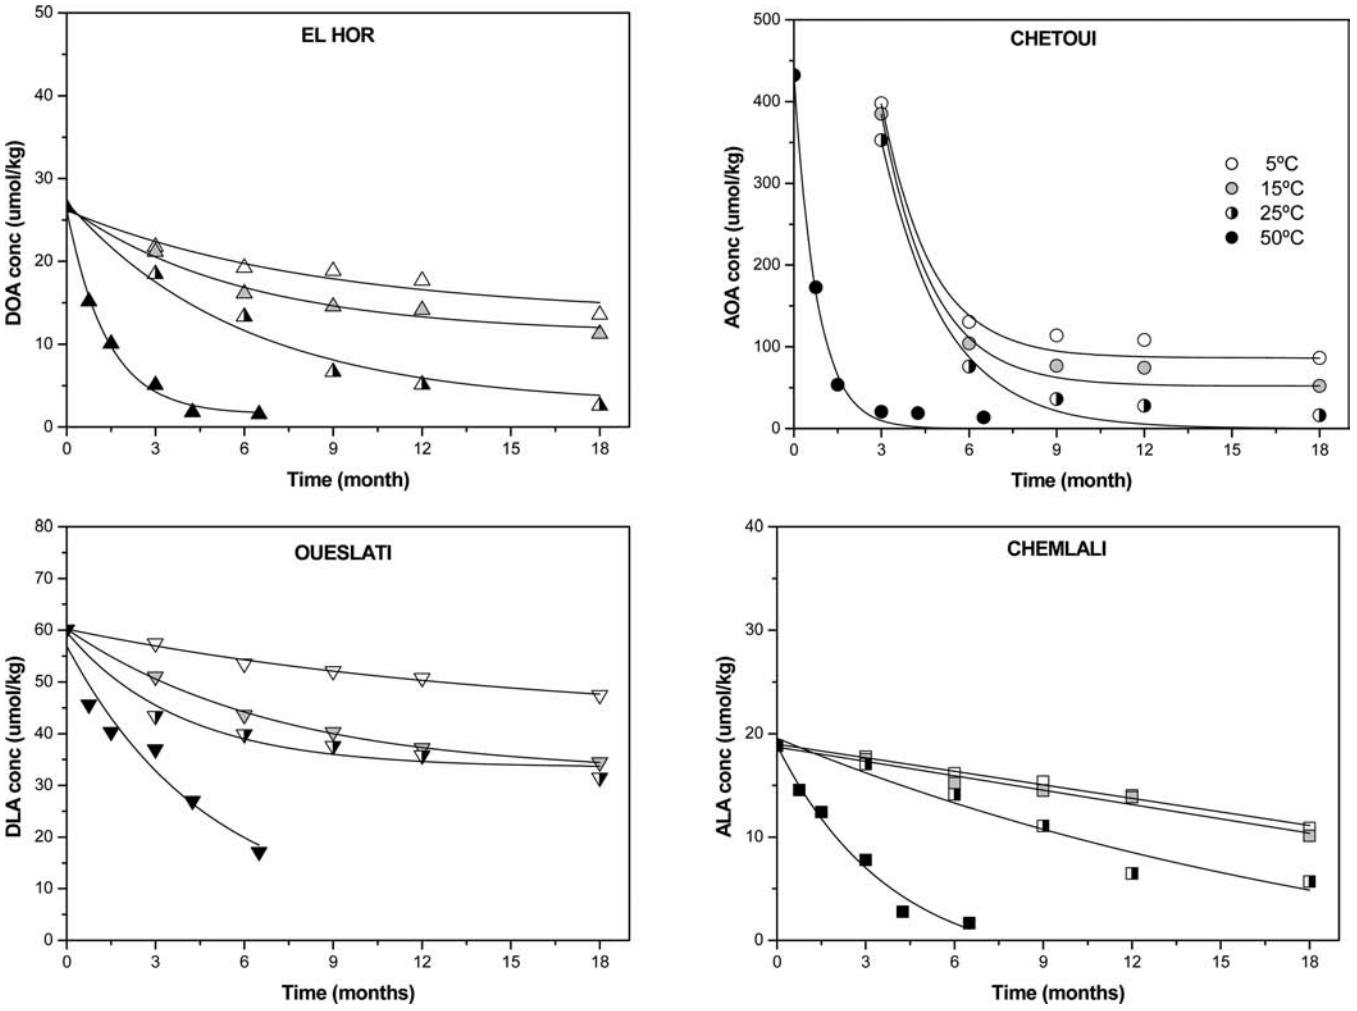

Figure 3. Stability of phenolic secoiridoids during storage at different temperatures (5−50 °C). VOO variety: ●, Chétoui; ▲, El Hor; ▼, Oueslati; ■, Chemlali. Storage temperature: 5 °C (open symbols); 15 °C (gray symbols); 25 °C (half-solid symbols); 50 °C (solid symbols). DOA and AOA, hydroxytyrosol secoiridoid derivatives: dialdehydic and aldehydic form of elenolic acid linked to hydroxytyrosol (also known as 3,4-DHPEA-EDA and 3,4-DHPEA-EA). DLA and ALA, tyrosol secoiridoid derivatives: dialdehydic and aldehydic form of elenolic acid linked to tyrosol (also known as p-HPEA-EDA and p-HPEA-EA). Standard deviation of the mean value of the phenolic compound concentrations was <10%.

the length of time for which the health claim is valid. This finding is particularly relevant for high-added-value products, sometimes defined as premium or superior VOO.

Kinetics of Degradation of Phenolic Compounds. The degradation of secoiridoid phenolics during storage fit a pseudo-first-order kinetics equation reasonably well ($r > 0.96$ and $p < 0.005$) at all of the temperatures and for all of the VOO varieties studied, as previously reported.[13] The reaction equation was $\ln(C_t/C_0) = kt$, where C_0 is the initial concentration and C_t the residual concentration at time t. The stability of tyrosol secoiridoid derivatives was greater than that of hydroxytyrosol derivatives as demonstrated by the lower slope of the degradation kinetics, especially at higher storage temperatures (i.e., -0.099 ± 0.005 as compared to -0.068 ± 0.002 for hydroxytyrosol and tyrosol derivatives at 25 °C in Chemlali oils; or -0.452 ± 0.046 vs -0.184 ± 0.015 for hydroxytyrosol and tyrosol derivatives at 50 °C in Oueslati oils), in agreement with other studies.[13,17]

The initial degradation rate was generally similar at storage temperatures of 5 and 15 °C but increased considerably at 25 °C and was even faster at 50 °C (Table 2). For example, in El Hor olive oil, the degradation rate of DOA increased from 2.52 μmol/kg/month at 15 °C to 3.97 μmol/kg/month at 25 °C and to 17.5 μmol/kg/month at 50 °C. Similarly, ALA in Chemlali VOO increased from 0.44 and 0.46 μmol/kg/month at 5 and 15 °C, respectively, to 1.18 μmol/kg/month at 25 °C and to 5.63 μmol/kg/month at 50 °C.

Both storage temperature and oil variety affected degradation rates (Table 2). The observed differences in the initial degradation rate of the secoiridoid compounds in the different VOO varieties studied (Table 2) may be explained by the difference in their initial phenolic contents.[21] Figure 2 plots the concentration of each of the main complex phenolic compounds (DOA, AOA, DLA, and ALA) versus their initial degradation rate (16 data points of four oil varieties for each of the four secoiridoids for each temperature). An approximately linear relationship ($r > 0.98$, and at 50 °C, $r = 0.91$, $p < 0.01$) between initial degradation rate and initial phenolic concentrations is observed at phenolic concentrations <100 μmol/kg at all storage temperatures assayed (Figure 2a). Moreover, with the higher phenolic content observed in this study (350 μmol/kg) also taken into account, the initial degradation rate fits an exponential growth curve $C_t = C_0(1 + r)^t$, where r is the growth rate (Figure 2b). Therefore, the effect of the oil variety on the stability of the phenolic compounds may be explained simply by their

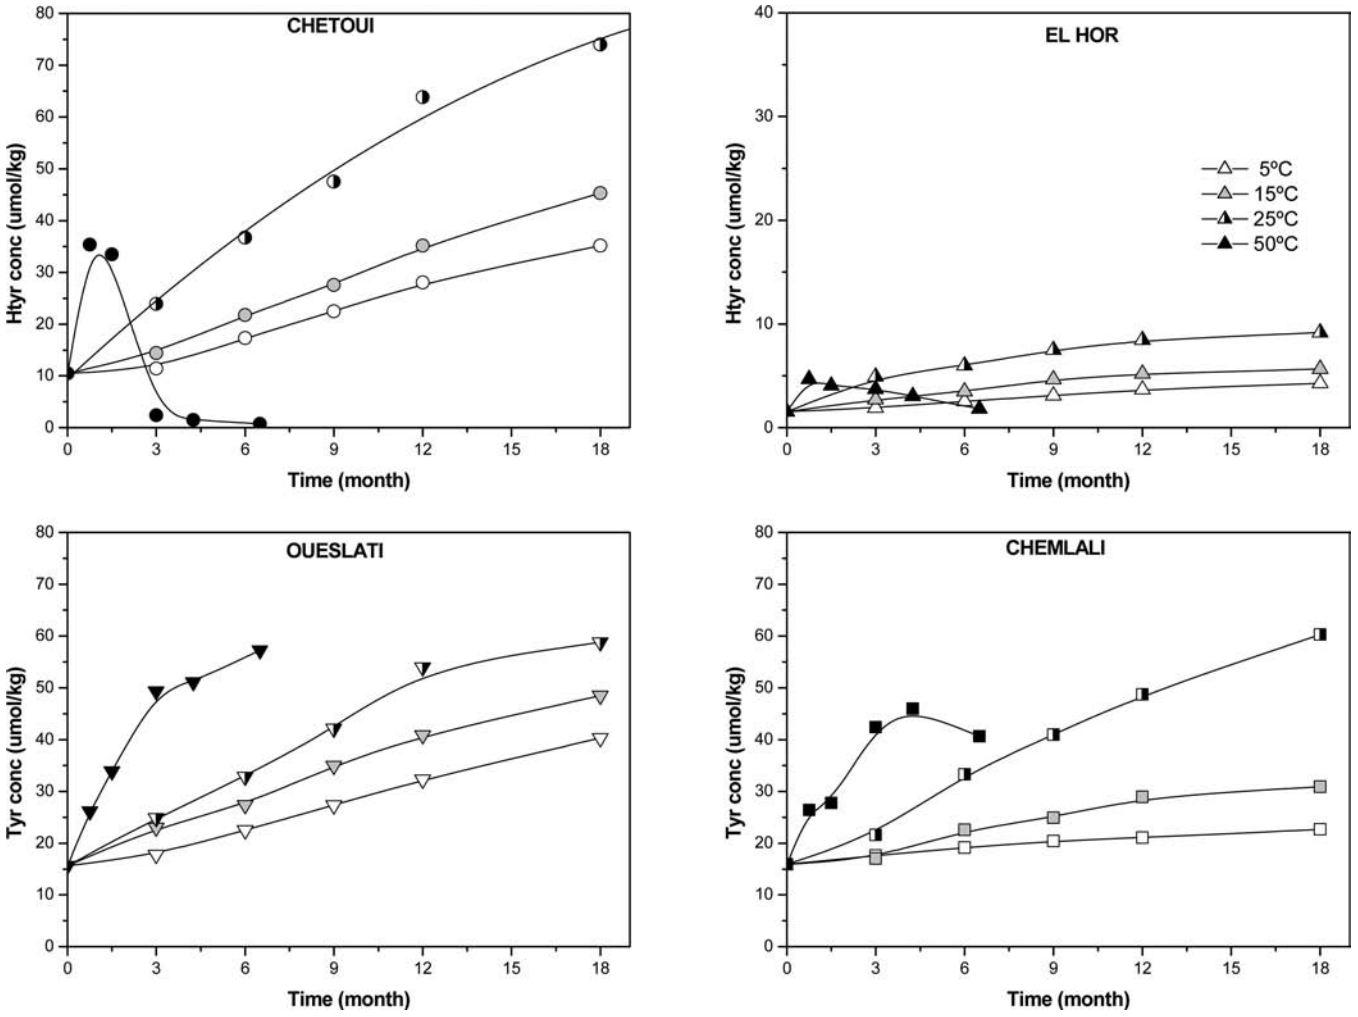

Figure 4. Evolution of hydroxytyrosol and tyrosol during storage at different temperatures (5−50 °C). VOO variety: ●, Chétoui; ▲, El Hor; ▼, Oueslati; ■, Chemlali. Storage temperature: 5 °C (open symbols); 15 °C (gray symbols); 25 °C (half-solid symbols); 50 °C (solid symbols). Htyr, hydroxytyrosol; Tyr, tyrosol. Standard deviation of the mean value of the phenolic compound concentrations was <10%.

different initial concentrations. Furthermore, the relationship between initial degradation rate and initial concentration of phenolics was very similar for all four main complex phenolic compounds, and therefore their stability should also be similar.

The stability of the main phenolic secoiridoid compounds (DOA, AOA, DLA, and ALA) is depicted in Figure 3; their behavior over time fit an exponential decay curve well ($r^2 > 0.96$). As discussed above, the different initial phenolic compound concentrations in different oil varieties and the different storage temperatures explained the different behaviors of the varieties.

It is of interest that in Chétoui olive oil, the variety with the greatest initial concentration of phenolic compounds (Table 2), a lag phase is apparent for AOA and ALA, but not for DOA or DLA (data not shown). In contrast, the behavior of the other three varieties was similar, taking into account the different initial concentrations of the individual phenolic compounds and the effect of the temperature.

Behavior of Simple Phenolics. The content of simple phenolics such as hydroxytyrosol and tyrosol, in fresh VOO is very low (e.g., Gomez-Rico et al.[23]). During storage there was an increase in the content of these simple phenolics due to the degradation of their complex derivatives (Figure 4), as observed in other studies.[14,24,25] The behavior of simple phenolics was similar and clearly related to the storage temperature and the initial concentration of their complex forms that determined the rate of the degradation of their complex derivatives. For example, a small amount of hydroxytyrosol was formed in El Hor olive oil (Figure 4; 8.4 μmol/kg after 12 months at 25 °C) because only a small initial amount of its derivatives was present (Table 2): a total of 60 μmol/kg, made up of 26 μmol/kg of DOA and 34 μmol/kg of AOA that had individual initial degradation rates at 25 °C of 3.97 and 3.84 μmol/kg/month, respectively (Table 2). In contrast, tyrosol was formed in greater amounts under the same conditions (48 μmol/kg after 12 months at 25 °C), because the concentration of its derivatives was initially higher: a total of 258 μmol/kg, made up of 242 μmol/kg of DLA and 21 μmol/kg of ALA (degradation rates of 24.8 and 2.58 μmol/kg/month, respectively).

In all cases a plateau was apparently reached probably because these compounds were also degraded during storage. Indeed, at 50 °C a decrease in hydroxytyrosol was clearly visible in all VOO varieties studied after reaching a maximum value.

The increase in the content of simple phenolics, the decrease in their secoiridoid derivatives, or the ratio of simple to secoiridoid phenolics can be used as indices of the oxidative and hydrolytic degradation of VOO phenolics[25,26] and may be used as freshness or aging indices of the VOO during its shelf life.

DOI: 10.1021/acs.jafc.5b02187
J. Agric. Food Chem. 2015, 63, 6779−6786

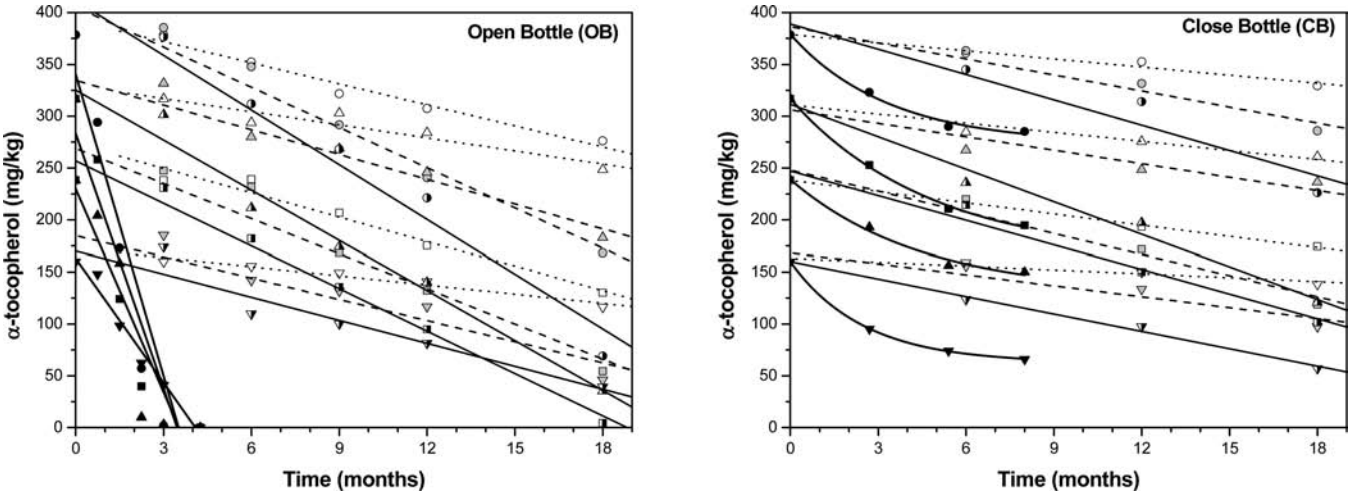

Figure 5. Evolution of tocopherol during storage at different temperatures (5−50 °C) in closed (CB) and open bottles (OB). VOO variety: ●, Chétoui; ▲, El Hor; ▼, Oueslati; ■, Chemlali. Storage temperature: 5 °C (open symbols); 15 °C (gray symbols); 25 °C (half-solid symbols); 50 °C (solid symbols). Standard deviation of the mean value of the tocopherol content was <10%.

Stability of Tocopherols. The most important tocopherol in VOO by far is α-tocopherol (e.g., Cunha et al.[27]); therefore, the other isomers were not investigated in this study.

In contrast to complex phenolics, α-tocopherol degradation apparently followed a simpler zero-order kinetic ($C_t = C_0 + kt$; $r > 0.97$ and $p < 0.01$; Figure 5).

A lag phase of a few months may be hidden, because the decrease from the initial concentration of α-tocopherol was very small up to 3 months in storage at all temperatures studied except at 50 °C storage conditions.

As observed for phenolics, the degradation in CB conditions was less due to the limited oxygen availability, as clearly noticeable at 50 °C when a plateau was reached (Figure 5).

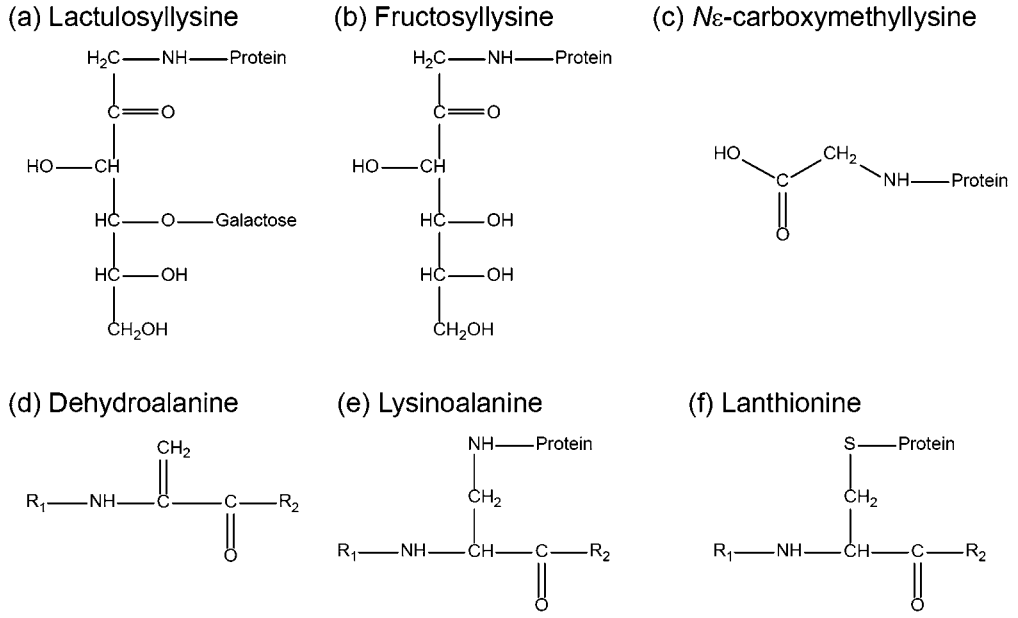

Figure 1. Chemical structures of heat-derived protein modifications. Lactulosyllysine (a) and fructosyllysine (b) are early Maillard reaction products, which are subsequently oxidized to N^{ε}-carboxymethyllysine (CML; c) as an advanced Maillard reaction product. Dehydroalanine (d) is the precursor of cross-linked products, lysinoalanine (e), and lanthionine (f).

analysis and in vitro/in vivo digestion as done previously,[12] and the relationship between protein modifications and protein digestibility is discussed.

MATERIALS AND METHODS

Milk Samples. Milk-based liquid formulas, simulating enteral formulas, were manufactured at the pilot plant of Morinaga Milk Industry (Zama, Japan) with ingredients such as high-heat skim milk powder, sodium caseinate, vegetable fat, maltodextrin, vitamins, minerals, and emulsifiers. The ratio of casein (CN) to whey protein was approximately 7:1. The heating conditions were set to mimic those for the manufacturer's enteral formula products (Table 1).

Table 1. Heat Treatment of Milk-Based Liquid Formulas[a]

treatment	holding temp/time	F_0 value
steam injection	151 °C for 4 s	65
in-can sterilization[b]	123 °C for 8 min	20

[a]Heating conditions were set by reference to those of the manufacturer's commercial products. [b]This heat treatment involves slow rates of temperature rise/fall, which also contributed to the F_0 value.

The heated formulas were homogenized at 30 MPa, followed by lyophilization. The lyophilized formula powders were stored at 4 °C until use. Nutrient composition of the products was determined by the Analytical Research Center of Morinaga Milk Industry (Table 2).

Table 2. Nutrient Composition of Lyophilized Enteral Formulas

component	g/100 g
protein	18.1
fat	12.3
carbohydrate	65.5
ash	3.2
water	0.9

Sodium Dodecyl Sulfate–Polyacrylamide Gel Electrophoresis (SDS-PAGE) of Milk Samples. Six grams of lyophilized formulas were reconstituted with 24 mL of Milli-Q water (Millipore, Billerica, MA), subjected to centrifugation at 8500*g* for 30 min twice, and the upper fat layer was removed. The tiny pellet, formed after centrifugation, was thoroughly mixed with the defatted supernatant. We confirmed, using a Dumas method (Sumigraph NC-220F, Sumica Chemical Analytic Center, Tokyo, Japan) that no notable loss in protein content (as measured by nitrogen (N) amount) was accompanied by removal of fat layer.

Protein concentrations were determined by the Bradford method,[18] and were adjusted to 7.5 g/L with Milli-Q water. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) was performed under reducing/nonreducing conditions to separate the proteins (Bio-Rad, Hercules, CA). Fifty micrograms of protein was loaded for each sample onto Mini-PROTEAN TGX Any kD gel (Bio-Rad). Electrophoresis was run at 120 V for 50 min, and gels were stained with Bio-Safe Coommassie Stain (Bio-Rad).

Proteomic Analysis. Proteomic analysis was conducted at the Proteomic Core Facility at the University of California, Davis, as described previously,[12] in order to site-specifically semiquantify lactulosyllysine, fructosyllysine, CML, dehydroalanine formed from phosphoserine and Cys, and phosphorylation of serine (Ser) residues in major milk proteins such as α-lactalbumin (α-LA), β-lactoglobulin (β-LG), and CNs.

In-Gel Digestion. In-gel reduction, alkylation, and tryptic digestion were done using similar protocols as published previously.[19] Briefly, lyophilized formulas were reconstituted with Fisher Optima water (Fisher Scientific, Pittsburgh, PA), loaded onto a Novex 10% Tris-glycine gel (Life Technologies, Grand Island, NY), and applied to electrophoresis at 80 V for 20 min. The fraction containing the entire protein band was excised, and the gel piece was washed twice with 100 mM ammonium bicarbonate (AmBic) and dehydrated twice with 100% acetonitrile (ACN). The gel piece was reduced using 10 mM dithiothreitol (in 100 mM AmBic) at 56 °C for 30 min. The gel piece was then alkylated using 55 mM iodoacetamide (in 100 mM AmBic) at room temperature (RT) for 20 min in the dark. The gel piece was washed twice with 100 mM AmBic, dehydrated twice with 100% ACN, and then mechanically dried using vacuum centrifugation. Finally, sequencing grade modified trypsin (Promega, Madison, WI; in 50 mM AmBic) was added in a 1:30 ratio (trypsin:protein) to rehydrate the gel. After replacing the excess solution with 50 mM Ambic, the gel piece was incubated overnight at 37 °C. While the supernatant was collected into a new tube, 60% ACN (in 0.1% trifluoroacetic acid) was added to the remaining gel piece, which was then sonicated and centrifuged for collecting another supernatant. The supernatants were then dried by vacuum centrifugation.

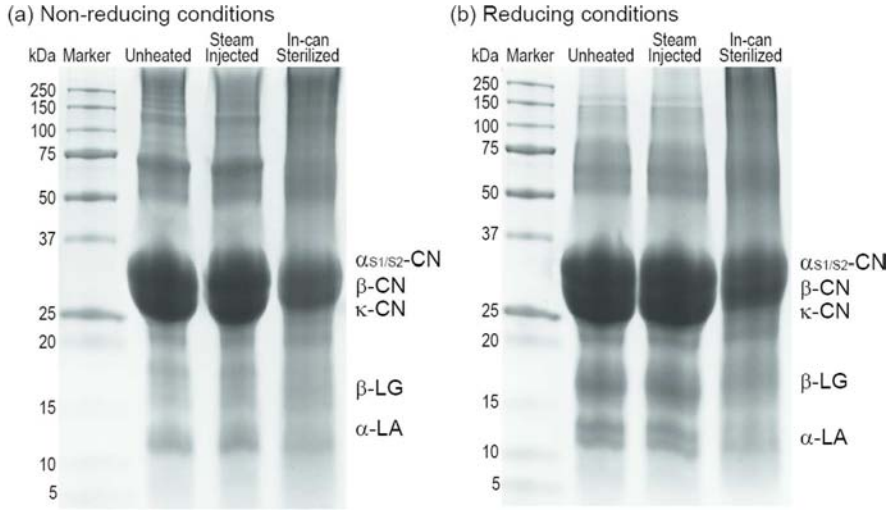

Figure 2. Electrophoresis of proteins in milk-based enteral formulas. Formula samples were applied to SDS-PAGE analysis under (a) nonreducing and (b) reducing conditions. Fifty micrograms of protein was loaded on a gel, and the gel was stained with Bio-Safe Coommassie Stain.

Liquid Chromatography coupled with tandem mass spectrometry (LC-MS/MS). Digested peptides were analyzed by a Thermo Scientific Q Exactive Orbitrap mass spectrometer in conjunction with a Paradigm MG4 HPLC (Michrom Bio Resources, Auburn, CA). The digested peptides were loaded onto a Michrom C18 trap and desalted before they were separated using a Michrom 200 μm × 150 mm Magic C18 AQ reverse phase column. A flow rate of 2 μL/min was used. Peptides were eluted using a 90 min gradient composed of buffer A (0.1% formic acid) and B (100% ACN), with 2% B to 35% B over 70 min, 35% B to 80% B for 5 min, 80% B for 2 min, and then a decrease from 80% to 2% B in 1 min, and held at 2% B for 12 min. A spray voltage of 2.2 kV was used with a transfer capillary temperature of 200 °C. A MS survey scan was obtained for the m/z range of 300–1600. MS/MS spectra were acquired using a top 15 method, where the top 15 ions in the MS spectra were subjected to high energy collisional dissociation. An isolation mass window of 2.0 m/z was used for the precursor ion selection, and normalized collision energy of 27% was used for fragmentation. A 5 s duration was used for the dynamic exclusion.

Data Analysis. All MS/MS samples were analyzed using X! Tandem (The GPM, thegpm.org; version TORNADO (2010.01.01.4)). X! Tandem was set up to search the digestion enzyme trypsin. Iodoacetamide derivative of Cys was specified in X! Tandem as a fixed modification. One of the targeted modifications [lactulosyllysine (+324.105647), fructosyllysine (+162.052824), CML (+58.005479), phosphorylation on Ser, threonine and tyrosine (+79.966331), dehydration of Ser (−18.010565), or dehydroalanine on Cys (−33.987721)], as well as acetylation of the N-terminus, ammonia-loss of the N-terminus, *pyro*-glutamination of the N-terminus, and oxidation of methionine and tryptophan were specified in X! Tandem as variable modifications. Scaffold (version Scaffold_4.1.1, Proteome Software Inc., Portland, OR) and Skyline (version 1.4.0.4421, MacCoss Lab, Department of Genome Science, University of Washington) were used to validate MS/MS based peptide and protein identifications,[20−22] and to determine retention time and peak areas of peptides with targeted modifications, respectively. Three different monoisotopic peak areas (M, M + 1, M + 2) were integrated for each specified peptide with Xcalibur (version 2.2 SP1.48, Thermo Scientific, Waltham, MA), and they were summed up to obtain higher confidence. For normalization between samples, the summed peak area was normalized by dividing it with the exclusive spectrum counts of all modified and nonmodified peptides derived from the parental protein, in Scaffold.

In Vitro Digestion. Powdered formulas were reconstituted with Milli-Q water and defatted, and protein concentration was adjusted to 7.5 g/L as above. Six mL of samples were aliquoted into 15 mL centrifuge tubes. Samples were subjected to in vitro digestion as described previously.[12] Conditions for the in vitro digestion in general,[23] the digestion times,[24] and pH of the gastric digestion,[24−28] had been reviewed carefully and selected accordingly.

Simulated gastric digestion was started with adjusting the pH to 2.0 (adult model) or 4.0 (infant model) with 1 M HCl. Porcine pepsin (Sigma-Aldrich; 2% in 1 mM HCl) was added to the sample in a 1:12.5 ratio (pepsin:protein). Samples were placed in a water bath equipped with an incubation shaker (Yamato Scientific, Tokyo, Japan) in the dark at 140 rpm at 37 °C for 30 min. After incubation, pH of the samples was adjusted to 7.0 with 0.1 mol/L $NaHCO_3$.

Simulated intestinal digestion was performed following the gastric digestion (at pH 2.0 or 4.0). After the pH was adjusted to 7.0, pancreatin (Sigma-Aldrich; 0.4% in 0.1 mol/L $NaHCO_3$) was added to the samples in a 1:62.5 ratio (pancreatin:protein). Samples were placed in a water bath equipped with an incubation shaker in the dark at 140 rpm at 37 °C for 60 and 240 min. After incubation, the enzymes were inactivated in a water bath at 85 °C for 3 min.

The digested samples were applied to reducing SDS-PAGE as described above, and each lane was loaded with the equivalent of 50 μg of protein before digestion. Protein digestibility of the samples subjected to digestion assays was determined using a Dumas method (Sumigraph NC-220F) and with a procedure as described previously.[29] Briefly, total N and nonprotein N [NPN; soluble fraction after trichloroacetic acid (TCA; 12% final concentration[30]) precipitation] were measured in milk samples before/after the digestion. Protein digestibility was defined as the ratio of ($NPN_{after\ digestion} - NPN_{before\ digestion}$)/(total $N_{before\ digestion} - NPN_{before\ digestion}$). Protein digestibility was analyzed six times for each pH condition/time period tested (i.e., pepsin digestion at pH 2.0/4.0 for 30 min, and pepsin digestion at 2.0/4.0 for 30 min + pancreatin digestion at pH 7.0 for 60 min).

In Vivo Digestion. A suckling rat pup model was used to investigate in vivo digestion of milk samples as described previously.[12,31] The study was approved by the Animal Research Committee of Morinaga Milk Industry (protocol no. 14-006). Sprague–Dawley rats with litters of 12 pups (6 males + 6 females) were obtained commercially (Charles River Japan, Yokohama, Japan), maintained in polycarbonate cages with wood shavings in a temperature-, humidity-, and light-controlled facility (24 °C, humidity 55%, and 12 h light/dark circle), and allowed to consume water and standard rat chow diet (F-2, Funabashi Farm, Funabashi, Japan) ad libitum. Pups were randomly assigned as 3 males + 3 females/formula sample/time point. After acclimation to facility conditions, on day 14 postpartum, pups were separated from their dams for 6 h and then intubated with unheated, steam-injected, or in-can sterilized formula (reconstituted and defatted as above; protein concentration was adjusted to 30 g/L), in a 1:36 v/w ratio (formula (mL)/body weight (g)), as done in our previous cow's milk study.[12] Pups were euthanized with CO_2 asphyxiation at 0.5, 1, or 2 h after intubation. As experiment control, 3 male pups + 2 female pups

were separated from their dams for 6 h and euthanized with CO_2 asphyxiation without formula samples administered.

Coagulates in the stomach were collected and weighed. Small intestine was cut into upper and lower parts, and each part was perfused twice with 0.2 mL of phosphate buffered saline (PBS) containing protease inhibitor cocktail (P2714, Sigma-Aldrich). Collected perfusates were stored at −80 °C until analysis. The perfusates underwent Western blotting. β-LG was set as an index of in vivo protein digestibility, as done previously.[12] The perfusates

(5 μg of protein) were applied to reducing SDS-PAGE, and proteins were transferred to a Trans-Blot Turbo PVDF membrane (Bio-Rad). The membrane was blocked with 2% bovine serum albumin (in PBS containing 0.05% Tween-20 (PBST)) for 45 min at RT. After the membrane was washed three times with PBST, it was probed with rabbit anti-bovine β-LG antibody (Bethyl Laboratories Inc., Montogomery, TX) in a 1:20000 dilution (antibody:blocking buffer) at RT for 45 min. After washing three times with PBST, the membrane was probed with donkey anti-rabbit IgG antibody conjugated with horseradish peroxidase (GE Healthcare, Pewaukee, WI) in a 1:20000 dilution (antibody:blocking buffer) at RT for 45 min. After washing three times with PBST, β-LG was detected by Pierce ECL Western Blotting Substrate (Thermo Scientific), with the chemiluminescence signal imaged by a ChemiDoc XRS+ (Bio-Rad).

Blood samples were taken by cardiac puncture using syringes treated with ethylenediaminetetraacetic acid disodium (Sigma-Aldrich). They were subjected to centrifugation at 1700*g* for 10 min, and upper plasma layers were collected and stored at −80 °C until analysis. Amino acid patterns were analyzed for the plasma samples. The samples were subjected to TCA (5% final concentration) precipitation, and soluble fractions were filtrated through 0.2 μm PVDF filters (Thomson Instrument Company, Oceanside, CA). The filtrates were applied to an amino acid analyzer (L-8900, Hitachi High-Technologies, Tokyo, Japan).

Statistical Analysis. Data on in vitro protein digestibility and coagulates in stomach (weight and pH) and plasma amino acid concentrations obtained from in vivo digestion assays were analyzed by one-way ANOVA and post-tested by Tukey test using JMP software (version 5.1.1, SAS Institute, Cary, NC), and significance was demonstrated at $p < 0.05$.

RESULTS

Electrophoresis of Milk Proteins. Formula samples were applied to SDS-PAGE, and the band patterns were compared

DOI: 10.1021/acs.jafc.5b02189
J. Agric. Food Chem. 2015, 63, 6787−6798

(Figure 2). Proteins smeared in a wide range of molecular weight for all three formulas under reducing/nonreducing conditions. While band patterns of unheated and steam injected formulas were similar, in-can sterilized formula showed a notably different band pattern; bands of intact major milk proteins such as α-LA, β-LG, and CNs decreased and a smear band above 37 kDa increased. All three formulas exhibited strong smear bands around 250 kDa under nonreducing conditions, during which disulfide bonds are kept intact. In contrast, under reducing conditions, a smear band at the high molecular weight fraction was observed only for in-can sterilized formula. These results suggest that milk proteins are associated prior to heat treatment, and that in-can sterilization caused newly formed protein modifications that are considered noncovalent interactions other than disulfide bonds.

Proteomic Analysis. Formula samples were applied to LC-MS/MS analysis following in-gel tryptic digestion for identifying and semiquantifying modifications involved in protein digestibility. It should be noted that some peptides containing the specified modifications were identified but could not be quantified probably due to low quantity.

Formation of lactulosyllysine and fructosylysine was targeted as early Maillard reaction products (Tables 3 and 4) because raw materials include skim milk powder and maltodextrin, which contain reducing sugars such as lactose and glucose. Formation of CML was also targeted as an advanced Maillard reaction product (Table 5). Maillard reaction products could be semiquantified in all the major milk proteins. Steam injected and in-can sterilized formulas had higher signals for lactulosyllysine and fructosyllysine than unheated formula at many modified sites in major milk proteins, but no clear trend was observed between steam injected formula and in-can sterilized formula. Similarly, steam injected and in-can sterilized formulas had higher signals for CML at most of the modified sites in CNs in comparison with unheated formula, but the signals were principally higher in in-can sterilized formula than in steam-injected formula.

As for targeting cross-linked structures, lysinoalanine and lanthionine are not compatible with the analysis of Maillard reaction products, and therefore their precursor, dehydroalanine on Ser and Cys residues, was analyzed instead (Table 6).

[a]Formula samples were treated with trypsin, followed by LC-MS/MS analysis for identifying and semiquantifying tryptic peptides containing dehydroalanine in major milk proteins. [b]Peak areas of the specific peptides are normalized to unheated formula.

Formation of dehydroalanine has been reported to reflect thermal history to a considerable extent.[32] It was identified at 18 Ser/Cys residues in major milk proteins and could be quantified at 11 of these sites. Steam-injected and in-can sterilized formulas had higher signals than unheated formula at about half of the identified sites. No clear trend was observed between steam injected formula and in-can sterilized formula.

In addition to the above-mentioned modifications, phosphorylation of Ser was semiquantified (Table 7), as it may provide further information in the context of heat treatment of proteins.[33] In-can sterilized formula had the lowest signals at all the modified sites of CNs, while steam injection did not appear to have any significant effects on phosphorylation. Thus, dephosphorylation of CNs was caused only by in-can sterilization.

In Vitro Digestion of Formula Samples. SDS-PAGE analysis of formula samples after in vitro digestion is shown in Figure 3. While proteins were digested to a limited extent by pepsin at pH 4.0, peptic digestion proceeded at pH 2.0 and digestion patterns were quite similar for the three formulas except for smear bands resisting digestion in in-can sterilized formula. Protein digestion was facilitated extensively by pancreatin treatment. However, undigested smear bands remained more pronounced in in-can sterilized formula compared with the other

[a]Formula samples were treated with trypsin, followed by LC-MS/MS analysis for identifying and semiquantifying tryptic peptides containing phosphoserine in major milk proteins. [b]Peak areas of the specific peptides are normalized to unheated formula.

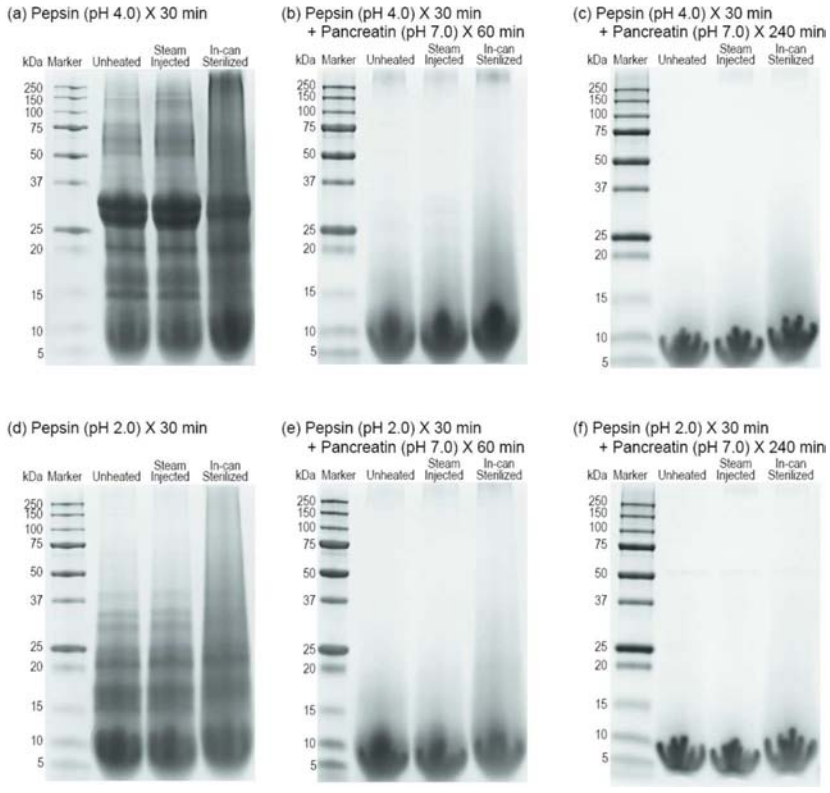

Figure 3. Electrophoresis of proteins in milk-based enteral formulas after in vitro digestion. Formula samples were subjected to in vitro digestion using pepsin and pancreatin. Both infant (a-c) and adult (d-f) digestion conditions were simulated by adopting different pH values during the peptic digestion. Fifty micrograms of protein (before digestion) was loaded on a gel, and the gel was stained with Bio-Safe Coommassie Stain. Pep and Pan denote pepsin and pancreatin, respectively.

two formulas, which could be recognized even after digestion for 240 min. In vitro protein digestibility was determined for some of the digestion conditions using a Dumas method in combination with TCA precipitation (Figure 4). Steam-injected formula showed the highest protein digestibility for all the digestion conditions, although the differences did not reach statistical significance.

In Vivo Digestion of Milk Samples. White coagulates, likely acid-precipitated CNs, were observed in stomachs of the rat pups after intubation with the formula samples. Weights of the coagulates decreased over time (Figure 5a), but we observed no significant difference, at any time point, among the groups fed the three formulas. The pHs were also quite similar

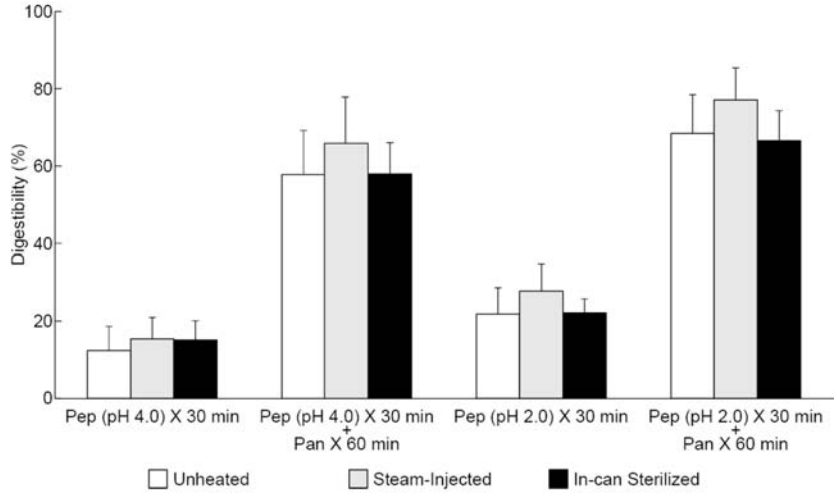

Figure 4. Digestibility of proteins in milk-based enteral formulas after in vitro digestion. Protein digestibility was defined as the increase in NPN after in vitro digestion, which was determined by a combination of TCA precipitation and a Dumas method. Each digestion and the subsequent procedures were conducted six times. No significant difference was observed among the formulas for the same digestion conditions. Pep and Pan denote pepsin and pancreatin, respectively.

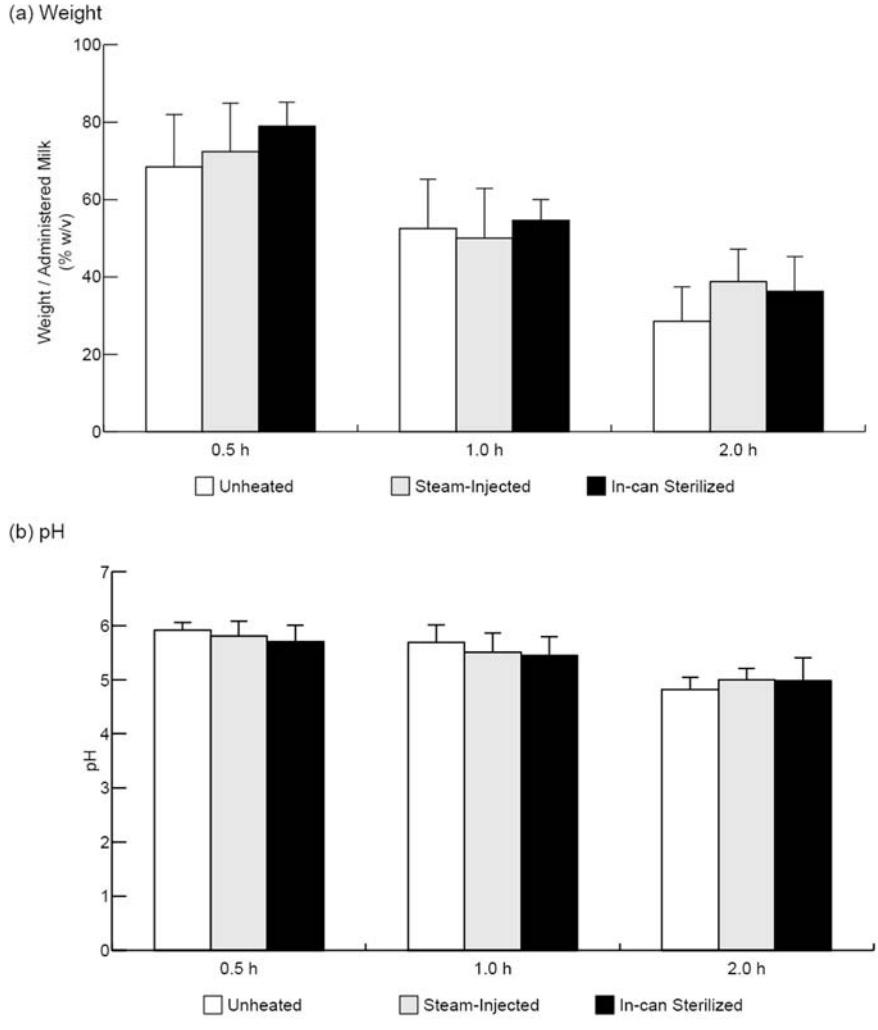

Figure 5. Coagulates in stomach of suckling rat pups. Rat pups fed different formula samples were killed at 0.5, 1, and 2 h after intubation, and coagulates in the stomach were obtained. Weight (a) and pH (b) were measured, and data are expressed as means ± SD (n = 3 males + 3 females). No significant difference was observed among the formula-fed pups at any time point.

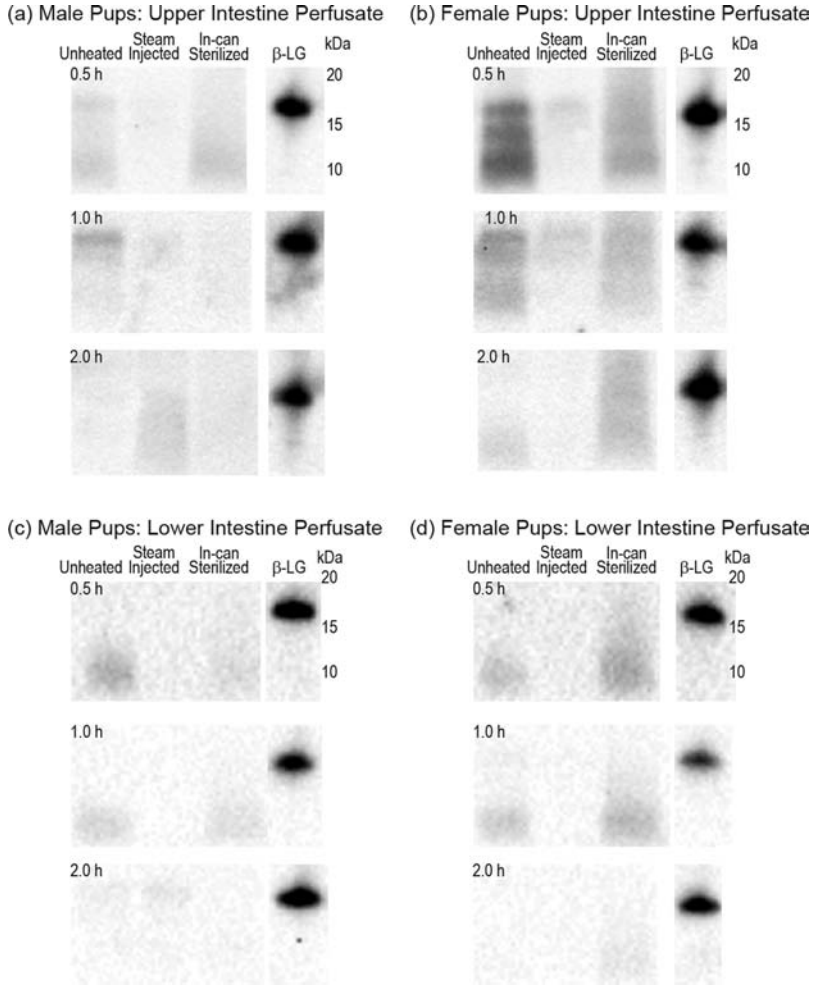

Figure 6. Western blotting of β-LG in upper/lower intestine perfusates from suckling rat pups. Rat pups fed different formula samples were killed at 0.5, 1, and 2 h after intubation, and the upper intestines (a) and lower intestines (b) were perfused with PBS containing protease inhbitor. Five micrograms of protein was loaded and β-LG was detected by Western blotting as an index of in vivo protein digestibility.

among the three formulas and decreased only slightly over time (Figure 5b).

Western blotting of β-LG was conducted for upper intestine perfusates (Figure 6a,b) in order to assess in vivo digestibility as done previously.[12] Each time point was assayed six times, using three male and three female pups per sample, and we observed no trend in terms of sex difference. While β-LG was barely observed in intact form in the perfusates obtained, fragmented forms and/or smear bands, supposedly degradation products from β-LG, were detected at fractions with molecular weights lower than that of β-LG. The smear bands generally became weaker over time. At 0.5 and 1.0 h, smear bands were weaker for the steam-injected formula-fed pups in 5 out of the 6 pups assayed. In contrast, at 2.0 h, results were inconsistent and the trend observed at 0.5 and 1.0 h was not confirmed. Western blotting of β-LG was also conducted for lower intestine perfusates. Like upper intestine perfusates, bands were observed principally in smear forms (Figure 6c,d). Bands were less intense than those in upper intestine perfusates, and they also became weaker over time. The bands for steam-injected formula were the weakest in all the six assays at 0.5 and 1.0 h, while the bands were hardly recognized and the trend was not observed at 2.0 h. Further, western blotting of CNs was conducted using a commercial anti-CN antibody that recognizes α_s- and β-CNs because they dominate proteins in the formulas. However, the antibody appeared to react with endogenous proteins in rats as well as partially digested CNs (data not shown), which hindered interpretation of the results and no conclusion could be drawn from the assays.

To further explore protein quality, as part of evaluating amino acid bioavailability, plasma amino acid patterns were analyzed. In pups fed unheated formula, total and essential plasma amino acids increased at 0.5 h, decreased at 1.0 h, and stayed at the similar level at 2.0 h (Figure 7). This trend held true for most of the respective amino acids (Table 8). In pups fed steam-injected and in-can sterilized formulas, the increases in total and essential plasma amino acid levels were less responsive and the concentrations were also lower for most of the respective amino acids than those in unheated formula-fed pups at 0.5 h; the differences were significant for leucine in steam-injected formula-fed pups and isoleucine in in-can sterilized formula-fed pups. When it comes to Lys, the amino acid of major interest in the context of proteomic analysis, the unheated formula-fed pups exhibited the highest plasma level, followed by steam-injected and in-can sterilized formula-fed pups. However, the differences did not reach statistical significance.

DISCUSSION

Aiming to elucidate the relationship between protein modifications and protein digestibility of milk-based infant/enteral

J. Agric. Food Chem. 2015, 63, 6787−6798

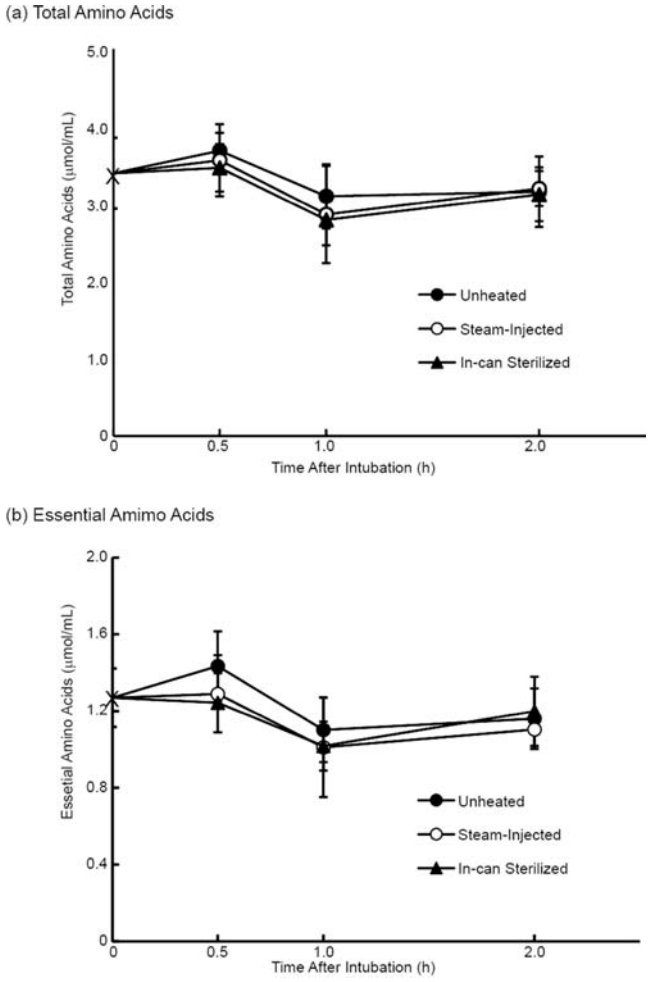

Figure 7. Plasma total and essential amino acid concentration in suckling rat pups. Rat pups fed different formula samples were killed at 0.5, 1, and 2 h after intubation, and blood was collected by cardiac puncture. Plasma was separated by centrifugation and applied to amino acid analysis. Total and essential amino acid levels are expressed as means ± SD (n = 3 males + 3 females) except for baseline, where it is shown as means ± SD (n = 3 male + 2 female pups). No significant difference was observed among the formula-fed pups at any time point.

formulas, enteral formulas with two types of industrial heating processes were industrially prepared, and these formulas as well as unheated formula were investigated as we did previously for cow's milk.[12]

Electrophoresis of the three formulas showed that in-can sterilization greatly influenced protein associations, while steam injection did not exert any significant effects. This observation was partly in disagreement with our previous study,[12] where both in-can sterilization and steam injection of raw milk affected protein band patterns (although the former had greater effects). This discrepancy may partly be attributed to protein damage potentially present in raw materials for enteral formulas; proteins are generally heat-treated and sometimes subjected to long terms of storage as raw materials. In the case of CN ingredients, industrial isolation involves isoelectric precipitation followed by neutralization at alkaline pH. These processes/conditions facilitate protein modifications such as formation of Amadori products and cross-linked products.[34,35] Proteomic analysis is also likely to unravel protein damage in raw materials; dehydroalanine formation could be identified and quantifiable at 8 Ser and 2 Cys residues in proteins of unheated enteral formula, while it was quantifiable only at 3 Ser residues in raw milk proteins of our previous study,[12] although some caution is needed for making a direct comparison between the two independent studies. Thus, proteins were associated with each other to a considerable extent in ingredients of enteral formulas, which may obscure the existence of newly formed aggregates caused by subsequent industrial heating (especially by steam injection) as shown in our electrophoretic analysis. Proteomic analysis further elucidated effects of heat treatment on proteins. Both steam injection and in-can sterilization progressed the Maillard reaction in major milk proteins, and the highest signals for CML were observed at many Lys residues of CNs in in-can sterilized formula. These results indicate that in-can sterilization facilitates the reaction to a greater extent, resulting from its more severe thermal history including slow rates of temperature rise/fall and longer hold time at high temperature. The severity of the in-can sterilization process is also likely to be manifested as a progression of dephosphorylation of CNs in the formula, while this was not found in steam-injected formula. This notion may also be supported by a study of Birlouez-Argon et al.; they reported higher CML amounts in sterilized infant formula than in UHT formula.[17] In contrast to CML and dephosphorylation, formation of lactulosyllysine, fructosyllysine, and dehydroalanine generally proceeded after both steam injection and in-can sterilization, and we observed only minor and inconsistent difference between the two heat treatments. Both lactulosyl/fructosyllysine and dehydroalanine are intermediates of CML and cross-linked products, respectively.[3,6,36] Rufián-Henares et al. formulated an infant/enteral formula-resembling mixture, dissolving whey protein isolate and lactose/maltodextrin in phosphate buffer, and they reported a time-induced increase and subsequent decrease in furosine contents after heating the mixture at 140 °C. They concluded that formation of Amadori products would first be facilitated, which is followed by degradation into advanced Maillard reaction products.[37] van Boekel reported that dehydroalanine formation paralleled heating time in β-CN solutions at 110 and 120 °C, but the amounts got saturated over time when heated at 130 and 140 °C,[32] suggesting its conversion into cross-linked products. Thus, formation of these intermediate structures may not always parallel intensity of the heat treatment.

Electrophoretic analyses of in vitro digestion assays demonstrated that in-can sterilized formula had smeared bands that persistently resisted pepsin/pancreatin digestion. Protein digestibility determined by a Dumas method in combination with TCA precipitation showed that steam-injected formula exhibited higher digestibility than unheated formula, while milk proteins in in-can sterilized formula were digested to an extent similar to those in unheated formula. Similarly, although it was only assessed by immuno-reactive materials for β-LG in in vivo digestion assays, β-LG in steam-injected formula showed more extensive digestion than in unheated formula, while β-LG in in-can sterilized formula was digested to an extent similar to that in unheated formula. Thus, as reported previously,[13] UHT treatment appears superior to in-can sterilization in terms of protein digestibility; steam injection principally improved protein digestibility, possibly by denaturation, but the heat-induced improvement in protein digestibility may be overwhelmed by adverse effects caused by formation of proteolytic-resistant aggregates to a greater extent in in-can sterilized formula. In contrast, it seems that both steam injection treatment and in-can sterilization equally had negative impact on amino acid bioavailability, as manifested by lower levels in plasma amino acids

[a]Three-letter codes are used for all the amino acids. Note that cysteine (measured as cystine) were below the detection limit in all the plasma samples. [b]Each amino acid concentration is expressed as mean value (n = 3 male + 2 female pups). [c]Each amino acid concentration is expressed as mean value (n = 3 male + 3 female pups). [d]$P < 0.05$ (vs unheated formula-fed pups at 0.5 h). [e]$P < 0.05$ (vs unheated formula-fed pups at 0.5 h).

of rat pups fed these heated formulas at a specific time point compared with those of unheated formula-fed pups. Further, this trend was the case for most of the amino acids (but not for specific amino acids), and an involvement of decreased protein digestibility, rather than damage/modifications of specific amino acids, is therefore suggested. One possible explanation may be that digesta from steam-injected formula, as well as those from in-can sterilized formula, may contain large amounts of small proteolytic-resistant peptides that cannot be detected by SDS-PAGE/Western blotting nor be precipitated by TCA (12% final concentration), which would significantly compromise amino acid absorption. However, amino acid bioavailability discussed here was evaluated only by amino acid levels at a single time point, warranting further investigation with expanded experimental conditions. In a proteomic context, the extent of CML formation and dephosphorylation of Ser residues implicates the greatest protein damage in in-can sterilized formula, followed by in steam-injected formula. Progressed formation of proteolytic-resistant structures can therefore be suggested, as previously discussed by Cattaneo et al.,[34] but it should be remembered that protein modifications such as lysinoalanine and lanthionine per se could not be measured due to technical limitations.

When it comes to comparisons between our two studies,[12] protein digestibility of milk-based enteral formulas may be inferior to that of cow's milk, although there are some differences in milk protein composition and experimental procedures. Values for in vitro protein digestibility determined for unheated, steam-injected, and in-can sterilized formulas were principally lower than those for raw, steam-injected, and in-can sterilized cow's milk. In our in vivo study, rats fed enteral formulas exhibited a slower decrease in weights of coagulates in stomach and insignificant changes in their pH over time in comparison with cow's milk-fed rats, indirectly suggesting slower gastric emptying rates for enteral formulas caused by their poorer protein digestibility. Even though experimental settings for the Western blots were somewhat different, immuno-reactive materials from β-LG could be detected in lower small intestine of formula-fed rats, but not in cow's milk-fed rats, further supporting the inferiority in protein digestibility of enteral formulas. Differences in protein digestibility between cow's milk and enteral formulas are further supported by some studies,[13,16] and these may be explained by protein damage in raw materials as discussed above[34,35] and the fact that proteins are further damaged by subsequent heating in production of formula products.

In conclusion, heat treatment of milk protein-based enteral formulas facilitates protein modifications and apparently attenuates protein digestibility and amino acid bioavailability. These adverse effects are more likely to be prominent in enteral formulas in comparison with our previous study on cow's milk. In-can sterilization may have greater impact on protein modifications and digestibility than steam injection treatment, but the differences might be of limited significance in terms of amino acid bioavailability. It should be noted that the conditions for heat treatments used here may not be representative of UHT treatment and in-can sterilization in general, and the observations reported here may not always be applicable to other similar products. Still, raw materials and types of heat treatment should be carefully selected in terms of protein quality, for achieving better nutritional potential of milk-based enteral formulas.

d'Aquitaine (BA) breed, characterized by good muscle development, producing tender meat[20] but with a relatively pale color.

MATERIALS AND METHODS

Animals and Sampling. This study was part of the European ProSafeBeef project (FOOD-CT-2006-36241). Twenty-one Blond d'Aquitaine (BA) young bulls reared under intensive conditions and finished over two consecutive years (two replicated groups) were used. At 12 months of age, they were subjected to a 105 day finishing period until slaughter. Diets consisted of concentrate (75%) and straw (25%). Before slaughter, all animals were food deprived for 24 h and had free access to water. The animals at a live weight of 635 ± 52 kg were slaughtered at the experimental abattoir of the INRA Research center in compliance with the current ethical guidelines for animal welfare. Bulls were directly transported (4.5 ± 0.1 min) in a lorry (3 × 2 m livestock compartment) from the experimental farm to the experimental abattoir situated 2 km from the rearing building, with two bulls of the same home pen per transport to avoid social isolation stress. After unloading, they were slaughtered within 3 min.[21] The mean hot carcass weight was 410 ± 42 kg (range from 337 to 500 kg). The carcasses were not electrically stimulated, and they were chilled and stored at 4 °C from 1 h until 24 h post-mortem. *Longissimus thoracis* (LT, mixed fast oxido-glycolytic) muscle samples were excised from the left side of the sixth rib 30 min post-mortem and frozen in liquid nitrogen before storage at −80 °C until protein extractions for Dot-Blot analysis or myosin heavy chain (MyHC) quantification.

pH Measurements. For $pH_{45\ min}$ measurement, biopsies were made from the carcasses (10th rib), whereas $pH_{3\ h}$ and ultimate pH (30 h; pH_u) were measured directly on the carcass (right side). pH was determined as in Bourguet et al.[21] Briefly, 2 g of each LT sample excised 45 min after slaughter was immediately homogenized in 18 mL of 5 mM sodium iodoacetate and stored at 4 °C. The pH of the homogenate was measured the following day at 6 °C. For $pH_{3\ h}$ and pH_u, the pH was recorded directly on the carcass between the sixth and seventh rib using a pH meter (Hanna Instruments, HI9025) equipped with a glass electrode suitable for meat penetration. For each time point, five measurements were made (positioned on a horizontal line with about 1.5 cm between two measurements).

Meat Color. The LT muscle was excised from the stored carcass at the level of the sixth rib *thoracis* vertebra 24 h post-mortem to determine color attributes. Instrumental meat color measurements were recorded for lightness (L^* = measures light reflected), redness (a^* = measures positive red and negative green), and yellowness (b^* = measures positive yellow and negative blue) directly on the tissue of the muscle using a Minolta CR-300 chromameter (Minolta Co., Ltd., Osaka, Japan), with a 0° viewing angle, C illuminant, and 8 mm measurement aperture. Fresh-cut slices of muscle of not less than 2.5 cm thick and overwrapped were left on a polystyrene tray to refrigerate at 1 °C for 1 h to allow blooming. Calibration was performed by using standard white tiles (Y = 93.58, x = 0.3150, and y = 0.3217) prior to color determination. Three replicate measurements were taken, and an average value was used for analysis. Color coordinates were expressed as L^*, a^*, b^* following the CIE-$L^*a^*b^*$ system.

Protein Extractions. Total protein extractions were performed to use subsequently the soluble fractions for Dot-Blot analysis according to the method of Bouley et al.[22] Briefly, 80 mg of muscle was homogenized in a denaturation/extraction buffer containing 8.3 M urea, 2 M thiourea, 1% DTT, and 2% CHAPS. After 30 min of centrifugation at 10000*g* at 8 °C, the supernatant was stored at −20 °C until use. The protein concentrations of the extracts were determined according to the Bradford method[23] using the Bio-Rad protein assay. Bovine serum albumin (BSA) at a concentration of 1 mg/mL was used as standard.

Dot-Blot Analysis. The abundances of 18 proteins (including intact molecules and their fragments) corresponding to five different biological functions (Table 1), muscle fiber structure (actin, MyBP-H, CapZ-β, and MyLC-1F), metabolism (ENO3, LDHB, and MDH1), proteolysis (μ-calpain), oxidative resistance (DJ-1, Prdx6, and SOD1), and heat shock proteins (αB-crystallin, Hsp20, Hsp27, Hsp40, Hsp70-1A/B, Hsp70-8, and Hsp70-Grp75), were determined using the Dot-Blot technique.[14,15] Compared to Western blot, Dot-Blot is a fast technique, but with a similar coefficient of variation inter- and intra-assay (10%). Optimal dilution ratios of the antibodies were determined, using the conditions indicated by the supplier and adapted to bovine muscle samples (Table 1). For that, Western blots were used to check the specificity of all antibodies. An antibody was considered specific against the studied protein when only one band at the expected molecular weight was detected by Western blot. Western blots with all primary antibodies show that all of the antibodies used bound specifically to the bovine protein with the expected theoretical molecular weight.

Conditions retained and suppliers for all primary antibodies dilutions are summarized in Table 1. Protein extracts (15 μg) of each of the 21 muscle samples were spotted (four replications per muscle sample) on a nitrocellulose membrane with the Minifold I Dot-Blot apparatus from Schleicher & Schuell Biosciences (Germany) in a random order on the 96-spots membrane. In addition, a mixed standard sample (15 μg) was deposited for data normalization as reported by Guillemin et al.[15] The Dot-Blot membrane was air-dried for 5 min, blocked in 10% milk blocking buffer at 37 °C for 20 min, and then hybridized and incubated with the specific primary antibody of each protein (Table 1). Infrared

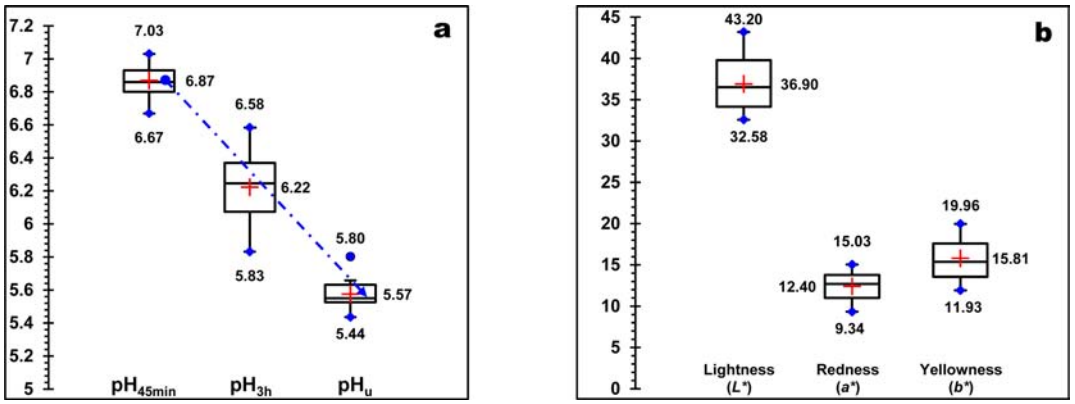

Figure 1. Average means of (a) pH (45 min, 3 h, and ultimate (u)) and (b) $L^*a^*b^*$ meat color parameters of *Longissimus thoracis* muscle of Blond d'Aquitaine young bulls (n = 21). The parameters are presented as box−whiskers plots: for each variable independently, the central point represents the average value calculated over all of the observations. The box represents the average value ± one standard deviation; the bar represents the minimum and maximum values.

fluorescence detection was then used for quantification of the relative protein abundances. Subsequently, the membranes were scanned by the Odyssey scanner (LI-COR Biosciences) at 800 nm. The relative protein abundances for each sample are given in arbitrary units.

Electrophoresis and Quantification of Myosin Heavy Chain Isoforms. Three other biomarkers corresponded to MyHC and were determined according to the method of Picard et al.[24] using an adequate SDS-PAGE and expressed in percentage. Briefly, 100 mg of frozen muscle was ground in 5 mL of extraction buffer solution containing 0.5 M NaCl, 20 mM sodium pyrophosphate, 50 mM Tris, 1 mM EDTA, and 1 mM dithiothreitol. After 10 min at 4 °C on ice, the sample was centrifuged for 5 min at 5000*g*. Following centrifugation, the supernatant was diluted 1:1 (v/w) with glycerol at 87% and stored at −20 °C until use. The samples were then mixed with an equal volume of loading buffer containing 4% SDS (w/v), 125 mM Tris, pH 6.8, 20% glycerol (v/v), 10% β-mercaptoethanol (v/v), and 0.02% pyronin Y (w/v). The proteins were separated using 9.2% polyacrylamide gels. After staining, the gels were scanned, and the proportions of the different MyHCs bands were quantified by densitometry with ImageQuant Software 5500 (Amersham Biosciences/GE Healthcare). The band quantification revealed the existence of MyHC-IIb isoforms in only some animals (4 animals of 21). Consequently, MyHC-IIb percentages were totaled with those of MyHC-IIx, creating a new variable "MyHC-IIx+b" (fast glycolytic fibers).

Statistical Analysis. For descriptive statistics, raw data were used. For statistical analyses all data were standardized for replicate using the Proc Standard of SAS 9.2 to obtain Z scores. A Z score represents the number of standard deviations each observation is relative to the mean of the corresponding animal: $Z = ((x - \mu)/\sigma)$, where x is the raw value, μ is the mean of the population, and σ is the standard deviation of the same population.

The PROC CORR of SAS was used to determine the Pearson's correlation coefficients between the 21 biomarkers with pH and CIE-$L^*a^*b^*$ color coordinates. Correlation values were considered significant at $P < 0.05$.

For each pH value and each color coordinate, a principal component analysis (PCA) was carried out using PROC PRINCOMP of SAS, using only the correlated biomarkers. PCA aimed to illustrate visually the correlated biomarkers with pH and color coordinates. The overall Kaiser's measures of sampling adequacies of the performed PCAs were >0.68 for pH parameters and >0.80 for $L^*a^*b^*$ color coordinates.

Multiple regression analyses were performed using PROC REG of SAS to create best models (maximal adjusted R^2) for pH and color coordinates (as dependent variables) using the 21 protein biomarkers (as independent variables). Partial R-squares and significance of each retained variable are given for the models. Regression analyses were further conducted on L^*, a^*, and b^* color coordinates to study specifically the relationships with pH values and muscle fiber type composition.

The absence of collinearity was systematically verified for each model, by producing condition indices and variance proportions using the COLLIN procedure of SAS. Variables were identified as collinear if they possessed both a high condition index >10 and a proportion of variation >0.5 for two or more traits.

RESULTS

pH Parameters, Color Traits, and Biomarker Abundances. Average means of pH and color parameters are shown in Figure 1. pH measured 45 min post-mortem was 6.87 (±0.10) and declined to 6.22 (±0.20) 3 h post-mortem, reaching 5.57 (±0.08) 30 h post-mortem (Figure 1a). Mean color coordinates were 36.9 (±3.32) for lightness (L^*), 12.40 (±1.74) for redness (a^*), and 15.81 (±2.65) for yellowness (b^*) (Figure 1b). Relative abundances of biomarkers expressed in arbitrary units or in percentage (MyHC) are summarized in Table 2. The LT muscle was characterized by 19.2% (±3.6) of type I fibers, 3.9% (±4.3) of IIa, and 56.9% (±4.0) of IIx/b.

Relationships between Biomarkers and pH Parameters. pHu was correlated with $pH_{45\ min}$ (r = 0.47; $P < 0.05$) and $pH_{3\ h}$ (r = 0.59, $P < 0.01$). $pH_{45\ min}$ was correlated with $pH_{3\ h}$ (r = 0.47, $P < 0.05$). pH was further correlated with 11 biomarkers (Figure 2a). Prdx6 was negatively correlated with $pH_{45\ min}$ (r = −0.49, $P < 0.05$), $pH_{3\ h}$ (r = −0.47, $P < 0.05$), and pH_u (r = −0.66, $P < 0.01$). Hsp70-Grp75 and DJ-1 were negatively correlated with both $pH_{3\ h}$ (r = −0.45 and −0.56, $P < 0.05$, respectively) and pH_u (r = −0.45 and −0.43, $P < 0.05$, respectively). Actin was negatively correlated with $pH_{45\ min}$ and pH_u (r = −0.40, $P < 0.05$). MDH1 was negatively correlated (r = −0.48, $P < 0.05$) with $pH_{45\ min}$ only. MyBP-H (r = −0.43), ENO3 (r = −0.46), LDH-B (r = −0.43), and Hsp20 (r = −0.50) were significantly ($P < 0.05$) and negatively correlated with $pH_{3\ h}$. MyHC-IIx/b (positively) and CapZ-β (negatively) were correlated with ultimate pH only (r = 0.40 and −0.55, $P < 0.05$, respectively). The biomarkers that were significantly correlated with pH were introduced into PCAs (Figure 3). The first two PCA axes explained 80.7, 69.4, and 73.2% of the variability between animals of $pH_{45\ min}$ (Figure 3a), $pH_{3\ h}$ (Figure 3b), and pH_u (Figure 3c), respectively.

Regression Analyses of pH Parameters. The multiple linear regression analyses, using pH parameters as dependent and biomarker abundances as independent variables, revealed significant relationships (Table 3; Figure 4). For $pH_{45\ min}$, 47% of the variability ($P < 0.01$) was explained by MDH1 and actin

(negative) and Hsp70-8 (positive). For $pH_{3\ h}$, the model was almost similar to the $pH_{45\ min}$ model and explained 59% of the variability ($P < 0.001$) in terms of LDH-B and actin (negative) and Hsp70-8 (positive). If included, Hsp27 (negative) was retained ($P < 0.05$) in the model, which then explains 67% of the variability. For ultimate pH, it was not possible to construct a significant model with three variables. Hence, a fourth variable was included, producing a model explaining 58% of the variability

($P < 0.001$): Prdx6 and Hsp40 (negatively) and Hsp70-1A/B and MyLC-1F (positively).

Relationships between Biomarkers and Meat Color Traits. Pearson correlation analyses revealed that the three measured color parameters were not correlated ($r < 0.29$). L^*, a^*, and b^* values were correlated with 12 biomarker abundances ($P < 0.05$; in Figure 2b). Hsp70-1A/B and μ-calpain were correlated with all color coordinates: negatively with L^* and positively with a^* and b^* (Figures 5 and Figure 6). These two proteins were correlated together ($r = 0.69$, $P < 0.001$). Five common correlations were found for L^* and b^*, although directions differed. L^* and b^* were correlated with αB-crystallin ($r = -0.56$ and 0.55, $P < 0.05$, respectively), Hsp70-8 ($r = -0.68$ and 0.41, $P < 0.05$; respectively), MyHC-I ($r = -0.53$ and 0.50, $P < 0.05$, respectively), ENO3 ($r = 0.73$ and -0.55, $P < 0.01$, respectively), and MyBP-H ($r = 0.44$ and -0.53, $P < 0.05$, respectively). Hsp40 was positively correlated with both a^* and b^* ($r = 0.65$ and 0.45, $P < 0.01$, respectively). Actin (negatively) and MyHC-IIa (positively) were correlated with L^* only ($r = -0.51$ and 0.46, $P < 0.05$, respectively). MDH1 and Prdx6 were positively correlated with a^* only ($r = 0.63$ and 0.46, $P < 0.01$, respectively). These two proteins were closely related ($r = 0.50$, $P < 0.05$). PCAs were carried out for each color coordinate, introducing only the correlated biomarkers. The first two axes of the PCA explained 68.8, 77.2, and 75.5% of the variability between animals of L^* (Figure 5a), a^* (Figure 5b), and b^* (Figure 5c), respectively.

Regression Models for Meat Color Traits. Simple correlations between pH values and color coordinates were not significant ($-0.34 < r < 0.10$; $p > 0.13$). The regression models using $L^*a^*b^*$ coordinates as dependent and pH and fiber types as independent variables found a significant model only for L^*, explaining 37.9% of the variability with pH_u (13.5%; $P < 0.05$) and MyHC-I (24.4%; $P < 0.01$): $L^* = -0.4^*\ pH_u - 0.7^*$ MyHC-I. The regression models using $L^*a^*b^*$ color traits as dependent and biomarker abundances as independent variables are presented in Table 4 and Figure 7. The models were significant and explained between 47 and 65% of variability. The model of L^* explained 65% of the variability between animals ($P < 0.0001$) by ENO3 (positive) and Hsp70-Grp75 (negative). The model of a^* explained 62% of the variability ($P < 0.001$) by Hsp40 (positive) and SOD1 and Hsp70-8 (both negative). The model of b^* explained 47% of the variability ($P < 0.01$) by μ-calpain (positive) and Hsp70-Grp75 (negative). Both L^* and b^* models included Hsp70-Grp75, explaining 17 and 24%, respectively. All of the L^*a^* b^* color coordinate models included heat shock proteins, which explained between 17 and 50% of the variability.

DISCUSSION

Results indicate that L^*, a^*, and b^* color coordinates were unrelated among themselves and that only L^* was weakly correlated with ultimate pH. Earlier studies on pork and cattle found correlations between ultimate pH, L^*, and b^*.[4] The absence of strong correlations with ultimate pH in the present study can be explained by the fact that ultimate pH values were within the normal range.[5] Redness (a^*) is generally more influenced by early post-mortem pH. Particularly, at least in

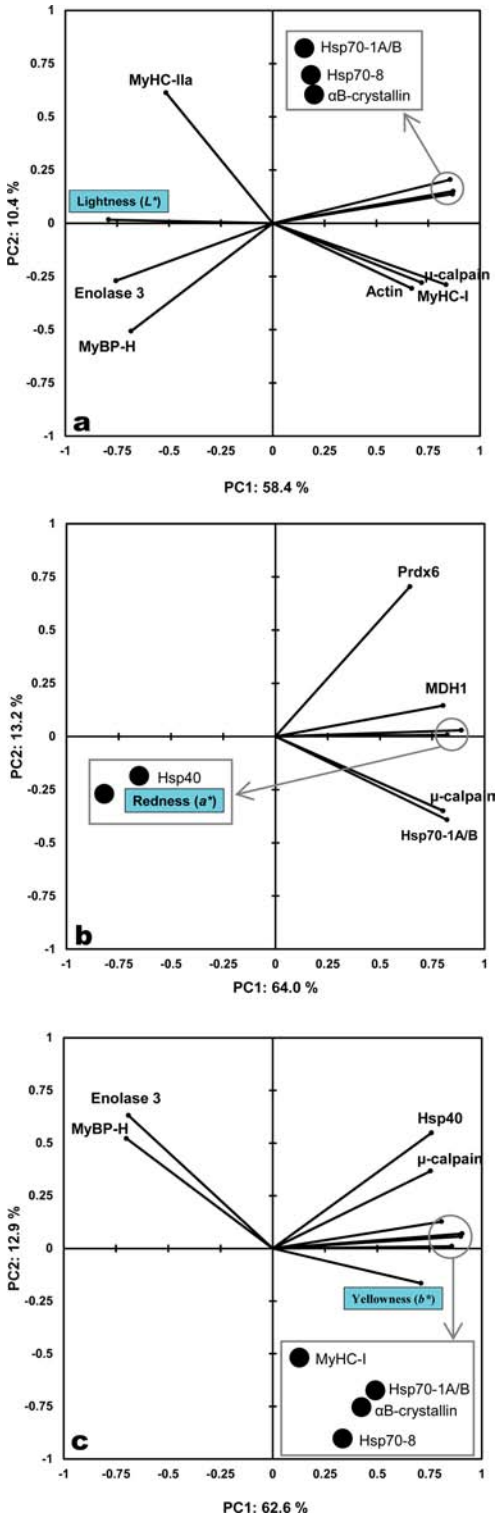

Figure 5. Principal component analyses showing relationships between (a) lightness (L^*), (b) redness (a^*), and (c) yellowness (b^*) and the correlated biomarkers.

pork, the combination of low early post-mortem thigh muscle temperature results in protein denaturation that leads to early inactivation of oxygen-consuming enzymes.[5] This promotes formation of MbO_2, leading to higher a^* values.[25] The absence of a correlation in the present study may be due to the use of cattle rather than pigs and/or the narrow range of early post-mortem pH values, compared to the study by Lindahl et al.[5]

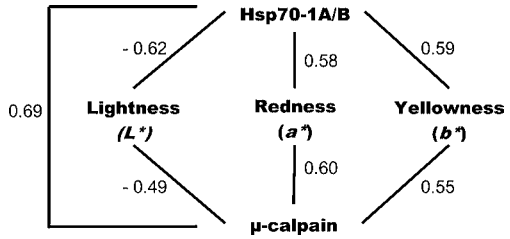

Figure 6. Pearson correlation analysis showing significant correlations ($P < 0.05$) between $L^*a^*b^*$ color coordinates and both Hsp70-1A/B and μ-calpain.

To increase our understanding of the biochemical mechanisms underlying post-mortem pH decline and color development in young Blond d'Aquitaine bulls, the following sections will discuss the relationships between these variables and the proteins (biomarkers) measured in the present study using the Dot-Bot technique.

Relationship between Biomarkers in the Early Post-Mortem Period and Post-Mortem pH Decline. *$pH_{45\ min}$.* PCA and regression analyses show that $pH_{45\ min}$ was correlated with four proteins (Actin, MDH1, Prdx6, and Hsp70-8), all implicated in apoptosis. Apoptosis is considered to start a few minutes after bleeding and to play a major role in the conversion of muscle to meat.[12,26] Apoptosis is initiated due to the hypoxic state of the muscle cells resulting in changes in the inner mitochondrial cell membrane that cause the release of pro-apoptotic proteins into the cytoplasm.[26] These events activate the caspase cascade, which is central in the apoptotic process. Actin is the first protein targeted by caspases. Actin fragments can induce morphological changes resembling apoptotic cells and may be used as a probe for apoptosis detection.[12,27] In coherence with our findings, proteomic studies found that in the early post-mortem period, actin fragments are released and that pH decline and actin degradation were closely related.[12,28,29]

In the early post-mortem period, as long as glycolytic enzymes are not inhibited by low pH, glycolysis will continue, thus contributing to the acidification process. MDH1 plays a pivotal role in the malate−aspartate shuttle operating between cytosol and mitochondria, which may explain the correlation between MDH1 and $pH_{45\ min}$.[30] MDH1 may also be implicated in apoptosis, as in response to glucose deprivation, MDH1 regulates p53-dependent cell-cycle arrest and apoptosis.[31]

In our study, low $pH_{45\ min}$ was also associated with higher Prdx6, a bifunctional protein with both glutathione peroxidase (GPx, antioxidative) and phospholipase A2 (PLA_2) activities.[32] The relationship between Prdx6 and pH decline may be partly explained by the activity of the PLA_2 group. This group plays a significant role in the hydrolysis of phosphatidylcholine (PC), which is a basic phospholipid present in cell membranes.[33] Phosphatidylserine (PS) is the acid phospholipid present in cell membranes. At the early stages of apoptosis, the phospholipid distribution in the cell membranes is inverted: PS switches to the external and PC to the internal leaflet of the membrane by a flip-flop process.[26,34] Due to this inversion, protons generated by glycolysis may be partly absorbed and the acidification process may be slowed. Due to PLA_2 activity, PC will be hydrolyzed, reducing its buffering capacity and thus enhancing the rate of pH decline in the cytosol.

Hsp70-8, a member of the Hsp70 kDa family, was positively related to early post-mortem pH. This Hsp is constitutively expressed in most tissues and essential for survival. It has many

housekeeping chaperoning functions including folding of nascent polypeptides, protein translocation across membranes, chaperone-mediated autophagy, and prevention of protein aggregation under stress conditions.[35] Due to its protective functions, increased metabolic activity may have led to increased levels and vice versa, explaining its relationship with early post-mortem pH.

$pH_{3\ h}$. PCA and regression analyses show that 3 h post-mortem, the biological pathways appear partly similar to those involved in $pH_{45\ min}$. Several other proteins are also involved, and these new relationships become apparent due to the greater time span during which protons have been able to accumulate. The correlated proteins are implicated in glycolysis (ENO3 and LDH-B), heat stress (Hsp20, Hsp70-Grp75, and Hsp70-8), oxidative resistance (Prdx6 and DJ-1), and structure (actin and MyBP-H). Results show that high levels of these biomarkers 45 min post-mortem predict low pH about 2 h later. ENO3 and LDH-B are glycolytic enzymes, and their negative association with $pH_{3\ h}$ is undoubtedly explained by a faster energy metabolism resulting in a faster pH decline.

High levels of MyBP-H proteins at 45 min post-mortem predicted also low $pH_{3\ h}$ post-mortem. MyBP-H is a cytoskeletal protein interacting with myosin thick filaments in the A-band.[36] Its relationship with $pH_{3\ h}$ may have been indirect as higher MyBP-H levels were associated with higher levels of ENO3 and LDH-B. The Dot-Blot protocol used in the present study allowed revealing both intact and fragmented protein molecules in the soluble fraction. Higher MyBP-H levels in the early post-mortem period would suggest a faster fragmentation of these structural proteins, which may result from a faster early post-mortem metabolism.

Higher Hsp20 levels may occur in response to metabolic activity and pH decline, to stabilize myofibrillar proteins.[37] For example, Lomiwes et al.[38] demonstrated that a slight decrease in post-mortem muscle pH induces a rapid binding of another small Hsp of the same family, αB-crystallin, to the myofibril. Higher Hsp20 levels 45 min post-mortem may thus have been indicative of a faster metabolism and consequently be predictive of lower $pH_{3\ h}$.

Hsp70-Grp75 was related to $pH_{3\ h}$, pH_u, and L^* and b^* color coordinates. Hsp70-Grp75 is a cytoprotective chaperone present in nearly all cellular compartments and induced by glucose deprivation, Ca^{2+} influx, or agents perturbing glycolysis.[39] It assists in the import and folding of mitochondrial proteins and protects cells from glucose deprivation and ROS accumulation.[40] Its protective function may explain the relationship between its higher levels at 45 min post-mortem and the subsequent faster pH decline. Hsp70-Grp75 sequesters and inactivates p53, preventing its nuclear translocation and apoptosis.[41] Hsp70-Grp75 may thus slow apoptotic and other processes involved in the conversion of muscle to meat. In addition, Hsp70-Grp75 links the inositol 1,4,5-trisphosphate receptor of the endoplasmic reticulum to the mitochondrial voltage-dependent anion channels, presumably enhancing Ca^{2+} trafficking from the endoplasmic reticulum toward the mitochondria.[12] This mechanism may also contribute to the relationship between Hsp70-Grp75 and pH decline as Ca^{2+} exerts regulatory effects on many enzymes and proteins involved in metabolic and apoptotic processes including in the post-mortem muscle.[12,42]

The different functions of Prdx6 have been discussed above. Hence, increased Prdx6 levels 45 min post-mortem predicted low pH 3 h post-mortem probably partly due to its PLA_2 activity on pH decline. In addition, 3 h post-mortem pH was around 6.2 and less unfavorable for the activity of the GPx group of Prdx6.[32] Thus, approaching 3 h post-mortem, Prdx6 may have acted as an antioxidant, thereby protecting metabolic activity.

DJ-1 is another antioxidant protein present in the cytoplasm as well as in intracellular organelles and scavenges H_2O_2 through oxidation of Cys-106.[43] DJ-1 is further believed to promote the expression of a number of mitochondrial enzymes involved in reactive oxygen species (ROS) removal.[44] Its association with increased levels of glycolytic enzymes and Prdx6 is coherent with its association with a faster early post-mortem pH decline.

Ultimate pH. Ultimate pH was earlier found to be correlated with levels of various muscle proteins present in beef and pork muscles 45 min post-mortem.[11] In the present study, high levels of structural proteins (actin, CapZ-β, MyLC-1F, and MyHC-IIx/b), chaperones (Hsp70-Grp75, Hsp70-1A/B, and Hsp40), and oxidative resistance (DJ-1 and Prdx6) proteins 45 min post-mortem predicted low pH_u. In contrast to $pH_{45\ min}$ and $pH_{3\ h}$, low pH_u was not predicted by high levels of glycolytic enzymes, although pH values at different post-mortem intervals were correlated. This is coherent with the knowledge that the glycolytic rate is not the sole determining factor for pH_u. The extent of pH decline may be reduced if glycogen reserves are limiting. In the present experiment, preslaughter stress levels were low and glycogen levels were not the limiting factor as we have recently showed that 24 h post-mortem the muscles of the same BA bulls contained residual glycogen.[21] If glycogen content is not the limiting factor, glycolysis stops due to other factors, probably related to the disappearance of AMP and the inactivation of glycolytic enzymes.[45]

High actin and CapZ-β contents 45 min post-mortem predicted low pH_u. CapZ-β is located in the Z band of the muscle sarcomere and caps the barbed (plus) end of actin filaments, inhibiting polymerization.[46] A proteomic study found that CapZ-β was retained in the insoluble fraction of the protein extraction and that levels declined during the 48 h following slaughter,[10] indicative of progressive CapZ-β fragmentation or detachment from the Z band. As for MyBP-H (cf. above), the higher levels of actin and CapZ-β in the early post-mortem period would suggest a relatively fast fragmentation of these structural proteins. The association between faster structural protein degradation and higher levels of protective proteins (Prdx6, DJ-1, Hsp70-Grp75) 45 min post-mortem may thus express a faster metabolism. The association between higher levels of protective proteins and lower pH_u suggests that these pathways effectively protected the cell against adverse events such as oxidative stress, presumably retarding apoptosis and preserving energy metabolism. The association between high MyHC-IIx/b content and high ultimate pH may seem unexpected. A higher MyHC-IIx/b content is usually associated with higher glycogen content and a potential for a faster metabolism, which, depending on the slaughter conditions, may result in a lower, rather than a higher, pH_u.[3]

Meat Color Traits. Mean L^* values of the meat samples of the BA breed were within the range of normal values.[47] The redness (a^*) values were lower and yellowness (b^*) values were higher than those reported in the literature.[48] This may be partly due to the relatively high content of glycolytic fibers of the LT muscle of the BA breed.[20] These fibers contain less myoglobin, resulting in lower redness, and are less efficient in oxygen exchange compared to oxidative fibers, resulting in a less reductive environment and thus promoting MbO_2 formation with a net result of greater yellowness.[25]

Relationships between Biomarkers and Meat Color Traits. PCA and regression analyses showed that L^*, a^*, and b^* values were correlated with 10, 7, and 10 biomarker abundances, respectively. L^* and b^* showed seven correlations with the same proteins but in the opposite direction. The present study used proteins related to various beef sensory qualities including tenderness.[14] Although proteomic studies on pork, beef, and fish found relationships between color and proteins involved in muscle contraction, metabolism, heat stress, signaling, and other functions,[16−19] little information exists on the relationships between beef color and biomarkers validated for other meat qualities.[49]

In the present study, μ-calpain and Hsp70-1A/B were correlated with the three color coordinates. Similarly, Joseph et al.[18] identified three overabundant chaperone proteins that were related to beef meat color stability, including a Hsp-1B of 70 kDa. Kwasiborski et al.[11] found a negative correlation between abundance of an Hsp70 isoform (Hsp72 or Hsp70-1A/B) 45 min post-mortem and L^* in pig LT muscles. Hsp70-1A/B is a member of the inducible Hsp70 family and is abundantly induced in response to cellular stress, possibly due to its function to preserve proteins.[40] One hypothesis is that inducible Hsp70s and μ-calpain influence certain meat color coordinates interactively. First, post-mortem ROS damage of the endoplasmic reticulum of the cells leads to the liberation of Ca^{2+} in the cytosol, which activates μ-calpain. Structural proteins are a major substrate of μ-calpain, and their characteristics influence meat color aspects. Second, inducible Hsp70s may interfere in this process. Post-mortem, oxidative stress induced by a product of lipid peroxidation, 4-hydroxy-2-nonenal (4-HNE), an α,β-unsaturated aldehyde,[8] causes carbonylation of Hsp70,[50] thus inactivating it. It was recently reported that in monkey hippocampal CA1 neurons, carbonylated Hsp70s are key substrates of μ-calpain.[51] If this pathway exists also in muscle, the carbonylated forms of inducible Hsp70 may be hydrolyzed by μ-calpain.[51] 4-HNE may also contribute to the phenomenon as it may cause disruption of Ca^{2+} homeostasis, membrane and structure damage, and cell death.[52] In support of this hypothesis, 4-HNE was reported to affect meat color by formation of several adducts with muscle proteins, thus modifying protein functionality.[53,54] Thus, increased levels of carbonylated Hsp70s will protect structural proteins against μ-calpain activity, thereby deferring changes in the structure of pigment and myofibrillar proteins, influencing hence reflectance and other aspects of meat color. Inducible Hsp70 binds also with membrane phospholipids[55] and interacts with PLA2 activity[56] and may thus participate in reactions involving phospholipids, pH decline, and apoptosis onset.

Other Hsps were also correlated with color coordinates. Hsp70-8 and αB-crystallin were negatively and positively correlated with L^* and b^*, respectively. Hsp40 was positively correlated with a^*. Other studies found also relationships between Hsp contents of the early post-mortem muscle and color coordinates. Zhang et al.[57] reported opposite relationships between Hsp90 contents in the early post-mortem muscle and L^* and b^* in pigs. The involvement of Hsps in meat color may be in part related to their protective role against protein denaturation known to affect the reflectance of meat aspects.[19] Overall, these relationships indicate that inducible and constitutively expressed Hsps may play a major role in the determination of meat color.

The association between slow twitch oxidative fibers (type I) and L^* and b^* coordinates may be related to their relatively high content of myoglobin, which explains part of the variation in meat color.[25] In addition, they contain high levels of inducible Hsp70, of which the potential role has been described above.

The positive correlation between redness (a^*) and Prdx6 can be explained by the involvement of the GPx group, which has antioxidative properties. Tang et al.[58] reported that adding glutathione to bovine muscle cytosol improved MbO_2 redox stability, allowing increased redness. The present study found

DOI: 10.1021/acs.jafc.5b02615
J. Agric. Food Chem. 2015, 63, 6799−6809

also a positive correlation between MDH1 and a^* values. Glycolytic enzymes were earlier found to be positively correlated with redness (a^*) in beef.[16,18] In the presence of a reductor, MetMb can be converted back into Mb. The reduction process is primarily enzymatic in nature with NADH as cofactor and can take place under anaerobic or aerobic conditions.[1] The glycolytic pathway allows the production of NADH,[1,59] which may explain the correlation between a^* and MDH1.

While many studies have shown relationships between beef color and protein biomarkers after ≥24 h post-mortem, the present study shows that protein biomarkers present in the early post-mortem period may predict subsequent pH decline and color development. Overall, the results show that correlations between pH decline, meat color coordinates, and protein biomarkers reflect existing knowledge on post-mortem muscle processes involved in pH decline and meat color determinism. The role of the distribution of muscle fibers is probably due to their myoglobin content, directly influencing color, and mitochondria content, involved in the initiation of the apoptosis process. The involvement of Hsps and oxidative proteins is explained by their protective functions, thereby preserving metabolism and retarding proteolysis and apoptosis onset. Antioxidants maintain further the redox state, thus stabilizing myoglobin. Prdx6 plays an important role, probably due to its dual functions of antioxidant and phospholipase activities. Enzymes of the glycolytic pathways influence pH decline and thus, indirectly, color stability, but deliver also energy and cofactors (NADH) allowing reduction of MetMb. The degree of fragmentation of structural proteins reveals the proteolytic and apoptotic status of the cell, and being substrates that may also enhance these processes. pH plays an important role as it influences the activity of at least part of the proteins (e.g., sHsps and Prdx6).

Thus, several of the tested biomarkers have been identified as being relevant for the traits of interest, and their relationships with the traits have been discussed in terms of possible underlying biochemical mechanisms. Before these biomarkers can be used as an industrial tool, further developments are needed. For example, the robustness of the relationship, in terms of breed, gender, feeding regimen, and muscle, should be investigated. The knowledge presented here should allow a greater understanding of similarities but also of differences that may exist with other animal types than the one studied. In addition, techniques for routine measurements must be developed (for example, Dot-Blot or antibody microarray techniques[13,60]). Once developed, the meat industry may benefit from the use of biomarkers as a tool for investigation, monitoring, or decision/management. In addition, knowledge of the biochemical pathways involved in meat color development and stability may be used to control or improve meat aspects under field conditions. As indicated above, addition of pyruvate to beef cuts improved meat color, as pyruvate regenerates NADH through the TCA cycle, leading to MetMb reduction.[8] Similar results were obtained for the addition of NAD^+, lactate, or LDH.

Table 1. Potato Cultivars for Metabolite Profiling Studies

cultivar	flesh	periderm russeting	skin
Norkotah Russet	white	russeted and netted	dark tan
Atlantic	white	lightly netted to heavily scaled	white
Chipeta	white	small russeted areas	light to buff
Yukon Gold	light yellow	smooth, finely flaked, yellowish white	yellowish

comprehensive chemical picture of the wound-healing process and its dependence on potato variety, the current study draws on a concurrent partitioning strategy to add cultivar-specific differences in the metabolite profiles and scavenging abilities of nonpolar extracts as well as chemical compositions of the corresponding insoluble material that remains after polar and nonpolar metabolite extraction. Contrasts are also drawn between the metabolites and solid materials present at early (day 3) vs late (day 7) time points after wounding, representing formation of the suberized closing layer as an initial healing response and when the nascent wound periderm is developing, respectively.[9,10,12] The nonpolar compounds signifying those metabolites that distinguish the two wound-healing time points (day 3 vs day 7 in all cultivars) or that discriminate among the four cultivars (at a given time point) are referred to as potential wound-healing and potential cultivar markers, respectively. These compounds were detected using multivariate statistical analysis, then identified and elucidated by matching their GC/MS data with suitable databases. Knowledge of the marker compounds involved in the wound healing process can guide the design of methods to expedite this process, thus improving crop protection during growth and after harvesting. Taken together, these studies can promote the development of food staples possessing beneficial antioxidant capabilities, robust wound healing, and reduced agricultural waste.

MATERIALS AND METHODS

Reagents. The following chemicals were used for extraction and GC/MS analysis: HPLC−MS grade water, methanol, and chloroform (J. T. Baker, Phillipsburg, NJ); hexadecyl hexadecanoate, C_7−C_{40} saturated alkane standards, and formic acid (Sigma-Aldrich, St. Louis, MO); GC/MS grade *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA) + 1% trimethylchlorosilane (TMCS) (Thermo Scientific, Bellefonte, PA); pyridine (EMD Millipore Corporation, Billerica, MA). Potassium peroxosulfate (Sigma-Aldrich), 2,2′-azinobis (3-ethylbenzothiazoline-6-sulfonic acid ammonium salt) (ABTS), and 6-hydroxy-2,5,7,8 tetramethylchromane-2-carboxylic acid (TCI, Tokyo, Japan) were used for the antioxidant assay.

Plant Material. Potato tuber cultivars from the 2011 crop year were provided by Joe Nuñez, University of California Cooperative Extension (Davis, CA). Differences in their overall phenotypic characteristics are summarized in Table 1.

Sample Preparation. The dormant freshly harvested potato tubers were peeled, sectioned, and allowed to heal as described previously.[12] Briefly, internal flesh tissues were sectioned longitudinally with a mandolin slicer to obtain disks about 5 mm thick. Healing in the dark at 25 °C was accomplished by placing the slices on wet cellulose filter paper inside closed humidified plastic boxes equipped with wire netting supports. The new brown surface layer of wound-healing tissue is identifiable because it is easily excoriated and detached, then removed by sweeping a flat spatula under the layer. During tissue collection, flesh (parenchyma) contamination under the wound healing surface was avoided to the extent possible. The samples were harvested at 3 and 7 days after wounding, corresponding to early healing in which the suberized closing layer had formed and to the developing wound periderm, respectively. Samples were frozen immediately in liquid nitrogen and stored at −80 °C. Processing involved grinding under liquid nitrogen, freeze-drying, and again storing at −80 °C.

For chemical analysis, concurrent extraction and partitioning of polar and nonpolar constituents were carried out using a slightly modified version of the method introduced by Choi et al.[13] for metabolomics of plant materials.[14] Extraction of 10 mg samples by 1 min of pan ultrasonication (Branson Ultrasonics, Danbury, CT) in 2 mL of 60% (v/v) methanol−water was followed by addition of 2 mL of chloroform and an additional 1 min of sonication in a 4-mL glass vial. Extracts were then incubated in a shaker at room temperature for 10 min, followed by tabletop centrifugation (Beckman Coulter, Fullerton, CA) at 1089*g* and 25 °C to produce three phases: upper soluble polar, lower soluble nonpolar, and an interphase of suspended particulates. After removal of the liquid polar and nonpolar extracts with a glass Pasteur pipet, the remaining residue of interfacial particulate solids was filtered, washed, and dried under a flow of nitrogen. Six biological replicates per cultivar were extracted in parallel for each of the day-3 and day-7 time points.

GC/MS Analysis. The samples were prepared according to Yang et al.[8] For metabolite separation and identification, a 500-μL aliquot of each nonpolar extract was placed in a glass vial and evaporated. Each sample was then reconstituted with 50 μL of pyridine and derivatized using 50 μL of *N*-methyl-*N*-(trimethylsilyl) trifluoroacetamide (MSTFA) + 1% trimethylchlorosilane (TMCS) at 50 °C for 1 h. Samples were analyzed with a QP2010 GC/MS (Shimadzu USA, Canby, RI) spectrometer with the injector oven set at 250 °C. The injection mode was splitless, and the volume injected for each sample was 1 μL. A Durabond-5 column (30 m × 0.25 mm i.d., film thickness 0.25 μm; Agilent Technologies, Santa Clara, CA) was used. The temperature program was based on the published method of Yang et al.[8] with minor modifications. After an initial delay of 5 min at 70 °C for the solvent to clear the system, the oven temperature was raised to 310 °C at a rate of 5 °C/min. The oven was kept at this temperature for 11 min and allowed to cool afterward to 70 °C. A 1-μL injection of 0.3 μM hexadecyl hexadecanoate provided a reference standard.

Preprocessing of GC/MS Data. The GC/MS data with a .qgd extension were converted to ANDI (CDFNET) format. MZmine version 2.4 (VTT Technical Research Center, Helsinki, Finland and Turku Center for Biotechnology, Turku, Finland) that included filtration, deconvolution, peak alignment, and data normalization was used for processing.[15] The region between 0 and 15 min, which contains peaks from derivatization artifacts, was excluded from the analysis. These peaks were also observed in blanks consisting of the solvent, pyridine, and derivatization reagent.

Multivariate Statistical Analysis. Simca-P+ software version 13.0 (Umetricas, Umea, Sweden) was used to carry out principal component analysis (PCA) of GC/MS data processed with MZ Mine using Pareto scaling.[16] This method organizes the data by relating the observations, cultivar types, and variables of the LC−MS data. The method tests the consistency of each set of biological replicates and discriminates among the different sample types.

Orthogonal partial least-squares discriminate analysis (OPLS-DA) of the data followed by the generation of S-plots helped to identify compounds that account for the differences among cultivars and between different wounding time points, which were designated as potential cultivar and potential wound-healing markers, respectively (Supporting Information, Figure S1). OPLS-DA is a regression and prediction method that finds information in the X data (e.g., variables from the LC−MS experiments) that is related to information in the Y data (e.g., discrete variables specifying cultivar type or wound-healing time point). This method shows how these two sets of information vary together and if they are dependent on each other, facilitating classification studies and potential marker identification. The S-plot serves to visualize OPLS-DA results in a scatter plot.[17] The variables (e.g., MS ions) at the extreme ends of the S-plot had $p(\mathrm{corr})[1] > 0.8$, indicating high reliability;[17] they were further examined using a variable line plot to check how specific they were to the sample type and if they qualified as potential marker ions (Supporting Information, Figure S1).

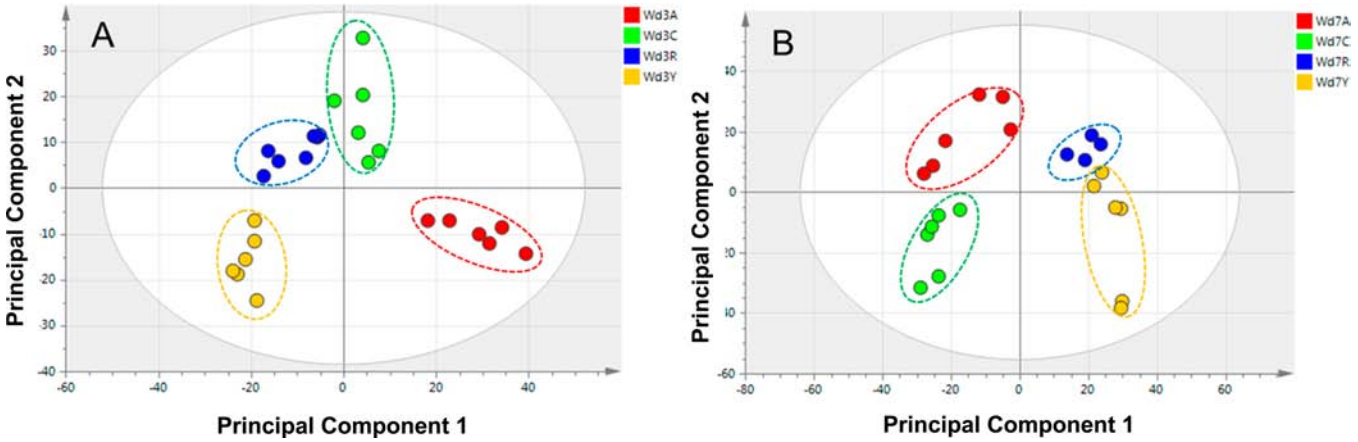

Figure 1. PCA score plot of GC/MS data from nonpolar extracts, showing consistency of each set of biological replicates and discrimination among the differently russeted cultivars at each of two time points after wounding. Included are wound-healing samples at day 3 (Wd3, A), and day 7 (Wd7, B), designated as Atlantic (red, A), Chipeta (green, G), Norkotah Russet (blue, R), and Yukon Gold (gold, Y) cultivars. The *x* and *y* axes of the plots represent the score values of principal components 1 and 2, respectively.

The PCA model was validated by calculating the values of R^2 and Q^2, which indicate fitness and predictive ability, respectively.[16] The Q^2 value, which is reported as a result of cross validation of the model, exceeded 0.5.[17] Cross validation using SIMCA-P+ divided the data into seven groups, one of which was removed. The model was then generated with the remaining groups, and the deleted group was predicted by the model. The partial predictive residual sum of squares (PRESS) was calculated. This procedure was repeated seven times to sum the partial PRESS values, obtain the overall PRESS, and calculate the Q^2 value. R^2 was larger than Q^2, but the difference between R^2 and Q^2 was small, as recommended.[17] For OPLS-DA, in addition to Q^2, the model diagnostics included R^2X and R^2Y values calculated for the X and Y variables, respectively.[17]

Metabolite Structural Identification. The ions corresponding to markers and other metabolites were identified using the Wiley Library (9th edition/NIST 2008). The ionic spectrum of each metabolite was matched against the spectra of known compounds from the library using a similarity index to identify hits. In addition, the observed spectra were compared with those of the known compounds for the ratio of ion intensities. C7−C40 saturated alkane standards (Sigma-Aldrich, St. Louis, MO) were injected. On the basis of their retention times and m/z values and using the NIST library peaks, they were assigned to standard reference compounds. There is a direct correlation between retention time and chain length.

ABTS$^{\bullet+}$ Scavenging. Antioxidant assessment of the nonpolar extracts was conducted using an ABTS$^{\bullet+}$ scavenging assay essentially as described by Dastmalchi et al.[12] Reaction of an aqueous ABTS solution (7 mM) with $K_2S_2O_8$ (2.45 mM) in the dark for 12−16 h at room temperature yielded ABTS$^{\bullet+}$, for which the absorbance at 734 nm was adjusted to 0.70 (±0.02) with ethanol. To a 2-μL aliquot of the extract of interest was added 198 μL of the ABTS$^{\bullet+}$ reagent; the absorbance at 734 nm was monitored after initial mixing and at 5 min intervals up to 45 min using a Spectra$_{max}$ M5 microplate reader (Molecular Devices, Sunnyvale, CA). Each percentage inhibition value was calculated as

$$\frac{\mathrm{Abs}_{\mathrm{control}} - \mathrm{Abs}_{\mathrm{sample}}}{\mathrm{Abs}_{\mathrm{control}}} \times 100$$

A calibration plot of percentage inhibition versus concentration was made for the reference standard, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), permitting calculation of the Trolox equivalent antioxidant capacity (TEAC, mmol Trolox/g dried sample) for each extract.

Isolation of Suberin-Enriched Tissues. The interfacial solid from the partitioned mixture was passed through a Whatman no. 4 filter paper and then washed with distilled water. To remove unsuberized cell-wall materials, the sample was treated with 0.1% (w/v) *Aspergillus niger* cellulase (MP Biomedicals, Illkirch, France) in a 50 mM pH 5.0 acetate buffer for 48 h each at 37 and 44 °C, respectively. The residue was then treated with 0.4% (v/v) *A. niger* pectinase (Sigma-Aldrich) in a 50 mM pH 4.0 acetate buffer for 24 h each at 28 and 31 °C, respectively. After the enzyme treatments, the sample was filtered, washed with deionized water, and dried at 50 °C. Soxhlet extraction was conducted under reflux conditions to remove any remaining waxes and soluble lipids, using a succession of solvents of varying polarity: methanol, chloroform, and hexane for 48 h each. The resulting solid suberin-enriched samples were reserved for solid-state NMR analysis.

Solid-State NMR Analysis. The chemical moieties present in the suberin-enriched materials were identified and quantitated using cross-polarization and direct polarization magic-angle spinning ^{13}C NMR experiments (CPMAS, DPMAS) on 3−4 mg powdered samples. A four-channel Agilent (Varian) DirectDrive I (VNMRS) NMR spectrometer (Agilent Technologies, Santa Clara, CA, USA) operating at a ^1H frequency of 600 MHz (^{13}C at 150 MHz) and equipped with a 1.6 mm HXY FastMAS probe operating at a spinning rate of 10.00 kHz (±20 Hz) was used. The spectral data were typically processed with 100 Hz line broadening and analyzed in parallel using VNMRJ (version 2.2C; Agilent) and ACD/NMR Processor Academic Edition (version 12; Advanced Chemistry Development, Inc., Toronto, ON, Canada). Chemical shifts were referenced externally to the methylene ($-CH_2-$) group of adamantane (Sigma-Aldrich) at 38.48 ppm.

For typical CPMAS experiments used to identify the carbon-containing functional groups via their respective chemical shifts, conditions included 90° pulse durations of 1.3 and 1.2 μs for ^1H and ^{13}C, respectively, a contact time of 1.5 ms, acquisition delay of 4 μs, and recycle delay of 3 s between successive acquisitions. Heteronuclear decoupling was applied with a ^1H field strength of 204 kHz using the SPINAL method.[18] The spectral width was 46296 Hz, and the number of transients was 21500. For DPMAS experiments used to estimate the relative proportions of each carbon type, a 100-s recycle delay was used to collect 2600 transients.[19] Alternatively, quantitatively reliable ^{13}C NMR spectra of suberized cell walls were obtained by acquiring 100 transients with the multiple-CPMAS method[20] after validation with a *t*-BOC alanine standard (Sigma-Aldrich) and through DPMAS measurements for the Norkotah Russet day-7 wound suberin. Radiofrequency (rf) fields of ω_{1H} = 204 kHz and ω_{1C} = 189 kHz were used for all 90° pulses. Transfer of polarization from ^1H to ^{13}C nuclei was achieved via the condition $\omega_{1C} - \omega_{1H} = \omega_{\mathrm{rotation}}$, with rf frequencies of ω_{1H} = 53.3 kHz and ω_{1C} = 63.4 kHz; a 10% linear ramp of the ^1H radiofrequency power was used during the CP period. Recycle times between successive cross-polarizations were 1.0 s; 11 contact times of 1.0 ms were used to acquire each transient. SPINAL

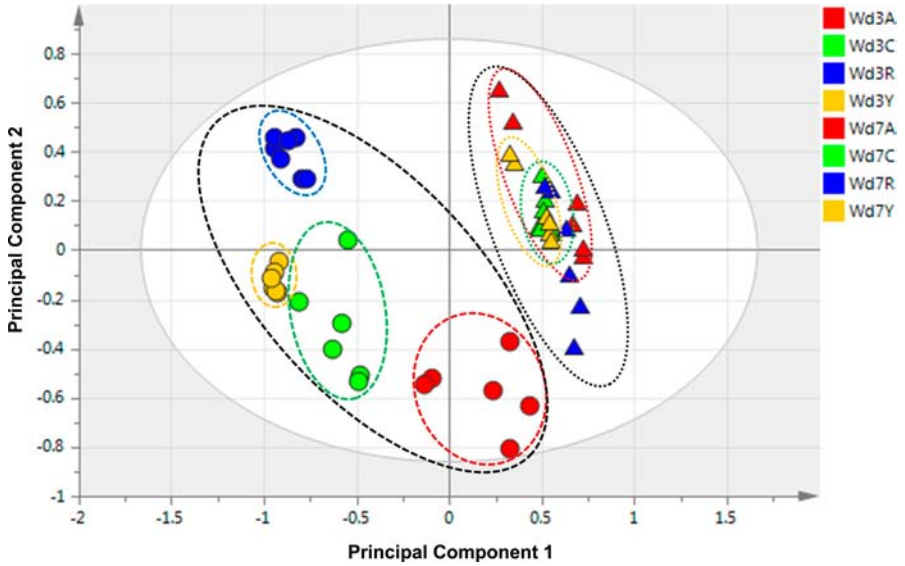

Figure 2. PCA score plot of GC/MS data from nonpolar extracts, showing overall differences among the metabolite profiles for wound-healing samples of four cultivars at day 3 (circles) and day 7 (triangles). The samples are color-coded as Atlantic (red, A), Chipeta (green, C), Norkotah Russet (blue, R), and Yukon Gold (gold, Y) cultivars. The *x* and *y* axes of the plots represent the score values of principal components 1 and 2, respectively.

heteronuclear decoupling[18] with ω_{1H} = 204 kHz was applied during an acquisition period of 22 μs.

The 3-day wound healing samples required 5000 transients (~20 h), whereas 7-day samples required only 1500 transients (~6 h). Integrated signal intensities were measured by counting pixels with the image manipulation software GIMP (www.gimp.org) and using the following chemical shift ranges to denote major structural components of suberin: carboxyl and amide groups (168−180 ppm, region 1); arenes and alkenes (115−160 ppm, region 2); alkoxy groups (96−108, 80−92, 67−80, 59−67 ppm; regions 3−6); methoxy groups (45−59 ppm, region 7); alkyl chain methylenes (15−45 ppm, region 8). Each chemical shift range was extended by ±1 ppm to ensure that the regions were not truncated in the middle of a resonance. Each quoted quantitative estimate was the result of measurements on two biological replicates, quoted as mean ± standard error.

Statistical Analysis. The antioxidant and solid-state NMR data were presented as mean values ± standard error. Significant differences between the values were determined using Tukey's pairwise comparison[21] at a level of $P < 0.05$, assessed with JMP software version 12 (http://www.jmp.com).

RESULTS AND DISCUSSION

GC/MS Multivariate Analysis Reveals Distinctive Metabolite Profiles for the Four Cultivars. The PCA score plots derived from GC/MS of the day-3 nonpolar samples show clear, nonoverlapping clusters representing the respective metabolite profiles of the four cultivars (Figure 1A), but those differences are less distinct for the day-7 time point (Figure 1B). For the GC/MS data considered collectively from both time points, the PCA plot of Figure 2 clearly shows that the cluster corresponding to all of the day-7 extracts is more compact compared with the overall day-3 cluster. This trend, which was also reported for the corresponding polar extracts[12] and for Russet Burbank wound-healing samples,[8] is likely to reflect a common biosynthetic pathway induced by wounding in each of the four cultivars. Thus, similar phytochemicals associated with wound healing are expected to become increasingly dominant with respect to the initially distinct metabolite pools of each cultivar. For the Atlantic extracts, the similar values of the first principal component (PC1) observed for day-3 and day-7 clusters (Figure 2) indicate that its nonpolar metabolites change more modestly, or at a slower rate, in response to wounding.

The nonpolar compounds that distinguish the two wound-healing time points (3-day vs 7-day for all cultivars) or the four cultivars at a particular time point can be considered as potential wound-healing and cultivar markers, respectively. These compounds were identified from the "wings" of S-plots generated by OPLS-DA[12] (Supporting Information, Figure S1) and elucidated structurally by matching their GC/MS data against the spectra of known compounds from the Wiley Library as described above. A total of 28 identified potential marker compounds were detected from the S-plots and variable line plots as noted above.

