In this study, the ratios of Z11–14:Ac to Z9–14:Ac through the entire photoperiod were not very constant, with some ratios being close to our previously found ratio of 1.77 (Kou et al., 1990). Although the "pooled sample" technique was used in this study, ratio changes were within the range of the most frequently observed ratios from individual analysis (Kou and Chow, 1991). The ratio change through the third day may be attributed to the precise regulation mechanism of biosynthesis and/or release rate of these two compounds.

The result of field tests showed that male response specificity to alternating sex pheromone component ratios observed at different times during the calling period did not differ significantly, but the most attractive ratio (Z11–14:Ac/Z9–14:Ac = 1.78 and 1.94) was very close to our previously identified ratio (Z11–14:Ac/Z9–14:Ac = 1.77). Although in the red-banded leaf-roller, *Argyrotaenia velutinana*, the ratio of Z11–14:Ac/*E*11–14:Ac was found to be precisely regulated to 91:9 (Miller and Roelofs, 1980), males of some moths can respond to a large variation in the ratio of sex pheromone components (Löfstedt et al., 1985; Schlyter and Birgersson, 1989). We shall further investigate the emission rate and the blend ratio of the released sex pheromone of *A.* sp.

Recent studies suggest that in most moth species calling is controlled by input from the brain or other nervous centers (Itagaki and Conner, 1987), whereas the production of pheromone is under neuroendocrine control. A peptide, which in *H. zea* is composed of 33 amino acids, has a molecular weight of 3900 and is localized in the suboesophageal ganglion portion of the brain complex where it regulates pheromone production (Raina et al., 1989). Whether *A.* sp. also uses the same physiological mechanism to control calling behavior and pheromone production needs further study.

Acknowledgments—I thank the Taiwan Tea Experiment Station for supplying the smaller tea tortrix moths; this study was supported in part by a grant from the National Science Council, NSC 78-0414-P 001-01 A.

(Received August 25, 1991; accepted January 29, 1992)

Abstract—Trapping experiments were carried out near Winnipeg, Canada, in the spring of 1987 and 1988 to test attraction of crucifer-feeding flea beetles to volatile glucosinolate (GS) hydrolysis products released from glass vials. Nine isothiocyanates (IC) or mustard oils and three nitriles (CN) were tested. The pattern of attraction was the same for both flea beetle species, *Phyllotreta cruciferae*, and *P. striolata*. Captures in traps baited with allyl IC increased as release rates increased from 0.04 mg/day to 40 mg/day. The lowest rate that attracted large numbers of beetles was 4 mg/day; therefore this rate was used for further experiments. More beetles were captured in traps baited with allyl IC than with any other compound. In 1988 only, four IC in addition to allyl IC were attractive to both species; namely, benzyl IC, ethyl IC, and a mixture of ethyl and methyl 4-isothiocyanatobutyrate (ICB). When captures of the two species were pooled, 3-methylthiopropyl IC, methyl ICB, and *n*-butyl IC were also found to be significantly attractive. Nitriles were the least attractive compounds. The high release rates of mustard oils required to attract flea beetles indicate that fields of *Brassica* crops would release sufficient quantities of IC to attract flea beetles from a distance but individual or small groups of plants normally would not. It is concluded that *Brassica* varietal resistance to flea beetles is unlikely to be affected by manipulating IC release.

Key Words—Coleoptera, Chrysomelidae, Alticinae, *Phyllotreta cruciferae*,

INTRODUCTION

All plants of the Brassicaceae as well as species in several other plant families are known to contain one or more glucosinolates (GS), a group of naturally occurring anionic compounds whose known number totals almost 100. Cells of these plants also contain the enzyme myrosinase, which facilitates hydrolysis of these compounds to isothiocyanates (IC) or mustard oils, nitriles (CN), and other compounds, depending upon pH and other conditions (Chew, 1988). Some hydrolysis probably takes place during normal catabolysis, particularly during early seedling development, but also occurs rapidly when plant tissue is damaged (Van Etten and Tookey, 1979). As IC have toxic properties to birds, insects, and monogastric mammals (Van Etten and Tookey, 1979; Ahman, 1986), their formation in response to damage is thought to be, at least in part, a plant defense mechanism.

However, a number of insect species feed primarily or exclusively on plants containing GS. Many of these insects are known to suffer no adverse effects from naturally occurring concentrations of GS and IC. It has been well documented that at least some crucifer-specialist insects are stimulated to feed or oviposit in the presence of GS. Some insects are also attracted by one or more of the IC (Chew, 1988).

It has been known for over 30 years that flea beetles are attracted to allyl IC (Görnitz, 1956), a volatile hydrolysis product of allyl GS or sinigrin. It has been assumed that this was the major means by which crucifer-feeding flea beetles located their host plant (Feeny et al., 1970). However, more recent work has demonstrated that this relationship is not nearly so simple. The striped flea beetle, *Phyllotreta striolata* (F.) (Lamb and Palaniswamy, 1990), and the crucifer flea beetle, *P. cruciferae* (Goeze) (Pivnick, unpublished), do not necessarily discriminate between host and nonhost plants until after they are either in very close proximity or have landed on them. These are the two major pest species of flea beetles in western Canada (Lamb and Turnock, 1982), and their host-plant range is confined to the Brassicaceae (Feeny et al., 1970).

Phyllotreta spp. are stimulated to feed in the presence of GS and most GS tested have been similar in their effect (Hicks, 1974; Nielsen, 1978). To date, most feeding specificity of flea beetles within the family Brassicaceae is thought to be due to the presence of various feeding deterrents such as cucurbitacins and cardenolides (Nielsen, 1978). The nonspecificity of the response to GS suggests that attraction to IC would also be nonspecific; indeed, this has often been assumed. However, in a recent study of the northern false chinch bug, *Nysius niger* Baker, a polyphagous insect that has a preference for crucifers, response

to different IC was highly variable (Pivnick et al., 1991). As one step toward understanding the ecological significance of the response to IC by flea beetles and, possibly, toward using this response to manage the pest species, an understanding of the specificity of response to mustard oils is needed. In this paper, we examine the attraction of flea beetles to a number of different GS degradation products, both IC and CN, in field trapping experiments.

METHODS AND MATERIALS

Field trapping was carried out in 1987 on the University of Manitoba campus in Winnipeg, and at Glenlea, Manitoba, and in 1988 at Glenlea only. Trapping sites were next to cultivated fields, along the edge of wooded areas where beetles overwinter, except for one replicate set out on a trail through the woods at Glenlea in 1987. Traps were set out on the ground in a randomized complete block design, with three replicates and a minimum of 10 m between traps within a replicate. Yellow plastic boll weevil traps with a clear plastic funnel and ball trap top were used (Pest Management Specialists, Starkville, Mississippi). Baits were held upright in the center of the bases of the trap with adhesive tape. IC and CN baits, all neat liquids, were released from vials made from glass tubing, 3.5-ml serum vials, and pipets, all sealed at one end, as in Pivnick et al. (1991). The release rate of any given compound was directly proportional to the internal diameter of the container and inversely proportional to the length of the air column above the meniscus of the compound. The dimensions used were designed to give the approximate desired release rates with little change over the period of the tests, which lasted up to a maximum of 25 days. Control of release rates was always approximate, as weather conditions could modify the release rates but would do so uniformly across all baits.

The compounds tested were obtained from: Aldrich Chemical Co. (allyl IC, benzyl IC, 2-phenylethyl IC, ethyl IC, allyl CN, benzyl CN, methyl CN); Eastman-Kodak Co. (*n*-butyl IC, phenyl IC); or synthesized at the Plant Biotechnology Institute (PBI) according to methods described or referenced in Pivnick et al. (1991) [3-methylthiopropyl IC, a 1 : 1 mixture of ethyl and methyl 4-isothiocyanatobutyrate (ethyl/methyl ICB; these are IC), and methyl and ethyl ICB, synthesized individually]. All compounds are known to occur in plants except ethyl ICB and phenyl IC.

Vial dimensions used for release of allyl IC in 1987 were as follows. Air column lengths were 40 mm and internal diameters were 3.3, 0.85, and 0.27 mm for intended release rates of 4, 0.4, and 0.04 mg/day, respectively (based on prior empirical tests). For 40 mg/day, a half-filled 7-dram serum vial was used, capped with a rubber septum with a pipe cleaner inside as a wick. Actual release rates for all compounds were determined by measuring the length of the

air column both before and after the experiment. As vial dimensions used in 1988 for compounds other than allyl IC gave release rates much closer to the desired rates than for the same compounds in the second experiment in 1987, only 1988 dimensions for vials of these compounds are reported here. However, actual release rates are reported for both years. For allyl IC, allyl CN, methyl CN and ethyl IC at 4 mg/day in 1988, dimensions were as for allyl IC at the same rate in 1987. Internal diameters and air column lengths for release at 4 mg/day were 3.3 and 5 mm for methyl ICB, 5 and 5 mm for 2-phenylethyl IC, and 5 and 10 mm for all the other compounds. At 0.04 mg/day, internal diameters and air column lengths were 0.27 and 40 mm for ethyl IC, 0.60 and 10 mm for 2-phenylethyl IC, and 0.60 and 20 mm for the three other compounds.

From April 21 to 28, 1987, a dose–response experiment was carried out with allyl IC released at 0.04, 0.4, 4, and 40 mg/day, to determine the lowest rate at which enough beetles could be captured for comparison of attraction to different compounds. From April 30 to May 25, 1987, a second experiment was carried out to compare the attraction of 11 compounds, plus a mixture of two compounds at an estimated release of 4 mg/day and a blank control. From May 9–16, 1988, the same compounds and blank were tested again, along with one additional IC released at the same rate plus five of the compounds additionally tested at a release rate of 0.04 mg/day. These five compounds had shown weak evidence of attractiveness to flea beetles the previous year. In the two 1987 experiments, traps were emptied five times while in 1988 they were emptied only once at the end of the experiment.

Square-root-transformed data were analyzed by two-way ANOVA followed by unprotected LSD tests. Treatments where no beetles were captured in any of the replicates were not included in the analyses.

RESULTS

In the 1987 allyl IC dose–response experiment, the number of beetles captured increased with release rate in a similar pattern over the entire range tested for all three species caught in significant numbers: *P. cruciferae*, *P. striolata*, and *P. pusilla* Horn (Table 1). A release of 0.4 mg/day appeared to be the lowest rate at which beetles were attracted, although the number caught at this rate was not significantly higher than at 0.04 mg/day. Additional beetles were collected on the tapes that held the baits in place as well as in the bait vials. Beetles in the vials were not abundant enough to significantly affect release rates. This experiment indicated that 4 mg/day was the lowest rate that attracted high numbers of beetles, and thus was the standard rate used in subsequent experiments.

In the second experiment in 1987, only two beetle species were collected:

P. cruciferae and *P. striolata*, and again the trap captures were very similar between the two species (Table 2). Of the baits tested, allyl IC was the only bait that attracted large numbers of beetles, and it was the only bait that attracted significantly more beetles of each species than did the blank. However, there was an indication that other baits might be attractive as several caught more than the blanks. The measurements of change in bait compound levels indicated

a lack of uniformity of release rates that may have affected trap captures. Eight of the compounds were released from the baits at approximately one tenth of the desired rates. Partly because of this, and because of the ambiguous results with some of the baits, the experiment was repeated in 1988.

In 1988, trapping took place over a shorter period of time: only one week as compared to 26 days in 1987. Even so, a greater number of beetles were caught in the second year (Table 3). In this experiment, release rates were more uniform, although rates could not be measured in some vials for a variety of reasons. For example, many flea beetles accumulated in the vials of allyl IC making accurate measurement impossible. Relatively more beetles were captured with baits other than allyl IC than in the previous trapping experiment although captures in traps baited with allyl IC were still significantly greater

than with any other compound for both species of flea beetle. Three IC—benzyl IC, ethyl IC, and ethyl/methyl ICB—were also significantly attractive for both species. When captures of the two species were pooled, 3-methylthiopropyl IC, methyl ICB, and *n*-butyl IC were also significantly attractive. Because the blank traps caught no beetles, it is likely that captures in traps with some of the other baits also were indicative of attraction. Nitriles were among the least attractive. In all cases, traps baited with compounds at standard release rates (4 mg/day) caught more beetles than did those traps that released at 1% of the standard rates. No important differences were detected in the attractiveness of the baits for the two flea beetles species. In 1988, there was a correlation between the number of beetles caught in the traps and those caught in the vials (for *P. cruciferae*, $r = 0.54$, and for *P. striolata*, $r = 0.61$, with $P < 0.001$ in both cases).

Small numbers of additional flea beetle species, two in 1987 and 13 in 1988, were caught but not included in the tables.

DISCUSSION

These results are the first demonstration that *P. cruciferae* and *P. striolata* discriminate among the hydrolysis products of glucosinolates. Most of the IC tested were attractive to the beetles, whereas the CN tested were only weakly so or not attractive. This difference in the attractiveness of IC and CN is perhaps not surprising; when intact or macerated at room temperature, most crucifers release much more IC than CN, although the relative release rates vary among species (Cole, 1976). The beetles also discriminated among the IC; allyl IC was consistently the most attractive to both flea beetle species. This result contrasts with results for the cabbage stem flea beetle, *Psylliodes chrysocephala* L., which has a strong electroantennogram response to three other IC but not to allyl IC (Blight et al., 1989). The other IC were much less attractive than allyl IC; 2-phenylethyl IC, ethyl ICB, and phenyl IC released at 4 mg/day were not significantly attractive.

In a similar test, the northern false chinch bug also showed strong IC preferences (Pivnick et al., 1991). In this case, ethyl ICB, which does not occur naturally, was the most preferred, although several other IC tested were also attractive. In neither the chinch bug study nor the present one is there an obvious ecological reason for the specificity. Presumably, the most preferred compound or a closely related one is given off by an important present or ancestral host plant.

The pattern of attraction to the baits was similar in both years that the tests were conducted, but there were quantitative differences between years. The relative attraction of allyl IC compared to the other IC was much less in 1988

than in 1987, although allyl IC was the most attractive in both years. Trap saturation did not occur with the numbers caught and could not account for this difference between years. Variation in release rates was also an unlikely explanation for the difference, as can be seen by a comparison of the release rates of ethyl IC, which were similar in the two years, and yet the catches in the traps baited with ethyl IC were relatively much higher in 1988 than in 1987. The release rates of allyl IC in 1988 might have been slightly higher than in 1987 because of the large number of beetles that entered the vials in 1988; a laboratory simulation of this situation showed that the release rate would rise temporarily under these circumstances. However, the dose–response test with allyl IC indicates that an increase in the release rate above 4 mg/day would have increased the attractiveness of the traps baited with allyl IC, not reduced its attractiveness, as required to explain the relatively small difference between allyl IC and ethyl IC in 1988. The relative response of the beetles probably differed in the two years because of differences in the availability of food and their hunger level. In 1987, soil moisture was plentiful and both weedy and crop hosts were abundant, whereas in 1988 there was a severe spring drought and few host plants were available to the beetles. Therefore, the beetles were likely hungrier in 1988 than in 1987. Hungry beetles may have been more likely to respond to the less attractive odors than well-fed beetles (Miller and Strickler, 1984).

Our results do not suggest that both *P. cruciferae* and *P. striolata* are attracted equally to IC, simply that the pattern of attraction is the same. Vincent and Stewart (1984) found that *P. cruciferae* was more strongly attracted to allyl IC than *P. striolata*. We have no way of independently assessing abundance, as our control traps caught very few beetles. This low capture in control traps was surprising, as Vincent and Stewart (1986) found a strong response of the same two species to yellow and white traps in the absence of odors. The low response to our control traps was likely because our traps were old and faded. *P. pusilla*, normally a relatively rare species, was also attracted to allyl IC, but only in the first experiment, which was the only experiment to take place in April.

A release rate of 0.04 mg/day was tested for some compounds in 1988 because our results in 1987 suggested that these compounds may be attractive. Matsumoto (1970) found that some of the less volatile IC were attractive to the vegetable weevil, *Listroderes obliquus* (Klug), at lower rates of release than were some of the other IC. However, his results could also be interpreted to mean that his preparation technique, which involved heating the release substrate to 65°C for 30 min to evaporate solvent, may have eliminated most of the more volatile IC. In any case, we have no evidence of dose–response patterns that differ between IC. Captures in response to all baits at the lower rate were all less than the same baits at 4 mg/day, indicating a pattern similar to the dose–response for allyl IC.

Oriental mustard, *Brassica juncea* (L.) Czern., contains primarily allyl GS and hence releases primarily allyl IC. Measured release rates of allyl IC from *B. juncea* indicate that a trap releasing 4 mg/day of allyl IC is equivalent to the release from 2000 freshly damaged plants or 270,000 intact plants of *B. juncea* at the flower bud stage (Pivnick and Jarvis, 1991). If the plants were younger, even more would be required. Therefore, our results indicate that allyl IC release by individual or small groups of plants normally would not attract many beetles, although release by whole fields certainly would. Canola varieties of *B. napus* L. and *B. rapa* (= *campestris*) L. contain low levels of GS and no allyl GS and hence should release low levels of IC and no allyl IC. The primary mustard oils released by these species, butenyl and pentenyl IC (unpublished data), were not tested but are undoubtedly released in very small quantities. Canola varieties should, therefore, be less attractive than *B. juncea*, although fields of these crops should nonetheless be attractive. Lamb and Palaniswamy (1990) found that intact 2-week-old plants of nine species of crucifers, including *B. juncea*, *B. campestris*, and *B. napus*, were weakly or not at all attractive to *P. striolata*, indicating that long-distance host-plant location of small groups of plants may be largely a random event. Beetles may use IC for host recognition once they are in close proximity to a plant, in which case they would be exposed to greater concentrations of IC than is indicated by release rate measurements from plants. They clearly are not repelled by relatively high concentrations, as evidenced by the flea beetles captured in the vials themselves.

Flea beetles may also use IC to detect sites of damage on a plant, either because of advantages to feeding on weakened plant tissue or to locate conspecifics for group feeding or for mating. *N. niger* and *P. cruciferae* form aggregations that could result from responses to host plant odors released during feeding; they both have very definite IC preferences (Pivnick et al., 1991; this paper).

For purposes of breeding for varietal resistance, it seems unlikely that flea beetle response to IC would be an important consideration in view of the high IC release rates required for attraction. This conclusion is supported by the lack of clear differences in intensity of flea beetle attack between *B. juncea* and the two canola species (Lamb and Palaniswamy, 1990; Palaniswamy and Lamb, 1992), even though *B. juncea* produces much more IC than the other species and is the only one of the three that produces allyl IC, the most attractive IC. However, IC may be important in attraction of flea beetles to fields of *Brassica* crops or in short-range attraction (within centimeters). Of course, glucosinolate (and consequently IC) levels have been and will be manipulated by plant breeders for other reasons; they are important constituents of taste and odor and can affect nutritive qualities (Fenwick et al., 1983). It is also possible that the specific responsiveness to allyl IC may be of use in other ways in the management of flea beetle pests of cruciferous crops.

Acknowledgments—We thank C.E. Shearer for assistance with field trapping. K. Downey, M. Erlandson, P. Mason, and P. Raney reviewed an earlier version of this manuscript.

(Received October 28, 1991; accepted January 31, 1992)

Abstract—Laboratory olfactometer bioassays and field trapping experiments showed that the flea beetle, *Phyllotreta cruciferae* (Goeze), was highly attracted by oilseed rape (*Brassica napus* L.) when flea beetles were on the plant. This attraction was mediated by a flea beetle-produced aggregation pheromone based upon: (1) Oilseed rape damaged mechanically, or by *P. cruciferae*, or by diamondback moth, *Plutella xylostella* (L.), did not attract *P. cruciferae*. (2) Contact with the plants or feeding was required for the production of aggregation pheromone because oilseed rape alone was not attractive when separated from flea beetles by a screen. (3) Equal numbers of males and females were attracted.

Key Words—Aggregation pheromone, olfactometer, field trapping, Coleoptera, Chrysomelidae, *Phyllotreta cruciferae*, *Brassica napus*, crucifer.

INTRODUCTION

The flea beetle, *Phyllotreta cruciferae* (Goeze), feeds primarily on Cruciferae. In the northern Great Plains, it is the most serious pest of spring-planted oilseed rape, *Brassica napus* L. and *B. rapa* L. (Lamb, 1989; Weiss et al., 1991). Damage is caused mainly by the overwintering adult beetles, which feed on the cotyledons and slender stems in the early spring, causing seedling mortality and the crop to mature unevenly (Burgess, 1977; Lamb, 1989).

Our study originated from a field observation that crambe, *Crambe abys-*

*To whom correspondence should be addressed.

0098-0331/92/0600-0875$06.50/0 © 1992 Plenum Publishing Corporation

sinica Hochst., sustained significantly less damage by *P. cruciferae* than oilseed rape, *B. napus* L., although these two plant species both belong to the family Cruciferae (Anderson et al., 1992; Peng et al., 1992). The first objective of this study was to test the hypothesis that oilseed rape releases host-finding cues for *P. cruciferae* that are lacking in crambe.

Aggregative feeding behavior has been reported for *P. cruciferae* by Anderson et al. (1992) and Peng et al. (1992). The factors that determine the feeding behavior of *P. cruciferae* have been sought in the chemistry of the host plants themselves (Hicks, 1974; Feeny et al., 1970; Feeny, 1977; Lamb and Palaniswamy, 1990) and virtually nothing is known about the physiology of the beetles that may be relevant to feeding behavior and host-plant location. Therefore, the second objective was to investigate effects of the beetles on host plant location.

Here we present the first account of an aggregation pheromone in this important pest species.

METHODS AND MATERIALS

Laboratory Bioassays

Plants and Insects. Oilseed rape (*B. napus* cv. Westar) and crambe (*C. abyssinica* cv. Meyer) were grown in greenhouse flats using Sunshine Mix #3 as a potting media. Plants were watered as needed and were fertilized the third or fourth day after emergence with 14.5 g/liter 20:19:18 (N/P/K) Peatlite and 0.28 g/liter iron chelate, diluted approximately 1:15. Seedlings were used five to six days after emergence.

Flea beetles were collected from field pennycress, *Thalaspi arvense* L., in the early spring. They were maintained in the greenhouse on horseradish, *Armoracia rusticana* P. Gaertn., B. Mey & Scherb., in vented cages (Burgess and Wiens, 1976) at about 23°C and a photoperiod of 16:8 hr light–dark.

Olfactometer. A two-choice olfactometer (Figure 1) was designed for this study. The olfactometer consisted of a response chamber and two Plexiglas chambers, which are connected with glass tubes. There was an introduction hole on the cover of the response chamber through which beetles were introduced. The response chamber was sealed with sticky foam rubber stripping. Each Plexiglas chamber was divided by a screen into two subchambers: one functioned as a beetle trap and the other as a test chamber in which the test materials were placed. The top and bottom covers of the Plexiglas chambers were removable to facilitate collection of beetles and change of test materials.

Bioassay. All tests were conducted in the laboratory at about 25°C and 30–40% relative humidity between 0900 and 1600 hr (CST) on each date during the summer of 1990 and 1991. Illumination was furnished by two 30-W flu-

orescent lamps positioned 1 m above the olfactometer. Air flowed through each glass tube at approximately 300 ml/min.

Timing was begun when about 15 unsexed adult beetles were introduced into the response chamber. After 20 min, the beetles trapped in each chamber and glass tube were counted and removed. The response chamber and two glass tubes were cleaned using 95% ethanol and then dried for about 5 min after each run. Each test treatment was replicated at least eight times. The Plexiglas chamber containing test materials was alternated in consecutive replicates. Blank tests (nothing in the test chambers) were also run.

Three tests were conducted in the summer of 1990. The first test involved a choice between oilseed rape and crambe. Flea beetles were preconditioned for 17 hr in four different ways; beetles were exposed to: (1) oilseed rape; (2) crambe; (3) both plant species; and (4) neither species. Beetles were preconditioned in the growth chamber at 22–24°C, 50–60% relative humidity, and a 16:8-hr light–dark photoperiod (Table 1).

The second test investigated the attractiveness of six odor sources to the flea beetles: intact oilseed rape or crambe, flea beetles, damaged oilseed rape or crambe, and oilseed rape plus beetles (Table 2). A 40-ml glass beaker con-

[b] Paired *t* tests (SAS Institute, 1987).

taining soil was used as a control. Eight to 10 seedlings were transferred to a 40-ml glass beaker containing soil, one day before the test. In tests with damaged plants, seedlings were damaged with a pipet tip (2 mm diameter) by crushing the cotyledons in six locations immediately before tests; six new locations were repeated after each three replicates of a bioassay. Tests with flea beetles as an attractant were carried out by releasing about 50 unsexed beetles in the test chamber. Oilseed rape plus beetles were prepared by placing 14 beetles on oilseed rape seedlings in a glass beaker in the test chamber 17 hr before the test. The seedlings and beetles were maintained in the growth chamber described as above. Damage to the cotyledons (i.e., feeding pits) by the beetles was observed before the test.

The third was a choice test conducted with oilseed rape plus beetles versus intact or damaged oilseed rape, respectively. These odor sources were prepared using the method described for the second test.

In 1991, three odor sources were tested in the olfactometer to determine the possible source of attractants: oilseed rape plus beetles, infested oilseed rape

with frass, and infested oilseed rape without frass (Table 3). Test plants were transferred, and a control was prepared in the same way as in the previous tests. Oilseed rape plus beetles was prepared by caging plants and insects in the test chamber immediately before the test, instead of after 17 hr as in the second and third tests of 1990. Infested oilseed rape with frass was prepared by placing a glass beaker containing oilseed rape seedlings and about 50 beetles in a Plexiglas cage (20 × 20 × 30 cm) 17 hr before the test. Beetles were removed from the plants before the test. Frass was observed mostly on the bottom of the cotyledons. Infested oilseed rape without frass was prepared in a similar way. Flea beetles were starved for 24 hr before they were released into the Plexiglas cage and allowed to feed for about 2.5 hr. The feeding that resulted was similar to the damaged area of infested oilseed rape with frass except frass was not observed on the cotyledons.

Field-Trapping Experiment

To measure the attraction of *P. cruciferae* to different combinations of crucifer plants and flea beetles in the field, trapping studies were conducted at Fargo, North Dakota, in the spring of 1991. Flea beetles used in this study were from the same source as in previous tests. Oilseed rape and crambe were grown in 12-cm plastic pots using Sunshine Mix #3 as a potting medium, about 40–50 seedlings per pot, in the greenhouse until they were placed outdoors five to six days after emergence. Plants in the greenhouse were watered and fertilized using the methods described above.

The trap design illustrated in Figure 2 was used to catch *P. cruciferae* adults. Each pot was covered with a fine mesh organdy before test. Therefore volatile chemicals readily passed through the mesh, but field flea beetles were excluded. Each pot was placed on a wooden block in the center of a circular white plastic tray 30 cm diameter and 8 cm deep (Duraco Products, Inc., Streamwood, Illinois). The tray was filled with soapy water to collect flea beetles.

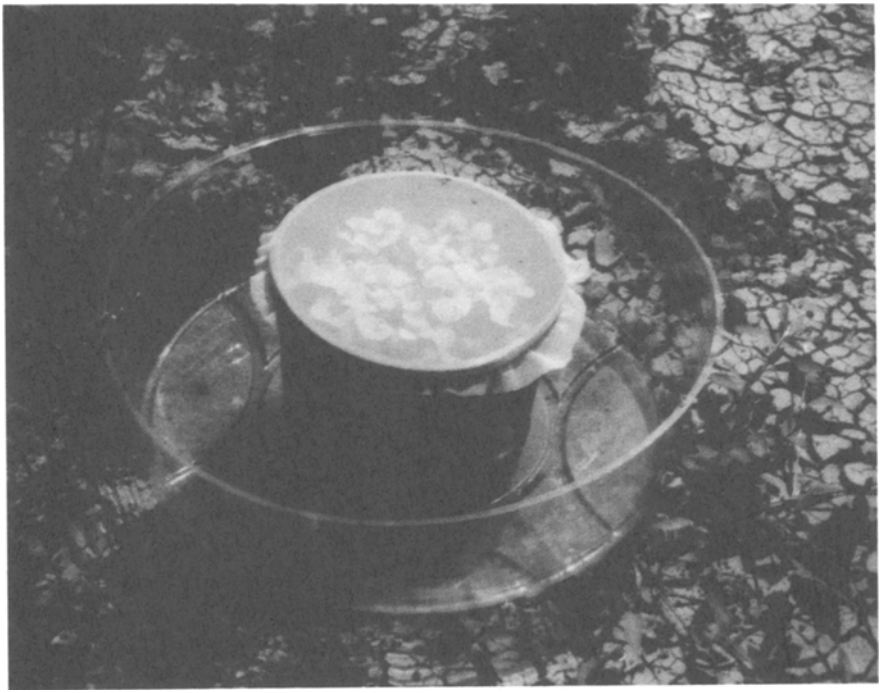

FIG. 2. Trap design for capture of *P. cruciferae*.

Two trapping tests were conducted. Each test consisted of four replications, arranged in a randomized complete block design. The distance between pots in a replicate was about 3 m and about 5 m or more between replicates. Test 1 was conducted May 31 to June 4, 1991, in an area with an array of trees to the east. All traps were positioned about 10 m away from the trees. Six treatments and a control were used: oilseed rape, crambe, beetles, oilseed rape plus beetles with access to the plants, oilseed rape plus beetles without access to the plants, crambe plus beetles with access to the plants, and soil alone (control) (Table 4). Oilseed rape or crambe plus beetles with free access were prepared by releasing approximately 50 beetles into a pot immediately before test. Oilseed rape plus beetles without access was used as a bait by placing a 15-ml vial containing about 50 beetles in a pot. The vial was screened to prevent beetles from feeding on the seedlings present in the pot. In the treatment of beetles, about 50 beetles were released into a pot containing soil only. The second test was conducted June 8–11, 1991, in a field with pennycress, to determine if volatiles released from oilseed rape after damage are attractive to flea beetles. Three treatments and a control were used: oilseed rape plus beetles with access

to the plants, damaged oilseed rape, oilseed rape plus diamondback moth larvae with access to the plants, and soil alone (control) (Table 5). Oilseed rape plus beetles with free access and control were prepared in the same way as in the first test. Oilseed rape was damaged with a scissors by making eight 1-cm-long cuts on the cotyledons immediately before test. Eight fresh cuts were added at 1000 hr (CST) daily. In the treatment of oilseed rape plus diamondback moth larvae, *Plutella xylostella* (L.) (Lepidoptera: Plutellidae), eight second to third instars were placed in each pot before tests. Diamondback moth larvae were from a colony maintained on crambe in the greenhouse. The beetles caught in the traps were counted and retained for sex determination.

Data Analysis

Results of all olfactometer bioassays were analyzed with a paired t test (SAS Institute, 1987). For the field-trapping experiment, the numbers of *P. cruciferae* caught were analyzed by analysis of variance (ANOVA) and Tukey's studentized range test at the 5% level of significance (SAS Institute, 1987).

RESULTS

Laboratory Bioassays

P. cruciferae did not prefer oilseed rape or crambe, regardless of preconditions (Table 1). Beetles and intact oilseed rape or crambe seedlings themselves were not attractive to *P. cruciferae*. Mechanical damage of the cotyledons on two plant species resulted in significant repellency to *P. cruciferae*. Oilseed rape plus beetles trapped significantly more beetles than the control (Table 2). Attractancy of oilseed rape plants plus beetles was significantly higher than both intact

TABLE 5. MEAN NUMBERS OF ADULT FLEA BEETLES CAUGHT PER TRAP BY TREATMENTS, JUNE 8–11, 1991

Treatment[a]	$\bar{X} \pm$ SD (range)[b]	Sex ratio (M:F)
OR + beetles with access to OR	74.00 ± 58.06(18–154)a	1:1
Damaged OR	1.25 ± 1.89(0–4)b	1:0.7
OR + DBML with access to OR	3.00 ± 0.82(2–4)b	1:1.4
Soil only, control	1.00 ± 0.82(0–2)b	1:3

[a]OR, soilseed rape; DBML, diamondback moth larvae.
[b]Means followed by the same letters are not significantly different [$P = 0.05$, Tukey's studentized range test (SAS Institute, 1987)].

oilseed rape (90 vs. 38, replicate = 12, $N = 174$, $t = 3.7100$, $P = 0.0035$) and damaged oilseed rape (86 vs. 49, replicate = 12, $N = 179$, $t = 3.8442$, $P = 0.0027$).

In the 1991 test (Table 3), oilseed rape and beetles were strongly attractive to *P. cruciferae* when they were put together immediately before tests. Oilseed rape infested by beetles with frass on the cotyledons was significantly attractive to *P. cruciferae*. However, oilseed rape infested by beetles without frass was not attractive.

Field-Trapping Experiment

There were significant differences in numbers of beetles caught by treatments in both tests (test 1: $F = 11.13$, $df = 6, 18$, $P = 0.0001$; test 2: $F = 3.72$, $df = 3, 9$, $P = 0.0385$). Only oilseed rape plus beetles with free access was significantly attractive to *P. cruciferae* among all treatments, and it attracted male and female beetles equally (Tables 4 and 5). Unequal numbers of male and female beetles caught in some of other treatments may be due to minimal catches.

DISCUSSION

Both olfactometer and field-trapping experiments demonstrated that oilseed rape and crambe alone were not attractive to *P. cruciferae*. This result did not support the hypothesis that oilseed rape releases host-finding cues for *P. cruciferae* and crambe lacks the host finding cues. However, oilseed rape plus beetles was strongly attractive to *P. cruciferae*. This attraction was mediated by a flea beetle-produced aggregation pheromone because oilseed rape alone was not attractive to *P. cruciferae*, mechanically damaged oilseed rape or oilseed rape damaged by *P. cruciferae* was not attractive, oilseed rape damaged by

diamondback moth was not attractive, and male and female beetles were caught equally.

The volatiles released from damaged oilseed rape or crambe seedlings were strongly repellent to the flea beetles in olfactometer tests. The cause is yet unknown. Although allyl-isothiocyanate has been shown to be a powerful attractant for *P. cruciferae* (Feeny et al., 1970; Vincent and Stewart 1984), its parent compound, allyl-glucosinolate, was undetectable in the cotyledons of *B. napus* cv. Westar (Bodnaryk and Palaniswamy, 1990). The major glucosinolate in the cotyledons of *B. napus* cv. Westar is glucobrassicin (3-indolylmethyl glucosinolate) (Bodnaryk and Palaniswamy, 1990), which has no volatile hydrolysis products. Allyl-glucosinolate was also not detected in crambe (McGhee et al., 1965).

Feeding or contact with the plants is necessary for the production of aggregation pheromone because use of beetles alone or oilseed rape plus beetles separated by a screen did not attract *P. cruciferae*. Our findings suggest two possible modes of aggregation pheromone production. First, *P. cruciferae* may release pheromone as soon as it has selected a suitable host plant. This is supported by the olfactometer test in which oilseed rape and beetles were attractive when placed together immediately before tests (Table 3). Alternatively, pheromone may be released through frass excreted by beetles on the cotyledons because infested oilseed rape with frass was attractive to *P. cruciferae*, and infested oilseed rape without frass was not attractive (Table 3). These modes of aggregation pheromone production occur in other species of Coleoptera (Birch, 1984; Borden, 1985).

This is the first demonstration of semiochemically induced aggregation in *P. cruciferae*. The aggregation pheromone may play a role in host-plant location because beetles plus crambe (nonhost) were not attractive to *P. cruciferae*. This finding has opened new fields of investigation for a potential improvement of *P. cruciferae* control. Our results have prompted chemical investigations to identify the *P. cruciferae* aggregation pheromone. Synthetic pheromone could be used as a beetle lure to monitor populations and to control them in combination with pesticides.

(Received November 4, 1991; accepted January 31, 1992)

Abstract—The chemical basis of feeding responses to the acceptable nonhost plant *Vigna sinensis* (cowpea) by larvae of *Manduca sexta* was investigated using chemical isolation techniques directed by a novel chemosensory-based bioassay. The presence of feeding stimulatory and inhibitory compounds in leaves or leaf extracts was determined in a two-choice preference test using leaf disks or glass fiber filter paper disks laced with leaf extract as test substrate and filter paper disks laced with water as control. Larvae strongly prefer the control disks over leaf disks, indicating the presence of feeding inhibitory compounds in the leaf. An ethanol extract of both fresh and dried leaves neither stimulated nor inhibited feeding. The cause of this inactivity was examined by using larvae that respond strongly to either feeding stimulatory or inhibitory compounds due to selective chemosensory deprivation. Larvae having chemosensory organs remaining only on the maxillary palps are stimulated to feed by whole leaf disks and by the ethanol extracts. In contrast, larvae having only the medial and lateral maxillary sensilla styloconica and the epipharyngeal sensilla remaining are strongly inhibited by whole leaf disks and the ethanol extract of fresh leaves. Thus, the ethanol extract contains both feeding stimulatory and inhibitory compounds, which elicit opposite behavioral effects in unoperated larvae, therefore nullifying any stimulatory and inhibitory activity. These compounds can only be demonstrated by using discrimination-enhanced larvae in the choice tests. Further isolation of the feed-

ing stimulatory principle in *V. sinensis* yielded two separate fractions of neutral compounds, suggesting at least two different chemicals belonging to two different classes: nonpolar and polar lipids. Feeding inhibitory chemicals have apparently polar properties because strong activity was found in the ethyl acetate and methanol extracts of dried leaves. The role of feeding stimulatory and inhibitory compounds in food selection of *M. sexta* larvae is discussed.

Key Words—*Manduca sexta*, Lepidoptera, Sphingidae, food selection, nonhosts, extracts, sensory deprivation, Vigna sinensis.

INTRODUCTION

The oligophagous tobacco hornworm, *Manduca sexta*, confines its food range in nature to selected members of the plant family Solanaceae. Nonhost plant species can be divided in two main groups based on the feeding response by first-instar larvae having no previous contact with food. Unacceptable nonhosts do not stimulate feeding. Acceptable nonhost plant species stimulate feeding and support growth and development (Yamamoto and Flowers, 1982; de Boer and Hanson, 1984). Feeding responses by other instar larvae to these acceptable nonhosts depend on the plant species on which the larvae have been reared. Host-reared larvae are inhibited to feed on acceptable nonhost plant species, while larvae reared on an acceptable nonhost are stimulated to feed on both species (de Boer, 1992). This increased preference found for the rearing plant species relative to the nonrearing plant species is called a diet-induced food preference (de Boer and Hanson, 1984; de Boer, 1992) and also has been demonstrated in several other insect species (cf. Szentesi and Jermy, 1990). Thus, these acceptable nonhost plant species act as nonhosts or to some extent as hosts, depending on the food experience of the larvae. What are the properties of these acceptable nonhost plants that determine their degree of acceptability to *M. sexta* larvae?

Like many phytophagous insects, tobacco hornworm larvae select their food mainly on the basis of its chemical content, particularly feeding stimulatory and inhibitory chemicals. Acceptance or rejection of the food is then based on the balance between sensory inputs that invoke opposite behavioral responses (Dethier, 1982). The chemoreceptor cells involved in food selection by *M. sexta* larvae are located within five different peripheral sensory organs (Schoonhoven, 1987). Each of these chemosensory organs by itself mediates a particular feeding response to a certain plant species (de Boer and Hanson, 1987a, de Boer, 1991). For example, the acceptable nonhost plant cowpea, *Vigna sinensis*, stimulates feeding if sensory input from only the maxillary palps is used for feeding decisions. In contrast, input from the medial and lateral maxillary sensilla styloconica and the epipharyngeal sensilla each mediate inhibition of feeding, and input from the antennae results in neither stimulation nor inhibition. These results

strongly suggest that *V. sinensis* contains both feeding stimulatory and inhibitory chemicals. What are these phytochemicals controlling acceptance of *V. sinensis*?

In this paper we report the isolation of chemicals from *V. sinensis* affecting acceptance of this plant by *M. sexta* larvae. In addition to using chemical fractionation methods, a new technique was developed to distinguish between inactive fractions due to the absence of an active principle and "inactive" fractions due to the presence of both stimulatory and inhibitory chemicals, each counteracting the behavioral effect of the other. During screening for active fractions larvae were used whose detection of either feeding stimulatory or inhibitory chemicals was enhanced by removing selected chemosensory organs. The results show that extracts that are "inactive" for unoperated larvae are active for discrimination-enhanced larvae. Furthermore, some feeding stimulatory compounds in *V. sinensis* belong to the group of nonpolar lipids and others to the group of polar lipids.

METHODS AND MATERIALS

Insects and Plants. Larvae of the tobacco hornworm, *M. sexta* (Lepidoptera: Sphingidae), were reared from eggs obtained from the U.S.D.A. (Beltsville, Maryland). Upon hatching, they were fed foliage of tomato, *Lycopersicon esculentum*. Leaves of the acceptable nonhost plant cowpea, *V. sinensis*, were used as substrates in two-choice food preference tests. All plants were grown in the university glasshouse under long day conditions and kept pest free without using pesticides. Rearing and test conditions of food preference experiments were 16:8 hr light–dark at 28 ± 1°C.

Bioassay. The two-choice test of de Boer and Hanson (1988) was used to assay food preferences of larvae. Three test and control disks of glass fiber filter paper (Whatman GF/A, 14 mm in diameter) were placed in ABAB . . . order around the circumference of transparent containers (10 cm in diameter). The floor of the containers was a layer of paraffin wax into which were inserted pins holding the disks ca. 5 mm above the substrate. Small retainers (3 mm in diameter) punched from acetate sheets (or Teflon when diethyl ether or methylene chloride was used as solvent) kept the disks from sliding down the pin. A wire screen covered a moist piece of filter paper on the floor of the container. A freshly molted fifth-instar larva, deprived of food for 12–24 hr after the molt, was placed in the center of the container. The containers were covered with transparent lids to maintain high humidity. When the larva had eaten approximately 50% of the total area of either test or control disks (time: T_{50}), the larva was removed and the area consumed of each disk was estimated visually. Larvae were tested only once, then discarded. The tests were repeated, usually with 15 or more larvae. The mean area eaten of each substrate (A or B) was expressed

as the percentage of the total area of all disks consumed (e.g., A/A + B) at T_{50}. This value (range 0–100) was taken as a measure of food preference. No effect of the above-mentioned levels of starvation upon food choices was shown in studies using similar choice tests (de Boer and Hanson, 1987a).

The test disks were laced with 0.05 ml of the test solution, which is enough to wet each disk completely. The control disks received 0.05 ml of solvent only. After evaporation of the organic solvent from test and control disks, each disk was wetted with 0.05 ml of distilled water because *Manduca* does not eat dry disks. Every extract and fraction obtained during the isolation procedures was tested in the bioassay at approximately natural concentrations; i.e., the concentration was adjusted by redissolving the dried material in solvent such that 0.05 ml would contain the chemicals from an area of leaf containing 0.05 ml water.

Data were accumulated in a balanced design for experiments within treatment groups as much as possible. The differences in food choices for the test substrates are expressed in a choice index (range -100 to $+100$), which measures the mean percent of total consumption of substrate A minus that of substrate B. Since such consumption scores are not normally distributed, nonparametric statistics were used; a two-tailed Mann-Whitney test was selected for the analysis of the raw scores to determine the significance of difference in food choices.

Sensory Ablation. To screen more effectively for plant chemicals affecting food selection, discrimination-enhanced larvae were tested. Using the microsurgical procedures of de Boer and Hanson (1987a), larvae were deprived of those sensory organs that were shown to differentially mediate stimulation or inhibition of feeding on *V. sinensis* (de Boer, 1991). After immobilizing larvae on melting ice for about 20–45 min, the antennae and the maxillary palps were removed using microdissection scissors to yield larvae having only the medial and lateral maxillary sensilla styloconica, and the epipharyngeal sensilla remaining (MLE larvae). Similarly, the antennae, the medial and lateral maxillary sensilla styloconica, and the epipharyngeal sensilla were removed to produce larvae having only the maxillary palps remaining (MP larvae). Extirpations were performed in the middle of the fourth stadium, except for ablations of the medial and lateral maxillary sensilla styloconica, which were made in fifth stadium within 12 hr of the final larval molt. Operated fourth-instar larvae recovered and fed on leaves until the final larval molt. Ablated larvae appeared to feed normally. The remaining chemosensory organs were examined under the dissecting microscope; animals having unsuccessful operations were withdrawn from further consideration.

Extraction and Isolation. Fresh whole leaves of cowpea (193 g) were soaked in 2 liters of cold ethanol for 24 hr at room temperature. Evaporation of the extract below 40°C yielded 4.1 g of dried material, which was stored at 5°C in the dark. In addition, 20 g of cowpea leaves dried at room temperature was

cut in small pieces and extracted with 300 ml of cold ethanol for 24 hr. This extract was stripped of solvent at room temperature and yielded 0.8 g of dry material. All dried extracts were redissolved in ethanol before testing in the bioassay. The plant residue remaining from the cold ethanol extract of dried cowpea leaves was reextracted with hot ethanol. Further isolation of plant chemicals was done by extraction using another 20 g of air-dried powered cowpea leaves in a glass column using an eluotropic series of solvents (hexane, diethyl ether, methylene chloride, ethyl acetate, and methanol). This sequential extraction leaches from the leaves compounds that dissolve in solvents of increasing polarity. The above extraction methods assume complete extraction within the limits of the technique. All extracts were dried and stored at 5°C in the dark.

Additional chemical separation was accomplished by fractionation of the diethyl ether extract into subclasses of grossly related chemicals using bulk transfer methods (Mitscher et al., 1987). The scheme shown in Figure 1 is widely used to separate natural product mixtures. The diethyl ether extract (called extract 1) is partitioned between 5% hydrochloric acid and chloroform to produce extract 2 (chloroform layer contains neutral substances and acids) and extract 3 (aqueous phase contains alkaloids and water-soluble materials such as sugars, amino acids, and the like). Extract 2 is further fractionated by extraction with 5% sodium hydroxide to produce extract 4 [chloroform layer contains

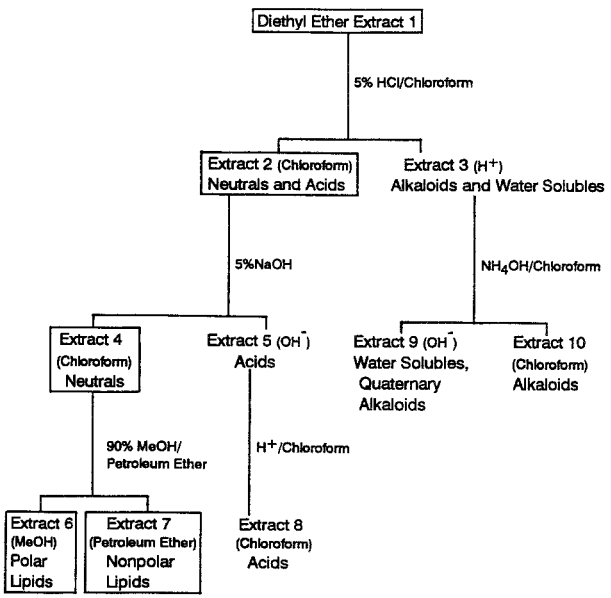

FIG. 1. Bioassay-directed fractionation of *V. sinensis* extracts. Extracts in boxes contain feeding stimulatory activity ($P > 0.05$, $N = 15$ or more).

neutral (neither acidic nor basic) compounds] and extract 5 (basic phase contains acids). Extract 4 is further fractionated by partitioning between 90% methanol and petroleum ether to yield extract 6 (methanol layer contains polar lipids) and extract 7 (petroleum ether phase contains nonpolar lipids). Extract 5 is partitioned between dilute aqueous acid and chloroform to produce extract 8 (chloroform phase contains acids). Extract 3 was partitioned between ammonia and chloroform to yield extract 9 (aqueous phase contains water solubles and quaternary alkaloids) and extract 10 (chloroform layer contains alkaloids).

RESULTS

Larvae significantly preferred the control disks over leaf disks of *V. sinensis* (Table 1: unoperated larvae; choice index −64), suggesting feeding inhibitory chemicals in the leaves. Several extraction methods were used to obtain an active extract from leaves of *V. sinensis*. Larvae consumed equal amounts from disks laced with an ethanol extract of fresh cowpea leaves or no extract, indicating no significant preference for either substrate. (Table 1: unoperated larvae; fresh leaves, choice index −6). Similar results were found with an ethanol extract of dried leaves of *V. sinensis* (Table 1: unoperated larvae; dried leaves, choice index −6). The question arises whether feeding activity remained in the plant residue after cold ethanol extraction. Therefore, this plant residue was reex-

[c] Larvae having only the medial and lateral maxillary sensilla styloconica and the epipharyngeal sensilla remaining.

tracted with hot ethanol and tested for feeding activity. However, consumption of the test disks with hot ethanol extract of the plant residue did not differ significantly from consumption of the control disks (Table 1: unoperated larvae; plant residue, choice index +6). Thus, feeding inhibitory chemicals in the ethanol extracts could not be demonstrated.

Perhaps, the above absence of feeding inhibitory activity is due to a loss of a volatile active principle. However, if odors of *V. sinensis* inhibit feeding, then larvae may need to consume very little (bites) or no plant material due to the noncontact mode of olfactory detection. This is not supported by the amount of leaf material consumed by the larvae (18% of total material consumed is from *V. sinensis*). Perhaps the isolates contain both feeding stimulatory and inhibitory compounds. Detection of both groups of chemicals may result in neither feeding stimulation nor inhibition. To distinguish between extracts void of compounds affecting food selection and extracts containing both stimulatory and inhibitory chemicals, we used discrimination-enhanced larvae that were made more selective to either group of chemicals by chemosensory ablations (MP larvae and MLE larvae). Results of a previous study (de Boer, 1991) showed that larvae having only the maxillary palps remaining are stimulated to feed on *V. sinensis* leaves (Table 1: MP larvae, fresh leaves, choice index +56) and larvae having only the medial and lateral maxillary sensilla styloconica and the epipharyngeal sensilla remaining are inhibited from feeding (Table 1: MLE larvae, fresh leaves, choice index −86). Thus, fresh leaves contain both feeding stimulatory and inhibitory chemicals. When MP larvae were used to test the ethanol extract of fresh and dried leaves of *V. sinensis*, a significant stimulation of feeding was found (Table 1: choice indices +34 and +28, respectively, for MP-larvae). In contrast, MLE larvae were strongly inhibited from feeding on the ethanol extract of fresh leaves (choice index −64). However, the ethanol extract of dried leaves did not significantly affect food choice. Thus, an ethanol extract of fresh leaves seems to contain both feeding stimulatory and inhibitory chemicals. On the other hand, the ethanol extract of dried leaves contains mainly or perhaps exclusively feeding stimulatory compounds. Therefore, the dried leaves were used to further isolate the feeding stimulatory principle.

Dried-leaf material was extracted sequentially by solvents of increasing polarity: hexane, diethyl ether, methylene chloride, ethyl acetate, and methanol. Larvae were used that have the same complement of chemosensory organs as those in the above experiments. The results show that unoperated larvae are significantly stimulated to feed by the diethyl ether and the methanol extract (Table 2: unoperated larvae, choice indices; +18). MP larvae were stimulated to feed by all extracts (Table 2: MP larvae). MLE larvae were stimulated to feed by the hexane extract of dried leaves (Table 2: MLE larvae, choice index +10). In contrast, these larvae are significantly inhibited from feeding by the ethyl acetate and methanol extracts (Table 2: MLE larvae, choice indices −24

TABLE 2. FEEDING ACTIVITY OF *M. sexta* LARVAE ELICITED BY DIFFERENT EXTRACTS FROM LEAVES OF ACCEPTABLE NONHOST *V. sinensis*

Extraction solvent	Feeding activity[a]

[c] Larvae having only the medial and lateral maxillary sensilla styloconica and the epipharyngeal sensilla remaining.

and −70, respectively). The diethyl ether extract stimulates, but does not inhibit, feeding, suggesting a relatively pure extract of feeding stimulatory compounds. This extract was used in the continued isolation of feeding stimulatory chemicals from *V. sinensis*.

Fractionation by bulk transfer starting with the diethyl ether extract (extract 1 in Figure 1) and using MP larvae resulted in stimulatory activity in extracts 2, 4, 6, and 7. Fractions 6 and 7 were repartitioned between 90% methanol and petroleum ether, and again both layers contained feeding stimulatory activity. No activity was found in extracts 8 and 9. Extract 10 did not yield any material. The activity of extracts 6 and 7 must be due to chemicals that belong to the classes of polar and nonpolar lipids, respectively.

DISCUSSION

Although larvae of *M. sexta* are inhibited to feed on leaves of *V. sinensis*, feeding inhibitory chemicals in ethanol extracts or in the plant residue could not be demonstrated (Table 1). This may be due to the absence of a volatile principle lost during the extraction process. However, plant odors seem to play a small, if any, role in the strong inhibition to feed on *V. sinensis*, because most larvae take more than a couple of bites from this plant before they stop feeding. Perhaps, the chemical content of the actual leaf sap sampled by the larvae differs

from the extracts due to mixing all pools of plant chemicals during extraction. Other plant factors also may contribute to the deterrency of this plant species, such as leaf texture. Another possibility is that the isolates contain both feeding inhibitory and stimulatory chemicals, resulting in neither stimulation nor inhibition of feeding. In the latter case, an alternative method to detect feeding activity in "inactive" isolates is needed to understand the chemical basis of feeding responses to *V. sinensis* by *M. sexta* larvae.

In this study a new tool to screen for compounds controlling feeding was developed. Larvae deprived of certain chemosensory organs are used to detect either feeding stimulatory or inhibitory chemicals from *V. sinensis*. This tool became available through detailed studies on the chemosensory basis of feeding responses to *V. sinensis* by *M. sexta* (de Boer, 1991). Extracts inactive on unoperated larvae are now active on larvae having only certain chemosensory organs remaining (Tables 1 and 2). The ability to detect feeding activity using these discrimination-enhanced larvae made it possible to continue the isolation of plant chemicals controlling food choice.

Feeding stimulatory activity was found in extracts that vary in content from mostly nonpolar to mostly polar compounds (Table 2: MP larvae). This suggests that the feeding stimulatory principle in *V. sinensis* may contain compounds with polar and nonpolar properties. The polar extracts may contain the commonly found plant chemicals sucrose and inositol, which have been shown to stimulate feeding in the tobacco hornworm (Städler and Hanson, 1978). The nonpolar extracts and two subfractions from the fraction containing neutral compounds stimulated feeding (Figure 1). These results suggest the presence of at least two different chemicals: one belonging to the class of nonpolar lipids, such as waxes and fats, and the other to the class of polar lipids, such as terpenes and sterols. These findings support and extend the results of de Boer and Hanson (1988), which showed that feeding in tobacco hornworm larvae was stimulated by a leaf surface extract from *V. sinensis* containing neutral compounds. Interestingly, preliminary studies on the isolation of plant chemicals controlling feeding on the host *L. esculentum* also showed that extracts with neutral compounds stimulate feeding (de Boer and Hanson, 1988). Thus, at this level of determination of plant chemicals controlling feeding by *M. sexta*, some similarities are seen between the host *L. esculentum* and the acceptable nonhost *V. sinensis*. Perhaps, the neutral compounds in these two plant species are chemically similar and play the same role in the acceptance of both plant species. Further isolation and identification of these neutral compounds is needed to determine their role in food selection by *M. sexta*.

Feeding inhibitory chemicals in *V. sinensis* must have rather polar properties because inhibitory activity was found in the ethyl acetate and methanol fractions (Table 2). The inhibitory compounds in the methanol fraction deter feeding very strongly (choice index -70 out of a maximum of -100). The

ethyl acetate and methanol fractions also contain feeding stimulatory compounds detected by MP larvae. Therefore, MLE larvae are required in the bioassay for further isolation of feeding inhibitory chemicals from *V. sinensis*.

Larvae detect both feeding stimulatory and inhibitory compounds in extracts of *V. sinensis*. Preliminary isolation studies using *L. esculentum* also yielded fractions containing feeding stimulatory and inhibitory compounds (de Boer and Hanson, 1988). Thus, decisions to feed on an acceptable nonhost as well as a host plant appears to be largely determined by the balance between chemosensory inputs eliciting feeding preference and deterrent responses. This does not support the assumption of Wrubel and Bernays (1990) that maintenance of the restricted host range in *M. sexta* larvae does not rely on avoidance of nonhosts due to feeding deterrence but on attraction and stimulation to feed on hosts. Wrubel and Bernays' conclusion is based on the finding that tobacco hornworm larvae are relatively insensitive to a variety of plant secondary compounds known to occur in some nonhosts compared to other phytophagous insect species tested. Perhaps, nonhosts are less acceptable than hosts because they contain more effective feeding inhibitory and/or less effective stimulatory chemicals than do hosts.

It is important to note that the refinement of the bioassay using MP and MLE larvae is only effective when studying feeding responses to *V. sinensis*. Other plant species may require a different combination of chemosensory organs to mediate feeding responses as was shown by de Boer and Hanson (1987a). In addition, the above two groups of larvae are not exclusively selective for feeding stimulatory or inhibitory compounds. This is shown in Table 2 where feeding of MLE larvae is stimulated by the hexane extract and inhibited by the ethyl acetate and methanol extracts. The chemosensory organs remaining after ablation contain many receptor cells, each with their own selectivity. Indeed, some receptor cells in the maxillary sensilla styloconica have been shown to respond best to feeding stimulatory compounds, while others in the same sensillum respond most strongly to feeding inhibitory compounds (Schoonhoven, 1972). Thus, although the use of discrimination-enhanced larvae can redirect an otherwise halted bioassay-guided isolation procedure, it may not prevent the recurrence of an "inactive" fraction. The latter could be due to chemicals acting on different receptor cells within the same chemosensory organ and eliciting opposite behavioral effects. However, the use of larvae having selected chemosensory organs remaining may be sufficient to evaluate the "inactivity" of a certain fraction, after which unoperated larvae may be used again to complete the isolation process.

The use of discrimination-enhanced larvae in this chemical isolation study underscores the importance of understanding the chemosensory basis of food selection by insects. Moreover, once the particular chemosensory organs and their receptor cells have been identified as the critical mediators for feeding

responses to a certain plant extract, isolation procedures can be directed by measuring receptor cell activity using electrophysiological techniques. Such a screening method promises to be less time consuming and more sensitive than behavioral methods due to the very small amounts of material needed for neural stimulation.

Acknowledgments—We thank Dr. J. Svoboda of the U.S.D.A., Beltsville, Maryland, for supplying eggs of the tobacco hornworm. We are also indebted to Ravi Gargesh and Ric Roggero for their valuable assistance. This investigation was supported by the University of Kansas General Research Allocation No. 3494 to G.d.B. and a grant from the Deutsche Forschung Gemeinshaft to A.S.

(Received November 4, 1991; accepted February 3, 1992)

Abstract—Phenylacetic acid (PAA), one of the phytotoxic compounds in corn (*Zea mays*) pollen, was identified by GC-MS and by direct comparison with a pure commercial sample of PAA. Bioassays were carried out by testing whole pollen, methylene chloride extract of the pollen, and pure PAA on germination and radical growth of *Amaranthus leucocarpus* and *Echinochloa crusgalli*. The effect of corn pollen was compared with that of *Zea mexicana* (Teosinte), one of the wild relatives of cultivated maize.

Key Words—Pollen, corn, *Zea mays*, teosinte, *Zea mexicana*, allelopathy, phenylacetic acid, phytotoxicity, *Amaranthus leucocarpus*, *Echinochloa crus-galli*.

INTRODUCTION

It has been confirmed that pollen of different species have different growth requirements and contain different amounts of growth hormones. In general, six classes of plant growth hormones have been found in pollen and can potentially

*To whom correspondence should be addressed.

0098-0331/92/0600-0897$06.50/0 © 1992 Plenum Publishing Corporation

influence their growth: auxins, gibberellins, kinins, brassins, ethylene, and inhibitors (Stanley and Linskens, 1974).

Some evidence exists on the allelopathic effects of pollen (Kanchan, 1975). Kanchan and Jayachandra (1980) reported that the fruit yield by *Crotalaria pellida* and *Desmodium heterocarpon* was poor when *Parthenium hysterophorus* pollen naturally spread on the leaves and stigmas of the former species. Under culture conditions, germination and pollen tube growth of the test species were inhibited in the presence of *Parthenium* pollen or its extracts. Pollen grains deposited on leaves in large quantities also reduced the chlorophyll content in these target species. Thomson et al. (1982) found that *Diervilla lonicera* (Caprifoliaceae) fecundity was strongly depressed when pollen from *Hieracium floribundum* (Compositae) mixed with *Diervilla* pollen was applied to their stigmas. Murphy and Aarsen (1989) found that the pollen of *Phleum pratense* had allelopathic effects on the pollen germination of 16 sympatric target species.

Jiménez-Osornio and Schultz (1981), in a study of relationships between weeds and cultivated plants in a traditional agroecosystem (chinampa) in the Valley of Mexico, found that weed growth decreased in the middle of the crop cycle when maize was mature and flowering. Jiménez-Osornio et al. (1983) confirmed that a strong inhibitory effect on the radicle growth of *Cassia jalapensis* was observed when corn pollen was sprinkled on its seeds. In relation with this, some peasants of the Valley of Mexico (temperate climate), Tabasco, and Yucatan (tropical climates) assert that the fruiting of squash, bottle gourd, and watermelon is reduced, and also some leaves of beans are "burnt", when corn pollen falls over them (Anaya et al., 1987, 1992). Cruz-Ortega et al. (1988) tested the effects of an ethanolic extract of corn pollen on growth, respiration, and cell division of watermelon and showed the mechanisms of action of the phytotoxic substances of corn pollen.

The chemical analysis of corn pollen has shown various organic compounds to be present, such as: carbohydrates, proteins, lipids, phytosterols, saturate hydrocarbon, phosphatide, and vitamins (Anderson, 1923; Nilsson et al., 1957; Kvanta, 1968; Stanley and Linskens, 1974). Some brassinosteroids (castasterone, typhasterol, and teasterone) found in corn pollen have been associated with stimulating effects (Maugh, 1981; Suzuki et al., 1986). Other compounds reported from corn pollen are the flavonoids quercetin, isorhamnetin, kaempferol, and β-carotene (Katsumata et al., 1974; Ceska and Styles, 1984).

As part of a research program directed towards the isolation of active compounds from Mexican plants, this work describes the identification of one of the bioactive principles from corn pollen (*Zea mays* L., Gramineae) and the results of different bioassays on germination and radicle growth of *Amaranthus leucocarpus* Wats (Amaranthaceae) and *Echinochloa crusgalli* (L.) Beauv (Gramineae).

METHODS AND MATERIALS

General Experimental Methods. GC was carried out on a Hewlett Packard-5890; a methyl silicon 5-m × 0.53-mm column, a temperature program from 150°C to 270°C, and 5°C/min heating speed, using hydrogen as a carrier gas with a 5 ml/min flux. GC-MS was carried out on a Hewlett Packard-5985 B, GC-MS system. The capillary column used in GC was a 30-m × 0.32-mm Bonden FSOT RSL-400. 3UM (OV-210, QF-1, DB-210) of trifluoropropylsiloxane, using helium as a carrier gas and a temperature program of 100°C to 240°C at a rate of 5°/min (EI^+, 70 eV).

One of the preparative TLC fractions (see below), where PAA seems to be present, and a commercial sample of PAA were methylated with CH_2N_2, and a GC-MS analysis of the methylated products was performed. The GC conditions were: 5% HP phenyl methyl silicone 25 m × 0.32 mm × 0.52 μm film capillary column, helium as a carrier gas, and a temperature program of 50°C to 240°C at a rate of 10°/min.

Plant Material. Corn pollen was collected from mature male inflorescences in a field monoculture of corn at Mixquiahuala, Hidalgo, in the months of July and August 1989. The material was dried at room temperature, cleaned, and sieved. A small sample of teosinte pollen [*Zea mexicana* (L.) Schrad] was collected from mature male inflorescences at Ciudad Universitaria, UNAM campus, in August 1989.

Bioassay-Guided Isolation Procedures. Crude extracts of pollen were obtained by macerating at room temperature the dried pollen (450 g) in CH_2Cl_2 (225 ml) for 48 hr. The dried extract was tested for allelopathic activity by the seed germination and radicle growth assay method on *Amaranthus leucocarpus* and *Echinochloa crusgalli* (Anaya et al., 1990).

A preparative TLC (Merck 60F-254) of the CH_2Cl_2 extract was performed using hexane–EtOAc (1:1) as eluent. The bands were visualized under UV light. All the fractions obtained were assayed for allelopathic effects.

General Bioassay Procedure. Whole corn pollen, crude CH_2Cl_2 extract from the pollen, chromatographic fractions of the crude extract, and commercial PAA, all at different quantities and concentrations, were tested on the seeds of *Amaranthus leucocarpus* and *Echinochloa crusgalli*. The bioassays were carried out in Petri dishes containing filter paper or agar (1.5%) as a substrate, as described by Anaya et al. (1990). A complete random block design with four repetitions per treatment was used. The bioassays were carried out using 40 seeds per treatment, at 27°C in the dark during 24 hr for *Amaranthus* and 48 hr for *Echinochloa*. After this time, the percentage of germination and radicle length were measured. All the data were statistically analyzed by ANOVA (Ostle, 1963).

A bioassay comparing the effect of sprinkled whole pollen of corn and teosinte on the radicle growth of *Amaranthus* was carried out in the same manner as described in the case of pollen extracts and their fractions.

RESULTS AND DISCUSSION

Chemical Analysis. The preparative TLC of the crude CH_2Cl_2 extract of the corn pollen showed six bands at R_f 0.05 (fraction 1), 0.11 (fraction 2), 0.22 (fraction 3), 0.28 (fraction 4), 0.51 (fraction 5), and 0.64 (fraction 6), respectively.

The GC analysis of the fraction 3 (Figure 1A) showed a major peak (approximately 10% of the fraction) with a R_T of 1 min. The EI-MS of this peak produced a molecular ion at 136, and a base peak of m/z at 91 (Figure 1B), which confirmed the presence of PAA in this fraction. The identification

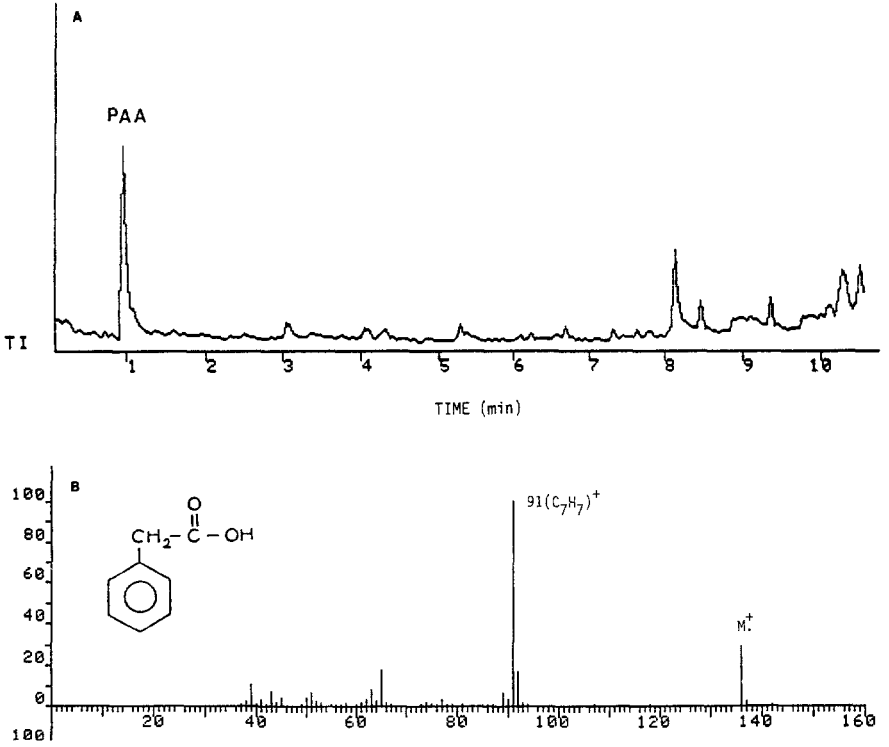

FIG. 1. (A) GC of fraction 3 showing PAA peak. (B) EI-MS spectrum of isolated phenylacetic acid (PAA) from fraction 3.

was further corroborated by comparing it with a commercial sample of PAA. GC-MS analysis of the PAA methyl ester from fraction 3 also was in agreement with the GC-MS data of the methyl ester of commercial PAA.

Biological Analysis. The results obtained from bioassays with the sprinkled corn pollen on germination and radicle growth of *Amaranthus* and *Echinochloa* are shown in Table 1. The radicle growth of both species was significantly affected by the pollen.

The results of the bioassays with the CH_2Cl_2 extract of corn pollen at three concentrations, and the chromatographic fractions of this extract at 100 ppm on the germination and radicle growth of *Amaranthus* are shown in Table 2. The CH_2Cl_2 crude extract caused a significant inhibition at all concentrations tested. On the other hand, almost all the TLC fractions of the CH_2Cl_2 extract (except fraction 6) produced a significant reduction of radicle growth of *Amaranthus*. However, fraction 5 produced a stimulatory effect (28%) on radicle growth. Fraction 3 was the most inhibitory on germination and radicle growth of *Amaranthus*.

Figure 2 shows the comparative effect of fraction 3 and PAA at two concentrations on the radicle growth of *Amaranthus* and *Echinochloa*. This fraction showed the highest inhibition activity on *Amaranthus*. On the other hand, PAA showed the highest inhibition activity on *Echinochloa*. These differences are probably due to the presence of other compounds, in addition to PAA, in fraction 3. The effects of sprinkled pollen of corn and teosinte on the radicle growth of *Amaranthus* are shown in Figure 3. The results confirmed that teosinte pollen has no effect on this test species.

In general, we observed that the percentage of germination was less affected than radicle length in all treatments. This was true of both test species.

Our results indicate that PAA content in corn pollen contributes to the

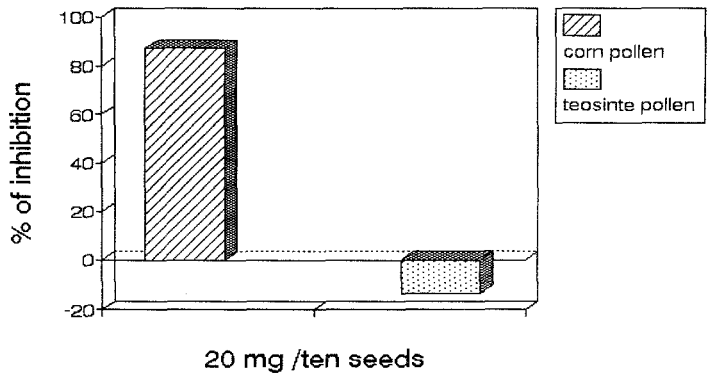

FIG. 3. Effects of sprinkled pollen of corn and teosinte on the radicle growth of *Amaranthus leucocarpus*.

allelopathic effects observed. PAA is a naturally occurring substance in a variety of biological systems. Wightman and Lighty (1982) have demonstrated that PAA fulfills the definition of a nonindolylic auxin and assumed that the amount of PAA present in the shoots of a range of crop plants varies between 1 and 3 $\times$ 10^{-6} M and suggested that the endogenous levels of PAA and IAA are considerably higher in rapidly growing regions. In the case of corn, the PAA content could be higher in pollen.

PAA has been shown to occur in the alga *Undaria pinnatifida*, and it appears to act as an auxin in the red alga *Porphyra tenera* (Abe et al., 1974). Nair and Burke (1988) characterized PAA from *Aspergillus niger* and reported that PAA inhibited the germination of cress and lettuce seeds and also showed antifungal activity against *Cladosporium herbarum*. Chou and Patrick (1976) reported that PAA and other compounds produced during decomposition of corn and rye residues in soil were highly inhibitory to the growth of lettuce.

PAA has been isolated in addition to myrmicacin, IAA, and other acids from metathoracic glands of the leaf-cutting ants *Atta sexdens* from South America. These substances are reported to be used by ants to prevent sprouting of seeds, intrusion of spores, and growth of bacteria in their fungal gardens (Schildknecht and Koob, 1971). Rasmussen et al. (1990) found PAA in temporal gland secretions collected from an Asian bull elephant during a four-month musth episode and examined the role of such secretions as agents for chemical communication between elephants. PAA has also been identified as one of the aromatic acids of sun-cured Greek and Turkish tobacco (Kimland et al., 1973; Chuman and Noguchi, 1977) and was isolated among diverse volatile compounds from swine manure (Yasuhara and Fuwa, 1983). Of special note were the different effects that corn and teosinte pollen had on the radicle growth of

Amaranthus. This is especially interesting considering the taxonomic proximity of both *Zea* species.

The presence of biologically active compounds in corn pollen could be an adaptive mechanism that benefits the species in some way or it could be due to chance. The comparative study of the allelopathic effect of corn pollen and teosinte pollen suggests that the production of allelopathic substances in corn pollen could be an adaptation to management and selection by man or to the new ecological circumstances faced by this plant during its cultivation. The variation of growth regulators in the pollen of both species also confers on them different reproductive and ecological adaptations.

Acknowledgments—We are grateful to Rogelio Pereda-Miranda for the critical review of the chemistry in this paper, to María del Carmen Márquez for her help in GC techniques, and to Viola Miglio and José María Ramos for the English revision. The study was partially sponsored by project PCECCCNA-050954 of CONACyT.

(Received September 26, 1991; accepted February 3, 1992)

Abstract—Mated and virgin female and virgin male tobacco budworm moths, *Heliothis virescens* (F.), responded via directed upwind flight in wind-tunnel bioassays to volatiles from floral extracts of cotton, *Gossypium hirsutum* L. Significantly more male and female moths landed on cloth dispensers treated with a methylene chloride extract of debracted flowers than on control dispensers treated only with methylene chloride. Only mated females landed in significant numbers on the dispensers treated with extract of cotton squares, flowers (including bracts), or flower petals. After landing, most of the moths examined the dispensers by probing with their antennae, proboscis, and/or ovipositor.

Key Words—Tobacco budworm, *Heliothis virescens*, Lepidoptera, Noctuidae, cotton, *gossypium hirsutum*, oviposition, attractant, floral extracts.

INTRODUCTION

Phytophagous insects often use volatile chemicals emitted from plants to locate suitable oviposition sites and food sources for themselves or their progeny. In studies on the behavioral effects of host and nonhost allelochemicals on *Heliothis* (Lepidoptera: Noctuidae) , we have observed attraction and oviposition stimulation of *H. virescens* (F.) and *H. subflexa* (Guenée) moths by host-plant extracts (Mitchell and Heath, 1987; Mitchell et al., 1990; Tingle et al., 1989, 1990). Volatiles from extracts of cotton leaves and squares (flower buds) and leaves

*To whom correspondence should be addressed.

from tobacco and *Desmodium tortuosum* (Swartz) de Candolle (a wild host) induced mated *H. virescens* females to exhibit a full array of behaviors (upwind flight, landing, surface examination with antennae, and oviposition on treated substrates) expected of gravid individuals seeking sites to oviposit. Virgin female and male moths were significantly less responsive to the attractant than were mated females. Mitchell et al. (1991) presented data suggesting that cotton squares have a greater concentration of flight- and orientation-stimulating compounds than do the leaves.

Wiesenborn and Baker (1990) found in wind tunnel bioassays that pink bollworm moths, *Pectinophora gossypiella* (Saunders), were attracted to a hexane extract of cotton flowers. They proposed that the flower volatiles act as a food lure, attracting moths to extra floral nectaries. Similarly, Haynes et al. (1991) demonstrated in wind-tunnel assays that olfactory stimuli played an important role in the cabbage looper's, *Trichoplusia ni* (Hübner), ability to locate nectar on honeysuckle flowers, *Abelia grandifora* (Andre). The study reported here describes the behavioral responses exhibited by *H. virescens* females (virgin and mated) and virgin males in wind-tunnel assays when exposed to extract from the flowering parts of cotton, *Gossypium hirsutum* L.

METHODS AND MATERIALS

A Plexiglas wind tunnel (0.6 × 0.6 × 1.95 m) was used to observe flight and other behavioral responses by *H. virescens* to crude extracts of cotton squares (flower buds), whole blooms, blooms with bracts removed, and petals (including pistils and stamens) from blooms. The extracts were prepared from field-grown cotton (variety McNair 220) by washing ca. 400 g of fresh plant material for 30 sec in 1 liter of solvent (methylene chloride), which was filtered and stored in glass containers at 0°C until used (Mitchell and Heath, 1987). Before testing, the extracts were concentrated in a rotary evaporator to 2-g equivalents (2 gE) per 200 μl methylene chloride. Mitchell et al. (1991) determined previously, that 2 gE of cotton square extract attracted over 50% of the mated female *H. virescens* tested in wind-tunnel bioassays.

Test insects were reared in our laboratory on a modified pinto bean diet using the methods described by Guy et al. (1985) and Mitchell et al. (1988). Pupae were held in 5.5-liter plastic cages with screened tops until emergence. Upon eclosion, virgin females and males were held separately or combined for mating (21 females and 14 males/cage). The moths were fed a 10% honey–water solution and held under a reversed 14 : 10-hr light–dark cycle in a holding room maintained at 26 ± 1°C and 65 ± 5% relative humidity for two to four days prior to testing.

On the day of testing, the sex of each moth was verified by gently squeezing

the abdomen to extrude the genitalia. Mated and virgin females and virgin males were confined separately in three 25 × 25 × 25-cm Plexiglas holding cages and placed in the flight tunnel room (3.0 × 2.6 × 2.1 m) ca. 1 hr before scotophase. An intake vent in the wall allowed a continuous flow of fresh unfiltered air from the outdoors into the room, which was maintained at the same environmental conditions as the holding room. An electric timer was used to control overhead fluorescent lights (two banks of two 40-W bulbs). The flight tunnel was the same as described by Tingle et al. (1989). Three incandescent 25-W red light bulbs equally spaced above the tunnel remained on continuously. The light level during scotophase was 2.4 lux inside the tunnel. Air was pulled through the tunnel at ca. 0.4 m/sec, when measured at the center of the tunnel, and exhausted ca. 3 m above the roof covering the flight-tunnel room via a 30-cm-diam. flexible pipe equipped with a fan.

Crude extract (2-gE) from either cotton squares, whole blooms, debracted blooms, or petals from blooms was applied to white cotton muslin cloth that was secured over the end of a glass cylinder dispenser (3.5-cm opening) with a rubber band. On a second cloth-covered dispenser, 200 μl of methylene chloride was applied as a control. After waiting 5 min for the solvent to evaporate, the two dispensers were placed 30-cm apart at the upwind end of the tunnel. Treated and control dispensers were rotated between positions after each replication. Air was blown through each cylinder with an aquarium pump at the rate of 1 liter/min to provide a continuous flow (plume) of the extract odor through the tunnel. The location and form of the plumes were verified by introducing smoke into the dispenser system and observing the smoke trails. The plume from each dispenser remained separate until merging ca. 65 cm from the opposite (downwind) end of the tunnel.

Each moth was removed from the holding cage and placed into a cylindrical 4.0 × 6.5-cm plastic release cage with screened ends. After placement of the release cage into the downwind end of the flight tunnel, the moth was released immediately and observed with the aid of a low-light video camera for 3 min. Behavioral responses, including random and oriented flight, and contacts, landings, and oviposition on extract-treated and control substrates were recorded. Five replicates each of 10 mated females, virgin females, or virgin males were tested individually for responses to each of the four extracts. The data were converted to arcsin $\sqrt{\text{percentage}}$ and analyzed using either the paired or unpaired *t*- test (Steel and Torrie, 1960).

RESULTS AND DISCUSSION

Volatiles from extracts of whole (intact) cotton flowers, flowers without bracts, and the extract of petals, pistils, and stamens from flowers attracted significantly more (paired *t*-test) mated and virgin female and male *H. virescens*

to extract-treated substrates than did the corresponding controls (Figure 1, top). The extract from cotton squares attracted significantly more virgin males and mated females (but not virgin females) than did the control. When response to each extract, as demonstrated by upwind flight toward the treated substrate, was compared with the response to each of the other extracts (unpaired *t*-test), the highest significant response was recorded for mated and virgin females to volatiles emitted from the extract of debracted flowers (Table 1). There were no significant differences among the extracts attracting virgin males toward the

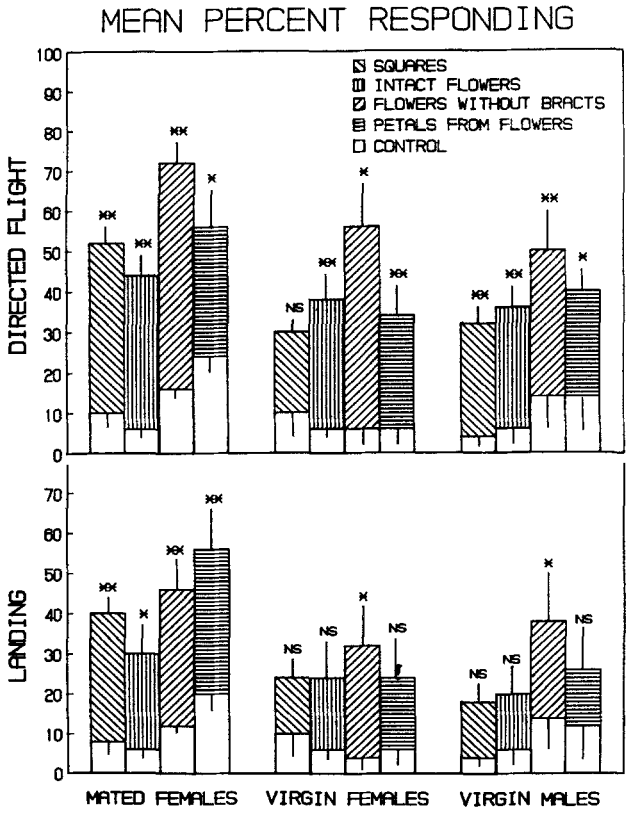

FIG. 1. Response of *Heliothis virescens* moths exposed in a wind tunnel to extracts from cotton. Mean percentages indicate positive anemotactic response by directed flight toward the odor source (top) or landing on extract-treated substrates (bottom). Thin lines above or below the tops of bars indicate standard error of the mean. Significance determined by Student's paired *t*-test from percentage of moths flying to or landing on treated and untreated (control) substrates in choice tests: NS = nonsignificant at $P < 0.05$; * = significant at $P < 0.05$; ** = significant at $P < 0.01$.

treated substrates. The flight sequence was similar to that previously described by Tingle et al. (1989, 1990) and Mitchell et al. (1991). Most of the moths exited the release cage and began random flight in an upwind direction. Moths that detected the odor plume from the extract flew upwind in a zigzag pattern toward the dispenser. A few moths flew directly to the dispenser after exiting the release cage and landed on the cloth substrate.

Significantly more mated females landed on dispensers treated with each of the extracts (paired t-test) than on control dispensers (Figure 1, bottom). Virgin females and males landed in significant numbers only on the dispensers treated with the extract of debracted flowers. Most of the moths that landed examined the cloth substrates by probing with their antennae, proboscis, and/or ovipositor. Where 20% of the landings by mated females resulted in egg deposition on the treated substrates, only 4% of the landings by virgin females resulted in egg laying. There were no apparent differences in the effect of the various extracts on oviposition. Because it is unclear whether the chemicals that induced the moths to respond by anemotaxis in the flight tunnel are the same

compounds that stimulated oviposition, the oviposition olfactometer developed by Mitchell and Heath (1987) is a better system than the flight tunnel for evaluating oviposition behavior per se.

During previous tests, we had not observed probing of substrates with the proboscis (Tingle et al., 1989, 1990; Mitchell et al., 1991; Tingle and Mitchell, 1991). However, by using a low-light video camera to record behavioral responses to the cotton extracts, we were able to observe extension of the proboscis by males and females (virgin and mated) in this study. Over 50% of the landings on treated substrates by mated females resulted in proboscis extension, which did not vary significantly among the various substrates ($P < 0.05$, unpaired t test). All of the virgin females and males that landed on substrates treated with the extract from whole flowers exhibited proboscis extension, but significantly fewer ($P < 0.05$, unpaired t test) of the moths (47 and 66%, respectively) that landed on the other extract-treated substrates showed this response. Proboscis extension was not surprising because Lepidoptera have contact chemoreceptors located on the proboscis, as well as on the antennae, tarsi, and ovipositor. In a review of contact chemoreception, Stadler (1984) stated that after phytophagous insects have located a potential host plant using olfactory or visual cues, contact with the plant surface appears to be essential before feeding or oviposition is initiated.

Information received via probing with the proboscis may be assessed in conjunction with that from the tarsi, as suggested by Blaney and Simmonds (1988). Their work indicated that feeding behavior by *H. virescens*, *H. armigera* (Hübner), and *Spodoptera littoralis* (Boisdval) adults was correlated with the electrophysiological response of sensilla on the proboscis. They reported that responses of the sensilla to sugar and amino acids were significantly correlated to feeding behavior in each of these species. Additionally, Stadler and Seabrook (1975) determined that sensilla on the proboscis of the eastern spruce budworm, *Choristoneura fumiferana* Chem., were sensitive to sugars, which are involved in feeding behavior, but not to host-specific chemicals that promote oviposition.

We have not yet determined the chemical composition of the cotton extracts that stimulated host-finding, oviposition, and feeding-like responses noted here for *H. virescens*. We also do not know if the same chemical components are present in leaves, squares, and flowers, or if all the components exist in varying ratios throughout the plant. Identification of the chemicals and blends thereof that attract tobacco budworm moths and that stimulate them to feed or oviposit may permit development of systems to regulate populations of this important insect pest.

Plant-produced semiochemicals provide a variety of opportunities to develop manipulative schemes for controlling insect pests on crops. Such schemes may involve: (1) the elimination or reduction of attractants or oviposition stimulants from otherwise desirable cultivars via plant breeding; (2) the development of

baits using attractive substances from plants alone; or (3) the development of baits containing plant-attractive substances in combination with sex pheromones. Such baits could be used to detect or monitor pest insects or for direct control of pest populations using attractive baits containing a toxicant.

The vast majority of attractant chemicals identified have been sex-specific pheromones, primarily produced by females and attractive to males (Mayer and McLaughlin, 1991). Therefore, the use of sex attractant pheromones as predictive tools to forecast pest numbers or potential damage levels in specific crops has been significantly limited because attractants are usually directed at only one sex. Thus, identification of plant constituents that attract *H. virescens* adults, especially females, and that directly affect their feeding or reproductive behavior would greatly expand opportunities for manipulation of the biological and environmental events that control the establishment, development, and dispersal of this important crop pest.

DO DEFOLIATION AND SUBSEQUENT PHYTOCHEMICAL RESPONSES REDUCE FUTURE HERBIVORY ON OAK TREES?

STANLEY H. FAETH

Department of Zoology
Arizona State University
Tempe, Arizona, 85287-1501

(Received December 9, 1991; accepted February 3, 1992)

Abstract—Perennial plants are thought to respond to partial or complete defoliation by producing new foliage that is less susceptible to herbivores because of induction of allelochemicals. Here, I tested this hypothesis by manually removing primary foliage from branches of *Quercus emoryi* (Fagaceae) at two different times in the season and monitoring changes in protein and tannin levels and the amount of herbivory relative to control branches. New, secondary leaves had 2.5 × greater hydrolyzable tannin content than mature foliage of control branches. Condensed tannins, which constitute a relatively low fraction of leaf mass, were lower, while protein content was temporarily greater, in new secondary leaves relative to mature leaves. Despite large increases in hydrolyzable tannins, herbivory levels were greater on refoliated branches than on control branches. New foliage is susceptible to herbivory regardless of when it is produced in the season, possibly because lower toughness and higher water content override any induced or developmentally related changes in allelochemistry. My results do not support the hypothesis that postherbivore changes in phytochemistry protect perennial plants from future herbivory, at least within a growing season.

Key Words—Oak, *Quercus emoryi*, Fagaceae, defoliation, allelochemical induction, herbivory, tannins, defense.

INTRODUCTION

The foliage of many perennial plants changes in nutrition, allelochemistry, phenology, and morphology following herbivory (for reviews, see Spencer, 1988; Tallamy and Raupp, 1991). These induced responses to herbivory have been viewed as another level of plant defense against herbivore attack, in addition to

0098-0331/92/0600-0915$06.50/0 © 1992 Plenum Publishing Corporation

constitutive variation in phytochemistry, phenology, and morphology (cf. Tallamy and Raupp, 1991). Induced responses can be shown to decrease feeding, slow development, or increase mortality of some herbivores in both laboratory and field settings (cf. Tallamy and Raupp, 1991). The critical assumption underlying the notion of induced responses as plant defenses is that responses following herbivory reduce future tissue losses or increase fitness of perennial plants (Schultz, 1988). For example, induced chemical responses may increase mortality of herbivorous insects, but no fitness gain is realized by the plant because compensatory mortality factors maintain constant herbivore population size (Schultz, 1988; Faeth, 1991a; Karban, 1991).

I tested the hypothesis that defoliation reduces future herbivory in *Quercus emoryi* (Fagaceae) by manually removing leaves from branches within trees and monitoring phytochemical changes and amount of arthropod herbivory on new, secondary foliage. Branches were defoliated at two different times in the growing season to assess how timing of defoliation affects regrowth, phytochemistry, and subsequent herbivory.

METHODS AND MATERIALS

Study Trees and Site. Quercus emoryi, Emory oak, is a dominant, semievergreen tree in central Arizona ranging from elevations of 1060 m to 2600 m (Kearney and Peebles, 1960). Emory oak usually grows determinately with new leaves produced in a single flush in mid-April to mid-May as year old leaves abscise. However, secondary, new leaves are produced later in the growing season if primary leaves are damaged physically or consumed by herbivores (Faeth, 1987).

The study site is at the Sierra Ancha Experimental Station (USDA) in a riparian zone surrounding Parker Creek (Gila County, Arizona) at 1554 m elevation, approximately the midrange of Emory oak. Rainfall is high (62.7 cm/year) and soils in the riparian zone are well-developed (Pase and Johnson, 1968) relative to other habitats of Emory oak in Arizona.

Defoliation and Estimation of Herbivory. Ten trees were selected randomly in May 1988 at the study site from a pool of similar-sized trees within a 100-m radius. Within each tree, four branches were chosen randomly from a pool of similar-sized branches at the same canopy height (1–3 m) and same aspect (i.e., cardinal direction) within a tree. One randomly-selected branch was defoliated early in the season, June 2, 1988, and paired with a randomly selected control branch (no defoliation). Paired branches were adjacent secondary branches on the same primary branch. A second randomly selected branch within each tree was defoliated later in the season (June 28, 1988) and also paired with a control branch. Branches within trees were selected as experimental units for

two reasons. First, complete defoliation of branches mimics natural herbivory events for this oak. Arthropod herbivores rarely defoliate entire trees, but early season defoliators such as the western tent caterpillar commonly defoliate whole branches and these branches reflush leaves later in the growing season. Second, the amount of simulated herbivory is $<1\%$ of the total leaf area of the trees. This experimental level of damage is less than that typically removed by endemic herbivores (5–20%) (Faeth, 1987). Previous studies (Faeth, 1986, 1987, 1990) show that induction of allelochemicals is localized within Emory oak trees (i.e., there are no systemic responses in nondamaged branches or leaves within trees) even at much higher levels of simulated and insect damage. Using paired branches within trees permitted better control of biotic and abiotic factors that can influence rates of herbivory among Emory oak trees (Faeth, 1985, 1991b).

Defoliation was accomplished by carefully plucking individual leaves until all leaves were removed from experimental branches. Artificial herbivory may not always produce the same phytochemical responses as does herbivory by arthropods (Baldwin, 1990). However, at least for *Q. emoryi*, artificial herbivory results in similar quantitative changes in tannin and protein content relative to damage by native arthropod herbivores (Faeth, 1986). I artificially defoliated branches to control both extent and timing of damage in the field, which is not feasible with native herbivores.

All defoliated branches were monitored weekly for evidence of refoliation. Budbreak was defined as first appearance of unfurled, secondary leaves from swelled buds. Time of refoliation was measured in days from defoliation and difference between early and late defoliation branches was tested by a Student's t test.

Entire branches were removed at the end of the growing season (April 4, 1989) before leaf abscission began and returned to the laboratory. All leaves were counted and examined for herbivory. Mean ($\pm$SD) number and range of leaves from branches were: control (early and late) $\bar{X} = 662.1 \pm 206.1$, range = 331–957; early defoliation $\bar{X} = 169.4 \pm 117.2$, range = 29–335, and late defoliation $\bar{X} = 262.8 \pm 208.3$, range = 94–735.

The amount of herbivory on new, secondary leaves was compared to leaves on control branches to test the hypothesis that induced responses in secondary leaves of Emory oak reduced further tissue loss. Amount of herbivory was measured in two ways. First, the percent of damaged leaves was calculated by dividing the number of damaged leaves by the total number of leaves for each branch. Second, total leaf area removed was estimated by either randomly selecting a subset of 50 damaged leaves from each branch or, if there were less than 50 damaged leaves within a branch, all of the damaged leaves. The area of each damaged leaf was measured with a leaf area meter, and this area was subtracted from the area of a reconstructed leaf (with opaque tape) to obtain area removed. Each branch was examined thoroughly for petiole scars, which indicate whole

missing leaves. The area of missing leaves was estimated by using the average area of leaves remaining in a terminal cluster. The mean damaged area per leaf was calculated and multiplied by percent of damaged leaves to obtain the total area removed (cm^2). The percent of damaged leaves (arcsine square root transformed), and percent total area removed (arcsine square root transformed) was compared statistically between early and late defoliation and control branches with paired t tests.

I compared size of refoliated leaves to mature leaves by weighing 50 randomly selected, undamaged leaves from each branch and comparing means with a paired *t* test.

Phytochemical Analyses. A small, haphazard sample of leaves (2–20 leaves) was removed from refoliated branches and paired control branches at three 30-day intervals, June 30, July 29, and August 28, 1988, for phytochemical analyses. Leaves were immediately frozen on Dry Ice in the field and returned to the laboratory, where they were lyophilized and then examined for herbivory (see above). Leaves were then ground to a fine powder in a Wiley mill and stored in airtight jars with a desiccant at 5°C until analyses of protein and tannins could be performed.

Details of the phytochemical methods and standardization are in Faeth (1985, 1986). Briefly, relative protein content was determined by the BioRad method (Richmond, California), after washing samples 2× with acetone to remove pigments and tannins. Condensed tannins were determined by a modified acidified vanillin method (Broadhurst and Jones, 1978) after extraction in acetone. Monomeric phenols were first isolated and quantified by removing tannin polymers with a selective adsorbent (Sephadex LH-20). Condensed tannins then were determined by subtracting monomers from total vanillin positive (monomers plus condensed tannin polymers), using a catechin standard prepared for each run. Only results from condensed tannins are presented here since total vanillin positive shows similar trends and because monomeric fractions were very low and varied little among samples. Hydrolyzable tannins were determined by a modified potassium iodate technique (Bate-Smith, 1977) and expressed as percent dry mass tannic acid equivalents. The method is specific for only the galloyl group of hydrolyzable tannins, not ellagitannins, but it is commonly used as an estimate of hydrolyzable tannin content (Schultz and Baldwin, 1982; Baldwin and Schultz, 1983; Faeth, 1990).

All phytochemical analyses were run in triplicate for each leaf branch sample at each date. All phytochemical methods have been standardized and have produced consistent results for Emory oak over an 8-year span (Faeth, 1985, 1986, 1988).

The objective was to sample branches that had just refoliated and then to resample branches 30 days later to determine temporal changes relative to controls. However, since not all branches had refoliated by these dates, especially

the more variable late defoliated branches, and two branches did not refoliate due to insect damage to buds, two consecutive sampling periods were available from six of the early defoliated branches (June 30, July 29) and only three of the late defoliated ones (July 29, August 28). I used ANOVA to determine if phytochemical samples from late defoliated branches could be pooled with early defoliated ones. In other words, I statistically determined if the phytochemistry of new, secondary leaves and 30-day-old leaves on late defoliated branches was the same as that of new and 30-day-old leaves on early defoliated branches, but separated by a 30-day time period. None of the phytochemical parameters varied significantly ($F < 5.10$, $df = 1,7$, $P > 0.10$ for all comparisons) between secondary leaves of the same developmental age on early and late defoliated branches, so samples were pooled in subsequent statistical analyses. I used paired t tests to compare statistically phytochemical measures (arcsine square root transformed) from new, secondary leaves and 30-day-old leaves to their control branch counterparts.

RESULTS

Time to Refoliation. Branches defoliated early in the season produced secondary leaves earlier ($\bar{X} = 21.9 \pm 5.7$ days) than branches defoliated later in the season ($\bar{X} = 36.5 \pm 20.6$ days, $t = 2.05$, $df = 15$, $0.05 < P < 0.10$).

Herbivory Levels. The percentage of leaves damaged by arthropods on branches defoliated early was not significantly different from control branches (Figure 1, $t = 1.13$, $df = 7$, $P > 0.20$). Similarly, the percentage of leaves damaged on branches defoliated late was not different from paired control branches (Figure 1, $t = .37$, $df = 7$, $P > 0.40$).

Percent leaf area removed from branches defoliated early was not significantly different from paired control branches (Figure 2, $t = 1.27$, $df = 7$, $P > 0.20$). However, percent leaf area on branches defoliated late in the season was greater than that removed from control branches (Figure 2), although this difference was only marginally significant ($t = 2.33$, $df = 7$, $0.05 < P < 0.10$). Generally, herbivory tended to be greater on experimentally defoliated branches than control branches (Figures 1 and 2), opposite to predictions that refoliated branches are more resistant to herbivory.

Refoliated leaves on experimental branches were significantly smaller than mature leaves on control branches ($\bar{X} \pm$ SE, refoliated leaves = 19.16 mg $\pm$ 4.92; $\bar{X} \pm$ SE, mature leaves = 47.89 mg $\pm$ 11.97; $t = 9.38$, $df = 15$, $P < 0.0001$). Refoliated leaves were approximately 60% of the size of the mature leaves.

Phytochemistry. Protein content of new, secondary leaves on defoliated branches was significantly greater ($t = 3.32$, $df = 8$, $P < 0.05$) than paired

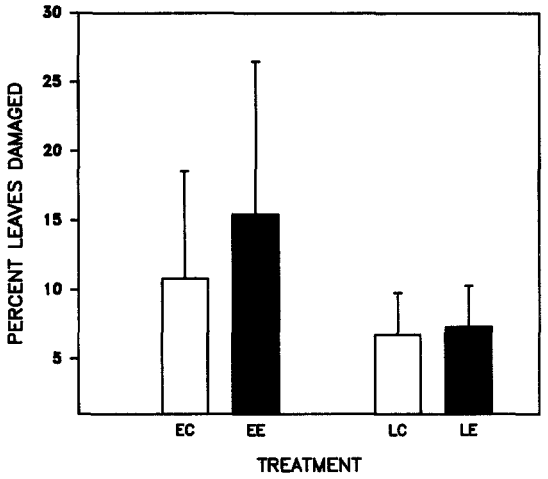

FIG. 1. Mean (±SE) percent of leaves damaged by arthropod herbivores on early-season control (EC) and experimental (EE) and late-season control (LC) and experimental (LE) branches. Data shown are untransformed; percentages were arcsine transformed for statistical tests.

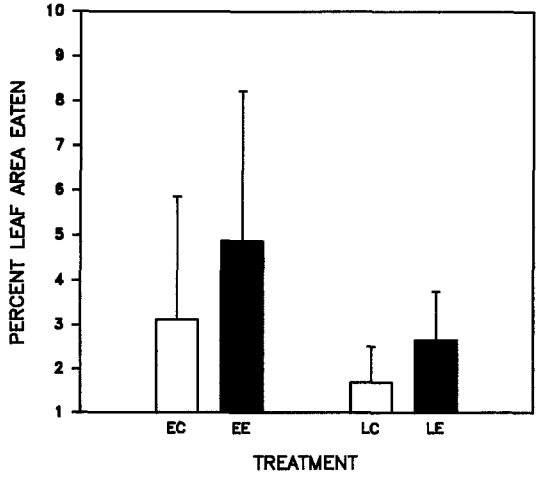

FIG. 2. Mean (±SE) percent of leaf area consumed by arthropod herbivores on early-season control (EC) and experimental (EE) and late-season control (LC) and experimental (LE) branches. Data shown are untransformed; percentages were arcsine transformed for statistical tests.

control branches (Figure 3). Thirty days after reflushing, however, protein content of replacement leaves declined and was not different ($t = 1.03$, $df = 8$, $P > 0.20$) from mature foliage of paired control branches (Figure 3).

Hydrolyzable tannin content of new, secondary leaves on defoliated branches was significantly greater ($t = 5.34$, $df = 8$, $P < 0.001$) on defoliated branches relative to control foliage (Figure 4). Although declining after 30 days, hydrolyzable tannin content on experimental branches was still significantly greater ($t = 6.68$, $df = 8$, $P < 0.001$) than that of control branches.

Condensed tannin content of new, secondary leaves on defoliated branches was significantly less ($t = 3.67$, $df = 8$, $P < 0.01$) than that of control branches (Figure 5). Condensed tannin content of defoliated branches remained significantly lower than control branches ($t = 3.54$, $df = 8$, $P < 0.01$) 30 days after reflushing (Figure 5).

DISCUSSION

New, secondary leaves contain 2.5× more hydrolyzable tannins than mature foliage. Such increases in hydrolyzable tannins in replacement leaves after partial defoliation have been considered induced defenses in *Q. rubrum* against future herbivory (Schultz and Baldwin, 1982). However, it is unclear if changes in secondary foliage of Emory oak are induced responses or simply reflect

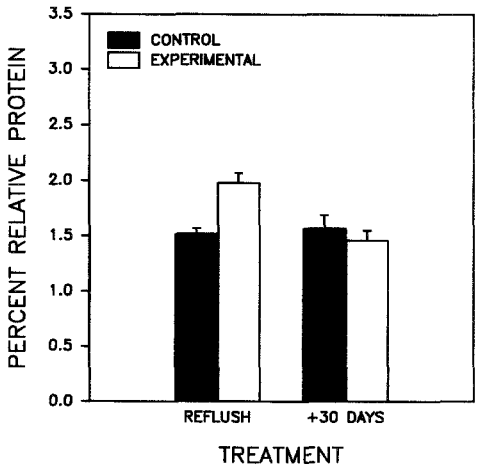

FIG. 3. Mean (±SE) percent relative protein content of control and experimental branches at the time of reflushing of defoliated branches and 30 days later. Data from early and late control and experimental branches were pooled after ANOVA showed no significant differences (see text). Data shown are untransformed; percentages were arcsine transformed for statistical tests.

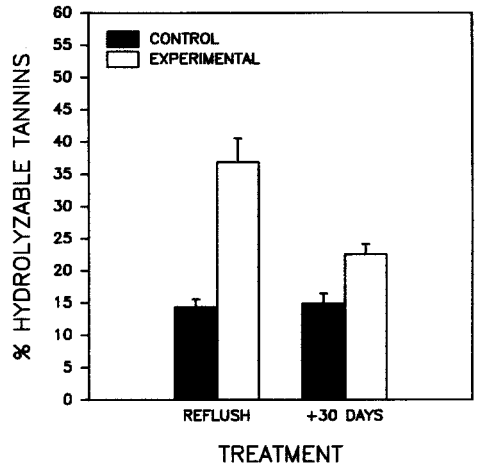

FIG. 4. Mean (±SE) percent hydrolyzable tannin content of control and experimental branches at the time of reflushing of defoliated branches and 30 days later. Data from early and late control and experimental branches were pooled after ANOVA showed no significant differences (see text). Data shown are untransformed; percentages were arcsine transformed for statistical tests.

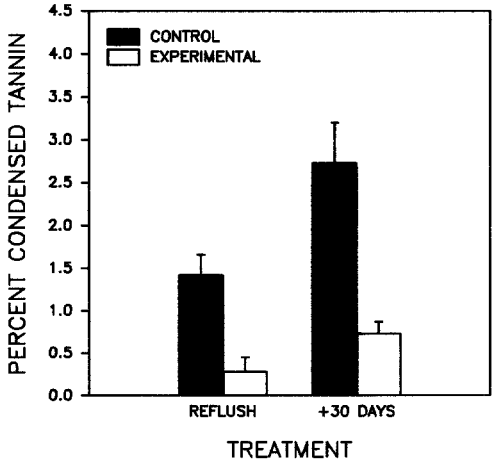

FIG. 5. Mean (±SE) percent condensed tannin content of control and experimental branches at the time of reflushing of defoliated branches and 30 days later. Data from early and late control and experimental branches were pooled after ANOVA showed no significant differences (see text). Data shown are untransformed; percentages were arcsine square transformed for statistical tests.

developmental age of new leaves. The latter is supported by two lines of evidence. First, new foliage on early and late defoliated branches did not differ significantly in protein or condensed or hydrolyzable tannin content (see Phytochemical Analyses in Methods and Materials), indicating secondary leaves are phytochemically similar regardless of when they are produced in the growing season. Secondly, secondary leaves on both types of experimental branches are very similar to new, primary leaves in initial phytochemical composition and subsequent seasonal changes (Faeth, 1985, 1986). Protein and hydrolyzable tannin content of primary leaves is initially high but rapidly declines after 30 days, while condensed tannin content is initially very low but gradually increases throughout the remainder of the growing season (Faeth, 1985).

Whether one considers increased hydrolyzable tannin levels in new, secondary leaves as induced responses or as a consequence of developmental age, these leaves are not less susceptible to future herbivory from arthropods. On the contrary, secondary foliage tended to be more vulnerable to herbivores (Figures 1 and 2). This susceptibility is even more pronounced when one considers that secondary foliage on early and late defoliated branches was exposed to herbivores 54 and 95 days, respectively, (approximate number of days from spring budbreak to refoliation) less, on average, than their paired control counterparts in the year-long growing season. Moreover, two experimental branches were excluded from analysis because their buds were completely destroyed by herbivores before they could unfurl. Clearly, increases in hydrolyzable tannins in secondary foliage do not reduce tissue losses for this perennial plant.

New leaves of defoliated branches were lower in condensed tannin and higher in protein content relative to mature foliage on control branches. These differences may have increased quality of leaves for herbivores and could explain higher rates of folivory on new leaves. However, the increased protein in new leaves is transitory and declines to that of mature leaves within 30 days. Condensed tannins constitute a relatively small fraction of leaf mass compared to hydrolyzable tannins (Figures 4 and 5), and condensed tannins are thought to be less effective deterrents against arthropod herbivores than are hydrolyzable tannins (Zucker, 1983). It is possible that some qualitative change in specific tannin compounds or some other unknown chemical changes explain differences in herbivory levels. However, a more parsimonious explanation may be that higher water content and lower "toughness" of new oak leaves (Feeny, 1970; Faeth, 1985) makes them more susceptible to herbivory no matter when they appear in the growing season and overrides any differences in allelochemistry. Other studies examining defoliation and refoliation in the same growing season indicate that foliage produced after defoliation events is generally more susceptible to herbivory (Rockwood, 1974; Auerbach and Simberloff, 1985; Pullin, 1987; Silva-Bohorquez, 1986; Faeth, 1987; Hunter, 1987) than mature foliage.

There is considerable debate about both the short- and long-term effects of

induced changes on feeding, development, and survival of arthropod herbivores (e.g., Fowler and Lawton, 1985; Schultz, 1988, see reviews in Spencer, 1988; Barbosa and Letourneau, 1988; Karban and Myers, 1989; Tallamy and Raupp, 1991) as well as the mechanisms for plant responses (cf., Bryant et al., 1991). The key, however, to the defensive role of induced responses from the plant's perspective is a reduction in tissue loss or an increase in fitness (Schultz, 1988). Although this study examined only one type and temporal scale of herbivory, defoliation of branches within trees in a growing season, the results do not support a defensive role of postdefoliation chemical changes, regardless of whether the changes are induced in response to herbivory or "incidental" (sensu Neuvonen and Haukioja, 1991) to plant development. Other studies of this oak involving partial damage to individual leaves and long-term effects of past episodes of herbivory on future resistance also fail to support the defensive role of induced changes (Faeth, 1987, 1992).

Acknowledgments—I thank K. Hammon, R. Rooney, C. Febus, A. Nabee, and S. Reeser for assistance in the field or lab. D. Arnott, B. Clark, K. Cristofaro, K. Hammon, T. Kingrey and J. Simmons made helpful comments on earlier versions of the manuscript. P. Chase, Center for Environmental Studies, ASU, provided accommodations and a pleasant working atmosphere at the Sierra Ancha Experimental Station. This research was supported by NSF grants BSR 8715743 and BSR 9107296.

Book Review

Insect Chemical Ecology. Ivan Hrdý (ed.). Prague, Czechoslovakia: Academia Praha, 1991. 513 pp.

This book consists of a compilation of 75 papers presented at a conference in Tábor, Czechoslovakia, in August 1990. The invited speakers had been asked to present either comprehensive or introductory reports and, as a result, the contributions are of variable length and nature, ranging from relatively extensive reviews to brief research communications.

The book is divided into three sections: (1) chemical communication in insects; (2) chemical insect–plant relationships; and (3) prospects of practical application of pheromones and juvenoids.

Section 1 begins with a review of new methodology for pheromone isolation and identification, with examples of structure–activity studies and some discussion of perception mechanisms. This is followed by a report on the use of photoaffinity labeling to characterize receptors and carrier proteins involved in transport and transduction processes. Subsequent papers describe specific examples of pheromone systems, with emphasis on structure–activity relationships, species specificity, control of pheromone production, and factors affecting insect responses. Included in this group is a well-conceived study of the evolution of moth pheromones. Some additional papers deal with more novel types of pheromones produced by social as well as phytophagous insects. Several contributions are devoted to synthetic methods for pheromones and their intermediates, and others are concerned with factors affecting release rates of pheromones, or perception by and subsequent behavior of the target insect.

Section 2 starts with an introductory review of phytoecdysteroids, followed by several more specific studies of ecdysteroids from various natural and synthetic sources. Other contributions deal with plant compounds that affect feeding, reproduction, or orientation. The methodology for analysis, collection, and identification of active phytochemicals is addressed by several authors.

Section 3 provides many examples of efforts to use pheromones or juvenoids in the control of insect pests. A large number of these reports focus on population monitoring or mass trapping, whereas others describe preliminary attempts to control specific insects using various juvenoids. Also included here are studies of formulation for controlled release of active compounds and metabolic investigations to determine the fate of certain juvenoids. The opening presentation in this section gives several convincing examples of promising

0098-0331/92/0600-0927$06.50/0 © 1992 Plenum Publishing Corporation

research areas and new approaches to the practical development of semiochemicals. A review of insect neuropeptides is also included in this section, and another significant paper addresses structure–activity relationships of juvenoids and anti-juvenile hormone compounds.

The quality of papers, although quite variable, is generally good. The involvement of English-speaking coeditors has undoubtedly been useful in the final editing of manuscripts, although some linguistic errors have nevertheless been overlooked. The research appears to be sound in most cases, and some unique ideas have been presented. Since the majority of contributors are from Eastern European countries, this book has particular value as a vehicle for dissemination of ideas and results that were previously suppressed or had limited distribution due to political barriers. The recruitment of participants from a wide variety of other countries has helped to create a truly international flavor and to provide a balance of contributions from both established scientists and developing young investigators.

Book Review

Herbivores: Their Interactions with Secondary Plant Metabolites—Volume 1. The Chemical Participants, 2nd ed., G.A. Rosenthal and M.R. Berenbaum (eds.). San Diego: Academic Press, 1991. 468 pp.

The first edition of *Herbivores: Their Interaction with Secondary Plant Metabolites*, edited by G.A. Rosenthal and D.H. Janzen, played a major role in providing a conceptual framework for studying the chemical ecology of plant–herbivore interactions. In 1979, when the first edition was published, the study of plant–herbivore interactions was in a very rapid stage of growth and change, and it was inevitable that *Herbivores* would be out of date very quickly. The appearance of a revision has been awaited with great impatience and with high expectations. At last the second edition is out, and it meets all of the expectations that have been held out for it.

The second edition is a two-volume set, with the first volume, *The Chemical Participants*, corresponding to Part II of the first edition. Volume I contains 468 pages divided into 12 chapters, which compares with 349 pages divided into 12 chapters in Part II of the original edition. The chapter titles in the second edition are: Nonprotein Amino Acids as Protective Allelochemicals (G.A. Rosenthal), Cyanide and Cyanogenic Glycosides (D.S. Siegler), Alkaloids (T. Hartmann), Glucosinolates (S. Louda and S. Mole), Terpenoids (J. Gershenzon and R. Croteau), Coumarins (M.R. Berenbaum), Cardenolide-Mediated Interactions between Plants and Herbivores (S.B. Malcolm), Iridoid Glycosides (M.D. Bowers), Lectins (I.E. Liener), Tannins and Lignins (A.E. Hagerman and L.G. Butler), Flavonoid Pigments (J.B. Harborne), and Insect Hormones and Antihormones in Plants (W.S. Bowers).

The second edition is a brand new book; it is not a mere update of the first edition. Of the 15 contributors to the second edition, only four had chapters in the first. Of the nine topics covered in both editions, seven are discussed by different authors in the second edition. The second edition includes three chapters devoted to topics (coumarins, cardenolides, and iridoid glycosides) not covered in the first edition. The three topics not revisited in the new edition are toxic seed lipids, saponins, and proteinase inhibitors.

The quality of the individual chapters is uniformly high. Each chapter provides references for isolation and assay procedures, a review of the occurrence and natural distribution of the particular class of chemicals under consideration, and an excellent description of definitive studies of the role of the

0098-0331/92/0600-0929$06.50/0 © 1992 Plenum Publishing Corporation

chemicals in plant–herbivore systems. A cursory scan of the bibliographies at the end of each chapter turned up numerous references to articles published in 1989 and 1990, and even a handful from 1991. The structure and style of the second edition, combined with the current state of development of the fields of chemical ecology and plant–herbivore interactions, suggest that obsolescence will not overtake the second edition as rapidly as it did the first.

Clearly, the thrust of this review is that I consider *Herbivores—Volume I. The Chemical Participants* to be an excellent and important book. In trying to construct statements that reflect my judgment that this revision has been a highly successful endeavor, I repeatedly found myself trying to take statements from the Preface and reword them so that I would not be guilty of outright plagiarism. I finally gave up; I simply cannot improve on the review that the editors have written of their own book. I will, therefore, conclude this review by fully endorsing the following comments from the Preface: "This new edition is richer in basic methodology and far more effective in assisting the interested reader who would like to bring the study of plant allelochemicals into their research activities. . . . The second edition focuses sharply on the kinds of important ecological and chemical ecology questions that have been addressed by the study of these compounds and provides insights into current research directions. . . . The second edition is offered because the time has come for an in-depth, updated consideration of how allelochemicals color and shape the many fascinating interactions between plants and herbivores."

6-METHOXY-2-BENZOXAZOLINONE: A SEMIOCHEMICAL FOR HOST LOCATION BY WESTERN CORN ROOTWORM LARVAE

LOUIS B. BJOSTAD* and BRUCE E. HIBBARD

Department of Entomology
Colorado State University
Fort Collins, Colorado 80523

(Received September 16, 1991; accepted December 10, 1991)

Abstract—A bioassay-driven sequential fractionation scheme was used to isolate all portions of a crude dichloromethane corn seedling extract behaviorally active to larvae of the western corn rootworm, *Diabrotica virgifera virgifera* LeConte. 6-Methoxy-2-benzoxazolinone (MBOA) was identified as one of the most important components of an attractive crude corn extract. MBOA was found on or in the intact root tissues by injecting an extract of undamaged roots onto an HPLC immediately after extraction. MBOA was demonstrated to be volatile and functions as a semiochemical in conjunction with carbon dioxide in host location by western corn rootworm larvae, which are oligophagous on the roots of maize and several other species of grasses. Because MBOA occurs almost exclusively in maize and other grasses, it offers a simple way for the larvae to distinguish possible hosts from non-hosts. MBOA has previously been reported as a chemical defense against other insect species. This is the first report in grasses of a secondary compound that is toxic or a deterrent to nonadapted insect herbivores but that is used as a semiochemical in host location by a specialist insect species.

Key Words—*Diabrotica virgifera virgifera*, 6-methoxy-2-benzoxazolinone, hydroxamic acids, semiochemical, attractants, western corn rootworm, host location, Coleoptera, Chrysomelidae, *Zea mays*, kairomone.

INTRODUCTION

The western corn rootworm, *Diabrotica virgifera virgifera* LeConte, is a serious pest of maize (*Zea mays* L.) throughout much of the maize-growing regions of

*To whom correspondence should be addressed.

0098-0331/92/0700-0931$06.50/0 © 1992 Plenum Publishing Corporation

North America. Larval damage to maize roots results in reduced plant height, reduced yield, and lodging of maize, which interferes with harvesting (Branson et al., 1980). An estimate of crop losses and treatment costs for corn rootworms is in the range of $1 billion annually (Metcalf, 1986).

Unlike host location in many other herbivorous insect species, western corn rootworm adults do not lay their eggs on a host plant. The eggs are laid in the soil in late fall, and the larvae emerge the following spring (Krysan and Miller, 1986). Host location is then carried out underground by the neonate larvae, which are oligophagous on the roots of a few species of grasses (Branson and Ortman, 1967, 1970). The larvae can distinguish the roots of maize from the roots of broad-leaved plants on the basis of olfactory cues. In choice test bioassays with cut roots, significantly more western corn rootworm larvae were attracted to the roots of maize than to the roots of soybean, squash, or sunflower (Branson, 1982).

We previously found that cryogenic collections of volatiles from germinating maize seeds were attractive to western corn rootworm larvae in laboratory behavioral bioassays (Hibbard and Bjostad, 1988, 1989). One of the attractive compounds is carbon dioxide, which is attractive to western corn rootworm larvae (Strnad et al., 1986; Strnad and Bergman, 1987; Hibbard and Bjostad, 1988) and many other soil organisms (Jones and Coaker, 1977; Doane et al., 1975; Pline and Dusenbery, 1987; and references therein). Carbon dioxide is released into the soil by the roots of maize and many other plant species (Massimino et al., 1980), but because it is a general plant metabolite, it does not appear to provide a basis for selective attraction of western corn rootworm larvae to maize over broad-leaved plants. We also found in choice test bioassays that western corn rootworm larvae rely on chemical cues in addition to carbon dioxide to locate maize plants. In choice test bioassays with equal levels of carbon dioxide on both sides of the choice (verified by infrared gas analysis), larvae chose the maize volatile source significantly more often than the source with carbon dioxide alone (Hibbard and Bjostad, 1988). We used a sequential fractionation scheme modified from Silverstein et al. (1967) to isolate several behaviorally active compounds (Hibbard and Bjostad, 1990). We now report the chemical identification of a volatile secondary maize metabolite that western corn rootworm larvae use in orienting to their host.

METHODS AND MATERIALS

Larvae and Maize Source. A nondiapausing strain of *D. virgifera virgifera* was obtained in June 1986 from the USDA-ARS laboratory in Brookings, South Dakota, and was maintained with the methods of Jackson (1986) as modified by Hibbard and Bjostad (1988). Second-instar larvae (5–7 days old and 5–8 mm

long) were chosen for bioassays because initial bioassays indicated that they behaved similarly to first-instar larvae (the instar that must locate a host), and second-instar larvae were more robust for the large numbers of bioassays required. To prevent possible effects from previous testing, larvae were not reused in the bioassays. Dried whole kernels of maize (3090, Pioneer Hi-Bred International, Inc., Johnston, Iowa), not treated with insecticide or fungicide, were washed and soaked (Hibbard and Bjostad, 1988), and maize seedlings [pre-stage 0 germinated seed (Hanway, 1966)] were removed after 3 to 5 days to obtain maize semiochemicals.

Extraction and Isolation of Behaviorally Active Compound. Approximately 80 g of moist maize seedlings was extracted by placing them in a glass seed-holding tube (30 cm × 30 mm, tapering to 12 mm) for 3 to 6 hr and subsequently dripping dichloromethane through them until 4 ml of solution had been collected. The dichloromethane maize extract was then separated into fractions by column chromatography on 60- to 200-mesh silica gel (J.T. Baker Chemical Co., Phillpsburg, New Jersey), eluted batchwise with mixtures of dichloromethane and diethyl ether (100:0, 97:3, 90:10, 75:25, 50:50, and 0:100). The most active fraction in choice test bioassays with equal concentrations of carbon dioxide in both choices was the 75:25 fraction. The major compound in this fraction was isolated by gas chromatography as described by Hibbard and Bjostad (1990). A 2-mm-ID × 1.83-m 3% OV-101 (100/120 mesh) on Chromosorb Q (Alltech Associates, Inc., Deerfield, Illinois) packed column was temperature programmed at 60°C for 1 min, then 10°C/min to a final temperature of 260°C, in a Hewlett-Packard 5890 gas chromatograph. The 4-ml extract was concentrated to 8 μl under a nitrogen stream and injected onto the gas chromatograph. With the detector and noncolumn gases turned off, the fraction with a retention time of 16–17 min (the retention time on the major component in the 75:25 silica gel fraction) was collected with clean pipettes that were snugly connected to the end of the column with a specially fitted Teflon connector (collection efficiency, 70–85%). The collection was repeated 10 times with fresh extract, and the collection pipette was rinsed with the same 300 μl of solvent each time.

Bioassays with Purified Maize Volatile. Fifteen-microliter aliquots (approximately 28 g equiv of 3-day-old corn seedlings) of the 300-μl sample of purified maize volatile in dichloromethane were placed on 0.1 g of glass wool, and an equal amount of dichloromethane was placed on another piece of glass wool. After the solvent had evaporated, the pieces of glass wool were tested in choice test bioassays with equal levels of carbon dioxide (4 mmol/mol at bioassay onset) on both sides of the choice (verified with infrared gas analysis) as described by Hibbard and Bjostad (1990). Ten larvae were placed in the center dish of the choice test (see Hibbard and Bjostad, 1990), and the number of larvae that had reached either of the end dishes was recorded after 1 hr. Bio-

assays were conducted in the dark at room temperature and were replicated 15 times.

Chemical Analysis. Solid probe electron-impact (EI, 70 eV) and chemical ionization (CI, NH_4^+) mass spectra of the purified maize volatile were obtained with a VG, Inc., mass spectrometer (Model MM-16F). A ^1H NMR spectrum of the purified maize volatile in $CDCl_3$ was obtained with a Bruker AM500 (500 MHz). A diffuse reflectance infrared spectrum was obtained on a Nicolet 60SX Fourier transform spectrometer. A synthetic sample of 6-methoxy-2-benzoxazolinone (MBOA) was obtained (donation from Frank Stermitz, Chemistry Department, Colorado State University, and later from Lancaster Synthesis Ltd., Windham, New Hampshire) and was also analyzed by EI-MS, CI-MS, NMR, and IR as described above. A sample of synthetic MBOA was analyzed by coinjection with the purified maize volatile using an RSL-150, 30-m × 0.33-mm (ID) methyl silicone capillary column programmed at 60°C for 1 min, then 10°C/min to a final temperature of 240°C, in a Hewlett Packard 5890 gas chromatograph. The injection port was set at 240°C and the detector was set at 250°C.

Behavioral Bioassays with Synthetic MBOA. Serial dilutions of synthetic MBOA (Lancaster Synthesis Ltd., Windham, New Hampshire) were prepared and 700 ng of synthetic MBOA was tested in choice test bioassays as described above, with equal amounts of carbon dioxide on both sides of the choice. Seven hundred nanograms was chosen, because the amount of MBOA present in the bioassays of the purified maize volatile was determined to be 700 ng. The number of larvae that were found in either side of the choice test was recorded after 1 hr and the experiment was replicated eight times.

MBOA on Corn Seedlings. The primary naturally occurring precursor to MBOA in corn is DIMBOA-glucoside (Wahlroos and Virtanen, 1959). Hofman and Hofmanová (1971) later corroborated this conclusion, but the limits of detectability of the aglucones in these early papers were not given. Recently, Zúñiga and Massardo (1991) detected a significant amount of the aglucone in the intact tissues of wheat despite inhibiting the β-glucosidase with liquid nitrogen and methanol. They also found only the aglucone in 2-day-old wheat and in undifferentiated wheat cell cultures. Because the limits of detection of the aglucones in corn were not given in the early manuscripts, we wished to test specifically for free MBOA.

Untreated corn kernels were washed and soaked as described above and were placed on moist germination paper for three days. The major root of the germinated seed was then quickly dipped into a 4-ml solution of dichloromethane. A total of 70 germinated seeds was extracted over a time period of 5 min. A portion of the extract (300 μl of 4 ml) was concentrated to 50 μl in a nitrogen stream (which took approximately 1 min) and was immediately injected onto a 25 cm × 4.6-mm, 5-μm Econosphere C-18 HPLC column with a Kratos

Spectroflow UV absorbance detector set at a wavelength of 290 nm. Flow through the system was held constant at 1 ml/min. Operating conditions were as follows: mobile phase, solvents A (20 mmol phosphoric acid, pH 2.3) and B (methanol)—0–5 min 0% B isocratic; 5–20 min 0% B–50% B linear gradient; 20–25 min 50% B–100% B linear gradient; 25–27 min 100% B isocratic, 27–30 min 100% B–0% B linear gradient. In addition to injection onto the HPLC, the same amount of the "quick dip" extract was also injected onto an RSL-150 nonpolar methyl silicone capillary GC column (30 m × 0.25-μm ID × 0.25-μm film thickness). Temperature conditions were as described above. As with the HPLC, the crude extract was also coinjected with synthetic MBOA under the same conditions.

MBOA Volatility. MBOA is a high-melting solid [melting point, 158°C (Chen and Chen, 1976)], but other high-melting solids such as camphor [melting point, 180°C (Weast and Astle, 1981)] have appreciable volatility under ambient conditions. It has been questioned whether MBOA is volatile at room temperature. In order to address this question, we conducted three types of experiments. First, because retention time on a methyl silicone GC column is highly correlated with vapor pressure ($r^2 = 0.724$) (Heath and Tumlinson, 1986), we injected synthetic MBOA and a series of known lepidopteran pheromone components. We used our RSL-150 methyl silicone capillary column with the conditions described above. Second, we extracted MBOA-formulated clay granules after being exposed to room air in a layer of granules one granule thick for periods of 0, 1, 2, 4, 8, and 16 days. Each sample consisted of 0.313 g of clay granules that had previously been formulated with 1600 μg of MBOA/g of clay granules. The samples were extracted with 0.5 ml of dichloromethane and 1 μl was injected onto the RLS-150 capillary column under the conditions described above. The experiment was replicated three times. In a third experiment, volatilized MBOA was collected in a cold trap for analysis. Ten milligrams of synthetic MBOA was placed in a 6.35-mm Teflon tube and held in place by 7.6 cm of tightly packed glass wool. One end of the tube was then connected with Swagelock fittings to a nitrogen tank with a two-stage regulator, and the other end of the tube was connected to a loop of Teflon tubing that was bathed in liquid nitrogen. Glass wool (7.6 cm) was placed in the bottom of the loop in the liquid nitrogen as a condensation site. The nitrogen flow rate through the system was held constant at 10 ml/min. After 26 hr, the tube was removed from the liquid nitrogen and extracted with 4 ml of dichloromethane. One milliliter of the extract was concentrated to 50 μl and injected onto the HPLC system as described above.

Statistical Analysis. The statistical package SAS (SAS Institute, 1990) was used in all data analysis. Proc ANOVA was used alone for tests with only two means, and with Duncan's (1955) multiple-range test for analysis with more than two means.

RESULTS

Behavioral Bioassays with the Purified Maize Volatile. The purified maize volatile was significantly attractive ($P < 0.01$) in choice tests with equal levels of carbon dioxide on both sides of the choice (Figure 1A).

EI and CI Mass Spectra. The EI mass spectrum of the purified maize volatile included peaks at *m/z* 165 (100), 150 (63), 136 (4), 122 (11), 109 (16), 106 (34), and 80 (15). The CI mass spectrum included peaks at 183 (100, M + NH_4), 166 (33, M + 1), 165 (50), 153 (2), 139 (2), 124 (5), 106 (4). The EI and CI mass spectra of the purified maize volatile indicated that the M^+ ion

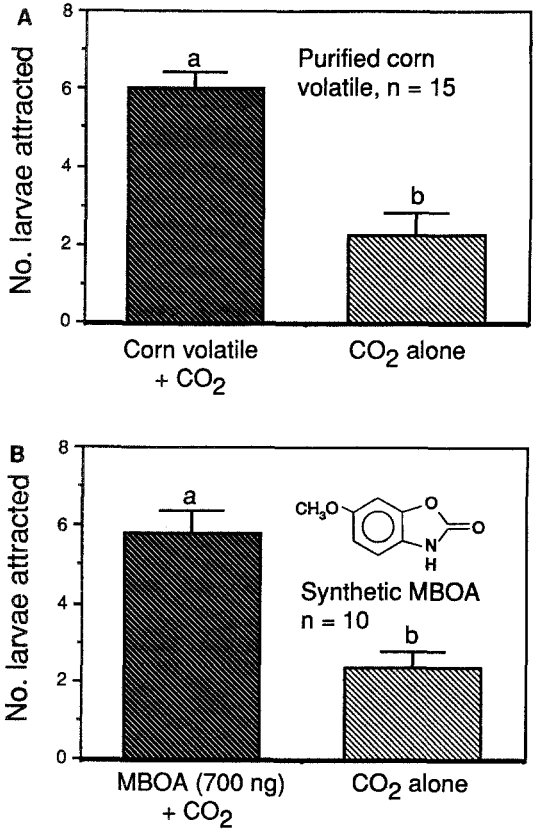

FIG. 1. Choice test bioassays of (A) purified maize volatile and (B) synthetic 6-methoxy-2-benzoxazolinone (MBOA) with equal levels of carbon dioxide on both sides. Treatment means labeled with different lowercase letters were significantly different ($P < 0.01$) according to a one-way analysis of variance (ANOVA). Error bars indicate the standard error of the mean (negative portions not shown).

is m/z 165. The odd molecular weight was consistent with the presence of a nitrogen atom in the molecule.

NMR Spectrum. The ^1H NMR spectrum of the compound is shown in Figure 2. The singlet at δ 3.89 (3H) indicated a methoxy group. The doublets at δ 6.92 (1H) and δ 6.82 (1H) and the double doublet at δ 6.69 (1H) indicated three aromatic hydrogens, with two of the hydrogens adjacent on the aromatic ring. The singlet at δ 8.19 (1H) indicated a proton on nitrogen.

IR Spectrum. The IR spectrum of the purified maize volatile indicated absorptions at 3150, 1770, and 1680 cm^{-1}, which was consistent with N—H, C=O, and C—N, respectively.

Identification. On the basis of the MS, NMR, and IR spectra of the natural and synthetic compound, the structure was determined to be 6-methoxy-2-benzoxazolinone (MBOA). The retention times of synthetic MBOA and the purified maize volatile on an RSL-150 capillary gas chromatograph column were both 14.3 min and this was verified by coinjection. The spectra from EI-MS, CI-MS, NMR, and IR of synthetic 6-methoxy-2-benzoxazolinone were in full agreement with the spectra of the isolated maize volatile.

Behavioral Bioassays with Synthetic MBOA. Synthetic MBOA was significantly attractive ($P < 0.01$) to western corn rootworm larvae at the dose present

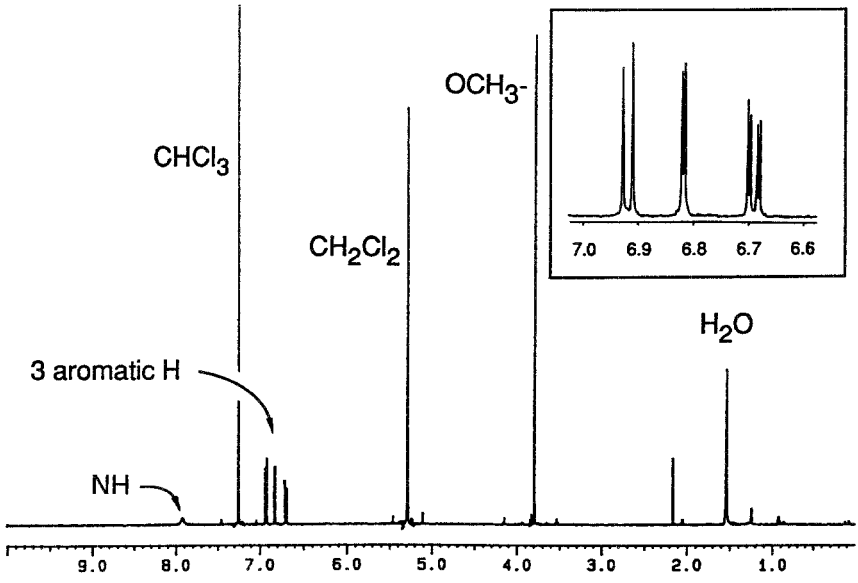

FIG. 2. ^1H NMR spectrum of the purified maize volatile. Inset: Magnification of the three aromatic protons.

in the purified maize volatile (700 ng) on glass wool in choice test bioassays with equal levels of carbon dioxide on both sides of the choice (Figure 1B).

MBOA on Corn Seedlings. Corn root extracts were analyzed using HPLC and GC within 8 min of the extraction of the first corn roots and within 3 min of the extraction of the last corn roots. Using HPLC, 98.7 ng of MBOA/g of 3-day-old corn roots (fresh weight) was found. MBOA was one of the largest peaks in the GC chromatogram, accounting for over 30% of the detected peak area. Over 8 μg of MBOA/g of 3-day-old corn roots (fresh weight) was found by GC with this "quick dip" method. The difference between the two methods can be explained by thermal degradation of MBOA derivable compounds in the injection port of the GC (240°C).

MBOA Volatility. The retention time of MBOA under the described GC conditions was 14.04 min. The retention time of (Z)-7-dodecenyl acetate was 12.49 min; (Z)-11-tetradecenyl acetate, 14.76 min; hexadecyl acetate, 16.74 min; and octadecyl acetate, 18.63 min. Since each of these compounds is known to be a volatile pheromone component for various lepidopteran species, and since retention time on nonpolar methyl silicone columns correlate well with vapor pressure (Heath and Tumlinson, 1986), the retention time of MBOA on our methyl silicone column supports the assertion that it is volatile. In the MBOA volatilization experiment, an average of 298 $\pm$ 35 μg of MBOA was extracted from 0.333 g of clay granules at time 0, 165 $\pm$ 10 μg after 1 day, 135 $\pm$ 20 μg after 2 days, 87 $\pm$ 5 μg after 4 days, and 20 $\pm$ 5 μg after 8 days. After 16 days, no detectable MBOA was found without concentration of the sample. In the cold-trapping experiment of synthetic MBOA crystals, over 40 ng of MBOA was recovered from 26 hr of passing a nitrogen stream over 10 mg of MBOA at a rate of 10 ml/min.

DISCUSSION

We have used a bioassay-driven sequential fractionation scheme to isolate behaviorally active portions of a crude dichloromethane corn seedling extract, and we have identified 6-methoxy-2-benzoxazolinone (MBOA) as one of the most important components of an attractive crude corn extract. Choice test bioassays with equal levels of carbon dioxide of both sides of the choice were used with the crude extract, each fraction of two separate types of separations, the purified natural compound, and the synthetic of our identification. MBOA is the first compound—other than carbon dioxide—identified from corn roots as behaviorally active to western corn rootworm larvae, one of the most important insect pests in the North America.

It was previously believed that MBOA is not an *in vivo* constituent of maize tissue but is produced through the decomposition of a glucoside that occurs in

the maize plant, 2-*O*-glucosyl-2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (Wahlroos and Virtanen, 1959). When the plant is injured, the glucoside is enzymatically hydrolyzed, releasing the aglucone 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA), which is subsequently degraded to MBOA (Willard and Penner, 1976). Recently, however, the lack of aglucones in grass tissue has been questioned. Zúñiga and Massardo (1991) concluded that a significant amount of aglucones are present in the intact tissue of wheat. In the present study, we found 98.7 ng of MBOA/g of 3-day-old corn root (fresh weight) by quickly dipping the roots of undamaged corn seedlings in dichloromethane and immediately injecting the sample onto the HPLC. The enzymatic conversion of DIMBOA-glucoside to DIMBOA takes 30 min at room temperature (Lyons et al., 1988). The conversion of DIMBOA to MBOA has a half-life of 5.3 hr at 28°C and pH 6.75 (Woodward et al., 1978a). Since our injection was made within 12 min of the first corn root extracted, our data support the assertion that MBOA is present on or in the tissues of 3-day-old germinated corn.

Many plant species contain specific allelochemicals that provide an effective toxic defense against herbivorous insects (Waller, 1987). Despite this, even a plant species that is chemically well defended may be attacked successfully by a few specialist insect species that not only withstand a particular plant toxin, but use it as a semiochemical to locate and recognize their plant host (Waller, 1987; Harborne, 1988; Rosenthal and Janzen, 1982). No examples of this have been reported for insect herbivores of maize, one of the principal agricultural plant species worldwide. We now report that an important toxin produced by maize and other grasses, 6-methoxy-2-benzoxazolinone (MBOA), is used as a semiochemical for host location by western corn rootworm larvae.

The toxic and antifeedant effects of MBOA have been documented for several insect species, including the European corn borer, *Ostrinia nubilalis* (Hübner) (Klun and Brindley, 1966; Campos et al., 1988; Nicollier et al., 1982), the southwestern corn borer, *Diatraea grandiosella* Dyar (Nicollier et al., 1982), the fall armyworm, *Spodoptera frugiperda* (J.E. Smith) (Nicollier et al., 1982), the cereal aphid, *Metopolophium dirhodum* (Walker) (Argandoña et al., 1980), the silkworm, *Bombyx mori* (L.) (Kubo and Kamikawa, 1983), the dried fruit beetle, *Carpophilus hemipterus* (L.) (Dowd, 1990), *Spodoptera exempta* (Walker) (Kubo and Kamikawa, 1983), the German cockroach, *Blatella germanica* (L.), and the southern armyworm, *Spodoptera eridana* (Cramer) (Beck and Stauffer, 1957), as well as bacteria (Nicollier et al., 1982; Beck and Stauffer, 1957), and fungi (Beck and Stauffer, 1957; Wahlroos and Virtanen, 1958; Beck and Smissman, 1961). However, MBOA is not toxic to western corn rootworm larvae (Abou-Fakhr et al., 1992).

DIMBOA, the precursor to MBOA, is generally considered a more potent toxin and is toxic to fungi (Long et al., 1975; Guthrie et al., 1985), and bacteria (Woodward et al., 1978b; Corcuera et al., 1978), the European corn borer (Klun

et al., 1967; Reed et al., 1972; Robinson et al., 1982; Campos et al., 1989), the greenbug, *Schizaphis graminum* (Rondani) (Argandoña et al., 1983), other aphids (Beck et al., 1983; Bohidar et al., 1986), and western corn rootworm larvae (Xie et al., 1990). Techniques have been developed that can quantify the amounts of known hydroxamic acids from corn roots (Xie et al., 1991a). The toxicity of DIMBOA to western corn rootworm larvae may be relevant to the isolation of strains of maize that have an antibiosis effect on the insect since quite high amounts of DIMBOA equivalents have been found in the cortex tissues of maize roots (Xie et al., 1991b). DIMBOA acts as a feeding deterrent at high concentrations (Argandoña et al., 1983; Corcuera et al., 1985). DIMBOA is an inducible chemical defense in maize, increasing significantly in concentration after feeding by larvae of *Sesamia nonagrioides* (Lefebvre) (Gutierrez et al., 1988). For more comprehensive reviews of the biology and chemistry of cyclic hydroxamic acids, see Willard and Penner (1976) and Niemeyer (1988).

Hydroxamic acids such as MBOA are well suited as semiochemicals for host location by a soil insect. MBOA has sufficient vapor pressure to diffuse in air, yet it is appreciably water soluble as well. MBOA is volatile under ambient conditions despite its relatively high melting point (158°C) and crystalline structure at room temperature, just as other volatile compounds such as camphor (m.p. 180°C) have similar melting points and crystalline structure at room temperature. In the present paper we demonstrated that MBOA is a volatile compound with vapor pressure comparable to that of many insect pheromones. These characteristics may allow it to move effectively through the soil under a wide range of soil moisture conditions. Hydroxamic acids have been documented in 10 genera of the Gramineae, but there are only two reports outside the Gramineae (Niemeyer, 1988). MBOA provides a simple way for western corn rootworm larvae to limit their orientation to grasses rather than to plants in general. Western corn rootworm larvae are not infallible in their location of appropriate hosts, in that they will orient to many nonhost grass species as well as they do to maize (Branson, 1982), perhaps because MBOA or related compounds are common to both. Larvae are attracted to the roots of sorghum and feed on them, despite the fact that sorghum roots contain cyanogenic glycosides that quickly kill western corn rootworm larvae (Branson et al., 1969; Strnad and Dunn, 1990).

MBOA and carbon dioxide are not the only compounds involved in host selection by western corn rootworm larvae. We have isolated an additional attractive fraction and two repellent fractions by GC separations of dichloromethane extracts of germinating maize (Hibbard and Bjostad, 1990). It is possible that the repellent fractions include compounds that are toxic to western corn rootworm larvae. These behaviorally active fractions are currently under

investigation and may be additional compounds used in discrimination of host plants from nonhosts.

Acknowledgments—We thank Greg Bogart, Don Dick, and the NMR Center at Colorado State University for assisting in obtaining the IR, EI and CI-MS, and NMR spectra, respectively, of the purified maize volatile and of synthetic 6-methoxy-2-benzoxazolinone. We thank Frank Stermitz for providing an authentic sample of synthetic 6-methoxy-2-benzoxazolinone for analysis. Pioneer Hi-Bred International, Inc., provided seed corn for isolation of maize volatiles and for rearing of western corn rootworm larvae. We thank Wendy Meyer and Mary Kroening for reviewing an early version of the manuscript. This research was funded by Colorado Agricultural Experiment Station Project 622 and by USDA Competitive Grant 90-01320.

Abstract—Hydroxamic acids have been shown to be toxic to many pest insects and pathogens. In this study, the behavioral responses of western corn rootworm larvae to naturally occurring and synthetic hydroxamic acids were investigated. In a choice test between corn roots treated with hydroxamic acids and roots treated with distilled water (control), western corn rootworm larvae chose to burrow into the control roots significantly more often than compound-treated roots. In addition, when corn roots were treated with different hydroxamic acids in a designed searching-behavior test, neonate larvae of western corn rootworm responded by significantly reducing the number of turns, while the area searched and locomotor rate significantly increased. The responses were dependent on the concentrations of the test compounds. These results suggested that hydroxamic acids were acting as behavior-modifying and possibly feeding-deterrent chemicals.

Key Words—1,4-Benzoxazin-3-ones, hydroxamic acids, 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA), Coleoptera, Chrysomelidae, *Diabrotica virgifera virgifera*, corn rootworms, nonpreference, search behavior, chemical ecology.

INTRODUCTION

The western corn rootworm, *Diabrotica virgifera virgifera* LeConte, is a serious insect pest of maize in North America. The eggs are laid in late summer and

*To whom correspondence should be addressed.

fall and overwinter in the soil. The larval stage is the most destructive, causing a reduction in yield directly through damage to the root system and through lodged plants. Feeding by adults can also cause minor damage by feeding on silks, kernels, and leaves (Branson, 1986). The amount of insecticide used for *Diabrotica* spp. control is more than for any other pest of corn in the United States (Suguiyama and Carlson, 1985).

Behavioral bioassays for western corn rootworm larvae have been developed to determine both the role of carbon dioxide (CO_2) released by roots of corn plant and the effect of volatile semiochemicals from corn seedlings on host location by western corn rootworm larvae (Strnad et al., 1986; Strnad and Bergman, 1987; Hibbard and Bjostad, 1988, 1990). Research has revealed that both a plant primary metabolite (CO_2) and secondary metabolites (volatile semiochemicals) are involved as the attractive agents in the orientation of western corn rootworm larvae. In addition, volatile chemicals from corn silks have been demonstrated to be attractants to adults of western and northern corn rootworm (Prystupa et al., 1988). However, the behavioral response of western corn rootworm larvae to the major group of corn secondary metabolites, the hydroxamic acids, is unknown, although several dichloromethane extracts of germinating corn possibly containing these substances have been found to be attractive or repellent to western corn rootworm larvae (Hibbard and Bjostad, 1990).

The search orientation in animals is recognized to take place in two phases: ranging and local search (Jander, 1975). The former is characterized by relatively straight locomotion in which the animal has limited resource information, and the latter is characterized by increased turning rate and decreased locomotor rate when animals receive information of suitable resources (Bell, 1985). In a host search behavior study with corn rootworms, Strnad and Dunn (1990) demonstrated that search area and locomotor rate decreased and turning rate and path crossings increased after western corn rootworm larva contacted with host roots as compared with nonhost roots.

The hydroxamic acids (1,4-benzoxazin-3-ones) are plant secondary metabolites, that are naturally present as the 2-*O*-β-D-glucosides in intact tissue in several species of Gramineae, such as corn, wheat (Wahlroos and Virtanen, 1959), and rye (Honkanen and Virtanen, 1960). In corn, some of these compounds have been shown to be associated with resistance to insect pests and pathogens (e.g., Klun and Brindley, 1966; Long et al., 1977; Campos et al., 1988, 1989), including corn rootworm (Xie et al., 1990). However, it is not clear what behavioral responses western corn rootworm larvae have after contact with naturally occurring and/or synthetic hydroxamic acids, and it is unknown if the host searching behavior is affected by these secondary metabolites. The objective of this investigation was to characterize the searching behavior of western corn rootworm larvae after contact with maize roots treated with various

hydroxamates and to determine the choice behavior shown by western corn rootworm larvae on maize roots treated with these compounds.

METHODS AND MATERIALS

Source of Compounds. The compounds used in this study include those naturally occurring in maize roots and those synthesized. All compounds were synthesized in our laboratory and represent a good range of known chemical trends, either unimolecular decomposition rates or reduction by thiol (Atkinson, 1989). Complete synthetic details are described by Atkinson (1989). The structures of these chemicals are shown in Figure 1.

Maize Root Materials. Maize kernels of Funks G4017, a currently used Ontario hybrid with a low (<100 μg/g fresh wt) hydroxamic acid content, were washed in detergent solution for 3 min, rinsed thoroughly, and soaked in distilled water for 24 hr. Soaked seeds were rinsed again with distilled water, placed on moistened paper, covered with moistened paper towels, kept in a closed plastic container, and incubated at room temperature (25 °C). Three to four days later, fresh maize roots (2–3 cm long) were removed for bioassays.

Choice Tests. Fresh maize roots were dipped for 30 sec in an ethanolic solution of various hydroxamates (500 ppm) or distilled water with the same amount of solvent (0.1% EtOH) (solvent control). This concentration was within the range found for 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) in maize root (Xie, 1991). One treated and one control root were placed 1 cm apart on moistened filter paper in a plastic petri dish (9 cm). Then one neonate western corn rootworm was immediately placed between the roots. The dish was covered, sealed with parafilm, and kept in an incubator (25 °C, dark condition). The larval position (in root, on root, or out of root) was examined for each root (treated and control) at 24 hr after infestation. A no-choice control (control roots only) was added in order to determine larval position under untreated condition. Thirty replicates (30 larvae) were prepared for each compound, and the whole experiment was repeated four times.

Host Searching Behavior. The behavioral responses of western corn rootworm neonates to maize roots treated with related compounds were recorded by a modification of the method described by Strnad and Dunn (1990). Fresh maize roots were dipped in a solution of compound (500 ppm) for 30 sec. Distilled water alone served as a true control and distilled water with the same amount of solvent (0.1% EtOH) served as a solvent control. Individual neonates (<24 hr old) of western corn rootworm were placed on the surface of treated roots. After a 5-min period of contact, the larva was transferred to the center of a moistened filter paper (Whatman No. 1, 24 cm) on a square glass plate

6-methoxy-benzoxazolin-2-one (MBOA)

FIG. 1. Chemical structures of naturally occurring and synthetic hydroxamic acids (1,4-benzoxazin-3-ones) and 6-methoxy-benzoxazolin-2-one (MBOA) used in this study.

(30 × 30 cm) with four supports (3 mm high) in each corner and then covered with a second glass plate. An acetate sheet was placed on top of the second glass plate. During a 5-min period, the path of larval travel was traced on the acetate sheet by following the larval travel with a felt pen. Meanwhile, the number of turns (defined as any change of the larval body in axis of travel) was recorded using a hand counter. Thirty larvae were used for each treatment (compounds and controls), and a fresh area of filter paper was used for each larva. Finally, acetate sheets were copied to grid paper (1 square/mm). The area searched (mm^2) was determined by counting the number of squares intersected by the path. Path lengths were measured with a map wheel and converted to locomotor rate (mm/min).

Concentration Dependence of Localized Search. To determine if the effects of hydroxamic acids on the localized search of western corn rootworm neonates depend on the concentrations of the related compounds, different concentrations of the selected compounds were used for testing the search behavior of western corn rootworm larvae. Two compounds, DIMBOA and MBOA, were selected, and three concentrations, 250, 500, and 1000 ppm, for each were used in this study. Number of turns, area searched, and locomotor rate were determined as described above.

Statistical Analysis. The data from choice test were also calculated as percentage control, which was the ratio of the number of larvae responding in the treated group divided by the number of larvae responding in the control group. Since there were no larvae found "on root" or "out of root" in some treatments of the choice test, the number of larvae on root and out of root was transformed [square root $(X + 1)$] (Snedecor and Cochran, 1980) for calculating percentage control. All data were tested by Bartlett's test for homogeneity of variance (Snedecor and Cochran, 1980; Anonymous, 1991), and if the variances were equal, parametric statistics was performed. A t test was applied to compare means of control and treated in the choice test (Table 1).Analysis of variance (ANOVA) and Duncan's multiple-range test were applied for comparisons of data with more than two means. An arcsin transformation was performed for the percentage data before analysis (Steel and Torrie, 1980; SAS Institute, 1982).

RESULTS AND DISCUSSION

Choice Study. All hydroxamates used in this study were shown to be effective deterrents in the choice-test design. The number of larvae found burrowing in the roots of the control side were significantly more than that of the treated side for all test compounds (Table 1). Of the three naturally occurring compounds (1, 2, 9) in maize roots, two (1, 9) strongly affected rootworm choice of the position inside the root, which was only 58.4 and 55.1% of the control and is significantly different from the control (Table 1). Compound 3 showed the least effect, possibly due to its previously observed rapid decomposition, which was the highest of all compounds tested (Atkinson, 1989). There were no significant differences ($P > 0.05$) between the results obtained with the 7-substituted series, except for 7-Cl, which showed the highest behavioral effect (Table 1).

Generally, choice designs are useful in detecting small differences in food acceptability (Schoonhoven, 1982). It is clear that when fresh maize roots were treated with various hydroxamates, the percentage of rootworms found inside the roots significantly decreased and the percentage of rootworms staying on the surface of roots increased (approximately 20–75% more than on the control,

although not statistically significant) (Table 1). Although these results suggest a change in food acceptability, more direct observation of feeding events is required to confirm this.

Host Searching Behavior. Two controls were designed in order to see if the control with solvent (0.1% EtOH) affected the behavioral responses of western corn rootworm larvae. The results indicated that there were no significant differences ($P > 0.05$) between the solvent-treated control and the true control (distilled water alone) in all behavioral parameters studied (Table 2). Figure 2 illustrates the very distinct path pattern resulting from a 5-min contact with corn roots treated with the hydroxamate 6,7-diMeO as compared to the control. Compared to controls, the searching behavior of neonate western corn rootworm larvae was clearly affected by treating maize roots with hydroxamate solution (Figure 2, Table 2). Neonate western rootworm larvae exposed to maize roots treated with various hydroxamates significantly ($P < 0.05$) decreased the number of turns but increased their search area and locomotor rate significantly ($P < 0.05$) (Table 2). The naturally occurring compounds, DIMBOA, as well as its amide HMBOA and its decomposition product MBOA, and DIM_2BOA showed similar effects on number of turns, area searched (except MBOA), and locomotor rate. In general, the synthesized compounds 3, 4, 5, and 7 of 7-substituted series showed higher activities in this respect (Table 2).

Concentration Dependence of Localized Search. Localized search orientation of insects can be modified by sensory information from internal and external sources (Bell, 1985). For example, the search path of a starved fruit fly, *Drosophila melanogaster*, on and around a 3.5-cm patch of sucrose is dependent on surcose concentration (Bell, 1985). The area searched by *D. melanogaster* on a patch of 0.5 *M* sucrose is significantly larger than that on a patch of 0.125 *M* sucrose (Bell, 1985). The present results show that the effects of hydroxamic acids on the localized search of western corn rootworm larvae are also dependent on the concentrations used (Figure 3). As the concentrations of DIMBOA and MBOA increased, larvae exposed to treated maize roots significantly decreased the number of turns but increased their searched area (except for MBOA) and locomotor rate. At 250 and 500 ppm of DIMBOA and MBOA, the trends were evident but not significant ($P > 0.05$). However, the parameters were significantly different ($P < 0.05$) when insects were exposed to maize roots treated with 1000 ppm of DIMBOA and MBOA (Figure 3). Considering that DIMBOA and MBOA were found to be toxic to western corn rootworm (Xie et al., 1990; Xie, 1991), it is not surprising to find that the number of turns decreased and the area searched and locomotor rate increased when larvae were exposed to maize roots treated with higher concentrations of the compounds.

Generally, an insect's search orientation is controlled by information either stored genetically or learned from sensory systems (Bell, 1985). After neonate

larvae of western corn rootworm made contact with maize roots, they switched from ranging to a localized search. Our assay involves contact of neonate larvae with maize roots, and hence chemoreception of volatiles is possible. After encountering food resources of the controls in which feeding stimuli are present, neonate rootworm larvae shift their locomotion from a straight to a convoluted patterns. Our results are consistent with the concept of local search (Bell, 1985;

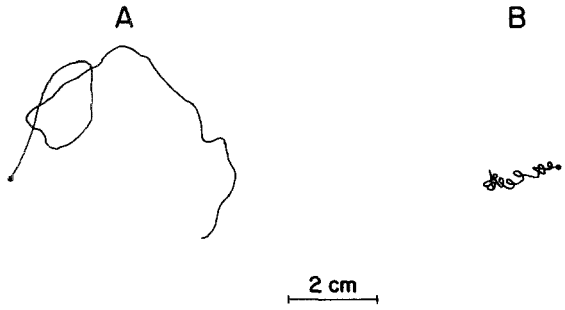

FIG. 2. Pathways of neonate western corn rootworm larvae during a 5-min localized search resulting from 5 min of contact with maize roots treated with hydroxamate (6,7-diMeO) (A) and with distilled water (control) (B). Dot indicates beginning point in each path.

Visser, 1988). When maize roots were treated with different hydroxamates which act as feeding deterrents in other insects (Campos et al., 1988, 1989), neonate larvae of western corn rootworm responded significantly by reducing the number of turns ($P < 0.05$), while the area searched and locomotor rate significantly ($P < 0.05$) increased. The path patterns recorded after larvae contacted maize roots treated with test compounds in our study are similar to those recorded with nonhost plants or possible host plants which contain feeding deterrents (Strnad and Dunn, 1990).

Toxicity of DIMBOA and MBOA against several organisms, including western corn rootworm, has been well documented (Long et al., 1977; Argandoña et al., 1983; Campos et al., 1988, 1989; Xie et al., 1990; Xie, 1991). In this study, when maize roots were treated with hydroxamic acid solutions (500 ppm), western corn rootworm larvae showed significant nonpreference, in three ways: (1) the larvae chose to burrow into untreated roots significantly more than treated roots, (2) the number of larvae avoiding roots was higher in the hydroxamate-treated roots, and (3) host searching behaviors were significantly modified, showing that larvae switched from a localized host-finding behavior to a ranging behavior after contact with treated roots (Table 2, Figure 2). These results strongly indicated that the hydroxamic acids were acting as behavior-modifying and possibly feeding-deterrent chemicals. The deleterious effects of hydroxamic acids on western corn rootworm larvae are similar to those observed with other insects such as greenbug and European corn borer (Robinson et al., 1982; Argandoña et al., 1983; Campos et al., 1988, 1989). Further study of corn rootworm food consumption and utilization is required to clarify the mode of action of hydroxamic acids on this insect.

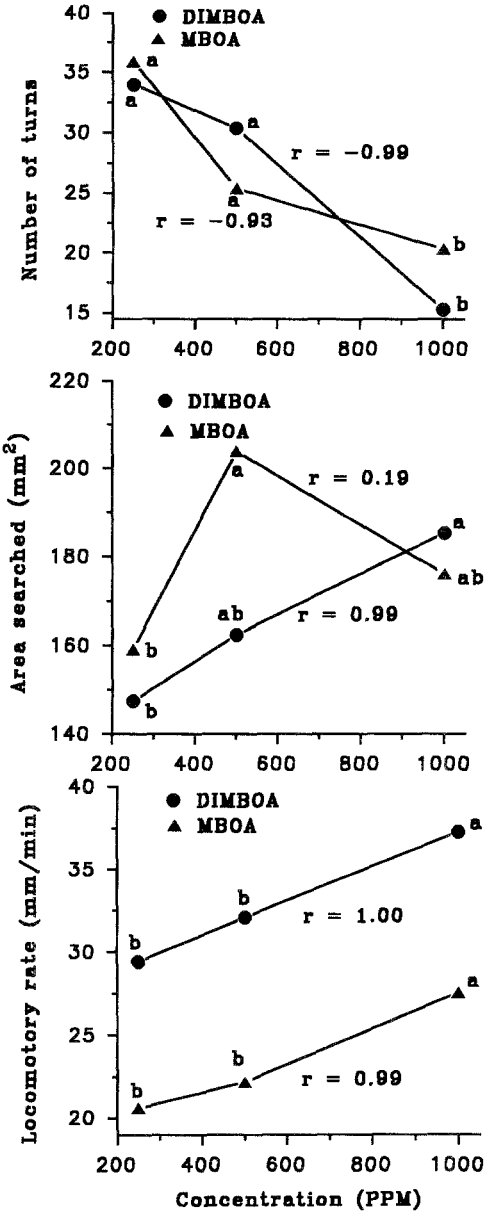

FIG. 3. Number of turns, area searched, and locomotor rate of neonate western corn rootworm larvae during a 5-min host-searching period resulting from 5 min of contact with maize roots treated with various concentrations (250, 500, and 1000 ppm) of DIMBOA and MBOA. Each figure is the mean of 30 larvae tested individually. Means followed by the same letter (within the data for the same compound) are not significantly different ($P > 0.05$; Duncan's multiple-range test).

(Received August 12, 1991; accepted February 18, 1992)

Abstract—Field studies with three common local species of hermit crabs, *Clibanarius vittatus*, *Pagurus longicarpus*, and *Pagurus pollicaris*, showed that these crabs responded behaviorally to chemicals originating from crushed conspecifics. Hermit crabs are attracted specifically and in a manner similar to previously reported crab responses to odors from dead gastropods. Responses by *C. vittatus* to both kinds of odor are of three types: (1) aggregation/shell investigation responses (previously reported for odors from dead gastropods), characterized by increased locomotor activity, investigation of shells in the vicinity, and switching into empty shells; (2) alarm responses, in which crabs flee the area; and (3) withdrawal responses, in which crabs pull into their shells and do not come out. Studies with *C. vittatus* showed that the stimulatory chemicals originate from hemolymph, are less than 500 D, adsorb to octadecyl silica, and are recovered by elution with 20% methanol. Responses of *C. vittatus* are dependent upon crab size, type of shell occupied, and shell fit. Chemicals originating from dead conspecifics provide a forum for shell acquisition by crabs in relatively small shells and alarm by crabs in relatively large shells.

Key Words—Hermit crabs, shell fit, aggregation cues, alarm cues, anomuran, chemical sensing, *Pagurus*, *Clibanarius*, behavior.

INTRODUCTION

In soft-bottom environments such as the sounds and estuaries of the southeastern Atlantic and Gulf of Mexico coasts of the United States, gastropod shells are

*To whom correspondence should be addressed.

0098-0331/92/0700-0959$06.50/0 © 1992 Plenum Publishing Corporation

important as hard substrata (McLean, 1983). The gastropods that produce the shells, predators that empty the shells, and secondary shell users such as epibionts, octopus, fish, and hermit crabs form a community described as the gastropod shell habitat web (McLean, 1975; 1983). Hermit crabs are central in maintaining the shell habitat web. They locate new shells by chemicals given off by the dying gastropod (Rittschof, 1980a). Occupation of the shell ensures that it is not lost to the community by burial in the sediment.

Shells are an important resource for hermit crabs (reviewed by McLean, 1983; Spight, 1985). Shells may control hermit crab population size (Provenzano, 1960; Childress, 1972; Vance, 1972; Bach et al., 1976; Kellogg, 1976; Spight, 1977). With respect to individuals within the population, shells are central to protection and growth (Fotheringham, 1976; Spight, 1985), fecundity (Childress, 1972; Bach et al., 1976; Wilber, 1989), and even copulatory success (Hazlett, 1989; Hazlett and Baron, 1989).

In addition to obtaining shells at gastropod predation events (McLean, 1974, 1975, 1983; Rittschof, 1980a; Hazlett and Herrnkind, 1980; Wilber and Herrnkind, 1982, 1984; Gilchrist and Abele, 1984), crabs find empty shells that resurface after being buried and actively interact inter- and intraspecifically to trade shells (Hazlett, 1966, 1970a,b, 1972, 1983).

Shells could be lost to hermit crab populations through two major pathways: (1) degradation due to erosion, fouling, and shell-crushing predators (see McLean, 1983) and (2) loss of the shell by burial upon the death of the hermit crab occupant. Although degradation of shells is an irreversible process, the ability to recycle occupiable shells that became available through the death of a hermit crab could be a very important means of maintaining the resource. Chemical detection of dead and dying crabs could occur and would be similar to the chemical detection of dying snails (Rittschof, 1980a). Detection of chemicals from dead and dying hermit crabs could enable efficient location of potential shells and would ensure that reusable shells were maintained in the population.

We report here that hermit crabs can chemically locate crushed conspecifics in the field and are stimulated to perform shell acquisition behaviors. The responses of hermit crabs to odors from crushed conspecifics and from fresh conspecific hemolymph are similar to responses to gastropod odors. As is the case for odors from dying gastropods, responses of hermit crabs to dying hermit crabs are highly specific. Although a complex issue (cf. Kuris and Brody, 1976; Liszka and Underwood, 1990; Wilber, 1990), shell fit is important in responses to both odors. Our studies show that small hermit crabs in poor-fitting shells (small shells) are attracted by odors and stimulated to investigate shells in the area. Small crabs in large shells are repelled and flee the area. Crabs in large shells do not respond actively odors. We suggest that hermit crabs actually spend little time in the undirected search for shells. Chemical cues function to stimulate aggregation of crabs "in the market for a new shell" and act as alarm substances

for crabs that are in shells that fit "correctly." As observed by McLean (1974, 1983), Rittschof (1980a), and Chase et al. (1988), the introduction of a single new shell into an aggregation of hermit crabs that is chemically primed (Hazlett, 1979; Rittschof, 1980a) results in a cascade of shell exchanges that may benefit many crabs in the area that are in shells smaller than the introduced shell.

METHODS AND MATERIALS

Reagents and Materials

Seawater used in preparation of odor sources was filtered septically through a 100-kD filter, allowed to stand for a minimum of 3 days, and gravity-filtered through a sterile 0.22-μm filter immediately before use. HPLC-grade methanol and water were from Mallinckrodt, Inc., Paris, KY. Dialysis tubing was 20.4 mm in diameter, 12,000- to 14,000-D cutoff (Spectrum Medical Industries, Inc., Los Angeles, CA). Pressure dialysis membranes were 43-mm-diameter YM2 1000-D cutoff (Amicon Inc., Lexington, MA). Reversed-phase columns were 500 mg octadecyl silica Solid Phase System product 9004 (Burdick and Jackson Inc., Muskegon, MI) .

Test odors were from blood and body tissues. The amount of tissue used to generate odors for bioassays (see below) was based upon weight of both freshly killed and frozen and subsequently thawed tissues.

Gastropod tissues were selected that were known to be attractive to the hermit crabs being tested and included *Busycon carica* (attractive to *C. vittatus*), *Ilyanassa obsoletus* (attractive to *Pagurus longicarpus*), and *Fasciolaria hunteria* (attractive to *P. longicarpus*, *C. vittatus*, and *P. pollicaris*). Body tissue from all three species of hermit crabs and the brachyuran crab *Panopeus herbstii* was also tested. A mass of 3 g of tissue was chosen as a standard sample weight. For large gastropods *Busycon carica* and *Fasciolaria hunteria*, only foot muscle tissue was used. It was collected as three 1-g cubes, approximately 0.5 cm on a side. For the smaller *Ilyanassa obsoleta* we used the flesh of an entire snail without its shell. Approximately 30 *I. obsoleta* provided 3 g of crushed flesh for each experiment. Flesh was not separated from crushed shell. For hermit crabs smaller than 3 g (*P. longicarpus*), several crab bodies totaling the sample weight were crushed and used. Hermit crabs greater than 3 g in body weight (*P. pollicaris* and *C. vittatus*) were sectioned from anterior to posterior to give the correct weight. Hermit crab muscle (*C. vittatus*) was obtained from autoclaved chelae. Exoskeleton was removed, and muscle was blotted and weighed.

Hemolymph was obtained from a major sinus in the chelae. Shells of large *Clibanarius vittatus* were chipped down until the chelae were exposed. The chelae were extended and hemolymph was drawn from the sinus of the major chelae with a 20-gauge needle on a 1-ml tuburculin syringe. The needle was

inserted through the thin cuticle at the second joint from the distal end of the chelae into the hemolymph sinus. Depending on the size of the hermit crab, 0.2 to 1.2 ml of hemolymph was extracted from the sinus.

Hemolymph Fractionation

Nine milliliters of hemolymph was collected and pooled from approximately 25 hermit crabs. Blood cells were removed by centrifugation for 2 min at 1500*g* in a microfuge. One milliliter of hemolymph supernate was saved for assay. Hemocyanin was removed from the remaining 8 ml of hemolymph supernate by centrifugation for 4 hr at 319,000*g* (Beckman TL-100 ultracentrifuge and a TLN-100 Rotor). Five milliliters of supernate was collected and mixed with 5 ml of 100-kd filtered seawater sterilized by gravity filtration through a 0.22-μm membrane filter. The 10 ml of diluted supernate was subjected to pressure dialysis through an Amicon YM 2 (1000-D cutoff) membrane at 60 psi of nitrogen. The first 9 ml through the 1000-D membrane was frozen at $-20°C$ in 1-ml aliquots. Molecules in the >1-kDa fraction were reduced by washing. The 1 ml remaining above the 1000-D membrane was diluted with 5 ml of 0.22-m seawater and reduced to 1 ml three times. The material above the membrane was then diluted to 10 ml with sterile seawater and stored frozen at $-20°C$ in 1-ml aliquots.

Hemolymph factors less than 1000 D were separated on octadecyl silica. Octadecyl silica (500 mg) was prepared for use by washing with 3 ml of 100% methanol and then 3 ml of HPLC-grade water. All of the liquid was extracted with a 3-ml syringe. For each experiment, 1 ml of sample of <1000-D hemolymph was applied to the column. All liquid was pulled through the column by syringe. Next, depending upon the experiment, 1 ml of a test solvent was applied to the column and the procedure repeated. All of the liquid was drawn through with the syringe. Extracted materials were tested in interaction bioassays (see below).

In Situ *Observations of Hermit Crab Behavior in Response to Odors from Crushed Conspecifics*

A preliminary experiment showed that *C. vittatus* were attracted to freshly killed conspecifics. In tests with killed crabs their shells were crushed and placed in a wire-mesh cage so as to prevent removal of the carcass by scavengers. Crushed hermit crabs were placed in approximately 30 cm of water in areas inhabited by conspecific hermit crabs. Crab densities are so low that fewer than one crab would normally pass through the observation area in an hour (Kratt and Rittschof, 1991). The behavior of attracted hermit crabs was identified as feeding or investigatory. Observers stood motionless next to the odor source and recorded behavior of crabs in the immediate vicinity as well as down current

from the source. In a final experiment, a large female hermit crab approximately 40 mm in cephalothorax (carapace length) was taken out of her shell, crushed, and placed in a tide pool being drained by a tidal channel. The female crab was placed in the pool shortly after the tide began to ebb. *C. vittatus* that became active in the tide pool and that moved into the tide pool up the tidal channel were observed. Responding hermit crabs, as determined by shell investigation behavior (see below), were collected and their sex was determined. Observations of crabs in tide pools at low tide showed that most were normally inactive. Crabs did not travel up tidal channels unless chemically stimulated to do so.

Observation of Responses of C. vittatus *in Response to Crushed Conspecifics in the Absence and Presence of an Empty Shell*

Tide pool conditions were simulated by placing 10 freshly collected small- to medium-sized (crabs mainly in *Ilyanassa*, *Littorina*, and oyster drill shells; see last paragraph of Methods and Materials) *C. vittatus* in a bucket containing 3 L of seawater from the environment. After a 15-sec acclimation interval, shell investigation was observed for 3 min. Shell investigation is characterized by the manipulation of other shells with the chelipeds and walking legs and the placement of the legs, chelipeds, and head into the apertures of other shells. Next, a crushed *C. vittatus* was added to the bucket and shell-investigation activity was observed for an additional 3 min. Finally, an empty shell was added and observations of shell investigation and shell switching were made for a period of up to 20 min. When a hermit crab switches shells, it leaves its original shell and enters an empty shell, abdomen first. A total of 50 hermit crabs was tested.

Biological Assays

Three kinds of biological assays described in detail below were used in field trials to test responses of crabs to odors. The first assay, an attraction assay, was a modification of previous hermit crab field assays (Rittschof, 1980a,b; Rittschof et al., 1990; Kratt and Rittschof, 1991) (see below). This assay measured the ability of crabs to find hidden odor sources. The second assay measured chemically stimulated interactions between groups of crabs. The third assay tested chemically stimulated responses of hermit crabs in depressions left by feeding stingrays. This assay was used to separate crabs into specific behavioral categories: (1) no response, (2) investigation behavior, and (3) flight.

Hermit Crab Attraction Assay. Field assays, modified after Kratt and Rittschof (1991), measured responses of hermit crabs to potential sources of attractants. Tests were conducted with *Clibanarius vittatus*, *Pagurus longicarpus*, and *Pagurus pollicaris*. An individual test unit consisted of a 500-ml disposable cup covered with fiberglass window screen, secured with a rubber band. Cups, three

or four for each test substance, were buried along a transect line parallel to the shore 2–3 m apart in approximately 25 cm of seawater, with the screen tops flush with the surface of the sand. Cups contained test substances or were empty (controls). Treatments were alternated in a repeating series. The observer monitored the series of cups by walking the transect slowly. A positive response was recorded when a crab touched the window screen. Responding crabs were captured and held until the end of the 45-min assay. This minimized social interactions and ensured that each crab was counted only once. When a responding crab was captured, other crabs in the area pulled into their shells but returned quickly to normal activity. Frequency distributions of crabs responding to the different treatments were compared using the G statistic [Goodfit (Sokal and Rohlf, 1981)].

Hermit Crab Interaction Bioassay. Observations of behavior of *Clibanarius vittatus* in response to chemicals in tide pools were used to develop a bioassay of hermit crab interaction. Preliminary observations in tide pools and in buckets showed that crabs investigated and switched shells but did not feed. The bioassay used a plastic 12-L bucket as an artificial tide pool. Ten freshly collected *C. vittatus* were placed in a bucket filled with 3 L of seawater. The hermit crabs were then separated manually from each other so that no two were touching. The water was mixed gently, and after 15 sec the hermit crabs were observed for 1 min. Each hermit crab that investigated another hermit crab's shell by touching it with the chelae and first pair of walking legs was scored as an investigator. Each hermit crab was scored only once, and all of the hermit crabs were left in the bucket for the full minute. Next a control value was determined by following the above procedure, with the addition of 100 μl of seawater after the hermit crabs were separated. An experimental trial was then run using the same procedure as the control, with 100 μl of test solution replacing the seawater. Preliminary test odors were presented in all conceivable sequences to determine if order of presentation had an effect. When no effect was observed an ordered sequence of presentation was chosen for simplicity.

Test solutions included 100-μl additions of snail flesh odors, 3 g flesh in 5 ml seawater, crab flesh, hemolymph, and fractionated hemolymph. Three groups of 10 crabs were tested for each test solution. The proportion of crabs responding before addition was compared to the proportion after seawater addition and the proportion responding after seawater addition was compared to the proportion responding after test addition [Z statistic; proportions test (Walpole, 1974)].

Hermit Crab Behavior Assay. To perform a behavior assay, tide pools (0.3–0.5 m in diameter and 2.5 to 10 cm deep) resulting from stingray feeding activity were located. *C. vittatus* were collected haphazardly. Ten to 20 hermit crabs were placed in each tide pool and 0.4 ml of seawater containing *Busycon carica* odor (6 g *B. carica* flesh soaked in 10 ml seawater for 1 hr) was injected into

each pool. Hermit crabs that investigated the shells of other hermit crabs with their walking legs and chelipeds were scored as investigating. Hermit crabs that left the tide pool and walked onto land were scored as fleeing. Hermit crabs that were inactive, that partially buried, or that did not come out of their shells were scored as not responding. In initial experiments, crabs were divided only into categories of "investigating" and "not investigating." In early assays, the "not investigating" group included crabs that either fled or did not respond.

Sex and Shell Fit

Sex and shell fit were determined for hermit crabs attracted to snail flesh in attraction assays. Sex, shell species, carapace length, and shell weight were recorded for each hermit crab. Shells occupied at a low frequency were grouped into categories based upon relative size and shape. The category "oyster drills" was comprised of shells from *Urosalpinx cinerea*, *Eupleura caudata*, and *Pisania tincta*. The "other" category was a mixture of medium- to large-sized shells including shells from *Polinices duplicatus*, *Thais haemostoma floridana*, *Busycon carica*, *Busycon contrarium*, and *Busycon canaliculatum*. The ratio of carapace length to shell weight was used as a measure of shell fit. This ratio has been shown previously to discriminate between crabs attending simulated predation sites and crabs that do not attend (Rittschof, 1980a). Carapace length was measured to the nearest 0.1 mm with vernier calipers. Shells were dried at 60°C for 3 hr and weighed to the nearest 0.1 g.

RESULTS

Preliminary Observations

In preliminary experiments, observations of hermit crab responses to crushed conspecifics were made for *P. pollicaris*, *P. longicarpus*, and *C. vittatus*. All species of hermit crabs responded similarly to crushed conspecifics. The description that follows of responses by *C. vittatus* to a crushed *C. vittatus* is representative of the observations that were made.

A large female *Clibanarius vittatus* approximately 40 mm in cephalothorax length was removed from its shell, killed by crushing, and placed in approximately 2 cm of water on a descending tide in an area containing inactive hermit crabs. Nearby *C. vittatus* became active and were attracted immediately. Directed movements were observed toward the dead hermit crab from as far as 10 m downstream from the source! (These crabs eventually reached the source.) While moving to the source, the hermit crabs crawled upcurrent in and out of the small pools of water. *C. vittatus* reaching the crushed crab did not feed on the flesh. Most did not go directly to the crushed crab source. They investigated shells in

the area including oyster shells and shells occupied by other hermit crabs. The hermit crabs manipulated the shells, turned them over, and tried to crawl into them. Most of the hermit crabs that responded were in small gastropod shells or were in heavily fouled shells. Crabs of both sexes at a 1 : 1 ratio, including ovigerous crabs, were attracted to both sexes of crushed conspecific [$G = 0.15$, $P > 0.05$, 1 df, H_0 1 : 1 ratio (male to female) for crabs responding to a crushed female and $G = 1.0$, $P > 1.05$, 1 df, H_0 1 : 1 (male to female) ratio for crabs responding to a crushed male].

In a final, preliminary experimental series, freshly collected *C. vittatus* were placed in groups of 10 in buckets containing 3 L of seawater and their behavior in response to odor additions was observed. Without chemical additions, approximately one-third of the hermit crabs manipulated and investigated other's shells. The addition of crushed *C. vittatus* immediately resulted in elevated levels of locomotor activity. From 75 to 100% of the hermit crabs displayed shell-seeking activity. Overall, small *C. vittatus* were visibly more active than large *C. vittatus*. After an empty shell was placed in the bucket, one to three hermit crabs smaller than the added shell immediately began to investigate it. The remainder of the crabs continued to investigate each other's shells. When only one hermit crab investigated the shell, it (1) immediately switched shells, (2) displayed repeated shell-search activity on the empty shell and then switched, (3) switched and then switched back to its original shell, or (4) repeatedly investigated the empty shell but did not switch. If there was more than one hermit crab, the crabs fought until one of them managed to switch into the empty shell. The same series of events occurred with each newly vacated shell until the smallest shell in the bucket was empty. Thus, the suggestion from preliminary observations was that hermit crab responses to crushed conspecifics were chemically mediated and involved behaviors associated with shell acquisition.

Hermit Crab Attraction Assays

Three attraction assays with concealed odor sources were used to assess the responses of *C. vittatus*, *Pagurus longicarpus*, and *Pagurus pollicaris* to chemical cues from a series of flesh sources. The test items were crushed hermit crabs of each species, snail flesh known to be attractive to one or more species of hermit crab, and a crushed brachyuran crab *Panopeus herbstii*. Crabs responding by locating and touching the concealed odors were collected and scored as responding (Table 1). Each species of hermit crab responded significantly (P at least < 0.05 compared to blank control) to odors from gastropod flesh whose shell they occupied and to crushed conspecifics. Assay 1 tested responses of *C. vittatus* to four odor sources and blanks. Of the 36 crabs responding, 14 were attracted to crushed conspecific and 22 were attracted to snail odor. No *C.*

TABLE 1. ATTRACTION ASSAY RESULTS[a]

Assay No.	Hermit crab responding	Odor source										
		C.v.	P.h.	P.l.	P.p.	F.h.	I.o.	*B*	H_o	df	*G*	*P*
1	*C. vittatus*	14	0	0	0	22		0				
	C. vittatus	14		0	0	22			1:1:1:1	3	50.05	<0.001
	C. vittatus	14				22			1:1	1	1.77	<0.2
2	*P. longicarpus*	6		48	12			0				
	P. longicarpus	6		48	12				1:1:1	2	44.31	<0.001

	P. pollicaris	0		0	4		0		1:1:1:1	3	9.78	<0.05

[a]C.v., *Clibanarius vittatus*; P.h., *Panopeus herbstii*; P.l., *Pagurus longicarpus*; P.p., *Pagurus pollicaris*; F.h., *Fasciolaria hunteria*; I.o., *Ilyanassa obsoleta*; *B*, cup and screen, no added order; H_o, null hypothesis.

vittatus responded to crushed *P. herbstii* or to the blank control. *C. vittatus* was not attracted to either of the crushed pagurid species. Assays 2 and 3 were conducted at night in a region occupied by *P. longicarpus* and *P. pollicaris*. In assay 2, 66 *P. longicarpus* and 17 *P. pollicaris* responded. No crabs responded to the blank controls. Four times as many *P. longicarpus* responded to crushed conspecific odor as to crushed congeneric odors. Twice as many *P. longicarpus* responded to crushed congeneric odor (*Pagurus pollicaris*) as to crushed *C. vittatus* odor. *P. pollicaris* are much less common on the test area, and as a consequence, only one-quarter as many *P. pollicaris* responded. The strongest response of *P. pollicaris* was to crushed conspecific odor.

In assay 3 crushed *Ilyanassa obsoleta* was added to the test series (Table 1). One hundred fifty *P. longicarpus* and four *P. pollicaris* responded. Of the *P. longicarpus*, 58% responded to *Ilyanassa obsoleta* odor and 35% responded to crushed conspecific. The remaining 7% responded to crushed congeneric odor. No crabs in this experiment responded to odor from crushed *C. vittatus*. Regressions of shell weight vs carapace length were similar for the crabs responding to *I. obsoleta* and *P. longicarpus* odors. Carapace-to-shell length ratios were computed for the 87 crabs attracted to *I. obsoleta* and the 53 crabs attracted to *P. longicarpus* odors. Carapace length-to-shell weight ratios were compared by frequency and found to be similar ($G = 4.94$, $P > 0.05$, 4 df; Figure 1). Thus, shell fit of crabs responding to gastropod odors was similar to that of crabs responding to conspecific hemocyanin. Only four *P. pollicaris* responded in assay 3 and they were attracted to the odor of crushed conspecific.

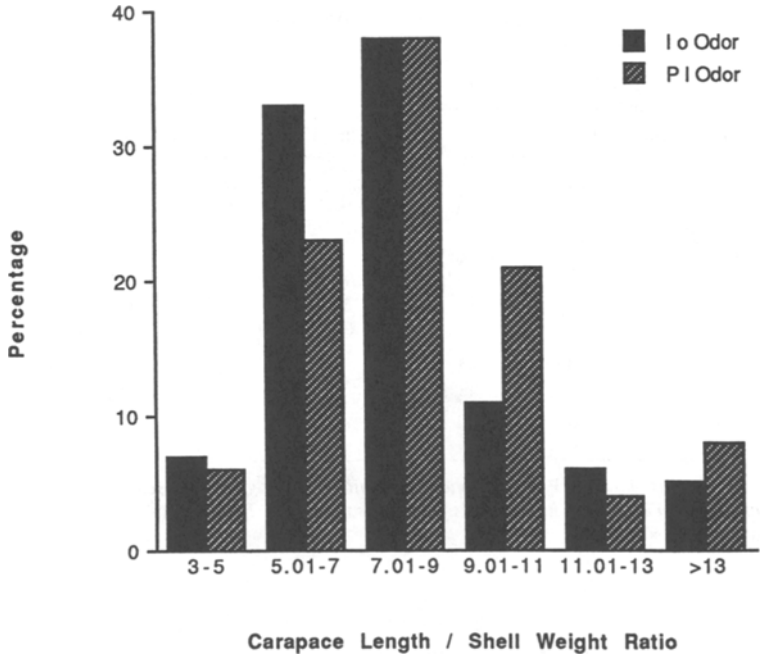

FIG. 1. Frequency distributions of carapace length-to-shell weight ratios for *P. longicarpus* attracted to *Ilyanassa obsoleta* (I o) or to crushed *P. longicarpus* (P l). Virtually all crabs occupied *Ilyanassa obsoleta* shells. Low ratios indicate relatively large shells for the size of the crab.

Shell Occupation by C. vittatus

A fourth assay tested attraction of *C. vittatus* to simultaneous presentation of odors of frozen and thawed *F. hunteria* and *B. carica* flesh, crushed conspecifics, and blanks. In this experiment 96 cups, 24 of each type, were established simultaneously in habitats around the Duke University Marine Laboratory (Beaufort, NC). Sites were monitored for 45 min. At the termination of the experiment every hermit crab within 10 m of the cups was collected and scored as a nonresponder. This search was conducted by 12 people for 20 min. In total, 215 crabs responded by touching a hidden odor source and 73 did not respond. *C. vittatus* were attracted in similar numbers to all three flesh odor sources (H_0, 1:1:1; $G = 1.099$, $P > 0.05$, 2 df).

Frequency distributions of shells occupied by *C. vittatus* attracted to crushed *Clibanarius vittatus*, *Fasciolaria hunteria*, and *Busycon carica* flesh were compared (Figure 2). Shell species distributions for crabs attracted to *C. vittatus* and *F. hunteria* were similar ($G = 1.6$, $P > 0.05$, 4 df). Shell species distri-

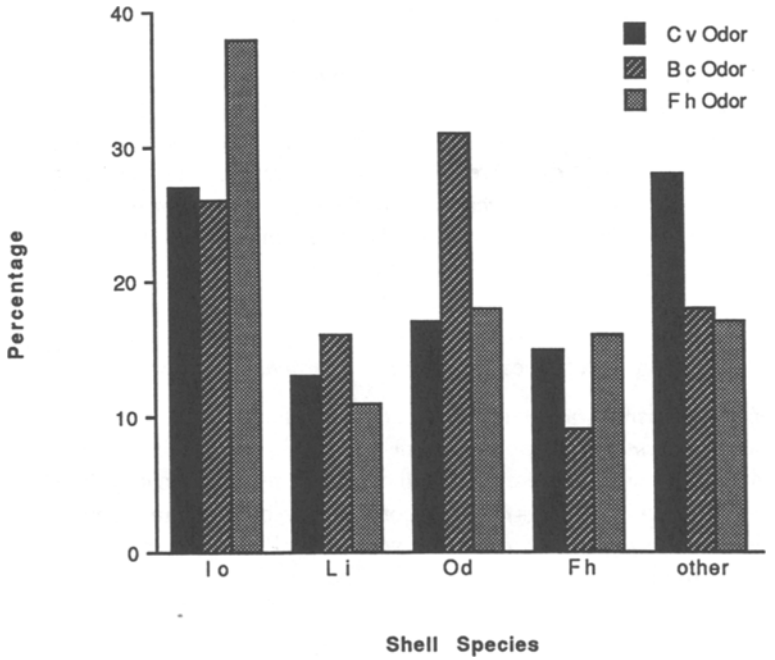

FIG. 2. Shell occupation by *Clibanarius vittatus* attracted to *C. vittatus* (C v) odor, *Busycon carica* (B c) odor, and *Fasciolaria hunteria* (F h) odor. Shell species occupied by the crabs are ordered from smallest, I o (*Ilyanassa obsoleta*), to largest, other (mainly *Busycon* spp. and including *Polinices duplicatus, Murex ponoma, Pleuroploca gigantea*, and *Phalium granulatum*). L i—*Littorina irrorata*; O d—(*Pisania tincta, Urosalpinx cinerea*, and *Eupleura caudata*; F h—*Fasciolaria hunteria*. The "oyster drill" and "other" categories were constructed by combining relatively high frequencies of *P. tincta* and *B. carica*, respectively, with low frequencies of similar-shaped shell species (mainly *U. cinerea* for the oyster drill category and mainly *B. canaliculatum* and *B. contrarium* for the "other" category).

butions for crabs attracted to *C. vittatus* and *B. carica* flesh were not similar ($G = 9.9$, $P < 0.05$, 4 df). Proportionately more crabs in *F. hunteria* shells were attracted to *C. vittatus* odors, and proportionately more crabs in oyster drill shells (mainly *Pisania tincta*) were attracted to *B. carica* odor. Shell species distributions for crabs attracted to *F. hunteria* and *B. carica* were also significantly different from each other ($G = 13.785$, $P < 0.05$, 4 df). Proportionately more crabs in *I. obsoleta* shells were attracted to *F. hunteria* odors and proportionately more crabs in oyster drill shells were attracted to *B. carica* odors (Figure 2). Thus, in more rigorous study of crab shell species in response to odor, some differences in shell occupation behavior by crabs attending *B. carica*

sites as compared to crabs attending crushed *C. vittatus* or *F. hunteria* sites were observed.

Shell occupations of the groups of *C. vittatus* not responding and responding to odors of *C. vittatus* and *B. carica* were compared. Hermit crabs that responded to odors occupied different shell types than nonresponders (G = 107.839, $P < 0.01$, 4 df). Over 80% of the nonresponding crabs were in large shells such as *Fasciolaria hunteria* and *Busycon* spp. Approximately 33% of attracted crabs were in these larger shells. Thus, there were extreme differences in shell occupation frequencies between responsive and unresponsive crabs (Figure 3).

Responses to Busycon carica *Odor in the Interaction Bioassay*

Busycon carica, a potent hermit crab attractant in field tests, was tested in interaction bioassays. Response before the addition of seawater did not change significantly after the addition of 100 μl of seawater [approximately 30% response (Z = 1.04, $P > 0.05$, n = 30)]. In contrast, the hermit crabs responded to the addition of 100 μl of *B. carica* odor with a significant increase in shell investigation activities [approximately 70% response (Z = 12.98, $P < 0.01$, n = 30)].

Responses to Odors from Panopeus herbstii *and* Clibanarius vittatus *Hemolymph and* C. vittatus *Muscle in Interaction Bioassays*

The response of *C. vittatus* was measured with seawater, freshly drawn hemolymph, and odor from hermit crab chelae muscle. Responses to the addition of seawater and *P. herbstii* hemolymph were similar (Z = 0.55, $P > 0.05$, n = 30). Compared to seawater, *C. vittatus* hemolymph significantly increased investigation (Z = 12.97, $P < 0.01$, n = 30). *C. vittatus* claw muscle odor did not increase investigation (Table 2).

Shell Occupation by Investigating and Noninvestigating Crabs in the Interaction Bioassay

An interaction assay using *B. carica* odor and *C. vittatus* hemolymph was performed, with the goal of dividing a large number of haphazardly collected *C. vittatus* into behavior classes so that behavior could be analyzed with respect to shell occupation.

Using the interaction assay hermit crabs were divided into 126 responders and 181 nonresponders. Of the 126 responders, 71 responded to *B. carica* odor and 55 responded to *C. vittatus* odor. Of the nonresponders 96 were to *B. carica* odor and 85 to *C. vittatus* odor. The frequency of responders and nonresponders was similar to both odors (H_0 1 : 1, G = 0.6, 1 df, ns). Shell species distributions

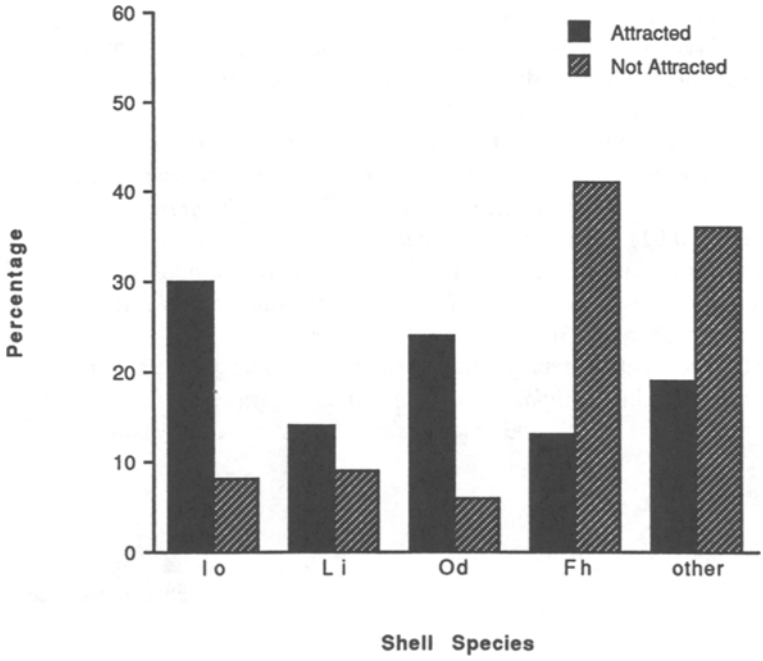

FIG. 3. Shell occupation by *Clibanarius vittatus* attracted to odors in Fig. 2 and in the area but not responding. Shell species are ordered from smallest, I o (*Ilyanassa obsoleta*), to largest, other (mainly *Busycon* spp. and including *Polinices duplicatus, Murex pomona, Pleuroploca gigantea*, and *Phalium granulatum*). L i—*Littorina irrorata*; O d—(*Pisania tincta, Urosalpinx cinerea*, and *Eupleura caudata*; F h—*Fasciolaria hunteria*.

TABLE 2. *C. vittatus* RESPONSE TO HEMOLYMPH FROM *C. vittatus* AND *P. herbstii* AND *C. vittatus* CLAW MUSCLE ODOR

Condition	*n*	Percentage responding	*Z* value	*P*
100 μl seawater	30	40		
100 μ *P. herbstii* hemolymph	30	37	0.55	NS
100 μl seawater	30	33		
100 μl *C. vittatus* hemolymph	30	73	12.97	<0.01
100 μl seawater	30	40	1.13	NS
100 μl *C. vittatus* claw muscle odor	30	47	1.13	NS

of responding and nonresponding crabs were compared and found to differ significantly ($G = 108$, 4 df, $P < 0.01$). Shell species distributions of crabs responding to *B. carica* odor were significantly different from those responding to *C. vittatus* odor ($G = 10.5$, 4 df, $P < 0.05$). This difference was due in large part to responses of crabs in *F. hunteria* shells to *B. carica*. Frequencies of responders within the crabs tested against each odor occupying *F. hunteria* shells were compared. Significantly more crabs in *F. hunteria* shells ($G = 7.4$, 1 df, $P < 0.01$) responded to *B. carica* odor than to *C. vittatus* odor. Shell species distributions of crabs not responding to *B. carica* odor were not different than shell species distributions of crabs not responding to *C. vittatus* odor ($G = 2.8$, 4 df, $P > 0.05$).

Shell occupation data (Figure 4) show that nonresponders were comprised mainly of crabs in *Fasciolaria hunteria* and other large shells, while responding crabs occurred in mainly the smaller shells. Most striking was the response of

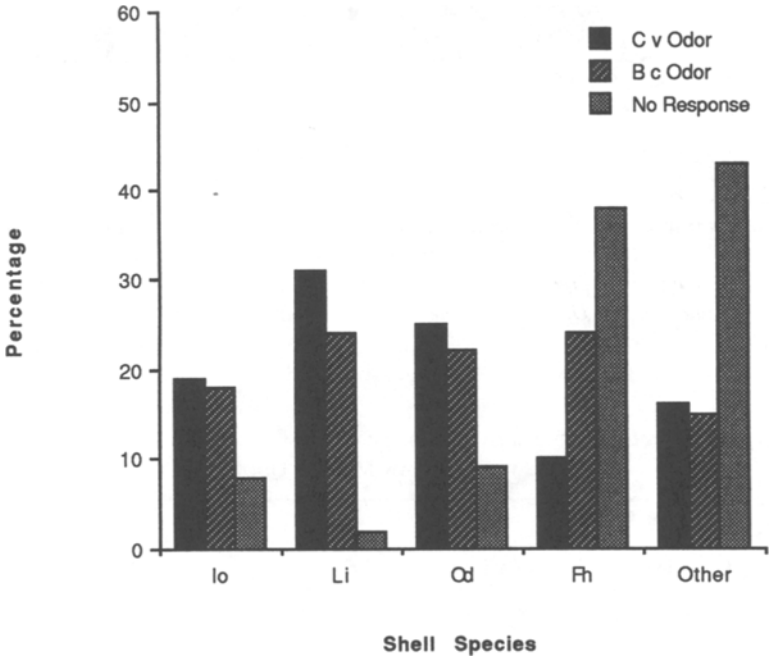

FIG. 4. Shell occupation by *Clibanarius vittatus* attracted to *C. vittatus* (C v) odor or *Busycon carica* (B c) odor and in the area but not responding. Shell species are ordered from smallest, I o (*Ilyanassa obsoleta*), to largest, other (mainly *Busycon* spp. and including *Polinices duplicatus, Murex pomona, Pleuroploca gigantea*, and *Phalium granulatum*). crabs in *Littorina irrorata* shells. Of the 37 crabs in *L. irrorata* shells tested, 34 (92%) responded by investigating. This was in contrast to the response of crabs in the "other" (mainly *Busycon* spp.) shell category. Of the 64 crabs in this category tested, 87% did not respond.

Hermit Crab Behavior Assay

In tide pool behavior assays, *Busycon carica* odor was used to evoke response from *C. vittatus*. *B. carica* odor was added to a tide pool containing 10 to 20 hermit crabs. The crabs responded in one of three ways: (1) they investigated each other's shells and formed aggregations reminiscent of rugby scrums (Rittschof, 1980b), (2) they exited, or (3) they did not respond by either investigating or leaving. In the first series of tide pool assays hermit crabs in category 1 were labeled as "responders," while those in categories 2 and 3 were called "nonresponders." The distribution of shell types between responders and nonresponders was significantly different ($G = 12.401$, $P < 0.05$, 4 df). Significantly more responders were in small shells (*I. obsoleta*, *L. irrorata*), and oyster drill shells: $z = 3.68$, 3.41, and 3.40, respectively; $P < 0.01$ for all categories). Significantly more nonresponders were medium- to large-sized shells, such as *F. hunteria*, and other shell types, which include *Polinices duplicatus*, *Thais haemostoma floridana*, *B. carica*, *B. contratium*, and *B. canaliculatum* ($Z = 6.85$ and 3.76, respectively; $P < 0.01$ for both categories).

