(Received June 10, 1991; accepted September 13, 1991)

Abstract—Root exudates of *Sorghum bicolor* consist primarily of a dihydroquinone that is quickly oxidized to a *p*-benzoquinone named sorgoleone. The aim of this investigation was to determine the potential activity of sorgoleone as an inhibitor of weed growth. Bioassays showed 125 μM sorgoleone reduced radicle elongation of *Eragrostis tef*. In liquid culture, 50-μM sorgoleone treatments stunted the growth of *Lemna minor*. Over a 10-day treatment period, 10 μM sorgoleone in the nutrient medium reduced the growth of all weed seedlings tested: *Abutilon theophrasti*, *Datura stramonium*, *Amaranthus retroflexus*, *Setaria viridis*, *Digitaria sanguinalis*, and *Echinochloa crus-galli*. These data show sorgoleone has biological activity at extremely low concentrations, suggesting a strong contribution to *Sorghum* allelopathy.

Key Words—Sorgoleone, phytotoxin, allelochemical, allelopathy, root exudate, *Sorghum bicolor*, Sorghums, weed inhibition.

INTRODUCTION

Several *Sorghum* species, including *Sorghum halepense*, *S. vulgare*, *S. sudanense*, and *S. bicolor*, have been shown to cause allelopathic interference (Breazeale, 1924; Abdul-Wahab and Rice, 1967; Hussain and Gadoon, 1981; Putnam and DeFrank, 1983; Putnam et al., 1983; Alsaadawi et al., 1986). Both autotoxicity and interspecific allelopathic effects have been noted in sorghums (Rice, 1984). They produce and release cyanogenic glycosides and an array of

phenolic acids that can contribute to suppression of plant growth (Martin et al., 1938; Guenzi and McCalla, 1966; Nicollier et al., 1983; Lehle and Putnam, 1983; Rice, 1984; Weston et al., 1989).

Work in Michigan demonstrated that *S. bicolor* (grain sorghum) could be used as an allelopathic cover crop to control weeds in vegetable crops and orchards (Putnam and DeFrank, 1983; Putnam et al., 1983). Weeds were suppressed by either fall-planted–winter-killed or spring-planted–herbicide-desiccated grain sorghum. Forney et al. (1985) found a sorghum–sudangrass hybrid (*S. bicolor* × *S. sudanense*) was effective in suppressing weeds prior to late-summer, no-till planting of alfalfa (*Medicago sativa*). Purvis (1990) reported that wild oat (*Avena sterilis*) germination was suppressed in *S. bicolor* stubble when compared to its germination in the stubble of four other crops. Einhellig and Rasmussen (1989) showed that inhibitory effects of grain sorghum on weeds carried over from one growing season to the next in a field situation in northeastern Nebraska. It is not likely that this carryover is due entirely to inhibitory phenolic acids that are released from the residue, since their activity seems to diminish substantially in a few months (Guenzi et al., 1967).

Netzly and Butler (1986) isolated several hydrophobic *p*-benzoquinones in exudates from grain sorghum roots. Subsequently, these compounds were identified and named sorgoleones (Netzly et al., 1988). The initial exudate consists of related dihydroquinones, which appear to be natural stimulants of witchweed (*Striga asiatica*) germination (Chang et al., 1986; Netzly et al., 1988; Fate et al., 1990). The dihydroquinones readily oxidize to the more stable quinones. Netzly et al. (1988) reported these quinones may have herbicidal activity. They also found that soil containing sorghum roots had methylene chloride-extractable sorgoleone equivalent to 10^{-4} to 10^{-5} mol/liter in the soil (Netzly et al., 1988). In personal communication, Dr. Larry Butler (Purdue University) stated they recovered sorgoleone from the soil in the spring where a sorghum plant was grown the year before. Hence, sorgoleone may be an integral part of the explanation for some of the allelopathic effects of grain sorghum.

Our objectives in these investigations were to determine the relative toxicity of sorgoleone as an allelopathic chemical and to investigate this compound as a possible inhibitor of weed growth under laboratory conditions.

METHODS AND MATERIALS

Exudate Collection. Grain sorghum [*Sorghum bicolor* (L.) Moench; Dekalb Hybrid DK28] root exudate was collected, as needed, by germinating seeds in 9-cm-diameter Petri dishes on Whatman No. 1 filter paper moistened with deionized water. Ten seeds were placed in each of 40 Petri dishes and germinated for five days under room light (day: 10 $\mu E/m^2/sec$) and temperature (23

± 2°C) conditions. Seedling roots were dipped in 20 ml of methylene chloride containing 50 μl of concentrated acetic acid (Netzly et al., 1988). The methylene chloride solution was evaporated to dryness and the residue recovered. Fate et al. (1990) indicated that the methylene chloride-soluble hydrophobic exudate collected in this way contains only sorgoleone and its dihydroquinone (Figure 1). The exudate collected will be referred to as sorgoleone, since the dihydroquinone readily oxidizes to the quinone (Netzly et al., 1988). Analysis of the exudate components by high-pressure liquid chromatography (HPLC: Spectra Physics, model SP8800) using a Spherisorb 5 μM ODS2 column (4.6 × 250 mm) showed approximately 90% of the exudate corresponded to the sorgoleone peak. HPLC methods followed procedures of Netzly and Butler (1986) and Netzly et al. (1988) with Dr. Larry Butler (Purdue University) providing the initial sample of sorgoleone for comparison. In the numerous repetitions of exudate collection, the quantity of sorgoleone obtained ranged from 1.3 to 1.8 mg/100 roots dipped. Sorgoleone was stored at −4°C until used.

Growth Bioassays. Initial investigations of the effects of sorgoleone on plant growth employed a bioassay with *Eragrostis tef* (Zucc) Trotter, commonly known as teff. *E. tef* is a small-seeded cereal crop common to northern Africa that is being tested in South Dakota and other areas of the northern Great Plains as a forage crop (Boe et al., 1986). This bioassay was developed in our laboratory to test the biological activity of a natural product when only a small quantity of test compound is available. *E. tef* germination approaches 100%, radicle elongation is rapid, and many seeds can be germinated in a small volume of test solution.

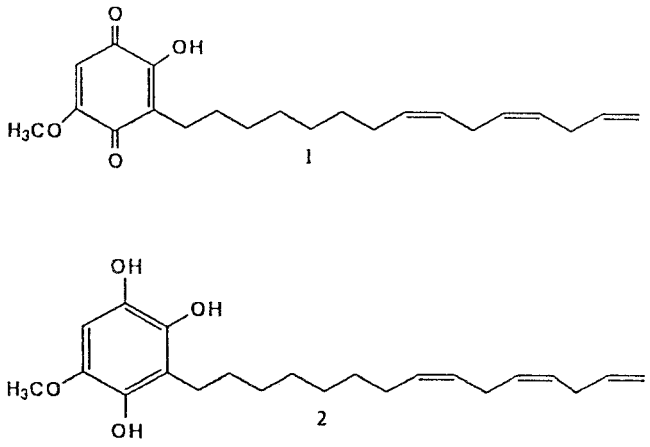

FIG. 1. Structures of (1) sorgoleone and (2) dihydroquinone of sorgoleone (Chang et al., 1986; Netzly et al., 1988; Fate et al., 1990).

Seed germination and radicle elongation studies were conducted in 4.5-cm-diameter Petri dishes with three replicates per treatment. Twenty-five seeds were germinated in a Petri dish on Whatman No. 1 paper moistened with 700 μl of test solution. Sorgoleone was first added to each Petri dish in 50 μl of ethanol, the ethanol evaporated by air drying, and deionized water was then added. The same protocol was used for controls, except they received no sorgoleone. Tests were conducted with 0, 125, and 250 μM sorgoleone. All references to sorgoleone concentrations used in these treatments and subsequent work assume that the compound dissolved in the aqueous test solutions. This is probably an overestimation of true concentration due to the relative hydrophobicity of sorgoleone. Petri dishes were placed in the dark at 25 ± 1°C and percentage germination and radicle lengths were obtained after 48 hr.

A *Lemna minor* L. bioassay was used to determine the effects of sorgoleone on whole plant growth and chlorophyll content (Einhellig et al., 1985). *L. minor* was grown in 24-well tissue culture cluster dishes. The culture media was E medium (Cleland and Briggs, 1967) modified to contain no sucrose or tartaric acid. Each culture dish well contained 1.5 ml of sterile medium and sorgoleone was added in 5 μl of methylene chloride; the control group also received 5 μl of methylene chloride. Treatment solutions were 0, 10, 50, and 100 μM sorgoleone. Efforts to enhance the solubility of sorgoleone by utilizing Tween 20 or Triton X were abandoned because *L. minor* was very sensitive to these surfactants. Each well was inoculated with three fronds, and six replications were used per sorgoleone treatment. *L. minor* was grown under continuous light (200 $\mu E/m^2/sec$) and 28°C. Frond condition, number, and dry weight (24 hr, 80°C) were obtained after seven days. In other experiments with the same design, the chlorophyll content of fronds was determined at the end of the treatment. Fronds were soaked in ethanol for two 24-hr periods, and the absorbance of the chlorophyll extract was read at 665 and 649 nm for quantification using standard equations (Wintermans and DeMots, 1965; Ramirez-Toro et al., 1988; Einhellig and Rasmussen, 1979).

Sorgoleone was tested against six commonly occurring field weeds (three broadleaf and three grass weed species) using an aqueous growth system. Seedling growth of velvetleaf (*Abutilon theophrasti* Medic.), jimsonweed (*Datura stramonium* L.), redroot pigweed (*Amaranthus retroflexus* L.), green foxtail [*Setaria viridis* (L.) Beauv.], crabgrass [*Digitaria sanguinalis* (L.) Scop.], and barnyard grass [*Echinocholoa crus-galli* (L.) Beauv.] was studied. Seeds were germinated in vermiculite in the greenhouse for seven to 10 days; then seedlings were individually transplanted into opaque vials containing 70 ml of one-half strength Hoagland's solution that contained two and one-half times the normal iron (Hoagland and Arnon, 1950). After two days acclimatization, seedlings were selected for uniformity and transferred to fresh nutrient solution, which contained either 0, 10, 50, or 100 μM sorgoleone. Eight plants were utilized

for each treatment and the control. Since sorgoleone was not fully soluble in the growth media, each treatment concentration was prepared by direct addition of sorgoleone rather than by a dilution process from the most concentrated solution. Seedlings were grown in the greenhouse for 10 days and harvested. Shoot and root dry weights were obtained after drying for 48 hr at 105°C. Leaf area and leaf weight were also obtained from the broadleaf weeds with the exception that dried and dead leaves in pigweed treatments did not allow for collection of leaf area measurements. Shoot–root ratios and the specific leaf weight (SLW = leaf weight/leaf area) were computed for *A. theophrasti* and *D. stramonium*.

Data Analyses. Comparisons among treatments in an experiment were analyzed using analysis of variance (ANOVA) and Duncan's multiple-range test.

RESULTS

The small volume of solution required for a test fostered the use of *E. tef* as the first bioassay for potential inhibitory effects of sorgoleone. In repeated trials, *E. tef* seed had a germination rate above 95%, with the radicle first appearing by 24 hr. No sorgoleone concentration tested inhibited or delayed this initial evidence of germination. However, 48-hr radicle elongation was almost completely stopped by 250 μM sorgoleone, and radicle lengths of seeds germinated in 125 μM sorgoleone were about half those of controls (Table 1).

Tests with *L. minor* showed that sorgoleone was inhibitory to the total growth of this plant. After seven days of treatment, *L. minor* grown with a 100-μM concentration of sorgoleone had only 73% of the frond count and 78% of the dry weight of controls (Table 2). *L. minor* fronds growing in this treatment also exhibited less total chlorophyll, but there was no difference from control plants in the ratio of chlorophyll a to b (data not shown). The treatment of 50 μM sorgoleone significantly inhibited frond number. Although not statistically significant, the 10-μM sorgoleone treatment resulted in a slight increase in frond number and dry weight.

[a] Values ($N = 6$) in a row not followed by the same letter are significantly different, $P < 0.05$, ANOVA with Duncan's multiple-range test.

The growth of each of the broadleaf weeds tested was markedly inhibited by 10 μM and higher concentrations of sorgoleone in the nutrient medium (Table 3). Inhibition was concentration-dependent, with the most severe effects occurring from 100 μM sorgoleone. In the case of *A. theophrasti* and *A. retroflexus*, plants grown with 100 μM sorgoleone appeared slightly smaller than controls at the end of three days of treatment. Differences in growth between the treated plants and controls became more apparent as the experiment progressed, and by the time of harvest several 100-μM treated *A. retroflexus* seedlings had wilted or dried leaves and appeared dead. The visible effects of sorgoleone on *Datura stramonium* seedlings were not as severe as for the other two species.

Leaf area and shoot, root, and leaf weights of all weed species were inhibited by sorgoleone even at 10-μM treatments (Table 3). However, the shoots of *A. theophrasti* and *D. stramonium* seedlings were more affected than the roots, as shown by the lower shoot–root ratios among treated plants. The reduction in shoot–root ratio was greatest in plants grown with 100 μM sorgoleone. A similar reduction in the shoot–root ratio occurred in sorgoleone-treated *A. retroflexus* plants except at the highest treatment level. This exception was probably due to early cessation of growth and/or death of *A. retroflexus* seedlings grown in 100-μM sorgoleone solutions. Calculations of SLW (specific leaf weight) for *A. theophrasti* and *D. stramonium* did not show any clear trends across treatment levels.

Similar to effects found with broadleaf weeds, growth of the three grass weeds evaluated was suppressed by each of the sorgoleone concentrations tested, and the extent of the inhibition was concentration-dependent (Table 4). *D. sanguinalis* seedlings showed the greatest reductions in plant weight with the 10-, 50-, and 100-μM sorgoleone treatments having 34%, 23%, and 22%, respectively, of the weight of untreated plants at harvest. Most of the 100-μM treated *D. sanguinalis* seedlings were dead by the time of harvest. Because of the strong

[c] SLW (specific leaf weight) = leaf weight/leaf area.

sorgoleone effects found in other species, *E. crus-galli* seedlings were not tested at the 100-μM level. In the experiments with each of the grass weeds, shoots and roots were about equally inhibited and no significant differences in the shoot–root ratio were evident.

DISCUSSION

This research clearly shows that sorgoleone is a potent inhibitor of plant growth that may likely be involved in allelopathic interference from *Sorghum* species. Sorgoleone addition at low concentrations resulted in suppressions of radicle elongation in the *E. tef* bioassay and reduction in total plant growth in

L. minor. Growth suppression was also pronounced in the six weed species tested. Even the 10-μM treatments of sorgoleone significantly reduced growth of each of the weed seedlings over the 10-day treatment. In general, growth reductions were nonselective, as sorgoleone affected both broadleaf and grass weeds. Tests of the effects of sorgoleone on a greater diversity of weed species are needed to confirm this lack of selectivity. However, it appears that the action of sorgoleone alone cannot explain the findings of Einhellig and Rasmussen (1989) that broadleaf weed abundance and biomass were more reduced after a crop of grain sorghum than were grass weeds.

It is important to recognize that the treatment concentrations that reduced seedling growth were very low in comparison to many allelopathic chemicals that have been tested in similar experimental designs. Inhibition of seedling growth by 10 μM sorgoleone in the nutrient medium is one to two orders of magnitude lower than the concentration required for growth reduction by many phenolic acids, which is often in the 100–1000 μM range (Einhellig, 1986, 1989). Allelopathic coumarins, flavonoids, and sesquiterpene lactones are typically inhibitory in a concentration range similar to phenolic acids (Einhellig et al., 1970; Scholes, 1987; Haar, 1990). We did not test sorgoleone concentrations below 10 μM, but the data suggest the threshold for growth inhibition of

some seedlings, such as *D. sanguinalis*, may be below this level. Inhibition by sorgoleone at micromolar concentrations is even more surprising when it is recognized that sorgoleone was not completely soluble in the aqueous nutrient medium. Hence, the treatment concentrations cited for the tests must be considered somewhat higher than what was available in the treatment solutions.

Relatively few quinones have been implicated in allelopathy, and even fewer as allelochemicals from higher plants (Rice, 1984). Juglone (5-hydroxy-1,4-naphthoquinone) is well known as the principle chemical responsible for walnut (*Juglans nigra*) allelopathy. Its potency is similar to the effects of sorgoleone. Micromolar levels of juglone have been reported to suppress the growth of several herbaceous species even though no visible signs of injury occurred (Rietveld, 1983).

We speculate that sorgoleone interferes with membrane functions. Investigations are now in progress to elucidate its possible physiological effects. Regardless of the mechanism(s) of sorgoleone action, it is a powerful inhibitor of plant growth. The occurrence of sorgoleone as a relatively pure compound in root exudates indicates it must be considered a part of the explanation for the allelopathic activity of the *Sorghum* crops in conjunction with the action of phenolic acids and other allelopathic compounds known to be released from *Sorghum* species (Guenzi and McCalla, 1966; Nicollier et al., 1983; Lehle and Putnam, 1983; Panasiuk et al., 1986; Weston et al., 1989). In summary, sorgoleone is a novel allelochemical that has biological activity at extremely low concentrations.

(Received May 17, 1991; accepted September 16, 1991)

Abstract—(3Z,6Z,9Z)-3,6,9-Heptadecatriene and (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene have been identified in female sex pheromone gland extracts of *Abraxas grossulariata* L. (Lepidoptera: Geometridae). The compounds were detected by gas chromatography with electroantennographic detection (GC-EAD) and identified by GC-mass spectrometry (GC-MS). The amounts of hydrocarbon and epoxide were 0.13 and 0.42 ng/female, respectively. These identifications were confirmed by synthesis; the absolute configuration of the epoxide remains to be determined. Another isomeric epoxide, (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene, was tentatively identified in small amounts (0.04 ng/female). Racemic (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene elicited the largest electroantennogram response within a series of heptadecadiene and nonadecadiene monoepoxides and the corresponding trienic hydrocarbons and, in field tests, attracted male *A. grossulariata* into traps. Addition of 10% (3Z,6Z,9Z)-3,6,9-heptadecatriene to this epoxide enhanced attractiveness; addition of (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene had no effect at low proportions while higher proportions caused a reduction in the numbers of males caught.

Key Words—Pheromone identification, (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene, (3Z,6Z,9Z)-3,6,9-heptadecatriene, *Abraxas grossulariata*, Lepidoptera, Geometridae.

INTRODUCTION

The currant moth, *Abraxas grossulariata* L., is a beautiful geometrid with black and brown dots on its white wings. The species is rather polyphagous and can cause significant damage in gooseberries, currants, and similar berries (Alford, 1983; Bognár, 1978; Vereschagina and Vereschagin, 1969). In the early 1980s, when a severe outbreak was observed in the northern part of Hungary, we started analyzing pheromone extracts prepared from insects collected in the wild. Further work was hampered by a sudden decrease of the insect population and, for a successful continuation of the project, a rearing method capable of producing hundreds of insects was required. The insect overwinters as small larvae on the plants, and all efforts to break this diapause were unsuccessful. Rearing of one generation took one year in each case. Here we report the identification of sex pheromone components of *Abraxas grossulariata*.

METHODS AND MATERIALS

Insects. The insect culture derived from eggs of female moths collected from the wild. The larvae were reared in an outdoor cage, where they were left to overwinter. They were fed with fresh leaves of black currant until pupation. The pupae were removed from their pupal cocoons, sexed, and the sexes were held separately under a reversed 18:6 light–dark photoregime and 25°C in the laboratory for bioassays and observations on calling behavior. Emerging adults were collected daily and were transferred to 1-liter glass jars where they were supplied with water on cotton wool.

Extracts. Females were observed calling from the second day of their adult life, after the onset of the dark period. For preparation of pheromone extracts, the terminal segments of the abdomina of unmated calling females were excised and extracted in small volumes (5 μl/female) of *n*-pentane or *n*-hexane (Merck, analytical grade) for 15 min.

Analysis. Female gland extracts were analyzed by gas chromatography with flame ionization and electroantennographic detection (GC-FID/EAD) (Arn et al., 1975) using a male antenna of *A. grossulariata*. A Carlo Erba 5360 gas chromatograph equipped with a homemade 25-m Silar 10c high-resolution (HRGC) glass capillary (0.32 mm ID) column was used. This column was tem-

perature programmed as follows: 70°C, 1 min isothermal, 10°C/min to 100°C, then at 3°C/min to 180°C, followed by an isothermal hold at this temperature. Splitless injections (injector temperature: 220°C) were made of 1 female equivalent (1 FE) in 2 μl of solvent.

Analysis by GC-mass spectrometry (GC-MS) was carried out initially with a Finnigan 4023 quadruple mass spectrometer and the Silar 10c HRGC column. Final GC-MS analysis was made on a VG Tribrid double-focusing magnetic sector mass spectrometer (VG Analytical Ltd., Manchester, England) operating in the electron ionization (El, 70 eV, 180°C) mode. El mass spectra (*m/z* 35–485, 1.16 sec/scan) were recorded at unit mass resolution. In this case a 25-m SE 54 HRGC fused silica column (0.32 mm ID; Mega, Legnano, Italy) was used and temperature programmed as follows: 50°C, 2 min isothermal, 20°C/min to 140°C, then at 5°C/min to 280°C, followed by an isothermal hold at this temperature. The samples (2 μl in *n*-hexane) were on-column injected at 50°C. Extracts of up to 10 female glands of 1 to 3-day-old females (40 μl carefully concentrated to 2 μl) were injected. Data acquisition was started at 60°C and retention times were measured from this point. Retention indices (RI) were calculated relative to *n*-alkanes (C_{12}–C_{31}; RI 1200–3100) present in the samples or coinjected; linear interpolation was used in the temperature programmed runs.

Synthesis. The synthesis and characterization of (3*Z*,6*Z*,9*Z*)-3,6,9-heptadecatriene and the preparation of the racemic 3,4-, 6,7-, and 9,10-epoxides by random epoxidation and separation of the three isomers by liquid chromatography was described by Tóth et al. (1991).

Electroantennograms. Electroantennograms (EAG) were recorded from excised antennae of 2- to 3-day-old male moths, applying platinum electrodes to the base and tip of the antenna. Connection between the electrodes and the insect tissues was accomplished with an electrically conducting gel (Valleylab, Boulder, Colorado). Responses were amplified by a high-impedance amplifier (Rumbo, 1981) and displayed on an OH850 chart recorder (Radelkis, Budapest, Hungary). One microgram of the test compound applied to a 10 × 10-mm piece of filter paper inside a Pasteur pipet was used as the odor source. Stimuli were provided by injecting 1 ml of air through the Pasteur pipet into a continuous airstream (1300 ml/min) flowing over the antenna. The interval between stimuli was ca. 60 sec. Responses were normalized to the compound with highest activity.

Field Trapping. Field tests were conducted at several locations in Hungary. Traps similar to those described by Arn et al. (1986) made from transparent polyethylene sheets were used. Traps were hung at the height of 1.5 m from branches of bushes and small trees. Traps containing different baits were set up in rectangular blocks. The distance between traps within a block was 4–5 m. There were six to eight traps in a block; the distance between blocks

ranged between 100 and 1000 m. At every inspection, trap positions were rotated and sticky inserts renewed. In statistical analysis, catches recorded at each trap inspection were regarded as replicates; data were transformed to log $(x + 1)$ and differences between means were tested for significance by Duncan's new multiple-range test (NMRT). In case of treatments with zero catches, the Wilcoxon-Mann-Whitney test was used for paired comparisons of the remaining treatments.

For preparing the baits, the compounds were applied to 1 × 1-cm pieces of rubber tubing (Taurus, Budapest, Hungary, No. MSZ-9691/6; extracted three times in boiling 70% ethanol for 10 min, then three times in methylene chloride overnight, prior to usage) in *n*-hexane solutions. Dispensers were individually wrapped in aluminum foil and were stored at −65°C until use.

RESULTS AND DISCUSSION

Analysis. GC-EAD analysis on a Silar 10c column showed the presence of two biologically active components, an earlier-eluting component I (RI = 1731) and a later-eluting component II of very high EAD activity (RI = 2091). Both components gave very weak mass spectra (6 FE injected) using the quadrupole mass spectrometer. Full identification of the two compounds was not possible; nevertheless, characteristic ions (*m/z* 79, 80, 91, 93, 95, 107 or 108, and 178) were indicative of polyunsaturated aliphatic compounds for both components. A further extract (10 FE) was then analyzed on the VG Tribrid mass spectrometer using an SE 54 column. In this case the mass spectra indicated the presence of a series of *n*-alkanes (C_{23}–C_{31}; odd members C_{23}–C_{31} predominating), as well as some branched species (2- and 3-methylalkanes, C_{27}–C_{31}) and later-eluting steroids (major component cholesterol). Also present was a series of carboxylic acids (C_{16}–C_{20}; saturated, and mono-, di-, and triunsaturated). On this column, components I and II showed RI values of 1672 and 1845, respectively. In Figure 1, a partial chromatogram of this extract shows the elution of components I and II; also indicated is the elution of some *n*-alkanes present in this sample. Mass spectra of the biologically active components I and II are given in Figure 2A,B.

The mass spectrum of component I (RI_{SE54} = 1672; see Figure 2A) showed the characteristic ions previously observed for this component (see above), and new ions at *m/z* 205 and 234. The small difference between the retention indices on the two columns ($\Delta RI = RI_{Silar} - RI_{SE54} = 1731 - 1672 = 59$) suggested component I to be a hydrocarbon. The signals in the lower mass range (*m/z* 35–150) were very similar to those from (3*Z*,6*Z*,9*Z*)-3,6,9-nonadecatriene (M^{+} = 262; RI = 1940 and 1870 on Silar and SE 30, respectively), previously iden-

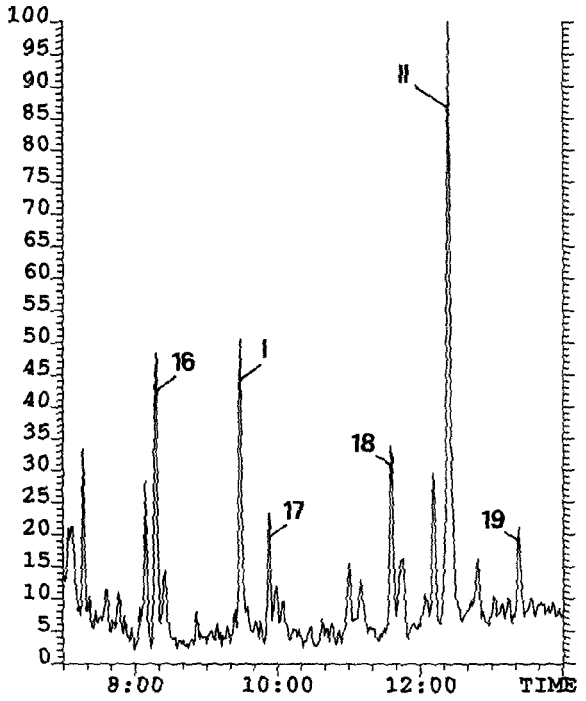

FIG. 1. Reconstructed total ion chromatogram (retention time 7–14 min, 25-m SE 54 HRGC column, VG Tribrid) of a female gland extract of *A. grossulariata* (10 FE injected) showing elution of the biologically active components I (RI_{SE54} = 1672) and II (RI_{SE54} = 1845). Elution of *n*-alkanes (C_{16}–C_{19}) present in the sample as indicated.

tified as a female sex pheromone component of *Peribatodes rhomboidaria* Schiff. (Buser et al., 1985). The signals at *m/z* 234 and 178 for component I and its retention indices suggested it to be a lower homolog, presumably a 3,6,9-heptadecatriene (M^+ = 234; M^+-C_4H_8, *m/z* 178). As methylene-interrupted unsaturations in sex pheromones of moths have been *Z* in all cases reported (see Buser et al., 1985; Millar et al., 1987; Li et al., 1988; Tóth et al., 1989; among others), we decided to synthesize (3*Z*,6*Z*9*Z*)-3,6,9-heptadecatriene according to known methods (Tóth et al., 1991); its EI mass spectrum and retention index proved to be identical to that of component I.

The mass spectrum of component II (see Figure 2B) showed signals at *m/z* 79, 80, 91, 93, 107 and 178, and very weak signals at *m/z* 232 and 250. The ions in the lower mass range also suggested this compound to be polyunsaturated. This and the characteristic ion at *m/z* 178 indicate a possible relationship to component I. The difference between the retention indices (ΔRI =

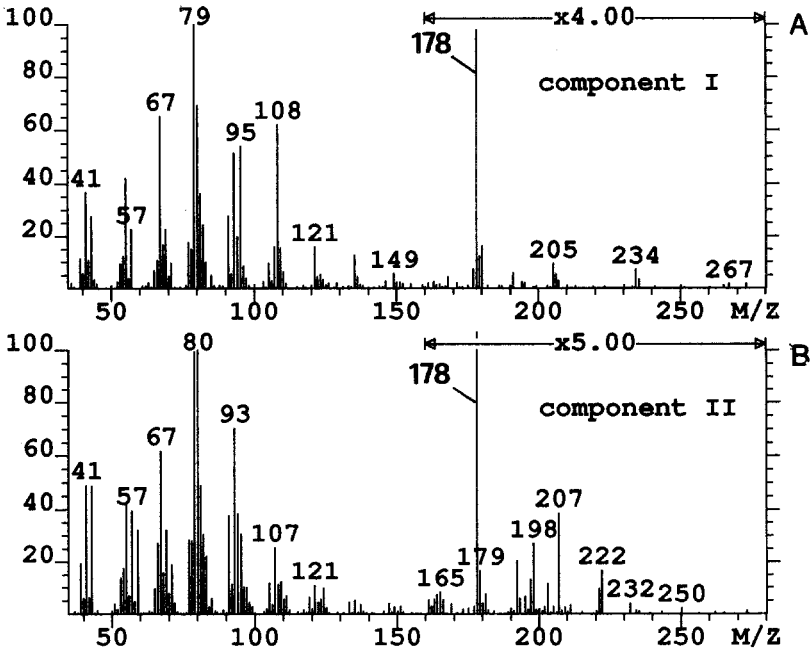

FIG. 2. (A) El mass spectrum of component I (RI_{SE54} = 1672), identified as (3Z,6Z,9Z)-3,6,9-heptadecatriene (M^+ = 234); (B) El mass spectrum of component II (RI_{SE54} = 1845), identified as (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene (M^+ = 250; note presence of signals *m/z* 198, 207, 222 from coeluting compound). Note vertical expansion in mass range *m/z* 160–280.

$RI_{Silar} - RI_{SE54}$ = 2091 − 1845 = 246) suggested component II to be considerably more polar than a hydrocarbon, presumably an oxygenated analog of component I. Furthermore, the retention indices (RI_{SE54}) of components I and II showed a difference (ΔRI = 171), similar to the differences previously observed for a series of monoepoxy analogs of (3Z,6Z,9Z)-3,6,9-heneicosatriene, (3Z,6Z,9Z)-1,3,6,9-heneicosatetraene, (3Z,6Z,9Z)-3,6,9-nonadecatriene and the parent hydrocarbons (Buser et al., 1985; Tóth et al., 1989). The signal at *m/z* 178 would indicate an oxygen function (epoxide) within the first four carbons. A 3,4-epoxide rather than 6,7- and 9,10-epoxides was also indicated by the presence of a *m/z* 59 ion ($C_3H_7O^+$). This information led us to conclude that component II could be a monoepoxy analog of component I, presumably the (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene (M^+ = 250).

The three positional monoepoxy analogs of the (3Z,6Z,9Z)-3,6,9-heptadecatriene were then synthesized as racemates (Tóth et al., 1991). The mass spectra of the three closely eluting epoxides (RI_{SE54} = 1845, 1842, and 1850

for the 3,4-, 6,7-, and 9,10-epoxy analogs, respectively) are reported in Figure 3A–C, and show characteristic differences. The mass spectra were very similar to the spectra previously reported for these compounds (Millar et al., 1987). The mass spectrum of (6*Z*,9*Z*)-6,9-*cis*-3,4-epoxyheptadecadiene (RI_{SE54} = 1845) showed the characteristic signals (particularly *m/z* 59, 79, 80, 107, 178, and others) previously observed and matched that of component II. The retention index of this epoxide and component II also matched. However, the absolute configuration of the epoxide remained unknown. From mass chromatograms (*m/z* 178) the amounts of (3*Z*,6*Z*,9*Z*)-3,6,9-heptadecatriene (component I) and

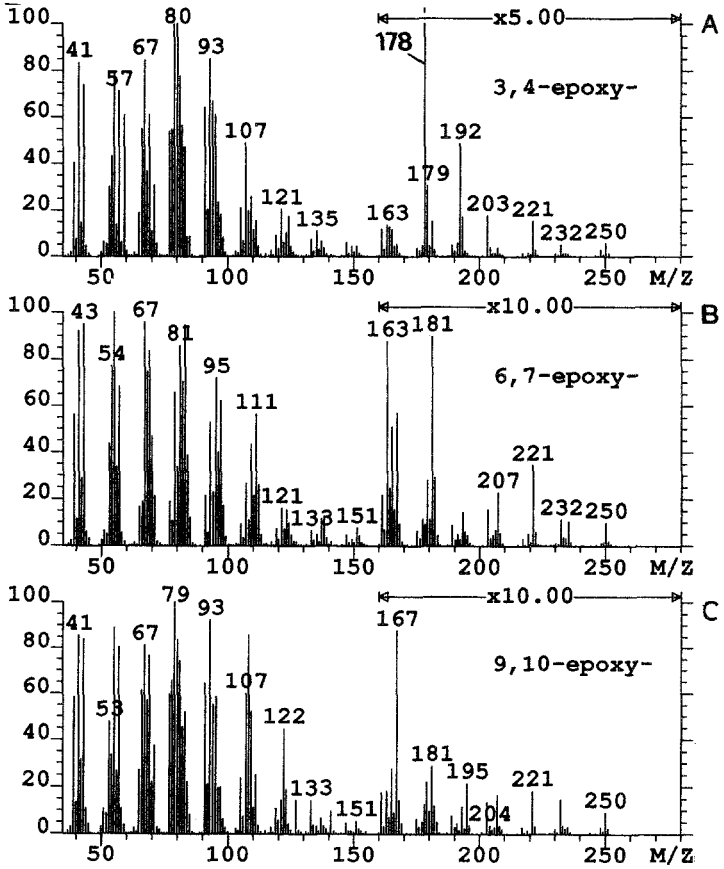

FIG. 3. EI mass spectra of three isomeric monoepoxy analogs (M^+ = 250) of (3*Z*,6*Z*,9*Z*)-3,6,9-heptadecatriene: (A) (6*Z*,9*Z*)-6,9-*cis*-3,4-epoxyheptadecadiene (RI_{SE54} = 1845); (B) (3*Z*,9*Z*)-3,9-*cis*-6,7-epoxyheptadecadiene (RI_{SE54} = 1842); (C) (3*Z*,6*Z*)-3,6-*cis*-9,10-epoxyheptadecadiene (RI_{SE54} = 1850).

(6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene (component II) were determined to be 0.13 and 0.42 ng/FE, respectively.

The mass spectra of the female *A. grossulariata* extract were searched for the presence of the other two monoepoxy analogs. Mass chromatograms showed the elution of a third polyunsaturated component (III) as a trailing shoulder to component II with the correct retention index (RI_{SE54} = 1849) of the (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene. The presence of this epoxide was supported from signals at *m/z* 79, 80, 93, 107, and particularly at *m/z* 108 (see Figure 4); characteristic is the changed intensity ratio for ions *m/z* 107 and 108 of the 3,4- and the 9,10-epoxides (see also Figure 3A,C). The amount of (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene possibly present was estimated at 0.04 ng/FE. This amount was too low to allow confirmation of its presence by higher mass ions (*m/z* 167 and others), and its identification therefore remained tentative. No indication for the presence of (3Z,9Z)-3,9-*cis*-6,7-epoxyheptadecadiene (RI_{SE54} = 1842) was obtained (limit of detection, 0.04 ng/FE).

Electrophysiology. In the EAG tests racemic (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene was found to be highly active on the male antenna (Figure 5). Among the other C_{17} compounds, responses in decreasing order were elicited by racemic (3Z,9Z)-3,9-*cis*-6,7-epoxyheptadecadiene, (3Z,6Z,9Z)-3,6,9-heptadecatriene, and racemic (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene. Responses to the C_{19} compounds showed a parallel trend, with highest response to the 3,4-epoxide and lower responses to the other compounds.

Field Trapping. When the three positional C_{17} epoxides were screened in traps, (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene caught a total of 148, 4, 4, 2, 13, and 8 male *A. grossulariata* at Adony (Fejér County, mixed poplar forest), Aszód (Heves County, mixed oak forest), Budakeszi (Pest County, mixed oak forest), Gyöngyös (Heves County, row of mixed bushes along the edge of an alfalfa field), Gyöngyössolymos (Heves County, mixed oak forest), and Ladánybene (Bács-Kiskun County, juniper and poplar vegetation), respectively, even in habitats where the species was not expected in high numbers (e.g., alfalfa field at Gyöngyös). The highest catches were observed at the flood area of Danube (Adony), so that all other comparative tests were set up at this site.

Racemic (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene was combined with (3Z,6Z,9Z)-3,6,9-heptadecatriene and racemic (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene at the approximate proportions present in the gland extract. At doses of 100 and 10 μg, this mixture caught less than (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene on its own (Figure 6). At lower dosages catches were generally very low but showed a similar trend.

Since the proportions determined in female gland extracts may not reflect optimal proportions for attraction, (3Z,6Z,9Z)-3,6,9-heptadecatriene and (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene were added in varying amounts to

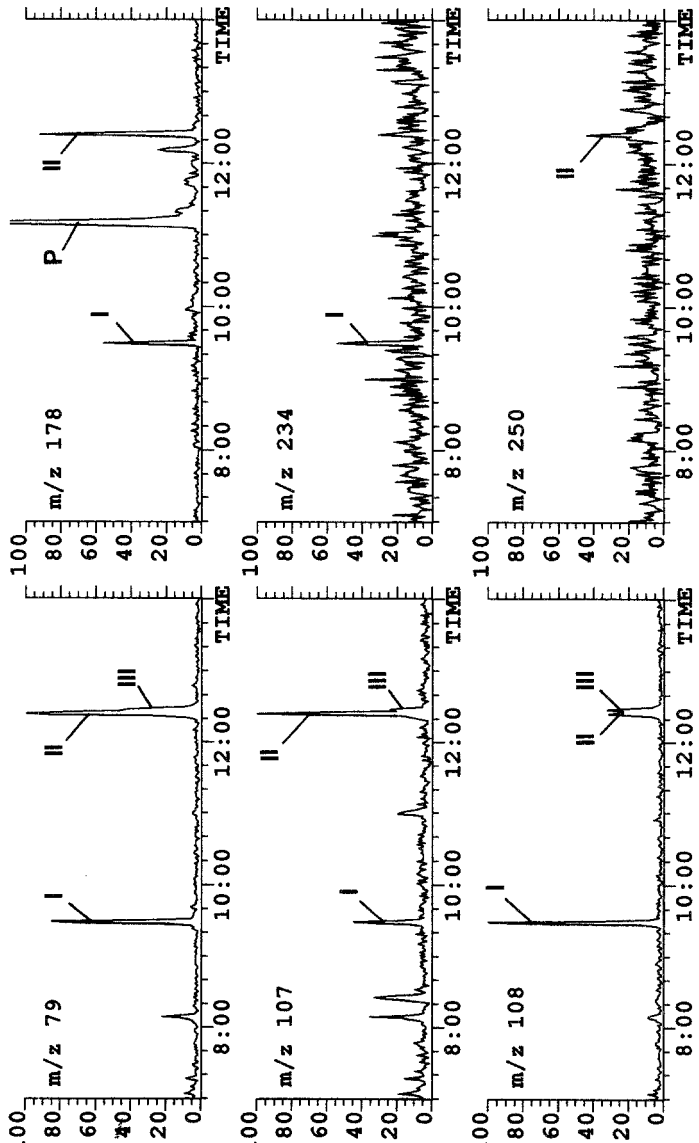

FIG. 4. Mass chromatograms (retention time range 7–14 min) of a female gland extract of *A. grossulariata* showing presence of (3Z,6Z,9Z)-3,6,9-heptadecatriene (I), (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene (II), and a third component, tentatively identified as (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene (III). Also indicated is elution of phenanthrene (P; $M^+ = 178$).

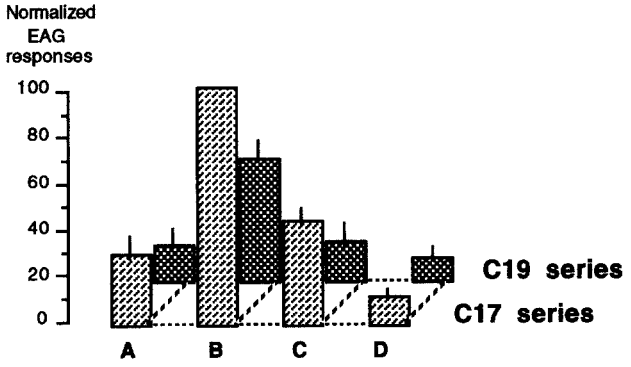

FIG. 5. Average EAG responses of five male *A. grossulariata* antennae to (3Z,6Z,9Z)-3,6,9-heptadeca- and -nonadecatriene, and to their monoepoxy analogs: A = (3Z,6Z,9Z)-3,6,9-hepta- or -nonadecatriene, respectively, B = (6Z,9Z)-6,9-*cis*-3,4-epoxy-, C = (3Z,9Z)-3,9-*cis*-6,7-epoxy-, and D = (3Z,6Z)-3,6-*cis*-9,10-epoxyhepta- and -nonadecadiene, respectively; bars show SD; responses normalized against response to (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene.

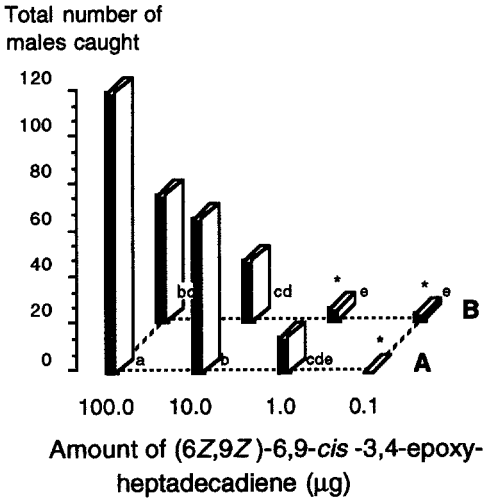

FIG. 6. Total number of male *A. grossulariata* caught in traps baited with racemic (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene alone (A), or in combination (100:10:30) with racemic (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene and (3Z,6Z,9Z)-3,6,9-heptadecatriene (B) at different dose levels. (Adony, Hungary, June 15–25, 1990; 5 traps/bait combination; traps inspected every second day; captures with same letter are not significantly different at $P = 5\%$ by Duncan's NMRT; captures labeled by an asterisk are not significantly different from zero capture by the Wilcoxon-Mann-Whitney test).

(6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene (Figure 7A). The only lure that was slightly more attractive than (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene was a mixture of this compound with 10% of (3Z,6Z,9Z)-3,6,9-heptadecatriene added. A mixture with 30% of hydrocarbon added caught similar numbers of males, whereas the mixture with 100% of hydrocarbon added was almost inactive, indicating a possible antagonism of the hydrocarbon at such a ratio. A similar trend was observed when 1% of (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene was

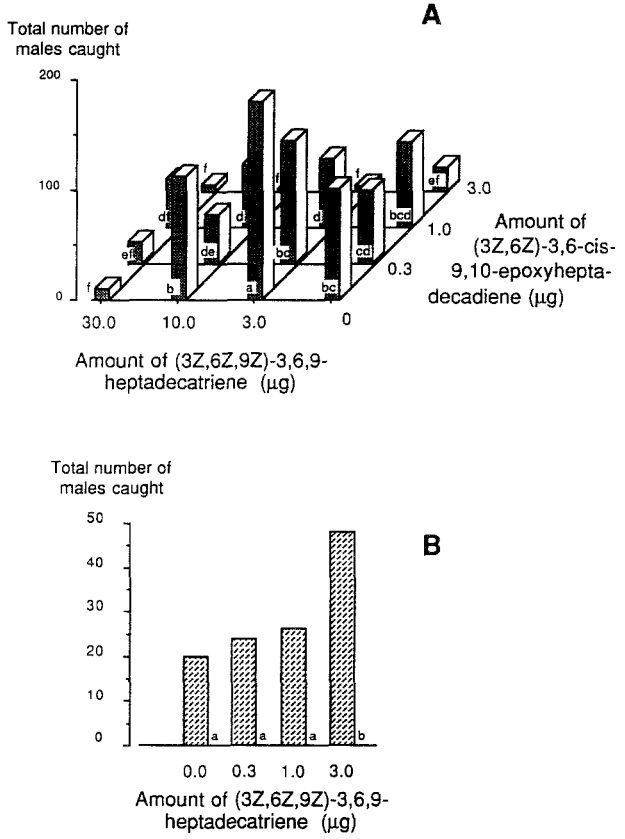

FIG. 7. Total number of male *A. grossulariata* caught at Adony, Hungary, 1990, in traps baited with racemic (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene or with its binary and ternary mixtures with racemic (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene and (3Z,6Z,9Z)-3,6,9-heptadecatriene at different ratios. The basic attractant was 30 μg of (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene in each case. (A) June 21–29; 8 traps/bait combination; (B) June 30–July 13; 10 traps/bait combination; in both tests traps were inspected every second day. Captures with same letter within one test are not significantly different at $P = 5\%$ by Duncan's NMRT.

added to the other two compounds, although here the catch of the blend with 10% of the hydrocarbon was not significantly different from that of the epoxide mixture without the hydrocarbon. At lures with 3–10% of (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene, catches decreased to low values, indicating a possible inhibitory effect of this compound. This effect could also be responsible for the low catches of the mixtures (10% of this epoxide added) observed in the first test (Figure 6).

The increased activity of the mixture of (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene and (3Z,6Z,9Z)-3,6,9-heptadecatriene was confirmed in another test (Figure 7B); the addition of (3Z,6Z,9Z)-3,6,9-heptadecatriene at less than 10% had no effect.

Based on the above chemical data and the biological activity, we conclude that (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene is the main pheromone component of *A. grossulariata*; the absolute configuration of this epoxide remains unknown. The racemic synthetic epoxide is highly active on the male antenna and acts as an attractant in the field. Addition of 10% of (3Z,6Z,9Z)-3,6,9-heptadecatriene, also identified in pheromone gland extracts, enhances the catch. Since the synergistic activity of the triene is not dramatic, the seasonal flight pattern of *A. grossulariata* can be monitored adequately with traps containing racemic (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene on its own. Another epoxide tentatively identified in the female gland, (3Z,6Z)-3,6-*cis*-9,10-epoxyheptadecadiene, did not augment trap catches when added to the main component; at higher amounts added it seemed to be inhibitory.

Unsaturated hydrocarbons with an odd number of carbons in their chain and their oxygenated derivatives form an important group of sex pheromone components of Geometridae. (6Z,9Z)-6,9-*cis*-3,4-Epoxyheptadecadiene and (3Z,6Z,9Z)-3,6,9-heptadecatriene were previously reported as sex pheromone components of *Semiothisa signaria dispuncta* Wlk. (Millar et al., 1987). Their presence was inferred from GC-FID/EAD and field trapping; the presence of the hydrocarbon was confirmed by GC-MS, but the amount of the epoxide ($\sim$ 1 ng/FE) was too low for this confirmation. The same compounds have been identified in the sex pheromone of *Tephrina arenacearia* Hbn. and *Chiasma clathrata* L. (Tóth et al., 1991), and a Chinese *Semiothisa* species (Li et al., 1988). Enantiomers of (6Z,9Z)-6,9-*cis*-3,4-epoxyheptadecadiene were found to be attractive to two *Itame* species and *Epelis truncataria* Wlk. (Millar et al., 1990b). *Lomographa semiclarata* Wlk. was reported to be attracted to (3Z,6Z,9Z)-3,6,9-heptadecatriene (Millar et al., 1990a), and the same compound was tentatively identified in *S. bicolorata* Fabr. and *S. neptaria* Guenée (Millar et al., 1987).

(Received August 19, 1991; accepted September 16, 1991)

Abstract—The composition of the territorial marking pheromones from mandibular glands of males of the beewolves *Philanthus crabroniformis*, *P. barbatus*, and *P. pulcher* have been determined. The structures of the components were elucidated by gas chromatography–mass spectrometry and gas chromatography–Fourier transform infrared spectroscopy. The major compound of *P. crabroniformis* is isopropyl tetradecanoate, with somewhat lesser amounts of 2-tridecanone, 3-methyl-3-butenyl tetradecanoate, and 92:8 (*Z*):(*E*)-11-eicosen-1-ol. The major compounds of *P. barbatus* are ethyl tetradecanoate and hexadecanal, which are present in approximately a 60:40 ratio. These two compounds comprise over 95% of the neutral lipids. Also present in lesser amounts are ethyl dodecanoate, tetradecanal, hexadecan-1-ol, a Δ^x-octadecen-1-ol, and octadecan-1-ol. The major compounds of *P. pulcher* are ethyl (*Z*)-7-hexadecenoate and geranylgeraniol acetate, which comprise nearly 90% of the neutral lipid fraction, with smaller amounts of tetradecanal, pentadecanal, and ethyl hexadecanoate; trace amounts of Δ^x-hexadecenal, hexadecanal, and octadecanal are also present.

Key Words—*Philanthus crabroniformis*, *Philanthus barbatus*, *Philanthus pulcher*, Hymenoptera, Sphecidae, beewolf, mandibular glands, pheromones, semiochemicals, mass spectrometry, infrared spectroscopy.

INTRODUCTION

Males of many species of philanthine wasps (Hymenoptera: Sphecidae: Philanthinae) exhibit the unusual wasp behavior of scent-marking territories. These territories are usually in open, sunny areas, often near female nesting sites. After they are scent-marked with mandibular gland pheromones, they are actively defended against conspecific males and other intruders (Simon Thomas and Poorter, 1972; Alcock, 1974, 1975; Gwynne, 1978; O'Neill, 1979, 1983; Borg-Karlson and Tengo, 1980; Evans, 1982; Schmidt et al., 1985). Philanthini scent-marking and territorial behavior is best characterized for the beewolves of the genus *Philanthus*, a large, nearly cosmopolitan group that contains over 130 species. In North America, all but one of the 18 species for which male behavior has been studied scent-mark (Evans and O'Neill, 1988). Scent-marking appears to play a crucial role in the reproductive biology of beewolves and apparently functions both to bring the sexes together and to provide species recognition cues (Schmidt et al., 1985; Evans and O'Neill, 1988).

In our previous investigations of male *Philanthus* mandibular gland chemistry, we reported that two North American species, *P. bicinctus* and *P. basilaris* (both members of the *zebratus* group), possessed idiosyncratic blends of 13- to 20-carbon ketones, alcohols, aldehydes, esters, and fatty acids (Schmidt et al., 1985, McDaniel et al., 1987). The European species, *P. triangulum*, contained a mixture of 18- to 20-carbon lipids that included an aldehyde, a ketone, an alcohol, and an acid (Schmidt et al., 1990). We have now investigated the chemistry of three more *Philanthus* species—*P. crabroniformis* and *P. barbatus* in the *gibbosus* group and *P. pulcher* in the *pacificus* group—in an effort to elucidate further the diversity of mandibular gland compounds synthesized by *Philanthus*.

METHODS AND MATERIALS

Specimens of *Philanthus crabroniformis* were collected July 11, 1989; those of *P. barbatus* were collected July 25, 1988, both in an area approximately 56 km northwest of Fort Collins in Larimer County, Colorado. *Philanthus pulcher* wasps were collected in late June 1989 in the same area. Male wasps were collected while they were on their territories, and three replicates of 8–10 pooled heads and thorax–abdomens of each species were separately placed in methylene chloride (Burdick and Jackson Laboratories, Inc., Muskegon, Michigan[4]). These extracts were separated into hydrocarbon, carboxylic

[4]Mention of a company, trade name, or commercial product is for identification purposes only and does not imply endorsement by the USDA.

acid, and neutral fractions as previously described (Schmidt et al., 1985, 1990; McDaniel et al., 1987).

Most derivatizations were conducted in 5-ml Reactivials (Pierce Chemical Company, Rockford, Illinois) and heated when necessary in a Thermdyne Dri-Bath (Fisher Scientific, Pittsburgh, Pennsylvania). *N,N*-Dimethylhydrazones were prepared as previously described (McDaniel and Howard, 1985).

Double bond positions were determined by mass spectral analysis of dimethyl disulfide (DMDS) derivatives (Scribe et al., 1988, Buser et al., 1983, Dunkelblum et al., 1985, Francis and Veland, 1981).

Pentenyl esters of tetradecanoic (myristic) acid were prepared by reacting ca. 50 mg of myristoyl chloride (Pfaltz and Bauer, Inc., Waterbury, Connecticut) with approximately 200 μl of the appropriate pentenol for ca. 8 hr at 40°C. After reaction, approximately 2 ml of hexane were added, and the mixture was shaken with a 1 M solution of $NaHCO_3$. Microhydrogenation of pentenyl esters of myristic acid was accomplished by placing the esters onto melting-point capillary columns packed with palladium chloride (Pfaltz and Bauer, St. Louis, Missouri) on Celite 545 (Johns-Manville Co., Baltimore, Maryland) and passing a stream of hydrogen through the capillary (Schwartz et al., 1972). The hydrogenated products were then eluted with ca. 20 μl of CS_2.

Acetate esters were prepared by placing microgram amounts of the alcohols in a vial and reacting them with acetic anhydride and pyridine, followed by the customary work-up of the reaction mixture.

Authentic samples of (*E*)- and (*Z*)-11-eicosen-1-ol and (*E*)- and (*Z*)-9-hexadecenoic acid ethyl esters were obtained from Nu-Chek-Prep, Inc., (Elysian, Minnesota).

Gas chromatography–mass spectrometry (GC-MS) analyses were performed on a Hewlett-Packard 5890 gas chromatograph interfaced to a 5970 Mass Selective Detector. The system was connected to a Series 9000-216 computer. The column employed was a 30-m × 0.25-mm DB-5 (J&W Scientific, Inc., Folsom, California) with the following chromatographic parameters: injection port temperature 250°C; transfer line 280°C; oven temperature 50°C initially, then programmed to 150°C at 25°C/min, then programmed to 325°C at 4°C/min. The carrier gas was chromatography-grade helium at a head pressure of 105 kPa. All spectra were obtained at 70 eV.

Relative abundances and Kovats indices of the neutral lipids were obtained from a Shimadzu GC-6AM gas chromatograph equipped with a flame ionization detector and a 15-m × 0.53-mm Megabore DB-1 column (J&W Scientific, Inc.) and a Hewlett-Packard integrator. The chromatographic parameters were: injection port and detector temperatures 275°C; oven temperature 130°C initially, programmed to 275°C at 5°C/min. The carrier gas was chromatography-grade nitrogen at a flow rate of 5 ml/min.

Fourier-transform infrared (FTIR) vapor-phase spectra were obtained on a

Hewlett-Packard 5890 GC with a 5965A FTIR detector and a 7958 data system. The column employed was a 0.32-mm × 30-m DB-5 (J&W Scientific, Inc.) with chromatographic parameters identical to those previously given.

RESULTS

Philanthus crabroniformis males had the least complex mandibular gland composition of any North American species yet examined (Table 1). 2-Tridecanone was readily characterized by mass spectrometry, with a characteristic McLafferty rearrangement ion at *m/z* 58 as the base peak and a molecular ion at *m/z* 198. FTIR showed a carbonyl absorption at 1731 cm^{-1}. The *N,N*-dimethylhydrazone had a mass spectrum consistent with the assigned identity: the ion at *m/z* 100 had a relative abundance of 83%, and the molecular ion at *m/z* 240 had a relative abundance of 42%. Isopropyl tetradecanoate (isopropyl myristate) was the most abundant compound in the mixture. The mass spectrum had a base peak at *m/z* 228 and a small molecular ion (1%) at *m/z* 270. The ion at *m/z* 228 may be interpreted as the molecular ion of myristic acid that arises from proton transfer from the isopropyl group with subsequent loss of neutral propene. FTIR data showed a characteristic C=O at 1747 cm^{-1}, a C—O—C absorption at 1113 cm^{-1}, and other diagnostic bands at 1177 and 1244 cm^{-1}. A computer search of the FTIR library yielded a 99% match with isopropyl myristate. Likewise, the compound had a retention time and mass spectrum identical to that of an authentic sample synthesized as previously described. The 3-methyl-3-buten-1-ol ester of myristic acid, 3-methyl-3-butenyl tetradecanoate, had a base peak at *m/z* 68 and a small molecular ion (2%) at *m/z* 296. There were two other small (<5%) ions at *m/z* 228 (M−68), and at *m/z* 211 (M−85). The *m/z* 68 ion is a C_5 diene fragment that arises through proton transfer to form myristic acid (*m/z* 228). FTIR data included the C=O absorption at 1752 cm^{-1}, bands at 3050 cm^{-1} (=C—H stretch), 897 cm^{-1} (C—H out of plane deformation), and 1653 cm^{-1} (C=C stretch). The compound had a retention time and mass spectrum identical to that of the synthesized ester. In

TABLE 1. MANDIBULAR GLAND NEUTRAL LIPIDS, THEIR RELATIVE ABUNDANCES, AND KOVATS INDICES IN *Philanthus crabroniformis* MALES

Component	Relative abundance (%)	Kovats index
2-Tridecanone	20	1481
Isopropyl tetradecanoate	55	1814
3-Methyl-3-butenyl tetradecanoate	16	2125
11-Eicosen-1-ol	9	2250

addition, microhydrogenation of the compound yielded 3-methylbutyl tetradecanoate (isoamyl myristate), which was identified by comparing the mass spectrum and retention time with that of an authentic synthesized sample. The two 11-eicosen-1-ol isomers had mass spectra consistent with those of alcohols. There is no molecular ion at *m/z* 296, but there is a significant ion (6%) at *m/z* 278 (M−18). FTIR data of the alcohols contained an absorption at 3739 cm^{-1} (OH), 3012 cm^{-1} (=C−H), 1458 cm^{-1} (OH), and at 1039 cm^{-1} (C−OH prim). A computer search of the FTIR library yielded alcohols as the three best matches (98%). The double bond positions were determined by GC-MS of the vicinal dithiomethyl ether derivatives of the acetates. Large α-cleavage fragments at *m/z* 173 and at *m/z* 259 established the double bond at the Δ^{11} position. Similarly, comparison of the mass spectra and retention times of the acetates with the spectra of the synthesized acetates of (*E*)-11-eicosen-1-ol and (*Z*)-11-eicosen-1-ol indicated that the *P. crabroniformis* alcohols consisted of 92% *Z* isomer and 8% *E* isomer.

In *P. barbatus* (Table 2), the neutral lipids of the mandibular gland extract were composed of three compound types: ethyl esters, aldehydes, and alcohols. The ethyl esters, ethyl dodecanoate and ethyl tetradecanoate, were characterized by rearrangement ions at *m/z* 88, which were base peaks; by M−45 ions that corresponded to the loss of an ethoxy group from the parent compound at approximately 10% relative abundance; and by molecular ions that had relative abundances of 8–10%. The mass spectra of the 1,1-dimethylhydrazones of the aldehydes had the rearrangement ions at *m/z* 86 as base peaks and molecular ions at relative abundances of approximately 20%. The alcohols, hexadecan-1-ol, Δ^x-octadecen-1-ol, and octadecan-1-ol, which were minor constituents of the lipid mixture, were identified by the mass spectra of their acetate derivatives. The presence of the *m/z* 61 ion characterized them as acetates, and their

[a]tr = <0.1%.

molecular ions and M−60 ions further established their identities. The octadecen-1-ol was not present in sufficient abundance for the double bond position to be determined. The two compounds ethyl tetradecanoate (ethyl myristate) and hexadecanal, present in approximately a 60:40 ratio, comprised over 95% of the total neutral lipids of the mandibular gland of *P. barbatus*.

In *P. pulcher* (Table 3), as in *P. barbatus*, ethyl esters and aldehydes were found, but the compounds present were different, and they were further differentiated by the presence of the acetate of the diterpene alcohol, geranylgeraniol. The ethyl ester of (*Z*)-7-hexadecenoic acid and geranylgeraniol acetate comprised nearly 90% of the total neutral lipids of the mandibular glands. Mass spectral analysis of the vicinal dithiomethyl ether of ethyl (*Z*)-7-hexadecenoate yielded fragments at *m/z* 173 and at *m/z* 203 that show the double bond position to be at the 7 position. Our evidence for the stereochemistry is somewhat indirect, since it is based on comparison of the retention times of similar compounds, the ethyl esters of (*E*)- and (*Z*)-9-hexadecenoic acid. The ethyl ester from *P. pulcher* eluted very slightly (KI = 1978) before the authentic sample of *Z* ethyl ester (KI = 1987) and appreciably (KI = 2009) before the *E* ethyl ester. We therefore concluded that the configuration is most likely *Z*. The mass spectrum of geranylgeraniol acetate had a base peak at *m/z* 69, which corresponds to the isoprene group and is characteristic for many acyclic terpenoids. FTIR data showed a strong C=O absorption at 1763 cm^{-1} and bands at 1234 cm^{-1} (C−O−C str. vib.) and at 1026 cm^{-1} (*trans* C=C). A computer search of the FTIR library yielded geranyl acetate as the closest match, and a visual comparison of the spectra also showed a very good match. A comparison of the Kovats index of the compound and its hydrolysis product with published values (Ahlquist et al., 1978) yielded acceptable matches. In addition, the mass spec-

[b] ND = not determined; components detected as their dimethylhydrazones.

trum of the hydrolysis product of the compound was quite similar to the published spectrum of geranylgeraniol (Ahlquist et al., 1978). As with *P. barbatus*, the aldehydes were identified by mass spectra of their *N,N*-dimethylhydrazones. The C_{16} aldehydes, in fact, were present in such small amounts that their presence was unnoticed until the mixture was treated with DMH. Their identities were established by the definitive rearrangement ion at *m/z* 86 as their base peaks and their parent ions at *m/z* 280 and *m/z* 282.