These compounds were classified as alkanes, α,ω-fatty diacids, α,ω-hydroxyfatty diacids, fatty acids, hydroxyfatty acids, fatty alcohols and aldehydes, and glyceryl esters (Table 2, **1**−**28**). Seven compounds that distinguish the day-7 time point (hentriacontane (**3**, 31:0), 2-hydroxysebacic acid (**8**, 10:0), tetradecanoic (myristic) acid (**10**, 14:0), hexadecanoic (palmitic) acid (**12**, 16:0), heneicosanoic acid (**19**, 21:0), tetracosanoic acid (**21**, 24:0), and pentacosanoic acid (**22**, 25:0)) are referred to as potential wound-healing markers. These compounds, which include an alkane, an α,ω-hydroxyfatty diacid, and several fatty acids, are more abundant at day 7 in all cultivars. Hentriacontane (**3**) has been reported to be cytotoxic to in vitro L5178Y-R lymphoma murine model.[22] Tetradecanoic (**10**, 14:0) and hexadecanoic (**12**, 16:0) acids have been reported to inhibit the growth of phytopathogenic fungi.[23]

By plotting the number of nonpolar potential marker compounds in each structural class by cultivar type and time point (Figure 3), it was possible to discern additional trends and lay the groundwork to align our metabolite findings for the extracts with the solid interfacial layers described below. Whereas most potential cultivar markers are found at day 7 postwounding, when suberin biosynthesis is well underway, nine of the markers are found in day-3 extracts of the various

[h]Detected among the metabolites identified in native periderms of these four cultivars (Huang et al., unpublished).

cultivars. All four Yukon Gold day-3 markers are fatty acids, three of which appear later as day-7 Chipeta markers (Table 2). The largest numbers of fatty acid markers are present at day 3 for Yukon Gold and at day 7 for Chipeta, followed by Norkotah Russet, respectively (Figure 3A). Fatty acids, which can be substrates for subsequent elongation, hydroxylation, or esterification steps during suberin biosynthesis, comprise nearly 40% of the nonpolar potential markers overall. Therefore, we

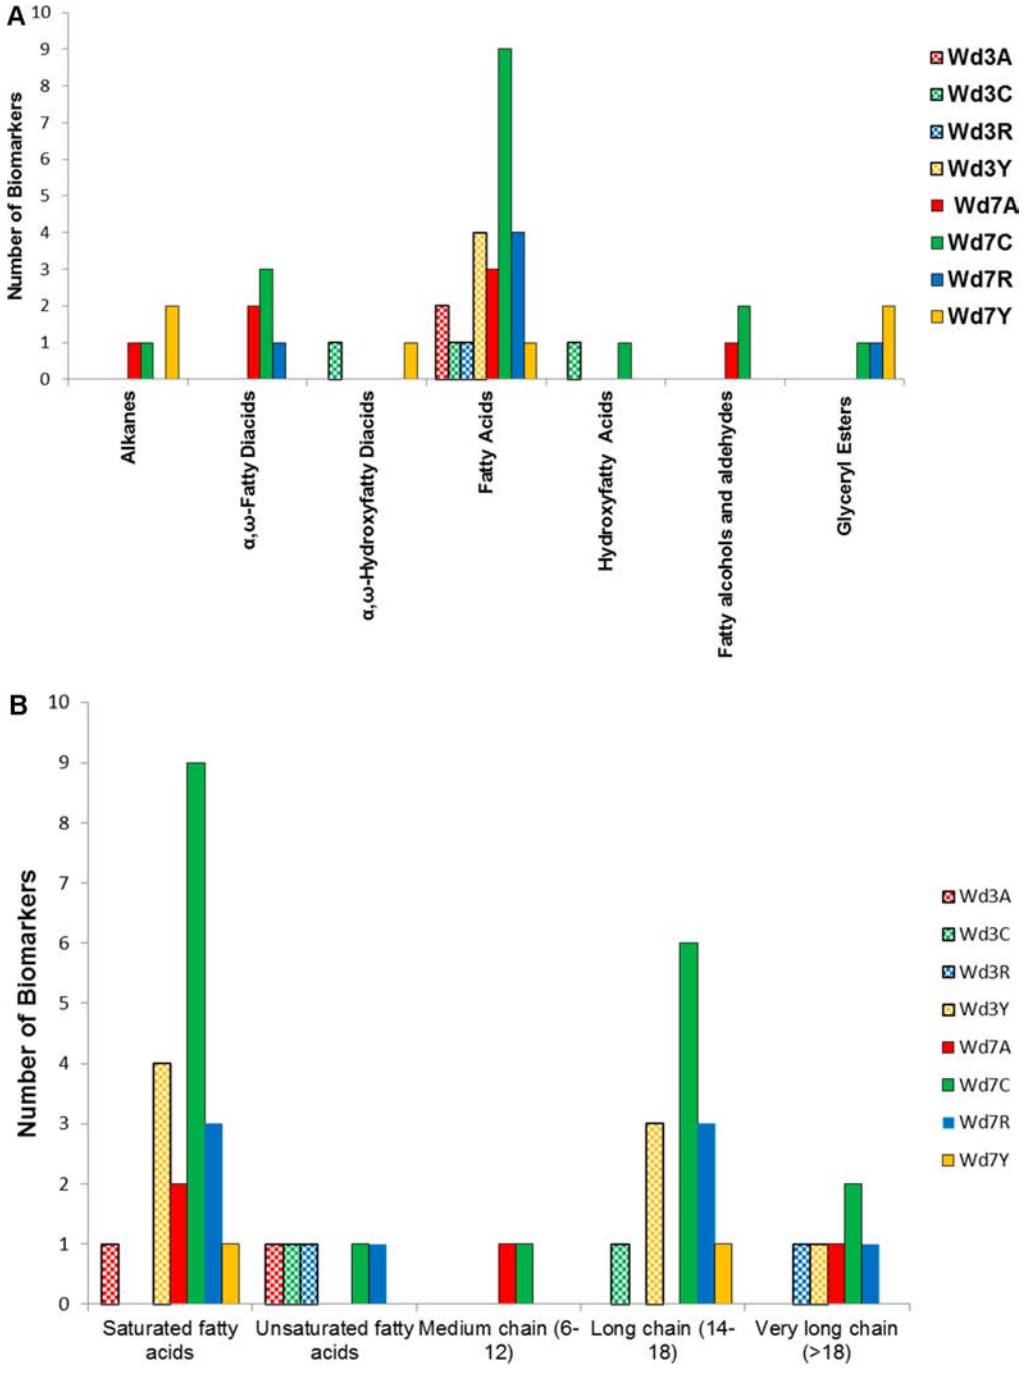

Figure 3. Accumulation of nonpolar marker compounds as a function of chemical class and time point after tissue wounding. (A) Nonpolar markers of day-3 and day-7 potato periderm extracts; (B) a detailed view of the fatty acid potential marker class. The samples are coded for Atlantic (red, A), Chipeta (green, C), Norkotah Russet (blue, R), and Yukon Gold (gold, Y), using checkerboards for day-3 and solid colors for day-7 markers, respectively.

examined this chemical class of markers in greater detail (Figure 3B), finding a significant portion (21%) of unsaturated homologues overall, although none in the Yukon Gold extracts. The fatty acid markers exhibit a broad distribution of chain lengths (11−25), with the majority in the range of 14 to 18 but no clear correlations of length according to healing time point.

The Chipeta cultivar contains nearly all potential marker classes (specifically at the day-7 time point), but a progressively diminished range of these abundant nonpolar metabolites is observed for Yukon Gold, Norkotah Russet, and Atlantic varieties. All Yukon Gold markers are saturated. Each of the less numerous marker classes is absent in one or more cultivars; hydroxyfatty acid and fatty alcohol markers are unique to the Chipeta cultivar at the day-7 time point. The absence of glyceryl ester, hydroxyfatty acid, and α,ω-hydroxyfatty diacid markers in the Atlantic cultivar is notable: the paucity of these key building blocks of suberin[2] could indicate limited development of its protective suberin polymer, particularly if the trend is confirmed in the solid biopolymer (see below).

Given that aliphatic compounds in general and free fatty acids in particular offer protection against fungal (*Fusarium sambucinum*) infections,[10,24] these compounds that have been

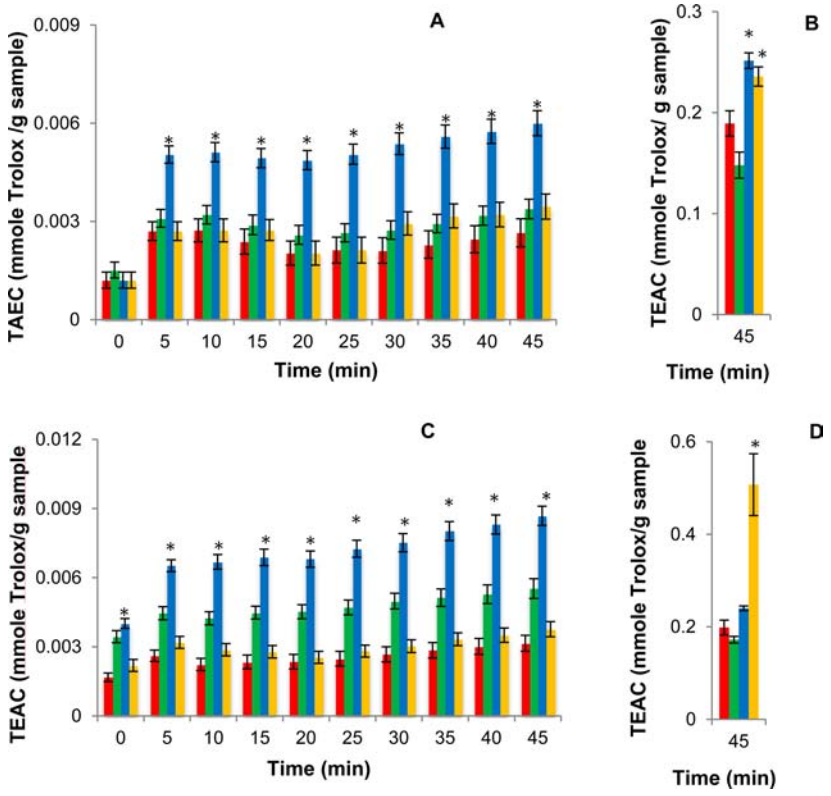

Figure 4. Antioxidant activity throughout the 45 min ABTS assay period for wound-healing potato extracts from Atlantic (red), Chipeta (green), Norkotah Russet (blue), and Yukon Gold (gold) cultivars, showing activities at day-3 post wounding for nonpolar (A) and polar (B) extracts; day-7 postwounding for nonpolar (C) and polar (D) extracts revealing diminished radical scavenging for nonpolar extracts (~50-fold at the 45 min assay time illustrated herein, ~100-fold at the 0 min assay time based on our prior report[12]). Scavenging activities for the nonpolar extracts were examined herein; polar extracts have been reported previously.[12] The data represent the mean ± standard error of the mean of six biological replicates for each cultivar. The highest significant scavenging activity ($P < 0.05$) at each time interval, calculated by means of Tukey pairwise comparisons, is denoted by an asterisk (*).[21]

found abundantly in all cultivars could provide strong protection against fungal infection. Unsaturated fatty acid markers such as 9-octadecenoic acid (oleic acid) (**15**, 18:1) and 9,12-octadecadienoic acid (linoleic acid) (**17**, 18:2) have also been implicated as active compounds against plant pathogenic fungi[25] and may contribute to the antioxidant activities described below.

Diacids such as markers **4**–**8** provide potential sites for the developing suberin biopolymer: for attachment to glycerol forming glyceryl esters, for esterification with long-chain alcohols forming linear esters, or for covalent linkages at either end.[6] Thus, these metabolites can build cross-links within the suberin polyester.[4] All fatty diacid markers emerge in day-7 extracts; namely, at a later time point in the healing process when the wound periderm is developing. Moreover, it is striking that these diacids have relatively short acyl chains compared with native periderm constituents (Huang et al., unpublished). However, medium-chain (C8–C12) species with saturated aliphatic chains have also been reported in wound-healing potato tissues as suberin triglyceride degradation products,[26] in contrast to the typical C16, C18, and longer chain lengths found as suberin monomers.[4,6] One of the diacid markers, 2-hydroxysebacic acid (**8**, 10:0), is up-regulated in all cultivars at day 7 (Table 2). Among the diacid markers, azelaic acid (**6**, 9:0) has been implicated in the plant immune system of *Arabidopsis*, offering protection against pathogens.[27]

Some of the potential markers identified in the current study (Table 2) have been reported previously as metabolites in wound tissue extracts[8] of potato tubers. Those marker compounds reported for the first time in the nonpolar extracts from potato wound tissues included α,ω-fatty diacids (**4**–**7**), an α,ω-hydroxyfatty diacid (**8**, 10:0), a fatty acid (**9**, 11:0), a hydroxyfatty acid (**23**, 18:0), an alcohol (**26**), an aldehyde (**24**, 16:1), and an alkane (**3**, 31:0). Conversely, some longer-chain fatty acid (28:0–30:0) and alcohol (20:0–27:0 and 29:0) metabolites reported previously[8] were not detected in the current study (Supporting Information Table 1). Since our GC/MS protocol successfully detects long-chain metabolites, we attribute this discrepancy to cultivar differences or unintended variations in tissue preparation procedures. Longer chain fatty acids, fatty alcohols, and alkanes have also been found previously in native potato periderms[5,7] (Huang et al., unpublished), but their absence in wound-healing tissues is sensible in light of their well-established anatomical and physiological differences.[28] The identified fatty acids included odd-numbered homologues, which have also been reported previously in the wound tissues of potato tubers[8] and are known elsewhere in the plant kingdom.[29] Some polar compounds, such as phenolic acids, sugars, and amino acids, were found in the nonpolar extracts, presumably as a result of bleed-through effects during the partitioning of the soluble layers.

ABTS$^{\bullet+}$ Scavenging Varies with Cultivar, Time Point, and Extract Polarity. It has been proposed that wounding of potato tubers contributes to the formation of reactive oxygen species and subsequent oxidative stress.[30] Nonetheless, both

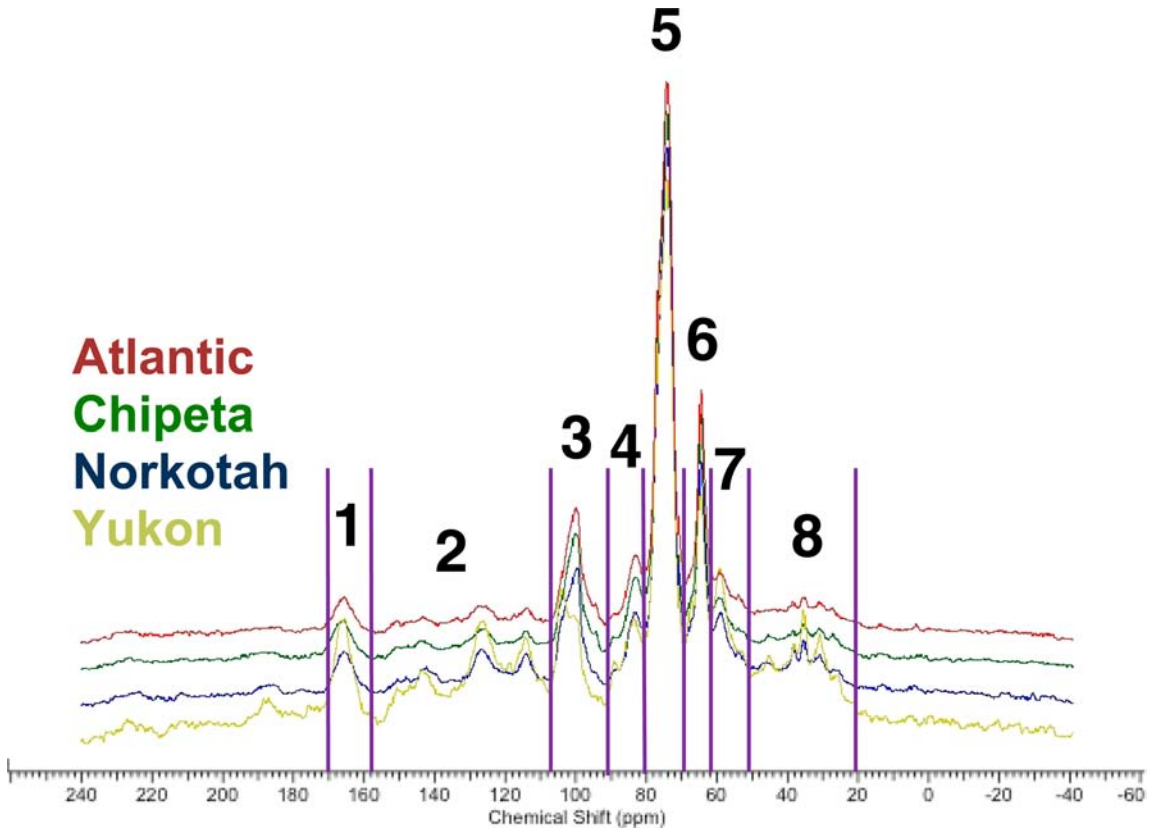

Figure 5. Stacked multi-CP solid-state ^{13}C NMR spectra of representative suberin-enriched tissue samples from each of the four cultivars at the day-7 post wounding time point, showing the chemical moieties present in the solid interfacial layer. The separated regions in the spectra are carboxyl and amide groups (168−180 ppm, region 1); arenes and alkenes (115−160 ppm, region 2); alkoxy groups (96−108, 80−92, 67−80, 59−67 ppm; regions 3−6); methoxy groups (45−59 ppm, region 7); and alkyl chain methylenes (15−45 ppm, region 8). Each spectrum was normalized by setting the largest peak to full scale.

increasing and decreasing stress responses of potato tissues by production of antioxidant chemical compounds have been reported by the same authors in response to wounding.[30,31] To avoid the established limitations of the diphenylpicrylhydrazyl free radical scavenging assay used in prior studies (narrow pH range, steric hindrance, spectral interference),[32,33] we selected an $ABTS^{\bullet+}$ assay. The latter method also permits clean comparisons with our previous investigation[12] of antioxidant activity in polar extracts derived concurrently from the same potato tissue samples. The end result is a more comprehensive picture of antioxidant activity in the potato wound tissues from these four cultivars.

Figure 4 shows that the activities of nonpolar extracts at day 7 postwounding (Figure 4C) are significantly higher than at day 3 postwounding (Figure 4A), supporting an accumulation of antioxidant constituents during the wound-healing process. The order of activity for day-3 nonpolar samples is Norkotah Russet > Chipeta ~ Yukon Gold > Atlantic, whereas at day 7 the trend changes slightly to Norkotah Russet > Chipeta > Yukon Gold ~ Atlantic. Thus, the heavily russeted Norkotah Russet cultivar exhibits the highest scavenging activity for both day-3 and day-7 nonpolar extracts.

As noted above, the applicability of the $ABTS^{\bullet+}$ scavenging assay for antioxidant activity of both polar and nonpolar compounds[32,33] makes it possible to compare the respective data directly. As a group, the antioxidant activities after 45 min of free radical scavenging reaction for both day-3 and day-7 extracts are 50- to 100-fold smaller for the nonpolar samples (Figure 4), reflecting the relative dearth of phenolic and other unsaturated molecular moieties among the nonpolar metabolites. Conversely, it can be deduced that the majority of the antioxidant compounds produced within the healing tissues in response to wounding stress are polar in nature, consistent with prior reports that resistance to infection directly after tuber wounding is related to the appearance of phenolic monomers that subsequently serve as substrates for suberin polyphenolic biosynthesis.[34] The increase in antioxidant activity for nonpolar extracts as healing progresses from day 3 to 7 is in contrast with our observations for the polar portions, which tend to maintain their antioxidant activity levels, except for the Yukon Gold cultivar (Figures 4B and D).[4]

In addition, the $ABTS^{\bullet+}$ assay allows us to evaluate the capacity of both fast- and slow-acting antioxidants.[32] The TEAC values displayed in Figure 4 for both 3- and 7-day time points show overall increases in antioxidant activity throughout the assay period (0−45 min). This trend, which parallels observations made for the corresponding polar tissue extracts,[12] demonstrates the presence of both fast- and slow-acting antioxidants. Finally, the absence of steric hindrance in the $ABTS^{\bullet+}$ assay allows sampling of the scavenging activity of substances with diverse molecular weights and architectural features.[32,33]

Solid-State NMR Tracks Postwounding Development of Suberin Biopolymers. A stacked plot of the quantitatively reliable multi-CP MAS ^{13}C NMR spectra for solid interfacial layers from the four day-7 wound-healing tissues shows largely

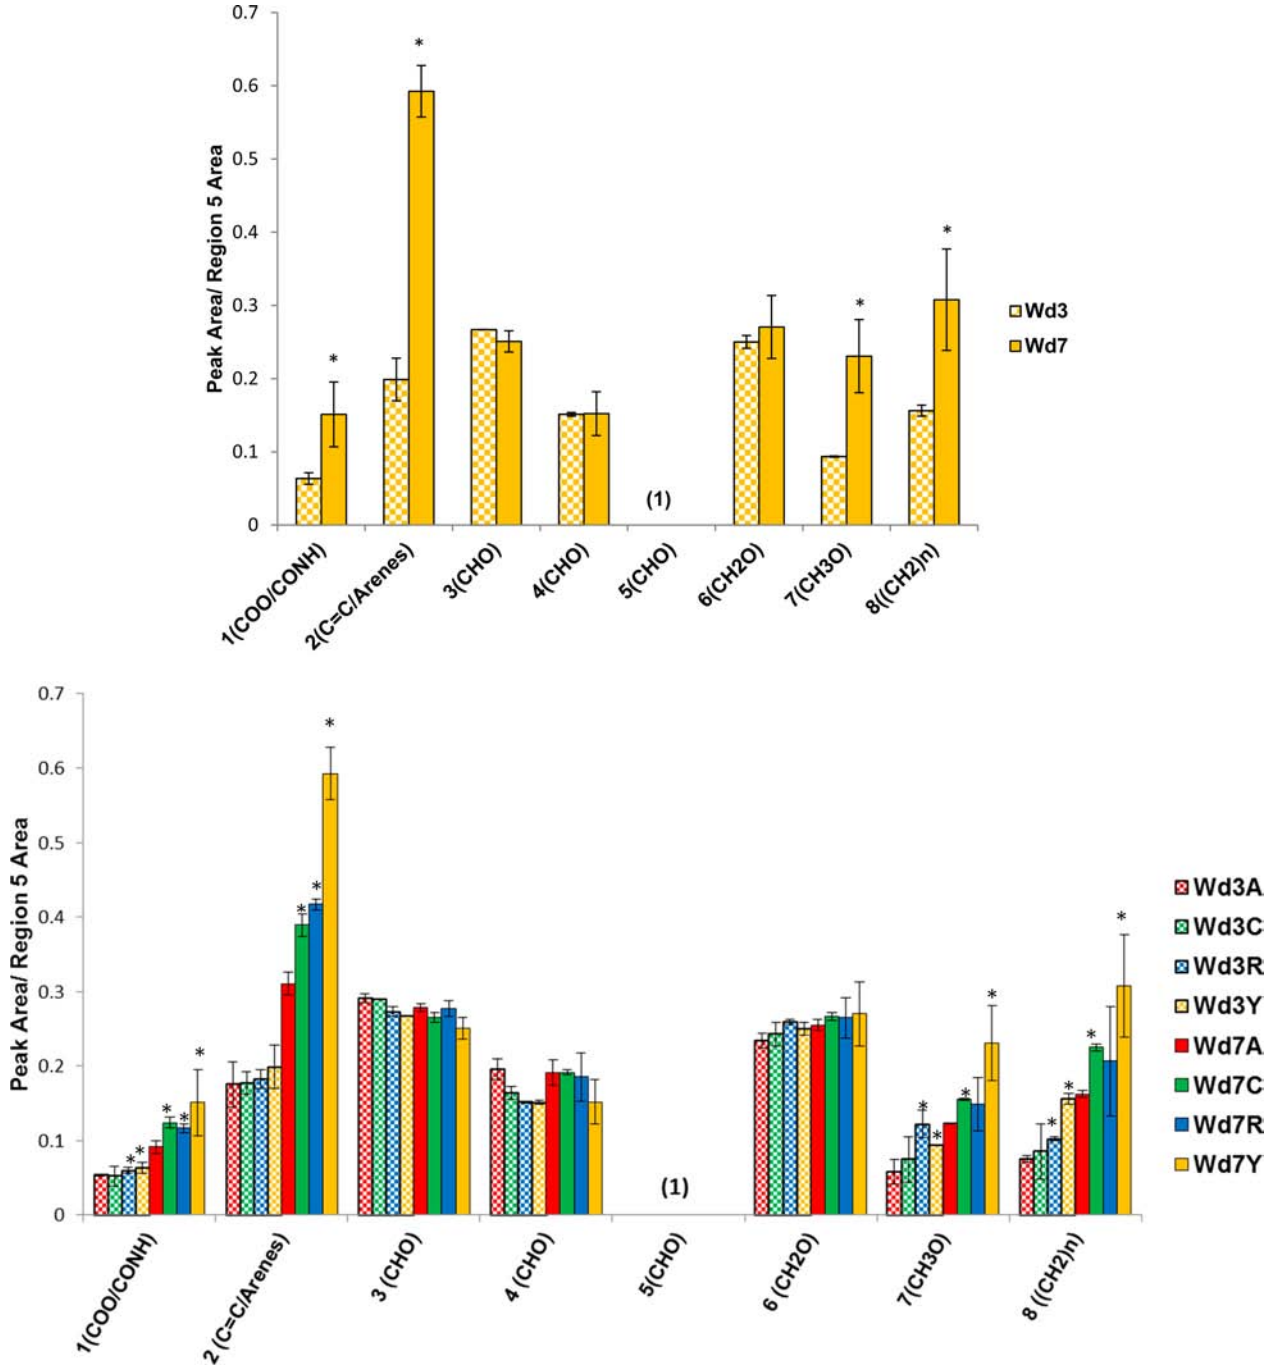

Figure 6. Peak ratios from 150 MHz multi-CP MAS ^{13}C NMR spectra for the solid interfacial layer from suberin-enriched potato wound-healing samples of the Yukon Gold cultivar (top) and all four cultivars (bottom) at days 3 (Wd3) and 7 (Wd7) postwounding, calculated with respect to the major polysaccharide CHO peaks in region 5 (67−80 ppm). The samples are coded for Atlantic (red, A), Chipeta (green, C), Norkotah Russet (blue, R), and Yukon Gold (gold, Y). The data represent the mean ± standard error of the mean of two biological replicates. Asterisks (*) are used to denote the most significant differences in peak area ratio with respect to day 3 (top) and with respect to Atlantic at any wounding time point (bottom) ($P < 0.05$, from Tukey pairwise comparisons).[21]

concordant chemical shifts but clear differences in relative peak intensities (Figure 5). The spectra of the suberin samples at day 7 are similar in appearance to those obtained from the day-7 wound periderm in prior studies of potato tubers.[19,35] (A unique peak at 198 ppm in the Yukon day-7 sample is attributable to a carbonyl within an aldehyde group.) Because quantitative comparisons *between* spectra of different plant materials can be skewed by inconsistencies in mass and instrumental conditions,[36] relative peak ratios *within* each spectrum were used to make compositional comparisons of the interfacial solids at each time point after wounding; the resulting trends were then interpreted in conjunction with metabolomic analyses of the soluble periderm extracts. Illustrative comparisons were made with respect to the major polysaccharide CHO group (region 5; Figure 6) and to the suberin carboxyl/amide groups (region 1; Figure 7).

With respect to the Yukon Gold polysaccharides (region 5), the integrated peak areas of the carboxyl/amide (region 1),

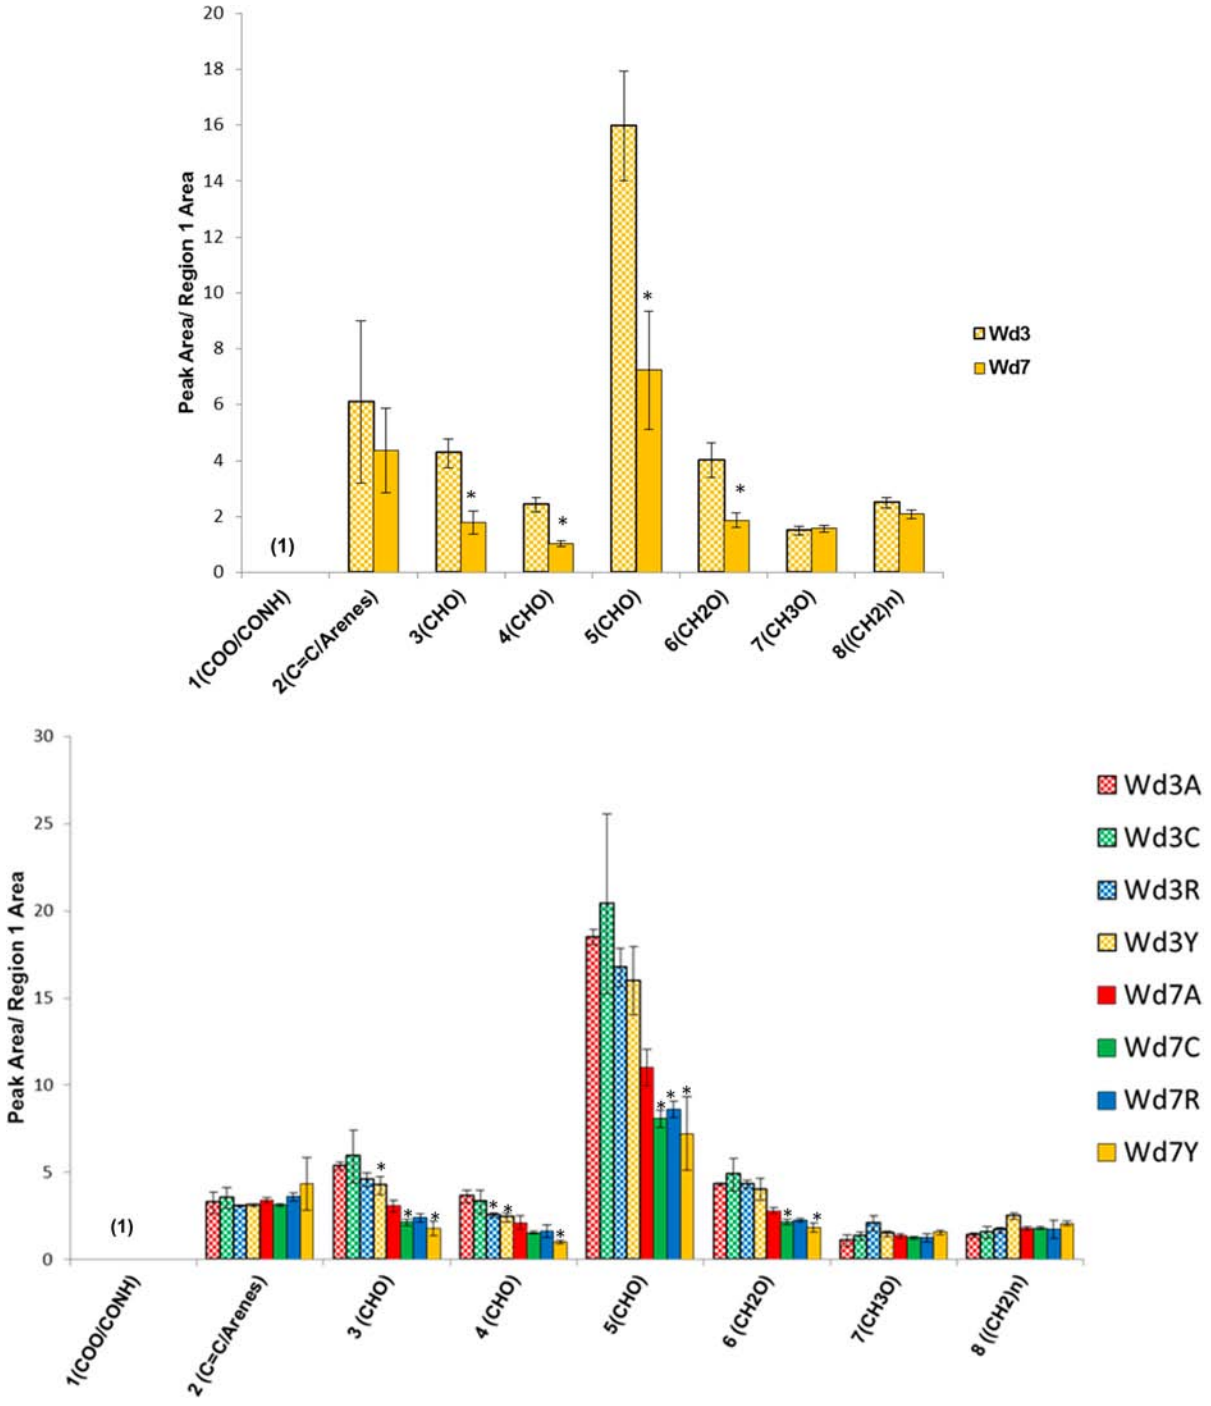

Figure 7. Peak ratios from 150 MHz multi-CP MAS ^{13}C NMR spectra for the solid interfacial layer from suberin-enriched potato wound-healing samples of the Yukon Gold cultivar (top) and all four cultivars (bottom) at days 3 (Wd3) and 7 (Wd7) postwounding, calculated with respect to the carbonyl peak in region 1 (168−180 ppm). The samples are coded for Atlantic (red, A), Chipeta (green, C), Norkotah Russet (blue, R), and Yukon Gold (gold, Y). The data represent the mean ± standard error of the mean of two biological replicates. Asterisks (*) are used to denote the most significant differences in peak area ratio with respect to day 3 (top) and with respect to Atlantic at any wounding time point (bottom) ($P < 0.05$, from Tukey pairwise comparisons).[21]

aromatic/alkene (region 2), methoxy (region 7), and chain methylene groups (region 8) increase significantly at day 7 compared with day 3 postwounding (Figure 6, top). Similar trends are observed for all cultivars (Figure 6, bottom). The relative increase in methylene peak areas for the interfacial layers at day 7 indicates increased hydrophobicity of the wound tissue, which should result in better protection against water loss. The increase in the ratio of methylene chain compounds ($(CH_2)_n$, region 8) is also in accord with the potential marker compounds identified above primarily in day-7 nonpolar extracts, which are mostly compounds containing long-chain aliphatic moieties. Analogously, the increases in peak area ratios involving the carboxyls/amides (COO/CONH, region 1), aromatics (C═C/arenes, region 2), and methoxy groups (CH_3O, region 7) align with the findings of amide-, methoxy-, and carboxyl-containing phenolic markers in our polar wound-

DOI: 10.1021/acs.jafc.5b03206
J. Agric. Food Chem. 2015, 63, 6810−6822

healing tissue extracts.[12] These latter markers include phenolic acids and phenolic amines, including derivatives of ferulic acid that become more abundant at day 7. Moreover, the larger aromatic-to-CHO ratios observed in day-7 Yukon Gold suberin samples (Figures 6) fit with trends observed for the marker compounds in the polar extracts: an increased number of aromatic markers is detected for this cultivar.[12] Together, these correlations suggest that both nonpolar and polar[4] soluble compounds can be viewed as precursors of the suberized cell wall layer that is being formed during the healing process.

At the day-7 time point, when the wound periderm layer is forming, peak area ratios for carboxyl/amide (COO/CONH, region 1), aromatic/alkene (C═C/arenes, region 2), methoxy (CH_3O, region 7), and chain methylene ($(CH_2)_n$, region 8) groups are found to be the highest in Yukon Gold and lowest in Atlantic (Figure 6, bottom, and Figure S2). This observation suggests that the suberin formed in Yukon Gold at day 7 has a higher proportion of long-chain aliphatic compounds, which can provide increased hydrophobicity and lead to decreased water permeability. The small ratio of COO/CONH groups with respect to polysaccharides observed for Atlantic also supports the hypothesis of diminished suberization that was proposed from analysis of the nonpolar soluble marker compounds.

When measured with respect to the carboxyl/amide signals (region 1), the integrated peak areas for oxygenated aliphatic compounds in regions 3−6 are found to decrease for all cultivars between day 3 and day 7 (Figure 7). This trend supports and extends the ratios outlined above: whereas (region 5)/(region 1) is just the inverse of the carbonyl-to-CHO ratio, additional polysaccharide peak areas in regions 3, 4, and 6 also decrease with respect to the suberin esters and amides that contribute to region 1 of the spectrum. Thus, these latter results reinforce the conclusion that deposition of the aliphatic-aromatic suberin polyester within the phellem cell-wall tissues during development of the wound periderm diminishes the polysaccharide-to-fatty acyl ester ratio. As noted above, the relative increase in carbonyl, aromatic, and olefinic groups can be related to both soluble polar and nonpolar potential marker compounds, many of which contain these functional groups. At day 7, Yukon has the lowest and Atlantic the highest peak area ratios for each of the oxygenated aliphatics in regions 3−6 (Figure 7 and Figure S3).

It is also notable that, among the suberin-associated groups, the aromatic/alkene moieties (C═C/arenes, region 2) show the most dramatic increase in relative intensity with respect to the polysaccharide carbons (Figure 6). This finding suggests that the majority of the compounds being deposited in the polyphenolic domain of suberin during the 3-to-7 day time frame originate from the polar extracts, as this is the layer that is rich in aromatic and olefinic structures (phenolic amines, flavonoids, and phenolic acids).[4]

Coordinated Measurements Provide a Chemical Picture of Potato Tuber Wound Healing. GC/MS multivariate analysis shows convergence of the nonpolar soluble metabolite composition at the day-7 time point after wounding of the potato tubers, suggesting induction of a common biosynthetic pathway as a result of wounding and suberization in all four cultivars. A similar trend was observed among the potential polar markers.[12] Analysis of the GC/MS data leads to the identification of 28 potential cultivar-specific and wound-healing marker compounds that discriminate among cultivar types and between wound healing time points day 3 and 7, during closing layer and periderm development. The distribution of nonpolar soluble markers (Figure 3) dovetails with the trends observed in the solid suberin composition of the cultivars at the same time point (Figures 6 and 7). That is, at day 7, Yukon Gold has the highest and Atlantic has the lowest relative amount of solid chain methylene-containing compounds in their respective suberin samples. This observation parallels the trend among the soluble nonpolar fatty acid markers (Figure 3B, Table 2), which at day 3 display the highest number of long-chain and very-long-chain homologues for Yukon Gold but at day 7 are diminished and putatively undergoing incorporation into the solid suberin biopolymer. It is sensible to propose, then, that the hydrocarbon chains of the fatty acid compounds contribute to the solid-state ^{13}C NMR resonance corresponding to the long-chain aliphatic suberin constituents. Conversely, the nonpolar extracts from the Atlantic cultivar exhibit no day-3 markers from these two classes or from glyceryl esters. The paucity of glyceryl esters, dioic acids, and hydroxyfatty acids in nonpolar Atlantic extracts, when considered in conjunction with the lowered proportions of COO/CONH groups in the interfacial solids, suggest a diminished extent of suberization.

For the solid suberized tissues (Figure 7), elevated ratios of methylene chain-containing compounds in the wound-healing tissues of all cultivars at day 7 can increase the periderm hydrophobicity, thereby offering the potential for more protection against water loss. The presence of flavonoid, phenolic acid, and phenolic amine marker compounds, all of which contain carboxyl or amide groups, in the polar extracts at both day-3 and day-7 time points, could also correlate with the deposition of such carbonyl-containing compounds in the Yukon Gold suberin at both time points.[12] The most vigorous deposition of alkenes and arenes at day 7, which is observed for Yukon Gold suberin samples (Figures 6 and 7), is in accord with trends observed among the aromatic markers found in the polar extracts of this cultivar.[12] Nonetheless, we note that rigorous validation of the metabolite profiling and solid-state NMR results for various cultivars at different wound-healing time points would require consideration of cultural, environmental, and geographic factors. A large-scale study including additional earlier and later wound-healing time points would also provide greater insight into these dynamic changes.

The antioxidant results show definitively that the scavenging activities of the nonpolar wound tissue extracts are 50−100 times smaller than those of the corresponding polar extracts, for each time point and for all four cultivars (Figure 4). Therefore, it can be concluded that the majority of the antioxidant compounds produced in the wound tissues are polar compounds, such as phenolic acids and flavonoids. At both day 3 and day 7, the nonpolar extract of Norkotah Russet demonstrated the highest antioxidant activity, an observation that can be attributed to the presence of unsaturated fatty acids among its potential markers. Among the nonpolar metabolite markers are compounds that may offer protection against invasion by plant pathogens based on their previous antimicrobial activity reported in vitro. They include unsaturated fatty acids, oleic acid (**15**, 18:1) and linoleic acid (**17**, 18:2); saturated fatty acids, tetradecanoic acid (**14**, 14:0) and hexadecanoic acid (**12**, 16:0); and the diacid azaleic acid (**5**, 9:0). In addition, we have previously identified marker compounds in polar extracts of the wound tissues that include phenolic amines, glycoalkaloids, flavonoids and phenolic acids, for which in vitro antimicrobial, insecticidal, and antioxidant

DOI: 10.1021/acs.jafc.5b03206
J. Agric. Food Chem. 2015, 63, 6810−6822

properties have been reported and which might offer protection to the wounded tuber surface.[12,37,38] Thus, the chemical picture of the defensive armor of the potato tuber that emerges from the current study encompasses both polar and nonpolar metabolites that may possess antimicrobial, antioxidant, and insecticidal properties and also the solid suberin biopolymer, which can provide robust defensive barriers in diverse cultivars.

Kober 5 BB	K5BB	*V. berlandieri* × *V. riparia*	American hybrid	American	Germany

[a]All samples were collected at 18 °Brix during the 2013 season. Sample names are from the *Vitis International Variety Catalogue* website www.vivc.de; the FEM collection is reported at the website with the number ITA362.

Conversely, explorative untargeted analysis of the metabolomes of wild American grapes is lacking. From our point of view, it is necessary to extend the analytical coverage of the metabolites present in wild grape berries and try to understand which undesirable (and desirable) traits are present in these species. It may be the case that wild American grapes have metabolic pathways not present in *V. vinifera*, producing "interesting" classes of metabolites. For example, hydrolyzable tannins are present in *Vitis rotundifolia*,[16] and lignans are accumulated in *Vitis thunbergii*.[17] These classes of metabolites might be present in other species, or different classes might be accumulated in unstudied *Vitis*. The transfer of such desirable traits to new hybrids could be worth considering.

All of the grapes used in this study are from the Fondazione Edmund Mach, where this research was carried out; here we maintain a large collection of grape varieties, including interspecific hybrids, rootstocks, and wild American grapes, recently genotyped[11] and uploaded to the *Vitis International Variety Catalogue* repository (www.vivc.de, institute no. ITA362). In this "proof of principle" study, the aim was to study comparatively the metabolic profiles of the berry tissues of four different wild American grapes as compared to seven commonly used *V. vinifera* cultivars, through untargeted LC-MS analysis, with two different goals: (1) to find differences in the metabolomes of the American *Vitis* and *V. vinifera* and (2) to discuss their importance in terms of grape quality (especially for wine production). Three interspecific hybrids were also included in the study. Two of them are first-generation inbreeds (41B and Isabella), whereas the third, Nero, is a PIWI variety obtained after numerous backcrosses with *vinifera* material. The inclusion of these three varieties aimed at understanding how the differences found between the two groups can be transferred to the hybrids. The inclusion of Nero, a variety registered for vinification in 1993, made it possible to understand, for this case study, whether the selection performed without the use of molecular markers was able to eliminate all of the undesirable traits and keep the desirable ones.

MATERIALS AND METHODS

Reagents. Acetonitrile, methanol, and formic acid of LC-MS grade were purchased from Sigma-Aldrich (Milan, Italy). Water was of Milli-Q grade obtained from a Millipore system (Millipore, Billerica, MA, USA). Phloroglucinol was purchased from Sigma-Aldrich. We built a standard set of around 600 common grape and wine metabolites, purchased from Sigma-Aldrich or Extrasynthese, and they were injected under the conditions described by Theodoridis et al.[18] Each standard spectrum was manually extracted and used to automatically assign the name to the compounds from the sample analysis.[22] The whole standard set used in this experiment has already been reported by Shahaf et al.[19]

Sample Preparation. One kilogram of each grape at technical maturity (using criteria similar to those of Liang et al.[14]) was harvested from the germplasm collection of the Fondazione Edmund Mach at San Michele all'Adige (TN), Italy. The skin, pulp, and seeds of fresh berries were manually separated, ground under liquid nitrogen, and stored at −80 °C until analysis. A list of the grapes analyzed in this work is available in Table 1.

Extraction for untargeted analysis was performed according to the optimized method of Theodoridis et al.,[18] slightly modified. Briefly, 1 g of ground tissue was extracted with methanol/water/chloroform 2:1:2 and 0.1% formic acid, vortexed, sonicated for 10 min, further agitated in an orbital shaker for 15 min, and then centrifuged at 5000 rpm for 5 min. The upper organic phase was collected and filtered through 0.22 μm PVDF Millipore Millex-GV filters before injection. Three replicates per variety, each from a different bunch of grapes, were selected for the analysis. Only healthy berries have been chosen.

Sample preparation for the quantification of the condensed tannin fraction by phloroglucinolysis was performed using a validated protocol.[20] Briefly, 1 g of ground tissue was extracted with 5 mL of methanol for 24 h, dried in a Rotavapor, and reconstituted with 10 mL of water. The water extract was loaded onto a C18 Sep-pak, washed with 40 mL of water, and eluted with 30 mL of methanol. The elute was dried in a Rotavapor and reconstituted with 1 mL of methanol. Nine hundred microliters of this extract was diluted 1:1 with methanol, filtered, and injected into the LC-MS system. The remaining 100 μL of the elute was added to 100 μL of phloroglucinol (100 g/L) at a reaction temperature of 50 °C. After 20 min, the reaction was stopped with 1 mL of sodium acetate (40 mM), diluted 1:5 with water/methanol, and injected for targeted condensed tannins analysis.

LC-MS Workflow, Analysis and Data Treatment. Untargeted LC-MS analysis was performed using a UPLC, interfaced through the ESI source to a "Synapt" (UHPLC-ESI-Q-TOF-MS), supplied by Waters (Manchester, UK). We used our standard LC method recently published.[21] Briefly, starting with 100% eluent A (0.1% formic acid in water), switching at 1.5 min to 10% of eluent B (0.1% formic acid in methanol) up to 3 min, then a gradient of up to 40% eluent B in 18 min, passing to 100% eluent B in 21 min, holding for up to 25 min, and then re-equilibrating back to 100% eluent A for a total run of 28 min. The MS settings were kept the same as the ones used for the standard set injection.[18]

All of the samples of the three different tissues were injected in the same injection sequence. The analysis workflow consisted of a starting

DOI: 10.1021/acs.jafc.5b01999
J. Agric. Food Chem. 2015, 63, 6823−6834

queue of one blank, one standard mix (a mixture of 15 common grape metabolites, STDmix), three "quality controls" (QCs), which consisted of three pooled samples specific for each tissue (one for the skin, one for the flesh, and one for the seeds from all of the grapes), and one pooled sample containing all of the tissues (the whole berry). During the analysis we injected a standard mix every 20 analyses and a QC representative for each tissue after every 8 sample injections. The acquired spectra were directly converted to NetCDF files using Databridge software (Waters). Peak picking, alignment, and principal component analysis (PCA) were performed using the automated data analysis pipeline MetaDB, developed at our institution.[22] This package supports the execution of experiment compatible with the concept of interoperable bioscience data, including both the production of a validated experimental data set with the relevant metadata in ISA-Tab format. The workflow of MetaDB consists of six different steps: (1) upload of metadata in ISA-Tab format; (2) preparation of MS acquisition sequence, including sample randomization; (3) upload of raw and derived spectral data files; (4) data processing for feature alignment and detection with metaMS (http://www.bioconductor.org/packages/release/bioc/html/metaMS.html); (5) visualization of data for quality assessment; (6) preparation of data for upload to public repositories (Metabolights).

Targeted LC-MS/MS analysis was performed using a UPLC-adapted version of the method described by Fortes Gris et al.[20] The samples were injected into a UPLC chromatograph, interfaced to a TQ mass spectrometer (UHPLC-ESI-QqQ-MS, Waters, Manchester, UK) through an ESI source. The eluents used were water with 0.1% formic acid (eluent A) and acetonitrile with 0.1% FA (eluent B). The gradient was as follows: starting from 95% of A, to 20% of B in 3 min; isocratic flow to 4.3 min, and then ramping to 45% of B at 9 min. Then 100% of B at 11 min, holding up to 13 min, and returning to the initial conditions of 95% of A for a total run of 17 min. The quantification of catechin, epicatechin, procyanidins B1 and B2, gallocatechin, epigallocatechin, and epicatechin gallate was done using a linear regression curve built on the injection of pure chemical standards, in the same analytical conditions through MRM. Quantification of phloroglucinol-bound flavanols was done as for epicatechin, epigallocatechin, and epicatechin gallate equivalents, respectively.

Statistical Analysis. The stability of the untargeted analysis was assured during the workflow, checking the repeatability of the QCs and STDmix injections manually by integrating representative peaks and through PCA. We also checked that the CV percentage of the internal standards (gentisic acid, 3-indole-propionic acid, and 4-stilbenol) was below 25%. The metabolic differences between the *V. vinifera* varieties and the wild American *Vitis* was obtained using two statistical tests: (1) univariate *t*-test analysis with corrected *p* values using the "fdr" function setting 0.05 corrected *p* value and 10-fold change as thresholds in R environment;[23] (2) multivariate statistical analysis using SIMCA-P +12.0 software performing OPLS-DA analysis, using 1 VIP value as threshold.[24] The boxplots on the procyanidin content have been created using Statistica 9.1 software (Statsoft, 2010).

Database Matching. The identification of compounds is one of the main bottlenecks in untargeted LC-MS analysis, due to the multiple signals from the same metabolite in the MS spectrum. An automatic identification pipeline based on injected standards has been established in our institution,[22] but the whole standard set was injected in a chromatographic gradient that we did not use in this experiment. To overcome this problem, we aligned the two chromatographic runs using standards injected in both, and we performed retention time prediction using the Web site predret.org.[25] The list of biomarkers was matched against the peak table using the db.comp.assign function in the R package "Chemhelper" (github.com/stanstrup/chemhelper), with 30 ppm mass accuracy and a 1 min retention time window. The biomarkers spotted by the Chemhelper package were further manually verified for correctness against pure chemical standards injected under the same chromatographic conditions. This allowed us to unambiguously assign MSI identification level 1 to all matching biomarkers.[26]

The remaining biomarkers not present in our standard database were considered as unknowns and underwent further identification steps summarized under Compound Identification Strategy below.

MS/MS Analysis. All of the analysis was done in V mode (improved sensitivity, nominal resolution 10000); precursor ions were selected in the quadrupole and fragmented in the collision cell through a collision energy profile ranging from 20 to 35 eV, with leucine enkephaline as internal calibrant. Collected MS/MS spectra were queried in MetFrag[27] and MetFusion[28] using KEGG, Chemspider, or PubChem as compound databases and MassBank-EU as the spectral database.

Isotopic Pattern Recognition and Formula Assignment. The isotopic patterns of all biomarkers were obtained using a strategy already published,[29] based on intensity-weighted means of the isotopes automatically identified by CAMERA.[54] Putative chemical formulas were obtained using these isotopic patterns through the getFormula function of the Rdisop package in the R environment.[30]

Compound Characteristics Comparison. An important identification step was "Compounds Characteristics Comparison" (CCC): This method was established in our group, and it is currently being prepared for publication. The idea behind the method is that the characteristics (RT, *m*/*z*, isotopic pattern, etc.) of the pseudomolecular ion of a compound detected in LC-MS are typical of its structure, so comparing the characteristics of the standards in our database with those from the unknown biomarkers allows us to reduce the number of possible structures to just a few plausible structures (L.N., Ph.D. thesis, chapter 6). It is a multivariate regression model built on retention time, *m*/*z*, and the isotopic intensities of standard collection that predicts the main substructures present in the compounds. Therefore, the values of these parameters are used together to validate the prediction properties of the model and estimate the presence of particular substructures in the compound (phenolic groups, aliphatic chains, acidic groups, glycosides, and so on). From the predicted substructures, the structure is further rebuilt and makes it possible to exclude all of the nonmatching structures proposed by the in silico analysis of the MS/MS spectra. It aids both formula calculation and structure elucidation.

Nonetheless, this method is a supplementary step in the common identification strategy described by Stanstrup et al.;[29] the method only helps to filter out improbable candidates, but it is not a stand-alone method, and the final identifications still rely on the common MS/MS analysis (Supplementary Figure 1).

Compound Identification Strategy. The following identification strategy is schematically summarized in Supplementary Figure 1. After database matching, the remaining unknown markers were subjected to MS/MS analysis. The acquired spectra were queried against MetFrag/MetFusion, and the chemical structure list obtained was compared to the putative chemical formula and the CCC method and manually verified for correctness. If any of the structure matched all of the characteristics, this biomarker was considered to have been identified at MSI level 2. Otherwise, if no match was found, a tentative structure was sketched, based on the putative class predicted by the CCC method, the putative formula calculated by both Rdisop and CCC methods, and the losses and neutral losses observed in MS/MS analysis. The putative structure was queried again against MetFrag; when a higher score was found for the sketched structure in comparison to the previous ones, the biomarker was labeled as MSI level 2 or 3, depending on how likely the spectral matching was.

Data Mining. Heatmaps were drawn using the heatmap.2 function of the gplots package in the R environment. The data were scaled to unit variance prior to calculation of the dendrograms. The dendrograms were constructed by hierarchical clustering analysis using "Canberra" as the distance function and Ward.D2 as the hierarchical clustering function.

Data Sharing. The whole experimental data set is available in the Metabolights repository under the code MTBLS209.

RESULTS AND DISCUSSION

Statistical Analysis. In the data analysis, we used both univariate and multivariate statistical tests. The tests are not mutually exclusive, whereas their combined use is suggested especially when the "curse of dimensionality" arises.[23,31] Tens to hundreds of "features" were recognized as markers in the different tissues. The marker lists were merged, and duplicates were excluded. Features in the same CAMERA[54] group were

DOI: 10.1021/acs.jafc.5b01999
J. Agric. Food Chem. 2015, 63, 6823−6834

excluded, keeping only the supposed pseudomolecular ions. The pseudomolecular ions were subsequently integrated using Targetlynx to manually supervise the data and eliminate false positives and incorrect peak-picking. The results of statistical analysis are shown in Table 2.

Table 2. Markers and Identified Pseudomolecular Ions: Number of Total Features Detected, Total Biomarkers in Each Tissue, Total Pseudomolecular Ions, and Identified Compounds[a]

			marker features		pseudomolecular ions		identified	
tissue	ionization mode	features	Vv	AV	Vv	AV	Vv	AV

skin	negative	15826	36	280	13	29	12	29

[a]Vv, *Vitis vinifera*; AV, American *Vitis*.

Identified Compounds. The biomarkers underwent all of the identification steps described under Materials and Methods. In total, we were able to identify 32 biomarker metabolites in the flesh, 26 in the seeds, and 44 in the skin at MSI level 1 (Supplementary Table 1). The rest of the markers were considered "unknowns" and underwent compound identification strategy.

The whole identification strategy is described in Supplementary Figure 1. In total we could identify 13 compounds as MSI level 2 in the flesh, 13 compounds as MSI level 2, and 6 as MSI level 3 in the seeds as well as 42 compounds as MSI level 2 and 1 as MSI level 3 in the skin (Supplementary Table 1).

Comparative Analysis. All of the identified metabolites were grouped according to their biosynthetic pathway, and the hierarchical clustering analysis was performed on all of the samples using this information. The results are shown in Figures 1 and 2 (skin and seeds, respectively) and in Supplementary Figure 2 (flesh). Procyanidins, hydrolyzable tannins, aroma precursors, polar lipids, sugars, organic acids, anthocyanins, flavonols, and stilbenoids showed different accumulations in the two groups. The latter three compound classes have already been

reported to be differently accumulated in *V. vinifera* and wild American grapes in previous papers[14,32,33] and will be discussed only briefly below. In the following section, we focus in particular on the first three compound classes, because their behavior has not been reported previously and it is very interesting from both enological and biological points of view.

Flavan-3-ols and Procyanidins. Flavan-3-ols are a very important class of polyphenols in grape and wine production, especially in their polymeric forms, that is, procyanidins. Procyanidins are a type of condensed tannins responsible for the astringency in wine and constitute the body of the wine, together with the alcohol and some lipids. Their content is very important, especially in red wine production: lack of procyanidins means poor-quality red wines.[55] The procyanidins are also recognized as the main antioxidants accumulated in grapes, and they have multiple health-related characteristics.[34,35] Unfortunately, the whole accumulation and polymerization pathway of procyanidins is still unknown, as reported in the KEGG repository in the map http://www.kegg.jp/pathway/map01061+C06562.

Flavan-3-ols via Untargeted Metabolomics. Differences were found in the accumulation of flavan-3-ols and procyanidins in the skin and seeds of the two groups. In the skin, *V. vinifera* was richer in catechin, epicatechin, catechin-rhamnoside, and procyanidin B3 (Figure 1). It is also richer in other dimeric, trimeric, and tetrameric forms of procyanidins, but this difference did not exceed the selected threshold (10-fold). Surprisingly, American *Vitis* accumulated higher levels of catechin-gallate and epicatechin-gallate. *V. vinifera* seeds were richer in all of the flavan-3-ols and procyanidins that we identified directly in untargeted analysis (Figure 2). A recent paper[15] reported a similar result: in this study, *V. vinifera* contained a higher level of monomeric, dimeric, and trimeric procyanidins in the seeds, in comparison to many different *Vitis* species except for *Vitis palmata*. Another study[36] obtained a similar result when comparing *V. vinifera* with *Vitis labrusca* seeds.

Procyanidins via Targeted Protocols. As stated earlier, the accumulation of procyanidins is related with many desirable characteristics; we therefore decided to perform targeted analysis of procyanidins, to quantify the difference between the two groups precisely, using a validated method.[20] The results obtained from targeted analysis are summarized in Figure 3. *V. vinifera* varieties showed a higher accumulation of both free flavanols and polymeric procyanidins, especially the latter, in the skin. The amount of procyanidins accumulated in *V. vinifera* skin was on average 30 times higher (from 5500 to 17000 mg/kg) in comparison to wild American grapes (200−650 mg/kg). The difference in free flavanols was about 8 times higher in *V. vinifera*, whereas American grapes accumulated a higher percentage (≈3%) of galloylated forms in comparison to *vinifera* grapes (≈1%) (reported in supplementary tables—skin procyanidins). As expected, the mean degree of polymerization (mDP) was higher in *V. vinifera* (25−52 units), in comparison to wild American grapes (4−17 units). The hybrid varieties showed a

DOI: 10.1021/acs.jafc.5b01999
J. Agric. Food Chem. 2015, 63, 6823−6834

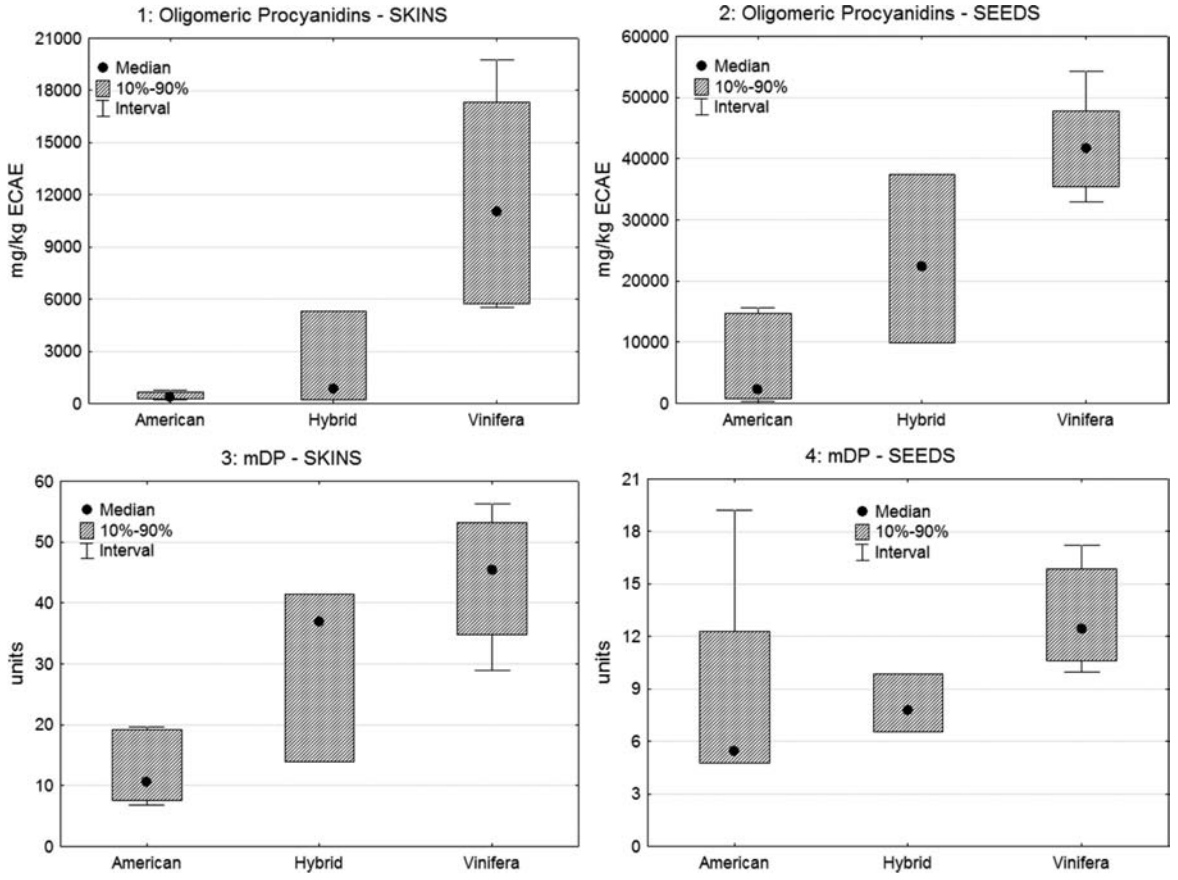

Figure 3. Box plots of oligomeric procyanidins content in the skin and seeds of different classes of grapes (1, 2) and mean degree of polymerization (mDP) of procyanidins (3, 4). Procyanidin content is expressed as epicatechin equivalents (ECAE), whereas mDP is expressed as average units.

different pattern: Isabella and 41B had a higher percentage of galloylated units (5−7%) in comparison to all other samples. Nero had slightly higher levels of free flavanols and polymeric procyanidins comparable to those of Sauvignon blanc (5000 mg/kg) and a mDP similar to that of the *V. vinifera* group. Isabella had an mDP superior to that of Nero (around 39 units on average).

V. vinifera varieties accumulated more flavanols and polymeric procyanidins in the seeds, but the difference was not as large as in the skin. Indeed, *Vitis cinerea* accumulated levels of catechin and epicatechin comparable to those of the *vinifera* varieties, whereas it had a lower amount of dimeric forms. The level of polymeric procyanidins in *V. cinerea* (10000 mg/kg) was lower than the level in *V. vinifera* (40000 mg/kg), but not so low as the rest of the American grapes (2000 mg/kg). These data indicate that the accumulation of procyanidins in the seeds may vary considerably between different species. Among the hybrids, Nero showed an accumulation pattern similar to those of the *vinifera* varieties, whereas 41B and Isabella both had levels of polymerization degree and accumulation intermediate between the two groups.

Wines produced from French−American hybrids were reported to be poor in terms of mouthfeel, due to a lack of astringency, indicating the scarcity of condensed tannins.[37] Previous authors have attributed the scarcity of condensed tannins in wines to their low availability and solubility,[7,37] due to the procyanidin-binding properties of pectin and proteins from the cell wall materials. Procyanidins have been demonstrated to be present inside the tonoplast and in the cell wall of grape cells, bound to proteins or pectins,[37−39] and their binding to the cell wall material is resistant to ultrasound and solvents.[40,41] Therefore, the differences reported in this work might depend on both availability and solubility of the procyanidins in the American grapes, especially in the skin. The American grapes might have stronger and wider procyanidin binding properties than *V. vinifera*. This would explain also why the American grapes had a lower polymerization degree in comparison to the *vinifera* grapes.[42] From a biological point of view, we must also consider that studying multiple plants of the Tracheophyta phylum, Bindon et al[40] proposed a single model for procyanidin production in the chloroplasts and a further transport of the procyanidins into the vacuole through vesicles structures. These authors concluded that all of the studied plants showed a similar model.[40] Therefore, production and accumulation must be similar inside the lone genus *Vitis*. As the polymerization process is still unknown, and their localization and binding in the tonoplast are only partially explained, it is impossible to discern whether the difference is due to different concentration, different binding or both. A more in-depth study into the reasons for such a marked difference between the two groups (especially in the skin) was beyond the aim of this study, and it was not investigated further.

It was very interesting to note that the procyanidin accumulation level in Nero (a recent hybrid variety) was more similar to that of *V. vinifera* than those of 41B and Isabella (old hybrid varieties), indicating that multiple backcrosses with *V. vinifera* increased the extractability and availability of procyanidins and that their availability is a characteristic likely controlled by multiple factors.

Hydrolyzable Tannins, Precursors, and Their Derivatives. Hydrolyzable tannins are polymeric compounds constituted by gallic acid subunits bound through a glycosidic

moiety. The gallic acid unit can create C−C bonds joined to each other to create hexahydroxydiphenic acid (HHDP) subunits and/or hydrolyze their acidic moiety to form ellagic acid subunits. The different combinations of gallic acid, HHDP, ellagic acid, and glycosides create diverse hydrolyzable tannins. The accumulation and degradation pathways of these metabolites are still unknown.

From an enological point of view, hydrolyzable tannins are desirable markers of quality. These metabolites are not found naturally in red wines from *V. vinifera*. Indeed, red wines are often aged in oak (or different woods) barrels, where the wine's alcohol

extracts lignans and hydrolyzable tannins from the wood, improving wine body.[55] Furthermore, hydrolyzable tannins and their catabolic derivatives (ellagic acid and its conjugates) have many health-related properties.[41] For these reasons, their accumulation is welcome in the wines. To our knowledge, only gallic acid, galloyl-glucose, digalloyl-glucose, and ellagic acid have been reported in *V. vinifera* grapes. Of the *Vitis* germplasm, only *Vitis rotundifolia* has been reported to accumulate some hydrolyzable tannins and derivatives in its skin and seeds.[16,17]

In our experiment, we found that American grapes accumulated many hydrolyzable tannin precursors, such as gallic acid, galloyl-glucose, digalloyl-glucose, ellagic acid, methyl-gallate, galloyl-syringic acid, and galloyl-ethyl-gallate in the skin (Figure 1). Oligomeric hydrolyzable tannins were also found in the skin of American grapes, especially K5BB and *Vitis arizonica* Texas. They accumulated a total of eight oligomeric compounds in this class, reported here: ellagic acid-arabinoside, ellagic acid-glucoside, galloyl-ellagic acid, three different isomers of HHDP-galloyl-glucose, a punicalin-like compound, and HHDP-digalloyl-glucose (MSMS spectra in Table 3). We did not observe any hydrolyzable tannin, precursor, or derivative signal in *V. vinifera* skins, except for those already reported in the literature (gallic acid, galloyl-glucose, digalloyl-glucose, and ellagic acid). Moreover, the American grapes showed a concentration of ellagic acid around 1000 times higher than *vinifera* grape skin. Ellagic acid is the catabolic product of the hydrolyzable tannins. The putative structures of all identified hydrolyzable tannins are shown in Figure 4.

The lack of commercial standards available for this class of compounds did not allow us to confirm the identifications to MSI level 1. The presence of many putative compounds in the same class makes us confident about the identification. Interestingly, when looking selectively for previously reported ellagitannins, we observed that K5BB and *V. arizonica* Texas also had an m/z of 933.0692, the same mass of castalagin and vescalagin. Many fragments in the MS/MS spectrum corresponded as well, but they had different relative intensities and different retention times (5 and 6 min versus 12 min, data not shown). In this experiment, the signal for this ion was too low and was excluded from the statistical analysis, due to the intensity threshold selected, but it was clearly present in the chromatograms of K5BB and *V. arizonica* Texas. As shown in Figure 1, among the

DOI: 10.1021/acs.jafc.5b01999
J. Agric. Food Chem. 2015, 63, 6823−6834

hybrids, only 41B showed some accumulation of these compounds in the skin, whereas Nero and Isabella did not accumulate it, as for *vinifera* grapes. The genetic basis of hydrolyzable tannin accumulation is still unknown, so it is difficult to understand why there is a different behavior in the hybrids.

The situation became more complex when the accumulation of these compounds was observed in the seeds. All of the American grapes also showed accumulation of this class of compounds in the seeds but in lower intensities in comparison to the skin. Of the *vinifera* grapes, only Moscato Rosa showed a signal for many hydrolyzable types of tannin, usually higher than that from wild American grapes. This is extremely interesting, because no other *vinifera* showed any clear signal. These hydrotannic units were also observed in a preliminary pilot experiment (data not shown). In that experiment, Moscato Rosa and an intraspecific hybrid Pinot × Merlot showed a clear accumulation of such compounds. Their presence in Moscato Rosa's seeds is why this class of compounds was not recognized as a marker for American grapes in seeds.

Hydrolyzable tannins have been reported in numerous fruits and plants,[44] but this is the first time that they have been reported in species other than *V. rotundifolia* within the *Vitis* genus.

Aroma Precursors. Aroma precursors are all of the volatile metabolites stored in the vacuole through glycosylation, and they are supposed to serve as a reservoir for biotic and abiotic stress response. Many of these glycosylated volatiles undergo hydrolysis during vinification and wine aging, determining most of the wine's aroma.[43] For this reason, is important to study the intact aroma precursors found in the berries to understand the aroma potential of grapes. These metabolites are mostly accumulated in the skin and, to a lesser extent, in the flesh. Our group recently reported an untargeted LC-HRMS method to identify and semiquantify aroma precursors in grape.[53]

The American grapes are often reported to have a different range of aromas, including the undesirable "foxy" taste[5] and some herbaceous flavors.[5,6] The goal was to establish whether the putative precursors of these volatiles can be found in any of the tissues of the American grapes. Surprisingly, none of the markers obtained in this work corresponded to a putative precursor of this kind of metabolite.

It was interesting to see whether *V. vinifera* accumulates precursors with a pleasant aroma, such as terpenols, differentially (Figure 1). Our experiment showed that *vinifera* grapes accumulated a high amount of glycosylated-terpenoids in the skin, whereas the American grapes included in our experiment did not accumulate any. Nevertheless, high concentrations were found in Iasma Eco 3, Moscato Ottonel, Gewürztraminer, and Moscato Rosa, which are commonly recognized as aromatic varieties. Aromatic is a phenotypic definition: a fruity-smelling variety of grape is "aromatic". Recently, a single locus (VvDXS) encoding for a 1-deoxy-D-xylulose-5-phosphate enzyme has been found to be responsible for the aromatic qualities of grapes.[44] This locus is involved in the accumulation of isoprenoid precursors; isoprenoids are the building blocks for the monoterpenoids. The remaining *vinifera* varieties showed a lower accumulation of these aroma precursor volatiles, similar to those of American grapes. We assume that this difference is likely due more to the locus VvDXS, as reported in the literature, than to a difference between species. On the other hand, this locus was not derived from the natural evolution, but human-selected during the domestication of *V. vinifera*:[44] so it has been reproduced and is presently common in the *vinifera* grapes, whereas it is probably very rare in wild American grapes.

We noted the same aroma precursors' accumulation pattern in the flesh, with a lower concentration in comparison to the skin, as reported in previous works[45] (Supplementary Figure 2). The hybrids showed a level of accumulation of these metabolites similar to that shown by nonaromatic *vinifera* and wild American grapes, indicating that they probably do not have the active allele of the *VvDXS* gene. In the seeds (Figure 2), we were able to identify two aroma precursors with accumulations 10 times higher in *vinifera* seeds than in American seeds: vanillyl-glucoside and benzyl-alcohol-rhamnosyl-glucoside. Both compounds are catabolic derivatives of the lignin's production pathway. In this tissue, the hybrid grapes showed similar levels to the *vinifera* grapes. The putative structures of the identified volatile precursors are shown in Supplementary Figure 3.

Anthocyanins and Stilbenoids. Anthocyanins are the main pigments found in grapes, determining the visual impact of both grapes and wines. Anthocyanins are accumulated in the vacuole of the cells after glycosylation and are believed, inter alia, to defend the cells from oxidative damage caused by exposure to sunlight.[46] Anthocyanidins (i.e., the aglycones) cannot be found in grapes, because the aglycone form is very reactive and unstable. They share most of their metabolic pathway with flavan-3-ols, and probably they compete for the substrates during the accumulation process.

A differential accumulation of anthocyanins in wild American grapes and *V. vinifera* has been reported since the 1950, and it has been used historically to determine whenever a wine has been blended with non-*vinifera*/hybrid grapes. The wild American grapes tend to accumulate mostly diglycosidic anthocyanins, whereas *V. vinifera* contains most exclusively monoglycosidic anthocyanins.[47] Recently, it has been reported that the gene encoding for a 5-*O*-uridil-diphosphate-glycosyl-transferase (5-UFGT) has different alleles in *V. vinifera* and wild American grapes.[48] The alleles present in the *vinifera* grape are almost all nonfunctional; they do not produce the 5-UFGT enzyme able to bind the glycosides to the 5-terminal end of anthocyanins.

In our experiment, five different basic units of anthocyanins were found to be differently accumulated in the skin and in the flesh of the two groups (Figure 1 and Supplementary Figure 2): cyanidin, peonidin, petunidin, delphinidin, and malvidin. In the skin, berries from *vinifera* accumulated only anthocyanins glycosylated at position 3, sometimes with a *p*-coumaroyl or caffeoyl moiety attached to the glucoside. American *Vitis* was richer, from tens to hundreds of times, than *vinifera* in all of the anthocyanins identified, including 3-glucosylated forms. Furthermore, the American *Vitis* accumulated anthocyanins diglycosylated in positions 3 and 5, as shown in Figure 1. As expected, all of the hybrids showed lower accumulation of diglycosylated anthocyanins than the wild American grapes.

The flesh of the *vinifera* grapes did not accumulate anthocyanins, whereas all the American *Vitis* showed the typical red color in their flesh, indicating the presence of a high number of anthocyanins (Supplementary Figure 2). Tenturier (red-fleshed) *vinifera* do exist, but they are a minority in its germplasm, whereas white-fleshed American grapes exist only in *Vitis riparia* and *Vitis berlandieri*. The anthocyanin accumulation pattern seems to be similar in the flesh and skin of wild American grapes, but the relative amount was lower in the flesh. Among the hybrids, only Nero showed a certain degree of accumulation of anthocyanins in the flesh, due to a red layer on the external part of

DOI: 10.1021/acs.jafc.5b01999
J. Agric. Food Chem. 2015, 63, 6823−6834

the flesh, but this was likely due to the cold storage effect more than a physiological accumulation.

The stilbenoids are polyphenolic compounds that have a strong antifungal activity in plants and possess health-related characteristics (e.g., resveratrol belongs to this class). Their accumulation is reported to be directly correlated with the accumulation of anthocyanins during ripening stages. As expected, due to the high concentration of anthocyanins in the skin and flesh of American grape berries, these were also richer in stilbenoids, especially *V. arizonica* Texas and *V. californica*. We found larger amounts of isorhapontin, *cis*-ε-viniferin, *trans*-resveratrol, *trans*-piceid, and *cis*-resveratrol in the skin (Figure 1). Higher amounts of *trans*-resveratrol, *trans*-piceid, and *cis*-resveratrol were also found in the flesh. As hybrid flesh is colorless (without anthocyanins), 41B, Nero, and Isabella showed small amounts of stilbenoids in the flesh. Despite the strong anthocyanin color in their skins, the accumulation of stilbenoids in the skin of 41B and Isabella was poor, whereas Nero skin had a pattern similar to that of *V. cinerea*, which contains the lowest amount of the American grapes investigated.

Flavonols and Dihydro-flavonols. Flavonols are very strong antioxidants and have health-related properties.[49] Flavonols are yellow pigments and may contribute to the color of white grapes and white wines. In plants, they are believed to defend the tissues from oxidative damage by UV-B rays.[46]

In our experiment, we were able to identify four basic units of flavonols differently accumulated between the two groups: quercetin, myricetin, laricitrin, and syringetin. These were present in glucosylated or rutinosylated forms. The main differences were found in the skin, where *vinifera* tended to accumulate more quercetin-glucoside and galactoside than American grapes, whereas American grapes accumulated more myricetin, laricitrin, and syringetin-glucoside. Nevertheless, considering grape color and comparing the American varieties with only Merlot and Moscato Rosa, the differences were not so big, being only 2.5 times more concentrated. White grapes do not accumulate flavonols trihydroxylated in the B ring[50] (myricetin, laricitrin, and syringetin), whereas red ones do accumulate triydroxylated flavonols, so this difference seems to be due mostly to grape color rather than to grape species.

Interestingly, we could observe a similar pattern for dihydro-flavonols. This class of compounds has only recently been reported in grapes,[51] and, in our experiment, it seemed to follow the same pattern as flavonols' accumulation; American grapes, Merlot, and Moscato Rosa accumulated the trihydroxylated forms (dihydro-syringetin, dihydro-laricitrin, and dihydro-myricetin), whereas the remaining *vinifera* had only dihydro-quercetin. The dihydro-flavonols are the direct precursors of flavonols, and considering that the hydroxylation of the B ring happens earlier in the metabolic pathway,[52] a similar pattern for dihydro-flavonols and flavonols would seem to be legitimate. Nevertheless, further investigations, considering a wider population of red and white grapes (similar to the experiment performed by Mattivi et al.,[50]), are necessary to confirm these important results.

Other Identified Metabolites. Many other classes of metabolites were found to accumulate differently in wild American grapes and *V. vinifera*. Some sugar precursors, polar lipids, (putative) lignans, flavones, and some organic acids showed a different accumulation in the two groups. Nevertheless, it was not possible to determine the difference found in these classes of metabolites, because many of the identifications were putative and under-represented and had a nonunique accumulation pattern.

The putative identified polar lipids were all accumulated in larger amounts in *vinifera* tissues. Hydroxy-hexanoate-glucoside, decyl-pentosyl-glucoside, mascaroside-like, and hexyl-rhamnosyl-glucoside accumulated more in the seeds of the *vinifera* group than in the wild American grapes seeds; Nero had levels similar to those of the *vinifera* group. A similar pattern was observed in the skin for the compounds hydroxy-decanoic acid-pentosyl-glucoside, undecanoic acid-pentosyl-glucoside, and undecadioic acid-pentosyl-glucoside, with Nero again having levels similar to those of *vinifera*.

Among the remaining classes, lignans stand out as an interesting class: two signals, *m*/*z* 505.2080 and 491.1940, were found exclusively in the American group, specifically in . *arizonica* Texas and *V. cinerea*. Their identification is merely putative, but their fragmentation spectra were very similar to the spectrum of lariciresinol with a xyloside and rhamnoside moiety, respectively (data not shown). These metabolites have been previously identified in *V. thunbergii*,[17] and they are considered to be a very desirable marker because of health benefits related to lignans.

Potential and Limits of the American Grapes and Interspecific Hybrids in Wine Production. The aim of this work was to determine the chemical and metabolic differences that make *vinifera* suitable for wine production, in comparison to some American *Vitis* that are not ideal in quality wine production. The results clearly show that the method adopted (untargeted analysis) allowed us to have a broad picture on many metabolites involved in grape quality. We found that the American grapes considered in our study are poor in some important components of the wine, such as procyanidins and volatiles precursors (especially terpenols-glycosides). These differences were known and reported in previous papers,[5,6,37−39] but they were never comparatively studied against *V. vinifera* and never stated clearly in a single work. Breeders producing interspecific hybrids between *V. vinifera* and wild American grapes have to take in account these limitations and obtain an extensive characterization of the chemical phenotype of the parents to be used in the crosses and of the progeny in order to import the positive characteristics from the *V. vinifera* progenitors.

The American grapes, interestingly, showed accumulation of metabolites not commonly present in *V. vinifera*, such as hydrolyzable tannins and (likely) lignans. These characteristics represent the positive heritage of the American progenitors, and they might be the target of future breeding programs (for example, to obtain wines rich in hydrolyzable tannins without oak aging). Moreover, these compounds, if retained in the progeny, could be useful markers to identify the wines produced from the new varieties. Complementary analytical tools able to analyze in depth the primary metabolites, the lipids, and the volatiles may help in the description of other characteristics that differentiate the wild American grapes from the *V. vinifera*. Moreover, a wider number of accessions from the *Vitis* germplasm might be analyzed using the same approach.

The analysis of three hybrid varieties showed how the different characteristics are inherited from the progenies. All of the hybrids investigated showed a low content in procyanidins, a variable content of volatile precursors, anthocyanin content similar to that of the American grapes, and absence of hydrolyzable tannins. These observations indicate the need for targeted breeding programs to transfer the desired characteristics to the progenies. Phenotypic evaluation of the hybrid (as in Nero) has not been

DOI: 10.1021/acs.jafc.5b01999
J. Agric. Food Chem. 2015, 63, 6823−6834

sufficient to obtain a variety comparable to *V. vinifera*. Extensive coverage of the chemical phenotype should become an essential part of future breeding studies, and support for future research on the factors that limit the heritage of positive characteristics to the hybrid progeny is needed to facilitate breeders' work and shorten breeding programs.

production of sound waves that create cavitation bubbles near the sample tissue, which break down to disrupt the cell walls, thereby releasing cell contents.[22−24] Probe and bath systems are the two most common ways of applying ultrasound waves to the sample (Figure 2). Probe sonicators are constantly in contact with the sample and make reproducibility and repeatability difficult.[25]

Recently, an overview of some novel technologies to extract valuable compounds from plant materials concluding that UAE is a promising technique with various benefits was given.[26] In fact, it could be applied with small volumes of organic solvents (1−15 mL) at atmospheric pressure, ambient temperature, and during a very short time of extraction compared to conventional solvent extraction. Additionally, UAE is harmless for operators, safe to use, and has low maintenance costs. Compared to conventional methods, UAE is one of the most simple, inexpensive extraction systems, and can be operated rapidly in a broad range of solvents for large-scale preparations suited for industrial purposes.[27,28]

Possible industrial scale up of UAE has been reported in the literature for the extraction of polyphenols from apple pomace. The process appeared to be a relevant, rapid and sustainable alternative to the conventional procedure.[29,30]

Nevertheless, it has been reported that the exposure of the product to ultrasound may involve compound degradation. In fact, the impact of ultrasound treatment on sunflower oil during ultrasound processing was studied.[31] The authors reported the detection of some off-flavors, which can incite depreciation by consumers. This behavior has been reviewed, describing component degradation, especially for high lipid containing products.[32] For instance, UAE has been used to recover antioxidant compounds and especially steviol glycosides from *Stevia rebaudiana* leaves. Some of the main findings are described below and in Table 1.

Steviol Glycosides. In a recent work, the authors investigated the most appropriate procedure to maximize the yield of steviol glycosides, total phenolic compounds, and flavonoids as well as antioxidant activity in *Stevia* extracts.[33] Authors compared UAE with the conventional solvent one. Conventional extraction was carried out with water (100 °C/24 h) and 70% of ethanol (70 °C/30 min) as solvent. UAE was conducted with directly immersed sonotrodes of maximum nominal power of 400 W with 7 and 22 mm in diameter, and 2,

Table 1. Impact of Ultrasound and Microwave Assisted Extraction on the Recovery of High-Added Value Compounds from *Stevia rebaudiana* Bertoni Leaves

treatment conditions	solvent(s)	major findings	ref
		Ultrasound Assisted Extraction (UAE)	
400 W/7 and 22 mm sonotrodes/2−10 min	water	maximum recovery found using 22 mm probe and 10 min; 96.48 and 36.92 mg/g of extract, for stevioside and rebaudioside A, respectively; 77.89 mg/g of extract for total phenolic compounds (TPC); 62.48 and 15.41 mg/g of extract for flavonoids and non-flavonoids, respectively	33
20−100 W/40−80 °C/10−60 min	water	optimal ultrasound treatment (60 W/68 °C/32 min) using RSM; significant increase of 19 and 43% in rebaudioside A and stevioside yields, respectively, compared to conventional values	34
2 mm ultrasonic horn transducer (30 kHz and 50 W) and an ultrasonic bath (40 kHz and 100 W), 60−100% nominal power, 20−80% pulsed range	water/ethanol	significant increase of stevioside recovery, almost 7 times higher than conventional extraction at the same treatment time; higher extraction solvent leads to higher extraction yield	35
20 kHz/360 W/6−24 min	water	maximum extraction yield of soluble molecules (18%) after 24 min of treatment time; maximum recovery of rebaudioside A (28.72 g/100 g) after 24 min of treatment time	36
24 kHz/480 W/30 °C/18 min	water, ethanol, isopropyl alcohol	maximum recovery of rebaudioside A: 37.10 g/100 g; shorter extraction time, lower energy consumption	37
1st phase: 25 kHz/10−30 min/30 °C 2nd phase: 25 and 50% *Stevia*-based osmotic solution, then drying step	water	partial removal of sucrose, fructose, and glucose from the strawberries; incorporation of stevioside and rebaudioside as low caloric sweeteners	38
0 and 25 kHz frequency/30 °C/10−60 min	water	sugar substitution in Malay apples by stevia-derived natural sweetener; the highest water loss (22.48%) and the greatest sweetener gain (9.8%), using 50% (w/w) stevia-based solution for 45 min	39
20 kHz/400 W/20 °C/0−2 min	water	recovery of phenolic compounds, chlorophylls, and carotenoids; significant improvement in the recovery of phenolic compounds, compared to conventional extraction	21
ultrasonic bath (160 W)/50 mL extraction solvent/25 °C/25 min	acetonitrile/water	maximum DPPH inhibition of 89.94% for the extracted high added value compounds	40
		Microwave Assisted Extraction (MAE)	
2.45 GHz/0−400 W/70−110 °C/1−5 min	water	extraction rate increased and the stevioside content reached a maximum value in <5 min; significant relationship among stevioside concentration, temperature increase, and type of waves used to intensify the mass transfer	50
2.45 GHz/20−160 W/10−90 °C/0.5−5 min	water/methanol	MAE yielded 8.64 and 2.34% of stevioside and rebaudioside A, respectively	51

4, 6, 8, and 10 min of treatment time. Full duty cycle of ultrasonic propagation was applied with maximum amplitude and without cooling the system. The authors also concluded how UAE is an environmental friendly technique for the extraction of functional compounds out of *Stevia* leaves due to the significantly shortened treatment time and lower energy consumption compared with those of conventional extraction.

Response surface methodology (RSM) was used to optimize the UAE of steviol glycosides from *Stevia rebaudiana* Bertoni.[34] Experiments were done at different extraction temperatures (40−80 °C with water circulation system), sonication power (20−100 W), and extraction times (10−60 min in increments of 10 min). The authors found a significant increase of 19 and 43% in rebaudioside A and stevioside yields, respectively, under the optimal ultrasound treatment (60 W/68 °C/32 min) in comparison to that of classic treatment with boiling water. Moreover, extraction time was substantially shortened compared to that in classical extraction. They attributed this effect to the mechanical action of ultrasound waves on cell walls, thus increasing the accessibility and extractability of the molecules.

In another study, the potential of UAE to recover steviol glycosides from *Stevia* was evaluated.[35] Two types of ultrasound assisted extractors were employed: an extractor equipped with a 2 mm ultrasonic horn transducer (30 kHz and 50 W) and an ultrasonic bath (40 kHz and 100 W). The yields obtained by UAE after 20 min were comparable with those achieved after maceration during 24 h. The same behavior was noticed with an ultrasound bath (the process is almost completed after 20 min). The optimum parameters for UAE were water as solvent, 1/10 (g/L) as solid concentration in extraction media, and 20 min for extraction time.

Moreover, the influence of UAE on steviol glycoside recovery was also investigated.[36] Ultrasound was used by immersing a sonotrode (20 mm diameter, 300 mm length) into the treated samples with processing conditions of 20 kHz frequency and 1200 W maximum power. The effect of ultrasound treatment on the extraction yield of rebaudioside A (g/100 g) and total soluble solids (%) was mainly due to both prolonged treatment time and particle size reduction. The experimental conditions for UAE were carried out using 20 kHz frequency, 360 W power, and 6−24 min of ultrasound propagation time. Results showed a significant increase of the total soluble compounds with 11.16, 12.23, 13.37, and 18% at 6, 12, 18, and 24 min of extraction time, respectively. The yield of rebaudioside A, however, decreased with increasing US treatment time, giving thus 32.79, 30.45, 28.66, and 28.72 g/100g at the same time range. The authors also compared their results with conventional extraction studies showing significant advantages of UAE as an innovative and emerging technology. In addition, they reported that *Stevia* leaves represent an important source of carbohydrates and fibers.

Special emphasis was also dedicated to rebaudioside A and its extraction yields from *Stevia* leaves using various concentrations (10−60% w/w) of 3 different solvents (water, ethanol, and isopropyl alcohol) using UAE.[37] The optimal extraction conditions were found using 60% (w/w) isopropyl alcohol and 24 kHz/18 min/480 W/30 °C, leading to 37.10 g/100 g of rebaudioside A recovery yield. Furthermore, after the comparison of conventional extraction technologies and UAE, the authors concluded that UAE could be successfully incorporated into existing industrial plants for more sustainable and eco-friendly processing. Many issues like shortening the processing time, safer environment for operators, increased

DOI: 10.1021/acs.jafc.5b01994
J. Agric. Food Chem. 2015, 63, 6835−6846

yield and lower energy consumption have been taken into consideration.

In addition, other authors studied the possibility of inducing the substitution of sweeteners in strawberries by replacing the high caloric sugars in the fruit with low caloric ones but without losing the well-known sweetness of the fruits.[38] The process was performed using UAE and was compared to conventional extraction. Experiments were carried out in two separate phases with first the partial removal of sucrose, fructose, and glucose from the strawberries and second the incorporation of stevioside and rebaudioside as low caloric sweeteners. Strawberry slices were first pretreated to remove the high caloric sugars by immersion in an ultrasonic bath filled with distilled water (25 kHz/10−30 min/30 °C). The second step consisted of immersing the pretreated samples into *Stevia* powder (25% and 50% *Stevia*-based osmotic solution) as a natural and low caloric sweetener with/without sonication, followed by an air-drying step. The authors showed that the application of utltrasound for sugar removal provides better results compared to that of the untreated samples. It was also found that the samples treated with 50% w/w *Stevia* osmotic solution had the highest values of water loss and soluble solid gain response. For the second stage, low caloric sugar incorporation was conducted using 20 min of sonication time, thus leading to the maximum gain response of soluble solids.

In the same manner, the feasibility of sugar's substitution in Malay apples by *Stevia*-derived natural sweetener using ultrasonic pretreatments in osmotic solutions was studied.[39] The first stage of pretreatment consisted of removing sugars by ultrasound, performed using an ultrasonic bath (25 kHz and 30 °C). The second stage consisted of sugar substitution by a *Stevia*-based natural sweetener structured in five time intervals (10−60 min); three solutions (distilled water and two osmotic concentrations (25% and 50%, w/w)); and two frequency levels (0 and 25 kHz). The highest water loss (22.48%) was observed in Malay apple subjected to ultrasonic energy in both stages of the process (sugar removal stage and sweetener incorporation stage) and immersed in the 50% (w/w) *Stevia*-based solution for 45 min. The first pretreatment stage (sugar removal stage) showed high soluble solid loss from Malay apples immersed for 20 min in distilled water at an ultrasound frequency of 25 kHz. The process resulting in the greatest sweetener gain (9.8%) was also observed for Malay apples subjected to ultrasound in the sugar removal stage followed by immersion in the 50% w/w *Stevia*-based osmotic solution for 45 min subjected to ultrasonic application.

Antioxidant Compounds. The influence of UAE on the recovery of phenolic compounds, chlorophylls, and carotenoids from *Stevia* leaves at room temperature and using only water as solvent, making the extraction process more environmentally friendly, was recently investigated.[21] When comparing with the conventional method, the authors observed a significant improvement in the recovery of phenolic compounds after using UAE with the highest energy input conditions. However, no significant changes in chlorophylls a and b, as well as in carotenoid content, were observed after US treatment compared to those of control samples at equivalent diffusion times.

In another study, the recovery of stevioside, rebaudioside A, total phenolic compounds, and flavonoids from *Stevia* leaves, using UAE, were evaluated and compared to conventional extraction.[33] The obtained results showed that the compound recovery yields using UAE were 96.5, 36.9, 77.9, and 62.5 mg/g, respectively. However, with conventional extraction, the yields for stevioside, rebaudioside A, total phenolic compounds, and flavonoids were 74.7, 22.3, 53.9, and 35.8 mg/g, using water, and 82.68, 24.39, 56.72, and 37.94 mg/g, using ethanol, respectively. In addition, the antioxidant activity (ABTS values) was also higher when using UAE (2.58 ± 1.84 mM Trolox) than that obtained for conventional hot water extraction (2.10 ± 1.06 mM Trolox) and ethanolic extraction (2.24 ± 1.11 mM Trolox).

The recovery of valuable compounds from 10 plant matrices, including *Stevia*, using UAE and pressurized fluid extraction (PFE) was investigated.[40] The UAE method was carried out in an ultrasonic bath (160 W) using 50 mL of extraction solvent (30% acetonitrile in water), at 25 °C and during 25 min. For all extracts, the antioxidant capacity based on the reduction of free DPPH (2,2-diphenyl-1-picrylhydrazyl) radical was determined. Results ranged from 82.04 to 94.43% of DPPH radical inhibition for the PFE method and from 76.01 to 89.94% when using the UAE method.

MICROWAVE ASSISTED EXTRACTION (MAE)

Microwaves are nonionizing radiation with frequencies between 300 MHz and 300 GHz. The advantages of microwave assisted extraction (MAE) techniques compared to conventional methods (such as maceration and heat reflux) include reduced use of organic solvents, reduced extraction time (generally less than 30 min), and increased extraction yields.[41] The hot solvents generated in MAE penetrate easily into the matrix and extract compounds from the lysed plant cells. Figure 3 shows a schematic representation of the MAE system used at a laboratory scale.

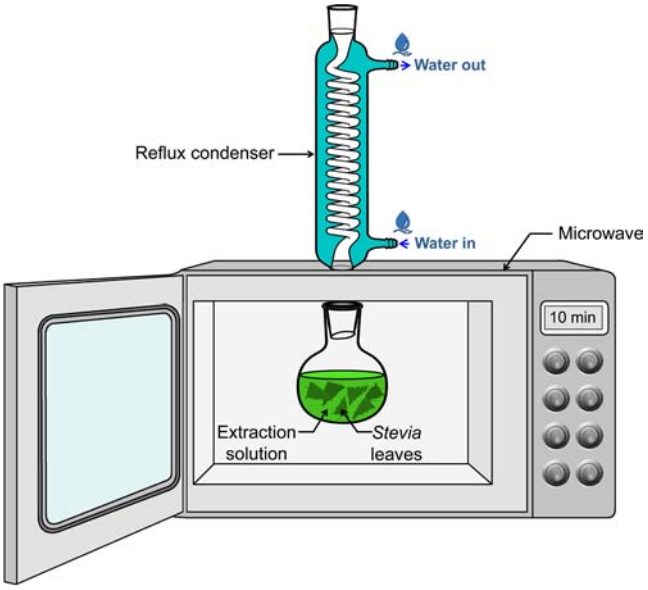

Figure 3. Laboratory scale equipment for microwave assisted extraction.

Some other benefits of MAE, compared to those of conventional extraction methodologies, were overviewed.[42] This method could be applied to a wide variety of plant matrices due to its minimal degradation of aimed and targeted functional and valuable compounds and increased selectivity.

DOI: 10.1021/acs.jafc.5b01994
J. Agric. Food Chem. 2015, 63, 6835−6846

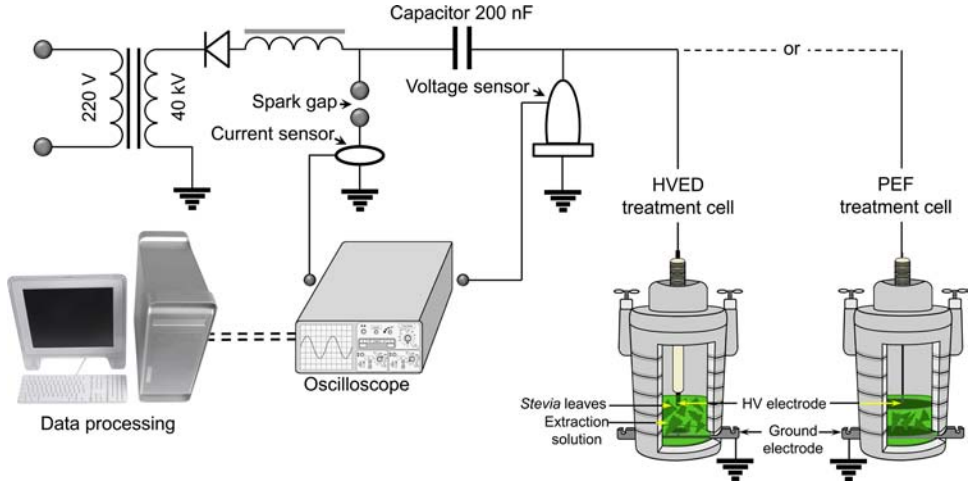

Figure 4. Typical scheme used for high voltage electrical discharges (HVED) and pulsed electric field (PEF) units.

Special emphasis was reported in the available literature regarding the feasibility of MAE process industrialization for green extraction of high-added value compounds from plant matrices and industrial byproducts.[43−46] Among the proposed processes for possible industrialization, solvent-free microwave extraction of essential oil from aromatic herbs[47] and the separation of volatile and nonvolatile organic compounds of boldo leaves[48] were discussed.

Despite the encouraging reports concerning the possible industrialization of the MAE process and even more the effective antimicrobial properties of microwaves for pasteurization and sterilization, this technique is facing numerous obstacles limiting its industrial uses. One of these limitations, is the high cost of industrial microwave heating-based equipment.[49] The potential of MAE to recover high-added value compounds from *Stevia rebaudiana* Bertoni was tested by several research groups, and Table 1 summarizes the main obtained results.

Steviol Glycosides. The effects of UAE, MAE, and conventional heat extraction on the recovery of stevioside from *Stevia* were evaluated and compared.[50] UAE was done using ultrasonic horn transducer (20 kHz and 750 W), sample temperature (up to 100 °C), and a microwave enclosed extractor (2.45 GHz), in the range of powers from 0 to 400 W and temperatures between 40 and 250 °C. UAE was conducted for 1−5 min at 50−100% amplitude of output power, without stirring. MAE was done for 1−5 min at 70−110 °C, with stirring. When using ultrasound and microwave fields, the extraction rate increased, and the stevioside content reached a maximum value in less than 5 min. The increase in stevioside content was observed when ultrasound treatment was applied using 50, 80, and 100% amplitude and an input power of 750 W. Compared to thermal extraction, these two techniques ensured high purity values of active substances. Moreover, they justified the use of ultrasound as an alternative extraction technology for steviol glycoside recovery as this technology can have economic benefits (relatively low-cost method) in comparison to conventional methods as well as for its simple use and significant efficiency. In addition, the authors observed a significant relationship between stevioside concentration, temperature increase, and type of waves used to intensify the mass transfer.

In the same manner, Jaitak, Bandna, and Kaul extracted stevioside and rebaudioside A from *Stevia* using dried and powdered leaves by conventional, UAE, and MAE techniques, using methanol, ethanol, and water as single solvents as well as in binary mixtures.[51] Conventional cold extraction was performed at 25 °C for 12 h, UAE was carried out at 35 ± 5 °C for 30 min, and MAE was carried out at 80 W power level, for 1 min at 50 °C. MAE yielded 8.64 and 2.34% of stevioside and rebaudioside A, respectively, while conventional and UAE yielded 6.54 and 1.20%, and 4.20 and 1.98% of stevioside and rebaudioside A, respectively.

Other authors developed a feasible and cost-effective system for the regeneration of *Stevia rebaudiana* with enhanced steviol glycosides production.[52] They used two different agar concentrations (3.5 and 7.0 g/L) and added plant growth regulators (PGRs) in the medium, adjusted pH, and boiled the media in a microwave oven. Media were placed in a growth room (25 °C) following a 16 h/8 h photoperiod. The results showed that lower agar concentrations are more effective for callus cultures and root induction, while higher agar concentration influences the shoot's organogenesis.

Moreover, the effects of pressurized hot water and microwave assisted water extractions were compared,[53,54] observing either similar or higher steviol glycoside recovery compared to that of conventional heating treatment.

Antioxidant Compounds. An artificial neural network (ANN) model was proposed to predict the extraction yields and rates for the recovery of bioactive molecules (the polyphenolic acids and flavonoids content) from three medicinal plants: *Stevia rebaudiana* leaves, *Cynara scolymus* leaves, and *Arctium lappa* roots.[55] MAE was done in a closed vessel system, in a temperature range of 40−250 °C, a power range of 0−400 W, and a pressure range of 0−20 bar.

PULSED ELECTRIC TECHNOLOGY ASSISTED EXTRACTION

Over the last years, the use of pulsed electric technologies, especially pulsed electric fields (PEF) and high voltage electrical discharges (HVED), have been shown as a potential tool to recover valuable compounds from plant food, from a green and sustainable point of view.[21,56] PEF consists of an electrical treatment for a short time (from several nanoseconds to several milliseconds) with pulse amplitude from 100−300 V/cm to 20−80 kV/cm. Under the effect of PEF, the biological membrane is electrically pierced and losses its semipermeability temporarily or permanently.[27,57] Scale-up of PEF food

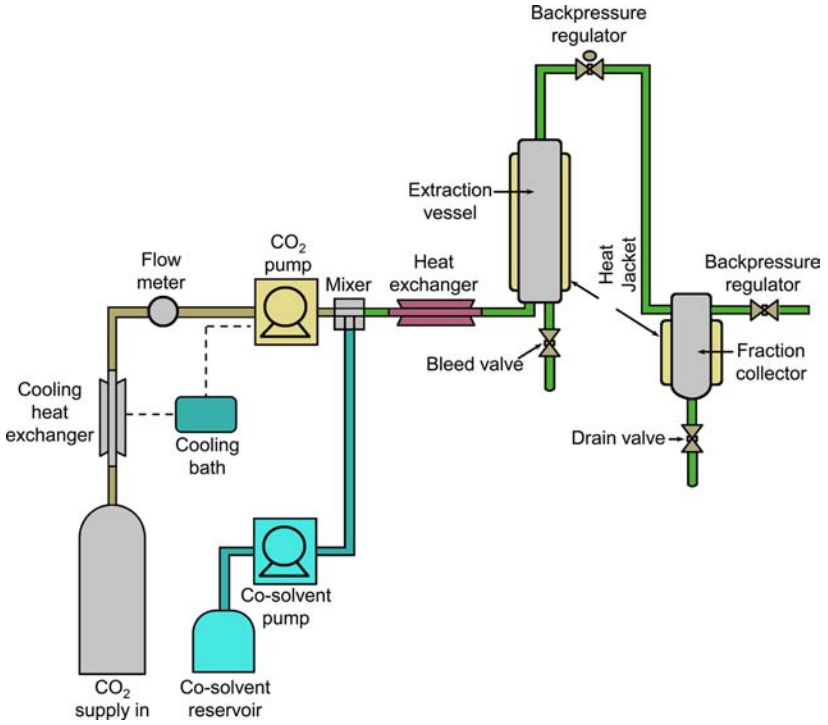

Figure 5. Schematic presentation of a supercritical carbone dioxide extraction system coupled with cosolvents and used at the laboratory scale.

processing as well as equipment design is already acquired by numerous food industries.[58,59] Regarding the field homogeneity as well as cleanability and flow behavior, several treatment chamber configurations were used, and equipment with 5, 30, and 80 kW average power levels was developed to process up to 10.000 l/h capacity.[60] The down side effects of using PEF treatment for industrial purposes are mainly the high industrial cost. In fact, the price for a PEF unit processor for inducing cell disintegration was estimated to be around $197,000, for a processing flow rate of 10 t/h, with an energy input of 10 kJ/kg, and an average output power of 30 kW.[61]

However, HVED is based on both chemical reactions and physical processes. When HVED is produced directly in water, it injects energy directly into an aqueous solution through a plasma channel formed by a high-current/high-voltage electrical discharge (>40 kV; >10 kA) between two submersed electrodes.[27,62−64] This technique, although more efficient for cell disintegration than PEF, requires a high investment too and produces free radicals in the submerging medium that reduce the total antioxidant activity of the extract. Nowadays, the performance of the industrial application of HVED treatment was not evaluated, thus requiring more research developments, but in any case, it is important that new steps be taken to help build a more rational use of our natural resources.

For instance, some authors have evaluated the potential of these technologies to recover nutritionally valuable compounds from *Stevia rebaudiana* leaves. Figure 4 shows a schematic representation of PEF and HVED processing systems. Moreover, some of the most important findings are listed below and in Table 2.

Steviol Glycosides. The impact of PEF assisted extraction on steviol glycosides recovery from *Stevia rebaudiana* leaves was previously studied.[65] It was found that PEF pretreatment (20 kV/cm and 0.5−2 ms) prior to conventional water extraction at ambient temperature (20 °C) improved both the kinetics and extraction yield of steviol glycosides from *Stevia*. A significant reduction in extraction time was also obtained (9 folds less) for achieving the maximum of steviol glycosides extraction compared to that of untreated samples at equivalent diffusion times and at 20 °C. In another study, it was observed that the effect of PEF-pretreatment can be observed at moderate (60 °C) and high (80 °C) extraction temperatures.[66]

Antioxidant Compounds. The potential of electrotechnologies to recover polyphenols from *Stevia rebaudiana* Bertoni has been recently evaluated.[21] These authors compared the effects of PEF and HVED on polyphenol's recovery at equivalent energy inputs (0, 24, 47, 71, 94, 118, and 141 kJ/kg). They found that HVED and PEF treatments enhanced the polyphenol's content of the obtained *Stevia* water extracts compared to that of control diffusion samples at equivalent treatment times. It was also found that the content of total polyphenolics increased proportionally to the energy input.

Moreover, the authors reported that HVED was the most effective technology to recover polyphenols (14.22−29.14 mg/g GAE DM), especially caffeic and chlorogenic acids, in terms of energy input and treatment time, compared to that of PEF (10.28−20.85 mg/g GAE DM) treatments. They justified the higher recovery of polyphenols after HVED treatments to the electric and mechanical disruption of *Stevia* leaves, thus facilitating the extraction of soluble biomolecules.

The recovery of coloring and antioxidant pigments (carotenoids and chlorophylls) from *Stevia rebaudiana* Bertoni leaves induced by pulsed electric technologies (PEF and HVED) at equivalent energy inputs was also investigated.[21] Increase of chlorophylls a and b contents in *Stevia* water extracts obtained from HVED-treated samples was observed and compared to the control. However, they did not find significant differences in chlorophylls a and b content in PEF-treated *Stevia* samples compared to those of the control at the same diffusion time.

Proteins. The effects of PEF and HVED on the recovery of proteins from *Stevia* at equivalent energy inputs (0, 24, 47, 71,

DOI: 10.1021/acs.jafc.5b01994
J. Agric. Food Chem. 2015, 63, 6835−6846

94, 118, and 141 kJ/kg) were also evaluated.[21] In this study, a significant improvement in protein yield was found after applying HVED treatment compared to that of control samples, obtaining the higher protein yield (1.127 g/100 g) when HVED was used at the highest energy input. Moreover, they also found a significant increase in protein yield, proportionally to HVED energy input.

SUB- AND SUPERCRITICAL FLUID EXTRACTION

The supercritical fluid state is reached when the pressure and the temperature of the system are above its critical point. At this state, the fluid could be considered either as expanded liquid or compressed gas. Supercritical fluids have relatively high density and therefore exhibit high solvation power that enables them to be used as solvents. Supercritical carbon dioxide ($SC-CO_2$), having a critical point of 7.38 MPa and 304.2 K, is the most widely used supercritical fluid. In fact, it has a low critical temperature, thus allowing operations near room temperature and a mild critical pressure. Furthermore, this fluid is nontoxic, nonflammable, nonexpensive, and readily available at good purity. $SC-CO_2$ has the feature to be used for hydrophobic or slightly hydrophilic compound extraction. Generally, when the pressure inside the extraction vessel increased, additional hydrophilic compounds could be extracted. When more hydrophilic compound extraction is targeted, the solvent's polarity has to be changed by using more polar organic solvents (i.e., ethanol, methanol, and ethyl acetate), mixed or not with water, and known as cosolvents or modifiers (Figure 5).

Although there are a few industrial applications for SFE (e.g., extraction of nicotine from tobacco, caffeine from coffee, theine from tea leaves, and few other examples),[67] the use of SFE in the food industry remains limited by its high equipment and installation costs.[68] The other major negative impact of applying SFE in the food industry is the processing cost, mainly related to the high CO_2 consumption, which is in most of the cases being lost at the end of the extraction and not recycled. One of the challenging solutions recently proposed to reduce the extraction time and the CO_2 consumption, consists of using continuous gas assisted mechanical expression (GAME) equipment.[69] Such equipment was successfully tested for oil extraction from oilseeds, paving the way toward possible large-scale continuous flow industrial applications of SFE. The current applications of SFE technology to recover high-added value compounds from *Stevia* are described below.

Steviol Glycosides. The impact of SFE, using CO_2 and either water or different mixtures of ethanol−water as cosolvents, on the recovery of steviol glycosides from *Stevia* has been studied by several research groups (Table 2). For instance, an increase in steviol glycoside's recovery was found after applying SFE (3−3.4%), in two steps, (a) the pretreatment of the leaves by SFE; (b) the extraction of the *Stevia* glycosides by SFE using CO_2 as solvent and water and/or ethanol as cosolvent, compared to that of the conventional extraction process.[70] In this line, other authors also obtained 50% and 72% recovery of the original stevioside and rebaudioside A, respectively, when using a two-step SFE process: (1) CO_2 extraction and (2) CO_2 + water extraction.[71]

In another study, a similar steviol glycoside yield was obtained when comparing SFE and conventional water extraction, concluding that SFE can be an alternative technique to conventional solvent extraction mainly due to the reduction extraction time of steviol glycosides.[72] The optimized conditions through this work were used later to obtain glycosides from *Stevia* leaves, then the raffinate was used to produce bioethanol. The operational conditions applied were 211 bar pressure, 80 °C temperature, 17.4% cosolvent, and a solvent/feed ratio of 30.[73]

Similarly, the effects of conventional organic extraction and SFE to extract steviol glycosides from *Stevia* were compared.[74] The authors found a 150% increase in steviol glycosides content when SFE was used compared to that in conventional extraction.

The use of subcritical fluids for the extraction of high-added value compounds from *Stevia rebaudiana* was also investigated. For instance, the extraction of steviol glycosides from *Stevia rebaudiana*, including stevioside, rebaudioside A, rebaudioside C, and dulcoside A by subcritical fluid extraction (SubFE) was studied.[75] The authors reported that the extraction efficiency increased proportionally to the pressure, at 40 °C, when using a 20% methanolic aqueous solution. The maximum recovery of steviol glycosides was ≈88% at 368 atm pressure, after 90 min of extraction time.

The potential of subcritical water extraction to recover steviol glucosides from *Stevia rebaudiana* leaves was also studied.[76] A Box-Bhenken experimental design was used to evaluate the effects of temperature (100−150 °C), extraction time (30−60 min), and flow rate (2−6 mL/min) at 230 bar pressure, and using a solid/liquid ratio of 1/10 (m/v). The optimal extraction conditions were found at 125 °C, 45 min, and 4 mL/min flow rate. At these conditions, the yields of stevioside and rebaudioside A were 38.67 mg/g and 35.68 mg/g, respectively.

Antioxidant Compounds. The total phenolic, flavonoid contents, and DPPH free radical scavenging activity were followed after the extraction of steviol glucosides using subcritical water. The authors found 48.63 mg of gallic acid equivalent/g extract for TPC, 29.81 mg of quercetin equivalent/g extract for flavonoids, and 92.50% for DPPH inhibition.[76]

ENZYME ASSISTED EXTRACTION

The use of enzyme assisted extraction constitutes another attractive "green" alternative to conventional methods in order to recover valuable compounds from plant food materials and, in particular from *Stevia rebaudiana* Bertoni leaves, thus reducing the consumption of organic solvents. In this line, some recent studies have shown the ability of enzyme assisted extraction to promote the breakdown of the plant cell wall, thus facilitating the recovery of intracellular compounds.[77]

For instance, the effects of enzyme assisted extraction (cellulase, pectinase, and hemicellulase) at different enzyme concentration, incubation time, and temperature to recover stevioside from *Stevia* leaves were evaluated, and the optimal conditions were evaluated.[77] The authors reported the high efficiency of this method compared to that of conventional solvent extraction. Moreover, they found that hemicellulose led to higher steviose yield (369 μg) after 60 min of extraction compared to cellulase (359 μg) and pectinases (333 μg), thus showing the importance of selecting the most appropriate enzyme.

GREEN IMPACT OF NONCONVENTIONAL TECHNOLOGIES

Developing new nonconventional technologies (UAE, MAE, SFE, EAE, etc.) to recover high-added value compounds from

DOI: 10.1021/acs.jafc.5b01994
J. Agric. Food Chem. 2015, 63, 6835−6846

agricultural resources and industrial byproducts has received increased interest compared to conventional methods. These emerging technologies may allow reducing extraction time, processing temperature, and solvent consumption, thus resulting in increasing the extraction yield and decreasing the energy cost.[67,78] In fact, thermal extraction processes, although considered as safe, require high-energy input and are not suitable for thermolabile compound extraction, being thus degraded.

The use of UAE brings many benefits such as shorter analysis time, simplified manipulation, and higher purity of the final product.[79] This technology has been widely applied to extract bioactive compounds (e.g., essential oils, antioxidants, and colorants) from plant matrices and industrial byproducts.[67] The green impact of UAE for the intensification of extraction of natural products has been reviewed by Shirsath and co-workers.[80]

When comparing conventional heating to emerging technologies, the heat transfer induced by microwaves remains cheaper, thus requiring moderate investment in equipment.[68] Moreover, it has been reported that when coupling conventional methods (e.g., hydrodistillation) with microwaves, the energy cost is reduced by almost 2-fold (compared to hydrodistillation alone); decreasing thus from 0.12 kWh/kg (430 kJ/kg, $6/t) to 0.07 kWh/kg (270 kJ/kg, $3.5/t).[81] In addition to the energy cost, the heat transfer generated by microwaves is much faster than the conventional one. This fact is due only to the dependence of the rate of heat loss and power applied and not limited to thermal conduction or convection currents.[82]

PEF technology represents a useful tool to recover selectively valuable compounds from different plant matrices from an economical and sustainable point of view.[83−85] This characteristic is mainly due to its ability to permeabilize the cell membrane, thus releasing the intracellular compounds,[21,56,57,86] although the rise of temperature during PEF treatment remains far lower than that reached during conventional thermal processing. PEF assisted drying and dehydration processes have been used for drying food products (vegetables and fruits), demonstrating not only higher drying rates but also great nutritional quality compared to that of conventional drying methods.[49] PEF treatment was able to produce the highest drying rate of okra, compared to that of both microwave heating and blanching.[87] It has also shown better mass transfer during osmotic dehydration of apples.[88] The drying character of PEF as well as nutritional quality retention were reported in other food products such as potato,[89,90] carrot,[91] beetroots,[92] and others. Morevover, the combination of nonconventional processes (i.e., PEF + US and PEF + HVED) with traditional extraction technologies (i.e., US/PEF/HVED + hot water extraction at mild temperatures or US/PEF/PEF + hydroethanolic extraction) could lead to the development of new and optimized extraction processes, thus shortening the extraction times, reducing the temperature, and minimizing the solvent consumption as well as the use of toxic solvents.

On the other hand, SFE has received great interest as a green technology to decrease or replace the consumption of toxic solvents, involving health and environmental related issues. Supercritical fluids have liquid-like solvent power and gas-like diffusivity, giving them great properties as ideal clean solvents for valuable compound recovery from plant matrices, thus having a green impact on the environment. In fact, green chemistry is mainly dominated by three aspects, which are waste, hazards (health, environmental, and safety), and energy.[68] Using nongreen organic solvents (e.g., hexane, diethyl ether, or chloroform) during food processing has a rising impact on human awareness as they must be removed from the extracts before being used as food additives. These impacts on both environment and health led to the use of emerging technologies, such as SFE.

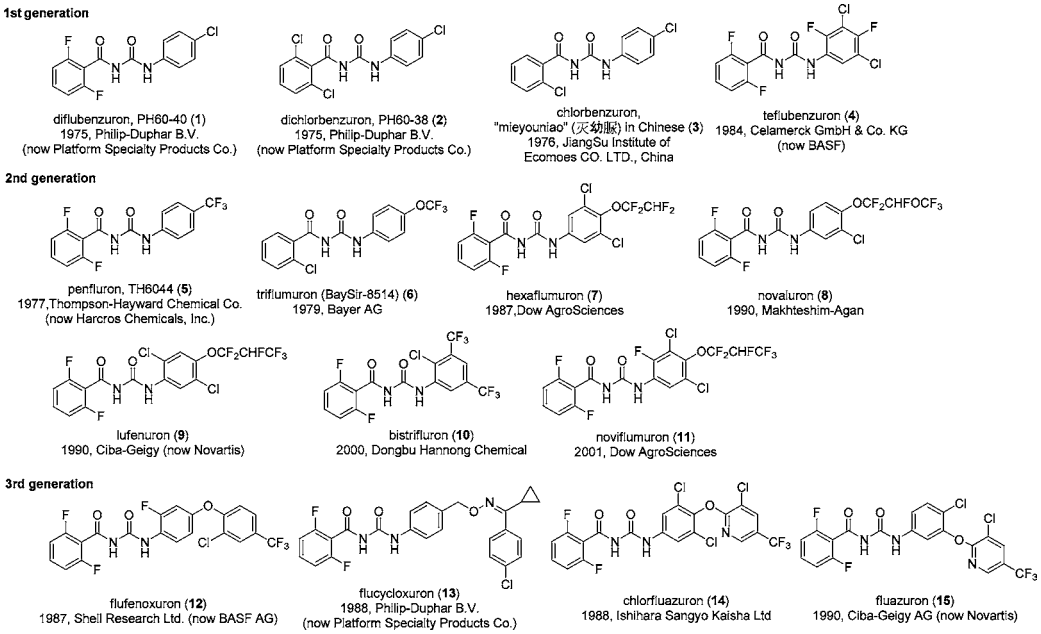

Figure 1. Chemical structures of commercial benzoylphenylurea chitin synthesis inhibitors.