A second series of behavior assays with *Busycon carica* odor was used to divide crabs in tide pools into three behavior categories: (1) those that investigated, (2) those that fled the tide pool, and (3) those that did not respond. Carapace, shell species, and shell weight were determined for each behavior class. This series of assays divided 161 *C. vittatus* collected haphazardly into three behavior classes: (1) 37 crabs that did not respond, (2) 65 crabs that left the tide pools , and (3) 59 crabs that investigated. Binary comparisons of frequency distributions of shell species occupied, shell weight, and carapace length were made. Analysis showed highly significant ($P < 0.01$) differences between behavior classes for seven of the nine tests and significant ($P < 0.05$) differences for the other two measures (Table 3).

Inspection of the percentile data for the three behavior classes with respect to shell species occupied, shell weight and carapace length, and carapace length-to-shell weight ratios revealed patterns for each behavior group (Figure 5). Approximately 46% of nonresponding crabs occupied large shells (*Polinices duplicatus*, *Fasciolaria hunteria*, *Busycon* spp.); 21% of the crabs that left the pools occupied these same shell species, while only 7% of the crabs that investigated in response to odor occupied these shells (Figure 5A). Differences observed in shell species occupied were reflected in shell weight and carapace length for the three behavior categories (Figures 5B and C). Finally, comparison

TABLE 3. ANALYSIS OF ANIMAL SIZE AND SHELL WEIGHT FOR *C. vittatus* TIDE POOL ASSAY[a]

Condition	*G* value	df	*P*
Shell species			
No response vs left pool	18.0	3	<0.001
No response vs investigated	48.8	3	<0.001
Left pool vs investigated	11.0	3	<0.02

[a]The null hypotheses were that carapace length, shell weight, and shell species distribution were equal for all groups. Groups were determined by dividing the smallest frequency into four categories with no less than five observations in a category.

of frequency distributions of carapace length-to-shell weight ratios showed significant differences in all three behavior classes (all G values >6.7, all P's $<$ 0.05, all df = 3). Nonresponding crabs had the lowest carapace length-to-shell weight ratio, crabs that left had the next smallest ratio, and crabs that investigated had the highest ratio (smallest-sized shells relative to body size).

Characterization of C. vittatus *Hemolymph Factor*

A series of attraction and interaction assays was used to characterize the biological activities in crab hemolymph with respect to molecular size and adsorption/desorption characteristics on octadecyl silica.

An attraction assay compared hermit crab responses to blanks containing 5 ml seawater in dialysis bags (14-kDa cutoff) with responses to dialysis bags containing 5 ml seawater and 200 μl fresh hemolymph. Twenty-two *C. vittatus* were attracted to the hemolymph sites, as opposed to only one to seawater (G = 23.16, 1 df, $P < 0.001$).

Next, *C. vittatus* hemolymph was fractionated and biological activity determined in the interaction bioassays (Table 4). The blood was separated into three parts: (1) whole hemolymph, (2) hemolymph with molecules less than 1 kDa, and (3) hemolymph molecules greater than 1 kDa. Assays showed that 50- and 100-μl samples of whole blood contained significant biological activity (all Z values >3.52, $P < 0.001$, $n = 30$). The samples of molecules greater than 1 kDa showed low biological activity. One of six tests yielded a significant

[a] Every test with the same assay number was performed on the same group of crabs. The entire assay was performed as a continuous series.

response ($Z = 2.53$, $P < 0.01$). All of the samples of hemolymph molecules less than 1 kDa contained significant biological activity (all: $Z > 4.39$, $P < 0.001$, $n = 30$).

The attractant compound in the <1-kDa fraction of hemolymph was fractionated on octadecyl silane using a C18 column. One milliliter of the attractant compound was tested for biological activity in a *C. vittatus* interaction assay. All responses were measured to 100-μl additions of the samples. The first experiment showed that biological activity was retained by the column ($Z = 0.49$, $P > 0.05$, $n = 30$) and could be recovered by 100% methanol elution ($Z = 3.15$, $P < 0.001$, $n = 30$). In the second experiment <1-kDa hemolymph was applied to octadecyl silane. Most activity was retained but a measurable fraction passed through the column ($Z = 2.09$, $P < 0.05$, $n = 30$). Activity was recovered from the column with 20% methanol ($Z = 6.12$, $P < 0.001$, $n = 30$). Some activity was also recovered in the 100% methanol elution ($Z = 2.47$, $P < 0.01$, $n = 30$). More biological activity was present in the 20% methanol elution than in the 100% methanol elution ($Z = 2.01$, $P < 0.05$, $n = 30$). In the third experiment <1-kDa hemolymph was separated into unretained, HPLC-grade water elution and 20 methanol elutions; some material was unretained ($Z = 2.31$, $P < 0.05$, $n = 30$). Elution with HPLC-grade water did recover activity ($Z = 0$, $P > 0.05$, $n = 30$). Elution with 20% methanol recovered most of the biological activity ($Z = 3.92$, $P < 0.001$, $n = 30$). Thus, biological activity in hemolymph adsorbs to octadecyl silane, can be desalted with HPLC-grade water, and can be recovered with 20% methanol.

DISCUSSION

Hermit crabs respond to odors from crushed conspecifics in a manner similar to their previously demonstrated specific response to odors from dead gastropod flesh (McLean, 1975, 1983; Rittschof, 1980a). They have heightened activity, do not attempt to feed upon the carcass, and actively investigate all shells in an area. Hermit crabs attracted by odors from crushed conspecifics aggregate and a cascade of shell switching occurs when an empty shell of the correct size is introduced. All three species of hermit crabs tested are attracted most strongly to odors of specific dead snails (cf. McLean, 1975; Rittschof, 1980a; Herrnkind et al., 1981; Wilber and Herrnkind, 1982; Gilchrist and Abele, 1984; Rittschof et al., 1990) and to the odors of crushed conspecifics. The specificity of the response to crushed conspecifics is reflected in the fact that hermit crabs did not respond to odors from the hemolymph of brachyurans (see also Rittschof, 1980a). Of the hermit crabs tested, the pagurids showed the least specificity, responding at some level to odors from the hemolymph of all three

species of hermit crabs tested. *C. vittatus* was the most specific, responding only to odors from the hemolymph of conspecifics. *C. vittatus* did not respond to odors from *C. vittatus* muscle. There is no evidence for changes in behavior in *C. vittatus* response to food as reported in laboratory studies of *Pagurus pollicaris* (Hazlett, 1979). It is unclear at this time if the specificity of the response is related to similar cues from gastropod flesh and crab hemolymph.

Shell species composition and shell fit are similar for crabs responding to crushed conspecifics and to gastropod flesh. Although similar in size, the *C. vittatus* responding to crushed conspecifics and to *B. carica* occupied shell species in significantly different frequencies. However, differences in shell occupation in response to *B. carica* odor and to *C. vittatus* odor were opposite in the attraction assay and in the behavior assay. Because shells are such an important resource [see Reese (1963) and Spight (1985) for a comprehensive review of the older ecological and behavioral literature on shell fit and Wilber (1990), Hazlett (1990), and Liszka and Underwood (1990) for more recent literature], a variety of factors associated with the shell (Kuris and Brody, 1976; Wilber, 1990) and with the physiological state of the crabs may be involved. These factors warrant further study.

The above observations indicate that odors from crushed conspecifics are potent cues for shell availability. The attraction and resultant aggregation and behavior of crabs are similar to those evoked by shell availability cues from dead and dying gastropods (McLean, 1973, 1974, 1975, 1983; Rittschof, 1980a,b; Hazlett and Herrnkind, 1980; Lepore and Gilchrist, 1988; Gilchrist and Abele, 1984; Rittschof et al., 1990; Kratt and Rittschof, 1991). Thus, specific chemical cues signal the availability of previously used shells from dying hermit crabs just as they signal the availability of new shells from dying gastropods. This suggests that knowledge of hermit crab mortality and its mechanisms is important in assessing the flow of shells through hermit crab populations. Crab mortality could be important in ecological studies of resource use and in the development concepts of shell utilization (cf. Abrams, 1980; Spight, 1985; Chase et al., 1988; Liszka and Underwood, 1990; Wilber, 1990).

In general, *C. vittatus* in large shells were not attracted by odors from either snail flesh or crushed hermit crabs. Large *C. vittatus* did not respond in the interaction bioassay. In the tide pool behavior assay, most larger crabs remained withdrawn and did not respond by investigating or by leaving. This was true even when chemicals were applied directly to the crabs. Finally, shell species occupation by crabs that did not respond and shell fit data suggest that crabs that did not respond were in different species of shells and that they were relatively large crabs in larger shells. These data do not support the hypothesis of Gilchrist and Abele (1984) that chemicals from predation sites somehow signal the size of the prey snail. This suggests that, in spite of the fact that the

only empty shells found during this 5-week study were whelk shells too large and shells too small to be occupied by *C. vittatus*, shells may not be a limiting resource for large *C. vittatus*.

That shells are not limiting for larger crabs, or that most larger crabs do not respond to chemical shell availability cues, explains the observations of Gilchrist and Abele (1984) that classical sampling techniques and chemical attraction techniques resulted in very different population estimates. These observations also explain the discrepancy reported in conclusions on shell fit of responding crabs between Hazlett and Herrnkind (1980) and Rittschof (1980a). Hazlett and Herrnkind (1980) studied shell fit of *C. vittatus* coming within 1 m of simulated gastropod predation sites and reported that responding crabs were in shells similar to the population at large. In contrast, Rittschof (1980a) required that responding hermit crabs touch a 5-cm-diameter target and found differences between shell occupation of crabs responding and that of crabs not responding. The response criteria of Hazlett and Herrnkind (1980) appear to have included large crabs in the area that were actually unresponsive to the cue but that happened to be near the site, while Rittschof (1980a) did not. Thus, minor differences in methods appear to explain this discrepancy in the literature.

In addition to attracting hermit crabs, dead snail and crushed conspecific odors induce increased shell investigation activity. When odors are presented to crabs in tide pools, crabs behave in one of three ways: (1) increasing activity and shell investigation, (2) fleeing onto the land, and (3) remaining inactive. Shell occupation distributions, size of shell patterns, size [carapace length = SHE (Wilber, 1990)], and frequency distributions of shell fit ratio are all significantly different for all three behavior categories. Crabs that are active and investigate shells are smaller crabs in relatively small shells. Crabs that flee the odor onto land are small crabs in relatively large shells. Crabs that are unresponsive are large crabs in large shells. These data support the concept of Herrnkind et al. (1981) that predation sites are gathering areas for shell exchange and the chemical attractants are aggregation cues.

Crabs in low-quality shells responded to aggregation cues. The possibility of trading shells with other attendants gives crabs a potentially large selection of shells. Small crabs in high-quality shells actively leave the area. Leaving is theoretically advantageous because it reduces the likelihood of an encounter with another crab or a predator that could result in the loss of the good shell. Spight (1985) proposes that larger crabs get larger shells through the encounter of larger crabs in smaller shells with smaller crabs in larger shells. The lack of response of large crabs in large shells suggests that the most advantageous response for the larger crabs is to remain withdrawn in their large and relatively roomy shells.

Shell cues for each species of hermit crab are specific, originating from the flesh of different species of gastropods (Rittschof, 1980b), not gastropod he-

molymph (Kratt and Rittschof, 1991), and from the hemolymph of conspecifics. Some of the chemicals responsible for attraction are small peptides that are products of proteolytic activity on protein substrates (Rittschof et al., 1990; Kratt and Rittschof, 1991). Digestion of purified gastropod muscle protein or foreign protein substrates such as porcine chymotrypsinogen or chicken ovalbumin by the correct peptide generating enzymes results in hermit crab attractants. Enzymes can be pure enzymes such as porcine or bovine trypsin (Rittschof, 1980b; Rittschof et al., 1990; Kratt and Rittschof, 1991) or enzymes found in the salivary glands of predatory gastropods (Rittschof et al., 1990).

In contrast to attractant peptides from gastropods, the attractant chemicals in *Clibanarius vittatus* hemolymph are immediately available in the hemolymph and do not originate from hermit crab muscle (Table 2). If these molecules are peptides, they have a very different origin than the peptides from snail muscles (Rittschof et al., 1990).

The behavior altering odors from crushed *C. vittatus* are factors from the hemolymph. The attraction factor is less than 14,000 D. The investigation behavior and fleeing behavior inducers are < 1000 D. We hypothesize that all behaviors are mediated by the same molecules and that behaviors are directly influenced by shell fit. Hemolymph is stimulatory immediately upon removal from hemolymph sinuses. Thus, the factor is probably already present in the blood, and not generated by proteolytic activity, as are hermit crab attractant odors from snail muscle and other proteins (Rittschof, 1980a; Rittschof et al., 1990; Kratt and Rittschof, 1991). If hermit crabs have a complement cascade in the hemolymph (for review see Schiffman, 1982), it is possible that attractants are similar to (but lower in molecular weight than) those that function in leukocyte attraction (Schiffman, 1982) in vertebrates. We look forward to the resolution of this issue.

Factors that stimulate the crabs to leave the area can be considered alarm substances (Hrbacek, 1950; Pfeiffer, 1963; Snyder, 1967; Snyder and Snyder, 1970; Atema and Burd, 1975; Stenzler and Atema, 1976). As is the case for snail alarm substances (Atema and Burd, 1975; Stenzler and Atema, 1976; Atema and Stenzler, 1977), passive release from hemolymph is the source of substances from hermit crabs and response specificity may be related to phylogeny. In contrast to snail alarm substances (Atema and Stenzler, 1977; Stenzler and Atema, 1977), alarm substances from hermit crab hemolymph are relatively small molecules (< 1000 D), while those from snail hemolymph that cause alarm in mudsnails are large, > 100 kDa. The molecular size of the former coupled with the ability to extract and desalt the active material with a reversed-phase column makes it a likely candidate for future purification and structural determination as was accomplished for alarm pheromone from a sea anemone (Howe and Sheikh, 1975).

Thus, depending upon the type of shell and its size relative to the size of

the crab, chemical factors from snail flesh and crab hemolymph act as attractant cues or as alarm substances which may result in inactivity. Because of their chemical sensing capabilities, crabs can detect and locate or avoid potential sources of shells from over 10 m away. Contrary to the reasoning of Spight (1985), hermit crabs that respond to chemical cues by attraction greatly increase the likelihood of obtaining a new shell. Hermit crabs have many more options for obtaining a new shell when in an aggregation than just the one potentially available new shell [which, as Spight (1985) suggests, probably does not fit them!] (Chase et al., 1988). For example, they have the potential of trading with other hermit crabs attracted to the area by the chemicals. In addition, if a new shell becomes available, all crabs in smaller shells benefit. A routine observation at both natural and simulated predation sites is every crab in a shell smaller than the new shell trades up to the next larger size (McLean, 1975; Rittschof, 1980a; Chase et al., 1988). This is because attracted crabs actively determine where the next larger crab is and take a position next to that crab (McLean, 1975; Rittschof, 1980a). Thus, although only one new shell is added, it replaces the smallest shell in the population of crabs attending the site (Rittschof, 1980a; Chase et al., 1988). The empty shell is continually replaced by a smaller shell until the empty shell is buried in the sediment due to lack of manipulation by crabs in the area.

In summary, chemicals from conspecific hemolymph cause dramatic alteration in behavior. The specific behavior response is related to the size of the crab, the size of the shell, and the species of shell occupied. Chemical detection of dead snails and conspecifics increases the ability of crabs to obtain new shells directly from the source of the cue as well as indirectly from other hermit crabs attracted by the odors.

(Received August 26, 1991; accepted February 18, 1992)

Abstract—Variation in concentrations of leaf nitrogen and iridoid glycosides was examined in replicate plants of five genotypes of *Plantago lanceolata* (Plantaginaceae) grown in an experimental garden. Nitrogen concentration and iridoid glycoside concentration were affected by leaf age. New leaves had nitrogen concentrations 1.7 to 2.7 times higher than mature leaves. Catalpol concentration was highest in new and intermediate-aged leaves. The concentration of aucubin, the biosynthetic precursor to catalpol, was higher in intermediate-aged leaves than in mature leaves, in three of five genotypes. Consequently, the proportion of aucubin relative to total iridoid glycosides increased as leaves aged. Concentration of iridoid glycosides was not correlated with plant size. Plant genotype significantly affected concentration of nitrogen and iridoid glycosides, as well as plant size. Thus, major indicators of hostplant quality for insect herbivores varied considerably both within and among plant genotypes and individuals.

Key Words—*Plantago lanceolata*, iridoid glycosides, aucubin, catalpol, nitrogen, plant size, plant–insect interactions, chemical variation.

INTRODUCTION

A population of plants represents a heterogeneous resource for herbivorous insects. Individual plants may vary in their morphology and architecture (Law-

ton, 1986); the biomass available to be eaten; and in their location and abundance, which may affect their susceptibility to being found (Rausher, 1981; Mackay and Singer, 1982; Singer et al., 1989; Thomas, 1989, 1990). They may also differ in their nutritional and secondary chemistry (McKey, 1979; Mattson, 1980; Scriber and Slansky, 1981; Louda and Rodman, 1983; Berenbaum et al., 1989; Stamp and Bowers, 1990). At least some of the observed variation in plant secondary chemistry in several plant taxa is genetically based (Gouyon et al., 1983; Berenbaum et al., 1986; Lincoln et al., 1986; Mihaliak et al., 1989), although environmental factors may enhance or override the genetic effects (Lindroth et al., 1987; Mihaliak et al., 1989; Waterman and Mole, 1989).

Within a plant, nutritional quality of leaves may vary, depending on their position and age (Mattson, 1980; Raupp and Denno, 1983; Harper 1989), and phytochemicals may occur in very different amounts in leaves, depending on the location of the leaf, the age of the leaf, and the presence or absence of herbivore damage to the leaf (Lincoln and Langenheim, 1978, 1981; McKey, 1979; Raupp and Denno, 1983; Haukioja and Neuvonen 1987; Baldwin, 1988). For example, new leaves are often higher in nitrogen, water, and secondary metabolites (McKey, 1979; Mattson, 1980; Harper, 1989; Stamp and Bowers, 1990) than mature leaves. Damage to a leaf may induce the production of additional secondary metabolites, which can then alter the suitability of that leaf as food (Haukioja and Neuvonen, 1987; Baldwin, 1988; Baldwin et al., 1990).

Plantago lanceolata (Plantaginaceae), narrow-leaved plantain, is a common introduced weed in North America (Cavers et al., 1980) that serves as a host plant for several species of herbivorous insects (Tietz, 1972; Scott, 1986). *Plantago lanceolata* contains two iridoid glycosides, aucubin and catalpol (Duff et al., 1965). These compounds serve as feeding and oviposition stimulants for some species of specialist insects, including the buckeye butterfly, *Junonia coenia* (Nymphalidae) (Bowers, 1984; Pereyra and Bowers, 1988). Iridoid glycosides are sequestered by buckeye larvae and may help protect them from potential predators (Bowers and Collinge, 1992). Some iridoid glycosides, including aucubin and catalpol, are toxic or deterrent to generalist and nonadapted specialist insects (Bernays and DeLuca, 1981; Bowers and Puttick, 1988, 1989; Puttick and Bowers, 1988).

In this study, we assessed variation in leaf nitrogen content and iridoid glycosides as indicators of food quality for insect herbivores. Plantain can be vegetatively propagated (Wu and Antonovics, 1975), so we were able to analyze replicates of each of five genotypes. In addition, we divided each individual plant into three leaf age classes—new, intermediate, and mature—and measured the nitrogen and iridoid glycoside concentration of the leaves in each age class. Thus we were able to assess the genetic basis for individual variation in these components, as well as the variation within individual plants.

METHODS AND MATERIALS

Five genotypes of *P. lanceolata* were vegetatively propagated in the SUNY Binghamton greenhouse in early May 1989. These genotypes were chosen from an array of genotypes, collected outside Providence, RI, that had been used in other experiments (Fajer et al., 1992; Schmitt et al., 1992). We consider these entities to be separate genotypes for the following reasons: (1) the original parent plants (=genotypes) were collected at least a meter distant from any other parent plant (see Schmitt et al., 1992), (2) *P. lanceolata* is self-incompatible and thus all offspring are the result of out-crossing (Ross, 1973; van Dijk, 1985), and (3) *P. lanceolata* does not reproduce by rhizomes and thus clones of identical individuals do not occur in the field. Three of the genotypes (F8, F9, F14) were originally collected from an old field; the other two genotypes (L11, L15) were from a frequently mowed lawn.

The ramets of each genotype were initially similar in size (three to five leaves) and were grown in pots in the greenhouse for 8 weeks. On June 12, 1989, they were planted in a common garden in Binghamton, NY. The planting design was determined by a concurrent experiment for which these plants served as one type of control. Four pairs of plants of each genotype were planted (N = eight plants of each of five genotypes for a total of 40 plants). Plants within a pair were 0.25 m apart and the pairs were 1.0 m apart. The pairs were oriented alternately, the first pair north–south, the second east–west, and so forth. The planting location in the garden for each pair was determined randomly.

These plants grew in the garden for 4 weeks, after which all of the above-ground parts were harvested. After removing the scapes (=reproductive parts), leaves were separated into new, intermediate, and mature age classes, and the length of each leaf was measured. Leaves of *P. lanceolata* grow in a rosette, allowing leaves to be easily aged. We designated leaf age in the following way: "new" leaves were the five central, incompletely expanded leaves; "mature" leaves were the five most basal leaves; and "intermediate" leaves were the remainder. The number of intermediate leaves therefore varied, depending on the size of the individual plant. Leaf material and scapes were then dried at 50°C to a constant weight and weighed. All leaves of each age class, from each individual, were ground together to a homogeneous powder, then analyzed for iridoid glycosides and nitrogen content.

Iridoid glycoside content of leaf samples was analyzed by gas chromatography (Gardner and Stermitz, 1988; Fajer et al., 1989; Belofsky et al., 1989; Bowers, 1991; Bowers and Collinge, 1992). Twenty-five milligrams of each sample of powdered leaves was extracted overnight in 95% MeOH. GC analyses of iridoid glycosides were performed on the trimethylsilylated derivatives. Phenyl-β-D-glucose was used as an internal standard. The results from two

injections of each plant sample were averaged, and the mean of those was used for statistical analyses.

Total Kjeldahl nitrogen content was determined using a Lachat Flow Injection Ion Analysis system. Samples of 100 mg of dried, powdered plant material were digested in sulfuric acid and a copper sulfate catalyst (1000:30:47, K_2SO_4:anhydrous $CuSO_4$:$CuSO_4 \cdot 5H_2O$) at 360°C for 3 hr. Each run of 40 samples included a set of standards of *P. lanceolata* with known nitrogen concentrations. The *P. lanceolata* standards were from a large batch (several kilograms) of powdered leaves that had had the nitrogen concentration independently analyzed.

Statistical analyses were performed using ANOVA, with both genotype and leaf age as fixed effects. Where appropriate, ANOVAs were followed by Student–Newman–Keuls range tests. Proportions were arcsine-transformed for analysis.

RESULTS

Plants of the five genotypes differed significantly in total biomass (one-way ANOVA, $F = 9.44$, df = 4,35, $P < 0.001$). The plants of genotype L15 were significantly smaller than the others (Table 1). The differences among genotypes in the sum of leaf lengths and plant biomass per unit of leaf length reflected the differences in leaf morphologies among the five genotypes (sum of leaf lengths, $F = 16.90$, df = 4,35, $P < 0.001$; biomass per unit of leaf length, $F = 3.19$, df = 4,35, $P < 0.025$) (Table 1). There were no significant differences among genotypes in number of leaves ($F = 2.01$, $P > 0.10$) or number of scapes ($F = 1.04$, $P > 0.35$) (Table 1).

Nitrogen concentration (Table 2) was significantly affected by both genotype and leaf age (Table 3). New leaves contained 1.7 to 2.7 times as much nitrogen as mature leaves (Table 2). The five genotypes varied in nitrogen concentration by a factor of approximately 1.5 (Table 2).

Percentage dry weight total iridoid glycosides in an entire plant ranged from a mean of 3.36% in genotype L15 to a mean of 5.66% in genotype F8 (Table 1). In addition, iridoid glycoside concentration varied significantly with genotype and leaf age (Tables 2 and 3). Total iridoid glycoside content was highest in new and intermediate leaves and lowest in the mature leaves (Table 2). In three of five genotypes, aucubin was higher in intermediate leaves than in mature leaves, whereas catalpol was highest in new and intermediate leaves (Table 2). The proportion of aucubin relative to total iridoid glycosides (Table 2) increased with leaf age (Table 3) and differed significantly among genotypes (Table 3). For four of five genotypes, new leaves had more catalpol than aucubin, but in intermediate and mature leaves, the amount of aucubin, on average, was as much as three times higher than catalpol (Table 2).

To test the hypothesis that plants allocating more resources to growth and reproduction might have less to allocate to chemical defense (i.e., there was a cost of chemical defense) (Gulmon and Mooney, 1986), we tested for a negative correlation between iridoid glycoside concentration and biomass. Concentration of iridoid glycosides was not significantly correlated with plant size, except for the aucubin concentration of genotype L15, which was positively correlated ($r^2 = 0.53, P < 0.05$).

DISCUSSION

Our results showed that these five genotypes of *P. lanceolata* were quite different in terms of biomass, nitrogen content, and iridoid glycoside content. The plant biomass varied substantially among genotypes. The biomass of genotype L15 was about half that of the next smallest genotype, F9, and one-fifth that of the largest genotypes, F8 and L11 (Table 1). Thus, individuals of L15 may be much more quickly decimated by herbivore attack. However, these L15 plants might escape female butterflies searching for suitable oviposition sites, if the females do not notice these small plants or prefer larger ones (Rausher, 1983; Rausher et al., 1981; MacKay, 1985; Thomas, 1989, 1990).

The genotypes also differed significantly in their nitrogen content (Table 2). Because the location of replicate individuals of each genotype in the common garden was randomly determined, the differences in nitrogen content probably reflect differences in photosynthetic capacity (Harper, 1989) or nutrient utilization efficiency, rather than soil nutrient availability. Nitrogen is a limiting factor for insect herbivores (Mattson, 1980; Scriber and Slansky, 1981), and thus a genotype, such as F9, that was relatively low in nitrogen content might be a less adequate nutritional resource than the other genotypes. For example, *Pieris rapae* (Pieridae) caterpillars on low-nitrogen collards grew much more

slowly than caterpillars eating high-nitrogen plants (Loader and Damman, 1991). However, herbivorous insects may consume less biomass from plants that are higher in nitrogen, resulting in relatively more damage to plants lower in nitrogen.

Genotypes also differed significantly in their total iridoid glycoside content, as was found in another experiment with *P. lanceolata* (Fajer et al., 1992). However, in that experiment, plants were grown in pots in environmental chambers, not in the field, and leaves were not separated into different age classes as they were in this experiment. Our data in the present experiment indicate not only that there is a significant genotype effect on iridoid glycoside content but that an individual plant is quite heterogeneous in terms of iridoid glycoside content; new leaves contained an average of twice as much iridoid glycosides as mature leaves.

Our data showed a change in the relative proportion of the two iridoid glycosides, aucubin and catalpol, as the leaves aged. New leaves, in general, were highest in catalpol, except in genotype F14, in which amounts of aucubin and catalpol were about equal. In the biosynthesis of iridoid glycosides in plants, aucubin is the precursor of catalpol (Damtoft et al., 1983). Our data suggest that as leaves age, (1) less catalpol is synthesized, (2) it is more quickly broken down, and/or (3) it is translocated out of the leaf.

We found no indication that higher amounts of iridoid glycosides in these *P. lanceolata* plants resulted in decreased growth or reproduction; that is, there was no cost of a higher investment in chemical defense (Gulmon and Mooney, 1986). These plants were harvested in mid-July and had not completed flowering. Our results suggest that early in the life cycle of a *P. lanceolata* plant, there is no detectable cost (in terms of biomass) to producing higher amounts of iridoid glycosides.

Such chemical variation within as well as among genotypes may affect insects feeding on *P. lanceolata*, and this in turn may determine the impact of those herbivores on the fitness of *P. lanceolata*. For example, laboratory experiments have shown that larvae of the buckeye, *Junonia coenia* (Nymphalidae) grow better on artificial diets with higher amounts of iridoid glycosides (Bowers and Puttick, 1989) and that female *J. coenia* prefer to oviposit on substrates with higher amounts of iridoid glycosides (Pereyra and Bowers, 1988). Herbivory by such specialist insects may selectively remove genotypes high in iridoid glycosides from *P. lanceolata* populations. For insects that feed on *P. lanceolata* and sequester iridoid glycosides, such as larvae of the checkerspot butterfly, *Euphydryas phaeton* (Nymphalidae) (Bowers, 1991), and larvae of the buckeye butterfly, *Junonia coenia* (Nymphalidae) (Bowers and Collinge, 1991), the ability to choose plants and plant parts high in iridoid glycosides may increase their protection from potential predators. Furthermore, the catalpol content of insects appears to be the critical component of unpalatability in those species that

sequester iridoid glycosides (Bowers, 1980; Belofsky et al., 1989). There was a significant effect of genotype on the amount of catalpol in these *P. lanceolata* plants; thus the plant genotype a caterpillar feeds on may determine its relative palatability or unpalatability to potential predators. In addition, new leaves contained more catalpol than intermediate or mature leaves, so preference for new leaves by a caterpillar that sequesters iridoid glycosides may also enhance its unpalatability.

In conclusion, our study shows that nitrogen, an indicator of plant nutritional quality, and iridoid glycosides, major components of plantain defensive chemistry, vary considerably both within and among plant parts. This variation may be important in the relative susceptibility of particular genotypes or plant parts to insect attack and may be important for insects feeding on *P. lanceolata* as well.

(Received November 14, 1991; accepted February 18, 1992)

Abstract—Nitrogen fixation in root nodules formed by strain 2143 of *Bradyrhizobium japonicum* and *Glycine max* (L.) Merr. cv Williams 82 reaches a maximum at 21 to 28 days postinoculation and then begins to decline. The phytoalexin, glyceollin, accumulates in nodules coincident with the decline in nitrogen fixation. Nodules formed by strain 3122, which are unable to fix nitrogen, accumulate even higher levels of glyceollin and do so beginning 21 days postinoculation even though these nodules contain no recoverable bacteria. The typical phytoalexin response occurs within days of infection. The mechanism by which this response in the *Bradyrhizobium japonicum*–soybean combination is delayed 2 to 3 weeks after infection is presently unknown but phytoalexin accumulation could contribute to the inability of the soybean–*Bradyrhizobium japonicum* combination to maintain high levels of nitrogen fixation throughout the growing season.

Key Words—Nitrogen fixation, glyceollin, phytoalexin, *Bradyrhizobium japonicum*, nodulation.

INTRODUCTION

Isoflavonoids and flavonoids are plant-produced, secondary metabolites. Interest in these classes of compounds was renewed in the middle of the 1980s with

*To whom correspondence should be addressed.

reports that they acted as signal molecules for activation of *nod* genes in *Rhizobium meliloti* (Peters et al., 1986) and *Bradyrhizobium japonicum* (Kosslak et al., 1987). Historically, however, interest in isoflavonoids has centered on their antimicrobial activity and their production by the plant in response to pathogenic insult (Albersheim and Valent, 1978; Ingham, 1982; Hahn et al., 1985; Keen and Kennedy, 1974).

With respect to phytotoxicity and antimicrobial activity, the most widely studied soybean isoflavonoids are the pterocarpans. The pterocarpans include glycinol and the multiple isomers of glyceollin. Their phytotoxicity has been attributed to disruption in membrane functions (Weinstein et al., 1983) and inhibition of electron transport processes (Boydson et al., 1983). Glyceollin has been reported to be bacteriostatic (Fett and Osmond, 1982) and is known to cause at least transient growth inhibition of *B. japonicum* strains (Parniske et al., 1991) of both DNA homology groups, I and II (Hollis et al., 1981).

Only limited information is available about the importance of glyceollin accumulation in the formation and maintenance of functional soybean root nodules. Werner et al. (1985) have investigated the possible role of glyceollin in determining whether combinations of specific strains of *B. japonicum* and soybeans are effective (capable of nitrogen fixation) or ineffective (not capable of nitrogen fixation). They reported that glyceollin I was detected in mature nodules. Since it appeared at much higher levels in ineffective symbiotic combinations, they suggested that it might contribute to the failure of the symbiotic interaction.

Our research is directed toward understanding the maintenance of (rather than the formation of) the effective combination. In our studies on the biochemistry of developing bacteroids in the *B. japonicum*–soybean symbiosis, we see the characteristic rise in nitrogenase activity. This increase is accompanied by a rise in metabolic activities that are presumed to be involved in providing energy for nitrogen fixation (Karr et al., 1984). The rise in nitrogen fixation capacity is transient and is followed by a drop in nitrogen fixation capacity and bacteroid plating efficiency and a cessation or drop in the various indicators of ongoing metabolic activity (Karr et al., 1984; Karr and Emerich, 1988). This decline in nitrogen fixing capacity precedes pod set and should result in a decrease in available biologically fixed nitrogen for pod fill. The purpose of the work described here was to determine whether the failure to maintain maximum nitrogen fixation capacity in effective combinations is accompanied by accumulation of glyceollin in nodules.

METHODS AND MATERIALS

Bacterial Strains and Plant Material. B. japonicum strain 2143, a natural mutant of USDA143 selected for resistance to rifampicin (80 μg/ml) and nalidixic acid (100 μg/ml), forms an effective combination with cv Williams 82

(Karr and Emerich, 1988). *B. japonicum* strain 122 L, a naturally occurring mutant of USDA122 that was selected for large colony size (Emerich et al., 1979), forms an ineffective combination with cv Williams 82. Strain 3122 is a natural mutant of strain 122 L selected for resistance to rifampicin (80 μg/ml). *B. japonicum* strain 122 S, a naturally occurring mutant of USDA122 selected for small colony size (Emerich et al., 1979), forms an effective combination with cv Williams 82. Strain 2122 is a natural mutant of strain 122 S selected for resistance to rifampicin (80 μg/ml). Strains 2143, 3122, and 2122 are members of serogroup 122 and DNA homology group I. Strains USDA143, 122 S, and 122 L were kindly provided by Harold Evans, Laboratory for Nitrogen Fixation Research, Oregon State University. Strain USDA 110 was provided by Dale Blevins, Agronomy Department, University of Missouri.

Soybean seeds [*Glycine max* (L.) Merr. cv Williams 82] were surface-sterilized by washing sequentially for 1 min each in 1.2% (w/v) sodium hypochlorite, sterile, deionized, distilled water, 70% (v/v) ethanol and rinsing thoroughly in sterile, deionized, distilled water. Seeds were germinated on water agar until the roots reached 1 to 2.5 cm in length. Plants were inoculated with the appropriate *Bradyrhizobium japonicum* strain by suspending them for 30 min in a bacterial culture (A_{630} = 0.7) which had been grown for 8 days in yeast extract mannitol medium (YEM) (Vincent, 1970) at 30°C. The inoculated seedlings were planted in perlite–sand–vermiculite potting medium in sterile, modified Leonard jars irrigated with nitrogen-free nutrient solution (Ahmed and Evans, 1960). Growth conditions are detailed elsewhere (Karr and Emerich, 1988). The nodulation pattern of the effective and ineffective strains was different. Nodules formed by *B. japonicum* strains 2143, 2122, and USDA 110 clustered near the crown area of the tap root, while those formed by strain 3122 showed no clustering and were scattered over the entire root system.

Bacteroid Viability and Nitrogen Fixation Capacity. Bacteroid viability was determined from the plating efficiencies of nodule extracts on agar plates in YEM medium amended with rifampicin as described previously (Karr and Emerich, 1988).

Nitrogen-fixation capacity was determined by measuring the capacity of intact root-nodule matrix to reduce acetylene (Schwinghamer et al., 1970). Ethylene formation was measured every 3 min for 18 min. The rate of ethylene formation was calculated from the initial rate and is expressed as micromoles of C_2H_4/hr/g nodule fresh weight (μmol/hr/gfw).

Isolation and Measurement of Glyceollin. Glyceollin was isolated from nodules, the nodulated-root zone, approximately 0.5 cm to either side of the position from which nodules had been detached, and the nonchlorophyllous stem segment just above the root crown. A modification of the procedure described by Keen et al. (1971) was used. The plant material was frozen in liquid nitrogen as it was harvested, and its weight measured. Two to six-gram batches of frozen tissue were macerated in 95% ethanol (2 ml/g tissue) at −20°C with the aid of

a Polytron homogenizer. Debris was removed by 20 min of centrifugation at 20,000*g*. Solvent was removed under vacuum at 40°C on a rotary evaporator. The residue was dissolved in 95% ethanol (2 to 6 g frozen plant material per 2 ml ethanol); 2 ml of the ethanol-soluble fraction was diluted with 4 ml deionized distilled water. This solution was applied to a precleaned C_{18}-RP Seppak (Waters) cartridge and recovered as described previously (Abdullah et al., 1984). Glyceollin recovery was at least 85% as determined by the recovery of authentic glyceollin added to macerated nodules or roots. Glyceollin-containing samples were protected from light and stored at −20°C until analysis.

Samples were analyzed by HPLC; the chromatograph consisted of two Waters 6000A pumps, a U6K injector, a Model 660 gradient programmer, and a Model 440 detector. Glyceollin was separated on a 3-μm C_8-RP column (Supelco, Inc., Bellefonte, PA) using gradient 7 from 60 to 75% (v/v) methanol (1 ml/min). After HPLC, glyceollin was quantitated using a UV detector and an ϵ_{280} of 10,000, a value in agreement with a recent report (Parniske et al., 1991). Glyceollin was identified by UV spectra and by chromatographic identity with authentic glyceollin when subjected to TLC. Analytical TLC was performed on Kodak (Eastman Kodak Company, Rochester, NY) silica gel sheets with fluorescent indicator developed with hexane–ethyl acetate–methanol, 60:40:5 (Keen et al., 1972); benzene–methanol, 95:5; or ethylacetate–hexane, 70:30 (Weinstein et al., 1981). Authentic glyceollin was kindly supplied to us by Dr. N. Keen, University of California—Riverside, and Dr. J. Paxton, University of Illinois. Experiments measuring accumulation of glyceollin in nodules and surrounding root tissues have been repeated five times over a 3-year period and the pattern of glyceollin accumulation was the same in all experiments. The data given in Figures 1 and 2 are from one of the five replications; each data point is the average of at least four samples (three samples for day 13) and three injections of each sample.

Sensitivity to Glyceollin. The sensitivity of *B. japonicum* to glyceollin was measured by the plate bioassay method (Fett and Osman, 1982; Skipp and Bailey, 1977; Wyman and Van Etten, 1978). YEM (Vincent, 1970) agar plates were overlaid with 2.5 ml of 0.8% YEM agar containing 10^7 to 10^8 cells of *B. japonicum* strains that had been cultured for 5 days on YEM liquid culture medium before use. Five-microliter aliquots of glyceollin dissolved in 50% (v/v) methanol or 50% (v/v) ethanol were spotted onto the freshly solidified overlays. Plates were incubated at 28°C, in darkness, and scored after 3 or 4 days of growth. Glyceollin caused the formation of plaques which became hazy with time. The plaque phenotype presumably results from the transient nature of glyceollin-caused growth inhibition of *B. japonicum* (Parniske et al., 1991). The sensitivity of each of the strains was recorded as the lowest glyceollin concentration which caused formation of a visible plaque.

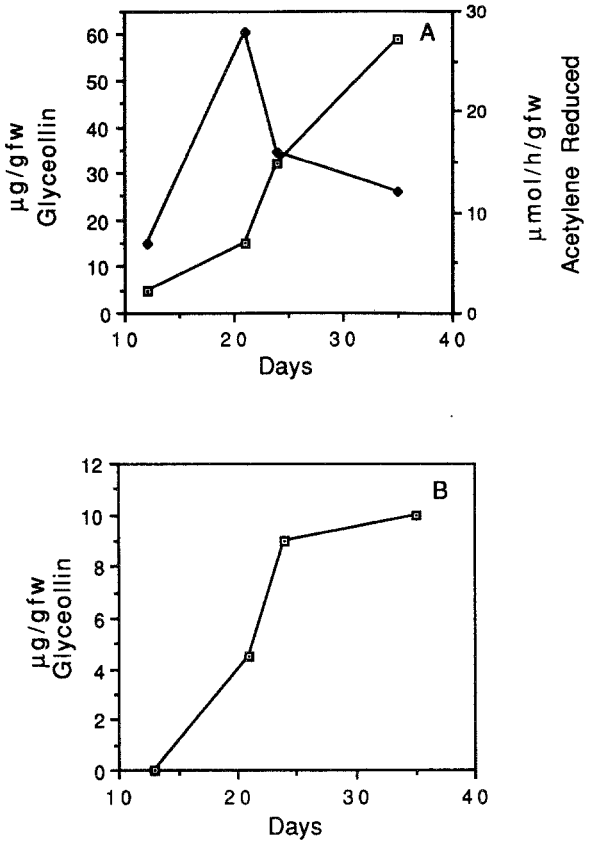

FIG. 1. (A) The relationship between the level of acetylene reduction activity (diamonds) and glyceollin accumulation (open squares) in nodules formed by strain 2143. Glyceollin concentrations in the nodule tissue represent means derived from nodules from four sets of plants (3 for day 13), with each sample being analyzed three times by HPLC. Standard deviations were less than ±10% of the mean for days 21, 24, and 35. The standard deviation for day 13 was ±80%. (B) Accumulation of glyceollin in root tissue adjacent to nodules formed by strain 2143. Standard deviations were less than ±10% of the mean for days 21, 24, and 35.

RESULTS

The pattern of acetylene reduction exhibited by nodules formed by *B. japonicum* strain 2143 on cv. Williams 82 is shown in Figure 1A. Normally, acetylene reduction activity is measurable by the fifteenth day postinoculation

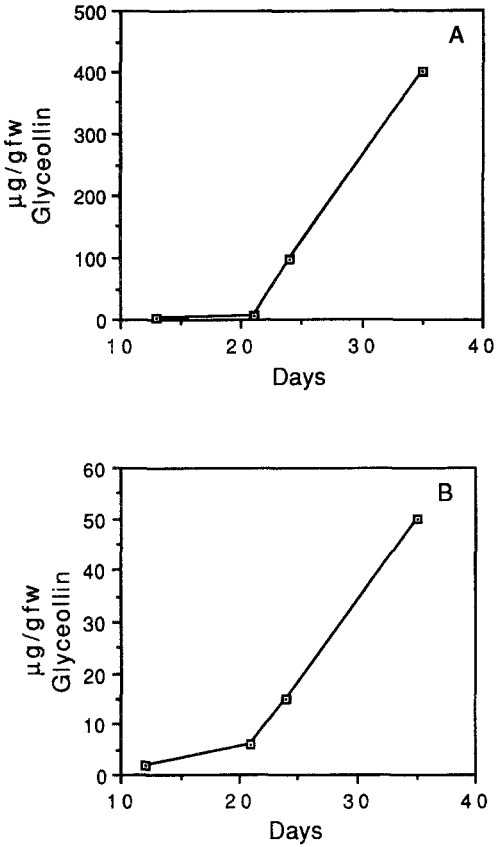

FIG. 2. (A) Glyceollin accumulation in nodules formed by strain 3122. Acetylene reduction was less than 2 µmol/hr/gfw at all time points. Standard deviations were less than ±10% of the mean for days 21, 24, and 35 and ±50% for day 13. (B) Accumulation of glyceollin in root tissue adjacent to nodules formed by strain 3122. Standard deviations were less than ±10% of the mean for days 21, 24, and 35.

(PI), rises to a peak between day 20 and day 28, and then begins to decline. By day 45 acetylene reduction activity is typically no higher than 5 µmol/hr/gfw. This transient pattern of acetylene reduction activity is not specific to nodules formed on cv. Williams 82 by strain 2143. An identical pattern was observed with nodules formed by strains 2122 and USDA 110 on cv. Williams 82 and with nodules formed by strain 2143 on cv. Clark and Chamberlain. The same pattern has been reported previously for nodules formed with a commercial inoculum of *B. japonicum* on cv. Chippewa (Wong and Evans, 1971). Finally, this pattern of acetylene reduction is not specific to plants grown in Leonard

jars and was observed with nodules formed by strain 2143 on cv. Williams 82 grown in commercial potting soil (unpublished data of this laboratory). Acetylene reduction activity was less than 2 μmol/hr/gfw at all sampling times in nodules formed by strain 3122.

This decline in acetylene reduction activity after day 21 was accompanied by a decline in the viability of isolated bacteroids. In the experiment described here (Figure 1A) bacteroids isolated from nodules 21 days PI gave a viability of 105 ± 10%. By day 35 PI bacteroid viability had declined to 39 ± 5%. Viable bacteroids were not recovered from nodules formed by strain 3122.

Glyceollin was readily detectable in nodules formed by strain 2143 by 21 days PI (Figure 1A). Levels of glyceollin continued to rise through day 24 and reached a concentration of 59 μg/gfw by day 35. Glyceollin levels did not increase significantly after day 35 (data not given). A much lower level of glyceollin was also detected in the root zone from which the nodules had been detached (Figure 1B). Glyceollin reached a maximum concentration of only 10 μg/gfw by day 35. The pattern and timing of glyceollin accumulation were the same in roots and nodules. No glyceollin was detected in the nonchlorophyllous stem tissue from plants inoculated with strain 2143.

Glyceollin was also detectable in nodules formed by strain 3122 by 21 days PI (Figure 2A). Levels of glyceollin continued to rise through day 24 and reached a concentration of 400 μg/gfw by day 35. After day 45, nodules formed by strain 3122 became brown inside, presumably due to the accumulation of phenolic, secondary metabolites. The timing and pattern of glyceollin accumulation in nodules formed by strain 3122 were the same as those observed for nodules formed by strain 2143. In plants inoculated with strain 3122, glyceollin levels in root tissue adjacent to the excised nodules (Figure 2B) and stem tissue reached concentrations of 50 and 10 μg/gfw, respectively.

Nodule extracts contained three additional UV-absorbing compounds (designated I, II, and III) which eluted from the HPLC column prior to glyceollin and which appeared in the nodules just previous to the rise in glyceollin levels. Compound I eluted coincident with and had a UV spectrum identical to the isoflavone, genistein. Compounds I and II did not inhibit the growth of *B. japonicum* in the plate assay. Compound III, which is unidentified, caused the formation of a clear plaque in the plate assay.

These experiments were repeated five times over a 3-year period. In separate experiments, the measured peak of nitrogen fixation varied between 21 days (Figure 1A) and 28 days PI. Maximum glyceollin levels obtained from nodules formed by strain 2143 at day 35 PI ranged from 40 to 64 μg/gfw, while levels from nodules formed by strain 3122 at day 35 ranged from 400 to 800 μg/gfw (Table 1). The timing (relative to the period of peak nitrogen fixation) and pattern of glyceollin accumulation were the same in all experiments.

B. japonicum strains 2122, 2143, and 3122 were tested for sensitivity to

glyceollin (Table 2). Sensitivities were reported as end points, because the transient nature of glyceollin inhibition of *B. japonicum* growth makes calculation of ED_{50} values difficult. The three strains differed in their sensitivity to glyceollin. Strain 2122 was the least sensitive, with no plaque formation being observed after application of solutions containing glyceollin at less than 30 μg/ml. The end point for strain 2143 was 10 μg/ml. Strain 3122 was markedly more sensitive to glyceollin. Its growth was inhibited by solutions containing 5 μg/ml, the lowest levels used in this study. The data in Table 2 were obtained using solutions of glyceollin in methanol. Strains 2122 and 2143 were twice as sensitive when glyceollin was applied in 95% ethanol. Glyceollin recovered

TABLE 1. LEVELS OF GLYCEOLLIN DETECTED IN NODULES FORMED BY *B. japonicum* STRAINS 35 DAYS POSTINOCULATION

Experiment No.	Strain	μg/gfw glyceollin in nodule tissue 35 days PI

after HPLC from nodules formed by either strain caused the formation of hazy plaques in the plate assay.

DISCUSSION

The decline of nitrogen fixation in nodules formed by *B. japonicum* strain 2143 clearly coincides with an accumulation of glyceollin in nodule tissue (Figure 1A). A similar pattern of glyceollin accumulation was detectable in roots adjacent to where nodules were detached but not in plant stem tissue. Glyceollin became detectable just preceding the time of maximum measured nitrogen fixation and continued to increase through day 35 postinoculation (PI), after which no further increase was detected. Glyceollin also accumulated at the same time PI in nodules formed by strain 3122. In agreement with the report of Werner et al. (1985), this ineffective combination resulted in the accumulation of much higher levels of glyceollin than the effective combination formed by strain 2143. Root tissue adjacent to nodules formed by strain 3122 and stem tissue also accumulated detectable levels of glyceollin. Indeed, glyceollin levels in such adjacent root tissue were nearly as high as those that accumulated in nodules formed by strain 2143.

It is not surprising that glyceollin accumulation is elicited during infection by *B. japonicum*. Glyceollin belongs to a class of plant-produced, antimicrobial compounds termed phytoalexins whose synthesis is elicited by pathogenic organisms (Paxton, 1980). Phytoalexins have been proposed to play a role in plant disease resistance responses (e.g., Ebel and Grisebach, 1988), and Vance (1983) has noted the similarities between plant diseases and plant nodulation by members of the Rhizobiaceae. What is surprising in the plant nodulation system as reported here is that glyceollin accumulation does not begin until 2 weeks after introduction of the microorganism with maximum accumulation beginning 1 week later. In other plant–microbe combinations where glyceollin is proposed to play a role, glyceollin accumulation is detectable early in the infection process. Parniske et al. (1988) have observed such an early elicitation of accumulation of glyceollin in root hairs soon after infection by *B. japonicum*. That is clearly a different elicitation event than the one described here. It is noteworthy that glyceollin accumulation also begins approximately 3 weeks after infection by strain 3122. Nodules formed by this strain are incapable of nitrogen fixation and do not form detectable leghemoglobin. Plants inoculated with strain 3122 become yellow and stunted if not provided with an exogenous source of nitrogen. While ultrastructural studies have shown that nodules formed by strain 3122 do contain some bacteria in infection thread structures and scattered single bacteroids enclosed in peribacteroid membranes (unpublished results of this laboratory), viable bacteria cannot be isolated from the nodules. These results indicate

that neither the establishment of active nitrogenase nor even the presence of a large number of bacteroids is necessary for triggering the accumulation of glyceollin 2 to 3 weeks PI. While the nature of the elicitation event is unknown, it is possible that the elicitation signal is transmitted early in the infection process and not acted upon by the plant for several weeks or that elicitation of glyceollin accumulation is a natural part of the program of nodule development. While still speculative, the best candidate for elicitation of the defense responses is an oligosaccharide released from the bacterial cell surface. The enzyme responsible for liberation of the oligosaccharide is produced by the bacterial cells at the highest levels in the time period just preceding the decline in nitrogen fixation (unpublished results of this laboratory). Further work will be needed to establish the importance of the oligosaccharide in elicitation of glyceollin accumulation.

While the concentration of glyceollin that accumulates in nodules formed by strains 2143 and 3122 is clearly high enough to inhibit the growth of the respective strain when assayed in culture, it is not certain that glyceollin alone is responsible for the bacteroid viability decline and the observed decline in nitrogen fixation capacity. Parniske et al. (1991) have demonstrated that although the growth of *B. japonicum* in culture is inhibited by glyceollin, this inhibition is transient. Upon continued exposure to glyceollin or treatment with the isoflavonoid genistein, the cells become glyceollin-resistant and resume growth. Yet the situation in soybean nodules 30 days PI is much different than growth in culture. Bacterial division in the determinant nodules formed by *B. japonicum* and soybean has either declined or ceased at 30 days PI. Furthermore, nodule bacteroids exist in an oxygen-limited environment. The effect of glyceollin on *B. japonicum* cells under these conditions is unknown. In addition, other putative plant defense responses are activated in nodules coincident with the accumulation of glyceollin. Such responses include, among others, accumulation of chitinase, β-glucanase, and enzymes of oxygen radical metabolism (unpublished results of this laboratory). These responses may act in concert with glyceollin to cause the decrease in bacteroid viability and decline in nitrogen fixation capacity.

Maximum levels of nitrogen fixation in nodules formed by *B. japonicum* and its economic host, soybean, are clearly transient in nature (Figure 1A) (Karr et al., 1984; Emerich et al., 1979). This observed decline in nitrogen fixation capacity has two important consequences for soybean production. First, biological nitrogen fixation is declining during a period when the plant has a high demand for protein for the production of seeds. Second, since that demand can be met only by removing protein from plant vegetative tissues (Wittenbach, 1983; Craft-Bradner et al., 1984), the value of soybeans as a nitrogen-rich rotation crop is diminished. It is clear that both soybean production efficiency and the utility of soybeans as a rotation crop would benefit if maximum levels of nitrogen fixation activity could be maintained through the period of pod fill.

It is not yet clear that glyceollin-induced growth inhibition alone or glyceollin acting in concert with other putative defense responses is responsible for the decrease in bacteroid viability. It is possible that glyceollin accumulation results from some other, as yet undetected event, which also results in bacteroid death. Whatever the case, it appears likely that an understanding of the unique delayed elicitation response in soybean nodules will permit development of bacterial strains which retain higher levels of nitrogen fixation throughout the lifetime of the plant.

Acknowledgments—We thank M.C. Huber for supplying unpublished electron micrographs of developing nodules and M. Mohammadi for providing unpublished data documenting putative defense system enzymes in soybean nodules. Support for this research was provided in part by the Missouri Soybean Merchandising Council. This is contribution No. 11,550 of the Agricultural Experiment Station of the University of Missouri.

(Received January 7, 1992; accepted February 18, 1992)

Abstract—Trypsin and chymotrypsin inhibitors are proteins that are developmentally regulated in foliage of cabbage plants, appearing at high concentrations in young foliage on mature plants. This temporal and spacial regulation of foliar proteinase inhibitors is synchronized with the appearance and distribution of foliar feeding Lepidoptera. When insects were allowed to select their feeding sites, larval *Pieris rapae* fed on the young foliage of cabbage plants, while larval *Trichoplusia ni* fed on the mature foliage on cabbage plants. Larval *P. rapae* that fed on mature plants were significantly smaller than larvae feeding on young plants, while there was no significant difference between larval *T. ni* feeding on mature plants and those feeding on young plants. Thus, there was a significant inverse correlation between the level of proteinase inhibitory activity in cabbage foliage and larval growth. When *P. rapae* and *T. ni* were provided with an artificial diet containing total protein (including significant levels of proteinase inhibitors) that was extracted from cabbage foliage, there was a significant reduction in growth and development of both species of Lepidoptera.

Key Words—*Pieris rapae, Artogeia rapae, Trichoplusia ni*, Lepidoptera, Noctuidae, Pieridae, trypsin inhibitors, chymotrypsin inhibitors, serine proteinase inhibitors, cabbage, Cruciferae.

INTRODUCTION

Proteinase inhibitors are polypeptides or proteins that commonly occur in plants (Whitaker, 1981). These naturally occurring compounds act *in vitro* as com-

*To whom correspondence should be addressed.

petitive inhibitors of proteinases by binding tightly to the active site of the enzyme, thus preventing the proteinase from binding to and cleaving the peptide bonds of proteins (Laskowski and Kato, 1980). The role of proteinase inhibitors in plants has not been clearly established, but extensive evidence suggests that they have the potential to act as defensive agents against herbivores (Ryan, 1989). One of the most common and widely studied group of plant proteinase inhibitors inhibits the serine proteinases (e.g., trypsin and chymotrypsin). This group of inhibitors is of particular interest because serine proteinases are commonly found in animals and microorganisms, but they are rarely detected in plants (Ryan and Walker-Simmons, 1981). This suggests that the serine proteinase inhibitors have little or no regulatory function in the plant but may significantly inhibit the primary proteinases in herbivores and pathogens, thus acting as a defensive agent against these pests.

Insect digestive enzymes can be inhibited *in vitro* by plant proteinase inhibitors (Broadway, 1989a; Broadway and Duffey, 1986; Christeller and Shaw, 1989; Gatehouse et al., 1985; Hines et al., 1991). In addition, the growth of herbivorous insects can be significantly reduced by the chronic ingestion of artificial diet supplemented with plant proteinase inhibitors (Birk and Applebaum, 1960; Broadway and Duffey, 1986; Shukle and Murdock, 1983; Steffens et al., 1978). However, proteinase inhibitors can protect plants against herbivores only if the inhibitors are present at the site of attack at effective concentrations.

Very few studies have examined the phenology, *in situ* concentration, and regulation of plant proteinase inhibitors. The most complete study focuses on the serine proteinase inhibitors in solanaceous plants (Pearce et al., 1991; Ryan, 1978). These inhibitors are environmentally regulated in the foliage of cultivated tomato and potato. Mechanical or natural wounding of a single leaf results in the systemic induction of proteinase inhibitors in the foliage of the plant (Broadway et al., 1986; Green and Ryan, 1972). Thus, active proteinase inhibitors are present at maximal levels in the foliage on the plant within hours after herbivory begins. Tomato or tobacco foliage containing high levels of these inhibitors will significantly inhibit the growth of herbivorous Lepidoptera (Broadway et al., 1986; Johnson et al., 1989).

In contrast, some proteinase inhibitors are developmentally regulated, as exemplified by cabbage (Broadway and Missurelli, 1990). Low (background) levels of trypsin inhibitory activity are present in foliage on the young cabbage plant. As the plant matures, trypsin inhibitory activity significantly increases in young and mature foliage but does not significantly increase in senescing foliage. When the plant develops a firm cabbage head, the foliar trypsin inhibitory activity reaches a plateau. At this time the trypsin inhibitory activity is significantly highest in the young foliage (i.e., cabbage head and surrounding cupped leaves), at intermediate levels in the mature foliage (i.e., fully expanded leaves not

touching head), and present at background levels in senescing leaves (Broadway and Missurelli, 1990).

The major lepidopterous pests on cabbage in New York are diamondback moth [*Plutella xylostella* (L.)], imported cabbageworm [*Pieris rapae* (L.)], and cabbage looper [*Trichoplusia ni* (Hübner)] (Andaloro et al., 1982, 1983). Larval *Trichoplusia ni* and *Pieris rapae* primarily secrete trypsin-like and chymotrypsin-like enzymes for the digestion of protein (Broadway, 1989a). In addition, the phenology of trypsin inhibitors in cabbage foliage (Broadway and Missurelli, 1990) is synchronized with the appearance of herbivorous Lepidoptera in cabbage fields (Hoy and Shelton, 1987). This information suggests that the serine proteinase inhibitors in cabbage foliage may function, at least in part, as phytochemical protection against herbivorous Lepidoptera. The following study examines the biological activity of cabbage proteinase inhibitors *in situ* against the growth of larval *Pieris rapae* (L.) (Lepidoptera: Pieridae) and *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae).

METHODS AND MATERIALS

Insects

Eggs from *Trichoplusia ni* were provided by Dr. W.L. Roelofs (NYS Agricultural Experiment Station, Geneva, NY) from a colony that was maintained on a pinto bean-based diet as previously described (Broadway, 1989a). The colony of *Pieris rapae* was established in 1987 with field-collected pupae, and the population was supplemented, annually, by 25–50% with field-collected individuals. Larval *P. rapae* were maintained on a high wheat germ-based meridic diet as previously described (Broadway, 1989a).

Plants

Seeds for the cabbage cultivar Superpack were from Johnny's Selected Seeds (Albion, ME). The seeds were germinated in Cornell Mix (Boodley and Sheldrake, 1977) in 7.5-L plastic pots. The seedlings were thinned to one plant per pot and maintained in a greenhouse under 1-kW metal halide lamps (12L : 12D) at 28°C. The plants were watered daily and fertilized once a week with a water-soluble nutrient mix (16–32–16).

Whole-Plant Bioassays

Two types of whole-plant feeding studies were tested. Type 1 was designed to allow larvae to move about freely on the entire plant, while the Type 2 bioassay confined larvae to a specific leaf on the plant by containing the larvae in a 5-cm-diameter leaf clip cage that was clamped over the leaf and moved

when the foliar tissue inside the cage was consumed. Each type of bioassay used three young (i.e., 10–12 true leaves) and three mature (i.e., 9–11 frame leaves and a 7-cm-diameter cabbage head) plants. In addition, each set of experiments included a control plant (without larvae) that was placed in the same environmental conditions as the treated plants. Foliage on all plants was chemically analyzed at the end of the experiment.

Type 1 experiments employed 40 *T. ni* eggs or 100 *P. rapae* eggs that were placed on each of three young plants per insect species and 70 *T. ni* or 200 *P. rapae* eggs that were placed on each of three mature plants per insect species. (The number of *P. rapae* eggs that was placed on each plant was greater than that for *T. ni.* because there was a greater loss of larval *P. rapae* during experiments.) Each plant was individually caged (to prevent insect migration to other plants) in the greenhouse maintained at 27°C, 12L : 12D. The entire experiment was terminated when a single type of foliage (e.g., the young leaves on a young plant) was almost completely consumed (leaving enough tissue for chemical analyses). All larvae were weighed, and plants were chemically analyzed for trypsin inhibitory activity, chymotrypsin inhibitory activity, total protein, and total glucosinolates. Glucosinolates were measured because they have been implicated as a phytochemical factor that protects crucifers against generalist herbivores and competing plants (Blau et al., 1978; Erickson and Feeny, 1974; Feeny, 1977; Oleszek, 1987).

Type 2 experiments also consisted of three young plants and three mature plants per insect species. Fifty eggs of *P. rapae* or 30 eggs of *T. ni* that were placed inside each small cage (with a recovery of 10–20 first-instar larvae), and as the larvae grew, the group of insects was separated into cages containing three to five larvae. A cage was placed on an expanding leaf (i.e., leaf 3–5, based on the designation of leaf 1 as the youngest expanding leaf and each successive number indicating the next oldest leaf on the plant) on each young plant. For each mature plant, one cage was placed on a young expanding leaf (i.e., leaf 2–4) and one cage was placed on a mature leaf (i.e., leaf 8–10). The entire experiment was terminated when a single type of foliage (e.g., the young leaf tissue on a young plant) was almost completely consumed (leaving enough tissue for chemical analyses). All larvae were weighed, and plants were chemically analyzed for trypsin inhibitory activity, chymotrypsin inhibitory activity, total protein, and total glucosinolates.

Total Plant Protein Bioassay

Total protein was isolated from three types of cabbage foliage: (1) young leaves (i.e., leaf 1–4) from mature plants (i.e., 9–11 frame leaves and a 7-cm-diameter cabbage head), (2) mature leaves (i.e., leaf 8–10) from mature plants, or (3) all leaves from young plants (i.e., total of 8–10 true leaves). Cabbage

foliage (700 g) was homogenized in 500 ml 0.01 *M* sodium citrate, 1 *M* potassium chloride, pH 4.5, buffer (the pH of the leaf fluid). Homogenate was pressed through two layers of cheesecloth, and the liquid was collected, on ice. The leaf tissue was homogenized a second time in 500 ml of buffer, then pressed through the cheesecloth, and the collected liquid was pooled with the first set. The liquid was centrifuged at 4200*g* for 15 min at 4°C. The supernatant was collected, and ammonium sulfate was added to 70% saturation. The mixture was stored overnight at 4°C, then centrifuged at 4200*g* for 15 min at 4°C. The pellet was resuspended in a small volume of distilled water, then dialyzed (12,000–14,000 MWCO) against ice-cold dH_2O for 72 hr. The dialysate was centrifuged at 4200*g* for 15 min at 4°C, then the supernatant was lyophilized. Total recoveries from the young foliage on young plants, young foliage on mature plants, and mature foliage on mature plants were 610, 650, and 710 mg, respectively. The lyophilized powder was chemically analyzed for trypsin inhibitory activity, chymotrypsin inhibitory activity, and total protein. Six hundred milligrams of each protein isolate was used to prepare 600 ml of artificial diet for the determination of the effect of total foliar protein on larval growth and development. The diet used for these tests was the same wheat germ-based diet used for mass rearing of larval *P. rapae*, except that the concentration of casein was reduced from 3.2 to 1.6% (w/v). The bioassays for both species of insect included four treatments, 3 cups/treatment, 30 eggs/cup. Each bioassay was replicated three times. Larvae were provided with diet ad libitum, from neonate until the controls reached the ultimate instar. Then all larvae were weighed.

Chemical Analyses

A standard spectrophotometric assay was used to determine the presence of trypsin inhibitory activity in the cabbage foliage (Walsh, 1970). Leaf juice was expressed from the cabbage foliage, then centrifuged, and the supernatant was diluted to 0.1× with 1 m*M* HCl. The diluted supernatant was mixed 1:1 (v/v) with bovine trypsin (0.1 mg/ml 1 m*M* HCl) and incubated at room temperature for 10 min. Then 100 μl of the mixture was added to 2.9 ml of buffer (0.05 *M* Tris, pH 8.0) containing 1.04 *M* *p*-toluene-sulfonyl-L-arginine methyl ester (TAME) (Sigma). Trypsin activity was monitored at 247 nm for 3 min (UV160U, Shimadzu Scientific). A 50-μl aliquot of trypsin was used to determine uninhibited trypsin activity. Each assay was performed in triplicate.

Chymotrytic inhibitory activity was determined by mixing (1:1, v/v) the diluted leaf juice (prepared as above) with TLCK-treated bovine chymotrypsin (0.1 mg/ml 1 m*M* HCl) for 10 min at room temperature. Then 100 μl of the mixture was added to 2.9 ml substrate (1 m*M* benzoyl-L-tyrosine ethyl ester in 50% MeOH, mixed 1:1 with 0.05 *M* Tris, pH 8.0), and monitored at 256 nm for 3 min (Walsh and Wilcox, 1970). A 50-μl aliquot of chymotrypsin was used

to determine uninhibited chymotrypsin activity. Each assay was performed in triplicate.

To quantify total glucosinolates in cabbage foliage (Heaney and Fenwick, 1981), leaves were ground with a mortar and pestle, and the leaf fluid was collected by centrifugation. A 500-μl aliquot of the supernatant was applied to a 1-ml DEAE-Sephadex A25 column. The column was washed with distilled water, then washed two times with 0.5 ml 0.02 *M* pyridine/acetic acid buffer. Myrosinase, extracted from white mustard meal (Heaney and Fenwick, 1981), was applied, at a concentration of 250 μl of 25 mg/ml pyridine–acetic acid buffer, to the column and allowed to incubate at room temperature for 2 hr. The column was then eluted with distilled water, collecting 1.25 ml of eluant. Three 250-μl aliquots of the eluant were assayed for glucose (Kit 115, Sigma Chemical Co, St. Louis, MO). The standard sinigrin (Nutritional Biochemicals Corp., Cleveland, OH) was also assayed in triplicate.

Total protein concentration was estimated, in triplicate, using bicinchoninic acid (BCA) reagent (Smith et al., 1985) (Pierce Chemical Co.). Purified protein from cabbage foliage was used as the standard.

Statistics

The significant differences ($P < 0.05$) between treatments were determined by analysis of variance (ANOVA) followed by orthogonal comparisons (with P adjusted by the Bonferroni procedure), multiple-range tests, or correlation determinations, using the statistical computer package Systat (Systat Inc., Evanston, IL).

RESULTS

Whole-Plant Bioassay

Larvae that hatched on plants in the large cages were allowed to select their feeding sites. Larval *T. ni* fed on the underside of the oldest leaves of both the young and the mature plants, although they did move up the plant to the fully expanded mature leaves as the oldest leaf tissue was consumed. There was no significant difference in larval weight when comparing *T. ni* feeding on the oldest leaves on young plants with larval *T. ni* feeding on the oldest leaves on mature plants ($P = 0.460$, $n = 220$) (Figure 1). Chemical analyses of the leaf tissue indicated that there was no significant difference in the trypsin inhibitory activity ($P = 0.383$, $n = 35$), chymotrypsin inhibitory activity ($P = 0.389$, $n = 35$), total protein ($P = 0.563$, $n = 35$), or total glucosinolate ($P > 0.05$, $n = 35$) in the oldest foliage from the young and mature plants (Table 1).

Free-roaming larval *P. rapae* fed on the youngest tissue on the plant. They

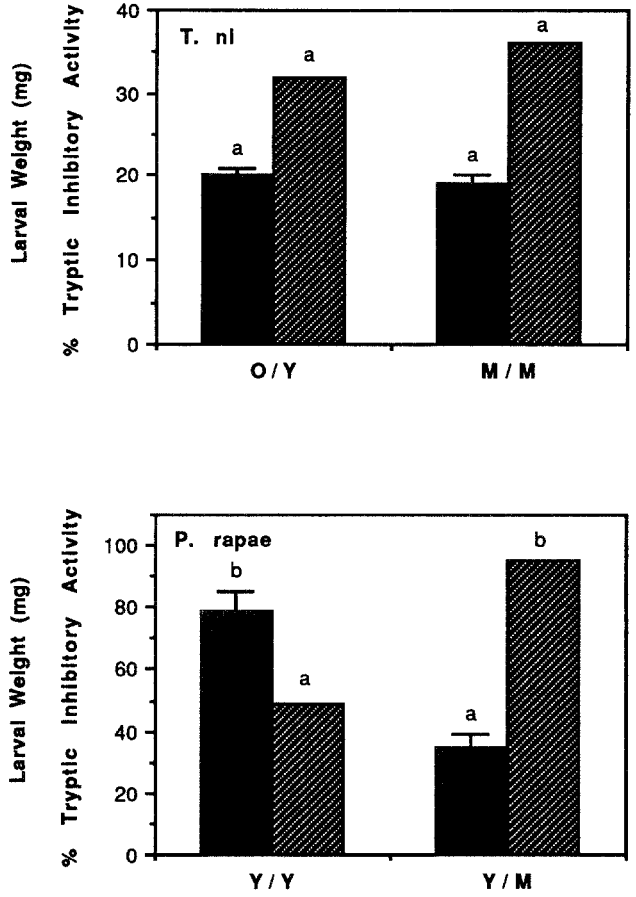

FIG. 1. The relationship between *in situ* trypsin inhibitory activity and growth of larvae allowed to select their feeding site. Inhibitory activity is reported as percentage inhibition of 5 μg trypsin by a 0.05× dilution of leaf fluid. Y/Y indicates young foliage on young plants, O/Y indicates the oldest foliage on young plants, Y/M indicates young foliage on mature plants, and M/M indicates mature foliage on mature plants. Black bars indicate larval weight; hatched bars indicate percentage trypsin inhibitory activity in cabbage foliage consumed by the larvae. Vertical lines indicate standard error of the mean; bars labeled with the same letter are not significantly different at $P < 0.05$.

consumed the apical meristem, then moved down, feeding on the nonvascular tissue at the base of the youngest leaves. They generally did not feed on the fully expanded or oldest leaves of either the young or mature plant. *P. rapae* that fed on the youngest foliage on mature plants were significantly smaller than larvae that fed on the youngest foliage on young plants ($P < 0.001$, $n = 87$)

[e] Site of larval herbivory.

(Figure 1). A comparison of the chemical composition of the young foliage from these two ages of plants indicated that the trypsin and chymotrypsin inhibitory activity in the young foliage on the mature plant was significantly higher than in the young foliage on the young plant ($P < 0.001$, $n = 35$, for both trypsin

and chymotrypsin) (Table 1). Since larval *P. rapae* selectively fed at the base of the young leaves, the trypsin and chymotrypsin inhibitory activities were measured for three sections of the leaf (apex, middle, and base). The results indicate that the trypsin and chymotrypsin inhibitory activities are uniformly distributed within a leaf (Table 2).

Larval *T. ni* that were confined to the oldest leaves on mature plant were significantly larger than larvae feeding on the young leaves on the young plant ($P < 0.001$, $n = 45$) (Figure 2). The larvae restricted to feeding on the young leaves on the mature plant attempted to feed (as indicated by feeding pits on the surface of the leaf), but there was 100% mortality of the larvae in the second instar. Chemical analyses of the plant foliage indicated that there was a significant inverse correlation between larval growth and the level of trypsin or chymotrypsin inhibitory activity (for trypsin inhibitory activity $y = 104.07 - 1.226x$, $r^2 = 0.777$; for chymotrypsin inhibitory activity $y = 153.3 - 4.067$, $r^2 = 0.875$) (Table 1); the trypsin and chymotrypsin inhibitory activities were significantly highest in the young leaves on the mature plant ($P < 0.001$, $n = 35$), at an intermediate level in the young leaves on the young plant ($P < 0.001$, $n = 35$), and at the significantly lowest level in the old leaves on the mature plant ($P < 0.001$, $n = 35$). There was no significant correlation between larval growth and total foliar protein or glucosinolate (for total protein $y = 134.7 - 0.144x$, $r^2 = 0.114$; for total glucosinolate $y = -66.44 + 1.037x$, $r^2 = 0.633$). When larval *P. rapae* were confined to a specific feeding site inside a small cage (Figure 2), their survival was very low on the mature plant (1–6 larvae/treatment). Therefore, although larval growth is not statistically different for larvae feeding on the three types of leaf tissue ($P = 0.348$, $n = 40$), the reliability of the data is questionable.

Total Plant Protein Bioassay

An alternative bioassay, using an artificial diet containing total protein isolated from cabbage foliage, was evaluated, because larval *T. ni* did not feed on foliage with high levels of proteinase inhibitor, and when confined to a single

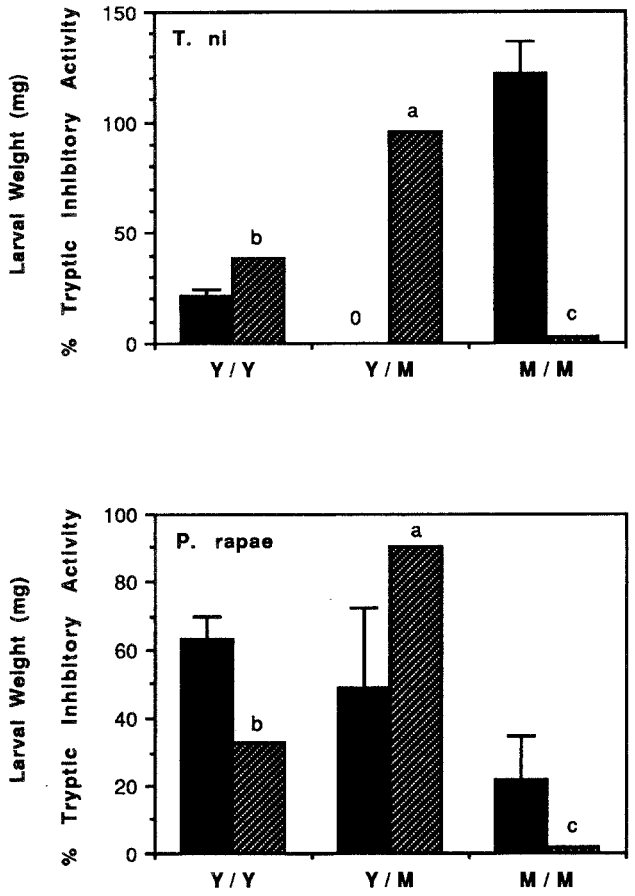

FIG. 2. The relationship between *in situ* trypsin inhibitory activity and growth of larvae confined to a specific feeding site. Inhibitory activity is reported as percentage inhibition of 5 μg trypsin by a 0.05× dilution of leaf fluid. Y/Y indicates young foliage on young plants, Y/M indicates the young foliage on mature plants, and M/M indicates mature foliage on mature plants. Black bars indicate larval weight; hatched bars indicate percentage trypsin inhibitory activity in cabbage foliage consumed by the larvae. Vertical lines indicate standard error of the mean; bars labeled with the same letter are not significantly different at $P < 0.05$.

leaf on a plant, the caged larvae of both species showed poor survival. Chemical analyses of the total protein isolates from the three ages of cabbage leaf indicated that the proteinase inhibitory activity was significantly different in the three isolates (Figure 3). Growth and development of *T. ni* were significantly reduced by dietary amendment with total protein that was extracted from young foliage

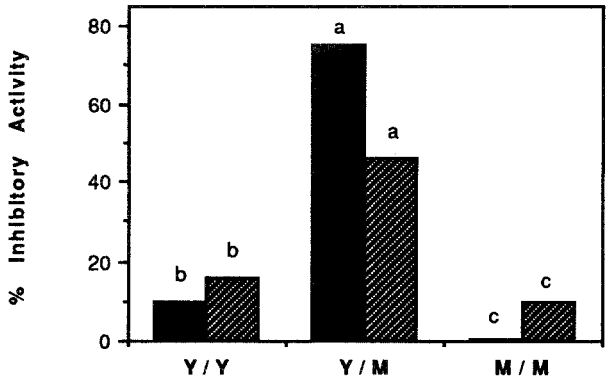

FIG. 3. The level of trypsin and chymotrypsin inhibitory activity in the total protein extracts from cabbage foliage. Inhibitory activity is reported as percentage inhibition of 5 μg trypsin or chymotrypsin by a 0.05× dilution of leaf fluid. Black bars indicate trypsin inhibitory activity; hatched bars indicate chymotrypsin inhibitory activity. Bars labeled with the same letter are not significantly different at $P < 0.05$. Y/Y indicates young foliage on young plants, Y/M indicates young foliage on mature plants, and M/M indicates mature foliage on mature plants.

on mature plants ($P = 0.001$, $n = 915$) (Figure 4). The growth and development of *P. rapae* were significantly reduced by ingestion of protein extract from young foliage on young plants or young foliage on mature plants ($P < 0.001$, $n = 362$) (Fig. 5). In addition, there was a significant inverse correlation between dietary proteinase inhibitory activity and the growth of larval *P. rapae* (for trypsin inhibitory activity $r^2 = 0.919$, $b = -1.02$, $P < 0.001$; for chymotrypsin inhibitory activity $r^2 = 0.939$, $b = -2.16$, $P < 0.001$).

DISCUSSION

Identification of natural phytochemical resistance factors that are effective against specific herbivorous insects requires examination of both the phytochemical producer and the target insects. The present study focused on cabbage and its lepidopterous pests. Cabbage foliage contains proteinaceous inhibitors of trypsin and chymotrypsin (Broadway, 1989b) that have the potential to inhibit the primary proteases in the digestive system of larval *T. ni* and *P. rapae* (Broadway, 1989a), two economically important pests of cabbage (Andaloro et al., 1982). These proteinase inhibitors are not induced in cabbage foliage by mechanical or natural wounding of the tissue (Broadway and Missurelli, 1990). Trypsin inhibitory activity is developmentally regulated in cabbage foliage, appearing at the highest concentration in young foliage on mature plants (Broad-

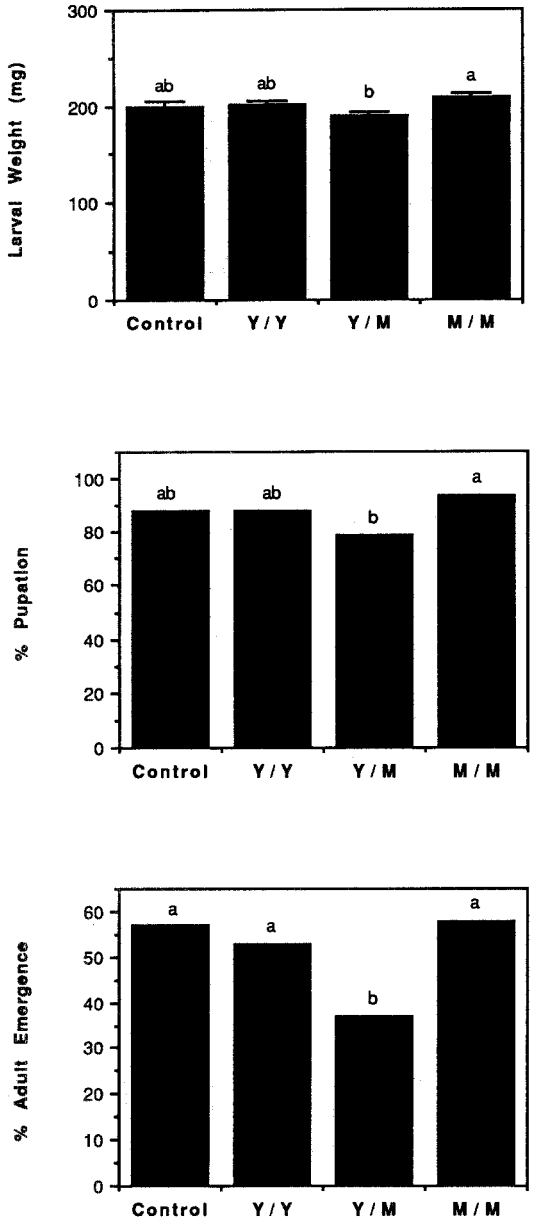

FIG. 4. Growth and development of *T. ni* feeding on artificial diet supplemented with total protein extracted from cabbage foliage. way and Missurelli, 1990). The phenology of trypsin inhibitory activity in cabbage foliage is synchronized with the appearance of herbivorous Lepidoptera in cabbage fields. *P. rapae* appears in the field when the cabbage plants reach the six- to eight-leaf stage (Hoy and Shelton, 1987), which is the developmental stage when the level of foliar trypsin inhibitory activity begins to rise. *T. ni* normally appears in the field when the plant reaches the 9- to 12-leaf stage (Andaloro et al., 1982, 1983), which is the developmental stage when the plant is approaching maximum trypsin inhibitory activity. Thus, trypsin inhibitory activity is present in cabbage foliage at the time of invasion by lepidopteran insects and increases as the insect populations increase. Do these proteinase inhibitors function as protective agents *in situ* against lepidopterous pests of cabbage?

The present study indicated that there was a significant inverse correlation between the level of foliar proteinase inhibitory activity and the growth of larval *T. ni* and *P. rapae* and that cabbage proteinase inhibitors may have the potential to inhibit significantly the growth and development of *P. rapae* in the field.

The first criterion for evaluating the potential of a phytochemical to act as a resistance factor is to show that the chemical is present at the site of herbivory. When comparing herbivory of larval *T. ni* and *P. rapae*, the preferred feeding sites were quite different. Larval *T. ni* fed on the underside of the oldest leaves on the cabbage plant, while larval *P. rapae* selected the youngest foliage on the plant. These two different types of foliage contained significantly different levels of trypsin and chymotrypsin inhibitory activity (Table 1). Mature foliage contained little or no proteinase inhibitory activity. Young foliage on young plants contained background levels of proteinase inhibitory activity, while young foliage on mature plants contained significant levels of inhibitory activity. Thus, when larval *T. ni* fed on their preferred cabbage foliage, they did not consume significant levels of serine proteinase inhibitory activity. The results indicate that there was no significant difference in the growth of free-roaming larval *T. ni* feeding on young plants or mature plants (Figure 1). However, when larval *P. rapae* fed on their preferred cabbage foliage, they did consume high levels of proteinase inhibitory activity when feeding on mature plants. Young foliage on mature cabbage plants had two to three times the level of proteinase inhibitory activity as that found in the foliage on young cabbage plants (Table 1). Larval *P. rapae* feeding on young foliage on mature plants were 56% smaller than larvae feeding on the young foliage on young cabbage plants (Figure 1). Thus, under natural conditions, larval *P. rapae* would consume cabbage proteinase inhibitors, while larval *T. ni* would not. Therefore, the proteinase inhibitors *in planta* would not influence the growth of *T. ni*.

However, under artificial conditions, the cabbage proteinase inhibitor mixture did influence the growth of *T. ni*. Growth and development of both *T. ni* and *P. rapae* were significantly reduced when these insects were provided with

an artificial diet that contained a biologically realistic concentration of cabbage proteinase inhibitors (in addition to all other proteins that were extractable from the cabbage foliage at pH 4.5) (Figures 3–5).

These findings are in agreement with the results reported for the wound-inducible proteinase inhibitors in tomato foliage (Broadway et al., 1986; Johnson et al., 1989); there is a significant inverse correlation between the concentration of foliar proteinase inhibitors and the growth of larval Lepidoptera. However, these studies are correlational; there is no indication of causation. Future research will focus on the biological efficacy and mechanism of action of purified cabbage proteinase inhibitors against herbivorous Lepidoptera.

(Received October 17, 1991; accepted February 19, 1992)

Abstract—The known compounds friedelin, maytensifolin B, ginkgetin, bilobetin, and amentoflavone as well as the new triterpene 3β-hydroxyfriedelan-16-one were isolated from *Celaenodendron mexicanum* (Euphorbiaceae), an endemic tree of the Pacific Ocean coast of Mexico. The compounds' structures were established on the basis of spectral analysis. The biological effects of aqueous leachates, a $CHCl_3$–MeOH extract and the isolated compounds of leaves and twigs were evaluated on the radicle growth of two plants, *Amaranthus leucocarpus* and *Echinochloa crusgalli*, and on the radial growth of three phytopathogenic fungi, *Fusarium* sp., *Helminthosporium* sp., and *Alternaria* sp. The organic extracts of both leaves and twigs inhibited *Amaranthus* and stimulated *Echinochloa* radicle growth. On the contrary, friedelin and maytensifolin B stimulated *Amaranthus* and inhibited *Echinochloa*. The target fungi showed a different response to each treatment, from inhibition to stimulation.

Key Words—Biological effects, *Celaenodendron mexicanum*, Euphorbiaceae, friedelin, maytensifolin B, ginkgetin, bilobetin, amentoflavone, 3β-hydroxyfriedelan-16-one, *Amaranthus leucocarpus*, *Echinochloa crusgalli*, *Alternaria* sp., *Fusarium* sp., *Helminthosporium* sp., phytopathogenic fungi.

INTRODUCTION

Euphorbiaceae is a heterogeneous and vast family, particularly in the warmer parts of the world. Many Euphorbiaceae species produce bioactive compounds that have some medicinal uses (*Euphorbia lathytris*, *E. ipecacuanhae*, *Ricinus communis*, *Jatropha* spp., *Manihot utilissima*, *inter alia*).

Furthermore, several species including *Euphorbia corollata*, *E. esula*, *E. supina*, *Croton pyramidalis*, and *C. bonplandianum* have been implicated in allelopathy (Rice, 1984; Anaya et al., 1987).

Celaenodendron mexicanum Standl. is an endemic tree of México which grows in the tropical caducifolia forests in the Pacific Coast (Ferris, 1927). It has a discontinuous distribution and, as distinguished from other trees of this type of forest, *C. mexicanum* keeps its leaves during almost all the dry season and forms dense monospecific stands, with a very sparse understory vegetation, whereas the understory is dense under other species of trees. Furthermore, the leaves of *C. mexicanum* decompose at a very low rate, resulting in a dense mat of dead leaves accumulating on the ground (Filip et al., 1992).

This tree is commonly known as "palo prieto," and it is used as an antiseptic medicinal plant. It is suggested that *C. mexicanum* possess some bioactive compounds that could be ecologically important.

As a part of a project dedicated to search for distinctive natural products in endemic Mexican species, we initiated a study to evaluate the biological activity of secondary metabolites produced by *C. mexicanum* and to identify the more active compounds.

METHODS AND MATERIALS

General Bioassay Procedures

Leaves and twigs from the tree and dead leaves on the soil surface were collected in January 1990. Samples were taken on the route to Barra de Navidad-Puerto Vallarta (km 15), near the Biological Station of UNAM in Chamela, Jalisco State.

Air-dried leaves, twigs, and dead leaves were soaked for 4 hr in distilled water (1 g/100 ml). The leachates were filtered, and the osmotic pressure was measured in a freezing-point osmometer in order to avoid the effects of this factor on germination and growth (Anaya and Rovalo, 1976). The bioassays were performed in petri dishes. Each leachate was mixed (1/1) with 1.5% agar. Distilled water mixed with agar was used as the control. Bioassays were performed with seeds of *Amaranthus leucocarpus* (Amaranthaceae) and *Echinochloa crussgalli* (Gramineae). A completely randomized block design with four repetitions for each target species was used. Ten seeds were sown in each petri

dish. Petri dishes were kept at 27°C in the dark. The radicle length was measured after 24 hr for *Amaranthus* and 48 hr for *Echinochloa*. The data were analyzed by ANOVA ($P < 0.05$).

The effects of a $CHCl_3$–MeOH extract of dry leaves and twigs, and the isolated compounds **(1–6)** also were determinated. In these bioassays, the materials were dissolved at 100 ppm in DMF (dimethylformamide) and then poured on a filter paper disk in petri dishes. After evaporation of the solvent, distilled water was added and the bioassays were carried out under the same general conditions.

Bioassays with Phytopathogenic Fungi

The target species chosen were *Alternaria* sp., *Fusarium* sp., and *Helminthosporium* sp. The bioassays were carried out by incubating a fungal bud in a PDA (potato–dextrose–agar) sterile cultivation medium, to which the aqueous leachates of leaves (1%), the organic extract of leaves and twigs (100 ppm), or pure compounds (100 ppm) were added. Buds 5 mm in diameter were obtained from pure 8-day-old fungal culture. The sown fungi were inoculated in darkness at 27°C. A randomized complete block design with three replications was utilized. The effect of compounds was determined by measuring the radial growth of the mycelium, for which two perpendicular measurements of the colony's diameter were taken and the mean value was obtained. The measurements were made at 3 and 8 days. The mean values of replications were analyzed by ANOVA ($P < 0.05$).

Chemistry

[^{1}H]- and [^{13}C]NMR spectra were performed in $CDCl_3$ or DMSO-d_6 on a Varian VXR-300S spectrometer. Chemical shifts expressed as δ units are reported as parts per million downfield from the internal standard TMS ($\delta = 0$). Mass spectra were determined on a Hewlett-Packard 5985 B spectrometer. IR spectra were obtained in KBr on a Perkin Elmer 599B spectrophotometer. UV spectra were taken on a Beckman DU-7 apparatus. Optical rotations were measured with a Jasco DIP 360 digital polarimeter.

Commercial Merck silica gel 60 (70- to 230-mesh) ASTM was used for column chromatography. Analytical TLC was carried out using precoated silica gel Merck 60F 254 plates. The chromatograms were sprayed with 0.1% $CeSO_4$–2 *N* H_2SO_4 and heated to detect the spots.

Extraction and Preliminary Fractionation

Air-dried and ground leaves of *Celaenodendrum mexicanum* (2.6 kg) were macerated four times at room temperature with 60 L of a mixture of $CHCl_3$–MeOH (1 : 1). The extracts were evaporated at reduced pressure to yield 210 g

of a residue that was column chromatographed on 1.3 kg of silica gel. Elution was accomplished with a solvent gradient of increasing polarity (hexane gradually enriched with $CHCl_3$, and $CHCl_3$ with increasing amounts of MeOH). Fractions of 500 ml were collected.

Isolation of Friedelin (1)

Fractions 119–131 of the original column, eluted with hexane–$CHCl_3$ (8:2), yielded 285 mg of friedelin, mp 245–246°C. The IR, MS, and NMR data were in agreement with those of an authentic sample and its spectral properties were identical to those described previously (Gunatilaka et al., 1983).

Isolation of Maytensifolin B (2) and 3β-Hydroxyfriedelan-16-one (3)

Preparative TLC of fractions 224–286 of the original column eluted with hexane–$CHCl_3$ (7:3), using $CHCl_3$–EtOAc (9:1) as the eluants, allowed the isolation of 103 mg of maytensifolin B **(2)** and 80 mg of 3β-hydroxyfriedelan-16-one **(3)**. The spectral properties of **2** were identical to those described previously (Nosaki et al., 1986). 3β-Hydroxyfriedelan-16-one **(3)**, mp 112–115°C, $[\alpha]_D$ + 10.9° (C 2, MeOH). IR (KBr): 3460, 2920, 2860, 1680, 1440, 1380, 1230, 1190 cm^{-1}. [^{1}H]NMR ($CDCl_3$): 0.84 (s, 3H), 0.88 (s, 3H), 0.92 (s, 3H), 0.96 (d, 3H), 1.04 (s, 3H), 1.17 (s, 3H), 1.25 (s, 3H), 1.28 (s, 3H), 1.3–2.4 (m), 3.74 (dd, J = 3 Hz, 1H). [^{13}C]NMR ($CDCl_3$): 219.3 (C-16), 72.5 (C-3), 61.0 (C-4), 52.3 (C-8), 50.07 (C-15), 49.03 (C-10), 45.2 (C-17), 43.8 (C-18), 41.3 (C-5), 40.3 (C-2), 39.1 (C-6), 37.8 (C-14), 37.2 (C-13), 35.3 (C-9), 35.2 (C-11), 35.08 (C-30), 31.5 (C-19), 31.04 (C-21), 30.7 (C-22), 29.6 (C-12), 29.14 (C-29), 27.5 (C-20), 27.3 (C-28), 20.1 (C-26), 17.89 (C-7), 17.6 (C-1), 16.3 (C-25), 16.1 (C-27), 15.8 (C-24), 11.6 (C-23). EIMS *m/z* (rel intensity): 440 (M^+, 20), 425 (M-15, 31), 355 (17), 275 (6), 219 (43), 124 (29).

Isolation of Ginkgetin (4), Bilobetin (5), and Amentoflavone (6)

Three grams of a yellow powder was precipitated from fractions 551–590 eluted with 95:5 $CHCl_3$–MeOH. Preparative TLC on silica gel (8:2 $CHCl_3$–MeOH) yielded 313 mg of ginkgetin **(4)**, 210 mg of bilobetin **(5)**, and 183 mg of amentoflavone **(6)**.

Ginkgetin **(4)**, mp 198–200°C; $[\alpha]_D$ + 31° (C 2, $CHCl_3$); IR (KBr): 3200, 1680, 1610, 1560, 1480, 1420, 1340, 1280, 1220, 1140, 800 cm^{-1}. UV (MeOH): λ_{max} = 271 nm. *Anal.* Calcd. for $C_{30}H_{18}O_{10}$: C, 66.91%; H, 3.44%. Found: C, 66.86%; H, 3.44%. The spectral and physical properties of compounds **4–6** were in good harmony with those described previously for bilobetin (Baker et al., 1963; Joly et al., 1980), ginkgetin (Baker et al., 1963; Garg and Mitra, 1971), and amentoflavone (Garg and Mitra, 1971; Horhammer

et al., 1965; Varshney et al., 1973; Chari et al., 1977). The [^{13}C]NMR data of compounds **4** and **5** have not been previously reported.

Oxidation of 3β-hydroxyfriedelan-16-one **(3).** To a solution of **3** (20 mg) in pyridine (1 ml) was added CrO_3 (24 mg) in pyridine (0.4 ml). The mixture was kept at room temperature for 18 hr, after which up to 7 mg of a pure compound, identical to the natural product **(2),** was obtained.

RESULTS AND DISCUSSION

Chemical Analysis

Ground air-dried leaves of *Celaenodendrom mexicanum* were extracted with $CHCl_3$–MeOH (1 : 1). The resulting extract was fractionated via column chromatography on silica gel, and extensive preparative TLC on silica gel of the primary fractions yielded friedelin **(1),** maytensifolin B **(2),** 3β-hydroxyfriedelan-16-one **(3),** ginkgetin **(4),** bilobetin **(5),** and amentoflavone **(6)** (Figure 1).

Compound **(3)** is a new naturally occurring substance. All the isolated compounds were identified by spectral means: in the case of **1,** by comparison of the spectral data with those described previously in the literature. Compound **3,** $C_{30}H_{50}O_2$, was obtained as a white crystalline solid. The NMR (Nozaki et al., 1986; Patra and Kumar, 1987; Kikuchi et al., 1973a,b) and mass spectra (Nozaki et al., 1986; Courtney and Shanon, 1963) data of **1** supported the assignment of a friedelane-type triterpenoid and showed strong similarities to those of maytensifolin B**(2)** (Nosaki et al., 1986). Comparative analysis clearly indicated that the keto group at C-3 in **2** was replaced by a hydroxyl moiety in **3.** Consistent with this proposal were the presence of a signal attributable to a secondary hydroxyl group in the NMR spectra of **3** (δ 72.5 in the [^{13}C]NMR and δ 3.74 in the [^{1}H]NMR) and the chemical conversion of **3** into a diketone identical to maytensifolin B **(2)** by treatment with CrO_3–pyridine. The diagnostically important peaks at *m/z* 355, 219, and 124 in the mass spectra of **3** (Nosaki et al., 1986) as well as the chemical shift value of C-4 (δ 61.0) and C-23 (δ 11.6) were in agreement with the placement of the ketone and hydroxyl groups at C-16 and C-3, respectively. The stereochemistry at C-3 was unequivocally ascertained from the chemical shift and the splitting pattern observed for the signal at 3.74 (dd, J = 3 Hz) in the [^{1}H]NMR of **3** (Kikuchi et al., 1973a,b).

Bioassays with Seeds

Aqueous leachates of dry leaves produced a significant stimulation of radicle growth of *Amaranthus* and *Echinochloa* (Table 1). In the case of the organic extract of leaves and twigs, a selective inhibitory effect on the growth of *Ama-*

ranthus was observed. On the other hand, these extracts induced a significant stimulation of radical growth in *Echinochloa*.

In general, the growth responses of *Amaranthus* and *Echinochloa* (with the isolated compounds **1–6**) were opposites (Figure 2). Two of the compounds,

TABLE 1. EFFECTS OF AQUEOUS LEACHATES AND CHLOROFORM–METHANOL EXTRACT OF THE LEAVES AND TWIGS OF *Celaenodendron* ON THE RADICLE GROWTH OF *Amaranthus* AND *Echinochloa*

Treatment	Amaranthus		Echinochloa	
	Radicle growth (mm)	% of inhibition (stimulation)	Radicle growth (mm)	% of inhibition (stimulation)
Aqueous leachates				
Control	9.25 + 0.65	0	12.45 + 3.45	0
Dry leaves	11.47 + 2.24	(24)*	15.42 + 0.38	(24)*
Dead leaves	9.07 + 0.04	2.2	13.92 + 1.35	(8)
Chloroform-methanol extract				
Control	16.0 + 1.46	0	18.55 + 2.77	0
Dry leaves	8.82 + 0.1	45*	20.05 + 3.43	(12.4)*

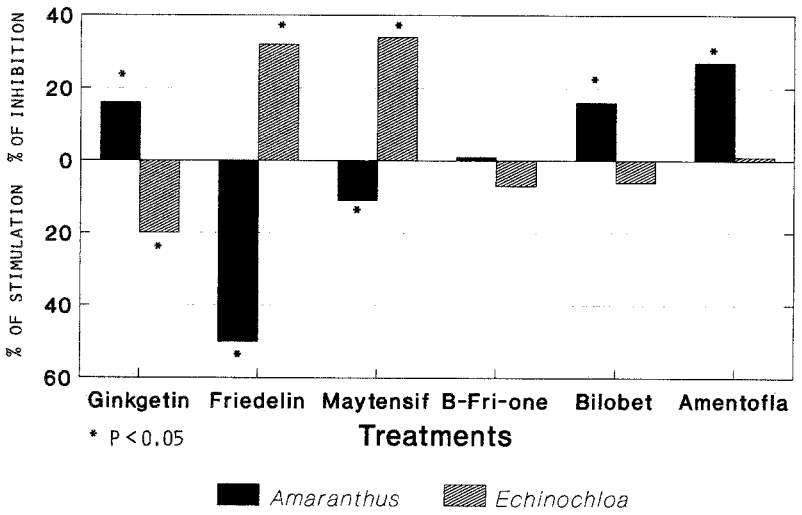

FIG. 2. Growth responses of *Amaranthus* and *Echinochloa*.

friedelin **(1)** and maytensifolin B **(2)**, produced a stimulatory effect on the radical growth of *Amaranthus*. However, they were the only compounds that significantly inhibited *Echinochloa*. The biflavonoids tested **(4–6)** inhibited the radical growth of *Amaranthus*; however, ginkgetin **(4)** significantly stimulated that of *Echinochloa*.

Bioassays with Phytopathogenic Fungi

Aqueous leachates produced only two significant effects on the target fungi (Table 2). Dry and dead leaves stimulated *Alternaria* and *Fusarium*, respectively, at 3 days of growth. Organic extracts of dead leaves stimulated *Alternaria* at 3 days of growth, but that of dry leaves significantly inhibited this species at 8 days. Organic extract of dry leaves significantly stimulated *Helminthosporium* at 3 and 8 days. On the other hand, a significant inhibitory effect of dead leaves on this species can be observed at three and eight days of growth.

The effects of compounds **3–6** on the fungi are shown in Figures 3 and 4. Ginkgetin had no effect on the three fungal species tested. 3β-Hydroxyfriedelan-16-one **(3)** produced a significant inhibition on *Alternaria* at 3 days, whereas *Fusarium* at 3 days and *Helminthosporium* at 8 days were significantly stimulated by this compound. Bilobetin **(5)** produced only a significant stimulation on *Alternaria* at 3 days. Finally, amentoflavone **(6)** significantly inhibited *Helminthosporium* at 3 and 8 days and stimulated *Alternaria* at 3 days. These results show that the target fungi had a clear difference in sensitivity and in response to each compound.

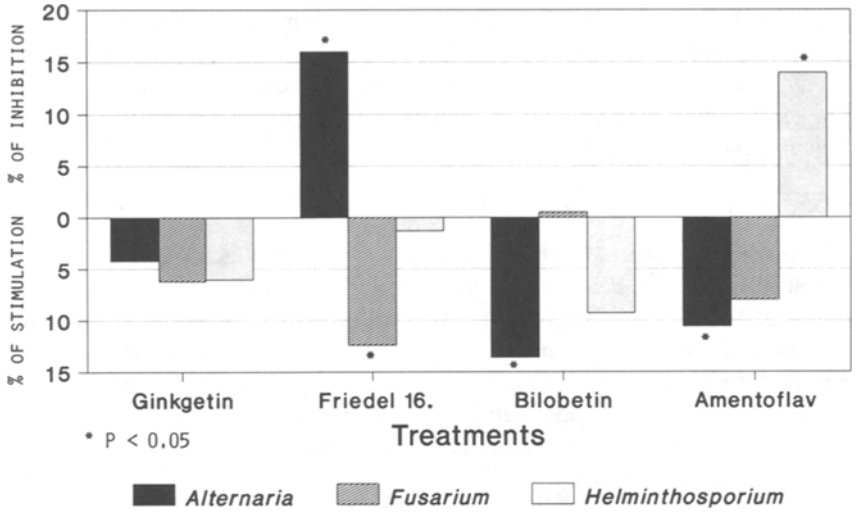

FIG. 3. Effects of compounds **3–6** on the fungi (3 days).

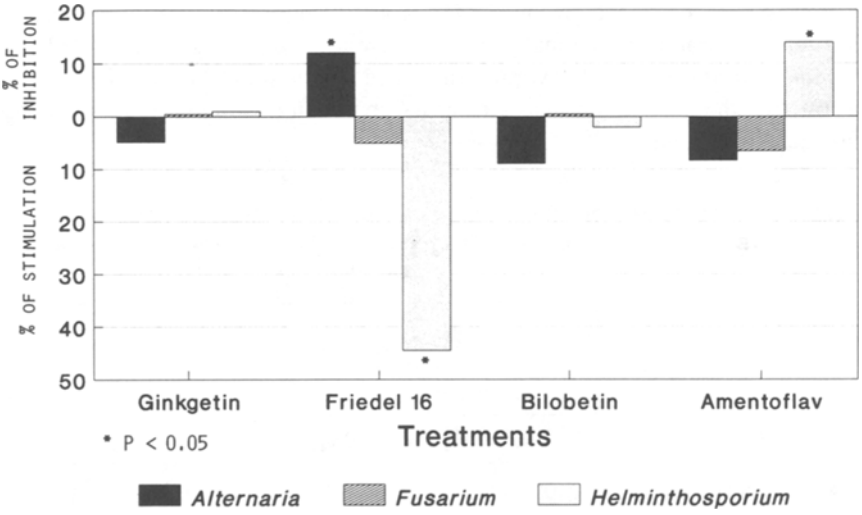

FIG. 4. Effects of compounds **3–6** on the fungi (8 days).

In relation to the two types of compounds identified in *Celaenodendron*, monoterpenes and sesquiterpenes are the terpenes more commonly involved in allelopathic effects on plants and microorganisms. (Rice and Pancholy, 1973; Del Amo and Anaya, 1978; González de la Parra et al., 1981; Robinson, 1983; Rice, 1984). Triterpenes have not been studied as allelopathic agents.

Flavonoids are compounds that have a wide range of biological activity. Some of these are implicated in allelopathy and antifeedant activities (Borner, 1959; Williams, 1960; Fottrell, 1964; Rice and Pancholy, 1974; Lodhi and Killingbeck, 1980; Corcuera et al., 1987; Moreland and Novitzky, 1987). As a result of the present study, it is possible to observe in general, that under *in vitro* conditions, biflavones inhibited *Amaranthus* and triterpenes inhibited *Echinochloa*.

In natural conditions, *Celaenodendron* cause a significant ecological effect on different organisms in the community. For example, the bearing of foliage almost year-round creates a constant light reduction by the tree that necessarily affects the growth of other species. In addition to the physical qualities of the microenvironment created by *Celaenodendron*, we hypothesize that the richness of this species in secondary compounds could contribute to this influence.

Acknowledgments—The authors thank the following people: Ms. Nora Martijena, for the collection of plant material and comments on field observations; QFB Graciela Chávez and Q Marisela Gutiérrez for recording the UV and IR spectra, Facultad de Química, UNAM; and MS Federico del Río from the NMR Laboratory and IQ Luis Velasco from the mass spectrometry Laboratory, Instituto de Química, UNAM.

This study was sponsored by Project D-111-903551 from Consejo Nacional de Ciencia y Tecnología (CONACyT) and by Project PADEP FQ 9126.

(Received August 3, 1991; accepted February 20, 1992)

Abstract—Recently completed studies from our laboratories have demonstrated that the characteristic human male axillary odors consist of C_6 to C_{11} normal, branched, and unsaturated aliphatic acids, with (*E*)-3-methyl-2-hexenoic acid being the most abundant. To investigate the mechanism by which the odor is formed, it is necessary to determine the nature of the odorless precursor(s) found in the apocrine secretion which is converted by the cutaneous microorganisms to the characteristic axillary odor. Pooled apocrine secretion was obtained from several male volunteers by intracutaneous injection of epinephrine. Partitioning this secretion into aqueous and organic soluble fractions was followed by hydrolysis of each fraction with NaOH or incubation with axillary microorganisms (cutaneous lipophilic corynebacterium). Analysis by gas chromatography/mass spectrometry (GC/MS) revealed the presence of (*E*)- and (*Z*)-3-methyl-2-hexenoic acid in the aqueous phase hydrolysate and aqueous phase incubated with bacteria; however, only a trace amount was seen in the resultant organic phase mixtures. These results

suggest that a water-soluble precursor(s) is converted by the axillary flora to the characteristic axillary odors.

Key Words—Human axillary odors, human apocrine gland secretion, (*E*)-3-methyl-2-hexenoic acid, axillary odor precursors, androstenol.

INTRODUCTION

Recent reports from our laboratory have shown that the compounds imparting the characteristic odor to axillary secretions consist of C_6–C_{11}, normal, branched, and unsaturated acids, with the most abundant being (*E*)-3-methyl-2-hexenoic acid (3M2H) (Zeng et al., 1991; Leyden et al., 1990). Although organoleptic descriptions (Labows, 1988) and instrumental analysis (Preti et al., 1987; Labows et al., 1981) had previously suggested the presence of C_2–C_{18} acids in axillary secretions and extracts of this fluid, the exact structure of the acids and their relationship to the characteristic axillary odor was only recently determined (Zeng et al., 1991). Prior to this, the compounds suggested as responsible for axillary odor were thought to be volatile androst-16-enes, such as androstenone (5α-androst-16-en-3-one), androstadienone (androst-4,16-en-3-one), and androstenol (5α-androst-16-en-3α-ol) as well as isovaleric acid (Froebe et al., 1990; Labows, 1988, Gower, 1988).

In an attempt to better understand the mechanism by which the characteristic axillary odor is formed, the precursors to the axillary odors have been sought in the apocrine secretion. Our study is the first to look for the precursor(s) to 3M2H since it was not previously reported in axillary sweat or thought to be related to the characteristic axillary odor.

The research of Hurley and Shelly (1960) as well as Shehedah and Kligman (1963) demonstrated that freshly produced secretion is odorless and that the action of the cutaneous microorganisms upon the secretion creates the odor. Most of the published studies in this area have examined the apocrine secretion for steroidal-type molecules, namely, C_{19}-androgen sulfates and/or glucoronides (Labows 1988; Gower, 1988; Froebe et al., 1990). However, several lines of evidence suggested that the precursors to the odor might be lipid in nature. First, the axillary diptheroids, which are generally regarded to produce the more characteristic malodors (Leyden et al., 1981; Labows, 1988), have a lipid requirement for growth (McGinley et al., 1985); second, the structures of the compounds constituting the characteristic odor suggest that they are not formed by catabolism of amino acid substrates but may be secreted bound to glycerol and hydrolyzed to the free acids; third, the odor is formed fairly rapidly when axillary diptheroids are mixed with apocrine secretion (personal observations), suggesting that a rapid process (hydrolysis?) forms the odor; and fourth, other researchers have also alluded to possible nonvolatile, lipid-type molecules such as

triglycerides being present in the apocrine secretion, which could be degraded to give aliphatic acids such as 4-ethyloctanoic acid (Labows et al., 1981; Labows, 1988).

In this paper we report fractionation of apocrine secretion in aqueous and organic phases with subsequent saponification via NaOH and incubation with axillary diphtheroid bacteria. These experiments show that the precursor(s) to the characteristic axillary odors does not appear to be a lipid but is found in the water-soluble portion of the apocrine gland secretion.

METHODS AND MATERIALS

Apocrine Secretion Donors

Several collections of apocrine secretion were made to supply the material necessary for the experiments performed. Healthy male volunteers between 20 and 40 years of age served as paid voluntary donors. Informed consent was obtained prior to each collection. In the first collection, eight donors supplied a total of 8 μl of materia; seven donors supplied 6 μl in the second collection, and seven donors supplied 120 μl for the third collection, and six donors supplied 30 μl for the fourth collection.

The axillae was prepared for sampling by shaving the underarm area on the morning of the collection day (Labows et al., 1979). The donors rested in a supine position, the axillary region was washed with a nonionic detergent (0.1% Triton X-100), rinsed with water, dried, and finally, washed with hexane.

By this procedure, desquamated horny cells, most of the cutaneous flora, and skin surface lipids were removed, yielding apocrine secretion with minimal contamination by bacteria, cell debris, and sebum. To stimulate the apocrine glands, 0.1 ml of 1:2000 adrenalin (in physiologic saline) was intradermally injected. Droplets of apocrine secretion, which emerge from the ductal orifices, were collected with 10 μl glass micropipettes.

The secretions collected in the pipettes were pooled in 0.2-ml conical-shaped vials precooled to 0°C (React-a-Vial, Pierce, Rockford, IL). The four collections yielded the amounts detailed above. The third collection was unusual due to the large amount obtained. We think that it was due to several new donors being used. Since they were not familiar with the procedure, it was stressful enough to cause a larger volume of secretion to be expressed. The secretions were stored at −60°C until analysis.

Separation of Apocrine Secretions

The apocrine secretion microdroplets were diluted first with 300 μl distilled water, followed by 400 μl chloroform. The chloroform was mixed well with the apocrine secretions, and the mixture centrifuged for 5 min to form two layers.

The bottom chloroform layer was removed via pipette. The remaining aqueous layer was extracted two more times with chloroform (2 × 400 μl) and subsequently separated by the same procedure as above. This procedure gave a total volume of 1.2 ml of chloroform solution and 300 μl of aqueous apocrine solution.

In the experiment where the large amount (120 μl) of apocrine secretion was employed, aliquots of the aqueous (10 μl) and chloroform layers (10 μl) were set aside for analysis using sodium dodecyl sulfate (SDS)/polyacrylamide gels, as described later.

Aqueous Phase Hydrolysis of Apocrine Secretion

The aqueous apocrine solution was refluxed for 20 min with 1 ml of 5% sodium hydroxide aqueous solution under a stream of nitrogen. The mixture was allowed to cool to room temperature and acidified with 2*M* HCl to pH 2. A slight axillary-like odor developed in the reaction mixture upon acidification. The acidified mixture was extracted with 3 × 150 μl chloroform.

In the first two experiments, the combined chloroform extracts were concentrated to approximately 5 μl for organoleptic evaluation and GC/MS analysis. However, in the experiments employing the larger volumes of apocrine secretion, we concentrated to approximately 12 μl.

Organic Phase Hydrolysis of Apocrine Secretion

In each experiment, the chloroform extract obtained from apocrine secretion was concentrated to approximately 100 μl and refluxed for 20 min with 5% NaOH in 2 ml of a 1 : 1 solution of methanol : water under a stream of nitrogen: the same conditions used for the aqueous phase hydrolysis. After removal of the solvent, the reaction mixture was acidified with 2 *M* HCl to a pH of 2; no odor was detected. This acidic solution was extracted with chloroform (3 × 0.5 ml) and concentrated to approximately 5 μl.

Incubation of Apocrine Secretion Aqueous and Organic Phases with Diphtheroid Bacteria

A combined male apocrine secretion sample (~30 μl) from six donors was separated into aqueous and organic soluble phases as described above. Each phase was transferred to 50-ml, round-bottomed flasks, and the $CHCl_3$ removed from each by rotary evaporation. To each of these flasks was added 200 μl of McFarland Barium Sulfate Standard No. 2 (Balows, 1991) containing ~600,000,000 colony forming units/ml of cutaneous lipophilic corynebacterium (CLC). These are the most abundant species of diphtheroid bacteria found in the human axillae. An equal amount of McFarland Standard No. 2 with CLC

was added to an empty, sterile, 50ml round-bottom flask to use as a blank. All three flasks were sealed with parafilm and incubated at 37°C for 24 hr.

Following this time the contents of each flask were transferred to three centrifuge tubes. Each flask was rinsed with 300 μl doubly distilled water and each rinse was combined with its respective solution. Sodium chloride (20 mg) was added to each centrifuge tube, and the three solutions were extracted separately with chloroform (3 × 500 μl). The extraction procedure was identical to that described above following the hydrolysis with NaOH. Each chloroform extract was concentrated to 10 μl by the vacuum concentration and analyzed by GC/MS.

Sodium Salt of 3-Methyl-2-Hexenoic Acid: Extraction and Hydrolysis

To form the sodium salt, 500 ng of a 10:1 synthetic mixture of *E*- and *Z*-3-methyl-2-hexenoic acid was added to a solution (0.5 ml) of 5% NaOH in a (1:1) water:ethanol mixture. This solution was adjusted to pH 2 by dropwise addition of 6 *N* HCl. The acidified solution was extracted with chloroform (2 × 1 ml). The chloroform was divided into two equal portions. One of these portions as well as the remaining aqueous layer was treated with the 5% NaOH solution and refluxed under N_2 for 20 min. The solutions were cooled to room temperature, acidified to pH 2 with 6 *N* HCl, and extracted with chloroform (2 × 0.5 ml). These two extracts and the unreacted half of the chloroform extract (see above) were each concentrated to approximately 5 μl by vacuum concentration for GC/MS analysis.

Examination of Apocrine Secretion for the Sodium Salt of 3-Methyl-2-Hexenoic Acid

To test if the 3-methyl-2-hexenoic acids are present in apocrine secretion as their sodium salts and therefore remain in the aqueous phase during the partitioning with $CHCl_3$, a sample of combined apocrine secretion from 12 donors (~40 μl) was adjusted to pH 2 by the addition of approximately 50 μl 6*N* HCl. The acidified sample was diluted to 300 μl with doubly distilled water and extracted with 3 × 400 μl of $CHCl_3$. One microgram of D_{19}-decanoic acid was added to each phase as an internal standard to gauge efficiency of recovery. One-half the $CHCl_3$ extract and the remaining aqueous phase were subjected to hydrolysis and analyzed as described above. The portion of extract not subjected to hydrolysis was concentrated to ~10 μl by vacuum concentration and analyzed by GC/MS.

Synthesis of Both 3-Methyl-2-Pentenoic and 3-Methyl-2-Octenoic Acids

The synthesis of these compounds was similar to that employed for (*E*)- and (*Z*)-3-methyl-2-hexenoic acid (Zeng et al., 1991).

To a mixture of NaH (1.33 g, 55.3 mmol) and toluene (80 ml), triethyl

phosphonoacetate (12.4 g, 55.3 mmol) was added dropwise at room temperature for 30 min. The temperature was raised to 40°C. After 1 hr of stirring, 2-butanone (3.98 g, 55.3 mmol) or 2-heptanone (6.31 g, 55.5 mmol) was added dropwise, and stirring was continued at 40°C for 2 hr. The reaction mixture was poured into ice water (70 ml) and extracted with diethyl ether (3 × 40 ml). The extract was dried over anhydrous sodium sulfate. The solvent was removed *in vacuo*, and the residue was added to a solution of KOH (5.0 g) in methanol (30 ml) and water (30 ml). The reaction mixture was refluxed for 2 hr, cooled to room temperature, then poured into ice water (100 ml) and extracted with diethyl ether (2 × 60 ml). The aqueous layer was acidified with dilute sulfuric acid and extracted with *n*-hexane (3 × 100 ml). The extract was dried over anhydrous sodium sulfate and concentrated to give an oil (5.04 g, 80% yield for 3-methylpentenoic acids; and 7.14 g, 83% yield for 3-methyl-2-octenoic acids).

Analysis by GC/MS showed that both products contain the (*E*)- and (*Z*)-isomers at a ratio of approximately 3.6:1. The H^1 and C^{13}-NMR data for these isomers have been previously reported (Ogura et al., 1970; Gahiez et al., 1976; Hagen et al., 1980). The mass spectra and relative chromatographic retention times [ethyl ester unit; EEU (van den Dool and Kratz, 1963)] are given here.

Gas Chromatography/Mass Spectrometry (GC/MS) Analysis

A Finnigan 4510 GC/MS data system equipped with a split/splitless injector, a fused silica capillary column, and capabilities for operation in both electron impact and chemical ionization modes, was used for analysis. The column employed was a 30 m × 0.32-mm (I.D.) fused silica column with a 1.00-μm coating of Stabilwax (cross-bonded polyethylene glycol; Restek, Port Matilda, PA). The mass spectrometer is interfaced to a Nova 4X computer, which utilizes the Super Incos software for data acquisition, analysis, and quantitation. The

mass range employed during these analyses was m/z 40–400. This mass range was scanned once each second and a typical run included 4000 scans. The data system also included the NBS library of 42,000 compounds.

Identifications were based on comparison of unknown spectra with both the NBS library and interpretation of the resulting spectrum with mass spectra generated from synthetic standard compounds. In addition, the relative chromatographic retention times of unknown and known standards were compared. A mixture of fatty acid ethyl esters was used to determine the relative retention times (van den Dool and Kratz, 1963).

Organoleptic Evaluation of Hydrolyzed Apocrine Secretion Samples

This procedure was performed using a panel of three or four judges in a manner similar to that used for evaluation of chromatographic eluants (Zeng et al., 1991). Judges were presented in a blind manner with the acidified, hydrolyzed aqueous or organic portions of apocrine secretion and asked which had an odor that most resembled axillary odor. A small (2- to 5-μl) aliquot of concentrated axillary extract on a filter-paper strip (in a sealed vial) was on hand for reference if requested by a judge.

Sodium Dodecyl Sulfate–Polyacrylamide Gel Electrophoresis (SDS-PAGE) of Apocrine Secretion and Extracts

SDS-PAGE was done according to Laemmli (1970). The stacking gel was 5% acrylamide and the separating gel was 15%. Samples of interest were dried down to approximately 5 μl, then mixed with 5 μl sample buffer containing 2% SDS, 5% β-mercaptoethanol, 10% glycerol, 0.001% bromophenol blue, and 50 m*M* Tris–HCl at pH 6.8. After electrophoresis, the gels were stained with Coomassie blue.

RESULTS

The amount of apocrine secretion collected in each of the collections was highly variable and appeared to be dependent on the nature of the subject rather than their number. Certain individuals yielded as much as 20–30 μl, possibly due to their being tense about the collection procedure.

The first two experiments, performed with small amounts of apocrine secretion (7 and 6 μl, respectively), yielded identical results: the concentrated chloroform extract made from the acidified aqueous layer hydrolyzate had a weak but distinct axillary odor when $\sim$2 μl was allowed to evaporate to dryness on clean, odorless filter-paper strips. The identical extract obtained from the organic layer hydrolyzate had no axillary odor or any other odor quality distinguishable from solvent.

Gas chromatography/mass spectrometry (GC/MS) analysis of the axillary smelling extract did not yield any distinct mass spectra which could point to the presence of odorous components such as (*E*)-3-methyl-2-hexenoic acid (*E*-3M2H) or any of the other acidic components known to be present in the axillary odor bouquet (Zeng et al., 1991). This result is consistent with the olfactory threshold of these compounds being below the instrumental detection level.

The third experiment performed with a large amount of apocrine secretion (~ 120 μl) yielded a chloroform extract from the acidified aqueous layer hydrolysate, which had a strong axillary odor upon concentration (~ 12 μl). One microliter (1 μl) was employed for GC/MS analysis, as was 1 μl of the concentrated extract of the organic layer hydrolyzate.

Figure 1 shows the area in the computer reconstructed chromatogram where previous studies (Zeng et al., 1991) have shown the characteristic axillary odors, (*E*)- and (*Z*)-3M2H elute. Figure 1A is the organic phase hydrolysate, while Figure 1B is the aqueous phase hydrolysate. Above each of the chromatograms is a plot of *m/z* 128, the ion representing the intact, ionized, 3-methyl-2-hexenoic acids, eluting in this area. Only a trace amount of the (*E*)-3M2H, is seen in the organic phase hydrolysate (Figure 1A). From comparison of the area of the ions for *m/z* 128 with injection of known amounts of 3M2H, we estimate that the aqueous phase hydrolysate contained approximately 50.0 ng/μl of the (*E*)-isomer and 4.2 ng/μl of the (*Z*)-isomer. The organic phase hydrolysate contained approximately 0.5 ng/μl of the (*E*)-isomer. We recently reported (Zeng et al., 1991) that the (*E*)-isomer-to-(*Z*)-isomer ratio in a combined male extract was 10:1; the same approximate ratio is also seen here (Figure 1B).

Similar results were obtained from the experiment involving incubation of the diphtheroid bacteria with separate samples of apocrine secretion aqueous and organic phases. Analysis of these samples showed that bacteriolysis of the aqueous phase produced 5.13 ng/μl of the *E*-isomer and 0.12 ng/μl of the *Z*-isomer, while the organic phase yielded only a trace of the *E*-isomer (0.02 ng/μl). Analysis of the blank, which contained only the McFarland medium, did not show any *E*- or *Z*-3M2H. The results of both the NaOH hydrolysis and the bacteriolysis are summarized in Table 1.

Figure 2 shows the portion of the computer-reconstructed chromatogram where previous studies have shown the C_6 to C_{11} acids constituting the axillary "bouquet" elute (Zeng et al., 1991). Each of the compounds is labeled and its identity is given in Table 2. These data show that the aqueous and organic phase hydrolysates contained many of the straight-chained acids which we have reported in the axillary extract (Preti et al., 1987; Zeng et al., 1991), albeit at relatively low levels. In addition, the aqueous phase extract also contained small amounts of three other unsaturated acids. We have identified two of these as 7-octenoic acid (Peak I), (*E*)-3-methyl-2-pentenoic acid (Peak B, a lower homologue of

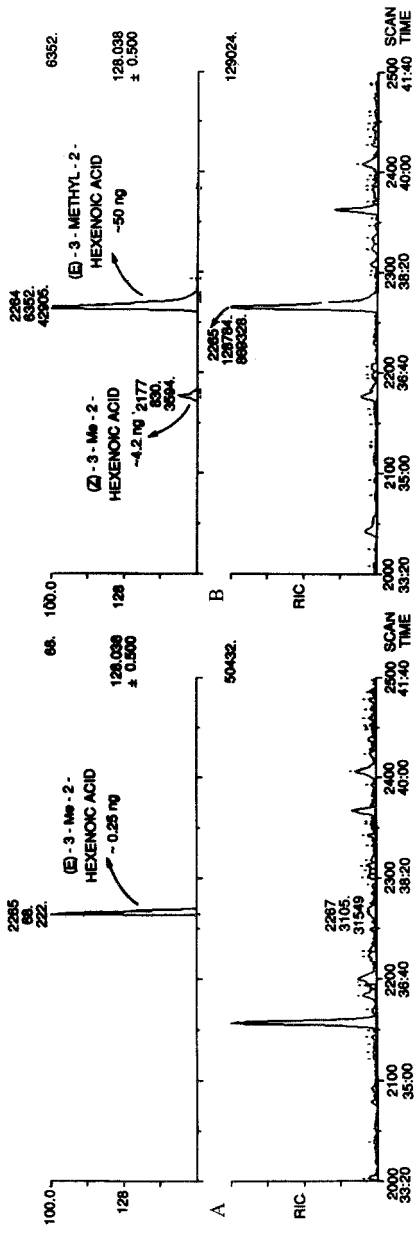

FIG. 1. Reconstructed ion chromatogram showing the area where (Z)- and (E)-3-methyl-2-hexenoic elute. (A) The organic phase hydrolysate; (B) the aqueous phase hydrolysate. The top half of A and B shows a mass chromatogram of m/z 128, the intact, ionized molecular ion of (E)- and (Z)-3-methyl-2-hexenoic acid. The aqueous phase hydrolysate contains approximately 200 times more 3-methyl-2-hexenoic acid than the organic phase hydrolysate.

TABLE 1. AMOUNTS OF 3-METHYL-2-HEXENOIC ACID LIBERATED FROM APOCRINE SECRETION BY NaOH HYDROLYSIS AND BACTERIOLYSIS

	Nanograms per microliter			
	5% NaOH hydrolysis		Bacteriolysis	
	E-Isomer	*Z*-Isomer	*E*-Isomer	*Z*-Isomer
Aqueous phase	50.0	4.20	5.13	0.12 ng/μl
Organic phase	0.25	0	0.02	0

3M2H), and a C_9-unsaturated acid (Peak L). The structure of 3-methyl-2-pentenoic acid was confirmed by comparison (MS and relative retention time) to a synthesized sample. The C_9-unsaturated acid had a mass spectrum and relative retention time identical to that of an unknown C_9-unsaturated acid we reported in our study of male axillary odor components (Zeng et al., 1991). We also synthesized 3-methyl-2-octenoic acid to see if it corresponded to this unknown C_9-unsaturated acid; it did not (see Table 2). No evidence was seen for these three unsaturated acids in the organic phase hydrolysate.

We tested the possibility that 3M2H and other acids might be present in apocrine secretions as their salts and therefore left in the aqueous phase after extraction with $CHCl_3$. To do this we first determined what would result from the $CHCl_3$ extraction and subsequent hydrolysis of a basic solution containing a known amount (500 ng) of *E*- and *Z*-3M2H. Acidification of the basic solution produced the characteristic axillary-like odor of the 3M2H. After extraction with $CHCl_3$ half of this extract (E_1) and the remaining aqueous phase (A_R) were refluxed with 5% NaOH as described above. The other half of the extract (E_2) was concentrated and analyzed by GC/MS. The results of the GC/MS analysis of each sample are given in Table 3. These data show that all the 3M2H were extracted out of the aqueous phase and approximately 58% of the acids extracted into the $CHCl_3$ were recovered.

This experiment was repeated using a 40-μl sample of apocrine secretion. Upon adjusting to pH 2, we noted a weak but distinct odor. The smell was not that of 3-methyl-2-hexenoic acid but a burnt/onion, sulfurous odor. After dilution and extraction of the acidified sample, half the $CHCl_3$ extract (AE_1) and the remaining aqueous phase (AAR) were refluxed with 5% NaOH and analyzed as described above. The other half of the $CHCl_3$ extract (AE_2) was concentrated and analyzed. The results of each analysis are given in Table 4. The recovery of the D_{19}-decanoic acid internal standard for each of the three samples was 44, 52, and 71% for AE, AAR, and AE_2, respectively.

The data in Table 4 shows that the hydrolysis procedure liberated 3-methyl-

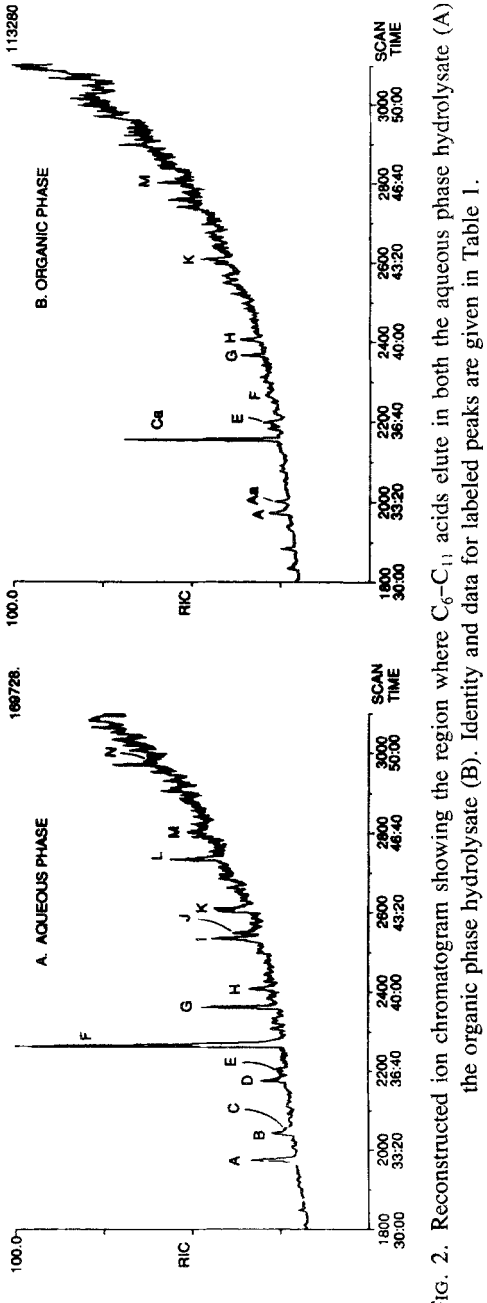

FIG. 2. Reconstructed ion chromatogram showing the region where C_6–C_{11} acids elute in both the aqueous phase hydrolysate (A) and the organic phase hydrolysate (B). Identity and data for labeled peaks are given in Table 1.

2-hexenoic acid from the aqueous phase; this is in contrast to A_R in Table 3, where no 3-methyl-2-hexenoic acids were found.

The apocrine secretion aqueous and organic phase hydrolysates were also investigated for the presence of volatile steroids and/or steroid sulfates by GC/MS using previously established procedures employing bonded methyl silicone columns (Preti et al., 1987; Zeng et al., 1991). No evidence of these compounds was found in the organic phase hydrolysate. In contrast, the aqueous

phase hydrolysate contained detectable amounts of the steroid sulfates; 17-oxo-5-androsten-3α-yl sulfate (dehydroepiandrosterone sulfate) and 17-oxo-5α-androstan-3α-yl sulfate (androsterone sulfate) were seen as their pyrolysis products (Labows et al., 1979; Preti et al., 1987). The free steroids, androsterone and dehydroepiandrosterone, were also present. No evidence of the volatile steroids (e.g., androstenone and androstenol) was seen in these samples.

Similar analyses were carried out on the aqueous and organic phase following bacteriolysis. No evidence was found for the presence of C_{19}-steroids in the organic phase. However, the aqueous phase contained both dehydroepiandrosterone sulfate and androsterone sulfate. In addition, androsternol was found in this sample along with dehydroepiandrosterone and androsterone. Although quantitation was not done, the level of androstenol was comparable to the levels of dehydroepiandrosterone sulfate.

To determine how much of the steroid sulfates would be converted to the free steroids by the hydrolysis procedure, we performed an experiment employing 100 μg of dehydroepiandrosterone sulfate and 50 μg of androsterone sulfate. These are the approximate amounts expected in 120 μl of apocrine secretion as per previous studies (Labows et al., 1979). One milliliter of 5% aqueous NaOH was added to 0.12 ml of doubly distilled water containing the above sulfate levels and the hydrolysis performed as described under Methods and Materials. Workup and analysis of the resultant hydrolysate showed that only 17% of the sulfates were cleaved by the procedure. Previous studies have shown that these

sulfates do not appear to be precursors for androstenol (Labows, 1988; Froebe et al., 1990).

Further investigation of the nonhydrolyzed organic and aqueous layers was performed using SDS/polyacrylamide electrophoresis. Figure 3 shows the Coomassie blue-stained gel on which were loaded comparable aliquots of organic soluble compounds (lanes 1 and 2) and aqueous soluble compounds (lane 3) prior to hydrolysis. These were saved from the experiment which utilized the large amount (~ 120 ml) of apocrine secretion (as noted above).

The aqueous portion of the apocrine secretion appears to be extremely rich in proteins, while little or no protemaceous material is seen in the organic phase. Several protein bands can be seen in lane 3 including major protein components found at apparent molecular weights of 66,000, 40,000, and 26,000.

DISCUSSION

The finding that the water-soluble components of apocrine secretion contained nonodorous molecules that could be hydrolyzed to yield (*E*)- and (*Z*)-3M2H by both hydrolysis with NaOH and incubation with axillary diphtheroids was unexpected. It suggests that an important, characteristic human axillary odor is not being synthesized on the skin surface. Possibly, this is made elsewhere in the body, stored in the apocrine gland, and secreted in the apocrine secretion with the water soluble components. Consequently, this axillary odor appears on the axillary skin surface bound to a precursor and is liberated by the action of the cutaneous microflora.

The experiments in which the sodium salts of *E*- and *Z*-3M2H and apocrine secretion were acidified, extracted, and hydrolyzed further support our conclusion of an aqueous soluble precursor. Acidification of the basic solution containing the sodium 3M2H yielded the distinct characteristic odor of the 3M2H; subsequent extraction of the aqueous phase with $CHCl_3$, hydrolysis with NaOH, and analysis by GC/MS showed no 3M2H in the resulting hydrolysate (Table 3, Ar). This suggests that the 3M2H was removed from the acidified aqueous phase. However, such a result was not seen when the similar procedure was performed with apocrine secretion. The odor produced by the acidified apocrine secretion was not that of the 3M2H but had a distinct burnt, sulfur/onion odor, which suggested that a reaction was occurring which liberated 3M2H as shown in Table 4. However, a larger amount of 3M2H remained in the aqueous phase of the acidified apocrine secretion than in its $CHCl_3$ extract.

These data are consistent with the 3M2H being associated, in some fashion, with a water-soluble precursor molecule. Addition of HCl to the apocrine secretion either cleaves a precursor–3M2H covalent bond or disrupts the intermolecular forces holding the precursor–3M2H together. If the precursor molecule is

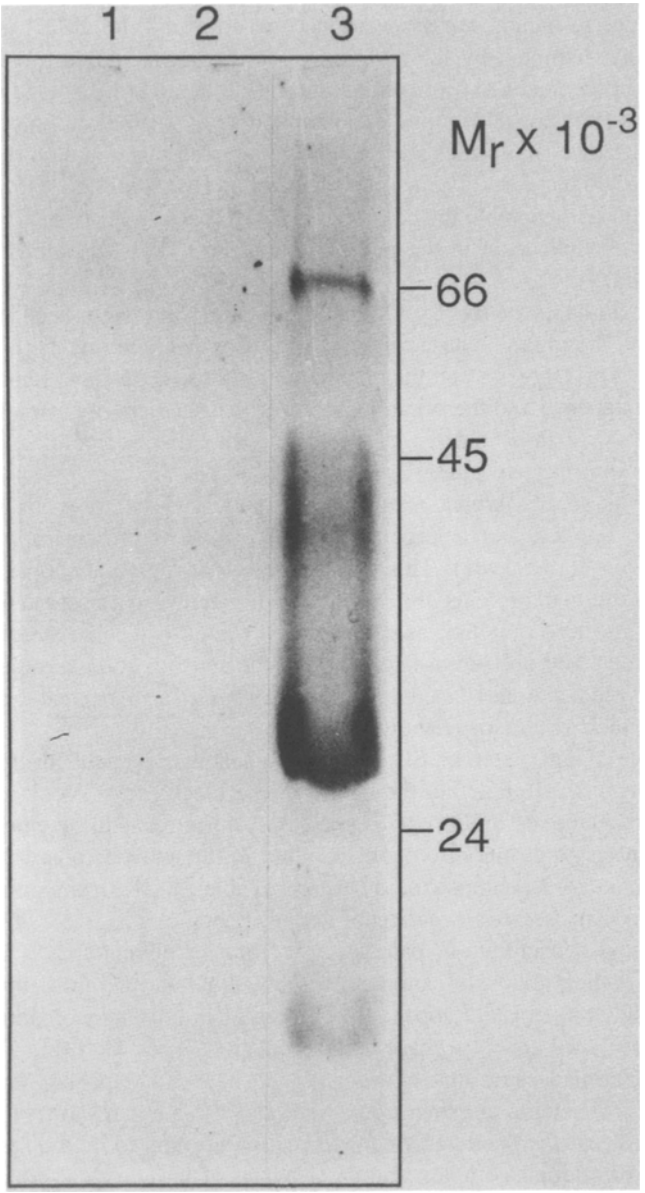

FIG. 3. The SDS–polyacrylamide gel electrophoretic profile of the unhydrolyzed organic phase (lanes 1 and 2) and aqueous phase (lane 3). The aqueous soluble molecules contain a number of proteins as shown by Coomassie blue staining. No proteinaceous material is seen in lanes 1 and 2. Molecular weight markers (not shown) were used to generate the scale at the right.

proteinaceous in nature, the association between it and the 3M2H may be one that is easily disrupted by the addition of acid or base. Some proteins, under acidic conditions, even at room temperature, will begin to hydrolyze and/or lose their three-dimensional structure (Hunkapillar et al., 1983; Kopple, 1966). In the latter instance, molecules such as 3M2H intercathelated within the protein's structure would be released. The odor noted when HCl was added to the apocrine secretion did not resemble the acid but may have been indicative of bond cleavage (thioester linkages?) in the putative precursor. These are areas for further investigation.

Small amounts of the C_6–C_{11} straight-chain acids were seen in both the aqueous and the organic phase mixtures following bacterial incubation and base hydrolysis. This suggests that the precursors for these acids have some solubility in both the aqueous and the organic phases or that they are present at low levels (below olfactory threshold) in the collected apocrine secretion and partition themselves into the two phases, prior to hydrolysis.

Previous studies which examined the apocrine secretion for its various components suggest that a large amount of protein is present: approximately 10% (Labows et al., 1981). This percentage seems high and should be reevaluated. In addition to proteins, the steroid sulfates were also present in the aqueous portion of apocrine secretion as expected. However, a volatile steroid (androstenol) was detected only upon interaction of the aqueous soluble molecules with the diphtheroid bacteria; consequently, axillary bacteria are needed to metabolize them from their precursor (Labows, 1988).

Our initial data based on SDS-PAGE suggest that the aqueous phase is rich in proteinaceous material, but the nature of the precursor molecules associated with the characteristic axillary odor (i.e., 3M2H) remains to be elucidated.

One interesting minor component found in the aqueous phase hydrolysate was (*E*)-3-methyl-2-pentenoic acid (Peak B, Table 2). This compound does not appear in axillary secretions collected in pads (Zeng et al., 1991). This may be due to its low concentration, precluding it from instrumental detection and its coelution, in the previously examined combined extract with 3-methylhexanoic acid. The latter compound appears to be present in only trace quantities in the freshly hydrolyzed aqueous phase component (i.e., Peak C, Table 2).

Our data also show that hydrolysis with base accomplishes much of the same effect as bacterial enzymes do *in vivo*, albeit in a much shorter time frame. The main role of the bacteria in odor formation appears to be the disruption of the precursor/odorant complex and/or cleavage of the covalent bonds holding the acid molecules to the precursor.

Acknowledgments—The authors wish to thank Mr. John Chicchi of K.G.L./Ivy Labs for recruiting apocrine secretion donors and aiding Dr. Leyden in secretion collection. We also thank Mrs. Linda Robinson and Mrs. Janice Blescia for preparing the manuscript. This study was supported in part by a postdoctoral fellowship awarded to the Monell Chemical Senses Center by Takasago International Corporation.

(Received August 23, 1991; accepted February 20, 1992)

Abstract—3Z,6Z,9Z-Nonadecatriene (3Z,6Z,9Z-19:H; other abbreviations follow the same pattern) has been identified as a female sex pheromone component of the geometrid moth *Epirrhoe sperryi* (H.). 3Z,6Z,9Z-18:H and 6Z,9Z-19:H were also identified in pheromone gland extracts but had no apparent biological activity. 3Z,6Z,9Z-21:H was tentatively identified as a female sex pheromone component of a second geometrid species, *Lobophora nivigerata* (Wlk.). Attraction of male moths to this compound was strongly synergized by the addition of small amounts of 6Z,9Z-21:H to lures.

Key Words—Sex attractant, pheromone, 3Z,6Z,9Z-octadecatriene, 3Z,6Z,9Z-nonadecatriene, 3Z,6Z,9Z-heneicosatriene, 6Z,9Z-nonadecadiene.

INTRODUCTION

Unsaturated hydrocarbons with one to four *cis* double bonds separated by single methylene units have been identified as sex attractants and sex pheromone components for a variety of moths from several insect families. Compounds of this type are usually produced by the female but can also be produced by males (Heath et al., 1988; Descoins et al., 1990). These types of compounds have been found as single component pheromones in the winter moth and Bruce spanworm (Roelofs et al., 1982; Underhill et al., 1987), which both use

1,3Z,6Z,9Z-nonadecatetraene as a single-component pheromone. More commonly, unsaturated hydrocarbons occur as blends, either with each other or with similar components such as unsaturated epoxides, aldehydes, or ketones (Millar et al., 1990a, and references therein). Hydrocarbon blends may occur as mixtures of homologues with the same number of double bonds [*Anticarsia gemmetalis* (Heath et al., 1983); *Mocis disseverans* (Landolt et al., 1986); *Caenurgina erechtea* (Underhill et al., 1983)] or as mixtures of compounds with the same or different carbon-chain lengths, with different numbers of double bonds [*Arctia villica* (Einhorn et al., 1984); *Utetheisa ornatrix* (Jain et al., 1983); *Alsophila pometaria* (Wong et al., 1984); *Paleacrita vernata* (Millar et al., 1990a)].

Wong et al. (1985) reported 3Z,6Z,9Z-nonadecatriene (3Z,6Z,9Z-19:H; other abbreviations follow the same pattern) as a sex attractant for male *Epirrhoe sperryi* (H.) moths. We report here (1) the identification of 3Z,6Z,9Z-18:H, 3Z,6Z,9Z-19:H, and 6Z,9Z-19:H in *E. sperryi* female pheromone glands, (2) the tentative identification of 3Z,6Z,9Z-21:H in *L. nivigerata* female pheromone glands, and (3) the results of field tests with blends of the identified components.

METHODS AND MATERIALS

Insects and Electroantennography. Male moths were captured in light traps, in sweep nets, or in traps baited with synthetic sex attractants. Female moths of unknown mating status were taken in light traps or in sweep nets. Male antennal responses to synthetic compounds were measured by EAG (Chisholm et al., 1975), using 1-μg amounts of compounds applied to filter-paper disks and by the GC-EAD method of Arn et al. (1975). Synthetic compounds tested in EAG and/or GC-EAD studies included C_{17-22} chain lengths of the following types of compounds: 6Z,9Z-, 3Z,6Z,9Z-, 1,3Z,6Z,9Z-, 3Z,6Z,9Z,11Z-, and 3Z,6Z,9Z,11*E*-unsaturated hydrocarbons; combined mixtures of the monoepoxide regioisomers from nonselective oxidation of the diene or triene hydrocarbons above (combined monoepoxides, CME); racemic and chiral forms of 3Z,6Z-*cis*-9,10-, 3Z,9Z-*cis*-6,7-, and 6Z,9Z-*cis*-3,4-epoxydienes; and racemic and highly enantiomerically enriched forms of 6Z-*cis*-9,10- and 9Z-*cis*-6,7-epoxymonoenes.

Extracts of sex pheromone glands from field-collected female moths were prepared by a 20-min pentane extraction of the terminal three or four abdominal segments. The extracts were concentrated under a stream of nitrogen, internal standards (*n*-heptadecane and *n*-tetracosane) were added, and the extract was submitted to coupled gas chromatography–electroantennogram detection (GC-EAD) as described previously (Arn et al., 1975). The signals from the flame ionization detector and the insect antenna were recorded simultaneously with a

matched pair of Hewlett-Packard 3392A integrating chart recorders (Hewlett-Packard, Avondale, PA).

Coupled gas chromatography–mass spectrometry (GC-MS) analyses were carried out in the selected ion monitoring (SIM) mode, using chemical ionization (methane), with a Finnigan 4000E instrument interfaced to an Incos 2300 data system. A DB-5 column (50 m × 0.32-mm ID; J&W Scientific, Folsom, CA) or an Ultra-2 column (50 m × 0.32-mm ID; Hewlett-Packard) were used for analyses.

GC-MS analysis of an *E. sperryi* female pheromone gland extract was conducted as follows. Full-scan CI mass spectra of synthetic standards were obtained to select characteristic ions. A pentane solution of the standards with octadecane and tetracosane internal standards (100 or 400 pg of each compound injected) was then run in the SIM mode, followed by a blank run. Finally, the concentrated pentane extract of the pheromone glands from field-collected female moths of unknown mating status was analyzed in SIM mode (pentane solution of octadecane and tetracosane internal standards added prior to injection).

Insect Trapping. Field experiments were carried out in a mixed forest area approximately 100 km northeast of Saskatoon. Phero Tech wing traps (Phero Tech Inc., Delta, B.C., Canada), similar in design to Pherocon 1 CP traps (Scentry Inc., Buckeye, AZ) were used throughout and were baited with red rubber septa containing the synthetic lure blends. These lure blends (usually 500 μg of test compound total weight) were loaded onto septa as hexane solutions. Baits were stabilized by the addition of several drops of a dilute acetone solution of butylated hydroxytoluene.

Traps were hung from branches 10–15 m apart, at a height of ca 1.5 m, and were set out in a randomized block design. Moth captures were recorded twice weekly throughout the flight season. Because some treatments had no captures, the raw data were subjected to a nonparametric Kruskal–Wallis test, followed by a Waller–Duncan *K*-ratio comparison of means test (SAS Institute, 1988).

Field survey traps in 1984 were baited with the following C_{18-22} compounds, alone or as binary mixtures at ratios of 10:1 and 1:10: 3*Z*,6*Z*,9*Z*-trienes, 6*Z*,9*Z*-dienes, mixtures of the combined monoepoxides derived from nonspecific monoepoxidation of those dienes and trienes (CME-X:H), racemic *cis*-3,4-, *cis*-6,7-, and *cis*-9,10-epoxydienes, and 3*Z*,6*Z*,9*Z*,11*E*-tetraenes.

Field survey traps in 1985 were baited with the following compounds, generally in chain lengths of C_{16-22}, alone or as binary mixtures at ratios of 10:1 and 1:10: 3*Z*,6*Z*,9*Z*,12*Z*-, 3*Z*,6*Z*,9*Z*,13*E*-, 3*Z*,6*Z*,9*Z*,13*Z*-, 3*Z*,6*Z*,9*Z*,14*Z*-, or 3*Z*,6*Z*,9*Z*,14*E*-tetraenes with 3*Z*,6*Z*,9*Z*-trienes; 3*Z*,6*Z*,9*Z*-trienes with enantiomers of *cis*-6,7- and *cis*-9,10-epoxydienes; and epoxide enantiomers with each other or with regioisomers. Blends were made up with compounds of the same chain length or differing by one carbon in chain length.

Field survey traps in 1986 were baited with the following compounds, generally in chain lengths of C_{16-21}, alone or as binary mixtures at ratios of 10:1 and 1:10: 3Z,6Z,9Z-trienes; 1,3Z,6Z,9Z-tetraenes; enantiomers of 6Z,9Z-*cis*-3,4-epoxydienes; 6Z,9Z-dienes; enantiomers of 6Z-*cis*-9,10- and 9Z-*cis*-6,7-epoxymonoenes; and 6Z,9Z-dien-3-ols and 6Z,9Z-dien-3-ones.

Synthetic Chemicals. The syntheses of the compounds used in the field surveys and EAG or GC-EAD studies described in this paper have been published elsewhere, as follows: 6Z,9Z-and 3Z,6Z,9Z-unsaturated hydrocarbons and the corresponding racemic *cis*-3,4-, *cis*-6,7-, and *cis*-9,10-monoepoxides (Underhill et al., 1983; Wong et al., 1985; Millar et al., 1987); enantiomers of *cis*-9,10-epoxydienes (Wong et al., 1985); enantiomers of *cis*-6,7-epoxydienes (Millar and Underhill, 1986); and enantiomers of *cis*-3,4-epoxydienes (Millar et al., 1990d).

With regard to the specific experiments described in this report, the trienes and dienes were >99% chemically and isomerically pure by capillary gas chromatography (DB-5 and DB-1701 columns).

RESULTS

Lobophora nivigerata *Wlk.* Male moths of this species were caught in low numbers for several years in traps baited with lures containing 3Z,6Z,9Z-21:H as a single or major component. For example, in 1984, 35 specimens were attracted to 17 different lures, 13 of which contained 3Z,6Z,9Z-21:H as the major component.

In EAG studies, strong antennal responses (approx 2 mV) were obtained by antennal stimulation with 3Z,6Z,9Z-21:H, 3Z,6Z,9Z-20:H, and 3Z,9Z-*cis*-6,7-epoxy-20:H and -21:H. Smaller responses (approx 1.5 mV) were seen to 6Z,9Z-21:H, 6Z,9Z-20:H, and homologues of the above compounds. In GC-EAD studies, a male antenna gave strong responses to C_{20-21} trienes and 3Z,9Z-*cis*-6,7-epoxy-21:H and lesser responses to 6Z,9Z-21:H and to homologues.

GC-EAD analysis of a female gland extract revealed a single strong response at the retention time of 3Z,6Z,9Z-21:H (Figure 1, bottom traces). In the same run, a flame ionization detector (FID) peak was obtained at the retention time of 3Z,6Z,9Z-21:H but not at that of 6Z,9Z-21:H.

A pheromone gland extract from a second female moth was analyzed by coupled gas chromatography–mass spectrometry, using chemical ionization (CI; methane) in the selected ion monitoring (SIM) mode, with a DB-5 column. An exact retention time match and a fair ion ratios match were obtained for 3Z,6Z,9Z-21:H versus a 100-pg standard [standard, *m/z* 291 (74, M + 1), 289 (100, M − 1), 275 (23); insect extract *m/z* 291 (83), 289 (100), 275 (11)]. 6Z,9Z-21:H was not detected in the extract.

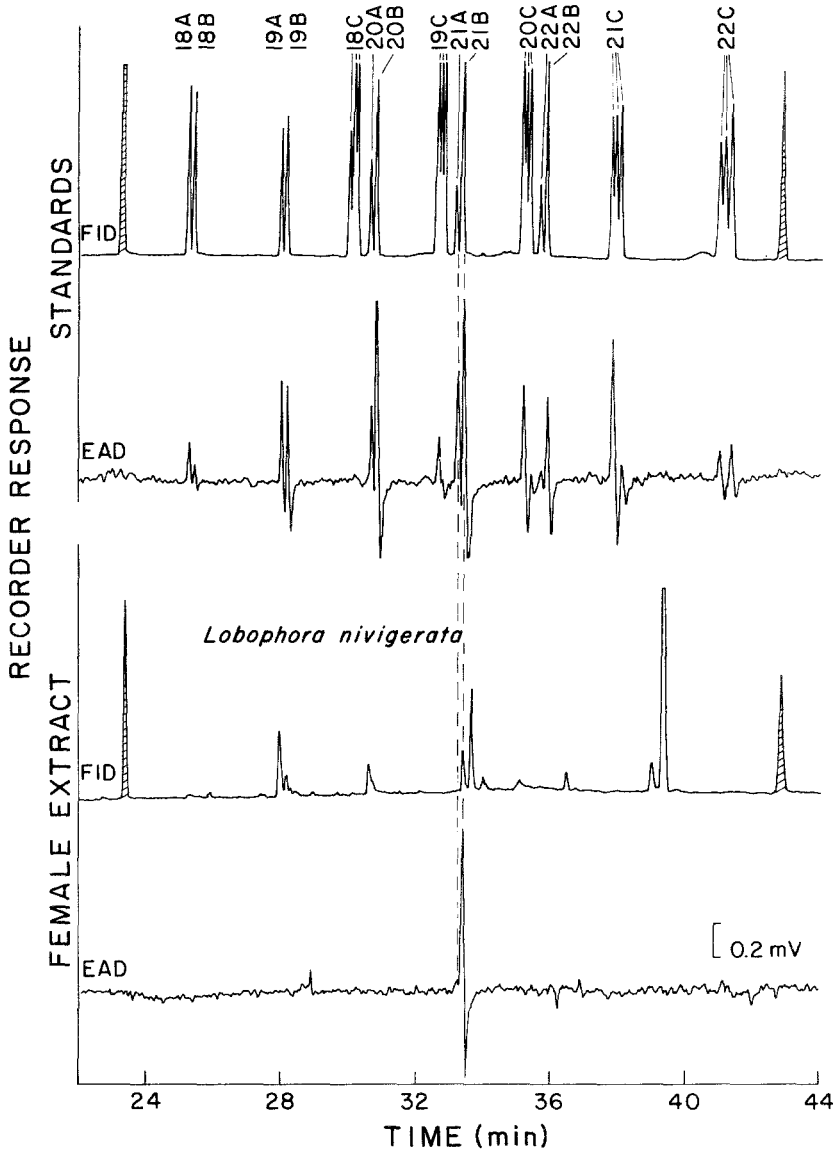

FIG. 1. Simultaneously recorded flame ionization detector (FID) and electroantennographic detector (EAD) traces using antennae of male *Lobophora nivigerata*. Upper pair of traces is in response to a mixture of C_{18-22} 6Z,9Z-diene hydrocarbons (designated by the letter A and preceded by the carbon-chain length), 3Z,6Z,9Z-triene hydrocarbons (designated by the letter B), and their monoepoxydiene analogues (designated by the letter C); the latter eluted from the DB-5 column in the order 6,7-, 3,4-, and 9,10-monoepoxydiene. Internal standards: 17:H and 24:H (shaded). Lower pair of traces is in response to a pheromone gland extract from a conspecific female. GC conditions: splitless, 40°C/0.5 min, 20°/min to 90°C, 4°/min to 230°C and hold.

In 1985 field tests, 3Z,6Z,9Z-21:H and 6Z,9Z-21:H as single components and a 1:1 blend were inactive, whereas mixtures of 19:1 and 4:1 (triene:diene) were attractive (Table 1). There was strong synergism between the two components, and the blend ratio was obviously important.

Epirrhoe sperryi *(H).* GC-EAD analysis of a female gland extract revealed EAD-active compounds at the retention times of 3Z,6Z,9Z-18:H, 3Z,6Z,9Z-19:H, and 6Z,9Z-19:H (Figure 2). The compounds were present at a ratio of 1:98:1, respectively.

A second female extract was submitted to GC-MS analysis in the SIM mode on an Ultra-2 column with methane CI. Exact retention time matches were obtained for all three compounds, and excellent ion ratio matches versus synthetic standards were obtained for 3Z,6Z,9Z-18:H [400-pg standard, *m/z* 249 (45, M + 1), 247 (47, M − 1), 109 (100); insect extract, *m/z* 249 (45), 247 (46), 109 (100)] and 6Z,9Z-19:H [400-pg standard, *m/z* 263 (100, M − 1), 249 (12), 109 (50); insect extract 263 (100), 249 (19), 109 (52)]. The SIM match between the 3Z,6Z,9Z-19:H standard [400 pg, *m/z* 263 (45, M + 1), 261 (48, *M* − 1), 247 (6), 206 (18), 109 (100)] and the compound in the insect extract [*m/z* 263 (100), 261 (100), 247 (18), 206 (46), 109 (100)] was poor because the amount of material in the extract was so large that the resulting signal saturated the detector.

In 1985, 530 male moths were attracted to 56 lure blends, the majority of which contained 3Z,6Z,9Z-19:H as the major component. There was no clear indication of synergistic or antagonistic effects due to the minor components, which included dienes, tetraenes, and monoepoxydienes. In 1986, traps containing 37 different lure blends caught 619 specimens, of which 610 were caught in traps baited with 3Z,6Z,9Z-19:H as a significant (> 10%) or major component.

In a second 1986 field test (Table 2), 3Z,6Z,9Z-19:H alone was signifi-

TABLE 1. ATTRACTION OF *Lobophora nivigerata* MOTHS TO LURES CONTAINING 3Z,6Z,9Z-21:H AND 6Z,9Z-21:H AS SINGLE COMPONENTS OR BLENDS

Lure (μg)	Male moths captured[a]

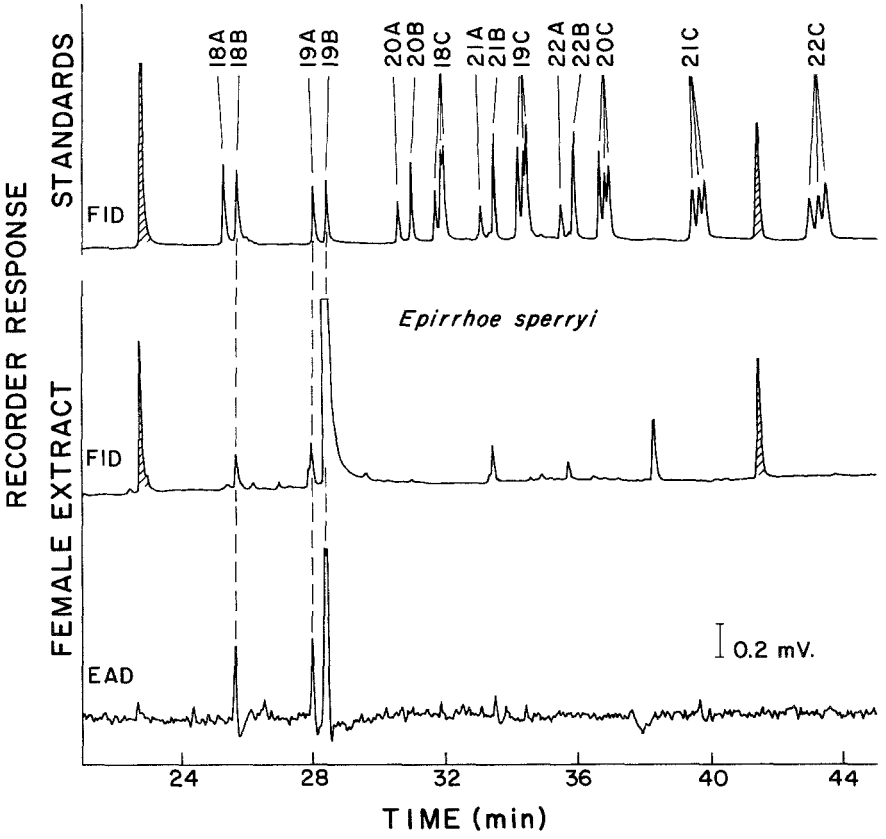

FIG. 2. FID and EAD traces (antennae of male *Epirrhoe sperryi*); upper trace is an FID trace from standards blend. Lower pair of traces is in response to a pheromone gland extract of a conspecific female. Number/letter designations and GC conditions the same as in the legend to Fig. 1.

cantly attractive, whereas 3Z,6Z,9Z-18:H and 6Z,9Z-19:H were not. When added in amounts equivalent to 1 or 10% of the total lure blend, 3Z,6Z,9Z-18:H had no significant effect on trap captures. 6Z,9Z-19:H had no significant effect at the 1% level but completely suppressed trap captures when present as 10% of the blend.

The three-component blend of 3Z,6Z,9Z-19:H, 3Z,6Z,9Z-18:H, and 6Z,9Z-19:H (100:1:1, the approximate ratio found in the pheromone gland extract) was not significantly more attractive than 3Z,6Z,9Z-19:H alone. However, the same three components at a ratio of 9:1:1 were significantly less attractive, supporting our finding that increased amounts of 3Z,6Z,9Z-18:H decreased trap captures.

DISCUSSION

Male *L. nivigerata* moths were attracted to the synergistic blend of 3Z,6Z,9Z-21:H and 6Z,9Z-21:H, with the presence and ratio of both compounds being important. No other potential pheromone components were detected, either by GC-EAD or by GC-MS examinations of pheromone gland extracts. Blends of dienes and trienes are not uncommon as lepidopteran pheromones. For example, the sex pheromone of the noctuid species *Mocis latipes* consists of a blend of the same two components (Descoins et al., 1986), and the arctiid species *Creatonotos transiens, C. gangis*, and *Utetheisa ornatrix* have both these compounds admixed with several other components in their pheromones (Jain et al., 1983; Bell and Meinwald, 1986; Wünderer et al., 1986). There have also been several reports of homologous diene and triene blends as lepidopteran sex pheromones [*Paleacrita vernata* (Millar et al., 1990a)] or sex attractants [*Alsophila quadripunctata* (Szöcs et al., 1984); *Boarmia repandata* (Bogenschütz et al., 1985)].

Preliminary data on attraction of male moths of *E. sperryi* to 3Z,6Z,9Z-19:H have been published (Wong et al., 1985), along with EAG data showing strong responses of male moth antennae when stimulated by C_{18-20} 3Z,6Z,9Z-trienes and the combined monoepoxides derived therefrom. *E. sperryi* antennae are highly receptive to three components from the female pheromone gland, but only one of these, 3Z,6Z,9Z-19:H, is significantly attractive alone to males. The other two components have variable biological activity, depending on the

blend ratio at which they are presented. At low doses, the combination of the two minor components appears to synergize the response to the major component, while at higher doses, at least one of the minor components (6Z,9Z-19:H) appears to be inhibitory. It is possible that a wider ratio of 3Z,6Z,9Z-19:H to the other two components (e.g., 1000:1:1) may have enhanced trap catches.

E. sperryi is also unusual in that its behavioral responses to the attractive 3Z,6Z,9Z-19:H were not affected by a wide variety of homologues and other similar compounds, including 6Z,9Z-dienes, 3Z,6Z,9Z,X-tetraenes (*X* = 12*E* or *Z*, 13*E* or *Z*, 14*E* or *Z*), chiral or racemic *cis*-3,4-, 6,7-, or 9,10-epoxydienes, and 6Z,9Z-dien-3-ones or 6Z,9Z-dien-3-ols. Of all the compounds tested in combinations with 3Z,6Z,9Z-19:H, the only compound which significantly altered trap captures, either positively or negatively, was 3Z,6Z,9Z-20:H, which strongly suppressed trap captures, as had been previously reported (Wong et al., 1985). None of the epoxides, either of the same chain length or homologues, had any apparent effect, despite the strong responses to these compounds by male antennae in EAG studies (Wong et al., 1985).

In our region of Saskatchewan, *E. sperryi* fly from mid-May to early July (e.g., 1984, first moth caught May 21; last moth caught July 10). During this period, there is a wide variety of geometrid and noctuid moths flying, and 3Z,6Z,9Z-19:H is a common component of sex attractants and sex pheromones for some of these species (Wong et al., 1985; Millar et al., 1990b,c,d, 1991a). *E. sperryi* males were attracted to a wide variety of lures containing 3Z,6Z,9Z-19:H as a component (e.g., in 1986, 619 moths caught with 37 different lure blends), suggesting that other physiological or behavioral mechanisms (e.g., closely synchronized female calling and male response) are operative in minimizing male attraction to pheromone blends containing 3Z,6Z,9Z-19:H produced by female moths of sympatric species.

Obtaining hard analytical data to support conclusive identifications of the pheromone components has been difficult, as we have obtained only a few hand-collected female moths of unknown mating status for analysis of pheromone gland chemistry. The evidence that has been presented in support of the identification of 3Z,6Z,9Z-21:H as a pheromone component for *L. nivigerata* consists of retention time matches on two capillary GC columns and a reasonable CI SIM ion ratios match versus a synthetic standard, plus the strong electroantennogram activity and biological activity of the synthetic compound as an attractant. Furthermore, previous studies in our laboratory have shown that under the GC-EAD conditions used, only one (an *EEZ* isomer) of the eight possible geometric isomers of 3Z,6Z,9Z-21:H is chromatographically indistinguishable from 3Z,6Z,9Z-21:H (Millar et al., 1991b). However, until hard analytical evidence can be obtained to determine unambiguously the double-bond geometries and positions, our identification remains tentative.

The evidence for the identification of 6Z,9Z-21:H as a pheromone com-

ponent is tenuous, consisting of antennal responses to standards by male moth antennae in GC-EAD studies and antennal responses in EAG studies. This identification is strongly supported by the obvious synergism between this compound and 3*Z*,6*Z*,9*Z*-21:H in field trials (Table 1).

Much stronger evidence was obtained for the identifications of the components isolated from *E. sperryi* pheromone glands. The major biologically active compound, 3*Z*,6*Z*,9*Z*-19:H, had retention times identical to those of a synthetic standard on two capillary GC columns. The SIM mass spectral match was poor, due to the saturation of the detector by the large amount of 3*Z*,6*Z*,9*Z*-19:H in the gland extract. However, the major ions at *m/z* 263 ($M + 1$) and 261 ($M - 1$) provided support for the molecular weight and formula, and the major ion at *m/z* 109 $(C_8H_{12} + H)^+$ was diagnostic for the 3,6,9-triene structure (Heath et al., 1983). Furthermore, we have previously demonstrated that under the GC-EAD conditions used, only the *EEE* isomer and one of the *EEZ* isomers had retention times which were potentially indistinguishable from that of 3*Z*,6*Z*,9*Z*-19:H. Given the strong field attraction (Table 2) and EAD responses (Fig. 2) to this compound, the chance of the pheromone component being one of the other two isomers seems remote.

Evidence to support the identity of 3*Z*,6*Z*,9*Z*-18:H in pheromone gland extracts consisted of exact retention time and CI SIM matches versus a synthetic standard, including the presence of a strong *m/z* 109 ion confirming the 3,6,9 placement of the double bonds. The same types of data confirmed the gross structure of 6*Z*,9*Z*-19:H in the extract, and in addition, all four geometric isomers of this compound are readily distinguishable by capillary GC (Millar et al., 1990a).

Acknowledgments—We thank Lawrence Hogge for running the mass spectra, Harry Holfeld for constructing and trouble-shooting the electroantennogram amplifier, Ian Warkentin, David Charest, and Leah Richardson for assistance with field trapping, and the Biosystematics Research Institute, Ottawa, for identification of voucher specimens.

ROLE OF THE ISOFLAVONOID COUMESTROL IN THE CONSTITUTIVE ANTIXENOSIC PROPERTIES OF "DAVIS" SOYBEANS AGAINST AN OLIGOPHAGOUS INSECT, THE MEXICAN BEAN BEETLE

B.J. BURDEN* and D.M. NORRIS

Department of Entomology
University of Wisconsin
Madison, Wisconsin 53706

(Received October 25, 1991; accepted February 20, 1992)

Abstract—The antixenosic properties of the isoflavonoid, coumestrol, were tested in dual-choice leaf disk bioassays with the Mexican bean beetle (*Epilachna varivestis* Mulsant). *E. varivestis* preferred the methanol-treated (solvent-control) disk when the coumestrol concentration was 1.8 or 0.9 μg/leaf disk. No preference was observed between the coumestrol-treated and the solvent-control disks when the coumestrol concentration was higher, at 3.6, or lower, at 0.45 μg/leaf disk. Coumestrol alone clearly is not responsible for the significant constitutive antixenosic properties of "Davis" soybeans, *Glycine max* (L.) Merrill, because the amount of coumestrol in these plants is significantly less than the minimum concentration which was antixenosic in this study. However, it might contribute to a constitutive antixenosis in "Davis" involving a profile of allelochemicals. A computer-aided densitometer, adapted to measure the leaf disk area, increased the resolution of the leaf area 250 (×)-fold as compared to the standard LI-COR leaf area meter.

Key Words—Allelochemicals, isoflavonoids, coumestrol, antixenosis, *Epilachna varivestis*, Mexican bean beetle, Coleoptera; Coccinellidae, *Glycine max*, *Phaseolus lunatus*, feeding bioassay.

INTRODUCTION

A holistic interpretation of plant resistance to herbivores entails multiple interacting parameters involving anatomical, morphological, and biochemical entities

*To whom correspondence should be addressed.

(Norris and Kogan, 1980). In *Glycine* the anatomical traits associated with certain resistance include stem diameter, shorter stem internodes, and secondary xylem (Chiang and Norris, 1983a). Morphological characteristics include trichome density and length (Norris and Kogan, 1980; Chiang and Norris, 1983b; Khan et al., 1986). Regarding interactions between phytochemistry and insect behavior, growth, development, or reproduction as components of plant resistance, at least two levels of resistance have been identified in *G. max*. One involves both volatile straight-chain hydrocarbons (Liu et al., 1988, 1989) and relatively nonvolatile metabolites, e.g., phenylpropanoids (Chiang et al., 1987; Khan et al., 1986; Norris et al., 1988; Norris, 1990). This at least dual-based chemical resistance is effective against polyphagous insects such as the cabbage looper, *Trichoplusia ni* (Hubner). A second, and lesser, level of *G. max* resistance involving phenylpropanoid metabolites is effective against oligophagous species such as the Mexican bean beetle (*Epilachna varivestis* Mulsant), which feeds exclusively on Leguminosae (Turnipseed and Shepard, 1980). The latter resistance, which is effective against some oligophages, needs further investigation regarding whether the causal chemistry is one or a few compounds or is a more complex mixture (profile) of chemicals. To address this question experimentally, the profiles of phenylpropanoids of two legumes, "Henderson" lima bean (*Phaseolus lunatus* L.) and "Davis" soybean (*G. max*), were analyzed in the present study. *E. varivestis* completes its life cycle on the preferred host "Henderson" lima beans, but larvae do not complete development and female adults experience reproductive failure (Burden and Norris, 1993) on the "Davis" cultivar, which has phenylpropanoid resistance.

Phenylpropanoid-based resistance in *G. max* especially involves flavonoids (Hedin and Waage, 1986). Some isoflavonoids, a subgroup of flavonoids, are important as phytoalexins and antiherbivory compounds in legumes (Fischer et al., 1990; Neupane and Norris, 1990, 1991; Sharma and Norris, 1991). Isoflavonoid-based constitutive and inducible resistance in *G. max* to *E. varivestis* has been correlated with phenylalanine ammonia lyase (PAL) and tyrosine ammonia lyase (TAL) activities, two key enzymes in phenylpropanoid (e.g., isoflavonoid) biosynthesis (Chiang et al., 1986, 1987). Phytoalexin-rich, and thus presumably isoflavonoid-rich, soybean hypocotyls deterred feeding by adult and fourth-instar *E. varivestis* (Hart et al., 1983). Glyceollins, a major group of isoflavonoids, were identified as feeding deterrents to *E. varivestis* (Fischer et al., 1990). Coumestrol, an isoflavonoid in the same general biosynthetic pathway with glyceollins (Ebel, 1986), is a feeding deterrent to the scarab beetle, *Heteronychus arator* (F.) (Sutherland et al., 1980).

Coumestrol is present in several of the host legumes of the beetle, *E. varivestis*, and was reported in the extractables from *G. max*: leaf tissue (Vaughn and Hymowitz, 1984; Smith, 1985; Porter et al., 1986), hypocotyls (Keen et al., 1972), and roots (Morandi and Le Quere, 1991; Cho and Harper, 1991).

Coumestrol is also present in *Phaseolus vulgaris* (L.) leaf tissue (Beggs et al., 1985) and in the seedlings of *P. lunatus* L. (O'Neill et al., 1986); these are the two primary host plants of *E. varivestis*. Thus, in the present study the role of coumestrol as an antixenosic agent in "Davis" soybean against *E. varivestis* was emphasized.

Accurate analysis of any effects of isoflavonoids such as coumestrol on insect feeding requires highly sensitive bioassays. Analyzing such effects on *E. varivestis* feeding has been especially difficult because both the adults and the larvae eat by a unique piercing-chewing action which does not create cleanly cut holes through the leaves. Most previous studies of *E. varivestis* feeding have used leaf area measurements lacking the resolution required to detect a significant correlation between feeding preference and some test compound. Jones et al. (1981) only visually estimated the percentage of leaf disk marked by *E. varivestis* feeding ridges. The majority of other previous studies used a LI-COR leaf area meter (Lambda Instrument Corporation, Lincoln, NE) to estimate the unconsumed leaf tissue (Chiang et al., 1987; Fischer et al., 1990; Lin et al., 1990). The sensitivity of the LI-COR is only 1 mm^2 (LI-COR Instrument Manual); thus, accurate measurement of the area removed (consumed) from the leaf by *E. varivestis* is not possible. In this paper we report bioassay results on the effects of coumestrol concentration on *E. varivestis* adult feeding as quantified by a high-resolution computerized densitometer system. These findings are also discussed within the perspective of the differential constitutive concentrations of coumestrol in the leaves of the *G. max* nonhost, "Davis," and the preferred host, *P. lunatus*.

METHODS AND MATERIALS

Plants

"Henderson" lima bean (*Phaseolus lunatus*) and "Davis" soybean (*G. max*) were used for high-performance liquid chromatography (HPLC). They were grown in the University of Wisconsin Biotron under the controlled conditions: 70% relative humidity, a 14-hr photoperiod, and day and night temperatures of 28 and 21°C, respectively. Plants were harvested every 24 hr until 120 hr. The 0-hr plants were at the V7 stage (Fehr et al., 1971). The "apical" leaves involved node four and above for the *G. max* leaves and nodes three and above for the lima beans. The leaf tissue was quick-frozen, lyophilized, and then sealed at room temperature in a darkened glass jar in a desiccator.

"Henderson" lima beans used for the feeding bioassays were grown in a greenhouse (14:10 hr, L:D) in a potting mixture of field soil, sand, and vermiculite (2:1:1). The plants were uniformly watered once a day and were maintained at 27 ± 5°C and 60 ± 10% relative humidity.

HPLC Analyses

The lyophilized leaf tissue was ground with a mortar and pestle, divided into 0.5-g aliquots, and homogenized with a TekMar Tissuemizer (Tekmar Company, Cincinnati, OH) for 60 sec at 55% maximum speed in 40 ml methanol. The homogenized tissue–methanol mixture was filtered by vacuum filtration using a Buchner funnel and Whatman No. 1 filter paper. The filtrate was collected and stored at 5°C, and the tissue residue was added to 100 ml of methanol in an Erlenmeyer flask and placed on a shaker for 16 hr. Two 16-hr extractions of each residue with methanol were conducted. The two extractions were pooled, reduced to 2 ml by rotoevaporation, and stored in a sealed vial at −5°C. Each concentrated extract was filtered through a Gelman Nyaflo 0.45-μm filter, and the volume was adjusted to 7.5 ml either by adding methanol or by reducing the volume with a stream of nitrogen (N_2) gas. At least three 20-μl injections of each extract were analyzed by HPLC using a Beckman Ultrasphere ODS column (4.6 × 250 mm). The elution gradient was 90:10 2% acetic acid:acetonitrile for 5 min, then a linear gradient to 100% acetonitrile in 15 min. The total chromatographic time was 30 min. The elution was monitored with a UV detector at 254 nm and the peak area was integrated with a Spectra Physics 4400 integrator. Each sample's analyses are an average of at least three replicate injections. Each harvest time represents at least three plants. The coumestrol peak in each extract was quantified based on a standard curve constructed from the HPLC-resolved mean peak areas for known concentrations of injected authentic coumestrol.

Insects

The *E. varivestis* were raised on "Henderson" lima beans in a greenhouse under the conditions described previously for growing lima beans. To obtain precisely aged *E. varivestis* adults for use in assays, pupae were collected and enclosed individually in 13 × 100-mm test tubes. Emergence of adults was monitored daily, and each was sexed and aged; males and females were placed in separate cages. Sex determination was based on the method of Burden and Norris (1993).

Bioassays

The feeding arena was a 6-cm plastic petri dish with a base of paraffin (2–3 mm) in its bottom, which was covered with filter paper (5.5-cm-diameter, Whatman No. 2). A similar wetted paper lined the inside of the top of the petri dish. The moistened filter paper in the lid helped to maintain the turgidity of the leaf disks. The first-trifoliolate (T1) leaf from 10-day-old, V2 "Henderson" lima beans was used as the feeding substrate for bioassays. In two-choice feeding

tests, one leaf disk was treated with a known concentration of coumestrol (ICN, Cleveland, OH) dissolved in methanol and the other disk was treated with methanol. The solutions (20 μl) were applied to the abaxial surface of the leaf. The two disks per assay were centered, abaxial side up, in an opposed manner in each arena and were secured with insect pins (7 mm long). One 5- to 6-day-old virgin adult female *E. varivestis*, starved but water satiated for 24 hr, was randomly placed in each feeding arena. An individual beetle was used only once in the assays. Coumestrol was tested at 3.6, 1.8, 0.9, and 0.45 μg/leaf disk. The highest treatment value (3.6 μg) represents the saturation concentration of coumestrol in methanol. The average weight and abaxial surface area of a leaf disk was 1.39 mg and 56.6 mm^2, respectively. A series of the feeding arenas containing methanol-treated leaf disks was exposed to *E. varivestis*; this control treatment was termed 0.0 μg/leaf disk. This solvent–solvent control thus tested for potential biases in feeding preference due to the nontreatment conditions of the bioassay (i.e., positioning of the leaf disks, side effects due to lighting, etc.).

Each assay was conducted in darkness, or light, as indicated in an incubator at 25°C. The amount of feeding was monitored every 2 hr. Each assay was terminated when at least 50% of one leaf disk was consumed and a clear preference for one of the disks was established. If a preference was not observed, that individual assay was excluded from the analyses. The beetle was then removed from the arena and the disks were stored at 5°C until they were measured.

Quantitation of Feeding

The two leaf disks from each assay were mounted between two microscope slides and the areas were measured. Leaf disk images were scanned into files using a computer system which consisted of a Microtek MSF-300G image scanner (Microtek Lab, Inc., Torrance, CA), a Microtek MS-SCSI computer adapter, a MacIntosh II computer (Apple Computer, Inc., Cupertino, CA), and a GrayScan image scanning software program (Microtek Lab, Inc.). Images were analyzed for remaining disk area using the information extraction and reduction program, Collage (Image Dynamics, Madison, WI).

Statistics

The coumestrol concentrations in "Henderson" lima beans and "Davis" soybeans for all harvest times were evaluated by analysis of variance, and the differences between the individual means within a cultivar were separated with a least-significant difference test. The total means of coumestrol content for all harvest times were compared between "Henderson" lima bean and "Davis" soybean by a two-sample t test. Chi-square tests were used to generate the probabilities of insect feeding preference between coumestrol-treated and meth-

anol (solvent)-treated leaf disks. The chi-square tests were followed by Z tests to check for differences in feeding preference between and within the different coumestrol concentrations (SAS Institute, 1985).

RESULTS

Coumestrol in Plant Tissue

HPLC chromatographs of the resolved methanol extractables from apical "Henderson" lima bean and "Davis" soybean leaves are shown in Figure 1; the small resolved coumestrol peak is identified in each chromatograph. Cou-

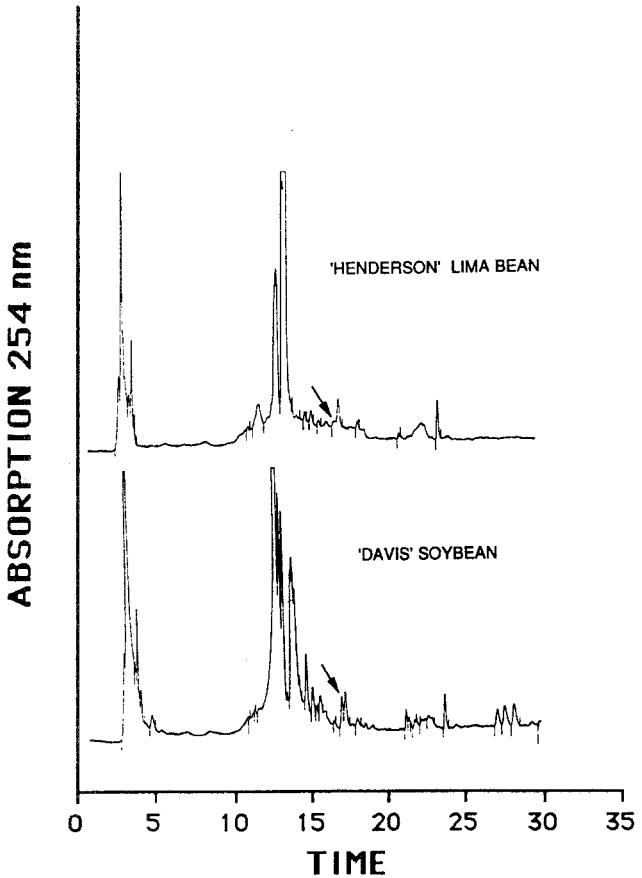

FIG. 1. HPLC chromatographs of methanol extractables from the leaves of "Henderson" lima bean and "Davis" *G. max*. The arrow marks the coumestrol peak in each chromatograph.

mestrol concentration was significantly lower ($P < 0.05$) in lima bean than in soybean. The standard line, $y = -435.36 + 511.4x$, used to quantify the coumestrol concentration in leaf tissue has $r^2 = 0.996$. Based on this curve, "Davis" soybean and "Henderson" lima bean leaves contained 0.069 and 0.018 μg coumestrol/mg dry leaf wt, respectively (Table 1). These data are averages of all samples from all harvest times (0–120 hr). There were 56 analyses for both "Davis" and "Henderson." Due to limitations in the peak recognition threshold of the HPLC integrator, 30 smaller "Henderson" coumestrol peaks were not integrated. Thus, there are fewer quantified peak area values for "Henderson" than for "Davis," thus resulting in a larger variance for "Henderson." The coumestrol peak was integrated in all of the 56 "Davis" analyses. The coumestrol concentration in "Henderson" and "Davis" at 24-hr intervals is also given in Table 1. The amount of coumestrol in "Davis" peaked to 0.092 μg/mg dry leaf wt at 72 hr. The relatively low coumestrol content of "Henderson" gradually increased with time but remained significantly lower than "Davis" except for 48 and 72 hr.

Bioassay Conditions

Bioassays were initially conducted in darkness. In these cases the cumulative percentage of assays completed in 12 hr was below 40% (Figure 2). A much higher percentage (>95%) of the bioassays was completed in 12 hr when they were conducted under light. The accelerated feeding rate of *E. varivestis* in light versus darkness is well illustrated by the difference in the percentage of

completed assays under the two conditions at 2 hr after the beginning of the assays (Figure 2).

Effects of Assayed Coumestrol on Insect Feeding

Dosages of 1.8 and 0.9 μg coumestrol/leaf disk caused a significant ($P < 0.05$) *E. varivestis* feeding preference for the methanol (solvent)-treated versus the coumestrol-treated lima bean disk (Figure 3). At 0.45 μg/leaf disk *E. varivestis* favored numerically the coumestrol-treated disk, but this difference was not statistically significant at $P < 0.05$. A neutral response was also obtained at the higher dosage, 3.6 μg/leaf disk. There was a significant ($P < 0.05$) difference in feeding preference between 0.9 μg/leaf disk and 0.3 and the 0.0 μg/leaf disk.

DISCUSSION

Coumestrol, an isoflavonoid in legumes, has received considerable study as an allelochemical (Hart et al., 1983; Smith, 1985; Rose et al., 1988; Sharma and Norris, 1991). The present study demonstrates that coumestrol can be a feeding deterrent to *E. varivestis* but that such antixenosis depends on concentration. There appears to be a small window between 0.9 and 1.8 μg coumestrol/leaf disk where coumestrol is antixenosic to *E. varivestis*.

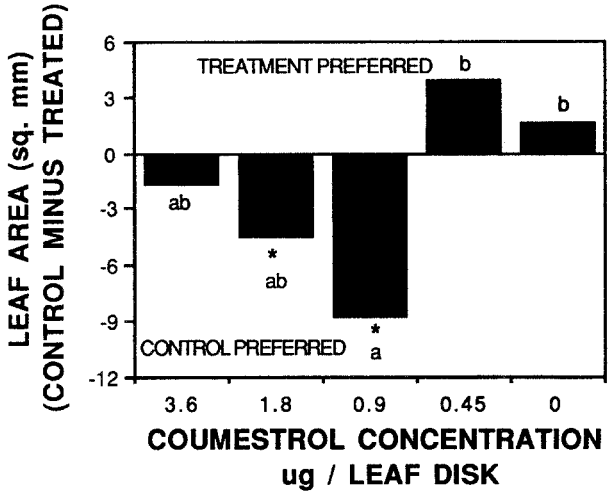

FIG. 3. Each bar represents the average nonconsumed leaf disk area for the coumestrol-treated disk subtracted from that area for the methanol-treated (solvent-control) disks. There were 84, 100, 66, 47, and 80 replicate bioassays for the concentrations of 3.6, 1.8, 0.9, 0.45, and 0.0 μg coumestrol/leaf disk, respectively. One asterisk (*) indicates a significant ($P < 0.05$) preference for the control versus the coumestrol-treated disk within a concentration. Bars labeled by the same letter are not significantly ($P < 0.05$) different.

Our bioassay results indicate that the constitutive antixenosic properties of "Davis" soybean apical leaves to *E. varivestis* apparently are not dependent on coumestrol. This conclusion is based on the fact that the "Davis" leaves contain about 10 (×)-fold less coumestrol than our smallest tested amount (0.7 μg coumestrol/mg dry leaf wt) which had a significant ($P < 0.05$) effect on the insect's feeding. The endogenous amount of coumestrol in the "Henderson" leaf disk used in the bioassays apparently would not have influenced *E. varivestis* feeding preference, because the amount, 0.018 μg coumestrol/mg dry leaf wt, is much below the minimum deterrent concentration of 0.7 μg/mg (0.9 μg/leaf disk).

The effect of coumestrol on feeding by other insects appears to depend also on concentration and on the species of insect. Lane et al. (1985) found that coumestrol at 0.2 to 2 × 10^{-3} μg/mg cellulose powder was not a significant feeding deterrent to the polyphagous root-feeding grass grub, *Costelytra zealandica* (White). Coumestrol at 200 μg/ml of cellulose powder (formed into a disk) deterred feeding in *Heteronychus arator* (F.) (Sutherland et al., 1980). Conversely, coumestrol at up to 1000 ppm was not a feeding deterrent to the pea aphid, *Acyrthosiphon pisum* (Harris) (Dreyer et al., 1987).

Coumestrol quantities do significantly change temporally. During a 5-day period the coumestrol concentration fluctuated in the nonhost "Davis" but just gradually increased in the host "Henderson." The plants were harvested at the same time each day, so it is doubtful that the variation is due to diurnal effects. These temporal changes probably reflect generic differences between *Glycine* and *Phaseolus*. Intraspecific variation in flavonoid concentrations is also known to occur, and this variation is often temporal (Bohm, 1987).

Developing a bioassay which adequately mimics the natural situation can be difficult. Our bioassay using leaf disks has the limitation that the distribution of the test chemical(s) in the total disk tissue is unknown. Because the coumestrol was topically applied to just the abaxial leaf surface (56.6 mm^2), it may be assumed that it was not uniformly distributed within the 1.4-mg dry weight disk. The resultant coumestrol per milligram of dry disk would vary with the percentage of the disk which actually received the chemical (Figure 4).

The timing of, and the environmental conditions for, antixenosic bioassays with *E. varivestis* were refined. The cumulative percentage of completed *E. varivestis* bioassays plateaued at 12 hr regardless of whether the tests were conducted in light or darkness. Similar results were reported by Jones et al. (1981). These combined results indicate that the more efficient bioassays with

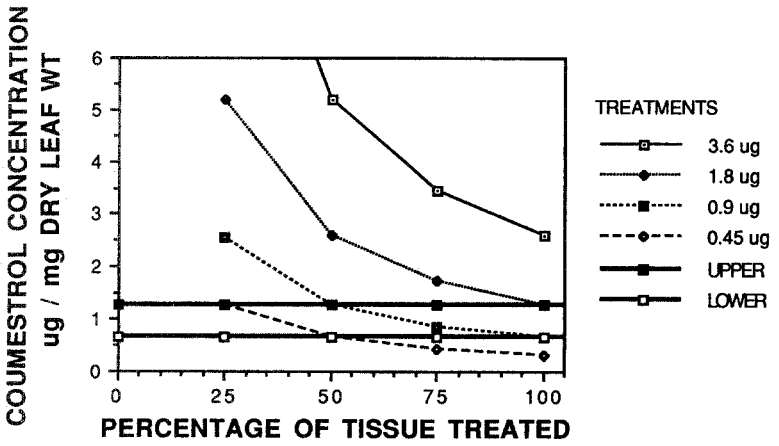

FIG. 4. Resultant coumestrol concentration per milligram leaf disk from each of the four quantities applied to the abaxial surface of the leaf disk assuming the indicated four percentages (*X* axis) of leaf disk tissue involvement. A significant *E. varivestis* preference for the methanol-treated (solvent-control) disk occurred in the two-choice assay with the two coumestrol treatments illustrated as upper (1.6) or lower (0.65) horizontal lines. The area between these two horizontal lines and the plot of each of the four applied amounts (0.45–3.6 μg coumestrol) per disk indicate the μg/mg concentrations which would exist assuming the indicated (*X*-axis) percentage of disk involvement.

E. varivestis should be conducted in light and do not need to extend beyond 12 hr.

The Collage measurement program used in this study increased the resolution of leaf area by 250 (×)-fold as compared to a LI-COR machine. The major basis for this improvement is that the Collage program resolves 1 pixel, which is 1/250 mm^2, whereas the resolution limit for the LI-COR machine is 1 mm^2. A second factor in the improved measurement is that the remaining *E. varivestis* "skeletonized" portion of the leaf tissue is not counted as "eaten area" by the densitometric-based Collage system, but is by the LI-COR machine.

Our results clearly indicate that statements regarding the constitutive antixenosic and antibiotic properties of given isoflavonoids to a given herbivore should include the involved plant cultivar(s), the specific compound, its detected concentration, and the specific involved plant tissue. Our overall findings indicate that the feeding response of a herbivore to a plant tissue is likely determined by the "net input" provided by the complex profile of negative and positive plant stimuli. In this regard, we are currently studying the temporal phenylpropanoid profiles of other host-versus-nonhost legumes of *E. varivestis*.

Acknowledgments—This research was supported by the College of Agricultural and Life Sciences, University of Wisconsin, Madison, and, in part, by funds from Graduate School Project No. 901145, Hatch Project No. 3040, and CRGO/USDA Research Grant No. 88-37153-4043. We are grateful to R. Bremel for the use of the Collage system and to J. Haanstad for the technical training in the Collage system.

Abstract—A bioassay system was developed to test the effects of volatile compounds on the growth of hyphae from germinating fungal spores. Volatiles from crushed tomato leaves inhibited hyphal growth of two fungal pathogens, *Alternaria alternata* and *Botrytis cinerea*. Aldehydes, including C_6 and C_9 compounds formed by the lipoxygenase enzyme pathway upon wounding leaves, inhibited growth of both fungal species. Terpene hydrocarbons, 2-carene and limonene, had no significant effect on hyphal growth. The quantities of volatile compounds in the vapor phase of the bioassay system were measured by direct headspace sampling and GC analysis.

Key Words—Headspace, aldehydes, *E*-2-hexenal, monoterpenes, lipoxygenase, spores, hyphae, wounding, *Lycopersicon esculentum*, *Alternaria alternata*, *Botrytis cinerea*.

INTRODUCTION

Previously, we screened foliage from several plant species to evaluate the effects of volatile compounds released from the tissues on pollen germination and growth *in vitro* (Hamilton-Kemp et al., 1991). Crushed tomato leaves emitted volatiles that were inhibitory, and among these the most active substances detected were unsaturated aldehydes derived from the lipoxygenase pathway [reviews by Galliard and Chan (1980) and Hatanaka et al. (1987)]. Since spores from pathogenic fungi may come in contact with volatiles from wounded or damaged leaves, we

decided to evaluate the effects of vapors from tomato leaves and the major classes of their volatile components, namely, terpenes and aldehydes, on spores of two widely occurring pathogens, *Alternaria alternata* (Fr.) Keissl. (*A. tennis* Nees) and *Botrytis cinerea* Pers. ex Fr. (Nyvall, 1979). A bioassay for these fungi was developed and the concentrations of individual compounds in the vapor phase to which the organisms were exposed were estimated by GC analysis.

METHODS AND MATERIALS

Fungal cultures were established by isolating *A. alternata* from lesions of tobacco leaves onto V-8 juice agar saturated with $CaCO_3$ at pH 6.2 (Spurr, 1973) and maintained on this medium. *B. cinerea* was isolated from infected strawberry fruit, established on potato dextrose agar, and maintained on V-8 juice agar at pH 7.2. Both cultures were kept at laboratory temperature (24 ± 2°C) and continuous fluorescent lighting was used to stimulate sporulation of *A. alternata*.

The system developed to test effects of volatiles on conidiospores from *A. alternata* and *B. cinerea* is shown in Figure 1. Spores were placed on a 1-cm^3 block of 2% water agar by adding a drop of spore suspension or brushing the spores over the surface of the block with a sterile cotton swab followed by the addition of a drop of water. The agar block had been placed in the bottom portion of a 5-cm-diameter glass petri dish. This dish was in a 9-cm-diameter glass petri dish which contained either crushed leaf tissue or a 1-cm-diameter glass sample dish. The sample dish contained 1 ml of water, to which 10 μl of a solution of the test compound (10 μl of solvent in controls) was added. The

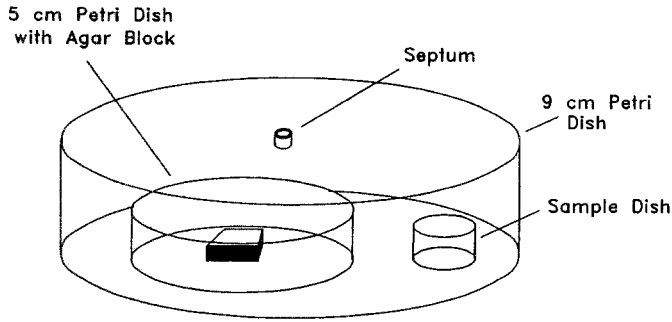

FIG. 1. Bioassay system for testing the effects of volatile compounds on *A. alternata* and *B. cinerea*. Spores were spread on the surface of the 2% water agar block and 10 μl of a solution of the volatile test compound was placed in the sample dish. Headspace samples from the system were withdrawn through the septum with a syringe and analyzed by GC. At the conclusion of an experiment hyphal lengths were measured.

top cover of the large petri dish was placed over the system (volume 120 ml), which was wrapped with Parafilm. All glassware was sterilized prior to setup of an experiment, and the spores were handled under aseptic conditions. The bioassays with *A. alternata* were carried out for 5–6 hr, and those with *B. cinerea* were for 12–14 hr.

At the conclusion of an experiment, the hyphal lengths were measured using a microscope with a net micrometer ocular at 100× magnification. (A drop of neat *E*-2-hexenal could be added to the 9-cm petri dish to stop a bioassay and permit subsequent measurements at a convenient time.) At least two petri dishes were set up for each concentration of compound evaluated. The lengths of five hyphae from each agar block were measured, means calculated, and the data analyzed statistically by analysis of variance.

For bioassays of plant tissue, 5-g samples of immature succulent leaves from " Mountain Pride" tomato plants grown in a greenhouse were harvested and crushed with a mortar and pestle.