DISCUSSION

In this study, we assumed that the lipids of the head extract would be identical to those found when excised mandibular glands were extracted, as had been found with *P. basilaris* and *P. bicinctus* (Schmidt et al., 1985). The territorial marking pheromone of *P. crabroniformis* consists of oxygenated compounds of moderate to low volatility. The most volatile compound, 2-tridecanone is a common insect allomone or pheromone found in termites (*Schedorhinotermes putorius*), notodontid caterpillars (*Heterocampa manteo*), and Hymenoptera, where it is found in a variety of stingless bees, formicine ants, and *Philanthus* wasps (see Blum, 1981, for specific references; Schmidt et al., 1985). Isopropyl tetradecanoate is a minor component distilled from ants, *Iridomyrmex humilis* (Cavill and Houghton, 1974), in the pheromone blend of the dermestid beetle *Dermestes maculatus* (Francke et al., 1979), has been found in the defensive secretion of rove beetles, *Coprophilus striatulus* and *Deleaster dichrous* (Dettner, 1984), and is a minor active component of the southwestern corn borer moth, *Diatraea grandiosella*, sex pheromone (Hedin et al., 1986).

The compound 3-methyl-3-butenyl tetradecanoate is an unusual natural product that previously has been reported only in bees. It made up less than 1% of the total volatiles from the Dufour's gland secretion of the sweat bee *Nomia nevadensis* (Duffield et al., 1982). In the sweat bee this compound functions as part of the macrocyclic lactone-rich blend used to line and waterproof the underground cells in which the larvae are reared. The long-chain fatty alcohol 11-eicosen-1-ol was known previously only from the honey bee *Apis mellifera* (Free et al., 1982) and its predator, the beewolf *P. triangulum* (Schmidt et al., 1990). In *P. crabroniformis*, however, this alcohol is found in not only the *Z* configuration, as in the other two species, but also in the *E* configuration, although in lesser amounts.

The major components (aldehydes and ethyl esters) found in *P. barbatus* are similar to those found in *P. bicinctus*, but the compounds themselves are different (Schmidt et al., 1985). In addition, there is a series of fatty alcohols present as minor components.

The diterpene alcohol ester geranylgeraniol acetate that was found in *P.*

[a] tr = <0.1%.

pulcher has been identified previously in Dufour's glands of *Formica nigricans*, *F. rufa*, and *F. polyciena*. It also has been found in the male labial gland secretion of bumblebees of the genera *Bombus* and *Psithyrus* (Ahlquist et al., 1978), where it was interpreted to function as a marking and species-isolation pheromone. The other major compound, ethyl 7-hexadecenoate, differs from the ethyl hexadecenoate previously reported in *P. bicinctus* (McDaniel et al., 1987) in the double bond position. Both compounds, however, have the *Z* stereochemical configuration.

The particular components in the pheromone blends of male *P. crabroniformis*, *P. barbatus*, and *P. pulcher* appear to have physical properties well suited to territorial marking pheromones. The fatty alcohols have low ability to wet surfaces and spread, as do the aldehydes and ketones. The esters, however, particularly isopropyl tetradecanoate, possess excellent wetting, solubilizing, and spreading properties, hence their widespread use (50,000 kg annually) in the pharmaceutical, cosmetic, and toiletry industries (Opdyke, 1976). The combined physical properties of the components in these pheromone blends make wetting and spreadable solutions that can be applied to waxy plant surfaces, where they can volatilize.

These species of *Philanthus*, as do several other *Philanthus* species, frequently nest sympatrically in similar habitats at a given location (Evans and O'Neill, 1988). The nearby presence of other related species raises the potential for interbreeding with the usual concomitant deleterious effects. A territorial marking pheromone that contains a species-specific blend can function to maintain species isolation. Our previous investigations of *Philanthus* marking pheromones, in conjunction with those reported here, reveal that for the six analyzed species, each clearly possesses a unique blend of 13- to 20-carbon compounds (Schmidt et al., 1985, 1990; McDaniel et al., 1987). Not only do the individual components vary among the species, but the classes of compounds also vary among the species (Table 4). Specifically, *P. barbatus* contains esters and aldehydes while lacking ketones; *P. basilaris* contains mainly ketones and lacks esters; *P. bicinctus* contains predominantly esters and ketones and lacks alcohols; *P. crabroniformis* contains all three of those classes and lacks aldehydes; *P. pulcher* contains mainly esters and lacks both ketones and alcohols; and, finally, *P. triangulum* contains primarily a single alcohol and lacks esters. Whether these differences are true reflections of evolutionary selection pressure for species isolation remains to be seen.

Acknowledgments—We are indebted to Howard Evans of Colorado State University for providing the wasps used in this study and for reviewing the manuscript. We thank Kevin O'Neill and Larry Jackson of Montana State University; Steve Buchmann of USDA-ARS, Tucson, Arizona; and Tappey Jones of NIH, Bethesda, Maryland; for reviewing the manuscript. We also thank Billie Dunn and Janet Terry for their technical assistance.

ALLELOPATHIC EFFECTS OF WATER EXTRACTS OF *Artemisia princeps* var. *orientalis* ON SELECTED PLANT SPECIES

BONG-SEOP KIL* and KYEONG WON YUN

Department of Biology Education
Wonkwang University
Iri, 570-749, Republic of Korea

(Received May 20, 1991; accepted September 20, 1991)

Abstract—The allelopathic effects of wormwood plants (*Artemisia princeps* var. *orientalis*) and their possible phytotoxicity on receptor species were investigated. The aqueous extracts of mature leaf, stem, and root of wormwood plants caused significant inhibition in germination and decreased seedling elongation of receptor plants, whereas germination of some species was not inhibited by extracts of stems and roots. Dry weight growth was slightly increased at lower concentrations of the extract, whereas it was proportionally inhibited at higher concentrations. The calorie value of the organic matter in receptor plants measured by bomb calorimeter was reduced proportionally to the extract concentration. However, results with extracts of juvenile leaf did not correlate with inhibition or promotion of elongation and dry weight.

Key Words—*Artemisia princeps* var. *orientalis*, allelopathy, water extract, concentration, germination, growth, juvenile leaf extract.

INTRODUCTION

Plants in the genus *Artemisia* (Anthemideae, Asteraceae) are widely distributed (Mata et al., 1985) and are known to exhibit allelopathic effects. It is a Korean

*To whom correspondence should be addressed.

custom to uproot wormwood plants in old tomb areas because wormwood retards turf growth. Volatile substances emitted from wormwood plants have special fragrances and the burning smoke of the plants has been used as a mosquito repellent during summer nights. Thus, it may be postulated that wormwood contains phytotoxic substances.

The purpose of the present study was to find evidence of allelopathic characteristics of wormwood plants by evaluating seed germination and seedling growth in various concentrations of water extracts.

METHODS AND MATERIALS

Donor and Receptor Plants. To study the allelopathic potential of wormwood [*Artemisia princeps* var. *orientalis* (Pampan.) Hara], nine receptor plants were selected. The receptor species included *Lactuca sativa* L., *Achyranthes japonica* (Miq.) Nakai, *Artemisia princeps* var. *orientalis* (Pampan.) Hara, *Oenothera odorata* Jacq., *Plantago asiatica* L., *Zoysia japonica* Steud., *Echinochloa crus-galli* (L.) Beauv., *Hordeum vulgare* var. *hexastichon* Aschers., and *Chrysanthemum boreale* Makino.

Germination and Growth Test. Aqueous extracts were made from leaf, stem, and root of the wormwood plant. One liter of distilled water was added to 200 g of each type of explant at 20°C. After 24 hr, each aqueous extract was filtered through a 0.5-mm sieve, and the filtrates were either diluted to 10, 30, 50, and 70% extracts or used as an undiluted 100% extract.

The germination test was carried out in glass Petri dishes (12 cm) on one layer of filter paper wetted with the extracts. Fifty seeds were evenly dispersed in each dish. The control was treated with distilled water instead of an aqueous extract. The Petri dishes were held at 20°C by day and 15°C at night. The experiment extended over a period of 10 days to allow maximum seed germination. The results were determined by counting the number of germinated seeds and measuring the length of seedlings in millimeters.

Seeds of each type of receptor plant were sown in four plastic pots (10 cm) containing vermiculite. After germination was completed and small plants were eliminated, the 10 largest seedlings were grown for four to five weeks. Various concentration extracts (40 ml) were added to each pot every two to three days. The results included determination of the total length of each seedling and its dry weight. After the samples were oven-dried at 80°C to constant weight, dry weight of the seedlings was measured and the caloric content was determined by using a calorimeter (Shimadzu, CA-4). Ratio of germination, elongation, dry weight, and caloric ratios were calculated as suggested by Rho and Kil (1986):

$$\text{Relative germination ratio (RGR)} = \frac{\text{Germination ratio of tested plant}}{\text{Germination ratio of control}} \times 100$$

$$\text{Relative elongation ratio (RER)} = \frac{\text{Mean length of tested plant}}{\text{Mean length of control}} \times 100$$

$$\text{Relative dry weight ratio (RWR)} = \frac{\text{Dry weight of tested plant}}{\text{Dry weight of control}} \times 100$$

$$\text{Relative caloric ratio (RCR)} = \frac{\text{Calorie of tested plant}}{\text{Calorie of control}} \times 100$$

To test allelopathic effects of juvenile leaf of wormwood, sprouting wormwood leaves were collected in April 1990 and used in experiments as described above.

Osmotic potentials below 143 mosm/kg had no influence (Elakovich and Wooten, 1991); the extracts in this study were diluted to osmotic potentials no greater than 100 mosm.

The results of the bioassays were based on three or four replicates. Comparisons between treatments were made at the 5% level using Duncan's multiple-range test.

RESULTS

The effects of wormwood aqueous extract on receptor plants are shown in Tables 1–6. The germination percentages of *L. sativa*, *A. japonica*, and *A. princeps* var. *orientalis* were reduced at increasing concentrations of wormwood leaf extract. Germination of *P. asiatica* and *Z. japonica* also was inhibited at lower concentrations but germination did not occur at concentrations higher than 70%. RGR of *O. odorata* was little influenced at concentrations below 70% extract (RGR > 90%), but RGR was 48.3% at 100% extract. RGR of *E. crus-galli* was above 96.0% at all concentrations. In the case of *H. vulgare* var. *hexastichon*, germination percentage was similar to the control at 10, 30, and 50% extract but inhibition occurred at 70% and 100%.

Germination reduction of receptor plants by the stem extract was divided into three types. First, the higher the concentration of extract, the lower the germination percentage in *H. vulgare* var. *hexastichon*, *A. japonica*, and *Z. japonica*. Second, the germination percentage decreased in the test treatments compared to the control, and it was concentration-independent. Third, germination percentage was almost the same in all the test treatments.

In germination tests with root aqueous extracts, the germination percentage of *A. japonica* and *C. boreale* was lowered by increasing the extract concentration and showed significant differences between treatments. However, germination percentage of *L. sativa*, *H. vulgare* var. *hexastichon*, and *Z. japonica*

[a] Values in rows having the same letters are not significantly different at the 5% level by Duncan's multiple-range test.

were similar to that of the control, and *E. crus-galli* and *P. asiatica* showed uneven germination percentage with increased extract concentration.

Seedling elongation of *L. sativa* was promoted slightly at 10% leaf extract but inhibited at concentrations higher than 30%. RER of *E. crus-galli* was more than doubled at 100% than in the 30% extract, whereas higher reduction in elongation at other concentrations was remarkable. The elongation of other plants was inversely proportional to concentration of the leaf extract at the 5% level.

The seedling elongation of plants such as *L. sativa*, *O. odorata*, *E. crus-galli*, and *P. asiatica* was promoted at low concentrations of the stem extracts, whereas the others were inhibited at high concentrations. *H. vulgare* var. *hexastichon*, *A. japonica*, *C. boreale*, *A. princeps* var. *orientalis*, and *Z. japonica* were inhibited evenly as the extract concentration was increased.

As shown in Figure 1, elongation of *L. sativa* by leaf extract was by far lower in the test treatment than in the control, and there was no growth at the

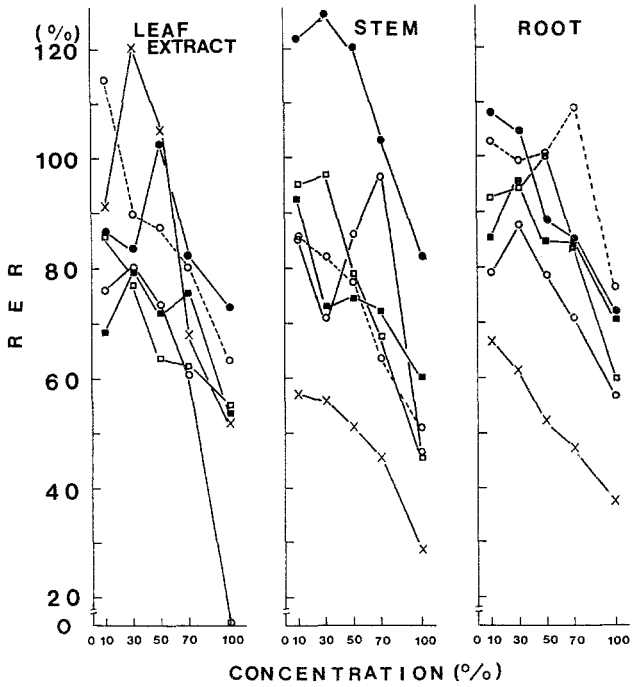

FIG. 1. Relative elongation ratio (RER) of receptor plants grown in pots at different concentrations of wormwood extracts. ○ —— ○, *Lactuca sativa;* × —— ×, *Achyranthes japonica;* □ —— □, *Artemisia princeps* var. *orientalis;* ● —— ●, *Oenothera odorata;* ○ ---- ○, *Plantago asiatica;* ■ —— ■, *Echinochloa crus-galli.*

100% extract. In the case of *A. japonica*, RER were 120.8% and 105.2% in 30% and 50% extracts, respectively, but decreased at 70% and higher extracts. RER of the wormwood plant itself was comparatively low regardless of the extract concentration and was 55.2% at 100% extract. The elongation rate of receptor plants, except in some species, was in inverse proportion to the extract concentration.

RWR of seedlings grown with extracts of leaf, stem, and root are shown in Figure 2. Dry weight reduction of *L. sativa*, *A. princeps* var. *orientalis*, and *P. asiatica*, which was grown with leaf extract, was inversely proportional to the extract concentration, but the dry weight of *A. japonica* was somewhat increased at 10%, 30%, and 50% extracts and reduced at concentrations over 70%. This tendency of dry weight changes was found in other receptor species.

The extracts of wormwood stem and root also induced lower dry weights in receptor plants.

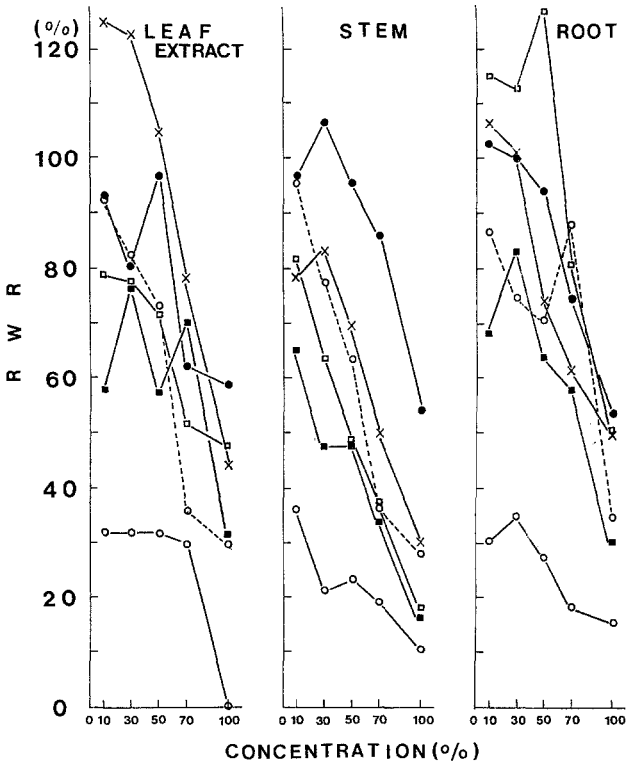

FIG. 2. Relative dry weight ratio (RWR) of receptor plants grown in pots at different concentrations of wormwood extracts. Key to species as in Figure 1.

The calorie measurement of *A. japonica* grown at different concentrations of wormwood leaf, stem, and root extracts demonstrated that remarkable growth inhibition occurred at higher concentrations of the three extracts, but there was a slight growth promotion at lower concentrations of root extract (Figure 3).

In Table 7 are shown the germination rates of receptor species by extracts of juvenile wormwood leaf, which were quite different from extracts of mature wormwood leaf; germination of *L. sativa* was somewhat promoted at 50% and 70% extracts over the control, and the germination percentages at 10%, 30%,

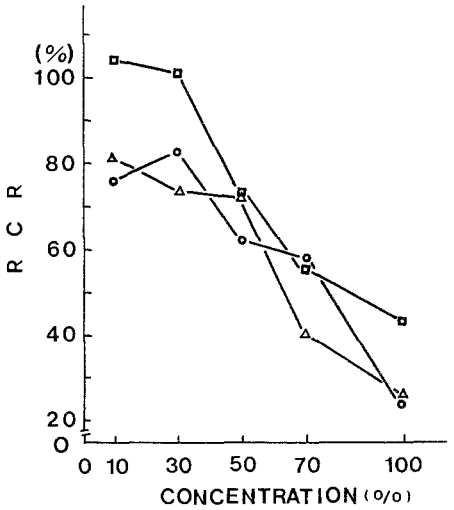

FIG. 3. Relative calorie ratio (RCR) of *Achyranthes japonica* grown in pots at different concentrations of wormwood extracts. ○ —— ○, leaf extract; △ —— △, stem extract; □ —— □, root extract.

and 100% extracts were similar to those of the control. In the case of *A. japonica*, germination percentage was considerably decreased with increasing concentration. As to *A. princeps* var. *orientalis*, germination percentage was the lowest at 10% extracts and almost the same at extracts over 30%. In contrast, seedling length of receptor plants grown in Petri dishes with juvenile leaf extracts was less inhibited, in general, than those with mature leaf extract (Table 8).

Seedling growth of all the receptor plants with extract of juvenile leaf was far greater in the test treatment than in the control. The higher the extract concentration, the greater the elongation rate of the receptor plant (Figure 4). All

receptor plants also showed a rapid increase in dry weight: *L. sativa* and *A. japonica* at 70% extract showed more than three times that of the control (Figure 5).

DISCUSSION

Allelopathy has been claimed to exist between numerous species. Data presented here suggest the toxic potential of *Artemisia princeps* var. *orientalis* against some species.

Phytotoxic extracts from leaf, stem, and root of wormwood were studied using 10 receptor plants. Germination and seedling elongation were significantly inhibited by the extracts. Rates of inhibition were increased with increasing extract concentration. Jobidon (1986) described extract solutions prepared by soaking 10 g of leaves in 100 ml of distilled water for 24 hr at 20°C; the initial solution was termed 10%. In this study, water extracts were prepared by soaking 200 g of leaf, stem, and root of wormwood in 1000 ml of distilled water for 24 hr at 20°C and the undiluted solution was termed 100%.

Grant (1964) pointed out that the extracts of four legumes and four grasses affected the germination, root growth, and shoot growth of the same species and found that extracts of aerial portions of the plants had greater inhibitory effects than root extracts. Bieber and Hoveland (1968) found that extracts from aerial portions of six crop and four weed species were more inhibitory than

those from roots. Ballester *et al.* (1979) noted that the strongest effect of the *Erica* plants was produced by flower extracts, followed by stem and leaf extracts. Smith (1989) stated that leaf extracts of bitter sneezeweed were more phytotoxic than either stem or root extracts, and seedling growth of alfalfa and Italian ryegrass was reduced more than seed germination, results that are very similar to those of the present studies. Based on the effects of aqueous extract, wormwood plant tissues inhibited the germination and growth of tested species, and the response was dependent upon the source of extract, the extract concentration, and the species tested.

There seemed to be species specificity in RGR and RER of receptor plants tested in leaf, stem, and root extracts of the wormwood plant. At 10% leaf extract (Tables 1 and 4) several species were slightly affected by the extracts but *Z. japonica* was heavily inhibitory, while many receptor species, except *E. crus-galli*, were almost suppressed in 100% leaf extracts.

It is likely that the tested species could be classified into three types according to the sensitivity of receptor plants to the wormwood toxicity. The first group, the susceptible species, showed low germination and seedling growth in wormwood extracts. The second group, the nonsusceptible species, showed comparatively high germination and seedling growth in the extracts. The third group, the intermediate species, showed moderate germination and seedling growth in the extracts. The susceptible species, for example, *A. japonica*, *Z. japonica*, *P. asiatica*, *H. vulgare* var. *hexastichon*, and *C. boreale*, grow well outside wormwood stands, including farm land, but are so sensitive to the toxic substances emitted from the wormwood plants that they are rarely observed in wormwood fields. The nonsusceptible species, such as *O. odorata*, *E. crus-galli*, *L. sativa*, and *A. princeps* var. *orientalis*, have grown well either in or outside wormwood stands, and they are less influenced than the susceptible species by the toxic substances. Rice (1984) indicated that some pioneer weed stages produce substances inhibitory to their own seedlings and seedlings of other species in that stage, but not to next stage species, *Aristida oligantha*. He hypothesized, therefore, that several species of pioneer stage eliminate the species of that next stage and that *A. oligantha* invades after that because it is not inhibited by the substances that are toxic to the pioneer species.

Park (1966) has described that the early stage of grassland succession in Korea would be composed of *P. asiatica*, *A. priceps* var. *orientalis*, *O. odorata*, and *Z. japonica* community, in that order. However, seed germination and seedling growth of *Z. japonica* was inhibited greatly by the wormwood extracts in this study. These contrasting views could result from differences between laboratory work and field observations.

Wormwood plants showed autotoxicity in bioassays with water extracts. Many plants exhibit such autotoxicity: *Kochia scoparia* (Lodhi, 1979), cuc-

umber seed (Lockerman and Putnam, 1981), *Parthenium hysterophorus* (Picman and Picman, 1984; Kumari and Kohli, 1987).

Unlike the mature leaf extract, juvenile leaf extract inhibited germination but promoted the elongation and dry weight of lettuce and wormwood. The growth of these species was proportional to the extract concentration. Edward et al. (1988) reported that juvenile leaves of the pokeweed plant seemed to lack extractable compounds inhibitory to seed germination, unlike mature leaves.

We plan to continue our search for other factors for the allelopathic potential of *Artemisia princeps* var. *orientalis*.

(Z)-10-HEPTADECEN-2-ONE AND OTHER 2-KETONES IN THE AGGREGATION PHEROMONE BLEND OF *Drosophila martensis*, *D. buzzatii*, AND *D. serido*

ANGELA M. SCHANER and LARRY L. JACKSON*

(Received June 24, 1991; accepted September 20, 1991)

Abstract—(Z)-10-Heptadecen-2-one was identified as the major aggregation pheromone component in *Drosophila martensis*, *D. buzzatii*, and *D. serido*. Aliphatic 2-ketones were not detected in newly eclosed males or in virgin females of any age. The amount of (Z)-10-heptadecen-2-one in the ejaculatory bulb and on the cuticle of males increased with age. Only trace quantities of (Z)-10-heptadecen-2-one were transferred to the female during mating. 2-Tridecanone was found in the ejaculatory bulb and on the cuticle of male *D. martensis* and *D. buzzatii*, but not *D. serido*. The amount of 2-tridecanone increased with age. Unexpectedly, 2-tridecanone inhibited the aggregation activity of (Z)-10-heptadecen-2-one in *D. buzzatii*. In *D. martensis*, 2-tridecanone was significantly less attractive than controls but did not decrease the attractiveness of one fly equivalent of (Z)-10-heptadecen-2-one. *D. serido* males did not have any 2-tridecanone and the activity of (Z)-10-heptadecen-2-one was not diminished in *D. serido* by the presence of 2-tridecanone.

Key Words—*Drosophila martensis*, *D. buzzatii*, *D. serido*, Diptera, Drosophilidae, (Z)-10-heptadecen-2-one, 2-tridecanone, aggregation pheromone.

INTRODUCTION

Aliphatic unsaturated and saturated 2-ketones in combination with a variety of other compounds compose the aggregation pheromone blend in a number of *Drosophila* species. In the *repleta* group, *Drosophila hydei* (*hydei* subgroup) (Moats et al., 1987) and *D. repleta* (*repleta* subgroup) (Schaner and Jackson,

*To whom correspondence should be addressed.

0098-0031/92/0100-0053$06.50/0 © 1992 Plenum Publishing Corporation

unpublished) produce 2-tridecanone that is highly synergistic with a mixture of tiglate esters to make the aggregation pheromone blend. *D. mulleri* (*mulleri* subgroup) were attracted to (*Z*)-10-heptadecen-2-one [abbreviated (*Z*)-10-H], which was synergistic with the coattractant (*S*)-2-tridecanol acetate (Bartelt et al., 1989). *D. busckii* (*Dorsilopha* subgenus) employed 2-pentadecanone, which was synergistic with (*S*)-2-pentadecanol acetate (Schaner et al., 1989d).

Here we identify and characterize similar, but slightly different blends of unsaturated and saturated 2-ketones as aggregation pheromone components of *D. martensis*, *D. buzzatii*, and *D. serido*.

METHODS AND MATERIALS

Flies, Extraction, Chromatography, and Bioassay. Drosophila martensis (strain 15081-1321), *D. buzzatii* (strain 15081-1291), and *D. serido* (strain 15081-1431) were obtained from the National *Drosophila* Species Resource Center at Bowling Green, Ohio. *D. buzzatii* were reared on Instant *Drosophila* Medium Formula 4-24 (Carolina Biological Supply Co., Burlington, North Carolina) and *D. martensis* and *D. serido* were reared on banana–cactus medium (Yoon, 1985). Details of rearing, extraction, chromatography, and bioassay of the flies have been described previously (Bartelt and Jackson, 1984). Briefly, flies were separated by sex when 0–12 hr old, aged in 3.5-cm-diameter × 10-cm food vials to 6–8 days, and extracted at that time by soaking the flies in hexane at room temperature for 24 hr. The hexane extracts of males were fractionated on open columns of silica gel (100–200 mesh; Bio-Rad), eluted with hexane, 5% ether in hexane, 10% ether in hexane, 50% ether in hexane, and 10% methanol in methylene chloride.

Gas chromatography (GC) was conducted on a 15-m × 0.53-mm-ID Megabore DB-1 (J & W Scientific) capillary column, and on a 50-m × 0.2-mm ID HP-1 narrowbore capillary column (Hewlett-Packard) in a Varian 3700 gas chromatograph. Electron impact mass spectra were obtained on a VG-MM16 mass spectrometer using a 30-m × 0.25-mm-ID DB-5 capillary GC column for introduction of the sample.

Bioassays were conducted in a wind-tunnel olfactometer containing ca. 1000 flies (1–4 days old) that had been without food and water for approximately 16 hr. An extract, fraction, synthetic compound, or control solvent was applied to a filter paper strip inserted around the lip of a glass vial. Each bioassay test consisted of placing two differently treated vials, to be compared, into the olfactometer for 3 min. After 3 min, the vials were capped and removed, and the captured flies were sexed and counted. Tests were separated by 7–10 min, and as many as 18 tests could be run in a single day after stocking the olfactometer once. All experiments consisted of more than two treatments, and

these were tested in pairs, in all possible combinations (a randomized, balanced incomplete block design). The bioassay data were transformed to the log $(X + 1)$ scale before analysis to stabilize variance, and analysis was done by the method of Yates (1940).

Inclusion of some "food odor" in all treatments in the bioassay does not greatly increase the fly catch in the control, but does increase the fly catch in the pheromone-containing assays (Schaner et al., 1989a). For *D. martensis* assays, 10 μl of 0.1% acetic acid in hexane were added to all treatments as a coattractant. Since *D. serido* and *D. buzzatii* utilize *Opuntia* for feeding and breeding sites (Richardson, 1982), an extract of the fruit from *Opuntia* was prepared by extracting 100 ml of blended fruit with 50 ml of methylene chloride for 2 hr, and 10 μl of *Opuntia* fruit extract were added to all treatments for *D. serido* and *D. buzzatii*.

Synthetic 2-ketones were prepared as previously described (Moats et al., 1987; Bartelt et al., 1989).

Production, Transfer, and Dispersal of Pheromone Components. The methods were fully described previously (Schaner et al., 1989a,d). Briefly, ejaculatory bulbs were removed from males at various ages and extracted in hexane for 2 hr ($N = 3$ sets of 3). A cuticular extract of the remainder of the fly was obtained by soaking the fly in 40 μl of hexane for 5 min. Both the ejaculatory bulbs and cuticular extracts were analyzed by GC relative to an internal standard of nonadecane. The transfer of pheromone component during mating was quantitated by removing reproductive tracts of females and ejaculatory bulbs of males immediately after mating, followed by a 5-min cuticular soak of the fly ($N = 3$ sets of 5). To determine if males were capable of emitting the pheromone component, virgin males (8–9 days old) were placed for 18 hr in 8-ml vials fitted with wire mesh caps ($N = 3$ sets of 5). The vials were then extracted with 300 μl of hexane and analyzed by GC relative to an internal standard of nonadecane.

RESULTS

Bioassay of Crude Extracts and Fractions. For all three species, the crude extract of mature males was clearly active in bioassay (Table 1) and attracted flies of both sexes. The crude extract of mature females has little if any activity. After fractionation of the male-derived crude extracts on silica gel, the 10% ether–hexane fractions were substantially more active than controls (Table 1). GC of the 10% ether–hexane fractions from all three species revealed one common peak with the retention times on GC of synthetic (*Z*)-10-H (Bartelt et al., 1989).

Ketone Components. The common GC peak to all three male-derived 10%

[a] All extracts and fractions were used at one hexane extractable fly equivalent per test.
[b] Relative response = (fraction − control)/(crude extract of males − control) × 100.
[c] * and *** differ from control at $P < 0.05$ and $P < 0.001$ (LSD).
[d] Numbers in parentheses are mean bioassay catches for solvent control, treatment, and crude extract of males, respectively.

ether–hexane fractions had the same retention time on two GC columns (KI = 1855 and 1870 on HP-1 and DB-5, respectively) and a $AgNO_3$ HPLC column (Bartelt et al., 1986) as (*Z*)-10-H. (*E*)-10-Heptadecen-2-one eluted from the $AgNO_3$ HPLC column ca. 2 min earlier than (Z)-10-H. The GC-MS of the peak and of the dimethyl disulfide adduct (Nichols et al., 1986) with M^+ ion at *m/z* 345 (18%) and with peaks at *m/z* 201 (100%), 145 (50%), and 43 (35%) were identical to synthetic (Z)-10-H (Bartelt et al., 1989).

The male-derived 10% ether–hexane fractions from *D. martensis* and *D. buzzatii* (but not *D. serido*) also contained 2-tridecanone, (Z)-10-pentadecen-2-one, 2-pentadecanone, and 2-heptadecanone (Table 2).

Bioassay of Synthetic Ketones. A quantity of synthetic (Z)-10-H, equal to that in the male-derived 10% ether–hexane fractions (Table 3A) accounted for all the activity of the male-derived 10% ether–hexane fractions for *D. serido* and *D. martensis*. A quantity of synthetic (Z)-10-H equal to that in the male-derived 10% ether–hexane fraction of *D. buzzatii* was more attractive than the male-derived 10% ether–hexane fraction (Table 3A). Bioassay of a synthetic mixture of all the ketones equal in quantity to the male-derived 10% ether–hexane fraction (Table 2) was also not as active as pure (Z)-10-H (Table 3A).

TABLE 2. KETONE CONTENT OF MALE EXTRACTS AND RESPONSE OF FLIES TO KETONES RELATIVE TO (Z)-10-HEPTADECEN-2-ONE

Synthetic ketone	Relative response[a] (Amount per male in ng) (N = 8)		
	D. martensis at 200 ng/assay	*D. buzzatii* at 700 ng/assay	*D. serido* at 100 ng/assay
2-Tridecanone	−19*[b] (400 ng)	−83*** (240 ng)	−5 (0 ng)
(Z)-10-Pentadecen-2-one	31** (2 ng)	75** (25 ng)	50** (0 ng)
2-Pentadecanone	2 (9 ng)	5 (55 ng)	−10 (0 ng)
(Z)-10-Heptadecen-2-one	100*** (200 ng)	100*** (690 ng)	100*** (100 ng)
2-Heptadecanone	61*** (10 ng)	−13 (65 ng)	−9 (0 ng)

[a]Relative response (test ketone − control)/((Z)-10-heptadecen-2-one − control) × 100.

TABLE 3. BIOASSAY OF 10% ETHER–HEXANE FRACTION OF MALES FOR THREE SPECIES IN *D. martensis* COMPLEX

Treatment	Mean bioassay catch (N = 8)		
	D. martensis	*D. buzzatii*	*D. serido*
A. Comparison of 10% ether–hexane fraction of males and synthetic (Z)-10-heptadecen-2-one at levels equivalent to that in one male fly			
Control	2.2 a[a]	4.0 a	4.9 a
(Z)-10-Heptadecen-2-one	8.7 b	23.7 b	15.7 b
Male 10% ether–hexane fraction	9.1 b	8.6 c	14.9 b
All synthetic ketones	ND[b]	10.5 c	ND
B. Inhibition of (Z)-10-heptadecen-2-one with one fly equivalent of 2-tridecanone			
Control	1.6 a	6.8 a	2.3 a
(Z)-10-Heptadecen-2-one + 2-tridecanone	8.8 b	12.9 b	8.1 b
(Z)-10-Heptadecen-2-one	8.6 b	38.2 c	8.7 b

[a]Means followed by the same letter were not significant at the 0.05 level (LSD). Comparisons of means between columns are not meaningful because the experiments were done on different days, with different species of flies.
[b]Not determined.

The activity of (Z)-10-H in the male-derived 10% ether–hexane fraction of *D. buzzatii* appeared to be inhibited by one or more of the other ketones present in the fraction.

To determine which, if any, of the male-produced ketones other than (Z)-10-H had activity, a control and each ketone, equal in quantity to the amount of (Z)-10-H extracted per male fly (Table 2), were bioassayed. Synthetic (Z)-

10-pentadecen-2-one was the only ketone other than (Z)-10-heptadecen-2-one that was preferred over controls by all three species (Table 2). However, the quantity of (Z)-10-pentadecen-2-one used for this bioassay was much higher than is present in the flies (22 times, 13 times, and 100 times for *D. martensis*, *D. buzzatii* and *D. serido*, respectively). In *D. buzzatii*, (Z)-10-pentadecen-2-one in combination with (Z)-10-H at the dose of one fly equivalent (Table 2) was not significantly different from (Z)-10-H alone. In *D. martensis*, 2-heptadecanone was preferred over controls when tested at 20 times one fly equivalent (Table 2).

2-Tridecanone [at a concentration equal to the (Z)-10-H concentration] was not attractive to any of the three species. For *D. martensis* and *D. buzzatii*, synthetic 2-tridecanone was significantly less attractive than controls (Table 2). 2-Tridecanone inhibited the response of *D. buzzatii* more than the response of *D. martensis* ($P < 0.001$ and $P = 0.02$, respectively). When tested at one fly equivalent, synthetic 2-tridecanone inhibited the activity of (Z)-10-H for *D. buzzatii* (Table 3B). 2-Tridecanone had no inhibitory effect on (Z)-10-H for *D. serido* and *D. martensis* (Table 3B). The quantity of 2-tridecanone relative to (Z)-10-H differs markedly in the last two species. In *D. martensis*, the quantity of 2-tridecanone is twofold greater than the quantity of (Z)-10-H (Table 2 and Figure 1), and in *D. serido* there is no 2-tridecanone.

Location of Pheromone Components. For all three species, the primary location of both unsaturated and saturated 2-ketones was the ejaculatory bulb,

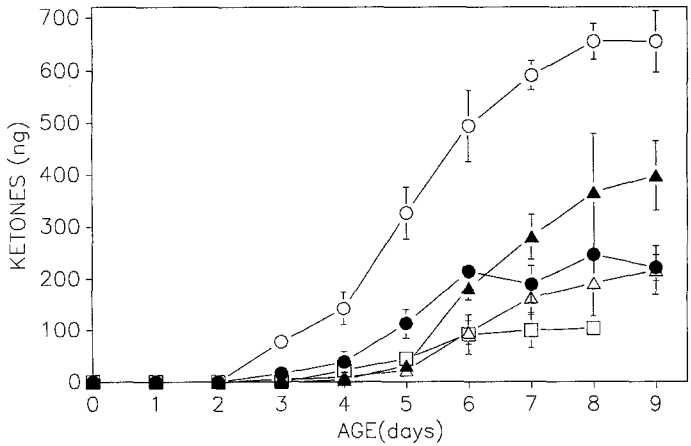

FIG. 1. Content (mean ± SD, $N = 3$ sets of 5) of (Z)-10-heptadecen-2-one and 2-tridecanone in the ejaculatory bulb of male flies as they age past eclosion. Open symbols are for (Z)-10-heptadecen-2-one and closed symbols are for 2-tridecanone. Circles, triangles, and squares are for *D. buzzatii*, *D. martensis*, and *D. serido*, respectively.

and there was a dramatic increase in 2-ketone content in the ejaculatory bulb as the flies mature posteclosion (Figure 1). *D. martensis* and *D. buzzatii* started to produce the 2-ketones at three days and *D. serido* at four days. With increasing age, there was an increase in (*Z*)-10-H in the bulb up to a plateau at six days for *D. serido* and eight days for *D. martensis* and *D. buzzatii*. The plateau level of (*Z*)-10-H was ca. 200, 690, and 100 ng/ejaculatory bulb for *D. martensis*, *D. buzzatii*, and *D. serido*, respectively. The amount of 2-tridecanone also increased with age to a plateau of 230 ng/ejaculatory bulb at six days for *D. buzzatii* and 400 ng/ejaculatory bulb at eight days for *D. martensis*.

Cuticles of male *D. martensis*, *D. buzzatii*, and *D. serido* contained appreciable quantities of (*Z*)-10-H representing 85 $\pm$ 21 (mean $\pm$ SD, $N = 3$ sets of 5), 125 $\pm$ 39 and 20 $\pm$ 9 ng/cuticle, respectively. Cuticles of *D. martensis* and *D. buzzatii* males also contained 12 $\pm$ 4 and 17 $\pm$ 12 ng of 2-tridecanone, respectively.

Release of Pheromone Compounds. In 18 hr, males released a small quantity of unsaturated and saturated 2-ketone to the surrounding vial. *D. serido* released 24 $\pm$ 8 ng/fly (mean $\pm$ SD) of (*Z*)-10-H, while *D. martensis* and *D. buzzatii* released only 14 $\pm$ 6 ng/fly of (*Z*)-10-H and even less 2-tridecanone (8 $\pm$ 2 ng/fly and 5 $\pm$ 2 ng/fly, respectively).

Transfer of Pheromone Components. Virgin females of all three species did not possess 2-ketones at any age. During mating, about 3% of the (*Z*)-10-H from the male in each species was transferred to the female reproductive tract, and only trace quantities were transferred to the cuticle of the female.

In an attempt to understand the role of the apparent "antiaggregation" activity of 2-tridecanone in *D. buzzatii*, a preliminary study of activity and production of 2-tridecanone was undertaken. In the assay of the male-derived 10% ether–hexane fractions and of the individual and mixed synthetic 2-ketone preparations (Tables 2 and 3), there was no clear preference for any of the 2-ketones by either sex of the responding flies (42–57% males in each assay). The density of male flies in the rearing vials (1, 10, 50, or 100 flies/vial) did not affect the production of either (*Z*)-10-H (626 $\pm$ 30 ng/bulb) or 2-tridecanone (214 $\pm$ 18 ng/bulb) at 8–9 days of age. Attempts were made to provide the males with controlled quality food sources to determine if especially 2-tridecanone production depended on food-source quality. We were unsuccessful in controlling food-source quality for the 8 to 9-day maturation process. We did determine that decreases in food-source quality delayed maturation. However, when delayed flies were put on a high-quality food source, the maturation was rapid and rapidly reached full production of (*Z*)-10-H and 2-tridecanone. When we attempted to determine whether sex ratio in the rearing vial (5:35, 20:20, 35:5) had any affect on 2-ketone production, we found that the males appeared to mature and produce 2-ketones quicker (1–2 days) when there

was a majority of females present. In all but one case ($N = 5$), the apparent quality of the food source was better (not as dry, better yeast growth) when more female flies were present in the rearing vials.

DISCUSSION

Although they have very different 2-ketone profiles in their ejaculatory bulbs, *D. martensis*, *D. buzzatii*, and *D. serido* are all similar in that they produce and perceive (Z)-10-H as a major component of the aggregation pheromone blend. When tested at a dose much higher than found in the flies, all three species also responded to (Z)-10-pentadecen-2-one, and *D. martensis* was attracted to 2-heptadecanone. This suggests that either the receptors for (Z)-10-heptadecen-2-one lack specificity and can detect (Z)-10-pentadecen-2-one and 2-heptadecanone or that the specific receptors for detection of (Z)-10-pentadecen-2-one and 2-heptadecanone require higher levels of compound than are present in individual flies. Since species of both the *martensis* and *mulleri* (Bartelt et al., 1989) complexes of the *mulleri* subgroup produce and respond to (Z)-10-H, we suggest that production and perception of (Z)-10-H is a primitive trait. More species of the *hydei* and *repleta* subgroups need to be investigated to determine if (Z)-10-H production and perception are present in other species of these subgroups, but was subsequently lost during speciation to *D. hydei* and *D. repleta*. These investigations also would be an attempt to determine whether the proposed "primitive I" form (Wasserman, 1982) might have produced and perceived (Z)-10-H.

2-Tridecanone is the first compound identified in *Drosophila* that inhibits the aggregation activity of another compound. A similar reduction in the bioassay activity of the sex pheromone blend in *Heliothis* species was observed with the presence of (Z)-10-hexadecenol [a precursor to the pheromone (Z)-10-hexadecenal] (Kehat et al., 1980; Teal et al., 1981, 1984). It is not known if 2-tridecanone is a precursor to (Z)-10-H since the biosynthetic pathways to both saturated and unsaturated 2-ketones are unknown. The inhibitory activity in *D. buzzatii* was also surprising because 2-tridecanone has been identified as an aggregation pheromone component in two other members of the *repleta* group, *D. hydei* (Moats et al., 1987) and *D. repleta* (Schaner and Jackson, unpublished). Production of 2-tridecanone also appears to be a primitive trait, which is lost in *D. serido*. The perception of 2-tridecanone appears to have undergone considerable change somewhere in the evolutionary pathway to the *martensis* cluster, such that it is perceived as an inhibitor of aggregation in *D. buzzatii* but not in *D. martensis* or *D. serido*.

In most *Drosophila* species of the *melanogaster* group, the aggregation pheromone components were transferred from the male ejaculatory bulb to the

female reproductive tract and/or cuticle during mating (Bartelt et al., 1985; Schaner et al., 1987, 1989a–d). Large amounts of pheromone were transferred (ca. 30–60% of the ejaculatory bulb content), and the female would then release the aggregation pheromone to the substrate within a few hours after mating where the pheromone along with fermenting food odors could attract additional flies. However, in *D. martensis*, *D. buzzatii*, and *D. serido*, the amount of (*Z*)-10-H transferred to the female was about 3% of that possessed by the male. The small quantity that was transferred to the female reproductive tract was directly proportional to the male ejaculatory bulb content rather than the cuticle content. Although mated females are capable of releasing a minor amount of (*Z*)-10-H, the major sources of (*Z*)-10-H vapor are either directly from the male cuticle or from the substrate where the male deposited the (*Z*)-10-H. Whether (*Z*)-10-H on the cuticle of mature males plays a role in sexual selection is yet to be determined.

Unlike members of the *melanogaster* group that had either (*Z*)-11-octadecenyl acetate, (*Z*)-11-eicosenyl acetate, or a combination of both in their ejaculatory bulb (Bartelt et al., 1985; Schaner et al., 1987, 1989a–c), the lipid contents of the ejaculatory bulb of the *repleta* group species are more diverse, and the variation in composition of the ejaculatory bulb lipids seems to follow the phylogenetic lines of Wasserman (1982). In the *repleta* group, 2-tridecanone is a primary component of the aggregation pheromone of *D. hydei* (Moats et al., 1987) and *D. repleta* (Schaner and Jackson, unpublished) as well as a postulated precursor to the 2-tridecanol acetate pheromone component of *D. mulleri* (Bartelt et al., 1989). In *D. buzzatii*, 2-tridecanone inhibits the aggregation activity of (*Z*)-10-H, and although present in *D. martensis*, 2-tridecanone has no effect on aggregation of that species. *D. serido* does not make 2-tridecanone nor do they show any attractive or inhibitory activity to the compound. (*Z*)-10-H is a minor component of the aggregation pheromone of *D. mulleri* (Bartelt et al., 1989) and is the major aggregation pheromone component for *D. martensis*, *D. buzzatii*, and *D. serido*. The involvement of (*Z*)-10-pentadecen-2-one, 2-pentadecanone, and 2-heptadecanone is less clear, but their presence in the ejaculatory bulb of some species and their absence in others is important information contributing to the remarkable evolutionary story that is developing around the aggregation pheromone components from species of the *repleta* group.

In addition to the aggregation pheromone activity in *Drosophila*, medium chain-length saturated methylketones (2-tridecanone, 2-pentadecanone, and 2-heptadecanone) are common insect allomone or pheromone components found in termites (*Schedorhinotermes putorius*), notodontid caterpillars (*Heterocampa manteo*), and Hymenoptera, where they are found in many formicine ants, a variety of stingless bees (Luby et al., 1973; Franke et al., 1983), two species of beewolfs (Schmidt et al., 1985; McDaniel et al., 1987), and *Philanthus* wasps

(reviewed by Blum, 1981). The methyl-branched-methylketone 10-methyl-2-tridecanone is the sex pheromone of the southern corn rootworm, *Diabrotica undecimpunctata howardi* (Guss et al., 1983).

Unsaturated methylketones (10-heptadecen-2-one, 10-nonadecen-2-one, etc.) are usually considered to be more novel arthropod chemicals but have, in addition to *Drosophila*, been isolated from the scent-marking pheromone of a species of beewolf (Schmidt et al., 1990), the Argentine ant (*I. humilis*) (Cavill et al., 1980) and, along with saturated methylketones, from the defensive secretions of *Uloma tenebrionoides* (Gnanasunderam et al., 1985).

Resistance of the wild tomato *Lycopersicon hirsutum* f. *glabratum* to attack by important insect pests including the tobacco hornworm, *Manduca sexta* (L.), the tomato fruitworm, *Heliothis zea*, the tobacco budworm, *H. virescen*, and the Colorado potato beetle, *Leptiotarsa decemlineata* (Say) is due, in part, to the presence of toxic 2-tridecanone in the glandular tricomes (Kauffman and Kennedy, 1989, and references cited therein).

It is clear that medium chain-length methylketones are produced by a variety of species to provide signals and protection. In a majority of the insect species that produce methylketones, the methylketones are involved in chemical warfare in the form of defensive secretions to repel intruders; yet in some species, methylketones are functioning in scent-marking, aggregation, and sex attraction. Methylketones are clearly unique compounds used to transmit attractive signals in some cases and repulsive signals in other cases.

(Received April 22, 1991; accepted September 20, 1991)

Abstract—The exocrine secretions from the nymphs and the adults of both sexes in *D. cingulatus* were chemically investigated. Seven compounds were identified in the anterior glands, and eleven in the median dorsoabdominal glands of nymphs and adults of both sexes. Fifty-five compounds were identified in the defensive glands (34 in posterior dorsoabdominal glands of nymphs and 21 in metathoracic glands of adults), and six in the sternal glandular epithelium of the males. The biological function of the glandular secretions and of their identified compounds were investigated and are discussed.

Key Words—*Dysdercus cingulatus*, Heteroptera, Pyrrhocoridae, exocrine glands, pheromones, bug, aggregation, allomones, cotton stainer, defensive secretions.

INTRODUCTION

Most adults and nymphs of terrestrial Heteroptera emit volatile substances from their scent glands when they are disturbed or attacked by predators. The morphology of scent glands and the chemistry of their secretions have been studied extensively in many heteropteran species (Dazzini and Pavan, 1978; Staddon, 1979, 1986; Blum, 1981; Aldrich, 1988a). These glands are usually involved

in alarm and/or defense and produce repulsive and/or toxic chemicals; however, in some true bugs, scent glands could exhibit a strong sexual dimorphism and are involved in the sexual behavior (Aldrich et al., 1978, 1984; Hamilton et al., 1985). In other species, chemicals act as command signals, both for aggregation and alarm, according to the concentration at which they are emitted (Ishiwatari, 1974; Lockwood and Story, 1985, 1987; Kou et al., 1989).

D. cingulatus is an aposematic species that lives in dense and conspicuous aggregation on cotton plants (Fuseini and Kumar, 1975; Duviard, 1981). Preliminary studies (Farine and Lobreau, 1984) indicated that the complex behavior observed in this species required a complete survey of the glandular system and chemicals produced in the nymphs and the adults of both sexes. The morphology of the glandular system was studied exhaustively (Farine, 1987, 1988). This paper deals with the chemistry of the secretions of the three dorsoabdominal glands of the nymphs, of the two functional dorsoabdominal glands and the metathoracic glands of the adults in both sexes, and of the sternal glandular epithelium (sternal glands) in adult males. The chemical composition, with special attention to minor compounds, is reported for the secretion of each gland and discussed in regard to its possible function as a chemical signal in alarm, defense, aggregation, and sexual behavior.

METHODS AND MATERIALS

Insects. A laboratory culture of *D. cingulatus* was developed from specimens obtained from Rhône-Poulenc in Lyon. The bugs were reared on cotton seeds and water-soaked cotton pads at 27°C and 70% relative humidity under a 14 : 10 hr day–night period.

Preparation of Nymph Extracts. All the nymphs dissected were at the fifth instar. Two thousand anterior dorsoabdominal glands (DAGs 1) and 2000 median dorsoabdominal glands (DAGs 2) were quickly dissected from chilled insects and dipped into 1 ml of pure distilled pentane for 24 hr at −20°C. Then, samples were concentrated to 100 μl under gentle nitrogen flow.

Preparation of Adult Extracts. Two thousand of each of the two functional dorsoabdominal glands (DAG 1 and DAG 2) of 3-day-old adults from both sexes, and 5000 sternal glands (STGs) (sterna 2–6) of 3-day-old males were dissected and extracted as described above.

Preparation of Extracts of Defensive Glands of Nymphs and Adults. The secretions of the defensive glands (posterior dorsoabdominal gland of fifth instar nymphs (DAG 3) and metathoracic glands (MTGs) of adults) were collected by immersing about 10,000 living insects in distilled pentane for 30 sec. The extracts were concentrated to 500 μl by microdistillation and stored at −20°C. Our conditions of GC analysis showed no differences between the extracts

obtained by immersion of living insects in pentane and those from dissected glands. In addition, due to the very brief extraction time, the cuticular hydrocarbons were not extracted and no carbon chains between C_{19} and C_{40} were detected in the insects' extracts, so only the former method was used.

Chemical Analysis. Gland extracts were analyzed by gas-chromatography (GC) and gas chromatography–mass spectrometry (GC–MS). GC analyses were performed on a Packard 429 with a flame ionization detector. Two fused silica capillary columns of different polarity were used: a DB 5 (30 m × 0.32 mm ID, J & W Scientific) and a CP Wax 58 CB (30 m × 0.22 mm ID, Chrompack). Injector and detector temperatures were, respectively, 250 and 270°C. One microliter of each sample was injected in split-splitless mode with the oven at 50°C for 5 min, then programmed at 2°C/min to 250°C using helium as carrier gas at a flow rate of 5 ml/min. Reported compound percentages were based on millivolt output from the detector using a CR 3 A Shimadzu recorder (Kyoto, Japan).

GC–MS was carried out on a Nermag R 10-10 C quadrupole mass spectrometer coupled with a Girdel 31 gas chromatograph. Fused silica capillary column (J & W Scientific) coated with DB 5 (30 m × 0.32 mm ID) was used for analysis. The GC conditions were those described above. Electron impact mass spectra were obtained at 70 eV.

The compounds were tentatively identified by comparison of their spectra to those of various library data (Heller and Milne, 1980; mass spectra from the library of the Laboratoire de Recherches sur les Arômes de l'I.N.R.A., Dijon, France). As mass spectra are subject to variability caused by experimental conditions, correct identification is confirmed if the GC characteristics of the identified compound are the same as those of the reference compound analyzed in the same conditions on DB 5 and CP Wax 58 CB columns. For spectral confirmations, commercial compounds were purchased (Interchim, Montluçon, France) or were obtained as gifts (I.N.R.A., Dijon). Biological extracts and pure compounds were coinjected on the polar and apolar columns. (*E*)-4-Oxo-2-hexenal and (*E*)-4-oxo-2-octenal were identified by comparing their mass spectra to those published by Gilby and Waterhouse (1965) and MacLeod et al. (1975), respectively.

RESULTS

Anterior Dorsoabdominal Glands of Nymphs and Adults. These sac-shaped glands open between terga 3 and 4. Morphological studies (Farine, 1987, 1988) indicated that the DAGs 1 of males and females are similar to their counterparts in nymphs.

The seven compounds present in the nymph, male, and female secretions

are listed in Table 1. Besides three hydrocarbons, two terpenes, and one aromatic compound, the major compound, 1-decyne, represents more than 80% of the secretion.

Median Dorsoabdominal Glands (DAGs 2) of Nymphs and Adults. A little more enlarged than DAGs 1, these glands open between terga 4 and 5. They are morphologically similar in nymphs, males, and females (Farine, 1987, 1988).

The GC analysis reveals the presence of 11 compounds (Table 1): five terpenes, four saturated hydrocarbons, one aromatic compound, and one alkyne. In nymphs, 70% of the secretion is composed of tridecane, 1-decyne, and *m*-cymene, whereas in males tridecane and *m*-cymene are the major components. In females, *m*-cymene alone represents 50% of the secretion.

Posterior Dorsoabdominal Gland (DAG 3) of Nymphs. Only active in nymphs, this gland opens between terga 5 and 6 and is about five times as large as the other glands (Farine, 1987).

The 34 compounds present in the secretion are listed in Table 2. Ninety-six percent of the secretion is composed of four aldehydes [(*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-4-oxo-2-hexenal, and (*E*)-4-oxo-2-octenal] and one hydrocarbon (tridecane). Twenty-nine minor components were identified: 11 aldehydes, four saturated hydrocarbons, four alcohols, three terpenes, two alkenes,

and five other compounds. Identification of (*E*)-4-oxo-2-nonenal and (*E*)-4-oxo-2-decenal was made by comparison of their spectra with those of (*E*)-4-oxo-2-hexenal and (*E*)-4-oxo-2-octenal. In addition, the variations between the retention time of the four identified (*E*)-4-oxo-2-alkenals are identical when using a polar or an apolar column. All these observations confirm the presence of a series of homologous compounds.

Metathoracic Glands (MTGs) of Males and Females. These paired glands open at the base of the hind legs. No morphological differences were found between sexes (Farine, 1988).

No remarkable differences were observed between males and females (Table 2). Among the 21 identified compounds, five represent 97% of the male secretion: (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-2-hexenyl acetate, *m*-cymene, and linalool. In females, the four major compounds are (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-2-hexenyl acetate, and linalool. The remainder of the secretion is a mixture of 16 compounds only present in small or trace amounts: five aldehydes, three acetates, two alcohols, two terpenes, and four other products.

Sternal Glands (STGs) of Males. In *D. cingulatus* we noticed a conspicuous sexual dimorphism characterized by the secretory activity of a sternal glandular epithelium in the male (sterna 2–6); this activity is correlated with their sexual maturity (Farine, 1988).

The GC analysis reveals that 88% of the secretion is composed of three major components (Table 3): methyl (*Z*)-4-decenoate, β-caryophyllene, and α-humulene. 8-Ethoxy-*p*-cymene, β-cadinene, and β-caryophyllene oxide are present in small amounts. Several other compounds, only present in trace amounts, were not identifiable by their mass spectra and additional analytical techniques were not usable.

DISCUSSION

In Hemiptera, the existence of an alarm pheromone in *D. intermedius* was first reported by Calam and Youdeowei (1968). When they are attacked by predators (e.g., ants), nymphs and adults of *D. cingulatus* straighten their legs, raise their body, and try to orient their glandular orifices toward the attacker (Farine, 1989). The chemicals produced by the MTGs of adults and DAG 3 of nymphs deter predators and elicit an alarm response, warning conspecifics and inducing their dispersion. The secretion may also be considered as defensive, the ants not only being repelled but also paralyzed (Farine, 1989).

As in *D. intermedius* (Calam and Youdeowei, 1968) and *Pyrrhocoris apterus* (Staddon and Daroogheh, 1982; Schmuck, 1987), the major components of the DAG 3 secretion in nymph *D. cingulatus* are (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-4-oxo-2-hexenal, (*E*)-4-oxo-2-octenal, and tridecane. Carayon (1971)

TABLE 3. *Dysderscus cingulatus:* VOLATILE COMPOUNDS IDENTIFIED BY GC–MS IN SECRETIONS OF STERNAL GLANDS (STG) FROM MALES[a]

Compound	M.W.	%
Methyl (*Z*)-4-decenoate	184	26
β-Caryophyllene	204	50
α-Humulene	204	12
8-Ethoxy-*p*-cymene	178	1
β-Cadinene	204	4
β-Caryophyllene oxide	220	3

[a]For further information refer to caption in Table 1.

reported that adult MTGs in Heteroptera are morphologically and functionally analogous to the nymphal DAG 3, so the presence in *D. cingulatus* of 15 identical components in both nymphs and adults is not surprising. Nevertheless, our observations reveal the chemical complexity of the secretions and the existence of numerous components that are characteristic of nymphs or adults.

Various authors emphasized the possible function of the chemical compounds found in the defensive glands. Aldehydes are able to act as nonspecific irritants and intoxicants (Blum, 1981; Pasteels et al., 1983). Because saturated hydrocarbons and alkenes are frequently present along with more polar components, their primary function was thought to be as wetting and spreading agents that could promote the penetration of the most polar compounds into the cuticle of the predators (Blum and Brand, 1972; Eisner, 1970).

It is well known that *Dysdercus* species form aposematic aggregations (Giles, 1958; Youdeowei, 1967; Gupta, 1979; Farine and Lobreau, 1984) and have smaller scent apparati than the non-warningly colored families (Schaeffer, 1972). In *D. intermedius*, Youdeowei (1967, 1969) pointed out the fact that visual and tactile stimuli are necessary together with semiochemicals to maintain aggregation. In this species, the aggregation of nymphs and adults is induced and maintained by DAG 1 and DAG 2 secretions (Youdeowei, 1967). In *D. cingulatus* (Farine, 1987, 1988), DAGs 1 and DAGs 2 of nymphs and adults are morphologically identical to their counterparts in *D. intermedius* (Youdeowei, 1967). Regarding the qualitative variations of composition between DAG 1 and DAG 2 secretions, an exclusive aggregative function for these glands is questionable and needs further investigation.

In the field, *Dysdercus* species are attracted to specific volatile chemicals from their host plants (Saxena, 1965; Duviard, 1981). Numerous chemicals identified in the exocrine secretions of nymphs and adults in *D. cingulatus* [i.e., (*E*)-2-hexenal, (*E*)-2-octenal, hexanal, (*E*)-2-hexenol, linalool, 1-decyne, ter-

pinen-4-ol, decane, undecane] are also found in the cotton plant (Hedin et al., 1971; Thompson et al., 1971; Hedin, 1976; Berni and Stanley, 1982). The major compound, 1-decyne, which had been identified in *D. cingulatus*, was never noted previously in animal semiochemicals. 1-Decyne was found among the volatiles from the cotton plant (Berni and Stanley, 1982) and was also identified as a degradative product of cotton seed oil (Fan et al., 1983).

Sun (1986) showed that various volatiles from cotton plant attract nymphs and adults of *D. cingulatus*. Linalool elicits feeding reactions in *D. intermedius* (Everton et al., 1979). The function of the aldehydes and hydrocarbons found in the defensive glands of the Heteroptera varies according to their concentration or according to the way they are emitted. Such a dual function of the aldehydes was first reported in *Cimex lectularius* (Cimicidae) (Levinson and Bar Ilan, 1971) and *Eurydema rugosa* (Pentatomidae) (Ishiwatari, 1974, 1976). (*E*)-2-Hexenal is an alarm pheromone when it is sprayed suddenly, but it acts as an aggregation pheromone when exuded gradually and in small amounts. In the first instars of *Nezara viridula* (Pentatomidae), tridecane also functions as a bimodal pheromone causing dispersal at high concentrations (1–10 individual equivalents) and aggregation at low concentrations (0.01 individual equivalent) (Lockwood and Story, 1985, 1986). Similar observations were reported for *D. intermedius* (Calam and Youdeowei, 1968) and *P. apterus* (Schmuck, 1987), and the first studies in *D. cingulatus* and *D. fasciatus* (Farine, 1989) are in keeping with these results. Consequently, production and release by nymph and adult *D. cingulatus* of chemicals found in the cotton plant aroma may enhance the potential attractivity of the food plant towards conspecifics, thus increasing gregariousness.