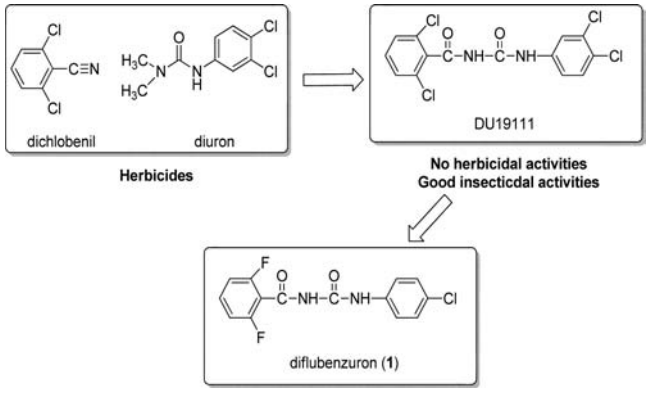

Figure 2. Discovery of benzoylphenylurea chitin synthesis inhibitor diflubenzuron (**1**).

introduced to the market with the trade name Dimilini in 1975.[7]

By virtue of the unique action mechanism and low toxicity for bees, birds, and humans along with their high biological activity against pests, many companies focused on the research of benzoylurea chitin synthesis inhibitors. Then dichlorbenzuron (PH60-38, **2**) and penfluoron (TH6044, **5**) were developed commercially as insecticides at Philip-Duphar B.V. Co. and Thompson-Hayward Chemical Co. Penfluoron (TH6044, **5**) was found to possess a high larvicidal activity, about 3 times as active as diflubenzuron (**1**) when tested against *P. brassicae* in laboratory tests. At the same time, chlorbenzuron (**3**) was discovered at JiangSu Institute of Ecomoes and Soochow University, China (Figure 2). Teflubenzuron (**4**) is a multihalo-substituted BPU and was introduced in Thailand by Celamerck GmbH & Co. KG (now BASF). Teflubenzuron (**4**) exhibited better ovicidal and larvicidal activities against the African armyworm (*Spodoptera exempta*) than diflubenzuron (**1**).[8]

The most successful benzoylurea compound after diflubenzuron (**1**) is triflumuron (**6**), which was discovered by Bayer (now Bayer AG) and it is the first commercial product of the second generation BPUs. Triflumuron (BaySir-8514, **6**) exhibited higher ovicidal and broad-spectrum larvicidal activity in comparison with the first-generation BPUs; for example, triflumuron (**6**) had larvicidal activity against cotton bollworm (*Helicoverpa armigera*), whereas teflubenzuron (**4**) and diflubenzuron (**1**) were inactive.[9] Hexaflumuron (**7**) was intended to be used in products to control termites at Dow AgroSciences. Dow AgroSciences was recognized by the U.S. EPA with the U.S. Presidential Green Chemistry Challenge Award in 2000 for the Sentricon System (active ingredient, hexaflumuron).[10] In the following years, novaluron (**8**), lufenuron (**9**), and noviflumuron (**11**) were developed successively at Makhteshim-Agan, Ciba-Geigy (now Novartis), and Dow AgroSciences, respectively. In 2011, the sale amounts of lufenuron (**9**, U.S. $165 million) and novaluron (**8**, U.S. $80.4 million) were the first and third of all commercial BPUs. Bistrifluoron (**10**) was obtained from more than 2000 BPUs at DongbuHannong Chemical Co., Korea. It is active against lepidopteran pests and especially whitefly as an insect growth regulator.

The third-generation BPUs exhibit stronger topical insecticidal activity and broader spectrum larvicidal activity (such as high acaricidal activity). Flufenoxuron (**12**) was developed at Shell Research Ltd. (now BASF AG). It is a broad-spectrum acaricide and insecticide that is effective against Lepidoptera, Homoptera, Diptera, and Hemiptera pests and *Tetranychus urticae*.[11,12] Flucycloxuron combines a high insecticidal activity with a high acaricidal activity against both tetranychid and eriophyid mites. It is the result of an optimization program with benzoylphenylureas on acaricidal activity at Philip-Duphar B.V. (now Platform Specialty Products Co.).[13] Chlorfluazuron (**14**) was launched in 1989, which was discovered and developed by Ishihara Sangyo Kaisha Ltd. It was very effective against oriental leafworm moth (*Spodoptera litura*) and diamondback moth (*Plutella xylostella*) larvae and was 10-fold more inhibitory than diflubenzuron (**1**).[14] Fluazuron (**15**) was discovered and developed at Ciba-Geigy AG (now Novartis). The chemical structure of fluazuron (**15**) is very similar to that of chlorfluazuron (**14**), but the insecticidal spectrum is different.

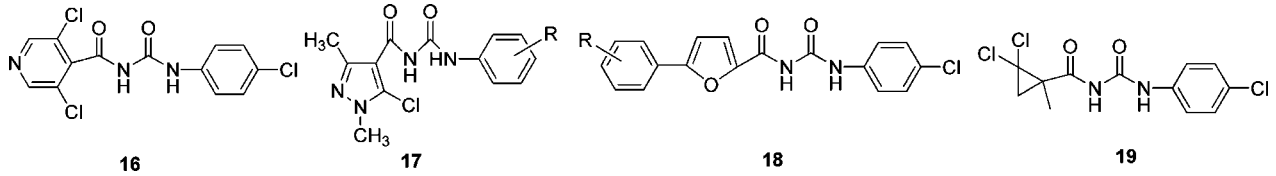

Figure 4. Chemical structures of benzoylphenylurea analogues.

Fluazuron is a tick development inhibitor, which controls the cattle tick (*Boophilus microplus*).[15]

SYNTHETIC METHODS OF BENZOYLPHENYLUREAS

The three synthetic approaches shown in Scheme 1 have been employed most widely in the construction of the typical benzoylphenylurea bridge.[5b] In all of the methods listed in Scheme 1, method 1 is the most commonly used for the laboratory synthesis of benzoylphenylureas. The reaction is both high-yield and highly atom efficient. In addition, the required benzoylisocyanates are readily accessed from the corresponding benzoylamides by reaction with oxalyl chloride (phosgene or triphosgene) under several conditions. The disadvantage of this method is that benzoylisocyanates are easily polymerized at room temperature. Method 2 is the most commonly used for the industrial production of benzoylphenylureas. The arylisocyanates are readily prepared by the reaction between the corresponding arylamines and phosgene (or triphosgene) and then combined with the benzoylamides under heating to give benzoylphenylureas. The disadvantage of this method is that the synthetic procedure needs high temperature. The advantage of method 3 is low environmental pollution along with cheap raw materials and high yields.

STRUCTURE–ACTIVITY RELATIONSHIPS (SARs)

The benzoylphenylureas can be separated into three parts for analysis of the SARs, namely, the benzoyl ring (**A**), aniline ring (**B**), and urea bridge (**C**) (Figure 3). Each part can be examined independently, as they appear to play distinct and different

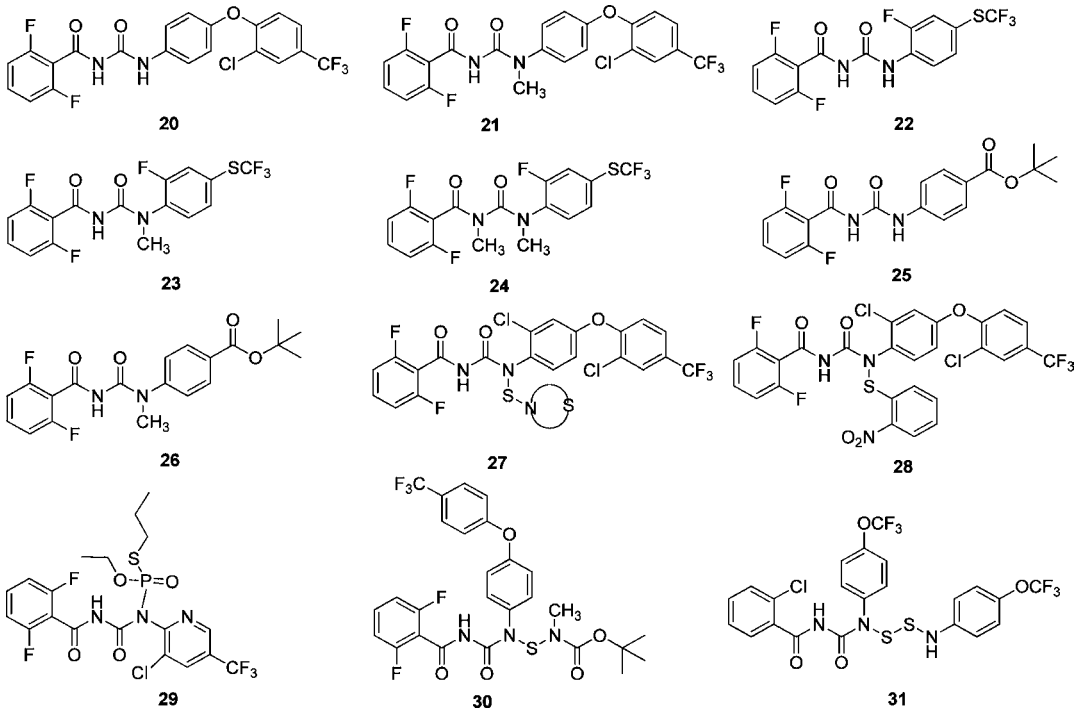

Figure 5. Chemical structures of *N*,*N*′-substituted benzoylphenylureas.

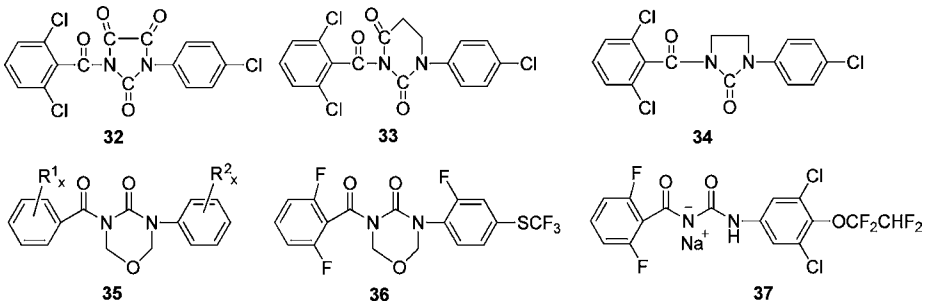

Figure 6. Chemical structures of benzoylphenylureas containing a cyclic urea structure.

roles in the overall expression of larvicidal activities. Nakagawa et al. have reported a series of the quantitative SAR studies of BPUs.[16] At the beginning of BPU research, it was established that a 2-Cl, 2,6-diCl, or 2,6-diF substitution pattern on the benzoyl moiety (**A**) was required for optimal activity, with the 2,6-diF substitution pattern being most effective.[17] The larvicidal activities against *P. brassicae* of the 2,6-difluorobenzoylphenylureas were about 20 times higher than the activities of the 2,6-dichlorobenzoylphenylureas. These results suggested that the conformation having an angle of 30° between the −CO(NH)− moiety and the benzoyl ring (**A**) has optimum larvicidal activity.[18] After more than 40 years of BPU research, this original optimal substitution pattern still seems to be valid, based on the analysis of published patents and the structure of commercial products (Figure 1). According to the bioisosterism principles, the benzoyl ring (**A**) of BPUs could be replaced by the aromatic heterocycles or cyclic alkylsubstituents (such as pyridine, pyrazole, furan, and cyclopropyl groups, Figure 4),[19] but the larvicidal activities decreased significantly, for example, the larvicidal activity against *A. aegypti* of dichlorbenzuron (**2**) was about 10 times higher than the activity of compound **16**.[17a]

In terms of the urea bridge (**C**) moiety (Figure 3), the larvicidal activity of thiourea derivatives with the same substructure was worse than that of the urea derivatives.[20] Research has shown that *N*′-substituted benzoylureas can improve the poor solubility of BPUs in organic solvents. Generally, *N*′-alkyl products displayed better solubility but worse larvicidal activity in comparison with their parent structure.[21] However, *N*′-methyl BPUs exhibited the same (or better) larvicdial activity as the parent structure but low toxicity to aquatic macroinvertebrates.[22] For example, the larvicidal activity of compound **21** was equivalent to that of compound **20**, whereas the toxicity of compound **21** against *Daphnia magna* (EC_{50} < 0.4 ppb) was reduced significantly (EC_{50} = 150 ppb) (Figure 5).[22a] Compounds **23**, **24**, and **26** exhibited 80−100% larvicidal activity against second-instar larvae of *Plutella xyllostella* at 25 mg L^{-1}; on the other hand, the comparative compounds **22** and **25** displayed only 5 and 0% larvicidal activity, respectively, at 25 mg L^{-1}.[22b] When *N*′-substituted groups at the urea bridge (**C**) moiety may be easily released in vivo, compounds **27**, **28**, and **29** displayed better solubility and almost the same level of larvicidal activity as their parent structure (Figure 5).[23] According to the literature, several series of novel *N*′-carbamylosulfenyl, *N*′-alkylaminothio, *N*′-arylaminothio (or dithio), and *N*′,*N*′-thio (or dithio) derivatives of benzoylphenylureas were designed and synthesized in our

DOI: 10.1021/acs.jafc.5b02460
J. Agric. Food Chem. 2015, 63, 6847−6865

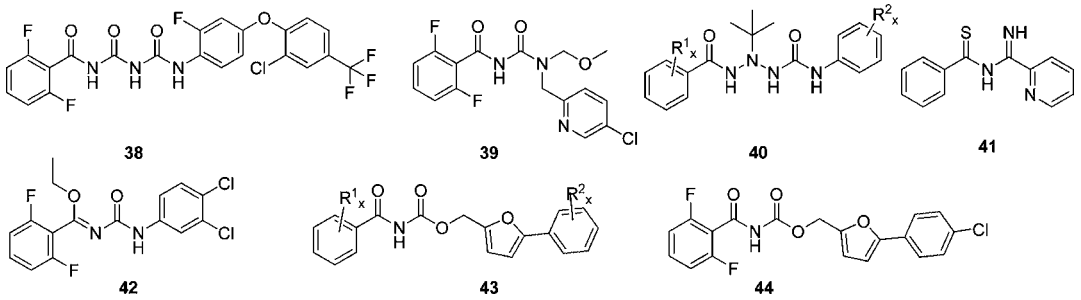

Figure 7. Chemical structures of benzoylurea analogues.

laboratory, and all compounds showed better solubility compared to their corresponding parent BPUs, which should make them easier to apply in the field (Figure 5, compounds **30** and **31**).[24] A series of novel BPUs containing a cyclic urea structure were first designed and synthesized by Philips-Duphar B.V. Co.[25] For example, compound **32** exhibited 90−100% larvicidal activity against second-instar larvae of *P. brassicae* at 0.1 mg L^{-1}, but compounds **33** and **34** did not display larvicidal activity under the same test conditions (Figure 6).[17a] As we know, BPUs are not plant systemic and do not penetrate the plant tissue. To our delight, a series of benzoylurea derivatives (Figure 6, compound **35**) containing a cyclic urea structure were discovered by researchers at Sumitomo Chemical Co., Ltd., and these compounds displayed excellent systemic activities with stomach action.[26] For example, compound **36** exhibited 100% systemic activities in roots against second-instar larvae of *P. xylostella* and *Spodoptera littoralis* at 25 mg L^{-1} and at the same time exhibited 96 and 100% systemic activity against second-instar larvae of *P. xylostella* in soil with 20 mg/plant and seeds with 1 mg/seed, respectively.[26] Therefore, these compounds can be used for soil and seed treatment, which will make a huge contribution to reducing the labor in agriculture and improve the insecticide safety of workers and the environment. Drabek et al. synthesized the benzoylurea salts (such as compound **37**) to improve their water solubility, and this compound exhibited good insecticidal activity against *M. domestica*.[27] The change of acylurea group into other functional groups will reduce the larvicdal activities, such as compounds **38**−**44** (Figure 7).[28] Interestingly, compound **43** (Figure 7) exhibited good fungicidal activities against *Corynespora cassiicola*, *Thanatephorus cucumeris*, *Botrytis cinerea*, and *Fusarium oxysporum*. The morphological result suggested that compound **44** (Figure 7) had disturbed the cell wall formation of *C. cassiicola*.[28d]

The structural optimization of the aniline moiety (**B** ring, Figure 4) is the focus for most researchers, and various functional groups on the aniline (**B** ring) produced three generations of commercial benzoylphenylureas (Figure 1). Research on the QSARs of BPUs has shown that different functional groups and pests have different SARs.[16] In general, bulky groups at the 2,6-position of the aniline moiety (**B** ring) are adverse to the larvicidal activities, and electron-withdrawing groups at the 4-positon of the aniline moiety (**B** ring) are helpful to the insecticidal effects (Figure 4). When the aniline moiety is replaced with other aromatic heterocycles, the insecticidal activities were kept the same or reduced in most conditions.

The earliest research was halo-substitutioon at the aniline moiety (**B** ring, Figure 3) after the discovery of DU19111, and the results of bioassay showed that 3,4-diCl- or 4-Cl-substituted BPUs exhibited the best larvicidal activity, whereas a 4-I substituted compound had little larvicidal activity, which can increase sharply by introducing a 2-F or 3-F group on the aniline (compound **45**, Figure 8).[17a] Mutihalo-substituted

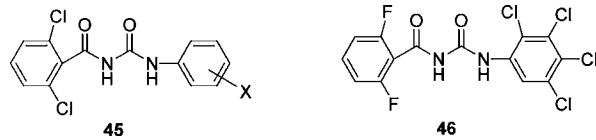

Figure 8. Chemical structures of halo-substituted benzoylphenylureas.

BPUs always exhibited better larvicidal activity, for example, compound **46** (Figure 8) exhibited 10 times higher larvicidal activity against *A. aegypti* and *S. littoralis* than that of diflubenzuron (**1**).[29]

It was found that the larvicidal activity of alkyl-substituted BPUs was worse than that of halo-substituted compounds, and 4-alkyl-substituted BPUs displayed better larvicidal activity than multialkyl-substituted derivatives.[17a] Many companies were engaged in the research of multihaloalkyl BPUs, especially multifluoroalkyl derivatives since penfluoron (TH6044, **5**, Figure 1) was introduced to the market by Thompson-Hayward Chemical Co. in 1977. Compound **47** exhibited 100% larvicidal activity against second-instar larvae of *S. littoralis* at 0.5 mg L^{-1}, but penfluoron (**5**) and teflubenzuron (**4**) displayed only 5 and 20% larvicidal activity, respectively, at the same concentration.[30a] The larvicidal activities of compound **48** (Figure 9) against *S. littoralis* and *A. aegypti* were at the same level as diflubenzuron (**1**).[30b] Bistrifluoron (**10**), which was active against the lepidopteran pest and especially whitefly, was developed and commercialized by DongbuHannong Chemical Co.[30c] Recently, Qian et al. designed and synthesized a series of heptafluoroisopropyl-containing benzoylphenylureas (**50**) inspired by the structure of flubendiamide (**49**) (Figure 9).[31a] These compounds showed excellent insecticidal effect, and their activity resembled that of diflubenzuron (**1**). Compound **50** (Figure 9) showed nearly the same larvicidal activity as novaluron (**8**) on African cotton leafworm (*S. littoralis*). Furthermore, results from a field trial indicated that 5% EC of TXH09 (**51**) (Figure 9) exhibited similar efficacy in comparison with chlorfluazuron (**14**) and hexaflumuron (**7**) against cabbage worm (*Pieris rapae*) and diamondback moth (*P. xylostella*).[31a] Due to the high price of heptafluoroiodopropane, which was the starting material to prepare TXH09 (**51**), a series of 2′-chloro-hexafluoroisopropyl-containing benzoylphenylureas were obtained using hexafluoroacetone with lower price as the starting material.[31b] These compounds showed excellent insecticidal effect. For example, the results from fields trial indicated that the efficacies of 5%

EC **52** (Figure 9) against *S. littoralis* in capsicum and *S. littoralis* in vegetables were 76.7 and 69.0%, respectively. The efficacy of 5% EC **52** was higher than that of hexaflumuron (**7**) and a little lower than that of flubendiamide (**49**) at the same concentration.[31b]

The larvicidal activities of alkyl(aryl)amino-substituted benzoylphenylureas (compound **53**, Figure 10) were first studied by Ciba-Geigy Corp. (now Novartis).[32a] Most of these compounds exhibited both larvicidal and ovicidal activities against lepidopteran pests, and arylamino-substituted derivatives displayed unexpectedly high acaricidal activity.[32] For example, compound **54** (Figure 10) exhibited 80−100% larvicidal activity against *S. littoralis* (at 3 mg L^{-1}) and *Laspeyresia pomonella* (at 0.75 mg L^{-1}).[32a] Compounds **55** and **56** displayed 80−100% larvicidal activity against *S. littoralis* at 0.75 and 3 mg L^{-1}, respectively (Figure 10), and both possessed 80−100% ovicidal activity against *L. pomonella* at 12.5 mg L^{-1}.[32b,c] The researchers at Duphar International Research B.V. Co. found that arylamino-substituted derivative **57** (Figure 10) had 90−100% larvicidal activity against *P. brassicae* at 0.3 mg L^{-1}, whereas compound **58** (Figure 10) displayed 90−100% acaricidal activity against *Tetranychus cinnabarinus* at 1 mg L^{-1}.[32e]

Dow Chemical Co. Ltd. provided a series of 4-phenyldiazene-substituted benzoylphenylureas (compound **59**, Figure 11) that could be used as insecticides or acaricides.[33] The results of bioassay showed that when R^1, R^2, and R^5 were halogen atoms and R^3 and R^4 were methyl groups, compounds exhibited the best insecticidal activity, but CF_3, CN, and NO_2 groups were adverse to the insecticidal activity. For example, both compounds **60** and **61** (Figure 11) displayed 90−100% larvicidal and ovicidal activities against *S. littoralis* at 10 mg L^{-1},

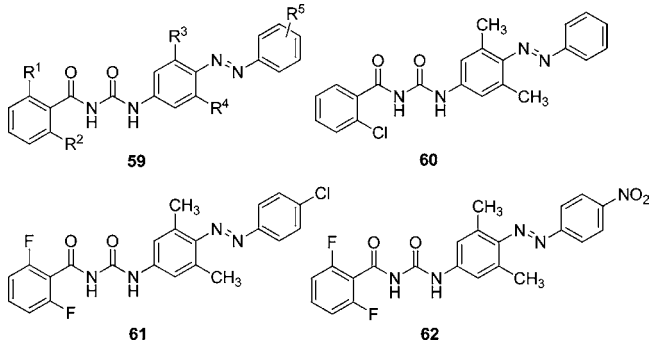

Figure 11. Chemical structures of phenyldiazenyl-substituted benzoylphenylureas.

whereas compound **62** had less than 24% larvicidal and 74% ovicidal activities in the same conditions.[33]

The insecticidal activities of alkoxyl(multihaloalkoxyl)phenyl benzoylureas (compound **63**, Figure 12) were studied mainly at Bayer AG Co., Ciba-Geigy Co. (now Novartis), and Dow Chemical Co.[34] These benzoylphenylureas (such as first commercial product, triflumuron (**6**, Figure 1) display both larvicidal and ovicidal activities and have a broader spectrum of effectiveness than the first generation of benzoylphenylureas. The SARs showed that multihaloalkoxy-substituted BPUs were much more effective than alkoxy-substituted BPUs and that 3,5-diCl substitutions at aniline moiety (compound **63**) were important to the insecticidal effects. For example, compounds **64** and **65** (Figure 12) and triflumuron (**6**) had 100% insecticidal activity against *Phaedon cochleariae* (at 10 mg L^{-1}) and *Laphygma exigua* (at 0.1 mg L^{-1}), but diflubenzuron (**1**) and DU19111 had no inhibition in the same conditions.[34a]

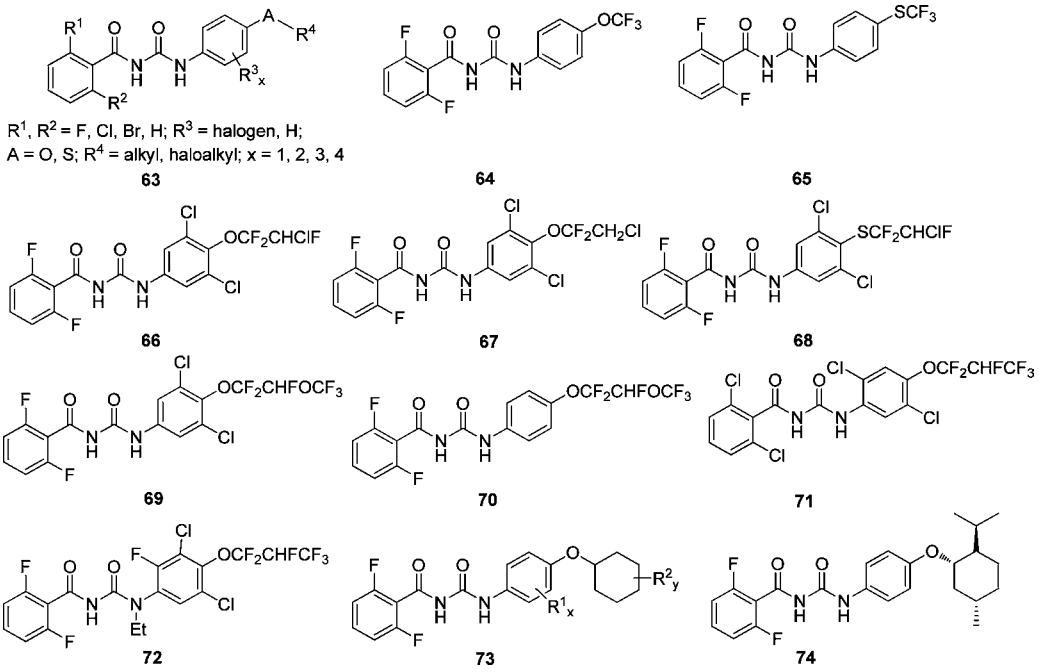

Figure 12. Chemical structures of alkoxy(mutihaloalkoxy)-substituted benzoylphenylureas.

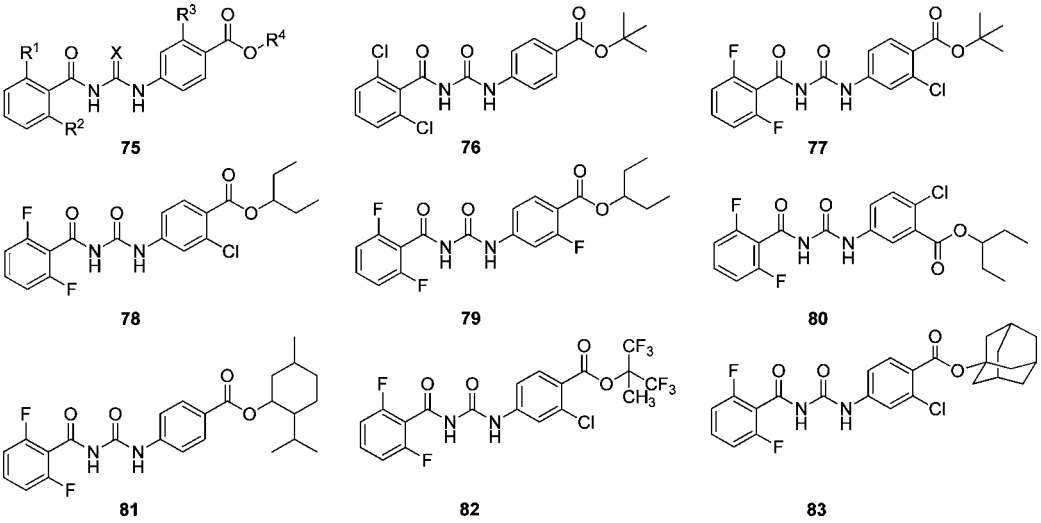

Figure 13. Chemical structures of alkoxycarbonyl-substituted benzoylphenylureas.

Compound **66** (Figure 12, LD_{90} = 1.2 mg L^{-1}, 1.2 mg L^{-1}) and hexaflumuron (**7**, LD_{90} = 1.6 mg L^{-1}, 1.6 mg L^{-1}) exhibited similar larvicidal activity against *Spodoptera exigua* and *Heliothis virescens*, whereas the inhibitory effects of compounds **67** (Figure 12, LD_{90} = 100 mg L^{-1}, 100 mg L^{-1}) and **68** (Figure 12, LD_{90} = 200 mg L^{-1}, >400 mg L^{-1}) possessing a slight structural difference from compound **66** reduced significantly.[34c] Compounds **69**, and **70** (Figure 12) and novaluron (**8**) had 96, 40, and 0% larvicidal activity against *S. littoralis*, respectively, at 0.05 mg L^{-1}; at the same time, they displayed 100, 0, and 0% larvicidal activity against *A. aegypti* at 0.002 mg L^{-1} and 100, 95, and 17% larvicidal activity against *Leptinotarsa decemelineata* at 5 mg L^{-1}, respectively.[34d] Lufenuron (**9**) effected 80−100% mortality against *S. exigua* larvae and *H. virescens* larvae at 0.75 mg L^{-1}, and compound **71** (Figure 12) effected 80−100% mortality against *S. exigua* larvae at 12.5 mg L^{-1} and against *H. virescens* larvae at 100 mg L^{-1}.[34e] Recently, lufenuron (**9**) has been put forward as an effective treatment for dermatophytosis in dogs and cats.[34f] A study indicated good efficacy at a single oral dose of 54−68.3 mg/kg orally in dogs and 51.2−266 mg/kg in cats.[34g] Under continuous exposure, noviflumuron (**11**, LC_{50} < 2.2 mg L^{-1} at 21 days and LC_{50} < 0.78 mg L^{-1} at 42 days) and compound **72** (Figure 12, LC_{50} = 0.35 mg L^{-1} at 21 days and LC_{50} = 0.26 mg L^{-1} at 42 days) were far more active than hexaflumuron (**7**, LC_{50} > 200 mg L^{-1} at 21 and 42 days) against German cockroach (*Blattella germanica*) second instars. Under limited exposure (48 h), noviflumuron (**11**, LC_{50} < 22.2 mg L^{-1} at 21 days and LC_{50} < 9.1 mg L^{-1} at 42 days) and compound **72** (Figure 12, LC_{50} = 21.1 mg L^{-1} at 21 days and LC_{50} = 12.8 mg L^{-1} at 42 days) were more potent than hexaflumuron (**7**, LC_{50} > 10000 mg L^{-1} at 21 and 42 days).[21] Generally, electron-donating groups at the aniline moiety (Figure 3, ring B) are unfavorable to the insecticidal activity; however, compound **73** (Figure 12)

DOI: 10.1021/acs.jafc.5b02460
J. Agric. Food Chem. 2015, 63, 6847−6865

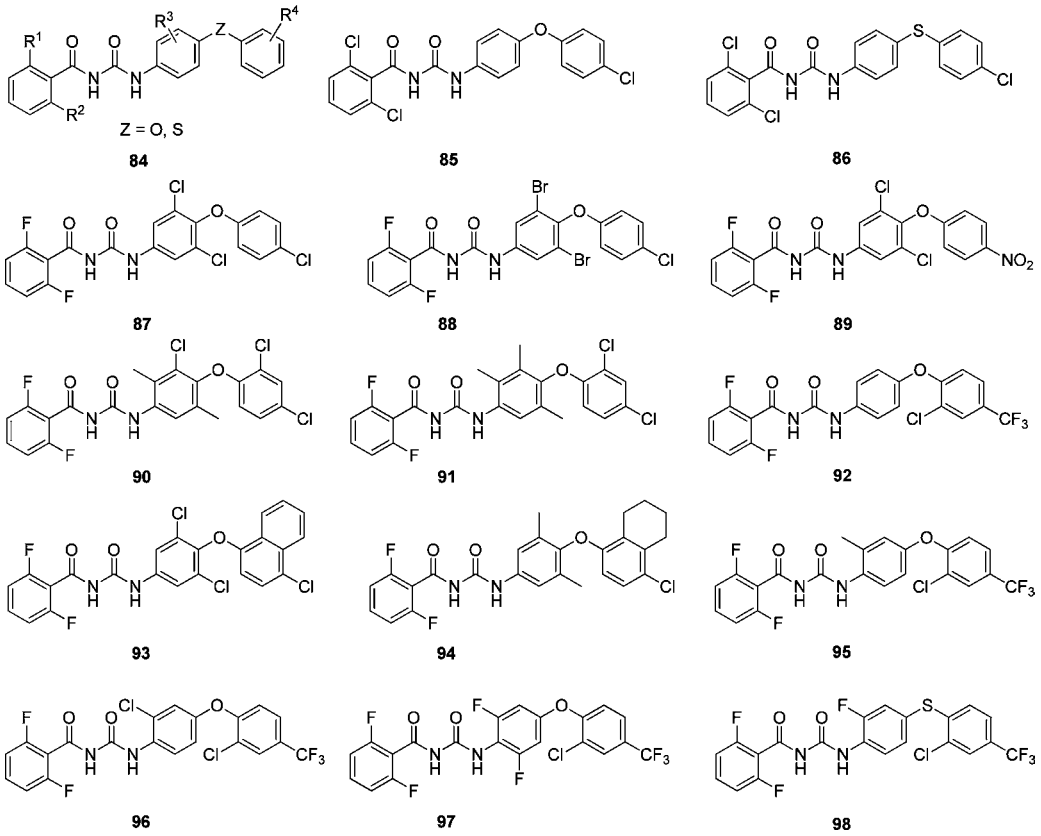

Figure 14. Chemical structures of phenoxyphenylbenzoylureas.

showed a broad spectrum of insecticidal activity. For instance, compound **74** (Figure 12) displayed 90−100% larvicdal activity against *P. brassicae* (at 0.1 mg L^{-1}), *A. aegypti* (at 0.003 mg L^{-1}), *S. littoralis* (at 3 mg L^{-1}), and *Leptinotarsa decemlineata* (at 10 mg L^{-1}).[34i]

The insecticidal activities of alkoxycarbonyl-substituted benzoylphenylureas (Figure 13, compound **75**) were reported at Bayer AG Co. for the first time,[35a] and the following research were conducted at BASF[35b,c] and Duphar International Research B.V. Co.[35d] These compounds could be used as pesticides to control Lepidoptera, Hemiptera, and Coleoptera pests. A survey of the patent literature[35] suggested that 3-Cl or 3-F substitution (compound **75**, R^3 = Cl, F) and certain bulky 4-alkoxycarbonyl (especially fluoroalkoxycarbonyl) groups (compound **75**, R^4) were favorable for the larvicidal activity. For example, compounds **76** and **77** had more effective larvicidal activity against *Plutella maculipennis* than DU19111 (Figure 13).[35a] Compound **78** showed better action against *Dysdercus intermedius* than compounds **77**, **79**, and **80** (Figure 13) at 10% active ingredient.[35b] The insecticidal activity improved greatly when a fluoroalkoxycarbonyl group was introduced, for example, compound **82** (Figure 13) had 100% mortality against *A. aegypti* at 0.004 mg L^{-1}, which exhibited the same level insecticidal activity as diflubenzuron (**1**) and much better activity than compound **77**.[35c] Compound **81** (Figure 13) reported by BASF exhibited 90−100% larvicdal activity against *P. brassicae* (at 0.3 mg L^{-1}), *S. littoralis* (at 1 mg L^{-1}), and *L. decemlineata* (at 3 mg L^{-1}),[35d] but compound **83** had poor insecticidal effects, probably because the group it contained was too bulky.[35b]

The phenoxyphenyl and phenthiophenylbenzoylureas (compound **84**, Figure 14) were first reported by Wellinga et al. at Phlip-Duphar B.V. Co., and only seven compounds were disclosed in the paper.[17a] These compounds had poor larvicidal activity in the bioassay except compound **86** (Figure 14), which exhibited 90−100% larvicidal activity against *A. aegypti*, *S. littoralis*, and *L. decemlineata* at 0.003, 10, and 100 mg L^{-1}, respectively, whereas compound **85** (Figure 14) had no insecticidal effects in the same conditions.[17a] Bayer AG, Ishihara Sangyo Kaisha, Ltd., BASF AG, Union Carbide Corp., Sumitomo Chemical Co., Ltd., and Shell International Research M.B.V. published 56 patents in the following years.[36] On the basis of an analysis of the published patents, it was established that 2,6-F or Cl substituents at the benzoyl moiety (Figure 14, compound **84**, R^1, R^2 = F, Cl), 3,5-Cl or CH_3 substituents at the aniline moiety (R^3 = 3,5-diCl, 3,5-diCH_3, 3-Cl-5-CH_3), and 4-Cl, CF_3, or NO_2 substituents at the phenoxy moiety (R^4 = 4-Cl, CF_3, NO_2) were required for optimal insecticidal activity. For example, compound **87** (Figure 14, LC_{50} = 0.0046 mg L^{-1}) exhibited excellent larvicidal activity against *S. littoralis*, which was much better than those of compound **86**, diflubenzuron (**1**, LC_{50} = 0.018 mg L^{-1}), and compound **88** (Figure 14, LC_{50} = 0.015 mg L^{-1}).[36a] Compound **90** had 100% larvicidal activity against *Spodoptera eridania* at 0.125 mg L^{-1} and atainst *Ephilachna varivestis* at 0.25 mg L^{-1}; on the other hand, compound **89** (Figure 14) exhibited only 10% larvicidal activity against *S. eridania* at 0.125 m $\cdot L^{-1}$ and 30% larvicdal activity against *E. varivestis* at 0.5 mg L^{-1}, whereas compound **92** had no larvicidal effect at the same concentration.[36b] Compound **91** (Figure 14) had 100% mortality against *S. eridania* at 0.4 mg L^{-1} and *E. varivestis* at 1.6 mg L^{-1}.[36b] Compounds **93** and **94** (Figure 14) had 100% mortality against *E. varivestis* at 8 mg L^{-1}, but diflubenzuron (**1**) had 60% mortality using the same bioassay process.[36c] The

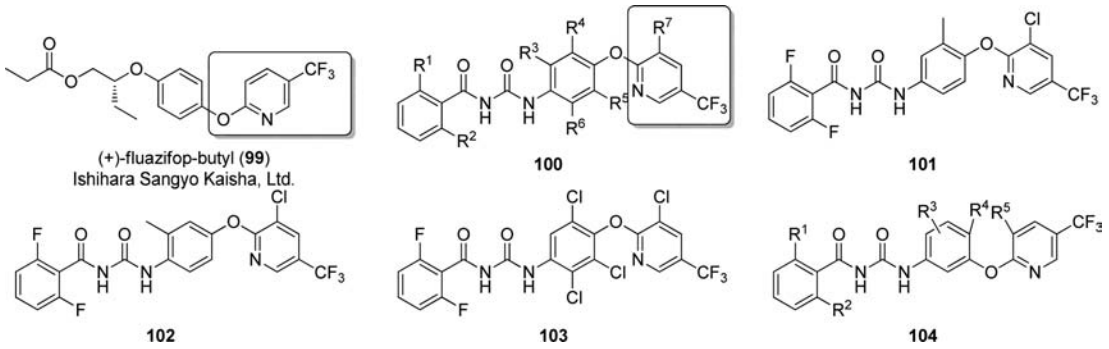

Figure 15. Chemical structures of pyridyloxyphenylbenzoylureas.

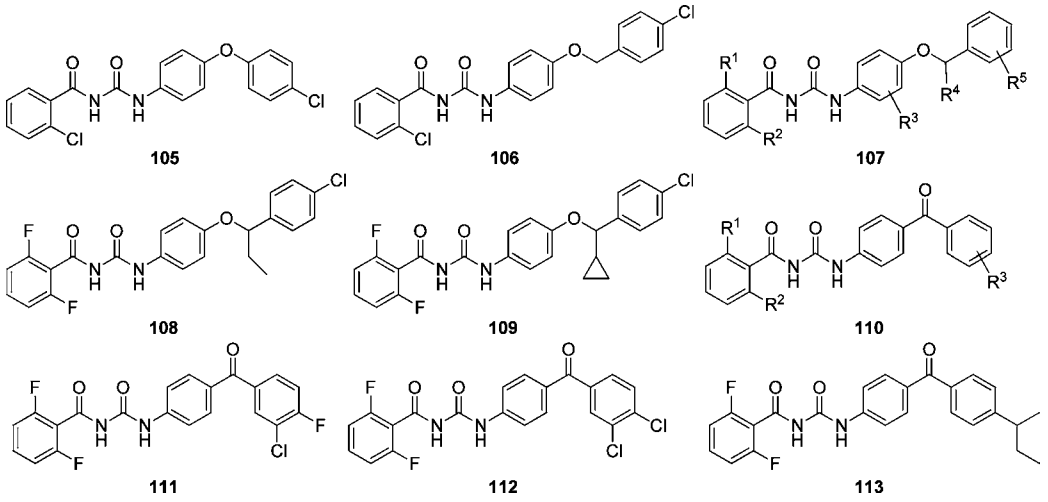

Figure 16. Chemical structures of benzyloxyphenyl and benzoylphenylbenzoylureas.

LC_{50} values of compounds **95**, **96**, and **97** (Figure 14) and flufenoxuron (**12**) against *Tetranicus urticae* were 32, 6.9, 1.5, and 1.3 mg L^{-1}, respectively.[36d] The adult emergence inhibitory ratio, sterilization ratio, and ovicidal ratio of compound **98** (Figure 14) against *T. cinnabarinus* were 100, 95, and 100%, respectively, at 100 mg L^{-1}, and those of flufenoxuron (**12**) were 60, 0, and 10%.[36e]

In the research of phenoxyphenylbenzoylureas (Figure 14, compound **84**) and SAR of fluazifop-butyl (Figure 15, **99**) at Ishihara Sangyo Kaisha, Ltd., a 5-trifluoromethyl-2-pyridinyloxy group was introduced into the structure of benzoylphenylureas and a series of novel pyridyloxyphenyl-benzoylureas (Figure 15, compound **100**) were designed and synthesized.[37] The results of bioassay showed that these compounds exhibited far surpassing insecticidal activity against specific target insects such as Lepidoptera, Diptera, and Orthoptera at their larval stages.[37a] From the literature, it was established that 2,6-F substituents at the benzoyl moiety (Figure 15, compound **100**, R^1, R^2 = F), 3,5-Cl, 2,6-H substituents at aniline moiety (R^3, R^6 = H, R^4 = Cl, CH_3, R^5= Cl, H) and 3-Cl or Br substituents at the phenoxy moiety (R^7 = Cl, Br) were required for optimal insecticidal activity. For example, compound **101** (Figure 15) had 100% larvicidal activity against *P. xylostella* (at 50 mg L^{-1}) and *Culex pipens molestus* (at 50 mg L^{-1}), but compound **102** (Figure 15) had no insecticidal activity in the same condition. Chlorfluazuron (**14**) has much more larvicidal activity against specific target insects such as Lepidoptera than the lead diflubenzuron (**1**). The LC_{50} values of chlorfluazuron (**14**) against *P. xylostella*, *S. littoralis*, and *S. exigua* were 0.021, 0.028, and 0.043 mg L^{-1}, respectively;[37a] however, compound **103** (Figure 15) exhibited no larvicidal activity against *P. xylostella* at 50 mg L^{-1}.[37b] The movement of the 3-chloro-5-trifluoromethyl-2-pyridinyloxy group in chlorfluazuron (**14**) from the *para*-position to the *meta*-position resulted in a series of novel benzoylphenylureas (Figure 15, compound **104**) at Ciba-Geigy Corp. (now Novartis).[38] These compounds displayed worse insecticidal activity against Lepidoptera and Diptera larvae than chlorfluazuron (**14**), however, the anthelmintic activity had an unexpected significant improvement. For example, the anthelmintic activity of fluazuron (**15**) was much more effective against *Hemonchus contortus* than chlorfluazuron (**14**) at 10 mg kg^{-1} day^{-1}.[38c]

As we have known that phenoxyphenylbenzoylureas (Figure 14, compound **84**) had excellent larvicidal activity against *S. littoralis*, for example, compound **105** (Figure 16) had 90−100% mortality against *P. brassicae* at 10 mg L^{-1}, it was surprisingly found that the corresponding benzyloxy compound **106** (Figure 16) had the same insecticidal effect against the larvae of *P. brassicae* at 0.3 mg L^{-1} at Duphar International Research B.V. Co.[39a] Then a series of novel benzyloxyphenylbenzoylureas (Figure 16, compound **107**) were obtained, and they found compound **108** (Figure 16) had 90−100% mortality against *P. brassicae* at 0.03 mg L^{-1} and compound **109** (Figure 16) had 90−100% insecticidal activities against *Panonychus ulmi*, *T. cinnabarinus*, *T. urticae*, and *Trialeurodes vaporariorum* at 10 mg L^{-1}.[39b] Carmellino et al. synthesized a series of benzoylphenylbenzoylureas that had a highly effective activity against *A. aegypti* larvae (Figure 16, compound **110**).[39c]

DOI: 10.1021/acs.jafc.5b02460
J. Agric. Food Chem. 2015, 63, 6847−6865

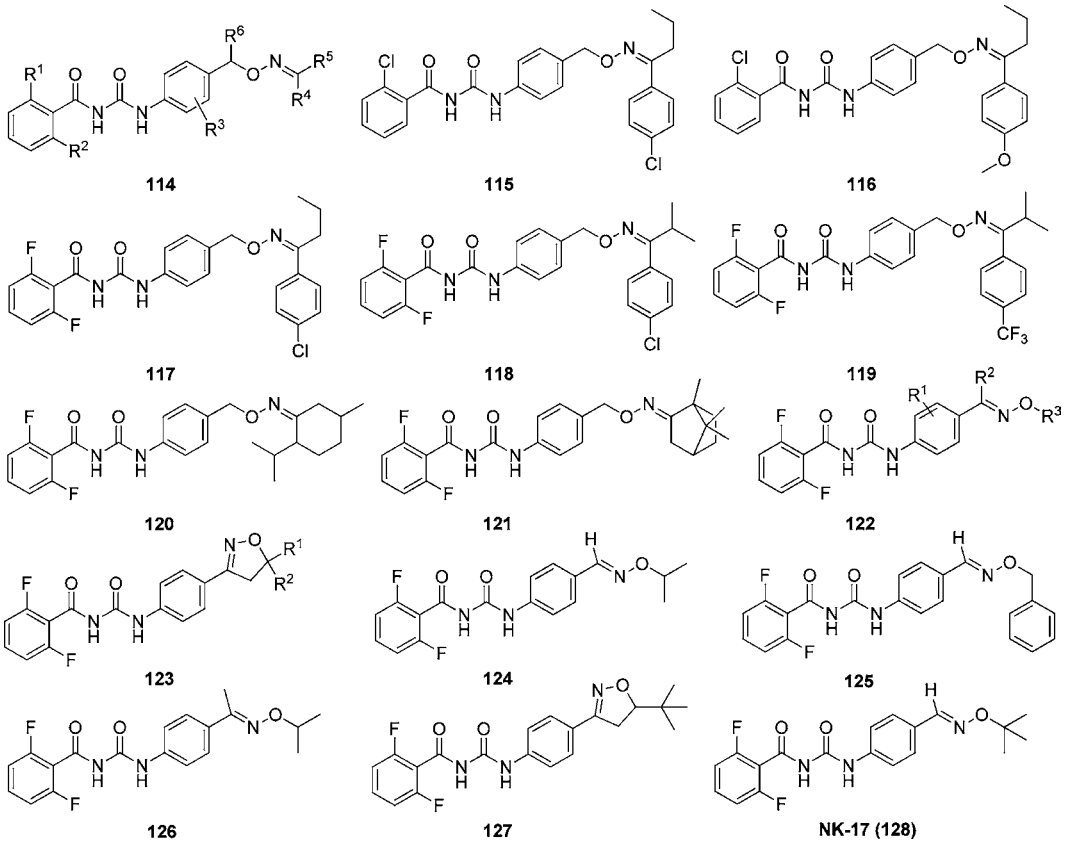

Figure 17. Chemical structures of benzoylphenylureas containing an oxime ether group.

With regard to the substituents on the benzophenone unit, generally the activity of halo derivatives was much higher than that of alkyl derivatives. In particular, with the dihalo-substituted compounds, especially a fluorine atom such as compound **111**(Figure 16), 100% mortality of *A. aegypti* larvae was achieved at very low doses (2×10^{-6} mg L^{-1}), whereas compound **112** (Figure 16) had a lower insecticidal activity (12% mortality achieved at 2×10^{-5} mg L^{-1}). Alkyl derivatives had much lower insecticidal activity, such as compound **113** (Figure 16), which exhibited 69% mortality at 2×10^{-3} mg L^{-1}.[39c]

During the research of benzyloxyphenylbenzoylureas (Figure 16, compound **107**), it was found that some of these compounds had good acaricidal activity such as compound **109**.[39b] Therefore, a series of novel benzoylphenylureas containing an oxime ether group (Figure 17, compound **114**) were first developed by Philip-Duphar B.V. Co., and flucycloxuron (**13**) was introduced to the market in 1988.[40a−c] On the basis of the SAR analysis from the literature, when R^1 and R^2 were F or Cl and R^3 and R^6 were H, compound **114** had the optimal activity. When R^4 was an alkyl group and R^5 was a substituted phenyl group, a 4-chlorophenyl group was the optimal group for insecticidal activity, and electron-withdrawing or electron-donating group are adverse to the activity. For example, compound **115** had 90−100% mortality against *P. brassicae* at 0.3 mg L^{-1}, and compound **116** exhibited the same insecticidal effects at 1 mg L^{-1} (Figure 17). Furthermore, compounds **117** and **118** had 90−100% mortality against *P. brassicae* at 0.1 mg L^{-1}, whereas compound **119** had no inhibitory activity at 0.1 mg L^{-1} (Figure 17).[40b] Compound **120** had 90−100% mortality against *T. urticae* at 0.1 mg $L^{-1}$and *L. decemlineata* at 5 mg L^{-1}, but compound **121** showed no insecticidal effect in the test (Figure 17).[40c] Inspired by the literature of alkoxycarbonyl substituted benzoylphenylureas (compound **75**, Figure 13), which exhibited high larvicidal activity against Lepidoptera and Hemiptera pests, a series of novel benzoylphenylureas containing an oxime ether group (compound **122**) and isoxazoline group (compound **123**) were designed and synthesized in our laboratories (Figure 17).[40d−f] The results of bioassay indicated that most compounds had excellent larvicidal activity against *M. separata* and that some compounds exhibited higher larvicidal activity than flucycloxuron (**13**).[40d] In general, R^2 is hydrogen, R^1 is fluorine, chlorine, or hydrogen, and R^3 is bulky alkyl groups, which are favorable for insecticidal effects. For example, compound **124** had 100% mortality against *M. separata* at 1.0 mg L^{-1}; on the other hand, compound **125** had 40% mortality at 200.0 mg L^{-1} and compound **126** had only 10% mortality at 1.0 mg L^{-1} (Figure 17).[40d,e] Compound **127** had 100% mortality against *Mythimna separata* and *P. xylostella* at 10 and *X* mg L^{-1}, respectively[1] (Figure 17).[40f] NK-17 (compound **128**) was chosen as an insecticide candidate through conventional screening. The toxicity against *M. separata* of compound NK-17 (LC_{50} = 0.017 mg L^{-1}) is about 18 times as active as hexaflumuron (LC_{50} = 0.31 mg L^{-1}). The field trial showed that the effects of 5% NK-17 EC (60 g ai ha^{-1}) on controlling *P. xylostella* and *S. exigua* were 88 and 89%, respectively, after 7 days of spraying, which were better than that of chlorfluazuron (**14**) and as active as hexaflumuron (**7**).[40g] In addition, NK-17 has the following features: novel skeleton structure, high insecticidal activity, simple synthesis (only four steps, each step accomplished under mild conditions, 82% overall yield), fewer fluorine atoms, and far better solubility than most commercial benzoylurea pesticides (20 °C in acetone, 168 g L^{-1}), which is

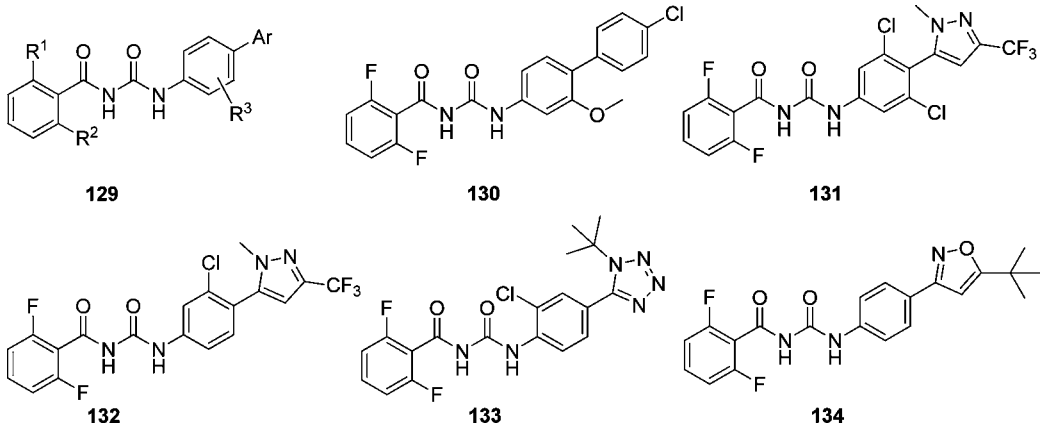

Figure 18. Chemical structures of arylphenylbenzoylphenylureas.

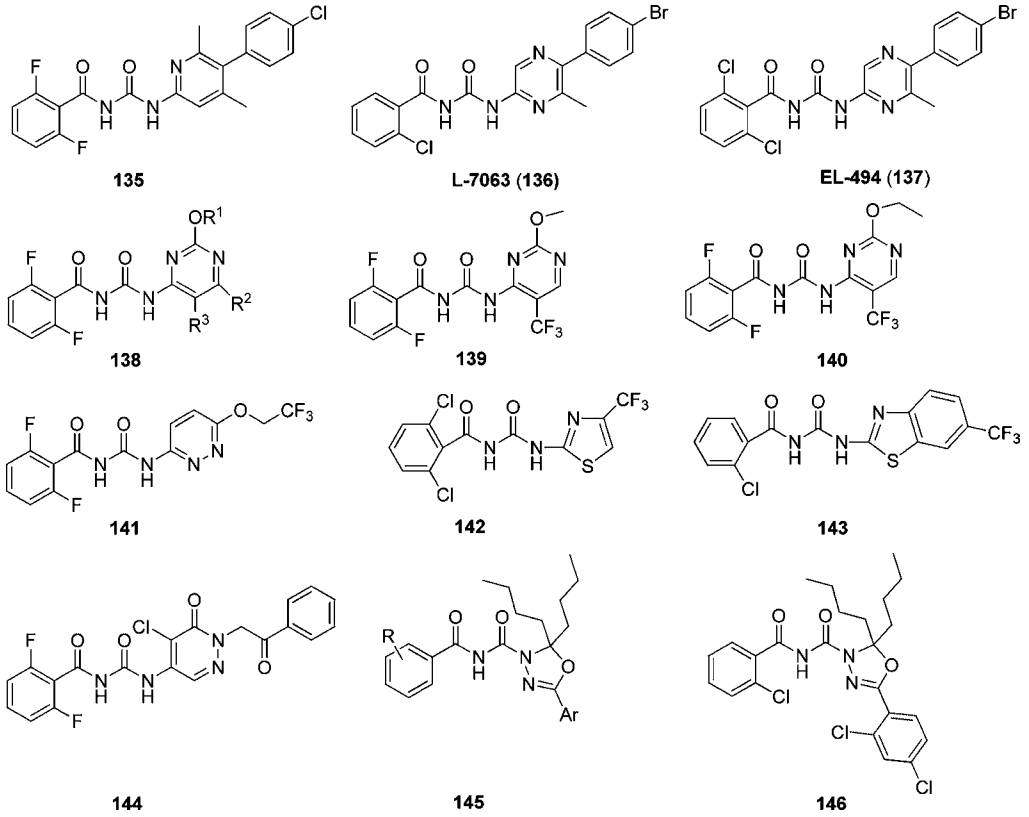

Figure 19. Chemical structures of aromatic heterocyclic benzoylureas.

more favorable for formulation process and application. NK-17 is being developed by Jiangsu Lanfeng Biochemical Co., Ltd., China.[40h]

The insecticidal activities of arylphenylbenzoylureas (Figure 18, compound **129**) were studied by some companies.[41] For example, diphenyl-benzoylurea derivative **130** exhibited 100% mortality against *S. eridania* and *Trichoplusiani* larvae at 2.0 mg L^{-1}.[41a] Pyrazolphenyl-benzoylurea derivative **131** (Figure 18) reported by Korea Research of Chemical Technology displayed better insecticidal effects against *P. xylostella* (LC_{50} = 0.15 mg L^{-1}) than diflubenzuron (**1**), and compound **132** (Figure 18) had better insecticidal activity against *S. litura* (LC_{50} = 0.04 mg L^{-1}) larvae than diflubenzuron (**1**) as well.[41b,c] Tetrazoylphenylbenzoylureas were prepared and used as pesticides at Bayer Cropscience. For instance, compound **33** (Figure 18) exhibited 100% insecticidal activity against *Heliothis virescens*, *P. cochleariae* larvae, *P. xylostella* larvae, *Spodoptera frugiperda* larvae, and *Diabrotica balteata* larvae at 1000 mg L^{-1}.[41d] Compound **134** (Figure 18), which had 60% mortality against *P. xylostella* at 0.2 mg L^{-1}, has been synthesized in our laboratories, and when the 5-*tert*-butyl group of the isoxazole moiety was changed to other alkyl groups, the insecticidal reduced significantly.[40f]

The phenyl ring of the aniline moiety (Figure 4, ring **B**) has been replaced by aromatic heterocycles, such as pyridine,[42a−e] pyrimidine,[42f−k] diazine,[42k,l] thiazole,[42m] and benzothiazole.[42n] The results of bioassay showed that most of these compounds had the same or worse activity in comparison with the corresponding benzoylphenylureas. The pyridinyl and pyrimidinylbenzoylurea derivatives were mainly studied at Eli Lilly and Co.; for example, compound **135** exhibited 100% mortality against *S. eridania* larvae at 0.125 mg L^{-1} (Figure 19). (**136**) and EL-494 (**137**) both showed a high degree of biological activity against mosquito larvae, the LC_{50} values of L-7063 and EL-494 against *Lymantria dispar* third-larvae were 0.176 and 0.76 mg L^{-1}, respectively (Figure 19).[42p,q] Compound **138** was reported by Yang et al. and compounds **139** and **140** showed 100% larvicidal activity against *Mythimna sepatara* at 100 mg L^{-1}(Figure 19).[42j] Compound **141** was synthesized in our laboratory, and it had 80% mortality against *M. separata* at 10.0 mg L^{-1} (Figure 19).[42k] Compound **142** had 100% mortality against *S. eridania* larvae at 8.0 mg L^{-1},[42m] and compound **143** had 100% mortality against *S. litura* larvae at 2.0 mg L^{-1} (Figure 19).[42n] Yang et al. reported a series of 5-benzoylphenylurea-3(2*H*)-pyridazinones that had good activity against the third-instar nymphs of locusts (*Locusta migratoria manilensis*) at 200.0 mg L^{-1}; for example, compound **144** displayed 65.5% mortality at 200.0 mg L^{-1} (Figure 19).[42l] Qian et al. reported two series of 1,3,4-oxadiazoline heterocycle derivatives **145**, and bioactivity assays showed that all synthesized compounds inhibited chitin synthesis in yeast, suggesting they might be a novel class of potential inhibitors against chitin biosynthesis; for example, compound **146** exhibited the highest inhibitory activity (about 86%) on chitin biosynthesis at 250 μM (Figure 19).

■ ACTION MECHANISM

Research on the mechanism of benzoylurea insecticides has been a focus of concern to scientists since the appearance of the first benzoylureainsecticide diflubenzuron (**1**) in 1975.[43−53]

Matsumura gave a review of studies on the action mechanism of diflubenzuron in 2010.[54] From the review, we know that it has been identified that diflubenzuron indeed inhibits the process of incorporation of *N*-acetylglucosamine into insect chitin in vivo, but there are no direct biochemical effects on enzymes, receptors, or intracellular organelles under a cell-free system. In addition, benzoylphenylureas show no inhibitory actions on fungal systems in vivo as well as in cell-free systems, which have roughly equivalent chitin synthesis pathways as insects. As diflubenzuron does not compromise chitin synthesis when vesicles are mechanically destroyed, a direct effect of diflubenzuron on chitin synthases can be excluded. There was a breakthrough in the action site of BPUs when a sulfonylurea receptor (SUR) was identified in *D. melanogaster* by Matsumura's research group, and it was established that insect SUR in the above intracellular vesicles preparation from *P. americana* as well as *B. germanica* was likely the actual target site of diflubenzuron to cause inhibition of chitin synthesis. The role of SUR in this case was determined, by using glibenclamide, a typical SUR specific inhibitor as an aid, to be helping the exocytotic movement of these vesicles as was the case of other members of the group of ABC-transporters to which insect SUR belongs. In this case both diflubenzuron and glibenclamide have been shown to cause the depolarization of the vesicle membrane through inhibition of the K^+ channel, which leads to their inhibition of chitin synthesis. The assays of competitive binding of [^{3}H]-glibenclamide in *B. germanica* cuticular vesicles indicated that all unlabeled compounds were capable of completely displacing the radioligand, but among them glibenclamide appeared to be most potent, followed by diflubenzuron and then dechloro-diflubenzuron, a much less active analogue of diflubenzuron.[52d] NK-17 (compound **128**, Figure 17) was chosen as a novel and potent insecticide for further development. It is very important that the evaluation of insecticidal activity is a critical step to a new insecticide candidate with independent intellectual property right before it is introduced to the market. Matsumura et al. have established a method of studying the action mechanism of diflubenzuron on SUR proteins by utilizing isotope labeling technology.[52d] Due to the restriction on the level of laboratory condition and for the safety of the researchers, the isotope labeling technology cannot be quickly and easily used in a regular laboratory. Hence, the fluorescence polarization method was explored for the first time in our laboratories to be used in studying the insecticidal mechanism of NK-17.[40g] The results showed that NK-17 could bind to the SUR of *B. germanica* with stronger affinity compared to diflubenzuron and glibenclamide, which suggested that NK-17 may also act on the site of the SUR to inhibit the chitin synthesis in insect body, and the result can well explain that NK-17 exhibited stronger toxicity against *B. germanica* than diflubenzuron and glibenclamide in vivo. Although the above results indeed support the hypothesis that SUR protein is the major target of DFB in causing disruption of chitin synthesis in *D. melanogaster* and *B. germanica*, there are many questions to answer, and the most important one is the functional relationship between SUR and chitin synthesis. Recently, Moussian et al. found that cuticle architecture is normal and chitin amounts are not diminished in the cuticle of *D. melanogaster* larvae, which had been made of the phenotype suffering complete elimination of the SUR function.[53] The results indicated that SUR was dispensable for chitin synthesis. They concluded that there must be another sulfonylurea-sensitive ABC-transporter that either instead of SUR was the true sulfonylurea-sensitive transporter involved in chitin synthesis or was able to substitute SUR function during cuticle formation. In fact, Nasonkin et al. who studied the

DOI: 10.1021/acs.jafc.5b02460
J. Agric. Food Chem. 2015, 63, 6847–6865

expression of D_{SUR} in *Drosophila* egg development up to stage 16, showed the expression of D_{SUR} only in the tracheal system, salivary gland, and dorsal vessels in the early stages of development, not in the cuticle of developing embryos of *D. melanogaster*.[55] Therefore, the exact action site of benzoylurea insecticides has not been identified, and more efforts are needed for further research.

■ ENVIRONMENTAL FATE AND ECOTOXICOLOGY

The pesticide physicochemical and ecotoxicological data of commercial benzoylphenylureas are obtained from the Pesticide Properties Database (PPDB), U.S. Environmental Protection Agency (EPA), TOXNET Databases, Google Web Search, and Web of Science.

Benzoylurea insecticides possess favorable environmental properties and low acute toxicology to mammals and birds as well as crop pollinators such as bees (Tables 1 and 2). These specific features usually provide a large margin of safety with regard to ecological and toxicological effects. There are several processes steering pesticides in the environment, such as adsorption, transfer, breakdown, and degradation. Transfer is a process in which pesticides move away from the target site, such as "volatilization, spray drift, runoff, leaching, absorption and crop removal" (Ministry of Agriculture and Land, British Columbia http://www.agf.gov.bc.ca/pesticides/c_2.htm). Decomposition is the breakdown of the pesticide molecules. Such a process leads to their total or partial degradation. Complete degradation of complex molecules is known as mineralization, which generates molecules of water, CO_2 and other small molecules depending on the pesticide chemical composition. Breakdown processes are the routes of degradation undergone by pesticides. Such degradation can be due to microbes, chemical reactions (hydrolysis, oxidation, and others), and photodegradation. As such processes depend on the chemical properties of the pesticides, such as susceptibility to oxidation, reduction, hydrolysis, photolysis, and substitution, these processes may have different timings, from hours or days to years. Besides, physical properties also influence pesticide breakdown, such as solubility in water, dissociation constant, partition coefficient, and sorption to soil. Different degradation rates occur in a diverse range of environmental conditions, as it also depends on climatic conditions, clay/silt/sand ratio in soil and sediments, water content, organic matter, pH, microbial biomass, and temperature. Metabolism in aerobic soils and water represents a significant dissipation mechanism for pesticides in the environment. Most BPUs suffer a rapid degradation in both soil and water by photolysis and hydrolysis (Table 1). The half-life of benzoylureas in the environment varies by type of medium such as soil, water, or sunlight.[56] The half-life of diflubenzuron ranges from hours to months, that of novaluron in tropical soils ranges from 11 to 59 days,[56j] and noviflumuron and chlorfluazuron do not readily break down in the environment.[57] The metabolites of BPUs may have adverse effects to humans. For example, diflubenzuron is quickly degraded in the environment mainly by hydrolysis and photodegradation, producing as major metabolites 2,6-difluorobenzamide, 4-chlorophenylurea, 4-chloroacetanilide, 4-chloroaniline, and *N*-methyl-4-chloroaniline, the latter three being classified as mutagens.[58]

Bioconcentration is the accumulation of a chemical in or on an organism when the source of the chemical is solely water.[59] Bioconcentration is a term that was created for use in the field of aquatic toxicology.[59] Bioconcentration can also be defined as the process by which a chemical concentration in an aquatic organism exceeds that in water as a result of exposure to a waterborne chemical. Bioconcentration factor (BCF) can be expressed as the ratio of the concentration of a chemical in an organism to the concentration of the chemical in the surrounding environment. The BCF is a measure of the extent of chemical sharing between an organism and the surrounding environment.[59] All of the commercial BPUs have a threshold of concern for bioconcentration potential (BCF > 100), and lufenuron (BCF = 5300) and flufenoxuron (BCF = 33856) have high bioconcentration potentials (Table 2). Flufenoxuron was banned in the European Union in 2011 due to its high potential for bioaccumulation in the food chain and high risk to aquatic organisms.[60] Flufenoxuron is marketed as having "high persistence" in the environment, and the product data-sheet states that it does not biodegrade easily.[61]

Most BPUs have low to moderate toxicity to fish; however, BPUs exhibit high toxicity to aquatic invertebrates and crustaceans because these chitin synthesis inhibitors may adversely affect nontarget organisms including beneficial insect species and crustaceans with chitin as a component of the exoskeleton (Table 2).[62−68] For example, flufenoxuron, hexaflumuron, teflubenzuron, and chlorfluazuron have very high toxicity against *Daphnia magna*, and their EC_{50} values are 0.000043, 0.0001, 0.0028, and 0.000908 mg L^{-1}, respectively (Table 2). Some studies show that several BPUs may affect nontarget arthropods, such as teflubenzuron, hexaflumuron, and flufenoxuron, at concentrations that are probably environmentally relevant. Hexaflumuron application had significant effects on *C. septempunctata* end points in the 33-day test, including effects on development duration (no observed effect application rate, NOER, 1.52 g ai ha^{-1}), hatching (NOER 3.04 g ai ha^{-1}), pupation (NOER 3.04 g ai ha^{-1}), and survival (NOER 1.52 g ai ha^{-1}). These NOERs are lower than the reported maximum field application rate of hexaflumuron (135 g ai ha^{-1}) in cotton cultivation, suggesting potential risks to beneficial arthropods.[69]

■ FUTURE PROSPECTS OF BENZYLPHENYLUREAS

Benzoylphenylurea chitin synthesis inhibitors possess the valuable property of having a non-neurotoxic mode of action at a target site that is absent in vertebrates, which means in turn that they are generally safe to mammals. The availability of a target site that is distinct from that of the more commonly employed neurotoxic insecticides also allows these molecules to be used as important tools in insecticide resistance management (IRM) programs.[70] In addition, the low contact activity of benzophenylureas reduces their impact on predatory insects, which in turn promotes their use in IRM programs. Resistance to the benzoylphenylureas has been measured both in the field and in the laboratory, but is usually correlated with insects acquiring an increased capacity to metabolize and eliminate the compound,[71,72] as opposed to the generation of target-site resistance. Typically, the onset of action of the benzoylphenylureas is slow, with several days being required before any reduction is observed in larval numbers, although cessation of larval feeding often occurs much earlier. This slow activity has resulted in a need to educate farmers and growers, who are accustomed to the rapid knockdown activity of neurotoxic pesticides, regarding the correct application timing of these compounds and the time required to observe their full activity. The lack of or limited contact activity of the benzoylphenylur-

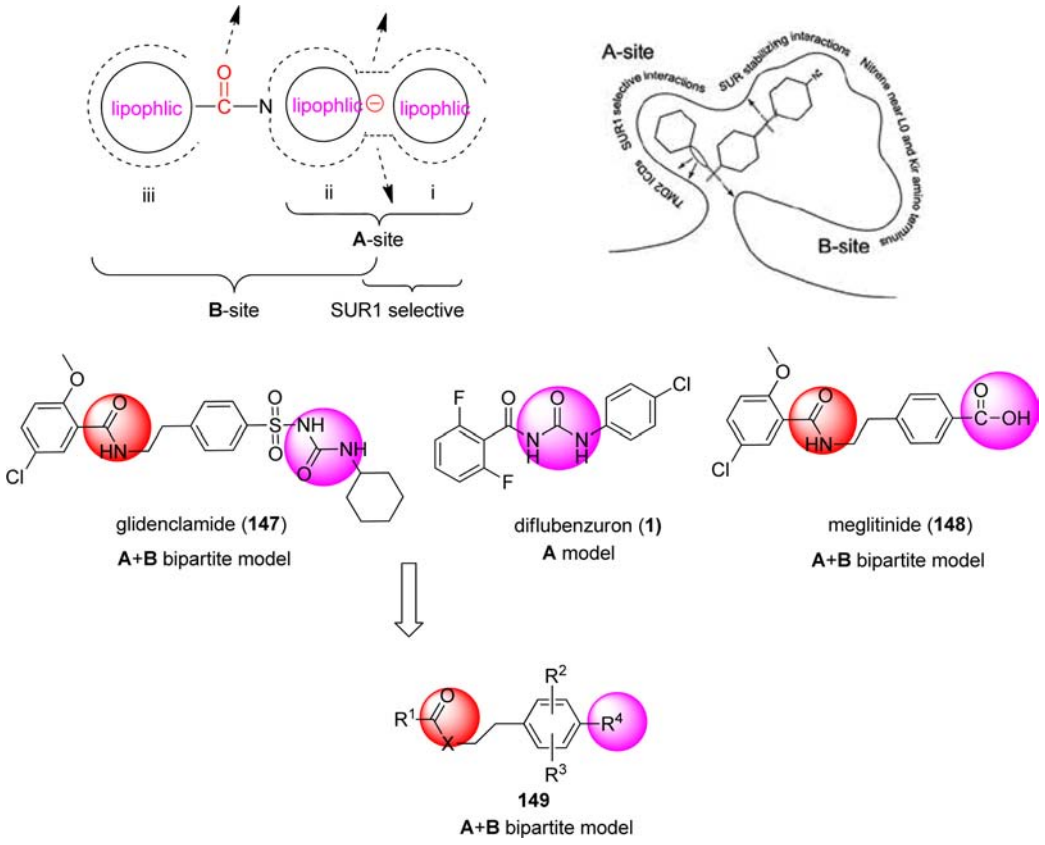

Figure 20. Sulfonylurea bipartite model and design strategy of bipartite BPU analogues.

eas has also limited their use against insects that are hidden feeders.[73]

Although the exact action site of diflubenzuron is in dispute,[52,53] glibenclamide (**147**) really can disrupt chitin synthesis in isolated cuticular integuments in both *B. germanica* and *D. melanogaster* at the same low concentration, and both compounds showed high competitive affinity binding with SUR isolated from *Drosophila* larvae as well.[52d] As we know, the urea bridge moiety (**C**, Figure 3) is essential to the insecticidal activity of BPUs and may be the functional group in binding the target protein. On the basis of an analysis of the literature and SAR of BPUs, we propose that the *para*-substituent at the anilide (**B**, Figure 3) of benzoylphenylureas should be the functional group. Vila-Carriles et al. found the substitution of lipophilic aromatic or heterocyclic groups at position iii (Figure 20) increased the potency of compounds such as glibenclamide (**147**, Figure 20) by 100−1000-fold in accord with their affinities for SUR1, 50 μM versus 0.5 nM. Studies with half-molecules such as meglitinide (**148**, Figure 20) suggested that the increase in affinity was a result of interactions with two overlapping binding sites, termed the A and B sites (Figure 20).[74−76] According to these facts, BPU analogues (**149**, Figure 20) with a bipartite model could be designed and synthesized (Figure 20) and may lead to novel insecticides through bioassay screening.

hexachlorobenzene[a]	0.000616	0.000424	1.08	2.18

[a]Not present in commercial AFs but intentionally spiked to serve as a tracer in this study.

In 2012, 192 counties in the United States were designated as not attaining the 2008 ozone standard of 75 ppb over an 8 h averaging period.[4] Proposed revisions would further reduce this standard.[5] Given the Clean Air Act mandate to achieve attainment with the ozone standard, states must develop plans to meet this air quality objective. A key component of plans to reduce ground-level ozone often involves limiting VOC emissions from various sources, although oxides of nitrogen are precursors that can limit ozone formation. Understanding the nature and magnitude of VOC emissions is of particular concern in agricultural areas of California.[6] In such regions, VOCs are evolved naturally from plants, from the use of farm equipment, and from the use of pesticides. To address this challenge, California has developed a framework to assess and manage the potential ozone formation associated with pesticide formulations.[7]

The ozone formation potential (OFP) of a pesticide formulation allows the reactivity weighted emissions to be estimated in terms of ozone equivalents. The OFP is calculated as

$$\mathrm{OFP} = M \times \mathrm{EF} \times \mathrm{AMAF} \times \mathrm{IR} \quad (1)$$

where OFP = ozone formation potential of pesticide formulation (kg ozone/day), M = mass of product applied (kg product applied/day), EF = mass emission fraction of product (kg VOC in product/kg product applied), AMAF = application method adjustment factor (kg VOC emitted/kg VOC in product), and IR = incremental reactivity (kg ozone formed/kg VOC emitted).

The EF term is based on a thermogravimetric analysis (TGA) laboratory test, which involves heating a sample from 35 to 115 °C at a rate of 5 °C/min. The sample is then held at a final temperature of 115 °C to facilitate volatilization and loss of water in the formulation until the rate of sample mass loss drops below a defined threshold. The mean of three replicate loss measurements is used to estimate a product's EF. When TGA data are not available, the EF can be estimated given the weight composition and estimated vapor pressure (VP) of ingredients having VP at 25 °C of ≥0.05 Pa.[8] However, this vapor pressure cutoff is considerably lower than the value of 10 Pa that is commonly applied to define VOCs internationally[9] as adopted by IUPAC.[10] A key disadvantage of the TGA method is that the temperatures that the sample is exposed to are not representative of any naturally occurring environment; also, no chemical emission information is collected, and recent studies have shown that TGA can overestimate emissions quantified using GC-MS analysis.[11] A more direct approach is to use evaporation data measured under standard test conditions or to estimate this rate from a simple linear correlation with vapor pressure.[12] Furthermore, fate modeling has shown that partitioning to soil and water decreases the mobility of substances with vapor pressures below approximately 10 Pa, thus lowering the fraction of the emitted mass available to react in the atmosphere and serve as ozone precursors.[13] Nevertheless, the results of TGA or application of the calculation method yields a conservative EF estimate.

The IR term reflects the differential reactivity of formulation components in producing ozone under set assumptions. Although this parameter depends on the reactivity scale selected, the intent is to provide a consistent basis for comparing relative ozone formation potentials of different products on a mass basis. The AMAF term has been included to account for the fact that not all VOCs associated with the product will necessarily be emitted to air. Application of multimedia fate models suggests other fate processes such as sorption and biodegradation may reduce VOC losses following spray application. However, because quantitative data are generally lacking, use of adjustment factors is often not considered. Thus, in the case of aromatic fluids with VP ≥ 0.05 Pa, a worst-case scenario is applied in which all of the mass that is applied in pesticide formulation is assumed to be VOCs (EF = 1) that are emitted to air and available to contribute to ozone formation (AMAF = 1). Further research is therefore needed to assess the validity of this assumption and incorporate refinements if justified.

The objective of this study is to provide a model framework to estimate AMAF in spray application of aromatic fluid (AF) used in ECs. This objective is accomplished by (1) conducting spray chamber studies that simulate the fate of an EC containing aromatic fluid under field conditions and (2) using the resulting data to calibrate a predictive fate model, the agrochemical derived volatile organic compound air transfer evaluation (ADVOCATE) tool, to estimate VOC emissions that incorporates salient fate processes (volatilization, soil partitioning, and biodegradation) of constituents that comprise this fluid.

MATERIALS AND METHODS

Test Materials. Two ECs without an active ingredient were prepared from the following substances. A sample of AF (CAS Registry No. 64742-94-5) was obtained from ExxonMobil Chemical, Houston, TX, USA. This substance contains aromatic hydrocarbons predominantly with 10−13 carbons. TOXIMUL 3473, which is a blend of calcium sulfonate and nonionic surfactant, and TOXIMUL 3474, which is surfactant mixed with aromatic solvent, was obtained from the Stepan Co., Northfield, IL, USA. Hexachlorobenezene (CAS Registry No. 118-74-1) with a purity of 99% was purchased from Sigma-Aldrich and spiked into test EC formulations to serve as a conserved, involatile tracer. A fluorometric tracer dye was also included to determine spray recoveries. EC1 was prepared by mixing the above ingredients in water to yield the following composition on a

DOI: 10.1021/acs.jafc.5b01076
J. Agric. Food Chem. 2015, 63, 6866−6875

volumetric basis; AF (2.5%); TOXIMUL 3473 (0.095%); TOXIMUL 3474 (0.12%); HCB (0.025%); and tracer dye (0.0125%). EC2 was prepared using twice these volumetric concentrations for all components.

The two key substance properties determining the dissipation of ECs are vapor pressure (VP) and biodegradation rates in soil. The vapor pressures of the EC constituents were characterized using EPISuite MPBPWin v. 1.43 module[14] and were then temperature corrected using the Clausius−Claperyon equation at 20 °C and study temperatures (Appendix S1). Predicted biodegradation half-lives were calculated using EPISuite BioHCWin v. 1.01a[15] and compared to empirical estimates generated in this study. Table 1 shows the pertinent physical−chemical properties and amounts of EC constituents in the two spray formulations.

Spray Chamber Studies. The fate study was performed in collaboration with the U.S. Department of Agriculture, Agricultural Research Service (USDA-ARS), in College Station, TX. Researchers at the USDA-ARS have expertise in aerial application of pesticide formulations and have developed a spray chamber used to mimic agricultural spray applications. The methodology is described in detail[16] and is intended to simulate EC spraying under scenarios that are typical of ground application conditions. An agricultural sandy-loam soil with an organic matter content of 1.2% collected from the Central Valley of California near Fresno, CA, USA, was used in these studies. Soil was placed in six aluminum containment boxes (0.61 L × 0.91 W × 0.15 H m^3) with holes drilled in the bottom to allow for drainage. The filled boxes were placed in a greenhouse and watered over a 3 week period to return soil to conditions found in agricultural fields. Soil boxes were then placed on a table in a chamber that was equipped with automated spray nozzles that traverse the entire length of the chamber 1.4 m above the soil surface at a speed of 2.7 m/s. Air temperature at the time of spray application ranged from 16 to 19 °C.

Two different spray nozzles were employed to deliver a high volume (188 L/ha of EC1) spray with larger droplets (volume median diameter of 227 μm) representative of residual soil applications and a lower volume spray (94 L/ha of EC2) that gave smaller droplets (volume median diameter of 166 μm) representative of foliar and insecticidal treatment applications. Both nozzles were operated at 30 psi and provided average nozzle flow rates for larger and smaller droplet spray of 25 and 14.3 mL/s, respectively. Good spray recoveries ranging from 93 to 99% were reported on deposition samplers that were previously reported as part of this study.[16]

Six soil containment boxes were sprayed with each of the two selected nozzles (three boxes for each nozzle). Four of the boxes were sprayed with each nozzle (1, 2) in duplicate (A, B) for a short-term study to quantify volatilization losses of AF after spraying. The remaining two boxes were used to provide a single replicate for each spray nozzle to investigate longer term losses of AF due to soil biodegradation (designated boxes C1 and C2).

Soil samples were obtained from each location using a sharpened 1.6 cm diameter plug cutter inserted through the soil surface to a depth of 2.5 cm. The soil sample was then placed into a labeled 40 mL glass vial with an airtight screw-cap lid. The plug cutter was cleaned by rinsing with hexane between each sampling point. Four replicate soil samples were randomly collected from 20 gridded box locations at 0, 1, 4, 12, and 36 h for the volatilization study. Samples were frozen after collection to prevent biodegradation and then shipped for analysis. For the biodegradation study, samples were collected and frozen as above to serve as the day 0 time point. For the remaining samples, soil was collected immediately after spraying, placed in capped vials and shipped to the laboratory at ambient temperature to allow biodegradation to proceed in sealed vials. Samples were then analyzed after 0, 2, 4, 7, and 14 days of incubation taking into account elapsed transit time. Five replicates were included at time 0 and three replicates for subsequent sampling times. Control soil samples that were not sprayed were also collected and sent for analysis to determine background concentrations of AF components and HCB. All t = 0 samples were obtained while the containment boxes were on the spray table. Following initial soil sampling, the boxes were then moved to an adjacent greenhouse for subsequent sampling. Air temperature in the greenhouse during each soil sampling period ranged from 21 to 29 °C.[16]

Hydrocarbon Analysis. Two separate aliquots, equivalent in concentration, of emulsifiable concentrate (EC) amended with 1% HCB were received from USDA-ARS by the analytical chemistry laboratory of ExxonMobil Biomedical Sciences, Inc., Annandale, NJ, USA. Equal volumes of these EC aliquots were combined and diluted in acetone, yielding a single stock analytical standard solution. This stock solution was subsequently diluted in 1:1 methylene chloride/acetone providing a series of analytical standards used for subsequent GC-MS analysis of treated soil extracts. The concentrations of the total AF in the standards were 89, 356, 890, and 3560 ng/mL. The corresponding HCB concentrations in the standards were 1, 4, 10, and 40 ng/mL. Each analytical standard also contained a constant 209 ng/mL concentration of deuterated (d_8) dichlorobenzene as an internal standard.

Treated soil samples were extracted and analyzed by GC-MS. Briefly, 5 g samples of soil were dried with an approximately equal amount of Hydromatrix (Varian) and extracted on a Dionex Accelerated Solvent Extractor 200 at 1500 psi and 100 °C with a solvent 1:1 mixture of methylene chloride and acetone. The extracts were adjusted to a final volume of 20 mL of which a 1.0 mL aliquot was spiked with the equivalent of 209 ng/mL d_8 dichlorobenzene internal standard prior to analysis.

GC-MS analysis was performed in the selective ion monitoring mode (SIM) using an Agilent HP6890N GC and 5975 MSD with Gerstel MPS2 autosampler. A 30 m × 0.25 mm id Rtx-5Sil MS capillary column (Restek) with 0.25 μm film thickness preceded by an uncoated 10 m Integra guard column was used. Thirty microliter injections were made in the solvent vent mode into a Gerstel CIS 4 inlet. The inlet liner was packed with 10 mm of PDMS to trap the more volatile hydrocarbon components during the solvent vent process of the large-volume injections.

The AF consists of one- and two-ring aromatic compounds with various methyl or other alkyl substitutions. Using constituent analysis provided by ExxonMobil Chemical Co., structures were assigned to component groups (e.g., methyl and dimethyl (C5/C6) benzenes, dimethylindanes (C2), naphthalene, methyl (C1) naphthalenes, dimethyl and ethyl (C2) naphthalenes, C3 naphthalenes, C2−C4 biphenyl) comprising the AF. The concentration in the analytical standard for each group accounted for the fact that the AF comprised only 90% of the EC with the balance comprising other formulation components, including surfactants and HCB. Specific retention time and SIM windows were established for each of the individual groups plus the HCB conserved marker and deuterated dichlorobenzene internal standard. This technique permitted internal standard normalized calibration curves for each component group and subsequent quantification in soil extracts.

Data Analyses. The volatilization loss of each hydrocarbon component during spraying was estimated from the ratio of the measured concentrations of the AF components relative to HCB in the spray formulation and in the soil samples assuming that the relatively involatile and stable HCB (Table 1) is conserved. Direct measurement of the quantity of hydrocarbon sprayed and measured in soil samples is less accurate because of spray heterogeneity and possible spray drift. However, preliminary spray trials using the spray chamber and nozzle applied in this study indicated measured loss by spray drift was small (only 1−7%)[16] and would not likley affect the hydrocarbon/HCB ratio.

The predicted concentration of chemical in the soil at t = 0 and the fraction of the component volatilized X_i% can be estimated from eqs 2 and 3. The "predicted" concentrations assume the same ratio of hydrocarbon/HCB reaches the soil as is in the sprayed solution. The "observed" ratios are lower as a result of volatilization of the hydrocarbon components.

$$C_{\text{soil pred},i} = C_{\text{soil obs, HCB}} \times C_{\text{ECi}}/C_{\text{ECHCB}} \quad (2)$$

$$X_i = (C_{\text{soil pred},i} - C_{\text{soil obs},i})/C_{\text{soil pred},i} \times 100\% \quad (3)$$

[a] n is the number of analytical measurements taken from the sample boxes and used in analysis; for calculations at time zero, all six boxes were used; for subsequent times, analyses for boxes A1, A2, B1, and B2 were used.

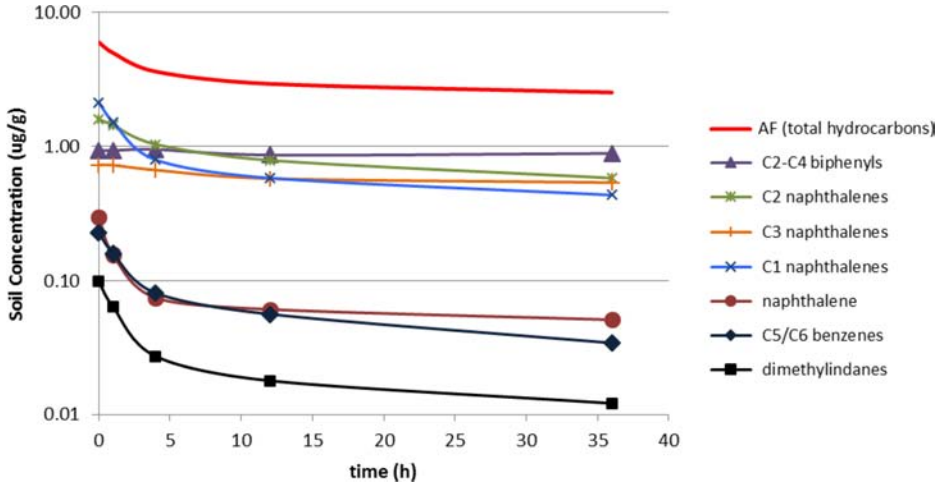

Figure 1. HCB-normalized soil concentrations of hydrocarbon components in the short-term volatilization study, showing the initial fast loss during the first 12 h followed by a slower rate of loss.

$C_{soil\ pred,i}$ is the predicted soil concentration (μg/g dry wt) of component i, where i can be the selected hydrocarbon component or the sum of all AF components, $C_{soil\ obs,HCB}$ is the measured HCB soil concentration (μg/g dry wt), and $C_{EC,i}/C_{EC,HCB}$ is the concentration ratio of component i to HCB in the EC formulation, which is known on the basis of analytical characterization of the EC formulation (unitless).

Biodegradation rates were estimated by measuring concentration ratios in samples from box C maintained in closed vials to prevent volatilization, again assuming HCB is conserved. The use of HCB as a nondegradable benchmark chemical that facilitates derivation of biodegradation half-lives has been reported in previous studies.[17] The rate constant k_{bio} was estimated by fitting the observed concentration ratios of component(s) to HCB over time using eq 4:

$$\ln[(C_{soil\ obs,i}/C_{soil\ obs,HCB}) = -k_{bio} \times t \quad (4)$$

Corresponding half-lives were calculated as $\tau_{1/2bio} = 0.693/k_{bio}$.

RESULTS

HCB Concentrations in Soil. The initial concentrations of HCB in soil were found to be close to the expected concentration in soil based on mass balance calculations assuming no losses. Furthermore, whereas absolute concentrations were variable over time, no significant decline in measured HCB soil concentrations was observed over the study period (Figure S1). These data support the assumption that HCB served as a conserved tracer in this study. On the basis of mass balance calculations described in Appendix S2, the quantity of AF sprayed is sufficient to saturate only a fraction of a millimeter depth of soil. Thus, subsaturation conditions must exist in the 2.5 cm deep soil samples, indicating that component concentrations are not homogeneously distributed in the soil compartment.

Volatilization Study. HCB-normalized concentrations for total AF hydrocarbons as well as component groups were used to calculate cumulative percent losses from 0 to 36 h for each spray nozzle using eq 3 (Table S1). Given limited data and lack of clear differences in calculated losses between the two nozzle types (Tables S2−S7), average values were determined as summarized in Table 2 and plotted in Figure 1. For t = 0, all six boxes were used; for subsequent times only the four boxes (A and B) comprising the volatilization study were used.

At time 0, immediately after spraying, a significant fraction of the AF is lost into the air by volatilization (Table 2). Most of this loss is attributable to the more volatile, higher vapor pressure components. Following this loss there appears to be a further initial fast drop in concentration within the first 12 h followed by a slower reduction to 36 h (Figure 1). This behavior suggests a change in loss mechanism over time and indicates that a simple first-order volatilization model cannot be used to adequately simulate this empirical loss profile. This observation casts doubt on the practice of assigning a single half-life to pesticides and carrier fluids that are applied to soil by spraying. Figure 1 also shows that the HCB-normalized concentrations of C3 naphthalenes and C2−C4 biphenyls

DOI: 10.1021/acs.jafc.5b01076
J. Agric. Food Chem. 2015, 63, 6866−6875

appear to increase at t = 1 h, then level out, showing very little loss over the entire 36 h of the volatilization study. The apparent increase in concentration results in negative calculated losses and is likely an artifact of the small changes observed (±1−14% as per Table 2) and the large variation within those observations in comparison to the lighter hydrocarbons.

Biodegradation Study. As the microbial community becomes acclimated to the presence of the AF hydrocarbons in soil, biodegradation processes are expected to contribute to observed losses. Figure 2 shows the decline in total AF

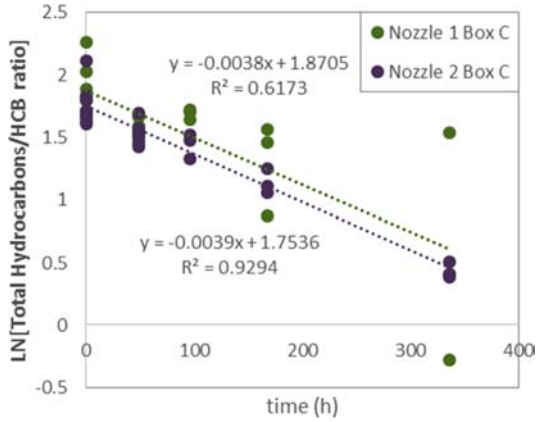

Figure 2. Regression of HCB-normalized soil concentrations of total hydrocarbons with time for the two spray nozzles in replicate boxes during biodegradation study.

hydrocarbons normalized to HCB over the 14 day (330 h) test period. The source of the increased variability in normalized values at the end of the test in nozzle 2 box C is not known. However, exclusion of these data in the analysis has little influence on the regression analysis results. The average half-life for total AF hydrocarbons derived from results with both spray nozzles was 180 h (7.5 days), corresponding to a mean biodegradation rate constant (k_{bio}) of 0.00385 h^{-1}.

For model calibration, the biodegradation rate of each component is required. Analogous plots and observed regressions for each of the AF components are included in Figure S2. Data for C5/C6 benzenes were highly variable, and estimated biodegradation rates are less certain. As the estimated biodegradation rates derived from tests with the two nozzles were similar across the different constituents as indicated by the individual regression equations included in Figure S2, values were averaged for input to model simulations as summarized in Table 3. Measured half-lives varied by a factor of 5 across the different components. The soil biodegradation half-lives

Table 3. Estimated Biodegradation Rates from Tests with Both Spray Nozzles and Corresponding Measured and Predicted Half-Lives Using HCBioWin

component	measured k_{bio} (h^{-1})	measured $t_{1/2}$ (h)	predicted $t_{1/2}$ (h)	ratio

C2−C4 biphenyls	0.0023	308	718	0.43

reported in this study are up to an order of magnitude lower (i.e., faster rates) than assumed in earlier modeling studies predicting the multimedia fate of hydrocarbons.[18,19] However, past laboratory studies have reported shorter, measured biodegradation half-lives for naphthalene and methyl naphthalene in agricultural soil of 1−2 days,[20,21] which is in agreement with values observed in this study. A modest agreement between empirical and predicted half-lives is observed. Differences of about a factor of 4 indicate HCBioWin predictions are within the correct order of magnitude but less precise in discriminating between hydrocarbon structures.

Model Formulation. It is hypothesized that volatilization of AF components during and after spraying is best treated in three distinct stages: stage 1, during the spray application (ending at t = 0 h); stage 2, volatilization of EC coating the surface of the soil (t = 0−12 h); and stage 3, combined transport into soil vapor from chemical sorbed to soil solids with subsequent volatilization and biodegradation (t = 12−36 h and beyond).

Stage 1: Volatilization during Spraying. During the spray event, a fraction of the AF evaporates or drifts to a downwind location. This fraction is likely dependent on the vapor pressure of the component and the dynamics of the spray process. The relationship of the percent loss of chemical with its vapor pressure can be determined and used to predict the percent mass lost to the air during such spray events.

We assume a spray droplet to contain V mol of hydrocarbon, each individual component having an initial mole fraction concentration x_0. As the droplet falls some of the hydrocarbon evaporates and the mole fraction x falls according to

$$dx/dt = -k_V \times A \times C_A \text{mol/h} \quad (5)$$

where k_V is a mass transfer coefficient, A is the surface area of the droplet, and C_A is the equilibrium concentration in the air intimately in contact with the drop. C_A can be estimated as xPM/RT, where P is the component's vapor pressure (Pa) and R, T, and M are the gas constant (8.314 m^3·Pa/mol·K), temperature (K), and molar mass (g/mol), respectively. This assumes that Raoult's law applies and that the partial pressure of each component is proportional to its mole fraction in a fluid of constant volume and composition; thus, the prediction may not be highly accurate, but the structure of the correlation equation is believed to be satisfactory. A rigorous equation would represent the batch or Rayleigh volatilization of a multicomponent mixture of changing volume and would be excessively complex for the present purposes.

Integration from $x = x_0$ at t = 0 gives

$$x = x_0 \cdot \exp[-Y \cdot P] \quad (6)$$

where

$$Y = k_V \cdot A \cdot M \cdot t/(V \cdot R \cdot T)$$

Because of the complexity of the mass transfer process, it is impossible to estimate the parameter Y a priori, but it can be estimated from empirical data quantifying losses during spraying. Furthermore, the process is more complex than is assumed here because V changes with time and there is a spectrum of droplet sizes. Thus, the parameter Y consolidates this information on droplet size, dynamics, and spray time into a single fitted parameter. It is preferable to express the percentage of the original mass remaining in the soil at each stage as M_{it}/M_{i0}.

DOI: 10.1021/acs.jafc.5b01076
J. Agric. Food Chem. 2015, 63, 6866−6875

The percentage loss (L_1) of a specific hydrocarbon during spraying is

$$L_1 = 100[1 - M_{i1}/M_{i0}] = 100[1 - \exp(-YP)] \quad (7)$$

Specifically M_{i0} is the original mass of component i. M_{i1} is the mass deposited by the spray; thus, the spray loss is $M_{i0} - M_{i1}$. Similarly M_{i2} is the mass after volatilization during stage 2, and M_{i3} is the mass after volatilization and biodegradation during stage 3. It follows that

$$M_{i1} = M_{i0} \exp(-YP) = (1 - L/100) \text{ or } YP = -\ln(M_{i1}/M_{i0}) \quad (8)$$

In this study, the HCB normalized data are used to reduce the noise associated with spatial variation in the spray pattern. The most reliable data are those of the five most volatile components for which Y is shown to average 0.066 Pa^{-1} (Figure 3). There is no significant difference in losses between

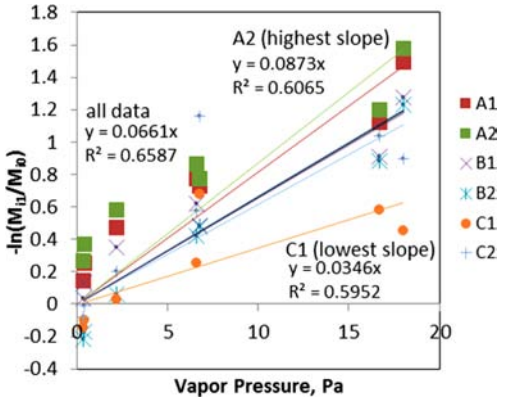

Figure 3. Regression of $-\ln(M_{i1}/M_{i0})$ against vapor pressure at 20 °C for the two spray nozzles in replicate boxes during spray loss for the five most volatile EC components. Differences are within the standard errors. The highest and lowest rates of loss were observed for A2 and C2.

the nozzles during stage 1. Box A2 shows the largest value of Y (0.0873 Pa^{-1}), and C1 shows the smallest value (0.0346 Pa^{-1}). The box C results from the degradation study for both nozzles are less consistent with boxes A and B from the volatilization study than they are within that study, but are included in the t = 0 spray loss analysis to increase the degrees of freedom in the analysis from $n - 1 = 15$ to $n - 1 = 25$.

Because AF is a mixture, it is impossible to assign a single vapor pressure; however, assuming Y to be 0.066 Pa^{-1}, a mean effective vapor pressure of the AF used in this study during spraying is 4.96 Pa. The model provides a simple method for predicting percent loss following spraying, as a function of vapor pressure during the stage 1 spray event.

Volatilization during Stage 2. When the sprayed fluid reaches the soil surface, it coats the soil particles and may not homogeneously distribute over the surface area depending on the nature of the spraying process. Volatilization then occurs directly from the deposited fluid to the atmosphere. In their studies of pesticide volatilization, Woodrow and Seiber[22] and Woodrow et al.[23] have suggested that this period may last up to 24 h, but it is observed here to be shorter, for example, 8–12 h for some of the more volatile hydrocarbons present in the EC applied. During stage 2 when free or pure phase hydrocarbon is present at the surface, the volatilization rate will likely be controlled by diffusive mass transport of the near-saturated vapor from the fluid surface and is best expressed as being first order in hydrocarbon concentration and will be proportional to the vapor pressure. It is assumed that there is no biodegradation during this stage.

During the 12 h following spraying the concentration of AF fell from ~6 to ~3.2 μg/g, that is, a loss of 47%, suggesting an overall half-life of approximately 13 h. Figure 4 shows that

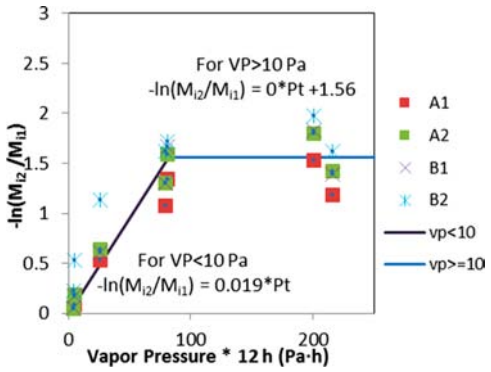

Figure 4. Regression of $-\ln(M_{i2}/M_{i1})$ against the product of vapor pressure at 20 °C and 12 h for the two nozzles tested in duplicate spray boxes during stage 2.

dependence of the total rate of loss is stronger for the less volatile components during stage 2; components with vapor pressures of >10 Pa are likely to volatilize quickly during the first stage, thus showing less dectectable loss by stage 2.

Assuming that volatilization rates are first order, the volatilization loss during stage 2 (L_2) for the less volatile components (VP < 10 Pa at 25 C) can be expressed as a function of vapor pressure P (Pa), time period of the stage, t (h), and a volatilization rate parameter that is common to all components, k_{v2} ($h^{-1}\cdot Pa^{-1}$), as follows:

$$L_2 = 100[1 - M_{i2}/M_{i1}] = 100[1 - \exp(-k_{v2} \times P \times t)] \quad (9)$$

$k_{v2} \times P$ is the rate constant (h^{-1}) for volatilization. This volatilization rate constant for stage 2 was deduced as for stage 1 as 0.019 and can be used to predict the volatilization of chemical as a function of vapor pressures up to 10 Pa (commonly used to define substances as VOCs) and for times up to 12 h postspray, assuming there is limited sorption of the AF to the soil. At a VP of 10 Pa the rate of change with vapor pressure levels off. Components with VP > 10 Pa at 25 °C exhibit a 36–70% loss during stage 1 and have much lower concentrations prior to stage 2. During stage 2 (between 0 and 12 h postspray), these more volatile components experience a 69–86% loss with an average of 79%, independent of vapor pressure (Figure 4). Because the y-intercept is constant at 1.56, the predicted percent stage 2 loss for hydrocarbons with VP > 10 Pa simplifies to $100[1 - \exp(-1.56)]$. The y-intercept of 1.56 can be prorated for a time to estimate losses between 0 and 12 h. For example, at 1 h, the y-intercept is $1.56 \times 1/12 = 0.13$, which corresponds to a stage 2 loss of $100[1 - \exp(-0.13)]$ or 12%.

Thus, 100 g of an AF component with a vapor pressure 10 Pa (6.8 Pa at 20 °C) will experience a 40 g loss during stage 1 and a further 47 g loss during stage 2, making a total cumulative loss of 87 g. One hundred grams of a hydrocarbon with a vapor pressure of 0.05 Pa (0.034 Pa at 20 °C) will experience a loss of

DOI: 10.1021/acs.jafc.5b01076
J. Agric. Food Chem. 2015, 63, 6866–6875

0.25 g during stage 1 and a further 0.77 g loss during stage 2, thus making the total cumulative loss about 1 g by 12 h.

Volatilization and Biodegradation in Stage 3. The volatilization study results provide an estimate of the rate of volatilization during stage 3 from approximately 12 to 36 h. During stage 3, the fluid increasingly sorbs into the soil particles and diffuses into the soil matrix, especially into the soil organic matter. Volatilization then occurs as a result of transport of soil vapor in equilibrium with the fluid present primarily in a sorbed state through the pore air space and a boundary layer to the atmosphere. The partial pressure or fugacity of the fluid component in stage 2 likely corresponds to that of the sprayed fluid, but in stage 3 it drops to a lower value corresponding to that of the sorbed state. In addition, as the hydrocarbon penetrates more deeply into the soil matrix the rate of mass transfer slows because of the increased path length for diffusion. The net result is relatively fast stage 2 volatilization, followed by a slower rate in stage 3 that is also assumed to be first-order in chemical concentration. During these periods the rates are controlled by the different air−fluid equilibrium relationships of the components and kinetic or mass transport terms.

Estimating Volatilization and Biodegradation in Stage 3. During stage 3, an attempt was made to regress the total loss (which includes both volatilization and biodegradation) against the product of vapor pressure and the 24 h duration (12−36 h) to obtain a total loss rate constant. However, no discernible pattern of loss during stage 3 was observed for spray nozzle 2. In fact, data show an increase in concentration for many components (evidenced by points below the *x*-axis), so results cannot be reliably modeled (Figure 5). In contrast, a decrease in concentration was observed for all components with nozzle 1. Further observed losses showed a positive relationship with vapor pressure. These findings suggest AF sprayed at a lower spray rate and smaller droplet size is better retained by the soil after 36 h; that is, there is less volatilization. To provide a conservative model parametrization of stage 3 losses an estimate of k_{3total} was derived using only nozzle 1 data. The biodegradation rate constant was then subtracted from this value to give the rate constant for volatilization (that depends on vapor pressure). The stage 3 volatilization rate parameter k_{v3} common to all components in the EC for spray nozzle 1 is then estimated to be 0.0023 Pa^{-1} h^{-1} (Figure 5). The rate constant for volatilization is then $k_{v3}P$ h^{-1} and the half-time is $0.693/(k_{v3}P)$ h. This is an order of magnitude slower rate than applies to stage 2. The total loss for stage 3, L_3, is then calculated as

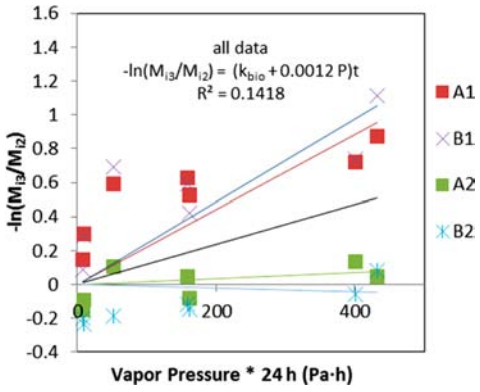

Figure 5. Regression of $-\ln(M_{i3}/M_{i2})$ against vapor pressure at 20 °C for both nozzles in replicate spray boxes during stage 3. A1, k_v = 0.0022 and R^2 = −0.239; B1, k_v = 0.0024 and R^2 = 0.2602; A2, k_v = 0.0002 and R^2 = 0.1696; B2, k_v = −0.0001 and R^2 = −1.481.

$$L_3 = 100[1 - M_{i3}/M_{i2}] = 100[1 - \exp(-(k_{bio} + k_{v3} \times P)t)] \quad (10)$$

where t is the length of time (24 h) between sampling at the beginning and end of stage 3 (12−36 h). It is likely that this rate constant for volatilization, k_{v3}, decreases with time as the AF components becomes more deeply sorbed into the soil matrix.

The relative contribution of volatilization to the total loss of the AF during stage 3 can be determined. The ratio of rates of biodegradation to volatilization is $k_{bio}/k_{v3}P$; thus, the total quantities of hydrocarbon components after 12 h, M_{i2}, that are volatilized and biodegraded can be estimated as respectively $M_{i2} \times (k_{v3}P/(k_{v3}P + k_{bio}))$ and $M_{i2} \times (k_{bio}/(k_{v3}P + k_{bio}))$. The losses of low-volatility chemicals are dominated by biodegradation, and the ratio $k_{bio}/k_{v3}P$ is >1. This ratio is quite small for the two most volatile components; thus, volatilization dominates the overall loss processes. Table 4 shows that biodegradation is more significant for the more methylated naphthalenes and the predominant loss process for the biphenyls. Clearly biodegradation occurs and it is likely responsible for long-term removal of the less volatile hydrocarbons, but it is inconsequential for the more volatile components because for these components the rate of biodegradation cannot effectively compete with volatilization. To a first approximation, the biodegradation half-lives of the components are similar in magnitude, but the volatilization rates differ by almost 2 orders of magnitude depending on component vapor pressure.

Table 4. Relative Importance of Biodegradation and Volatilization to Overall Loss of Components during Stage 3

component	biodegradation k_{bio} (h^{-1})	volatilization $k_{v3}P$ (h^{-1})	ratio $k_{bio}/k_{v3}P$

Combined Model of All Three Stages. The regressions described above have been combined in a spreadsheet model that estimates the fate of the hydrocarbon components and the AF for the sequence of stages 1, 2, and 3. It can be used, with appropriate caution, to provide a conservative estimate of the cumulative quantity of hydrocarbon lost and remaining for longer times on the order of weeks using eqs 7, 9, and 10 as shown in eqs 11 and 12.

For VP < 10 Pa at 25 °C

$$L_T = 100 \times [1 - \exp(-0.066 \times P) \times \exp(-0.019P \times 12) \times \exp(-(k_{bio} + 0.0023 \times P) \times t)] \quad (11)$$

For $P \geq 10$ Pa at 25 °C

$$L_T = 100 \times [1 - \exp(-0.066) \times \exp(-1.56) \times \exp(-(k_{bio} + 0.0023 \times P) \times t))] \quad (12)$$

[a]Cumulative percent degraded in parentheses for stage 3. Bold values indicate cumulative percent degraded is greater than the cumulative percent volatilized.

where P is VP in Pa at 20 C, t is time in hours during stage 3 (i.e., time from spraying minus 12 h), and k_{bio} is the first-order substance-specific soil biodegrdation rate constant in h^{-1} (Table 3).

The model input is the AF composition treated as seven groups or "pseudo-components". Other hydrocarbon groups can be included as desired. For each group a temperature-dependent vapor pressure is assigned and used to estimate rate constants for all stages. The biodegradation half-life in Table 3 is assigned and used in stage 3. The model calculates masses remaining after stages 1 (spray loss), 2 (12 h), and 3 (36 h) as described earlier. It also estimates the masses remaining in soil for up to 2 weeks. The masses volatilized and biodegraded are also calculated. The altered AF compositions are calculated at all stages. The spreadsheet is "open"; thus, any desired times and hydrocarbon properties can be input and simulated and can be accessed in Appendix S3 as an MSExcel spreadsheet.

Table 5 gives the mass balance estimated by the model for the test conditions and comparison with the experimental data (given below in parentheses). For the AF, 27% is predicted to be lost in stage 1 (28%). After stage 2, a loss of 64% is predicted (66%). After 36 h, the predicted loss is 71% (70%). After 1 week, the predicted percentage lost is 86%, and at 2 weeks the loss is >92% as biodegradation removes the residual hydrocarbons. It is shown that for C2−4 biphenyls, biodegradation becomes the dominant loss process by 120 h (5 days).

Figure 6 shows the measured versus the modeled predicted soil concentrations for each of the AF components for 0−36 h.

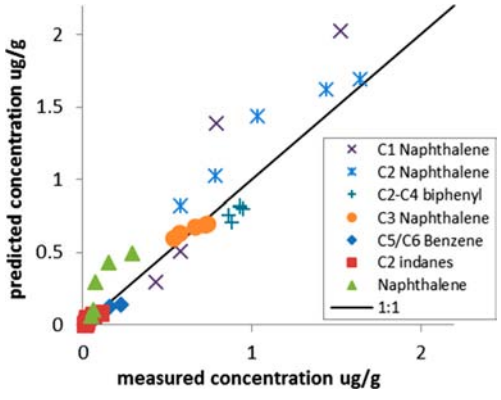

Figure 6. Comparison of measured and model-predicted soil concentrations for all sampling times during volatilization study (0, 1, 4, 12, 36 h). R^2 = 0.92.

The C2−C4 biphenyls and C3 naphthalenes experience the least loss (lowest spread) in the mid-concentration range. The lighter C1 and C2 naphthalenes experience relatively fast loss, mainly through volatilization. The model appears to overpredict soil concentrations in the beginning of stage 2 by approximately 25%, but then brings the predictions closer to measured values by stage 3 (Appendix S4). The R^2 obtained by regressing the predicted against the observed losses for all components and sampling times of 0.92 is regarded as an indication of satisfactory model performance.

DISCUSSION

On the basis of the model framework presented, it is instructive to consider how different conditions will influence the potential for AFs included in ECs to be emitted to air and potentially contribute to ozone formation.

Application Rate Per Unit Area. In this study the EC application rate was 4.7 kg/ha or 0.47 g/m^2. The model estimates the fraction of the mass of hydrocarbon sprayed that volatilizes, not the actual volatilization rate, although this can be calculated from the results. To a first approximation, an increase in application rate by, for example, a factor of 2 should not affect the volatilized fraction in stage 1, and it should have little effect on the fractions in stage 2, although the duration of the stage 2 period may be prolonged as more hydrocarbon must volatilize from a thicker coating on the soil before the onset of stage 3. The spray rates (L/Ha) were varied in this study, but the EC application rates (kg/Ha) were the same (the higher EC concentration solution was sprayed at a lower rate).

Variations in Organic Matter (OM) Content of the Soil. The OM content of the tested soil was 1.2%. No experimental determinations of the effect of OM content were performed; however, there is little doubt that increasing OM content may reduce volatilization rates. Doubling the OM content to 2.4% may not have an effect on stage 2, but the increased sorptive capacity of the soil is likely to reduce the volatilization rate in stage 3 and subsequently at longer times, probably by a factor of approximately 2. The model can thus directionally simulate the effect of soil OM content.

Other Hydrocarbon Components. The volatilization characteristics of other hydrocarbon components or groups can be estimated by input of the appropriate vapor pressure and biodegradation half-lives obtained experimentally or from estimation methods.

Relative Losses of Hydrocarbons. The model tends to overpredict the volatilization of the more volatile hydrocarbons. This can be accounted for in part by reducing the volatilization

0.01	0.05	0.06	0.10	0.20	0.24	0.32	0.35	0.41

rate constant as was done between stages 2 and 3. It appears that the most volatile hydrocarbons fail to achieve the expected losses at longer exposures. It is believed that this is due to some of the volatile hydrocarbons being "trapped" in the bulk of the EC mixture and being less available for volatilization. Essentially there appears to be a diffusive resistance to mass transfer when concentrations are low. The model inherently assumes well-mixed conditions in the EC mixture. In reality, there is likely extensive volatilization of water and AF components, thereby increasing the density and viscosity of the mixture. There may be some phase separation of the solid hydrocarbons as the "solvent effects" of the more volatile components are dissipated. To accommodate such effects would greatly increase the complexity of the model; thus, the simple and conservative assumptions used here are regarded as justified.

Implications for Estimating the AMAF. Table 5 shows that for hydrocarbons with vapor pressures of 0.337−18 Pa at 20 °C, 38.9−99.99% of the applied substance is predicted to be volatilized by 7 days postapplication. Several hypothetical components with 0.01−30 Pa vapor pressures (at 25 °C, adjusted to 20 °C for modeling predicted losses) and a degradation half-life of 100 h were also simulated to estimate the cumulative percent volatilized over time (Table 6). This model provides a practical method to quantify the application method adjustment factor (AMAF, kg VOC volatilized/kg VOC in product) term in the calculation of the ozone formation potential (OFP) included in eq 1.

This work shows that the regulatory assumption that AMAF is 1 for all hydrocarbons with a vapor pressure >0.05 Pa is overly conservative as only about 2% is predicted to have volatilized by 2 weeks postspray for a hypothetical chemical of a vapor pressure of 0.05 Pa and a degradation half-life of 100 h. Factors such as the degradation rate constant and the time post application as well as the vapor pressure are influential in determining the magnitude of the AMAF. For example, 7 days after application, only 18% of C2−4 biphenyl (VP = 0.34 Pa) losses are attributed to volatilization and 25% to degradation; after 14 days, only 24% is lost to volatilization, and the majority of the loss, 41%, to biodegradation. The model was used for determining cutoff values reflecting 67% losses by volatilization after 12, 24, 96, and 168 h, based on a typical biodegradation half-life of 100 h. The resulting cutoff values range between 2 and 3.5 Pa, nearly 2 orders of magnitude larger than the proposed cutoff (Appendix S5).

Summary and Future Work. After spraying, three stages of AF loss in an EC formulation can be characterized: initial loss during the spray event, which is related to the component vapor pressure; then loss from the pure phase of fluid coating the soil directly after the spray event; and, third, the volatilization and biodegradation of the remaining fluid that has been absorbed by the soil beyond 12 h postapplication. The mechanisms of volatilization and the corresponding models developed here give an adequate quantitative description of the fate processes of the seven components comprising the AF investigated during the complex series of events that occur following spraying. The model is simple, robust, and consistent with the experimental results and is intuitively in accord with expectations based on conventional descriptions of the salient equilibrium and kinetic processes; uncertainty analysis could further refine and add confidence to the framework. This model has practical utility in refining current default regulatory assumptions for estimating the ozone formation potential of ECs used in agricultural sprays.

A logical focus of future modeling work would be incorporation of photodegradation process at the soil surface and one or more vegetation compartments to account for substance bioaccumulation and degradation by plants as these processes are known to influence fate behavior of substances released to soil.[24−27] The present study also provides an initial model framework that can potentially be extended to other applications such as evaluating substances used in dust suppression control or petroleum substance spills to soils.

the soil bacterial communities. However, these values are very high compared to the treatments used in the present study. There exists a need to explore engineered nanoparticle effects on the rhizophere microbiome[19] and their possible role in nutrient management in agricultural soils.

In plant nutrition, NPs are not often considered as a factor affecting phytoavailable P. However, a recent study reported increased accumulation of P (3686 mg kg^{-1}) in roots of wheat at 250 mg kg^{-1} of CeO_2 NP treatment compared to the control (2417 mg kg^{-1}), while CeO_2 NPs at 500 mg kg^{-1} improved plant growth, shoot biomass, and grain yield by 9.0, 12.7, and 36.6%, respectively.[20] In another work, Al_2O_3 NP-bound P was reported to enhance P uptake by plants in aqueous solutions at a very low concentration of even 10 mg L^{-1}.[21] Pradhan et al.[22] studied the effects of Mn NPs on nitrogen uptake, assimilation, and metabolism in mung bean plants. The majority of these studies are short period assays up to 2 weeks and, in rare cases, up to months. In this context, the objectives of the present study were (1) effects of TiO_2 and Fe_3O_4 NP application on phytoavailability of P to *L. sativa* and plant growth, (2) rhizosphere changes in response to NP applications in soil, and (3) localization of metallic NPs in plants. To the best of our knowledge, this is the first report on P availability trends over an extended contact period (90 days) with different kinds of NPs under soil conditions.

MATERIALS AND METHODS

Synthesis of TiO_2 NPs by the Sol−Gel Method. TiO_2 NPs were synthesized using a slightly modified sol−gel method that was developed earlier for synthesis of molecularly imprinted titania.[23] The titania precursor was added in 0.5 M acidic solution. As $TiCl_4$ was added, the color of the solution turned yellowish. When the solution became transparent, it was neutralized with 0.5 M NH_4OH until pH became 7.0, followed by stirring until the gel-like network formed. The gel was allowed to settle. The supernatant was discarded, and the rest of the sol was dried in a vacuum oven at 105 °C. Dry gel was ground and calcined at 400 °C for 6 h.

Synthesis of Fe_3O_4 NPs by the Co-precipitation Method. For preparation of Fe_3O_4 NPs, $FeCl_2$ (0.1 M) was mixed with $FeCl_3$ (0.2 M) and NaOH (0.1 M) was added to the mixture. The solution turned black and was placed upon heating until a slurry was left. It was washed several times with distilled water until pH 7.0 was achieved. The slurry was dried in an oven at 80 °C. The dried magnetite clusters were ground to obtain NPs.[24]

Characterization of Synthesized NPs. The phase composition, crystal structure, and crystallite size measurements for the TiO_2 and Fe_3O_4 NPs were performed by X-ray diffraction (XRD, Theta/Theta STOE, Germany) at 40 keV and 40 mA. Processing of XRD results was performed with the X'Pert High Score software package (PANalytical B.V., Almelo, Netherland). The surface morphology of TiO_2 and Fe_3O_4 NPs was analyzed using scanning electron microscopy (SEM, Jeol, JSM 6490 A, Japan) equipped with energy-dispersive X-ray spectroscopy (EDX, Jeol, JED 2300) and an ion-sputtering device (Jeol, JFC 1500). Suspensions of TiO_2 and Fe_3O_4 NPs in ethanol were made-up on quartz slides. The sputtering technique was used to evaporate the volatile substances or moisture and stabilize the NPs on the substrate to avoid interference or prevent contamination. The technique can be used for several conductive materials.[25] Then, the slides were observed under SEM.