Synthetic samples of volatile aldehydes tested in bioassays, *E*-2-hexenal, hexanal, and *E*-2-nonenal, were dissolved in 1,2-propanediol (Sigma). Nonanal, 2-carene, and (*D*)-limonene were dissolved in paraffin oil 335/350 (Fisher) due to insolubility in 1,2-propanediol. The solutions were prepared as for the pollen experiments; that is, a 10% solution (w/w) of the test compound was made and diluted serially (w/w) to obtain 1 and 0.1% solutions.

A rubber septum was fitted into a hole within the top cover of the bioassay system (Figure 1). The concentrations of *E*-2-nonenal and nonanal in the vapor phase within the bioassay dishes were determined at 24 ± 2°C after 1 hr in a manner similar to that described for pollen bioassays (Hamilton-Kemp et al., 1991). (The vapor phase concentrations of the remaining compounds had been determined earlier.) A 250-μl sample of headspace vapor from the bioassay system was withdrawn through the septum with a gas-tight syringe and injected into a Varian 3700 GC equipped with a 0.53 mm × 1-m fused silica precolumn and a 0.53 mm × 30-m DB-wax (polyethylene glycol) or DB-5 (methylsilicone) column for *E*-2-nonenal and nonanal, respectively. The operating conditions were as follows: inlet, 220°C; column oven, 50°C for 3 min, then programmed at 2°/min to 200°C; FID, 240°C; He flow rate, 6 ml/min. The response factors for the volatiles on the GC were determined using a 2-liter static dilution bottle following an EPA method (Winberry et al., 1988) using argon for dilution.

RESULTS AND DISCUSSION

The bioassay system used in these studies provided a convenient means for testing the effects of volatile compounds on spore germination and hyphal growth. The spores could be spread over the top surface of the agar block and kept moist during the bioassay. Hyphal lengths in controls and treatments were readily

measured on the agar surface. The vapor phase levels of compounds within the bioassay system could be measured by withdrawing gas samples through the rubber septum using a gas-tight syringe and analyzing them by capillary GC.

The results obtained from exposure of *A. alternata* and *B. cinerea* spores to compounds emitted by crushed tomato leaves are shown in Figures 2 and 3. In the case of both organisms the length of hyphae which emerged after germination was significantly inhibited by foliage vapors. Hyphal length was subsequently used to evaluate the effects of individual compounds at various concentrations. Tube growth from germinated pollen in earlier bioassays (Hamilton-Kemp et al., 1991) was not as markedly affected as hyphal growth by vapor phase concentrations of volatiles.

Tomato leaf tissue is known to produce lipoxygenase pathway-derived volatile compounds such as *E*-2-hexenal and hexanal, which increase markedly

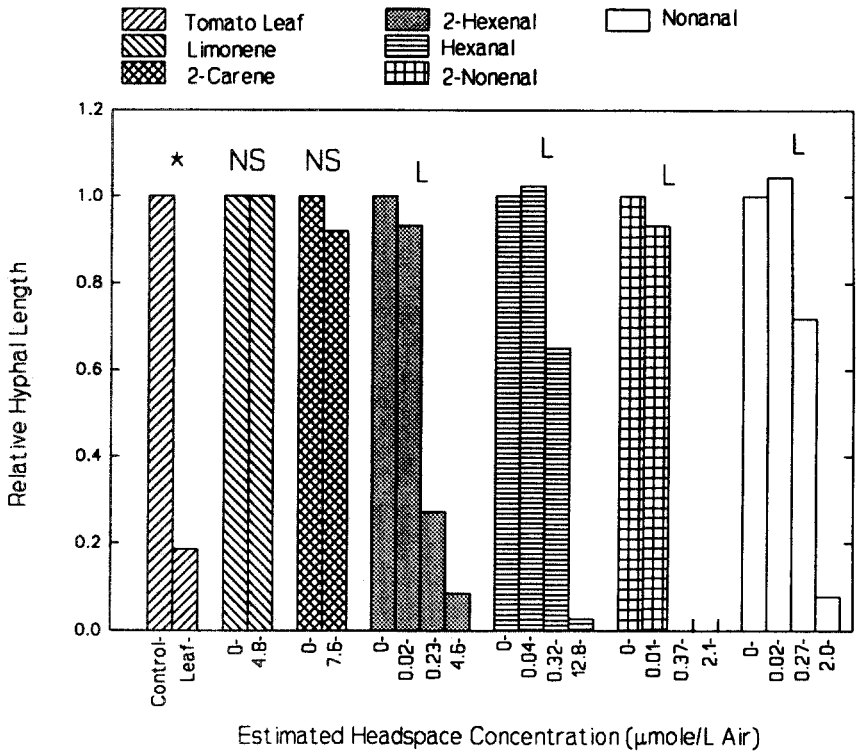

FIG. 2. Lengths of hyphae, relative to controls, after exposure of *A. alternata* spores to crushed leaves and various vapor phase concentrations of aldehydes and monoterpene hydrocarbons. An asterisk denotes a significant difference, and NS no significant difference, between means at $P < 0.05$ using Student's t test. L denotes a significant linear correlation ($R^2 > 0.90$) between hyphal length and volatile concentrations.

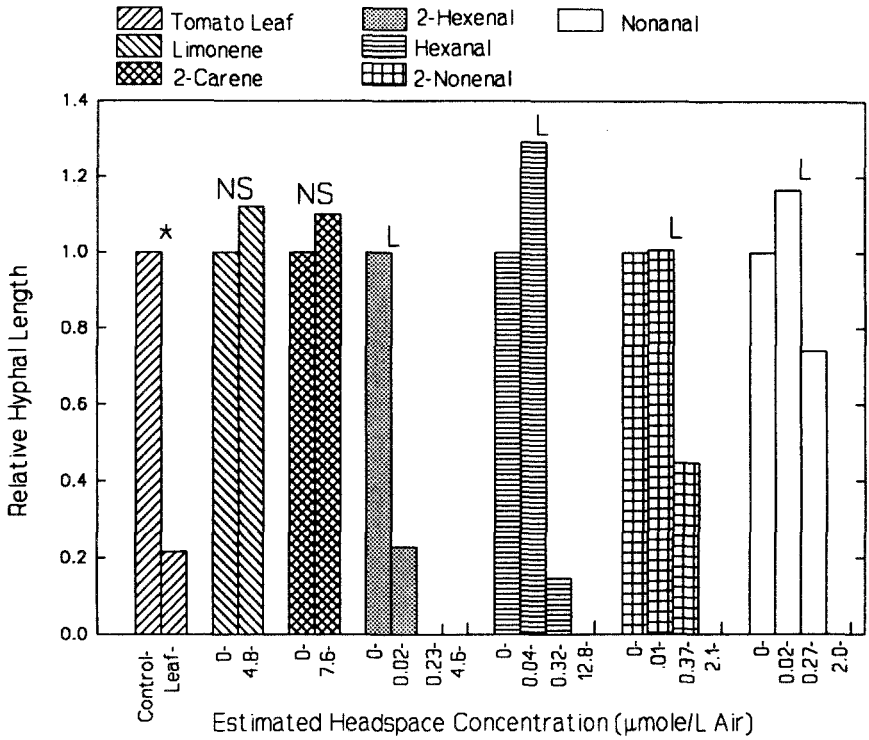

FIG. 3. Lengths of hyphae, relative to controls, after exposure of *B. cinerea* spores to crushed leaves and various vapor phase concentrations of aldehydes and monoterpene hydrocarbons. An asterisk denotes a significant, and NS no significant, difference between means at $P < 0.05$ using Student's t test. L denotes a significant linear correlation ($R^2 > 0.90$) between hyphal length and volatile concentrations.

upon wounding (Buttery et al., 1987; Hamilton-Kemp et al., 1991). Preliminary tests indicated that the amounts of these compounds released depended on the stage of development of the leaves, and young expanding leaves emitted the largest quantities of lipoxygenase pathway products. In addition, tomato leaves also released monoterpene hydrocarbons as the other major fraction of their volatile component emission.

Bioassays with synthetic samples of the tomato leaf components *E*-2-hexenal and hexanal showed that these compounds inhibited *A. alternata* hyphal growth (Figure 2). These compounds were tested by adding the three levels of solutions as described under Methods and Materials to the bioassay system and the resultant mean concentrations of compounds in the headspace vapor phase as estimated by GC are shown in Figure 2. Tests with vapors from neat solvents indicated that these materials alone had no significant effects on the growth of

fungal hyphae. *B. cinerea* spores responded similarly to those of *A. alternata* when exposed to the six-carbon aldehydes (Figure 3). Bioassays of the homologous nine-carbon aldehydes, *E*-2-nonenal and nonanal, showed that these volatile compounds also inhibited hyphal growth in both fungal species (Figures 2 and 3). The results obtained after treatment of *A. alternata* spores with the highest concentration of *E*-2-nonenal compared to the results with a control are shown in Figure 4. The nine-carbon homologues are found in certain crushed tissues such as wheat leaves (Hamilton-Kemp et al., 1987).

In previous studies we found that the concentration of *E*-2-hexenal produced by 5 g of crushed tomato leaves in the bioassay system was approximately 0.2 μmol/L air (Hamilton-Kemp et al., 1991). As noted above, there was inhibition of hyphal growth for both fungi observed at this concentration of *E*-2-hexenal. Thus, it appears that the level of this compound in the vapor phase was high enough to contribute significantly to the inhibition observed in crushed tomato leaf tests.

Among the aldehydes studied, *E*-2-hexenal has often been reported previously as an inhibitory compound in processes such as seed germination (Bradow and Connick, 1990; Gardner et al., 1990), fungal spore germination (Major et al., 1960), mycelial growth (Urbasch, 1984; Zeringue and McCormick, 1989), and protozoan movement (Schildknecht and Rauch, 1961).

Tests with other major types of volatile components from crushed tomato

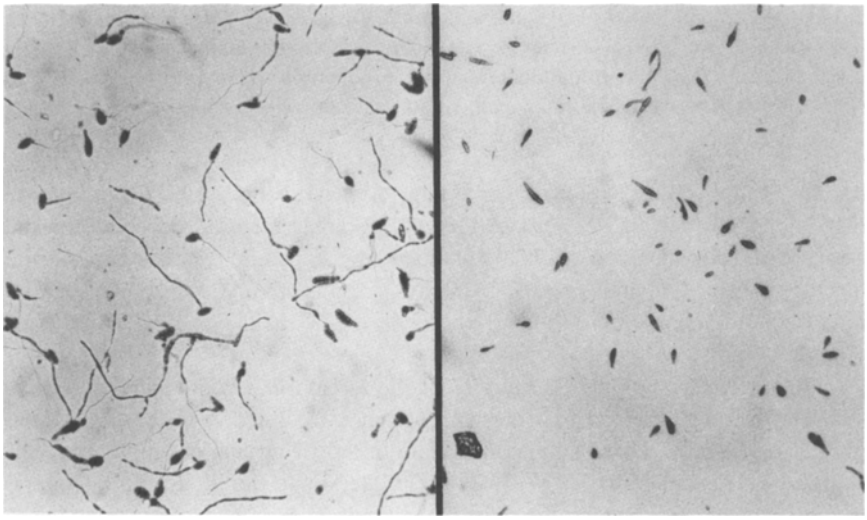

FIG. 4. Photomicrographs of bioassay of *Alternaria alternata* spores after 6 hr: (l) control and (r) *E*-2-nonenal (2.1 μmol/L air).

leaves, terpene hydrocarbons, were also carried out. The commercially available terpenes, 2-carene and limonene, at concentrations comparable to the highest concentrations of the aldehydes tested had no significant effect on either *A. alternata* or *B. cinerea* (Figures 2 and 3). The bioassay vapor phase concentrations of 2-carene and limonene were 7.6 and 4.8 μmol/L and greatly exceeded the levels produced by tomato leaves, 0.2 and 0.1 μmol/L air (Hamilton-Kemp et al., 1991). Hence these terpenes did not contribute to the inhibition produced by crushed tomato leaves. However, the possibility cannot yet be excluded that there are certain synergistic or additivity effects on the bioactivity of volatiles that result from the combination of the various compounds released from the crushed leaf tissue.

The observation that crushed tomato leaves inhibited growth of both *A. alternata* and *B. cinerea* hyphae was consistent with the inhibition exhibited by crushed leaves against pollen in earlier studies. In addition, the observation that the aldehyde components but not the terpene hydrocarbon components inhibited the fungi also agrees with the results for pollen. In pollen bioassays, the α,β-unsaturated aldehyde, *E*-2-hexenal, was considerably more active than the saturated aldehyde, hexanal. The unsaturated aldehydes, *E*-2-hexenal and *E*-2-nonenal, appeared to be more active than their saturated counterparts in bioassays with both fungal species, although the differences were not as pronounced as in the pollen bioassays.

Two compounds that were identified in tomato earlier, the monoterpene β-phellandrene and *Z*-3-hexenal, were not available commercially and were not tested. Synthetic *Z*-3-hexenal was inhibitory to pollen; however, this compound can isomerize enzymatically (Phillips et al., 1979) or chemically rearrange to *E*-2-hexenal and a similar reaction may have occurred with pollen.

Previous studies showed that α,β-unsaturated aldehydes can react with thiol groups in proteins or form Schiff's bases with amino groups as described by Schauenstein et al. (1977). Also, certain members of this class of compounds oxidize and form adducts with DNA (Sodum and Chung, 1989). Saturated aliphatic aldehydes were found to react with tryptophan residues to cause protein cross-linking as described by Kaneko et al. (1989). However, the mode of action of the aldehydes in inhibiting the growth of fungal hyphae remains to be elucidated. One area which merits investigation in the future is the interaction of volatile compounds with fungal membranes.

The concentrations of volatile aldehydes produced at the boundary layer of plant tissues after wounding and during infection processes involving fungal pathogens are not known. Since plants are capable of rapidly producing lipoxygenase pathway-derived aldehydes such as 2-hexenal, which are inhibitory to fungal growth, future studies are needed to clarify the possible role of natural volatile compounds in plant–fungal interactions.

Urbasch (1984) studied the effects of *E*-2-hexenal and hexanal, referred to

as wound gases from tomato leaves, on the radial growth of a culture of *B. cinerea*. She found that *E*-2-hexenal was more inhibitory than hexanal when aliquots of the neat liquids were compared. Levels of the vapors in the bioassay dishes to which the cultures were exposed during the experiments were not reported. Urbasch (1987) subsequently showed that *B. cinerea* cultures converted *E*-2-hexenal to the corresponding unsaturated alcohol, *E*-2-hexen-1-ol, or to 1-hexanol. Wilson et al. (1987) recently tested the effects of fruit volatiles on spore germination and fungal growth and found that aromatic compounds such as benzaldehyde inhibited germination and growth of *B. cinerea*.

French and co-workers, in numerous studies on fungal pathogens that cause rusts and other diseases, showed that several volatile compounds stimulate germination (French and Gallimore, 1971; French et al., 1977; French, 1990). In the present work, the saturated aldehydes, hexanal and nonanal, appeared to stimulate hyphal growth at their lowest concentrations. However, further studies involving additional dilutions would be needed to establish such an effect.

Interpreting these data, it seems useful to note results in which both organisms (which represent different genera) gave a similar response, such as inhibition of hyphal growth caused by the aldehydic function and the absence of effects resulting from exposure to terpenes. The specific response observed for one organism to a single compound, for example, should probably be interpreted cautiously since several variables such as the strain of the organism and culture conditions could affect the results of an experiment. Accordingly, only general trends observed for both organisms are noted here.

In conclusion, a rapid, simple bioassay system for the evaluation of the effects of volatile compounds on fungal spore germination and hyphal growth has been developed. Volatile compounds produced by crushed tomato leaves inhibited growth of both *A. alternata* and *B. cinerea* hyphae. Aldehydes which constitute a major group of volatiles from the leaves were inhibitory, whereas the terpene hydrocarbons 2-carene and limonene yielded no significant effect on hyphal growth. The results with aldehydes and terpenes were similar to those observed earlier in pollen bioassays.

(Received October 7, 1991; accepted February 25, 1992)

Abstract—In field tests synthetic (3*E*,5*Z*)-3,5-tetradecadienyl acetate was found to attract large numbers of males of *Recurvaria leucatella* Clerck into sticky traps. The other geometrical isomers did not influence catches. Of the corresponding monoenic compounds, (3*E*)-3-tetradecenyl acetate was highly attractive to a close relative, *Recurvaria nanella* Hübner. The catches of the latter species were suppressed by higher amounts of (5*Z*)-5-tetradecenyl acetate added to the bait, and the addition of (3*E*)-3-tetradecenol or (3*Z*)-3-tetradecenyl acetate was without effect. The attractive compounds can be used in traps for monitoring the two pests.

Key Words—Sex attractant, (3*E*,5*Z*)-3,5-tetradecadienyl acetate, (3*E*)-3-tetradecenyl acetate, (5*Z*)-5-tetradecenyl acetate, *Recurvaria leucatella*, *Recurvaria nanella*, Lepidoptera, Gelechiidae

INTRODUCTION

Presently, there are several hundred moth species for which sex pheromone components have been identified (Arn et al., 1986; Mayer and McLaughlin, 1991). Information can be obtained on the types of chemical structures involved

*To whom correspondence should be addressed.

in reproductive communication of Lepidoptera from conventional, complete, identification projects or by screening compounds structurally similar to known pheromones. Such sex attractants, once established, can be applied in practical, plant-protection programs by similar methods as natural pheromonal products, despite the fact that their natural occurrence in the female emitted pheromone has not been firmly established. In the present paper, we report the discovery of two sex attractants for orchard pests; the white-barred groundling moth (*Recurvaria leucatella* Clerck) and the lesser bud moth (*R. nanella* Hübner) (Lepidoptera: Gelechiidae).

METHODS AND MATERIALS

Instrumentation

Instrumentation used in the purifications and final analyses included a Hewlett-Packard Model 5890A gas chromatograph equipped with a split injection system. The column was a 50 m × 0.32-mm-ID, 0.25-μm film thickness, 007 series methyl silicone (Quadrex Corporation, New Haven, CT). The oven temperature was held at 60°C for 1 min, then programmed to 160°C at 40°C/min and held at that temperature for 47 min. High-performance liquid chromatography was performed with a Kratos Spectroflow 400 solvent delivery system with the mobile phase (ethyl acetate–hexane, 0.35:99.65) delivered at a flow rate of 5.0 ml/min. A Kratos Spectroflow 757 variable-wavelength ultraviolet absorbance detector set at 230 nm was used for sample detection. The column used was 250 × 12.5-mm-ID stainless steel, packed with Lichrosorb 60 (5 μm) (E. Merck).

Chemicals

The four isomers (E,Z; E,E; Z,E; Z,Z) of 3,5-tetradecadienyl acetate were prepared as described by Doolittle and Solomon (1986). The monoene acetates and alcohols were either purchased from commercial sources or synthesized by standard, well-documented procedures (Sonnet, 1984; Mori, 1979, 1981; Henrick, 1978; Rossi, 1977) and were purified by high-performance liquid chromatography (HPLC) on silver-nitrate-impregnated silica gel as described by Heath et al. (1977). Gas chromatographic analysis by capillary gas chromatography (GLC) as described by Doolittle and Solomon (1986) gave isomeric purities >99%; overall purities were >99.8%.

Purification of Diene Acetates

(3Z,5E)-3,5-Tetradecadienyl Acetate. The material used for this purification contained small amounts (≤2%) of each of the other three isomers. The E,E isomer was removed by treatment with an excess [relative to the estimated

(GLC) amount of E,E present] of *N*-phenylmaleimide in benzene. This produced a Diels-Alder adduct that could be removed from the diene acetates by simple gravity flow chromatography on a silica-gel column with hexane as the eluting solvent. The remaining two isomers were removed by HPLC on the column described above. The final GC analysis on the product used in the 1990 field test had traces of E,E, Z,Z, and E,Z lower than 0.1% (which was our detection limit).

The diene alcohols were purified by low-temperature recrystallization from dilute (10%) solutions in hexane using a modification (Figure 1) of equipment described by Schlenk (1961). The temperature in the apparatus was reduced slowly and uniformly, then held at that temperature where crystals of each alcohol began to form, by circulating methyl alcohol through the coil in the apparatus from a thermostatically controlled Multi-Cool Model MC-8-80A-2 low-temperature circulating system (FTS Systems, Inc., Stone Ridge, NY). The purified alcohols were subsequently acylated with acetic anhydride by standard techniques.

The analyses (GLC) of the diene acetates used in the 1990 field tests were as follows:

E,E had 0.26% Z,Z, 0.4% E,Z, and 0.4% Z,E.
E,Z had 0.5% E,E and $\leq$0.1% Z,E and Z,Z.
Z,Z had 1% Z,E, 1% E,Z, and 1.7% E,E.

The purities (GLC) of the diene acetates tested in 1987 and 1989 were as follows:

E,Z had 2.5% E,E, 1.2% Z,Z, and 1.2% Z,E.
E,E had 0.4% Z,Z, 4.0% E,Z, and 3.6% Z,E.
Z,Z had 2.5% Z,E, 2.3% E,Z, and 0.66% E,E.
Z,E had 5.5% E,Z, 4.8% Z,Z, 5.8% E,E.

Dispensers

The diene acetates were impregnated into 11-mm silicone rubber stoppers (Wheaton Co., Millville, NJ; Catalog No. 224091). The stoppers were extracted with methylene chloride before use. The test samples were placed on the stoppers as dilute solutions in hexane (50–200 μl) and the solvent was allowed to evaporate in a fume hood in a stream of air for a minimum of 24 hr, then sealed in screw-cap jars. The jars were stored in a freezer (-30°C) except while in transit to Hungary. Sustane 6 (Universal Oil Products Co., East Rutherford, NJ) was added to all samples at a ratio of 10 parts Sustane 6 to 1 part test chemical. Sustane 6 is a food-grade antioxidant containing tertiary-butyl-4-hydroxyanisole (BHA) and 2,6-ditertiary-butyl-4-methylphenol (BHT) in corn, cottonseed, or

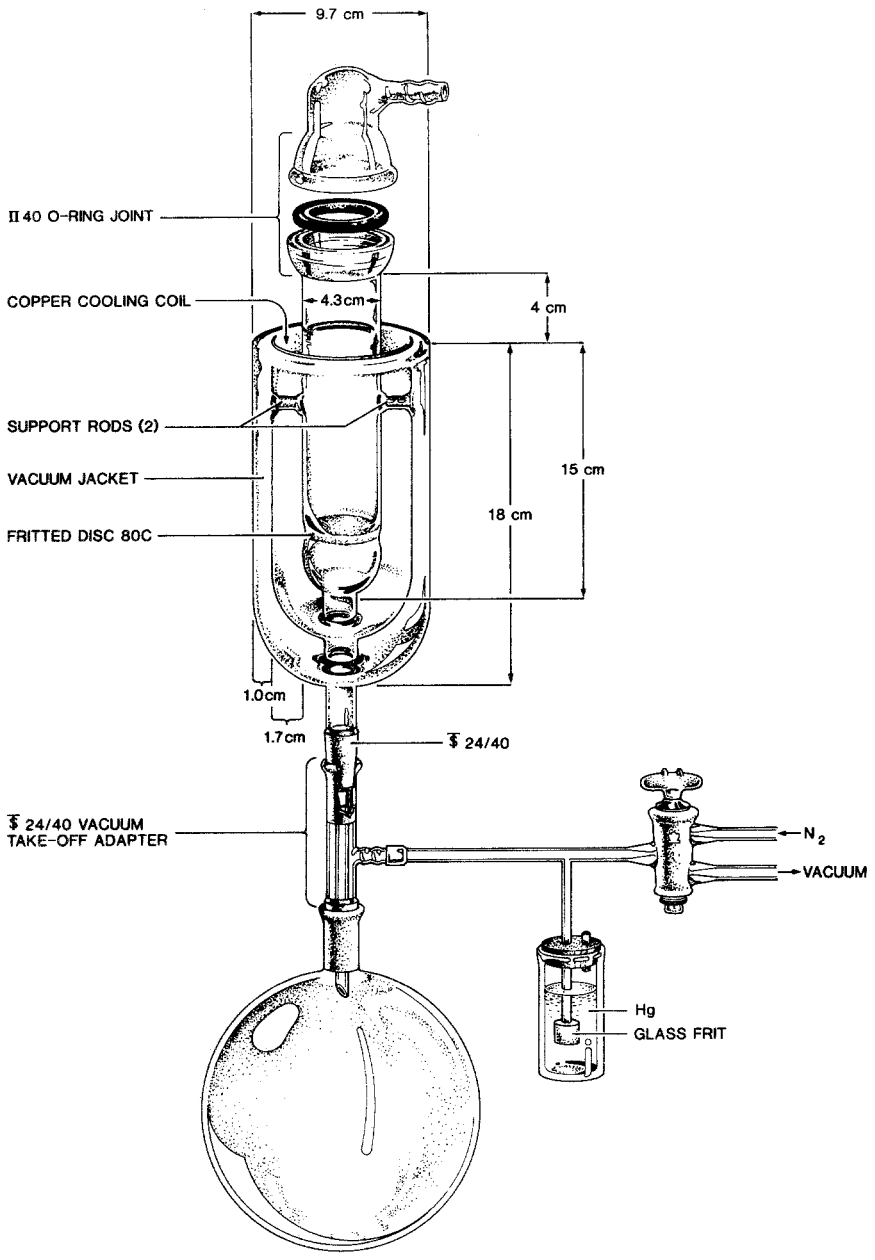

FIG. 1. Low-temperature crystallization apparatus used in purification of synthetic tetradecadienols.

soybean oil and has been used routinely in field tests with these diene acetates (Doolittle et al., 1976a, 1980).

Dispensers for tests with monoenes were prepared in Budapest, using pieces of rubber tubing (Taurus, Budapest, Hungary; No. MSZ 9691/6; extracted three times in boiling ethanol for 10 min, then three times in methylene chloride overnight, prior to usage). To make each lure, the required amounts of compounds were administered to the surface of the dispensers in hexane solutions. Prepared lures were stored at −65°C until use.

Trapping

Field tests were conducted at the Julianna major Experimental Station of the Plant Protection Institute, Hungarian Academy of Sciences, Budapest (Hungary), in an apple orchard (*R. nanella*), or at the edge of an apple orchard and a mixed oak forest (*R. leucatella*). In the tests triangular traps with removable sticky inserts made from polyethylene sheets, similar in shape and size to those described by Arn et al. (1979), were used. Traps were suspended 1.5 m above the ground from the branches of orchard trees. Traps containing different lures were set up in rectangular blocks. The distance of traps within a block was 4–5 m. The distance between blocks ranged from 100 to 1000 m. Traps were moved one position forward within a block at each occasion when the traps were inspected. At the same time, the number of captured males was recorded and sticky inserts changed to new ones. In statistical analyses, capture data were transformed to $\log(x + 1)$ and differences between means were tested for significance by Duncan's new multiple-range test (DNMRT). Catch of a trap at an inspection was taken as a replicate.

RESULTS

R. leucatella

When the four geometrical isomers of 3,5-tetradecadienyl acetate and the corresponding alcohols were screened preliminarily in 1987 in Hungary, large catches of male *R. leucatella* were observed at two sites in traps baited with 100 μg of (3*E*,5*Z*)-3,5-tetradecadienyl acetate [E3Z5-14Ac; names of compounds are abbreviated according to Arn et al. (1986)]. Few males were caught in traps baited with the other acetates. The alcohols alone or added to the active acetates did not increase catches.

In more detailed tests conducted in 1989, aimed at the comparison of the activity of the different geometrical isomers of the acetate, the E,Z isomer was the most effective (Table 1). Again, fewer moths were caught in some traps baited with the other three isomers. We hypothesized that the small catches by the other isomers can be attributed either to the low attractive activity of the

[a] For each treatment four traps were set up. Traps were inspected at 2- to 3-day intervals. Means followed by the same letter are not significantly different at $P \leq 0.05$ (DNMRT).

compound itself or to the small amounts of the E,Z isomer known to be in the synthetic samples. Since the numbers attracted to the respective baits were similar when bait dispensers were renewed at 2- to 3-day intervals or when the same dispenser was used throughout the test period (Table 1; $t = 1.43$, $F = 23$; not significantly different in comparison to baits containing E3Z5-14Ac by Student's t test), the ratio of the E,Z isomer in the samples did not seem to increase through isomerization under the field conditions of this test.

No moths were caught in traps baited with the corresponding monoenic acetates or in traps baited with a 1 : 1 mixture of (3*E*)-3-tetradecenyl and (5*Z*)-5-tetradecenyl acetates (E3-14Ac; Z5-14Ac) (Table 1), showing that attractive activity was restricted to the dienic compound.

The comparison of the activity of the isomers was evaluated again in 1990 using newly purified samples (Table 2). The purities of the samples used in the 1990 tests are listed under Methods and Materials. In these tests, only the purified E,Z isomer showed attractive activity; catches of the other acetates did not differ significantly from the controls.

In a test designed to determine the possible effect of the addition of small amounts of the other isomers to E3Z5-14Ac, no significant effect was observed by addition of the other three isomers to the E,Z isomer (Figure 2). When pure E3Z5-14Ac was compared with a mixture containing this isomer and 3% of each of the other three isomers, no difference was observed between catches of the two treatments at any of the dose levels tested (Figure 3). Finally, in a dosage test of pure E3Z5-14Ac, traps baited with 3000, 1000, 300, 100, 30, 10, 3, and 1 μg captured an average of 35.80 (a), 22.10 (b), 6.60 (c), 4.35 (c), 2.75 (d), 1.10 (d), 0.25 (e), and 0.20 (e) males (per trap per inspection; means followed by the same letter are not significantly different at $P \leq 0.05$ by DNMRT), respectively.

TABLE 2. CATCHES OF MALES OF *R. leucatella* IN TRAPS BAITED WITH 3,5-TETRADECADIENYL ACETATES (JUNE 28–JULY 2, 1990)[a]

Chemical applied to lure (μg)				Mean No. of males/ trap/inspection (SE)
Z3E5-14Ac	Z3Z5-14Ac	E3Z5-14Ac	E3E5-14Ac

—	—	100	—	6.87 a (1.42)
—	—	—	100	0.00 b (0.00)

[a]From each treatment 10 traps were set up. Traps were inspected daily. Means followed by the same letter are not significantly different at $P \leq 0.05$ (DNMRT).

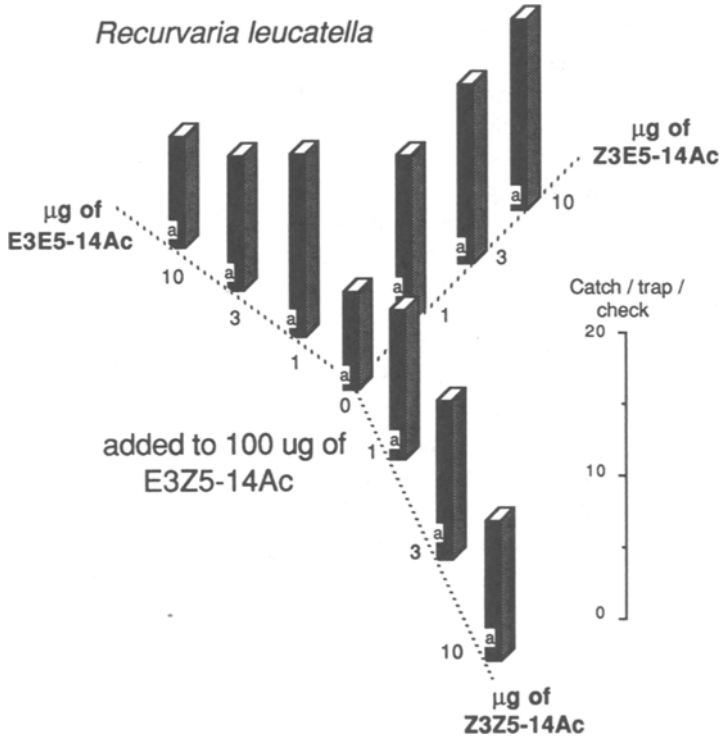

FIG. 2. Catches of male *R. leucatella* in traps baited with E3Z5-14Ac and its binary mixtures with the geometrical isomers (June 28–July 2, 1990). Ten traps of each treatment were used. Traps were inspected daily. Columns labeled with the same letter are not significantly different at $P \leq 0.05$ by DNMRT.

R. nanella

In the 1989 tests, which were originally aimed at studying *R. leucatella* (results shown in Table 1), traps baited with 100 µg of E3-14Ac caught a total of 578 specimens of *R. nanella* males, a close relative to *R. leucatella*. No other compounds caught any males of *R. nanella* in this test, and the mixture of E3-14Ac with Z5-14Ac was not attractive.

In the 1990 tests, the effect of the addition of the corresponding geometrical isomer (3*Z*)-3-tetradecenyl acetate (Z3-14Ac), and of the corresponding alcohol (3*E*)-3-tetradecenol (E3-14OH), to E3-14Ac was determined (Figure 4). No significant change in catches was observed when these compounds were added at 3, 10 or 30% to E3-14Ac (Fig. 4A). However, since catches with the lower amounts of the alcohol or with the highest amount of Z3-14Ac added were numerically higher than in traps with E3-14Ac alone, further binary and ternary

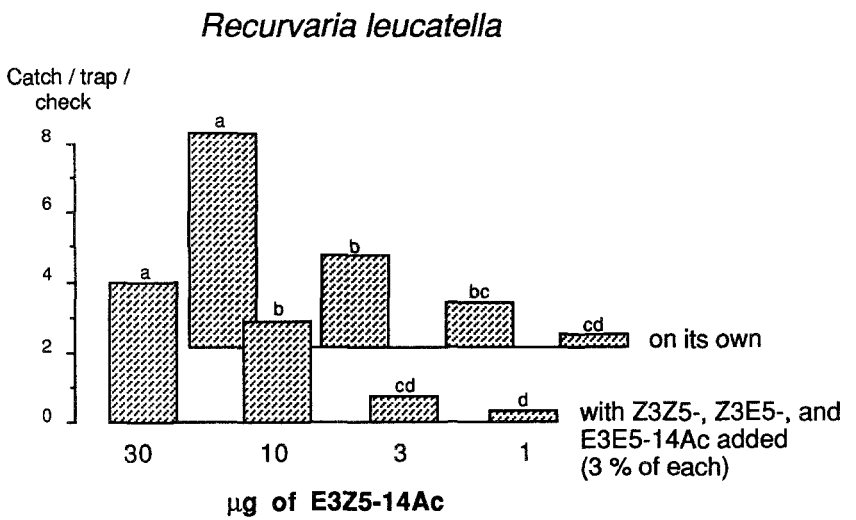

FIG. 3. Catches of male *R. leucatella* in traps baited with different dosages of E3Z5-14Ac or a quaternary mixture containing all four geometrical isomers (July 10–20, 1990). Five traps of each treatment were used. Traps were inspected each second day. Columns labeled with the same letter are not significantly different at $P \leq 0.05$ by DNMRT.

combinations of the three compounds were compared. In this test, none of the combinations caught significantly higher numbers of moths compared to the catch of pure E3-14Ac (Figure 4B).

When Z5-14Ac was tested in binary mixtures with E3-14Ac, the addition of 3 or 10% was without significant effect, while the addition of 30% decreased catches (Table 3). This agreed with the results of the 1989 test, where no insects were caught with a 1 : 1 mixture of the two compounds (Table 1).

In a dosage test of E3-14Ac, equally high numbers of males were caught by 3000, 1000, and 300 µg (Table 4). Significantly less males were caught at lower doses.

DISCUSSION

In the present study, E3Z5-14Ac and E3-14Ac were established as male sex attractants for the orchard pests *R. leucatella* and *R. nanella*, respectively. The described compounds can be used in amounts of 1 mg as baits in traps for monitoring the respective pest species.

E3-14Ac has already been found to attract one other gelechiid, *Chionodes perpetuella* H. Sch. (Priesner, 1987). The corresponding Z isomer has also been reported as sex attractant in a number of other gelechiids (Priesner, 1987). The

shorter-chain length homologue, (3*E*)-3-dodecenyl acetate, besides being attractive to some gelechiids in the field (Priesner, 1987; Renou et al., 1980), has been found in the pheromone of *Scrobipalpa ocellatella* Boyd. (Renou et al., 1980) and *Scrobipalpopsis solanivora* Povolny (Nesbitt et al., 1985). (3*E*)-3-Tridecenyl acetate, a similar compound having an odd number of carbons in its chain, has been identified from the pest *Scrobipalpa heliopa* Lower (Baker et al., 1985). So far, tetra-, tri-, or dodecenyl compounds with an unsaturation at the δ3 position have been described almost exclusively from Gelechiidae. The only exception is the cossid *Prionoxystus robiniae* Peck (Doolittle and Solomon, 1986), where E3-14Ac was found to synergize the attraction of (3*Z*,5*E*)-3,5-tetradecadienyl acetate.

The compound attracting *R. leucatella* in this investigation, E3Z5-14Ac, has not been described as a pheromonal component for any other species. Its geometrical isomers have been known to attract the cossids *Acossus centerensis* Litner (Doolittle et al., 1976b), *Prionoxystus piger* Grote (Landolt et al., 1985), and *P. robiniae* (Doolittle et al., 1976a; Doolittle and Solomon, 1986). The occurrence of this structure in gelechiids is not unexpected, as isomers of the shorter-chain length homologue, (3*E*,5*Z*)-3,5-dodecadienyl acetate, and (3*Z*,5*E*)-3,5-dodecadienyl acetate attract males of *Chionodes lugubrella* Fabr. (Reed and Chisholm, 1985).

At present, it is not known whether the attractant chemicals described in the present investigation are components of the sex pheromones of female *R. leucatella* and *R. nanella*. The compounds share chain length (14 carbons), functional group (acetate), and 3*E*-unsaturation. If indeed they represent the major components of the natural pheromone, the possible evolutionary splitting of these two *Recurvaria* species may have happened via pheromone biosynthesis mutation, i.e., the introduction of a second double bond into E3-14Ac at the fifth carbon atom, yielding E3Z5-14Ac. More effective reproductive isolation of the *leucatella* form from the *nanella* form may have resulted from the apparent inhibitory activity of the 5*Z* double bond toward males of the latter form. The inhibitory activity of Z5-14Ac toward *R. nanella* in this study may represent indirect evidence supporting the above hypothesis.

Acknowledgments—The research in Hungary was partially supported by Grants OTKA and OMFB of the Hungarian Academy of Science. The authors are indebted to Drs. Gy. Sziràki and Cs. Szabòky (Budapest) for checking the species identity of the moths captured and to Dr. G. Szöcs for suggestions in the course of making up the manuscript.

Abstract—Tall fescue (*Festuca arundinacea* Schreb.) is a C-3 perennial grass noted for its persistence in harsh environments. Tall fescue persistence is enhanced by *Acremonium coenophialum*, a mutualistic fungal endophyte that increases resistance to drought, pathogens, and insects. This research was conducted to identify and elicit biochemical mechanism(s) that could account for tall fescue persistence. In initial studies, two cultivars known to differ in persistence were analyzed for chitinase, an antifungal hydrolase associated with disease resistance in other plants. *Acremonium*-infected Kentucky 31 (KY31), a persistent cultivar, and Johnstone, a nonpersistent cultivar, were inoculated with the parasitic nematode, *Meloidogyne marylandi*, grown for 50 days, and analyzed at 10-day intervals. Chitinase fluctuated throughout the 50-day period of seedling development, and activity was highest in the persistent *Acremonium*-infected KY31. In addition, chitinase was elicited by parasitic *M. marylandi* and expressed systemically. Subsequent studies were conducted to determine whether or not mutualistic *Acremonium* could increase chitinase activity. Genetically identical KY31, with and without *Acremonium*, were grown for 25 days and analyzed for chitinase at 5-day intervals. After 20 days, *Acremonium*-infected KY31 expressed more chitinase than *Acremonium*-free KY31. We concluded that chitinase is related to tall fescue persistence; it was highest in the most persistent cultivar, increased under pathogen attack, and increased in the presence of *Acremonium*, a symbiont known to enhance disease resistance.

INTRODUCTION

Tall fescue (*Festuca arundinacea* Schreb.) is a pasture grass widely used throughout the world. It is often preferred over other grasses because it persists under adverse environmental conditions (Burns and Chamblee, 1979). The use of tall fescue has extended pastureland into environmental zones which would not normally support livestock production; it currently represents approximately 35 million acres of pastureland in the United States [National Research Council (NRC), 1989]. Unfortunately, tall fescue is infected with *Acremonium coenophialum* Morgan-Jones and Gams (Bacon et al., 1977; Morgan-Jones and Gams, 1982), an endophytic fungus that causes fescue toxicosis and costs U.S. beef producers in excess of $200 million annually (Siegel et al., 1985).

In an effort to remove toxicity, *Acremonium*-free cultivars have been developed. Although the new cultivars are nontoxic, they are less persistent (Bacon and Siegel, 1988). According to recent studies, *Acremonium*-free cultivars are more susceptible to drought (West et al., 1988), insects (Johnson et al., 1985; Clay et al., 1985), and pathogens (West et al., 1990; Kimmons et al., 1990). While mechanisms that account for drought and insect resistance are being postulated (Johnson et al., 1985; West et al., 1988), those responsible for disease resistance have not been described. When these mechanisms are identified, they can be incorporated into *Acremonium*-free germplasm and permit development of a persistent, non-toxic fescue.

In other plants, disease resistance reactions are associated with a complex of plant responses, often including the accumulation of pathogenesis-related (PR) proteins (Van Loon, 1985). Synthesis of such proteins may be elicited by either biological or chemical stresses (Van Loon, 1983). The mechanism by which PR proteins contribute to disease defense responses is unknown, but certain of the proteins, such as β-1,3-glucanases, are capable of releasing elicitors of phytoalexin synthesis (Keen and Yoshikawa, 1983; Takeuchi et al., 1990). Other PR proteins, such as chitinases, possess antifungal activity (Schlumbaum et al., 1986; Boller, 1985). PR proteins are present in annual grasses (Fink et al., 1988; Sock et al., 1990; White et al., 1987) and may be present in perennial grasses, such as tall fescue.

This research included several objectives. The first was to identify chitinase activity in tall fescue. If activity was detected, an additional objective was to determine if chitinase activity was higher in a persistent cultivar and elicited with the pathogenic nematode, *M. marylandi*. The final objective was to deter-

mine if chitinase increased in the presence of the mutualistic endophyte, *Acremonium coenophialum*. If these objectives resulted in positive data, that is, that chitinase activity was highest in the persistent cultivar, was elicited by pathogenic stress, and increased in the presence of a mutualistic organism known to increase persistence, then chitinase could be postulated as a possible mechanism for disease defense in tall fescue.

METHODS AND MATERIALS

Chitinase in Persistent Cultivars and as Affected by Nematodes

Two cultivars of tall fescue were treated with the parasitic nematode, *Meloidogyne marylandi* (Jepson and Golden) (Jepson, 1987), a species reported to infect tall fescue (Kimmons et al., 1990). Cultivars were selected with persistence as the primary criterion; they included *Acremonium*-infected Kentucky 31 (KY31), a highly persistent cultivar (Stuedemann and Hoveland, 1988), and Johnstone, a less persistent, low-alkaloid, *Acremonium*-free, *Festuca* × *Lolium* hybrid (Buckner et al., 1983). Seed were surface-sterilized with 30% Clorox, then rinsed with sterile distilled water, and 10-g lots were planted in 500 g of autoclaved, sandy soil. Soil was inoculated with 0 or 16,000 eggs and second-stage juveniles (J2) of *M. marylandi*, while controls were not inoculated. Plants were allowed to grow in a greenhouse for 60 days. Each pot received 25 ml of a modified Hoagland's solution every 5 days (Epstein, 1972). Nematode root infection was verified under magnification (Byrd et al., 1983). Plant samples were collected at 10-day intervals throughout the first 50 days of seedling development. The main effects of nematode, cultivar, and time were arranged in a factorial design, and each combination was replicated three times.

As plants were collected, root and foliar tissues were separated and stored at −20°C. Tissues were allowed to thaw and duplicate 3-g samples were analyzed for chitinase activity according to the procedure of Boller et al. (1983). Briefly, this procedure involved homogenation in a 0.1 *M* sodium acetate buffer (pH 5.1), incubation with washed, powdered chitin for 20 hr at 30°C, colorimetric assay with a blank control as reported by Reissig et al. (1955), and protein quantification as reported by Bradford (1976). Main effects and interactions were considered significant at the 0.05 probability level in analysis of variance (Snedecor and Cochran, 1989).

Chitinase as Affected by Acremonium

In order to evaluate the isolated effect of endophytic *Acremonium* on chitinase activity, the confounding effect between plant genotype and *Acremonium* level was eliminated by evaluating genetically identical populations of tall fes-

cue. Two lots of KY31 seed were secured (International Seeds, Inc., Halsey, OR); one lot was *Acremonium*-free, while the other was *Acremonium*-infected. Ten grams of seed was surface-sterilized with 30% Clorox, then planted into 500 g of autoclaved vermiculite and allowed to grow for 25 days. Seedlings were collected at 5-day intervals, beginning at germination. Tissues were stored and analyzed for chitinase activity according to the procedure described previously (Boller et al., 1983). Statistical analyses were performed according to procedures cited previously (Snedecor and Cochran, 1989).

RESULTS AND DISCUSSION

Chitinase in Tall Fescue

Results indicated that tall fescue contained chitinase in both roots and foliage (Figures 1 and 2). To our knowledge, these data report the first instance of chitinase production in a perennial grass. Results also indicated that activity fluctuated throughout seedling development. Chitinase activity in the roots

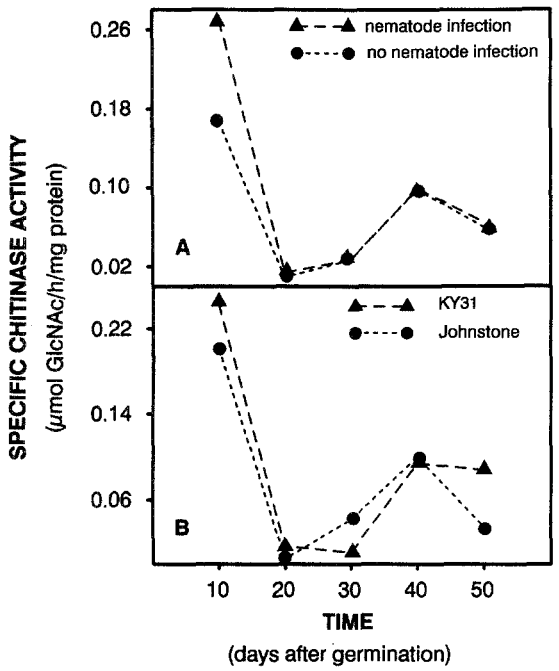

FIG. 1. Chitinase activity in tall fescue roots (A) inoculated with the parasitic nematode, *Meloidogyne marylandi*, and (B) in two fescue cultivars.

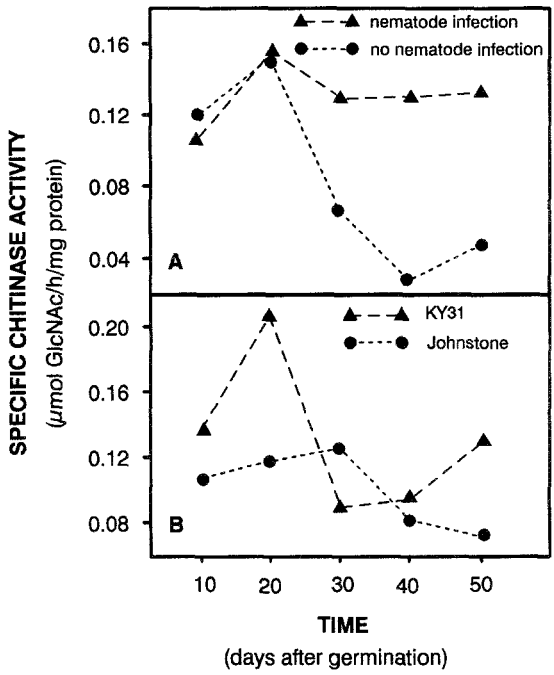

FIG. 2. Chitinase activity in tall fescue foliage (A) inoculated with the parasitic nematode, *Meloidogyne marylandi*, and (B) in two cultivars.

decreased sharply upon germination and remained low throughout the 50-day period. Activity in the foliage decreased also, yet the decrease was delayed by a slight increase 10 days after germination.

Chitinase as Elicited by Nematodes

In general, chitinase in the roots was not affected by nematode infection (Figure 1A). Activity in the roots of inoculated and control plants was almost identical except for 10 days after germination, when a significantly higher response was measured in the inoculated plants. Chitinase in the foliage, however, was greatly affected by nematode infection (Figure 2A). When tall fescue was inoculated with nematodes, chitinase activity remained high throughout the 50-day period of seedling development. At 40 days after germination, activity in inoculated plants remained at 0.13 μmol GlcNAc/hr/mg protein, while in control plants, activity had decreased to 0.02 μmol GlcNAc/hr/mg protein.

These data do not prove that chitinase is involved in a disease resistance mechanism. They do, however, support the hypothesis. If chitinase is involved, activity would be expected to increase over constitutive levels under pathogen

attack. In this study, plants responded systemically (Métraux and Boller, 1986; Roby et al., 1988) when infected with nematodes, producing a hydrolase specific for chitin, a product not found in higher plants, yet ubiquitous in insect exoskeletons and fungal cell walls. It is probable, then, that chitinase is involved in a defense response, and is not merely an expression of evolutionary speciation. When elicited with nematodes in other crops, protein accumulation was associated with disease resistance (Hammond-Kosack et al., 1989).

Chitinase Levels Among Cultivars

Chitinase activity in the roots did not differ greatly between cultivars (Figure 1B). Root chitinase was similar until 50 days after germination and then increased only slightly in *Acremonium*-infected KY31 while it remained low in Johnstone. In the foliage, however, the difference between cultivars was more pronounced (Figure 2B); activity in *Acremonium*-infected KY31 was high and variable, while in Johnstone it was lower and more constant.

These data support a hypothesis that involves PR proteins in fescue persistence. If chitinases are involved in a resistance mechanism, the highest activity would be expected in the persistent cultivar, *Acremonium*-infected KY31. As expected, *Acremonium*-infected KY31 exhibited high chitinase activity, and its chitinase level was related to visual observations of persistence (Figure 3A). *Acremonium*-infected KY31 persisted throughout the 50-day growing period, while Johnstone did not. By the end of the growing period, Johnstone, the cultivar with low chitinase activity, was easily recognized by its thin, senescent stand (Figure 3B).

These data do not establish a relationship between endophytic *Acremonium* and chitinase activity; although KY31 is *Acremonium*-infected and Johnstone is not, the cultivars differ genetically. With this in mind, the study was continued in order to investigate the possible relationship between endophytic *Acremonium* and chitinase activity.

Chitinase as Increased by Acremonium

Chitinase levels were higher in *Acremonium*-infected KY31 fescue (Figure 4). Since the populations were genetically identical, it is obvious that elevated levels of chitinase resulted from the presence of the endophyte. It was not possible to determine whether the excess chitinase activity originated from the endophytic fungus or the plant. It is likely, however, that the increased activity originated from the plant; *Acremonium* is not highly concentrated in seedling development.

Like data from the initial studies, these data do not prove that chitinase is involved in a disease defense mechanism. Nevertheless, they do establish a relationship between chitinase and *Acremonium* (Figure 4) and, thereby, support

FIG. 3. Two cultivars of tall fescue treated with the parasitic nematode, *Meloidogyne marylandi*, and grown for 50 days. *Acremonium*-infected Kentucky 31 (A), a cultivar noted for its persistence in adverse environments, contained high chitinase activity (Fig. 2) and persisted well throughout the entire study. In contrast, Johnstone (B), a *Festuca* × *Lolium* hybrid, exhibited lack of persistence, which corresponded with low chitinase activity (Fig. 2).

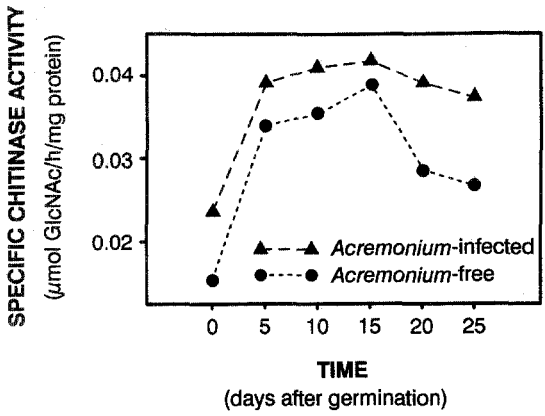

FIG. 4. Chitinase activity in genetically identical populations of Kentucky 31 tall fescue seedlings as influenced by the mutualistic endophyte, *Acremonium coenophialum*.

the hypothesis that involves chitinase in disease defense. The highest chitinase level was in *Acremonium*-infected KY31, a symbiosis known for tolerance and resistance to pathogens and insects.

CONCLUSIONS

Since there is presently no information on the nature of disease defense responses in tall fescue, we chose to measure chitinase, a PR protein associated in plant defense reactions in a wide variety of host–pathogen combinations. As expected for a PR protein, chitinase activities in fescue increased in response to infection by a nematode. Potentially important to tall fescue ecology, chitinase increased also in response to the mutualistic fungus, *Acremonium*. If these and other fescue PR proteins can be individually characterized, they can provide markers for plant geneticists attempting to develop persistent, *Acremonium*-free germplasm. Chitinase and other PR proteins are already being incorporated into other plants using recombinant DNA technology (Dixon, 1991).

(Received November 12, 1991; accepted February 28, 1992)

Abstract—Females of the scarabaeid beetle *Cyclocephala lurida* produce a volatile sex pheromone which attracts conspecific males. Field experiments demonstrated that larvae of both sexes also emit volatile chemicals that stimulate similar responses in adult males, including attempts by the attracted males to mate with the nonreproductive immature stage. Significantly more adult males were caught in traps baited with conspecific male or female larvae or adult females than in blank control traps. Hexane extracts of both male and female grubs were at least as effective as live larvae in trapping male adults, demonstrating that the behavioral responses are mediated by volatile chemicals. Sensory and behavioral responses of males to sex pheromones emitted by adult females are part of the functional communication system. However, their response to grubs is not functional, because grubs are normally temporally and spatially inaccessible to mate-seeking males. In theory, the evolution of a communication system is problematic because it requires the development of a signal in one sex and the sensory and behavioral attributes to respond to that signal in the other sex. The ontogeny of sex pheromone communication in *C. lurida* suggests a partial solution to this evolutionary problem. We propose that this sex pheromone communication system is probably derived from noncommunicative volatile chemicals that are lost in adult males and retained by adult females.

Key Words—*Cyclocephala lurida*, Coleoptera, Scarabaeidae, sex pheromone, chemical communication, evolution of signals.

INTRODUCTION

Sex pheromone communication involves release of a chemical signal by individuals of one sex and specialized sensory receptors for, and behavioral responses to, that signal in members of the other sex (Payne et al., 1986). The evolution of chemical communication and systems relying on other sensory modalities is problematic because of the disparate requirements for effective communication in the signaler and receiver (Krebs and Dawkins, 1984; Otte, 1974; Ryan and Wilczynski, 1988; Smith, 1977). The initial evolution of chemical communication may be facilitated by modification of existing cues and/or biosynthetic pathways for signal production. For example, in the crab *Pachygrapsus crassipes*, the female's excretion of crustecdysone, a hormone that regulates molting, stimulates search and display mating behaviors in males and thus takes on a pheromonal function in this context (Kittredge and Takahashi, 1972). In scolytid bark beetles, biosynthetic modification of host-tree compounds is often involved in the production of species-specific aggregation pheromones (see references cited by Vanderwel and Oehlschlager, 1987). The ontogeny of the sex pheromone signal in the southern masked chafer, *Cyclocephala lurida* (Coleoptera: Scarabaeidae), suggests another, previously undescribed evolutionary route for the development of chemical communication, in which sex pheromones are derived from larval odors.

As is typical of other scarabaeid beetles and many other insects (Tamaki, 1985), adult females of *C. lurida* produce a sex pheromone which attracts conspecific males (Potter, 1980). Release of this pheromone is behaviorally controlled by the female beetle, which emerges from the soil beneath pasture or turfgrass shortly after sunset, in close daily synchrony with the emergence and flight of conspecific males. Unmated females remain on the ground or climb grass blades. Males fly close to the ground, zigzagging upwind toward females. Mating follows, often with several males attempting to copulate with a single female (Figure 1A). Male beetles will show a similar response to hexane or ether extracts of adult females, demonstrating the chemical nature of this communication system (Potter, 1980). Mated females quickly burrow into the soil, often before the male has disengaged. After the mating period, which lasts from dusk until about 11 PM (EST), the remaining beetles burrow into the soil. If unmated females are held aboveground in traps after this mating period, they are attractive to a closely related sympatric scarabaeid species, *C. borealis*, which normally mates after midnight (Potter, 1980). This provides evidence that effective pheromone emission is behaviorally controlled by emergence of the female beetle from the ground. There is one generation per year, mating flights generally occurring during late June and early July (Potter, 1981).

Initially we observed male beetles attempting to mate with conspecific grubs, which if developing normally would not be present when males are active.

FIG. 1. (A) Normal mating behavior of *Cyclocephala lurida*. Male beetles are attracted to a sex pheromone emitted by the female. (B) Males are attracted to and attempt to mate with the nonreproductive grub. Males will mount grubs and probe the grub with their aedeagus.

These grubs were naturally infected with milky disease [*Bacillus popilliae* (*Cyclocephala* strain)], a bacterial disease that delays their development. For an unknown reason a few infected individuals were found on the ground surface. In this report, we provide evidence that both healthy male and female larvae produce a volatile chemical cue that attracts adult male beetles and stimulates them to attempt to copulate with the nonreproductive immature stage. This response of males to the immature stage is clearly not an adaptive feature of sexual communication, because the root-feeding grubs are not ordinarily present during late June and July when males are active, nor are they normally above-

FIG. 1. Continued.

ground. However, the response suggests that sex communication in this species may have evolved by loss of the signal in males and specialization of the males' sensory system to detect the same signal from the adult female.

METHODS AND MATERIALS

Last-instar grubs were collected in May by digging up grass sod and examining the root systems for the feeding larvae. Grubs were stored in sod at 18°C to delay development. Grubs were separated by sex, based on well-defined sexual characteristics (Tashiro, 1987). Adult male and female beetles displaying characteristic precopulatory behavior were collected on a golf course fairway the night before an experiment. Adult females can be distinguished from males by their behavior, the structure of their tarsal claws, and other morphological differences (Potter, 1980; Tashiro, 1987). When an individual was collected, its sex was determined and it was placed with other members of the same sex in a paper carton with moistened paper towels. The beetles were stored until the next day at 8°C.

The following evening, traps were baited with male or female adults or male or female grubs and placed on golf course fairways or adjacent roughs. Experiments were conducted at the Lexington Country Club Golf Course, Lexington, KY, in late June 1991. We used standard metal Ellisco Japanese beetle traps placed on the ground and supported by wire stands. Traps were at least 5 m apart and were arranged in a randomized complete block with five replications. Three individuals were placed in the bait well of each insect-baited trap. One trap per replicate was left unbaited to serve as a control. The position of traps was rerandomized within each block at 15-min intervals. After the nightly flight period, traps were retrieved and beetles were counted. Data were analyzed using a two-way (treatments and experimental blocks) analysis of variance on log-transformed data [log $(x + 1)$]. Means of insect-baited traps were compared to blank traps using the LSD procedure for preplanned comparisons.

In the second experiment, grubs were collected at field sites in May and brought back to the laboratory to be extracted. The extraction procedure followed a protocol that has proved to be successful in extracting pheromone from adult females (Potter, 1980; Haynes and Potter, unpublished data). Seventeen male and 19 female grubs were rinsed with 5 ml of hexane in separate 50-ml flasks. Approximately 4 ml of the hexane was recovered, and the extract was then diluted to 3 grub equivalents/ml. At sunset, traps were baited with hexane extracts of male or female grubs by dispensing 1 ml of these solutions into a 3.5-cm-diameter aluminum dish. Other traps were baited with aluminum dishes containing three male or three female grubs. Blank traps contained an aluminum dish treated with 1 ml of hexane. Other procedures were identical to the first experiment.

RESULTS AND DISCUSSION

Both male and female grubs attracted large numbers of adult male beetles (Figure 1B). Traps baited with larvae of either sex caught significantly more male *C. lurida* than blank traps (Figure 2A). Adult female *C. lurida* also attracted conspecific male beetles as expected. In contrast, traps baited with adult males and blank control traps caught very few beetles. Thus, males become unattractive to other males as adults, while females retain their attractiveness to males.

Attraction of males to grubs is mediated by a hexane-extractable chemical or chemicals. Hexane extracts of male or female grubs attracted significantly more male *C. lurida* than hexane alone (blank traps) (Figure 2B). Male or female grub extracts were as attractive as live grubs.

Attraction of other adult arthropods to signals from conspecific immature stages is not without precedent (Thornhill and Alcock, 1983). However, in each of the previously documented examples this attraction represents an adaptive

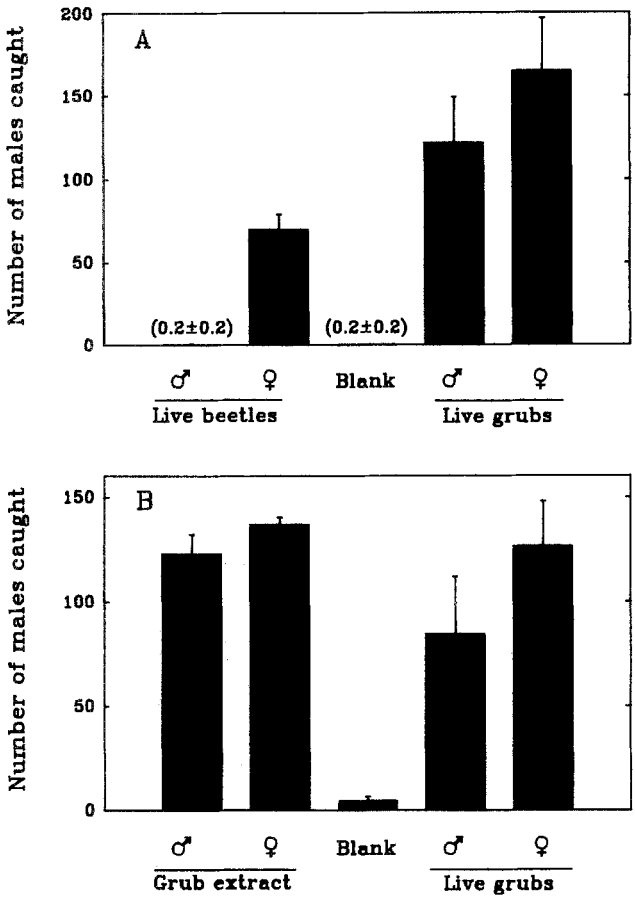

FIG. 2. (A) Attraction of adult male *Cyclocephala lurida* to live adults and grubs. Traps baited with adult females, male grubs, or female grubs caught significantly more males than blank control traps (LSD test after two-way analysis of variance; $P < 0.001$, df = 4,16, $F = 183.5$). Error bars show 1 SE. (B) Extracts of both male and female grubs caught significantly more adult male beetles than blank control traps (LSD test after two-way analysis of variance; $P < 0.001$, df = 4,16, $F = 31.5$).

feature of reproductive behavior with the immature individual close to maturation. For example, male spider mites are attracted to quiescent female deutonymphs, which they guard until emergence and mating (Potter et al., 1976). The pupal stage of some heliconiid butterflies is attractive to males, with mating usually occurring on the pupal case as the female emerges (Gilbert, 1976).

In normal circumstances grubs and reproductively active adult male *C.*

lurida do not co-occur. Activity of grubs is confined to underground feeding on grass roots, while mating activity occurs aboveground. The combined prepupal and pupal period lasts 15–21 days. This species has a single generation per year, with adult activity confined to a few weeks (Potter, 1981). Thus, there would normally be little or no temporal overlap between adult males and grubs. Because chemically mediated sex attraction of adult males to larvae of holometabolous insects is unexpected, it may not have been investigated before. This phenomenon may be common to scarabaeid beetles (a family which includes many species of economic importance) or may even be phylogenetically widespread in species in which adults and larvae do not co-occur in the same habitat.

The evolution of communication systems is complicated by the fact that signaler and receiver must coevolve. De novo and simultaneous evolution of both signal and receptors is unlikely. The attraction of male *C. lurida* beetles to the immature grub stage suggests that it may be possible for the evolution of sex pheromone communication to begin with odors common to all developmental stages. Apparently, males lose the attractive components during metamorphosis.

An alternative explanation of the lack of attraction to adult males could be that they produce a repellent. This possibility is not supported by observations or experimentation. It is common to find clusters of males surrounding a single pheromone-releasing female (Potter, 1980). Traps baited with females captured large numbers of males. When extracts of males and females are combined, there is no decrease in the number of males captured (unpublished data).

In summary, these experiments have demonstrated that adult females and both male and female larvae produce a volatile sex attractant. This observation appears to be unprecedented for *C. lurida* or for any other insect species. We hypothesize that the evolution of the communication system in this species involved sex-specific loss of this chemical cue in the male, combined with specialization of the adult male's sensory receptors to detect that cue.

Acknowledgments—G. Gilmore, C. Redmond, and J.Z. Zhao helped with field experiments. This work was supported by grants from the O.J. Noer Turfgrass Research Foundation and the U.S. Golf Association. Voucher specimens of larval and adult *C. lurida* have been placed in the Entomology Museum at the University of Kentucky. This investigation (Paper No. 91-7-151) was conducted in connection with projects of the Kentucky Agricultural Experiment Station.

Abstract—Rooted cuttings of *C. jambhiri* were grown under enhanced levels of UVB radiation for 95 days. Bacterial phototoxicity and furanocoumarin content were determined in extracts made from various tissues from the aboveground biomass. Young, newly expanded leaves contained significantly higher concentrations of furanocoumarins than older leaves and stems. Additionally, the proportional concentration of psoralen was higher in young leaves than in old leaves. While treatment with UVB did not result in a change in the overall level of furanocoumarins, it did cause an increase in the ratio of psoralen to bergapten. Bacterial phototoxicity paralleled the distribution of furanocoumarin content among tissue types; analysis of covariance suggested that the phototoxic properties of the extracts could be accounted for on the basis of furanocoumarin content alone.

Key Words—*Citrus jambhiri*, furanocoumarins, phototoxins, ultraviolet-B radiation, plant-herbivore interactions, psoralen, bergapten.

INTRODUCTION

Gradual reductions in levels of stratospheric ozone, attributable at least in part to anthropogenic inputs of chlorofluorocarbon and nitrogen oxide pollutants, are

*To whom correspondence should be addressed.

0098-0331/92/0700-1125$06.50/0 © 1992 Plenum Publishing Corporation

associated with an increase in the incidence of shortwave solar ultraviolet-B radiation (UVB; 280–320 nm), particularly in the region between 290 and 315 nm (Caldwell et al., 1989). Enhanced UVB radiation disrupts a number of physiological processes in plants; exposure to high levels of UVB radiation is associated with decreases in rates of photosynthesis and nitrogen fixation, reduced enzyme activity, destruction of chlorophyll, growth anomalies, and lowered levels of soluble protein (Teramura, 1983; Caldwell et al., 1989).

There is also great potential for enhanced UVB radiation to influence ecological interactions between plants and their pathogens and herbivores. Enhanced UVB radiation alters patterns of secondary, as well as primary, metabolism and can induce biosynthesis of a number of shikimic acid derivatives, including flavonoids and coumarins (Caldwell et al., 1989). In that these compounds frequently serve as defensive agents against pathogens and herbivores, alterations in levels of secondary metabolism may affect the relative susceptibility of plants to damage. For instance, treatment with UVB can increase disease severity in cucumbers (Orth et al., 1990), although the mechanism by which susceptibility increases is not known. Ecological alterations may be particularly striking for those plants with secondary metabolites that are photoactive—that is, compounds that can absorb ultraviolet light to form an excited state. These excited molecules can react directly with biological macromolecules such as DNA or proteins to disrupt biological function or can react with ground-state oxygen to form a variety of toxic oxygen species, which can then proceed to damage cells and tissues (Downum et al., 1991). The efficacy of UVB radiation in activating plant photosensitizers is largely unknown, but the possibility exists that UVB may be as effective as UVA (ultraviolet-A; 320–400 nm) at enhancing the toxicity of photosensitizers.

Species in the genus *Citrus* are grown worldwide in tropical, subtropical, and semitropical areas where levels of UVB are naturally high (Caldwell, 1981); herbivores and pathogens on exposed foliar surfaces will be exposed to these high irradiance fluxes. Foliage of *Citrus* and other rutaceous species is phototoxic to a variety of organisms, including humans (Knowlton and Ockert, 1950; White, 1986; Israel, 1985). Like many other rutaceous species (Waterman and Grundon, 1983; Fisher and Trama, 1979), *C. jambhiri* produces furanocoumarins. These UV-absorbing compounds are phototoxic to a wide variety of organisms (Berenbaum, 1991; Murray et al., 1982) and are responsible, at least in part, for the resistance of some *Citrus* species to pathogenic fungi (Martin et al., 1966; Pirone et al., 1960). *Citrus jambhiri* is frequently used as a rootstock in commercial citriculture, where it is valued for its disease resistance (Whiteside et al., 1988). Although not reported from *C. jambhiri*, rutaceous plants produce a number of other photosensitizers that are biosynthetically and structurally distinct from the furanocoumarins; these include benzylisoquinoline alkaloids, β-carboline alkaloids, simple coumarins, and pyranocoumarins (Towers, 1984).

In this study, we examined the effects of UVB radiation exposure on furanocoumarin production in *C. jambhiri* foliage. In addition, we used an ultrasensitive bacterial bioassay to estimate changes in phototoxicity resulting from UVB exposure (Tuveson et al., 1986; Ashwood Smith et al., 1986; Downum et al., 1991). Such an assay is particularly suitable for our purposes for several reasons. It allows for rapid and sensitive screening of multiple extracts, and it provides data that correlate well with phototoxicity against a broad spectrum of organisms, including insects (Downum et al., 1991; Larson et al., 1988). Further, it allows us to estimate total phototoxicity of foliar extracts, including not only that attributable to furanocoumarins but also to other, as yet uncharacterized, phototoxins in the plant.

METHODS AND MATERIALS

Plants. Apical cuttings from three randomly selected clones of *C. jambhiri* were rooted in the greenhouse with a commercially available rooting compound. Clones had been taken from a group of about 80 parental plants donated by a commercial supplier. After 6 weeks, the cuttings had begun to produce roots and were transplanted into a light soil mixture (Perlite:Peat:Soil, 2:1:1) in 10.2-cm clay pots. After 3 weeks in these pots, the cuttings were established and growing vigorously. We then selected 10 plants of similar size and degree of apical dominance from each clone. Half of the plants within each clone were randomly assigned to the control group. Thus, there were 15 plants, 5 in each clone, in the control and treatment groups. The plants were then repotted to 15.2-cm clay pots and placed on a greenhouse bench for UVB exposure. UV light was supplied by banks of Westinghouse FS-72 fluorescent bulbs which were filtered on the control side of the bench with Type S Mylar film (Gar-Ron Plastics, Baltimore, MD). This film does not transmit UVB wavelengths (280–320 nm); bulbs on the treatment side of the bench were filtered with cellulose acetate film (3 mil, Folex, Inc., Palmyra, NJ), which allows UVB transmission but filters wavelengths below 280-nm (Mirecki and Teramura, 1984). A sheet of Mylar, suspended between the two light banks, shielded the control side of the bench from the treatment side. The UVB bulbs were turned on for 8 hr daily, centered in the 14-hr photoperiod of the experiment. Plants were irradiated with a UVB dose of 19.1 kJ day^{-1} BE_{300} (biologically effective radiation, normalized at 300 nm). This dose measurement expression gives the integrated fluence over the UVB waveband weighted according to Caldwell's generalized plant damage spectrum for UVB normalized to 300 nm (Caldwell et al., 1983). Constancy of this dose was maintained by adjusting the height of the bulbs over the plants or by occasionally lengthening the period of exposure as needed. Supplemental visible light was supplied by 8 HID metal halide lamps situated

over the UVB light banks. Maximum levels of photosynthetically active radiation at midday ranged from 600 to 1000 μmol m^{-2} sec^{-1}, depending on the cloudiness of the day.

We grew the rough lemon plants under UVB for 95 days through the spring and summer of 1990. Plants were watered as needed and fertilized ca. every 2 weeks with 20–20–20 NPK supplemented with $MgSO_4 \cdot 7H_2O$. UVB fluence levels were checked and adjusted frequently (five times per week) using a UVB radiometer (SED-240, International Light Inc., Newburyport, MA) that was periodically calibrated with a spectroradiometer (Optronics OL 752, Optronics Labs. Inc., Orlando, FL). Periodically, the bench sides were switched and the plants were randomized within a bench side. Cellulose acetate and Mylar were changed as needed.

Following the period of growth under enhanced UVB, the plants were harvested and the aboveground biomass was divided into four tissue classes. Young leaves were defined as the soft, bright green leaves that either were not fully expanded or had been fully expanded for a short period. Intermediate leaves were fully expanded leaves that had begun to harden but were still a light green shade. Old leaves were easily distinguished by their dark green color and extreme hardness in comparison to intermediate leaves. Finally, aboveground tissue remaining after all leaves had been removed was harvested as stems. Harvested tissues were immediately frozen and stored at −25°C. The frozen material was then freeze-dried and ground in a Wiley Mill to pass through a 40-mesh sieve.

Furanocoumarin Assay. Three 50-mg (±1.5-mg) subsamples were taken from each plant/tissue combination. The subsamples were homogenized in 5 ml cold Tris buffer (50 m*M*, pH 8) with a polytron. Furanocoumarins were then extracted with 3 × 2 ml EtOAc with vortexing. Clean phase separation was achieved by first bringing the aqueous homogenate to 0.0125% cetyltriammonium bromide (CTAB), followed by mild heat denaturation of solubilized proteins (60°C, 20 min). Particles were removed and phase separation was effected by centrifugation at 2000*g* for 10 min. The combined extracts from each subsample were evaporated and redissolved in 400 μl EtOAc. Furanocoumarins present in the resulting solution were assayed by normal-phase HPLC (Berenbaum et al., 1984). The presence of psoralen and bergapten had been previously confirmed by GC-MS of the nonphenolic lactone fraction (Berenbaum, 1981; McCloud, unpublished data) and by retention time matching in normal- and reversed-phase HPLC systems. After HPLC, the remaining liquids from each subsample were combined, evaporated, and redissolved in MeOH at an approximately constant level of tissue representation, ca. 0.75 mg dry weight of tissue/ml. After resolvation in MeOH, phototoxicity of the tissue extracts to *Escherichia coli* was measured.

Bacterial Culture and Bioassay. The complete genotype of the *E. coli* strain, RT7h(tet^r), used in these investigations is described by Leonardo et al.

(1984) and Sammartano et al. (1986). The bacteria were grown on modified Luria-Bertani (LB) medium (Miller, 1972). The minimal medium used to assess survival consisted of minimal A medium (Miller, 1972) supplemented with arginine, lysine, and histidine (40 μg ml^{-1}).

Cells were grown at 37°C in a side-arm flask (Bellco) containing 50 ml of LB, and growth was monitored with a Klett-Summerson colorimeter. When the culture had reached stationary phase, it was diluted with an additional 450 ml of LB containing 25% glycerol. Ten-milliliter samples of the cells were dispensed into 15 × 150-mm screw-top sterile test tubes and quickly frozen in a dry ice–ethanol bath. The frozen cells were stored at −55°C. Prior to bioassay, a 10-ml sample of the frozen cells was removed from the freezer and rapidly unfrozen by running cold tap water over the tube. The cells were then transferred to a sterile 15-ml Corex tube and pelleted in a Sorvall refrigerated centrifuge at 10,000 rpm for 10 min. The supernatant was poured off and the cells were resuspended in cold (ice bath-temperature), 0.067 *M*, pH 7.0, phosphate buffer (K-K). The cells were pelleted two additional times at 4k, with resuspension being in the same buffer. Final cell density was about 5.0 × 10^8 cells ml^{-1}. One-milliliter aliquots of the cell suspension were distributed into 13 × 100-mm test tubes. To each tube either 10 μl of extract in methanol (experimental) or 10 μl of methanol (control) was added, following which the experimental tubes were exposed to UVA (4.8 kJ m^{-1}). The approximate tissue representation in each tube was 7.4 μg dry weight/ml of cells. Following exposure to UVA, the cells were diluted appropriately in 0.067 *M*, pH 7.0, phosphate buffer and three 100-μl samples were spread on three plates of supplemented minimal A medium to obtain colony counts. The plates were incubated at 37°C for 2 days. The mean colony counts from the experimental tubes were divided by the mean colony counts from the control tubes, giving the surviving fraction. The reciprocal of the surviving fraction was taken as a measure of the relative toxicity of the particular extract.

The broad-spectrum UVA source used for the bacterial experiments (Tuveson and Jonas, 1979) consisted of a bank of four lamps (GE40BLB, integral filter) with a range of emission from 300 to 425 nm with a maximum emission at 350 nm as in the study by Tuveson and Jonas (1979). The source was maintained in a cold room at 10°C to reduce heating effects. Sham UVA irradiation of foil-wrapped cell suspensions showed no inactivation (Tuveson and Jonas, 1979). The fluence rate was between 40 and 43 J sec^{-1} m^{-2}.

Statistical Analyses. Data on furanocoumarin concentrations and bacterial toxicity were analyzed as a three-way ANOVA in a completely crossed design with the SAS statistical package [Statistical Analysis System (SAS) Institute, 1982]. Bacterial toxicity was scored as the log-transformed reciprocal of the surviving fraction, and since all extracts could not be assayed simultaneously, we tested the extracts in five batches that were completely balanced with respect

to the independent variables. Thus, we used the assay batch as an additional blocking factor. Furanocoumarin ratios were compared by the distribution-free Kruskal–Wallis nonparametric one-way analysis of variance (Sokal and Rohlf, 1982). We estimated variability around mean furanocoumarin proportions as the back-transformed 95% confidence intervals in order to provide the most meaningful estimate of dispersion (Sokal and Rohlf, 1982). For simplicity, interaction terms were dropped from the model when the P value was much greater than 0.25. Because we anticipated a relationship between furanocoumarin levels in extracts and bacterial toxicity (Tuveson et al., 1986), we examined this relationship using linear regression. In addition, the effect of the independent variables, corrected for furanocoumarin concentration and tissue representation in the assay, was investigated using ANCOVA. Differences between individual means were examined with Bonferroni's test as needed [Statistical Analysis System (SAS) Institute, 1982].

RESULTS

Psoralen and bergapten levels varied with tissue type (Table 1); higher levels of furanocoumarins were present in young leaves, and leaves had higher amounts than stems. Also, we found that clonal origin accounted for a significant portion of the variation in bergapten content $F_{2,22} = 7.03$, $P = 0.0043$). Psoralen and bergapten concentrations were highly correlated ($r^2 = 0.83$, $P = 0.0001$) over all plant parts and treatments; UVB exposure resulted in a slight decrease in the degree of correlation between them ($r^2 = 0.89$, $P = 0.0001$, UV−; $r^2 = 0.82$, $P = 0.0001$, UV+).

While exposure to UVB had no significant effect on mean levels of bergapten or psoralen in aerial parts of *C. jambhiri*, UVB treatment increased the

ratio of psoralen to bergapten (Table 2). This increase in relative psoralen concentration was apparent in all tissues. Also, the ratio showed significant variation among plant parts (Figure 1). In a pattern similar to that for the combined levels of psoralen and bergapten, the proportional representation of psoralen was higher in younger leaves and, overall, leaves had a higher relative concentration than stems.

Bacterial toxicity was highly correlated with the furanocoumarin content of extracts (Figure 2); samples with higher levels of bergapten and psoralen

were more toxic in our assays. Also, psoralen-to-bergapten ratios showed a highly significant correlation with toxicity; however, the amount of variation that could be accounted for by the correlation was low (Figure 2). UVB treatment had no significant effect on the toxicity of extracts, although the effect of plant part was highly significant (Table 3). Clonal variation in bergapten levels was not sufficient to elicit a clonal effect on bacterial toxicity.

We used ANCOVA to examine the effect of plant part corrected for furanocoumarin content. In this way, we sought evidence for other effects of plant part extracts on bacterial toxicity which could not already be explained by furanocoumarin variation among the extracts. Neither tissue, clonal origin, nor UVB irradiation could account for any additional variation in bacterial toxicity when corrected for furanocoumarin content (Table 4). Similar results were obtained when psoralen or bergapten concentrations alone were used as covariates. Further, a heterogeneity of slopes analysis showed that there was no

difference in the relationship between furanocoumarin content and bacterial toxicity in different tissues.

DISCUSSION

Our analysis of furanocoumarin variation in aerial parts of *C. jambhiri* revealed several patterns consistent with those reported in other species. Furanocoumarin concentrations are highest in young foliage and lower in older leaves and stems. Similar patterns have been reported in several umbellifers and rutaceaous species (Berenbaum, 1981; Zobel and Brown, 1989, 1991). Variation in mean furanocoumarin levels of leaves amounted to a nearly fourfold difference in total foliar furanocoumarins. The difference between leaves and stems was even greater (up to 11.5 fold). Moreover, the relative concentration of psoralen was higher in younger leaves. Zobel and Brown (1991) termed bergapten a "senescence compound" based on its higher relative concentrations in older

leaves and callus tissue from *Ruta graveolens*. Here, our results show a parallel trend; the proportion of psoralen is highest in young leaves and bergapten proportions are highest in old leaves. The age-dependent change in relative representation of psoralen is due to a more rapid decline in psoralen concentration than bergapten (Table 2) (see Zobel and Brown, 1991). Psoralen precedes bergapten in furanocoumarin biosynthesis (Murray et al., 1982). Our results suggest that, as leaves age, furanocoumarins are degraded at a greater rate and that psoralen is more rapidly converted to bergapten. This scenario remains speculative and depends on the extent to which turnover occurs. Alternatively, Mihaliak et al. (1991) have recently demonstrated lack of monoterpene turnover when assays were performed on whole plants. So if furanocoumarin turnover in *C. jambhiri* is low or constant, then furanocoumarins accumulated after an initial burst of synthesis early in leaf ontogeny might then be continuously degraded at a constant rate. Psoralen would be converted to bergapten, and bergapten to nonfuranocoumarin degradation products.

Regardless of the mechanism, there are several possible implications of furanocoumarin distribution among tissues for herbivores and pathogens of *Citrus* spp. Young foliage of *Citrus* spp. is less tough and has a higher water content than older leaves (McCloud, unpublished data). Because preference for younger foliage is a hallmark of many leaf-chewing herbivores of woody perennials (Scriber and Slansky, 1981; Slansky and Rodriguez, 1987), our results suggest that *Citrus*-feeding herbivores may have to consume larger quantities of furanocoumarins in order to feed on young, nutrient-rich foliage. Similarly, leaf pathogens on citrus may face a tradeoff between penetration of more sclerophyllous older leaves and increased phototoxicity in tender young leaves. Consumers of young citrus foliage, then, not only will ingest higher levels of phototoxins, but also will experience a higher light regime on these young, terminal leaves.

Foliar bergapten levels vary significantly between *C. jambhiri* clones. That we were able to detect clonal variability in furanocoumarin accumulation using only three different clones suggests that such variability may be quite high in this species.

Analysis of covariance suggests that phototoxicity in leaves of *C. jambhiri* can be accounted for on the basis of furanocoumarin content alone. While phototoxicity in our bacterial assay varied nearly 44-fold with the type of tissue extract, tissue type had no significant influence on phototoxicity over and above furanocoumarin content.

Levels of UVB reaching the earth's surface are expected to increase in the coming decades as a result of continuing stratospheric ozone depletion (Bowman, 1988; Blumthaler and Ambach, 1990). Our results suggest that, given this predicted change in incident UVB, phototoxin-mediated effects on *Citrus* enemies will depend on the genetic identity of the variety in question, the species,

and the tissue-specific furanocoumarin content as well as the amount of UVB enhancement. In our study, we failed to document effects of UVB enhancement on the phototoxicity of leaf and stem extracts, although we found changes in furanocoumarin concentration. *Citrus* species are native to subtropical habitats and several authors have presented evidence that plant populations native to low latitudes are more resistant to UVB (Robberecht et al., 1980; Caldwell et al., 1982; Barnes et al., 1987). Inasmuch as increased accumulation of phenylpropanoids constitutes a stress response, lack of increase in mean furanocoumarin concentrations suggests that our dose (equivalent to 39% O_3 reduction at 28°N, latitude) did not stress the plants. DeLucia et al. (1991) have shown that penetration of UVB into the leaves of woody perennials is limited; thus, damaging wavelengths may not reach their targets in *Citrus*. However, the change in the ratio of psoralen to bergapten observed indicates that UVB radiation did affect furanocoumarin metabolism in this plant despite its possibly limited penetration. While we designed our *E. coli* assay system to be a sensitive model of possible effects on herbivore and pathogen interactions with *C. jambhiri*, we sought only phototoxin-mediated effects. Other changes induced by exposure to UVB remain untested, as do effects of proportionally altered furanocoumarin accumulation. Our results, then, warrant future work, in which the consequences of increased UVB exposure for herbivores and pathogens are directly addressed.

POSSIBLE FUNCTION OF ECDYSTEROID-22-*O*-ACYLTRANSFERASE IN THE LARVAL GUT OF TOBACCO BUDWORM, *Heliothis virescens*

MINLI ZHANG and ISAO KUBO*

(Received January 21, 1991; accepted March 2, 1992)

Abstract—In the larval gut of the tobacco budworm, *Heliothis virescens*, most ingested ecdysteroids are transformed to ecdysteroid-22-acyl esters by a novel enzyme, ecdysteroid-22-*O*-acyltransferase. This conversion is different from the normal metabolic pathway in which the compounds are usually transformed to more water-soluble products. Most ecdysteroid-22-*O*-acyltransferase activity was found in the midgut epithelial-cell membrane and was active only during feeding stages. The activity decreased as the larvae became committed to pupation, and it was not enhanced by feeding ecdysteroids to the fifth-instar larvae. Our preliminary results showed that the esterification was very specific to 22-OH in ecdysteroids. We suggest that detoxification is the major function of ecdysteroid-22-*O*-acyltransferase.

Key Words—Detoxification, ecdysteroid, metabolism, brush border membrane, epithelial cell.

INTRODUCTION

Ecdysteroid metabolic studies, most of which were made through the injection of ^{3}H-ecdysteroids, have shown that hydroxylation and conjugation were the major metabolic pathways by which ecdysteroids are converted to more polar products (Koolman, 1982; Lafont and Koolman, 1984), although apolar metabolites, such as ecdysteroid-22-acylesters, which might serve as storage forms, are found in ovaries and eggs of some insects (Connat, and Diehl, 1986; Hof-

*To whom correspondence should be addressed.

mann, 1986; Slinger et al., 1986; Slinger and Isaac, 1988a,b; Whiting and Dinan, 1988a,b, 1989). Ecdysteroids fed to insects such as *Heliothis virescens* (Kubo et al., 1987) and *H. armigera* (Robinson et al., 1987), as well as to other arthropods (Connat et al., 1988a,b), however, are metabolized in a different way. They are converted to apolar products, ecdysteroid-22-acyl esters, which were excreted with the feces. Unlike the production of ecdysteroid-22-acyl ester in the insect ovaries, the conversion of the ecdysteroids to their 22-acyl esters might be a pathway of detoxification of ingested noxious compounds (Kubo et al., 1987; Connat et al., 1988a,b; Robinson et al., 1987).

One of the enzymes involved in this ecdysteroid esterification is a novel enzyme, ecdysteroid-22-*O*-acyltransferase, which is being characterized in our lab. Because most of the ingested ecdysteroid was transferred to its ester and excreted into the feces, we suggest that the major function of the ecdysteroid-22-*O*-acyltransferase is to detoxify the foreign compounds ingested with the food.

There are some common characteristics of the detoxifying enzymes. First, they are located in the tissues where toxins are first encountered or most abundant, e.g., in the fat body and gut tissues. Second, most of the detoxifying enzyme activity can be observed during the feeding stage because most of the toxins are obtained through feeding (Ahmad et al., 1986). Third, the detoxifying enzyme can be induced by the introduction of the toxins (Yu, 1986). In this paper we demonstrate that ecdysteroid-22-*O*-acyltransferase shares most of these characteristics.

METHODS AND MATERIALS

Insects. H. virescens larvae were reared on artificial diet (Chan et al., 1978) under the conditions described by Kubo et al., 1987. Fifth-instar larvae were used for the experiment.

*Location of Ecdysteroid-22-*O*-Acyltransferase.* Fifth-instar larvae at the digging phase (Webb and Dahlman, 1985) were dissected at 4°C in Tris buffer containing 50 m*M* Tris–HCl, pH 7.4, 50 m*M* 2-mercaptoethanol, and 1 m*M* EDTA. Different tissues were collected and homogenized in Tris buffer with a Duall Tissue Grinder. Protein content in the homogenate was measured using the method described by Bradford (1976).

In ecdysteroid-22-*O*-acyltransferase assay, 0.5 ml of mixture containing homogenate (containing 0.1 mg of protein), 10 m*M* phosphate buffer, pH 7.0, 0.06 m*M* oleoyl-CoA, and 4.2×10^{-7} m*M* ^{3}H-ecdysone (47.3 Ci/mmol; NEN Wilmington, DE) was incubated at 20°C for 20 min. The reaction was stopped by adding 200 μl of 1 *N* HCl. Two hundred microliters of 1 *N* KOH was then

added to neutralize the acid condition. Two milliliters of *n*-hexane–ethyl acetate (3 : 1) was added to the mixture and mixed on a vortexer 10 times (2 sec each time) to extract ecdysone-22-oleate. Using authentic ecdysone-22-oleate synthesized by the method of Dinan (1988), we have found that the efficiency of hexane–ethyl acetate extraction was over 99%. An aliquot of extract was added to 4 ml of Ready Safe liquid scintillation cocktail (Beckman, Fullerton, CA), and the radioactivity was measured in LS 5000 TA liquid scintillation counter (Beckman), One unit of enzyme activity (IU/mg) is defined as the formation of 1 μmol of ecdysone-*O*-oleate/min/mg of protein at 20°C. Controls were treated identically but lacked oleoyl-CoA in the assay mixture to determine the radioactivity background in the product extract.

In the gut tissues alkaline phosphatase has been reported to localize in the epithelial-cell membrane and concentrate in the brush border region, which will remain in the supernatant when centrifuged at 3000*g* and will precipitate when further centrifuged at 30,000*g* (Wolfersberger et al., 1986). We used the alkaline phosphatase as a marker for the region in the epithelial-cell centrifugal fractions, which were obtained as follow: the gut homogenates were centrifuged at 3000*g* for 15 min to give precipitate (3000*g* pp) and supernatant (3000*g* sp) which were further centrifuged at 30,000*g* for 30 min to give precipitate (30,000*g* pp) and supernatant (30,000*g* sp). Ecdysteroid-22-*O*-acyltransferase activities in these fractions were compared with the alkaline phosphatase activities, which were measured as described by Ferreira and Terra (1982).

*Ecdysteroid-22-*O*-Acyltransferase Activity in the Fifth-Instar Larval Stadium.* The developmental phases of fifth-instar larvae of *H. virescens* were identified as described by Webb and Dahlman (1985). The gut tissues from these larvae were dissected and the ecdysteroid-22-*O*-acyltransferase activities were measured as described above.

*Induction of 20-Hydroxyecdysone to Ecdysteroid-22-*O*-Acyltransferase.* First-day fifth-instar larvae were fed diet containing 0, 50, 100, 200, 400, or 800 ppm of 20-hydroxyecdysone for 2 days and the effect of the ingested 20-hydroxyecdysone on the change of ecdysteroid-22-*O*-acyltransferase activity was determined by measuring the enzyme activity (IU/mg) in the 30,000*g* centrifuged precipitate of the epithelial homogenate which was obtained from the treated larvae.

*Competition of Different Ecdysteroids as Substrates for the Ecdysteroid-22-*O*-Acyltransferase.* Each 0.5 ml of enzyme assay mixture contained 10 m*M* phosphate buffer, pH 7.0, 0.06 m*M* oleoyl-CoA, 100 μg epithelial-cell homogenate, and 10–100 μ*M* ecdysone (2×10^{-4}–2×10^{-2} μCi/ml), plus 0.5 m*M* 20-hydroxyecdysone or 0.5 m*M* 20-hydroxyecdysone-22-acetate as the competitors.

In another assay, the normal assay mixture (see assay for location of the

enzyme) was added with 0.02–0.5 μM 20-hydroxyecdysone, 20-hydroxyecdysone-2-acetate, and 20-hydroxyecdysone-22-acetate, respectively, to compete with ecdysone as the substrate.

Ecdysone-22-oleate formed after 20 min of incubation at 20°C in the presence or absence of competitors was extracted with *n*-hexane : ethyl acetate (3 : 1) and quantified by measuring the radioactivity.

HPLC Analysis. To confirm the major product formed in the enzyme assay, we analyzed the extract in HPLC. An aliquot of hexane–ethyl acetate extract was pooled, evaporated to dryness, and redissolved with methanol. HPLC (Eyela PLC-5 with a UV spectrometer set at 254 nm; Tokyo Rikakikai Co., Ltd., Tokyo) analyses were performed in a Zorbax ODS column (4.6 mm × 25 cm; Dupont) with 93% methanol eluted at 1 ml/min. Fractions (1 ml each) were added to 4 ml of Ready Safe liquid scintillation cocktail and the radioactivity was measured. Authentic ecdysone-22-oleate used for cochromatography with enzyme product extracts in HPLC analysis was synthesized by the method of Dinan (1988).

RESULTS

*Identification of Ecdysteroid-22-*O*-Acyltransferase Product.* The major product formed in the enzyme assay was found to cochromatograph with the synthetic ecdysone-22-oleate in the HPLC analysis (Figure 1). The major background of radioactivity in the product extract was due to the partition of some ^{3}H-ecdysone into the organic phase.

*Location of the Ecdysteroid-22-*O*-Acyltransferase.* Most of the ecdysteroid-22-*O*-acyltransferase activity was observed in the gut tissue. However, we could not detected this enzyme activity in hemolymph, fat body, or Malpighian tubules. When the gut tissues were further analyzed, the ecdysteroid-22-*O*-acyltransferase activity was found to concentrate in the anterior part of the midgut (Figure 2).

When we compared the ecdysteroid-22-*O*-acyltransferase activity and alkaline phosphatase activity in different epithelial fractions, we found that the distribution of these two enzymes was very similar (Figure 3), suggesting that ecdysteroid-22-*O*-acyltransferase localized in the epithelial cell membrane and possibly concentrated in the brush border membrane.

*Age Distribution of the Ecdysteroid-22-*O*-Acyltransferase.* Ecdysteroid-22-*O*-acyltransferase activity was found to be very high in the fifth-instar larvae feeding stage (Figure 4). The activity decreased as the larvae stopped feeding and entered the stage committed to pupation.

*Induction of the Ecdysteroid-22-*O*-Acyltransferase.* No induction of ecdysteroid-22-*O*-acyltransferase activity was observed in fifth-instar larvae of *H. virescens* fed diets containing 20-hydroxyecdysone of different concentrations

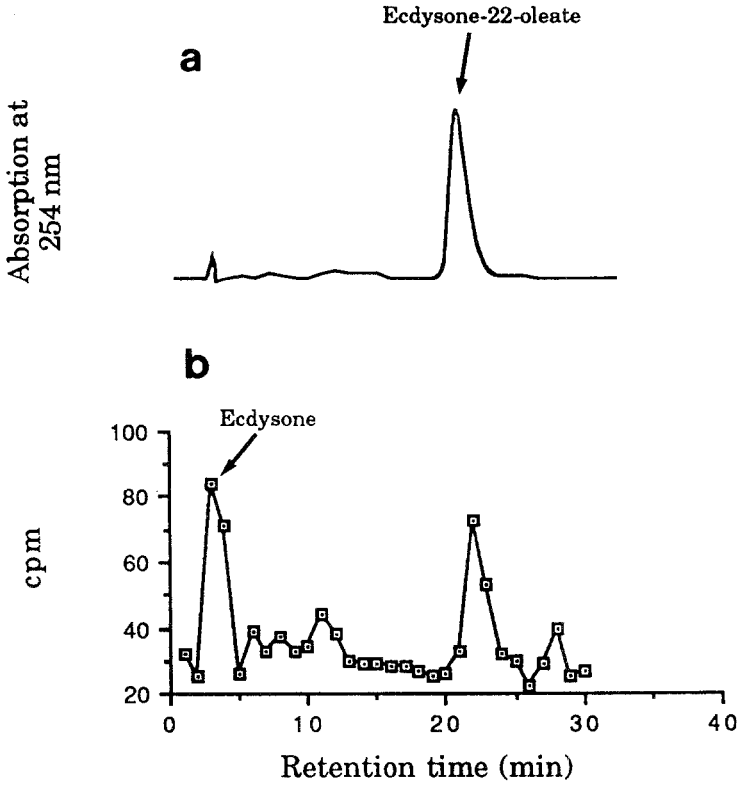

FIG. 1. HPLC analysis of ecdysteroid-22-*O*-acyltransferase product. (a) Synthetic ecdysone-22-oleate; (b) extract of the enzyme product.

(Figure 5). The enzyme activity was already high even without the introduction of 20-hydroxyecdysone.

Substrate Competition. When the ecdysteroid-22-*O*-acyltransferase assay mixture contained 20-hydroxyecdysone, ecdysone-22-oleate formation was inhibited (Figure 6), and the amount of ecdysone-22-oleate formed decreased as the concentration of 20-hydroxyecdysone or 20-hydroxyecdysone-2-acetate increased (Figure 7). But 20-hydroxyecdysone-22-acetate had no effect on ecdysone-22-oleate formation (Figures 6 and 7).

DISCUSSION

Our studies have shown that the majority of the ecdysteroid-22-*O*-acyltransferase activity was in the anterior part of the midgut. The ecdysteroid-22-*O*-acyltransferase activity detected in the foregut was probably due to the presence of some midgut tissue in the foregut homogenate.

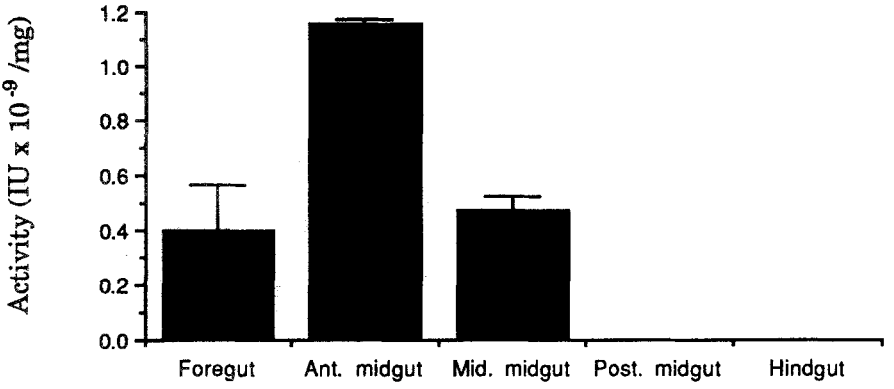

FIG. 2. Ecdysteroid-22-*O*-acyltransferase activities in different parts of gut tissues: anterior (ant.) midgut, middle (mid.) midgut, and posterior (post.) midgut. Each result is the mean of three replicates ± SE.

The codistribution of the ecdysteroid-22-*O*-acyltransferase and alkaline phosphatase activity in different epithelial centrifuge fractions suggested that ecdysteroid-22-*O*-acyltransferase localizes in the epithelial plasma membrane and possibly concentrates in the brush border membrane, which serves as a first barrier to the ingested noxious compounds.

Many noxious chemicals are commonly found in natural diets, and high detoxifying enzyme activities in the insect feeding stage are required in many cases. This may also be true for the ecdysteroid-22-*O*-acyltransferase activity, which is also very high during the feeding stage, to metabolize the noxious compounds.

However, the naturally occurring substrate for this enzyme has not been determined because it is still questionable whether ecdysteroids occur in the host of *H. virescens*. Besides, ecdysteroid-22-*O*-acyltransferase activity was very high even without the introduction of 20-hydroxyecdysone, and the activity did not increase after the introduction of 20-hydroxyecdysone (Figure 5), indicating that there may be other compounds that had already existed in the diet and that could induce this enzyme activity.

Substrate competition studies can give us some structural characteristics of the possible natural substrates of the ecdysteroid-22-*O*-acyltransferase. Our studies have shown that 20-hydroxyecdysone and its acetyl esters which contain unesterified 22-OH can compete with ecdysone as the substrate for ecdysteroid-22-*O*-acyltransferase and that, when 22-OH was blocked by forming an acetyl

ester, leaving the other hydroxyl groups intact, the ecdysteroids cannot compete with ecdysone in the enzyme assay, suggesting that this enzymatic esterification was restricted to the 22-OH in ecdysteroids and that the potential substrates occurring in nature should have similar structural characters.

Based on the fact that ecdysteroid-22-*O*-acyltransferase shares some common characteristics with other detoxifying enzymes with regard to location and

age distribution, we suggest that the major function of ecdysteroid-22-*O*-acyltransferase is to detoxify the noxious compounds ingested with the food. As the result of this enzyme reaction, the noxious compounds would be deactivated and excreted with feces. We have shown that ecdysteroid-22-acyl esters were over 100 times less active than 20-hydroxyecdysone in inducing the evagination of *Drosophila* imaginal disks (unpublished). Some of the deactivated products might be reabsorbed in the gut, but because of their high lipophilicity they would be restricted to the fat bodies and kept from reaching the target tissues. More studies are required to determine the spectra of naturally occurring substrates for this enzyme.

Abstract—This study investigated the influence of the plant antifeedants, pinosylvin and pinosylvin methyl ether (PME), on suppression of feeding by snowshoe hares (*Lepus americanus*). Screening bioassays showed clearly that pinosylvin suppressed feeding by hares when sprayed directly on coniferous tree seedlings. Pinosylvin odor, when associated with food (but not mixed with it), also significantly reduced consumption of rabbit chow by hares. Large pen bioassays indicated that both pinosylvin and PME significantly reduced feeding on tree seedlings by hares when the antifeedants were sprayed directly on trees. In field bioassays near Prince George, British Columbia, Canada, pinosylvin sprayed on trees and encapsulated in controlled-release devices of PVC plastic, with an internal wire as a twist-tie for attachment to tree, significantly reduced feeding by hares. Thus, pinosylvin will generate an "avoidance response" in terms of feeding by snowshoe hares. This response is likely triggered by an olfactory pathway based on positive results with controlled-release devices attached to seedlings. Our study reports the first practical utilization of plant antifeedants for forest crop protection and wildlife management.

Key Words—Plant antifeedants, pinosylvin, pinosylvin methyl ether,

snowshoe hare, *Lepus americanus*, herbivore, lodgepole pine, forest plantation, release devices, feeding suppression, crop protection.

INTRODUCTION

The snowshoe hare (*Lepus americanus*) is widely distributed across the boreal and subboreal forests of North America. This rabbit population fluctuates dramatically in abundance, with peaks occurring every 9–10 years (Keith, 1963). Hares prefer habitats dominated by early and midsuccessional deciduous and coniferous trees and shrubs which provide both food and cover (Conroy et al., 1979; Wolff, 1980; Pietz and Tester, 1983; Sullivan and Sullivan, 1983).

During peak years of the cycle, intense browsing may severely damage this natural food supply (Fox, 1978; Pease et al., 1979; Wolff, 1980). A consequence of this damage is the production of adventitious shoots which are very unpalatable to snowshoe hares (Bryant and Kuropat, 1980). These adventitious shoots of several common boreal forest trees contain significantly higher concentrations of terpene and phenolic resins than the mature growth form twigs of the same species (Bryant, 1981). In general, these resins are repellent to snowshoe hares and likely explain the avoidance of adventitious shoots by hares (Bryant, 1981).

One such boreal tree species associated with snowshoe hares is Alaskan green alder (*Alnus crispa*). Hares will feed on internodes but avoid juvenile growth forms of this species. This feeding preference is governed by concentrations of two deterrent secondary metabolites, pinosylvin and pinosylvin methyl ether; laboratory bioassays have confirmed the repellency of these two compounds to hares (Bryant et al., 1983; Clausen et al., 1986).

Feeding damage to coniferous plantations by the snowshoe hare (*Lepus americanus*) is a serious problem in many areas of forest regeneration in boreal and subboreal forests of North America (Radvanyi, 1987; Bergeron and Tardiff, 1988). Hares damage seedlings by clipping terminal and lateral shoots and by girdling stems. The most severe damage occurs in the 2–3 years during each peak in the 10-year cycle (Sullivan and Sullivan, 1982, 1988).

Repellents have been advocated as a potential means to reduce this damage (Sullivan and Crump, 1984; Radvanyi 1987). Some success has been achieved with predator odor repellents at the field level (Sullivan and Crump, 1984, 1986), but there have been no investigations of plant antifeedants as repellents for tree seedlings and snowshoe hares.

This paper reports on the influence of two plant antifeedants, pinosylvin and pinosylvin methyl ether, in suppressing snowshoe hare feeding on coniferous tree seedlings. The study was designed to test the hypothesis that these phenolic resins, when associated with tree seedlings, will elicit an "avoidance response" in terms of feeding by snowshoe hares.

METHODS AND MATERIALS

Synthesis of Compounds. Pinosylvin (3,4-dihydroxystilbene) **(5)** (Figure 1) was prepared in the following manner: the bistetrahydropyranyl ether of ethyl 3,5-dihydroxy benzoate **(1)** was reduced with lithium aluminium hydride in diethyl ether to the benyl alcohol **(2),** which was subsequently oxidized with pyridinium chlorochromate in dichloromethane to the benzaldehyde derivative **(3).** ^{1}H NMR ($CDCl_3$, 60 MHz): 3.2–3.9 (2H, bm, H_1'', and H^1), 7.0 (H, bs, H_4), 7.3 (2H, bs, H_2, H_6), 9.9 (1H, S, CHO). Benzyl bromide (11 ml) and triethylphosphite (29 ml) were heated under reflux for 2 hr and then excess reagents were distilled out (70°C water pump vacuum). The crude diethylbenzyl phosphonate was added to sodium hydride (3.4 g) in dimethyl formamide at 0°C, followed by the benzaldehyde derivative **(3)** (21.8 g). The mixture was stirred for 1 hr at 15°C, heated at 100°C for 1 hr, and then stirred at 15°C overnight. Workup and purification by silica gel chromatography gave the protected stilbene **(4),** 17.6 g. Deprotection was effected by heating the crude product in aqueous methanoic oxalic acid on a steam bath for 2 hr. Neutralization with $NaHCO_3$ followed by ether extraction gave pinosylvin, 9.4 g; mp 55–57°C (lit. 55–56°C). ^{1}H NMR ($CDCl_3$ 60 MHz): 6.45 (1, m, H_4), 6.90 (2, m, H_2, H_6), 7.10 (2, s, alkene), 7.10–7.50 (5, m, phenyl).

Pinosylvin methyl ether (3-hydroxy-5-methoxystilbene) **(6)** was similarly prepared from ethyl 3-hydroxy-5-methoxybenzoate. ^{1}H NMR ($CDCl_3$, 90 MHz): 3.78 (3, s, OCH_3), 6.35 (1, m, H_4), 6.40 (2, m, H_2, H_6), 6.67 (2, s, alkene), 7.24–7.44 (5, m, phenyl); M^+ 226. Purities of pinosylvin and PME were greater than 95%.

The vanillin PME analogue, 4-hydroxy-3-methoxystilbene **(7),** was similarly prepared from vanillin (4-hydroxy-3-methoxybenzaldehyde). ^{1}H NMR ($CDCl_3$, 60 MHz): 3.8 (3, s, OCH_3), 7.0 (2, bs, alkene), 6.8–7.6 (8, bm, aromatic); M^+ 226.

Compounds and Preparations. With respect to compounds and preparations, pinosylvin was tested as a 20% solution in methanol at 50 mg/tree. Seedlings were dipped in the solution and allowed to dry prior to the start of a given trial. As a prelude to the testing of controlled-release devices, a 5-cm-wide cloth band was impregnated with pinosylvin and attached around a 500-ml plastic bowl containing commercial rabbit chow. This compound was also tested in a clay pellet (activated alumina, Catalog No. H026-00-050, Edwards High Vacuum, Oakville, Ontario, Canada) which acted as a controlled-release device, in Wheaton vials, and on paper sohxlet extraction thimbles. Four or five pellets (or an extraction thimble) were attached to each seedling in a collar of Scotch tape. Untreated pellets (or thimbles) were attached to control trees. A final screening bioassay assessed the influence of a pinosylvin methyl ether **(7)** analogue on feeding. Feeding by hares on seedlings or chow (amount eaten)

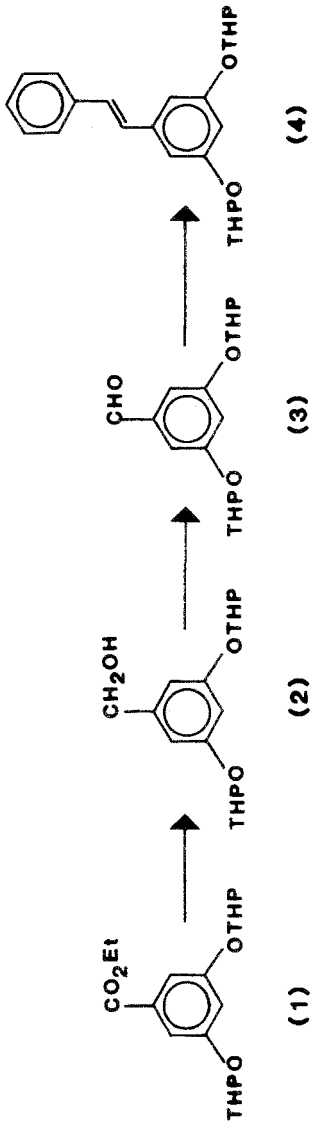

FIG. 1. Structural formulas of compounds.

was recorded daily in a given trial. Three bioassays were conducted with pinosylvin directly on trees, and two bioassays were done for each of the clay pellets, Wheaton vials, and thimbles.

Screening Bioassays. Bioassays were conducted at the Applied Mammal Research Institute, Langley, B.C., Canada. The bioassay enclosure (9.15 × 18.3 m) was composed of three sections or pens set in a natural environment (see Sullivan and Crump, 1984). The entire enclosure was covered by a fiberglass roof to eliminate effects of adverse weather. The control and experimental pens (A and B) were enclosed by polyethylene on the walls to keep odors within the respective treatment section. These pens had all natural vegetation cleared prior to start of trials. Douglas fir (*Pseudotsuga menziesii*) bark mulch covered the ground of each pen to a depth of 20 cm. Each pen had three experimental units, each composed of 10 Styrofoam blocks to anchor coniferous seedlings. One-year-old (nursery stock) lodgepole pine seedlings were used in all trials with one seedling per block. Thus, there was a maximum of 30 seedlings in each of the control and treatment pens (A or B) at the start of a given trial.

The natural habitat (pen C) was not cleared of native vegetation and provided cover and some grasses and forbs for hares. Thus, this pen served as a potential refuge area for hares. Access of hares to pens A or B from pen C was through 30 × 30-cm openings in each adjoining wall. Hares moved freely among all three pens and new animals were always allowed at least 5 to 7 days to acclimate to this experimental configuration. To exert adequate feeding pressure on the experimental material and keep social interactions at a minimum, one or two hares were used in each trial. All hares used were from our northern study areas at Prince George, B.C. Hares were replaced at regular intervals to overcome potential variability and habituation among animals. Rabbit pellets, grass hay, and water were available ad libitum throughout these trials.

Large Pen Bioassays. Two trials were conducted in a 4.5-ha enclosure at the Pineridge Forest Nursery, 130 km northeast of Edmonton, Alberta. The pen was composed of 2-m-high steel mesh and was buried in the ground to a depth of 30 cm. This study area was located in the boreal mixed wood zone (Strong and Leggat, 1981), with jack pine (*Pinus banksiana*) and aspen (*Populus tremuloides*) being the main tree species. Wild rose (*Rosa* spp.) and saskatoon berry (*Amelanchier alnifolia*) were the dominant shrub species. Within this area, four blocks (30 m × 30 m) were established and separated by at least 100 m. In July 1984, each block was cleared of trees and scarified in a manner similar to a typical logging and site preparation prescription. After planting, these blocks acted as plantations of lodgepole pine (*P. contorta*) seedlings in trials. Lodgepole pine is preferred by snowshoe hares over all other coniferous species (see Sullivan et al., 1985). Each block had 100 (10 × 10) seedlings for a given trial. The enclosure was stocked with snowshoe hares captured locally and from Prince George. This stocking allowed us to approach a peak population [4–5

hares/ha (Keith and Windberg, 1978)] of hares, thereby providing a rigorous test of various predator odor compounds in a simulated "field" situation. Both spring and fall represent periods when coniferous seedlings are particularly vulnerable to snowshoe hare feeding attacks. Snow cover is not adequate to protect seedlings and alternative summer herbaceous foods are not available.

In the first trial, pinosylvin and pinosylvin methyl ether (PME) were each made into 20% solutions with methyl alcohol. Fifty seedlings were dipped in the pinosylvin solution and another 50 seedlings were dipped in the PME solution. The 100 seedlings were then planted in a random manner in the experimental block. Methanol was applied to 50 trees in a control block which also had a total of 100 seedlings. The trial commenced on October 9, 1985, with browsing of seedlings checked on October 18 and 29 and November 7 (snow had essentially covered the seedlings by this time). Feeding (clipping) on the terminal was considered as mortality to a given seedling. All trees were completely covered with snow by mid-November and remained so until the spring assessment on May 2, 1986.

In the second trial, a solution of pinosylvin (5 g/37.7 ml methanol) was sprayed/dripped by syringe onto 50 (5 × 10) planted trees. A second set of 50 trees was treated with a similar solution of PME (5 g/37.7 ml methanol). The pinosylvin-treated trees were planted in one-half of the experimental block and the PME-treated trees in the other half. A second block acted as a control and had methanol only applied to 50 (5 × 10) of 100 trees. The trial began on May 2, 1986, and hare browsing of seedlings was checked on May 9, 22, and 28 and June 18.

A common observation in the pen trials at Pineridge Nursery was the apparent preference by hares to feed on seedlings adjacent to the forest edge within each block. Therefore, separate analyses have been conducted which exclude one row of perimeter trees from each block in the overwinter and spring trials. These adjusted results are compared with the standard results for each trial.

Field Bioassays. Two trials were conducted in central British Columbia during a snowshoe hare peak in population in 1988–1990. In the first trial, a plantation was located both at Shelley, 30 km northeast of Prince George, and near the Salmon River, approximately 60 km northwest of Prince George. Both sites were planted in the spring of 1988, interior spruce (*Picea glauca* × *Picea engelmannii*) at Shelley and lodgepole pine at Salmon River. In each plantation, all control and treatment blocks were located adjacent to areas with heavy vegetation cover within or on the perimeter of the plantations. Feeding damage by snowshoe hares tends to be most severe near such cover. Three blocks of 200 trees each were chosen at each plantation. A 20% solution of pinosylvin in methanol was sprayed directly on each of the 200 trees in one treatment block at each plantation. The same concentration of pinosylvin encapsulated in a

6-cm-long PVC plastic rope with internal copper wire as a twist-tie (PheroTech Inc., Delta, B.C., Canada) was attached to each tree in the second treatment block at each plantation. The third block acted as a control. Prior to application, 10% of the trees on each respective treatment and control block were flagged as sample trees. The applications were installed on October 30–31, 1988, and efficacy of treatments was evaluated on May 15–16, 1989. As for the large pen trials, feeding on the terminal was considered as mortality to a given seedling.

In the second trial, three plantations were located near the Salmon River, and one large plantation was located 80 km east of Quesnel. Again, control and treatment blocks were established near heavy vegetation cover or on the perimeter of the plantations. At each study site, pinosylvin was dispensed via a spray application (50 mg/tree) directly onto trees (1-year-old lodgepole pine and interior spruce seedlings planted in spring 1989), in controlled-release devices (25 mg/tree) of PVC plastic with the internal wire, plastic bubble caps, and C-flex rubber tubing. Each treatment was applied to a total of 400 trees with three replicate blocks at the Salmon River site and four replicates at the Quesnel site. Replicate control blocks completed the experimental design at each site. This trial was installed during October 15–30, 1989, and feeding damage to seedlings was assessed during May 21–31, 1990.

Statistical Analysis. Comparison of the number of seedlings surviving in control and treatment blocks was analyzed by chi-square, with significance levels of $P < 0.05$ and $P < 0.01$.

RESULTS

Screening Bioassays. In the initial two bioassays, pinosylvin sprayed directly on trees reduced feeding by hares over a 2-day period with respect to percentage of seedlings surviving (trial 1—control, 0.0 and 0.0, treatment, 66.7 and 33.3; trial 2—control, 13.3 and 0.0, treatment, 90.0 and 90.0). A more intensive assessment was conducted in trial 3 (Figure 2). Pinosylvin clearly suppressed feeding by hares compared with the control block and declined in efficacy only after control trees stopped being replaced at day 8.

The excellent results of trial 3 set the stage for testing controlled-release devices for pinosylvin. A contact repellent will not protect new tree growth and is not durable to prevailing weather conditions. Some type of encapsulation is necessary since an effective repellent should be present as an odor in the plantation environment but not necessarily attached to tree foliage. Results of four replicate trials assessing the influence of pinosylvin odor (soaked in cloth) on feeding by hares indicated a significant reduction in percentage of chow consumed after each 24-hr trial: (1) control, 39.0%, and treatment, 0.0%; (2) control, 54.3%, and treatment, 8.4%; (3) control, 68.2%, and treatment 7.2%;

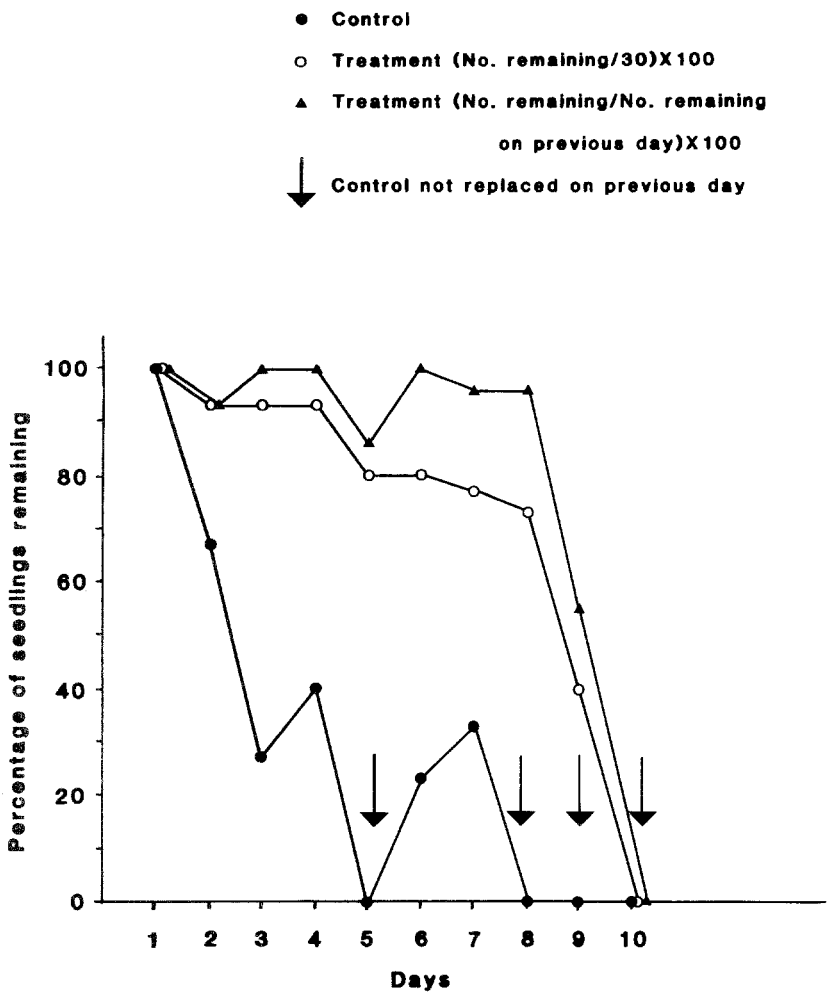

FIG. 2. Screening bioassay of the efficacy of pinosylvin in suppressing feeding on lodgepole pine seedlings by snowshoe hares.

(4) control, 46.0%, and treatment, 16.9%. The Wheaton vials and extraction thimbles attached to trees were not effective as controlled-release devices for pinosylvin. However, the clay pellets, when soaked in the pinosylvin for 24 hr prior to a trial, did significantly reduce feeding over a 2-day period with respect to the percentage of seedlings surviving (control, 10.0 and 0.0; treatment, 87.0 and 53.0). A lower concentration of pinosylvin in the pellets or fewer pellets per tree did not reduce feeding.

A final screening bioassay on the pinosylvin methyl ether analogue (7) showed that this compound had no effect on feeding by hares with respect to the percentage of seedings surviving over a 2-day period: control, 50.0 and 3.3; treatment, 43.3 and 10.3.

Large Pen Bioassays. Pinosylvin and PME significantly reduced hare feeding on pine seedlings throughout the fall trial of 1985 and, again, in the spring of 1986 (Figure 3A). There was no difference between pinosylvin and PME in reduction of feeding, and so these data were combined. In addition, survival of nonperimeter trees was significantly higher than that recorded when perimeter trees were included in the analysis. This trial was terminated on May 2. The spring 1986 trial with pinosylvin and PME, in separate halves of the block, also indicated that these compounds significantly reduced hare feeding (Figure 3B). These results provide temporal replication and, when combined with the screening bioassays, clearly show the impressive potential of pinosylvin as an antifeedant for snowshoe hares.

Field Bioassays. In the first trial, pinosylvin sprayed directly on trees and as an antifeedant odor from a plastic controlled-release device significantly reduced feeding damage to lodgepole pine seedlings (Table 1). There was insufficient browsing on spruce seedlings but the tendency was for less feeding in the pinosylvin-treated blocks.

In the second trial, one of three plantation replicates had sufficient feeding pressure to make comparisons among control and treatment blocks at the Salmon River site. The pinosylvin spray and PVC + wire and plastic bubble cap significantly reduced feeding compared with the control and C-flex tubing treatment blocks (Table 2). There was insufficient browsing on seedlings throughout all control and treatment blocks to make any statistical comparisons at the Quesnel site.

DISCUSSION

This study has clearly demonstrated that the plant antifeedant, pinosylvin (and PME), will suppress feeding by snowshoe hares. This feeding suppression corroborates those results obtained by Bryant et al. (1983) and Clausen et al. (1986) for bioassays with pinosylvin and laboratory foods. Our study reports the first test and use of pinosylvin associated with tree seedlings as a plant antifeedant repellent. Therefore, we accept the hypothesis that pinosylvin will generate an "avoidance response" in terms of feeding by snowshoe hares. This response is likely triggered by an olfactory pathway based on our results with the controlled-release devices attached to seedlings. The odor of pinosylvin was clearly an effective means of discouraging hares from feeding.

There are several studies of other plant antifeedants deterring snowshoe

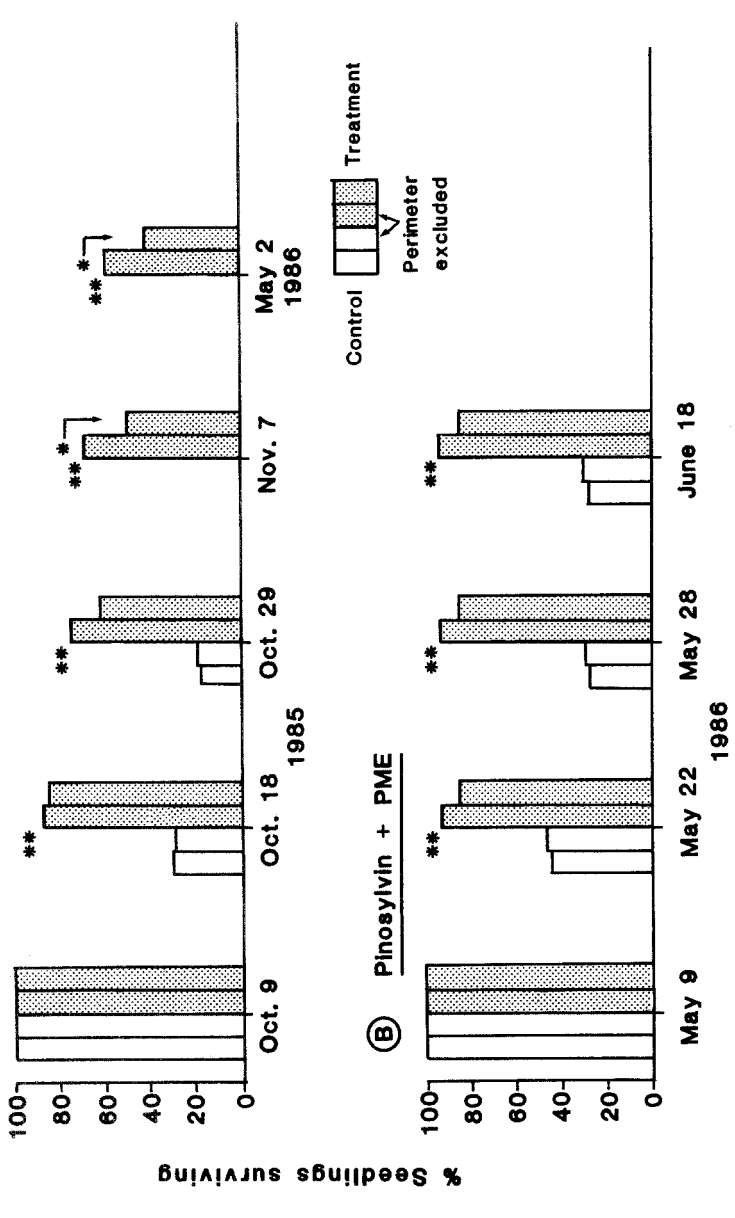

FIG. 3. Efficacy of pinosylvin + pinosylvin methyl ether (PME) in suppressing feeding on lodgepole pine seedlings by snowshoe hares during: (A) fall (October–early November) and overwinter to the spring (early May); (B) spring (May–June). Analyses were conducted with and without one row of perimeter trees in each block. (*) $P < 0.05$; (**) $P < 0.01$; significant difference by chi-square.

hares from feeding. These include papyriferic acid from Alaska paper birch (*Betula resinifera*) (Reichardt et al., 1984), phenolglycoside and catechin fractions of willow (*Salix* spp.) bark (Tahvanainen et al., 1985), camphor from white spruce (Sinclair et al., 1988), germacrone from labrador tea (*Ledum groenlandicum*) (Reichardt et al., 1990a), and several compounds from balsam poplar (*Populus balsamifera*) (Jogia et al., 1989; Reichardt et al., 1990b). An intriguing follow-up to these studies would be testing of the various antifeedants on tree seedlings to determine their repellency to snowshoe hares. In particular, camphor from juvenile white spruce suppresses feeding on rabbit chow by hares in a laboratory situation (Sinclair et al., 1988). Plantations of nursery-raised white and interior spruce seedlings on cutover forest land are fed on by snowshoe hares during peak populations. Therefore, a critical test for camphor as an antifeedant is to apply the compound to tree seedlings in a field situation as we have done in our study. Camphor is presumably at a low concentration in nursery-raised spruce, or other metabolic constituents may mask the antifeedant effect of this compound.

Similar feeding damage to tree seedlings is often caused by high populations of voles of the genus *Microtus* (Green, 1978; Roy and Bergeron, 1990a; Sullivan and Martin, 1991). Preference for certain coniferous species and rejection of others was related to concentration of phenolic compounds (Hansson et al., 1986; Roy and Bergeron, 1990a). In addition, voles will manipulate their food resource by cutting branches of young seedlings, and after 3 days, the cut branches have significantly less phenolics and condensed tannins (Roy and Bergeron, 1990b). By this manipulation, a low-quality resource is transformed into one compatible with vole feeding patterns and detoxification mechanisms. The senior author has also observed this behavior in snowshoe hares, which may cut and leave seedlings in plantations. Thus, mammals are able to evaluate the palatability of potential foods on the basis of secondary metabolites. Pinosylvin clearly plays a role in this selection for snowshoe hares and, along with other plant antifeedant compounds, may regulate the 10-year cycle of abundance (Bryant and Kuropat, 1980; Bryant et al., 1983; Coley et al., 1985).

The specificity of chemical structure of pinosylvin appears to be of critical importance to the snowshoe hare. Presumably pinosylvin and other repellent antifeedants have specific receptor sites within the olfactory system of the snowshoe hare and perhaps other small mammal herbivores. The ineffectiveness of the PME analogue (7) as an analogous compound to pinosylvin supports this specificity. This result is similar to that recorded for mustelid scent gland compounds and their analogues (Sullivan and Crump, 1984).

The use of avoidance-inducing compounds as area repellents to reduce feeding damage to tree seedlings is clearly important to forest protection and management. A plant-derived repellent, pine oil, which is a mixture of terpene alcohols and monoterpenes has reduced feeding by snowshoe hares and voles (*M. townsendii*) when mixed with laboratory rations (Bell and Harestad, 1987). Similarly, red deer calves (*Cervus elaphus*) consumed less laboratory rations when this food was mixed with odors of crushed lodgepole pine and various monoterpenes (Elliot and Loudon, 1987). Again, as discussed previously, the critical test for plant antifeedants, as repellents to reduce feeding by herbivores, is application of the synthetic compounds to tree seedlings in field situations. Our study reports the first practical utilization of plant antifeedants for crop protection and wildlife management.

Acknowledgments—We thank the Forest Research Branch of the Alberta Forest Service (AFS) and the Forest Resource Development Agreement (British Columbia Ministry of Forests and Forestry Canada) for financial support and provision of seedlings. We thank Lakeland Mills Ltd. for logistical support and A. Chadderton, V. Craig, N. Daintith, and C. Sutherland for field assistance. We are grateful to Pineridge Forest Nursery, AFS, for the enclosure facility and assistance of P. Au and B. Court. Special thanks to J. Soos, former director of the Research Branch, AFS, for his vision and support of this work. We thank S. Bloor, DSIR Chemistry, for preparing the PME analogue.

EVIDENCE FOR THE ACCESSORY GLANDS AS THE SITE OF PRODUCTION OF THE OVIPOSITION ATTRACTANT AND/OR STIMULANT OF *Lutzomyia longipalpis* (DIPTERA: PSYCHODIDAE)

MARTIN J. DOUGHERTY,* RICHARD D. WARD, and GORDON HAMILTON

Department of Medical Entomology

(Received July 16, 1991; accepted March 4, 1992)

Abstract—The phlebotomine sandfly *Lutzomyia longipalpis* Lutz and Neiva, the vector of visceral leishmaniasis in South America, has recently been shown to produce an oviposition semiochemical. In the present study it was found that a nonpolar extract of eggs was attractive and/or stimulatory to ovipositing females. A chromatographic investigation indicated the presence of similar compounds in accessory glands and egg extracts. Extract of accessory gland was also found to elicit a positive oviposition response. It is concluded that the pheromone is produced in the accessory glands and is secreted onto the eggs during oviposition.

Key Words—*Lutzomyia longipalpis*, Diptera, Psychodidae, oviposition, pheromone, accessory gland, bioassay.

INTRODUCTION

Pheromones from the eggs of a number of heamatophagus Diptera have been shown to attract ovipositing females; these include *Culex quinquefasciatus* Say Wiedmann (Bruno and Laurence, 1979; Sakaibara et al., 1984; Laurence et al., 1985; Laurence and Pickett, 1985; Hwang et al., 1987). A review of the various *Culex* species oviposition site selection cues, including orientation toward egg pheromone sources, is given by Bentley and Day (1989). Ovipositing *Aedes atropalpus* Coquillett are also attracted to an oviposition attractant produced by immature stages (Kalpage and Brust, 1973). Furthermore, Soman and Reuben

*To whom correspondence should be addressed.

0098-0331/92/0700-1165$06.50/0 © 1992 Plenum Publishing Corporation

(1970), showed that gravid *Aedes aegypti* (L.) females were attracted to water containing immature stages of the same species.

Recently, Elnaiem and Ward (1990, 1991a) showed that eggs of the sandfly *Lutzomyia longipalpis* Lutz and Neiva have an attractant and/or stimulant effect, related to the presence of a semiochemical, perceived by conspecific, ovipositing females. When eggs were washed in a series of polar and nonpolar solvents, the oviposition response was no longer elicited. This demonstrated that the oviposition attractant and/or stimulant effect was chemically mediated, and not due solely to a visual or tactile effect of the eggs.

The field behavior of *L. longipalpis* during oviposition is little studied. The females are known to be gonotrophically concordant and pass through more than one gonotrophic cycle (Guilivard et al., 1980, Dye et al., 1987). A major problem in the study of the transmission of leishmaniasis is the very high mortality rate found at oviposition. This is attributed to the difficulty in matching laboratory and field conditions. Females are known to lay up to 100 eggs in a single oviposition but the normal number is 40. In the wild, the eggs are thought to be laid in microhabitats, such as cracks and crevices (Young et al., 1926; Lewis and Kirk, 1954; Ward, 1974), rich in organic nutrients and are difficult to find in normal circumstances. The eggs are laid in humid conditions and it is known that control of temperature and humidity is an essential requirement of colony maintenance (Killick-Kendrick, 1977).

The photoperiod does not affect the success of oviposition of *L. longipalpis* but does markedly alter the oviposition periodicity (Ready, 1976). Based on laboratory observations it appears that some species are capable of long periods of dormancy (Johnson and Hertig, 1961). While capable of withstanding desiccation, the eggs are resistant to prolonged immersion (Chaniotis, 1967). This is a useful adaptation in a terrestrial insect that may often suffer temporary inundation due to rainfall.

Accessory glands of many female insects produce secretions which are present in or on oviposited eggs (Adiyodi and Adiyodi, 1989). In the present study, therefore, we investigated if organic or aqueous extracts of *L. longipalpis* eggs retained biological activity similar to that induced previously by the use of whole eggs. In addition, a chromatographic investigation was carried out to determine if the female accessory glands had a role in the production of the semiochemical.

METHODS AND MATERIALS

Colonization

The sandflies used in the experiments were *L. longipalpis* established from flies collected at Jacobina, Bahia, Brazil, and maintained in the laboratory for

6 years using methods described by Modi and Tesh (1983), at 95% RH, a room temperature of 28°C, and a 12h L:D photoperiod.

Female *L. longipalpis* were fed on Syrian hamsters anesthetized with 12 mg/ml of sodium pentabarbitone and were kept for 4 days to allow for complete defecation and oogenesis before use in bioassays.

Sample Preparation

All eggs used for extraction purposes were taken from colony rearing pots 1 to 2 days after oviposition. To prepare the nonpolar egg extract, 1000 eggs were placed in a 2-ml microvial (Alltech) and left for 24-hr at −70°C in 100 μl of pesticide-grade hexane (BDH Chemicals). Accessory gland extracts were prepared from 50 gravid females that had been blood-fed 4 days previously. The glands were excised under a stereoscopic microscope and the tissue was transferred to a 2-ml microvial using a micropipette and extracted as described above. The remaining female bodies were also similarly extracted, to provide material for a negative control. To prepare the polar extract 1000 eggs were placed in a 2-ml microvial and extracted in 100 μl of double-distilled, deionized H_2O at 3°C for 24 hr; 100 accessory glands and the remainder of the female bodies were also similarly extracted. The preparation of material for HPTLC and GC analysis used the same protocol as described above. Five hundred *L. longipalpis* eggs and 50 excised female accessory glands were extracted in 20 μl of hexane. Further, for GC analysis, five whole male, whole female, and female flies without accessory glands were extracted in 40 μl of hexane. Samples were stored at −70°C.

Bioassay

Only eggs laid in the test and control sites were counted. The bioassay was an adaptation of that used by Elnaiem and Ward (1991). The bioassay chambers were modified polymethylpentene (BDH apparatus) rearing pots. Modifications included the use of two oviposition areas, 2 cm^2, termed test and control, with lightly demarcated perimeter grooves on the plaster of paris base.

Six bioassays were conducted, each with 10 replicates, using 20 females per replicate. In each oviposition chamber a 10 μl aliquot of sample extract was pipetted onto the plaster of paris base at the test site. The control was 10 μl of pure extraction solvent. This test volume consistently gave an equivalent of 100 eggs, accessory glands from five females, or five female bodies without accessory glands. Bioassays performed were (a) nonpolar egg extract versus hexane control, (b) nonpolar accessory gland extract versus hexane, (c) polar egg extract versus water control, (d) polar accessory gland extract versus water, (e) nonpolar extract of females without accessory glands versus hexane, and (f) polar extract of females without accessory glands versus water.

After loading the oviposition areas in the bioassay chambers with the test

and control samples, 20 gravid females were introduced and left for 3 days under normal colonization conditions. The females were provided with a small wad of cotton wool, soaked with a saturated solution of sucrose, placed on top of the oviposition chamber. Provision of a sugar meal is known to increase the number of eggs laid per sandfly (Ready, 1979).

Statistical Analysis

The bioassay design gives a matched pair of results, which was found to be nonparametric. As such, Wilcoxon's rank paired test was employed to a 95% confidence level.

Chemical Analysis

High-Performance Thin-Layer Chromatography (HPTLC). High-performance TLC plates were 10 × 20 cm, coated with a 200-μm-thick layer of silica (Whatman Lab Supplies). The developing solvent was a 1 : 1 chloroform/hexane solution (BDH Chemicals), described by Kates (1986), for nonpolar lipids. HPTLC plates were prepared by baking at 200°C for 24 hr and then cleaned by running twice in the solvent system. Twenty-microliter aliquots of egg and accessory gland extract (25 female equivalents) were applied to the plates with 2-μl capillary tubes. Twenty micrograms of each of five standards (cholesterol, cholesterol linolenate, cholesterol stearate, squalene and caryophyllene oxide; Sigma Chemicals) was applied to the plate. Plates were visualised by ultraviolet light at 302 nm, followed by charring with concentrated H_2SO_4/EtOH solution (1 : 1, v/v) and baking at 110°C for 10 min. Comparisons of samples and standards were carried out using R_f values.

Gas Chromatography. Gas chromatography was performed on a Shimadzu GC-15a (Dyson Instruments), fitted with a Grob splitless injection system with a 0.6-min sampling time. The column used was a 30-m, fused silica DB1 capillary column, with a 0.25-μm film thickness (J. and W. Scientific). The temperature program was as follows: 45°C initial, increased at 15°C min^{-1} to 250°C, held for 4 min, increased at 10°C min^{-1}, and then held at 350°C for 4 min. The carrier gas was helium at a pressure of 4.5 kg cm^3 and the injection block and detector temperatures were 250 and 350°C, respectively. Integration was carried out with the Shimadzu CR5a Chromatopac (Dyson Instruments).

Only nonpolar extracts were analyzed by GC. Samples included extracts of eggs, female accessory glands, whole males, whole females, and females without accessory glands prepared as described above. Before being analyzed by GC, extracts, cooled on ice, were reduced under N_2 to 1 μl.

RESULTS

Bioassays

The bioassay results are summarized in Table 1. The response of *L. longipalpis* during oviposition to hexane extracts of egg and accessory gland material showed a highly significant difference between the test and the control sites. Neither the hexane nor the aqueous extracts of female bodies without accessory glands produced a statistically different number of eggs at the test and control sites. Aqueous extracts of both egg and accessory glands failed to induce an oviposition response. Thus nonpolar extracts of both egg and accessory gland material were the only samples to elicit the biological response which has previously been associated with whole eggs.

Thin-Layer Chromatography

The HPTLC analysis demonstrates chemicals present in both egg and accessory gland samples that are of a very similar polarity (Table 2). A compound which has a R_f value similar to that of cholesterol, lane 1 ($R_f = 0.12$), is present in both, as is a compound that is more polar than cholesterol. Two other pairs of matching spots are observed on the HPTLC plate. The spots at $R_f = 0.51$ (accessory, lane 6) and $R_f = 0.50$ (egg, lane 7) are only slightly less polar than caryophyllene oxide, lane 4 ($R_f = 0.48$). At $R_f = 0.62$ (accessory) and $R_f = 0.66$ (egg) two spots were exhibited of a polarity similar to that of cholesterol stearate, lane 5, and cholesterol linolenate, lane 1.

all the samples, with peaks 1 and 2 being specific to eggs and accessory glands. Male *L. longipalpis* has two major peaks, at 11.052 and 11.511. These are known to originate from the tergal glands (Hamilton, personal communication). Whole-female extract has major peaks at 11.887 and 13.509, which are not

present in the whole male samples. These two peaks (peaks 1 and 2 on the chromatogram) do occur in female accessory gland extract (11.896 and 13.502) and in egg material (11.862 and 13.521) and are greatly reduced in samples of females with excised accessory glands.

DISCUSSION

This is the first demonstration that the oviposition semiochemical present on the eggs of *L. longipalpis* may be extracted in hexane, indicating that the molecule is a relatively nonpolar organic compound. Furthermore, the extract does not lose its oviposition attractant and/or stimulant properties when bioassayed. The hexane extract of the accessory gland material also elicited similar biological activity. In contrast, hexane extracts of female bodies from which accessory glands had been excised did not elicit an oviposition response, nor did any of the aqueous extracts.

The gas chromatographic analysis revealed that two compounds which occur in extracts of whole female flies and accessory glands are also present in extracts of eggs. These compounds are absent in females without accessory glands and from whole males. The HPTLC results indicate that two compounds of comparable polarity are present in egg and accessory gland material. These compounds are of a polarity similar to that of cholesterol linolenate or cholesterol stearate and caryophyllene oxide, all of which are oxygenated compounds.

Chromatographic and bioassay evidence suggests that the semiochemical(s) present on *L. longipalpis* eggs is produced by the accessory glands of the female. It appears that as eggs are laid, the semiochemical is coated onto them from this gland. It is known that secretions from the accessory gland include a sticky substance, which is used to adhere the egg to oviposition substrates (Davis, 1967; Wu and Tesh, 1989). Adiyodi and Adiyodi (1989) reviewed the role of the accessory glands of female insects, noting them to have a secretory role in both egg maturation for ootheca production and during oviposition.

In contrast, the presence of oviposition-deterring pheromones in sticky secretions used to adhere eggs to oviposition substrates has been shown in the sorghum shoot fly, *Atherigona soccata* (Raina, 1981). Here, a water-soluble glue is used to stick eggs to the leaves of sorghum.

Little is known about the attractant and/or stimulant role of the *L. longipalpis* oviposition pheromone. It is possible that the pheromone acts over a limited range, with the female being directed to oviposition sites by long-range volatile chemicals from organic substrates and physical characteristics of the oviposition substrate. In this situation the pheromone would be the final phase in the oviposition site selection mechanism. Elnaiem and Ward (1991b) produced some circumstantial evidence for the above hypothesis, showing that

oviposition *L. longipalpis* females were attracted to an aqueous extract of rabbit feces, a component of the laboratory larval rearing medium. Schlein et al. (1990) also found that *Phlebotomous papatasi* chose oviposition sites by physical and chemical stimuli in the oviposition substrate. Furthermore, it is known that *Culex* females select oviposition sites by environmental, physical, chemical, and pheromonal cues.

Use of an oviposition pheromone by *L. longipalpis* may lead to larval aggregation, which may be advantageous in overcoming factors such as predation and parasitism (Manning, 1979). However, attempts to locate sandfly larval breeding sites in soil samples have only shown sparsely scattered immature stages (Hanson, 1961; Thatcher, 1968; Rutledge and Mosser, 1972). However, Bettini et al. (1986), using emergence traps, were successful in collecting 27,405 emergent flies from a 25-m^2 breeding site in 1 year. Further investigation is therefore needed to clarify the apparent disparity between the results from these two sampling techniques and to investigate the role of the oviposition pheromone in the field. It is recognized that some oviposition pheromone-like activity has been associated with the presence of volatiles from bacterial activity, as with *Lucilia cuprina* Wiedmann (Emmens and Murray, 1983). As accessory gland extract of female *L. longipalpis* elicited a response and samples of female bodies without these glands did not, it is thought that this phenomenon is not occurring here. Further work is currently being carried out to clarify this point and to determine the structure of the components of egg and accessory gland material that are responsible for the biological activity.

Acknowledgments—This work was carried out with financial support from the Wellcome Trust, London.

(Received January 9, 1992; accepted March 4, 1992)

Abstract—The thoracic glands of males in two ant-lion species *Synclysis baetica* and *Acanthaclisis occitanica*, which occur sympatrically in Israel, were found to contain a volatile secretion with two-component blends of nerol oxide and (*R*,*Z*)-6-tridecen-2-ol (approx 1:5) and nerol oxide and 10-homonerol oxide (approx. 1:2), respectively. Chemical analyses were performed using gas chromatography–mass spectrometry, chiral gas chromatography, and ozonolysis, and the proposed structures were confirmed by synthesis. The species-specific, few-component volatile signals are thought to function as a

reproductive isolation mechanism between the two sympatric species. Biochemical relationships between the nerol derivatives and between the unsaturated secondary alcohols are discussed.

Key Words—Ant lions, Neuroptera, Myrmeleontidae, (*R*,*Z*)-6-tridecen-2-ol, nerol oxide, 10-homonerol oxide, biosynthesis, enantiomers, gas chromatography–mass spectrometry, sympatric species isolation.

INTRODUCTION

Synclysis baetica and *Acanthaclisis occitanica* belong to Acanthaclisini, a tribe well defined by larval and adult characteristics that, in contrast to most other tribes, exhibits limited diversity (Stange and Miller, 1985). Both species have a holo-Mediterranean distribution and are widespread sympatrically along the coastal sand dunes of Israel. Aspects of their biology and coexistence in Israel were described by Simon (1988).

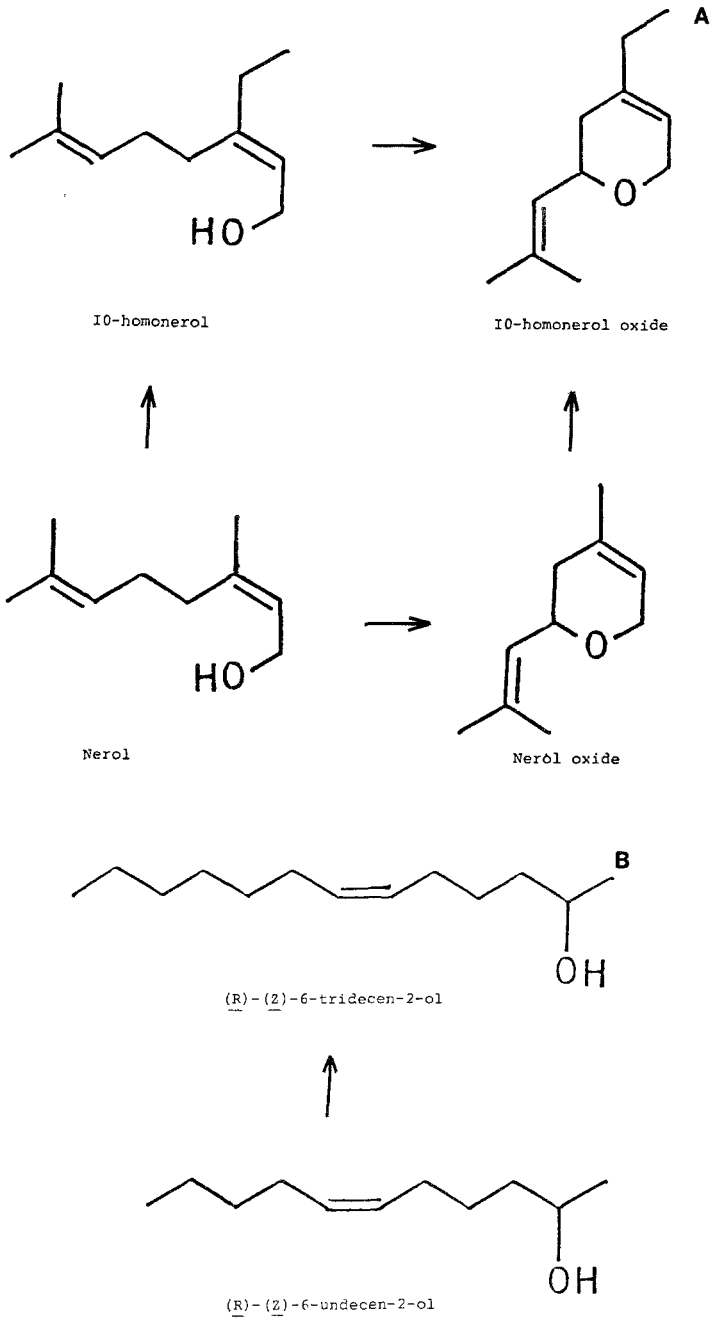
Male ant lions produce two-component secretions in their thoracic glands, which are species specific and thought to function as a reproductive isolation mechanism (Elofson and Löfqvist, 1974; Löfqvist and Bergström, 1980; Baeckström et al., 1989). Components of the secretions in three species have been identified as derivatives of the monoterpene alcohol nerol and a straight-chain, unsaturated C_{11}-alcohol, "nostrenol" (Baeckström et al., 1989). Females of the same species contain nerol oxide in small amounts.

In the present report we have analyzed the thoracic gland secretion of two additional species from Israel, *Synclysis baetica* Rambur 1842 and *Acanthaclicis occitanica* Villers 1789, as a part of an evolutionary study of volatile signals in ant lions. The biochemical pattern of volatile compounds reported earlier in *Euroleon nostras*, *Grocus bore*, and *Myrmeleon formicarius* (Baeckström et al., 1989) is now reinforced by the finding that, also in the two species now studied, each produces a different two-component combination on the same theme (Scheme I). It is thus shown that even in these species, specificity is achieved by a blend of just two compounds.

METHODS AND MATERIALS

Collection and Preparation of Insect Material

Third-instar larvae of both species were collected from the coastal sand dunes of Israel. They were reared individually in plastic vials and fed house fly maggots. Emerging adults were kept alive for 2–4 days, after which they were



SCHEME I. Possible biochemical relationship between the chemical compounds identified from five species of ant lions. (A) Nerol-related compounds; (B) monounsaturated, secondary alcohols.

frozen and immediately dissected under water. The thoracic glands were removed and placed in methylene chloride for extraction.

Identification of Volatiles

Methylene chloride extracts of thoracic glands were analyzed by GC-MS (Finnigan 4021 equipped with an Incos data system) on a fused silica capillary column coated with Superox FA (25 m × 0.15-mm I.D., df = 0.3 μm). Nerol oxide and 10-homonerol oxide were identified by comparing gas chromatographic retention values and mass spectra of the natural components with those of synthetic reference compounds (Baeckström et al., 1989).

Gas Chromatography of Enantiomers

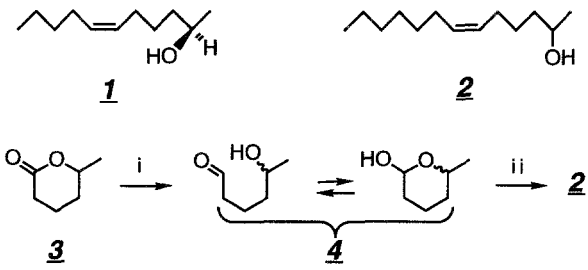
Separation of the nerol oxide and 10-homonerol oxide enantiomers was carried out on Ni(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate] (CC&CC, Postfach 14, D-7402 Kirchentellinsfurt, Germany) and Mn(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate] columns. Enantiomers of (*Z*)-6-tridecen-2-ol were separated as isopropyl carbamate derivatives on a XE-60-(*S*)-valine-(*S*)-2-phenylethylamide column, according to König and Francke (1982). For further GC data, see Fig. 3.

Ozonolysis

The unknown compound was isolated by preparative gas chromatography (Carlo Erba 4160), according to Wassgren and Bergström (1984), on a capillary column coated with OV-351 (20 m × 0.32-mm I.D., df = 0.64 μm). The collected fraction was then dissolved in hexane and ozonized according to Beroza and Bierl (1967). Separation and identification of the ozonolysis products were obtained by GC-MS.

Synthesis

5-Hydroxyhexanal or Cyclic Hemiketal (Compound 4; Scheme II). δ-Hexanolide (**3**) was prepared from 5-oxohexanoate (Merck) according to the literature (Ansell et al., 1968). δ-Hexanolide (**3**; 0.5 g, 4.2 mmol) was stirred in dry tetrahydrofuran (THF; 5 ml) in an argon atmosphere at −50°C. Diisobutylaluminium-hydride (1.5 *M* in toluene, 20 mmol, 13.3 ml, dissolved in THF, 5 ml) was added dropwise during 20 min and stirred at −50°C for an additional 40 min. GC analysis indicated no remaining starting material. At the same temperature $Na_2SO_4 \cdot 10H_2O$ (6 g) mixed with the same volume of Celite was then added. The reaction mixture was slowly warmed to room temperature, then filtered, and the solids were washed with diethyl ether. The solution was dried (with $MgSO_4$), filtered, and concentrated carefully to give a toluene solution.



SCHEME II. (i) Diisobutylaluminiumhydride, tetrahydrofuran, −50°C. (ii) $CH_3(CH_2)_5CH{=}P(Ph)_3$, dimethyl sulfoxide, 25°C.

Most of the toluene was removed by distillation through a column at 100 mm Hg, leaving a mixture of toluene and the desired product, **4**) (shown in Scheme II) in its hemiketal form, which was used directly in the next step. IR (film): 3650–3100 s broad, no peak in the carbonyl region. NMR (60 MHz, $CDCl_3$): δ1.1 and 1.2 (3H, two d, J = 5 Hz), 1.3–2.0 (6H, m), 3.2–4.1 (1H, m, on irradiating at δ1.15 ppm, two broad s appeared), 4.2–4.7, (1H, disappeared on shaking with D_2O), 4.6–5.0, and 5.1–5.3 (1H, two broad m) ppm and signals due to toluene.

(Z)-6-Tridecen-2-ol (Compound 2; Scheme II). Sodium hydride (50% in oil, 0.405 g, 8.26 mmol) was washed twice with dry THF and the residual THF was evaporated in an argon atmosphere. Dimethyl sulfoxide (DMSO; 30 ml freshly distilled from CaH_2, stored over 4-Å mol sieves) was added under argon at room temperature. The mixture was stirred and warmed at 60°C until hydrogen evolution stopped and a clear grayish solution formed (2 hr). After cooling to 20°C, heptyltriphenylphosphonium bromide (3.65 g, 8.26 mmol) was added under a blanket of argon. The deep red heptylidenephosphorane was formed instantaneously. After 0.5 hr the toluene solution (from the step above) containing product **4** (approximately 4.2 mmol) was diluted with DMSO (10 ml) and added dropwise during 0.3 hr under cooling. After stirring for an additional 1.5 hr, the brownish-black solution was poured into water and extracted with hexane several times. The combined organic extracts were dried (with $MgSO_4$) and concentrated to 10 ml. Storage in the freezer overnight caused the triphenylphosphine oxide to separate, and it was then removed by filtration. After evaporation of the solvent the residue was distilled bulb to bulb (110°C/0.1 mm), furnishing a colorless oil (0.450 g, 54% calculated on the hexanolide) that tested pure by GC. Attempts to analyze the *Z/E* ratio by GC on several phases were not successful. However, the *Z/E* ratio was estimated to be 91/9 on the basis of analysis of the *N*-isopropyl carbamate derivative (see Figure 2). *Anal.* Calc. for $C_{13}H_{26}O$: C, 78.7%; H, 13.2%. Found: C, 78.6%; H, 13.4%. n_D 1.4563. IR (film): 3500–3100 s broad, 3025, no medium or strong peak at

950–1000 cm^{-1}. NMR (60 MHz, $CDCl_3$): δ0.93 (3H, t), 1.32 (3H, d, J = 5 Hz), 1.12–1.45 (12H, m), 1.7 (1H, b s, disappeared on shaking with D_2O), 1.80–2.30 (4H, m), 3.62–4.0 (1H, m, gave a narrower m when the δ1.32 peak was irradiated), 5.40 (2H, distorted t, gave a broad s on irradiation at δ2.05) ppm. MS (70 eV, m/e; rel intensity): see Figure 1.

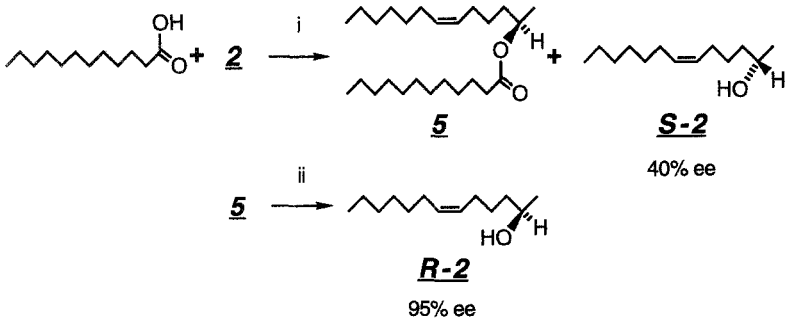

SCHEME III. (i) Porcine pancreas lipase (PPL), heptane, 70°C, 16 hr. (ii) KOH, MeOH, 25°C, 16 hr.

tiomeric Purity. δ-Hexanolide was chromatographed on triacetylated cellulose using the methodology described earlier (Högberg et al., 1987). The combined fractions with positive rotations containing [*R*]-(+)-**3** (Pirkle and Adams, 1979) were subjected to the reaction sequence described above, yielding the title compound with [*R*] configuration $[\alpha]_D^{20}$ −0.4° (neat), which corresponds to approximately 5% ee (enantiomeric excess).

Enzymatic Resolution of rac-(Z)-6-Tridecen-2-ol. Dodecanoic acid (200 mg, 1 mmol) and rac-(*Z*)-6-tridecen-2-ol **(2)** (198 mg, 1 mmol) and PPL (porcine pancreas lipase) (Sigma L-3126; 4 g) were stirred in heptane (40 ml) at 70°C for 16 hr. The reaction was stopped by cooling and filtering off the enzyme. Chromatography of the concentrated filtrate on silica gel (60, 230–400 mesh, eluted with 0–10% ethyl acetate in hexane) furnished the dodecanoate ester (120 mg, 32%) and (*S*)-(+)-(*Z*)-6-tridecen-2-ol **S-2,** 110 mg (55%; $[\alpha]_D^{20}$ +3.0°; c 5.4, hexane), after bulb-to-bulb distillation (120°C/0.3 mm Hg), which was then analyzed as an *N*-isopropyl carbamate derivative and found to be of 40% ee, i.e., 70% **S-2** and 30% **R-2.**

(R)-*(−)-(Z)-6-Tridecen-2-ol* ***(R-2).*** The dodecanoate ester from above was saponified by stirring under argon in methanol (15 ml) containing dissolved potassium hydroxide (0.5 g). After 16 hr the solution was poured into water (50 ml) and extracted several times with hexane. After drying ($MgSO_4$) the hexane solution was concentrated and the residue chromatographed as described above for **S-2** to give a colorless oil which was distilled bulb to bulb (120°/0.3 mm Hg), 40 mg (20%). $[\alpha]_D^{20}$ −8.0° (c 1.8, hexane). GC analysis as an *N*-isopropyl carbamate derivative established that this compound was of >95% ee (i.e., >97.5% *R*) and that it was identical to the natural unknown compound from *S. baetica.*

Manganese-Chelate Stationary Phase

Manganese(II)–bis[3-heptafluorobutyryl-(*1R*)-camphorate] was prepared from 3-heptafluorobutyryl-(*1R*)-camphor and manganese(II) chloride, according to Shurig et al. (1981). The product was obtained as a green solid in a total yield of 48%.

Preparation of Mn-Chelate Capillary Column

The fused silica capillary column was leached with 6 *N* hydrochloric acid, sealed at both ends, heated for 3 hr at 100°C, rinsed with 0.01 *N* hydrochloric acid, and dried.

Deactivation. A capillary was deactivated with Superox-4 0.2% in methylene chloride twice with the static method. Then the capillary was deactivated for 1 hr at 336°C.

Coating. A column was coated with a 0.8% solution of OV-101 in pentane

by the static method, then filled with a mixture of 30 mg OV-101 and 5.7 mg Mn-(II)–bis-[3-heptafluorobutyryl-1 (*R*)-camphorate] dissolved in 5 ml pentane, using the static procedure.

RESULTS AND DISCUSSION

Chemical Analysis of S. baetica *Males*

Analysis by GC-MS (one sample from 1985 and five samples from 1987) showed that the thoracic gland secretion was composed of nerol oxide (MW = 152) and (*Z*)-(*R*)-6-tridecen-2-ol (MW = 198). The proportion between the two components was 1:5. The former was found to be racemic. A mass spectrum of natural (*R*,*Z*)-6-tridecen-2-ol is shown in Figure 1. The double-bond position in the alcohol was determined by ozonolysis, producing the two aldehydes with molecular weights ($C_7H_{14}O$) = 114 and ($C_6H_{12}O_2$) = 116. The (*Z*,*R*) configuration was proved by comparison with the synthetic product; see Figure 2.

Chemical Analysis of A. occitanica *Males*

This species was found to contain nerol oxide and 10-homonerol oxide in the proportion 1:2. Gas chromatography on chiral phases, (a) Ni- and (b) Mn-chelates, respectively, showed that both compounds occurred as racemates; see Figure 3. The enantiomer separation of 10-homonerol oxide was unsatisfactory on the Ni-chelate column; however, the Mn-chelate column gave better results.

Confirmation of Chemical Structures

The structure of the unknown compound (Figure 2) isolated from *S. baetica* was established in the following way. Its mass spectrum indicated that it was a chain-elongated homologue of nostrenol, **1** (Scheme II), containing two methylene groups in the hydrocarbon end relative to the double bond. The proposed structure, **2** (Scheme II), was then confirmed by synthesis.

The synthetic procedure (Scheme II) was similar to that used earlier by us for the preparation of racemic nostrenol, **1** (Baeckström et al., 1989). Thus racemic δ-hexanolide, **3** (Ansell et al., 1968), was reduced to a mixture of the two cyclic ketals of the corresponding hydroxyaldehyde, **4**, or its ring-closed hemiketal forms, and this mixture was reacted with heptylidenetriphenylphosphorane in dimethyl sulfoxide to give racemic (*Z*)-6-tridecen-2-ol **2** (*Z*/*E* ratio, 91/9). Reactions in this solvent give predominantly the *Z*-isomer (Baeckström et al., 1989), which was also confirmed by the IR spectrum (no large peak at 950–1000 cm^{-1}). This compound gave both a mass spectrum and GC retention

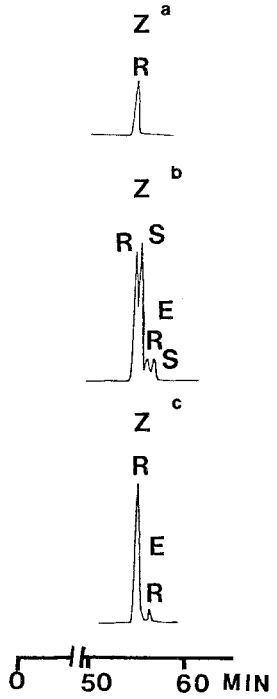

FIG. 2. Enantiomer separation of (*Z*)-6-tridecen-2-ol as isopropyl carbamate derivatives on a 30 m × 0.23-mm-I.D fused silica capillary column, coated with XE-60-(*S*)-valine-(*S*)-2-phenylethylamide, df = 0.24 μm. Temperature program: isothermal at 130°C for 5 min, then programmed temperature 2°C/min to 170°C. Carrier gas, nitrogen (13 psi). (a) Natural (*Z*)-6-tridecen-2-ol, obtained from *S. baetica*; (b) synthetic (*R,S*)-(*Z*)-6-tridecen-2-ol, isomer composition ×91% (*Z*) and 9% (*E*); (c) (*R*)-(−)-(*Z*)-2-tridecen-2-ol ×95% (*Z*) and 5% (*E*).

times on several phases which were identical to those of the natural compound, thus establishing its structure apart from its stereochemistry.

Tridecenol *2* has one chiral center and the natural compound could be either one of its two enantiomers or a mixture of them. When analyzed as the *N*-isopropyl carbamate derivatives on a chiral capillary GC column [XE-60-(*S*)-valine-(*S*)-2-phenylethylamide], the natural compound gave only one peak with the same retention time as the first of the two major peaks that were obtained from the racemic synthetic material (two minor peaks due to the pair of *E*-enantiomers were also observed) (see Figure 2.). When natural or synthetic nostrenol is subjected to the same GC conditions, the natural *R*-form gives rise to the first peak (see Figure 2). If the tridecenol, **2** (Scheme II), behaves as nostrenol, the configuration of the natural material should also be *R* (Scheme

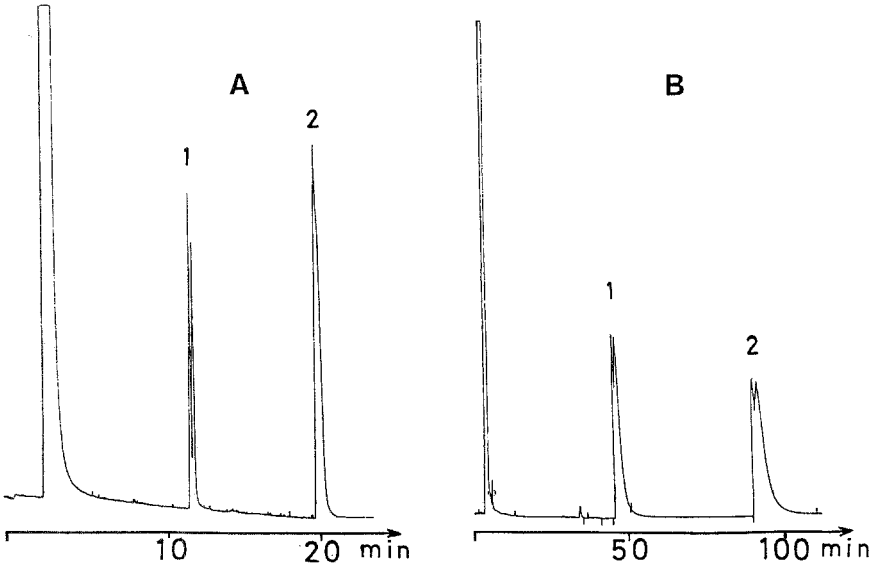

FIG. 3. Separation of extract from *A. occitanica* containing the two enantiomeric pairs (1) nerol oxide and (2) 10-homonerol oxide. Chromatographic conditions: (A) column, Ni-(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate], 25 m × 0.25-mm i.d; 93°C isothermal; N_2 (8 psi). (B) column, Mn-(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate], 25 m × 0.25-mm i.d.; 63°C isothermal; N_2 (8 psi).

III). To confirm this we synthesized the two enantiomers of *Z*-6-tridecen-2-ol (**2**) using an enzyme-catalyzed resolution. PPL is known to resolve 2-octanol through selective partial esterification with dodecanoic acid at 70°C in heptane (Gerlach et al., 1987). Thus, (*S*)-(+)-2-octanol and the dodecanoic acid ester of (*R*)-(−)-2-octanol are formed. In analogy with this, we found that when treated with PPL in heptane at 70°C for 16 hr, (*Z*)-6-tridecen-2-ol **2** (Scheme II) and dodecanoic acid gave a 30% yield of the ester and an approximately 60% yield of the (+)-alcohol of approximately 40% ee (compare below). Alkaline hydrolysis of the dodecanoate furnished (*Z*)-(−)-6-tridecen-2-ol **(R-2)** of 95% ee, which was found to be identical to the natural material when analyzed as described above. Secondary alcohols (Beilstein, 1973) such as (*R*)-2-butanol, (*R*)-2-hexanol, (*R*)-2-octanol, and nostrenol **(1)** (Baeckström et al., 1989) all show negative rotation, and by analogy, the natural tridecenol should again be **R-2**.

Independent proof for this assignment was gained from the following experiment. We found that the starting δ-hexanolide, **3** (Scheme II), was partially resolved into its enantiomers by preparative liquid chromatography on triacetylated cellulose using the methodology described earlier (Högberg et al., 1987).

The (+)-form is known to have the (*R*)-configuration (Pirkle, 1979), which was obtained in approximately 5% ee and was converted to (−)-(*R*,*Z*)-6-tridecen-2-ol, **R-2** ($[\alpha]_D^{20}$ −0.4°) using the synthetic protocol described above, thus proving the assigned configuration.

Biochemical Relationships Between Ant-Lion Volatiles

The two species fall into the biochemical pattern found in the three species analyzed earlier. Both species, like *E. nostras*, have nerol oxide (racemic) as one of their two components. *A. occitanica* is characterized by possessing 10-homonerol oxide (racemic), similarly found in *G. bore*, whereas *S. baetica* is characterized by the newly identified tridecenol.

Scheme I shows possible biogenetic relationships (a) between the nerol-derived compounds and (b) between the monounsaturated, secondary alcohols. Mechanisms that could lead to structure variation of the nerol basic skeleton are cyclization (to nerol oxide) and side-chain elongation (to 10-homonerol). The two mechanisms could combine to produce 10-homonerol oxide. Compare, though, studies on the biosynthesis of homoterpenes by Boland and Gäbler (1989) and Gäbler et al. (1991). Nerol oxide occurs in three of the five species studied so far. Furthermore, it is the sole compound, in small amounts, in the females of the first three species studied. Chain elongation of (*Z*)-6-undecen-2-ol adds two carbon atoms.

The composition of the two-compound blends in the five species studied is summarized in Table 1. The six compounds give 15 different theoretical two-compound combinations. Of these, five are seen in the five species; see Scheme I. It is interesting to note that *M. formicarius*, which possesses the biochemically most "simple" (original) composition, is also considered to be a "primitive" species. It is our intention to study other Myrmeleontidae species from other regions, thereby comparing sympatric and nonsympatric species. Behavioral and electrophysiological experiments are planned.

(Received November 4, 1991; accepted March 4, 1992)

Abstract—UPD-glucose transferases are found in the cytosolic and microsomal fractions of the grain aphid *Sitobion avenae* F. Gel filtration and SDS-PAGE revealed that the microsomal fraction contained several forms of the enzyme. The molecular weights of the three most active fractions might be 68,000, 66,000, and 36,500. There was a negative correlation between the enzymes' activity in extracts of aphids and the concentration of DIMBOA-aglucone in the winter wheat variety fed on by the aphid. A strong inhibition of the activity of the UPD-glucose transferases was observed *in vitro* at a concentration of DIMBOA as low as 0.01 m*M*. There was a greater activity of the enzymes in aphids fed on seedlings of susceptible than on moderately resistant wheat cultivars. Prolonged feeding on resistant cultivars resulted in a further reduction in the activity of the aphid's enzymes. The significance for cereal aphids of the role of their UDP-glucose tranferases in the detoxification of plant allelochemicals and adaptation to resistant varieties of cereals is discussed.

fying enzymes, UDP-glucose transferases, resistance, cereal allelochemicals, DIMBOA.

INTRODUCTION

Three groups of allelochemicals—phenols, hydroxamic acids, and indole alkaloids—are involved in the resistance of cereals to aphids (Todd et al., 1971; Argandoña et al., 1980; Leszczynski et al., 1985; Zuñiga et al., 1985; Dixon, 1987). At least two of them, phenols and hydroxamic acids, are present in undamaged host-plant tissues as glucosides (Wahlross and Virtanen, 1959; Pridham, 1960; Harborne, 1989). When herbivorous insects disrupt plant cells, the glucosides are enzymatically converted into aglucones (Katagiri, 1979; Chipoulet and Chararas, 1985; Lindroth, 1988). As the aglucones are more toxic to insects than glucosides, this results in an increase in the antibiotic effect of the allelochemicals (Ahmad et al., 1986).

Previously it was found that aphid feeding causes an increase in the level of the free aglucone of the hydroxamic acid 2,4-dihydroxy-7-methoxy-2H-1,4-benzoxazin-3(4)-one (DIMBOA) in wheat (Niemeyer et al., 1989a; Leszczynski and Dixon, 1990). Hydroxamic acids are ingested by cereal aphids (Niemeyer et al., 1989b), and almost all of them are subsequently excreted in the glucoside form (Leszczynski and Dixon, 1990). Thus there is a strong indication that cereal aphids, at least to some extent, can metabolize the toxic aglucones.

One mechanism involves the use of detoxifying enzymes, e.g., polysubstrate monooxygenases, which can actively catalyze NADPH-linked cytochrome P-450 reactions and enzymes that conjugate toxic aglucones with either glutathione or a sugar (Morello et al., 1971; Ahmad et al., 1986; Lindroth, 1989). In the aglucone–glucoside interaction the most important detoxifying enzymes are UDP-glucuronyl transferases (EC 2.4.1.17) and UDP-glucose transferases (EC unclassified) (Morello and Repetto, 1979). Detoxification by means of β-glucoside formation occurs widely in the animal kingdom, especially in insects (Smith, 1968). The UDP-glucose transferases (UDPGT) are relatively unknown biochemically and occur in some species in the soluble portion of the cytoplasm (cytosolic fraction) and in others in the microsomes and/or mitochondria (microsomal fraction) (Mehendale and Dorough, 1972; Yang, 1976). A little is known about their role in the metabolism of insecticides (Dorough, 1979; Dauterman, 1985), but nothing about their role in the detoxification of plant allelochemicals.

The activity of UDP-glucose transferases in grain aphid tissue was measured and the molecular weights of some of the UDPGTs present in the microsomal fraction were determined. In addition, the effect of DIMBOA on the activity of these enzymes *in vivo* and *in vitro* was studied.

METHODS AND MATERIALS

Plants. Four varieties of winter wheat were investigated: two moderately resistant, Grana and Saga; and two susceptible, Emika and Liwilla (Leszczynski, 1987). Seeds of the wheats were germinated in a glasshouse kept at 20–25°C during the 16-hr day and 10–15°C during the 8-hr night. The seedlings were grown in a nutrient medium, consisting of fine compost plus sand (F3, Fisons plc), in 10 × 10-cm plastic pots. Twenty-five plants were grown per pot. The plants were regularly watered and no extra fertilizer was added.

Aphids. A green-color form of the grain aphid, *Sitobion avenae* (F), from a stock culture kept at the University of East Anglia, was used. The aphids were reared on 3-week-old seedlings of winter wheat. Aphid performance was measured by placing two fourth-instar aphids on each of 40 seedlings, of each variety, and recording the number of aphids present 7 days later.

Chemicals. DIMBOA was isolated from 500 g of etiolated 6-day-old seedlings of maize var. Gracia using the method of Queirolo et al. (1983). Chemicals used in the protein assay were purchased from BioRad Laboratories (Richmond, CA). Gel filtration was done on a Superose 12 column obtained from Pharmacia Fine Chemicals (Uppsala, Sweden). Chemicals required for sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) came from Serva (Heidelberg, Germany). All reagents used for estimating the activity of UDPGT were obtained from Sigma Chemical Co. (St. Louis, MO).

DIMBOA Analysis. The concentration of DIMBOA was determined in 5-day-old seedlings using HPLC as described earlier by Leszczynski and Dixon (1990).

Effect of Feeding on Susceptible and Resistant Cultivars of Wheat on the Activity of the Aphid's UPD–Glucose Transferases. Four-day-old seedlings of the four wheat varieties were infested with grain aphids, which were allowed to feed for either 1, 2, 4, or 8 days. Then a mixture of 100 third- and fourth-instar aphids was collected from each cultivar and immediately bioassayed to determine the activity of their UDPGTs.

Enzyme Preparation. The batches of 100 aphids were each placed in 6 ml of cold 0.1 *M* Na-phosphate buffer, pH 7.5, and ground in a glass homogenizer. The homogenate was centrifuged on a L8-70M Beckman Ultracentrifuge at 3000*g* for 15 min and the residue discarded. The supernatant remaining after centrifugation was further centrifuged at 105,000*g* for 1 hr to separate the cytosolic and microsomal fractions. The supernatant, which contained the cytosolic fraction was collected and stored at 0°C until required for analysis, and the precipitate was dissolved and homogenized in another 6 ml of 0.1 *M* Na-phosphate buffer, pH 7.5. All extractions were done at 0–4°C. The cytosolic and microsomal fractions were used to determine the UDP–glucose transferases activity of aphid tissue.

Enzyme Assay. The general activity of UDP-glucose transferases was determined using a slightly modified version of Morello and Repetto's (1979) method. The activity was measured, after several trial runs, in a mixture that appeared to be optimum for such measurements, especially considering the results of Morello and Repetto (1979). It consisted of 1 ml of aphid extract in 0.1 *M* Na-phosphate buffer, pH 7.5, and 0.833 m*M* UDP-glucose, 0.167 m*M* p-nitrophenol, 16.7 m*M* $MgCl_2$, and 0.8% Triton X-100 buffered to pH 7.5. The reaction was started by the addition of UDP-glucose and then the mixture was incubated at 30°C for 30 min, after which the reaction was stopped by the addition of 4 ml of 0.1 *M* trichloroacetic acid. The mixture was then centrifuged at 4000*g* for 15 min, after which 0.1 ml of 12 *M* KOH was added to the supernatant and its absorbance at 400 nm, compared to the blank (without UDP-glucose), was measured in a UV/VIS spectrophotometer. The protein content of the cytosolic and microsomal fractions was determined using the method of Bradford (1976). The activity of the UDP-glucose transferases is expressed as micromoles of conjugated *p*-nitrophenol per 30 min per milligram of protein.

Effect of DIMBOA on the Activity of UDP-Glucose Transferases. The grain aphids used in this study were fed for 24 hr on 4-day-old seedlings of Emika. The activity of the enzymes present in aphid extracts was measured using the method described above. The control contained all the chemicals except DIMBOA and the test mixtures contained either 0.005, 0.01, 0.05, or 0.1 m*M* DIMBOA. All samples were measured against a blank lacking UDPG and DIMBOA.

Gel Filtration. The microsomal fraction extracted from 2000 aphids fed on seedlings of Emika was freeze-dried and suspended in a small volume of 0.1 *M* Na-phosphate, pH 7.5. After centrifugation at 14,000*g* for 30 min, 200 μl of the supernatant was loaded onto a Superose 12 gel filtration column (Pharmacia Fine Chemicals) previously equilibrated with 0.1 *M* Na-phosphate buffer, pH 7.5, contained in 0.15 *M* NaCl. The column was calibrated with reference proteins of known molecular weights. The fplc separation was done on a Pharmacia Fine Chemicals (Uppsala, Sweden) apparatus, the column of which had been eluted with 20 ml of 0.1 *M* Na-phosphate buffer, pH 7.5, contained in 0.15 *M* NaCl (flow rate, 0.5 ml/min). Fractions of 0.25 ml were collected and their enzyme activity was determined.

Gel Electrophoresis. Polyacrylamide gel electrophoresis (PAGE) was done on pooled fractions following the method of Laemmli (1970). The gel (70 × 100 × 1 mm) contained 12.5% acrylamide. Bromophenol blue was the tracking dye, and electrophoresis was carried out at 10 mA. After separation the protein bands were stained with Coomassie brilliant blue R-250 and destained in 10% acetic acid. The presence of subunits of UDPGT was revealed using SDS-PAGE as described by Webber and Osborn (1969). The relative mobility of the subunits of UDPGT and the standard proteins—lysozyme (MW 14,300), β-lactoglobulin

(MW 18,400), trypsinogen (MW 24,000), ovalbumin (MW 45,000), and albumin (MW 66,000) was used to estimate the molecular weights of the subunits of UDPGT.

Statistical Analyses. The results given in all the tables and figures are averages of three replicates. The grain aphid performance, the quantity of hydroxamic acids in the wheat seedlings, and the activity of UDP-glucose transferases in the aphid's tissues were subjected to an analysis of variance followed by Duncan's test.

RESULTS

Intracellular Location of the UDP-Glucose Transferases. The UDPGTs were found in extracts of whole aphids. The enzymes were present in both the microsomal and the soluble fractions (Table 1). The general level of activity of the enzymes was greater in the microsomal than in the cytosolic fraction. Gel filtration of the microsomal fraction revealed several forms of the UDPGT. There were three major peaks in the enzymes' activity. The greatest activity occurred in fractions 36–39, with a lesser activity in fractions 52–59 and fractions 67–69 (Figure 1). Apart from the third peak of the UDP-glucose transferase activity, there was no association with absorbance at 280 nm. SDS-PAGE of the active fractions 36–39 revealed two protein bands, which had molecular weights of 68,000 and 66,000, and of fractions 52–59, a protein of molecular weight 36,500, which might be the molecular weights of the enzymes concerned. However, no clear protein band staining with Coomassie brilliant blue R-250 could be detected in fractions 67–69 (Figure 2).

Effect of Feeding on Moderately Resistant and Susceptible Wheats on the Activity of the Aphid Enzymes. The activity of the UDP-glucose transferases in the aphids fed on moderately resistant wheat varieties was much lower than in the aphids fed on susceptible wheats. For the resistant wheats, lower activities

TABLE 1. THE ACTIVITY (μMOL *p*-NITROPHENOL CONJUGATED/30 MIN/MG PROTEIN ± SE) OF THE UDP-GLUCOSE TRANSFERASES PRESENT IN THE CYTOSOLIC AND MICROSOMAL FRACTIONS OF GRAIN APHIDS FED ON THE WHEAT VARIETIES EMIKA AND GRANA

	Intracellular fraction	
Wheat variety	Cytosolic	Microsomal
Emika	0.246 ± 0.048	0.824 ± 0.245
Grana	0.146 ± 0.021	0.550 ± 0.209

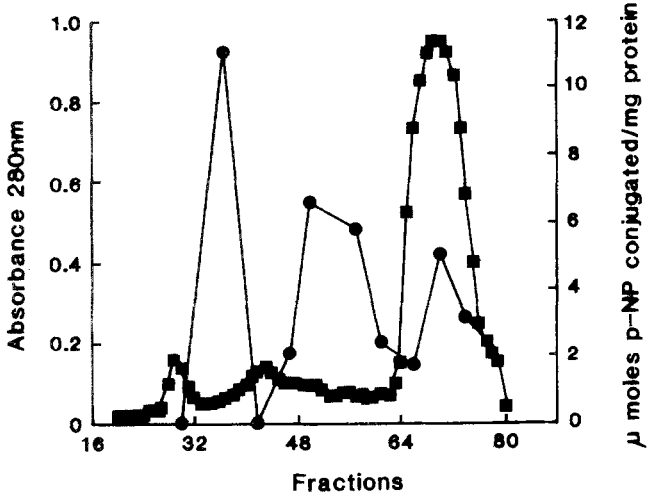

FIG. 1. The protein content, indicated by absorbance at 280 nm (■——■), and the UDP-glucose transferase activity as μmol p-NP conjugated/mg protein (•——•), of fractions of the microsomal extract of the grain aphid.

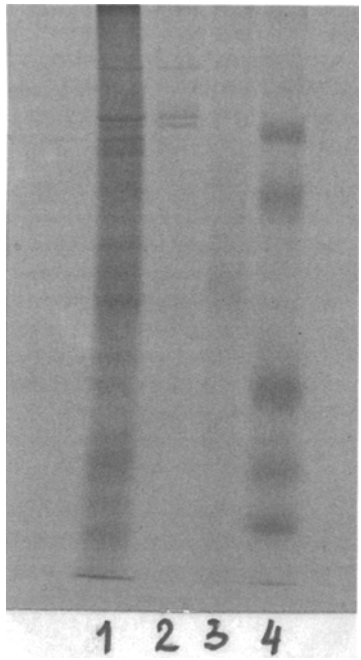

FIG. 2. SDS-polyacrylamide gel electrophoresis of the grain aphid's UDP-glucose transferases: (1) microsomal fraction; (2, 3) fplc of fractions 36–39 and 52–59, respectively; (4) standards lysozyme, β-lactoglobulin, trypsinogen, ovalbumin, and albumin.

were recorded in the aphids fed on seedlings of Saga than in those fed on Grana (Table 2). There was a positive correlation between aphid performance and the activity of UDPGTs in their tissues. However, there was a negative correlation between the activity of the aphid's enzymes and the concentration of hydroxamic acids in the seedlings, especially DIMBOA-aglucone (Table 2).

The highest activity of UDP-glucose transferases was found in aphids that had fed for 24 hr on the wheat seedlings. The activity slowly decreased with time spent feeding on all the varieties (Figure 3). There was a much higher activity in the aphids fed on Emika than on the moderately resistant Saga and Grana varieties. During the aphids' adaptation to feeding on the different varieties of wheat, a bigger reduction in enzyme activity was observed in the aphids fed on the susceptible variety (Figure 3).

Effect of DIMBOA on UDPGT Activity in Vitro. In comparison to the control without DIMBOA (1.308 μM p-NP conjugated/mg protein = 100%), all the concentrations of this allelochemical, which ranged from 0.005 to 0.1 mM, decreased the relative activity of the UDP-glucose transferases (Figure 4). A concentration as low as 0.01 mM reduced the activity of the enzymes by about 65%. Further increases in the amount of hydroxamic acid caused a further reduction in the activity of the UDPGT, but not to the same dramatic extent.

DISCUSSION

Conjugation of a foreign compound with glucose appears to be one of the major means of detoxification in insects. They then excrete and/or store allelochemicals in the less toxic glucoside form (Kent and Brunet, 1959; Smith and Turbert, 1961; Teas, 1967). Although UDP-glucose transferases have been reported from many insects (Smith, 1968), they are reported here for the first time from cereal aphids. There is some UDPGT activity in the cytosolic fraction, but most of it occurred in the microsomal fraction. Because of their microsomal location, these enzymes can easily interact with the cytochrome P-450-linked monooxygenases.

There was a clear negative correlation between the activity of the UDP-glucose transferases in aphids and the concentration of DIMBOA in the wheat variety on which they had been reared. This suggests that high concentrations of DIMBOA, the main hydroxamic acid in wheat (Niemeyer, 1988), reduces the activity of the grain aphid's UDPGT. This was particularly clear when the aphids fed on Saga, which contains the highest concentration of the highly toxic DIMBOA-aglucone. The inhibitory effect of DIMBOA on the activity of UDPGT was confirmed *in vitro*, where a marked reduction in enzyme activity (about 65%) was observed even at a concentration as low as 0.01 mM. However, from our results it is not clear whether it is acting as a competitive or a non-

TABLE 2. THE ACTIVITY (μMOL *p*-NITROPHENOL CONJUGATED/30 MIN/MG PROTEIN ± SE) OF THE UDP-GLUCOSE TRANSFERASES IN EXTRACTS OF GRAIN APHIDS FED FOR 48 HR ON SEEDLINGS OF MODERATELY RESISTANT AND SUSCEPTIBLE VARIETIES OF WHEAT AND THE CONCENTRATION OF DIMBOA DERIVATIVES (μMOL/G FRESH WEIGHT ± SE) AND APHID PERFORMANCE (NUMBER OF APHIDS/SEEDLING ± SE AFTER 7 DAYS) ON THESE VARIETIES[a]

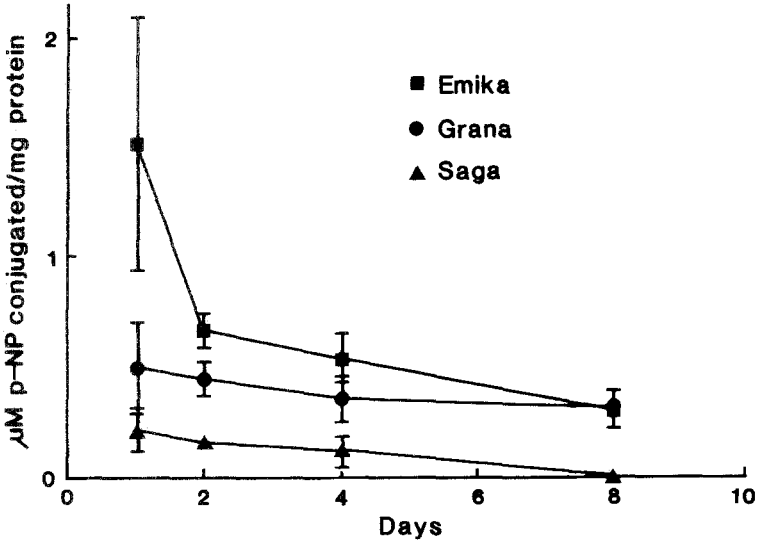

FIG. 3. The activity of the UDP-glucose transferases (±SE) in extracts of grain aphids fed on moderately resistant and susceptible winter wheat cultivars for 1, 2, 4, or 8 days.

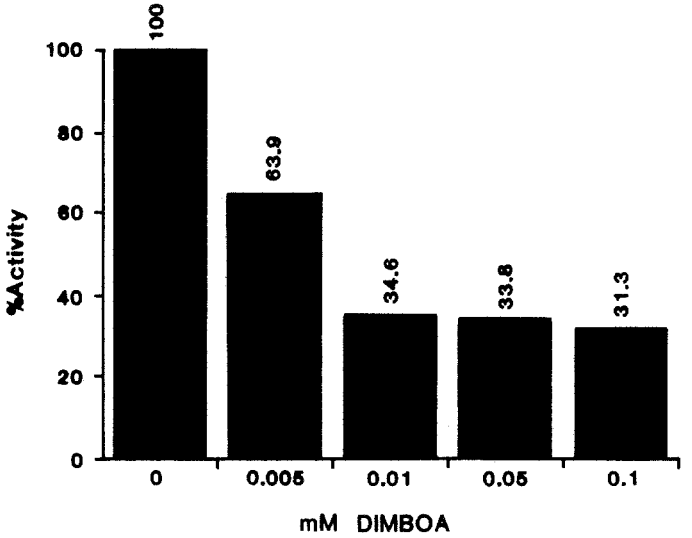

FIG. 4. Effect of a range of concentrations of DIMBOA on the activity of the grain aphid's UDP-glucose transferases.

competitive inhibitor, but hydroxamic acids are well-known as inhibitors of other enzymes such as ribonucleotide reductase (Kjoller et al., 1982), urease (Fishbein, 1982), ATPase, and enzymes involved in ATP synthesis (Queriolo et al., 1983) as well as α-chymotrypsin (Cuevas et al., 1990) and papain (Perez and Niemeyer, 1989).

Therefore it is possible that some of the DIMBOA-glucoside ingested passes through the aphid's alimentary canal and is excreted in the honeydew. However, because there may be several forms of UDP-glucose transferases, which are able to conjugate many substances differing in molecular structure (Trivelloni, 1964), it is possible that not all of the izoenzymes are inhibited by DIMBOA. In addition, it is also possible that the biosynthesis of the DIMBOA-glucoside is another mechanism by which DIMBOA is detoxified.

However, our results indicate that the hydroxamic acids in moderately resistant wheat cultivars not only exert a direct antibiotic influence on cereal aphids (Argandoña et al., 1983) but also seriously reduce the effectiveness of one of the most important biochemical means of detoxifying other groups of xenobiotics. This is especially so for the phenolic compounds, which have a very adverse effect on cereal aphid performance (Todd et al., 1971; Dreyer and Jones, 1981; Leszczynski et al., 1985), because UDP-glucose transferases play a significant role in the detoxification of phenolic aglucones (Smith, 1968; Ahmad et al., 1986). Thus the allelochemicals in moderately resistant wheat cultivars

might act synergistically (Berenbaum, 1985) and protect the wheat's resistance mechanisms against the grain aphid's detoxifying enzymes.

The results presented here and in an earlier study (Leszczynski and Dixon, 1992) indicate that, of the two groups of transfer enzymes in the grain aphid, the glutathione *S*-transferases are less sensitive to the concentration of hydroxamic acids naturally occurring in wheat tissues than are the UDP-glucose transferases. Thus the cytosolic glutathione *S*-transferases seem to be more effective in detoxifying cereal allelochemicals and might play a more important role in the aphid's adaptation to their host plants. To prove this, a further study of the aphid detoxification system, in particular the role of the cytochrome P-450-dependent polysubstrate monooxygenases in detoxifying cereal allelochemicals, is needed.

(Received November 20, 1991; accepted March 4, 1992)

Abstract—Female Douglas-fir beetles, *Dendroctonus pseudotsugae*, produced an average 45:55 mixture of the (*S*)-(−)- and (*R*)-(+)-enantiomers of 1-methylcyclohex-2-en-1-ol (MCOL). The (*S*)-(−):(*R*)-(+) ratio of 3-methylcyclohex-2-en-1-ol (seudenol) produced by this population of females was 34:66. Lindgren funnel traps baited with (*R*)-(+)-MCOL attracted significantly more males and females than (*S*)-(−)-MCOL-baited traps, which captured significantly more beetles than unbaited controls. The combined effect of the enantiomers was additive, rather than synergistic. Either enantiomer of MCOL increased catches by frontalin-baited traps. Racemic MCOL can be used for trapping Douglas-fir beetles in south-central British Columbia.

Key Words—*Dendroctonus pseudotsugae*, Douglas-fir beetle, Coleoptera, Scolytidae, aggregation pheromone, production, response, methylcyclohexenol, seudenol, enantiomers, trapping.

INTRODUCTION

The chemical ecology of the Douglas-fir beetle, *Dendroctonus pseudotsugae* Hopkins, is perhaps better known than for any other species of North American bark beetles (Borden, 1982; and references therein). The main aggregation pheromones, frontalin [1,5-dimethyl-6,8-dioxabicyclo(3.2.1)octane] and seudenol (3-methylcyclohex-2-en-1-ol), and the antiaggregation pheromone MCH (3-methylcyclohex-2-en-1-one) have been known for this insect for many years (Pitman and Vité, 1970; Kinzer et al., 1971; Vité et al., 1972). Libbey et al. (1983) identified MCOL (1-methylcyclohex-2-en-1-ol), an isomer of seudenol, as an additional aggregation pheromone for this species.

In recent years chiral-specific activity of pheromones and the intra- and interspecific roles of their enantiomers have been studied in scolytids (Birch et al., 1980; Borden et al., 1980, 1986; Miller et al., 1989). Data of Mori et al. (1987) suggested that racemic MCOL acted synergistically with frontalin for *D. pseudotsugae*, but additional tests were proposed to determine the effect of the two enantiomers.

The objective of this study was to determine the mean ratio of MCOL enantiomers produced in a Douglas-fir beetle population and the response by *D. pseudotsugae* to the enantiomers alone and in combination when used as attractants by themselves and in combination with frontalin.

METHODS AND MATERIALS

Experimental Beetles and Volatile Collection. Douglas-fir bolts, *Pseudotsuga menziesii* (Mirb.) Franco, naturally infested with Douglas-fir beetles, *D. pseudotsugae*, were obtained near Kamloops , British Columbia. Beetles emerging from caged logs were collected daily and sexed. Females were confined individually with gelatin capsules (Borden, 1967) on uninfested, overwintered Douglas-fir logs. Female-produced frass was removed from the capsules every 24 hr and accumulated in a cylindrical Pyrex glass aeration chamber over the 5-day aeration. In this manner a total of 50 cm^3 of frass from 150 females was used in order to obtain sufficient material for the analysis. Charcoal-filtered air was drawn through the aeration chamber by a water aspirator at 0.5 ml/min for 5 days, and volatiles continuously trapped on Porapak Q. Volatiles were eluted from the Porapak Q with 30 ml of redistilled pentane. The solution was cooled in ice water and concentrated under a fine stream of nitrogen to 0.2 ml.