As suggested by Aller and Caldwell (1979), aggregation pheromones may serve as sex pheromones by promoting the encounters between males and females. Release of sex pheromones by females has been demonstrated in various heteropteran families (Aldrich, 1988b and references therein) and several species of Pyrrhocoridae (Osmani and Naidu, 1966; Zdarek, 1970, Gupta, 1979; Hebbalkar and Sharma, 1982; Siddigui and Khan, 1982). In *Dysdercus koenigii* (Hebbalkar and Sharma, 1982) and *D. cingulatus* (Siddiqui and Khan, 1982), the sealing of the female MTG openings causes about a 50% decline in the sexual responses of the males, but there is no sexual dimorphism in the morphology (Farine, 1988) or in the chemistry of the MTGs in adult *D. cingulatus*. However, females of this species are about twice as big as males. Consequently, the amount of exudate female secretion is larger than in males. If we consider that one of the functions of adult MTG secretions is to be aggregative, a larger amount of female secretions may increase their long-range attraction on the males.

In the STGs of the males of *D. cingulatus*, we identified three major compounds: methyl (*Z*)-4-decenoate, β-caryophyllene, and α-humulene. The ses-

quiterpenoids had been found in the DAG secretions of *Hotea gambiae* (Scutelliridae) (Gough et al., 1985). β-Caryophyllene and β-caryophyllene oxide are present in the cotton volatiles (Thompson et al., 1971). β-Caryophyllene preferentially increases the attraction of female *D. cingulatus*, but only at close range (Sun, 1986). Methyl (*Z*)-4-decenoate has never been reported previously in insect exocrine secretions but is very similar in structure to many well-known lepidopteran sex pheromones. Several authors have reported that the sternal glandular areas of adult male Pentatomoidea (Carayon, 1981, 1984; Aldrich, 1988b; Staddon, 1990), Scutelleridae (Knight et al., 1985), and *D. fasciatus* (Lawrence and Staddon, 1975) are likely sources of sex pheromones or of aphrodisiacs. However that may be, the greatest care must be taken in the interpretation of such behavioral observations. For example, in the field, the major components of the sternal glandular epitelia of some male pentatomids do not attract only females, but also conspecific males and nymphs (Aldrich et al., 1987; Kochansky et al., 1989). It is well known that reproductive females, but not males, of *Dysdercus* species histolyzed their flight muscles (Duviard, 1981), so that female reproduction is physiologically limited to the host plants. In contrast, males retain the potential to fly to feeding clusters among host plants. All these observations postulated an intricate role of the male sternal glands in close-range attraction and/or aggregation rather than a sexual attraction sensu stricto.

The present chemical data emphasized the complexity of the chemical communication in *D. cingulatus*. Although the composition of the glandular secretion has been identified and quantified in many Heteroptera, the biological function of each compound in the scent secretion still needs further study. Using *D. cingulatus* as a model, we will attempt an overview of the chemical communication in this species.

(Received August 5, 1991; accepted September 23, 1991)

Abstract—The ultrastructure and chemical composition of paper and pedicel from nests of *Polistes metricus* that were constructed in the laboratory from known building material were compared to paper and pedicel from nests constructed in the field. Scanning electron micrographs showed the addition of a gluelike secretion from the wasp to the construction material. Solid-state [^{13}C]NMR, elemental analyses, and amino acid analyses indicate that this secretion is a silklike protein with serine, glycine, alanine, and proline comprising 65–73% of the identified residues.

Key Words—Scanning electron microscopy, CP/MAS [^{13}C]NMR, Hymenoptera, Vespidae, social wasps, *Polistes metricus*, nest paper, nest pedicel.

INTRODUCTION

Nests of social wasps serve as a site to rear brood and are clearly the center of colony activity (Starr, 1991). Social wasps construct nests that have a variety of architectural designs and that vary in the building materials utilized (Jeanne,

*To whom correspondence should be addressed.

0098-0031/92/0100-0077$06.50/0 © 1992 Plenum Publishing Corporation

1975; Edwards, 1980; Akre, 1982; Hansell, 1984; Wenzel, 1991). Many wasps use primarily woody fibers, which they masticate and mix with an oral secretion in order to produce their nest paper. The salivary secretion used in nest construction by *Pseudochartergus chartergoides* has been characterized as chitin (Schremmer et al., 1985). However, chemical examination of the nest paper of *Dolichovespula maculata* (McGovern et al., 1988) and *Ropalidia opifex* (Maschwitz et al., 1990) and of the paper and pedicel of *Polistes annularis* nests (Espelie and Himmelsbach, 1990) indicates that for several genera of social wasps this secretion is composed primarily of protein.

In the present paper we examine the ultrastructure and chemical composition of the oral secretion utilized by *Polistes metricus* in nest construction. We compare the secretion found on the paper of field-made nests to that found on nests constructed in the laboratory where the wasps were provided with a uniform building material of known chemical composition.

METHODS AND MATERIALS

Insect Collecting. Thirty colonies of *Polistes metricus* Say were collected from various locations in Clarke County, Georgia, in May and June 1990. Most colonies had a single adult and a nest with fewer than 10 cells. The colonies were immediately returned to the laboratory where they were maintained separately for continued nest building and colony growth (Matthews and Ross, 1985; Downing and Jeanne, 1988). Portions of each nest that were constructed in the laboratory from filter paper were white and, therefore, they were distinguishable from the portions of each nest (grey/brown) that were made in the field. Field-made nests were collected later in the summer (August 1990).

Insect Rearing. Nests brought into the laboratory were attached to thin wooden strips that previously had been glued to the ceiling of Plexiglas chambers (20 × 20 × 20 cm). The top of each chamber had a ventilation opening (11 cm diameter) that was covered with plastic mesh. The chambers, which were open on the bottom so that food and materials could be easily offered to the wasps, were kept on glass plates (20 × 20 cm) (Singer and Espelie, 1992). Whatman No. 1 filter paper (15 cm diameter) was cut into pieces (approximately 20 cm^2) that were placed into the chambers to provide nest construction material for the wasps. Wasps were provided with water and with 20% honey–water. Once wasp larvae were present in the nest, the wasps were provided daily with mature caterpillars (either *Spodoptera frugiperda* or *Helicoverpa zea*).

Laboratory-made nests were removed from their chamber when two or more workers had emerged and at least four pupae were present. The wasps that were left in the chamber were utilized in kin recognition bioassays (Singer and Espelie, 1992). In the chambers where the wasps constructed a new nest,

the pedicel was used for ultrastructural and chemical analysis of laboratory-made pedicels.

Microscopy. Nest paper samples (approximately 5 mm^2) were cut from two laboratory nests and from two field nests. The paper samples were cut from nest cells that had not been used as pupal cells and, therefore, did not contain larval silk. A sample (approximately 5 mm^2) also was cut from the Whatman No. 1 filter paper that had been provided to the wasps for lab nest construction. The samples were mounted on aluminum stubs and adhered with sticky tabs and silver paint so that the outer surface of the nest paper could be observed. Nest pedicels were removed carefully from laboratory-made nests and from field-made nests and then mounted onto aluminum stubs with sticky tabs and silver paste. A razor blade was utilized to cut pedicel samples into cross-sections. A 50-nm layer of gold–palladium was applied to the samples with a Hummer x Sputter Coater (Anatech). A Phillips 505 scanning electron microscope operated at 20 keV and a Jeol 35 scanning electron microscope operated at 15 keV were utilized for observing and photographing samples.

Amino Acid Analyses. Samples of nest paper and pedicel from laboratory-made and field-made nests (10–20 mg) were hydrolyzed in 6 N HCl at 110°C for 24 hr in sealed, evacuated tubes. Amino acids were analyzed with a Microsystems HPLC (Espelie and Himmelsbach, 1990).

Elemental Analysis. Carbon, hydrogen, and nitrogen analyses were performed on nest paper and pedicels from laboratory-made and field-made nests and Whatman No. 1 filter paper by Atlantic Microlab, Inc. (Atlanta, Georgia). Samples of pedicels contained material from several nests.

Solid-State NMR Spectroscopy. Solid-state NMR spectra of paper from laboratory-made and field-made nests, of pedicels from field-made nests, and of Whatman No. 1 filter paper were obtained by employing the CP/MAS technique. A Bruker MSL 300 NMR spectrometer operating at 75.47 MHz for ^{13}C and equipped with high-power amplifiers and a medium-bore (89 mm) high-speed probe was utilized for this purpose. The samples were packed in 4-mm-diameter zirconia rotors and were spun at approximately 6.0 kHz. Data were collected by taking 8K scans using a 3.0-μsec 90° 1H pulse, a 1.5-msec contact time, and a 5-sec delay time. All spectra were smoothed with Lorentzian broadening (LB = 20) and externally referenced to the benzene ring signal in hexamethylbenzene at 132.3 ppm with respect to tetramethylsilane.

RESULTS

The paper of nests that were constructed in the laboratory by *P. metricus* wasps had a very distinct appearance, with that portion of the nest made from filter paper easily recognized (Figure 1A). Scanning electron micrographs of

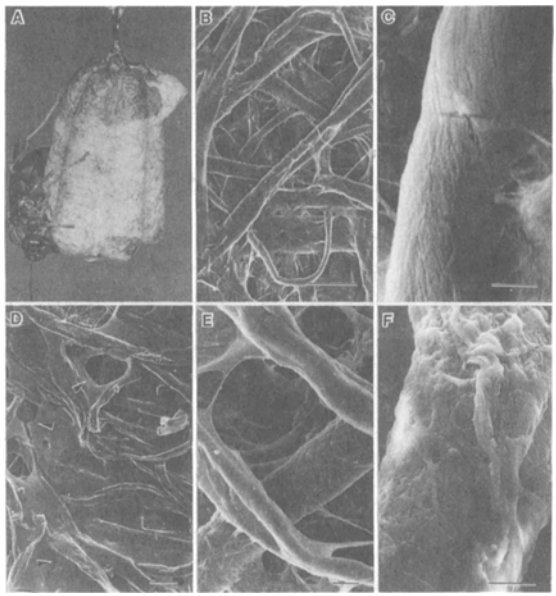

FIG. 1. (A) *Polistes metricus* and nest that was started in the field and continued in the laboratory. Scanning electron micrographs of: (B and C) filter paper; and (D–F) paper from *P. metricus* laboratory-made nests. Scale bars = 40 μm in B and D; 5 μm in C and F; and 10 μm in E.

the filter paper that the wasps utilized in the laboratory for nest construction (Figure 1B) show fine threads that bind together larger fibers of the paper. Longitudinal striations that form the texture of individual fibers of the filter paper are seen at higher magnification (Figure 1C).

Micrographs of the laboratory-made nest paper (Figure 1D) show a smooth, amorphous layer covering the fibers of the filter paper. This layer covers and connects most of the filter paper fibers, although some regions contain cracks or openings (Figure 1D, arrows). At higher magnification, this layer appears thick and gluelike and seems to serve as a binding between fibers (Figure 1E). The striations that were seen in the fibers of filter paper (Figure 1C) are no longer apparent in individual fibers of the laboratory-made nest paper (Figure 1F), presumably because they are covered by the gluelike material.

Low magnification scanning electron micrographs of nest paper from field-made nests of *P. metricus* (Figure 2A) reveal a surface that is rougher and has less of the gluelike coating than the laboratory-made nest paper. The layer of coating material, however, is still evident at higher magnification (Figure 2B). Examination of an individual fiber from a field-made nest shows a coating layer on the fiber as well as pollen grains scattered on the nest paper (Figure 2C).

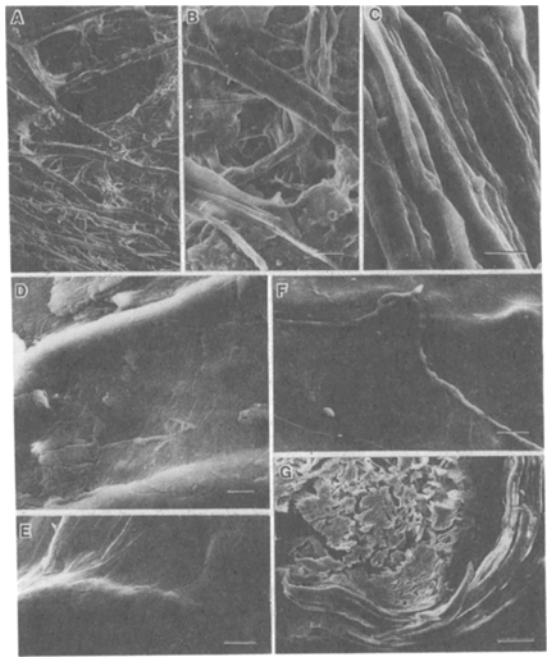

FIG. 2. Scanning electron micrographs of: (A–C) the paper of a *Polistes metricus* field-made nest; (D and E) surface of the pedicel of a *P. metricus* laboratory-made nest; (F) surface of the pedicel of a *P. metricus* field-made nest; and (G) cross-section of pedicel of *P. metricus* field-made nest. Scale bars = 40 μm in A and G; 10 μm in B and E; 7 μm in C and D; and 20 μm in F.

Scanning electron micrographs of the surface of laboratory-made pedicels of *P. metricus* nests show fibers that appear to be from the filter paper and a covering of an amorphous material laid down in random arrays (Figure 2D). At higher magnification, this material has a very smooth appearance (Figure 2E). Pedicels from field-made nests have a very similar surface with a random array of fibers and a smooth, amorphous matrix (Figure 2F). A cross-sectional view of a field pedicel shows that the outer portion consists of a series of concentric rings with fibrous material in the center (Figure 2G).

Elemental analyses indicated that nitrogen was present in both the paper and pedicel of laboratory- and field-made nests of *P. metricus* (Table 1), but there was no nitrogen detectable in the filter paper that was utilized by the wasps for the nests made in the laboratory. The nitrogen content of pedicels from field-made nests was much higher (8.4%) than it was in the pedicels of laboratory-made nests (3.2%).

CP/MAS [^{13}C]NMR spectroscopy indicated that the paper of laboratory-

made nests is composed primarily of cellulose (Figure 3A). The narrow resonance bands for C_1 (104–106 ppm), and the small signals for C_4 and C_6 (84 and 63 ppm, respectively) from amorphous cellulose, indicate that the cellulose is highly crystalline (Atalla, 1984). The spectrum shows that there is also some protein present in the nest paper. There is a small carbonyl band at 175 ppm and aliphatic carbon resonances between 20 and 60 ppm that are indicative of protein (Figure 3A). The filter paper that the wasps utilized for nest construction also consists of highly crystalline cellulose, as shown by the splitting of C-1 in the spectrum of the filter paper (Figure 3B). The cellulose in the laboratory-made nest paper had the same degree of crystallinity as the filter paper, indicating that the cellulose portion of the filter paper had not been modified during nest construction. The paper from field-made nests also contains cellulose and protein. Here the resonance bands of the carbohydrate carbons are much broader, and the signals for C_4 and C_6 from amorphous cellulose are larger, thus indicating that this cellulose is noncrystalline (Figure 3C). The spectrum of the pedicel from field-made nests (Figure 3D) also contains the less crystalline cellulose and a much higher proportion of protein than the nest paper from either field- or laboratory-made nests.

Amino acid analysis of the hydrolysate of paper from laboratory-made nests gave a composition that was dominated by glycine (32%), serine (16%), alanine (14%), and proline (11%) (Table 2). Laboratory-made pedicels and the paper and pedicels from field-made nests contained protein with essentially the same amino acid composition.

DISCUSSION

The scanning electron micrographs of *Polistes metricus* nest paper clearly show that these wasps utilize secretions to construct and fortify their nests. Comparison of the scanning electron micrographs of the paper from nests made in the laboratory (Figure 1D–F) with those of the filter paper that the wasps utilized (Figure 1B and 1C) indicates that the adult wasps use a gluelike salivary secretion to bind together the paper fibers. This secretion, detectable as strands or plates interconnecting the construction fibers, is also seen on the paper of nests made in the field (Figure 2A–C). The secretion is not as evident in the micrographs of the field-made nests, possibly because there is less secretion in these nests. The diversity of building materials used by the wasps may also cause the secretion to be more difficult to discern in the micrographs of the field-made nests than it is in the nests that are made from filter paper.

The strands and plates of secretion seen in the scanning electron micrographs of the laboratory nests of *P. metricus* are very similar in appearance to those seen in the nests of the Oriental hornet, *Vespa orientalis* (Ishay and Ganor,

1990). The cracks in the plates of secretion (Figure 1D and 1E, arrows) are also similar to those seen in *V. orientalis* nests. These cracks may be a result of the hardening of the secretion, and they may serve to provide ventilation in the nest (Ishay and Ganor, 1990).

Previous chemical analyses of social wasp field-made nests have shown the nests to be composed of cellulose and protein (McGovern et al., 1988; Espelie and Himmelsbach, 1990; Maschwitz et al., 1990). The CP/MAS [^{13}C] NMR spectra in this study also show cellulose and protein to be the major components of the laboratory- and field-made nest paper (Figure 3). The protein found in both the nest papers and pedicels (Table 2) is similar in amino acid composition to that found in several insect silks (Lucas and Rudall, 1968a,b; Crewe and Thompson, 1979) with very high proportions of glycine, alanine, and serine. The relatively large amount of proline (10.6–12.5%) found in both the paper and pedicel proteins (Table 2) is comparable to that found in the nest pedicel of *Polistes annularis* (Espelie and Himmelsbach, 1990) and in the nest paper of *Dolichovespula maculata* (McGovern et al., 1988). Proline also has been found to comprise 10–15% of the protein in the nest paper of several species of South American and Asian social wasps (Wenzel and Espelie, in preparation). Proline is frequently a dominant residue in structural proteins

(Bursell, 1981; Chen, 1985), and its presence in the protein secreted by social wasps may give added strength to their nests.

Several species of social wasps rub onto the pedicel of the nest a sternal gland secretion that serves to deter predators (Jeanne, 1970; Turillazzi and Ugolini, 1979; Post and Jeanne, 1981; Kojima, 1983; Jeanne et al., 1983). The sternal gland of *Polistes fuscatus* has been shown to contain methyl hexadecanoate (Post et al., 1984), which is applied to the pedicel and functions as an ant deterrent (Henderson and Jeanne, 1989). Hexadecanoic acid and octadecenoic acid have been found on the nest pedicel of *P. annularis*, and these components may also deter potential predators (Espelie and Hermann, 1990). Cross-sections of the pedicel of the *P. metricus* field-made nests show concentric rings of hardened, crisp material encircling a fibrous core (Figure 2G). The outer layers may be a combination of material applied from both oral and sternal gland secretions of the wasps. The [^{13}C]NMR spectrum (Figure 3D) and elemental analysis (Table 1) indicate that the pedicel has a high protein content. This protein may be primarily on the outer region of the pedicel, while the central fibrous region is mainly cellulose. Chemical and ultrastructural examination of the thickening of the pedicel of *P. metricus* nests throughout the colony season should yield additional evidence regarding the origin and function of this outer layer of material.

THE ROLE OF CHEMOSENSORY CUES IN DISCRIMINATION OF PREY ODORS BY THE AMPHISBAENIAN *Blanus cinereus*

PILAR LÓPEZ* and ALFREDO SALVADOR

(Received June 3, 1991; accepted September 30, 1991)

Abstract—Responses of amphisbaenians (*Blanus cinereus*) to deionized water, a control for pungency (cologne), and integumental prey odors (coleopteran larvae and adult ants) on cotton swabs were studied in experiments with a randomized blocks design to discover whether amphisbaenians use chemical cues to detect and identify prey. No individual bit the applicators. Amphisbaenians tongue-flicked at lower rates than epigean saurians, which are active foragers. Tongue-flick rate differed among treatments, but responses to prey odors were not significantly different from those to cologne. The number of directed tongue-flicks emitted during the 60-sec trials was, however, lower in response to deionized water than in response to cologne or prey odors. Response details, the low rate of tongue-flick, and absence of biting are discussed in relation to the foraging behavior and fossoriality of amphisbaenians. Evidence from this study indicates that the vomeronasal sense is used by amphisbaenians to identify odors, but our experiments failed to demonstrate that amphisbaenians discriminate between prey and nonprey odors.

Key Words—Lacertilia, Amphisbaenidae, *Blanus cinereus*, prey odor, tongue-flicking, fossoriality.

INTRODUCTION

Epigean saurians use visual and olfactory senses to locate prey. The prevalence of one of these senses seems to be related to foraging mode. Active foragers

*To whom correspondence should be addressed.

appear to use chemosensory senses. They regularly tongue-flick during foraging and can detect and recognize prey by chemical cues. Sit-and-wait predators, however, do not tongue-flick at high rates and detect prey visually while foraging (Bissinger and Simon, 1979; Huey and Pianka, 1981; Cooper, 1989, 1990). There have been few studies on senses used in prey detection by subterranean saurians (Hetherington, 1989).

Amphisbaenians are squamate reptiles showing many adaptations to a burrowing life (Gans, 1978). Their foraging behavior is unknown, specially in relation to prey detection. Vision is reduced. Hearing and olfactory capabilities, however, are enhanced (Gans and Wever, 1975; Gans, 1978), indicating an important role in predation. Nevertheless, no evidence is available of a chemosensory role in any amphisbaenian species.

Blanus cinereus is an amphisbaenian endemic to the Iberian Peninsula (Busack, 1988). Its diet mainly consists of insect larvae and ants, which are the most abundant invertebrates in their habitat, but insect larvae of large size are selected (López et al., 1991). The use of chemosensory cues by *B. cinereus* in the discrimination of prey was tested using responses to prey chemicals presented on cotton-tipped applicators (Cooper and Burghardt, 1990). We tested the ability of *B. cinereus* to detect prey odors and to discriminate between prey odors and nonprey odors. We also address the way fossoriality influences the foraging behavior of a burrowing reptile, in comparison to epigean saurians.

METHODS AND MATERIALS

Eighteen *Blanus cinereus* (six adult males, three adult females and nine immatures; snout-vent length: $\bar{X} \pm SE = 147 \pm 8$ mm), were captured in March 1990 near Torrelodones (40°35′N, 3°56′W; Madrid Province, Spain). They were housed at "El Ventorrillo" Field Station laboratory (Navacerrada, Madrid Province). The photoperiod was that of the surrounding region, but ambient temperature was maintained at a constant 20°C. Individuals were maintained in 5-liter glass jars containing sand substrate from the capture area. They were fed twice weekly on coleopteran larvae, adult ants, ant eggs, and earthworms, which they readily consumed. Humidity was raised daily with a spray. All animals were acclimatized to laboratory conditions and the experimenter's presence for at least one month before testing. Amphisbaenians were not fed for five days prior to the study.

In a first experiment, each of 18 amphisbaenians was tested with coleopteran larvae odors, deionized water, and cologne (Eau Jeune, L'Oréal). The water served as an odorless control. Cologne was used to determine response to an odorous but nonprey stimulus. Every amphisbaenian was tested with each stimulus once in a randomized block design. Order of presentation was coun-

terbalanced. One trial was conducted per day for each animal. We prepared stimuli by dipping the cotton tip (1 cm) of a wooden applicator (10 cm) in deionized water. Other stimuli were added by dipping the wetted cotton in diluted cologne or by rolling it over the body surface of coleopteran larvae. A new stimulus was used in each trial. The experiment was conducted April 23–28, 1990, between 0930 and 1900 hr. A second experiment was made using ant odor (*Pheidole pallidulla*), deionized water, and cologne. This experiment was conducted May 2–10, 1990, between 0930 and 1900 hr., using the procedures described for experiment 1.

Because the amphisbaenians showed defensive and escape behavior on the soil surface, we simulated fossorial conditions to perform experiments by using transparent plastic tubes (one for each individual). Inside each tube, the lower half of the surface was covered with sand using adhesive. Individuals were kept in their tubes 6 hr per day during the acclimatization period, during which they showed normal behavior and were fed with larvae and ants. Individuals were kept in their tubes 10 min before trials, closing both sides with cotton. Between trials, we opened both sides of the tube for 10 min to avoid odor mixture. During experiments the laboratory was darkened and observations were made using a 50-W red light.

To begin a trial, we slowly approached a tube, removed the cotton from one side and slowly put the cotton-tipped applicator to a position 2 cm anterior to the amphisbaenian's snout. We counted total number of tongue-flicks (TFs) for 60 sec beginning with the first TF. We also noted the number of TFs directed to the swabs during this period. Latency to the first TF was computed as the period elapsed between closing the tube and the first TF. If an individual did not tongue-flick in 30 sec, we touched its snout with the swab. If it still did not tongue-flick, the data were discarded. To demonstrate that lack of responsiveness to stimuli was not caused by satiation, food was given to the amphisbaenians at the conclusion of trials.

To examine differences in number of TFs between trials we used nonparametric Friedman two-way ANOVA (Siegel, 1956). Individual comparisons were made using Wilcoxon signed rank-matched pairs test. Spearman rank correlations were conducted between latency to first TF and number of TFs (Sokal and Rohlf, 1981).

RESULTS

Experiment 1: Using Coleopteran Larvae as Prey Odor. All of 18 individuals tongue-flicked. Fifteen tongue-flicked in all conditions, and three in only two conditions. Analyses were conducted only on those 15 individuals. No amphisbaenians bit an applicator. There were significant differences ($\chi^2 = 7.58$;

$df = 2,28$; $P = 0.001$) in total number of TFs in responses to different odor conditions ($\bar{X} \pm$ SE: prey = 4.9 ± 0.7; cologne = 7.7 ± 1.0; water = 3.9 ± 0.5). The tongue-flick rate in response to prey odor was significantly higher (Wilcoxon test, $T = 2.0$, $P < 0.05$) than to deionized water but did not significantly differ ($T = 1.88$, $P = 0.06$) from those to cologne odor. Response to cologne was significantly higher ($T = 3.0$, $P = 0.002$) than to water. Number of TFs directed to the cotton-tip were also significantly different between treatments ($\chi^2 = 7.96$; $df = 2,42$; $P = 0.019$) (Figure 1).

Latency to first TF and total number of TFs in 60 sec in all trials had a negative Spearman rank correlation ($r_S = -0.40$; $P = 0.008$), and latency to first TF was negatively, but not significantly, correlated with the number of TFs directed to the cotton-tip ($r_S = -0.21$; $P = 0.17$). There was a significant treatment effect on time of latency to first TF ($\chi^2 = 14.53$; $df = 2,28$; $P < 0.001$). Latency to first TF in response to distilled water ($\bar{X} \pm$ SE = 29.2 ± 6.8 sec) was significantly higher than to either prey ($\bar{X} \pm$ SE = 13.1 ± 2.5 sec; $T = 2.87$, $P = 0.004$) or cologne odor ($\bar{X} \pm$ SE = 10.2 ± 1.9 sec; $T = 2.73$, $P = 0.006$). Latency in response to prey odor and cologne did not differ significantly ($T = 0.68$, $P = 0.49$).

Experiment 2: Using Ants as Prey Odor. This experiment was conducted on 16 animals. All 16 individuals tongue-flicked. Fifteen tongue-flicked in all treatments, and one in only two treatments. Analyses were conducted only on those 15 individuals. No amphisbaenians bit the applicator. The total number of TFs emitted in responses to different odor conditions ($\bar{X} \pm$ SE: prey = 7.5 ± 1.1; cologne = 7.8 ± 1.1; water = 3.7 ± 0.5) were significantly different ($\chi^2 = 21.83$; $df = 2,28$; $P < 0.0001$). The tongue-flick rate in response to water odor was significantly lower than to either prey ($T = 3.38$, $P = 0.0007$) or cologne ($T = 3.26$, $P = 0.001$). Responses to prey and to cologne did not

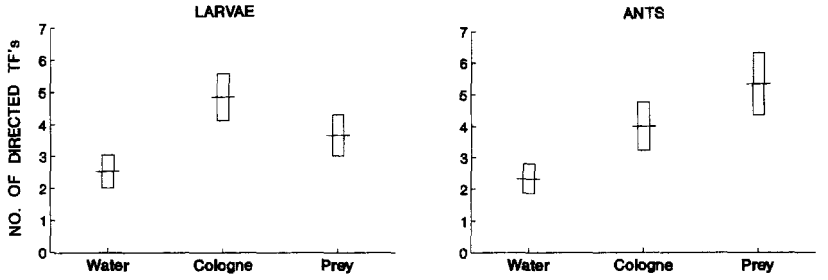

FIG. 1. Number of directed tongue-flicks (TFs) emitted in 60 sec in response to odor stimuli presented on cotton-tipped applicators. Responses shown are for *Blanus cinereus* to larval prey (experiment 1) and to ant prey (experiment 2). Data are means (horizontal lines) ± 1 SE.

differ significantly ($T = 0.44$, $P = 0.66$). The number of TFs directed at the cotton-tip were also significantly different between treatments ($\chi^2 = 9.25$; $df = 2,42$; $P = 0.0098$) (Figure 1).

Latency to first TF was negatively, but not significantly, correlated with the total number of TFs in 60 sec ($r_S = -0.24$; $P = 0.11$), and with the number of TFs directed at the cotton-tip ($r_S = -0.16$; $P = 0.29$). Latency to first TF in response to distilled water ($\bar{X} \pm$ SE $= 15.8 \pm 2.6$ sec) was not significantly different ($\chi^2 = 4.28$; $df = 2,28$; $P = 0.12$) from either cologne ($\bar{X} \pm$ SE $= 9.5 \pm 1.9$ sec) or prey odor ($\bar{X} \pm$ SE $= 11.8 \pm 2.7$ sec).

DISCUSSION

Blanus cinereus can detect odors but did not demonstrate an ability to discriminate prey odors from nonprey odors as tested in the present experiment. The greater number of tongue-flicks was in response to cologne compared to water, but does not rule out recognition of food odor. However, their failure to do so does not necessarily indicate an inability to recognize food stimuli by tongue-flicking. Critical tactile or hearing stimuli needed to release attack may have been absent. Lizards need not rely exclusively on one sensory cue to detect prey (Cooper, 1990). *B. cinereus* may use many cues to locate prey, and the ability to detect odors by chemical cues could be useful to confirm identification of potential prey (Graves and Halpern, 1990).

The tongue-flick rates of *B. cinereus* are close to those produced by epigean saurians, which are unable to detect prey odors. Nevertheless, the iguanid lizard *Dipsosaurus dorsalis*, although emitting a relatively low number of TFs, discriminates food odors in opposition to cologne (Cooper and Alberts, 1991). Amphisbaenians may discriminate quickly, on the basis of a few or even a single tongue-flick. Low rates of tongue-flicking could also reflect low metabolic requirements related to fossoriality (Withers, 1981; Kamel and Gatten, 1983).

Compacted particles of substrate that separate amphisbaenians from their potential prey probably complicate detection of invertebrates by the vomeronasal system. Cues associated with moving prey could be much more effective, as they can be used at greater distances (Hetherington, 1989). Olfactory cues may help to identify nearby prey items whose odor can be detected through particles of substrate. The absence of attacks on applicators may indicate that amphisbaenians were not previously stimulated by hearing cues.

The construction of a permanent system of tunnels is unknown in *B. cinereus*; however, we observed permanent galleries under stones that allowed access for heating (Martín et al., 1990). Vomerolfaction may aid detection of potential predators or prey in galleries. Both sexes of *B. cinereus* possess femoral pores,

and their secretion may impregnate the walls of tunnels, in which case the vomeronasal system may be used in individual and sex recognition (Alberts, 1991; Cooper and Vitt, 1986).

The experimental design used in this paper was able to demonstrate that *B. cinereus* can detect odors using its tongue, probably via vomerolfaction. Nevertheless, it did not demonstrate discrimination between prey odors and nonprey odors. Alternative experimental techniques, such as sealing of vomeronasal ducts (Graves and Halpern, 1990) or teaching the animals to respond to a particular chemical stimulus to be rewarded with food could be useful to determine the chemosensory abilities of amphisbaenians.

Acknowledgments—The paper has been improved by helpful comments from William E. Cooper. We thank José Martín for his help in the field and in the elaboration of the manuscript, Ross D. Johnston for critical comments and checking the English in early drafts of the manuscript, and "El Ventorrillo" MNCN Field Station for use of their facilities. Financial support was provided to Pilar López by a Museo Nacional de Ciencias Naturales-Comunidad de Madrid grant. This project was funded by DGICYT grant PB88-0009.

Abstract—An alternative synthesis of (*Z*)-3-dodecen-1-yl (*E*)-2-butenoate without use of carcinogenic ethylene oxide and HMPA is described. By coupling of the tetrahydropyranyl (THP) ether of 3-butyn-1-ol with 1-bromooctane with sodamide in liquid ammonia, 12-(2-tetrahydropyranyloxy)-9-dodecyne was obtained; subsequent hydrolysis and semihydrogenation afforded (*Z*)-3-dodecen-1-ol. The alcohol was then reacted with crotonyl chloride to give the desired crotonate with a total yield of 29.8%. Males of sweet-potato weevil, *Cylas formicarius* were strongly attracted to the synthetic sex pheromone. The attraction from the dispenser of polyethylene tube was better than the attraction from the dispenser of rubber septum in the field.

Key Words—Sweet-potato weevil, Coleoptera, Curculionidae, *Cylas formicarius*, sex pheromone, (*Z*)-3-dodecen-1-yl (*E*)-2-butenoate, ethylene oxide, hexamethylphosphoric triamide, 3-butyn-1-ol, liquid ammonia.

INTRODUCTION

The sex pheromone of (*Z*)-3-dodecen-1-yl (*E*)-2-butenoate (I) was attractive to the male sweet-potato weevil *Cylas formicarius elegantulus* (Summers) (Heath

*To whom correspondence should be addressed. TACTRI Journal Article No. 11.

et al., 1986; Hwang et al., 1989), and also to *Cylas formicarius formicarius* (F.) (Talekar and Lee, 1989). The compound was first synthesized by Heath et al. in 1986, and the key step in the synthesis of (*Z*)-3-dodecen-1-yl (*E*)-2-butenoate was the synthesis of 3-dodecen-1-ol (III) by coupling 1-decyne (II) with ethylene oxide (EO), using *n*-butyllithium (BuLi in dry THF) as a base, and hexamethylphosphoric triamide (HMPA) as a cation complexing agent for metalation (Scheme 1).

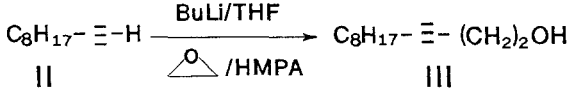
Traditionally, EO is a good alkylation agent and commonly has been used in many alkylation reactions (Henrick, 1977), such as in the synthesis of key intermediates for the sex pheromones (*Z*)-13-octadecen-3-yn-1-ol and (*E*)-13-octadecen-3-yn-1-ol (Voerman, 1979), or 3,13-octadecadiyne-1-ol and (*Z*)-13-octadecen-3-yn-1-ol (Doolittle et al., 1980). HMPA also is used extensively as a solvent for many alkylation reactions due to its ability to form cation ligand complexes (Normant, 1967; Henrick, 1977; Lo and Chao, 1990).

However, EO should be considered a carcinogenic chemical (Kolman et al., 1986), and the U.S. National Institute for Occupational Safety and Health (NIOSH) recommended that the EO exposure level should be reduced to 0.1 ppm (NIOSH, 1981). HMPA has also been shown to be carcinogenic in rats, and a permissible airborne exposure limit of 0.5 ppb was suggested (Schmutz, 1978).

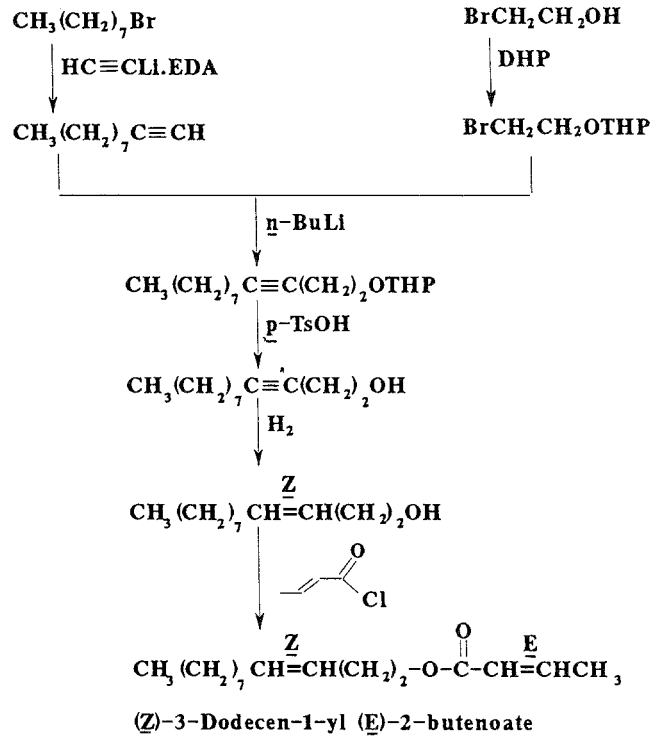
Thus, a safe substitute for carcinogenic agents EO and HMPA in the synthesis of the key intermediate 3-dodecyn-1-ol of (*Z*)-3-dodecen-1-yl (*E*)-2-butenoate is necessary, especially when large-scale synthesis of this sex pheromone is required for the possible application in the sweet-potato fields of 20,000 hectares in Taiwan.

A possible route is to synthesize 12-(2-tetrahydropyranyloxy)-9-dodecyne[$CH_3(CH_2)_7C{\equiv}C(CH_2)_2OTHP$], a precursor of 3-dodecyn-1-ol, without EO and HMPA. The synthesis shown in Scheme 2 was considered. However, 2-bromoethanol($BrCH_2CH_2OH$) induced mutagenic response in the histidine-dependent *Salmonella typhimurium* strains TA155 and TA100 (Pfeiffer and Dunkelbery, 1980). Further evidence suggested that 2-bromoethanol might be converted into ethylene oxide *in vivo* (Jones and Wells, 1981). Thus, use of 2-bromoethanol or other halohydrins should be avoided.

The alkylation agent 3-butyn-1-ol seems to be noncarcinogenic, its toxicity being attributed to the inactivation of alcohol dehydrogenase in horse liver (Alston et al., 1979), and this hepatoxicity is typical for alcohols. DMPU (1,3-dimethyl-



SCHEME 1.



SCHEME 2.

2-oxo-hexahydropyrimidine) has been reported to be a safe substitute for HMPA in many reactions (Mukhopadhyay and Seebach, 1982; Bengtsson and Liljefors, 1988), although our review has indicated that a potential toxicological risk to man should be considered (Lo and Chao, 1990). DMI (1,3-dimethyl-2-imidazolidinone) is also recommended as a safe substitute for HMPA (Barker et al., 1979), and if an alkylation reaction can be conducted at temperature higher than 0°C, use of DMI should be safer than use of DMPU or HMPA (Lo and Chao, 1990).

We have worked out an alternative procedure of synthesizing the sex pheromone (*Z*)-3-dodecen-1-yl (*E*)-2-butenoate (I), which allows the synthesis of the key intermediate 3-dodecen-1-ol (III) without carcinogenic risk (Figure 1). Starting with 3-butyn-1-ol (IV), the alcohol was first protected by 3,4-dihydro-2*H*-pyran (DHP), then ω-tetrahydropyranyloxy-1-butyne (V) was alkylated with 1-bromooctane and sodamide in liquid ammonia, followed by treatment with *p*-toluenesulfonic acid (TsOH) in methanol to give the corresponding alcohol (III). The remaining procedures were basically the same as those of Heath et

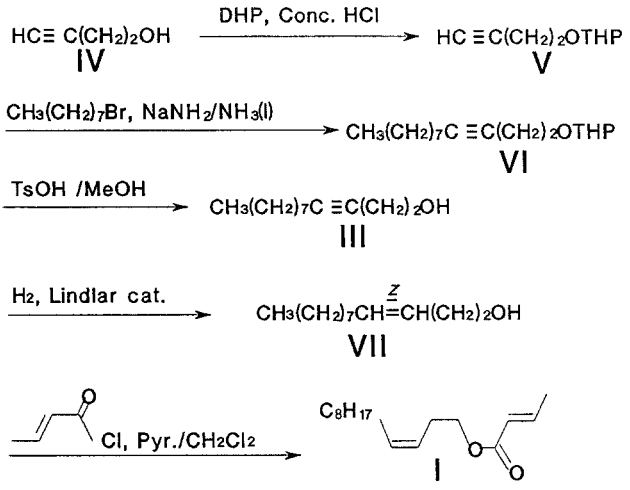


FIG. 1. Synthesis of (*Z*)-3-dodecen-1-yl (*E*)-2-butenoate.

al. (1986), except that the final work-up procedures were modified because of a serious emulsion that occurred when methylene chloride was used to extract the sex pheromone (I); there was no emulsion when ethyl acetate was used as extraction solvent.

METHODS AND MATERIALS

Gas–liquid chromatography (GLC) was performed on the synthetic materials with a Hewlett-Packard 5890 equipped with a flame ionization detector (FID). A glass column of 3% OV-1 on 80–100 Chromosorb W HP, 2 mm × 1.8 m, was used to analyze the synthetic intermediates with the initial oven temperature at 100°C (1 min), then programmed to 230°C (8°C/min). A glass column of 3% OV-17 on 100–120 Chromosorb W HP was used to analyze the final synthetic pheromone; the initial oven temperature was set at 180°C (1 min), then programmed to 230°C (8°C/min). Nitrogen was used as carrier gas at the rate of 29.9 ml/min, and air and hydrogen flows were set as recommended for FID.

GC-MS measurements were recorded on a Hewlett-Packard 5890A GLC combined with a 5970B mass selective detector (EI, 70 eV). Infrared data were obtained with a Perkin-Elmer 882 infrared spectrophotometer, and [^{1}H] nuclear magnetic resonance data were obtained with a Varian VXR-300 spectrometer.

ω-Tetrahydropyranyloxy-1-butyne (V). For the synthesis of ω-tetrahydropyranyloxy-1-butyne, we added 5.30 g (0.076 mol) of 3-butyn-1-ol (IV) in a

three-neck flask, cooled the contents of the flask to 0°C in an ice bath, added five drops of concentrated HCl (35.0–37.0%) and then 3,4-dihydro-2*H*-pyran (DHP) (9.54 g, 0.11 mol) dropwise. The cold solution was stirred for 3 hr at 0°C, 2 g of sodium bicarbonate ($NaHCO_3$) was added, and the solution was stirred for 1 hr. The precipitate was filtered and washed with ether. The solvent was removed, and the distillate was collected at 73–75°C, 5 mm. Yield 9.40 g (80.6%) of compound V; IR (cm^{-1}film) 3294 (terminal≡C−H), 2120 (C≡C), 1200–1036 (tetrahydropyranyl), and 639 (≡C−H).

12-(2-Tetrahydropyranyloxy)-9-dodecyne (VI). A three-neck flask was precooled below −50°C (Dry Ice–acetone), liquid NH_3 (300 ml) was added via a Dry Ice–acetone-filled, modified Dewar condenser (with a release vent for excess gaseous NH_3). Sodium amide (2.84 g, 0.073 mol) was added, and compound V (9.25 g, 0.06 mol) was injected from a syringe. The contents of the flask were cooled below −50°C and stirred for 1.5 hr. 1-Bromooctane (22.66 g, 0.12 mol) was injected, the mixture was stirred for 3 hr, and the mixture was allowed to rise to room temperature overnight for NH_3 evaporation. Ice was added and the mixture was extracted with ether three times. The ether extract was washed with water and dried over Na_2SO_4. The residue after removal of the solvent was purified by column chromatography through silica gel (eluent: *n*-hexane: EtOAc = 200:3, v/v). After removing the solvent with a rotary evaporator, 10.23 g of compound VI was obtained (yield 64.0%). The IR spectrum of the product showed no absorption at 3294 cm^{-1} (terminal≡C−H).

3-Dodecyn-1-ol (III). Compound VI (9.89 g, 0.037 mol) was converted to the alcohol by treatment with *p*-toluenesulfonic acid (TsOH, 19.2 g) in methanol (100 ml) for 3 hr. After removing the solvent with a rotary evaporator, the residue was extracted with ether, then the extract was washed with saturated aq. $NaHCO_3$, saturated aq. NaCl, and dried over Na_2SO_4. The ether was removed by rotary evaporation to afford a yellow oily crude compound. The oily compound was further purified by silica gel column chromatography (eluent: *n*-hexane: ether = 20:1, v/v) to obtain compound III (5.53 g, 81.7%; purity 97.4%). The IR spectrum showed peaks at 3353 (OH), and no typical tetrahydropyranyl peaks (1200–1036 cm^{-1}) were found.

(Z)-3-Dodecen-1-ol (VII). To synthesize (Z)-3-dodecen-1-ol, a solution of the alcohol (III) (5.24 g, 0.029 mol) in hexane (98.4 mole %) was hydrogenated at room temperature using a Lindlar catalyst (1.05 g, 20% by weight of the alkyne substrate) and quinoline (0.19 ml, d = 1.09, 20% by weight of the catalyst) (Ho and Liu, 1987). When no more hydrogen was absorbed, the reaction was stopped. The catalyst was removed by filtration, the hexane was evaporated at reduced pressure, and the residue was dissolved in ether. The ether solution was washed with 5% HCl, saturated aq. $NaHCO_3$, water, and brine, dried over $MgSO_4$, and concentrated in a rotary evaporator to give product VII

5.16 g (yield 97.4%; chemical purity 95.8%). IR (cm^{-1}film) 3335, 3306, 2955, 2854, 1467, 1378, 1178, 1050, 968 (*trans* HC=CH), 874, 723 (*cis* HC=CH).

(Z)-*3-dodecen-1-yl* (E)-*2-butenoate (I).* Crotonyl chloride (3.3 ml of 90% technical grade, 0.034 mol) and compound VII (5.10 g, 0.028 mol) were dissolved in methylene chloride (50 ml), and the solution was cooled in an ice bath. Pyridine (2.2 ml, 0.027 mol) was added in methylene chloride (10 ml) dropwise. The resulting mixture was stirred cold for 1 hr, and then worked up with water and ethyl acetate (methylene chloride produced serious emulsion). The organic phase was dried ($MgSO_4$) and concentrated. The crude ester (6.16 g) was purified by silica gel column chromatography (eluent: *n*-hexane: EtOAc 200:3, v/v) twice to obtain product I, 5.08 g (yield 72.7%; chemical purity: 94.2%; active isomeric purity: 82.2%) with overall yield for the synthesis of 29.8%. The EI mass spectrum showed the diagnostic peaks of fragment ions at *m/e* 167 ($M^{+\cdot}-C_4H_5O_2$, 3.4%), 166 ($M^{+\cdot}-C_4H_6O_2$, 31.7%), 87 ($C_4H_7O_2^{+\cdot}$, 5.5%), and 69 (100%). Other major fragmention ion peaks were 138 (14.2), 124 (8.8), 109 (9.5), 96 (33.8), 82 (42.1). IR (cm^{-1} film) 3012 (C=CH), 2920, 2854, 1728 (C=O), 1662 (C=C), 1459 (CH—O—C=O), 1379, 1310, 1294, 1259, 1184, 1103, 1017, 970 (*trans* HC=CH), 838 (C=CH), 723 (*cis* HC=CH), 689. The [^{1}H]NMR spectrum was identical to that of Heath et al. (1986).

The product was further purified with a 20% silver nitrate-impregnated silica gel column (eluent: 1% ether in *n*-hexane) for field tests; two fractions were collected and concentrated to give a colorless liquid of 1.12 g (85.3% isomeric purity) for the first fraction, and 1.99 g (94.6% isomeric purity) for the second fraction.

Field Tests. Field testing was carried out in Houlung, Miaoli during November 13–December 12, 1990. Polyethylene tube dispensers (5.5 cm × 1.0 mm OD, sealed at one end), and rubber septa (1.8 cm OD) were used to load the synthetic pheromones of 1.0 mg containing antioxidant BHT (10%). The dispenser was mounted 2 cm above the poly(ethylene terephthalate) (PET) bottle (Figure 2) (Hwang et al., 1989). Traps were set 10 m apart, 5 cm below the ground, and were rotated regularly every week in a randomized block design with three replications in three blocks. The number of trapped *Cylas formicarius elegantulus* (Summers) was recorded every two days. In all experiments, blank dispensers (with solvent only) were used as controls.

RESULTS AND DISCUSSION

The initial attempt to prepare the compound (*Z*)-3-dodecen-1-yl-(*E*) 2-butenoate (I) was through the alkylation of ω-tetrahydropyranyloxy-1-butyne (V) (in DMI) with 1-bromooctane (in DMI) and use of *n*-butyllithium as metalating

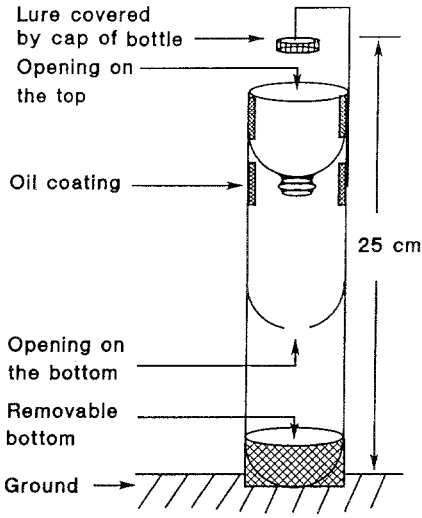

FIG. 2. Trap design of PET bottle developed by Hwang.

agent, but it was unsuccessful, no compound VI was detected. When the solvent DMI was replaced by tetrahydrofuran (THF), DMPU, or HMPA, or when 1-bromooctane was replaced by 1-chlorooctane or 1-iodooctane, the reactions were also unsuccessful.

We decided to try the alkylation in a protic basic solvent system, instead of in an aprotic one. Alkylation of compound V with 1-bromooctane was conducted in liquid ammonia, using sodamide as base (suspended in the reaction medium). We have found that this reaction produced the expected compound VI in good yield (64.0%) and finally produced the sex pheromone (compound I), 5.08 g of 82.2% active isomer. Semihydrogenation of 3-dodecyn-1-ol in 99 mole % hexane at 0°C followed by crotonation was also conducted to give the sex pheromone of 84.9% active isomer; the result indicated that a low temperature was preferred for the synthesis of the *Z* isomer.

Purification of synthetic sex pheromone on a silver nitrate-impregnated silica gel column was applied to collect purified samples for field evaluation, and two portions of isomeric purities of 85.3% and 94.6% were obtained. The purified synthetic sex pheromones were then tested for the field attraction. The influence of polyethylene tubes and rubber septa dispensers on the male attraction was also evaluated. Tests were carried out in November and December 1990. Poly(ethylene terephthalate) bottles were used to trap the male weevils.

The results of field tests indicated that the synthetic sex pheromone was effective. There was no major difference between isomeric purities of 85.3% and 94.6%, indicating that further purification with the expensive silver nitrate-

TABLE 1. INFLUENCE OF SEX PHEROMONE PURITY AND TYPE OF DISPENSER ON ATTRACTION OF MALE *C. formicarius elegantulus* (SUMMERS)

	Tube	Septum	Tube	Septum	Tube	Septum
Males attracted	4672	431	5042	454	0	0

impregnated silica gel column was not necessary. The same situation was also found when different isomeric purity of *cis*-9-*trans*-11-tetradecadien-1-yl acetate was used to trap the cotton leafworm *Spodoptera litura* (Fabricius); no significantly different attractiveness existed between isomeric purities of 86% and 95% (Lo et al., 1988). However, the total male catch was significantly influenced by the type of dispenser, and the field tests showed that the polyethylene tube was a better dispenser than the rubber septum (Table 1).

CONCLUSION

A new route to synthesize the sex pheromone of sweet-potato weevils proved to be a practical method when the carcinogenic reagent EO and carcinogenic solvent HMPA were replaced by the noncarcinogenic reagent 3-butyn-1-ol and the noncarcinogenic solvent NH_3. Polyethylene tubes with one end sealed were effective dispensers.

EVALUATION OF FLAVONOIDS IN *Gossypium arboreum* (L.) COTTONS AS POTENTIAL SOURCE OF RESISTANCE TO TOBACCO BUDWORM[1]

PAUL A. HEDIN,* JOHNIE N. JENKINS, and WILLIAM L. PARROTT

Crop Science Research Laboratory
USDA-ARS
Mississippi State, Mississippi 39762-5367

(Received August 21, 1991; accepted October 3, 1991)

Abstract—Asiatic cottons [*Gossypium arboreum* (L.)] have been investigated as a source of resistance to the tobacco budworm [*Heliothis virescens* (Fab.)] because their diversely colored petals have been presumed to contain various allelochemicals. However, we found that larvae fed *G. arboreum* squares (buds) grew about equally compared with those fed squares from commercial *G. hirsutum* lines. The best source of resistance was found in several *G. hirsutum* double-haploid (DH) lines. In our investigation of allelochemicals, *G. arboreum* lines were found to contain much less gossypol in leaves, squares (buds), and petals than *G. hirsutum* L. lines. Flavonoids were significantly higher in *G. arboreum* lines only in petals. Of 22 *G. arboreum* lines from which squares were gathered and fed to tobacco budworm (TBW) larvae in the laboratory, larval growth was not significantly decreased on any, but larval survival was decreased on six. When the square flavonoids were isolated and incorporated in laboratory diets for the TBW, moderate toxicity was observed. However, the estimated toxicities were not greater than those of the same flavonoid isolates from *G. hirsutum* lines. The most prevalent flavonoids, all previously found in *G. arboreum* plant tissues, were gossypetin 8-0-glucoside and gossypetin 8-0-rhamnoside, neither of which were present in *G. hirsutum* tissue. Quercetin 3-0-glucoside, quercetin-3′-0-glucoside, and quercetin 7-0-glucoside were also present in significant amounts in both species. Gossypetin 8-0-rhamnoside and gossypetin 8-0-glucoside were the most toxic flavonoids tested (the ED_{50}% was estimated to be 0.007 and 0.024) and therefore may prove to be contributing factors of resistance to TBW feeding.

Key Words—Cotton, *Gossypium arboreum*, tobacco budworm, *Heliothis virescens*, Lepidoptera, Noctuidae, resistance, allelochemicals, flavonoids, gossypetin 8-0-rhamnoside, gossypetin 8-0-glucoside.

INTRODUCTION

Cottons of *Gossypium arboreum* (L.), so-called Asiatic cottons, have been periodically investigated as a source of resistance to the tobacco budworm (TBW) *Heliothis virescens* (F) (Altman et al., 1990). There has been speculation that *G. arboreum* cottons may be resistant because of their apparently high flavonoid content, given that petals are diversely colored, generally yellows, oranges, and reds. However, these Asiatic cottons are not high in gossypol-type terpenoid aldehydes, which are the greatest source of insect resistance in other gossypium species (Altman et al., 1990).

In previous work with *G. hirsutum* cottons (Ramolho, 1983; Ramolho et al., 1984; Parrott et al., 1989; Hedin et al., 1991), we have shown that the feeding behavior of the TBW is subject to and modified by both the morphology of the plant and its chemical constituents (allelochemicals). Female moths oviposit in the terminals of the cotton plant. The hatched larvae first feed on terminals, and then migrate to small squares (buds) on which they feed, finally burrowing into the anthers, where they grow and develop. They attempt to avoid gossypol glands as they feed (Parrott et al., 1983). The flavonoids, although found to be toxic in laboratory feeding studies (Hedin et al., 1983a,b, 1988, 1991), have never been shown to have a primary role in insect resistance in field studies of *G. hirsutum*.

Parks (1965) identified 24 flavonoids in *G. arboreum* (L.), including gossypetin 7-0-glucoside, gossypetin 8-0-glucoside, quercetin 3-0-glucoside, quercetin 3-0-rhamnoglucoside, quercetin 7-0-glucoside, kaempferol 3-0-glucoside, and kaempferol 3-0-rhamnoglucoside. Waage and Hedin (1984) found two additional flavonoid glycosides in *G. arboreum* flower petals, gossypetin 8-0-rhamnoside and quercetin 3′-0-glucoside. These later compounds along with quercetin 3-0-glucoside and quercetin 7-0-glucoside showed antibacterial activity against *Pseudomonas maltophilia* and *Enterobacter cloacae* (Hedin and Waage, 1986).

Altman et al. (1990) analyzed eight typed race stocks of *G. arboreum* (L.) for terpenoid aldehydes (TAs). *G. arboreum* accession A2-2 was devoid of hemigossypolone, contained only 5.8% of total terpenoid aldehydes as gossypol, and the remainder (75.9%) was comprised of the heliocides, chiefly H_1. Four *G. arboreum* race stocks contained small amounts of hemigossypolone. H_1 was the predominant TA in each *G. arboreum* line except accession A2-198, which did not contain H_1 but had a large amount of H_2.

In this study, laboratory tests in which TBW larvae were fed squares were

conducted to determine the relative resistance of *G. arboreum* lines. Laboratory feeding tests were also carried out with the flavonoid isolates to estimate their relative contributions, if any, to insect resistance. The content of flavonoids and three other allelochemicals in squares, leaves, and petals of 22 *G. arboreum* lines and six *G. hirsutum* lines was determined to identify any correlations that might exist between content and resistance.

METHODS AND MATERIALS

Cultivars and Agronomic Practices. Seeds of cotton lines were planted in field plots in early May 1987. No insecticides were used on plants in these plots after they began to produce squares. There were 22 experimental lines of 17 *G. arboreum* accessions identified with PI numbers, three doubled haploids of *G. hirsutum*, Stoneville 213 (ST213), Stoneville 213 glandless, and Stoneville 825 (ST825) in the experiment.

Gathering and Processing of Plant Tissue. Leaves, squares, and petals were harvested on July 21 and July 24, frozen, freeze-dried, and ground through a 40-mesh screen. The powders were stored in vials at −20°C until they were evaluated.

Insect and Feeding Regimens. Neonate TBW larvae used in the various tests were obtained from a colony at the Crop Science Research Laboratory, Mississippi State, Mississippi, that was maintained as described by Jenkins et al. (1982).

Squares (8 mm diameter) were harvested throughout the summer, washed in a 0.5% sodium hypochlorite solution, and placed individually into 30-ml plastic cups with 2% agar in the bottom (6.4 mm) to prevent desiccation. For the *G. arboreum* lines, an equal number of neonate TBW larvae were placed on each square and allowed to feed. Fresh squares were introduced every two days. Larvae were weighed at seven days. The test was a completely randomized design with eight squares per line, and the test was repeated twice. Data were subjected to analysis of variance (ANOVA). Least significant differences ($P = 0.05$) were calculated from the data analyzed by ANOVA. These statistical procedures were performed with SAS software (SAS Institute, 1985).

In order to obtain estimates of ED_{50} values (percent of compound required to reduce weight gain by 50%) for various flavonoid isolates and authentic compounds, larvae were reared on the standard TBW larval diet with addition of flavonoids (Hedin et al., 1991). Severely limited availability of tissue (with no expectation of future availability) restricted the scope of the test. Generally, less than 5 g of plant tissue was available, so that total flavonoid isolates seldom exceeded 35–40 mg. Because 50 g of diet yielded only 16 growth cells (a minimum requirement) and 25 mg of isolate was generally required to decrease

growth by about 50%, typically, tests could only be conducted at two levels. The ED_{50} of the commercially available flavonoid, rutin, was obtained by conducting growth tests at six levels with the results being plotted on semilog paper to establish a straight-line growth slope ($y = 122.87 - 27.53x$). Then, on the assumption that slope lines for other flavonoids would be roughly parallel to the rutin line, ED_{50} values were determined using the available data points. The larvae were weighed after seven days.

Analysis of Allelochemicals. Analyses for gossypol and related terpenoid aldehydes (total gossypol) were performed on cyclohexane–ethyl acetate–acetic acid (500:500:1; CHEA) extracts of plant (whole bud and leaf) tissue by the phloroglucinol reaction [2% in absolute EtOH–concentrated HCl (1:1)] and were let stand for 1 hr, with subsequent spectrometric analysis at 550 nm. The concentration was determined by comparison with data obtained from authentic gossypol and is expressed as gossypol equivalents. Condensed tannin analyses were performed on 70% aqueous methanol (MW) extracts of tissue. The anthocyanidin chromophore was developed from the tannin by boiling 1 hr with 1-butanol–HCl (95:5) (Hedin et al., 1983a,b). The concentration was determined by comparison with the absorbancy at 550 nm of a purified cotton condensed tannin sample, the structure of which was elucidated by Collum et al. (1981). The anthocyanin content was determined by measuring the absorbancy at 540 nm of an extract of freeze-dried tissue extracted with methanol–water–HCl (79:19:3), using the molar extinction coefficient (E) of cyanidin 3-β-glucoside (Hedin et al., 1967). Flavonoids were determined after extraction of freeze-dehydrated tissue with 70% aqueous acetone. Diphenylboric acid–ethanolamine complex (Natural Product Reagent A, Aldrich Chemical Co., 1%) in methanol was added, and the chromophore absorptivity at 440 nm was determined and compared to that obtained from a purified sample of isoquercitrin, a representative flavonoid in *G. hirsutum*.

HPLC Analyses of Terpenoid Aldehydes. HPLC analysis of the gossypol-type terpenoid aldehydes was performed on a reverse-phase C-18 column according to the procedure of Stipanovic et al. (1988), who also kindly provided samples of hemigossypolone, and heliocides H_1 and H_2 for column calibration.

Isolation of G. arboreum *Flavonoids for Feeding Tests and Semiquantitative Analysis.* For use in feeding tests, freeze-dried leaf, square, and petal samples, 2 g of each, were extracted two times with 70% aqueous methanol, the extracts were combined, evaporated to a small volume, freeze-dried, and weighed. The samples were redissolved into 20 ml of 50% aq. methanol and chromatographed on a Polyamide 6 (J.T. Baker Chemical Co., Phillipsburg, New Jersey) column (2 cm high × 6 cm diameter), to elute amino acids, carbohydrates, salts, etc. The total flavonoids were then eluted with 70% aqueous methanol and methanol. The samples were evaporated to near dryness, resuspended in H_2O, and freeze-dried. The yields (2.5–4.0%) paralleled the analysis data (see previous section).