Soil Preparation. For the present study, sandy loam soil was selected. The air-dried soil was ground by ball mill and passed through a mechanical sieve (<2 mm) shaker to remove roots, shoots, and other materials. For the plant culture experiments, 300 g of soil was amended individually with NP suspensions to achieve 0, 50, 100, 150, 200, and 250 mg kg^{-1} levels, and it was filled in plastic pots (10 cm diameter and 9 cm height). Each treatment had four replicates, and the experiment was repeated twice.

Plant Culture and Growth Response. *L. sativa* seeds were sown in control soil to prepare the nursery. The 2 week old seedlings were uprooted and washed carefully with distilled water. These seedlings were then transferred to pots (one plant per pot) containing soil amended with TiO_2 and Fe_3O_4 NPs at 0, 50, 100, 150, 200, and 250 mg kg^{-1}. There were four replicates for each concentration level. Plants were watered as per requirement. At harvesting, roots and shoots of the plants were collected separately and their lengths were measured. The fresh weight of *L. sativa* roots and shoots was recorded. The plant material was placed in an oven at 70 °C for 48 h and then weighed to find out the dry weight. The moisture content was calculated using fresh and dry weight. The dried plant material was ground with a mortar and pestle separately and stored in airtight sampling bags for further analysis.

Soil and Plant Analysis. At harvesting, the plants were uprooted from the pots carefully and shaken gently to remove the loosely bound soil from the roots. The soil adhered to the roots, and the rhizosphere soil in this study was separated from the roots with gentle washing in 100 mL of distilled water taken in a glass beaker. The pH of rhizosphere soil solutions was immediately determined, and the solutions were filtered. The filtrate was placed at 4 °C for Raman spectroscopy analysis of plant primary metabolites in it. The filter papers containing humid rhizosphere soil were air-dried, and the soil collected was used for the phytoavailable P concentration using Olsen's method.[26]

For plant analysis, 100 mg of plant samples was taken and 5 mL of acid mixture (2:1 $HNO_3/HClO_4$) was added. The mixture was heated on a hot plate to obtain clear aliquots. These aliquots were filtered with Whatmann filter paper no. 42 and subjected to P analysis using the vanadomolybdophosphoric acid colorimetric method.[27] The P uptake per plant was calculated using the following equation:

$$\text{P uptake per plant (mg)} = [(\text{shoot dry weight} \times \text{shoot [P]}) + (\text{root dry weight} \times \text{root [P]})] \quad (1)$$

Microscopic and Spectroscopic Analyses of Soil and Plant Material. To find out the possible entry of NPs in *L. sativa* plants, shoots and roots were cut and washed with distilled water to remove electrolytes and dirt from the surfaces. The plant material was oven-dried at 70 °C for 48 h. The sputtering technique was used to coat fine pieces of shoots and roots to avoid the charge effect during SEM analysis. The plant material was then observed under SEM coupled with EDX to illustrate the elemental composition of the sample. Raman spectra of rhizosphere soil extracts were obtained from Micro Ramboss using a diode laser (532 nm λ) as an excitation source to determine the presence/absence of plant primary metabolites. Fourier transform infrared spectroscopy (FTIR) was performed with Nicolet 6700 (Thermo Corporation) to identify functional groups in the control and treated samples. The powdered plant samples of *L. sativa* shoots were scanned at room temperature (25 ± 2 °C) within a spectral range of 800−3600 cm^{-1}.

Statistical Data Analysis. The statistical significance of results was checked using Student's *t* test and standard deviation (SD). Statistically significant differences were reported when the probability of the result assuming the null hypothesis was $p \leq 0.05$.

RESULTS AND DISCUSSION

Synthesized NP Characteristics. The XRD analysis of TiO_2 NPs indicated the crystalline form and peak with the anatase phase at the (101) plane. The average crystallite size calculated by the Scherer formula was 15 nm with a tetragonal crystal system. While the XRD pattern of Fe_3O_4 showed a peak at the (311) plane with a crystallite size of 14.9 nm having a cubic crystal structure. The surface morphology of TiO_2 and Fe_3O_4 NPs analyzed through SEM confirmed the size of these NPs in the 12−20 nm range (Figure S1).

Growth Response of *L. sativa*. Results regarding plant length and biomass of *L. sativa* grown on soil amended with TiO_2 and Fe_3O_4 NPs have been presented in Table 1. Shoot length showed maximum values of 14.2 and 13.0 cm when treated with Fe_3O_4 (200 mg kg^{-1}) and TiO_2 (250 mg kg^{-1}) NPs, respectively, while the minimum value of 9.5 cm was observed in the control. This resulted in a 49 and 36% increase in shoot growth by Fe_3O_4 and TiO_2 NPs, respectively, relative to the control. In the case of root length, maximum values of 21.4 and 18.1 cm were observed in TiO_2 and Fe_3O_4 NP-treated groups, respectively, at 250 mg kg^{-1}, whereas the minimum value of 15.9 cm was observed in the control. Similarly, the shoot and root dry weight increased 1.2- and 1.6-fold at 250 mg kg^{-1} in TiO_2 and Fe_3O_4 NP-treated groups compared to the untreated group. As shown in Table 1, the values of plant biomass for TiO_2 and Fe_3O_4 NPs were 2450 and 2437 mg, respectively, and 1728 mg in the control. Therefore, the total biomass of *L. sativa* was significantly ($p \leq 0.05$) increased up to 1.4-fold of the control at the highest concentration (250 mg kg^{-1}) of both NPs applied. Application of NPs can affect various physiological processes within a plant. In our case, nutrient uptake, particularly that of P_i, was probably the main driver for improved plant growth and biomass of *L. sativa*, as supported by the results presented later. In the literature, TiO_2 NPs (with the anatase phase) applied to spinach improved the chlorophyll content (37.48%), fresh and dry biomass (91 and 99%), and total nitrogen concentration (23.35%) compared to the control.[28] In another study, 2.5% TiO_2 NPs were reported to increase the fresh and dry weight of spinach by 63 and 76%, respectively, compared to the control.[6] Our results (Table 1) are well in accordance with the reports in the literature.

Table 1. Influence of TiO_2 and Fe_3O_4 NP Concentrations on Plant Length and Biomass of *L. sativa*[a]

concentration (mg kg^{-1})	shoot length (cm)	root length (cm)	shoot dry weight (mg)	root dry weight (mg)	total biomass (mg)
control	9.5	15.9	969.7	758.3	1728.0

[a]Values represent means of four replicates. [b]Means, in each column, followed by similar values are not significantly different at the 0.05% probability level (*t* test).

Root and Shoot P Concentrations and Moisture Content. Results in Figure 1 are the effects of TiO_2 and Fe_3O_4 NPs on P concentrations in plant parts (shoot and root) of *L. sativa*. Higher P concentrations of 2272 and 2648 mg kg^{-1} were found in *L. sativa* shoots treated with 250 mg kg^{-1} TiO_2 and Fe_3O_4 NPs, respectively, compared to the control, i.e., 1371 mg kg^{-1}. In the case of all TiO_2 NP treatments, i.e., 50, 100, 150, 200, and 250 mg kg^{-1}, a relative increase of 14, 25, 74, 42, and 66% was observed, respectively, while 26, 51, 89, 77, and 93% improvement was observed by Fe_3O_4 treatments, respectively, compared to the control. These differences are statistically significant ($p \leq 0.05$). In roots, the values of 2904 and 2439 mg kg^{-1} of P concentrations were observed in TiO_2 and Fe_3O_4 NP-treated groups, respectively, which were 2−2.5 times higher than the control (1162 mg kg^{-1}). Differential trends were observed in the case of both NP-treated groups, such as the P concentrations being 0.9 times higher in roots compared to shoots in response to TiO_2 treatment. In the case of Fe_3O_4 NPs, P concentrations in shoots were 0.1 times higher compared to those in roots. Although the P concentration increased at all of the tested levels of both NP-treated groups, the minimum feasible concentration is considered to be 150 mg kg^{-1} for TiO_2 NPs. In the case of Fe_3O_4 NPs, apparently, there is no difference between 150 and 250 mg kg^{-1}, but with respect to NP application, the preferred value will be 150 mg kg^{-1}. Besides these NP concentration levels, the P uptake also depends upon a number of factors, such as the soil type, nutrient availability in soil, properties of NPs, and plant species. In the literature, studies have suggested that TiO_2 NPs may have some similar effects of plant hormones, such as cytokinins,[29] that affect the P uptake. Our results are in conformity with those reported by Servin et al.,[13] who observed an increased concentration of 34% P and 35% K in cucumber fruit of plants treated with 500 mg kg^{-1} of TiO_2 NPs. Lopez-Moreno et al.[30] reported an increase of 62% fruit yield from *Capsicum annuum* L. as a result of TiO_2 application when grown under the lowest P feed.

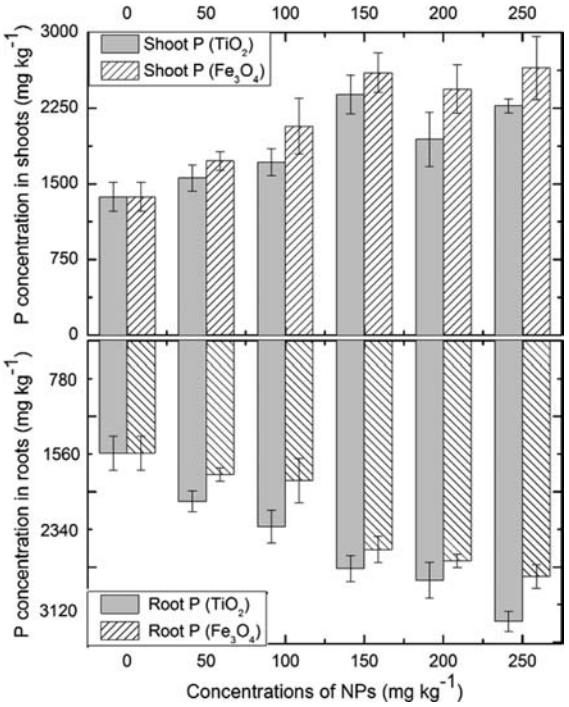

Figure 1. Concentrations of P in shoots and roots of *L. sativa* cultivated for 90 days on soil amended with TiO_2 and Fe_3O_4 NPs up to 250 mg kg^{-1}. Error bars stand for SD.

Figure 2 shows results regarding the NP effects to mobilize soil P for plant uptake. The minimum value of 14.2 mg kg^{-1} of P was observed in soil without NP treatment, whereas values of 31.7 and 24.5 mg kg^{-1} were observed in the rhizosphere soil amended with 250 mg kg^{-1} of TiO_2 and Fe_3O_4 NPs. Therefore, this significant ($p \leq 0.05$) increase in phytoavailable P in soil

DOI: 10.1021/acs.jafc.5b01611
J. Agric. Food Chem. 2015, 63, 6876−6882

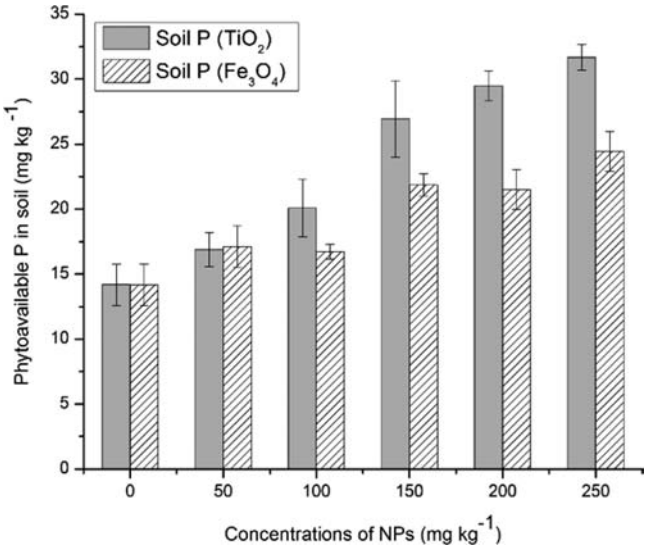

Figure 2. Concentrations of phytoavailable P in soil treated with 0–250 mg of TiO_2 and Fe_3O_4 NPs kg^{-1} of soil. Data are means of four replicates ± SD.

also enhanced the shoot and root P concentrations at different NP treatment levels, as discussed earlier. This effect may occur as a result of the increased absorption of P (converted from fixed to orthophosphate P_i form) because of applied NPs and especially their small size that favored the diffusion into the root structure and induced its positive functions during the phase of plant development.

Figure 3 shows that moisture contents increased up to 3.5 and 3.8% at 150 mg kg^{-1} of TiO_2 and Fe_3O_4 NP treatments,

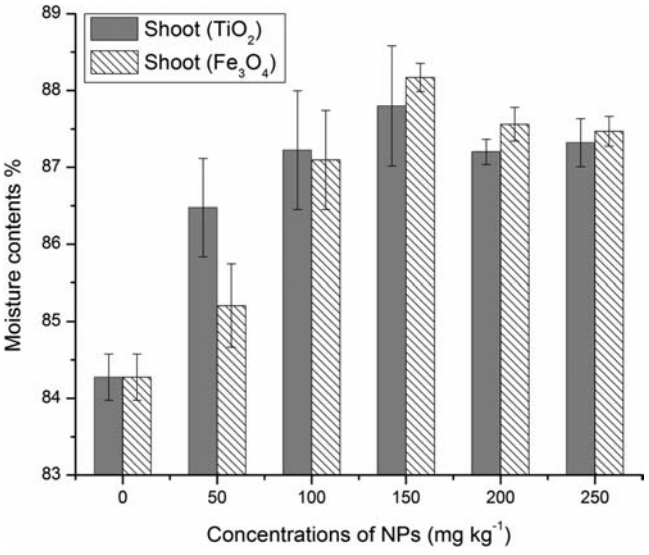

Figure 3. Effect of TiO_2 and Fe_3O_4 NPs on the moisture contents (%) of *L. sativa* shoots.

respectively, compared to the control. Because of the size of these particles (12–20 nm), they could easily be absorbed by the plant roots and translocated to the aerial parts of the plant. With these NPs having photocatalyzed attributes, they could trigger photosynthetic activity and ultimately increase the water uptake from soil. In another study, because of nano-anatase TiO_2 treatment, the photosynthetic rate in spinach was reported to improve by 31.87% compared to the control.[31] Similarly, the translocation of these NPs to shoots could result in improved chlorophyll formation[13] and increased root exudation (plant metabolites). Therefore, we hypothesized that this increased water movement and photosynthetic activity also favored the increased nutrient (P) uptake in the present study. Consequently, an increased moisture content percentage in *L. sativa* shoots was observed, which was also verified by the FTIR spectra (Figure 5b).

Rhizosphere Changes and P Uptake. Phosphorus uptake per plant and changes in rhizosphere soil pH plotted in response to NP treatments has been presented in Figure 4.

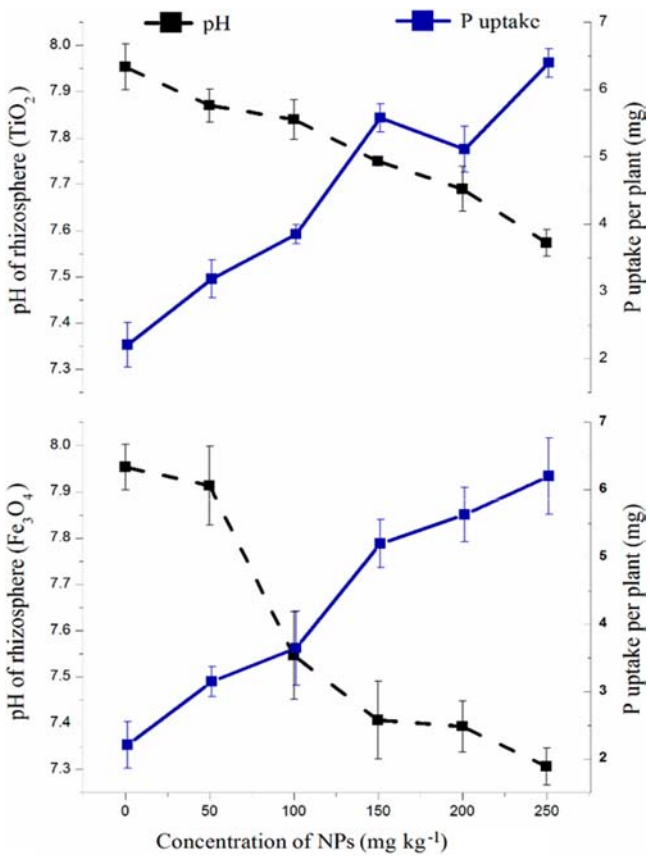

Figure 4. P uptake per plant and changes in rhizosphere pH in soil amended with 0–250 mg kg^{-1} of TiO_2 and Fe_3O_4 NPs for 90 days. Each data point represents the mean of four replicates ± SD. Error bars show SD.

Total P uptake was calculated from the P concentration and dry biomass using eq 1 mentioned earlier. The pH changes observed in the rhizosphere soil were dependent upon NP treatments and modified the P uptake in plants. The negative values of pH changes indicate the acidification of rhizosphere soil. The pH of rhizosphere soil without NP treatments was 7.95. A change of up to −0.38 pH units was observed in response to TiO_2 NPs, with a significant ($p \leq 0.05$) increase of 2.9-fold in P uptake. In a similar manner, Fe_3O_4 NP treatments also changed the pH up to −0.64 units, with a significant ($p \leq 0.05$) increase of 2.8-fold in P uptake per plant. In another study, Al_2O_3 NPs bound P at a very low concentration of 10 mg L^{-1} increased plant P uptake in hydroponics.[21] The P availability is mainly dependent upon (a) pH, (b) concentrations of metallic cations, such as Ca^{2+}, Fe^{3+}, and Al^{3+}, (c) release of competing inorganic (bicarbonate and sulfate) and

DOI: 10.1021/acs.jafc.5b01611
J. Agric. Food Chem. 2015, 63, 6876–6882

organic ligands (carboxylic anions) and gaseous (O_2/CO_2) exchanges. Therefore, the bioavailability of P_i in soil could be enhanced by modifying these factors.[32] Separate experiments with buffer solution were performed, and no significant change was found on pH in response to both TiO_2 and Fe_3O_4 NPs. Similarly, in soil medium without plant culture, both kinds of NPs at all concentration levels were unable to change the pH but increased the P availability (data not shown). In the present study, pH of rhizophere soil without NP treatment was slightly alkaline (7.95); therefore, the dominant cations would be Ca^{2+} and Mg^{2+}. The introduction of TiO_2 and Fe_3O_4 NPs in soil provided more adsorption sites to the PO_4^{3-} ions because of the increased polarizing power of Fe^{3+} (9.9 C/m^2) and Ti^{3+} (6.7 C/m^2) compared to Ca^{2+} (2.2 C/m^2) and made covalent bonds with the PO_4^{3-} groups. Because NPs had no direct influence on soil pH, the pH variations can be attributed to enhanced root exudation upon improved P uptake as a result of more available P fractions and TiO_2 and Fe_3O_4 NP entry into the plants triggering physiological mechanisms to cope with the stress through exudation. However, further research is required to explore this possible mechanism in detail.

In the literature, it is reported that adsorption of phosphate (PO_4^{3-}) on the solid phase of the soil could be the primary mechanism regulating P availability.[33] On the other hand, desorption of sorbed PO_4^{3-} mostly occurred through a ligand-exchange reaction as a result of plant root exudation that could alter the adsorption−desorption equilibrium toward improved desorption. This could occur because of either an decrease in the concentration of PO_4^{3-} ions in the soil or an increase in the concentration of competing anions produced.[32] In another study, the availability of trace metals in soil affected by organic ligands was also observed.[34] Mihajlovic et al. reported that charged zeolites that interacted in the plant rhizosphere induced the gradual release of nutrients as a result of chemical dissolution and ion-exchange reaction.[35] Wang et al. also reported the increased exudation of organic acids in response to Al treatments in the wheat root zone.[36] It is therefore suggested that the exudation by *L. sativa* roots resulted in solubilization of Fe- and Ti-bound phosphates in the rhizosphere, consequently improving the uptake of P per plant.

Translocation of NPs in *L. sativa*. SEM−secondary electron imaging (SEI) and −backscattering electron (BSE) images and EDX spectra illustrating the elemental composition of *L. sativa* shoots are provided in Figures S2 and S3. In the control group (Figures S2 and S3a), the SEM images of the shoot showed clear surfaces, whereas the aggregates of TiO_2 and Fe_3O_4 NPs are visible in NP-treated groups (Figure S2 and panels b and c of Figure S3). The EDX spectra confirmed the translocation of NPs into shoots of *L. sativa*. EDX analysis (Figure S2) revealed that major elemental variations, such as P, Ca, Mg, and Al levels, were modified in response to NP treatments. The root apex sections of *L. sativa* were also analyzed through a SEM−BSE detector and EDX (Figure S4). Both kinds of NPs dispersed in the soil were able to cover root epidermis and formed nanostructured agglomerates. NPs can be transported by capillary action to distinct sites where the passage was wider than their size. When they reached a point where the passage was narrow, NPs became accumulated in the form of aggregates. The uptake of ultra-small nano-anatase TiO_2 has been reported in *Arabidopsis thaliana* by Kurepa et al.[37] Larue et al. reported the presence of TiO_2 NPs into roots and shoots of hydroponically grown wheat (*Triticum aestivum*), confirmed through SEM.[38] Fe oxide NPs have been reported as facilitators for iron and photosynthate transfer to the leaves of the peanut plant.[39] In another study, no significant accumulation of Ti in plant tissues was observed in soil-grown wheat.[40] Diverse results could be seen using the same species with reference to the effects of NPs. NPs could behave differently depending upon their size, shape, and phase but also the concentration levels applied, experimental conditions, and plant species as well as their mechanisms of uptake.[41]

Primary Metabolites and P Speciation. Figure 5a shows Raman spectra of rhizosphere soil extracts, which were used to identify plant metabolites. The individual contents of primary metabolites, such as cystine and methionine, were found to increase in extract with NP application by the appearance of Raman peaks at 510 and 630 cm^{-1}. Cystine and methionine possess particular amino acid structures, such as S−S and S−H, act as growth regulators, and ultimately improve nutritional composition of crop plants.

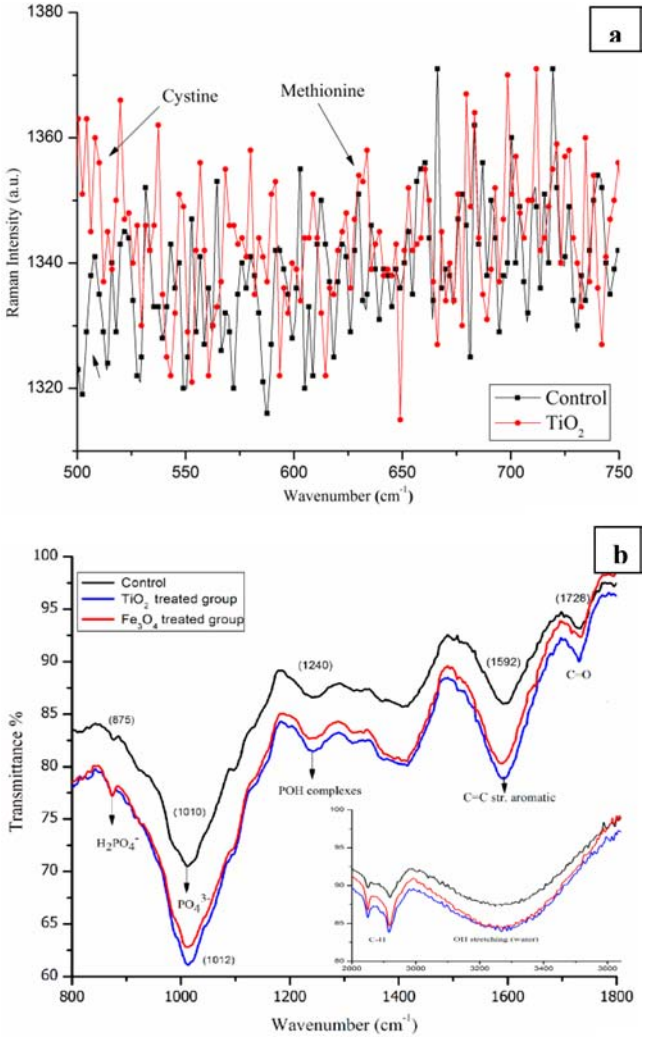

Figure 5. Spectroscopic analysis of rhizopshere soil and shoots: (a) Raman spectra of rhizosphere soil extract treated with 0 and 250 mg kg^{-1} of TiO_2 NPs and (b) FTIR spectra of *L. sativa* shoots treated with 0 and 250 mg kg^{-1} of TiO_2 and Fe_3O_4 NPs.

The results of FTIR spectral data presented in Figure 5b verified the above-mentioned results. The target species, i.e., PO_4^{3-}, showed high similarity in both of the NP-treated groups compared to the control. At the *x* axis, a slight shift in the

DOI: 10.1021/acs.jafc.5b01611
J. Agric. Food Chem. 2015, 63, 6876−6882

stretching vibration of the PO_4^{3-} group was observed from 1010 to 1012 cm^{-1} in both of NP-treated groups, indicating the strength of PO_4^{3-} bonds in TiO_2- and Fe_3O_4-treated groups compared to the control. The three phosphate species, including $H_2PO_4^-$, PO_4^{3-}, and POH, complexes and the functional groups (C−C and C═O) showed intense peaks in NP-treated groups that indicate their increased presence. These results are consistent with the above-mentioned results of P uptake by plant. In the literature, results of increased PO_4^{3-} complexes with acidification have been reported.[42] In another study, FTIR analysis of cucumber fruit from TiO_2 NP (250−750 mg kg^{-1}) treated plants showed significant modifications in lipids, amide, lignin, and carbohydrates.[13] Similarly, in the present study, NP-treated groups showed stronger OH bonds (water) relative to the control. These findings are relevant to the results of the moisture content percentage in shoots (Figure 3). Thus, *L. sativa* shoots with TiO_2 and Fe_3O_4 treatments contained more phosphate, hydroxyl, and carbonyl groups. Overall, results of Raman and FTIR support the findings presented in different sections and validate the accuracy of the experiments.

In conclusion, the application of TiO_2 and Fe_3O_4 NPs increased phytoavailability of P, growth, biomass, and moisture content of *L. sativa* at all tested concentrations compared to the control. The best feasible concentration of both TiO_2 and Fe_3O_4 NPs that increased the P uptake by 74 and 89%, respectively, was 150 mg kg^{-1}. In nutrient-uptake mechanisms, the affinities of NPs to adsorb PO_4^{3-} ions affected by the speciation of P, which made it phytoavailable, and their subsequent release through acidification caused by root exudation are the traits that could increase the solubility of soil-bound P_i in the rhizosphere. The findings suggest developing an innovative strategy of using NPs for improved nutrient management to ensure food security.

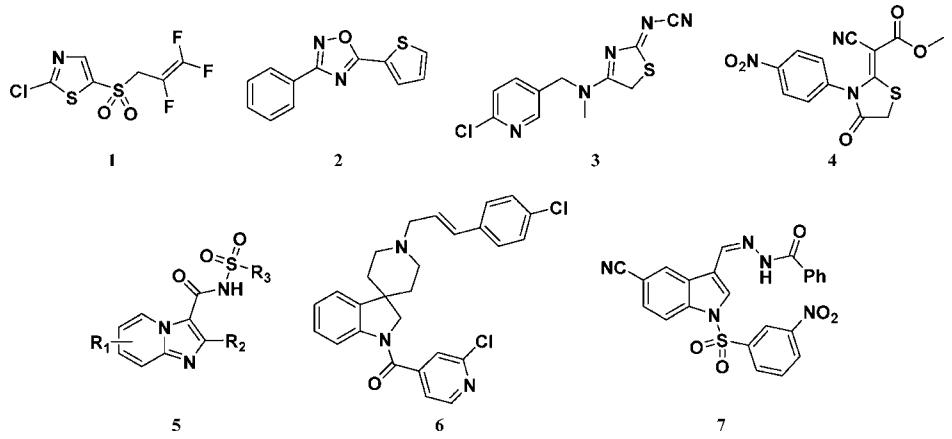

Figure 1. Nematicidal chemicals developed in recent years.

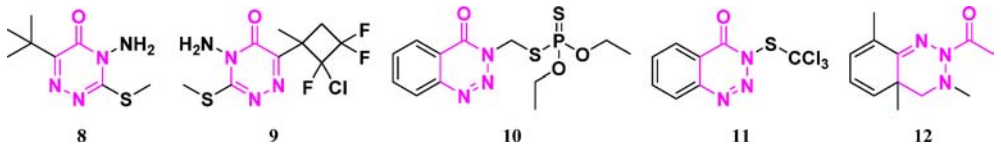

Figure 2. Bioactive agrochemicals containing triazinone skeletons.

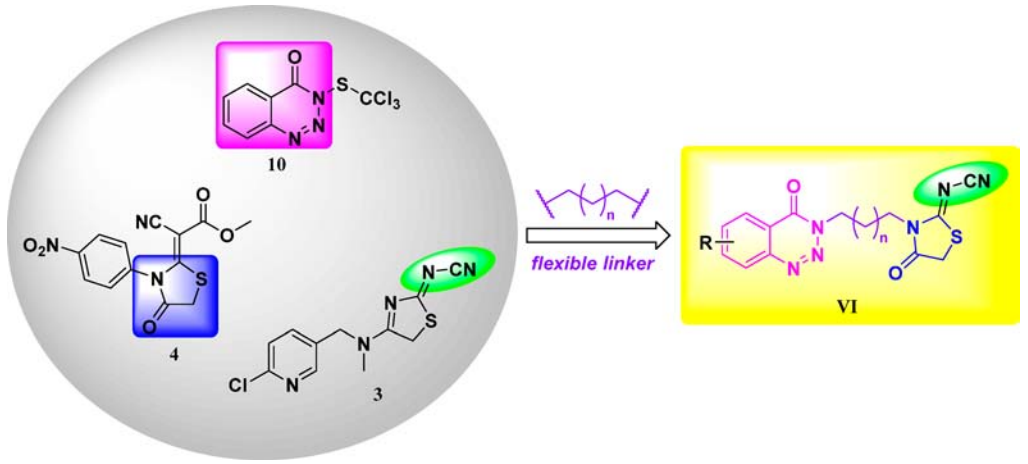

Figure 3. Design of title compounds (**VI-1**–**VI-23**).

and compound **12** had certain nematicidal activity against *Caenorhabditis elegans*.[31] However, little work has been performed on nematicidal 1,2,3-benzotriazin-4-one derivatives against plant-parasitic nematodes.

During the design of 1,2,3-benzotriazin-4-one derivatives, we found that thiazolidin-4-one compounds exhibited good inhibitory activities against *M. incognita*,[20] and the neonicotinoid derivative **3** had significant nematicidal activity against *M. incognita* at the concentration of 20.0 mg L^{-1}.[19] Hence, we attempted to introduce 2-cyanoiminothiazolidin-4-one moieties into the 1,2,3-benzotriazin-4-one structure, while the active fragment of compound **3** was also considered, aiming to obtain more active compounds against *M. incognita* (Figure 3).

In the present study, we reported for the first time 1,2,3-benzotriazin-4-one derivatives containing 2-cyanoiminothiazolidin-4-one moieties and their *in vivo* and *in vitro* biological activities against *M. incognita*. We also discussed the relationship between structure and nematicidal activity preliminarily and tried to illuminate the mechanism of our compounds against nematodes.

MATERIALS AND METHODS

Chemicals. Anthranilic acids (**I-1**–**I-13**) and triphosgene were purchased from Shanghai Darui Fine Chemicals Co., Ltd. Ammonium carbonate, sodium nitrite, hydrochloric acid, potassium hydroxide, potassium carbonate, anhydrous sodium sulfate, and all solvents were purchased from Shanghai Lingfeng Chemical Reagent Co., Ltd. *N*-Cyanodithiocarbonimidate, 1,2-dibromoethane, 1,3-dibromopropane, 1,4-dibromobutane, 1,5-dibromopentane, 1,6-dibromohexane, and potassium iodide were purchased from Shanghai Aladdin Chemistry Co., Ltd. All reagents and solvents were of reagent grade without further purification.

Instrumental Analysis. Analytical thin-layer chromatography (TLC) was performed on precoated glass plates (silica gel 60 F_{254}), visualizing the spots by an ultraviolet (UV) lamp (254 nm). All melting points were determined on a Büchi melting point B540 apparatus (Büchi Labortechnik AG, Flawil, Switzerland) and are uncorrected. ^{1}H, ^{13}C, and ^{19}F nuclear magnetic resonance (NMR) spectra were recorded in DMSO-d_6 on a Bruker AM-400 (400 MHz) spectrometer at ambient temperature. Chemical shifts are reported in δ (parts per million) values, with tetramethylsilane (TMS) as the internal standard. Coupling constants (J) are reported in hertz. High-resolution mass spectra (HRMS) were recorded under an electrospray

ionization condition on a Waters Micromass liquid chromatography−time of flight (LC−TOF) spectrometer.

General Procedures. *Synthesis of Isatoic Anhydrides*[32] ***(II-1−II-13)***. A mixture of anthranilic acid (**I-1−I-13**, 40 mmol) and tetrahydrofuran (THF, 100 mL) was stirred at −10 °C for 30 min. Then, a solution of triphosgene (BTC, 40 mmol) in THF (20 mL) was added dropwise to the above mixture. After that, the mixture was stirred for 1 h from −10 to −5 °C, followed by 18 h at room temperature. The solvent was removed under reduced pressure, and anhydrous ether (150 mL) was added to the obtained residue with vigorous stirring. The precipitate was collected by filtration, washed with anhydrous ether, and dried to afford compounds **II-1−II-13** in yields of 85−95%.

Synthesis of Anthranilamides[33] ***(III-1−III-13)***. A suspension of isatoic anhydride (**II-1−II-13**, 35 mmol), ammonium carbonate (140 mmol), and 1,4-dioxane (150 mL) was heated at 60 °C. After stirring for 5−8 h, the reaction mixture was cooled to room temperature and evaporated under reduced pressure, and then water (200 mL) was added to the residue, which was extracted with EtOAc (80 mL × 3). The organic layer was washed with brine (80 mL), dried over anhydrous Na_2SO_4, and concentrated to give compounds **III-1−III-13** in yields of above 73−94%.

Synthesis of 1,2,3-Benzotriazin-4-ones[34] ***(IV-1−IV-13)***. A solution of sodium nitrite (4.14 g, 60 mmol) in 0.5 N HCl (240 mL) was stirred at 0 °C for 20 min. Then, anthranilamide (**III-1−III-13**, 30 mmol) dissolved in *N*,*N*-dimethylformamide (DMF, 15 mL) was added dropwise to the above solution for 40 min. After another 1 h of stirring at 0 °C, 30% aqueous ammonia was added slowly to adjust the pH to 10.0. The reaction mixture was allowed to stir vigorously for 15 min and then reacidified to pH 2.0. After stirring for 30 min, the precipitated product was filtered off with suction, washed with water (200 mL), and dried to afford compounds **IV-1−IV-13** in yields of 84−92%.

Synthesis of Potassium Salt of 2-Cyanoimino-4-oxothiazolidine.[35] A stirring mixture of dimethyl *N*-cyanodithiocarbonimidate (11.68 g, 80 mmol), ammonium carbonate (4.22 g, 44 mmol), and EtOH (120 mL) was heated at 60 °C for 3 h. To this, methyl thioglycolate (7.15 mL, 80 mmol) and 50% KOH (aqueous, 8.96 g, 80 mmol) were added separately in one portion. The reaction mixture was heated to reflux for 5 h and then cooled to room temperature. The precipitate was collected by filtration, washed with cold EtOH, and dried to give the desirable potassium salt as a light yellow solid, with a yield of 73%.

Synthesis of 3-Bromoalkyl-1,2,3-benzotriazin-4-ones[36] ***(V-1−V-23)***. A stirring suspension of 1,2,3-benzotriazin-4-one (**IV-1−IV-13**, 6 mmol), dibromoalkane (30 mmol), potassium carbonate (1.66 g, 12 mmol), and acetone (50 mL) was refluxed for 5−8 h and then cooled to room temperature. The reaction mixture was evaporated under reduced pressure, and water (100 mL) was added to the residue, which was extracted with CH_2Cl_2 (50 mL × 2). The organic layer was dried over anhydrous Na_2SO_4, concentrated, and purified with flash chromatography on silica gel, eluting with petroleum ether (60−90 °C)/EtOAc to afford compounds **V-1−V-23** in yields of 46−62%.

General Synthetic Procedure for Title Compounds ***(VI-1−VI-23)***. To a mixture of compound **V** (2 mmol), potassium iodide (0.332 g, 2 mmol), and DMF (10 mL) was added potassium salt of 2-cyanoimino-4-oxothiazolidine (0.358 g, 2 mmol), and then the mixture was stirred at 100 °C. The reaction process was monitored by TLC. After the complete consumption of compound **V**, the reaction was cooled to room temperature. The solvent was removed under reduced pressure, and water (50 mL) was added to the residue, which was extracted with CH_2Cl_2 (30 mL × 2). The organic layer was dried over anhydrous Na_2SO_4, concentrated and purified with flash chromatography on silica gel, eluting with petroleum ether (60−90 °C)/EtOAc to afford compounds **VI-1−VI-23**. The data of compounds **VI-1−VI-10** are shown as follows, whereas data of compounds **VI-11−VI-23** are deposited in the Supporting Information.

Assay of Nematicidal Activity. The second-stage juveniles (J2) of *M. incognita* used in all tests were cultured by Huzhou Modern Agricultural Biotechnology Innovation Center, Chinese Academy of Sciences, China.

In Vivo. All compounds (**VI-1**−**VI-23**) were dissolved with DMF and diluted with distilled water to obtain series concentrations of 40.0, 25.0, 10.0, 5.0, and 1.0 mg L^{-1} for bioassays. The final concentration of DMF in each treatment never exceeded 1% (v/v). The 1-week-aged cucumber seedlings were replanted in sterilized sand in test tubes (one seedling per test tube; tube size, 20 × 250 mm), and the roots of each seedling were treated with 3 mL of test solution. Then, approximately 2000 living J2 nematodes were inoculated into the rhizosphere sand of each host plant. Fenamiphos and avermectin (B1) at concentrations of 5.0 and 1.0 mg L^{-1} served as a positive control, and the negative control group was prepared in the same way but lacked the tested compound. Distilled water without nematodes served as the blank control. Each treatment was replicated 4 times, and the experiment was repeated 3 times. All of the above test tubes were incubated at 20−25 °C for 20 days, with 10 h in the daylight and 14 h in the dark per day. The number of root knots in each test tube was counted and recorded as a score. The inhibition rate on J2 of *M. incognita* was calculated by comparison to the negative control group.

$$\text{inhibition rate (\%)} = [(\text{score of negative control} - \text{score of treatment})/(\text{score of negative control})] \times 100$$

Scoring criteria: 0, 0−5 knots; 5, 6−10 knots; 10, 11−20 knots; and 20, more than 20 knots.

In Vitro. Pure compounds (**VI-1**−**VI-23**) were dissolved in DMF and diluted with distilled water to obtain stock solutions of double the treatment concentration. Then, 2 mL of J2 aqueous suspension containing approximately 200 living nematodes was added to a 6 cm diameter Petri dish and treated with 2 mL of the above solution, meanwhile providing series concentrations of 50.0, 25.0, 10.0, 5.0, and 1.0 mg L^{-1}. The final concentration of DMF in each treatment never exceeded 1% (v/v). Avermectin (B1) at the above same treatment concentrations served as a positive control, and the negative control group was prepared in the same way but lacked the tested compound. Distilled water served as a blank control. All of the above test dishes were covered with the laboratory parafilm to avoid the possible evaporation or pollution. Each treatment was incubated at 25 °C for 24 h and had three repetitions. Nematodes in each test dish were collected after washing in sterile water through a 500-mesh sieve, and finally, the activities of tested compounds were monitored under a microscope by recording the death rates of tested nematodes. Nematodes that did not move when prodded with a needle were considered to be dead. The LC_{50} values of tested compounds were calculated using the probit method.

RESULTS AND DISCUSSION

Synthesis. Starting from anthranilic acids (**I-1**−**I-13**), the desired isatoic anhydrides (**II-1**−**II-13**) were readily prepared via the annulation reaction with BTC.[32] As shown in Figure 4, various substituents at nearly every position of the benzene ring were well-tolerated, except 5-NO_2 and 8-NO_2. 5-NO_2 or 8-NO_2 isatoic anhydride could not be obtained from the corresponding anthranilic acid because of the possible formation of an intramolecular hydrogen bond between NO_2 and adjacent carboxyl or amino. Subsequently, **II-1**−**II-13** reacted with ammonium to afford anthranilamides[33] (**III-1**−**III-13**). Notably, ammonium carbonate was used here as an ammonium source, which made synthetic manipulation relatively easier. 1,2,3-Benzotriazin-4-ones (**IV-1**−**IV-13**) were synthesized from compounds **III-1**−**III-13** through the combination of diazotization, nucleophilic addition, and cyclization in one pot.[34]

The synthesis of 3-bromoalkyl-1,2,3-benzotriazin-4-ones (**V-1**−**V-13**) was carried out through *N*-alkylation of compounds **IV-1**−**IV-13** at the 3 position, using dibromoalkane as an alkylation agent[36] (Figure 6). To minimize the "bis-" product, 5 equiv of dibromoalkane was necessary, owing to the existing two reaction sites of dibromoalkane. Potassium salt of 2-cyanoimino-4-oxothiazolidine was prepared following the procedure reported in the literature[35] (Figure 5). The

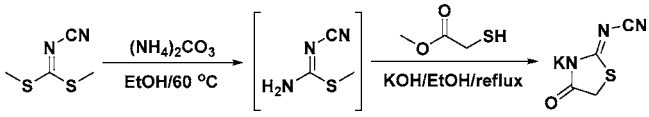

Figure 5. Synthetic route of potassium salt of 2-cyanoimino-4-oxothiazolidine.

potassium salt of 2-cyanoimino-4-oxothiazolidine has higher nucleophilic activity than 2-cyanoimino-4-oxothiazolidine, which promoted the nucleophilic substitution. Then, the title compounds (**VI-1**−**VI-23**) were synthesized by the reaction of 3-bromoalkyl-1,2,3-benzotriazin-4-ones with potassium salt of 2-cyanoimino-4-oxothiazolidine in the presence of potassium iodide (Figure 6). The structures of the title compounds were well-characterized by ^{1}H NMR, ^{13}C NMR, and HRMS (ESI).

Nematicidal Activity. As shown in Table 1, the *in vivo* nematicidal activities of title compounds (**VI-1**−**VI-23**) against

[a]pt = phytotoxic. [b]FM = fenamiphos. [c]AVM = avermectin.

M. incognita were initially evaluated at the concentration of 40.0 mg L^{-1}. Some compounds, such as **VI-1**, **VI-3**, **VI-6**, and **VI-7**, showed high nematicidal activities with inhibition rates of 100%, whereas others were severely toxic to plants with a symptom of root rot. To minimize the phytotoxicity of test compounds, a lower treatment concentration was tried. When treated at the concentration of 25.0 mg L^{-1}, the phytotoxicity was significantly improved and quite a few compounds exhibited moderate to high nematicidal activities. Among them, compounds **VI-2**, **VI-5**, **VI-8**, **VI-14**, **VI-20**, and **VI-23** were 100% inhibitory against *M. incognita*. When the treatment concentration was reduced further to 10.0 mg L^{-1}, all compounds were nematicidal without phytotoxicity and compounds **VI-2**, **VI-9**, **VI-14**, **VI-20**, and **VI-23** still keep 100% inhibitory activities.

On the basis of the *in vivo* data at 10.0 mg L^{-1} in Table 1, it was found that compounds **VI-2** (7-Cl; $n = 1$), **VI-9** (6-NO_2; $n = 1$), **VI-14** (7-Cl; $n = 0$), **VI-20** (7-NO_2; $n = 4$), and **VI-23** (7-OCH_3; $n = 4$) still exhibited 100% inhibitory rate. However, we did not observe the obvious trend with electron-withdrawing or -donating substituents. When Cl, NO_2, and OCH_3 were located at the 7 position (**VI-2**, **VI-14**, **VI-19**, **VI-20**, and **VI-23**), CF_3 and NO_2 were located at the 6 position (**VI-5** and **VI-9**), or Br was located at the 5 position (**VI-8**) on the 1,2,3-benzotriazin-

DOI: 10.1021/acs.jafc.5b01762
J. Agric. Food Chem. 2015, 63, 6883–6889

4-one ring, compounds with proper linkers displayed >90% inhibitory activity. It indicated that high inhibitory activity seemed not to depend upon the type of substituents on the 1,2,3-benzotriazin-4-one ring. When the linker was fixed as a three-carbon chain, the activity of compound **VI-2** (7-Cl) was the highest among the compounds (**VI-1**−**VI-13**), considering that compound **VI-9** (6-NO_2) had phytotoxicity at 25.0 mg L^{-1}. Moreover, for other compounds with a three-carbon chain, it showed that compound **VI-8** (5-Br) had higher activity than compounds **VI-3** (8-Br) and **VI-10** (7-Br), and compounds **VI-6** (8-CH_3), **VI-7** (8-OCH_3), and **VI-9** (6-NO_2) were more active than compounds **VI-11** (6-CH_3), **VI-13** (7-OCH_3), and **VI-12** (7-NO_2), respectively. Thus, it seemed that the inhibitory activity was affected by the co-effect of substituent type and substituted position on the premise that the length of the flexible linker was fixed.

Furthermore, when the NO_2 or OCH_3 group was fixed at the 7 position, the effect of linker length on inhibitory activity was investigated. It was observed that the activities of compounds increased with the increasing linker length, except compound **VI-13**. However, for Cl at the same substituted position, the activities did not present a certain regularity with the increasing linker length. Thus, it also suggested that inhibitory activities did not always have positive correlation with linker length. From the results above, it can be concluded preliminarily that the inhibitory activity of our synthesized compounds was influenced by the combination of substituent type, substituted position, and linker length, not relying on only one factor. It is different from the results reported by Che et al. and Li et al.[37,38] Che et al. reported that a shorter chain length of R^3 and electron deficiency of the indolyl ring were favorable to nematicidal activity,[37] while Li et al. reported that electron richness of the benzyl ring was favorable to nematicidal activity.[38]

To determine the strength of activity of title compounds, the nematicidal evaluation of the compounds with >90% inhibitory activities at 10.0 mg L^{-1}, such as **VI-2**, **VI-5**, **VI-8**, **VI-9**, **VI-14**, **VI-19**, **VI-20**, and **VI-23**, was continued at lower concentrations of 5.0 and 1.0 mg L^{-1}; however, it was found that the inhibitory activities decreased very quickly with the decreasing of the treatment concentration. All of the inhibitory rates were less than 41% at these two concentrations. The reason why the inhibitory rates decreased so quickly still needs to be investigated further.

In addition, the *in vitro* nematicidal evaluation of compounds **VI-1**−**VI-23** against *M. incognita* was conducted. As a positive control, avermectin had the LC_{50} of 1.0 ± 0.1 mg L^{-1}. Unexpectedly, all synthesized compounds showed only <5% corrected mortalities at 50.0 mg L^{-1} (not listed here), which indicated that these compounds had no direct inhibition against *M. incognita*. The significant difference between *in vivo* and *in vitro* data attracted our attention. One possible reason is that these compounds could not kill the nematodes directly, like some nervous toxicants, such as avermectin, but affect the movement and host finding of nematodes,[39,40] or they could change the rhizosphere microbiology of the plant, strengthening antagonism against nematodes,[41] somewhat like the DiTera nematicide. Further research is still needed to verify the possible mechanism.

In conclusion, a series of novel 1,2,3-benzotriazin-4-one derivatives bearing 2-cyanothiazolidin-4-one were synthesized, and both *in vivo* and *in vitro* nematicidal activities against *M. incognita* were evaluated. Despite no direct inhibition *in vitro*, some of them exhibited good *in vivo* inhibitory activities at 10.0 mg L^{-1}, which implied that 1,2,3-benzotriazin-4-one is a potential active structure worth studying further.

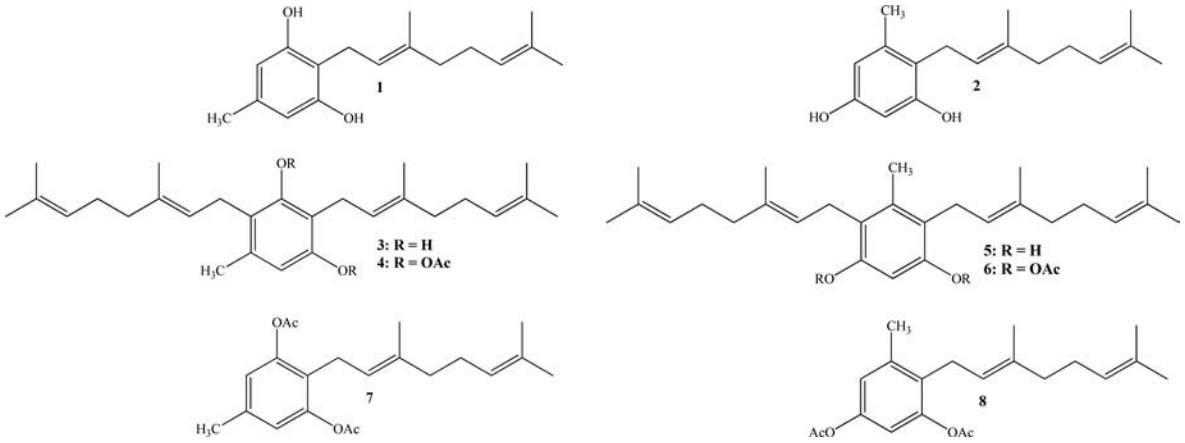

Figure 1. Structure of geranylphenols/diacetates synthesized in this work and tested against *B. cinerea*.

PPO), were used. The latter is a commercial polymer known as Pluronic F-127. In this work, we report the enhancement of antifungal activity of geranylphenols when they are solubilized in polymer micelles. In addition, the synthesis and structural determination of the studied compounds are discussed.

MATERIALS AND METHODS

Chemicals. Unless otherwise stated, all chemical reagents purchased (Merck, Darmstadt, Germany, or Aldrich, St. Louis, MO) were of the highest commercially available purity and were used without previous purification. Silica gel (200−300 mesh, Merck) was used for column chromatography (CC) and silica gel plates HF_{254} for thin-layer chromatography (TLC). TLC spots were detected by heating after spraying with 25% H_2SO_4 in H_2O.

Spectroscopies. Infrared (IR) spectra (32 scans per sample) were recorded as thin films in a Fourier transform infrared (FTIR) Nicolet 6700 spectrometer (Thermo Scientific, San Jose, CA), and wavelengths are reported in cm^{-1}. Low-resolution mass spectra were recorded on an Agilent 5973 spectrometer (Agilent Technologies, Santa Clara, CA) at 70 eV ionizing voltage in a DB-5 m, 30 m × 0.25 mm × 0.25 μm column, and data are given as m/z (percent relative intensity). High-resolution mass spectra were recorded on a LTQ Orbitrap XL spectrometer (Thermo Scientific, San Jose, CA) by applying a voltage of 1.8 kV in the positive ionization mode and 1.9 kV in the negative ionization mode. The spectra were recorded using full-scan mode, covering a mass range from m/z 100 to 1300. The resolution was set to 50 000, and maximum loading time for the ion cyclotron resonance (ICR) cell was set to 250 ms. Nuclear magnetic resonance (NMR) experiments were performed on a Bruker Avance 400 digital NMR spectrometer (Bruker, Rheinstetten, Germany), operating at 400.1 MHz for ^1H and 100.6 MHz for ^{13}C. ^1H, ^{13}C, ^{13}C distortionless enhancement by polarization transfer (DEPT-135), selective gradient-selected one-dimensional (1D) ^1H nuclear Overhauser effect spectrometry (NOESY), gradient-selected two-dimensional (2D) heteronuclear single-quantum coherence (HSQC), and gradient-selected 2D heteronuclear multiple-bond correlation (HMBC) spectra were recorded in $CDCl_3$ solutions and are referenced to the residual peaks of $CHCl_3$ at δ = 7.26 and 77.0 ppm for ^1H and ^{13}C, respectively. Chemical shifts are reported in δ parts per million (ppm), and coupling constants (J) are given in hertz.

Dynamic Light Scattering (DLS). Aqueous solutions of PEO−PCL and Pluronic F-127 (1 mM) in the absence and presence of geranyl derivatives (100 mM) were thermostated at 25 °C, and DLS measurements were performed using a Zetasizer Nano ZS (Malvern Instruments, Malvern, U.K.) equipped with a He−Ne laser (633 nm, 4 mW).

Fluorescence Probing. Steady-state fluorescence spectra of pyrene were recorded using a Horiba Jobin Yvon Fluoromax 4 fluorometer by exciting at 337 nm. All emission spectra were corrected for detector response using a correction curve supplied by the instrument manufacturer. The ratio I_1/I_3 corresponds to the ratio of intensities of peak one (λ = 372 nm) to peak three (λ = 384 nm), whereas the ratio I_M/I_E corresponds to the ratio of intensities of the monomer band to the excimer band (λ = 450 nm).

Synthesis of Geranyl Derivatives. *(E)-2-(3,7-Dimethylocta-2,6-dienyl)-5-methylbenzene-1,3-diol (**1**), (E)-4-(3,7-Dimethylocta-2,6-dienyl)-5-methylbenzene-1,3-diol (**2**), 2,4-Bis((E)-3,7-dimethylocta-2,6-dienyl)-5-methylbenzene-1,3-diol (**3**), and 4,6-Bis((E)-3,7-dimethylocta-2,6-dienyl)-5-methylbenzene-1,3-diol (**5**).* $BF_3{\cdot}OEt_2$ (0.46 g, 3.2 mmol) was slowly added dropwise, at room temperature and under a N_2 atmosphere, to a stirred solution of orcinol (6.1 g, 49 mmol) and geraniol (7.55 g, 49 mmol) in acetonitrile (2 mL) saturated with $AgNO_3$. After the addition was completed, the stirring was continued for 48 h. The end of the reaction was verified by TLC, and then the mixture was poured onto crushed ice (approximately 30 g) and salt (NaCl) vacuum filtration and extracted with EtOAc (3 × 20 mL). The organic layer was washed with $NaHCO_3$ (15 mL, 5%) and water (2 × 15 mL), dried over Na_2SO_4, and filtered. The solvent was evaporated under reduced pressure. The crude was redissolved in CH_2Cl_2 (5 mL) and chromatographed on silica gel with petroleum ether/EtOAc mixtures of increasing polarity (0:20 → 6:14). Five fractions were obtained: fraction I, 1554.8 mg of dark yellow viscous oil (9.9% yield, compound **3**); fraction II, 1281.8 mg of yellow viscous oil (12.5% yield, compound **1**); fraction III, 955.3 mg of dark yellow viscous oil (6.1% yield, compound **5**); fraction IV, 415.4 mg of dark yellow viscous oil (mixture of compounds **2** and **5**); and fraction V, 2816.2 mg of yellow viscous oil (27.6% yield, compound **2**). Unreacted orcinol (3.38 g) was recovered. Spectroscopic data of compounds **1** and **2** were consistent with those reported in the literature.[29−31] Spectroscopic data are given in the Supporting Information.

Acetylation of Geranylated Phenols. Geranylated phenols were acetylated by standard acetylation using Ac_2O and 4-dimethylaminophenol (DMAP) in CH_2Cl_2. In a typical reaction, Ac_2O (1.08 g, 10.6 mmol) is added to a solution of a geranylated phenol (0.284 mmol), DMAP (3.0 mg), and pyridine (1.0 mL) in dichloromethane (10−20 mL). The end of the reaction is verified by TLC (1.5 h), and then the mixture is extracted with EtOAc (2 × 20 mL). The organic layer is washed with 5% $KHSO_4$ (2 × 10 mL) and water (2 × 10 mL), dried over Na_2SO_4, and filtered. The solvent is evaporated under reduced pressure. The crude is redissolved in CH_2Cl_2 (5 mL) and chromatographed on silica gel with petroleum ether/EtOAc mixtures of increasing polarity (19.8:0.2 → 18.4:1.6).

*2,4-Bis((E)-3,7-dimethylocta-2,6-dienyl)-5-methyl-1,3-phenylene Diacetate (**4**).* Compound **4** was obtained by standard acetylation of compound **3** (170 mg, 0.429 mmol) with Ac_2O (1.0 mL), DMAP (3.0 mg), and pyridine (1.0 mL) in dichloromethane (15 mL). Compound **4** was obtained as dark yellow viscous oil (185 mg, 90.5% yield). Spectroscopic data are given in the Supporting Information.

*4,6-Bis((E)-3,7-dimethylocta-2,6-dien-1-yl)-5-methyl-1,3-phenylene Diacetate (**6**).* Compound **6** was obtained by standard acetylation

DOI: 10.1021/acs.jafc.5b01920
J. Agric. Food Chem. 2015, 63, 6890−6896

of compound **5** (245 mg, 0.618 mmol) with Ac_2O (1.0 mL), DMAP (3.0 mg), and pyridine (1.0 mL) in dichloromethane (20 mL). Compound **6** was obtained as dark yellow viscous oil (267.5 mg, 89.8% yield). Spectroscopic data are given in the Supporting Information.

*(E)-2-(3,7-Dimethylocta-2,6-dienyl)-5-methyl-1,3-phenylene Diacetate (**7**).* Compound **7** was obtained by standard acetylation of compound **1** (74 mg, 0.284 mmol) with Ac_2O (1.0 mL), DMAP (2.0 mg), and pyridine (1.0 mL) in dichloromethane (10 mL). Compound **7** was obtained as dark yellow viscous oil (93.3 mg, 96.4% yield). Spectroscopic data are given in the Supporting Information.

*(E)-4-(3,7-Dimethylocta-2,6-dienyl)-5-methyl-1,3-phenylene Diacetate (**8**).* Compound **8** was obtained by standard acetylation of compound **2** (362 mg, 1.39 mmol) with Ac_2O (1.0 mL), DMAP (3.0 mg), and pyridine (1.0 mL) in dichloromethane (20 mL). Compound **8** was obtained as dark yellow viscous oil (444.6 mg, 92.8% yield). Spectroscopic data are given in the Supporting Information.

Structure Determination. Spectroscopic evidence of double substitution on the aromatic nucleus by geranyl chains in compound **3** was established from the ^{1}H NMR spectrum by the following observations: a unique Ar−H signal at 6.30 ppm (s, 1H, H-6), four olefinic protons at 5.32 ppm (t, J = 6.9 Hz, 1H, H-2′), 5.19 ppm (t, J = 6.6 Hz, 1H, H-2″), 5.11 ppm (t, J = 6.6 Hz, 2H, H-6′ and H-6″), and two doublet signals at 3.46 ppm (J = 6.9 Hz, 2H, H-1′) and 3.35 ppm (J = 6.6 Hz, 2H, H-1″). Finally, the complete determination of the asymmetrical structure was established by 2D HMBC and selective 1D NOESY experiments. The major 2D HMBC correlations confirming the structure of compound **3** are $^2J_{H-C}$ coupling between H-1′ and C-2 (δ_C = 111.5 ppm), $^3J_{H-C}$ coupling of H-1′ with C-3 and C-1 (δ_C = 153.4 and 152.2 ppm), respectively, $^2J_{H-C}$ coupling of H-1″ with C-4 (δ_C = 118.1 ppm), and $^3J_{H-C}$ coupling of H-1″ with C-5 (δ_C = 135.1 ppm) and C-3 (δ_C = 153.4 ppm) (Figure S1 of the Supporting Information). From selective 1D NOESY experiments, the *E* geometry in the C-2′−C-3′ and C-2″−C3″ double-bond position of the geranyl chain was established. In this case, the most important correlations are between H-1′ with the methyl group in the C-3′ position (δ_H = 1.86 ppm) and with both OH groups (δ_H = 5.50 and 5.44 ppm), whereas H-1″ correlates with CH_3−Ar (δ_H = 2.25 ppm), CH_3−C3″ (δ_H = 1.84 ppm), and OH group (δ_H = 5.50 ppm) (Figure S2 of the Supporting Information).

A similar spectroscopic analysis was performed to determine the structure of compound **5**. Spectroscopic evidence of double substitution on the aromatic nucleus by geranyl chains in compound **5** was obtained from the ^{1}H NMR spectrum through the following observations: a unique Ar−H signal at 6.25 ppm (s, 1H, H-6), four olefinic protons at 5.11 ppm (t, J = 6,4 Hz, 2H, H-2′), 5.05 ppm (t, J = 6.6 Hz, 2H, H-6′), and a unique doublet signal at 3.33 ppm (d, J = 6.6 Hz, 4H, H-1′). Finally, the complete determination of the symmetrical structure was established by 2D HMBC and selective 1D NOESY experiments. The main 2D HMBC correlations used to confirm the structure of compound **5** were a $^2J_{H-C}$ coupling of H-1′ (δ_H = 3.33 ppm) with C-4 and C-6 (δ_C = 118.5 ppm) and $^3J_{H-C}$ with C-1 and C-3 (δ_C = 152.9 ppm). The *E* geometry in the C-2′−C-3′ double-bond position of the geranyl chain was established by selective 1D NOESY experiments. The most important spatial correlations were observed between H-1′ with CH_3−Ar (δ_H = 2.07 ppm) and with the CH_3−C-3′ position (δ_H = 1.79 ppm). The main 2D HMBC and 1D NOESY correlations are shown in Figure 2.

The presence of diacetylated derivatives **4** and **6**, obtained by standard acetylation of compounds **3** and **5**, respectively, was confirmed by NMR spectroscopy. The ^{1}H NMR spectrum of compound **4** shows two singlet signals at δ_H = 2.28 ppm (s, 3H, CH_3CO) and 2.26 ppm (s, 6H, CH_3CO and CH_3−Ar), whereas ^{1}H NMR of compound **6** show a singlet signal at δ_H = 2.28 ppm (s, 6H, 2× CH_3CO). Additionally, in the ^{13}C NMR spectrum of compound **6**, two singlet signals at δ_C = 169.2 ppm (2× C═O) and 20.7 ppm (2× CH_3CO) were observed as a result of the symmetry of the molecule.

Finally, the ^{1}H NMR spectrum of symmetric diacetylated derivative **7** shows a singlet signal at δ_H = 2.27 ppm (6H, 2× CH_3CO), whereas in the ^{13}C NMR spectrum, the signal at δ_C = 169.2 ppm (2× C═O) confirms the presence of the diacetylated derivative. On the other hand, the ^{1}H NMR spectrum of diacetylated derivative **8** shows a singlet signal at δ_H = 2.28 ppm (6H, 2× CH_3CO), whereas in the ^{13}C NMR spectrum, two singlet signals are observed at δ_C = 169.3 ppm (C═O) and 169.2 ppm (C═O) as a result of the asymmetry of the molecule, confirming the presence of the diacetylated derivative.

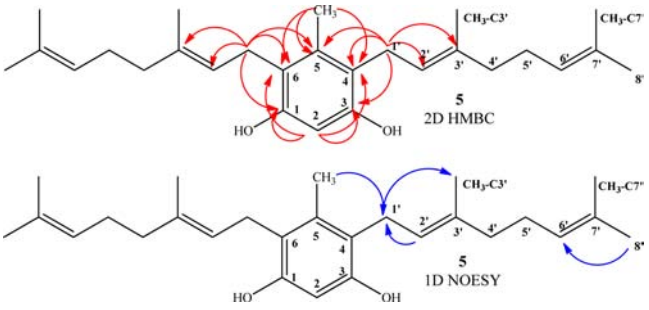

Figure 2. Most important 2D ^{1}H−^{13}C HMBC and selective 1D NOESY correlations for compound **5**.

Poly(ethylene oxide)-*b*-Poly(caprolactone) (PEO−PCL). PEO−PCL was synthesized in bulk by ring-opening polymerization using stannous octanoate (SnOct) as a catalyst. Briefly, freshly distilled ε-caprolactone was added under a nitrogen atmosphere to poly(ethylene oxide) monomethyl ether (Aldrich, M_n = 2000 g/mol). After complete dissolution of PEO, 0.01% of SnOct was added and the flask was heated at 135 °C with constant stirring. After 24 h, the resulting viscous liquid was cooled to room temperature, dissolved in 5 mL of tetrahydrofuran (THF), precipitated into a large excess of cold *n*-hexane, filtered, redissolved in THF, and precipitated in *n*-hexane. The white precipitate was collected by filtration and vacuum-dried at 35 °C for 2 days. Yield = 94%. Absolute molecular weight was measured using matrix-assisted laser desorption/ionization−time-of-flight (MALDI−TOF) (MW = 3409 g/mol). The data indicate that the degree of polymerization of ε-caprolactone is 14, and therefore, the resulting block copolymer composition is PEO_{43}-*b*-PCL_{14}.

Preparation and Characterization of Polymer Micelles. Polymer micelles were prepared by direct dissolution of block copolymers in water at a concentration well above the critical micelle concentration (cmc) (1 mM). The cmc was determined by a photophysical technique that consists of measuring the ratio I_M/I_E of pyrene fluorescence as a function of the polymer concentration. The size distributions of polymeric micelles were determined by DLS.

Fungal Isolate and Culture Condition. In this study, a strain of *B. cinerea* isolated from a naturally infected grape (*Vitis vinifera*) was used in all experiments. This strain was maintained on potato dextrose agar (PDA) medium (Difco, Detroit, MI) at 4 °C. The inoculum of the pathogen was grown on PDA in a photoperiod of 16 h light/8 h dark at 23 °C for 5 days.

Antifungal Activity. To determine the antifungal activity of geranyl derivatives, two different stock solutions were prepared for each compound. Homogeneous stock solutions were formulated by dissolving 20−40 mg of each compound in 500 μL of ethanol and then diluting in water (5 mL) to obtain a 5000 ppm concentration. On the other hand, micro-heterogeneous solutions were obtained using the emulsion method. Briefly, aliquots (100 μL) of each compound dissolved in dichloromethane were added to 10 mL of an aqueous polymer solution (1 mM). After an emulsion has been formed, the organic solvent is eliminated by heating and sonication. In this process, compounds **1**−**8** are incorporated into the hydrophobic micelle core, reaching a concentration of 0.1 M. Before their application to Petri plates, these solutions are diluted to 650−1250 ppm but keeping the polymer concentration constant (1 mM).

The radial growth rate assay on PDA medium was used to determine the antifungal activity of test compounds.[32,33] Test compounds, in ethanol/water solution or aqueous polymer solution, were added to Petri plates containing PDA medium at 50 °C to give 50, 150, and 250 ppm. When the medium was almost solidified, 4 mm

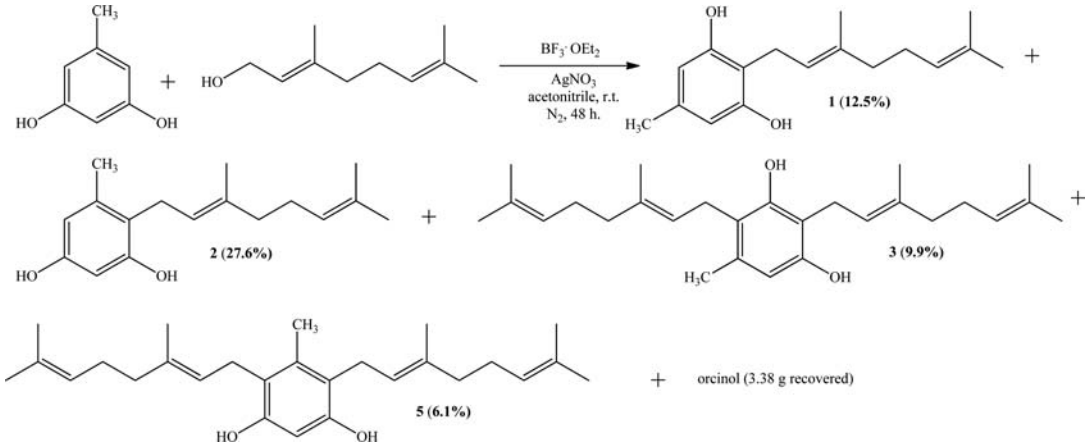
J. Agric. Food Chem. 2015, 63, 6890−6896

Scheme 1. Synthesis of Compounds 1−3 and 5



diameter disks of fungus cut were placed in the center of the plate. Negative controls (C−) are used in the corresponding stock solution with pure solvent (1% ethanol) or polymer solution (1 mM PEO−PCL or Pluronic F-127). Captan, a commercial fungicide, is used as the positive control (C+) at the same concentrations and conditions of test compounds. After incubation by 48 h (ethanol) and 72 h (polymer) at 23 °C under a photoperiod of 16 h light/8 h dark, diameters of colonies were measured with a ruler and the inhibition percentage was calculated as the average of three replicas compared to the negative control.

RESULTS AND DISCUSSION

The direct geranylation of orcinol using the acetonitrile/BF_3·Et_2O/$AgNO_3$ system leads to compounds **1** and **2** with 12.5 and 27.6% yields, respectively, which are almost identical to those reported for the standard conditions, i.e., the dioxane/BF_3·Et_2O system.[29] However, with the modified method, two additional digeranyl derivatives **3** and **5** were identified and isolated from the reaction products with 9.9 and 6.1% yields, respectively.

The synthesis of compounds **1**−**3** and **5** is described in Scheme 1.

It should be mentioned that incorporation of two geranyl chains to the aromatic ring has been previously described in the geranylation of methoxyphenols using ether as the solvent.[13] However, the reaction of 2,4,5-trimethoxyphenol with geraniol in dioxane follows a completely different reaction pathway, and no digeranylated phenols were obtained.[17] On the other hand, diprenyl phenols have also been obtained in the reaction between dihydroxybenzenes and 1,3,5-trihydroxybenzene with 3-methyl-2-buten-1-ol, using a mixture of ethyl ether/dichloromethane as the solvent.[18] Finally, digeranyl phenols have also been obtained in the geranylation of 1,3,5-trihydroxybenzene using the modified electrophilic aromatic substitution (EAS) reaction.[7] These results emphasize the important role played by solvent in this kind of reaction. Diacetylated derivatives **4** and **6** were obtained by standard acetylation of compounds **3** and **5** with 93.3 and 92.8% yields, respectively. Finally, derivatives **7** and **8** were obtained by standard acetylation of compounds **1** and **3** with 90.5 and 89.8% yields, respectively.

The physical and spectroscopic properties of compounds **1** and **2** were consistent with those previously reported.[11,29,31] The structural determination of new compounds **3**−**6** is described in detail in the Materials and Methods.

Formation of Polymer Micelles. In aqueous solution and at concentrations above the cmc, amphiphilic block copolymers self-aggregate forming spherical micelles. The values of cmc, determined by measuring the ratio I_M/I_E of pyrene fluorescence as a function of the polymer concentration, are 2.7×10^{-6} and 5.5×10^{-5} M for Pluronic F-127 and PEO−PCL, respectively. Thus, to ensure the presence of micelles, a polymer concentration of 1 mM was used in all experiments. The formation of micelles has also been evidenced by DLS measurements, which give the size and size distribution of the formed aggregates. The results shown in Figures 3 and 4

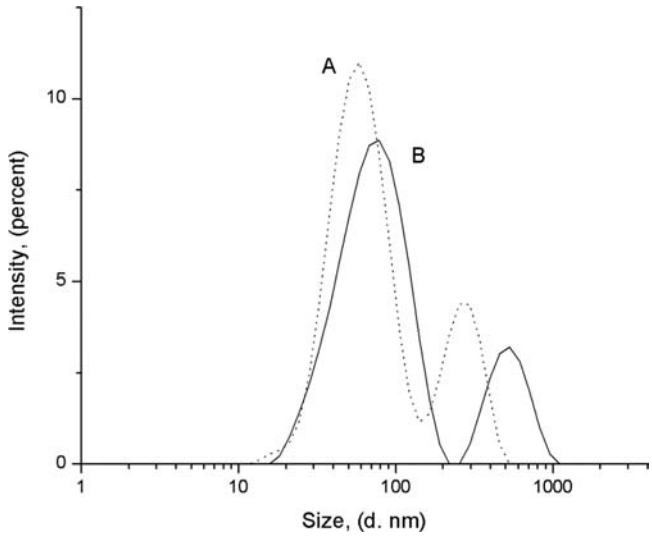


Figure 3. Distribution sizes of aggregates formed by PEO−PCL (1 mM) in the (A) absence and (B) presence of compound **1** (10 mM). DLS measurements were made at 25 °C.

indicate that small micelles and larger aggregates are formed at this polymer concentration. This agrees with previous studies, made with transmission electronic microscopy (TEM), where it has been shown that PEO−PCL forms spherical and elongated aggregates, and the sizes obtained from TEM were consistent with those obtained by DLS.[34,35] Additionally, the inclusion of geranylphenols into the micelles brings about a change in the size distribution. In both cases, the solute induces the formation of stable aggregates with a larger average diameter. This behavior is similar to that reported for solubilization of a family of alkylphenols in Pluronic F-127.[36]

J. Agric. Food Chem. 2015, 63, 6890−6896

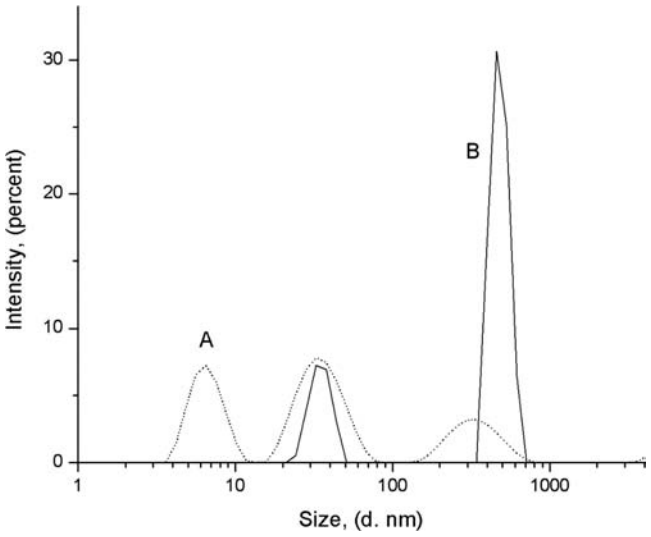

Figure 4. Distribution sizes of aggregates formed by Pluronic F-127 (1 mM) in the (A) absence and (B) presence of compound **1** (10 mM). DLS measurements were made at 25 °C.

The micropolarity of the hydrophobic micelle core was assessed by measuring the ratio I_1/I_3 in the pyrene fluorescence spectrum. It has been shown that this ratio strongly depends upon the polarity of the medium where pyrene is located,[37] and a Py polarity scale has been proposed.[38] The results indicate that the micelle formed by PEO−PCL (I_1/I_3 = 1.13) is much more hydrophobic than that formed by Pluronic F-127 (I_1/I_3 = 1.56). Consequently, nonpolar substrates should be more easily incorporated into the core of PEO−PCL micelles.

Antifungal Activity against *B. cinerea*. The effect of geranylphenols on the mycelial growth of plant pathogen *B. cinerea* was evaluated *in vitro* after 72 h of incubation using the radial growth rate assay with PDA as the medium. The test compounds were added to the incubation media in either homogeneous solution (using 1% ethanol in water as the solvent) or dissolved in an aqueous solution of polymer micelles (1 mM). The inhibitory effect is evaluated as a percentage of inhibition, which is calculated as the ratio of the area of *B. cinerea* in the presence and absence of geranylphenols. The means of three independent assays are summarized in Tables 1 and 2. For comparison, the values of the percentage of inhibition obtained with Captan, a molecule that is widely used to control the growth of *B. cinerea*, are included (measured at the same concentration used to determine the activity of geranylphenols).

Analysis of the results given in Table 1 shows that the inhibitory effect increases with increasing the compound concentration and that the antifungal activity depends upon the chemical structure of geranylphenol derivatives. Thus, monogeranyl phenols **1** and **2** exhibit inhibitory activity similar or slightly lower than that observed for diacetylated compounds (**7** and **8**) at 250 ppm. These results are in line with those reported previously for other series of geranylphenol derivatives[7] and, all together, suggest that the activity is mainly determined by the presence of the geranyl chain. On the other hand, the addition of a second geranyl chain brings about an increase on antifungal activity for all studied compounds (Table 1 compares compounds **3** and **1**, compounds **5** and **2**, compounds **4** and **7**, and compounds **6** and **8**). Compound **4** exhibits the highest inhibitory effect, i.e., 69 and 97% at 150 and 250 ppm, respectively. However, in previous work, it has been found that digeranyl derivatives exhibit lower activities than the corresponding monogeranyl compounds and that their activity strongly depends upon the presence of hydroxyl groups.[7] This structure effect on activity may be attributed to the higher solubility of digeranyl phenols, which would increase the biodisponibility of these compounds. To verify this hypothesis, a study of solubilization into polymer micelles was carried out.

Table 1. Effect of Geranylphenols on Mycelial Growth of *B. cinerea* Measured as a Percentage of Inhibition[a]

	percentage of inhibition on mycelial growth of *B. cinerea* *in vitro*[b]		
compound	50 mg/L	150 mg/L	250 mg/L
1	37	65	82
2	0	25	63
3	25	61	93
4	5	69	97
5	12	56	83
6	11	54	85
7	8	51	82
8	24	55	78
C−[c]	0	0	0
C+[c]	88	94	94

[a]Geranyl phenols were added to the incubation media from a stock solution using ethanol/water (1%) as the solvent. [b]The percentage of inhibition of mycelial growth is based on colony diameter measurements after 48 h of incubation. Each point represents the mean of at least three independent experiments. [c]C− refers to the negative control and corresponds to stock solution with pure solvent (1% ethanol), and C+ refers to the positive control (Captan).

The results given in Table 2 indicate that the inhibitory activity of all test compounds against mycelial growth of *B. cinerea* changes in the presence of micelle-forming polymers. In the case of PEO−PCL, the effect on mycelial growth depends upon the structure of geranyl compounds, i.e., at all studied concentrations, an increase is observed for compounds **2**, and **5**, whereas a decrease in activity was found for the other studied compounds. However, in the presence of Pluronic F-127, the increase in activity is very dramatic, changing from no effect to 80% of inhibition at a low concentration (compare data of compound **2** at 50 mg/L in Tables 1 and 2). This activity is independent of the geranylphenol structure and is almost the same obtained with Captan, the positive control. These results suggest that encapsulation into micelles formed by Pluronic F-127 might improve some properties of the molecules (stability or availability) or might provide new environmental conditions (homogeneous distribution), allowing for an inhibitory activity of test compounds on the growth of *B. cinerea*, even at a lower concentration, such as 50 mg/L.

The structure of the polymer micelle seems to be a determinant factor in the magnitude of the inhibitory effect exhibited by each compound. This effect could be attributed to differences in micellar sizes and polarity of the micellar core. Polymer micelles formed by Pluronic F-127 are smaller and the core is more polar than in micelles formed by PEO−PCL. These physical parameters might affect the distribution coefficients of these compounds between the aqueous phase and the pseudo-micellar phase provided by the block copolymers; i.e., these coefficients should be larger in the presence of micelles formed by PEO−PCL. On the other hand, the release rates of compounds solubilized in these micelles

C−[b]	0	0	0	0	0	0
C+[b]	93	99	99	98	99	99

[a]The percentage of inhibition of mycelial growth is based on colony diameter measurements after 72 h of incubation. Each point represents the mean of at least three independent experiments. [b]C− refers to the negative control and corresponds to aqueous polymer solution (1 mM PEO−PCL or Pluronic F-127), and C+ refers to the positive control (Captan).

should also be lower than in micelles of Pluronic F-127. The direct consequence of these two effects is that nonpolar compounds incorporated into PEO−PCL micelles are less available during the development of mycelial growth halo. A study where these physicochemical parameters are evaluated as a function of the substrate structure is currently being carried out. Additionally, the possibility that polymer micelles penetrate the fungus membrane and releasing of entrapped compounds occurs inside of a fungus cell should also be considered. The proposal of this alternative mechanism of action is based on results that have demonstrated that both polymer micelles can be internalized into cells by endocytosis.[34,39]

The results in Table 2 also show that the activity of all encapsulated test compounds is quite similar to that measured for Captan, a fungicide widely used to protect crops. In addition, an aqueous solution of polymer micelles can be easily applied *in vivo* by simple spraying. These interesting properties turn polymer micelles into very promising systems for control of *B. cinerea* in the field. Obviously, these results should be validated evaluating *in vivo* the biological effect of encapsulated test compounds on plant tissues infected by this fungus. Finally, it is worth mentioning that these polymers are biocompatible and Pluronic F-127 copolymers are listed in U.S. and British Pharmacopoeia as pharmaceutical excipients.

principal entry path of veterinary antibiotics is the application of manure on agricultural fields for fertilization.[9] In addition, the transport of veterinary antibiotics via dust in stables of medicated animals has already been reported.[10]

For FQs used in livestock husbandry, the recommended treatment dose ranges from 2.5 to 10 mg per kg of body weight and day[6,7] and consequently, manure was found to contain considerable amounts of these substances. Up to 61.3 mg kg^{-1} enrofloxacin and 18.8 mg kg^{-1} of its metabolite ciprofloxacin could be detected in feces of chicken.[11] Studies on composting processes of manure revealed that, in contrast to sulfadiazine and chlortetracycline, the FQ ciprofloxacin could not be removed completely from the composting mass.[12] Thus, using manure as fertilizer can lead to an administration of remarkable residues of antibiotics to the soil. An uptake of veterinary antimicrobials by plants used for human consumption has been shown.[7,13] For example, up to 2.8 μg kg^{-1} enrofloxacin could be detected in carrot roots.[7] Furthermore, the occurrence of FQ antibiotic residues in the environment may provide suitable conditions for the selective pressure toward resistant bacteria. Although found in trace levels, the reduction of antibiotics in the environment is required to prevent further selection of (multi)resistances among bacterial pathogens.

Numerous fungal and bacterial species have been shown to be useful in biotransformations of FQ antibiotics.[14−16] Among the degradation pathways used by fungi, esterification, oxidation due to introduction of hydroxyl groups, decarboxylation, addition of formyl or acetyl groups, defluorination, partial loss or complete replacement of the piperazine moiety by an amino group, and formation of conjugates at the piperazine ring or replacing the carboxyl group at C3 have been described.[17−19] Even the mineralization of FQs to CO_2 has been reported for various fungi.[18] Biotransformations of DFX by *Candida lipolytica* and *Penicillium* spp. led to a removal of the substituted piperazine ring.[15] The fungus *Rhizopus arrhizus* metabolized DFX to the *N*-desmethyl metabolite and to danofloxacin *N*-oxide (DFX-O) as presumed by the authors.[15]

In past decades, the formation of *N*-oxides by microorganisms, especially fungi, has been frequently described in metabolism studies not only of enrofloxacin but also of alkaloids, several xenobiotics, and other organic compounds.[18,20−25] For instance, bacterial methane monooxygenase from *Methylococcus capsulatus* and fungal peroxygenase from *Agrocybe aegerita* were reported to catalyze the oxidation of pyridine to pyridine *N*-oxide.[26,27] However, most of these studies did not perform state of the art analysis to confirm the molecular structures of the metabolites and to quantitate their formation during the degradation process.

Thus, the purpose of this study was three-fold: first, to evaluate the potential of the ascomycetous fungus *Xylaria longipes* to transform DFX in liquid media; second, to elucidate the structures of the biotransformation products; and, third, to determine their residual antibacterial activity. With this approach, we demonstrate for the first time that *X. longipes* quantitatively transforms DFX into DFX-O having a very low residual antibacterial activity.

MATERIALS AND METHODS

Microorganism. The ascomycetous fungus *X. longipes* was isolated from a wood trunk in the Schloss Rauischholzhausen Park located near Giessen (Ebsdorfergrund, Germany). The identification of the fungus was performed based on internal transcribed spacer similarity searches using the National Center for Biotechnology Information Blast search program within the GenBank database (http://www.ncbi.nlm.nih.gov/blast/). The fungus is deposited in the fungal culture collection of the Institute of Food Chemistry and Food Biotechnology (Justus Liebig University Giessen, Germany). Stock cultures of *X. longipes* were maintained on 2% malt extract agar (MEA) plates (20 g L^{-1} malt extract, 15 g L^{-1} agar−agar) at 4 °C in a refrigerator.

Chemicals. DFX (CAS Registry No. 112398-08-0, purity ≥ 98.0%) was obtained from Santa Cruz Biotechnology, Inc. (Dallas, TX, USA). For media preparation, malt extract was obtained from Fluka Analytical (St. Gallen, Switzerland); NH_4NO_3 was acquired from Acros Organics (Geel, Belgium); and agar−agar, glucose, KH_2PO_4, and $MgSO_4{\cdot}H_2O$ were purchased from Carl Roth (Karlsruhe, Germany). HPLC grade methanol was obtained from VWR (Darmstadt, Germany), and formic acid and ammonium acetate were acquired from Bernd Kraft (Duisburg, Germany) and Merck (Darmstadt, Germany), respectively. All chemicals were of the highest purity available. High-purity water was prepared in-house with a laboratory water system (Sartorius, Goettingen, Germany) resulting in a specific resistivity of >18 MΩ.

Experimental Procedures. *Biodegradation Experiment.* Inoculation material for submerged cultures was grown on MEA plates at 24 °C for 3 weeks. For preparation of precultures, agar pieces (1 cm diameter) from the leading mycelium edge of the fungus were transferred into 250 mL Erlenmeyer flasks containing 100 mL of malt extract medium (20 g L^{-1} malt extract) previously sterilized at 121 °C for 20 min. For homogenization, an Ultra-Turrax disperser (IKA, Staufen, Germany) was used for 30 s at 9800 rpm. Precultures were incubated in the dark at 24 °C for 7 days on an Orbitron orbital table shaker (150 rpm, Infors HT, Bottmingen, Switzerland). Afterward, the precultures were homogenized (30 s, 9800 rpm) and an aliquot of 4 mL was centrifuged (4000 *g*, 10 min, 4 °C) using sterile 15 mL centrifuge tubes (Greiner Bio-One, Frickenhausen, Germany). The sedimented mycelium was resuspended in 4 mL of sterile water and rinsed three times following the protocol described above. The washed mycelium was resuspended in 4 mL of sterile water and used as inoculum (10% of medium volume) for main cultures. These cultures were grown in 100 mL Erlenmeyer flasks with a final volume of 40 mL using a chemically defined medium (composition per liter: 8.0 g of glucose, 1.5 g of KH_2PO_4, 0.5 g of $MgSO_4{\cdot}H_2O$, 0.1 g of NH_4NO_3, and 1 mL trace element solution according to the method of Fraatz et al.[28] The pH of the medium was adjusted to 6.0 with 1 M NaOH prior to sterilization. DFX was dissolved in water, sterilized (0.22 μm sterile syringe filter, Carl Roth, Karlsruhe, Germany), and added to the main culture to give a final concentration of approximately 20 mg L^{-1}. The main cultures were incubated in the dark at 24 °C for 10 days as described above. During the time course experiments, 1 mL samples were withdrawn at the beginning of the trial (day 0) and after 2, 4, 6, 8, and 10 days. Samples were stored at −20 °C before analyses. Pure medium containing DFX and fungal cultures without DFX were employed as abiotic and biotic controls, respectively. All experiments were conducted in duplicate.

DFX-O Production. For metabolite isolation and characterization, the biodegradation experiment was repeated on a larger scale. Ten 250 mL Erlenmeyer flasks, each containing 100 mL of the chemically defined medium, were inoculated as described above and dosed with sterilized DFX solution to obtain a desired concentration of approximately 50 mg L^{-1}. Cultures were incubated as long as in periodically withdrawn samples analyzed by high-performance liquid chromatography with diode array detection (HPLC-DAD) the maximum peak area of the metabolite could be detected. After separation of the mycelia by filtration and centrifugation, combined supernatants were lyophilized, resuspended in 25 mL of water, and fractionated using a preparative HPLC system (see below).

Analytical Procedures. *HPLC-DAD Analysis of DFX.* The residual concentrations of DFX in main cultures were determined by HPLC-DAD. HPLC was performed using a LaChrom L-7100 low-pressure pump, an autosampler L-7200, and an L-7455 diode array detector combined with D-7000 HSM software (version 4.1, Merck-Hitachi, Darmstadt, Germany). A Hypersil GOLD PFP column (150 × 4.6 mm, 5 μm) (Thermo Scientific, Dreieich, Germany) was employed, and analytes were eluted with a binary gradient of methanol (A) and 1 mM

DOI: 10.1021/acs.jafc.5b02343
J. Agric. Food Chem. 2015, 63, 6897−6904

ammonium acetate in 0.5% formic acid (B) as follows: 0−1 min, 1% A; 1−6 min, ramp to 50% A; 6−13 min, ramp to 99% A; 13−15 min, hold at 99% A; 15−16 min, ramp to 1% A; 16−19 min, hold at 1% A. The flow rate was 1 mL min^{-1}. The detection wavelength was 284 nm, and the DAD recorded ultraviolet (UV) spectra were from 200 to 370 nm with a spectral interval of 1.6 s and a wave step of 4 nm. Blank analyses were included regularly to check for memory effects. For quantitation, a calibration curve for DFX was obtained by linear regression corresponding to the correlation between the peak area and the analyte concentration in the range from 0.02 to 30 mg L^{-1}. Linearity was evaluated with 11 different concentrations (n = 8) using standard solutions diluted in medium (0.02, 0.04, 0.06, 0.08, 0.1, 1.0, 2.5, 5.0, 10.0, 20.0, and 30.0 mg L^{-1}). Limit of detection (LOD) and limit of quantitation (LOQ) were calculated by the signal/noise ratio (S/N) employing the peak-to-peak method. S/N of 3:1 and 10:1 were used for estimating the LOD and LOQ, respectively. LOD was confirmed when the average of all measurements of the lowest standard concentration showed an S/N > 3.

Preparative Isolation of DFX-O. Preparative HPLC was performed using a Young Lin quaternary pump (YL 91105), an ultraviolet detector (YL 91205) set at 284 nm, and a CHF 122SC fraction collector (Advantec, Dublin, CA, USA) combined with YL-Clarity software (version 3.0.4.444, Young Lin Instruments, Anyang, Korea). In general, 0.7 mL of the resuspended lyophilisate extract was resolved on a Nucleosil C18 column (250 × 16 mm, 7 μm) (Macherey-Nagel, Düren, Germany) preceded by a 10 × 16 mm guard column of the same stationary phase. Methanol and 1 mM ammonium acetate in 0.5% formic acid (45:55, v/v) were used as solvent system for isocratic separation (run time = 14 min) with a flow rate of 10 mL min^{-1}. After isolation metabolite fractions were combined and lyophilized.

Mass Spectrometry. High-resolution mass spectra (HRMS) were acquired on an Orbital trapping mass spectrometer (Q Exactive, Thermo Fisher Scientific, Bremen, Germany) using a nanospray ionization source in positive mode (NSI^+) (capillary temperature = 250 °C, spray voltage = 1.5 kV) and nanoelectrospray needles for online measurements (Silica Tips, 5 μm, New Objective, Woburn, MA, USA). MS^2 experiments were performed with higher energy collision dissociation (HCD). Data acquisition was performed with Tune 2.4, and spectra were analyzed with Xcalibur 2.2.SP1.48 (Thermo Fisher Scientific). The mass spectrometer was operated in positive ion mode at a mass resolution of 140000 at m/z 200 (scan range m/z 50−400). Mass accuracy was better than 2 ppm. DFX and DFX-O were dissolved in methanol/water (1:3, v/v) with addition of 0.03% TFA (concentration of each substance = 47 μg mL^{-1}).

MS^3 was carried out using the 3200 QTRAP System (AB Sciex, Darmstadt, Germany) that allows fragmentation experiments based on hybrid triple-quadrupole/linear ion trap technology. An electrospray ionization source in positive mode (ESI^+) at a capillary voltage of 5.5 kV was used. Further mass spectrometry (MS) detection settings were as follows: source temperature = 40 °C, nebulizer gas = 14 psi, curtain gas = 10 psi, declustering potential = 40 V, and entrance potential = 10 V. Data acquisition was performed with Analyst 1.6.2 (AB Sciex).

NMR Spectroscopy. Nuclear magnetic resonance (NMR) spectroscopy data were acquired in D_2O (Euriso-top, Gif-Sur-Yvette, France) on a Bruker Avance III 600 MHz NMR spectrometer (Bruker BioSpin, Rheinstetten, Germany) equipped with 5 mm broad band BBO Z-gradient probe, operating at 600 MHz (for ^1H) and 150 MHz (for ^{13}C). For structural elucidation, 1D NMR experiments such as ^1H, ^{13}C, and distortionless enhancement by polarization transfer experiments using a 135° decoupler pulse (DEPT-135) as well as 2D NMR experiments such as ^1H, ^1H correlation (^1H, ^1H-COSY), heteronuclear single-quantum correlation (^1H, ^{13}C-HSQC), and heteronuclear multiple-bond correlation (^1H, ^{13}C-HMBC) were performed. The spectra were recorded at room temperature. The data were collected and processed by TopSpin software (Bruker). The NMR experiments were performed using Bruker standard pulse sequences and parameters. Chemical shifts are reported in parts per million (δ scale). ^1H chemical shifts were referenced to the residual solvent peak. The ^{13}C spectra were referenced to external 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid (TSP) in D_2O.

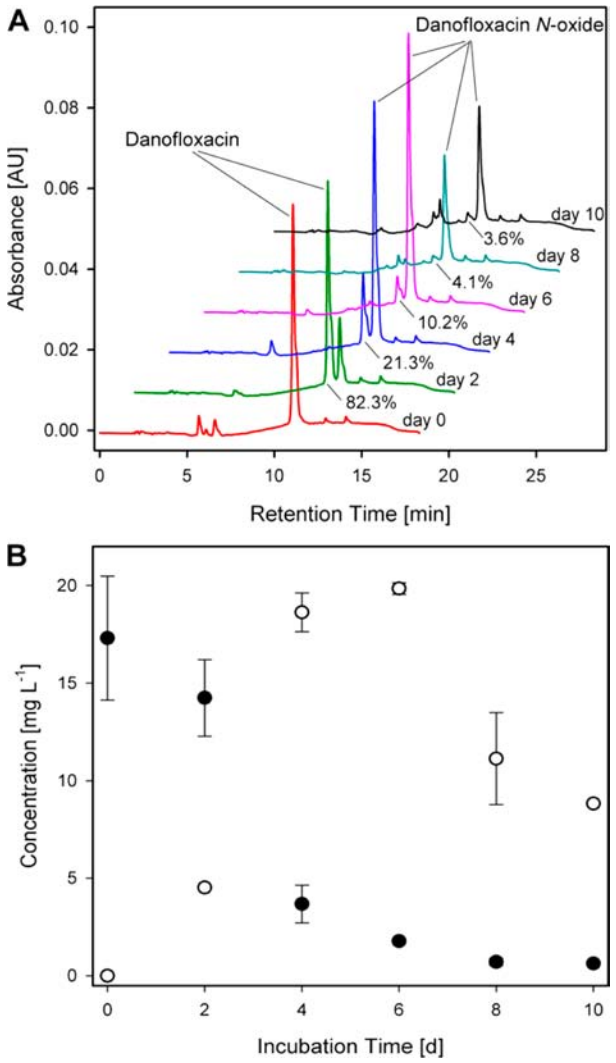

Figure 2. Degradation of danofloxacin (DFX) and formation of the main metabolite danofloxacin *N*-oxide (DFX-O) produced by *X. longipes*: (A) HPLC-DAD chromatograms (284 nm); (B) detected concentrations of DFX (solid circles) and DFX-O (open circles) in fungal culture supernatants. Values plotted are expressed as the mean of duplicates ± mean range.

Photometric Analyses. For determination of UV absorption spectra and molar extinction coefficients ε, a Specord 50 ultraviolet−visible spectrophotometer utilizing the wavelength range from 190 to 450 nm combined with WinAspect software (version 2.2.1.0, Analytik Jena, Jena, Germany) was used. The spectra were recorded using Suprasil quartz cuvettes (path length = 10 mm; Hellma, Müllheim, Germany).

Residual Antibacterial Activity. Residual antibacterial activity of the biotransformation product DFX-O was determined in comparison to DFX using the brilliant black reduction (BRT) maximum residue level (MRL) screening test (AiM, Munich, Germany). Adapted from the agar diffusion test, this microbiological test is based on the reduction of the agar−agar added synthetic black diazo dye brilliant black by the test bacterium *Geobacillus stearothermophilus* var. *calidolactis* C953. It was developed for semiquantitative determination of antibiotic residues in milk according to Commission Regulation (EU) 37/2010.[29] This test is characterized by high sensitivity against β-lactam antibiotics. Thus, penicillins are detected at MRL level, but other antibiotics can also be determined. During the incubation, brilliant black is completely reduced by the growing test organism due to reductive cleavage of the azo bonds, resulting in yellow and colorless compounds. Hence, the color of the test medium changes from blue to yellow. The presence of antibiotic residues in a sample inhibits the

J. Agric. Food Chem. 2015, 63, 6897−6904

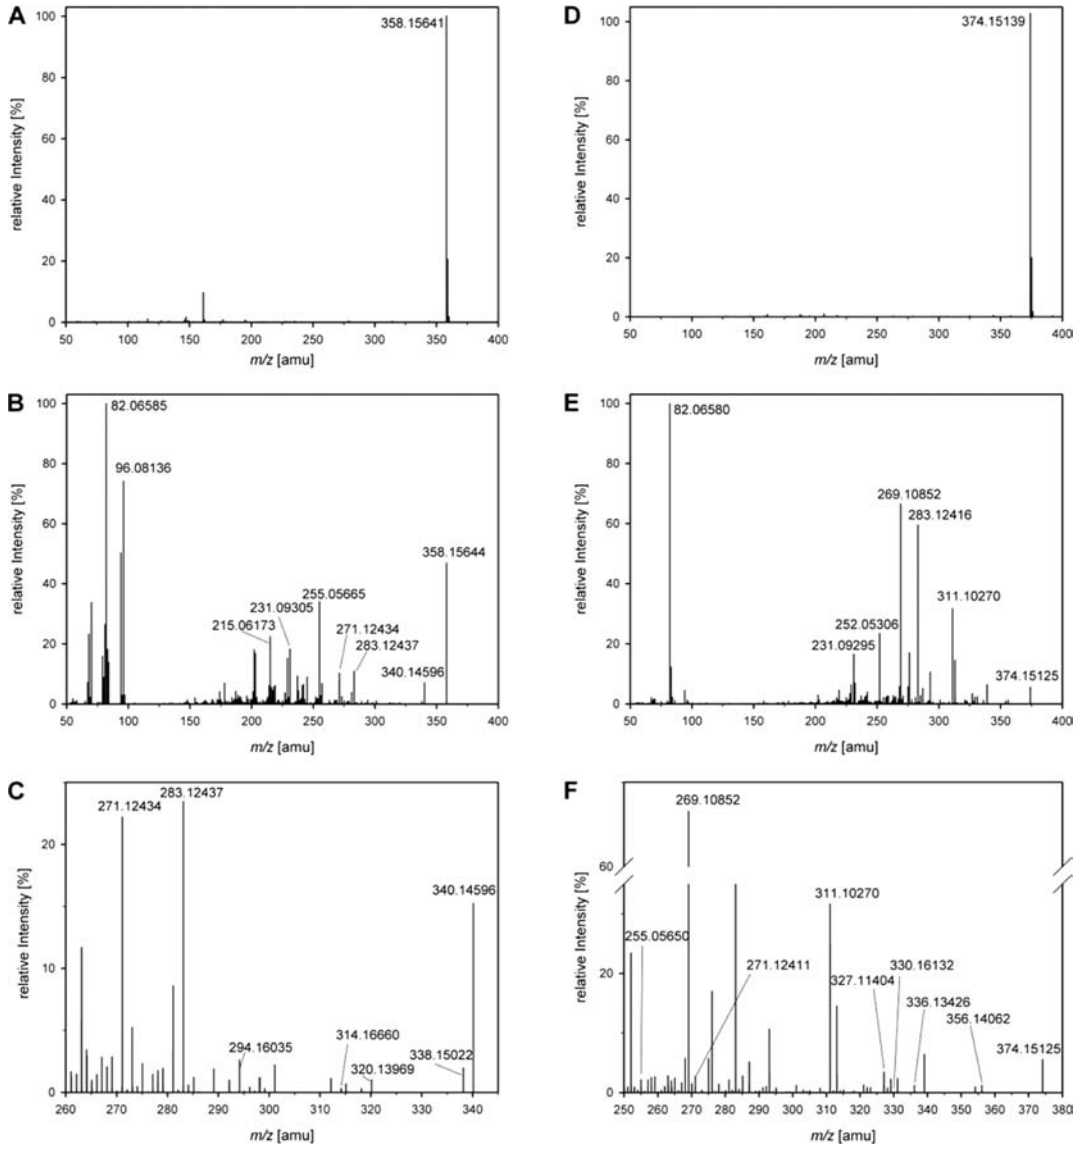

Figure 3. Accurate high-resolution MS and MS^2 spectra of danofloxacin (DFX) and danofloxacin *N*-oxide (DFX-O): (A) NSI^+-FTMS (full scan) spectrum of DFX; (B) NSI^+-$FTMS^2$ product ion spectrum of DFX with higher energy collision dissociation (HCD) at normalized collision energy of 60%; (C) zoomed range of (B); (D) NSI^+-FTMS (full scan) spectrum of DFX-O; (E) NSI^+-$FTMS^2$ product ion spectrum of DFX-O with a HCD at normalized collision energy of 45%; (F) zoomed range of (E).

growth of the test organism. Therefore, the test medium does not change the color and remains blue. Because the test was developed for detection of inhibitors in milk, stock solutions of both compounds were diluted with inhibitor-free milk (commercially available milk, 3.5% fat content) to obtain concentrations of 0.1−200 mg L^{-1}. Into each cavity of the 96-well plate were pipetted 0.1 mL of the sample solution and the positive control (penicillin G standard, 4 μg L^{-1}) or the negative control (inhibitor-free milk). The procedure for the determination of antibacterial activity in culture supernatants slightly deviated from the instructions given by the manufacturer. Penicillin G (99.4%; Sigma-Aldrich, Seelze, Germany) dissolved in medium in a concentration of 4 μg L^{-1} and medium only served as positive and negative controls, respectively. The sample volume was 0.1 mL for controls and culture supernatants. The cavities were sealed with adhesive film and incubated in a heating block at 65 °C until the cavity with the negative control turned yellow (about 2.25 h ± 15 min). After removal of the milk, each cavity was simultaneously analyzed using an Eon microplate spectrophotometer (BioTek Instruments, Bad Friedrichshall, Germany) at measurement and reference wavelengths set at 450 and 620 nm, respectively. All analyses were performed in triplicate.

RESULTS AND DISCUSSION

Degradation of DFX. HPLC-DAD analysis of a DFX standard solution showed that the retention time of DFX was 11.0 min, the LOD was found to be 8 μg L^{-1} (S/N values ranged from 2.8 to 3.4), and the LOQ was determined at 20 μg L^{-1} with a precision of 9% (n = 8).

DFX was efficiently transformed by *X. longipes* within 10 days using an initial concentration of approximately 20 mg L^{-1}. The HPLC-DAD analyses of the culture supernatants showed one apparent metabolite eluting at 11.6 min as well as residual DFX (Figure 2A). Other peaks (e.g., at 9.1 or 9.5 min) were also found in the biotic controls after the same incubation period. Thus, these signals were not considered as potential DFX metabolites.

After 6 days of incubation, about 90% of DFX had been transformed to the product according to the peak areas at 284 nm. The metabolite showed the same UV spectrum as DFX with λ_{max} (H_2O) = 280 nm (ε_{280} (H_2O, 20 °C) = 34724 L mol^{-1} cm^{-1}; for DFX, ε_{280} (H_2O, 20 °C) = 38740 L mol^{-1} cm^{-1}). Thereafter, only

[a]Measured accurate masses, predicted elemental compositions, theoretical masses, and mass deviations of DFX and DFX-O and their MS^2 fragments.

a minor decrease of the residual DFX concentration was observed to 3.6% after 10 days. The decline of the DFX concentration was accompanied by an increase of the metabolite concentration during the first 6 days (19.85 mg L^{-1} at day 6) (Figure 2B). However, the peak area of the metabolite decreased within the next 4 days giving a final concentration of 8.82 mg L^{-1} beyond very low amounts of DFX (0.63 mg L^{-1}). The HPLC elution profiles indicated only one main metabolite reaching maximum concentrations after 4 and 6 days. Hence, an incubation time of 4 days was chosen to produce a sufficient quantity of the metabolite for structure elucidation by NMR and MS.

In the larger scale biodegradation experiment fungal cultivation was stopped after 73 h. After preparative isolation, the yield of the metabolite was 10 mg with a purity of 94%.

Structure Elucidation of DFX and DFX-O. NSI^+-HRMS measurements of DFX and the isolated compound revealed the exact masses of $[M + H]^+$ = 358.15641 and $[M + H]^+$ = 374.15139, respectively (Figure 3A,D), suggesting that the metabolite had been formed by the addition of one oxygen atom to DFX ($\Delta m/z$ = 15.99498, theoretical mass of oxygen is 15.99492 Da). Product ion analyses of the protonated molecular ions at m/z 358 and at m/z 374 revealed common fragment ions at m/z 283, 271, 255, and 231 (DFX, 283.12437, 271.12434, 255.05665, 231.09305; DFX-O, 283.12416, 271.12411, 255.05650, 231.09295) for both compounds (Figure 3 and Table 1). The mass deviations for these fragments ranged from 0.82 to 1.11 ppm and from −0.03 to 0.57 ppm for DFX and the metabolite, respectively, indicating a very good accuracy. In the product ion spectrum of the protonated DFX molecule several fragments were observed, that is, at m/z 314.16660 generated by the elimination of CO_2, at m/z 340.14596 due to the loss of water, and at m/z 255.05665 due to the loss of water and the loss of *N*-methylpyrrolidine ($C_5H_{11}N$) from the substituted piperazine moiety (Figure 3B,C). Accordingly, the product ion spectrum of the protonated metabolite molecule included a fragment ion caused by the elimination of a CO_2 group (m/z 330.16132) and an ion corresponding to the loss of water (m/z 356.14062) as well as an ion at m/z 255.05650 that results from m/z 356.14062 due to the loss $C_5H_{11}NO$ group from the substituted piperazine moiety (Figure 3E,F). The presence of a common product ion at m/z 283 indicated that the fluoroquinolone core of both compounds was intact, suggesting that the addition of an oxygen atom could be found only on the substituted piperazine moiety.

ESI^+-MS^3 fragmentation experiments were carried out to further confirm the assumed structure of the metabolite (data not shown). Fragmentation of a precursor ion at m/z 327 generated by the neutral loss of CH_5NO moiety revealed one intense fragment ion at m/z 283 corresponding to the elimination of CO_2 also detected in fragmentation experiments of DFX. The presence of the fragment ion at m/z 327, which was not observed in MS spectra of DFX, indicated the addition of an oxygen atom to the methylated nitrogen at the substituted piperazine moiety of DFX. Given the fact that the oxidized substituted piperazine moiety was present in the first-appearing product ions after the loss of water (m/z 356) and CO_2 (m/z 330), respectively, whereas the loss of the oxidized substituted piperazine moiety is observed in all following product ions, these data confirmed the assumed structure, which would be supported by previously published fragmentation patterns reported by Liu and co-workers.[30]

For further structure confirmation, a combination of 1D and 2D NMR techniques including ^1H and ^{13}C NMR, DEPT-135, $^1H,^1H$-COSY, $^1H,^{13}C$-HSQC, and $^1H,^{13}C$-HMBC was performed. The experimentally established ^1H NMR and ^{13}C NMR spectral data for DFX and DFX-O are given in Table 2. Numbering of the atoms is shown in Figure 1. To the best of our knowledge, this is the first detailed report of ^{13}C NMR data of DFX and ^1H NMR and ^{13}C NMR data of DFX-O. The protons H5 and H8 appeared as doublets due to the coupling

to the ^{19}F atom. The coupling constant between carbons and fluorine was found to be helpful for the assignment of aromatic ^{13}C signals. The ^{1}H NMR data given here for DFX agree with those found in the literature.[2] The ^{13}C NMR data (Table 2) obtained for the fluoroquinolone core of DFX were very similar to those from the same part of ciprofloxacin, which differs structurally from DFX only in the substitution of the piperazine moiety.[31]

DFX-O proton and carbon assignments were made in analogy to those of DFX. First, the ^{1}H spectrum showed an intensive singlet at 8.29 ppm, which coupled to a carbon atom at 169.4 ppm. However, there was no correlation with the NMR signals of DFX-O. After the addition of some microliters of deuterated ammonia solution ($ND_3 \cdot D_2O$), both signals disappeared, indicating that these signals might be caused by formic acid added to the eluent for preparative isolation by HPLC. The ^{1}H and ^{13}C NMR chemical shift values agree with those in the literature for formic acid.[32] The ^{1}H NMR data of DFX-O revealed a remarkable shift of the protons of the methyl group (H8′) from 2.98 ppm (DFX) to 3.53 ppm (Table 2). Other ^{1}H NMR chemical shifts of the metabolite remained similar to those of DFX. For DFX-O, carbons at position C3′, C5′, and C8′ suffered a low-field shift of 11.3−15.1 ppm compared to the analogous signals of DFX. Corresponding to ^{1}H NMR data, the chemical shifts of the remaining carbon atoms were similar to the data obtained for DFX. Therefore, the NMR data confirmed the results of the MS analyses, indicating an unchanged fluoroquinolone core with the addition of an oxygen atom on the substituted piperazine moiety. HSQC and HMBC spectra, showing direct and long-range couplings of protons with carbons, fortified the assumption of the metabolite. Hence, the isolated metabolite was identified as danofloxacin *N*-oxide (1-cyclopropyl-6-fluoro-7-[1*S*,4*S*]-5-methyl-5-oxido-2,5-diazabicyclo[2.2.1]hept-2-yl]-4-oxo-1,4-dihydro-3-quinolinecarboxylic acid, DFX-O) with the oxygen atom attached to the terminal nitrogen of the substituted piperazine ring (Figure 1B).

On the basis of metabolism studies of alkaloids, *Xylaria* sp. is known to form selectively *N*-oxides.[24,25] Among FQs, the formation of *N*-oxides was observed in transformation studies using enrofloxacin and *U. ramanniana* (syn. *M. ramannianus*), *G. striatum*, and other fungi.[18] DFX was metabolized by *R. arrhizus* to the corresponding *N*-desmethyl and *N*-oxide metabolites, whereas the formation of DFX-O was assumed due to detection of the expected mass of DFX-O ($[M + H]^+$ m/z 374) in fungal cultures. Further structural elucidation of the *N*-oxide metabolite was not performed.[15] However, such a fast, quantitative, and regioselective conversion of FQs as described here has not been reported yet.

Residual Antibacterial Activity. The antibacterial activities of DFX and DFX-O were calculated on the basis of the

DOI: 10.1021/acs.jafc.5b02343
J. Agric. Food Chem. 2015, 63, 6897−6904

positive control penicillin G, which was considered as 100% in the BRT MRL screening test. As assumed, the test was much less sensitive to FQs in comparison to penicillin G. For DFX and DFX-O, concentrations <2 mg L^{-1} caused no inhibition, whereas concentrations >30 mg L^{-1} led to an inhibition corresponding to that of the positive control (data not shown). However, a DFX concentration of 4 mg L^{-1} as well as a DFX-O concentration of 20 mg L^{-1} led to an inhibition of >60% (Figure 4). Thus, the residual antibacterial activity of DFX-O corresponded approximately to 20% of the DFX activity.

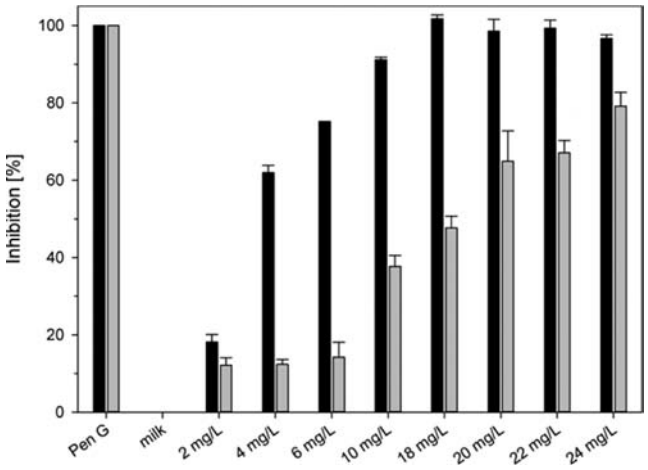

Figure 4. Antibacterial activity of DFX (black bars) and DFX-O (gray bars) in comparison to penicillin G (Pen G, 4 μg L^{-1}) as positive control and inhibitor free milk as negative control using BRT MRL screening test. Values plotted are expressed as the mean of triplicates ± standard deviation.

Fungal culture supernatants from the degradation experiment were tested as well (data not shown). Briefly, the antibacterial activity of culture supernatants of days 0 and 2 corresponded to that of the positive control, whereas in samples of day 4 an inhibition of 30% was detected. No antibacterial activity was observed in culture supernatants from day 6 until the end of the study, demonstrating a strong inactivation of DFX.

Oxidation of the nitrogen of the substituted piperazine moiety of FQs is known to cause a strong reduction of the antibacterial activity. For instance, ofloxacin *N*-oxide possesses a weaker antibacterial activity against various bacterial strains such as *Bacillus pumilus* (minimum inhibitory concentration (MIC) > 20 mg L^{-1}).[33] Compared to the parent compound (MIC = 0.675 mg L^{-1}), the MIC for ofloxacin *N*-oxide is > 29-fold higher, and thus the metabolite is quite inactive.[33] Similar results have been reported for amifloxacin and its *N*-oxide.[34] All of these findings are in good agreement with our results.

Some white rot fungi have been found to metabolize the FQs flumequine, norfloxacin, ofloxacin, and ciprofloxacin.[17,35] For flumequine, the antibacterial activity corresponded to the residual concentration of the compound remaining in the *Panus tigrinus* and *Pleurotus ostreatus* cultures. In contrast, for ciprofloxacin, although the compound was completely degraded by *Irpex lacteus*, a high residual activity was determined.[17,35] However, a decrease of the antibacterial activity in the degradation mixtures was achieved as well as generation of potentially antibacterial active metabolites, indicating that fungal biotransformation of FQ antibiotics does not necessarily lead to their inactivation. These diverse findings demonstrate that the outcome of fungal biotransformations of FQ antibiotics strongly depends on the microorganisms and individual compounds utilized, even though their structures are closely related.

In microbial biotransformation processes of antibiotics it is important to investigate the structure of the transformation products as well as their residual antibacterial activity. Even though the reduction of antibacterial activity is desirable, attention should be paid to degradation products that may promote the development of resistance in bacterial populations.[36] The evidence of potential metabolism of antibiotics is of interest because their occurrence in the environment raises serious concerns about possible risks for microorganisms, animals, and humans. Thus, fungal biotransformations of antibiotics accompanied by a remarkable reduction of their residual antibacterial activity may have an important ecological impact and are useful in biotechnological processes. In future investigations, the enzyme(s) responsible for this highly selective transformation should be identified and may be used in bioreactors to inactivate danofloxacin and potentially other FQs.

Many attempts have been done to improve or modify the volatiles of tea leaves either by treating leaves during growth of the plants (raw materials) or by postharvest treatment of leaves during the tea manufacturing process.[1] Biotic stress (insect attack) and abiotic stress (light) have been utilized for the improvement of volatiles in raw tea leaves. As a typical example of biotic factors, the famous Taiwan oolong tea (Oriental Beauty) has a unique aroma reminiscent of ripe fruit and honey that is induced by the attack of tea green leafhoppers.[16] As an example of abiotic factors, Gyokuro and Tencha, known as the finest teas in Japan, are produced from tea leaves under shading treatment. It was found that tea leaves kept in darkness significantly increased levels of volatiles, especially volatile phenylpropanoids/benzenoids.[17] Besides the modification of raw materials, the manufacturing processes have significant influences on the compositions of volatiles in final tea products. In general, fermented teas including oolong tea and black tea have more volatiles and aroma properties than nonfermented green tea. This was generally thought to be due to the involvement of hydrolysis of GBVs in the manufacturing process.[18] The GBVs are present within vacuoles, while β-primeverosidase, one major glycosidase involved in the hydrolysis of GBVs, was presumed to be localized in cell walls.[18] This compartmentation of substrates and enzymes in plant cells implies that interactions between the enzyme and the substrate do not happen in intact tea leaves.[19] However, during the manufacturing process, tea leaf tissues and cells are disrupted, which results in the possibility of interactions between the glycosidase and the GBVs and liberation of the free volatiles. During the manufacturing process of black tea, the levels of primeverosides of the volatiles decreased greatly, and the glycosidase activities showed a peak during withering but were drastically reduced after rolling, suggesting that enzymatic hydrolysis of GBVs mainly occurred during the stage of rolling.[20] Therefore, enzymatic hydrolysis of GBVs is proposed as an important process during the manufacturing of black tea. In contrast, most GBVs showed no reductions in their contents during the manufacturing process of oolong tea. The contents of GBVs increased after the solar-withering stage, and reached their highest levels in the final stages of oolong tea production.[21] This result led us ask whether enzymatic hydrolysis of GBVs really contributes to the formation of volatiles during the oolong tea manufacturing process. To answer this question, we monitored changes in contents of free volatiles and GBVs, glycosidase enzyme activities, and *β-glycosidase* gene expression level during the manufacturing process of oolong tea. We attempted to give direct evidence of subcellular localization of β-primeverosidase, and also investigated the effect of the manufacturing process on the leaf cell structure. Finally relatively potent odorants occurring in oolong tea product were evaluated by gas chromatography−mass spectrometer/olfactometry (GC−MS/O). The results help us find out the truth of formation of volatiles in oolong tea, and advance our understanding of differences of formation of volatiles between oolong tea and black tea.

MATERIALS AND METHODS

Chemicals. Benzaldehyde, benzyl alcohol, β-damascenone, δ-decalactone, ethyl decanoate, Furaneol, 2-hexen-1-ol, 3-hexenyl acetate, indole, β-ionone, jasmine lactone, 3-methylnonane-2,4-dione, methyl salicylate, 2-phenylethanol, and vanillin were purchased from Wako Pure Chemical Industries Ltd., Japan. α-Farnesene, (*Z*)-3-hexen-1-ol, linalool, linalool oxides, methyl jasmonate, *trans*-nerolidol, geraniol, polyvinylpolypyrrolidone (PVPP), XAD-2, and β-glucosidase were purchased from Sigma-Aldrich Company Ltd., USA. β-Primeverosidase and *p*-nitrophenyl-β-primeveroside were purchased from Amano Enzyme Inc., Japan. *p*-Nitrophenyl-β-D-glucopyranoside was purchased from Aladdin Industrial Co. Shanghai, China. [^{15}N]Anthranilic acid (^{15}N% = 98%) was purchased from Cambridge Isotope Laboratories Inc., Cambridge, MA. Porapak Q cartridge was purchased from Waters Corporation, USA. Coomassie Blue R250, 30% acrylamide/Bis solution, *N*,*N*,*N*′, *N*′-tetramethylethylenediamine (TMEMD), sodium dodecyl sulfate (SDS), and 2× SYBR Green Universal PCR Mastermix were purchased from Bio-Rad Laboratories, USA. Quick RNA isolation Kit was purchased from Huayueyang Biotechnology Co., Ltd., China.