Volatile Analyses. GC and GC-MS analyses of volatiles were carried out with a Hewlett Packard 5830A gas chromatograph equipped with a glass column (30 m × 0.5-mm i.d.) coated with SP-1000 (Supelco Inc., Bellefonte, PA 16823) and a Hewlett Packard 5985B GC/MS/DS fitted with a fused silica column (30 m × 0.32-mm i.d.) coated with SP-1000 (J&W Scientific Inc.,

Folsom, CA 95630). Micropreparative GC was conducted with a Varian 1200 instrument fitted with a 3.05 m × 3.18-mm o.d. stainless-steel column packed with 10% SP-1000 on Chromosorb W AW (100/120) (Supelco Inc. Bellefonte, PA 16823), a 10:1 effluent splitter, and a thermal gradient collector (Brownlee and Silverstein, 1968). Helium was used as carrier gas at a flow rate of 40 cm/sec. Optical isomers of MCOL and seudenol were analyzed with a Hewlett Packard 5985B GC-MS fitted with a Chirasil-Dex (8) column (25 m × 0.25-mm i.d.) (V. Schurig, University of Tübingen, Germany).

Field Experiments. Two hundred milligrams each of (*R*)-(+)-MCOL and (*S*)-(−)-MCOL were produced as described by Mori et al. (1987). The enantiomers were loaded (20 μl) into glass capillaries (45 × 1-mm i.d.) sealed at one end. The release rate from each capillary was estimated at 0.1 mg/24 hr at 24°C by measuring the drop of the meniscus. Actual release rates in the field are temperature dependent. The enantiomeric purity of the enantiomers was estimated by Mori et al. (1987) as about 90% enantiomeric excess (95:5 ratio) for both enantiomers.

On May 3, 1989, Lindgren 12-funnel traps were set up in a 4 × 4 Latin square design experiment at the Malcolm Knapp Research Forest, Maple Ridge, in the coastal Douglas-fir zone of British Columbia. Treatments consisted of (1) unbaited control, (2) one capillary of (*R*)-(+)-MCOL, (3) one capillary of (*S*)-(−)-MCOL, and (4) one capillary of each enantiomer. In this manner the release rate of each enantiomer was held constant among treatments 2 to 4. Beetles were collected on May 10 and May 16 and stored at −18°C until the beetles could be counted and their sex determined.

A second 4 × 4 Latin square was established on May 24 at Scottie Creek Road, near Cache Creek, in the interior Douglas-fir zone. The traps were set up in a stand of mature Douglas-fir with patches of immatures. The treatments were as above except that all traps were also baited with frontalin released from Flex lures (Phero Tech Inc., Delta, B.C., Canada) at 0.6 mg/24 hr at 24°C as measured by GC analysis of Porapak Q-collected volatiles in the laboratory. Beetles were collected on June 5 and stored as above until counting and sex determinations could be done.

At the end of the second experiment all frontalin release devices were removed, and the MCOL treatments were reallocated by rerandomization. Beetles from this experiment were collected on June 15 and stored as above.

Statistical Analysis. Pooled data from each of the experiments were subjected to analysis of variance ($\alpha = 0.05$), and when significant, means were separated by Duncan's multiple-range test. There was no treatment by experiment interaction in experiments 1 and 3, so these were analyzed as a replicated Latin square (Steel and Torrie, 1960). Furthermore, there were no other significant interactions, so these effects were pooled into the error term. Prior to analysis of numbers of beetles captured, the data were transformed as $x' =$

$\log(x + 1)$ to correct for heterogeneity of variances. Percentage data were transformed as $p' = \arcsin\sqrt{p}$, where p is a proportion.

RESULTS AND DISCUSSION

Volatile Analyses. Frass volatiles of female *D. pseudotsugae* contained all four known pheromones: frontalin, MCOL, seudenol, and MCH (Figure 1). MCOL produced by this population of female *D. pseudotsugae* was comprised of 45 and 55% of the (*S*)-(−)- and (*R*)-(+)-enantiomer, respectively (Figure 2). Seudenol produced by these females contained 34 and 66% of the (*S*)-(−)- and (*R*)-(+)-enantiomer, respectively. Intrapopulation variation in the production of MCOL enantiomers could not be determined since the amount produced by individual beetles is too low to be analyzed. Therefore, it is possible that considerable variation within and among populations occurs, as was found for *I. pini* (Miller et al., 1989).

Field Experiments. Traps baited with (*R*)-(+)-MCOL caught significantly more *D. pseudotsugae* of both sexes than traps baited with (*S*)-(−)-MCOL

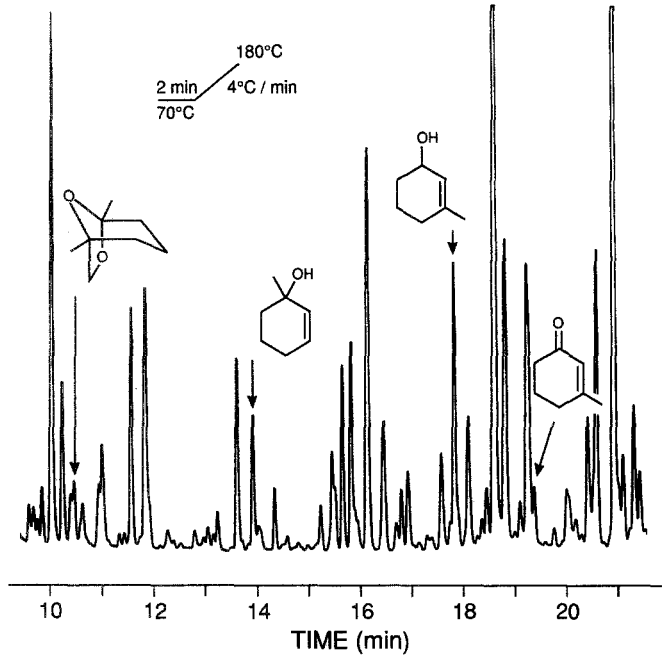

FIG. 1. Gas chromatogram of volatiles from frass of female *D. pseudotsugae*. Unidentified peaks are mainly terpenoid host compounds.

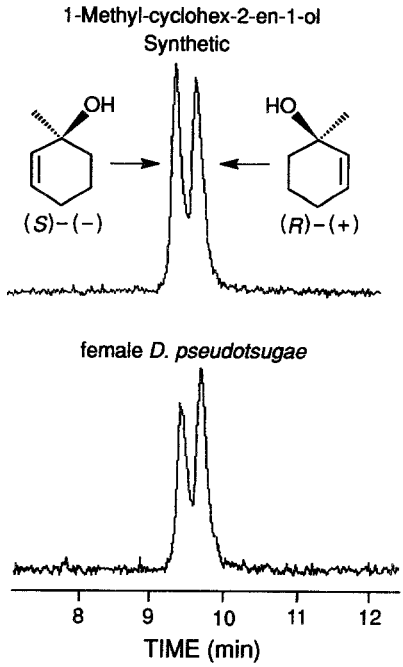

FIG. 2. Selected ion chromatogram of the base ion (m/z 97) of synthetic (top) and female-produced MCOL (bottom). Column, Chirasil-Dex (8); temperature program, 50°C (0.5 min)-20°C/min-85°C (10 min).

(Table 1). (*S*)-(−)-MCOL-baited traps caught significantly more beetles than unbaited control traps when both sexes were analyzed together (Table 1). Traps baited with racemic MCOL did not capture significantly more beetles than (*R*)-(+)-MCOL (Table 1). However, the analysis of variance of enantiomer interaction indicates that the combined effect of (*R*)-(+)- and (*S*)-(−)-MCOL is additive ($P = 0.841$ for males, $P = 0.998$ for females, and $P = 0.631$ for males and females), rather than synergistic, and both enantiomers are required for maximum response. Due to the limited availability of the enantiomers, their optimal ratio could not be determined in this study.

In the second experiment MCOL significantly increased catches to frontalin-baited traps (Table 2). Racemic MCOL significantly increased the proportion of females over (*S*)-(−)-MCOL and frontalin alone. (*R*)-(+)-MCOL significantly increased the proportion of females over (*S*)-(−)-MCOL but was not different from racemic MCOL or frontalin. (*S*)-(−)-MCOL did not change the proportion of females captured significantly compared to frontalin alone.

As (*R*)-(+)-MCOL caught significantly more beetles than (*S*)-(−)-MCOL

(Table 1) and, when combined with frontalin, significantly increased the proportion of females captured (Table 2), there is evidence of enantiospecific activity of MCOL. Enantiospecific production, reception, and behavioral activity of scolytid pheromones such as bicyclic acetals and terpene alcohols have been documented previously (Vanderwel and Oehlschlager, 1987). Our data show that *D. pseudotsugae* successfully discriminates between enantiomers of a

cyclohexenol. Since the spruce beetle, *D. rufipennis* (Kirby), produces and responds to the same pheromone components as *D. pseudotsugae*, it is possible that enantiospecific responses to MCOL prevent cross attraction in areas where the two species are sympatric. For example, in south-central British Columbia *D. rufipennis* responds preferentially to (*R*)-(+)-MCOL, while the (*S*)-(−)-enantiomer is inhibitory (J.H. Borden, Simon Fraser University, Burnaby, B.C., Canada, personal communication).

From a management perspective, racemic MCOL can be used for monitoring or mass trapping of Douglas-fir beetle populations, at least in the areas where these experiments were conducted. However, there may be merit in further investigating geographic variation in production and response by Douglas-fir beetles to MCOL and determining the optimal enantiomeric ratio, MCOL dose, and optimal ratios of MCOL and frontalin.

Considering the 34:66 ratio of the (*S*)-(−)- and (*R*)-(+)-enantiomers of seudenol produced by female Douglas-fir beetles, and sex-specific effects of seudenol at higher doses (Lindgren and Miller, unpublished), the role of this pheromone should be further investigated. Furthermore, there is a potential of interaction between MCOL and seudenol which may be important for optimum aggregation. Further refinement of a lure for Douglas-fir beetle trapping may provide a useful tool for population management.

Abstract—A system is described for the collection of volatiles produced by plants and insects that minimizes stresses on the plant or insect in an environment that is free from chemical impurities. Air entering a volatile collection chamber containing insects and/or plants was purified using a nonwoven fabric medium infused with charcoal. When three layers of this material were used, the total amount of impurities detected by gas chromatography was less than 40 ng/hr at a collection rate of 1 L/min. The air filtration system can maintain this level of air purification for 96 hr at an air flow of 0.43 m/sec, or a total volume of approximately 750,000 L of air. The air filtration system did not alter the relative humidity of the purified air compared to the relative humidity of ambient air. A multiport collector system was developed for use with the insect volatile collection system and enabled up to three samples to be collected without disturbing the system.

Key Words—Collection system, volatile collections, air purification, charcoal cloth.

INTRODUCTION

To understand insect chemical communication systems fully and to maximize the potential development and practical use of volatile semiochemicals produced by insects and plants for insect control, the chemicals emitted must be collected

*To whom correspondence should be addressed.

and analyzed both qualitatively and quantitatively. Although it is possible to gain much information about insect semiochemicals from solvent extracts of insects or parts of insects (see, e.g., Sower et al., 1973; Klun et al., 1980; Teal et al., 1981), the blend of volatiles actually emitted by the insect is often uncertain. Many compounds found in extracts of insect ovipositor glands are not volatilized by the insect, and often those compounds that are volatilized are not released at the same ratio as found in the gland (Teal et al., 1986; Heath et al., 1991). Similarly, identification of "volatile" components from plants using methods such as extraction with solvent or steam distillation most often results in the identification of a large number of organic compounds that are not representative of the chemicals released by the plant (Tollsten and Bergstrom, 1988). The results of these studies prompted us to develop systems that can be used to collect volatiles from various biological sources in such a manner that we minimized the stress that is placed on the organism being studied, as well as minimizing the collection of unwanted background organic compounds from the surrounding environment.

Several systems for the collection of volatiles from insects have been published (e.g., Baker et al., 1981; Tumlinson et al., 1982; Golub et al., 1983; Shani and Lacey, 1984; Golub and Weatherston, 1984). However, the efficiency of these collection systems has not been well defined and the stress placed on the plants and/or insects contained in these systems is often considerable. Development of systems for collection of volatiles from unaltered plants in their natural environment has been limited. Advances in this area of research have been restricted due to the inability to purify the large volumes of air at high flow rates that are needed to surround completely either the whole plant or the parts of the plant under investigation. These large volumes of pure air are required to prevent the intrusion of ambient air from back-flowing into the system, resulting in contamination of samples collected from a plant.

We report in this paper a method that permits purification of large volumes of air and the development of systems for use in the collection of volatiles from insects and plants.

METHODS AND MATERIALS

Volatile Collection System (VCS)

The collection system consisted of four main components (Figure 1). An air delivery system (ADS) is attached to a passive air filtration system (AFS) which purifies the incoming air. Attached to the AFS is a volatile collection chamber (VCC), a cylindrical glass sleeve in which purified air surrounds the subject from which volatiles are being collected, and finally, the volatile col-

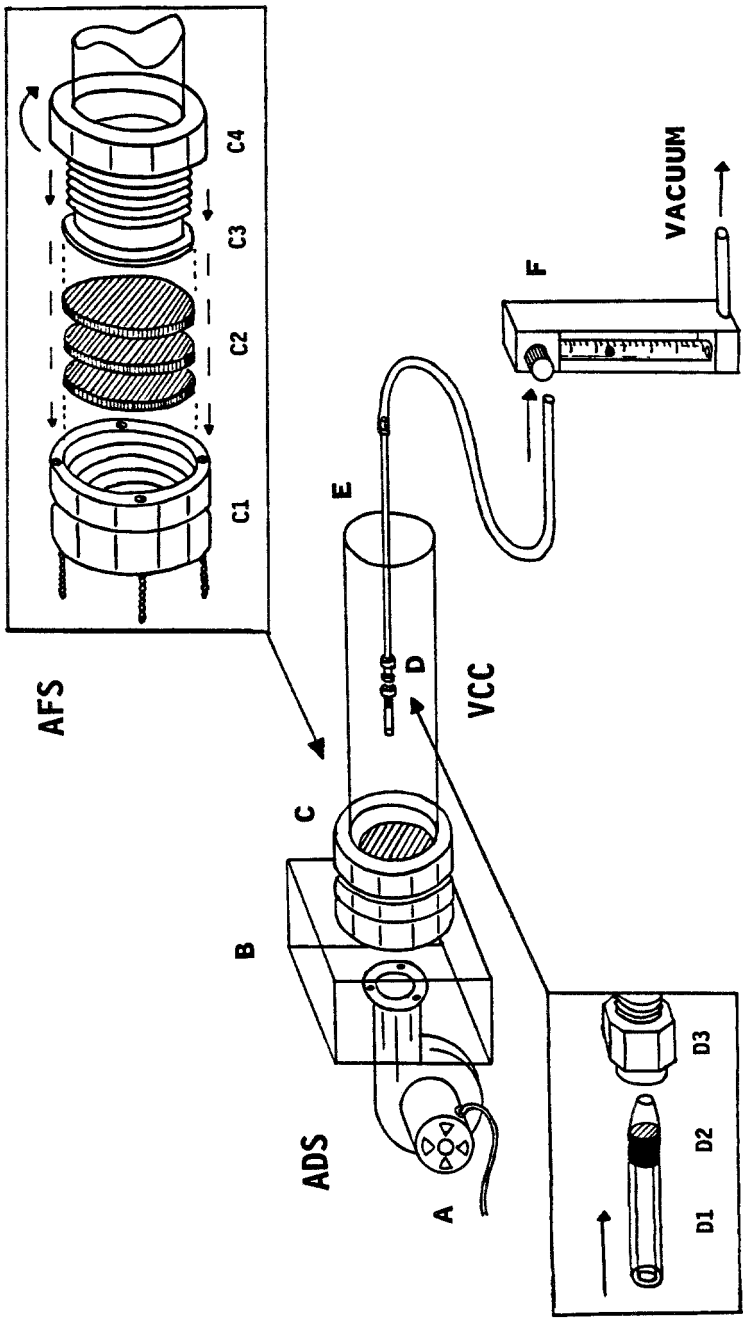

FIG. 1. Drawing of the collection system designed for the collection of volatiles released from plants. System components are as follows: air delivery system (ADS), air filtration system (AFS), volatile collection chamber (VCC), and volatile collector trap (VCT).

lector trap (VCT), which contains a polymeric adsorbent used to entrap volatile organics within the chamber for further chemical analyses.

Air Filtration System (AFS)

The AFS consists of two components, the filtering medium and the holder (Figure 1, C-AFS). The filter holder assembly (Figure 1, C1–C4) is an 8.9-cm phenolic coupler (Model S-6750-010, Southern Scientific Inc., Micanopy, FL). Filter material used in this assembly (Figure 1, C2) was a nonwoven polyester fiber infused with activated carbon. The filter media tested in this investigation included 9.0 oz (fabric weight) material containing 150% activated carbon (13.5 oz carbon/sq yd, P/N ACF-NWPE-9-150P) and 12.0 oz material also containing 150% activated carbon (18 oz carbon/sq yd, P/N ACF-NWPE-12-150P). This material was obtained from Lewcott Corp. (Millbury, MS). The activated carbon material (1.27 cm in thickness) was cut into 9.5-cm-diameter circles and placed between the first half of the coupler (C1) and the glass flange (C3) as shown in Figure 1. The other half of this coupler (C4) is placed over the open end of the collection chamber glass tube (E) and slid down till it reaches a glass flange (vide infra) on the opposite end. This piece (C4), along with the glass flange (C3), is then used to compress one to three sections of filter material on an internal flange on the mounted coupler (C1). The entire assembly is screwed together by hand force.

Air Delivery System (ADS)

Ambient air was pushed through the filters using a "squirrel-cage" type shaded pole blower (Figure 1, A) capable of delivering 15 cfm in free air at 3160 rpm at 115 AC and 0.21 A, with an air-flow cutoff at 0.22 in. of water static pressure (Dayton Electric Model 2C782, W.W. Grainger, Jacksonville, FL). The blower was connected to an AC variable autotransformer (Powerstat Type 116B, Superior Electric Co., Bristol, CT) and adjustment of the line voltage to the blower motor varied the air velocity through the volatile collection system. The output of the blower was directed through a 2.54-cm-diameter hole contained in a 13.5 cm square × 6.7 cm wide Plexiglas box. This box (Figure 1, B) was used for connecting the blower motor to the filter section as well as serving as an air diffuser to ensure an evenly distributed air flow across the filter medium. The AFS (C) was mounted to the air diffuser box by four bolts centered on an 8.9-cm-diameter hole.

For comparing this system with previously developed air purification systems, air provided by a laboratory air compressor was pushed through two in-line charcoal filters. These filters were made of 1.6-cm-OD (0.05-mm wall thickness) × 12.7-cm stainless-steel tubing and contained 28-mesh activated charcoal (Alfa Products, Danvers, MA) packed between two 325-mesh stainless-

steel screens held in place by 1.6- to 0.64-cm reducing unions (Swagelok Co., Solan, OH). Prior to use the two in-line filters were cleaned by baking them at 200°C for 24 hr with a flow of ultrapure nitrogen at 2 ml/min. These filters were placed in a vertical position to prevent the formation of channels or voids that might allow air to pass without being filtered by the charcoal.

Volatile Collection Chamber (VCC)

Two chamber configurations for the VCS were constructed of 0.32-cm-thick Pyrex glass by Southern Scientific Inc. Both chambers were 25.7 cm long and 7.6 cm in ID and contained a 9.21-cm-OD × 0.064-cm-thick flange (Figure 1, C3) attached to one end of the Pyrex glass cylinder. The system used for providing purified air over plants (P-VCS) used a chamber that was open at one end (Figure 1, E). The insect volatile collection system (I-VCS), shown in Figure 2, used a VCC that contains a 50/55-mm male ground-glass joint. A multiport collector base (Figure 2, MCB) constructed of Pyrex contained (in addition to the 50/55-mm female ground-glass joint for connecting to the insect chamber), two 10/18-mm joints and one 14/20-mm female ground-glass joint. A vacuum tube thermometer adapter was connected to the 14/20-mm joint and provided a port (Figure 2, MCB-A) that could be used to purge the system. A 0.64-cm-OD × 0.5-cm-ID stainless-steel tube is inserted through each of the three joints and connected using Teflon thermometer adapters (Ace Glass, Vineland, NJ). The collector traps were connected to the stainless-steel tubing using 0.64-cm unions and 0.64-cm-ID Teflon ferrules. The outlet of the stainless-steel tubes and the purge outlet were connected to a vacuum manifold using Tygon tubing. The vacuum manifold (Figure 2, MPV) consisted of a four-way, multiport valve (Whitey B-43ZF2, Swagelok Co., Solan, OH), a flow meter set at 1 L/min, and a vacuum pump. The manifold directed the vacuum flow for the collection of volatiles to one of the three collector traps or enabled the purging of the system. Initially, all glass was acid-washed and heated to 400°C for 48 hr. Before each volatile collection, the I-VCC or P-VCC was washed with deionized water and acetone and heated at 400°C for a minimum of 6 hr.

Volatile Collector Trap (VCT)

The collector traps (Figure 1, D, and Figure 2, VCT) used to trap organic volatiles were made from a 4.0-cm-long × 4.0-mm-ID piece of glass tubing (Figure 1, D1) and contained 20 mg of Super-Q (Altech Assoc. Inc., Deerfield, IL) as the adsorbent. Two stainless-steel frits were used to contain the adsorbent (Figure 1, D2). The collector traps were connected to stainless-steel tubing using 0.64-cm unions and 0.64-cm-ID Teflon ferrules (Figure 1, D3). These traps were cleaned by soxhlet extraction using ultra-high-purity methylene chloride (Burdick & Jackson GC^2 GC-MS grade solvent, Catalog No. GC60616-4,

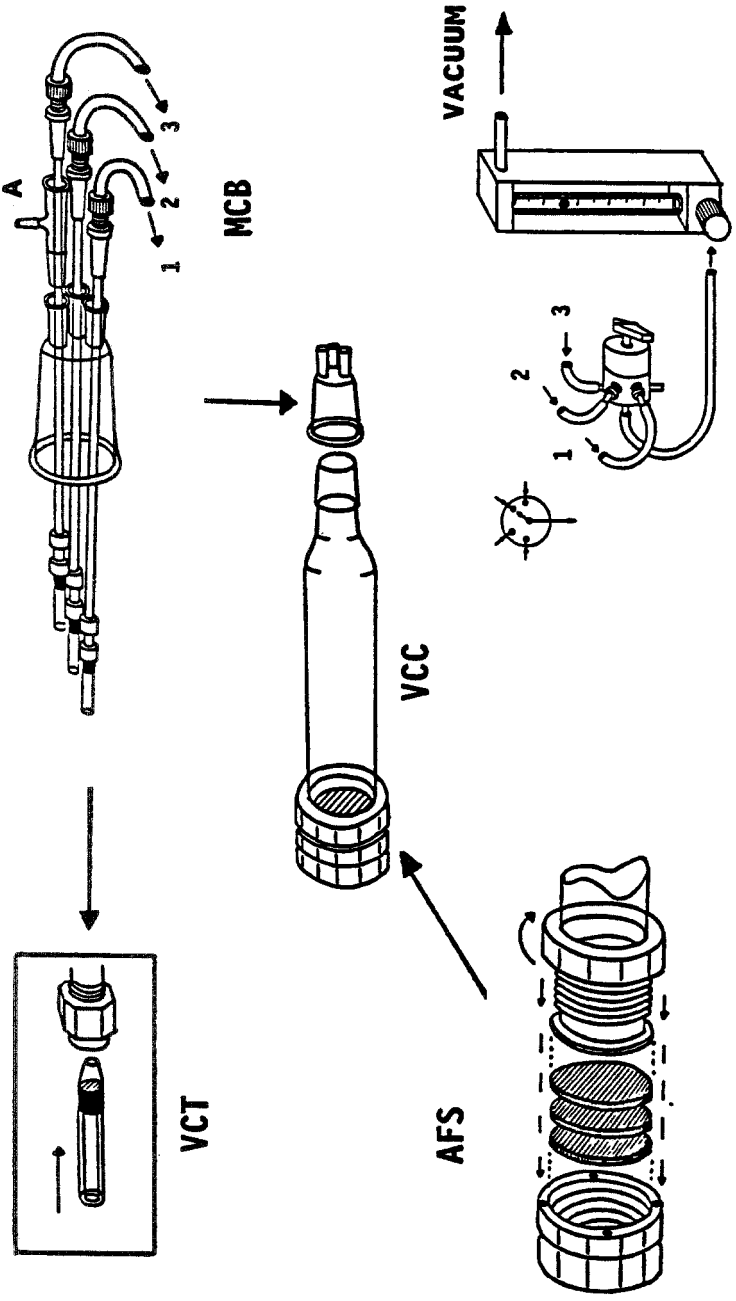

FIG. 2. Drawing of the collection system designed for the collection of volatiles released from insects. System components are as follows: air filtration system (AFS), volatile collection chamber (VCC), volatile collector trap (VCT), and multiport collector base (MCB).

Muskegon, MI) for 24 hr and dried in a fume hood prior to use. Volatiles collected on the traps were eluted with 100 μl of the high-purity methylene chloride and then an appropriate amount of tridecan-1-ol acetate was added as internal standard for subsequent analyses.

Analyses of Volatiles

Gas chromatographic analyses were conducted using a Hewlett-Packard Model 5890A gas chromatograph, equipped with a cool on-column capillary injector (septum injector) and flame ionization detector (FID). Helium was used as the carrier gas at a linear flow of 18 cm/sec and the temperature program was initially isothermal at 60°C for 2 min, then temperature programmed at 20°/min to 180°C. The chromatographic data were collected and processed using the Perkin-Elmer Nelson Turbochrom II chromatographic software package running on an IBM-type PC/AT/386 system. Capillary gas chromatography (CGC) was done using a retention gap column prior to the capillary column. This system permitted the injection of samples without concentration in 5–100 μl of solvent (Grob, 1982; Murphy, 1989). A combination of three fused silica columns connected in series using GlasSeal connectors (Supelco Inc., Bellefonte, PA) was used. The primary deactivated fused silica column, 8 cm × 0.5-mm ID, was connected between the injector and the retention gap column. This primary column permitted the use of 0.4-mm-OD stainless-steel needles with a septum injector. The retention gap columns used were 10 m × 0.25-mm-ID deactivated fused silica (Quadrex, New Haven, CT). The analytical columns used for analyses were a 30 m × 0.25-mm-ID Supelcowax 10 (bonded Carbowax) and a 50 m × 0.25-mm-ID BP-1 purchased from Quadrex.

Experiment 1. Initial tests were conducted to determine the volume of air that could be supplied through the AFS containing one to three layers of the 12-oz, 150-carbon infused fabric. Various air flows were obtained via control of the fan motor voltage. Air velocities were measured using a Teledyne Hastings-Raydist hot-wire anemometer (Model AB-27, Hampton, VI). System back-pressures developed at these various air velocities using one to three filters were recorded using an MKS Instruments baratron tube electromechanical pressure transducer (Model 223BD-00010AA, Burlington, MS) attached to a Hewlett Packard 4.5-digit system voltmeter (Model HP3437A, Loveland, CO) capable of sampling voltages at rates up to 5700 samples/sec. The pressure transducer measured the system back-pressures between the blower and the filter medium, covering a range of 0 to 5 in. of water static pressure ("H_2O" SP) and producing a linearized DC voltage output between 0 and 5 V DC.

Experiment 2. Additional tests were conducted to determine the ability of the AFS to pass water vapor through its filtering medium in order to provide a humid environment for either plants or insects. Tests were performed by increas-

ing the relative humidity (RH) content of the incoming ambient lab air by using a household centrifugal-type humidifier (Kaz Model 564B, New York). Equilibrium times for changes in percentage relative humidity (% RH) were determined by initially measuring the ambient humidity inside the volatile collection chamber and then comparing the humidity over time in the VCC when 100% RH saturated air was introduced and then removed from the air intake of the blower. RH measurements were made using an Omega digital thermohygrometer (Model RH411, Stamford, CT) with simultaneous digital and linearized DC voltage output of both temperature and RH connected to a strip-chart recorder.

Experiment 3. The ability of the AFS to purify air at an air flow of 0.43 m/sec was determined using one, two, and three filters of the 12-oz, 150-carbon material over a 144-hr period using the P-VCS. Air samples were collected for 60 min at 1 L/min at 24-hr time intervals during a 144-hr period and analyzed by CGC. This experiment was replicated five times. Similarly, 60-min collections ($n = 3$) were made from an AFS containing three layers of 12-oz, 150-carbon material at 0.43, 0.23, and 0.12 m/sec after the filter material had been on line for 24 hr at an air velocity of 0.44 m/sec. Air samples were also collected and analyzed ($n = 5$) from the AFS using three layers of the 9-oz, 150-carbon material. Similarly, experiments were performed on the I-VCS using the same method described for the P-VCS except air was pulled through the system at 1 L/min. Impurities that were not removed by the AFS and collected on the VCT were determined by analyses of CGC peak areas obtained from analyses using the Supelcowax 10 column. The volatile collector traps were extracted with a total of 100 μl of methylene chloride in three aliquots and a total of 20 ng of internal standard was added to this extract. Areas of detected peaks were then converted to amounts per hour based on the FID response obtained with the 20 ng of tridecan-1-ol acetate internal standard for all analyses of purified air. For analyses of ambient air, 2 μg of tridecan-1-ol acetate was added as the internal standard. The impurities not removed by the AFS were compared with air purified with two in-line charcoal filters and also to compounds detected in the ambient laboratory air.

Experiment 4. We demonstrated the use of the system in collecting pheromone from insects by using sexually mature male Caribbean fruit flies, *Anastrepha suspensa* (Loew). Flies used in this study were obtained as pupae from the Florida Department of Agriculture, Division of Plant Industries, Gainesville. Adult flies were sorted by sex 2 days posteclosion and placed in screen cages (30 × 30 × 30 cm). The flies were given water and a 3:1 mixture of refined cane sugar:protein hydrolysate. Males were maintained in a greenhouse located in Gainesville at ambient temperature and humidity during September 1991. Five males 9–11 days old were placed in the I-VCS and collection of pheromone was made from 1800 to 2000 in the greenhouse. Volatiles collected from the flies extracted from the VCT, 500 ng of tridecan-1-ol acetate was added as the

internal standard, and the samples were analyzed on the BP-1 column. Pheromone collections were compared to collections made with the I-VCS which did not contain flies.

Experiment 5. We demonstrated the use of the system in collecting volatiles from plants by using mature cotton plants *Gossypium hirsutum* that were in their flowering stage. Selected branches containing a flower were enclosed in the P-VCS system and collections were made from 1300 to 1400 in the greenhouse during September 1991. Volatiles collected from the flower, leaves, and branch were extracted from the VCT, 20 ng of tridecan-1-ol acetate was added as the internal standard, and the samples were analyzed on the Supelcowax 10 column. The collection from the cotton plant was compared to background collection of the P-VCS.

RESULTS AND DISCUSSION

Static back-pressures of one, two, and three filters containing 12-oz, 150-carbon infused fabric at various air velocities are shown in Table 1. It is interesting to note that the volume of air required to provide an air velocity of 0.43 m/sec for a 24-hr period through a cylinder having an ID of only 8.9 cm is approximately 170,000 L/day. Thus, sampling of volatiles from plants for a 5-day period would require in excess of 850,000 L of purified air. Static back-pressure through three filters approaches the capacity of the blowers used in these experiments when an air velocity of 0.43 m/sec was used.

Experiments to determine the equilibrium time for changes in relative humidity indicated that three layers of the 12-oz, 150-carbon material provided sufficient flow-through of water vapor to track changes in ambient relative humidity. Tests done at a constant air velocity of 0.25 m/sec (approximately 0.5 mph wind speed), moved 69.5 L of air/min (4171 L/hr) through the system. This slower speed (instead of the 0.43 m/sec used in other experiments) was used because it was the maximum capacity of the humidifier to supply 100% humidified air to the intake of the blower. Results presented in Figure 3 show that humidity inside the VCC increased immediately once the humidified air was introduced into the blower intake. The humidity increased from 45% RH (ambient) to 62% RH in under 1 min and continued to increase until it equilibrated at 98% RH in 20 min with the incoming air supply (time to saturate the material completely). This demonstrated that the filter material does not block a significant amount of water vapor from passing through and will allow for changes in the humidity of the air in a very short time within a VCC. When the humidity source was removed, the humidity within the chamber began to drop within 1 min and shortly returned to the initial ambient conditions. Equilibrium time for the P-VCS when RH was decreased from 98 to 49% (ambient

RH) was 27 min at this air flow, however, the largest changes occurred in 10 min while taking the remaining time to return to ambient humidity (see Figure 3). The ability for the P-VCS to track changes in RH suggests that, under normal environmental conditions, plants in the P-VCS and surrounded by purified air will not be subjected to large differentials in RH compared to plants in the environment.

The results of analyses of air purification provided by one, two, and three layers of the 12-oz, 150-carbon charcoal-infused medium after 48 hr in the P-VCS at an air velocity of 0.43 m/sec demonstrated that the use of additional layers of filtering material resulted in increased air purification (Figure 4). With one layer of the 12-oz material, $860.6x \pm 468$ ng/hr ($n = 5$) of impurities was

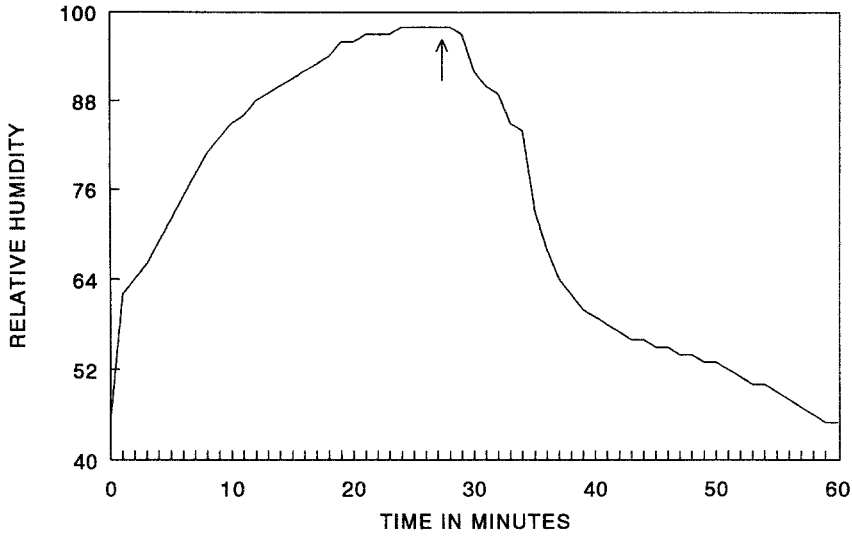

FIG. 3. Graph of the time required for air purified through the three layers of 12-oz, 150-carbon-impregnated cloth to change relative humidity. Air velocity was 0.25 cm/sec and 0 time indicates inlet RH changed from ambient (46%) to 100%. Inlet RH was returned to ambient (47%) after 28 min (indicated by arrow).

detected in 60 L of air collected in 1 hr based on the summation of the 70 major peaks detected by CGC from 6 to 30 min. The impurities detected when two layers of filter material were used decreased to 440.8 $\pm$ 165.8 ng/hr (n = 5). When three layers of filtering material were used, total impurities detected were 36.0 $\pm$ 6.4 ng/hr. Three sections of filter material were the maximum number of layers that could be compressed within the coupler/flange assembly (Figure 1, C1–C4) of this size AFS. Additionally, three layers of filter material produced a system back-pressure that approached the blower cutoff static pressure, and thus the desired air velocity of 0.43 m/sec was reduced. Any additional layers would prevent air flow at the required velocities using this size system and blower motor size. The use of three layers of the 9-oz, 150-carbon material resulted in the detection of 583.2 $\pm$ 42.2 ng/hr of impurities. Because of its reduced performance relative to the 12-oz material, additional evaluation of this material was not pursued. Analyses of impurities detected after 24, 48, 72, and 96 hr of continued air purification using three layers of 12-oz, 150-carbon material indicated that for the first 96 hr, the average amount of impurities detected at the various time intervals was similar to those found at 48 hr. At 120 hr the average amount of impurities detected was 77.68 $\pm$ 5.8 ng/hr (n = 3), and at 144 hr the average amount of impurities detected increased to 87.8 $\pm$ 8.8 ng/hr (n = 3). Studies conducted with decreased air velocities of 0.23 and 0.12

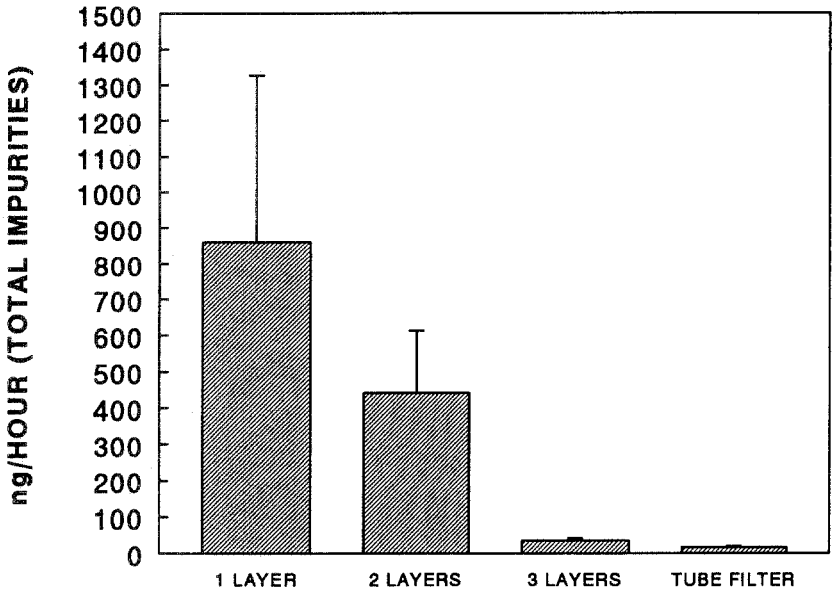

FIG. 4. Comparison of the amount of impurities found in air that was purified by one, two, and three layers of 12-oz, 150-carbon charcoal fabric material using the plant volatile collection system and impurities detected in air purified by two charcoal line filters. Error bars indicate standard deviation (n = 5).

m/sec indicated that air purification was related to the total air flow through the AFS. At 0.23 m/sec the average total amount of impurities present was determined to be 28.8 $\pm$ 9.2 ng/hr (n = 3), and at 0.12 m/sec the amount of impurities decreased to 22.3 $\pm$ 7.1 ng/hr (n = 3).

A comparison of impurities detected using CGC was made among ambient laboratory air, air purified by three layers of 12-oz, 150-carbon material in the P-VCS, and air purified by two charcoal in-line filters (Figure 5). Two charcoal in-line filters provided the best air purification (Figures 4 and 5), with only 8.2 $\pm$ 1.2 ng/hr (n = 3) of impurities detected in the 60 L of air collected. Impurities detected in volatiles collected with the P-VCS consisted of 16 peaks using a peak detection threshold of greater than 0.5 ng/hr. Major impurities occurred with retention times less than 9 min and were typically less than 5 ng/hr. Impurities detected in air collected using the I-VCS were identical in retention time to impurities seen in the P-VCS system. The average amounts of impurities seen in the I-VCS was approximately 3% of that detected in the P-VCS due to the decreased amount of air being purified. The volume of air purified by the I-VCS is 1 L/min, compared with 118.2 L/min of air purified by the P-VCS. Figure 6 shows the retention times and the average amount of the impurities

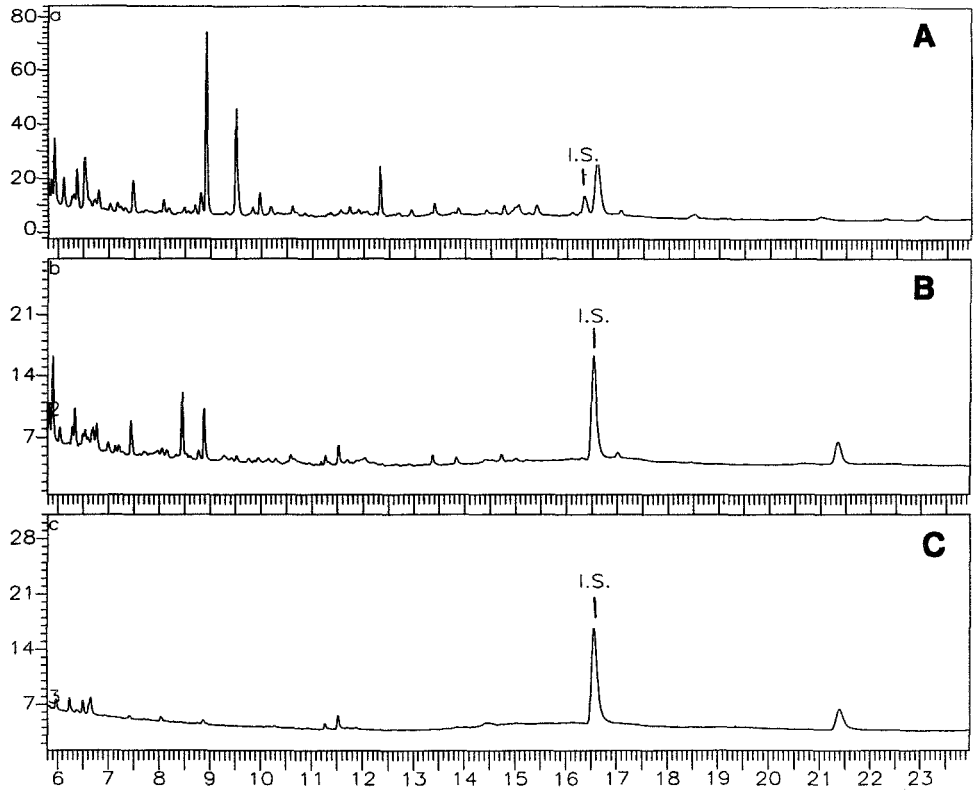

FIG. 5. Typical chromatogram obtained from a 15-min collection of laboratory air (A), a 1-hr collection of air purified by three layers of 12-oz, 150-carbon material in the plant volatile collection system (B), and a 1-hr collection of air purified by two charcoal line filters (C). I.S., internal standard—2 μg of tridecan-1-ol acetate for A and 20 ng for B and C. Column used was a 30 m $\times$ 0.25-mm-ID Supelcowax 10 (see text for operating conditions).

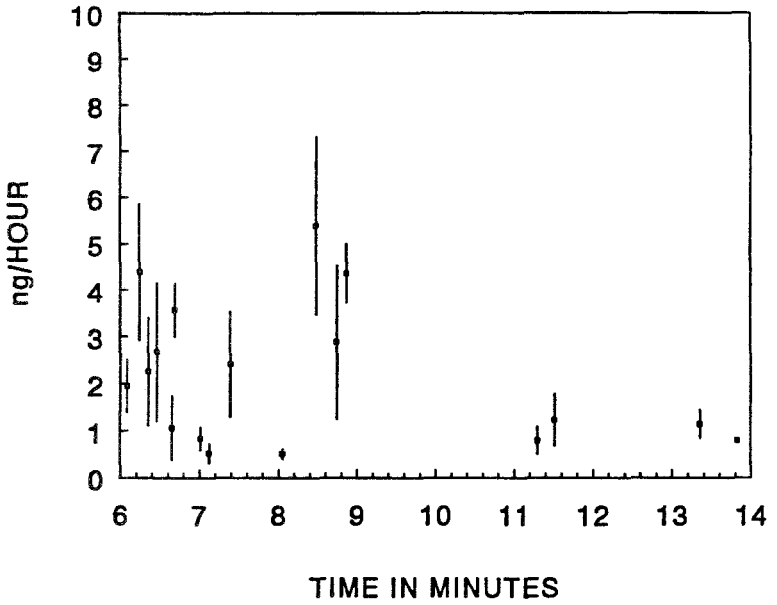
detected from five systems assembled using three layers of 12-oz, 150-carbon-infused fabric as filters. Analyses of air samples from 15-min collections of laboratory air (n = 2) indicated that approximately 55012.8 $\pm$ 856 ng/hr of volatile material was detected by CGC (Figure 5A).

Gas chromatography analysis shown in Figure 7A of volatiles collected from male Caribbean fruit flies indicated that the previously identified compounds, i.e., ocimene [retention time (RT) of 8.4 min], (Z)-3-nonenol and (Z,Z)-3,6-nonadienol (RT, 9.3 min), suspensolide (RT, 14.2 min), E,E-α-farnesene (RT, 14.5 min), β-bisabolene (RT, 14.7 min), anastrephin (RT, 15.3 min), and epi-anastrephin (RT, 15.6 min), were collected in amounts and at



RETENTION TIME	AMOUNT	± STD	RETENTION TIME	AMOUNT	± STD
6.09	1.95	1.14	7.40	2.41	2.25
6.25	4.39	2.96	8.06	0.51	0.23

FIG. 6. Retention times of impurities detected by gas chromatography and average amount of the impurities ($n = 5$) detected in air purified with three layers of 12-oz, 150-carbon-infused fabric as filters. Column used was a 30 m × 0.25-mm ID Supelcowax 10 (see text for operating conditions).

ratios similar to those previously reported (Nation, 1990). Impurities not removed by the charcoal filters in the I-VCS are minimal and, as shown in Figure 7B, would not compromise detection of pheromonal components volatilized by male flies.

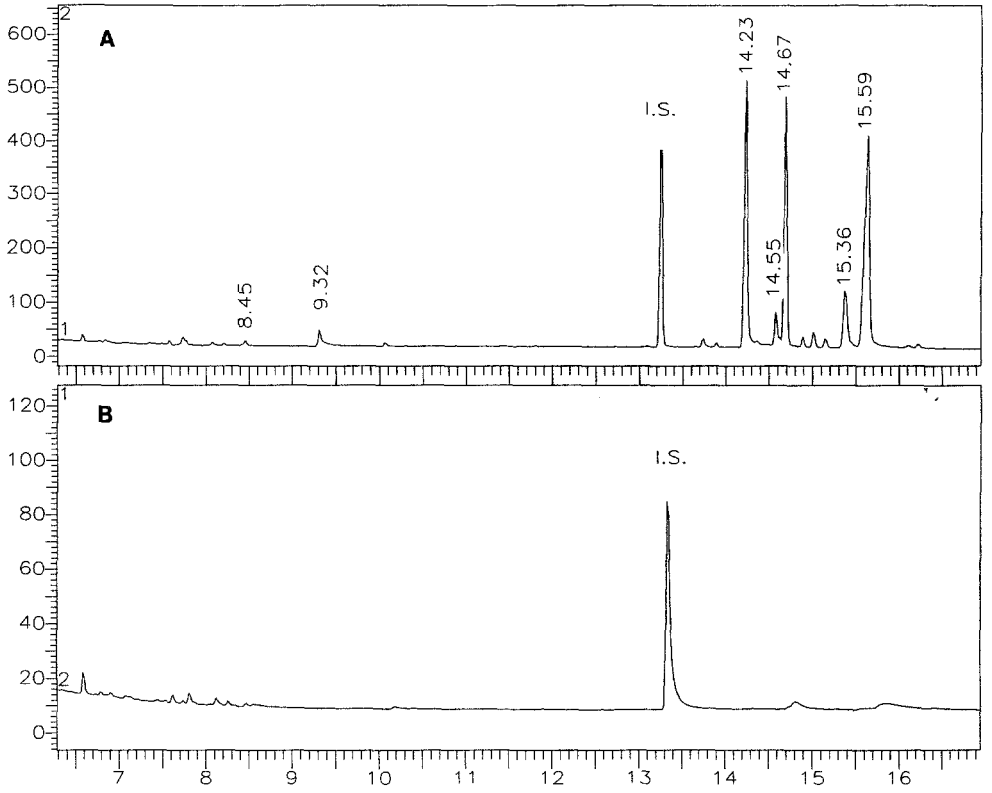

FIG. 7. Comparison of gas chromatograms using the insect volatile collection system for collection of pheromone from sexually mature male Caribbean fruit flies (A) and volatiles collected using the system without flies (B). Column used was a 50 m × 0.25-mm-ID BP-1 (see text for operating conditions and pheromonal peak identification). I.S., internal standard—500 ng tridecan-1-ol acetate.

Analysis of volatiles from a cotton flower, surrounding leaves, and branch resulted in the detection of numerous peaks in relatively small amounts (Figure 8A). Amounts of impurities not removed with the P-VCS are shown in Figure 8B. Although the identification of the compounds is unknown at this time, the chromatograms shown in Figure 8 illustrate the ability to use the P-VCS for collection of plant volatiles. It is apparent that the amount of volatiles collected from the cotton plant investigated was minimal. It is important to note that the amount of air that was subjected to collection on the VCT is only 60 L of the total air (calculated to be approximately 6600 L) that was passed over the plant during the 1-hr collection period. Reduced total air flow and increased air flow through the VCT would increase the amount of material collected.

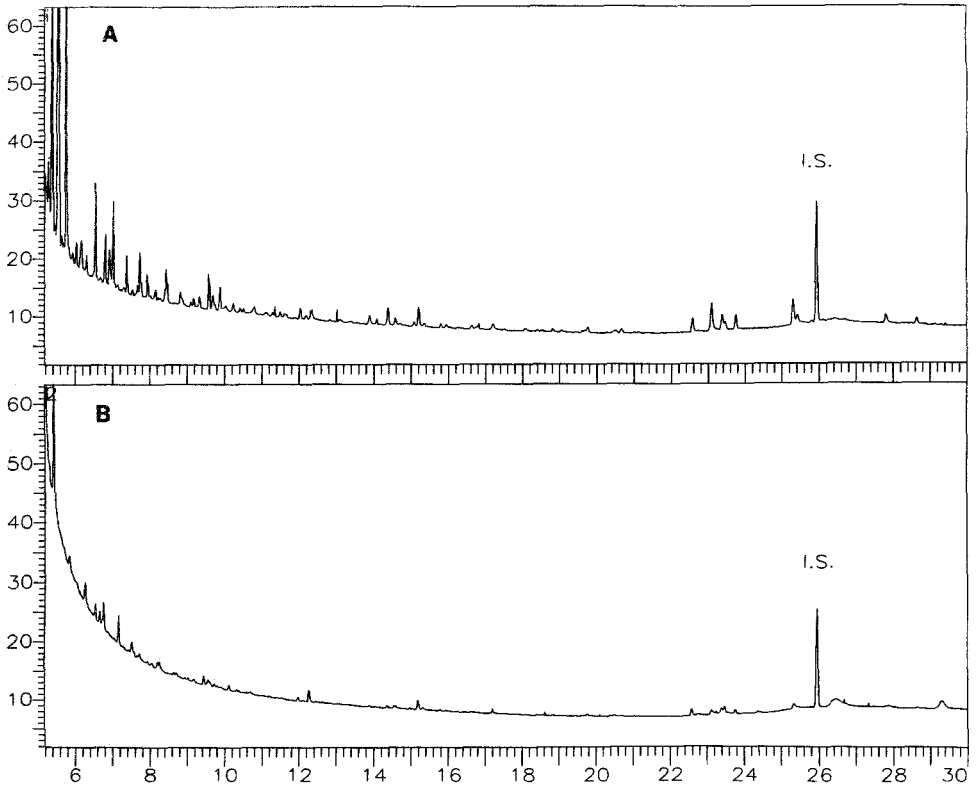

FIG. 8. Comparison of gas chromatograms obtained using the plant volatile collection system for collection of volatiles from a flower, leaves, and branch of a cotton plant (A) and volatiles collected using the system without a plant (B). I.S., internal standard—20 ng of tridecan-1-ol acetate. Column used was a 30 m × 0.25-mm-ID Supelcowax 10 (see text for operating conditions).

CONCLUSION

The air filtration system (AFS) using three layers of 1.27-cm-thick, 12-oz, 150-carbon fabric containing a 150% activated carbon loading provides a purification of laboratory air sources by a factor of approximately 1500 over ambient air, while air purified using two charcoal traps in series provides a purification factor of approximately 3100. The performance of the current volatile collection system (VCS) design demonstrates that a considerable air filtration factor can be obtained using the charcoal-infused fabric to purify very large volumes of air at high flow rates. Evaluation of this material suggests that it can perform well for at least 96 hr or the equivalent of the purification of approximately

760,000 L of air through a 70.88-cm^2 (7.07-$in.^2$) cross section of filter. Currently, systems used for the collection of volatiles from insects generally are done at system air flows of 0.1 to 1 L/min (Shani and Lacey, 1984; Teal et al., 1986; Heath et al., 1991). This suggests that a filter system containing three layers of the 12-oz, 150-carbon material at the diameter tested will perform at these reported levels for approximately 1.5 years before they need to be replaced (760,000 L at 1 L/min flow). The ability of the AFS to adjust quickly to changes in RH and not block water vapor from passing through is important because large volumes of dry air passed over the plants (or insects) would cause them to desiccate.

The design of air filtration systems required for the collection of plant volatiles is more difficult than those needed for collections from insects. This is due largely to the fact that studies of whole plants or plant segments often require a much larger system. The volumes of air that must be purified are also large, and the corresponding flow rates associated with these volumes cannot be pushed through ordinary in-line charcoal trap filters. Another factor which adds to the large volumes of air required for plant collection systems is the increased flow rates through the system used for positive purging to provide a barrier to the intrusion of unpurified air from entering the system from the open end. High air velocities are needed to minimize any momentary disruptions in flow or turbulence caused by movements of objects passing by the volatile collection system. In addition to the problems with size and flow rates, the level of purity of incoming air must be at least the same as, or greater than, that often used to collect insect pheromones. Therefore, relatively low background impurities in air sources must be obtained before any released organic volatiles can be discerned.

The need for still larger systems like the one evaluated, for delivering purified air to plants so that trace semiochemical emissions can be detected, is apparent when one wants to study whole plant and insect interactions in an undisturbed, natural, or artificially duplicated environment. This requires that the system fully enclose the plant or plant and insects without damaging the plant by cutting it to a smaller size to fit a vessel or remove it from its roots or soil. In either case, it is difficult to discern whether the chemical release is caused by the plant–insect interaction or by the plant itself, since it has been severely stressed due to physiological damages or drastic changes to its environment. The nonwoven-fiber carbon medium has the potential for use in such larger-scale systems requiring larger volumes and flow rates that cannot be achieved using standard in-line filtration methods for purifying air.

ODORS INFLUENCE CHOICE OF OVIPOSITION SITES BY *Diabrotica virgifera virgifera* (COLEOPTERA: CHRYSOMELIDAE)[1]

D.R. LANCE*

USDA-ARS
Northern Grain Insects Research Laboratory
Brookings, South Dakota 57005

(Received December 13, 1991; accepted March 9, 1992)

Abstract—Female *Diabrotica virgifera virgifera* LeConte were allowed to choose between oviposition substrates that were and those that were not associated with potential sources of semiochemicals. Females deposited over five times more eggs on moist towelettes that were treated with homogenates of female abdomens than on towelettes treated with distilled water. Similar results were obtained when screening separated the homogenates from the towelettes, indicating that odors alone could elicit the response. In contrast, females did not choose towelettes that had previously been used for oviposition or towelettes containing eggs over unused towelettes. Further tests with homogenates of abdomens and a bacteriostatic agent (sorbate) indicated that the females were probably responding to bacterial odors rather than an oviposition-enhancing pheromone. Four strains of bacteria were isolated from a homogenate of female abdomens; females deposited 4 to 16 times more eggs on substrates with odors of the bacteria than on substrates with odors of uninoculated nutrient agar. In no-choice tests, bacterial odors did not increase the number of eggs deposited per female beetle; however, in choice tests with dishes that tended to retain any beetles that entered, there were more eggs per female (but not more beetles) after 24 hr in dishes with bacterial odors than in those without the odors. Females also chose dishes with odors of excised maize (*Zea mays* L.) roots or elevated levels of carbon dioxide over "control" dishes.

Key Words—Western corn rootworm, *Diabrotica virgifera virgifera*, Coleoptera, Chrysomelidae, bacteria, carbon dioxide, pheromone, semiochemicals, *Zea mays*.

INTRODUCTION

Semiochemicals mediate a variety of important life-history events for western corn rootworms, *Diabrotica virgifera virgifera* LeConte. Mating is facilitated by a female-produced sex attractant, 8*R*-methyl-2*R*-decyl propanoate (Guss et al., 1984). Volatiles from the beetles' primary host, maize (*Zea mays* L.), attract adult beetles (Prystupa et al., 1988), and first-instar larvae are attracted by carbon dioxide and other volatiles from maize seedlings (Strnad et al., 1986; Hibbard and Bjostad, 1990). Feeding stimulants (cucurbitacins) and volatile attractants have also been identified from Cucurbitaceae, which are ancestral hosts of *Diabrotica* beetles (Metcalf et al., 1980; Andersen and Metcalf, 1986; Lampman and Metcalf, 1987; Lampman et al., 1987; Metcalf and Lampman, 1989).

Semiochemicals have not been reported to play a role in selection of oviposition sites by *D. v. virgifera*. Females deposit several batches of eggs beneath the soil surface in late summer. The eggs hatch late in the following spring, and the larvae can develop on roots of several species in the family Graminae (Branson and Ortman, 1970). Due to the restricted motility and limited host range of the larvae, the choice of oviposition site is an important determinant of subsequent survival (Branson and Krysan, 1981). In the rearing facility of the USDA–ARS Northern Grain Insects Research Laboratory, female *D. v. virgifera* appear to concentrate their eggs arbitrarily in one of the two or more egg dishes (petri dishes filled with moist soil) in any given cage (T.F. Branson, personal communication). This indicates that semiochemicals might be involved in the selection of oviposition sites. This study was designed to identify possible sources of semiochemicals that influence choice of oviposition sites by female *D. v. virgifera*.

METHODS AND MATERIALS

General Protocol. Adult *D. v. virgifera* were taken from F_1–F_7 laboratory cultures that were maintained at the Northern Grain Insects Research Laboratory. Larvae were reared on seedling maize (Branson et al., 1988). Adult beetles were held in screen cages (30 × 30 × 30 cm) at 25°C, 40–50% relative humidity, and a 14-hr photophase. Each cage that was used for assays initially contained 100 females (newly eclosed) and 50 males (5–7 days old). Beetles were provided with artificial diet (Branson and Jackson, 1988) and a moisture source (0.6% agar).

An oviposition substrate was continually available to all females that were 2 weeks or more past adult eclosion. Female *D. v. virgifera* readily oviposit on moist, loosely crumpled kitchen towelettes (Handi Wipes, Colgate Non-woven Co., New York; approximately 13 × 27 cm). Each towelette was placed into

a 100 × 20-mm plastic petri dish with five 17-mm holes in the lid. Branson et al. (1975) noted that *D. v. virgifera* "prefer to oviposit beneath an object" (p. 6), so a fluted sheet of aluminum (9-cm diameter) was placed on top of each dish (Figure 1A). New towelettes were boiled through several changes of distilled water to remove manufacturer's cleaning agents; previously used towelettes were also boiled for 10–15 min before being placed in cages.

Oviposition choice tests were initiated when females were 2 to 3 weeks old. Two or three oviposition dishes, each representing an individual treatment, were placed simultaneously into a single cage for 1–3 days, depending on the test. Eggs were then rinsed from towelettes onto filter paper and counted under

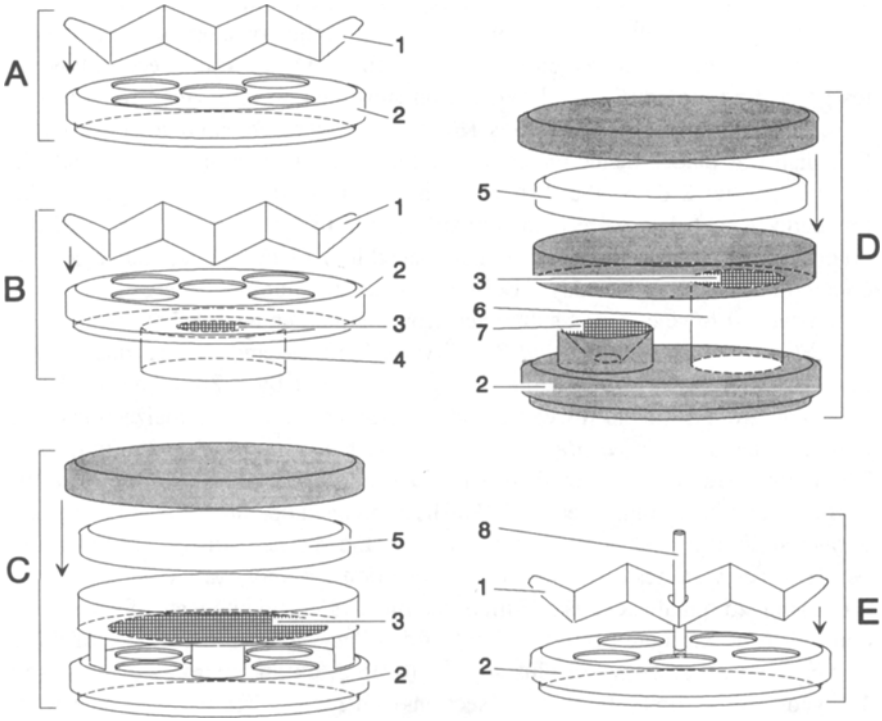

FIG. 1. (A–E) Dishes used in oviposition choice tests (shaded portions were painted black). (1) Circular fluted sheet of aluminum. (2) Plastic petri dish that contains oviposition substrate (moist towelette). (3) Screen (1.2 mm) to keep beetles from touching the sources of odor. (4) Reservoir dish; holds sources of odors that were tested for effects on oviposition. (5) Bottom of petri dish (inverted) containing nutrient agar. (8) Tube for introducing gasses into oviposition dish.

a dissecting scope. Results of a test were discarded if a total of < 100 eggs was deposited in the cage during the period. Individual tests were replicated 8 to 20 times, although greater numbers of replicates were run in some cases if results of initial tests were inconclusive or accurate quantitative estimates were desired. Wilcoxon's rank-sign test was used to analyze data from two-way choice tests; data from three-way tests were analyzed with Friedman's test (Wilkinson, 1990).

Tests for an Oviposition Pheromone. Two types of tests were conducted to detect possible pheromonal influences on choice of oviposition sites by *D. v. virgifera*. In the first type, homogenates of tissues from *D. v. virgifera* were assayed for activity. Initially, entire reproductive tracts were removed from 25 females, homogenized at room temperature in approximately 7 ml of distilled water, and applied directly to a towelette in an oviposition dish (Figure 1A). Females were offered the choice of ovipositing on this towelette or on a second towelette that had been treated only with distilled water. In the second type of test, eggs and previously used oviposition substrates were assayed for activity. Three dishes containing towelettes (Figure 1A) were prepared for each cage. One dish was placed inside the cage, and the other two were placed just outside the cage. After 2 days, the dish was removed from the cage; all eggs on the towelette in that dish were manually transferred to the towelette in one of the other dishes. All three dishes were then placed into a single cage, and eggs were counted after another 2–3 days. Before analysis, the number of eggs transferred to the second towelette was subtracted from the egg count for that towelette.

Effects of Homogenates and Root Tissue. For these and all subsequent tests, potential sources of semiochemicals were separated by 1.2-mm mesh plastic screening from both the towelette and the beetles. Effects of maize roots and homogenates of *D. v. virgifera* tissues were tested using the dish in Figure 1B. The bottom side of the petri dish was glued concentrically to the top of a 50-mm-diameter × 20-mm-"reservoir" dish; a screened opening (25-mm diameter) allowed odors to pass between the reservoir and the petri dish. The following odor sources were tested in various combinations: homogenate of reproductive tracts from 25 female beetles in 7 ml of distilled water, homogenate of abdominal contents from 25 male beetles in 7 ml of distilled water, homogenates of these tissues from *D. v. virgifera* plus sorbate (0.01 g, an antimicrobial agent), and 1.5 g of maize roots (1- to 4-cm sections) on moist filter paper. Roots were obtained from postflowering maize plants (various varieties) that were grown in pots in a greenhouse.

Odors from Bacterial Cultures. Bacteria were isolated from homogenates of female *D. v. virgifera* abdomens that had been held at approximately 23°C for 24 hr. Loops of the homogenate were streaked on plates of Bacto Nutrient Agar (Difco Laboratories, Detroit, MI) so as to produce isolated colonies. After 48 hr, four types of colonies (based on visual characteristics) appeared to be prevalent on the plates. Four strains were isolated by streaking bacteria from

four colonies (one of each type) onto individual plates of sterile nutrient agar. The four newly inoculated plates were incubated at room temperature (22–27°C) for 2 days; bacteria were then removed from one isolated colony on each plate and streaked onto a separate plate of sterile nutrient agar. The latter process was repeated several times to ensure pure cultures. The four strains were tentatively identified using the following criteria: cell morphology, characteristics of colonies, gram reaction, indophenol oxidase activity (oxidase reagent droppers, Marion Scientific, Kansas City, MO), and growth on MacConkey agar (Difco Laboratories, Detroit, MI). In addition, 20 metabolic tests were run using Minitek identification system (Marion Scientific, Kansas City, MO).

To determine the effects of bacterial odors on oviposition, sterile petri dishes of nutrient agar were heavily inoculated with one of the four strains. After 24 hr, petri dishes were placed (culture side down) over oviposition dishes (Figure 1C). For the next 2 days, female *D. v. virgifera* were offered the choice of ovipositing in dishes with odors from bacterial cultures or in dishes with odors from nutrient agar alone. Data were not used if >5% of one or both culture plates was covered with contaminating organisms at the completion of the test.

Odors from bacterial cultures were also tested for adult attraction and oviposition using the dishes shown in Figure 1D. With these dishes, beetles entered through a 0.5-cm-diameter hole in the bottom of a screen cone (Figure 1D, No. 7). The screen cones were to retain beetles that entered the dish. To test how readily beetles escaped from the dishes, dishes containing 25 females were placed in empty cages for 24 hr. Tests were then run by placing dishes (without beetles) for 24 hr in cages containing 100 females and 50 males. At the end of a test, females in each dish, as well as eggs, were counted.

Effects of Carbon Dioxide. In a final series of tests, female *D. v. virgifera* were allowed to choose between dishes that did and dishes that did not contain elevated levels of carbon dioxide. Air or 5% carbon dioxide in air was pumped (peristaltic pump) from large Mylar balloons into dishes (Figure 1E) at 17, 40, 70, or 140 ml/hr for 48 hr.

RESULTS

Tests for an Oviposition Pheromone. Mixed results were obtained in initial tests to determine if oviposition of *D. v. virgifera* was influenced by a pheromone. Oviposition was greatly enhanced by homogenates of female reproductive tracts. Females deposited a mean of 405 ± 41 (SE) eggs on towelettes that had been treated with homogenate but only 79 ± 14 ($N = 47$; $P < 0.001$) on towelettes treated with distilled water. In contrast, a female's choice of towelette did not appear to be influenced by the presence of eggs or by the previous use

of a towelette as an oviposition substrate. In those tests, females deposited 328 ± 67 eggs on the single towelette that was initially placed in each cage. When those eggs were transferred onto one of two unused towelettes and all three towelettes were placed in the cage, females deposited 312 ± 62 eggs on the towelette that had previously been used as an oviposition substrate, 811 ± 349 additional eggs on the towelette containing eggs (but only 485 ± 133 without one replicate in which 5383 eggs were deposited in the dish for this treatment), and 484 ± 229 eggs on the towelette containing only distilled water ($N = 15$; $P = 0.76$).

Effects of Homogenates and Root Tissue. Odors of homogenated *D. v. virgifera* tissues or excised roots of maize were sufficient to enhance oviposition. In tests with the reservoir dishes (Figure 1B), homogenates of female reproductive tracts clearly enhanced oviposition, and odors from homogenates of male abdomens had a similar effect (Table 1). In several of the tests, the odor of the homogenate (i.e., to human senses) at the end of the test strongly suggested the presence of putrifying bacteria. In an attempt to reduce bacterial growth, sorbate

(0.01 g) was added to the 7 ml of homogenate in each dish. The sorbate eliminated overt putrification of homogenates during the tests and did not, by itself, affect the beetles' choice of oviposition substrate (Table 1). Despite this, sorbate reduced the effect of the homogenate on oviposition (Table 1), suggesting that the females' responses to the homogenates were actually, at least in part, responses to microbial metabolites. Regardless, females deposited somewhat greater numbers of eggs in dishes with homogenate plus sorbate than in dishes with sorbate in distilled water (Table 1). Females in the latter test also may have been responding to microbial metabolites rather than to volatiles from the beetles because sorbate often does not completely inhibit microbial growth.

Odors from Bacterial Cultures. The bacterial strains from homogenates of female *D. v. virgifera* abdomens were tentatively identified as *Bacillus* sp., *Flavobacterium* sp., an unpigmented biotype of *Serratia marcescens*, and a second *Serratia* species that was likely either *S. liquefaciens* or a second strain of *S. marcescens*.

Dishes with odors of bacterial cultures received an average of 4 to 16 times more eggs than did dishes with odors from only nutrient agar (Table 2); the differences were statistically significant for three of the four strains. Data obtained with dishes that tend to retain beetles (Figure 1D) were pooled across bacterial strains before analysis (Table 3) because the beetles appeared to respond to odors from all of the bacterial cultures. When 25 females were placed directly in dishes that were designed to retain beetles, odors from the bacteria did not affect the number of eggs deposited on the towelettes or the percentage of females (approximately 60% of the original 25) that were present in the dishes after 24 hr (Table 3). In contrast, when the same dishes were placed, without beetles, into cages of beetles, females deposited significantly more total eggs and more eggs per female in dishes with bacterial odors than in those without the odors (Table 3). The number of females trapped per dish, however, was

only slightly (and not significantly) higher for the bacteria-odor treatment than for the blank agar treatment.

Effects of Carbon Dioxide. Female *D. v. virgifera* chose oviposition dishes with elevated levels of carbon dioxide over those from the air treatment (Table 4). The effect was evident at all flow rates of 40 ml/hr of 5% carbon dioxide (2 ml/hr carbon dioxide) or higher but not at 17 ml/hr (0.85 ml/hr carbon dioxide).

DISCUSSION

Although odors clearly influenced the selection of oviposition sites by *D. v. virgifera*, data from these studies do not support the hypothesis that a pheromone is involved. Initial tests with tissue homogenates suggested a possible pheromonal effect, but this effect was greatly reduced by adding a bacteriostatic agent. A bacterial influence on choice of oviposition sites is also consistent with the females' lack of selectivity among unused towelettes, towelettes that had previously been used for oviposition, and towelettes containing eggs. Benzon and Apperson (1988) likewise demonstrated that responses to bacterial odors had initially been mistaken as the influence of an oviposition-enhancing pheromone in *Aedes aegypti* (L.).

Odors from bacteria are known to have direct or indirect effects on oviposition-site selection in a number of insect species, primarily in the Diptera (e.g., Eddy et al., 1975; Hough et al., 1982; Drew and Lloyd, 1987; Benzon and Apperson, 1988; Hough-Goldstein and Bassler, 1988). In some instances, the bacteria are presumably indicative of suitable larval habitats (e.g., Benzon and Apperson, 1988) or are a source of food for adults (e.g., Drew and Lloyd, 1987). Bacteria appear to be important in the nutritional ecology of the soil-dwelling larvae of onion maggots, *Delia antiqua* (Meigen), and seedcorn maggots, *D. platura* (Meigen). Accordingly, adults of these species are attracted by odors of specific bacteria in association with host tissues (Hough et al., 1982; Hough-Goldstein and Bassler, 1988).

With *D. v. virgifera*, an oviposition-enhancing effect specific to bacterial odors would not serve any obvious ecological function. At this point, very little is known of possible ecological associations of *Diabrotica* with bacteria. Species of *Serratia* and *Flavobacterium* have been isolated from other *Diabrotica* spp. (Schalk et al., 1987; Tran and Marrone, 1988), although members of these genera (as well as *Bacillus*) are common in the environment and may have been contaminants in the tissue homogenates. Regardless, because female *D. v. virgifera* appeared to respond to odors from all four strains, the effect is probably a generalized response to carbon dioxide and perhaps other compounds rather than a response to specific bacteria. Such odors could perhaps indicate suitable soil conditions, the presence of host roots, or host root tissue that is decaying following attacks by rootworm larvae. First-instar *D. v. virgifera* locate roots, in part, by being attracted to sources of carbon dioxide (Strnad et al., 1986). Other compounds emitted by maize also influence responses of the larvae and presumably increase the specificity of their host-seeking efforts (Hibbard and Bjostad, 1990). In laboratory assays, odors from excised maize roots enhanced oviposition by female *D. v. virgifera*, but these odors may have differed substantially from those produced by intact roots in the soil. In any case, possible

ecological functions of oviposition-enhancing odors are made more obscure by the fact that eggs of *D. v. virgifera* overwinter before hatching.

The behavioral or physiological mechanisms by which odors influence oviposition-site selection are also obscure. Specifically, contrasting results were obtained in the tests with oviposition dishes that tend to retain beetles (Figure 1D). In the no-choice tests (females placed directly into the dishes), bacterial odors affected neither the number of eggs deposited nor the proportion of females remaining in the dishes after 24 hr. In those tests, the dishes retained approximately 60% of females for 24 hr; for the choice tests, those dishes may provide an index of relative visitation rates to dishes with and without bacteria. In the choice tests, however, numbers of eggs per female (but not females per dish) were greater for dishes with bacteria than for those without. Thus, results of the no-choice tests indicate that bacterial odors enhance oviposition primarily by acting as attractants or arrestants, whereas results of the choice tests indicate that the odors were primarily stimulants or primers of oviposition behavior. One possible explanation for this discrepancy is that bacterial odors did, in fact, attract females that were seeking oviposition sites but that the bulk of the eggs was deposited by very few beetles. In that case, most females in the dishes of the choice tests could have crawled in by chance, obscuring any differences in numbers of females that had been attracted by the odors.

Overall, the findings presented here clearly demonstrate that odors can influence the choice of oviposition sites by *D. v. virgifera*. Understanding the ecological relevance and behavioral mechanisms involved in this phenomenon will require additional study.

(Received January 30, 1992; accepted March 9, 1992)

Abstract—Sixteen chemicals found in fermented chapote fruit odor were evaluated as attractants for hungry adult Mexican fruit flies. Ethyl octanoate, ethyl benzoate, terpinyl acetate, ethyl salicylate, and (−)-α-copaene proved slightly attractive. Several of the chemicals also were tested for their ability to increase the attractiveness of the previously developed chapote-derived attractant (CEH) consisting of 1,8-cineole, ethyl hexanoate, and hexanol. Combinations containing CEH with ethyl octanoate, ethyl benzoate, 4-terpineol, (−)-α-cubebene, or α-terpineol were significantly more attractive than CEH alone. The two most attractive four-component combinations were ethyl octanoate with CEH (CEHO) and ethyl benzoate with CEH. No combinations containing greater numbers of chemicals were significantly more attractive than CEHO. Therefore, CEHO was selected for further study in this paper. Of CEHO component ratios that were tested, the most attractive was 10:1:1:100 for the chemicals 1,8-cineole, ethyl hexanoate, hexanol, and ethyl octanoate, respectively. Formulations of CEHO into rubber septa and polyvinyl chloride (PVC) were aged 0–15 days and tested against *Torula* yeast in competing McPhail traps in a flight chamber. Summed over all lure ages, rubber septa and PVC dispensers, respectively, were 1.2 and 1.5 times more attractive than *Torula* yeast. PVC dispensers aged 10–15 days were approximately 2.1 times more attractive than *Torula* yeast.

Key Words—Attractants, Mexican fruit fly, Diptera, Tephritidae, *Anastrepha ludens*, host fruit, chapote fruit, 1,8-cineole, ethyl hexanoate, hexanol, ethyl octanoate.

INTRODUCTION

Robacker et al. (1990a) demonstrated that odor from fermenting, immature fruit of yellow chapote, a native host of the Mexican fruit fly (*Anastrepha ludens* Loew), was attractive to hungry male and female adult *A. ludens* of almost any age and at most times of the day. Robacker (1991) determined that hunger for sugar rather than hunger for protein was the drive primarily responsible for attraction to the odor. Robacker et al. (1990b) developed a three-component mixture of chemicals found in the fruit odor that was at least as attractive as natural volatiles collected from the fermented fruit. Also, the mixture was 1.8 times as attractive as *Torula* yeast, a commonly used bait for *A. ludens*, in greenhouse flight chamber experiments. The mixture was composed of 1,8-cineole, ethyl hexanoate, and hexanol (CEH) at a 10:1:1 ratio.

This paper reports further research toward developing an attractant for *A. ludens* from odor of fermented chapote fruit. Sixteen chemicals identified by Robacker et al. (1990b) but not tested previously were evaluated for individual attractiveness and for their ability to increase the attractiveness of CEH when combined with it. The final four-component mixture developed in this work was formulated into rubber septa and polyvinyl chloride (PVC) and the attractiveness to *A. ludens* of these formulations was evaluated in greenhouse flight chamber experiments.

METHODS AND MATERIALS

Insects and Test Conditions. Flies were from a culture that originated from yellow chapote fruit from Nuevo Leon, Mexico, in 1987 and had been maintained on laboratory diet for about 24 generations. Mixed-sex groups of 180–200 flies were kept in 473-ml cardboard cartons until used in tests. Flies were tested when 2–3 days old and had never been fed as adults. Flies were not deprived of water. All tests were conducted between 0830 and 1400. Responses to chapote odor are relatively constant during this period of the day (Robacker et al., 1990a). Laboratory tests were conducted under a combination of fluorescent and natural light. Laboratory conditions were 22 ± 2°C, 50 ± 20% relative humidity, and photophase from 0630 to 1930.

Identification of Chemicals from Chapote Fruit. The fermented, immature chapote fruit, collection of volatiles, and identification of chemical components were described previously (Robacker et al., 1990a,b).

Gas Chromatography–Mass Spectrometry. A Finnigan MAT 4500 GC-MS data system (Finnigan MAT, San Jose, CA) was operated in the electron-impact ionization mode (emission current, −0.30 mA; electron energy, 70 eV; multiplier voltage, −1300 V) to identify impurities in commercial-grade ethyl octanoate. Mass spectral data were acquired over a mass range of 33–350 amu, using

a 1-sec scan rate. A DB-Wax fused silica column was used for sample component separation (J & W Scientific, Folsom, CA; 60 m × 0.32-mm ID, 0.25-μm film thickness; 12-psi constant head pressure; temperature programmed from 50 to 230°C at 4°/min.).

Chemicals Evaluated in Bioassays. Sixteen chemicals previously identified in volatiles from fermented chapote fruit by GC-MS but not evaluated in earlier work were obtained for behavioral assays. These chemicals were chosen because their retention times coincided with attraction behavior of Mexican fruit flies in a tandem GC/behavior bioassay conducted previously (Robacker et al., 1990b). All 16 chemicals had retention times greater than those tested in the earlier work. Names, sources, and purities of the chemicals are listed in Table 1. Purities stated on product labels were verified by GC. Note that Table 1 lists

specific enantiomers for several chemicals even though GC-MS does not distinguish optical isomers. Since we did not know which were the natural enantiomers of yellow chapote, we tested those that were readily available.

Cage-Top Bioassay Procedure. Cage-top bioassays were used to evaluate attractiveness of chemicals and mixtures of chemicals in most experiments. Although this bioassay does not rigorously separate attraction from locomotor arrest of flies, observations from this and previous work indicated that responses of flies are best described as attraction.

Bioassays were conducted by placing four filter papers (3 cm/side) containing test chemicals or controls near the corners on the top of an insect cage (30 cm/side, aluminum-screened) and counting the numbers of flies beneath each filter paper once each min for 5 min, then rotating the positions of the papers by 90° on the cage top and counting flies for another 5 min. Generally, two papers contained test chemicals and were positioned diagonally from each other on the cage top, and likewise for two papers containing controls. The filter papers were raised 5 mm above the cage top using plastic rings as in Robacker et al. (1991) to ensure that olfaction and not contact chemoreception was solely responsible for the response of the flies. One carton containing 180–200 flies was used in each bioassay cage. Certain other modifications were made for each experiment.

Experiments 1–3. Cage-Top Bioassays of Individual Chemicals and Combinations of the Chemicals with CEH. Solutions of the 16 chemicals from chapote volatiles were prepared in hexane and tested using cage-top bioassays in three experiments. The bioassay procedure was modified in that one filter paper was loaded with hexane, one with one of the chemicals (in hexane), one with CEH (1,8-cineole, ethyl hexanoate, hexanol in hexane), and one with the chemical and CEH. Five counts of flies were made, at 1-min intervals, at each of the four treatments in their initial positions on the four corners of the cage-top. Then new papers with new loadings of the same four treatments were placed on the corners but rotated by 90° into new positions for five more counts, and so on, until all four treatments occupied each of the four positions for five counts. The CEH mixture contained 1,8-cineole, ethyl hexanoate, and hexanol at 40:4:4 ng/μl. Each of the 16 test chemicals from chapote volatiles was prepared at 40 ng/μl. Two amounts of each chemical were tested in separate experiments: 400 ng in 10 μl (Expt 1) and 4 μg in 100 μl (Expt 2). Amounts of CEH solution were varied accordingly: 10 μl of CEH was used in bioassays of 400 ng of the test chemicals, and 100 μl of CEH was used with the 4-μg quantities. In Experiment 3, the same bioassay procedure was used to test 100 μl of hexane, 40-μg quantities of the test chemicals ethyl octanoate or ethyl benzoate in 100 μl of hexane, 100 μl of CEH, and the combination of 40 μg of test chemical with 100 μl of CEH.

The two objectives of these experiments were (1) to determine which of

the 16 chemicals were more attractive than hexane and (2) to determine which of them in combination with CEH were more attractive than CEH alone. The two objectives were accomplished simultaneously in each of the three experiments using the bioassay procedure described above. The numbers of replications that were conducted were set initially at five for Experiment 1 and four for Experiment 2, pending the outcomes of those replications. Chemicals that had not increased the attractiveness of CEH by at least 30% after the preset number of replications were not tested further. The others were tested two or three more replications and reevaluated. Those that were borderline were tested further, up to 12 replications. Six replications of Experiment 3 were conducted.

Experiments 4–8. Cage-Top Bioassays of Complex Mixtures. The purpose of these experiments was to determine the most attractive combination of chemicals identified from fermented chapote fruit that contained the fewest components. Because the complete procedure would have required testing hundreds of thousands of combinations of the various chemicals, we chose an arbitrary set of rules to select and eliminate components so that the task could be simplified to a manageable level, hopefully without sacrificing too much accuracy.

Complex mixtures were those containing five or more chemicals, usually CEH plus two or more chemicals from Table 1. Selection rules for incorporation of chemicals into complex mixtures were (1) 1,8-cineole, ethyl hexanoate, and hexanol were included because they had proven the most attractive combination in earlier work (Robacker et al., 1990b); (2) each chemical must have been identified from an attractive fraction of the gas chromatogram (Robacker et al., 1990b); (3) the chemical must have significantly increased the attractiveness of CEH at either the 400-ng or the 4-μg test quantity in Experiments 1 and 2; and(4) chemicals were incorporated into mixtures at 4 ng/μl if the 400-ng test quantity used in Experiment 1 was more attractive than the 4-μg test quantity used in Experiment 2 or at 40 ng/μl if the 4-μg test quantity used in Experiment 2 was more attractive than the 400-ng test quantity used in Experiment 1. Application of these rules led to Mix 8 (Table 2).

A set of elimination rules was used to develop Mixes 7A, 7B, 6A, 6B, and 6C (Table 2): (1) (−)-α-cubebene was deleted from Mix 7A because it was relatively unattractive alone (Expts 1–2), it increased the attractiveness of CEH only at the 4-μg test quantity (Expt 2), and it is relatively expensive (for development of an inexpensive commercial lure); (2) 4-terpineol was deleted from Mixes 7B–6C because it was relatively unattractive alone (Expts 1–2), it increased the attractiveness of CEH only at the 400-ng test quantity (Expt 1), it is relatively expensive, and it is similar in structure to the less expensive α-terpineol, which was not deleted from any of these mixes; and (3) ethyl benzoate, ethyl hexanoate, and ethyl octanoate were deleted sequentially from Mixes 6A–6C to determine the relative importance of each in the blend.

Low quantities (10 μl) of Mixes 8–6C were tested as Experiment 4 (n =

15 replications) and high quantities (100 μl) as Experiment 5 (n = 15 replications). Both experiments were randomized complete blocks with test days as blocks containing each of the six treatments. Cage-top bioassays as described under Cage-Top Bioassay Procedure were conducted. Controls were 10 and 100 μl of CEH (as described in Experiments 1–3), respectively, for the low and high test quantities of Mixes 8-6C. The results of these experiments were used to develop Mixes 6D, 5A, 5B, and 5C.

Mix 6D contained all chemicals of Mix 8 except (−)-α-cubebene and 4-terpineol, which added no attractiveness to the blend in the presence of the other components (Expts 4–5). Ethyl benzoate, ethyl octanoate, and α-terpineol were deleted sequentially from Mixes 5A–5C to determine the relative importance of each in the remaining blend. Cage-top bioassays like those used to test Mixes 8–6C were conducted. Low quantities (10 μl) of Mixes 6D–5C were tested as Experiment 6 (n = 18 replications) and high quantities (100 μl) as Experiment 7 (n = 12 replications), both as randomized complete block designs.

Experiment 8 evaluated Mix 5C vs a four-component mixture (Mix 4) equal to Mix 5C minus ethyl benzoate. The two mixtures were tested using a cage-top bioassay in which Mix 5C was loaded onto two filter papers and Mix 4 onto the other two papers, serving as the control. Forty-one replications were conducted.

Experiment 9. Cage-Top Bioassays of Impurities of Commercial Ethyl Octanoate. The purpose of this experiment was to determine if the attractiveness of commercial-grade ethyl octanoate was due to impurities. Each of three major impurities of commercial-grade ethyl octanoate was evaluated for attractiveness in mixtures containing CEH (40, 4, and 4 ng/μl) and one or all three components at 20 ng/μl each, relative to the attractiveness of CEH alone. Cage-top bioassays

like those used to test complex mixtures were used. Only 10-μl quantities were tested. Nine replications were conducted. Sources and purities of the three chemicals (methyl octanoate, ethyl decanoate, and undecane-2-one) are shown in Table 1.

Experiment 10. Cage-Top Bioassays to Evaluate Ratios of Ethyl Octanoate to CEH. The purpose of this experiment was to determine the most attractive ratio of ethyl octanoate to the three components of CEH. Test solutions (in hexane) contained CEH (40, 4, and 4 ng/μl) with either 4, 40, 400, or 4000 ng/μl of ethyl octanoate. Each mixture (10 μl) was tested against 10 μl of CEH as the control in a randomized complete block design. Cage-top bioassays like those used to test complex mixtures were used. Twenty-two replications were conducted.

Experiment 11. Comparison of TY and CEHO in McPhail Traps. The purpose of this experiment was to compare the attractiveness of CEHO to an aqueous solution of *Torula* dried yeast and borax (TY), a common bait used for detection of *A. ludens* and other *Anastrepha*.

TY traps were prepared using six *Torula* yeast/borax "bait pellets" (Sit-Khem Corp., Michigan City, IN) in 300 ml of water in a McPhail trap (Baker et al., 1944). The TY was allowed to ferment for 4–5 days before tests.

CEHO was also tested in McPhail traps. For use in these traps, CEHO was formulated into rubber septa and polyvinyl chloride (PVC) by Scentry, Inc. (Buckeye, AZ). Rubber septa and PVC dispensers were loaded with 110 and 120 mg, respectively, of a neat mixture of 1,8-cineole, ethyl hexanoate, hexanol, and ethyl octanoate (CEHO) at relative concentrations of 10:1:1:50. CEHO dispensers were suspended in the entrance holes on the undersides of the traps. Traps also contained 300 ml of amber-colored water to mimic the color of TY. Amber-colored water was prepared from red, yellow, and green McCormick food colors (McCormick & Co., Inc., Baltimore, MD). The amber-colored water also contained 0.01% Triton X-100 (Rohm and Haas Co., Philadelphia, PA) as a wetting agent. Dispensers were aged 0–15 days in the greenhouse before testing.

The two McPhail traps containing TY and CEHO were compared in an aluminum-screened flight chamber (2.0 m long $\times$ 0.7 m wide $\times$ 1.3 m high) with an airflow of 1–2 m/sec in the greenhouse. Approximately 800–1000 2-day-old flies were released into the downwind end of the cage at the beginning of each replication. Pupae were irradiated with 7000–9200 rads (cobalt 60 source) 1–3 days before adult eclosion in this experiment because it was conducted in an unsecure greenhouse and *A. ludens* is a quarantined insect in Texas. The traps were removed from the cage after 1 hr. A total of 22 replications was conducted using rubber septa of various ages and 28 replications using PVC.

Emissions from CEHO Dispensers. To measure emission rates of the four chemicals from rubber septa and PVC, dispensers were suspended in the entrance

holes on the undersides of McPhail traps in a greenhouse with an airflow of 1–2 m/sec to age for 1–21 days. Periodically, dispensers were taken into the laboratory and put into an emission-collection apparatus for 1 hr, then returned to the greenhouse. The collection apparatus was designed and built by Heath and Manukian (1992). Briefly, air was pulled through three 7-cm-diameter, 0.5-cm-thick charcoal discs (Activefilter, ACF-NWPE-9-150 Lewcott Corp., Millbury, MA), then passed over the dispenser and through a trap containing 20 mg of Super-Q (Alltech Associates, Inc., Deerfield, IL). Chemicals were extracted from the traps with 200 μl of methylene chloride. To analyze emissions, we used a Shimadzu GC-9A instrument (Shimadzu Scientific Instruments, Inc., Columbia, MD) with a flame ionization detector. Analyses were made on a SPB-1 capillary column (Supelco, Inc., Bellefonte, PA) (60 m, fused silica, 0.32-mm ID, 1-μm film).

Statistical Analyses. Experiments 1–3 and 8–9 were analyzed by paired t tests to compare total counts beneath the control papers to total counts beneath treatment papers. Experiments 4–7 and 10 were randomized complete block designs and were analyzed by analyses of variance to compare treatments with each other. This was done by subtracting total counts at control papers from total counts at treatment papers to obtain differences that were then subjected to analyses of variance. Means were compared by Fisher's protected least significant difference method. For Experiment 11, captures in McPhail traps containing CEH were compared with captures in McPhail traps containing TY by paired t tests.

RESULTS AND DISCUSSION

Experiments 1–3. Objective 1. Attractiveness of Chemicals vs Hexane. Five of the 16 chemicals were more attractive than hexane controls. At the 400-ng test quantity, ethyl octanoate, (−)-α-copaene, terpinyl acetate, and ethyl salicylate were significantly attractive at the 5% level by paired t tests (smallest $t = 2.8$, df = 4) (Table 3). At the 4-μg test quantity, only ethyl octanoate and ethyl benzoate were significantly attractive at the 5% level (smaller $t = 5.0$, df = 11) (Table 4). At the 40-μg test quantity, ethyl octanoate (mean = 26.5 flies/rep) was significantly more attractive than hexane (mean = 14.3) ($P < 0.01$, $t = 6.8$, df = 5), but ethyl benzoate (mean = 27.3) was not significantly more attractive than hexane (mean = 18.7) ($P = 0.1$, $t = 2.1$, df = 5).

Experiments 1–3. Objective 2. Attractiveness of Chemicals + CEH vs CEH Alone. Only two of the five chemicals that were more attractive than hexane also significantly increased the attractiveness of CEH when added to it. They were ethyl octanoate at the 4- and 40-μg test quantities and ethyl benzoate at the 4-μg test quantity. Data for the 4-μg quantities are shown in Table 4. For

Ethyl salicylate	5	16.8	26.0[b]	45.4	49.4

[a] CEH—400 ng 1,8-cineole, 40 ng ethyl hexanoate, 40 ng hexanol.
[b] The mean response to an individual chemical is significantly greater than the response to hexane by paired *t* tests ($P < 0.05$).
[c] The mean response to a combination is significantly greater than response to CEH by paired *t* tests. ($P < 0.05$).

the 40-μg quantity of ethyl octanoate, the mean response to the ethyl octanoate + CEH combination was 57.0 flies/rep, compared to 39.8 for CEH alone ($P < 0.05$, $t = 2.7$, df = 5). In contrast, the mean response to the 40-μg quantity of ethyl benzoate in combination with CEH was 43.8 flies/rep compared to 41.2 for CEH alone ($P > 0.5$, $t = 0.6$, df = 5).

In addition, 4-terpineol significantly increased the attractiveness of CEH at the 400-ng test quantity (Table 3) and (−)-α-cubebene and α-terpineol significantly increased the attractiveness of CEH at the 4-μg test quantity (Table 4). Ethyl octanoate, ethyl benzoate, 4-terpineol, (−)-α-cubebene, and α-terpineol were chosen for further testing in more complex mixtures because they increased the attractiveness of CEH in Experiments 1–3.

Experiments 4–8. Attractiveness of Complex Mixtures. Mixtures containing five to eight components were all significantly more attractive than CEH by paired *t* tests (smallest $t = 2.6$, df = 29, $P < 0.05$). These paired *t* tests were conducted on the combined data from low and high test quantities. Within low

[a]CEH—4 μg 1,8-cineole, 400 ng ethyl hexanoate, 400 ng hexanol.
[b]The mean response to an individual chemical is significantly greater than the response to hexane by paired *t* tests ($P < 0.01$).
[c]The mean response to a combination is significantly greater than the response to CEH by paired *t* tests. ($P < 0.01$).
[d]The mean response to a combination is significantly greater than the response to CEH by paired *t* tests. ($P < 0.05$).

and high test quantities, Mixes 8, 7A, 7B, 6A, 6B, and 6C were not significantly different from each other in attractiveness (Table 5). Likewise, Mixes 6D, 5A, 5B, and 5C were not significantly different from each other. Note that experimental design did not allow direct comparisons of Mixes 8–6C with Mixes 6D–5C or of low with high test quantities.

Experiments 4–7 demonstrated that all test mixtures containing any five or more components (within the limits of those tested) were more attractive than CEH. However, the results also suggested that some chemicals were more attractive than others despite the lack of significant differences among the eight mixtures in Table 5. Ethyl hexanoate is one such attractive chemical. Evidence includes its attractiveness in previous work (Robacker et al., 1990b) and the relatively low attractiveness of Mix 6B (Table 5), the only mixture that did not contain ethyl hexanoate (Table 2). The conservative decision was made to retain ethyl hexanoate along with the other components of CEH in the blend.

TABLE 5. MEAN COUNTS OF *A. ludens* AT FILTER PAPERS CONTAINING CEH OR COMPLEX MIXTURES CONTAINING FIVE TO EIGHT CHEMICALS IN CAGE-TOP BIOASSAYS (EXPERIMENTS 4–7)[a]

	Low test quantity[b]			High test quantity[c]			Overall (L + H)		
Mix	*n*	CEH	Mix	*n*	CEH	Mix	CEH	Mix	Mix/CEH

5B	18	49.8	68.4	12	37.5	48.4	44.9	60.4	1.35
5C	18	43.4	65.1	12	35.4	46.3	40.2	57.6	1.43

[a] All mixes were significantly more attractive than CEH, but no mixes were significantly different from each other in attractiveness by Fisher's protected LSD.
[b] CEH—400 ng 1,8-cineole, 40 ng ethyl hexanoate, 40 ng hexanol in 10 μl of hexane; mix—10 μl of mix solution (Table 2).
[c] CEH—4 μg 1,8-cineole, 400 ng ethyl hexanoate, 400 ng hexanol in 100 μl of hexane; mix—100 μl of mix solution (Table 2).

Other decisions regarding retention or deletion of chemicals were based on combinations of factors. The five-component mixtures (Mixes 5A, 5B, 5C), which contained the least expensive and generally most attractive components in Experiment 1–3 (Tables 3 and 4), were at least as attractive as six- to eight-component mixtures (Table 5), which contained the additional components (−)-α-cubebene and 4-terpineol. Thus, the conservative decision was made not to include the more expensive and generally less attractive components (−)-α-cubebene and 4-terpineol. This decision left only six components under consideration: hexanol, ethyl hexanoate, 1,8-cineole, ethyl octanoate, ethyl benzoate, and α-terpineol. Because Mix 5C was numerically the most attractive of the five-component mixtures and contained the most attractive components in Experiments 1–3 (Tables 3 and 4), the conservative decision was made to consider further only the five chemicals in Mix 5C and to delete α-terpineol from the blend.

Ethyl octanoate and ethyl benzoate were about equally attractive in Experiments 1–2 (Tables 3 and 4) and Experiments 6–7 (Table 5: Mixes 5A vs 5B). However, in Experiment 3, the 40-μg quantity of ethyl octanoate significantly increased the attractiveness of CEH, while the 40-μg quantity of ethyl benzoate did not. The decision was made to keep ethyl benzoate under consideration only

if it further increased the attractiveness of the mixture containing CEH and ethyl octanoate. In Experiment 8, Mix 5C was 8% more attractive than Mix 4, which contained the same components as Mix 5, except ethyl benzoate ($P < 0.05$, $t = 2.2$, df = 40). Because of the added cost of ethyl benzoate and the limited gain in attractiveness, we eliminated ethyl benzoate from further consideration in this study. The attractant blend that we chose for comparison with *Torula* yeast thus contained hexanol, ethyl hexanoate, 1,8-cineole, and ethyl octanoate. Further testing of ethyl benzoate with CEH or with CEH + ethyl octanoate would be a logical extension of the present study.

Impurities of Commercial Ethyl Octanoate. The commercial ethyl octanoate used in this study was found to be >99% pure by GC-MS. The three major contaminants were as follows: ethyl decanoate, 0.062%; undecane-2-one, 0.055%; and methyl octanoate, 0.050%. Thus, at the most attractive test quantities of ethyl octanoate (4–40 μg), 2.5–25 ng of ethyl decanoate also was present on the filter papers. The other contaminants were present in lower quantities.

Experiment 9. Cage-Top Bioassay of Impurities of Commercial Ethyl Octanoate. Mixtures containing combinations of CEH with 200 ng of ethyl decanoate, undecane-2-one, methyl octanoate, or all three chemicals were not significantly more attractive than CEH alone. The most attractive of the four mixtures, CEH plus ethyl decanoate, was only 1.05 times more attractive than CEH. It seems unlikely that these chemicals would be maximally attractive at 2.5–25 ng and not at all attractive at 200 ng, especially since similar chemicals such as ethyl hexanoate and hexanol were maximally attractive at quantities of 40–400 ng and were only slightly attractive at 4 ng (Robacker et al., 1990b). We conclude that the attractiveness of commercial ethyl octanoate was due to ethyl octanoate.

Experiment 10. Cage-Top Bioassays to Evaluate Ratios of Ethyl Octanoate to CEH. Figure 1 shows the results of Experiment 10. The most attractive mixture contained 400 ng of 1,8-cineole, 40 ng of ethyl hexanoate, 40 ng of hexanol, and 4000 ng of ethyl octanoate. Although the apparent optimum ratio is 10:1:1:100, the actual optimum could lie anywhere between 10:1:1:10 and 10:1:1:1000, at least for the test quantity range that was tested. The optimum ratios and test quantities of the components of CEH were determined previously (Robacker et al., 1990b). It is possible that addition of ethyl octanoate to CEH could alter optimum ratios and concentrations of 1,8-cineole, ethyl hexanoate, and hexanol to each other, but this was not tested.

Receptor-Site Physiology. Robacker et al. (1990b) argued that 1,8-cineole, ethyl hexanoate, and hexanol bind to separate receptor sites owing to the additivity of their attractivenesses and the finding that each could not be replaced in the mixture with greater concentrations of the others. We now suggest that ethyl octanoate binds to yet another receptor site. There are several lines of evidence. First, its effect on attractiveness is additive to the three components of CEH.

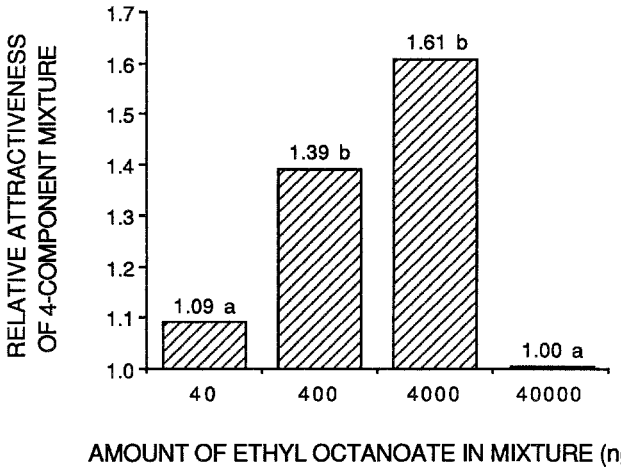

FIG. 1. Means of counts of *A. ludens* at filter papers containing various amounts of ethyl octanoate combined with CEH (400 ng of 1,8-cineole, 40 ng of ethyl hexanoate, and 40 ng of hexanol), divided by counts at filter papers containing only CEH, in cage-top bioassays (Experiment 10). Means followed by the same letter are not significantly different from each other at the 5% level by LSD.

Second, ethyl hexanoate, the component of CEH most similar to ethyl octanoate in structure, remains an important part of the mixture even in the presence of ethyl octanoate (Table 5: Mix 6B). Third, increasing the concentration of ethyl hexanoate decreased the attractiveness of CEH (Robacker et al., 1990b), while ethyl octanoate was most attractive at concentrations 100 times higher than ethyl hexanoate.

Relationship to Chapote Odor. Although the four chemicals of CEHO are found in chapote odor, all four are very minor components. Therefore it is not correct to refer to CEHO as odor of chapote fruit. Further, experiments showing how attractiveness of chapote odor extract to *A. ludens* adults is affected by physiological state of the fly and by environmental factors (Robacker et al., 1990a) do not necessarily hold true for CEHO.

Emissions from Rubber Septa and PVC Dispensers. PVC dispensers emitted CEHO more uniformly over the course of the 21 days than did rubber septa, in both the amounts emitted and the ratios of the components to each other (Figure 2). Neither dispenser type emitted the chemicals at the apparent optima of 10:1:1:100 determined in Experiment 10. Average emission ratios from rubber septa were closer to the optima than those from PVC, but as discussed above, they were not consistent.

Experiment 11. Comparison of TY and CEHO in McPhail Traps. McPhail traps baited with either rubber septa or PVC dispensers of CEHO captured more

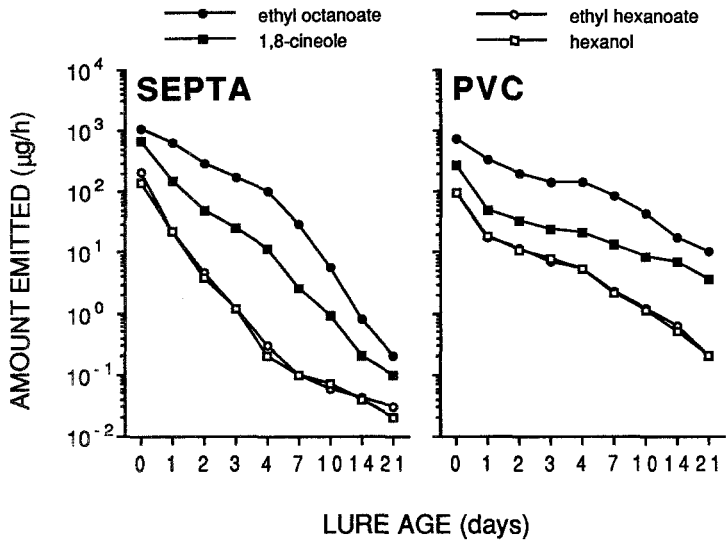

FIG. 2. Emissions of four chemicals from rubber septa and PVC dispensers of various ages.

male and female flies than McPhail traps with TY, at all lure ages between 0 and 15 days. Summed over lure ages of 0–15 days, these results were significant for both rubber septa and PVC traps (Table 6). Captures in traps with PVC dispensers generally increased with lure age by 1.1% of the flies in the cage per day of lure age ($F = 8.1$; df = 1,16; $P < 0.05$). Captures in traps with rubber septa did not change significantly with lure ages between 0 and 15 days.

Traps with PVC dispensers captured more flies than traps with rubber septa, although the difference was not significant by a t test of capture ratios (PVC/TY vs rubber septa/TY). It is noteworthy that McPhail traps baited with polyethylene microcentrifuge tubes containing 25 or 100 µl of CEH captured 1.8 times as many flies as TY in tests identical to those conducted here except that the flies were from a different laboratory culture and microcentrifuge tubes were not aged before tests (Robacker et al., 1990b). This is a surprising result considering that CEHO was 1.3–1.6 times more attractive than CEH in direct comparisons in this work (Tables 3 and 4; Figure 1). Perhaps the explanation is that the rubber septa and PVC dispensers emitted CEHO at suboptimal levels most of the time. If only data from PVC ages 10–15 days are considered, then traps with PVC dispensers captured 2.1 (±0.2 SE) times as many flies as those with TY. The attractiveness of CEH and CEHO relative to TY in the field remains to be tested.

TABLE 6. CAPTURES OF ADULT *A. ludens* BY COMPETING PAIRS OF MCPHAIL TRAPS BAITED WITH RUBBER SEPTA OR PVC DISPENSERS LOADED WITH A 10:1:1:50 MIXTURE OF 1,8-CINEOLE, ETHYL HEXANOATE, HEXANOL, AND ETHYL OCTANOATE (CEHO) VS *Torula* YEAST (TY) IN A FLIGHT CHAMBER IN A GREENHOUSE (EXPERIMENT 11)[a]

Bait	Number of replications[b]	Males[c]	Females[c]	Males + females[c]	CEHO/TY (M + F)
Rubber septa	22	30.3b	24.6b	27.4b	1.22
TY		24.5a	20.5a	22.5a	
PVC	28	35.1b	32.3b	33.7b	1.52
TY		23.9a	20.6a	22.2a	

[a]TY traps contained 300 ml of water and six *Torula* yeast bait pellets; rubber septa and PVC dispensers were loaded with 110 and 120 mg of CEHO, respectively; CEHO traps contained 300 ml of amber-colored water to mimic TY color.
[b]Summed over dispenser ages of 0–15 days following removal from −20°C.
[c]Data are mean percentages of the total flies in the flight chamber captured by each trap. Means of competing traps followed by different letters are significantly different at the 1% level by paired *t* tests.

Acknowledgments—The authors thank Aleena Tarshis Moreno and Maura Rodriguez for technical assistance, Sammy Ingle for insects, A.W. Guenthner (USDA-APHIS, Mission, TX) for irradiation of pupae, and R.R. Heath (USDA-ARS, Gainesville, FL) for use of his volatile collection apparatus. Special thanks are also extended to Jack Jenkins (Scentry, Inc., Buckeye, AZ) for preparation of PVC and rubber septa dispensers. (Received September 3, 1991; accepted March 9, 1992)

Abstract—Chemical analyses of pheromone-gland extracts and volatiles released by male *Galleria mellonella* (L.), the greater wax moth, resulted in the identification and quantification of the aldehydes, primary alcohols, and fatty acids of nonane and undecane. Adult females released none of these six compounds. Mean percentages of the aldehydes and alcohols in the gland extracts were 19.0% undecanal, 3.9% nonanal, 48.3% 1-undecanol, and 28.8% 1-nonanol. Mean percentages of the aldehydes and alcohols in volatiles collected during the first hour of scotophase from moths 1 to 9 days old were 77.4% undecanal, 20.8% nonanal, 1.46% 1-undecanol, and 0.36% 1-nonanol. Age did not significantly affect the amount of each compound collected. The collection of volatiles from moths 3 to 5 days old during a 12-hr scotophase indicated that production was greatest during the first and third quarters of the period. Methylation of group volatile samples allowed the quantification of the fatty acids.

Key Words—Lepidoptera, Pyralidae, Gallerinae, *Galleria mellonella*, greater wax moth, sex pheromone gland, nonanoic acid, undecanoic acid, 1-nonanol, 1-undecanol.

INTRODUCTION

The greater wax moth (GWM), *Galleria mellonella* (L.), is an important pest of the honey bee, *Apis mellifera* L. The larval stage of the GWM feeds on the

*To whom correspondence should be addressed.

wax, pollen, and honey produced by honey bees. Wax moth infestations in strong active colonies are effectively controlled by worker bees which remove GWM larvae and adults. However, extensive losses occur when the members of active colonies have been weakened by exposure to pesticides or bee diseases and are unable to defend the colony. The heaviest economic losses occur when beekeeping equipment containing only comb and debris has been placed in storage.

Some studies have been conducted on the use of pheromone traps for capturing the GWM (Finn and Payne, 1977; Flint and Merkle, 1983). Male adults of the GWM produce a sex pheromone in glands located on their forewings (Roller et al., 1968). The pheromone attracts females during mating (Finn and Payne, 1977). Female adults are not known to produce any pheromone. In a study by Flint and Merkle (1983), traps were baited with nonanal and undecanal, the reported male sex pheromone components for the GWM (Roller et al., 1968; Leyrer and Monroe, 1973). The response of females to the synthetic bait was not as high as their response to live males, suggesting that the pheromone blend tested by Roller et al. (1968) and Leyrer and Monroe (1973) may have been incomplete. Minor but biologically active components of the pheromone may have escaped detection in the original chemical analyses.

Since the success of pheromone traps is dependent on the identification of all pheromone components and an accurate estimate of the relative ratios and amounts of the components, studies were initiated to verify the components of the pheromone of the GWM and establish their release rates. Two sources of male pheromone were analyzed: volatiles of the GWM collected by a glass-adsorption technique and glands extracted with solvent.

METHODS AND MATERIALS

Insect Rearing

Adults were obtained from the first, second, or third generation of laboratory cultures initiated from wild stock collected at the Townsend House—Apiculture Field Station, University of Guelph. Insects were reared on an artificial diet (Dutky et al., 1962) in jars kept in the dark at 27 ± 3°C and 70% RH. Last-instar larvae were transferred to containers with fan-folded pieces of stiff paper and were maintained at 25°C in a growth chamber with a reverse photoperiod of 12L:12D. Individuals were separated by sex during the pupal stage. Adult males and females were collected daily 2 hr prior to the initiation of the scotophase and were kept individually in 14-ml plastic vials in growth chambers maintained in separate buildings. Adults were not provided with food because this stage does not feed (Oertel 1962).

Gland Extracts

Forewings were dissected from live unanesthetized male moths. Scales on the dorsal and ventral surfaces of the wings were removed by gentle scraping with the edge of a metal spatula. The wing tissue was cut so that a rectangular piece of the wing containing the pheromone gland was excised. Six glands from three moths of the same age were dipped for 0.5 min in 30.0 μl of isooctane (Caledon, distilled in glass) which also contained 30.0 ng of an internal standard, tridecanyl acetate (C13 : AC). Glands from moths 0 to 5 days old were extracted. The time of extraction was recorded with all extractions occurring between the first and the sixth hours after the initiation of scotophase. Five controls were prepared by extracting pieces of female forewings in the same manner as described for the males. Gland extracts were allowed to evaporate at room temperature to a volume of <5.0 μl. Two microliters of the extract was injected into a Hewlett Packard 5790A gas chromatograph. A total of 32 samples of pheromone gland extracts was analyzed.

Volatiles

Study I: Release by Male GWM of Different Ages. Volatiles were obtained with a glass-adsorption technique similar to Baker et al. (1980). Individual moths were placed in stoppered 100-ml volumetric flasks. Prior to the introduction of the moths, 1000 ng of the internal standard, C13 : AC, dissolved in 10 μl of isooctane, was added to each flask and the solvent was allowed to evaporate. Male moths aged 1, 3, 5, 7, and 9 days were placed in flasks 2 hr prior to the initiation of scotophase to allow the insects to become accustomed to the containers. Total production for each moth was measured 0, 1, 2, or 3 hr after scotophase initiation. Measurements were taken at the beginning of scotophase because male GWM have been observed to be sexually active during this period (Nielson and Brister, 1977). Only one sample per moth was taken. Four replications of each combination of age and collection time were obtained ($n = 80$). To collect the extract, flasks were placed in the freezer at $-15°C$ for 10 min, after which the moths were removed. Flasks were rinsed three times, once with 1.0 ml isooctane and twice with 0.5 ml isooctane. For each rinse, the isooctane was swirled continuously for 30 sec and then filtered through glass wool. The glass wool was rinsed once with 0.2 ml isooctane.

Study II: Release by Male GWM During a 12-hr Scotophase. Results from Study I indicated that moths 3 to 5 days old produced the greatest quantities of pheromone. Therefore, in Study II, production by moths 3 to 5 days old was monitored for the entire scotophase. Individual moths were placed in stoppered 500-ml boiling flasks 2 hr prior to the initiation of scotophase. Each flask contained 1500 ng of the internal standard, C13 : AC. Total production was measured 3, 6, 9, or 12 hr after the initiation of scotophase. Only one sample per

moth was taken. A total of five replications for each combination of age and collection period was obtained ($n = 60$). Flasks were rinsed twice with 2.0 ml isooctane, and the rinses were filtered through glass wool. The glass wool was rinsed once with 0.4 ml isooctane.

Study III: Release by Groups of Male GWM. Group effects on production were studied by placing five male moths of the same age in a 500-ml boiling flask. Each flask contained 20.0 μg of C13:AC. Male moths aged 3, 4, or 5 days old were placed in flasks 2 hr before the start of scotophase. Total production was measured 3 hr after the initiation of scotophase so that comparisons could be made between the results of the 3-hr collection periods in each of Studies I, II, and III. Flasks were rinsed as described in Study II. Four replications of each age were prepared for a total of 12 samples. Three controls were prepared by placing five female moths of the same age (3, 4, or 5 days old) in each of three flasks and collecting the volatiles in the same manner as described for the males.

Methylation of Fatty Acids

Quantification of fatty acids from six arbitrarily selected samples in Study III was achieved by converting them to their methyl esters (Morrison and Smith, 1964). A 100-μl aliquot was transferred from a volatile sample to a glass vial. The isooctane was allowed to evaporate and 100 μl of 14% boron trifluoride in methanol (Sigma Chemical Co., St. Louis, MO) was added. The vial was capped and the contents were heated for 45 min at 60°C. One hundred microliters of distilled water was added, and the sample was extracted three times with isooctane (total volume, 1.0 ml). Crystals of sodium sulfate were added to the combined extract to absorb any water remaining in the sample. The sample was concentrated to a volume of <100.0 μl using low heat. Two microliters of the concentrate was injected into the gas chromatograph.

Chemical Analyses

All pheromone samples and synthetic standards were analyzed on a Hewlett Packard 5790A gas chromatograph equipped with a splitless injector and a flame ionization detector. The gas chromatograph was interfaced to a Hewlett Packard 3390A integrator. The fused silica capillary column used was a Supelcowax10, 30 m × 0.25-mm i.d. (Supelco, Oakville, Ontario). Hydrogen was used as a carrier gas at a linear flow velocity of 38 cm/sec. Injector and detector temperatures were set at 225 and 250°C, respectively. Samples were injected splitless at an initial oven temperature of 75°C. For the gland extracts, the oven temperature remained at 75°C for the first 2.00 min and then increased at 25°/min to a final temperature of 160°C. For the volatile extracts, the GC temperature rose at 15°/min to a final temperature of 200°C. Chromatograms were run for

at least 30 min. Retention times of major peaks were compared to the retention time of the internal standard, C13 : AC, tridecanyl acetate. The relative retention times of authentic standards were determined. Compounds identified from the natural product samples were quantified by comparing the peak heights to those produced by authentic standards of C9 : Al, C11 : Al, C9 : OH, and C11 : OH and the synthetically produced methyl esters of C9 : acid and C11 : acid. All chemicals were obtained from the Sigma Chemical Co. (St. Louis, MO) with the exception of nonanal, which was obtained from the Aldrich Chemical Company Inc. (Milwaukee, WI).

Peak assignments determined from the analyses on the Supelcowax10 column were confirmed by the analysis of selected samples and synthetic standards on a 15 m × 25-mm-i.d. SPB1 nonpolar column (Supelco, Oakville, Ontario). GC conditions were as described previously with the exception of the temperature program, which had an initial temperature of 75°C, a final temperature of 160°C, and a temperature change of 15°/min.

Mass spectral analyses were performed on a Kratos MS890 double-focusing mass spectrometer interfaced to a Carloerba/Kratos gas chromatograph fitted with a 30 m × 0.32-mm DB-5 column (J and W Scientific, Folsom, CA). Helium was used as a carrier gas at a flow rate of 1 ml/min. The injector temperature was 230°C. Samples were injected at an oven temperature of 75°C. The temperature was held at 75°C for 2 min, then increased at 15°/min to a final temperature of 250°C. Both electron impact (EI) and chemical ionization (isobutane) (CI) spectra were obtained. All spectra were generated at 70 eV. Spectra of compounds from the pheromone extracts were compared to those of authentic compounds.

Statistical Analyses

Data were transformed by natural log prior to an analysis of variance. The ages of the moths, the date of sampling, and the time of collection were considered in the model. Data were analyzed twice: (1) to determine the mean amounts of the compounds in the samples and (2) to determine the relative percentages of the compounds in the samples. A Protected LSD test was performed on the transformed data to compare mean values at the 5% level (Fisher, 1935).

RESULTS

Isolation and Identification of Chemical Compounds

GC–mass spectral analyses of male GWM volatiles demonstrated the presence of six compounds. Two of the peaks had fragmentation patterns and retention times identical to those of nonanal (C9 : Al) and undecanal (C11 : Al), the

previously reported sex pheromone components of the GWM (Roller et al., 1968; Leyrer and Monroe, 1973). Two other peaks had EI and CI spectra which suggested that the compounds were 1-nonanol (C9:OH) and 1-undecanol (C11:OH). The two remaining peaks gave EI and CI spectra which corresponded to those of nonanoic acid (C9:acid) and undecanoic acid (C11:acid).

The parent ion peak for the compound identified as C9:OH (MW 144) did not appear in the EI spectrum, while the M + 1 peak *m/e* = 145 (addition of H^+) did not appear in the CI spectrum. This is quite common for alcohols (Pavia et al., 1979). In the EI spectrum, a small peak at *m/e* = 126 corresponded to the loss of water from the parent ion (M − 18). Another peak at *m/e* = 98 corresponded to the simultaneous loss of water and ethylene (M − 46). In the CI spectrum, a peak at *m/e* = 127 corresponded to the loss of water from the M + 1 peak. In the CI spectrum, a small peak at *m/e* = 143 could have been a M − 1 peak, although this is not common for alcohols (G. King, personal communication).

The parent ion peak for the compound identified as C9:acid (MW 158) appeared in the EI spectrum, while the M + 1 peak *m/e* = 159 was the most intense peak in the CI spectrum. An intense even-numbered peak at *m/e* = 60 in the EI spectrum resulted from a McLafferty rearrangement, which is common for carboxylic acids (Pavia et al., 1979).

The interpretation of the EI and CI spectra of the compound identified as C11:OH (MW 172) was similar to that given for C9:OH. The EI spectrum had fragments corresponding to M − 18 (154) and M − 46 (126). The CI spectrum had a fragment corresponding to M + 1 − 18 (155). A peak at *m/e* = 171 could have been a M − 1 peak.

The parent ion peak for the compound identified as C11:acid (MW 186) appeared in the EI spectrum, while the M + 1 peak *m/e* = 187 appeared as the most intense peak in the CI spectrum. An intense even-numbered peak appeared at *m/e* = 60 in the EI spectrum as the result of a McLafferty rearrangement.

All six peak assignments from the GC–mass spectral analyses of male GWM volatiles were confirmed by cochromatography of the natural product samples with authentic standards on both the slightly polar Supelcowax10 column and the nonpolar SPB1 column. The aldehydes, C9:Al and C11:Al, and the alcohols, C9:OH and C11:OH, were consistently found in the gland extracts and the volatiles of the males. The tentative assignments of the alcohols from the GC–mass spectral analyses were confirmed by cochromatography of authentic C9:OH and C11:OH with the natural product samples on the Supelcowax10 column. The two acids, C9:acid and C11:acid, produced broad tailing peaks on the Supelcowax10 column with retention times which varied according to the concentrations of the compounds. Peaks for the acids on the SPB1 column were more distinct but C9:acid could not be resolved from the large peak for

C11 : Al. The presence of peaks for C9 : acid and C11 : acid in the gland extracts and volatiles of the GWM males was variable due to the fact that acids chromatograph so poorly without conversion to their methyl esters. Methylation of selected volatile samples indicated that the acid assignments were correct because the methyl esters of the acids, methyl nonanoate and methyl undecanoate, were detected by cochromatography with synthetic standards.

Gland Extracts. The relative percentages of the aldehydes and alcohols in the gland extracts of the males were 3.9% C9 : Al (95% CI = 3.39–4.34), 19.0% C11 : Al (95% CI = 17.09–20.51), 28.8% C9 : OH (95% CI = 27.11–29.66), and 48.3% C11 : OH (95% CI = 45.36–50.02). C9 : acid and C11 : acid are not included because peaks for these compounds were not always detectable. Wing extracts from the females did not contain any of the aldehydes, alcohols, or acids or nonane and undecane that were found in the male extracts.

Volatile Samples. The aldehydes, C9 : Al and C11 : Al, and the alcohols, C9 : OH and C11 : OH, were found in all volatile samples. However, chromatograph peaks for C9 : acid and C11 : acid were not always detectable. Volatiles collected from female GWM did not contain the aldehydes, alcohols, and acids of nonane and undecane that were found in the male volatiles.

Study I: Release by Male GWM of Different Ages. Although the largest quantities of the aldehydes and alcohols were collected from moths which were 3 to 5 days old, age did not significantly affect the amount of each component collected ($P > 0.05$, ANOVA). Variations between individuals were thus greater than any variations which may have been due to age. In addition, the date of sampling also did not significantly affect the amounts of the aldehydes and alcohols collected ($P > 0.05$, ANOVA). However, the time of collection was a highly significant factor ($P < 0.0001$, ANOVA). Data from moths of all ages were pooled and mean values for the amounts of four components collected at the four sampling times (i.e., 0, 1, 2, and 3 hr into scotophase) were calculated (Table 1).

From Table 1, it can be seen that the release rates for C11 : Al during the first, second, and third hours of the scotophase were 25.5, 8.6, and 6.7 μg, respectively. Similarly, the release rates for C9 : Al were 6.8, 2.7, and 2.4 μg. The release rates for the alcohols for the first, second, and third hours of scotophase were 0.38, 0.66, and 0.61 μg for C11 : OH and 0.11, 0.23, and 0.17 μg for C9 : OH.

Mean percentages of the aldehydes did not change significantly during the first 3 hr of scotophase ($P > 0.05$, ANOVA) although the mean percentages for the alcohols did change ($P < 0.0001$, ANOVA) (Table 2).

Study II: Release by Male GWM During a 12-hr Scotophase. The mean cumulative amounts of C11 : Al and C9 : Al for the collections made at 3 hr into scotophase and 6 hr into scotophase were not significantly different ($P > 0.05$, protected LSD), indicating that the aldehydes collected in the second quarter

[a]Amounts collected for each hour were cumulative, from 2 hr prior to the initiation of scotophase (n = 20 for each hour). C11:Al, undecanal; C9:Al, nonanal; C11:OH, 1-undecanol; C9:OH, 1-nonanol. Raw data were transformed by natural log prior to statistical analyses. Within each column, means followed by the same letter are not significantly different at $P < 0.05$ (protected LSD).

were not appreciable (Table 3). The amounts of the aldehydes in the samples collected at 9 hr into scotophase were almost double the amounts collected in the 3- and 6-hr samples, suggesting that the insects also released aldehydes during the third quarter of the 12-hr scotophase. The amounts of the two aldehydes in the samples collected at 12 hr into scotophase were not significantly different ($P > 0.05$, protected LSD) from the amounts collected in the 9-hr samples, suggesting that the aldehydes were not released during the last quarter of the 12-hr scotophase.

The quantities of C11:OH collected in the samples at 3 and 6 hr into scotophase were significantly different ($P < 0.05$, protected LSD) (Table 3), suggesting that C11:OH was being released during the second quarter of the 12-hr scotophase. Amounts of C9:OH collected in the samples at 3 and 6 hr

into scotophase were not significantly different ($P < 0.05$, protected LSD) (Table 3). The amounts of the alcohols collected at 9 hr into scotophase were significantly greater ($P < 0.05$, protected LSD) than the amounts collected at 6 hr into scotophase. However, the amounts of C11:OH and C9:OH collected in the 9- and 12-hr into scotophase samples were not significantly different ($P > 0.05$, protected LSD), suggesting that the alcohols also were not released during the last quarter of the 12-hr scotophase.

Mean percentages of the aldehydes for the 3- and 6-hr samples were significantly different ($P < 0.05$, protected LSD) from the mean percentages of the aldehydes for the 9- and 12-hr samples (Table 4). The mean percentage of C11:Al decreased over time, while the mean percentage of C9:Al increased.

[a] Amounts collected for each hour were cumulative, from 2 hr prior to the initiation of scotophase ($n = 15$ for each hour). C11:Al, undecanal; C9:Al, nonanal; C11:OH, 1-undecanol; C9:OH, 1-nonanol. Raw data were transformed by natural log prior to statistical analyses. Within each column, means followed by the same letter are not significantly different at $P < 0.05$ (protected LSD).

The mean percentages of the alcohols increased over time. However, the mean percentages of C9:OH and C11:OH for the 9- and 12-hr samples were not significantly different ($P > 0.05$, protected LSD).

Study III: Release by Groups of Male GWM. Mean percentages of the aldehydes and alcohols in the samples collected from groups of five male GWM in glass flasks were 69.5% C11:Al (95% CI = 65.44–72.50), 27.5% C9:Al (95% CI = 23.50–31.68), 1.96% C11:OH (95% CI = 1.63–2.31), and 0.97% C9:OH (95% CI = 0.81–1.15).

Methylation of six of the group samples resulted in the conversion of the fatty acids to their methyl esters and the aldehydes to dimethyl acetals (Figure 1). The mean percentages of the derived dimethyl acetals, fatty acid methyl esters, and alcohols in the six group samples were 57.76% C11:DMA (95% CI = 50.99–62.96), 27.06% C9:DMA (95% CI = 23.14–30.45), 1.52% C11:OH (95% CI = 1.18–1.87), 0.78% C9:OH (95% CI = 0.63–0.95), 10.35% C11:Me (95% CI = 5.61–18.35), and 2.53% C9:Me (95% CI = 1.68–3.66). The concentrations of the two fatty acids were thus intermediate to the concentrations of the aldehydes and the alcohols. Eleven-carbon compounds were always at higher concentrations than their corresponding nine-carbon compounds.

DISCUSSION

In our study, chemical analyses of volatiles and pheromone gland extracts of male GWM resulted in the isolation and identification of six related compounds, four of which had not previously been identified. The compounds were the aldehydes, alcohols, and fatty acids of nonane and undecane. The aldehydes have already been demonstrated to play a role in the attraction of female GWM (Finn and Payne, 1977; Flint and Merkle, 1983). Even though the acids and alcohols represent a small percentage of the volatiles in comparison to the aldehydes, they also may be components of the pheromone blend. Studies of other species have shown that the minor components of a pheromone may not be attractive by themselves but when they are combined with the major components, they induce a greater response than would be achieved with the major components alone (Sweeney et al., 1990). The roles of the fatty acids and alcohols produced by the GWM should be established. If these compounds are proven to be pheromone components, the addition of these compounds to synthetic lures could result in greater attraction of females than was achieved previously (Finn and Payne, 1977; Flint and Merkle, 1983).

Behavioral bioassays should probably be initiated with a blend similar to that collected at the beginning of scotophase since this appears to be the period during which male GWM usually mate (Nielson and Brister, 1977). In Study

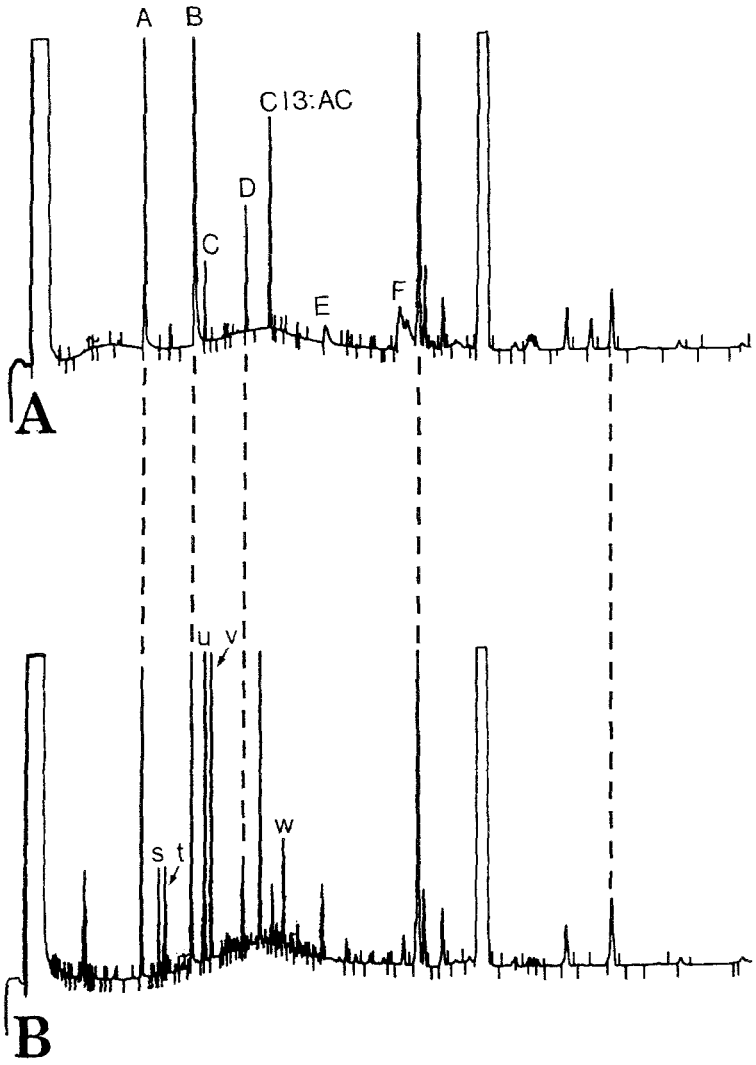

FIG. 1. A comparison of GC chromatograms from (A) a volatile sample collected from a group of five adult males of *G. mellonella* kept for 3 hr in a glass flask and (B) the same sample after methylation with 14% boron trifluoride in methanol. Dashed lines connect corresponding peaks. C13:AC, tridecanyl acetate = internal standard; A, nonanal (C9:Al); B, undecanal (C11:Al); C, 1-nonanol (C9:OH); D, 1-undecanol (C11:OH); E, nonanoic acid (C9:acid); F, undecanoic acid (C11:acid); s, 1,1-dimethoxy nonane; t, methyl nonanoate; u, 1,1-dimethoxy undecane; v, methyl undecanoate; w, tridecanol (product of methylation of C13:AC).

II, GWM males appeared to release pheromone during the third quarter of the 12-hr scotophase. However, behavioral studies have shown that GWM males do not call extensively during this time period (Romel and Scott-Dupree, unpublished). Pheromone release, which is usually initiated in response to the onset of scotophase, may have a rhythm independent of the length of scotophase.

Leyrer and Monroe (1973) conducted quantitative studies on the release of pheromones by male GWM and obtained a 3:7 ratio of C11:Al to C9:Al in the volatiles. In our study, C11:Al was the major component of the GWM pheromone, with the ratio of C11:Al to C9:Al at approximately 3:1. Leyrer and Monroe (1973) collected male GWM volatiles for 24 consecutive hr from newly emerged adults which may not have been fully mature. Also, different strains of the same species sometimes have different pheromone blends (Foster et al., 1989). Studies of different strains of the GWM should be conducted prior to any testing of synthetic pheromone in the field.

A comparison between the mean percentages of the compounds in the gland extracts and the volatiles illustrates that the alcohols were predominant in the gland extracts, while the aldehydes were predominant in the volatiles. Teal et al. (1986) determined that the alcohols found in pheromone gland extracts of *Heliothis virescens* (F.) and *H. zea* (Boddie) were the immediate precursors of their analogous aldehydes found in the volatiles. The two alcohols, C9:OH and C11:OH, in the pheromone glands of the GWM may be the precursors to C9:Al and C11:Al in the volatiles. The two acids, C9:acid and C11:acid, are also structurally similar to the main components of the GWM volatiles and the biosynthesis of these compounds may be interrelated.

The compounds found in the volatiles of male GWM could also have roles in interspecific communication. The major component, C11:Al, in the volatiles of the GWM is a pheromone component of the lesser wax moth (LWM), *Achroia grisella* F., although the function of C11:Al in the communication system of the LWM has not yet been determined (Dalm et al., 1971). The GWM also shares two components of its volatiles with *Achroia innotata obscurevittella* Ragonot, a pest of both *Apis cerana japonica* F., the Japanese honey bee, and *Apis mellifera* L. *A. innotata obscurevittella* releases a pheromone composed of 96.8% C9:OH and 3.2% C9:Al (Nemoto et al., 1990). C9:Al has no known function in the communication system of *A. innotata obscurevittella*. The major pheromone component of *A. innotata obscurevittella*, C9:OH, is a minor component in the volatiles of the GWM. Reproductive isolation of these related wax moth species is probably maintained by differences in the release rates and/or ratios of the common components and by the release of compounds unique to each species.

Behavioral bioassays will be necessary in order to determine the roles of the various components of the volatiles of male GWM in wax moth commu-

nication. A pheromone blend which is as attractive to female GWM as that emitted by live males could then be developed. At the very least, this pheromone blend could be used in traps in apiaries and storage facilities for beekeeping equipment for the monitoring and detection of GWM populations.

ATTRACTION OF FEMALE FATHEAD MINNOWS, *Pimephales promelas*, TO CHEMICAL STIMULI FROM BREEDING MALES

KATHLEEN S. COLE[1] and R.J.F. SMITH*

Department of Biology

(Received October 28, 1991; accepted March 9, 1992)

Abstract—Female fathead minnows, *Pimephales promelas*, were attracted to water that had contained conspecific males in breeding condition. The attraction was particularly strong in the morning and occurred in both females with mature gonads and gonadally regressed females. Females were also attracted to water that had contained other females but this attraction was weaker than the attraction to breeding males and tended to occur in afternoon trials. When offered a choice, females preferred breeding male water over regressed male water or female water. Swarming behavior, in which females formed a very active group near the water inlet, occurred primarily in test locations receiving water from breeding males. Our results indicate that breeding male *P. promelas* produce water-borne chemical stimuli that attract females and that females distinguish breeding male stimuli from female or regressed-male water-borne stimuli.

Key Words—Pheromone, fathead minnow, *Pimephales promelas*, Cyprinidae, mate attraction, breeding behavior, fish behavior.

INTRODUCTION

Pimephales promelas, the fathead minnow, inhabits freshwater systems of North America (Andrews, 1970). In southern Saskatchewan, large aggregations of males and females form in the spring (e.g., Smith and Lemly, 1986). As day

length and water temperature increase, males exhibiting breeding tubercles, a dorsal mucus pad, and nuptial coloration associated with elevated androgen levels (Smith, 1974) move into the shallows. There they establish breeding territories associated with either rock cobble, floating, or submerged objects (Lord, 1927; Marcus, 1934; Isaak, 1961; Andrews and Flickinger, 1973). Spawning occurs when females leave the aggregation, move inshore, and oviposit on a suitable spawning substrate within a male's territory, after which the male tends the embryos until hatching (Marcus, 1934; McMillan and Smith, 1974; Sargent, 1988, 1989; Unger, 1983; Unger and Sargent, 1988).

During reproduction, male *P. promelas* use visual displays to solicit female attention and to indicate their readiness to spawn (Cole and Smith, 1987a) and females release chemical stimuli that increase male courtship behavior (Cole and Smith, 1987b). This study tested the hypothesis that mature male *P. promelas* release chemical stimuli that are attractive to females.

METHODS AND MATERIALS

Experimental Fish

Major collections of *P. promelas* were made at Bradwell Reservoir, 45 km southeast of Saskatoon, Saskatchewan (latitude 52°, longitude 106°) from late May to mid-July, which includes the reproductive season and the period directly preceding it. Fish of both sexes were collected by dip net from offshore aggregations, while sexually mature males, with breeding tubercles, dorsal pad, and nuptial coloration, were collected by dip net from spawning sites near shore. Although no direct examination was made of the testicular state, the presence of tubercles, dorsal pad, and nuptial coloring is associated with mature testis (Smith 1978). Some of these fish were brought directly into the laboratory for experimentation, while others were placed in large, outdoor holding pools under natural photoperiod and seasonally appropriate temperatures for use the following winter.

Eight weekly collections of 20 or more fish each were made throughout this period in order to provide baseline information on seasonal gonad development. All individuals from the weekly collections were killed with the fish anesthetic, 2-phenoxyethanol, and body weight and gonad weight were determined for each to provide gonosomatic index values (GSI = gonad weight as percentage of total body weight).

Experimental Apparatus

The experimental apparatus was designed to simulate the choices faced by female fathead minnows in nature. Females may remain offshore away from

male spawning sites or they may approach suitable sites and choose among those sites, some unoccupied and others occupied by males of various status. Our apparatus allowed females to remain in the open area of the tank or to enter spawning sites containing chemical stimuli from conspecifics.

This was done by introducing donor water (obtained from donor tanks) at separate point sources located in suitable spawning sites at either end of a 216-L test tank. Any subsequent attraction to particular donor waters on the part of recipient fish could then be measured by recording the time spent in close proximity to either donor water source.

Donor tanks (28.4 L) receiving a continuous flow from a central water supply (20 ml/min) contained with a single male (male donor tanks; $n = 4$), a single female (female donor tanks; $n = 4$), or no fish (control donor tanks; $n = 4$) (Figure 1). Donor water taken from donor tanks was then transferred to

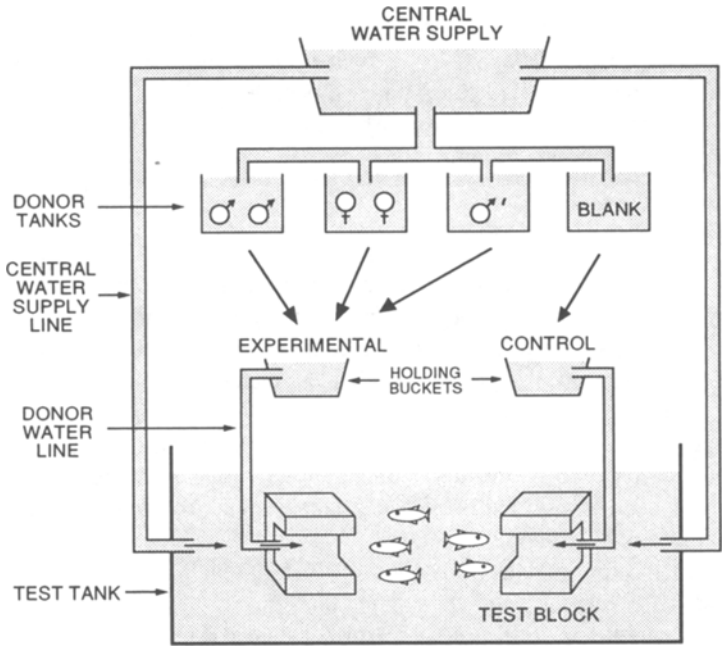

FIG. 1. The experimental apparatus. Water could flow into the test tank directly from the central water supply or stimulus water from donor tanks containing fish in various combinations of sex, maturity, and number could be introduced into the cavities of test blocks. Stimulus waters could be switched from one test block to another. The test blocks were inherently attractive to minnows but test stimuli could alter the relative attractiveness of the two blocks.

1-L holding buckets. From there, donor water could be introduced into test tanks holding recipient females.

Four 216-L test tanks were used in all experimental trials. Each test tank contained a pair of vertically stacked c-shaped concrete blocks in each corner. These blocks (190 × 190 × 190 mm) attract *P. promelas* because of the visual presence of overhanging ceilings that are preferred as spawning surfaces (McMillan and Smith, 1974). Water, which was taken from donor tanks during experimental trials and the central water supply at all other times, entered the test tanks via the top block (test block) in each pair (Figure 1). This block was placed so that the open portion was directed forward, while clear plastic plates on each side formed a partially enclosed space that received the donor water. Water was introduced into the cavity through a rigid, J-shaped tube that passed through a hole in one of the plastic plates and which could be connected with plastic tubing to various elevated holding buckets of donor water or to the central water supply. Donor water then flowed by gravity into each of the two concrete test blocks, with a constant flow rate (30 ml/min) controlled by tubing clamps.

Both donor and recipient fish in the laboratory were maintained in flow-through water conditions at 20–22°C both prior to and during portions of the experimental trials and at all times under a photoperiod matched to natural day length. Prior to experimental trials, fish were fed twice daily to satiation with commercial fish food (Tetramin).

Experimental Protocol

Each experimental trial consisted of recording the responses of a group of five female *P. promelas* before and after the introduction of various donor waters. Each five-fish test provided one comparison, or replicate. Each experimental trial consisted of eight such replicates, using new females for each test ($n = 8$ groups).

Experimental donor water was obtained by taking (1) an equal mixture of water taken from two of the four donor tanks (chosen at random) containing same-sex fish or (2) a mixture of water taken from two control donor tanks, containing no fish, for control water.

For each experimental trial, each of 20 test females was marked with a unique set of notches on the caudal fin, then placed in a small aquarium for several hours until any release of alarm substance (Smith, 1973) was likely complete. After this, marked females were divided into four groups of five each and placed in one of four test tanks. In addition, several white cloud minnows (*Tanichthys albonubes*) were added to each of the test tanks to provide a dither effect (Barlow, 1967). Trials began 24 hr after females had been marked and placed in test tanks.

A trial consisted of recording female behavior during three intervals: (1) a

prestimulus 15-min interval, with water from the central supply flowing into both blocks; (2) an initial 15-min stimulus interval, with control water entering one block and experimental donor water entering the other; and (3) a second 15-min stimulus interval, with the water lines interchanged so that control water flowed into the former experimental block and experimental water into the former control block. In each of the intervals, female response was measured by recording the amount of time each of the five females spent in each of the two test blocks, then summing their responses for a group total.

In addition to block occupancy, test females in summer trials frequently exhibited an unusual and conspicuous behavior that we termed "swarming." Swarming was defined as occurring when three or more females aggregated in one of the test blocks and exhibited rapid and jerky swimming motions inside the block, rapid circling of the test block ceiling, and nibbling motions directed toward the ceiling or the inlet tube. Occasionally one or more of the females appeared to rub the ceiling with the head or dorsum. Aggressive interactions were markedly absent during swarming behavior. The number and duration of swarming bouts were recorded and compared among the various experimental conditions.

Following testing, females were killed with 2-phenoxyethanol and GSI values calculated. Although GSIs provide only a rough index of gonadal state, they do distinguish between fish that are near sexual maturity and those that are not in breeding condition. In addition, these values could be compared with those obtained from females collected from the field in weekly collections made from May to July.

Experimental Trials

Summer Trials. Following collection from the field, fish were brought back to the laboratory and placed in holding tanks for 24 hr to adjust to the laboratory environment. Subsequently, test females (summer females) were marked with caudal fin notches as described above, placed in groups of five in test tanks with whitecloud minnows, then tested 24 hr later.

In the morning (A.M. trials), each group was tested with control water versus water from either male or female donors. Then 5–6 hr later, during the afternoon (P.M. trials), the same females were tested with control water versus water from donor tanks of the other sex. Eight groups of summer females were tested with female donor water first and eight with male donor water first.

Winter Trials. A second series of trials used females that had been held in outdoor pools for 6 months following the end of the reproductive season (winter females). Winter temperatures in the pools were maintained near 10°C. Following a 36-hr acclimation period to adjust to the 18–20°C temperature in the

laboratory, groups of five females were individually marked with caudal notches, placed in test tanks with white cloud minnows, then tested 24 hr later.

Donor water was obtained from tanks containing one of three types of fish: (1) adult males showing full breeding morphology, tubercle development, dorsal pad, and nuptial coloration (i.e., developed males); (2) gonadally regressed males (i.e., regressed males); or (3) winter-condition (i.e.,gonadally regressed) females. All donor fish were held at a density of one per tank. As in summer trials, water from two of four tanks of similar donor type were chosen at random and mixed together prior to introduction into test tanks.

Unlike summer trials, recipient females in winter trials were given a choice between two simultaneously presented, conspecific stimuli, following a 15-min prestimulus interval. In 12 recipient female groups, donor water from developed males was introduced at the same time as donor water from regressed males during the first 15-min stimulus interval. The donor lines were then changed for the second 15-min stimulus interval so that the stimulus conditions in the two test blocks were reversed. In nine additional recipient winter-condition female groups, developed male donor water was paired with water from regressed females.

All winter trials were carried out in the morning. At the end of each trial the test females were killed and GSI values were calculated, as described above, for each individual. At the end of the experiment the donor fish were also killed and their gonadal status was checked by determining GSI values.

Data Analysis

In all trials, the total number of fish-seconds spent by the five recipient females in each of the two test blocks was recorded for each interval of the test. Since each test interval was 15 min long, each group of five test females could accumulate a maximum of 4500 fish-sec. Comparisons were then made between prestimulus (before introduction of donor water) and successive stimulus intervals. First, the total number of fish-seconds spent in each of the two test blocks during the prestimulus interval was compared with that of the first 15-min stimulus interval (the introduction of either experimental or control donor water into the test blocks in summer trials, the simultaneous introduction of two types of experimental donor water into test blocks in winter trials). Second, the total number of fish seconds spent in each of the two test blocks during the first stimulus interval was then compared with that of the second 15-min stimulus interval which followed the exchange of donor types between test blocks. The Wilcoxon matched-pairs, signed-rank test (Siegel, 1956) was used to test for significance. Since trials were conducted on eight sets of five females, there were eight comparison pairs ($n = 8$) for the Wilcoxon tests. In some tests, ties reduced the effective sample size to seven.

RESULTS

Summer Trials

Summer females with mature ovaries showed a strong attraction to test blocks receiving water from reproductive males during the first stimulus interval, compared to the prestimulus interval, in both morning and afternoon trials (Figure 2). When donor sources were interchanged in the second stimulus interval,

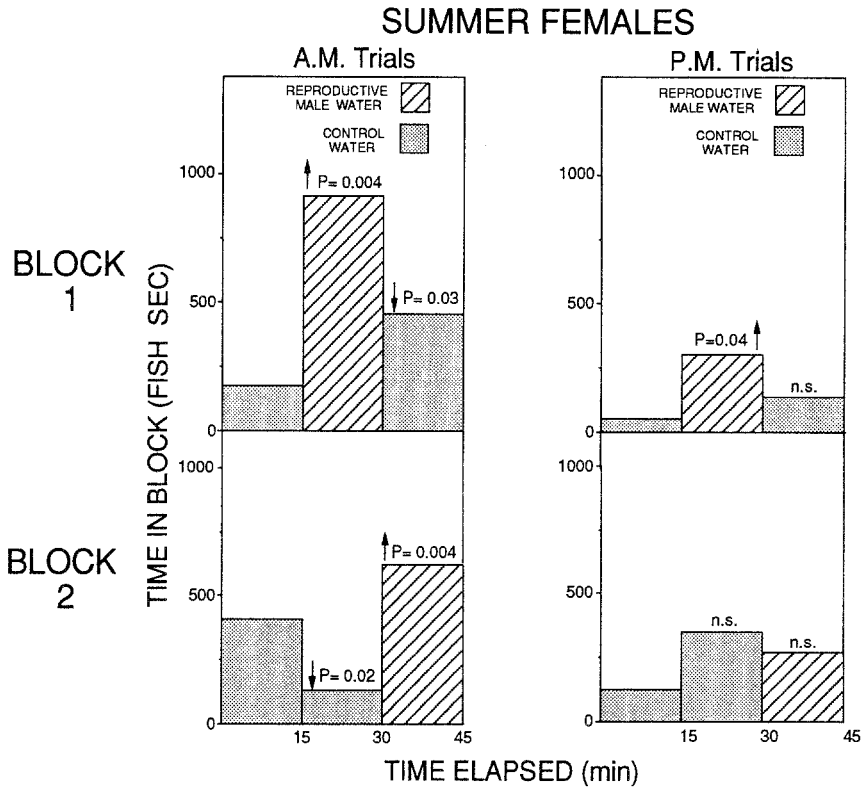

FIG. 2. Median times (fish-seconds) spent by summer test females in two test blocks during the introduction of control water to both blocks for 15 min, followed by the introduction of reproductive-male donor water into the least favored block for 15 min, then interchange of the two stimuli for a final 15 min. Eight groups of five females were tested in morning trials (A.M. trials) and eight groups of five in afternoon trials (P.M. trials). Probabilities are based on comparing occupancy rates in the same test block for successive observation periods in eight separate trials [Wilcoxon matched-pairs, signed-rank test (Siegel, 1956)].

the attraction to reproductive male donor water persisted in A.M. trials but not in P.M. trials (Figure 2).

A difference was also evident in females' response to test blocks in the morning compared to the afternoon. There was a significantly greater degree of test block occupancy (both control and experimental test blocks) in morning trials than in afternoon trials in the first stimulus interval [$U = 8$, $N = 8$, $P = 0.005$, Mann–Whitney U (Siegel, 1956)]. Also, response to male donor water was less pronounced in afternoon trials compared to morning trials (Figure 2) and block occupancy did not change significantly after the exchange of experimental and control stimuli.

Summer females were unresponsive to female donor water during morning trials (Figure 2). A significant attraction was evident during afternoon trials, but only at its initial introduction; when experimental and control lines were interchanged, the attraction response disappeared (Figure 3).

In male donor trials, the occurrence and duration of swarming behavior was significantly greater during stimulus intervals (9 of 16 trials; durations per trial, 13, 63, 15, 37, 399, 420, 17, 169, and 22 sec) than during prestimulus trials [one instance, 120 sec; $N = 9$, $P = 0.002$, sign test (Siegel, 1956)] and occurred more frequently in the male-donor blocks (seven trials) than in the control-donor blocks (two trials) [$P = 0.005$, Fisher exact test (Siegel, 1956)]. Swarming frequency declined in the second stimulus interval, occurring in only 2 of 16 trials, both in the male-donor block.

There was also a temporal pattern to swarming behavior. Male donor water induced swarming behavior in morning trials for longer periods than in afternoon trials [$N = 8$, $P = 0.014$, Mann–Whitney U (Siegel, 1956)].

The introduction of male donor water also induced more swarming behavior than did the introduction of female donor water, regardless of the time of the trial [$N = 9$, $P = 0.01$, Wilcoxon matched-pairs, signed-ranks test (Siegel, 1956)]. Within female donor water trials, swarming did occur but did not significantly increase from prestimulus levels after the introduction of female donor water [prestimulus interval—one 10-sec swarming event; first stimulus interval—four events of 15, 16, 6, and 6 sec, respectively, all in experimental donor blocks; $N = 5$, $P = 0.188$, sign test (Siegel, 1956)]. No swarming was seen during the second stimulus interval of female donor water trials.

There was a wide range of gonadal development in field-caught females in the eight collections made over 53 days covering the natural breeding season (Table 1). Test females used in the summer trials also exhibited a wide range of GSIs but reflected elevated values typical of midbreeding season (mean GSI $= 11.2 \pm 3.9$ SD; range, 3.1–20.9; $n = 73$).

Among test groups of summer females that were responsive to male stimuli, there was no correlation between responses of individual females, as measured

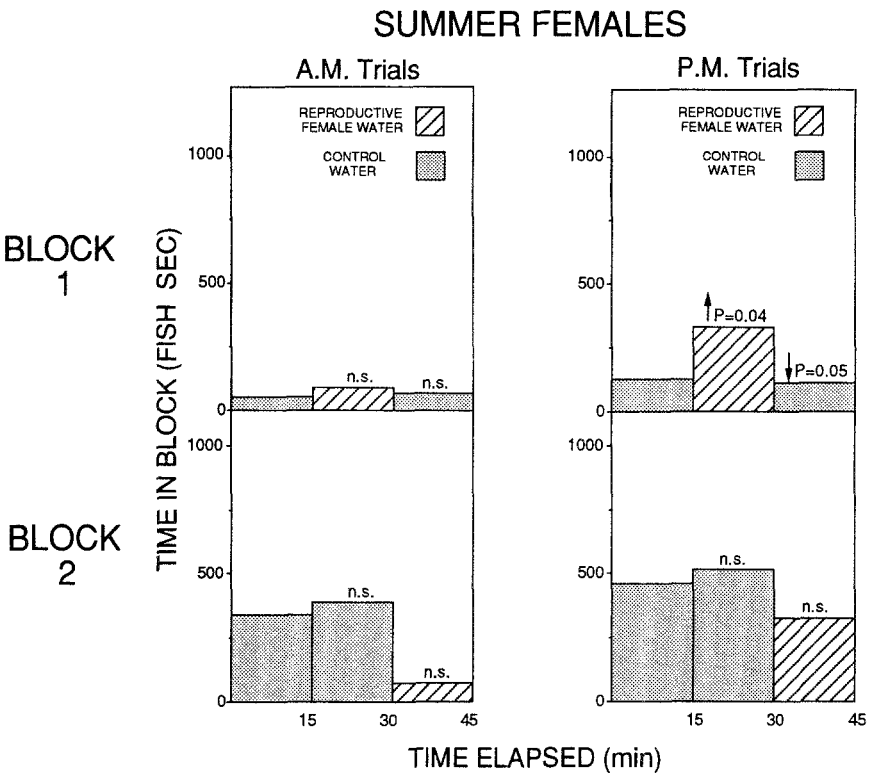

FIG. 3. Median times (fish-seconds) spent by summer test females in two test blocks during the introduction of control water to both blocks for 15 min, followed by the introduction of reproductive-female donor water into the least favored block for 15 min, then interchange of the two stimuli for a final 15 min. Eight groups of five females were tested in morning trials (A.M. trials) and eight groups of five in afternoon trials (P.M. trials). Probabilities are based on comparing occupancy rates in the same test block for successive observation periods in eight separate trials [Wilcoxon matched-pairs, signed-rank test (Siegel, 1956)].

by occupancy time in experimental test blocks, and their GSI value (slope = 0.0149; $r = 0.2980$; $n = 50$).

Winter Trials

In winter trials, females showed an increase in occupancy of the test block receiving reproductive-male donor water. However, these same recipient females made no distinction between blocks receiving donor water from either nonre-

TABLE 1. MEAN GSI VALUES AND STANDARD LENGTHS (SL; MM) OF FIELD-CAUGHT FEMALES OBTAINED IN EIGHT COLLECTIONS[a]

[a] Standard deviations for each mean value are given in parentheses. *n* is sample size.

productive males or females (Figure 4). The attraction to reproductive male donor water was short-lived, however, compared to summer trials since switching of the donor sources in the second stimulus interval did not lead to a change in block occupancy patterns by test females.

Winter females also exhibited swarming behavior. In nine trials using donor water from sexually mature males tested against water from regressed males, no swarming was seen during the prestimulus interval but swarming did occur during the first stimulus interval in four of the nine trials (durations, 111, 37, 240, and 82 sec). In all cases, the swarming occurred in the block receiving developed-male water. In the second stimulus interval, after donor lines were interchanged, swarming was seen in three trials, twice in the developed-male donor tank (69 and 3 sec) and once in the regressed-male donor block (41 sec).

In developed-male versus undeveloped-female donor trials, swarming increased significantly following the first introduction of the two donor waters [prestimulus interval—one 68-sec swarming event; first-stimulus interval—12 swarming events, of 55, 388, 122, and 92 sec in the developed-male test block and 280, 341, 9, 49, and 21 sec in the undeveloped-female block; $X = 0$, $N = 10$, $P = 0.001$, sign test (Siegel, 1956)]. However, no preference was seen for swarming in a block receiving a particular donor water [$P = 0.30$, Fisher exact test (Siegel, 1956)].

The calculation of GSIs for 103 winter test females (gonads of two fish were damaged during histological preparation) confirmed that females were in a gonadally regressed state (mean female GSI of test females in male versus female donor trials = 5.0 ± 1.1, range = 2.6–7.4, $N = 60$; mean female GSI in developed male versus undeveloped male trials = 3.6 ± 2.5, range = 1.7–14.4, $N = 43$).

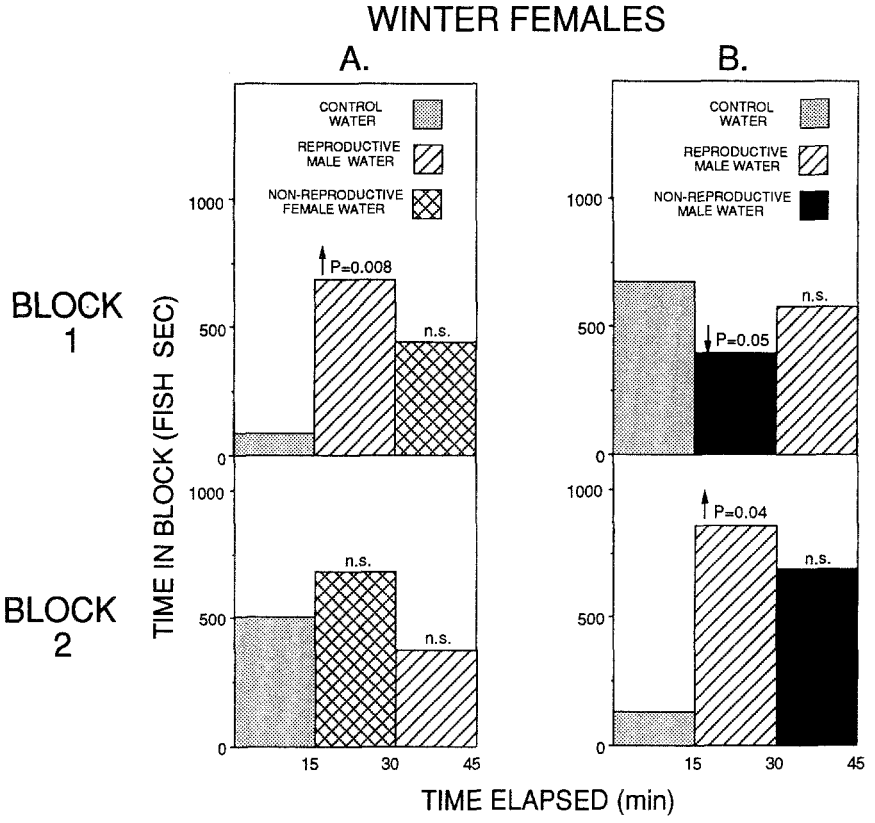

FIG. 4. (A) Median times (fish-seconds) spent by eight groups of five winter test females in two test blocks during the introduction of control water to both blocks for 15 min, followed by the introduction of reproductive-male donor water into the least favored block and nonreproductive female water into the other block for 15 min, then interchange of the two stimuli for a final 15 min. Probabilities are based on comparing occupancy rates in the same test block for successive observation periods in eight separate trials [Wilcoxon matched-pairs, signed-rank test (Siegel, 1956)]. (B) Median times (fish-seconds) spent by eight groups of five winter test females in two test blocks during the introduction of control water to both blocks for 15 min, followed by the introduction of reproductive-male donor water into the least favored block and nonreproductive male water into the other block for 15 min, then interchange of the two stimuli for a final 15 min.

Visual examination of the gonads of undeveloped males and females that were used as donor sources confirmed their sex and their regressed gonadal state.

DISCUSSION

Female *P. promelas* tested during the reproductive season were strongly attracted to water taken from tanks holding male conspecifics with mature gonads and secondary sexual characters during both morning and afternoon trials. Water from female *P. promelas* was also attractive to summer females, but only during afternoon trials, and responses to both male and female donor water in afternoon trials were consistently lower than the response to male water in the morning. Gonadally regressed females tested in the winter were also attracted to water from tanks holding developed males but not to water, introduced at the same time, from tanks holding either undeveloped males or undeveloped females.

The increased occupancy by test females at sites receiving water that had contained reproductive male *P. promelas* suggests that males produce a waterborne chemical substance(s) that is(are) attractive to females. These cues may function to direct females to males that are ready to spawn. The stronger response of summer females in morning trials indicates either diel variation in female responsiveness to male and female cues or diel variation in the release of chemical stimuli by the donor fish. Spawning in *P. promelas* has been reported to occur primarily in the morning. Gale and Buynak (1982) found that captive *P. promelas* spawned 73.8% of their eggs between midnight and 1000. Our findings are consistent with this observation, inasmuch as females were significantly more responsive to male chemical stimuli in the morning than in the afternoon.

Substances that are produced by males and attract females to suitable spawning sites have been described in various fish species, including rainbow trout, *Oncorhynchus mykiss* (Newcomb and Hartman, 1973), *Blennius pavo* (Laumen et al., 1974), zebrafish, *Brachydanio rerio* (Bloom and Perlmutter, 1977), and the black goby, *Gobius jozo* (Colombo et al., 1980). Additional examples are reviewed by Stacey et al. (1986). Colombo et al. (1980) suggest that male *G. jozo* that defend contiguous territories may contribute to a group signal that attracts females at some distance from the spawning site. The active component is apparently a steroid glucuronide. This is consistent with the finding that male African catfish, *Clarias gariepinus*, release steroid glucuronides from the seminal vesicles that attract females and stimulate ovulation and vitellogenesis, acting through the olfactory receptors and the medial olfactory tract (Resink et al., 1989a–c,; 1990; Van Weerd et al., 1990). In *P. promelas*, breeding males often defend closely associated territories and other members of the population tend to form aggregations near the spawning areas (Cole and Smith,

personal observation). Hence, attractive substances produced by male *P. promelas* may identify nest sites of defending males.

Substantial research has been conducted on steroid and prostaglandin pheromones released by female fish (e.g. Sorensen et al., 1988; Sorensen et al., 1990). However, less is known about the sources and chemistry of the water-borne cue(s) released by male fish. The results presented here indicate that *P. promelas* may provide a potential assay system for the analysis of the female-attracting chemical cue(s) produced by males. Potential anatomical sources of such cues include the gonads and the secretory dorsal pad (Smith and Murphy, 1974).

The occurrence of a strong attraction to water-borne reproductive male cues in both summer females in a range of gonadal states and winter females with regressed ovaries indicates that female responsiveness to male stimuli is not tightly linked to ovulation or to a developed ovarian state. This is in contrast to female *G. jozo*, which respond to attractant pheromones from males only between the time of ovulation and egg deposition (Colombo et al., 1980). In a related study we have found that female *P. promelas* can express sexual behavior, including elements of ovipositing behavior (without egg release), while in a gonadally regressed state (Cole and Smith, 1987a).

While gonadally regressed female *P. promelas* were attracted to blocks receiving water exposed to reproductive males, occupancy rates in blocks receiving water exposed to either nonreproductive females or nonreproductive males did not show a similar increase. However, due to the experimental protocol used, undeveloped female and undeveloped male donor water were both introduced into test blocks previously having high occupancy rates. Any minimal attraction response that would have been obvious in low-occupancy blocks may have been obscured. Thus, we cannot rule out the possible occurrence of a weak attraction of winter females to a conspecific chemical(s) from females or nonreproductive males.

Swarming behavior by test females in reproductive condition was exhibited primarily in response to reproductive-male donor water. However, it is unclear whether swarming was triggered solely by chemical cues or if successive females were attracted by the behavior of the first females entering the test block; some combination of chemical and visual cues from introduced donor water, other females, or potential spawning surfaces may release swarming responses. The function of swarming behavior is unknown but is resembles behavior seen in the field and laboratory when several females intrude into a male's territory together, some attempting to spawn and others eating eggs (R.J.F.S., personal observation).

In winter trials, gonadally regressed females also exhibited swarming behavior but they swarmed equally in blocks receiving water from developed males and regressed females. Chemical substances released by males artificially

maintained in a reproductive state may differ in form or potency from those of naturally reproductive males, resulting in more ambiguity in female response. Alternatively, conspecific odors from gonadally regressed females may also stimulate swarming responses in other gonadally regressed females. If so, the virtual absence of swarming in response to female donor water in summer female trials suggests that the production of this stimulus may be absent in summer females, or its stimulus value minimized in females with mature ovaries.

The attraction of female *P. promelas* to water exposed to reproductively developed male conspecifics suggests that male *P. promelas* release a waterborne chemical substance(s) that attracts females to male territories and spawning sites. Such attractants may be particularly important in the turbid habitat often occupied by *P. promelas* and during the predawn hours when spawning often occurs in nature. Our findings, however, leave several phenomena that deserve further study. These include the apparent diel variation in female responsiveness, the source and nature of the attractant male chemical cues, and the role of the endocrine system in the control of the male and female components of the system.

Book Review

Ecological Chemistry and Biochemistry of Plant Terpenoids, Proc. Phytochem. Soc. Europe No. 31. J.B. Harborne, and F.A. Tomas-Barbenan. Oxford, UK: Clarendon Press, 1991. $115.00, 459 pp.

The title of a book should convey the essence of its contents. It is therefore unfortunate that the 31st publication from the Proceedings of the Phytochemical Society of Europe pretends to cover ecological chemistry and biochemistry of plant terpenoids when it gives ecological chemistry a scant one-eighth of the contents: two chapters, to be more precise—one of which comes at the very end, when it would have made a nice introduction, particularly in the absence of an overall survey of plant terpenoids.

The editors, in their introduction, claim that the book is divided "somewhat arbitrarily into four sections: chemistry and chemotaxonomy; biochemistry, biosynthesis and physiology; pharmacology and toxicology; and ecological biochemistry." All these topics are indeed covered, but there is so much overlap that the desirable sections are unfortunately far from evident. The book is divided into 16 chapters, with contributions coming mainly from the United Kingdom and Spain (the venue for the September 1989 meeting on which the proceedings are based). It therefore took 2 years to put all this information together, a rather slow process. Papers, however, do include references which appeared in 1990 (e.g., Perspectives on Plant Competition, edited by T.A. Grace and D. Telman). There is a table of contents, subject index, and index of organisms, the latter being very useful indeed. The illustrations are of excellent quality.

The introduction is in fact an overview of the book contents, and it is difficult to review this publication without repeating what the introduction states. The first four chapters, which, according to the editors, constitute the first section (Chemistry and Taxonomy), discuss the recent chemistry of conifer terpenoids, the terpenoids of marine plants, the chemistry, biogenesis, and chemotaxanomy of the diterpenoids of *Salvia* (of the Labiatae family—a genus quite restricted in its geographic distribution), and environmental control of essential oil production in Mediterranean plants.

Chapters 5 to 8 are devoted to several aspects of the biochemistry and physiology of terpenoids. This section starts with an interesting review of terpenoids production in plant cell cultures, followed by the biosynthesis and distribution of plant iridoids in angiosperms. Chapter 7 deals with various aspects of biosynthesis, catabolism, and regulation of terpenoid phytoalexins, the latter

0098-0331/92/0700-1285$06.50/0 © 1992 Plenum Publishing Corporation

term following the definition of Paxton (1981): low molecular weight, antimicrobial compounds synthetized and accumulated in plant cells after exposure to microorganisms. This chapter contains a useful table of terpenoid phytoalexins produced in nine plant families; the last chapter in the section deals with inhibition of phytosterol biosynthesis and the consequences for plant growth.

Section three is essentially devoted to pharmacology and toxicology. Chapter 9 concentrates on the newer (diterpenoids) and the more interesting findings from a pharmacological point of view, while Chapter 10 is devoted to the chemistry and molluscicidal action of saponins. As expected, the molluscicidal saponins of *Phytolacca dodecandra* berries are discussed, considering the importance of this plant for an eventual natural control of Schistosomiasis.

The chemical ecology announced in the title of the book finally gets its meaning from Chapter 11 (Chemical Ecology of Terpenoid and Other Fragrances of Angiosperm Flowers). Chapter 16 (Recent Advances in the Ecological Chemistry of Plant Terpenoids) would have been a better introduction to this fourth section. Other contributions deal mainly with various aspects of plant–insect relationships where terpenoids play a role: lower terpenoids as natural insect control agents; sequestration of iridoids by insects. A chapter is also devoted to plant terpenoids as allelopathic agents.

Altogether, this book, which covers mostly the literature appearing in the second part of the 1980s, will provide researchers with ample material for further investigations in what remains an exciting area of natural products chemistry and potential promising applications.

(Received October 7, 1991; accepted March 16, 1992)

Abstract—Hydroxy-, dihydroxy-, trihydroxy-, methoxy-, dimethoxy-, hydroxy- + methoxy-, amino-, chloro-, and nitro-substituted benzoic, phenylacetic, phenylpropanoic, and phenylpropenoic (cinnamic) acids were evaluated for activity against the growth of *Phytophthora parasitica* var. *nicotianae*, Races 0 and 1, in a laboratory bioassay. Several substituted coumarins were also tested. In general, for Race 0, the phenylpropenoic acids were more active (on a millimolar basis), than the corresponding benzoic, phenylacetic, or phenylpropionic acids (9 of 14 series). Among the most active acids were *o*-hydroxycinnamic and the chloro- and methoxycinnamic acids. The activities of unsubstituted benzoic and phenylpropionic acids were comparable to the most active compounds tested. Monohydroxyaromatic acids were more active than most dihydroxy acids of the same chain length. Dihydro-3,4-dihydroxycinnamic acid was slightly more active than the corresponding cinnamic acid, while the reverse was true for the mono-*p*-hydroxycinnamic acid versus *p*-hydroxyphenylpropionic acid. Coumarin was more active than its hydroxy, methyl, hydroxymethyl, or methoxy derivatives. In general, Race 1 was even more significantly affected by the aromatic acids. Glycosylated coumarins were inactive in the bioassay, compared to their aglycones.

Key Words—*Phytophthora parasitica* var. *nicotianae*, black shank, aromatic acids, bioassay, growth inhibition.

INTRODUCTION

Phenols inhibit the growth of microorganisms. Several reports have shown that phenolic compounds of tobacco increase in tissues infected by tobacco mosaic virus (Fritig and Hirth, 1981), *Peronospora tabacina* (blue mold) (Cohen and Kuc, 1981), *Pseudomonas solanacearum* (bacterial wilt) (Sequeira, 1969), and *Thielaviopsis basicola* (black root rot) (Gasser et al., 1988). Preliminary studies have shown that the major phenolic compounds of tobacco roots, 3-*O*-caffeoylquinic acid (chlorogenic acid) and the coumarins, scopolin and scopoletin, are also increased in healthy tissue adjacent to tissue infected with the black shank fungus (*P. parasitica* var. *nicotianae;* Snook et al., 1991). Chlorogenic acid inhibited the growth of the fungus in a laboratory bioassay, and the activity resided in the caffeic acid moiety of the molecule. Scopoletin was also shown to inhibit *P. parasitica* var. *nicotianae* growth. The objectives of this research were to further elucidate this structure–activity relationship by testing a number of aromatic acids and coumarins for inhibition of growth of *P. parasitica* var. *nicotianae* (Races 0 and 1).

METHODS AND MATERIALS

All aromatic acids and coumarins (except scopolin, see below) were obtained commercially. Except for 7-hydroxycoumarin (which was sublimed), all were used as received. The laboratory bioassay of compounds for inhibition of growth of *P. parasitica* var. *nicotianae* (PPN) was similar to that described (Csinos et al., 1986). Each concentration of test material and untreated controls was replicated 10 times. Cork borer plugs (5 mm, No. 2 cork borer) of the fungus stock culture, were placed with fungal culture side down on the edge of the test plates. Plates were placed in Ziploc bags and incubated at 27°C for 14 days or until fungal growth had nearly reached the opposite edge of the agar control plates. Radial mycelial growth was measured, and the percentage inhibition of growth was determined relative to the control. Averages of the 10 replications at each compound concentration and the controls were used in the calculations.

Effective dose for 50% growth inhibition (ED_{50}) was calculated for each compound tested by plotting percent inhibition versus concentration (straight lines were drawn between each data point) and determining from the graph the concentration (mM) of the compound that would produce a 50% inhibition of fungal growth. An example is given in Figure 1 and shows a plot of the percentage inhibition of growth versus concentration of monohydroxybenzoic acids. The shape of the concentration–activity curves shown was characteristic for all of the compounds tested. From the curves in Figure 1, ED_{50} can be determined to be 78, 179, and 246 mM for *o*-, *p*-, and *m*-hydroxybenzoic acid respectively.

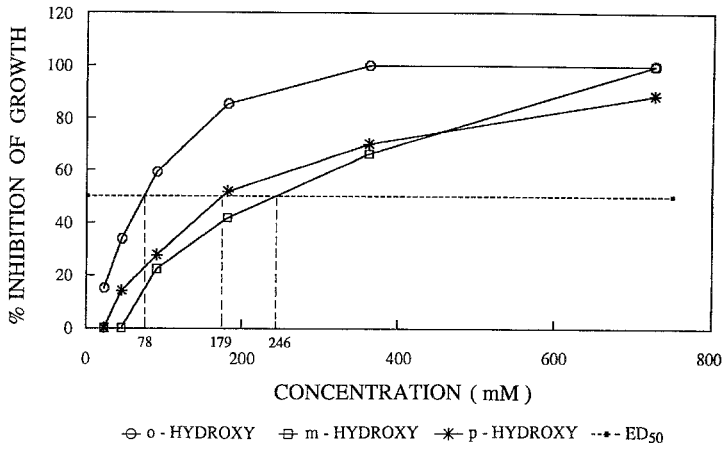

FIG. 1. Percent inhibition of growth of *P. parasitica* by hydroxybenzoic acids.

The lower the ED_{50}, the more active the compound. For several compounds, only the highest concentration of compound gave any inhibition of growth, and ED_{50}s were estimated by a simple proportion from that value to 50% inhibition.

Scopolin was isolated by the following new procedure from freeze-dried, flue-cured tobacco roots. The ground roots (230 g) were extracted with MeOH (3 × 400 ml), and the extract was filtered with the aid of celite. The solvent was reduced to about 200 ml with a rotary evaporator and 30 g of silicic acid (Mallinkrodt 100 mesh, washed with MeOH and heated at 150°C for 16 hr) and 100 ml isooctane added. The solvent was removed and the sample–silicic acid mixture was deposited onto the top of a silicic acid column (100 g packed in a 3 × 33-cm column with methylene chloride, CH_2Cl_2). The column was eluted with the following solvents: 50% ethyl acetate (EtOAc)–CH_2Cl_2, 1 liter; 75% EtOAc–CH_2Cl_2, 1 liter; EtOAc, 1 liter; 20% acetone–EtOAc, 1 liter; 40% acetone–EtOAc, 1 liter; 60% acetone–EtOAc, 1 liter; 80% acetone–EtOAc, 8 liters. The last solvent eluted the scopolin, was evaporated to dryness, and the residue dissolved in 40 ml MeOH–H_2O (1:1). This mixture was divided into two equal portions and each chromatographed on a preparative reverse-phase column (Waters PrepPak 500 material repacked into a Cheminert LC column, 2.54 × 58 cm) and eluted at 2 ml/min with 35% MeOH–H_2O to yield 388 mg of >95% pure scopolin with mp 222–224°C; Lit. mp 226–228°C (Pollock and Stevens, 1965). Apparently, due to tightly bound water, the scopolin isolated from the reverse-phase column would not crystallize. A convenient method of displacing this water of hydration was to dissolve the scopolin in MeOH and add an equal volume of acetonitrile. After this solution was evaporated to dryness, the solid residue could readily be crystallized from MeOH.

RESULTS AND DISCUSSION

Laboratory Bioassays of Aromatic Acids against Race 0 PPN. Our previous work on the activity of chlorogenic acid and its component parts, caffeic acid and quinic acid, against inhibiting the growth of *P. parasitica* var. *nicotianae* (PPN) showed that the activity of chlorogenic acid lies in the caffeoyl moiety of the molecule (Snook et al., 1991). This prompted us to examine other substituted aromatic acids for activity against *P. parasitica* in our laboratory bioassay. The effect of alkyl chain length on activity was investigated by examining the series: benzoic, phenylacetic, phenylpropionic, and phenylpropenoic acids. The results of this study are given in Table 1 and allowed structure—activity relationships to be determined.

For the monohydroxy aromatic acids, the order of activity was: *o-* > *p-* > *m-*, except for the phenylpropenoic acids, where *m*-hydroxy was more active than *p*-hydroxy. In examining the effect of chain length on the activity of the monohydroxy acids, it was found that phenylpropenoic acids were the most active in each series (*o-*, *m-*, or *p-*), while the phenylacetic acids were the least active. *p*-Hydroxyphenylpropenoic acid (*p*-coumaric acid) exists in either the *cis* or *trans* configuration; both isomers were tested. The data (Table 1) showed that the *trans* isomer was slightly more active than the *cis* isomer.

The six isomers of dihydroxybenzoic acid were tested for inhibition of growth of *P. parasitica* and the ED_{50}s are presented in Table 1. The 2,3-dihydroxy isomer was the most active, while the isomers without an *o*-hydroxyl group were inactive. Of the three trihydroxybenzoic acids tested, only the 2,3,4- isomer showed activity. Based on the results with the dihydroxybenzoic acids, expected activity for 2,4,6-trihydroxybenzoic acid, with two *o*-hydroxyls, was not found.

As mentioned before, caffeic acid (3,4-dihydroxyphenylpropenoic acid), is a component part of the tobacco root compound, chlorogenic acid. It exhibited an ED_{50} of 211 mM (Table 1). Of the 26 hydroxy acids tested, 11 were more inhibitory than caffeic in the laboratory bioassay. Dihydrocaffeic acid [β-(3,4-dihydroxyphenyl)propionic acid] was slightly more active than caffeic acid (198 mM vs. 211 mM), which is the opposite result of that found for the three monohydroxy acids. 2,5- and 3,4-Dihydroxyphenylacetic acids were inactive in the bioassay. Thus, the activity of the 3,4-dihydroxy acids was: phenylpropionic $\geq$ phenylpropenoic (cinnamic) >> benzoic >>>> phenylacetic.

Methoxy and dimethoxy aromatic acids were some of the most inhibitory compounds evaluated (Table 1). The methoxybenzoic acids were two to seven times more active than the corresponding hydroxy acids, while the activity of the methoxycinnamic acids ranged from one to four times the activity of their hydroxy counterparts. While the *p*-methoxybenzoic acid was found to be the

[a] Variance around the concentration for ED_{50} is $\pm 10\%$ at the 95% confidence level.
[b] Race 1 in parenthesis.
[c] No activity at maximum concentration tested (DiOH 595 mM, TriOH 588 mM).
[d] Estimated by simple proportion from highest concentration and percent inhibition to 50% inhibition.
[e] Activity plateaued at 43% inhibition at concentrations between 255 and 510 mM.

most active of the three isomers, the *o*- and *m*-methoxycinnamic acids were about equal, but more active than the *p*-isomer.

2,5- and 3,4-Dimethoxyaromatic acids were also evaluated (Table 1). Except for the benzoic acids, the 2,5- isomers were much more active than the 3,4- isomers. 3,4-Dimethoxyphenylacetic acid was the least active, while 2,5-dimethoxycinnamic acid (phenylpropenoic) was the most active.

We also examined the activities of several hydroxymethoxy aromatic acids, including: vanillic (4-OH-3-MeO-benzoic), ferulic (4-OH-3-MeO-cinnamic), isoferulic (3-OH-4-MeO-cinnamic), and sinapic (4-OH-3,5-DiMeO-cinnamic) acids (Table 1). The introduction of the methoxy group at the *m*-position of *p*-hydroxybenzoic acid resulted in an acid (vanillic) that was more active (ED_{50} = 106 mM) than the corresponding hydroxy acid (ED_{50} = 179 mM), but not as active as *p*-methoxybenzoic acid (ED_{50} = 22 mM). The same trend was observed in a comparison of *p*-coumaric, ferulic, and *p*-methoxycinnamic acids. Isoferulic acid (3-OH-4-MeO-cinnamic) was much more active than ferulic acid (4-OH-3-MeO-cinnamic). This acid contains a *m*-hydroxyl and a *p*-methoxyl and was almost equal in activity to the *m*-methoxycinnamic acid and was more active than *m*-coumaric acid. Sinapic acid (4-OH-3,5-DiMeO-cinnamic) was much less active than either *p*-coumaric or *m*-methoxycinnamic acids.

The amino- and nitro-substituted aromatic acids that were tested are listed in Table 1. The order of activity was phenylpropenoic > benzoic >> phenylacetic for amino-substituted acids, while the activity of the nitro-substituted acids was benzoic >> phenylpropenoic > phenylacetic.

The ED_{50}s of hydroxy-, methoxy-, nitro-, and chlorocinnamic acids, for which all three positional isomers were available, are presented graphically in Figure 2. The most active acids for inhibiting the growth of *P. parasitica* were *o*-hydroxy-, *o*- and *m*-methoxy-, and the three chlorocinnamic acids.

In order to fully assess the contribution of substituents, it was necessary to determine the activity of the unsubstituted aromatic acids (Table 1). Benzoic and phenylpropanoic acid were found to have very high activities. Their activities were comparable to the highest activities of substituted acids (Table 1).

The high activity of benzoic acid prompted us to compare its activity to metalaxyl [*N*-(2,6-dimethylphenyl)-*N*-(2-methoxyacetyl)alanine methyl ester], which is the recommended fungicide for control of *P. parasitica* on tobacco. Accordingly, the percent inhibition of growth of *P. parasitica* versus concentration of metalaxyl and benzoic acid was plotted (Figure 3). Analysis of the data indicates that metalaxyl is about 130 times more active than benzoic acid at the 50% inhibition level (0.11 mM vs. 15 mM) but only 14 times more active at the 92–95% level (3.6 mM vs. 51.2 mM).

A summary of the activity of all the aromatic acids (except the hydroxymethoxy acids) tested is presented in Figure 4. For each substituent and chain length, only the most active isomer listed in Table 1 is plotted. In some cases,

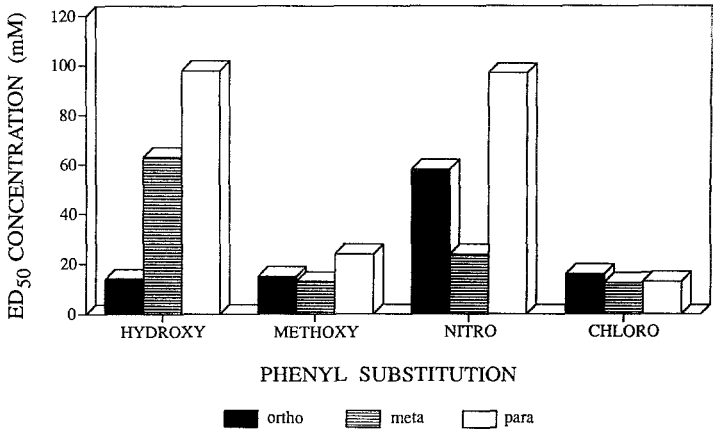

FIG. 2. ED_{50} for growth inhibition of *P. parasitica* by substituted cinnamic acids.

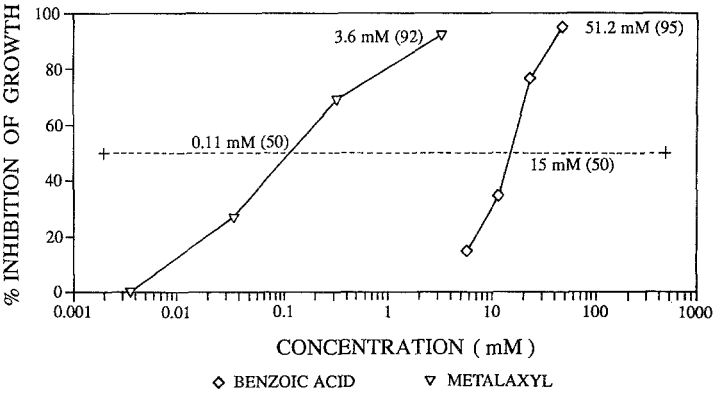

FIG. 3. Percent inhibition of growth of *P. parasitica* by benzoic acid and metalaxyl.

only one or two of many possible isomers were available for testing. Thus, the activities of *o*-hydroxy-, 2,3-dihydroxy-, *p*-methoxy-, and 3,4-dimethoxybenzoic acid are presented (Figure 4) to give a few examples of the most active isomer of a group. Consequently, the most active acids are *o*-hydroxycinnamic, *m*-methoxycinnamic, *m*- + *p*-chlorocinnamic, benzoic, and phenylpropionic acids.

Laboratory Bioassays of Aromatic Acids against Race 1 PPN. Race 1 of *P. parasitica* appears to be more susceptible to inhibition of growth (lower ED_{50}) by the tested aromatic acids than Race 0 (Table 1). Of the 49 aromatic acids tested against both races of *P. parasitica*, 33 (67%) exhibited ED_{50}s towards Race 1 that were lower or equal to those for Race 0. Further, the ED_{50}s of 22

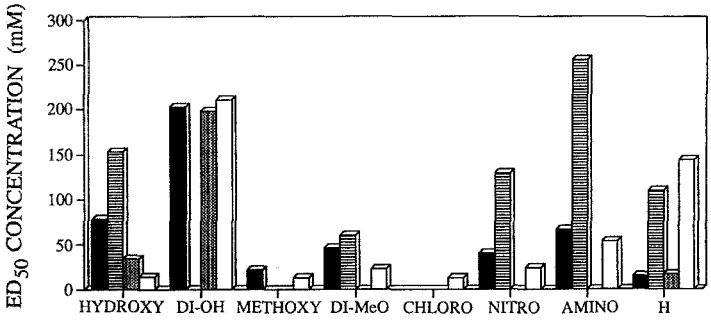

FIG. 4. ED_{50} for growth inhibition of *P. parasitica* by the most active aromatic acids. (Most active substituted phenyl isomer plotted.)

of the 33 compounds were significantly lower for Race 1. Several compounds, however, were considerably less toxic to Race 1 of the fungus. The ED_{50}s for the dimethoxyaromatic acids, benzoic, cinnamic, and *p*-aminobenzoic acids were 3–10 times higher than those for Race 0.

Laboratory Bioassays of Coumarins. Coumarins have been reported as inhibiting the growth of fungus (Batra et al., 1989; Jurd et al., 1970; Singh et al., 1987, 1988). As noted above, several coumarins in tobacco roots, scopoletin (6-methoxy-7-hydroxycoumarin) and scopolin (7-glucosylscopoletin), increase in concentration in root tissue adjacent to *P. parasitica*-infected tissue. Consequently, it was of interest to determine the activity of scopoletin, scopolin, and other substituted coumarins in this laboratory bioassay. The resulting data (Table 2) are given as percent inhibition of growth versus concentration. Due to the low activity of the coumarins, it was not possible to calculate ED_{50}s for most of these compounds. Scopolin, isolated from tobacco roots, was tested for activity along with esculetin (6,7-dihydroxycoumarin) and its glucoside, esculin. The dihydroxycoumarin, (esculetin) was as active as the methoxyhydroxy compound, scopoletin. Thus, the presence of a free hydroxyl group at position 6 is not required for activity. The substitution of a glucose on the hydroxyls of both compounds resulted in the loss of activity. Gasser et al. (1988) reported similar results with the activity of scopolin against *Thielavopsis basicola*. The substitution of methoxyls for hydroxyls in the aromatic acids, but not in coumarins, resulted in enhanced activity (Table 2). 6,7-Dimethoxycoumarin was slightly more active than dihydroxy- or monomethoxycoumarin, while 5,7-dimethoxycoumarin was completely inactive.

Coumarin itself was active in the laboratory bioassay, and an ED_{50} of 430 ppm (295 mM) could be calculated for the compound. 4-Hydroxycoumarin was about twice as active as coumarin (ED_{50} = 236 ppm, 162 mM). 7-Hydroxycoumarin was much less active than the 4-hydroxy isomer. Jurd

et al. (1970) tested 4- and 7-hydroxycoumarin against 15 different fungi and found both compounds inhibited the growth of only *Byssochlamys fulva*. 7-Hydroxycoumarin and 6,7-dihydroxycoumarin have similar activities. However, addition of a methyl group to the 4-position of 7-hydroxycoumarin doubled its activity, while the addition of a methyl to the 4-position of 6,7-dihydroxycoumarin resulted in almost a complete loss of activity.

In comparison to the aromatic acids, the coumarins are much less inhibitory towards the fungus and, thus, would probably only have a minor potential as antifungal candidates. The data for the aromatic acids should be of importance in the design and synthesis of new *P. paracitica* fungicides.

Acknowledgments—The authors would like to thank Wanda Tillery for her fine technical assistance.

HOST MARKING PHEROMONE OF *Rhagoletis cerasi*: FORAGING BEHAVIOR IN RESPONSE TO SYNTHETIC PHEROMONAL ISOMERS

MARTIN ALUJA[1,*] and ERNST F. BOLLER

Swiss Federal Research Station
CH 8820 Wädenswil, Switzerland

(Received November 27, 1991; accepted March 16, 1992)

Abstract—We studied the foraging behavior of *Rhagoletis cerasi* females in trees treated with synthetic cherry fruit fly host marking pheromone (HMP) under seminatural conditions (potted trees enclosed in a screen cage). Results show that synthetic HMP (particularly the 8*RS*-15*R* isomer configuration (racemic mixture)) was highly effective in eliciting behavioral responses similar to those reported in studies using natural HMP. Flies exposed to synthetic pheromone exhibited short tree residence times (i.e., emigrated faster), increased flight frequency rates (measured as number of alightings per/minute), higher irritation indices while on a tree or a fruit, and oviposited fewer eggs per fruit visit than flies exposed to clean trees and fruit (not treated with synthetic HMP). Furthermore, we provide evidence showing that when flies were continuously exposed to an HMP-saturated environment, they exhibited an increased tendency to lay eggs in marked fruit.

Key Words—*Rhagoletis cerasi*, Diptera, Tephritidae, foraging behavior, host marking pheromone.

INTRODUCTION

Work on insect host marking pheromones (HMPs) [also referred to as oviposition deterring pheromones (ODPs)] was recently revolutionized when Hurter et al. (1987) succeeded, after 20 years of work, to chemically characterize and synthesize the HMP of the cherry fruit fly, *Rhagoletis cerasi*. The pheromone

*To whom correspondence should be addressed.

is a complex molecule {*N*[15(β-glucopyranosyl)oxy-8-hydroxypalmitol]-taurine} exhibiting four stereoisomers. This breakthrough opened up the possibility of testing and eventually incorporating synthetic HMPs as a novel element into fruit fly management schemes.

Fruit fly host marking pheromones were first reported by Prokopy (1972) and Cirio (1972), who described a pheromone deterring repeated oviposition in apple maggot (*Rhagoletis pomonella*) and walnut husk flies (*R. completa*), respectively. Shortly thereafter, a similar pheromone was described in the cherry fruit fly (*Rhagoletis cerasi*) (Katsoyannos, 1975). Subsequent work by a number of authors [reviewed by Prokopy (1981), Roitberg and Prokopy (1987) and Averill and Prokopy (1989a)] has revealed that HMPs are quite common among tephritid fruit flies: they have been reported in three of the five economically important genera: *Rhagoletis*, *Anastrepha*, and *Ceratitis* (the two remaining genera being *Dacus* and *Toxotrypana*). In the case of *Dacus*, studies on *D. oleae* have shown that the deterrent substances diverting females from ovipositing on already attacked fruit are contained in the juice that trickles from oviposition wounds (Girolami et al., 1981).

HMPs elicit a number of complex electrophysiological (Bowdan, 1984; Städler and Katsoyannos, 1979; Städler et al., 1987) and behavioral responses: oviposition deterrence (generally resulting in an even egg distribution within trees) (Prokopy, 1972; Averill and Prokopy, 1989b); male arrestment (Prokopy and Bush, 1972; Katsoyannos, 1975); increased emigration from heavily utilized resource sites (Roitberg et al., 1982, 1984); clutch size regulation (Papaj et al., 1990); and regulation of number of clutches oviposited per fruit visit (Papaj et al., 1989). Roitberg and Prokopy (1981, 1983) have further shown that experience is required for HMP recognition and that host deprivation influences responses to HMPs.

Here we describe certain behavioral responses of *R. cerasi* to the synthetic HMP (stereoisomers) identified by Hurter et al. (1987) both under laboratory and seminatural conditions. The isomers selected for testing were those eliciting the highest discrimination in laboratory studies (Boller and Aluja, 1992). Work reported here represents a stage-setting phase for subsequent studies aimed at testing synthetic HMPs in the field as a cherry fruit fly control mechanism (Aluja and Boller, 1992).

METHODS AND MATERIALS

Insects. Fly collection methods are described in Boller et al. (1987). Adults (ca. 60 females and 15 males) were kept in 30 × 30 × 40-cm Plexiglas cages on a diet of sucrose, enzymatic yeast hydrolysate, and water. Cherry tree branches with leaves were placed on both lateral sides of the cage to provide

natural resting sites. These branches were replaced every three days. Once sexual maturity was reached and mating activity commenced, ca. 25 freshly picked and washed cherries, in an optimal ripening stage for *R. cerasi* oviposition, were introduced into the cage to allow females to oviposit. Cherries were replaced twice daily to avoid high HMP concentrations.

Test Compounds. We tested two of the four synthetic stereoisomers of the cherry fruit fly HMP described by Hurter et al. (1987) and Ernst and Wagner (1989). The pheromone is a complex molecule {*N*[15(β-glucopyranosyl)-oxy-8-hydroxypalmitol]-taurine} containing two chiral centers at the C-8 and C-15 positions (thus allowing for the formation of four stereoisomers). Isomer configurations tested were: (1) 8*R*-15*R* (*RR*) and (2) 8*RS*-15*R* (racemic mixture). All isomers were diluted in MeOH and tested at a concentration of 10^{-3} mg/ml. In the case of isomer 8*RS*-15*R* (racemic mixture), a concentration of 10^{-2} mg/ml was also utilized (Table 1).

Research Arena. In the laboratory tests the bioassay arena consisted of a Plexiglas cage (30 × 40 × 40 cm) into which freshly picked cherry branches with leaves were placed on both lateral sides to provide natural resting sites for the test flies. Thirty freshly picked cherries were presented to the flies (12 per cage) on a mobile wooden platform. Of these, 15 cherries served as controls and 15 were treated with different HMP isomers (five fruits per treatment). Each bioassay lasted 60 min. Using a data sheet showing graphically the arrangement of the 30 numbered cherries, an observer recorded the following information: landings on each fruit, oviposition attempts (i.e., boring into fruit) and successful oviposition (i.e., boring followed by ovipositor dragging). The bioassay arena utilized, procedures followed during laboratory tests and type of flies utilized are described in more detail by Boller and Aluja (1992).

TABLE 1. DESCRIPTION OF FIVE DIFFERENT TREATMENTS TESTED DURING STUDY

Treatment	HMP characteristics	HMP concentration (mg/ml)	HMP application protocol
1	No HMP applied (control treatment)		
2	Racemic mixture 8*RS*-15*R*	10^{-3}	Fruit and foliage
3	Isomer 8*R*-15*R*	10^{-3}	Fruit and foliage
4	Racemic mixture 8*RS*-15*R*	10^{-3}	Only fruit
5	Racemic mixture 8*RS*-15*R*	10^{-2}	Fruit and foliage

The greenhouse experiments were conducted using six 3-year-old potted cherry trees whose canopies were ca. 1 m (diam.) × 2.5 m (height). Four trees (placed in corners corresponding to the four cardinal points) were enclosed in a 2.9-m-diam × 2.9-m-tall cylindrical clear Saran-screen cage. The roof of the cage was covered with commercial greenhouse shading material. The cage was built inside a greenhouse where temperature was controlled (experiments were conducted during April–May when ambient temperature is too low for flies to be active). Following a technique used by Aluja et al. (1989), we manipulated the architecture of each tree until an approximately even distribution of foliage throughout the tree was obtained. Distance between different tree canopies in the cage was ca. 0.8 m. We also clipped away ca. 35% of all leaves to allow the researcher to view clearly almost any point within the tree from any location in the cage. The tree canopy was divided into eight sectors, each of which was clearly tagged (numbers 1–8).

Each tree was sprayed with a different HMP solution with the aid of a garden mist sprayer (one separate sprayer was used for each test solution). All leaves (top and bottom parts) and branches were treated until runoff. Spraying was performed outside the cage at five-day intervals. To avoid wind drift contamination while applying the different isomers, trees were covered with a plastic sheet. The control treatment consisted of untreated trees with untreated fruit. Every morning, four trees were selected at random and introduced into the cage for testing. Eight fruit were hung in the tree (one per tree sector). All fruit used was picked in nearby orchards from early-fruiting cherry varieties and kept overnight in a cold room at 8°C.