For semiquantitative analysis, small quantities (~5 mg) of the freeze-dried total flavonoids were subjected to two-dimensional TLC on 10 × 10-cm cellulose (EM Laboratories, Inc., Elmsford, New York) plates using *t*-butanol–acetic acid–water 3:1:1 in the first dimension and 15% aq. acetic acid in the second dimension (Mabry et al., 1970). The plate was sprayed with Natural Product Reagent (see previous section) and individual flavonoids (visualized spots) were carefully scraped into test tubes and eluted with 1 ml of 70% aqueous methanol. After addition of additional Natural Product Reagent (1 ml of 1% reagent in 70% aqueous methanol) the chromophores were analyzed at 440 nm, and the content was determined with reference to a standard curve (see previous section). Finally, the data was normalized by conversion to percent of total flavonoids.

Identification of G. arboreum *Flavonoids.* Individual flavonoids were isolated by one-dimensional TLC procedures (see previous section) and then were identified by making spectral and chromatographic comparisons with authentic samples retained from our previous work (Waage and Hedin, 1984). For verification, flavonoid isolates from both *G. arboreum* and *G. hirsutum* tissues were hydrolyzed with 1 N aq. HCl. The aglycone fraction was extracted from the reflux mixture with ethyl acetate and examined by both TLC and EI-MS methods. Gossypetin was found in *G. arboreum* samples, but not in *G. hirsutum* samples.

RESULTS AND DISCUSSION

Allelochemicals in G. arboreum *and* G. hirsutum *Plant Tissues.* The average contents of flavonoids, total gossypol, anthocyanins, and tannins in leaves, squares, and petals of multiple lines of these two species are listed in Table 1. All tissues of *G. arboreum* were low in gossypol relative to *G. hirsutum*. Anthocyanin levels were nearly identical except for the much higher level (0.05 vs. 0.45%) in petals of *G. arboreum*. Tannin levels of *G. arboreum* in squares and petals were also much higher, but tannin levels were higher in *G. hirsutum* leaves. The flavonoid content of *G. arboreum* was higher than *G. hirsutum* in squares and petals, but lower in leaves. The average contents of these allelochemicals in *G. hirsutum* were similar to those found by us in earlier work (Hedin et al., 1983a,b, 1991).

Because the distribution of terpenoid aldehydes is the most important factor of resistance in *G. hirsutum* to the TBW, it was considered important to determine their distribution in composited square and petal samples of *G. arboreum* tissue. The terpenoid aldehydes in petals were comprised of 98.1% gossypol, 1.6% hemigossypolone, and only traces of heliocides. Those in squares were comprised of 3.1% hemigossypolone, 12.9% gossypol lactone, 69.5% gossy-

TABLE 1. ALLELOCHEMICALS IN *G. hirsutum* AND *G. arboreum* PLANT TISSUES, AVERAGES FOR MULTIPLE LINES OF EACH WITH STANDARD ERROR OF MEANS[a]

pol, 10.4% heliocide H_1, and 4.1% heliocide H_2. In *G. hirsutum* lines that were resistant to the tobacco budworm, hemigossypolone and heliocides H_1 and H_2 were high relative to susceptible lines (Hedin et al., 1991) and gossypol was unchanged. Therefore, resistance in *G. hirsutum* appeared to be closely associated with hemigossypolone and the heliocides. By comparison, based on gossypol content, *G. arboreum* lines would not be expected to be resistant because total gossypol was relatively low in squares and petals, and gossypol was the dominant terpenoid aldehyde in *G. arboreum* lines. Therefore it seems unlikely that terpenoid aldehydes are a decisive factor of resistance in *G. arboreum* lines.

Previously, we found that survival of TBW larvae was less on nonglanded *G. hirsutum* red petals than on the first-day (younger) white petals (Hedin et al., 1983a,b). In those lines, chrysanthemin was greatly increased as expected in the second-day red petals and gossypol was low. In glanded lines, both gossypol and anthocyanin were higher in the red petals and larval growth was lower. However, the effect of allelochemicals in the petals of intact plants on larval growth may be marginal because the larvae do not consume significant amounts of petals in their normal feeding patterns (Parrott et al., 1989). In fact, as previously discussed (Ramolho, 1983; Ramolho et al., 1984; Parrott et al., 1989; Hedin et al., 1991), feeding behavior of the TBW on cotton is subject to and modified by both the morphology of the plant and its chemical constituents in the various tissues.

Effects of Cotton Flavonoids and Other Allelochemicals on Survival and Growth of the TBW. Table 2 lists data on growth and survival of TBW larvae fed squares of several *G. arboreum* and *G. hirsutum* lines. It also lists ED_{50}

[a] ED_{50} as per cent of isolated flavonoids in larval diet required to decrease growth by 50%.
[b] Significantly less than control at 0.05 level LSD.
[c] LSD for *G. arboreum* line comparisons with control ST213.

values (percent of compound required to reduce weight gain by 50%) for larvae fed diets in which *G. hirsutum* and *G. arboreum* flavonoid isolates (a mixture of flavonoids) were incorporated. Finally, it lists the content of the four major allelochemical groups (total gossypol, flavonoids, anthocyanins, and condensed tannins) of the squares of 10 of 22 *G. arboreum* lines on which larval weight was equal to or less than on ST213, and 12 of 22 lines on which larval weight was equal to or greater than on ST213. For comparison, additional data on several other *G. hirsutum* lines, some resistant to the TBW, were included.

None of the *G. arboreum* lines, except PI 408758 (which had very few glands) was statistically significant (lower or higher) with regard to larval growth, and only six were so with regard to larval survival at seven days, while all of the double haploid *G. hirsutum* lines produced smaller larvae. Estimates of ED_{50} values of the *G. arboreum* flavonoids (when incorporated in laboratory diets) varied from 0.034 to 0.090%. The average ED_{50} for lines decreasing growth was 0.06% vs. 0.07% for lines not decreasing growth (not significant). The average total flavonoid content (2.05%) of lines producing smaller larvae was lower than that of lines on which larvae were larger (2.67%), not suggestive that flavonoids were important resistance factors. On the other hand, lines decreasing growth were higher in total gossypol and tannins.

Distribution and Toxicity (ED_{50}, %) of G. arboreum *and* G. hirsutum *Flavonoids.* Table 3 lists the major flavonoids found in *G. arboreum* and *G. hir-*

TABLE 3. DISTRIBUTION OF *G. hirsutum* AND *G. arboreum* FLAVONOIDS IN LEAVES, SQUARES, AND PETALS; PERCENT OF TOTAL FLAVONOIDS AND LARVAL TOXICITY

Flavonoid	ED_{50} (%)	*G. hirsutum* (%)			*G. arboreum* (%)		
		Leaves	Squares	Petals	Leaves	Squares	Petals
Gossypetin 8-0-glucoside	0.024	0	0	0	25.8	44.7	49.8

Quercetin	0.042	0	0	3.9	0	0.1	0

sutum leaves, squares, and petals expressed as percent of total flavonoids and their estimated relative toxicities expressed as ED_{50}, %. These flavonoids were the most prevalent in *G. arboreum* of those reported by Parks (1965) and Waage and Hedin (1984) and in *G. hirsutum* (Hedin et al., 1968).

Gossypetin 8-0-glucoside and gossypetin 8-0-rhamnoside were the most toxic (ED_{50} = 0.024 and 0.007%). They were prominent flavonoids in *G. arboreum* plant tissues, but they were not found in *G. hirsutum*. Quercetin 3-0-glucoside and quercetin 7-0-glucoside were the most prevalent flavonoids in *G. hirsutum*, and they were also prominent in *G. arboreum*. Quercetin 3′-0-glucoside was also present in significant quantities in tissues of both species.

The ED_{50} values are of the same magnitude as those reported earlier (Hedin et al., 1983a,b). Four of the flavonoid glycosides could not be isolated in sufficient quantities for dietary tests. Of those tested, rhamnosides were somewhat more toxic than glucosides, supporting previous work by us (Hedin and Waage, 1986) in which it was shown that rhamnosides inhibited the growth of two bacterial species more than glucosides. Although *G. arboreum* square flavonoids were not more toxic in our dietary test than those isolated from *G. hirsutum* (Table 2), gossypetin 8-0-glucoside and gossypetin 8-0-rhamnoside may yet be contributing factors of resistance to TBW growth, considering that they are the most prevalent flavonoids in these lines. The development of cotton lines with higher levels of rhamnosides either by breeding or genetic strategies, may become a research objective.

Acknowledgments—The authors thank Phillip Wilcox for technical support.

(Received June 13, 1991; accepted October 3, 1991)

Abstract—The synthesis of (3*S*,6*R*)-3-hydroxy-1,7-dioxaspiro[5.5]undecane **(8)** and its (4*R*)-4-hydroxy isomer **(11)** from (3*R*,4*S*,6*R*)-3,4-dihydroxy-1,7-dioxaspiro[5.5]undecane **(1)**, obtained from D-fructose, has been accomplished by regioselective deoxygenation at C-4 and C-3, respectively, of the appropriately protected derivatives.

Key Words—Enantiospecific synthesis, enantiomers, spiroacetal, pheromone, Dacus oleae, olive fruit fly, Diptera, Tephritidae, D-fructose.

INTRODUCTION

The title compounds, minor components of the pheromone bouquet of olive fruit fly (*Dacus oleae*), were isolated and identified by Baker et al. (1982). Lately, several racemic (Kocienski and Yeates, 1983; Kay and Williams, 1983; Baker and Herbert, 1987; DeShong et al., 1988) and enantiospecific syntheses (Redlich and Francke, 1984; Mori et al., 1985; Bestmann and Schmidt, 1986) have been reported, where the D-glucose, *S*-malic acid and 2,3-*O*-isopropylidene-D-glyceraldehyde were used as chiral precursors, respectively. We report herein an enantiospecific synthesis of such compounds starting with D-fructose as the chiral pool.

METHODS AND MATERIALS

General Methods. Solutions were dried over $MgSO_4$ before concentration under reduced pressure. [^{13}C]- (75.4 MHz) and [^{1}H]NMR spectra (300 MHz, internal Me_4Si) were recorded with a Bruker AM-300 spectrometer of solutions in $CDCl_3$. The assignment of resonances for **8** and **11** were assisted by [^{13}C–^{1}H]COSY spectra. Infrared spectra were recorded with a Perkin-Elmer 782 spectrophotometer and mass spectra with a Hewlett-Packard HP-5988-A spectrometer. Optical rotations were measured on solutions in chloroform (1-dm tube) with a Perkin-Elmer 141 polarimeter. Thin-layer chromatography (TLC) was performed on silica gel G (Merck) (0.25 mm) with detection by charring with sulfuric acid. Column chromatography was done with silica gel Merck (7734). Tetrahydrofuran (THF) was distilled from sodium–benzophenone ketyl and stored over 4-Å molecular sieves prior to use. All compounds were shown to be homogeneous by chromatography and characterized by NMR and mass spectrometry.

(3R,4S,6R)-4-Benzyloxy-3-hydroxy-1,7-dioxaspiro[5.5]undecane **(3)** *via Dibutylstannylene Derivative* **(2)**. To a solution of 0.9 g (4.8 mmol) of (3*R*,4*S*,6*R*)-3,4-dihydroxy-1,7-dioxaspiro[5.5]undecane **(1)** (Izquierdo et al., 1991) in anhydrous methanol (15 ml), di-*n*-butyltin oxide (1.2 g, 4.8 mmol) was added and the suspension heated under reflux for 2 hr to give a clear solution. Then the solvent was removed to afford the 3,4-dibutylstannylenedioxy derivative **(2)** as a solid foam that was dried under vacuum over P_2O_5 overnight. Compound **2** was taken up in dry *N*,*N*-dimethylformamide (10 ml), treated with benzyl bromide (1.7 ml, 14.5 mmol) and heated at 110–120°C for 45 min. TLC (ether) revealed the presence of a faster-running product. Concentration of the solvent gave a residue that was dissolved in dichlorometane, washed with brine, water, and concentrated to give a residue. Column chromatography (ether–hexane, 1:2 to 1:1) afforded **3** as a syrup (620 mg, 47%), $[\alpha]_D$ −75° (*c* 1.2); ν^{film} 3469 (OH), 3092, 3066, and 3034 (C—H, aromatic), 2944 and 2874 (C—H), 1222, 1172, 1113, 1096, 1072, 1052, 1042, 1029, 1000, and 989 (C—O—C), 737 and 698 cm^{-1} (aromatic). [^{1}H]NMR (80 MHz): δ 7.30 (bs, 5 H, $CH_2\underline{Ph}$), 4.53 (s, 2 H, $\underline{CH_2}Ph$), 4.00–3.40 (m, 6 H, H-2,2′,3,4,8,8′), 2.43 (bs, 1 H, HO-3), 2.00–1.00 (m, 8 H, H-5,5′,9,9′,10,10′,11,11′). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 279 (1, M^+; pl1), 278 (4, M^+), 217 (5), 172 (5), 157 (9), 139 (11), 127 (15), 101 (20, $C_5H_9O_2^+$), 99 (22), 91 (100, $C_7H_7^+$), 83 (11), 71 (11), 65 (13), 55 (20) and 43 (20, Ac^+).

(3R,4S,6R)-3-Benzoyloxy-4-benzyloxy-1,7-dioxaspiro[5.5]undecane **(4)**. Compound **3** (0.62 g, 2.2 mmol) was benzoylated in dry pyridine (2 ml) with benzoyl chloride (0.5 ml) in the usual manner to yield, after column chromatography (ether–hexane, 1:5), **4** as a colorless syrup (0.66 g, 77%), $[\alpha]_D$ −127° (*c* 1); ν^{film} 3067 and 3035 (C—H, aromatic), 2946 and 2873 (C—H), 1721

(C=O), 1453 (benzyl), 1275, 1119, 1098, 1044, and 984 (C—O—C), 737 and 712 cm^{-1} (aromatic). [^{1}H]NMR: δ 8.15–8.00 and 7.60–7.20 (2 m, 10 H, COPh and $CH_2\underline{Ph}$), 5.50 (m, 1 H, H-3), 4.69 and 4.49 (2 d, 2 H, J = 11.7 Hz, $\underline{CH_2}Ph$), 4.05 (ddd, 1 H, $J_{3,4}$ = 3, $J_{4,5a}$ = 9.4, $J_{4,5e}$ = 8 Hz, H-4), 3.94 (dd, 1 H, $J_{2a,2e}$ = 12.8, $J_{2a,3}$ = 2.1 Hz, H-2*a*), 3.82 (dd, 1H, $J_{2e,3}$ = 1.3 Hz, H-2*e*), 3.65–3.58 (m, 2 H, H-8*a*,8*e*), 2.01–1.97 1.85–1.75, and 1.65–1.50 (3 m, 8 H, H-5*a*,5*e*,9*a*,9*e*,10*a*,10*e*,11*a*,11*e*). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 383 (1, M^++1), 382 (2, M^+), 260 (1, M^+-PhCOOH-C_7H_7), 154 (12), 139 (7), 105 (100, $PhCO^+$), 101 (4, $C_5H_9O_2^+$), 98 (23), 91 (43, $C_7H_7^+$), 77 (41), 55 (19), and 54 (12).

*(3*R*,4*S*,6*R*) -3-Benzoyloxy-4-hydroxy-1,7-dioxaspiro[5.5]undecane* ***(5)***. A solution of **4** (1.64 g, 4.3 mmol) in dry methanol (80 ml) was hydrogenated at 1.5 atm over palladium oxide (780 mg) for 6 hr. TLC (ether–hexane, 3:2) revealed the presence of a new compound of lower mobility. The catalyst was removed by filtration, washed with methanol, and the filtrate concentrated to a residue that was chromatographed (ether–hexane, 1:2 to 1:1) to afford **5** as a syrup (1.25 g, quantitative), $[\alpha]_D$ −121.2° (*c* 0.9); ν^{film} 3471 (OH), 3067 and 3037 (C—H, aromatic), 2948 and 2876 (C—H), 1724 (C=O), 1453, 1273, 1226, 1172, 1119, 1073, 1044, 981 (C—O—C), 734, and 714 cm^{-1} (aromatic). [^{1}H]NMR: δ 8.10–8.00 and 7.60–7.40 (2 m, 5 H, relative intensity 2:3, COPh), 5.22 (m, 1 H, H-3), 4.29 (ddd, 1 H, $J_{3,4}$ = 3.4, $J_{4,5a}$ = 12, $J_{4,5e}$ = 5.2 Hz, H-4), 3.93 (dd, 1 H, $J_{2a,2e}$ = 13, $J_{2a,3}$ = 2 Hz, H-2*a*), 3.82 (dd, 1 H, $J_{2e,3}$ = 1.4 Hz, H-2*e*), 3.60 (m, 2 H, H-8*a*,8*e*), 2.10 (bs, 1 H, HO-4), 1.95 (ddd, 1 H, $J_{5a,5e}$ = 11.8, $J_{3,5e}$ = 1 Hz, H-5*e*), 1.80 (t, 1 H, H-5*a*), 1.88–1.72 and 1.64–1.48 (2 m, 6 H, H-9*a*,9*e*,10*a*,10*e*,11*a*,11*e*). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 293 (1, M^++1), 292 (5, M^+), 261 (2), 192 (7, M^+-$C_5H_8O_2$), 187 (11, M^+-PhCO), 175 (4), 170 (4, M^+-PhCOOH), 140 (7), 139 (9), 127 (6), 123 (6), 105 (100, $PhCO^+$), 101 (5, $C_5H_9O_2^+$), 98 (13), 84 (14), 77 (46), and 55 (22).

*(3*S*,6*R*)-3-Benzoyloxy-1,7-dioxaspiro[5.5]undecane* ***(7)***. To a solution of **5** (1.15 g, 4 mmol) in dry 1,2-dichloroethane (25 ml), 1,1′-thiocarbonyldiimidazole (1.1 g, 6.2 mmol) was added and the mixture heated at 90° for 45 min. TLC (ether–hexane, 2:1) revealed the presence of a new compound of slightly higher mobility. The mixture was diluted with dichloromethane (25 ml), washed with 10% aqueous hydrochloric acid, water, 10% aqueous sodium hydrogen carbonate, and water. Concentration of the solvent gave a residue that was chromatographed (ether–hexane, 1:3) to afford the corresponding 4-imidazol-1-yl-thiocarbonyloxy derivative **6** (1.55 g) as a pale yellow syrup that was slightly impure.

A solution of **6** (1.55 g) and azo-bis-isobutyronitrile (100 mg) in dry toluene (30 ml) was added dropwise to a stirred solution of refluxing tri-*n*-butyltin hydride (1.7 ml, 6 mmol) in the same solvent (20 ml) under N_2. Refluxing was

continued for 6 hr. TLC (ether–hexane, 2:1) revealed that **6** had disappeared and that a new compound of higher mobility was present. Concentration of the solvent, followed by column chromatography (ether–hexane, 1:4) of the residue afforded syrupy **7** (0.9 g, 81.5% from 5), $[\alpha]_D$ −81.5° (*c* 1); ν^{film} 3067 (C—H, aromatic), 2949 and 2872 (C—H), 1717 (C=O) 1452, 1276, 1114, 1082, 1063, 996, 986 (C—O—C), and 709 cm^{-1} (aromatic). [^{1}H]NMR: δ 8.10–8.04, 7.58–7.51, and 7.46–7.39 (3 m, 5 H, relative intensity 2:1:2, COPh), 5.05 (m, 1 H, H-3), 3.91 (dd, 1 H, $J_{2a,2e}$ = 12.7, $J_{2a,3}$ = 1.7 Hz, H-2*a*), 3.83 (dt, 1 H, $J_{2e,3} = J_{2e,4e}$ = 1.9 Hz, H-2*e*), 3.69–3.63 (m, 2 H, H-8*a*,8*e*), 2.20 (ddt, 1 H, $J_{4a,4e} = J_{4a,5a}$ = 13.3, $J_{3,4a}$ = 3, $J_{4a,5e}$ = 4.7 Hz, H-4*a*), 1.95–1.81 (m, 3 H, H-5*a*,10*a*,11*e*), 1.74 (dm, 1 H, H-4*e*), 1.67–1.51 (m, 4 H, H-5*e*,9*a*,9*e*,10*e*), 1.48 (td, 1 H, $J_{11a,11e} = J_{10a,11a}$ = 13.2, $J_{10e,11a}$ = 4.2 Hz, H-11*a*). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 278 (0.1, M^++2), 277 (0.5, M^++1), 276 (3, M^+), 176 (20, M^+-$C_5H_8O_2$), 154 (5, M^+-PhCOOH), 141 (3), 124 (7), 105 (100, $PhCO^+$), 98 (60), 77 (36), and 55 (20).

(3S,6R)-3-Hydroxy-1,7-dioxaspiro[5.5]undecane ***(8)***. Conventional debenzoylation of **7** (420 mg, 1.52 mmol) in anhydrous methanol (5 ml) and 0.2 N sodium methoxide (5 ml) for 12 hr was carried out. Work-up of the reaction mixture followed by column chromatography (ether–hexane, 1:1) yielded **8** (160 mg, 61%) as a colorless syrup, $[\alpha]_D$ −134° (*c* 0.9), {lit. (Mori et al., 1985) $[\alpha]_D$ −129° (*c* 0.93, ether); lit. (Bestmann and Schmidt, 1986) $[\alpha]_D$ −135° (*c* 1, CH_2Cl_2)}; ν^{film} 3421 (OH), 2943 and 2873 (C—H), 1235, 1106, 1083, 1066, 1051, 994, 988, and 940 cm^{-1} (C—O—C). [^{1}H]NMR (C_6D_6) data were in accord with those found in the literature (Bestmann and Schmidt, 1986). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 172 (2, M^+), 155 (2, M^+-OH), 149 (5), 142 (5), 141 (4), 117 (8, $C_5H_9O_3^+$), 105 (11), 101 (17, $C_5H_9O_2^+$), 98 (34), 85 (100), 84 (56), 57 (18), 55 (24, M^+-$C_5H_9O_2$), and 47 (42).

(3R,4S,6R)-4-Benzyloxy-3-[(thiomethyl)thiocarbonyloxy]-1,7-dioxaspiro[5.5]undecane ***(9)***. A solution of **3** (740 mg, 2.7 mmol) in anhydrous THF (10 ml) was added to a stirred solution of sodium hydride (330 mg, 13.7 mmol) (80% oil dispersion) in the same solvent (5 ml) and imidazole (50 mg) under N_2 at room temperature. The mixture was refluxed for 30 min, cooled, and carbon disulfide (0.4 ml, 6 mmol) was added dropwise. The reaction was refluxed again for 30 min, cooled, and methyl iodide (0.3 ml, 4.7 mmol) was added slowly and the mixture was heated under reflux for 1 hr. TLC (ether–hexane, 3:2) revealed the presence of a new compound of higher mobility. The excess hydride was destroyed by cautious addition of ether saturated with water (30 ml) and water (15 ml). The organic phase was separated, and the aqueous phase extracted with ether (2 × 10 ml). The combined extracts were washed with brine, water, concentrated, and the residue chromatographed (ether–hexane, 1:4) to yield syrupy **9** (780 mg, 80%), $[\alpha]_D$ −118° (*c* 1); ν^{film} 3092, 3065 and

3032 (C—H, aromatic), 2948 and 2873 (C—H), 1221 (C=S), 1096, 1074, 1063, 1045, and 977 (C—O—C), 737, and 698 cm^{-1} (aromatic). [^{1}H]NMR: δ 7.40–7.20 (m, 5 H, $CH_2\underline{Ph}$), 6.10 (bs, 1 H, H-3), 4.64, and 4.46 (2 d, 2 H, J = 11.8 Hz, $\underline{CH_2}Ph$), 4.04 (ddd, 1 H, $J_{3,4}$ = 3.1, $J_{4,5e}$ = 5.4, $J_{4,5a}$ = 11.6 Hz, H-4), 4.03 (dd, 1 H, $J_{2a,3}$ = 2, $J_{2a,2e}$ = 13 Hz, H-2*a*), 3.74 (dd, 1 H, $J_{2e,3}$ = 1.2 Hz, H-2*e*), 3.62–2.95 (m, 2 H, H-8*a*,8*e*), 2.56 (s, 3 H, Me-S), 2.03–1.70, and 1.70–1.45 (2 m, 8 H, relative intensity 1:1, H-5*a*,5*e*,9*a*,9*e*,10*a*,10*e*,11*a*,11*e*). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 368 (0.1, M^+), 336 (2), 335 (12, M^+-SH), 321 (5, M^+-MeS), 261 (1.5, M^+-OCSSMe), 260 (5, M^+-MeSH—OCS), 169 (9), 154 (12), 98 (30), and 91 (100, $C_2H_3S_2^+$).

*(4*R*,6*R*)-4-Benzyloxy-1,7-dioxaspiro[5.5]undecane* ***(10)***. A solution of **9** (640 mg, 1.7 mmol) and bisazoisobutyronitrile (50 mg) in dry toluene (10 ml) was added dropwise to a stirred solution of refluxing tri-*n*-butyltin hydride (0.7 ml, 2.3 mmol) in the same solvent (5 ml) under N_2. Refluxing was continued over night. TLC (ether–hexane, 1:1) revealed the absence of **9** and the presence of a new compound of slightly lower mobility. Concentration of the solvent, followed by column chromatography (ether–hexane, 1:5) of the residue gave **10** (360 mg, 79%) as a colorless syrup, $[\alpha]_D$ −74° (*c* 1); ν^{film} 3091, 3066 and 3033 (C—H, aromatic), 2946 and 2875 (C—H), 1369, 1221, 1182, 1164, 1117, 1092, 1074, 1064, 1044, 984, and 798 (C—O—C), 736, and 697 cm^{-1} (aromatic). [^{1}H]NMR: δ 7.37–7.20 (m, 5 H, $CH_2\underline{Ph}$), 4.54 (s, 2 H, $\underline{CH_2}Ph$), 3.87 (tt, 1 H, $J_{3a,4}$ = $J_{4,5a}$ = 11.2, $J_{3e,4}$ = $J_{4,5e}$ = 4.6 Hz, H-4), 3.73 (ddd, 1 H, $J_{2a,2e}$ = 11.4, $J_{2e,3e}$ = 1.8, $J_{2e,3a}$ = 5.4 Hz, H-2*e*), 3.63 (dt, 1 H, $J_{2a,3a}$ = 11.4, $J_{2a,3e}$ = 2.3 Hz, H-2*a*), 3.63 (dt, 1 H, $J_{8a,8e}$ = $J_{8a,9a}$ = 12.7, $J_{8a,9e}$ = 2.2 Hz, H-8*a*), 3.54 (dm, 1 H, H-8*e*), 2.14 (dddd, 1 H, $J_{3e,5e}$ = 2.1, $J_{5a,5e}$ = 12.6 Hz, H-5*e*), 1.99 (ddq, 1 H, $J_{3a,3e}$ = 12.5 Hz, H-3*e*), 1.93–1.73, and 1.72–1.43 (2 m, 7 H, H-3*a*, 9*a*,9*e*,10*a*,10*e*,11*a*,11*e*) and 1.37 (dd, 1 H, H-5*a*). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 263 (0.2, M^++1), 262 (1, M^+), 189 (1), 171 (7, M^+-C_7H_7), 162 (10, M^+-$C_5H_8O_2$), 161 (5, M^+-$C_5H_9O_2$), 156 (11), 155 (8, M^+-C_7H_7O), 154 (7, M^+-C_7H_8O), 141 (19), 108 (19), 107 (19), 101 (28, $C_6H_9O_2^+$), 100 (23), 99 (25), 96 (35), 91 (100, $C_7H_7^+$), 79 (32), 77 (27), 65 (18), 55 (25), and 43 (14, Ac^+).

*(4*R*,6*R*)-4-Hydroxy-1,7-dioxaspiro[5.5]undecane* ***(11)***. A solution of **10** (280 mg, 1.1 mmol) in methanol (3 ml) and triethylamine (0.1 ml) was hydrogenated over Raney-Nickel (100 mg) at 1.5 atm for five days. TLC (ether–hexane, 3:2) revealed the presence of a new compound of lower mobility. Removal of the catalyst by filtration and concentration of the filtrate gave a residue that was chromatographed (ether–hexane, 3:2) to yield **11** (110 mg, 77.5%) as a colorless mobile oil, $[\alpha]_D$ −104° (*c* 1, *n*-pentane) [lit. (Mori et al., 1985) $[\alpha]_D$ −116° (*c* 2.45, *n*-pentane)]; ν^{film} 3410 (OH), 2947 and 2876 (C—H), 1220, 1182, 1161, 1090, 1063, 1048, 985, 873, and 798 cm^{-1}

RESULTS AND DISCUSSION

In a previous paper (Izquierdo et al., 1991), we reported on the synthesis of (3*R*,4*S*,6*R*)-3,4-dihydroxy-1,7-dioxaspiro[5.5]undecane **(1)** from D-fructose. When **1** was allowed to react with di-*n*-butyltin oxide the (not isolated) intermediate (3*R*,4*S*,6*R*)-3,4-dibutylstannylenedioxy-1,7-dioxaspiro[5.5]undecane **(2)** was obtained. Subsequent reaction of **2** with benzyl bromide occurred with

SCHEME 1.

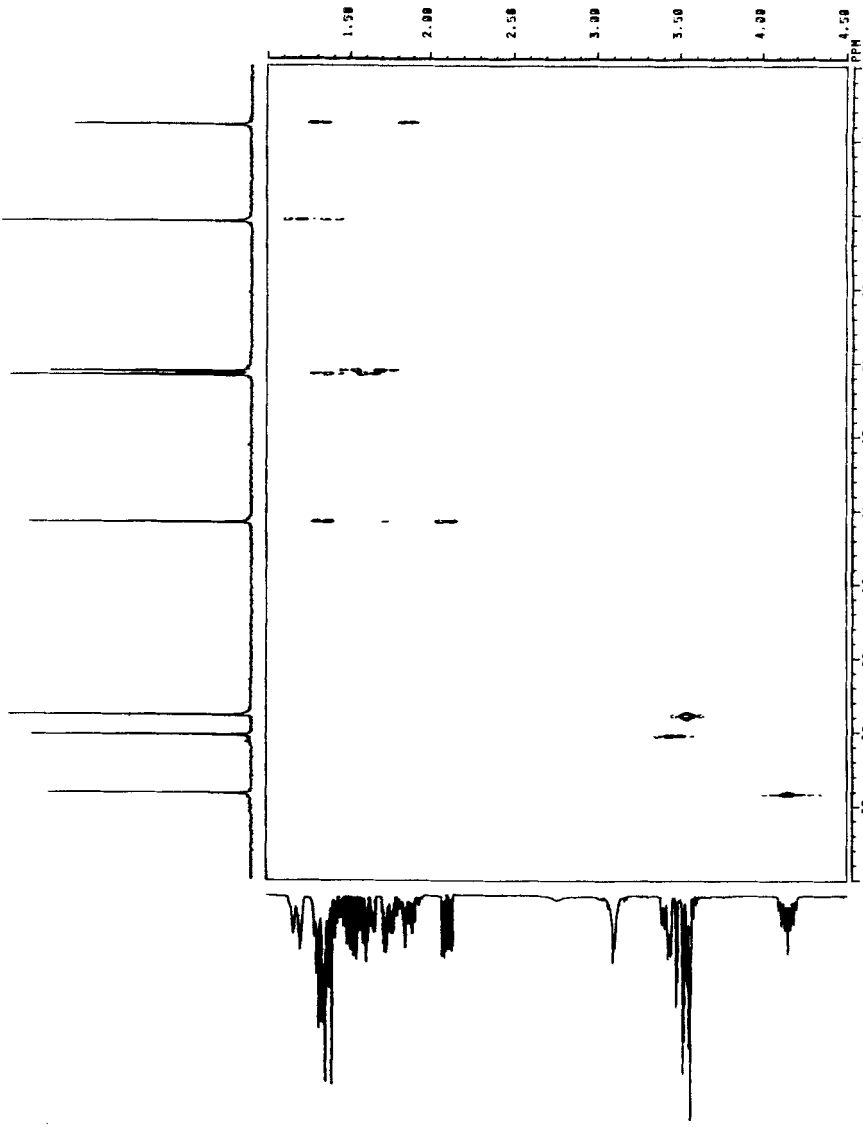

FIG. 1. Two-dimensional $^{13}C-^{1}H$ Heteronuclear shift-correlation spectrum of **8**, at a ^{1}H frequency of 300 MHz. To clarify the spectrum, [^{1}H]-and [^{13}C]NMR spectra have been included along the axes of the two-dimensional spectrum.

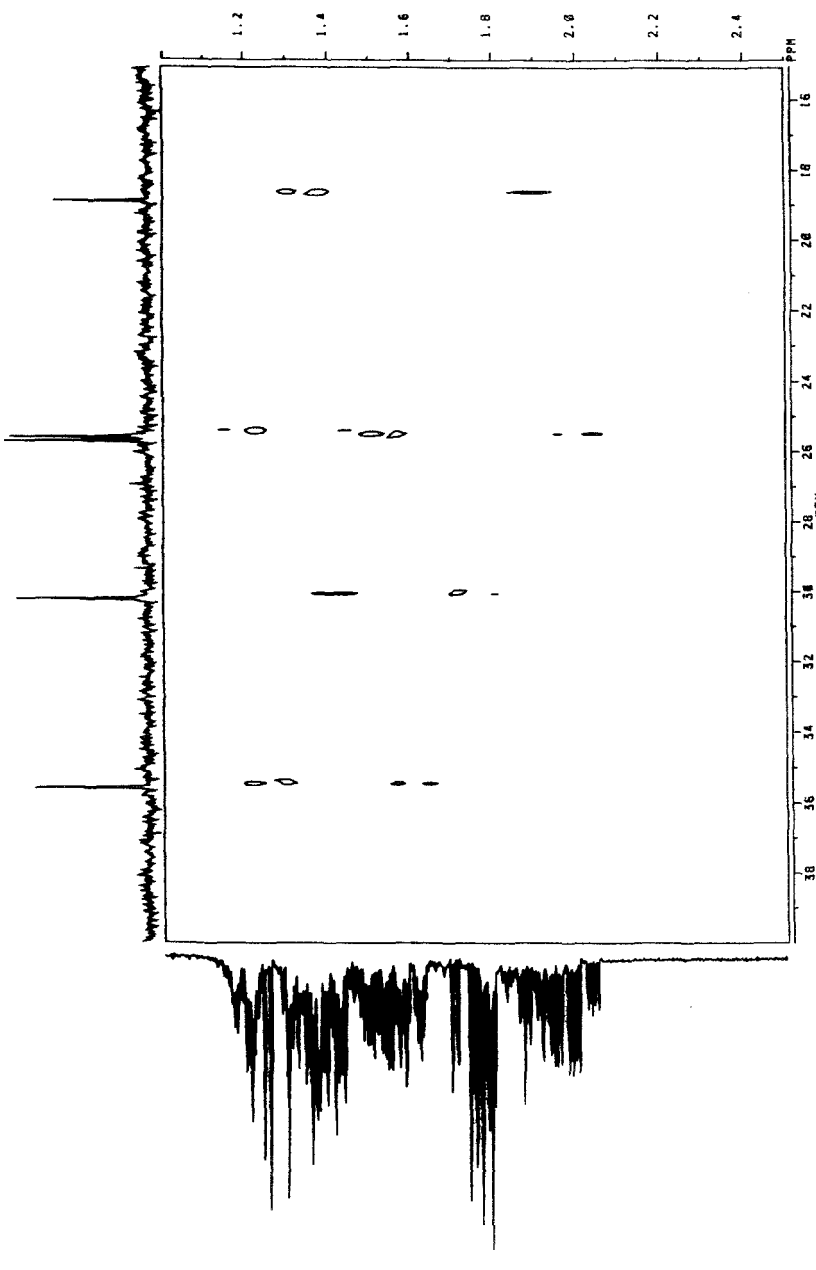

FIG. 2. Two-dimensional $^{13}C-^{1}H$ heteronuclear shift-correlation spectrum of **11**, at a ^{1}H frequency of 300 MHz. To clarify the spectrum, [^{1}H]- and [^{13}C]NMR spectra have been included along the axes of the two-dimensional spectrum.

a high regioselectivity (Nashed and Anderson, 1977; Izquierdo and Plaza, 1986, 1990), to afford the 4-*O*-benzyl derivative of **1** (**3**).

Compound **3** was transformed into the corresponding 3-benzoyloxy derivative **4**. Hydrogenolysis of the benzyl group at C-4 gave (3*R*,4*S*,6*R*)-3-benzoyloxy-4-hydroxy-1,7-dioxaspiro[5.5]undecane (**5**) that was subsequently deoxygenated by reduction (Seo, 1983) of its 4-imidazol-1-yl-thiocarbonyloxy derivative (**6**) to yield (3*S*,6*R*)-3-benzoyloxy-1,7-dioxaspiro[5.5]undecane (**7**), since an attempt to carry out the deoxygenation by a Barton's reduction (Barton and McCombie, 1975) caused the migration of the benzoyl group to the oxygen atom at C-4.

Finally, conventional debenzoylation of **7** afforded the target compound (3*S*,6*R*)-3-hydroxy-1,7-dioxaspiro[5.5]undecane (**8**), whose physical and spectroscopic data were in good agreement with those found in the literature (Mori et al., 1985; Bestmann and Schmidt, 1986) (Scheme 1).

On the other hand, compound **3** was transformed into the related (3*R*,4*S*,6*R*)-4-benzyloxy-3-[(thiomethyl)thiocarbonyloxy]-1,7-dioxaspiro[5.5]-undecane(**9**) that was reduced by the Barton's method to yield the corresponding 3-deoxy derivative (**10**). Hydrogenolysis of the benzyl group at C-4 gave the expected (4*R*,6*R*)-4-hydroxy-1,7-dioxaspiro[5.5]undecane (**11**), which showed physical and spectroscopic data in agreement with those previously reported (Mori et al., 1985). We have included the assignment of the [^{1}H]- for **11** and [^{13}C]magnetic resonance data for **8** and **11** (Figures 1 and 2).

(Received June 13, 1991; accepted October 9, 1991)

Abstract—A nematicidal toxin was purified from *Pleurotus ostreatus* NRRL 3526 grown on moistened, autoclaved wheat straw for 30 days at room temperature (21–33°C). The active compound, at a concentration of 300 ppm, immobilized 95% of test nematodes (*Panagrellus redivivus*) within 1 hr. Immobilized nematodes did not recover, even after being rinsed with deionized water. The toxin was identified as *trans*-2-decenedioic acid.

Key Words—*trans*-2-Decenedioic acid, *Pleurotus ostreatus*, fungus, nematotoxin, *Panagrellus redivivus*, fatty acids, ostreatin, dicarboxylic acids, natural nematicides, nematoda, *Penagrellus redivivus*.

INTRODUCTION

Several species of wood-rotting basidiomycetes capture and consume nematodes as a supplementary source of nitrogen and other nutrients to the fungus (Thorn and Barron, 1984). Barron and Thorn (1987) described the mechanism used by *Pleurotus ostreatus* (Jacq. ex Fr.) Kummer (the oyster mushroom) to rapidly immobilize the nematodes, enabling fungal hyphae to penetrate, colonize, and digest the host. Droplets from specialized secretory cells produced in older portions of the fungal colony contain a potent, but unidentified, nematotoxin that was assigned the trivial name ostreatin. Once a nematode touches these

[1]The mention of firm or trade names does not imply that they are endorsed or recommended by the U.S. Department of Agriculture over other firms or similar products not mentioned.

droplets, it is immobilized in as little as 30 sec. We have confirmed their findings. In this paper, we report the isolation and structure elucidation of a nematotoxic compound from *P. ostreatus* NRRL 3526 grown on moistened, autoclaved wheat straw, a substrate on which the fungus produced massive numbers of secretory cells and toxin droplets.

METHODS AND MATERIALS

Cultures. Pleurotus ostreatus NRRL 3526 was obtained from the U.S. Department of Agriculture, Agricultural Research Service Culture Collection, Peoria, Illinois, and maintained on potato dextrose agar (PDA). We observed that this fungal strain captured nematodes when grown on water agar as described by Thorn and Barron (1984). The test nematode *Panagrellus redivivus* L. was supplied by Professor B.M. Zuckerman, Massachusetts Agricultural Experiment Station, Amherst, Massachusetts. The nematode culture was maintained on a uracil-requiring strain (OP-50) of *Escherichia coli* (Migula) Castellani & Chalmers on NG agar (Brenner, 1974) and transferred weekly.

Toxin Production. Pleurotus ostreatus was cultured on moistened, autoclaved wheat straw for the production of nematotoxin(s). We observed that *P. ostreatus* produced massive numbers of secretory cells and toxin droplets when grown on Arthur variety wheat (*Triticum aestivum* L.) straw, a lignocellulosic substrate. The wheat straw was cut into 2.5- to 7.5-cm lengths and ca. 60 g packed loosely in individual Fernbach flasks, which were then filled with tap water and the straw allowed to soak for 1 hr. The water was then decanted, and the flasks cotton-stoppered and autoclaved twice on two consecutive days at 15 psi for 60 min. After the flasks cooled, the substrate in each flask was inoculated by transferring two mycelial plugs (8 mm) excised from the growing margin of the fungal colony on a PDA plate. The cultures were incubated statically at room temperature (21–23°C) for 30 days, during which time the fungus colonized the entire mass of wheat straw.

Toxin Purification. Following incubation, 750 ml water was added to each flask, and the contents (i.e., mass of fungus-colonized straw) were agitated with a glass rod, followed by wrist-action shaking for 15 min. The aqueous extract was filtered first through a single layer of tissue paper (Kimwipes, Kimberly-Clark Corp.), and then through Whatman No. 1 filter paper. The water extract was then lyophilized in shallow trays. After the residue from 12 flasks was reconstituted in 50 ml water, 50 ml methanol was added, and the resulting precipitate was removed by centrifugation. The supernatant was evaporated to dryness in a rotary evaporator. After the residue was dissolved in 10 ml water, 90 ml methanol was added, and the resulting precipitate was removed by centrifugation. The supernatant was again evaporated to dryness, and the residue

was dissolved in 5 ml water. Forty-five milliliters of acetone was added, and insoluble materials were separated by centrifugation. The fractions from each precipitation step were redissolved or suspended in water, and then checked for nematicidal activity. The acetone-soluble fraction was purified further by high-pressure liquid chromatography (HPLC). A Beckman HPLC system equipped with a UV detector containing a preparative flow cell and a semipreparative C-18 column (10 × 250 mm) was used throughout the purification process. The system was operated isocratically with various methanol–water mobile phases at a flow rate of 2 ml/min. The elution was monitored at 210 nm. Each fraction was evaporated to dryness and redissolved in water prior to the nematotoxin bioassay. An uninoculated flask of autoclaved wheat straw was extracted and processed the same way to serve as a control.

Bioassay. The nematotoxin bioassay was performed in 400-μl flat-bottomed microtiter wells. Nematodes were removed from a 7-day-old culture with a stream of deionized water from a wash bottle. The nematodes were transferred to an 18 × 150-mm culture tube and allowed to settle to the bottom. After 15 min, most of the liquid containing the bacteria was aspirated, and fresh deionized water was added to suspend the nematodes to a population of 2000–4000/ml. No attempt was made to remove the bacteria completely. One hundred to two hundred nematodes in a volume of 50 μl were added to each well containing 50 μl aqueous solution of toxin sample. When the test material was in organic solvent, the solvent was removed in a rotary evaporator and the residue suspended in water for the assay. The nematodes were monitored for 1 hr with the aid of a dissecting microscope. Tests for toxicity were scored positive when 95% of the nematodes were immobilized within 1 hr. The relatively short test duration should limit any interference from the contaminating bacteria (*E. coli*) in the bioassay.

To quantify the nematotoxicity of pure compounds, the materials were dissolved in ethanol and serial twofold dilutions were made directly in the microtiter wells. The solvent was allowed to evaporate, and 100–200 nematodes in 100 μl water were then added. The results were recorded after 1 hr. The concentration that immobilized 95% of the nematodes within 1 hr was termed ED_{95}. Besides the *Pleurotus* toxin, other structurally related compounds and two commercial nematicides were also tested for comparison. The compounds were the simple fatty acids (C_6–C_{18}, Sigma Chemical), dicarboxylic acids (C_6–C_{12}, Sigma Chemical), chloethocarb [2-(2-chloro-1-methoxyethoxy)-phenyl methylcarbamate, BASF], and oxamyl [methyl 2-(dimethylamino)-*N*-{[(methylamino)carbonyl]oxy}-2-oxoethanimidothioate, DuPont].

Reversibility of Immobilization. After the nematodes were immobilized by *Pleurotus* toxin (300 ppm, 1 hr), they were transferred from the microtiter well to 100 ml deionized water in a 400-ml beaker. The nematodes were collected on an 8-μm Millipore membrane filter, rinsed with 10 ml deionized water, and

then transferred to a 60 × 15-mm Petri dish with 5 ml deionized water. The nematodes were observed for sign of recovery for 2 hr and were rechecked after 24 hr.

Structure Determination. Proton and carbon NMR data were obtained in CD_3OD on a Bruker WM-300 spectrometer, and chemical shifts were recorded using the signals for the residual protiated solvent and deuterated solvent as references (3.30 ppm for ^1H; 49.0 ppm for ^{13}C). Carbon multiplicities were established by a DEPT experiment. The CI mass spectrum of the toxin was obtained with the solids probe on a Finnigan TSQ 46 instrument. An aliquot of the *Pleurotus* toxin was methylated with diazomethane and analyzed by GC-MS on a Finnigan/Mat TSQ 46 instrument. The column was a DB-1 capillary column (15 m, 0.25 μm film, J & W Scientific). The temperature of the GC was 70°C for the first 2 min and was increased to 250°C at a rate of 10°/min.

RESULTS

Toxin Purification. Nematicidal activity was not detected in the initial water extract, but it was detected in the concentrated solution following lyophilization. When methanol was added to this toxin solution to a concentration of 90%, the toxic principle remained soluble, and no activity was detected in the precipitate. The methanol-soluble fraction was further purified by an acetone precipitation step. All the nematotoxic activity was found in the acetone-soluble fraction, which was further purified by HPLC. Extracts from the uninoculated flask did not have any biological activity.

With HPLC, the toxic principle was eluted in the void volume by 50% methanol. When the active fraction was rechromatographed with a mobile phase of 40% methanol, the toxic activity was eluted at 48 min. The peak was broad and nonsymmetrical. Finally, the mobile phase was changed to 0.1% acetic acid in 40% methanol. The toxic activity was eluted as a single peak at 62 min. The purified compound was a colorless solid, very soluble in methanol and acetone, and slightly soluble in water. The yield from 1800 g fermented wheat straw (36 Fernbach flasks) was 5 mg.

Structure Determination. The CI mass spectrum showed a protonated molecular ion (MH^+) peak at *m/z* 201, suggesting a molecular weight of 200 ($C_{10}H_{16}O_4$). The proton NMR data (Table 1) show a one-proton doublet at 5.79, which is coupled to a one-proton multiplet at 6.94, indicating a double bond between a carbonyl group and a CH_2 group. The observed coupling constant (15.5 Hz) demonstrates a *trans* configuration for the double bond. The carbon NMR data (Table 1) show six methylene carbons, two olefinic carbons, and two carboxyl carbons. No end methyl group was detected. After methylation with diazomethane, the methylated sample emerged from the gas chromatograph

as a single peak with a retention time of 7 min, 36 sec. The CI mass spectrum had an intense protonated molecular ion at *m/z* 229, indicating the formation of two methyl ester groups. All these data suggest a structure of *trans*-2-decenedioic acid for the toxin (Figure 1).

Nematotoxicity Test. The nematode *P. redivivus* was very active in water, wiggling from side to side. In the presence of the *Pleurotus* toxin, the movement gradually slowed, and eventually the nematodes became totally immobile. The immobilized nematodes did not recover, and after 24 hr they were considered dead because their bodies became straight and opaque. However, we do not know exactly when death occurred. At a concentration of 300 ppm, the purified *Pleurotus* toxin immobilized 95% of the nematodes within 1 hr. At higher concentrations, paralysis occurred more rapidly, often within minutes. In some tests, we rinsed the nematodes soon after immobilization and placed them in fresh deionized water but not a single nematode, out of approximately 200, recovered.

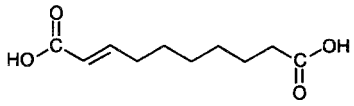

FIG. 1. The nematicidal toxin from *Pleurotus ostreatus* NRRL 3526 *trans*-2-decenedioic acid.

Several simple fatty acids and dicarboxylic acids were also tested for their toxicity to nematodes. The medium-chain fatty acids (C8–C12) were more toxic than the corresponding dicarboxylic acids and the *Pleurotus* toxin (Table 2). At high concentrations (>2500 ppm), the medium-chain fatty acids killed the nematodes instantaneously. By contrast, chloethocarb, at a concentration of 10,000 ppm, did not immobilize the nematodes within 24 hr, while oxamyl immobilized the nematodes only at concentrations of 2500 ppm or higher. However, although the nematicides did not immobilize or kill the nematodes, they effectively disabled the nematodes at low concentrations. At a concentration as low as 25 ppm, the rhythmic motion of the nematodes ceased, their bodies appeared contorted, and they moved only feebly.

DISCUSSION

Nematode-destroying fungi produce elaborate traps to capture nematodes (Barron, 1977). Once captured, the nematodes do not struggle much and become quickly paralyzed. The general belief is that fungal toxins produced in the traps paralyze or kill the captured nematodes. Several such toxins have been reported from nematode-trapping species of *Arthrobotrys* (Olthof and Estey, 1963; Balan

[a]Toxin concentration that immobilizes 95% of the test nematodes within 1 hr.

and Gerber, 1972; Balan et al., 1974), *Dactylaria* (Krizkova et al., 1976), *Monacrosporium* (Balan et al., 1974), and *Nematoctonus* (Giuma and Cooke, 1971; Giuma et al., 1973; Kennedy and Tampion, 1978). Other than ammonia implicated as a nematotoxin (Balan and Gerber, 1972), none of the toxins has been purified.

Unlike the nematode-trapping fungi, *P. ostreatus* does not produce traps or adhesive cells. Instead, it produces tiny droplets of toxin from minute spatulate secretory cells. Once a nematode touches the droplets, it is immobilized in as little as 30 sec (Barron and Thorn, 1987). Because *P. ostreatus* does not produce any mechanical device to restrain a struggling nematode, it may be likely to produce a more potent toxin than those produced by the trap-forming fungi, so that the nematodes are paralyzed quickly and cannot escape.

We used a solid substrate to culture *P. ostreatus* for the production of the nematotoxin, because *P. ostreatus* does not produce toxin droplets in liquid culture (Barron and Thorn, 1987). Wheat straw provides a low-nutrient natural substrate with a large surface area for *P. ostreatus*. Massive numbers of droplet-producing secretory cells could be seen on fungal hyphae colonizing individual lengths of wheat straw. We used water to extract the nematotoxin, because the nematotoxin from *Nematoctonus* species has been reported to be water soluble (Giuma et al., 1973). In addition, our strategy was to focus on the toxin-containing droplets and to minimize our chances of removing metabolites from the fungal mycelium. While this gentle extraction procedure should cause little damage to fungal cells, we have no direct evidence that the nematotoxin we isolated was from the droplets. The toxin droplets are only 2–5 μm in diameter (Barron and Thorn, 1987). At the present time, we do not know of any practical way to harvest the droplets and to determine the toxin concentration in the droplet.

Our test nematode, *P. redivivus*, is free-living and is highly active in water, in contrast to most plant parasitic nematodes, which move feebly. *P. redivivus* is, therefore, a more suitable test organism to detect nematoxins, as sublethal toxic effects can be perceived easily by observing any reduction in motility. On the other hand, it is more difficult to count the fast-moving nematodes, and the background mortality rate was high. Therefore, accurate determination of LD_{50} is unrealistic, so we express our results as ED_{95}, which is defined as the concentration of toxin that immobilizes 95% of the nematodes. We also limited our bioassay to 1 hr and discarded any fraction that did not immobilize the nematodes within 1 hr, because we were searching for fast-acting nematotoxins that would explain the immobilization we observed on Petri plates.

The toxin was purified by HPLC and was identified as *trans*-2-decenedioic acid by NMR and mass spectrometry. This structure has been reported previously by Cram and Tishler (1948) for a microbiologically inactive compound isolated from a crude penicillin preparation from *Penicillium notatum*. Since

trans-2-decenedioic acid was fast-acting, it is probably the ostreatin described by Barron and Thorn (1987). It is probably formed by enzymic oxidation of linolenic acid via the intermediates 10-hydroperoxy-*E*-8,*Z*-12,*Z*-15-octadecatrienoic acid and 10-oxo-*E*-8-decenoic acid, as described in the fungus *Psalliota bispora* (Wurzenberger and Grosch, 1986).

trans-2-Decenedioic acid immobilized 95% of the nematodes within 1 hr at 300 ppm. Under the same test conditions, oxamyl did not immobilize or kill the nematodes within 24 hr until the concentration was increased to 2500 ppm, whereas chloethocarb was not lethal at 10,000 ppm for 24 hr. Although the commercial nematicides did not immobilize or kill the nematodes immediately, they effectively disabled 95% of the nematodes at 25 ppm. Therefore, *trans*-2-decenedioic acid acts quite differently from the acetylcholinesterase inhibitors.

After we identified the toxin as a dicarboxylic acid, we screened several structurally related compounds for nematicidal activity. Maximum biological activity was associated with a 10-carbon backbone (Table 2). *trans*-2-Dodecenedioic acid (traumatic acid), which is a plant hormone with two more carbon atoms than *trans*-2-decenedioic acid, had no nematicidal activity. The monocarboxylic acids (fatty acids) were more active than the corresponding dicarboxylic acids. Medium-chain fatty acids have been shown to be toxic to nematodes (Munkata, 1983), insects (Fogleman and Kircher, 1986; Puritch, 1978), fungi (Teh, 1974), and yeasts (Hunkova and Fencl, 1977). However, there were no prior reports of similar biological activity for dicarboxylic acids.

Because of their fast action, we believe that *trans*-2-decenedioic acid, medium-chain dicarboxylic acids, and fatty acids act by affecting membrane permeability. Many useful drugs, which are lipophilic acids, act in this way (Freese, 1978). The change in cell membrane permeability would affect the normal function of the nerve and muscle cells, resulting in a reduction and cessation of muscle contraction. After prolonged exposure, leakage of the cytoplasm into the surroundings would eventually cause death. When we rinsed the nematodes with deionized water soon after they were immobilized, they did not recover. Presumably, enough leakage of the cytoplasm had already occurred by the time they were paralyzed, and the damage became irreversible. Our result confirms the finding of Barron and Thorn (1987), who reported that when immobilized nematodes on *P. ostreatus* culture on water agar were transferred to a fresh water agar plate, only one out of 25 recovered.

trans-2-Decenedioic acid and related compounds are simple natural compounds and are, thus, biodegradable. They should be safer to use than most synthetic nematicides. Our results showed that a 10-carbon backbone is required for maximal biological activity. Better nematicides may be synthesized by adding other functional groups to the 10-carbon backbone.

So far, we have found only one nematicidal compound from *P. ostreatus*: *trans*-2-decenedioic acid. It is likely that *P. ostreatus* produces, in addition to

attractants, several toxins that may act synergistically. Even the presence of a common, nontoxic organic acid (i.e., acetic acid) in the toxin droplets should produce a synergistic effect, since the penetration of the cuticle of the nematode by *trans*-2-decenedioic acid would be enhanced at low pH. It is possible that we may have missed other more lipophilic nematotoxic compounds because we used water to extract the toxins.

To the best of our knowledge, *trans*-2-decenedioic acid is the first nematotoxin ever purified from nematode-destroying fungi. Additional investigations are needed on natural nematicides from these fungi.

Acknowledgments—We thank our colleagues, John Richard, Harold Gardner, and Susan McCormick for critical review of the manuscript and valuable suggestions. We acknowledge helpful discussions with Professor G.L. Barron, University of Guelph.

(Received August 12, 1991; accepted October 15, 1991)

Abstract—A glass slide bioassay was used to evaluate male twospotted spider mite, *Tetranychus urticae* Koch, arrestment caused by quiescent deutonymph extract. Males that were guarding quiescent deutonymphs prior to being tested were arrested by a 3-mm-diameter circle of quiescent deutonymph extract; nonguarding males and adult females were not arrested. Extracts of all *T. urticae* instars tested caused male arrestment, but mean arrestment duration was longest with quiescent deutonymph extract. Arrestment by volatile perception of pheromone and upwind orientation to point sources of extract were not observed. The mono- and sesquiterpene alcohols previously identified as components of the pheromone did not arrest males. HPLC separation of extract resulted in four active fractions; a subtractive bioassay showed that three were essential to elicit maximum male response.

Key Words—*Tetranychus urticae*, twospotted spider mite, Arachnida, Tetranychidae, quiescent deutonymph, female sex pheromone, bioassay, arrestment, active components.

INTRODUCTION

Twospotted spider mite, *Tetranychus urticae* Koch, is a serious pest of more than 150 economically important hosts throughout the world. Despite numerous instances where biological control has been used for control of *T. urticae*, acaricides are the most widely used control method in commercial situations (Jeppson et al., 1975).

Efforts to combat the resistance and registration problems that have beset many commercially available acaricides have encouraged the development of alternative control strategies. One possible *T. urticae* control method is mating disruption by use of synthetic pheromones. Numerous Acari-specific pheromones and other semiochemicals have been identified (Sonenshine, 1985 and references therein), and semiochemicals have been used to control Ixodid ticks (Ziv et al., 1981). Therefore, use of pheromones to manage *T. urticae* in commercial situations warrants investigation.

T. urticae mating behavior has been described extensively (Ewing, 1914; Lehr and Smith, 1957; Cone et al., 1971b; Potter et al., 1976; Potter and Wrensch, 1978; Cone, 1985). Female deutonymphs deposit webbing on the leaf surface and become quiescent. Males encountering quiescent deutonymphs can become arrested locally near the female; the probability of arrestment increases as ecdysis approaches (Cone et al., 1971b; Potter et al., 1976). Arrested male behavior has been described as "guarding" (Ewing, 1914; Lehr and Smith, 1957; Cone, 1979, 1985); arrested males may remain immobile, touch the idiosoma of the female with their forelegs and palps, and attack other males that encounter the quiescent female. Males assist females in emergence from the exuviae and immediately attempt mating (Laing, 1969; Potter et al., 1976; Cone, 1985).

Cone et al. (1971a) concluded that quiescent deutonymphs contained chemicals attractive to *T. urticae* males. They labeled the chemical(s) a female sex pheromone, but concluded that their bioassay was inadequate to aid in the identification of the pheromone. Subsequent efforts to identify the chemical composition of the sex pheromone are inconclusive. Regev and Cone identified the sesquiterpene alcohols farnesol (1975a) and nerolidol (1976a), and the monoterpene alcohol citronellol (1980) as possible pheromonal components. They also observed that topical applications of farnesol increased the fecundity of *T. urticae* adult females (Regev and Cone, 1976b), and suggested that the observed positive correlation between host-plant farnesol content and the plant's susceptibility to *T. urticae* was due to the gonadotropic effect of farnesol or to its pheromonal activity (Regev and Cone, 1975b; Regev, 1978). However, identification of compounds was done solely on the basis of gas chromatographic retention times; no mass spectroscopy was performed.

Our studies were done to reaffirm that a sex pheromone is involved in the guarding behavior of *T. urticae* males towards quiescent deutonymphs. Fulfillment of this objective involved extraction of female sex pheromone from quiescent deutonymphs and the development of a quick, discriminating bioassay for male *T. urticae* response. The bioassay was used to describe male response, to identify the mechanism of pheromone perception, and to bioassay the terpenoid compounds previously identified by Regev and Cone as pheromonal components. We also separated the components of the sex pheromone and determined

the combination of fractions necessary to elicit maximum male *T. urticae* response.

METHODS AND MATERIALS

Arrestment by Contact Chemoreception: Evidence of Female Sex Pheromone. T. urticae were reared on Henderson lima beans, *Phaseolus lunatus* L., at 25°C, 60% relative humidity, and on a 14:10 light–dark photoperiod. Two hundred fifty quiescent deutonymphs were immersed in 1.0 ml of HPLC grade hexane (Mallinckrodt, Inc., Paris, Kentucky) for 48 hr. All extractions used in our studies were stored under N_2 in the dark at 0–5°C to preserve potential activity.

The arrestment activity of the extract was bioassayed by placing one quiescent deutonymph equivalent (QDE) (4.0 μl) of extract on a glass microscope slide using a 5-μl syringe (Hamilton Co., Reno, Nevada). The extract was placed in a 3-mm-diameter circle. The slide was dried in air for 30 min to allow the solvent to evaporate. Controls consisted of 4.0 μl of hexane deposited in a 3-mm-diameter circle. Using this method, the response of mites observed in our studies could be attributed solely to chemicals extracted from quiescent deutonymphs (Waage, 1978).

One randomly selected *T. urticae* was placed on the edge of the circle using a camel-hair brush. Care was taken to transfer the mite as quickly and gently as possible; the mite was discarded if it stuck to the brush or was damaged during the transfer process. Arrestment was described by the amount of time the mite spent within the circle of extract. Arrestment ended if the mite left the circle of extract for >5 sec.

We tested the arrestment activity of the extract on guarding adult males, nonguarding adult males, and adult females. Arrestment of guarding and nonguarding males by the control also was measured. To ensure that mites did not respond to the hexane control, the response of 20 guarding males to the 3-mm circle of hexane was compared to their response to an untreated circle [t test (Snedecor and Cochran, 1967)].

Each treatment was replicated with 20 mites. Differences in response between sexes, guarding behaviors, and the extract and control were described by analysis of variance with a randomized complete block design and the Student-Newman-Keuls test (Snedecor and Cochran, 1967; CoHort Software, 1986). This statistical procedure was used for all subsequent bioassays unless otherwise specified.

Arrestment by Contact Chemoreception: Comparison of Solvents. Two hundred fifty quiescent deutonymphs were immersed in 1.0 ml of either hexane, diethyl ether, or methanol (HPLC grade) (Mallinckrodt, Inc.) for 48 hr. Extrac-

tions were done using solvents with differing polarities to ensure that all pheromone components were eluted from the mites.