Plant Materials and Manufacturing Process of Oolong Tea. One bud and two or three leaves of *Camellia sinensis* var. Jinxuan were plucked at the Tea Experiment Station in the South China Agricultural University (Guangzhou, China) in October, 2014. The manufacture of oolong tea was carried out according to the general method,[21] as shown in Figure S1 (Supporting Information). The freshly plucked tea leaves (P) were exposed to sunlight (43 °C and 93,500 Lux) for 70 min as solar withering (SW). Afterward, the tea leaves were indoor-withered (IW) for 2 h at temperature of 27 °C and a relative humidity of 70%, and subsequently turned over by 5 times (T1−T5) every 1.5 h. Then the tea leaves were parched in a tea-firing roller machine at 250 °C for 2−3 min to inactivate the enzymatic activity and fix the sample (F). Finally, the tea leaves were rolled at room temperature for 15 min and dried at 105 °C for 1.5 h. The samples from P, SW, IW, and T1−T5 were immediately frozen by liquid nitrogen for enzyme activity and gene expression profiling. Three replicates were processed according to the oolong tea manufacturing.

Extraction and Analysis of Volatiles in Tea Samples. One gram of samples (finely powdered) was extracted by 2.5 mL of dichloromethane containing 5 nmol of ethyl decanoate as an internal standard in a shaker at room temperature overnight. The extraction solution was dried over anhydrous sodium sulfate and concentrated to 400 μL using nitrogen stream (MIULAB NDK200-1, MIU Instruments CO., Ltd., Hangzhou, China). One microliter of the concentrate was subjected to GC−MS QP2010 SE (Shimadzu Corporation, Japan) equipped with a SUPELCOWAXTM 10 column (30 m × 0.25 mm × 0.25 μm, Supelco Inc., Bellefonte, PA, USA). The injector temperature was 240 °C. The splitless mode was used with a splitless time of 1 min, and helium was the carrier gas with a velocity 1.0 mL/min. The GC oven temperature was 60 °C for 3 min, ramp of 4 °C/min to 240 °C, and then 240 °C for 20 min. The mass spectrometry was operated with full scan mode (mass range *m*/*z* 40−200).

Extraction and Analysis of GBVs in Tea Samples. Analysis of GBVs used the enzymatic hydrolysis combined with the GC−MS analysis method, which was the same as described previously.[15,22] Five hundred milligrams (fresh weight) of sample (finely powdered) was extracted with 2 mL of cold methanol by vortexing for 2 min followed by ultrasonic extraction in ice-cold water for 10 min. The extracts were mixed with 2 mL of cold chloroform and 0.8 mL of cold water for phase separation. The resulting upper layer was dried and dissolved in 1 mL of water. The resulting solution was mixed with 30 mg of PVPP, stood for 90 min, and was centrifuged (16400*g*, 4 °C, 10 min), and repeated with the supernatant. The final supernatant was loaded to an Amberlite XAD-2 column (1 mL) and eluted with 5 mL of water, 5 mL of pentane:dichloromethane (2:1), and 5 mL of methanol. The methanol eluent was dried using nitrogen stream, and redissolved in 400 μL of 50 mM citric acid buffer (pH 6.0) containing β-primeverosidase and β-glucosidase, and reacted at 37 °C for 14 h. Afterward, 144 mg of sodium chloride was added to the reaction solution, and stood for 15 min followed by addition of 5 nmol of ethyl decanoate as an internal standard. The solution was extracted with 400 μL of dichloromethane and centrifuged, and the dichloromethane fraction was dried over anhydrous sodium sulfate, followed by GC−MS analysis. The GC−MS conditions were the same as described above.

Determination of Enzyme Activities of β-Glucosidase and β-Primeverosidase. The enzyme assay method referred to the previous

reports.[20,23] One gram of finely powdered tea leaves was ground in ice-cold acetone and filtered using a suction pump (T-50.2L, Tianjin Jinteng Experiment Equipment Co., Ltd., Tianjin, China). The acetone-insoluble powder on the filter paper was washed with ice-cold acetone several times until clean and colorless acetone filtrate was obtained. The acetone-insoluble powder was dried by nitrogen stream to remove residual acetone and stored at −80 °C. For each 0.25 g of acetone-insoluble powder, 6.25 mL of ice-cold 50 mM sodium citrate buffer (pH 6.0) was added to dissolve the powder, accompanied by 0.125 g of PVPP. After vortexing twice for 30 s at 0 °C and centrifuging at 10000*g* (4 °C, 20 min), the supernatant was used as the crude enzyme solution. The substrate, either *p*-nitrophenyl-*β*-D-glucopyranoside or *p*-nitrophenyl-*β*- primeveroside, was dissolved in 90 μL of 50 mM sodium citrate buffer (pH 6.0) and incubated at 37 °C for 5 min. Ten microliters of crude enzyme solution was added, and then the whole reaction mixture was incubated at 37 °C for 60 min. The reaction was stopped by adding 140 μL of 0.2 M sodium carbonate, resulting in yellow color of the mixture, which was

measured at 400 nm by a spectrophotometer (Infinite M200 PRO, TECAN, Switzerland). The amount of *p*-nitrophenol was determined according to a calibration curve.

Transcript Expression Analysis of *β-Primeverosidase*, *9/13-Lipoxygenase (LOX)*, and *Terpene Synthases* (*TPS*). Total RNA was isolated immediately after dissection. The reactions were performed using Power SYBR Green PCR Master Mix in a 20 μL volume containing 10 μL of Power SYBR Green PCR Master Mix (2×), 0.2 μM each specific forward and reverse primer. Two microliters of 10-fold diluted template was used for a 20 μL PCR reaction. The encoding elongation factors (EFs) were used as internal reference gene.[24] The *EFs*, *β-primeverosidase*,[15] *LOX*,[25] and *TPS*[26] specific primers of qRT-PCR are shown in Table S1 (Supporting Information). The qRT-PCR was carried out on Roche LightCycle 480 (Roche Applied Science, Mannheim, Germany) under the condition of one cycle of 95 °C for 10 min, 40 cycles of 95 °C for 15 s, and 60 °C for 1 min. A melt curve was performed at the end of each reaction to verify PCR product specificity. The $2^{-\Delta\Delta ct}$ method was used to calculate the relative expression level.[27] Changes in mRNA levels of the target genes were normalized to that of EFs.

Observation of Tea Leaf Cell Structure. The tea leaf samples of P, T1, T2, and T5 stages were cut into approximately 1 mm × 2 mm pieces and fixed in 0.1 M phosphate buffer (pH 7.2) containing 2% glutaraldehyde and 2.5% paraformaldehyde. After 6 times washing with 0.1 M phosphate buffer, the leaf samples were postfixed in 1% osmium tetroxide for 4 h and washed with 0.1 M phosphate buffer. Then the fixed leaf samples were dehydrated and embedded in flat molds using EPON812 resin. Ultrathin sections (80 nm) were cut by ultramicrotome (Leica UC7, Leica Microsysteme GmbH, Wetzlar, Germany), which then were stained by 4% uranyl acetate and 2% lead citrate. Ultrathin sections were observed by a transmission electron microscope (JEOL JEM-1010, Tokyo, Japan) operating at 100 kV.

Subcellular Localization of *β*-Primeverosidase in Tobacco. To construct vectors for expression of GFP-fusion protein, the stop codon of *β*-primeverosidase coding sequence was replaced by *Xma*I restriction site, with the following primers: 5′-GTCGACATGATGGCAGCGAAAGGG-3′ (forward), 5′-CCCGGGGCTTGAGGAGGAATTTCTT-3′ (reverse). The PCR product of *β*-primeverosidase cDNA fragment, in which the stop codon was eliminated, was cut with *Sal*I/*Xma*I and then cloned into the *Sal*I/*Xma*I sites of the pCAMBIA3300-GFP vector. The reorganization vector was transformed into *Agrobacterium* GV3101 by freeze−thaw. The overnight *Agrobacterium* cultures were sedimented at 5000*g* for 1 min. The pellet was resuspended in a solution containing 10 mM $MgCl_2$, 10 mM morpholineethanesulfonic acid (pH 5.6), and 100 μM acetosyringone to OD_{600} = 0.4.[28,29] Leaves of *Nicotiana benthamiana* were infiltrated by using a syringe without a needle, and then the tobacco was grown on a 16 h light/8 h dark under 25 °C regime for 4−5 days. Protoplasts were prepared as follows: tobacco leaves were cut into 2−3 cm^2 pieces

Lower photos: Green fluorescence was not shown in the protoplast cell prepared from the tobacco leaves (the upper photos), which proved that the GFP-β-primeverosidase protein is localized in the cell wall.

microscope images were taken using a Zeiss LSM 510 META confocal laser microscope (Cal Zeiss, Jena, Germany) with a 100× oil objective under 488 nm excitation wavelength for GFP detection.

Effect of Disruption of Tea Leaf Cell on Amounts of Free Volatiles and GBVs. After turn over 1 (T1), parts of tea leaves were completely crushed to cause disruption of leaf cell, and indoor-withered at room temperature for 4.5 and 6.0 h, respectively. Afterward, 1 g of treated sample was used for analyses of free volatiles and GBVs, which methods are described as above. The amounts of free volatiles and GBVs of the treated samples were compared with those of T4 and T5, respectively.

Administration of [^{15}N]Anthranilic Acid into Tea Leaves and Analysis of [^{15}N]Indole. Fifty microliters of solution of [^{15}N]-anthranilic acid (20 mM) was injected into each tea leaf at the T1 stage. One part of the tea leaves with [^{15}N]anthranilic acid was completely crushed to cause disruption of leaf cell and indoor-withered at room temperature for 6.0 h, while the other part of the tea leaves with [^{15}N]anthranilic acid followed the oolong tea manufacturing and was processed to the T5 stage. The amount of [^{15}N]indole was analyzed by GC−MS as described above. The characteristic ion of [^{15}N]indole is m/z 118.

Identification of Relatively Potent Odorants of Oolong Tea. The relatively potent odorants were evaluated using GC−MS/O and aroma extraction and dilution analysis (AEDA), as described previously.[30−33] The oolong tea product powders (2 g) were incubated in hot distilled water (40 mL, 80−90 °C) for 5 min and centrifuged for 10 min at 3000g. The resultant supernatant (30 mL) was loaded on a Porapak Q cartridge (2 mL volume, 50−80 mesh), eluted with 3 mL of water, and 3 mL of pentane:diethyl ether (1:1, v/v) as aroma extract. Afterward, the aroma extract was added with ethyl decanoate (20 μg/20 μL) as an internal standard, dried over anhydrous sodium sulfate, and concentrated to 100 μL in a stream of nitrogen to give an original odor concentrate sample.

The original odor concentrate of the sample infusion was stepwise diluted with pentane:diethyl ether (1:1, v/v) 1:4 = 4^1, 1:16 = 4^2, 1:64 = 4^3, 1:256 = 4^4, 1:1024 = 4^5, 1:4096 = 4^6, and 1:16384 = 4^7. The aliquots (2 μL) of each sample were analyzed by GC−MS/O. The flavor dilution (FD) factors of the odorants were determined by AEDA.

The GC/MSD (5975C, Agilent Technologies Inc., USA) equipped with a DB-WAX capillary column (60 m × 0.25 mm i.d., 0.25 μm film thickness, Agilent Technologies Inc., USA) was used for mass spectrometric identification. The splitless mode was used with a splitless time of 1 min. The split ratio at the time of the split vent liberation was 20:1. Helium was used as a carrier gas with a flow rate of 2 mL/min. The injector temperature was 240 °C. The GC oven was maintained at 40 °C for 2 min, increased by 5 °C/min to 240 °C, and was kept at this temperature for 25 min. The mass spectrometer was operated in full scan mode with a mass range of m/z 20−280. For GC−MS/O, the effluent was split into the olfactory detection port (Gerstel K.K., Japan) and MS using two deactivated, uncoated fused silica capillaries (106 cm × 0.15 mm i.d., 139 cm × 0.1 mm i.d.) at the end of the capillary. Volatile compounds were identified by direct comparison with the Kovats GC retention indices (RI), mass spectra, and those of the authentic specimens.

RESULTS AND DISCUSSION

Indole, Jasmine Lactone, and *trans*-Nerolidol Were Significantly Increased at the Turn Over Stage. To find out which volatiles, especially those also occurring in glycosidically bound form, have big changes during the manufacturing process, we monitored changes of free volatiles from the plucking process to fixing process (enzymatic reaction termination) of oolong tea. Among the manufacturing processes, the turn over process (T1−T5) had a significant influence on the contents of volatiles (Figure 1). In the present study, not all the free volatiles had big changes during the manufacturing process of oolong tea. The three volatiles including indole, jasmine lactone, and *trans*-nerolidol had significantly big increase at the turn over process (Figure 1). In addition, most fatty acid-derived volatiles such as 1-hexanol, (*E*)-2-hexen-1-ol, (*Z*)-hexen-1-ol, etc., linalool oxides, and α-farnesene increased at T1−T5, whereas some free volatiles such as linalool, geraniol, diendiol I, benzyl alcohol, 2-phenylethanol, and methyl salicylate, which also occur in glycosidically bound form, did not show significant changes during the process (Figure 1). Wang et al. first reported that the contents of free alcoholic aroma compounds remained almost unchanged or slightly decreased, but jasmine lactone and indole significantly increased in the final oolong tea products compared to dried fresh tea leaves.[21] In addition, increase of indole during the oolong manufacturing process was also demonstrated by a direct analysis in real time mass spectrometry.[34] Our previous study on comparison of volatiles of green teas, oolong teas, and black teas from different cultivars and regions also proposed that jasmine lactone and indole were characteristic volatiles in oolong tea products.[35] Furthermore, the present study indicated that these volatiles mostly accumulated at the turn over

process.[36,37] During the oolong tea manufacturing process, tea leaves are exposed to various stresses, such as plucking (wounding), solar withering (drought, heat, and UV/light radiation), indoor withering (drought), and turn over (wounding).[16] Therefore, the aroma formation in tea leaves during the manufacturing process of oolong tea is proposed to be the stress-responsive biochemical reactions of juvenile leaves of tea plants. Indole is a very representative stress-responsive volatile compound in the manufacturing process of oolong tea. Indole occurs with very trace amount in intact tea leaves. However, indole level increases rapidly after plucking.[38] Also indole increased during the withering process of green tea leaves even at a relatively low temperature (15 °C, for 16 h).[33] In the present study, the turn over led to more accumulations of indole (Figure 1). This evidence suggests that wounding stress from the turn over process is a key factor

Table 1. Identification of Potent Odorants (FD Factor $\geq 4^4$) in Oolong Tea

regulating formation of indole. Interestingly, black teas contain much less indole,[35] although wound stress is also involved in the manufacturing process of black tea. Tea leaves are still relatively intact and alive from the plucking to the turn over process of oolong tea, whereas the structure of the leaf cells is disrupted during the rolling process and the contents of the cells are completely mixed during the rolling process of black tea.[20,21] Amounts of indole, jasmine lactone, and *trans*-nerolidol reduced after tea leaf cell disruption (Figure 2), suggesting that mechanical damage with tea leaf cell disruption, which is similar to the manufacturing process of black tea, does not induce the accumulation of indole, jasmine lactone, and *trans*-nerolidol. As anthranilic acid is one of precursors of indole,[33] we investigated the formation of indole by feeding of stable isotope-labeled compound [^{15}N]anthranilic acid to the tea leaves. It was found that the amount of [^{15}N] indole in tea leaf with cell disruption was much lower than that in tea leaf without disruption (Figure 3). This suggests that indole may be oxidized by P450 enzymes after the leaf cell disruption.[39] Therefore, the pathway leading from anthranilic acid to indole may be a key step of formation of indole during the oolong tea process. As the genes involved in the pathway leading from anthranilic acid to indole are still unknown in plants, we are attempting to identify the involved genes and will investigate their responses to the stresses from the manufacturing process of oolong tea. In addition, it would be very interesting to investigate whether disruption of leaf cell and complete mixture of contents of cell may lead to the pathway competition between indole, jasmine lactone, and *trans*-nerolidol and other metabolites.

Most GBVs Did Not Show Reduction during the Manufacturing Process. To confirm whether enzymatic hydrolysis of GBVs occurs during the manufacturing process of oolong tea, we monitored changes of GBVs from the plucking process to fixing process (enzymatic reaction termination) of oolong tea. No GBVs were reduced in their contents during the enzyme-active process (Figure 4), which is consistent with the previous report.[21] This suggests that enzymatic hydrolysis of GBVs may not happen during the manufacturing process of oolong tea. The GBVs occur in vacuoles, whereas hydrolases such as β-primeverosidase were presumed to be localized in cell walls.[18] This compartmentation of substrates and enzymes in plant cells leads to little possibility of hydrolysis of GBVs in nondisrupted tea leaf cells. After additional treatment was done to disrupt tea leaf cell, GBVs were reduced (Figure 2), further demonstrating that lack of disruption of tea leaf cell during the oolong tea process resulted in unavailability of interaction of

J. Agric. Food Chem. 2015, 63, 6905−6914

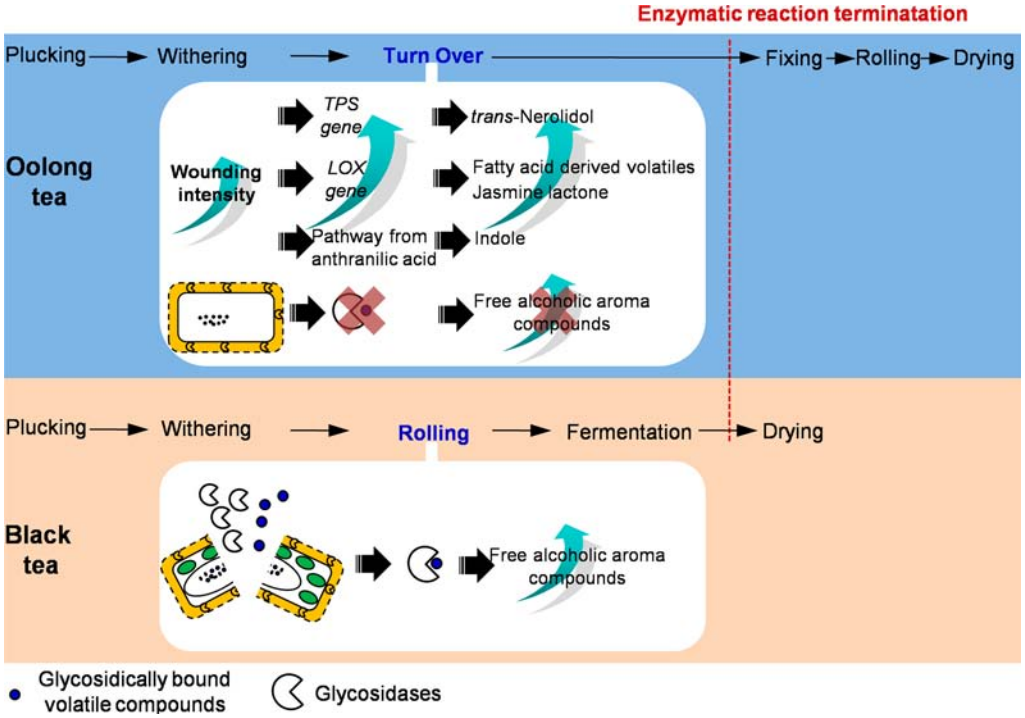

Figure 8. Hypothetical model of different formations of volatiles between the oolong tea process and the black tea process.

substrates and enzymes and no hydrolysis of GBVs. Interestingly, the previous report[21] and the present study found that the amounts of some GBVs increased (Figure 4). Currently, most studies on GBVs have concentrated on glycosidases, whereas little information on glycosyl transferases is available.[1] Recently glycosyl transferases in tea leaves have been functionally characterized;[40] it will be helpful for our understanding of the accumulation of GBVs during the oolong tea manufacturing process.

β-Glycosidases Were Not Activated during The Manufacturing Process, and Interaction of β-Glycosidases and GBVs Were Unavailable. To investigate whether β-glycosidases were activated during the manufacturing process, we monitored enzyme activities and gene expression levels of β-glycosidases from the plucking process to the fifth turn over process of oolong tea. The enzyme activities of β-glucosidase and β-primeverosidase did not show increase during the manufacturing process (Figures 5A and 5B). Moreover, expression level of *β-primeverosidase* showed reduction trend at the turn over process (Figure 5C). Although many stresses including drought, heat, wounding, and UV/light radiation are involved in the oolong tea manufacturing process, our study indicates that β-glycosidases were not activated under these stresses. This also reveals that contact of substrate (GBVs) and enzyme (β-glycosidases) is a key point determining whether enzymatic hydrolysis of GBVs happens in the tea manufacturing process.

Previously, Mizutani et al. found that β-primeverosidase is *N*-glycosylated, and has an *N*-terminal signal sequence, thus presumed that β-primeverosidase may locate in the cell wall.[18] However, a direct evidence of subcellular localization of β-primeverosidase in tea leaves is still unavailable. In the present study, subcellular localization of β-primeverosidase provided more evidence that β-primeverosidase is located in the leaf cell wall (Figure 6). Moreover, we investigated the cell structures of tea leaves from the manufacturing process of oolong tea. From the P to T1 process, the leaf cells showed complete and unwounded. The content was divided into several parts and showed the clear boundary (Figure 7A–F). From the T2 to T5 process, the cells shrank and distorted intensely, while the cell walls remained well and unwounded (Figures 7G–L). These results strongly support that lack of disruption of tea leaf cell during the oolong tea process resulted in unavailability of interaction of GBVs (substrates located in vacuole) and β-glycosidases (enzymes).

Besides *β-primeverosidase*, we also investigated the expression levels of *LOX* that is a key gene that involved in formation of fatty acid-derived volatiles and jasmine lactone,[1,25] and *TPS* that are possibly involved in formation of *trans*-nerolidol in tea leaves.[26] *LOX* is proposed as a wounding stress-response gene.[25] *LOX* gene expression level significantly increased at the turn over process (Figure 5D), which may be one of the reasons that most free fatty acid-derived volatiles and jasmine lactone increased at that process (Figure 1). Similarly, *TPS*1, 2, and 3 gene expression levels also significantly increased at the turn over process (Figures 5E,F,G). The present study provides important hints that the wounding stress at the turn over process may activate some key genes involved in formation of volatiles.

Furaneol, Jasmine Lactone, δ-Decalactone, Linalool, Vanillin, β-Ionone, β-Damascenone, 3-Methylnonane-2,4-dione, and Indole Were Identified as Relatively Potent Odorants in Oolong Tea. The above evidence shows that enzymatic hydrolysis of GBVs did not significantly contribute to the formation of volatiles of oolong tea. To further find out which volatiles contribute to flavor of oolong tea, GC–MS/O and AEDA were employed to determine the contribution of each volatile to the quality of the tea's aroma and flavor. The results revealed 49 odor-active peaks with FD factors between 4^1 and 4^7 in the final oolong tea product. Among them, the 11 compounds showed as relatively potent odorants with the higher FD factor ($\geq 4^4$) (Table 1). AEDA is most frequently used for identifying ordor-active compounds in

tea, and evaluating the flavor changes that occur during the manufacturing of tea beverages.[33,41−45] Based on this technique, many volatile compounds were identified as the most important components in Japanese and Chinese green teas and black tea beverages. However, little information on potent odorants in oolong tea is available. In the present study, Furaneol, jasmine lactone, δ-decalactone, linalool, vanillin, β-ionone, 3-methylnonane-2,4-dione, β-damascenone, indole, and two other compounds were identified as relatively potent odorants in oolong tea (Table 1). Although linalool was one of the potent odorants, its formation was not from enzymatic hydrolysis of glycosides of linalool (Figures 1 and 4). Jasmine lactone and indole were identified as relatively potent odorants, further suggesting that they were characteristic compounds derived from the manufacturing process of oolong tea (Figures 1 and 2) and partly contributed to the aroma of oolong tea. Other compounds showed high FD factors, suggesting that some compounds with low concentrations may have a comparatively low olfactory threshold detected by human and contribute to the characteristic aroma of oolong tea.

Formation of Volatiles Is Different between Oolong Tea and Black Tea. Oolong tea and black tea are fermented teas and have more aroma characters than green tea. Therefore, analysis and identification of volatile compounds during the manufacturing process of oolong tea and black tea have been well done. Based on the previous reports and the present study, we propose a hypothetical model of different formations of volatiles between the oolong tea process and the black tea process (Figure 8). (1) For oolong tea, turn over is a key process to produce tea aroma and increase of wounding intensity could lead to accumulations of indole, jasmine lactone, and *trans*-nerolidol, which may be characteristic aromas of oolong tea. However, such wounding is not sufficient for disruption of tea leaf cell, which is essential for interaction of substrates and enzymes. (2) For black tea, rolling is a key process to produce tea aroma. At this process, complete disruption of tea leaf cell leads to interaction of substrates and enzymes and many GBVs are hydrolyzed to release free alcoholic aroma compounds. The results help us find out the direct evidence of formation of volatiles in oolong tea, and advance our understanding of differences of formation of volatiles between oolong tea and black tea.

Fermentation of Wort by *T. versicolor*. Wort (Kölsch type, 13 °Plato) was provided by the University of Applied Sciences (Giessen, Germany).[7] Erlenmeyer flasks containing standard nutrition solution (100 mL/250 mL, medium volume/flask volume) were inoculated with fungal mycelia as reported previously.[6] The precultures were incubated on a rotary shaker (24 °C, 150 rpm, 25 mm shaking diameter) for 5 days in the dark. The mycelium of 10 mL of preculture broth was precipitated by centrifugation (2150*g*, 10 min, 20 °C) and washed three times with sterile water. The fungal pellets were resuspended in 10 mL of sterile wort. The suspension was added into an Erlenmeyer flask (250 mL) containing 100 mL of wort, and fermentation was carried out at 24 °C for 38 h under aerobic conditions on a rotary shaker (150 rpm). Subsequently, the mycelium was removed by centrifugation (2150*g*, 10 min, 4 °C), and the fermented beverage was used for the determination of nutritionally relevant parameters, for flavor analysis, and for safety assessment.

Determination of Nutritionally Relevant Parameters. The glucose content was determined with a D-glucose kit from R-Biopharm AG (Darmstadt, Germany). The total amount of reducing sugars was analyzed according to the method of Luff-Schoorl, and crude protein was quantified by Kjeldahl analysis. Oxalic acid was determined by ion exclusion chromatography with direct conductivity detection (883 basic IEC system, Metrohm AG, Filderstadt, Germany) as described by Marten.[13] Quantitation of ethanol was carried out by gas chromatography combined with headspace solid phase microextraction (HS-SPME) using standard addition.[14]

Liquid–Liquid Extraction (LLE) and Headspace Solid Phase Microextraction. For LLE, 90 mL of wort or fermented beverage was used as described previously.[7]

For HS-SPME, a CAR/PDMS fiber (75 μm carboxen/polydimethylsiloxane, fiber length = 1 cm) (Supelco, Steinheim, Germany) in combination with an MPS 2 XL multipurpose sampler (GERSTEL, Mülheim an der Ruhr, Germany) was used according to the method of Zhang et al.[8]

Aroma (Extract) Dilution Analysis. For LLE, the flavor dilution (FD) factors were determined by aroma extract dilution analysis (AEDA).[15] The organic extracts were diluted with pentane/diethyl ether (1:1.12, v/v) in a series of 1:1 dilutions. For HS-SPME, aroma dilution analysis (ADA) was performed by increasing the GC inlet split ratios.[7] After extraction, the volatiles of the beverage were diluted stepwise by controlling the split ratio as follows: splitless (splitless time = 2 min), 2:1, 4:1, 8:1, 16:1, 32:1, 64:1, 128:1, and 256:1. After dilution, each sample was sniffed twice until no odorants were perceived at the ODP 3 olfactory detection port (GERSTEL) of the GC-MS/MS-O system.

GC-MS/MS-O Analysis. GC-MS/MS-O analysis was based on the method described by Zhang et al.[7,8]

Multidimensional Gas Chromatography–Mass Spectrometry (MDGC-MS). Chiral separations were performed on an MDGC-MS system (Shimadzu Europa GmbH, Duisburg, Germany), which consists of two Shimadzu GC-2010 Plus gas chromatographs (GC 1 and GC 2), equipped with a multi Dean's switch (MDS), a Shimadzu QP2010 Ultra mass spectrometer, and a Shimadzu AOC-20i autoinjector.

GC 1. Helium (5.0) was used as carrier gas. A polar Agilent J&W VF-WAXms column (30 m × 0.25 mm i.d. × 0.25 μm film thickness) (Agilent Technologies, Waldbronn, Germany) was used for initial separation. The operational conditions were as follows: constant inlet pressure, 208.1 kPa; inlet temperature, 250 °C; splitless, 2 min; initial linear velocity, 25 cm/s; temperature program, 40 °C (3 min), raised at 10 °C/min to 200 °C (6 min). The FID (250 °C; H_2 flow, 40 mL/min; air flow, 400 mL/min; makeup gas N_2 (5.0), 30 mL/min) was connected via a stainless steel retention gap to the MDS.

GC 2. A Hydrodex β-TBDAc column (heptakis-(2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin; 25 m × 0.25 mm i.d.; Macherey-Nagel, Düren, Germany) was applied for the analysis of linalool. The oven temperature program was held at 40 °C for 1 min, ramped at 10 °C/min to 80 °C, held for 50 min, increased at 20 °C/min to 200 °C, and finally held for 4 min. An Astec Chiraldex B-DM column ((2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin; 30 m × 0.25 mm i.d. × 0.12 μm film thickness; Sigma-Aldrich, Taufkirchen, Germany) was applied for the analysis of 2-methylbutanoic acid. The oven temperature program for the analysis of 2-methylbutanoic acid was held at 40 °C for 1 min, ramped at 10 °C/min to 65 °C, held for 45 min, increased at 20 °C/min to 200 °C, and finally held for 4 min. Further conditions were as follows: transfer line temperature between GC 1 and GC 2, 200 °C; initial linear velocity, 47.2 cm/s; switching pressure, 129.1 kPa; MS modes, selected ion monitoring (*m*/*z* 57, 74, 87) for 2-methylbutanoic acid and scan mode (*m*/*z* 33–300) for linalool; electron ionization energy, 70 eV; source temperature, 200 °C; quadrupole temperature, 150 °C; MS transfer line temperature, 200 °C. All data were collected using Shimadzu MDGC solution software 1.01.

Compound Identification. The aroma compounds were identified by comparison of their respective odor impressions, their retention indices (RI) on two columns of different polarity (VF-WAXms and DB-5MS), and their mass spectra with those of authentic standards and published data.

Quantitative Analysis and Calculation of Odor Activity Values (OAVs). The concentrations of aroma compounds extracted by LLE were estimated via internal standard (IS) method (100 μL of IS; 888 mg thymol/L pentane/diethyl ether). The corresponding response factors (Rf) were calculated for each analyte according to eq 1

$$\mathrm{Rf} = \frac{A_{\mathrm{IS}} m_{\mathrm{a}}}{m_{\mathrm{IS}} A_{\mathrm{a}}} \quad (1)$$

where *A* = peak area, *m* = mass (μg), IS = internal standard, and a = analyte.

The aroma compounds extracted by HS-SPME were quantitated by standard addition.[8] A standard solution mixture was prepared containing the target compounds in their respective concentrations.

The quantifier and qualifier ions of each compound are listed in Table 1.

Table 1. *m*/*z* Fragments (Quantifier and Qualifier Ions) Used for Quantitative Analysis

compound	MS mode[a]	quantifier ion (*m*/*z*)	qualifier ion (*m*/*z*)
ethyl 2-methylpropanoate[b]	SIM	71	116

[a]Mean of RI values from LLE and SPME. [b]Flavor dilution (FD) factor of the corresponding compound. [c]–, odor was not perceived. [d]Odor corresponded to two coeluting compounds. [e]Retention indices (RI) were calculated on the basis of the retention time of the odor impression perceived at the ODP. [f]nd, no distinct MS spectrum on the DB-5MS column. [g]The peak area was below the limit of detection; the compound was tentatively identified on the basis of RI, odor impression, and literature data.[25] [h]MS spectrum was obtained from wort.

The OAVs of the key aroma compounds were calculated as the ratios of the concentrations in the beverage to their respective odor thresholds in water.

Concentrations of Key Aroma Compounds during the Fermentation Process. The concentrations of the key aroma compounds were quantitated after 0 (before fermentation) and 38 h (after fermentation) by means of LLE and HS-SPME and GC-MS/MS-O analysis. Quantitative changes were expressed by the relative peak areas of each target compound. Each sample was analyzed in duplicate.

Cytotoxicity in Rat Hepatocytes in Primary Culture. Cytotoxicity of the beverage and of the nonfermented wort was determined in rat hepatocytes in primary culture by means of the resazurin reduction assay and the lactate dehydrogenase leakage assay. Before use, the pH of the beverage was adjusted to neutral.

Rat livers were perfused according to the two-step method of Seglen to isolate primary rat hepatocytes.[16] The viability of cell preparations always exceeded 90%. The procedure of hepatocyte preparation was authorized by the Ethical Committee of the State of Rhineland-Palatinate. Hepatocytes were treated with the beverage or wort at concentrations of 0.1, 1, and 10% (v/v) in culture medium and incubated at 37 °C and 5% CO_2. Addition of 0.1% (w/v) saponine (added as aqueous solution) served as a positive control, culture medium as a negative control.

DOI: 10.1021/acs.jafc.5b02167
J. Agric. Food Chem. 2015, 63, 6915−6921

For the resazurin reduction assay,[17] cells were seeded in collagenated 24-well plates at a density of 100,000 cells/cm^2. After 48 h of treatment, cells were incubated with medium containing resazurin for 90 min. The fluorescent metabolite resorufin was measured in a fluorescence plate reader.

For the lactate dehydrogenase (LDH) leakage assay,[18] cells were seeded in collagenated 60 mm dishes at a density of 100,000 cells/cm^2. After 6 h of treatment, the integrity of cell membranes was determined by measuring the activity of the cytosolic enzyme LDH leaked out of cells into the culture medium in comparison to the total amount of LDH activity (medium + cell pellet). LDH activity was measured by the fluorescence of metabolized NADH.

Mutagenicity Testing in Ames Fluctuation Assay. The mutagenicity of the beverage was tested according to the method of Maron and Ames in *Salmonella typhimurium* in a variation of the Ames fluctuation test (ISO 11350, 2012).[19,20] Strain TA98 was used to detect frameshift mutations and strain TA100 to detect base pair substitutions. The tests were performed with and without metabolic activation by rat hepatic S9 mix.

Hepatic S9 mix was prepared from the livers of rats treated with Aroclor 1254 according to the method of Maron and Ames.[19] The procedure of S9 preparation was authorized by the Ethical Committee of the State of Rhineland-Palatinate.

Bacteria suspensions were treated with the beverage at concentrations of 0.1, 1, and 10% (v/v) in histidine-deficient medium and incubated at 37 °C. 4-Nitro-*o*-phenylenediamine (for strain TA 98 without S9), nitrofurantoin (for strain TA 100 without S9), and 2-aminoanthracene (for both strains with S9) served as positive controls and medium, water, and DMSO as negative controls.

The growth of revertants in histidine-deficient medium was measured in 384-well plates by means of the pH indicator dye bromocresol purple, and the percentage of positive wells was calculated accordingly.

Statistical Analysis of Cytotoxicity and Mutagenicity Results. Statistical values (means and standard deviations) and data used in charts (bar graphs) were calculated by use of the software package Origin 9.1 (OriginLab, Northampton, MA, USA). Statistical significance was determined by ANOVA and Dunnett post test with the software InStat 3.0 (GraphPad, La Jolla, CA, USA). All experiments were performed in triplicate.

RESULTS AND DISCUSSION

Nutritionally Relevant Parameters. Due to the steadily declining consumption of beer and to satisfy market needs for non- or low-alcoholic alternatives, new fermentation systems have been developed. In the past, predominantly yeasts and lactic acid bacteria have been utilized to ferment wort.[21,22] In our study, wort was fermented by the basidiomycete *T. versicolor* for the first time.

During the fermentation, the concentrations of total reducing sugars and glucose decreased significantly by 21 and 43%, respectively (Table 2). The protein concentration decreased by about 5%, and the concentration of oxalic acid, which is typically present in wort, was reduced from 28 to 23 mg/L. Oxalic acid might be converted to formic acid and carbon dioxide by oxalate decarboxylase produced by *T. versicolor*.[23] Oxalic acid may cause haze-forming and gushing of beer. In the fermented beverage the concentration of ethanol was determined to be 0.39% (v/v), whereas no ethanol was detected in wort. An alcohol dehydrogenase of *T. versicolor* has been described previously by Kudahettige et al.[24] In most of the European Union countries and the United States, an upper limit of 0.5% alcohol by volume has been defined for alcohol-free beer.[21] Therefore, the novel beverage may still be considered a nonalcoholic refreshment.

Flavor Analysis of the Novel Fermented Beverage. The odor of the fermented beverage was perceived as fruity, fresh, sweetish, and slightly floral. It was strikingly different from the typical odor of wort and most cereal beverages fermented by lactic acid bacteria, yeasts, or lower fungi. To understand the formation of the unique aroma, the flavor of the beverage was analyzed.

Extraction and Identification of Key Aroma Compounds. Two different extraction methods were used together with GC-MS/MS-O analysis to comprehensively analyze the beverage's aroma. Previous studies have shown that fibers containing porous carbon in their stationary phase were highly effective in extracting various types of volatile compounds.[7] Therefore, a CAR/PDMS fiber was chosen for extracting the volatile compounds.

By GC-MS/MS-O analysis, 17 and 24 odor-active regions from the fermented beverage were detected at the ODP after LLE and HS-SPME, respectively (Table 3). Only seven of them were detected by both methods. Thus, in total 34 different odor impressions were perceived. Twenty-seven aroma compounds including inter alia acids, alcohols, aldehydes, ketones, and esters/lactones were identified. Most odor-active regions were attributed to a single compound. Only two odor impressions (no. 9 and 23) originated from coeluting compounds (Table 3). The mixture of 2-methylbutanol and 3-methylbutanol imparted a fresh and sourish odor (no. 9). A cheesy, stinky, and sourish odor was perceived from 2-methylbutanoic acid accompanied by 3-methylbutanoic acid (no. 23).

By performing an A(E)DA for each extraction method (Table 3), the key aroma compounds of the beverage were identified (FD factors from 8 to 128 for at least one of the two extraction techniques). A compound assigned to a high FD factor after LLE might exhibit a low FD factor after HS-SPME and vice versa (cf. 2-/3-methylbutanoic acid, 2-phenylethanol, 2-phenylacetic acid, methional, linalool, 2,3-butanedione, and ethyl 2-methylbutanoate). Compared to HS-SPME, LLE performed better in trapping organic acids and higher molecular weight alcohols and showed lower sensitivities for highly volatile compounds as well as for some trace compounds. By combining the two different extraction techniques, the aroma compounds of the beverage were trapped in a wide range.

Several of the main odor-active compounds of the beverage, such as 2-methylbutanoic acid (FD 128) and linalool (FD 64), are chiral. The enantiomeric purities of both odorants were determined by means of an MDGC-MS system. Both components showed high enantiomeric excess (ee) values of 91.5% for (*R*)-linalool and >95% for (*S*)-2-methylbutanoic acid. The aroma of (*R*)-linalool is described as floral, whereas the (*S*)-enantiomer imparts an intense green note.[34] The chiral analysis supported the perceived "floral" odor impression (Table 3). The aroma of (*S*)-2-methylbutanoic acid is perceived as sweetish and fruity.[35] However, 2-methylbutanoic acid coeluted with 3-methylbutanoic acid, which imparts a sourish and sweaty odor. Therefore, it seems reasonable that the corresponding odor impression (no. 23) was perceived as cheesy, stinky, and sourish (Table 3). As methyl 2-methylbutanoate (FD 2), 2-methylbutanol (FD 1), and γ-nonalactone (FD 4) showed only low flavor dilution factors, their ee values were not determined. No authentic enantiopure standard of ethyl 2-methylbutanoate (FD 32) was commercially available, and the absolute configuration of this compound could thus not be assigned.

Quantification and Calculation of the OAVs of Key Aroma Compounds. To evaluate the contribution of a single

DOI: 10.1021/acs.jafc.5b02167
J. Agric. Food Chem. 2015, 63, 6915−6921

compound to the overall aroma, OAVs of the key aroma compounds of the beverage were calculated. Therefore, the concentrations of 15 odorants with FD factors of 8−128 were quantified. 2-Methylbutanoic acid, 3-methylbutanoic acid, 2-methylpropanoic acid, 2-phenylacetic acid, and 2-phenylethanol were quantified in the organic extract according to the internal standard thymol. The other compounds were quantified by HS-SPME using standard addition.

2-Phenylacetaldehyde, ethyl 2-methylpropanoate, linalool, 2,3-butanedione, and methional showed high OAVs (≥10) (Table 4). Additionally, 3-methylbutanoic acid, β-damascenone, 2-methylpropanoic acid, 2-methylbutanoic acid, and ethyl 2-methylbutanoate presumably contributed to the overall aroma.

Table 4. Quantitative Data, Odor Thresholds, and Odor Activity Values (OAVs)

compound	concentration in the beverage (μg/L)	odor threshold (μg/L)	OAV
ethyl 2-methylpropanoate	0.6 ± 0.16	0.02[26]	31
2,3-butanedione	30 ± 7.4	3[27]	10
ethyl 2-methylbutanoate	0.18 ± 0.039	0.15[27]	1.2
2,5-dimethylpyrazine	2.68 ± 0.034	1700[28]	<0.1
methional	14 ± 1.1	1.4[29]	10
benzaldehyde	4.8 ± 0.66	25[26]	0.2
linalool	2.30 ± 0.011	0.14[30]	16
2-phenylacetaldehyde	162 ± 28	4[28]	40
2-acetylthiazole	2.68 ± 0.22	10[31]	0.3
β-damascenone	0.13 ± 0.013	0.056[29]	2.3
2-methylbutanoic acid	205 ± 12	100[32]	2.0
3-methylbutanoic acid	154 ± 20	22[26]	7.0
2-methylpropanoic acid	432 ± 15	190[33]	2.3
2-phenylacetic acid	84.2 ± 0.77	360[26]	0.2
2-phenylethanol	31 ± 2.0	390[29]	0.1

Changes of Key Aroma Compounds during the Fermentation Process. To control the quality of the beverage in a future industrial process, relative changes in the concentrations of the key aroma compounds were investigated before and after the fermentation process (Figure 1). Whereas

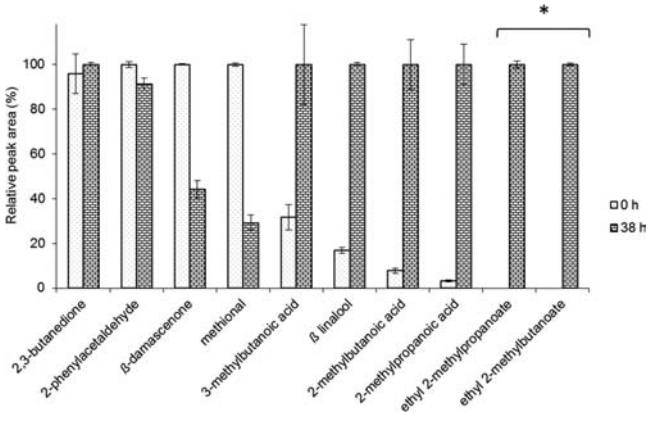

Figure 1. Relative changes of the concentrations of the key aroma compounds in the beverage during the fermentation (0 vs 38 h) (*, compounds detected only in the fermented beverage).

most of the odorants were already present in the substrate wort (0 h), the fruity aroma compounds ethyl 2-methylpropanoate and ethyl 2-methylbutanoate were synthesized de novo by *T. versicolor*. The concentrations of β-damascenone and methional were reduced, whereas those of linalool, 2-methylbutanoic acid, 3-methylbutanoic acid, and 2-methylpropanoic acid increased during the fermentation. The degradation of β-damascenone and methional and/or adsorption to the cell wall have been reported for yeasts.[36,37] Linalool with its floral odor is a known constituent of the aroma of fruiting bodies of *T. versicolor* as well as of many other fungi (e.g., *Clitocybe odora*, *Hydnum repandum*, *Lactarius salmonicolor*, *Lepista nuda*, *Mycena rosea*, and *Tricholoma sulfureum*).[38,39] Although basidiomycetes have a huge potential for producing terpenoids, relatively few biosynthetic pathways of fungal terpenoids have been described.[40] The formation of 2-methylbutanoic acid, 3-methylbutanoic acid, and 2-methylpropanoic acid might be related to the transformation of L-isoleucine, L-leucine, or L-valine present in wort.[41] The biotransformation of branched-chain amino acids by shiitake to volatiles has been described recently by Zhang et al.[9]

The odor qualities of ethyl 2-methylpropanoate and ethyl 2-methylbutanoate have been described as "fruity, strawberry"- and "fruity, green apple"-like. To our knowledge, this is the first time that these two ethyl esters have been detected in cultures of *T. versicolor*. Ethyl 2-methylpropanoate has been reported as a flavor compound formed by *Tuber melanosporum*, *Tuber indicum*, *Ceratocystis fimbriata*, yeasts, and fruits.[42−45] Ethyl 2-methylbutanoate was identified in the pine-mushroom (*Tricholoma matsutake* Sing.).[46] Comprehensive information on the pathways and control mechanisms of the biogenesis and accumulation of these two ethyl esters in basidiomycetes is not available yet. However, it is well-known that branched-chain amino acids, branched-chain fatty acids, and branched-chain alcohols serve as precursors of fruity esters in yeasts and fruits (e.g., apple, banana, and melon).[47−50] The relative concentrations of 2-methylpropanoic acid and 2-methylbutanoic acid increased significantly during fermentation.

Cytotoxicity and Mutagenicity of the Beverage and Nonfermented Wort. *Cytotoxicity in Rat Hepatocytes in Primary Culture.* Compared to the negative control, neither in the resazurin reduction assay nor in the LDH leakage assay was a statistically significant decrease in metabolic activity and membrane integrity, respectively, observed after treatment of the cells with the beverage or nonfermented wort. The functionality of both assays was validated by negative and positive controls.

Mutagenicity in the Ames Fluctuation Test. Neither in *Salmonella typhimurium* strain TA 98 used for screening for frameshift mutations nor in strain TA 100 employed for base pair substitutions were statistically significant mutagenic events detected compared to the negative control after treatment of bacteria suspensions with the beverage or nonfermented wort with or without metabolic activation by S9 mix. The functionality of the assay was validated by negative and positive controls.

In conclusion, a novel fermented beverage was developed by incubation of wort with *T. versicolor*. Due to the fermentation, changes in the concentrations of carbohydrates, proteins, and oxalic acid were observed. Its aroma was perceived as fruity, fresh, sweetish, and floral, which was significantly different from the sourish odor of traditional nonalcoholic fermented cereal beverages. Ten key aroma compounds significantly contributed

DOI: 10.1021/acs.jafc.5b02167
J. Agric. Food Chem. 2015, 63, 6915−6921

to the overall aroma of the beverage. Most of them originated from wort, but their concentrations changed during the fermentation process. The fruity odorants ethyl 2-methylbutanoate and ethyl 2-methylpropanoate were detectable only in the fermented beverage and thus synthesized by *T. versicolor*. Comprehensive toxicological studies indicated no cytotoxicity and mutagenicity activity.

Taken together, a beverage fermented by *T. versicolor* may present an interesting option for novel cereal-based products. Prior to the final product development, that is, up-scaling and control of the product quality, reconstitution and omission experiments should be performed in further studies.

J. Agric. Food Chem. 2015, 63, 6915−6921

the QUENCHER approach.[12−15] Up to now, these assays have been successfully applied to some foods for which the antioxidant activity is largely dependent on the insoluble part, such as cereals and bakery products, seeds, nuts, pulses, and dietary fibers.[12−19] It must also be noted that a mixture of ethanol/water (50:50, v/v) has been suggested as the most appropriate reaction medium to carry out QUENCHER assays, and "neutral" powdered materials such as cellulose have been proposed as suitable diluting agents when products under study are very rich in antioxidants.[11,12]

Despite the advantages and previous applications of the QUENCHER methods, these assays are not yet extensively used, probably due to a lack of validation studies of these methodologies. In addition, to the best of our knowledge, the QUENCHER concept has still not been adapted to the methodologies that target biologically relevant radicals (SRSC, HRSC, and LPSC), and a statistical validation and correlations between the different Q-TAC and Q-FRSC assays have not yet been performed. These verifications are important to encourage the applicability of QUENCHER protocols as valuable tools for the in vitro antioxidant capacity assessment of different products such as foods, food ingredients, and others.

Therefore, to increase the use of the QUENCHER approach, the first aim of the present study was to develop new QUENCHER protocols to evaluate the scavenger capacity of some of the most biologically relevant radicals (superoxide, hydroxyl, and lipid peroxyl); the second aim was to optimize and, for the first time, validate different QUENCHER assays (Q-FC, Q-FRAP, Q-ABTS, Q-DPPH, Q-ORAC, Q-SRSC, Q-HRSC, and Q-LPSC) using three model products of different chemical properties. Secondarily, the best combination of QUENCHER assays for routine analysis was identified, and several factors that might influence the Q-TAC results, such as the presence of ethanol in the reaction medium and the use of cellulose as a diluting agent, were assessed. The study was carried out with three powdered model products, all of them rich in antioxidant compounds, but each containing antioxidants of different polarity. Powdered products were made in our pilot plant from wine pomace so that we could work with familiar products for which characteristics and composition were well-known.

MATERIALS AND METHODS

Chemicals. ABTS, cellulose, DPPH, deoxyribose (2-deoxy-D-ribose), 2,2′-diazobis(2-aminodinopropane) dihydrochloride (AAPH), gallic acid (GA), 6-hydroxyl-2,5,7,8-tetramethyl-2-carboxylic acid (Trolox), 4-nitroblue tetrazolium chloride (NBT), phenazin methosulfate (PMS), 2,4,6-tris(2-pyridyl)-*S*-triazine (TPTZ), and 2-thiobarbituric acid (TBA) were obtained from Sigma-Aldrich Co (St. Louis, MO, USA). Ethylenediaminetetraacetic acid (EDTA), iron(III) chloride acid ($FeCl_3$), iron(II) sulfate ($FeSO_4$), FC reagent, hydrogen peroxide (H_2O_2), L-ascorbic acid ($C_6H_8O_6$), potassium persulfate ($K_2O_8S_2$), sodium acetate ($NaC_2H_3O_2$), sodium carbonate (Na_2CO_3), sodium pyrophosphate anhydrous ($Na_4P_2O_7$), and trichloroacetic acid (TCA) were purchased from Panreac (Barcelona, Spain).

Samples. Red wine pomace was kindly supplied by different wineries located at Burgos (Spain). All red wine pomace was mixed and dehydrated until reaching a final water content of <10%. Dried materials were separated, ground, and sieved, thus obtaining three different powdered products,[20] which were used as model matrices. One of them was derived from grape seeds (Sd) separated from the wine pomace; this model product represented foods with a significant content of fat and rich mainly in hydrophobic antioxidants. Another product was obtained from the wine pomace free of seeds, which was mainly constituted by grape skins (Sk); this model product represented food matrices rich in hydrophilic antioxidant and without or with very low levels of fat. The third powdered product was obtained from whole (W) wine pomace; this model product represented food materials with some fat and rich in both hydrophilic and hydrophobic antioxidants. The particle size of these model products was <0.250 mm in the cases of Sk and W and <0.355 mm for Sd.[21]

QUENCHER Antioxidant Capacity Methods. The adapted Q-TAC and Q-FRSC methodologies were fixed end-point procedures with the exception of the Q-ORAC method, which was a kinetic assay. Results are given as mean values ± standard deviation of three independent samples.

Q-FC Assay. This method was adapted from the FC assay developed by Singleton and Rossi.[22] Briefly, 1 ± 0.005 mg of the tested products was weighed in a microbalance (MicroPro11, Sartorius) and mixed with 0.2 mL of Milli-Q (MQ) water and 0.2 mL of FC reagent. After 5 min of reaction, 4 mL of a 0.7 M Na_2CO_3 solution was added, and the final volume was made up to 10 mL with MQ water. After 1 h of incubation in an orbital shaker, the absorbance at 750 nm was measured using an UV−vis spectrophotometer (U-2000 Hitachi). The FC index was expressed as micromoles of gallic acid equivalents per gram of product (μmol GAE/g) by means of a dose−response curve for different quantities of the standard.

Q-FRAP Assay. The Q-FRAP procedure was adapted from the method described by Benzie et al.[23] The reactive mixture was freshly prepared by mixing 10 mM TPTZ and 20 mM $FeCl_3$ in 300 mM $NaC_2H_3O_2$ buffer (pH 3.6) at a ratio of 1:1:10 (v/v/v) and diluted 10:1 (v/v) in MQ water. Ten milliliters of the FRAP solution was added to 1 ± 0.005 mg of the samples and incubated at 37 °C for 30 min with continuous stirring. The absorbance at 593 nm was measured. The results were expressed as micromoles of iron(II) equivalents per gram of product (μmol Fe(II)E/g) using linear calibration obtained with different amounts of $FeSO_4$.

Q-ABTS Assay. The method was adapted from the assay developed by Re et al.[24] and modified by Rivero-Pérez et al.[25] The stock solution of $ABTS^{\bullet+}$ was diluted with MQ water to an absorbance of 0.70 ± 0.02 at 734 nm; 1 ± 0.005 mg of the assessed products was weighed, and the reaction was started by adding 10 mL of $ABTS^{\bullet+}$ working solution. After 30 min of incubation in darkness with continuous stirring, the absorbance of the samples at 734 nm was measured and subtracted from the absorbance of the $ABTS^{\bullet+}$ working solution. The results are expressed as micromoles of Trolox equivalents per gram of product (μmol TE/g), using the dose−response curve described by different amounts of this standard.

Q-DPPH Assay. This method is based on the scavenging of the radical $DPPH^{\bullet}$.[26] A 0.1 mM $DPPH^{\bullet}$ working solution in pure methanol was prepared and diluted until an absorbance at 517 nm of 0.70 ± 0.02.[25] Then, 1 ± 0.005 mg of the powdered products was transferred into a test tube and mixed with 10 mL of $DPPH^{\bullet}$ working solution. The absorbance at 517 nm was measured after 30 min of continuous stirring at room temperature in the samples and subtracted from the absorbance of the $DPPH^{\bullet}$ working solution. Trolox was used as standard to perform a calibration curve, and the results were expressed as micromoles of TE per gram of product (μmol TE/g).

Q-ORAC Assay. This assay was adapted from the method described by Ou et al.[27] The analysis was conducted in a four-cell fluorometer (Cary-Eclipse, Varian) with continuous stirring in the cuvette and at 37 °C. Briefly, 0.2 ± 0.005 mg of the assessed products was weighed and resuspended in 0.8 mL of 75 mM phosphate buffer (pH 7.0, warmed to 37 °C) just before use. A Trolox quality control (T10, equivalent to 10 μg of Trolox) and a 300 mM AAPH solution in phosphate buffer were also freshly prepared. At least one T10 and one blank were analyzed with every set of samples (same AAPH solution). In a glass cuvette, 0.4 mL of the samples (the resuspended products, the T10 control or just phosphate buffer for the blank) was mixed with 2 mL of a freshly prepared 87.5 nM fluorescein solution in phosphate buffer. The fluorescence reading (λ_{exc} = 493 nm and λ_{em} = 511 nm) was started, and 0.1 mL of the AAPH solution was added after 2.5 min. The fluorescence decay curve was monitored for 100 min. The net area under the curve (net AUC) was calculated for each sample by

DOI: 10.1021/acs.jafc.5b01644
J. Agric. Food Chem. 2015, 63, 6922−6931

subtracting the blank AUC from the sample AUC. Regression equations between net AUC and different quantities of Trolox were obtained and used for the expression of the Q-ORAC values as micromoles of TE per gram of product (μmol TE/g).

Q-SRSC Assay. The Q-SRSC procedure was adapted from the method described by Liu et al.[28] and Rivero-Pérez et al.[25] Briefly, 1.5 ± 0.005 mg of the products was added to the test tube and mixed with a 1.5 mL final volume of 78 μM NADH, 50 μM NBT, and 10 μM PMS in 16 mM buffer Tris-HCl (pH 8.0). After the mixture had been shaken for 10 s, the absorbance (A) of the samples (S) at 560 nm was measured. "Oxidized controls" (OC; without products) and "sample controls" (SC; products and buffer) were also prepared. The results are expressed as oxidation inhibition percentages by the equation

$$\text{oxidation inhibition } \% = (A_{OC} - (A_S - A_{SC}))/A_{OC} \times 100 \quad (1)$$

Q-HRSC Assay. The Q-HRSC assay was adapted from the method developed by Halliwell et al.[29] and modified by Rivero-Pérez et al.[25] Briefly, 1 ± 0.005 mg of the powdered products was weighed and transferred into a screw-top test tube. A 1 mL final reaction volume contained a mixture of 1 mM deoxyribose, 0.1 mM $C_6H_8O_6$, 1 mM H_2O_2, 0.1 mM $FeCl_3$, and 0.1 mM EDTA in 5 mM phosphate buffer (pH 7.4). OC and SC were also prepared. The tubes were incubated for 60 min at 37 °C with continuous stirring. Then, 1.5 mL of TCA (28% w/v) and 1 mL of TBA (1% w/v) were added, and the capped tubes were shaken and heated at 100 °C for 15 min. The absorbance was recorded at 532 nm, and the results were expressed as oxidation inhibition percent following eq 1.

Q-LPSC Assay. This assay was adapted from the method described by Rivero-Pérez et al.[25] The experiments were carried out in rat liver microsomal preparations,[30] and lipid peroxidation was induced using AAPH as oxidant. The total microsomal protein content was determined using the Bradford method.[31] A microsomal solution containing 10 mg/mL protein in 0.1 M $Na_4P_2O_7$ buffer (pH 7.4) was prepared and stored at −80 °C until the day of analysis; 0.2 ± 0.005 mg of the tested products was placed into a screw-top tube, and 400 μL of 50 mM Tris-HCl buffer (pH 7.0), 50 μL of the microsomal solution, and 50 μL of 100 mM AAPH solution in the Tris-HCl buffer were added. OC and SC (replacing the AAPH solution by Tris-HCl buffer) were also prepared. The tubes were incubated at 37 °C for 90 min under continuous stirring. Then, 750 μL of TCA (2.8% w/v) and 500 μL of TBA (1% w/v) were added, and the capped tubes were shaken and heated at 100 °C for 15 min. Finally, 750 μL of the reaction mixture was transferred to another tube, and the TBA reactive substances were extracted with the same volume of butanol. The absorbance at 532 nm of the butanol extract was measured, and the results were expressed as oxidation inhibition percent with respect to the OC sample following eq 1.

Statistical Analysis. The statistical validation of the methods was performed using Statgraphics Centurion XVI version 16.2.04 software (Statpoint Technologies, Inc., Warranton, VA, USA). The statistical analysis of the Q-TAC data was carried out using one-way analysis of variance (ANOVA). Fisher's least significant difference (LSD) test was applied to determine the statistical significance of differences among various groups. A minimum significance level of $p < 0.05$ was considered. Pearson's correlation coefficients were determined to study linear correlations between pairs of the Q-TAC methodologies.

RESULTS AND DISCUSSION

Adaptation and Optimization of the Q-TAC and Q-FRSC Methods. This study shows some modifications with respect to Q-TAC protocols (Q-ABTS,[12] Q-DPPH,[12] Q-FRAP,[14] Q-ORAC,[13] and Q-FC[15]) previously published. Moreover, three new QUENCHER methodologies were developed (Q-SRSC, Q-HRSC, and Q-LPSC), which were adapted from validated classical FRSC methods.[25]

The main modification from other Q-TAC assays was the selection of aqueous reaction mediums whenever the methodologies allowed for the use of both organic and aqueous solvents. Aqueous medium might better represent the real environment surrounding any food matrix or biological system. Therefore, MQ water or aqueous buffer was initially used in all protocols except in the Q-DPPH assay, which required an organic solvent to dissolve the radical.

The particle size of the powdered products is a factor that might influence the results of the Q-TAC and Q-FRSC measurements, and this aspect should be taken into account for comparisons among powders of different particle size. Nevertheless, Serpen et al.[17] did not find a remarkable effect of this factor, and Gökmen et al.[11] suggested the use of powdered samples of particle size ranging from 0.3 to 0.1 mm in QUENCHER assays.

All protocols in this study were optimized for the direct measurement of small quantities of powdered products, considering the final reaction volume and amount of sample weighed.

The Q-FC, Q-FRAP, Q-ABTS, and Q-DPPH methods are rather inexpensive and simple methodologies, which allow for the adjustment of the assay volumes (maintaining the proportionality among the reagents) without a relevant increase in the cost of the analysis. Preliminary studies were conducted to establish 1 mg as an advisable amount of product, although satisfactory results can also be obtained with smaller or larger quantities (0.2−5 mg), depending on the TAC of the products and the sensitivity of the assay.

In the case of the Q-ORAC method, the reaction volume is restricted by the maximum volume of the cuvette because the fluorescence decay needs to be continuously monitored (kinetic assay). Amigo-Benavent et al.[13] proposed that the Q-ORAC assay be carried out in alternating stages of incubation at 37 °C in a test tube with centrifugation, transfer to a cuvette, and fluorescence reading. The Q-ORAC method proposed in the present study avoids several centrifugation/transfer steps, is more similar to classical protocols, and reproduces more effectively the advantages of the ORAC assay with respect to other TAC methods.[2,4,8] However, a fluorometer with a temperature control chamber and constant stirring in the cuvette is required, and the assay might not be suitable for products of very high Q-TAC.

With regard to the Q-SRSC, QHRSC, and Q-LPSC methods, the final reaction volume and amount of sample weighed must be adjusted to give results in the range of 0−100% oxidation inhibition. The Q-SRSC assay is a rather simple and quick methodology that can be directly performed in the cuvette or in a test tube. However, the Q-HRSC and the Q-LPSC assays involve more tedious protocols. It is suggested that the amount of sample used be adjusted rather than increasing the final volume, although it must be remarked that the precision of the QUENCHER methods might be compromised when <0.2 mg of the samples is weighed.

QUENCHER fixed end-point procedures allow for transferring an aliquot of the reaction medium to a microplate for the absorbance reading step. This alternative increases the repeatability and reduces the time between different measurements, so it is especially appropriate for the simultaneous analyses of multiple samples. On the other hand, QUENCHER kinetic assays cannot be carried out directly in a microplate due to the interference of solid products on the absorbance measurement. Furthermore, the extremely small quantity of solid sample required, proportional to the small volume of wells, could put at risk the validity of this procedure.

[c]Estimate of repeatability (S_r) determined by one-variable analysis of seven replicates on one day (Rp, repeatability experiment). [d]Estimate of repeatability (S_r) determined by one-way ANOVA of three replicates on three different days (IP, intermediate precision experiment). [e]Intermediate precision acceptance criteria: CV < 10%. [f]Estimate of intermediate precision (S_R) determined by one-way ANOVA of three replicates on three different days (IP, intermediate precision experiment).

Validation of the Q-TAC and Q-FRSC Methods. The validation study was done by the examination of the following parameters: linearity, proportionality, detection limits, and precision (repeatability and intermediate precision).[32] In the case of Q-FRSC assays (Q-SRSC, Q-HRSC, and Q-LPSC), only the precision was evaluated because in these methods a calibration curve is not needed. In the Q-TAC methodologies (Q-FC, Q-FRAP, Q-ABTS, Q-DPPH, and Q-ORAC), a dose−response curve was obtained by testing different amounts of the standard used in each method. The calibration was performed using linear models and the least-squares (LS) method. All of the models presented coefficient of determination (R^2) values >0.995 (Table 1).

Once the parameters were estimated, the models were validated by verifying the assumptions related to the residuals and the functions.[33] The studentized residuals were normally distributed (Kolmogorov−Smirnov, chi-square, and Shapiro−Wilk tests), independent (Durbin−Watson test), and homoscedastic (Cochran and Bartlett tests) in all cases. The functional part of each linear model was first validated in a linearity test. According to the results (Table 2), all of the models were suitable for describing the linear relationship between the standard concentration and the response of each assay. The Q-FC method obtained the best values for all of the parameters tested, whereas the Q-ORAC assay linearity response was the least satisfactory, although within the acceptance criteria. In addition, a proportionality test to determine whether the mathematical model could be used for predictive purposes was performed (Table 2). The conditions of proportionality were corroborated for all methods except Q-

[a]Q-TAC and Q-FRSC values are the mean ± standard deviation (n = 3). Roman letters indicate significant differences among the model products (Sk, W, Sd) within each QUENCHER methodology. [b]GAE, gallic acid equivalents; Fe(II)E, iron(II) equivalents; TE, Trolox equivalents.

ORAC, where the ordinate at origin did not meet any of the criteria. In this assay the Q-TAC is assessed by the net AUC determination and a lag time is observed during oxidation of the fluorescein in the presence of an antioxidant.[1,27] The unsatisfactory result of the ordinate at origin is explained by the lack of proportionality of this lag time at very small amounts of Trolox. However, a linear response was observed at higher quantities of the standard, as previously observed by Ou et al.[27] in the classical approach of this assay.

Having studied the acceptability of the linear models, the detection limits y_d (detection signal) and x_d (capability of detection) of the assessed methodologies were determined as described by Ortiz et al.[33] In general, low limits of detection were observed (Table 2), which confirmed the acceptability of all methodologies to determine the TAC of very small quantities of antioxidants. Among the assays using Trolox as standard, the lowest x_d value corresponded to the Q-ORAC assay, which was corroborated as a highly sensitive methodology, and the highest limits of detection were obtained by the Q-ABTS method. A similar observation was previously reported for a comparison of classical TAC methodologies.[25]

Finally, two different terms of the precision were evaluated, the repeatability (Rp) and the intermediate precision (IP), determining their estimates (S_r and S_R, respectively) and coefficients of variance (CV).[32] The IP refers to the precision under reproducibility conditions when only some of the factors are varied. In this study a single factor (different days) was investigated. The results of the Rp and IP experiments for each methodology are shown in Table 3. It can be seen that similar S_r values were obtained in both Rp and IP experiences for all of the methods. The CV of the assays was the criteria selected to evaluate their acceptability. The Rp of the longest protocols (Q-ORAC, Q-HRSC, and Q-LPSC) exceeded the CV < 5% cutoff value, whereas those assays with just one or two steps (Q-FC, Q-ABTS, and Q-DPPH) showed a high Rp between measurements. By comparison with the Rp obtained in classical protocols validated using different wines as samples,[25] slightly higher CV were observed in the Q-TAC, and especially in the Q-FRSC methods, as all classical assays obtained CV < 5%. The only exception was the Q-ABTS assay, which showed better Rp than the classical approach. In terms of IP (Table 3), all of the methodologies presented satisfactory results, with the lowest CV (%) obtained again by two of the simplest methods (Q-FC and Q-ABTS). Therefore, the differences in the Rp and IP among the methodologies were mainly attributed to the complexity of the protocols. The sensitivity of the assays could also affect the precision observed, as might be the case for the Q-ORAC method mentioned above.

Q-TAC and Q-FRSC of the Model Products. To provide comprehensive information on the actual TAC of food, it is recommended that at least two TAC assays be used.[6,8] Similarly, in this study, a broad overview of the antioxidant capacity of the three model products (Sk, W, and Sd) was achieved with the different QUENCHER methodologies under study.

As shown in Table 4, model product W (rich in both hydrophobic and hydrophilic antioxidant compounds) showed the highest Q-TAC and Q-FRSC values in most of the methods, with the exception of the Q-FRAP assay, where Sk (model product especially rich in hydrophilic antioxidant) presented the most elevated antioxidant capacity and the Q-DPPH assay, where Sd (model product especially rich in hydrophobic antioxidant) exhibited the highest Q-TAC values. The difference between the antioxidant capacity of Sk and W was not significant in the Q-FC and Q-ORAC protocols. No significant differences were found between Sk and Sd in the Q-ABTS and Q-SRSC assays. From a comparison of the responses obtained by the three methodologies where Trolox was used as standard, Q-ORAC obtained the highest TAC values, but it must be noted that the sensitivity of this method to Trolox was also more elevated than in the Q-DPPH and Q-ABTS assays.

The obtained results were contrasted with those obtained by classical determinations, and considerable differences were found, except with the Q-DPPH method. Several studies comparing extracts from wine pomace reported a higher antioxidant capacity exhibited by seeds than skins, obtaining the same tendency using different assays (FC,[34−37] FRAP,[34,36,37] ABTS,[36] DPPH,[34−37] ORAC,[36] SRSC,[35] and HRSC[34]). This fact may be explained because classical protocols involve extraction with solvents, which are capable of extracting both hydrophobic and hydrophilic antioxidants. Therefore, the extracts obtained might not be representative of the antioxidant capacity that solid foods could actually exert, whereas QUENCHER assays may provide more reliable information.[11]

Correlation Study between the QUENCHER Methodologies. Pearson's correlation coefficients (r) between pairs of the assays were determined using the Q-TAC and Q-FRSC values obtained for Sk, W, and Sd by the different QUENCHER methodologies.

In the literature, due to the wide spectrum of analytical techniques and reaction conditions available, it is difficult to find an agreement on the correlations among different TAC methodologies.[2,8,38] To the extent of our knowledge, the

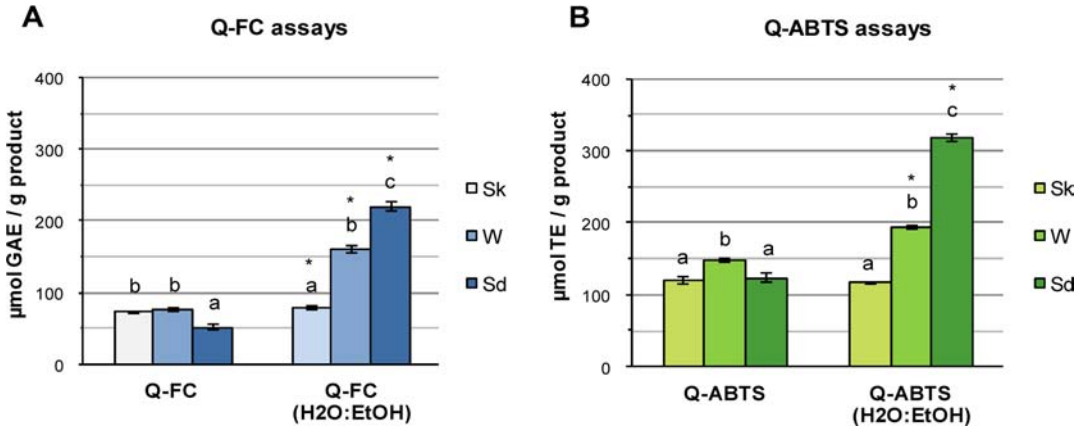

Figure 1. QUENCHER total antioxidant capacity (Q-TAC) of the model products (Sk, skins; W, whole; Sd, seeds): (A) Q-FC assays; (B) Q-ABTS assays. GAE, gallic acid equivalents; TE, Trolox equivalents. Data are expressed as mean values ± standard deviation (n = 3). Roman letters indicate significant differences among the model products (Sk, W, Sd) within each assay. The asterisk (∗) refers to significant differences between the Q-TAC and Q-TAC (H_2O:EtOH) approaches for each wine pomace product.

correlation between different QUENCHER methodologies has not been described yet. In this study, an interesting correspondence among the assays was observed, especially for the Q-FC and Q-ABTS assays with the rest of methods. A highly significant ($p < 0.01$) positive correlation was detected between Q-FC and Q-FRAP (r = 0.847), between Q-FC and Q-ORAC (r = 0.974), and between Q-FC and Q-LPSC (r = 0.926). The correspondence between Q-FC and Q-FRAP is due to the fact that both methods measure the reducing capacity of the sample,[38] also detected between the classical approaches.[36,37] Furthermore, the significant correlation between Q-ORAC and Q-LPSC (r = 0.914) may be explained because peroxyl radicals are involved in both assays.[39] The positive correlation of the Q-FC with the Q-ORAC and Q-LPSC assays is very convenient as they are more biologically relevant methods, but these assays are also more complicated, and their validation study showed some unsatisfactory results. However, the obtained results contrast with the weaker correlation (R^2 = 0.409) found between the classical approaches of the FC and the ORAC assays by Ky et al.[36] using also wine pomace as samples. In the present study, interesting high positive correlations ($p < 0.01$) between Q-ABTS and Q-SRSC (r = 0.935) and between Q-ABTS and Q-HRSC (r = 0.903) were also observed. According to Rivero-Pérez et al.,[25] such strong correlations were not detected in the classical approaches of these assays using wines as samples. On the other hand, negative correlations ($p < 0.05$) between Q-DPPH and Q-FC (r = −0.781), between Q-DPPH and Q-FRAP (r = −0.986), and between Q-DPPH and Q-ORAC (r = −0.808) were found in the present study, and the Q-DPPH method was not significantly correlated with any of the biologically relevant Q-FRSC assays. In classical methodologies, the DPPH and HRSC assays were not found to be correlated either,[34] but high positive correlations were usually detected between the DPPH and other TAC methods (FC,[35−37] FRAP,[34,37] and ABTS[25]). It must be noted that the Q-DPPH is the only QUENCHER methodology that was performed in an organic reaction medium, and its lack of positive correlation with the rest of the protocols indicates the elevated influence of the solvent used in these assays.

The different contents of hydrophilic and lipophilic compounds[40,41] of the three model products used in this study allow for assessing the response of each method toward matrices with compounds of high or low water solubility. Anyway, it would be advisable to confirm the correlations found in the current study by evaluating a wider range of products.

With the results of both the validation and correlation studies taken into account, the combination of both Q-FC and Q-ABTS assays is suggested as a good selection for a general Q-TAC analysis of powdered foods. The Q-SRSC, Q-HRSC, and Q-LPSC methods, first adapted to the QUENCHER approach in this study, might give a more biologically relevant overview of the antioxidant capacity of the samples. However, the Q-HRSC and Q-LPSC assays are complicated protocols for routine analysis, and it has been shown that the combination of the Q-FC and Q-ABTS methods covers the correspondence with the results obtained by the three biologically relevant Q-FRSC assays.

Effects of the Reaction Medium in the Q-FC and Q-ABTS Assays. In the QUENCHER methods there is no extraction step, but the reaction medium is a key factor that determines the solubility of the compounds present in the solid powdered product, as well as the interactions between the antioxidants and the radicals used as probes in the assays.

Serpen et al.[42] proposed a water/ethanol (H_2O:EtOH) 50:50 (v/v) ratio as a suitable working solution, providing accurate Q-TAC results for most of the food matrices studied. Therefore, the effect of using water or a mixture H_2O:EtOH 1:1 (v/v) as reaction medium was assessed in the current study using the two previously selected Q-TAC methods (Q-FC and Q-ABTS).

The Q-FC (H_2O:EtOH) and Q-ABTS (H_2O:EtOH) assays were validated as previously described for the rest of the methodologies and presented satisfactory results for all parameters evaluated (Supporting Information 1). Slight formation of white solids was observed in the Q-FC (H_2O:EtOH) method, probably due to the precipitation of Na_2CO_3 in the presence of ethanol. Nevertheless, these solids did not interfere in the measurement. The responses of the Q-FC and Q-FC (H_2O:EtOH) assays to different standard concentrations were not significantly different (similar slopes in the calibration models), whereas a 2.54 times lower response to Trolox in the Q-ABTS than in the Q-ABTS (H_2O:EtOH) method was detected. In contrast, Serpen et al.[42] found similar slopes of the dose−response lines obtained in the Q-ABTS assays using different solvent ratios H_2O:EtOH (0:100, 25:75, 50:50, 75:25, 100:0). A possible explanation might be that the

[a]Q-TAC values are the mean ± standard deviation (n = 3). TE, Trolox equivalents. Roman letters indicate significant differences among the different amounts of sample and the dilutions with cellulose tested within each method (Q-ABTS or Q-ABTS (H_2O:EtOH)) for each product (Sk or Sd).

calibration curves of Q-TAC methodologies carried out in this study were performed by weighing directly the standards, without their previous dilution in any solvent. Thus, the lower solubility of Trolox in water than in organic solvents played a critical role in the response observed in each method, as previously described by other authors.[9] This fact may lead to lower Q-TAC values in the Q-ABTS than in the Q-ABTS (H_2O:EtOH) assay due intrinsically to the methods used rather than the samples analyzed. Therefore, as the numeric Q-TAC values obtained by the Q-ABTS assays may not be directly comparable, the tendency observed among the samples (higher or lower Q-TAC values) was the main interest of these analyses.

The Q-TAC of Sk, W, and Sd obtained using the Q-FC and Q-ABTS assays can be seen in Figure 1. As previously described for classical methods,[1,39] the reaction medium greatly influenced the Q-TAC results, with both soluble compounds and insoluble antioxidants attached to the powdered products being affected by the solvent used in the Q-TAC assays. A similar tendency was observed in both Q-FC and Q-ABTS assays when water was replaced by a mixture of H_2O:EtOH (1:1, v/v) as reaction medium. A significant increase in the Q-TAC values of Sd was observed, reaching higher antioxidant capacity than W, for which Q-TAC was also enhanced, but to a lesser extent. The Sk product showed the lowest Q-TAC in both Q-FC (H_2O:EtOH) and Q-ABTS (H_2O:EtOH) assays. Similar results were obtained in previous studies[21] carried out using conventional methodologies including extraction steps with organic solvents. Indeed, a good correlation between general results obtained using Q-TAC (H_2O:EtOH) and classical methods was observed. In contrast, this fact was only found between Q-TAC (carried out in water) and classical methods when the matrices under study were rich in hydrophilic antioxidants (Supporting Information 2).

Differences among results obtained for the three model products using the different Q-TAC methods can be partly explained by their chemical composition, the solubility of their antioxidant compounds in the reaction medium, and their redox reactions with the radical probes or reagents used in each assay. With regard to the chemical composition of the model products tested, it is important to have in mind that skins of grapes are a rich source of anthocyanins and hydroxycinnamic acids, although they also contain some flavanols and flavonol glycosides, whereas gallic acid, flavanols, and proanthocyanidins are mainly present in the seeds of grapes.[35,37,43] According to these facts, the Sk model product was rich mainly in anthocyanins and hydroxycinnamic acids, whereas Sd was rich in flavanols from monomers to polymers (proanthocyanins and tannins). A description of the solubility of food antioxidants, including main phenolic classes, can be found in Gökmen et al.[11] In general, the water solubility of polyphenols increases with the number of glycosylated hydroxyl groups and with the amount of sugars constituting the carbohydrate moiety. On the other hand, in the case of polymerized polyphenols (such as proanthocyanidins or tannins), the water solubility considerably drops with an increased number of units and with the formation of intramolecular bonds.[44] Thus, the higher polarity of the polyphenols found in the grape skins allows that they are well solubilized when water is used as reaction medium,[44] whereas the presence of ethanol seems to favor the extraction of hydrophobic antioxidants present in the grape seeds. It must be pointed out that lower H_2O:EtOH ratios are not advised because it may cause the shrinking of the major constituents of the food matrices, such as cellulose and proteins.[17,42] This could hamper the release of the compounds or the diffusion of the radicals into the solid matrices where they can react with inner bound insoluble antioxidants, leading to lower Q-TAC values.[11]

The reaction medium also affects the interactions between the antioxidants and reagents involved in the methods by enhancing or decreasing the equilibrium constant of their redox reactions. In the QUENCHER approaches, when the redox equilibrium constant of an antioxidant compound in a determinate medium is higher than its solubility constant, the extraction of this antioxidant from the insoluble matrix and its solubilization in the reaction medium can be thermodynamically enhanced.[42]

The study of the correlations between the Q-TAC assays carried out in the same reaction medium showed a strong correspondence ($p < 0.01$) between Q-FC (H_2O:EtOH) and Q-ABTS (H_2O:EtOH) (r = 0.971), whereas there was no significant correlation between Q-FC and Q-ABTS (r = 0.496). This finding shows that, in the Q-TAC (H_2O:EtOH) methods, the factors related to the assay reaction medium (solubilization of the antioxidant compounds) play a more critical role than those related to the method used (reaction with the probes or reagents). Therefore, the mixture H_2O:EtOH 50:50 (v/v) proposed by Serpen et al.[42] might be adequate to evaluate the global TAC of food materials, but the Q-TAC of hydrophobic

DOI: 10.1021/acs.jafc.5b01644
J. Agric. Food Chem. 2015, 63, 6922−6931

antioxidants could be overestimated under certain conditions and, then, their real antioxidant role in food matrices.

Moreover, the correlations between the biologically relevant Q-FRSC assays and both Q-TAC (H_2O:EtOH) methods were not significant in the case for the Q-SRSC and Q-HRSC methods, and even a significant ($p < 0.01$) negative correlation between Q-LPSC and Q-ABTS (H_2O:EtOH) ($r = -0.716$) was found. These results further support the selection of the Q-FC and Q-ABTS assays in water as preferred protocols to assess a potentially more biologically relevant Q-TAC of food products and dietary supplements.

Effects of Using Cellulose as a Diluting Agent in the Q-ABTS Assays. Cellulose has been suggested as a diluting agent in previous Q-TAC protocols.[11,12] However, the affinity of polyphenols to cellulose is well-known,[45] so it is possible that interactions between the cellulose and these antioxidant compounds interfere in the quantification.

The possible influence of cellulose on the Q-TAC measurements was evaluated with the Q-ABTS assays (the most widely used Q-TAC assay up to now), and it was compared with the effects of weighing different amounts of sample. The two model products that presented more differences between them (Sk and Sd) were chosen to carry out this study. Two dilutions or product/cellulose ratios (2:1 and 1:2) were used. The quantities of product weighed were adapted to those required by each method to give results within their detection range. As can be seen in Table 5, no influence of the amount of sample or the presence of cellulose on the Q-TAC values was observed for Sk in the Q-ABTS assay and for Sd in the Q-ABTS (H_2O:EtOH) method. However, Q-ABTS results of Sd showed significantly higher Q-TAC values when lower amounts of sample were used, and this effect was more marked when the product was diluted with cellulose. In contrast, the opposite tendency was found for Sk in the Q-ABTS (H_2O:EtOH) assay. In this case, inferior Q-TAC values were obtained when a lower amount of Sk was used, which were only significant in Sk/cellulose (1:2) with respect to the nondiluted Sk sample.

The observed effect of weighing different amounts of Sd in the Q-ABTS assay could be due to a better water extraction of its slightly soluble hydrophobic polyphenols[11,36] when they are at a lesser concentration. Moreover, possible hydrophobic interactions between the antioxidant compounds (favored in the aqueous medium)[46] could be more relevant when a higher amount of sample is present, thus decreasing their ability to scavenge the soluble $ABTS^{\bullet+}$ radicals present in the reaction medium.

With regard to the influence of cellulose in the measurements, absorbance values similar to those of the $ABTS^{\bullet+}$ working solution were obtained in both methods (Q-ABTS and Q-ABTS (H_2O:EtOH)) when only cellulose was used as sample (data not shown), corroborating that cellulose alone is inert toward the $ABTS^{\bullet+}$ reagent, as has been previously described.[12] Therefore, the results obtained in this study could be due to the effects of cellulose in the solubility of the hydrophilic or lipophilic compounds present in the products and their capacity to interact with the $ABTS^{\bullet+}$ radicals, both factors influenced by the reaction medium. Hydrogen-bonding and hydrophobic interactions between cellulose and polyphenols have been described,[45] which are also dependent on the solvent systems used. Hydrophobic interactions are favored in hydrophilic solvents, whereas hydrogen bonding is favored in the more hydrophobic ones. Thus, the affinity of polyphenols (such as gallotannins and ellagitannins) to cellulose is expected to correlate with their hydrophobicity, their number of galloyl groups, and their molecular size.[44,45] This evidence explains that cellulose effects are of particular importance in the hydrophilic solvents when hydrophobic compounds are tested, as happened when Sd was assessed by the Q-ABTS assay. The monomeric and oligomeric proanthocyanidins of the grape seeds might remain insoluble in aqueous reaction mediums.[40,41] However, their interaction with cellulose through their hydrophobic moieties might raise their water solubility and leave the hydroxyl groups available to interact with the $ABTS^{\bullet+}$ radicals, leading to the increased Q-TAC values observed when the product/cellulose ratio was decreased. On the other hand, in the case of Sk in the Q-ABTS (H_2O:EtOH) assay, the contrary effect may take place. Hydrogen bonding between cellulose and the hydrophilic phenolics present in wine pomace skins could be favored in the presence of organic solvents. Thus, the number of hydroxyl groups available in the molecules to scavenge the radical probes of the assay is reduced.

On the basis of the cited results, the use of cellulose as a diluting agent is discouraged in the Q-TAC methodologies, especially if the antioxidant products tested are a source of polyphenols. The main motive is the possible interaction of cellulose with the phenolic compounds involved in the assays, leading to an under- or overestimation of the Q-TAC of the products.

In summary, a wide range of QUENCHER analytical techniques to provide a comprehensive initial assessment in vitro of the TAC and FRSC of food materials have been adapted and validated (Q-FC, Q-ABTS, Q-DPPH, Q-FRAP, Q-ORAC, Q-SRSC, Q-HRSC, and Q-LPSC). The Q-TAC and Q-FRSC assays skip the extraction step of the classical antioxidant capacity protocols and are simple, quick, inexpensive, and precise methodological approaches. The QUENCHER methodologies validated in this paper working with powdered model products are suitable for application to other foods and food ingredients, both rich in fat (as seeds) and not, as skins, which are rich in fiber and minerals among others. The combination of the Q-FC and Q-ABTS assays using water as reaction medium is proposed as the best choice to analyze a large number of samples. They provide more biologically relevant information than the classical TAC methods using extracts or other Q-TAC approaches using nonaqueous solvents. It is suggested that the same amount of sample be weighed, especially when products rich in hydrophobic antioxidants are assessed. The use of cellulose as a diluting agent is not recommended in the Q-TAC methods. Finally, it must be pointed out that, despite the advantages of the proposed QUENCHER assays over other in vitro methodologies, the Q-TAC or Q-FRSC of food materials and dietary supplements cannot be directly translated into healthful effects provided in vivo.

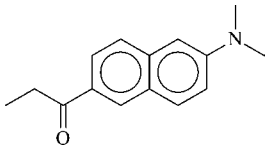
method relies on using Prodan, 6-propionyl-2-(dimethylamino)naphthalene), a fluorescent probe frequently used in probing the polarity of chemical and biological systems due to its high sensitivity to the medium (Scheme 1).[16−20] Indeed, Prodan's maximum emission varies from around 390 nm in alkanes to 530 nm in water.[20−22]

Scheme 1. Structure of Prodan, log K_{ow} = 3.48[a]



[a]Calculated using the software available http://www.molinspiration.com/cgi-bin/properties.

Although considerable research has been focused in recent years on using fluorescent probes for characterizing membrane polarity and transport through lipid membranes in biological media,[23−27] no study has reported the application of Prodan for probing the composition of leaf cuticle. Prodan is sensitive to both polarity and hydrogen bond donor ability of the solvent.[28,29] Prodan−solvent interactions were investigated using the Kamlet−Taft solvatochromic comparison method,[30] and it was shown that the emission band frequency can be correlated to the polarity/polarizability of the solvent π^*, to its hydrogen bond donor ability α, and to its hydrogen bond acceptor or electron pair donor ability to form a coordinated bond.[31] However, these data are available only for common solvents[32] and not for long-chain components of cuticles. On the basis of these correlations, we propose a simple model that relates the emission band frequency of Prodan to the chain-length constituents.

We report herein for the first time a new experimental protocol to study the polarity of plant cuticles by using Prodan and fluorescence spectroscopy. The limitations and advantages of the method are discussed, and perspectives for future applications are summarized.

EXPERIMENTAL PROCEDURES

Chemicals. Prodan (2-dimethylamino-6-propionylnaphthalene, >98%) was purchased from Sigma and used as received. Polyethylene PE-LD was obtained from SODIPRO, and wax paraffin (melting point = 53−57 °C, analysis given in the Supporting Information, Figure S1 and Table S1) and docosanol (>98%) were from Aldrich. The other chemicals and solvents were of the highest grade available.

Preparation of Solutions and Model Films Containing Prodan. Films of wax paraffin, mixtures of wax paraffin and *n*-docosanol, and mixtures of wax paraffin and were prepared as follows. Powder or pellets of the long-chain alkanes were mixed in the chosen proportions and heated until melting. Prodan was added to the melted mixture. Then the mixture was poured on aluminum foil to obtain a thin film after cooling.

Isolation of Cuticles. Leaves of *Zamioculcas zamiifolia* were refrigerated at −18 °C for several hours until frozen. Then, cuticles could be detached from the breakable leaves. Cuticles were first cleaned by gentle scraping of remaining flesh with a scalpel. Green peppers were refrigerated at −18 °C for several hours until frozen. Then, cuticles were detached with a scalpel and sonicated for 10 min to eliminate most of the epidermal remnants. Peels of white grapes were cleaned by gentle scraping of remaining flesh with a scalpel. Then cuticles were sonicated for 10 min to eliminate the epidermal remnants. All of the cuticles were finally washed with Milli-Q water.

Impregnating Films and Cuticles with Prodan. Two methods were used to impregnate polyethylene films and cuticles with Prodan: filtration and free diffusion. In the case of filtration, 5 mL of a solution of Prodan at 10^{-3} M in a mixture water/ethanol (50:50, v/v) was poured on the films or cuticles mounted on the sintered glass filter of a filter flask. Prodan solution was forced to diffuse through the films or cuticles using a vacuum. A light vacuum was maintained for 15 h, enabling the liquid to slowly diffuse. In the case of free diffusion, drops of the Prodan solution were deposited on the films or cuticles. The system was left to evolve freely for 24−48 h. Generally, the solvent was fully evaporated after 2 h. The film thickness was measured using a micrometer MI20.

Spectroscopic Analyses. UV−vis absorption spectra were recorded on an Agilent Technology Cary 300 UV−vis spectrophotometer equipped with an integration sphere model DRA-CA-301 Labsphere and the fluorescence spectra on a PerkinElmer LS55 fluorescence spectrophotometer. Prodan was excited at 340 nm. The emission spectra were corrected from the instrumental response using the files given by the manufacturer. Cuticles and polyethylene films were attached on a sample holder during the analysis. In all cases, the cuticles and polyethylene films were carefully washed with Milli-Q water prior to analysis to remove any Prodan crystals remaining at the surfaces. Rehydration of cuticles through this simple washing also greatly improved fluorescence detection by making them smooth. Fluorescence microscopy was performed on an Olympus CellR apparatus equipped with a xenon lamp using objective UPLANSApo 20x/0.75 and objective UPLANSApo 40x/1.3. The filter was 403 DAPI. In some figures, wavelengths of emission are expressed in wavenumbers (ν) according to ν (cm^{-1}) = $10^7/\lambda$ (nm).

Statistical Analyses. All of the spectra were recorded in duplicate. In the case of solid samples, at least three different positions in the sample holder were tested for each sample. Differences in the emission intensities might be observed as samples are not rigorously homogeneous, but emission maxima were very close. Uncertainty of measurement is ±1.5 nm due to the relatively flat maximum of Prodan.

RESULTS

Emission Characteristics of Prodan in Solution and Solids. Prodan shows an absorption band above 300 nm with a maximum located between 340 and 370 nm depending on the solvent.[20] Figure 1A presents the normalized emission spectra of Prodan in a variety of solvents and in films of several long-chain alkanes, wax paraffin, and docosanol, representative of long-chain alkanes contained in plant waxes. In *n*-heptane, the most hydrophobic solvent, the emission maximum is located at 390 nm. In water, the most hydrophilic solvent, two emission bands are found, one corresponding to dissolved Prodan (522 nm) and the other to solid particles of Prodan in suspension (433 nm). The other solvents exhibit emission maxima in the middle: acetonitrile gives an emission maximum at 452 nm and alcohols, 2-propanol and methanol, give maxima at 475 and 502 nm, respectively. Figure 1B also shows the influence of Prodan concentration on the emission in *n*-heptane. At 2×10^{-6} M, the emission maximum is located at 390 nm. Interestingly a shift is observed when the Prodan concentration is increased. A 2 nm shift is detectable at 5×10^{-5} M. It reaches 12 nm at 10^{-3} M. Although Prodan is freely soluble in this solvent, some interactions between Prodan molecules occur at high concentration, shifting the emission to the red. This is different from real molecules' aggregation observed in water or for crystals, giving an emission maximum around 430 nm.[33]

Interestingly, Prodan embedded into wax paraffin or in *n*-heptane solution shows the same emission maximum. The only difference between the two emission spectra is a small increase of the full width at half-maximum of 2 nm (6%). This finding shows that (1) Prodan is fully impregnated in the paraffin and

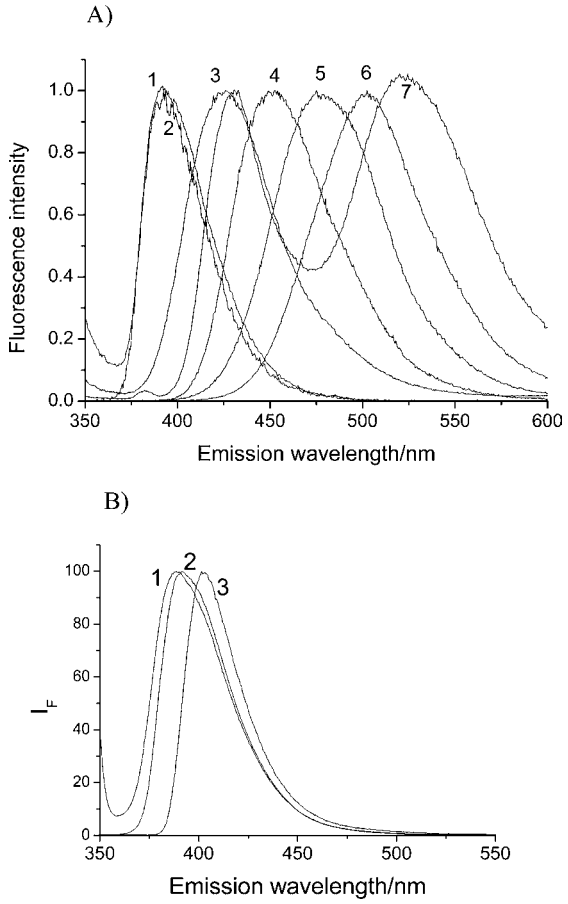

Figure 1. (A) Normalized emission spectra of Prodan in wax paraffin and in different solvents: 1, wax paraffin; 2, *n*-heptane; 3, docosanol; 4, acetonitrile; 5, 2-propanol; 6, methanol; 7, suspension in water. (B) Fluorescence of Prodan in heptane: 1, 2×10^{-6} M; 2, 5×10^{-5} M; 3, 10^{-3} M.

does not form aggregates that should give an emission around 430 nm, (2) the emission of Prodan is not influenced by the physical state of the medium, but by its chemical nature, and (3) a small band broadening occurs in solid state, which is attributed to interactions of Prodan with the solid environment.[10]

Relationship between the Emission Characteristics of Prodan and Properties of the Medium. To explain the experimental shift of emission maximum of Prodan embedded in different solid media, we attempted to establish a correlation between emission frequency and the properties of the heterogeneous media (docosanol and wax paraffin). One of the useful approaches for elucidating and quantifying different solute–solvent interactions is the Kamlet–Taft solvatochromic comparison method (KTSCM). According to the KTSCM, emission band frequency can be correlated with three parameters (Table 1), polarity–polarizability (π^*), hydrogen bond donor ability (α), and hydrogen bond acceptor ability (β), using eq 1:

$$\nu = \nu_0 + s\pi^* + a\alpha + b\beta \quad (1)$$

The *s*, *a*, and *b* coefficients measure the relative sensitivity of ν to the indicated solvent property. In recent work, the values of these coefficients have been determined by Moyano et al.,[31] on the basis of comparison with experimental data of Prodan absorption and emission in various common solvents.[32]

Table 1. KTSCM Parameters for Four Alcohol Solvents and for Docosanol[a]

solvent	π^*	α	β	$\nu/10^3$ (cm^{-1})
methanol	0.6	0.98	0.66	19.92
ethanol	0.54	0.86	0.75	20.35
n-butanol	0.47	0.84	0.84	20.73
n-octanol	0.4	0.77	0.81	21.19
docosanol	0.035	0.374	0.81	23.47 (23.62)

[a] π^* is polarity–polarizability, α represents the hydrogen bond donor ability, and β represents the hydrogen bond acceptor ability.

$$\nu^{em}_{obsvd}/10^{-3} = 25.2 \pm 0 - (2.6 \pm 0.2)\pi^* - (2.5 \pm 0.2)\alpha - (1.0 \pm 0.1)\beta$$

These results showed that the excited state of Prodan experiences a bathochromic shift with the π^*, α, and β parameters. Thus, the emission frequency shift of Prodan can be explained by the change in polarity and hydrogen-bonding interaction with the environment. To confirm if this equation applies also in our experimental conditions, we compared the measured values of ν for three alcohols (methanol, ethanol, octanol) with those reported by Moyano et al.[31] The results were almost identical, indicating that the model presented in eq 1 is valid. After validation of the model, we explored the applicability of the same model for solid media such as paraffin and docosanol. However, because the values of π^*, α, and β are not reported for these molecules, an estimation was made by plotting the variation of π^* and α as a function of the number of carbon atoms (n_C) for four primary alcohols (methanol, ethanol, butanol, octanol). As shown in Figure 2A, a linear relationship is found between π^* and n_C, which, if extrapolated to C_{22}, allows the estimation of the parameter π^* for docosanol. Similarly, we applied the same method in the case of α, which resulted in values of π^* and α of 0.035 and 0.374, respectively. On the basis of data reported by Moyano et al.,[31] it was found that β variation with the length of the carbon chain in a primary alcohol is very small and rangse between 0.81 and 0.84.[32] Therefore, we chose a value of 0.82 for docosanol.

Using these three KTSCM parameters, we estimated the predicted average value of ν for docosanol to be 23.37×10^3 cm^{-1} (minimum, 23.00×10^3; maximum, 23.73×10^3). Interestingly, this value is very close to that measured when Prodan is embedded in 100% docosanol ($\nu_{obs} = 23.47 \times 10^3$ cm^{-1}). This finding suggests that the KTSCM can be extrapolated to explain the shift in emission frequency of Prodan in heterogeneous solid media, as corroborated by the excellent linear correlation between n_C and the ν (Figure 2B). In addition, given that the emission frequency for wax paraffin was identical to that of heptane, we assumed that the KTSCM parameters of paraffin are identical to those of heptane, especially knowing that α and β are negligible and are thus not involved in the equation. Hence, we calculated the values of ν for various compositions of heptane/docosanol taking into account the relative contribution of each chemical, assuming that the overall value of ν of Prodan in the mixture is the sum of specific ν of each chemical ($\nu_{heptane}$, $\nu_{docosanol}$) multiplied by their relative mass fraction. Table 2 presents the calculated values of ν and compares them with those measured experimentally for various compositions heptane/docosanol (paraffin/docosanol). As shown in Figure 3, the predicted values of emission maximum of Prodan (ν_{calcd}) are in very good agreement with those measured (ν_{obsd}) when the percentage of

Table 2. Estimates of KTSCM Parameters for Various Compositions of Paraffin/Docosanol and Comparison of Observed and Calculated Maximum Emission Wavelength of Prodan

solid medium	π^*	α	β	$\nu/10^3$ (cm^{-1})	λ_{calcd} (nm)	λ_{obsd} (nm)
paraffin (heptane)	−0.08	0	0	25.57	NA	391
90:10 paraffin/ docosanol	−0.069	0.037	0.081	25.20	397	401
80:20 paraffin/ docosanol	−0.057	0.075	0.162	25.00	400	406
70:30 paraffin/ docosanol	−0.046	0.112	0.243	24.80	403	406
50:50 parafin/ docosanol	−0.023	0.187	0.405	24.39	410	410
25:75 paraffin/ docosanol	0.006	0.280	0.608	23.88	419	419
100 docosanol	0.035	0.374	0.81	23.37	428	426

docosanol in the mixture is significant (>30%). On the other hand, for low docosanol percentage, the measured values of emission maximum are higher than those predicted by the KTCSM model, suggesting that the docosanol is not evenly distributed in the wax paraffin but forms microdomains attributed to its self-association. The formation of microdomains in the mixture of long-chain alkanes was already demonstrated by a thermodynamic analysis.[34] Despite this, these findings indicate clearly the feasibility of using the KTSCM commonly used for solvents to characterize the solvatochromic properties of heterogeneous solid media such as those reported in this work. Moreover, it appears that Prodan is sensitive enough to detect such a medium heterogeneity.

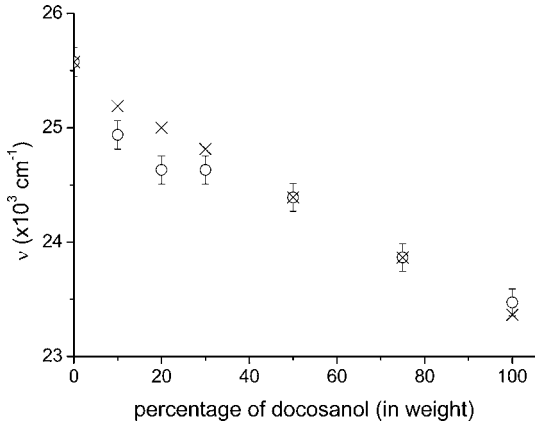

Figure 3. Shift of the maximum emission frequency of Prodan with the percentage in weight of docosanol in mixture with wax paraffin: (○) docosanol, experimental values (ν_{obsd}); (×) docosanol, calculated data (ν_{calcd}) (see text).

Impregnating Films with Prodan. In a second approach, we tested the possibility of impregnating films with Prodan. In the previous section, Prodan was introduced in films by hot mixing. This technique is not applicable in the case of real samples, especially when the objective is to work on untouched cuticles. Therefore, two methods of infiltration were tested: filtration of a Prodan solution in a water/ethanol, 50:50, mixture; and free diffusion of Prodan applied as 10 drops of 5 μL or as a single 200 μL drop. These experiments were carried out using a film of polyethylene that has the great advantage of being transparent. The two methods of infiltration give the same emission maximum at 405 ± 4 nm, indicating that in both cases the solvent has been fully eliminated and does not interfere in the result (Figure 4A). The intensity of fluorescence is, however, larger in the case of the single drop or infiltration under vacuum than in the case of small drops. To confirm that the method allows embedding Prodan in the polymer, we recorded the emission spectrum of Prodan deposited on a quartz plate in crystallized form. In this case, the emission maximum occurs at 427 nm (Figure 4A). Thus, the emission of Prodan in the polyethylene films is governed by the interaction of the single molecules with polymer chains and informs on the polarity of the medium. The maximum occurs at a wavelength slightly higher than in wax paraffin or *n*-heptane. This shift may be due to the presence of some polar additives in the polymer. Alternatively, it could be explained by a concentration effect. Indeed, the averaged concentration of Prodan is 2×10^{-3} M (see below), and in this case the maximum of emission is expected to be a little above 404 nm as experimentally observed. To clear up this question, it would be necessary to work on a polymer free of additives.

Emission of Prodan in Cuticles. Three samples were chosen to validate the analytical method: the leaf of *Zamioculcas zamiifolia*, a succulent plant, and the skins of white grape berries and green pepper. In all cases, the extracted cuticles were transparent enough for enabling Prodan to absorb light and thus generate measurable fluorescence. Figure 4A depicts emission spectra obtained for model supports to illustrate the broad range of emission wavelength. Films of wax paraffin and polyethylene show thin bands centered around 400 nm indicating that the medium is homogeneous and that there is likely one type of interaction. Emission of Prodan deposited on a thin layer plate of chromatography made of C_{18} was also

DOI: 10.1021/acs.jafc.5b02779

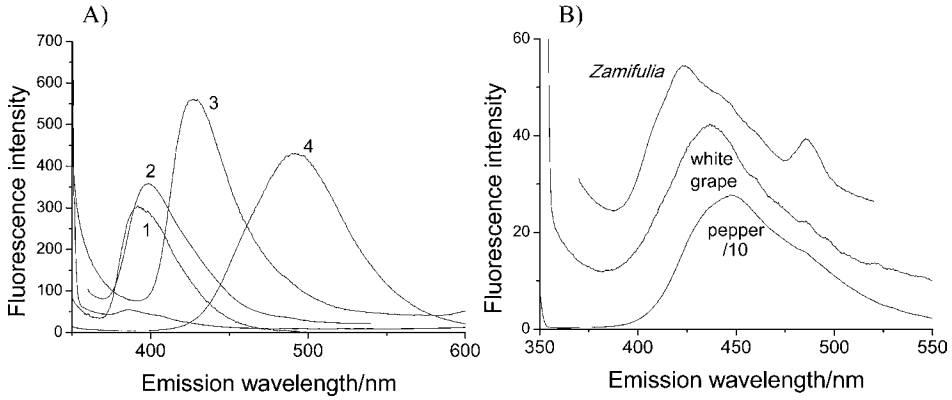

Figure 4. (A) Emission spectra of Prodan in model support: (1) film of wax paraffin; (2) film of polyethylene impregnated with a solution of Prodan 10^{-3} M in water/ethanol, 50:50 v/v added as a drop of 200 μL; (3) Prodan deposited on a quartz plate; (4) plate of thin layer chromatography C_{18} on which Prodan was deposited in heptane. (B) Emission spectra of Prodan in cuticles: *Zamioculcas zamiifolia*; white grape; green pepper.

measured. The emission maximum is at 491 nm, indicating that Prodan is located in the vicinity of free silanol groups. The emission spectra measured in the cuticles are shown in Figure 4B. The following characteristics appear:

- The main emission maximum varies from 423 nm for *Z. zamiifolia* to 436 nm for the white grape and to 448 nm for the green pepper.
- The results of the preliminary experiments strongly support that Prodan is embedded in the cuticles, and therefore these emissions are related to the chemical characteristics of the different cuticles.
- The emission intensities vary with the cuticle in the order green pepper > white grape ≫ *Z. zamiifolia*. They are expected to depend on several parameters, in particular the capacity of Prodan to enter the cuticle and the cuticle transparency between 340 and 400 nm, the wavelength range where Prodan absorbs. Transparency of cuticles depends on the cuticle constituents and especially on the presence of absorbing secondary metabolites (polyphenols or carotenoids for instance) and can vary drastically from one species to another.[35]
- Emission bands are broad compared to those measured in the model supports, and detailed examination of the spectra reveals the presence of shoulders and broad long-wavelength emissions on both sides of the maximum. For *Z. zamiifolia*, shoulders are observed at 408, 444, and around 460 nm. For white grape, there is a small shoulder at 426 nm and a broad emission extending up to 525 nm. For green pepper, one can see a clear shoulder at 433 nm and the same broad emission at long wavelength as for white grape. These fingerprints indicate that Prodan is located in zones of different polarity. In a first approach, these data can be analyzed using the relationship established between the emission characteristics of Prodan and the number of carbon atoms in primary alcohols constituting the solid medium of Figure 3B. For *Z. zamiifolia*, the maximum at 423 nm (23640 cm^{-1}) would correspond to primary alcohols in C_{23}; for the white grape, the maximum at 436 nm would correspond to primary alcohols in C_{19}; and for the green pepper, the maximum at 448 nm would correspond to primary alcohols in C_{15}.

In a second approach, we examined whether these data match the chemical composition of cuticules (wax and cutin) as reported in the literature. In the case of grape berries cuticle, alcohols (n-C_{20}−n-C_{34}) are reported to account for 40−67% of the soft wax fraction with predominating C_{26}.[34] Embedded in such a medium, Prodan should emit around 414 nm. Even though such an emission seems present in the blue part of the spectrum of Figure 4B, the maximum is significantly red-shifted, indicating that Prodan is mainly located in a more polar zone, probably the cutin. Pepper fruit waxes contain many components, among which long-chain alkanes C_{29} and C_{31} and fatty acids C_{24} and C_{26} are the most abundant, representing around 35 and 25%, respectively, of the constituents on average.[35] The former would give a maximum of emission around 390 nm and the latter around 420−425 nm if we refer to methyl tetracosanoate data (see Figure S2). Both are far from the observed maximum, indicating that Prodan is not located in the pepper fruit waxes unless polar minor constituents shift significantly the emission maximum. The other compartment in which Prodan can be inserted is the cutin. The pepper cutin is a mixture of C_{16} and C_{18} monomers and their oxygenated derivatives, dominated by 10,16-dihydroxyhexadecanoic acid that represents >50% of the total monomers.[35] These constituents are expected to give a polarity higher than corresponding primary C_{16} and C_{18} alcohols. This is not far from what we found.

This analysis points out two conclusions. First, it appears difficult to rationalize the data of Figure 4B using the reported cuticle composition because of the presence of a great variety of constituents in the cuticles, the possible great effect of some minor compounds on polarity, and the possible partitioning of constituents creating specific zones. The emission spectra of Prodan in these complex media bring, however, important information on the average polarities, and Prodan can be considered as a polarity indicator. Second, Prodan is probably mainly embedded in the cutin. The presence of Prodan in the cutin seems logical, first, because this inner compartment is larger than the outer one consisting of waxes[36] and, second, because the solubility of organic compounds can be 10-fold higher in cutin than in cuticular waxes.[36]

Experimental Proofs of the Diffusion of Prodan into the Cuticles. The amount of Prodan included in the polyethylene film was directly obtained by measuring the film transmittance at 340 nm by taking into account that the thickness is 50 μm and the extinction coefficient of Prodan is equal to 2.3×10^4 L mol^{-1} cm^{-1} in n-heptane at 340 nm. Accordingly, a film measuring an area of 6 cm^2 contained 7.1

μg. Prodan was extracted from the film by sonication for 30 min in 1 mL of ethanol. Using fluorescence, we could estimate that 7.5 μg of Prodan had been extracted, in full agreement with the result obtained by UV absorption measurements.

For the cuticles that are much less transparent, the amount of Prodan was evaluated by extraction through sonication in ethanol. In the case of *Z. zamiifolia* cuticle, we found that the film of 6 cm^2 and 19 μm thickness contained 2.4 μg. In the case of green pepper, we found 40.2 μg for a thickness of 59 μm. Results for polyethylene film and *Z. zamiifolia* cuticle are thus similar if we take into account that the polyethylene film is 2.6-fold thicker than the *Z. zamiifolia* cuticle. They both absorbed 16.3% of the deposited Prodan (45.4 μg). Green pepper took much more, 88% of the deposited Prodan being embedded in the green pepper.

To gain insights into the surface distribution of Prodan in cuticles and polyethylene films, images of Prodan fluorescence were recorded using a fluorescence microscopy. As shown in Figure 5, Prodan is clearly embedded into the polyethylene film, whereas small microcrystals remain on the surface, which might explain the unexpected emission maximum for Prodan in a nonpolar medium such as polyethylene film. When applied on green pepper cuticle, it appears that Prodan quickly diffused into cuticle and reached the residual epidermal cells, confirming that the emission spectrum of Prodan is a result of interactions within the inner cuticle. It remains, however, difficult to identify the exact type of interactions and the chemical nature of the environment that influences the fluorescence emission of Prodan.

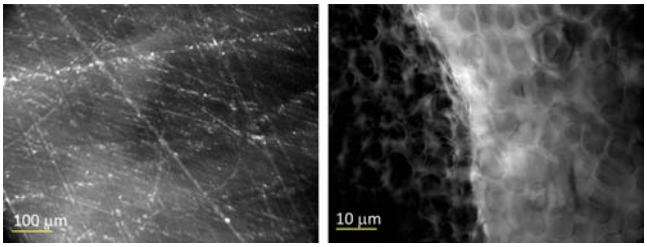

Figure 5. Fluorescence images of Prodan impregnated into polyethylene film (left panel) and into green pepper cuticle (right panel). Prodan is mainly dissolved in polyethylene, even though small microcrystals are observed at the surface. In green pepper cuticle, Prodan diffuses until it reaches the residual epidermal cells, so that emission is a result of interactions within the inner cuticle.

This case study shows that it is possible to impregnate Prodan into polymer (polyethylene) and extracted cuticles in sufficient amount to detect its fluorescence. The emission spectra obtained with the three cuticles are significantly different, confirming that Prodan is sensitive enough in these conditions and can be used as an indicator of the cuticles' polarity. The proposed method has the great advantage of being straightforward because the fluorescent probe needs to be simply deposited on the cuticle and the analysis is performed directly on the cuticle without further manipulations. One of the limits of the method is related to the optical properties of cuticles. The use of other possible fluorescent probes absorbing above 400 nm could help to overcome this issue. The method proposed could be extended to investigate changes in the chemical environment of surfaces due to reactions and/or aging. Future work will explore the potential application of Prodan and other alternative fluorescent probes to monitor the diffusion and reactivity of polar pesticides through cuticles.

[a]NM, not measured. [b]An asterisk (*) indicates overlapped signals.

and **5** on a Bruker-Avance DRX800 spectrometer operating at frequency of 200 MHz (^{13}C NMR). Samples were prepared in Aldrich deuterated dimethyl sulfoxide (DMSO-d_6). The mass spectrometry analyses were conducted in two different spectrometers, both equipped with electrospray ionization source (ESI) in negative mode over a mass range of m/z 50−1500. Mass spectra obtained for compound **3** were recorded on a Bruker Daltonics time-of-flight mass spectrometer (a) and those for compounds **4**, **5**, and **6** on a Thermo Scientific LTQ-FT-Ultra mass spectrometer (b). The following instrument settings were used: (a) nebulizer gas nitrogen (0.4 bar), dry gas nitrogen (4 L/min), 220 °C, capillary voltage of 4500 V, end plate offset −500 V, sample (0.5 g mL^{-1}) dissolved in MeOH/H_2O 1:1 and introduced in the electrospray source with a direct infusion pump operating at a flow of 5 μL/min; (b) nebulizer gas nitrogen (0.4 bar), dry gas nitrogen (9 L/min), 270 °C, capillary voltage of 47.96 V, source voltage of 40 V, samples dissolved in MeOH/H_2O 8:2 and introduced in the electrospray source with a direct infusion pump operating at a flow of 5 μL/min. Melting points were performed using Fisatom device (model 431, Brazil, series 1237344).

Plant Material. Leaves of *C. langsdorffii* were collected in the Campus of the University of São Paulo, Ribeirão Preto, Brazil. The plant material was identified by Dr. Milton Gropo from the herbarium of the Faculdade de Filosofia, Ciências e Letras, Ribeirão Preto, Brazil, where a voucher specimen (SPFR 10120) was deposited.

Extraction and Isolation. Dried leaves of *C. langsdorffii* (200 g) were ground and exhaustively extracted with ethanol/H_2O (7:3) (1.2 L, three times) by maceration at room temperature. The lyophilized extract (50 g) was suspended in MeOH/H_2O (9:1, 300 mL) and partitioned first with hexanes (300 mL, three times). The MeOH/H_2O phase was evaporated until elimination of the methanol. The remaining fraction was added of water and successively partitioned with dichloromethane (CH_2Cl_2, 300 mL, three times) and ethyl acetate (EtOAc, 300 mL, three times). After evaporation of the solvents, the hexanes-soluble fraction (9.7 g), CH_2Cl_2-solube fraction (2.6 g), EtOAc-soluble fraction (13.8 g), and the H_2O-soluble fraction (21 g) were obtained. The EtOAc-soluble fraction (3 g) was subjected to HSCCC using interconnected 2 mm diameter columns C (102 mL) and D (105 mL). Solvent system was optimized on the basis of the partition coefficients K_d of compounds **1** and **2** after dissolution of the EtOAc-soluble fraction in the upper and lower phases. Values of (K_d) were assessed by the relation of their peak areas from the analytical chromatograms of both upper and lower solutions. The final solvent system consisted of hexanes/*n*-BuOH (1:1) (upper phase) and MeOH/H_2O (0.4:1) (lower phase), which exhibited a settling time of 25 s, and optimized K_d values for **1** (K_d = 0.6) and **2** (K_d = 0.95). The coil was filled with the stationary phase (lower phase) in a tail-to-head mode, and after a starting rotation program, the mobile phase was pumped into the coil until equilibrium, that is, when only mobile

J. Agric. Food Chem. 2015, 63, 6939−6945

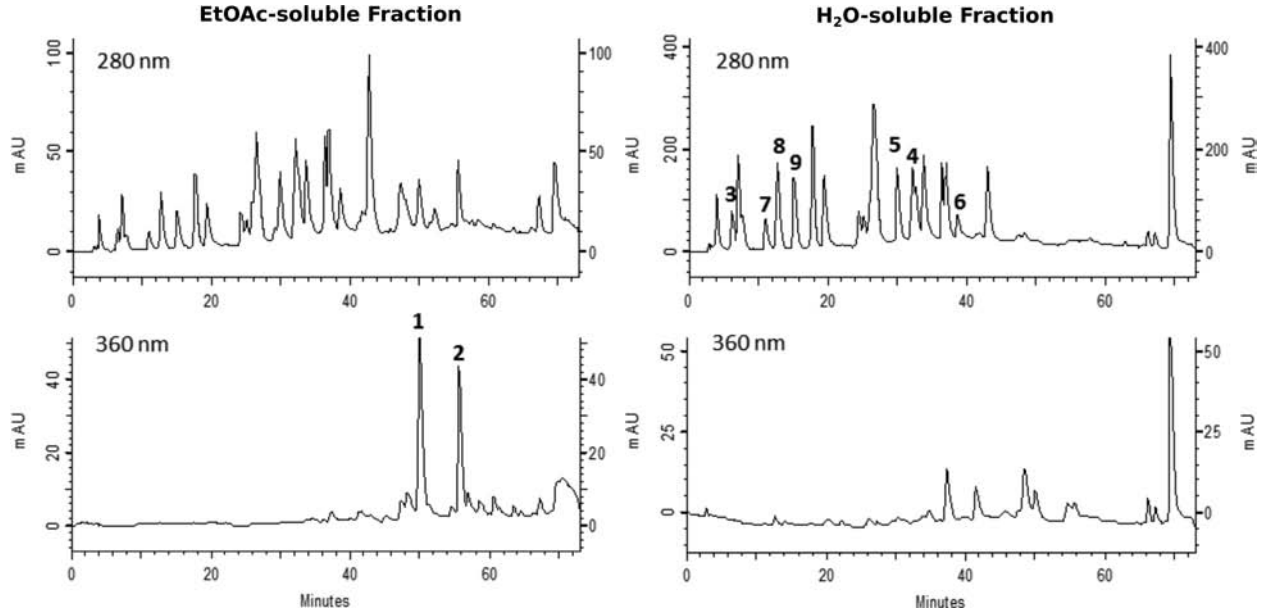

Figure 1. Chromatographic profile of the EtOAc- and H_2O-soluble fractions of the leaf hydroalcoholic extract of *C. langsdorffii* acquired by HPLC-DAD detected at the typical relative absorption maxima of flavonols (360 nm) and galloyquinic acids (280 nm). Peaks: 1, quercetrin; 2, afzelin; 3–9, methoxy-galloylquinic acid derivatives.

phase came out from the coil. Nearly 85% retention of the stationary phase inside the coils was obtained before sample injection. Fractions were combined after TLC analysis furnishing F8–14 (320 mg), F15–23 (215 mg), F24–26 (65 mg), F27–33 (93 mg), F34–41 (267 mg), and F42–51 (570 mg). Fractions F15–23 (90% of **1**) and F34–41 (90% of **2**) were subjected to preparative HPLC, performed with an elution program of 35–80% MeOH/H_2O in 20 min to yield **1** (108 mg) and **2** (94 mg). The H_2O-soluble fraction (3.5 g) was subjected to counter-current chromatography with an optimized solvent system consisting of *n*-BuOH/EtOAc/H_2O (0.1% formic acid) (1:1:1) and a settling time of 15 s, suitable for the distribution of four compounds in both upper and lower phases. The K_d values obtained for those compounds were 0.37, 0.46, 0.60, and 1.05. The coil was filled with the stationary phase (lower phase) in a tail-to-head mode. Retention of the stationary phase before sample injection of 84% was obtained. Fractionation furnished the subfractions F15–18 (134 mg), F21–25 (132 mg), F26–29 (75 mg), and F30–38, which were later purified by preparative HPLC to yield compounds **3**, **7**, **8**, and **9**. After purification and storage, three of them underwent chemical degradation. Therefore, only compound **3** (31 mg), obtained from F15–18, was fully elucidated. The H_2O-soluble fraction (3.5 g) was subjected to chromatography on a Sephadex LH-20 column, eluted with MeOH to afford several subfractions. Those subfractions were purified in preparative HPLC to yield **4** (28 mg), **5** (33 mg), and **6** (25 mg). The mobile phase optimized for the PREP-HPLC consisted of water (A) (0.01% TFA) and MeOH (B) in gradient condition as follows: 5–15% of B (20 min), 15–34% of B (20–40 min), and 34–80% of B (40–85 min); flow rate = 9 mL/min. Compounds **4**–**6** had their chemical structures elucidated.