Foraging Behavior Tests (Greenhouse Experiments). On the test day, a Plexiglas cage holding flies and ca. 25 cherries was transported from the laboratory to the field cage. Fruit in the fly-holding cage was replaced every 2 hr to avoid accumulation of HMP. Once a fly started to oviposit on one of the cherries (inside the Plexiglas cage), the fruit was removed and, after ovipositor dragging, the fly was transferred to a predesignated leaf in the lower half of the canopy of one of the four available test trees. Trees were selected for testing at random.

Once released, a fly was followed continuously for up to 1 hr as it foraged within the test tree. All behaviors (as well as times performing each behavior) exhibited by foraging flies were recorded. If a fly flew to a neighboring tree or to the cage wall before the 1-hr time limit, the test was concluded and another fly released.

Laboratory Tests. To ascertain if continuous exposure to HMP reduced fly sensitivity to HMP-treated trees or fruit (through habituation or sensory adaptation), we saturated several fly-holding cages with a HMP solution (including cherry leaves placed inside cages as resting sites). The HMP solution consisted of the racemic mixture (8*RS*-15*R*) diluted in water with 0.1% Ajoutol. Sexually mature flies were released (ca. 60 females and 15 males) into each cage and

kept there under continuous HMP exposure during 24 hr. After this period, 12 females were tested under the protocol described under "research arena" (also see Boller and Aluja, 1992). The control treatment consisted of flies held in clean cages (no HMP exposure) and tested under the conditions described above.

Data Collection and Analysis. All information was recorded using a Radio Shack TRS 80 (model 102) computer programmed in BASIC to function as an event recorder. Raw data files were later transferred to an IBM portable computer for summarization and statistical analysis. The following dependent variables were examined: mean time spent on tree (minutes), flight frequency (no. alightings per minute), mean time spent on fruit (minutes), mean number of ovipositions per fruit visit, irritation index while on tree, *sensu* Boller et al. (1987) (number of behavioral transitions while on tree; e.g., foraging–resting–foraging–cleaning–resting–foraging), irritation index (number of behavioral transitions) while on a fruit.

We tested for homogeneity of variances using Cochran's test and Bartlett's test (Statgraphics procedure; Statgraphics, 1986). Variables termed mean time spent on tree, flight frequency, and mean number of ovipositions per fruit visit were analyzed by a one-way analysis of variance since they passed the homogeneity of variance test (Statgraphics procedure; Statgraphics, 1986). All remaining variables that exhibited unacceptable inequality in variances were analyzed by a Kruskal-Wallis procedure. Where appropriate, multiple-range analysis by the 95% confidence intervals method was performed. In the case of the HMP saturation experiment, we computed the fruit discrimination index using the formula provided by Boller and Hurter (1985).

Environmental Conditions during Tests. Even though ambient temperature outside the greenhouse was very low (4–8 °C at midday), conditions inside the greenhouse were optimal. Flies were tested under the following mean temperatures: treatment 1, 24.9 $\pm$ 0.4, treatment 2, 26.1 $\pm$ 0.5; treatment 3, 25.4 $\pm$ 0.6; treatment 4, 26.2 $\pm$ 0.3; and treatment 5, 26.8 $\pm$ 0.3.

RESULTS

Effect of HMP on Tree and Fruit Residence Time. Overall, treatment effect on the variable termed residence time on a tree was marginally insignificant ($P = 0.067$; confidence level 95%). Nevertheless, important trends can be detected in Figure 1. For example, flies exposed to untreated trees (treatment 1, Figure 1) exhibited the longest mean tree residence time (30.3 min). This contrasts sharply with results obtained when flies were exposed to trees treated with the racemic mixture at concentrations of 10^{-3} and 10^{-2} mg/ml (treatments 2 and 5, respectively; Figure 1). Under these conditions fly residence time on a tree was cut by almost half. Importantly, flies foraging in a clean tree where only

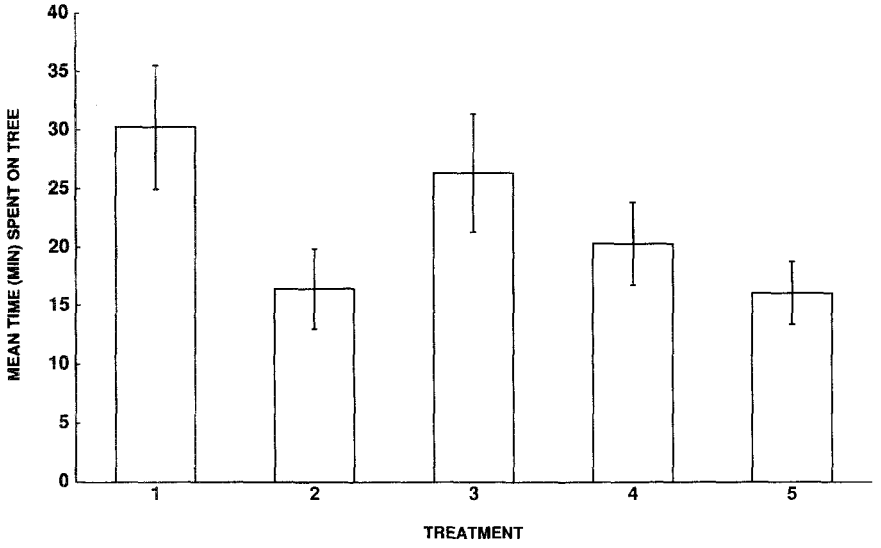

FIG. 1. Tree residence time exhibited by *R. cerasi* females exposed to an untreated cherry tree or a cherry tree sprayed with different HMP solutions at varying concentrations (see Table 1 for treatment description). $N = 20$ in every treatment. Differences between means marginally insignificant (one-way ANOVA, $P = 0.067$).

fruits were treated (treatment 4, Figure 1) spent on average 10 min less time in the tree than flies exposed to an untreated tree with clean fruit (treatment 1, Figure 1).

Flies spent the least time on cherries if fruit but not tree foliage was treated with HMP (treatment 4, Figure 2). The same effect was seen if HMP sprayed on both fruit and foliage was highly concentrated (treatment 5, Figure 2). In contrast, the time flies spent on cherries hung in an untreated tree was four times greater (treatment 1, Figure 2). Flies foraging in trees treated with HMP isomer 8*R*-15*R* and racemic mixture 8*RS*-15*R* at a concentration of 10^{-3} mg/ml, spent almost half as much time on cherries as flies foraging in clean trees (treatments 2 and 3, Figure 2).

Effect of HMP on Flight Frequency (Number of Alightings per minute). Flies alighted most often within the tree when exposed to trees treated with a high concentration of HMP racemic mixture 8*RS*-15*R* (treatment 5, Figure 3) and alighted least often when exposed to untreated trees (treatment 1, Figure 3). Intermediate values were observed with treatments 2, 3, and 4 (Figure 3).

Effect of HMP on Tree and Fruit Irritation Indicies. Irritation index while on a tree was lowest for flies foraging in trees treated with HMP in its 8*R*-15*R* isomer configuration and untreated trees (treatments 3 and 1 respectively; Figure

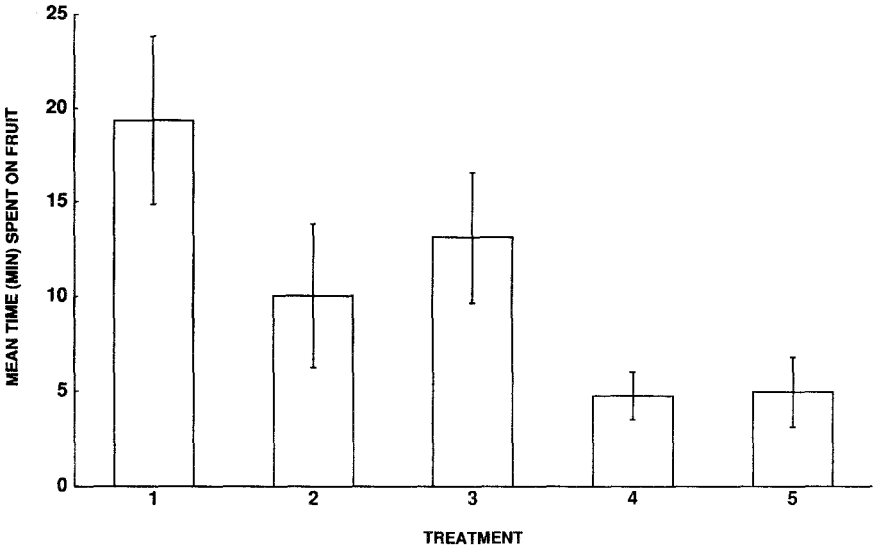

FIG. 2. Fruit residence time exhibited by *R. cerasi* females exposed to an untreated cherry tree or a cherry tree sprayed with different HMP solutions at varying concentrations (see Table 1 for treatment description). $N = 20$ in every treatment. Differences between means marginally significant (Kruskal-Wallis, $P = 0.047$).

4). The highest index was observed in flies treated with HMP in its 8*RS*-15*R* isomer configuration at a concentration of 10^{-2} mg/ml (treatment 5, Figure 4). Intermediate values were observed with treatments 2 and 4 (tree treated with 8*RS*-15*R* at a concentration of 10^{-3} mg/ml and only fruit (not foliage) treated with 8*RS*-15*R* at a concentration of 10^{-3} mg/ml) (Figure 4). Importantly, when only fruit (not foliage) was treated, the irritation index when flies were on fruit was significantly increased when compared to flies foraging in trees where both fruit and foliage were treated with varying HMP solutions (treatment 4, Figure 5).

Effect of HMP on Number of Ovipositions per Fruit Visit. Flies laid the least number of eggs per fruit visit when only fruit (not foliage) was treated with a low concentration (10^{-3} mg/ml) of the 8*RS*-15*R* HMP (treatment 4, Figure 6) or when exposed to trees and fruit treated with a high concentration (10^{-2} mg/ml) of the same HMP isomer mixture (treatment 5, Figure 6). The most eggs per fruit visit were laid when flies were exposed to clean trees and fruit (treatment 1, Figure 6). Intermediate values were obtained when trees and fruit were treated with HMP isomer 8*RS*-15*R* and racemic mixture 8*R*-15*R* at a concentration of 10^{-3} mg/ml (treatments 2 and 3, Figure 6).

Effect of Continuous HMP Exposure on Fly Discrimination Ability. We

found that flies continuously exposed to an HMP-saturated environment exhibited an increased tendency to lay eggs in marked fruit (Table 2).

DISCUSSION

We feel that the experiments reported here are significant for three reasons. First, we showed for the first time that synthetic HMPs are highly effective at eliciting behavioral responses similar to those reported in studies using natural HMPs (e.g., Roitberg et al., 1982). Second, we provide evidence that a racemic mixture of two synthetic stereoisomers of the cherry fruit fly HMP outperforms single isomers in causing a reduction in fruit infestation and in enhancing emigration from a host tree. Third, we document the fact that flies continuously exposed to synthetic HMP exhibited an increased tendency to lay eggs in marked fruit.

Our results indicate clearly that synthetic HMP isomers are highly effective at eliciting behavioral responses similar to those reported in studies using natural host marking pheromones. Roitberg et al. (1982) and Roitberg and Prokopy (1984) reported that the active search time of *Rhagoletis pomonella* females foraging in potted trees (similar to those used in this study) was reduced sig-

HMP-saturated	18.0 (±8.5)

nificantly if, previous to release, females were exposed to HMP-marked fruit or encountered low-quality resources while foraging (i.e., HMP-marked fruit), when compared to flies that, previous to release, had been exposed to unmarked fruit or encountered high-quality resources while foraging (i.e., clean fruit). We observed a similar pattern in our studies (Figure 1, treatments 1 vs. 4).

The fact that the racemic mixture 8*RS*-15*R* proved highly effective at reducing fruit infestation, increasing flight frequency rates, and promoting emigration from host trees is significant because synthesis of this racemic mixture is not only easier to accomplish but also cheaper than the synthesis of individual isomers (Hurter, personal communication). Aluja and Boller (1992) report that the same racemic mixture reduced fruit infestation by approximately 90% under field conditions.

Two findings reported and discussed here could support the development of a cherry fruit fly control scheme using HMPs. First, continuous exposure to synthetic HMPs causes flies to exhibit an increased tendency to lay eggs in marked fruit and in general seems to reduce sensitivity to the HMP (presumably through habituation or sensory adaptation). Should HMPs ever be used as a large-scale management tool, the key to success will be the development of an effective HMP field deployment strategy. Based on our results, we suggest a discontinuous application, treating certain parts of the tree and leaving others untreated. This approach would allow foraging flies to encounter both treated and untreated tree parts without the concomitant increase in sensilla desensitization caused by constant HMP exposure. Second, synthetic HMP caused flies to move at a higher rate and emigrate faster when compared to flies foraging in untreated trees. We thus feel confident that discontinuous HMP deployment (i.e., leaving certain tree parts untreated), in addition to utilizing yellow sticky traps (Remund and Boller, 1975) to capture activated, host-deprived flies during the process of emigration will become an effective cherry fruit fly management strategy in organic cherry orchards (such as originally postulated by Boller, 1981; and Prokopy, 1981).

Acknowledgments—We are grateful to G. Schneider, M.Y. Quezada, U. Remund, M. Hochstrasser, and S. Boller for technical assistance. We thank Dr. E. Roth, ETH, for advice on statistical analysis and C. Candolfi and C. Fragoso for assistance while carrying out statistical analysis. Special thanks are owed to C. Brändli-Henrici for writing a computer program that summarized and partially analyzed field-cage data and to J.J. Chan and M. Candolfi for drawing the figures presented here. We thank J. Hurter and T. Ramp for providing the HMP solutions used during laboratory and field testing and D. Papaj for commenting on an earlier version of the manuscript. We also thank two anonymous reviewers for important comments. This work was supported by Ciba-Geigy, Switzerland.

LABORATORY COLONIZATION HAS NOT REDUCED CONSTITUTIVE OR INDUCED POLYSUBSTRATE MONOOXYGENASE ACTIVITY IN VELVETBEAN CATERPILLARS

(Received January 6, 1992; accepted March 16, 1992)

Abstract—We evaluated whether velvetbean caterpillars (*Anticarsia gemmatalis*) from a laboratory colony had reduced constitutive (basal) and/or induced activities of their polysubstrate monooxygenase (PSMO) detoxification enzyme system as a result of long-term rearing (>100 generations) on artificial diet without introduction of field-collected individuals. Larvae from the laboratory colony and those from a recently collected field strain were fed either a standard artificial diet (control), one containing the inducing allelochemical, flavone, or foliage of *Indigofera hirsuta* (a host plant of this species), and their midgut PSMO activity was assessed by measuring the in vitro rate of aldrin epoxidation. Compared with the field-strain larvae, caterpillars from the laboratory colony had 1.9-fold greater constitutive activity (standard artificial diet) and 2.3-fold greater induced activity (flavone-treated diet). In addition, the magnitude of induction was somewhat greater for the laboratory-colony larvae (induced activity was 2.0-fold greater than constitutive activity) compared with those from the field-strain (1.6-fold). In contrast, no difference in strain activity was found when larvae were fed *I. hirsuta* foliage. The lower PSMO activity of the field-strain larvae when fed artificial diet may have been caused by their reduced feeding and growth performance compared with laboratory-colony larvae, and it may explain their greater sensitivity to allelochemicals incorporated in the artificial diet, as we found previously. The results of this study indicate that long-term rearing of the *A. gemmatalis* laboratory colony on artificial diet, without the introduction of field individuals, apparently has not selected for low constitutive activity or decreased inducibility of PSMO, and thus these larvae provide a suitable model for studying xenobiotic detoxication. In addition, they suggest that using an arti-

ficial diet to evaluate resistance to pesticides or other xenobiotics in field-collected insects, as is frequently done, may underestimate the level of resistance if the diet, through various causes, reduces the activity of detoxification enzymes contributing to the resistance.

Key Words—Allelochemical, *Anticarsia gemmatalis*, detoxification, field strain, flavone, *Indigofera hirsuta*, induction, laboratory colony, Noctuidae, Lepidoptera, polysubstrate monooxygenase.

INTRODUCTION

Polysubstrate monooxygenases (PSMOs) (also known as mixed-function oxidases or MFOs) are considered the most important detoxification enzyme system for the metabolism of pesticides and other lipophilic xenobiotic compounds into more easily excretable polar products (Brattsten, 1979; Hodgson, 1985). Insects feeding on plants or artificial diets that contain particular xenobiotics frequently have increased levels of PSMO and other detoxification enzyme activity compared with the constitutive (basal) activity of larvae consuming a control diet (Yu, 1986; but not always, e.g., Sheppard and Friedman, 1989). There are many studies demonstrating that induced enzyme activity can increase an insect's tolerance to several synthetic pesticides (Brattsten, 1988a; Soderlund and Bloomquist, 1990). In addition, induction by allelochemicals can increase the rate of metabolism of such compounds measured in vitro (Yu, 1987; Wadleigh and Yu, 1988; Cohen et al., 1989; Nitao, 1989; Harwood et al., 1990), but whether an insect's tolerance to an ingested allelochemical is increased following induction of detoxification enzymes by the same compound has been seldom studied (Kennedy, 1984; Lindroth, 1991; Slansky, unpublished data; Wheeler et al., unpublished data).

Clearly, additional research is essential if we are to understand the role of detoxification enzymes in the ability of plant-feeding insects to cope with allelochemicals (see discussion in Lindroth, 1991). Insects from laboratory colonies provide convenient subjects for such studies, but they may not be representative of insects in the field. Substantial changes can occur in the amount of genetic variation and biology of field-collected insects after they have been reared in laboratory colonies for various durations (Chambers, 1977; Berlocher and Friedman, 1981; Mason et al., 1987; Pashley et al., 1987; Guthrie and Jarvis, 1988; Henneberry and Clayton, 1990). Because of this, Huettel (1976) emphasized the need to monitor the quality of laboratory-reared insects, including their flight capacity, ability to locate host plants and mates, mating competitiveness, vision, and other traits.

Huettel (1976) described larval feeding and development as additional measurable traits, but he did not mention detoxification enzyme activity. It is likely that such activity will be reduced in individuals from laboratory colonies

compared with those from field populations, based on the following line of reasoning. If, as suggested by certain authors (Krieger et al., 1971; Whittaker and Feeny, 1971; Brattsten, 1979, 1988a,b), PSMOs are metabolically expensive to produce and maintain (but see Neal, 1987; Appel and Martin, 1992), or if higher levels of detoxification enzyme activity otherwise have deleterious pleiotropic effects, then continuous rearing of insect colonies for many generations on artificial diets (presumably with relatively low, more-or-less constant levels of allelochemicals) may select for insects with lower detoxification enzyme load and thus with increased sensitivity to xenobiotics. Although we are unaware of any studies examining intergeneration variation in detoxification enzyme activity for insects from laboratory colonies, such changes have been documented for pesticide-resistant insects. In the absence of a pesticide challenge, resistant individuals often have reduced fitness relative to susceptible ones (Roush and McKenzie, 1987; Campanhola et al., 1991), and the level of resistance can decline in a few generations (e.g., Brown et al., 1978; Leonard et al., 1988).

In contrast to laboratory colonies, insects and other plant-feeding arthropods in field populations may be selected for increased levels of detoxification enzymes because of their exposure to various allelochemicals in different host plants and to changes in the allelochemical content of any one host plant, such as associated with leaf maturation and with induction of the compound(s) caused by feeding damage (Karban and Myers, 1989). For example, when Gould et al. (1982) selected a strain of spider mite (*Tetranychus urticae* Koch) to survive on a previously toxic plant species, the mites became more resistant to certain pesticides, which suggests that their detoxification enzyme levels had been increased relative to the unselected strain (see Mullin and Croft, 1983). Furthermore, increased constitutive-level detoxification enzyme activity occurs often in field populations exposed frequently to synthetic pesticides (Brattsten, 1988a; Soderlund and Bloomquist, 1990), although the magnitude of induction of insects from resistant strains is not consistently greater, and indeed is often less, than that of individuals from susceptible strains (Yu and Terriere, 1973; Yu, 1984).

As part of an investigation on the effects of ingested allelochemicals on insects, we are studying caterpillars of several noctuid moths reared in laboratory colonies, including the velvetbean caterpillar, *Anticarsia gemmatalis* Hübner. To assess the appropriateness of investigating allelochemical detoxification by *A. gemmatalis* larvae from a laboratory colony maintained on artificial diet for over 100 generations without infusion with field-collected individuals, we compared their PSMO activity with that of larvae from a recently collected field strain. Constitutive PSMO activity was measured for larvae fed the standard artificial diet used to rear the laboratory colony. In addition, induced PSMO activity was assessed for larvae fed the artificial diet to which was added flavone, an allelochemical known to induce several detoxification enzyme systems, including PSMO (Yu, 1984; Yu and Hsu, 1985; Christian and Yu, 1986). To

further investigate dietary influences on PSMO activity, an additional treatment consisted of larvae fed foliage of hairy indigo, *Indigofera hirsuta* L. (Leguminosae), a host plant of this species (Buschman et al., 1977) that caused a low level of PSMO induction in larvae from the same laboratory colony used in the present study (Christian and Yu, 1986).

METHODS AND MATERIALS

Collection and Rearing of Insects. Field-strain larvae (instars 3–6) were collected in September 1990 from soybean [*Glycine max* (L.) Merrill, var. Jupiter] in Gainesville, Florida. Larvae were brought back to the laboratory and fed fresh soybean leaves until pupation. Prior to feeding, the leaves were surface sterilized by washing in a dilute solution of sodium hypochlorite (1% v/v) and blotted dry. To maintain leaf moisture, petioles were inserted into water-filled vials and replaced every one to two days. Adults were fed a 10% honey–water solution on cotton and maintained (about 20/container) in 3.8-liter (1-gallon) cardboard containers topped with paper toweling and lined with white paper for oviposition substrate. Eggs from these adults provided the field-strain larvae used in the enzyme assays. The laboratory strain was acquired as eggs from the ARS-USDA Insect Attractants, Behavior and Basic Biology Research Laboratory in Gainesville, Florida, and reared en masse on an artificial diet following Greene et al. (1976), but lacking formalin and tetracycline. This laboratory colony (established from insects collected in Gainesville, Florida) had been reared continuously for more than 100 generations (about 10 years) without infusion with field-collected individuals. All rearing occurred at 27 ± 1°C, 50 ± 10% relative humidity, and 14:10 hr light–dark photoperiod.

Larvae used in the enzyme assays were fed *I. hirsuta* foliage selected from the upper half of field plants in the pod-filling stage (field strain) or standard artificial diet (laboratory colony) from the neonate stage until day 1 of the sixth instar. Individual larvae were then transferred to inverted 30-ml plastic cups with tightly fitting plastic caps and fed one of three foods for two days prior to dissection and enzyme analysis: (1) artificial diet alone (control); (2) artificial diet with flavone (Sigma Chemical Co., St. Louis, Missouri); and (3) *I. hirsuta* leaves. We used 0.08% fm (fresh mass) flavone because studies conducted with another noctuid species, the fall armyworm, *Spodoptera frugiperda* (J.E. Smith), indicated that at this concentration, flavone induced maximum PSMO activity with no increase in mortality of the latter instars and only a slight (ca. 12%) reduction in larval dry mass gain (unpublished data). Flavone was dissolved in a minimum of acetone, mixed with alphacel (1% fm), rotoevaporated to dryness (about 60°C), and mixed with the artificial diet as it cooled following cooking.

Aldrin Epoxidase Analysis. Polysubstrate monooxygenase activity was

determined by measuring the rate of epoxidation of aldrin to produce dieldrin using NADPH as a cofactor. Methods followed Yu (1982) and Christian and Yu (1986) for measurement of aldrin epoxidase activity from midgut crude homogenates. Ten to 15 larval midguts were dissected from 2-day-old sixth-instar larvae and washed in 1.15% KCl (1–4°C). Midguts were homogenized in 20 ml 0.1 M sodium phosphate buffer (pH 7.5) for 30 sec and filtered through cheesecloth. Homogenates (0.5–1.0 mg protein/ml) were incubated in duplicate for 15 min at 30°C, and the reaction was stopped by the addition of 10 ml of hexane. Samples were analyzed by gas chromatography on a 122-cm × 2-mm-ID glass column packed with 3% SE 30 on 100/120 Gas Chrom Q. Activity was expressed as picomoles of dieldrin per minute per milligram of protein.

Statistical Analysis. A factorial design was used for the enzyme activity experiment (three to five replicates per treatment combination) with strains (field and laboratory) and food (control diet, flavone-treated diet, and *I. hirsuta* foliage) as the main effects. Activity data were analyzed with PC/SAS (SAS Institute, 1987) by two-way analysis of variance (ANOVA; PROC GLM) with interaction. When the interaction was significant ($P < 0.05$), each strain was analyzed independently by a one-way ANOVA (Montgomery, 1984). When more than two means were compared, Tukey's HSD method was used.

RESULTS

Aldrin epoxidase activity was influenced significantly by both food and strain; the interaction of these two factors was also significant (Table 1). Larvae from the laboratory colony fed the control artificial diet and those fed the flavone-

TABLE 1. TWO- AND ONE-WAY ANALYSIS OF VARIANCE OF ALDRIN EPOXIDASE ACTIVITY OF FIELD AND LABORATORY STRAINS OF *A. gemmatalis* LARVAE FED CONTROL OR FLAVONE-TREATED ARTIFICIAL DIETS, OR *I. hirsuta* FOLIAGE

treated diet had significantly greater activity (1.9- and 2.3-fold, respectively) than the field-strain larvae (Figure 1). However, enzyme activity of the larvae fed *I. hirsuta* leaves did not differ significantly between strains.

Within-strain comparisons indicated that activity was significantly greater for both the laboratory- and field-strain larvae fed the flavone diet compared with those fed the artificial diet alone or *I. hirsuta* foliage (Table 1 and Figure 1). Enzyme activities for larvae of either strain fed the latter two diets were comparable. The magnitude of induction (i.e., increase in PSMO activity for larvae fed the flavone diet compared with those fed the control diet) was somewhat greater for the laboratory strain (2.0-fold) compared with the field strain (1.6-fold).

DISCUSSION

Our results indicate that the field and laboratory strains differed in their PSMO activity when fed the artificial diet. Larvae from the laboratory colony had both higher constitutive (standard artificial diet) and induced (flavone-containing diet) activity and a somewhat greater magnitude of induction. Reduced PSMO (and possibly other detoxification enzyme) activity of the field-strain

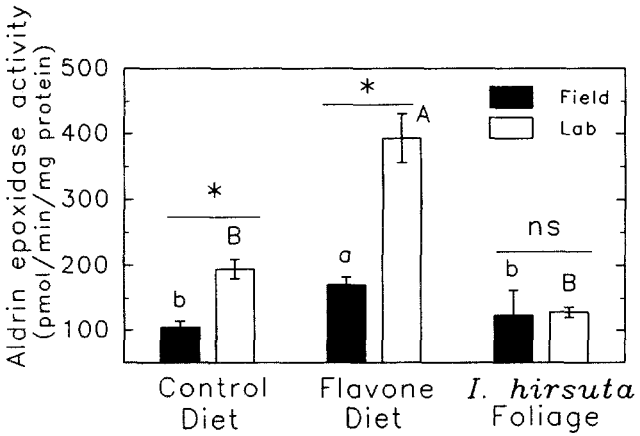

FIG. 1. Aldrin epoxidase activity (mean ± SE) of *A. gemmatalis* larvae from field and laboratory strains. Sixth instars were fed the control artificial diet alone and with flavone (0.08% fm), or *I. hirsuta* foliage for two days prior to enzyme analysis. An asterisk above a pair of bars (or ns = not significant) indicates a significant difference between strains within diets according to a one-way ANOVA. Different lowercase letters above solid bars and uppercase letters above open bars indicate significant differences (Tukey's HSD, $P \leq 0.05$) among foods for field and laboratory strains, respectively.

larvae fed the artificial diet may explain their increased mortality compared with larvae from the laboratory colony when caffeine or coumestrol were added to the diet, although little is known about the detoxification of these two allelochemicals by insects (see Slansky and Wheeler, 1992). In contrast to the differences found when the artificial diet was the food source, enzyme activity was similar between the strains when larvae were fed foliage of *I. hirsuta*.

Aldrin epoxidase activity for the *A. gemmatalis* sixth instars (2-days-old) from the laboratory colony fed artificial diet in our study was similar to that found previously using larvae of the same age from the same colony (Christian and Yu, 1986). Additionally, the induction occurring in the present study in the laboratory strain when fed diet containing flavone (0.08% fm) was similar in magnitude (2.0-fold) to that reported previously (1.8-fold; Christian and Yu, 1986), although the flavone concentration used in that study was slightly higher (0.1% fm). It is likely that PSMO activity increases with the ingested dose of an inducing substance (e.g., Brattsten and Wilkinson, 1973), but that it may already have peaked in *A. gemmatalis* larvae fed the 0.08% fm flavone diet, as found for caterpillars of *S. frugiperda* (unpublished data). These similarities between the results of our study and those of Christian and Yu (1986) indicate that, at least during the past five years (>60 generations), constitutive and flavone-induced PSMO activities of the laboratory colony larvae have not declined. The midgut aldrin epoxidase activities of *A. gemmatalis* found in our study also are comparable to those reported for many other foliage-feeding lepidopteran larvae (Krieger et al., 1971; Rose, 1985).

PSMO activity of the laboratory-colony larvae fed *I. hirsuta* foliage in our study was not significantly different from that of larvae fed the control artificial diet, whereas Christian and Yu (1986) found slightly but significantly higher activity in their *I. hirsuta* foliage-fed larvae (1.3-fold greater than the control). Variation in *I. hirsuta* leaf quality during leaf and plant maturation and under different growing conditions [e.g., the foliage we used was field-collected, whereas Christian and Yu (1986) used greenhouse-grown plants] may account for this difference between the two studies. At least one allelochemical (a flavonoid glycoside) has been reported from *I. hirsuta* (Harborne and Williams, 1988).

Other than in the context of pesticide resistance, there appear to be few studies of insects from laboratory colonies that have examined intergeneration changes in detoxification enzyme activity or sensitivity to xenobiotics that could reflect such activity. In one study, Salloum and Isman (1988) found that larvae of an F_1 generation of field-collected variegated cutworms, *Peridroma saucia* (Hübner), gained more weight when fed an artificial diet than larvae from a laboratory colony reared for over 12 generations, but larvae from both strains had their weight gain reduced about 75% by addition of an ethanolic extract of *Artemisia* to the artificial diet. Larvae of the European corn borer (*Ostrinia*

nubilalis Hübner) from a 6-year-old laboratory colony showed reductions in feeding and survival similar to those from a 1-year-old colony when both were fed resistant corn genotypes, compared with larvae fed susceptible genotypes (Manuwoto and Scriber, 1985). These results suggest that sensitivity to allelochemicals did not increase with long-term laboratory rearing.

There are at least two possible causes for our finding of lower PSMO activity of the field-strain larvae compared with the laboratory colony larvae when fed the artificial diet with or without added flavone. One is that larvae from the two sources differed genetically in their detoxification enzyme capacity (e.g., Scriber et al., 1989; Roush and Daly, 1990). However, our data do not appear to support this hypothesis, because under this scenario, we would predict that the field strain likely would have at least higher constitutive activity, as described in the Introduction. The lack of a significant difference between the strains when fed foliage of *I. hirsuta* also suggests there are no substantial interstrain genetic differences in constitutive detoxification capacity.

A second cause of the lowered enzyme activity of the field-strain larvae when fed the artificial diet may be a decrease in their ingested dose of any inducing allelochemicals occurring in the plant material ingredients of the control diet (i.e., soy protein, pinto beans and wheat germ) (Greene et al., 1976) and of the added flavone. We previously found that the mean biomass-relative consumption rate (RCR) of the field-strain *A. gemmatalis* larvae fed artificial diet was reduced over 30% compared with that of the laboratory-colony larvae (Slansky and Wheeler, 1992). Because the field-strain larvae used in the present study were from the same F_1 generation as those used by Slansky and Wheeler (1992), their RCR when fed the artificial diet, with or without flavone, probably also was lower than that of larvae from the laboratory colony. Dose-dependent induction of PSMO activity by ingested flavone has been demonstrated in *S. frugiperda* (unpublished data) and for other allelochemicals in other lepidopteran larvae (e.g., Brattsten and Wilkinson, 1973; Yu, 1984). The similarity in PSMO activity between the laboratory- and field-strain larvae fed *I. hirsuta* foliage may be explained by their similar RCR when fed this food plant (Slansky and Wheeler, 1992), because larvae of each strain would have ingested allelochemicals and nutrients at comparable rates.

An inadequate availability of nutrients for the diet-fed field-strain caterpillars resulting from their reduced consumption rate, as reflected in their decreased growth rate compared with the laboratory-colony larvae (Slansky and Wheeler, 1992), also may have contributed to their lower PSMO activity. The level of PSMO and other detoxification enzymes in insects can be reduced by nutrient deficiencies (Patil et al., 1990) and other apparent stresses (e.g., parasitism; Fix and Plapp, 1987), as in mammals (Boyd and Campbell, 1983), although activity is not always lowered on the reduced-quality diets (Lindroth et al., 1990, 1991). Switching the field-strain larvae from one diet (foliage of *I. hirsuta*) to another

(artificial diet) during the first day of the sixth instar may have contributed to their reduced performance (e.g., Scriber, 1979, 1981). However, the laboratory-colony larvae switched from artificial diet to *I. hirsuta* foliage showed no significant difference in PSMO activity compared with the colony larvae fed artificial diet continuously, suggesting that a dietary switch does not necessarily result in reduced PSMO activity.

Obviously, more research is required to determine the impact of nutritional influences on detoxification enzyme activity, but whatever the cause, the reduced PSMO activity of the field-strain larvae fed artificial diet suggests a need for caution when field populations of insects are evaluated for pesticide resistance. Frequently, individuals from the field are fed artificial diet in the laboratory and the LD_{50}s for pesticides are determined and/or their detoxification enzyme activity is measured relative to susceptible individuals from laboratory colonies. If feeding larvae the artificial diet results in reduced levels of detoxification enzymes that contribute to the resistance, then the degree of resistance may be underestimated.

The metabolic cost of detoxification enzyme load in insects has been hypothesized to be significant (Whittaker and Feeny, 1971; Brattsten, 1979). Reduced fitness of pesticide-resistant individuals (Roush and McKenzie, 1987; Campanhola et al., 1991), and a decline in the level of resistance in a few generations (e.g., Brown et al., 1978; Leonard et al., 1988) in the absence of a pesticide challenge, support the hypothesis that high detoxification enzyme loads have biologically significant metabolic costs or exert deleterious pleiotropic effects. Recent empirical studies, however, have failed to detect increased metabolic costs associated with a high level of PSMO induction (Neal, 1987) or with presumed increases in allelochemical detoxification (Appel and Martin, 1992). Moreover, fitness of pesticide-resistant insects is not always reduced relative to susceptible individuals in the absence of pesticides (Longstaff, 1991).

Our results suggest that these enzymes, at least at constitutive levels, are not metabolically expensive. If they were, it is likely that individuals with low enzyme levels would dominate the laboratory colony, which has been reared over many generations without infusion of wild-caught individuals on a more-or-less chemically constant artificial diet, probably with low levels of allelochemicals. Alternatively, metabolism of endogenous compounds (Hodgson, 1985) and exposure to allelochemicals in the artificial diet (e.g., isoflavones in the soybean flour; Liener, 1980) may select for maintaining a certain constitutive level of detoxification enzymes. Further, selection would not necessarily favor a reduced ability to induce these enzymes, unless there were negative pleiotropic effects, because inducibility likely conserves resources and limits metabolic costs until a higher level of the enzymes are needed for xenobiotic metabolism (Brattsten, 1988a). Whatever their cost, PSMO enzymes have not been reduced to an unusually low constitutive level in our laboratory-colony *A. gemmatalis* larvae,

and they can be induced to high levels of activity (present study and Christian and Yu, 1986). Thus, the laboratory-strain larvae provide a suitable model system for studying xenobiotic metabolism and detoxification enzyme induction, although the results may not be directly comparable to field-strain insects.

INTRA- AND INTERSPECIFIC SEX PHEROMONE RESPONSES OF SCREWWORM AND SECONDARY SCREWWORM FLIES

L. HAMMACK[1]

Biosciences Research Laboratory
Agricultural Research Service, US Department of Agriculture
Fargo, North Dakota 58105

(Received January 24, 1992; accepted March 19, 1992)

Abstract—A laboratory behavioral assay examined intra- and interspecific responses to sex pheromone by screwworms, *Cochliomyia hominivorax*, and secondary screwworms, *C. macellaria*, in relation to the duration of colonization of *C. hominivorax* test males. Females of *C. macellaria*, like those of *C. hominivorax*, were found to produce a pheromone that stimulates male copulatory attempts on contact. Newly colonized (<22 generations) *C. hominivorax* males did not respond to *C. macellaria* pheromone, indicating that pheromone contributes to reproductive isolation between these two closely related species. Although long-colonized (>200 generations) *C. hominivorax* males did respond to *C. macellaria* females or their extract, this behavior was infrequent and significantly less common than intraspecific responses. Depriving *C. macellaria* adults of dietary protein did not affect the potency of female extracts, but did reduce male responsiveness to pheromone. These results provided little evidence that colonization reduces the ability of *C. hominivorax* males to differentiate between *C. hominivorax* and *C. macellaria* females using sex pheromones.

Key Words—Screwworm, *Cochliomyia hominivorax*, *Cochliomyia macellaria*, Calliphoridae, Diptera, sex pheromone, laboratory adaptation, species recognition.

INTRODUCTION

Sex pheromones in many Diptera act at close range or on contact, where they function in sex and species recognition (Haynes and Birch, 1985; Blomquist et al., 1987). Females of the screwworm, *Cochliomyia hominivorax* (Coquerel), also known as the primary screwworm because of its role as a primary agent of wound myiasis, likewise produce a pheromone that stimulates male copulatory attempts on contact (Mackley and Broce, 1981; Hammack, 1986). Sexually active male screwworms (Krafsur, 1978; Guillot et al., 1978) and other Diptera with similarly reduced mating flights (Downes, 1969) occupy waiting stations or territories, from which they take flight in pursuit of a variety of suitably sized moving targets. Upon contact, mating attempts ensue when the targets are female screwworm flies, otherwise mating flights are aborted and males return to their waiting stations. This behavior suggests that the screwworm sex pheromone functions on contact and is important for species discrimination.

Changes in screwworm mating behavior and sex pheromone communication occur during colonization. Male responsiveness to pheromone increases and potency of female extracts drops with time in colony (Hammack, 1987, 1991); these factors apparently combine to produce the asymmetric mating patterns that typify crosses between old and new screwworm strains. Mating is asymmetric in that copulatory attempts occur more readily between old-strain males and new-strain females than in the reciprocal direction (Alley and Hightower, 1966; Spates and Hightower, 1967; Hammack, 1987; Mangan, 1988).

Changes in sex pheromone communication with colonization are relevant to screwworm eradication programs in Central America and North Africa that are based on the sterile insect technique (SIT) (Krafsur et al., 1987; Beesley, 1991). Population suppression via SIT requires that sterile released males mate with wild females and thereby render their eggs infertile (Knipling, 1955). Even long-colonized screwworm males would be expected to vigorously attempt copulation with a wild conspecific female, but their ability to discriminate species has not been examined.

The closest relative of the screwworm (SW) is the secondary screwworm (SS), *Cochliomyia macellaria* (F.). Morphological differences are subtle, at least in the adult female, and the two were not recognized as separate species in this country until 1933 (Cushing and Patton, 1933). Although their larval habitats are distinct in that SW feeds on living tissue of homeotherms whereas SS breeds in carrion or necrotic flesh (Laake et al., 1936), the adults occur together. Indeed, SS greatly outnumber SW at baits used to monitor SW adults (Lindquist, 1938; Mackley, 1986).

This study compares the ability of SW males differing in duration of colonization to discriminate SW and SS females using sex pheromone cues. In doing so, it establishes the existence of a sex pheromone in SS females and

examines the effect of protein in the adult diet on SS pheromone production and reception.

METHODS AND MATERIALS

SS were collected in the state of Chiapas, Mexico, and tested after about 40–60 generations in the laboratory. Two SW strains were used. The 009 SW strain was collected in Texas in 1974–1975 and colonized for more than 200 generations. The OW-87 SW strain was collected in Belize in 1986 and tested within 21 generations. SS larvae were reared on ground beef that was aged at room temperature for several days before use. SW were reared on a beef-based larval diet (Melvin and Bushland, 1940) that was treated with formaldehyde and changed twice daily to retard putrefaction. Adults of both species were separated by sex within 24 hr of adult emergence to ensure virginity. They were held at 25± 1°C in a 12:12 hr light–dark photoperiod and provided corn syrup and separate water ad libitum. In addition, SS adults in protein-fed treatments had continuous access from emergence until 5 days of age to fresh beef liver changed daily. Females of both species were tested four to six days after adult emergence. Males were 1–2 weeks old.

Sex pheromone was extracted with *n*-hexane from lots of 100 females, unless stated otherwise. Extract, concentrated to 1.0 or 5.0 female equivalents (FE) in 5 μl hexane, was applied to hexane-washed males that served as decoy flies in bioassays. Controls were treated with 5 μl of hexane instead of extract. Whole females killed by freezing, and controls for whole dead females (previously frozen females washed in hexane and additionally treated with 5 μl hexane) were also used as decoys in some tests. Each decoy was mounted on a cork (No. 6) that was used to stopper glass test tubes containing individual test males. Inversion of the tubes forced the test males into contact with the decoys. Bioassays determined whether or not the test males attempted copulation with decoys during 1 min of forced contact. Decoys were tested with a series of 10 males and then discarded. Males were tested only once. More detailed descriptions of the extraction and assay techniques have been reported previously (Hammack, 1987).

Intraspecific and reciprocal interspecific responses to pheromone were initially measured with dead SW and SS female decoys tested with males of each species. A second test substituted 1.0 FE of extract on a washed male decoy for each dead female. A third also examined intraspecific and reciprocal interspecific responses, but decoys treated with SS extract received 5.0 FE, whereas those treated with SW extract again received 1.0 FE. These tests were first done with the newer OW-87 SW strain. They were then repeated with OW-87 females but test males of the longer-colonized 009 strain. The hexane-washed male

decoys to which extract was applied were in all cases the same species and strain as the responding males.

Fifty SS females that had been fed protein and 50 not fed protein (unfed) were extracted six days after emergence. Each extract was applied at 1.0 FE to separate washed decoys (unfed SS males) and assayed with protein-fed and unfed SS test males. The response to 1.0 FE of SS extract was also compared with that to control, using only protein-fed SS flies.

Statistical analysis was limited to treatments assayed simultaneously with males matched in age and larval rearing group. Except for the SS protein feeding test, analyses compared treatments with regard to the total numbers of flies responding and not responding using chi-square calculated from 2×2 contingency tables. Treatment variances were more uniform in the protein feeding test, where percentage response data ($N = 10$ decoys per treatment) were transformed (arcsin $\sqrt{}$) and analyzed by ANOVA and Student-Newman-Keuls multiple range test (SAS Institute, 1988).

RESULTS

In tests involving SS and OW-87, the more newly colonized of the two SW strains, females or female extract elicited copulatory attempts from significantly more conspecific males than did solvent controls (Table 1, tests 1–3). The response of males to conspecific females or their extract was at least 65% within SW and 23% within SS. No interspecific or control responses were observed with OW-87 SW or SS males. Males of the longer-colonized 009 SW strain reacted to SS females or their extract at rates significantly exceeding those to controls in two of three tests (Table 1, tests 4–6). However, no more than 16% of the 009 males reacted to SS extract, even when 5.0 FE was tested, whereas 97% of them responded to 1.0 FE of conspecific extract.

Feeding liver to SS adults had no effect on the potency of female pheromone extracts but did significantly enhance male responsiveness to pheromone (Table 2). About twice as many fed as unfed males responded to 1.0 FE of extract. The difference in response to female extract compared with control was more marked when SS flies fed protein were tested; 1.0 FE of extract elicited responses from 58% of test males, whereas solvent alone produced no responses ($\chi^2 = 38.1$, $df = 1$, $P < 0.001$).

DISCUSSION

The results show that SS females, like SW females (Mackley and Broce, 1981; Hammack, 1986), produce a mating-stimulant pheromone that elicits copulatory attempts from conspecific males. The absence of interspecific copulatory

TABLE 1. INTRA- AND INTERSPECIFIC MATING ATTEMPTS BY MALES OF SCREWWORM (SW), *C. hominivorax*, AND SECONDARY SCREWWORM (SS), *C. macellaria*, IN RELATION TO TIME IN COLONY OF SW MALES

Test	Time in colony of SW test males	Males tested (*N*)	Female stimulus	Males responding (%) to female stimulus[a]					
				SW males			SS males		
				SW	SS	Control[b]	SW	SS	Control[b]
1	Short[c]	150	Whole dead females	74	0	—	0	51	—
2	Short	100	Female extract (1.0 FE[d] SW or 1.0 FE SS)	65a	0	0b	0	23a	0b

[a] Within tests and species of male, members of a pair followed by the same letter are not significantly different at $P = 0.05$ by contingency chi-square.
[b] Hexane washed insects treated with hexane in place of female extract.
[c] Belize SW strain colonized fewer than 22 generations.
[d] Female equivalent.
[e] 009 SW strain colonized more than 200 generations.

TABLE 2. EFFECT OF FEEDING PROTEIN TO *C. macellaria* ADULTS ON MEAN PERCENTAGE OF MALES ATTEMPTING COPULATION UPON EXPOSURE TO HEXANE EXTRACT OF FEMALES (1.0 FEMALE EQUIVALENT)[a]

	Female	
Protein feeding status/sex	Unfed	Fed
Unfed male	31a	27a
Fed male	61b	55b

[a] Values followed by the same letter are not significantly different at $P = 0.05$ by Student-Newman-Keuls multiple-range test following arcsin $\sqrt{}$ transformation of the percentage data and a significant ANOVA ($F = 5.51$; $df = 3, 36$; $P < 0.003$).

attempts when SS and the more newly colonized SW strain were tested indicates that SW and SS pheromones are distinct. Pheromonal differences may thus contribute to reproductive isolation between these two closely related species, which produce no hybrid progeny and only occasionally attempt interspecific matings when caged together (Chamberlain and Hopkins, 1978).

The SS protein feeding tests were done because SS, unlike SW, is anautogenous and SS fed only carbohydrate responded poorly in intrastrain comparisons. Protein in the adult diet has been shown to affect sexual behavior in other anautogenous blow flies (Parker, 1968; Bartell et al., 1969; Barton Browne et al., 1976). If dietary protein were to enhance the pheromone activity of SS females, as it does for *L. cuprina* females (Bartell et al., 1969), then protein-deprived SS females should not have been used to compare responses of old and new strain SW males. However, access to liver for five days after adult emergence had no effect on the pheromone activity of SS females, although it did double the number of males that responded to pheromone. Considering that males were forced to contact pheromone during bioassays, the effect on males appears to involve altered sensitivity to pheromone rather than just a generalized change in locomotory activity. Protein deprivation also vastly reduces oriented mounts by males of *Protophormia terrae-novae* R.-D., although reduction may be mediated by means other than pheromone responsiveness (Parker, 1968).

Although some 009 SW males did attempt mating in response to SS females or their extract, this behavior was infrequent, especially when compared with intraspecific responsiveness. As already noted, infrequency of the interspecific interactions was not attributable to low potency of the SS extracts caused by lack of dietary protein. Thus, in spite of a generalized increase in response levels, the present experiments provided little evidence that longer colonization detrimentally affects the ability of SW males to discriminate *C. hominivorax* from *C. macellaria* females using pheromone cues.

The degree of spatial and temporal overlap that occurs in the field between SW and SS mating activities needs to be clarified before the importance of pheromones in maintaining reproductive isolation can be fully evaluated. Although both species are trapped at proteinaceous baits, it has not been established that both mate at these locations. Many other blow flies do apparently mate near carrion, where females obtain the protein needed for oogenesis, and some species oviposit (Parker, 1968; Shorey et al., 1969; Barton Browne et al., 1976; Woodburn and Vogt, 1982). Meskin (1986) described the assumption of waiting stations on or around carrion by sexually active males of six calliphorid species that use the stations to intercept approaching females. The observation that carrion and wounds attract about equal numbers of SS males and females (Lindquist, 1938; Krafsur, 1978) suggests that protein resources also serve as mating aggregation sites in this species. In contrast, carrion baits attract at least five times more SW females than males (Lindquist, 1938; Coppedge et al., 1977), and few SW males are trapped on host wounds attractive to SW females (Parish, 1937; Guillot et al., 1977; Thomas and Mangan, 1989). The rarity of SW males at the host and their failure to respond to host odors attractive to females (Hammack et al., 1987, 1989) or to volatiles associated with virgin females (unpublished data) argue against SW mating at the host. The substantial predominance of inseminated over virgin females at the host (Guillot et al., 1977) and their monogamous habit (Knipling, 1955) are consistent with this view. Indeed, were males present on the host, their mating attempts could interfere with oviposition, considering that female sex pheromone activity is unaffected by insemination (Hammack, 1987). Evolution of parasitism by a presumed carrion-breeding ancestor of the screwworm apparently offered not only a more consistent larval habitat with reduced interspecific competition for limited food resources (see Hanski, 1987, for references), but also the opportunity for spatial separation of mating and ovipositional behaviors.

In spite of the success of SIT in controlling screwworms, their mating behavior has been observed only rarely in the field. Sterile released SW mate on flowering vegetation, where both sexes feed on nectar or honeydew and where, compared with host, the higher proportion of virgin females increases the opportunity for males to encounter receptive females (Guillot et al., 1978; Mackley and Long, 1983). Broce (1980) reported increased sexual activity among SW males exposed to components of swormlure-2, a chemical bait used for population monitoring (Mackley, 1986). Food odors associated with aggregation sites are known to stimulate male sexual activity in other Diptera, including *L. cuprina* and *Drosophila melanogaster* (Shorey et al., 1969). Although swormlure was originally formulated from likely decay products of proteins and fats (Jones et al., 1976) and attracts at least four times more females than males (Coppedge et al., 1977), Broce (1980) suggested that it mimics the odor of floral sites where screwworms aggregate. However, Krafsur (1978) reported aggre-

gation by sexually active wild SW males on nonflowering vegetation away from obvious food resources. Similar but isolated observations of sterile males on nonflowering vegetation led Mackley and Long (1983) to consider the possibility that SW mating at floral feeding sites is an artifact stemming from the abnormally high density characteristic of sterile released populations. Thus, it is uncertain whether screwworms mate mostly on flowers, around carrion, or away from food resources. The significance of the observed pheromonal divergence in maintaining reproductive isolation between SW and SS can be fully evaluated only when this important issue is resolved and the degree of spatial and temporal overlap between SW and SS mating activities clarified.

Acknowledgments—I would like to thank Patsy L. Evenson and Philip T. Meyer for insect rearing and technical assistance. Richard D. Peterson II (USDA-ARS Livestock Insects Research, Lincoln, Nebraska), J. George Pomonis, and David B. Taylor (USDA-ARS Livestock Insects Research, Lincoln, Nebraska) provided useful criticism of an earlier draft of the manuscript.

segetum were tested for field attractancy at six, two, and three sites in Europe, Asia, and Africa, respectively. At all of the sites in Eurasia and in northern Africa the ternary mixture of the acetates captured most males, while at the sites south of the Sahara in Africa, (Z)-5-decenyl acetate alone was responsible for attraction. Differences in male attraction among the populations studied confirm the existence of significant population variation in the pheromone of *A. segetum*. Interpretation of the present results together with earlier studies suggests that this variation is more or less continuous in Eurasia and north Africa, while a clearly distinct pheromone type is present in the areas south of the Sahara desert.

Key Words—Sex pheromone, *Agrotis segetum*, Lepidoptera, Noctuidae, field trapping, (Z)-5-decenyl acetate, (Z)-7-dodecenyl acetate, (Z)-9-tetradecenyl acetate, geographical population variation.

INTRODUCTION

Several earlier reports have dealt with the chemical identity of the female sex pheromone of the turnip moth (*Agrotis segetum* Den. & Schiff.). Today it is generally accepted that (Z)-5-decenyl acetate (Z5–10 : Ac; names of compounds are abbreviated according to Arn et al., 1986), (Z)-7-dodecenyl acetate (Z7–12 : Ac) and (Z)-9-tetradecenyl acetate (Z9–14 : Ac) are the three behaviorally important components present (Bestmann et al., 1978; Arn et al., 1980; Tòth et al., 1980; Löfstedt et al., 1982). In a trapping study conducted in four European countries, the ternary mixtures of these compounds were generally more attractive to male moths than binary combinations or the single compounds (Arn et al., 1983). However, minor differences at some of the sites indicated possible geographical variation in the responses of males. In France, Z5–10 : Ac on its own captured a sizable number of moths, and these catches did not differ significantly from some catches of the ternary mixtures (Arn et al., 1983). Corresponding results were obtained with a binary Z7–12 : Ac/Z9–14 : Ac bait in Hungary (Arn et al., 1983) and Bulgaria (Subchev et al., 1986), and some combinations of Z5–10 : Ac/Z7–12 : Ac in Denmark (Arn et al., 1983).

Further evidence supporting the idea of pheromone differences between populations has been provided by analysis of female-extracted pheromone components, and investigations of olfactory sensilla on male antennae of turnip moth populations from various places in Europe (Löfstedt et al., 1986; Hansson et al., 1990).

The turnip moth is present within the entire temperate zone of Eurasia, in the Mediterranean, as well as in several regions of Africa, down to its southernmost parts (Cayrol, 1966). In the present study, selected combinations of the three pheromone components were tested at six, two, and three sites in Europe, Asia, and Africa, respectively, in order to provide further evidence for differ-

ences and similarities in the male response to pheromone components of the respective geographical populations.

METHODS AND MATERIALS

Compounds used in the tests were purchased from the Institute of Pesticide Research (Wageningen, The Netherlands). Gas chromatographic analysis revealed that *Z*5–10:Ac contained <3% of the corresponding *E* isomer and <5% of the corresponding alcohol; *Z*7–12:Ac <3% of the *E* isomer with no detectable alcohol, and *Z*9–14:Ac <8% of the *E* isomer with no detectable alcohol. Baits were prepared using 0.5 × 1-cm pieces of rubber tubing (Taurus, Budapest, Hungary; No. MSZ 9691/6; extracted three times in boiling ethanol for 10 min, then three times in dichloromethane overnight, prior to use). Baits were made with the required amounts of compounds from the same stock solutions in hexane administered to the surface of the dispensers. Prepared dispensers were wrapped individually in aluminum foil, and stored at −65°C until use, or sent air mail to the different test sites. Before setting up the test, the dispensers were stored at −20°C by each respective cooperator. Bait variations tested are summarized in Figure 1.

Unless stated otherwise, field tests were conducted by using sticky traps similar in shape and size to those described by Arn et al. (1979), but made from polyethylene sheets. Traps containing different baits were set up in pentagonal blocks. The distance between traps within a block was 4–5 m. The distances between blocks ranged from 100 to 1000 m. When checked, the traps were moved one position forward within a block. At the same time, captured males were recorded and sticky inserts changed to new ones. At each test site, five traps were operated from each bait variation. In statistical analyses, catches recorded at a trap inspection were regarded as replicates. Captured moth specimens from each test were sent to Budapest, and their species identity was determined on the basis of wing pattern characters by L. Ronkay (Hungarian Natural History Museum, Budapest).

Capture data were transformed to log $(x + 1)$ and differences between means were tested for significance by Duncan's new multiple-range test (NMRT). Cluster analysis of relative male responses to the five different blends in the 11 populations was performed using SYSTAT (Wilkinson, 1989). Clustering was accomplished by the Ward minimum-variance method.

Details of Testing Procedures According to Sites

Bulgaria. Polski Trumbesh, May 30–June 22, 1990; vineyard; old bait replaced by new one on June 6; traps inspected every two days.

Egypt. El-Tahrir region, Shibin El Kom, March 19–April 6, 1990; lime plantation; traps inspected every two days.

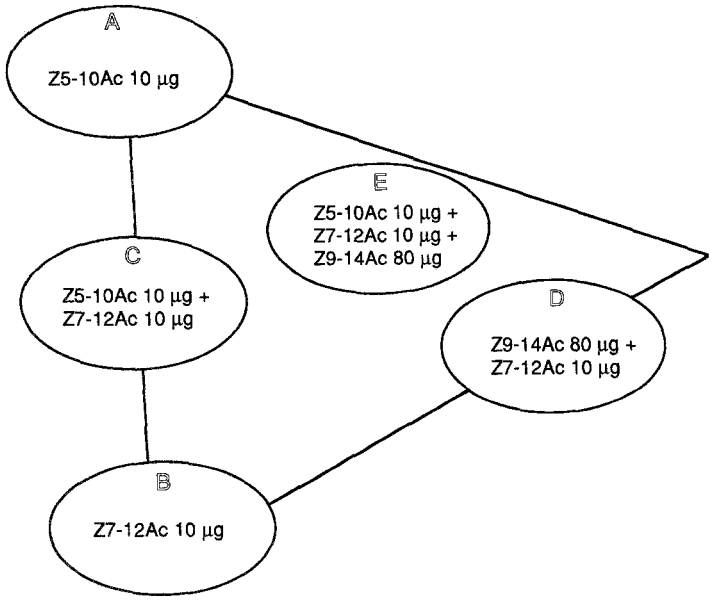

FIG. 1. Composition of baits used in field trapping tests for catching male *A. segetum* in various geographical regions. For ease of comparison, baits are presented according to the triangular arrangement scheme of Arn et al. (1983).

Hungary. Budakeszi, Pest county, May 30–June 9, 1989; vineyard; traps inspected every two days.

Italy. Bologna, September 8–22, 1989; mixed vegetable fields; traps inspected once weekly; from each bait variation only one trap was operated.

Kazakhstan (U.S.S.R.). Alma-Ata, July 9–23, 1990; apple orchard; traps inspected every three to four days.

Moldavia (U.S.S.R.). Kishinev, July 17–30, 1990; mixed vegetable fields; traps inspected every three to four days.

Republic of South Africa. Cathedral Peak, Forestry Research Station, February 22–April 10, 1990; extensive and partly abandoned fields, overgrown orchards; old baits replaced by new ones on March 12; traps inspected every three to four days.

Spain. Granada, July 17–August 2, 1989; fields of various vegetables; traps inspected every two days.

Sweden. Knästorp, outside the city of Lund, July 7–12, 1989; sugar beet field; traps inspected every two to three days; trap model Lund II (Anderbrant et al., 1989) was used.

Turkmenistan (U.S.S.R.). Bayram Ali, Mariyskaya oblast, August 14–23, 1989; alfalfa field; traps inspected every three to four days.

Zimbabwe. Kutsaga Research Station, Harare, December 28, 1989–January 26, 1990; tobacco field; traps inspected every three days; delta traps (made from white corrugated polyethylene; PLA Insect Monitoring and Control Systems, Southampton, U.K.) were used.

RESULTS

Catches of A. segetum. In all of the tests in Eurasia and the single test in north Africa (Egypt), the ternary mixture of the three acetates clearly caught better than any of the other combinations (Figure 2), substantially confirming results of previous trapping tests in four countries in Europe (Arn et al., 1983). The binary mixture of Z5–10:Ac/Z7–12:Ac caught significantly less than the ternary blend in all places except in Spain. The combination of Z7–12:Ac/Z9–14:Ac catches were close to nil in Sweden, Hungary, Kazakhstan, and Turkmenistan, whereas in Spain, Moldavia, Bulgaria, and Egypt the captures were somewhat greater, but still lower than catches with the ternary blend. The Z7–12:Ac/Z9–14:Ac blend generally caught less than the Z5–10:Ac/Z7–12:Ac blend, except in Moldavia, Kazakhstan, and Egypt. Z5–10:Ac, or Z7–12:Ac as single components hardly caught any moths.

In contrast, at the two sites south of the Equator in Africa, the largest number of males was captured by Z5–10:Ac alone (Figure 2). Smaller catches in other combinations could be attributed to the Z5–10:Ac content of the respective variations.

Cluster analysis suggested classification of the investigated populations into two major types (Figure 3). The two southern African populations form a clearly distinct group (I), in which more than 75% of the moths are trapped by the pure Z5–10:Ac bait. All the Eurasian populations form one cluster together with the population from Egypt (II). These populations are characterized by high responses to the three-component blend. However, two subgroups may be distinguished within this second cluster. All the European populations form one subgroup (a) together with the Egyptian population. These populations are characterized by the highest responses to the three-component blend (mean = 55%, range 45–68%), and relatively large responses to some of the binary blends. The populations from the Asian sites in Kazakhstan and Turkmenistan cluster together and form a second subgroup (b), which differs from the European populations by outstandingly high catches with the three-component blend (95% and 77%, respectively, for the two populations). The difference between clusters (a) and (b) is obviously small compared to the difference between clusters I and II, and its biological significance is not clear. However, it is interesting to note that the two Asian populations, which are geographically relatively close, actually cluster together.

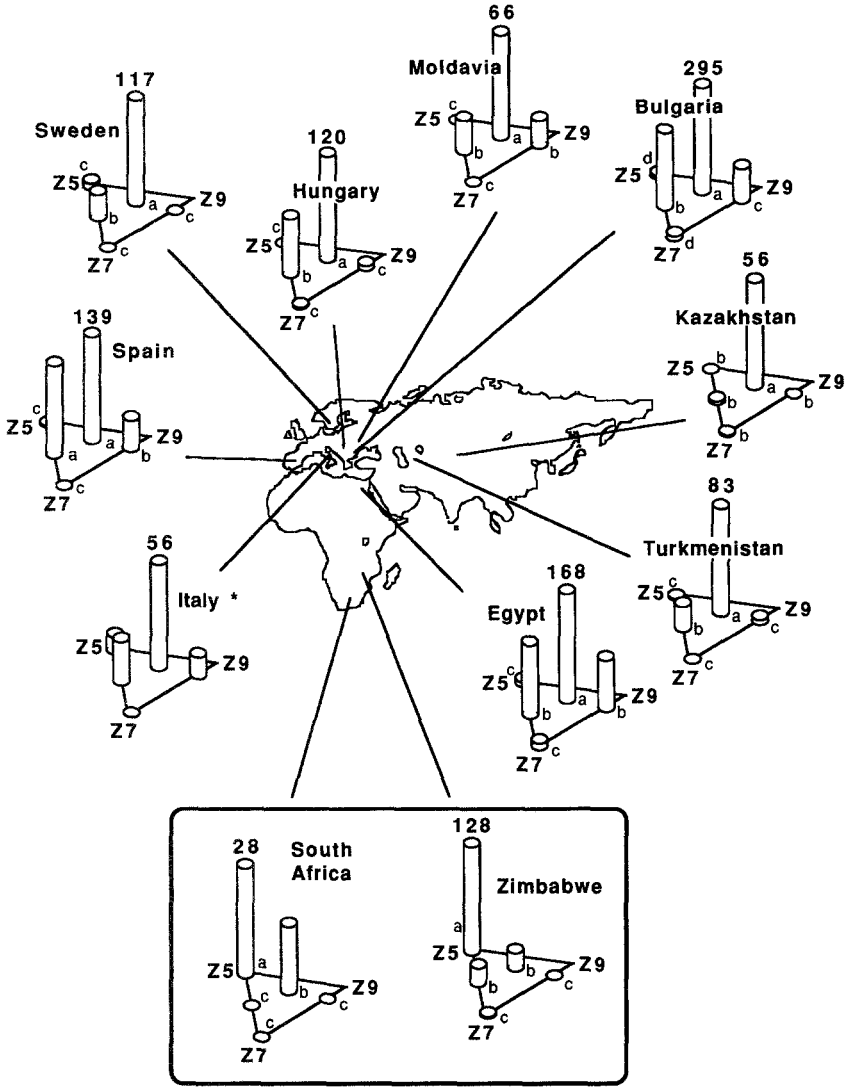

FIG. 2. Percentage catches of male *A. segetum* at 11 sites in Eurasia and Africa. Numbers above columns show total catch of best bait in the given test. Z5 = Z5–10:Ac; Z7 = Z7–12:Ac; Z9 = Z9–14:Ac. Columns with same letter within a diagram are not significantly different at $P = 0.05$ by Duncan's NMRT. Triangular arrangement of baits is the same as in Figure 1. *In Italy only one trap per bait variation was set up, and data were not statistically analyzed for significance.

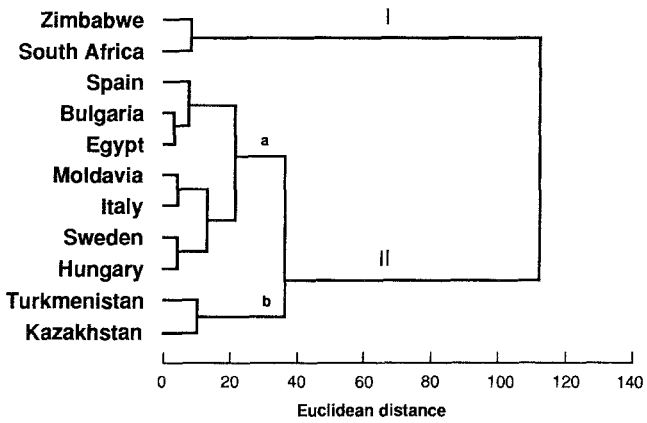

FIG. 3. Dendrogram resulting from cluster analysis of relative trap catches by five different pheromone blends in 11 populations. The analysis was performed on the data in Figure 2.

Catches of Other Species. Apart from male *A. segetum*, other species captured in the test included *Autographa gamma* L., and *Emmelia trabealis* Scop., attracted to Z7-12:Ac and Z5-10:Ac, respectively, at many of the sites in Eurasia and north Africa. Sizable numbers of male *Mythimna loreyi* Duponchel were caught by the two baits containing both Z7-12:Ac and Z9-14:Ac (i.e., D and E) in Spain.

A total of 51 *Agrotis clavis* Hfn. males was caught by Z5-10:Ac in the Hungarian test. No males were captured by any of the other treatments.

In the Zimbabwean trial, a total of 14 *Chrysodeixis acuta* Wlk. was caught by the bait containing Z5-10:Ac/Z7-12:Ac, while in Sweden 2 and 51 male *Cnephasia pasiuana* Hbn. (Tortricidae) were captured by Z5-10:Ac and Z5-10:Ac/Z7-12:Ac, respectively.

DISCUSSION

Results from South Africa and Zimbabwe in the present study clearly demonstrate the presence of a male type distinct from previously described ones, since here Z5-10:Ac alone caught more than any of the other baits. It is at variance with earlier data from France, where Arn et al. (1983) reported that Z5-10:Ac alone caught as many moths as the ternary blend. The addition of Z7-12:Ac or Z9-14:Ac seemed to decrease catches at both sites in southern Africa (Figure 2). Our results of pheromone extract analyses and of studies on male antennal receptors on insects from Kenya further confirm the occurrence of a distinct pheromonal type of *A. segetum* for Africa (to be published in detail

elsewhere). The Sahara desert appears to be an ecological barrier that has separated the Eurasian and sub-Saharan African populations.

Electrophysiological studies and analyses of female-extracted pheromone components of different *A. segetum* populations (Löfstedt et al., 1986; Hansson et al., 1990) have suggested the existence of at least three main pheromone populations in Europe: a population found in France, producing more Z5–10:Ac in the pheromone, and possessing many Z5–10:Ac-tuned receptors on the male antennae; a population found in Sweden, producing less Z5–10:Ac and possessing fewer receptors for this compound (but still more abundant than the Z7–12:Ac receptors); and a population found in Armenia/Bulgaria, producing very little Z5–10:Ac and possessing fewer receptors tuned to Z5–10:Ac than to Z7–12:Ac. The cooccurrence of males similar to the Swedish and Armenian/Bulgarian type has also been proven for Hungary (Hansson et al., 1990). When studying the antennal receptors of males captured by traps baited with the Z7–12:Ac/Z9–14:Ac blend, males belonged almost exclusively to the Armenian/Bulgarian type; while both Armenian/Bulgarian and Swedish types of males were caught in about equal numbers by ternary baits (Hansson et al., 1990). Consequently, the higher numbers caught with ternary baits in a former (Arn et al., 1983), as well as in the present study, could be attributed to this bait being able to attract both types of males, while binary combinations can be attractive mainly to one of the male types.

On the other hand, this explanation strongly suggests the cooccurrence of both male types not only in Hungary (Hansson et al., 1990), but also at the other Eurasian and north African sites (Figure 2). The coexistence of such pheromonal types also in Sweden is indicated in retrospect by the results of the analysis of pheromone extracts from single females (Löfstedt et al., 1985), where a high variation in ratios between the three acetate components was demonstrated.

In the present study, no catches similar to earlier results from a French site (Arn et al., 1983) were observed at any of the sites in Eurasia. Likewise, high catches with the Z7–12:Ac/Z9–14:Ac blend, as previously described from Bulgaria (Subchev et al., 1986), were not confirmed at the Bulgarian site in this study, nor by a preceding preliminary trapping trial conducted in 1989, where similar baits were tested with very much the same results as the ones presented here (Tòth and Subchev, unpublished). We suggest that the above deviations in capture data may result from local or temporal variations in relative abundance of the cooccurring pheromonal types. It could be that in the year and at the site of the study by Subchev et al. (1986), the Armenian/Bulgarian male type was much more abundant than the other one, due to unknown selection pressures or the effects of random fluctuations of the local conditions on the two pheromonal types.

Distinct pheromone differences between populations of the same or sibling species have been shown to depend on allelic differences at a small number of loci (Löfstedt, 1990). This might explain the distinct pheromone difference between the Eurasian and southern African populations of *A. segetum*. However, the more or less continuous variation in the pheromone communication systems among the Eurasian populations seems to involve either several different alleles at the response and production loci or quantitative inheritance variation.

In *Agrotis fucosa* Butler, a noctuid pest in Japan, two components, Z5–10:Ac and (Z)-7-decenyl acetate (Z7–10:Ac), have been identified as pheromone components (Wakamura, 1978, 1980). Some authors mention *A. fucosa* as synonymous with *A. segetum* (Dunkelblum and Gothilf, 1984; Steck et al., 1979; Wakamura et al., 1981) and suggest that *A. fucosa* may represent the Japanese pheromonal type of *A. segetum*. As for the taxonomists' opinion, a taxonomic checklist of lepidopterous species from Japan states that: ". . . *fucosa* Butler Trans. Ent. Soc. Lond. *1881*, 179 (1881) = *segetum* part., auct., nec. Schiffermüller et Denis, 1775 . . ." (Sugi, 1958), which means that some authors erroneously refer to *A. fucosa* as *A. segetum*. According to this checklist, *A. segetum* is not present in Japan (Sugi, 1958). However, in a later edition, *A. fucosa* is listed as being synonymous with *A. segetum* (Sugi, 1982).

During several years of extensive field-trapping tests in Hungary with binary mixtures of Z5–10:Ac and Z7–10:Ac, we never caught any male *A. segetum* with any of the baits (Tòth and Szöcs, unpublished). Consequently, based on differences of pheromone composition, it may be more probable that *A. fucosa* and *A. segetum* are separate species.

From an ecologist's point of view it is important to determine if the observed variation between populations is adaptive or not. If differences in blend attractivity between populations were accompanied by large catches of nonspecific moths in the suboptimal blends, this would be evidence for the importance of interspecific competition in the evolution of the communication channel. Continuous trapping during the whole flight season at all sites would have been necessary to allow any definite conclusions to be drawn. However, it is interesting to note that in Eurasia and north Africa several other species were attracted by Z5–10:Ac alone, whereas this compound only attracted *A. segetum* in Zimbabwe and South Africa. This supports an adaptive interpretation of the observed differences in attraction between the *A. segetum* populations.

Captures of *A. gamma*, *E. trabealis*, and *M. loreyi* in this study confirm earlier descriptions of the sex attractant of the respective species (Szöcs et al., 1983; Tòth et al., 1983; Takahashi et al., 1983). No male attractant has been described previously for *A. clavis*, *C. acuta*, and *C. pasiuana*. Of these, *A. clavis* is a species very similar to *A. segetum* in appearance and is recorded as a potential pest of vegetables in Eurasia (Cayrol, 1966).

(Received August 14, 1991; accepted March 23, 1992)

Abstract—The garden geranium (*Pelargonium xhortorum*) has been shown to secrete anacardic acids in the form of a viscous sticky exudate from tall glandular trichomes, and this exudate provides a sticky trap defense against small pest species. The anacardic acids from genetically related pest-resistant and -susceptible plants have been characterized, and resistance has been shown to depend upon the presence of $\omega 5$ unsaturated anacardic acids. In this study, the biosynthesis of these anacardic acids was comparatively investigated by incubating [^{14}C]methyl palmitate, margarate, stearate, oleate and linoleate on floral buds of resistant and susceptible plants. In addition, the incorporation of [^{14}C]valine, -isoleucine, and -leucine into anacardic acids was also studied. Nineteen anacardic acids were quantitated utilizing an improved HPLC technique. Fatty acids and, to a much lesser extent, amino acids were incorporated into anacardic acids. There are at least two pathways of biosynthesis operating: direct elongation, and β-oxidation with reincorporation of the [^{14}C]acetate, the latter being more prevalent in the resistant plant. The amino acids were processed into branched chain anacardic acids, isoleucine being the precursor of the anteiso compounds, and valine the iso branched ones. The major difference between resistant and susceptible plants was the ability of resistant plants, but not the susceptible plants, to synthesize $\omega 5$ unsaturated anacardic acids. Both types of plants were capable of directly incorporating ^{14}C-labeled fatty acid methy esters into anacardic acids regardless of the plant's normal anacardic acid composition, thus bypassing the plant's tightly controlled regulation of the chemical structures of anacardic acids. No evidence was found for $\omega 5$ desaturation of saturated anacardic acids. A revised biosynthesis scheme is presented.

Key Words—Biosynthesis, anacardic acids, glandular trichomes, geraniums, *Pelargonium xhortorum*.

INTRODUCTION

Geraniums (*Pelargonium xhortorum*) have been shown to possess tall glandular trichomes, which secrete a viscous sticky exudate, providing sticky trap resistance against small pest species, such as the two-spotted spider mite (*Tetranychus urticae* Koch) and the foxglove aphid (*Acyrthosiphon solani* Kaltenbach) (Craig et al., 1986; Gerhold et al., 1984; Stark, 1975; Walters, 1988, Walters et al., 1988, 1989a,b, 1990a; Hesk et al., 1990). Chemical analysis of the exudate in both insect-resistant and -susceptible geraniums has shown it to be composed of anacardic acids, which are 6-alkyl salicylic acid derivatives possessing varying side chain lengths, degrees of side chain unsaturation, and branching (Walters et al., 1988; Hesk et al., 1990).

Analysis of the exudate from resistant plants has shown that it is predominantly composed of unsaturated anacardic acids, with C_{22} $\omega5$ and C_{24} $\omega5$ unsaturated anacardic acids accounting for over 80% of the exudate composition (Walters, 1988; Hesk et al., 1990). In addition, there are small but significant quantities of C_{23} $\omega6$, C_{25} $\omega6$, and C_{23} anteiso anacardic acids and the saturated C_{22} and C_{24} analogs. In contrast, the exudate from susceptible plants is predominantly saturated, with the C_{22} and C_{24} saturated anacardic acids being the major components and accounting for 50% of the total. The anacardic acids with an $\omega5$ or $\omega6$ double bond are all but absent in the susceptible plant. Instead, the remaining 50% is made up of a complex mixture of anacardic acids, of which the most notable are the C_{23} anteiso, the C_{23} saturated, and two unsaturated anacardic acids not seen in the resistant plant, the C_{24} $\omega6,9$ and the C_{24} $\omega9$ (Hesk et al., 1990). Anacardic acids have been shown to be the critical factor in small pest resistance of geraniums (Walters et al., 1989b), and resistance is dependent upon the presence of $\omega5$ unsaturated anacardic acids.

Geissman (1963) and Gerhold et al. (1984) proposed that these compounds are synthesized from fatty acid precursors in similar manner to fatty acid biosynthesis. The first experimental evidence for this mechanism was presented by Walters et al. (1990b), who studied the incubation of ^{14}C-labeled fatty acid methyl esters on the sepals of pest-resistant geraniums. It was found that saturated fatty acids were predominantly incorporated into saturated anacardic acids via the addition of three acetate units, thus supporting the hypothesis. This finding also gave rise to the conclusion that the $\omega5$ anacardic acids must be derived from $\omega5$ fatty acid precursors because no evidence could be found for the $\omega5$ desaturation of saturated anacardic acids. The appearance of ^{14}C label in the C_{22} $\omega5$, C_{24} $\omega5$, and C_{22} saturated anacardic acids, in addition to the

expected C_{24} saturated compound when [^{14}C]stearate was incubated, suggested that a second mechanism was operating. Hence, it was suggested that a portion of applied ^{14}C-labeled fatty acids was degraded into [^{14}C]acetate by β-oxidation, and then the [^{14}C]acetate was reincorporated into the anacardic acid biosynthesis. Thus this pathway was termed the indirect pathway (Figure 1).

While the biosynthesis of anacardic acids has been studied in the resistant plant (Walters et al., 1990b), no data are available on the biosynthesis in susceptible plants. This is particularly important since genetic experiments indicated susceptible plants differed from resistant plants by one or two genes (Winner, 1975, and unpublished data). Hence the present paper describes the biosynthesis of anacardic acids in the susceptible plant, with a wider range of fatty acids than previously used and with a more thorough analysis of the products using an improved HPLC separation technique, and compares the results to experiments carried out in parallel in the resistant plant. It was thought likely that the branched-chain and odd-chain-length anacardic acids were derived, in part, from

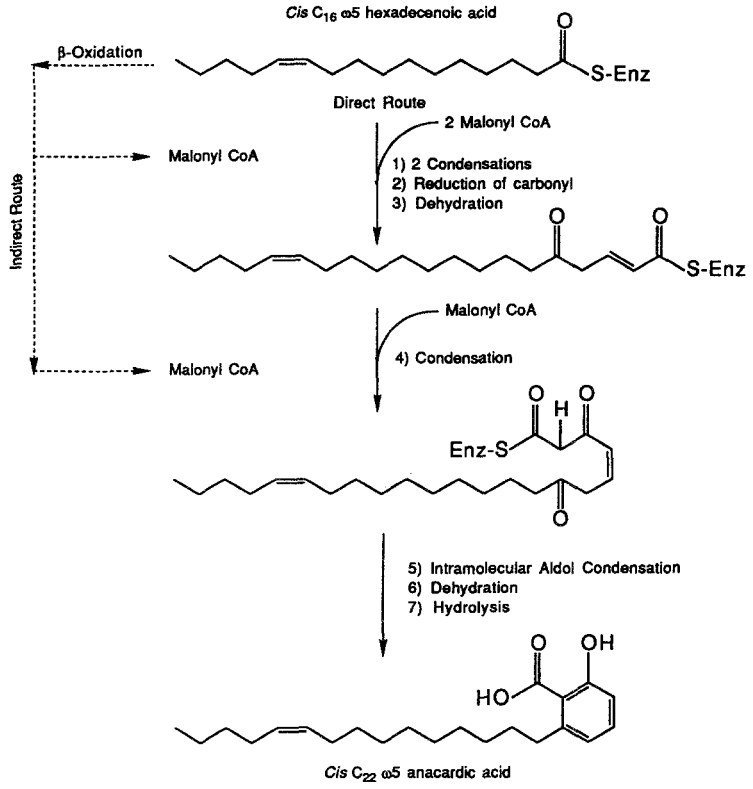

FIG. 1. Biosynthesis of an anacardic acid from a fatty acid precursor.

amino acids; thus three ^{14}C-labeled amino acids were incubated in both plant lines to test this hypothesis. The relative composition of anacardic acids, found within the resistant and susceptible plants, was determined by HPLC using UV detection to provide a base for comparison with the ^{14}C data and to determine the relative contribution of the two proposed biosynthetic pathways.

These studies are part of our continuing effort to further understand plant defense mechanisms with the expectation that some day we will be able to transfer these mechanisms to other plants.

METHODS AND MATERIALS

Radiochemicals. [1-^{14}C]palmitate, [1-^{14}C]margarate, [1-^{14}C]stearate, [10-^{14}C]oleate (C_{18} $\omega 9$ or $\Delta 9$), [1-^{14}C]linoleate (C_{18} $\omega 6,9$, or $\Delta 9,\Delta 12$), L-[U-^{14}C]isoleucine, L-[U-^{14}C]valine and L-[2-^{14}C]leucine were obtained from Research Products International Corporation, Mount Prospect, Illinois, or from ICN Radiochemicals, Irvine, California. All had a specific activity of 45–60 mCi/mmol. The purity of each was checked by TLC and autoradiography prior to use, and all were found to have a radiochemical purity in excess of 98%.

Plant Source. The geraniums used for the study were maintained in a growth chamber at 24°C using standard cultural practices, with a 16-hr photoperiod and an 8-hr nyctoperiod. The plant line 71-17-7 had previously been determined to be resistant to the two-spotted spider mite (*Tetranychus urticae* Koch) and the foxglove aphid (*Acyrthosiphon solani* Kaltenbach), and the line 85-26-8 had previously been determined to be mite and aphid susceptible (Gerhold et al., 1984; Stark, 1975; Walters et al., 1989b, 1990a). These two plant lines were used throughout the study, as chemical analysis of the anacardic acids produced by a number of resistant and susceptible plants showed that the anacardic acid profile was constant within each plant line (Walters et al., 1988, 1990c; Hesk et al., 1990).

Fatty Acid Incubation Experiments. The methyl esters of [1-^{14}C]palmitate, [1-^{14}C]margarate, [1-^{14}C]stearate, [10-^{14}C]oleate, and [1-^{14}C]linoleate were applied in turn to the sepals of the resistant and susceptible plants in a hexane solution. The incubation was performed on floral tissue, because earlier work had shown that there was a high density of glandular trichomes, and hence a high production of anacardic acids in these tissues (Walters et al., 1989b, 1990a). The labeled compound (2–4 μCi) was dissolved in a small volume of hexane (5–20 μl) and applied in 0.5- to 2-μl batches by a syringe to the surface of each unopened flower (sepal), which usually led to 10–12 flowers being treated. A small volume was used to minimize tissue damage by the solvent. In the early stages of the study, 2 μl of hexane solution was applied to the sepals of each flower, but it was subsequently found that the tissue damage could be further

reduced and the radiochemical incorporation greatly improved by applying only 0.5 μl of hexane solution. Hence this procedure was used for the remainder of the study.

The labeled acids were administered in two doses, half at the beginning of the experiment, and the second three days later. Each incubation was allowed to proceed for 7–10 days. At the conclusion of the incubation, the inflorescences (minus the petals) were soaked in methylene chloride for 1 hr. The extract was then dried over anhydrous sodium sulfate, filtered, and evaporated to leave the crude ^{14}C anacardic acid residue. This procedure had previously been shown to produce a representative extract of anacardic acids (Hesk et al., 1990; Gerhold et al., 1984; Walters et al., 1989a).

Amino Acid Incubation Experiments. Five microcuries of ^{14}C-labeled isoleucine, leucine, and valine were pipetted into 1-ml microvials, and freshly cut third node leaves and flowerheads were placed into the vials. On absorption of the amino acid solutions into the stems of the leaves and flowers, water was added in sufficient quantity to ensure that the leaf or flower stem remained in water. After the incubations had been run for one week, the leaves and flowers were removed from the vials, and the anacardic acids were extracted as described above.

TLC Analysis. The ^{14}C-labeled extracts were analyzed by TLC autoradiography to determine the extent of incorporation of the fatty acid precursor into anacardic acids and also to partially purify the anacardic acids prior to radio HPLC analysis. The carboxyl group in the anacardic acids was methylated (diazomethane-diethyl ether, 5-min treatment) (Walters et al., 1988) prior to TLC. Merck 20 × 20-cm silica gel F254 plates with a preconcentration zone were used, and the plates were developed in a two-step solvent system consisting of benzene–diethyl ether–ethanol–acetic acid (50:40:1:0.5, by volume) followed by hexane–diethyl ether–acetic acid (84:15:1, by volume). Development was allowed to proceed to about half the length of the plate in the first step and the entire length of the plate in the second. After the plates were dried, the plates were exposed to X-ray film for 1–10 days, depending on the radioactivity of the material. The monomethylated anacardic acid band was located by viewing at 254 nm and comparing the R_f (approximately 0.65) value with that of a monomethyl anacardic standard, before it was scraped from the plate and eluted with methylene chloride (3 × 2 ml). The methylene chloride extract was filtered through a Pasteur pipet containing a glass wool plug, and then evaporated to leave the anacardic acid extract. Finally the phenolic group on the anacardic acids was methylated (diazomethane-diethyl ether plus a few drops of methanol, 30-min treatment) (Walters et al., 1988) to give the dimethylated anacardic acids.

HPLC Analysis. The anacardic acids were analyzed by reverse-phase HPLC to determine those acids into which the fatty acid precursor had been incorpo-

rated. A 25-cm × 4.6-mm Supelcosil 5 μ LC8 DB column was used with a solvent system of isopropanol, acetonitrile, and 0.01 M acetic acid (490 : 147 : 343) run isocratically at 1 ml/min. The radioactive peaks were detected using a Packard Tricarb RAM 7500 radioactive monitor, with a solid fluor packed flow cell. The anacardic acids were also monitored at 212 nm using a Waters Lambda Max 480 UV detector.

In the case of the ^{14}C anacardic acids recovered from the ^{14}C amino acid incubations, the recoveries were too low to be quantified with the radioflow monitor. Hence, for each amino acid incubation, the eluent from the entire HPLC run was collected into scintillation vials, blended with 15 ml of liquid scintillator, and counted in a Beckman LS8000 counter to determine the distribution of the radioactivity in the anacardic acid profile.

These ^{14}C data are presented as analysis of pooled sample extracts from 10 to 12 separately treated flower heads.

RESULTS AND DISCUSSION

The results for the incubation experiments in the susceptible and resistant plants are given in Tables 1–4. Because of the improved HPLC technique and structural elucidation studies (Hesk et al., 1990), 19 anacardic acids were analyzed for the relative ^{14}C incorporation, as compared to only six anacardic acids in the previous biosynthesis experiments with resistant geraniums (Walters et al., 1990b). Approximately 10–25% of the administered dose was recovered in the methylene chloride extract and of that, 10–20% was found in anacardic acids, giving an overall incorporation of between 1 and 2%. This compares favorably with the earlier biosynthesis experiment (Walters et al., 1990b).

In the case of the amino acid incubations, the overall incorporation into anacardic acids was much lower, with only 0.05–0.6% of the administered dose recovered in the methylene chloride extract. This lower incorporation rate is presumably due to the amino acids principally being used in other biosynthetic pathways.

Palmitate Incubation. The results showed that [^{14}C]palmitate was primarily incorporated into the C_{22} saturated anacardic acid by the proposed direct chain elongation mechanism, approximately 70% in both plants. The remaining 30% in the resistant plant was represented by C_{22} $\omega 5$, C_{24} $\omega 5$, and C_{24} saturated anacardic acids. The two unsaturated acids are presumably derived from β-oxidation of the palmitate into [^{14}C]acetate units, which are then reincorporated into the ^{14}C anacardic acids and appear in a similar relative proportion to that seen in the UV profile. As the ^{14}C C_{24} saturated anacardic acid is present in larger ^{14}C relative amounts than would be expected from the β-oxidation mechanism (UV concentration), it is likely that a portion of the added

[^{14}C]palmitate has undergone chain elongation to [^{14}C]stearate. This elongation mechanism is well recognized in plants (Stumpf, 1987). We propose that normally the palmitate undergoes a Δ11 desaturation followed by elongation to form ω5 anacardic acids; however, when we add [^{14}C]palmitate or any other acid externally, it bypasses the normal desaturation step in the resistant plant and gets directly incorporated, in part, into anacardic acids. It is conceivable that the plant has a sufficient pool of C_{16} ω5 fatty acid and, thus, does not need to form any more ω5 desaturated fatty acids.

Similarly, in the susceptible plant, the two minor radiolabeled peaks, the C_{24} ω6,9 and the C_{24} saturated acid, are present in lower relative amounts than that observed in the UV profile. The C_{24} saturated anacardic acid can be formed by chain elongation of palmitate to stearate, and the C_{24} ω6,9 from the β-oxidation of [^{14}C]palmitate to [^{14}C]acetate and reincorporation of the $^{14}CO_2$ mechanism. There is also the possibility that the C_{24} ω6,9 is formed from the Δ9,Δ12 desaturation of any stearate that is formed from elongation of the pal-

mitate. However, in view of the fact that this does not happen in the stearate incubation, which is described later, this possibility can be discounted.

Figure 2 illustrates the various pathways of metabolism operating for palmitate, with the unbroken arrows showing the major pathway and the broken arrows showing minor routes of metabolism. The same pathways of degradation and biosynthesis are functioning for all the incubated fatty acids.

Margarate Incubation. [^{14}C]Margarate was incorporated in a straightforward manner in both the resistant and susceptible plants, with 76% in the resistant and 87% in the susceptible being processed by the direct elongation synthesis into the C_{23} saturated anacardic acid. As in the case of the palmitate experiment, the radio HPLC trace from the resistant plant showed a small amount of degradation of the [^{14}C]margarate had occurred, resulting in the minor peaks corresponding to C_{22} ω5, C_{24} ω5, and the C_{22} acids. In the susceptible plant, there is evidence for an even smaller amount of β-oxidation and reincorporation, as indicated by the very small amounts of the C_{24} ω6,9 and C_{22} and C_{24} acids showing up in the radio HPLC trace. The C_{25} anacardic acid, by analogy with

the palmitate experiments, very likely arises from chain elongation of [^{14}C]margarate to [^{14}C]nonadecylate (C19:0), prior to anacardic acid biosynthesis.

Stearate Incubation. This experiment gave an interesting contrast between the resistant and susceptible plants. In the resistant plant, only 57% of the [^{14}C]stearate was incorporated into C_{24} anacardic acid via the direct pathway. The remaining peaks in the radio HPLC trace were the C_{22} ω5 and C_{24} ω5 acids, formed from β-oxidation of [^{14}C]stearate (similar to UV profile). In contrast, in the susceptible plant over 90% of the ^{14}C label had been incorporated via the direct elongation mechanism into the saturated C_{24} anacardic acid. Only a small amount of the β-oxidation was operating as evidenced by the minor peaks corresponding to the C_{24} ω6,9 and C_{22} acids.

Oleate Incubation. The radiolabeled products from the [^{14}C]oleate incu-

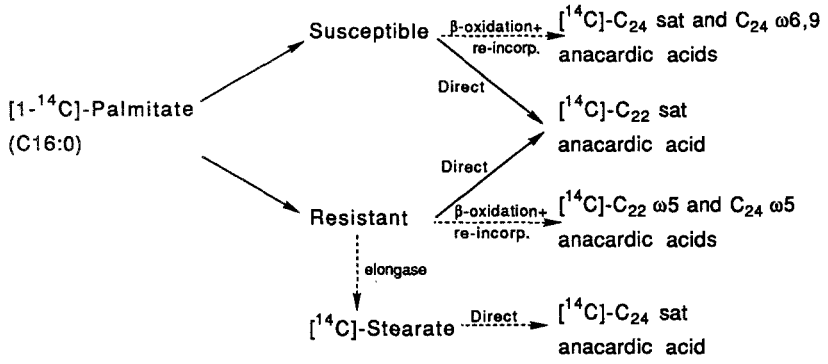

FIG. 2. Metabolism of palmitate in resistant and susceptible geraniums.

bation in the resistant plant showed a complicated pattern. The major peaks, which all contained about 28% of the label, corresponded to the C_{22} $\omega5$, C_{24} $\omega5$, and C_{24} $\omega6,9$ acids. In addition, there were small amounts of C_{22} and C_{24} $\omega9$ acids, the latter arising from the direct elongation of the oleate. The $\omega5$ and C_{22} saturated anacardic acids are readily accountable from the indirect synthetic pathway, involving β-oxidation. It should be noted that the label in the [^{14}C]oleate was in the 10 position, rather than in the carboxyl group, as was the case of the other radiolabeled fatty acids. The fact that a majority of the ^{14}C label was found in the C_{22} $\omega5$, C_{24} $\omega5$, and C_{22} anacardic acids, suggests that degradation of the [^{14}C]oleate proceeds along most of the length of the chain. The high amount of ^{14}C C_{24} $\omega6,9$ found in the resistant plant incubations is unusual, for the $\omega6,9$ is not normally found in resistant plants. Its biosynthesis does not fit either proposed pathway. Alternately, we propose the [^{14}C]oleate is, in part, desaturated to [^{14}C]linoleate and then processed to the C_{24} $\omega6,9$ unsaturated anacardic acid via the direct method. A $\Delta12$ desaturase is well known in plants (Jaworski, 1987).

The conversion of [^{14}C]oleate into C_{24} $\omega6,9$ is a major product (64.9%) in the susceptible plant. The UV trace shows it only represents 16.6% in the normal exudate. About 20% of [^{14}C]oleate is processed by the direct synthesis pathway into the C_{24} $\omega9$ anacardic acid. The remainder of the ^{14}C activity is located in the saturated C_{22} and C_{24} acids, which are presumably derived by the β-oxidation pathway or reduction of the oleate to sterate and subsequent incorporation. However, it should be noted that the degradation pathway of oleate is much less important in the susceptible plant when compared to the resistant plant.

Linoleate Incubation. The incubation of [^{14}C]linoleate in the resistant plant, like the incubation of [^{14}C]oleate, produced a complicated profile. Nearly half of the label was found in the C_{24} $\omega6,9$ peak and presumably formed via the direct elongation pathway. The remaining peaks in the radiochromatogram, the C_{22} $\omega5$, C_{24} $\omega5$, and saturated C_{22} anacardic acids, can be readily explained from the β-oxidation of the [^{14}C]linoleate to [^{14}C]acetate units followed by their reincorporation into the anacardic acids (consistant with UV profile). In the susceptible plant, the linoleate incubation was much more straightforward, with only about 10% of the [^{14}C]linoleate found incorporated into anacardic acids via the indirect pathway. The vast majority was processed by the direct elongation into the C_{24} $\omega6,9$.

L-Isoleucine Incubation. [^{14}C]Isoleucine was incorporated into ^{14}C anacardic acids in both resistant and susceptible flowers, and also in resistant leaves, although the amount of labeled anacardic acids from susceptible flowers was only about a tenth of that recovered from the resistant flower incubation. No labeled anacardic acids could be detected in the susceptible leaf incubation. It is possible that the lower rate of anacardic acid biosynthesis seen in the leaves compared to the flowers may be a reflection on the much lower number of

glandular trichomes seen on the susceptible leaves, or that the leaves are more completely utilizing the amino acid in biosynthesis of other biomolecules.

Looking first at the resistant plant incubations (Table 3), it can be seen that major labeled peaks were the C_{22} $\omega5$, C_{24} $\omega5$, and C_{23} $\omega6$ unsaturated anacardic acids and the C_{21}, C_{23}, and C_{25} anteiso compounds. The C_{22} $\omega5$ and C_{24} $\omega5$ are readily explainable by considering that it is well documented that isoleucine is degraded to succinyl CoA via the succinate pathway (Lehninger, 1975). Succinyl CoA is subsequently converted to acetyl-CoA via the Krebs cycle. In addition, the degradation of α-methylacetoacetyl-CoA gives rise to acetyl-CoA and propionyl-CoA. Thus, [^{14}C]isoleucine is degraded to [^{14}C]acetyl-CoA, and hence is incorporated into [^{14}C]anacardic acids at potentially each longation step. It would be expected that, if this mechanism was operating, the relative amounts of the radiolabeled C_{22} $\omega5$ and C_{24} $\omega5$ anacardic acids should closely match the anacardic acid UV profile as is found.

The propionyl-CoA formed during the degradation of isoleucine can give rise to C_{17} fatty acid and explains the relatively high incorporation of label into the C_{23} $\omega6$ anacardic acid, and to a lesser degree as the C_{25} $\omega6$ acids. The high degree of ^{14}C incorporation found in the anteiso branched chain anacardic acids, particularly the C_{23} anteiso acid, is readily explained by considering that α-methylbutyryl-CoA is a precursor (Lehninger, 1975). Despite the lower rates of incorporation of [^{14}C]isoleucine in the susceptible plant, the overall picture was much the same as in the resistant plant, with ^{14}C C_{22}, C_{23}, C_{24} saturated and C_{24} $\omega6,9$ peaks (Table 4) occurring in a similar proportion to that of the UV trace. Similar to the resistant plant experiment, much of the label was present in the C_{21}, C_{23}, and C_{25} anteiso peaks. As expected the susceptible plant did not form any $\omega5$ or $\omega6$ acids.

L-Valine Incubations. The valine incubation showed a similar pattern to that of isoleucine. Thus the overall incorporation was higher in the resistant experiments, and flowers gave a higher amount of labeled anacardic acids than leaves. In a similar manner to isoleucine, no detectable incorporation of valine into anacardic acid was seen in the susceptible leaf.

The pattern of labeled anacardic acids in the resistant leaves and flowers showed that the basic mechanisms described in detail for isoleucine were operating. Hence, the C_{22} $\omega5$, C_{24} $\omega5$, and C_{22} saturated anacardic acids arise from degradation of [^{14}C]valine to [^{14}C]succinate and ultimately [^{14}C]acetyl-CoA. The high amounts of activity in the two iso peaks, particularly the C_{22} iso, is explained from the formation of [^{14}C]isobutyryl-CoA via the degradation of [^{14}C]valine in the succinate pathway. In the susceptible flower, valine was incorporated into the iso anacardic acids. The C_{22} and C_{24} saturated and C_{24} $\omega6,9$ anacardic acids were derived as above from the formation of [^{14}C]acetyl-CoA. Again, no labeled $\omega5$ or $\omega6$ anacardic acids were seen in the susceptible plant.

L-Leucine Incubations. With leucine incubations, the resistant plants gave

higher recoveries of radiolabeled anacardic acids than that observed with susceptible plants, and the flowers gave much better incorporations than leaves. As was found in the other two amino acid incubations, no labeled anacardic acids were recovered from susceptible leaves. The profile of anacardic acids in both resistant and susceptible plants closely matched the profile in the UV trace, suggesting that virtually all the [^{14}C]leucine was degraded to [^{14}C]acetyl-CoA and subsequently reincorporated into fatty acids.

It is interesting to note that during the degradation of leucine, a branched chain CoA intermediate, isovaleryl-CoA is formed. If this were to be used in fatty acid biosynthesis, as the intermediates isobutyryl-CoA and α-methylbutyryl-CoA were, iso branched chained fatty acids with an odd-numbered chain length would result, and hence anacardic acids with an odd number of carbons and an iso branched product would be formed. The iso branched chain anacardic acids have not been found in the glandular trichome exudate from either resistant or susceptible plants, which is consistent with the fact that iso branched fatty acids with an odd chain length are not found to any great extent in nature (Baker and Holloway, 1975; Radunz, 1987).

Relevance of ω6 Anacardic Acids in Resistant Plants. The finding of C_{23} ω6 and C_{25} ω6 unsaturated anacardic acids provided a new insight into how the desaturation to form the C_{22} ω5 and C_{24} ω5 anacardic acids takes place (Hesk et al., 1990). It had been previously proposed that palmitate and stearate were desaturated via a ω5 desaturase, which counts in from the methyl end of the chain, to form the ω5 C_{16} and ω5 C_{18} unsaturated fatty acids (Walters, 1988; Walters et al., 1990b). These compounds were then thought to be selected preferentially from all the other fatty acids in the pool and synthesized into the corresponding C_{22} ω5 and C_{24} ω5 acids via anacardic acid synthetase, thus accounting for their high predominance in the exudate from resistant plants.

The mechanism for how ω6 unsaturation arises can be explained by considering that instead of the ω5 desaturase counting in from the methyl end of the chain, the desaturase counts in from the carboxyl end of the fatty acid. Hence it would be a Δ11 desaturase, rather than an ω5 desaturase. This mechanism has the attraction that, in the desaturation of the C_{17} fatty acid, the Δ11 enzyme would give rise to a double bond between carbns ω6 and ω7, thus giving rise to a C_{17} ω6 fatty acid and ultimately the C_{23} ω6 unsaturated anacardic acid. The C_{25} ω6 unsaturated anacardic acid could be formed by elongation of the C_{17} ω6 fatty acid to the C_{19} ω6, by analogy with the elongation of palmitate to stearate (Stumpf, 1987), followed by anacardic acid synthesis. Similarly the C_{24} ω5 unsaturated anacardic acid is likely synthesized by elongation of the C_{16} ω5 fatty acid, formed from the Δ11 desaturase, to the C_{18} ω5 unsaturated fatty acid, followed by anacardic acid synthesis.

Support for this idea can be seen from the work of Bjostad et al. (1987), where a Δ11 desaturase has been observed in insects during biosynthesis of sex

pheromones in *Trichoplusia ni*. Incubations with [^{14}C]acetate gave rise to significant quantities of a ^{14}C-labeled C_{16} ω5 fatty acid, along with smaller amounts of labeled C_{18} ω5, C_{14} ω5, and C_{12} ω5 analogs. A further experiment using [16-^{3}H]C_{16} ω5 was shown to produce a significant amount of the labeled C_{14} ω5 fatty acid. It was thus concluded that the C_{14} ω5 and also the observed C_{12} ω5 fatty acids were derived from the chain shortening of the C_{16} ω5 and not from desaturation of the C_{12} and C_{14} saturated analogs. Similarly, it was proposed that the C_{18} ω5 derived from chain elongation of the C_{16} ω5, rather than desaturation of the C_{18} saturated fatty acid. These data would be consistent and analogous with our proposed Δ11 desaturase in geraniums.

Resistant and Susceptible Differences. From the experimental data presented, it is clear that the two plant lines metabolize the fatty acid and amino acid precursors in a similar manner, but with some important differences. Both plant lines seem to be able to accept whatever precursor ^{14}C fatty acid and amino acid they are given and incorporate them into anacardic acids. However, resistant plants more readily β-oxidize and reincorporate the acetate of the applied fatty acids, as compared with the susceptible plant. For example, in the incubation of stearate, over 90% was converted directly to the C_{24} saturated anacardic acid in the susceptible plant, whereas in the resistant plant, nearly half of the applied ^{14}C label was degraded and reincorporated into the ω5 acids. It

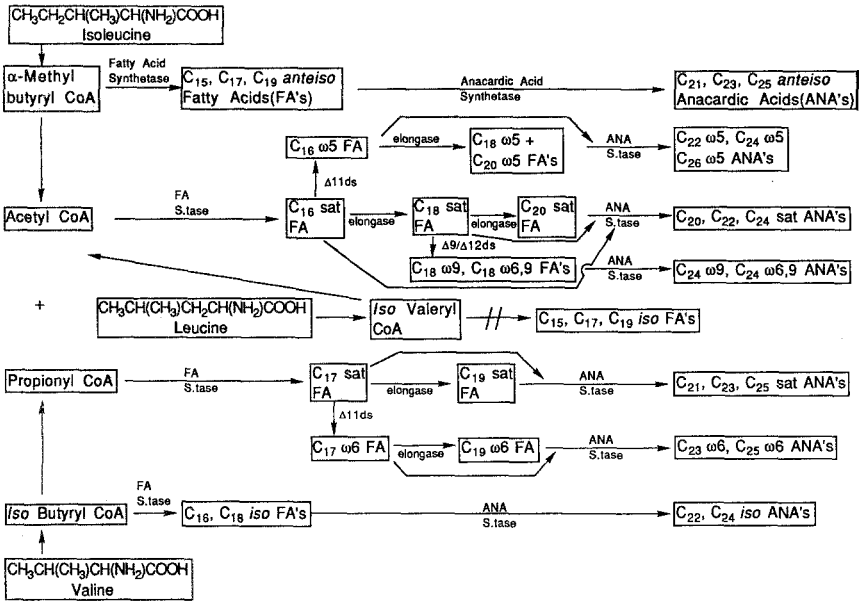

FIG. 3. Biosynthesis of anacardic acids from amino acid precursors.

is possible the β-oxidation and reincorporation is used by the resistant plant to convert non-ω5 fatty acids into ω5 anacardic acids via this indirect route. These biosynthesis data do support the earlier findings that ω5 anacardic acids are not found in susceptible plants. Hence, in the susceptible plant it is possible that the Δ11 desaturase enzyme is absent, or marginally active, and may be the potential genetic difference between the resistant and susceptible plants. It is clear that both susceptible and resistant plants similarly synthesize anacardic acids when presented with a common substrate fatty acid; however, only the resistant plant possessed the ω5 fatty acids, which are preferently incorporated into anacardic acids. Collectively, these data have resulted in a revision of the biosynthesis scheme for anacardic acids as presented in Figure 3. This scheme considers the biosynthetic differences between the resistant and susceptible plants, the presence of a Δ11 desaturase, the significant chain elongation step, and the formation of iso and anteiso anacardic acids.

CHESTNUT BARK TANNIN ASSAYS AND GROWTH OF CHESTNUT BLIGHT FUNGUS ON EXTRACTED TANNIN

SANDRA L. ANAGNOSTAKIS

The Connecticut Agricultural Experiment Station
New Haven, Connecticut 06504

(Received November 6, 1991; accepted March 27, 1992)

Abstract—Tannins extracted from the green bark of each of two Chinese, Japanese, and American chestnut trees were assayed in a protein-binding test. Four levels of tannins were added to a buffered, minimal growth medium, and a standard, virulent strain of the chestnut blight fungus was grown. There were only slight differences in protein binding between the extracts from different species. Fungal growth was better with tannin than without, but there was no difference between species extracts in their ability to improve fungal growth rate. There was also no inhibition of blight fungus growth by any of the tree tannins, so tannin toxicity is not the reason for Asian chestnut tree resistance.

Key Words—chestnut, *Castanea*, tannin, chestnut blight, *Cryphonectria parasitica, fungus.*

INTRODUCTION

Tannins and their phenolic breakdown products have been implicated in the resistance of plants to their pathogens (Cruickshank and Perrin, 1964). When the chestnut blight epidemic began in the United States in 1904 (Anagnostakis, 1987), explanations were sought for the resistance of Asian chestnut trees to this fungus disease. Chestnut trees have high levels of tannin in their bark and wood, and these were implicated by early studies (Cook and Wilson, 1916; Graves, 1926) in Asian tree resistance. Attempts have been made to prove this hypothesis (Nienstaedt, 1953; Hebard and Kaufman, 1978, J.R. Elkins, unpublished), but no conclusive data have been published. In reviewing the subject,

Roane et al. (1986) suggested that different tannin forms in different species, or different breakdown products might explain Asian tree resistance.

To further pursue the question, I have used Hagerman's (1987) protein-binding assay for the amount of total tannin (condensed and hydrolyzable) present in extracts. This was described by Hagerman and Butler (1989) as suitable for determining the potential biological activity of the tannin in a sample. Extracted tannins were mixed with a buffered growth medium, so that pH would not be a factor in affecting the blight fungus, and fungal growth rate was used as an index of effect.

METHODS AND MATERIALS

Assay Method. Radial diffusion plates were prepared as described by Hagerman (1987). A 1% agarose solution (w/v, SeaKem GTG, from FMC) was mixed and melted in a pH 5.0 buffer of 50 mM acetic acid and 60 μM ascorbic acid. When this solution had cooled to 45°C, bovine serum albumin (Sigma) was added (0.1% w/v). Aliquots of 9.5 ml were dispensed into sterile plastic Petri dishes (''100 × 15'' actually 87 × 13 mm) and allowed to cool overnight.

Uniform wells were punched in the agarose with a 4-mm-diameter cork borer. Solutions were added to the wells, and the plates were incubated at 30°C for 120 hr. The diameters of the resultant rings were measured to the nearest millimeter diameter, and when faint diffusion was evident beyond the ring only the dense white ring was measured. Baker Analyzed Tannic Acid was always included as a control.

Tannin standards were all dissolved in 70% acetone. Used were Baker Analyzed Tannic Acid, Mallinckrodt AR Tannic Acid, and quebracho (condensed) tannin purified as described by Asquith and Butler (1985) and modified by Hagerman (personal communication). The crude quebracho tannin was a gift of A.E. Hagerman.

Bark Extraction. The chestnut trees that were used for bark samples are growing at our Experiment Station Farm and our Chestnut Plantation, both in Hamden, Connecticut, and have been used in inoculation tests to compare their resistance to chestnut blight (Anagnostakis, submitted to *Can. J. Forest Res.*). Branches cut were all growing rapidly in an orchard setting (not suppressed). The two Americans [*Castanea dentata* (Marsh.) Borkh.] were R1T18 and Scientists Cliff, the two Chinese (*C. mollissima* Bl.) were R1T15 Mahogany and R9T3 Tiger Paw, and the two Japanese (*C. crenata* Sie. Zuc.) were R7T7 (an orchard type) and R34T6 (a forest type). Stems were harvested on August 9, 1990, and February 26, March 4, April 16, and June 20, 1991. Some stems were cut and stored in plastic bags in a freezer for later use.

Hagerman (1988) has shown that plant tannins are most efficiently extracted using a solution of 70% acetone. Chestnut stems with green bark (no dead bark tissue) were cut into 5-cm lengths and pieces with four or five growth rings were used. Bark was cut in strips about 3 mm wide and placed immediately into 70% acetone. Two grams of bark were extracted in 20 ml in a beaker sealed with parafilm ("M," American Can Co.) for 1 hr at room temperature. The solution was then decanted into another beaker and another 2 g of bark added and extracted for 1 hr. The extracts were filtered (Whatman No. 1 paper) and stored in tightly capped scintilation vials in a freezer.

Extract levels were calculated as "protein precipitation units," which were in square millimeters and were the squared diameters of the circles measured in the radial diffusion tests of the extracts. This number was corrected by subtracting the squared diameter of the wells, and means of replicates and the total standard error of the means calculated.

Fungal Growth Experiments. The tannin levels encountered by the fungus are grams of tannin per gram live weight of bark. Therefore, for each experiment, the number of grams of tannin per gram (fresh weight) of bark was calculated by comparing the sizes of the precipitation rings of the bark extract to the sizes of the rings formed by Baker Tannic Acid solution. The milligrams of tannin used per milliliter of agar medium ranged from 0.33 to 21 in the four experiments, with levels within each experiment about the same for the extracts used. The highest level used was equivalent to the level in fresh bark; i.e., all the extract from 1 g (fresh weight) of bark in each gram of agar medium. The second highest level was equivalent to two to five times the amount of tannin (1 mg/ml) used as a supplement in media (Anagnostakis, 1982). The other experiments used about 1 mg/ml and about half that amount. Baker (hydrolyzable) tannin, Mallinckrodt (hydrolyzable) tannin and quebracho (condensed) tannin were also used in media to test their effect on fungal growth.

Extracts and tannin standards in 70% acetone, and 70% acetone as a control, were placed in sterile 125-ml beakers and the liquid evaporated in a stream of sterile air in a laminar flow hood. Double-strength minimal medium (Puhalla and Anagnostakis, 1971) buffered with 1.0 M MES [2-(*N*-morpholino)-ethanesulfonic acid, Sigma] was added to the beakers, mixed to dissolve the dried, extracted materials, and the pH was adjusted to 6.0. These media were filter-sterilized (Nalgene disposable filters). Noble agar (Difco) was mixed as 4% in demineralized water in a separate solution and autoclaved at 18 lb of steam pressure for 50 min. The media and cooled agar solutions were mixed in equal amounts and poured into sterile plastic Petri dishes.

Rapidly growing cultures of *Cryphonectria parasitica* (Murr.) Barr strain 155 (ATCC No. 38755) on potato dextrose agar (PDA, Difco) were used for inoculum. Pieces were cut from the margin of cultures less than 7 days old with a 4 -mm - diameter cork borer and placed in the center of the media to be tested.

Cultures were grown at 28°C in 12 hr/day white fluorescent light. Colony diameters were measured to the nearest millimeter daily, and expansion per day (the slope of a linear regression line ± the standard error of the slope) was used to express growth rate (Anagnostakis and Aylor, 1984).

RESULTS

The precipitation circles formed by the control tannins were not the same in all experiments (Table 1). This is probably due to slight variations in the amount of tannin in the standard solutions or to oxidation of the tannins in solutions kept from one experiment to another. Within experiments, the results were quite consistent for control tannins and for bark extracts. A linear regression of square millimeters versus milligrams of tannin using all of the results from Baker Tannic Acid reported in Table 1 (total of 48 tests) resulted in an R^2 of 0.91, suggesting that even though there is a fourfold difference in PPT units per milligram in the six experiments, the results are comparable. The calculated total error factors for combined data (column "All" in Table 1) are low.

Amounts of tannin recovered from bark of the same trees harvested in late February, early March, mid-April, late June, and mid-August ranged from a high of 0.03 mg tannin per mg bark (August) to a low of 0.01 (June). This may have been due to the spring bark having more moisture, and thus 4 g of bark appeared to have less tannin. Samples harvested and extracted throughout the year and tannin levels compared to dry bark weights would answer this question. However, in two experiments the extracted bark was dried and weighed for comparison. Table 2 lists the amount of tannin calculated for the bark harvested in August, late February, or early March, and late June (calculation based on the PPT units of the Baker Tannic Acid in each test). With the exception of the August bark from American tree R1T18, differences are small. More tests of this are certainly needed.

Fungal growth rates in four experiments are listed in Table 3. There were no differences between fungal growth rates with three orders of magnitude difference in extract amount used. The fungus grew a little better with bark extract than with commercial tannins in two of three experiments and better with tannin than without in two of four experiments (statistics in Table 3). There was no indication of inhibition due to tannins from any of the trees, even at levels assumed to be like those in fresh bark. The small amount of purified quebracho tannin available was used in one experiment, and 0.01 mg/ml, two orders of magnitude less than the amount of tannic acid used to supplement media, supported good growth.

DISCUSSION

Nienstaedt (1953) used old mycelium for his tests of toxicity (15 and 31 days old) and I used mycelium from the edges of rapidly growing colonies less than 7 days old. The older age of his cultures resulted in highly variable results, but there were still no significant differences between growth rates of a virulent culture on purified tannins from a Chinese, a Japanese, and an American tree in (unbuffered) PDA. A similar conclusion was reached by G. Farias (unpublished) in her study of tannases. Delen (1975) reported differences in the amount of tannin in bark of 11 varieties of European chestnut trees (*C. sativa* Ml.), but extraction and assay techniques are not detailed. He also found no inhibition of fungal growth using commercial tannin in the growth medium.

J.R. Elkins, P. Graham, and W. Pate (unpublished) have found that *C. parasitica* can use hamamelitannin extracted from chestnut bark as a carbon source. J.R. Elkins (unpublished) extracted (with water) large amounts of hamamelitannin from American chestnut bark, but little from the bark of Asian trees. He suggests that this form of tannin encourages the growth of the blight fungus

in American bark but not in Asian bark. Since both condensed and hydrolyzable tannins are detected by the plate diffusion method used in my study, this cannot be confirmed. However, the fact that no differences were seen in fungal growth rates on media with extracts used at bark levels suggests that tannins from American chestnut bark are not a better food source for the blight fungus than those from Asian chestnut bark.

Factors other than tannins have been implicated in the resistance of Asian chestnut trees to the chestnut blight fungus. A preliminary report by Samman et al. (1978) described a long-chain unsaturated fatty acid that inhibited fungal growth, and McCarroll and Thor (1985) described a protein isolated from the inner bark of Chinese chestnut trees that strongly inhibited the activity of polygalacturonase from the blight fungus. It is possible that the water extracts used by Cook and Wilson (1916) and by Nienstaedt (1953) contained some of these compounds. Tannin toxicity does not appear to supply the answer.

GENETIC COMPONENT OF VARIATION IN CHEMICAL DEFENSE OF *Oreina gloriosa* (COLEOPTERA: CHRYSOMELIDAE)

F. EGGENBERGER and M. ROWELL-RAHIER*

Zoologisches Institut der Universität
Rheinsprung 9, CH-4051 Basel, Switzerland

(Received November 13, 1991; accepted April 2, 1992)

Abstract—Defensive secretions of adult *Oreina gloriosa*, liberated at the surface of the pronotum and elytra, contain a complex mixture of cardenolides, and ethanolamine. Proportions and concentrations of constituents determined by reverse-phase HPLC show considerable variation among individual beetles. Heritabilities of proportions of five main components were estimated by mother–offspring regression providing a validation of the less reliable full-sib correlation estimates. Average heritabilities based on the two methods were 0.51 and 0.58, respectively, estimated by using offspring of two age groups. Regression estimates of 2- and 10-week-old offspring differed significantly for one secretion constituent (RT16). Heritability estimates of concentrations of 16 secretion components were calculated by full-sib correlation analysis. Average heritability was 0.45, indicating a significant genetic component. Estimates did not differ significantly between the two age groups. We also estimated heritabilities of concentrations by a two-way model including data from offspring of both age groups. Heritability estimates based on this model are thought to correspond approximately to estimates based on samples from natural populations. The average of these estimates was lower ($h^2 = 0.31$) than the average heritability of each age group separately ($h^2 = 0.45$), suggesting a developmental effect on variation in chemical defense of *O. gloriosa*.

Key Words—*Oreina gloriosa*, Coleoptera, Chrysomelidae, chemical defense, allomone, cardenolides, quantitative variation, heritability.

INTRODUCTION

The alpine beetle *Oreina gloriosa* belongs to one of the most conspicuous families of Coleoptera, the Chrysomelidae. Adult *O. gloriosa* are slow-moving,

*To whom correspondence should be addressed.

0098-0331/92/0800-1375$06.50/0 © 1992 Plenum Publishing Corporation

brightly colored, and they often densely aggregate on their host plant *Peucedanum ostruthium* (Apiaceae), resulting in high visual exposure to predators. Nevertheless this chrysomelid shows a high survival rate (0.73–0.96 per week) (Eggenberger, 1989) and can live as long as three years (Rowell-Rahier, unpublished data), suggesting an effective protection by its chemical defense (Pasteels et al., 1988). The defensive strategy of adult *O. gloriosa* is based on the exocrine secretion of a complex mixture of cardenolides and ethanolamine at the surface of the pronotum and elytra (Van Oycke et al., 1988). Since the host plant of this monophagous beetle is known to contain no cardenolides, *O. gloriosa* produces its defensive chemicals de novo. The ability of leaf beetles to synthesize cardenolides de novo has been confirmed by labeling experiments (Van Oycke et al., 1987).

Chemical defense is an important component of the interaction between prey and predator, which is thought to be under strong selection for efficiency, since production, particularly de novo biosynthesis, of defensive chemicals is costly (Rowell-Rahier and Pasteels, 1986). In order to produce evolutionary change, however, selection requires heritable variation, which is measured and expressed as additive genetic variance. The ratio of additive genetic variance to phenotypic variance is defined as the heritability (h^2), which is estimated from the degree of resemblance between relatives by regression of offspring on parents or correlation between sibs (Falconer, 1989).

Although genetic sources of variation in exocrine secretions were shown to exist in pheromones of butterflies (Sappington and Taylor, 1990) and hypothesized for the kairomones of a prey–predator interaction (Herms et al., 1991), this is the first report dealing with heritabilities of chemical defense characters.

We recently reported on variation in chemical defense between populations of *O. gloriosa* (Eggenberger and Rowell-Rahier, 1991). Interpopulational variation in the constituents of the defensive secretion proved to be significantly correlated with genetic variation of six enzyme loci, suggesting that a considerable part of the total phenotypic variation in chemical defense is caused by genetic differences.

In this study we demonstrate a significant genetic component to the intrapopulational variation in chemical defense of *O. gloriosa*.

METHODS AND MATERIALS

Collection and Culture of Beetles. One hundred fifty adult *O. gloriosa* were collected randomly in July 1989 in Saas (Wallis, Swiss Alps) and brought in cooled boxes to the laboratory. The beetles were maintained individually in separate plastic containers on their food plant *P. ostruthium*, which was shipped weekly from the original locality. The offspring of the 48 collected females,

which had mated in the field with unknown males, were reared in plastic containers at constant temperature (17°C) and a constantly changing light–dark regime corresponding to natural conditions. In September 1989 all larvae buried themselves in the substrate provided: soil covered with regularly moistened spruce bark. Pupation was not completed by November, and the temperature was decreased to 2°C. At the end of June 1990, the temperature was raised to 17°C, triggering pupation and the emergence of 553 adults. The offspring of 27 females were maintained separately under the conditions previously described. The 27 families were selected so that there were at least five offspring per family.

Sample Preparation and Chromatographic Analysis. Pronotal secretion liberated as a result of mechanical irritation was collected in a capillary tube (0.2 mm ID) and quantified. The parental generation was "milked" in July 1989, a few days after arrival in the laboratory. Samples were dissolved in 50 μl acetonitrile–water 1 : 10 and stored individually at −70°C. The secretions of one group of offspring were sampled in July 1990 (two weeks after emergence) and those of the other group in September 1990 (10 weeks after emergence). Individual samples were dissolved in 50 μl acetonitrile–water 1 : 10 plus 2 μg ouabain (Merck), as internal standard. After filtration (0.2 μm pore size), 20-μl aliquots were analyzed by HPLC, [two-pump system (Waters 510); detector: photodiode array (Waters 994), 220 nm; column: Macherey-Nagel cartridge, C-18, 3 μm, 4 × 130 mm; eluent: chromatography grade acetonitrile (Baker) and water (Merck), 15–42% acetonitrile linear in 36 min, 0.45 ml/min; data analysis system: Maxima 820 data station] (Figure 1). The proportions of the main secretion components (RT3, RT9, RT16, RT28, and RT32) were calculated by dividing the respective peak area by the total area of main peaks. Concentrations (micrograms ouabain equivalents per microliter secretion) of 16 secretion components were twice their peak area divided by the area of the internal standard peak (ouabain) and the secretion volume. Since samples of the parental generation were run without an internal standard, concentrations could be calculated only for offspring.

Statistical Methods. Data were analyzed using SAS (SAS Institute Inc., 1990) on a VAX 8840. Weighted regression of offspring on mother was carried out using PROC REG. Weighting factors for regression were calculated by the procedure of Falconer (1989). Heritability estimates were twice the slope of the regression with a precision of twice the standard error of the slope. Random effect model analyses of variance were performed using PROC GLM. Prior to analyses of variance, proportions were arcsine transformed (Sokal and Rohlf, 1981). Concentrations were square-root transformed since residual distributions showed a poorer fit to Gaussian distributions (PROC UNIVARIATE) if other commonly applied transformations (Sokal and Rohlf, 1981) were used. Variance components were estimated by the maximum likelihood method (PROC VARCOMP), which agreed better with heritability estimates based on mother–off-

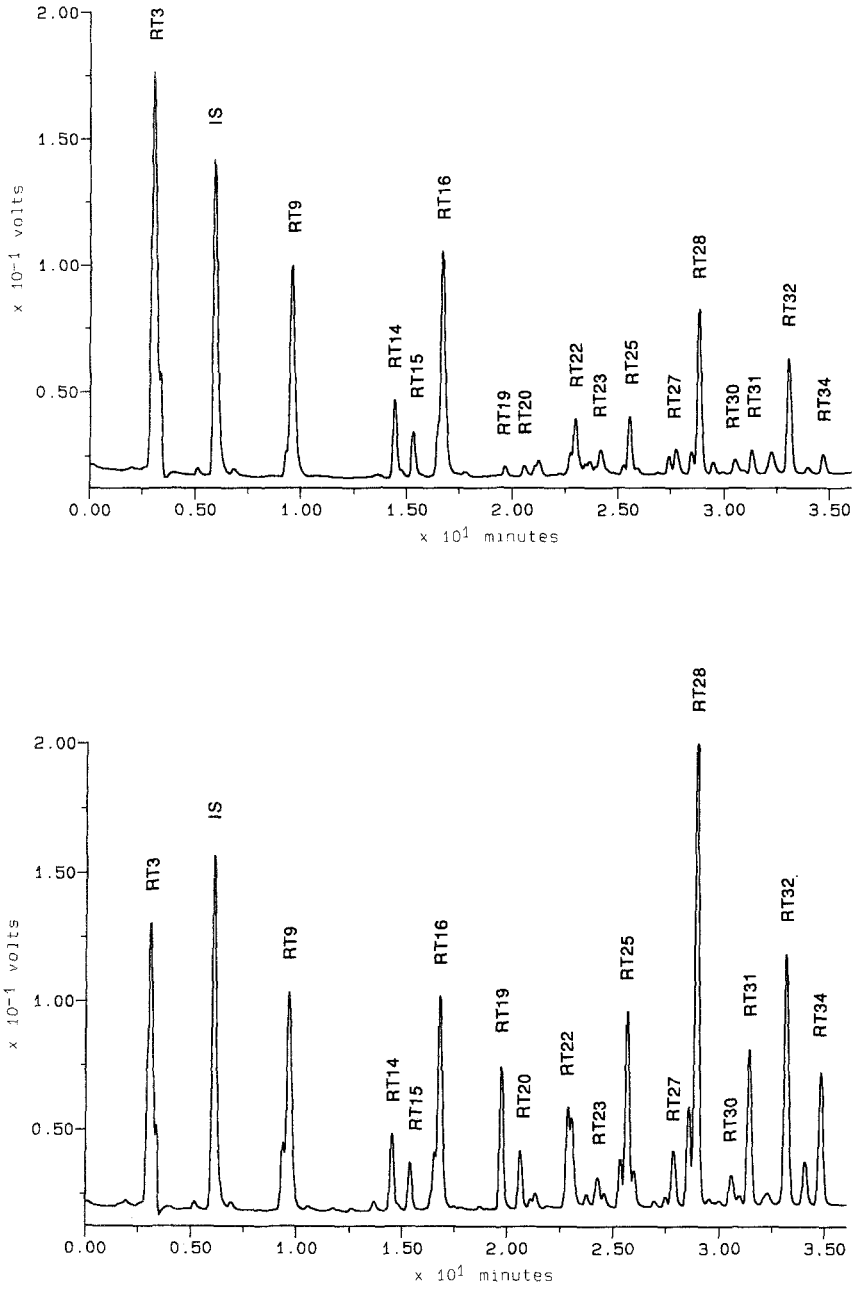

FIG. 1. Chromatograms obtained by reverse-phase HPLC of the defensive secretions emitted by individual beetles.

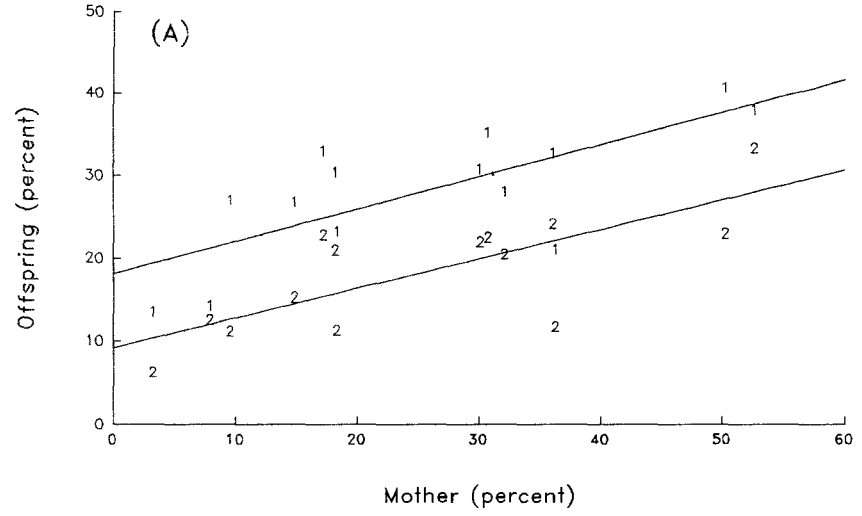
spring regression than either the restricted maximum likelihood method or the type-1 sum-of-squares method. Genetic and developmental effects were designated as random since we were interested in the variation that exists when genotype and age are randomly distributed as in natural populations. Heritability estimates based on full-sib analysis were twice the intraclass correlation coefficient (among-family variance component divided by total variance) with standard errors estimated by the delta technique (Bulmer, 1985).

Heritability estimates of proportions of secretion components were estimated using both parent–offspring regression and full-sib correlation analysis. Parent–offspring regression was carried out with data from 14 females and two different groups of their offspring, which were "milked" two and 10 weeks after emergence, respectively. The proportions of each of the five main components in the secretion of individual offspring were averaged per family and regressed for each age group separately on the proportions measured in their individual female parents. Full-sib correlation analysis was performed using data from the 138 living 2-week-old offspring belonging to 27 families and 92 10-week-old offspring of 25 females, respectively. (The numbers of families used for estimating heritabilities were different for parent–offspring regression and full-sib correlation because secretions of female parents were not always available.) The data for each group were tested for differences among families, which was assumed to be a random factor.

Heritabilities of concentrations of secretion components were estimated using full-sib correlation analysis. (Parent–offspring regression was not used since concentrations were not available for the parental generation.) Full-sib correlation was carried out on the same two age groups as used to estimate heritabilities of proportions. However, since some data on secretion volume were lost, the number of analyzed offspring was different. Data for each age-group were tested for differences among families.

RESULTS

Proportions of Five Main Components. Heritability estimates based on parent–offspring regression were significant ($P < 0.05$) for RT9 and RT16 of both age groups (Figure 2) and for RT3 of 2-week-old offspring (Table 1). Estimates for RT16 differed significantly ($P < 0.05$) between the two age groups. The among-family variance term was significant (Tables 2 and 3) for all secretion components in both age groups, with the single exception of RT3 in 10-week-old offspring. Heritabilities estimated by full-sib correlation analysis were significant for RT9, RT16, and RT28 in both age groups and for RT3 in 2-week-old offspring (Tables 2 and 3). Mother–offspring estimates were slightly lower than full-sib estimates, which are known to be biased by dominance and



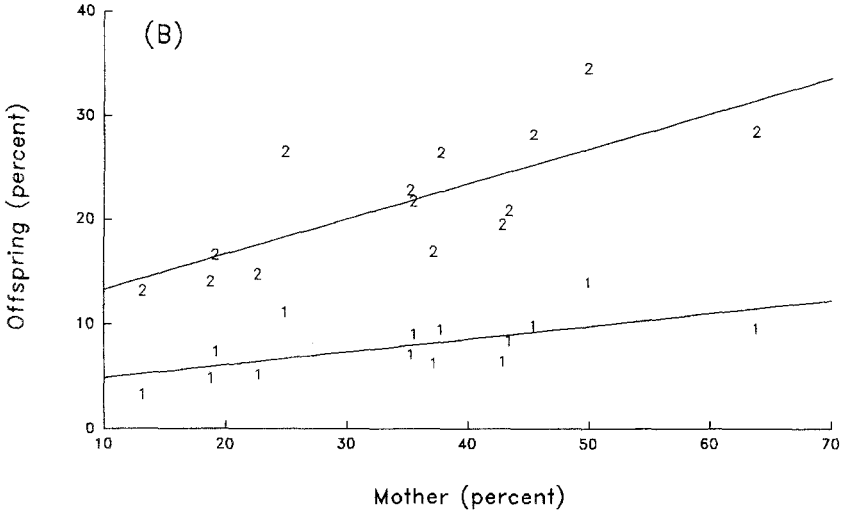


FIG. 2. Proportions of constituents in the secretion of offspring (averaged per family) in relation to those from the secretion of their mothers. Regression were carried out with 2-week-old (1) and 10-week-old (2) offspring. Slopes did not differ significantly for RT9 (A) but were significantly ($P < 0.05$) different for RT16 (B).

and RT31) were significant for one age group only (Tables 4 and 5). Although average heritabilities of the two age groups were almost identical, some estimates showed apparent differences that were not significant when tested using Fisher's z-transformation (Zar, 1984). Heritabilities for both age groups together were estimated by a two-way model designating family, age, and the interaction term as random effects. P values for among-family variance components are listed in Table 6, showing 13 significant among-family variance components of which nine were also significant for each age group separately (Tables 4 and 5). Heritability estimates were significant for seven secretion components (RT9, RT15, RT20, RT22, RT28, RT31, and RT34). However, only two estimates (RT9 and RT34) were also significant for each age group when considered separately. Average heritability was lower (0.31) than the estimates of each age group considered separately (0.44 and 0.46), because variance associated with age increased the total variance and because some genetic variance was accounted for by the interaction term.

DISCUSSION

Heritable variation is required for evolutionary adaptation. Chemical defense is thought to be the result of evolutionary adaptation. In this study we found significant heritabilities for quantitative traits of chemical defense as estimated by mother-offspring regression and full-sib correlation analysis. Hence, predators may be directing the evolution of the chemical defense of *O. gloriosa*.

Since heritability estimates based on full-sib correlation are likely to be inflated by variance due to common environment (Falconer, 1989), we tried to minimize the environmental variance component by experimental design: all adult beetles were kept randomly distributed under the same controlled environmental conditions. Full-sib estimates are further biased by dominance variance (Falconer, 1989), a part of nonadditive genetic variance due to dominance (heterozygote not intermediate between homozygotes) or overdominance (hetero-

zygote more extreme than either homozygote). Mother–offspring regression estimates are known to be less biased and therefore more reliable than full-sib estimates (Falconer, 1989). Because data on secretion concentrations in the parental generation were not available, mother–offspring estimates could be calculated only for proportions. However, full-sib estimates were not significantly different from mother–offspring estimates, providing a validation of the less reliable full-sib estimates.

Standard errors of heritability estimates based on full-sib correlation are rather large, due to the relatively low power of maximum likelihood estimates (Scheiner and Lyman, 1989). This is obvious, since many heritability estimates are not significantly different from zero, even though the ANOVAs show significant among-family variance components.

We have suggested previously that quantitative variation in chemical defense between populations of *Oreina gloriosa* is partly genetically determined (Eggenberger and Rowell-Rahier, 1991). The present study shows the average heritability of proportions to be 54% of the intrapopulational variation, confirming this hypothesis.

There were no significant differences between the full-sib estimates of 2-week-old and 10-week-old offspring, not even for RT16, which shows significantly different mother–offspring regression estimates (Figure 2). Since heritability is the ratio of additive genetic and phenotypic variance, heritability change during development is a consequence of drift of this ratio, which can be due to change in both genetic and environmental variance. Change in genetic variance is thought to be the result of different gene expression. Genetic control of physiological response is reviewed by Humphreys (1991). Change in phenotypic variance may be caused by environmental or interaction effects. The pattern of change in the relative magnitude of phenotypic and additive genetic variance during growth can be rather complex (e.g., Henrich, 1989).

We also present heritabilities of concentrations based on a two-way model including data from both age groups. These estimates are thought to correspond more closely to estimates of populations with natural age structure than do estimates based on data from each age group separately. However, it should be emphasized that heritabilities depend on the magnitude of all variance components and therefore are valid only for the population for which they are estimated.

The biological significance of the complexity of exocrine secretion mixtures is obscure. It is thought that different components of the secretion may exert different effects or that the proportions of different components may confer specificity (Chapman, 1982). In a three-component allomone system investigated by Dettner and Grümmer (1986), the ratio of constituents was shown to correlate with the maximal penetration rate through the integument of a predatory arthropod. The secretion of *O. gloriosa* may be even more complex than pre-

sented here, since only major components detectable at UV 220 nm were quantified. All constituents are highly polar and, with the exception of RT3, show UV spectra typical of cardenolides. Because of the similarity of the constituents, the complexity of the mixture may be the inevitable consequence of its biosynthesis rather than of significance for chemical defense (or both). The exocrine secretion of *O. gloriosa* may also act as a pheromone (e.g., sex pheromone) and the mixture of constituents may therefore be a component of reproductive fitness. However, to our knowledge, there is no evidence supporting pheromonal function of the secretion.

In summary, heritability estimates show a considerable part of the variation in chemical defense of *Oreina gloriosa* to be genetically determined. Physiological and environmental sources of this variation will be discussed in following papers.

(Received December 5, 1991; accepted April 2, 1992)

Abstract—The ability of (*E*)- and (*Z*)-6-nonen-2-one to serve as precursors of the common scolytid pheromones *endo*- and *exo*-brevicomin was examined in vivo. When mountain pine beetles (MPB), *Dendroctonus ponderosae* Hopkins, or western balsam bark beetles (WBBB), *Dryocoetes confusus* Swaine, were exposed to [6,7-D_2](*E*)-6-nonen-2-one, the *endo*-brevicomin produced was enriched with two deuterium atoms per molecule (as determined by GC-MS), indicating that (*E*)-6-nonen-2-one served as a precursor of this pheromone. Similarly, when the beetles were exposed to [4,4-D_2](*Z*)-6-nonen-2-one, the *exo*-brevicomin produced was enriched with two deuterium atoms per molecule. Evidence in support of biological relevance of the latter observation include: (1) (*Z*)-6-nonen-2-one was found in the volatiles of male MPBs and WBBBs, indicating that this is a natural metabolite; (2) the *exo*-brevicomin produced by MPB was shown to be of natural (+) chirality by complexation chromatography; and (3) female WBBBs and MPBs (which are not known to produce *exo*-brevicomin) produced significantly less *exo*-brevicomin when exposed to the precursor than did the males.

Key Words—Bark beetles, *exo*-brevicomin, *endo*-brevicomin, Coleoptera, deuterium, (*E*)-6-nonen-2-one, (*Z*)-6-nonen-2-one, pheromone biosynthesis, Scolytidae.

INTRODUCTION

Scolytid bark beetles are well known as economically important forest pests. There is little doubt that effective communication between conspecific individuals during activities such as host-colonization and mate-finding has contributed to the reproductive success of these beetles. Beetles use visual and vibrational cues for communication, but olfactory signals (pheromones) may be most important (Borden, 1985). Most of the scolytid pheromones identified to date are either terpenoid alcohols, the corresponding ketones, or bicyclic oxygen heterocycles (Borden, 1985; Vanderwel and Oehlschlager, 1987). Most terpenoid pheromones appear to be derived from host monoterpenes (Vanderwel and Oehlschlager, 1987), while the biosynthetic origins of the other pheromones are unknown. Silverstein (cited by White et al., 1980) speculated that the biosynthetic pathways to the bicyclic compounds may be similar to laboratory routes to these pheromones. Francke (1981) suggested that (*Z*)-6-nonen-2-one may serve as the natural precursor of *exo*-brevicomin. (*Z*)-6-Nonen-2-one is produced in conjunction with brevicomin by males of the ash bark beetle, *Leperisinus varius* F. (Francke, 1978, 1981). The two ketoalkenes (*Z*)- and (*E*)-6-nonen-2-one have served as precursors of *exo*- and *endo*-brevicomin, respectively, in laboratory syntheses (Rodin et al., 1971).

Our objective was to test the hypothesis that (*Z*)- and (*E*)-6-nonen-2-one serve as precursors to the brevicomins in vivo (Figure 1), in two species of bark beetles: mountain pine beetles (MPB), *Dendroctonus ponderosae* Hopkins, and western balsam bark beetles (WBBB), *Dryocoetes confusus* Swaine. Newly emerged, adult male MPB and WBBB produce both *exo*- and *endo*-brevicomin (Borden, 1985; Borden et al., 1987). In the past, investigations of the biosynthesis of these pheromones were limited by the technical difficulties involved in working with small quantities of volatile compounds. However, these difficulties

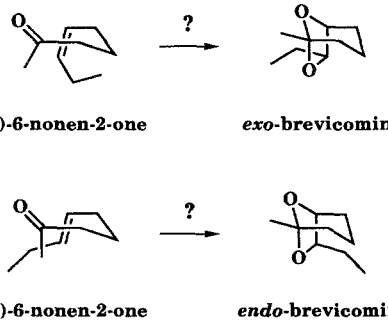

FIG. 1. (*Z*)- and (*E*)-6-nonen-2-one, logical precursors of *exo*- and *endo*-brevicomin, respectively.

were overcome by the use of stable isotope-labeled precursors, and detection of their incorporation by gas chromatography–mass spectroscopy (GC-MS).

METHODS AND MATERIALS

Insects

Lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann, infested with MPB was collected near Princeton, British Columbia. The cut ends of the logs were sealed with hot paraffin wax to prevent desiccation. The logs were either used fresh or stored at 4°C until they were placed in cages held at approximately 28°C. Emergent beetles were collected daily, and their sex was immediately determined by the shape of the seventh abdominal tergite (Lyon, 1958). The insects were either used the same day or were stored on moistened paper at 4°C in loosely capped jars for a maximum of one week. Only healthy appearing individuals were selected for experiments.

Subalpine fir, *Abies lasiocarpa* (Hook.) Nutt., infested with WBBB was collected near Merritt, British Columbia. The logs and beetles were treated as described for MPB. The sex of the emergent beetles was determined by the presence (females) or absence (males) of the setal brush on the frons (Bright, 1976).

Treatment of Insects

The approach taken to determine if (*E*)- and (*Z*)-6-nonen-2-one could serve as precursors of *endo*- and *exo*-brevicomin, respectively, in vivo was to expose insects to vapors of the deuterated analogs of (*E*)- and (*Z*)-6-nonen-2-one ([6,7-D_2] and [4,4-D_2], respectively) and to check (by GC-MS analysis) for the incorporation of deuterium into the brevicomins produced by the insects.

Newly emerged male MPB or WBBB were individually caged in 3.5 ml screw-cap vials (Gries et al., 1990), into which either 0 (control), 0.1 (for MPB) or 0.05 (for WBBB) μl of the labeled hypothesized precursor was placed. The sealed vials were stored at room temperature in the dark. After 24 hr insects were either: (1) extracted immediately (whole beetles were individually extracted with hexane); or (2) individually aerated. Purified, moisturized air was drawn over the beetles, and the volatiles emanating from them were trapped on Porapak Q (50–80 mesh, Applied Science Laboratories). After 48 hr, the aerated insects were individually extracted to give a second whole beetle extract. Captured volatiles were eluted from the Porapak Q with diethyl ether.

Analyses of exo- *and* endo-*Brevicomin in Extracts*

Analyses by GC were performed on a Hewlett-Packard 5890 GC equipped with a capillary inlet system and an FID. Samples were introduced by splitless injection onto a DB-1 column (15 m × 0.25 mm ID, 0.25 μm film thickness). The oven temperature program was: 50°C for 1 min, then 4°C/min to 80°C for 10 min, followed by an increase of 25°C/min to a final temperature of 275°C for 10 min. The brevicomins were identified by comparing their GC retention times and MS fragmentation patterns with authentic standards and were quantified using 3-octanol as an internal standard.

Mass spectra were recorded on a Hewlett-Packard 5985B GC-MS system by electron impact (EI, 70 eV) or by chemical ionization (CI, using isobutane as the ionizing gas). GC–Selected Ion Monitoring–Mass Spectroscopy (GC-SIM-MS) was performed as described by Vanderwel (1991).

Determination of Chirality of exo-*Brevicomin*

The chirality of *exo*-brevicomin produced by MPB was determined by complexation chromatography (Schurig et al., 1983).

Prior to analyses nonvolatile residues were removed from the extracts. The crude extracts from control (untreated) and [4,4-D_2](*Z*)-6-nonen-2-one-treated male and female MPBs (15 per treatment) were pooled and soaked onto a glass wool plug placed at the front end of a glass tube (30 × 0.8 cm), which had been bent into an ω shape, leaving the first 2 cm straight and horizontal. The bottom half of the ω-shaped tubing was cooled with liquid nitrogen, thus forming two traps. The crude beetle extract was volatilized by passing a gentle stream of nitrogen gas through the glass wool plug, which was finger-warmed through the glass. Volatiles were collected in the glass traps, concentrated to 30 μl, and purified by preparative GC on a Varian model 1200 gas chromatograph equipped with a 10:1 effluent splitter, FID, thermal gradient collector, and a stainless-steel column (3.0 m × 3.2 mm ID) packed with 10% SP-1000 on Chromosorb W (100/120). The oven temperature program was: 70°C for 2 min, then 6°C/min to 180°C. The chirality of the brevicomin produced by the insects was determined by comparison of the retention times with authentic standards on a 25-m × 0.25-mm (ID) fused silica capillary column coated with nickel-*bis*(1*R*)-3-heptafluorobutyrylcamphorate (50°C for 2 min, then 2.5°C/min to 85°C for 30 min) (Schurig et al., 1983).

Collection of Airborne Volatiles from Male MPB and WBBB

Three hundred male MPB or 180 male WBBB were inserted into a "tube aeration apparatus" (Gries et al., 1992). Purified air was drawn through the tube for 10 days, while the volatiles were trapped on Porapak Q. Captured

volatiles were eluted from the Porapak Q with pentane–diethyl ether (95:5), and analyzed by GC-MS.

Statistical Analyses

Data were analyzed by analysis of variance (ANOVA). Where more than two treatments were used, means were separated by Tukey's multiple range test ($P = 0.05$).

Purchased/Donated Chemicals

$LiAlD_4$ (98 atom % D) and $NaBD_4$ (98 atom % D) were purchased from Sigma Chemical Company; deuterium oxide (D_2O, 99.9 atom % D) was purchased from Merck-Sharp-Dohme. Leaf alcohol [(*Z*)-3-hexen-1-ol] was purchased from Bedoukian Research Inc. Palladium on activated carbon (10%) was purchased from Strem Chemicals, Inc. Phero Tech, Inc. donated (*E*)- and (*Z*)-6-nonen-2-one.

Synthesis of Stable Isotope-Labeled Chemicals

All reactions were performed in flame-dried glassware with magnetic stirring. Where necessary, inert atmospheres of either Ar or N_2 were employed. After quenching, the usual workup involved: extraction of the aqueous phase three times with diethyl ether; combination of the organic extracts and washing once with brine; drying the organic layer with anhydrous $MgSO_4$; filtration; and removal of solvent by rotary evaporation under reduced pressure (without heating).

[^{1}H]NMR spectra were recorded at 400.13 MHz in $CDCl_3$ (unless stated otherwise) on a Bruker WM-400 Spectrometer. Signal positions are in δ; coupling constants (J) are in Hz.

Preparation of [4,4-D_2](Z)-6-Nonen-2-one

(Z)-3-Hexenoic Acid. Chromic acid, 2.5 M, was added dropwise to a solution of leaf alcohol [(*Z*)-3-hexen-1-ol, 60 mmol] in acetone (200 ml) at 0°C, until the yellow color persisted (about 80 mmol). The solution was stirred for an additional 15 min at room temperature, then 2-propanol was added dropwise until the green color persisted. The reaction mixture was then filtered through Celite. The acetone was removed in vacuo. The remaining oil was dissolved in diethyl ether, washed with brine, and dried over anhydrous $MgSO_4$. Removal of the solvent in vacuo gave a green oil. Distillation under vacuum left a colorless oil (4.15 g, 61% yield), bp 104–110°C (ca. 10 mm Hg), 79% pure by GC analysis. [^{1}H]NMR: 0.97 (3H, t); 2.04 (2H, dt); 3.10 (2H, d); 5.43–5.52

(1H, m); 5.54–5.63 (1H, m); 10.25–10.90 (br s). MS (EI), *m/z* (relative abundance): 114 (M^+, 56); 68 (82); 60 (58); 55 (100); 41 (90).

[*1,1-D*$_2$] *Leaf Alcohol.* (*Z*)-3-Hexenoic acid (26 mmol) was dissolved in anhydrous diethyl ether (20 ml), and the solution was added dropwise to a cooled (0°C) suspension of $LiAlD_4$ (21.7 mmol) in anhydrous diethyl ether (50 ml). After the addition was complete, the reaction mixture was stirred at 0°C for an additional 1 hr. The reaction was quenched by pouring into ice-cold 2% HCl and worked up in the usual fashion to yield a colorless oil (2.21 g, 82% yield), 93% pure by GC analysis. [^{1}H]NMR: 0.96 (3H, t); 1.50 (1H, br s); 2.07 (2H, p); 2.30 (2H, d); 3.64 (0.3H, t); 5.27–5.37 (1H, m); 5.50–5.60 (1H, m). MS (EI) *m/z* (relative abundance): 102 (M^+, 34); 84 (58); 69 (100); 68 (45); 67 (48); 41 (90).

[*4,4-D*$_2$](Z)-*6-Nonen-2-one.* The [1,1-D_2] leaf alcohol thus formed was subjected to the reaction conditions described by Rodin et al. (1971) to form [4,4-D_2](*Z*)-6-nonen-2-one in an overall yield of 26%. The final product was 96% pure by GC analysis. [^{1}H]NMR: 0.95 (3H, dt, J = 1 Hz, J = 8 Hz); 1.57–1.67 (0.5H, m); 1.96–2.07 (4H, m); 2.12 (3H, s); 2.40 (2H, br s); 5.23–5.31 (1H, m, J = 1); 5.35–5.44 (1H, m, J = 1). MS (EI) *m/z* (relative abundance): 142 (M^+, 11); 84 (86); 69 (100); 68 (50); 67 (63); 43 (78). By GC-SIM-MS analysis the product was 88% enriched with two deuteriums and 12% unenriched.

Preparation of [*4,4-D*$_2$](Z)-*6-Nonen-2-ol*

$NaBH_4$ (ca. 3 mmol) dissolved in 95% ethanol (1 ml) was added dropwise to [D_2](*Z*)-6-nonen-2-one dissolved in 95% ethanol (1 ml). The reaction mixture was stirred at room temperature for 1 hr, before it was quenched with 2% HCl (10 ml). The usual workup yielded a colorless oil (86 mg, 85% yield), 98% pure by GC analysis. [^{1}H]NMR: 0.94 (3H, t, J = 7.5); 1.18 (3H, d, J = 6.0); 1.39–1.47 (2H, m); 1.50–1.54 (0.7H, br s); 1.97–2.07 (4H, m); 3.74–3.83 (1H, sx, J = 6.0); 5.27–5.41 (2H, m). MS (EI) *m/z* (relative intensity): 144 (M^+, 10); 84 (100); 73 (53); 69 (79); 68 (60); 67 (44).

Preparation of [*6,7-D*$_2$](E)-*6-Nonen-2-one*

1-Tetrahydropyranyloxy-3-hexyne. To a mixture of 4-tetrahydropyranyloxy-1-butyne (100 mmol) in THF (200 ml) was added dropwise *n*-butyllithium (44 ml, 110 mmol) at −78°C. After addition the mixture was stirred for 30 min. 1-Bromoethane (150 mmol) followed by HMPA (30 ml) were added at −78°C, and the mixture was allowed to warm to room temperature over a period of 18 hr. After adding brine, the reaction mixture was worked up as usual to yield 16 g (88% yield) of product which was 90% pure by GC analysis. [^{1}H]NMR: 1.04

(3H, t, J = 6.75); 1.16–1.83 (6H, m); 1.91–2.21 (2H,); 2.43–2.64 (2H, m); 3.22–3.64 (2H, m); 3.72–4.1 (2H, m); 4.76 (1H, t, J = 4).

3-Hexyn-1-ol. The above product and *p*-toluenesulfonic acid (2–3 crystals) in methanol (100 ml) were stirred for 2 hr at room temperature. Methanol was removed and the product purified by silica gel column chromatography to give the product in 68% yield. [^{1}H]NMR: 1.0 (3H, t, J = 7.98); 1.42 (1H, bs); 1.9–2.08 (2H, m); 2.16–2.34 (2H, m); 3.5 (2H, t, J = 7.98). MS (EI) *m/z* (relative intensity): 98 (65); 83 (24); 68 (100); 53 (22).

[3,4-D_2](E)-3-Hexen-1-ol. $LiAlH_4$ (119 mmol) in a mixture of dry diglyme (50 ml) and THF (10 ml) was heated and nearly 7 ml of low boiling fraction was distilled off. 3-Hexyn-1-ol (60 mmol) in diglyme (10 ml) was added at 0°C. After addition the mixture was heated at 140°C for 48 hr. The mixture was hydrolyzed with 20% DCl in D_2O at 0°C. The aqueous layer was extracted with pentane (8 × 25 ml) and the combined organic layers washed with brine (8 ×), dried, and the solvents removed as usual to provide 4.6 g (75% yield) of the product, 92% pure by GC analysis. [^{1}H]NMR: 1.0 (3H, t, J = 7.9); 1.47 (1H, t, J = 6.5); 1.89–2.15 (2H, q, J = 7.9); 2.26 (2H, t, J = 6.5); 3.55–2.72 (2H, q, J = 6.5).

[3,4-D_2](E)-3-Hexenyl Tosylate. To [3,4-D_2](*E*)-3-hexen-1-ol (45.5 mmol) was added *p*-toluenesulfonyl chloride (49.8 mmol) and powdered KOH divided into five portions that were added over 20 min. The solution was stirred for 1 hr and quenched by pouring into ice water (200 ml). The usual workup yielded 10 g of product (86% yield), which was 95% pure by GC analysis. [^{1}H]NMR (C_6D_6): 0.83 (3H, t, J = 6.55); 1.77–1.81 (2H, q, J = 6.55); 1.86 (3H, s); 2.06 (2H, t, J = 6.55); 3.86 (2H, t, J = 6.55); 6.72 (2H, d, J = 9.8); 7.77 (2H, d, J = 9.8).

[6,7-D_2](E)-6-Nonen-2-one. To a mixture of sodium salt of ethyl acetoacetate (46.87 mmol) in anhydrous ethanol (60 ml) at 0°C was added the tosylate prepared above (39 mmol) in ethanol (10 ml). The reaction mixture was refluxed (100°C) for 16 hr. The ethanol was removed, and brine was added to the syrupy residue. The usual workup, followed by silica gel column chromatography (CH_2Cl_2) gave the semipure product (4.8 g). The semipure ester was subjected to basic hydrolysis. After stirring with aqueous NaOH (3 g in 50 ml) for 72 hr at room temperature, the basic solution was washed once with ether and acidified with 18 N sulfuric acid, and heated for 6 hr at 90°C to complete the decarboxylation. The aqueous solution was extracted with pentane (5 × 30 ml). The organic layers were combined and washed successively with saturated $NaHCO_3$ and brine, dried over anhydrous $MgSO_4$, and the solvents removed at atmospheric pressure to give the product (1.6 g, 29% yield), which was 96% pure by GC. [^{1}H]NMR: 0.92 (3H, t, J = 6.55); 1.57–1.64 (2H, q, J = 6.55); 1.91–2.08 (4H, m); 2.11 (3H, s); 2.37 (2H, t, J = 6.55). MS (EI) *m/z* (relative intensity): 142 (M^+, 5); 127 (4); 113 (4); 98 (4); 84 (73); 69 (100); 58 (17);

43 (73). The final product was >98% enriched in two deuteriums as determined by GC-SIM-MS analysis.

Preparation of [6,7-D_2](E)-*6-Nonen-2-ol*

The alcohol was prepared by reduction of [6,7-D_2](*E*)-6-nonen-2-one with $NaBH_4$ as described above. The product was obtained in 90% yield, and was >99% pure by GC analysis. [^{1}H]NMR: 0.89 (3H, t, J = 7.5); 1.16 (3H, d, J = 6.0); 1.30–1.45 (4H, m); 1.78 (1H, br s); 1.93–2.00 (4H, m); 3.72–3.81 (1H, sx, J = 6.0). MS (EI) m/z (relative intensity): 144 (M^+, 11); 97 (30); 84 (100); 71 (58); 69 (85); 68 (48).

RESULTS AND DISCUSSION

Biosynthesis of endo-*Brevicomin from* (E)-*6-Nonen-2-one*

(*E*)-6-Nonen-2-one served as a precursor of *endo*-brevicomin in both MPBs and WBBBs. As hypothesized (Figure 2), male MPBs and WBBBs exposed to vapors of [6,7-D_2](*E*)-6-nonen-2-one produced *endo*-brevicomin enriched in two deuteriums (Figure 3). The incorporation of two deuterium atoms is clearly shown by the shift in the base peak from m/z = 157 to m/z = 159. The MS of deuterium-enriched *endo*-brevicomin isolated from WBBBs (not shown) was virtually identical.

endo-Brevicomin production was significantly enhanced in male and female MPBs exposed to the precursor (Table 1). In addition to *endo*-brevicomin, volatiles extracted from beetles exposed to vapors of (*E*)-6-nonen-2-one included unused precursor, as well as (*E*)-6-nonen-2-ol, which the insects likely produced through reduction of the ketone.

Biosynthesis of exo-*Brevicomin from* (Z)-*6-Nonen-2-one*

We hypothesized that changing the geometry of the olefinic bond in 6-nonen-2-one from *E* to *Z* would lead to the production of *exo*-, rather than *endo*-, brevicomin in vivo (Figure 4). This hypothesis was verified by the fact that MPB and WBBB exposed to [6,7-D_2](*Z*)-6-nonen-2-one produced *exo*-brevicomin that was enriched in two deuteriums (Figure 5). The MS of deuterium-

FIG. 4. Expected incorporation of [4,4-D_2](*Z*)-6-nonen-2-one into [D_2]-*exo*-brevicomin in vivo.

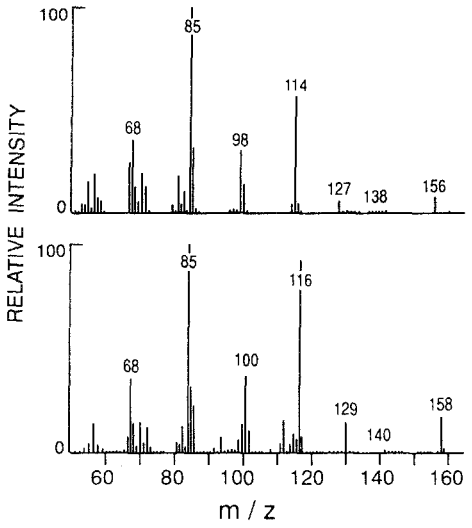

FIG. 5. MS (EI) of *exo*-brevicomin extracted from unexposed male MPBs (top panel) and from males exposed to [4,4-D_2](Z)-6-nonen-2-one (bottom panel).

enriched *exo*-brevicomin isolated from MPB and WBBB were virtually identical. As with (*E*)-6-nonen-2-one, extracts of both MPB and WBBB exposed to (*Z*)-6-nonen-2-one also contained excess precursor and the corresponding alcohol, (*Z*)-6-nonen-2-ol.

It is not clear from previous work if female MPBs and WBBBs produce *exo*-brevicomin. According to Pitman et al. (1969) emergent and fed female MPBs contained trace amounts of *exo*-brevicomin, but Pierce et al. (1987) failed to detect *exo*-brevicomin in fed female MPBs. *exo*-Brevicomin was not detected in female WBBBs (Borden et al., 1987). In our study, emergent unfed female MPBs and WBBBs did not contain detectable levels of *exo*-brevicomin unless they were exposed to (*Z*)-6-nonen-2-one. As in males, the *exo*-brevicomin produced by females exposed to the [4,4-D_2]-(*Z*)-6-nonen-2-one was enriched in two deuteriums. Although the quantity of *exo*-brevicomin produced varied from experiment to experiment (likely due to such factors as the health of the beetles, temperature and atmospheric conditions), female MPBs and WBBBs exposed to (*Z*)-6-nonen-2-one invariably produced less *exo*-brevicomin than exposed males, although this difference was not always statistically significant (Table 2).

Control (unexposed) male MPBs, and male and female MPBs exposed to [4,4-D_2](*Z*)-6-nonen-2-one, continued to emit *exo*-brevicomin after the initial treatment (Figure 6). *exo*-Brevicomin emitted by exposed male MPBs during the 48-hr aeration period was as enriched in two deuteriums as the first whole beetle extract. However, the *exo*-brevicomin extracted from these beetles after

[a]The relative abundance of the $(M + 2)^+$ peak in the MS of the putative precursor [4,4-D_2](*Z*)-6-nonen-2-one is provided for comparison.

the aeration period was less enriched in deuterium (Table 3), indicated by a larger proportion of unenriched molecules (M^+) relative to the enriched molecules [$(M + 2)^+$]. During the 48-hr aeration following the nonenone exposure, the exogenously supplied labeled precursor may have dropped to low enough levels to be significantly diluted by endogenously produced unlabeled precursor.

Male and female MPBs exposed to (Z)-6-nonen-2-one produced enough *exo*-brevicomin to determine its chirality by complexation chromatography (Schurig et al., 1983). Beetles of both sexes produced (+)-*exo*-brevicomin (Figure 7), as is naturally produced by male MPBs (this study; Johnston and Oehlschlager, 1982).

Although (Z)-6-nonen-2-one was undetectable in extracts of whole male MPBs and WBBBs, it was present in airborne volatiles of both beetles (Figure 8), indicating that it is a natural metabolite.

The biosynthetic origin of (Z)-6-nonen-2-one is not known. The compound (or a precursor thereof) may be supplied by the host tree or by fungi associated with the beetles (Borden, 1985; Vanderwel and Oehlschlager, 1987). Alternatively, the beetles themselves may produce (Z)-6-nonen-2-one, either through de novo synthesis or through the derivatization of compounds that contain a double bond in the ω-2 position. W. Francke (personal communication[4]) has

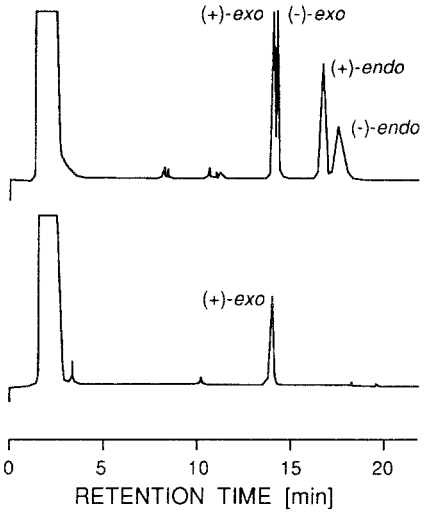

FIG. 7. Determination of chirality of *exo*-brevicomin produced by male MPB exposed to (Z)-6-nonen-2-one: GC trace of the standards (top panel) and purified extract from male MPB (bottom panel).

[4]Present address of Professor W. Francke: Institut für Organische Chemie und Biochemie der Universität, 2000 Hamburg 13, Martin-Luther-King-Platz 6, Germany.

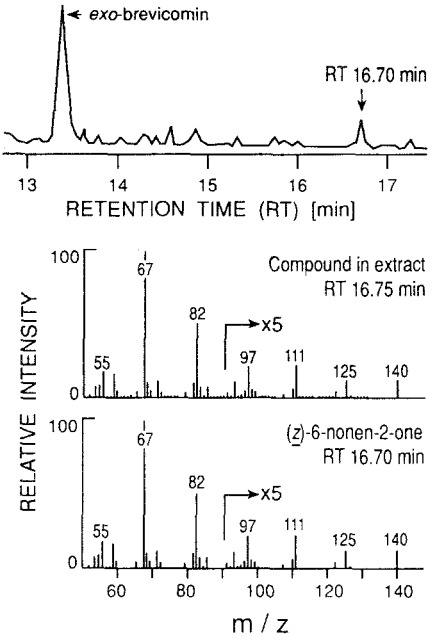

FIG. 8. GC-MS trace of a compound emitted by male WBBBs (top panel) with identical GC retention time and mass spectral characteristics as authentic (Z)-6-nonen-2-one (bottom panel).

suggested that (Z)-6-nonen-2-one might be derived from a 3-keto-(Z)-7-decenoyl intermediate, which could be biosynthesized through the oxidation of a (Z)-7-decenoyl intermediate. This 10-carbon fatty acyl intermediate might, in turn, be derived from a longer-chain fatty acyl precursor such as a (Z)-11-tetradecenoyl intermediate through limited chain shortening, as has been proposed to occur in tortricid moths (Roelofs and Bjostad, 1984).

Incorporation of (Z)-*6-Nonen-2-one into* exo-*Brevicomin: Biologically Relevant?*

A plausible mechanism for the observed conversion of (Z)-6-nonen-2-one into *exo*-brevicomin is through the epoxidation of the keto-alkene, followed by the cyclization of the thus-formed keto-epoxide, as hypothesized by Francke (1978) for *L. varius*. It is conceivable that poly-substrate monooxidases (PSMOs) might nonspecifically epoxidize exogenously supplied (Z)-6-nonen-2-one. Once formed, 6,7-epoxynonan-2-one is known to cyclize to brevicomin in the absence of an enzyme catalyst. Spontaneous cyclization of the keto-epoxide is known to be catalyzed by acid (Bellas et al., 1969), or it can be induced thermally under

neutral conditions (Wasserman and Barber, 1969). Thus, in the absence of other factors, one might not conclude that the conversion of (*Z*)-6-nonen-2-one to *exo*-brevicomin reported herein is biologically relevant.

Several facts provide compelling evidence that (*Z*)-6-nonen-2-one is indeed a natural precursor of *exo*-brevicomin in MPBs and WBBBs. (*Z*)-6-Nonen-2-one is a natural metabolite in male MPBs and WBBBs (Figure 8). The *exo*-brevicomin produced by MPBs exposed to the precursor was of the natural (+) chirality (Figure 7). Finally, although female MPBs weighed about 1.5 times as much as males, and would be expected to have PSMOs at least as active as the males, they did not "out-produce" males. To the contrary, female MPBs exposed to (*Z*)-6-nonen-2-one invariably produced less *exo*-brevicomin than males (Table 2) and, unlike males, did not continue to emit large quantities of *exo*-brevicomin during the 48-hr aeration period (Figure 6).

In conclusion, exogenously applied (*Z*)- and (*E*)-6-nonen-2-one are incorporated into *exo*-and *endo*-brevicomin, respectively, by both sexes of MPB and WBBB. The biochemical origin of these precursors and the biochemical mechanisms by which they are transformed to the brevicomins remain to be determined.

Acknowledgments—We thank W. Francke and H.D. Pierce, Jr., for helpful discussions, G. Owen for assisting with the mass spectral analyses, D.R. Miller and A.J. Stock for supplying many of the insects used in this study, and R.W. Currie for assisting with the statistical analyses. (Received November 7, 1991; accepted April 7, 1992)

Abstract—A negative correlation has been found between the amounts of pterosins A and B and ptaquiloside per biomass unit, and the growth stage of the blade of bracken. Their concentration decreased progressively from the crozier to the mature frond, where it attained less than 5% of the initial value. The growth was measured following the total blade length, its height, moisture content, and time of emergence from the soil surface. Quantitation of these compounds was achieved by HPLC using a water extraction, methylene chloride treatment, and silica gel microcolumn cleanup sequence. Pterosins were unevenly distributed in the blade, whereas ptaquiloside maintained a constant concentration throughout. Rhizomes contained only minor amounts of these compounds. Their possible role as semiochemicals in bracken is discussed.

Key Words—Bracken fern, *Pteridium aquilinum* var. *caudatum*, tropics, ptaquiloside, pterosin A, pterosin B, quantitation, HPLC, blade growth, semiochemicals.

INTRODUCTION

It has been known for nearly a century (Penberthy, 1893; Storrar, 1893) that bracken fern is the cause of various diseases in cattle (W.C. Evans, 1986), horse

(W.C. Evans et al., 1951), sheep (W.C. Evans et al., 1973) and other farm and laboratory animals (W.C. Evans, 1986). Of major importance is the cancer scenario caused by the ingestion of bracken that is expressed as bovine enzootic hematuria in cattle (Rosenberger, 1971; I.A. Evans, 1979), in addition to carcinomas that affect liver, kidney, urinary bladder, mammary gland, and intestine of rats (Hirono et al., 1984a,b; Pamukcu and Price, 1969) and mice (Villalobos-Salazar et al., 1988). Furthermore, the milk produced by cattle exposed to feeding on *P. aquilinum* may be responsible for the high incidence of stomach cancer among people in Costa Rica (Villalobos-Salazar, 1985; Villalobos-Salazar et al., 1987, 1989a,b) and other countries (Galpin and Whitaker, 1989).

Nearly 100 metabolites of diverse structure have been isolated from bracken (Fenwick, 1988; Jones, 1983). Of these, ptaquiloside, an unstable illudane glucoside (Van Der Hoeven et al., 1983; Niwa et al., 1983; Ojika et al., 1987), was found to possess most of the carcinogenicity of the fern (Hirono et al., 1984a,b, 1987; Ojika et al., 1989).

Bracken is a cosmopolitan plant that grows in large thickets in the mountainous areas of the tropics (Ortega, 1990) in addition to the temperate regions of the world (Tryon, 1941). The dominance of *P. aquilinum*, reflected in its quick infestation of vast tracts of grazing land and its negative economic impact, provided impetus to the study of its ecological chemistry. In particular, it was of interest to evaluate the risk of exposing mammal herbivores to bracken in terms of ptaquiloside content as a function of frond development stage. While larger fronds are more easily perceived by grazing animals, they are also tougher and less palatable. In turn, smaller, younger fronds, albeit more difficult to find, are more tender and therefore may be more attractive as food to these animals.

The semiochemical composition and concentration of many plants are known to vary, inter alia, with the plant part and age (McKey, 1979). In bracken and other polypodiaceous ferns, the concentration of some sesquiterpenoids (Murakami and Saiki, 1989), flavonoids (Cooper-Driver, 1976), cyanogenic glycosides and phenolic acids (Cooper-Driver and Swain, 1976), pterosin F (Jones and Firn, 1979), and other bioactive compounds (Jones, 1983) have been found to vary significantly along the growing season. In the case of ptaquiloside, it is also known that it appears in higher concentration in the crozier than in the mature frond (Saito et al., 1989; Santos et al., 1989; Smith et al., 1989). However, this conclusion was based on plant samples collected nonsystematically in several regions and at different times of the year.

Hence, it was deemed desirable to obtain data on the systematic appearance of ptaquiloside in bracken in order to determine the cancerous risk potential of the plant for herbivorous mammals as a function of frond development. Pterosins A and B were also examined since their biological activity has also been reported (Saito et al., 1975). The results would also be an addition to the little known

chemistry of the carcinogenic var. *caudatum* (Villalobos-Salazar et al., 1988) that is the subject of the present study.

METHODS AND MATERIALS

Chemicals. A sample rich in ptaquiloside was isolated by water extraction of freshly cut fronds at room temperature following the method of Ojika et al., (1985). Pterosin B was obtained by extraction of fresh fronds with 0.03 N aqueous sodium hydroxide to convert the ptaquiloside into the desired pterosin B and increase its yield. This was followed by extraction with chloroform without neutralization to keep organic acids in the aqueous layer as sodium salts. The organic layer was dried over anhydrous magnesium sulfate, filtered, and evaporated over silica gel 60 (70–230 mesh) to prepare a column head for vacuum chromatography (Targett et al., 1979; Pelletier et al., 1986). Elution with hexane–ethyl acetate (EtOAc) 4:1 yielded 11 fractions of which fractions 3–6 contained pterosin B. Analytical samples were obtained by preparative thick-layer chromatography on silica gel 60, 2 mm thick, 20 × 20-cm glass plates using acetone–dichloromethane (DCM) 7:3 as developing solvent. Elution of the $R_f = 0.8$ band with warm EtOAc, evaporation, and recrystallization from hexane–DCM gave pure pterosin B as white needles, mp 106–107°C. This material was compared (IR, [^{1}H]- and [^{13}C]NMR) with an authentic sample that was recrystallized from the same solvent mixture.

Pterosin A was obtained from the *n*-butanol extraction of the initial frond water extract. The alcoholic layer was diluted with water previously saturated with *n*-butanol and washed in succession with petroleum ether and diethyl ether. The latter was evaporated to dryness and chromatographed through a silica gel column. Fractions eluted with hexane–EtOAc 7:3 contained pterosin A, which was purified further with the aid of thick-layer chromatography using DCM–acetone 3:7. Elution of the $R_f = 0.75$ band with warm EtOAc, evaporation, and recrystallization with hexane–DCM yielded pure pterosin A, mp 129–130°C (Yoshihira et al., 1971). Comparison of spectral data as above with an authentic sample provided confirmation of its identity.

Plant Sampling. Three flat 100-square-meter plots located at La Hechicera, Mérida, western Venezuela, at 1850 m altitude with low-density tree clusters of 8- to 10-m-high canopies and sparsely vegetated undergrowth, except for bracken, were chosen as study sites. As soon as the croziers could be seen to emerge from the soil surface, they were marked with sticks 30 cm from the stipe to avoid damage to the rhizome or roots. Growth was then followed through maturation by measuring the length of the stipe, the height of the blade by the length of the central rachis, and the total length of the laminae (see Figure 5).

Thirty fronds in each plot were measured weekly. Samples for chemical analysis were drawn weekly between 8:00 and 9:00 AM from January to April (dry season in the area) 1990 and the same period of 1991. Three fronds of the same age and approximately the same size were divided in two halves along the symmetry axis of the blade, one for moisture determination by drying to constant weight in an oven at 105°C and the other for extraction and chemical assay. Samples were clipped off with scissors, placed in previously weighed plastic clip bags, immediately stored in an ice box in the field, and carried to the laboratory within 15–20 min of collection. Typically fresh samples weighed 8–10 g (1.2–2.0 g dry weight). The bag contents were weighed, pooled in groups representing three fronds, and extracted with water in triplicate as described below. Rhizomes were sampled by cutting them approx. 10 cm from the base of the stipe. Collection, moisture content determination, and extraction was performed similarly.

Quantitative Extraction Procedure. Only nonreproductive fronds devoid of visible sporangia were used. After weighing, the fresh frond clippings were blended in distilled water (250 ml) with occasional stirring at room temperature for 2 hr. During this time little if any decomposition of ptaquiloside was expected to occur. The suspension was filtered through cheesecloth and around 60 ml of the filtrate was centrifuged (3000 rpm, 15 min). An aliquot (40.0 ml) of the clear supernatant was extracted exhaustively (5 × 25 ml) with DCM (extract 1). Emulsions were broken by centrifugation (3500 rpm, 10–15 min). The organic and aqueous phases were carefully divided. Aqueous sodium hydroxide (0.003 N, 10 ml) was added to the latter and the slightly alkaline mixture was warmed at 40–45°C for 2 hr to decomposed ptaquiloside quantitatively. The brownish solution was cooled to 10–15°C and extracted (5 × 25 ml) with DCM. The organic layer was centrifuged as above, dried over anhydrous magnesium sulfate, and filtered through DCM-soaked Whatman No. 1 filter paper into a 100-ml volumetric flask. The volume was corrected to 100.0 ml with chloroform and homogenized; four aliquots (20.0 ml) were drawn with the aid of a volumetric pipet and transferred to each of four pear-shaped 50-ml evaporation flasks, each containing 50 mg of silica gel 60 (70–230 mesh). Solvents were evaporated and the powdery residue was quantitatively transferred as column head to a Pasteur pipet fitted with a small cotton plug at the narrowing bottom neck that was previously filled with 250 mg of the same silica gel support. The procedure was repeated with an additional 25 mg of silica in all four replicates. The four microcolumns thus prepared (LeRoy and Goerlitz, 1970) were eluted first with 2.0 ml of hexane–EtOAc, 9:1, followed by 2.5 ml of the same mixture in a 1:2 ratio. The latter contained the ptaquiloside-derived pterosin B and was collected directly into a 2.0-ml volumetric flask. Solvents were evaporated under a current of dry argon or nitrogen gas, redissolved in HPLC grade methanol, and centrifuged to settle residual solids in suspension. The volume was corrected

to 2.0 ml with methanol and evaluated for pterosin content by HPLC. Extract 1 containing naturally occurring pterosins A and B was prepurified similarly and its quantitation achieved by HPLC. The recovery yields of pure analytes along the extraction–prepurification sequence was: 93 ± 2.1% for pterosin A; 94 ± 2.0% for pterosin B, and 93.8 ± 0.6 for ptaquiloside.

HPLC Analysis and Quantitation. Eight standard solutions of pterosin B were prepared in methanol in the 4.6×10^{-5} to 9.17×10^{-8} molar concentration range and were kept in tightly sealed volumetric flasks at 5°C until used. Optimal HPLC conditions were worked out using a LDC Milton Roy HPLC system equipped with two Constametric II pumps, a Waters Associates 490E, four-channel UV detector set at 220 and 260 nm (the UV maxima of pterosin), and a Waters Associates 10-cm reverse-phase radial microbondapack C-18 column of 10 μm particle size fitted to a 5-cm precolumn of the same stationary phase (40 μm). A water–methanol 35:65 mixture running at 1.0 ml/min at room temperature was found to give the best peak resolution. Retention times were 6 min 40 sec for pterosin A and 10 min 10 sec for pterosin B. Quantitation was derived from a minimum of seven 20-μl (loop size) injections per sample and coinjection with standards of the closest peak height range.

RESULTS

Frond Growth and Age. From the moment of emergence from the soil surface to the fully developed blade, bracken fronds in the site of this experiment reached maturity in around 70 days. Age (days from emergence) and the percentage of blade growth could be correlated as shown in Table 1. Growth measurements were made using a number of parameters such as length of the

TABLE 1. CORRELATION BETWEEN PERCENTAGE OF BLADE GROWTH AND TIME OF CROZIER EMERGENCE FROM SOIL SURFACE OF *Pteridium aquilinum* VAR. *caudatum* ($N = 30$, $P < 0.05$)

Days of emergence	Growth (%)
6	5.1 ± 1.5
12	11.3 ± 3.9
20	28.0 ± 14.3
26	41.9 ± 9.5
33	60.7 ± 9.9
40	80.2 ± 20.4
47	96.0 ± 29.6
68	100.0 ± 35.4

stipe from the ground level to the first division, L_s; length of the rachis, L_r, representing height attained by the frond; and total length of the frond L_t. Results are portrayed in Figure 1a–c. Moisture content was also found to decrease smoothly with age (Figure 1d).

The frond size spread over a wide range, depending on sunlight and competing vegetation, including earlier bracken blades. In order to avoid the chemical variance that frond size might introduce, only croziers and fronds representing the median population were chosen. However the median measurements cannot be determined until the frond has completed its growth, and it is essential to learn whether specimens for analysis are members of this median

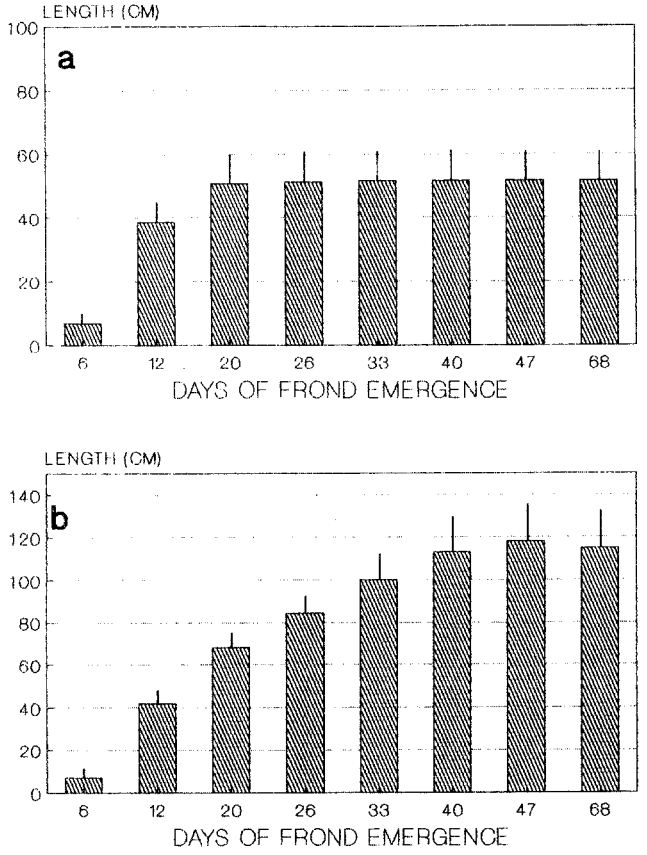

FIG. 1a–d. variation of blade growth parameters of *Pteridium aquilinum* var. *caudatum* with time of crozier emergence from the ground level, in the understory of a tropical cloud forest in the Andes of western Venezuela, during the dry season: (a) length of stipe; (b) length of rachis; (c) total blade length; (d) % moisture.

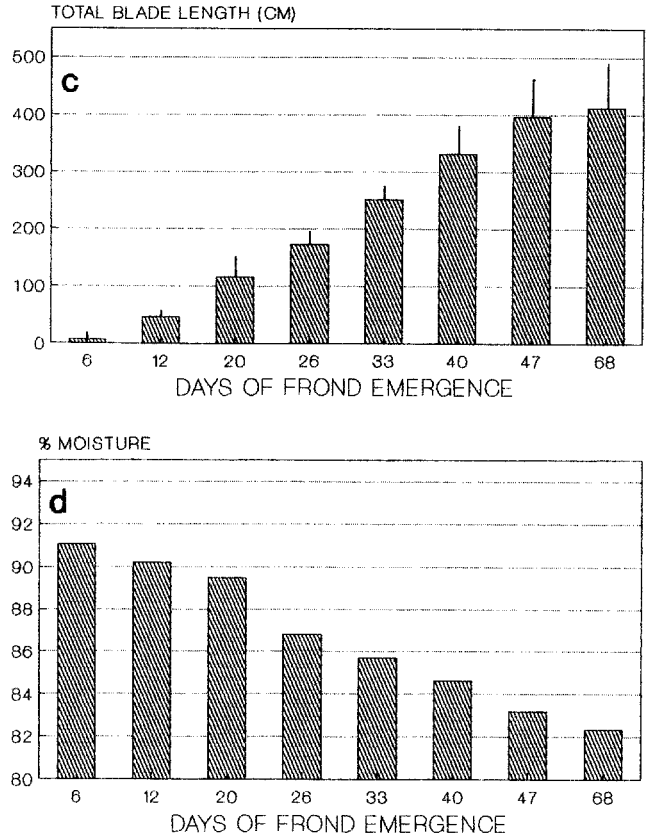

FIG. 1. Continued

population at all growth stages. To circumvent this problem, the length of the stipe to the first ramification L_s was employed. It was found that after two weeks of crozier emergence L_s reaches a maximum value that is maintained throughout frond development (Figure 1a). In addition, L_s correlated positively ($r = 0.80$) with the total blade length and expansion (Figure 2a). Hence, L_s is a nondestructive parameter for predicting at an early stage of development future frond size and allows sampling within the population of desired size range. L_r also correlated well ($r = 0.906$) with the frond expansion (Figure 2b).

Attempts to use leaf area as a criterion for growth was obstructed by the fact that croziers begin to develop unfolded leaflets only after 15–20 days, and thereafter the blade continues to grow in long, cylindrical shoots, sometimes reaching 60 cm upward, that do not contain segments or leaflets until several days later. Therefore, leaf area would not be representative of real growth. Data

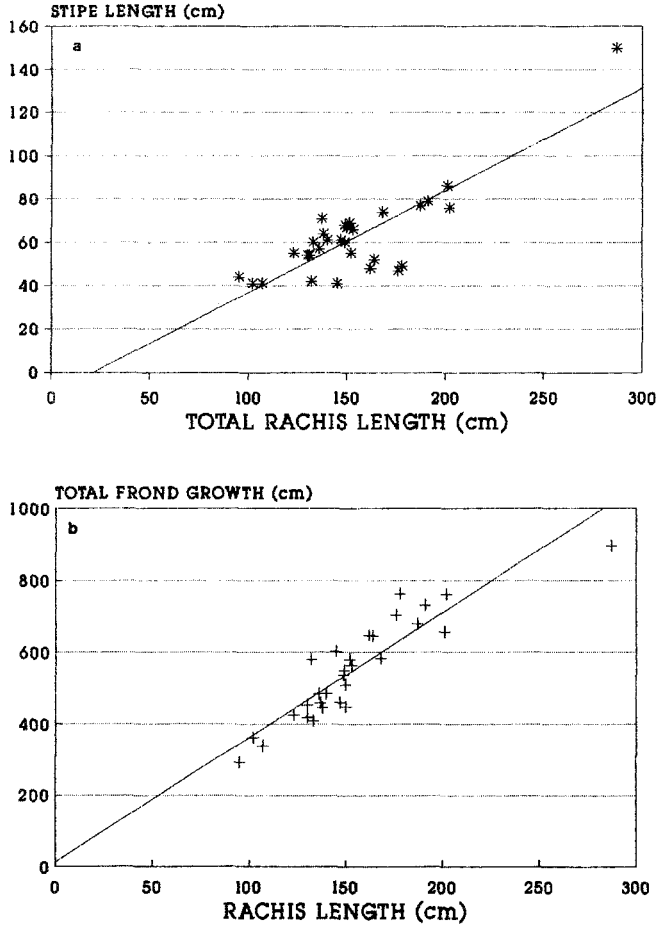

FIG. 2. Linear correlation of growth parameters: (a) rachis vs. stipe length; (b) rachis length vs. total frond growth.

on leaf area development in the literature (Jones, 1983) would be of little use for the present study as it refers to bracken varieties other than *caudatum* and a disparate environment.

Variation in Chemical Composition with Growth. Liquid chromatograms of extracts 1 and 2 containing naturally occurring pterosins A and B, and pterosin B derived from ptaquiloside, respectively, appear sufficiently well resolved for quantitation (Figure 3). Only mature, 68-day-old fronds produced an undetermined metabolite that interfered with the pterosin B peak in extract 1 and consequently could not be measured. Conversion of the base-produced pterosin B

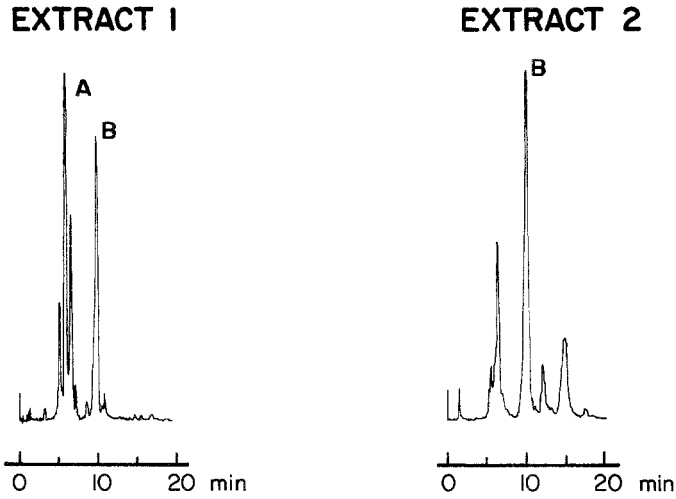

FIG. 3. HPLC chromatograms of extract 1 (naturally occurring pterosins A and B), and extract 2 (base hydrolysate of ptaquiloside) of bracken fern. Peak A refers to pterosin A and peak B to pterosin B. For instrument conditions, see text.

to ptaquiloside equivalents was achieved by multiplying the observed concentration by the molecular weight ratio of ptaquiloside to pterosin (1.8257).

The concentration of all three compounds examined varied markedly with blade growth. The highest amount was found in the 12-day-old crozier, typically representing a 41.8 ± 6.5-cm shoot without ramification or leaflets. The content of pterosin A rapidly contracted from 0.272 ± 0.06 ($P < 0.05$) to 0.012 ± 0.001 mg/g of dry frond weight during the first 33 days of crozier emergence from the ground and then underwent a sharp increase to 0.289 ± 0.004 by the 47th day when the frond was fully developed (Figure 4). The concentration of pterosin B followed a different course since it decreased progressively with growth from 0.66 ± 0.04 mg/g of dry fern tissue in the 12-day-old crozier to 0.084 ± 0.005 mg/g by the 47th day but showed no significant increase thereafter (Figure 4). Ptaquiloside exhibited the highest concentration of the three components, at 1.67 ± 0.31 mg/g at the crozier stage and was reduced to 0.113 ± 0.03 mg/g in the mature frond (Figure 4). On the other hand, the rhizomes around the base of the blade contained only a small fraction of the pterosins and ptaquiloside in the plant, being 0.0029 ± 0.0004 mg/g for pterosin A, 0.0044 ± 0.0007 mg/g for pterosin B, and 0.0046 ± 0.0009 mg/g for ptaquiloside.

Variation in Chemical Composition with Plant Part. Three fronds of equal size and grade of development (42–45 days old, 80–85% of development) were sampled as indicated in Figure 5. Being at an intermediate stage, these fronds featured three distinct structures: the lower base pair with fully developed, albeit

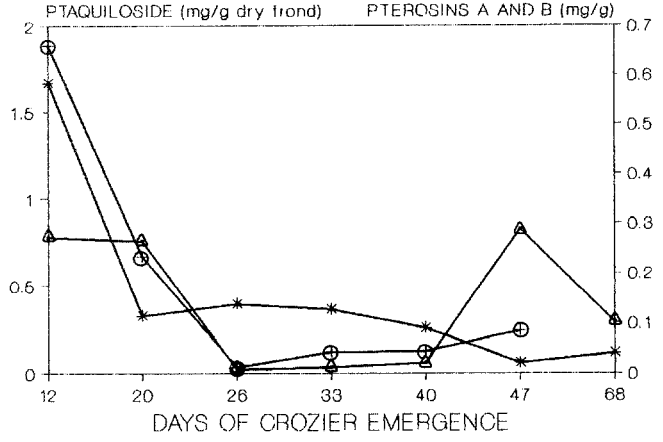

FIG. 4. Variation in chemical composition of bracken fern blades in milligrams of compound per gram of dry frond, with frond age: ★: ptaquiloside (left ordinate scale); △: pterosin A (right ordinate scale); ⊕ ; pterosin B (right ordinate scale).

tender leaflets; the second middle pair with unfolding leaflets; the upper part composed of unfolding, curled tops only. Results appear in Figure 5. While pterosins A and B are unevenly distributed, with the highest concentration in the middle pair, ptaquiloside concentration remains constant in all parts examined.

DISCUSSION

Ptaquiloside is so unstable that its isolation and characterization proved to be a task of utmost difficulty (Hirono, 1986). This quality renders its direct quantitation nearly impossible, although a recent attempt has been reported (Agnew and Lauren, 1991). Nevertheless, ptaquiloside is known to undergo transformation into pterosin B under heat, acid, or base (Matoba et al., 1987) according to Scheme 1. The stable 1-indanone obtained therefrom has a strong UV active chromophore (261 nm, log e = 4.19) as opposed to the weakly absorbing ptaquiloside. The base decomposition of ptaquiloside was preferred over the direct quantitation (Agnew and Lauren, 1991) or the thermal transformation (Saito et al., 1989), owing to its mildness (pH 11.5, 40°C) and completeness within a short period of time. In addition, HPLC offered higher sensitivity over TLC photodensitometry (Saito et al., 1989) for the quantitation of the derived pterosin B.

Bracken, like many other ferns, may be a large organism (Shefield et al., 1989) of which only the blades are visible. The complex array of rhizomes

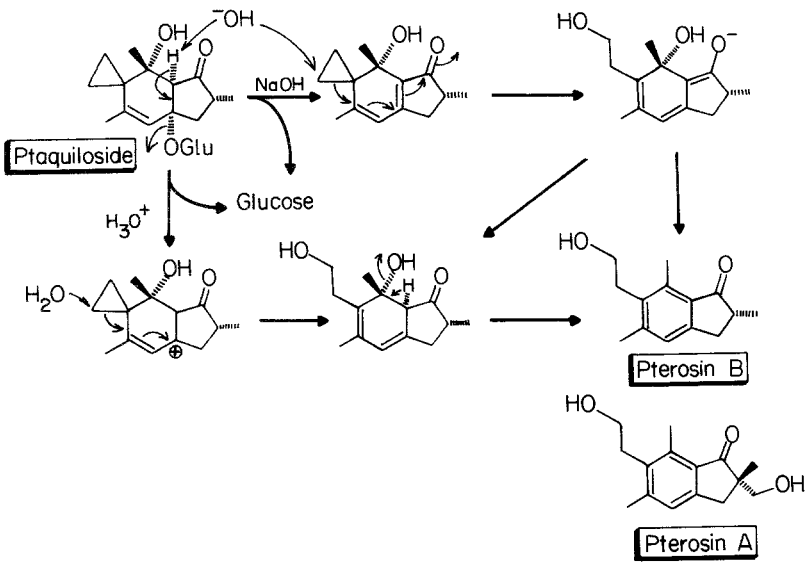

SCHEME 1.

overwinters or remains active after fire to yield new frond growth when conditions become appropriate. Therefore blade development represents the growth of only part of the fern. In spite of this, metabolites in the fronds may be expected to vary with the age of the fronds as in many other plants because photosynthesis and a major portion of the metabolic process occur there.

While season is a crucial parameter to take into account to measure plant development in temperate climates, it is of less importance in tropical areas because temperature and photoperiod show very little variance. Only rainfall shows a consistent yearly cycle, although the dry season is usually short (60–90 days) in the tropical Andes above 1000 m altitude, and soil undergoes desiccation only in the first few centimeters of depth except in steep slopes and well-drained soils. In fact, bracken in the Mérida area, either in the open savanna or in the forest understory, develops viable croziers without interruption all year round. Therefore, chronological age of the frond rather than stage of the growing season was found more appropriate to follow plant growth in our location.

The present results show that even under the tree canopy where sunlight is partially blocked, bracken fronds grow very fast, reaching the mature stage in only 60–70 days. By comparison, competing grasses in the open sunlight require much longer periods, extending from three months to one year (Baruch et al., 1989). This fast development becomes a source of perennial food for herbivores, particularly during the dry season when planted or natural grasses become scarce.

Cattle frequently wonder along the edges of forest or into the understory where moisture is better preserved and bracken develops softer blades, thus becoming more palatable to them. The combination of frond availability and the higher concentration of ptaquiloside found in younger, savory tissue increases considerably the risk of poisoning of farm animals and other mammalian herbivores during the dry season.

The concentration pattern of pterosins A and B and ptaquiloside with frond development stage found here runs in parallel with earlier findings (Saito et al., 1989; Santos et al., 1989; Smith et al., 1989). In particular, Jones and Firn (1979) observed a gradual seasonal decrease in pterosin F concentration and deterrence activity of bracken (var. *aquilinum* from England) leaves against several nonadapted phytophagous insects between May and October. However, the frond development stage of plant specimens was not specified, and the growth rate was conceivably different owing to climatic and soil dissimilarity, so care must be exercised when comparing their results with the present report. Their study revealed, on the one hand, that the seasonal variation in pterosin F concentration was similar to the seasonal variation in deterrence activity of crude extracts of the fronds. On the other, not all the deterrence activity could be attributed to pterosin F alone; other active, noncharacterized fractions were present as well. The dynamics of pterosins A and B and ptaquiloside found here show the same pattern, thus suggesting a protective role against herbivory by these compounds also. In spite of its small apparency (Feeny, 1976) the tender crozier requires the highest protection because damage at this stage is more likely to be deleterious to plant fitness. In burned land around Mérida where bracken is the first and dominant growth, and thus the only food source available to insects or rodents in a relatively large area, crozier stumps with the growing tips removed are observed. Croziers sustaining such damage do not develop further and die. Therefore bracken may have evolved metabolic mechanisms to concentrate qualitative chemical defenses (Feeny, 1976) in these fragile tissues.

The disparate concentration of pterosins A and B as opposed to the uniform distribution of ptaquiloside in blades of intermediate development suggests different allocation mechanisms for these compounds. While the water-soluble ptaquiloside may be concentrated and transported in the vascular system, the less soluble pterosins may be deposited in appropriate structures within the fresh segments. Pterosin B results from light-induced decomposition of ptaquiloside (Saito et al., 1989). Hence, it is conceivable that the latter is a relocalizable source of pterosin B in the frond in addition to the light-stable pterosides (pterosin glycosides) also present in bracken. By the same token, pterosin A may have a ptaquiloside-like precursor of its own. In fact, such a compound, dennstoside A, has just been reported (Koyama et al., 1991) in *Dennstaedtia scabra*, a fern of the pteridaceae family to which *P. aquilinum* belongs, but still awaits discovery in bracken. This may be part of a complex array of chemical defenses

that makes *P. aquilinum* one of the most resistant and successful species in the plant kingdom (Harper, 1977; Page, 1979, 1982).

Acknowledgments—The financial support of Consejo de Desarrollo Cientifico, Humanistico y Tecnológico (CDCHT, grant C-420-90) of Universidad de Los Andes, Mérida, Consejo Nacional de Investigaciones Cientificas y Tecnológicas (CONICIT, grant PC-64) Caracas, and Fundación Polar, Caracas, is acknowledged. We thank Professor Iwao Hirono for kindly sending authentic samples of bracken compounds, and Drs. Sarah Pekerar and Matilde Gómez of Instituto Venezolano de Investigaciones Científicas, IVIC, in Caracas, for running high-field NMR and mass spectra.