The arrestment activity of 1 QDE of each extract–solvent mixture was bioassayed as described previously. Each solvent–extract mixture was tested with 20 adult male mites. Males that were guarding quiescent deutonymphs on lima bean leaves were selected. A 2-min preobservational period was included to allow the mites to acclimate to their new surroundings. Arrestment was described by the amount of time the male spent within the circle of extract. The male was considered unarrested if it left the circle of extract for >5 sec.

Arrestment by Contact Chemoreception: Effect of Different Extraction Times. Extracts were prepared by soaking 250 quiescent deutonymphs in 1.0 ml of methanol or hexane for one of 11 different time intervals ranging from 5 min to 96 hr. Bioassays (1 QDE) of guarding *T. urticae* adult male response to the different extraction times were done as described in the solvent comparison study. Fifteen male mites were tested for each extraction. *T. urticae* male response times were regressed on extraction times using SYSTAT MGLH (Wilkinson, 1990).

Arrestment by Contact Chemoreception: Effect of Concentration and Extractions from Other Instars. Previous bioassays demonstrated that guarding adult males were arrested by quiescent deutonymph extract. Because males occasionally are observed guarding other instars, female sex pheromone may be present in instars other than quiescent deutonymphs. We tested for the presence of *T. urticae* female sex pheromone in protonymphs, quiescent protonymphs, female deutonymphs, and adult males and females. Extracts were prepared by soaking 1000 mites of each instar in separate 250-μl aliquots of hexane for 72 hr. Nine concentrations of each extraction, ranging from 0.01 to 25 mite equivalents (ME), and a 4.0-μl hexane control were tested by the response of 22 guarding male *T. urticae*. A 2-min preobservational period was included to increase the discriminatory power of the bioassay. Data were analyzed by regressing log(duration of arrestment) on log(mite equivalents + 1) to determine the concentration ranges of extracts necessary to elicit maximum male response. CoStat Statistical Software (CoHort Software, 1986) was used for the regression analysis.

Arrestment by Volatile Chemoreception. Behavior of adult male mites in an extract-laden airstream was used to test for *T. urticae* volatile chemoreception. The airstream apparatus was constructed by placing a circular piece of Fisherbrand P5 filter paper (Fisher Scientific, Pittsburgh, Pennsylvania) in a 65-mm Buchner funnel. The funnel was attached to a 500-ml Erlenmeyer flask, and the flask connected to a cold-water aspirator to create a vacuum. A glass tube (7 mm diameter × 100 mm long) was suspended vertically 4 mm above the filter paper. The mite extract was spread on the inside surface of the tube 50 mm from the filter paper and a 5-cm/sec airstream blown downwards through

the tube. The extract-laden airstream emerging from the tube was sucked through the filter paper by the vacuum apparatus so that a 7-mm-diameter extract–air column was maintained directly beneath the mouth of the glass tube. The air was filtered with activated charcoal before entering the glass tube to remove impurities.

Each assay consisted of one adult male *T. urticae* placed on the edge of the air column. Males that were guarding quiescent deutonymphs on lima bean leaves were selected. Arrestment was described by the amount of time the male spent within the circular air column. A 1-min preobservational period was included to allow the mite to become acclimated.

Two concentrations (1 and 10 QDE) were tested for each solvent; 4.0 μl hexane was used for the control. Each assay was replicated with 19 male *T. urticae*.

Orientation by Volatile Chemoreception to an Extract Source. Previous researchers have concluded that the attraction of males to quiescent deutonymphs occurred from an approximate maximum distance of 2–3 mm (Cone et al., 1971a; Penman and Cone, 1974); therefore, our upwind orientation studies were done in moving air on glass microscope slides. A 24-mm × 35-mm rectangular arena was outlined on each slide with lanolin to prevent the mites from escaping. Two point sources (3 mm diameter) of quiescent deutonymph extract were placed on the slide approximately 8 mm apart and 7 mm from the upwind edge of the arena. The male mite was placed 1 cm downwind from the extract points, and a 5-cm/sec airstream was blown over the extract towards the mite. Two concentrations (0.5 and 5 QDE/point) were assayed for each solvent extraction (hexane, diethyl ether, and methanol). The control consisted of two 2.0-μl points of hexane. In addition, 1 QDE of the hexane extract was tested in still air for comparison.

Total time for each test was 3 min. The time the mite took to reach one of the extract deposits was subtracted from 3 min, hence a male's failure to locate the extract during the 3-min period was scored as a zero response. Twelve replicates of each treatment were tested.

Bioassay of Terpenoid Compounds. Four quantities (ranging from 4 to 4000 ng in 4.0 μl methanol) of farnesol, nerolidol, geraniol, and citronellol (Sigma Chemical Co., St. Louis, Missouri) were tested. Response of male *T. urticae* to each terpenoid, to the four terpenoids combined, and to 1 QDE of methanol extract were tested as described in the previous contact chemoreception bioassays. It was anticipated that the terpenoid compounds would not cause arrestment for the entire 2-min preobservational period. Therefore the acclimation period was not included to provide more accurate comparisons with the methanol control.

Each synthetic terpenoid was tested by the response of 14 male *T. urticae*. Mean male response times to the terpenoids and extract were compared to the

mean response to the methanol control by analysis of variance and Dunnett's procedure (1955).

Initial Isolation of Active Components. Concentrated extract (2500 QDE/250 μl hexane) was prepared as described in previous bioassays. A 100-μl (1000 QDE) sample of extract was fractionated using a Hewlett Packard model 1090 liquid chromatograph with an HP Hypersil silica column (5-μm particle size; 200 mm × 2.1 mm internal diameter). The mobile-phase program (flow rate = 1 ml/min) consisted of 2 ml hexane, an 8-ml linear conversion from hexane to diethyl ether, a 6-ml linear conversion to CH_2Cl_2, and 4 ml CH_2Cl_2 column flush. Eighteen 1-ml fractions were collected.

Response of guarding adult male *T. urticae* to the 18 fractions and the original extract was evaluated as described in the previous contact chemoreception bioassays. The concentration tested was reduced to 0.25 QDE to increase bioassay discrimination (Baker and Cardé, 1984). Each fraction was tested by the response of 16 males. Controls consisted of 1.0 μl hexane.

Subtractive Bioassay of Active Fractions. Eight 1-ml HPLC fractions from the initial separation bioassay were tested further using a subtractive bioassay technique. The purpose of the subtractive bioassay was to determine the fractions that contained components necessary to elicit maximum arrestment of male *T. urticae*. First, all eight fractions were combined (0.5 QDE of each) and bioassayed, and the observed arrestment compared to that caused by the extract. Next, individual fractions were subtracted from the combination and the remaining fractions tested. If male arrestment caused by a new combination was significantly less than that caused by all the fractions, the subtracted fraction was considered to contain an essential component of the pheromone.

Each treatment was tested by the response of 16 male *T. urticae*. We suspected that fraction 3 probably contained small amounts of the active components found in fractions 2 and/or 4; therefore, this fraction was subtracted in combination with both 2 and 4 when testing for reduced activity in the two latter fractions. Similarly, fractions 15–17 were tested as one combined fraction.

RESULTS AND DISCUSSION

Arrestment by Contact Chemoreception: Evidence of Female Sex Pheromone. Data showing the arrestment response of guarding males, nonguarding males, and adult females to the circle of extract and to the hexane control are presented in Figure 1. Males that were guarding a quiescent deutonymph immediately prior to the bioassay were arrested by the extract for a significantly longer period relative to the control [$F = 52.42$; $df = 4, 76$; $P = 0.0001$; W_p (critical value for the Student-Newman Keuls test) = 48.02 sec]. These data suggest that chemicals are present in the quiescent deutonymph extract that arrest the

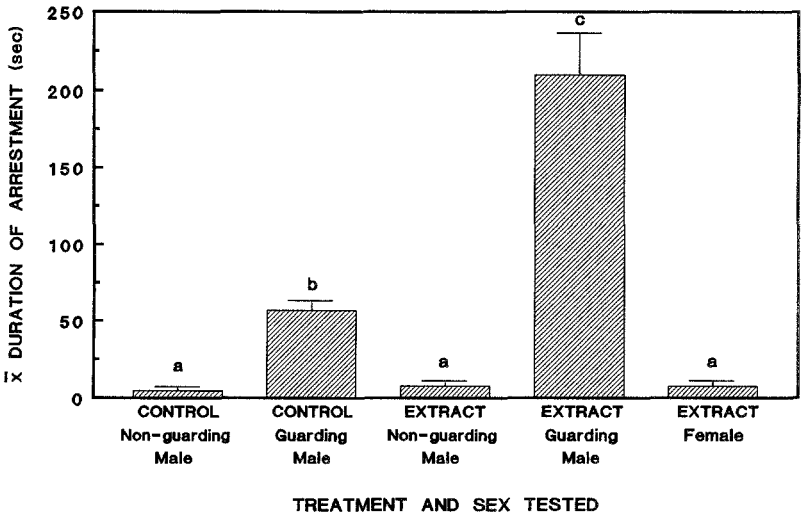

FIG. 1. Mean duration of adult male and female *T. urticae* arrestment caused by 1 QDE of extract. Error bars are standard errors of means. Means with the same letter were not significantly different [$P = 0.05$; Student-Newman-Keuls test (Snedecor and Cochran 1967)].

movement of guarding adult males. Typically, arrested males walked in tight circles within the 3-mm circle of extract. Upon moving out of the circle, the males immediately reversed direction until they reencountered the extract. Arrested males occasionally became immobile, or pivoted back and forth on their hind legs, dragging the tarsi and tibiae of the forelegs across the glass slide. Unarrested mite movement was more linear; these mites often walked off the glass slide 5–10 sec after placement. Although these responses were not quantified, the circular ambulatory movement may be a localized searching behavior; upon pheromone perception the male attempts to locate a source in the vicinity through tactile or visual stimuli. Males also exhibit circling behavior while covering quiescent deutonymphs with webbing (Penman and Cone, 1974).

The time spent in the hexane circle by guarding males also was significantly longer than the time spent by nonguarding males. Guarding males remained within the 3-mm circle for nearly a minute despite the absence of extract. Positive response to the control was not a result of the arresting effects of hexane, as guarding males also remained within an untreated 3-mm circle longer than nonguarding males ($P = 0.05$, $N = 20$; t test). Continuation of localized ambulatory behavior after stimulus removal suggests that response to the presence or absence of sex pheromone is not instantaneous. Therefore, a 2-min preobservational period was included in subsequent studies to allow the guarding males to acclimate to their surroundings.

The time spent in the extract circle by adult females did not differ significantly from the response of nonguarding males to the hexane controls. These data suggest that the chemical is sexually specific to male *T. urticae*. Response of nonguarding adult males to extract also did not differ significantly from their response to the controls. The lack of response by nonguarding males along with the positive response of guarding males to the hexane control suggest that the pheromone is context specific; initiation or cessation of the male's guarding behavioral mode is not controlled solely by the presence of female pheromone. Observations of male behavior under natural conditions support this conclusion; males often walk next to and over quiescent deutonymphs without becoming arrested (Ewing, 1914; Lehr and Smith, 1957; Cone et al., 1971b; Penman and Cone, 1974; Potter et al., 1976). Guarding behavior is initiated by perception of pheromone, tactile, and/or visual stimuli, but male sensitivity to these stimuli probably depends on other factors as well. Possible factors regulating initiation or cessation of adult male *T. urticae* guarding behavior are abiotic environmental conditions. Cone et al. (1971b) observed more frequent male response to quiescent deutonymphs at higher temperatures and lower humidities. Host plant quality also could affect the onset of mating behavior. Males frequently wander the surface of the leaves and intermale conflicts over quiescent deutonymphs are rare when *T. urticae* are colonizing nutrient-rich host plants, while during periods of host-plant decline males guard quiescent deutonymphs almost exclusively and conflicts are observed frequently (Potter et al., 1976; Potter, 1978; Potter and Wrensch, 1978). Conflict with other males often results in cessation of arrestment (Potter et al., 1976), and internal factors such as the male's sperm supply, past mating history, or physiological age (Cone and Pruszynski, 1972; Potter and Wrensch, 1978) also may affect male guarding behavior.

The fact that only guarding males were arrested may explain the low response rates observed in earlier studies (Cone et al., 1971a,b; Penman and Cone, 1974). Since nonguarding males did not respond to quiescent deutonymph extract, we used only guarding males in all subsequent bioassays.

Arrestment by Contact Chemoreception: Comparison of Solvents. No significant differences were observed in the guarding adult male *T. urticae* response to any of the quiescent deutonymph extract–solvent combinations, and all combinations arrested *T. urticae* longer than the control [$F = 6.86$; $df = 3, 57$; $P = 0.001$; $W_p = 107.03$ sec (Figure 2)]. These results show that the three solvents extracted all the pheromonal components from quiescent deutonymphs, as reported previously by Cone and Pruszynski (1972). Therefore, all subsequent bioassays were done using the hexane extract.

Arrestment by Contact Chemoreception: Effect of Different Extraction Times. Relationships between extraction time ($\hat{Y}$) and duration of arrestment (x) for the hexane and methanol extractions were best described by the Michaelis-Menton equation $\hat{Y} = ax/(b + x)$, where a_{hexane} ($\pm$SEM) = 192.82 $\pm$ 8.37,

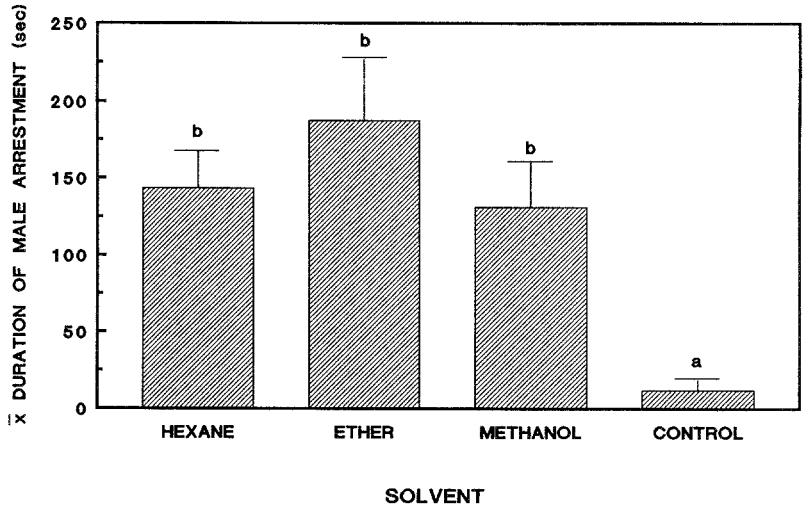

FIG. 2. Mean duration of male *T. urticae* arrestment caused by 1 QDE of extracts in different solvents. Error bars are standard errors of means. Means with the same letter were not significantly different [$P = 0.05$; Student-Newman-Keuls test (Snedecor and Cochran 1967)].

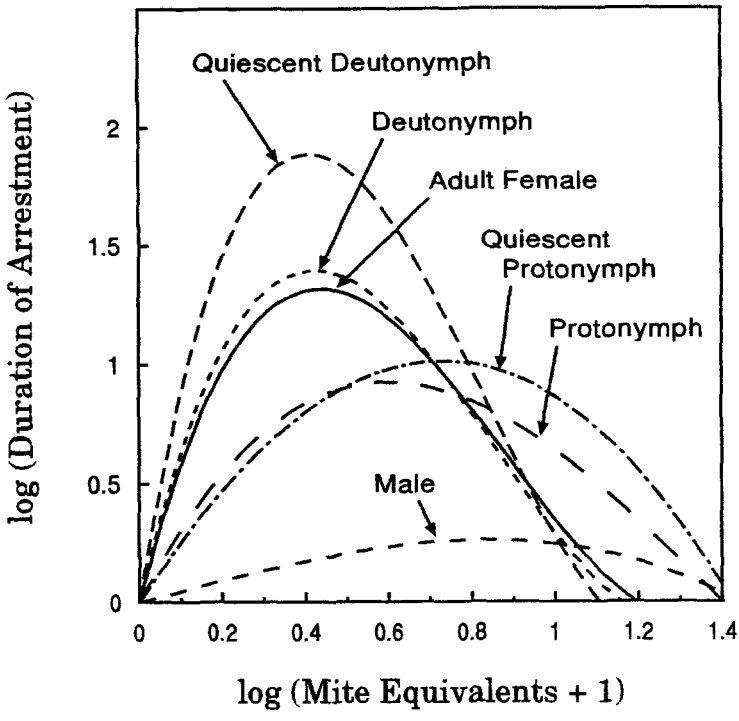
$b_{\text{hexane}} = 0.22 \pm 0.09$; $F = 355.52$, $df = 2, 163$; $P = 0.00001$; $r^2 = 0.74$, $a_{\text{methanol}} = 206.06 \pm 8.38$, $b_{\text{methanol}} = 0.16 \pm 0.06$; $F = 389.53$; $df = 2, 163$; $P = 0.00001$; $r^2 = 0.74$). No differences were observed in the extraction rates of the two solvents (b_{hexane} vs. b_{methanol}) ($t = 0.52$; $df = 2, 326$; $P = 0.05$) or in the maximum amount of pheromone extracted (a_{hexane} vs. a_{methanol}) ($t = 1.12$; $df = 2, 328$; $P = 0.05$). These results show that male *T. urticae* response to the extracts, and therefore extraction of pheromone from quiescent deutonymphs, was substantial even at short extraction times (≤ 1 hr), and did not increase substantially at times >2 hr.

Arrestment by Contact Chemoreception: Effect of Concentration and Extractions from Other Instars. Regressions of log(duration of arrestment) ($\hat{Y}$) against log(mite equivalents + 1) (x) show that extracts from all *T. urticae* instars elicited a response by guarding males (Figure 3). Relationships were best described by third-order polynomials, suggesting that maximum male *T. urticae* response to extracts occurred at a range of 1–10 ME for all instars. No male response occurred at concentrations <0.1 ME, and males usually avoided concentrations >10 ME (although a few individuals were arrested for extended time periods).

Maximum male *T. urticae* response to quiescent deutonymph, deutonymph, and adult female extracts occurred at approximately 1 ME, but mean durations of arrestment caused by deutonymph and adult female extracts were substantially



Regression Equations[a]

Adult Female	$\hat{Y} = 6.19x - 8.43x^2 + 2.65x^3$; $r^2 = 0.58$; $F = 88.19$
Quiescent Deutonymph	$\hat{Y} = 10.43x - 16.91x^2 + 6.90x^3$; $r^2 = 0.66$; $F = 127.24$
Deutonymph	$\hat{Y} = 7.65x - 12.44x^2 + 5.07x^3$; $r^2 = 0.58$; $F = 89.40$
Quiescent Protonymph	$\hat{Y} = 2.42x - 0.32x^2 - 1.44x^3$; $r^2 = 0.46$; $F = 50.88$
Protonymph	$\hat{Y} = 1.58x + 2.12x^2 + 2.86x^3$; $r^2 = 0.47$; $F = 52.52$
Male	$\hat{Y} = 0.46x + 0.02x^2 - 0.24x^3$; $r^2 = 0.11$; $F = 8.85$

[a] df = 3, 195 for all regressions.

FIG. 3. Regression of log(mean duration of male *T. urticae* arrestment) on log(mite equivalents) of extracts from different instars.

shorter than were caused by quiescent deutonymph extract. One explanation for these data is that deutonymphs and adult females lack pheromonal components essential to elicit maximum male response. It also is possible that quiescent deutonymphs contain greater quantities of female sex pheromone than adult females and deutonymphs. Higher concentrations (>2 ME) of deutonymph and adult female extracts may have contained sufficient sex pheromone to elicit arrestment comparable to that observed with 1 QDE of quiescent deutonymph extract, but the consequent increased concentrations of pigments and other chemicals in the extracts may have interfered with the guarding males' ability to perceive or respond to the sex pheromone.

Cone et al. (1971a) reported arrestment over a narrow concentration range, but observed maximum activity at 0.01–0.1 QDE. The disparity in results probably is due to the difference in experimental methods. Cone et al. (1971a) applied extract to plastic clumps approximately 1 mm in diameter, and placed the clumps on hop, *Humulus lupulus* L., leaf disks. These clumps concentrated the extract to an area smaller than the 3-mm circle used in our study, in addition to supplying the males with visual and tactile stimuli. Another difference between the two studies was the host plants used for mite cultures (hops vs. lima beans); Cone and Pruszynski (1972) reported that males reared on hops were arrested more frequently by extract-treated clumps than were males reared on beans.

The regression equations predict that maximum responses to the protonymph, quiescent protonymph, and male extracts were observed at the 5- to 8-ME range. The protonymph and quiescent protonymph extracts probably were either missing one or more of the components or contained lower concentrations of pheromone than the more mature instars. The relationship between concentration of male extract and duration of response was minimal. However, arrestment of a few males was observed at the 1-ME concentration, suggesting that male *T. urticae* probably contain small quantities of at least some of the components.

Orientation and Arrestment by Volatile Chemoreception to an Extract Source. No significant differences in *T. urticae* male response to the column of extract-laden air were observed among solvents, and none of the treatments differed significantly from the control ($F = 0.75$; $df = 6, 108$; $P = 0.05$; $W_p = 40.99$ sec). Similar data were collected for the upwind orientation study; no significant differences in the latency until arrestment [3 min − (time until male arrestment)] were observed among solvents at either 1 or 10 QDE, and no treatment differed from the control ($F = 0.70$; $df = 6, 66$; $P = 0.05$; $W_p = 22.97$ sec). Failure of male *T. urticae* to become arrested by the extract-laden airstream or to orient towards the upwind extract source suggests an inability to perceive sex pheromone in the air. Further evidence demonstrating *T. urticae*'s inability to detect extract via volatile chemoreception is the number of males that reached the point sources and became arrested during the upwind orientation

study. Initial placement of male *T. urticae* was 1 cm from the extract point sources, yet only 25% of males tested in this study became arrested at the point sources during the 3-min observation period.

The negative results of the arrestment and upwind orientation by volatile chemoreception studies disagree with Penman and Cone (1972). They observed a positive correlation between male *T. urticae* linear movement and duration of male exposure to quiescent deutonymphs, and therefore concluded that male perception of female sex pheromone volatiles initiated a searching behavior characterized by linear motion. They also observed that the mat of webbing deposited by the deutonymph prior to the final molt amplified this linear relationship. Our studies show that arrested males become immobile or move in tight circles and that unarrested male movement is more linear. A reinterpretation of Penman and Cone's results may explain this difference. Penman and Cone stopped observing males that became arrested by deutonymphs, thus failing to include the circling behavior of guarding males in their calculations. By the end of their study, they were measuring the movement only of males that had not become arrested. Consequently, what they described as linear searching behavior initiated by chemoreception of pheromone may have been a combination of orientation to quiescent deutonymphs through visual cues, orientation by tactile or chemoperception of the webbing spun by the deutonymph prior to becoming a chrysalis, and linear motion typical of unarrested males.

Bioassay of Terpenoid Compounds. Mean response time of male *T. urticae* to any of the four terpenoids did not differ from response to the control at any concentration [$F_{4ng} = 17.38$, $d'_{4ng} = 66.50$; $F_{40ng} = 17.87$, $d'_{40ng} = 63.80$; $F_{400ng} = 16.21$, $d'_{400ng} = 66.45$; $F_{4000ng} = 28.99$, $d'_{4000ng} = 56.88$; $df = 6, 78$; $P = 0.0001$; $t_{Dunnett} = 2.48$ (Table 1)]. In addition, all synthetics combined did not elicit a response that differed from the control. These results show that farnesol, nerolidol, geraniol, and citronellol probably are not components of *T. urticae* female sex pheromone.

Our results differ substantially from those obtained by Regev and Cone (1975a, 1976a, 1980). One possible explanation for the differing results are the bioassays used in the two studies. We collected data continuously for a maximum time period of 10 min, while their data were collected intermittently for several hours; no continuous observations were made. Another difference was their use of polyvinylpyrrolidone clumps as the pheromone source. Substantial numbers of males were observed guarding the control clumps, indicating male visual or mechanoperception of the clumps. Therefore, although significantly greater numbers of male guarding responses were observed with farnesol-, nerolidol-, and citronellol-treated clumps than with ethanol-treated controls, the frequency of male arrestment by control clumps suggests that the observed number of positive responses to treated clumps may have been exaggerated by the mites' tactile or visual perceptions of the source.

Initial Isolation of Active Components. Bioassays of HPLC-fractionated extract (Figure 4) showed that four of the 18 fractions (2, 4, 9, 12) caused significantly greater male *T. urticae* arrestment than the hexane control (F = 10.82; df = 19, 361; P = 0.0001; W_p = 53.01 sec). The presence of inactive

	$\bar{X}$ response time (sec) ± SEM[a]			
Terpenoid	4 ng	40 ng	400 ng	4000 ng
Farnesol	85.7 ± 18.9a	77.7 ± 14.3a	73.0 ± 14.3a	47.1 ± 10.9a
Nerolidol	60.4 ± 10.2a	47.3 ± 10.2a	52.1 ± 9.5a	38.4 ± 7.1a
Geraniol	49.4 ± 11.0a	64.1 ± 16.2a	81.4 ± 21.3a	32.6 ± 7.5a
Citronellol	66.4 ± 10.1a	91.6 ± 8.8a	61.6 ± 8.8a	27.3 ± 4.5a
Combined	63.3 ± 10.2a	54.4 ± 9.3a	63.2 ± 12.6a	26.9 ± 7.4a
Extract (1 QDE)	268.0 ± 38.1b			
Control	76.3 ± 13.3a			

[a]Means followed by the same letter are not significantly different from the control [P = 0.05; Dunnett's procedure (1955)].

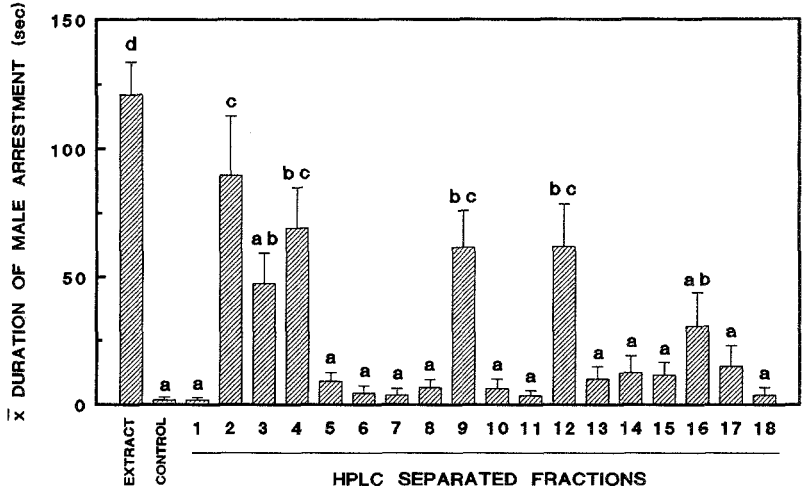

FIG. 4. Mean duration of male *T. urticae* arrestment caused by 0.5 QDE of HPLC-separated extract fractions. Error bars are standard errors of means. Means with the same letter were not significantly different [P = 0.05; Student-Newman-Keuls test (Snedecor and Cochran 1967)].

fractions between the four peaks of activity and the fact that the active fractions were eluted from the column by solvents of differing polarities suggest that each active fraction contained a different pheromonal component.

Fractions 3 and 16 also caused noticeable male *T. urticae* arrestment, although activity of these fractions did not differ significantly from the control. The apparent activity of fraction 3 may have been due to the presence of small quantities of the active components found in 2 and/or 4. Fraction 16, however, was collected in a solvent of greater polarity than the other active fractions. Therefore, the possible activity observed during the bioassay of this fraction probably was caused by a different pheromonal component.

The arrestment durations caused by the four active fractions were significantly shorter than the duration caused by the unseparated extract. The greater activity caused by the extract suggests that more than one pheromonal component is necessary to elicit maximum male response.

Subtractive Bioassay of Active Fractions. No significant differences were observed between the arrestment time caused by the extract and all of the fractions combined [$F = 6.38$; $df = 8, 152$; $P = 0.0001$; $W_p = 80.08$ sec (Figure 5)]. Therefore, all the active pheromonal components found in the extract probably were contained in the eight combined fractions.

No significant differences were observed among the durations of arrestment caused by all fractions combined and combinations lacking fractions 3, 12, or

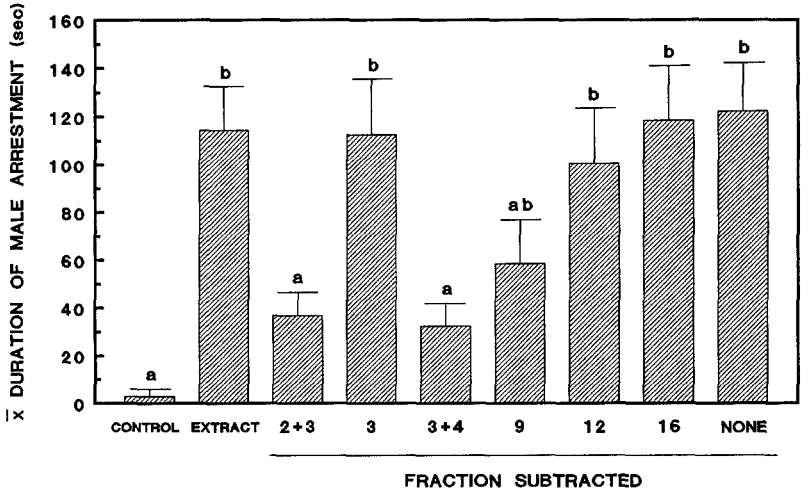

FIG. 5. Mean duration of male *T. urticae* arrestment from 0.5 QDE subtractive bioassay of active extract fractions. Error bars are standard errors of means. Means with the same letter were not significantly different [$P = 0.05$; Student-Newman-Keuls test (Snedecor and Cochran 1967)].

15–17. These results show that these three fractions were not essential to elicit maximum male *T. urticae* response. In addition, the insignificant arrestment caused by fractions 3 and 15–17 in the bioassay of individual fractions suggests that they probably do not contain pheromonal components.

Subtraction of fractions 2, 4, or 9 did cause a significant reduction in the duration of *T. urticae* male arrestment, as the duration of arrestment caused by their omissions did not differ significantly from the control. Therefore, the components of these three fractions are necessary to elicit maximum male response.

Our studies confirm that sex pheromone is present in *T. urticae* that arrests adult males. Extracts of adult females, males, and all immature instars elicited male response, but maximum duration of male response was observed with pheromone extracted from quiescent deutonymphs. These data agree with previous observations that while males frequently guard all *T. urticae* instars (including other males), they guard quiescent deutonymphs most frequently. Guarding quiescent deutonymphs is the optimum reproductive strategy for males, as mating with newly molted virgin females ensures that the male's sperm will be used for fertilization (Helle, 1967; Potter et al., 1976; Potter and Wrensch, 1978). Therefore it is logical to expect that the instar most likely to arrest males would be the quiescent deutonymph.

Only males that were guarding quiescent deutonymphs immediately prior to testing were arrested; nonguarding males did not respond. These data show that initiation of arrestment and guarding behavior probably is dependent on perception of other stimuli as well as the physiological state of the male; the primary function of sex pheromone is to prolong arrestment and guarding behavior.

Upwind orientation to point sources of pheromone and arrestment within a moving column of pheromone-laden air were not observed. These results suggest that volatile perception of pheromone by male *T. urticae* does not occur, and therefore males do not use volatile pheromone to locate quiescent deutonymphs.

HPLC separations showed that *T. urticae* female sex pheromone consists of at least four distinct active components. The three least polar fractions were necessary to elicit maximum male response, but full activity was observed when the most polar fraction was subtracted from the combination. Unlike Regev and Cone, we were unable to show that farnesol, nerolidol, and citronellol were components of *T. urticae* sex pheromone; if these alcohols are produced by *T. urticae*, they probably are not the essential components isolated in our studies.

Penman and Cone (1972, 1974) concluded that males locate quiescent deutonymph females through volatile chemoreception of sex pheromone. However, the range of male arrestment described in their studies was limited [1–2 mm (Penman and Cone, 1974)]. In addition, male response to extract sources was significantly greater on 10.3-mm leaf disks than on 21.0-mm disks (Cone and Pruszynski, 1972); the effect of disk area on source location by males

probably would have been negligible if males could perceive and/or orient to pheromone sources by olfaction. Our volatile chemoreception and upwind orientation studies do not support the hypothesis that male *T. urticae* perceive sex pheromone by olfaction. We suggest that males wandering on the leaf surface probably locate quiescent deutonymphs by short-range orientation to cues such as mechano- or chemoperception of the webbing spun by the deutonymph prior to becoming quiescent (Penman and Cone, 1972), visual perception of the quiescent deutonymph, or by chance. Males perceive sex pheromone by contact chemoreception; perception initiates localized searching behavior characterized by frequent turning and/or pivoting. Males recognize the source of pheromone as a quiescent deutonymph by assimilating tactile, visual, and contact chemoreceptive information, and guarding behavior subsequently begins. Future studies will attempt to determine the chemical composition of *T. urticae* female sex pheromone and to define more clearly the role of the various cues in the intersexual interaction of *T. urticae*.

Acknowledgments—We thank Beth A. Lucius for help in collecting quiescent deutonymphs and for maintaining *T. urticae* cultures, and R.A.J. Taylor for help with statistical analyses. Dana L. Wrensch, Richard K. Lindquist, and Heng Chen Lin provided helpful comments on early drafts of the manuscript. (Received June 10, 1991; accepted October 15, 1991)

Abstract—Furocoumarin distribution patterns in the fruits and seeds of *Psoralea macrostachya* and *P. onobrychis* were investigated. Both species contain the linear furocoumarin psoralen and its angular isomer, angelicin. In the monospermous indehiscent fruit of *P. macrostachya*, furocoumarins occur in the pericarp and all seed parts. In *P. onobrychis*, the pericarp of which is easily detached at ripeness, no furocoumarins were found in the pericarp tissues and only traces occur in the embryo axis; cotyledons are the preferential accumulation site. The within-fruit and -seed furocoumarin variations associated with the developmental stages of fruit were followed in *P. onobrychis*, in view of changes in the defensive value of the pericarp before and after ripening. Rapid furocoumarin biosynthesis after fertilization was observed in both pericarp and seed; ripening is associated with furocoumarin decrease in the seed and complete disappearance in the pericarp tissues. Such findings are consistent with the chemical defense role of these substances. The cooccurrence of linear and angular isomers seems to be a chemical marker of the genus *Psoralea:* the biosynthetic pathway leading to the angular isomer as an evolutionary response to selective pressure from herbivore insects is suggested.

Key Words—*Psoralea macrostachya* DC., *P. onobrychis* Nutt., furocoumarins, psoralen, angelicin, within-fruit and -seed allocation, chemical defense, germination inhibitors, allelopathy.

INTRODUCTION

Natural products such as furocoumarins have been regarded as protective agents in plants against predation by insects (Berenbaum and Feeny, 1981; Muckensturm et al., 1981; Berenbaum et al., 1984; Berenbaum, 1985) and by vertebrates (Ivie, 1978). A number of coumarin derivatives show antimicrobial (Fowlks et al., 1958; Fischer et al., 1976) and antifungal (Chakraborty et al., 1957) activities and may therefore prevent seed decay before germination (Rice, 1984).

Furocoumarins also act as seed germination inhibitors (Rodighiero, 1954; Fukushi, 1960) and plant growth regulators (Bennett and Bonner, 1953; Shimomura et al., 1982), and their role as allelopathic agents has been suggested (Junttila, 1976; Friedman et al., 1982). Whether furocoumarins function as autoinhibitors of germination is still an open question: they are believed to be responsible for the inhibition of seed germination in *Psoralea subacaulis* (Baskin et al., 1967) and *Angelica archangelica* (Zobel and Brown, 1991), whereas other umbelliferous species exhibit resistance or avoidance of autointoxication (Friedman et al., 1982, and references therein).

Furocoumarin distribution patterns within reproductive structures are of interest in connection with their suggested roles as germination regulators for the plant itself, as allelopathic agents, and as chemical defense against herbivores and pathogens. The importance of recording phenological changes of furocoumarin content within reproductive structures in order to evaluate the physiological and/or ecological significance of these compounds has been stressed (Berenbaum and Zangerl, 1986; Nitao and Zangerl, 1987).

As part of research on species belonging to the genus *Psoralea* as natural sources of biologically active furocoumarins of pharmaceutical interest (Cappelletti et al., 1984; Innocenti et al., 1977, 1984, 1991), we examined furocoumarin distribution patterns within the reproductive structures of *P. onobrychis* and *P. macrostachya* (for furocoumarin contents in the vegetative organs of these species, see Innocenti et al., 1991).

The fruits of *P. onobrychis* have never previously been investigated with respect to their coumarin content, whereas *P. macrostachya* fruits are known to contain psoralen and angelicin (Innocenti et al., 1977); their distribution within fruits and seeds, however, has not been studied.

In *P. macrostachya* the pericarp is free from the ripe seed and the monospermous fruit is indehiscent, which is typical of the genus according to Hutchinson (1964). In contrast, in *P. onobrychis* the pericarp is detached at ripeness, releasing the seed.

In order to evaluate the ecological significance of furocoumarins in chemical defense, we compared the distribution patterns of these compounds within

the reproductive structures of these two *Psoralea* species, in which very different ecological values and roles must be attributed to the pericarp tissues.

METHODS AND MATERIALS

Plant Material. Plants of two American *Psoralea* species [*Psoralea onobrychis* Nutt. of moist areas from Ohio to Missouri and southward to South Carolina and Tennessee (Rickett, 1967) and *P. macrostachya* DC. of moist areas and salt marshes of California (Mason, 1957)] were cultivated under identical environmental conditions in the Botanical Garden of the University of Padova. For both *Psoralea* species, ripe fruits collected in September were used.

To record phenological changes in furocoumarin contents of the reproductive structures of *P. onobrychis*, samples were collected at the following stages: stage 1: flowers; stage 2: fertilized ovaries (just after petal fall); stage 3: ovaries 5 mm long; stage 4: ovaries 8 mm long; stage 5: ovaries 11 mm long; stage 6: ripe fruits.

Fruit and Seed Morphology. Fruit and seed samples were prepared for SEM examination following the previously described procedure, which consists of sample fixation in 6% glutaraldehyde in 0.1 M cacodylate buffer (pH 6.9) in the dark at 0°C for 24–48 hr, gradual dehydration in acetone of increasing concentrations, critical-point drying in a Balzers Union critical point dryer, coating with gold in an Edwards S 150 A sputter coater, and observation under a Cambridge Stereoscan 250 at the accelerating voltage of 20 kV (Cappelletti and Trevisan, 1983).

Sample Preparation. Three different plants of the two *Psoralea* species were investigated. Each sample consisted of tissues taken from at least 10–20 fruits from a single plant. Ripe fruits (and also fruits of stage 5), were separated by microdissection under a binocular microscope, and the following subsamples were obtained: (1) pericarp, (2) seed coats, (3) cotyledons, and (4) shoot–hypocotyl–root axis of embryo. Sample and subsample weights ranged from 0.6 to 2.5 g.

Chemical Analysis. The extraction procedure takes into account the cooccurrence of both free and bound furocoumarins in the fruits of leguminous plants (Stöll et al., 1950; Innocenti et al., 1984). Samples dried *in vacuo* (20°C) were extracted with MeOH in a Soxhlet extraction apparatus for 48 hr, and the methanolic extract was concentrated (fraction I). Fraction I contained the furocoumarins occurring in the plant in the free form. The extracted marc was refluxed for 2 hr in 30 ml of 5% HCl. After cooling and filtration, an acid residue and an aqueous–acid phase were obtained. Following a previously described procedure for exhaustive psoralen extraction (Innocenti et al., 1984), the acid res-

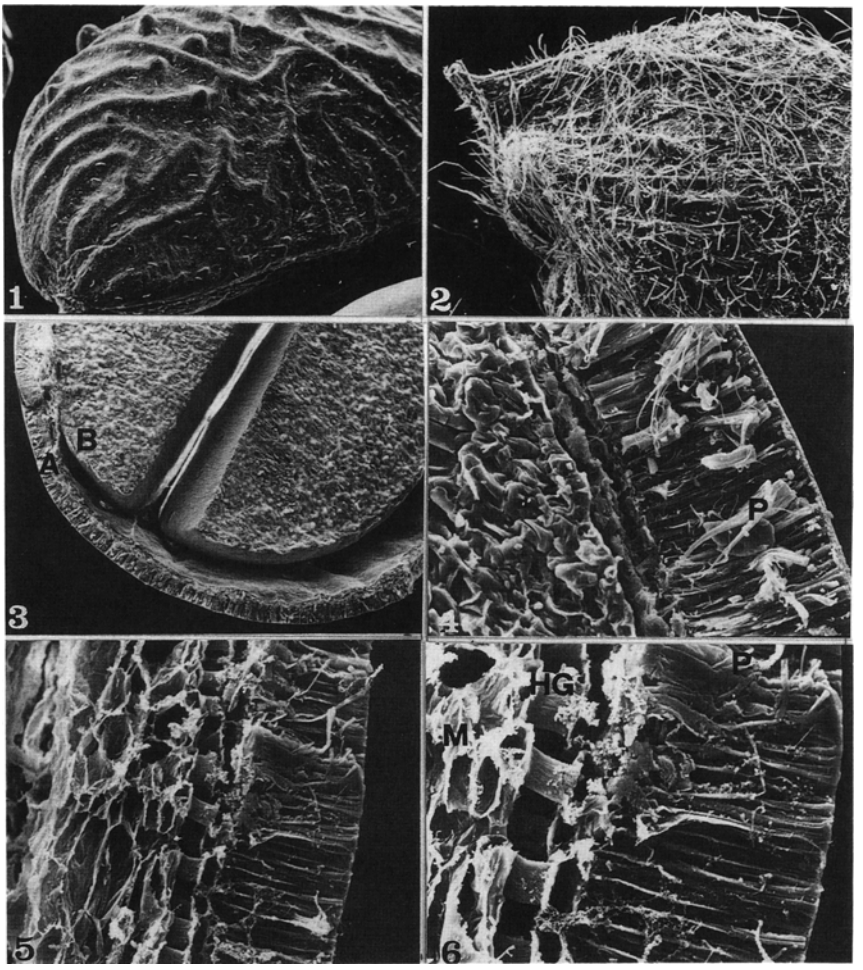
idue was extracted with MeOH for 48 hr and the methanolic extract was then concentrated (A). The aqueous-acid phase was extracted with Et_2O (48 hr); after distillation of the solvent, the residue was dissolved in MeOH (B). Methanolic solutions A and B were combined (fraction II). This fraction contained the furocoumarins occurring in the plant in bound form. Fractions containing both free and bound coumarin forms were combined and analyzed.

Psoralen and angelicin were isolated by TLC (silica gel plates with $CHCl_3$ or EtOAc–cyclohexane in different ratios as eluents) (Innocenti et al., 1989, 1991) and identified by their UV and mass spectra and by comparison with authentic samples. The furocoumarin contents in the different plant parts were determined by HPLC under the following conditions: Si gel column VIOSIL SI 10 μm (Violet) 250 × 4.6 mm ID with a small precolumn (25 × 4.6 mm ID) packed with Si gel Spherisorb 10 μm, mobile phase *n*-hexane–$CHCl_3$ (71:29; v/v); flow-rate 2 ml/min; sample size injected 10 μl, detection at 300 nm. Retention times: angelicin 2.34 min, psoralene 2.93 min. For each solution, quantification was carried out using 5,8-dimethoxypsoralen (5,8-DMOP) as the internal standard. Calibration curves were determined using a series of standard solutions containing a constant amount of internal standard and varying amounts of stock psoralen and angelicin (Innocenti et al., 1991). The quoted data are the average values of quantitative determinations performed on the three samples each taken from a single plant. Standard deviation was shown to be less than 5%. Authentic samples of psoralen, angelicin, and 5,8-DMOP were supplied by the Department of Pharmaceutical Sciences of the University of Padova.

RESULTS AND DISCUSSION

The main morphoanatomical features of the fruits and seeds of the studied *Psoralea* species are shown in Figures 1–6. In both species, the embryo (two large cotyledons and a shoot–hypocotyl–root axis) is easily detached from an outer seed part consisting of the seed coats together with a residual film of endosperm (Figure 3), as previously described for *P. corylifolia* (Cappelletti et al., 1984). The outer seed coat epidermis consists of prismatic, radially elongated, and compactly arranged cells with thickened but not lignified walls (palisade or Malpighian cells). A layer of columnar, slightly waisted cells with wide airspaces in between (so-called hourglass cells) can also be found; the mesophyll and a residual layer of endosperm follows inward (Figures 4–6).

The furocoumarin contents of the whole fruits and their distribution patterns within the reproductive organs are reported in Table 1. The total furocoumarin amounts found in the whole fruits of *P. macrostachya* and *P. onobrychis* are fairly high with respect to those occurring in other species of the same genus, although far from the very high contents present in *P. corylifolia* (both psoralen



FIGS. 1–6. (1) *Psoralea onobrychis* fruit surface (×12); (2) *P. machrostachya* fruit surface (×20); (3) *P. onobrychis* seed, seed coats, and endosperm (A) easily detached from *cotyledone* (B) (×30); (4) *P. onobrychis* seed coat with palisade or malpighian cells (P), hour-glass cells, and mesophyll (×290); (5) *P. machrostachya* seed coat (×215); (6) *P. machrostachya* seed coat with palisade (P), hour-glass (HG), and mesophyll (M) cells (×390). [Figure reduced 77% for placement.]

and angelicin about 2500 ppm) and *P. plumosa* (psoralen 2500 ppm; angelicin 3000 ppm) fruits (Innocenti et al., 1984).

P. macrostachya fruits seem to be a much more interesting natural source of furocoumarins than previously supposed. In fact, fruits of *P. macrostachya*

TABLE 1. FUROCOUMARIN DISTRIBUTION PATTERNS WITHIN REPRODUCTIVE ORGANS OF INVESTIGATED *Psoralea* SPECIES (ppm OF DRY WEIGHT)

Species	Plant parts	Psoralen (Ps)	Angelicin (Ang)	Total	Ps/Ang ratio
P. macrostachya	whole fruit	278 ± 14	928 ± 45	1206 ± 47	0.30
	pericarp	121 ± 6	334 ± 15	455 ± 16	0.36

cultivated in the Botanical Garden of Padova were found to contain only 50 ppm of psoralen and 300 ppm of angelicin (Innocenti et al., 1977). This discrepancy is attributable to the different extractive procedure used in the present research: milder extraction conditions and hydrolysis of the bound forms, along with a more sensitive quantitative method (Innocenti et al., 1984), allowed more complete recovery of furocoumarin compounds.

In *P. macrostachya* whole fruit, furocoumarin contents comparable with those found in the vegetative organs of the same plant were observed; in contrast, in *P. onobrychis*, fruits seem to be the preferential accumulation site (Innocenti et al., 1991).

In the whole fruits of *P. onobrychis* a high proportion of the total furocoumarin is present in bound form (80% and 65% for psoralen and angelicin, respectively). In contrast, *P. macrostachya* fruits contain mainly unbound furocoumarins (bound psoralen and angelicin 23% and 20%, respectively). This proportion varies greatly among *Psoralea* species. In fact, species in which the unbound forms are most prevalent (*P. corylifolia*, *P. lacnostachys*) and species in which more than 90% of the total furocoumarins are bound (*P. plumosa*), have been described (Innocenti et al., 1984).

Very different distribution patterns of furocoumarins within reproductive structures were found in the two species (Table 1). In *P. macrostachya* a situation similar to that recorded in *P. corylifolia* (Cappelletti et al., 1984) was observed, furocoumarins occurring in the pericarp and in all seed parts. Whereas the pericarp is the preferential accumulation site in *P. corylifolia*, similar contents are found in the pericarp and embryo axis in *P. macrostachya*. No furo-

coumarins were found in the pericarp and only traces occur in the embryo axis of *P. onobrychis*; furocoumarins are present in the seed coats but accumulate mainly in the cotyledons.

In view of changes in the defensive value of the pericarp as the fruit progresses in its development, and in agreement with optimal defense theory (Nitao and Zangerl, 1987), the within-fruit furocoumarin variation associated with the developmental stages of *P. onobrychis* fruit was followed (Table 2). No furocoumarins occur in the flower (stage 1), in contrast with a previous report for *Coronilla vaginalis* (Innocenti et al., 1989). After fertilization (stage 2), rapid biosynthesis of furocoumarins takes place, as previously described for umbelliferous fruits (Nitao and Zangerl, 1987; Bicchi et al., 1990). When the fruits reach a convenient size, allowing separate sampling and analysis (stage 5), furocoumarins are found in both pericarp and seed, with significantly higher concentrations in the seed. Ripening (stage 6) is associated with a decrease of furocoumarins in the seed and their complete disappearance in pericarp tissues.

The differences in furocoumarin allocation within the fruits of these species is consistent with the suggested role of these compounds as protective agents. In fact, in *P. onobrychis*, pericarp tissues may have a defensive significance as long as they act as an envelope for the seed, i.e., until fruit ripening. In *P. macrostachya*, the persisting defensive role of the pericarp, which does not become detached from the seed, may account for the different furocoumarin distribution. In the present research, cultivated plants have been analyzed; however, in order to evaluate the actual ecological significance of furocoumarins as

TABLE 2. *P. onobrychis:* CHANGES IN FUROCOUMARIN CONTENTS (ppm OF DRY WEIGHT) ASSOCIATED WITH FRUIT DEVELOPMENTAL STAGES

protective agents for these two *Psoralea* species, plants in their natural habitats should be investigated.

The linear (psoralen) and angular (angelicin) isomers were found in both species. These findings are in agreement with the analytical data from all *Psoralea* species hitherto investigated (Jois and Manjunath, 1936; Kohlmuenzer, 1965; Akubakirov and Khalmurzaev, 1967; Ahmad and Basha, 1972; Samylina and Ladygina, 1975; Cappelletti et al., 1984; Innocenti et al., 1977, 1984, 1991) and give further support to the hypothesis (Innocenti et al., 1984, 1991) that the cooccurrence of linear and angular furocoumarins is a chemical marker of the genus *Psoralea*. In contrast, in another genus of the same family, *Coronilla*, only the linear isomer, psoralen, is present (Stöll et al., 1950; (Innocenti et al., 1986, 1989).

The angular isomer, angelicin, is more abundant than psoralen in both the investigated *Psoralea* species. However, interspecific differences in ratios were described. The psoralen–angelicin ratios in the whole fruits range from 2.0–2.5, as in *P. lacnostachys* and *P. pustulata*, to about 0.3–0.4, as in the present species and in *P. cinerea* (Innocenti et al., 1984). Very few data on ontogenetic changes of the isomer ratio within the different plant organs are available; therefore, no hypothesis on the possible significance of these changes can be put forward.

Angular compounds seem to be more advanced biosynthetically than linear furocoumarins (Berenbaum and Feeny, 1981). The biosynthetic pathway leading to angular attachment of the furan ring in advanced tribes of the Umbelliferae has been regarded as an evolutionary response to selective pressure by insects adapted to feeding on plants containing linear furocoumarins (Berenbaum and Feeny, 1981). Chemical mixtures of furocoumarins are in fact more effective as toxicants than single component compounds at equivalent concentrations (Berenbaum and Feeny, 1981; Berenbaum, 1985). Similarly, the biosynthetic pathway leading to angular furocoumarins may have arisen in *Psoralea* in response to selective pressure by insect herbivores.

Although our data on furocoumarin allocation within the fruits of the investigated *Psoralea* species are consistent with the role of chemical defense, the occurrence of considerable amounts of furocoumarins in embryos raises the question of their role as germination inhibitors. In *P. subacaulis*, furocoumarins have been shown to be both inhibitory to other unrelated species and autoinhibitory (Baskin et al., 1967).

Therefore, in *Psoralea*, furocoumarins may have many ecological functions: as chemical defense against predators and as germination inhibitors to reduce interspecific competition and regulate seedling densities within the population (intraspecific inhibition).

More research is needed in order to evaluate the role of *Psoralea* furocoumarins as germination inhibitors. We believe that recording within-seed furo-

coumarin distributions and variations during imbibition and germination may provide valuable information on the ecological role of these compounds. Research on this topic is in progress.

(Received November 26, 1990; accepted October 15, 1991)

Abstract—(*Z*,*Z*)-6,9-*cis*-(3*S*,4*R*)-Epoxynonadecadiene **9a** and (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene have been identified as sex pheromone components in female ovipositor extracts and effluvia of the geometrid *Boarmia selenaria*. The identification was based on relative retention times on gas chromatographic columns, GC-MS, chemical enantioselective syntheses, EAG, wind-tunnel behavioral experiments, and field tests. A single female ovipositor extract contained an average of 42 ng of (*Z*,*Z*)-6,9-*cis*-3,4-epoxynonadecadiene and 2 ng of (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene. EAG, wind-tunnel behavioral studies, and field tests demonstrated that male *B. selenaria* exhibit preferential attraction for the (3*S*,4*R*)-enantiomer of (*Z*,*Z*)-6,9-*cis*-3,4-epoxynonadecadiene. Only in effluvia and ovipositor extracts of calling females was (*Z*,*Z*)-6,9-*cis*-3,4-epoxynonadecadiene detected, whereas relatively high amounts of (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene were found in noncalling females. Wind-tunnel behavioral studies showed that (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene did not elicit any response in the males, and when tested in combination with a mixture of monoepoxynonadecadienes, (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene decreased the observed behavioral responses. A possible precursor role for (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene in the pheromonal system is discussed.

Key Words—*Boarmia selenaria*, giant looper, sex pheromones, Lepidoptera, Geometridae, (*Z*,*Z*)-6,9-*cis*-(3*S*,4*R*)-epoxynonadecadiene, (*Z*,*Z*)-6,9-*cis*-

INTRODUCTION

Boarmia selenaria Schiffermüller, the giant looper, is a serious pest of fruit and foliage in avocado orchards in various regions of Israel (Wysoki et al., 1975). The identification of the sex pheromone of *B. selenaria* was undertaken as part of a study to develop an integrated management program for this insect species based on the use of *Bacillus thuringiensis* (Berliner) and pheromone monitoring traps. In 1982, efforts were made to replace the virgin female-based monitoring system by a monitoring system based on the synthetic pheromone of *B. selenaria*. Using material extracted from the abdomen of virgin females, Becker et al. (1983) isolated two fractions by gas chromatography and liquid chromatography, which were found to be active by electroantennograph measurements. The less polar fraction was subsequently identified as (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene whose presence was demonstrated in the female extract by GC-MS. Recently, the second fraction was identified as (*Z*,*Z*)-6,9-*cis*-(3*S*,4*R*)-epoxynonadecadiene **9a** (Becker et al., 1990). We report here, in detail, the isolation and identification of those two sex pheromone components of *B. selenaria*, together with the enantioselective synthesis of two enantiomers of (*Z*,*Z*)-6,9-*cis*-3,4-epoxynonadecadiene, and the results of electroantennogram, wind-tunnel, and field-trapping experiments using the synthetic materials.

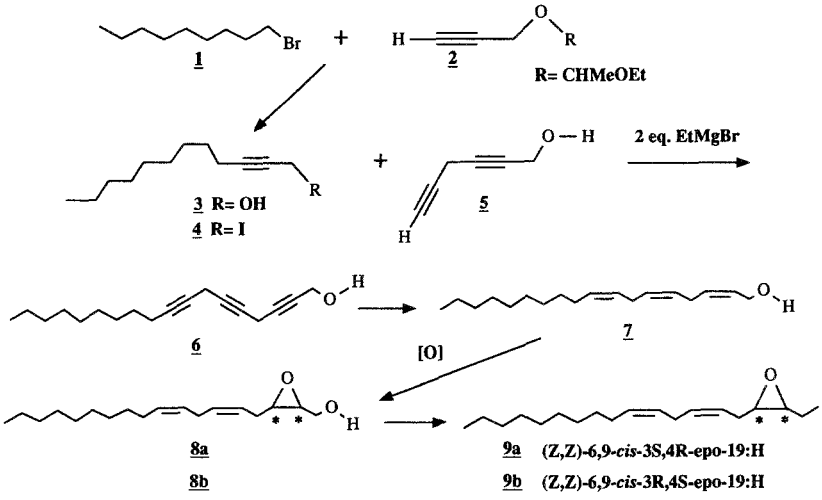
METHODS AND MATERIALS

Synthetic Chemicals. Compounds were analyzed by GC and were shown to be ≥98% pure. The two enantiomers of (*Z*,*Z*)-6,9-*cis*-3,4-epoxynonadecadiene were synthesized following the methodologies of Mori and Ebata (1986), and Millar et al. (1990c), modifications to these methods are described below (see Scheme 1).

Preparation of (Z,Z,Z)-*3,6,9-Nonadecatriene.* (*Z*,*Z*,*Z*)-3,6,9-Nonadecatriene (*Z*3,*Z*6,*Z*9–19:H) was prepared from linolenic acid and a 20-fold excess of propanoic acid by a Kolbe electrolysis according to the procedure of Conner et al. (1980). Pure *Z*3,*Z*6,*Z*9–19:H was obtained after column chromatography (silica gel, elution with hexane).

Preparation of cis-*Monoepoxynonadecadienes.* The *cis*-monoepoxynonadecadienes (MED-19:H) were prepared from *Z*3,*Z*6,*Z*9–19:H as previously described for the homologous C_{17}–C_{22} compounds (Wong et al., 1985), using *m*-chloroperbenzoic acid in dry methylene chloride.

Preparation of (Z,Z)-*6,9*-cis-*(3*S,*4*R*)-*Epoxynonadecadiene* ***9a*** *and its*



SCHEME 1.

(3R,4S)-enantiomer ***9b***. 1-Nonanol (41 g, 0.28 mol) was dissolved in HBr (100 ml, 48%) to which H_2SO_4 (25 ml) was added dropwise. After reflux overnight, methylene chloride (100 ml) and H_2O (100 ml) were slowly added. The organic layer was separated and the aqueous layer was extracted with methylene chloride. The combined organic solutions were washed with satd. $NaHCO_3$, dried ($MgSO_4$) and concentrated under reduced pressure to yield an oily compound that was distilled (115°C, 20 mm Hg) to give 56 g (96%) of 1-bromononane **1**.

Protected propargyl alcohol **2** was prepared by acid-catalyzed addition of propargyl alcohol to ethyl vinyl ether as described by Brandsma (1971).

To a solution of protected propargyl alcohol **2** (25,6 g, 200 mmol) in dry THF (500 ml) at −5°C was added dropwise a solution of Bu^nLi (2.3 M in hexane, 100 ml, 230 mmol), followed by the addition of HMPA (100 ml). After adding dropwise 1-bromononane **1** (36.5 g, 177 mmol), the reaction was heated up to room temperature. After 3 hr at room temperature, the protecting ethyl vinyl ether was cleaved by adding 2 ml of conc. HCl in 20 ml of methanol at room temperature. The mixture was stirred for 1 hr and then poured into H_2O (100 ml), followed by the removal of the solvents under reduced pressure. The residue was extracted with hexane, washed with H_2O, and dried ($MgSO_4$). The solvent was removed under reduced pressure to yield an oily compound that was distilled (90°C/0.01 mm Hg) to give 28.3 g (88%) of 2-dodecyn-1-ol **3**.

2-Dodecyn-1-ol **3** (13.4 g, 74 mmol) was converted to the corresponding 1-iodo-2-dodecyne **4** by published procedure (Corey et al., 1983), using PhP_3 (21 g, 80 mmol), imidazole (5.4 g, 80 mmol), and I_2 (20.3 g, 80 mmol) in

ether–CH_3CN 3:1 (160 ml) for 2 hr at room temperature. After work-up, the crude mixture was chromatographed over silica gel column, eluted by hexane to give 18.4 g (85%) 1-iodo-2-dodecyne **4**.

Protected propargyl alcohol **2** (10 g, 78 mmol) was converted to 2,5-hexadiyn-1-ol **5** (4.7 g) in 64% yield as described by Brandsma (1971).

To a solution of EtMgBr (36 mmol) in THF (40 ml) was added dropwise a solution of 2,5-hexadiyn-1-ol **5** (1.7 g, 18 mmol) dissolved in THF (20 ml) at room temperature. After stirring for 2 hr, CuI (0.6 mg, 3.1 mmol) was added, followed 25 min later by the addition of a solution of 1-iodo-2-dodecyne **4** (4 g, 13.7 mmol) dissolved in THF (20 ml). The mixture was stirred overnight and then poured into a solution of NH_4Cl (30 g) and NaCN (1 g) dissolved in H_2O (100 ml). The organic layer was separated and the aqueous layer was extracted with ether. The combined organic solutions were washed with satd. NH_4Cl and dried ($MgSO_4$). The solvent was removed under reduced pressure to yield a dark brown oil. The product was crystallized from hexane (0°C) to yield 2 g (58%) of 2,5,8-octadecatriyn-1-ol **6** (mp ≈ 20°C). 2,5,8-Octadecatriyn-1-ol was rather unstable and was therefore immediately reduced.

2,5,8-Octadecatriyn-1-ol **6** (1 g, 3.9 mmol) was reduced (H_2, 1 atm., hexane) over Lindlar catalyst (5% w/w) to give (*Z,Z,Z*)-2,5,8-octadecatrien-1-ol **7** in quantitative yield.

HRMS calcd. for $C_{18}H_{32}O$: 264.2453, found: 264.2462. [^{1}H]NMR (400 MHz, $CDCl_3$) δ 5.60 (1H, m, =C—H 2), 5.52 (1H, m, =C—H 3), 5.33 (4H, m, =C—H 5, 6, 8, 9), 4.20 (2H, d, J = 7 Hz, C—H 1), 2.82 (2H, t, J = 7 Hz, C—H 4), 2.78 (2H, t, J = 7 Hz, C—H 7), 2.02 (2H, q, C—H 10), 1.24 (12H, s, C—H 11–17), 0.85 (3H, t, C—H 18). IR ($CHCl_3$): 3600, 3420, 2920, 2860, 1460 cm^{-1}.