RESULTS AND DISCUSSION

C. langsdorffii leaf hydroalcoholic extract was dissolved in MeOH/H_2O and partitioned with hexanes, dichloromethane, and ethyl acetate (EtOAc) to furnish fractions soluble in these solvents and a water-soluble fraction. A high content of phenolic compounds was found in the EtOAc- and H_2O-soluble fractions (Figure 1), including the known flavonoids quercetin-3-*O*-α-L-rhamnopyranoside (quercetrin, **1**) and kaempferol-3-*O*-α-L-rhamnopyranoside (afzelin, **2**), which were previously reported as validated markers for flavonoid quantification in *C. langsdorffii* leaf extracts.[14] As the reported pharmacological potential of the extract was primarily suggested to be due to its phenolics content, phytochemical investigations were oriented toward the EtOAc- and H_2O-soluble fractions.

J. Agric. Food Chem. 2015, 63, 6939–6945

The method developed in HSCCC was selective for separation of **1** and **2** from the EtOAc-soluble fraction to yield subfractions containing >90% of these compounds. They were identified by comparison of their UV and ^{1}H NMR spectra (Supporting Information) with the literature.[13,17] The separation of those compounds by liquid−liquid chromatography brought several advantages compared to separations previously performed in silica gel or Sephadex column chromatography, as follows: (a) no content loss due to adsorption and suitability for polar fractions; (b) higher purity for compounds of similar molecular size as the separation is based on their K_d; (c) reproducibility; and (d) lower solvent consumption for preparative separations. Column chromatography performed on Sephadex LH-20 and HSCCC, followed by preparative HPLC purification, led to the isolation of three galloylquinic acid derivatives (**4**−**6**) from the H_2O-soluble fraction, which accounts for roughly 45% (w/w) of *C. langsforffii* leaf extract (Figure 1). Method of separation in HSCCC was also performed for the H_2O-soluble fraction. Four semipurified subfractions yielded compounds **3**, **7**, **8**, and **9** after purification in preparative HPLC. Compounds **7**−**9** underwent chemical degradation most probably by hydrolysis of ester bonds due to remaining acid from the mobile phase on the fractions. The UV absorption (typical λ_{max} at 220 and 275 nm, Figure 1), along with ^{1}H NMR spectra of the isolated compounds (Supporting Information) indicated that the fraction is composed of a series of galloylquinic acid derivatives. The isolated compounds peculiarly bear a methyl group in at least one of their galloyl moieties. Leaf extraction with aqueous ethanol, followed by direct HPLC analysis, was undertaken, confirming that these methylated compounds are truly present in the plant biomass (data not shown).

The methoxy-galloylquinic acids (**3**−**6**) (Figure 2) are, to the best of our knowledge, first reported. Their structural elucidation is discussed in detail in this work. Numeration of the quinic acid is rather controversial in the literature for galloylquinic acids.[18−22] Therefore, to avoid misinterpretation when accessing some references cited throughout this work, the assignments to C-2, C-3, C-5, and C-6 positions might be inverted to C-6, C-5, C-3, and C-2, respectively. The numbering form we adopted has been also described in recent papers related to quinic acid derivatives.[23−27]

	R'	R''	R'''
3	MeG	H	H
4	MeG	MeG	H
5	G	MeG	G
6	MeG	G	MeG

Figure 2. Chemical structures of compounds **3**−**6**.

Correlations between the quinic acid protons were established via HMBC spectra, along with ^{1}H−^{1}H COSY cross-peaks H-2/H-6, H-2/H-3, H-3/H-4, H-4/H-5, and H-5/H-6 (Figure 3). Inference of the quinic acid chair conformation and assignment of its proton signals was reasoned primarily on the large vicinal coupling constants between the signals of H-4 and H-5 and between H-5 and H-6_{ax}.

The presence of one galloyl moiety bearing a methoxyl group (MeG) in compound **3** was indicated by loss of 166 units in the negative ESI-MS spectrum. This was confirmed by the signals of two aromatic protons meta coupled at δ 7.12 and 7.15 in the ^{1}H NMR spectrum, one methoxyl group (δ H, 3.79; and δ C, 56.0), and the signal of the aromatic hydroxyl carbon C-3′ (δ 147.7) shifted downfield in comparison to C-6′ (Table 1). The long-range correlation in the HMBC spectrum between C-3′ and the methylic protons (δ 3.79) confirmed the substitution at position C-3′ (Figure 3). The quinic acid unit was indicated by the ^{1}H NMR chemical shifts of four sp^3 methylene protons at δ 1.81, 1.92, 1.95, and 2.05, along with three oxymethine protons at δ 3.55, 3.92, and 5.27. Those resonances were in agreement with two sp^3 methylene and three oxymethine carbons in the ^{13}C NMR spectrum (Table 1). The ^{1}H−^{13}C long-range correlation between the proton H-3 (δ 5.27) and the carbonyl carbon signal at δ 165.4 (COO−′) indicated that the MeG moiety was linked to the quinic acid by an ester bond at C-3.

In the ^{1}H NMR spectrum, the signal of a dd (J = 7.5 and 3.2 Hz) was assigned to the proton H-4, indicating the axial position of H-4 vicinal to an equatorial proton at δ 5.27 (H-3) and an axial proton at δ 3.92 (H-5). The signal for H-4 in quinic acid derivatives is usually well-defined, even in ^{1}H NMR spectra from low-field instruments,[28] by its $^3J_{H,H}$ magnitudes (Table 1) and the ^{1}H−^{1}H COSY cross-correlation with both protons H-3 and H-5 (Figure 3).

The proton H-6_{ax} (δ 1.81, dd) was distinguished from another three methylene protons by the greater $J_{H,H}$ magnitudes ($^2J_{6ax,6eq}$ = 13.5 Hz and $^3J_{6ax,5ax}$ = 7.5 Hz). The signal at δ 1.92 (m) was associated with C-6 in the HSQC spectrum and, therefore, it was assigned to 6-H_{eq}. As the equatorial−equatorial and axial−equatorial coupling constants between the protons at C-2 and the proton H-3 assumed similar magnitudes, roughly 4 Hz, the relative position of the pair of methylene protons at C-2 (δ 1.95 and 2.05) was not defined. Therefore, they were rather assigned as H-2_a and H-2_b. The assignment of H-2_{ax} and H-2_{eq} has been previously described by using the signal multiplicity pattern, dd for H-2_{ax} and ddd for H-2_{eq}, in the ^{1}H NMR spectra in the analysis of dicaffeoylquinic and divanilloylquinc acids.[29,30] Particularly for H-2_{eq} and H-6_{eq} a pattern of ddd has been observed in these derivatives, to which the smallest coupling constant value (nearly 1.5 Hz) is attributed an $^4J_{2eq,6eq}$ W-coupling.[23,30,31]

Negative ESI-MS data for compound **4** suggested the presence of two MeG moieties. They were confirmed by signals of two sets of aromatic protons meta coupled in the ^{1}H NMR spectrum (Table 1) and two methoxyl signals (δ H, 3.77/δ C, 55.8; and δ H, 3.75/δ C, 55.8). The substitution position was suggested by the aromatic hydroxyl carbons C-3′ (δ 147.8) and C-3″(δ 147.7) shifted downfield in comparison to the carbons at δ 145.25 (C-5′ and C-5″) and confirmed by the long-range correlations in the HMBC spectrum (Figure 3).

The signal of the oxygenated methine proton at δ 5.07 (dd, J = 7.8 and 2.6 Hz) was assigned to proton H-4. Among four methylene proton signals, that at δ 1.91 was assigned to H-6_{ax} due to a greater axial−axial coupling constant (^3J = 7 Hz). The

J. Agric. Food Chem. 2015, 63, 6939−6945

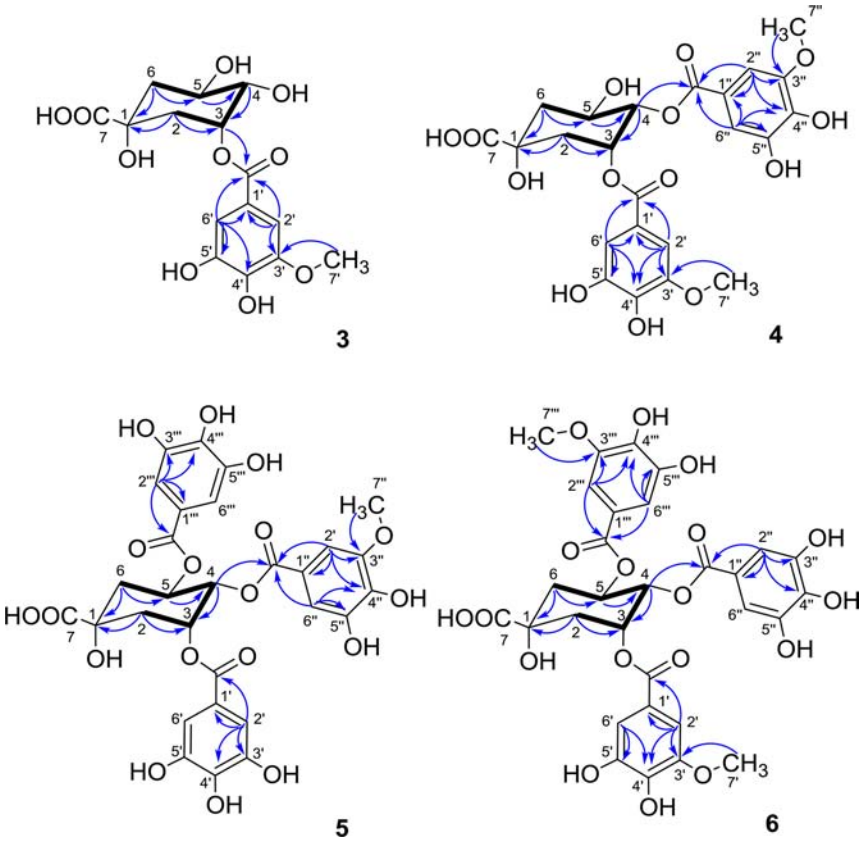

Figure 3. $^{1}H-^{1}H$ COSY (bold) and key HMBC correlations of compounds **3**–**6**.

signal at δ 4.26, which was cross-correlated in the $^{1}H-^{1}H$ COSY (Figure 3) with the signal of H-6_{ax} and H-4 (δ 5.07), was assigned to proton H-5. The lasting oxygenated methine signal at δ 5.49 was assigned to H-3.

The $^{1}H-^{13}C$ long-range correlation of the H-4 proton at δ 5.07 with the carbonyl carbon at δ 164.8 (COO−″) indicated one MeG moiety was linked to the quinic acid at the C-4 position. Due to a lack of correlation between quinic acid protons and the carbonyl carbon at δ 165.3 in the HMBC spectrum, the linkage position of the second MeG group was solved by the chemical shift of the proton signals. Acylation of an hydroxyl group produces a paramagnetic shift from 1.3 to 1.8 Hz on the oxymethine proton.[23,28,29,31] Therefore, the MeG moiety should be attached to the hydroxyl group at C-3, as the signal of H-3 (δ 5.49) was shifted downfield in comparison to H-5 (δ 4.26).

As protons H-3 and H-5 appeared as broad singlets or coalesced signals in the ^{1}H NMR spectrum (Figure 9 in the Supporting Information), they could not be unambiguously assigned by differences in $^{3}J_{H,H}$ magnitudes. Nevertheless, they should be alternatively differentiated by their signal half-width values ($J_{hw/2}$). Assuming the vicinal proton−proton angular dependence of the coupling constants, as the protons H-3, H-4, and H-5 are in equatorial, axial, and axial positions, respectively, a smaller half-width is expected for H-3, which couples with protons H-2 and H-4 at smaller values. For H-5, which couples at greater values with H-6_{ax} and H-4, a larger half-width is expected. However, their values in compound **4** were similar ($J_{hw/2}$ = 8 and 10.5) and lower than usually described in the literature ($J_{hw/2}$ = 8−10 Hz, H-3; $J_{hw/2}$ = 20−28 Hz, H-5).[22] This may be explained by the presence of two main relative conformers of the quinic acid in a ratio of nearly 1:1 (H-5_{eq}:H-5_{ax}) at 20 °C, as shown in a molecular model performed in molecular operations environment (MOE; 2010.09) (Figure 28 in the Supporting Information). It is noteworthy that in case H-6_{ax} is not assigned, unambiguous assignment of H-3 and H-5 in compounds alike may be possible only by optimizing the NMR experiments to favor the equilibrium toward one or the other conformer, that is, by performing analysis in different temperatures. Detailed experimental proof of the quantitative conformation equilibrium in quinic acid derivatives has been described by Pauli and et al.[31]

In compound **5**, the presence of two G moieties was confirmed by the ^{1}H NMR signals of two pairs of symmetric aromatic protons at δ 7.02 (H-2′/H-6′) and δ 6.88 (H-2‴/H-6‴). The MeG unity was confirmed by the signals of asymmetric aromatic protons at δ 6.85 (H-2″) and δ 6.97 (H-6″). Methylation on the hydroxyl at C-3″ position was confirmed by the long-range correlation between C-3″ and the methylic protons (δ 3.53) (Figure 3).

Cross-correlation of the proton H-5 (δ 5.72) with two methylene protons at δ 2.11−2.22 in the $^{1}H-^{1}H$ COSY spectrum indicated their position at C-6. Thus, the second pair of methylene protons (δ 2.02 and 2.37) should be attached at the C-2 position, which was confirmed by their cross-correlation with H-3 (δ 5.58) in the $^{1}H-^{1}H$ COSY spectrum. $^{1}H-^{13}C$ long-range correlation between the proton H-4 (δ 5.32) and the carbonyl carbon at δ 165.0 (COO−″) indicated the linkage of the MeG moiety at the C-4 position. No $^{1}H-^{13}C$ long-range correlations were observed between the oxymethine protons H-3 and H-5 with the carbonyl carbons at δ 165.2 and 165.6 in the HMBC spectrum. However, the paramagnetic shifts of those proton signals in the ^{1}H NMR spectrum

DOI: 10.1021/acs.jafc.5b01588
J. Agric. Food Chem. 2015, 63, 6939−6945

suggested that the two G moieties should be linked to quinic acid at the C-3 and C-5 positions.

In the ^{1}H NMR spectrum of compound **6**, signals of two pairs of asymmetric aromatic protons at δ 7.20 (H-2′)/δ 7.01 (H-6′) and δ 7.20 (H-2‴)/δ 6.97 (H-6‴) and two aromatic protons meta coupled at δ 6.8 (H-2″/H6″) (Table 1) confirmed the presence of two MeG and one G, respectively. The methylated position was confirmed by the long-range correlations in the HMBC spectrum between C-3′ and the methylic protons at δ 3.7 and between C-3‴ and the methylic protons at δ 3.78 (Figure 3).

The signal at δ 2.15 was assigned to H-6$_{ax}$ ($^2J_{6ax,6eq}$ = 12.5 Hz, $^3J_{6ax,5}$ = 8 Hz). Proton H-3 (δ 5.54) was easily assigned by its signal multiplicity (ddd) and coupling constant magnitudes ($^3J_{3,4}$ = 3.5 Hz, $^3J_{2ax,3}$ = 3 Hz, $^3J_{2eq,3}$ = 3 Hz). In the ^{1}H−^{1}H COSY spectrum, the signal of H-3 was cross-correlated with protons at δ 1.96 and 2.39, which were assigned to the pair of methylene protons at the C-2 position. The presence of a ^{1}H−^{13}C long-range correlation between H-4 (δ 5.28) and the carbonyl carbon at δ 165.2 and between H-3 (δ 5.54) and the carbonyl carbon at δ 165.3 indicated the linkage of G and MeG at the C-4 and C-3 positions, respectively. MeG, with the carbonyl carbon at δ 164.9, was linked therefore into the C-5 position.

This study will proceed to further pharmacological investigation of the isolated compounds.

J. Agric. Food Chem. 2015, 63, 6939−6945

glucuronides,[9] and a small fraction is sulfated or left unconjugated.[1] Although it is generally believed that aglycones are the most active biological compounds in humans, conjugates have also been postulated as displaying biological activities,[10] and some of them, such as sulfates, have been reported to have higher activities than the corresponding aglycones.[11]

Whereas daidzein and genistein are present in soy foods, equol is a metabolite of daidzein, the production of which depends upon the individual gut microflora;[12] only 30−50% of the adult Caucasian population is able to produce it.[1] Unlike daidzein or genistein, equol presents a stereogenic center at C-3, and therefore different enantiomeric forms exist. In humans, (*S*)-equol is the only enantiomer that is produced by intestinal bacterial flora.[13] This fact is of clinical relevance because both enantiomers have different activities; (*S*)-equol, but no (*R*)-equol, displays high affinity for the estrogen receptor beta (ERβ), and its activity is even higher than that of estradiol.[13]

Because of the beneficial health effects that soy isoflavones may provide to humans, several brands of isoflavone extracts have been commercialized over the past decades. However, there is little information concerning these preparations with respect to their specific isoflavone profile and quantity. Differences in bioavailability and pharmacokinetics may have an impact on isoflavone biological and pharmacological activities.

A number of analytical methods have been developed to detect and quantify isoflavone concentrations in biological fluids (plasma, serum, and urine). The most commonly used include gas chromatography coupled to mass spectrometry (GC-MS),[14] high-performance liquid chromatography (HPLC) with electrochemical detection,[15] HPLC with UV detection,[16] and liquid chromatography coupled to mass spectrometry (LC-MS).[4,17] At present, LC-MS/MS is the most commonly employed analytical technique due to its high sensitivity and selectivity.

The aim of the present study was to develop and validate an LC-MS/MS method for bioavailability studies of commercial isoflavone preparations that would be subsequently used in clinical research. A randomized, crossover, bioavailability study of two different, commercially available soy isoflavone extracts (Super-Absorbable Soy Isoflavones (Life Extension, USA) and Fitoladius (Merck, Spain)) was performed.

MATERIALS AND METHODS

Chemicals and Reagents. Daidzein, orthophosphoric acid (85%), β-glucuronidase from *Helix pomatia* (H-2 and H-1), β-glucuronidase from *Escherichia coli*, citric acid monohydrate, and sodium citrate dihydrate were purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). Equol and genistin were purchased from LC Laboratories (Woburn, MA, USA). Genistein was purchased from Extrasynthèse (Lyon, France). Daidzein-4-sulfate disodium salt, daidzein-7-β-D-glucuronide potassium salt, daidzein-7-β-D-glucuronide-4-sulfate disodium salt, and equol-4-sulfate were custom synthesized by Toronto Research Chemicals Inc. (Toronto, ON, Canada). Daidzein-d_6 and equol-d_4 were purchased from Medical Isotopes Inc. (Pelham, NH, USA). Methanol, acetonitrile (HPLC gradient grade), ammonium hydroxide, and acetic acid were purchased from Merck (Darmstadt, Germany). Ultrapure water was obtained using a Milli-Q purification system (Millipore Ibérica, Barcelona, Spain). Drug-free plasma was obtained from the Hospital del Mar blood bank (Barcelona, Spain).

Working Standards. Standard stock solutions of all analytes and their corresponding internal standards (IS), with the exceptions of daidzein-7-β-D-glucuronide and daidzein-7-β-D-glucuronide-4-sulfate, where water was used, were prepared by dissolving 10 mg of each substance in 10 mL of methanol. Working solutions were prepared by further diluting the starting solutions and were kept in dark flasks at −20 °C.

Instrumentation: LC-MS/MS Conditions. Identification and quantification analysis was performed using an Agilent 1200 series HPLC system (Agilent Technologies) coupled to a triple-quadrupole (6410 Triple Quad LC-MS; Agilent) mass spectrometer with an electrospray interface. Nitrogen was employed as a drying and nebulizing gas. A capillary voltage of 4 kV in negative ionization mode was used, and the source temperature was set to 325 °C.

The liquid chromatographic separation of daidzein, equol, and genistein was performed at 40 °C on an Acquity UPLC BEH C_{18} column (100 mm × 3.0 mm i.d., 1.7 μm particle size) (Waters Corp.). The mobile phase was an isocratic solvent system consisting of 0.01% ammonium acetate at pH 5 and methanol (40:60, v/v) at a flow rate of 0.3 mL/min. The injection volume was 10 μL. The total run time was 5 min per sample. All compounds were monitored in negative ionization using the multiple reaction mode. Daidzein and genistein were quantified by comparing their peak area ratios with that of daidzein-d_6 (IS1), whereas equol was quantified using equol-d_4 as internal standard (IS2). Due to the chemical structure similarities between daidzein and genistein, daidzein-d_6 was used as the internal standard of genistein.

Sample Preparation. First, a 1 mL aliquot of plasma sample was transferred into a glass tube and spiked with 30 μL of IS1 solution (containing daidzein-d_6 10 μg/mL) and 10 μL of IS2 (containing 10 μg/mL of equol-d_4). Approximately 3000 units of β-glucuronidase H1 (2 mg/mL, in 0.1 M sodium citrate buffer, pH 5) was added, and the sample was incubated at 37 °C for 16 h in a shaking water bath. Hydrolysis time could be reduced to 1 h if the temperature of the water bath was increased to 55 °C.

After the sample had cooled to room temperature, 1 mL of 4% H_3PO_4 was added, and all of the tubes were centrifuged at 3500 rpm for 5 min. They were then submitted to a solid-phase extraction (SPE) procedure using Oasis MAX cartridges (3 cm^3, 60 mg; Waters Corp., Dublin, Ireland). Cartridges were conditioned with 2 mL of methanol and equilibrated with 2 mL of water. After sample loading, interferences were washed away with 2 mL of 5% NH_4OH and 2 mL of 2% HCOOH containing 10% methanol. The compounds of interest were then eluted with 2 mL of a solution of methanol containing 2% HCOOH. After the evaporation of the solvent (<29 °C, <10 psi), analytes were reconstituted in 100 μL of CH_3COONH_4 0.01%, pH 5/MeOH (50:50). Finally, samples were centrifuged at 12000 rpm for 10 min at 4 °C and supernatants analyzed by HPLC-MS/MS.

Method Validation. *Calibration Curves and Linearity.* Calibration standards of daidzein, equol, and genistein were prepared each analysis day and consisted of two replicates at six different concentrations (5, 50, 200, 500, 750, and 1000 ng/mL). Calibration curves were prepared by adding the appropriate volume of working solutions, evaporating the solvent under N_2 (25 °C, 10 psi), and adding 1 mL of isoflavone-free plasma. Calibration curves with their corresponding slope (s), intercept, and correlation coefficient (r) were calculated by weighting ($1/x$) the least-squares linear regression of the peak area ratio (analyte/IS) versus the concentration of the standards. The method was considered linear if the coefficient of determination was >0.99.

Intra-assay Accuracy and Precision. To evaluate the precision and accuracy of the method, quality control (QC) samples were prepared by spiking known amounts of the analytes to isoflavone-free human plasma to achieve final concentrations of 5 ng/mL (lower limit of quantification; LLOQ), 10 ng/mL (low QC), 100 ng/mL (medium QC), and 800 ng/mL (high QC) of daidzein, equol, and genistein. Five replicates of each QC were analyzed against the calibration curve, and the obtained concentrations were compared to their nominal value.

Intra-assay accuracy was expressed as the percent relative error of the estimated concentrations. It was evaluated by five replicates of the QC samples that were analyzed in 1 day, at each concentration level. Accuracy was acceptable if the mean concentration was within 15% of

DOI: 10.1021/acs.jafc.5b02891
J. Agric. Food Chem. 2015, 63, 6946−6953

the nominal values with the exception of the LLOQ, which was acceptable if it was within 20% of the nominal value.

Intra-assay precision of the method was calculated as the relative standard deviation (RSD, %) of the estimated concentrations obtained for five replicates of the QC samples that were analyzed in 1 day, at each concentration level. Precision was acceptable if the RSD was within 15% of the nominal values with the exception of the LLOQ, which was acceptable if it was within 20% of the nominal value.

Interassay Accuracy and Precision. Interassay accuracy and interassay precision were calculated as described for intra-assay accuracy and precision with data obtained during three validation assays that took place during three different days.

Limit of Detection (LOD). The LOD was calculated using the standard deviations (SD) of the obtained concentrations from five replicates of the LLOQ (5 ng/mL) and the slope (s) of the calibration curve, according to the following formula: LOD = 3.3 × (SD/s). Additionally, at the estimated LOD of the surrogated analytes, it was confirmed that the LOD was at least 3 times the signal-to-noise ratio of a blank plasma sample.

Lower Limit of Quantification (LLOQ). The LLOQ was the lowest concentration calibrator experimentally tested that presented acceptable accuracy (80−120%) and precision (±20%).

Extraction Recovery. The extraction process recovery was evaluated by comparing the responses of a mixture of standards with and without extraction. For this purpose, six different sources of isoflavone-free plasma were spiked at a low (5 ng/mL) and high (800 ng/mL) level of concentration. The extraction recovery was calculated as the quotient of response of standard solutions spiked into plasma before extraction (with standard) and the response of standard solutions spiked into plasma after extraction. Results are expressed as a percentage.

Matrix Effect. In a similar way, the matrix effect was analyzed using six different batches of isoflavone-free plasma at two concentrations (5 and 800 ng/mL). It was evaluated according to the following formula: % matrix effect = 100 × [(response of the post extracted spiked sample/response of the nonextracted neat solvent with analytes) − 1]. A negative percent value indicated ion suppression, whereas a positive percent value indicated ion enhancement.

Stability. Stability of working solutions of daidzein, daidzein-d_6, equol, equol-d_4, and genistein in methanol was evaluated to ensure that neither sample preparation nor stored conditions could affect the concentration of the analytes. For this purpose, freeze and thaw stability, short-term stability at room temperature, and long-term stability in the freezer were evaluated.

Application to Real Samples: Quantification of Daidzein, Equol, and Genistein in Human Blood Samples. *Study Design.* A randomized, crossover, bioavailability study with a washout period of 3 days was performed. The study was conducted in accordance with the Helsinki Declaration, approved by the local Ethical Committee (CEIC-Parc de Salut Mar), and took place in the Clinical Research Unit of Hospital del Mar Medical Research Institute (IMIM, Barcelona, Spain). Written informed consent was obtained from all of the participants prior to any study-related procedure. Participants were financially compensated for any inconvenience caused.

Subjects. A total of 12 healthy, nonsmoker volunteers (4 females and 8 males), aged between 20 and 37 years (average 26.1 ± 5.5 years), were selected through a volunteer database. Their mean weight and height were 67.8 ± 10.3 kg and 172.5 ± 12.4 cm, respectively. The body mass index of each subject was within 19.6 and 25.4 kg/m^2 (22.7 ± 1.9 kg/m^2). The women had regular menstrual cycles (26−32 days). Subjects underwent a general physical examination, complete chemistry and hematology blood test, urinalysis, and 12-lead ECG. Moreover, during the 3 days prior to the intervention, they were asked to follow a diet free from daidzin, genistin, daidzein, and genistein (including soybeans and soy-derived foods). A list of isoflavone-rich food was provided. Alcoholic beverages were not permitted 72 h prior to each intervention.

Commercial Isoflavone Preparations. The soy isoflavone preparations used in this study were two commercially available brands: Super-Absorbable Soy Isoflavones (Life Extension, USA; hard gelatin capsules) and Fitoladius (Merck, Spain; soft gelatin capsules). As provided by the manufacturer, each capsule of Super-Absorbable Soy Isoflavones contains 123 mg of soy extract, with 54 mg of isoflavones (44%), 22 mg of which are daidzin and daidzein; 28 mg, genistin and genistein; and 6 mg, glycitin and glycitein. Each capsule of Fitoladius contains 60 mg of soybean seed extract (*Glycine max*), with 24 mg (40%) of total isoflavone content; the specific amounts of each isoflavone are not, however, described in the information leaflet.

Drug Administration and Sample Collection. The treatment with Super Absorbable Soy Isoflavones consisted of a single oral intake of 2 capsules (total dose = 108 mg of isoflavones), whereas that of Fitoladius was 4 capsules (total dose = 96 mg of isoflavones). The objective of this approach was to compensate the previously mentioned differences in isoflavone content of the extracts, as provided by the manufacturers (54 vs 24 mg in each capsule). On the intervention days, each volunteer received an oral dose of a soy isoflavone extract. To avoid batch-to-batch differences in isoflavone composition, all of the capsules of each treatment were from the same batch number. Moreover, as explained below, the composition of five different capsules corresponding to that batch was analyzed.

Subjects arrived at the clinical trial unit on the intervention day at 7:45 a.m. after an overnight fast. Spot urine samples were collected for drug testing (opiates, cocaine, amphetamines, and cannabis) by a rapid test device (Instant-View, Alpha Scientific Designs, Inc., Poway, CA, USA). In addition, a breath ethanol test was also conducted. A positive screen test was considered an exclusion criterion. Intervention days were separated by at least a 3-day washout period. An in-dwelling intravenous catheter was inserted into a subcutaneous vein in the forearm of the nondominant arm, and blood samples were collected at baseline and 1, 3, 5, 6, 7, 8, 9, 12, and 24 h after treatment administration. Blood was collected into 10 mL tubes containing EDTA and centrifuged (3000 rpm, 10 min, 4 °C). The plasma samples were then separated and frozen at −20 °C until analysis.

Quantification of Isoflavones in Soy Extract Capsules. Although the treatment dosages (based on the information provided by the manufacturers) were designed to contain similar doses of isoflavones, it was expected that there would be differences in the plasmatic concentrations of specific isoflavones (e.g., genistein and daidzein) as in the Fitoladius preparation their composition was not declared. Consequently, it was necessary to measure the exact content of isoflavones of the capsules. The isoflavone content of the preparations [aglycones (daidzein and genistein) and β-glycoside conjugates (daidzin and genistin)] was determined by LC-MS/MS as follows: a sample stock solution (1 mg/mL) from each was prepared by dissolving 10.0 mg of capsule content in 10 mL of methanol and sonicating it for 5 min to achieve complete dissolution. Analysis solutions of 100 and 10 μg/mL were prepared by further diluting the stock solution. One milliliter of the analysis solution, spiked with 30 μL of a solution containing 10 μg/mL daidzein-d_6, was subjected to the previously described solid phase extraction procedure. Ten microliters of the solution was injected in the LC-MS/MS system. Each determination was performed by analyzing five different capsules corresponding to the same batch used for the study. The separation of the compounds was carried out using the same conditions described earlier. The aglycones were quantified directly, whereas the glycosides were quantified indirectly after hydrolysis. Calculations were based on the response factor of the ratio of the analyte versus internal standard.

Pharmacokinetic Analysis. The maximum plasma concentration (C_{max}) and the time to reach C_{max} (t_{max}) were determined from the curves constructed by plotting the plasma concentrations over time. The terminal slope (k_e) of the concentration−time curve was determined by log−linear regression using at least the last three points. The elimination half-life ($t_{1/2}$) of the terminal log−linear phase was calculated following the equation ln 2/k_e. The area under the curve (AUC_{0-24h}) was calculated by the trapezoidal method during the 24 h following the ingestion of the corresponding soy isoflavone extract. All of the plasma samples collected from each subject were analyzed in the same batch of analysis. To compare the pharmacokinetics of genistein and daidzein in both preparations, the AUC_{0-24h} and C_{max} were adjusted for the dose administered (AUC_{0-24h}/dose and C_{max}/dose). Taking into account that the

equol-d_4	2.87	10	245	150, 138, 123	0.03	100
genistein	3.09	30	269	159, 133, 107	0.03	120

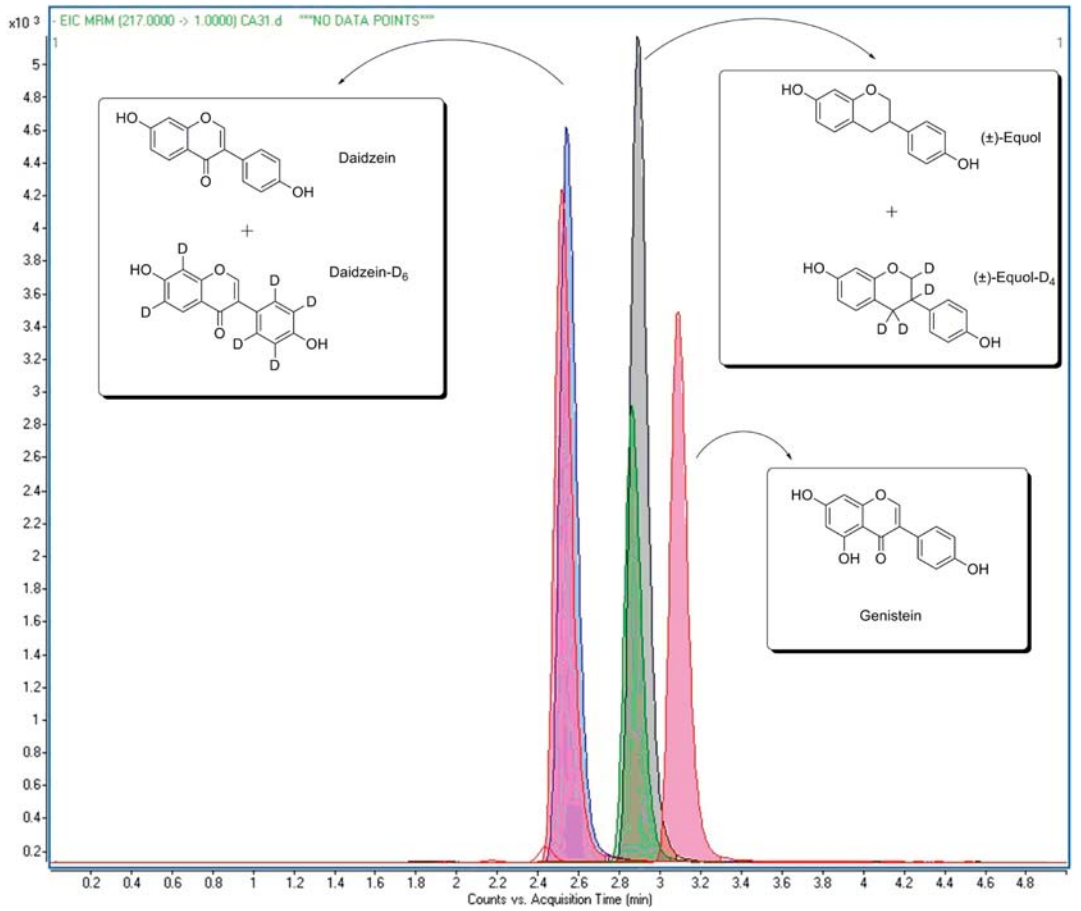

Figure 2. Chromatogram of an extracted plasma sample. A blank plasma was spiked with daidzein, equol, and genistein (500 ng/mL) and their corresponding internal standards (300 and 100 ng/mL). Following extraction and using an isocratic gradient, analytes were separated within 5 min.

isoflavone extracts contained a mixture of glycosides and aglycones, the dose administered was calculated as the sum of the amount of glycoside and aglycone, expressed in milligrams of aglycone.

Statistical Analysis. A Student's t test for paired samples was used for the statistical comparison of AUC_{0-24h}, C_{max}, $t_{1/2}$, k_e, AUC_{0-24h}/dose, and C_{max}/dose. A nonparametric method was used (Wilcoxon signed-rank test) for t_{max}. Analyses were performed using SPSS Statistics for Windows (version 18.0; SPSS Inc., Chicago, IL, USA). Significance was defined as $p < 0.05$.

RESULTS AND DISCUSSION

Method Development and Optimization. *Optimization of MS/MS Conditions.* To evaluate ionization sources and multiple reaction monitoring (MRM) transitions, the three most intense fragments of each compound (daidzein, daidzein-d_6, equol, equol-d_4, and genistein) were selected using pure standards at 10 μg/mL in negative ion mode. To further improve MRM conditions, the effect of gas temperature and collision and fragmentor energies were investigated over the ranges of 300−350 °C, 0−45 eV, and 60−140 V, respectively. The optimal gas temperature was determined at 325 °C, and the optimized values for fragmentor and collision energy of each metabolite, as well as the selected MRM transitions, are detailed in Table 1.

Optimization of LC Conditions. Different chromatographic columns were tested to study their effect on peak shapes and separation efficiency. Depending on the polarity of the stationary phase, these included cyanopropylsilyl (CN; Acquity UPLC HSS cyano 1.8 μm, 2.1 × 50 mm), n-octylsilyl (C_8; Zorbax SB-C_8 RRHT 1.8 μm, 2.1 × 100 mm), phenylhexylsilyl (Acquity UPLC BEH Phenyl 1.7 μm 2.1 × 100 mm), and n-octadecylsilyl (C_{18}; Acquity UPLC BEH C_{18} 1.7 μm, 3.0 × 100 mm) moieties on silica. After having compared the four chromatographic columns, the latter was chosen to continue with the optimization of the methodology because it provided the best separation with good resolution for equol, daidzein, and genistein.

Chromatographic separation of the analytes was optimized by evaluating four mobile phases (0.1% HCOOH, 0.01% NH_4CH_3COO, acetonitrile, and methanol). A rapid separation

equol	0.999	0.9	−7.6	−4.8	79.0	84.5
equol-d_4			−12.3	−17.2	76.7	80.2
genistein	0.996	1.0	−1.8	−9.4	79.1	80.5

(<5 min) of the three compounds of interest was achieved using an isocratic solvent system consisting of 0.01% ammonium acetate at pH 5 and methanol (40:60, v/v) (Figure 2).

Optimization of the Solid Phase Extraction Procedure. To optimize the extraction of the analytes of interest from plasma, several solid-phase extraction procedures were evaluated by spiking known amounts of the analytes and calculating the corresponding recoveries and matrix effect. Five different cartridges were evaluated. These included Oasis MCX, WAX, MAX, WCX, and HLB (Waters Corp.). The highest recovery of the analytes was achieved when MAX cartridges were used, although a marked matrix effect was present. To avoid the coeluting matrix components affecting the ionization efficiency of the analytes, different washes were evaluated. Neither basic washes with 5% NH_4OH nor additional washing steps using methanol improved the matrix effect. However, when acidic washes were studied using mixtures of methanol and 2% formic acid, the matrix effect was enhanced. The best results were obtained when 2% HCOOH and methanol (90:10; v/v) were employed.

Optimization of the Hydrolysis. The efficacy of different enzymes to hydrolyze the sulfate and glucuronic acid moieties present in the phase II conjugates of equol, genistein, and daidzein was evaluated. Different enzyme preparations (β-glucuronidases from *H. pomatia* H-2, purified H-2, H-1, and β-glucuronidase from *Escherichia coli*), glucuronidase and sulfatase units, incubation times, and temperatures were studied. Several custom synthesized products containing sulfate and/or glucuronide moieties (daidzein-4-sulfate, equol-4-sulfate, daidzein-7-β-D-glucuronide, daidzein-7-β-D-glucuronide-4-sulfate) were used as substrates, and the percentage of hydrolysis achieved in each case was evaluated.

The best results were obtained when the samples were treated with 3000 units of β-glucuronidase H-1 from *H. pomatia* at pH 5 after an incubation at 37 °C for 16 h. Interestingly, similar results were achieved when the hydrolysis time was reduced to 1 h and the temperature of the water was increased to 55 °C. This glucuronidase has been previously used in the analysis of soy isoflavones.[18−21]

Under the conditions described above, the percentage of hydrolysis of daidzein-4-sulfate, daidzein-7-β-D-glucuronide, and daidzein-7-β-D-glucuronide-4-sulfate was >95%. With greater amounts of β-glucuronidase (5000 units), the percentage of hydrolysis was constant, although the matrix effect increased. Whereas the hydrolysis of most of the metabolites was successful, none of the studied conditions was able to hydrolyze equol-4-sulfate, the yield being below 5%. Studies regarding equol metabolism in humans, monkeys, and rats have reported that sulfation is a minor metabolic pathway of this compound.[22] As described below, despite having detected equol in plasma samples from three volunteers, the pharmacokinetics of this metabolite has not been evaluated in this study.

It is worth noting that a total quantification of isoflavones was chosen due to the large number of isoflavone glucuronide and sulfate metabolites conjugates that have been described to date in humans[16] and animals.[9] Although some of these conjugates are commercially available, the lack of an appropriate commercially available IS for all of them for their proper quantification was a major limitation for their inclusion in the bioavailability study. For this reason, a total quantification of the isoflavones was performed following sample hydrolysis. To do so, four different representative metabolites presenting glucuronides and/or sulfate moieties were custom synthesized. The hydrolysis procedure was optimized to ensure that the conditions used were able to release the aglycones. Finally, the quantification of total isoflavones was performed in real plasma samples using the optimized hydrolysis procedure.

Method Validation. Validation of the analytical method was performed following the European Medicines Agency guidelines on bioanalytical method validation (http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2011/08/WC500109686.pdf, accessed April 30, 2014).

The linearity of the calibration curve was evaluated from three different prepared batches as described above. Satisfactory determination coefficients (r^2 > 0.99) were obtained for all of the analytes in the selected range of 5−1000 ng/mL.

Intra- and interday accuracies presented acceptable percent relative error for the three compounds, and the intra- and interday precisions were constantly below 15% RSD (Supplementary Table 1).

The LODs for daidzein, equol, and genistein were 0.6, 0.9, and 1.0 ng/mL, respectively. The LLOQ for these three isoflavones was 5 ng/mL.

The percent matrix effects for daidzein, equol, genistein, and their corresponding IS assessed at 5 and 800 ng/mL indicate that ion suppression was lower than 17.2% and ion enhancement was not higher than 17.8%. The extraction recoveries were between 77.5 and 86% (Table 2).

No significant degradation of daidzein, equol, and genistein in human plasma took place after long-term storage at −20 °C during the analysis period. The low and high QC samples presented acceptable values (±15% the nominal values) during at least 8 months after their preparation.

Quantification of Isoflavones in Soy Preparations. Supplementary Table 2 shows the quantification of daidzein, genistein, daidzin, and genistin present in one capsule of the commercially available soy preparations studied. Both commercial sources presented predominantly β-glycoside conjugates (98%), the free forms representing only a small percentage of the isoflavone content (approximately 2%). In Fitoladius, daidzin was found to account for 37.4% of the total isoflavone

weight, whereas genistin was the most abundant isoflavone, representing 60.3%. On the other hand, Super Absorbable Soy Isoflavones had almost the same amount of daidzin as genistin (50.0 and 48.1%, respectively). The aglycones were present only in very low amounts, daidzein being at a higher proportion (1.1−1.7%) than genistein (0.6−0.7%). The total isoflavone content of Fitoladius was found to exactly match the content provided in the information pamphlet (23.8 vs 24 mg). In the case of Super-Absorbable Soy Isoflavones, the content of genistin and genistein was 1.2-fold that described by the manufacturer (35.5 vs 28 mg). As for daidzein and daidzin concerns, the amount quantified (34.5 mg) was 1.6-fold that given in the specifications (22 mg). This fact is of relevance because the dosages administered to the volunteers were based on the information provided by the manufacturer. To compensate for these differences, the pharmacokinetic parameters were normalized by the dose administered. To do so, each plasmatic concentration value (derived from the calibration curve) was divided by the amount administered of the corresponding isoflavone.

The other constituents present in the soy preparations were excipients. In the case of Fitoladius, and according to the manufacturer, these are primrose oil, glyceryl monostearate, glycerol, cuprosodic chlorophyll, gelatin, titanium dioxide, and purified water. In the case of Super-Absorbable Soy Isoflavones, these are ascorbyl palmitate and vegetable cellulose. The analysis of these excipients is beyond the scope of this paper.

Quantification of Isoflavones in Human Plasma Samples. *Equol.* Only 3 of the 12 volunteers were found to be equol producers. In these volunteers, equol concentrations started to increase between 5 and 6 h after the treatment administration and could still be detected at 24 h. Therefore, the pharmacokinetics of this metabolite is not evaluated in this study.

Daidzein and Genistein Pharmacokinetics. Time course plasma concentrations of total genistein and daidzein are shown in Figure 3. Some studies have described that daidzein presents higher bioavailability than genistein,[23] whereas others have reported the contrary.[24] In our study, no differences in bioavailability were observed between daidzein and genistein after the treatment with Super Absorbable Soy Isoflavones or Fitoladius. The double peak found in the time course plasma concentrations suggests an enterohepatic circulation, which is characteristic of these compounds (Figure 3).[6,25] To a lesser extent, the small percentages of aglycones present in the soy extracts could also contribute to this pharmacokinetic profile, as the free forms are absorbed more quickly than the glycosides.[26]

The pharmacokinetic parameters studied (AUC_{0-24h}, C_{max}, AUC_{0-24h}/dose, C_{max}/dose, t_{max}, $t_{1/2}$, k_e) are reported in Table 3. As shown using the AUC_{0-24h}/dose ratio, the bioavailability of daidzein and genistein was higher after the intake of Fitoladius ($p < 0.05$ and $p < 0.001$, respectively), compared to Super Absorbable Soy Isoflavones (Figure 3).

C_{max}/dose values of genistein also differed significantly between treatments ($p < 0.001$). After the intake of Fitoladius, these values were higher than the other studied preparation. No differences were observed in t_{max}, $t_{1/2}$, and k_e.

Several factors can influence the metabolism and bioavailability of isoflavones in humans. These include age, ethnic background, dietary habits, food matrix, intestinal microflora,

DOI: 10.1021/acs.jafc.5b02891
J. Agric. Food Chem. 2015, 63, 6946−6953

intestinal transit time, previous exposure to isoflavones, and glycosidase production.[27,28] In our case, the differences in bioavailability suggest that the excipients/matrix in which these products are present may play an important role in the absorption process, which could have a direct impact on the bioavailability of soy isoflavones. This fact would explain the different pharmacokinetic profile observed between treatments when the same 12 volunteers received two different soy extracts.

Our study has strengths and limitations. One of the strengths is the crossover design, which allowed the same participants to be included in the different treatments, thus minimizing interferences with other confounder variables. Another strength lies in the fact of including both genders among the participants, thus providing a better representation of the overall population. One limitation of our study is that, due to the available commercial sources of the soy extracts, the isoflavone composition of the two tested products differed significantly. Consequently, the participants did not receive exactly the same doses in the two soy isoflavone extracts. To minimize these differences, the exact amount of each isoflavone was first analyzed, and normalization by the dose administered was performed prior to pharmacokinetic analyses.

In conclusion, in the present study we developed a LC-MS/MS method based on an enzymatic hydrolysis with β-glucuronidase H1 followed by a SPE procedure using Oasis MAX cartridges. The analytical method was successfully validated following the European Medicines Agency guidelines on Bioanalytical Method Validation. This methodology presents a good recovery of the analytes, very low matrix effects, a rapid chromatographic separation, and high sensitivity. The limits of detection for daidzein, equol, and genistein in 1 mL of plasma sample were 0.6, 0.9, and 1.0 ng/mL, respectively. Once the method was validated, a crossover, randomized, bioavailability study was performed. The method was then applied to the plasma samples of the 12 volunteers. The pharmacokinetic profiles of daidzein and genistein were studied.

After having been normalized, Fitoladius presented higher bioavailability and achieved higher C_{max} values than Super Absorbable Soy Isoflavones for daidzein and genistein. As the other pharmacokinetic parameters were similar between both treatments, we suggest that these differences in bioavailability come from the matrix/excipients present in the capsules of the isoflavone extracts.

The preparations studied are over-the-counter dietetic preparations, they do not require medical prescription, and some of them can be purchased on the Internet. Thus, the regulation of these products probably is not as strict as that applied to prescription drugs. Consequently, a detailed and accurate description of the specific isoflavone content present in the capsules is lacking. Indeed, describing the content of the capsules as "*X* mg of isoflavones" or "*Y* mg of genistin and genistein" does not provide clear and accurate information about composition. This is an important fact because there are a number of different isoflavones, which vary in molecular weight, pharmacokinetic profile, and biological activities.[29] As a consequence, the exact content of each isoflavone should be provided by the manufacturers in order to have better knowledge of the content of the capsules and their corresponding beneficial health effects.

The purpose of this study was the selection of one isoflavone extract preparation for its use in a clinical trial with the aim of treating drug addiction. In this context we performed the bioavailability study. Results from this study show that isoflavone extracts vary not only in their composition (not unexpected) but also in the amounts reported by manufacturers in each preparation. In a clinical pharmacology context and looking at therapeutic indications with methodologically robust designs, the results from this study are quite disturbing.

[a]Fragment ions in the MS^2 and MS^3 spectra are generated from the quasi-molecular ion and its dominant MS^2 product ion, respectively. [b]Each pair of isobaric coeluting species is marked with same number (including 21 groups). [c]No analytical standard available, exact mass data shown. −, not available.

ization or semiquantitation of certain classes of adulterants,[5,6,16] advances in modern LC-MS technology have greatly improved its analytical capability to meet the new requirements. To speed the targeted screening procedure, some LC-free MS techniques based on ion mobility, flow injection, or ambient ionization have been explored to detect illicit additives in dietary supplements.[5,7,17,18] To expand the coverage of the classical LC-MS method, we have recently reported a homologue-targeted approach by using unique QqQ-based scan or data-dependent hybrid linear ion trap (IT) toward nontarget screening, quantitation, and confirmation of multianalyte analogues in food matrices.[12,19−21] To meet the new challenge in detecting emerging food fraud adulterants and unknown illegal derivatives, the current use of high-resolution MS (HRMS) analyzers with time-of-flight (TOF) or Orbitrap has gained increasing popularity in nontargeted screening of general unknowns. Owing to the increased mass-resolving power (≥10000 fwhm) and inherent sensitive full-spectrum scanning with mass measurement errors <10 ppm, HRMS can unbiasedly detect and unambiguously identify a theoretically unlimited number of analytes via retrospective post-targeted data interrogation without either prior analyte-specific information or use of authentic standards.[2,4−7,11,13,22] However, a single-stage HRMS with an ultrahigh resolution (>50000 fwhm),[23] or its use in conjunction with high-resolution LC separation,[24] is generally required for reliable mass assignment in complex matrices. In some cases even multiplexed tandem HRMS (such as Q-TOF, IT-Orbitrap, and Q-Orbitrap) is needed to improve confirmation accuracy by means of fragment ions and isotopic patterns.[25−27] IT-TOF is a hybrid instrument that serves as an alternative technique to combine the multistage fragmentation (MS^n) capability of IT with the high resolving power of a TOF for structural elucidation.[28] By taking advantages of rapid polarity-switching and data-dependent acquisition of accurate MS^n spectra "on-the-fly" in a single run, LC-IT/TOF has been reported for the global identification of herbal components, discovery of drug metabolites, and metabolomics.[29−31] However, this method has not been previously used for multiclass screening and identification of undesirable substances in food matrices.

In this work, we explore the potential of the hybrid LC-IT(MS^n)/TOF technique for wide-scope screening and library searching for over 100 illegal adulterants in various types of dietary supplements. To the best of our knowledge, this is the first report on developing a generic workflow for adulteration screening of functional foodstuffs. In addition, a new straightforward sample preparation procedure based on single-tube extraction[19−21,32,33] is adapted to expand the screening spectrum.

MATERIALS AND METHODS

Chemicals. The analytical standards of adulterant listed in Table 1 were of high purity (>92%) and purchased from TLC PharmaChem (Vaughan, Canada), Sigma-Aldrich (Shanghai, China), or the National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). Individual stock standard solutions (ca. 1.0 mg/mL) were prepared in pure methanol, acetonitrile, or water. An intermediate standard mixture of the reference compounds was prepared by appropriate dilution of the individual stock solutions in methanol/water (50:50, v/v). The selected 106 adulterants were divided in 10 mixtures with around 10 analytes each at a concentration of 50 μg/mL. Mixed standard working solutions (0.1−50 μg/mL) used to spike control samples were prepared by diluting the multianalyte intermediate standard mixture with methanol/water (25:75, v/v). All of the stock and working solutions were stored at −20 °C in the dark when not in use. HPLC-grade methanol and acetonitrile were obtained from Merck (Darmstadt, Germany). Analytical-grade sorbents of primary−secondary amine (PSA, 40 μm) and octadecylsilane (ODS, C_{18}, 40 μm) were purchased from Varian, Inc. (Palo Alto, CA, USA). Unless otherwise specified, all other reagents were of analytical grade. Ultrapure water prepared by a Milli-Q-Plus system (Millipore, Bedford, MA, USA) was used throughout the study.

Dietary Supplement Samples. Dietary supplements, which claimed functions of supporting healthy blood pressure (15), blood sugar management (16), antiobesity effect (17), hypolipidemic effect (12), antiinflammatory analgesic effect (13), sedative−hypnotic effect (18), or enhancement of sexual performance (22), were purchased from Internet vendors and local markets in China, in five different oral forms including 25 liquids, 25 capsules, 23 tablets, 22 softgels, and 18 pills.

To provide the negative controls ("blank" samples), the collected materials were preliminarily confirmed to be free from contamination of the test adulterats by LC-MS screening after sample handling with the procedure described below. Fortified samples serving as matrix-matched standards for method development and validation were prepared by spiking with the respective working standard solutions into an accurately weighed aliquot (approximate 2.0 g) of the individual analyte-free "blank" matrices. All of the collected specimens, subsamples, and control samples for both blanks (negative controls) and spikes (positive controls) were stored at −20 °C (in the dark) until analysis.

Sample Preparation Procedure. After collection, the tablets and pills (pellets) were crushed into fine powder; the capsules and softgels were cut open and the contents mixed and then thoroughly homogenized. For oral liquids, three samples were evenly mixed and divided into fractions. Then a representative portion of 2 g of the resulting powder or liquid sample was accurately weighed (precision = 0.1 mg) and transferred to a 50 mL screw-cap (Teflon-lined) centrifuge tubes. All of the test sample aliquots were processed with the subsequent procedures prior to LC-IT/TOF analysis.

Single-Tube Multifunction Adsorption Cleanup (stMAC). The protocol was carried out by using a single-tube extraction procedure based on one-pot extraction/partitioning−multifunction adsorption

DOI: 10.1021/acs.jafc.5b02222
J. Agric. Food Chem. 2015, 63, 6954−6967

sample cleanup introduced earlier with minor modifications.[20] In brief, an aliquot of the test sample was first blended with 20 mL of methanol for 5 min, and then the mixture was extracted with 20 mL of acetonitrile containing 1% formic acid by vortex for 1 min and sonication for 15 min, followed by centrifugation at 5000*g* for 3 min. Afterward, a dispersive adsorbent mixture consisting of 0.2 g of PSA and 0.4 g of ODS was added to the supernatant (crude extract) within the same tube for multifunction cleanup.[21,33] The tube was shaken vigorously for 2 min and centrifuged again for 2 min at 9000*g*. The resulting clarified supernatant was transferred for next filtration/dilution pretreatment.

In-Vial Filtration–Dilution–Injection (ivFDI). After the above centrifugation, a 0.5 mL aliquot of the final *st*-MAC extract (upper phase) was immediately withdrawn and filtered through a 0.22 μm pore PTFE syringe filter (Phenomenex, Torrence, CA, USA) into an autosampler vial containing 1.0 mL of methanol/water (1:1, v/v) for "dilute-and-shoot" LC-MS analysis.

LC-IT/TOF MS Instrumentation. LC-IT/TOF analyses were carried out on a hybrid LCMS-IT-TOF instrument (Shimadzu, Kyoto, Japan) equipped with an electrospray ionization (ESI) source interfaced to a Prominence LC system consisting of an LC-10AD binary pump, a DGU-14A degasser, an SIL-20AC autosampler, and a CTO-20AC column oven. Instrument control, data acquisition, and analysis were performed using Shimadzu LCMSsolution software (version 3.6).

Chromatographic separation was achieved on a reversed-phase Agilent ZORBAX Eclipse AAA column (150 mm × 4.5 mm i.d., 5 μm), with a binary mobile phase composed of 0.1% (v/v) acetic acid in water (eluent A) and 0.1% (v/v) acetic acid in acetonitrile (eluent B) pumped at a flow rate of 0.50 mL/min.The column temperature was maintained at 40 °C. The elution gradient started with 5% B and was changed linearly as follows: 8 min, 20% B; 26 min, 50% B; 33–40 min, 100% B; 40.1–45 min, 5% B. The total run time was 45 min, and the injection volume was 10 μL.

High-resolution mass spectrometric data were acquired with the hybrid IT/TOF mass analyzer in both the positive and negative ESI modes using an automatic polarity-switching system in full scan and multiple stage fragmentation (MS^n) modes. The optimized MS parameters were set as follows: interface voltages, 4.5 kV (for ESI+) and −3.5 kV (for ESI−); detector voltage, 1.7 kV; nebulizing gas (N_2) flow, 1.5 L/min; drying gas (N_2) pressure, 0.1 MPa; curved desolvation line (CDL) temperature, 200 °C; heat block temperature, 200 °C. The MS^n spectra were generated by collision-induced dissociation (CID) of the target precursor ions with argon (Ar) as the cooling gas and collision gas, and the relative collision energy was set at 50%. All ions were first accumulated in the IT for automatic MS^n analyses over m/z scan ranges of 100–800 for MS^1, 100–600 for MS^2, and 50–400 for MS^3, and then the selected ions were subsequently introduced into the TOF instrument for accurate mass measurements. The ion trap pressure was 1.7×10^{-2} Pa and ion accumulation time was 100 ms; the isolation width of precursor ions was 3.0 amu. A solution of sodium trifluoroacetate clusters was used as reference for calibrating the mass axis across the range of m/z 50–2000 with error below 5 ppm.

Automatic Screening by LC-IT(MS^n)/TOF MS. *Accurate Mass Database Construction.* The compound name, CAS Registry No., elemental composition, molecular weight, and theoretical exact mass of each food adulterant were collected in an Excel spreadsheet. The retention time, quasi-molecuar ion (or dominant adduct ion), MS^2 spectrum of each target parent ion, MS^n spectrum of the most intense fragment ion in the MS^{n-1} spectrum ($n \leq 4$), and characteristic fragments from the CID mass spectra acquired in the format of the instrument's raw file were also included in the database. The resulting raw data files were transformed to JCAMP format (*.jdx files), and the Excel table built was automatically converted to Access format using the Shimadzu LCMSsolution data analysis software. As such, the user-created accurate mass database was generated in which different information can be used as searching parameters, including chemical name, retention time, accurate mass, molecular formula, and characteristic fragments. When a sample is processed with the searching database, the monitoring program consists of initial rapid diagnostic test for screening out suspected noncompliant samples and further reliable confirmation of the positive samples.

Automated Library Searching. In targeted screening of the adulterants with reference standards, the LCMS-IT-TOF was operated in a multiple precursor ion scan, followed by a data-dependent MS/MS fragmentation triggered dynamically by these selected molecular ions. In the nontarget screening procedure to identify expected or unexpected analytes, the hybrid system was operated in both ionization modes for full scanning with m/z 100–800 (ESI±), followed by a two-step protocol including component extraction and database searching.[34] For nontarget compounds without analytical standards but anticipated to be present in the database, the whole total ion chromatogram (TIC) was examined and automatically searched against the custom database by in-laboratory software (MetID Solution) to pick out the peaks, acquire the CID spectrum, and determine the presence of the expected adulterants in the sample, with a user-defined search criterion of 10 mDa accurate mass tolerance. For unexpected compounds without any a priori knowledge, only intense peaks with high signal intensities above 500,000 counts (component filter) were considered for further ion extraction (XIC) and subsequent full-scan MS^n acquisition to create a list of the detected peaks.

Multiparameter Confirmation/Identification. Finally, the target analytes can be fully confirmed (or absolutely quantitated) with the standards. For expected compounds, a part of the searching parameters was entered into an in-house ACD/MS Manager program, and an Excel spreadsheet was constructed to include, per analyte, the measured accurate mass data, the molecular formula, structural fragment ions, and retention time. The matching filter for final confirmation by comparing experimental data to the database was set to be below 5 ppm mass-accuracy window, along with a threshold limit value of ±0.3 min for retention errors. For the automatic nontarget screening of every suspected peak found, the molecular mass (m/z) data corresponding to particular elemental composition was calculated and thus the proposed empirical formula was generated by using Shimadzu's Formula Predictor. Further tentative structure elucidation of unexpected molecules can be achieved by multiparameter matching algorithm to minimize the number of possible formulas, based on evaluation and interpretation of the isotopic profile, multistage accurate mass, and characteristic MS^n fragmentation pattern.

Validation Protocol. Validation of the qualitative screening method was conducted on the basis of European analytical guidelines described in Directive 2002/657/EC, its supplement CRLs 20/1/2010, and new Document SANCO 12495/2011.[35−37] The performance characteristics of the developed LC-IT/TOF approach include specificity, matrix effect (ME), extraction recovery (ER), decision limit (CCα), decision capability (CCβ), screening detection limit (SDL), and limit of confirmation (LOC) for method validation.

The specificity was checked by testing 20 unspiked blank samples for each matrix and monitoring the presence of false detects and possible overlapping peaks appearing to interfere with the target analytes. The latent matrix effect on ESI-MS detection and analyte extraction recovery were calculated as described elsewhere.[21] As established for screening methods, SDL or CCβ (beta error probability 5%), which was defined as the validation analyte concentration at which the method can detect truly contaiminated samples with a statistical certainty of 95% (i.e., a false-negative rate of 5% is accepted), was calculated from CCα, which was determined as the lowest amount of the analyte at which the response signal was 3 times the average noise level age noise level (S/N = 3) of 20 replicates of blank samples per matrix. For reliable confirmation, LOC was established to estimate the threshold concentration for unequivocal identification.[20]

RESULTS AND DISCUSSION

Accurate MS^n Acquisition by Dual-Polarity LC-IT/TOF MS. In this work, 106 prescription drugs used as potential adulterants in dietary supplements including weight-loss drugs, impotence drugs (PDE-5 inhibitors), antihypertension drugs,

DOI: 10.1021/acs.jafc.5b02222

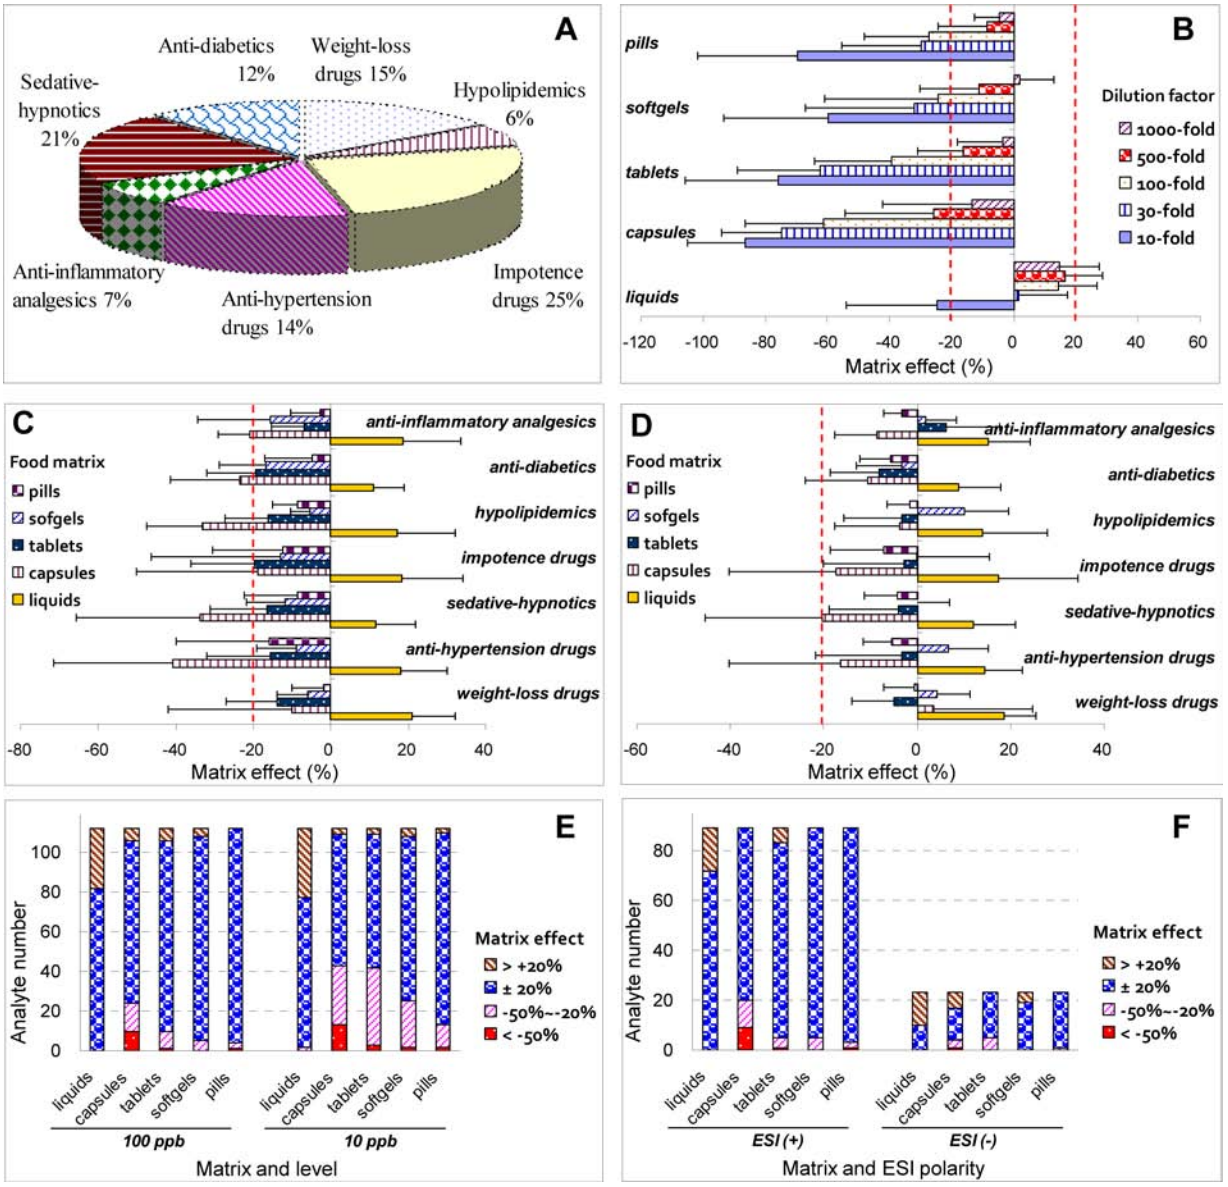

Figure 1. Optimization and validation of the *st*MAC/*iv*FDI procedure for extraction/cleanup of seven classes of adulterants in five types of food matrices: (A) pie chart of the compound proportion sorted by medical usage; matrix-induced effects obtained by (B) direct dilution-and-shoot; (C) *st*MAC protocol; (D) *st*MAC/*iv*FDI procedure, and *st*MAC/*iv*FDI procedure under (E) different analyte levels or (F) different ESI polarities.

antidiabetics, sedative−hypnotics, hypolipidemics, and anti-inflammatory analgesics (Table 1) were selected for method development for which reference standards were available in our laboratory.

Because the analytes cover a wide spectrum of polarities including very polar compounds such as biguanide antidiabetics and nonpolar molecules such as statins, the LC conditions applied were optimized to obtain the broadest distribution of all the target compounds across the whole chromatographic space. We used a long-gradient elution program with a total run time of 45 min and the retention time (RT) ranging from 2.7 min (metformin) to 35.6 min (simvastatin), which provides significantly better separation of isomers or coeluting components. Different solvent compositions were investigated for the mobile phase consisting of methanol or acetonitrile as organic phase and water with formic acid, acetic acid, ammonium formate, ammonium acetate, or ammonium hydroxide as modifier. Satisfactory results were obtained using 0.1% (v/v) acetic acid in both water (eluent A) and acetonitrile (eluent B), giving better peak shapes and higher sensitivity for the major analytes.

Although most of the analytes can be detected under positive ESI conditions, 23 compounds gave higher ionization efficiencies (sensitivity) or signal-to-noise ratios (specificity) in negative ESI mode, highlighting the necessity of using both ionization polarities to extend the screening scope. However, most TOF-based instruments cannot acquire simultaneously in both polarity modes, and thus two separate injections[38] or two temporal time segments[39] are required for this purpose. Like the new Orbitrap technique, the hybrid IT/TOF analyzer is capable of acquiring high-resolution spectra for both polarities in a single run.[40−42] Considering a fast polarity-switching (0.1−0.4 s) and data-dependent acquisition of accurate MS^n spectra (10−1000 scans/s,[28] 10 Hz[40]), an overall cycle time for acquiring MS^{1-3} scanning functions (ca. 0.8 s) was estimated to be ∼2.5 s. Under the optimized LC conditions, a peak width of

DOI: 10.1021/acs.jafc.5b02222
J. Agric. Food Chem. 2015, 63, 6954−6967

ca. 20 s obtained for each analyte accommodates well the acquisition time for these scan events, allowing for at least 8 scans/peak to ensure reliable identification.

Matching of both dual-polarity detection and high mass resolution can further increase the detection selectivity to reduce risks of false results due to coeluting isobaric interferences.[42] In general, however, an increase in mass resolution (thereby selectivity) will decrease sensitivity and scanning speed.[2,42] The IT/TOF mass spectrometer provides a resolving power of over 10000 fwhm (at m/z 1000), with a typical error lower than 5 ppm,[43] at the range of m/z 200−2000 after mass calibration with the reference standard.[28] Table 1 shows that, with few exceptions, the measured masses for all precusor ions were in accordance with the theoretical values with a sufficiently high level of confidence. Furthermore, another advantage of this hybrid IT/TOF analyzer is the ability to acquire multistage MS^n spectra ($n \leq 10$) with accurate mass (error <10 ppm) in both MS and MS^n modes in a single run, as exemplified below for confirmation and elucidation purposes.

Sample Pretreatment Optimization. There is a clear trend toward using fast generic pretreatment methods such as QuEChERS for multianalyte, multimatrix extraction in a single procedure.[38,44−46] Currently, we have shown that the combination of liquid extraction and dispersive solid-phase extraction (dSPE) cleanup in a single tube can provide more flexible alternatives to QuEChERS to cover a broad array of analyte−matrix combinations,[20,21,32,33] based on one-pot spontaneous extraction/in situ multifunction cleanup for direct LC-MS injection. In this work, a straightforward nonselective extraction/"dilute-and-shoot" procedure, which involves *st*MAC and *iv*FDI, is proposed to permit simultaneous extraction/purification of seven classes of adulterants in five types of sample matrices (Figure 1).

The *st*MAC/*iv*FDI procedure was optimized for minimizing matrix-induced effects without sacrificing extraction recovery. Matrix effects are a major concern in LC-MS bioanalysis as they can adversely affect quantitative reliability as well as mass measurement accuracy.[43,46] Direct dilution of samples is an easy approach to reduce matrix interference in popular dilute-and-shoot ESI-MS methods.[17,44−47] To examine the occurrence of matrix effect in the dilute-and-shoot analysis, we compared the response of analyte standards spiked to each control extract after extraction by acetonitrile/methanol/formic acid (70:29.5:0.5, v/v/v) under different dilution factors (10, 30, 100, 500, and 1000) with that in the extracting solvent. Of the five matrices studied, liquid was the one with the least matrix-induced effects, whereas capsules exhibited the strongest signal suppression. As shown in Figure 1B, considerable matrix effects (<−20% or >+20%) were observed for most of the resulting 530 combinations (106 analytes × 5 matrices) when the extract was directly injected after a dilution up to 500-fold. In the case of capsule samples, higher dilution factors were required for further removing the extensive matrix effects. Despite the low matrix equivalent in the dilute-and-shoot extract, strong matrix interferences were still observed, indicating additional cleanup treatment was necessary.

In the *st*MAC protocol, such severe matrix suppression was significantly improved (Figure 1C), by multifunction dSPE with a lower dilution factor of about 20 (i.e., an absolute amount of 2 g sample extracted to a final volume of 40 mL). To further diminish the matrix effects, the *st*MAC extract was processed with an *iv*FDI protocol, by which a clarified filtrate and another 3-fold dilution of the final extract was obtained for direct injection. Therefore, the combination of *st*MAC and *iv*FDI yields a moderate dilution of extracts by a factor of 60, corresponding to 16.7 mg/mL (i.e., 1/3 × 2 g/40 mL) of matrix equivalent in the final extract, which resulted in acceptable sensitivity and consistent low matrix effects (within ±20%) for all of the analyte/matrix pairs (Figure 1D), even at relatively low parts per billion levels (Figure 1E), regardless of the matrix complexity (capsules and tablets) or the ESI polarity mode (Figure 1F). Overall, the newly developed *st*MAC/*iv*FDI procedure can minimize most of the matrix effects by coextracted or coeluting residual components on nontargeted LC-IT/TOF screening of samples.

Qualitative Validation with Target Analytes. For wide-scope screening methods, the objective of a qualitative validation is typically focused on detectability, that is, to ensure the sensitive detection and reliable confirmation of the presence and identity of an analyte in a fortified sample at a certain level of concentration. To examine the feasibility of the *st*MAC/*iv*FDI-based LC-IT/TOF approach, the method was validated for the "easiest" matrix (liquids) and two of the most problematic matrices (capsules and tablets). The performance characteristics in terms of CCα, CCβ (SDL), LOC, and ER, for which the analytical criteria of sensitivity, specificit,y and reliability were met, are evaluated and summarized in Table 2.

The detection limits of the 106 analytes reached a sensitivity at low picogram level (i.e., a 10 μL injection of 0.2−5 ng/mL extract). In all of the tested matrices, almost 70% of the adulterants have CCα values ≤30 μg/kg, and only 6% have

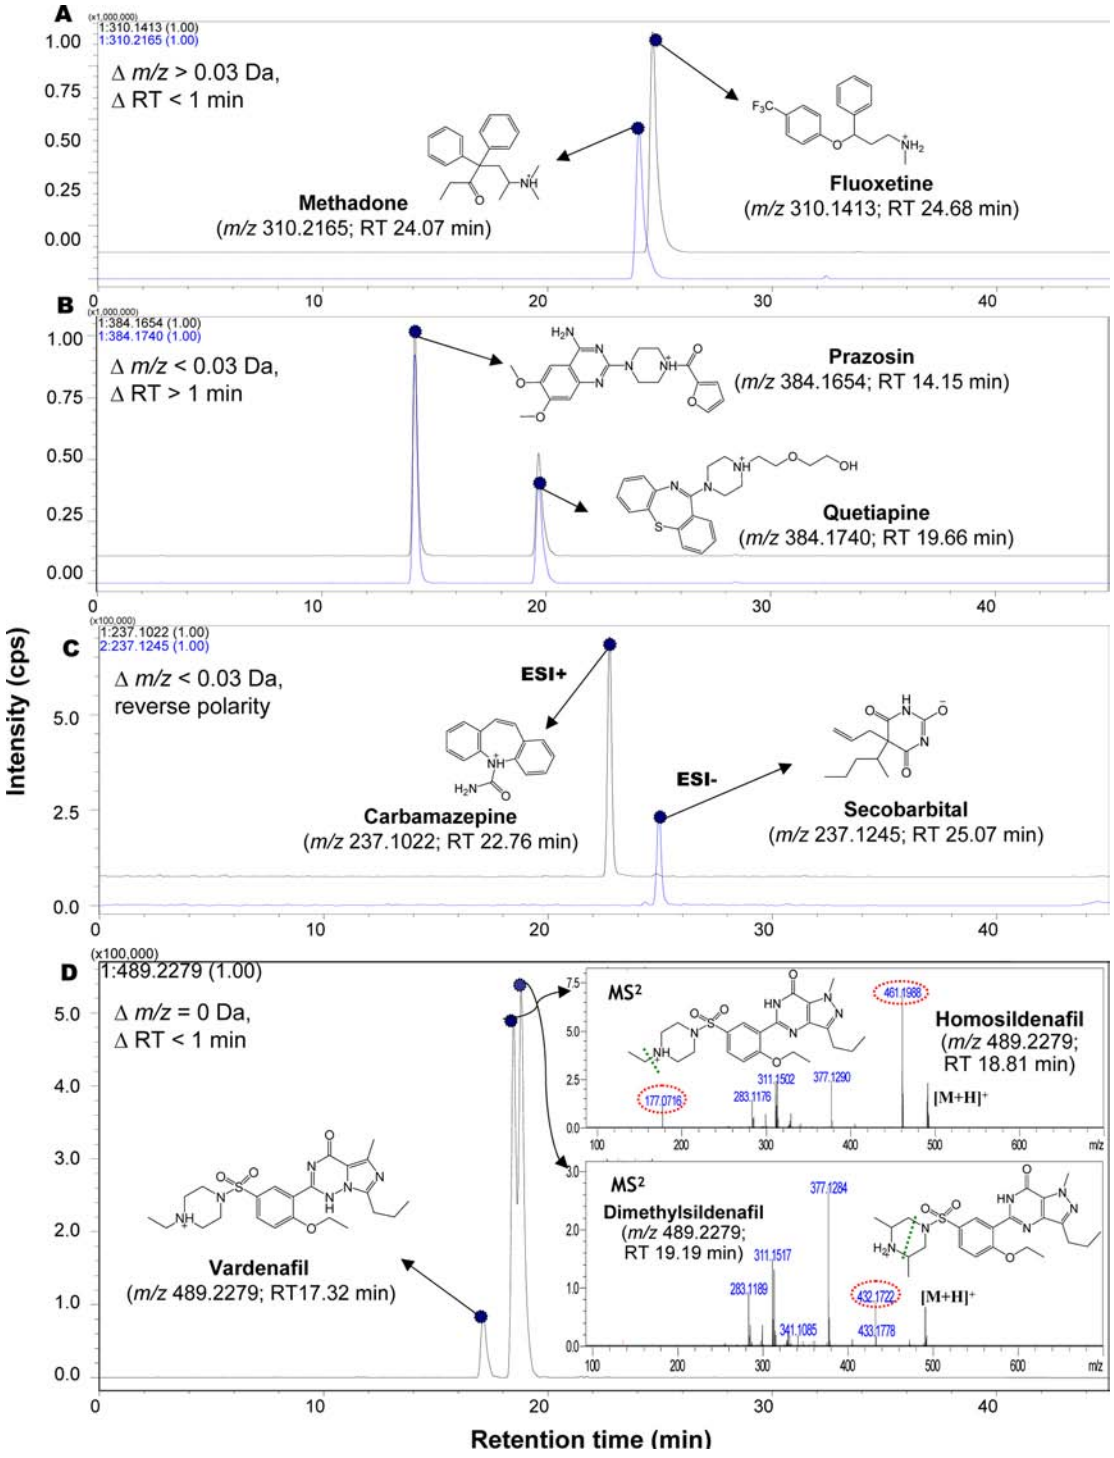

Figure 2. LC-IT/TOF-based targeted screening, discrimination, and confirmation of isobaric or isomeric species coexisting in a representative tablet sample extract spiked at 20 μg/kg, by (A) accurate mass and narrow XICs of coeluting isobars (Δ m/z > 0.03 Da, Δ RT < 1 min), (B) chromatographic separation of isobars with small mass defects (Δ m/z < 0.03 Da, Δ RT > 1 min), (C) dual-polarity detection channels, and (D) chromatographic separation of isomers (Δ m/z = 0, Δ RT > 1 min) or MS/MS fragmentation spectra of coeluting isomers (Δ m/z = 0, Δ RT < 0.5 min).

detection limits >50 μg/kg, indicating the sensitivity of this screening method is sufficient for most of the analyte/matrix combinations for adulterated dietary supplements. The statistical limit of CCβ is considered as SDL to evaluate the critical levels above which the screening method is valid with 95% confidence (i.e., 19 of 20 samples). All of these analytes were satisfactorily validated in all samples at 0.05 mg/kg spike level except for capsules, for which a SDL of 0.4 mg/kg was finally established (Table 2). The LOCs of the target compounds, which were achieved at 0.1 and 0.4 mg/kg for 73 and 97% of the detected adulterants, respectively, are sufficient to verify compliance of the majority of the test adulterated samples.

[a]Adulteration level is calculated by multiplying the LOC data by the sample dilution factor. [b]For nontarget compound, the LOC data are estimated to be identical to those of its structural analogue (given in parentheses).

The detection specificity is also a key feature to assess the viability of the LC-IT/TOF screening procedure. As exemplified by elucidating isobaric or isomeric species[24] occurring in the database (46 species in 21 groups found in Table 1), a highly reliable identification could be achieved with the multimode selectivity provided by the LC-IT(MS^n)/TOF procedure from accurate mass measurement, chromatographic retention, and multistage fragmentation data.

The TOF-based analysis allows isobars to be readily discriminated from differences in mass defect (Δ m/z > 0.03 Da) without sufficient prior LC separation of the coeluting compounds (Figure 2A). With respect to isobars with small mass defects (Δ m/z < 0.03) or isomeric compounds (Δ m/z = 0), efficient chromatography is a common tool to discriminate these species (Figure 2B,D). In Table 1, most (14 pairs) of the isobars or isomers were resolved by significant retention differences (Δ RT > 1 min), demonstrating the importance of chromatographic separation for simultaneous screening purpose. Also, detection polarity may increase the discrimination selectivity, as exemplified in Figure 2C for complete separation of carbamazepine and secobarbital by their reverse ESI polarity without any difference in mass defect or retention index. As for some more closely related isobaric coeluting species (Δ m/z < 0.03 Da, Δ RT < 0.5 min), neither exact mass nor retention time could itself be enough for reliably distinguishing the overlapped peaks. In this case, complementary information on molecular fragmentation and additional isotopic profiles if available must be explored for isomeric differentiation and unambiguous structural confirmation. As observed in Figure 2D, there were considerable differences in the MS^2 spectrum between the coeluting isomers homosildenafil (m/z 461, 177) and dimethylsildenafil (m/z 432),[6] highlighting the need and advantages of using the hybrid LC-IT/TOF instrument to generate high-resolution multistage fragmentation spectra, but for stereoisomers ephedrine and pseudoephedrine, the present method could not distinguish between them successfully, and a further chiral separation would be required for stereoselective detection of the epimer mixtures.

Library-Based Postrun Nontarget Screening. To evaluate the feasibility of LC-IT(MS^n)/TOF for qualitative screening in dietary supplements of nontarget or expected adulterants without analytical standards but that were present in the database, a mixture of sample extracts from 20 capsule products intended for weight loss, hypotension, hypolipid, or antiphlogosis was processed using the library-based postrun screening algorithm. Figure 3A shows the base peak chromatograms (BPCs) in both polarity modes for the capsule mixture, in which only the most intense peak in the spectrum at every point was monitored and thus the BPC is cleaner and more informative than the TIC mass chromatogram. The acquired spectra were automatically searched for in the database, and some adulterants including three nontarget compounds (4-

J. Agric. Food Chem. 2015, 63, 6954−6967

acetamidophenol, doxepin, and felodipine) were tested positive in the samples. For nontarget compounds, because no reference standards were available and thus the retention data were not included in the database, their identification was made only through comparison of spectra based on the precursor ion (mass error) and its characteristic MS^n fragments (similarity).

Figure 3B shows the narrow-window XICs and the corresponding mass spectra of two nearly coeluting compounds, norephedrine (m/z 152.1066, −2.6 ppm error) and 4-acetamidophenol (m/z 152.0714, 4.6 ppm error). The exact mass difference (about 36 mDa) could be enough to differentiate both compounds with the instrument resolution. In addition, 4-acetamidophenol also exists as adducts of $[M + Na]^+$ (m/z 174.0534) and $[M + K]^+$ (m/z 190.0265) with errors of 4.7 and 0 ppm, respectively. In Figure 3C, there are two m/z 280 isobars that cannot be differentiated by the exact mass difference (Δ m/z < 20 mDa). However, they can be well separated with the LC retention (Δ RT > 5 min). Moreover, the isotopic abundance ratio[24,41] at M + 2 (1:3) indicates one chlorine atom is present in the ion at m/z 280.1816 (3.9 ppm error) corresponding to sibutramine (Table 1). As shown in Figure 3D, matching dual polarity detection[42] and high-abundant M + 2 isotopic signatures in both synchronous ESI− and ESI+ chromatographic windows around 33.9 min allows reducing the possibilities of false identification of felodipine, which contains two chlorine atoms in the molecule. Besides, the MS^2 and MS^3 product ions matched well with the expected fragmentation data in the MS library, further confirming the presence of felodipine. A second small peak observed at 29.2 min in the ESI+ XIC of m/z 384 seemed to correspond to the sodium adduct ion of bezafibrate by matching retention time and mass spectrum against the authentic standard, which shows the base peak $[M + H]^+$ at m/z 362 along with its ^{37}Cl-isotope profile in the mass spectrum (data not shown).

It should be noted that the mass accuracies of the protonated felodipine, sodiated bezafibrate, and MS^3 ions of felodipine might be worse than 5 ppm error (Figure 3D), mainly due to matrix complexity, low abundance of these ion species, or kinetic energy differences between fragment ions in MS^n mode.[43] In fact, there is a general consensus that at lest two physicochemical parameters (i.e., retention time, accurate mass, isotope profile, and fragment ion[26]) are required to confirm an analyte identity. In the present case, unique MS^n fragment ions and dual polarity spectra may be useful alternatives to distinguish between isomers and identify unexpected compounds.

Application to Qualitative Screening of Real Samples. To check the applicability of the new LC-IT(MS^n)/TOF method for real-world sample analysis, the presence of illegal adulterants was assessed in dietary supplements of different origin labeled for antihypertension, antidiabetes, antihyperlipidemia, anti-inflammation, sedation−hypnotization, antiobesity, or anti-impotence. These samples were processed automatically using the generic workflow. The proposed screening strategy allowed the detection and further identification of target, nontarget, or unexpected adulterants in the suspected positive samples (Table 3).

As an example, Figure 4 illustrates the screening process of discovery, confirmation, and identification of dimethylsildenafil (aildenafil) and its unknown analogue in a representative positive sample (L019), which is used as a health wine product for aphrodisia. The mass chromatograms in Figure 4A indicate that at least three main peaks (1, 2, and 3) appeared around 19−26 min. The chromatograms were automatically screened from the database with MetID Solution by mass accuracy (±5 ppm), and the searching result is shown in Figure 4B. According to the XIC peaks table, the peaks 1, 2, and 3 were initially assigned to dimethylsildenafil ($C_{23}H_{32}N_6O_4S$, 19.2 min), udenafil ($C_{25}H_{36}N_6O_4S$, 25.1 min), and thiodimethylsildenafil ($C_{23}H_{32}N_6O_3S_2$, 26.0 min), respectively. In the next step, their retention times and fragment ions were subsequently searched against the user-created database by ACD/MS Manager. Compound **1** was further confirmed to be dimethylsildenafil on the basis of the high degree of retention precision and spectrum similarity. As can be seen from the MS/MS patterns in Figure 4C, the product ions and their relative intensities agree well with the MS^n library (similarity = 71−93%), demonstrating a high level of confidence for correct identification of the target analyte. Also, the combined MS^n spectra of the third peak at 26 min (compound **3**) revealed diagnostic ions at m/z 393, 327, and 299 (in MS^2) and at m/z 347 and 328 (in MS^3) with acceptable deviations (−3.6 to 5.1 ppm), proving the presence of thiodimethylsildenafil (target compound) in the sample.

For compound **2** (m/z 517.2613, RT 25 min), despite the closest match by accurate mass (4.1 ppm error) with udenafil (m/z 517.2592, RT 21 min), the resulting unique empirical formula ($C_{25}H_{36}N_6O_4S$) produced a false-positive identification with any library compounds, because its retention time and MS/MS spectra contrast unfavorably with the standard library data (Figure 4D). In the MS^3 spectrum of its major product ion at m/z 489.2289, the presence of m/z 377.1285, 311.1511, and 283.1198 confirms that it belongs to the sildenafil family.[13−15] More interestingly, its accurate multistage fragmentation spectra of MS^{3-5} (in Figure 4D) were in perfect accordance with the CID MS^{2-4} spectra of dimethylsildenafil (in Figure 4C), respectively. These good matches indicate compound **2**, as an udenafil isomer, is a precursor of dimethylsildenafil, which may be generated by loss of C_2H_4 from an unknown molecule. Because the structural modifications of sildenafil are commonly carried out on the piperazine ring,[4] it is a good indication of the insertion of one ethyl group attached to the nitrogen in the piperazine ring of dimethylsildenafil, in which the 2,6-dimethylpiperazine moiety is replaced with *N*-ethyl-2,6-dimethylpiperazine. As expected, the loss of C_2H_4 in MS/MS fragmentation probably corresponds to the piperazine N-deethylation. The chemical structures and the proposed fragmentation pathways for its main fragment ions are outlined in Figure 4E, which matches the findings reported by other authors,[4,13−15] further confirming the unexpected compound as N-ethylated dimethylsildenafil.

In conclusion, the nontarget screening of illegal adulterants in dietary supplements is a difficult crucial task, due to the increasing and concealed adulteration with undeclared chemical ingredients for which no analytical standards or structural information is available. A generic and efficient hybrid LC-IT/TOF workflow for wide-scope screening, library searching, and confirmation of over 100 illegal adulterants was first developed and validated in various types of dietary supplements. By combining the advantages of rapid polarity-switching and accurate multistage mass measurements in a single LC-MS run, the hybrid LC-IT/TOF system offers the potential to expand coverage of analyte species. Particularly, the use of the consecutive MS^n spectra enables a more comprehensive and precise structural assignment and confident identity confirma-

tion of unexpected compounds. On the whole, the integration of the rapid "*st*MAC/*iv*FDI" procedure, the unique LC-IT(MS^n)/TOF acquisition with accurate database searching, may serve as an alternative nontargeted discovery strategy for large-scale qualitative screening and confirmatory analysis of complex real-life samples.

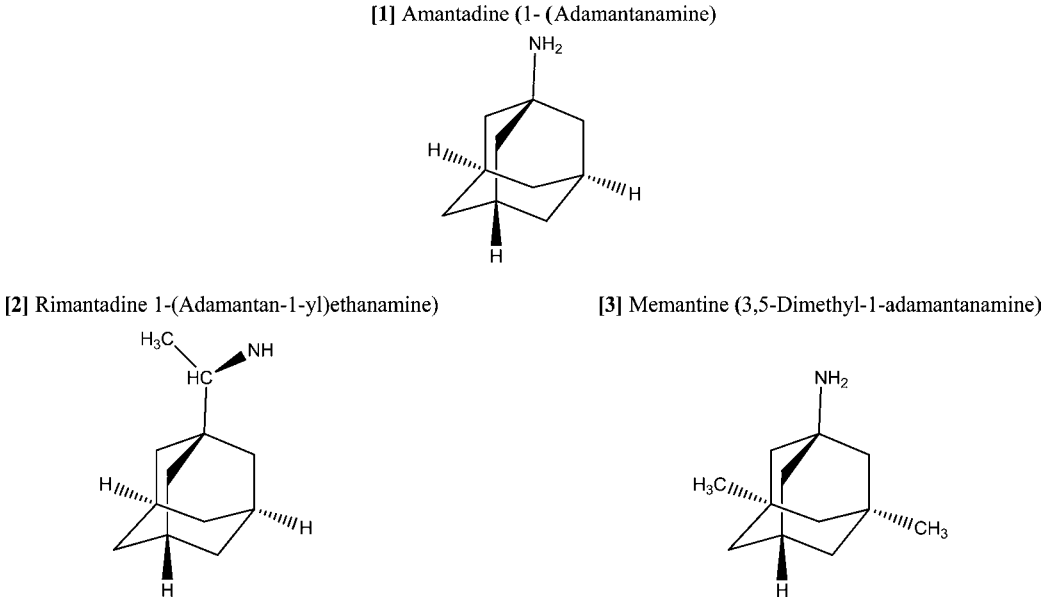

Figure 1. Structures of amantadine and its analogues.

solution and a QuEChERS (Quick, Easy, Cheap, Effective, Rugged, Safe) cleanup. Reversed-phase UPLC separation was coupled to high resolution MS (Orbitrap) detection. Similarly, Zhao et al.[7] utilized a QuEChERS approach for the analysis of amantadine and rimantadine and the antihistamine chlorphenir-amine in a variety of tissues including chicken. In this case, a primary−secondary amine dispersive sorbent was used for sample cleanup, and analysis was performed on a triple quadrupole LC-MS/MS instrument. Wu et al.[8] modified QuEChERS methodology to include multiwalled carbon nanotubes as a reversed-dispersive SPE material for the extraction of amantadine, rimantadine, and memantine in chicken muscle also using LC-MS/MS detection. Although none of these methods are specific to the analysis of antiviral residues in jerky prepared from chicken muscle, they served as a useful starting point for the analysis of amantadine and its analogues in chicken-based pet treats. One published method was developed specifically for chicken jerky pet treats for the analysis of antibiotic residues (sulfaquinoxaline, sulfaclozine, sulfamethoxazole, trimethoprim, tilmicosin, and enrofloxacin).[9] With this method, the jerky samples were prepared by grinding to a fine powder (Retch mill with 0.75 mm screen) followed by extraction with a water/acetonitrile mixture and analysis by UPLC triple quadrupole MS without any extensive cleanup procedures. Chicken jerky treat sample preparation techniques from this procedure were also incorporated into our method development.

To quantitate and confirm the presence of amantadine in imported chicken jerky treats, as well as investigate possible contamination with other adamantane residues, analytical methodology for routine laboratory monitoring was needed. Methods utilizing two complementary LC-MS technologies for detection of the antiviral residues after extraction from the pet jerky treats with a QuEChERS procedure were developed and validated.

MATERIALS AND METHODS

Instrumentation. Two different types of LC-MS instruments were used for this method in both the CAHFS laboratory and FDA laboratories. The first was an ion trap instrument. This was either a Thermo (San Jose, CA) Velos Pro LC-MS^n with a Thermo/Dionex Ultimate 3000 HPLC system (CAHFS laboratory) or a Thermo Velos Pro LC-MS^n coupled to a Thermo Accela 1250 LC pump and CTC autosampler (FDA). An ESI (FDA) or heated ESI (CAHFS) ion source was used in positive ion mode along with XCaliber (V2.1) data acquisition and analysis software. The second LC-MS system for both laboratories was a Thermo single-stage Orbitrap (Exactive) high-resolution MS equipped with an Agilent (Santa Clara, CA) 1100 Rapid Resolution HPLC system (CAHFS) or a Thermo Accela 1250 LC pump and CTC autosampler (FDA). A heated ESI ion source was used in positive ion mode along with XCaliber (V2.1) data acquisition and analysis software.

Reagents and Standards. Standards of amantadine, rimantadine, and memantine were purchased from Sigma Aldrich (St. Louis, MO). The internal standard, amantadine-d_{15} was purchased from Toronto Research Chemicals (North York, ON, Canada). Stock solutions were prepared as individual 100−200 μg/mL solutions for amantadine, amantadine-d_{15}, rimantadine, and memantine in methanol. Corrections were made for salt (HCl salts) and purity. For the FDA method, magnesium sulfate and sodium chloride were obtained from Thermo Fisher (Houston, TX) and EMD Millipore (Billerica, MA), respectively. Alternative sources, including a QuEChERS packet containing a preweighed amount of salts, could be used (Thermo Fisher or equivalent). The C18 (Bondesil 40 μm) sorbent material used was obtained from Agilent or tubes containing preweighed amount of C18 (DSC-18) sorbent could be purchased from Sigma Aldrich. Preweighed tubes containing 6 g of magnesium sulfate and 1.5 g of sodium acetate (UCT, Bristol, PA.) were used for the QuEChERS extraction at the CAHFS lab. Reagents used for sample extraction including acetonitrile, methanol, and acetic acid were chromatographic and spectrophotometric grade from EMD Millipore or equivalent. Syringe filters were Acrodisc 13 mm syringe filter with 0.2 μm nylon membrane (Sigma Aldrich) or 0.22 μm polyethersulfone membrane from Thermo Fisher or Millipore Corp.

Initial Screening and Confirmatory Method at the CAHFS Laboratory. Amantadine was first found and confirmed in chicken- and duck-based pet treats by the CAHFS laboratory. The CAHFS general screening method was as follows:

Sample Preparation. A Stein mill with carbide-tipped blades (Steinlite Corp., Atchison, KS) was used to grind pet treat samples until the contents were uniform and had the consistency of a fine powder.

Sample Extraction. The ground material was weighed (1 ± 0.05 g) into a 50 mL plastic centrifuge tube, and 5 mL of 0.1% formic acid in

J. Agric. Food Chem. 2015, 63, 6968−6978

water was added. The samples were further processed by adding two ball bearings and placing the tubes into a GenoGrinder (SPEX SamplePrep, Metuchen, NJ) for 5 min at 900 strokes/min. The ball bearings were removed, and 15 mL of 0.1% formic acid in acetonitrile were added. The sample was then extracted by shaking the tubes with the GenoGrinder without any ball bearings for another 5 min. The extracts were then centrifuged (1300*g* for 10 min), and the supernatant was decanted into a 50 mL tube containing 6 g of magnesium sulfate and 1.5 g of sodium acetate. The tubes were capped tightly and shaken well immediately. Following centrifugation (1300*g* for 10 min), the acetonitrile layer was transferred into a 15 mL glass tube. The acetonitrile was evaporated to dryness under nitrogen and reconstituted in 200 μL of 20% methanol in 0.1% aqueous formic acid. The final extract was filtered using a 0.20 μm polyethersulfone syringe filter into an autosampler vial.

LC-MS Conditions. Amantadine was initially tested at the CAFHS laboratory by analysis of a standard solution using an LC-MS screening method with the single stage Orbitrap platform that has been described earlier, with some minor modifications.[10] Briefly a heated electrospray ion source (HESI) was used and the MS was scanned from m/z 80−1000. The resolution was set to 50000, automatic gain control at 1×10^6, and the maximum inject time was 50 ms. An Agilent Eclipse Plus C18 LC column (100 mm × 2.1 mm i.d., 1.8 μm) was used with an LC gradient that consisted of 0.1% formic acid in water (solvent A) and acetonitrile (solvent B). The gradient was programmed from 99% A to 5% A over 5 min at a flow rate of 0.35 mL/min. The injection volume was 20 μL, and the column was maintained at 30 °C. For some analyses, a second scan function utilizing high collision dissociation (HCD) fragmentation at 35 V was included. Using these conditions, the expected accurate mass ion of the protonated molecule of amantadine at m/z 152.1434 was found at a retention time of 3.9 min. Furthermore, a single fragment ion produced by amantadine under HCD fragmentation conditions corresponding to loss of NH_3 (m/z 135.1168) was also present in these samples.

The initial findings of amantadine in these pet jerky samples were confirmed at the CAHFS laboratory with an ion trap LC-MS^n method. Again, electrospray ionization was used in positive mode. The instrument was tuned with an amantadine solution and the conditions were: sheath gas (N_2, 50 arbitrary units). auxiliary gas (N_2, 5 arbitrary units), and sweep gas (N_2, 0 arbitrary units). S-lens RF level 52.5%, capillary temperature 350 °C, spray voltage 4.5 kV. The ion trap parameters were: isolation width (IW) 1.5 Da for all transitions, and the collision energies were 25 V for both MS^2 and MS^3 transitions. The $[M + H]^+$ ion for amantadine at m/z 152 was fragmented to an ion at m/z 135, which was then fragmented to produce a full scan spectrum with three prominent ions at m/z 79, 93, and 107. The LC column was a 50 mm × 2.1 mm, 1.8 μm Zorbax SB-C18 (Agilent, Wilmington, DE). The LC mobile phase consisted of 0.1% aqueous formic acid (solvent A) and 0.1% formic acid in acetonitrile (solvent B). Flow rate was 0.30 mL/min, and the column was kept at 35 °C. In this case, the gradient initially started at 95% A (held for 1 min) and was then ramped to 30% A in 2 min and held at 30% A for an additional minute.

Although the methods used at CAHFS were not validated for quantitation, estimates of amantadine levels were determined. Calibration curves consisting of jerky treats spiked at 1, 5, 20, 50, and 100 μg/kg were extracted and analyzed as above on both the high resolution and linear ion trap LC-MS systems.

Antiviral Residue Method: Optimization and Validation at the FDA Laboratory. A second method specific to the antiviral residues (amantadine, rimantadine, and memantine) in pet treats prepared from chicken muscle was optimized and validated in the FDA laboratory.[11] The initial level of interest for all three compounds was 5 μg/kg.

Sample Sources. Several sources of chicken-based pet treats were purchased at the local market for method development and validation. These included chicken tenders, dried chicken breasts, chicken jerky, chicken meatballs, and soft chicken bites. If the samples were found to be free of amantadine, they were used as matrix controls for method validation.

Sample Preparation. Samples were blended with dry ice in a blender/homogenizer (RobotCoupe USA, Inc., Ridgeland, MS) with pulsed action until the contents were uniform and had the consistency of a fine powder. The homogenate was placed in a Whirl-Pak bag, loosely sealed, and stored in the freezer (−25 °C) overnight to allow the carbon dioxide to dissipate, and then sealed until the time of analysis. A Stein mill with carbide-tipped blades was used to grind smaller (<50 g) samples. Then 3 grams (±0.05 g) of sample were weighed into a 50 mL centrifuge tube and stored frozen (−25 °C) until use.

For each sample batch, a matrix blank and at least two matrix spikes were analyzed. A mixed intermediate standard containing 200 ng/mL of amantadine, memantine, and rimantadine in methanol was used to prepare matrix spikes. An internal standard fortification solution (600 ng/mL) was also prepared in methanol. As an example, to prepare a matrix spike with 5 μg/kg of amantadine, rimantadine, and memantine and 10 μg/kg of internal standard (amantadine-d_{15}), 75 μL of the mixed intermediate standard and 50 μL of the amantadine-d_{15} fortification solution would be added to 3 g of sample. The internal standard solution (50 μL, 600 ng/mL amantadine-d_{15}) was added to all samples prior to extraction.

Sample Extraction. Water (6 mL) was added to 3 (±0.05) g of ground sample in a 50 mL centrifuge tube. The sample was vortex mixed for 5 min and then sonicated for 5 min. The residues were extracted by adding 10 mL of 1% acetic acid in acetonitrile and vortex mixing for another 5 min. A combination of 4 g of $MgSO_4$ and 1 g of NaCl was then added to the tubes and mixed by vortex mixing for 5 min. The samples were then centrifuged at 17000*g* for 10 min at 4 °C. Then 6 mL of the supernatant were combined with 150 mg of C18 sorbent in a 15 mL centrifuge tube and vortex mixed for 1 min. These tubes were centrifuged at 17000*g* for 5 min at 4 °C. Then 5 mL of the supernatant was transferred to a glass test tube and evaporated to dryness using a Turbovap with N_2 at 45−50 °C. The extracts were reconstituted in 0.5 mL of 80:20 0.1% formic acid:methanol. The samples were filtered with a 0.2 μm nylon syringe filter into 2 mL of polypropylene LC vial with conical insert. The sample extraction procedure resulted in a 3× concentration of the residues.

LC-MS Conditions. The primary LC-MS method was an ion trap procedure similar to the one described above in the CAHFS laboratory method for amantadine that has been modified to include amantadine-d_{15}, rimantadine, and memantine. An Agilent Zorbax SB-C18 (100 mm × 2.1 mm i.d., 3.5 μm) LC column was used with a gradient of 0.1% aqueous formic acid in channel A and 0.1% formic acid in acetonitrile in channel B. The flow rate was 0.30 mL/min, and the column was kept at room temperature. Injection volume was 10 μL. The mobile phase gradient consisted of 90% A for 1 min, ramping to 30% A in 7 min, then holding at 30% A for an additional 2 min. Positive ions were generated using ESI (not heated), and MS^3 scans were used to detect the residues. Amantadine tuning solution (10 ug/mL) introduced through a T-junction into the LC mobile phase (0.3 mL/min 30:70 A:B) was used to optimize the source voltages and gases: sheath gas (N_2, 40 arbitrary units), auxiliary and sweep gas (N_2, 0 arbitrary units), S-lens RF level 58%, capillary temperature 275 °C; spray voltage 5 kV. The ion trap parameters were: isolation width (IW) 2 Da for all transitions, Q = 0.25, and activation time = 10 ms. Tuning solutions for all of the compounds were infused separately to optimize for their collision energy (CE) values. The following ion trap MS parameters were used: amantadine (1−4 min, MS^2 m/z 152 → m/z 135, CE 27; MS^3 m/z 135 → m/z 65−140, CE 30 monitoring MS^3 ions at m/z 79, 93, 107), amantadine-d_{15} (1−4 min, MS^2 m/z 167 → m/z 150, CE 27; MS^3 m/z 150 → m/z 65−155, CE 30 monitoring MS^3 ions at m/z 86, 102, 118), rimantadine and memantine (4−7 min, MS^2 m/z 180 → m/z 163, CE 30; MS^3 m/z 163 → m/z 65−140, CE 30 monitoring MS^3 ions at m/z 81, 107, 121, 135).

A complimentary HRMS method was also used at FDA using a Thermo single stage Orbitrap LC-MS instrument and a heated electrospray ion source (HESI). The Orbitrap was tuned similarly to the ion trap using amantadine solution combined with LC flow (0.5

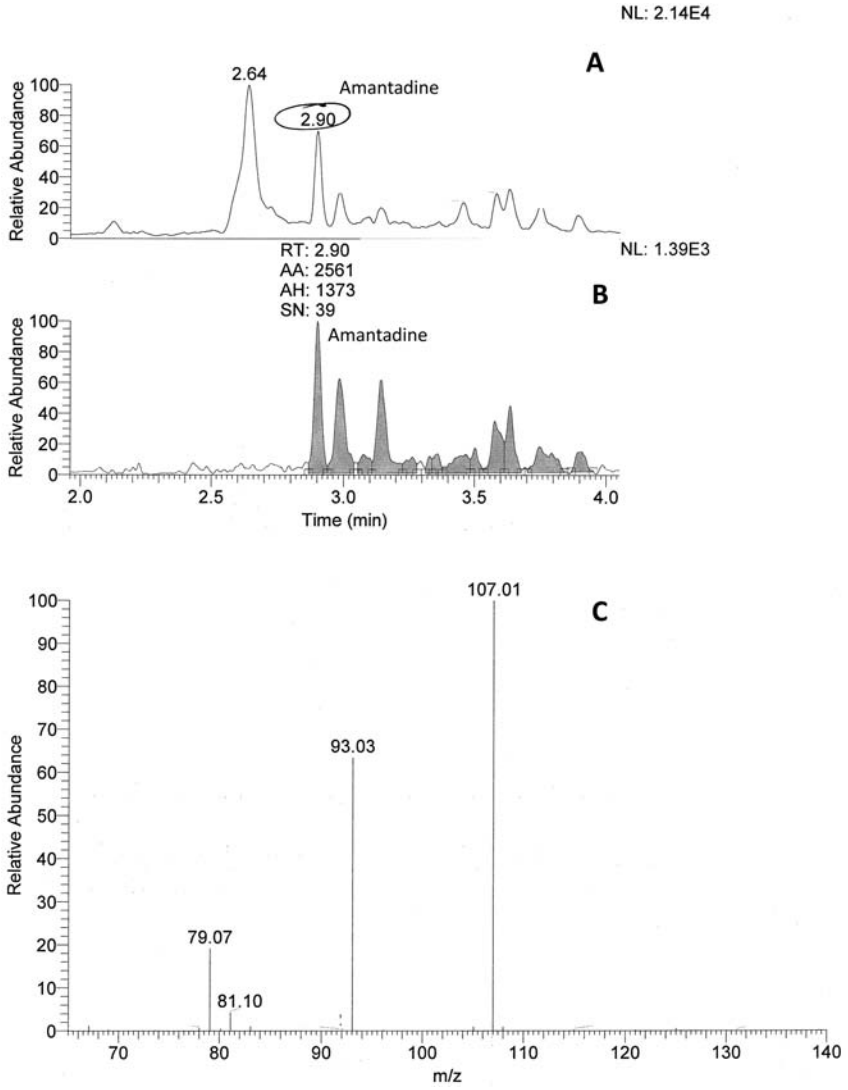

Figure 2. Ion trap LC-MS^3 analysis of matrix fortified with 1 μg/kg amantadine (CAHFS method). (A) Total ion chromatogram (TIC) of m/z 152 → m/z 135. (B) TIC of m/z 152 → m/z 135 → m/z 79. (C) Amantadine MS^3 product ion spectrum.

mL/min 50:50 A:B). Optimized MS conditions include: HESI Positive (350 °C), spray voltage 3.5 kV, capillary temperature 380 °C, capillary voltage 55 V, skimmer 18 V, sheath gas N_2 (50 arbitrary units), auxiliary gas N_2 (10 arbitrary units), sweep gas N_2 (0 arbitrary units), tube lens 75 V. The MS was scanned from m/z 70−400. Data from a second scan event using in-source collision-induced dissociation (CID) at 20 V were also collected (m/z 70−350) to detect the $[MH - NH_3]^+$ ions. No additional fragment ions were observed using either in-source CID or the high collision dissociation (HCD) cell on the single stage Orbitrap. For both scan events, resolution was set to 50000, automatic gain control at 1× 10^6, and the maximum inject time was 50 ms. For this procedure, a gradient of 0.1% aqueous formic acid (A) and acetonitrile (B) was used with an Ascentis Express C18 (75 mm × 2.1 mm i.d., 2.7 μm) from Supelco (St. Louis, MO) column, and the flow rate was 0.50 mL/min. The column was kept at room temperature; injection volume was 10 μL. The mobile phase gradient was held at 97% A for 1.5 min, ramped to 50% A in 7 min, and quickly ramped to 1% A in 0.5 min.

Data Analysis and Quantification of Amantadine. Solvent-based calibration curves using amantadine-d_{15} as an internal standard were used to quantify residues of amantadine. Solvent standards with amantadine, rimantadine, and memantine at 7.5, 15, 30, 60, 150, and 300 ng/mL (corresponding to 2.5, 5, 10, 20, 50, and 100 μg/kg in samples) and amantadine-d_{15} at 30 ng/mL (corresponding to 10 μg/kg in samples) were prepared in 0.1% formic acid. If any of the three residues were detected in samples analyzed by the ion trap LC-MS^n with a calculated value ≥50% of the lowest calibration standard (2.5 μg/kg), then the MS^3 ion ratios were examined to determine if the identity is confirmed according to FDA Center for Veterinary Medicine (CVM) Guidance no. 118.[12] A complementary high resolution HRMS LC-MS method was also used to obtain additional quantitative and confirmatory data by measuring the exact mass of relevant ions. Samples found to have levels of amantadine below the level of quantification (2.5 μg/kg) that also met criteria for confirmation of identity would be reported as "amantadine identified at levels below LOQ". Samples with levels of amantadine well above the highest calibration solution (100 μg/kg) were reanalyzed by mixing 0.5 (±0.02) g with 2.5 g of matrix control and re-extracting the sample.

RESULTS AND DISCUSSION

CAHFS: Initial Screening and Confirmatory Method. The FDA has been receiving reports of illnesses in pets associated with jerky treat consumption since 2007.[2] These illnesses involve GI tract disturbances, renal injury, and Fanconi syndrome, a rare tubular dysfunction that can be induced by some toxicants. In 2012, as part of a larger investigation into a potential cause for these illnesses, CAHFS began analyzing

DOI: 10.1021/acs.jafc.5b02416
J. Agric. Food Chem. 2015, 63, 6968−6978

various jerky samples made from chicken and duck muscle, as well as sweet potato-based treats, for a wide variety of toxic chemicals. One of the analyses used was the broad range LC-MS screen on the Orbitrap platform. In late 2013, FDA toxicologists indicated that a number of antiviral compounds, including amantadine, should be included in the jerky treat investigation. Amantadine, in particular, had been reported to have been widely used in the Chinese poultry industry.

Amantadine was initially tested by analysis of a standard solution using the Exactive platform under the chromatographic conditions used for the HRMS LC-MS screen,[10] giving the expected accurate mass ion at m/z 152.1434 and a retention time of 3.9 min (data not shown). Several samples of jerky treats were then spiked and analyzed in order to demonstrate that amantadine is recoverable from jerky using the QuEChERS method. Retention time and accurate mass data were then used to retrospectively review data from previously analyzed jerky treats in order to determine whether this compound was potentially present in the samples. A number of these samples showed a peak with the correct accurate mass and retention time for amantadine. Furthermore, the single fragment ion produced by amantadine under HCD fragmentation conditions (m/z 135.1168) was also present in these samples. All of the samples that tested positive for amantadine residues contained chicken or duck muscle; amantadine was not detected in pet treats made primarily from sweet potatoes.

A confirmatory method using an ion trap LC-MS was developed and tested by spiking five aliquots of ground chicken jerky with amantadine at levels of 1.0, 5.0, 10, 50, and 100 μg/kg. Quantitation was performed using the peak at m/z 79 (the lowest-intensity ion in the MS^3 spectrum). The 1 μg/kg spike gave signal-to-noise measurements greater than 10 for m/z 79 (Figure 2). The response for amantadine was linear (r^2 >0.995) when analyzed by either the ion trap LC-MS or the Orbitrap LC-MS instrument.

Extracted standard curves were analyzed on the ion trap LC-MS along with fresh extracts from samples that had tested positive for amantadine using the Orbitrap LC-MS screening method to estimate the amount of residue present. The batch of samples was extracted and analyzed with two control jerky samples spiked at 5.0 μg/kg. Spike recoveries for these samples as measured against the curve were 66% and 80%. A second calibration curve using the same spiking levels was then extracted and analyzed for confirmation of samples from another second group of pet treats. Two spiked controls were extracted with the batch of samples at 1 μg/kg and a third at 5 μg/kg. Recoveries for these three samples were 93%, 112%, and 124%.

FDA Antiviral Residue Method: Optimization. The ion trap LC-MS^n method was adapted from the procedure used at CAHFS laboratory. Some modifications were made to separate rimantadine and memantine, which are isomers and share the same product ions. The HRMS chromatographic conditions were also optimized to separate the two analogues. The only product ion observed with the HRMS method was the loss of NH_3. It was found that the abundance of this ion was greater when formed using in-source collision induced dissociation (skimmer offset) as opposed to using the high collision dissociation (HCD) in the mass analyzer.

Several extraction methods for amantadine in chicken muscle were tested including one that uses a cation exchange solid phase extraction (SPE) to isolate amantadine from the matrix[6] and a QuEChERS type extraction with a C18 dispersive cleanup step.[4] Another method[5] for amantadine and rimantadine in chicken tissue described in the literature that also included a cation exchange SPE was more complicated because it was a multiresidue method that included a wider scope of antiviral compounds. Several variations of a procedure using the cation exchange SPE were tested for amantadine in chicken jerky, but they did not provide adequate cleanup of the extracts. The jerky matrices had a large amount of oily, yellow residue and seemed to saturate the cation SPE; this oily residue became positively charged with the addition of acid and did not rinse off the SPE column with organic solvents but would elute off the SPE under basic conditions. Recoveries as compared to solvent standards were quite low (10−20% for amantadine, less than 5% for rimantadine and memantine). The procedure described by Yan et al.[4] provided much better results for the recovery and detection of these compounds from chicken pet treats. This method is similar to that used at CAHFS laboratory but includes additional cleanup with C18 sorbent. Variations of the method were also attempted using two different Z-Sep matrix cleanup products, but these did not improve recoveries as compared to using a C18 sorbent. Uncorrected recoveries calculated using a standard curve were ∼40−50% for amantadine and ∼30−50% for the other compounds depending on the matrix and the fortification level. A deuterated internal standard (amantadine-d_{15}) was added to the method for more robust quantification, and these results are described below.

FDA Antiviral Residue Method: Qualitative Validation. The antiviral-specific method was validated according to the agency's guidelines for chemical methods for the FDA foods program[11−13] and focused on chicken-based pet treats. Initially, a small set of controls and fortified samples (at 2.5, 5, and 10 μg/kg in duplicate) were analyzed using five different sources of chicken-based pet treats including several jerkys, meatballs, and soft chicken bites. Additional validation data were collected using a larger number of spike replicates, and these results were also analyzed for confirmation of amantadine, rimantadine, and memantine.

With the ion trap LC-MS^n method, CVM Guidance for Industry no. 118[12] for MS^n partial scan data was used to determine confirmation of identity along with retention time matching. The ratio of ions m/z 107, 93, and 79 in the MS^3 spectra for amantadine in spiked samples were compared to that found in standards. The relative abundances from the spectrometric tabulations in samples compared to standards were required to be within 20%; typical ion ratios found were m/z 107 (100%), m/z 93 (∼60%), and m/z 79 (∼20%). Similar data analysis was performed for m/z 135, m/z 121, m/z 107, and m/z 81 in the MS^3 spectra for rimantadine and memantine. Official confirmation of identity guidelines have not yet been published by the U.S. FDA for high resolution MS data, but the presence (using extracted ion chromatograms of ± 5 ppm) of both m/z 152.1434 (MH^+) and 135.1168 ($[MH - NH_3]^+$) in the HRMS data for amantadine (m/z 180.1747 and 163.1481 for the analogues) was used as additional information to confirm identity of these residues.