(Received December 9, 1991; accepted April 8, 1992)

Abstract—The sex pheromone emitted by individual calling females of the oriental fruit moth, *Grapholita molesta*, was trapped within glass capillaries, and the composition and release rates were determined by gas chromatography–mass spectrometry. Aerial release of (*Z*)-8-dodecenyl acetate ranged up to 25.3 ng/hr, while the mean release rate was 8.48 ± 7.26 ng/hr (±SD). The proportion of (*E*)-8-dodecenyl acetate to (*Z*)-8-dodecenyl acetate was remarkably constant (4.20 ± 0.60%). Significant amounts of dodecyl acetate were also recovered but, contrary to previous reports, only trace quantities of (*Z*)-8-dodecenol were detected in the effluvium.

Key Words—*Grapholita molesta*, Lepidoptera, Tortricidae, sex pheromone, effluvium, release rates, GC-MS, (*E*/*Z*)-8-dodecenyl acetate.

INTRODUCTION

Control of the Oriental fruit moth, *Grapholita molesta* (Busck), (OFM), by dissemination of synthetic sex pheromone has been operational in Australia for several years (Vickers, 1990), but little is known about how the synthetic pheromone affects moth behavior to bring about mating disruption. An understanding of this process might lead to improved efficacy and also help in the application of mating disruption for other pest species.

In any study of mating behavior, including mating disruption, it is important

to have accurate measurements of the chemical composition of the pheromone released by the female moths and of the amount of pheromone released by the moths under natural conditions. The major component of the sex pheromone of OFM was identified by Roelofs et al. (1969) as (Z)-8-dodecenyl acetate (Z8–12:OAc). Subsequently, Cardé et al. (1979) identified three additional components, (*E*)-8-dodecenyl acetate (*E*8–12:OAc), (Z)-8-dodecenol (Z8–12:OH) and the saturated alcohol dodecanol (12:OH), although 12:OH may be redundant in the communication system (Linn et al., 1986). Previous studies have also been made of the composition and quantity of sex pheromone released by female OFM (Cardé et al., 1979; Baker et al., 1980), but these determinations were from material collected on the inside surfaces of containers housing groups of insects. The capillary trapping method of Shani and Lacey (1984) enables determination of pheromone released by individual female moths and correlation with calling behavior (Barrer et al., 1987). The technique used here is a refinement of this for making simultaneous collections from individual females and is designed to improve the efficiency and accuracy compared to previous methods.

METHODS AND MATERIALS

Insects. The female moths were from a laboratory colony maintained at the Division of Entomology, CSIRO, Canberra. The colony was established from insects collected from a peach orchard near Cobram, Victoria. A few insects were collected between January 15 and 17, 1990, but survival was poor, and a further 15 female moths and a surplus of males were collected from bait pails (Rothschild et al., 1984) between February 15 and 17, 1990. The colony was maintained on green apples. Pupae were segregated by sex and the females kept at 25°C on an advanced 16:8 light–dark cycle (scotophase 1200–2200), and variable relative humidity (between 30 and 60%). Emerged moths were collected each morning and kept in 8-oz waxed cardboard cups (85 mm diameter, 50 mm high) and supplied with a 5% sugar solution.

Calling Behavior. We carried out limited observations on the calling behavior of female moths to ensure that the behavior of the Australian population is similar to that reported previously for the North American population (Baker and Cardé, 1979a). About 5 hr before lights-off on the day of observation, female moths were placed individually in glass vials (2 cm diameter, 5 cm high), which were covered by fine mesh cloth. The individual moths were then observed at 15-min intervals and their behavior recorded. Observations were begun 30 min after the females were placed in the vials and ended at lights-off.

Pheromone Collections. The collection apparatus consisted of six inverted filter flasks (50 ml), each supported by a retort stand. Air (Medical Grade, CIG,

Australia) was introduced through a glass wool plug in the side arm of each flask at 100 ml/min to preclude the entry of volatile contaminants during the collection.

Approximately 5 hr before lights-off, a female moth was placed in each flask and the opening was covered by a steel gauze. The moths were from collections of emerged moths made two days previously, i.e., they had experienced two, or possibly three, scotophases before the start of the pheromone collection. A glass capillary (60 cm long, 0.9 mm ID, 2.0 mm OD) supported by a retort stand, was inserted into the flask through the gauze cover and carefully positioned with the tip close (< 1 mm) to the tip of the female's abdomen. In most instances, it was possible to position the capillary orifice so that it cupped the tip of the abdomen, although care was taken to ensure that at no stage was there any contact between capillary and insect. Air was then drawn through each capillary at a rate of 25 ml/min, and the effluvium from each calling female was trapped on the glass walls of the capillaries.

Behavior of each female was noted every 5 min. Collection of the effluvium was begun from each female when she started calling and continued for as long as she remained stationary. In some instances, where the females maintained the calling position for several hours, the capillaries were changed at hourly intervals (maximum 3 hr). On a few occasions, collections were made from female moths that were not visibly calling, but that had remained stationary for over 1 hr. At the end of the collection period, the inner surface of each ice-cooled capillary was washed by gravity flow with 5×2 μl quantities of pentane (Mallinckrodt nanograde redistilled) from the inlet to outlet end (previously sealed to retain the washings). Known quantities of internal standard [(Z)-10-dodecenyl acetate] were then added to each solution and mixed thoroughly. The pheromone solutions were sealed within the capillary tubes and stored at -20°C until required for mass spectroscopic analysis.

Pheromone Determinations. Gas chromatography–mass spectrometry (GC-MS) was carried out on a VG 70-70 mass spectrometer (VG Analytical, Manchester) interfaced directly to an HP 5792A capillary gas chromatograph (Hewlett Packard) and a VG 11-250 data system. Solutions for analysis were introduced by way of an HP 19290A on-column injector. The cross-linked chromatography columns used (DBWax, J&W, 30 m length, 0.32 mm ID, 0.5 μm phase thickness; BP20, SGE, 25 m length, 0.33 mm ID, 1.0 μm phase thickness) were preceded by retention gaps of deactivated fused silica (SGE, 4 m length, 0.33 mm ID).

The on-column GC methodology used here to analyze the effluvia enabled transfer of mixtures through the gas chromatograph with minimal molecular discrimination (Grob, 1987). The use of a retention gap as a fore-column preserved the column's integrity and permitted the injection of large volumes without seriously jeopardizing the chromatographic resolution. Large injection

volumes allow the full dynamic range of sensitivity to be exploited because the concentration of solutions to very small volumes often leads to major loss of the solutes on surfaces or by evaporation. While very long retention gaps are normally prescribed for accommodating large injections (Grob, 1987), it was found in the present work that equivalent results could be obtained by injecting small aliquots (2–3 μl) in sequence onto a short retention gap such that the solvent evaporated between injections. The high conductance of the source diffusion pump was adequate to dispose of the vapor without electrical discharge.

The GC columns and retention gaps were reserved for effluvium analyses. Helium (ultra-high purity, CIG Australia) was used as a carrier gas, and a typical temperature program for elution of the pheromone constituents was 30°C isothermal followed by a gradient of 30°/min to 165°C isothermal (DB Wax). Injections of samples could be accomplished at 20- to 25-min intervals under such conditions.

The ionization mode adopted for determination of the pheromone components in the present study was negative-ion chemical ionization (NICI) using hydroxyl ions as the reagent. The OH^- ions were formed in the source by the addition of nitrous oxide (instrument grade, CIG Australia) to methane (ultra-high purity, CIG Australia) at a combined pressure of 40 Pa. The ionization energy was 100 eV, the source temperature 190°C, and the filament emission 1 mA. Selected ion monitoring of $(M - H)^-$ ions was accomplished at constant magnetic field by alternation of the accelerating and electric sector voltages under data system control, with dwell times of 75 msec per channel.

The origins of the reference chemicals were as follows: Acetates and alcohols were synthetic standards (Shin-Etsu, Tokyo, Japan) while aldehydes were prepared as required by Jones oxidation of the analogous alcohols. Purities were assessed by gas chromatography and gas chromatography–mass spectrometry. The compounds were stored at −80°C and stock solutions were stored at −20°C.

RESULTS

Calling Behavior. Postures of female OFM during the 5 hr before scotophase varied considerably. Of 148 observed females, 130 (88%) visibly extruded their ovipositors at some stage, although the degree to which they did this varied. Of these, 23 (16% of the total) spread or raised their wings for at least part of the time that they had their ovipositors extruded. The remaining 18 (12%) showed no visible calling behavior during the observation period, although they did remain stationary for most of the time, with their antennae raised and curved back over the body in an "alert" position. If undisturbed, most females that were visibly calling remained in the calling position for 2–3 hr.

At constant temperatures of 21–22°C, the first females started to call about

$4\frac{1}{2}$ hr before lights off (Figure 1) and the maximum rate (75% of the females) was achieved $2\frac{1}{2}$ hr before lights off and continued until lights off. At 24°C, the onset of calling was delayed about $1\frac{1}{2}$ hr and the maximum rate was not achieved until just before lights off.

Efficacy of Capillary Traps. The capacity of the capillary trap to retain the main pheromone component, Z8–12:OAc, under the conditions in this study was assessed by collecting the effluvia over an extended period of time from females that were clearly calling throughout the collection period. In one case, 46.3 ng of Z8–12:OAc was trapped over a period of 110 min, in another, 60.2 ng over 170 min. In both cases, <0.1% of the total amount of Z8–12:OAc was found in the downstream 30 cm of the 60-cm-long capillary. Although these data indicate that 30-cm capillaries would be sufficiently long to retain the pheromone constituents if they are replaced at hourly intervals, we preferred 60-cm-long capillaries to minimize possible breakthrough of more volatile potential minor components.

Individual Release Rates of Z8–12:OAc. Among individuals that exhibited

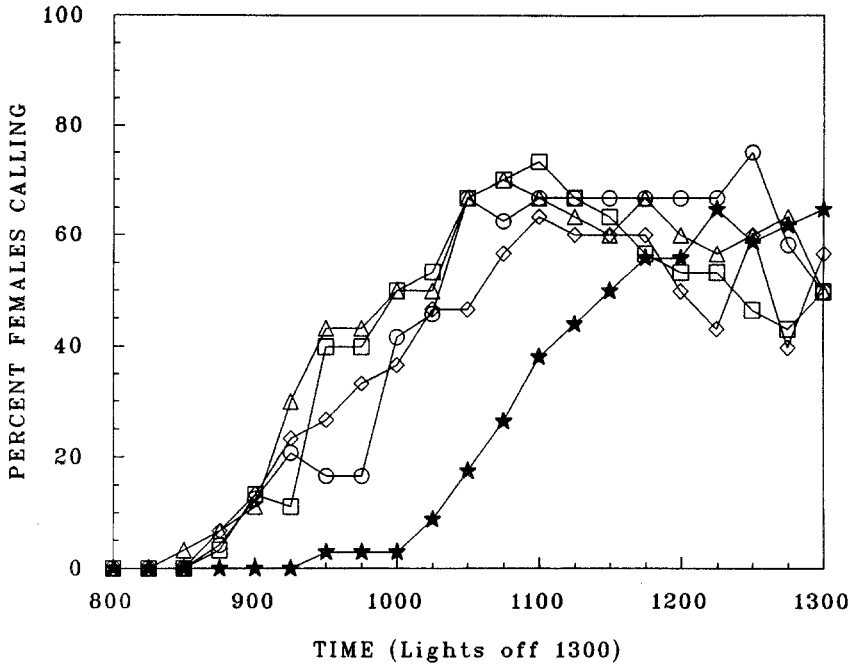

FIG. 1. Percentage of female oriental fruit moths calling, showing effects of age and temperature. Circles, 1-day-old females (N = 24); triangles, 2-day-old (N = 30); square, 3-day-old (N = 30); diamond, 4-day-old (N = 30); all kept at 21°C. Solid stars, 1- to 5-day-old females kept at 24°C (N = 34).

calling behavior during at least some of the collection period, the mean release rate (±SD) of Z8–12:OAc was 8.48 ± 7.26 ng/hr (N = 40, range 0.0–25.3 ng/hr) (Figure 2). Those females that did not exhibit any calling during the collection period released little if any Z8–12:OAc (range 0.0–0.12 ng/hr, N = 6).

For some females that exhibited prolonged calling behavior, effluvia were trapped over several successive intervals of about an hour each. The results (Table 1) indicate that most females maintain about the same rate of release throughout their calling period.

Ratio of Z *to* E*8–12:OAc in Effluvium.* The E:Z8–12:OAc ratios were measured in the effluvia from 32 individual females (Figure 3). The mean was 4.20% E isomer (SD = 0.596) to 95.8% Z isomer, with a range of 3.00 to 5.30% E isomer.

Additional Constituents of Effluvium. The alcohol, Z8–12:OH, was detectable in the effluvia of all strongly calling females, but the amount was only 0.45 ± 0.19% of the Z8–12:OAc (N = 11). Another minor constituent of the effluvia was (Z)-8-dodecenal (Z8–12:Ald) with a relative abundance of 0.42 ± 0.17%, similar to that of the Z8–12:OH. E8–12:Ald was also present in the effluvia

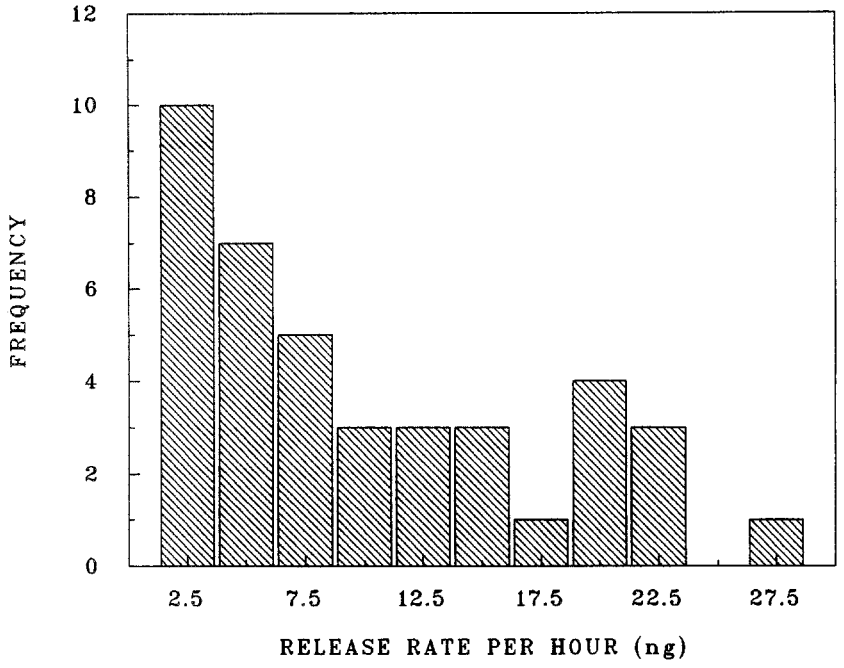

FIG. 2. Frequency distribution of release rates of (Z)-8-dodecenyl acetate (ng/hr) by female oriental fruit moths (N = 40).

of some calling females, but only in trace amounts.

Another identified constituent was the saturated acetate, dodecyl acetate (12:OAc), which had, on average, an abundance of $3.44 \pm 1.16\%$. Also detectable in the effluvia were the saturated alcohol and aldehyde, dodecanol and dodecanal. These are present in only trace amounts, and blank experiments demonstrated that the presence of both can be attributed predominantly, if not entirely, to trace impurities in the hydrocarbon solvent (pentane).

DISCUSSION

The calling behavior and the periodicity of calling of OFM female moths in our experiments are similar to those described by Baker and Cardé (1979a) for OFM in the United States. From these two studies we conclude that during the first generation of moths in each field season in Australia, when temperatures are in the low 20°C range (Rothschild and Minks, 1974), sexual activity starts about $4\frac{1}{2}$ hr before sunset, and if temperatures drop below the threshold of 15°C, calling ceases (Rothschild and Minks, 1974; Baker and Cardé, 1979a). In subsequent generations, when temperatures rise into the 30s, the onset of calling is

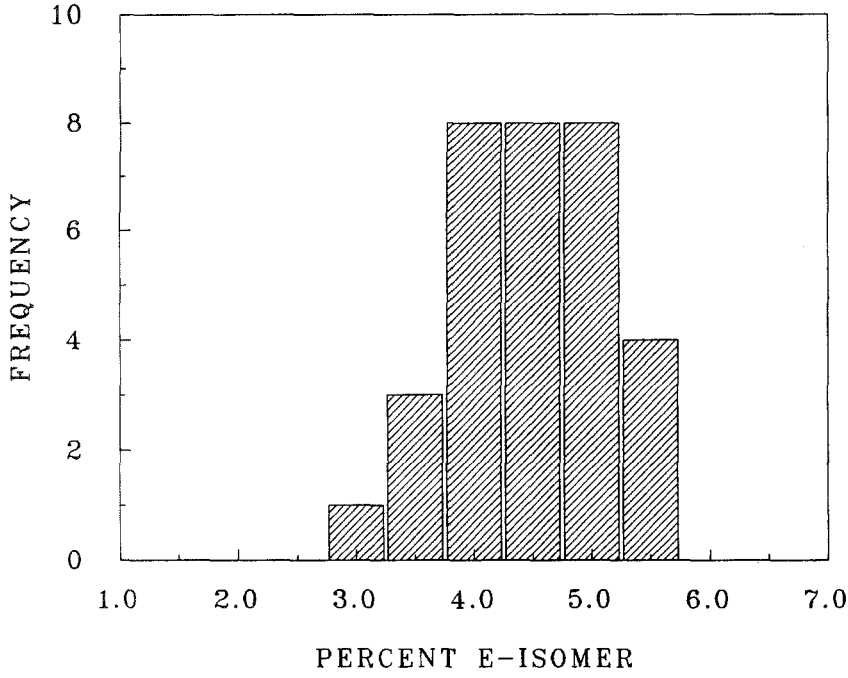

FIG. 3. Frequency distribution of percent *E* isomer of Δ-8-dodecenyl acetate in pheromone collected from individual female oriental fruit moths ($N = 32$).

delayed, and because all sexual activity ceases soon after dark, the period of sexual activity is restricted to only one or two hours (Rothschild and Minks, 1974; Vickers et al., unpublished data). Considerable variation was found in the postures adopted by calling female moths. Conner and Best (1988) have shown that airflow is faster around female moths that adopt a raised-wing calling posture, which in turn increases the volatilization rate of pheromone from the gland surface. Some of the highest release rates in the present study were from females with raised wings, although these could not be attributed to air currents because there was little air movement inside the flasks. Under field conditions, however, where moving air would be a factor, even greater differences in release rate among females can be expected.

Several investigators have used glass-adsorption techniques, involving either static or moving air, to collect the pheromone released by calling female moths. Placing moths in a closed container with static air is a simple and convenient technique, and recovery rates of synthetic standards up to 90% have been reported. However, 75% of the pheromone emitted by the moths can be lost due to adsorption onto the bodies of the insects themselves (Baker et al., 1980;

Ramaswamy and Cardé, 1984; Robacker and Johnson, 1989) and by enzymatic breakdown by the moth scales (Morse and Meighen, 1984), which introduces a major source of error. The situation can be improved by introducing an airflow (Weatherston et al., 1981), but some losses due to adsorption by the moths and by enzymatic breakdown can still occur. Furthermore, the results provide only average figures for groups of moths. This problem can be avoided by confining individual insects in glass tubes and forcibly extruding the gland into an airstream (Haynes et al., 1983, 1984; Haynes and Hunt, 1990). However, forcibly confining the female interferes with normal behavior and precludes the determination of natural release rates of pheromone, which was the main objective of the present study.

In a significant improvement in technique, the female is allowed to call spontaneously in a glass container while its effluvium passes through a small trap (Bjostad et al., 1980; Barrer et al., 1987; Schal et al., 1987; Witzgall and Frérot, 1989). However, the methods of Bjostad et al. (1980) and Schal et al. (1987), which require relatively large amounts of solvent in order to recover pheromone from Porapak Q adsorbent in the traps, are inappropriate for identification and quantification of subnanogram quantities of components and can vitiate accurate assessments of fractional composition. Moreover, while these limitations are easily obviated by methods that use bare glass capillaries as individual traps (Barrer et al., 1987; Witzgall and Frérot, 1989), their design does not guarantee an unimpeded passage of aerially released pheromone from gland to trap (Shani, 1990). The capillary method used in the present study solves all these problems. The female moth is free to adopt a natural calling position, and the emitted effluvium is drawn immediately into the glass capillary before it can come into contact with the body of the moth and from where it can be removed with small amounts of solvent. The technique is particularly well suited to insects such as the OFM, where the female moths will call in a small container, adopt a characteristic calling position and remain stationary for long periods of time. Loss of material from the air drawn into the capillaries was unlikely. At a flow rate of 25 ml/min there was no breakthrough with a 30-cm length of glass tubing (ID 0.9 mm), and for most of the collections a 60-cm length was used. However, the quantity of pheromone collected will be affected by the positioning of the capillary. This was dependent upon the position adopted by the female, which, when vertical with a well-extruded gland, allowed precise positioning of the capillary.

It was from females such as these that successive collections were made. This involved the insertion and positioning of new capillaries for each collection. Similar results were obtained on each occasion (Table 1), which demonstrates the reliability of the technique when the females are positioned conveniently. However, it was difficult to position the capillary accurately on females that adopted horizontal positions either on the sides or the roof of the flasks. For

this reason it is probable that the estimates for some females are low and the distribution of release rates is probably biassed towards the low end of the range.

The average release rate of 8.5 ng of Z8–12:OAc/calling hour is nearly three times the rate per insect (3.2 ng/hr) recorded from groups of female OFM by Baker et al. (1980). The reason for this discrepancy probably lies in the methods of collection. As pointed out above, the capillary method appears to be highly efficient when the capillary can be well positioned and, because the effluvium is drawn into the capillary immediately, there is little chance for it to be adsorbed onto the moth's body or to be broken down enzymatically. Baker et al. (1980) placed groups of 50 females in flasks, left them for 3 hr in static air, and then rinsed the walls of the flasks with hexane to collect the effluvia adsorbed onto the glass. They estimated that 90% of the material was adsorbed onto the moths, and they had to correct their estimates accordingly, which introduces a large uncertainty. Furthermore, it is very probable that there was considerable disturbance among the 50 moths in each flask and, although estimates were adjusted for the numbers of females calling, disturbed females probably produce less pheromone per hour because of delays in start-up.

Comparisons with other species of Lepidoptera are difficult because of the different collection techniques used and the different durations of collection. However, the release rates for OFM are similar to those recorded for other Tortricidae. Female spruce budworm, *Choristoneura fumiferana* (Clem.), release about 10 ng/calling female per hour (Silk et al., 1980; Ramaswamy and Cardé, 1984) with bursts of up to 50 ng/hr (Morse et al., 1982). Female carnation tortrix moths, *Cacoeciomorpha pronubana* Hbn., average 27 ng/hr with peaks close to 50 ng/hr (Witzgall and Frérot, 1989). The lowest rates reported from female Lepidoptera are a few nanograms per hour from the almond moth, *Ephestia cautella* (Wlk.) (Barrer et al., 1987; Shani, 1990). Forcibly extruded glands of the artichoke plume moth, *Platyptilia carduidactyla* (Riley) (Haynes et al., 1983), the pink boll-worm, *Pectinophora gossypiella* (Saunders) (Haynes et al., 1984), *Heliothis virescens* (F.) (Pope et al., 1982), and *H. zea* (Boddie) (Pope et al., 1984) all gave release rates of around 1–3 ng/min. Unconfined female *H. virescens* released about 400 ng/day, with a peak of about 140 ng/2 hr, while *H. subflexa* (Guenée) released about 870 ng/day with a peak of 335 ng/2 hr (Heath et al., 1991). A release rate of 880 ng/day was recorded from *Trichoplusia ni* (Hübner), with bursts of up to 50 ng/5-min period (Bjostad et al., 1980). Measurements of the release rate of pheromone from female gypsy moths, *Lymantria dispar* L., vary from 28 ng/2 hr (Charlton and Cardé, 1982) to as much as 4 μg/day (Ma and Schnee, 1983) with a peak rate of about 840 ng/30 min (Richerson and Cameron, 1974). The highest release rates recorded are from females of the arctiid, *Holomelina lamae* (Free.), which achieve a rate of 350 ng/10 min in short pulses (Schal et al., 1987).

These different release rates are associated with different calling behaviors.

The high rates achieved by the Arctiidae are associated with frequent extrusions and retractions of the gland, a strategy that presumably increases the effective range of threshold amounts of pheromone for male perception, but that provides an intermittent signal. Tortricids, such as OFM, spruce budworm, and carnation moth, which leave the gland extruded for long periods, release less pheromone per unit time, but provide a continuous signal. These different strategies will influence the efficacy of attempts to control populations by mating disruption and illustrate the need for a full understanding of how mating disruption works. If disruption is achieved by "false-trail following" (Bartell, 1982), then massive amounts of pheromone will have to be released to disrupt the arctiids, compared to species such as OFM. However, if adaptation and/or habituation are important, then the continuous release of lower amounts of pheromone may be equally effective for both types of insect.

Even though the release rates varied quite widely among the OFM females, the isomeric ratio remained remarkably constant. The standard deviation of 0.6% is much lower than those recorded for other species, 2.3–5.4% for the pink boll-worm (Haynes et al., 1984; Collins and Cardé, 1985) and 2.6% for *Argyrotaenia velutinana* (Walker) (Miller and Roelofs, 1980). One possible explanation is that low standard deviations for isomeric ratios are, in fact, normal for most species and that higher variation is the result of artifacts, such as differential destruction of isomers through enzymatic action, which is avoided by the improved collection procedure of the present study. Another possibility is that OFM, at least in Australia, is under considerable selection pressure from other insects using *E*8- and *Z*8–12:OAcs, resulting in a precise *E*:*Z* isomer ratio. A further possible explanation for the low variability is that the laboratory population originated from only a few insects from one location. The mean figure of 4.2% *E* isomer is lower than that reported for OFM from elsewhere. Biwer et al. (1979) reported the proportion of *E*- to be 8% in Europe, while Cardé et al. (1979) reported 6.5% in the United States. Possibly this difference is because of genetic drift in the Australian population, although logically this should also lead to a less precise *E*:*Z* ratio. A more likely explanation is that the Australian population has come under more intense selection pressures due to other species using the same compounds and which do not occur in Europe or North America.

The amount of the alcohol, *Z*8–12:OH, found in the present study (0.45% of the *Z*8–12:OAc) is considerably lower than the 17% reported by Cardé et al. (1979). Possibly this again reflects a difference between Australian and North American populations. Experiments in North America show that *Z*8–12:OH has a profound effect on behavior. Baker and Cardé (1979b) obtained a 10-fold increase in trap capture of OFM males when *Z*8–12:OH was added to the acetates. In wind-tunnel assays, Linn and Roelofs (1983) showed that the addition of *Z*8–12:OH over the range 2–100% of the acetates increased responses.

However, there was little difference due to different loadings over this range, although the durations of the responses were affected. Linn and Roelofs (1983) concluded that a loading of around 10% Z8–12:OH was optimum [which will produce a release rate from the rubber septa of around 30% that of the acetates (Baker et al., 1980; Heath et al., 1986)]. The role of Z8–12:OH in the behavior of OFM in Australia has not been thoroughly addressed, but its presence at loadings of 5% of the acetates on rubber substrate enhances wind-tunnel responses and trap-catches (Sanders, unpublished data).

The role of the saturated alcohol, 12:OH, is questionable. Cardé et al. (1979) reported that it represented about 4.5% of the total pheromone titer, but Biwer et al. (1979) were unable to detect any above their detection threshold of 2%. Early bioassays (Cardé et al., 1975) indicated that 12:OH had a synergistic effect when present at high dosages (three times the amount of the acetates), but later work suggested that 12:OH is redundant, showing synergistic effects only when in blends containing reduced amounts of the Z8–12:OH (Baker and Cardé, 1979b; Linn et al., 1986). In the present analyses we found traces of 12:OH, but attribute these to impurities in the solvent. We also found traces of the saturated aldehyde, 12:Ald, but also attribute these to impurities. An homologous series of saturated normal alcohols and aldehydes is present at trace levels in petroleum-derived hydrocarbon solvents such as pentane and hexane, which probably arise by reforming and oxidation during the refining.

The presence of the saturated acetate, 12:OAc is perhaps of greater significance. It has not been reported previously in the pheromone of OFM, but we found fairly constant amounts (3.44 $\pm$ 1.66%). Rothschild (1974) found that the presence of large amounts of 12:OAc (exceeding the amount of the unsaturated acetates) reduced trap catch. The 12:OAc therefore has biological activity, which could be expressed differently at lower concentrations. Possibly its role in the pheromone of OFM has been overlooked. It is a common impurity in Δ8–12:OAc and may well have been present in small amounts in pheromone blends tested previously in laboratory and field.

It is generally believed that disruption of mating behavior is most efficiently achieved by using the blend that most closely approximates that of the virgin female moth (Minks and Cardé, 1988). Although disruption of OFM can be achieved by a binary blend of the acetates, E8- and Z8–12:OAc, apparently with or without the addition of Z8–12:OH (Vickers and Rothschild, 1985), it is possible that this could be achieved more efficiently, and perhaps more cheaply, by blends containing Z8–12:OH and additional minor pheromone components. Mating disruption, as a method of controlling OFM populations, aims at preventing the male moths from locating the calling female moths. To understand how disruption works, it is therefore essential to know how potent the virgin females are, and for this the maximum release rate must be known, not merely

the average. This study has established that the maximum release rate of Z8–12:OAc by calling female OFM is at least 25 ng/female/hr.

Abstract—Surface-active lysophospholipids are thought to interfere with tannin–protein interactions and may comprise an adaptation in Lepidoptera to tannin-rich diets. We found several lysophospholipids and phospholipids at about eight times the critical micelle concentration (CMC) in the midguts of gypsy moth larvae, which exhibited appropriately reduced surface tensions. We confirmed the interfering activity of lysophosphatidylcholine (lysolecithin) in a model astringency assay using tannic acid and hemoglobin (hemanalysis), but discovered that tannic acid and red oak tannin extracts precipitate the lipid from simulated midgut solutions quantitatively, even at pH 10. Leaf tannin extracts from trees on which gypsy moths grew and reproduced poorly precipitated lysolecithin more effectively than did extracts from trees on which gypsy moths performed well. Adding tannic acid to midgut fluid elevated surface tension, and about 25% of larvae feeding on oak leaves exhibited elevated midgut surface tension, suggesting a loss of surfactants. Larvae appear able to replace lost surfactants to a limited degree. An important effect of leaf tannins, and perhaps other phenolics, may be to reduce concentrations of surface-active phospholipids in the midgut and produce lipid or other dietary deficiencies in insects.

Key Words—Tannins, phenolics, surface tension, surfactants, lysolecithin, lysophosphatidylcholine, lipids, detergents, protein, *Lymantria dispar* L., gypsy moth, Lepidoptera, Lymontriidae, red oak, *Quercus rubra* L.

INTRODUCTION

Tannins and other phenolics that occur widely in plants are capable of binding to proteins to form soluble (Hagerman and Robbins, 1987) or insoluble (Sumere et al., 1975; Hagerman and Butler, 1981) complexes, via hydrogen (Hagerman, 1988) or covalent (Felton et al., 1989a) bonding. This affinity for proteins can result in enzyme inhibition (Goldstein and Swain, 1965; Felton et al., 1989b), the repellent taste sensation called astringency or digestion inhibition (Feeny, 1970; Felton et al., 1989a). However, although tannin activity against pathogens and vertebrate herbivores has been demonstrated, there have been few successful attempts to show a negative impact of plant tannins on herbivorous insects (Bernays, 1981; Martin and Martin, 1984; Schultz, 1989).

As is the case for many insect species that feed on plants containing toxins, natural selection should favor traits that reduce negative tannic influences on individuals. Traits such as alkaline midgut pH (Feeny, 1970; Berenbaum, 1980; Schultz and Lechowicz, 1986), high cation concentrations (Martin et al., 1985), reducing midgut conditions (Appel and Martin, 1990), and the presence of detergents (Martin and Martin, 1984; Martin et al., 1985) have been proposed as influences on the activity of dietary tannins in insects (Appel and Schultz, 1992). Each of these factors can reduce the affinity of tannins for proteins (Felton and Duffey, 1991).

Martin et al. (1985) suggested that midgut detergency represents a widespread adaptation to dietary tannins in Lepidoptera larvae. They showed that detergency caused by the presence of lysophosphatidylcholine (lysolecithin) is more effective than high alkalinity in reducing the amount of plant protein precipitated by tannins under simulated midgut conditions in vitro. Other work done in vitro (Felton and Duffey, 1991) suggests that lysolecithin enhances protein solubility and diminishes oxidative activation of tannins by polyphenol-oxidase. These results have led these authors to call into question the assertion (Feeny, 1970) that plant tannins can actually have a negative impact on insects in a general, dose-dependent way.

In this study we confirmed that lysolecithin, which commonly occurs in insect guts, does interfere with a model tannin–protein binding–precipitation system. However, at least part of the interference is due to binding between the detergent phospholipid and tannin, ultimately resulting in precipitation. As a result of this interaction, dietary tannins or other phenolics could deplete surfactant phospholipids in the gut, increasing gut surface tension. Because surfactant phospholipids such as lysolecithin are critical to the bioavailability of dietary lipids in Lepidoptera (Turunen, 1983; Turunen and Kastari, 1979), and because high concentrations are necessary to inhibit tannin–protein binding, tannins could act as dose-dependent antidigestive factors under commonly occurring gut conditions. We present evidence to suggest that these factors influence

the performance of the gypsy moth (*Lymantria dispar* L.), an herbivorous lepidopteran feeding primarily on tannin-rich hosts.

METHODS AND MATERIALS

Phospholipid Content of Larval Midgut Fluid. We attempted to determine whether surfactant lysophospholipids were present in the midgut lumens of larvae of the gypsy moth using two-dimensional, thin-layer chromatography (Harborne, 1984). This organism, as larvae, feeds primarily and successfully on tannin-rich tree species worldwide (Barbosa and Krischik, 1988). All larvae for this and subsequent experiments were reared from eggs obtained from the USDA/ARS Otis Methods Development Laboratory, Otis AFB, Massachusetts.

Midguts were surgically removed from several diethylether-anesthetized fifth-instar larvae reared on artificial diet (Odell and Rollinson, 1966). The midgut fluid was removed and centrifuged at 13,000*g* for 2 min. Lipids were extracted from the supernatant according to the method of Bligh and Dyer (1959). The lipid extract was applied to a 20 × 20-cm silica gel glass TLC plate (Sigma). The solvent system in the first direction was $CHCl_3$–methanol–glacial acetic acid–water, 170:25:25:4. After the lipids were separated in the first dimension, the plate was rotated 90 degrees and subjected to a second solvent system, the composition of which was $CHCl_3$–Methanol–NH_4OH, 65:30:4. The spots were visualized using the phospholipid reagent of Fried and Sherma (1982). Spots were identified by cochromatography with phospholipid standards. The standards used were lysophosphatidylcholine, lysophosphatidylethanolamine, lysophosphatidylglycerol, lysophosphatidylinositol, lysophosphatidylserine, lysophosphatidic acid, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, phosphatidylserine, and phosphatic acid (Sigma).

Surface Tension and Critical Micelle Concentration of Gypsy Moth Larval Midgut Fluid. Surface tension of midgut fluid was determined using an inclined-tube manometer (Fisher) according to the method of Ferguson (1943) for microvolume quantities. Midgut fluid from 100 larvae fed on artificial diet (Odell and Rollinson, 1966) was individually measured to determine mean surface tension expressed in dynes per centimeter. Midgut contents were isolated from diethylether-anesthetized larvae as above and subjected to a 2-min, 13,000*g* centrifugation. The supernatant was drawn into a 25-μl micropipet. The surfactant concentration, in multiples of the critical micelle concentration, was also determined using the method of Martin et al. (1987). The critical micelle concentration (CMC) is that concentration of a surfactant at which there is a transition between the surfactant in the free, disassociated state and the micellar state (Martin et al., 1987). This transition is characterized by an abrupt change in

the surface tension of the solution. For this determination, the midgut fluids of 78 caterpillars were combined and a midgut fluid dilution series was prepared using distilled water. Surface tension was determined as above.

In vitro Inhibition of Tannin–Protein Precipitation by Lysolecithin. The impact of lysolecithin on astringency (Bate-Smith, 1973) was quantified using hemoglobin as the protein substrate and tannic acid (Sigma, batch T-1025) solutions (Bate-Smith, 1973; Schultz et al., 1981). For this and subsequent experiments, tannic acid was purified using Sephadex LH-20 columns as described by Hagerman and Klucher (1986). Hemoglobin solutions were diluted with either distilled water or a solution of lysophosphatidylcholine (lysolecithin; Sigma) in water to give a blank absorbance of 2.0 at 578 nm. This wavelength was used because it is an absorption maximum for hemoglobin. One milliliter of tannic acid in distilled water was added to 2 ml of these hemoglobin solutions while vortexing. Final concentration of tannic acid solutions ranged from 0 to 10 mg/ml. Hemoglobin–lysolecithin–tannin solutions had final lysolecithin concentrations of either 0.06% or 0.09% (w/v); these concentrations were chosen to represent likely physiological levels in larvae (Martin and Martin, 1984). The final pH of the solutions was found to be about 7 throughout the range of tannic acid added. In all cases, vortexed solutions were centrifuged at 13,000*g* and the absorbance of the supernatant read at 578 nm to quantify protein (hemoglobin) precipitation (Schultz et al., 1981).

In vitro Precipitation of Lysolecithin by Tannic Acid and Oak Leaf Extracts. Tannic acid or red oak (*Quercus rubra* L.) leaf extracts were used to precipitate lysolecithin from a radiolabeled lysolecithin solution. A lysolecithin solution having a specific activity of 17 μCi/mM was prepared by mixing 53 mCi/mM of [^{14}C]lysopalmitoylphosphatidylcholine (New England Nuclear) in methanol–toluene (1 : 1, v/v) with unlabeled lysopalmitoylphosphatidylcholine (Sigma). Aliquots of this lysolecithin solution, containing 1.2 μmol, were then placed in 1.5-ml polypropylene microcentrifuge tubes.

After the organic solvents were evaporated to dryness, 0.5 ml of a stock saline solution and 0.25 ml of a buffer solution were added to the tubes and vortexed for 2 min. Final composition of the saline solution was 2.5 mM NaCl, 131 mM KCl, 16 mM $CaCl_2$, and 25 mM $MgCl_2$. These were chosen to approximate the conditions in the midgut of lepidopteran larvae (Martin et al., 1985). It is known that the pH of a gypsy moth gut can vary over a wide range, depending upon larval age, larval diet, and gut region (Schultz and Lechowicz, 1986). Because of this, several different buffers were used, over a range of pHs, to determine the effects of pH on the ability of tannin to precipitate lysolecithin. The buffers used were 50 mM MES [2(*N*-morpholino)ethanesulfonic acid, pH 6.0], 50 mM HEPES (*N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid, pH 7.0), 40 mM CHES [2(*N*-cyclohexylamino) ethanesulfonic acid, pH 9.0], and 50 mM CAPS (3-cyclohexylamino-1-propanesulfonic acid, pH 10.0).

For precipitation assays, 0.25 ml of either the tannic acid (Sigma, T-1025) solutions or aqueous red oak leaf extracts were added to the lysolecithin solutions. Final lysolecithin concentration in both cases was 0.06% (w/v) (1.2 mM). This concentration of lysolecithin is about 15 times the critical micelle concentration (Martin and Martin, 1984), which was calculated to be 80 μM. Final tannic acid concentrations used ranged from 0 to 0.60 mg/ml.

Leaf extracts were obtained from the mature leaves of two red oak individuals as in Rossiter et al. (1988). The two trees used were numbered 34 and 43. These two trees were selected because they had the lowest and highest hemoglobin-binding capacity and supported the best and worst growth by gypsy moth larvae, respectively, in a concurrent study (Rossiter et al., 1988). An extract dilution series in 10% increments from 0 to 100% full strength was prepared for the two extracts using distilled water. The astringency of the extracts was determined in the absence of lysolecithin using hemoglobin as the protein substrate (Schultz et al., 1981).

After the addition of either the tannin or oak leaf extract solutions, the tubes were vortexed for 1 min, allowed to stand at room temperature for 15 min, and then centrifuged at 13,000*g* for 4 min. The supernatant was carefully and completely removed from each microcentrifuge tube, placed in a scintillation vial with 10 ml of scintillation cocktail (Hydrocount, Baker) and vortexed for 15 sec. Disintegrations per minute (dpm) were determined in a Beckman scintillation counter (model LS8000) with automatic quench correction. The amount of lysolecithin remaining in the supernatant after tannic acid or leaf extract addition was determined from the disintegrations per minute and expressed as micromoles per milliliter.

Impact of Tannic Acid on Surface Tension of Larval Midgut Fluid and Lysolecithin Solutions. Midgut fluid of gypsy moth larvae reared to the fifth instar on artificial diet was collected as described above and pooled. Nonbuffered tannic acid solution was added to subsamples of this midgut fluid in a ratio of 1:3 tannic acid solution to midgut fluid. The final concentration of tannic acid ranged from 0 to 2.4 mg/ml. Surface tension of the resulting solution was measured. The influence of tannic acid on the surface tension of buffered, saline, lysolecithin solutions, simulating midgut fluid, was also determined. Final composition of the saline solutions was as before, 2.5 mM NaCl, 131 mM KCl, 16 mM $CaCl_2$, and 25 mM $MgCl_2$. The final lysolecithin concentration was 0.06% (w/v). The pH of the solutions was either 6 (buffer: 50 mM MES) or 10 (buffer: 50 mM CAPS). Tannic acid, dissolved in water, was added to the above, yielding final concentrations ranging from 0 to 0.60 mg/ml. The solution was vortexed and the surface tension measured. Significance of differences among treatments was determined using general linear models (GLM) procedures (SAS Institute, 1985).

Impact of Oak Leaf Diets on Midgut Surface Tension. To determine the

effects of dietary tannins on midgut fluid surface tension, 77 fifth-instar gypsy moth larvae reared on artificial diet were switched to randomly selected, fresh red oak leaves. Other red oak leaves from the same tree were harvested and an astringency profile was determined for the tree (see below). The larvae were allowed to feed freely for 24 hr, at which time the surface tension of their midgut fluid was measured.

Astringencies of Red Oak Leaves. We randomly collected 64 leaves from the same red oak tree used for the effects of dietary tannins on midgut surface tension to ascertain the frequency with which gypsy moth larvae might encounter and ingest leaves having astringencies high enough to influence midgut surface tension. Four hundred milligrams of lyophilized powder from each leaf were extracted with acetone. The astringency of the extract was measured as its ability to precipitate hemoglobin from solution (Bate-Smith, 1973; Schultz et al., 1981; Rossiter et al., 1988). Astringency of the extract is expressed as percent tannic acid equivalents (% TAE) using purified tannic acid as a standard (Sigma, batch T-1025). The % TAE is therefore the equivalent fraction of the dry weight of the original leaf that would have to be tannic acid to produce a measured affinity for hemoglobin, although tannic acid per se is not likely to be present in red oak leaves. This measure of astringency was then converted to an equivalent concentration of tannic acid in water for comparison with other experimental results.

Impact of Variation in Dietary Lipids on Surface Tension. To determine what effect dietary lipids had on the surface tension of midgut fluid, 150 larvae were reared on a lipid-rich artificial diet (Odell and Rollinson, 1966). Upon reaching fifth instar, half were switched to a low-lipid diet in which wheat germ was replaced with casein, on a gram for gram basis. A lipid extraction (Bligh and Dyer, 1959) of the components of the diet, followed by gravimetric determination, indicated that the original artificial diet was about 6.6% dietary lipid by dry weight, whereas the lipid-reduced diet was approximately 0.8% lipid. At intervals of 24 hr, 10 larvae were randomly harvested from each group and the surface tension of their midgut fluids measured individually.

Significance of variation in midgut surface tensions among treatments (diets) and dates was determined using GLM procedures (SAS Institute, 1985).

RESULTS

Phospholipid Content of Larval Midgut Fluid. Two-dimensional, thin-layer chromatographic analysis of the phospholipids of midgut fluid of fifth-instar gypsy moth larvae revealed three principal phospholipids in addition to several minor ones (data not shown). The three were identified, by cochromatography with known standards, as lysolecithin, phosphatidylcholine, and phosphatidyl-

ethanolamine. Some of the minor phospholipids cochromatographed near the position of some of the other lysophospholipid standards, but they could not be positively identified.

Surface Tension and Critical Micelle Concentration of Gypsy Moth Larval Midgut Fluid. The mean surface tension of undiluted midgut fluid from larvae reared on artificial diet was 32.4 ± 1.4 (standard deviation) dynes/cm. The surfactant concentration of pooled midgut fluid from moth larvae reared on artificial diet was estimated to be eight times that of the CMC.

In vitro Inhibition of Tannin–Protein Precipitation by Lysolecithin. The relationships among protein precipitation, lysolecithin concentration, and tannic acid concentration are illustrated in Figure 1. At 0% lysolecithin, there was a threshold of 1.0 mg/ml tannic acid before significant amounts of hemoglobin were precipitated. Once this concentration was reached there was a linear relationship between percent hemoglobin precipitated and tannic acid concentration (slope = 0.586; r^2 = 0.989). The addition of lysolecithin raised the threshold concentrations of tannic acid required to precipitate hemoglobin. As the tannic acid concentration was increased to 4.0 mg/ml in the presence of 0.06% lysolecithin, more hemoglobin was precipitated, but to a lesser extent than without lysolecithin. Only at tannic acid concentrations greater than 4.0 mg/ml were significant amounts of hemoglobin removed from solution in 0.06% lysolecithin.

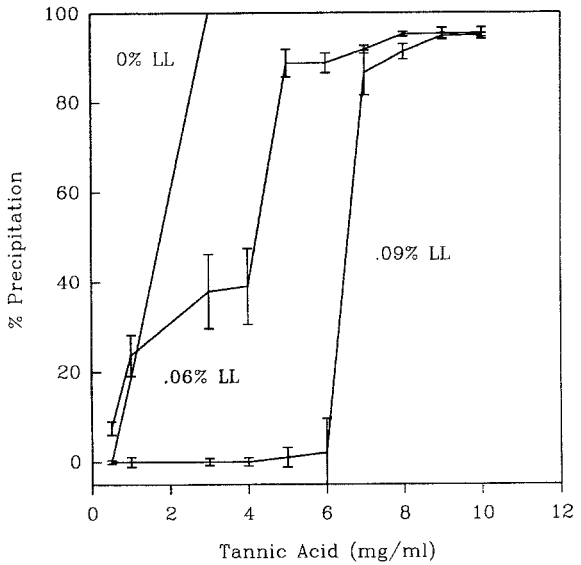

FIG. 1. Precipitation (as percent of maximum) of hemoglobin by purified tannic acid with 0%, 0.06%, and 0.09% lysolecithin (w/v) present. Vertical bars are one standard deviation.

In 0.09% lysolecithin, tannic acid concentrations greater than 6.0 mg/ml were required for hemoglobin precipitation.

In vitro Precipitation of Lysolecithin by Tannic acid and Oak Leaf Extracts. Tannic acid precipitated lysolecithin from solution quantitatively (Figure 2). At pH values of 6.0 and 7.0, there was a linear relationship between tannin concentration and lysolecithin precipitation above a threshold concentration of 0.24 mg/ml. Tannic acid, at a concentration of 0.60 mg/ml, precipitated lysolecithin to the point that it was below its CMC at both pH 6.0 and 7.0. For pH 9 and 10, a threshold tannic acid concentration was not evident; some lysolecithin was removed at the lowest tannic acid concentration, although more tannic acid was required per unit lysolecithin precipitated. As a result, more lysolecithin remained in solution at high tannin concentration at pH 9 and 10 than at 6 or 7. However, the lysolecithin remaining in solution at 0.60 mg/ml tannic acid at pH 9 was still near the critical micelle concentration of 80 μM.

Oak leaf extract also precipitated lysolecithin from solution (Figure 3). The extract from tree 43, which had an estimated astringency (affinity for hemoglobin) of 30.1% TAE, was more effective at precipitating lysolecithin than was the extract from tree 34, which had an astringency of 10.5% TAE (Figure 3). Both extracts precipitated lysolecithin more effectively at pH 6 than at pH 10.

Impact of Tannic Acid on Surface Tension of Larval Midgut Fluid and Lysolecithin Solutions. The effect of tannic acid on the surface tension of midgut fluid is illustrated in Figure 4. The pH of the gut fluid was 8.0. Tannic acid

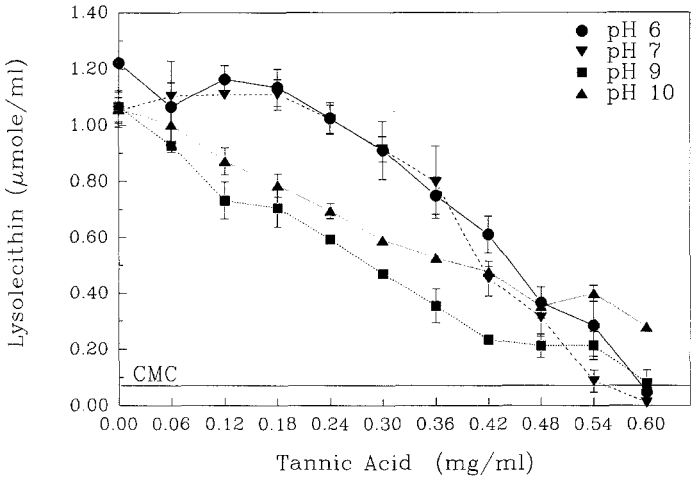

FIG. 2. Precipitation of radiolabeled lysolecithin by purified tannic acid at 4 pH values. CMC = critical micelle concentration of lysolecithin. Vertical bars are one standard deviation.

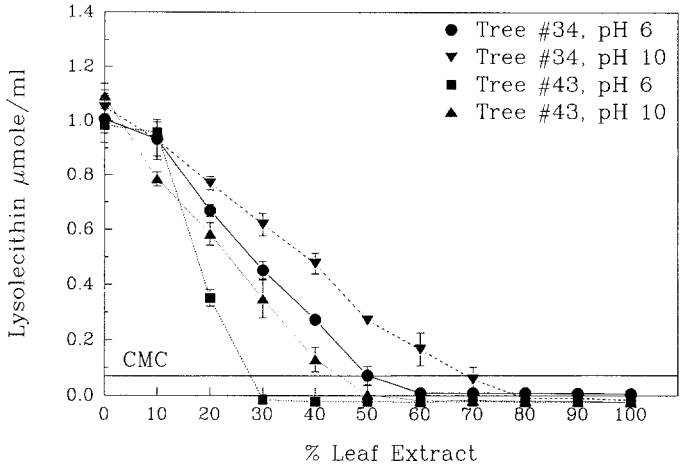

FIG. 3. Precipitation of radiolabeled lysolecithin by a dilution series of red oak leaf extracts; 100% leaf extract = undiluted extract. Extracts from tree 43 had three times the astringency of those from tree 34 and supported gypsy moth growth half as well (Rossiter et al., 1988). CMC = critical micelle concentration of lysolecithin. Vertical bars are one standard deviation.

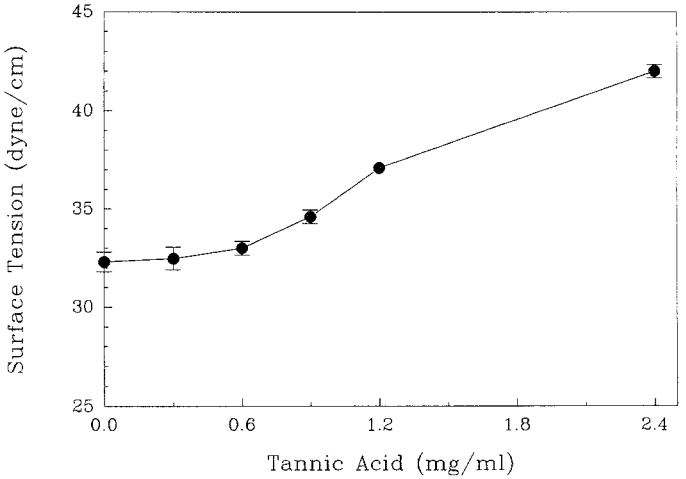

FIG. 4. Effect on surface tension of adding tannic acid to gypsy moth midgut fluid. Tannic acid concentrations are final concentrations. Vertical bars are one standard deviation. Surface tension is significantly greater above 0.9 mg/ml tannic acid (ANOVA, $P < 0.01$).

concentration of about 1.2 mg/ml in the midgut fluid caused an increase in surface tension. Tannic acid also caused an increase in the surface tension of a 0.06% lysolecithin solution in a dose-dependent, pH-sensitive fashion (Figure 5). At pH 6.0, tannic acid concentration in a range of 0–0.54 mg/ml had no effect on the surface tension of a lysolecithin solution. However, there is a distinct rise in surface tension at a tannic acid concentration of 0.60 mg/ml. Tannic acid, in the range of 0–0.60 mg/ml, had no effect on surface tension of a 0.06% lysolecithin solution at pH 10.0.

Impact of Oak Leaf Diets on Midgut Surface Tension. The consequences of switching larvae from artificial diet to red oak leaves can be seen in Figure 6. The 100 larvae reared on artificial diet had a mean midgut fluid surface tension of 32.4 ± 1.4 dynes/cm. Although the mean midgut fluid surface tension of the larvae that had consumed oak leaves for 24 hr was not significantly different (33.2 ± 2.5 dynes/cm; $P > 0.05$), the shapes of these two frequency distributions were significantly different (chi-square analysis, $P < 0.05$). This difference was due mainly to greater variation in midgut fluid surface tension among leaf-fed larvae (coefficient of variation = 7.5%) than in artificial diet-fed larvae (coefficient of variation = 4.3%). In our experiments, midgut fluid ranged between 32 and 33 dynes/cm. Approximately 22% of leaf-fed, but only 9% of diet-fed, larvae had midgut surface tensions above 33 dynes/cm; 36% of leaf-fed and 23% of diet-fed larvae had midgut surface tension below 32 dynes/cm.

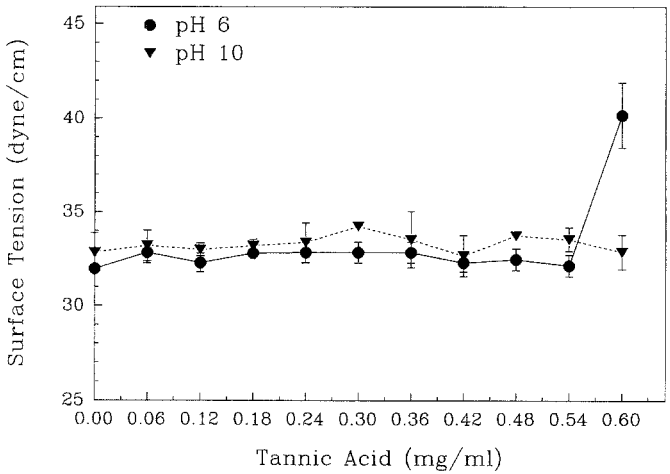

FIG. 5. Effect on surface tension of adding tannic acid to simulated midgut fluid with 0.06% (w/v) lysolecithin at 2 pH values. Surface tension was different only at tannic acid concentration of 0.60 mg/ml, pH 6 (ANOVA, $P < 0.05$). Vertical bars are one standard deviation.

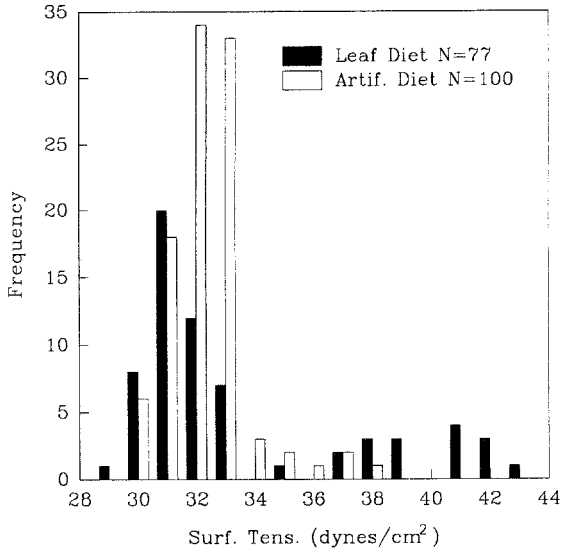

FIG. 6. Frequency distribution of midgut fluid surface tensions of fifth-instar gypsy moth larvae fed artificial diet (light bars) or red oak leaves (dark bars) for 24 hr.

Astringencies of Red Oak Leaves. The majority of the red oak leaf extracts assayed exhibited astringencies high enough to permit protein binding with physiological concentrations (0.06%) of lysolecithin present. In the protein-binding inhibition studies described above (Figure 1), hemoglobin precipitation in a 0.06% lysolecithin solution proceeded above tannic acid concentrations of 4 mg/ml. An extract from leaf powder having an astringency of 10% TAE has the same ability to precipitate hemoglobin as if it was 10% tannic acid by weight (Schultz et al., 1981). Because we used 400 mg dry weight of leaf powder and concentrated the extract to 10 aqueous ml, an extract from leaf material exhibiting 10% TAE has the same astringency as a 4 mg/ml tannic acid solution. Hatched bars represent leaves having TAE values above this level in Figure 7.

Impact of Variation in Dietary Lipids on Midgut Surface Tension. Larval midgut surface tension on normal and a reduced-lipid diet are shown in Figure 8. Initially, the mean midgut surface tension was 33.1 dynes/cm. The midgut fluid surface tension from larvae that remained on the lipid-rich diet did not vary significantly from this value over a seven-day period. After 24 hr, there was no significant change in the midgut fluid surface tension of larvae eating the reduced-lipid diet. However, at 48 hr and beyond, there was a significant increase in the surface tension of the midgut fluid (ANOVA, GLM procedure $P < 0.01$). The size of the larval fat bodies decreased over several days (unpublished observation). Midgut contents of larvae on reduced-lipid diet included exoskeleton parts,

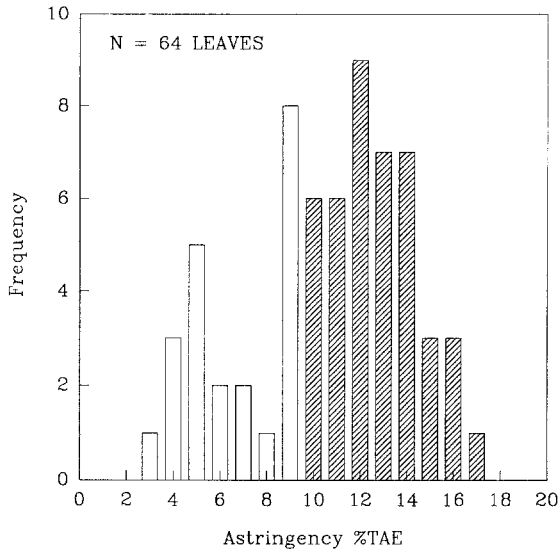

FIG. 7. Frequency distribution of the astringencies of 64 leaves from a single red oak tree (used to feed larvae in Figure 6). Astringencies greater than 10% (hatched) are calculated to be high enough to increase midgut surface tension of gypsy moth larvae.

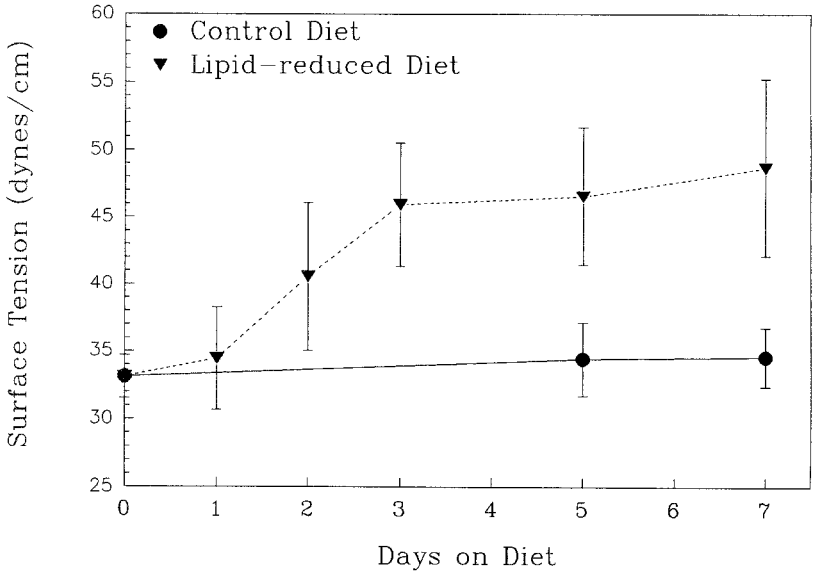

FIG. 8. Surface tension of midgut fluid from fifth-instar gypsy moth larvae reared on normal and reduced-lipid artificial diets. Values differ significantly after two days (ANOVA, $P < 0.02$). Vertical bars are one standard deviation.

and the number of caterpillars remaining in the common feeding container decreased at a rate greater than could be accounted for by harvest (unpublished observations). This strongly suggests that the surviving larvae were engaging in cannibalistic behavior. No such behavior was noted for larvae fed lipid-rich diet.

DISCUSSION

We found that surfactant phospholipids, including lysophosphatidylcholine (lysolecithin), occur in the midguts of gypsy moth larvae, where they appear to alter the surface tension of gut fluid. Larvae on tannin-free, lipid-containing diets had gut fluid surface tensions indicating lysolecithin concentrations up to eight times the critical micelle concentration. These results are similar to those of other workers (Martin and Martin, 1984, Felton and Duffey, 1991) for several other lepidopteran species. Martin and Martin (1984) pointed out that such gut fluid surfactants have been found in every insect species that has been studied. For this reason, and because the gypsy moth focuses much of its feeding on tannin-rich host plants (Barbosa and Krischik, 1988), it is not surprising to find detergents present in its midgut.

Larvae feeding on astringent red oak leaves exhibited more variable midgut surface tension than did larvae fed artificial diet. This is not surprising, given the numerous ways in which oak leaves must differ from the homogenous lab diet, and the fact that we could not measure the actual components of the leaf portions consumed and did not know how recently they had been consumed. These results suggest that dietary variation can influence concentration of surface active phospholipids. About 25% of leaf-fed larvae exhibited elevated midgut surface tensions, suggesting a reduction in surfactant concentrations. We hypothesized that surfactant activity might be lost (and surface tension increased) on diets having high tannin and/or low lipid concentrations.

As predicted, adding tannic acid to gypsy moth larval midgut fluid did increase surface tension. A significant rise in surface tension occurred above 1.2 mg/ml tannic acid, suggesting the existence of a threshold. A sharp threshold increase in surface tension was found above 0.54 mg/ml tannic acid in aqueous lysolecithin solutions buffered to pH 6. Although no such increase was seen in lysolecithin solutions buffered to pH 10, we only worked with tannic acid concentrations up to 0.60 mg/ml. This amount is insufficient to reduce the lysolecithin concentration at pH 10 below its CMC and half the amount seen to increase surface tension in midgut fluid. These results support our hypothesis that dietary tannin can reduce or eliminate surface activity of midgut phospholipids. More tannin is required for this impact at higher pH levels.

The mechanism by which tannin reduces midgut surfactance apparently involves tannin–lipid complexing. Takechi and Tanaka (1987) reported that

gallotannins were able to bind to basic lipids, such as lecithin and lysolecithin, although no precipitation was noted. We showed that the ability of lysolecithin to inhibit precipitation of hemoglobin (astringency) is lost above threshold tannin concentrations. These results, plus the observation of precipitates formed in tannin–lysolecithin solutions at low protein concentrations, indicated that tannins might actually be able to remove phospholipids from solution.

Indeed, we found that both tannic acid and red oak tannin extracts precipitate lysolecithin quantitatively from solution under conditions that simulate midgut cation concentrations and over a range of pH values. At lower pH values, this effect exhibited a prominent threshold; the threshold is less evident at higher pH values. Although we have not carried out a competitive binding study, our results lead us to hypothesize that the anticomplexing activity of midgut surfactants may be due to competitive binding with dietary tannins.

Surfactant concentrations in simulated gut fluid were reduced below the CMC by leaf extracts as dilute as 50% of full strength, even at pH 10. Larvae consuming these leaves are likely to experience a loss of surfactance. Extracts from tree 43 had a stronger effect on surfactant loss than did those from tree 34. These two trees were chosen for these experiments because extracts from tree 43 had three times the astringency of extracts from tree 34, and female gypsy moths reared on tree 43 had 50% lower pupal mass and fecundity than did females reared on tree 34 (Rossiter et al., 1988). Individual egg dry weights were also significantly lower on tree 43 than on tree 34 (Rossiter, personal communication).

We suggest that the ability of higher concentrations of leaf phenolics to reduce phospholipid concentrations below midgut CMC may be responsible for reduced growth and reproduction in gypsy moth larvae. Surface active lysophospholipids play a direct role in glyceride transport across mucosal cells in *Pieris brassicae* (Lepidoptera; Pieridae) (Turunen and Kastari, 1979) and facilitate lipid solubilization in many insects, activities analogous to those of bile in vertebrate digestive systems (Turunen and Kastari, 1979; Turunen, 1983; Turunen and Chippendale, 1989). Tannin-induced loss of surfactants in the midgut therefore could produce lipid deficiency, reduced adult weight, and reduced egg production and egg weight.

Dietary tannins might also be able to bind to the lipid component of epithelial cell membranes. This could lead to the disruption of membrane integrity and/or function. Such a phenomenon would explain why gut lesions are often observed in insects fed on high tannin diets (Steinly and Berenbaum, 1985). If epithelial cell membranes are vulnerable to tannin and/or phenolic binding, lysolecithin in the gut fluid may play a role in protecting these cells.

Two lines of evidence suggest that gypsy moth larvae may be able to "recharge" lost midgut lysolecithin from some source other than the diet for at least a limited time. First, caterpillars did not exhibit elevated midgut surface

tensions for 48 hr after being deprived of any phospholipid substrates. Second, fewer larvae than expected exhibited elevated midgut surface tensions when fed oak leaves that probably had high enough astringencies to reduce midgut surfactant concentrations.

The possibility that larvae may "recycle" or synthesize lysophospholipids to "recharge" midgut surfactants is inconsistent with present views of the sources and fate of these molecules in Lepidoptera. The lysolecithin in lepidopteran midguts is thought to arise from ingested lysolecithin and the hydrolysis of ingested dietary lecithin (Turunen, 1983). Lysolecithin is then absorbed by midgut mucosal cells, where it is resynthesized into the corresponding phosphatide (lecithin), which passes into the hemolymph (Turunen, 1983). Turnover time for lecithin in midgut cells is estimated at under 11 hr, and there is at present no known pathway by which it is returned to the midgut lumen (Turunen, 1983); in *P. brassicae*, "... dietary lecithin was found to be utilized by the larvae almost completely" (Turunen and Kastari, 1979). The means by which gypsy moth larvae maintained elevated midgut surface tensions 48 hr after their last meal containing phospholipids is therefore unknown. Some of the observed fat body depletion in these insects could have been caused by the use of fat reserves in maintaining midgut surfactant levels.

We have shown that gypsy moth larvae can suffer reduced midgut surfactance if they consume diets with moderate to high tannin concentrations. This effect appears to be due to precipitation of detergent lipids from solution by tannins and maybe other phenolics and is pH dependent. Reducing the midgut phospholipid concentration below its CMC should produce lipid deficiencies or reduced protein availability, depending on the tannin concentrations actually consumed. Because leaf tannin concentrations high enough to reduce lysolecithin concentrations below the CMC occur frequently in nature and seem to have a negative impact on gypsy moth growth and reproduction (e.g., Rossiter et al., 1988), we postulate that the loss of surfactant activity might comprise an important impact of plant tannins on this insect.

Acknowledgments—This research was supported by NSF grants BSR 8813433 and 8918083, and USDA grant 9100926 (J.C.S.). (Received February 3, 1992; accepted April 13, 1992)

Abstract—An in vitro study was performed to determine the potential application of tissue culture in determining allelopathic potential of *Artemisia princeps* var. *orientalis* (wormwood). Aqueous extracts and volatile substances of *A. princeps* var. *orientalis* were tested to determine their effects on callus induction and growth of several tested species. Extracts of 5% *A. princeps* var. *orientalis* caused some reduction in concentration, induction, and growth of callus, although they looked normal, whereas the explants of most receptor plants did not develop callus at higher concentration. Lettuce and *Eclipta prostrata* were the most sensitive species, and *A. princeps* var. *orientalis* was affected by its own extracts. The growth of calluses in MS 121 medium treated with essential oil of *A. princeps* var. *orientalis* was inhibited, and the degree of inhibition was proportional to the concentration of the essential oil.

Key Words—*Artemisia princeps* var. *orientalis*, allelopathy, aqueous extract, essential oil, callus induction, callus growth

INTRODUCTION

Several species of the genus *Artemisia* have been identified as having allelopathic potential (Funke, 1943; Halligan, 1976), based on seed germination and seedling growth bioassays. These findings were shown from aqueous extracts and volatile substances of *Artemisia*. Inhibition was due to various allelopathic chemicals

*To whom correspondence should be addressed.

(Yun, 1990). Microtests for allelochemicals using culture medium or extracts were first devised by Gressel and Holm (1964). Hogan and Manners (1990) reported that media and media extracts from callus cultures of small everlasting (*Antennaria microphylla*) inhibited leafy spurge callus tissue growth in suspension culture. The chronic involvement of hydroquinone, a previously isolated allelochemical from small everlasting, was implicated in the allelopathic interaction.

The present work deals with the effect of extracts and volatile substances of *A. princeps* var. *orientalis* on in vitro callus induction and growth of several plants.

METHODS AND MATERIALS

Preparation of Tissue Explants. Seed coats from the healthy seeds of *Artemisia princeps* var. *orientalis*, *Raphanus sativus* var. *hortensis* for. *acanthiformis*, *Eclipta prostrata*, *Zoysia japonica*, *Oryza sativa*, *Oenothera odorata*, and *Lactuca sativa* were removed. Seeds were rinsed in 75% ethyl alcohol for 30 sec and then placed in a 5% sodium hypochlorite solution for 15 min. The sterilized seeds were then washed with sterile distilled water three times. Two to three seeds were germinated on the surface of Murashige and Skoog's agar (MS) medium (Murashige and Skoog, 1962) in test tubes (2 × 15 cm). Callus culture medium containing 0.8% agar was adjusted to pH 5.6, and was autoclaved for 20 min at 121°C (Hogan and Manners, 1990).

Induction and Subculture of Callus for Testing. Leaf (5 mm^2) or hypocotyl (5 mm) explants of *A. princeps* var. *orientalis*, *R. sativus* var. *hortensis* for. *acanthiformis*, *E. prostrata*, *O. odorata*, and *L. sativa* were obtained from 7- to 12-day-old seedlings. Twelve segments were placed on the surface of 20-ml MS medium supplemented with 1 mg/liter of 2,4-D, 2 mg/liter of NAA and 1 mg/liter of kinetin (MS 121 medium) in a Petri dish (10 × 1.5 cm). The calluses of *Z. japonica* and *O. sativa* were directly induced from sterilized seeds on MS 121 medium. Induced calluses were subcultured every 30 days on the MS 121 medium to maintain continued growth, and the subcultured calluses were used for all experiments. The calluses were cultured in the dark at 25 ± 2°C (Lee et al., 1979).

Induction of Callus in Medium Containing Extracts. Leaf explants (5 mm^2) of *A. princeps* var. *orientalis* and lettuce were cultured in four-compartment Petri dishes containing MS 121 medium supplemented with different concentrations of the *A. princeps* var. *orientalis* water extracts. Water extracts were obtained as follows: One liter of distilled water was added to 200 g of the leaf at 20°C. After 24 hr, the aqueous extract was filtered through a 0.5-mm sieve, and the filtrates were either diluted to 5, 10, 20, 30, and 50% extracts or used

as an undiluted 100% extract. Three explants were put into each compartment with 5 ml of medium. The Petri dishes were sealed with parafilm (Whatman Co.) and incubated at 25°C in the dark to initiate callus induction. The callus induction was estimated and graded according to callus volume; good, bad, and none (Krikorian and Katz, 1968).

Callus Growth in Medium Containing Extracts. Calluses obtained from *A. princeps* var. *orientalis*, *R. sativus* var. *hortensis* for. *acanthiformis*, *Z. japonica*, *O. sativa*, *E. prostrata*, *O. odorata*, and *L. sativa* were cultured in the four-compartment Petri dishes containing MS 121 medium supplemented with different concentrations of *A. princeps* var. *orientalis* water extracts. The initial calluses were about 0.5 mm in diameter, and three callus masses were cultured in each compartment. The biomass of calluses was monitored by measuring dry weight (80°C, 48 hr) at 30–50 days. Dry weight of 10 calluses per treatment were obtained: Biomass as % of control = (Dry weight of callus on the extract medium/Dry weight of callus on the control medium) × 100.

Callus Growth Exposed to Essential Oil of Wormwood Plants. Essential oil was obtained as follows: Crushed wormwood leaf was placed in a glass flask (2000 ml) and water distillation was performed in Karlsruker's apparatus (Stahl, 1973). The water distillate was saturated with sodium sulfate and then extracted with ether. The ether extract was concentrated in an evaporator. Calluses obtained from *A. princeps* var. *orientalis*, radish, *E. prostrata*, and *Z. japonica* were placed in four-compartment Petri dishes containing 20 ml of MS 121 medium. Circles of filter paper with different amounts of essential oil from wormwood were put in the central well of the solid medium (0, 5, 10, 20, 30, 50, 100 μl per Petri dish). The Petri dishes were sealed with parafilm and incubated at 25°C in the dark. The biomass expressed as percent of control of calluses was monitored by the same method mentioned above.

RESULTS

Effect of Aqueous Extract on Induction and Growth of Callus. The induction of callus of *L. sativa* and *A. princeps* var. *orientalis* was affected by concentrations of *A. princeps* var. *orientalis* extracts as low as 5%. Growth of leaf explant was initiated after five to seven days, and induction of calluses from injured tissue occurred in about 10 days. The fresh callus tissue stayed white to pale yellow in color for 30 days. The induction rate of callus of *A. princeps* var. *orientalis* and *L. sativa* in the control was 96% and 100%, respectively (Table 1 and 2). At lower concentrations of the extract, callus induction recurred, but leaf explants at the higher concentrations did not form callus. The callus induced at the higher concentrations were very small and dark brown, and their biomass was very reduced. The induction rate of the callus of *A. princeps* var. *orientalis* was higher than that of *L. sativa*.

TABLE 1. CALLUS INDUCTION OF *Lactuca sativa* ON MS 121 MEDIUM WITH *A. princeps* VAR. *orientalis* EXTRACTS AFTER 30 DAYS OF CULTURE

Extract concentration (%, 200 g/1000 ml)	Callus induction (%)[a]		
	++	+	−
0 (control)	100	0	0
5	70	18	12
10	66	22	12
20	62	16	22
30	22	30	48
50	0	0	100
100	0	0	100

[a] ++, good; +, bad; −, none.

TABLE 2. CALLUS INDUCTION OF *Artemisia princeps* VAR. *orientalis* ON MS 121 MEDIUM WITH *A. princeps* VAR. *orientalis* EXTRACTS AFTER 30 DAYS OF CULTURE

Extract concentration (%, 200 g/1000 ml)	Callus induction (%)[a]		
	++	+	−
0 (control)	96	0	4
5	62	18	20
10	48	16	36
20	36	26	38
30	28	36	36
50	4	40	56
100	0	28	72

[a] ++, good; +, bad; −, none.

The biomass of subcultured callus of the receptor plants was inhibited by the *A. princeps* var. *orientalis* aqueous extract (Table 3). The biomass of *L. sativa* was the most inhibited of the receptor plants.

Effect of Essential Oil on Growth of Callus. The biomass of callus was reduced when the MS 121 medium was supplemented with any of the amounts of *A. princeps* var. *orientalis* essential oil that were tested (Table 4). *A. princeps* var. *orientalis* had the highest biomass. The biomass of *E. prostrata* was reduced the most among test species. The callus mass of *Z. japonica* was good for 5 μl and 10 μl/60 ml of essential oil, but it was greatly inhibited at higher concentration of the essential oil. In general, the callus biomass or size of receptor plants was inversely proportional to the concentration of the essential oil.

TABLE 3. BIOMASS OF CALLUS EXPRESSED AS PERCENT OF CONTROLS ON MS 121 MEDIUM AT DIFFERENT CONCENTRATIONS OF *A. princeps* VAR. *orientalis* EXTRACTS AFTER 30 DAYS OF CULTURE[a]

Receptor plant	Extract concentration (%, 200 g/1000 ml)

DISCUSSION

Helgeson (1984) suggested that tissue culture systems may be grown under controlled environments, in the absence of pathogens, and this allows for observation at the tissue and/or cellular level. The water extract and essential oil obtained from *A. princeps* var. *orientalis* affected the induction and growth of callus derived from the several species used in the bioassay. The color of calluses that were treated with low concentrations of extract turned from white and/or yellow to light brown but were changed to dark brown by high concentrations of extract. The calluses of *A. princeps* var. *orientalis* and rice were the most resistant, and those of lettuce and radish were the most sensitive. We suggest that the tissue of *A. princeps* var. *orientalis* explants are resistant due to their hard seed-coat texture and their metabolism, which overcomes the toxins of the extracts. Our results are similar to those of Wolf and Earle (1990), who found growth of susceptible callus from corn inhibited at 5 μg/ml of a *Helminthosporium carbonum* toxin, while that of resistant callus was inhibited only at the 50 μg/ml concentration.

Although induction and growth of *A. princeps* var. *orientalis* callus was more resistant than other receptor plants to the extracts or essential oil, they still showed autotoxicity and did much more poorly than controls. In vitro, this phenomenon was reported in the microspore culture of oilseed rape (Kott et al., 1988) and in cultures of tobacco or rice (Tsay, 1982).

We suggest that susceptible and resistant plant tissue cultures, i.e., callus induction and growth, are more sensitive than seed germination and plantlet growth bioassays and field experiments (Yun, 1990). Yet, we have no direct information explaining these differences in comparing the bioassay of tissue culture to other bioassays of allelopathic activity from *A. princeps* var. *orientalis*.

Book Review

Plant Kairomones in Insect Ecology and Control. Contemporary Topics in Entomology 1. Robert L. Metcalf and Esther R. Metcalf. New York and London: Chapman and Hall, 1992, 168 pages. ISBN 0-412-01991-4.

This is a monograph written by two members of one of the most illustrious families in the history of North American entomology. Robert Metcalf has been a pioneer in research on the structure and activity of synthetic organic insecticides. He was also one of the early critics of the dangers of overeliance upon and overuse of pesticides in agriculture. His foresight led him to shift his multiple talents toward investigating basic chemical and ecological aspects of plant kairomones (= plant chemicals that "convey adaptive advantages to the insect receiver") and their potential practical value in reducing the need for insecticide use in agroecosystems. For more than two decades, he and his wife Esther (recently deceased) have been exploring plant kairomones that have powerful stimulating effects on two of our most economically important groups of insect pests: Diabroticite rootworm beetles and tephritid fruit flies. The Metcalfs and their coworkers have written numerous journal articles about their findings on these two groups. The major thrust of this monograph is a broad treatment of these findings.

The monograph is comprised of six chapters. The first two chapters on the chemical ecology of plant kairomones and volatile kairomones as lures for insects provide sufficient background information to enable a relatively uninitiated reader to appreciate the meat of the monograph: the next three chapters on basic and applied chemical ecology of Japanese beetles, rootworm beetles, and tephritid flies. The sixth and final chapter is a brief treatment of plant-produced chemicals that lure solitary bees as pollinators, particularly of orchids. To my knowledge, the Metcalfs have conducted little if any research on Japanese beetles and solitary bees. Their reasons for highlighting the chemical ecology of these two groups, as opposed to other insect groups in which plant kairomone effects have been studied in some depth (e.g., bark beetles, hymenopterous parasitoids), may not seem readily apparent. It is based on an underlying theme that surfaces in every chapter of the monograph: the prominent role of phenylpropanoids as plant kairomones in the evolutionary history of Japanese beetles, rootworm beetles, tephritid flies, and solitary bees.

In my judgement, the greatest strength of the monograph lies in the chapters on rootworm beetles and tephritid flies and the opportunity for side-by-side

0098-0331/92/0800-1463$06.50/0 © 1992 Plenum Publishing Corporation

comparison of the chemical ecology of these two groups. For both, an attempt is made to paint an evolutionary scenario that traces present-day kairomonal insect preferences to ancestral roots. The extensive chemical characterization presented of kairomones associated with an array of plant species visited by rootworm beetles and tephritid flies affords a considerably greater level of knowledge-based speculation on the evolutionary history of the chemical ecology of these two groups than can be had for most other groups of insects. Even so, the Metcalfs rightly point out that the evolutionary basis of some of the insect–plant chemical relationships dealt with remains a mystery. For example, Diabroticite beetles are highly attracted to eugenol-type phenylpropanoid plant compounds, even though considerable search has failed to turn up such compounds either in blossoms of cucurbits or in corn silk, both of which are presently highly attractive resources to the beetles. In the case of Dacine tephritid flies, males (but not females) of some species are extraordinarily highly attracted to plant blossoms containing methyl eugenol, feeding on methyl eugenol to the point of extreme engorgement. Yet, the value of methyl eugenol to Dacine males is unknown. Interestingly, the Metcalfs point out more than once that the beginning of modern chemical ecology of insects can be traced to the discovery by Howlett in 1915 of the high attractiveness of two species of Dacine flies to methyl eugenol that Howlett isolated from lemon grass oil. This chemical characterization of a plant kairomone (albeit of undetermined benefit to the responding insect) predates by more than 40 years the first characterization of an insect pheromone (bombykol).

Besides the insights into evolutionary relationships portrayed, another major thread of the chapters on rootworms and tephritid flies is the practical value of plant kairomones and parakairomones (= synthetic analogs of kairomones) in monitoring and controlling species that are pests. Over the years, a variety of compounds attractive to rootworm and tephritid adults has been discovered through mass screening of shelf chemicals or by serendipidity. Here, the Metcalfs compare molecular structures of, and receptor sites for, such attractants with those of known plant kairomones, often with illuminating results. Of particular value to pest management is the painstaking process described for chemically altering the architecture of parakairomones and natural kairomones to render them yet more attractive to pest adults by, for example, increasing release rate and atmospheric transport while at the same time diminishing potential disadvantages, such as carcinogenicity.

Each of the chapters on Japanese beetles, rootworm beetles, and tephritid flies concludes with specific examples of how parakairomones and kairomones for these groups have been employed in pest management. Here is where the Metcalfs' strong desire for judicious insecticide use comes prominantly into play. In several examples, the Metcalfs illustrate how only minuscule amounts

of insecticide combined with attractants and feeding stimulants can achieve effective pest control as baits in agricultural situations.

The monograph should be of most value to those who have an interest in the application of basic elements of insect chemical ecology to pest management. It is especially illustrative of how a strong appreciation for evolutionary aspects of chemical interactions of insects with plants can be turned to applied advantage. It is written by a team whose research is exemplary of this approach. If there are shortcomings, they lie in the Metcalfs' emphasis of their own research (understandable) but omission of several recent relevant studies by others (therefore falling short of completely fulfilling the concept of a monograph as a thoroughly documented treatise on a limited area of biology). In addition, the concept of coevolution is sometimes applied in an overly loose fashion, and there are instances of overoptimism of the success rate to date of using parakairomones and kairomones in control of Japanese beetles, rootworms, and tephritids. On the whole, however, these shortcomings are relatively minor in relation to the value of having in one volume a compilation of the insights and accomplishments of such important contributors as Robert and Esther Metcalf.

(Received October 15, 1991; accepted April 15, 1992)

Abstract—A bioassay was used to evaluate the effects of cuticular leaf components, isolated from *N. tabacum*, *N. glutinosa* (accessions 24 and 24a), and 23 other *Nicotiana* species, on germination of *P. tabacina* (blue mold). The leaf surface compounds included α- and β-4,8,13,-duvatriene-1,3-diols (DVT-diols), (13-*E*)-labda-13-ene-8α-,15-diol (labdenediol), (12-*Z*)-labda-12,14-diene-8α-ol (*cis*-abienol), (13-*R*)-labda-8,14-diene-13-ol (manool), 2-hydroxymanool, a mixture of (13-*R*)-labda-14-ene-8α,13-diol (sclareol), and (13-*S*)-labda-14-ene-8α,13-diol (episclareol), and various glucose and/or sucrose ester isolates. The above in acetone were applied onto leaf disks of the blue mold-susceptible *N. tabacum* cv. TI 1406, which was then inoculated with blue mold sporangia. Estimated IC_{50} values (inhibitory concentration) were 3.0 μg/cm^2 for α-DVT-diol, 2.9 μg/cm^2 for β-DVT-diol, 0.4 μg/cm^2 for labdenediol and 4.7 μg/cm^2 for the sclareol mixture. Manool, 2-hydroxymanool, and *cis*-abienol at application rates up to 30 μg/cm^2 had little or no effect on sporangium germination. Glucose and/or sucrose ester isolates from the cuticular leaf extracts of 23 *Nicotiana* species and three different fractions from

*To whom correspondence should be addressed.

N. bigelovii were also evaluated for antimicrobial activity at a concentration of 30 $\mu g/cm^2$. Germination was inhibited by >20% when exposed to sugar esters isolated from *N. acuminata, N. benthamiana, N. attenuata, N. clevelandii*, and *N. miersii*, and accessions 10 and 12 of *N. bigelovii*. These results imply that a number of compounds may influence resistance to blue mold in tobacco.

Key Words—*Nicotiana*, *Peronospora tabacina*, blue mold, leaf surface chemistry, diterpenes, sugar esters.

INTRODUCTION

The leaf surfaces of most higher plants have trichomes, which produce natural secretions that serve as mitigating factors in herbivory and disease development in some plant species (Behnke, 1984). In some tobacco (*Nicotiana tabacum* L.) and *Nicotiana* species, chemical compounds found in trichome exudates affect host plant resistance to several insect pests (Severson et al., 1985, 1991), but their role in disease resistance in tobacco is less clear. Removal of the leaf surface chemicals by washing the leaves with water or acetone increased the plants' susceptibility to *Peronospora tabacina* Adam (Hill, 1966; Reuveni et al., 1987), the obligate fungal pathogen responsible for tobacco blue mold, a disease of major economic importance (Main, 1991). In other studies, specific trichome exudate constituents have been reported to have fungicidal properties against germination of *P. tabacina* sporangia (Bailey et al., 1974; Cruickshank et al., 1977; Cutler et al., 1986; Lawson et al., 1988). These constituents include the diterpenes α- and β-4,8,13-duvatriene-1,3,-diols (DVT-diols), and the labdane, (12-*Z*)-labda-12,14-dien-8α-ol, which are synthesized in the gland cells of tobacco trichomes (Keene and Wagner, 1985; Kandra and Wagner, 1987).

In in vitro experiments, Menetrez et al. (1990) found that germination of *P. tabacina* sporangia was completely inhibited when exposed to 10 $\mu g/cm^2$ of the DVT-diols and was stimulated at much lower concentrations. Inhibition of germination of *P. tabacina* sporangia by *cis*-abienol was also reported, but this compound was less active than the DVT-diols (Menetrez et al., 1990). Sucrose esters, another exudate constituent common to many tobacco genotypes (Severson et al., 1991), reportedly had no effect on *P. tabacina* sporangium germination (Menetrez et al., 1990). The sucrose ester fraction tested in that experiment was isolated from a single tobacco genotype. It is possible that sucrose esters isolated from other genotypes may have antimicrobial activity as genetic variation for sugar ester type, and ester moiety composition does exist among *N. tabacum* genotypes and *Nicotiana* species (Severson et al., 1991). The objective of our research was to determine the effects of certain trichome exudate components on *P. tabacina* sporangium germination using an in vivo system. This included further characterization of the fungicidal activity of the

DVT-diols and *cis*-abienol and testing of additional exudate compounds, including several labdanes and a number of sugar esters isolated from *Nicotiana* species.

METHODS AND MATERIALS

Plants. Seed of Tobacco Introduction (TI) 1406 were germinated in a commercial soil mix in the greenhouse. Plants were transferred into plastic pots (8.5 cm diameter) containing steam-sterilized soil mixture (soil–sand–peat, 2:2:1 v/v/v) and then moved to a growth chamber kept at 24°C with a 12-hr photoperiod of fluorescent light. Plants were fertilized twice a week with Peters 20:20:20 (N/P/K) water-soluble fertilizer.

Isolation and Purification of Leaf Surface Compounds. Cuticular components were extracted from *N. tabacum* cultivars NC 2326 and NFT, *N. glutinosa* (accessions 24 and 24a), and 24 other *Nicotiana* species grown in field plots at Georgia Coastal Plain Experiment Station, Tifton, Georgia, and the Crops Research Laboratory, Oxford, North Carolina. Tops cut from plants six to eight weeks after transplantation were extracted with methylene chloride (Baker Resi-analyzed reagent grade) as previously described (Jackson et al., 1986; Severson et al., 1988). *cis*-Abienol (from NFT), α-DVT-diol, and β-DVT-diol (from NC 2326) were isolated in 98+% purity as described by Severson et al. (1988). The (13-*E*)-labda-13-ene-8α,15-diol (labdenediol) (from *N. glutinosa* no. 24a) and the sclareols, a mixture of (13-*R*)- and (13-*S*)-labda-14-ene-8α,13-diol (sclareol and episclareol), and (13-*R*)-labda-8,14-diene-2α,13-diol (2-hydroxymanool) (from *N. glutinosa* no. 24) were obtained in 98+% purity as described by Jackson et al. (1986). (13-*R*)-labda-8,14-diene-13-ol (manool) was obtained from Aldrich Chemical Co.

The cuticular extracts from the other *Nicotiana* species in Table 1 were taken to dryness on a rotoevaporator, and the residue was partitioned between hexane and 80% methanol–water as described by Severson et al. (1988). The methanol–water-soluble fraction (100–200 μg) containing the sugar esters was dissolved in 0.5 ml of 90% methanol–water, loaded into an injection loop, and chromatographed on a Bio-Sil C-18 (HL Silica, fully endcapped; 40–63 μm; Bio-Rad Laboratories) preparative reverse phase column (1.25 cm ID × 15 cm). The column was eluted with 225 ml 60% methanol–water, 90 ml 90% methanol–water, and 125 ml 100% methanol, and 5-ml fractions were collected. The solvent was removed on a Savant SpeedVac and fractions with observable residue were analyzed by capillary gas chromatography (Severson et al., 1984; Jackson et al., 1986). Fractions containing glucose and/or sucrose esters were combined to yield the sugar ester isolates tested. The chromatography cleanly separated the glucose and sucrose ester fractions in the *N. attenuata* sample, and they were combined separately.

[d] Blue mold-resistant species (Rufty et al., 1990).

Inoculum Production. P. tabacina inoculum was maintained following a procedure adapted by Cohen and Kuć (1980). Six-week-old plants of the blue mold-susceptible tobacco cultivar KY 14 were sprayed to runoff with a fresh sporangial suspension (2×10^5 sp/ml) of *P. tabacina* isolate KY-79. Plants were held at 22–24°C in a dark chamber with 100% relative humidity for 18 hr. Plants were then transferred to a growth chamber with 75% relative humidity and a 12-hr photoperiod for disease development. Sporangium formation was induced when chlorotic lesions developed (seven to eight days after inoculation) by placing plants in darkness for 24 hr at 20°C and 100% relative humidity. Fresh inoculum for each experiment was obtained by lightly brushing the sporulating leaf surface with cold sterile distilled water. To remove any germination inhibitors, sporangium suspensions were filtered and rinsed thoroughly using a 3.0-μm Millipore filter system. Sporangia were resuspended in sterile distilled water, and sporangium concentration was calculated with the aid of a hemacytometer.

Bioassay. Leaf disks (50 mm^2) excised from interveinal areas of leaves from 5- to 6-week-old TI 1406 plants were placed adaxial side up on wet filter paper in a Petri dish. A stock solution of each leaf surface compound was prepared by dissolving each compound in acetone. Chemical concentrations were prepared by diluting portions of the stock solution with acetone. A 10-μl aliquot of each treatment solution was applied evenly to the entire surface of each leaf disk using an Eppendorf repeater pipet. Leaf disks were then set aside to dry prior to inoculation. The following control treatments were included in each experiment: (1) no chemical or acetone was applied and (2) an acetone blank in which there was no leaf surface chemical.

Using an airbrush sprayer (Paashe Airbrush Co., Harwood Heights, Illinois), leaf disks were uniformly inoculated with a 500-μl sporangium suspension of *P. tabacina* (10×10^4–15×10^4 sp/ml) at 50 psi. To maintain a high humidity, the inner surface of the Petri dish covers were sprayed with distilled water. Plates were incubated for 24 hr at 15°C in the dark. Leaf disks in each plate were then sprayed with 500 μl of a 0.01% solution of the fluorescent stain CalcoFluor White MR2 (Polysciences, Inc., Warrington, Pennsylvania), removed from the filter paper, and arranged on glass slides. Slides were fixed by applying drops of ACCU-Mount 60 Mounting Medium (Stephens Scientific, Denville, New Jersey) and topped with cover slips. Sporangium germination was evaluated by fluorescence microscopy differentiation as developed by Wigglesworth et al. (1990). The study included a series of separate experiments. First, those chemicals reported previously to have antimicrobial activity were tested using a dilution series. Second, sclareol, labdenediol, manool, and 2-hydroxymanool were tested at a relatively high concentration. A dilution series experiment was performed for any of these compounds that displayed activity at the high concentration. Third, glucose and/or sugar ester mixtures from 24

Nicotiana species were tested at a concentration of 30 $\mu g/cm^2$. A completely randomized design was used for each experiment with 10 replications per treatment.

Analysis. Percent inhibition was calculated individually for each experiment by using the following formula: % inhibition = [(% germination of control treatment − % germination at each concentration tested)/% germination of control treatment] × 100. The log dose (concentration)–response relationship for each of the treatments was linearized using probits and inhibitory concentrations (IC_{50}) were estimated (SAS Institute Inc., 1985).

RESULTS

The in vivo bioassay was used to approximate the natural infection process and to permit observation of germ tube growth and infection plug formation. An integral part of this bioassay is the leaf tissue to which we applied the test chemicals and inoculum of the obligate pathogen, *P. tabacina*. We selected the blue mold-susceptible TI 1406 to provide the leaf tissue for the bioassay because this genotype is classified as having nonsecreting glandular trichomes, and it lacks the trichome exudate mass typically found on other tobacco genotypes such as those from which the test chemicals were extracted. To further reduce any possible complicating exudate compounds that may be produced by TI 1406, we used leaf tissue from juvenile plants grown under fluorescent lighting (Severson et al., 1985). Young plants produce little exudate and synthesis of trichome secretory product is low for plants grown under fluorescent lamps. Although TI 1406 has only minimal exudate compounds under optimum growth conditions, it does have cuticular waxes. Capillary gas chromatograms of the leaf surface washes of TI 1406 and several genotypes that have secreting glandular trichomes have similar profiles except for those compounds found in the trichome exudate (Nielsen and Severson, 1990). Thus, TI 1406 would likely have few if any leaf surface compounds that could influence detection of the activity of the test compounds.

Microscopic evaluation using fluorescence revealed that sporangia and germ tubes fluoresced bright blue against a red leaf surface background; thus, germination assessments were readily attainable. Sites of germ tube penetration of the leaf were apparent, and in some cases appressoria formation was visible. No morphological differences were observed among sporangia, and germ tube length did not appear to be affected when exposed to any of the chemical or control treatments. In all experiments, the acetone control had little or no effect on sporangium germination when compared to the untreated leaf disks, and thus only the acetone control was used for comparison purposes. A different batch of fresh inoculum was used for each experiment, and this resulted in some

variation in sporangium germination from one experiment to the next. Germination of sporangia for the control treatments was from 31% to 70% among the different experiments with a mean of 49%. Data from these different experiments were not compared directly as these experiments were performed separately.

IC_{50} values were 3.0 $\mu g/cm^2$ for α-DVT-diol and 2.9 $\mu g/cm^2$ for β-DVT-diol (Table 2). A similar inhibitory response was observed when sporangia were exposed to the α- + β-DVT-diol mixture. Percent inhibition after exposure of sporangia to α- + β-DVT-diol at the highest concentration tested was similar to inhibition levels of sporangia when exposed to the individual isomers at the same concentration. Sporangia were not completely inhibited from germinating at concentrations up to 120 $\mu g/cm^2$ of α-DVT-diol or β-DVT-diol. However, sporangium germination was reduced nearly 80% at DVT-diol concentrations of 30 $\mu g/cm^2$. There appeared to be little additional effect of increasing DVT-diol beyond 30 $\mu g/cm^2$. Furthermore, at very low concentrations of DVT-diols, including the mixture of the two isomers, there was no indication of any consistent stimulatory effect of these chemicals on sporangium germination.

The next leaf surface chemical tested was *cis*-abienol, which also had been reported previously to affect *P. tabacina* sporangium germination. In a dilution series experiment (data not shown), *cis*-abienol was tested for inhibitory effects at concentrations ranging from 3.75×10^{-4} $\mu g/cm^2$ to 120 $\mu g/cm^2$. Sporangium germination was not greatly reduced when exposed to any of the 10 concentrations of *cis*-abienol when compared to the control treatment. At the two lowest concentrations of *cis*-abienol (3.75×10^{-4} and 3.75×10^{-3} $\mu g/cm^2$), sporangium germination was greater than for the acetone control treatment.

Sclareols, manool, labdenediol, and 2-hydroxymanool, were initially tested at a single concentration of 30 $\mu g/cm^2$ to determine if any of these inhibited *P. tabacina* sporangium germination. Manool appeared to have no activity at this concentration. Although 2-hydroxymanool significantly reduced sporangium germination, the magnitude of the reduction was much less than that observed for the sclareol mixture and labdenediol. Thus, dilution series experiments were conducted only for the latter two chemicals.

Labdenediol and the sclareol mixture had IC_{50} values of 0.4 $\mu g/cm^2$ and 4.7 $\mu g/cm^2$, respectively (Table 3). Percent inhibition after exposure to additional amounts of the sclareol mixture (>15 $\mu g/cm^2$) was similar to inhibition levels of sporangia when exposed to 15 $\mu g/cm^2$. A similar response in sporangium germination was observed among concentrations of labdenediol ranging from 3.75 $\mu g/cm^2$ to 30 $\mu g/cm^2$. However, 60 $\mu g/cm^2$ of labdenediol caused nearly a 90% reduction in sporangium germination.

A mixture of DVT-diols, labdenediol, and sclareols were tested to determine if there was a synergistic effect among these compounds. The chemicals were mixed in a 1 : 1 : 1 ratio at all the concentrations. The ratio of the α and β isomers of DVT-diol was 2 : 1 within the DVT-diol component of the mixture.

[c] Figures in parentheses are the mean percent germination.
[d] Inhibitory concentration ($\mu g/cm^2$) estimated by probit analysis.

Sporangium germination was not inhibited completely following exposure to the mixture at any concentrations tested. The IC_{50} value was 4.2 $\mu g/cm^2$ for this mixture (Table 4).

Sugar ester mixtures from 23 *Nicotiana* species and three different fractions from *N. bideglovii* were tested for antimicrobial activity at a single concentration of 30 $\mu g/cm^2$. Compared to the control treatments, leaf washes from five of the species, *N. acuminata*, *N. attenuata*, *N. benthamiana*, *N. clevelandii*, and *N. miersii*, and accessions 10 and 12 of *N. bigelovii* inhibited sporangium germination by > 20% (Table 1).

DISCUSSION

The data presented provide further support for the hypothesis that certain tobacco leaf surface components may influence resistance to blue mold in tobacco. Menetrez et al. (1990) observed in in vitro experiments total inhibition by the DVT-diols at 10 $\mu g/cm^2$ and a stimulation in germination as the DVT-diols were diluted.

Using an in vivo bioassay, we found that although sporangium germination was never inhibited completely, a 78% reduction in germination was observed when sporangia were exposed to 30 $\mu g/cm^2$ of the individual DVT-diol isomers or an isomer mixture. The concentrations at which we found α- and β-DVT diols inhibited sporangium germination were well within those levels reported to be found on leaves of field-grown plants of *N. tabacum* (Severson et al. 1985). IC_{50} values of 5.0 $\mu g/cm^2$ for the DVT-diols were less than is often applied for commercial fungicides. Cruickshank et al. (1977) reported the β isomer of the DVT-diols was more inhibitory than the α isomer, and recently Menetrez et al. (1990) suggested that the α isomer was more toxic. No relative differences were observed between the individual isomers in separate experiments of our study. On tobacco leaves these compounds are often found together as part of the exudate mass in a 2:1 ratio of α and β isomers, and therefore their individual activity may be of minor importance.

Menetrez et al. (1990) applied *cis*-abienol to the surface of water agar and found that *P. tabacina* sporangium germination was significantly inhibited. However, they found *cis*-abienol activity was suppressed when it was combined with other compounds including hydrocarbons and sucrose esters, which are also found in the leaf surface. We did not find *cis*-abienol to have any inhibitory activity at any of the concentrations tested. Possible interactions between *cis*-abienol and other leaf surface components not produced by trichomes may explain the lack of biological activity from *cis*-abienol in this in vivo system. Moreover, purified *cis*-abienol in acetone readily recrystallizes upon solvent reduction, and

crystalline masses on the leaf surface may not interact with the blue mold sporangium.

Sclareol, a leaf surface diterpene isolated from *N. glutinosa*, also has been reported to have biological activity. Bailey et al. (1974) exposed a wide range of fungal colonies and sporangia to sclareol and found that sclareol did not affect germination, but it did inhibit mycelial development on agar media. We found that when sporangia were exposed to 3.75 $\mu g/cm^2$ of a mixture of sclareol and episclareol, germination was inhibited by 56%. We believe this is the first report to find that sclareol inhibits sporangium germination.

In dilution series experiments, labdenediol, having a IC_{50} value of 0.4 $\mu g/cm^2$, was the most active leaf surface component tested. Higher concentrations of labdenediol further reduced sporangium germination, and at the highest concentration tested germination was nearly 90% inhibited.

Cutler et al. (1986) found sucrose esters inhibited the growth of gram-positive bacteria such as *Bacillus subtilis* but were not effective against the growth of gram-negative bacteria and the fungi *Curvularia lunata* and *Aspergillus flavus*. *P. tabacina* sporangia were not affected by sucrose esters in in vitro experiments (Menetrez et al., 1990). In our experiments, sugar esters from the different *Nicotiana* species showed less antimicrobial activity than the terpenoid compounds. Germination was reduced from 20% to 40% by the different sugar esters from six *Nicotiana* species, none of which have been reported to have blue mold resistance. This anomaly may have several explanations. Among these are that the sugar esters exist with a matrix of other compounds in the trichome exudate and their antimicrobial activity may be obscured by this matrix in evaluations for blue mold resistance. Additionally, tests identifying the relative resistance of *Nicotiana* species to blue mold may not have been conducted under plant growth conditions suitable for optimal biosynthesis of exudate compounds. These glucose and sucrose esters vary with the type of acid substitution on the glucose or sucrose moieties and most often consist of mixtures of these different esterified compounds. Because these sugar esters make up a small portion of the leaf surface profile, their individual significance in blue mold resistance needs further investigation.

In addition to genetic background, other factors have been reported to influence the leaf surface composition, including age of development and agronomic and environmental factors (Severson et al., 1985). While fungi-toxic leaf surface chemicals may not provide complete resistance to blue mold, we believe that they may have a significant role in the epidemiology of the disease. Elucidation of inheritance patterns for specific exudate constituents and trichome traits in tobacco permits plant breeders and geneticists to manipulate the composition and concentration of trichome exudate (Nielsen and Severson, 1990). This capability, coupled with the knowledge of antimicrobial or insecticidal

activity of exudate compounds, could enable the development of genotypes with enhanced pest resistance.

Acknowledgments—We thank L. Poneleit and J. McKinney for technical assistance, M.D. Wigglesworth and E.M. Nuckles for technical advice, and J. Kuć for providing *P. tabacina* inoculum. This research was funded, in part, by a USDA Cooperative Agreement. This paper (91-7-181) is published with the approval of the Director of the Kentucky Agricultural Experiment Station.

(Received December 4, 1991; accepted April 15, 1992)

Abstract—A compiled program, JCE-REFS.EXE (coded in the QuickBASIC language), for use on IBM-compatible personal computers is described. The program converts a DOS text file of current B-I-T-S (BIOSIS Information Transfer System) or BIOSIS Previews references into a DOS file of citations, including abstracts, in a general style used by scientific journals. The latter file can be imported directly into a word processor or the program can convert the file into a random access data base of the references. The program can search the data base for up to 40 text strings with Boolean logic. Selected references in the data base can be exported as a DOS text file of citations. Using the search facility, articles in the *Journal of Chemical Ecology* from 1975 to 1991 were searched for certain key words in regard to semiochemicals, taxa, methods, chemical classes, and biological terms to determine trends in usage over the period. Positive trends were statistically significant in the use of the words: semiochemical, allomone, allelochemic, deterrent, repellent, plants, angiosperms, dicots, wind tunnel, olfactometer, electrophysiology, mass spectrometry, ketone, evolution, physiology, herbivore, defense, and receptor. Significant negative trends were found for: pheromone, vertebrates, mammals, Coleoptera, Scolytidae, *Dendroctonus*, lactone, isomer, and calling.

Key Words—BIOSIS Previews, key word search algorithm, data base, reference manager, word processing, personal computer software, semiochemical, pheromone

INTRODUCTION

The field of chemical ecology is interdisciplinary since chemistry, including analytical methods of separation and chemical identification as well as organic synthesis, is merged with ecology, including areas of behavior, physiology, genetics, and evolution. This diverse subject area becomes even more complex as studies of animals, plants, and microorganisms are reported. The number of articles published in the field of chemical ecology has continued to expand yearly, and it becomes increasingly difficult for the scientist to assimilate these results. However, the personal computer can be used to store, manipulate, and retrieve knowledge from data bases to aid in managing this ever expanding base of knowledge. Commercial services such as B-I-T-S (BIOSIS Information Transfer System) can provide the latest references on computer disk for viewing by personal computers. BIOSIS Previews also can often be used at a university library for retrospective searches on a particular topic. The located references from such a search of the many bioscience journals and publications, from the present back to 1969, can be downloaded to disk for a fee.

I have developed a compiled BASIC program, JCE-REFS.EXE, which runs on IBM-compatible computers from the DOS command line. The program can take DOS text files of either current monthly B-I-T-S listings or of retrospective searches of BIOSIS Previews and make a data base. This data base can then be searched for text strings (key words) and the located references/abstracts marked for export to a word processor in a format resembling a standard scientific citation. Other commercial data bases can be imported, such as MEDLINE (National Library of Medicine) and CA Search (American Chemical Society), but exported citations may not be formatted entirely accurately due to differences in punctuation.

In addition to describing the program and its general use, the objective was to download the entire 2133 references (October 1991) of the *Journal of Chemical Ecology (JCE)* with abstracts and make a data base. The data base then was searched repeatedly for many different key word phrases for each year (1975–1991) in order to illustrate certain trends in chemical ecology. The general areas covered were use of terms describing: (1) semiochemicals, (2) taxonomic groups, (3) methods, (4) chemical classes, and (5) general or specific subjects used in chemical ecology.

METHODS AND MATERIALS

An IBM-DOS text file from BIOSIS Previews (retrospective search) or B-I-T-S (monthly update) is required for processing by the program. Files from retrospective searches can be downloaded from a number of commercial com-

puter data bases such as Data-Star, ESA-IRS, DIALOG, and STN. References in a BIOSIS Previews text file may contain the subject identification codes (field tags) of AN (accession number), AU (author), TI (title), SO (source), IN (author affiliation), KW (key words), BC (biosystematic codes), and ST (supertaxa). Other field codes may include CD (coden), LG (language), YR (year), CC (concept codes), and AB (abstract). Monthly updates of recently published articles are formatted slightly differently by BIOSIS, such that the AN field code is replaced with an ID (identification) code and the CS (corporate source, author address) may substitute for the IN code above. The program can be adapted to use different field codes in BIOSIS files, as well as codes in other data bases (as will be explained subsequently).

The program JCE-REFS.BAS was developed with the QuickBASIC programming language (version 4.5, Microsoft). The source code was compiled to JCE-REFS.EXE, a binary, machine-coded, executable file, by the Microsoft compiler version 4.50 and overlay linker version 3.69. IBM-compatible personal computers can execute the program in monochrome or color using character-based monitors and DOS 2.1 or higher.

The major facilities and operation of JCE-REFS.EXE are diagrammed in Figure 1. The arrows between boxes indicate relationships between program

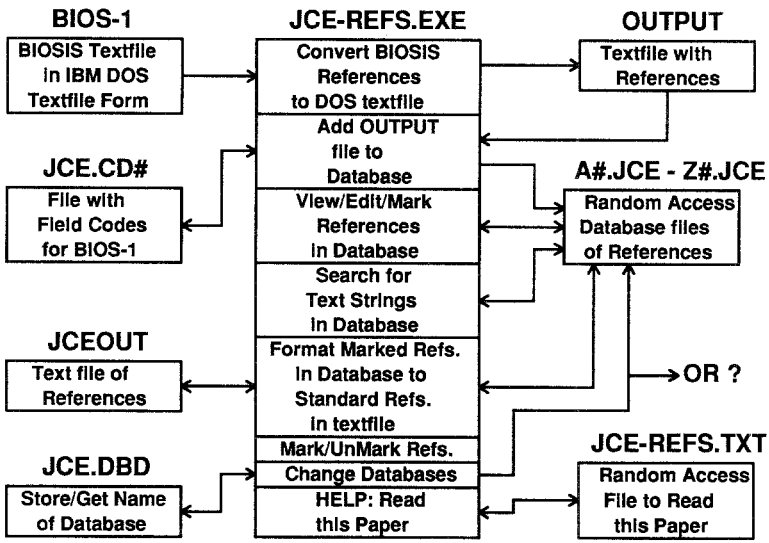

FIG. 1. Relationships of program parts of JCE-REFS.EXE, a BIOSIS file conversion and data-base searching utility for scientific reference management on the IBM-compatible personal computer.

parts but do not necessarily denote program flow. JCE-REFS.EXE is used by typing *jce-refs* at the DOS command line. The program loads and checks to see if a name of a data base is in the file JCE.DBD. If no name is present, then the default extension name (#.JCE) is placed in the file. The menu has seven options to choose from (Figure 1) besides a help section, DOS shell (DOS commands), or exiting from the program.

The first option is to convert BIOSIS files to a standard scientific reference format in a DOS textfile, always given the name OUTPUT. This is done by entering the name of the BIOSIS Previews file (e.g., named BIOS-1 and rep-

FIG. 2. The JCE-REFS.EXE program processes a BIOSIS text file (A) into a DOS text file (OUTPUT) as shown in (B), which is imported into the random access database file (B#.JCE) as in (C) that can be searched. The reference in the data base also can be exported as a DOS text file (B) or Pro-Cite style (not shown) for use with MacIntosh and IBM-compatible personal computers.

resented in Figure 2A). The user may look at the BIOS-1 file to see if the formatting is such that all text is indented three spaces except for the field codes. Rarely, the file can be received from BIOSIS in a corrupted condition; in this case a reformatting facility is selected to correct the file. Otherwise the user continues and is presented with a list of files (ending in .CD#) that contain various field codes appropriate to the commercial data base. The user enters one of the names or a new name, and the field codes are loaded and presented on a menu for editing. The field codes can be used without editing or new codes added for the respective authors, title, journal, and so forth. These codes make it possible to accommodate any of several types of BIOSIS formats as well as other data base styles such as CA Search and MEDLINE. The program then reformats the BIOSIS file (BIOS-1) using the field codes. The first letters of authors are capitalized and appropriate punctuation is added. The date (1900s or 2000s) is extracted from the journal string. The title and journal letters are uncapitalized and then the first letter of each word in the journal is capitalized. This saves time in the word processor as most letters need to be lowercase in a standard citation. The abstract text is also uncapitalized so that all text searches can be in lowercase. The resulting sequential file, OUTPUT (Figure 2B), is overwritten each time, so one must process the contents, as described subsequently, before another BIOSIS file is reformatted.

After reformatting the BIOSIS file, the second option is used in which the OUTPUT file is entered as the source of references for alphabetical placement in the 26 data base files (e.g., A#.JCE to Z#.JCE). Each reference is formed into a long text string of 36 lines by 80 characters, so the abstract can be included (Figure 2C). These 26 files are random access in which references from additional BIOSIS Previews files can be added by running options one and two again. Alternatively, another name can be chosen (option seven) in order to create additional data bases (e.g., for another journal).

The third option "View/Edit/Mark References in Data Base" allows one to scroll through the data base and view the references. Any references that are desired for word processing can be exported as a citation in the file JCEOUT by marking them (pressing the Insert key). References are unmarked with the Delete key. A global unmarking of all references also can be done (in option six). Facilities for searching for a text string and viewing the located reference and highlighted string are provided while viewing the data base.

The fourth option, "Search for Text Strings in Data Base," allows complex logic searches of the data base fields for up to two sets of 20 text strings simultaneously. The searches employ Boolean logic in one of four ways. Up to 20 text strings can be searched for in either an: (1) *OR* or (2) *AND* way. These also can be combined into: (3) *AND/OR* or (4) *AND+OR* searches with a total of up to 40 text strings. For example, an *AND+OR* search might look for

("pheromone" AND "Scolytidae") and ("1980." OR "1981." OR "1982.") in each reference. Note the use of the space and period in the dates in order to avoid finding page numbers.

Prior to searching for the text strings, the user is asked whether he or she wants to save this search profile for later recall. If the search profile is saved, then the next time a search is made the user may select option five to load the search profile and begin the search without the need for entering the text strings. During the search of the data base, the program displays any located references on screen and waits for keyboard input to mark (or unmark) or continue without marking until all references in the data base are searched. Options include searches of various combinations of authors, date, title, key words, abstract, and address. A search record showing the number of references found out of the total number in the data base is displayed at the end of the search (searches take only some seconds for 2133 references).

The fifth option, "Format Marked Refs. in Data Base to Standard Refs. in Text File," is used to take the author, date, title, journal, and, optionally, the key words, abstract (if present), and address strings and export them. These are saved in a DOS text file called JCEOUT (style as in Figure 2B), which is overwritten each time this option is chosen. This file can then be imported into any word-processing program (e.g., WordPerfect, WordPerfect Corp., Orem, Utah) as well as into the scientific reference manager, CardCat (Byers, 1991).

A sixth option includes either a global unmarking or global marking of all references in the data base. The "Change Data Bases" option allows for an almost unlimited number of databases, 208 available ASCII characters for file names $= [\Sigma_{i=1}^{8} P_i^{208}][\Sigma_{i=1}^{3} P_i^{208}] = 2.7 \times 10^{25}$. Each time the program is started, it gets the current data base, which is permanently stored in the file JCE.DBD until changed by the user. The user can receive help from within the program by reading the file JCE-REFS.TXT, which includes the contents of this paper with figures. This file appears to be a standard sequential DOS text file but is actually a random access file that allows scrolling the text forward and backward on the screen.

BIOSIS Previews (from Data-Star, Radio-Suisse) was searched for all articles published in the *Journal of Chemical Ecology* (including abstracts and addresses) from 1975 until October 1991. The resulting search file was downloaded into 16 files of about 200K each to a personal computer. The files were imported into the JCE-REFS program, which made a data base of 26 files with a total of 6 megabytes. This data base was searched by year, as described below, for certain key words as shown in Figures 3–5 and Tables 1–5 below. Except for the super taxonomic designations of BIOSIS (ending in #, as in Table 2 and Figure 4), it should be noted that the incidence of various key words found in the titles, key words, and abstracts are minimal estimates since the entire article was not searched. Furthermore, certain key words are more likely to be men-

tioned in the abstract than others due to the nature of the words. However, key words merely mentioned in the body of the paper, and not in the title, key words, or abstract, quite often are not of primary relevance to the article.

RESULTS AND DISCUSSION

It is commonly accepted that the number of scientific publications is increasing annually, although opinion would vary as to whether the function was geometric, exponential, or linear. The actual quantities of publications available to scientists as reflected in the BIOSIS data base is also not well known. In Figure 3A, the trend in publication rate is increasing, and a linear function ($r^2 = 0.89$) describes the relationship about as well as a geometric ($r^2 = 0.88$) or exponential equation ($r^2 = 0.90$). In 1990 more papers were published than ever before, with over 540,000 publications from more than 9000 journals available to the chemical ecologist (BIOSIS Previews). The number of papers in the *Journal of Chemical Ecology (JCE)* in 1990 also was highest (281). Here too a positive linear equation ($r^2 = 0.90$) describes the trend of increasing publication rate as well as do other curvilinear functions, although an exponential curve fits the data slightly better ($r^2 = 0.94$). However, from Figure 3B it can be seen that the number of papers in *JCE* has increased relatively faster than the publication rate in general in BIOSIS ($r^2 = 0.65$, positive slope, $P < 0.001$).

The number of "pheromone" papers in BIOSIS has increased linearly during the period from 1975 to 1990 ($r^2 = 0.92$) at the same rate as the increase in publications in BIOSIS (same percentage, Figure 3B, slope not significantly different from 0). On the other hand, the rate of pheromone papers in *JCE* has decreased (Figure 3B, Table 1). The uses of other semiochemicals such as "allomone," "allelochemic," and "semiochemical" have increased, although use of any combination of these in papers has not changed significantly over the period (Table 1). Uses of the words "deterrent" and "repellent" have increased (Table 1).

Most papers in *JCE* concern "animals" (average yearly percentage of 89.4), and "insects" make up the majority of these (79%) while "vertebrates" involve 13.9% of all papers, and "microorganisms" only 7.4% (Table 2). The percentage of animal papers has remained relatively constant, as has that for insects and "Lepidoptera," while the trend in vertebrate papers has decreased (Table 2), although the vertebrate trend over the last 15 years has been stable (Figure 4). In addition to vertebrates, other taxa in Table 2 show significant negative trends: "mammals" and "Coleoptera" (including "Scolytidae" and "*Dendroctonus*"). Significant positive trends are shown for plants (only "vascular") and "angiosperms" and "dicots," but "gymnosperms" and "monocots" show no significant relative changes (Table 2, Figure 4). The increase in

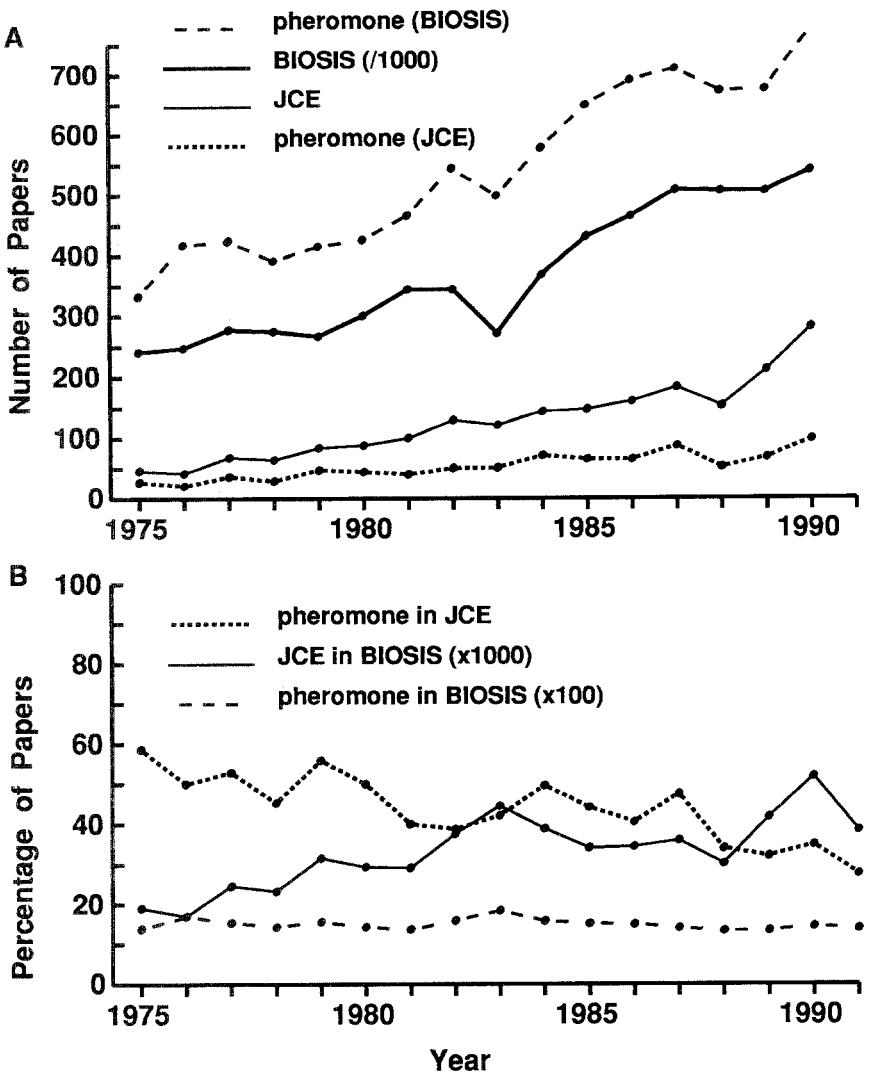

FIG. 3. (A) Number of papers with key word "pheromone" and total papers published per year in BIOSIS or *Journal of Chemical Ecology* (JCE), and (B) percentage of papers with "pheromone" in JCE or BIOSIS, and percentage of JCE papers in BIOSIS.

papers on plants may be real in part, but part of the increase also may be due to more often mentioning the "plant–insect" relationship than was done earlier.

There has been no significant change in the percentage of papers mentioning a "method" or "technique" useful to chemical ecology (Table 3). The use of

TABLE 1. POSITIVE AND NEGATIVE TRENDS FROM 1975 TO 1991 IN PERCENTAGE OF PAPERS IN *Journal of Chemical Ecology* USING VARIOUS SEMIOCHEMICALS IN TITLE, KEY WORDS, OR ABSTRACT (LINEAR REGRESSION WITH ARCSIN SQUARE ROOT TRANSFORMATION OF PERCENTAGES)[a]

[a] P values with asterisks indicate slopes are significantly different from zero ($\alpha = 0.05$).

"wind tunnel" appears to have increased (although found in only 1.6% of the papers), while "bioassay" use has not changed but is used by 15.4% of *JCE* papers. The use of "olfactometer," "electrophysiology" (and related words), and mass spectrometry (GC-MS) have increased, while no significant trends were found for gas chromatography (including "GLC"), thin layer chromatography ("TLC"), capillary GC, high (pressure or performance) chromatography ("HPLC"), and nuclear magnetic resonance spectroscopy ("NMR," Table 3).

There were no significant trends in the frequency of use of several chemical groups (Table 4) except for lactone and isomer (negative trends) and a positive trend for ketone. Surprisingly, the use of "enantiomer" or "optical isomer" has not changed significantly over the period. Even when all chemical groups are searched for in an *OR* way, there is no significant change in relative frequency, with about 47% of the papers mentioning one or more chemical group. Searches of various prefixes indicating carbon chain length from 11 to 19 (undec, dodec, tridec, tetradec, pentadec, hexadec, heptadec, octadec, and nonadec) substantiated the commonly held view that even-carbon chains are more frequently part of semiochemicals than are odd-carbon chains (Figure 5). The most common chain unit mentioned was 14 carbons (Figure 5) and was found in 22.3% of the Lepidoptera papers, or 86.3% of the papers with "tetradec" (e.g., tetradecenyl acetate) also included "Lepidoptera."

Chemical ecology combines the biological fields of ecology, behavior, evolution, genetics, and physiology with chemistry. There are no significant trends in the use of the words "ecology" or "behavior," probably since these

fields were well established as central to chemical ecology by 1975. In fact, "behavior" is by far the most commonly mentioned field (22.9% of the papers) with "physiology" and "ecology" next at only 3.6% (Table 5). There is a positive trend in the use of "evolution" and "physiology," while "genetic" increases but is not quite significant.

Electrophysiological studies account for the majority of the physiology papers since 61% of these had "antennogra" or "electro" (*AND* + *OR* search). The word "receptor" also increases in frequency during the period due to the increase in electrophysiological studies. Uses of "herbivore" and "defense" also show increasing trends. The regression line for the percentage of studies mentioning "synergism," "synergist," or "synergistic" (only 3.6% average) does increase but the slope was not statistically significant from zero (Table 5). It is surprising that synergism is mentioned so sparingly, since it is well estab-

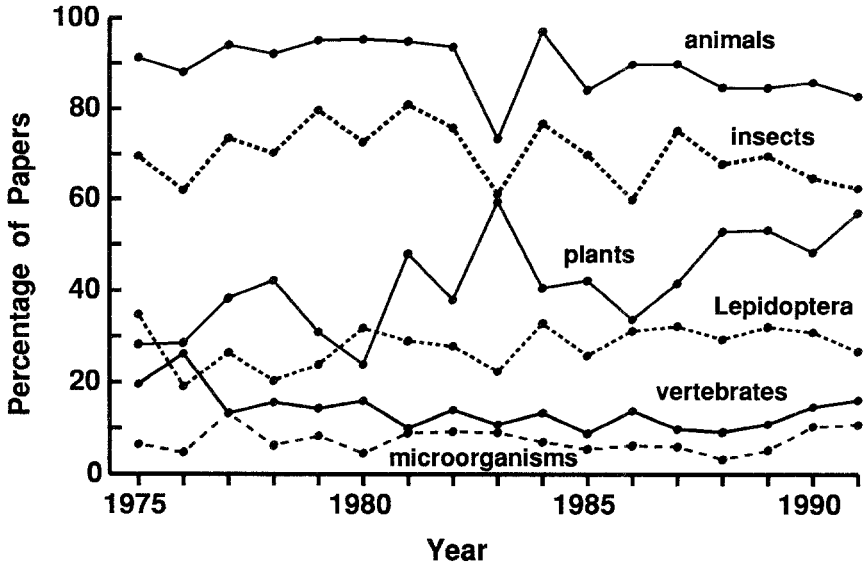

FIG. 4. Percentage of annual papers published in the *Journal of Chemical Ecology* that concern various supertaxa (as classified by BIOSIS Previews) from 1975 to October 1991.

lished that most pheromones, and probably most semiochemicals, are blends of several synergistic components (Silverstein, 1981; Byers, 1992a).

Deitz and Osegueda (1989) discuss the effectiveness of retrieving entomological literature from several data bases including AGRICOLA, AGRIS International, BIOSIS Previews, CAB Abstracts, Dissertation Abstracts Online, Life Sciences Collection (Cambridge Scientific Abstracts), SCISEARCH, and Zoological Record Online. They show that pertinent literature for a particular subject is likely to be found in any of these data bases in varying proportions and redundancy. While the cost effectiveness may vary depending on the blend of data bases used, it was apparent that BIOSIS Previews had the most relevant references. I have searched CA Search and BIOSIS Previews for all references in the *Journal of Chemical Ecology* and found that the former contained only about 86% of the articles while BIOSIS had all of them. Several key word searches and reference retrieval strategies have been proposed (Marshall, 1979; Harvey, 1979; Chiang and Chiang, 1984; Eyers and Taylor, 1988; Resh, 1988; Deitz and Osegueda, 1989). The results of these articles indicate that an exhaustive search of the literature is more costly and difficult than one might anticipate due to the scattering of references and the complexity of designing a key word search profile.

The advantage of building one or more personal data bases from a com-

mercial data base such as BIOSIS is that the references in the personal data bases can be searched in many different ways over the course of one's career. This may be much less costly and more convenient than to search the commercial data bases multiple times. The drawback is that some references will be missed but this problem minimizes as the personal data base is enlarged. The located references in the data base usually will contain most of the other references in their "literature cited" sections. Of course, articles dated before 1969–1970 can only be found by searches of these sections.

BIOSIS (2100 Arch St., Philadelphia, Pennsylvania 19103-1399) has informed me that they would like presented the "fair use and copyright" issue concerning the use of their data bases. Their policy on downloaded information is that it "may be freely used without further payment to BIOSIS when temporarily stored in lieu of hard copy or printout form which is the normal medium delivered by a VENDOR." However, the temporary storage/use ceases when USER alters the archival characteristic and incorporates BIOSIS information into an "active" system of any type. Currently, a payment of 15 cents per reference per year is due BIOSIS when one has more than 500 references in an active system.

INFLUENCE OF MONOTERPENE VAPORS ON SPRUCE SPIDER MITE, *Oligonychus ununguis*, ADULT FEMALES

STEPHEN P. COOK

Department of Entomology
Box 7626
North Carolina State University
Raleigh, North Carolina 27695

(Received February 24, 1992; accepted April 20, 1992)

Abstract—Adult female spruce spider mite, *Oligonychus ununguis* (Jacobi), were exposed to various concentrations of four host conifer monoterpene vapors (limonene, β-pinene, α-pinene, and Δ^3-carene) for 24 hr to determine the lethal and sublethal effects. All four compounds were toxic to the mites. Further, at concentrations below the calculated LC_{50}s, all four compounds decreased oviposition by the mites and three of the compounds (limonene, β-pinene, and α-pinene) influenced movement. Whereas *O. ununguis* populations may not normally be exposed to high concentrations of host monoterpenes, trees continuously emit some monoterpene vapors, and when trees are damaged or under stress, oleoresin may accumulate at points on the external surface of tree tissues thereby exposing mites to the influence of monoterpene vapors.

Key Words—Arachnida, Acari, Tetranychidae, *Oligonychus*, conifer, monoterpene, toxicity, oviposition, dispersal

INTRODUCTION

The spruce spider mite, *Oligonychus ungungis* (Jacobi) (Acari: Tetranychidae) is a serious pest of conifers throughout the world. It is capable of attacking most genera of conifers including spruce (*Picea*), pine (*Pinus*), fir (*Abies*), larch (*Larix*), and juniper (*Juniperus*) (Löyttyniemi, 1970; Jeppson et al., 1975; Johnson and Lyon, 1976; Drooz, 1985). Spruce spider mite is probably the most destructive conifer-feeding spider mite in the United States (Johnson and Lyon,

0098-0331/92/0900-1497$06.50/0 © 1992 Plenum Publishing Corporation

1976) and has been suggested to be the only mite capable of causing economic injury in nurseries and plantations of coniferous trees (Kielczewski, 1966). Damage by spruce spider mite includes yellowing or browning of needles (Garman, 1923; Kielczewski, 1966), resulting in potential premature needle abscission (Peterson and Hildahl, 1969) and possible reductions in tree shoot growth (Löyttyniemi, 1971).

As with many herbivores, spider mite performance on a host plant may be influenced by the plant's chemical content. Researchers working with other spider mite species have demonstrated that nutritional components located in leaf tissue, especially nitrogen and amino acids directly impact spider mite biology (i.e., Cannon and Connell, 1965; Tulisalo, 1971; Dabrowski and Bielak, 1978; Hanna et al., 1982). Furthermore, there was a positive correlation reported between the essential amino acid content in spruce needles and the occurrence of spruce spider mite (Löyttyniemi and Tulisalo, 1972). However, along with nutritional compounds, plants have secondary metabolites within leaf tissues that may have negative impacts on the attacking mite population. Many terpenoid compounds may be placed within this category of potential plant protectants. For example, some components of the essential oils of spice plants are oxygenated monoterpenes, and when these essential oils are sprayed on the spider mite *Tetranychus cinnabarinus* (Boisd.), the result was an increase in mortality and repellancy (Mansour et al., 1986). Furthermore, sesquiterpenes present in tomato have been demonstrated to be both toxic and repellent to the spider mite *T. urticae* Koch (Patterson et al., 1975), and exposure of female *T. urticae* to the three principal monoterpenes in the essential oil of peppermint leaves (pulegone, menthone, and menthol) resulted in reduced oviposition and increased mortality (Larson and Berry, 1984) and spider mite injury increased the relative amounts of menthone and menthol in peppermint leaf essential oils (DeAngelis et al., 1983).

The potential influence of conifer needle monoterpenes on spruce spider mite has not been investigated. However, conifers usually have many terpenoid compounds present within their tissues, and these have been demonstrated to be toxic to several bark beetle species including *Dendroctonus frontalis* Zimmermann, *D. brevicomis* LeConte, *Ips calligraphus* (Germar), and *Scolytus ventralis* LeConte (Smith, 1965; Coyne and Lott, 1976; Raffa et al., 1985; Cook and Hain, 1988). Further, needle monoterpene content has been suggested to be important in tree resistance to the western spruce budworm, *Choristoneura occidentalis* Freeman (Cates et al., 1983). As part of an investigation of the interaction between spruce spider mite and its host conifers, this experiment was conducted to examine potential lethal and sublethal effects of four common conifer monoterpenes on adult female *O. ununguis*. Specifically, monoterpene influences on adult mortality, oviposition, and movement were examined.

METHODS AND MATERIALS

Experimental work was conducted from April 1990 through July 1991. Adult female *O. ununguis* were removed from an insectary-reared colony maintained on cuttings of Fraser fir, *Abies fraseri* (Pursh) Poir. Each adult female mite was placed on a single fir needle. The needles were individually placed either in a 1.0-ml glass vial that was sealed with a cotton plug (just enough to prevent mite escape) or on a circular (diameter = 16 mm) piece of black construction paper affixed with Tanglefoot, five per dish, to the bottom of an open-topped Petri dish (diameter = 9.0 cm). Vials and/or Petri dishes were placed in a 2-liter desiccator with an NaCl slurry to maintain relative humidity at ca. 75% (Winston and Bates, 1960). Desiccators were maintained for 24 hr at 26°C in a constant-light environment.

Monoterpene treatments were applied within each desiccator by suspending, from the top of the desiccator just prior to sealing, a piece of round no. 1 filter paper (diameter = 5.5 cm), which had the appropriate concentrations of the given monoterpene applied topically to it. In this manner, as the monoterpene volatilized, mites were exposed to various levels of monoterpene vapors. The monoterpenes tested were obtained from Aldrich Chemical Company and were (*S*)-(−)-limonene (92% purity), 1(*S*)-(−)-β-pinene (98% purity), 1(*S*)-(−)-α-pinene (98% purity), and Δ^3-carene (95% purity). The concentrations injected onto the filter paper were 0, 5, 10, 25, 50, 70, and 100 μl, which corresponds to ca. 0, 2.5, 5.0, 12.5, 25.0, 35.0, and 50.0 ppm within the sealed containers, respectively.

At 24 hr the mites were removed from the desiccators and those in vials were examined under a dissecting microscope for mortality at all monoterpene concentrations and oviposition at the 0-, 5-, 10-, 25-, and 50-μl injection levels. Mites on the round black arenas were examined to determine if they had moved beyond the 16 mm disk and were stuck in the surrounding Tanglefoot. This test was conducted at monoterpene injection concentrations of 0, 10, 50, 70, and 100 μl. Mites were exposed to the various treatments five per replicate with four replicates conducted at the 5-, 70-, and 100-μl injection levels, eight replicates at the 10-, 25-, and 50-μl injection levels, and 31 zero microliter (control) injections.

The influence of the monoterpenes on survival was determined using probit analyses to obtain LC_{50} estimates for each monoterpene. Regression analyses were conducted to determine the influence of the individual monoterpenes on oviposition (eggs per live female) and dispersal tendency (percentage of mites moved off the 16-mm disks). Correlation analyses were conducted between percent survival and oviposition and between percent survival and dispersal tendency for the mites exposed to each monoterpene. All statistical analyses

were conducted using the SAS statistical package (Statistical Analyses System 1982).

RESULTS AND DISCUSSION

All four monoterpenes tested were toxic to adult female *O. ununguis* (Table 1). The order of toxicity based upon the LC_{50} calculations was limonene $\geq$ β-pinene $\geq$ α-pinene $\geq$ Δ^3-carene. Limonene is also one of the most toxic host monoterpenes to several conifer-feeding scolytid bark beetles (Smith, 1965; Coyne and Lott, 1976; Raffa et al., 1985; Cook and Hain, 1988). Host monoterpene vapors from peppermint have been demonstrated to be toxic to the mite *T. urticae* (Larson and Berry, 1984) as have topical applications of tomato sesquiterpenes (Patterson et al., 1975).

There was a significant decrease in oviposition (eggs per live female) as the concentration of each monoterpene increased {limonene, $F(4,26) = 6.16$, $[P > F] = 0.0013$; β-pinene, $F(4,26) = 4.49$, $[P > F] = 0.0068$; α-pinene, $F(4,26) = 4.43$, $[P > F] = 0.0080$; Δ^3-carene, $F(4,26) = 4.59$, $[P > F] = 0.0061$} (Figure 1). It is not surprising therefore to find a positive correlation between oviposition and survival of *O. ununguis* females for each of the monoterpenes {limonene, $r = 0.5687$, $[P > r] = 0.0008$; β-pinene, $r = 0.6631$, $[P > r] = 0.0001$; α-pinene, $r = 0.2403$, $[P > r] = 0.1930$; Δ^3-carene, $r = 0.4912$, $[P > r] = 0.0050$} . The decrease in oviposition began at monoterpene concentrations less than those resulting in significant mortality. Similarly sublethal affects of host monoterpene vapors have been reported for *T. urticae* exposed to peppermint monoterpenes (Larson and Berry, 1984).

There was also a significant relationship between monoterpene concentration and dispersal tendency (movement off of the circular disk) for *O. ununguis* females exposed to limonene $\{F(4,27) = 4.73, [P > F] = 0.0051\}$, β-pinene, $\{F(4,27) = 6.22, [P > F] = 0.0011\}$, and α-pinene $\{F(4,27) = 37.46, [P > F] = 0.0001\}$ but not for those mites exposed to Δ^3-carene $\{F(4,27) = 0.61, [P > F] = 0.6589\}$ (Figure 1). Again, given these results, it is not surprising to find a significant, positive correlation between dispersal tendency and survival of *O. ununguis* for three of the monoterpenes {limonene, $r = 0.4997$, $[P > r] = 0.0036$; β-pinene, $r = 0.5673$, $[P > r] = 0.0007$; α-pinene, $r = 0.7993$, $[P > r] = 0.0001$} but not for Δ^3-carene ($r = 0.0599$, $[P > r] = 0.7447$). The decreased movement at higher monoterpene concentrations for the three compounds may indicate a rapid effect of the toxic vapors with little movement by the mites being possible at these higher concentrations. The one monoterpene that did not demonstrate this result, Δ^3-carene, is the compound that had the highest LC_{50} concentration (Table 1). The increased movement in the presence of relatively low concentrations of host monoterpene

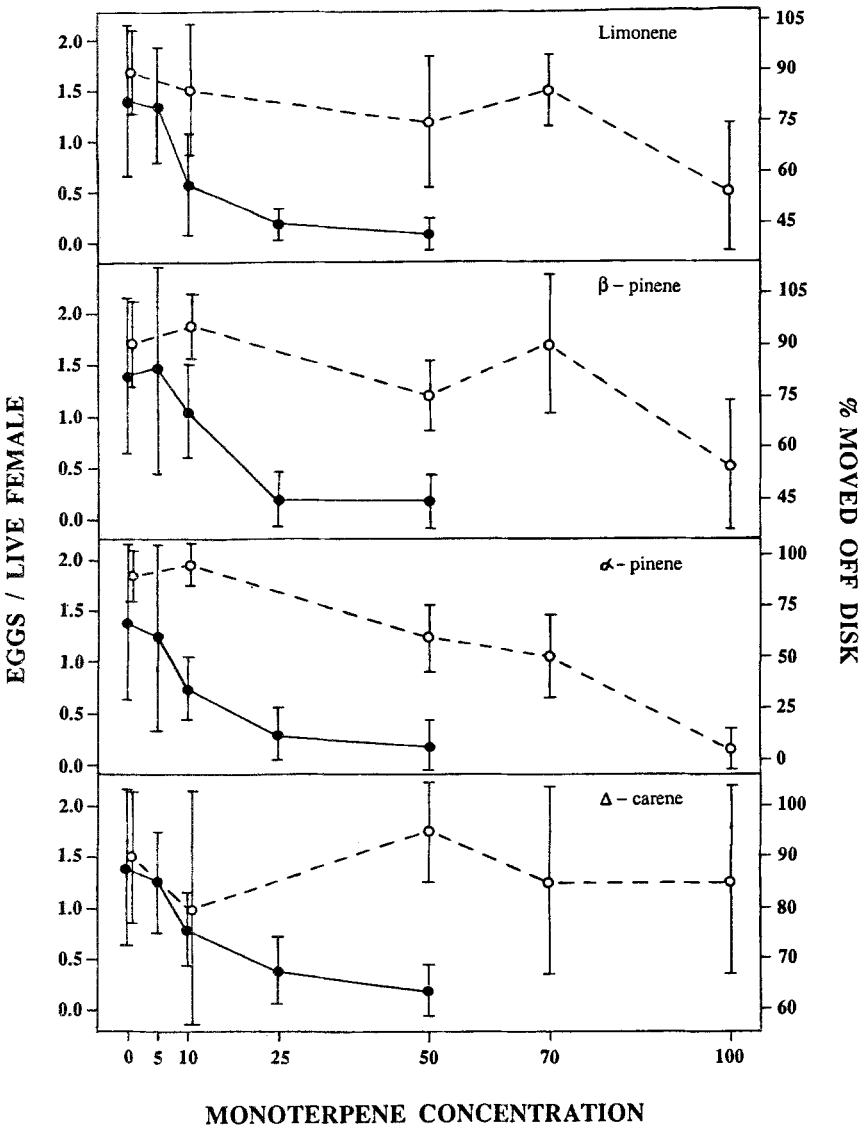

FIG. 1. Sublethal effects ($\bar{X} \pm$ SD) of monoterpene vapors on oviposition (●—●) and movement (○—○) of adult female spruce spider mites exposed to the vapors for 24 hr. 0 μl concentrations = control desiccators, one per replicate, which were pooled for these analyses.

vapors as was observed in the β-pinene and α-pinene exposures may be beneficial in the field by acting to disperse mites away from sites of needle or limb damage and the subsequent increased release of resin monoterpenes. However, a more accurate measure of dispersal tendencies in the presence of host monoterpene odors could possibly be obtained by placing mites on small twigs and monitoring movement in the presence of added host odors.

Although they feed by piercing leaf tissue and sucking out cell contents, *O. ununguis* may not normally be exposed to high concentrations of the monoterpenes contained within needle tissue. These compounds usually occur in specialized structures within the plant but they are continuously lost from tree tissue (Kramer and Kozlowski, 1960), which would constantly expose mites to a low dosage. Furthermore, under water stress, conifers may experience premature needle abscission with an accompanying deposition of resin droplets at the abscission point (Heikkenen et al., 1986). Since the leaf (or needle) is the basic microhabitat exploited by *O. ununguis* for population growth as opposed to the whole plant (Wanibuchi and Saitô, 1983), limited dispersal ability would expose the mites to higher monoterpene vapor concentrations released from these resin droplets and trapped within the canopy of the tree. Even if the concentration of these higher vapor concentrations was not great enough to cause mortality, populations of *O. ununguis* may experience some sublethal affects such as the decreased oviposition and movement observed during this experiment.

(Received January 27, 1992; accepted April 22, 1992)

Abstract—A previous report that the relative palatabilities of juvenile versus mature *Populus balsamifera* towards browsing snowshoe hares is due to the presence of 2,4,6-trihydroxydihydrochalcone in the juvenile growth form has been shown to be incorrect. Specifically, 2,4,6-trihydroxydihydrochalcone is present in internodes of *Populus balsamifera* in exceedingly low concentrations (<0.02% wet wt) and its concentrations are not elevated in internodes of the juvenile developmental stage. Its high levels in the buds (20–25% wet wt) of *Populus balsamifera*, however, probably makes it a deterrent substance for herbivores that cannot remove buds from twigs during foraging.

Key Words—2,4,6-Trihydroxydihydrochalcone, balsam poplar, *Populus balsamifera*, snowshoe hare, *Lepus americanus*, herbivory, plant defense.

INTRODUCTION

Recently two groups (Reichardt et al., 1990; Jogia et al., 1989) have reported upon the chemical defense of balsam poplar (*Populus balsamifera*) parts and growth stages against feeding by snowshoe hares (*Lepus americanus*). Of interest was the fact that these reports do not agree on the defensive agents respon-

sible for the selective utilization of balsam poplar growth stages (juvenile vs. mature). Reichardt et al. (1990) reported that hares avoid internodes of juvenile balsam poplar due to an interaction between three volatile secondary metabolites—salicaldehyde, 6-hydroxycyclohexenone, and 1,2-cyclohexadione. Jogia et al. (1989), however, attributed this avoidance to a single compound, 2,4,6-trihydroxydihydrochalcone (2,4,6-TDC), which Reichardt's group failed to report. Recently, however, Sinclair (personal communication) has verified that salicaldehyde, a substance reported by Reichardt et al. (1990), is a feeding deterrent to snowshoe hares using the bioassay protocol described by Jogia et al. (1989).

Hence, the relative importance of 2,4,6-TDC compared to the other three reported defensive substances of *P. balsamifera* as a snowshoe hare antifeedant has yet to be established. We developed three hypotheses to explain the omission of 2,4,6-TDC by Reichardt et al. (1990).

The first hypothesis is that balsam poplar from Kluane Lake in the study of Jogia et al. (1989) is different in its secondary chemistry than balsam poplar found in interior Alaska (Reichardt et al. 1990).

The second hypothesis is that while 2,4,6-TDC may be present in balsam poplar internodes at concentrations [0.8% according to Jogia et al. (1989)] low enough to have escaped detection by Reichardt et al. (1990), it may still act as the primary defensive agent in juvenile poplar. This hypothesis is consistent with both reports because the presence of one defensive compound does not preclude the presence of other defensive agents.

Finally, it is possible that the presence of 2,4,6-TDC in the internodes of balsam poplar as reported by Jogia et al. (1989) was due to contamination of internodes by bud oils in spite of the fact that buds were removed from the twigs prior to processing. This latter hypothesis arises from several observations. First, buds from other populations of balsam poplar contain copious quantities of 2,4,6-TDC (ca. 50% of extractable material; Greenaway et al., 1989). Secondly, buds of balsam poplar are extremely resinous, and, upon thawing, this resin tends to stick to anything, including internodes, which contacts buds. Finally, the secondary chemistry of balsam poplar internodes appears to be qualitatively different from that of buds (Mattes et al., 1987).

METHODS AND MATERIALS

Collection of Plants. Current season's growth (CSG) twigs from both mature and juvenile winter-dormant balsam poplar were collected in 1991 from five sites near Fairbanks, Alaska, along with five sites at Kluane Lake. Prior to transporting the twigs, buds were removed. Then the twigs were cut into two sections: internodes containing no bud scars (Alaskan, Kluane) and short sec-

tions containing bud scars (Kluane population only). In addition, the older growth twigs of mature poplars from Kluane were sampled for buds and internodes that contained no bud scars. Twig diameters were all less than 4 mm. Voucher specimens (Clausen 2) of the Alaskan population are stored at the museum located at the University of Alaska, Fairbanks.

Preparation of Extracts for Chemical Analysis. Approximately 1 g of each collection was accurately weighed and extracted in 20 ml of acetone for 48 hr. The extracted material was removed and the extract was diluted to 25 ml. A carefully measured portion (ca. 1 ml) of the extract was removed, and the acetone was allowed to evaporate overnight.

Internode and scar extracts were reconstituted with 2 ml of 50% aqueous acetonitrile containing 1 ml of benzyl gentisate as internal standard. Bud extracts were diluted to 1 ml with 50% aqueous acetonitrile and 100 μl of this solution was withdrawn and added to 10 ml of the above internal standard solution. These final solutions were analyzed directly by HPLC (see below). The effective concentrations (milligrams of plant tissue extract per milliliter) were 0.0125 (internodes/scars) and 0.00025 (buds).

2,4,6-TDC Quantifications. Twenty microliters of the above solutions were injected onto a C-18 reverse-phase analytical column (25 cm $\times$ 4.6 mm) and eluted with acetonitrile–water–acetic acid (50:47.5:2.5). Flow rate was 1 ml/min and peaks were detected with a variable wavelength detector set at 285 nm. The retention times for 2,4,6-TDC and benzyl gentisate (internal standard) were about 5.6 and 6.7 min, respectively. Response factors were calculated by injecting a standard solution of 2,4,6-TDC (0.023 mg/ml; see below) and benzyl gentisate (0.25 mg/ml).

Synthesis of 2,4,6-TDC. To a 100-ml round-bottom flask equipped with a stirbar, hot water bath, and nitrogen bubbler, was added 750 mg of phloroglucinol, 25 ml nitrobenzene and 1 g aluminum chloride. After stirring for 3 min, 1 ml of dihydrocinnamoyl chloride (Aldrich) was slowly added. The temperature was raised to 80°C for 3 hr after which TLC (Si Gel; ether–chloroform 15:85) of the reaction mixture indicated the reaction was complete. The crude reaction mixture was diluted with 100 ml pentane and loaded onto a 200-ml flash chromatography column (silica gel) that had been prepared with chloroform. The column was eluted first with chloroform to remove the nitrobenzene followed by 15% ether in chloroform. After combining the appropriate fractions and removal of solvent, 430 mg (28% yield) of pure 2,4,6-TDC was isolated. Final purification was accomplished by recrystallization from chloroform. The ^{1}HNMR spectrum was identical to that reported in the literature (Itufford and Lasswell, 1978). The [^{13}C]NMR spectrum (d4-methanol), which to our knowledge has not been reported before, is as follows (ppm relative to TMS): 206.1, 166.2, 165.8 (two carbons), 143.2, 129.4 (four carbons), 126.9, 105.4, 95.8 (two carbons) 46.9, and 32.2.

Statistical Analyses. All comparisons within a population (Kluane, Yukon Territory, Canada, or interior Alaska) were analyzed for significance using a paired t test. Comparisons between populations were analyzed using a t test.

RESULTS

Table 1 shows the results of the analysis of plant parts for 2,4,6-TDC. Buds contained about 20% of 2,4,6-TDC (wet wt) in agreement with earlier reports (Greenaway et al., 1989). There was no significant difference ($P > 0.1$) between 2,4,6-TDC concentrations in juvenile and mature buds from CSG or between the two poplar populations. Mature older growth buds, however, did contain ($P < 0.1$; paired t test) less 2,4,6-TDC than buds from either of the other growth stages.

Levels of 2,4,6-TDC in internodes ranged between 0.25% (in one mature older growth sample) to less than 0.005% (detection limit of analyses), and no set of internodes we examined had an average 2,4,6-TDC concentration of greater than 0.06%. Mature CSG internodes contained on the average about twice as much 2,4,6-TDC as juvenile CSG internodes, but this difference was not significant ($P > 0.1$; paired t test). Again, there was no significant difference between the Alaskan and Kluane Lake populations or between growth stages.

Bud scars from Kluane samples contained more ($P < 0.1$; paired t test) 2,4,6-TDC than the other sections of internodes, but the levels were all less than 0.22%. There was slightly more, but insignificant ($P > 0.1$; paired t test), 2,4,6-TDC in the juvenile bud scars compared to the mature bud scars. No

TABLE 1. LEVELS OF 2,4,6-TDC (PERCENT WET WEIGHT) IN BALSAM POPULAR PARTS AND GROWTH STAGES[a]

	Alaskan	Kluane Lake
A. Juvenile current season growth		
Buds	19.5 (3.6)	20.0 (1.8)
Internodes	0.0034 (0.0022)	0 (0)
Bud scars	no data	0.168 (0.022)
B. Mature current season growth		
Buds	17.0 (3.8)	25.3 (4.5)
Internodes	0.0067 (0.0035)	0.0160 (0.0104)
Bud scars	no data	0.135 (0.032)
C. Mature older growth		
Buds	no data	16.0 (1.1)
Internodes	no data	0.0629 (0.0476)

[a]Numbers in parentheses represent standard errors ($N = 5$).

comparison could be made between the two populations because no bud scars were sampled from the Alaskan population.

DISCUSSION

The data of Table 1 show that the concentrations of 2,4,6-TDC in parts and growth stages of balsam poplar from both Kluane Lake and interior Alaska are very similar. Thus the differences between the previous conclusions of Jogia et al. (1989) and Reichardt et al. (1990) are probably not due to differences in the secondary chemistry of plants from these two sites (hypothesis 1).

The very low levels of 2,4,6-TDC present in balsam poplar CSG internodes ($<0.02\%$) makes it unlikely that it plays a significant role in the defense of balsam poplar internodes unless it is a very active deterrent. The rather remote chance that 2,4,6-TDC is sufficiently active even at such low concentrations (hypothesis 2), however, cannot explain the relative palatabilities of juvenile vs. mature growth stages of balsam poplar to snowshoe hares. Even if 2,4,6-TDC was extremely potent as a deterrent, the levels of 2,4,6-TDC would have to be greater in internodes of the juvenile growth stage to explain hares' preference for the mature growth stage, a situation not substantiated by our results in either population.

It is also unlikely that the levels of 2,4,6-TDC in the budscars of juvenile twigs can explain hare preference for the mature stage. First, the results of Jogia et al. (1989) and Reichardt et al. (1990) indicate that hares prefer the mature growth stage about 30-to 100-fold. Such a large discrimination between developmental stages of a single species seems to require a relatively large difference in defensive chemistry. This, however, is shown not to be the case in this study. For instance, if one assumes that bud scars comprise about 33% of a twig (a considerable overestimate), then a simple calculation using the results from the Kluane population (Table 1) shows that the amount of 2,4,6-TDC in the twigs (including bud scars) of the mature and juvenile growth stages are equal. In addition, the difference between concentrations of 2,4,6-TDC in the bud scars of juvenile and mature CSG was not significant ($P > 0.1$, paired t test).

Finally, the results of Reichardt et al. (1990) suggest that the chemical defense relating to the preference of mature over juvenile twigs resides in the internodes themselves; when buds and budscars are removed, hares still prefer mature over juvenile growth stages by roughly the same factor as whole twigs. Because mature and juvenile internodes contain similar levels of 2,4,6-TDC, hares must use some other means to differentiate between growth forms. This refutation of hypothesis 2, however, does not necessarily mean that 2,4,6-TDC has no effect on the overall palatability of balsam poplar relative to other plant species. This may be especially true for those herbivores such as moose that are incapable of selectively feeding on the internode portion of the twigs.

The elimination of hypotheses 1 and 2 leads us to believe that differences between the results of Jogia et al. (1989) and Reichardt et al. (1990) concerning the defense of winter dormant balsam poplar against snowshoe hares must be due to contamination of the internodes samples of Jogia et al. with bud oil.

It is interesting to note that the 1990 paper by Reichardt et al. also dealt with the secondary chemical defense of balsam poplar buds, but failed to report the role of 2,4,6-TDC or even its presence. The results of that study demonstrated that the hares' rejection of buds could be explained solely on the basis of the deterrent properties of several volatile bud metabolites. Nonvolatile metabolites were, therefore, never investigated. They did state in this earlier report that other defensive substances could also be present in buds but their presence would not make buds any less palatable in conventional feeding trials. The demonstration by Jogia et al. (1989) of the antifeedant properties of 2,4,6-TDC and its concentrations in buds of winter-dormant Alaskan balsam poplar indicate that the statement of Reichardt et al. (1990) about "defensive overkill" in poplar buds is supported in the sense that other chemicals may be active.

In a similar vein, hares' preference for mature over juvenile internodes may be caused by aspects of this plant's complex chemistry that have not yet been discovered. For instance, it is not known if the deterrent substances reported by Reichardt et al. (1990) result in physiological stress to browsing hares or whether these substances advertise the presence of other chemicals that are not deterrent, but nonetheless are noxious. Equally intriguing is the unknown role of 2,4,6-TDC in the defense of balsam poplar against herbivores. Since it is now clear that 2,4,6-TDC does not affect hares' discrimination between juvenile and mature balsam poplar, the function of the antifeedant properties of this chemical needs to be further investigated.

(Received February 10, 1992; accepted April 23, 1992)

Abstract—Anal sac secretions of three social mongoose species (*Helogale parvula*, *Crossarchus obscurus*, and *Suricata suricatta*) were chemically analyzed by means of gas chromatography–mass spectrometry. Compounds with high molecular weights (greater than 250) were found to distinguish the three species. Differences in composition suggest a possible species-specific role in scent marking. Male *H. parvula* had vitamin E present in the anal sac, whereas it was absent in the females. This suggests a possible sex-specific function of vitamin E in *H. parvula*. No differences in chemical composition were found between male and female *S. suricatta*. Ten compounds were found in female *C. obscurus* that were not present in the male.

Key Words—Mongoose, *Helogale parvula*, *Crossarchus obscurus*, *Suricata suricatta*, anal gland, lipids.

INTRODUCTION

Mongooses are small to medium-sized carnivores that have a diverse array of social structures, from a solitary existence as in the small Indian mongoose, to a highly cooperative social structure as in the dwarf mongoose. Pocock (1916) related the size of mongoose scent sacs with the particular social structure they possess: gregarious mongooses have larger scent glands than more solitary mongooses, suggesting that more social species mark more frequently than more solitary species. Although this hypothesis has not been tested, it merits investigation. Pocock (1916) further described the morphology of the scent sacs of mongooses as distinctly different than other carnivores. There are several depressions and folds in the glands, which contain small glandular pits with several secreting pores. Secretions from these glands are thick waxy brown foul-smelling substances (Decker, personal observation).

Mongooses have very characteristic and stereotypical postures of scent marking (Gorman et al., 1974). Behavior patterns vary with the type of object being marked, especially with regard to its height above the ground (Rasa, 1973). Preferred objects for marking by dwarf mongooses are smooth, upright, horizontal, or sloping branches (Rasa, 1973). Such objects are marked from a "hand-stand" position (Gorman et al., 1974). Anal drag is a posture in which the animal strokes its anal surface across a very low or flat object. Rasa (1973) reports the anal drag to be used exclusively in allomarking. In the "leg lift" posture, the animal lifts its leg toward a low object. Again, this is most commonly used in allomarking (Rasa, 1973) but occasionally is used to mark low-lying objects such as the food dish.

Several functions of scent marking have been proposed (for reviews see Ralls, 1971; Eisenberg and Kleiman, 1972; Johnson, 1973; MacDonald, 1979). Conover and Gittleman (1989) have classified these potential functions into six general categories: (1) identity—information regarding individual, group, or sexual identification (Rasa, 1973; Gorman, 1976); (2) status—information on dominance status (MacDonald, 1979; Erlinge et al., 1982); (3) reproductive status—related to courtship and breeding (Gorman, 1980; Gorman and Trowbridge, 1989); (4) spatial information—serves a territorial function (Peters and Mech, 1975; Kruuk, 1978); (5) temporal information—reveals when individuals were at a particular location (Rasa, 1973); and (6) foraging—serves a bookkeeping function by informing an individual of whether it has previously looked for food in a particular area (Henry, 1977; MacDonald, 1979).

The objectives of this study were to establish methods of collection and analysis of mongoose secretions, to identify potential biologically active compounds present in the scent secretion of three species of mongooses, and to propose a potential function of scent marking in these mongooses.

METHODS AND MATERIALS

Materials. Solvents were chromatographic grade quality purchased from J.T. Baker Chemicals Co., Phillipsburg, New Jersey. Derivatizing agents were purchased from Supelco, Inc. (Bellefonte, Pennsylvania), Applied Science (State College, Pennsylvania), Aldrich, Inc. (Milwaukee, Wisconsin), Sigma Chemical Co. (St. Louis, Missouri), and Pierce Chemical Co. (Rockford, Illinois).

Collection. Anal gland secretions were collected from three species of social mongooses (*Helogale parvula*—two males, two females; *Crossarchus obscurus*—one male, two females; and *Suricata suricatta*—one male, one female) from the National Zoo, Washington, D.C., by swabbing the anal sacs with sterile cotton swabs. All chemical analyses were conducted at the Center for Environmental Biotechnology, University of Tennessee.

Extraction. The secretion was immediately extracted with a modified Bligh and Dyer solvent system (White et al., 1979), which consists of chloroform, methanol, and a phosphate buffer in a ratio of 1:2:0.8. The sample was left in the solvent system for a minimum of 4 hr. Subsequently, equal amounts of water and chloroform were added to the samples separating them into aqueous and organic phases. The aqueous layer was discarded, and the organic (lipid containing) phase was transferred to Teflon-lined screw-capped test tubes and dried under a stream of nitrogen at room temperature.

Lipid Isolation. Silicic acid columns were prepared using 0.5 g Unisil (100–200 mesh, Clarkson Chemical Co., Inc., Williamsport, Pennsylvania), activated at 100°C for 60 min and preextracted in a minimal volume of chloroform. Total lipid was applied to the top of the columns in a minimal volume of chloroform. Sequential washes of 5 ml of chloroform, acetone, and methanol eluted nonpolar, glyco-, and phospholipids. Each fraction was dried under a stream of nitrogen.

Mild Alkaline Methanolysis. The mild alkaline methanolysis procedure (White et al., 1979) was utilized to prepare methyl esters of the ester-linked fatty acids of each lipid fraction.

Gas Chromatography (GC). Dry methyl esters of nonpolar, glyco-, and phospholipids were dissolved in isooctane containing the internal standard of methyl nonadecanoate. Samples of 1 μl were injected onto a 50-m nonpolar, cross-linked methyl silicone fused silica capillary column (0.2 mm ID, Hewlett Packard) in a Shimadzu GC-9A GC. A 30-sec splitless injection at 270°C was used. Hydrogen at a linear velocity of 35 cm/sec was the carrier gas with a temperature program starting with an initial temperature of 100°C. The temperature was then increased at a rate of 10°C/min to 150°C. At 150°C the temperature was increased 3°C/5 min to 282°C. An equal detector response was assumed for all components. Peak areas were quantified with a program-

mable laboratory data system (Nelson Analytical 3000 Series Chromatography Data System, Revision 3.6).

Gas Chromatography–Mass Spectrometry (GC-MS). Tentative component identification prior to GC-MS was based on comparison of the retention times with authentic standards. GC-MS analysis was performed on a Hewlett Packard 5996A GC-MS fitted with a direct capillary inlet utilizing the same chromatographic system except for use of a helium carrier gas and the temperature program, which started at 100°C and increased to 280°C at 3°C/min for a total analysis time of 60 min. The electron multiplier voltage was between 1800 and 2000 V, the transfer line maintained at 300°C, the source 280°C, and analyzer 250°C, and the GC-MS was autotuned with DFTPP (decafluorotriphenylphosphine) at *m/z* 502 with an ionization energy of 70 eV. The data were acquired using the Hewlett Packard 6/VM data system. Compounds were identified using the GC-MS library, which provided an 80% or greater probability of being correct for all compounds.

Nonpolar Lipid Fractionation. Preliminary analyses suggested the importance of the heavier compounds in distinguishing the species. Therefore, to achieve greater separation of those compounds with high molecular weights (greater than 250), the nonpolar lipid portion was subsequently fractionated. In this procedure, silicic acid columns were prepared using 1.0 g Unisil (100–200 mesh, Clarkson Chemical Co., Inc., Williamsport, Pennsylvania) activated at 100°C for 60 min and preextracted with chloroform. Sequential washes of 10 ml of hexane, hexane–diethyl ether (90:10), and hexane–diethyl ether (80:20) eluted the compounds with smaller molecular weights (<250) so that better separation of the larger compounds (molecular weights >250) could be achieved. Ten microliters of BSTFA [*N,O*-bis(trimethylsilyl)trifluoroacetamide] were added to the fraction containing compounds with high molecular weights (>250). These samples were subsequently analyzed on the GC-MS. The temperature program initially began at 50°C for 1 min. The temperature was then raised 30°C/min until it reached 150°C. Subsequently, the temperature was raised 2°C/min to 250°C, then 5°C/min to 300°C with a final time of 30 min.

Statistical Analyses. A phenogram was generated from a similarity matrix using the Numerical Systems Program (Rohlf et al., 1982). Principal component analysis was performed to summarize variation among taxa.

RESULTS AND DISCUSSION

The Bligh-Dyer extraction was very effective in revealing a larger spectrum of compounds than previous analyses of carnivore scent secretions (Gorman et al., 1978; Davies et al., 1988; Apps et al., 1988, 1989). The primary difference between this study and previous studies is the choice of solvent systems used

to extract the compounds. Previous analyses have used *n*-hexane as the solvent, and this is only effective in revealing the straight-chain hydrocarbons, whereas the Bligh-Dyer system is effective in revealing more complex compounds.

An unweighted paired group cluster analysis showed differences among species in only the nonpolar lipid fraction (Figure 1). *Helogale parvula* males and females grouped together. Similar patterns were also detected in *C. obscurus* and *S. suricatta*. Separation of individuals within a single species was not apparent with the glyco- and phospholipid portions of the samples, and are therefore not reported here.

Although the sample sizes in this study are too small to assess significant differences in the chemical composition of the anal sacs between sexes and among species, we feel that it is worthwhile to present these differences as a descriptive measure.

Intraspecific Comparison of Helogale parvula. Sixty-six compounds were revealed in the neutral lipid fraction of *H. parvula* (Appendix 1). Other studies of carnivore scent secretions have revealed between 10 and 30 compounds (e.g., Gorman et al., 1978; Davies et al., 1988; Apps et al., 1989). This may suggest the complexity of scent marking in this species.

Eleven additional compounds were found in the dominant male *H. parvula*, which were not found in the subordinate male or females (see Appendix 1). Although Rasa (1973) has reported no differences in frequency of marking between dominant and subordinate males, the additional chemicals found in the dominant male suggests that the scent secretions of the dominant male may serve an additional or different function.

Vitamin E was present in the anal sac of male *H. parvula* and was absent in the female *H. parvula*. This compound may be sex specific in *H. parvula*.

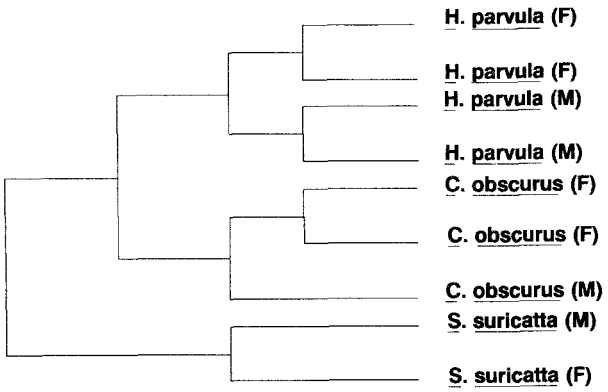

FIG. 1. A phenogram illustrating the similarity in nonpolar lipids among *Helogale parvula*, *Crossarchus obscurus*, and *Suricata suricatta*. M = males; F = female.

Although many studies (e.g., Silverstein et al., 1966) have shown that a combination of several chemicals are necessary for biological activity, some studies of carnivores have identified single compounds to be unique to the males (e.g., Apps et al., 1989). This may suggest that single compounds can play an important sex-specific role in some cases. A detailed study of the dwarf mongoose by Rasa (1973) has shown that they traverse their home range in 25–30 days. These mongooses were able to detect scent secretions from themselves or other mongooses for up to 30 days after the scent was deposited (Rasa, 1973). Rasa suggests that the primary function of anal marking, as animals traverse their home range, is to provide information on individual identity and to "date" the mark. Rasa also found that another mongoose can detect differences in intensity of a mark up to 1 hr after it has been deposited.

Intraspecific Comparison of Crossarchus obscurus. Eleven additional compounds were found in relatively large quantities in *C. obscurus* females, which were not found in *C. obscurus* males (Figure 2). Very little is known about the behavior and ecology of *C. obscurus* (for a review see Goldman, 1987). However, these results may suggest that the females rely more heavily on scent marking than do the males.

Intraspecific Comparison of Suricata suricatta. Few qualitative differences were found between the male and female meerkat (Figure 3). This may suggest

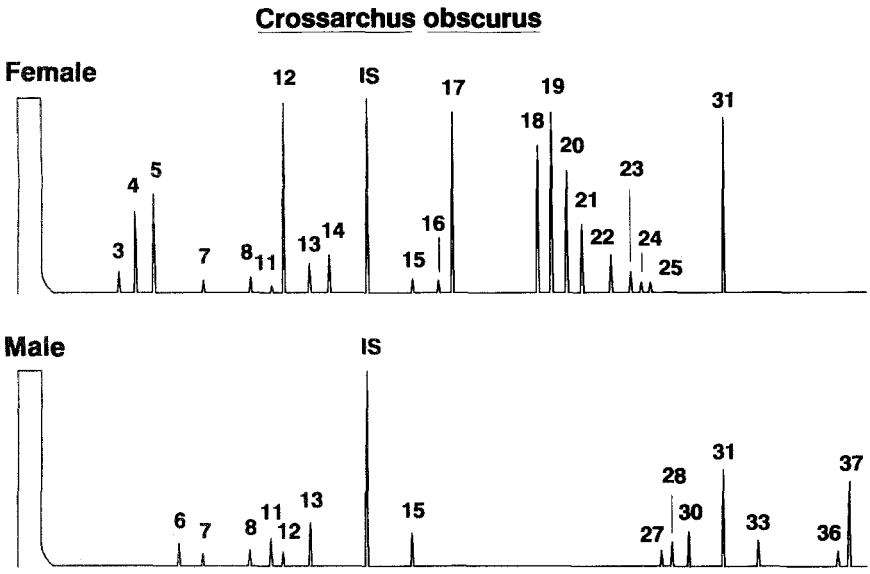

FIG. 2. Chromatogram of male and female *Crossarchus obscurus*. Numbers above peaks correspond to those in Appendix 1, where compounds and relative quantities of each are given. IS = the internal standard of methyl nonadecanoate.

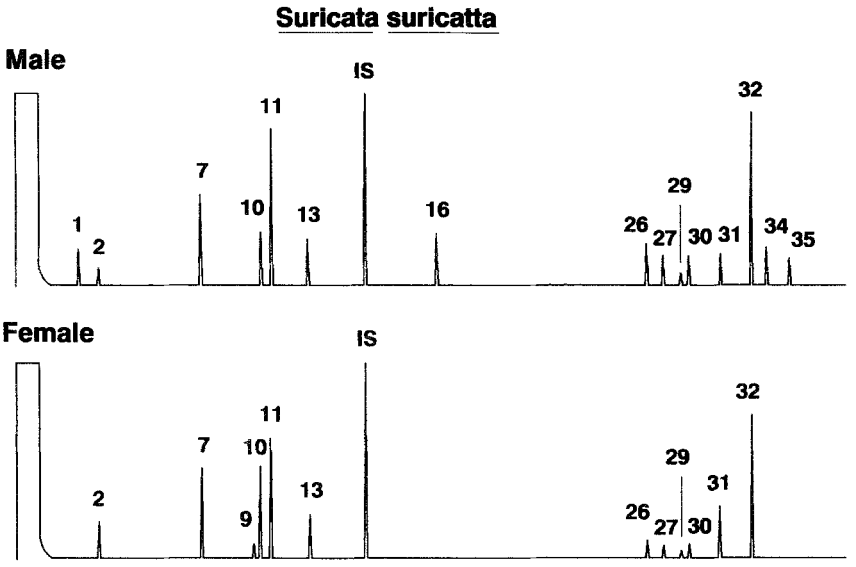

FIG. 3. Chromatogram of male and female *Suricata suricatta*. Numbers above peaks correspond to those in Appendix 1, where compounds and relative quantities of each are given. IS = the internal standard of methyl nonadecanoate.

that the function of scent marking in male and female meerkats does not differ. Additionally, Moran and Sorensen (1986) found no marked differences in the frequency of marking between male and female meerkats. Furthermore, large individual differences in scent marking were not tied consistently to sex or age.

Interspecific Comparison. Principal component analysis summarized 85% of the variation in the first two components (Figure 4). Figure 4 reveals that males and females of the same species are more similar to each other in the chemical composition of their scent sacs than with individuals of different species. Additionally, the species are clearly different from each other. If the "loadings" are overlayed onto the "scores" in Figure 4, we can see which compounds are best able to maximally separate the species. For example, cholesterol (denoted as sterol a) distinguishes the meerkats, the polybranched trienoic acid (denoted as 2464a) distinguishes the kusimanse, and a variety of compounds (18:0, sterol b, 713a, and 713d) distinguish the dwarf mongooses. The compounds that distinguish the species are relatively heavy compounds (molecular weights greater than 250) and, therefore, suggest a function that promotes long-term signaling of the scent mark. Female *C. obscurus* had a unique profile of compounds that were not present in the male (Figure 2). Few differences were found between male and female *H. parvula* or between male and female *S. suricatta* (see Figure 3 and Appendix 1).

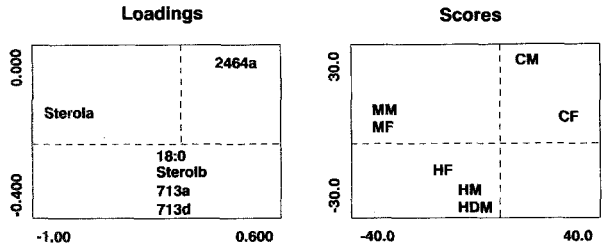

FIG. 4. Results of principal component analysis. "Loadings" represent those compounds which were maximally able to separate the species. "Scores" represent the relative separation of the species. CM = *Crossarchus obscurus* male; CF = *Crossarchus obscurus* female; MM = *Suricata suricatta* male; MF = *Suricata suricatta* female; HM = *Helogale parvula* male; HDM = *Helogale parvula* dominant male; HF = *Helogale parvula* female. 2464a = an unknown polybranched trienoic acid; sterol a = cholesterol; 18:0 = an 18-carbon saturated carboxylic acid; sterol b = cholestanol; 713a = pentadecanol; 713d = heptadecanol.

Three previous studies have chemically analyzed the anal sac secretions of mongooses. Gorman et al. (1974) found a series of short-chained (C_1–C_{10}) saturated carboxylic acids in the small Indian mongoose (*Herpestes auropunctatus*). Similar compounds were found in the yellow mongoose, *Cynictis penicillata*, by Apps et al. (1989). Hefetz et al. (1984) found heavier compounds, C_{10}–C_{22}, in the Egyptian mongoose, *Herpestes ichneumon*. Our results are most similar to those of Hefetz et al. (1984). Differences in results, to some extent, may be due to differences in collection regimes and analysis of secretions.

The short-chained (C_1–C_{10}) highly volatile fatty acids have been found to be present in the scent secretions of most carnivores analyzed (e.g., Gorman et al., 1974; Albone and Perry, 1976; Preti et al., 1976). These compounds are relatively simple and do not have a large number of possible structural isomers as opposed to more complex molecules (i.e., those with larger molecular weights). Since many animals have short-chain fatty acids in their scent secretions, it seems unlikely that these serve a unique communicative function. The short-chain fatty acids probably function in directing the animal to the scent, while the heavier compounds are actually the communicative part of the scent. The fact that animals actually go up to the scent to smell it (Decker, personal observation), lends some support to this argument.

Acknowledgments—We would like to thank P. Apps and J.L. Gittleman for critically reviewing earlier drafts of this manuscript. Two anonymous reviewers greatly improved upon the clarity and quality of this manuscript. We thank the National Zoo personnel for allowing us to collect the samples for this study; special thanks to Bill Xanten and Larry Newman for helping to collect the samples. Funds for this study were provided by the Center for Environmental Biotechnology.

[a] # = peak numbers corresponding to Figures 2 and 3. Those compounds without peak numbers are only present in *H. parvula* and are listed at the end of this appendix; MW = molecular weight; HDM = Dominant *H. parvula* male; HM = *H. parvula* male; HF = *H. parvula* female; CM = *C. obscurus* male; CF = *C. obscurus* female; SM = *S. suricatta* male; SF = *S. suricatta* female. Fatty acids are designated as a total number of carbon atoms : number of double bonds with the position of the double bond nearest the aliphatic (w) end of the molecule indicated. This is followed by the suffix c for *cis* and t for *trans* configuration of monoenoic acids. The prefixes i, a, or br indicate iso-, anteiso-, or branched (position undetermined). Mid-chain branching is indicated by the number of carbon atoms from the carboxyl end of the molecule and Me for the methyl group (10Me 16:0 is a 17-carbon fatty acid).

EFFECTS OF SALICYLIC ACID ON GROWTH AND STOMATAL MOVEMENTS OF *Vicia faba* L.: EVIDENCE FOR SALICYLIC ACID METABOLIZATION

BARBARA MANTHE, MARGOT SCHULZ, and HEIDE SCHNABL*

(Received February 25, 1992; accepted April 27, 1992)

Abstract—The influence of salicylic acid on the growth and stomatal movements of *Vicia faba* L. was investigated. Whereas shoot length, fresh weight, and transpiration rates, which are directly correlated with stomatal pore widths, were only affected at salicylic acid concentrations higher than 3.5 mM after long-term treatments, guard cells in epidermal peels exhibited a high sensitivity at concentrations as low as 0.001 mM, resulting in stomatal closing. HPLC analysis of methanolic extracts from roots and leaves revealed the presence of free salicylic acid and a metabolite, whose amount increased with time in plants previously incubated with a medium containing salicylic acid. The possible ability of *Vicia faba* to detoxify the phenolic acid may be one explanation of the discrepancy between the stomatal reaction in epidermal peels directly treated with the phenolic acid and after application through the transpiration stream. The results indicate that, under natural conditions, salicylic acid will not act as an allelopathic compound whose toxic properties severely affect the growth of *Vicia faba*.

Key Words—Allelopathy, growth inhibition, detoxification, salicylic acid, stomatal movements, *Vicia faba*.

INTRODUCTION

Allelopathy, as defined by Molisch (1937), comprises interactions among plants, including microorganisms, by heterogeneous, mostly phenolic substances. Allelochemicals interfere with the biochemistry and physiological processes of the plant by interaction with plant hormones, enzyme functions, respiration, water

status, and cell division. These effects result in an inhibition of plant development and growth, which is not only significant for the individual plant, but can influence an ecosystem by changing the pattern of vegetation (Muller and Chou, 1972; Rice, 1984).

Salicylic acid or its derivatives are naturally occurring substances, e.g., in the bark and leaves of *Salix alba* and *Quercus falcata* and in the rhizosphere of *Zea mays* and *Phaseolus vulgaris* (Harborne, 1977; Pareek and Gaur, 1973). During decomposition of plant residues from *Zea mays* and *Secale cereale*, salicylic acid is released into the soil (Chou and Patrick, 1976). This compound can also appear when flavonoids are degraded from decaying *Trifolium pratense* and can reduce growth and development of red clover (Chang et al., 1969). Evidence was obtained that salicylic acid may be synthesized in very low amounts by a larger number of plants than previously noted (Yalpani et al., 1991).

The influence of salicylic acid on stomatal movements was investigated by several research groups with conflicting results. Rai et al. (1986) reported that stomatal opening occurred when epidermal strips of *Commelina communis* were incubated with the phenolic acid, whether or not they were pretreated with ABA. Bhatia et al. (1986) observed stomatal closing in the presence of very low concentrations of salicylic acid. Patterson (1981) pointed out that allelochemicals such as salicylic acid may function on stomatal physiology, which, together with further effects, finally result in a general growth reduction. Inhibiting influences can be reduced, however, by various detoxifications. Involved reactions include oxidations, decarboxylations, methylations, and acylations of the allelochemical and/or its conjugation with amino acids or sugars, the latter being most widespread in the plant kingdom (Harborne, 1977). Detoxifications diminish the reactivity of harmful molecules as well as their permeability through membranes and allow the storage in suitable compartments such as the vacuole (Pridham, 1965).

In the present study, the influence of salicylic acid on the growth of *Vicia faba* L. was investigated with special regard to stomatal movements and a possible resistance of the plant against allelopathic attack by detoxification of the phenolic acid.

METHODS AND MATERIALS

Bioassay on Influence of Salicylic Acid on Growth of Vicia faba

Seeds of *Vicia faba* L. cv. Alfred (Lochow-Petkus, Bergen) were pretreated with methanol for 20 min and soaked in tap water overnight. The seeds were sown in five plastic pots, each filled with steamed soil. Seeds were allowed to germinate and grow for 18 days in a 12-hr photoperiod, provided by HQI400-lamps (Osram) with a light intensity of about 300 $\mu E/m^2$ at 21°C and 80%

humidity. Soil was kept moist for the first five days; afterwards the plants were treated either with 10 mM citrate buffer, pH 5.8, as control or with salicylic acid of defined concentrations (1, 2, 3.5, and 5 mM) dissolved in 10 mM citrate buffer. During the following 12 days, shoot length was measured, and at the end of this period, fresh weight of shoots and leaves was determined. For further experiments, plants were grown for maximally 21 days, normally watered or watered with salicylic acid solutions.

Effects of Salicylic Acid on Stomatal Apertures

Studies on Epidermal Peels. The abaxial epidermal tissue from leaves of 3-week-old plants was peeled off during the early light period and the cuticle incubated in one of the solutions described below for 3 hr. Illumination (170 $\mu E/m^2$) of the peels was provided by a cold light source (Schott, KL1500). Incubation solutions were prepared as follows: (1) 25 mM 4-morpholine-ethanesulfonic acid (MES)/Tris buffer, pH 6.5, supplemented with either 0, 0.001, 0.01, 0.1, or 1 mM salicylic acid (SA); (2) the same molarities were dissolved in distilled water; and (3) 10 mM citrate buffer, pH 5, 6, or 7, supplemented with 0.001, 0.01, or 0.1 mM SA. Controls were incubated only with citrate buffer pH 5, 6, or 7. All incubations were performed in Petri dishes covered by CO_2-depleted air. After treatments, 50 stomatal pore widths per peel were measured.

Measurements of Transpiration Rates. Fifteen plants were grown from seeds in a glasshouse at 20°C and a photoperiod of 12 hr. Light was provided by metal halide HQI400 lamps (Osram). The irradiance at plant level was 170–200 $\mu E/m^2$. Plants aged 14 or 21 days were then placed in an environmentally controlled chamber (volume 0.6 m^3) at a constant temperature of 20°C and 50% relative humidity. Partial pressure of CO_2 in the system was continuously monitored with an IR gas analyzer (URAS, Hartman & Braun) and maintained at 330 ppm CO_2. HQI400 lamps were used for illumination (170 $\mu E/m^2$). For measurements of transpiration rates, a steady-state porometer was used [PLC Parkinson leaf chamber and leaf chamber analyzer LCA2, Analytical Development Company (ADC)]. Leaves from whole plants were placed in the leaf cuvette (6.25 cm^2), continuously flushed with air. The flow rate (300 ml/min) of air, entering the leaf cuvette was monitored with a mass flowmeter (type ASU-MF, ADC). Transpiration rates (mmol $H_2O/m^2/sec$) were automatically recorded with a data logger 2 (Dl 2, ADC) and evaluated with an Epson HX10 computer (ADC).

Rates of transpiration were evaluated during treatments with salicylic acid. The compound was applied during watering with 10 ml of 10 mM citrate buffer, pH 5.8, containing 1.5, 3.5, or 7 mM salicylic acid. Applications with the buffer alone were performed as controls. When treatments were extended over

more than two weeks, plants were watered with salicylic acid solutions in the glasshouse for one week. Transpiration rates were monitored over five days (three data collections per day every 4 hr).

Preparations of Methanolic Extracts from Roots and Leaves

Roots and leaves from 3-week-old plants, placed in a 0.5 mM salicylic acid-containing medium (25 mM MES/Tris, 0.5 mM KCl, 0.25 mM $CaSO_4$ 0.1% Na ascorbate, 0.5 mM SA) or the medium alone for 14 hr, were harvested, washed thoroughly with distilled water, and ground to a powder in liquid nitrogen. The powder was extracted for 30 min with 10% methanol (1 ml/g plant material) at pH 4 and gently stirred. The mixture was filtered through eight layers of gauze and centrifuged for 10 min at 10,000*g*. The supernatant was evaporated to dryness at 30°C in vacuo. The residue was dissolved in 100 μl methanol/g plant material and centrifuged again for 10 min at 10,000*g*. The resulting supernatant was analyzed by HPLC.

High-Performance Liquid Chromatography (HPLC)

For HPLC analysis of the extracts, a Beckmann programmable solvent module 126 with UV/VIS detector 126 was used. Separation of phenolic compounds, detected at 280 nm, was performed with a RP-18 column (ODS type RP18, 46 × 250 mm, Beckman). Column temperature was kept at 20°C by a thermostat (WO, Industrial Electronic). Phenolics were eluted at a flow rate of 0.5 ml/min by the gradients described below, using 1% acetic acid in water and methanol as solvents A and B.

Gradient 1. 0–10 min, 100% A; 10–11 min, 92.4% A in B; 11–24 min, 77.3% A in B; 24–36 min, 77.3% A in B; 36–46 min, 50% A in B; 46–66 min, 100% B; 66–70 min, 100% B; 70–71 min, 100% A.

Gradient 2. 0–1 min, 100% A; 1–19 min, 71% A in B; 19–28 min, 55% A in B; 28–40 min, 44% A in B; 40–49 min, 24% A in B; 49–55 min, 100% B.

Gradient 3. 0–1 min, 77.3% A in B; 1–20 min, 50% A in B; 20–28 min, 32.8% A in B; 28–40 min, 25.8% A in B; 40–50 min, 100% B; 50–55 min, 100% A.

Data were evaluated by the system gold computer program (Beckman).

Isolation of Metabolite and Acidic Hydrolysis

The metabolite, detected by HPLC in methanolic extracts of incubated plant material, was collected after HPLC separation. Fractions of about 50 HPLC runs were combined, concentrated, and rechromatographed to prove purity of the collected substance. For acidic cleavage of the metabolite, 100 μl of the

pure concentrated fraction was mixed with the same quantity of 1 N HCl. The mixture was incubated at 60°C for 3 hr and analyzed for the decrease of the metabolite and the occurrence of salicylic acid by HPLC. The latter was identified by cochromatography with salicylic acid standards.

Statistics

Experiments were repeated three times. Significance of data was determined by Vierfelder test with Yates correction or by F test and Student's t test.

RESULTS

Salicylic Acid-Induced Growth Reduction

Seedlings of *Vicia faba* treated with the different concentrations of salicylic acid showed a significant reduction of shoot growth and fresh weight. The growth inhibition was dependent not only on the salicylic acid concentration, but also on the time of exposure. Significant differences between the controls and treated seedlings were obvious after 18 days of application (Figure 1). A 25% reduction of the growth was achieved by 5 mM salicylic acid after seven

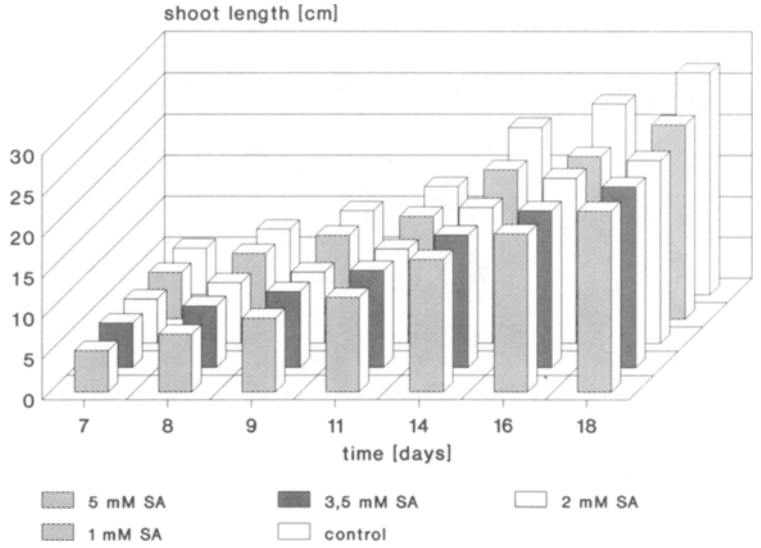

FIG. 1. Plants were watered with salicylic acid (SA) of the given concentrations over a period of 11 days. Highest SA concentrations inhibited shoot growth after two days of treatment. A significant inhibition was also achieved for the lower concentrations after 10 days.

days, indicating that the allelopathic action of the phenolic acid on *Vicia faba* is only developed at high salicylic acid concentrations or the uptake of the compound is insufficient. Thus an examination of plant material for the recovery of salicylic acid was necessary.

Effects of Salicylic Acid on Stomatal Movements

Incubations of epidermal peels in the presence of salicylic acid resulted in a concentration-dependent reduction of stomatal apertures. When incubations were performed with salicylic acid dissolved in distilled water, a concentration as low as 0.001 mM was sufficient to diminish stomatal pore widths more than 50%, whereas 0.1 and 1 mM caused a complete closure (Figure 2). Additionally, epidermal peels were incubated with MES/Tris (pH 6.5) to estimate pH influences. Under these conditions, the same effects were observed, but higher concentrations of the phenolic compound were necessary to induce stomatal closure, e.g., 0.001 mM caused only a 30% reduction of stomatal pore width and with 0.01 mM, a 76% reduction was noted (Figure 2). Stomatal closure in the presence of salicylic acid is therefore supposed to be an effect of the allelochemical, which may be superimposed on or intensified by low pH. The relatively large standard deviations may be due to the known and normally occurring heterogeneity in stomatal apertures appearing on the same leaf (Raschke et al., 1975).

The interaction of pH and salicylic acid was further studied by incubating

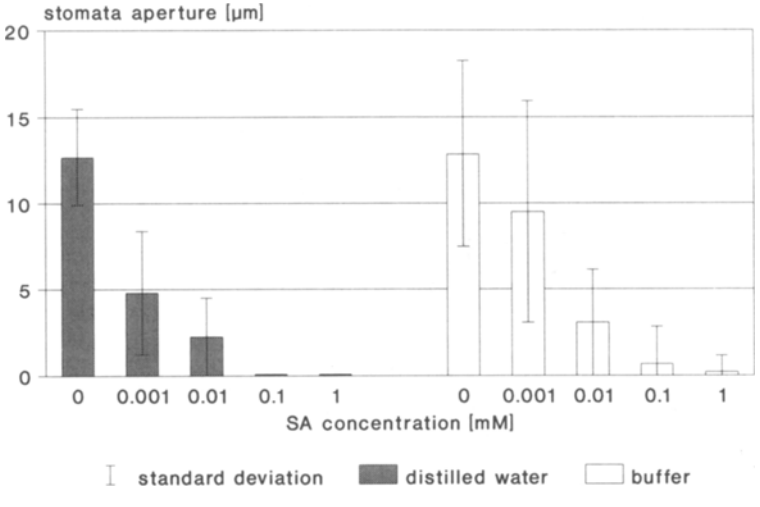

FIG. 2. When salicylic acid (SA) was dissolved in distilled water, 0.001 mM was sufficient to reduce stomatal pore widths to 50%, buffered SA solutions were effective at higher SA concentrations. Distilled water only or the buffer alone were used as controls.

epidermal peels in citrate buffer at pH 5, 6, and 7 alone or supplemented with 0.001, 0.01, or 0.1 mM of salicylic acid. At pH 5 and 6, stomatal apertures were reduced to about 46% compared to pore width at pH 7. In the presence of salicylic acid, however, reductions of apertures were higher at all three pH values, but SA was most effective at pH 5, at concentrations as low as 0.001 mM (pH 7: 52%; pH 6: 61%, pH 5: 67%) compared to the controls at corresponding pH (Figure 3). Although under low pH conditions alone, a reduction of the stomatal pore widths was observed, the results clearly indicate a further salicylic acid-induced stomatal closing. This is in accordance with the known fact that the nondissociated form of salicylic acid possesses a higher physiological activity than the dissociated one (Basund, 1962; Scharff and Perry, 1976).

Transpiration Rates after Treatments with Salicylic Acid

In subsequent studies, salicylic acid applications were performed by watering 3-week-old plants with 1.5, 3, 5, and 7 mM solutions of the allelochemical for five days. As illustrated in Figure 4, only the highest concentrations (5 and 7 mM) caused significant reductions (14%, 11%) of the transpiration rates at the fifth day of treatment. When 2-week-old plants were pretreated with salicylic acid solutions of the same concentrations over a period of six days, a remarkable reduction (between 60 and 40%) of the transpiration rate during the seventh and

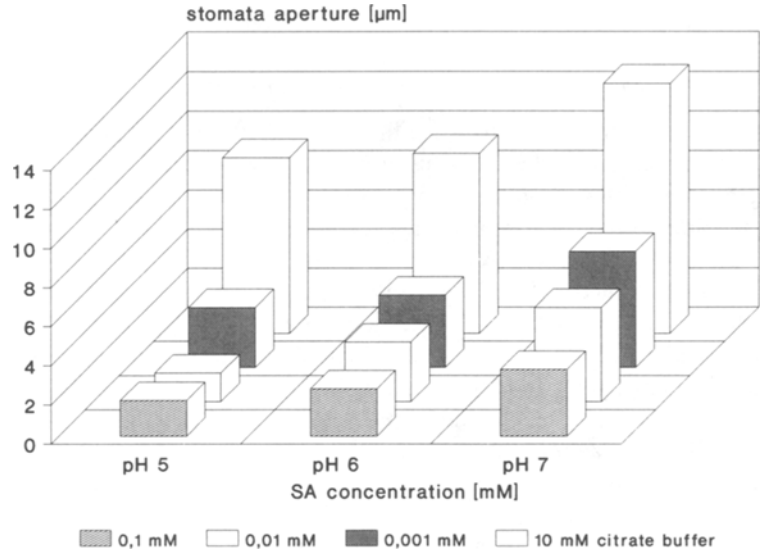

FIG. 3. Lower pH values of the solutions intensify the effect of salicylic acid (SA), inducing stomatal closure in epidermal peels.

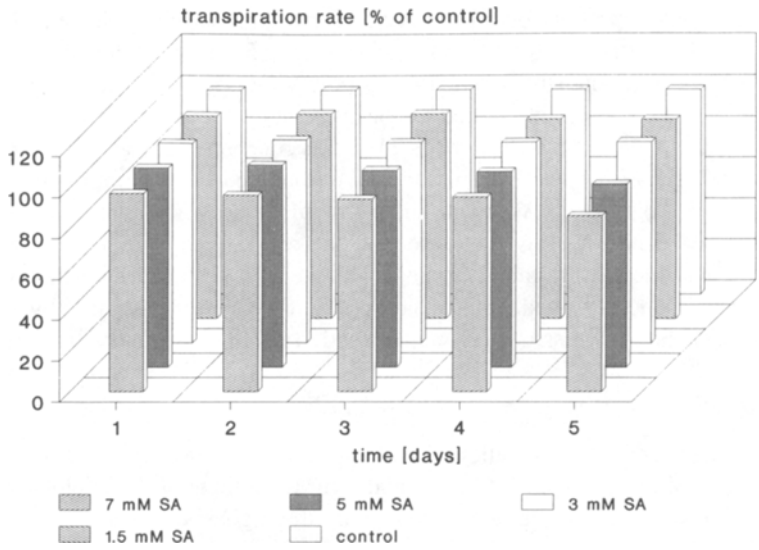

FIG. 4. Significant reduction of the transpiration rates (14%) was only achieved after the fifth day with the highest salicylic acid (SA) concentration used. Measurements were extended over a period of five days.

eleventh day of treatment was achieved for the highest salicylic acid concentrations used (Figure 5).

Appearance of Salicylic Acid and Its Metabolite in Roots and Leaves

The obvious differences between the reactions of guard cells in epidermal peels and the results of the bioassay on the allelochemical's effectiveness on plant growth as well as stomatal responses to salicylic acid treatments of whole plants required further studies on the appearance of salicylic acid in plant tissues and its possible metabolism. When whole plants were incubated for 14 hr in a medium supplemented with 0.5 mM salicylic acid, methanolic extracts of the roots and leaves, analyzed by HPLC (Figure 6B and C), contained free salicylic acid identified by cochromatography, and an additional new compound absent in controls (Figure 6A). In comparison with the root extracts, those of leaves contained a considerably higher amount of endogenous phenolics, but salicylic acid as well as the additional compound could be identified using gradient 2. Both compounds were also detectable in soil-grown, SA-treated plants (data not shown). When plants were incubated in the SA-containing medium, however, the amounts of salicylic acid and of the additional compound were higher.