(*Z,Z,Z*)-2,5,8-Octadecatrien-1-ol **7** (0.6 g, 2.27 mmol) was epoxidized applying a Sharpless epoxidation (Katsuki and Sharpless, 1980), using $Ti(OPr^i)_4$ (0.81 ml, 2.73 mmol), L-(+)-dimethyl tartrate (566 mg, 3.18 mmol), and Bu^tOOH (7.5 M in isooctane, 0.76 ml, 5.67 mmol) in dry methylene chloride (40 ml), 6 hr at −23°C followed by 63 hr at −10°C. After work-up, the product was chromatographed over silica gel, eluted with hexane–methylene chloride 1:2 to give 0.49 mg (77%) (*Z,Z*)-5,8-*cis*-(2*S*,3*R*-epoxyoctadecadien-1-ol **8a**, ee = 68% by GC.

HRMS calcd. for $C_{18}H_{32}O_2$: 280.2403, found: 280.2393. [^{1}H]NMR (400 MHz, $CDCl_3$) δ 5.48 (1H, m, =C—H 5), 5.39 (2H, m, =C—H 6,8), 5.27 (1H, m, =C—H 9), 3.81 (1H, bd, J = 15 Hz, C—H 1), 3.68 (1H, dd, J = 15, J = 7 Hz, C—H 1), 3.15 (1H, m, C—H 2), 3.04 (1H, m, C—H 3), 2.75 (2H, t, C—H 7), 2.44 (1H, m, C—H 4), 2.25 (1H, m, C—H 4), 2.0 (2H, q, C—H 10), 1.22 (14H, s, C—H 11–17), 0.84 (3H, t, C—H 18). IR ($CHCl_3$): 3520, 2960, 1650, 1460 cm^{-1}.

(*Z,Z,Z*)-2,5,8-Octadecatrien-1-ol **7** (0.4 g, 1.52 mmol) was epoxidized as

described for (*Z*,*Z*)-5,8-*cis*-(2*S*3*R*)-epoxyoctadecadien-1-ol **8a,** using D-(−)-diethyl tartrate (437 mg, 2.12 mmol), to give 0.3 g (70%) (*Z*,*Z*)-5,8-*cis*-(2*R*,3*S*)-epoxyoctadecadien-1-ol **8b**. The IR and NMR spectra were identical to those of the (2*S*,3*R*)-enantiomer, ee = 65% by GC.

To a solution of (*Z*,*Z*)-5,8-*cis*-(2*S*,3*R*)-epoxyoctadecadien-1-ol **8a** (200 mg, 0.71 mmol) in dry pyridine (10 ml) was added *p*-toluenesulfonyl chloride (340 mg, 1.78 mmol) with stirring at 0°C. The reaction was left overnight at 4°C. The mixture was poured into ice–H_2O and extracted with ether. The ether solution was washed with 10% aqueous cupric sulfate, H_2O and brine, dried ($MgSO_4$), and the solvent was removed under reduced pressure to give 264 mg (85%) (*Z*,*Z*)-5,8-*cis*-(2*S*,3*R*)-epoxyoctadecadienyl tosylate.

(*Z*,*Z*)-5,8-*cis*-(2*R*,3*S*)-Epoxyoctadecadien-1-ol **8b** (200 mg, 0.71 mmol) was tosylated as described for (*Z*,*Z*)-5,8-*cis*-(2*S*,,3*R*)-epoxyoctadecadienyl tosylate, to give 254 mg (82%) (*Z*,*Z*)-5,8-*cis*-(2*R*,3*S*)-epoxyocadecadienyl tosylate.

To a solution of CuI (290 mg, 1.52 mmol) in dry ether (5 ml) was added dropwise a solution of CH_3Li (1.6 M, 2.38 ml, 3.80 mmol) at −20°C. The mixture was stirred for 20 min, followed by the addition of (*Z*,*Z*)-5,8-*cis*-(2*S*,3*R*)-epoxyoctadecadienyl tosylate (264 mg, 0.61 mmol). The mixture was stirred for an additional 2 hr at −20°C and then poured into aqueous NH_4Cl. After stirring for 30 min, the organic layer was separated and the aqueous layer was extracted with ether. The combined organic solutions were washed with H_2O and brine, dried ($MgSO_4$), and the solvent was removed under reduced pressure. The residue was chromatographed over silica gel, eluted with hexane–methylene chloride 6:1 to give 130 mg (77%) (*Z*,*Z*)-6,9-*cis*-(3*S*,4*R*)-epoxynonadecadiene **9a** [*Z*6,*Z*9-*cis*-(3*S*,4*R*)-epo-19:H].

HRMS calcd. for $C_{19}H_{34}O$: 278.2609, found: 278.2594. [^{1}H]NMR (400 MHz, $CDCl_3$) δ 5.5–5.42 (2H, m, =C—H 6,7), 5.42–5.3 (2H, m, =C—H 9,10), 2.93 (1H, m, C—H 4), 2.87 (1H, m, C—H 3), 2.79 (2H, t, C—H 8), 2.39 (1H, m, C—H 5), 2.2 (1H, m, C—H 5), 2.02 (2H, q, C—H 11), 1.57 (2H, m, C—H 2), 1.35 (2H, m, C—H 12), 1.25 (12H, s, C—H 13–18), 1.04 (3H, t, C—H 1), 0.86 (3H, t, C—H 19). IR ($CHCl_3$): 2960, 2840, 1740, 1460 cm^{-1}.

(*Z*,*Z*)-5,8-*cis*-(2*R*,3*S*)-Epoxyoctadecadienyl tosylate (254 mg, 0.58 mmol) was alkylated as described for (*Z*,*Z*)-6,9-*cis*-(3*S*,4*R*)-epoxynonadecadiene **9a** to give 122 mg (75%) (*Z*,*Z*)-6,9-*cis*-(3*R*,4*S*)-epoxynonadecadiene **9b** [*Z*6,*Z*9-*cis*-(3*R*,4*S*)-epo-19:H]. The IR and NMR spectra were identical to those of the (3*S*,4*R*)-enantiomer.

Insects. The *B. selenaria* breeding used in this study was started with larvae obtained from avocado orchards in Regba, Western Galilee, Israel. Newly collected larvae were added to the breeding monthly. The insects were kept under a reversed 16-hr light–8-hr dark cycle at 27 ± 1°C, relative humidity 70%, and were fed on avocado leaves or on a semiartificial diet (Shorey and Hale, 1965).

Immediately after the caterpillars pupated (approx. 25–30 days after egg hatching), pupae were gathered, sexed, and kept in separate rooms.

Extraction of Female Glands and Collection of Airborne Volatiles from Females. One- to two-day-old virgin females were placed in a wire net cage under red fluorescent light (11 lux) at the beginning of the scotophase. After 5 hr of active calling, females were placed at −20°C for 20 min prior to excising their ovipositor. Ovipositors were excised from the middle of the ninth segment. In freeze-killed females the eighth, ninth, and tenth abdominal segments remain telescoped within the seventh segment. These last parts of the abdomen were pulled out with forceps and cut from the middle of the ninth segment. The cutting edges were blotted on filter paper before transferring the tissue to solvent. The sex pheromone gland is epidermal tissue located between the ninth and tenth abdominal segment (Wysoki et al., 1985). The ovipositor tips were extracted with hexane (redistilled and passed over Al_2O_3) for about 1 hr at room temperature. For quantitative analysis, excised ovipositors were extracted individually in cone-shaped microvials containing 200 μl of hexane. The samples were concentrated to 1 μl under a slow stream of N_2. The samples were directly analyzed by GC. Recoveries of synthetic materials were reproducible and were proven to be 100%.

The collection apparatus was a modified version of the one used by Charlton and Cardé (1982). The collection device consisted of two modified glass joints (B-55) forming the insect holding chamber, which incorporated a 2 × 3-cm metal screen, hung in such a way that it did not touch the sides of the chamber. The lower half of the holding chamber was connected to a pheromone trap. The pheromone traps consisted of glass liner tubes for the GC injector (78.5 ± 0.1 mm × 6.52 mm OD) and were each filled with 100 mg Chromosorb Q (80–100 mesh, Chromopack) between two glass wool plugs. The absorbent was pretreated by repeated washes with redistilled hexane followed by baking at 200°C for 24 hr under vacuum. The glass liners were filled with the pretreated absorbent and placed in the GC injector (250°C) for 16 hr under a constant stream of helium. The injector was cooled down and the liner removed and stored in individual glass vials under nitrogen. The airflow for the collection apparatus was supplied by a water-vacuum pump and set at 0.3 liters/min. The air, before entering the holding chamber, was passed through an air filter (70 mm × 20 mm ID) containing 6 g of activated charcoal (1.5 mm). A 1- to 2-day-old virgin female was placed in the collection apparatus just before the onset of the scotophase. Once the female became acquiescent and before calling started, the airflow was initiated. The aeration period lasted a maximum of 5 hr, during which the female was observed to be calling. Visibility was provided by a red fluorescent light (11 lux). An empty collection apparatus, operated under the same conditions as mentioned above, served as a control for collected volatiles that were unrelated to the female emitted volatiles. Breakthrough of

pheromone components did not occur as evidenced by the lack of detectable pheromone in the second pheromone trap placed in series with the first. At the end of the aeration period, the pheromone trap was removed and the collected volatiles were directly analyzed by GC by placing the trap into the GC injector.

Gas Chromatography (GC) and GC-Mass Spectrometry (GC-MS). GC analyses were performed on a Hewlett Packard 5890 equipped with a HP-3393A integrator, using the following columns: (1) SE-54, 25 m × 0.22 mm ID fused silica capillary column (S.G.E. Ltd.); (2) OV-101, 50 m × 0.25 mm ID fused silica WCOT capillary column (Packard, Inc.); (3) Supelcowax-10, 60 m × 0.25 mm ID fused silica capillary column (Supelco, Inc.); and (4) BD210, 30 m × 0.25 mm ID fused silica capillary column (J&W Scientific). Columns 1, 2, and 3 were operated in splitless mode with the following program: 3 min delay on inlet purge; 3 min at 50°C; 35°/min to various isothermal temperatures of 220–300°C for various runs. Samples were injected as hexane solutions. The three isomers of MED-19:H eluted as single fully separated peaks from the Supelcowax-10 column in the order 6,7-,3,4-, and 9,10-monoepoxydiene. The enantiomeric excess of **8a** and **8b** was determined by esterification with (2*S*)-2-acetoxypropionyl chloride as described by Millar et al. (1990c) on column 4, isothermal 215°C.

Components were identified by comparison of retention times on capillary columns 1, 2, and 3, of extracted, collected, and synthetic components and by their GC-MS spectra.

Capillary GC traces of extracted components of individual virgin female ovipositors were quantified by comparison of peak areas with peak area response curves of external synthetic materials.

For structural determination a Finnigan Mat ITS40 mass spectrometer (70 eV) linked to a Varian 3400 gas chromatograph was used. Separation was achieved on a DB5, 30 m × 0.22 mm ID fused silica capillary column (J&W Scientific), maintained for 1 min at an initial temperature of 80°C and then heated to 140°C at a rate of 35°C/min, followed by 5°C/min to 250°C with an isothermal hold of 15 min.

Electroantennogram (EAG) Measurements. The EAG responses of adult male *B. selenaria* to synthetic materials were determined and standardized according to the procedures of Moore (Moore, 1981; Moore et al., 1986).

Wind-Tunnel Behavioral Tests. The wind tunnel (350 × 90 × 90 cm), a modification of earlier designs (Miller and Roelofs, 1978; Cardé and Hagaman, 1979; Sanders et al., 1981), was of clear Plexiglas and had a flight compartment of 240 cm. Its upwind and downwind ends were closed with cheesecloth screens; one side of the tunnel was covered with black plastic. Tests showed that the airflow was almost laminar and started out pencil-thin at the release point and widened out to about 20 cm in cross section at the downwind end of the tunnel. The floor consisted of a stationary orange-and-black chessboard pattern (each

square 15 × 15 cm). Air was sucked through the tunnel by means of a ventilator (air speed: 25 cm/sec), its outlet leading outside the building. Temperature was controlled by means of a heating unit in the entrance duct of the ventilator. The wind tunnel was diffusely illuminated from above by means of four red fluorescent lamps with a light intensity of about 11 lux (measured at the floor of the flight compartment).

The tested materials were applied on filter paper disks (Whatman No. 1, 2 cm diam.) or on rubber septa (Abic, Natanya, Israel) in 100 μl hexane and placed in individual glass tubes after evaporation of the solvent. A thin glass rod, 18 cm downwind of the upwind cheesecloth screen and at a height aligned with the male release platform, served as a release support for the stimuli. Calling virgin females were placed individually in wire net cages and lowered from the tunnel ceiling. Female ovipositor extracts (FE) were obtained from individually extracted ovipositors in 200 μl hexane.

A χ^2 comparison of the daily values at similar temperatures showed no significant day-to-day variabilities in any of the examined responses. Since not all treatments were carried out on one single day of testing, the data from all testing days for each treatment were combined. Percentage responses were compared by χ^2. The 0.05 level was set for the rejection of all null hypotheses.

Field Attractancy Tests. Preliminary field test were carried out in avocado orchards in Regba, Western Galilee, Israel, using sticky (Rimipot, Rimi, Tel-Aviv, Israel), open-ended, cone-shaped, white polyethylene traps (20 cm long, 13–17 cm ID). Traps, baited with synthetic compounds impregnated in rubber septa, were hung from branches, 1.5 m above the ground and approximately 40 m apart. Traps were set out in a randomized block design and trap captures were recorded weekly.

RESULTS

GC analyses on three capillary columns of hexane extracts of giant looper female ovipositors showed five well-resolved and reproducible peaks. A typical chromatogram from an analysis of a single female ovipositor extract is shown in Figure 1A. Figure 1B shows the corresponding chromatogram from an analysis of collected volatiles of a single calling female. GC-MS analysis of the five peaks showed that the mass spectrum of component **1** ($M^+ = 262$) exactly matched that of the previously reported *Z*3,*Z*6,*Z*9–19:H (Becker et al., 1983). The mass spectrum of component **2** ($M^+ = 278$) coincided exactly with that of the synthetic *Z*6,*Z*9-*cis*-(3*S*,4*R*)-epo-19:H (Figure 2) and is in full agreement with published data (Hansson et al., 1990). The mass spectra of components **3**–**5** matched those of tricosane (23:H), pentacosane (25:H), and heptacosane (27:H), respectively. The GC analyses of extractions of different abdominal

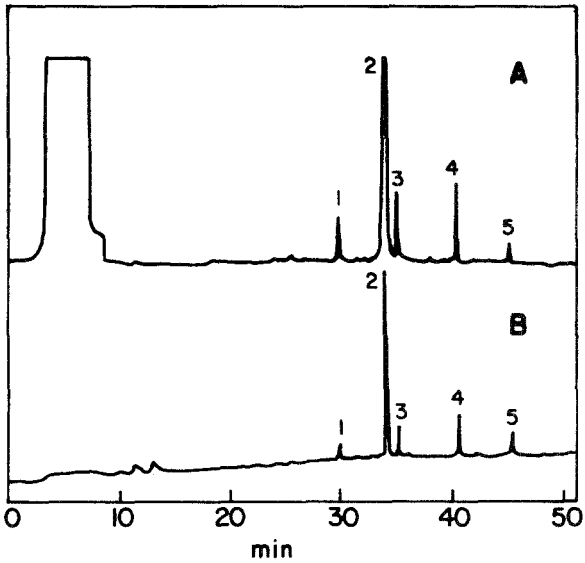


FIG. 1. Gas chromatogram of *B. selenaria* female ovipositor extract (A) and female collected effluvia (B). A 60-m Supelcowax-10 column was used.

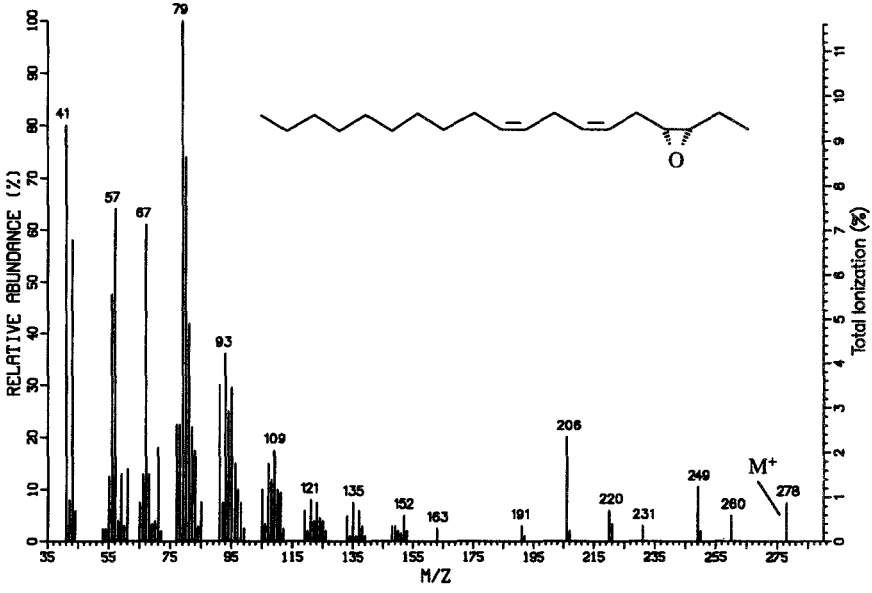

FIG. 2. Electron impact mass spectrum (70 eV) of (*Z*,*Z*)-6,9-*cis*-(3*S*,4*R*)-epoxynonadecadiene.

segments (eighth to tenth) showed that the identified alkanes were not only localized in the segment containing the pheromone gland but could be extracted from every segment. These alkanes were therefore not considered to be part of the pheromonal secretions. Comparison of peak areas with peak area response curves of Z3,Z6,Z9–19:H and Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H showed that from one female ovipositor extract an average of 42.3 ng ± 15.5 of Z6,Z9-*cis*-3,4-epo-19:H and 1.9 ng ± 0.8 of Z3,Z6,Z9–19:H ($N = 10$) could be extracted. Z6,Z9-*cis*-3,4-epo-19:H was only detected in effluvia and ovipositor extracts of calling females, whereas relatively high amounts of Z3,Z6,Z9–19:H were found in noncalling females.

EAG responses were recorded using Z3,Z6,Z9–19:H and its product after random epoxidation to a mixture of *cis*-monoepoxynonadecadienes (MED-19:H). The application of a range of doses (0.1 ng–1.0 μg) of MED-19:H resulted in responses ranging from 3.3 mV (0.1 ng) to 13.2 mV (1.0 μg) ($N = 10$). The highest dose in this range of Z3,Z6,Z9–19:H gave a stimulation of 4.4 mV, which was 3.0 times lower than that found for MED-19:H. Similarly, in EAG tests with 0.05-ng to 10-ng doses ($N = 7$) of MED-19:H and Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H, the chiral monoepoxydiene was significantly more active than MED-19:H with EAG recordings ranging from 1.4 to 2.4 mV for MED-19:H and from 4.3 to 6.8 mV for Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H. The EAG responses given by male *B. selenaria* antennae to Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H and its (3*R*,4*S*)-enantiomer showed significantly higher responses with 0.01-μg and 1.0-μg doses of Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H compared to those of the (3*R*,4*S*)-enantiomer.

Table 1 presents the results obtained when male *B. selenaria* moths were exposed in a wind tunnel to Z3,Z6,Z9-19:H, Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H, MED-19:H, and a calling female. The giant looper males exhibited wing fan-

TABLE 1. RESPONSES OF MALE *B. selenaria* IN A WIND TUNNEL TO Z3,Z6,Z9–19:H, MED-19:H, Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H, AND A CALLING FEMALE

Bait (μg)[a]	*N*	Percent		
		Wing fanning[b]	Upwind flight[b]	Landing on source[b]
Z3,Z6,Z9–19:H (250)	25	0c	0d	0b
MED-19:H (250)	26	85b	19c	12b
Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H (250)	20	85ab	55b	15b

ning, plume-oriented upwind flight, and landing on source in response to MED-19:H, *Z*6,*Z*9-*cis*-(3*S*,4*R*)-epo-19:H, and a calling female. No behavioral responses could be observed with *Z*3,*Z*6,*Z*9–19:H. The onset of wing fanning was rapid for all treatments and occurred within 1–5 sec after the plume had reached test males. Of the total tested males, 19% responded to MED-19:H with plume-oriented upwind flight and 12% landed on the source, whereas 55% and 15% of the males responded to *Z*6,*Z*9-*cis*-(3*S*,4*R*)-epo-19:H with plume-oriented upwind flight and landing on source, respectively. The males that terminated their upwind progress in response to *Z*6,*Z*9-*cis*-(3*S*,4*R*)-epo-19:H did this within 15 cm in front of the source. Males that flew upwards out of the *Z*6,*Z*9-*cis*-(3*S*,4*R*)-epo-19:H plume were repeatedly observed to realign themselves with the plume and to continue with plume-oriented upwind flight. Those males that landed on source extended their claspers with vigorous wing fanning and attempted to mate with either the dispenser or with the holding cage containing the calling virgin female. Males that initiated plume-oriented upwind flight in response to a calling female generally landed on source within 25 sec after takeoff. Although the response percentages towards the synthetic materials were significantly lower than those towards a calling female, no marked differences in behavior were noted. The presence of *Z*3,*Z*6,*Z*9–19:H in the natural pheromone has been clearly demonstrated (Figure 1), but its behavioral role is at this point still unclear. Combining a calling female with a filter paper disk containing 40 μg of *Z*3,*Z*6,*Z*9–19:H caused a significant decrease in the percentage wing fanning and the elimination of plume-oriented upwind flight and landing on source (Table 2). The behavioral responses towards MED-19:H were not significantly altered with the additions of increasing amounts of *Z*3,*Z*6,*Z*9–

19:H, with the exception of the 1:1 blend, where a significantly lower wing fanning percentage of 5% was noted. These data indicate no synergistic role for Z3,Z6,Z9–19:H; the results show more a trend towards a behavioral antagonist for relatively high amounts of Z3,Z6,Z9–19:H. Results of the males' behavioral responses towards various concentrations of Z6,Z9-*cis*-(3*S*,4*R*)-epo-19:H and Z6,Z9-*cis*-(3*R*,4*S*)-epo-19:H are presented in Table 3. As indicated, the behavioral responses towards the (3*S*,4*R*)-enantiomer showed a stronger decline in percentages of wing fanning and upwind flight with decreasing bait concentrations than towards the (3*R*,4*S*)-enantiomer. Furthermore, there were significant differences in behavioral activity between the 100-μg doses (wing fanning) and the 250-μg doses (upwind flight), indicating that the (3*S*,4*R*)-enantiomer is the more active compound of the two enantiomers. Landing-on-source percentages showed no difference for the three tested concentrations of enantiomers. A female ovipositor extract, containing approx. 40 ng of the natural monoepoxide and 2 ng of the triene, was highly attractive to males in the wind tunnel (Table 4). Of the total males tested, 75% completed the full behavioral sequence. Wind-tunnel experiments showed similar behavioral percentages when up to five times the female equivalent was used. Comparison between a female ovipositor extract and combinations of female ovipositor extracts with the two enantiomers of Z6,Z9-*cis*-3,4-epo-19:H showed that the addition of both enantiomers decreased the males' behavioral responses. No differences in wing fanning percentages were noted for either added concentration of enantiomers; however, there were significant differences between the 2.5 ng additions (landing on source) and the 10 ng additions (upwind flight). In both instances, addition of the (3*R*,4*S*)-enantiomer resulted in a greater reduction of the behavioral responses than with

the addition of the (3*S*,4*R*)-enantiomer. From these data, it seems likely that the natural epoxide has the 3*S*,4*R* configuration or that it is a mixture of both enantiomers with an enrichment in the (3*S*,4*R*)-enantiomer.

Overall capture of male *B. selenaria* with virgin female-baited traps was relatively low. During a three-year period (1973–1975), from March to November, the weekly average catches varied between 0 and 2 males. During the years 1986–1989, average weekly catches of males varied between 0 and 19. Preliminary field-trapping experiments, performed during two-week periods (September 1988 and May 1989), showed that on average a total of six male *B. selenaria* were attracted to baits impregnated with 500 μg of *Z6,Z9-cis*-(3*S*,4*R*)-epo-19:H, while no males were captured with baits that contained 500 μg of the (3*R*,4*S*)-enantiomer of 500 μg of *Z3,Z6,Z9*-19:H. Combinations of the (3*S*,4*R*)-enantiomer with *Z3,Z6,Z9*-19:H showed mixed results, but all tested combinations (9:1 to 1:9) attracted lower numbers of males than the (3*S*,4*R*)-enantiomer alone. However, overall capture of males was low, and field tests will have to be repeated in order to obtain statistically relevant data.

DISCUSSION

Only recently, in addition to multiunsaturated hydrocarbons, have monoepoxydienes been identified as sex pheromone components of the lepidopteran family Geometridae. (*Z,Z*)-6,9-*cis*-3,4-Epoxynonadecadiene, as part of a blend, has so far tentatively been identified in extracts of female sex pheromone glands

of the geometrid *Probole amicaria* (Millar et al., 1990b) and for several other geometrids as sex attractant (Millar et al., 1990b,c).

This study shows that female *Boarmia selenaria* moths are emitting a sex pheromone blend that is comprised of a binary mixture of (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene and (*Z*,*Z*)-6,9-*cis*-3,4-epoxynonadecadiene.

(*Z*,*Z*)-6,9-*cis*-3,4-Epoxynonadecadiene, either in the form of an enantiomerically enriched compound or as part of a mixture of monoepoxynonadecadienes, was shown to be attractive to male *B. selenaria* in the wind tunnel. We could demonstrate that male *B. selenaria* moths exhibit preferential attraction to the (3*S*,4*R*)-enantiomer of (*Z*,*Z*)-6,9-*cis*-3,4-epoxynonadecadiene in EAG tests, wind-tunnel behavioral studies, and preliminary field trials.

The wind-tunnel experiments showed that the males' behavioral responses towards the synthetic materials were significantly lower than towards a calling female or female ovipositor extract. One of the possible reasons for the low behavioral activity of the synthetic materials is that the synthetic monoepoxydiene may have a different enantiomeric composition than the natural monoepoxydiene. Our synthetic procedure used the Sharpless epoxidation in order to obtain the chiral monoepoxides. Previous studies, using the Sharpless epoxidation on similar compounds, showed enantiomeric purities to be within the range of 57–90% ee (Mori and Ebata, 1986; Mori and Takeuchi, 1989; Millar and Underhill, 1986; Millar et al., 1990c). Our analyses of the synthesized enantiomers, using known methods, such as NMR measurements in the presence of chiral shift agents, NMR measurements after derivatizations of the samples, HPLC analyses employing chiral phases, and GC and HPLC analyses after derivatizations of the samples, failed to determine the enantiomeric purities. The problem was solved by following Millar's procedure (Millar et al., 1990c), which enabled us to determine the enantiomeric purity of long-chain epoxyalcohol intermediates (see Scheme 1, **8**). Indications as to the importance of the enantiomeric purity of the synthesized enantiomers could be obtained from the experiment presented in Table 4: combinations of each of the enantiomers with a female ovipositor extract reduced the male behavioral responses in the wind tunnel. The decrease of males' behavior response can be explained by the fact that relatively low enantioselectivity has been achieved in the synthesis of *Z*6,*Z*9,-*cis*-3,4-epo-19:H (ee $< 70\%$). However, additions of the (3*R*,4*S*)-enantiomer decreased to a greater degree the behavioral responses when compared to the (3*S*,4*R*)-enantiomer.

(*Z*,*Z*,*Z*)-3,6,9-Nonadecatriene, in combination with homologs or with monoepoxide derivatives, has been shown to be attractive to male geometrids in wind-tunnel and in field tests (Wong et al., 1984, 1985; Szocs et al., 1984; Buser et al., 1985; Hansson et al., 1990; Millar et al., 1990a–d). Our results confirm the presence of the previously reported (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene (Becker et al., 1983) in female ovipositor extracts and, in the present study, it

was also identified in collected volatiles emitted by female *B. selenaria*. However, the wind-tunnel behavioral studies showed that (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene failed to elicit any response in the tested males. Furthermore, additions of (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene to a biologically active mixture of monoepoxynonadecadienes clearly decreased the behavioral responses of the males. Moreover, a combination of (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene with a calling virgin female eliminated the female's attractancy to the moths. Preliminary field trials showed that (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene alone was not attractive nor was an increase noted in number of catches when applied in combination with (*Z*,*Z*)-6,9-*cis*-(3*S*,4*R*)-epoxynonadecadiene. (*Z*,*Z*)-6,9-*cis*-3,4-Epoxynonadecadiene was only detected in effluvia and ovipositor extracts of calling females, whereas relatively high amounts of (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene were found in noncalling females. Rather than being a pheromone component, the above results corroborate earlier reports that triunsaturated hydrocarbons may function as precursors for monoepoxidienes (Kasang et al., 1974; Rule and Roelofs, 1989).

The recently reported single sensillum measurements on male antennae of the geometrid *Erannis defoliaria* showed two physiological types of sensilla: one type responded to (*Z*,*Z*)-3,9-*cis*-6,7-epoxynonadecadiene and to a lesser extent to (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene; a second type responded only to (*Z*,*Z*)-3,9-*cis*-6,7-epoxynonadecadiene, and this cell was inhibited by (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene (Hansson et al., 1990). With regard to the results discussed above, it is possible that similar types of sensilla are present in antennae of male *B. selenaria* and that (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene performs a dual role of precursor and pheromone component in the pheromonal system, but this remains to be investigated.

The synthesis of chiral methylene-interrupted epoxydienes has been based on the acetylene methodology. This approach has been used by Mori (Mori and Ebata, 1986; Mori and Takeuchi, 1989) in the syntheses of similar structures and last year by Millar et al. (1990c) in the synthesis of (*Z*,*Z*)-6,9-*cis*-(3*S*,4*R*)-epoxynonadecadiene. The main drawback in this route is the catalytic reduction of the 3,6,9-triene-1-ol over Lindlar catalyst, which often has to be repeated since the catalyst becomes poisoned. It has become clear to us that the removal of protecting groups by acid catalysis is one of the main problems. Probably at that stage some double bond rearrangement does occur and the formed conjugated systems poison the catalyst. Conjugated systems can be formed at the condensation steps that are performed in basic media. We have worked out a procedure that gives a general synthetic route for the synthesis of chiral methylene-interrupted epoxydienes and provides a solution to the problems mentioned. We have synthesized triynol from two units: 1-iodo-2-dodecyne, which has been prepared in three steps from commercially available starting materials in good yields, and a six-carbon unit, 2,5-hexadiyne-1-ol, which has been prepared in a straightforward two-step synthesis according to Brandsma (Brandsma,

1971) and remained stable at 5°C for weeks. The next step was crucial, since it led in one step to methylene interrupted triynol by condensation of 1-iodo-2-dodecyne with unprotected 2,5-hexadiyne-1-ol. The fact that no acid hydrolysis was needed after the condensation enabled us to obtain, after crystallization, a white solid compound that was reduced over Lindlar catalyst to give the stable 3,6,9-triene-1-ol in quantitative yield. It seems to us that for the time being this route is the procedure of choice for the synthesis of methylene interrupted 3,6,9-triene-1-ol.

Although the optimal synthetic pheromone formulation is not yet complete, current efforts to obtain enantiomerically pure monoepoxydienes, together with more detailed field tests and wind-tunnel experiments, should provide further information on the exact formulation of the natural pheromone.

(Received December 17, 1990; accepted October 18, 1991)

Abstract—The workers of the leaf-cutting ant *Atta laevigata* were found to mark a territory around their nest and along trunk trails. Elsewhere, we reported that the territorial mark had orientation and agonistic functions. The presence of this mark induced an alarm behavior in intruder workers and stimulated the residents' aggressiveness. Of the parts of the body tested, only the extracts from gaster or Dufour gland were able to induce the same agonistic behavior. The compounds *n*-heptadecane, (Z)-9-nonadecene, 8,11-nonadecadiene, and (Z)-9-tricosene, secreted by Dufour gland were identified on foraging trails in the field as components of the territorial odor.

Key Words—*Atta laevigata*, Hymenoptera, Formicidae, territorial pheromone, agonistic behavior, Dufour gland.

INTRODUCTION

The existence of a territorial pheromone in Attini is still a controversial subject. A compound secreted by the valves gland of the sting (Bazire-Benazet and Zylberberg, 1979) and identified as *n*-nonadecadiene had been first proposed for *Atta cephalotes* (Jaffe et al., 1979). The same authors suggest that the mandib-

ular gland secretions are laid down around the nest exits and propose the alarm pheromone as a colony-specific compound of the territorial mark. Hölldobler and Wilson (1986) were unable to confirm the existence of territorial pheromones in the nest vicinity of *Atta cephalotes*. They suggest that colony-specific marks of the nest entrances are used as orientation signals and find that the valves gland produces an alarm pheromone.

Vilela (1983) confirms the existence of a territorial pheromone in leaf-cutting ants, regulating intraspecific encounters. Excluding the role of the venom gland in the territorial secretion, he reports that the (Z)-9-nonadecene produced by the Dufour gland (Evershed and Morgan, 1981) is an important compound acting in the territorial behavior of *Atta sexdens rubropilosa*.

Salzemann and Jaffe (1990) made the first experimental demonstration of the existence of a colony-specific territory in field colonies of an Attini. *Atta laevigata* actively mark the area around their nests with a pheromone that is produced in the tip of the gaster (Salzemann and Jaffe, 1991), in a way similar to *Atta cephalotes* and *Atta sexdens rubropilosa* as demonstrated by Jaffe et al. (1979) and Vilela (1983). Ethological studies on *Atta laevigata* showed that the territorial mark serves two distinct but complementary functions. One is clearly agonistic, in that intruders become submissive whereas resident ants on marked territory show increased watchfulness and aggressiveness (Salzemann and Jaffe, 1991). The second function is orientation: workers from the same colony use the mark to differentiate the various nest mounds; this difference allows the ants to orient to a specific mound (Salzemann and Jaffe, 1990).

Here we report the effect of various extracts of glands on the territorial behavior of *Atta laevigata*. The ethological study was completed by a chemical analysis of the extracts of the exocrine glands tested and of the secretions collected from the foraging trails in the field.

METHODS AND MATERIALS

Extracts

Insect material was collected from nests in a 15-year-old commercial pine (*Pinus caribea*) plantation at the Estado Monagas, Venezuela. *Atta laevigata* were present at densities of more than 30 adult nests per hectare. Media workers were dissected to prepare the extracts tested. Exocrine glands and parts of body were macerated in methylene chloride (CH_2Cl_2), each extract containing six ant equivalents per milliliter of solvent. The following extracts were prepared: whole gaster, sting + valves gland, Dufour gland, poison gland, hindgut, tibia + tarsus (Figure 1).

To detect the territorial pheromone on ant trails, glass sheets (7.6 × 2.6 × 0.1 cm) were washed with acid and rinsed successively with water, acetone,

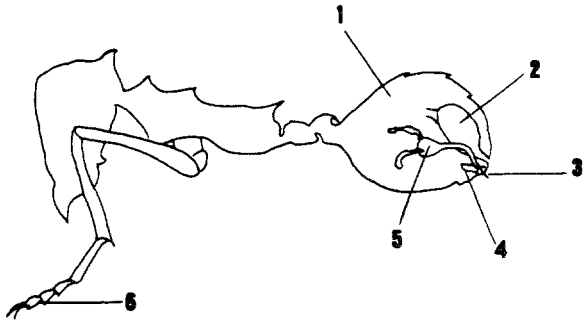

FIG. 1. Diagram of a worker of *Atta*. Parts of the body and glands dissected for the preparation of the extracts are: 1, gaster; 2, rectal sac (hindgut); 3, sting + valves gland; 4, Dufour gland; 5, poison gland; 6, tarsal gland (tibia + tarsus).

and CH_2Cl_2. The glass sheets were laid down on two trails of two close societies, near the nest entrance (first meter of the trail), in the middle, and at the end of the trail (foraging area), for 20 min each. Then they were collected once a day during the five following days and dipped in 200 ml of CH_2Cl_2 before evaporation to 4 ml with a Rotovapor. Two control samples were included: one in which the glass sheets were placed far from the nests where foraging activity was never observed (trail control); the second was a solvent control of pure CH_2Cl_2. All samples were concentrated under nitrogen to 20 μl frozen at $-30°C$ before the chemical analyses.

Ethological Study

To study the agonistic behavior of *A. laevigata* on different substrata, a confrontation test between media workers from neighboring nests was developed. The experiments were conducted in the pine tree plantations.

For each test, two ants were introduced into a Petri dish (9 cm diameter) containing clean sand. The experiment was performed in the field, far away from the nests to avoid any visual recognition of the site. Each worker was transferred to the experimental arena by making it climb a small pine branch and then placing it with the branch into the Petri dish without disturbing it. Encounters were studied on virgin territory (with only clean sand in the dishes) or on marked territories (sand impregnated with different gland extracts).

The first worker was always introduced 5 min after the impregnation of the sand by 1 ml of the extract. Its alarm behavior, characterized by rapid and uncoordinated movements and opening of mandibles, was quantified. Then, the agonistic behavior of ants was observed during the 5-min period following the introduction of the second worker into the Petri dish. Resident workers were

nestmates of the dissected ants used to prepare the extracts; intruder workers were taken from a different conspecific colony.

Results were compared to a control prepared by spreading the sand with pure solvent and to a series of tests performed on a natural marked territory (marked by workers in the field). In this case, the experimental arena was a bottomless plastic cylinder (9 cm diameter, 8 cm high) placed at the beginning of an active foraging trail (0–1 m from the resident nest mound).

Reference Compounds

n-Heptadecane and (*Z*)-9-tricosene were commercial standards provided by Sigma Co. Their purity (99%) was checked by capillary gas chromatography.

(*Z*)-9-Nonadecene was synthesized by palladium-catalyzed cross-coupling reactions between nonylzinc bromide and (*Z*)-1-iodo-1-decene, according to the following procedure.

(*Z*)-*1-Iodo-1-Decene.* One tenth mole of an etheral solution of octyllithium (prepared from 1-bromooctane and Li) was added to a stirred suspension of cuprous iodide (0.052 mol) in 100 ml Et_2O at −50°C. Stirring was maintained for 30 min at −35°C. Acetylene (0.11 mol) was bubbled into this blue solution at −35°C and after 30 min at −25°C, a greenish solution of (*Z*)-1-decenyl-cuprate was obtained. To this reagent was added at −60°C, 0.1 mol of iodine, and the stirred mixture was warmed to −15°C until discoloration. The mixture was hydrolyzed with NH_4OH–NH_4Cl solution (50:50), 100 ml, admixed with pentane (100 ml), filtered, and extracted with Et_2O. The organic phase was washed successively with $Na_2S_2O_3$, $NaHCO_3$, and NH_4Cl saturated aqueous solutions. It then was dried over $MgSO_4$ and concentrated on a Rotovapor. The residue was distilled over Cu powder to produce 1-iodo-(*Z*)-1-decene (80% yield) with isomeric purity >99.5%, Bp = 61°C/0.01 mm Hg.

(*Z*)-*9-Nonadecene.* To an etheral solution of nonyllithium (0.03 mol) in 50 ml of THF were added at 0°C an anhydrous $ZnBr_2$ solution (0.035 mol/50 ml THF). The stirred mixture was allowed to warm up to 20°C and at 15°C and 0°C was added successively a solution of tetrakis triphenyl phosphine palladium (0.4 mmol/20 ml THF) (2%) and 0.02 mol of (*Z*)-1-iodo-1-nonadecene. Stirring was maintained overnight at room temperature. The reaction mixture was hydrolyzed with H_2SO_4 solution (1 N). The crude residue then was filtered through a small column packed with silica gel in order to remove the palladium catalyst (eluting with pentane). The solvent was evaporated, and the crude residue was distilled to produce (*Z*)-9-nonadecene (87% yield), bp: 110–120°C/0.01 mm Hg; (Z) purity (>99.5%); *m/z:* 266 ($M^{+\cdot}$), 55 (100%); IR (neat) ν cm-1: 1450, 710 (HC=CH) *cis*; [^{1}H]NMR (δ ppm): 0.9 (t, 6H) CH_3, 1.3 (m, 26H) CH_2, 2.0 (m, 4H) CH_2−CH=, 5.3 (t, 2H) CH= (J = 4.5 Hz); [^{13}C]NMR (δ ppm): 129.9 (HC=CH).

Identification

All gland, trail, and control extracts were analyzed under the same conditions by gas chromatography (GC) on a nonpolar capillary column. A Fractovap 2900 (Carlo Erba) was equipped with a split/splitless injector (275°C) and a FID detector (275°C). The column was a fused silica capillary Ultra 2 (Hewlett Packard) measuring 25 m × 0.2 mm ID. The oven was programmed from 40 to 60°C at 20°C/min, 60°C for 5 min, then reprogrammed from 60 to 250°C at 6°C/min and held isothermally at 250°C for 20 min. The pressure of the carrier gas (helium) in the column was 1.2 bars, and there was a splitless period of 20 sec during each injection. Gas chromatography–mass spectrometry (GC-MS) studies of the Dufour gland components were conducted on a Girdel 32 GC (CP Sil5 CB, Chrompack, 25 m × 0.32 mm ID, 60–250°C at 8°C/min) coupled with a Nermag 10-10C quadrupole mass spectrometer incorporating a Sidar data system and using the NIH spectra library. Mass spectra were recorded at 70 eV. The interface was maintained at 150°C and the carrier gas (Helium) at a 0.5 bar pressure.

Identification of the components of the Dufour gland was made by comparison with reference spectra, interpretation of the fragmentation pattern, and by coinjection with appropriate standards on a nonpolar column (previously described) and a polar column (FFAP CB, 25 m × 0.32 mm ID, Chrompack, from 80 to 220°C at 6°C/min; other conditions identical to the previous analyses).

Positions of the double bonds in the mono- and diethylenic compounds were determined by ozonolysis of fractions obtained by micropreparative GC using a Wide Bore nonpolar capillary column (Malosse, 1990). The purified fractions checked by GC-MS and cooled in an ice bath were submitted for 5 min to a slow stream of ozone generated by a microozonolyzer. The production of derivatives was controlled by GC-MS.

RESULTS

Ethological Study

At the beginning of an active foraging trail, a clear dominance of the resident worker over an intruder could be observed, regardless of the order in which they entered the arena (Table 1: natural marked territory). The presence of the territorial mark also induced a significant difference between the alarm behavior and its duration (alarm prolonged over 1 min) in the intruder and the resident ant.

On virgin territory (clean sand without extract), the first ant to enter the arena seemed to have an advantage in aggressive encounters (frequency of men-

[a]Intruder was introduced into the arena with a 5-min delay after the resident (R-I) or vice versa (I-R).

[b]*, **, *** indicates $P < 0.05$, $P < 0.01$, and $P < 0.001$, respectively, if R-I is compared to I-R with a χ^2 or Fisher test when theorical samples were less than five.

acing shown by the first worker introduced in the arena). The intruder, instead of submission, menaced the resident worker. In this case, no significant difference could be detected between the alarm behavior of the two ants. The same results could be observed when encounters were studied on sand spread with pure solvent (Table 1: virgin territory and CH_2Cl_2).

Only two series of extracts (gaster and Dufour gland) indicated the presence of a territorial mark when spread on the bottom of the dishes. The resident ant dominated the encounters, whatever the order of entry into the arena, and the alarm behaviors were statistically significantly different ($P < 0.05$ in the repetition of the behavior during the test; Table 1: gaster and Dufour between resident and intruder). When the sand of the dishes was impregnated with the other extracts, the same agonistic behavior as that reported on virgin territory was observed. The extract of sting + valves gland was only able to induce a statistically significant difference ($P < 0.01$) when comparing the repetition of alarm behavior between both ants (Table 1: sting + valves, venom, hindgut, and tibia + tarsus).

Identification of Pheromone

The ethological study suggested that the Dufour gland is the site of production for the territorial pheromone. Gas chromatography of this extract (Figure 2) revealed the presence of 14 compounds, mainly long-chain hydrocarbons (Table 2). Only four products (peaks 2, 4, 5, 10) were found to be present on the trail extracts (Table 3, Figure 3). Compound 1 was present in very low amounts (0–18% of mixture 1, 2, 4, 5, 10 at the beginning of the trail). The proportion of the four products found on naturally marked trails suggested a possible colony-specific function for products 2, 5, and 10 (Table 4). Stable ratios of products 2 and 10 and 5 and 10 from different trails of the same nest (Table 5) suggested a colony specificity of products 5 and 10.

Compound 2 had a retention time on the two columns corresponding to the *n*-heptadecane. Retention times of compounds 5 and 10 matched those of nonadecene and tricosene on both columns. Their identity was confirmed by GC-MS, which gave a molecular weight for nonadecene of $M^{+\cdot} = 266$ ($C_{19}H_{38}$) and for tricosene of $M^{+\cdot} = 322$ ($C_{23}H_{46}$). The position of the double bond was given by the ozonolysis of the corresponding fractions: nonanal and decanal, nonanal and tetradecanal, respectively, were produced from (*Z*)-9-nonadecene and (*Z*)-9-tricosene.

The retention time of compound 4 compared to that of nonadecene and nonadecane, combined with the GC-MS data ($M^{+\cdot} = 264$, $C_{19}H_{36}$), suggested it to be nonadecadiene. The ozonolysis of the corresponding fraction only gave the octanal resulting from the cleavage of the symmetrical 8,11-nonadecadiene, as also found by Evershed and Morgan (1981) in *Atta sexdens* Dufour gland.

DISCUSSION

Many compounds detected on the foraging trails of *Atta laevigata* may be involved in territorial recognition. Ethological tests showed that the Dufour gland of the ant is the best candidate to interfere in the territorial marking. The principal compounds of the Dufour gland are alkenes in *Atta laevigata*; alkanes were reported by Evershed and Morgan (1980) in *Atta cephalotes*. The four compounds also found on natural marked territories [from major to minor: (*Z*)-9-tricosene, (*Z*)-9-nonadecene, 8,11-nonadecadiene, and *n*-heptadecane] were reported in various Attini by Evershed and Morgan (1980, 1981), but only nonadecadiene (Jaffe et al., 1979) and (*Z*)-9-nonadecene (Vilela, 1983) were

suggested as territorial compounds in *Atta*. The latter alkene was described in *Atta cephalotes* by Bradshaw et al., (1983) as a product regulating chain transport of leaves. (Z)-9-Tricosene is known as a sex pheromone of the house fly (Carlson et al., 1971). The absence of this compound in the sites where the territorial behavior of workers was never observed (end of the trails in the pine tree plantations) suggests its importance in the constitution of the territorial pheromone of *Atta laevigata*.

None of these compounds alone could define a clear species, colony, or nestmound specificity. Other compounds of the Dufour gland secretion could be laid down on the trails and chemically modified (e.g., oxidation of terpenes, Funes et al., 1973). Such compounds could interfere in the territorial behavior of the ants but their transformation makes difficult their detection in the gas chromatographic trace of the trails. Only the quality of the mixture could lend significance to the mark laid down around the nest. In *Atta laevigata*, proportions of (Z)-9-nonadecene and (Z)-9-tricosene showed a colony-specific property and 8,11-nonadecadiene could define, according to the other compounds, a nestmound specificity of the territorial pheromone.

Elsewhere, Salzemann and Jaffe (1990) reported that the territorial pheromone in *Atta laevigata* presented such high specificity that it was able to help the workers, without visual cues, differentiate the mounds of their nest. Therefore, this pheromone has a double function: to repel conspecific intruders and to orient resident ants on their return to the nest. All *Atta* species seem to show a nestmound fidelity of foraging workers (Porter and Bowers, 1982). We suggest that the Dufour gland secretion has this function in Attini where the territorial pheromone is also an orientation pheromone. Cammaerts et al. (1977) observed a similar phenomenon in *Myrmica rubra* and showed that workers used their Dufour gland secretions to conquer new territory and to recruit nestmates to it.

Our results excluded the role of the venom gland in territorial marking and confirmed observations reported by Vilela (1983) on *Atta sexdens rubropilosa*. Observing an attractive effect of the venom gland extract, Hölldobler and Wilson (1986) suggested that in *Atta cephalotes* a role for this secretion is in orientation. The same authors reported that other colony-specific substances are laid down around the nest exits but ignored their origin or relation to the orientation pheromones. They observed that the perception of these substances by workers of a foreign colony increased their marking behavior of the territory. This behavior, allowing covering the foreign mark and maintenance of the territorial property of the resident colony as reported by Vilela (1983) in *Atta sexdens rubropilosa* and Jaffe and Sanchez (1984) in *Camponotus rufipes*, indicates the value of this substance.

As was true for Hölldobler and Wilson (1986), we could find no evidence for a function in territorial behavior of the valves gland or sting sheet gland secretion. The only statistically significant that could be detected was difference

in the duration of the alarm behavior, showing that this extract had a colony-specific property, probably from contamination of the sting duct by the content of the Dufour gland. The valves gland was not the source of a territorial pheromone as suggested by Jaffe et al. (1979) in *Atta cephalotes*. The results reported by these authors are probably due to contamination of the gland extracts used in their experiments. In fact, we have observed that *n*-nonadecadiene, produced by the valves gland according to Jaffe (1979), was secreted by the Dufour gland, as reported by Evershed and Morgan (1981). We found that the venom gland, the Dufour gland, and the hindgut were easy to dissect but, as Hölldobler and Wilson (1986) reported, we found the valves gland difficult to isolate without portions of the sting or fragments of the adjacent tissues. Thus, contamination of the sting sheet gland extract by other gland secretions is inevitable. Due to this problem of obtaining clean preparations, we did not consider the tergal and the sternal glands.

Tarsal glands, recently observed in the attines (Billen, unpublished results) are not the source of a territorial pheromone in *Atta laevigata*. Few data are available about this glandular structure: first reported in *Apis mellifera* (Arnhart, 1923), their ultrastructure was studied by Lensky et al. (1985). In ants, tibial glands and tarsal glands were observed in *Crematogaster* (Pasteels et al., 1970; Billen, 1984) and *Solenopsis* (Billen, 1990), respectively. A possible function of this structure could be the production of compounds allowing the adherence of workers on smooth substrata as suggested by Lensky and Slabezki (1981) in *Apis* and by Billen (1986) in *Polistes*. Adhesive substances were also described in Diptera (Stork, 1983; Walker et al., 1985). In *Atta*, the structure and function of these glands will be the subject of future study (Salzemann and Billen, in preparation).

Abstract—The aim of this investigation was to determine if sorgoleone (SGL), a hydrophobic compound in *Sorghum bicolor* (L.) Moench root exudate, interferes with mitochondrial functions. Tests were conducted on mitochondria isolated from etiolated soybean [*Glycine max* (L.) Merr.] and corn (*Zea mays* L.) seedlings. The data show SGL is a potent inhibitor of state 3 and state 4 respiration rates in both soybean and corn. Using either NADH, succinate, or malate as substrate, the I_{50} was about 0.5 μM SGL for state 3 and 5.0 μM for state 4 based on 0.3–0.5 mg mitochondrial protein. Absorption spectra indicate SGL blocks electron transport at the b-c_1 complex. These data show that disruption of mitochondrial function may be a mechanism of SGL-mediated growth inhibition previously reported and demonstrate a probable role of SGL in *Sorghum* allelopathy.

Key Words—Sorgoleone, mitochondria, inhibitor, allelochemical, allelopathy, root exudate, *Sorghum bicolor*, electron transport.

INTRODUCTION

Cultivated *Sorghum* species have a reputation for suppressing weed growth (Overland, 1966; Putnam et al., 1983; Putnam and DeFrank, 1983; Forney et

*To whom correspondence should be addressed.

al., 1985; Einhellig and Rasmussen, 1989). Roots of *Sorghum* are known to exude several biological products, both hydrophilic and hydrophobic, that exhibit allelochemical activity (Panasiuk et al., 1986; Netzly and Butler, 1986; Einhellig and Souza, 1992). Some of the hydrophilic exudates include phenols, protein, and 3-deoxanthocyaninidin derivatives (Netzly and Butler, 1986). A major component of the hydrophobic exudate of grain sorghum [*Sorghum bicolor* (L.) Moench] roots is a compound identified as 2-hydroxy-5-methoxy-3-[(8′Z,11′Z)-8′,11′,14′-pentadecatriene]-*p*-hydroquinone, which oxidizes readily into the quinone form (Figure 1), and three minor *p*-benzoquinones that are structurally similar (Netzly and Butler, 1986; Chang et al., 1986; Netzly et al., 1988). The unstable dihydroquinone form of this compound was shown to be a potent germination stimulant for witchweed [*Striga asiatica* (L.) Kuntz. #STRLU]. The stable quinone form, which we will refer to as sorgoleone (SGL), causes inhibition of root elongation in lettuce and some weed species (Netzly et al., 1988). Recent studies in our laboratory indicate that SGL inhibits the growth of several weed species at micromolar concentrations (Einhellig and Souza, 1992).

The mechanisms through which allelopathic chemicals cause their effects remain obscure. Most of the literature reflects quantitative effects of individual allelochemicals on plant growth parameters, with only a limited number of investigations directed toward determining the actual physiological role of an inhibitor that leads to the growth reduction response. Specific allelochemicals have been shown to interfere with phytohormones, plant–water relations, mineral nutrition, stomatal function, carbon fixation and distribution, and respiration (Einhellig, 1986). It is unlikely that the mode of action of the large diversity of individual inhibitors is the same. However, understanding the specific physiological action of a compound is valuable information for potential applications

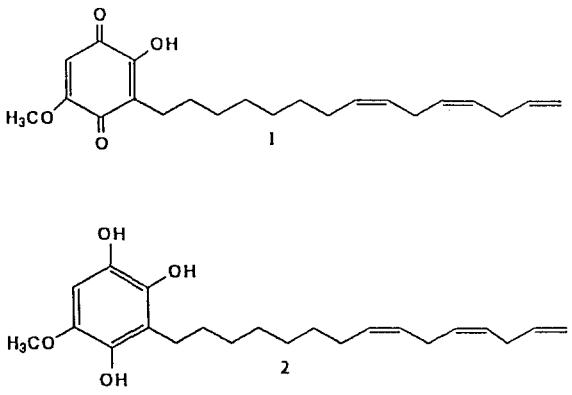

FIG. 1. Structures of **(1)** sorgoleone and **(2)** dihydroquinone of sorgoleone (Chang et al., 1986).

in agroecosystems. This information is also important because allelopathy is generally not the isolated effect of a single compound, and it is affected by the abiotic environment (Rice, 1984; Einhellig, 1986, 1989).

Several allelopathic compounds, as well as some synthetic herbicides, show an effect on respiration and oxidative phosphorylation (Stenlid, 1968, 1970; Koeppe, 1972; Demos et al., 1975; Moreland and Huber, 1979; Jacobson and Jacobson, 1980; Moreland and Novitzky, 1987). Koeppe (1972) found that juglone, a naphthoquinone, is a potent inhibitor of corn mitochondrial respiration. The lipophilicity of SGL suggested it would readily dissolve in plant membranes, and we suspected that SGL might interfere with mitochondrial respiration. The structural similarity between SGL and coenzyme Q, an intermediate in the mitochondrial electron transport chain, was another rationale to investigate possible effects of SGL on respiration.

The initial intent of this investigation was to determine if SGL impacts on oxygen uptake in isolated plant mitochondria. If this occurred, the aim was to determine if the site of inhibition was located in the electron transport pathway. The third objective was to see if response differences exist between mitochondria isolated from monocots and dicots.

METHODS AND MATERIALS

Extraction and Preparation of Sorgoleone. Sorghum root exudate was collected from the roots of grain sorghum seedlings [*Sorghum bicolor* (L.) Moench., Dekalb Hybrid DK 28] in a procedure modified from Netzly et al. (1988). The seeds were rinsed with distilled water and surface sterilized by soaking for 10 min in a 20% bleach solution. They were then grown on moistened filter paper in 9-cm petri dishes (10 seeds per dish) at approximately 27°C for five to seven days. The roots were individually dipped for 1 sec in an extraction solution consisting of 20 ml of methylene chloride acidified with 50 μl of glacial acetic acid, and the extract was filtered through Whatman No. 1 filter paper in a syringe–filtration system. The extract was then evaporated to dryness, resulting in 12–15 mg of residue per 1000 roots. Fate et al. (1990) indicated that the exudate collected in this way is remarkably clean and contains only two major components: sorgoleone and its dihydroquinone. The dihyroquinone readily oxidizes into the quinone. Analysis of this exudate by high-pressure liquid chromatography (HPLC) (Spectra Physics, model SP8800) using a Spherisorb 5 μM ODS2 column (4.6 $\times$ 250 mm) showed over 90% correlated to the SGL peak published by Netzly and Butler (1986) and Netzly et al. (1988). Since no commercial SGL is available, Dr. Larry Butler (Purdue University) provided the initial sample for comparison. This exudate, which we will call SGL, was stored at -4°C until used.

Isolation of Mitochondria. Mitochondria were isolated from 4- to 5-day-old dark-grown, etiolated corn (*Zea mays* L., Pioneer #3615) coleoptiles or soybean [*Glycine max* (L.) Merr., Pioneer #9202] hypocotyls grown in 10^{-4} M $CaCl_2$-saturated vermiculite at 25°C according to procedures modified from Miller et al. (1970). The isolation procedures consisted of grinding tissue in a defined aqueous medium followed by a series of refrigerated centrifugations (1–4°C). Approximately 80 g of tissue were placed in 100 ml of chilled grind mix (0–4°C) containing 0.3 M mannitol, 0.1% bovine serum albumin (BSA), 50 mM HEPES-KOH (pH 7.5), 4 mM L-cysteine, and 5 mM EDTA. Coleoptiles or hypocotyls were homogenized with a chilled mortar and pestle. The homogenate was strained through four layers of cheesecloth. The liquid suspension was placed in each of four, 50-ml tubes and centrifuged (Sorvall RC-5, SS-34 rotor) at 1500*g* for 12 min. The supernatant was reserved and centrifuged at 28,000*g* for 6 min to isolate the mitochondria in the pellet. Pellets were resuspended in chilled, 0.4 M sucrose using a soft camel-hair brush to gently loosen the pellet, and this suspension was centrifuged at 1500*g* for 12 min. The supernatant was reserved, underlain with 0.6 M sucrose, and centrifuged at 17,500*g* for 18 min. The supernatant was carefully aspirated to avoid disruption of the pellet containing the mitochondria. The pellets were resuspended for a final time with enough of a 0.4 M sucrose solution to yield a suspension that contained optimal concentrations for study.

The final mitochondrial suspension used for oxygen uptake studies contained 7–10 mg protein/ml and that used for cytochrome studies was 10–15 mg protein/ml. Mitochondrial suspensions were kept on ice until used. A small amount of suspension was frozen and saved for protein analysis using the Bio-Rad Protein Analysis Method (Bio-Rad Chemical Division) with BSA used as the protein standard.

Experimentation. Oxygen utilization was measured polarographically with a Hansatech instrument (King's Lynn, Norfolk, England), which has a Clark-type oxygen electrode. The 2-ml, water-thermostated reaction chamber was maintained at 25°C. The mitochondrial reaction medium consisted of: 2 mM KH_2PO_4, 10 mM TES (pH 7.6), 5 mM $MgCl_2$, 0.3 M mannitol, and either 10 mM succinate, 33 mM malate, or 1 mM NADH as substrate. Preliminary experiments included 0.1% BSA in this reaction medium. BSA was subsequently found unnecessary, and it was deleted from the reaction medium. A mitochondrial concentration of 0.3–0.5 mg was maintained in 2 ml of reaction medium. For certain tests, 1 μM FCCP (carbonyl cyanide *p*-trifluoromethoxyphenylhydrazone) was employed as an uncoupling agent.

SGL was dissolved in EtOH for use in mitochondrial studies. The concentration of SGL was adjusted so no more than 20 μl of EtOH were injected into the 2-ml reaction chamber. Controls run with 20 μl of EtOH had no impact on mitochondrial respiration rates.

The ADP-stimulated rate of respiration will be referred to as state 3, and the ADP-limited rate will be referred to as state 4 (Chance and Williams, 1955). A respiratory control ratio (RCR) and ADP/O ratio were determined at the onset of each set of experimental trials. The RCR was computed as state 3/state 4. The ADP/O ratio was computed from the moles of ADP utilized per moles of oxygen used in state 3 respiration. Percentage of inhibition was determined as: (control rate minus rate at inhibition)/control rate. An I_{50} is defined as the concentration required to inhibit respiratory rates by 50%.

Spectrographic methodology was used to determine if restricted electron flow occurred at specific cytochrome sites in the electron transport chain. A dilution of approximately two parts mitochondrial suspension (10–15 mg protein/ml) and one part aerated reaction medium was prepared in a 1-ml cuvette. The sample was scanned (Beckman DU70) from 500 to 650 nm using sodium dithionite to reduce all cytochromes, allowing definition of the region of the *b* (560–557) and *c* (554–550) peaks (Douce, 1985; Keightley, 1991). A similar mitochondrial preparation without sodium dithionite was scanned following amendments of SGL. The scans were compared for evidence of location of inhibition of electron transport.

RESULTS AND DISCUSSION

Oxidation of Substrates. Representative polarographic traces of NADH, succinate, and malate oxidation by mitochondria containing approximately 0.3–0.5 mg protein are depicted in Figure 2A–C. Corn mitochondria had average RCR values of 2.5, 2.3, and 2.4 for NADH, succinate, and malate, respectively. The ADP/O ratios for these substrates were 1.2, 1.3, and 1.9. The RCR and ADP/O values for soybean mitochondria were similar. Addition of 1 μM FCCP during state 4 elicited an increased rate of oxygen utilization that persisted until anaerobiosis, indicating the electron transport system could be uncoupled from its requirement for ADP (Douce, 1985).