All three residues were confirmed in all fortified samples (n = 64) using both ion trap and HRMS instruments; there were no instances of false negatives. The use of MS^3 on the ion trap provided excellent selectivity; in general, residues were not detected in the solvent blanks, reagent blanks, or matrix blanks. However, higher background signal was observed with some matrices, and adequate chromatography was required to resolve the residues of interest. With the Orbitrap HRMS, detection of

J. Agric. Food Chem. 2015, 63, 6968−6978

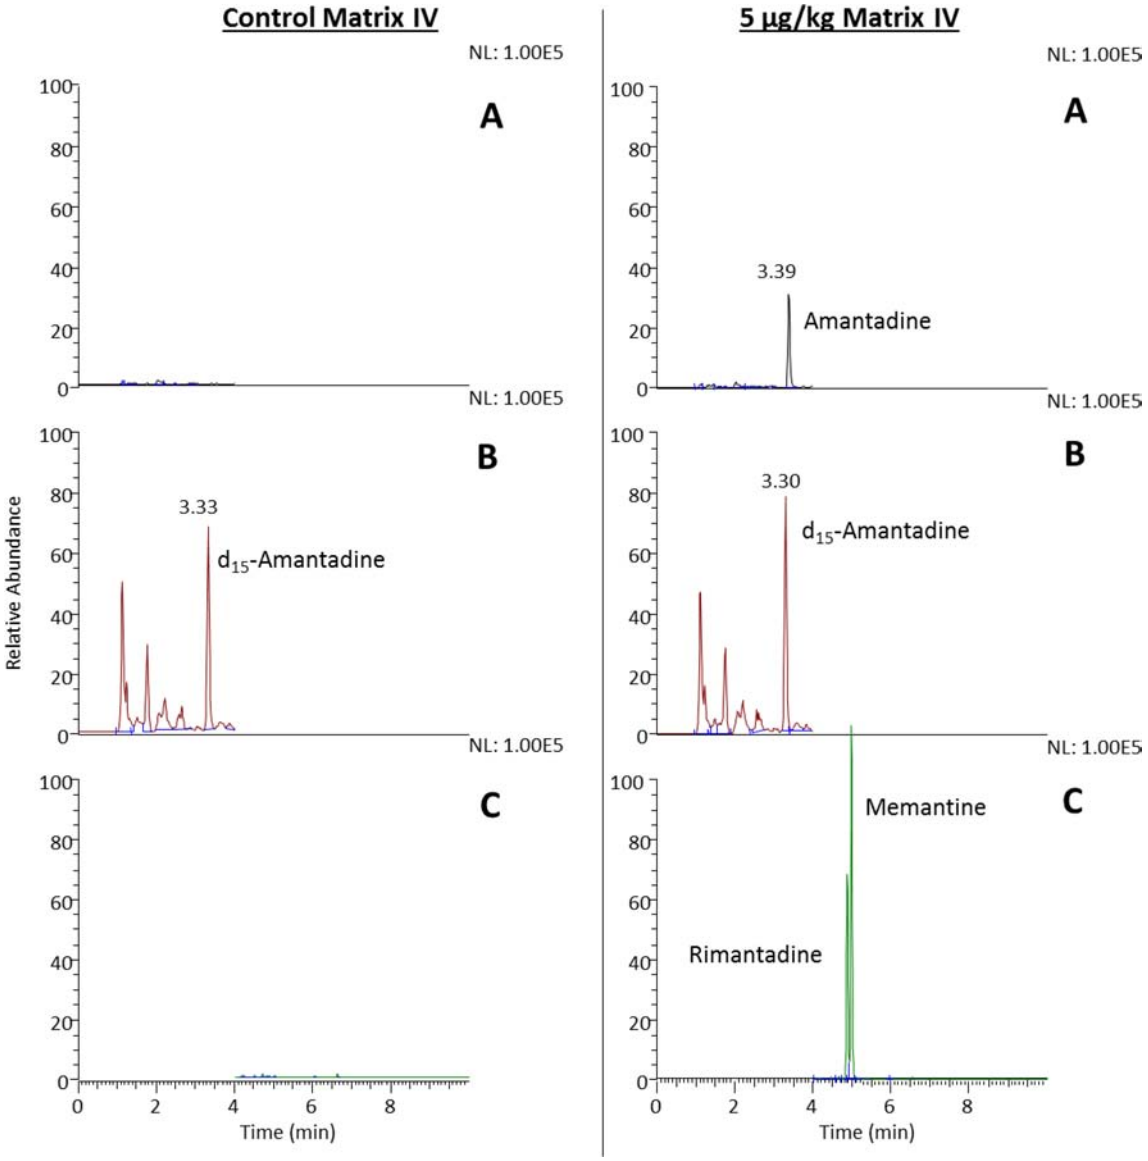

Figure 3. Ion trap LC-MS^3 analysis of control matrix and matrix fortified at 5 μg/kg with amantadine, rimantadine, and memantine. Amantadine-d_{15} (10 μg/kg) was added to both matrix blank and fortified matrix (FDA method). (A) Amantadine: total ion chromatogram (TIC) of m/z 152 → m/z 135→ m/z 65−140. (B) Amantadine-d_{15}: TIC of m/z 167 → m/z 150→ m/z 65−155. (C) Rimantadine/memantine: TIC of m/z 180 → m/z 163→ m/z 65−140.

both MH^+ and $[MH - NH_3]^+$ was required to confirm the presence of residues. In samples of chicken jerky purchased locally, amantadine was confirmed by both instrument methods in one product (at levels of <2.5 μg/kg). Amantadine was also detected, but did not meet confirmation of identity criteria, in another related product. Low levels of amantadine (2−3 μg/kg) were also found in similar products by the CAHFS laboratory, so these purchased samples were not considered to be false positives. Occasionally a peak corresponding to the retention time of memantine was detected in blanks (solvent, reagent, and matrix blanks) with approximately the correct ion ratios. However the signal-to-noise for these peaks was very low and the absolute signal was < 10% compared to what was found in the 2.5 μg/kg fortified samples; therefore, confirmation criteria were not met. Figures 3 and 4 show examples of data for control matrix and matrix fortified with antiviral compounds at 5 μg/kg for the ion trap LC-MS^n and HRMS, respectively.

FDA Antiviral Residue Method: Quantitative Validation. The quantitative validation focused on amantadine. A deuterated internal standard (amantadine-d_{15}) was purchased and added to samples prior to extraction at a level of 10 μg/kg. Additional sets of fortified samples (at 2.5 μg/kg, n = 5; 5 μg/kg, n = 5; 10 μg/kg, n = 5; 50 μg/kg, n = 1) were prepared and analyzed along with duplicate matrix blanks and a reagent blank for four different sources of chicken containing pet treats. Solvent-based calibration curves were used with standards prepared at levels corresponding to 2.5, 5, 10, 20, 50 and 100 μg/kg in tissue (7.5, 15, 30, 60,150 and 300 ng/mL). Calibration curves were linear with $R^2 \geq 0.995$. The sum of ions m/z 107, 93, and 79 for amantadine and m/z 118, 102, and 86 for amantadine-d_{15} from the MS^3 spectra were used for quantification with the ion trap. Quantitative results from the HRMS data were also calculated and compared to that from the Velos ion trap data. The ion at m/z 135.1168 $[MH - NH_3]^+$ was used to quantify amantadine because of significant

background that appeared at m/z 152.1434 for at least one matrix. The MH^+ ion for amantadine-d_{15} (m/z 167.2375) was used. These results are shown in Table 1. The lowest level of quantitation (LOQ) was 2.5 μg/kg based on signal-to-noise ≥10 and consistency in meeting identification criteria. A statistical method detection limit (MDL) was calculated with the data from samples fortified at 2.5 μg/kg by multiplying the standard deviation times the Student's t value (n = 20) and was found to be 0.68 μg/kg for the ion trap method and 1.68 μg/kg for the HRMS.

In addition, postfortified matrix-matched standards were prepared and curves were generated using this type of calibration. In general, with the use of an internal standard, the solvent-based curves provided similar recoveries as

[a]A-1 = brand "A", sample "1". [b]All replicates met confirmation of identity criteria[12] unless otherwise specified. [c]All replicates detected ions at m/z 152.1434 and m/z 135.1168. [d]Same pieces of sample tested. [e]Smaller sample size (0.5 g) was diluted with 2.5 g of matrix control, re-extracted, and reanalyzed. [f]Only 2 of 3 replicates met confirmation of identity criteria.

compared to the matrix-matched curves. Loss of signal (ion suppression) from matrix effects, as measured by the difference in slope for uncorrected solvent-based curves and matrix-matched curves, was typically 20−25%, but as much as 70% signal loss was observed for one matrix. Because it is expected that many different types of pet treats will be analyzed and providing a matrix-matched curve for each sample is not reasonable, solvent standards are preferred for routine analysis.

An evaluation of quantitative data for the other two compounds, rimantadine and memantine, was also performed. Data were acceptable for some matrices at higher fortification levels (10 μg/kg), especially using matrix-matched curves, but often the calculated recoveries were unacceptably low or high. This may indicate that the use of a deuterated amantadine as the internal standard does not always provide acceptable corrections for the calculation of rimantadine and memantine due to differences in matrix effects and/or extraction recovery. Deuterated standards of the rimantadine and memantine were not obtained as the focus of this method was amantadine; the method was not modified to optimize for the determination of these other residues. The method was able to detect the presence (confirm identity) of these compounds at levels greater than 2.5 μg/kg.

For ruggedness testing, experimental variables that were evaluated included use of different matrices, different sources of extraction salts and C18 sorbents, and several different analysts. For samples fortified at 5 μg/kg including validation data in Table 1, plus additional ruggedness testing and positive controls analyzed with test sample batches, the average recovery using the ion trap LC-MS^n method was 102% with RSD of 10.4% (n = 37). These data were collected over 9 days with four analysts performing different parts of the procedure. Most of these samples (n = 27) were also analyzed on the HRMS instrument with average recovery of 84% and RSD of 19%. The stock solutions, intermediate mixed standards, and LC-MS standard solutions were found to be stable when stored

in the refrigerator (4 °C) for at least one month. Extracts were stable for at least a few days. Long-term stability testing has not been performed.

Analysis of Test Samples. Test samples of chicken-based pet treats, including some collected from consumer reported cases, were obtained by the CVM Veterinary Laboratory Investigation and Response Network and analyzed by both the CAHFS laboratory and FDA laboratories. In some cases, the same pieces of sample were analyzed by the two laboratories; in other instances, the samples analyzed by FDA were similar (same brand/product but different bag) to those that had been analyzed previously by CAHFS laboratory. The levels of amantadine found in these samples varied from below the limit of quantitation (2.5 μg/kg) to above 600 μg/kg. Results were similar regardless of which instrument method was used and are listed in Table 2. Additional samples made from duck muscle were also analyzed at CAHFS (but not FDA), and amantadine was found in some of these samples at levels ranging from 2 to 23 μg/kg (data not shown).

The amount of amantadine found by FDA generally corresponded to levels of the residue found in similar samples previously analyzed by CAHFS laboratory. In general, the amount of amantadine found by FDA was higher (usually 2−3 times higher) than what was reported previously. This may be due to different approaches in obtaining quantitative data. For example, the FDA method used an internal standard (amantadine-d_{15}) to correct for recovery and matrix effects, while the CAHFS laboratory method utilized an extracted calibration curve with a similar matrix for all samples. Rimantadine and memantine were not detected in any of these test samples. Data from the analysis of test samples are shown in Figure 5 (ion trap LC-MS^n) and Figure 6 (Orbitrap HRMS).

In summary, amantadine residues were initially found in chicken and duck jerky using a wide-scope HRMS screening method. These results were verified with a method that was developed specifically to analyze and quantify amantadine in chicken-based pet food treats; the method was also suitable for the qualitative detection and identification of rimantadine and memantine. Analysis of these compounds in chicken jerky treats can be performed either by using ion trap LC-MS^n or a single stage Orbitrap LC-MS high resolution instrument. The use of these two complementary LC-MS analyses has unequivocally confirmed the presence of amantadine in test samples analyzed at both the CAFHS and FDA laboratories.

The relationship between residues of amantadine and toxicity in dogs is not known. In addition to being used as antiviral medicine, amantadine can be prescribed to dogs for pain management,[14] although caution is advised as some toxic effects have been observed in humans with compromised renal function.[15] The dosage that would cause toxicity is, however, much higher than what would be consumed in jerky treats. Nevertheless, residues of amantadine should not be present in chicken-based dog treats, and monitoring this compound, as

Chinese medicinal herb *Lycoris radiata*, is currently licensed for use in Europe as an acetylcholinesterase inhibitor for AD treatment.[19] Recent research has also reported anticancer[20] and anti-inflammatory[21] effects of plant extracts or active compounds isolated from *Lycoris* species. However, there has been no report on whether *Lycoris* directly affects AD pathological pathways, such as the formation of Aβ. More specifically, no biological effects have been reported for *Lycoris chejuensis* K. Tae et S. Ko (CJ), which originates from Jeju Island in Korea.[22,23] Because of their rich starch contents, *Lycoris* species plants, including CJ, have been traditionally used for hunger crops.[24,25]

In this study, we found that the CJ extract potently lowered Aβ levels in vitro and in vivo. CJ was also observed to decrease several byproducts of secretase activity. We assumed that the action of the CJ extract was related to decreased level of both immature and mature APPs, which is one of the novel mechanisms in APP processing. Furthermore, we were able to elucidate active components of the CJ extract that play a causal role in its effects. Taken together, we have revealed that CJ extract can reduce Aβ levels via the attenuation of APP while minimally altering the activity of β-, γ-, and α-secretases. Furthermore, we suggest that the effect of CJ extract is mediated by its active components, narciclasine, 7-deoxynarciclasine, and 7-deoxy-*trans*-dihydronarciclasine.

MATERIALS AND METHODS

Chemicals. Plant extraction and partition used an extra pure grade solvent (DUKSAN, Gyeonggi-do, Republic of Korea). All HPLC analyses used HPLC grade CHROMASOLV solvents (Sigma-Aldrich, MO, USA). Methanol-d_4 (99.8%, Cambridge Isotope Laboratories, MA, USA) and dimethyl sulfoxide (DMSO)-d_6 (99.9%, Cambridge Isotope Laboratories, MA, USA) were used for nuclear magnetic resonance (NMR) measurements. Diaion HP-20 (SUPELCO, MO, USA) was used as an adsorbent for flash column chromatography. Deionized (DI) water (18 MΩ-cm) was generated using a Barnstead Water Purification Systems (Thermo Fisher Scientific, MA, USA).

Plant Materials. CJ plants were obtained by collecting samples at the Hantaek Botanical Garden in Yongin, Gyunggi-do, Republic of Korea, from April to June 2010. The plant was identified by Jung Hwa Kang from Hantaek Botanical Garden. A voucher specimen was deposited in the herbarium of the Korea Institute of Science and Technology (Gangneung, Gangwon-do, Republic of Korea) under the number KNB00065. Samples were immediately stored at −20 °C until they were analyzed.

Spectroscopic Analyses. NMR spectra were recorded on a Varian VNMRS 500 MHz NMR spectrometer (Agilent, CA, USA) or a Bruker AVANCE III 400 MHz NMR spectrometer (Bruker, MA, USA). Low-resolution electrospray ionization mass spectrometry data were acquired by an Agilent 1200 series HPLC system/6120 quadrupole MSD (Agilent, CA, USA). A Waters 1525 binary pump/2996 photodiode array detector (Waters, MA, USA) with a Phenomenex Luna column (Phenomenex, CA, USA) [C18, 5 μm, 150 mm × 4.6 mm] was used for HPLC analysis. Preparative HPLC were performed with a Gilson 321 HPLC system with a Phenomenex Luna column [C18, 10 μm, 250 mm × 21.20 mm].

Preparation of CJ Extract. Air-dried bulbs (590 g) of CJ were extracted with 3 L of EtOH (50% v/v) by reflux for 3 h. The extract was then cooled at room temperature and filtrated. Finally, the filtrate was evaporated under reduced pressure at 40 °C to result in 200 g of CJ EtOH extract (yield 34%).

Isolation and Analysis of Active Compounds. First, 200 g of CJ EtOH extract was suspended in 1 L of water and then subjected to successive liquid partition chromatography. Using the same amount of *n*-hexane, CH_2Cl_2 and *n*-BuOH solvent gave 1, 1, and 5.5 g of organic soluble fractions, respectively. Then the *n*-BuOH soluble fraction (CJ-3) was refractionated by a Diaion-HP20 flash column chromatography with a stepwise elution of aqueous MeCN that was further divided to eight fractions (CJ-3-F1-8). For isolation of active compounds, preparative HPLC was conducted. To isolate 7-deoxynarciclasin and 7-deoxy-*trans*-dihydroxynarciclasine, fraction CJ-3-F4 (500 mg, 40% MeCN in water eluate) was subjected to reversed phase chromatography [C18, 250 mm × 21.20 mm, flow rate 10 mL/min, gradient elution of 10−20% aqueous MeCN containing 0.02% trifluoroacetic acid for 40 min]. Narciclasine was isolated from the CJ-3-F6 fraction (400 mg, 60% MeCN in water eluate) by reversed-phase chromatography [C_{18}, 250 mm × 21.20 mm, flow rate 10 mL/min, gradient elution of 10−50% aqueous MeCN containing 0.02% trifluoroacetic acid for 40 min]. The EtOH extract of CJ (20 mg) was dissolved in 1 mL of water, and 10 μL of the resulting sample solution was injected for HPLC analysis. The mobile phase used for analysis started at 10% MeCN in water (v/v) and was then changed to 20% MeCN in water (v/v) for 30 min. The flow rate was 1 mL/min. Narciclasine and 7-deoxynarciclasine were detected at 254 nm wavelength, and wavelength of 223 nm was used for 7-deoxy-*trans*-dihydronarciclasine detection.

Cell Culture. HeLa cells stably transfected with APP751 carrying the Swedish mutation (APPsw) were cultured at 37 °C with 5% CO_2. The culture media was Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% heat-inactivated fetal bovine serum containing 100 units/mL penicillin, 100 μg/mL streptomycin, 260 μg/mL Zeocin, and 400 μg/mL G418.

sAPPα, sAPPβ, and Aβ Peptide Assay. Cells at 80% confluence in a 35 mm dish were cultured for the times indicated in DMEM culture medium without serum but with CJ extract or active compounds solubilized in DMSO. Control cells were treated similarly and incubated with serum-free DMEM solution containing DMSO. For Aβ detection, the conditioned media were analyzed by a sandwich enzyme-linked immune-sorbent assay (ELISA; Invitrogen, CA, USA) according to the supplier's instructions. Similarly, sAPPα, sAPPβ-WT, and sAPPβ-sw were analyzed by ELISA (IBL, Hamburg, Germany).

Western Blotting. Cells were incubated at 37 °C with CJ extract for the times indicated. Cells were washed twice with ice-cold phosphate-buffered saline (PBS) and homogenized with lysis buffer (10 mM Tris·HCl, pH 7.4, 150 mM NaCl, 1% Triton X-100, 0.25% Nonidet P-40, 2 mM EDTA) using a cell scraper. Cell lysates were complemented with a protease inhibitor mixture (Calbiochem, MA, USA). The lysed cells were centrifuged at 12000*g* for 10 min at 4 °C, and the amount of protein in the supernatant was determined by Bradford assay (Biorad, CA, USA). A total of 40 μg of protein from each sample was subjected to SDS-PAGE using 4−20% gradient Tris/glycine gels (Invitrogen, CA, USA). Next, the proteins were transferred to a nitrocellulose membrane and blocked with 5% skim milk powder in Tris-buffered saline/Tween 20 for 1 h at room temperature. Membranes were then incubated with primary antibodies and rabbit anti β-tubulin (Sigma, MO, USA) overnight at 4 °C. After washing, membranes were incubated for 1 h at room temperature with horseradish peroxidase-conjugated goat antirabbit IgG antibody (1:2000 dilution; Invitrogen, USA) and washed. Peroxidase activity was visualized with enhanced chemiluminescence. Blots were quantified with Multi Gauge software using a LAS-3000 system (Fujifilm, Tokyo, Japan). The following antibodies were used: Anti-APP, C-terminal (Sigma-Aldrich, MO, USA), anti-Aβ, 6E10 (Covance, NJ, USA), anti-β-site APP cleaving enzyme, BACE1 (Chemicon, MA, USA), anti-ADAM9 (Cell Signaling, MA, USA), anti-ADAM10 (Calbiochem, MA, USA), and anti-TACE, ADAM17 (Chemicon, MA, USA).

Secretase Activity Assay. The activities of α- and β-secretases were measured using the InnoZyme TACE activity kit (Calbiochem, MA, USA) and the β-secretase activity assay kit (BioVision, CA, USA). Each of the α- and β-secretase activity assays were conducted according to the manufacturer's protocol. Subsequently, lysates, which were lysed with protein extraction reagent (Novagen, MA, USA), plated onto precoated plates, and the activities of bound secretases measured using the fluorescence of the substrates.

Animals and Drug Administration. Male APP/Presenilin-1 (PS1) double transgenic (TG) mice (Strain name, B6C3-Tg(APPswe/

DOI: 10.1021/acs.jafc.5b00889
J. Agric. Food Chem. 2015, 63, 6979−6988

PSEN 1dE9)85Dbo/J; stock number no. 004462) used in this study were obtained from Jackson Laboratory (ME, USA) at the age of 4 months. Mice expressed a chimeric mouse/human APP containing the K595N/M596L Swedish mutations as well as a mutant human PS1 carrying the exon 9-deleted variant under the control of mouse prion promoter elements. These promotor elements predominantly directed transgene expression to central nervous system neurons. All animals were housed in solid bottom cages with pellet food and water available ad libitum. The mice were also maintained on a 12/12 h light−dark cycle in a temperature and humidity-controlled room (23 °C, 50%). Starting at the age of 5 months, the TG mice were randomly distributed into groups of seven mice. One group of mice was administered CJ extract in doses of 50 or 150 mg/kg/10 mL daily per os until the end of all experiments. The other groups of mice served as controls and were administered saline during the drug administration period. The animal protocols used in this study were in accordance with and granted (grant no. AP-2010KB001) by the Korea Institute of Science and Technology Animal Care and Ethics Committee.

Morris Water Maze Test. At the age of 8 months, the mice were subjected to the Morris water maze (MWM) test. The MWM consists of a circular pool (120 cm in diameter and 60 cm in depth) filled with 24−26 °C water to a depth of 40 cm. The water was made opaque (white in color) with water-soluble nontoxic paint. A nonvisible escape platform, 8 cm in diameter, was submerged approximately 1 cm below the water surface in the center of the designated target quadrant of the pool. The two phases of the MWM tests, acquisition and retention, were conducted for six consecutive days. During the first five days, the acquisition phase was conducted by placing each mouse in the MWM to swim for a total of four trials per day, with a 1 h intertrial interval. During each trial, mice were given a maximum of 90 s to find the platform and had to remain on the platform for at least 5 s. If the mouse was unable to find the platform within the 90 s time frame, it was placed directly on the platform for 5 s and then returned to its cage. For each trial, the mouse was randomly placed under one of the four visual cues. During the acquisition phase, the amount of time it took for a mouse to find the hidden platform (escape latency) was measured. For those mice that did not find the hidden platform in the allotted time, a score of 90 s was given. The retention phase of the MWM occurred on the day immediately following the last day of the acquisition phase. During the retention phase, the platform was removed and mice were given 120 s to freely explore the pool. The total duration of time spent in the target quadrant, which had contained the escape platform during the acquisition phase, was measured. After the test, mice were removed from the pool and returned to their cages.

Novel Object Recognition Test. After the MWM test, mice were left to rest in their home cages for 1 week. After this period, a novel object recognition test (NORT) was conducted to test the spontaneous tendency of mice to explore a novel object more often than a familiar one.[26] A plastic chamber (50 cm × 50 cm × 50 cm) with 10 cm spaced grids at the bottom was used. The NORT procedure consisted of three different phases: three days of habituation, one day of acquisition, and one day of retention. During the habituation phase, each day mice were individually subjected to a single 10 min habituation session during which they were introduced to an empty arena. On the fourth day (acquisition phase), mice were subjected to a single 10 min exploring session, during which two floor-fixed objects (A and B) were placed in a symmetric position from the center of the arena with enough space between each other and from the walls. Both plastic objects were the same in color, smell, shape, and size. Mice were allowed to explore the objects freely in the arena. On the fifth day (retention phase), mice were subjected to a single 5 min exploration session. In this session, mice were placed in the arena, which contained two objects, A and C. Object C was a novel object with a different color, smell, and shape than object B. The memory index for each mouse was expressed as the ratio of the amount of time spent exploring the novel object C $(T_C \times 100)/(T_A + T_C)$, where T_A and T_C were the time spent exploring objects A and C during the 5 min, respectively.

In Vivo Soluble Aβ42 Detection. For in vivo detection of brain soluble Aβ42 peptides, after undergoing behavior tests, mice were anesthetized and decapitated at the age of 9 months. The cerebral cortex was dissected from the exposed brains, and the tissue samples were stored at −80 °C until use. The cerebral cortex samples (100 mg) were homogenized in Tris-buffered saline solution (20 mM Tris; 137 mM NaCl; pH 7.4) containing a complete protease inhibitors tablet (Sigma, MO, USA). The extraction ratio (brain tissue:Tris-buffered saline) was 1:5 or 1:10 (w/v). Tissue homogenates were centrifuged at 100000*g* for 1 h at 4 °C. Aβ42 levels in the resulting supernatants, but not in the pellet, were determined using the same sandwich ELISA kit used for in vitro detection.

Immunohistochemistry. At biopsy, three randomly selected mice from each group were killed and whole brains were removed. These brains were immersion-fixed in 10% neutral buffered formalin and processed in paraffin wax. Brains in paraffin blocks were sagitally sectioned (50 μm) across the hippocampus and were immunostained using 4G8, which recognizes the 17−24 amino acid segment within Aβ as the primary antibody. After washing, a goat antimouse secondary antibody was incubated for an additional 30 min at room temperature, and sections were visualized with avidin−biotin−horse radish peroxidase complex according to the manufacturer's instruction. The number of dark-stained plaques was counted and the groups were compared.

Statistical Analysis. All results are presented as the mean ± SEM. The overall significance of experimental results was examined by Levene's test for variance homogeneity. A One-Way analysis of variance (ANOVA) was then conducted along with a two-tailed Dunnett *t*-test. The threshold for statistical significance was $p < 0.05$ with the appropriate Bonferroni correction for multiple comparisons.

RESULTS AND DISCUSSION

CJ Extract Decreased Levels of Aβ40 and Aβ42 Secreted from Cells. We tested whether CJ extract can alter Aβ40 and Aβ42 production in HeLa cells stably transfected with APPsw. Transfected HeLa cells showed very reproducible results with Aβ production. Cells were incubated with 1, 5, 10, and 25 μg/mL of CJ extract for 8 h, and Aβ40 and Aβ42 levels from the conditioned media were measured using specific ELISA kits (Figure 1). Aβ40 and Aβ42 levels were

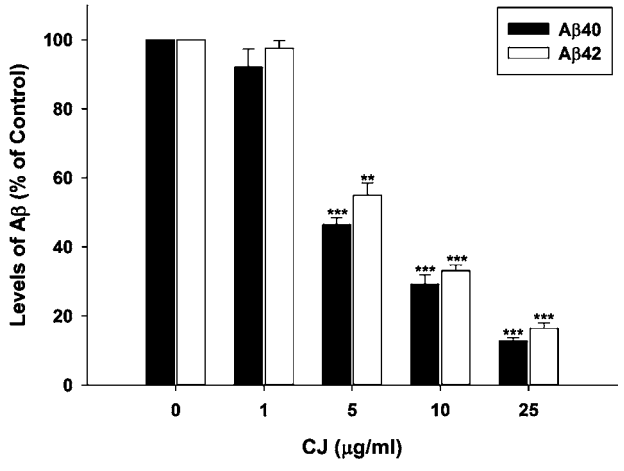

Figure 1. Effect of CJ extract on Aβ40 and Aβ42 secretion in cells. HeLa−APPsw cells were incubated with the indicated concentration of CJ extract for 8 h. The culture media were collected and analyzed for Aβ levels by using sandwich ELISA. Both forms of Aβ levels were significantly decreased by CJ extract treatment at 5, 10, and 25 μg/mL ($n = 6$). The results were quantified and expressed as mean ± SEM. (**,***) Significantly different ($p < 0.01$, $p < 0.001$) from the control group.

decreased in cells cultured with CJ extract in a dose-dependent manner. At 5 μg/mL, CJ extract significantly decreased the levels of Aβ40 and Aβ42 by 53.5 ± 2.1% and 45 ± 3.6%, respectively. Furthermore, incubating cells with CJ extract even at a concentration of 25 μg/mL for 8 h had no effect on cell viability according to the MTT-based assay (data not shown). These results suggest that the CJ extract significantly decreases levels of both Aβ40 and Aβ42 without inducing cell toxicity.

CJ Extract Decreased sAPPα, sAPPβ, and C-Terminal Fragments (CTFs) Levels. Aβ is produced through the sequential proteolysis of APP by β- and γ-secretases. Alternatively, the cleavage of APP can be mediated by α- and γ-secretases, precluding the production of Aβ. Thus, Aβ levels are determined by which secretase processes APP. If the effect of CJ extract on Aβ production occurs via modulation of β- or α-secretase, the levels of APP proteolytic products would have been altered accordingly. Therefore, we examined the effects of CJ extract on the levels of the APP proteolytic products sAPPα, sAPPβ, CTFα, and CTFβ.

First, the levels of sAPPα were measured from the conditioned media after cells were incubated with 1, 5, 10, and 25 μg/mL CJ extract for 8 h. CJ extract at 5 μg/mL significantly reduced the levels of sAPPα by 39.8 ± 2.0% (Figure 2A). Therefore, the CJ extract was able to reduce levels of the α-secretase product. We next measured levels of sAPPβ-wt (the product resulting from cleavage of the endogenous APP) and sAPPβ-sw (the product from the transfected APPsw) using specific ELISA kits. Both sAPPβ-wt and sAPPβ-sw levels were significantly decreased by CJ extract in a dose-dependent manner (Figure 2A). After culture with 5 μg/mL CJ extract, the levels of sAPPβ-wt and sAPPβ-sw were decreased by 25.6 ± 2.0% and 28.6 ± 2.6%, respectively. These results indicated that β-secretase products were also reduced by the CJ extract. We also examined the levels of C-terminal stubs of APP, CTFβ, and CTFα. CTFβ and CTFα are produced from APP by β- and α-secretases, respectively. Figure 2B shows a typical Western blot derived from cell lysates in which the band densities are expressed relative to β-tubulin density. At the 5, 10, and 25 μg/mL of CJ extract, the levels of CTFβ were decreased in a dose-dependent manner by 37, 70, and 87%, respectively. The CJ extract concentrations of 10 and 25 μg/mL were also effective in decreasing CTFα levels by 29 and 32%, respectively. These results demonstrate that CJ extract was effective in decreasing the products of APP cleavage from both pathways. Therefore, we can hypothesize that the inhibitory effect of CJ extract on Aβ production is unlikely to be mediated via the modulation of β- or α-secretase activities.

CJ Extract Decreased Levels of both ADAM10 and ADAM17. To confirm our hypothesis, we examined the effects of CJ extract on the expression of BACE1 and ADAMs in HeLa cells. BACE1 has been identified as the major β-secretase and is the rate-limiting factor in Aβ production.[24] The ADAM family, more specifically ADAM9, ADAM10, and ADAM17, are known to function as α-secretases that catalyze the shedding of the APP ectodomain. Among them, ADAM10 is accountable for the constitutive activity as it is the major ADAM family member, while ADAM9 and ADAM17 are responsible for the regulation of cleavage.[27,28]

In the current study, we treated cells with 1, 5, 10, and 25 μg/mL of CJ extract for 8 h. We then measured the expression of BACE1, ADAM9, ADAM10, and ADAM17 from cell lysates using Western blot analysis. Figure 3A shows typical results obtained from four different experiments. The CJ extract did not affect the expression of BACE1, and densitometry analysis of the bands corresponding to BACE1 clearly supports this conclusion (Figure 3B). ADAM9 exists as pro-ADAM9 and is converted to mature ADAM9. CJ extract did not change the level of pro-ADAM9, but it did show a trend toward increasing the level of mature ADAM9 as shown in Figure 3A,C. ADAM10 is present in the Golgi apparatus as a pro-enzyme at steady state, but its mature form is found in the plasma

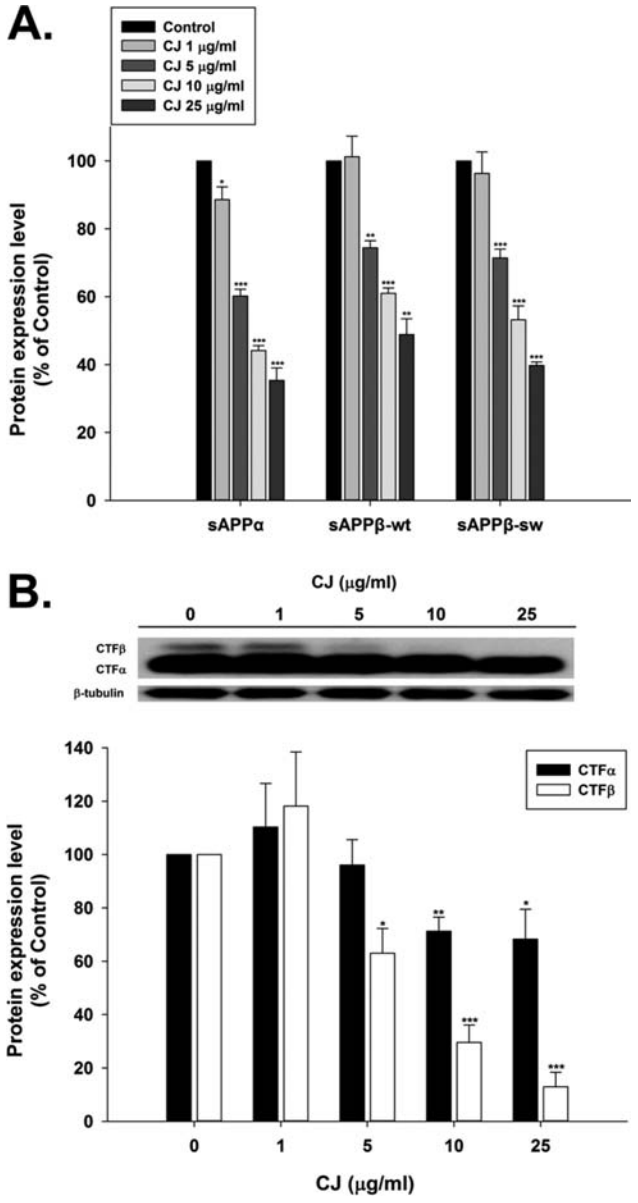

Figure 2. Effect of CJ extract on sAPPα, sAPPβ and CTFα, CTFβ formation. HeLa−APPsw cells were incubated for 8 h with 1, 5, 10, and 25 μg/mL CJ extract. (A) sAPPα, sAPPβ-wt, and sAPPβ-sw levels were quantified using sandwich ELISA. CJ extract significantly reduced the levels of sAPPα (n = 5), sAPPβ-wt (n = 4), and sAPPβ-sw (n = 5). (B) Representative Western blot result showed that the levels of CTFα and CTFβ decreased by CJ extract treatment. Proteins in the cell lysate were analyzed by the immunoblotting and immunoblotting results were quantified from 5 different experiments. The levels of CTFα and CTFβ were significantly decreased by CJ extract treatment. All of the results were quantified and expressed as mean ± SEM (*,**,***) Significantly different (p < 0.05, p < 0.01, p < 0.001) from the control group.

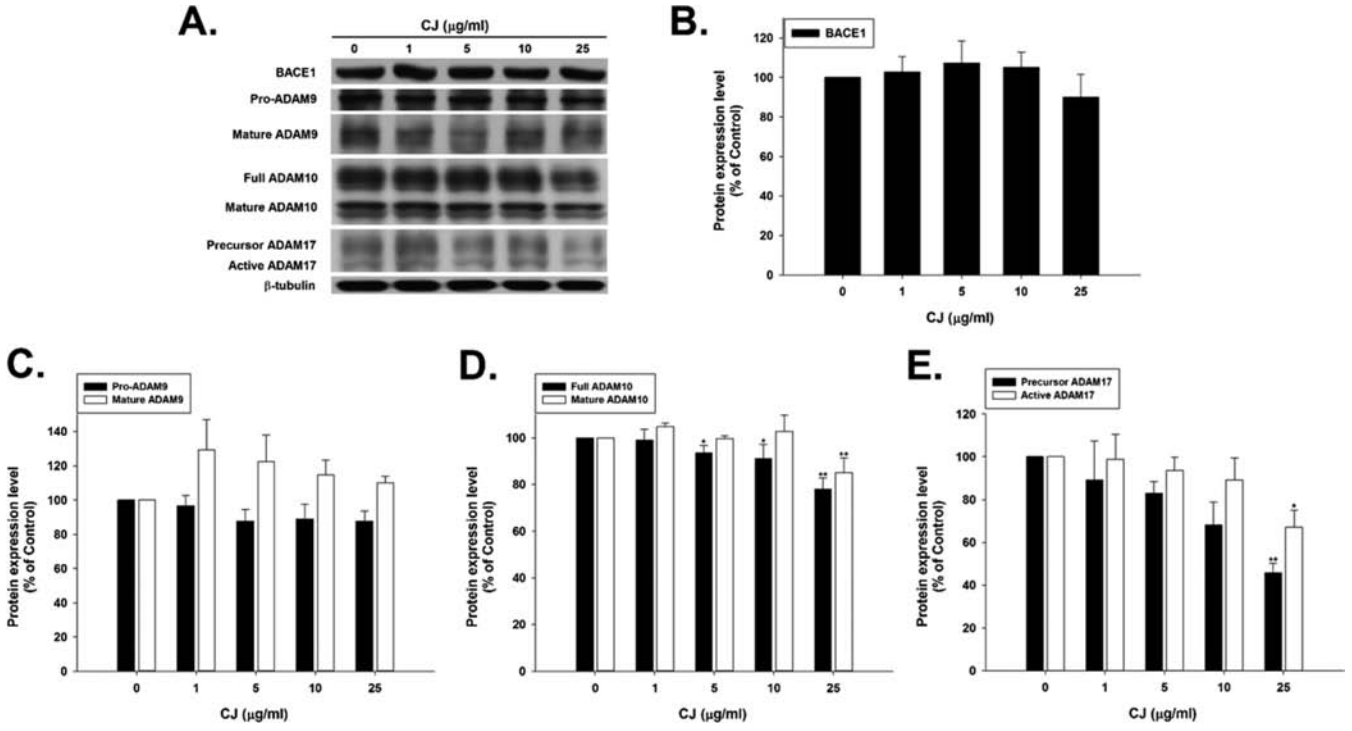

Figure 3. Effect of CJ extract on protein expressions of α-secretases and β-secretase. HeLa−APPsw cells were incubated for 8 h with 1, 5, 10, and 25 μg/mL CJ extract. Representative Western blot result showed that the expression levels of BACE1 (n = 5; (A,B) and ADAM9 (n = 4; (A,C)) were not significantly changed by CJ extract treatment. However, CJ extract reduced the expression of ADAM10 (n = 4; (A,D)) and ADAM17 (n = 4; (A,E)). The results were quantified and expressed as mean ± SEM. (∗,∗∗) Significantly different ($p < 0.05$, $p < 0.01$) from the control group.

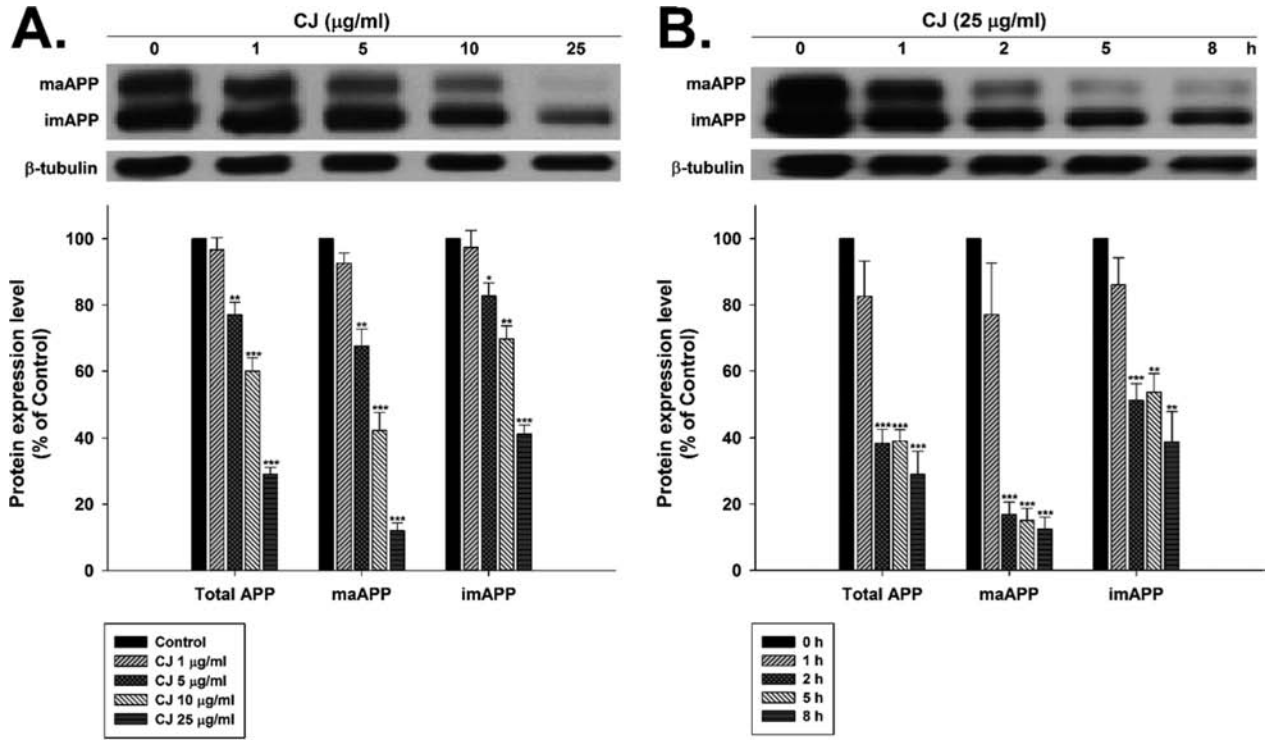

Figure 4. Effect of CJ extract on levels of mature and immature APP. (A) HeLa−APPsw cells were incubated for 8 h with 1, 5, 10, and 25 μg/mL CJ extract. A representative Western blot result showed that both maAPP and imAPP levels were significantly reduced by the CJ extract in a dose-dependent manner. (B) HeLa−APPsw cells were incubated with 25 μg/mL CJ extract for 1, 2, 5, and 8 h, respectively. A representative Western blot result showed that both maAPP and imAPP levels were significantly decreased in a time-dependent manner. The results were quantified and expressed as mean ± SEM (n = 5). (∗,∗∗,∗∗∗) Significantly different ($p < 0.05$, $p < 0.01$, $p < 0.001$) from the control group.

DOI: 10.1021/acs.jafc.5b00889
J. Agric. Food Chem. 2015, 63, 6979−6988

membrane.[8] We found that the level of the mature form of ADAM10 was slightly decreased by 15% with 25 μg/mL of CJ extract treatment (Figure 3A,D). Moreover, both precursor and active forms of ADAM17 were significantly decreased as shown in Figure 3A,E. Quantitative analysis showed that CJ extract at 25 μg/mL decreased precursor and active forms of ADAM17 by 54% and 33%, respectively. These data suggest that CJ extract did not affect the levels of BACE1 and ADAM9. Furthermore, CJ extract decreased ADAM10, which may underlie the constitutive α-secretase activity. However, the effect of CJ extract on ADAM10 is not large enough to fully account for the inhibitory effect of the extract on Aβ production.

CJ Extract Did Not Affect α- and β-Secretase Activities. Compared to the minimal effects of CJ extract on ADAM 9 and ADAM10, ADAM17 was significantly decreased by treatment with CJ extract (Figure 3E). To confirm if this reduction corresponded with changes in ADAM17 activity, we further investigated whether CJ extract would influence secretase activities. As a way to test the effect of CJ extract on α-secretase activity by ADAM17 in cell lysates, we utilized an ADAM17 activity assay kit. Briefly, an ADAM17-specific fluorogenic substrate was incubated in the presence of 1, 5, 10, and 25 μg/mL CJ extract, and then the quenched fluorescence substrate was measured. Using this approach, we found that CJ extract did not show any effect on ADAM17 activity (Supporting Information Figure S1). We also tested the effect of CJ extract on BACE1 activity in cell lysates using a BACE1 assay kit and found that CJ extract also did not show any effects on the BACE1-specific substrate (Supporting Information Figure S1). Both results are included as Figure S1 of the Supporting Information. These results show that CJ extract did not affect β- and α-secretase activity even though the extract slightly decreased ADAM10 and ADAM17 protein levels.

CJ Extract Decreased Levels of Both Mature and Immature APP. We observed that CJ extract decreased the levels of products generated by both β- and α-secretases while failing to change their activities. Therefore, we examined whether CJ extract affected the level of their common substrate, APP. APP undergoes N-glycosylation in the endoplasmic reticulum, where it is referred to as imAPP. This form of APP then transits to the Golgi apparatus, where it undergoes O-glycosylation to become maAPP. We measured the time-dependent effects of CJ extract on APP levels by incubating cells with 25 μg/mL of CJ extract for 1, 2, 5, and 8 h. A typical Western blot result shows that the levels of APP were decreased by CJ extract in a time-dependent manner. Quantitative analysis showed that after 2 h of treatment, CJ extract reduced the totalAPP, maAPP, and imAPP by 62%, 83%, and 49%, respectively (Figure 4A). We then measured the level of these APPs from cell lysates using Western blot analysis after cells were treated with 1, 5, 10, and 25 μg/mL of CJ extract for 8 h. By using this technique, we found that CJ extract decreased both maAPP and imAPP in a dose-dependent manner (Figure 4B). Moreover, the amount of maAPP was decreased by 32%, 58%, and 88% with 5, 10, and 25 μg/mL of CJ extract, respectively. However, imAPP levels were less sensitive to CJ extract when compared to those of maAPP. These results demonstrate that CJ extract may attenuate Aβ production via decreasing levels of both maAPP and imAPP.

CJ Extract Improved Performance in the Morris Water Maze Test. To confirm that the effect of CJ extract on Aβ reduction resulted in improvements in cognitive performance, we assessed the spatial memory of mice in the MWM. As shown in Figure 5A, the non-TG background mouse group

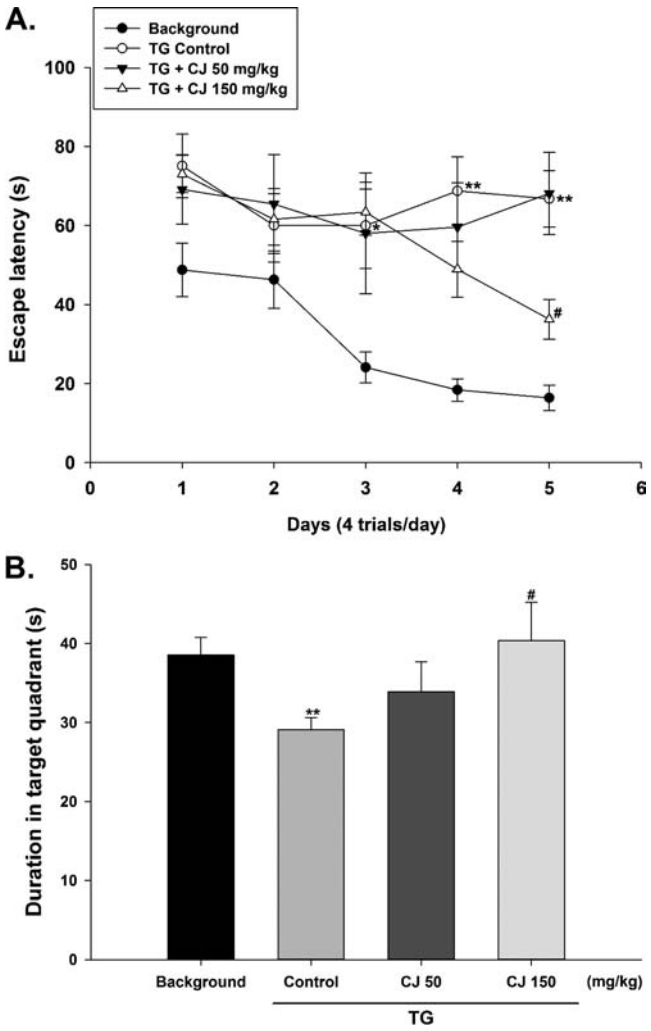

Figure 5. Effect of CJ extract on mouse performance in the Morris water maze test. CJ extract (50 or 150 mg/kg/day) or saline was administered orally to 5-month-old transgenic (TG) mice for 3 months and 1 h before the first trial of each acquisition day. The acquisition phase (A) consisted of five consecutive days in which each TG mouse underwent a total of four trials with a 1 h intertrial interval. During the acquisition phase, the amount of time taken for the mouse to find the hidden platform (escape latency) was measured. The retention phase (B) occurred the day immediately following the last day of the acquisition phase. During the retention phase, the platform was removed and the mice were allowed 120 s to explore the pool. The time spent in the target quadrant, which had contained the escape platform during the acquisition phase, was recorded. The data are shown as mean ± SEM (n = 7/group). (∗,∗∗) Significantly different ($p < 0.05$, $p < 0.01$) from the background group. (#) Significantly different ($p < 0.05$) from the TG control group.

showed a significant decrease in the escape latency from the first day (48.8 ± 6.8 s) to the fifth day (16.4 ± 3.2 s) of acquisition. In contrast, TG mice showed no progress in finding the escape platform from the first day (75.1 ± 8.0 s) to the fifth day (66.8 ± 7.2 s). Treating TG mice with the CJ extract (150 mg/kg) induced a significant improvement in learning, with the escape latency starting at 73.0 ± 4.7 s on the first day and progressing to 36.3 ± 5.0 s on the fifth day. Following the acquisition phase, we tested the retention of spatial memory on

DOI: 10.1021/acs.jafc.5b00889
J. Agric. Food Chem. 2015, 63, 6979−6988

the sixth day. As shown in Figure 5B, the time spent in the target quadrant, which had contained the escape platform, was significantly lower in the TG mouse group (29.1 ± 1.5 s) than the non-TG mouse group (38.5 ± 2.2 s). However, 150 mg/kg of CJ extract lead to a significant increase in the time mice spent in the target quadrant, increasing it to 40.4 ± 4.8 s. TG mice treated with 50 mg/kg of CJ extract also showed a trend toward spending more time in the target quadrant relative to the untreated TG mouse group.

CJ Extract Improved Object Memory Function in the Novel Object Recognition Test. In the NORT, non-TG mice spent over 80% of the total exploration time interacting with a novel object, whereas TG mice only spent 60% of their time with the same object. Both 50 and 150 mg/kg of CJ extract significantly increased the ratio of the time spent with the novel object, up to 79.2 ± 3.8 and 82.0 ± 4.5%, respectively (Figure 6). Taken together with the MWM test results, this

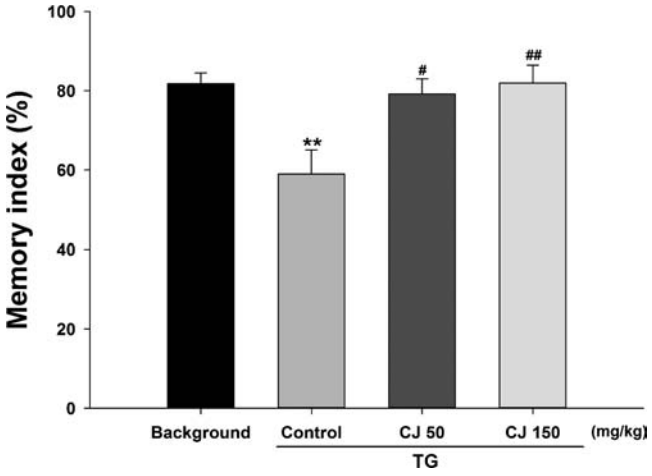

Figure 6. Effect of CJ extract on novel object recognition test. CJ extract (50 or 150 mg/kg/day) or saline was administered orally to 5-month-old transgenic (TG) mice for 3 months and 1 h before the acquisition phase test. During the acquisition phase test, mice were placed in a square-shaped arena and allowed to habituate to two identical objects for 10 min. On the following day, mice were placed in the same arena and and familiar object and one novel object were placed in the arena while the mice explored freely for 5 min. The total time spent exploring each object was measured and the memory index was calculated according to the following equation: Memory index (%) = (exploring time on novel object/total exploring time for both objects) × 100. The data represent the mean ± SEM (n = 7/group). (**) Significantly different (p < 0.01) from the background group. (#,##) Significantly different (p < 0.05, p < 0.01) from the TG control group.

suggests that the CJ extract significantly improved the cognitive performance of TG mice, which are a model for the major symptoms of AD in mice and humans.

CJ Extract Decreased Aβ42 Level in TG Mouse Brains. Aβ42 usually stays at undetectable levels in non-TG background mice. However, it is dramatically increased (up to 106.9 ± 9.7 pg/mL) in the cerebral cortex of TG mice. 150 mg/kg of CJ extract significantly reduced Aβ42, down to 81.0 ± 2.9 pg/mL. On the other hand, 50 mg/kg of CJ extract showed no change relative to the TG mouse group (Figure 7).

CJ Extract Reduced Aβ Plaques Detected by Immunohistochemistry. The extracellular accumulation of Aβ in the form of plaques is a pathological hallmark of AD. The

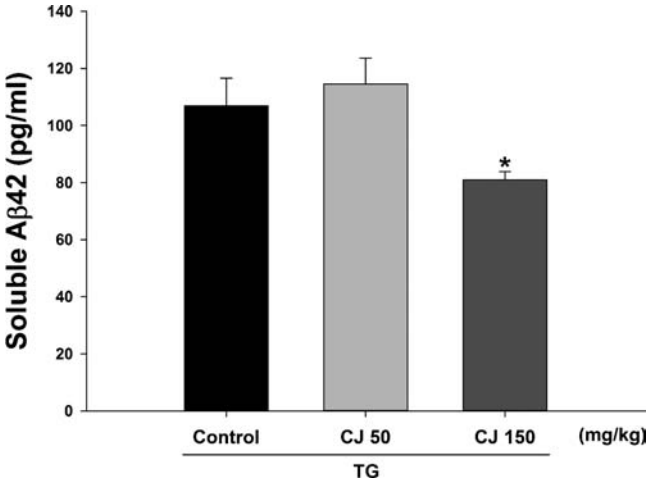

Figure 7. Effect of CJ extract on the level of soluble Aβ42 protein in mouse cerebral cortex. Transgenic (TG) mouse brain tissue was collected after behavioral tests at 9 months of age. The cerebral cortex samples (100 mg) were homogenized in Tris-buffered saline solution (20 mM Tris; 137 mM NaCl; pH 7.4) containing complete protease inhibitors tablets. The extraction ratio (brain tissue:Tris-buffered saline) was 1:5 or 1:10 (w/v). The tissue homogenates were centrifuged at 100000g for 1 h at 4 °C. The soluble Aβ42 level in the resulting supernatants was measured using the sandwich ELISA kit according to the manufacturer's protocol. The data represent the mean ± SEM (n = 4). * Significantly different (p < 0.05) from the TG control group.

amount of the plaque depends on the rates of its production, secretion, aggregation, and clearance.[29] We performed an immunohistochemical examination of TG and non-TG mouse brain sections and found that although non-TG mice did not exhibit significant Aβ plaques, TG mice showed significant accumulation of Aβ plaques in the cerebral cortex and hippocampal regions. Importantly, treatment with both 50 and 150 mg/kg of CJ extract for four months significantly reduced the amount of plaque in the cerebral cortex to 50.9 ± 4.5% and 44.9 ± 1.9%, and in the hippocampus to 64.8 ± 13.9% and 42.5 ± 9.2%, respectively (Figure 8). Taken together with the obvious enhancement of cognitive function, the decreased levels of Aβ42 and the changes in the amount of plaque in mouse brains clearly demonstrates that CJ extract has beneficial effects on the pathology and symptoms of these mouse models of AD.

Isolation and Analysis of Active Compounds. With its profound effect on both in vitro and in vivo AD models, we decided to determine which active components account for the effects of the CJ extract. To accomplish this, hydroethanolic extracts of CJ bulbs were further partitioned with n-hexane, CH_2Cl_2, and n-BuOH successively, then each organic soluble fraction was obtained as 1, 1, and 5.5 g, respectively. Flash column chromatography of the n-BuOH soluble fraction resulted in eight subfractions [CJ-3-F1−8]. 7-Deoxynarciclasine (40 mg) and 7-deoxy-*trans*-dihydronarciclasine (10 mg) were yielded from fraction CJ-3-F4. Narciclasine (80 mg) was isolated from another fraction, CJ-3-F6, by reversed-phase chromatography. The structures of the isolated compounds were confirmed by comparing previously reported spectral data.[30,31] To confirm the composition of the three active components in the CJ extract, a 50% EtOH extract of CJ (20 mg) was analyzed using HPLC. The results of this analysis are included as Figure S2 of the Supporting Information.

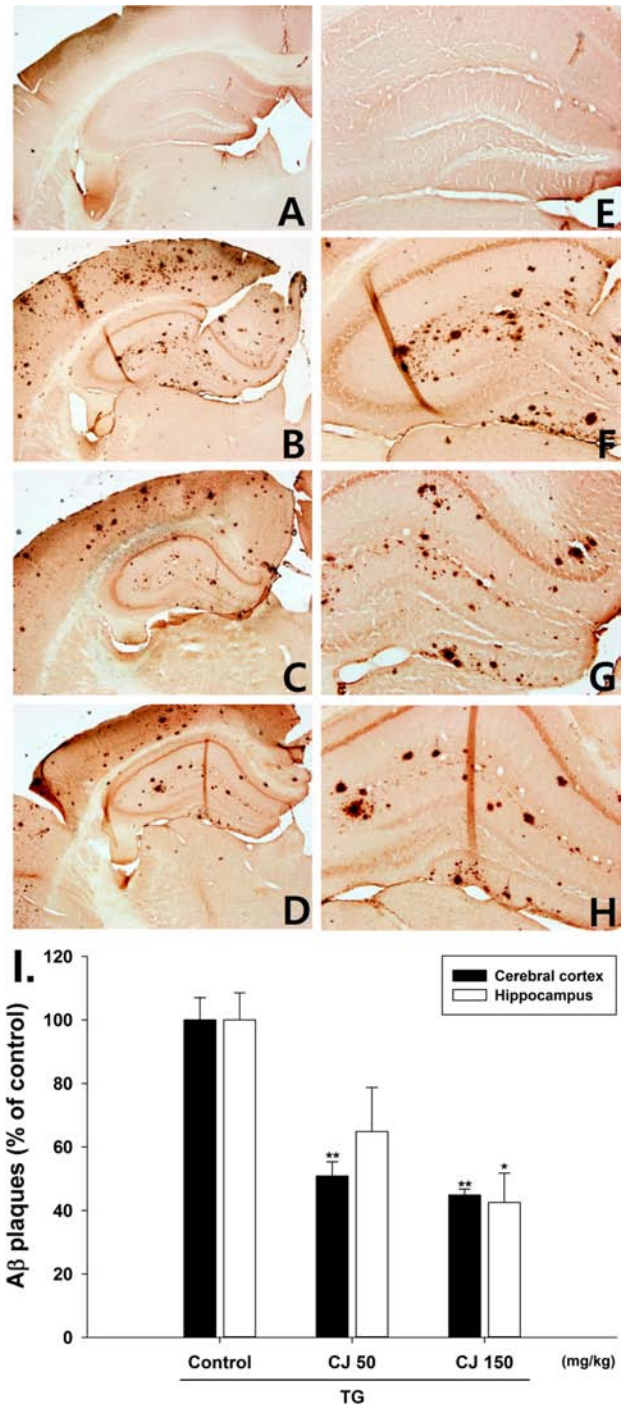

Figure 8. Effect of CJ extract on plaque deposition in the brains of transgenic mice. Mouse brain tissue was collected after behavioral tests at 9 months of age. Representative photomicrographs show the results of anti-Aβ antibody (4G8) staining in the cerebral cortex (A–D) and hippocampus (E–H) of mice from background group (A,E), transgenic (TG) control group (B,F), and TG mice treated with the CJ extract at 50 (C,G) and 150 (D,H) mg/kg. The numbers of Aβ plaques in each slice were counted and compared with the TG control group (I). The data represent the mean ± SEM (n = 3). (*,**) Significantly different (p < 0.05, p < 0.01) from the TG control group.

Active Compounds from CJ Extract Also Decreased Levels of Aβ40 and Aβ42 in Cells. Isolated narciclasine, 7-deoxynarciclasine, and 7-deoxy-*trans*-dihydronarciclasine were used to treat APPsw-transfected HeLa cells at various concentrations for 8 h. The levels of Aβ40 and Aβ42 in the conditioned media were determined using specific ELISA kits (Figure 9). Levels of both Aβ40 and Aβ42 were significantly decreased by all three active compounds in a dose-dependent manner without any cytotoxicity. Among them, 7-deoxynarci-

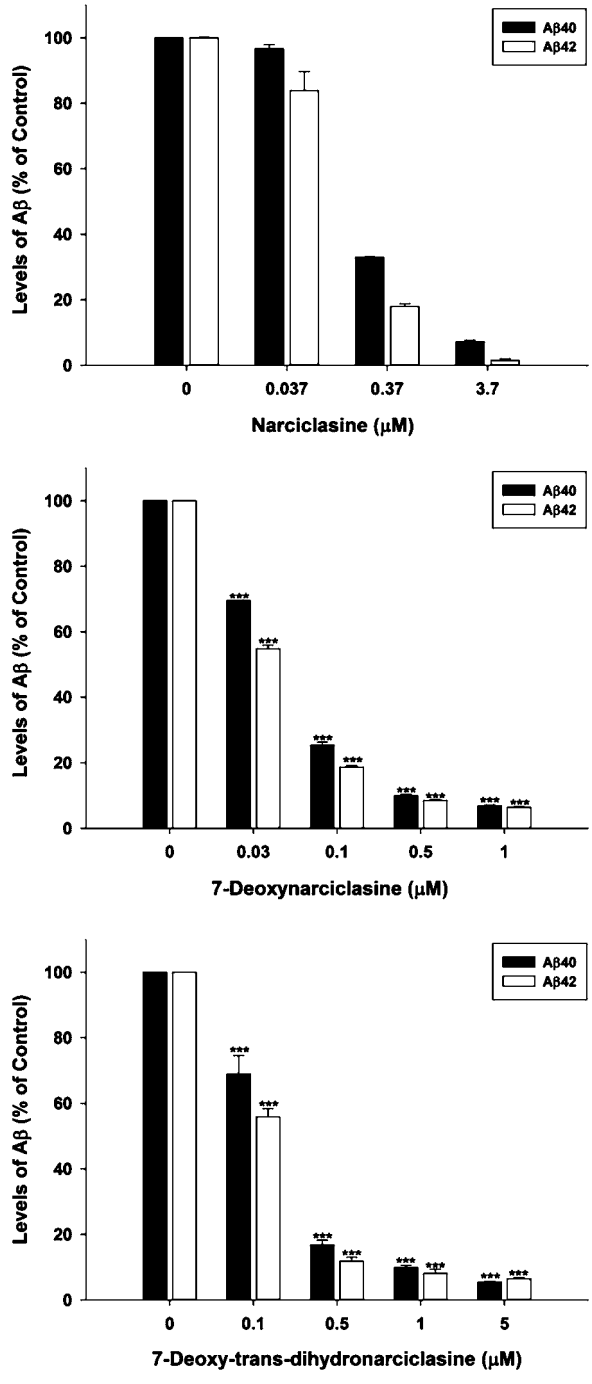

Figure 9. Effect of the three active compounds from CJ on Aβ40 and Aβ42 secretions in cells. HeLa–APPsw cells were incubated with the indicated concentrations of narciclasine, 7-deoxynarciclasine, and 7-deoxy-*trans*-narciclasine, the three active compounds from CJ, for 8 h. The culture media were collected and analyzed for Aβ levels by using sandwich ELISA. Both forms of Aβ levels were significantly decreased by three of the active components from CJ (n = 6). The results were quantified and expressed as mean ± SEM. *** Significantly different (p < 0.001) from the control group.

DOI: 10.1021/acs.jafc.5b00889
J. Agric. Food Chem. 2015, 63, 6979–6988

clasine and 7-deoxy-*trans*-dihydronarciclasine showed stronger Aβ reduction at lower concentrations. As such, the inhibitory effect of CJ extract on Aβ production is most likely due to these three compounds.

The effect of CJ on the reduction of APP levels is very interesting. This extract preferentially decreased maAPP over imAPP, which in turn induced a reduction of Aβ levels. We propose that CJ may delay the exit of imAPP from the ER and thereby decrease transport to the Golgi apparatus. This would lead to attenuation of maAPP formation. This reduction of APP maturation could impair APP trafficking to the plasma membrane and disrupt its cleavage by α-secretase.[5,6] Our data showed that CJ significantly reduced both sAPPα and CTFα levels. Once mature APP reaches the plasma membrane, it can undergo clathrin-dependent endocytosis. APP can also be cleaved by β-secretase in the early endosome.[32−35] Therefore, CJ may also affect the endocytosis of APP from the plasma membrane, which can explain the decreased levels of sAPPβ and CTFβ and subsequently the levels of Aβ40 and Aβ42. CJ extract also decreased the production of Aβ42 as well as the number of Aβ plaques in the brains of TG mice. Treatment with CJ extract recovered cognitive dysfunction observed in the MWM and NORT, consistent with decreases in Aβ42 and the number of plaques in the cerebral cortex and hippocampus. Such modulatory functions have not been previously reported in natural products. As such, this extract could prove beneficial as a treatment for AD. Moreover, CJ would not produce the various side effects that come from interfering with secretase activities.

In conclusion, we found a novel function of CJ that decreases Aβ levels via the attenuation of APP. This showed beneficial effects on cognitive function and plaque formation in animal models of AD. We also revealed that the active components of CJ extract were narciclasine, 7-deoxynarciclasine, and 7-deoxy-*trans*-dihydronarciclasine. Further study on these three active components should be conducted in vivo to elucidate the specific action of their mechanisms toward the goal of treating patients with AD, and additional research using human islet amyloid polypeptides may contribute to better understanding in interactions with Aβ proteins.[36]

scavenging free radicals, antioxidation, and antilipid peroxidation.[15] In vivo and in vitro studies have demonstrated that intestinal lipid absorption, chylomicron secretion by the intestine, and very low-density lipoprotein secretion by the liver are the processes that are most repressed by procyanidins, thus inducing hypolipidemia.[16] Furthermore, Zou reported that high molecular weight persimmon tannin was a pivotal constituent of persimmon fruit accounting for prevention of liver steatosis and its progression to NASH by activation of the AMP-activated protein kinase (AMPK) and regulation of its downstream targets, suppressing NF-κB activation, and inhibiting lipid and bile acid absorption.[17] However, there is no literature about the effect of procyanidins on NAFLD from an AGEs/RAGE perspective. In our previous studies, we have shown that LSOPC could inhibit AGE formation effectively in a simulated physiological environment and the underlying mechanism is to scavenge reactive carbonyls by forming adducts with them.[18] Therefore, we presumed that AGEs/RAGE might also be a central target for the antihyperlipidemic effect of LSOPC.

Therefore, the purpose of this study is to evaluate the protective potential of LSOPC against the development of NAFLD in a rat model of long-term HFD-induced obesity. We further identify the underlying molecular mechanisms involved in AGEs/RAGE expression and MAPK or NF-κB signaling pathways. This study provides possibilities for new applications of LSOPC as functional food ingredients.

MATERIALS AND METHODS

Chemicals. Mature lotus seedpods of *N. nucifera* Gaertn. (cv.: Number 2 Wuhan plant) were harvested from Honghu District (113°7′−114°5′ E, 29°39′−30°2′ N) in Hubei province, China, in late July 2012, and arrived in the laboratory within 24 h postharvest; they were kept at −20 °C prior to extraction. Lotus seedpod was identified by Prof. Xueming Ni from the Department of Botany, Wuhan Plant Institute of the Chinese Academy of Science.

Rabbit polyclonal antibodies against p38 MAPK (catalog no. 8690) and phospho-p38 MAPK (catalog no. 4631) were purchased from Cell Signaling Technology (Beverly, MA, USA). Rabbit polyclonal antibodies against p65 NF-κB (catalog no. ab72555) were purchased from Abcam Inc. (Hongkong, China). Commercial kits for determination of the total antioxidant capacity (T-AOC), nitrogen monoxide (NO), superoxide dismutase (SOD), malonaldehyde (MDA), glutathione reductase (GRAC), glutathione (GSH), cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), triglyceride (TG), aspartate aminotransferase (AST), alanine aminotransferase (ALT), and alkaline phosphatase (ALP) were purchased from Nianjing Jiancheng Bioengineering Institute (Nanjing, China). The enzyme-linked immunosorbent assay (ELISA) kits for measuring reactive oxygen species (ROS), free fatty acids (FFA), AGEs, and N^{ϵ}-(carboxymethyl)lysine (CML) were purchased from Cloud-Clone Corp. (Houston, TX, USA). All solvents and reagents were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China) and were of analytical grade.

Preparation of LSOPC. Fresh lotus seedpod fragments were extracted using 70% ethanol at 60 °C for 1.5 h. The crude procyanidin aqueous solution was loaded onto an AB-8 resin (weak polarity macroporous resin, 0.3−1.25 mm particle size, Nankai Hecheng Science & Technology Co., Tianjin, China) column (15 × 3.5 cm, i.d.), and the fraction eluted by 70% ethanol was collected. The eluent was evaporated, and the procyanidin extract of lotus seedpod was obtained. Subsequently, they were extracted by ethyl acetate to get LSOPC.

Ethics Statement. All experimental procedures involving animals followed the Guiding Principles in the Care and Use of Animals and were approved by the ethics committee of Reference Laboratory for the test of Veterinary Drug Residues of Huazhong Agricultural University (SYXK 2007-0044), Hubei Province, China. We made all efforts to minimize suffering, and the animals were killed by cervical dislocation under anesthesia.

Experimental Animals and Diets. Sprague−Dawley (SD) male rats (n = 40) were obtained at 6 weeks of age from the Animal Committee of Wuhan University (Wuhan, China). For adaptation, the rats were kept in a controlled environment at 23 °C and 55% relative humidity under a 12 h dark−light cycle, with free access to a pelleted diet (Tongji Medical College, Wuhan, China) and deionized water for 1 week. The experiment was performed in accordance with the *Guide for the Care and Use of Laboratory Animals*, prepared by the U.S. National Institute of Health (1996).

The SD rats weighing 180 ± 15 g were randomly divided into four groups (n = 10) and given different dietary supplements. Group 1 (C group) rats were fed the basic diet (20.34% protein, 4.14% fat, 50.75% carbohydrates; 12% calories from fat); group 2 (H group) rats were fed a high-fat diet (HFD) (16.60% protein, 17.50% fat (mainly from lard, cholesterol, and egg yolk powder), 47.45% carbohydrates; 38% calories from fat); group 3 (HD group) rats were fed the HFD plus 0.5% of LSOPC; group 4 (LD group) rats were fed the HFD plus 0.2% of LSOPC. Doses of LSOPC was referred to previous studies.[17,19,20] Rats were given free access to food and water during the experimental period. Food consumption and body weight were recorded daily and weekly. The experiment was terminated after 12 weeks. Before death, all animals were fasted for 14 h, blood samples were collected from the hepatic portal vein, and integral liver, epididymal, and retroperitoneal white adipose tissues were collected and weighed when dissected.

Histological Examination of the Liver. Small portions of the liver were immediately fixed with 10% formalin in water at the time of killing, dehydrated gradually in a graded series of ethanol, and then clarified in xylene and embedded in paraffin wax. The morphology of the liver was observed with the method of hematoxylin and eosin staining by using a Nikon Eclipse 80i advanced research microscope (Tokyo, Japan).

Blood Analysis. The serum levels of AST, ALT, TC, TG, and HDL-C were determined by enzymatic colorimetric methods using commercial kits ((Jiancheng, Nanjing, China). LDL was calculated by using the formula of Friedewald et al.[21] The serum free fatty acid (FFA) was measured using an ELISA kit (Houston, TX, USA).

Determination of Antioxidant Profiles and Lipid Peroxidation in Serum and Liver. The liver tissues were homogenized in cold saline (1 g of tissue in 9 mL of normal saline) and then centrifuged at 8000g for 10 min, and the supernatants were collected and stored at −20 °C before analysis. Protein concentrations were determined by Coomassie blue protein binding method using bovine serum albumin (BSA) as a standard.[22] All parameters were determined using the respective kits according to the manufacturer's specifications.

Western Blot Analysis. Each liver (500 mg) was homogenized in a lysis buffer (5 mL, 20 mM Tris-HCl, pH 7.4, 150 mM NaCl, 1% Triton X-100, 0.1% SDS, 1 mM EDTA, 1 mM EGTA, 2.5 mM sodium pyrophosphate, 1 mM sodium orthovanadate, 1 mM β-glycerolphosphate, 2 μg/mL leupeptin, 2 μg/mL aprotinin, 2 μg/mL pepstatin, and 1 mM PMSF) and kept for 30 min on ice. After centrifugation at 12000g for 15 min at 4 °C, the supernatants were used for Western blotting. Nuclear extracts from liver were isolated using a separate nuclear extraction kit (Beyotime, Shanghai, China), and the extracts were used for determining p65NFκB, p38MAPK, and p-p38MAPK levels by Western blotting. Protein concentrations were determined by BCA protein assay kit (Jiancheng, Nanjing, China). For Western blotting, 40 mg of protein was separated by 7.5% (FAS, the marker molecular weight from 10 to 250 kDa) or 10% (the marker molecular weight from 14 to 120 kDa) SDS−polyacrylamide gel electrophoresis (SDS-PAGE) in 25 mM Tris buffer, containing 250 mM glycine and 0.1% SDS and then electrotransferred to polyvinylidene difluoride (PVDF) membranes (Millipore, Bedford, MA, USA) in 25 mM Tris buffer, containing 192 mM glycine and 20% methanol. The membranes were blocked with 5% nonfat dry milk in TBST (50 mM Tris-HCl, pH 7.4, 150 mM NaCl, and 0.1% Tween 20) for 1 h at room temperature and incubated overnight at 4 °C with primary

[a]Results are means ± SD from 10 rats per group. C, normal control group; H, HFD group; HD, HFD plus 0.5% (w/w) LSOPC group; LD, HFD plus 0.2% (w/w) LSOPC group. Liver coefficient = liver weight/body weight × 100. (*) $p < 0.05$ versus C group; (#) $p < 0.05$ versus H group.

antibodies in TBST (p65NFκB, 1:800; p38MAPK, 1:800; p-p38MAPK, 1:800; β-actin, 1:800), followed by incubation with horseradish peroxidase-conjugated secondary antibodies (1:3000) for 45 min at room temperature. Immunoreactive bands were visualized by the enhanced chemiluminescent reagents (Beyotime). The intensity of bands was quantified using Image Lab software (Bio-Rad). The band density were normalized to β-actin.

Quantitative Real-Time PCR. Total RNA was isolated from liver using Trizol reagent (Invitrogen, Carlsbad, CA, USA). Reverse transcription was performed with a first-strand cDNA synthesis kit (Toyobo, Osaka, 21 Japan). After cDNA synthesis, quantitative real-time PCR was performed on a SLAN PCR system (Hongshi, Shanghai, China) using SYBR Green PCR Master Mix (Toyobo) according to the manufacturer's instructions. The reverse transcription consisted of an initial denaturation at 94 °C for 4 min, followed by 30 cycles of amplification by denaturation at 94 °C for 30 s, annealing at 56 °C for 30 s, and extension at 72 °C for 25 s. Primers were designed according to the GenBank database using Primer Express software (Table 4). Expression of mRNA values was calculated using the threshold cycle (C_T) value. For each sample, the $\Delta C_{T,sample}$ value was determined by calculating the difference between the C_T value of the target gene and the C_T value of the β-actin reference gene. The expression levels relative to control were estimated by calculating $\Delta\Delta C_T$($\Delta C_{T,sample} - \Delta C_{T,control}$) and subsequently using the $2^{-\Delta\Delta CT}$method.[23]

Measurement of AGE, CML, and RAGE Levels. Liver AGEs and CML were determined using the ELISA kits (Cloud-Clone Corp.) according to the manufacturer's instructions. The expression level of RAGE was measured using quantitative RT-PCR according to the method above.

Statistical Analyses. All statistical analyses were performed using Origin software 8.0. All data were presented as means ± standard deviation (SD) and calculated using one-way ANOVA of SPSS 17.0 followed by the Tukey's multiple-range test. The statistical significance was defined as $p < 0.05$ or $p < 0.01$.

RESULTS

Analysis of LSOPC. Using the butanol–HCl assay, we found that LSOPC was rich in procyanidins. The procyanidin content of LSOPC was 106.22 ± 0.46% compared with grape seed procyanidins, which was used as a standard product with purity >95%. Our laboratory has identified the structural information about procyanidins in the lotus seedpod previously.[24] The mean degree of polymerization of LSOPC was 3.2. The terminal units in LSOPC contained 74% catechin units and 26% epicatechin units. The extension units in LSOPC contained 26% catechin units, 43% epicatechin units, and 31% epigallocatechin. Figure 1A is the HPLC chromatogram of LSOPC. Peaks 1, 2, and 3 exhibited maximum absorption at 279 nm and corresponded to extracted ion current chromatogram (EIC) peaks of m/z 577, 289, and 865, suggesting that peaks 1, 2, and 3 were probably procyanidin dimer, monomer (i.e., catechin or epicatechin), and trimer, respectively. By coelution with procyanidins B1, B2, and B3, peak 1 was confirmed as procyanidin B3. From its ESI-MS spectrum (Figure 1B) injected by a syringe pump, the compounds in LSOPC could be tentatively identified according to their m/z ratios as follows: catechin or epicatechin (m/z 289), gallocatechin or epigallocatechin (m/z 305), quercetin glycoside (m/z 463), quercetin glucuronide (m/z 477), procyanidin dimers (m/z 577.1), proanthocyanidin dimer gallate (m/z 593.3), prodelphinidin dimers (m/z 609.1), procyanidin trimers (m/z 865.1), proanthocyanidin trimers with one gallocatechin or epigallocatechin unit and two catechin units (m/z 881.4), proanthocyanidin trimers with two gallocatechin or epigallocatechin units and one catechin or epicatechin unit (m/z 897.3), and procyanidin tetramers (m/z 1153.1). Thus, LSOPC

consisted of proanthocyanidin monomers, dimers, trimers, and tetramers.

Establishment of NAFLD Model Rats. After 12 weeks of HFD, the body weight and liver coefficient of NAFLD model rats (including groups H, HD, and LD) were significantly increased (Table 1), which proved that the establishment of the obesity rat model was successful according to the assessment of the study.[25] Furthermore, tissues from rats were also subjected to histopathologic examination, which proved that an excess of high-fat intake induced a significantly high degree of steatosis and inflammatory cell infiltration, accompanied by an apparent accumulation of fat in comparison with normal rats, matching the symptom of NAFLD (Figure 2). Taken together, this indicated that the establishment of the NAFLD model was successful. Meanwhile, fat deposition appeared to be inhibited in the livers of LSOPC groups, although some fat vacuoles were evident. Inflammatory cell infiltration was also alleviated in the livers from rats fed LSOPC compared with the animals in the H group (Figure 2). These results indicated that LSOPC may be an effective compound to inhibit hepatic steatosis.

Effect of LSOPC on Serum Lipid Profiles and Serum AST, ALT, and ALP Activities. The serum lipids and enzyme activities of AST, ALT and ALP are shown in Table 2. It was indicated that a HFD induced a significant increase in serum TC, TG, and FFA levels, accompanied by a notable decrease in the HDL-C level in comparison with normal rats ($p < 0.01$). Administration of 0.2 or 0.5% (w/w) LSOPC reduced serum level of TG in HFD-fed rats by 50.71 and 42.14%, respectively, compared to the animals in the H group. In addition, treatment with LSOPC also significantly decreased ($p < 0.01$) the serum TC and FFA contents and markedly elevated ($p < 0.01$) the level of serum HDL-C by 45.35 and 40.70%, separately, compared to the H group.

Moreover, after 12 weeks of HFD, the serum levels of AST, ALT, and ALP significantly increased by 1.6-, 1.9-, and 1.8-fold, respectively. As compared to the H group, supplementation of 0.2 or 0.5% (w/w) LSOPC resulted in the reduction of AST, ALT, and ALP notably ($p < 0.01$) by 11.23% (22.87%), 21.22% (20.38%), and 20.94% (6.59%), respectively.

Effect of LSOPC on Serum and Hepatic Oxidative Stress. Malondialdehyde (MDA) is a reactive aldehyde formed during lipid peroxidation. As shown in Table 3, the serum MDA levels in rats fed a normal diet and HFD were 3.77 and 4.33 nmol/mg protein, respectively. The serum MDA levels in rats fed HFD containing 0.2 or 0.5% (w/w) LSOPC were 3.80 and 4.04 nmol/mg protein, respectively, indicating that lipid peroxidation was attenuated by LSOPC treatment. The serum GRAC level in HFD-treated rats was increased by 54.58% compared to that of the control group, whereas treatment with 0.2 or 0.5% (w/w) LSOPC resulted in decreases in serum GRAC level by 35.26 and 40.64%, respectively. Similarly, LSOPC supplementation decreased the serum NO level significantly compared to the H group. In addition, 12 weeks of HFD feeding was accompanied by 12.12−29.25% inhibition of serum T-AOC, SOD, and GSH-PX activities compared to rats in the control group. The effect of HFD on the activities of these antioxidant enzymes was dose-dependently reversed by administration of LSOPC. Additionally, LSOPC significantly reversed HFD-induced hepatic ROS level after 12 weeks of treatment. Meanwhile, a quantitative real-time RT-PCR analysis showed the expression of NADPH and COX significantly decreased by treatment with LSOPC (Figure 5). Other hepatic parameters of oxidative stress were similar to those observed in serum.

Effect of LSOPC on Hepatic AGEs Production and RAGE Expression. AGEs are known to accumulate in diabetic subjects and may be important mediators of untoward effects of NAFLD.[26] CML is reportedly a major component of AGEs.[27] Therefore, we investigated the expression of AGEs and CML by ELISA. The results showed that AGEs and CML were significantly elevated in HFD-fed rats compared with the normal control rats. Treatment of rats with 0.2 or 5% (w/w) LSOPC in the diet for 12 weeks resulted in lowering of these elevated levels (Figure 3A,B).

Given that AGEs exert inflammatory and oxidative stress inducing NAFLD mainly through the receptor RAGE,[28] we examined the mRNA expression of RAGE in the livers by RT-PCR. The mRNA level of RAGE was markedly elevated by 4.5-fold in HFD-fed rats compared with the animals in the normal control group (Figure 3C). However, 0.5% (w/w) LSOPC treatment remarkably ($p < 0.01$) reversed the increasing tendency to normal level.

Effect of LSOPC on Hepatic p38MAPK, p-p38MAPK, and p65NF-κB Expression. We further examined the effects

J. Agric. Food Chem. 2015, 63, 6989−6998

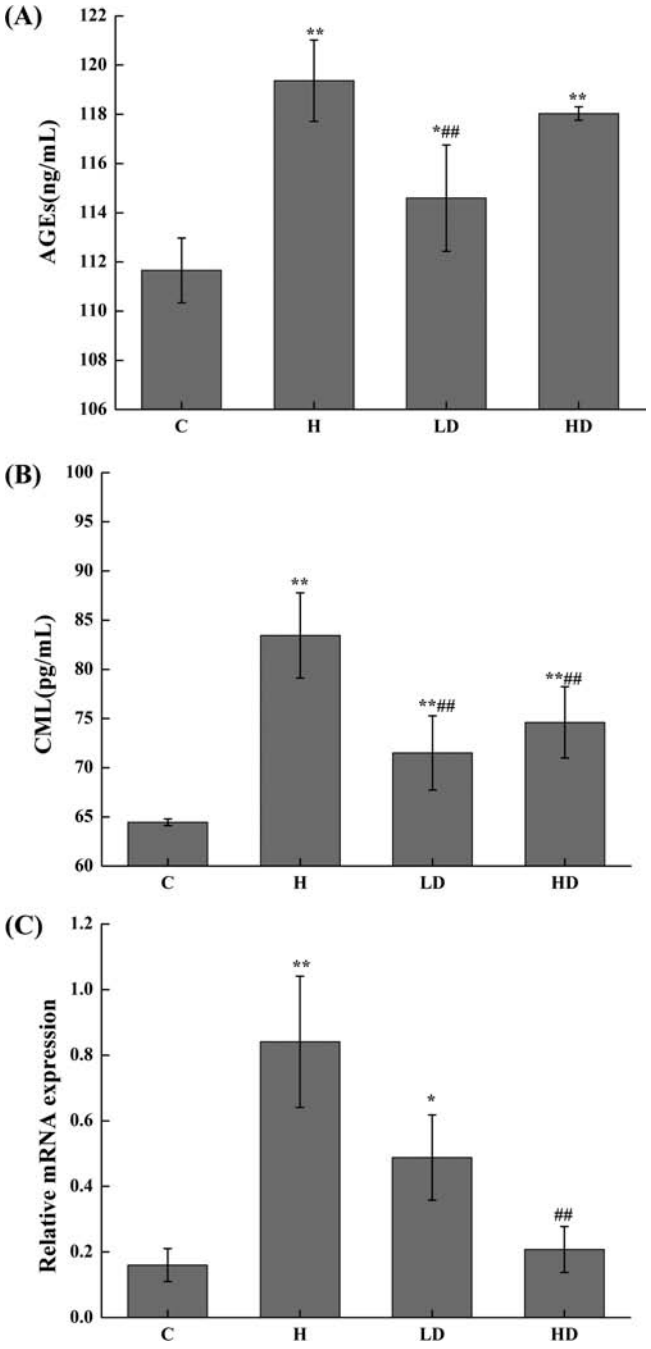

Figure 3. LSOPC prevented accumulation of AGEs and CML and led to a decreased RAGE level in liver: (A) detection of the liver AGEs level by ELISA; (B) detection of the liver CML level by ELISA (both AGEs and CML levels were normalized to total protein concentration in the tissue sample, $n = 5$ rats per group); (C) expression of RAGE by RT-PCR in liver. Results are means ± SD. C, normal control group; H, HFD group; HD, HFD plus 0.5% (w/w) LSOPC group; LD, HFD plus 0.2% (w/w) LSOPC group. (*) $p < 0.05$; (**) $p < 0.01$ versus C group; (#)$p < 0.05$; (##) $p < 0.01$ versus H group.

of LSOPC administration on several representative hepatic protein expressions related to lipid metabolism and oxidative stress modulation by Western blotting. As shown in Figure 4, expression levels of p38MAPK, p-p38MAPK, and p65NF-κB in HFD-fed rats were 4.7-, 6.7-, and 1.9-fold higher than that in the control group, respectively. When compared to those of the rats in the HFD-fed group, the levels of p38MAPK, p-p38MAPK, and p65NF-κB were significantly down-regulated by LSOPC treatments in a dose-related manner. The relative density values of the bands were normalized with that of β-actin and are presented in panels A and B of Figure 4, respectively.

Effects of LSOPC on Hepatic Injury and Inflammation. Both pro-inflammatory cytokines and adhesion molecules play an important role in the pathogenesis of NAFLD.[29] We finally measured the effects of LSOPC administration on several representative genes involved in hepatic inflammation in the livers of the rats. As a result of HFD, the liver levels of tumor necrosis factor-α (TNF-α), interleukin 1 (IL-1), IL-6, IL-8, intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), monocyte chemoattractant protein-1 (MCP-1), and E-selectin were significantly elevated, indicating a considerable level of inflammation compared with the normal control rats. Administration of 0.2 or 5% (w/w) LSOPC in the diet for 12 weeks resulted in a notably and dose-dependent reduction of these elevated levels. This reduction is shown in Figure 5.

DISCUSSION

NAFLD is emerging as one of the most common causes of chronic liver disease, and obesity is intimately related to chronic metabolic disorders. Rodent animal models of NAFLD induced by HFD, which shows the characteristics of metabolic disorders such as hyperlipidemia, obesity, inflammation, and oxidative stress, have been widely used due to its similar pathogenesis in humans.[30] In the present study, we fed male SD rats a HFD for 12 weeks and found that serum levels of TC, TG, LDL-C, AST, ALT, and ALP and liver weight significantly increased. In addition, moderate levels of oxidative stress and inflammation were induced. These results suggested that long-term consumption of a HFD by rat caused typical NAFLD, with clinical characteristics similar to those observed in NAFLD patients. This model could help elucidate the alterations seen in target organs and the molecular mechanisms underlying the development of NAFLD.

Traditional medicine and medicinal plants in most developing countries used as normative basis for the maintenance of good health have been widely studied.[31] In recent years, dietary plants with antioxidative property have been the center of focus. It is believed that these plants could prevent or protect tissues against the damage of free radicals.[32] Moreover, a number of plant-derived products have been shown to possess good capacities to adjust sugar and lipid metabolism.[33] LSOPC, which comprises natural plant polyphenols, was reported to have a broad spectrum of pharmacological and therapeutic properties against oxidative stress.[34,35] Therefore, we hypothesized that LSOPC was responsible for the protecting effect against NAFLD.

There has been major interest in the pathogenic effects of AGEs in a range of diseases, including, most importantly, diabetes, but also atherosclerosis and chronic renal disease. In addition to increasing during normal aging, AGEs are known to be elevated in the serum and accumulated in various tissues at an accelerated rate in NAFLD patients. Furthermore, accumulating evidence suggests that the binding of AGEs with their receptor (RAGE) results in generation of ROS from activated NADPH oxidase.[36] This culminates in the activation of p38MAPK and translocation of the NF-κB p65 submit into the nucleus, leading to the transcription of growth factors, inflammatory cytokines, chemokines, and adhesion molecules.[37,38] The promoter region of the RAGE gene contains

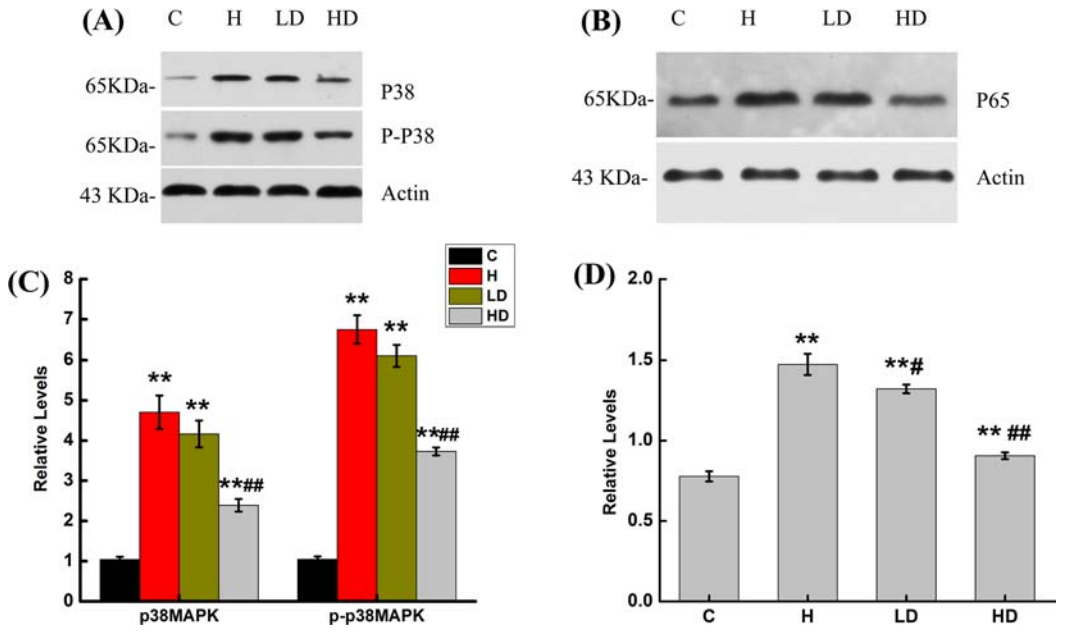

Figure 4. Protein level of NFκB, p38MAPK, and p-p38MAPK in liver of rats fed a HFD with/without high dose of LSOPC or low dose of LSOPC. The total protein extracts of 10 rats in the same group were combined. Equal amounts of liver protein extracts of each group (40 μg) were separated by 10% SDS-PAGE. Results are means ± SD. A representative blot from three independent experiments is shown. C, normal control group; H, HFD group; HD, HFD plus 0.5% (w/w) LSOPC group; LD, HFD plus 0.2% (w/w) LSOPC group. (**) $p < 0.01$ versus C group; (##)$p < 0.01$ versus H group.

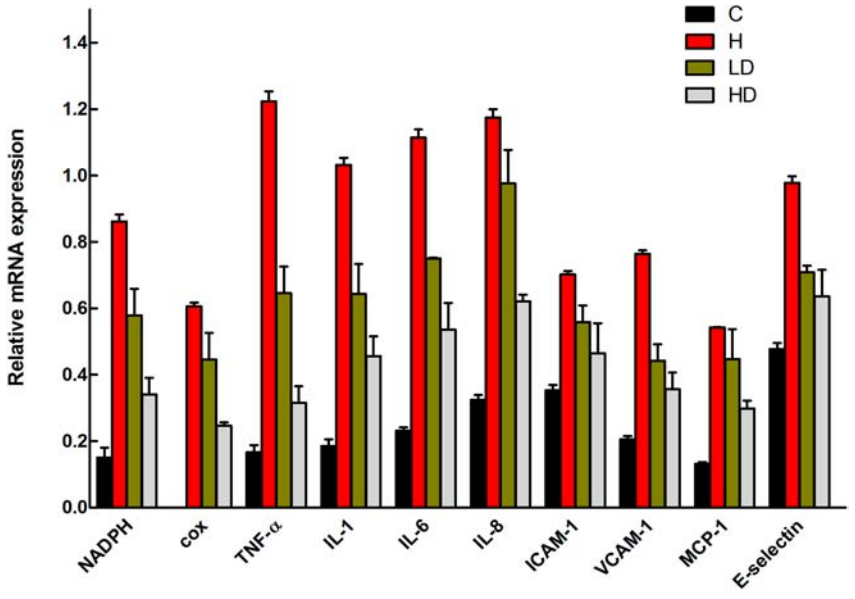

Figure 5. Gene expressions of lipid metabolism in liver of rats fed a HFD with/without LSOPC. Results are means ± SD. C, normal control group; H, HFD diet group; HD, HFD plus 0.5% (w/w) LSOPC group; LD, HFD plus 0.2% (w/w) LSOPC group. All $p < 0.01$ versus C group; all $p < 0.01$ versus H group.

an NF-κB binding site and, therefore, one of the important consequences of NF-κB activation and translocation is up-regulation of RAGE itself. This sets up a positive feedback loop and ensures maintenance of RAGE signaling. On the other hand, the generation of ROS via NADPH oxidase triggered by RAGE activation causes increased AGE formation and contributes to a vicious cycle of AGE formation, generation of oxidative stress, and further RAGE activation.[39,40] Our results demonstrate that administration of LSOPC reduced the hepatic ROS, NADPH overproduction and associated AGEs, and CML expression, which were in accordance with our previous studies in vitro.[18] Additionally, 0.5% (w/w) LSOPC treatment remarkably reversed the increasing tendency of RAGE to a normal level. Moreover, the protein expressions of hepatic p38MAPK and p65 NF-κB were significantly decreased dose-dependently by LSOPC treatment in HFD-fed rats. Thus, it was suggested that part of the beneficial effects of LSOPC included the disruption of the detrimental RAGE−MAPK−NF-κB pathways.

The two-hit hypothesis of NASH pathogenesis suggests that a second injury or cofactor is required for progression from simple benign steatosis to harmful steatohepatitis, which can

DOI: 10.1021/acs.jafc.5b01082
J. Agric. Food Chem. 2015, 63, 6989−6998

subsequently lead to fibrosis, cirrhosis, and hepatocellular carcinoma. There has been considerable interest in factors that could serve as this "second hit". Oxidative stress and the inflammatory response have emerged as important mechanisms involved in the development and progression of NAFLD.[41] Superoxide dismutase (SOD) is an important antioxidant enzyme and the primary means of free radical scavenging in organisms.[42] MDA is the advanced lipoxidation end product of the peroxidation reaction, which results from the action of free radicals on lipids.[43] The amount of hepatic MDA can indirectly reflect the degree of cell damage. The combination of SOD and MDA is usually used to evaluate the oxidative stress level in liver. Our results showed that administration of LSOPC remarkably decreased the serum and hepatic MDA and increased SOD compared to the H group in long-term HFD-fed rats.

Disorders of lipid metabolism also played a central role in the initiation and progression of NAFLD. When NAFLD occurs, excess FFA in the liver cells lead to the development of lipid peroxidation and the generation of a large number of ROS, which are the major indicators of oxidative stress.[40] Consequently, ROS prompted the generation of pro-inflammatory cytokines and adhesion molecules. Sustained inflammatory infiltrate upon chronic hepatocellular damage further induces the development of NASH.[44] In this study, LSOPC supplementation dose-dependently decreased the levels of pro-inflammatory cytokines (TNF-α, IL-1, IL-6, IL-8) and adhesion molecules (ICAM-1, VCAM-1, MCP-1, E-selectin) in the liver in long-term HFD-induced NAFLD. Although our results could not exclude the possibility that LSOPC directly suppress the activation of NF-κB and the expression of pro-inflammatory factors via its antioxidative effects, LSOPC inhibited the progression of NAFLD in HFD rats, at least partly, by suppressing the activation RAGE axis and subsequently decreasing adhesion molecule-induced monocyte/macrophage infiltration in the damaged endothelial cells; the proposed inhibition pathway is shown in Figure 6.

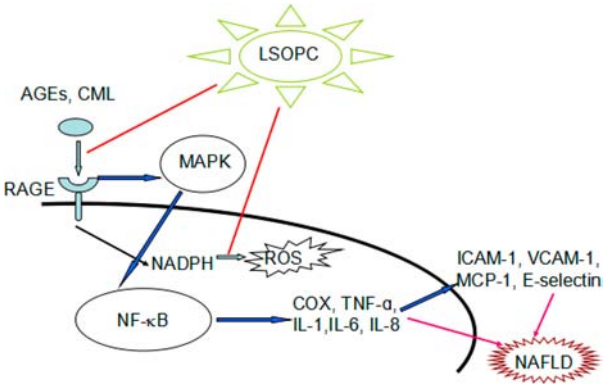

Figure 6. Proposed effect of LSOPC against NAFLD induced by HFD.

In summary, the present study clearly demonstrated LSOPC have potent protective effects against long-term HFD-induced NAFLD. Moreover, the protective effects on regulation of hepatic lipid metabolism, antioxidant defense system, and inflammatory response were mainly mediated through RAGE–MAPK–NF-κB signaling during NAFLD development. Thus, LSOPC could be considered as potent dietary supplements for preventing NAFLD-related metabolic diseases. Further research in vitro will be needed to explore the exact molecular mechanism by which LSOPC generate their protective effect against NAFLD injury.

contribute to the reported beneficial health effects in humans. Studies have shown that blueberry fruits have a positive effect on brain aging, diabetes, cancers, and vascular diseases.[23−25] To the best of our knowledge, no one has investigated the potential beneficial effects of blueberry polyphenols on periodontal disease. In the present study, we investigated the effect of a polyphenol-rich lowbush blueberry (*Vaccinium angustifolium* Ait.) extract on the growth and biofilm formation of *F. nucleatum*. We also assessed the inhibitory effect of the blueberry extract on the NF-κB signaling pathway and cytokine/MMP secretion in monocytes and macrophages.

MATERIALS AND METHODS

Plant Material. A blueberry extract (BlueCan NV Pure) prepared from the fruit of *V. angustifolium* Ait. was kindly provided by Nutra Canada (Champlain, QC, Canada). BlueCan NV Pure is a 70% ethanolic extract of whole blueberry from which sugar has been removed by passing the supernatant on an XAD-7 chromatographic column. According to the company data sheet, the total phenolic content of the extract is 40%, as determined by the Folin−Ciocalteu method.

Chemicals. The phenolic standards gallic acid, chlorogenic acid, protocatechuic acid, *p*-hydroxybenzoic acid, *p*-coumaric acid, *m*-coumaric acid, caffeic acid, ferulic acid, quercetin, quercetin 3-glucoside, kaempferol, myricetin, isorhamnetin, catechin, and epicatechin were purchased from Sigma-Aldrich Canada Co. (Oakville, ON, Canada). Delphinidin 3-glucoside was from Extrasynthèse (Lyon, France). Liquid chromatography grade solvents acetone, methanol, and acetonitrile were from EMD Millipore Canada (Mississauga, ON, Canada), and formic acid was from VWR International (Mississauga, ON, Canada). Ultrapure water was obtained using a Millipore Milli-Q water purification system (EMD Millipore Canada).

Phenolic Characterization of the Blueberry Extract. *Characterization of Anthocyanins and Procyanidins by HPLC.* Anthocyanins and procyanidins were characterized as described previously.[26] Briefly, anthocyanins were separated and analyzed by reverse-phase analytical HPLC with an Agilent 1100 series system (Agilent Technologies Canada Inc., Mississauga, ON, Canada) using the following gradient of 5% formic acid in ultrapure water (solvent A) and methanol (solvent B): 0−2 min, 5% B; 2−10 min, 5−20% B; 10−15 min, 20% B; 15−30 min, 20−25% B; 30−35 min, 25% B; 35−50 min, 25−33% B; 50−55 min, 33% B; 55−65 min, 33−36% B; 65−70 min, 36−45% B; 70−75 min, 45−53% B; 75−80 min, 53−55% B; 80−84 min, 55−70% B; 84−88 min, 70−5% B; 88−90 min, 5% B. Chromatographic data were acquired at 520 nm. Anthocyanins were quantified using an external calibration curve of delphinidin 3-glucoside standard, for which the LOD and LOQ were respectively 0.03 and 0.08 ppm. Procyanidins were separated and analyzed by normal-phase analytical HPLC using an Agilent 1260/1290 infinity system equipped with a fluorescence detector. The elution was performed using the following linear gradient of acetonitrile/acetic acid 98:2 (v/v) (solvent A) and methanol/ultrapure water/acetic acid 95:3:2 (v/v/v) (solvent B): from 0 to 40% B over 35 min, from 40 to 100% B over 5 min, 100% isocratic B for 5 min, and from 100 to 0% B over 5 min. Fluorescence was monitored at the excitation and emission wavelengths of 230 and 321 nm. Procyanidins, which eluted on the basis of their degree of polymerization, were quantified using epicatechin monomer as a standard.

Characterization of Phenolic Acids and Flavonoids by UHPLC-MS/MS. Phenolic acids and flavonoids were characterized as previously described[26] using an Acquity UHPLC-MS/MS coupled to a TQD mass spectrometer equipped with a Z-spray electrospray interface (Waters Ltd., Mississauga, ON, Canada). The phenolic acids and flavonoids were eluted using the following gradient of 0.1% formic acid in ultrapure water (solvent A) and acetonitrile (solvent B): 0−4.5 min, 5−20% B; 4.5−6.45 min, 20% B; 6.45−13.5 min, 20−45% B; 13.5−16.5 min, 45−100% B; 16.5−19.5 min, 100% B; 19.5−19.52 min, 100−5% B; 19.52−22.5 min, 5% B. The MS/MS analyses were performed in negative mode using the following electrospray source parameters: electrospray capillary voltage, 2.5 kV; source temperature, 140 °C; desolvation temperature, 350 °C; and cone and desolvation gas flows, 80 and 900 L/h, respectively. Data were acquired through multiple reaction monitoring using Waters Masslynx V4.1 software. Phenolic standards were analyzed using the same parameters and were used for the quantification.

Bacterial Strain and Growth Conditions. *F. nucleatum* ATCC 25586 was grown anaerobically (80% N_2, 10% CO_2, 10% H_2) for 24 h at 37 °C in Todd−Hewitt broth (THB; BD-Canada, Mississauga, ON, Canada) supplemented with 0.001% hemin and 0.0001% vitamin K.

Determination of Minimal Inhibitory and Minimal Bactericidal Concentrations. A microplate dilution assay was used to determine the minimal inhibitory concentration (MIC) and minimal bactericidal concentration (MBC) values of the blueberry extract against *F. nucleatum*. To determine the MIC, a 24 h culture of *F. nucleatum* was diluted in fresh culture medium to obtain an optical density of 0.2 at 660 nm (OD_{660}). Equal volumes (100 μL) of bacterial suspension and serial dilutions of the blueberry extract (from 1000 to 15.63 μg/mL) in culture medium were added to the wells of 96-well plates. Wells with no *F. nucleatum* or no blueberry extract were used as controls, whereas tetracycline was used as a reference antibiotic. After a 48 h incubation at 37 °C under anaerobic conditions, bacterial growth was monitored by recording the OD_{660} using a Synergy 2 microplate reader (BioTek Instruments, Winooski, VT, USA). The MIC value was the lowest concentration of the blueberry extract that completely inhibited the growth of *F. nucleatum*. To determine the MBC, 5 μL aliquots from the wells with no visible growth were spread on sheep blood-supplemented THB agar plates, which were incubated for 3 days at 37 °C. The MBC value was the lowest concentration at which no colony formation occurred. All assays were performed in triplicate to ensure reproducibility.

Determination of Siderophore Activity. The universal siderophore assay of Schwyn and Neils[27] was used to measure the iron-chelating activity of the blueberry extract. Ferrichrome (Sigma-Aldrich Canada Ltd.), a siderophore produced by *Ustilago sphaerogena*, was used as the positive control.[28]

Effect of the Blueberry Extract on Biofilm Formation. *Microplate Assay. F. nucleatum* was grown for 48 h under anaerobic conditions in the absence or presence of the blueberry extract (from 1000 to 15.63 μg/mL) as described above. The medium containing free-floating bacteria was removed by aspiration using a 26G needle. Then, the wells were washed three times with distilled water, and the biofilms were stained with 100 μL of 0.05% crystal violet. After a 15 min incubation, the wells were washed three times with distilled water and were dried for 2 h at 37 °C. Ethanol [100 μL, 95% (v/v)] was added to each well, and the plate was shaken for 10 min to release the dye from the biofilms. The absorbance at 550 nm (A_{550}) was recorded.

Scanning Electron Microscopy. The effect of the blueberry extract on *F. nucleatum* biofilm formation was also examined by scanning electron microscopy. One milliliter of *F. nucleatum* suspended to an OD_{660} of 0.2 in culture medium, with (62.5, 125, 250, or 500 μg/mL) or without the blueberry extract, was added to the wells of a 12-well plate containing a 13 mm diameter plastic coverslip. After a 48 h incubation under anaerobiosis, the medium and free-floating bacteria were removed by aspiration, and the plastic coverslips were washed twice with 0.1 M cacodylate buffer (pH 7.2). The biofilm-coated coverslips were incubated for 3 h in fixation buffer [2.5% (w/v) glutaraldehyde (grade I) and 1 mM $CaCl_2$ in 0.1 M cacodylate buffer, pH 7.2], washed three times (20 min each time) with 0.1 M cacodylate buffer (pH 7.2), and postfixed for 90 min at room temperature in 1% (w/v) osmic acid containing 2 mM potassium ferrocyanide and 6% (w/v) sucrose in cacodylate buffer. Samples were dehydrated using a graded series of ethanol (50, 70, 95, 100%), critical point-dried, gold-sputtered, and examined using a JEOL JSM6360LV scanning electron microscope operating at 30 kV.

Determination of Quorum Sensing Inhibitory Activity. The bioluminescence assay using the reporter strain *Vibrio harveyi* BB170 (ATCC BAA-1117) was performed as previously described.[29] *V. harveyi* BB120 (ATCC BAA-1116) was grown overnight in auto-

DOI: 10.1021/acs.jafc.5b01525
J. Agric. Food Chem. 2015, 63, 6999−7008

inducer bioassay (AB) medium at 30 °C with agitation and was then diluted 1:100 in fresh culture medium containing the blueberry extract at concentrations (31.25, 62.5, 125, 250 μg/mL) that did not interfere with the bacterial growth (data not shown). After a 16 h incubation at 30 °C, the supernatant was recovered by centrifugation at 10000*g* for 10 min, filter-sterilized (0.22 μm), and stored at −80 °C. The presence of autoinducer-2 (AI-2) was then assayed by adding 20 μL of cell-free supernatant from each test sample to the wells of a 96-well, clear bottom, black wall microplate. An overnight culture of *V. harveyi* BB170 diluted 1:5000 (180 μL) was added to each well containing a supernatant sample. The positive control consisted of 20 μL of cell-free supernatant from *V. harveyi* BB120 grown in the absence of blueberry extract, whereas the negative control consisted of AB medium. The plate was incubated for 15 h in a Synergy 2 microplate reader at 30 °C with agitation (200 rpm). The bioluminescence and OD_{660} were measured every 15 min during the incubation.

Effect of the Blueberry Extract on the Activation of the NF-κB Transcription Factor. The human monoblastic leukemia cell line U937 3xκB-LUC, a subclone of the U937 cell line stably transfected with a luciferase gene coupled to a promoter of three NF-κB-binding sites, was kindly provided by Dr. Rune Blomhoff (University of Oslo, Norway).[30] Cells were routinely cultivated in Roswell Park Memorial Institute 1640 medium (RPMI-1640; Life Technologies Inc., Burlington, ON, Canada) supplemented with 10% heat-inactivated fetal bovine serum (FBS), 100 μg/mL penicillin G/streptomycin, and 75 μg/mL hygromycin B at 37 °C in a 5% CO_2 atmosphere. First, the effect of the blueberry extract at concentrations ≤500 μg/mL on U937 3xκB-LUC viability was determined using a 3-(4,5-diethylthiazol-2-yl)-2,5-diphenyltetrazolim bromide (MTT) assay, according to the manufacturer's instructions (Roche Diagnostics, Laval, QC, Canada). Briefly, U937 3xκB-LUC cells were treated with the blueberry extract for 6.5 h prior to monitoring viability. To induce activation of the NF-κB transcription factor, the U937 3xκB-LUC cells (10^6 cells/well) were placed in the wells of a 96-well black bottom microplate (Greiner Bio-One North America Inc., Monroe, NC, USA) and were stimulated for 6 h (optimal activation based on preliminary assays) with *F. nucleatum* cells at a multiplicity of infection (MOI) of 2, 10, 50, or 100. To assess the effect of the blueberry extract on the pro-inflammatory potential of *F. nucleatum*, an overnight culture was pre-incubated with various concentrations of the blueberry extract (31.25−250 μg/mL) for 30 min with shaking. The *F. nucleatum* cells were then harvested by centrifugation (10000*g* for 10 min), washed three times, and suspended in RPMI supplemented with 1% FBS. They were then added to wells containing U937 3xκB-LUC cells at an MOI of 100. Finally, to investigate the effect of the blueberry extract on *F. nucleatum*-induced NF-κB activation, U937 3xκB-LUC cells were pre-incubated with the extract (15.6−500 μg/mL; in RPMI containing 1% FBS) for 30 min and were then stimulated for 6 h with bacteria at an MOI of 100. Wells with no *F. nucleatum* or no blueberry extract were used as controls to measure basal NF-κB activity. Assays using a commercial inhibitor (BAY-11-7082; 25 μM; EMD Millipore Canada) were used as negative control of the NF-κB signaling pathway. NF-κB activation was determined by measuring luciferase activity following the addition of Bright-Glo reagent (Promega Corp., Madison, WI, USA) in accordance with the manufacturer's protocol. Luminescence was monitored using a Synergy 2 microplate reader.

Effect of the Blueberry Extract on Cytokine and MMP Secretion by Macrophages. U937 human monocytes (ATCC CRL-1593.2) from the American Type Culture Collection (Manassas, VA, USA) were cultivated in RPMI-1640 supplemented with 10% FBS and 100 μg/mL penicillin G/streptomycin at 37 °C in a 5% CO_2 atmosphere. The monocytes (2.5×10^5 cells/mL) were then incubated in RPMI−10% FBS containing 100 ng/mL phorbol-12-myristate-13-acetate (PMA; Sigma-Aldrich Canada Ltd.) for 48 h to induce differentiation into adherent macrophage-like cells.[31] Adherent macrophage-like cells were harvested by scraping and were centrifuged at 1200*g* for 5 min. The cells were washed, suspended in RPMI−1% FBS at a concentration of 1×10^6 cells/mL, seeded into the wells of a 12-well microplate (1×10^6 cells/well), and incubated overnight at 37 °C in a 5% CO_2 atmosphere. The macrophage-like cells were treated with the blueberry extract (62.5−500 μg/mL) for 2 h. They were then stimulated with *F. nucleatum* at an MOI of 100. After a 24 h incubation at 37 °C in a 5% CO_2 atmosphere, the culture medium supernatants were collected and stored at −20 °C until used. Cells incubated in culture medium with or without the blueberry extract and stimulated or not with bacteria were used as controls. Enzyme-linked immunosorbent assay (ELISA) kits (eBioscience Inc., San Diego, CA, USA) were used to quantify IL-1β, IL-6, CXCL8, TNF-α, MMP-8, and MMP-9 concentrations according to the manufacturer's protocols. To exclude the possibility that cell toxicity due to the blueberry extract might have been responsible for a decrease in cytokine and MMP levels, the viability of the blueberry extract-treated macrophages was assessed using an MTT test and by Trypan blue exclusion.

Effect of the Blueberry Extract on MMP-9 Activity. Human recombinant MMP-9 (active form) purchased from AnaSpec (Fremont, CA, USA) was diluted in reaction buffer (300 mM NaCl, 50 mM Tris-HCl, 5 mM $CaCl_2$, 20 μM $ZnCl_2$, pH 7.5) to a final concentration of 50 ng/mL and was incubated for 4 h in the absence or presence of the blueberry extract (7.9−500 μg/mL) and the fluorogenic substrate Gelatin DQ (Molecular Probes, Eugene, OR, USA) at a concentration of 100 μg/mL. The fluorogenic substrate alone or with blueberry extract was used as control. An assay using a specific inhibitor of MMP (1 μM, GM6001; Calbiochem, San Diego, CA, USA) was also performed. The assay mixtures were incubated in the dark for 2 h at 37 °C. The fluorescence was measured using a fluorometer with excitation and emission wavelengths set at 495 and 525 nm, respectively. Two independent assays performed in triplicate were performed.

Statistical Analysis. Unless indicated otherwise, all experiments were performed in triplicate. The data are expressed as means ± standard deviations (SD). Statistical analyses were performed using a one-way analysis of variance with a post hoc Bonferroni multiple-comparison test (GraphPad Software Inc., La Jolla, CA, USA). All results were considered statistically significant at $p < 0.001$ or $p < 0.05$.

RESULTS

Phenolic Composition of the Blueberry Extract. The phenolic composition of the blueberry extract is presented in detail in Table S1. Phenolic acids, flavonoids (flavonols, anthocyanins, flavan-3-ols), and procyanidins made up 16.6, 12.9, and 2.7% of the blueberry extract, respectively. Chlorogenic acid (67%) was the most abundant phenolic acid, whereas flavonols and anthocyanins accounted for 99% of the total flavonoids, and quercetin and its sugar-conjugated derivatives accounted for 98% of the flavonols. The procyanidin content was mostly monomers, dimers, and polymers with a degree of polymerization >10.

Antibacterial and Antibiofilm Properties of the Blueberry Extract. The ability of the blueberry extract to interfere with the growth of *F. nucleatum* was assessed first. The MIC of the blueberry extract against *F. nucleatum* was 1 mg/mL (Figure 1). This concentration also corresponded to the MBC. The blueberry extract at a concentration of 500 μg/mL reduced the growth of *F. nucleatum* by 29.9 ± 12.3%, whereas it had no growth inhibitory effect at concentrations ≤250 μg/mL. Tetracycline used as a reference antibiotic showed a MIC of 0.39 μg/mL and a MBC of 1.56 μg/mL (data not shown). To identify the mechanism by which the blueberry extract exerted its antimicrobial activity against *F. nucleatum*, we investigated its ability to chelate iron. The blueberry extract dose-dependently chelated iron in a universal siderophore assay (Figure 2). This activity was comparable to that of ferrichrome, the positive control, a siderophore produced by *U. sphaerogena*.

We then tested the effect of the blueberry extract on biofilm formation by *F. nucleatum* (Figure 1). Blueberry extract

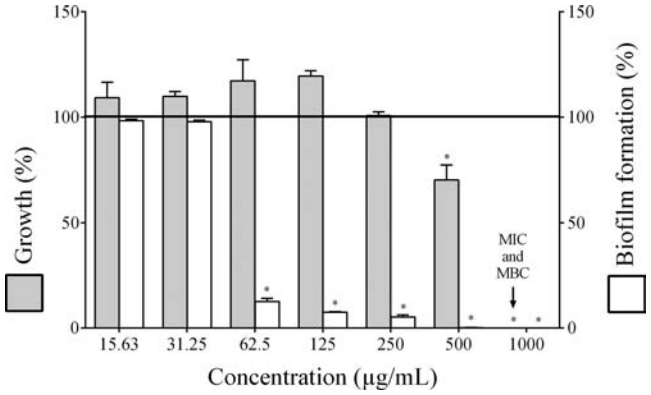

Figure 1. Effect of the blueberry extract on *F. nucleatum* growth and biofilm formation. A value of 100% was assigned to growth and biofilm formation in the absence of the blueberry extract. Results are expressed as the means ± SD of triplicate assays from two independent experiments. (∗) Significantly different from the control ($p < 0.001$).

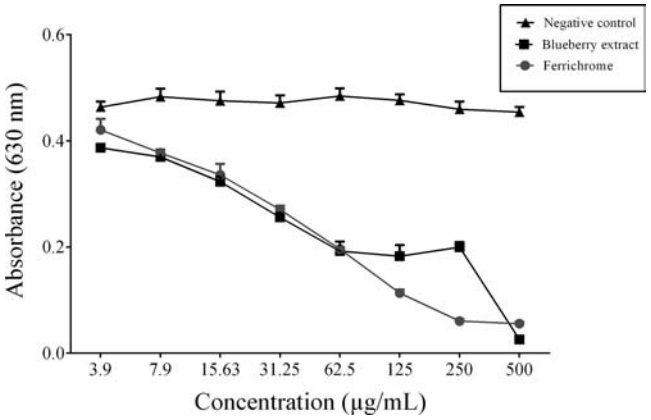

Figure 2. Iron-chelating activity of the blueberry extract determined using a chrome azurol sulfate colorimetric assay. A reduction in A_{630} values occurs when a strong chelator removes the iron from the chrome azurol dye. Ferrichrome, a siderophore produced by *U. sphaerogena*, was used as positive control. Results are expressed as the means ± SD of triplicate assays from two independent experiments. (∗) Significantly different from the control ($p < 0.05$).

concentrations ranging from 500 to 62.5 μg/mL had a significant effect on biofilm formation. More specifically, 62.5 μg/mL of the blueberry extract, which did not reduce the growth of *F. nucleatum*, inhibited biofilm formation by 87.5 ± 2.3%. The effect of the blueberry extract on biofilm formation by *F. nucleatum* was visualized by scanning electron microscopy. Electron micrographs clearly showed that there was a marked reduction in mature biofilm and that the architecture was disrupted when *F. nucleatum* was grown in the presence of the blueberry extract (Figure 3).

Given that the blueberry extract reduced biofilm formation by *F. nucleatum*, we then investigated the quorum sensing inhibitory activity of the blueberry extract. *V. harveyi* BB120 was grown in the presence of various concentrations of blueberry extract, and the supernatants were then collected. The levels of secreted AI-2 were determined by monitoring bioluminescence using the reporter strain *V. harveyi* BB170. The blueberry extract dose-dependently inhibited AI-2-mediated bioluminescence (Figure 4). Quorum sensing activity was inhibited at concentrations that had no effect on the growth of *V. harveyi* BB120 (data not shown).