The compound found in roots and leaves of treated plants was considered as a detoxification product of absorbed, exogenous salicylic acid. Showing a

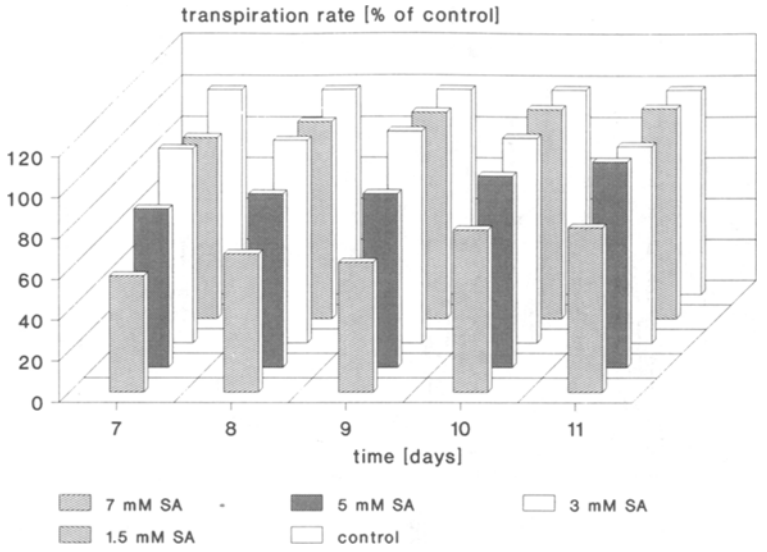

FIG. 5. Reduction (30%) of the transpiration rates after 11 days of treatment with 7 mM salicylic acid (SA).

lower retention time of 31.2 (gradient 2) or 37.5 (gradient 1) min compared to free salicylic acid (42.5 min, gradient 2/58.1 min, gradient 1), its increasing concentration with time is correlated with the presence of a decreasing amount of salicylic acid in the extracts (Figure 7). Especially for the purpose of isolating the assumed metabolite, further studies were performed with medium-incubated plants.

In a first attempt at identification, the new compound was collected after preparative HPLC and subsequently hydrolyzed with 1 M HCl. HPLC analysis of the hydrolyzed products revealed the release of salicylic acid (Figure 8). Thus an uptake of salicylic acid, its transport to leaves, and the appearance of a possible metabolite are evident.

DISCUSSION

The growth reduction of *Vicia faba* plants after treatment with salicylic acid is in agreement with the results of Kurogochi et al. (1978) and Leather and Einhellig (1985), who found similar effects in bioassays with *Oryza sativa* and *Sorghum bicolor*. The allelopathic action of the phenolic acid on *Vicia faba* occurred only at relatively high concentrations. This might be due to a small amount of uptake as a consequence of low availability in the soil, caused by

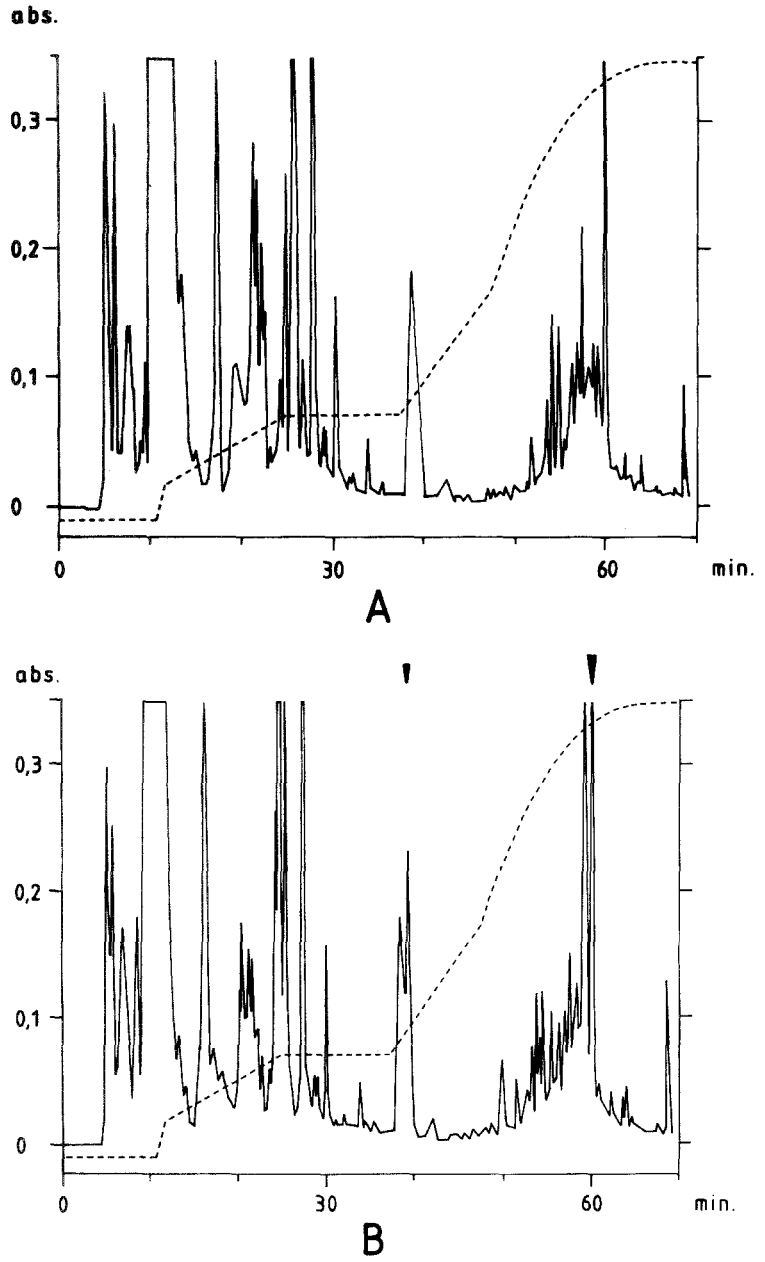

FIG. 6. HPLC chromatograms of (A) methanolic extract from roots, harvested from untreated plants (control), (B) root extract, prepared from salicylic acid (SA) -incubated plants, (C) leaf extract from SA-treated plants, illustrating free SA as well as the additional compound (retention time of salicylic acid: 42.6; retention time of metabolite: 32.1).

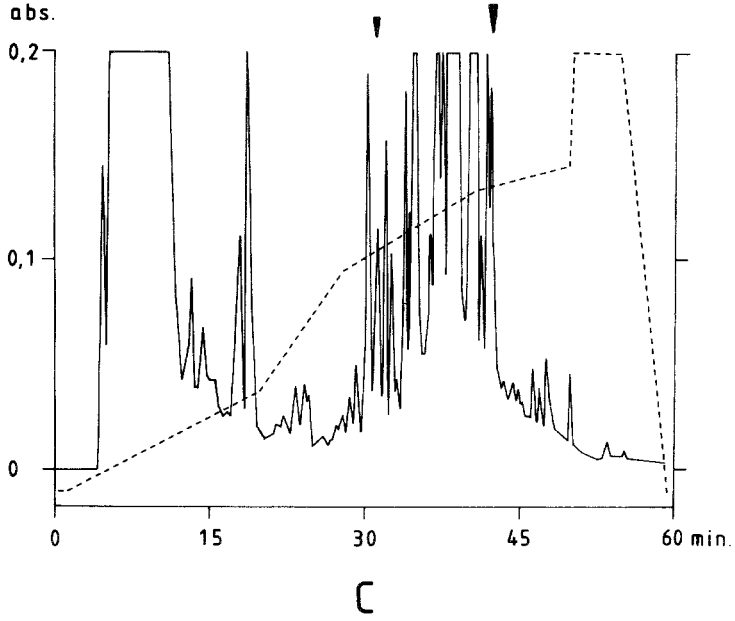

FIG. 6. Continued

adsorption to soil particles or decomposition of the allelochemical by microorganisms (Muller and Chou, 1972; Heisey, 1990). Therefore, the concentrations of salicylic acid used (0.1–5 mM) may not be identical with the amount available for uptake by the plant but, rather, should be lower (Dalton et al., 1983). The latter could be one explanation for the relatively late appearance of growth inhibition only at the highest concentration. A further reduction of inhibiting effects must be expected if the phenolic acid is detoxified after entering living cells.

Influences of allelochemicals on stomata, responsible for the regulation of gas exchange, are an important factor affecting growth and development of a plant (Patterson, 1981). One explanation for the growth inhibition observed is a possible effect on stomatal apertures. Guard cells in peels of abaxial epidermis were very sensitive to low concentrations of salicylic acid, resulting in stomatal closing. This is in agreement with the observation of Bhatia et al. (1986), who studied stomatal responses of *Euphorbia hirta* after salicylic acid applications of 5–25 ppm. Rai et al. (1986), however, described stomatal opening following salicylic acid treatments of epidermal peels from *Commelina communis*. The phenolic acid used here is assumed to produce membrane depolarization and to increase membrane permeability to inorganic ions (Macri et al., 1986; Balke, 1985). In different plants (*Hordeum vulgare:* Glass, 1973, 1974; *Avena sativa:*

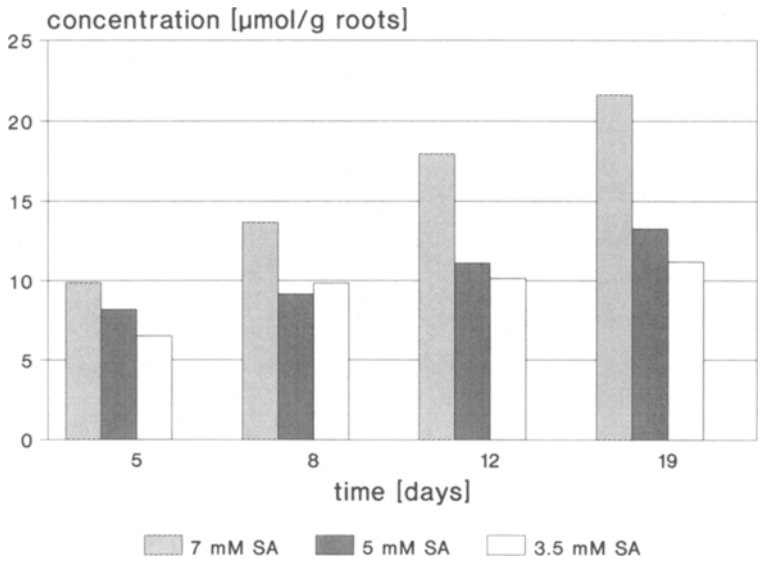

FIG. 7. Concentration of the assumed salicylic acid (SA) metabolite in extracts from roots of plants, watered with SA of the given concentrations. The amount of the metabolite increased with time and depended on the applied SA concentration.

Harper and Balke, 1981; *Saccharomyces cerevisiae:* Scharff and Perry, 1976; Hoeberichts et al., 1980), salicylic acid was responsible for an uncontrolled efflux of inorganic ions, especially K^+. Potassium, however, is known to be an essential factor in stomatal opening (Raschke and Schnabl, 1978; Schnabl, 1985, 1992; Michalke and Schnabl, 1990). A loss of K^+, due to changes of guard cell plasma membrane properties induced by salicylic acid, should therefore result in stomatal closing.

Measurements of transpiration rates after salicylic acid applications during plant watering were performed to avoid wounding effects, which may appear in isolated epidermal peels. As water loss through the cuticle layer was found to be negligible, transpiration rates are directly correlated with stomatal pore widths (Nonami et al., 1990). Additionally, applications during watering seem to simulate the more natural situation. A significant reduction of the transpiration rates occurred after five days of treatment, but again only for the highest concentrations used in this study. Thus stomata of intact plants showed much less sensitivity compared to those of isolated epidermal peels, coinciding with the result of the bioassay on growth inhibition. Similar effects are described by Patterson (1981) and Raschke et al. (1975). They found an impaired transpiration by allelochemicals for *Glycine max*, *Phaseolus vulgaris*, *Hordeum vulgare*, and *Xanthium strumarum*. For *Phaseolus vulgaris*, Larque-Saavedra (1978, 1979)

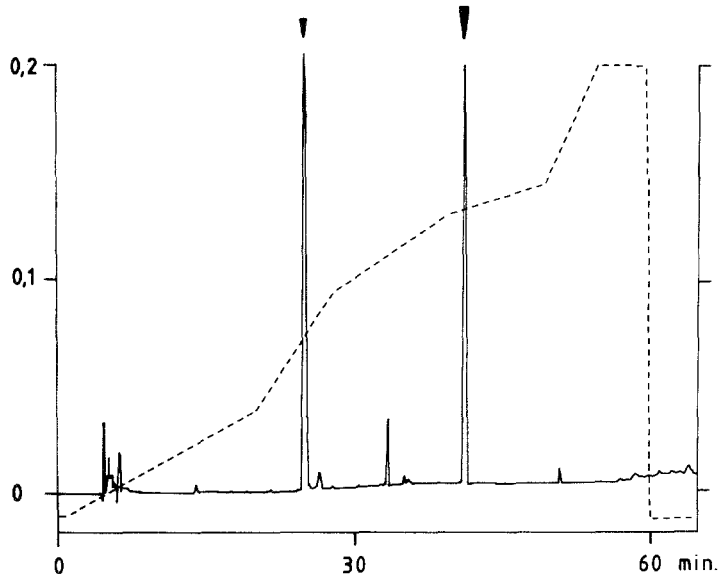

FIG. 8. Released salicylic acid showed a retention time of 41.47 min, the residual metabolite a time of 25.15 min.

demonstrated a 43% reduction of the transpiration rate after applications of 1 mM acetylsalicylic acid, when the compound was transported by the transpiration stream.

The results presented here indicate a growth reduction and a decrease of stomatal aperture and transpiration rate for *Vicia faba*. However, inhibiting effects were obvious only at high concentrations of the phenolic acid associated with long-term treatments. HPLC analysis of methanolic extracts prepared from roots and leaves contained salicylic acid and a metabolite, whose acidic hydrolysis released free salicylic acid. Hence, *Vicia faba* is able to absorb and to metabolize the allelochemical by altering its solubility, most probably by conjugation with a water-soluble nontoxic compound. The latter mechanism is a known strategy, existing in a large number of plants, to detoxify allelochemicals or endogenous phenolic compounds (Harborne, 1979; Balke et al., 1987; Tabata et al., 1988; Tanaka et al., 1990). It is therefore assumed that, under natural conditions, salicylic acid may be an allelochemical less harmful to the species studied here. The exact mechanism of detoxification as well as the identity of whole metabolite has to be elucidated in the future.

Acknowledgments—We thank Prof. Dr. F. Lenz (Institut für Obst und Gemüsebau, Universität Bonn) for placing the computer controlled porometer at our disposal.

(Received February 12, 1992; accepted April 30, 1992)

Abstract—*Euphorbia esula* (leafy spurge) suspension culture cell bioassays were used to determine whether sucrose accumulation enhanced the glucosylation (detoxification) of hydroquinone in this noxious weed. The bioassay results indicate that cold temperatures and exogenous hydroquinone represent a dual stress to spurge cell growth that can be partially ameliorated by hydrolysis of sucrose. The persistent susceptibility of leafy spurge suggests that hydroquinone-producing forage plants (which are not toxic to animals) might be used as natural competitors.

Key Words—Leafy spurge, *Euphorbia esula*, small everlasting, *Antennaria microphylla*, hydroquinone, arbutin, sucrose, tissue culture, biotransformation, allelopathy.

INTRODUCTION

The perennial weed, leafy spurge (*Euphorbia esula* L.), is endemic to the upper Great Plains of the United States and the prairie provinces of Canada. Infestations are deleterious to rangeland operations due to spurge competition with palatable forage species and toxicity to grazing livestock. It has not proven economically feasible to control the weed by either cultural and/or chemical methods (Manners, 1987).

The competitive advantage of leafy spurge is enhanced by its extensive

*To whom correspondence should be addressed.

root system, which produces new vegetative shoots from adventitious crown and root buds (Coupland et al., 1955). Abundant root carbohydrate reserves are correlated with the overwintering strategy and high regenerative potential of the plants (Cyr and Beweley, 1989), and efforts to control perennial weeds have concentrated on altering seasonal fluctuations of carbohydrate accumulation patterns.

Recent observations have shown that, in contrast to many other perennial plants, leafy spurge accumulates large amounts of free sucrose in the roots at the close of the growing season, instead of the more typical accumulation and conversion of sucrose to starch (Lym and Messersmith, 1987). Others have suggested that this pattern is important in development of winter hardiness in leafy spurge roots and elongation and winter survival of root buds, perhaps through exploitation of cryoprotectant properties of colligative molecules such as sucrose (Sakai and Yoshida, 1968). Cyr and Beweley (1989) suggested that it is more likely that sucrose serves as a readily phloem-mobile substrate for rapid spring regrowth.

Hydroquinone has been isolated from the low-growing forb, small everlasting (Manners and Galitz, 1985), and assays have established its phytotoxicity to leafy spurge (Hogan and Manners, 1990). Biotransformation of hydroquinone to its monoglucoside, arbutin, is mediated by a uridine diphosphoglucose (UDPG) -dependent glucosyltransferase (Hogan and Manners, 1991). The activity of this enzyme is substrate-induced in leafy spurge and is affected by various metabolic, as well as abiotic, factors. Since glucosylation of hydroquinone requires a readily available carbohydrate pool, seasonal accumulation of sucrose in spurge roots may affect the rate of hydroquinone biotransformation in vivo. In this investigation, a tissue culture bioassay was developed to determine whether the unusual carbohydrate accumulation patterns of leafy spurge at reduced temperatures affect glucosylation of hydroquinone, thereby providing seasonal amelioration of allelochemical effects of that compound on plant growth. The effect of sucrose accumulation and low temperatures on the glucosylation of exogenous hydroquinone was simulated by supplying increasing amounts of exogenous sucrose simultaneously with hydroquinone to suspension culture cells of leafy spurge maintained at low temperatures.

METHODS AND MATERIALS

Tissue Cultures. Suspension and callus cultures of leafy spurge and small everlasting were grown as previously described (Hogan and Manners, 1990). Hydroquinone (1,4-dihydroxybenzene) solutions (500 μM) were prepared in absolute methanol and introduced aseptically into flasks of leafy spurge suspension culture cells at a final methanol concentration of 1% or less (Davis et al.,

1978). This concentration of hydroquinone had previously been determined to produce a sublethal phytotoxic response during all stages of cell growth (Hogan and Manners, 1990). High-pressure liquid chromatographic analysis of media extracts showed that all the hydroquinone was absorbed by the cells within 24 hr (data not shown). HPLC analysis of extracts from leafy spurge suspension culture cells treated once with 500 μM hydroquinone showed that 85% of this compound (on a mole per mole basis) was converted to arbutin during a short exposure time (six days). This suggests that very little, if any, hydroquinone is bound in the media. Test concentrations of arbutin (*p*-hydroxyphenyl-β-glucoside) (0.05, 0.1, 0.25, 0.5, 0.75, 1.0, and 5.0 μM) were dissolved directly in the hot growth media for callus culture experiments.

Cell Viability Tests. Exogenous sucrose was added directly to the culture media at 0, 2, 3, 4, 5, and 6% by weight, respectively. Erlenmeyer flasks (250 ml) containing 50 ml media were inoculated with 5 ml suspended cells (1.5 g fresh weight) from a common culture. After seven days of growth (25°C, dark), the cells were harvested by vacuum filtration. Fresh-filtered cells (0.2 g) were washed with 20 ml phosphate buffer (pH 7.0) and suspended in 3 ml triphenyltetrazolium chloride (TTC, 0.6% in phosphate buffer, pH 7.0). After incubation overnight (27°C, dark), the cells were washed twice with distilled water and extracted with hot ethanol (5 min). Reduced TTC (red supernatant) was measured by absorbance at 485 nm, using a Spectronic 20 spectrophotometer (Yokoyama et al., 1990). Media in the absence of cells was used as a control to rule out the presence of competing reductants.

HPLC Analysis of Sugars. Cells exposed to varying temperatures (10, 15, 17, and 25°C), high exogenous sucrose concentrations, and/or hydroquinone for one week (dark) were harvested by vacuum filtration, rapidly frozen under liquid nitrogen, and stored frozen until used. The cells were Soxhlet-extracted with 80% ethanol overnight. The ethanol was removed in vacuo, and the residual aqueous solutions were filtered and analyzed for sucrose, glucose, and fructose, using high-performance liquid chromatography (HPLC, Waters carbohydrate analysis column, 3.9 × 300 mm; acetonitrile–water, 75:25 v/v; 1.5 ml/min; RI detection with Waters differential refractometer model R401; 20 μl injection). Retention times (observed): fructose, 4.64 min; glucose, 5.14 min; sucrose, 6.57 min. Data are expressed as micrograms of carbohydrate per gram fresh weight of cells.

Statistical Analysis. All bioassays included at least three replications. Individual determinations of TTC reduction (Figure 2 below) and carbohydrate accumulation (Figure 3 below) were averaged and subjected to one-way analysis of variance. *F* values were calculated to determine significant differences between treatments at the 0.05% level. Multiple regression analysis was performed on the data from Table 1 (cell weight as a function of sucrose concentration, temperature and the presence of hydroquinone).

RESULTS AND DISCUSSION

Cell Viability. Sucrose supplied in excess (up to a concentration of 4% sucrose) to the growth media of leafy spurge suspension culture cells enhanced cell growth (Figure 1) during all phases of the cell cycle. At higher concentrations of sucrose (>5%), cell dry weight leveled off and cell respiration rates

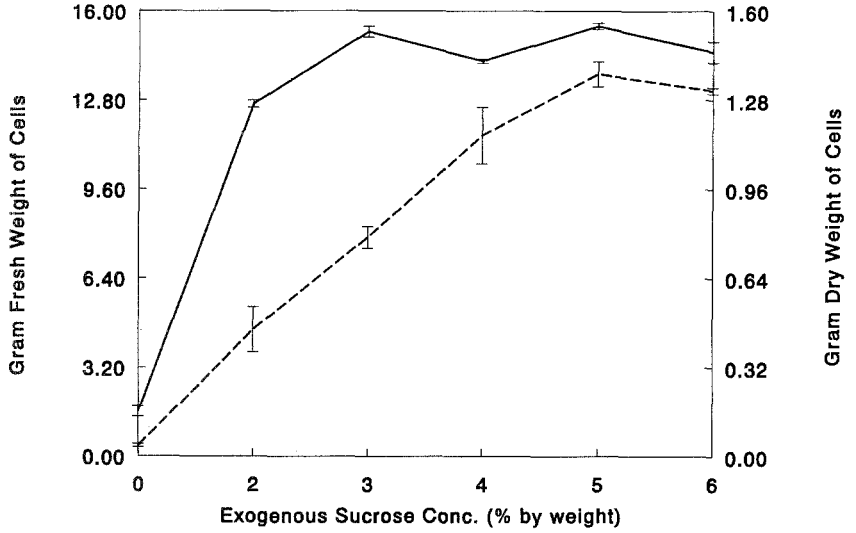

FIG. 1. Growth of leafy spurge suspension culture cells in the presence of excess sucrose: grams fresh weight of cells, solid line; grams dry weight of cells, dashed line.

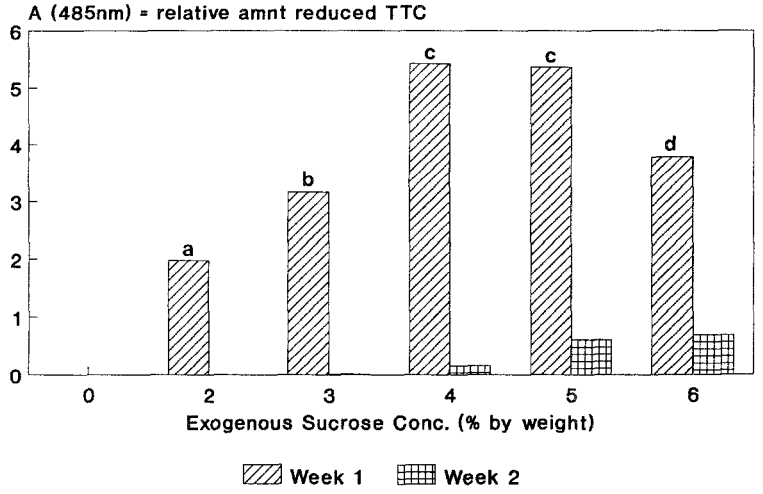

FIG. 2. Effect of sucrose on cell viability of leafy spurge suspension cultures. TTC = triphenyl tetrazolium chloride. Identical letters represent treatments that are not significantly different from each other at the 0.05% level.

declined. Cell respiration rate (TTC-reducing ability) and the ability to sequester free sucrose were reduced in the cells when exogenous levels of sucrose were greater than 4% and 5%, respectively (Figures 2 and 3). Although the cells were not plasmolyzed when exposed to levels of sucrose greater than 4%, it is clear that these supraoptimal levels impose an osmotic stress, resulting in a lack of cell dry weight increase beyond that observed in the 4% treatment (Figure 1). By the second week, most cells were dead due to media depletion (the cell cycle for this cell line is seven days). Supraoptimal levels of sucrose provided enough residual carbohydrate in the medium to support limited growth of cells exposed to 5% or 6% sucrose for two weeks (Figure 2).

Fructose and glucose levels remained steady over time, regardless of the amount of exogenous sucrose supplied in the media (Figure 3). No significant differences were found at the 0.05% level for fructose or glucose between any of the treatments, using one-way analysis of variance. Therefore, either the cells did not hydrolyze the free sucrose, or the free hexoses liberated in the cells were immediately metabolized to more conjugated forms not detected in the assay. The failure of cells to metabolize sucrose is consistent with the observations of Yokoyama et al. (1990), who did not detect metabolism of exogenous sucrose in cell cultures of *Catharanthus roseus*, and of Cyr and Beweley (1989), who observed only small winter increases in the glucose content of leafy spurge roots when fructose levels remained at or near detection limits throughout the year.

Suboptimal Temperature and Hydroquinone Effects on Suspension Culture Growth. Leafy spurge suspension cells are most efficiently cultured at 25–27°C (Hogan and Manners, 1990). At suboptimal temperatures plant cells are subjected to abiotic stress. Cell growth was reduced in leafy spurge suspension cultures when temperatures were lowered by 8–15°C and the typical cumulative increase in biomass was altered; i.e., the logarithmic phase of fresh weight increase occurred later and was less extensive (Figure 4). Additionally, the previously observed phytotoxicity of exogenous hydroquinone to spurge suspension cells (Hogan and Manners, 1990) was exacerbated at the lower temperatures (Table 1). The suboptimal temperatures slowed cell metabolism, thereby inhibiting pathways required for cell growth and hydroquinone biotransformation. The reduced temperature and increased hydroquinone therefore represent dual stresses to spurge cells that significantly lower cell growth and viability.

The observed late-season accumulation of sucrose in spurge roots was simulated in this investigation by addition of exogenous sucrose to the cell culture media and incubation at temperatures consistent with temperatures to which whole plants are exposed during the cool fall of the Northern Plains. The presence of sucrose enhanced cell biomass accumulation (as measured by fresh weight) at these reduced temperatures both with and without the addition of hydroquinone (Table 1). Sucrose (up to a concentration of 4%) also ameliorated

the phytotoxic effect of hydroquinone at lower temperatures (Table 1). However, there was no clear indication that sucrose sequestration was affected by hydroquinone (data not shown). The results of multiple regression analysis on these data predict that fresh weight is correlated with changes in sucrose concentration, temperature, and the presence of hydroquinone (HQ) by the following: cell wt = 1.225(temp) + 0.919(sucrose) − 6.419(HQ) − 11.594, $F_{3,44} = 29.6$, $P < 0.001$, $R^2 = 0.669$.

Accumulation of free sucrose in leafy spurge cells provides a potential source of glucose (via sucrose hydrolysis) for glucosylation of hydroquinone to form the less phytotoxic monoglucoside, arbutin. The detoxification of hydroquinone enlarges the arbutin pool, creating a shift in the equilibrium of the detoxifying reaction in favor of hydroquinone accumulation (Figure 5) (Hogan and Manners, 1991). In addition, arbutin and other structurally similar β-phe-

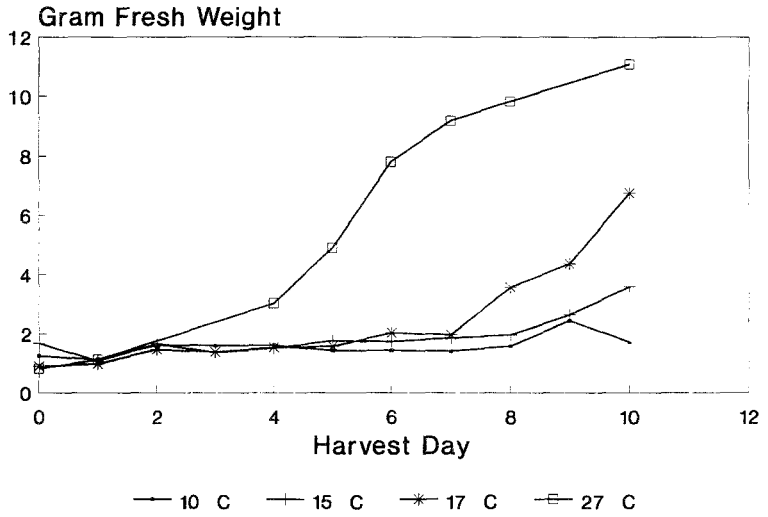

FIG. 4. Growth of leafy spurge suspension culture cells at reduced temperatures.

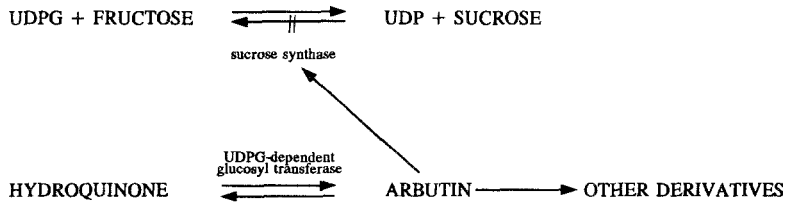

FIG. 5. Competitive inhibition by arbutin on sucrose synthase activity. UDPG = uridine diphosphoglucose.

nolic glycosides are competitive inhibitors of sucrose synthase, an enzyme responsible for sucrose degradation (Wolosiuk and Pontis, 1974). These factors represent a potential regulatory mechanism associated with the size of the arbutin pool in leafy spurge. Increases in arbutin concentration in spurge could both inhibit sucrose degradation (reduce detoxification of hydroquinone) and promote hydroquinone accumulation (increase autotoxicity).

Confirmation of the effect of arbutin was observed when it was exogenously supplied to leafy spurge callus. In comparison to small everlasting, spurge callus growth was significantly reduced in the presence of arbutin at concentrations above 100 μM (Table 2). This inhibition pattern continued until media depletion occurred after six weeks in continuous culture (data not shown), suggesting a constant turnover of arbutin to hydroquinone in leafy spurge. In contrast to the turnover observed in leafy spurge, small everlasting may divert arbutin into alternative pathways, to produce less phytotoxic derivatives (Figure 5) (Hogan and Manners, 1991).

The significance of this difference between the metabolism of the two species under field conditions could be exploited for weed control. Both small everlasting and leafy spurge can convert hydroquinone to arbutin (Hogan and Manners, 1991). However, the kinetics of the biotransformation reactions associated with hydroquinone detoxification differ in the two plants, resulting in the higher concentrations of hydroquinone found in leafy spurge (Hogan and Manners, 1991). The unusual sucrose accumulation by leafy spurge roots at the end of the growing season could also influence the equilibrium of these reactions and might exacerbate the effect of the allelochemical. Hydroquinone-producing forage species could act as natural competitors in spurge-infested areas, assum-

ing that hydroquinone is released from the roots of living plants and can persist in the soil. These studies have not been done, although work by Selleck (1972) showed that the susceptibility of leafy spurge to encroachment by small everlasting in the field was attributable to chemical rather than competitive factors. Intervention in the ability of leafy spurge to accumulate and metabolize sucrose (in the presence of allelochemicals requiring carbohydrate for detoxification) could compromise the competitive advantage of this plant and render it more susceptible to other control methods.

Acknowledgments—The authors wish to express their appreciation to Dr. David Davis of the USDA/Bioscience Research Laboratory in Fargo, North Dakota, for providing the leafy spurge suspension culture cells. The technical assistance of Deborah Mark is also gratefully acknowledged.

PHEROMONAL TRANSMISSION OF AN AVERSIVE EXPERIENCE IN DOMESTIC PIG

CAROLINE VIEUILLE-THOMAS and J.P. SIGNORET*

Laboratoire de Comportement Animal
INRA/CNRS URA 1291
F-37380 Nouzilly, France

(Received February 18, 1992; accepted April 30, 1992)

Abstract—The process of spontaneous learning in an automatic food dispenser by a group of domestic female pigs was studied when one of the animals of the group had an aversive experience. Restraining a gilt in the dispenser without access to food resulted in later avoidance of the system by other gilts, especially when the reactions of the restrained animal had been especially violent and associated with urination. The hypothesis of a delayed transmission of an unpleasant experience was tested. The food dispenser was sprayed with urine collected from either a control gilt or from an animal undergoing stress. In half of the cases, the presence of urine of a stressed animal resulted in a long-lasting avoidance of the food dispenser, suggesting the existence of some kind of alarm pheromone produced in the urine of a sow during an unpleasant experience.

Key Words—Stress, urine, alarm pheromone, pig.

INTRODUCTION

The possibility for an animal to transmit information from an unpleasant experience is of high functional significance. It would inform another animal of the risks coming from the environment, thus inducing avoidance of potential danger. A delayed transmission of such information would make it possible to avoid a place where some kind of aggression has occurred. The production of alarm pheromones during aggression or an unpleasant experience has been observed in laboratory mice (Müller-Velten, 1966; Carr et al., 1970; Rottmann and Snowdon, 1972; Zalaquett and Thiessen, 1991) and rats (Valenta and Rigby, 1968;

*To whom correspondence should be addressed.

Stevens and Köster, 1972; Mackay-Sim and Laing, 1980). Furthermore, when avoidance is impossible, chronically exposing mice to the odor of a conspecific stressed by electrical foot shocks depresses the immune system (Thiessen and Cocke, 1990). No similar system of communication has been described in non-rodent mammalian species.

During a study on learning in an automatized food dispenser by a group of domestic sows, some observations suggested the transmission of an unpleasant experience.

A computer-controlled pelleted food dispenser provides rations adapted to the individual animals' feeding requirements, even when the sows are housed in groups. However, under practical husbandry conditions, some animals are difficult to train to use such a system, and a period of training is necessary before all the animals adequately use the feeder (Vieuille-Thomas and Signoret, 1991). To facilitate the process of learning, the influence of the presence of an already trained animal in a group of naive sows has been observed (Vieuille-Thomas and Signoret, 1989). No social facilitation occurred in the presence of a trained animal, but, on the contrary, in some cases there was a considerable increase in the delay of the first contact of any animal with the food dispenser. Such a surprising reaction appeared to be related to difficulties during the process of training the demonstrator animal that had showed a strong fear reaction. Consequently, a series of experiments were designed to assess the existence of transmission of such an unpleasant experience and to test the hypothesis of the existence of an alarm pheromone in this species.

METHODS AND MATERIALS

The experiments took place in a large pig farm (1200 sows) located in central France in which groups of 10 naive gilts had to be trained each week, or fortnight, to the use of a computer-controlled food dispenser (Codeporc). Young females, ages 7–10 months, were inseminated when tethered in their stall. After confirmation of pregnancy one month later by ultrasonic echography, they were moved to a 40-square-meter pen with an automatic feeder with which they had never been in contact. The sows were identified by ear tags and a collar equipped with a transponder allowing access to the feeder. The success of the learning process was assessed by measuring the delay for the first naive gilt to use the food dispenser.

The food dispenser is a double-gated complex system, with a steel partition in the middle, designed to allow a single sow to feed without being disturbed by the others. When an animal enters the feeder and is identified by the electronic system and the transponder, the rear gates automatically close and food is dispensed at the rate of 240 g/min until the animal moves back, or the total amount programmed for this animal has been dispensed. Gate locking, and falling of

pelleted food in the metal trough are noisy and might startle the sows during their first experience of the dispenser. Furthermore, the animal that reacts to such noises by moving back violently could prevent the gates from opening and thus become trapped in the dispenser. The ineffective escape reactions are then associated with apparent panic involving sound emission, redness of the entire body, and urination.

Experiment 1. Eight experimental groups of 10 naive gilts were studied. Each consisted of nine pregnant gilts plus a nulliparous female that was neither pregnant nor in estrus. In the afternoon of the day before the onset of the process of learning, this female was individually introduced to the experimental pen and guided by plywood panels into the food dispenser. The back doors were locked, and the animal was thus kept trapped in the dispenser for 20 min without receiving any food as reinforcement. Such a treatment in an unknown environment could be considered an unpleasant experience. It induces violent reactions: escape attempts associated with frequent grunts, squeals, and eventually urination and defecation. The gilt was then reintroduced to her group. On the next morning, after a minimum delay of 14 hr, the whole group had free access to the food dispenser. They had not been fed since the morning of the previous day.

The results of learning to use the food dispenser were compared with those of 13 groups of 10 naive gilts in which no animal had experienced any contact with the dispenser. In all cases, one group was observed per week.

Experiment 2. Twenty groups of 10 naive pregnant gilts were observed. In each case, the back doors and the inside of the food dispenser were sprayed during late afternoon with urine produced either by a stressed or a control female. In 10 experimental groups, urine was obtained from a nonpregnant, nonestrous gilt tethered for the first time. The process of tethering generally induces strong reactions of escape attempts, biting of the chain, squealing, and sweating. Urine produced after a minimum delay of 15 min was collected. When no urine could be collected within 30 min, another sow was used in the same way. For the 10 control groups, urine was obtained from a quiet nonpregnant, nonestrous sow. In both cases, urine was used immediately to be sprayed on the dispenser.

As in the first experiment, the groups of naive gilts after having been fed in the morning, were moved during the late afternoon to a waiting pen. The next morning they were introduced to the experimental pen to learn the use of the food dispenser. Consequently, the delay between spraying the urine and the beginning of the learning process was a minimum of 14 hr.

RESULTS

Experiment 1. The experience of having been restrained in the dispenser did not change the reactions of the naive females except in two groups in which the latency to the first contact was exceptionally long (more than 10 hr, i.e.,

during the first day of the experiment), whereas in control groups, the maximum was only 133 min (Figure 1). However, the difference in the average latencies to the first use of the food dispenser between experimental and control groups was not statistically significant. When comparing the ranges of variations in the latencies, they were significantly larger for experimental than for control groups (Snedecor test; $P < 0.01$).

In two experimental groups out of eight, the experience of one gilt having been restrained in the dispenser induced a long-lasting avoidance by the other animals, whereas in the other six, no difference appeared when compared with control groups. Such a discrepancy might be explained by the different degree of reaction of the experimentally restrained animal to this situation. In the two experimental groups where the contact latency was considerably increased, the reaction of the experimental female had been the strongest during restraining. The number of sound emissions was higher than in the other six experimentally restrained gilts ($P < 0.05$), and urination had taken place in both cases (Figure 2). The long delay in approaching the food dispenser shows that, in these cases, the group witnessed the stress of the restrained gilt. However, no obvious behavior of the stressed animal can account for the avoidance of the food dispenser by the group. One possible hypothesis would be the emission of some kind of alarm pheromone. In stressed rats, alarm pheromones have been observed to originate from body odors and urine, but not feces (Mackay-Sim and Laing, 1981a,b). As the occurrence of urination during stress was associated with avoidance by our group of animals, the hypothesis of the transmission of the aversive experience by means of a pheromone present in urine of the stressed female was tested (experiment 2).

Experiment 2. The latencies to the use of the food dispenser by the first gilt are significantly longer in experimental groups compared with controls (315.7

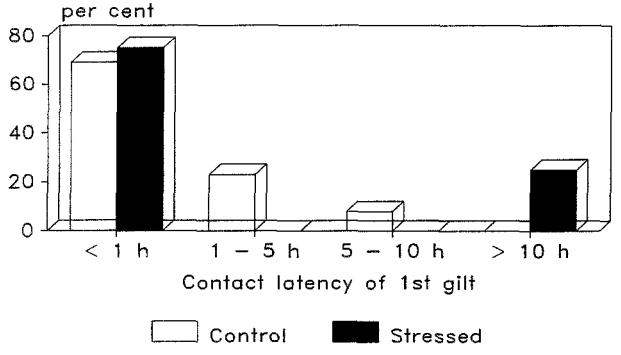

FIG. 1. Effect of the presence of a previously restrained animal (black) or control (no restraining) (open) on the contact latency of the other gilts with the food dispenser.

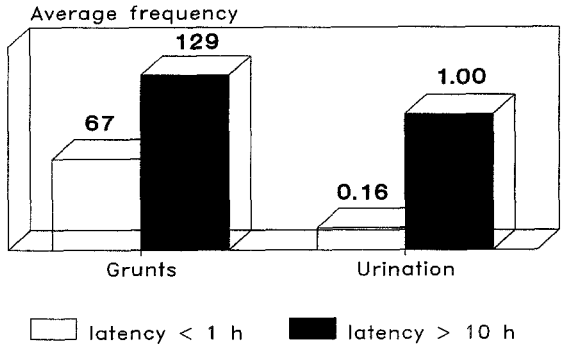

FIG. 2. Average numbers of grunts and urinations by restrained animal (ordinate) vs subsequent late (black) and short (open) contact latencies of the other gilts with the food dispenser.

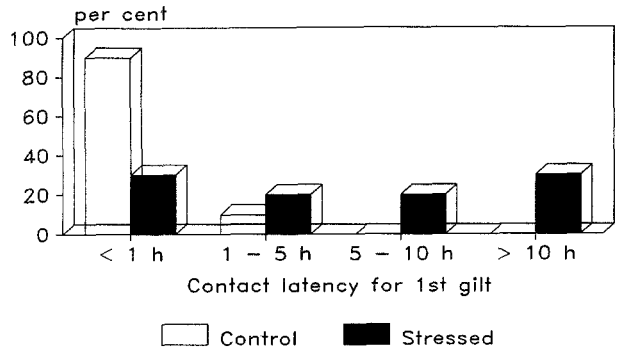

FIG. 3. Effect of spraying urine from a stressed (black) or control (open) animal on the contact latency for a group of gilts with the food dispenser.

±80.3 vs. 39.8 ±17.5 min) (Figure 3). As in experiment 1, the range of variation is extremely large among the experimental groups: In three cases no gilt had used the food dispenser during the first 10 hr, and only three used it during the first 3 hr. In the control groups the average latency was 39.8 min and the maximum 187 min. Finally, only 18% of the gilts in the experimental groups spontaneously learned to use the food dispenser during the first day, compared with 50% in controls.

The results demonstrate the avoidance of the place where the urine from a stressed sow has been sprayed, whereas the urine of a quiet female induced no delay in approaching the feeding device. In five groups, no animal approached the food dispenser during the first 6 hr, and for three of them this avoidance was still observed after 10 hr, although the animals had received no food since

the previous morning. The persistence of such an effect is remarkable as the urine had been sprayed more than 14 hr before the beginning of the observations. However, in half of the experimental groups, no avoidance was observed. In such cases no alarm pheromone appears to be present in urine. As different sows had been stressed in order to obtain urine for each experimental group, individual differences in reaction to restraining could account for such differences.

DISCUSSION

Olfactory communication is especially developed in pigs. Pheromones are involved in the organization of the sequence of sexual behavior in attracting estrous females and facilitating the display of the posture of receptivity (Signoret, 1970) and have been identified as androstenone (Melrose et al., 1971). A primer effect accelerating the occurrence of puberty has been described involving the interaction of pheromones and other sensory stimulations (Hughes et al., 1990). During aggressive encounters, urine and plasma from actively fighting pigs both efficiently reduce aggression in a group of test pigs (McGlone et al., 1987). This suggests that aggression-inhibiting pheromones could be produced under specific conditions of interspecific fighting. The results obtained in the present experimental series demonstrate the presence of an avoidance-inducing factor produced in the urine of the female domestic pig undergoing a stressful situation. It would logically result from metabolism of hormones secreted during acute stress. The identification of the chemical compounds involved and the conditions of their production would be of both theoretical and practical importance.

The relatively long persistence of this action allows an efficient spatiotemporal communication signaling those places that could be potentially dangerous. The functional significance of such a system of communication is evident in wild animals. Its persistence in a domestic species is interesting, and the consequences are of practical importance. The modern conditions of intensive animal production—restriction of movements and tethering—could result in stress reactions in at least some individuals, thus producing alarm pheromones. As large groups of animals are kept indoors, the occurrence of a stress situation in some of them would be sufficient to create a pheromonal environment of stress, which could influence the behavioral and physiological reactions of the whole group. It has been shown in mice (Cocke and Thiessen, 1986) that chronic exposure to such alarm pheromones could result in a decrease of immune defenses. The consequences of some kind of mismanagement could thus impair not only the welfare of some individuals, but influence the behavioral reactivity and the health of the whole herd.

EFFECTIVENESS OF CARDENOLIDES AS FEEDING DETERRENTS TO *Peromyscus* MICE

JOHN I. GLENDINNING[1]

Department of Biological Science
Florida State University
Tallahassee, Florida 32306

(Received January 21, 1992; accepted May 1, 1992)

Abstract—I compared the feeding responses of five species of *Peromyscus* mice (*aztecus*, *polionotus*, *melanotis*, *leucopus*, and *maniculatus*) to three bitter-tasting cardenolides (ouabain, digoxin, and digitoxin) that differ greatly in lipophilic character. *Peromyscus*, like other muroid rodents, are unusual in that they can ingest relatively large amounts of cardenolides without adverse physiologic effects. In experiment 1, I determined avoidance thresholds for the three cardenolides with 48 hr, two-choice tests. Mice exhibited large interspecific differences in avoidance threshold, and the interspecific ranking of the thresholds (*maniculatus* = *leucopus* > *melanotis* > *polionotus* > *aztecus*) was the same for each of the cardenolides. In experiment 2, I re-evaluated the avoidance thresholds, but this time monitored the pattern of intake (i.e., bout lengths) during initial feeding encounters with cardenolide-laced diets. For each cardenolide, mice were subjected to three tests. In test 1, they received a control diet; in test 2, a diet containing the cardenolide at a concentration 1 $\log_e$ unit below the avoidance threshold (as determined in experiment 1); and in test 3, a diet containing the cardenolide at the avoidance threshold concentration. Results were similar across all species and cardenolide types: Bout lengths in tests 1 and 2 were statistically equal, whereas those in test 3 were significantly shorter than those in test 1. The rapid rejection of cardenolide-laced diets in test 3 is consistent with a preingestive (i.e., gustatory) mechanism underlying the avoidance thresholds. I conclude (1) that *Peromyscus* species differ substantially in taste sensitivity to cardenolides and that these differences may influence each species' respective ability to eat cardenolide-laced insects; and (2) that a species' relative taste sensitivity to one cardenolide predicts its sensitivity to other cardenolides.

INTRODUCTION

As with many chemical defenses systems, the cardenolide defense of the monarch butterfly (*Danaus plexippus*) is effective against some but not all predators. For example, only two of the 25 insectivorous bird species that occur at the Mexican overwintering sites feed extensively on monarchs (Fink and Brower, 1981; Fink et al., 1983; Brower and Calvert, 1985; Arellano-G. et al., 1992). Similarly, among the potential mouse predators, only one of the five species (*Peromsycus melanotis*) eats large numbers of monarchs (Glendinning and Brower, 1990). Feeding studies show that at least two mouse species (*P. aztecus* and *Reithrodontomys sumichrasti*) are repelled by the unpleasant taste of the cardenolides (Glendinning, 1990, Glendinning et al., 1990). These species, like other muroid rodents, are unusually insensitive to the toxic effects of ingested cardenolides (Table 1). Thus, gustatory rather than toxicological sensitivity appears to determine how effectively these mice can exploit foods laden with cardenolides.

Based on the unexpected species differences in cardenolide responsiveness, I now describe experiments that further examine the gustatory response of *Peromyscus* mice to cardenolides. In particular, I address three questions: (1) how much interspecific variation in cardenolide taste sensitivity exists within the genus *Peromyscus*; (2) are the interspecific differences ecologically relevant; and (3) does a species' relative taste sensitivity to one cardenolide predict its sensitivity to cardenolides that differ greatly in lipophilic character?

METHODS AND MATERIALS

Experiment 1: Two-Choice Preference Tests

Subjects. *Peromyscus aztecus*, *P. melanotis*, and *P. polionotus* were obtained from outbred laboratory colonies at Florida State University. *Peromyscus maniculatus* and *P. leucopus* came from outbred colonies at the *Peromyscus* Stock Center, University of South Carolina (see Table 2 for sample sizes). (I will henceforth refer to mice in terms of their species designation only.) All mice were (1) reared in captivity on standard laboratory chow, (2) not used in previous experiments, and (3) adult males, owing to a shortage of females. Prior to testing, mice were housed individually in clear plastic cages (25 × 46 × 21 cm) with pine-shaving bedding, and maintained on pelleted

TABLE 1. TOXIC SENSITIVITY OF SEVERAL MAMMALS TO ORAL DOSAGES OF CARDIAC GLYCOSIDES

Species	Cardiac glycoside	Dosage (mg/kg)
Carnivora		
Felidae		
Felis sylvestris catus (domestic cat)	digoxin	0.2[a]
	digitoxin	0.2[a]
Rodentia		
Caviidae		
Cavia porcellus (domestic guinea pig)	digoxin	3.5[a]
	digitoxin	3.7[a]
Muridae		
Mus domesticus (domestic mouse)	digoxin	17.8[a]
	digitoxin	5.0–50.0[a]
Rattus norvegicus (Norway rat)	digitoxin	56.0[a]
Peromyscus maniculatus (deer mouse)	calotropin	>50.0[a]
Reithrodontomys sumichrasti (Sumichrast's harvest mouse)	digitoxin	>18.1[b]
P. aztecus (aztec mouse)	digitoxin	>72.2[b]
P. melanotis (black-eared mouse)	digitoxin	>107.0[b]

[a] Acute LD_{50} data from Tatken and Lewis (1983) and Marty (1983).
[b] Chronic LD_{50} data from Glendinning et al. (1990), where juvenile mice were maintained on a diet laced with digitoxin. The values indicate mean daily ingestion rates over 26 consecutive days. Despite the prolonged and high intake of digitoxin, no mice died or displayed signs of CG toxicity. In fact, the *P. melanotis* and *P. aztecus* grew slightly more rapidly on the digitoxin-laced diet than on a control diet.

chow (Purina lab chow pellets #5001) and tap water ad libitum on a 15:9 (light–dark) cycle.

Cardenolides and Artificial Diets. Three cardenolides of different lipophilic character were added to diets; ouabain was the least lipophilic and digitoxin the most (Figure 1). The diets were prepared by dissolving digitoxin, digoxin, or ouabain (Sigma Chemical Co.) in 95% ethanol, thoroughly mixing the solution with powdered chow (Purina lab chow meal #5001), and evaporating the ethanol for 14 hr at 60°C in a forced-draft oven (see Glendinning et al., 1990, for details). The control diet was prepared identically, except that no cardenolide was dissolved in the ethanol.

Test Conditions and Protocol. Mice were tested individually under the same housing and caging conditions described above, except that no pelleted chow was available. Two glass food cups (5 cm tall, 5.5 cm diameter, with a 3.0-cm-diameter hole in the plastic lid) were placed on the bottom of each cage, separated by about 7 cm; a stainless-steel water spout was positioned directly

TABLE 2. RANGE OF CARDIAC GLYCOSIDE CONCENTRATIONS USED IN TESTS

Peromyscus species	Mice tested (*N*)	Cardiac glycoside	Concentration[a]			
			mmol/kg diet		μg/0.1 g diet	
			Lowest	Highest	Lowest	Highest
aztecus	11	digitoxin	0.005	0.1	0.37	7.4
		digoxin	0.01	0.3	1.0	20.5
		ouabain	0.1	1.9	7.0	141
polionotus	12	digitoxin	0.1	1.9	7.4	148
		digoxin	0.1	1.9	7.6	152
		ouabain	0.3	5.3	19	383
melanotis	10	digitoxin	0.3	5.3	20	403
		digoxin	0.3	5.3	21	412
		ouabain	0.3	5.3	19	383
leucopus	10	digitoxin	0.3	5.3	20	403
		digoxin	0.3	5.3	21	412
		ouabain	0.7	14.3	52	1041
maniculatus	10	digitoxin	0.3	5.3	20	403
		digoxin	0.3	5.3	21	412
		ouabain	0.7	14.3	52	1041

[a] Two types of concentration units are provided: one based on the molecular density (mmol/kg diet) and the other on the mass (μg/0.1 g diet) of each CG. The latter concentration units help relate the findings of this study to those of other studies. Each mouse received an ascending series of four concentrations of each CG; the concentrations differed by whole, natural log increments. For example, *aztecus* received the following four concentrations (in mmol/kg diet) of digitoxin: 0.0048, 0.013, 0.036 and 0.097 (these values were rounded off for clarity).

between the food cups. One cup was designated the tastant and the other the control cup. Petri dishes were placed underneath each cup to recover spilled diet.

Each mouse was tested with all cardenolides. For each cardenolide, mice were subjected to five 48-hr, two-choice tests. In the tests, the control cup always contained control diet; the tastant cup contained control diet in test 1 and an ascending series of four concentrations of the cardenolide in tests 2–5. The four cardenolide concentrations spanned whole, $\log_e$ intervals (Table 2) and were selected (based on preliminary tests) so as to range from behavioral indifference to rejection. Owing to species differences in taste sensitivity, the concentrations of each cardenolide differed among species.

The order of testing the cardenolides was identical for all mice: ouabain, digoxin, and then digitoxin. Toxicity (i.e., oral, intraperitoneal, and intravenous LD_{50} values; Tatken and Lewis, 1983) and intestinal absorption (Lauterbach, 1981) data from laboratory rats and mice indicate that ouabain has the lowest

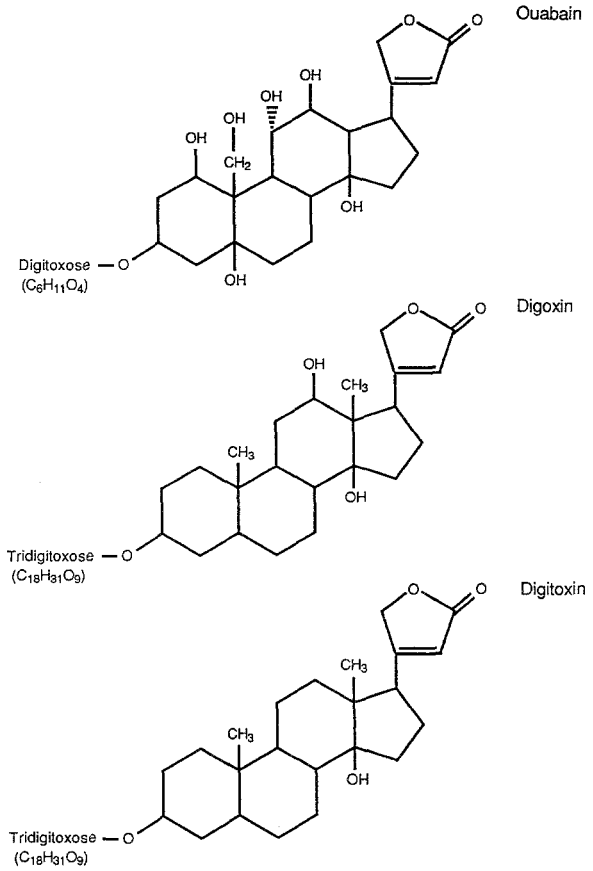

FIG. 1. Structure of the three cardenolides. Lipophilic character (log *P*), as indicated by octanol–water partition coefficient, of ouabain, digoxin, and digitoxin is −1.69, 1.25, and 2.80, respectively (Medicinal Chemistry Data bank, Pomona College). The difference in log *P* values can be attributed primarily to variable numbers of OH groups.

and digitoxin the highest potential toxicity in muroid rodents. Testing the cardenolides in an ascending order of toxicity minimized any potential order effects due to the formation of feeding aversions.

Each test lasted two days, and intake from both cups was determined gravimetrically after each day. At the onset of day 2, fresh cups and diet were provided, and the position of the cups was reversed to control for position preferences.

Data Analysis. For each test, the amount of diet consumed from the tastant cup was divided by the amount consumed from both cups to calculate the preference ratio. The taste avoidance threshold for each cardenolide was defined a

priori as the lowest cardenolide concentration at which the mean preference ratio was significantly below 0.5 [$P < 0.01$; one-sample (one-tail) t test].

To determine whether total food intake (i.e., control + tastant diet) changed across the 15 two-choice tests, I ran a two-factor, repeated measure ANOVA (Gagnon et al., 1991) with total food intake as the dependent measure and cardenolide concentration and cardenolide type as the main effects. This analysis was run separately for each species.

Even though muroid rodents are highly tolerant to ingested cardenolides (see Table 1), I nevertheless evaluated the mice for signs of sickness in two ways. First, I observed individual mice at the end of each 24-hr test period (in this and the next experiment) for signs of cardenolide toxicity such as cardiac failure, emesis, neurotoxicity, ataxia, dyspnea, severe tremors, and/or convulsions (Detweiler, 1967; Marty, 1983). Second, if negative postingestive feedback, rather than gustatory deterrence, was causing mice to limit intake of the cardenolide-laced diets, then I expected the nightly dosage of ingested cardenolide to remain constant across the range of test concentrations.

Experiment 2: Effect of Cardenolides on Feeding Bout Length

In laboratory rats, drinking bout length varies as a function of palatability. Thus, bout lengths are positively correlated with the concentration of sucrose (Smith, 1988) and negatively correlated with that of repellent tastants like quinine hydrochloride, sucrose octaacetate, caffeine, denatonium benzoate, and *n*-propyl-6-thiourea (Glendinning and Smith, 1990). In this experiment, I investigated whether diets containing threshold concentrations of ouabain, digoxin, or digitoxin (as determined in experiment 1) would shorten feeding bout length in the five *Peromyscus* species. To minimize involvement of postingestive (e.g., malaise) or experiential (e.g., gustatory habituation) effects, I considered only the initial feeding encounters with cardenolide-laced diets.

Subjects. Eight males of each of the five *Peromyscus* species were tested. The animals were caged and maintained as previously described.

Cardenolides and Artificial Diets. The same cardenolides and diets described previously were used here.

Test Conditions and Protocol. Each mouse was housed individually in a suspended stainless-steel cage (10 × 24 × 13 cm) equipped with a stainless-steel sipper spout and two adjacent feeding stations (each containing one food cup) (see Gannon et al., 1992, for details). To access powdered diet from either feeding station, a mouse had to insert its head through a restricted opening into a food cup. In so doing, it interrupted an infrared (IR) light beam. Beam breaks at each feeding cup were monitored by electronic circuitry, digitized, and transferred to a computer, which stored them in sequential 6-sec time periods (or sampling bins) over a 24-hr period. When a mouse's head broke the IR beam

for any part of a second during a sampling bin, a count of 1 was recorded. This resulted in a maximum of six counts per sampling bin. Later, the feeding records were parsed into distinct bouts, separately for each feeding cup. A bout began when ≥ 3 beam breaks occurred within a sampling bin and ended when no beam breaks occurred during a subsequent sampling bin.

Prior to testing, mice were housed in their respective test cages for five days to ensure they had acclimated to the feeding and drinking stations. Only one *polionotus* did not acclimate, and it was removed from the experiment.

Each mouse was tested with all cardenolides. For each cardenolide, individual mice were subjected to three 48-hr, two-choice tests. In test 1, control diet was present in both food cups. In test 2, the control diet was presented in one cup, while a diet containing a cardenolide at the concentration 1 $\log_e$ increment below the taste avoidance threshold (i.e., sub-AT diet) was presented in the other. In test 3, the control diet was presented in one cup, while a diet containing a cardenolide at the avoidance threshold concentration (i.e., AT diet) was presented in the other. The sub-AT and AT diets differed among mouse species and cardenolide type and were selected based on results from experiment 1. The order in which the three cardenolides were tested and the protocols for running the two-choice tests and preparing the diets were as in experiment 1.

Data Analysis. To assess the effect of cardenolide concentration on feeding bout length, I decided a priori to include in the analysis only a fraction of the data collected in each 48-hr test. First, I used only those feeding records from the tastant cup. Mice were offered both control and tastant cups merely to make the test situation (i.e., two-choice test) analogous to that of experiment 1.

Second, I attempted to include in the analysis only those feeding records from day 1. This was not always possible, however, as some mice showed strong sidedness in preliminary tests. Thus, a mouse may have avoided the tastant cup when it was in the right feeding station solely because the mouse habitually fed from the left station. To address this problem, I used records from day 1 only when a mouse fed from the tastant cup for ≥ 5 min during day 1 (i.e., exhibited ≥ 300 feeding counts), or for < 5 min during each of the test days. When a mouse did not meet these conditions (i.e., fed from the tastant cup for < 5 min during day 1 and ≥ 5 min during day 2), I used records from day 2. To quantify how often this latter situation occurred, I calculated the median number of times day 2 records were used across the nine tests (i.e., three two-choice tests for each of the cardenolides), separately for each species.

Third, I considered only the initial 10 feeding bouts from a given test day. I reasoned that this number of bouts was large enough to provide an accurate sample of the initial feeding encounters, but small enough to prevent postingestive or experiential effects from confounding the results. Preliminary feeding experiments indicated that mice of all five species routinely exhibited > 83 feeding bouts per test day when control diet was in both food cups.

For the analysis, I ran a two-factor ANOVA (separately for each species), using the mean length of the initial 10 feeding bouts as the dependent measure and cardenolide concentration and cardenolide type as main effects. Because cardenolide type and the interaction were nonsignificant for all five species, I collapsed the data across cardenolide type and employed orthogonal contrast analyses (Gagnon et al., 1991) to evaluate feeding bout lengths for the three diet types.

RESULTS

Experiment 1: Two-Choice Preference Tests

Concentration–response (C-R) functions for the three cardenolides are provided in Figure 2, and the avoidance thresholds derived from these functions are presented in Figure 3. Large differences in avoidance thresholds for each cardenolide were apparent among the five species, differing in one instance by over two orders of magnitude. In addition, the interspecific ranking of avoidance thresholds was the same for all three cardenolides: *maniculatus* = *leucopus* > *melanotis* > *polionotus* > *aztecus*. Thus, species with a relatively low avoidance threshold to one cardenolide (e.g., ouabain) also had a low threshold to the other two.

There were no significant effects of cardenolide type or cardenolide concentration on total food intake (for each species, $P > 0.05$ for the main effects and interaction). Thus, total food intake by individual mice remained constant across the 15 two-choice tests (mean grams ingested $\pm$ SE per 48-hr test by *aztecus* = 9.7 $\pm$ 0.2, *melanotis* = 6.8 $\pm$ 0.1, *maniculatus* = 5.5 $\pm$ 0.1, *leucopus* = 5.4 $\pm$ 0.1, and *polionotus* = 4.6 $\pm$ 0.1). Given this finding, the only way to explain the C-R functions in Figure 2 is that mice ate proportionally less tastant diet as the cardenolide concentration was increased.

Two lines of evidence argue against the hypothesis that aversive postingestive feedback caused mice to limit intake of the cardenolide-laced diets. First, no mice displayed any overt signs of cardenolide toxicosis in this or the next experiment. Second, in all species, the nightly cardenolide dosage (milligrams per kilograms mouse mass) actually increased as a function of cardenolide concentration in the tastant diet (Figure 4). There were only two exceptions to this pattern: *aztecus* and *melanotis* ingested relatively constant dosages of digitoxin across the range of test concentrations. However, it is unlikely that these exceptions can be explained by a postingestive mechanism, given that the highest nightly dosage of digitoxin for *aztecus* and *melanotis* was only 0.53 and 39.4 mg/kg, respectively. Both species can ingest substantially larger dosages with impunity (see Table 1).

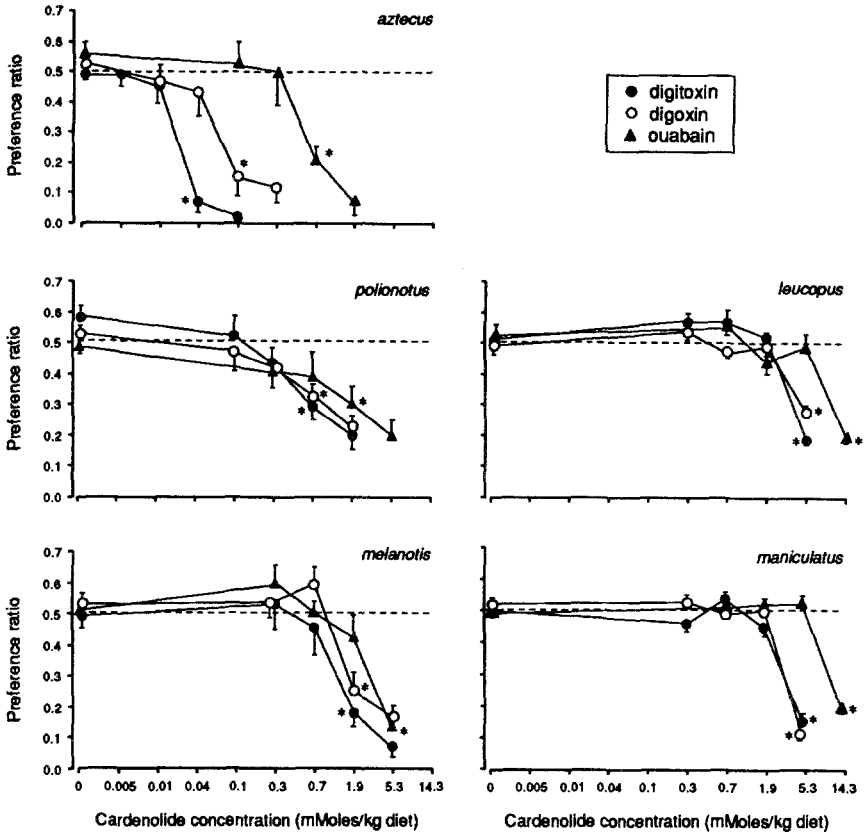

FIG. 2. Preference ratios (mean ± SE) across several concentrations of digitoxin, digoxin, and ouabain in five *Peromyscus* species. A preference ratio of 0.5 (indicated by the dotted line) represents no discrimination between the control or cardenolide-laced diet, whereas a ratio of 0.0 represents complete avoidance of the cardenolide-laced diet. Avoidance thresholds for each cardenolide are indicated with asterisks. The x axis tick marks span natural log increments.

Experiment 2: Effect of Cardenolides on Feeding Bout Length

There were significant cardenolide concentration effects for all species ($F_{2,28} \geq 27.15$; $P = 0.0001$). Otherwise, there were no significant effects of cardenolide type ($F_{2,28} \leq 2.41$; $P \geq 0.05$) or the interaction ($F_{4,28} \leq 1.82$; $P \geq 0.05$) in either species (Figure 5). Because the effect of cardenolide type on feeding bout duration was not significant, I collapsed the data across cardenolide type for contrast analyses. These analyses showed that, for all species, feeding bout length on the control diet was statistically identical to that on the sub-AT

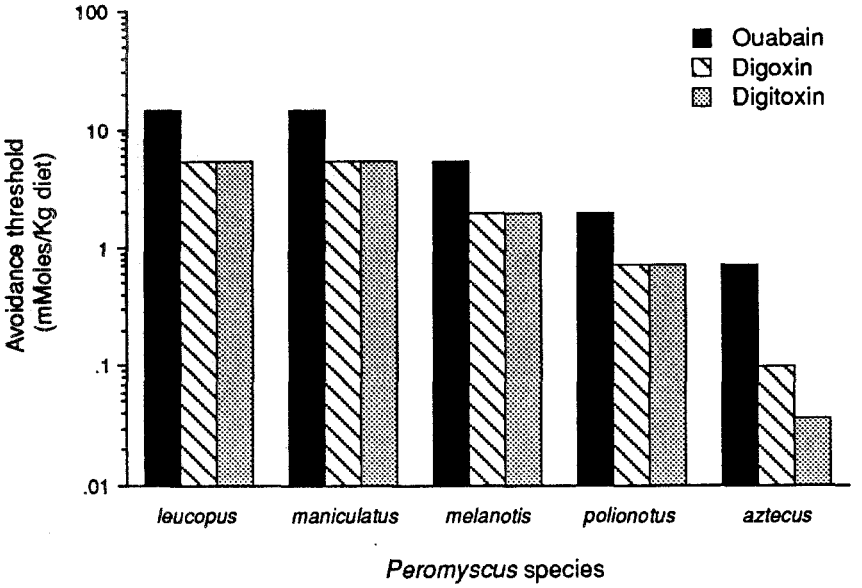

FIG. 3. Avoidance thresholds to ouabain, digoxin, and digitoxin in the five species of *Peromyscus*, as indicated by two-choice tests. The data from which the thresholds were derived are presented in Figure 2.

diet ($F_1 \leq 1.73$; $P \geq 0.05$), but significantly longer than that on the AT diet ($F_1 \geq 51.44$; $P = 0.0001$). For all species, the mean bout length on the control diet (after collapsing across cardenolide type) ranged between 31 and 41 sec; that on the AT diet ranged between 15 and 22 sec (see Figure 5). Thus, all five species rapidly detected and rejected diets containing cardenolide at the AT but not the sub-AT concentration.

Because the vast majority of mice fed from the tastant cup for ≥ 5 min during day 1, I rarely had to use day 2 records in the bout analyses. The median number of times day 2 records were used was 0 for *aztecus* and *polionotis* (range = 0–3 across the nine tests) and 1 for *melanotis*, *leucopus* and *maniculatus* (range = 0–3).

DISCUSSION

Two major findings are apparent. There are large interspecific differences in taste sensitivity to cardenolides within the genus *Peromyscus*, and taste sensitivity to one cardenolide predicts sensitivity to other cardenolides.

I conclude that a preingestive (i.e., gustatory) rather than postingestive

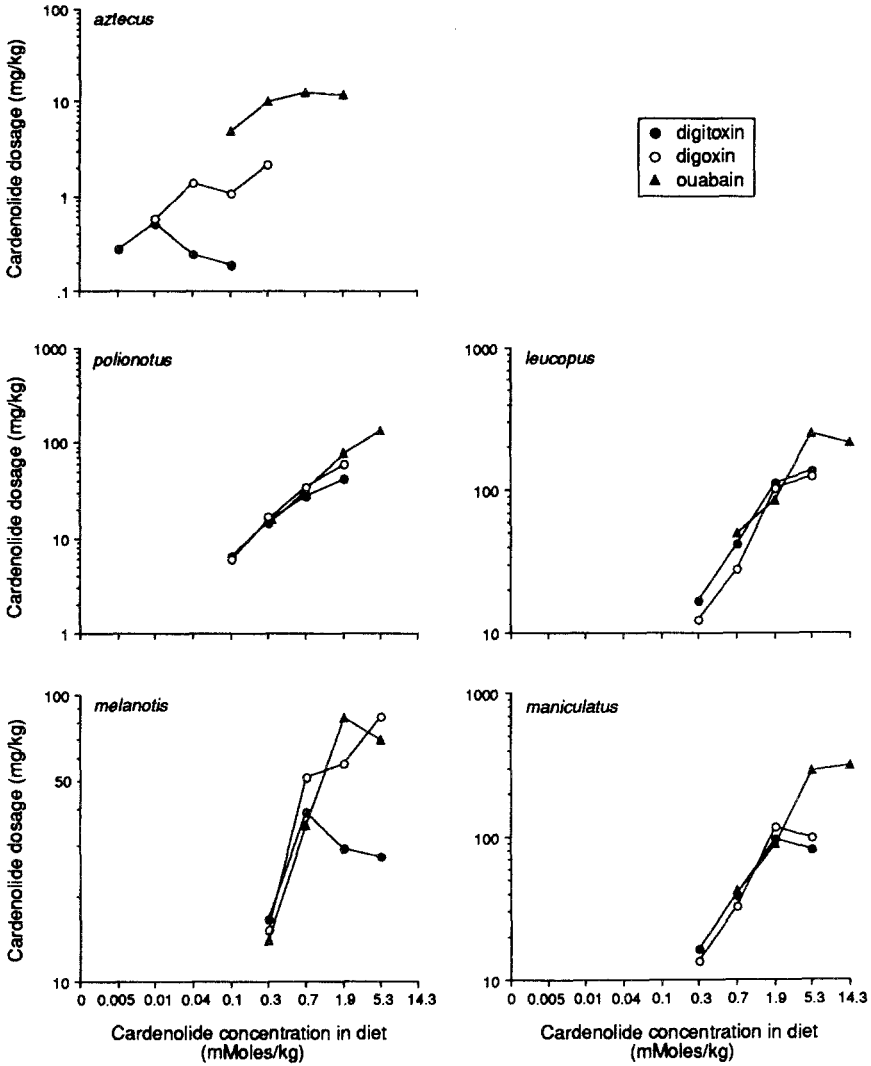

FIG. 4. Mean nightly dosage of digitoxin, digoxin, and ouabain ingested by the five *Peromyscus* species in experiment 1. In all species, nightly dosage increased as a function of cardenolide concentration in the tastant diet. Note that different scales were used on the *y* axis of the graphs.

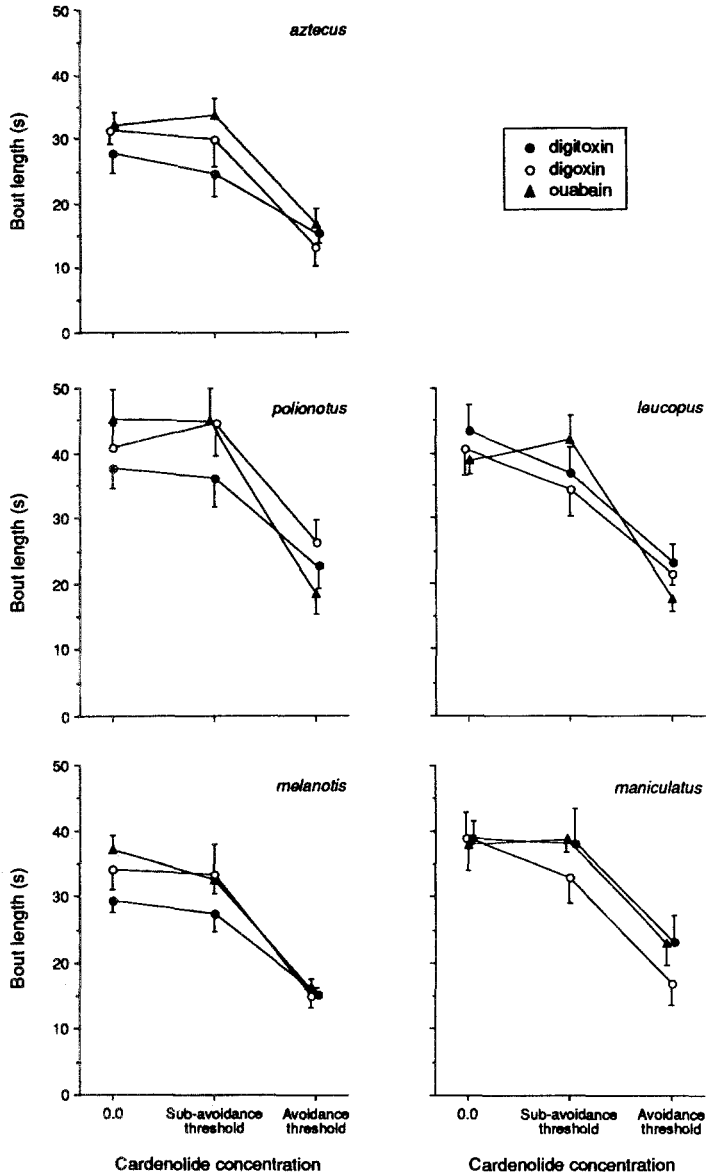

FIG. 5. Feeding bout lengths (mean ± SE) across several concentrations of digitoxin, digoxin, and ouabain in five *Peromyscus* species. Each cardenolide was presented at three concentrations: 0.0 mmol/kg diet, the subavoidance threshold (i.e., the concentration one $\log_e$ unit below the avoidance threshold), and the avoidance threshold. The actual subavoidance and avoidance threshold concentrations differed among the cardenolides and mouse species and were based on the results in Figures 2 and 3.

(i.e., toxicosis) mechanism underlies the avoidance thresholds in all species for several reasons. First, the AT diets (i.e., diets containing either of the cardenolides at the avoidance threshold concentration) caused an immediate decrease in feeding bout length. Second, I observed no evidence of aversive postingestive feedback from the cardenolide-laced diets. Third, cardenolides in general are absorbed extremely poorly across the intestinal wall of muroid rodents, including *maniculatus* (Lauterbach, 1981; Marty, 1983). Indeed, comparative studies of oral and intraperitoneal LD_{50} values within muriod rodent species show that oral values are invariably much higher (Tatken and Lewis, 1983; Marty, 1983).

Ecological Relevance of Avoidance Thresholds

To determine how the cardenolide concentration in the AT diets compared to the natural cardenolide concentration in potential insect prey, I first determined the median avoidance threshold for the three cardenolides (separately for each species). Then, I overlaid each species' median threshold value on: (1) the frequency distribution of cardenolide concentrations in Mexican overwintering monarchs, and (2) the range of cardenolide concentrations in milkweed bugs, *Oncopeltus fasciatus* (Figure 6). This comparison seemed valid given that the range of lipophilicity spanned by ouabain, digoxin, and digitoxin is similar to that spanned by cardenolides in monarchs and milkweed bugs (Moore and Scudder, 1985; Seiber et al., 1986; Malcolm et al., 1989).

Assuming results from artificial diets are relevant to insects, then it appears that more than 68% of the monarchs contain suprathreshold concentrations of cardenolides for *aztecus*, whereas only 29, 4, 0, and 0% do so for *polionotus*, *melanotis*, *leucopus*, and *maniculatus*, respectively. Extrapolation of these results to free-ranging mice supports earlier findings (Glendinning, 1990; Glendinning et al., 1990) that *aztecus* avoids eating monarchs, and *melanotis* eats them, because of their differential taste sensitivities to cardenolides. Even though *polionotus*, *leucopus*, and *maniculatus* do not naturally encounter overwintering monarchs, the results indicate that (like *melanotis*) they are preadapted, to varying degrees, for eating them.

A different story emerges with milkweed bugs: Nearly all of them contain cardenolide concentrations above the median avoidance thresholds for all five *Peromyscus* species. Thus, in contrast to the cardenolide defense of monarchs, that of milkweed bugs may effectively deter predation by all *Peromyscus* species.

These findings illustrate two important points often neglected in studies of predator responses to deterrents. First, even congeneric predators respond quite differently to deterrents. Consequently, one should use natural predators, rather than convenient or abundant predators that do not naturally encounter the focal prey species, because the latter may provide misleading results. Second, avoidance thresholds of predators to deterrents attain greater ecological significance

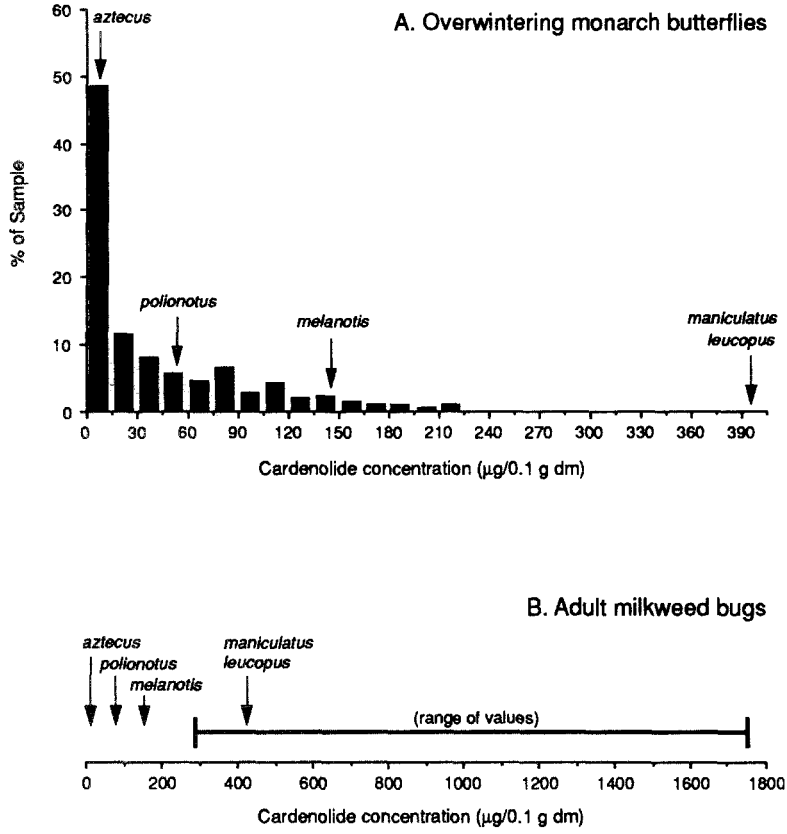

FIG. 6. (A) Frequency distribution of the whole body concentration of cardenolides in overwintering monarch butterflies on Sierra Chincua, a primary overwintering site in Mexico (data from Malcolm and Brower, 1989). (B) Concentration range of cardenolides in adult milkweed bugs, *Oncopeltus fasciatus*. For the milkweed bugs, only fresh mass concentrations of cardenolides were available (Moore and Scudder, 1985). Nevertheless, because adult milkweed bugs are on average 45% dry mass (Slansky, 1980), I was able to estimate the dry mass concentrations of cardenolides. The median avoidance thresholds for each of the *Peromyscus* species (i.e., the median of the digitoxin, digoxin, and ouabain avoidance thresholds) are indicated on graphs A and B. Since monarchs and milkweed bugs both contain several types of cardenolides, the units are represented as µg/0.1 g rather than mmol/kg. Note that different scales were used on the x-axis of the two graphs.

when they are related to the natural concentration range of the chemicals in prey.

Taste Sensitivity to One Cardenolide Predicts Sensitivity to Others

In all five species, the relative taste sensitivity to one cardenolide reliably predicted sensitivity to the other two. In related studies, the relative taste sensitivity of *aztecus* and *melanotis* to digitoxin was the same as that to cardenolides in both wild-caught and laboratory-reared monarch butterflies (Glendinning, 1990; Glendinning et al., 1990). It thus appears that a *Peromyscus* species with a relatively low taste sensitivity to a lipophobic cardenolide (e.g., ouabain) will be similarly insensitive to a lipophilic one (e.g., digitoxin).

I am presently examining the possibility that taste sensitivity to cardenolides may also predict sensitivity to other classes of deterrents. Studies with SWR inbred mice (*Mus domesticus*) indicate that taste sensitivity to the deterrent, sucrose octaacetate, accurately predicts sensitivity to structurally related (e.g., other acetlyated sugars) and unrelated (e.g., strychnine and denatonium benzoate) deterrents (Whitney et al., 1990, 1991). Likewise, in human populations, low taste sensitivity to three deterrents (PTC, PROP, and caffeine) predicts taste sensitivity to a host of structurally unrelated ones (Fischer et al., 1965; Hall et al., 1975; Tanimura and Mattes, 1989).

Effect of Lipophilic Character on Avoidance Threshold

Elsewhere, several investigators report significant inverse correlations between lipophilic character and bitter taste thresholds of numerous drugs, amino acids, and peptides in humans (Asao et al., 1987; Gardner, 1978, 1979). These correlations are thought to reflect the relative ease with which lipophilic chemicals contact or pass through lipid barriers (e.g., the mucous/lipid interphase and membrane of taste cells) and access physiological sites of action (Koyama and Kurihara, 1972; Wolkowski et al., 1977). The results of the present study are consistent with the human studies: (1) the cardenolide with the lowest lipophilic character, ouabain, elicited the highest threshold in all five species; and (2) in *aztecus*, the avoidance thresholds for the three cardenolides were inversely related to lipophilic character. In contrast, a study with blue jays suggests a positive relationship between avoidance threshold and lipophilic character of three cardenolides (digoxin, digitoxin, and digitoxigenin; Brower and Fink, 1985). To resolve these contradictory results, the mice and birds must be tested with a wider array of cardenolides.

Acknowledgments—I thank James Smith and Lloyd Beidler for counsel during all phases of this study and for use of their laboratory facilities; Frank Slansky Jr., Greg Wheeler, Glayde Whitney, and two anonymous reviewers for comments on the manuscript; Kimberly Gannon, Ross Henderson, and Walter Robertson for help in developing and building the feeding monitor system;

Corwin Hansch for the partition coefficient data; and Fran James for the *P. polionotus*. Financial support was provided by the Lloyd M. Beidler Postdoctoral Fellowship and a gift from the R.J. Reynolds Tobacco Company to L. Beidler and J. Smith.

(Received February 5, 1992; accepted May 4, 1992)

Abstract—In south-central British Columbia, the attraction of *Ips latidens* (LeConte) to its pheromone, ipsenol, was inhibited by (*S*)-(+)-ipsdienol, a pheromone for *I. pini* (Say). (*R*)-(−)-Ipsdienol had no effect on *I. latidens*. (*S*)-(+)-Ipsdienol probably plays a role in interspecific communication between the two species, facilitating reductions in interspecific competition for breeding material and/or interspecific mating interference.

Key Words—Coleoptera, Scolytidae, *Ips latidens*, *Ips pini*, interspecific communication, synomone, pheromone, ipsenol, ipsdienol, chirality, enantiospecificity.

INTRODUCTION

Ecological and reproductive isolation among bark beetles can be facilitated by the use of pheromones (Wood, 1970; Lanier and Burkholder, 1974; West-Eberhard, 1984; Kohnle et al., 1986, 1988; Miller, 1991). Beetles are generally attracted to sources of pheromones produced by conspecifics while avoiding sources of pheromones produced by individuals of other species (Wood, 1970; Birch, 1978, 1984; Borden, 1982). In western North America for example, interspecific inhibition of responses to pheromones occurs between various sympatric species such as *Ips paraconfusus* Lanier and *I. pini* (Say) (Birch and Wood, 1975; Birch and Light 1977; Birch et al., 1977, 1980; Birch, 1978;

*To whom correspondence should be addressed.

Light and Birch, 1977) and *I. paraconfusus* and *Dendroctonus brevicomis* LeConte (Byers and Wood, 1980, 1981).

Ips pini and *I. latidens* (LeConte) are broadly sympatric in western North America and breed in large single-species aggregations, primarily in the phloem tissue of lodgepole pine (Bright, 1976; Furniss and Carolin, 1980; Wood, 1982). Both species use pheromones. In south-central British Columbia, *I. pini* produce ipsdienol with a mean chiral ratio of 66:34 (*S*)-(+):(*R*)-(−) (Miller et al., 1989). Both sexes are attracted to sources of ipsdienol with chiralities ranging from 30:70 to 80:20 (*S*)-(+):(*R*)-(−) (Miller, 1991). In the same region, male *I. latidens* produce ipsenol and both sexes respond to ipsenol regardless of chirality, although there is a slight preference for the (*S*)-(−) enantiomer (Miller et al., 1991).

Ipsenol inhibits the attraction of *I. pini* to infested material in Idaho (Furniss and Livingston, 1979) and California (Birch and Light, 1977). In south-central British Columbia, ipsenol inhibits the attraction of *I. pini* to ipsdienol-baited funnel traps (Borden et al., 1992). However, the effect of ipsdienol, produced by *I. pini*, on *I. latidens* has not been determined. We hypothesized that one or both enantiomers of ipsdienol inhibit the attraction of *I. latidens* to sources of ipsenol.

METHODS AND MATERIALS

Racemic ipsenol and racemic ipsdienol (chemical purities, 98% and > 95%, respectively) were obtained from Bedoukian Research Inc. (Danbury, Connecticut) and Borregaard, A.S. (Sarpsborg, Norway), respectively. E.K. Czyzewska (Department of Chemistry, Simon Fraser University, Burnaby, British Columbia) supplied chiral ipsdienols (optical purities, 98% (*S*)-(+) and 98% (*R*)-(−), respectively, chemical purities, > 98%).

Each lure consisted of 10 Microcap disposable pipettes (2 μl) (Drummond Scientific Co., Broomall, Pennsylvania), each sealed at one end and filled with either racemic ipsenol, racemic ipsdienol, or one of the chiral ipsdienols, and placed in a polyethylene, microcentrifuge tube (1.8 ml) (Evergreen Scientific, Los Angeles, California). The release rates of ipsenol and ipsdienol from such lures were both approximately 100 μg/day at 24°C (determined by weight loss).

In all experiments, replicates of four eight-unit, multiple-funnel traps (Lindgren, 1983) (Phero Tech Inc., Delta, British Columbia) were set in grids of 2 × 2 in stands of lodgepole pine near Princeton, British Columbia. Replicate grids were placed at least 100 m apart, and traps were spaced 10–15 m apart within each replicate. Each trap was suspended such that the top of each trap was approximately 1.3–1.5 m above ground level. No trap was within 2 m of

any tree. For each experiment, insects were collected only at the termination of the experiment.

Experiment 1 tested the effect of various chiralities of ipsdienol on the attraction of *I. latidens* to ipsenol. Ten replicates were set from June 26 to August 22, 1985. The treatments were as follows: (1) racemic ipsenol alone; (2) ipsenol and (*S*)-(+)-ipsdienol; (3) ipsenol and (*R*)-(−)-ipsdienol; and (4) ipsenol and racemic ipsdienol. Lures were replaced on July 25, 1985.

Experiment 2 tested the effect of (*S*)-(+)-ipsdienol on the attraction of *I. latidens*. Nine replicates were set from June 4 to 18, 1985. The treatments were as follows: (1) blank control; (2) racemic ipsenol alone; (3) (*S*)-(+)-ipsdienol alone; and (4) ipsenol and (*S*)-(+)-ipsdienol.

The data were analyzed using the SAS statistical package version 5.0 (SAS Institute Inc., Cary, North Carolina). Trap catch data, transformed by ln (Y + 1) to remove heteroscedasticity, were subjected to either one- or two-way analyses of variance (ANOVA). Ryan-Einot-Gabriel-Welsch (REGW) multiple-range tests were used when $P < 0.05$.

RESULTS AND DISCUSSION

(*S*)-(+)-Ipsdienol significantly inhibited the attraction of *Ips latidens* to sources of ipsenol. In experiment 1, catches of *I. latidens* to traps baited with either racemic or (*S*)-(+)-ipsdienol were approximately 20-fold lower than those to traps baited with ipsenol alone (Figure 1). Catches to traps baited with ipsenol and (*R*)-(−)-ipsdienol were not significantly different from those to ipsenol alone. In experiment 2, in which significant levels of (*R*)-(−)-ipsdienol were not present, (*S*)-(+)-ipsdienol again significantly reduced the capture of *I. latidens* (Figure 2).

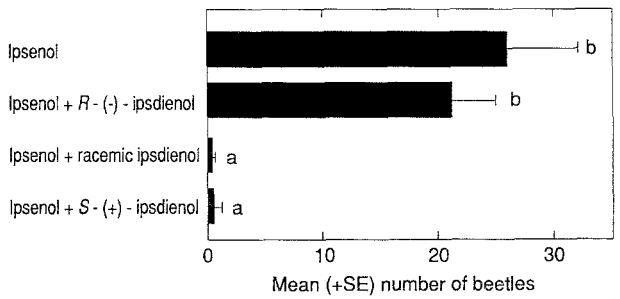

FIG. 1. The effect of chiral ipsdienol on the capture of *Ips latidens* in ipsenol-baited, multiple-funnel traps near Princeton, British Columbia, from June 26 to August 22, 1985 (N = 10). Means followed by the same letter are not significantly different at P = 0.05 [REGW multiple range test on data transformed by ln (Y + 1)].

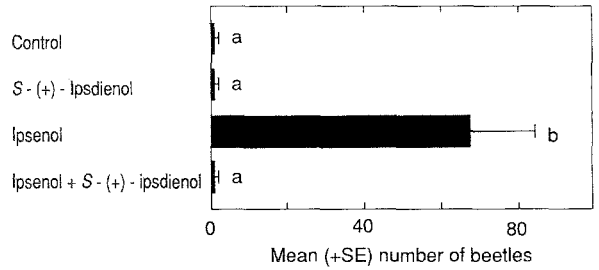

FIG. 2. The effect of the interaction between (*S*)-(+)-ipsdienol and racemic ipsenol on the capture of *Ips latidens* in multiple-funnel traps near Princeton, British Columbia, from June 4 to 18, 1985 ($N = 9$). Means followed by the same letter are not significantly different at $P = 0.05$ [REGW multiple range test on data transformed by ln $(Y + 1)$].

In south-central British Columbia, male *I. pini* produce substantial amounts of (*S*)-(+)-ipsdienol in their pheromone blend (Miller et al., 1989). Both *I. pini* and *I. latidens* breed in single-species aggregations in the phloem tissue of lodgepole pine, often in association with the mountain pine beetle, *Dendroctonus ponderosae* Hopkins (Bright, 1976; Furniss and Carolin, 1980; Wood, 1982). Both species seem to show ecological separation in their choice of breeding material; *I. latidens* seem to prefer drier phloem material than *I. pini* (Miller and Borden, 1985). It is probable, therefore, that (*S*)-(+)-ipsdienol plays a role in interspecific communication between *I. latidens* and *I. pini*, facilitating reduced interspecific competition for breeding material and/or reduced interspecific mating interference.

In contrast, *I. pini* in western United States and southeastern British Columbia use primarily (*R*)-(−)-ipsdienol as a pheromone (Stewart, 1975; Plummer et al., 1976; Birch et al., 1980; Miller et al., 1989). In these regions, (*R*)-(−)-ipsdienol may have a stronger effect on *I. latidens* than it does in south-central British Columbia. The response to (*S*)-(+)-ipsdienol is probably still present since other competing species such as *I. paraconfusus* utilize (*S*)-(+)-ipsdienol as a pheromone. Mutual inhibition between *I. pini* and *I. paraconfusus*, in these regions, is based, in part, on the chirality of ipsdienol (Light and Birch, 1977; Birch et al., 1980).

Acknowledgments—We thank B.S. Lindgren for his review of the manuscript and S. Seybold and D.L. Wood for their continual support and encouragement. D.E. Bright kindly verified the identification of *I. latidens*. Voucher specimens have been deposited with the Entomology Museum at Simon Fraser University. Assistance in the manufacture of release devices was provided by W. Brown and L. Wheeler. The research was supported by an H.R. MacMillan Family Fund Fellowship to the senior author and by Operating and Strategic grants from the Natural Sciences and Engineering Research Council, Canada.

OLFACTORY RECOGNITION OF NONHOSTS ASPEN AND BIRCH BY CONIFER BARK BEETLES *Tomicus piniperda* AND *Hylurgops palliatus*

L.M. SCHROEDER

Swedish University of Agricultural Sciences
Division of Forest Entomology
S-750 07 Uppsala, Sweden

(Received January 15, 1992; accepted May 5, 1992)

Abstract—The field response of *Tomicus piniperda* (L.) and *Hylurgops palliatus* (Gyll.) (Coleoptera: Scolytidae) to the attractant ethanol in combination with volatile wood constituents released from the nonhost tree species *Populus tremula* L. (Salicaceae) and *Betula pendula* Roth (Betulaceae) was studied using flight barrier traps. The attraction of both species decreased when aspen or birch wood was added to the ethanol bait. The same was true for *Rhizophagus depressus* (F.) (Coleoptera: Rhizophagidae), a predatory species associated with conifer bark beetles. *Glischrochilus quadripunctatus* (L.), *Epuraea bickhardti* St.-Claire Deville, *E. unicolor* (Oliv.) (Coleoptera: Nitidulidae), and *Rhizophagus parvulus* (Payk.) (Coleoptera: Rhizophagidae) were caught in higher numbers in traps baited with both ethanol and wood of aspen or birch than in traps baited with ethanol alone. In a separate experiment, landings of *T. piniperda* and *H. palliatus* on nonhosts (black plastic tubes) were demonstrated with sticky traps.

Key Words—*Tomicus piniperda*, *Hylurgops palliatus*, *Rhizophagus depressus*, *R. parvulus*, *Glischrochilus quadripunctatus*, *Epuraea bickhardti*, *E. unicolor*, Coleoptera, Scolytidae, Rhizophagidae, Nitidulidae, ethanol, nonhost volatiles, *Populus tremula*, *Betula pendula*, olfactory orientation, attraction, decreased attraction.

INTRODUCTION

Most scolytids, as well as many other bark- and woodboring insects, reproduce only in dead or weakened trees. This resource is generally scarce and tends to be distributed unevenly in space and time. Furthermore, host trees are often

0098-0331/92/0900-1583$06.50/0 © 1992 Plenum Publishing Corporation

present in mixed stands with nonhost species. Thus, such insects need effective means for finding and recognizing suitable breeding material.

Many bark beetles are attracted by host volatiles, alone or in combination with pheromones (e.g., Borden, 1982). Host odors may be characteristic of individual tree species. The major components of the volatile essential oils in trees responsible for characteristic odors are the terpenoids (see Harborne and Turner, 1984, and references therein). Some bark beetles, including both conifer and broad-leaved breeding species, are attracted by mono- and sesquiterpenes present in their host trees (e.g., Byers et al., 1985; Millar et al., 1986; Schroeder and Lindelöw, 1989).

Volatiles may also provide information about tree vitality. High concentrations of monoterpenes in the air may indicate the presence of damaged trees (Ikeda et al., 1980; Strömvall and Pettersson, 1991). Degradation processes in dead or dying tree tissue result in the formation of substances that are absent or present in only small amounts in healthy trees. One such substance is ethanol, which is formed in dying tissue of both conifers (Moeck, 1970; Cade et al., 1970; Ikeda et al., 1980; Sjödin et al., 1989) and broad-leaved trees (Elliot et al., 1983). Ethanol attracts some scolytids reproducing in broad-leaved trees (Roling and Kearby, 1975; Montgomery and Wargo, 1983) as well as some scolytids breeding in coniferous trees (e.g., Moeck, 1970; Schroeder and Lindelöw, 1989).

Little is known about the mechanisms underlying bark beetle rejection of nonhost tree species. Rejection could be based on a lack of certain host characteristics and/or a negative response to some nonhost stimuli. Two ambrosia beetles reproducing in broad-leaved trees, *Trypodendron domesticum* (L.) and *Anisandrus dispar* (F.), respond negatively to α-pinene, one of the major monoterpene constituents of both Scots pine, *Pinus sylvestris* L., and Norway spruce, *Picea abies* (L.) Karst. Both beetles are strongly attracted by ethanol alone, while α-pinene-baited and unbaited traps catch a few or no individuals. When α-pinene is released along with ethanol, attraction to the latter compound is inhibited or decreases strongly (Nijholt and Schönherr, 1976; Schroeder and Lindelöw, 1989). Single cell responses to the odor from birch bark have been demonstrated in the conifer scolytids *Trypodendron lineatum* (Oliv.) and *Ips typographus* (L.) (Tømmerås, 1989; Tømmerås and Mustaparta, 1989). For some scolytids, laboratory studies demonstrate that the rejection of nonhost tree species can be based on gustatory cues. *Ips paraconfusus* Lanier selected a host over a nonhost only after the beetles had bored through the outer bark (Elkinton and Wood, 1980). In the presence of certain nonhost substances, *Scolytus multistriatus* (Marsh.) rejected host-tree twigs suitable for maturation feeding (Gilbert and Norris, 1968).

The present study was initiated to give information about the behavioral response of the two conifer bark beetles, *Tomicus piniperda* (L.) and *Hylurgops*

palliatus (Gyll.), to nonhost trees. Both species are common throughout Scandinavia. The flight periods of both species occur in early spring. In Scandinavia *T. piniperda* reproduces almost exclusively in Scots pine while *H. palliatus* reproduces in both Scots pine and Norway spruce, the two major conifers in this region. Both species are restricted to weakened or dead trees for their reproduction, *H. palliatus* preferring a somewhat more decayed breeding substrate than *T. piniperda*.

The olfactory orientation to breeding material has been studied in both beetles in recent years. *T. piniperda* lacks an aggregation pheromone (Perttunen et al., 1970; Byers et al., 1985; Lanne et al., 1987). The only study conducted with *H. palliatus* in this respect did not present any evidence of an aggregation pheromone (Kohnle, 1985). *T. piniperda* is strongly attracted by certain Scots pine monoterpenes and weakly attracted by ethanol, while the reverse is true for *H. palliatus* (Byers et al., 1985; Kohnle, 1985; Klimetzek et al., 1986; Schroeder, 1988; Schroeder and Lindelöw, 1989). Monoterpenes and ethanol can interact synergistically in attracting *H. palliatus* and *T. piniperda* (Vité et al., 1986; Schroeder and Lindelöw, 1989).

In an initial experiment in the present study, the landing rates of *T. piniperda* and *H. palliatus* on hosts and nonhosts were estimated. In subsequent field experiments, the responses of *T. piniperda* and *H. palliatus* to volatiles from wood of the nonhosts European white birch, *Betula pendula* Roth (Betulaceae), and aspen, *Populus tremula* L. (Salicaceae), were studied.

METHODS AND MATERIALS

All experiments were conducted in 30- to 45-year-old Scots pine stands in the provinces of Uppland and Gästrikland in central Sweden. The landing frequencies of scolytids on vertical, black plastic tubes; healthy Scots pines; top-cut pines; and upright-standing, newly cut logs of Scots pine were compared in 1981. The diameter of the experimental trees was 14–17 cm. The top-cut trees were 6 m long, the logs 3 m long, and the tubes 1.5 m long. The top-cutting, which removed all green branches, was conducted in February, and the logs were cut in March 1982. The tubes (diam. 12 cm) were attached 0.5 m above ground. The four treatments were arranged in 14 randomized blocks. The distance between the treatments in each block ranged from 4 to 15 m and between blocks from 20 to 50 m. Each experimental tree and tube was surrounded by a trap cylinder (0.5 m high) constructed out of Stickem-Special-coated, 6.5-mm mesh wire netting. The cylinders were attached 1.5 m above ground. The distance between the trap and the surface of the trees and tubes was about 2 cm. All scolytids caught on the traps from April 4 to June 17, 1982 were collected. After the experiment, the top-cut trees and the logs were debarked and inspected.

The number of scolytid egg galleries and the presence of emergence holes were recorded. The healthy trees were carefully examined for boring dust and pitch tubes without being felled and debarked.

The attraction of beetles to combinations of 95% ethanol (5% water) and wood of aspen or European white birch was compared with the attraction to ethanol alone in 1990 and 1991. The attractiveness of the two tree species was studied in separate experiments, three with aspen and four with birch (Table 1). The treatments in each experiment were set out in pairs. The distance between the two traps in each pair was 10–15 m, and the distance between pairs was 20 m. In experiments 1 and 2 (1990), and 5 and 6 (1991) (Table 1), the same arrangements were used, but the positions of the treatments in each trap pair were switched between experiments. In each day of baiting, healthy aspen or birch trees were felled and cut into bolts (10–20 cm long), which were split with an axe. The cut wood was put into containers and covered with fine netting to keep bark beetles out. Wood volume differed between experiments (Table 1).

TABLE 1. OVERVIEW OF EXPERIMENTS WITH ASPEN AND BIRCH

Year and exp.	Type of wood combined with ethanol bait[a]		Trapping period	Bait replacements during tests	Replicates (*N*)
	Tree species	Volume (liters)			
1990					
1	aspen	55	March 17–20	new ethanol each day	6
2	birch	55	March 31		8
3	aspen	55	April 6–27	April 11, new ethanol; April 21, new wood and ethanol	7
4	birch	45	April 11–27	April 22, new wood and ethanol	8

6	birch	45	April 25–May 13 May 17–June 19	(May 13–17, no trapping) May 17, new wood and ethanol; May 27, new wood and ethanol refilled; June 7, new wood and ethanol refilled	9
7	birch	8	April 29–May 13 May 17–June 19	(April 29–May 13, no trapping) May 17, new wood and ethanol refilled; May 27, new wood and ethanol refilled; June 7, new wood and ethanol refilled	11

[a] Ethanol release rates given in text (estimated in laboratory) and in Table 2 (estimated in the field).

Ethanol was included in the experiments since previous studies demonstrated that, generally, only low numbers of *T. piniperda* and *H. palliatus* are caught in unbaited flight barrier traps (Schroeder, 1988; Schroeder and Lindelöw, 1989). Hence, a repellent effect of volatiles from wood of broad-leaved trees would be difficult to detect using unbaited traps as a control. Ethanol attracts both beetles, and the substance may be present in dying broad-leaved trees as well as in dying conifers.

Beetles were caught in flight barrier traps modified from the type described by Chapman and Kinghorn (1955). The barriers consisted of 15-cm-high, transparent plastic sheets. Water-filled trap troughs were placed directly beneath the barriers, on top of the containers. Sex determinations were made by dissection for all species except *Epuraea bickhardti* St.-Claire Deville (Coleoptera, Nitidulidae), whose males can easily be recognized based on the appearance of the middle tibia.

The ethanol dispensers were placed in the containers just under the net lids. In experiments 1 and 2, 10-ml polyethylene vials (6 ml ethanol) with 9-mm-diam. openings were used. In all other experiments 200-ml glass jars (185 ml ethanol) with 45-mm-diam. openings were used. The release rates of ethanol from the dispensers in laboratory at 15°C were 3.0 ± 0.3 g/24 hr for the polyethylene vials and 9.1 ± 1.0 g/24 hr for the glass jars. In 1991, the field release rates during the trapping periods were estimated by measuring the amount of ethanol left in the dispensers at the end of each experiment, or before refilling during an experiment (Table 2). The mean air temperature varied between 5.0 and 8.4°C during the trapping periods in 1991.

TABLE 2. AMOUNTS OF ETHANOL RELEASED FROM DISPENSERS PLACED IN TRAPS BAITED WITH WOOD (E & W) AND IN TRAPS WITHOUT WOOD (E) IN 1991[a]

Expt.	Trapping period	Days (N)	Amount released per day ($\bar{X}$ ± SD, g)	
			E & W	E
5	April 11–15	4	7.3 ± 1.6	5.8 ± 0.7
6	April 25–May 13	18	3.5 ± 0.9	3.0 ± 0.4
	May 17–27	10	4.2 ± 0.7	4.0 ± 0.6
	May 27–June 7	11	3.2 ± 0.8	2.8 ± 0.4
7	April 29–May 13	14	2.0 ± 0.8	1.5 ± 0.7
	May 17–27	10	2.4 ± 1.4	1.4 ± 1.1
	May 27–June 7	11	1.4 ± 0.5	1.0 ± 0.4

[a]For number of replicates, see Table 1.

RESULTS

The scolytids *T. piniperda*, *H. palliatus*, *Hylastes brunneus* Er., *H. cunicularius* Er., and *T. lineatum*, were caught on the traps on the plastic tubes (Table 3). The numbers of beetles caught on the tubes did not differ significantly from the numbers caught on healthy and top-cut trees for any of the species. Much higher numbers of *T. piniperda* and *H. brunneus* were caught on the newly cut logs than in the other treatments, and the differences in catch were statistically significant for both species. At the end of the experiment, the only scolytid breeding attacks found were caused by *T. piniperda* on logs. Twelve of the 14 logs were attacked ($\bar{X}$ = 26 egg galleries/log), and in 10 of the logs the attacks resulted in the emergence of a new generation of beetles.

The addition of aspen or birch wood to the ethanol bait resulted in reduced catches of *T. piniperda*, *H. palliatus*, and *Rhizophagus depressus* (F.) (Coleoptera, Rhizophagidae) (Tables 4 and 5). The reduction in catch in the different experiments varied between 58% and 96% for *T. piniperda*, 8% and 87% for *H. palliatus*, and 44% and 90% for *R. depressus*. The difference in number of beetles caught between treatments with wood and treatments without wood was statistically significant at the $P = 0.05$ level in one experiment for *T. piniperda* and in five experiments each for *H. palliatus* and *R. depressus*.

In contrast to the species mentioned above, 1.6–3.4 times as many *Glischrochilus quadripunctatus* (L.) (Coleoptera, Nitidulidae), 2.7–8.3 times as many *Epuraea bickhardti*, 5.3–20 times as many *E. unicolor* (Oliv.) and about twice as many *Rhizophagus parvulus* (Payk.) were caught in the wood-baited traps as in the traps baited with ethanol alone. These differences were statistically significant for *G. quadripunctatus* in two experiments, for *E. bickhardti* in six

TABLE 3. MEAN NUMBER OF BEETLES CAUGHT PER STICKY TRAP ATTACHED TO HEALTHY, TOP-CUT, AND NEWLY CUT LOGS OF SCOTS PINE AND TO PLASTIC TUBES

Species	Host-tree species	Mean catch			
		Plastic tube	Healthy pine	Top-cut pine	Pine log
T. piniperda	Scots pine	2.2	1.5	3.9	31.4[a]
H. palliatus	Scots pine Norway spruce	3.9	4.0	4.1	10.6
H. brunneus	Scots pine	1.4	0.5	1.3	23.6[a]
H. cunicularius	Norway spruce	1.6	1.4	1.4	1.6
T. lineatum	Scots pine Norway spruce	0.9	1.9	0.9	2.5

		E. bickhardti	240	797	0.010	47
		E. unicolor	14	280	0.013	76

[a] Two-tailed paired-sample t test.

experiments, for *E. unicolor* in three experiments, and for *R. parvulus* in the only experiment in which this species was present.

In all but one case there was no significant (χ^2 test, $P < 0.05$) difference in sex ratio between beetles caught in treatments with wood and those without wood for any of the beetle species in any of the tests (Tables 4 and 5). The exception was *R. depressus* in experiment 6, where the female percentage was significantly lower in the wood baited treatment (58%) than in the treatment with ethanol alone (69%).

As a result of the lower mean air temperature, the field release rates of ethanol (Table 2) are considerably lower than those measured in the laboratory at 15°C. Rates of release were somewhat higher from dispensers placed in traps with wood than from dispensers in traps without wood: 24% higher in experiment 5, 12% higher in experiment 6, and 48% higher in experiment 7.

DISCUSSION

The present study shows that rejection of the nonhosts aspen and birch by the bark beetles *T. piniperda* and *H. palliatus* may be based on volatiles emitted from these tree species. Both aspen and European white birch are among the

[a]Two-tailed paired-sample t test.

most common of the broad-leaved tree species in Sweden. Furthermore, they are often found in mixed stands together with Norway spruce and Scots pine. Thus the probability of *T. piniperda* and *H. palliatus*, as well as other conifer bark beetles, encountering aspen and birch is quite high. An olfactory response allowing the beetles to quickly reject nonhosts after or just before landing would save them valuable time for colonizing suitable breeding substrate.

The much higher number of *T. piniperda* caught on the pine logs than on the healthy unattacked pine trees can be ascribed to the large amounts of host volatiles released from the initiated egg galleries (cf., Schroeder, 1987) and from the end surfaces of the logs cut just before the start of the beetle flight period. *T. piniperda*, *H. palliatus*, and some other scolytids were caught in low numbers on the plastic tubes, demonstrating that when searching for breeding substrate these species may also land on objects lacking characteristics specific to their host-tree species.

The decreased attraction of *R. depressus* to ethanol in the presence of aspen and birch wood demonstrates that beetles associated with bark- and woodboring species also may respond to volatiles from nonhost tree species. *R. depressus*

is a predatory species inhabiting the galleries of bark beetles such as *T. piniperda* and *H. palliatus* in Scots pine and Norway spruce (Nuorteva, 1956). *R. depressus* was earlier demonstrated to be attracted by the conifer monoterpene α-pinene and by ethanol (Schroeder and Lindelöw, 1989).

Substances causing insects to make oriented movements away from its source are termed repellents according to designations of Dethier et al. (1960). The response of beetles to wood alone was not tested in the present study. Hence, it was not possible to determine if wood of birch and aspen has a true repellent effect. Moreover, since no unbaited traps were included in the experiments, it was not possible to establish whether the traps baited with wood and ethanol caught lower numbers of bark beetles than what would have been caught in unbaited traps. Thus, "decreased attraction" is used to account for the observed results.

Only a few reports of release rates of ethanol from cut wood were found in the literature. No information on ethanol release rates from aspen or birch is available. Ikeda et al. (1980) reported a daily average ethanol release of 0.7 μl/kg from bolts of red pine, *Pinus densiflora*, during a 14-day period following cutting. This suggests that if any ethanol were formed in the wood used in the present study, the release rates should have been negligible compared with the amounts released from the dispensers.

The somewhat higher release rate of the ethanol dispensers in traps baited with wood was probably due to the heat-storing capacity of the wood. The rate of release of ethanol from the type of dispenser used in the present study increases with temperature. Thus, as temperatures fell in the evenings, heat stored in the wood could have acted as a temperature buffer, thereby preventing release rates from dropping as fast as in the dispensers in the treatments without wood. Nevertheless, the somewhat higher release of ethanol from wood-baited treatments could not have caused the lower catches of the two bark beetles and *R. depressus*. In previous dose–response field experiments with ethanol, the beetle attraction increased as release rates of ethanol were increased from 0.002 to 50.4 mg/24 hr for *H. palliatus* and from 0.002 to 3.1 mg/24 hr for *R. depressus* (Schroeder, 1988; Schroeder and Lindelöw, 1989). About the same numbers of *T. piniperda* were attracted by all release rates covered by the latter dose range.

The combination of birch or aspen volatiles and ethanol was more attractive than ethanol alone to the nitidulid beetles *G. quadripunctatus*, *E. bickhardti*, and *E. unicolor* and to the rhizophagid beetle *R. parvulus*. These species inhabit fungi-infected bark and galleries of bark- and woodboring insects (Nuorteva, 1956; Palm, 1959). *R. parvulus* and *E. unicolor* are found almost exclusively on broad-leaved trees, and *G. quadripunctatus* is common on both conifer and broad-leaved trees. *G. quadripunctatus* is also attracted by ethanol and α-pinene (Schroeder and Lindelöw, 1989). In contrast to the other species, *E. bickhardti*

has been recorded mainly from Scots pine and Norway spruce in Scandinavia, and only a few reports of this species from broad-leaved trees exist (Saalas, 1917; Nuorteva, 1956).

(Received January 17, 1992; accepted May 5, 1992)

Abstract—Several properties of the compound 3,4-dihydro-2H-pyrrole (Δ^1-pyrroline), which has been reported as a component of the male-produced Mediterranean fruit fly pheromone, have been determined by [^{1}H]- and [^{13}C]nuclear magnetic resonance spectroscopy. The stability of Δ^1-pyrroline in several solvents and at moderately elevated temperatures has been investigated, and it has been established that it exists as both a monomer and trimer in solution. Although equilibrium studies indicate that the trimer is thermodynamically more stable than the monomer in solution, only the monomer was found in the vapor phase based on infrared analysis.

Key Words—3,4-Dihydro-2H-pyrrole, pheromone, Δ^1-pyrroline, [^{1}H]NMR spectroscopy, [^{13}C]NMR spectroscopy, equilibrium, Mediterranean fruit fly, *Ceratitis capitata*, Diptera, Tephritidae.

INTRODUCTION

The Mediterranean fruit fly (medfly), *Ceratitis capitata* (Wied.), is considered to be one of the major economic pests of deciduous and tropical fruits in the world. Previous small infestations in California and Florida have resulted in

*To whom correspondence should be addressed.

[1]This article reports the results of research only. Mention of a proprietary product does not constitute an endorsement or recommendation for its use by USDA.

expensive eradication procedures that include the widespread release of large amounts of pesticide. The most effective monitoring tool available for the medfly is trimedlure (Beroza et al., 1961), and it is routinely used in California, Texas, and Florida. Trimedlure predominantly attracts males, although a small percentage of females do respond to this chemical (Nakagawa et al., 1970). In the wild it has been demonstrated that medfly males release a pheromone that attracts females for mating (Féron, 1962). Baker et al. (1985) identified nine volatile compounds emitted and/or extracted from sexually mature male Mediterranean fruit flies. The identified components included 3,4-dihydro-2H-pyrrole, (*E*)-2-hexenoic acid, dihydro-3-methylfuran-2(3H)-one, 2-ethyl-3,5-dimethylpyrazine, linalool, ethyl (*E*)-3-octenoate, geranyl acetate, (*E*,*E*)-α-farnesene, and ethyl acetate. It was claimed that the 3,4-dihydro-2H-pyrrole was active, but no data were reported to support pheromonal activity of this or other identified compounds. Subsequently, Jang et al. (1989) determined electroantennogram responses of male and female medflies to those nine compounds and to an additional 56 compounds collected from air passed over male medflies. Recently, we reported the qualitative and quantitative analyses of three principal components, ethyl (*E*)-3-octenoate, geranyl acetate, and (*E*,*E*)-α-farnesene, as volatiles emitted by laboratory-reared and wild male medflies during the photophase (Heath et al., 1991). Additionally, we synthesized these compounds, developed a method to formulate each of the compounds, and investigated the attractiveness of the pheromone blend to wild female medflies in the field.

Efforts to quantitatively collect and analyze the compound 3,4-dihydro-2H-pyrrole (Δ^1-pyrroline) released by male medflies were without success (see Baker et al., 1985; Jang et al., 1989). To further evaluate the potential synergistic effect of Δ^1-pyrroline to the existing three-component blend, it was apparent that additional knowledge of this compound would be required. The chemical characterization of Δ^1-pyrroline is complicated by the fact that in solution it irreversibly transforms to unknown compound(s) at temperatures less than 30°C above ambient conditions. Attempts to synthesize the material result in the isolation of a trimeric species of Δ^1-pyrroline and not the desired monomer (Nomura et al., 1977). Attempts to isolate the trimeric species in the gas phase for microwave or infrared analysis, however, fail, and only the monomer is observed in the gas phase (Edwards et al., 1985). It has previously been determined by [^{13}C]NMR spectroscopy that in dilute solution the monomer can be observed (Poisel, 1978). This suggests that there may be an equilibrium established in solution that can be characterized by a series of temperature dependent experiments.

In this work, the equilibrium of synthetic Δ^1-pyrroline with the trimer is established and characterized in DMSO-d_6. The stability of Δ^1-pyrroline in D_2O, $CDCl_3$ solutions, and neat was examined, and the thermal stability was deter-

mined in DMSO-d_6. GC-FTIR analysis confirmed the exclusive presence of the monomer in the vapor phase.

METHODS AND MATERIALS

Synthesis. The trimer of Δ^1-pyrroline was synthesized according to the procedure of Nomura et al. (1977). The final reaction mixture was light orange in color. The crude material was worked up with CH_2Cl_2 and ice water. The CH_2Cl_2 layer was washed with brine, dried overnight at 4°C over Na_2SO_4 and anhydrous K_2CO_3, filtered through a plug of Na_2SO_4–K_2CO_3, and the solvent was removed by rotary evaporation without heating. The last traces of solvent were removed by a stream of dry nitrogen resulting in a viscous, transparent orange oil. No impurities were observed in the NMR spectrum.

IR Spectra. Capillary GC-FTIR analysis was performed on neat Δ^1-pyrroline using a Hewlett-Packard model 5890 gas chromatograph (GC) equipped with a cool on-column injector and a Nicolet model 20SXC FTIR equipped with a light-pipe GC interface. Helium at a linear velocity of 18 cm/sec was used as the carrier gas, and a 30-m × 0.25-mm-ID Carbowax column was used for the analysis. Various oven temperature programs and light-pipe interface temperatures were used in an attempt to find both the monomer and trimer in the gas phase. The final analysis was performed using an isothermal oven program at 150°C with the interface temperature set at 210°C. A neat liquid analysis was also performed using NaCl plates.

NMR Spectra. NMR spectra were obtained on a Bruker AC-300 spectrometer equipped with an Aspect 3000 computer and a 5-mm dual $^1H/^{13}C$ probe. The operating frequency was 300.135 MHz for ^1H and 75.469 MHz for ^{13}C. Standard Bruker automated acquisition programs were used for all experiments. All one-dimensional spectra were from 64K data points. The spectral width for ^1H was set at 6024 Hz and for ^{13}C at 18519 Hz with acquisition times of 5.439 and 1.769 sec, respectively. The resolution of the spectra was 0.565 Hz per point for ^{13}C and 0.184 Hz/pt for ^1H. The numbers of scans for ^1H and ^{13}C were 16 and 128, respectively.

The initial spectra and assignments were obtained in $CDCl_3$ with solutions of 50 μl of sample dissolved in 0.35 ml of $CDCl_3$ with TMS as internal reference. The spectral assignments were based on ^1H and ^{13}C (^1H decoupled) chemical shifts, ^1H coupled ^{13}C spectra, ^1H–^1H coupling constants, proton-splitting patterns, and integrated proton intensities. The monomer absorptions could be distinguished from those of the trimer by their relative intensities. A DEPT analysis and ^{13}C–^1H HETCOR experiment were performed to confirm initial assignments. A thermal degradation study was performed with 100 μl of sample

dissolved in 0.4 ml of DMSO-d_6. The molal concentration scale was used for the equilibrium study. The solution was prepared with 0.052 g of sample dissolved in 0.44706 g of DMSO-d_6. A neat sample was analyzed using an 8-μl insert obtained from Wilmad (Buena, New Jersey). In order to determine the stability of the material in water, a series of experiments were conducted in D_2O over the course of several days.

For all temperature-controlled experiments (5°C increments), 20 min of equilibration time was allowed before data acquisition was initiated. After each 10-degree change in temperature, a ^1H spectrum was obtained after equilibration for an additional 30 min to confirm temperature stability.

RESULTS

GC-FTIR Analysis. Edwards et al. (1985) collected IR and microwave spectra of Δ^1-pyrroline vapor phase directly. They reported that no trimer could be detected in the gas phase. Our GC-FTIR analysis yielded the same results. Only the monomer was detected, and the spectra obtained in our analysis were identical to that of Edwards et al. The major absorptions for the gas sample were found at 2974.1, 2954.1, 1626.0, 1454.3, 1302.5, 1072.7, and 913.3 cm^{-1}. The major absorptions for the neat sample were 2956.3, 2872.4, 2785.6, 1673.8, 1458.7, 1393.1, 1338.9, 1233.2, 1206.3, 1194.7, 1178.7, and 1066.0 cm^{-1}. No overlap between the neat and gas phase spectra could be found.

NMR Analysis. The initial NMR spectral data for both the monomer and trimer are listed in Table 1 with specific assignments found in Figure 1. The carbon spectra contained eight absorptions supportive of the presence of both

monomer and the assumed trimer of point group C_3. Nomura et al. (1977) reported only four ^{13}C resonances (20 MHz in $CDCl_3$) at 81.96, 45.79, 27.96, and 20.37 ppm. These are in agreement with our findings for the trimer. Initial small variations in absorption intensities with temperature indicated that the two species were in equilibrium. A neat sample was prepared in a capillary insert and ^{13}C spectra were recorded. There were only four absorptions present. If the absorption of lowest ppm magnitude in the neat sample is aligned with the trimer absorption at 20.33 ppm in $CDCl_3$, then the other three neat absorptions align with those of the trimer with a root mean square (RMS) difference of only 0.6 ppm. Based on this observation, the neat material is essentially purely trimer.

The material has been reported to be unstable in solution at moderate temperatures (Nomura et al., 1977). In order to determine the thermal stability, a sample was prepared in DMSO-d_6. The chemical shifts were identical to those observed in $CDCl_3$. The sample was studied at 5-degree increments from 295 to 340°K. From 295 to 320°K, only the original eight ^{13}C absorptions were apparent. The trimer absorptions decreased in intensity with increasing temperature, and the monomer absorptions increased for both ^{13}C and ^1H spectra. At 325°K, several additional low-intensity ^{13}C absorptions become evident. At 335°K numerous ^{13}C absorptions were apparent, and by 340°K the trimer ^{13}C absorption at 27.95 ppm was not detected. After cooling at ambient temperature for 16 h the pattern of ^{13}C absorptions observed at 340°K remained. From this experiment the original observation that the material is not stable at elevated temperatures is substantiated. The maximum temperature at which equilibrium is maintained without degradation was determined to be 320°K (47°C).

In order to establish the equilibrium and thermodynamic constants for the material, an equilibrium study was performed in DMSO-d_6 from 294 to 320°K. The integrated ^1H intensities for both trimer and monomer were tabulated for

the protons adjacent to the nitrogen (7.61 and 3.85 ppm for monomer; 3.01 and 2.32 ppm for trimer) and used to establish the ratio of monomer to trimer in solution. The preequilibrium concentration of trimer was $[T_i]$ = (0.5618 mol trimer)/(kg solvent) based on the fact that the neat material is $\approx 100\%$ trimer. Using the concentration ratio from experiment $[T_i]$, and the mass balance relationship between monomer and trimer (1 mol trimer $\rightarrow$ 3 mol monomer) allows the concentrations of monomer and trimer to be determined. The equilibrium constant can then be calculated at each temperature as $K_{eq}(T) = [M]^3/[T]$ where $[M]$ is the molal concentration of the monomer and $[T]$ is the molal concentration of the trimer. Using the standard thermodynamic relationships $\Delta G = RT \ln [K_{eq}(T)] = \Delta H - T\Delta S$ and assuming the changes in enthalpy and entropy are constant with temperature over the experimental range studied, the experimental data can be fitted to a linear model. The modeled enthalpy change is ΔH = 22.004 kcal/mol trimer. The modeled entropy change is ΔS = 0.0678 kcal/(mol-degree) trimer. The correlation coefficient for the fitting is 0.9827, and the data are tabulated in Table 2.

An attempt to study the rate of conversion from monomer to trimer was performed. The same sample used to perform the equilibrium study was equilibrated at 320°K and immediately cooled to 300°K and ^{1}H spectra were initiated. All spectra obtained at successive times were identical to the initial spectra, indicating that the reaction from excess monomer to trimer was faster than could be measured.

The stability of the material with time was also studied in the solvents used for analysis. These samples were maintained at laboratory ambient conditions

in 5-mm NMR sample tubes. They were not degassed, and the tubes were loosely covered with plastic NMR caps. Under these conditions solvent could escape and air could enter the tube. The volume of air to sample was approximately 10:1. Samples prepared in $CDCl_3$ showed no changes with time over the course of several weeks. A sample in DMSO-d_6 was stable during the four days it was used to record the thermodynamic and kinetic studies. However, analysis of the DMSO-d_6 solution after a three-week period resulted in the detection of approximately 20 additional ^{13}C absorptions. By the fourth week 30 absorptions were indicated, and the intensities of the new absorptions were of the same magnitude as those assigned to the monomer and trimer. In D_2O, the ratios of the intensities of the original carbon absorptions declined over the course of four days with the occurrence of several new ^{13}C absorptions. After two weeks, the trimer absorption at 27.95 ppm and the monomer absorption at 36.65 ppm were no longer observed. These two absorptions originate from the same carbon in the monomer and trimer. On the surface of the degraded samples, a rigid layer developed, suggesting that some type of polymerization occurred. The neat sample was stable with time at ambient temperature.

DISCUSSION

The purpose of this study was to characterize Δ^1-pyrroline so that mechanisms for a controlled release of volatiles could be developed and new test methods for analysis could be suggested. This has been accomplished. Δ^1-Pyrroline in neat form is stable and exists purely in the trimeric form. Although the neat material is purely trimer, only the monomer is found in the gas phase. This suggests that Δ^1-pyrroline can be formulated for release as neat material in capillary tubes similar to that described by Heath et al. (1991). The release rate is dependent on the diameter of the capillary and the height of the vapor–air column above the liquid (Weatherston et al., 1985).

The currently available methods often used for quantifying Δ^1-pyrroline involve the use of reagents that have a very short shelf life to form a stable oxidized derivative of Δ^1-pyrroline that is finally analyzed by GC (Sakamoto and Samejima, 1979). This method is not practical for the routine analysis of many samples, as is often the case with material collected in collaborating laboratories. Equilibrium between the monomer and trimer was established in all three solvents studied, and at the concentrations used for NMR analysis, the trimer was the predominant species. Since the equilibration of monomer and trimer is essentially instantaneous, we are developing techniques for direct chromatographic analysis of Δ^1-pyrroline that has been extracted from collections made using absorbent material. The present analysis indicates, however, that although water may be used for an extraction solvent, the short shelf life of

Δ^1-pyrroline in water would demand chromatographic analysis within one day of extraction. Although Δ^1-pyrroline is thermally unstable in solution, ambient temperatures are below the threshold of rapid degradation. The analysis of field-collected medfly pheromone and the formulation of synthetic medfly pheromone are currently under investigation.

(Received December 4, 1991; accepted May 6, 1992)

Abstract—Studies of chemical ecology of an organism are founded on the isolation and identification of a semiochemical, often comprised of two or more synergistic compounds (each synergist alone has little activity, but presented together they are bioactive). Chromatographic fractionation and bioassay methods of binary splitting, additive combination, and subtractive combination are compared for efficiency in isolating synergists. Formulas are derived for the latter two methods that calculate the expected number of bioassay tests required for isolation of from two to five synergists from biological extracts with any number of compounds, depending on the number of initial (major) chromatographic fractions. A computer program based on the formulas demonstrates the superiority of the subtractive-combination method. Simulations with the program were used to determine the optimal number of initial fractions for the additive- and subtractive-combination methods when isolating two to five synergists from extracts of from 25 to 1200 compounds. Methods of bioassay, isolation, identification, and field testing of semiochemicals are discussed.

Key Words—Pheromone, semiochemical, behavioral bioassay, chemical isolation, gas chromatography, chemical fractionation, synergist.

INTRODUCTION

Biological studies of olfactory perception, receptor biochemistry, pheromone biosynthesis, orientation behavior, and communication as well as many other areas require the use of the purified semiochemicals. Chemical ecology, in fact, is founded on the identification of chemicals that mediate the behavioral or

0098-0331/92/0900-1603$06.50/0 © 1992 Plenum Publishing Corporation

physiological phenomena. The first step, however, is not the identification of the chemicals present in extracts of organisms but rather observation of the behavioral or physiological changes induced by chemical emissions in a virtually natural environment. For example, a specific mating behavior that appears to be elicited by odors from others of the species would indicate the presence of a pheromone. The next step is development of a bioassay, which consists of describing a consistent set of behavioral reactions and movements stimulated by the release of a suspected pheromone under controlled conditions. The third step is then the isolation and identification of the chemicals comprising the pheromone. Most aggregation or sex pheromones of insects consist of two or more compounds that alone have moderate or no activity but released together are synergistic in eliciting maximum behavioral response (Silverstein and Young, 1976; Silverstein, 1981; Cardé and Baker, 1984; Byers, 1989). In Figure 1, a hypothetical chromatogram is shown of an insect extract in which three pheromone components (synergists) are depicted as eluting differently. The problem is to find efficient methods for locating them for subsequent chemical identification.

Behavioral tests (bioassays) can be coupled to chemical separation tech-

niques and fractionation of biological extracts with several methods. One common method could be described as binary splitting. The extract is fractionated into two parts and each tested for activity. This method either assumes that only one compound is active or that all active compounds are found in one fraction—so it would not work well for synergists. However, a variation could be used as in Figure 1, where successive binary fractionation would be tested in combination with other active fractions using a combinative scheme. This method will be discussed subsequently.

Another scheme, developed in the 1960s during the pioneering isolation of bark beetle pheromones, is here called the additive-combination method (Silverstein et al., 1966, 1967, 1968). In principle, the method uses chromatography, for example, gas chromatography (GC), to separate chemicals as they elute sequentially into fractions. The fractions then can be recombined and tested for behavioral activity in a bioassay. Silverstein et al. (1967) drew attention to the "notable feature" of the pheromone isolation work on the North American bark beetle, *Ips paraconfusus*, where attractant activity disappeared upon fractionation but reappeared upon recombination of appropriate fractions. They state that "no fraction can be discarded until it has been tested in combination with the other fractions." The exact methodology is unclear, but it can be assumed that all fractions would be tested individually first, then in two-way combinations, then three-way, and so forth in an additive-combination procedure. This method has been used on other important beetle species for isolation of their pheromone components: western pine beetle, *Dendroctonus brevicomis* (Silverstein et al., 1968), smaller elm bark beetle, *Scolytus multistriatus* (Pearce et al., 1975), and flat grain beetle, *Cryptolestes pusillus*, (Millar et al., 1985). However, because of the large number of combinations possible, relatively few other studies have attempted isolation of components using the additive-combination method due to the work involved.

A third method, subtractive-combination, also assumes that synergistic fractions must be tested in combination, but instead of combining smaller numbers of fractions together, it subtracts fractions from the whole blend of fractions. In 1976 L.E. Browne, while at the University of California, Berkeley, proposed that this method would be more efficient than the established method of additive combination of fractions (personal communication). My colleagues and I later used the subtractive-combination method for isolation of host (Scots pine) attractants of the pine shoot beetle, *Tomicus piniperda*, of Europe (Byers et al., 1985). However, the subtractive method was first used for isolation of synergistic pheromone components on the smaller spruce engraver of Europe and Asia, *Pityogenes chalcographus*, where a pheromonal structure not previously known for bark beetles, methyl (*E*,*Z*)-2,4-decadienoate, was identified (Byers et al., 1988, 1989, 1990a).

The objective of this paper is to describe and compare the three methods,

especially the additive-and subtractive-combination methods. The question is which of the methods is most efficient in terms of number of bioassay tests required and number of passes of compounds through the chromatograph. Assuming two fractionations, mathematical formulas will be derived for both the additive- and subtractive-combination methods that describe the probabilistic number of tests that would be required to ensure isolation of all active components given: (1) the number of fractions of the extract on the first fractionation, (2) the number of synergistic components, and (3) the number of total compounds in the extract. A computer program that uses the formulas will determine the optimal number of initial major fractions, which depends on the number of total compounds in the extract and the number of synergists.

METHODS AND MATERIALS

Descriptive examples of binary splitting and additive- and subtractive-combination procedures are presented to explain the methodology used for each. Hypothetically, an extract consisting of 20 compounds can be passed through a gas chromatograph (GC) resulting in the "chromatogram" shown in Figures 1 and 2. It is assumed that the third, fifteenth, and nineteenth eluting compounds are active only in synergism. The first method of binary splitting of fractions is outlined in Figure 1. Fractions A and B alone are not active; the conclusion is that both have synergists. Fraction A is divided into C and D and these fractions are combined with B in order to isolate the active compounds in A (Figure 1). Fraction C is active, D is not active, and further splitting of C into E and F (active), then F into I (active) and K, and finally I into L (active) and M reveals that L is a synergist. Fraction B is then fractionated similarly, with fractions tested with L (Figure 1) until the active compounds S and Y are found.

The second method, additive combination (Figure 2), fractionates the extract initially into four major fractions A–D. These are tested alone (none active), in binary combinations (none active) and then tertiary combinations (only ACD active). Next, fraction A is fractionated into five fractions and each tested with fractions C and D—showing that compound G is active. The same procedure is done with major fraction C, combining each minor fraction with G to find compound S active. Initially, major fraction D is fractionated and these minor fractions combined with G and S to find compound W active.

The third method, subtractive combination (Figure 2), also fractionates the extract into four initial fractions A–D, but the fractions are combined into four blends each with one of the fractions not present (subtracted). Since the removal of fraction B had no effect on the activity, it is concluded that this fraction does not contain synergists. Fractions A, C, and D when subtracted from the blend resulted in a loss of activity, so each has synergists. Fraction A is fractionated

into five fractions, which are combined and tested with major fractions C and D in five tests, with a different minor fraction subtracted. Subtraction of minor fraction G results in a loss of activity, indicating that compound G is a synergist. Similar fractionation and testing of major fraction C with D and G shows S active, and fractionation of D reveals that W is active.

Using the schemes shown in Figure 2, two equations (1 and 2, see Results) were derived that describe the number of bioassay tests that are required to ensure that all possible bioactive compounds are isolated using the additive- or subtractive-combination methods. The formulas assume that the extract is fractionated once into any number of major fractions (from two to the number of compounds), that these fractions are bioassayed, and that any of the indicated active fractions are fractionated into individual compounds (the second fractionation). The two formulas, however, are somewhat unrealistic since most insects

do not have any number of possible synergists but usually from two to five. It also must be considered that the active compounds will have various probabilities of being together or separated in the major fractions depending on (1) the number of synergists, and (2) the number of these fractions.

Formulas were derived that describe the probabilities of from two to five synergistic compounds being contained together, each separate, or in various combinations given any number of initial major fractions (see Results). The probabilities that all synergists elute together or separately were obtained from McCall (1970). The combinatorial notation used here is the following:

$$\text{All combinations of three things selected from five} = C_3^5 = \frac{5!}{3!(5-3)!} = 10$$

$$\text{All permutations of three things selected from five} = P_3^5 = \frac{5!}{(5-3)!} = 60$$

The probability formulas were combined with equations 1 and 2 (Results) for calculating the number of bioassay tests for the additive- and subtractive-combination methods. The resulting formulas, shown in Table 1, describe the expected number of tests that would be required to isolate from two to five synergists for any number of initial major fractions, the indicated number of bioactive major fractions, and for any number of compounds in the extract. The formulas were implemented in a BASIC language computer program (output shown in Figure 3). The program was used to obtain the expected number of tests required to isolate from two to five synergists in an extract of 60 compounds (Figure 4), or three synergists in extracts of 60–240 compounds (Figure 5), for each method. The program also generated the expected tests required to isolate two to five synergists from extracts of 25–1200 compounds (in steps of 25) using fractionations of 3–80 major fractions (fraction simulation run) for a total of 77 $\times$ 48 $\times$ 4 = 14,784 comparisons for each method. The minimum values for each fraction simulation run (total of 48 $\times$ 4 = 192) for each method, which are the optimal number of major fractions, were plotted in Figure 6 using geometric least-squares regression.

RESULTS

In Figure 1, the binary splitting method required 23 tests to isolate, in theory, the three synergists, compounds L, S and Y. The additive-combination method required 30 tests to isolate the three synergists, while the subtractive-combination procedure needed only 20 tests (Figure 2). However, the binary splitting method required 11 GC fractionation passes, while the additive- and subtractive-combination needed only two GC passes (at most four passes if each active fraction is fractionated separately).

TABLE 1. EXPECTED NUMBER OF BIOASSAY TESTS REQUIRED FOR ISOLATION OF TWO TO FIVE SYNERGISTS IN EXTRACTS OF ANY NUMBER OF COMPOUNDS (n) AND WITH INITIAL FRACTIONATION INTO ANY NUMBER OF FRACTIONS (f)[a]

Two synergists

$$\text{Additive-combination tests} = 1 + p_2 C_1^f + p_{1+1} \sum_{i=1}^{2} C_i^f + p_2 \sum_{i=1}^{2} C_i^n + p_{1+1} 2C_1^n$$

$$\text{Subtractive-combination tests} = 1 + f + p_2 C_1^n + p_{1+1} 2C_1^n$$

Three synergists

$$\text{Additive-combination tests} = 1 + p_3 C_1^f + p_{2+1} \sum_{i=1}^{2} C_i^f + p_{1+1+1} \sum_{i=1}^{3} C_i^f + p_3 \sum_{i=1}^{3} C_i^n + p_{2+1} \left[\sum_{i=1}^{2} C_i^n + C_1^n \right] + p_{1+1+1} 3C_1^n$$

$$\text{Subtractive-combination tests} = 1 + f + p_3 C_1^n + p_{2+1} 2C_1^n + p_{1+1+1} 3C_1^n$$

Four synergists

$$\text{Additive-combination tests} = 1 + p_4 C_1^f + p_{3+1} \sum_{i=1}^{2} C_i^f + p_{2+2} \sum_{i=1}^{2} C_i^f + p_{2+1+1} \sum_{i=1}^{3} C_i^f + p_{1+1+1+1} \sum_{i=1}^{4} C_i^f +$$

$$p_4 \sum_{i=1}^{4} C_i^n + p_{3+1} \left[\sum_{i=1}^{3} C_i^n + C_1^n \right] + p_{2+2} \left[\sum_{i=1}^{2} C_i^n + \sum_{i=1}^{2} C_i^n \right] + p_{2+1+1} \left[\sum_{i=1}^{2} C_i^n + 2C_1^n \right] + p_{1+1+1+1} 4C_1^n$$

$$\text{Subtractive-combination tests} = 1 + f + p_4 C_1^n + p_{3+1} 2C_1^n + p_{2+2} 2C_1^n + p_{2+1+1} 3C_1^n + p_{1+1+1+1} 4C_1^n$$

Five synergists

$$\text{Additive-combination tests} = 1 + p_5 C_1^f + p_{4+1} \sum_{i=1}^{2} C_i^f + p_{3+2} \sum_{i=1}^{2} C_i^f + p_{3+1+1} \sum_{i=1}^{3} C_i^f + p_{2+2+1} \sum_{i=1}^{3} C_i^f +$$

$$p_{2+1+1+1} \sum_{i=1}^{4} C_i^f + p_{1+1+1+1+1} \sum_{i=1}^{5} C_i^f + p_5 \sum_{i=1}^{5} C_i^n + p_{4+1} \left[\sum_{i=1}^{4} C_i^n + C_1^n \right] + p_{3+2} \left[\sum_{i=1}^{3} C_i^n + \sum_{i=1}^{2} C_i^n \right] +$$

$$p_{3+1+1} \left[\sum_{i=1}^{3} C_i^n + 2C_1^n \right] + p_{2+2+1} \left[2 \sum_{i=1}^{2} C_i^n + C_1^n \right] + p_{2+1+1+1} \left[\sum_{i=1}^{2} C_i^n + 3C_1^n \right] + p_{1+1+1+1+1} 5C_1^n$$

$$\text{Subtractive-combination tests} = 1 + f + p_5 C_1^n + p_{4+1} 2C_1^n + p_{3+2} 2C_1^n + p_{3+1+1} 3C_1^n + p_{2+2+1} 3C_1^n + p_{2+1+1+1} 4C_1^n + p_{1+1+1+1+1} 5C_1^n$$

[a] The probabilities of various combinations of synergists occurring together in fractions are represented as p_{1+1} etc. (see Results). The letter C represents the notation for combinations (see Methods and Materials).

FIG. 3. Output of a computer program that calculates the tests required to isolate the number of synergists entered (4) for the number of compounds entered (200) for up to 100 major fractions (N) for the subtractive-combination and additive-combination methods. The columns headed by P:4, P:3 + 1, etc., represent the probabilities that all four synergists occur in one fraction, or three synergists in one and the other in another fraction, respectively.

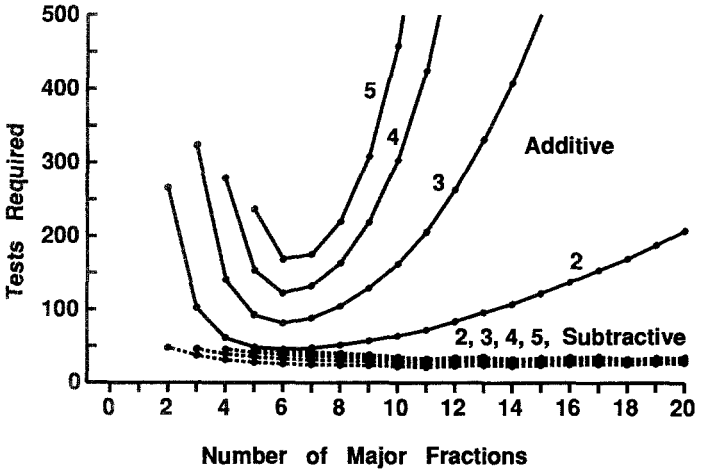

FIG. 4. The number of tests required to isolate from two to five synergists from an extract with 60 compounds with either the additive- or subtractive-combination methods, depending on the number of major fractions.

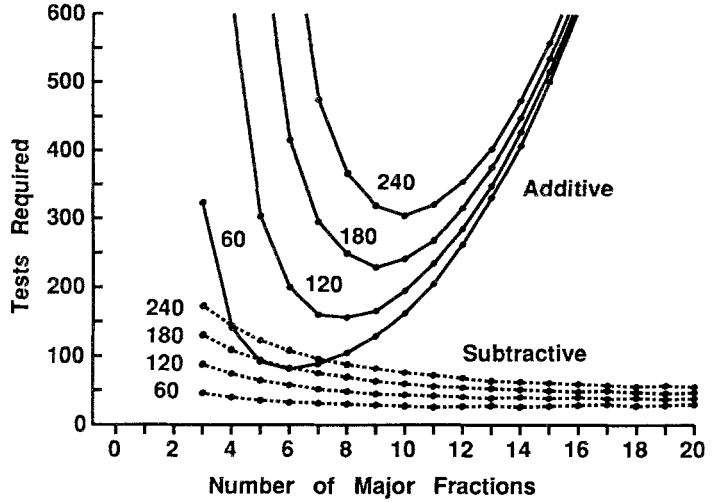

FIG. 5. The number of tests required to isolate three synergists from extracts with 60–240 compounds with either the additive- or subtractive-combination methods, depending on the number of major fractions.

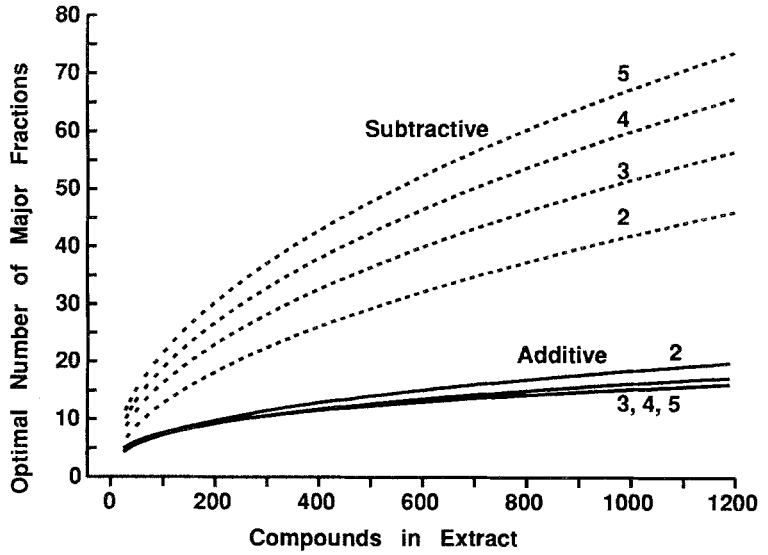

FIG. 6. The optimal number of major fractions for isolation of from two to five synergists from extracts with up to 1200 compounds using either the additive- or subtractive-combination methods.

The required number of tests to ensure the identification of all possible synergists using the additive-combination method and two fractionations is given by the following formula:

$$Tests = 1 + \sum_{i=1}^{a} \frac{f!}{i!(f-i)!} + a \sum_{i=1}^{v} \frac{v!}{i!(v-i)!} \quad (1)$$

where f = number of major fractions of the first fractionation, a = number of active major fractions, and v = average number of compounds per major fraction. The required number of tests to ensure identification of any number of possible synergists using the subtractive-combination method and two fractionations is:

$$Tests = 1 + f + v + a \quad (2)$$

The above formulas for calculating the number of bioassay tests assumes there is no limit on the number of synergists, since this is something that is not known prior to the study. However, it can be assumed that most studies of insect pheromones will encounter no more than two to five synergists responsible for a particular behavior. Thus, probabilities must be derived for the expected distribution of synergists among the major fractions. Intuitively, if the number of major fractions is small and the number of synergists is five, then the probability that several synergists would occur together in one fraction is large. If the number of fractions is large, then the probability is larger that each synergist is found alone in a fraction.

In the case of two synergists, they can occur either together in one fraction or each alone in a fraction. For three synergists there are three possibilities, each alone (1 + 1 + 1), two together and one alone (2 + 1) and all together (3). Four synergists can occur in five ways, (1 + 1 + 1 + 1), (2 + 1 + 1), (3 + 1), (2 + 2), and all together (4), assuming there are at least four fractions. Five synergists may be distributed in seven ways, (1 + 1 + 1 + 1 + 1), (2 + 1 + 1 + 1), (3 + 1 + 1), (4 + 1), (2 + 2 + 1), (2 + 3), and all together (5). The probability (p) that synergists occur each alone in a fraction is given by formula (a) below. The formula for the probability that all synergists occur together in a fraction is given in (b).

$$\frac{P_r^f}{f^r} \quad \text{(a)} \qquad \frac{P_1^f}{f^r} \quad \text{(b)}$$

where f is the number of major fractions and r is the number of synergists (P represents permutations). The probability that the synergists are distributed as (j + 1), (j + 1 + 1) or (j + 1 + 1 + 1), where j is 2, 3, or 4, is given by the general formula in (c), while the probability of the synergists occurring as (j + 2) is given in (d) below.

$$\frac{C_j^r P_k^{f-1} f}{f^r} \quad \text{(c)} \qquad \frac{C_j^r P_2^f}{f^r} \quad \text{(d)}$$

where C represents combinations, r is as above and k is the number of synergists alone (e.g., 1–3). For synergists distributed as (2 + 2), the probability can be calculated from equation (e) below. Finally, the probability that the synergists could be distributed as (2 + 2 + 1) is given by equation (f) below:

$$\frac{\frac{C_2^r P_2^f}{2}}{f^r} \quad \text{(e)} \qquad \frac{\frac{C_2^r C_2^f P_2^f}{2}}{f^r} \quad \text{(f)}$$

The probability formulas (a-f) above can be used with equations 1 and 2 to calculate the expected number of bioassay tests required to isolate from two to five synergists, for any number of major fractions, and for any number of compounds in the extract for the additive- and subtractive-combination methods (see Table 1). Output of a computer program (Figure 3) using the equations of Table 1 shows that the expected number of tests needed to isolate four synergists from an extract of $n = 200$ compounds and $f = 7$ major fractions with the additive method is 788 while the subtractive method requires only 101 tests.

The computer program was used to vary the number of major fractions and calculate the number of tests required to isolate from two to five synergists in an extract of 60 compounds for each method (Figure 4). From Figure 4 it can be seen that the minimum number of tests is most likely to occur at about six major fractions for the additive-combination method, while the minimum for the subtractive-combination method is ill-defined but occurs with higher numbers of major fractions. It is clear that in all cases the subtractive-combination method requires less tests than the comparable conditions with the additive method (Figure 4). The effect of varying the number of compounds in the extract when attempting to isolate three synergists is seen in Figure 5. Again there are optimal numbers of major fractions, i.e., for higher number of compounds in the extract the optimal number is larger. Again, however, in all cases, the subtractive-combination method is superior since it requires fewer biological tests.

The results of finding the minimum tests needed to isolate from two to five synergists for fractionations with from a few to 80 major fractions, for extracts from 25 to 1200 compounds, is shown in Figure 6. As the number of compounds per extract increases, the optimal number of major fractions increases for both methods. The number of synergists has little effect on the optimal number of fractions for the additive method, while an increasing number of synergists requires an increasing number of fractions for the subtractive method (Figure 6).

DISCUSSION

In regard to insect semiochemicals, there are two major bioassay methods in use today for isolation of components: (1) electrophysiological and (2) behavioral. The electronic recording of voltages at the electroantennogram, single-sensillum, or single-cell level has the advantage that it is consistently reproducible and more quantitative than behavioral observations. On the other hand, behavioral tests by their very nature are more descriptive of the actual phenomena of interest. Single-sensillum and single-cell electrophysiological recordings are dependent on the neuronal entities being tested. Of the literally thousands of sensillar cells on an insect (e.g., locusts: Greenwood and Chapman, 1984; Blaney and Simmonds, 1990), it is quite possible that various sensilla involved in a particular behavior could be overlooked and thus not probed. For example, in the moth, *Agrotis segetum*, of the receptor cells responding to one of the three pheromone components, only 2% were specialized to the Z9–14 : Ac component (Van Der Pers and Löfstedt, 1986).

Another disadvantage is that some insects such as locusts (Blaney and Simmonds, 1990) and bark beetles (Dickens et al., 1985; Lanne et al., 1987) contain either many generalist receptors or (more likely) many different kinds of more specialized receptors, since many chemicals elicit voltage potentials in the electroantennogram. This makes it more difficult to determine the importance of candidate chemicals to a specific behavior. Furthermore, synergism among pheromone components is not generally observed at the peripheral, antennal level, but in the realm of the brain (Mustaparta et al., 1980; cf. Byers, 1989; cf. Baker, 1989). The electrophysiological techniques thus are not truly rigorous when it comes to isolation of a pheromone that is usually a blend of synergistic chemicals (Silverstein and Young, 1976; Silverstein, 1981).

Using a computer program (Byers, 1992), I searched the titles, key words, and abstracts of all articles in the *Journal of Chemical Ecology* in 1990 (281 papers downloaded from BIOSIS Previews). Of the 182 papers on insects (65%), about 93 studies identified compounds in biological extracts. Of these papers, 34 studies primarily described chemicals found in extracts without ascribing bioactivity to individual compounds (e.g., Brown et al., 1990), eight studies used a combination of GC and electroantennogram (EAG) methods (e.g., Millar et al., 1990), while 51 studies identified one or more compounds and reported their biological activity. However, the majority of these latter studies appear to have selected compounds for bioassay based on whether they were: (1) major constituents of the extract (e.g., Riba et al., 1990; Sreng, 1990), (2) unique to male or female (e.g., Duffield et al., 1990), or (3) previously known to have activity in other species (e.g., Briggs, 1990). Thus many of these studies can be criticized as being biased since they do not treat all compounds equally but single out certain ones for special treatment—with the probability that many

ecologically relevant compounds are overlooked (until possibly a later study). Less than half the studies fractionated extracts, and it appears that very few reports used additive- or subtractive-combination methods to rigorously test for synergists. A search of all 281 papers also found that only 12 mentioned synergist, synergism, or synergistic. Of these, only six papers actually identified chemicals (2%)—three used additive or subtractive fractionation methods and three used comparative methods. Therefore, this indicates there is a need for a better understanding of the rationale and methods for isolation of semiochemicals so that more rigorous and complete studies can be done in the future.

The binary splitting method of fractionation has been used since the beginning of isolation studies. The fractions were not always split in two equal parts but into two solvent fractions with different polarities, or each "active" fraction was successively fractionated (e.g., Imai et al., 1990). The general assumption was that one chemical was responsible for the biological phenomenon (or alternatively that all synergists would fortuitously be contained in one fraction). This assumption is evident in work on isolation of insect host stimulants (e.g., in 1985: Dicke et al., 1985; Stubbs et al., 1985; McKibben et al., 1985; and in 1990: Shu et al., 1990) and ovipositional stimulants (e.g., in 1985: Maeshima et al., 1985; Kim et al., 1985; Hanula et al., 1985; and in 1990: Honda, 1990; Takahashi et al., 1990). The bioassay problem with host stimulants is not as severe as with pheromone components since quite often the former each have significant activity alone, although additive. Many times researchers have assumed, often correctly, that the chemicals with the largest quantities were bioactive, e.g., in isolation of locust pheromones (Nolte et al., 1973; Fuzeau-Braesch et al., 1988). The lack of tests for synergism may be one reason that locust pheromones have yet to be identified satisfactorily (cf. Byers, 1991).

With the finding that most insect pheromones consisted of two or more synergists, it becomes necessary to modify the binary method as in Figure 1. However, I was unable to find any use of the modified binary method in articles in the *Journal of Chemical Ecology*. The method is efficient in terms of bioassay tests required (Figure 1), but the large number of chromatographic passes (e.g., 11) is a disadvantage. At present, most insect pheromones are isolated with the use of GC, and multiple passes often cause the loss of biological activity due to gradual thermal breakdown of the compounds and to their adsorption on glass walls and chromatographic packing.

The additive- and subtractive-combination methods are both efficient in terms of fewer chromatographic passes (e.g., two to four passes, Figure 2). However, the subtractive-combination method requires fewer tests to isolate from two to five synergists in all possible ways to initially fractionate (Figure 4). There also is very little difference in the number of required tests regardless of the number of synergists that must be isolated, in contrast to the additive method where large differences occur (Figure 4). The number of compounds in

the extract affects the number of tests required in both methods, but the effect is much larger with the additive method (Figure 5).

The inflection points (troughs) in the curves are the optimal fractionation numbers, and they have been used in the power regressions in Figure 6. It is apparent that for the additive method there should be no less than five major fractions and no more than about the optimal number. For the subtractive method, the number of major fractions is not too important above five fractions. The optimal number (Figure 6) is, in fact, not critical since the curves are almost flat (Figure 5). The chemist must compromise between what is reasonable to fractionate (lower number of fractions) and the optimal number (usually a higher number). Of course, extracts with compounds that substitute for one another in activity will require fewer tests (with any method) to find a blend that is competitive in nature.

One of the more commonly used techniques for isolation of semiochemicals is called "differential diagnosis" (Vité and Renwick, 1971). With this method, the chemical elution patterns from the GC are compared between the sexes for unique differences. For example, the compounds found in male *Ips paraconfusus*, and which were not in the female, would be obtained commercially, by synthesis, or by up-scaling the isolation and then tested in the field. However, there are three major problems with this approach: (1) a unique pheromone component may not be discriminated from other compounds with the present GC column, (2) a pheromone component may be present in both sexes (e.g., *cis*-verbenol in *I. paraconfusus*; Renwick et al., 1976) and (3) the pheromone may consist of synergistic components, some of which are not unique or distinguishable, so that an incomplete blend would be tested with consequent failure to observe full activity.

In spite of these restrictions, the differential diagnosis method has allowed isolation of many pheromone components with a minimum of work, albeit with the consequence of some incomplete blends. Differential diagnosis can be used in conjunction with the subtractive-combination method. For example, Byers et al. (1990a) used subtractive tests to isolate two synergistic pheromone components of *P. chalcographus*, but one of the synergists could not be resolved from coeluting compounds on the GC column used. Thus the fraction, and adjoining fractions, containing the synergist (bioassay activity) was passed through a second GC column of different polarity in order to separate the compounds differently and obtain new fractions. Subtractive tests with the new fractions located the synergist in one of the fractions. Differential diagnosis using GC-MS extracted ion current profiles then was used to compare the two fractions with bioassay activity from both GC columns to pinpoint the synergist that was common to both of the fractions.

In addition to chromatographic fractionation or differential diagnosis in conjunction with behavioral or electrophysiological bioassay, there is the widely

used method of screening chemicals. The idea is to test previously identified pheromone components of closely related species on the species of interest (Booij and Voerman, 1985). This method is obviously the least rigorous of all but still can yield information, albeit often incomplete, on the pheromone components of a species. Of course the method relies on the use of the more rigorous chemical-fractionation and bioassay methods to identify the components in other related species. The screening method can be used in conjunction with chemical analyses of the insect to narrow the range of possibilities.

One problem with the screening method, and to a lesser extent with all methods, is that the quantities of component release must be close to natural rates in order to obtain an appropriate biological effect. Otherwise it is possible to either have too little (no response) or too much (confusion, inhibition, disruption). The ratio of the synergistic components may be very important as in the case of the *E* and *Z* isomers of straight chain hydrocarbons in moths (e.g., *Argyrotaenia velutinana*, Baker et al., 1976) or much less critical as in some bark beetles (*D. brevicomis*, Byers, 1988; *I. typographus*, Schlyter et al., 1987). De Jong (1987) describes a "direct search" method for determining the best blend of components given that the components are already identified. It is generally accepted that the optimal blend of components is that which approximates the ratio emitted by the organisms in nature (Cardé and Baker, 1984).

During the isolation study, or even when screening is done, the chemical amounts released should be known. The release rates of components in an extract or solvent fraction should be adjusted so that they reproduce approximately the rates of natural release that have been shown to be active. The diffusion-dilution method, where chemicals are released according to their mole percent in the solvent and the dimensions of the holding tube, is useful for laboratory and field bioassay (Byers, 1988). Other methods of adsorbents—wicks, capillary tubes, and semipermeable plastic membranes—have been used (cf. Byers, 1988; and review papers in Jutsum and Gordon, 1989; and Ridgway et al., 1990). Bengtsson et al. (1990) discusses a method for estimating the release of volatiles from adsorbents based on their vapor pressure.

Once the semiochemical components have been isolated and identified in the laboratory, it is important to verify their activity in the field. Ideally, the release rate should parallel the expected or measured rates of natural release (Byers et al., 1985). Usually, however, a range of rates that are expected to overlap the natural rate are used (Schlyter et al., 1987; Byers et al., 1988). As the release rate is increased, there is a point when activity begins (e.g., catch increases above the control), and this rate is assumed to be similar to the natural one. Of course, it is possible to erroneously conclude that a compound has activity when it does not if the compound is released at such high levels that minor impurities (such as pheromone components) elicit the behavior.

Field tests to confirm the activity of isolated semiochemical components

are also sometimes difficult to interpret due to the natural variation in population density with respect to trap position and time (Payne et al., 1978). In many previous studies a line of traps was fixed in the field and treatments were randomized to confirm the semiochemical identification (e.g., Byers et al., 1985). In spite of the replication and randomization, it is possible to have nonhomogeneous variation, thus often invalidating the statistical tests used. A recent field test method, the mechanical slow rotation of a pair of traps, evens the catch variation in position and time to allow more powerful statistics and more sensitive discrimination of semiochemical blends (Byers et al., 1990b).

The subtractive-combination method provides the most efficient fractionation and bioassay plan for the rigorous isolation and identification of semiochemicals. The program for determining the optimal number of major fractions based on assumptions of number of compounds and synergists is available from the author for IBM-compatible personal computers (send a formatted disk and $5 for shipping).

Acknowledgments—I thank the Swedish Agricultural and Forest Research Council (SJFR) for financial support during the studies. Other support was provided by Jan Löfqvist and the pheromone group in Lund. I thank colleagues for review of the manuscript.

COMPARISON OF VOLATILES FROM BEETLE-TRANSMITTED *Ceratocystis fagacearum* AND FOUR NON-INSECT-DEPENDENT FUNGI

HENGCHEN LIN and P. LARRY PHELAN*

Department of Entomology
Ohio Agricultural Research and Development Center/The Ohio State University

(Received December 20, 1991; accepted May 6, 1992)

Abstract—*Ceratocystis fagacearum* (Bretz) Hunt is the causative agent of oak wilt disease, which is transmitted primarily by nitidulid beetles. This fungus was compared with four non-insect-dependent fungi for their volatile profiles using gas chromatography and mass spectrometry (GC-MS) and for their attractiveness to nitidulids using a wind-tunnel bioassay. The four additional fungi included *Xerula radicata* Sing, *Pluteus atricapillus* Kumm, *Tyromyces chioneus* Karst, and *Botrytis cinerea*. Nitidulids have been reported in association with each of these fungi, but unlike *C. fagacearum*, they are dispersed primarily by wind or rain. Significant attraction of three nitidulid species, *Carpophilus hemipterus* (Linne), *C. lugubris* Murray, and *Stelidota geminata* (Say) was elicited by *C. fagacearum* and to a lesser extent by *X. radicata*, but not by the others. A comparison of headspace volatile profiles showed that the odor of *C. fagacearum* was the strongest, both with regard to the number of components and in their rates of production. Chemical characterization of the headspace profile of *C. fagacearum* revealed 16 components: one aldehyde, one ketone, five alcohols, and nine esters. These components were all common fruit-odor constituents and many of them were previously shown to be attractive to nitidulid beetles. The results of this study suggest that, by mimicking food odors, *C. fagacearum* odor is an adaptation for attracting nitidulid and possibly other insect vectors.

Key Words—Oak wilt, *Ceratocystis fagacearum*, headspace volatiles, Coleoptera, Nitidulidae, *Carpophilus hemipterus*, *Carpophilus lugubris*, *Stelidota geminata*.

INTRODUCTION

Oak wilt, caused by the fungus, *Ceratocystis fagacearum* (Bretz) Hunt, is a severe disease of oak trees and occurs over much of the United States (True et al., 1960; Gibbs and French, 1980; Appel et al., 1985). Insect vectors play an important role in its aboveground transmission by initiating new infection centers (Gibbs and French, 1980), and activity of nitidulid beetles is considered one of the three major factors responsible for the spread of oak wilt (Appel et al., 1987). Since the transmission of oak wilt by nitidulid beetles was first demonstrated (Dorsey et al., 1953; Norris, 1953), many studies have focused on the occurrence of nitidulid beetles in oak-wilt areas and the transmission of this disease to healthy trees (Dorsey and Leach, 1956; Skalbeck, 1976; Juzwik and French, 1983, 1985; Appel et al., 1986, 1987). *C. fagacearum* forms mycelial mats under the bark of oak trees that generate sufficient pressure to split the bark and expose their fruiting surface (Dorsey and Leach, 1956). The mycelial mats produce sticky spores that can not be transmitted by wind or rain (Dorsey and Leach, 1956; Collins and Kalnins, 1965); spores are characterized by a strong fruity odor, which is detectable around infected trees (Collins and Kalnins, 1965; Skalbeck, 1976). To better understand the relationship between *C. fagacearum* and nitidulids, we compared the volatile profile and attractiveness of *C. fagacearum* with those of four other wood-infecting, but non-nitidulid-dependent fungi.

METHODS AND MATERIALS

Fungal Cultures. A culture of oak-wilt fungus, *Ceratocystis fagacearum* (Bretz) Hunt, was initiated with an isolate from Department of Plant Pathology and Physiology, Virginia Polytechnic Institute and State University (Blacksburg, Virginia). *Xerula radicata* Sing, *Pluteus atricapillus* Kumm, and *Tyromyces chioneus* Karst were initiated with isolates from the Center for Forest Mycology Research, USDA (Madison, Wisconsin), and *Botrytis cinerea* was obtained from the Department of Plant Pathology, OARDC/The Ohio State University. All fungi were maintained on potato-dextrose agar (PDA) medium (BBL Microbiology System, Cockeysville, Maryland) at room temperature and were transferred every two to three weeks. Fungal cultures used for headspace-volatile collection and for bioassay were grown on the same medium in 240-ml Qorpak straight-sided jars at 24–26°C until at least $\frac{3}{4}$ of the medium surface was covered by fungal mycelia. Jars with PDA medium alone were incubated under the same condition to serve as the control. The lid of each jar was equipped with a 0.2-μm Bacterial Air Vent (Gelman Science, Ann Arbor, Michigan) for ventilation and a rubber septum (Thomas Scientific) for collection of headspace air samples.

Beetles and Wind-Tunnel Bioassay. Laboratory colonies of *Carpophilus hemipterus* (L.), *C. lugubris* Murray, and *Stelidota geminata* (Say) were maintained on artificial diet (Hall et al., 1978) under the conditions of 24 ± 1°C, 16:8-hr light–dark and 75–85% relative humidity. After eclosion from the pupae, both sexes were held with moisture in 360-ml plastic cups, but without contact with food or food odors. Six- to 7-day-old *C. hemipterus* and *C. lugubris* and 4-day-old *S. geminata* were used for bioassays, and beetles were discarded after each test.

Orientation of nitidulid beetles to fungal cultures and to PDA medium were evaluated in a wind tunnel as previously described (Lin and Phelan, 1991a). Conditions in the wind tunnel were 35–65% relative humidity, 24–27°C, 17 lx light at the wind-tunnel floor and wind speed of 0.5 m/sec. Two jars were placed on the tunnel floor 20 cm apart in the center of the upwind end of the tunnel. One jar was empty and the other contained the odor source; positions of the two jars were rotated between replicates. Ten beetles were released on the floor at the center of the downwind end of the tunnel at a distance of 180 cm from the jars, and those walking or flying to within 10 cm downwind of the jar in 10 min were counted as responders (Phelan and Lin, 1991). *S. geminata* was released at a distance of 120 cm from the jars because this beetle moved slower than the two *Carpophilus* species. Percent responses to the odorous and empty jars were compared by *t* test after arcsin-square root transformation.

Volatile Collection and Identification. Headspace-volatile collections followed the previously described method in which volatiles were trapped on Tenax GC and then thermally desorbed to a gas chromatograph (Phelan and Lin, 1991). Jars containing fungal cultures were opened for 3 min prior to collecting headspace samples. For a comparison of the volatile constituents of different fungi, a 20-ml headspace sample was injected into the Tenax trap using a gas-tight syringe, followed by a 2-min flush of the trap with helium (20 ml/min). The trap then was heated to 200°C and the helium flow through the trap was reversed, such that the retained constituents were desorbed and backflushed to the GC capillary column. This flushing method, used for qualitative comparisons, reduced the amounts of the highly volatile major components, ethanol and acetaldehyde, while enriching the levels of minor components of the profiles (Phelan and Lin, 1991). Volatile constituents were chromatographed using a Hewlett-Packard 5890A gas chromatograph (GC) with a direct interface to a Hewlett-Packard 5970C Mass Selective Detector. DB-FFAP column (30 m × 0.25 mm ID, 0.25 μm film thickness) was used in the among-fungi comparisons of headspace profiles. For a quantitative analysis of the *C. fagacearum* volatile profile, the trap was only flushed for 0.5 min, which removed air from the trap but retained all volatile constituents, as determined by breakthrough studies. Separation was carried out on a DB-1 capillary column (30 m × 0.32 mm ID, 5.0 μm film thickness). GC analyses were temperature-programmed from 30 to

200°C at 10°C/min, with a helium flow rate of 0.7 ml/min on DB-FFAP and 0.9 ml/min on DB-1. Volatile components were identified by comparison of mass spectra and retention times of authentic compounds. Amounts were peak areas with those of known quantities of authentic compounds. All chemicals were purchased from Aldrich Chemical Co. (Milwaukee, Wisconsin).

RESULTS

Beetle Attraction. C. fagacearum elicited significant levels of up-tunnel attraction in all three nitidulid species (Figure 1). PDA medium alone did not attract any beetles, and of the four non-nitidulid-dependent fungi, only *X. radicata* evoked beetle response at a level greater than that to a blank jar (Figure 1).

Comparison of Headspace Volatile Profiles. The volatile profiles of *C. fagacearum*, four non-nitidulid-dependent fungi, and PDA medium are shown in Figure 2. Ten components were identified from the profile of *C. fagacearum* (Figure 2, Table 1). Four of these constituents also were detected from *X. radicata*, and at a lower concentration from *P. atricapillus*: ethanol, 2-methylpropanol, 3-methylbutanol, and 2-methylbutanol. Only ethanol was found in the profiles of *T. chioneus* and PDA medium, and *B. cinerea* emitted none of the *C. fagacearum* components but produced two unidentified later-eluting vol-

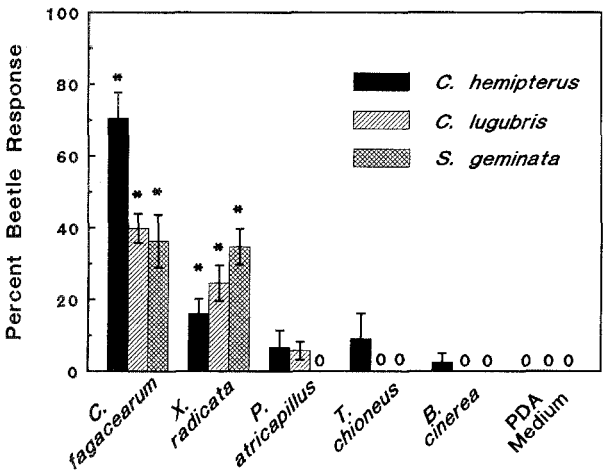

FIG. 1. Percent orientation ($\bar{X} \pm$ SEM) by *Carpophilus hemipterus*, *C. lugubris*, and *Stelidota geminata* to fungal cultures in a wind tunnel. N = four groups of 10 beetles. Bars marked with an asterisk indicate response significantly greater than that to a blank jar to which beetles never responded (Student's t test, $P < 0.05$).

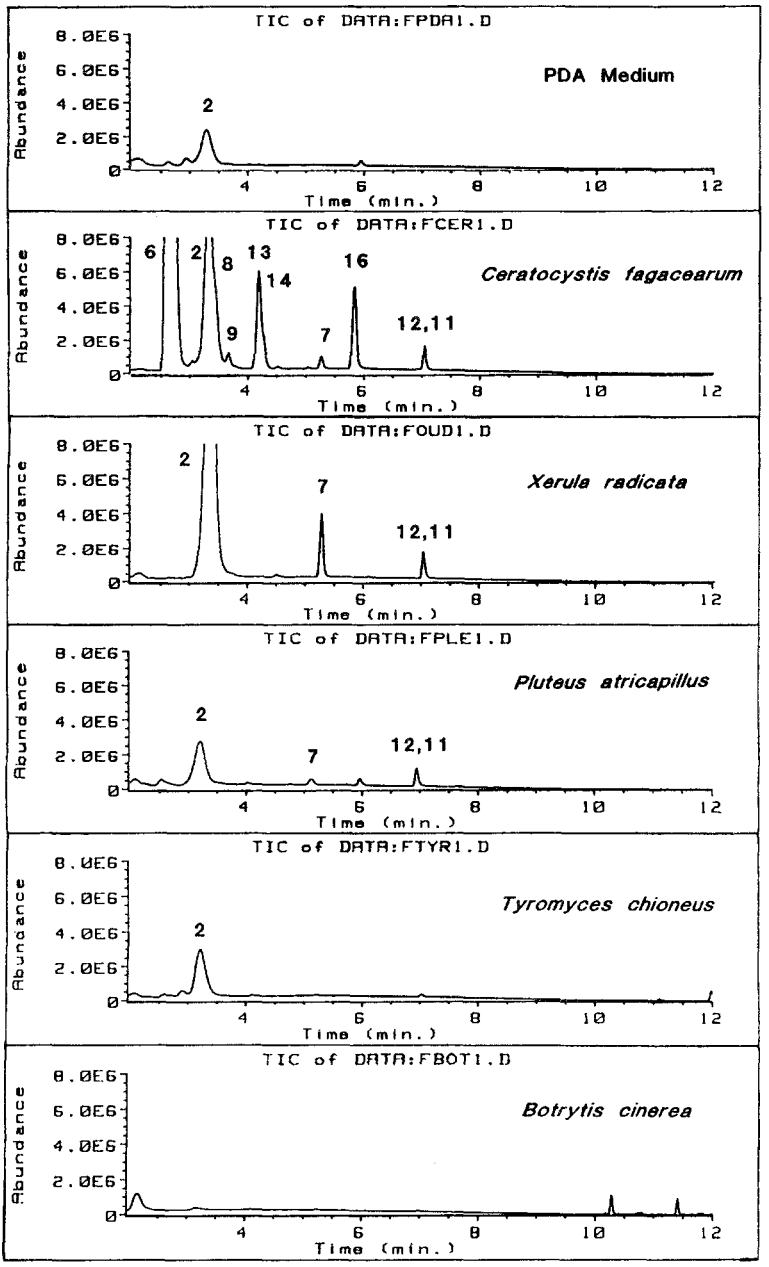

FIG. 2. Comparison of the volatile profiles of five fungi on PDA medium and of PDA medium alone. Note that the profiles were analyzed on DB-FFAP capillary column; component numbering follows Table 1, which was based on an analysis using DB-1. See text for explanation of methods for volatile collection and analysis.

TABLE 1. CHEMICAL CHARACTERIZATION AND QUANTIFICATION OF HEADSPACE ABOVE *Ceratocystis fagacearum* ON PDA

No.	Identity	*RT*[a]	Mass spectra (*m/z*)[b]	Amount (ng/ml)[c]	Percent[c]
1	Acetaldehyde	0.5	29, 41, 43, 44	<0.1	<0.1
2	Ethanol	1.4	27, 29, 31, 45, 46	4.0	2.8
3	Methyl acetate	2.9	29, 42, 43, 59, 74	0.4	0.3
4	1-Propanol	3.6	27, 29, 31, 42, 59, 60	0.1	0.1
5	2-Butanone	4.3	27, 29, 43, 57, 72	0.2	0.2
6	Ethyl acetate	4.9	43, 45, 61, 70, 73, 88	101.0	70.0
7	2-Methylpropanol	5.3	31, 33, 41, 42, 43, 55, 74	4.3	3.0
8	Ethyl propionate	7.3	29, 45, 57, 74, 75, 102	2.4[d]	1.7
9	Propyl acetate	7.4	27, 31, 41, 42, 43, 61, 73		
10	Methyl butyrate	7.6	27, 41, 43, 59, 71, 74, 87	0.1	0.1
11	3-Methylbutanol	7.9	41, 42, 43, 55, 56, 57, 70	8.7[d]	6.0
12	2-Methylbutanol	8.0	29, 41, 55, 56, 57, 70		
13	Isobutyl acetate	8.6	27, 29, 41, 43, 56, 62, 73	5.0	3.4
14	Methyl isovalerate[e]	9.0	39, 41, 43, 57, 59, 74, 85	6.1	4.2
15	Butyl acetate	9.8	27, 29, 41, 43, 56, 61, 73	0.3	0.2
16	Isopentyl acetate	11.2	39, 41, 43, 55, 61, 70, 87	11.9	8.2

[d] Components were combined due to their unresolved GC peaks. Estimated ratio of ethyl propionate and propyl acetate is 1 : 1 and that of 3-methylbutanol and 2-methylbutanol is 4 : 1.
[e] Authentic compound was unavailable, identification based on mass spectrum alone.

atiles. Thus, the volatile profile of *C. fagacearum* appeared quantitatively and qualitatively richer than did those of the non-beetle-dependent fungi.

Characterization of Headspace Profile of C. fagacearum. A more extensive analysis of *C. fagacearum* odor aimed at quantifying individual components of the volatile profile revealed six additional minor components ($\leq 0.3\%$ of total profile; Table 1, Figure 3). Ethyl acetate was the most abundant component of *C. fagacearum* odor; its headspace concentration was 101.0 ng/ml and it made up 70.0% of the odor. Concentrations of other odor constituents ranged from <0.1 (acetaldehyde) to 11.9 ng/ml (isopentyl acetate).

DISCUSSION

Nitidulids have been reported in association with a number of plant pathogens. Because of their sap-feeding habit, those beetles that come to feed on fungal mycelial mats or infected tissues pick up pathogens and may transmit

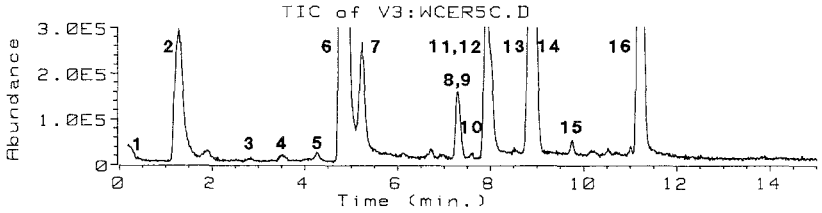

FIG. 3. Volatile profile from oak-wilt fungus, *C. fagacearum* on DB-1. See Table 1 for identity of peaks, and see text for explanation of methods for volatile collection and analysis.

them to healthy trees or fruits when they visit fresh wounds or ripening fruits. Nitidulids are important vectors of *Ceratocystis* canker of aspen in Colorado (Hind, 1972) and of almond in California (Moller and DeVay, 1968). In Hawaii, several species of nitidulids were proven to be important vectors of pineapple disease in sugarcane caused by *C. paradoxa* (Chang and Jensen, 1974). Nitidulids also were reported in association with *Monilinia fructicola*, the causative agent of brown rot in stone fruit in California (Tate and Ogawa, 1975), with *Fusarium* pathogens of corn (Windels et al., 1976; Attwater and Busch, 1983), and with yeasts responsible for diseases of figs (Miller and Mrak, 1953). Juzwik and French (1983) demonstrated that a seasonal peak for nitidulids coincided with the time of maximum mat production for *C. fagacearum*. Furthermore, both adults and larvae of *Glischrochilus* species have been observed feeding on mycelial mats of *C. fagacearum* in the field and adults may overwinter underneath these mats (Dorsey and Leach, 1956). *C. fagacearum* is hermaphroditic but self-sterile and, in addition to inoculating new hosts, nitidulids moving between mats bring about sexual reproduction by fertilizing receptive hyphae of one mat with endoconidia from another (Dorsey and Leach, 1956).

If this association represents a form of mutualism, it is not an obligatory one for the beetles. Nitidulids are not dependent on fungi as they can feed on a variety of ripening or decaying fruits and plant tissues; however, fungal infection does increase the attractiveness or even the nutritional value of food substrates for some nitidulids. *C. paradoxa*-infected sugarcane stalks were nine times more attractive to nitidulid beetles than healthy stalks in the field, and larvae of the nitidulid *Urophorus humeralis* reared on a diet of mixed sugarcane juice and the pathogen developed faster and gained more weight than those on sugarcane juice only (Chang and Jensen, 1974). Similarly, adults of *C. hemipterus* showed higher attraction to yeast-inoculated banana than to aseptic banana, and larvae feeding on yeast-inoculated banana developed faster and gained more weight than those on the aseptic substrate (Lin and Phelan, in preparation, a).

Our chemical characterization of *C. fagacearum* odor revealed 16 components including one aldehyde, one ketone, five alcohols, and nine esters (Table

1). Collins and Kalnins (1965) previously identified four aldehydes and one ketone from steam distillates of *C. fagacearum*; of these, only acetaldehyde was detected in the present study. All of the 16 components identified from the headspace profile of *C. fagacearum* have been found previously in the odors from various food substrates (Jennings, 1977; Macku and Jennings, 1987; Maarse and Visscher, 1988; Phelan and Lin, 1991; Lin and Phelan, 1991a), and 11 of them have been tested at natural release rates with one or more nitidulid species: *C. lugubris* (Lin and Phelan, 1991a), *C. hemipterus* (Phelan and Lin, 1991), *Glischrochilus quadrisignatus* and *G. fasciatus* (Lin and Phelan, 1991b), and *Stelidota geminata* (Lin and Phelan, in preparation, b). Acetaldehyde and ethyl acetate are essential components of attractive odor blends for all these species, except *C. lugubris*, for which ethyl acetate can be partially replaced by ethanol. The five alcohols present in the profile of *C. fagacearum* are attractive to these beetles except 2-methylpropanol and 3-methylbutanol, which have a negative effect on the response of *S. geminata*. Butyl acetate and isopentyl acetate are components of blends attractive to *S. geminata* , while isobutyl acetate has a negative effect on response (Lin and Phelan, in preparation, b). We have found ethanol to be attractive to all of the above species except *C. hemipterus* (Phelan and Lin, 1991). Alm et al. (1985, 1986, 1989) demonstrated that butyl acetate was attractive to *G. quadrisignatus* in the field but only at unnaturally high release rates (70–2000 mg/24 hr). Other components identified from the odor of *C. fagacearum* either have not been tested or have no significant effect on the nitidulid response.

In contrast to *C. fagacearum*, the volatile profiles of the other fungi in our studies were rather depauperate. These fungi were chosen for comparison because they are primarily dispersed by wind or rain, they can infect woody tissue, and they have been reported in association with nitidulids. *S. geminata* has been collected from *X. radicata*, *P. atricapillus*, and *T. chioneus* in nature (Weiss and West, 1921), and Wildman (1933) reported increased capture of nitidulids when cooked figs or peaches were inoculated with a *Botrytis* sp. However, the results of this study suggest that when these fungi are placed on agar, they elicit little or no attraction of nitidulids and generally do not produce attractive volatile blends. Of the non-insect-dependent fungi, only *X. radicata* elicited attraction at a level significantly greater than a blank jar, and this response was less than that to *C. fagacearum*.

We have contended previously that fungi generally enhance attraction of nitidulids through a simple increase in the release of volatiles common to fruit substrates rather through a qualitative change in the odor profile (Phelan and Lin, 1991). This quantitative change is likely brought about by some combination of increased fruit-cell lysis and/or fungal catabolism of fruit constituents that parallels processes characteristic of fruit ripening. Our results here support this contention for non-insect-dependent fungi inasmuch as such fungi involved

in the present study produced no or only small amounts of fruity volatiles in the absence of fruit. In contrast, *C. fagacearum*, a fungus dependent on insects for transmission of spores and for sexual reproduction, produced an odor blend that was both quantitatively and qualitatively rich when cultured on agar. We would submit that production of this more complex odor profile may represent an adaptation on obligatory dispersal by insects.

(Received December 30, 1991; accepted May 11, 1992)

Abstract—Previous work has shown that queen honeybees, *Apis mellifera*, produce waxy esters composed of 8–14 carbon acids and 6–14 carbon alcohols in their feces. We tested these esters for effects on nestmate recognition; 11 of the 12 esters tested significantly modified the recognition characteristics of worker honeybees. Pairwise tests showed that workers can discriminate between at least some pairs of queen esters and that workers can discriminate between a queen ester and hexadecane (another known nestmate recognition cue). These results suggest that a queen may use the esters to enable workers to recognize her or to scent-mark her colony.

Key Words—*Apis mellifera*, honeybee, Hymenoptera, Apidae, queen, fecal pheromones, esters, kin recognition.

INTRODUCTION

We tested the hypothesis that esters found in the feces of queen honeybees can modify the recognitive characteristics of their workers. Queens produce these compounds, but their glandular origins and possible functions are unknown. Blum et al. (1983) found six waxy esters in association with the sting apparatus of mated queens. Page et al. (1988; see also Blum and Fales, 1988) found the

*To whom correspondence should be addressed.

same esters, plus a number of similar compounds, in virgin queen feces. The acid moiety of these esters varies from 10 to 16 carbons and the alcohol from 6 to 14 carbons; it is the long chain length of the alcohol groups that makes these compounds unusual natural products (Blum et al., 1983; Blum and Fales, unpublished). One of these esters, decyl decanoate, is found on the tergal glands of honeybee queens (Espelie et al., 1990). A nonester in queen feces, *o*-aminoacetophenone, repels caged workers during fights between virgin queens, but no function has been suggested for the esters (Page et al., 1988).

Social insect queens often produce chemical signatures that identify themselves individually or that label the worker population in the colony (Breed and Bennett, 1987; Hölldobler and Wilson, 1990). Colony labels produced by the queen have been suggested in a number of ants (e.g., Carlin and Hölldobler, 1986) but have not been demonstrated in bees, termites, or wasps. Honeybee queens can be individually discriminated by workers; unfamiliar queens are attacked by workers in the colony (Breed, 1981). The identity of a queen can be learned by young workers, regardless of the genetic identity between the queen and workers (Breed, 1981). The chemical cues carried by genetically related queens appear to be similar (Breed, 1981; Boch and Morse, 1982; Page and Erickson, 1986), indicating that queens produce recognitive cues themselves.

Moritz and Crewe (1988) found that extracts of compounds from queen heads and tergal glands were less variable among closely related queens. In a metabolic activity, bioassay workers could not distinguish among head extracts but could distinguish among tergal extracts. This finding led Moritz and Crewe (1988) to conclude that tergal gland secretions might be a source of queen recognition cues.

In our tests, we first exposed workers to individual esters that are produced by queens, and then used a bioassay to determine if the exposure had affected the recognitive characteristics of the workers (Breed, 1983; Breed et al., 1985, 1988). All of the esters known to be produced by queens were used. Because the esters are structurally quite similar (similar chain lengths, identical functional groups), we also tested whether workers could, in fact, discriminate among esters. Because the large number ($N = 12$) of candidate esters made testing of all possible pairs unrealistic;, we paired esters to determine if overall carbon number affected the detectability of differences.

METHODS AND MATERIALS

The effects of queen esters on worker recognition were tested following the methods of Breed (1981, 1983) and Breed and Stiller (1992). Upon emergence, worker bees were established in 0.45-liter cardboard containers in the

laboratory with food and water provided ad libitum. Compounds were synthesized in the laboratories of M.S. Blum or T.H. Jones. The following esters are present in queen feces and were used in these experiments: hexyl decanoate, hexyl dodecanoate, decyl octanoate, decyl decanoate, octyl dodecanoate, hexyl tetradecanoate, octyl tetradecanoate, decyl dodecanoate, dodecyl decanoate, tetradecyl decanoate, tetradecyl dodecanoate, and hexadecyl decanoate. Statistical analyses were done on a Macintosh II computer using the Statview statistical package.

Effects of Queen Esters. To test the effects of the queen esters on recognition, 10 μg per bee of a compound were absorbed on filter paper and placed into a container (termed the source container) with 10 workers. After five days the workers were removed from the source container, one at a time, and placed into recipient containers with 10 bees each. Each source bee was used only once, and each recipient container was used only once. All the workers used in any given experiment emerged from the same brood frame and were half- or supersisters. The behavioral interactions were observed between the source and recipient bees for 5 min. An "attack" was recorded if, during this time, the source bee was bitten or stung. If not, an "acceptance" was recorded. All experiments were conducted blind; the observer did not know whether the source group had been treated or was a control. Control containers received filter paper but no compound in either container. We attempted to obtain a sample size of 50 for each ester.

Discrimination between Hexadecane and a Queen Ester. These tests were conducted using the methodology described above, but the source container received 10 μg per bee of hexadecane (Sigma) and the recipient container 10 μg per bee of hexadecyl decanoate. This quantity of hexadecane has the same magnitude of effect on recognition as the esters reported in this paper (Breed and Stiller, 1992).

Discriminations among Queen Esters. Pairwise combinations of queen esters were tested to determine if workers could distinguish between esters. These tests were conducted using the methodology described above, except that the donor and recipient containers both received 10 μg per bee of compound. In the experimental containers, the source container received one compound on filter paper and the recipient another. Controls received the same compound in both source and recipient containers. As not all 144 pairs of esters could be tested, the experimental design included two pairs with identical alcohol moieties, four with identical acid moieties, some with similar molecular weights, and some with very different molecular weights. We attempted to obtain a sample size of 40 for each pair of esters tested.

Control for Concentration Effect. Because the same quantity of each ester was used in the preceding experiment, bees could have discriminated on the basis of concentration, rather than structural differences between compounds.

As a control for the effect of concentration, one ester at the lower end of the molecular weight range of the compounds (decyl decanoate) and one ester at the high end of the range (tetradecyl dodecanoate) were presented to groups of bees. Bees receiving decyl decanoate were treated with 10 μg per bee; bees receiving tetradecyl dodecanoate received the molar equivalent. The experimental methodology was the same as in the preceding experiments.

RESULTS

Effects of Queen Esters. All of the esters tested except octyl tetradecanoate had significant effects on the acceptability of sister bees (Table 1). There is some variation in the magnitude of the effect among those with significant effects. Hexyl tetradecanoate was most similar to the controls and tetradecyl decanoate was least similar. There is no relationship between molecular weight and magnitude of effect. However, the lower-molecular-weight esters caused some mortality among the workers at the concentration used in these experiments. Seventy-one percent of the bees exposed to hexyl decanoate died, as compared to a mortality rate of 0–10% of bees observed in treatments with esters of 20 or more carbons.

Discrimination between Hexadecane and a Queen Ester. A representative queen ester, hexadecyl decanoate, was tested to determine if it could be distin-

Control	1141	21.5	

[a]Percent of bees rejected when the donor group was treated with the indicated compound and the recipient group received no compound. In the controls neither group received a compound. The number of carbons in each compound is indicated in parentheses. Probabilities are based on χ^2 comparisons between treatments and controls.

guished from hexadecane, an alkane known to affect nestmate recognition in honeybees (Breed and Stiller, 1992). Sixty percent of 87 source bees treated with hexadecane were attacked when placed into containers of sister bees treated with hexadecyl decanoate. This is significantly different ($\chi^2 = 41.75$, $P = 0.0001$) from the controls (12%, $N = 83$).

Discriminations among Queen Esters. Significant differences were found in six of 13 pairs tested between experimentals, in which the source group received ester 1 and the recipient group received ester 2, and controls, in which both groups received ester 1 (Table 2). No patterns were found relating overall compound size or chain length of either the acid or alcohol groups in determining whether discriminations are made (Table 2). Some quite similar pairs, e.g., tetradecyl dodecanoate and tetradecyl decanoate, are discriminated, while some quite dissimilar pairs, e.g., decyl octanoate and tetradecyl dodecanoate are not discriminated.

There were relatively few attacks in the treatments in which both groups received the same ester. Pooled across compounds, only 13.5% ($N = 510$) of these pairings resulted in attacks, which is significantly less ($\chi^2 = 23.92$, $P = 0.0001$) than the percentage of attacks in a sample of controls (Breed et al., 1992) in which no compound was present in either group (24.8%, $N = 741$). It is also significantly less than the controls in Table 1 ($\chi^2 = 14.4$, $P = 0.0001$).

[a] Percent of bees injected when the donor group was treated with ester 1 and the recipient group received ester 2. In the controls both groups received the same compound. Probabilities are based on χ^2 comparisons between treatments and controls.

and introduced into a group that had received the other compound were rejected 59% of the time ($N = 54$) while the controls (Table 2) were rejected only 17% of the time ($N = 52$) ($\chi^2 = 19.7$, $P < 0.0001$). This indicates that the discrimination is made even when concentrations are equal.

DISCUSSION

These findings support the conclusion that queen-produced esters can be used by worker honey bees to make discriminations among other bees. The function of these esters is not clearly understood, but these results suggest two possibilities. First, they may be used by the workers to discriminate among queens. Queens are individually recognizable (Breed, 1981), and they produce at least small amounts of these esters throughout their lives (Blum, unpublished). Second, the esters may be used by queens to scent-mark their colonies. Transfer of esters from the queen to the wax combs, or directly to workers, would result in a colony-level recognition signature. Virgin queens seem to produce large amounts of feces (30–100 μl in 48 hr), much of which is composed of these esters (Page, unpublished), but an attempt to quantify the relative amount of each ester in queen feces was not successful (Page and Blum, unpublished). However, the low level of ester production by older queens (Blum, unpublished) supports the first hypothesis, as scent marking should require continuous production of cues as new workers and comb are produced.

While the esters are found in feces, they are probably not normal defecatory products. Worker honeybee feces do not contain the esters, and the compounds are metabolic products, rather than undigested food materials (Page and Blum, unpublished). Our data support a role in recognition for these compounds because of the ability of workers to discriminate among the compounds and the rejection behavior elicited by the compounds. Given the at least partial overlap between fecal and tergal production of these esters (Espelie et al., 1990), our results are potentially consistent with those of Moritz and Crewe (1988) who argued that the tergal glands could be the source of queen recognition pheromones.

Eleven of the 12 esters tested had significant effects on recognition. This contrasts sharply with the findings of Breed and Stiller (1992) that only four of 18 alkanes, methyl esters, and organic acids had such effects. This effect does not vary with overall carbon number, or with carbon numbers in the alcohol or acid groups, through a substantial range of molecular weights. Thus, this is the most consistently effective class of compounds yet discovered in a recognition system.

The mortality caused by the lower-molecular-weight esters suggests a dual role for these compounds. Young queens release feces during fights in cages. One compound in queen feces, *o*-aminoacetophenone, has been shown to repel

workers (Page et al., 1988). The low-molecular-weight esters may also deter workers from entering the fight, or they may function as a chemical weapon against the other queen, or other workers that are antagonistic to the queen.

One pairwise comparison was performed between a queen ester and one of the alkanes, hexadecane, known to affect recognition (Breed and Stiller, 1992). As would be expected with such different structures, workers have no difficulty in discriminating between the two compounds. Based on this, we conclude that the esters can provide recognition cues that are, in general, distinguishable from the cues contained in wax produced by the workers (Breed et al., 1988).

Enough pairs of esters could be discriminated in the pairwise comparisons to support the hypothesis that several distinguishable signals are available among the esters for recognition. The pattern of discrimination is puzzling, as there is no apparent relationship between structural differences and differences demonstrated in our bioassay. This will present an interesting problem for further work on the chemosensory system. There is a possibility that discriminations could be made between pairs of esters based on the amount used, rather than on structural differences in the compounds. All treatments were made at 10 μg per bee; because molecular weight varied among compounds, different numbers of molecules were delivered. However, the difference in concentration is not associated with the pattern of discrimination, and our control for these effects showed no variation due to concentration.