Sorgoleone Inhibition. Numerous tests were conducted with SGL additions to the reaction medium during state 3 and state 4 mitochondrial respiration after a linear slope was established (Figure 2D and E). As illustrated, SGL is a strong inhibitor of oxygen uptake, and this inhibition is not overcome by FCCP. Although soybean was generally more affected, there were no trend differences between the responses of isolated corn and soybean mitochondria to the addition of SGL. In an average of six or more trials, the I_{50} for NADH substrate state 3 respiration for corn and soybean mitochondria was between 0.5 and 0.7 μM (Figure 3). This lack of differential action between effects on monocot and dicot mitochondria corresponds with our previous study, which showed that SGL strongly inhibited growth in both broadleaf and grass weeds (Einhellig and

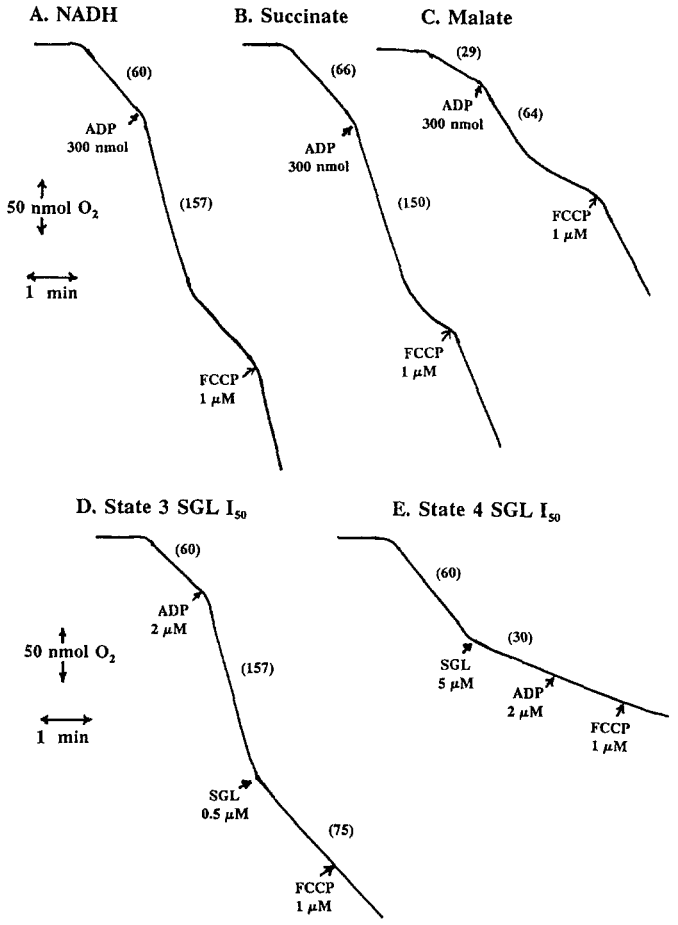

FIG. 2. Representative polarographic traces of oxygen utilization by soybean mitochondria. (A) oxidation of NADH; (B) oxidation of succinate; and (C) oxidation of malate. Traces D and E show sorgoleone inhibition of state 3 and state 4 respiration, respectively.

Souza, 1992). Hence, it appears that the action of SGL on mitochondria can not explain the differences that we found in broadleaf and grass weed abundance following a crop of *Sorghum bicolor* (Einhellig and Rasmussen, 1989).

SGL is a strong inhibitor of mitochondrial oxidation for all three substrates tested in these experiments (Figure 4). NADH, succinate, and malate oxidation were similarly inhibited by SGL concentrations between 0.1 and 0.5 μM, with the latter being the I_{50}. However, SGL approaches maximum inhibition of state-3 succinate oxidation at lower concentrations (0.8–1.0 μM) than when NADH and malate are the substrates. Perhaps this is because succinate provides elec-

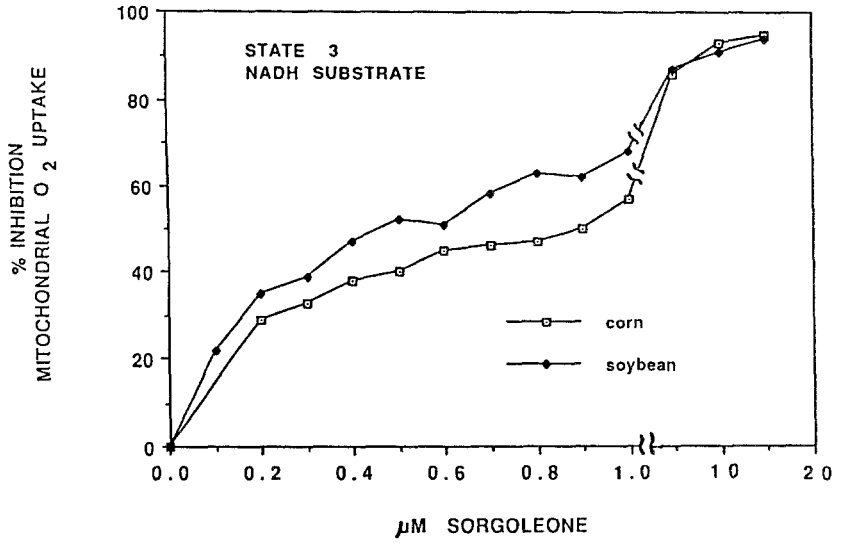

FIG. 3. Effects of sorgoleone on NADH state 3 oxygen uptake of isolated soybean and corn mitochondria, approximately 0.4 mg protein.

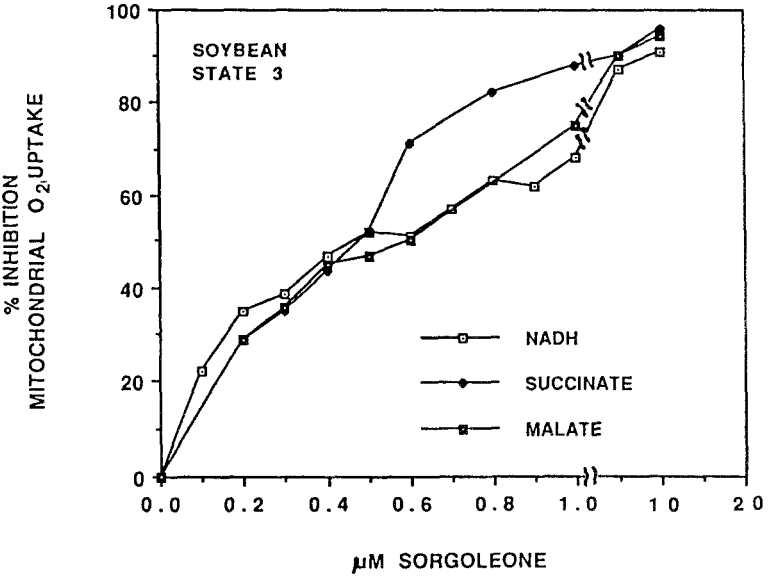

FIG. 4. Effects of sorgoleone on NADH, succinate, and malate state 3 oxygen uptake of isolated soybean mitochondria, approximately 0.4 mg protein.

trons to the electron transport system via complex II, whereas NADH and malate feed electrons through complex I (Douce, 1985). The maximum SGL inhibition of oxidation for each of the three substrates is approximately 90% even when the SGL concentration is raised 10-fold to 10 μM (Figure 4).

The extreme toxicity of SGL to state 3 mitochondrial respiration is highlighted by comparisons to other compounds reported in the literature (Table 1). It is in the same inhibitory range as rotenone, a commonly used mitochondrial respiratory inhibitor. These comparisons also show SGL is effective at several orders of magnitude below other reported allelochemicals.

State 4 respiration is also inhibited by SGL, but it is much less sensitive to the effects of this compound (Figure 5). The state 4 I_{50} was approximately 5.0 μM, which is 10 times the I_{50} of state 3 (Figures 4 and 5). It should be noted that SGL inhibition of state 4 soybean respiration is essentially identical with all three substrates. After the injection of SGL during state 4, state 3 respiration could not be elicited by the addition of ADP (Figure 2E). This is logical given the high concentrations required to inhibit state 4. As in all previous work, there was no material difference between effects of SGL on corn and soybean mitochondrial functions.

In both state 3 and state 4 respiration studies, the introduction of SGL elicited an immediate inhibitory response that persisted during the course of the experiment. The strongly hydrophobic nature of SGL with its long nonpolar, hydrocarbon chain (Figure 1) makes it very lipid soluble. Hence, it should readily solubilize in the mitochondrial membrane, providing a mechanism for immediate and persistent interaction with the site of electron transport.

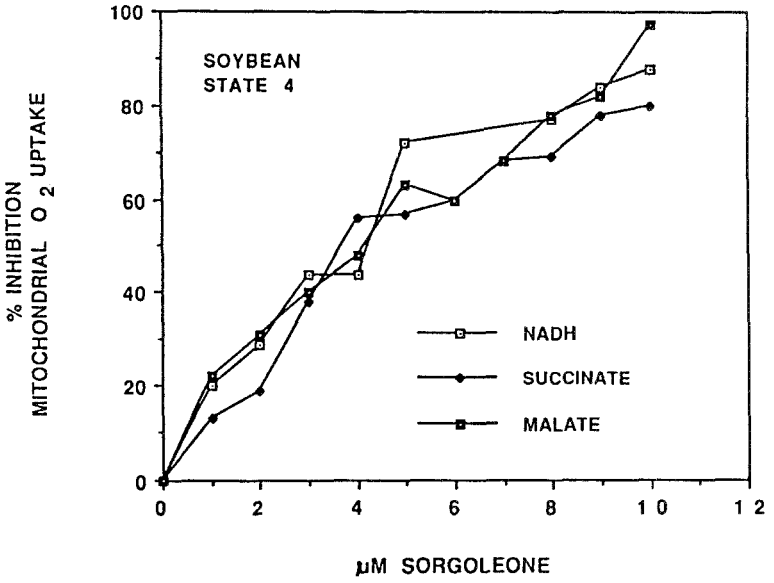

FIG. 5. Effects of sorgoleone on NADH, succinate, and malate state 4 oxygen uptake of isolated soybean mitochondria, approximately 0.4 mg protein.

The long hydrocarbon chain of SGL probably had another impact in the preliminary stages of the experiments when BSA was used in the reaction medium. In our early experiments BSA was utilized because Douce (1985) had reported its ability to bind free fatty acids. However, we found the presence of BSA in the reaction medium caused a profound effect on the I_{50} of SGL. With BSA in the reaction medium, the I_{50} for state 3 respiration of NADH in soybeans was 75 μM SGL compared to 0.5 μM SGL without BSA. It seems very probable that BSA in the medium binds to SGL, limiting the activity of SGL.

Site of Inhibition. The failure of FCCP to circumvent inhibition of state 3 and state 4 respiration by SGL (Figure 2D and E) suggests that SGL acts primarily as an electron-transport inhibitor (Moreland and Novitzky, 1987). When sodium dithionite was used to reduce the cytochromes of isolated mitochondria, characteristic peaks of the cytochrome *b* and *c* regions were revealed (Figure 6). The *b*-type cytochromes are reduced with the addition of SGL, but there is no evidence of a cytochrome $c_{1\text{-}554}$ peak. Since details of the cytochrome *b* complex are elusive, we can conclude that SGL blocks electron flow between the cytochrome *b* and c_1 complex. Several inhibitors of animal mitochondrial electron transport, including hydroquinone analogs, are known to block in this region (Von Jagow and Link, 1986).

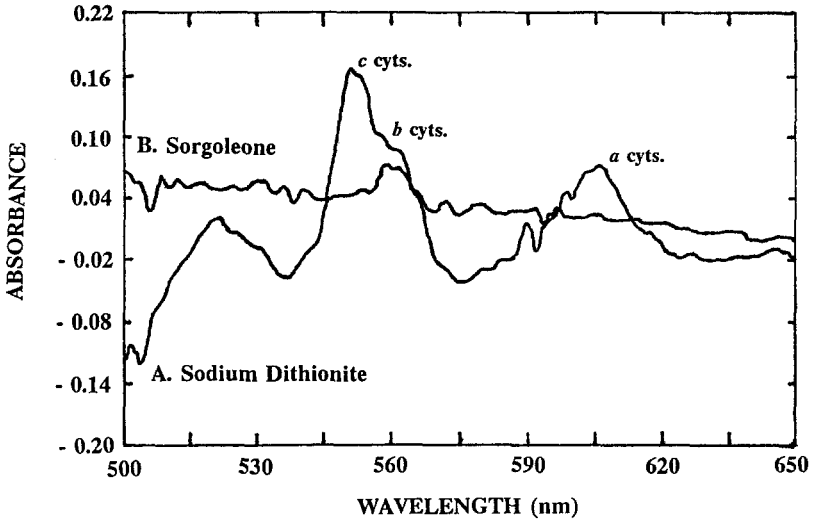

FIG. 6. Spectrophotometric traces of mitochondrial cytochromes (cyts.) after amendments of sodium dithionite (A) and sorgoleone (B).

CONCLUSION

The data demonstrate that SGL, a recently reported *Sorghum bicolor* root exudate, is a powerful inhibitor of respiration in isolated soybean and corn mitochondria. Spectrophotometric studies suggested one mechanism of SGL inhibition is a blockage of electron flow between the cytochrome *b* and c_1 complex.

The effects of SGL on mitochondrial respiration may be an important mechanism responsible for causing the inhibition of growth of several weed species that we have reported (Einhellig and Souza, 1992). This mitochondrial work, plus the evidence that SGL is abundant in *S. bicolor* root exudate, has been isolated from soil, and can persist for a substantial period in soil (Netzly et al., 1988), demonstrates SGL has a role in *Sorghum* allelopathy.

(Received March 8, 1990; accepted October 21, 1991)

Abstract—This study was designed to compare the chemistry of elaiosomes of three sympatric species of *Trillium* to discover if there are correlations between chemistry and dispersal rates by ants. We quantified the amount of proteins and neutral lipids and qualitatively analyzed the fatty acids occurring in triglyceride, diglyceride, monoglyceride, and free fatty acid fractions. *T. grandiflorum* had the highest lipid concentration per milligram of protein and the highest total lipid per elaiosome, followed by *T. erectum* and then by *T. undulatum*. Oleic acid (18:1) was abundant in all lipid fractions of each species. This fatty acid, which is responsible for corpse-carrying behavior in some ants, probably causes ants to pick up diaspores. Linoleic acid (18:2) is relatively abundant in *T. erectum* and *T. grandiflorum* but not in *T. undulatum* and may cause ants that have picked up diaspores to move (carry) those diaspores back to the nest. Total elaiosome mass and fatty acid composition appear to explain why *T. erectum* is dispersed most rapidly and why ants that have picked up elaiosomes move more *T. grandiflorum* than *T. undulatum* diaspores.

Key Words—*Trillium*, ant dispersal, Hymenoptera, Formicidae, elaiosomes, lipids, diglycerides, triglycerides, oleic acid, linoleic acid.

INTRODUCTION

The dispersal units (diaspores) of ant-dispersed plants consist of a seed and an attached elaiosome that is usually rich in lipids (Beattie, 1985). Ants grasp the

elaiosome and carry or drag the diaspore to their nest. The ants feed the elaiosome to larvae and discard the remaining seed in their refuse piles (Beattie, 1985). Such dispersal may provide the plant with escape from predation (O'Dowd and Hay, 1980; Culver and Beattie, 1978; Kjellsson, 1985a), escape from competition (Handel, 1978; Kjellsson, 1985b), enhanced germination (Culver and Beattie, 1980; Horvitz, 1981), or nutrient-rich germination sites (Beattie and Culver, 1983; Hanzawa et al., 1988; but see Horvitz and Schemske, 1986; Bond and Stock, 1989).

The elaiosome is the ant-attractive portion of the diaspore, as shown by numerous experiments where intact diaspores and elaiosomes were removed by ants but seeds without elaiosomes were not (Mesler and Lu, 1983; Kjellsson, 1985a; Ohara and Higashi, 1987; Skidmore and Heithaus, 1988; Brew et al., 1989). Elaiosomes vary in size (O'Dowd and Gill, 1986; Gunther and Lanza, 1989), as well as in chemical content, with sympatric species differing in amino acid content (Brew et al., 1989) and lipid composition (Bresinsky, 1963; Soukup and Holman, 1987; Brew et al., 1989; Kusmenoglu et al., 1989).

Most studies have shown that the lipid fraction, particularly the diglyceride fraction, is the major attractant to ants. Bresinsky (1963) concluded that the fatty acid ricinoleic acid (18:1) was the most important ant attractant of *Viola odorata* elaiosomes but later experiments have failed to support this conclusion. Instead, experiments by Marshall et al. (1979), Skidmore and Heithaus (1988), and Brew et al. (1989) have focused attention on the free fatty acid oleic acid (also 18:1) and the diglyceride containing two oleic acid chains (1,2-diolein). In addition, amino acids may contribute to ant attraction in *Tetratheca stenocarpa* (Brew et al., 1989).

Ants disperse up to 30% of the spring-flowering herbaceous species in the deciduous forests of eastern North America, including *Trillium* spp., *Hepatica americanum*, *Asarum canadense*, *Sanguinaria canadensis*, and *Viola* spp. (Berg, 1958; Beattie and Culver, 1981; Heithaus, 1981; Gunther and Lanza, 1989; Smith et al., 1989a,b). Ants respond differently to diaspores of different species; for example, *Aphaenogaster rudis* is more likely to disperse *Hepatica acutiloba* than *Viola* sp. (Beattie et al., 1979) and *Myrmica punctiventris* is more likely to disperse *Trillium erectum* than *T. grandiflorum* (Gunther and Lanza, 1989). The cause of these differences may be differences in elaiosome mass, morphology, chemistry, or, according to Smith et al. (1989a,b), spatial distributions and densities. Elaiosome size seems to explain the preference of *Lasius niger* for three species of plants in The Netherlands (Oostermeijer, 1989). Gunther and Lanza (1989) attempted to answer the question with regard to elaiosome mass by measuring elaiosome mass and elaiosome/diaspore mass ratios in three sympatric species of *Trillium* (*grandiflorum*, *erectum*, and *undulatum*) and correlating these comparisons with ant response to the diaspores of the three species. They discovered that elaiosome mass characteristics could account for only some

of the observed differences in dispersal rates and concluded that ants respond to a complex of characters, including elaiosome mass, morphology, and chemistry.

Might differences in lipid content explain the observed differences in dispersal of sympatric *Trillium* species? This study was designed to compare the chemistry of elaiosomes of three sympatric species of *Trillium* (*grandiflorum*, *erectum*, and *undulatum*) from the same populations studied by Gunther and Lanza (1989) to discover if there are correlations between chemistry and dispersal rates by ants.

METHODS AND MATERIALS

Diaspores of three species of *Trillium* were collected and stored at −18°C prior to chemical analysis. Fruits of *Trillium erectum* and *T. grandiflorum* were collected from the SUNY College at Fredonia campus woodlot, and fruits of painted trillium (*T. undulatum*) were collected from the Herbert C. Mackie Camp in Brocton, New York, approximately 16 km away. These populations were the ones Gunther and Lanza (1989) used for collecting diaspores for their study.

Prior to chemical analysis, elaiosomes were scraped from the diaspores, weighed to 16.0 ± 0.4 mg, transferred to microcentrifuge tubes, and stored at 0°C. Six samples were collected for each of the three species. Samples usually consisted of elaiosomes from a single fruit; in a few cases, when fruits had few seeds, elaiosomes from two fruits were pooled to make a single sample. Each elaiosome sample was then homogenized in 2.0 ml physiological saline (8.5 g NaCl/liter distilled, deionized water) for 10 sec using a Tissumizer (model TR-10, Tekmar Co., Cincinnati, Ohio) at 70% maximum speed. The sample was placed on ice for 1 min, homogenized for another 10 sec at 70% maximum speed, and rinsed with 1.0 ml physiological saline.

For total protein determinations, aliquots of the elaiosome homogenates were assayed in duplicate according to Lees and Paxman (1972). Lipids were extracted from the homogenate by the method of Folch et al. (1957). For total neutral lipids (triglycerides, diglycerides and monoglycerides) determination, 0.25-ml aliquots of the lipid extracts were assayed with a Sigma Diagnostics Kit (Procedure No. 335-UV). Total phospholipids concentrations were measured by the method of Raheja et al. (1973) but were too low to measure reliably and no further quantitative analysis was conducted; qualitative analyses were conducted but are not reported here because of the low concentrations.

Thin-layer chromatography (TLC) was used to separate the different groups of neutral lipids (Garland and Randle, 1963) in the lipid extracts of four randomly selected replicates of each of the three species. Silica gel containing triglycerides (TG), diglycerides (DG), monoglycerides (MG), and free fatty

acids (FFA) was scraped from the plates, and silica was deactivated with one drop of water; the lipids were eluted with 2.0 ml methanol:chloroform (2:1 v/v). The resultant lipid fractions were stored in Teflon-capped tubes at 4°C under nitrogen.

For fatty acid analysis, lipid fractions (TG, DG, MG, and FFA) were methylated (Lepage and Roy, 1984), and their fatty acid composition was examined as described by Awad et al. (1989). Briefly, fatty acid methyl esters were separated on a GC-9A Shimadzu (Columbia, Maryland) using a 6-ft × 1/8-in. glass column packed with 10% SP-2330 on 100–120 Chromosorb WAW (Supelco, Bellefonte, Pennsylvania). The temperatures of the injection port and oven were maintained at 260°C and 190°C, respectively. Nitrogen was used as the carrier gas. Peaks were identified using standards obtained from Supelco and Nu-Chek Prep (Elysin, Minnesota). Areas under the peaks were measured using an integrator and expressed as percent concentrations. Percentages were arc-sine transformed (Zar, 1984) and analyzed with two-factor ANOVAs on the Statview 512+ package for the Macintosh. Tukey's test for multiple comparisons (Zar, 1984) was used to determine significant differences among the three *Trillium* species in the amounts of individual fatty acids.

Statistical comparisons could only be made on the amounts of fatty acids, but two data summaries were useful for examining trends in lipid chemistry of the three species. We first calculated the percent of fatty acids that were saturated, monounsaturated, and polyunsaturated; some insects require polyunsaturated fatty acids in their diet to complete normal development (Chippendale, 1972). We also calculated an unsaturation index {[% monounsaturated + 2(% fatty acids with two double bonds) + 3(% fatty acids with three double bonds)]/(% saturated + % monounsaturated + % polyunsaturated)} to provide a single estimate of the average number of double bonds per fatty acid.

RESULTS

The three *Trillium* species differed in their protein content (Table 1; ANOVA, $F = 13.56$, $df = 2,15$, $P < 0.05$). *T. undulatum* had the lowest protein concentration per gram of elaiosome tissue and was significantly lower than both *T. erectum* (Scheffé $F = 5.33$; $P < 0.05$) and *T. grandiflorum* (Scheffé $F = 13.24$; $P < 0.05$). The protein content of *T. erectum* and *T. grandiflorum* did not differ significantly (Scheffé $F = 1.77$; $P > 0.05$).

The three *Trillium* species also differed in their total neutral lipids in relation to the protein concentration (Table 1; ANOVA, $F = 42.44$, $df = 2,15$, $P > 0.001$). *T. undulatum* had the lowest lipid concentration per milligram of protein and was significantly lower than both *T. erectum* (Scheffé $F = 16.82$; $P < 0.05$) and *T. grandiflorum* (Scheffé $F = 41.40$; $P < 0.05$). The lipid concen-

Species	Elaiosome mass (mg)[b]	Protein concentration (mg/g elai)	Neutral lipids concentration (mg/mg protein)	Total lipids/ elaiosome (mg)
T. grandiflorum	3.50 (0.93)c	117.55 (24.2)b	2.7 (0.04)c	1.10
T. erectum	3.90 (1.66)b	96.40 (23.2)b	1.9 (0.02)b	0.71
T. undulatum	1.05 (0.35)a	59.67 (3.8)a	0.7 (0.05)a	0.04

[a] Means (±SD) are shown for elaiosome mass, protein concentration per gram of elaiosome tissue, and neutral lipids concentration per milligram of protein; for protein and lipid measurements, $n = 6$. Total lipids per elaiosome = (elaiosome mass, g/elai) × (protein concentration, mg/g elai tissue) × (lipid concentration, mg/mg protein). Means in a column with different letters were significantly different.

[b] From Gunther and Lanza (1989).

tration of *T. erectum* was also lower than that of *T. grandiflorum* (Scheffé $F = 5.45$; $P < 0.05$).

The elaiosomes of *T. undulatum* contained much lower total amounts of lipids than *T. grandiflorum* and *T. erectum*, approximately 5% of the lipid content of *T. grandiflorum* elaiosomes (Table 1). The total lipids per *T. erectum* elaiosome was approximately 70% of the amount occurring in *T. grandiflorum*.

The fatty acid composition of the three *Trillium* species differed significantly in all four classes of lipids tested (Table 2). In all classes of lipids, concentrations of the 11 fatty acid types differed significantly. Furthermore, there was always a significant interaction between fatty acid type and species, meaning that the concentration of different fatty acids differed among species. Because the interaction effect was significant, we conducted Tukey multiple comparison tests to discover which fatty acids differed in concentration among the three species (Zar, 1984).

The triglyceride fraction (Tables 3 and 4) of the elaiosomes of *T. undulatum* had a lower unsaturation index (i.e., fewer fatty acids containing double bonds) than that of either *T. erectum* or *T. grandiflorum*. This difference was due to a lower concentration of linoleic acid (18:2) in *T. undulatum* than in the other two species and a concomitant increase in palmitic (16:0) and stearic (18:0) acids. *T. undulatum* also contained higher concentrations of myristic (14:0), heptadecanoic (17:0), and erucic (22:1) fatty acids than its congeners. The concentrations of only two fatty acids differed between *T. erectum* and *T. grandiflorum*, with *T. erectum* being richer in palmitoleic (16:1) and poorer in stearic than *T. grandiflorum*. In *T. erectum* and *T. grandiflorum*, the most abundant fatty acids, in decreasing order of concentration, were oleic (18:1), linoleic,

[a] Values are mean percentages ± SD ($N = 4$) for each fatty acid as a fraction of each lipid type (TG, DG, MG or FFA). * after a lipid type indicates the presence of significant differences in a given row. Means within a lipid class with different letters were significantly different (Tukey's multiple comparison test on transformed data, $P < 0.05$).

Again, this difference was primarily due to a lower concentration of linoleic (18:2) fatty acid and a higher concentration of palmitic (16:0) and stearic (18:0) acids in *T. undulatum* as compared to both *T. erectum* and *T. grandiflorum*. *T. grandiflorum* had higher levels of oleic (18:1) than did either of the other two species. The most abundant fatty acids in *T. erectum* and *T. grandiflorum* were oleic, linoleic, and myristic (14:0), whereas *T. undulatum* contained the largest amounts of palmitic, oleic, stearic, and myristic acids.

The degree of saturation of the fatty acids from monoglycerides (Tables 3 and 4) was more similar among the three *Trillium* species than in the tri- and diglyceride fractions but was still highest in *T. undulatum*. *T. undulatum* was lower in oleic (18:1) than *T. grandiflorum* and lower in linoleic (18:2) than *T. erectum*; it was higher than both in palmitic (16:0) and higher than *T. erectum* in stearic (18:0). *T. erectum* and *T. grandiflorum* also differed, with *T. erectum* having lower concentrations of myristoleic (14:1) and stearic acids but a higher concentration of linoleic. The three most abundant fatty acids varied among the species: myristic, oleic, and erucic (22:1) in *T. erectum*; oleic, myristic, and erucic in *T. grandiflorum*; and palmitic (16:0), myristic, and oleic in *T. undulatum*.

The free fatty acids (Tables 3 and 4) of *T. grandiflorum* were more saturated than those of *T. erectum* and *T. undulatum*. This difference was caused by a higher concentration of stearic acid (18:0) in *T. grandiflorum*, more oleic acid (18:1) in *T. undulatum*, and more linoleic acid (18:2) in *T. erectum*. *T. undulatum* was also lower in linoleic acid concentration than *T. erectum*. The most abundant fatty acid in all three species was oleic acid. The next most abundant fatty acids varied among the three species: linoleic, palmitic (16:0), and stearic

in *T. erectum*; stearic and palmitic in *T. grandiflorum*; and stearic in *T. undulatum*.

In comparing the three species, the largest difference in fatty acid chemistry occurred between *T. undulatum* and *T. erectum*. The unsaturation index for *T. undulatum* was lower than that of *T. erectum* in all four classes of lipids.

The most consistent differences between species occurred in the concentrations of fatty acids with 18 carbons. *T. undulatum* tended to have a higher concentration of stearic (18:0—three of the four classes of lipids) but lower concentrations of oleic (18:1—two of the four lipid classes) and especially linoleic (18:2—all four of the lipid classes).

DISCUSSION

The elaiosomes of all three *Trillium* species contained protein, triglycerides, diglycerides, monoglycerides, and free fatty acids. Elaiosomes of *T. undulatum*, the smallest of the three species (Gunther and Lanza, 1989), were lowest in protein and lipid content, both in absolute measurements (per elaiosome) and in concentration (per gram of elaiosome). *T. erectum* was lower in lipid content than *T. grandiflorum*. Our analyses appear comparable to two other less-detailed studies of *Trillium* elaiosomes. When the fatty acids of all neutral lipids are analyzed together, the three most common fatty acids of *T. grandiflorum*, *T. erectum*, and *T. undulatum* are oleic (18:1), linoleic (18:2), and palmitic (16:0) (Soukup and Holman, 1987). These fatty acids were common in our analyses as well, but we cannot make direct comparisons of amounts because Soukup and Holman did not separate the different neutral lipid fractions. Oleic, linoleic, and palmitic acids are also the most common in the other *Trillium* species that Soukup and Holman analyzed, although two species have substantial amounts of palmitoleic (16:1). In the triglyceride fraction of *T. sessile*, the three most abundant fatty acids in triglycerides are again oleic, linoleic, and palmitic (Kusmenoglu et al., 1989); these authors did not analyze the fatty acids of other neutral lipids in *T. sessile*.

Our analyses, in which we first separated the classes of neutral lipids and then assayed the fatty acids, allow more detailed comparisons of the elaiosomes of three species of *Trillium*. In all classes of neutral lipids, *T. erectum* produced the most unsaturated elaiosomes, although *T. grandiflorum* had similar unsaturation levels in the triglyceride fraction and *T. undulatum* had similar unsaturation levels in the free fatty acid fraction. In all lipid classes, polyunsaturated lipids were more abundant in *T. erectum* than in *T. undulatum*; similarly, in three of the lipid classes, polyunsaturated lipids were more abundant in *T. erectum* than in *T. grandiflorum*. In all lipid classes, *T. undulatum* contained less linoleic acid (18:2), a dietary requirement for some insects (Chippendale, 1972), than did *T. erectum*. Oleic acid (18:1) was a major fatty acid component of all three *Trillium* species in all four classes of lipids.

Differences in *Trillium* elaiosome mass and elaiosome/diaspore mass ratio account for some, but not all, of the differences in ant behavior observed by Gunther and Lanza (1989). The high dispersal rate of *T. erectum* is correlated with large elaiosome mass and high elaiosome/diaspore mass ratio; however, large differences in elaiosome mass and elaiosome/diaspore mass ratio between *T. grandiflorum* and *T. undulatum* are not correlated with overall differences in removal rates by ants. The diaspores of *T. undulatum* are initially very attractive to *Myrmica punctiventris*, for these ants repeatedly pick up the diaspores, but the diaspores do not maintain ant attention, for the ants remove them relatively infrequently from experimental arenas (Gunther and Lanza, 1989).

The total lipid content of elaiosomes may influence ant behavior but does not appear to be a major force controlling ant response to *Trillium* diaspores. Elaiosomes of *T. grandiflorum* represent the greatest lipid reward to potential seed-dispersing ants; even though *T. grandiflorum* elaiosomes are smaller than those of *T. erectum*, ants can collect a greater nutrient reward by gathering *T. grandiflorum* elaiosomes. However, *T. grandiflorum* is removed less quickly by *M. punctiventris* than is *T. erectum* (Gunther and Lanza, 1989). *T. undulatum* elaiosomes contain less total lipid than either *T. erectum* or *T. grandiflorum* but are intermediate in and not significantly different from either species in overall removal rate (Gunther and Lanza, 1989).

The fatty acid profiles of the three species were more closely correlated with ant behavior than was total lipid content. The abundance of oleic acid in our analyses and those of others (Soukup and Holman, 1987; Skidmore and Heithaus, 1988; Brew et al., 1989; Kusmenoglu et al., 1989) supports the idea that it is a major attractant of ants. Behavioral experiments of Marshall et al. (1979), Skidmore and Heithaus (1988), and Brew et al. (1989) showed that oleic acid, in diglyceride and free fatty acid fractions, is an important ant attractant. This is the fatty acid that, as a free fatty acid, elicits corpse-carrying behavior in several ants (Wilson et al., 1958; Haskins and Haskins, 1974) and foraging behavior in some social contexts (Gordon, 1983). The high concentration of oleic acid (59%) in the free fatty acid fraction of *T. undulatum* elaiosomes may account for their initial attractiveness to *M. punctiventris*. However, the fact that picked-up *T. undulatum* diaspores are not removed as frequently as those of *T. grandiflorum* (Gunther and Lanza 1989) suggests that some additional chemical components are important in seed dispersal behavior. Also, the concentrations of oleic acid do not, in any of the lipid fractions, parallel the ant preferences measured by Gunther and Lanza (1989), again indicating that oleic acid is not the only cue to which ants respond.

Linoleic acid, in several lipid fractions, may be a second fatty acid cue in *Trillium* diaspores to which ants may respond. Vinson et al. (1967) showed that linoleic acid (18:2), both as a triglyceride and as a free fatty acid, stimulates feeding by fire ants (*Solenopsis saevissima*). Skidmore and Heithaus (1988)

showed that two lipid fractions extracted from *Hepatica americanum* elaiosomes were attractive to ants and contained various fatty acids, including linoleic acid, either as a diglyceride or as a free fatty acid; however, Marshall et al. (1979) measured little response by ants to linoleic acid as a free fatty acid.

Linoleic acid concentrations, in the various lipid fractions of the three *Trillium* species, appeared correlated with *Myrmica punctiventris* behavior observed by Gunther and Lanza (1989). The linoleic acid concentrations were significantly lower in *T. undulatum* than in all four lipid fractions of *T. erectum* elaiosomes and in two of the four lipid fractions of *T. grandiflorum* elaiosomes, including the important diglyceride fraction. The low concentration of linoleic acid in *T. undulatum* may explain why ants were more likely to remove picked-up *T. grandiflorum* elaiosomes than picked-up *T. undulatum* elaiosomes from the experimental arenas of Gunther and Lanza (1989). This decrease in linoleic acid is concomitant with an increase in the proportion of saturated fatty acids, a group that in various lipid forms, does not contribute substantially to ant attraction (Skidmore and Heithaus, 1988; Brew et al., 1989).

The elaiosomes of three *Trillium* species vary chemically, but the ecological significance of this variation is uncertain. We do not know if this variation has been caused by the preferences of ants for elaiosomes of particular chemical composition, but our results, and those of Gunther and Lanza (1989), suggest that movement of diaspores involves at least two chemical cues: (1) diglyceride and other forms of oleic acid (18:1) and (2) diglyceride and other forms of linoleic acid (18:2). Although this idea must, at this point, remain an hypothesis, it is experimentally testable. Full evaluation of this idea will require: (1) tests of response by other ant species to *Trillium* diaspores, (2) detailed chemical analyses of elaiosomes from other ant-dispersed plants, (3) tests of responses by ants to the diaspores of these other ant-dispersed plants, and (4) observations of ant response to experimentally manipulated mixtures of diglycerides of oleic, linoleic, and other fatty acids.

We suggest that future workers investigate the effect on ant behavior of several fatty acids, especially in diglyceride form. Simply focusing on concentrations of oleic acid is unlikely to further our understanding of the factors involved in ant dispersal.

Acknowledgments—We would like to thank Roger Gunther, Dennis O'Dowd, and Jane Kapler Smith for commenting on the manuscript. This work was supported by funds from State University of New York at Buffalo, under the Graduate Research Initiative Visiting Professor Program.

(Received July 25, 1991; accepted October 21, 1991)

Abstract—Volatiles emitted by *Anastrepha suspensa* and *Anastrepha ludens* males were trapped and compared by GC-MS. Both species emitted previously reported nine-carbon alcohols, (*Z*)-3-nonenol and (*Z,Z*)-3,6-nonadienol, and epimeric lactones, anastrephin and epianastrephin. A third isomeric lactone, the macrolide suspensolide, which was previously known only from *A. suspensa* is reported here for the first time in the volatiles of *A. ludens*. We also report that both species released different proportions of the same three sesquiterpene hydrocarbons: α-farnesene, β-bisabolene, and α-*trans*-bergamotene. The β-bisabolene was isolated in sufficient quantity from *A. suspensa* volatiles to establish its absolute configuration as the (*R*)-(+)-enantiomer. Some plausible biosynthetic relationships of farnesol to the isoprenoid lactones and sesquiterpenes identified in this study are discussed. Finally, we report that *A. suspensa* produces the monoterpene (*Z*)-β-ocimene while *A. ludens* volatiles contained limonene.

Key Words—Diptera, Tephritidae, Caribbean fruit fly, *Anastrepha suspensa*, Mexican fruit fly, *Anastrepha ludens*, male volatiles, GC-MS, suspensolide, farnesene, bisabolene, bergamotene, ocimene, limonene.

INTRODUCTION

The Caribbean fruit fly, *Anastrepha suspensa* Loew, and the Mexican fruit fly, *Anastrepha ludens* Loew, display very similar male courtship and calling behav-

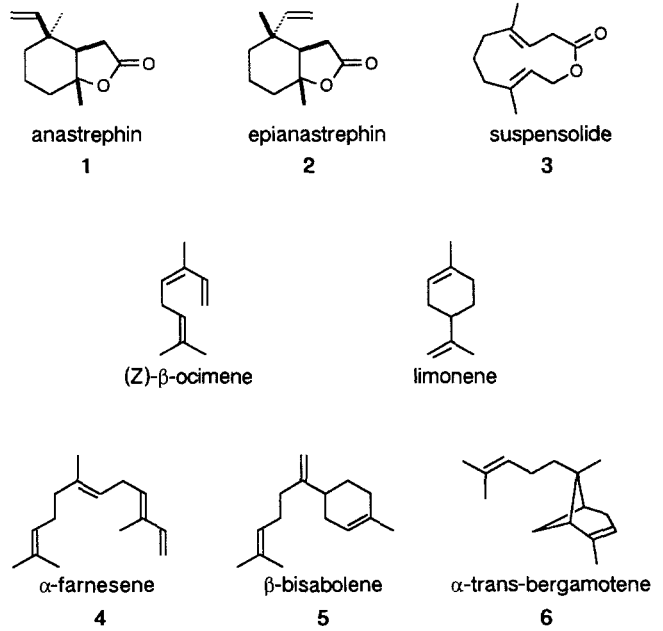
iors (Nation, 1972, 1990; Robacker and Hart, 1985a). Two nine-carbon alcohols, (Z)-non-3-en-1-ol and (3Z,6Z)-nona-3,6-dien-1-ol, have previously been identified from the multicomponent male sex pheromones of both *A. suspensa* (Nation, 1975, 1983) and *A. ludens* (Esponda-Gaxiola, 1977). The two isoprenoid 12-carbon γ-lactones shown in Scheme 1, anastrephin **(1)** and epianastrephin **(2)**, have also been characterized as components of the male pheromonal volatiles of *A. suspensa* (Battiste et al., 1983) and of *A. ludens* (Stokes et al., 1983). While behavioral roles for these four components have been demonstrated both in *A. suspensa* (Nation, 1989 and references therein) and in *A. ludens* (Robacker and Hart, 1985b, 1986; Robacker, 1988), the existence of unidentified or possible additional unknown compounds in the volatiles has also been mentioned for each species.

More recently, the 11-membered macrolide **(3)** shown in Scheme 1, isomeric with anastrephin and epianastrephin, was isolated from the volatiles of *A. suspensa* males and identified and named suspensolide by Chuman et al. (1988). Working closely with those who first identified this macrolide, Battiste



SCHEME. 1. Some of the volatile substances from *Anastrepha suspensa* and *Anastrepha ludens* males. The isoprenoid lactones, **1–3** ($C_{12}H_{18}O_2$, M = 194), and the sesquiterpenes, **4–6** ($C_{15}H_{24}$, M = 204), are present in the volatiles of both species. Of the two monoterpenes ($C_{10}H_{16}$, M = 136), the ocimene is from *A. suspensa* and limonene is from *A. ludens*.

et al. (1988) confirmed its structure and stereochemistry with the first synthesis of (3*E*,8*E*)-suspensolide. Our experience with suspensolide indicated that it was difficult to collect from whole-body extracts of *A. suspensa* because of its lability on contact with polar (acidic) solvents or materials. Thus, we wondered if it might also be present in *A. ludens* males, but not previously identified because the earlier work had been done with whole-body extracts; one of our objectives was to look specifically for this compound using gas chromatography–mass spectrometry (GC-MS). Another objective was to identify and compare additional components in the volatiles from *A. suspensa* and *A. ludens*. These new compounds include the monoterpenes and sesquiterpenes (**4, 5,** and **6**) shown in Scheme 1.

METHODS AND MATERIALS

Collection of Fruit Fly Volatiles

Volatiles from *A. suspensa* males were collected by a published procedure (Nation, 1989, 1990). Volatiles from 50 mature *A. ludens* males were entrained in an airstream and trapped on Porapak Q for 3 hr in Weslaco, Texas. The holding and aeration chamber for the flies was a 500-ml side-arm flask. The trapped volatiles were eluted from the Porapak Q with hexane, and the flask holding the flies was washed with hexane at the end of the collection period to determine if any material was left on the glass. These samples were sealed in vials and mailed to Gainesville, Florida. Before chemical analyses, the samples were diluted to a known volume (1–5 ml), depending upon the sample size and based on previous experience with similar samples from *A. suspensa*. The solutions were analyzed by GC without delay, using a procedure described by Nation (1990), to determine the suitability of the dilution and to ensure that the addition of internal standards would not mask any components in the samples. When satisfactory results were obtained in these preliminary procedures, the following quantitative standards were added: decanol, 4.6 μg; tetradecane, 6.4 μg; and methyl tridecanoate, 9.0 μg. These solutions were then analyzed by GC or GC-MS on the columns and spectrometers described below.

Instrumentation

Gas Chromatography. Samples of volatiles were examined by GC on the following two column–instrument combinations. GC-1: A 10-m × 0.5-mm, large-bore, RSL-160 (Alltech) capillary was fitted to a Varian 2400 chromatograph equipped with an FID. Data were recorded on a Hewlett-Packard 3390-A integrator. GC-2: A 25-m × 0.25-mm, narrow-bore, bonded-phase RSL-150 (Alltech) capillary was fitted to a Shimadzu G-14A chromatograph

equipped with an FID. Samples were introduced splitless into a capillary injector port, followed after 30 sec by a split-purge flow of helium. A typical temperature program started at 60°C, then immediately rose at 10°/min to 120°, followed by a 6 °/min rise to 150°C and hold. Data were recorded on a Spectra Physics 2400 integrator.

GC-MS System-1. This bench-top system (GC-MS-1) was used to produce the total ion current (TIC) chromatograms and mass spectra presented in Figures 1–5 below. Samples of volatiles were analyzed as dilute solutions (ca. 10–100 ng/μl) on a Hewlett-Packard 5995-B gas chromatograph–direct inlet quadrupole mass spectrometer system. Approximately 0.5–1 μl of solution was injected using the splitless-split mode into a 30-m × 0.25-mm fused-silica capillary with a 0.25-μm bonded methyl silicone stationary phase (HP-1), and eluted with helium at a rate of 0.5–1 ml/min. A typical temperature program for the GC was: 50° for 3 min, then 4°/min to 180°C and hold. The electron ionization (EI) mass spectra were recorded at 70 eV over a mass range of 40–350 amu with nominal unit resolution in mass–charge (m/z) ratio. The GC-MS software included a library search-and-match routine for comparing acquired spectra with various databases. The algorithm used for the library search compared the 10 most significant lines in the mass spectrum (significance = mass × abundance) with a library entry's 10 most significant lines. An estimate of the quality of the match between the reference data and the actual spectrum was given and is presented here as percent match, with a 100% match representing identity.

GC-MS System-2. Additional mass spectra were obtained with this bench-top system (GC-MS-2) consisting of a Perkin Elmer gas chromatograph interfaced directly to a Finnigan ion trap mass detector (ITD). The column used was a 30-m × 0.25-mm capillary containing a bonded DB-1 (J & W) stationary phase, eluted with helium at a linear flow velocity of 25 cm/min. The samples were introduced splitless into a capillary injector port at 180°C, followed after 30 sec by a split-purge flow of helium. The column was initially at 60°C, and the temperature was programmed to rise immediately at 10°/min to 120°, followed by a 6°/min rise to 150°C and hold. Data were stored on the hard disk of a Compuadd 286 computer. This system also compared acquired spectra with the data in several libraries, including approximately 40,000 spectra in the National Bureau of Standards Mass Spectral Library.

NMR Spectroscopy. Samples for ^{1}H nuclear magnetic resonance spectra were examined in deuteriochloroform ($CDCl_3$), at 300 MHz with digital resolutions of 0.25–0.5 Hz, using standard single-pulse techniques and routine homonuclear decoupling procedures on a Nicolet (General Electric) NT-300 spectrometer. As a reference, the residual $CHCl_3$ resonance was assigned a chemical shift of 7.24 δ.

Polarimetry. Samples of reference compounds and β-bisabolene from *Anastrepha suspensa* were analyzed in hexanes on a Rudolph Research Corp. (40

Pier Lane, P.O. Box 1446, Fairfield, New Jersey 07006) AUTOPOL III polarimeter with the following specifications: path length = 10 cm, λ = 589 nm, resolution = $\pm 0.001°$, reproducibility and accuracy up to 1° = $\pm 0.002°$.

RESULTS

Partial gas chromatograms of the volatiles trapped from males of these two *Anastrepha* species are presented in Figure 1A (*A. suspensa*) and Figure 1B (*A. ludens*). The figures are labeled with the same numbers used for the structures in Scheme 1. Although these chromatograms were obtained on a methyl silicone capillary column, we have found the MS compilation by Adams (1989) a useful reference for GC comparison to chemicals chromatographed on a similar, relatively nonpolar, phenylmethyl methyl silicone capillary column.

Suspensolide in Mexican Fruit Fly Volatiles

Peaks labeled 1, 2, and 3 in Figure 1A represent the isomeric lactones ($C_{12}H_{18}O_2$,M = 194) anastrephin, epianastrephin, and suspensolide, respectively. Synthetic samples of **1, 2,** and **3** were previously prepared in these laboratories and shown to correspond to volatiles from *A. suspensa* males (Battiste et al., 1983, 1988). These three lactones in the *A. suspensa* volatiles were compared with the corresponding peaks in Figure 1B, present in roughly similar proportions from *A. ludens*; they were found to have essentially identical mass spectra for peaks with the same retention times. This confirms the presence of the γ-lactones **1** and **2** (Stokes et al., 1983), previously identified as anastrephin and epianastrephin (Battiste et al., 1983), while demonstrating for the first time that the macrolide **3,** suspensolide, is also present in the volatiles from *A. ludens*. Figure 2 shows a mass spectrum for suspensolide (peak **3**) emitted by *A. ludens* males. The suspensolide peak is relatively large in the volatiles of *A. ludens*, as it is in the *A. suspensa* volatiles, and its retention time on all of the GC columns used in this comparison was always identical to that for (*E*,*E*)-suspensolide from *A. suspensa*. Hence, we conclude that (3*E*,8*E*)-suspensolide is a major component in the volatiles emitted by these *A. ludens* males.

Sesquiterpenes in Volatiles of Both Species

Volatiles from *A. suspensa* males were eluted from Porapak Q traps with pentane. Liquid chromatography of that solution on a small column of silica (monitored by GC) showed the presence of unidentified hydrocarbons eluting with the void volume of the column. GC-MS indicated that the major hydrocarbon ($C_{15}H_{24}$,M = 204) from *A. suspensa* was a sesquiterpene, and β-bisa-

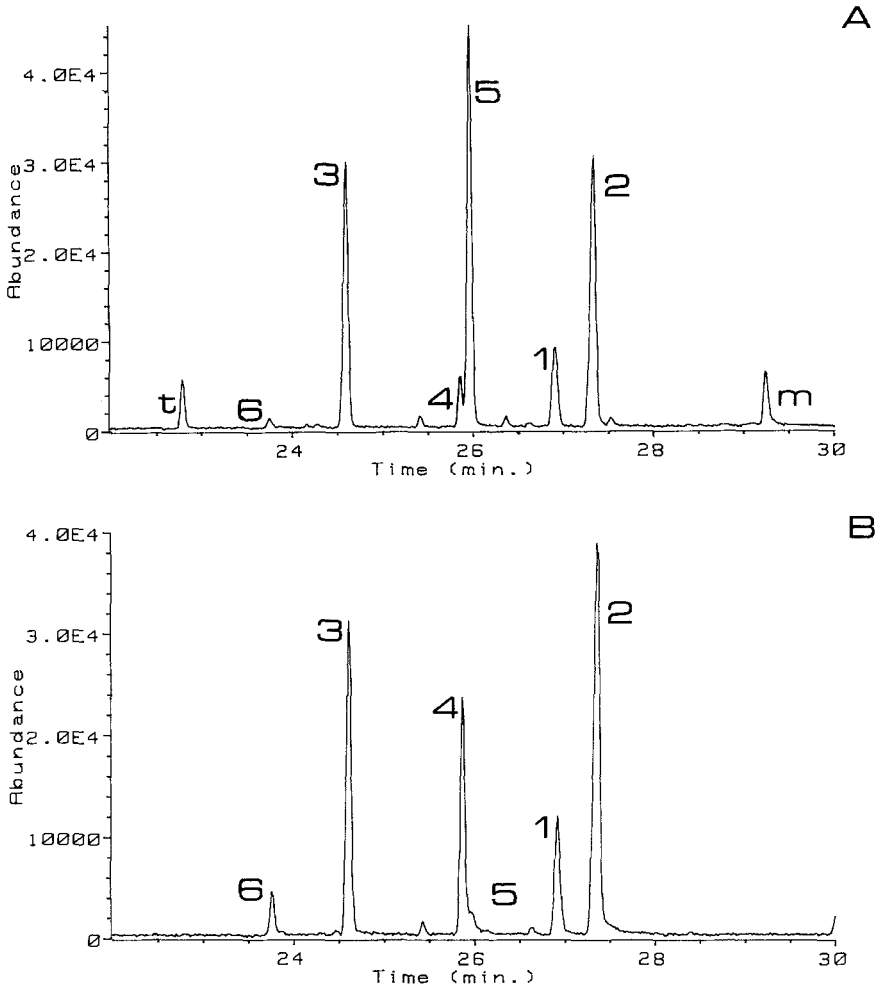


FIG. 1. Capillary gas chromatograms (GC-EI-MS) of the volatile compounds (M = 194–204) collected from *Anastrepha suspensa* and *Anastrepha ludens*. Peaks are numbered according to the structures in Scheme 1. (A) Volatiles from *A. suspensa*; t and m are synthetic internal standards, tetradecane and methyl tridecanoate, added to the volatiles solution. (B) Volatiles from *A. ludens*.

bolene has already been mentioned as a likely candidate (cf. Nation, 1989, p. 196 and Nation, 1990, p. 554).

β-Bisabolene. A 1.29-mg sample containing the major sesquiterpene present in the volatiles of *A. suspensa* males was isolated by short-column chromatography on silica. In addition to allowing polarimetry, this quantity was

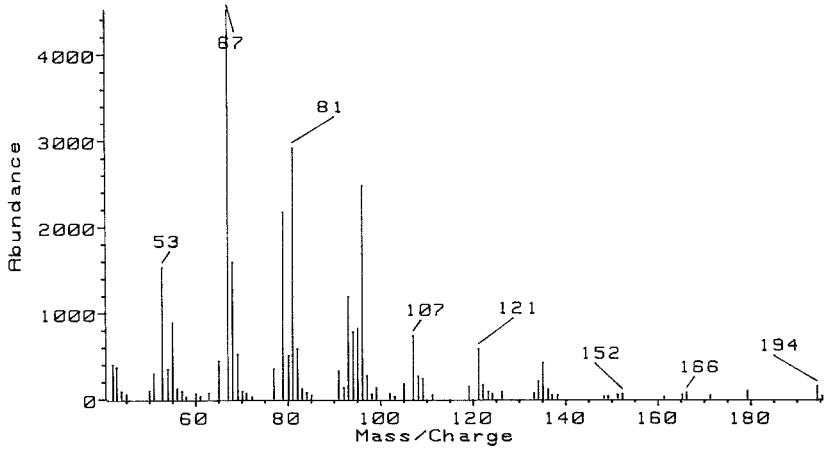

FIG. 2. Mass spectrum (EI) for the (*E*,*E*)-suspensolide peak (3) in Figure 1B from *Anastrepha ludens* males. The ion at $m/z = 41$ (not shown), with an abundance of 2600, is slightly smaller than the ion at $m/z = 81$ (abundance = 2928).

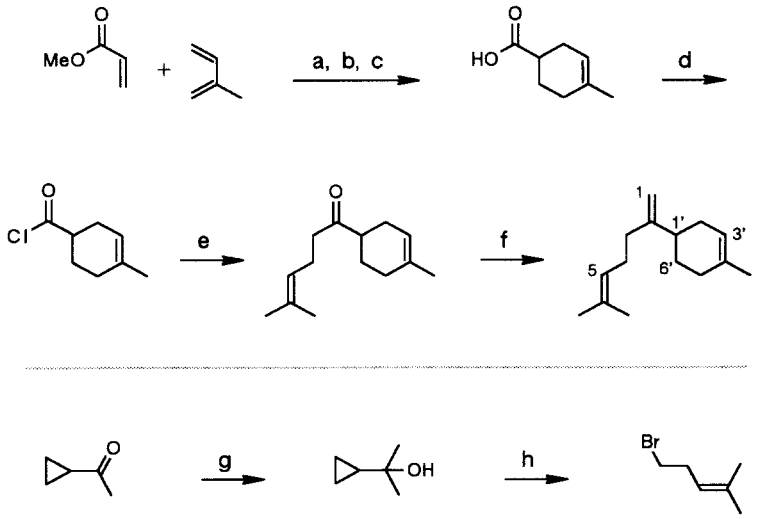
sufficient to permit comparisons of its NMR and mass spectra with those of authentic β-bisalolene as described in the following paragraphs.

A synthetic sample of (±)-β-bisabolene **(5)** was prepared with slight modification of the procedure described by Manjarrez and Guzmán (1966) as shown in Scheme 2. The Diels-Alder reaction between methyl acrylate and isoprene gave the expected mixture of methylcyclohexenyl esters, which upon hydrolysis and work-up gave the desired carboxylic acid in good yield after recrystallization. Conversion to the acid chloride, followed by coupling with the homoprenyl Grignard reagent in the presence of cuprous bromide (ether soluble, dimethyl sulfide complex), provided the expected ketone. That ketone was treated with a Wittig reagent, methylene triphenylphosphorane, to give racemic β-bisabolene. The requisite homoprenyl bromide was available from cyclopropyl methyl ketone in two steps: treatment with methyl Grignard reagent, and Julia rearrangement of the resultant α,α-dimethylcyclopropanemethanol in the presence of aqueous 48% hydrobromic acid.[4]

The [^{1}H]NMR spectrum of 1.2 mg of synthetic β-bisabolene in 0.5 ml of $CDCl_3$ contained the following resonances at 300 MHz [chemical shift, (integral, multiplicity, assignment/C-n according to Scheme 2)]: $\delta = 5.40$ (1H, broad line, C-3′); 5.12 (1H, triple multiplet, C-5); 4.74/4.76 (2H, broad AB pattern, C-1); 2.27–1.73 (9H, several multiplets, C-3, C-4, C-1′, C-2′, C-5′);

[4] Subsequent to the actual work described in this paper, one of us (J.R.R.) has also prepared this homoallylic bromide in excellent yield from the same alcohol using anhydrous $MgBr_2$ (commercial or from $BrCH_2CH_2Br$ and Mg) in diethyl ether.



SCHEME. 2. Synthesis (±)-β-bisabolene **(5)** after the method of Manjarrez and Guzmán (1966); 5-bromo-2-methyl-2-pentene required for the Grignard reagent in step (e) was prepared as shown in steps (g) and (h). Reagents and conditions: (a) 125–135°C for 2–5 hr; (b) KOH, CH_3OH, H_2O, 60°C for 1.5 hr followed by 12 N HCl; (c) warm hexane, slowly cool to −30°C, recrystallize 4×; (d) $(COCl)_2$, benzene; (e) $(CH_3)_2C{=}CH(CH_2)_2MgBr$, CuBr · $S(CH_3)_2$, Et_2O, 0°C for 2 hr then 23°C overnight followed by 5 NH_2SO_4; (f) $(Ph)_3PCH_3Br$, BuLi, Et_2O, reflux for 12 hr; (g) CH_3MgBr, Et_2O, 0°C for 1 hr then 23°C overnight followed by 10% NH_4Cl at 0°C; (h) 48% HBr at 0°C for 10 min.

1.69 (3H, singlet, vinyl methyl); 1.65 (3H, singlet, vinyl methyl); 1.61 (3H, singlet, vinyl methyl); and 1.47 (2H, multiplets, C-6′). Assignments of the vinyl protons are based on decoupling experiments as well as empirical calculations using the relevant table in the text of Silverstein et al. (1981). These data agree fairly well with the 100-MHz data accompanying the syntheses of Crawford et al. (1972), with the exceptions of the integral for the region of 2.3 to 1.7 δ and chemical shift for the doubly homoallylic protons at C-6′. Our spectrum for synthetic β-bisabolene accounted for all of the significant lines present in the [^{1}H]NMR spectrum of the major hydrocarbon from *A. suspensa* volatiles, excluding resonances due to solvent and other small impurities in the spectrum of the material from the flies.

The synthetic sample of β-bisabolene eluted at the same time as the natural material on three different capillary columns: GC-1, GC-2 and GC-MS-1. A mass spectrum of this synthetic sample is shown in Figure 3A. It compares favorably with the data given by Crawford et al. (1972) for β-bisabolene, as well as with the reference spectra in the compilations by Stenhagen et al. (1974,

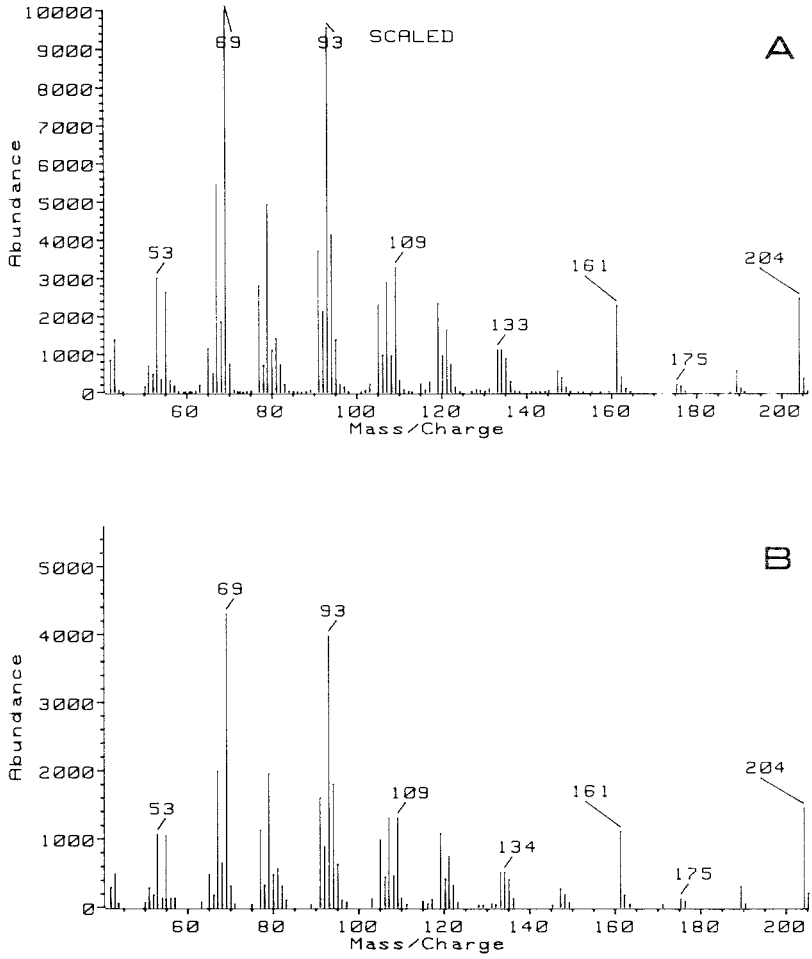


FIG. 3. Mass spectra (GC-EI-MS) of β-bisabolene. The ion at $m/z = 41$ (not shown) is the base peak in each spectrum with an approximate abundance of 1.4 times that of the $m/z = 93$ ion. (A) Top is from a synthetic sample of (±)-β-bisabolene prepared according to Scheme 2. (B) Bottom is for the major hydrocarbon peak (5) in Figure 1A, identified as (*R*)-(+)-β-bisabolene, from *Anastrepha suspensa* males.

entry A1-503-1) and by Adams (1989, entry DB5-1667). Figure 3B shows the mass spectrum for the major hydrocarbon (peak 5 in Figure 1A) in the volatiles of *A. suspensa*, which is essentially identical with that of the synthetic β-bisabolene. The small peak labeled 5, seen as a shoulder on peak 4 in Figure 1B of the *A. ludens* volatiles, was tentatively identified as β-bisabolene on the basis of its retention time and its relatively low abundance mass spectrum. Thus,

we conclude that β-bisabolene **(5)** is the major hydrocarbon component from the male *A. suspensa* volatiles, while it is probably present as a very minor component in the volatiles from *A. ludens* males.