Effect of the Blueberry Extract on NF-κB Activation in Monocytes. We first showed that *F. nucleatum* dose-dependently activates the NF-κB transcription factor, as indicated by the increase in luciferase activity (Figure S1). The strongest activity was obtained with an MOI of 100. A 30 min pre-incubation of bacterial cells (MOI = 100) with the blueberry extract reduced the ability of *F. nucleatum* to activate the NF-κB pathway (Figure 5). More specifically, 250 and 125 μg/mL of the blueberry extract decreased NF-κB activation by 33.19 ± 7.48 and 17.46 ± 0.32%, respectively.

We then determined whether the presence of blueberry extract prevented *F. nucleatum*-induced NF-κB activation in U937-3xκB cells. The blueberry extract dose-dependently inhibited the activation of NF-κB induced by *F. nucleatum* at an MOI of 100 (Figure 6). More specifically, 250, 125, 62.5, and 31.25 μg/mL of the blueberry extract reduced NF-κB activity by 97 ± 0.56, 88.6 ± 0.9, 68.8 ± 5.7, and 48.5 ± 2%, respectively. As expected, the commercial inhibitor BAY-11-7082 (25 μM) completely prevented NF-κB activation. The blueberry extract alone (in the absence of *F. nucleatum*) was not cytotoxic and had no effect on NF-κB activity (data not shown).

Effect of the Blueberry Extract on Cytokine and MMP Secretion by Macrophages. We used a macrophage-like model (PMA-treated U937 cells) stimulated with *F. nucleatum* to determine whether the ability of the blueberry extract to attenuate NF-κB activation in U937-3xκB cells also reduced inflammatory mediator secretion. Adherent macrophage-like cells were pretreated for 2 h with the blueberry extract and were then stimulated for 48 h with *F. nucleatum* (MOI = 100). We then measured the secretion of cytokines (IL-6, IL-1β, TNF-α, CXCL8) and MMPs (MMP-8, MMP-9) by the adherent macrophage-like cells. Using an MTT test and by Trypan blue exclusion, the blueberry extract displayed no cytotoxicity and had no effect on cell viability, which was ≥98 ± 6.8% for all concentrations tested compared to the untreated controls (data not shown). Therefore, a decrease in cytokine and MMP levels cannot result from loss of cell viability. *F. nucleatum* significantly increased the secretion of IL-6 (234.6 fold), IL-1β (5.2-fold), TNF-α (215-fold), CXCL8 (6.2-fold), MMP-8 (1.8-fold), and MMP-9 (1.3-fold) by macrophages (Figures 7 and 8). The secretion of pro-inflammatory cytokines (IL-1β, IL-6, TNF-α) by macrophages stimulated with *F. nucleatum* was significantly and dose-dependently attenuated by the blueberry extract compared to control cells. At a concentration of 62.5 μg/mL, the blueberry extract reduced the secretion of IL-1β by 87.3 ± 1.3% (Figure 7A), that of TNF-α by 80.7 ± 5.6% (Figure 7B), and that of IL-6 by 28.2 ± 9.3% (Figure 7C). Whereas the secretion of the chemokine CXCL8 was not affected by 62.5 μg/mL of the blueberry extract, 500, 250, or 125 μg/mL of the blueberry extract decreased CXCL8 secretion by 79 ± 6.3, 57.9 ± 0.2, and 11.2 ± 0.3%, respectively (Figure 7D). Treating the cells with the highest concentration of the blueberry extract (500 μg/mL) decreased IL-1β, TNF-α IL-6, and CXCL8 secretions to the same degree as the commercial inhibitor (Figure 7). The blueberry extract in the absence of *F. nucleatum* had no effect on the basal levels of secreted cytokine (data not shown). Finally, MMP-8 and MMP-9 secretion by *F. nucleatum*-stimulated macrophages was also attenuated by the blueberry extract, in some cases below basal levels. More specifically, 500, 250, and 125 μg/mL of the blueberry extract reduced the secretion of MMP-8 by 67.7 ± 0.4, 66.9 ± 0.4, and 60.2 ±

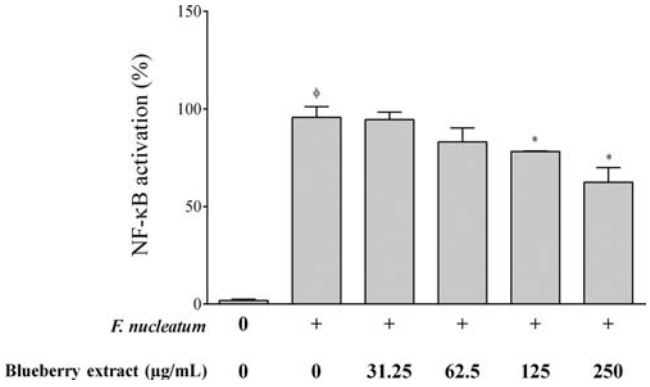

Figure 5. Effect of pre-incubating *F. nucleatum* with the blueberry extract on NF-κB activation using the U937-3xκB cell model. A value of 100% was assigned to the activation obtained after a 6 h incubation in the absence of the blueberry extract. Results are expressed as the means ± SD of triplicate assays from three independent experiments. (ϕ) Significant increase ($p < 0.001$) compared to nonstimulated control cells. (∗) Significant decrease ($p < 0.001$) compared to *F. nucleatum*-stimulated cells not treated with the blueberry extract.

0.2%, respectively, and the secretion of MMP-9 by 93.0 ± 2.24, 62.7 ± 1.7, and 26.7 ± 7.8%, respectively (Figure 8).

Effect of the Blueberry Extract on MMP-9 Activity. After demonstrating that the blueberry extract can decrease MMP-9 secretion in a macrophage model, we evaluated its effect on the gelatinase activity of MMP-9. As reported in Table 1, the blueberry extract at 500, 250, and 125 μg/mL reduced MMP-9 activity by 99.7 ± 1.8, 82.6 ± 2.4, and 56.7 ± 5.5%, respectively.

DISCUSSION

Conventional periodontal treatments rely primarily on removing the subgingival dental biofilm that modulates the host inflammatory response associated with periodontal tissue destruction. Whereas physical removal of the biofilm by scaling and root planing is usually sufficient to reverse the progression of the disease, adjunctive treatments, such as antibiotics, are occasionally required. Over the past two decades, natural compounds exhibiting both antibacterial and anti-inflammatory properties have received considerable attention as potential new therapeutic agents for the prevention and treatment of periodontal infections.[32] Blueberries are mainly native to North America and are recognized for their health benefits.[23,24] There are two main commercial species of blueberries: highbush (*Vaccinium corymbosum* L.) and lowbush (*V. angustifolium* Ait.). Lowbush blueberries, also known as wild blueberries, are often harvested from wild patches and are endemic to the boreal forests. They are smaller in size than *V. corymbosum* L. and have a distinct intense flavor and aroma. Lowbush blueberries are also grown commercially, especially in Maine, Atlantic Canada, and Quebec. Many studies have reported that blueberries

contain health-promoting compounds, including phenolic acids and flavonoids such as chlorogenic acid, ellagic acid, quercetin, anthocyanins, and procyanidins, which account for their pronounced antioxidant, anti-inflammatory, and immunomodulatory properties.[33,34] The blueberry extract used in our study was particularly rich in a variety of polyphenols and more specifically chlorogenic acid and flavonols, as well as monomers, dimers, and polymers of procyanidins. Given that blueberry polyphenols are potential candidates for the prevention and treatment of periodontal diseases, the present study was aimed at investigating the effects of a lowbush blueberry extract (*V. angustifolium* Ait.) on various aspects of the etiopathogenesis of periodontitis.

On the basis of our previous studies showing that cranberry proanthocyanidins interfere with the pathogenic properties of periodontopathogens,[35] we hypothesized that blueberry polyphenols may have a beneficial effect on periodontal diseases by attenuating the growth and pathogenic properties of *F. nucleatum*, a bacterial species that has been associated with various forms of the disease. The blueberry extract displayed potent antibacterial activity against *F. nucleatum*, with MIC and MBC values of 1 mg/mL. This finding was consistent with previous studies by Lacombe et al., who reported that North American lowbush blueberry polyphenols exhibit marked antibacterial effects against Gram-negative bacteria, including *E. coli* 157:H7, and foodborne pathogens.[36] Blueberry

polyphenols may alter the bacterial membrane by destabilizing the LPS and increasing the efflux of ATP from the cytoplasm.[37] Moreover, anthocyanins, phenolic acids (caffeic acid, chlorogenic acid, protocatechuic acid), and quercetin, which were present in our blueberry extract, have been associated with antibacterial and membrane permeabilizing activities.[38] In the present study, we showed that blueberry polyphenols possess marked iron-chelating activity, which may be another antimicrobial mechanism. Indeed, by chelating iron, which is an essential cofactor for bacterial growth, blueberry polyphenols may compete with bacteria for iron, creating an iron-deficient, bacteriostatic environment. Interestingly, Dastmalchi et al. investigated the antioxidative properties of a variety of edible neotropical blueberries and identified iron-chelating activity in some varieties of blueberry, although they did not test the lowbush blueberry.[39] Because the ferrous form of iron is responsible for the formation of reactive oxygen species (ROS), this iron-scavenging property may contribute to the antioxidative activity of blueberry polyphenols.[40] Moreover, given that ROS are known to activate MMPs, the iron-chelating property of blueberry polyphenols may also contribute to decreasing proteolytic activity in diseased periodontal sites.

Because *F. nucleatum* plays a critical role in subgingival biofilm formation by bridging early and late colonizers, we investigated the antibiofilm activity of the blueberry extract using concentrations that did not inhibit bacterial growth. On the basis of the results of a colorimetric microplate assay, the blueberry extract almost completely prevented *F. nucleatum* biofilm formation at concentrations as low as 62.5 μg/mL. The antibiofilm activity of the blueberry extract was confirmed by scanning electron microscopy. The above observations suggest that the blueberry extract may inhibit the attachment and maturation of periodontal biofilms through dynamic and sequential processes. This may help prevent or slow periodontal disease initiation and progression because biofilms, which are structured microbial communities attached to oral surfaces, enable bacteria to evade immune defenses, resist mechanical removal, and avoid chemotherapeutic agents. In addition, the blueberry extract disrupted biofilm formation, a major virulence property of *F. nucleatum*, at concentrations that were not antibacterial, indicating that bacteria may not develop resistance to bioactive molecules in blueberry extracts. Zimmer et al. studied hydroethanolic extracts of blueberries from various *Vaccinium virgatum* cultivars and reported that the caffeic and chlorogenic acids in the extracts were likely responsible for the inhibition of biofilm formation by *Staphylococcus epidermidis* and *Pseudomonas aeruginosa*, two major human bacterial pathogens.[41] These two compounds were also present in our blueberry extract.

Given the fact that blueberry polyphenols interfere with biofilm formation by *F. nucleatum*, we hypothesized that the blueberry extract might also possess antiquorum sensing activity. Quorum sensing refers to the coordinated regulation of virulence gene expression modulated by cell density. Using the *V. harveyi* quorum sensing model, we showed that the blueberry extract attenuated AI-2-mediated cell−cell signaling. Such an attenuation of bacterial virulence by the inhibition of quorum sensing has been suggested be a promising strategy for reducing antibiotic use.[42]

Although the colonization of subgingival sites and subsequent biofilm formation by periodontopathogens such as *F. nucleatum* is the initial step in the pathogenesis of periodontitis,[2] the host immune response, which results in the overproduction of a large variety of inflammatory mediators involved in tissue and bone destruction, is critical.[8−11] Given that polyphenols have anti-inflammatory properties that contribute to the human health benefits of berries,[43] we thus investigated the effect of the blueberry extract on the inflammatory response of host cells. Macrophages are major immune cells involved in the continuous and excessive host

responses that result in the secretion of large amounts of pro-inflammatory cytokines, chemokines, and MMPs, which in turn are involved in tissue and bone destructive processes.[7] In the present study, we showed that lowbush blueberry polyphenols significantly reduce the secretion of IL-1β, TNF-α, IL-6, and CXCL8 by *F. nucleatum*-stimulated macrophages. These results are in agreement with those of Kang et al.,[20] who showed that two phenolic acid extracts prepared from lowbush blueberries and highbush blueberries reduced the production of IL-6 and TNF-α by LPS-stimulated macrophages and that the anti-inflammatory activity of the lowbush extract was greater than that of the highbush extract. They also provided evidence that the decreased production of IL-6 and TNF-α was associated with the inhibition of the NF-κB signaling pathway and that chlorogenic acid (67% of all phenolic acids in our blueberry extract) was likely the main contributor to the anti-inflammatory property of blueberries.[20] Ruifeng et al.[44] reported that chlorogenic acid inhibits the TLR4-mediated and LPS-induced NF-κB signaling pathway and reduces the secretion of the pro-inflammatory cytokines TNF-α, IL-1β, and IL-6 involved in mastitis. Cheng et al. provided proof that blueberry anthocyanins (petunidin, peonidin, malvidin, and cyanidin) inhibit the expression of IL-1β, IL-6, and IL-12 genes in LPS-stimulated RAW264 macrophages, a further indication that blueberry extracts possess anti-inflammatory activity.[45]

Inhibitors of the NF-κB transcription factor hold great promise for the prevention and treatment of chronic inflammatory disorders.[46] Plant polyphenols act on host cells by activating or inhibiting various cell signaling pathways by, for example, modulating kinase activity and activating the NF-κB transcription factor.[43] The mechanism by which the blueberry extract used in the present study reduced inflammatory mediator secretion may be related to its capacity to block NF-κB activation because this signaling pathway is central to the inflammatory response.[43] Using the U937-3xκB cell model, we showed that the blueberry extract inhibited NF-κB activation induced by *F. nucleatum*, most likely its cell surface LPS. Whereas the exact bioactive molecule in our blueberry extract has not been identified, anthocyanins, which made up 23% of the total polyphenolic content of the extract, may be involved. Indeed, Taverniti et al.[34] previously reported that an anthocyanin-rich lowbush blueberry extract reduced IL-1β-induced NF-κB activation in Caco-2 epithelial cells. In addition, cranberry proanthocyanidins reduce the LPS-induced inflammatory response in oral epithelial cells via the NF-κB pathway.[47]

MMP-9 and MMP-8 have been strongly associated with the progression of periodontitis.[48] Interestingly, we showed that our blueberry extract reduced MMP-8 and MMP-9 secretion by *F. nucleatum*-stimulated macrophages. This result was in agreement with those of a previous study by Matchett et al.,[49] who reported that lowbush blueberry anthocyanins and proanthocyanidins down-regulate MMP-2 and MMP-9 activities in the DU-145 prostate tumor model and increase the expression of tissue inhibitors of metalloproteinases 1 (TIMP-1). Matchett et al. suggested that this effect was mainly due to proanthocyanidins and that it involved the protein kinase C (PKC) and mitogen-activated protein kinase pathways.[49] In addition to attenuating MMP-8 and MMP-9 secretion by macrophages, we also showed that the blueberry extract inhibits the catalytic activity of MMP-9 (gelatinase-2). Because MMPs are associated with periodontal tissue destruction, our results suggested that blueberry polyphenols may contribute to reducing host cell damage, including bone resorption. Interestingly, Zhang et al.[50] reported that feeding rats a blueberry diet inhibits bone resorption through suppression of receptor activator of nuclear factor-κB ligand (RANKL).

In conclusion, we showed that polyphenols in a lowbush blueberry extract are active against the two main etiologic components of periodontitis. On the one hand, the blueberry extract inhibited the growth and biofilm formation of the periodontopathogenic bacterium *F. nucleatum*. On the other, it reduced the secretion of cytokines and MMPs by macrophages by blocking the activation of the NF-κB signaling pathway. This dual action of lowbush blueberry polyphenols suggests that they may be promising candidates for novel therapeutic agents.

phenol-sulfuric acid method using glucose as a standard. Samples were tested for the absence of free sugars by thin layer chromatography on silica gel G type 60 plates (MERCK, Tokyo, Japan) using chloroform−methanol−water (3:3:1 v/v/v) as the mobile phase. The ethanol-precipitated and dried EPS was then finely milled and moderately sonicated to dissolve in distilled water (for the in vivo experiment) or saline (for the in vitro cell assay).

Characterization of NTM048 EPS. To determine the monosaccharide composition of purified NTM048 EPS, 3 mg of EPS was hydrolyzed by addition of 750 μL of perchloric acid (1.75 M) and incubated at 80 °C for 16 h. After incubation, 250 μL of KOH (5 M) was added to precipitate the potassium perchlorate. The solution was centrifuged, and then the supernatant was filtered through a 0.45 μm pore size filter and the monosaccharide composition was analyzed by high performance anion exchange chromatography and pulsed amperometric detection (HPAEC-PAD) using a 4 × 250 mm Dionex CarboPac PA1 column. A gradient of sodium acetate from 0 to 500 mM in 100 mM sodium hydroxide was used for elution over 40 min at 1 mL/min. Detection was performed using a Dionex ICS-3000 module. D-Glucose and D-fructose (Nacalai Tesque, Tokyo, Japan) were used as standards.

The average molecular mass of NTM048 EPS was determined by size exclusion chromatography using Sepharose CL6B (Sigma-Aldrich, Missouri, USA). Two types of commercially purchased dextrans (Sigma-Aldrich, average MW 36,000−45,000 and 9,000−11,000) were used as standards.

In Vitro Analysis of IgA-Inducing Activity of EPS on Peyer's Patch Cells. To evaluate the IgA-inducing activity of NTM048 EPS, mouse Peyer's patch (PP) cells were prepared according to our previous study[10] and resuspended at 2.5 × 10^6 cells/mL in RPMI 10 medium [RPMI 1640 (Gibco BRL, CA, USA) containing 100 U/mL penicillin, 100 μg/mL streptomycin, 55 μmol/L 2-mercaptoethanol, and 10% fetal bovine serum (FBS; Gibco BRL)]. Various concentrations of size-exclusion chromatography-purified NTM048 EPS were added to PP cells (1.25 × 10^6 cells/mL final concentration) and incubated in 96-well T-cell activation plates (Becton Dickinson, Franklin Lakes, NJ) at 37 °C in a humidified atmosphere of 5% CO_2 in air. After 5 days, the IgA levels in the supernatants were measured by ELISA using a mouse IgA ELISA kit (Bethyl Laboratories, Montgomery, TX).

Assay for Specific IgA-Inducing Activity of EPS. The specific IgA-inducing ability of NTM048 EPS to the H1N1 antigen was measured according to the method of Yasui et al.[11] with some modifications. Mouse PP cells (4 × 10^6 cells/mL) in Eagle's minimum essential medium (Nissui, Tokyo, Japan) were cultured with size exclusion chromatography-purified NTM048 EPS (250 μg/mL) and influenza A (H1N1) virus antigen (0.34 μg/mL) on 96-well T-cell activation plates (Becton Dickinson) at 37 °C in a humidified atmosphere of 5% CO_2 in air to which a 10% v/v aliquot of a nutrient mixture was added daily.[12] After 2 days of incubation, the medium containing H1N1 antigen was removed by centrifugation, and then the PP cells were further incubated with NTM048 EPS (250 μg/mL) for an additional 6 days. Specific IgA levels against H1N1 antigen in the cultured medium were measured by ELISA as follows. H1N1 antigens (3 μg/mL) were coated on the wells of a 96-well ELISA plate (Thermo Scientific, MA, USA), and the culture supernatant was added to each well. Horseradish peroxidase-labeled mouse IgA detection antibody (Bethyl Laboratories) was added to the wells, and then an aliquot of 3,3′,5,5′-tetramethylbenzidine substrate solution was added to each well. After 15 min, the reaction was stopped by addition of 1 M HCl, and the absorbance of the contents of the wells was measured at 450 nm.

In Vitro Analysis of Immune Responses on Splenocytes. To evaluate the response of NTM048 EPS stimulation on splenocytes, mice were euthanized by CO_2 gas, and their spleens were harvested. Their spleens were gently teased and dispersed through a 70-μm cell strainer to obtain single-cell suspensions. After centrifugation (100 × *g*, 8 min), red blood cell lysis buffer (NH_4Cl 0.83%, $KHCO_3$ 0.1%, EDTA-2Na 0.00372%) was added to the pellet and incubated for 5 min. After washing with RPMI 10 medium twice, the cells were used as splenocytes. The prepared splenocytes were cultured (5 × 10^5 cells/well) on 96-well T-cell activation plates (Becton Dickinson) with size-exclusion chromatography-purified NTM048 EPS (20 μg/mL) for 66 h, followed by fluorescence-augmented cell sorter (FACS) analysis to examine the frequency of T cells (CD4+ and CD8+). Aliquots of 1 × 10^6 splenocytes were incubated with 10 μg/mL of Purified Rat Anti-Mouse CD16/32 (BD Biosciences, San Diego, CA) for 15 min on ice and washed twice in stain buffer (PBS with 2% FBS). Cells were then stained with PE-Cy7 conjugated antimouse CD3e (clone 145-2C11), PE conjugated antimouse CD4 (clone RM4-5), and APC conjugated antimouse CD8a (clone 53-6.7) using Mouse T Lymphocyte Subset Antibody Cocktail (BD Biosciences) for 30 min at 4 °C. Flow cytometry was performed on 20,000 cells by using FACSAria and FACSDiVa4.1 software (Becton Dickinson).

The frequency of CD4+ cells producing IFN-γ, IL-4, and IL-17 in splenocytes cultured with NTM048 EPS was examined by intracellular cytokine staining (ICCS) using the BD Cytofix/Cytoperm Plus Fixation/Permeabilization Kit (BD Biosciences) according to the manufacturer's instructions. In brief, the NTM048 EPS-stimulated splenocytes were resuspended in 1 mL of stimulation medium [RPMI 1640 medium containing 10 ng/mL of phorbol 12-myristate 13 acetate (Sigma-Aldrich), 1 ng/mL of ionomycin calcium salt (Sigma-Aldrich), 0.6 μL/ml of BD Golgistop] and incubated at 37 °C in 5% CO_2 for 5 h. Cells were washed twice with staining buffer and incubated with fixation/permeabilization solution for 20 min in the dark. Cells were washed twice again and stained by CD4 PERCP-Cy5.5, IL-17 PE, IFN-γ FITC, and IL-4 APC antibodies using a Mouse Th1/Th2/Th17 Phenotyping Kit (BD Biosciences) for 30 min on ice in the dark. Cells were washed twice and resuspended in staining buffer. Staining was assessed by FACSAria (BD Biosciences) and analyzed using BD FACSDiVa 4.1 software (BD Biosciences). A total of 30,000 events/sample were analyzed.

In Vivo Analysis of Immune Responses for NTM048 EPS. After 2 weeks of acclimation, 20 mice were assigned to 5 groups of four each based on body weights and fecal IgA levels. Each group was administered ad labium the NTM048 EPS-containing experimental water at a concentration of 0, 0.05, 0.1, 0.5 or 1% w/v. The mice were individually housed and administered experimental water for up to 42 days. Feces were collected every 7 days, and the IgA content in the feces was analyzed according to our previous study.[10] On day 42, the mice were euthanized with excessive somnopentyl, and Peyer's patch cells, spleen, and blood were harvested.

Plasma aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were analyzed using the Transaminase CII kits (Wako Pure Chemical Industries, Osaka, Japan) to detect liver damage. Plasma creatinine (CRE) content was analyzed by the LabAssay Creatinine kit (Wako Pure Chemical Industries) to detect kidney disease. Measurements of plasma IgA and IgG levels were performed using a mouse IgA ELISA kit (Bethyl Laboratories) and a mouse IgG ELISA kit (Bethyl Laboratories), respectively.

Gene Expression Analysis of Peyer's Patch cells. Peyer's patch cells collected from the small intestine of mice were used for gene expression analysis. Total RNA samples were isolated using a QuickPrep total RNA extraction kit (GE Healthcare, Piscataway, NJ, USA). For preparation of cDNA, 1 μg of each total RNA sample was reverse-transcribed using Super Script III reverse transcriptase (Invitrogen, Carlsbad, CA, USA) and oligo (dT) primers (Invitrogen), and the obtained cDNA was then purified using a PCR Purification kit (Qiagen, Cambridge, MA, USA). Quantitative real-time RT-PCR was performed in a 7300 Fast Real-Time PCR system (Life Technologies Japan, Tokyo, Japan), using a Power SYBR Green Master Mix (Life Technologies) according to the manufacturer's instructions. A housekeeping transcript, glyceraldehyde 3-phosphate dehydrogenase (GAPDH), was used as an internal control to standardize the efficiency of each reaction. The sequences of the primers used were as follows: GAPDH (*Gapdh*), 5′-ctacactgaggaccaggttgtct-3′ and 5′-attgtcataccaggaaatgagctt-3′; IL-5 (*Il5*), 5′-tgaggcttcctgtccctactcataa-3′ and 5′-ttggaatagcatttccacagtaccc-3′; IL-6 (*Il6*), 5′-aatagtccttcctacccc-aatttc-3′ and 5′-atttcaagatgaattggatggtct-3′; IL-21 (*Il21*),[13] 5′-gcagcac-aggctaagagcttgta-3′ and 5′-tggctagtggagaagccttca-3′; BCL6 (*Bcl6*),[13]

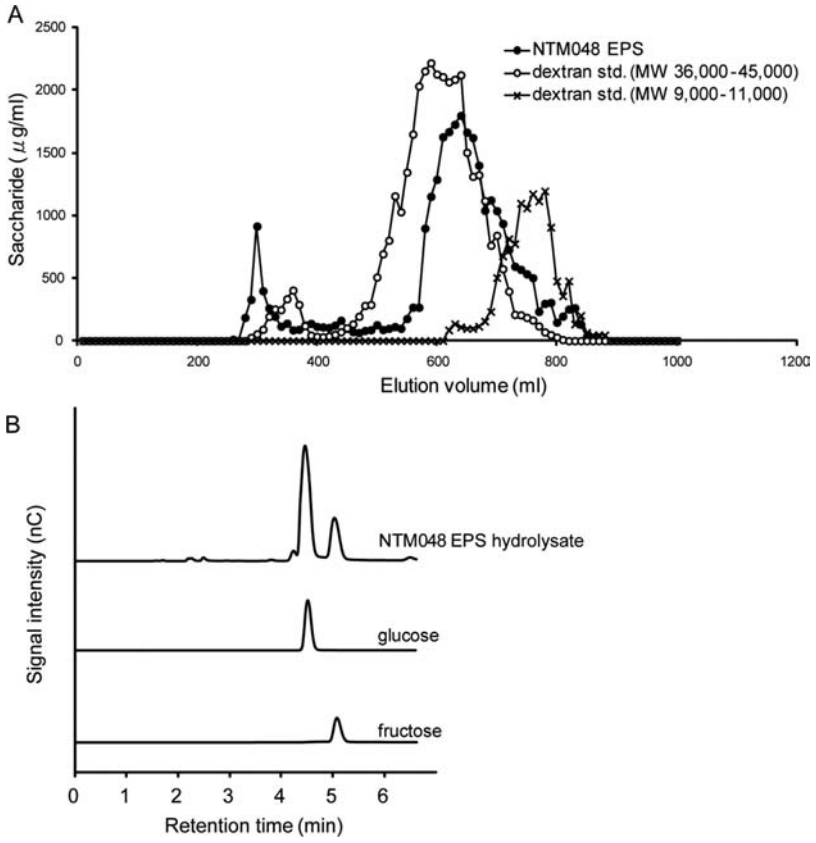

Figure 1. Characterization of NTM048 EPS. A: Molecular mass distribution of NTM048 EPS by size exclusion chromatography. Two kinds of industrial dextrans (average MW 36,000−45,000 and 9,000−11,000) were used as standards. B: HPAEC-PAD analysis of the monosaccharide composition of NTM048 EPS hydrolysate. Glucose and fructose were used as standards.

5′-gcactgggcaaacacaacat-3′ and 5′-agcgtgccgggtaaactg-3′; BAFF (*Tnfsf13b*),[14] 5′-tgctatgggtcatgtcatcca-3′ and 5′-ggcagtgttttgggcatattc-3′; APRIL (*Tnfsf13*),[14] 5′-tcacaatgggtcaggtggtatc-3′ and 5′-tgtaaatg-aaagacacctgcactgt-3′; RALDH1 (*Aldh1al*),[15] 5′-atggtttagcagcaggac-tcttc-3′ and 5′-ccagacatcttgaatccaccgaa-3′; CD40L (*Cd40l*), 5′-tttatc-cttgctgaactgtgagga-3′ and 5′-gatcctcatcacctctttgcattt-3′; TGF-β1 (*Tgfb1*),[15] 5′-tggagcaacatgtggaactc-3′ and 5′-tgccgtacaactccagtgac-3′; TGF-βR2 (*Tgfbr2*),[16] 5′-cctactctgtctgtggatga-3′ and 5′-gctcgtaatcct-tcacttctc-3′; and AID (*Aicda*),[17] 5′-aaattctgtccggctaacca-3′ and 5′-cattccaggaggttgctttc-3′. To confirm whether or not PCR correctly amplified the aimed genes, the PCR products were sequenced and identified by means of BLAST search (DNA Data Bank of Japan), and we analyzed their melting curves (data not shown). All experiments were performed in triplicate.

Flow Cytometric Analysis of Splenocytes. Single-cell suspensions of splenocytes were prepared, and the frequencies of T cells (CD4+ and CD8+) were examined as described above using a FACSAria (BD Biosciences) and analyzed by BD FACSDiVa4.1 software (BD Biosciences). A total of 20,000 events/sample were analyzed.

Statistical Analysis. Each result is expressed as the mean ± standard error (SE). Dunnett's test or two-way repeated-measures ANOVA with a posthoc analysis followed by Dunnett's test was used to compare multiple groups. Statistical analyses were conducted using Ekuseru-Toukei software version 2010 (SSRI, Tokyo, Japan). *P* values less than 0.05 were considered statistically significant.

RESULTS

Characterization of NTM048 EPS. We obtained 1.46 g of NTM048 EPS from a 50-mL culture in the EPS-production medium. To estimate the molecular mass of the NTM048 EPS, size exclusion chromatography was performed. The majority of NTM048 EPS was eluted between the two dextran standards whose sizes ranged from 36,000−45 000 Da and 9,000−11 000 Da, respectively, indicating the NTM048 EPS molecular mass range is approximately 10−40 kDa (Figure 1A). Next, we attempted to determine the monosaccharide composition of NTM048 EPS. HPAEC-PAD analysis was used to monitor the partial hydrolysis of the EPS to its monosaccharides. The chromatogram showed two monosaccharide peaks, which corresponded to the retention time of D-glucose and D-fructose, respectively (Figure 1B). This result suggests that NTM048 EPS contains glucose and fructose.

Effect of NTM048 EPS on Immune Cells in Vitro. Isolated PP cells and splenocytes were used to examine the effect of NTM048 EPS on immune cells. As shown in Figure 2A, total IgA production of PP cells was dose-dependently stimulated by NTM048 EPS (1.5-fold and 1.7-fold increases compared with that of the saline control in the presence of 25 and 250 μg/mL EPS, respectively). Moreover, costimulation of NTM048 EPS with H1N1 antigen significantly induced anti-H1N1 IgA production by 1.5-fold (Figure 2B). These results indicate that NTM048 EPS can stimulate PP cells to produce total and antigen-specific IgA (see Discussion). FACS analysis on the NTM048 EPS-stimulated splenocytes was also carried out. The isolated splenocytes were treated 20 μg/mL of NTM048 EPS. The number of CD3+ cells and the ratio of CD4+ T cells to CD8+ T cells from the NTM048 EPS-stimulated splenocytes were significantly higher ($P < 0.05$) than those of nonstimulated splenocytes (Figure 3A and B). Additionally, NTM048 EPS stimulation significantly expanded the CD4+ T cell population ($P < 0.01$) (Figure 3C upper

J. Agric. Food Chem. 2015, 63, 7009−7015

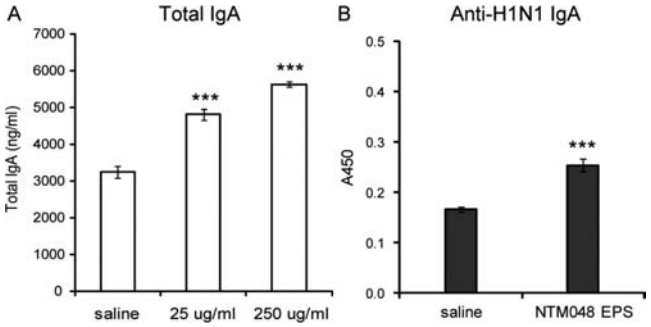

Figure 2. In vitro response of Peyer's patch cells stimulated by NTM048 EPS. A: IgA-inducing ability of NTM048 EPS. Each value is presented as the mean ± SE (n = 5; ***P < 0.001). B: Augmentation of anti-influenza virus H1N1 IgA antibody production by NTM048 EPS. Each value is presented as the mean ± SE (n = 8; ***P < 0.001).

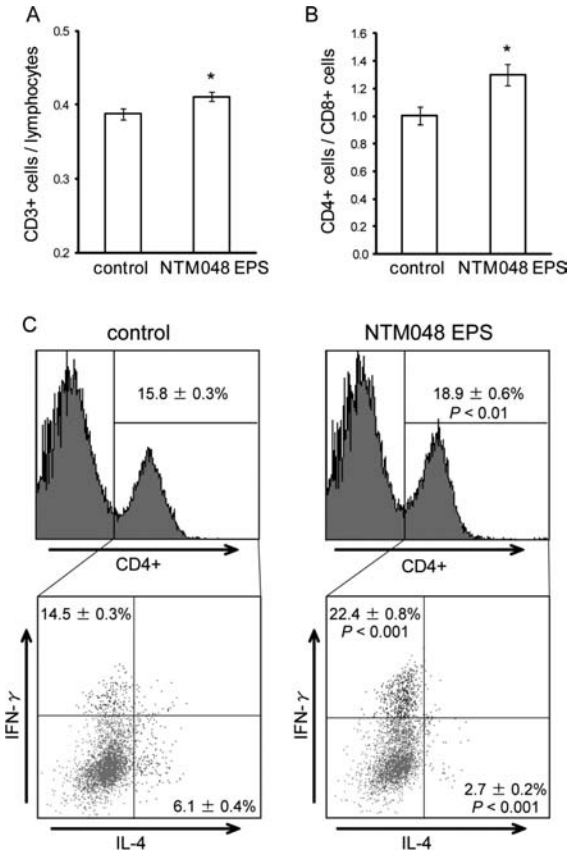

Figure 3. Flow cytometric analysis of splenocytes in vitro. Splenocytes were cultured with 20 μg/mL of NTM048 EPS or saline (control). Each value is presented as the mean ± SE (n = 5). A: Ratio of CD3+ cells/lymphocytes. B: Ratio of CD4+ cells/CD8+ cells (*P < 0.05). C: Ratio of CD4+ cells/lymphocytes, IFN-γ+ cells/CD4+ cells, and IL-4+ cells/CD4+ cells. Statistical results are shown in the panels.

panel). The ratio of a subset of CD4+ T cells producing IFN-γ was significantly increased by NTM048 EPS stimulation (14.5% vs 22.4%, P < 0.001) with a concomitant decrease in the ratio of a subset of CD4+ T cells producing IL-4 (6.1% vs 2.7%, P < 0.001) (Figure 3C lower panel). We also examined the effects of 100 μg/mL of EPS treatment on splenocytes, which results were almost the same as those of 20 μg/mL of EPS treatment (data not shown). This indicates that the immune stimulation of splenocytes by NTM048 EPS was induced enough at the concentration of 20 μg/mL. No change was observed in the frequency of CD4+ T cells producing IL-17 (nontreated, 1.7 ± 0.1%; NTM048 EPS treated, 1.7 ± 0.1% [data not shown]). These results suggest that EPS stimulation affects the Th1 and Th2 cell-mediated response in splenocytes.

Effect of NTM048 EPS on the Mouse Intestinal Immune System. Having established the in vitro effect of NTM048 on mucosal and systemic immune responses as described above, we next performed in vivo experiments using BALB/cA mice. Drinking water supplemented with NTM048 EPS at 0, 0.05, 0.1, 0.5, or 1.0% (w/v) was given to mice ad libitum for 42 days. All animals were in good health throughout the experimental period, and no side effects, such as diarrhea, occurred. There were no significant differences in food and water intake, body weight gain, and plasma AST, ALT, and CRE levels among the groups (Table 1).

In agreement with the in vitro study, oral administration of NTM048 EPS increased the fecal IgA concentration (Figure 4). While the fecal IgA content of the 0 and 0.05% groups were minimally changed through the experimental period, those of the 0.1, 0.5, and 1% groups were significantly increased after 35 days compared with their initial IgA content.

Peyer's patches are the main inductive sites for intestinal IgA responses.[18,19] To determine the mechanism responsible for the mucosal IgA production upon administration of NTM048 EPS, we analyzed the expression levels of genes involved in intestinal immunostimulation in isolated PP cells (Figure 5). The gene expression of the TGF-β receptor 2 (TGF-βR2) found on B cells was significantly increased in the 0.5 and 1% groups (P < 0.05), suggesting the occurrence of TGF-β1 signaling.[5] The gene expression of retinal dehydrogenase (RALDH), which is required for retinoic acid (RA) production from dendritic cells (DCs), was also increased in the 1% group (P < 0.05). The gene expression of B cell lymphoma 6 (BCL6), which is abundantly expressed by follicular helper T (T_{FH}) cells, tended to increase in the 0.5 and 1% groups (P = 0.14 and P = 0.17, respectively). On the other hand, the expression of IL-5, IL-6, IL-21, B cell-activating factor (BAFF), a proliferation-inducing ligand (APRIL), CD40 ligand (CD40L), TGF-β1, and activation-induced cytidine deaminase (AID) genes remained unchanged.

Effect of NTM048 EPS on the Systemic Immune System in Mice. To investigate the effect of NTM048 EPS administration on the systemic immune system, we examined the plasma IgA and IgG levels and carried out flow cytometric analysis on the isolated splenocytes of NTM048 administrated-mice. Oral administration of NTM048 EPS did not affect plasma IgA and IgG levels (Table 1), but a significant effect on T cell population in the spleen was observed. The CD3 positive T-cell population in total lymphocytes of the 0.5% and 1% groups were significantly higher than that of the control group (Figure 6A) (P < 0.05). Additionally, the CD4+ T cells/CD8+ T cells of the 1% group were significantly higher than that of the control group (Figure 6B) (P < 0.01), which was consistent with the in vitro result (Figure 3A and B).

DISCUSSION

One of the immunomodulating properties induced by LAB is the promotion of host mucosal IgA secretion to strengthen the first lines of defense, such as the mucosal barrier.[20−22] It has been reported that several types of LAB are effective against pathogenic infection via their IgA-inducing ability. *Lactobacillus pentosus* strain b240[23] and *Lactobacillus plantarum* strain AYA[24]

[a]Results are shown as the mean ± SE (n = 4).

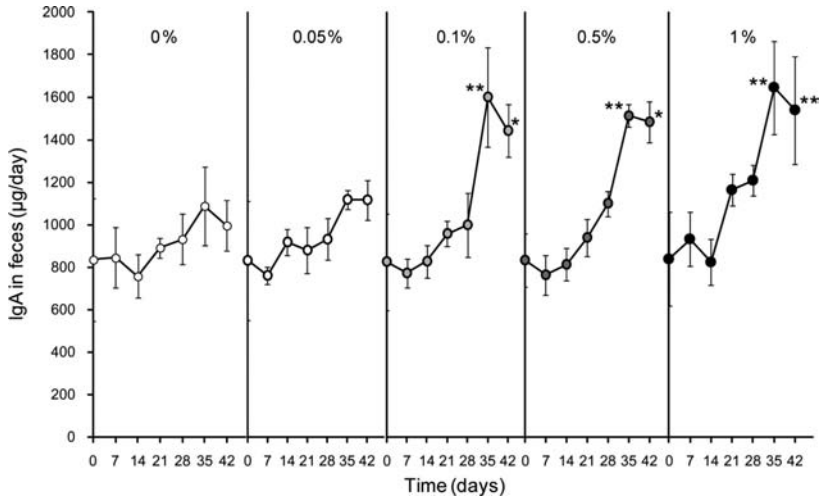

Figure 4. Fecal IgA content induced by NTM048 EPS intake. Mice were administered 0, 0.05, 0.1, 0.5, and 1% of EPS-containing water and the IgA content in feces were compared. Differences were assessed by a two-way repeated-measure ANOVA with a *post hoc* analysis by Dunnett's test. Each value is presented as the mean ± SE (n = 4). *P < 0.05, **P < 0.01 vs each initial IgA content (day 0).

were selected for their IgA-inducing potency on mouse PP cells, and oral administration of the cells could facilitate protection against influenza virus in mice. However, the IgA-inducible components of these LABs remain unclear.

In our previous study, we identified *Leuc. mesenteroides* strain NTM048 having IgA-inducing potency from among 173 LABs.[10] NTM048 cells were tolerant to gastric and intestinal digestion in vitro, and oral administration of this strain induced intestinal IgA secretion in mice. Moreover, the NTM048 EPS dose-dependently induced IgA secretion from PP cells, suggesting that NTM048 EPS plays a pivotal role as an immunostimulant of strain NTM048. To confirm that NTM048 EPS is an immunostimulant, we investigated the effect of NTM048 EPS on the intestinal and systemic immune system in the present study.

In agreement with the results from our previous study, NTM048 EPS dose-dependently enhanced total IgA secretion by isolated PP cells. Furthermore, we revealed that NTM048 EPS could induce specific IgA secretion by isolated PP cells. To effectively prevent mucosal infection, the ability to induce a specific IgA response is also important.[25] In particular, a successful influenza virus vaccine containing an adjuvant which stimulates mucosal antigen-specific IgA production is attractive because of the insufficient efficacy of the systemic IgG response. Therefore, NTM048 EPS might be useful as an effective adjuvant of mucosal vaccination.

The spleen contains various immune cells including T and B cells, DCs, and macrophages and regulates the systemic immune system to protect the body against blood-borne bacterial, viral, and fungal infections.[26] NTM048 EPS influenced the T cell population of splenocytes in vitro and in vivo. In both experiments, NTM048 EPS increased the T cell (CD3+ cell) population and the ratio of CD4+ cells/CD8+ cells. Given the results of its IgA-inducing ability, intake of NTM048 EPS influenced not only the mucosal immune system but also the systemic immune system. Medrano et al. reported that oral treatment of EPS produced by microorganisms present in kefier grains modulated the balance of immune cells in intestinal mucosa including the increase in IgA+ cells but did not affect the cells in the spleen.[27] Therefore, immunomodulation ability on the systemic immune system is considered as a marked characteristic of NTM048 EPS. Additionally, NTM048 EPS treatment of isolated splenocytes increased IFN-γ-producing CD4+ cells and decreased IL-4-producing CD4+ cells. IFN-γ is a cytokine associated with the Th1 immune response rather than the allergic Th2 response, and IL-4 is a cytokine required for Th2 cell differentiation and Th1 development suppression.[28] Hence, NTM048 EPS might influence the Th1 and Th2 cell-mediated response of systemic immune system.

IgA induction through a T cell-dependent pathway leads to the production of high-affinity IgA because of the occurrence of somatic hypermutation (SHM), which is responsible for affinity

DOI: 10.1021/acs.jafc.5b01960
J. Agric. Food Chem. 2015, 63, 7009−7015

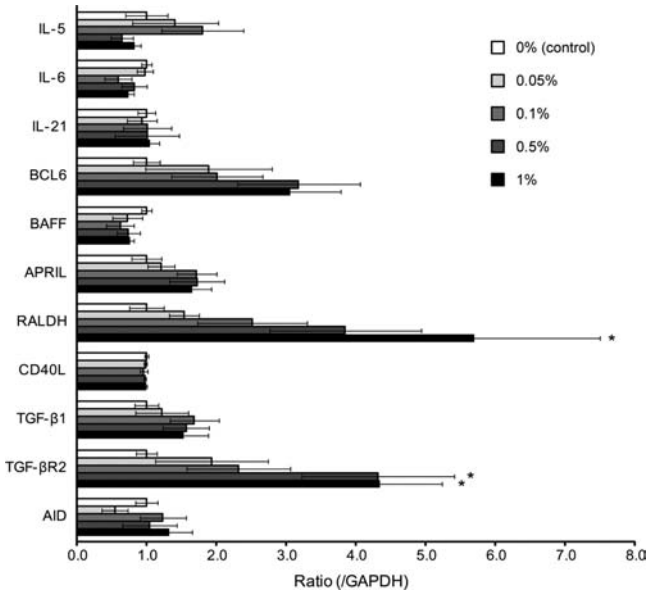

Figure 5. Gene expression analysis of Peyer's patch cells from mice treated with 0, 0.05, 0.1, 0.5, and 1% of NTM048 EPS. Gene expression was analyzed by SYBR Green-Based Real-Time RT-PCR. GAPDH was used as a control to standardize the efficiency of each reaction. Each value is presented as the mean ± SE (n = 4). Statistical analysis was performed with Dunnett's multiple comparison test. *P < 0.05 vs the control group.

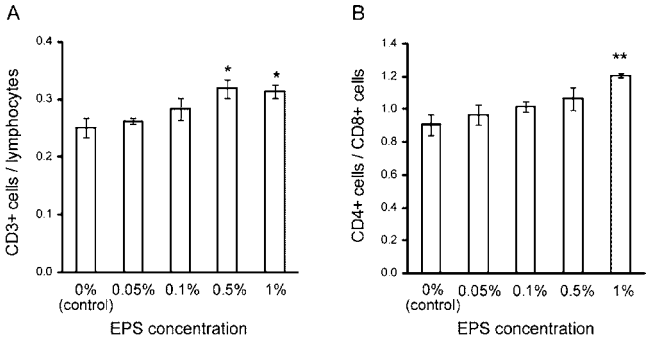

Figure 6. T cell stimulation in the spleen of mice fed water containing 0, 0.05, 0.1, 0.5 and 1% of NTM048 EPS. A: Ratio of CD3+ cells/lymphocytes. B: Ratio of CD4+ cells/CD8+ cells. Each values is presented as the mean ± SE (n = 4). *P < 0.05, **P < 0.01 vs the control group.

maturation.[22] On this pathway, T_{FH} cells, which highly express BCL6, are differentiated from Foxp3+ regulatory T cells and promote B cell responses toward intestinal antigens.[29] T_{FH} cell-signaling promotes B cells to undergo SHM with the help of TGF-β1, IL-21, and RA.[30] In this study, the gene expression levels of BCL6, TGF-βR2, and RALDH were upregulated or tended to be upregulated by NTM048 EPS intake. Given the in vitro observation of specific IgA-induction, NTM048 EPS may be inducing the production of high-affinity IgA through a T cell-dependent pathway.

Dextran is an extracellular bacterial polymer of D-glucopyranose containing predominantly α-(1,6) linkages in the main chain and a variable amount of α-(1,2), α-(1,3), α-(1,4) branched linkages and is produced primarily by *Leuconostoc* strains. Chemically modified dextrans, such as sulfated dextran,[31] diethylaminoethyl dextran,[32] and acetylated dextran,[33] were reported to act as adjuvants to enhance immunogenicity. Natural NTM048 EPS stimulated immune responses in mice without prominent side effects, suggesting its potency as a nontoxic mucosal adjuvant.[34] Some strains of *Leuc. mesenteroides* produce fructose-containing dextrans,[35] but their immunomodulating activity has not been reported yet. The precise determination of the NTM048 EPS structure is currently underway in our laboratory.

In summary, we showed that *Leuc. mesenteroides* NTM048-secreted EPS was a specific IgA-inducible immunostimulant and influenced systemic immunity in mice. These properties of NTM048 EPS indicate that it may be an effective immunostimulant useful for protection from mucosal pathogens.

MATERIALS AND METHODS

Chemicals. Fresh turkey muscle, frozen tuna, olive oils, both refined (ROO) and extra virgin (EVOO) (BORGES, Spain; expiration October 2015), and ω-3 supplement fish oil "Alsepa MAX" (Ocean-Nutrition, Canada; expiration June 2015) were obtained from a local store. Gallic acid, D-α-tocopherol, myoglobin, Folin−Ciocalteu reagent, 2-thiobarbituric acid (TBA), pepsin from porcine stomach mucosa, triphenylphosphin (TPP), hydrochloric acid (HCl), butylated hydroxytoluene (BHT), xylenol orange, and ammonium iron(II) sulfate were obtained from Sigma Chemical Co., St. Louis, MO, USA. Hydrochloric acid, sodium chloride, trichloroacetic acid, and sodium carbonate were obtained from Merck (Darmstadt, Germany). High-performance liquid chromatography (HPLC) grade methanol and pure water were obtained from J. T. Baker, Phillipsburg, NJ, USA. Petroleum ether was obtained from Bio-Lab Ltd., Jerusalem, Israel. Simulated gastric fluid (SGF) was freshly prepared according to the United States Pharmacopeia (Rockville, MD; 2000). The SGF contained NaCl (200 mg), pepsin (320 mg), and HCl (700 μL of 36%) was added to DDW (100 mL).

Muscle Tissue Lipid Peroxidation in Stomach Medium. Fresh turkey red muscle was divided in three portions; each portion was cut into small cubes of ∼1 cm^3 and heated for 1 min in a microwave (Dow, S-Korea, at 800 W), chilled, and kept at −80 °C until needed for the second stage of experiments. The oils were added to the muscle tissue (25g), repeated three times with each portion of muscle, and then ground with simulated gastric fluid adjusted to pH 3.0 (75 mL) for 60 s in a laboratory blender (Warring, New Hartford, CT, USA). The meat−liquid mixture in each treatment was divided among several open Erlenmeyer flasks and incubated in a shaking bath at 37 °C for 180 min or more, in the dark. At four time points (0, 30, 90, 180 min), lipid peroxidation was determined by measuring TBA levels. After incubation, each sample was mixed immediately with 15% TCA at 1:1 ratio and centrifuged for 10 min at 7000 rpm This treatment terminated lipid peroxidation and extracted the carbonyls into the supernatant. The intermediate supernatant was then treated with TBA (2.8 mg/mL) at a 1:1 ratio. The samples were heated in a boiling water bath for 20 min and then read at 532 nm (Synergy HT, Bio-Tek). Malondialdehyde was determined, as described by Bidlack et al.,[36] and calculated according to 1 μmol/L = 0.156 absorbance. D-α-Tocopherol (solubilized in ethanol) was added to red meat (control) before grinding or directly into oils.

Determination of Lipid Hydroperoxides. Lipid peroxides were determined according to the FOX-2 assay.[37] Red meat was treated as described for malondialdehyde. After incubation, 1 mL of the homogenate was mixed with 9 mL of methanol containing BHT (4.4 mM) for peroxide extraction and then centrifuged at 14500 rpm for 3.5 min. The supernatant (100 μL) was added (triplicates) to tubes containing 10 μL of methanol (or methanol + TPP) and incubated at 25 °C for 30 min. After incubation, FOX-2 reagent (890 μL), which contains BHT (4.4 mM), was added and incubated for an additional 30 min. The samples were measured by a spectrophotometer at 560 nm. Lipid hydroperoxides were calculated by taking into account reduction of the results of methanol alone from samples of methanol + TPP. A standard curve was performed using hydrogen peroxide of pure high grade.[23] Determination of H_2O_2 in oils was done with FOX2 reagent with and without catalase for determining the presence of H_2O_2 (1000 μM hydroperoxides is the same as 1 mmol equiv peroxides/kg oil).

Determination of Total Polyphenols in Olive Oil. The polyphenol content of the different olive oils was determined using Folin−Ciocalteu reagent. The polar fraction was extracted from 2.5 g of olive oil dissolved in 5 mL of hexane using an equal volume of methanol/water (60:40 v/v). After mixing for 2 min, the samples were centrifuged for 10 min at 3500 rpm. The isolated polar fraction (100 μL) was then subjected to 500 μL of Folin−Ciocalteu reagent (diluted at 1:10 with

DOI: 10.1021/acs.jafc.5b02149
J. Agric. Food Chem. 2015, 63, 7016−7023

DDW) and 400 μL of 7.5% w/w sodium bicarbonate. The solution was incubated for 30 min and measured at 765 nm by a spectrophotometer (Synergy HT, Bio-Tek). The working reagent was calibrated against gallic acid of known concentration.[38]

Fatty Acid Profile. Samples were analyzed using a gas chromatograph (Agilent 7890A) equipped with a flame ionization detector. Fatty acid methyl esters (FAMEs) were separated on a capillary column (DB-23, 60 m × 0.25 mm, 0.25 um, Agilent) using hydrogen as a carrier gas. Specific FAMEs were identified by superposition of retention times with standards of known FAMEs (Food FAMEs mix and Marine oil FAMEs mix, Restek). Oil samples were methylated by a transesterification reaction using 2 N KOH solution in methanol. Briefly, oil (100 μL) was mixed with 3 mL of derivatization solution, left for 15 min at room temperature, and extracted with 2 mL of hexane. Hexane phase (1 μL) was taken for GC-FID analysis similarly to the method described by Kristinova et al.[39]

Statistical Analysis. Results (means ± SD) were expressed on a molar basis. The results are the means of triplicates; each point was determined three times. In the figures, each error bar denotes the standard deviation. Data were analyzed by analysis of variance with one-way ANOVA post hoc Tukey–Kramer HSD test, using JMP Pro 10.0.0 (SAS Institute Inc.) software. Differences were considered significant at probability levels of $p < 0.05$ and indicated by different letters.

RESULTS

Fatty Acid Composition, Hydroperoxides, and Hydrogen Peroxide in Oils. The olive oils were found to be rich sources of oleic acid with levels of 70–71%, whereas tuna oil and Alsepa MAX ω-3 supplement contained only 19 and 3.3%, oleic acid, respectively. Linoleic (18:2) and linolenic (18:3) acids were at levels of 7.8 and 4.0% in ROO and EVOO, respectively, and also relatively low in fish oils. In contrast, long-chain highly unsaturated ω-3 fatty acids were abundant in fish oils, ∼24% in tuna and 82% in Alsepa MAX oils (Table 1). The hydroperoxides in the olive oils were almost the same but somewhat lower in Alsepa MAX oil but higher in tuna oil. The highest amount of H_2O_2 in oils was found in tuna oil, ∼680 μM (Table 2).

Table 2. Oil Hydroperoxide Concentration[a]

oil type	hydroperoxides (μM)	H_2O_2 (μM)
refined olive oil (ROO)	2253 ± 64bc	145 ± 42a
extra virgin olive oil (EVOO)	2187 ± 69c	225 ± 46ab
fish oil (Alsepa MAX)	1080 ± 61a	299 ± 42b
fish oil (tuna oil)	2353 ± 20b	679 ± 12c

[a]Differences were considered significant at probability levels of $p < 0.05$, indicated by different letters.

Red-Meat Lipid Peroxidation As Affected by Refined Olive Oil. Lipid peroxidation of heated turkey muscles in simulated gastric fluid was significantly affected by the addition of olive oil. ROO at concentrations of 10 and 15% (w/w) inhibited red-meat lipid peroxidation as determined by the accumulation of MDA by 40 and 60%, respectively (Figure 1A). However, the inhibition recorded by the determination of hydroperoxide accumulation was 75, 80, and 82% for ROO additions of 5, 10, and 15%, respectively (Figure 1B).

Red-Meat Lipid Peroxidation As Affected by Refined and Extra Virgin Olive Oils. To identify the possible effects of the polyphenols present in olive oil on inhibition of lipid peroxidation in red meat, two kinds of olive oils produced by the same producer, refined and extra virgin olive oils, were tested in the same system. The amount of polyphenols found in ROO was 16.0 mg/L and in EVOO, 159.6 mg/L (gallic acid equivalents). The results presented in Figure 2 demonstrate that the inhibitions of meat lipid peroxidation by both oils (added at 10%) were almost identical, as determined by MDA and hydroperoxide accumulation. These results demonstrate that the inhibition of lipid peroxidation is not due to the polyphenol content of the oil.

Red-Meat Lipid Peroxidation As Affected by the Trioleate Glyceride. To demonstrate a possible net effect by olive oil triglycerides, we replaced them with pure trioleate glyceride. The addition of 5, 10, and 15% of trioleate to red meat inhibited lipid peroxidation as determined by accumulation of MDA by 40, 85, and 90%, respectively. The inhibition of red-meat lipid peroxidation was more pronounced when the process was determined by the accumulation of hydroperoxides; at the same concentrations of trioleate inhibition was shown to be 86, 90, and 100%, respectively (Figure 3).

Red-Meat Lipid Peroxidation As Affected by Fish Oil. It has been shown that ω-3 fatty acids oxidize ∼200–400 times more rapidly than ω-9 fatty acids.[21] We evaluated the effects of addition of fish oil to red-meat lipid peroxidation determined by the two methods. The results obtained show that addition of 10% tuna oil increased meat lipid peroxidation as determined by MDA by almost 5-fold and hydroperoxides by almost 2.5-fold. These results led us to test the possible effects of taking ω-3 fatty acid pills together with a meal containing red meat. The addition of 10% fish oil (Alsepa MAX) was found to increase red-meat lipid peroxidation as determined by MDA by ∼2.5-fold and hydroperoxides by 2.0-fold (Figure 4).

Lipid Peroxidation in Stomach Medium, Correlation between MDA/ROOH. Results from all of the treatments obtained in this study calculated as MDA and its parallel LOOH were integrated to receive the correlation coefficient between the two methods: $r^2 = 0.88$ and $p < 0.0001$ (see Figure 5).

Red-Meat Lipid Peroxidation in the Presence of Olive Oil or Fish Oil As Affected by α-Tocopherol. The possible inhibition by α-tocopherol of red-meat lipid peroxidation affected by the addition of 5% ROO or fish oil (Alsepa MAX) was evaluated and is presented in Figure 6 (control, red-meat lipid peroxidation without oil addition was inhibited by ∼25% by the same concentration of α-tocopherol). The results show that the addition of α-tocopherol (18 μM, a concentration possible to attain by the amount present in olive oil) to ROO decreased meat lipid peroxidation at 180 min from 100 to 25 μM of MDA, a decrease of 75%. In contrast, the addition of α-tocopherol (18 μM) to fish oil increased red-meat lipid peroxidation from 100 to 300 μM of MDA ∼3.0-fold, acting as a pro-oxidant. This effect was achieved because α-tocopherol as a reducing compound could affect two active factors simultaneously, lipid free radicals and the Fe ions' oxidation state (Figure 6).

Lipid Peroxidation Affected by 10% Added Oils and Correlation between Results In-vitro and In-vivo (previous clinical studies). Figure 7, left panel, represents the results of MDA accumulation from all of the treatments containing the same amount of added oil (10%) to red meat after incubation in simulated gastric fluid for 180 min, at 37 °C. All of the results differ significantly, $p < 0.05$. The panel on the right represents the correlation of the results accumulating from our three clinical studies[3,4,7] with $R^2 = 0.9139$ between in vitro and in vivo results and incorporation/prediction to possible in vivo effects of supplementation of the fish and olive oil with red meat.

DISCUSSION

Our study demonstrated potentially hazardous health effects of consuming red meat combined with additional oil or other foods sensitive to oxidation. However, consuming red meat together with salads containing olive oil, vegetables, fruits, or beverages such as red wine, coffee, or tea containing antioxidants, is very common in the Mediterranean diet. Lipid peroxidation by meat proceeded rapidly because it contains high concentrations of iron catalyzers (~8.5 μg/g iron-heme and 2.5 μg/g free-iron ions) and

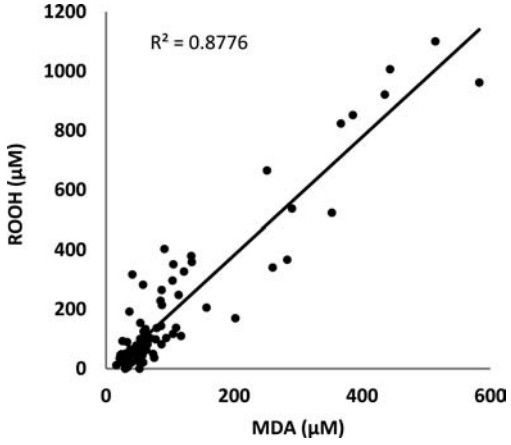

Figure 5. Correlation between two independent methods to determine lipid peroxidation, TBARS, as MDA/ROOH (hydroperoxides), r^2 = 0.88, $p < 0.0001$.

polyunsaturated fatty acids (PUFA) such as linoleic, linolenic, arachidonic, and docosahexaenoic acids.[40] In addition, lipid peroxidation proceeds rapidly when the raw meat structure is disrupted. This occurs after heating, during cooking, frying, roasting, or grilling, which disturbs cellular biochemical integrity and shifts the balance between pro- and antioxidants in favor of pro-oxidant activity.[40] In the stomach, red-meat lipid peroxidation is further enhanced because of the low pH and the presence of oxygen.[1,23] Meals supplemented with oils containing different fatty acids may readily affect lipid peroxidation, as found in our present research. The relatively low rate of autoxidation of oleic acid (18:1) could, in part, explain the lower levels of red-meat lipid peroxidation in the simulated stomach medium in the presence of added olive oil rich in this fatty acid. The decrease in lipid peroxidation by the olive oil could be explained by a sparing and dilution effect generated by oleic acid and saturated fatty acids. Decreasing lipid peroxidation by a pure oleic triglyceride was demonstrated in our study by using trioleate, which showed a high inhibition of lipid peroxidation as determined by both methods of measurement. The effect of oleic acid seems to act not only via an enthalpy effect, decreasing the energy required to attract a hydrogen atom, but also due to the possible chelation of transition metals by oleic acid. Such an effect has been reported previously for nonesterified fatty acids.[41] We believe that triglycerides act in a similar fashion, an effect produced by the nonbonding electrons of oxygen atoms around the ester bond and the carbonyl group, moving the iron catalyzers and the oxidation from the red-meat fatty acids to oleic acid triglycerides.

Our observation of the protective effects of oleic acid on red-meat lipid peroxidation in stomach medium presented here

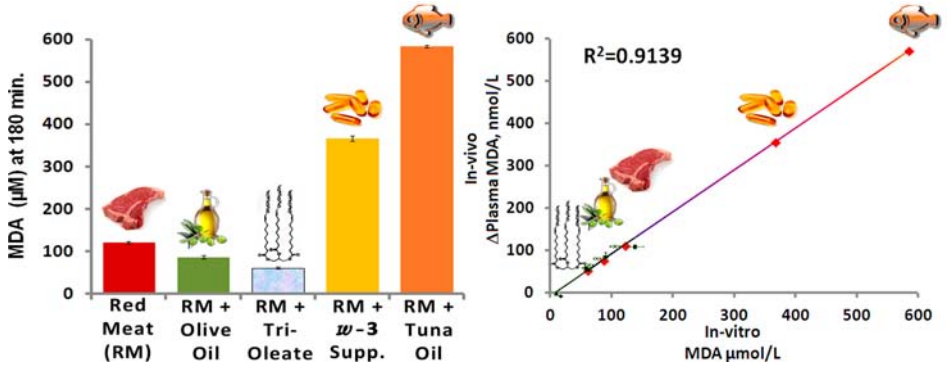

Figure 7. (Left) Results of MDA accumulation from all treatments (10% oils) and (right) correlation betweenr in-vitro and in-vivo (previous clinical studies).

indicated that the protective effect of olive oil is independent of its polyphenol content and is related to the high content of oleic acid. This conclusion fits well the results published recently by Khymenets et al.,[42] who suggested that the antioxidant activities of hydroxytyrasol, the main polyphenol in olive oil, do not contribute to the beneficial health effects after olive oil ingestion in humans. The effects of olive oil components were studied on LDL and biomarkers of oxidative stress, and it was found that only F_2-isoprostanes were inversely related with the oleic acid ratios in LDL, independent of the type of olive oil polyphenol consumed.[43] Hollman et al.,[44] in a recent review, concluded that the biological relevance of direct antioxidant effects of polyphenols in human cardiovascular health has yet to be established, including the effects of those from olive oils. In general, olive oil decreased red-meat lipid peroxidation in the stomach medium, whereas lipid peroxidation was greatly enhanced by fish oils such as tuna and Alsepa MAX, which contain high amounts of ω-3 fatty acids. These fatty acids not only oxidized more rapidly but produced relatively more MDA, other reactive carbonyls, and in general ALEs.[30,34,39,45]

A significant inhibition of lipid peroxidation of red meat in the presence of olive oil (added at 5%) was obtained in simulated stomach medium by the addition of vitamin E. Vitamin E, at the same concentration that inhibited red-meat lipid peroxidation in the presence of olive oil, paradoxically accelerated lipid peroxidation in the presence of fish oil. The inversion of catalysis from antioxidation to pro-oxidation most likely occurred because vitamin E can reduce ferric to ferrous ions along with the presence of hydroperoxides and the high oxidation rate of the unsaturated fatty acids present in fish oil (400-fold higher than oleic acid), which form new free radicals and hydroperoxides (reactions 1−3). Vitamin E, as a reducing compound, could both reduce free iron ions to ferrous state, acting as a pro-oxidant, and at the same time operate as a scavenger of lipid free radicals, acting as an antioxidant in a similar manner to polyphenols,[4] by the following reactions:

$$\text{T-OH} + \text{Fe}^{+3} \rightarrow \text{T-O}^{\bullet} + \text{Fe}^{2+} \quad (1)$$

$$\text{Fe}^{2+} + \text{LOOH} \rightarrow \text{Fe}^{3+} + \text{LO}^{\bullet} + {}^{-}\text{OH} \quad (2)$$

$$\text{LO}^{\bullet} + \text{LH} \rightarrow \text{LOH} + \text{L}^{\bullet}$$

$$\text{L}^{\bullet} + \text{O}_2 \rightarrow \text{LOO}^{\bullet} \quad (3)$$

$$\text{LOO}^{\bullet} + \text{LH} \rightarrow \text{LOOH} + \text{L}^{\bullet}$$

$$\text{T-OH} + \text{LO}^{\bullet}/\text{LOO}^{\bullet} \rightarrow \text{T-O}^{\bullet} + \text{LOH/LOOH} \quad (4)$$

$$\text{T-O}^{\bullet} + \text{LO}^{\bullet}/\text{LOO}^{\bullet} \rightarrow \text{T-OLO/T-OLOO} \quad (5)$$

Fe^{3+}/ Fe^{2+} = ferric/ferrous ions; T-OH = α-tocopherol; $\text{T-O}^{\bullet}$ = tocopheryl radical; $\text{L}^{\bullet}$ = allyl radical; $\text{LOO}^{\bullet}$ = peroxyl radical; $\text{LO}^{\bullet}$ = alkoxyl radical; LOOH = hydroperoxide; LH = unsaturated fatty acid; LOH = alcohol; T-OLO/T-OLOO = adducts of tocopherol with unsaturared fatty acids.

In our food system the balance between the reactions of lipid pro-oxidation and antioxidation is very much dependent on the type and concentration of the fatty acids, fatty acid hydroperoxides/H_2O_2, iron catalyzers. and type and amounts of antioxidants.[1,4,22,23]

The ALEs, mostly reactive carbonyls that are generated during lipid peroxidation in the stomach, can be absorbed into the blood system and potentially interact with functional proteins. This includes receptors or blood particles such as LDL, leading to production of modified-LDL, a well known atherogenic particle.[1,46] The RCs are absorbed from the gut into the blood system in proportion to the amount present in consumed foods[47] and/or generated in the stomach.[1−3] Absorption of these compounds is thought to be deleterious to human health.[1,47−50]

We hypothesize that there are meaningful differences in the health impact of the Western and Mediterranean diets due to the amount of ALEs generated in the stomach during the meal and subsequently absorbed into the bloodstream. Because lipid peroxidation in the stomach is propagated by free radicals, the timing of consuming foods or beverages containing antioxidants should be either prior to or during consumption of red meat. The Western diet contains higher amounts of red meat and unsaturated fatty acids oxidized by frying or other cooking processes and fewer reducing agents (plant food antioxidants), which can act pro-oxidatively. The Mediterranean diet, in contrast, contains lower amounts of red meat due to a higher consumption of vegetables, fruits, and other plant-derived foods and more monounsaturated fatty acids and plant food antioxidants. Overall, this Mediterranean pattern of diet appears to inhibit lipid peroxidation and ALEs formation, thus decreasing the risk of diet-related diseases.

MATERIALS AND METHODS

Chemicals. TNBS and RPMI 1640 were purchased from Sigma-Aldrich (St. Louis, MO, USA). Antibodies for inducible NO synthase (iNOS), cyclooxygenase (COX)-2, and β-actin were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Antibodies for transforming growth factor beta-activated kinase 1 (TAK1), p-TAK1, interleukin-1 receptor-associated kinase 1 (IRAK1), p-IRAK1, inhibitor of nuclear factor kappa-B kinase subunit beta (IKKβ), p-IKKβ, IκB kinase alpha (IκBα), p-IκBα, p65, p-p65, p38, p-p38, extracellular signal-regulated kinases (ERK), p-ERK, c-jun N-terminal kinases (JNK), and p-JNK were purchased from Cell Signaling Technology (Beverly, MA, USA). Enzyme-linked immunosorbent assay (ELISA) kits for cytokines were purchased from R&D Systems (Minneapolis, MN, USA). Heat-inactivated fetal calf serum (FCS) and fetal bovine serum (FBS) were purchased from Invitrogen (Carlsbad, CA, USA). Pan T Cell Isolation Kit II, anti-IL-17A, anti-FoxP3, anti-CD3, anti-CD28, recombinant IL-6, and recombinant tumor growth factor beta (TGFβ, 1 ng/mL were purchased from Miltenyi Biotec (Bergisch Gladbach, Germany). MR2 (purity, > 95%), pseudoginsenoside RT4 (PRT4; purity, > 95%), and ocotillol (purity, > 95%) were isolated according to the previously published method of Nguyen et al.[16,17]

Isolation of MR2, an Inhibitor of Th 17 Cell Differentiation. Vietnamese ginseng was collected in Mt. Ngoc Linh, Quang Nam province, Vietnam, and identified by one of the authors (M.D.N.). A voucher specimen was deposited in the herbarium of College of Pharmacy, Seoul National University (SNUP-2012-A-01). Vietnamese ginseng (150 g) was refluxed with MeOH to yield the MeOH extract (64 g), which was partitioned between EtOAc and H_2O. The water layer was evaporated to give ∼50 g of dried extract and suspended in distilled water, which was partitioned between water and *n*-BuOH to yield 25 g of *n*-BuOH fraction. The *n*-BuOH fraction (10 g) was applied to a silica gel column with a stepwise gradient of a $CHCl_3$–MeOH mixture (9:1 → 7:1 → 5:1) to yield 11 subfractions. Subfraction 6 (1000 mg) was further separated on C18 column chromatography eluting with MeOH-H_2O (1:1 → 2:1 → 1:0) to obtain MR2 (320 mg), which was the most potent inhibition against Th17 cell differentiation, as needles in EtOAc–MeOH mixture. The isolated compound was identified by the direct comparison of spectroscopic and chromatographic data to those of authentic samples.[17,18] MR2: white amorphous powder; purity, >95%; FAB-MS *m*/*z*, 785 $[M - H]^-$.

Analysis of MR2 Metabolites by Mouse Gut Microbiota. First, we orally administered MR2 (50 mg/kg) to five mice, killed 12 h after the oral administration, collected the colon fluid, and extracted with 1 mL of MeOH. The metabolite(s) in the supernatant was analyzed by HPLC.[18] HPLC was performed using a PerkinElmer series 200 HPLC (Waltham, MA, USA) system equipped with evaporative light scattering detector (Alltech ELSD 2000, Alltech, Deerfield, IL, USA) and Sunfire C18 column (250 mm × 4.6 mm i.d., 5 μm; Waters Corp, MA, USA). Mobile phase, water (A) and acetonitrile (B): 0–1 min (18% B), 1–5 min (18 → 25% B), 5–25 min (25 → 32% B), 25–29 min (32% B), 29–40 min (32 → 38% B), 40–45 min (38 → 49.5% B), 45–59 min (49.5 → 100% B), 59–69 min (100% B). The flow rate was 1 mL/min, and the injection volume was 10 μL. ELSD was set to a probe temperature of 80 °C, and the nebulizer gas (N_2) was adjusted to 1.5 L/min. Retention times of MR2, PRT4, and ocotillol were 15.9, 16.3, and 41.8 min, respectively.

Assay of Majonoside R2-Metabolizing Activity of Mouse Microbiota. To analyze the metabolic pathway of MR2, the reaction mixture (5 mL) containing 0.5 mL of the mouse colon fluid suspension (fecal bacterial suspension), 0.5 mL of 1 mM MR2, and 4 mL of diluted general anaerobic medium was anaerobically incubated at 37 °C for 24 h. The supernatant (0.5 mL) was periodically removed, and then 2 mL of MeOH was added to stop the reaction. The reaction mixture was centrifuged at 3000*g* for 10 min and the levels of MR2 and their metabolites PRT4 and ocotillol were analyzed by HPLC and TLC. TLC was developed with CH_3Cl:MeOH:H_2O (=75:25:10 lower layer), stained with 10% sulfuric acid in MeOH, and quantified by densitometry.

Animals. Male ICR mice (20–23 g, 4.5 weeks old) were supplied from Orient Animal Breeding Center (Sungnam, Korea). All animals were fed standard laboratory chow, housed in wire cages at 20–22 °C and 50 ± 10% humidity, and allowed water ad libitum. All experiments were performed in accordance with the NIH and Kyung Hee University guides for Laboratory Animals Care and Use and approved by the Committee for the Care and Use of Laboratory Animals in the College of Pharmacy, Kyung Hee University (IRB No. KHUASP(SE)-14-055).

Preparation of Splenocytes. Spleens were aseptically removed from mice, crushed into a single cell suspension, and washed with tris-buffered ammonium chloride.[19] The cell suspension was prepared in RPMI 1640 medium containing 10% fetal calf serum. T cells were isolated from splenocytes by Pan T Cell Isolation Kit II (Miltenyi Biotec 130-095-130) and plated. Cells were stimulated with anti-CD3 (1 μg/mL) and anti-CD28 (1 μg/mL) in the presence of recombinant IL-6 (20 ng/mL), recombinant TGFβ (1 ng/mL) with or without ginsenosides for 4 days, and analyzed by a flow cytometer (C6 Flow Cytometer System).

Preparation of Experimental Colitis in Mice. To measure the anticolitic effect of ocotillol in mice, mice were divided into five groups: normal and TNBS-induced colitic groups treated with or without ocotillol (10 and 20 mg/kg) or sulfasalazine (20 mg/kg). Each group consisted of 6 mice. Colitis was induced by the intrarectal injection of 2.5% (w/v) TNBS solution (100 μL) in 50% ethanol into the colon of lightly anesthetized mice via a round-tip needle equipped with a syringe.[20] Normal mouse group was treated with vehicle alone. TNBS solution quickly excreted mice were excluded: >95% of the mice caused TNBS enema. Test agents were orally administered once a day for 3 days from the first day after TNBS treatment. Mice were killed 20 h after the final administration of test agents. Colon was quickly removed, opened longitudinally, and gently washed with ice-cold phosphate-buffered saline. Macroscopic assessment of the colitis severity was scored according to a previously reported scoring method,[20] and the colon tissue was then stored at −80 °C until the experiment.

For the histological exam, colons were fixed in 10%-buffered formalin solution, cut into 10-μm sections, stained with hematoxylin–eosin, toluidine blue, or safranin O, and observed under a light microscope.

J. Agric. Food Chem. 2015, 63, 7024–7031

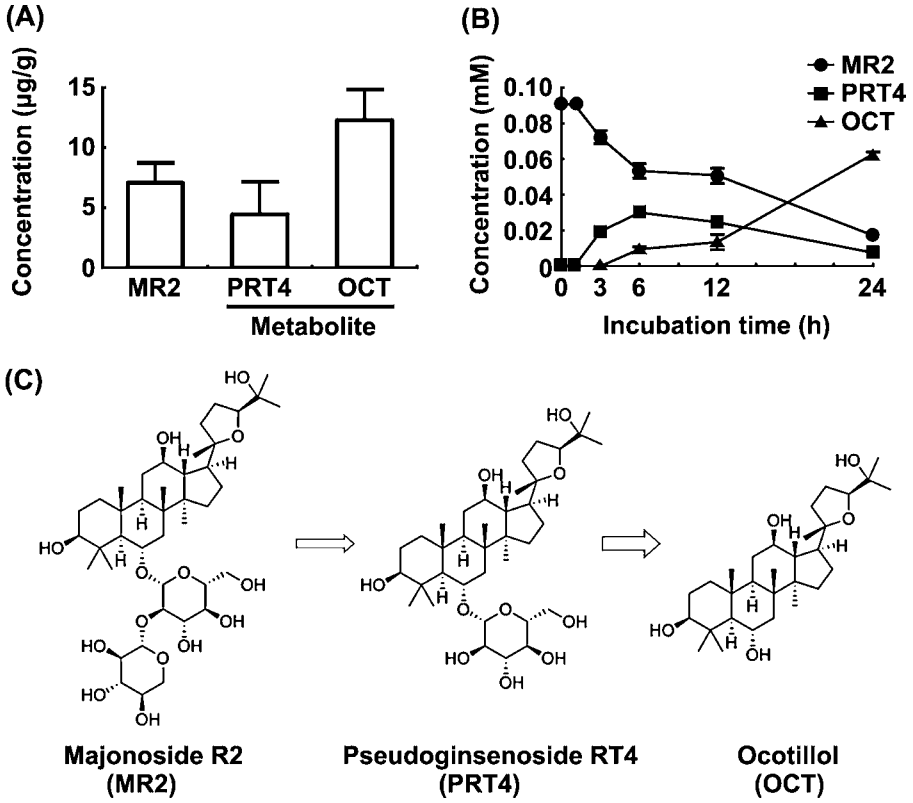

Figure 1. Metabolism of orally administered MR2 by the gut microbiota of mice. (A) Metabolism of orally administered MR2 in mice. MR2 was orally administered to mice and measured in the colon fluid of mice 12 h after the administration of MR2. (B) Metabolism of MR2 by the mouse fecal suspension. The fecal suspensions were incubated with MR2 (0.1 mM), and periodically extracted with ethyl acetate. The amounts of MR2 and its metabolites PRT4 and ocotillol (OCT) were analyzed using thin layer chromatography (solvent: CH_3Cl:MeOH:H_2O = 75:25:10 lower layer) and quantified by densitometry. (C) Proposed metabolic pathway of MR2 by gut microbiota.

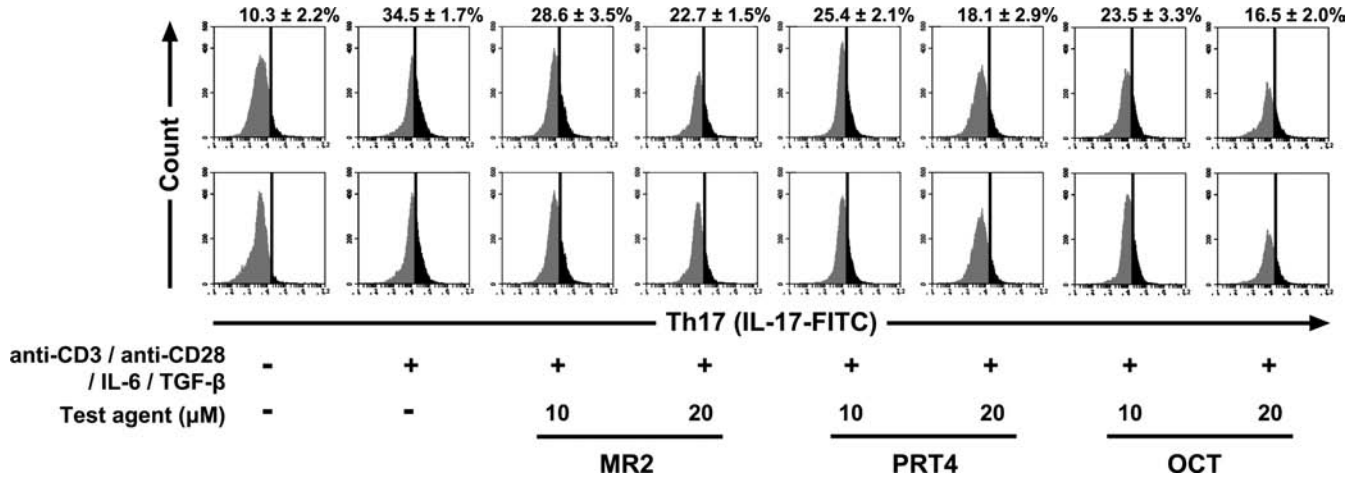

Figure 2. Effect of MR2 and its metabolites PRT4 and ocotillol (OCT) on Th17 cell differentiation. (A) Effect on Th17 cell differentiation. Splenocytes were stimulated with anti-CD3 (1 μg/mL) and anti-CD28 (1 μg/mL) with or without IL-6 (20 ng/mL) plus TGF-β (1 ng/mL) in the presence of MR2 and its metabolites (10 and 20 μM) for 4 days. Staining of cell surface CD4 antigen and intracellular IL-17 was performed and analyzed using flow cytometry. (B) Effect on cytotoxicity. For the cytotoxicity assay, cells were incubated for 4 days and survival was determined by the trypan blue method. All data indicate mean ± SD (n = 3). $^{\#}p < 0.05$ indicated a significant difference vs normal control. $^{*}p < 0.05$ indicated a significant difference vs cells stimulated with anti-CD3/anti-CD28 and IL-6/TGF-β.

Assay of Myeloperoxidase Activity. Colons were homogenized in 10 mM potassium phosphate buffer (pH 7.0) containing 0.5% hexadecyl trimethylammonium bromide, and centrifuged at 4 °C (20000g, 20 min). An aliquot (50 μL) of the supernatant was added to a reaction mixture containing 0.1 mM H_2O_2 and 1.6 mM tetramethylbenzidine and then incubated at 37 °C. The absorbance was measured at 650 nm over time.[21] Myeloperoxidase activity was defined as the quantity degrading 1 μmol/mL of peroxide and expressed in unit per mg protein. The protein amount was assayed using the Bradford protein assay reagent.

Real-Time Polymerase Chain Reaction (PCR). Reverse transcription was performed with 2 μg of total RNA isolated from the colon. Real-time PCR for IL-5, IL-10, IL-12/p35, IL-17, IL-23, TGFβ, IFN-γ, T-bet, GATA3, RORγt, Foxp3, and β-actin (Table 1) was

DOI: 10.1021/acs.jafc.5b02183
J. Agric. Food Chem. 2015, 63, 7024−7031

performed as described previously,[22] utilizing a Takara thermal cycler, which used SYBER premix agents, as per the instructions from Takara Bio Inc. Thermal cycling conditions were as follows: activation of DNA polymerase at 95 °C for 5 min, followed by 38 cycles of amplification at 95 °C for 10 s and at 60 °C for 30 s. The normalized expression of the assayed genes, with respect to β-actin, was computed for all samples by using the Microsoft Excel data spreadsheet.

ELISA and Immunoblotting. For the ELISA assay, colons were homogenized in 1 mL of ice-cold RIPA lysis buffer containing 1% phosphatase inhibitor cocktail and 1% protease inhibitor cocktail. The lysate was centrifuged (15000*g*, 4 °C) for 10 min, and the supernatant was transferred to 96-well ELISA plates.[20]

For the immunoblotting, colons were carefully homogenized in 1 mL of RIPA lysis buffer containing 1% phosphatase inhibitor cocktail and 1% protease inhibitor cocktail and centrifuged for 10 min, and the supernatant was subjected to 8−10% sodium dodecyl sulfate polyacrylamide gel electrophoresis and then transferred to nitrocellulose membrane.[20] Immunodetection was performed using an enhanced chemiluminescence detection kit.

Flow Cytometry of Th17 and Treg Cells in the Colonic Lamina Propria. To assay Th17 and Treg cells, the colons of mice were cut into small pieces, incubated with 2.5 mM EDTA at 37 °C with agitation for 20 min to remove cells, minced, and digested for 20 min with 1 mg/mL collagenase type VIII (Sigma) at 37 °C.[23] Colonic lamina propria cells were then filtered, and T cells were isolated using a Pan T cell Isolation Kit II. T cells isolated from colons were fixed and stained with anti-FoxP3 or anti-IL-17A antibodies and then analyzed by flow cytometry.

Statistical Analysis. The data are presented as the means ± standard deviation. The data of animal experiments were analyzed by one-way analysis of variance (ANOVA) followed by the Student−Newman−Keuls test for multiple comparisons. *P* values of 0.05 or less were considered statistically significant.

RESULTS

Metabolism of MR2 by Gut Microbiota. To understand the anti-inflammatory effect and absorbable metabolite(s) of MR2 in vivo, we administered MR2 orally and analyzed its metabolites in the feces after 12 h (Figure 1). The dominant metabolite was ocotillol, followed by PRT4. Next, we incubated MR2 with mouse fecal microbiota and investigated its hydrophobic metabolites absorbable from the intestine into the blood. MR2 concentration was gradually decreased, but that of ocotillol increased, followed by PRT4.

Effect of MR2 and Its Metabolites PRT4 and Ocotillol on Th17 Cell Differentiation. To understand the anti-inflammatory effects of MR2 and its metabolites, we measured their inhibitory effects against the differentiation of splenic T cells to Th17 cells, stimulated with IL-6 and TGF-β in the presence of anti-CD3 and anti-CD28 (Figure 2). Treatment with IL-6 and TGFβ significantly induced Th17 cell differentiation (34.5%). However, treatment with MR2, PRT4, or ocotillol significantly suppressed the Th17 cell population compared with nontreated cells, with the highest inhibition exhibited by ocotillol. Moreover, these ginsenosides inhibited IL-17 and RORγt expression, suggesting that MR2 and its metabolites may suppress IL-17 expression by regulating the expression of the transcription factor RORγt, resulting in the inhibition of Th17 cell differentiation.

Anticolitic Effect of Ocotillol. We investigated the anti-inflammatory effects of ocotillol in mice with TNBS-induced colitis (Figure 3). Treatment with TNBS significantly shortened the colon length and reduced body weight, similar to previous reports.[24] TNBS treatment also increased myeloperoxidase activity and showed severe disruption of mucosa and epithelial cell layers caused by ulcerations.

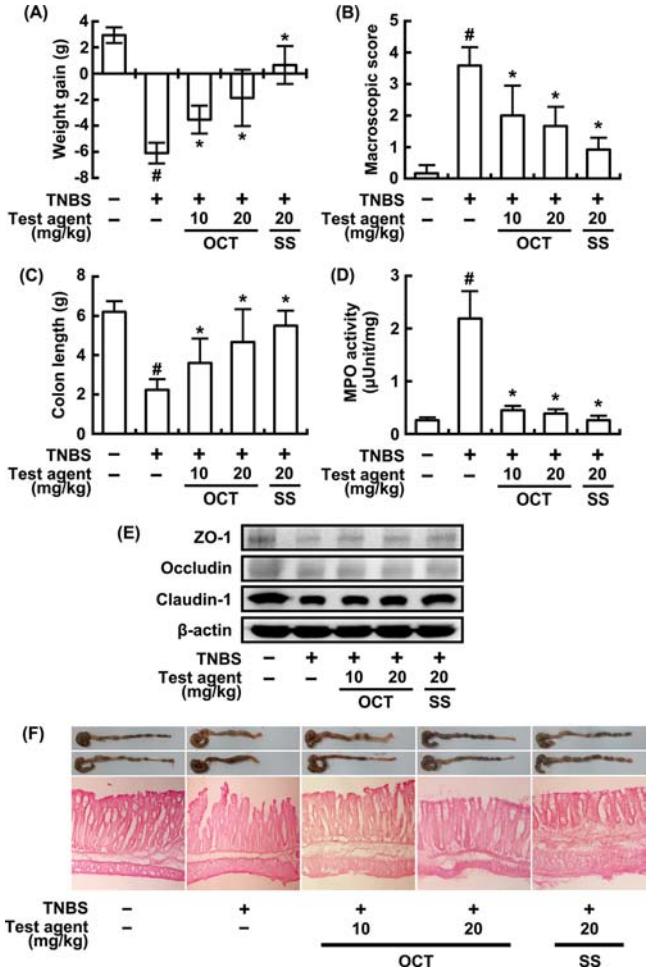

Figure 3. Effects of ocotillol on body weight (A), macroscopic disease (B), colon length (C), tight junction proteins (D), colonic myeloperoxidase (MPO) activity (E), and histological exam (F) in mice with TNBS-induced colitis. TNBS, except in the control group, was intrarectally administered to mice treated with saline, ocotillol (OCT), or sulfasalazine (SS). Test agent or saline was orally administered for 3 days after TNBS treatment. The mice were sacrificed 18 h after the final administration of test agents. All data are mean ± SD (n = 6). $^{\#}p < 0.05$ indicated a significant difference vs control group. $^{*}p < 0.05$ indicated a significant difference vs the TNBS group.

Moreover, TNBS suppressed the expression of tight junction proteins claudin, occludin-1, and ZO-1 in the colon. However, treatment with ocotillol suppressed TNBS-induced colon shortening, increased expression of the colonic tight junction proteins, and inhibited TNBS-induced myeloperoxidase activity.

Next we measured the effect of ocotillol on the expression of proinflammatory cytokines TNF-α, IL-1β, IL-6, and IL-17 and the anti-inflammatory cytokine IL-10 (Figure 4A). Ocotillol treatment suppressed TNBS-induced expression of TNF-α, IL-1β, IL-6, and IL-17. Additionally, ocotillol treatment increased TNBS-induced suppression of IL-10 expression. Ocotillol showed the greatest inhibition of TNBS-induced expression of proinflammatory cytokines and increased IL-10 expression. Next, we measured the effect of ocotillol on the expression of the inflammatory markers COX-2 and iNOS and the activation of their transcription factors NF-κB and MAPKs (Figure 4B). Treatment with ocotillol inhibited both TNBS-induced

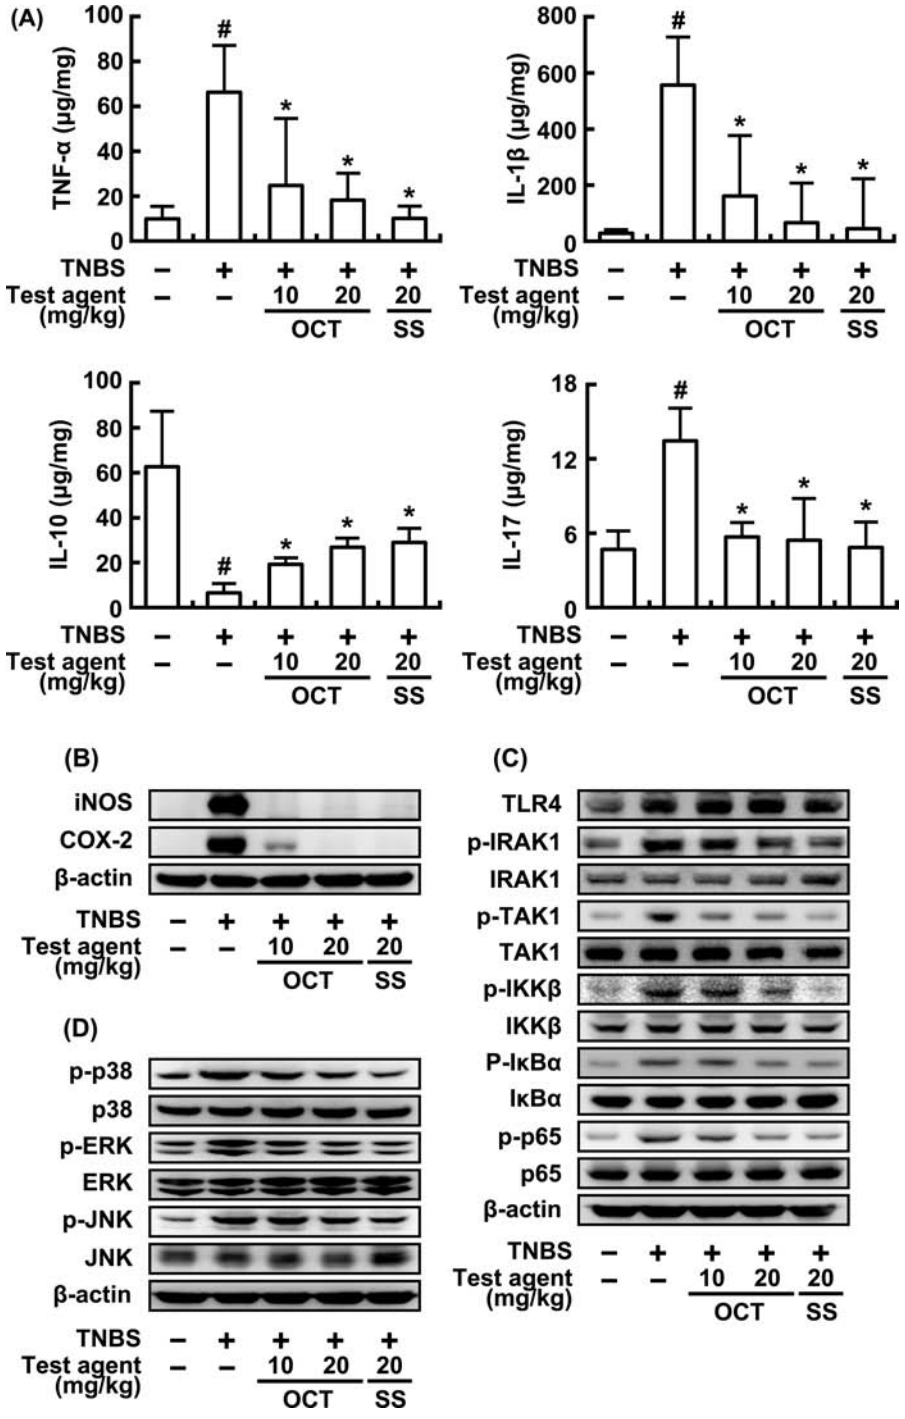

Figure 4. Effects of ocotillol on the expression of inflammatory cytokines (A), iNOS and COX-2 (B), and the activation of TLR4-NF-κB (C) and MAPKs (D) in mice with TNBS-induced colitis. TNBS, except in the control group, was intrarectally administered to mice treated with saline, ocotillol (OCT), or sulfasalazine (SS). Test agents or saline was orally administered for 3 days after TNBS treatment. The mice were sacrificed 18 h after the final administration of test agents. TNF-α, IL-1β, IL-10, and IL-17 were determined by ELISA. iNOS, COX-2, and NF-κB signaling molecules were determined by immunoblotting. All values are mean ± SD ($n = 6$). $^{\#}p < 0.05$ indicated a significant difference vs control group. $^{*}p < 0.05$ indicated a significant difference vs the TNBS group.

expression of COX-2 and iNOS and activation of NF-κB and MAPKs.

Furthermore, we investigated the effect of ocotillol on T cell differentiation in the luminal propria of the colon (Figure 5). Treatment with TNBS significantly increased Th17 cell differentiation and inhibited Treg cell differentiation. However, treatment with ocotillol inhibited TNBS-induced Th17 cell differentiation and increased Treg cell differentiation. We also measured T cell differentiation markers in the luminal propria of the colon using qRT-PCR (Figure 6). Treatment with TNBS significantly induced T-bet, RORγt, T-bet, interferon-γ, IL-5, IL-12, IL-17, and IL-23 expression and suppressed Foxp3 and IL-10 expression. Treatment with TNBS weakly, but not significantly, increased GATA3 and IL-5 expression. Ocotillol treatment, on the other hand, resulted in significant inhibition of TNBS-induced IL-12, IL-17, IL-23, and RORTγt expression,

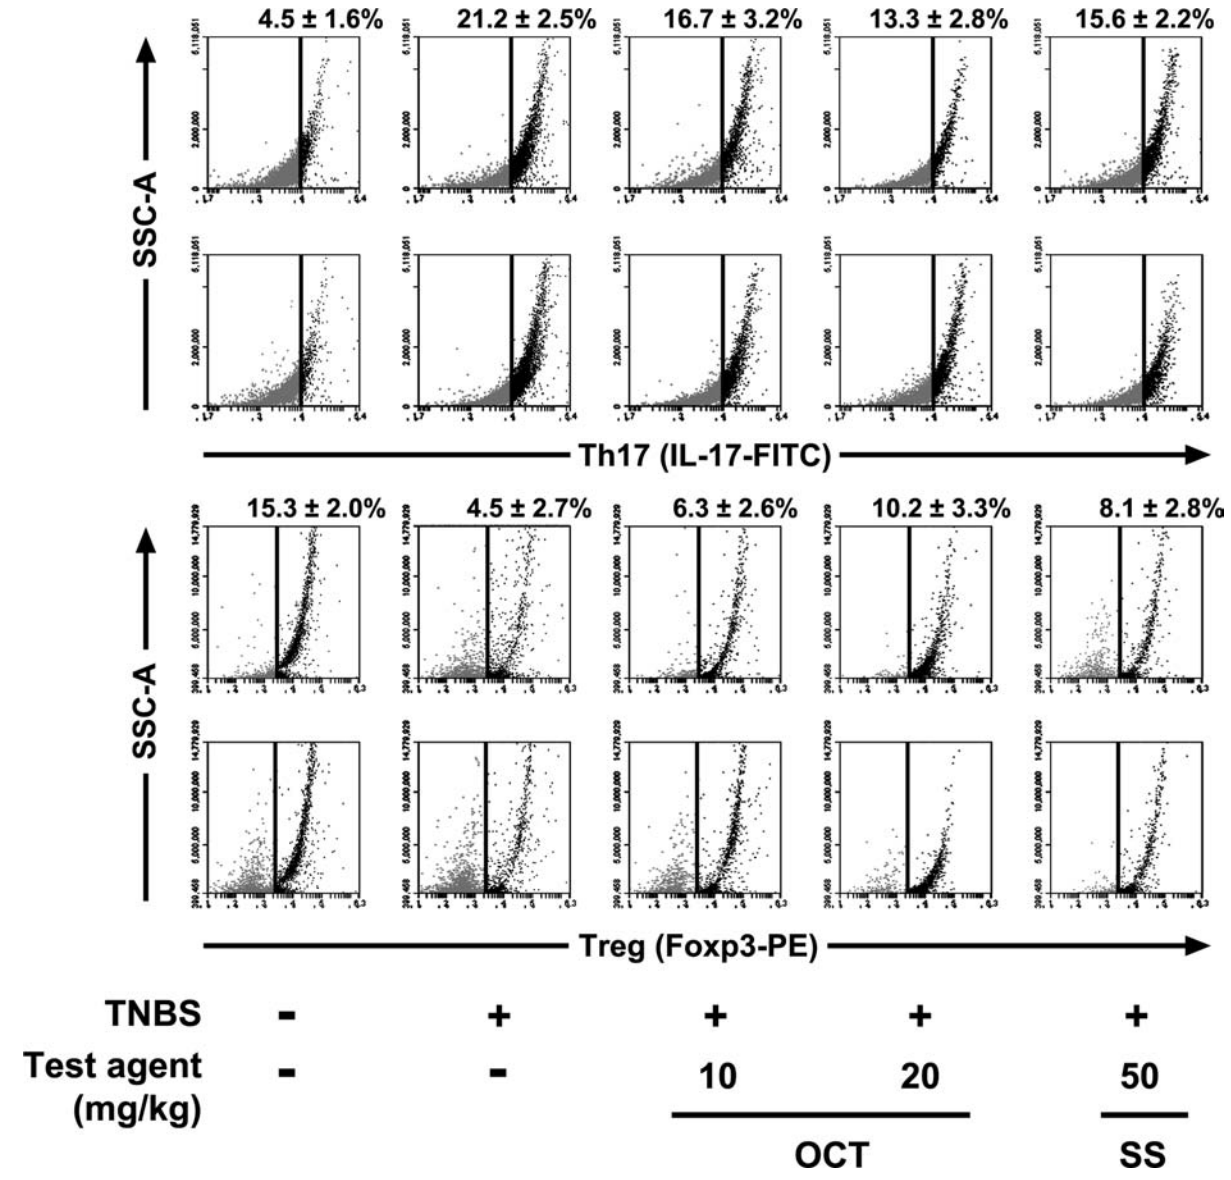

Figure 5. Effects of ocotillol on the differentiation to Th17 and Treg cells in mice with TNBS-induced colitis. TNBS, except in the control group, was intrarectally administered to mice treated with saline, ocotillol (OCT), or sulfasalazine (SS). Test agent (TO10, 10 mg/kg ocotillol; TO20, 20 mg/kg ocotillol; or SS50, 50 mg/kg SS) or saline was orally administered for 3 days after TNBS treatment. The mice were sacrificed 18 h after the final administration of test agents. The T cells were isolated from the lamina propria of the colon, and Th17 and Treg cells were then analyzed by flow cytometry. All values are mean ± SD (n = 6). $^{\#}p < 0.05$ indicated a significant difference vs control group. $^{*}p < 0.05$ indicated a significant difference vs the TNBS group.

whereas Foxp3 and IL-10 expression increased. Treatment with ocotillol, however, did not significantly influence GATA3 and IL-5 expression.

DISCUSSION

Mucosal dendritic cells and macrophages present pathogens as antigens to the adaptive immune system in the colon and direct the differentiation of naive CD4+ T cells to various effector T-helper (Th1, Th2, and Th17) and Treg cells.[25] Thus, dendritic cells and macrophages promote Th17 differentiation by secreting IL-23, thereby sustaining and reinforcing the Th17 phenotype. Moreover, IL-23 induces proinflammatory cytokines such as TNF-α, IFN-γ, and IL-6 in the colon and inhibits Foxp3+ Treg cells, resulting in chronic colitis. Foxp3+ Treg cells regulate immune responses by suppressing Th effector cells.[26] However, in IBD patients, the number of Foxp3+ Treg cells, which produce an anti-inflammatory cytokine IL-10, is reduced in the peripheral blood and intestinal mucosa. Additionally, Th17 cell differentiation is induced in inflamed colons of mice and patients with IBD,[27] which subsequently increases the production of IL-17A and IL-17F by regulation of transcription factor RORγt expression.[28] IL-17 simulates the inflammatory response, and therefore, excessive Th17 and deficient Treg responses contribute to IBD. The effects of several natural products such as icariin, apigenin, baicalin, and resveratrol have been studied for their roles in the activation of Foxp3+ Treg cell differentiation or/and the inhibition of Th17 differentiation in order to correct Th17/Treg imbalance in autoimmune diseases.[29−32]

Ginsenosides, which are representative constituents of *Panax ginseng*, *Panax quinquefolius*, and *Panax vietnamensis*,[33] are structurally classified into protopanaxadiol, protopanaxatriol,

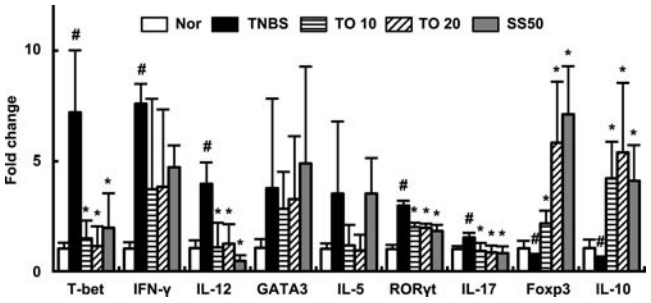

Figure 6. Effects of ocotillol on the expression of T cell cytokines, IL-23, and T cell transcription factors in mice with TNBS-induced colitis. TNBS, except in the control group, was intrarectally administered to mice treated with saline, ocotillol, or sulfasalazine (SS). Test agent (TO10, 10 mg/kg ocotillol; TO20, 20 mg/kg ocotillol; or SS50, 50 mg/kg SS) or saline was orally administered for 3 days after TNBS treatment. The mice were sacrificed 18 h after the final administration of test agents. IL-5, IL-10, IL-12, IL-17, IL-23, interferon (IFN)-γ, T-bet, GATA3, RORγt, and Foxp3 in colon were by real-time PCR. All values are mean ± SD (n = 6). $^{\#}p < 0.05$ indicated a significant difference vs control group. $^{*}p < 0.05$ indicated a significant difference vs the TNBS group.

ocotillol, and oleanane types depending on their aglycons. Many ginsenosides suppress inflammation.[24,34,35] Ginsenoside Rb1 and its metabolite compound K, which is a protopanaxadiol-type ginsenoside, ameliorate dextran sulfate sodium- or TNBS-induced colitis by inhibiting IRAK-1 activation in the NF-κB signaling pathway.[24,37] Ginsenoside Rd ameliorates TNBS-induced colitis in rats by inhibiting the signaling pathway of MAPKs (p38 and JNK).[36] Ginsenoside Rh2, which is a protopanaxadiol-type ginsenoside, improves dextran sulfate sodium-induced colitis by activating the TGFβ signaling pathway.[38] These results suggest that orally administered protopanaxadiol-type ginsenosides may be metabolized to compound K or ginsenoside Rh2 by gut microbiota and, in turn, these metabolites may ameliorate inflammation by inhibiting the NF-κB and MAPK signaling pathways as well as alleviating TGFβ signaling pathway. Protopanaxatriol-type ginsenoside Re also ameliorates TNBS-induced colitis in mice, by inhibiting the NF-κB signaling pathway.[39] However, the effects of ginsenosides in Th17 and Treg differentiation have not been studied thoroughly.

In the present study, when MR2 was orally administered to mice, MR2 was metabolized to ocotillol via PRT4. Therefore, we investigated anti-inflammatory effects of MR2 and its metabolites in vitro and in mice with TNBS-induced acute colitis, which is frequently used for understanding the anticolitic effects (efficacy and mechanism) of drugs and phytochemicals.[24,36] Ocotillol strongly ameliorated TNBS-induced iNOS and COX-2 expression, as well as activation of their transcription factors NF-κB and MAPKs in mice. Ocotillol was found to ameliorate TNBS-induced colitis in mice by reversing TNBS-induced shortening, myeloperoxidase activity, and attenuation of tight junction protein expression in the colon. Additionally, ocotillol inhibited the expression of proinflammatory cytokines TNF-α, IL-1β, IL-6, IL-17, IL-23, and IFN-γ, while increasing IL-10 expression. Moreover, ocotillol treatment inhibited Th17 cell differentiation in vitro and in vivo. These results suggest that ocotillol may regulate inflammation by regulating T cell differentiation. This was confirmed by the finding that ocotillol significantly inhibited TNBS-induced Th17 cell differentiation and increased Treg cell differentiation suppressed by TNBS in mice. Moreover, ocotillol suppressed TNBS-induced expression of Th1-producing cytokines IL-12 and interferon-γ, as well as their transcription factor T-bet in mice. Additionally, ocotillol inhibited TNBS-induced expression of Th17 cell-derived cytokine IL-17 and its transcription factor RORγt, while also increasing Treg cell-derived cytokine IL-10 and its transcription factor Foxp3, in mice with TNBS-induced colitis. However, ocotillol did not influence the expression of Th2 cell-derived cytokine IL-5 and its transcription factor GATA3. Moreover, ocotillol inhibited differentiation to Th17 cells in vitro. These results suggest that ocotillol may restore TNBS-induced imbalance of Th17/Treg cells. Additionally, the long-term administration of majonoside R2 may be quickly transformed to ocotillol, which may strongly show anticolitic effect. These findings suggest that orally administered MR2 may be metabolized to ocotillol via PRT4, which may ameliorate colitis by restoring Th17/Treg balance via the regulation of their cytokine expression.

alternative substrate and producing an *o*-quinone other than *o*-dopaquinone, rather than inhibiting the enzyme. Owing to the nonadjacent meta disposition of the two hydroxyl groups in HR, the diphenolase activity of tyrosinase is not possible on this compound but it can be hydroxylated in the ortho position due to the monophenolase activity of the enzyme. For the enzyme to act on monophenols, the presence of the enzymatic form, E_{ox}, is necessary. In the case of L-tyrosine, this can be achieved through the formation of *o*-diphenol from *o*-dopaquinone in the reaction medium.[32] Many monophenolic compounds have been described as tyrosinase inhibitors, although they are really alternative substrates, because, after their testing with the enzyme, it shows no activity. This is because the monophenol gives rise to an *o*-quinone that evolves chemically without originating *o*-diphenol in the medium, so there is no turnover on the part of the enzyme (and the E_{ox} form is not generated).

Our previous studies on the action mechanism of tyrosinase[33,34] revealed that the enzymatic form E_{ox} and, therefore, the monophenolase activity of the enzyme can be observed by adding one of the following to the reaction medium: (a) a reductant (ascorbic acid, AH_2) capable of transforming E_m to E_d, which, with oxygen, generates E_{ox}, b) hydrogen peroxide, which transforms E_m to E_{ox} or c) catalytic concentrations of *o*-diphenol (to transform E_m to E_d, which, with oxygen, becomes E_{ox}) and a reductant (AH_2 or NADH) to keep the quantity of *o*-diphenol in the medium constant, so that E_{ox} continues to be generated.[35−39]

The aim of this study is to demonstrate that HR is not an inhibitor but an alternative substrate of tyrosinase. We propose a kinetic mechanism to explain the action of the enzyme on this compound, the kinetic analysis of which leads us to obtain the analytic expression of the *o*-quinone formation rate. From the expression obtained, an experimental design that permits the kinetic characterization of the HR is established. This aspect should be taken into consideration by the food, cosmetics, and pharmaceutical industries when using HR as an antibrowning and depigmenting agent.

MATERIALS AND METHODS

Enzyme Source. Mushroom tyrosinase (3130 U/mg) was purchased from Sigma (Madrid, Spain) and purified as previously described.[40] Bradford's method was used to determine the protein content using bovine serum albumin as standard.[41]

Reagents. The substrate, L-dopa, 4-hexylresorcinol (HR, Figure 1), *tert*-butylcatechol (TBC), reduced β-nicotinamide adenine dinucleotide (NADH), hydrogen peroxide (H_2O_2) and ascorbic acid (AH_2) were obtained from Sigma. To prevent autoxidation, stock solutions of L-dopa, TBC, and HR were prepared in 0.15 mM phosphoric acid. Milli-Q system (Millipore Corp.) ultrapure water was used throughout.

Spectrophotometric Assays. These assays were carried out with a PerkinElmer Lambda-35 spectrophotometer, online interfaced with a compatible PC 486DX microcomputer controlled by UV-Winlab software, where the kinetic data were recorded, stored, and later analyzed.

The activity of tyrosinase on L-dopa[42,43] was measured at 475 nm, the maximum absorption wavelength of dopachrome. The activity of tyrosinase on HR as a substrate was measured in the presence of (a) hydrogen peroxide, (b) ascorbic acid, and (c) catalytic concentrations of TBC and NADH as reductant to maintain the *o*-diphenol in the medium constant and to ensure the constant generation of the enzymatic form E_{ox}.[35−37] Recordings were made at 490 nm, the maximum absorption wavelength of the *p*-quinone generated.

All of the assays were carried out at 25 °C, using 30 mM phosphate buffer, pH 7.0, and beginning the reaction by adding the enzyme to the reaction medium. Three repetitions of every experiment were made.

Kinetic Analysis Data. Initial rate values ($V_0^{p\text{-}Q}$) were calculated at different substrate concentrations. The assays were carried out in saturating conditions of H_2O_2 and oxygen.[44−46] In these conditions, the equation rate obtained (eq A1) using the REFERASS computer program[47,49] was simplified to eq 1 (equivalent to eq A12) (see the Appendix). $V_0^{p\text{-}Q}$ versus $[HR]_0$ data were represented and fitted to the Michaelis−Menten equation using the Sigma Plot 9.0 program for Windows,[50] obtaining the maximum rate ($V_{max}^{p\text{-}Q}$) and the Michaelis constant (K_M^{HR}).

Nuclear Magnetic Resonance. ^{13}C NMR spectra of HR and the rest of the monophenols were obtained in a Varian Unity spectrometer of 300 MHz at the optimum pH for mushroom tyrosinase (6.8) and using D_2O as solvent for the substrates. The δ values were measured relative to those for tetramethylsilane (δ = 0). The maximum line width accepted in the NMR spectra was 0.06 Hz. Therefore, the maximum accepted error for each peak was ±0.03 ppm.[51,52]

RESULTS AND DISCUSSION

4-Hexylresorcinol as an Apparent Inhibitor of Tyrosinase. HR was assayed as a possible inhibitor of the diphenolase activity of tyrosinase. Recording the enzyme's activity on L-dopa in the absence and presence of various concentrations of HR, a strong inhibitory effect was evident from the decrease in the dopachrome formation rate at very low concentrations of HR (Figure 2), as described in the bibliography.[5,6,9,11,13−31] The recordings enabled the degrees of inhibition to be calculated and, by nonlinear regression, the IC_{50} value: IC_{50} = 0.33 ± 0.02 μM (Figure 2, inset).

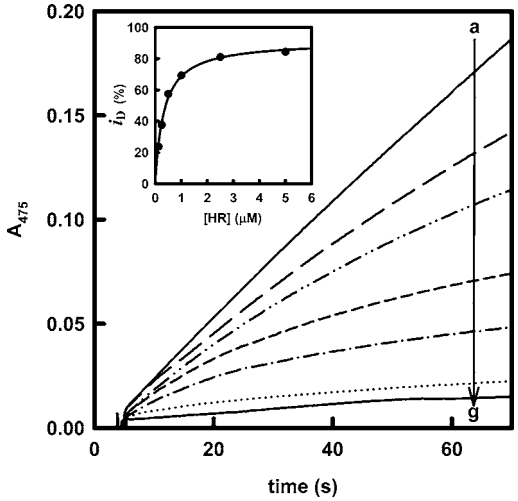

Figure 2. Diphenolase activity of tyrosinase on L-dopa in the absence (a) and presence of different concentrations of HR (μM): (b) 0.13; (c) 0.25; (d) 0.50; (e) 1.00; (f) 2.50; (g) 5.00. The rest of the experimental conditions were $[D]_0$ = 0.5 mM and $[E]_0$ = 8 nM. (Inset) Degree of inhibition of the diphenolase activity in the presence of HR obtained from the experimental assays.

Because HR has a structure analogous to that of monophenolic substrates of tyrosinase and bearing in mind studies that demonstrate that established inhibitors with structures similar to classic substrates of the enzyme act as alternative substrates of tyrosinase,[35−37,53,54] we decided to assess the activity of this enzyme on HR.

4-Hexylresorcinol as Substrate of Tyrosinase. After assaying the action of tyrosinase on HR, we observed zero

activity (data not shown). Given the structure of the compound, it can be deduced that even if it is a substrate of the enzyme, this result will always be negative, because the molecule is a *m*-diphenol and, among the three possible forms of the enzyme (E_m, E_d, and E_{ox}), only E_{ox} can act on it by hydroxylation (monophenolase activity). The E_m form cannot oxidize it because the molecule does not have hydroxyls in ortho position. Between 2 and 30% of the native enzyme may be in the form E_{ox},[55] which is the enzymatic form that initiates the action on monophenols. The E_{ox} form hydroxylates HR and is transformed into E_m, which has to regenerate E_{ox} for the catalysis to continue.

The regeneration of this enzymatic form (E_{ox}) in the assay medium can be attained in the presence of hydrogen peroxide, ascorbic acid, or catalytic concentrations of *o*-diphenol and a reductant such as ascorbic acid or NADH, which reduces the *o*-quinone generated from the *o*-diphenol, maintaining it constant in the reaction medium.[35−37] In this way, the activity of tyrosinase on HR was measured.

Enzymatic Activity in the Presence of Hydrogen Peroxide. To assay the action of tyrosinase on HR in the presence of H_2O_2, recordings were made of the changes in absorbance with time at different wavelengths (Figure 3). As

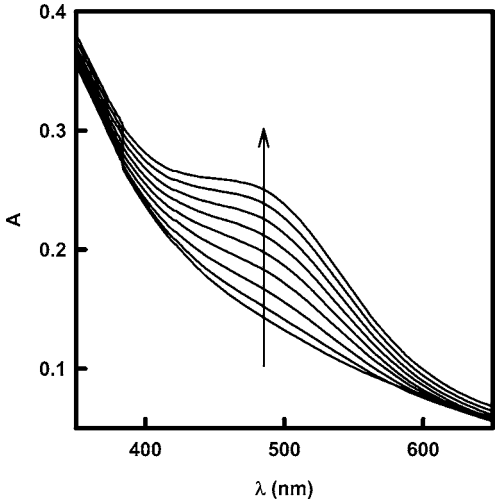

Figure 3. Scan spectra of the action of tyrosinase on HR in the presence of hydrogen peroxide. The experimental conditions were $[HR]_0$ = 100 μM, $[H_2O_2]_0$ = 30 mM, and $[E]_0$ = 345 nM. Recordings were made every 1 min.

can be seen, absorbance varied between 350 and 650 nm, with a maximum at 490 nm, indicating the formation of a new product during the reaction. To confirm that this product proceeded from the enzymatic reaction and not from the attack of HR by H_2O_2, we recorded the absorbance of the HR at 490 nm in the presence of H_2O_2 and in the absence of enzyme (Figure 4, recording a). Note that the absorbance signal did not change, meaning that the HR was not attacked by the H_2O_2 during the time that measurements were made, so that the compound generated was a product of the enzymatic reaction. Moreover, when the activity on HR was measured in the presence of different concentrations of tyrosinase, the initial rate increased with the concentration of enzyme (Figure 4).

To explain the activity of tyrosinase on HR in the presence of H_2O_2, we propose a structural mechanism (Figure 5). As can be seen in the figure, tyrosinase hydroxylates HR in position 6 and

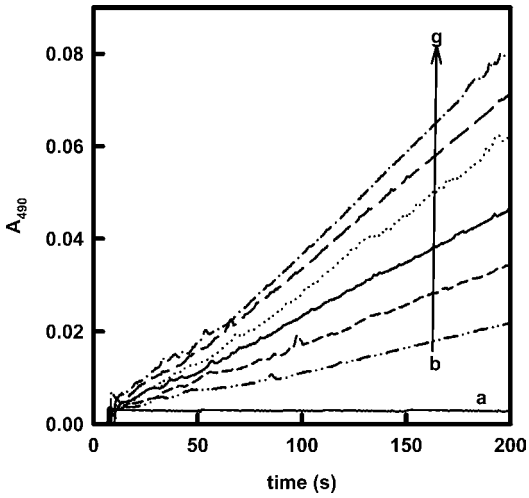

Figure 4. Spectrophotometric recordings at 490 nm of the action of tyrosinase on HR in the presence of different concentrations of tyrosinase (nM): (a) 0; (b) 140; (c) 210; (d) 275; (e) 345; (f) 415; (g) 485. The rest of the experimental conditions were $[HR]_0$ = 0.5 mM and $[H_2O_2]_0$ = 30 mM.

subsequently oxidizes it to *o*-quinone, which rapidly isomerizes to *p*-quinone.[56−59]

Enzymatic Activity in the Presence of Ascorbic Acid. Similarly to the above, the activity of tyrosinase on HR was assayed by adding ascorbic acid to the reaction medium, thus transforming E_m to E_d, which, with oxygen, gives rise to E_{ox}. Recordings were made of the absorbance with time at different wavelengths (Figure 6). As in the presence of H_2O_2, the presence of ascorbic acid led to an increase in absorbance between 350 and 650 nm, with a maximum once again at 490 nm. Figure 7 displays a kinetic mechanism to explain the action of tyrosinase on HR in the presence of ascorbic acid.