If these esters function in queen recognition, as suggested by these data, then they could provide the basis for discrimination among queens on the basis of relatedness. This could have some significance for intercolonial interactions during swarming (Getz et al., 1982) and/or for male–female interactions during mating. Smith (1983) has shown that recognition signals used for inbreeding avoidance in *Lasioglossum zephyrum*, a halictid bee, are also used in nestmate recognition. Finally, our data suggest a chemical system for genetic recognition of the queen as demonstrated by Breed (1981) and Boch and Morse (1982).

Acknowledgments—This research was supported by grant BNS 89-11078 from the Animal Behavior Program of the National Science Foundation, Michael D. Breed and Robert E. Page, Jr., Principal Investigators. Tappey Jones of the Laboratory of Biophysical Chemistry, National Heart, Lung, and Blood Institute, National Institutes of Health, synthesized some of the compounds. We thank Gloria Lipani, Stephanie Matlock, Scott Wagers, Bruce Wu, and Rob Pacheco for their assistance in collecting the data and Deane Bowers, Laura Snyder, and Terry Smith for their comments on drafts of this manuscript.

(Received January 29, 1992; accepted May 11, 1992)

Abstract—Electroantennograms (EAGs) were recorded from male and female cabbage seed weevils (*Ceutorhynchus assimilis* Payk.) in response to volatiles isolated and identified from the odor of oilseed rape (*Brassica napus* ssp. *oleifera* DC. cv. Ariana). Relatively large EAGs were obtained on stimulation with volatiles produced by the oilseed rape crop at the time when seed weevils were actively searching for host plants. Artificial rape odor without certain key volatile compounds was in most cases significantly less stimulatory than odor containing these volatiles. There were significant differences in the EAG response of the sexes of *C. assimilis* to the green leaf volatiles of oilseed rape and several terpenes present in rape flower odor. The importance of the qualitative and quantitative composition of host-plant odor in host location by *C. assimilis* is discussed.

Key Words—*Ceutorhynchus assimilis*, Coleoptera, Curculionidae, *Brassica napus*, semiochemicals, plant volatiles, olfaction, host plant, attractant, electroantennogram.

INTRODUCTION

Previous studies of the analysis and identification of volatiles from brassicas by distillation/extraction are numerous (Buttery et al., 1976; Cole, 1976; Wallbank and Wheatley, 1976; Daxenbichler et al., 1979; Uda et al., 1982; Kondo et al., 1985; MacLeod and MacLeod, 1990). However, few studies have used

0098-0331/92/0900-1641$06.50/0 © 1992 Plenum Publishing Corporation

porous polymers (such as Tenax and Porapak) to look at the volatiles actually in the headspace of intact or damaged plants (Finch, 1986). Tenax (or Porapak) headspace sampling of volatiles provides a true reflection of the volatiles an insect is exposed to in the atmosphere around a plant (Buttery et al., 1982) and has been used in many studies to identify plant volatiles that influence insect and mite behavior (Hamilton-Kemp et al., 1988; Auger et al., 1989; Liu et al., 1989; Lugemwa et al., 1989).

Previous studies of the chemistry of oilseed rape (*Brassica napus* ssp. *oleifera* DC.) volatiles have concentrated on single-low cultivars of rape which have a seed content low in erucic acid, but high in glucosinolates. Any changes in the volatiles associated with double-low cultivars of oilseed rape in which the seeds are low in erucic acid and glucosinolates, have not been assessed.

Earlier studies have shown that adult cabbage seed weevils, *Ceutorhynchus assimilis* Payk. (Coleoptera: Curculionidae), an important pest of oilseed brassicas in Europe (Lamb, 1989), are behaviorally responsive to the odor of its host plant (Görnitz, 1953; Finch, 1977; Free and Williams, 1978; Evans and Allen-Williams, 1989; Evans, 1990). Seed weevils have been shown to detect components of oilseed rape odor via antennal receptors both in electroantennogram (EAG) studies (Kozlowski, 1984) and single cell studies (Blight et al., 1989). Blight et al. (1989) have identified specific olfactory receptors on weevil antennae to components of oilseed rape odor.

This investigation was undertaken to identify components of the odor of double-low cultivars of oilseed rape that play a role in the perception and subsequent behavioral response to oilseed rape by *C. assimilis*.

METHODS AND MATERIALS

Chemistry. The volatile compounds emitted by a double-low cultivar of oilseed rape (*B. napus* ssp. *oleifera* cv. Ariana) were collected by adsorption onto Tenax GC (mesh size 60–80, Phase Separations Ltd., Queensferry, Clwyd, U.K.). Glass tubes containing 0.1–0.2 g of Tenax sandwiched between silanized glass wool were used to adsorb volatile compounds drawn through the tubes by a vacuum pump (Charles Royston Pumps Ltd., Byfleet, Surrey, U.K.). The Tenax traps were prepared for use by passing nitrogen through them at a flow rate of 10 ml/min in a Pye 104 gas chromatograph (Pye Unicam Ltd., Cambridge, U.K.) oven heated to 275°C for at least 5 hr (Vanhaelen et al., 1977). This process purges any contaminants from the Tenax, and allows the Tenax to be cleaned and reused.

Tenax entrapment of volatiles from rape flowers and macerated leaves was carried out by drawing air through a glass jar containing the plant material. Tenax entrapment of the volatiles released by a small caged plot of flowering oilseed rape (growth stage 4.5, 5.2; Sylvester-Bradley and Makepeace, 1984) was achieved by suspending a vacuum pump from the roof of the cage and drawing air through a larger Tenax trap (1 g of Tenax) suspended 0.5 m above the center of the crop (approx 2.5 m above the ground) for 12 hr from 0800–2000 hr. The volatiles adsorbed on the Tenax traps were eluted by infusing 500 μl of hexane (HPLC grade, BDH, Poole, England) through the trap in a flow of nitrogen, and the eluate concentrated to a volume of 10–20 μl in a Rotava por-R rotary evaporator (Büchi Laboratoriums-Technik, Switzerland).

Identification of Oilseed Rape Volatiles. The identification of the compounds obtained from plant material by Tenax entrapment was carried out using gas chromatography (GC) and coupled gas chromatography–mass spectrometry (GC-MS). A Pye 204 and a Pye GCD gas chromatograph were used, both equipped with a 1.5-m × 4-mm-ID glass column packed with 2.5% Carbowax 20 M on 100–120 mesh Diatomite CQ (J.J.'s Chromatography Ltd., Kings Lynn, Norfolk, U.K.). GC conditions were as follows: inlet temperature 250°C, column temperature isothermal for 1 min at 80°C and then programmed at 8°C/min to 200°C; flame ionization detector (FID) temperature 250°C, nitrogen carrier velocity 30 ml/min. The output from the FID was directed to a pen recorder and a Shimadzu C-R6A Chromatopac integrator (Dyson Instruments Ltd., Houghton-le-Spring, Tyne and Wear, U.K.). The integrator measured the peak area and retention times for each peak.

The GC-MS analyses were performed on a VG 16F mass spectrometer (VG Micromass Ltd., Winsford, U.K.) operated at an ionization potential of 70 eV, connected to a Pye 104 gas chromatograph, with a BP20 quartz capillary column 25 m × 0.22 mm ID and 0.25 μm film thickness. The GC conditions were as follows: inlet temperature 250°C, isothermal for 5 min at 80°C and then programmed at 8°C/min to 200°C, with a helium carrier velocity of 0.75 ml/min. The mass spectra were analyzed by a VG 2015 computerized Data system (VG Micromass Ltd., Winsford, U.K.).

Compounds obtained from Tenax trapping of plant material were provisionally identified by comparing their retention times to those of authentic compounds previously isolated from rape odor (Tollsten and Bergström, 1988). Confirmation of the identity of these compounds and of any unknown compounds was obtained by comparing the mass spectra of the compounds present in the extracts with previously published spectra (Kjaer et al., 1963; Jennings and Shibamoto, 1980; Spencer and Daxenbichler, 1980; Eagles et al., 1981; Kameoka, 1984, 1986) or with the spectra of authentic compounds.

Insects. Adult cabbage seed weevils (*C. assimilis*) were obtained from a

field of flowering oilseed rape by sweep-netting, segregated by sex, and placed in separate cages. Weevils were isolated from food and plant odor for at least 12 hr before being used.

Olfactory Stimuli. The choice of test compounds was based on those identified from oilseed rape odor (Table 1). Several chemically related compounds were also included. Most of the compounds used were obtained from commercial suppliers (Table 2). However, the compounds 4-pentenyl isothiocyanate and 3-butenyl isothiocyanate were prepared from precursor compounds, and the sesquiterpene hydrocarbon (*E,E*)-α-farnesene was obtained from the natural coating of apples, where it is a major constituent (Murray, 1969).

Both 3-butenyl and 4-pentenyl isothiocyanate were obtained by entrapment on Tenax after enzymatic treatment of the parent glucosinolates 3-butenyl glucosinolate (gluconapin) and 4-pentenyl glucosinolate (glucobrassicanapin) by the enzyme myrosinase (thioglucoside glucohydrolase). The volatiles adsorbed onto the Tenax traps were eluted with 500 μl of hexane and analyzed by GC-MS to confirm the identities of the isothiocyanates present.

The method of extraction of α-farnesene from apples was adapted from that used by Murray (1969) and involved the dipping of whole apples (total of 2–3 kg) in 150 ml of hexane for 2 min each. The hexane extract was filtered and concentrated in a Rotavapor-R rotary evaporator to a volume of approximately 3–5 ml. This extract was analyzed by GC-MS to confirm the identity of the major peak obtained as that of (*E,E*)-α-farnesene (>90% purity).

Rape leaf and flower odor obtained by Tenax entrapment were also used in the EAG studies. All test compounds and extracts were dissolved in hexane, a solvent that did not elicit any detectable EAG responses when tested against seed weevils.

Artificial equivalents of rape leaf and flower odor (Table 1) were based on the compounds and their relative proportions identified in this study and those of Tollsten and Bergström (1988). Several of the artificial rape leaf and flower extracts were made up without particular compounds to observe the effect of the absence of the compound(s) on the weevil EAG response.

Differences in volatility between test compounds was not corrected for, and, accordingly, comparisons between the responses elicited are relative.

EAG Setup. The recording of EAGs was based on the arrangement of Visser (1979) for recording Colorado beetle EAGs. The head of the insect was removed and mounted on one of the glass electrodes. The glass electrodes (tip diameter 10–20 μm) were filled with 0.1 M potassium chloride (KCl) in distilled water as an electrolytic medium (Guerin and Visser, 1980). Silver wire (OD 0.5 mm, FSA Laboratory Supplies, Loughborough, Leics, U.K.) coated with silver chloride (Ag–AgCl) in the glass electrodes connected the preparation to the recording instruments; a P-01 Universal probe connected to an AM-05 EAG Amplifier (both from Syntech, Hilversum, Netherlands). The output from the amplifier

was directed to a chart recorder (Chemlab, Hornchurch, Essex, U.K.) and a VELA data logger (Data Harvest, Leighton Buzzard, U.K.). The preparation, manipulators, probe, microscope, and light source were all housed in a Faraday cage.

Odor Delivery System. If an adequate signal (a steady baseline and low noise) was obtained from the preparation, the air flow over the preparation was adjusted to 500 ml/min using a flowmeter (Rotameter) and the end of a glass tube (OD 5 mm) delivering the air placed to within 5 mm of the preparation. Tenax filtered and humidified compressed air was passed over the antenna. A small air pump (Charles Austin Pumps Ltd., Byfleet, Surrey, U.K.) removed the air from around the preparation.

Experimental Procedure. Ten microliters of the test solution was pipetted onto an approximately 0.25-cm^2 piece of glass microfiber filter paper (GF/C, Whatman, Maidstone, Kent, U.K.), which was placed in a 1-ml disposable plastic syringe (Gallenkamp, Loughborough, Leics, U.K.). The test chemical was allowed to evaporate and equilibrate in the syringe before use. For many of the compounds, the responses of antennae to doses ranging from 10^{-6} to 10^{-1} (0.001 μl/ml–100 μl/ml in hexane) was recorded to observe any dose–response relationship differences between male and female weevils. The tip of the syringe needle was inserted into the air flow 20 cm from the preparation. The syringe plunger was quickly depressed to pass 1 ml of the syringe contents into the airstream passing over the preparation.

The EAG was recorded on the chart recorder and on the VELA data logger; the data logger was programmed to sample the signal from the amplifier every 50 msec. Typically, the amplifier multiplied the signal from the preparation $\times$ 1000. As the antennal responses of a preparation tend to decline with time, the responses to the test compounds (measured as maximum amplitude in mV) were expressed as a percentage of the EAG response to a standard compound (Visser, 1979). The standard compound used was 10^{-2} *cis*-hex-3-en-1-ol (C3H), a compound found in the general green leaf volatile complex (Visser et al., 1979) and used as a standard for other EAG studies of phytophagous insects (Visser, 1979; Guerin et al., 1983) including seed weevils (Kozlowski, 1984). The application of a standard 10^{-2} C3H stimulus (10 μl/ml of hexane) to the weevil antenna elicited a response from the preparation in the range 0.3–0.5 mV. The antenna was treated every two to three stimulations with the standard, and the amplitude of the response of the test compound expressed as a percentage of the mean of the two adjacent standard response amplitudes (Guerin and Visser, 1980). The time between stimulations was 90 sec.

The EAG responses were converted to percent response compared to the standard of 10^{-2} C3H and transformed using arcsin square root (Snedecor, 1956) to meet the assumptions of the analysis of variance (Sokal and Rohlf, 1981). A two-factor analysis of variance was used to determine the effect of sex (male

vs. female) and dose on the EAG responses obtained (Zar, 1984). For each test compound or extract, at least five individual weevils of each sex were used.

RESULTS

Chemistry. The volatiles emitted from Ariana, the double-low cultivar of oilseed rape (Table 1), were little different from those emitted by single-low cultivars (Finch, 1978; Drozdowska and Rogozinska, 1982; Tollsten and Bergström, 1988; Evans, 1991). Several compounds isolated by Tollsten and Bergström (1988) in minor amounts from single-low cultivars of oilseed rape were not found in this study (Table 1). However, one compound, *sec*-butyl isothiocyanate, was found in rape leaf odor (Table 1). It has not previously been reported in *B. napus*, although it is found in other brassicas such as *B. campestris* and *B. juncea* (Tollsten and Bergström, 1988).

The majority of rape leaf odor consists of fatty acid derivatives (Table 1) that constitute the green leaf volatile complex (Visser et al., 1979; Buttery, 1981). Isothiocyanates, which are breakdown products of glucosinolates, are characteristic of most cruciferous plants (Fenwick et al., 1983) and are present in rape leaf odor (Table 1).

Rape flower odor mainly consists of terpene compounds (Table 1) with the sesquiterpene α-farnesene the dominant volatile in rape flower odor and the odor of the rape crop (Table 1). The odor sampled from a small crop of flowering oilseed rape was made up of volatiles associated with the leaves and flowers (Table 1).

EAG Response. For most test compounds and extracts, there was a significant effect of dose on the EAG response of weevil antennae (Table 2), demonstrating a typical dose–response effect (as shown in Figures 1–4 below). There were also significant differences between male and female responses to many of the compounds tested (Table 2). The EAG amplitudes obtained were in the range of 0.01–1.5 mV.

Of the compounds identified from rape leaf odor (Table 1), hexan-1-ol, 3-butenyl isothiocyanate, and 4-pentenyl isothiocyanate elicited the strongest EAG responses (Table 2). For hexan-1-ol and 3-butenyl isothiocyanate, the response of female weevil antennae was significantly stronger than the males. The response to 4-pentenyl isothiocyanate by both sexes was virtually identical (Table 2). Female antennae were particularly sensitive to relatively low doses of 3-butenyl isothiocyanate and hexan-1-ol (Table 2), but there was a relatively weak EAG response to the *sec*-butyl and 2-phenylethyl isothiocyanates identified from rape leaf odor. The response to the isothiocyanate compounds not present in rape odor was comparatively strong in the case of allyl isothiocyanate and butyl isothiocyanate (Table 2).

There were significant differences in the response of male and female weevils to all of the green leaf volatiles identified from rape leaf odor (Table 2).

Female antennae were significantly more responsive to rape flower extract than the male antennae (Figure 1). There were significant variations in the response of male and female antennae to several of the compounds in rape flower odor (Table 2). α-Farnesene was the only compound in rape flower odor that evoked strong EAGs from weevil antennae at relatively low doses (Figure 2). The responses obtained at a concentration of 1.5×10^{-2} of α-farnesene (Figure 2) were the strongest EAGs observed to any compound at any concentration tested. The EAGs obtained from other terpenes were weak compared to α-farnesene (Table 2).

The response of weevil antennae to the artificial equivalents of rape leaf and flower extracts indicated that the absence of particular compounds can significantly reduce the EAGs (Figures 2–4). Both male and female weevil antennae had significantly reduced EAGs when stimulated with artificial rape flower extract with no α-farnesene compared to when α-farnesene was present (Figure 2).

Male antennae were significantly less sensitive to artificial rape leaf extracts without 3-butenyl and 4-pentenyl isothiocyanates (Figure 3), and female antennae were less sensitive to artificial rape leaf extract without *cis*-hex-3-en-1-ol and *cis*-hex-3-en-1-yl acetate (Figure 4).

DISCUSSION

The compounds that constitute the green leaf volatile complex are commonly found in the foliage of numerous plant species and contribute to the "green odor" of leaves (Visser et al., 1979). The green leaf volatiles constituted over 97% of the natural rape leaf odor used in these EAG studies (Table 1). The green leaf volatiles *cis*-hex-3-en-1-ol and *cis*-hex-3-en-1-yl acetate were found to constitute over 90% of the volatiles present in rape leaf odor (Table 1), and omission of these compounds from artificial rape leaf odor significantly reduced the EAGs of female seed weevils and considerably reduced the EAGs of the males (Figure 4). These two compounds, either by their presence or by their relatively high concentration in natural and artificial rape leaf odor influenced the olfactory signal obtained from weevil antennae. These compounds also elicit EAGs from other phytophagous insects including the Colorado potato beetle, *Leptinotarsa decemlineata* Say. (Visser, 1979), carrot fly, *Psila rosae* F. (Guerin and Visser, 1980), and boll weevil, *Anthomonus grandis* Boh. (Dickens, 1984). For the Colorado potato beetle, the ratio of these and other green leaf volatiles to each other determined the quality of the olfactory signal and ultimately the behavioral response of the beetle to the odor (Visser and De Jong, 1988). Because of the widespread occurrence of green leaf volatiles, it was

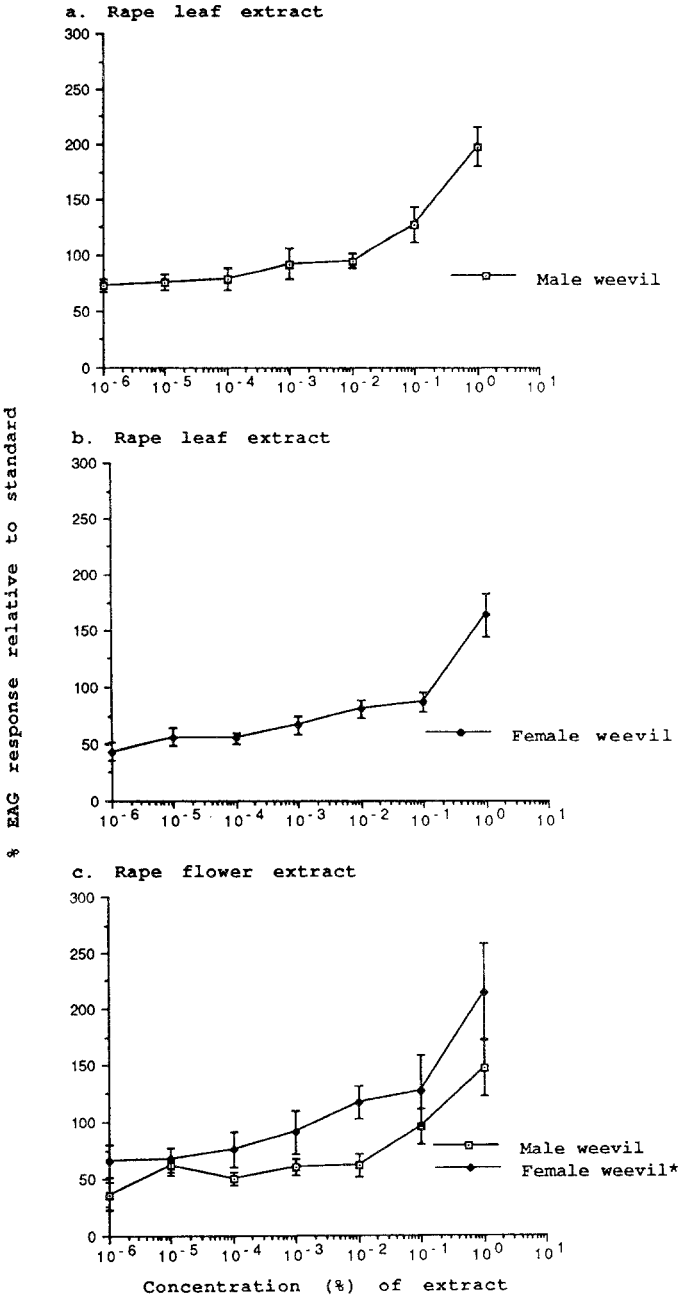

FIG. 1. Mean EAG response of male (a) and female (b) *C. assimilis* to dilutions of oilseed rape leaf and flower odor (c). FIG. 4. Mean EAG response of *C. assimilis* to dilutions of an artificial rape leaf extract with and without the green leaf volatiles *cis*-hex-3-en-1-ol and *cis*-hex-3-en-1-yl acetate. Vertical lines represent standard errors, $N \geq 5$, and asterisk represents significant difference in responsiveness (two-way analysis of variance, $P < 0.01$).

considered unlikely that perception of their qualitative presence could be used to discriminate between host and nonhost plants (Light et al., 1988). The degree of responsiveness of seed weevil and other insect antennae (Guerin and Visser, 1980; Van Der Pers, 1981; Guerin and Städler, 1982; Dickens, 1984) to green

leaf volatiles suggests that the sensory investment in perception of these compounds may be adaptive.

The compounds 3-butenyl and 4-pentenyl isothiocyanate only accounted for $<0.5\%$ of natural rape leaf odor and 1% of the artificial rape leaf odor (Table 1), but a considerable reduction in EAG response was obtained when they were absent (Figure 3). They elicited relatively strong EAGs when tested individually (Table 2). Blight et al. (1989) have identified receptors on the antennae of seed weevils that specifically respond to these isothiocyanate compounds. In the EAGs of artificial rape leaf odor with neither of the above isothiocyanates, none of these specific isothiocyanate receptors are contributing to the overall sensory output, which may explain the reduced EAG response. 2-Phenylethyl and *sec*-butyl isothiocyanate, the other isothiocyanate compounds present in artificial (and natural) rape leaf odor elicited relatively weak EAGs from weevil antennae when tested singly (Table 2), despite the presence of receptors that Blight et al. (1989) showed responded strongly to the 2-phenylethyl isothiocyanate in single cell studies.

Kozlowski (1984) observed strong EAGs to allyl and butyl isothiocyanate (which are not found in oilseed rape odor) from female seed weevil antennae, as did this study (Table 2), but the specific isothiocyanate receptors identified by Blight et al. (1989) appeared relatively unresponsive to allyl isothiocyanate at the concentration used.

The detection of low amounts of host-specific compounds such as isothiocyanates would be important in contributing to the overall EAG, as appeared to be the case in the perception of 3-butenyl and 4-pentenyl isothiocyanate in seed weevils. Carrot flies, for example, (Guerin et al., 1983) were shown to exhibit strong EAGs to minor constituents of carrot leaf odor, as did bark beetles to minor constituents of bark odor (Tommerås and Mustaparta, 1987), which would be important in host location for both these insects. However, the magnitude of an EAG is not always indicative of the behavioral response of the insect to the stimulating compound. For example, the strongest EAG responses obtained in this study were to a $>90\%$ pure sample of α-farnesene (Figure 2), but this compound when presented alone in an olfactometer did not elicit any discernible behavioral response (Evans, 1991). Similarly, yellow water traps baited with α-farnesene did not catch significantly greater seed weevils than control traps (Evans, 1991). However when α-farnesene was omitted from an artificial rape flower extract, it considerably reduced the EAGs obtained (Figure 2) and the attractive behavioral response elicited by artificial rape flower odor in an olfactometer was absent (Evans, 1991). The quality of an EAG, determined by the presence of other compounds, appears to be as important as the magnitude of the EAG.

Similarly, a large EAG response to a compound, as in the case of the female weevil response to hexan-1-ol (Table 2), did not necessarily imply that

the compound is attractive. The behavioral responses of both male and female seed weevils to hexan-1-ol in an olfactometer indicated that within the range of doses tested (0.01%–5%), hexan-1-ol was a strong repellent (Evans and Allen-Williams, 1989; Evans, 1990). This example indicates the need for behavioral experiments to be carried out in conjunction with electrophysiological studies. Hexan-1-ol is usually found in very low or undetectable amounts in rape leaf odor (Evans, 1991), so its repellent effect on seed weevils in the field may be limited or nullified by the perception of other compounds in rape odor.

Sexual dimorphism in EAGs to plant volatiles has not been reported for many other insect species, but male turnip moths, *Agrotis segetum* Schiff., are more sensitive to plant volatiles than females (Hansson et al., 1989). There were significant sexual differences in the EAG response of seed weevils to several host-plant compounds, including each of the green leaf volatiles tested (Table 2). This difference was especially apparent in the responses to hexan-1-ol and *trans*-hex-2-enal, where female weevils were most sensitive. Female antennae were also significantly more sensitive to 3-butenyl isothiocyanate (Table 2), to rape flower extract (Figure 1), and to sabinene, a compound found in rape flower odor (Table 2). The increased sensitivity to sabinene was also apparent in the behavioral response of female weevils in an olfactometer (Evans and Allen-Williams, 1989; Evans, 1990), where attraction to sabinene by males was absent at low doses, but females were attracted.

Behaviorally, rape flower odor was most attractive to seed weevils (Evans and Allen-Williams, 1989), yet only the rape flower volatile α-farnesene strongly stimulates seed weevil antennae of both sexes (Figure 2). This compound is the major component of rape flower odor (Table 1), and seed weevils are usually searching for host-plants such as rape when they are in flower (Free and Williams, 1979). α-Farnesene was also shown to be the dominant volatile in the flower odor of other weevil host-plants such as turnip rape (*B. campestris* L.) and black mustard [*B. nigra* (L.) Koch.] (Tollsten and Bergström, 1988). The odor of flowering rape plants was dominated by α-farnesene (Table 1), but other compounds were also present that strongly stimulate weevil antennae such as 3-butenyl and 4-pentenyl isothiocyanate and *trans*-hex-2-enal (Table 1). All the compounds that elicit strong EAGs from seed weevil antennae are liberated from the rape crop at the time when weevils are actively searching for a host plant.

Cabbage seed weevil antennal receptors are capable of detecting a wide range of compounds associated with the odor of its host plant. These receptors are also able to perceive changes in the concentration of these compounds. The perception of green leaf volatiles and specific host-related compounds, in particular, appear to have a significant role to play in the overall perception and recognition of host odor by seed weevils.

Acknowledgments—We are grateful to Peter Arnold for his technical assistance with the GC-MS and to Dr. R.G. Fenwick of the AFRC Food Research Institute, Norwich, U.K. for the supply of glucobrassicanapin and gluconapin. This research was supported by a SERC studentship (K.A.E.).

(Received October 15, 1991; accepted May 12, 1992)

Abstract—The role of toxins and deterrents in preventing *troilus* group species (Lepidoptera, Papilionidae) from feeding on magnoliaceous hosts was investigated using bioassay-directed isolation of *Magnolia virginiana* allelochemicals. A fraction consisting of three neolignan compounds significantly reduced survival of first instar *P. palamedes*, a *troilus* group member. Two of these compounds, magnolol and a biphenyl ether, were tested individually and were both toxic to *P. palamedes*. The larval survival of *P. troilus*, another *troilus* group species, was also significantly reduced by magnolol but not by the biphenyl ether. In contrast, *P. glaucus*, a polyphagous *glaucus* group species that feeds on magnoliaceous hosts, was not affected by either compound. The effect of these compounds against a polyphagous nonpapilionid was examined using the fall webworm (*Hyphantria cunea*, Lepidoptera: Arctiidae). The biphenyl ether but not magnolol significantly lowered webworm first-instar survival, demonstrating that polyphagy does not preadapt lepidopterans to feeding on this neolignan. These results demonstrate that although phagostimulants play a role in the specialization of the *troilus* group on the Lauraceae, the presence of toxins and/or deterrents in nonhosts is also important in determining food plant patterns in these species.

Key Words—*Papilio palamedes*, *Papilio troilus*, *Papilio glaucus*, *Hyphantria cunea*, Papilionidae, Arctiidae, Lepidoptera, swallowtail butterfly, magnolol, 5,5′-diallyl-2,2′-dihydroxybiphenyl, 4,4′-diallyl-2′,3′-dihydroxybiphenyl ether, herbivore-plant, toxins, deterrents.

INTRODUCTION

The *troilus* and *glaucus* species groups are closely related lineages in the swallowtail butterfly genus *Papilio* (Lepidoptera: Papilionidae) (Munroe, 1961; Hagen and Scriber, 1991, Sperling, 1991). Species within the *troilus* group are restricted in host use to the Lauraceae (Scriber et al., 1991a; Lederhouse et al., 1992). In contrast, members of the *glaucus* group have greater diet breadth and feed on plants from several plant families. One species, *Papilio glaucus* L. (formerly *P. glaucus glaucus*; Hagen et al., 1991), is especially polyphagous and uses plants in the Rosaceae, Tiliaceae, Oleaceae, Rutaceae, and Magnoliaceae (Scriber et al., 1991a). The use of magnoliaceous hosts is particularly noteworthy since only a few of the 220 *Papilio* species are able to grow on these plants (Scriber, 1984).

Scriber et al. (1991a) suggested that the polyphagous *glaucus* group evolved from an ancestor with a narrower range of host families similar to the *troilus* group species. Thus, the evolutionary divergence of the *glaucus* and *troilus* lineages has been accompanied by fundamental differences in host use behavior and physiology. To evaluate the importance of plant chemistry as a constraint on host-use evolution in swallowtail butterflies, we have sought to identify the phytochemical mechanisms of toxicity/deterrency underlying current host use patterns in *glaucus* and *troilus* lineages. If chemical traits of hosts present significant evolutionary barriers to herbivores such as *P. palamedes*, comparisons of the responses of phylogenetically related species to these traits may reveal patterns of adaptation in herbivore lineages.

We focused on the chemistry of sweetbay magnolia, *Magnolia virginiana* L. (Magnoliaceae), a host of *P. glaucus* but unsuitable for *troilus* group species. Phagostimulatory chemicals appear to be necessary for initiation of larval feeding in *troilus* group species (Scriber et al., 1991a; Nitao, 1992), but toxins and deterrents may also act as barriers to colonization of *M. virginiana* by these unadapted papilionids. A number of biologically active secondary compounds have been identified from magnoliaceous plants, including sesquiterpene lactones, alkaloids, and phenylpropanoids (Doskotch and Flom, 1972; El-Feraly and Yee-Ming, 1978; Kijjoa et al., 1989; Barbosa et al., 1990). In addition, Lindroth et al. (1986) hypothesized that toxic sesquiterpene lactones prevent *Papilio canadensis* Rothschild & Jordon larvae from feeding on another magnoliaceous host of *P. glaucus*, *Liriodendron tulipifera* L. (tuliptree). However, specific compounds active against *Papilio* species have not been identified.

Through bioassay-directed isolation of plant extracts, we tested the hypothesis that allelochemicals in *M. virginiana* prevent two *troilus* group species, *Papilio palamedes* Drury and *Papilio troilus* L., from using this as a food plant. We also bioassayed these compounds against *P. glaucus*, a *glaucus* group species that in certain parts of its geographic range uses *M. virginiana*. Finally, we

tested the compounds against *Hyphantria cunea* (Dru.) (Lepidoptera: Arctiidae), the fall webworm, to determine if these compounds possess activity against nonpapilionid lepidopterous herbivores. *H. cunea* has been reported to feed on over 230 plant species in at least 20 families, including the Magnoliaceae (Tietz, 1972; Johnson and Lyon, 1988), and serves as a model species to test for bioactivity against a polyphagous phytophage.

METHODS AND MATERIALS

Plant and Insect Material. Persea borbonia (L.) Spreng. and *Lindera benzoin* (L.) Blume are highly suitable hosts for *P. palamedes* and *P. troilus*, respectively (Lederhouse et al., 1992), whereas *Prunus serotina* (Rosaceae) is a host for *P. glaucus* and *H. cunea* (Scriber et al., 1991a; Tietz, 1972). Leaves of these plants were used as feeding substrates for bioassays. *P. borbonia* leaves were from potted trees originally purchased from Herren Nursery (Florida Division of Forestry) and subsequently grown in a greenhouse at Michigan State University for two to three years. *L. benzoin* and *P. serotina* leaves were collected from wild plants in Ingham Co., Michigan. *M. virginiana* leaves for chemical extraction were from trees of background similar to the *P. borbonia* plants.

P. palamedes were one generation removed from wild females (Highland County, Florida; Echols County, Georgia). *P. troilus* (Adams County, Ohio) and *P. glaucus* (Lawrence County, Ohio) were direct offspring of wild females. *H. cunea* were offspring of individuals originally collected as larvae from sweet gum, *Liquidambar styraciflua* L. (Hamamelidaceae) (Berkeley County, South Carolina).

Initial Separation and Bioassay of Crude Fractions. Fresh *M. virginiana* leaves (150 g) were homogenized and extracted with cold 80% methanol in water (3 × 500 ml) (Figure 1). The leaf residue was further extracted with 100% methanol (500 ml), followed with petroleum ether (35–60°C bp) (2 × 500 ml). The petroleum ether extract was concentrated in vacuo to dryness (1.1 g). The aqueous and absolute methanol extracts were combined, concentrated to remove the methanol, and the resulting aqueous mixture was extracted with dichloromethane (3 × 350 ml). The aqueous fraction was lyophilized (8.2 g) (fraction aqueous-1), and 5.5 g of this residue was dissolved in 150 ml water and extracted with ethyl acetate (3 × 150 ml). Dry masses of the ethyl acetate extractables and of the aqueous residue (aqueous-2) were 0.35 g and 4.6 g, respectively. The dichloromethane fraction was concentrated to dryness (4.2 g) (CH_2Cl_2 fraction), and 2.5 g of this residue was fractionated by flash chromatography (silica gel, 40–63 μm, Sigma, St. Louis, Missouri; 3:1 petroleum ether–ethyl acetate, 100% ethyl acetate, 100% methanol); after examination by

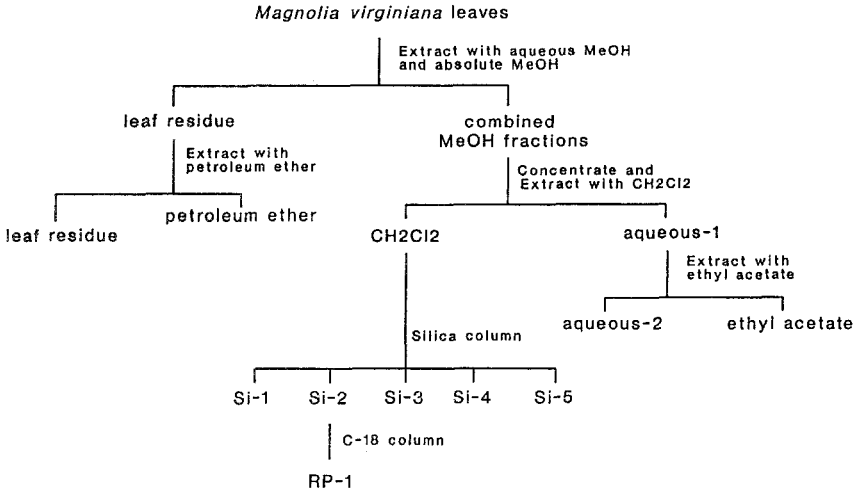

FIG. 1. Chemical fractionation scheme of *Magnolia virginiana* extracts.

thin-layer chromatography, fractions were combined to produce Si-1 through Si-5. Pigments were removed from fraction Si-2 with a reverse-phase flash column (octyldecyl, 40 μm, J.T. Baker, Phillipsburg, New Jersey; 80% methanol in water) (RP-1 fraction).

For initial identification of *M. virginiana* active fractions, we bioassayed all fractions using *P. palamedes* first instars. Extracts were applied to the top surfaces of detached host plant leaves in a manner similar to that of Lindroth et al. (1986). Extract residues were dissolved in appropriate solvents (water, MeOH, $CHCl_3$, or hexane) and uniformly applied with a microliter syringe to *Persea borbonia* leaves at concentrations equivalent to those occurring in *M. virginiana* leaves (grams of extract per gram of leaf). Each control leaf was treated with all solvents used for a particular round of bioassays. Bioassays were conducted at 24°C, 18:6 light–dark photoperiod. Neonate larvae in groups of 9–32 were fed treated leaves and their survival measured after three days. Newly treated leaves were added each day. Each bioassay was replicated two to three times.

Bioassay of Individual Compounds from Active Fraction RP-1. We bioassayed two of the major components of active fraction RP-1 individually against *P. palamedes*, *P. troilus*, *P. glaucus*, and *H. cunea* larvae. Components of fraction RP-1 were separated using preparatory thin-layer chromatography (PTLC) (silica gel, 2000 μm tapered Uniplate, Analtech, Newark, Delaware; developed twice in hexane–ether 4:1) (**1, 2,** and **3** in Figure 2). Compounds were identified using spectral means (NMR, MS, UV, and IR) (Nitao et al., 1991a). After identification, larger quantities of the two major components (**1,**

FIG. 2. *Magnolia virginiana* neolignans identified in the fraction active against *Papilio palamedes* first instars. **1** = 4,4′-diallyl-2′3′-dihydroxybiphenyl ether (a biphenyl ether); **2** = 5,5′-diallyl-2,2′-dihydroxybiphenyl (magnolol); **3** = 3,5′-diallyl-2′-hydroxy-4-methoxybiphenyl (4-methoxyhonokiol).

a biphenyl ether, and **2,** magnolol) were isolated by extraction of lyophilized leaves with hexane and purification using centrifugal partition chromatography and PTLC (Nitao et al., 1991a).

The biphenyl ether and magnolol were tested individually at 0.125%, 0.25%, and 0.5% (grams of compound per gram of fresh leaf) against neonates of *P. palamedes*, *P. troilus*, and *P. glaucus* in groups of 8–15 larvae. These two compounds were also tested against *H. cunea* neonates in groups of 11–27 larvae. Compounds were applied in methanol to leaves of *Persea borbonia* for *P. palamedes* bioassays, *Lindera benzoin* for *P. troilus*, and *Prunus serotina* for *P. glaucus* and *H. cunea*. Leaves treated with methanol served as controls.

Larval survival was recorded after three days. Bioassays were replicated three to five times.

Because *H. cunea* neonates feed on the leaf surface rather than the edge, it was necessary to prevent larvae from behaviorally avoiding the treated side of the leaf. Prior to bioassaying, leaves were embedded in warm agar solution in Petri dishes such that only the treated side was exposed after the agar cooled and solidified. *Papilio* larvae feed from the leaf edge so such precautions were unnecessary for the swallowtail bioassays.

Statistical Analysis. Effects of *M. virginiana* extracts on larval survival were tested using analysis of variance (ANOVA) (SAS Institute, 1985). Dose-dependent effects of purified compounds on survival of *Papilio* larvae were analyzed using a polynomial regression ANOVA model (Mize and Schultz, 1985) (SAS PROC GLM, lack-of-fit model; Freund et al., 1986). Prior to analysis, data were transformed to equalize variances; *P. glaucus* survival data on the biphenyl ether compound were square-root transformed, whereas all other *Papilio* data were square-root arc-sine transformed (Sokal and Rohlf, 1981). Transformations failed to yield equal variances among treatments for *H. cunea* bioassays; dose-dependent effects for these data were analyzed by calculating the Kendall tau correlation coefficient on ranks of percent survival and concentration of compound.

RESULTS

Initial Separation and Bioassay of Crude Fractions. Crude extracts of *M. virginiana* leaves significantly decreased *P. palamedes* larval survival (one-way ANOVA, $F = 20.96$; $df = 3, 4$; $P < 0.01$). Greatest mortality was found on the aqueous-1 and CH_2Cl_2 fractions (Table 1A). The aqueous phase (aqueous-2) retained activity after extraction with ethyl acetate (Table 1B; $F = 13.51$; $df = 2, 3$; $P < 0.05$) but was not processed further.

The CH_2Cl_2 extract was fractionated by silica flash chromatography and resulted in five fractions, of which Si-2 possessed highest activity (Table 1C; $F = 5.17$; $df = 5, 6$; $P < 0.05$). This activity was retained after decolorization with a reverse-phase column (fraction RP-1) (Table 1D; $F = 23.94$; $df = 1, 4$; $P < 0.01$). Isolation and identification of RP-1 constituents revealed that this fraction consisted of three biphenylpropenoid neolignans (Figure 2) (Nitao et al., 1991a). Compounds **1** (the biphenyl ether), **2** (magnolol), and **3** (4-methoxyhonokiol) (Figure 2) comprised 56%, 31%, and 13%, respectively, of the 300-mg total obtained in RP-1 (62.4 g leaf equivalents); thus, these three compounds constituted 0.27%, 0.15%, and 0.06% (g/g), respectively, of *M. virginiana* leaf wet weight. Subsequent isolation of these compounds with cen-

TABLE 1. PERCENT SURVIVAL OF FIRST-INSTAR *Papilio palamedes* AFTER 72 HR ON LEAVES TREATED WITH *Magnolia virginiana* EXTRACTS[a]

Fraction	*N*	Survival (%)
A. Control	2	86.0 ± 6.0
Aqueous-1	2	18.0 ± 7.0
CH_2Cl_2	2	0 ± 0
Petroleum ether	2	89.0 ± 11.0
B. Control	2	67.0 ± 10.0
Aqueous-2	2	6.0 ± 6.0
Ethyl acetate	2	63.5 ± 2.5
C. Control	2	46.5 ± 1.5
Si-1	2	21.5 ± 13.5
Si-2	2	0 ± 0
Si-3	2	49.0 ± 1.0
Si-4	2	55.0 ± 15.0
Si-5	2	37.5 ± 22.5
D. Control	3	74.7 ± 4.6
RP-1	3	8.0 ± 8.0

[a]Data are untransformed means ± SE.

trifugal partition chromatography resulted in slightly higher yields (0.46%, 0.31%, and 0.08% for the biphenyl ether, magnolol, and 4-methoxyhonokiol, respectively).

Bioassay of Individual Compounds from Active Fraction RP-1. When fed the biphenyl ether or magnolol, larvae of both *troilus* group species were significantly affected by either the latter or both. *P. palamedes* survival decreased linearly in relation to the concentration of magnolol (linear response: $F = 107.33$; $df = 1, 16$; $P < 0.0001$) and the biphenyl ether ($F = 26.02$; $df = 1, 8$; $P < 0.001$) (Figure 3A). *P. troilus* larvae were significantly affected by magnolol (linear response: $F = 32.97$; $df = 1, 8$; $P < 0.001$) but not the biphenyl ether (linear response: $F = 2.28$; $df = 1, 8$; $P = 0.17$) (Figure 3B). In contrast, survival of *P. glaucus*, a *glaucus* group member that normally feeds on magnoliaceous hosts, was not significantly affected by either magnolol (linear response: $F = 0.24$; $df = 1, 8$; $P = 0.24$) or the biphenyl ether (linear response: $F = 0.08$; $df = 1, 8$; $P = 0.78$) (Figure 3C). Although the polyphagous fall webworm, *H. cunea*, can feed on certain magnoliaceous plants, larval survival was significantly reduced on the biphenyl ether (Kendall tau $= -0.667$, $N = 16$, $P < 0.05$). Survival of fall webworm larvae also tended to decrease linearly with magnolol concentration, but the effect was not statistically significant (Kendall tau $= -0.152$, $N = 16$, $P > 0.05$) (Figure 3D).

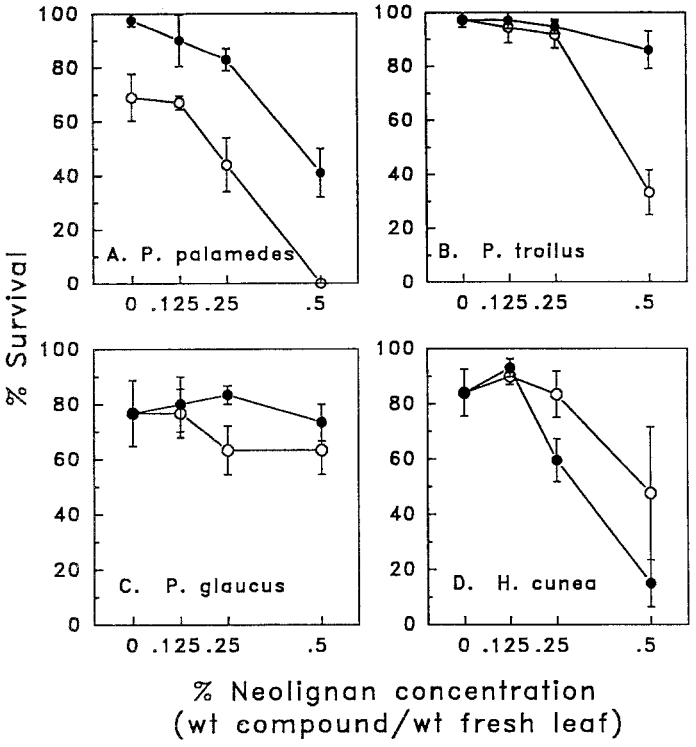

FIG. 3. Percent survival after 72 hr of first instars on various concentrations of magnolol and the biphenyl ether. (A) *Papilio palamedes*, (B) *P. troilus*, (C) *P. glaucus*, and (D) *Hyphantria cunea*. Open circles are magnolol treatments; closed circles are the biphenyl ether treatments. Data are untransformed means ± SE.

DISCUSSION

Host suitability for larvae is one of many factors determining host usage patterns of *troilus* group species (Scriber et al., 1991a; Nitao et al., 1991b; Lederhouse et al., 1992). This study indicates that the unsuitability of *M. virginiana* to *P. palamedes* and *P. troilus* larvae is in part due to neolignan compounds. Thus, allelochemicals in nonhosts, in addition to stimulatory cues necessary for host recognition (Scriber et al., 1991a; Nitao, 1992), serve to constrain the host range of *troilus* group larvae. In contrast, larval survival of *P. glaucus*, a closely related polyphage, was unaffected by *M. virginiana* neolignans.

Based on host use patterns and phylogenetic information, Scriber et al. (1991a) suggested that the polyphagous *glaucus* group species may have been

derived from a more specialized *troilus*-like ancestor. The authors proposed that evolutionary "release" from behavioral constraints characteristic of the *troilus* group freed the *glaucus* group species to expand their host range. This host range expansion was hypothesized to have been facilitated by generalized physiological adaptations capable of detoxifying chemicals shared by many of the new host families, such as those in the Rosaceae and Oleaceae. However, polyphagy by itself does not preadapt insect herbivores to feeding on the magnoliaceous neolignans described here; survival of another polyphagous species, *H. cunea*, was negatively affected by the biphenyl ether. Successful use of *M. virginiana* therefore appears to require specialized behavioral or physiological larval traits not associated with wide host breadth per se. Such specialization is indicated at a finer level by the existence of *P. glaucus* populations differentially adapted to *Magnolia* neolignan compounds (Nitao et al., in preparation).

These results are consistent with the suggestion of Scriber and coworkers (1991a) that more specialized mechanisms have evolved in certain *glaucus* group species, enabling the colonization of hosts with more unique chemistry, such as the Salicaceae, Rhamnaceae, as well as the Magnoliaceae. Similarly, *P. canadensis* and *Papilio rutulus* have been shown to possess esterase enzymes capable of detoxifying phenolic glycosides in their salicaceous hosts (Lindroth et al., 1988; Lindroth, 1989; Scriber et al., 1991b).

The mode of action of these neolignan compounds has yet to be determined. Postingestive toxicity is likely to play a part, since these allelochemicals possess broad biocidal activity against fungi, bacteria, mosquito larvae, and brine shrimp (Clark et al., 1981; El-Feraly et al., 1983; Nitao et al., 1991a). Phagodeterrency may also be involved, although in the feeding trials reported here, *P. palamedes*, *P. troilus*, and *H. cunea* larvae readily fed on neolignan-treated leaves, indicating that absolute gustatory deterrency was not the sole cause of mortality.

Neolignans, lignans, and other biphenylpropenoids are widely distributed in swallowtail host families, including the Lauraceae and Magnoliaceae (MacRae and Towers, 1984). Butterfly species are no doubt adapted to specific types of compounds within these broad phytochemical classes. The ability of *P. troilus* larvae to survive on the biphenyl ether but not magnolol illustrates such specificity. Similar chemicals occurring in the hosts of *P. troilus* may preadapt these larvae to feeding on plants containing biphenyl ether compounds. Behavioral and physiological preadaptation such as this may serve as "chemical facilitation" in the colonization of novel hosts by swallowtail butterflies (Feeny, 1991).

Compounds other than neolignans may also be involved in the inability of some *troilus* group members to use the Magnoliaceae. Unidentified compounds in the aqueous phase reduced *P. palamedes* larval survival. Polar constituents such as quaternary alkaloids and glycosides of lignans and phenols have been identified from other *Magnolia* species (Rao and Juneau, 1975; Rao and Davis, 1982) and are potentially responsible for the bioactivity against swallowtail

larvae. Sesquiterpene lactones have also been isolated from *Magnolia* species (El-Feraly and Yee-Ming, 1978); however, these probably were extracted into the ethyl acetate fraction of our protocol and therefore were unlikely to have caused the larval mortality.

The extent to which biphenylpropenoids affect host patterns within the *glaucus* group lineage has yet to be determined. Sesquiterpene lactones are thought to be responsible for the inability of *P. canadensis* to use *Liriodendron tulipifera*, a host for *P. glaucus* (Lindroth et al., 1986). However, biphenylpropenoids may also play a role. Although magnolol and the biphenyl ether have not been reported from *L. tulipifera*, another biphenylpropenoid has recently been identified from the leaves of this tree (Barbosa et al., 1990). That neolignans and lignans may influence host suitability for *glaucus* group species is suggested by the susceptibility of *P. canadensis* to low concentrations of magnolol and the biphenyl ether (unpublished data). More detailed study should elucidate the extent to which biphenylpropenoids have enhanced or restricted the radiation of swallowtail butterflies, such as those in the *troilus* and *glaucus* groups, onto their hosts.

(Received February 19, 1992; accepted May 14, 1992)

Abstract—The defensive secretions from the nymphs and the adults of both sexes in *P. apterus* were chemically investigated. Forty components were identified from the nymphal posterior dorsoabdominal glands and 35 from the adult metathoracic glands of both sexes. Within the 43 identified chemicals, we found 23 aldehydes, five saturated hydrocarbons, five alcohols, three ketones, three lactones, two terpenes, one phenol and one ester. Thirteen of these compounds had never been reported within the Heteroptera. Whereas eight components are specific to the nymphs, methyl pentenal, (*E*)-2-hexenol, and heptadecanal are the only adult-specific components. The biological role of all the identified chemicals is almost unknown in *P. apterus* and is discussed comparatively with regard to other Heteroptera.

Key Words—*Pyrrhocoris apterus*, Heteroptera, Pyrrhocoridae, bug, exocrine glands, pheromones, defense.

INTRODUCTION

Pyrrhocoris apterus L. is a phytophagous bug usually occurring in dense populations concentrated around linden trees (*Tilia* species) and feeding on them. Despite the well-known defensive gland in nymphs (posterior dorsoabdominal

*To whom correspondence should be addressed.

glands) and in adults (metathoracic glands) (Stein, 1966a, b, 1967), the chemical nature of the exocrine compounds was only investigated superficially in nymphs. Staddon and Daroogheh (1982) reported that the volatile constituents of the posterior dorsoabdominal gland of nymphs contained three compounds: (*E*)-2-octenal and 4-oxo-(*E*)-2-octenal are the major compounds, while the third component (molecular weight, 154) remains unidentified. In his study on the aggregative behavior of *P. apterus*, Schmuck (1987) showed that the nymphal posterior dorsoabdominal gland contains components typical of a defensive secretion. The secretion would contain only four chemicals. The major one (66.5% of the secretion) was unidentified, whereas the three others were (*E*)-2-octenal (23.5%), heneicosane (10%), and tridecane (3.5%). Nevertheless, these percentages, with a total of 103.5, are rather questionable. Except for *P. apterus* and *Dysdercus intermedius* (Calam and Youdeowei, 1968; Calam and Scott, 1969), *Dysdercus superstitiosus* (Daroogheh and Olagbemiro, 1982), and, more recently, *Dysdercus cingulatus* (Farine et al., 1992), no other Pyrrhocoridae species have been chemically investigated.

It is well known that communication through pheromones requires only minute amounts of compounds. Unfortunately, chemical data of the so-called defensive secretion in Heteroptera are generally devoted to the identification of the major chemicals. Within the Pyrrhocoridae, *D. cingulatus* is the only one in which exocrine secretions were extensively studied (Farine, 1989). The location of the exocrine glands encountered in *P. apterus* and *D. cingulatus* is the same (Farine, 1989): the nymphs possess three dorsoabdominal glands (DAG) (abdominal terga 3, 4, 5). The small anterior (DAG 1) and median (DAG 2) glands are still functional in adults, whereas the posterior defensive gland (DAG 3) is only active in nymphs. Paired metathoracic glands (MTGs), opening at the base of the hind legs, are observed in adults of both sexes and a sternal glandular epithelium (sterna 2–6) only occurs in males. Regarding these observations, it was interesting to compare the chemicals of the defensive secretions identified in the tropical *D. cingulatus*, which is able to fly in order to escape predators, with those identified in the wingless European *P. apterus*.

This paper deals with the chemical analysis of the exocrine defensive secretions in nymphs (DAG 3) and adults (MTGs) of both sexes, with special attention to the minor exocrine components.

METHODS AND MATERIALS

Insects. A laboratory culture of *P. apterus* was developed from specimens collected in the field near Dijon, France. The insects were fed on sunflower (*Helianthus* sp.) and mallow (*Malva* sp.) seeds and water-soaked on cotton pads. Development without diapause was induced by a long photophase (14 hr) at a constant temperature of 26°C and 70% relative humidity.

Preparation of Extracts. The extraction technique used was described and discussed in a previous paper (Farine et al., 1992). Extracts of about 1000 nymphs of the fifth instar, 1000 males, and 1000 females were necessary to identify the numerous minor compounds (less than 3% of the total secretion).

Chemical Analysis. Gland extracts were analyzed by gas chromatography (GC) and gas chromatography–mass spectrometry (GC-MS). The gas chromatograph was a Packard 437 A instrument with a flame ionization detector. Two different fused silica capillary columns were used: a DB 5 (30 m × 0.32 mm ID, J. and W. Scientific) and a CP Wax 58 CB (30 m × 0.22 mm ID, Chrompack). Injector and detector temperatures were, respectively, 250°C and 270°C. One microliter of each sample was injected in split–splitless mode with the oven at 50°C for 5 min, then programmed to 250°C at 2°C/min, using helium as carrier gas (5 ml/min). The relative proportions of the compounds were ascertained from GC peak-area integration using a CR 3 A Shimatzu recorder (Kyoto, Japan).

GC-MS was carried out on a Nermag R 10-10 C quadrupole mass spectrometer coupled with a Girdel 31 gas chromatograph. A fused silica capillary column coated with DB 5 (30 m × 0.32 mm ID, J. and W. Scientific) was used for analysis; the GC conditions were those described above. Electron impact mass spectra were obtained at 70 eV.

Identifications were made by comparison of the compound mass spectra to those of the EPA-NIH Mass Spectral Data Base (Heller and Milne, 1980) and the mass spectra from the library of the Laboratoire de Recherches sur les Arômes de l'I.N.R.A. (Dijon, France). Commercial compounds were purchased (Interchim, Montluçon, France) or were obtained as gifts (I.N.R.A., Dijon, France). Correct identification was confirmed if the GC characteristics of the identified compound were the same as those of the reference compound analyzed in the same conditions on DB 5 and CP Wax 58 CB columns. Identification was accomplished by coinjections of glandular extracts and pure compounds on the polar and apolar columns. Identification of 4-oxo-(*E*)-2-hexenal, 4-oxo-(*E*)-2-octenal, and 4-oxo-(*Z*)-2-octenal was matched with those published by Gilby and Waterhouse (1965) and MacLeod et al. (1977), respectively. Identification of other oxo-alkenals was conducted as described previously (Farine et al., 1992).

RESULTS

Posterior Dorsoabdominal Gland (DAG 3) of Nymphs. The 40 compounds identified in the secretion are listed in Table 1. Ninety-three percent of the secretion is composed of four aldehydes [4-oxo-(*E*)-2-octenal (57%), 4-oxo-(*E*)-2-decenal (15%), (*E*)-2-decenal (13%), (*E*)-2-octenal (8%)]. Thirty-six

[c] Newly identified compound in Heteroptera.

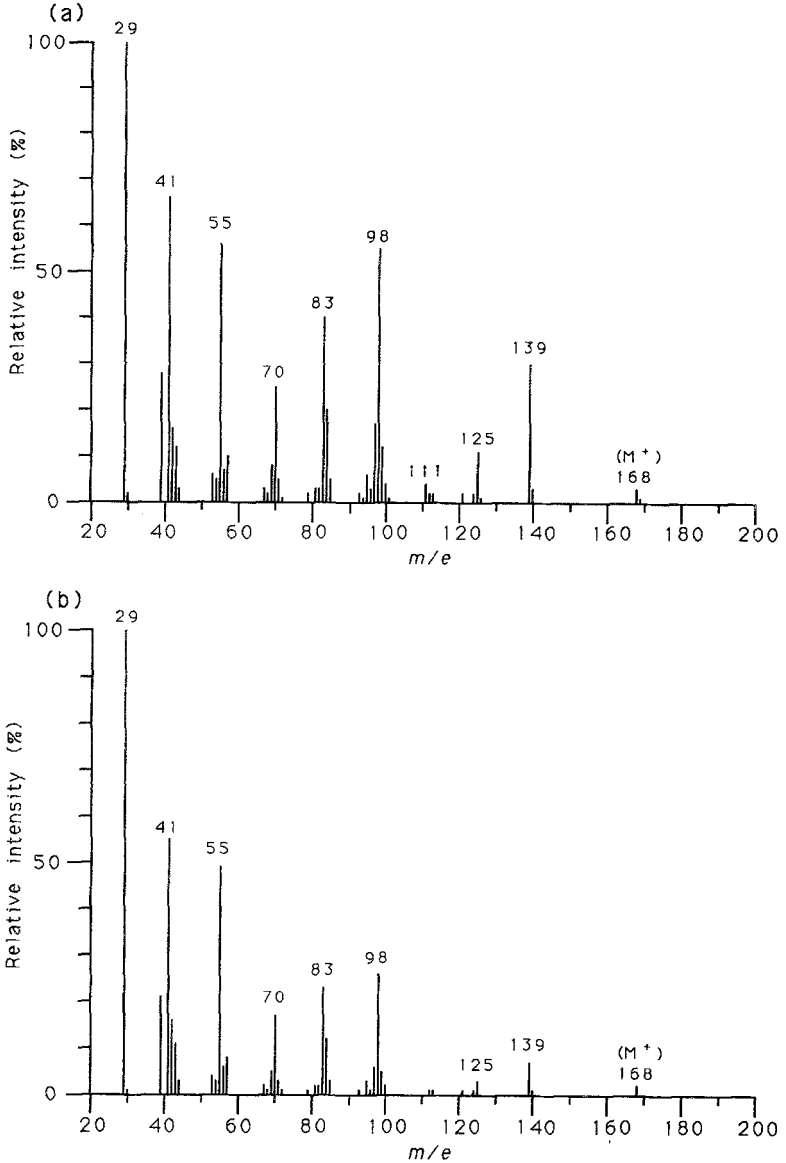

FIG. 1. EI mass spectra of 4-oxo-(*E*)-2-decenal (a) and 4-oxo-(*Z*)-2-decenal (b).

minor compounds were identified: 17 aldehydes, five saturated hydrocarbons, four alcohols, three lactones, three ketones, two terpenes, and two other compounds. It is the first time that spectra of 4-oxo-(*E*)-2-decenal (Figure 1a) and 4-oxo-(*Z*)-2-decenal (Figure 1b) have been published.

Metathoracic Glands (MTGs) of Males and Females. Thirty-five compounds were identified from the MTGs of both sexes (Table 1), and no noticeable difference was observed between males and females. Three compounds represent 90% of the secretion: (*E*)-2-hexenal (76%), (*E*)-2-octenal (10%), and tridecane (4%). The remainder of the secretion is a mixture of 16 aldehydes, four saturated hydrocarbons, five alcohols, two lactones, two terpenes, one ester, and two other compounds.

DISCUSSION

P. apterus is "warningly" colored and lives in dense and conspicuous aggregations (Bongers, 1968). Coincidence of aposematic coloration with a tendency to aggregate is the norm for insects (Pasteels et al., 1983; Borden, 1984), and it is well known that Pyrrhocoridae species form aposematic aggregations (Giles, 1958; Gupta, 1979; Farine and Lobreau, 1984). As in *D. cingulatus* (Farine, 1989), when the individuals are disturbed, the chemicals produced by the MTGs of adults and the DAG 3 of nymphal (*P. apterus*) deter predators (e.g., ants), elicit an alarm response for only a very short time, and induce the dispersion of the bugs (Schmuck, 1987; Farine, 1989). The exocrine secretion may also be considered as defensive, the ants not only being repelled but also paralyzed (Farine, 1989).

Most of the defensive secretions in the Heteroptera are highly volatile compounds of low molecular weight (mol wt) (Dazzini and Pavan, 1978; Staddon, 1979; Blum, 1981; Aldrich, 1988). In the nymphal DAG 3 of *D. cingulatus* (Farine et al., 1992), the molecular weight of the 34 identified compounds varies from 88 to 212, including 12 components below mol wt 120. In adults of both sexes, the 21 identified compounds in the MTGs vary from mol wt 92 to 184 and seven of them are less than mol wt 120. In nymphal and adult *P. apterus*, the molecular weight of the 43 identified compounds varies from 88 to 254. Only seven nymphal and nine adult components were determined to be less than mol wt 120. Consequently, the exocrine chemicals in *P. apterus* are enriched with high-molecular-weight constituents compared to their counterparts in *D. cingulatus*. The fact that *P. apterus* is essentially a terrestrial species and that the wingless adults cannot fly may explain the presence of a larger number of high-molecular-weight compounds. These chemicals, with a slow evaporation rate, could induce longer-lasting protection.

As in the other Pyrrhocoridae—*D. intermedius* (Calam and Youdeowei,

1968), *D. cingulatus* (Farine et al., 1992), and *D. superstitiosus* (Daroogheh and Olagbemiro, 1982)—the secretion of the nymphal DAG 3 of *P. apterus* is mainly a mixture of aldehydes. The nymphal secretions of *P. apterus* are characterized by the abundance of (*E*)-2-octenal, (*E*)-2-decenal, 4-oxo-(*E*)-2-octenal, 4-oxo-(*E*)-2-decenal, and by the lack of (*E*)-2-hexenal. 4-Oxo-(*E*)-2-decenal was first reported as a trace compound from *D. cingulatus* (Farine et al., 1992), but it is the first time that this oxo-alkenal has been found as a major constituent of an insect exocrine secretion. Besides the four major compounds, we determined that 7% of the secretion consisted of minor components. Our results differ from those of Schmuck (1987), who found tridecane and heneicosane as major compounds. Tridecane is effectively present in nymphal secretions, but as a minor component, whereas heneicosane has never been detected by us and certainly belongs to the cuticular hydrocarbons. To our knowledge, it is the first time that the adult defensive secretions have been investigated in *P. apterus*. Besides the major components (*E*)-2-hexenal, (*E*)-2-octenal, and tridecane, about 10% of the identified chemicals are minor compounds. Whereas the (*E*)-2-alkenals were identified as major components in *Dysdercus* species, tridecane was only found as a major compound in *P. apterus*. On the other hand, linalool, a major compound of the MTG secretions in *Dysdercus* species (Calam and Youdeowei, 1968; Daroogheh and Olagbemiro, 1982; Farine et al., 1992), has never been identified in *P. apterus*.

Many of the identified chemicals in *P. apterus* are considered to have a defensive function. Short-chain saturated and unsaturated aldehydes are very effective chemical irritants (Remold, 1963). The originality of the *P. apterus* secretions consists of abundant aldehydic compounds (23 of the 43 identified compounds are aldehydes). Hydrocarbons have defensive properties of their own (Blum, 1981) and in several insects serve to facilitate the penetration of the reactive aldehydes through the cuticle of arthropod predators (Remold, 1962). The five identified saturated hydrocarbons always appear as minor compounds (except tridecane in adults of both sexes) in *P. apterus*, and it is difficult to assert that these components have only a physicochemical action in this species. The same should be said concerning the identified esters in *P. apterus*. The ester could act as a wetting agent to facilitate the penetration of the main toxicant through the cuticle of the predators, but about 20% of the esters identified in the defensive secretions of insects (Blum, 1981) are produced by adult true bugs and are generally lacking in the nymphal defensive secretions. The only identified ester in *P. apterus* represents only 1% of the adult defensive secretions and appears as a minor compound in the nymphs. Volatile monoterpenes are common repellents in insects, particularly in the alarm-defense system of ants (Herout, 1970; Karlson, 1970). Within the identified terpenoid compounds in *P. apterus*, *p*-cymen-8-ol was described for the first time in *D. cingulatus* (Farine et al., 1992), and α-thujene was only reported in the defensive secretions of Termitidae (Everaerts et al., 1988).

The function of the aldehydes and hydrocarbons found in the defensive glands of the Heteroptera varies according to their concentration. The dual function of the aldehydes was first reported in *Cimex lectularius* (Cimicidae) (Levinson and Bar Ilan, 1971). In *Eurydema rugosa* (Pentatomidae), large amounts of (*E*)-2-hexenal act as an alarm pheromone, whereas small amounts of the same compound play an important part in the re-formation of the aggregation (Ishiwatari, 1974, 1976). In the nymphs of *Nezara viridula* (Pentatomidae) the dual function is played by various amounts of tridecane (Lockwood and Story, 1986). In *D. cingulatus* (Farine, 1989), large or small amounts of (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-2-decenal, 4-oxo-(*E*)-2-hexenal, 4-oxo-(*E*)-2-octenal and C_{11}–C_{15} saturated hydrocarbons have the same dual function.

In nymphal *P. apterus*, Schmuck (1987) showed that the aggregative behavior results mainly from an interindividual attraction guided by visual and chemical stimuli and that extracts of the DAG 1 and DAG 2 act as attractants. The nymphs are repelled when using high concentrations (10 individual equivalents) of C_{14}–C_{17} saturated hydrocarbons, while an arrestant effect is only shown when using low concentrations (0.1–1 individual equivalents) of the same compounds.

At the present time, numerous questions concerning chemical communication within the Heteroptera remain unanswerable and much theorizing is possible on the complexity of the defensive secretion. In *D. cingulatus* (Farine, 1989), we demonstrated the importance of most chemicals identified in the so-called defensive glands in nymphs and adults and proved that the trace components encountered are of primary importance in aggregation, alarm, defense, or sexual behavior. Compared to this species, the extensive chemical data in *P. apterus* also revealed the complexity of the defensive secretion in nymphs and adults of both sexes and the biological role of each compound still needs further study.

Acknowledgments—The author thanks E. Sémon of the Laboratoire de Recherches sur les Arômes, I.N.R.A., Dijon, for the GC-MS analyses.

Raleigh, North Carolina 27695-7612

(Received March 19, 1992; accepted May 18, 1992)

Abstract—Nonsterile soil transforms the rye metabolite 2(3H)-benzoxazolone (BOA) into 2-amino-3H-phenoxazin-3-one, which is an order of magnitude more toxic to barnyard grass than benzoxazolone. Benzoxazolone was recovered unchanged from sterile soil. However, *o*-aminophenol is converted to aminophenoxazinone by both sterile and nonsterile soil in the presence of air. Aminophenoxazinone is probably produced by microbial hydrolysis of benzoxazolone into *o*-aminophenol, which is oxidized to aminophenoxazinone in both sterile and nonsterile soil. No 2,2′-oxo-1,1′-azobenzene was found in any incubations of soil with benzoxazolone, *o*-aminophenol, or *o*-azophenol.

Key Words—2-Amino-3H-phenoxazin-3-one, 2(3H)-benzoxazolone, BOA, *o*-aminophenol, rye, *Secale cereale*, soil transformation, phytotoxicity, allelopathy, barnyard grass, *Echinocloa crus-galli*.

INTRODUCTION

The use of allelopathic mulches in reduced or no-till cropping systems has received attention in recent years. The practical and chemical aspects of using winter rye, *Secale cereale* L., mulch are perhaps the best studied (Worsham, 1989). Phytotoxic activity of rye mulch has been attributed largely to the cyclic hydroxamic acid 2,4-dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA) and its decomposition product 2(3H)-benzoxazolone (BOA) (**1**, Figure 1) (Barnes et al., 1987). A crystalline, red transformation product of BOA has recently been isolated from Michigan soil, and the structure 2,2′-oxo-1,1′-azobenzene (**2**) has

FIG. 1. Structures of 2(3H)-benzoxazolone **(1)**, 2,2′-oxo-1,1′-azobenzene **(2)**, and *o*-benzoquinone azine **(3)**.

been proposed for this pigment (Nair et al., 1990). This red transformation product proved more phytotoxic than BOA in vitro (Chase et al., 1991a) and is therefore a further possible allelochemical of rye mulch. The soil transformation of BOA was later determined to be mediated by the microorganism *Acinetobacter calcoaceticus* (Chase et al., 1991b).

Soil microorganisms are known to transform substituted anilines into azo compounds (Bartha and Pramer, 1972). However, microbial formation of an oxygen–oxygen bond between phenols is unprecedented. In fact, chemical attempts to generate phenolic peroxides by dimerization of ortho-, para-blocked phenolic radicals does not lead to stable phenolic peroxides (Pummerer et al., 1952), and yet the red soil transformation product appeared to be stable and to have a very high melting point with no decomposition reported. We have considered possible alternative structural interpretations of the data used to arrive at the 2,2′-oxo-1,1′-azobenzene structure. The published [^{1}H]- and [^{13}C]NMR data indicated an element of symmetry in the pigment leading to six carbon and four hydrogen signals for $C_{12}H_8N_2O_2$. All isomeric structures with the required symmetry can be rejected based on published melting point and spectral data except one, *o*-benzoquinone azine **(3)** reported to be the product obtained by silver(II) oxide oxidation of *o*-aminophenol (Ortiz et al., 1972). The ultraviolet–visible spectrum reported for this red oxidation product is the same as that reported for 2,2′-oxo-1,1′-azobenzene, and its high melting point is similar to that reported for the soil transformation pigment. It appeared that the red soil transformation product and the product of silver(II) oxide oxidation of *o*-aminophenol might be identical. Therefore we reinvestigated the properties of these red pigments.

METHODS AND MATERIALS

Soil Sample. Cecil and Appling gravelly sandy loam (Typic Kanhaludult), was collected from a fallow corn field at the North Carolina State University research farm at the Dorothea Dix property (plot number 163/H-2). Soil was stored in a sealed plastic bag at 4°C until needed.

Soil Transformation of BOA. A 2-g sample of BOA **(1)** was mixed into 400 g soil and incubated in the dark at 28°C. After 10 days, the soil was extracted twice with 400 ml methanol. The extract was concentrated to dryness (1.2 g), and the residue was redissolved in a small amount of ethyl acetate. After two days, crystals were collected from this dark red solution, which was allowed to stand for further crystallization. A final yield of 311 mg of red crystals was obtained.

Effect of Sterile and Septic Soil. To test whether soil microorganisms are required for transformation of BOA into the red pigment, sterile and nonsterile soil was supplemented with BOA and two potential intermediates, *o*-aminophenol and *o*-azophenol. A 50-g portion of soil was mixed with 50 mg of the test compound and 5 ml deionized water. The mixture was transferred to an Erlenmeyer flask, stoppered with a foam plug, and incubated in the dark at 25–28°C. In cases where sterile soil was used, the test compound was added aseptically to double-autoclaved soil. After 10 days the soil was extracted by stirring twice with 100 ml of methanol. The extracts were concentrated under vacuum and compared to the silver oxide oxidation product by thin-layer chromatography (TLC) in two solvent systems: toluene–ethyl acetate (50:40) and chloroform–methanol (95:5).

Silver(II) Oxide Oxidation of o- *Aminophenol.* Silver(II) oxide, AgO, was prepared according to the method of Hammer and Kleinberg (1953). The silver(II) oxide oxidation of *o*-aminophenol was carried out according to the method of Ortiz et al. (1972). A mixture of 6 g *o*-aminophenol and 31 g freshly prepared silver(II) oxide was stirred in benzene for 4 h. Insoluble silver oxides were removed by vacuum filtration. The dark red pigment in the filtrate was purified by flash column chromatography (chloroform–methanol 80:20). Preparative TLC (chloroform–methanol 9:1) yielded a dark red product (R_f 0.65 in chloroform–methanol 95:5), which was triturated with water to remove traces of *o*-aminophenol. The red solid was dissolved in the minimal amount of dimethylsulfoxide. Slow evaporation of some of the solvent from an open beaker produced fine, dark red crystals which were homogeneous by TLC in three solvent systems: chloroform–methanol 95:5 (R_f 0.6), hexane–acetone 70:30 (R_f 0.7), and toluene–ethyl acetate 50:40 (R_f 0.5). The dark red product diluted for TLC appeared as a bright orange spot, which was the only spot detected visually, by fluorescence quenching or by treatment with phosphomolybdic acid (Peña-Rodriguez et al., 1988).

Synthesis of Aminophenoxazinone. 2-Amino-3H-phenoxazin-3-one **(4)** was synthesized by the air oxidation of *o*-aminophenol as described previously (Kehrmann, 1906). In this procedure, 4 g of *o*-aminophenol were stirred in aqueous methanol at room temperature for three weeks. Production of the dark red aminophenoxazinone was monitored by TLC (chloroform–methanol 95:5). Solids that precipitated from the solution were collected and recrystallized from meth-

anol to give clusters of reddish black needlelike crystals. The aminophenoxazinone was further purified by washing with hot water and recrystallizing from methanol. The crystallized product was analyzed by TLC, UV, NMR, and MS. The yield of aminophenoxazinone after three weeks was 1.1 g. There was still some unoxidized *o*-aminophenol in the original methanolic solution after three weeks.

Spectroscopy. Ultraviolet spectra were measured on a Perkin-Elmer Lambda 4B UV/VIS spectrophotometer. [^{1}H]NMR was measured in DMSO-d_6 at 300 and 500 MHz on a General Electric Omega spectrometer. Proton-coupled and proton-decoupled [^{13}C]NMR spectra were measured at 125 MHz. Low-resolution mass spectral analysis was performed using a Hewlet-Packard 5985-B spectrometer.

Bioassay. Phytotoxicity was tested by a radicle elongation assay. A 1 mg/ml stock solution of the test compound was prepared in methanol. Volumes corresponding to 12.5, 25, 50, 100, 175, and 250 mg of test compound were applied evenly to 6-cm filter paper circles, and the solvent was allowed to evaporate completely. Filter paper wet with methanol and dried was used as a control. The dried paper impregnated with test compound was wet with 1.5 ml water in a 60 × 15-mm Petri dish, and 10 seeds of barnyardgrass (*Echinocloa crus-galli* L.) were added. After incubation in the dark for 72 h, the radicle lengths (mm) were measured and expressed as a percentage of the control radicle length.

RESULTS

Transformation of BOA and Other Compounds by Soil. BOA incubated with moist, nonsterile soil at 28°C was converted within 10 days into a dark red substance extractable by methanol. TLC showed the presence of a major orange pigment (red on concentration), higher R_f, very weak yellow and brown pigments, and a very small amount of unreacted, colorless BOA, detected by ultraviolet fluorescence quenching and by development with phosphomolybdic acid. Soil that had not been treated with BOA contained no extractable pigments.

The red pigment, recrystallized from methanol, had mp 252–258°C; UV maxima in methanol at 236 (31,000) and 432 nm (26,000); EIMS *m/z* 212 (100%, M^+), 185 (58%), 184 (28%); [^{1}H]NMR in DMSO-d_6 at 300 MHz: 6.34 ppm (s, 1H), 6.35 (s, 1H), 6.81 (broad, NH_2), 7.48 (m, 3H), 7.71 (dd, J = 1, 8 Hz, 1H). The singlets at 6.34 and 6.35 ppm were not resolved in pure DMSO but did resolve after addition of a drop of D_2O. The three-proton multiplet at 7.48 ppm was resolved at 500 MHz: 7.38 (dt, J = 1, 8 Hz,), 7.45 (dt, J = 1, 8 Hz,), and 7.48, (dd, J = 1, 8 Hz). Carbon resonances were assigned in the [^{13}C]NMR spectrum (Table 1) consistent with heteronuclear multiple bond

correlation spectra, multiplicities observed in [^{1}H]- and [^{13}C]NMR spectra, and model compounds.

Ten days after addition of BOA to doubly autoclaved soil, unreacted BOA was detectable in the methanolic extract, but no pigment was present. The concentration of BOA in sterile soil was undiminished judging from TLC spot intensity. On the other hand, TLC analysis showed that *o*-aminophenol was completely converted to the red pigment and no other product within 10 days in both sterile and non-sterile soil. *o*-Azophenol, a conceivable precursor to 2,2′-oxo-1,1′-azobenzene, or *o*-benzoquinone azine, was unaltered after 10 days of incubation in nonsterile soil.

Red Pigment Produced by Silver(II) Oxidation. The pigment produced by silver(II) oxide oxidation of *o*-aminophenol was purified by column chromatography and preparative TLC, followed by crystallization from dimethylsulfoxide. The red crystals had mp 268°C; UV maxima in methanol at 236 (23,000) and 432 nm (20,000); EIMS *m/z* 212 (100%, M^+), 185 (50%), 184 (21%); [^{1}H]NMR in DMSO-d_6 at 300 MHz: 6.42 ppm (s, 1H), 6.44 (s, 1H), 6.87 (broad, NH_2), 7.54 (m, 3H), 7.78 (dd, J = 1, 8 Hz, 1H); [^{13}C]NMR as in Table 1.

Comparison of Pigments to Aminophenoxazinone. 2-Amino-3H-phenoxazin-3-one **(4)** (Scheme 1) was prepared by air oxidation of *o*-aminophenol (Kehrmann, 1906) and recrystallized twice from methanol, mp 253–267°C (lit. mp 255–257°C). The red crystals had visible–ultraviolet maxima in methanol at 237 nm (22,000), 432 (19,600); EIMS *m/z* 212 (100%, M^+), 185 (53%),

184 (22%). The [^{1}H]- and [^{13}C]NMR agreed with spectra previously reported for 2-amino-3H-phenoxazin-3-one (Hasegawa and Ueno, 1985). The red pigments from soil transformation of BOA and from silver(II) oxidation of *o*-aminophenol were indistinguishable from 2-amino-3H-phenoxazin-3-one by UV, EIMS, and [^{1}H]- and [^{13}C]NMR. The red pigments prepared by soil transformation and by Ag(II) oxide oxidation also comigrated with aminophenoxazinone on silica gel TLC at R_f 0.5 in toluene–ethyl acetate, 50:40 and at R_f 0.6 in chloroform–methanol (95:5).

Phytotoxicity of Aminophenoxazinone. The radicle elongation assay on barnyard grass showed that aminophenoxazinone was more phytotoxic than its precursor BOA (Figure 2). Root elongation was inhibited 50% by 0.1 mM aminophenoxazinone, 0.7 mM BOA, and 1.2 mM *o*-aminophenol, the probable hydrolytic intermediate between BOA and aminophenoxazinone.

DISCUSSION

In an earlier study silver(II) oxide was found to oxidize 7 substituted anilines to azoarenes (Ortiz et al., 1972). Based on this analogy and elemental composition, but no NMR data, the structure *o*-benzoquinone azine **(3)** was proposed for the red crystals produced by oxidation of *o*-aminophenol with silver(II) oxide. We synthesized and characterized this compound by NMR and other spectroscopic techniques because this product has a similar high melting point, the identical elemental composition and ultraviolet spectrum, and the symmetry of the reported soil transformation product of 2(3H)-benzoxazolone (BOA) **(1)** previously assigned the structure 2,2′-oxo-1,1′-azobenzene **(2)** (Nair et al., 1990). We found that the product of silver(II) oxidation of *o*-aminophenol is in fact not *o*-benzoquinone azine, but rather 2-amino-3H-phenoxazin-3-one **(4),** from which it is indistinguishable by thin-layer chromatography, mass spectral fragmentation, [^{1}H]- and [^{13}C]NMR, and UV spectra. Aminophenoxazinone and its derivatives are the only known products of oxidation of *o*-aminophenol by air (Kehrmann, 1906), photoirradiation (Ikekawa et al., 1968), inorganic oxidants (Ikekawa et al., 1968; Hishida et al., 1974), mammalian tissue (Tomoda, 1986), and purified enzymes (Nagasawa, 1959; Barry et al., 1989). Aminophenoxazinone, also known as the antibiotic questiomycin A from *Streptomyces thioluteus* (Gerber, 1967), is produced by a number of fungi (Turner and Aldridge, 1983) and bacteria (Gerber and Lechevalier, 1964).

We have also identified the red pigment produced from BOA by nonsterile soil as 2-amino-3H-phenoxazin-3-one. We note the identity of the ultraviolet and mass spectra and near identity of the proton and [^{13}C]NMR spectra of aminophenoxazinone obtained from transformation of BOA by North Carolina soil to that of the red pigment obtained by transformation with Michigan soil. Aminophenoxazinone contains all of the ^{13}C signals reported for the Michigan transformation product plus six low-intensity quaternary carbon signals not previously reported (Table 1). The [^{1}H]NMR of aminophenoxazinone contains all of the signals reported for 2,2′-oxo-1,1′-azobenzene **(2),** with the same chemical shifts and multiplicities, but, in addition, contains two singlets (6.34 and 6.35 ppm) and a broad singlet due to an NH_2 (6.81 ppm) not reported for the Michigan soil transformation product.

Although nonsterile soil converts the allelochemical BOA into the phytotoxic pigment aminophenoxazinone, sterile soil does not. The probable route of transformation of BOA is its hydrolysis to *o*-aminophenol, followed by oxidation to aminophenoxazinone (Scheme 1). Since hydrolysis of BOA in the laboratory requires prolonged treatment with aqueous alkali or acid at 100°C or higher (Graebe and Rostovzeff, 1902) and does not occur in sterile soil, the hydrolysis of BOA to *o*-aminophenol must be a step requiring soil microorganisms. Sterile soil in contact with air is capable of accomplishing the subsequent oxidation of

o-aminophenol into aminophenoxazinone. Some microorganisms are also known to oxidize *o*-aminophenol to aminophenoxazinone, but their presence has not been demonstrated in soil samples capable of converting BOA or *o*-aminophenol into aminophenoxazinone. The present study does not exclude the possibility that microorganisms contribute to the rate of oxidation of aminophenol to aminophenoxazinone. The transformation product, aminophenoxazinone, is an order of magnitude more phytotoxic than BOA. It is significant that this compound has recently been identified as the phytotoxin of the plant pathogen *Acrospermum viticola* (Kinjo et al., 1987). Thus, the microbially produced aminophenoxazinone has the potential for increasing the allelopathic effect of rye mulch.

Acknowledgments—This study was supported in part by U.S. Department of Agriculture grant 91-37303-6433.

(Received January 30, 1992; accepted May 19, 1992)

Abstract—A lure based on the proportional composition of monoterpenes in *D. micans* larval frass and deployed in Theysohn slot traps was highly attractive to *R. grandis* released in the field. The relative response to frass and lure was consistent over a range of doses, and behavior close to traps baited with either lure or frass appeared to be similar. The monoterpenes, formulated with antioxidant, appear to be stable over several weeks when released from proprietary reservoir and wick "air fresheners." The lure may be of value in monitoring predator populations.

Key Words—Frass, kairomone, monoterpenes, traps, *Dendroctonus micans*, *Rhizophagus grandis*, Coleoptera, Scolytidae, Rhizophagidae.

INTRODUCTION

Rhizophagus grandis (Gyll.) (Coleoptera; Rhizophagidae) appears to play an important role in the natural control of its prey, larvae of the spruce bark beetle, *Dendroctonus micans* (Kug.) (Coleoptera; Scolytidae) (Grégoire, 1988). This predator has been used with some success in biological control programs against *D. micans* in France, Soviet Georgia, Turkey, and Britain (King and Evans, 1984; Grégoire, 1988; N. Uslu, Ormancilik Arastirma Institusu, Ankara, Turkey, personal communication).

Two strategies have been adopted for predator release, both of which have

resulted in successful establishment. In France, 50–1000 pairs were released per hectare in infested forests (Grégoire, 1988; Grégoire et al., 1985), whereas in Britain only 10–50 pairs were released at "infested sites" in and around a scheduled quarantine area (Wainhouse, 1987; Evans and King, 1989; Fielding et al., 1991). Establishment of *R. grandis* has been verified at some sites in Britain by felling trees in the year following release and searching *D. micans* galleries (N. J. Fielding, Forest Authority Research Station, personal communication). Despite the release of relatively few individuals per unit area, successful establishment is in part due to the kairomone response of the adult predator, which appears to be mediated by a blend of host-derived monoterpenes released from *D. micans* larval frass (Wainhouse et al., 1991).

In this paper, we report results of the release and recapture of unmarked laboratory-reared *R. grandis* adults (Evans and King, 1989) in experiments to determine the dose response to both *D. micans* larval frass and artificial lures based on a blend of monoterpenes.

METHODS AND MATERIALS

Release and Recapture of Unmarked R. grandis *Adults*

Four experiments were done in a 0.25-ha compartment of predominantly Sitka spruce (*Picea sitchensis*) planted in 1963 (OS ref. SO 500 734) near Ludlow, Shropshire, U.K. in which both *D. micans* and *R. grandis* were present at low density. In the compartment, thinned to about 2.5 m between trees, a 50-m/square trapping arena was formed using Theysohn slot traps (Speight and Wainhouse, 1989) at five positions about 10 m apart arranged on each of the four sides. The trap lines were either parallel or perpendicular to tree rows, which were oriented approximately WNW–ESE. Traps were at least 1 m from the nearest tree.

Frass and synthetic trap baits were used in experiments. Frass baits came from a mixed sample of *D. micans* larval frass (stored for several weeks at −18°C) from Norway and Sitka spruce. The frass was held in nylon 0.5-mm-mesh sachets, usually in units of 5 g occupying 5 × 2 × 1 cm. Smaller quantities of frass were packed to a similar density so that volume was approximately proportional to weight. Baits of liquid synthetic lures were dispensed, respectively, from: (1) 2.5 g of dried, diethylether-extracted Norway spruce bark powder, in nylon sachets, whose volume approximated that of 5 g of frass; and (2) a wick system using proprietary air freshener technology with the odor dispersing from a release pad (max. diam. 48 mm) supplied by a reservoir holding about 80 g of lure.

Experiments were carried out during July–September in both 1990 and 1991. Treatments of different trap baits were allocated at random to each trap-

ping position on each side of the arena. In each experiment, 2000–2500 laboratory-bred *R. grandis* (Evans and King, 1989) were released in moist sand in a plastic tray from which they could only disperse by flight. Females were assumed to outnumber males by about 1.8:1 (Wainhouse et al., 1991). Wire mesh over the tray prevented predation by birds. Releases were made from the center of the arena, usually around midday, when winds were light and variable. Following releases, temperatures subsequently rose to at least 19°C. Catches were collected at dusk on the day of release or the following morning before any further flight had occurred. The number of beetles in each trap and those remaining in the release tray were counted.

Experiment 1: Effect of Trap Number. At each trapping position, one to three traps were used, although only one was baited. Each trap was approximately 10 cm thick × 50 cm wide × 60 cm tall and occupied an upper, middle, or lower position. The tops of traps in the upper position were 2 m above the ground and traps were suspended one below the other to increase the vertical component of the visual silhouette. The arrangement of traps and the position of 5-g frass baits in this experiment are shown in Figure 1A. There were three trials using traps 1–5 and two using traps 6–10.

Experiment 2: Dose Response to Frass. Except for two trials with three traps per trapping position, this and subsequent trapping experiments employed

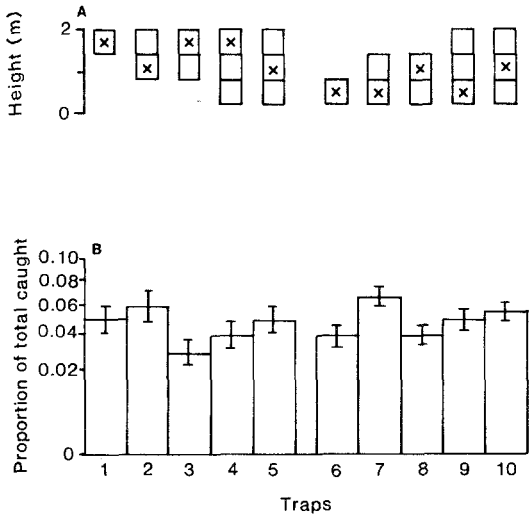

FIG. 1. (A) Arrangement of Theysohn slot traps and frass bait (×) in experiment 1. (B) Catch of *R. grandis* in each trap arrangement (A) as a proportion of the total caught in each trial. Means ± common SE. The total numbers caught were: traps 1–5 (three trials), 112, 247, 78; traps 6–10 (two trials), 198, 68.

two traps with the lower one baited (Figure 1A, trap 2). The following frass treatments were used in separate trials: (1) 4 and 10 g; (2 and 3) 2.5, 5, 10, and 15 g; and (4) 1, 2.5, 5, 10, and 15 g. Frass doses were made up in 2-g units (trial 1) or 1-, 2.5-, or 5-g units (trials 2–4). A control treatment of 2.3 ml of diethylether on 2.5 g of bark powder was included in trials 1–3.

Experiment 3: Response to Different Synthetic Lures. Lures were based on a mixture of monoterpenes, present in frass, that was highly attractive to *R. grandis* in laboratory wind-tunnel experiments (Wainhouse et al., 1991). Commercially available monoterpenes (95–99% purity) were used except for β-phellandrene, which was extracted from Sitka spruce resin or supplied by Glidco Organics, Jacksonville, Florida. The synthetic β-phellandrene was tentatively identified as the (−) enantiomer (D.R. Kelly, M.P.O. Orozco, unpublished observations).

Treatments comprised four lures with minor variations in composition (Table 1) and 5 g of frass. Lure 1, consisting of the five monoterpenes found in frass extracts, and lure 2 correspond to those used by Wainhouse et al. (1991). In lure 1a, *dl*-α-pinene and *dl*-limonene were used, and in 1c, (+)-α-pinene and (−)-limonene were used, which corresponded to the enantiomeric composition found in frass extract. Lure 2 contained myrcene as an impurity in the β-phellandrene extracted from Sitka spruce resin. Lure 3 was similar to lure 2 but was made using synthetic myrcene and β-phellandrene.

One-gram aliquots of each lure (+ approx. 1.2 g ether) were added to bark powder sachets for use in the field. All lures in this and subsequent experiments were formulated with 1% BHT by weight to retard oxidative reactions. There were two trials of this experiment.

Experiment 4: Dose Response to Lure 1a. Using the wick system, different release rates of the lure were obtained by using dispensers with different amounts

TABLE 1. PERCENT COMPOSITION OF LURES[a] USED IN TRAPPING EXPERIMENTS

	Lure 1a	Lure 1c	Lure 2	Lure 3
(+)-α-Pinene	14.0[b]	14.0	13.4	13.4
(−)-β-Pinene	28.0	28.0	26.8	26.8
3-Carene	14.0	14.0	13.4	13.4
dl-Limonene	11.5	11.5[c]	11.0	11.0
β-Phellandrene	32.5	32.5	31.2[d]	31.2
Myrcene			4.2[d]	4.2

[a] Lures 1a, c, and 2 correspond to those of Wainhouse et al. (1991).
[b] *dl*-α-Pinene.
[c] (−)-Limonene.
[d] Synthetic monoterpenes were used except these were extracted from Sitka spruce resin.

of the release pad exposed or by varying the number of dispensers used in traps. In each of seven trials of this experiment, treatments comprised four release rates of lure and a standard bait of 5 g of frass. Release rates of the lure, determined by weight loss during the trial, varied in each trial as follows (1) 0.006–0.05 g/hr, (2) 0.06–0.31 g/hr; (3–5) 0.07–0.26 g/hr, (6) 0.06–0.6 g/hr, and (7) 0.05–0.43 g/hr.

Temporal Changes in Release Rate and Composition of Lure 1a

Experiment 5: Release Rate from Wick Dispensers at Constant Temperature. The daily release rate of the lure was determined in the laboratory at temperatures of 15 ± 1°C and 20 ± 2°C from two or three wick dispensers with half the pad exposed in separate traps for 11 days. During experiments, relative humidity varied from 52% to 64%.

Experiment 6: Temporal Changes in Chemical Composition in the Field. Three wick dispensers in separate traps with a nominal initial release rate of 1–1.5 g/day at 20°C were deployed at three spruce forest sites near Ludlow for 32 days. Samples of lure were taken for chemical analysis at intervals.

A portion of each sample (0.05 ml) was added to 10-bromodecan-1-ol in methylene chloride (0.95 ml, 0.01 g/100 ml), and this mixture further diluted with methylene chloride (1 or 2 ml). The concentration of monoterpenes was determined relative to the 10-bromodecan-1-ol by GC-MS (Hewlett Packard 5890/VG Trio 1) using an EI source at 70 eV. A DB17 column (30 m × 0.322 mm) with a precolumn (10 m) was used for the separation under the following conditions: splitless 1 min, injector 170°C, program 45°C start, 1°C/min to 75°C then 10°C/min to 180°C for 11 min, helium 8 psi, 70 ml/min. The retention times (after a 3.7-min solvent delay) were α-pinene (5.50 min), β-pinene (7.80 min), myrcene (8.42 min), 3-carene (9.20 min), limonene (10.47 min) and β-phellandrene (11.07 min). The retention times were matched with standards and 3-carene and myrcene were confirmed by spiking.

RESULTS

Results from experiments 1–4 suggested that the majority of beetles caught were from releases made on the same day. Nevertheless, because beetles were unmarked, percent recapture could not be determined with certainty. In analyses of the recapture data, we have therefore used the proportion of the total caught responding to each treatment or, when treatments differed between trials, we used the actual number caught in traps. Total catches in the different trials of each experiment varied from 38 to 247.

Release and Recapture of Unmarked R. grandis *Adults*

Experiment 1: Effect of Trap Number. For each trial, the catch for each treatment (Figure 1A) was expressed as a proportion (p) of the total catch over all treatments in that trial. Data from the different trials of traps 1–5 were combined as were those for traps 6–10 (Figure 1B). The two sets of trials were then analyzed independently by analysis of variance of p transformed to angles (degrees) by the arcsin ($\sqrt{p}$) transformation. Differences between treatments were not significant, but in both sets of trials, more insects were caught in the two-trap arrangement in which the lower trap was baited (Figure 1A, traps 2 and 7). The prominence of the visual silhouette appeared to have no effect on trap catches. There was a significant difference between blocks (sides of the arena) ($F_{3,43} = 11.21$, $P < 0.001$) in the trials with traps 1–5.

Although most insects were caught in baited traps, some were also caught in the unbaited ones at the same trapping position. The overall mean for all trials (traps 1–10) was 6.1 *R. grandis* per baited trap and 0.9 for adjacent unbaited ones. The number of insects in the unbaited traps appeared to depend on the trap's position relative to the baited one. The total number of insects in traps above or below baited traps when there were two (Figure 1A, traps 2, 3, 7 and 8) or three traps (Figure 1A, traps 5 and 10) at each position are shown in Tables 2 and 3, respectively. The totals in Tables 2 and 3 were tested (χ^2 test) on the null hypothesis that the position of unbaited traps in relation to the baited trap has no effect on the probability of catches in unbaited traps. Significantly ($P < 0.01$–$P < 0.001$) more insects were trapped in unbaited traps above than below the baited trap in both the two- and three-trap arrangements (Tables 2 and 3). Possible interaction between rows and columns in Tables 2 and 3 was examined using Fisher's exact test. There was no significant evidence of inequality of probabilities.

Experiment 2: Dose Response to Frass. For each trial, the mean number of *R. grandis* caught relative to each dose of frass was determined and the pooled data analyzed by linear regression of log (ln) catch (+0.001) on log

TABLE 2. TOTAL CATCH IN TRAPS ABOVE OR BELOW A FRASS-BAITED TRAP IN TWO-TRAP ARRANGEMENTS IN FIGURE 1a[a]

	Traps 2 and 3	Traps 7 and 8	Total
Above baited trap	14	7	21
Below baited trap	2	3	5

[a]Data from experiment 1. $\chi^2_1 = 9.85$, $P < 0.01$ for departure of total from expectation of 13 in each cell. Fisher's exact test for interaction between rows and columns: probability of this table $P = 0.22$; P in the smaller tail of the distribution = 0.055.

dose. The regression, shown in Figure 2, was highly significant ($t_{13} = 3.89$, $R^2 = 53.81\%$, $P < 0.01$). No insects were caught in the control traps in this or any other experiments in which blank controls were used. Results from control traps were, therefore, omitted from the analysis.

Experiment 3: Response to Different Synthetic Lures. The catch for each treatment in the two trials was transformed as for experiment 1. Results from the two trials were combined in an analysis of variance, which revealed a significant difference between treatments ($F_{4,28} = 5.35$, $P < 0.01$) (Figure 3). Response to the frass was significantly different from that to the lures ($P < 0.05$ LSD test), but no significant differences in catch were detected between the four variants of the lure.

TABLE 3. TOTAL CATCH IN TRAPS ABOVE OR BELOW CENTRAL FRASS-BAITED TRAP IN THREE-TRAP ARRANGEMENT IN FIGURE 1a[a]

	Trap 5	Trap 10	Total
Above baited trap	23	17	40
Below baited trap	6	3	9

[a]Data from experiment 1. $\chi^2_1 = 19.6$, $P < 0.001$ for departure of total from expectation of 24.5 in each cell. Fisher's exact test for interaction between rows and columns: probability of this table $P = 0.26$; P in the smaller tail of the distribution = 0.19.

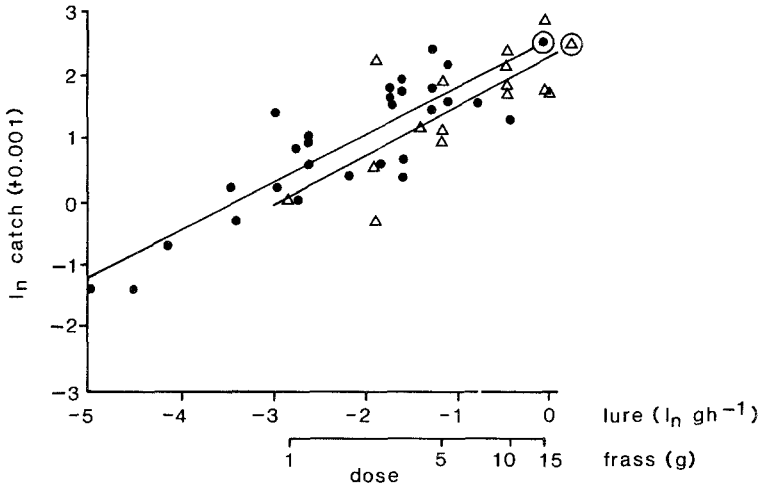

FIG. 2. Dose response to frass (△) ($y = 0.073 + 0.802x$) and lure 1a (●) ($y = 2.624 + 0.770x$) released from liquid dispensers. Relative position of axes adjusted assuming 5 g frass ≡ 0.29 g/hr of lure (see text).

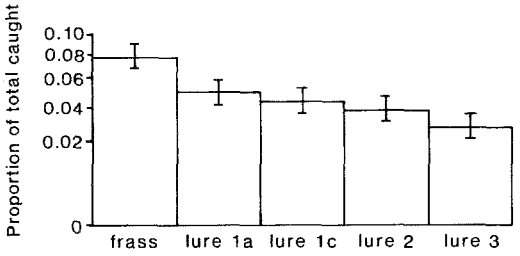

FIG. 3. Catch of *R. grandis* as a proportion of the total caught in each trial. Traps were baited with 5 g of frass or 1 g of lure on 2.5 g of bark powder. Means ± common SE. The total numbers caught (two trials) were: 118, 111.

Experiment 4: Dose Response to Lure 1a. The mean catch of *R. grandis* for each dose of lure was determined for each trial and the pooled data analyzed by linear regression of the log catch (+0.001) on log release rate (+0.001). The regression, shown in Figure 2, was highly significant ($t_{26} = 8.44$, $R^2 = 73.24\%$, $P < 0.001$). The log mean catch for the 5-g frass treatment was 1.67. From the regression of the dose response to lure, $y = 2.624 + 0.770x$, the response to the frass ($y = 1.67$) was estimated by substitution to be equivalent to a release rate of 0.29 g/hr of lure. This equivalence was used to determine the relative position of the x axis for frass and lure doses in Figure 2.

Using data from all the trials (Table 4), we compared the proportion of the total catch in the lower baited and upper unbaited trap in the frass and lure treatments (χ^2 test). There were no significant differences.

Temporal Changes in Release Rate and Composition of Lure 1a

Experiment 5: Release Rate from Wick Dispensers at Constant Temperature. There was a significant linear decrease in mean daily release rate from the wicks over a period of 11 days at 15°C ($t_8 = 8.46$, $R^2 = 89.96\%$, $P < 0.001$) and 20°C ($t_9 = 5.58$, $R^2 = 77.60\%$, $P < 0.001$) (Figure 4).

Experiment 6: Temporal Changes in Chemical Composition in the Field.

TABLE 4. TOTAL CATCH OF *R. grandis* IN BAITED AND UNBAITED TRAPS FROM ALL TRIALS OF DOSE–RESPONSE EXPERIMENT (EXPERIMENT 4)[a]

	Frass	Lure
Upper unbaited trap	36	73
Lower baited trap	136	311

[a] $\chi^2_1 = 0.17$, $P = 0.68$ (with Yates' correction for continuity).

The composition of the lure (Table 5) was estimated as the percentage of the total identified monoterpenes relative to the internal standard. The initial sample (day 0) shows good correspondence with the calculated concentration (Table 1). There was no evidence of oxidative changes in the monoterpenes over the 32-day period. An unidentified minor component in the sample was tentatively assigned as an isomer of limonene or β-phellandrene. Small amounts of other components totaled <3% of the sample.

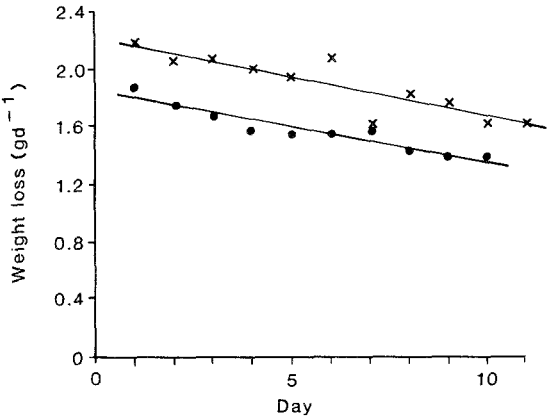

FIG. 4. Mean daily release rate of lure 1a from liquid wick dispensers at 20°C (×) ($y = 2.213 - 0.055x$) and 15°C (●) ($y = 1.841 - 0.048x$).

TABLE 5. COMPOSITION OF LURE 1a IN RESERVOIR OF LIQUID WICK DISPENSERS IN THEYSOHN SLOT TRAPS[a]

	DAY						
	0	2	4	8	16	32	± SE
(dl)-α-Pinene	14.5	14.6	14.5	14.9	15.0	14.7	0.15

3-Carene	15.2	15.4	15.5	15.3	15.1	15.4	0.09
dl-Limonene	15.7	15.3	15.5	14.8	14.5	15.2	0.24
β-Phellandrene	26.1	26.2	25.8	25.9	26.4	25.7	0.18
Unknown	2.0	1.9	1.9	1.9	1.9	2.0	0.06

[a] A single dispenser, with an initial release rate of 1–1.5 g/day, was used at each of three field sites. Values are means of the three sites except for initial value (day = 0) based on one sample of the newly formulated lure. SE estimated from the pooled variation within sites.

DISCUSSION

Results from wind-tunnel experiments (D. Wainhouse, T. Wyatt, unpublished observations) suggest that a distinct silhouette at the source of attractive odors stimulates a landing response. In our field experiment (experiment 1), there is no evidence that increasing the number of unbaited traps, and so enhancing the visual silhouette at a single trapping position, results in higher captures of *R. grandis* when a standard frass bait is used. This suggests that chemical rather than visual cues are the main factors governing the approach of *R. grandis* to traps. Only one trap was baited at each position, and this caught most of the insects. Some, however, were caught in unbaited traps, more entering those positioned above than below the baited trap (Tables 2 and 3). Based on wind-tunnel observations (D. Wainhouse, T. Wyatt, unpublished observations), we suggest this arises from an upward component to the flight close to traps as the predator searches for the source of the odor, followed by a landing response when the odor is lost or concentration declines. The relative numbers of insects caught in the lower baited and upper unbaited traps from the lure and frass treatments in experiment 4 (Table 4) are very similar, and this clearly suggests that the behavior of *R. grandis* in approaching and entering traps containing lure is comparable to that of the natural attractant. We attributed the difference in numbers caught between the sides of the arena for trials with traps 1–5 (experiment 1) to the effect of wind direction during trapping.

Fewer insects (Figure 3) were caught with lures containing myrcene (Table 1, lures 2 and 3) than those without, although the difference was not significant. In laboratory experiments, (Wainhouse et al., 1991), the presence of myrcene caused insects responding to lure to make more approaches to the target before eventually landing. This behavior may have contributed to the reduced catches in traps baited with lures containing myrcene. Myrcene was a minor component of our frass. The enantiomeric composition of α-pinene and limonene does not appear to be important in determining response to the lure, confirming results of laboratory experiments (Wainhouse et al., 1991).

In our traps, a release rate of 0.29 g/hr of lure (1a in Table 1) was estimated to give a catch similar to that of the odor released by 5 g of frass. Results from wind-tunnel experiments (Wainhouse et al., 1991) suggest that approximately 1 mg of lure was equivalent to 50 mg of frass, i.e., 0.1 g of lure to 5 g of frass. Comparison between results from the field and laboratory is not straightforward because, in the wind tunnel, response was assessed over a relatively short period (8 min), and we have no detailed information on relative release rates from frass or the bark powder used as a medium for the lure. Results suggest, however, that the lure is less active in the field by a factor of at least 3 (0.29 g/hr $\equiv$ 5 g frass in the field, 0.1 g $\equiv$ 5 g frass in the laboratory). Nevertheless, the data

presented in Figure 2 show clearly that the relative response to lure and frass in the field is consistent over a wide range of doses.

Oxygenated monoterpenes, quantitatively minor components of *D. micans* frass used in our experiments (Wainhouse et al., 1991), are attractive to flying *R. grandis* in wind-tunnel experiments but only at high concentrations, equivalent to 13–259 times their concentration in frass (Grégoire et al., 1992; D. Wainhouse and D. Kelly, unpublished observations). These chemicals probably function as oviposition stimulants (Grégoire et al., 1991) but could affect orientation close to prey galleries and so may affect trap entry.

The decline in the release rate of the lure from the wick dispensers (Figure 4) may be due to polymerization of the monoterpenes on the surface of the release pad, but the monoterpenes (with the antioxidant BHT) in the reservoir remain unchanged after several weeks of exposure in the field.

The attractiveness of the *R. grandis* lure, its relative stability in the field, and the results of preliminary trapping experiments in "natural" field populations (unpublished) suggest that the lure may be of value in IPM programs. Semiochemical lures for natural enemies have a number of suggested uses such as (1) monitoring activity and population size, (2) inducing host-seeking behavior, (3) reducing the innate tendency of released individuals to disperse, or (4) increasing rates of parasitism by released parasitoids (Lewis et al., 1972, 1982; Gross et al., 1975; Gross, 1981; Nordlund et al., 1981; Lewis and Nordlund, 1985; Powell, 1986).

The *R. grandis* lure could be used to confirm the establishment of the predator following release, to attract *R. grandis* to *D. micans*-attacked trees and to estimate dispersal following release. It may also be possible to monitor indirectly for *D. micans*, which is difficult to detect at low population density. Trapping *R. grandis* would be most useful around quarantine areas within which the predator is well established and where spread of the bark beetle could be prevented by destruction of infested trees.

Some female *D. micans* were caught in our frass- or lure-baited traps, usually when maximum temperatures were 21–25°C. This is probably a response to the monoterpenes, some of which have been shown to be attractive in laboratory experiments (Vasechko, 1978). A response to conspecific frass may explain the observation that on occasion several *D. micans* females may attack the same tree (D. Wainhouse, unpublished). Further work is needed to determine whether direct monitoring of *D. micans* would be possible.

Acknowledgments—We are grateful to the Scottish Forestry Trust for financial support to P.B.-G. Our thanks to Peter Higham and Alison Waters for rearing thousands of *R. grandis* adults and to Robert Ashburner and Owen Wainhouse for help with field work. Owen Jones gave helpful advice on the use of the wick release system. Tristram Wyatt and Tony Ludlow made helpful

comments on the manuscript. Glidco Organics, Jacksonville, Florida, kindly supplied the β-phellandrene, and Agrisence-BCS, Pontypridd, Mid-Glam, the blank air fresheners.

(Received December 31, 1991; accepted May 26, 1992)

Abstract—Two dispenser types for pine sawfly (Hymenoptera: Diprionidae) pheromones—glass capillaries and dental cotton rolls—are described, and release rates reported. Glass capillaries of different diameters were used in field tests to determine dose–response relationships of (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-yl acetate (diprionyl acetate), diprionyl propionate, and *trans*-perillenal on the trap catch of male *Neodiprion sertifer*. A linear relationship between the logarithm of the capillary cross-sectional area and the logarithm of the release rate was found. However, capillaries of the same diameter could vary in the amount released by as much as a factor of 10. Both the acetate and propionate were attractive alone, but no synergistic effect was found. *trans*-Perillenal did not show any behavioral activity. Dental cotton rolls have been used extensively in diprionid pheromone research without knowledge about release rates. The release rate from rolls loaded with different amounts of diprionyl acetate was determined by extracting rolls after different times under constant temperature and wind conditions or after use in field tests. Quantification of diprionyl acetate was done on GC. The release rate was found to be proportional to the amount applied over several orders of magnitude, and persisted for several weeks. Capillaries and rolls with similar release rates caught similar numbers of sawflies.

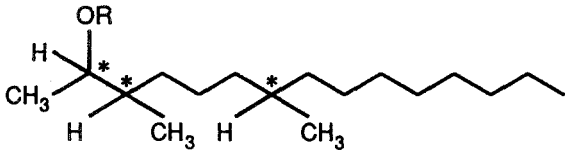
INTRODUCTION

Two factors are of vital importance when investigating the biological activity of semiochemicals: the chemical composition (including the purity of components) and the amounts of the various components released. Often, the first factor receives much more attention, while release rates and ratios are approximated or even unknown, especially under field conditions. Much effort has been made to determine and control release rates from commercial pheromone formulations, e.g., hollow fibers, plastic laminates, and microcapsules, mainly used for lepidopterous pests (see review chapters in Kydonieus, 1980; Mitchell, 1981; Leonhardt and Beroza, 1982; Kydonieus and Beroza, 1982; Jutsum and Gordon, 1989; Ridgway et al., 1990).

The pheromone system of several North American diprionid species has been investigated by e.g. Coppel et al. (1960), Jewett et al. (1976), and Olaifa et al. (1987, 1988). Most efforts have been made to identify the pheromone of different species, and to understand how reproductive isolation between sympatric species can be achieved by the use of different pheromone blends. For the 12 species studied so far, the main component of the sex pheromone has always been found to be the acetate (R=$COCH_3$) or propionate (R=COC_2H_5) of 3,7-dimethyl-2-pentadecanol (diprionol, R=H):



Diprionol has three optically active carbon atoms (*), and thus eight possible stereoisomers. In many species only one of the stereoisomers, the (2*S*,3*S*,7*S*)-, is active, but in some the addition of another stereoisomer synergizes or inhibits attractiveness (Kraemer et al., 1979, 1981, 1983; Kikukawa et al., 1982, 1983; Olaifa et al., 1984, 1987, 1988). In all field studies reported, female extracts or synthetic chemicals have been released from dental cotton rolls. However, so far there have been no published reports on release rates or on persistence of release ratios over time. Dental cotton rolls have also been used in several studies of lepidopteran pheromones, but the major drawback is a too rapid release of the pheromones (see review by Weatherston, 1989).

In an earlier paper we showed the importance of composition and purity

of optical isomers of 3,7-dimethylpentadecan-2-yl (diprionyl) acetate for the attraction of male pine sawflies, *Neodiprion sertifer* (Geoffr.) (Anderbrant et al., 1992). One basis of that study was a thorough knowledge about the relative release rates of the isomers when applied at different doses. In the present study we present release rates measured both in the field and in the laboratory and report results from field tests on *N. sertifer* using different release rates. The field tests were conducted to establish dose–response relationships for the known attractants (2*S*,3*S*,7*S*)-diprionyl acetate and propionate and, for a monoterpene, (*E*)-2-methyl-5-(3-furyl)-2-pentenal (*trans*-perillenal), found in the females (Ahlgren et al., 1979; Wassgren et al., 1992). Possible synergistic effects were also investigated.

METHODS AND MATERIALS

Chemicals

For the field tests in 1981 and 1982 (2*S*,3*S*,7*S*)-diprionyl acetate and propionate were prepared by Byström et al. (1981). These esters contained 14% of the inactive 2*S*,3*S*,7*R*-isomer and less than 0.02% of the inhibitory 2*S*,3*R*,7*R*-isomer. In 1982 (tests 82:1 and 3), release measurements were done using a *threo*-mixture, i.e., the 2*S*,3*R*,7*R*, 2*S*,3*R*,7*S*, 2*R*,3*S*,7*S*, and 2*R*,3*S*,7*R* isomers (Magnusson, 1978). In the 1988 tests the (2*S*,3*S*,7*S*)-diprionyl acetate was prepared by Högberg et al. (1990). This contained 2.3% of the 2*S*,3*S*,7*R* isomer, and less than 0.05% of the other isomers (Högberg et al., 1990; Anderbrant et al., 1992). The *trans*-perillenal (Baeckström et al., 1982) contained less than 2% of the *cis* isomer.

Measurements of Pheromone Release Rates

Two types of dispensers were used, glass capillaries of different inner diameters, and 4 × 1-cm dental cotton rolls (Celluron No. 2, Paul Hartmann S.A., France). The release from capillaries was measured after they had been used in field experiments, whereas measurements of release rates from cotton rolls were done both in the laboratory under defined conditions and after they had been used in the field.

Rate of Pheromone Emission from Capillaries in Field. Capillaries were purchased (Microcaps, Drummond Scientific Co.) or made by ourselves. Their inner diameters ranged from 0.0045 mm to 0.91 mm. Capillaries were filled by dipping one end into the neat chemical. Only part of the capillary was filled and was then tilted to move the substance off the end. The end that had been dipped was then cut off so no substance could emit from the outer capillary surface. The amount of substance was measured under a microscope before and after

field experiments. Capillaries were either open at both ends to give a relatively high release rate, or sealed with glue in one end after filling. Measurements were made of capillaries used in the tests in 1982 (82:1, 3, 4, and 6) and 1988 (88:1 and 2). For the tests done in 1981 the release rates were estimated based on the relationships found in the 1982 tests.

Rate of Pheromone Emission from Cotton Rolls in the Laboratory. Emission of (2*S*,3*S*,7*S*)-diprionyl acetate from dental rolls was studied at three different doses: 6, 60, and 600 μg per roll, and at two different wind speeds: 0.1 and 1.0 m/sec. The acetate was added to the rolls as a hexane solution (600 μl of 1 μg/μl, 0.1 μg/μl, and 0.01 μg/μl solutions, respectively). The dispensers were placed horizontally in a holder, well separated from each other, in a mini wind tunnel (20 cm $\times$ 12.5 cm diam.) at constant temperature (range: 19.5–20.1°C). After 1, 2, 4, or 5, 8, and 15 or 16 days (for 0.1 m/sec after 2, 8, and 16 days) three rolls were removed and each was placed in a round flask. To each flask 10 ml pentane (analytical grade) was added, the flask was stoppered, and left over night. The pentane portion was removed by pipet and known amounts of 18:OAc were added as internal standard. The rolls were extracted with two additional 10-ml portions of pentane, and the combined rinse solution was condensed to a volume suitable for GLC analysis. Capillary gas chromatography with flame ionization detection was performed on a Hewlett Packard model 5890A GC, equipped with a 25-m Carbowax column. Conditions of chromatography were: starting temp. 60°C, split valve opened after 1 min, temperature maintained at 60°C for 2 min following injection, then programmed at 30°C/min to 230°C.

To measure the recovery efficiency of diprionyl acetate by the described method, dispensers of each load were also extracted immediately after application of the pheromone.

Rate of Pheromone Emission from Cotton Rolls in the Field. Dental rolls loaded with 6, 60, 600, or 6000 μg diprionyl acetate were collected after about one month in the field (tests 88:1 and 2). The dispensers were kept frozen in sealed vials until extracted according to the procedure described above.

In addition, rolls loaded with 600 μg diprionyl propionate were hung under rain and sun shelter during the summer of 1988. Three rolls were collected after 3, 5, 9, 20, and 30 days, and then subjected to extraction as described above.

Tests of Behavioral Activity

The experiments in 1981 and 1982 were done in a young lodgepole pine, *Pinus contorta* Dougl., plantation near Ekshärad, province of Värmland, Sweden, from the end of August to the beginning of October. In 1988 the tests were done from August to October in young Scots pine, *Pinus sylvestris* L., plantations near Gryt, province of Östergötland, Sweden.

In 1981 cross-barrier traps made from two 35 × 35-cm white plastic-covered cardboard sheets were used. All sides were covered with Stikem Special (Seabright Enterprises, Emeryville, California). In 1982 and 1988, Lund-I sticky traps were used. These consist of two white, horizontal plastic-covered cardboard sheets approximately 6 cm apart with the upper surface of the bottom sheet covered with Stikem Special. Both traps are depicted in Anderbrant et al. (1989). Traps were hung in young pines about 2 m above the ground and at least 30 m apart. In order to reduce positional effects, traps were moved forward one step after each collection (in 1981 and 1982) or to a new random position restricted so that all baits should be in all positions at least once (in 1988).

In 1981 and 1982 substances were released from capillaries only, whereas a comparison between traps with capillaries or dental rolls was done in the 1988 tests.

RESULTS

Measurements of Pheromone Release Rates

Rate of Pheromone Emission from Capillaries in the Field. The release of diprionyl acetate was measured in tests 82:1, 82:3, and 82:4. In test 82:1 capillaries open at both ends were used, and the logarithm of the release rate showed a linear relationship with the logarithm of the cross-sectional area of the capillary (Figure 1A). Approximately the same capillary sizes were used in 82:4, resulted in a similar relationship (Figure 1A). In both experiments release rates from capillaries of a certain diameter varied over about one order of magnitude. In 82:3, one end of the capillaries was sealed. Twelve of 34 capillaries did not release any measurable substance, but if these zero-release capillaries were excluded from the analysis, a linear relationship appeared, with smaller intercept than for capillaries open at both ends (Figure 1A).

In test 82:6 the release of *trans*-perillenal from capillaries open at both ends showed a similar relation to capillary cross-sectional area as did diprionyl acetate (Figure 1B).

Rate of Pheromone Emission from Cotton Rolls in the Laboratory. The recovery efficiency of pheromone from dental roll dispensers by the described extraction procedure was high at all three doses investigated. For 600, 60, and 6 μg diprionyl acetate applied, 575 ± 25 (SD), 54.5 ± 2.7, and 5.5 ± 0.22 μg was detected in the rinse solution.

Two regression models, $y = a \exp [b \ln (x + 1)]$ and $y = a - b \ln (x + 1)$, where y is the remaining amount and x is the time in days, were fitted to the data. The models gave a similar fit for all data sets, and in Figure 2 the equations with largest r^2 value are given. The decrease in recovered amount over time for the three different doses applied showed the same type of rela-

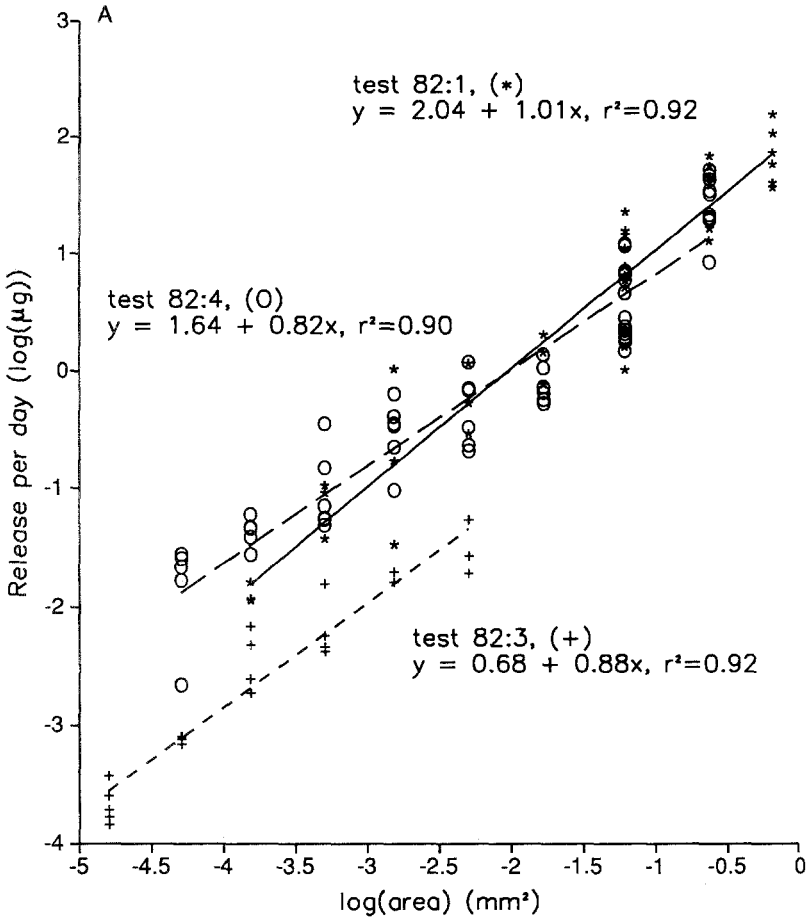


FIG. 1. Release of diprionyl acetate (A) and *trans*-perillenal (B) in the field from capillaries of different cross-sectional area. In tests 82:1, 4, and 6 capillaries were open at both ends, and in test 82:3 they were sealed at one end. The released amount was measured under a microscope after the experiment was finished, 82:1 after 5 days, 82:3 after 15 days, 82:4 after 7 days, and 82:6 after 9 or 17 days (see Table 3).

tionship when wind and temperature conditions were the same (Figure 2A, 1 m/sec and Figure 2B, 0.1 m/sec). This implies that the ratio between different doses persists for a long time. The derivatives of the regression equations in Figure 2 were used to compute the release rates over time, as shown in Figure 3. The release at both wind speeds decreased exponentially over time: rapidly during the first days but then the rate remained fairly stable, and decreased from

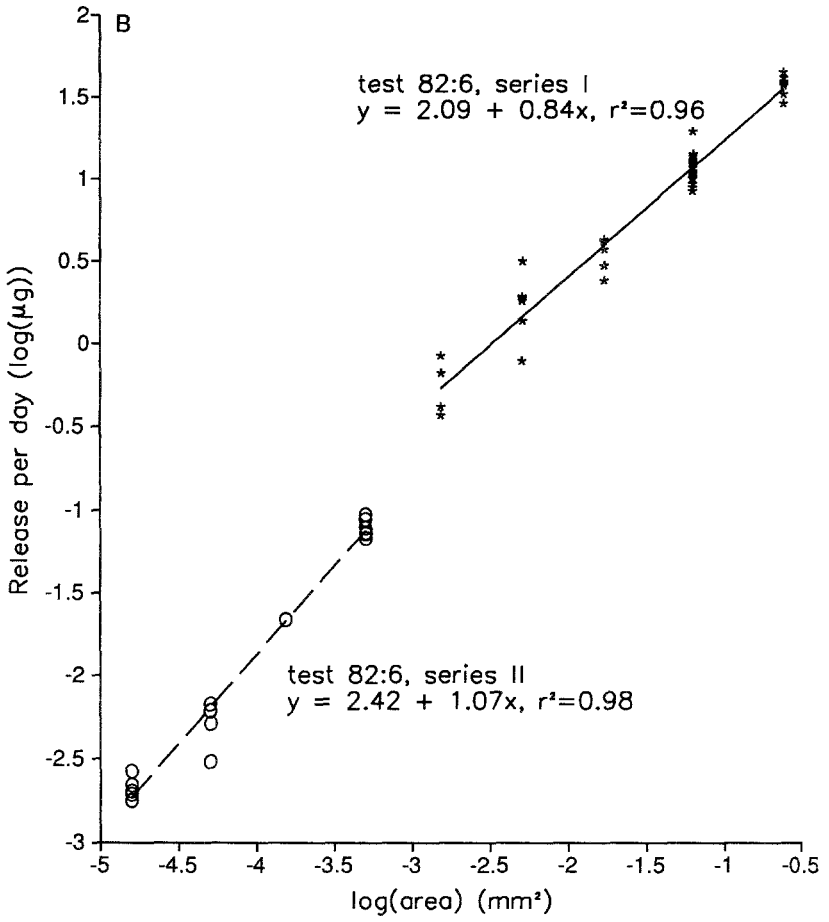

FIG. 1. Continued

about 3%/day after eight days to about 2%/day after 16 days when wind speed was 0.1 m/sec.

Rate of Pheromone Emission from Cotton Rolls in the Field. The described extraction technique was used also for dispensers from field experiments. The amounts of diprionyl acetate released during a month under field conditions were proportional to amounts applied (Table 1). When 10 times more pheromone was applied to a dispenser, the released amount increased approximately 10 times.

The release over time was calculated by using the regression equations from the laboratory data ($y = a \exp[b \ln (x + 1)]$, Figure 2A), and solving for

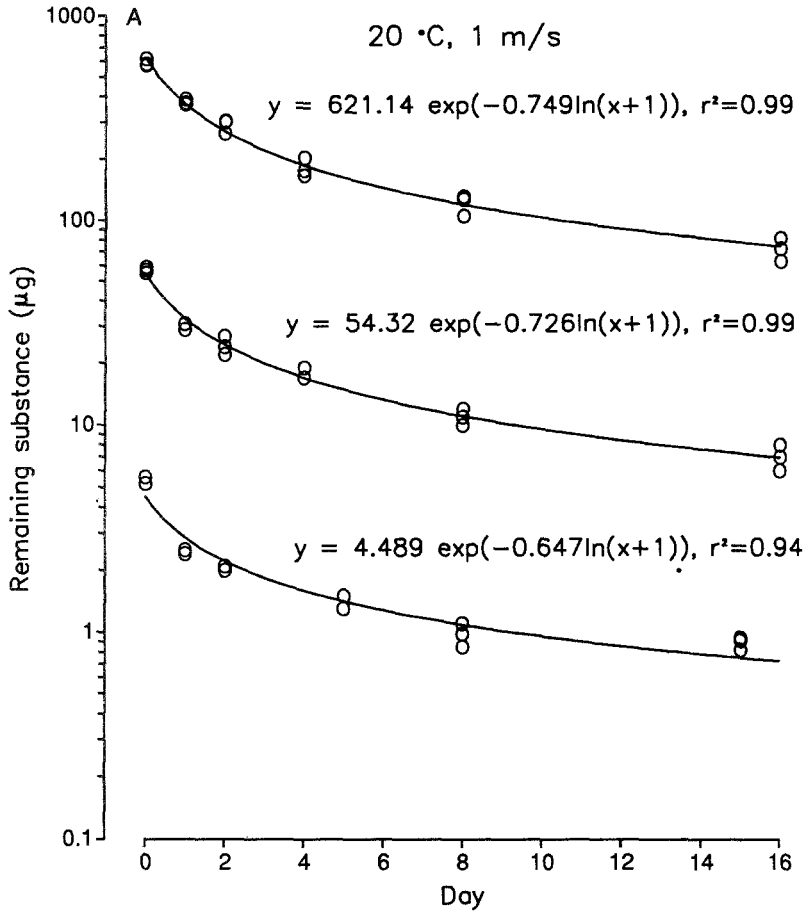

FIG. 2. The amount of diprionyl acetate remaining in dental rolls after different times in a mini wind tunnel at 20°C and 1.0 m/sec (A), or at 20°C and 0.1 m/sec (B).

the constant b. As y (remaining amount) the averages for each load from tests 88:1 and 2 were used (Table 1), and x was put to 33.5 days (average duration of the two experiments). For the highest amount used in the field (6000 μg), the constant a was put to 6000 since no regression equation from the laboratory was available. These calculations resulted in the curves shown in Figure 4.

The extracted amounts from dispensers containing 600 μg diprionyl propionate after different times in the field are also shown in Figure 4. A similar relationship as for the acetate was found. It should be mentioned that the propionate release test was done in the summer and thus under a higher average temperature than the acetate field test.

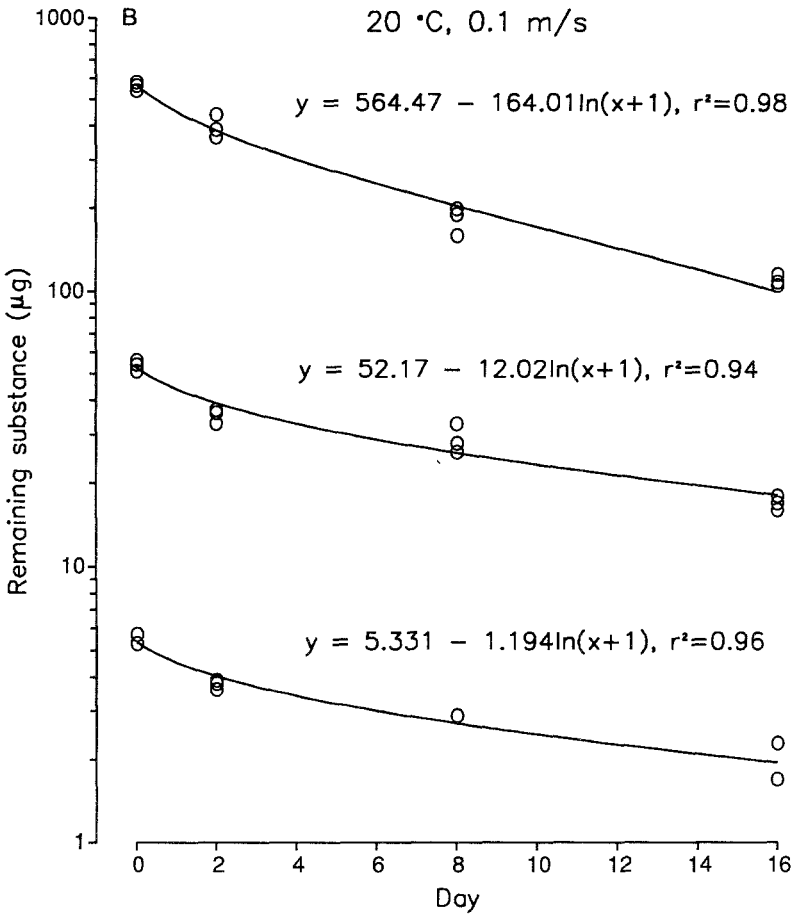

FIG. 2. Continued

Tests of Behavioral Activity

Tests 82:1 and 82:3 were part of an extensive study where the role of the different optical isomers of diprionyl acetate was investigated (Anderbrant et al., 1992).

Tests of Dose-Response Relationships (81:1, 82:4, 88:1, 88:2). In test 81:1, *trans*-perillenal, (2*S*,3*S*,7*S*)-diprionyl acetate, and (2*S*,3*S*,7*S*)-diprionyl propionate were released from different traps with approximate (estimated from the relationship found in the 82:1, 3, 4, and 6 tests, see Figure 1) release rates of 0.4–11.2 µg/day for the acetate and propionate, and 0.8–19.8 µg/day for *trans*-perillenal. No clear dose-response relationships were found, although for

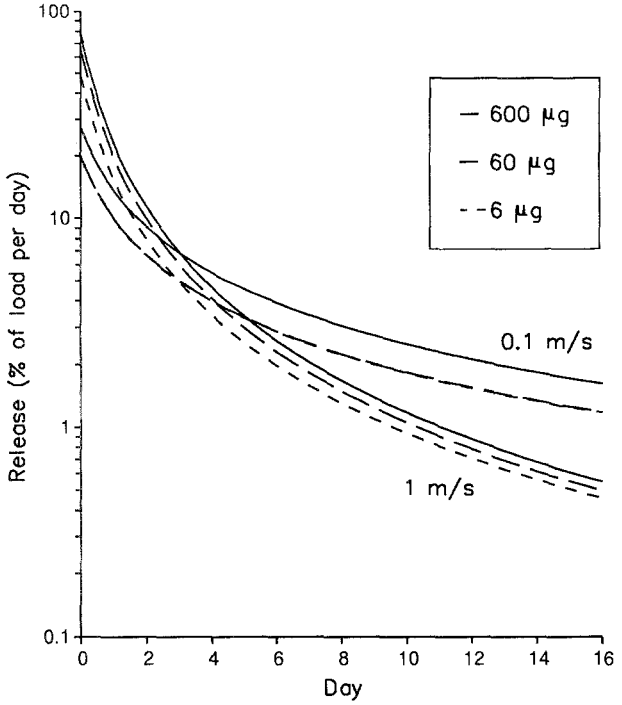

FIG. 3. Calculated instantaneous release of diprionyl acetate from dental rolls, expressed as percent of applied amount, at different wind speeds. Curves are the derivatives of the regression equations in Figure 2.

TABLE 1. AMOUNT OF DIPRIONYL ACETATE EXTRACTED FROM DENTAL ROLLS (ONE PER LOAD AND TEST) AFTER FIELD EXPOSURE IN TESTS 88:1 (31 DAYS) AND 88:2 (36 DAYS), AND THE CALCULATED RELEASE[a]

[a]For the number of male sawflies caught, see Figure 6.

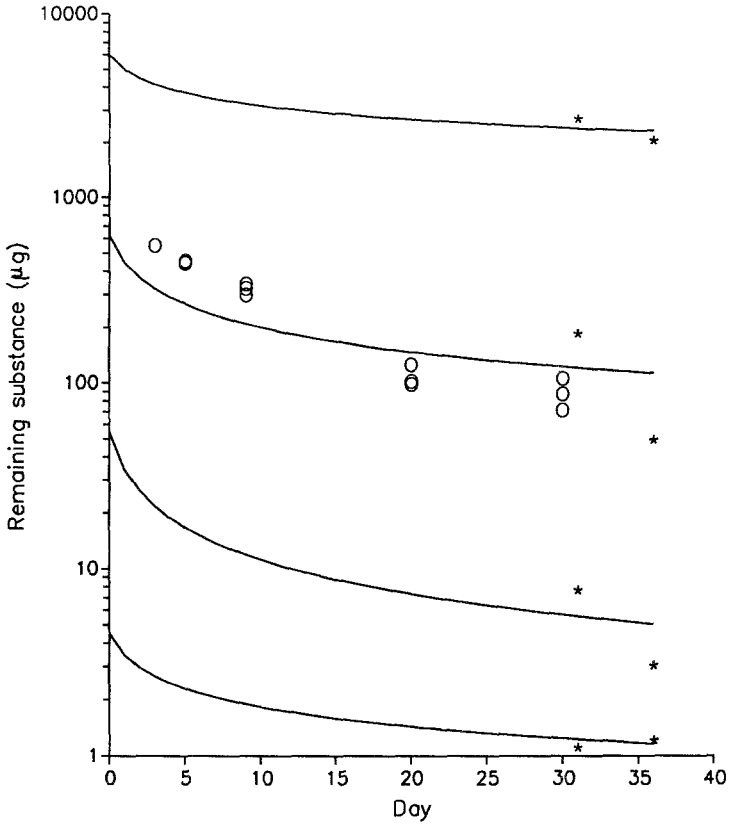

FIG. 4. Calculated remaining amounts of diprionyl acetate in dental rolls after different times in field. Curves are derived from the amounts extracted (*) after the experiments 88:1 and 2 were finished (Table 1) and from the shape of the regression curves in Figure 2a. The extracted amount of diprionyl propionate (600 µg applied) after different times in field is indicated by circles.

both acetate and propionate the catch was highest in the traps with strongest bait. For *trans*-perillenal most catches were not significantly larger than that of the unbaited trap (Table 2). When the three compounds were used in the same trap, no significant increase in catch compared to the acetate or propionate alone was noted.

However, in test 82:4 with release rates (measured) of (2*S*,3*S*,7*S*)-diprionyl acetate ranging from 0.01 to 300 µg/day, a clear dose–response relationship was found. Even for the lowest release rate, the average catch was significantly higher than in the unbaited trap (Figure 5).

The tests in 1988 (88:1 and 2) were designed to establish a dose–response

[a] Three sets of traps were used and they were repositioned seven times, i.e., 21 replicates, September 1–9, 1981. Substances were released from capillaries with release rates estimated from the measurements done in tests 82:1, 3, and 6.

[b] Figures followed by the same letter are not significantly different ($P = 0.05$) according to Duncan's multiple range test after ln(catch + 1) transformation. ANOVA $F = 5.05$, $P < 0.001$.

relationship for the diprionyl acetate when released from dental rolls and to compare rolls with capillaries. The dental rolls were loaded with 0.06, 0.6, 6, 60, 600, or 6000 μg diprionyl acetate, and three capillary sizes (0.080, 0.28, and 0.546 mm diameter) were used. The release rates of the capillaries and of the four strongest dental rolls were measured. For the two weakest dental roll baits, the release was set to 1% and 10%, respectively, of the 6-μg bait, because of analytical limitations of the procedure described above. The catch increased with release rate up to approximately 10 (test 88:1) or 100 (test 88:2) μg/day (Figure 6A and B). The catches in traps with capillaries were in good agreement with those of traps with dental rolls of comparable release rates. Since capillaries can be expected to give a relatively steady release rate over time, whereas that

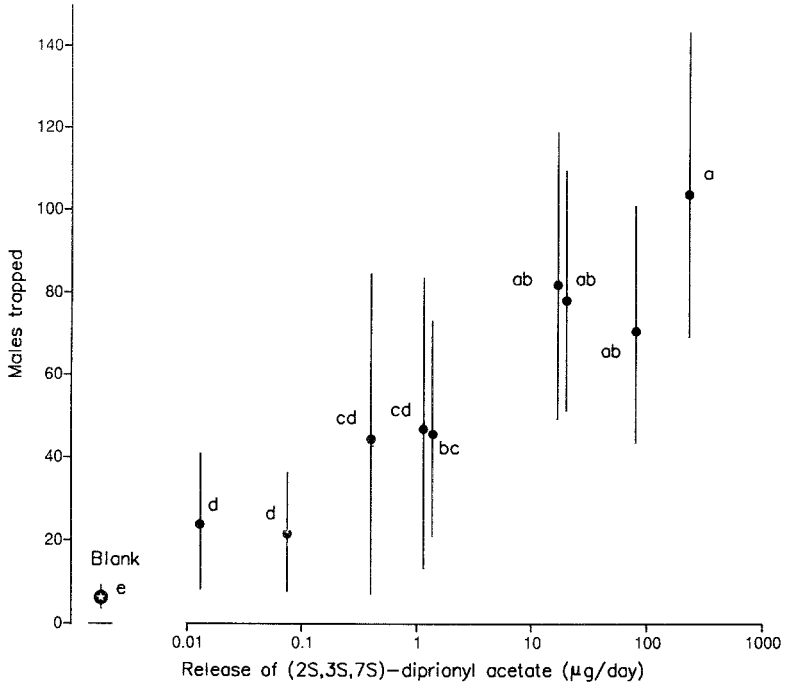

FIG. 5. Test 82:4. Average catch of male pine sawfly, *Neodiprion sertifer*, in horizontal Lund-I sticky traps releasing different amounts of (2*S*,3*S*,7*S*)-diprionyl acetate from capillaries. Three sets of traps were used, and they were repositioned five times, i.e., 15 replicates, August 31 to September 9, 1982. Bars indicate 95% CI. Means with the same letter are not significantly different ($P = 0.05$) according to Duncan's multiple range test after ln (catch + 1) transformation. ANOVA $F = 10.5$, $P < 0.001$.

of dental rolls was shown to decline over time, one would expect that traps baited with dental rolls caught comparatively more sawflies in the beginning of an experiment and less at the end than traps with capillaries. However, no such tendency was found, which partly may be due to large differences between positions and replicates.

Tests of Synergism between Diprionyl Acetate and Propionate (81:2, 82:5). In test 81:2 one of the substances was released at the same rate (1.5 µg/day) from several traps, while the release rate of the other substance varied between traps (0, 0.4, 0.9, 1.5, 3.3, 11.2, 33.6, 112 µg/day). Average trap catches ($N = 12$) varied from 43 to 117 males in the 16 differently baited traps, and on average, 41 males were caught in the blank traps. Traps with the strongest baits (112 + 1.5 µg) caught the most, but there was no indication of synergism between the acetate and propionate.

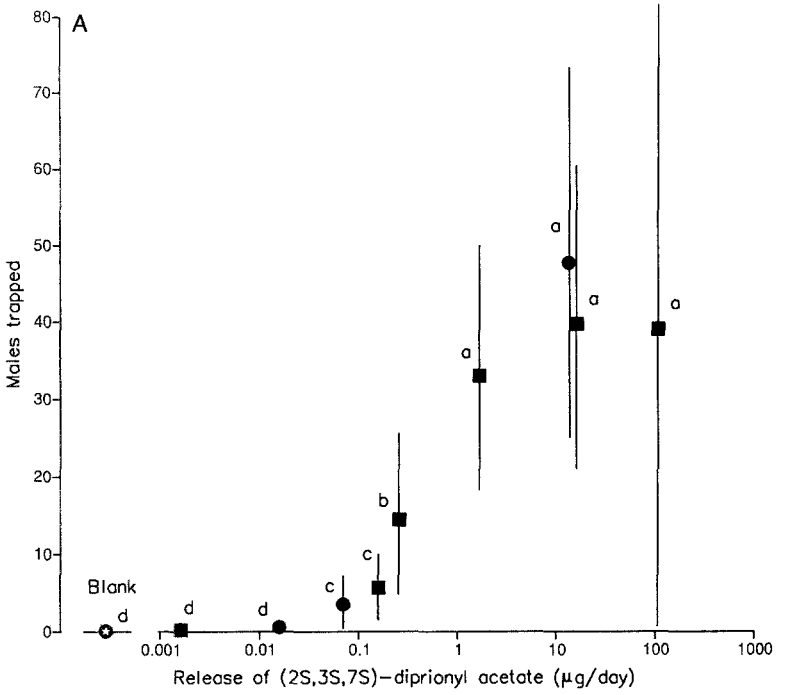

FIG. 6. Tests 88:1 (A) and 88:2 (B). Average catch of male pine sawfly, *Neodiprion sertifer*, in horizontal Lund-I sticky traps releasing different amounts of (2*S*,3*S*,7*S*)-diprionyl acetate from dental rolls (■) or capillaries (●). In 88:1, traps (one setup) were randomized 10 times, August 30 to September 30, 1988, and in 88:2, traps (one setup) were randomized 15 times, August 31 to October 6, 1988. Bars indicate 95% CI. Means with the same letter are not significantly different ($P = 0.05$) according to Duncan's multiple-range test after ln (catch + 1) transformation. ANOVA $F = 33.2$, $P < 0.001$ in 88:1 and $F = 67.9$, $P < 0.001$ in 88:2.

In test 82:5 two release rates of each compound were used (1.8 or 3.5 µg/day, release rates estimated from the measurements done in tests 82:1 and 3). Traps were loaded with the acetate or propionate (four different baits) or with the lower release rate of both substances. No significant difference between the baits was noted. Average catches ($N = 6$) were between 66 and 82 for all five baits, and thus no synergistic effect was found in this experiment either. The two substances seem to be equally active attractants when used alone.

Tests of Synergistic Effects of trans-*Perillenal (81:3, 81:4, 82:6).* In 81:3 (2*S*,3*S*,7*S*)-diprionyl acetate and propionate were released together (3.3 µg/day, release rates estimated from the measurements done in tests 82:1, 3, and 6)

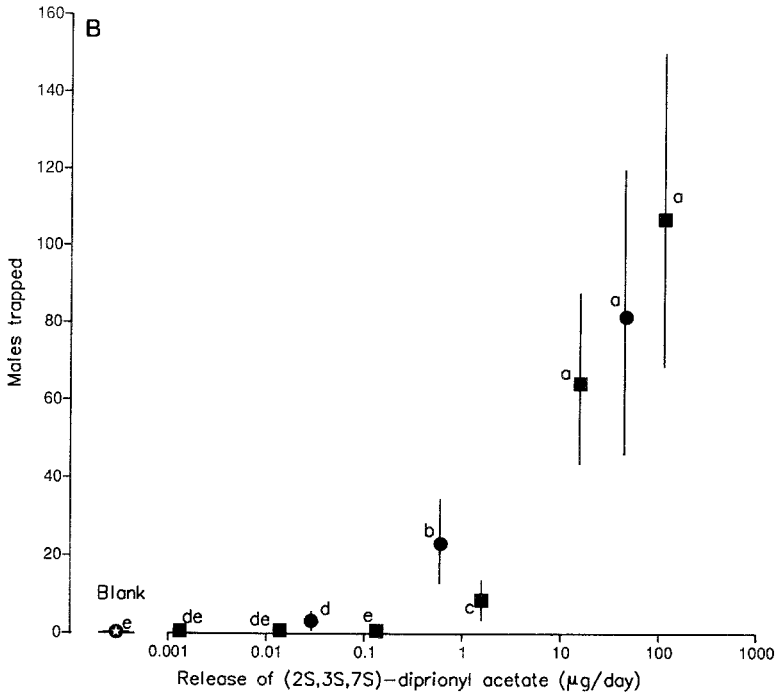

FIG. 6. Continued

with or without *trans*-perillenal (6.6 µg/day), at two localities. No significant differences in average trap catch ($N = 12$) between the two baits were detected in either locality (mean ± SD locality 1:212 ± 198 without *trans*-perillenal, 106 ± 91 with *trans*-perillenal; locality 2:180 ± 244 without, 204 ± 187 with). Also in 81:4 the acetate and propionate were released together. In each of two series, they were released at the same rate (11.2, series I) and (1.5, series II) µg/day each, respectively; the release rates were estimated from the measurements done in tests 82:1, 3, and 6) from all traps (except blank traps), while *trans*-perillenal was released at different rates (0, 0.8, 1.8, 3.4, 6.6, 18.5, 19.8 µg/day). In series I, the average catch ($N = 12$) of the unbaited traps was significantly lower (26) than the catch of the baited traps, but the catch of these did not differ from each other; averages ranged from 335 to 449. In series II, not even the average ($N = 9$) of the unbaited traps differed from the baited ones (averages from 36 to 62). The same approach was used in test 82:6, but here *trans*-perillenal was tested with the acetate only. However, no effect of *trans*-perillenal could be detected (Table 3).

TABLE 3. TEST 82:6—CATCH OF MALE PINE SAWFLIES, *Neodiprion sertifer*, IN HORIZONTAL LUND-I STICKY TRAPS BAITED (CAPILLARIES) WITH (2*S*,3*S*,7*S*)-DIPRIONYL ACETATE WITH ADDITION OF *trans*-PERILLENAL IN VARIOUS AMOUNTS [a]

[a] In both series the average release of acetate was 1.63 μg/day, while the release of *trans*-perillenal varied. In series I three sets of traps were used and they were repositioned four times, i.e., 12 replicates, September 5–14, 1982, and in series II three sets of traps were repositioned six times, i.e., 18 replicates, September 13–30, 1982.

[b] Figures followed by the same letter are not significantly ($P = 0.05$) different according to Duncan's multiple range test after ln(catch + 1) transformation. ANOVA $F = 50.2$, $P < 0.001$ for series I and $F = 50.5$, $P < 0.001$ for series II.

DISCUSSION

In many studies of chemical communication, it is essential to know for each substance of a blend the amount released per unit of time. An ideal dispenser should have a constant and predictable release rate. However, few such dispensers exist (Byers, 1988). We have documented two fundamentally different release systems, and have found one of them, the dental cotton rolls, very suitable for releasing pine sawfly pheromones, with relatively low volatility. The release rate of diprionyl acetate is relatively constant over a long period, and, most importantly, the proportional release is independent of the load. This means that ratios between diprionyl acetate isomers persist for long time periods, although the absolute release rates decrease. Furthermore, there is a very small variation in release rate between individual cotton rolls. The only major drawback with the cotton rolls is that they require a rain shelter in order to avoid disintegration. Thus, although they are suitable for use in traps in monitoring programs, they are not appropriate if mating disruption for large-scale forest protection is attempted. The usefulness of cotton rolls as reference dispensers was recently demonstrated by Leonhardt et al. (1990), when testing various

commercial dispensers for the gypsy moth, *Lymantria dispar* (L.). They obtained a good correlation ($r^2 = 0.97$) between dose and release rate of (+)-disparlure.

The capillaries should, in theory, be ideal dispensers for diprionyl acetate and propionate, since the low volatility of these substances would make the length of the vapor-air column, and thus the release, nearly constant over time (Weatherston et al., 1985a). However, we did not find the glass capillaries to be practical. They are complicated to fill and show a large between-capillary variation in release rate. In part, this variation might be due to different influences of wind, depending on direction of the capillary. Another factor that may be important is the occasionally observed condensation of water inside the capillary, which reduces the cross-sectional area. When sealing one end to reduce the release rate (test 82:3, Figure 1A), one third of the capillaries did not release any substance at all, probably because of condensation of water. In this test, the capillary radius was small, 0.002–0.04 mm. Other factors introducing between-capillary variation have been suggested by Weatherston et al. (1985b), but were applicable mainly to nonglass capillaries with a fairly rough surface.

The field experiments describe the development not only of dispenser reliability, but also of trap design. Although the cross-barrier traps used in 1981 caught large numbers of sawflies, they were not very suitable for sophisticated studies of sawfly pheromones. The differences in catch between traps with baits of varying strengths were small, and in many cases unbaited traps caught nearly as many sawflies as did baited traps. These problems were solved with the introduction of the Lund-I trap (Anderbrant et al., 1989), which is very selective and gives very low blank-trap catches.

The field experiments showed that both diprionyl acetate and propionate are highly attractive to male *N. sertifer* in Sweden. This was earlier shown in North America (Kikukawa et al., 1983; Kraemer et al., 1983; Olaifa et al., 1987) and has recently been confirmed by electrophysiological studies as well (Hansson et al., 1991). This reveals a pattern that is different from pheromone specificity in moths. Usually such a structural variation as that between an acetate and a propionate analog causes a very large electrophysiological as well as behavioral response difference (Liljefors et al., 1984). However, diprionid sawfly males apparently have a different system for pheromone perception than moths (Hansson et al., 1991). A similar response to the acetate and propionate has been reported also from other *Neodiprion* species (Kraemer et al., 1983; Olaifa et al., 1984).

The function of *trans*-perillenal in the chemical communication of diprionids, if any, is still unknown. One possibility is that it is a precursor to diprionol or a by-product in the biosynthetic path (Wassgren et al., 1992). However, in contrast to the extensive knowledge about pheromone biosynthesis in moths, nothing is known about the site or chemical path of pheromone production in diprionid sawflies.

Acknowledgments—We thank Göran Magnusson, Hans-Erik Högberg, and Erik Hedenström for the chemicals; Jörgen Jönsson for construction of the mini wind tunnel and equipment; Elisabeth Marling, Eva Annerfeldt, and Lars Franzén for technical assistance; and John Byers and Fredrik Schlyter for comments on the manuscript. EFRAPEPTIN PRODUCTION BY *Tolypocladium* FUNGI (DEUTEROMYCOTINA: HYPHOMYCETES): INTRA- AND INTERSPECIFIC VARIATION[1]

STUART B. KRASNOFF* and SANDEEP GUPTA[2]

USDA-ARS, U.S. Plant, Soil, and Nutrition Laboratory
Tower Road, Ithaca, New York 14853

(Received April 1, 1992; accepted May 27, 1992)

Abstract—Production of the mitochondrial ATPase inhibitory peptides efrapeptins was evaluated by HPLC analysis in 44 strains of nine species of the fungal genus *Tolypocladium* (Deuteromycotina: Hyphomycetes). Efrapeptin identification was confirmed by mass spectral data for the first time in the species *T. cylindrosporum*. HPLC retention time data indicated that *T. nubicola* and *T. tundrense*, two species not previously known to produce efrapeptins, also produce the peptides. No efrapeptins were detected (<0.3 mg/100 ml broth) in single strains each of *T. balanoides*, *T. extinguens*, *T. parasiticum*, and *T. microsporum*. Five strains of *T. geodes* produced detectable amounts of efrapeptins and had compound F, or F and G, as the major component(s) in the mixture with the order of abundance being F > or ~ G > H ~ D ~ E > C. Eleven strains of *T. niveum* produced detectable amounts of efrapeptins and had efrapeptins D and E as the primary and secondary components, respectively, in the mixture with the order of abundance being D > E > F > C ~ G. A single *T. niveum* strain had an efrapeptin profile similar to that of the *T. geodes* strains. Ten strains of *T. cylindrosporum* had detectable amounts of efrapeptins. Of these, nine had F and one had G as the major component. *T. cylindrosporum* had higher ratios of E to D than did *T. geodes*. Efrapeptins were detected in one of two *T. nubicola* strains analyzed (F > G > H) and one of three *T. tundrense* strains (F > G > H > E). *T. niveum* strains could, in most cases, be identified to species on the basis of their efrapeptin profiles.

Key Words—Chemotaxonomy, fungus, *Tolypocladium*, fungal toxin, mycotoxin, efrapeptins.

INTRODUCTION

The fungal genus *Tolypocladium* (Deuteromycotina: Hyphomycetes) includes species found in nature as pathogens of invertebrates as well as saprobic soil-inhabiting species, some of which are also capable of infecting arthropods in the laboratory (Bissett, 1983; Weiser, 1987). Because of their pathogenic characteristics, these fungi have attracted attention as potential biological control agents, especially for a number of mosquito species (Goettel, 1988 and references cited).

T. niveum and *T. geodes* produce efrapeptins, a microheterogeneous group of peptides rich in α-amino-isobutyric acid and other unusual amino acids, and having an unusual carboxy-terminal blocking group (Figure 1) that confers potent mitochondrial ATPase inhibitory activity on these compounds (Gupta et al., 1991, Gupta et al., 1992; Krasnoff and Gupta, 1991). Efrapeptins have insecticidal activity (Krasnoff et al., 1991), which may enhance the utility of these fungi as biological control agents.

Previously we reported that a strain of *T. geodes* was distinguished from a strain of *T. niveum* by the relative amounts of individual efrapeptins produced in the mixture (Krasnoff and Gupta, 1991). We hypothesized that efrapeptin profiles might be species-specific in this genus. To test this hypothesis, as well as to get a more complete picture of the production of efrapeptins in the genus as a whole, we carried out HPLC analyses of extracts of a variety of strains of these and other *Tolypocladium* species. In the process we isolated and identified efrepeptins from *T. cylindrosporum*, a species in which these compounds were previously unknown, and also found preliminary evidence of efrapeptin production by *T. nubicola* and *T. tundrense*. Herein we report these identifications,

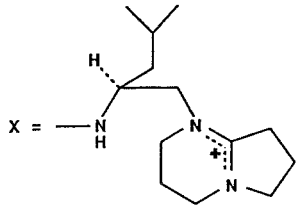

FIG. 1. Structure of efrapeptins C, D, E, F, and G. Amino acid residues are abbreviated as follows: alanine (ALA), glycine (GLY), leucine (LEU), α-aminoisobutyric acid (AIB), β-alanine (β-ALA), isovaline (IVA), and pipecolic acid (PIP). Ac = Acetyl, FW = formula weight.

describe variation in efrapeptin production in and among *Tolypocladium* species, and discuss the implications of this variation to the systematics of the group.

METHODS AND MATERIALS

Growth of Fungi. Fungal material from cultures maintained under liquid nitrogen in the USDA-ARS entomopathogenic fungi (ARSEF) collection was used to inoculate plates of Sabouraud dextrose agar + 1% yeast extract (SDAY) grown at 22 ± 1°C. For the study of interstrain variation in efrapeptin production, a small plug of this SDAY culture was used to inoculate 100-ml batches of Czapek-Dox (Difco) liquid medium supplemented with 0.5% bactopeptone (Difco) (CDB) in 250 Erlenmeyer flasks. All strains were grown in duplicate to afford duplicate extracts for HPLC analysis.

Conidia used as inoculum to grow *T. cylindrosporum* (ARSEF #962) for preparative HPLC (see below) were harvested in sterile 0.1% Tween-80 from a 20-day-old culture grown on SDAY slants at 22 ± 1°C. Concentrations of initial conidial suspensions were determined using an improved Neubauer hemacytometer. A suspension of ca. 3.4×10^6 conidia/ml was made by dilution of initial suspensions in sterile water and used to inoculate 100-ml batches of CDB in 250 Erlenmeyer flasks with 1×10^6 conidia. All liquid cultures were grown on a rotary shaker (160 rpm; 2.5 cm throw) for 11 days at 22 ± 1°C, exposed to natural light from a window.

Production of Extracts. Fungal extracts were produced as described previously (Krasnoff and Gupta, 1991). Briefly, fungal mycelium was separated from the culture broth by filtration. Following centrifugation of the broth, the pellet was discarded and the supernatant was extracted with dichloromethane. The organic layer was concentrated to dryness and weighed. Extracts were stored at −20°C. Prior to HPLC analysis samples were dissolved in methanol and filtered through a 0.45-μm membrane cartridge.

Isolation and Characterization of Efrapeptins. The efrapeptin fraction from the crude dichloromethane extract of culture broth of a single *T. cylindrosporum* strain (ARSEF #962) was prepared for fast atom bombardment mass spectrometry (FABMS) by repetitive semipreparative HPLC on a reverse-phase C8 column (0.9 × 50 cm) eluted with MeCN–12.5 mM $(NH_4)_2SO_4$ (75:25) at a flow rate of 5.5 ml/min. Detection was by monitoring UV absorption at 225 nm (0.5 aufs).

Efrapeptin profiles were analyzed by HPLC using a reverse-phase C8 analytical column (0.46 × 15 cm, particle size 5 μm, Supelcosil LC-8) eluted with MeCN–12.5 mM $(NH_4)_2SO_4$ (70:30) at a flow rate of 2 ml/min. Detection was by monitoring UV absorption at 225 nm (0.2 aufs). In samples from species for which the production of efrapeptins was confirmed by mass spectral data, indi-

vidual efrapeptin peaks were identified by comparison with HPLC retention times of a standard efrapeptin mixture of authentic efrapeptins from a *T. niveum* strain (ARSEF #616) partially purified by flash chromatography on silica gel and sephadex LH 20 (Gupta et al., 1992).

Quantification of efrapeptins was accomplished by comparing total efrapeptin peak area from an electronic integrator (Hewlitt Packard 3396B) with the peak area of a known amount of pure efrapeptin F. A calibration curve was generated to verify that the UV detector response to efrapeptin F was linear in the quantitative range analyzed. Total efrapeptin production for 100 ml of culture broth was calculated by dividing the estimated efrapeptin injected by the amount of crude extract injected and multiplying this factor by the total yield of crude extract.

RESULTS

Isolation and Identification of Efrapeptins. Preliminary HPLC analysis of a crude dichloromethane extract of *T. cylindrosporum* (ARSEF strain #962) indicated the presence of a mixture of efrapeptins. Peaks from the *T. cylindrosporum* extracts cochromatographed with authentic efrapeptins D, E, F, and G.

Identification of efrapeptins from *T. cylindrosporum* extracts was confirmed by FABMS analysis of an HPLC-purified mixture of efrapeptins, which showed molecular ions (M^+) at *m/z* 1606, 1620, 1634, 1648, and 1676. As noted previously (Gupta et al., 1992), the quaternary nitrogen in the C-terminal blocking group of the efrapeptins (Figure 1) produces unusually intense molecular ion peaks (M^+) instead of the usual $M+H^+$ under FABMS conditions. The spectrum obtained from *T. cylindrosporum* is consistent with the presence of efrapeptins C (1606), D (1620), E (1634), F (1634), G (1648), and a sixth compound of molecular weight 1676.

Retention time data and cochromatography with authentic efrapeptins indicated the presence of efrapeptins in strains of *T. nubicola* (ARSEF #3435), and *T. tundrense* (ARSEF #3401).

Efrapeptin profiles of 44 strains of nine *Tolypocladium* species were analyzed by HPLC (Table 1). In most cases, a 10-μl aliquot of a 5 mg/ml solution of crude dichloromethane extract of broth was sufficient to detect efrapeptins. In some cases it was necessary to inject a larger volume, concentrate the sample, or do both to detect efrapeptin peaks. Due to low signal-to-noise ratios in chromatograms of concentrated samples, efrapeptins were regarded as "undetected" in samples with an estimate of less than 0.3 mg (per 100 ml broth).

We analyzed six strains of *T. geodes*, four from Canada and two from Great Britain (Table 1). There were significant intraspecific differences in total

efrapeptin yield (ANOVA significant at $P < 0.0001$ for two replicates each of six strains). Efrapeptins were detected in five strains (Table 2). The three Canadian strains, ARSEF #3271, #3272, and #3274, produced efrapeptins F and G in approximately equal amounts. The two British strains, ARSEF #3275 and #3276, had 1.5 and 2.6 times as much F as G, respectively. For all efrapeptin-producing strains of *T. geodes*, minor components were efrapeptins D, E, and H, present in approximately equal proportions. Efrapeptin C was present in only trace amounts or undetectable.

We analyzed 14 strains of *T. niveum*, originating from material collected in North America, Europe, and Asia (Table 1). There were significant intraspecific differences in total efrapeptin yield (ANOVA significant at $P < 0.001$ for two replicates each of 14 strains). Efrapeptins were detected in 11 strains (Table 3). Ten strains produced efrapeptin D and E as the primary component and secondary components, respectively, with the order of abundance of the components being D > E > F > G > C. One of 11 efrapeptin-producing strains (ARSEF #3321) had efrapeptins F and G as major components in approximately equal amounts, with minor components D > E > H.

We analyzed 16 strains of *T. cylindrosporum* (Table 1). There were significant intraspecific differences in total efrapeptin yield (ANOVA significant at $P < 0.0001$ for two replicates each of 14 strains; analyses for two strains that were not duplicated were not included in the ANOVA). Efrapeptins were detected in 10 strains (Table 4). F was the primary component in nine and the secondary component in one strain. G was the major component in one strain, the secondary component in seven strains, and the tertiary component in two strains.

Efrapeptin E was more prominent in the profiles of *T. cylindrosporum* than in those of *T. geodes* as reflected in the ratios of E to D, which ranged from 2.3 to 11.6 for 10 strains of *T. cylindrosporum* versus 0.8 to 1.4 for five strains

of *T. geodes*. E was the secondary component in two strains, the tertiary component in seven strains (E ~ H in one of these), and present as a minor component in trace amounts in one strain. No clear consensus order of minor components emerged but F > G > E was the order of the major components in six strains. Although no efrapeptin C was detected by HPLC in any of the *T. cylindrosporum* strains (Table 4), the more sensitive FABMS analysis of the HPLC-purified efrapeptin fraction from ARSEF #962 indicated that it is being produced by this species ($M^+ = 1606$; see above).

Strains of several other species of *Tolypocladium* were also analyzed by HPLC. Peaks with retention times corresponding to efrapeptins were detected in one of two strains of *T. nubicola* (ARSEF #3435). The estimate for total efrapeptin production of this strain was 0.8 ± 0.3 mg (±SD) with the profile: *F* (50.0 ± 4.3%) (±SD) > H (28.1 ± 2.9%) > G (21.9 ± 1.4%). No C, D, or E were detected. One of three strains of *T. tundrense* (ARSEF #3401) produced detectable amounts of efrapeptins (1.4 ± 0.0 mg) with the profile: F (40.8 ± 3.3%) ~ G (37.0 ± 1.7%) > H (19.2 ± 1.7%) > E (3.0 ± 0.2%); no C or D were detected.

No efrapeptins were detected in single strains each of *T. balanoides*, *T. extinguens*, *T. parasiticum*, and *T. microsporum*.

DISCUSSION

T. cylindrosporum is the third species in the genus for which production of efrapeptins has been confirmed. This species is frequently found in nature as a pathogen of mosquito larvae and consequently has attracted attention as a potential biological control agent (Soares, 1982; Gardner and Pillai; 1986, Goettel, 1987; Ravallec et al., 1989). We observed considerable variability in total efrapeptin production in this species. The possibility that interstrain variability in virulence (e.g., Soares et al., 1985) may correlate with efrapeptin production might be a fruitful area of future investigation.

Our HPLC data provide the first chemical evidence that efrapeptins are produced by *T. nubicola* and *T. tundrense*. Insecticidal effects reported for extracts of these species, and of *T. cylindrosporum*, *T. geodes*, and *T. inflatum* (=*niveum*), have been attributed to an unidentified material referred to as "tolypin" (Matha et al., 1988a,b; Weiser and Matha, 1988; Weiser, 1991). However, given the production of efrapeptins by these species shown here, and the demonstrated insecticidal activity of these compounds (Krasnoff et al., 1991), it is likely that efrapeptins are the agents responsible for these insecticidal effects.

Previously (Krasnoff and Gupta, 1991) we hypothesized that efrapeptin profiles might be useful characters for species level diagnostics and phylogenetic analysis in *Tolypocladium*. Although no inviolate species-specific chemotypes

emerged from this study, definite trends were discernible. These can be illustrated in bivariate scatter plots showing how strains group by percent composition of pairs of efrapeptins in the profile (Figure 2) and by a cluster analysis based on percent composition of efrapeptins D, E, F, and G (Figure 3).

T. geodes showed what may be two distinct subspecific chemotypes linked to geographic origin (Figures 2 and 3). The three Canadian strains produced F and G in approximately equal amounts while the two British strains produced a clear predominance of F over G, the latter being a secondary but still major component relative to the others (Table 2). The possibility that there are geographic chemotypes within this species, as there are, for example, in *Fusarium* spp. (Miller et al., 1991), should be pursued with more extensive sampling of strains from divergent sites of origin.

T. cylindrosporum showed less intraspecific consistency in efrapeptin profiles than either *T. niveum* or *T. geodes*, but generally resembled the latter more than the former (Figures 2 and 3; Tables 2–4), especially in the preeminence of compound F and/or G, and in the production of H as a secondary component in two strains. Another salient feature is the higher ratios of E to D relative to *T. geodes* and *T. niveum* (Figure 2b).

Of the three major species sampled, *T. niveum* showed the greatest consistency in efrapeptin profiles. However, as seen in Figures 2 and 3, and as mentioned above (see Results), a single strain (ARSEF #3321) from eastern Canada more closely resembled the Canadian *T. geodes* strains in efrapeptin content than it did the other 10 *T. niveum* strains (Figure 3). In fact, it more closely resembled the Canadian *T. geodes* strains than the latter resembled the British *T. geodes* strains (Figure 3). We grew this strain repeatedly and made several independent analyses, which confirmed that the original results were not due to experimental error.

The utility of efrapeptin profiles as a species level diagnostic character depends on the interpretation of this outlier. Consequently, we offer several possible explanations for this apparent anomaly: (1) *T. niveum* could be polymorphic for this character. If this is the case, then more extensive sampling ought to turn up similar *T. niveum* strains. (2) This strain could be the result of a rare mutation. *T. niveum* almost always produces a predominance of efrapeptins D and E, which both have glycine (Gly) at position 13 in the peptide chain, while the other four efrapeptin-producing species make a predominance of efrapeptins F and G, both of which have alanine (Ala) at position 13. As we pointed out in a previous study (Krasnoff and Gupta, 1991), this suggests that, at a particular step in biosynthesis, *T. niveum* incorporates Gly where the other species incorporate Ala (see above). Although their unusual amino acids and terminal blocking groups indicate that efrapeptins are not translation products, it is reasonable to assume that the choice of a Gly or an Ala at position 13 is mediated by an enzyme that is subject to mutation. Showing that mutagenic

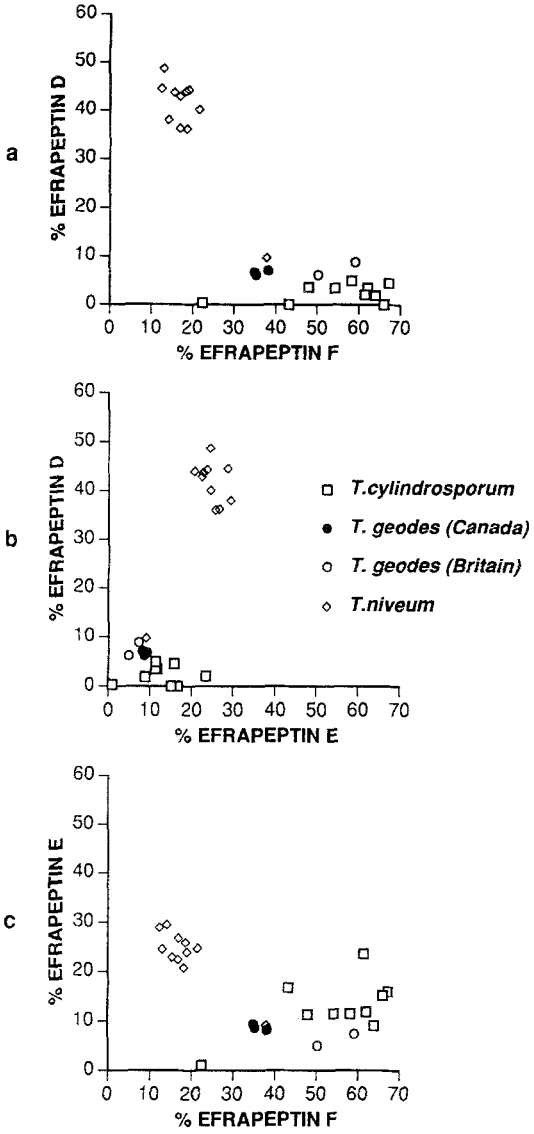

FIG. 2. Bivariate plots of percent efrapeptin composition for *Tolypocladium* species: (a) efrapeptin D vs. F, (b) efrapeptins D vs. E, (c) efrapeptins E vs. F.

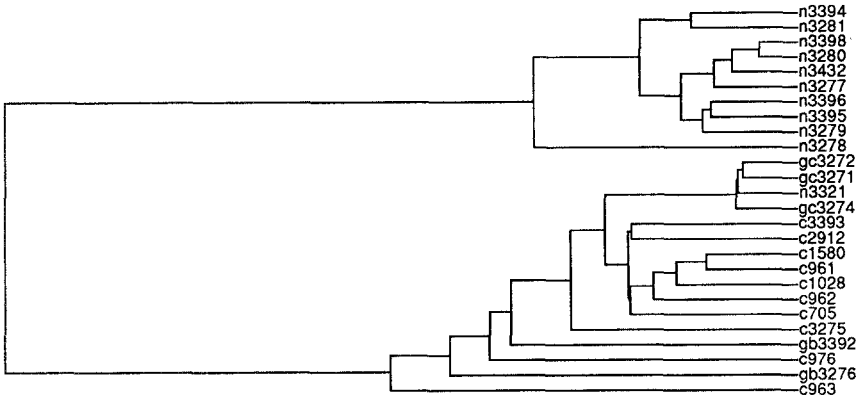

FIG. 3. Hierarchical single linkage euclidean distance cluster diagram (Anderberg, 1973) of *Tolypocladium* strains based on percent composition of efrapeptins D, E, F and G. Numbers at termini correspond to ARSEF # (Table 1) and are preceded by species designations: c = *T. cylindrosporum*, gc = *T. geodes* (Canadian strains), gb = *T. geodes* (British strains), n = *T. niveum*.

agents could change the efrapeptin profile of a strain from D-dominated to F-dominated would support this interpretation. (3) The strain might be a parasexual cross between *T. geodes* and *T. niveum*. Although liquid cultures of ARSEF #3321 did not have the characteristic earthy odor of liquid cultures of *T. geodes*, cultures of the strain on solid medium (SDAY) produced some phialides with swollen bases typical of *T. niveum* and some phialides more like those of *T. geodes*, which are less swollen basally with a more cylindrical shape. Thus the morphology of the phialides might be interpreted as intermediate between *T. geodes* and *T. niveum*. The collection of *T. cylindrosporum*, *T. geodes*, and *T. niveum* all from the same locality (albeit not the same locality from which ARSEF #3321 originated) establishes the possibility of contact among all three species (Table 1). Although we are unaware of any reports of *inter*specific parasexual crosses in the hyphomycetes, *intra*specific parasexual crosses have been produced in the laboratory with the entomopathogenic hyphomycetes, *Verticillium lecanii* (Jackson and Heale, 1987) and *Metarhizium anisopliae* (Messias and Azevedo, 1980).

In consideration of the chemically anomalous nature of ARSEF #3321, a *Tolypocladium* strain producing an efrapeptin profile dominated by F or G could not be diagnosed to species on the basis of the profile. However, of all the *Tolypocladia* sampled only *T. niveum* produced efrapeptin profiles dominated by compound D, so to this extent the character would still be useful in distinguishing most *T. niveum* from other species in the genus.

Gams (1971b) erected the genus *Tolypocladium* on the basis of defining

morphological features, phialides swollen basally, with a narrow, often bent neck, and small, one-celled conidia produced in "slimy heads" (Gams, 1971b; Bissett, 1983). Originally included in the genus were *T. cylindrosporum*, *T. geodes*, and *T. inflatum*. Barron described two new species, *T. parasiticum* (1980) and *T. trigonosporum* (1981). Bissett (1983) added two more new species, *T. nubicola* and *T. tundrense*, redisposed two others, *T. balanoides* and *T. microsporum*, which were previously described in other genera, and synonymized Gams' *T. inflatum* with *T. niveum*, proposing the latter as the name of the type species. Samson and Soares (1984) added *T. extinguens* to the genus. Finally, a new species, *T. terricola*, was proposed in an unrefereed forum (Weiser et al., 1989), so the species count for the genus stands at 10 officially with the possibility of an eleventh.

Tolypocladium taxonomy has several unresolved problems. The status of the genus was called into question by Von Arx (1986), who synonymized it with *Beauveria*, but this opinion has apparently not gained acceptance by others who have worked on the group (Gams, 1988). The placement of some species in the genus is also in dispute. There are countervailing opinions to Bissett's generic placement of *T. balanoides* and *T. microsporum*. The latter had been redisposed from *Verticillium* to *Sesquicillium* by Gams (1971a). Bissett (1983) moved it to *Tolypocladium* based on its production of spores in "minute" slimy heads rather than the "imbricate columns" indicative of *Sesquicillium*. *T. balanoides* was disposed to *Verticillium* by Dowsett et al. (1982), and this was supported by Gams (1988). Based on rRNA sequence data, Rakotonirainy et al. (1991) concluded that *T. extinguens* is more closely related to *Beauveria bassiana* than to *T. cylindrosporum* and, thus, that it does not belong in *Tolypocladium*.

We detected no efrapeptin production in *T. balanoides*, *T. extinguens*, and *T. microsporum*. While it is difficult to prove that a given strain or species does not produce a given metabolite, our negative evidence for these species may lend some support to those who argue for their placement in other genera. In view of the apparently widespread production of efrapeptins in the genus *Tolypocladium*, more extensive sampling needs to be done on species not represented in our sample, or represented here by only one or a few strains, before making any firm conclusions on generic disposition based on this chemical character.

Efrapeptin production is, so far, unknown outside of *Tolypocladium*. We have screened for it extensively in the genus *Beauveria* as well as in species of *Fusarium*, *Verticillium*, *Paecilomyces*, and *Hirsutella* (Krasnoff and Gupta, unpublished data). We suggest that efrapeptin production might be a defining synapomorphy for the genus, shared as it is among *T. geodes*, *T. niveum*, *T. cylindrosporum*, *T. tundrense*, and *T. nubicola*. Further taxonomic and chemical study may reveal it to be a less plastic and, therefore, more dependable character than some of the morphological features used to define the group.

In summary, we have reported the production of a mixture of efrapeptins by three new *Tolypocladium* species and have described a pattern of intra- and interspecific variation in efrapeptin profiles that supports their use in species determinations of *T. niveum*.

Acknowledgments—We thank C. Babcock and J. Bissett of Agriculture Canada for providing the fungal strains to the ARSEF collection, and M.L. Cummings and M. Chapple for excellent technical assistance, and R.E.B. Ketchum for helpful discussion of HPLC methods.

(Received February 25, 1992; accepted May 28, 1992)

Abstract—Female *Microplitis croceipes* wasps were tested in a wind tunnel for their ability to orient to various concentrations of eight different green leaf volatile (GLV) substances [hexanal, (*E*)-2-hexenal, (*E*)-2-hexen-1-ol, (*Z*)-3-hexen-1-ol, (*E*)-2-hexenyl acetate, (*Z*)-3-hexenyl acetate, (*Z*)-3-hexenyl propionate, and (*Z*)-3-hexenyl butyrate]. Overall, the esters elicited the greatest percentage of successful orientation flights, the alcohols elicited an intermediate response, and the aldehydes elicited a low response. The semilog dose–response curves were generally hill-shaped with high responses at medium release rates and low responses at high or low release rates. For the aldehydes, positive responses occurred at all GLV release rates between 0.01 and 100 nl/min. For some alcohols and esters, positive responses occurred at release rates as low as 1 pl/min and as high as 1 μl/min. These data show that *M. croceipes* wasps are strongly attracted to GLVs and are capable of orienting to GLV concentrations that would occur in nature when a caterpillar feeds on a green leaf. Hence, in nature, GLVs may be important clues, enabling *M. croceipes* to locate their hosts.

Key Words—Green leaf volatile, semiochemical, synomone, volatile attractant, *Microplitis croceipes*, Hymenoptera, Braconidae, *Heliothis zea*, Lepidoptera, Noctuidae, biological control, tritrophic, host location, parasitoid behavior.

INTRODUCTION

Many wasp parasitoids seek out and oviposit into plant-feeding caterpillars. Volatile semiochemicals originating from the caterpillars or their food plants

serve as important cues for these wasps, enabling the wasps to find their hosts (Nordlund et al., 1988; Whitman, 1988a; Lewis and Martin, 1990; McAuslane et al., 1991; Turlings et al., 1991a,b). Among the volatile substances released from damaged plants are the six-carbon alcohols, aldehydes, and derivative esters that are collectively known as green leaf volatiles (GLVs) (Hedin et al., 1973; Saijo and Takeo, 1975; Wallbank and Wheatley, 1976; Visser et al., 1979; Hamilton-Kemp et al., 1988, 1989; Tollsten and Bergström, 1988; Hernandez et al., 1989; Lwande et al., 1989). Recently, we suggested that caterpillars feeding on green leaves cause plants to release GLVs and that parasitic wasps orient to these substances and hence to their caterpillar hosts (Whitman and Eller, 1990). In this tritrophic interaction, the GLVs would serve as plant-to-parasitoid synomones; their release would benefit both the plant and the parasitoid but would be detrimental to the caterpillar.

In this paper we examine the ability of female *Microplitis croceipes* (Cresson) wasps to orient to various concentrations of individual GLVs in a wind tunnel. *M. croceipes* is a braconid wasp that attacks the corn earworm caterpillar, *Helicoverpa* (= *Heliothis*) *zea* (Boddie) (Lepidoptera: Noctuidae). We show that the GLVs vary in attractiveness, that wasps can successfully orient to GLV concentrations ranging over five orders of magnitude, that there is variability in the low and high response thresholds of wasps to various GLVs, and that the dose–response curves for various GLVs differ more in magnitude and capacity than in shape. We also show that wasps can orient to release rates similar to those produced naturally when a caterpillar feeds on a green plant.

METHODS AND MATERIALS

Insects. Larval *M. croceipes* were reared on *Helicoverpa zea* at the Insect Biology and Population Management Research Laboratory at Tifton, Georgia. The *Heliothis* were cultured on artificial diet (Burton, 1969). Adult parasitoids were kept communally and allowed to mate in Plexiglas cages (30 × 30 × 17 cm) at 28°C, 50–70% relative humidity, a 16:8 light–dark photoperiod, and provided daily with fresh water and honey (Lewis and Burton, 1979). Adults were isolated from plant and host materials until tested.

Flight Tunnel. The ability of wasps to orient to GLVs was tested in a 75 × 75 × 200-cm laminar-flow Plexiglas wind tunnel (wind speed: 31 cm/sec; temperature: 26–27°C; relative humidity: 40–80%; wind tunnel light provided by four overhead 80-W fluorescent bulbs). An electric fan, placed outside the building, pulled air through the tunnel at a constant rate and vented it outside, eliminating contamination from recycled air.

Chemicals. Various GLVs were obtained from Sigma Chemical Co. and Aldrich Chemical Co. Following the tests, chemicals were assayed by GCMS; purity ranged from 93 to 99%.

Preparation of Water Extract of H. zea *Frass.* Ten grams of fresh moist *H. zea* frass (collected from caterpillars raised on cowpea seedlings) was thoroughly blended with 100 ml of distilled water. The resultant slurry was filtered through Whatman No. 1 filter paper, producing a green-colored filtrate. This filtrate was kept frozen and served as the stock extract throughout the tests. To produce the dried extract, approximately 1 ml of stock extract was unfrozen and shaken. Then 30 μl of extract was collected into a micropipet and spotted onto the center of a 110-cm disk of Whatman No. 1 filter paper. After the 1-cm diameter moist area dried ($\sim$7 min.), the filter paper was used to stimulate wasps.

Experimental Design. Three- to eight-day-old female *M. croceipes* wasps were tested for their ability to orient in a wind tunnel to various concentrations of eight different GLVs (see Figure 1 below). Eight to 10 different release rates were tested for each GLV, resulting in 73 different treatments. Thirty or more wasps were flown to each treatment; each wasp was tested only once. Eight control treatments were also employed: Sixty wasps were flown to a blank control consisting of a 1-cm^2 paper disk and 15–30 wasps were flown to each of seven different hexane release rates, which encompassed the full range of GLV release rates tested. Wasps were individually tested, allowing individual responses to be recorded. All trials were single choice tests and were balanced for compound, dose, day, and time of day. The odor source was placed in the flight chamber 13 cm above the chamber floor, along the longitudinal midline of the chamber, and 20 cm downwind from the up wind end of the chamber.

Immediately prior to testing, a wasp was stimulated for 30 sec by contact with dried water extract of *H. zea* frass. The wasp was then placed into a clean 4-ml shell vial directly 100 cm downwind from the odor source. Wasps usually walked upwards to the opening of the shell vial, encountered the lower portion of the odor plume, faced into the wind, and after 5 sec to 5 min took flight. Wasps that did not take flight in 5 min or wasps incapable of normal flight were discarded. Each wasp was given two successive chances to fly to the odor source and then was discarded. If a wasp flew toward and landed on the odor source or a paper target placed 3 mm from the odor source, a positive response was recorded and the trial was ended. If the wasp took flight, but failed to land on the odor source or target, a negative response was recorded.

In the above trials, wasps were released 100 cm downwind from the odor source. To examine the effects of distance, a second set of trials was run with wasps released only 15 cm downwind from the odor source.

Release and Calibration of Green Leaf Volatiles. Different methods were used to obtain low, medium, and high GLV release rates. For low release rates, one end of a 5-, 10-, 20-, 50-, or 100-μl-capacity glass micropipet (Fisher Scientific, Pittsburgh, Pennsylvania) was flame sealed, and a measured amount of GLV was placed into the open end. The pipet was then spun in a centrifuge

to pull the liquid down to the sealed end of the tube. The resulting tube contained a measured amount of GLV at the sealed end. After a 24-hr equilibration period, a single pipet was placed vertically in the wind tunnel with the open end up, providing a relatively constant release rate of GLV. By using various sized micropipets, various release rates were produced. A standardized release rate among same-sized pipets was assured by maintaining a standard distance of 110 mm between the GLV meniscus and the pipet opening.

For medium release rates, 0.5- or 1-μl-capacity glass micropipets (Drummond Scientific, Broomall, Pennsylvania) or 5-, 10-, 20-, 50-, or 100-μl-capacity micropipets (Fisher Scientific) were filled with 10 mm of a selected green leaf volatile substance. A filled pipet was suspended crosswise in the wind tunnel, but at a 45° angle from vertical. This arrangement assured that the lower meniscus of test liquid always remained just at the lower orifice of the pipet, producing a uniform evaporative surface. If the pipet was placed vertically or horizontally, uniform evaporation was not achieved; with a vertical pipet, a droplet of test liquid sometimes emerged from the tube, increasing volatilization. With a horizontal pipet, capillary action sometimes pulled the liquid into the center of the tube, decreasing volatilization.

Higher release rates were achieved by inserting an 8-mm^2 or 30-mm^2 triangular filter paper wick into the open end of a 100-μl micropipet containing 20 mm of GLV. Pipets were positioned at a 45 degree angle from vertical, with the tube and surface of the wick perpendicular to the air flow.

For all pipets, a 1-cm^2 disk of white filter paper served as a landing target. The disk was attached to the micropipet in a vertical position so that the perimeter of the disk was 3 mm from the releasing end of the tube. With this arrangement, a wasp orienting to volatiles emerging from the end of the micropipet usually landed on the vertical paper disk.

Medium and high release rates were determined directly by measuring the change in volume of the internal liquid when the pipets were kept in the wind tunnel for 24 hr.

The release rates from the low-release pipets were determined indirectly as follows: The eight synthetic GLVs were loaded individually into 10-, 20-, 50-, and 100-μl micropipets as described above. After equilibrating in a fume hood for 24 hr, the pipets were placed vertically in a volatile collection system for 24 hr. The volatile collection system consisted of a 20-cm × 2.2-cm-ID glass tube sealed on each end with a cork stopper. The bottom cork held a prefilter (7-cm × 4-mm-ID glass tube) packed with 6 mm of Super Q (80–100 mesh; Alltech Associates, Inc., Deerfield, Illinois) held between a 325-mesh stainless-steel screen and a glass-wool plug. The top cork held a similar filter with 4 mm of Super Q to collect volatiles. Air was drawn up through the tube at a flow rate of 130 ml/min. Collected volatiles were extracted from the downwind filter with 240 μl methylene chloride. Ten microliters of a 250 ng/μl

solution (i.e., 2500 ng) of 1-octen-3-ol was added to each filter extract as an internal standard to quantify collected volatiles. Volatile collections were analyzed using a Hewlett Packard 5890 Series II gas chromatograph (Hewlett Packard Co., Avondale, Pennsylvania) equipped with a fused silica HP-5 column (0.17 μm, 25 m $\times$ 0.32 mm ID) (Hewlett Packard), a flame ionization detector, and a Spectra-Physics SP4400 integrator (Spectra-Physics, Inc., San Jose, California). Injections were made in the splitless mode and after 0.60 min changed to the split mode. The temperature program was: 40°C for 3 min, then 10°C increase/min to 110°C. The injector and detector temperatures were 170°C and 250°C, respectively. Three collections were made of each compound–pipet combination.

RESULTS

Dose–response curves for female *M. croceipes* wasps orienting to various individual GLVs in a wind tunnel are shown in Figure 1. The overall response of wasps appeared to vary according to the functionality of the compound tested. The aldehydes [hexanal and (*E*)-2-hexenal] were not very attractive and elicited few successful orientations. The alcohols (*E*)-2-hexen-1-ol and (*Z*)-3-hexen-1-ol elicited moderate responses, and the esters (*E*)-2-hexenyl acetate, (*Z*)-3-hexenyl acetate, (*Z*)-3-hexenyl propionate, and (*Z*)-3-hexenyl butyrate were more attractive and elicited the greatest number of successful orientations. In contrast, no wasps oriented to the blank or hexane controls.

The dose–response curves for the eight tested compounds tended to be similar in shape when displayed on a semilog plot (Figure 1). The curves were generally hill-shaped, with high responses at medium release rates and low responses at either very high or very low release rates. Maximum responses generally fell at release rates between 0.1 and 10 nl/min.

The data show that the range of attractive doses varied among the different GLVs. With aldehydes, wasps responded to release rates that ranged across four orders of magnitude; above and below this active range, wasps failed to orient. For each of the alcohols and esters, positive responses were observed for over five orders of magnitude. Note, however, that for the alcohols and esters, we did not test above or below this range (it is difficult to reliably produce such extreme release rates). Hence, wasps may be able to orient over a greater range of release rates than shown here. For example, 30% of wasps successfully oriented to the lowest (*Z*)-3-hexenyl butyrate release rate tested (0.5 pl/min) and 32% of wasps oriented to the highest (*Z*)-3-hexen-1-ol release rate tested (1 μl/min).

Our data also indicated that the low threshold for response varied for different GLVs. For (*Z*)-3-hexenyl butyrate, some wasps oriented to release rates as low as 0.5 pl/min. For hexanal, however, this figure was only 10 pl/min.

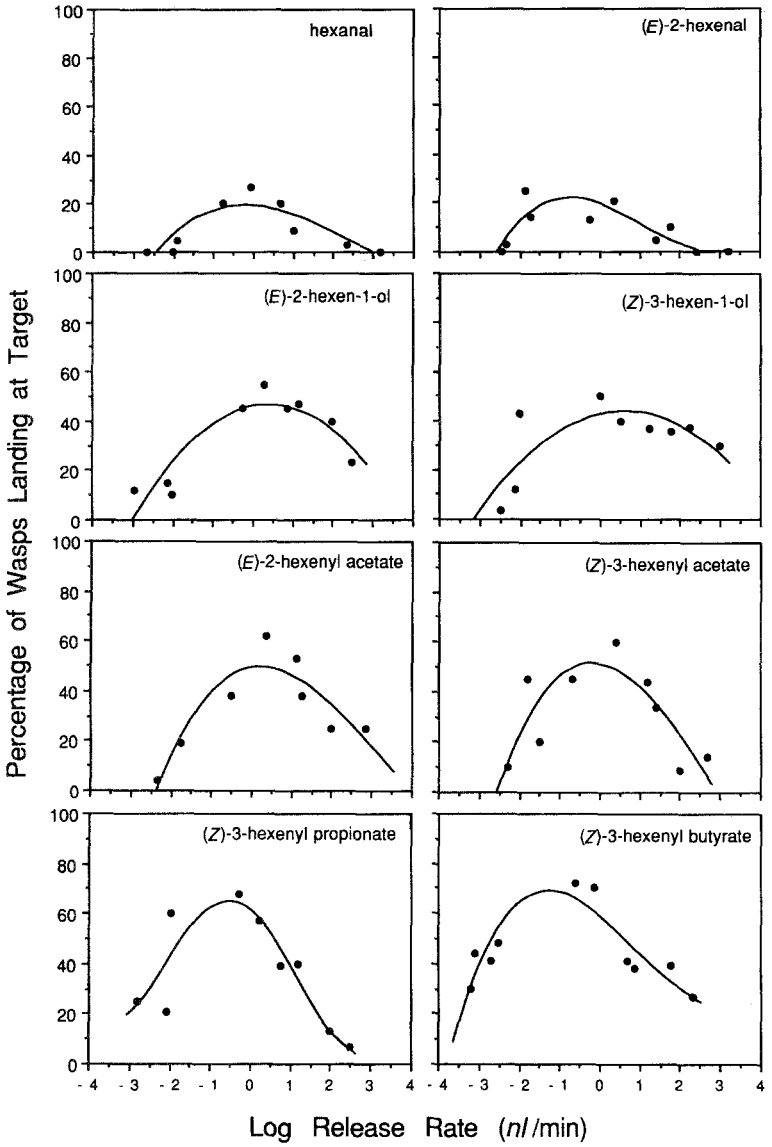

FIG. 1. Dose–response curves for female *Microplitis croceipes* wasps flying to various green leaf volatiles in a wind tunnel. Each point represents the results from 30 or more wasps. Curves generated and drawn by computer as second- or third-order polynomials. Each wasp was given two chances to successfully orient.

TABLE 1. ORIENTATION RESPONSE OF FEMALE *Microplitis croceipes* WASPS TO NEAR AND DISTANT SOURCES OF INDIVIDUAL GREEN LEAF VOLATILES

Volatile	Release rate (pl/min)	Percentage[a] of wasps successfully orienting to odor source from	
		100 cm[b]	15 cm[c]
(Z)-3-hexen-1-ol	3.2	3	80
(E)-2-hexenyl acetate	4.7	3	60
(Z)-3-hexenyl butyrate	1.9	40	80
(Z)-3-hexenyl butyrate	3.0	47	87

[a] Each wasp given two chances to orient.
[b] Thirty or more wasps tested to each volatile.
[c] Fifteen wasps tested to each volatile.

Wasps responded differently to high versus low release rates. At high release rates, wasps often oriented well when between 30 and 100 cm downwind from the odor source. However, when the wasps flew closer (between 5 and 20 cm from the odor source), they often turned sharply away and made no further attempts to enter the odor plume. In contrast, with low release rates wasps oriented poorly when 50–100 cm downwind from the odor source, but flew well when closer. When these wasps exited the odor plume, they often looped downwind or performed transverse zigzag flights until they reentered the plume. For example, when wasps were tested with (Z)-3-hexenyl propionate at a release rate of 10 pl/min, all 18 wasps that approached within 10 cm of the odor source landed, but at 13 nl/min, only 12 of the 22 wasps that approached within 10 cm landed. Likewise, at a release rate of 9 pl/min of (Z)-3-hexen-1-ol, all 13 wasps that approached within 10 cm of the odor source landed, but at 45 nl/min, only 12 of the 25 wasps that approached within 10 cm landed.

Table 1 shows that wasps were better able to orient to the low release rates of certain GLVs when the wasps were released close to the odor source.

DISCUSSION

Our results demonstrate that female *Microplitis croceipes* wasps can detect and orient to each of the eight GLVs tested. However, individual GLVs varied in attractiveness. Six-carbon aldehydes were the least attractive, with no responses above 30%. Six-carbon alcohols were moderately attractive, with some doses eliciting up to 55% successful flights. Eight- to 10-carbon esters were the most attractive, with 60–70% successful flights at some doses.

Our results also suggest that wasps can orient to extremely low doses of certain GLVs; release rates of approximately 2 pl/min for (*E*)-2-hexen-1-ol, (*Z*)-3-hexenyl propionate, and (*Z*)-3-hexenyl butyrate were attractive to some wasps. The fact that some wasps oriented to these low doses suggests that even lower release rates might be attractive.

The low release rates to which *M. croceipes* responded are comparable to GLV release rates that occur when a caterpillar feeds upon a green leaf. For example, 3–5 pl/min of GLVs are released when a *Heliothis zea* caterpillar feeds upon a cowpea leaf (Whitman and Eller, 1990), suggesting that *M. croceipes* are capable of responding to the levels of GLV that would be produced when a caterpillar feeds on a green leaf in nature. Undamaged plants release much lower levels of GLVs (Dicke et al., 1990a; Whitman and Eller, 1990; Turlings et al., 1991a,b). This difference in GLV release rates may allow *M. croceipes* to distinguish between undamaged and caterpillar-attacked plants; wasps might only orient to the higher release rates that occur when a caterpillar feeds on a leaf.