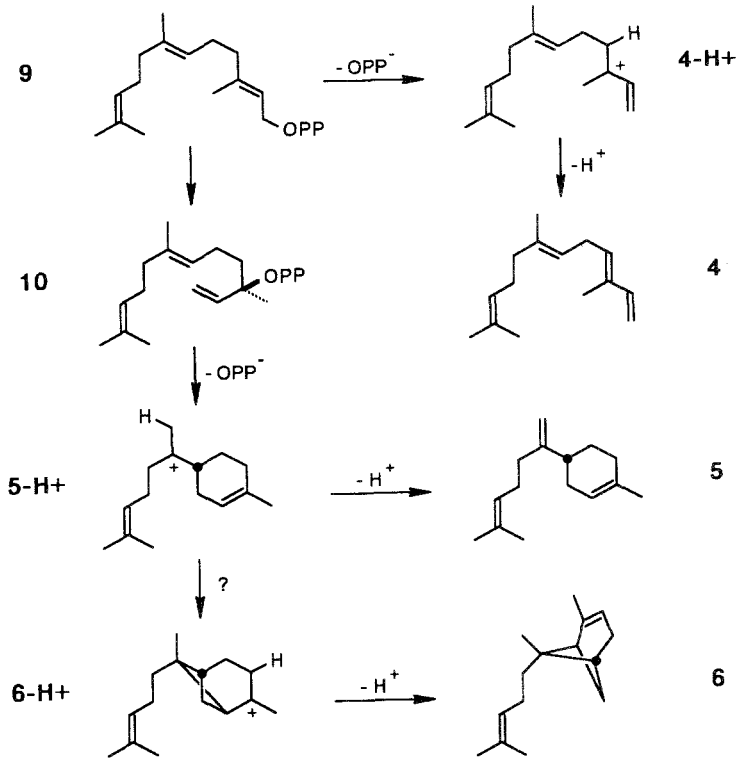
The natural material from *A. suspensa* was optically active and shown to be dextrorotatory by polarimetry at 23°C in hexanes (concentration = 1.29 mg/6 ml = 0.215 mg/ml, path length = 1 dm). The average measured rotation angle from four trials (± SD) with this solution was $\alpha_D = +0.0218° \pm 0.0023°$, and the specific rotation was then calculated as follows:

$$[\alpha]_D^{23} = \frac{(+0.0218° \pm 0.0023°) \times (1000 \text{ mg/g})}{(0.215 \text{ mg/ml}) \times (1 \text{ dm})} = +101° \pm 11°$$

The calculation above only accounts for variations in the actual measurement of α; allowing for a reasonable error in concentration of ±10%, a correct range for the true value of our specific rotation might easily be as much as ±20°. The (*R*)-(+)- and (*S*)-(−)-limonenes were synthetically correlated with the (*R*)-(+)- and (*S*)-(−)-β-bisabolenes by Crawford et al. (1972). The specific rotation they found for (*R*)-β-bisabolene, $[\alpha]_D^{30} = +74°$, is one of the highest that has been reported for this enantiomer at the sodium D line. Those same authors measured a specific rotation of slightly lower magnitude, $[\alpha]_D^{30} = -68°$, for the opposite enantiomer, although they did cite the value of Soucek et al. (1961), $[\alpha]_D^{20} = -84.4°$. That value, the highest-magnitude specific rotation recorded for either antipode, has also been cited by Buckingham (1982, entry B-01388) for the apparently more common (−)-enantiomer, while showing its absolute configuration as (*S*)-β-bisabolene. Given the small amount of material available from the fruit fly volatiles, the magnitude of our value agrees qualitatively with those previously reported rotations, and its sign indicates that the major sesquiterpene from the *A. suspensa* males is shown in Scheme 3 with the correct absolute configuration as (*R*)-(+)-β-bisabolene.

α-Farnesene. On the basis of approximate GC retention times, we also suspected that β-bisabolene might be emitted by *A. ludens*. Surprisingly, we found that these species differ with respect to the presence of two major sesquiterpenes in their volatiles. The mass spectrum for the major hydrocarbon ($C_{15}H_{24}$, M = 204) in the male *A. ludens* volatiles (peak 4 in Figure 1B) is shown in Figure 4. It is very similar to the spectrum for α-farnesene[5] given by Stenhagen et al. (1974) in the *Registry of Mass Spectral Data*. Furthermore, the mass spectrum and relative retention time of the natural substance from *A. ludens* are also quite similar to those given for a compound, DB5-1657, identified as (*E*,*E*)-α-farnesene (CAS #502-61-4) in the GC-MS compilation by Adams (1989). The stereochemistry for this common isomer of α-farnesene is

[5]Note that more than one farnesene isomer is given the same entry number, B22-199-2, in this edition of the *Registry of Mass Spectral Data.*



SCHEME. 3. A possible biosynthetic route from farnesol pyrophosphate **(9)** or nerolidyl pyrophosphate **(10)**, shown formally via the cations **4+**, **5+** and **6+**, to (*E*,*E*)-α-farnesene **(4)**, β-bisabolene **(5)**, and α-*trans*-bergamotene **(6)** in *Anastrepha suspensa* and *Anastrepha ludens* males.

shown in Scheme 1 as (3*E*,6*E*)-**4**; however, it would be difficult to distinguish this structure from its isomers on the basis of its mass spectrum alone. Baker et al. (1985) had demonstrated that (*E*,*E*)-α-farnesene is a major pheromonal component in the volatiles of male Mediterranean fruit flies, *Ceratitis capitata*, and we fortunately had access to an extract, collected by one of us (J.L.N.) in Europe, of *C. capitata* males. Thus, a comparison of the peak labeled 4 from the *A. ludens* volatiles within the (*E*,*E*)-α-farnesene in the *C. capitata* extract showed them to have identical retention times and mass spectra on GC-MS-2; coinjection of the two samples firmly established this assignment. The mass spectrum of a minor hydrocarbon (peak 4 in Figure 1A) in the male *A. suspensa* volatiles was virtually identical to that of the peak with the corresponding retention time from *A. ludens*. We therefore conclude that (3*E*,6*E*)-α-farnesene **(4)**

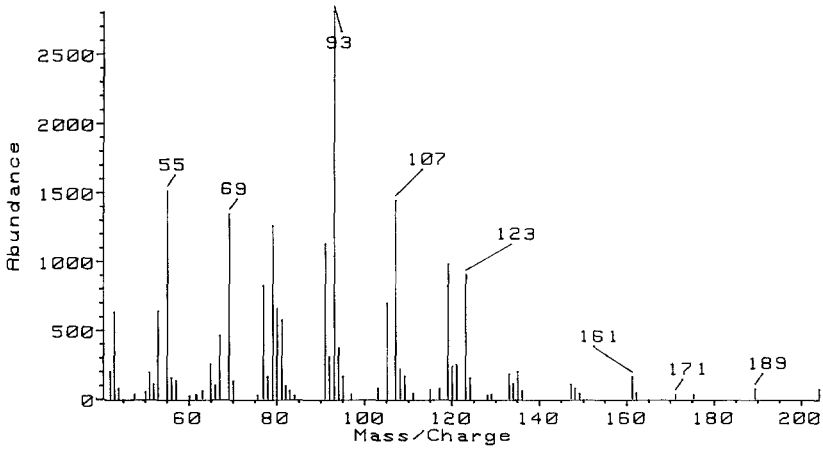


FIG. 4. Mass spectrum (EI) for the major hydrocarbon peak (4) in Figure 1B, identified as (*E*,*E*)-α-farnesene, from *Anastrepha ludens* males. The ion at *m*/*z* = 41 (not shown), with an abundance of 2796, has about the same intensity as the ion at *m*/*z* = 93 (abundance = 2811).

is a major component in the volatiles of *A. ludens* males and is probably a minor component in the *A. suspensa* volatiles.

α-trans-Bergamotene. The chromatograms of the volatiles from both *Anastrepha* species showed several small peaks representing previously unidentified compounds. The mass spectrum of a hydrocarbon ($C_{15}H_{24}$, M = 204) of moderate abundance in the male *A. ludens* volatiles (peak 6 in Figure 1B) is shown in Figure 5. This spectrum gave a 96% match with the that of the α-bergamotene in the National Bureau of Standards Mass Spectral Database (Library Index #16057, CAS #17699-05-7). Visual comparison of this spectrum with the one given by Stenhagen et al. (1974) for α-bergamotene, A1-501-1 in the *Registry of Mass Spectral Data*, provides additional support for the assignment of this basic structure (cf. Snider and Beal, 1988) to the peak labeled 6. This does not unambiguously define the substitution pattern at C-6 to be either *trans*, as in structure **6** (Buckingham, 1982, entry B-00924), or *cis* to the three-carbon bridge (Newman, 1972). However, based on matching the mass spectrum and relative retention time of peak 6 from GC-MS-1 with those of the corresponding isomer reported by Adams (1989; entry DB5-1485, CAS #13474-59-4), it can be assigned as α-*trans*-bergamotene. A comparison of these GC data is presented in Table 1. While our data were acquired with a 30-m HP-1 (Hewlett-Packard) column from 50° to 180°C at 4°/min, and Adams used a 30-m DB-5 column (J & W) from 60° to 240°C at 3°/min, the relative retention times of the hydrocarbons agree well enough to discount the *cis* isomer. Nevertheless, this

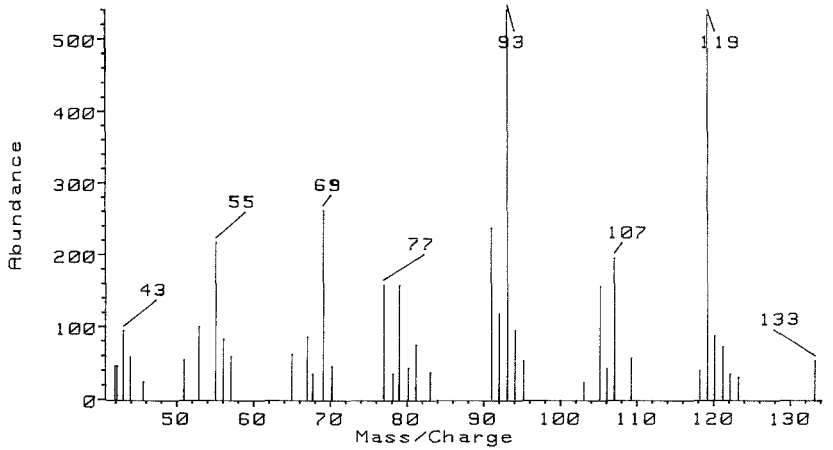

FIG. 5. Mass spectrum (EI) for the minor hydrocarbon peak (6) in Figure 1B, identified as α-*trans*-bergamotene, from *Anastrepha ludens* males. The ion at m/z = 41 (not shown), with an abundance of 512, is slightly smaller than the ion at m/z = 93 (abundance = 540).

TABLE 1. GC COMPARISON OF RELATIVE RETENTION TIMES (RT) OF SESQUITERPENE HYDROCARBONS (M = 204) FROM VOLATILES OF MALE CARIBBEAN FRUIT FLIES (*Anastrepha suspensa*) WITH STANDARDS FROM TEXT BY ADAMS (1989)

		Adams data		*A. suspensa*	
Peak label in Figure 1	Substance name	RT (sec)	RF[a]	RT (sec)	RF[a]

4	(*E*,*E*)-α-farnesene	1657	0.96	1552	0.97
5	β-bisabolene	1667	1.00	1558	1.00

[a] Retention factor = (RT of x − RT of t)/(RT of 5 − RT of t).
[b] Synthetic internal standard.

led us to obtain an authentic sample of α-*trans*-bergamotene in order to produce further evidence for this structure. That sample did indeed elute at the same time as the natural material from *A. ludens* on GC-MS-2, and our assignment was secured. A small analogous hydrocarbon peak, labeled 6 in Figure 1A, also occurred in the male *A. suspensa* volatiles, but the quality of its mass spectrum was poor because of low abundances. However, we believe that this peak can

also be assigned to *α-trans*-bergamotene, based on the match in retention time with the corresponding peak in the *A. ludens* volatiles. Thus, we identify *α-trans*-bergamotene as a minor component in the volatiles of *A. ludens* males and suggest that it may be present as an even smaller component in the volatiles from *A. suspensa*. Its presence with the other sesquiterpenes would be consistent, as described later, with the biosynthesis presented in Scheme 3.

Monoterpenes in Volatiles of Each Species

β-Ocimene. A minor hydrocarbon ($C_{10}H_{16}$, M = 136) in the volatiles from *A. suspensa* males has already been described as a monoterpene and a β-ocimene (cf. Nation, 1989, p. 196 and Nation, 1990, p. 554). Depending upon the source, the name ocimene has been used to describe various acyclic monoterpene trienes.[6] We presently refer to stereoisomers of the acyclic monoterpene shown in Scheme 1 as β-ocimenes, following the nomenclature of Dev (1986). We noticed that the mass spectrum of the monoterpene from *A. suspensa* was rather similar to the one accompanying a structure, which we would name as (*Z*)-β-ocimene, in Swigar and Silverstein's (1981) spectral compilation from Aldrich Chemical Co. A commercial sample described as β-ocimene, and characterized as a mixture of approximately 30% *E* and 70% *Z* isomers, was compared to the natural material from the flies. The (*E*)- and (*Z*)-β-ocimenes could be resolved on all the chromatograph columns used in this study, with the *E* isomer always eluting before the *Z* isomer. Using the conditions described in Methods and Materials, the authentic (*Z*)-β-ocimene eluted from GC-MS-2 at 484 sec, and the corresponding peak in the *A. suspensa* volatiles eluted at 487 sec (GC and MS data not shown, but available upon request). A coinjection of the fruit fly volatiles with the authentic sample confirmed that the natural substance eluted with the *Z* isomer. The mass spectrum of the fruit fly substance was significantly different from that of the (*E*)-β-ocimene, which eluted at 474 sec, but it matched the spectrum of the *Z* isomer fairly well. Thus, we conclude that *A. suspensa* males release (*Z*)-β-ocimene.

Limonene. The solution we received of volatiles from *A. ludens* males also contained a hydrocarbon ($C_{10}H_{16}$, M = 136) peak that eluted from the GC columns used in this study somewhat earlier than the monoterpene of the other species. This substance was identified as limonene, the cyclic monoterpene shown in Scheme 1, by comparison on GC-MS-2 with a genuine sample (GC and MS data not shown). The retention time, 473 sec using the conditions for

[6] For example, in the *Handbook of Chemistry and Physics, 55th Edition* (Weast, 1974) the name "ocimene" was given to a molecule with a terminal isopropenyl group, 3,7-dimethyl-1,3,7-octatriene. Swigar and Silverstein (1981), however, showed the structure (*Z*)-3,7-dimethyl-1,3,6-octatriene, which bears a terminal isopropylidene group, as "*cis*-ocimene." According to Dev (1986) the triene with an isopropenyl terminus is an α-ocimene, and the triene bearing the isopropylidene terminus is a β-ocimene.

the ocimenes described above, and mass spectrum of that hydrocarbon in the volatiles from *A. ludens* were essentially identical to those of authentic limonene.

Blend of Components in Mexican Fruit Fly Volatiles

The quantities of some of the components in the sample of *A. ludens* volatiles were determined by methods published for analyses of the *A. suspensa* components (Nation, 1990). The data, which were acquired using GC-1 and are presented in Table 2, show that two of the substances identified in this paper, (*E*,*E*)-suspensolide and (*E*,*E*)-α-farnesene, represent a significant fraction of the material trapped from *A. ludens* males. Since a single collection of volatiles from 50 individuals is involved here, such data should obviously be taken as an initial indication of the identities and quantities of the various compounds released by *A. ludens* males and used primarily for comparisons to similarly acquired data already published on the blend on components from *A. suspensa*.

DISCUSSION

The results from our comparison of these fruit flies, in conjunction with the information that has previously been published concerning their sex pheromones, indicate that males of both *Anastrepha* species synthesize and release the same volatile compounds with the exception of the two monoterpenes. The common substances, in order of elution from the HP-1 column, are: (*Z*)-non-3-enol with (*Z*,*Z*)-nona-3,6-dienol, α-*trans*-bergamotene, (*E*,*E*)-suspensolide, (*E*,*E*)-α-farnesene, β-bisabolene, anastrephin, and epianastrephin. We cannot make comprehensive statements about proportions among the principal components at present, because *A. ludens* has not yet been extensively sampled. Furthermore, because the data in Table 2 represent a single sampling of the

volatile compounds from *A. ludens* males, we should note that age, circadian rhythm, and density of flies have strong influences upon the ratio of components in *A. suspensa* volatiles (Nation, 1990). Such factors apparently influence *A. ludens* as well (Robert R. Heath, personal communication, USDA, Gainesville, Florida), and more exhaustive analyses of its volatiles will clearly be needed. Nevertheless, assuming that substances released in these experiments might serve semiochemical functions, we should identify the overt similarities and differences that emerged in this first direct comparison of the volatiles from *A. ludens* and *A. suspensa* males. Some of the GC-MS results are thus qualitatively summarized in Table 3, which emphasizes the compounds with 14 or 15 major atoms identified as common to the two fruit fly species.

Among these six common substances from the males, the relative proportions of the three isoprenoid lactones seemed roughly similar in this comparison, as each species presented larger quantities of both suspensolide and epianastrephin, along with a smaller amount of anastrephin. However, the two species differed quite markedly with regard to the hydrocarbon blend released, most notably in the relative proportions of the bisabolene and the farnesene. The volatiles of *A. suspensa* contained β-bisabolene, a cyclic sesquiterpene, as the major hydrocarbon component, a minor amount of (*E*,*E*)-α-farnesene, and a trace of α-*trans*-bergamotene. These proportions were redistributed in the *A. ludens* volatiles, which contained the acyclic (*E*,*E*)-α-farnesene as the major sesquiterpene, a minor amount of α-*trans*-bergamotene, and an even smaller quantity of β-bisabolene. The males of the two *Anastrepha* species also differed

with respect to the monoterpenes present in their volatiles; *A. suspensa* evidently released (*Z*)-β-ocimene, an acyclic compound, while *A. ludens* apparently emitted a cyclic isomer, limonene.

Possible Evolutionary Significance of These Volatiles

The similarity of the volatiles produced by these two flies, their similar behavioral biology during pheromone release, and the similarity in female and male response to the pheromones (Robacker and Hart, 1985a,b, 1986; Nation, 1972, 1989) suggest an interesting and close evolutionary relationship. The two species do not overlap in their distributions anywhere today, and how they might interact with each other in such a situation can only be conjectured. The *A. ludens* female is physically larger and also has a longer ovipositor sheath than the *A. suspensa* female. Thus, it is questionable whether the two species could actually intermate or whether they would even attempt to do so in the wild, but the differences in their terpenes may be related to the reproductive isolation of these flies. It seems probable that the two species shared a common ancestor that produced the C_9 alcohols with the C_{12} lactones and possible that it also produced at least one each of the monoterpenes and sesquiterpenes. We can only guess that the hydrocarbons may have functioned as semiochemicals for the ancestor, because it remains to be shown how the terpenes revealed in this comparison, or even the macrolide, serve these modern *Anastrepha* species. However, if the two monoterpenes and the different sesquiterpene proportions from *A. suspensa* and *A. ludens* males do prove behaviorally significant, this would allow the possibility that elaboration of the hydrocarbon blends occurred while the present species diverged.

We shall consider the relevance here of two mechanisms of speciation with distinct origins: (1) environmental disruption of a widely distributed ancestral species into isolated, divergent populations; or (2) reproductive isolation within an ancestral species by virtue of divergent host preferences in different population segments. It is unlikely that one of these processes occurs exclusively, because one can imagine scenarios that incorporate elements of each mechanism.

As mentioned before, the ranges of these species do not now overlap; *A. suspensa* is found principally in Florida as well as in islands of the northeastern Caribbean Sea, and *A. ludens* is distributed principally along the western end of the Gulf of Mexico. The first mechanism might therefore seem more obvious in this case, and it is also one that appears to be accepted more generally as a process of speciation.[7] Hence, because their ranges are now roughly divided by the Gulf of Mexico, it is possible that a once-continuous distribution of these species' ancestor became fragmented due to environmental change, and the

[7]This means of species divergence seems more likely to an anonymous reviewer of this paper. We acknowledge the reviewer's version of the description given here.

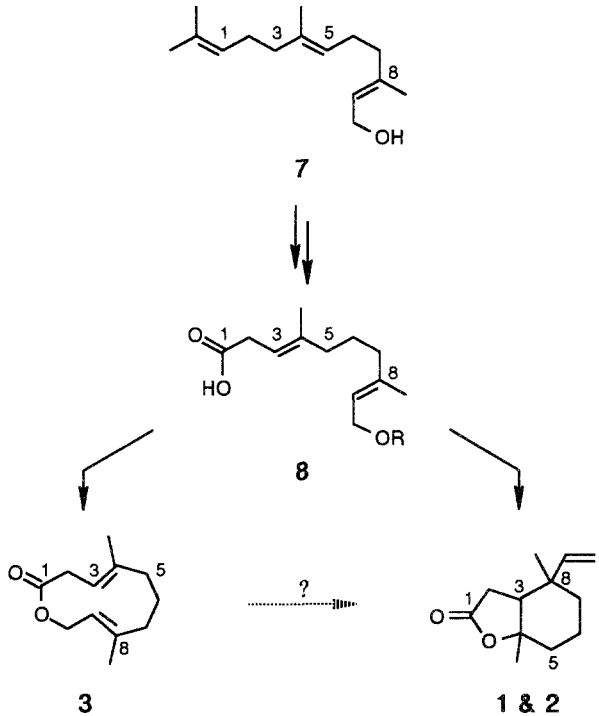
resulting isolated populations diverged. Differences in emitted hydrocarbons may have resulted from various external factors, including later contact with other divergent populations or even other *Anastrepha* species.

On the other hand, the two present species evidently also differ with respect to preferred ovipositional hosts, and these fruit preferences are the basis for invoking the second, albeit probably less well accepted, mechanism of species divergence. The immature fruit of chapote, *Sargentia greggii*, and the mature fruit of mango, *Mangifera indica*, have been described (e.g., Robacker and Garcia, 1990) as larval hosts for *A. ludens*, while guava, *Psidium guajava*, is a favored oviposition fruit for *A. suspensa*. Thus, a host race mechanism, such as discussed by Bush (1974), may have led to the initial reproductive isolation of the two (sub)species and consequently allowed time for pheromonal changes, physical size, and subtle differences in acoustical and visual displays to evolve further as reproductively isolating influences.

The authors recognize that our observations alone do not discriminate between these two mechanisms of speciation, but given the interest in evolutionary origins of natural products within the chemical ecology community, we wished to raise them as arguments in the context of this discussion. Scenarios that combine elements of both processes raise the question of which came first: was the environmentally driven segregation followed by the development of different host preferences, or was the earlier reproductive segregation of host races subsequently amplified by environmental changes? Evidence to support or reject the different mechanisms may ultimately lie in diverse aspects of the biochemistry, cytogenetics, and physiology of the insects or their host fruit plants. Perhaps even geological or paleontological data from the perimeters of the Caribbean Basin and the Gulf of Mexico could be pertinent. Additional information or experiments might reconcile our observations with one of these evolutionary hypotheses or might provide another explanation that accommodates these results.

Biosynthetic Implications for These Volatiles

A reasonable biosynthetic route from farnesol to the terpenoid lactones **1**, **2**, and **3** is presented in Scheme 4, with the numbering of all structures keyed to the central structure **8**. Saito and coworkers (1984) have shown that this intermediate (3*E*,8*E*)-10-hydroxy-4,8-dimethyldeca-3,8-dienoic acid (**8**, R = H) undergoes electrophilic cyclization to the anastrephins, **1** and **2**, while Battiste and others (1988) have carried out the macrolactonization of **8** to suspensolide, **3**. Farnesol could be converted enzymatically to this hydroxy acid in two steps: (1) oxidative loss of the terminal isopropylidene fragment, providing the carboxy carbon 1; and (2) isomerization of the double bond between carbons 4 and 5 into a new double bond between carbons 3 and 4. Derivatization of the terminal



SCHEME. 4. A possible biosynthetic route from farnesol (**7**) to suspensolide (**3**) and the anastrephins (**1** and **2**) in *Anastrepha suspensa* and *Anastrepha ludens* males via (3*E*,8*E*)-10-hydroxy-4,8-dimethyldeca-3,8-dienoic acid (**8**, R = H). All structures are numbered according to structure **8** for continuity.

hydroxy residue into a suitable leaving group (i.e., OH → OR) would allow cyclization, presumably via at least two enzymes and possibly in different glandular tissues (Nation, 1989), to either the γ-lactones or the macrolide. Feeding experiments with appropriate ^{2}H or ^{13}C precursors, such as mevalonolactones, might provide enough of these materials, isolated from trapped volatiles, to determine by NMR if this biosynthetic scheme is consistent with the fate of the labels. Finally, we also point out the possibility of some in vitro conversion of suspensolide to the anastrephins, indicated by the light arrow. In principle, this could occur via an open-chain structure like the hydroxy acid, but it raises the interesting question of additional isomeric lactone structures, which remain undetected as highly labile or trace materials.

Scheme 3 shows a likely biosynthetic route (cf. Newman, 1972) from farnesyl pyrophosphate to the sesquiterpene hydrocarbons **4, 5,** and **6**. The loss of pyrophosphate from **9** could give the 3°, allylic, farnesyl cation (**4+**), which,

after elimination of a proton from C-4, would give (3*E*,6*E*)-α-farnesene **(4)**. Although the α-farnesene from *A. ludens* males was identified as the *E*,*E* isomer on the basis of GC-MS, the possible presence of minor amounts of the isomeric (3*Z*,6*E*)-α-farnesene, formed via proton elimination from a different conformation of **4+**, should also be considered. Cane et al. (1989) have recently implicated the stereoselective enzymatic rearrangement of farnesyl pyrophosphate to nerolidyl pyrophosphate in the synthetic course to β-*trans*-bergamotene and structurally related antibiotics from fungi. We suppose a similar rearrangement occurs in these fruit flies of **9** to nerolidyl pyrophosphate, **10**, based upon the isolation of optically active β-bisabolene from *A. suspensa*; we can only presume that the minor substance from *A. ludens* has the same configuration. A facile cyclization of **10** following loss of pyrophosphate (cf. Cane et al., 1989, 1990) results in the bisabolyl cation **(5+)**, and elimination of the proton at C-1 from this cation gives β-bisabolene **(5)**. Note that obtaining (*R*)-(+)-β-bisabolene from the fruit fly by this cyclization requires (3*R*)-nerolidyl pyrophosphate as shown, and this would be opposite to the absolute configuration required by the experimental results of Cane et al. using the fungal enzyme. Further cyclization from a favorable conformation of the bisabolyl cation gives the *trans*-bergamotyl cation **(6+)**, which could eliminate a ring proton from C-3 giving α-*trans*-bergamotene **(6)**. If the bergamotene from these flies actually has its origin in the same cation as the bisabolene, i.e. **5+** with the chiral carbon's hydrogen shown beta as required for the *A. suspensa* substance, it should be possible in principle to correlate the absolute stereochemistry of the two hydrocarbons (cf. Cane et al., 1990).

The information in Table 3 suggests that these molecules may be significant taxonomically. From this point of view it would be interesting to compare the volatiles from these two flies with those from other *Anastrepha* species and other genera of tephritid fruit flies using GC-MS. It will require many more experiments to give a detailed understanding of the functions and glandular sources of these chemicals, especially with regard to learning how the hydrocarbons serve the flies. Still, one point clearly emerges from the results of this study and the structures in Schemes 3 and 4—farnesol must be a very important chemical precursor for the Caribbean and Mexican fruit flies. The males of these two species appear to exploit the basic farnesol structure for the production of at least six volatile substances.

Acknowledgments—We are indebted to David Robacker of the Crop Quality and Fruit Insects Research Laboratory, ARS, USDA, Weslaco, Texas, for providing samples from *A. ludens*. We also thank Norris Williams and Mark Whitten of the Department of Natural Sciences, Florida Museum, University of Florida, for generously granting us the use of their GC-MS facilities, for assistance in obtaining some of the data reported in this paper, and for useful discussions regarding experimental results. An authentic sample of α-*trans*-bergamotene was kindly provided by Ted Turlings of the Insect Attractants, Behavior and Basic Biology Research Laboratory, ARS/USDA,

Gainesville, Florida. Those of us from the Department of Chemistry are grateful to the Florida Citrus Commission, Department of Citrus, State of Florida, for partial financial support of this research.

(Received July 29, 1991; accepted October 21, 1991)

Abstract—*Migdolus fryanus* is a sugarcane pest restricted to South America that is becoming more important due to the inefficacy of control methods against it. The larvae bore into the plant root system and the available insecticides can not give adequate protection. So, the search for alternate control strategies is mandatory. However, the literature on bioethological studies of the species is scarce. This work investigates the attraction of adult males in the field by females that is mediated by a sex pheromone that remains to be identified. Dissected female thoraces were more attractive than other body parts. A trap design for monitoring field populations of this species also is presented.

Key Words—Natural attractant, pheromone, *Migdolus fryanus*, Coleoptera, Cerambycidade, male response, sugarcane pest.

INTRODUCTION

Every year *Migdolus fryanus* is becoming more important as a pest of sugarcane, coffee, and eucalyptus in Brazil. The lack of more detailed knowledge on the biology and behavior of this pest as well as of adequate methodology to evaluate its damage in infested areas has contributed to the poor efficacy of control methods.

These insects were first reported in sugarcane in 1927 (Lane, 1937) in Ibaté County, São Paulo State, Brazil. Taxonomic studies on this genus were carried out by Lane (1972) and Dias (1984). These insects have been associated with "cerrado" areas used for crops such as coffee, eucalyptus, and lately sugarcane (Fonseca, 1958; Roccia, 1977). They also have been reported from mullberry, grape, beans, and pasture (Arrigoni et al., 1986).

In sugarcane the larvae feed on the root system and, even though the attack may be localized, destruction of the infested sugarcane field may occur (Terán et al., 1983, 1984).

Little has been done on the biological aspects of *Migdolus fryanus*, which is one of the most common pest species in the genus (Nakano and Joko, 1969; Roccia, 1977; Terán et al., 1983, 1984).

Adult males are alate and live, on average, two to three days; adult females are wingless and live for 30 days or more (Roccia, 1977). From November to March in São Paulo, the newly emerged individuals mate after a characteristic male nuptial flight.

The orientation of the males towards the females is thought to be mediated by a female sex pheromone (Roccia, 1977; Terán, 1984; Pizano, 1991), since traps containing virgin females have caught up to 192 males (Roccia, 1977); however conclusive proof has been lacking.

The objectives of the present paper were to determine if the female produces a sex pheromone as well as the body part responsible for it. It was also our aim to develop a more efficient trap to capture the males and to determine the ideal number of females per trap.

METHODS AND MATERIALS

The experiment was set up in Olímpia County, São Paulo State (latitude 20° 46′ S; longitude 49° 40′ W) during February and March 1991 in sugarcane plantations.

The total area planted was 21,000 ha. Field bioassays were divided in two steps. The first had eight treatments and 12 replicates: (A) virgin female (trap design—OAL); (B) virgin female (trap design—UFV); (C) virgin females and virgin male (trap design—UFV); (D) virgin male (trap design—UFV); (E) virgin female head (trap design—UFV); (F) virgin female thorax (trap design—UFV); (G) virgin female abdomen (trap design—UFV); and (H) control (unbaited).

The experiments were run for three consecutive days (four replicates per day). The traps used were plastic water containers, 20-liter volume, with sections of the large sides cut out, leaving two rectangular windows (Figure 1). The OAL design had an acrylic box (60 mm diameter × 20 mm thick) with small holes centered in the top and the bottom and was hung by wire in the

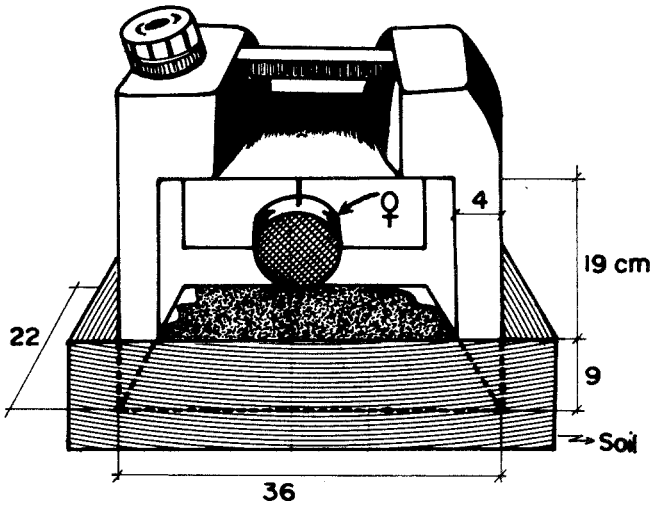

FIG. 1. Trap design used to capture males of *Migdolus fryanus* (Coleoptera: Cerambycidae) in sugarcane fields.

center of the container. One virgin female was placed inside the box together with a fine layer of soil. The UFV trap design was modified from the OAL by replacing the acrylic box with a PVC tube (85 mm diameter × 40 mm thick), which had the ends covered with a nylon screen. All traps were placed beside the sugarcane rows and 0.50 m inside these rows at the soil level with a distance of 22 m between.

The male buzzes the ground until he senses the females' presence. Then he lands and locates her with antennal movements. Finally he mounts her (Roccia, 1977; Arrigoni, 1986).

All traps without the attractants were placed the day before the data were to be collected. The attractant was then placed in the traps slightly before 7 AM, the time at which the nuptial flights normally started. The males were captured in water containing 5% detergent, which was placed in the base of the trap. The females had been collected and placed in individual containers the day before while the males were collected on the day of the experiment. Pinned specimens of both male and female *M. fryanus* are deposited in the Cerambycidae Collection of the Zoology Museum of the University of São Paulo, Brazil.

The experimental design was completely randomized and the average temperature and relative humidity on the three days were: 26.8°C, 25.7°C, 24.4°C, and 20.4%, 18.9%, 18.7%, respectively.

The second step of the field bioassay consisted of aerating 30 virgin females through 1 g Porapak Q for 24 hr at a flow rate of 9 liters/min, followed by

washing of the material in 1 ml dichloromethane. This solution was used to prepare six rubber septa by placing 40 μl of the washed material, which corresponded to 1.2 female equivalents, on each septum. These were immediately stored in a freezer for three days until taken to the field.

Six treatments and six replicates were carried out in the same sugarcane plantation following the methodology already described. The treatments were: (A) one virgin female; (B) two virgin females; (C) four virgin females; (D) rubber septum impregnated with material extracted from virgin female + dichloromethane; (E) rubber septum + dichloromethane; and (F) control (unbaited).

The trap design was UFV in all treatments. The captured males were counted after 24, 48, and 72 hr, and there was no substitution of virgin females or septa during this period. Average temperature and relative humidity on the three days were: 24.8°C, 25.2°C, 26.3°C, and 20.6%, 20.3%, 21.3%, respectively.

RESULTS AND DISCUSSION

Live virgin females of *Migdolus fryanus* strongly attracted males (Table 1). Far fewer males were attracted to the other treatments. The UFV trap design caught more male *M. fryanus* than the OAL. The soil layer in the acrylic box with the female, as in the OAL trap, seemed to interfere with female calling, as shown by the reduced number of males captured by that trap.

The presence of a male with the virgin female, even though they mated,

slightly reduced the capture of males, although this bait still proved to be superior to others. One female mates with more than one male before she returns to the soil to oviposit (Roccia, 1977; Terán et al., 1984), thus she remains attractive to the males after her first mating.

Treatments using dissected parts of a female were significantly different among themselves. The female thorax was more efficient than the other body parts in attracting males (Table 1). It has been shown that in the field, the receptive female remains at soil level with only the head and thorax exposed (Roccia, 1977); therefore it appears that the mating signal, although general over the body, is more pronounced on the thorax.

The results obtained with the rubber septa impregnated with female odor in dichloromethane (Table 2) strongly indicate the presence of a sex pheromone. Although this had been suggested previously (Roccia, 1977; Terán et al., 1984; Pizano, 1991), this is the first proof of the chemical origin of the attractiveness of female *M. fryanus*. The impregnated rubber septum continued to attract males after 24 hr, at levels greater than one, two, or four virgin females. Males also were observed trying to copulate with the rubber septa in the field.

Twenty-four hours after the virgin females were exposed in the field they died, probably due to the hot and sunny weather. However, they were still attractive for at least 72 hr after the beginning of the tests, although the number of males falling in the traps was much reduced. This attraction observed in the dead females suggests various possibilities. The pheromone could simply be retained on the insect bodies or substrate, or the sex pheromone could be released from a gland in one region and bathe the body with material. Finally, it could also suggest an association with cuticular hydrocarbons.

Based on the results, the use of two females per trap is recommended when the distance between traps is 22 m because it is more practical than four and safer than one female. Daily female replacement in the traps is also suggested.

The attraction potential of the female sex pheromone is so great that we believe monitoring could be a valuable tool, especially to determine population levels in the infested areas. However, pheromone identification and synthesis still have to be carried out.

Acknowledgments—We are grateful to Olímpia Agrícola Ltda for the experimental area and the workers who helped us in the field. We are also indebted to Dr. Ubirajara Martins for confirming the species identification and to Ricardo Della Lucia, J.J. Muchovej, Eduardo C. Nascimento, and Manoel A. Uchoa Fernandes for the valuable suggestions in the project and in manuscript.

(Received July 22, 1991; accepted October 22, 1991)

Abstract—The metabolism of xanthotoxin, a naturally occurring furanocoumarin photosensitizer, was studied in laying hens and a lactating goat treated with single oral doses equivalent to 10 mg xanthotoxin/kg of body weight. Within 48 h, essentially all of the administered radiocarbon was eliminated in the excreta of the laying hens, while in the goat 92% and 3% were excreted in the urine and feces, respectively. Radiocarbon residues in the milk, egg white, and egg yolk were low. Xanthotoxin, 8-hydroxypsoralen (xanthotoxol), 6-(7-hydroxy-8-methoxycoumaryl)-acetic acid (HCA) and 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyacetic acid (HCHA) were identified in the excreta of laying hens. In the goat, xanthotoxin was metabolized to HCA, HCHA, xanthotoxol, 5,8-dihydroxypsoralen, psoralenquinone, 5-hydroxy-8-methoxypsoralen and 3[5-(6-hydroxy-7-methoxybenzofuryl)]-propanoic acid. Thus, identified metabolites in one or both of these species arose through *O*-demethylation, oxidative cleavage of the furan ring, hydroxylation, reduction, oxidation, and hydrolysis of the lactone ring.

Key Words—Xanthotoxin, 8-methoxypsoralen, furanocoumarin, metabolism, detoxification, chicken, goat, egg, milk ^{14}C radiolabel.

INTRODUCTION

Linear furanocoumarins (psoralens) are photoactive compounds that occur naturally in many species of plants, particularly in the families *Umbelliferae* and *Rutaceae* (Pathak et al., 1962; Scott et al., 1976; Towers, 1984). Some of these plants are consumed occasionally by livestock or pasture- or field-raised poultry, which can lead to outbreaks of photosensitization (Egyed et al., 1977; Dollahite et al., 1978; Ivie, 1982; Perelman et al., 1987).

Direct exposure of humans to furanocoumarins occurs by handling or ingesting furanocoumarin-containing food plants such as parsnip, parsley, celery, figs, limes, and some spices (Scott et al., 1976). These compounds are not destroyed by normal cooking procedures (Ivie et al., 1981). In addition, furanocoumarins are phytoalexins in some food plants, and certain plant stresses, particularly diseases, induce biosynthesis of these toxic products (Beier et al., 1983; Ashwood-Smith et al., 1985; Chaudhary et al., 1985; Surico et al., 1987). Human exposure to appreciable levels of furanocoumarins may thus result from the consumption of "spoiled" or otherwise diseased plant foodstuffs. Furanocoumarins and long-wavelength ultraviolet radiation (320–400 nm) are used in human medicine for the treatment of vitiligo, psoriasis, mycosis fungoides, and cutaneous T-cell lymphoma (Bleehen et al., 1978; Edelson et al., 1987; Parrish et al., 1974), but with some apparent increase in risk of skin cancer (Stern and Lange, 1988; Stern, 1990).

Studies on the disposition and metabolism of linear furanocoumarins have been reported in mammalian species (including man), in insects, and in fungi. Most of these studies have focused on one of the linear furanocoumarins (xanthotoxin) because it is well known for its photoactivity, it occurs commonly and often predominantly in furanocoumarin-containing plants, and it is the furanocoumarin of choice in many medical applications. Studies on the metabolism of xanthotoxin have shown that the furan ring is an important site for metabolic transformation in man (Schmid et al., 1980), in the dog (Kolis et al., 1979), in rats (Mays et al., 1986), and in insects (Ivie et al., 1983).

In view of the biological effects associated with furanocoumarins, there is a need to obtain definitive data on the interaction of these compounds with avian and mammalian species, both to evaluate their ecological significance to wildlife and to determine the possibility of potentially toxic residues entering the human food chain. Although episodes of photosensitization in domesticated avian species are rare, furanocoumarin-caused photosensitization of pasture-raised birds has been observed (Eilat et al., 1974; Egyed et al., 1977; Perelman et al., 1987). Acute photosensitization in whitetail deer has been reported (Dollahite et al., 1978), although a link with furanocoumarins has not been established (Rowe et al., 1987).

A limited study of xanthotoxin metabolism in the domestic goat has been

reported (Ivie et al., 1986) but, because the radiolabel was on the *O*-methyl moiety, which was easily lost upon metabolism of the parent compound, >50% of the radioactivity was not recovered or accounted for. In the present studies, the radiolabel was on the metabolically stable 4 position of the coumarin ring (Figure 1), and thus a more complete picture of the fate of xanthotoxin in the goat, as well as the chicken, was determined.

METHODS AND MATERIALS

Chemicals. Specifics of the procedures used in these studies are detailed in a thesis by the senior author (Pangilinan, 1990). Unlabeled authentic samples of furanocoumarins included xanthotoxin (8-methoxypsoralen), xanthotoxol (8-hydroxypsoralen), psoralenquinone (PQ), 5,8-dihydroxypsoralen (DHP), and 5,8-dimethoxypsoralen (DMP, isopimpinellin). [^{14}C]Xanthotoxin labeled at the 4 position of the coumarin ring (26.47 mCi/mM, New England Nuclear, Boston, Massachusetts) was determined by thin-layer chromatography (TLC) to have a radiochemical purity >98% (Pangilinan, 1990).

Chromatography. [^{14}C]Xanthotoxin and its metabolites were analyzed by TLC on silica gel F-254 chromatoplates (0.25 mm or 0.5 mm gel thickness, 20 × 20 cm, with fluorescent indicator, E. Merck, Darmstadt, Germany). The plates were developed in one or more of 19 solvent systems, depending upon the sample and specific compound of interest (Pangilinan, 1990). In addition to TLC techniques, high-performance liquid chromatography (HPLC) was used in the isolation of [^{14}C]xanthotoxin metabolites. Mobile phases consisted of four buffered water, methanol–acetonitrile, and methanol–water systems, with gradients used in some cases. Detection was by absorbance at 248 nm or, in many instances, by the collection of eluent fractions (0.5–1.0 ml), which were subsequently assayed by liquid scintillation counting (LSC) (Pangilinan, 1990).

In Vivo Metabolism of [^{14}C]Xanthotoxin in Laying Hens. White leghorn laying hens were purchased from a local grower and held in individual cages housed in an environmentally controlled room. Throughout the study, the birds were maintained on a commercial pelleted feed, with water available ad libitum. The birds were allowed to acclimate one week prior to treatment.

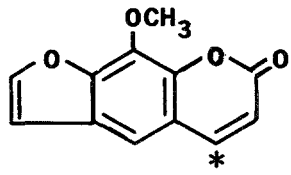

FIG. 1. Structure of xanthotoxin (8-methoxypsoralen), with the site of radiocarbon label incorporation indicated by the asterisk.

Two groups of birds were studied. The first group of four birds was kept for seven days after treatment and was used primarily to characterize residues in egg white, egg yolk, and tissue samples. The second group of eight birds was maintained for 24 hr posttreatment and was used primarily for the characterization of metabolites in the excreta. All birds were treated with single [^{14}C]xanthotoxin doses equivalent to 10 mg xanthotoxin/kg of body weight and a specific activity of 6000 dpm/μg for the first group of birds and 1500 dpm/μg for the second. The dose was dissolved in a small amount of acetone and added to pulverized feed in order to facilitate dispersion. The individual doses were sealed inside gelatin capsules (0.25 oz) and delivered orally to the birds. All the birds were in apparent good health and high (>90%) egg production.

Excreta from the first group of birds were collected at intervals until the birds were killed seven days posttreatment. Eggs were collected daily and egg yolk and white were separated. Selected tissue samples were quickly collected when the birds were killed for analysis. Excreta from the second group of birds were collected at intervals but analyzed as pooled 24-hr samples. Aliquots of excreta, egg yolk, egg white, and tissue were taken in triplicate, air dried, and pelleted. The remainder of each sample was stored in a glass jar and frozen at −60°C for future assay. The pelleted samples were analyzed for radiocarbon content by oxygen combustion; all values obtained were corrected for instrument efficiency and quench (Pangilinan, 1990).

Isolation and Identification of Chicken Excreta Metabolites. Because >90% of the administered dose was eliminated during the first 24 hr posttreatment, analytical efforts were limited to a composite of 24-hr excreta. Four-gram composites of chicken excreta were diluted with water, acidified, and extracted four times with ethyl acetate. The extracts were subsequently concentrated and analyzed by TLC and/or HPLC. In TLC studies, the ^{14}C-labeled components were visualized by exposing the developed plates to X-ray film, and specific radioactive components were quantitated by scraping the appropriate gel regions and subjecting them to LSC. For HPLC studies, the ethyl acetate extracts of chicken excreta were cleaned up prior to analysis using C_{18}Sep-Pak cartridges (recovery from the Sep-Pak was always 90–99%). Quantitative measurements were made by LSC of eluent fractions.

Sufficient quantities of xanthotoxin metabolites for characterization studies were obtained by ethyl acetate extraction of larger excreta samples. The ethyl acetate extracts were applied as bands to TLC plates, and the plates were developed in an appropriate solvent system. Major metabolite bands were scraped and eluted with methanol, ethyl acetate–glacial acetic acid (99:1), or ethyl acetate, depending upon metabolite polarity. Individual metabolites were purified further by HPLC. Metabolite identification was accomplished by TLC and HPLC cochromatographic techniques using authentic standards and in some

cases by mass spectrometry (MS) and nuclear magnetic resonance spectrometry (NMR) techniques (Pangilinan, 1990).

Isolation and Identification of Metabolites in Egg White and Yolk. Composite samples of egg white were lyophilized and then extracted with methanol. The extracts were then concentrated under vacuum and analyzed by TLC. Egg yolk composites were extracted with hexane–tetrahydrofuran (1 : 1), cleaned up by partitioning between hexane and acetonitrile, and the acetonitrile extracts were subsequently analyzed by TLC (Pangilinan, 1990).

In Vivo Metabolism of [^{14}C]Xanthotoxin in Lactating Goat. A lactating Nubian goat was purchased from a local source and allowed to acclimate for one week before treatment. The goat was provided an appropriate ration and water ad libitum and was hand milked twice daily, producing 0.7–1.2 liters of milk daily.

The administered dose consisted of [^{14}C]xanthotoxin diluted with unlabeled xanthotoxin to a specific activity of 500 dpm/μg. The dose was dissolved in acetone and adsorbed on a small amount of pulverized feed, which was administered orally to the animal via a gelatin capsule; the dosage was equivalent to 10 mg xanthotoxin/kg body weight. [Note: A second goat was identically treated but this animal performed poorly under confinement conditions and voided urine very sporadically. Data obtained from this animal are reported elsewhere (Pangilinan, 1990).]

Following treatment, total urine, milk, and excreta were collected at intervals until the animal was killed seven days posttreatment; selected tissue samples were collected at this time. Samples of urine, milk, feces, and tissue were analyzed for total radiocarbon content by LSC or oxygen combustion as appropriate. Other sample portions were held frozen for future analysis.

Isolation and Identification of Goat Urinary Metabolites. Aliquots of 24-hr goat urine were acidified and extracted three times with ethyl acetate. The extracts were cleaned up using C_{18} Sep-Pak cartridges and the purified samples were then analyzed by HPLC. Certain samples were, prior to extraction and analysis, subjected to acid hydrolysis or enzyme hydrolysis procedures to determine the presence and nature of metabolite conjugates. Certain goat urine metabolites were obtained in sufficient quantity through HPLC isolation techniques to allow their study by MS and NMR techniques (Pangilinan, 1990).

RESULTS

Excretion Patterns and Tissue Residues in Laying Hens. The elimination of radiocarbon in the excreta of hens treated orally with [^{14}C]xanthotoxin was rapid. Within 24 hr posttreatment, $>90\%$ of the dose had been eliminated in the excreta (Figure 2). Low levels of radiocarbon continued to be eliminated in

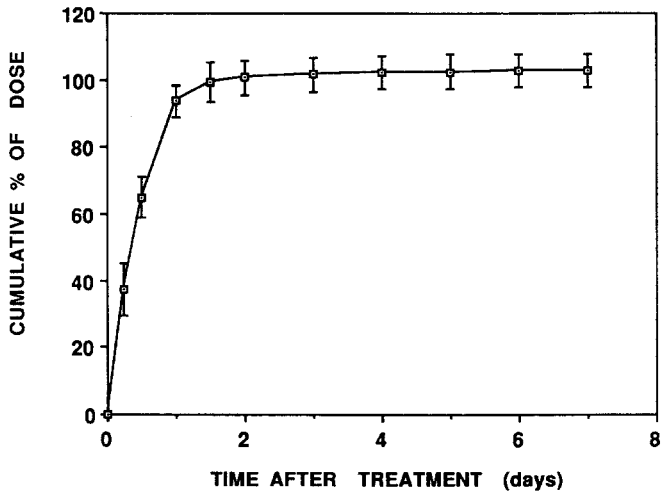

FIG. 2. Elimination of radiocarbon in excreta of laying hens treated with [^{14}C]xanthotoxin as a single oral dose equivalent to 10.0 mg xanthotoxin/kg body weight. Data points are mean ± standard deviation of four hens.

the excreta during the succeeding days until termination of the studies; however, radiocarbon elimination was almost total within just two days after dosing.

Very low levels of radiocarbon were eliminated in the egg yolk and white. Highest levels were observed two days after treatment for both egg fractions (0.8 ppm and 0.5 ppm xanthotoxin equivalent in yolk and white, respectively), and residues in the egg yolk were consistently higher than those detected in the egg white. The cumulative secretion of radiocarbon into the egg during the seven days posttreatment amounted to only about 0.5% of the total [^{14}C]xanthotoxin administered to the laying hens.

Of the different tissues collected from birds killed seven days posttreatment, only the blood, kidney, liver, and ovarian egg contained as much as 0.01% of the administered [^{14}C]xanthotoxin dose. Radiocarbon residues, expressed on a ppm basis, were highest in the liver, followed by kidney and lungs (Table 1).

Characterization of Metabolites in Excreta of Laying Hens. Ethyl acetate extraction of acidified excreta samples resulted in an average of 78% recovery of the radiocarbon present in the samples. Two-dimensional TLC analysis of the concentrated ethyl acetate extracts showed at least 13 distinct radioactive components, only six of which comprised 1% or more of the total radiocarbon in the sample. HPLC analysis of the ethyl acetate extracts similarly revealed six radioactive components that each comprised 1% or more of the radioactivity in the sample (Table 2).

Mass spectral analysis of the dimethyl ester derivative of metabolite C-1

[c]Radioactivity remaining in the water/residue slurry after ethyl acetate extraction of acidified samples.

(prepared by reaction with diazomethane) revealed a molecular ion at *m/z* 294 (Table 3) and a fragmentation pattern that was essentially identical to that of the dimethyl derivative of [6-(7-hydroxy-8-methoxycoumaryl)]-hydroxyacetic acid (HCHA) isolated from the insect *Papilio polyxenes* (Ivie et al., 1983). The NMR spectrum of the nonderivatized metabolite C-1 (Figure 3) was very comparable to that of the methyl ester derivative of HCHA isolated from the urine of the dog (Kolis et al., 1979). It was therefore concluded that chicken metabolite C-1 was in fact HCHA.

Metabolite C-4 was identified as 6-(7-hydroxy-8-methoxycoumaryl)-acetic acid (HCA). Mass spectral analysis of HPLC-purified C-4 revealed a molecular ion of *m/z* 250 (Table 3) and a fragmentation pattern that matched that of HCA previously isolated from the dog (Kolis et al., 1979), man (Schmid et al., 1980), insect (Ivie et al., 1983), goat (Ivie et al., 1986), and rat (Mays et al., 1986).

The mass spectra (Table 3) and HPLC retention times of C-5 and C-6 were identical to those of authentic xanthotoxol and xanthotoxin, respectively. Metabolite C-5 was identical to authentic xanthotoxol in TLC behavior using eight different solvent systems. Similarly, the TLC behavior in nine different solvent systems supported the assignment of C-6 as unmetabolized xanthotoxin (Pangilinan, 1990).

Characterization of Metabolites in Egg Fractions. Cochromatographic analysis of the acetonitrile extract of egg yolk with authentic xanthotoxin using eight TLC solvent systems revealed that >85% of the radiocarbon in the sample was unmetabolized xanthotoxin. Similarly, in the egg white, one radioactive component accounted for >92% of the radioactivity. Cochromatographic analysis of the egg white product also revealed it to be identical in TLC behavior (seven different solvent systems) to authentic xanthotoxin. Isolation of sufficient quantities of this metabolite for confirmation by GC-MS was not successful due to the very low levels present in the egg yolk and egg white and to the relatively large amount of interfering materials.

Excretion Patterns and Tissue Residues in Goat. Radiocarbon elimination in the urine of the goat was rapid (Figure 4). Within 24 hr posttreatment, >80% of the dose was excreted through the urine, although very low levels of radiocarbon continued to be eliminated in urine during the following six days.

Radiocarbon elimination in the feces of the goat was much lower than that in the urine (Figure 4). Maximum radiocarbon elimination in the feces occurred between 24 and 48 hr after treatment; however, low levels of radiocarbon continued to be eliminated in the succeeding days until the study was terminated.

Radiocarbon residues in milk of the goat were very low. Highest levels (<2 ppm xanthotoxin equivalent) were observed at 12 hr posttreatment; within two days after treatment, no radiocarbon residues were detected in the milk. Less than 0.4% of the administered radiocarbon was secreted into the milk.

Analysis of tissues from the goat killed seven days after treatment showed

TABLE 3. MASS SPECTRAL DATA OF METABOLITES OF XANTHOTOXIN IN LAYING HENS AND LACTATING GOAT

Metabolite and structure	m/z	Relative intensity	Fragment

that only the blood, liver, and muscle contained levels of radiocarbon equivalent to 0.01% of the administered dose or higher (Table 4). Radiocarbon residues, expressed on a parts per million basis, were highest in the liver (0.25 ppm), followed by the kidney (0.07 ppm).

Characterization of Metabolites in Goat Urine. HPLC analysis of the ethyl acetate extracts of goat urine indicated the presence of 18 radioactive components that each contained at least 1% of the sample radiocarbon. Five HPLC-resolved components each contained at least 5% each of the total sample radiocarbon in the urine samples analyzed (Table 5).

The HPLC retention time of metabolite G-12 matched that of authentic xanthotoxol. The mass spectrum and HPLC retention time of the methylated derivative of G-12 were identical to those of authentic xanthotoxin, confirming that G-12 was indeed xanthotoxol. The HPLC retention times of G-2, G-6, G-8, G-9, and G-17 matched those of authentic HCHA, psoralenquinone (PQ), HCA, dihydroxypsoralen (DHP), and xanthotoxin, respectively. Studies with the methylated derivative of G-8 indicated the product to have the same HPLC retention time as authentic methylated HCA.

Two metabolites from urine treated with deactivated enzyme prior to extrac-

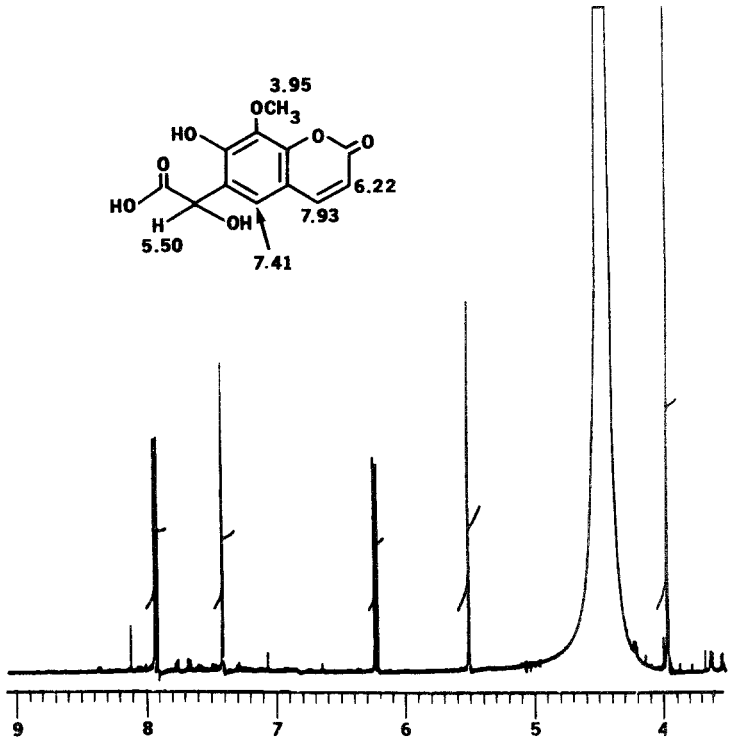

FIG. 3. NMR spectrum of chicken metabolite C-1 (deuteroacetone).

tion were poorly resolved by HPLC as two overlapping peaks. One of the peaks, however, was absent in extracts of active enzyme-hydrolyzed urine samples, suggesting that the product was a glucuronide or sulfate conjugate. The remaining component of this metabolite pair (G-11) was identified as 3[5-(6-hydroxy-7-methoxy-benzofuryl)]-propanoic acid (BFPA). The mass spectrum of methylated G-11 yielded a molecular ion of *m/z* 250 (Table 3) and a fragmentation pattern consistent with that of the major goat metabolite isolated in the previous work by Ivie et al., (1986).

The mass spectrum of metabolite G-15 (after methylation) matched that of authentic 5,8-dimethoxypsoralen (5,8-DMP) (Table 3). The unmethylated G-15 was clearly not dihydroxypsoralen (DHP) on the basis of chromatographic behavior; thus G-15 was identified as 5-HMP.

When the aqueous phase of extracted urine was subjected to acid hydrolysis and then reextracted with ethyl acetate, about 12% and 60% of the radiocarbon present in the extracts exhibited HPLC retention times identical to those of authentic xanthotoxin and xanthotoxol, respectively. These data are most con-

sistent with the hypothesis that these two compounds occurred in urine partly as lactone-ring-opened derivatives (probably conjugates), which were cleaved and then recyclized under strong acid treatment (Kolis et al., 1979).

DISCUSSION

Xanthotoxin was rapidly absorbed, metabolized, and excreted after oral administration of single 10 mg/kg doses to laying hens and to a lactating goat. Radiocarbon content in the feces of the goat was very low, indicating that absorption was nearly complete and that elimination of metabolites through the

bile or other fluids secreted into the gastrointestinal tract is a minor excretory route. In man given an oral dose of 40 mg of [*methoxy*-^{14}C]xanthotoxin, 71% of the dose was excreted in the urine and 6% in the feces within 24 hr post-treatment (Schmid et al., 1980). Almost all of a [*methoxy*-^{14}C]xanthotoxin dose administered orally to the insect, *Papilio polyxenes*, was found in the excreta 24 hr after treatment (Ivie et al., 1983).

Radiocarbon elimination in the egg yolk and white was very low. In both fractions, at least 85% of the radioactivity present was as unmetabolized xanthotoxin.

In the hen and goat, there was very little retention of unmetabolized xanthotoxin or its metabolites in tissues. At seven days after treatment, only the livers of both laying hens and lactating goat contained 0.05% or more of the administered dose. Similar studies on the tissue distribution of [^{14}C]xanthotoxin in beagle dogs and miniature pigs given single oral doses (10 mg/kg body weight) showed rapid clearance of the compound from the bodies of the animals (Ikeda et al., 1990). In the dog, small amounts of radioactive components were found in the liver (0.47% of dose) and blood (0.15% of dose) after four days, while in the pig seven days after treatment, highest levels of radioactivity were observed in the liver (0.5% of dose) and fat (0.27% of dose).

Ivie et al. (1986) reported the appearance of substantial radiocarbon residues (10.6% of administered dose) in the milk of a goat treated with [*methoxy*-^{14}C]xanthotoxin. The authors, however, hypothesized that this radiocarbon occurred as the result of biosynthetic incorporation of [^{14}C]CO_2 into normal milk constituents. Results from the present study showed that $<0.4\%$ of the administered radiocarbon was eliminated in the milk, results that seemingly confirm the earlier hypothesis.

In the chicken, xanthotoxin is rapidly metabolized via dealkylation, oxidation, hydrolysis, and conjugation mechanisms (Figure 5). Structural characterization of the major xanthotoxin metabolites in the chicken, HCHA and HCA, indicated that the major mechanism of metabolic degradation of xanthotoxin in the laying hen is through oxidative opening of the furan ring. These furan oxidation products also have been isolated as products of xanthotoxin metabolism in dogs (Kolis et al., 1979), humans (Schmid et al., 1980), and in the insects *P. polyxenes* and *Spodoptera frugiperda* (Ivie et al., 1983). Rats also metabolize xanthotoxin by oxidative cleavage of the furan ring; HCA but not HCHA is generated as the final product (Mays et al., 1986). In the chicken, HCHA and HCA account for $>60\%$ of the radiocarbon eliminated in the excreta of the laying hen. In *P. polyxenes* treated with [^{14}C]xanthotoxin, $>80\%$ of the dose is eliminated in the excreta as these two furan oxidation products (Ivie et al., 1983), and in humans treated with [^{14}C]xanthotoxin more than half of the urine radioactivity was products of oxidative cleavage of the furan ring (Schmid et al., 1980). The intermediate pathways involved in the formation of the furan

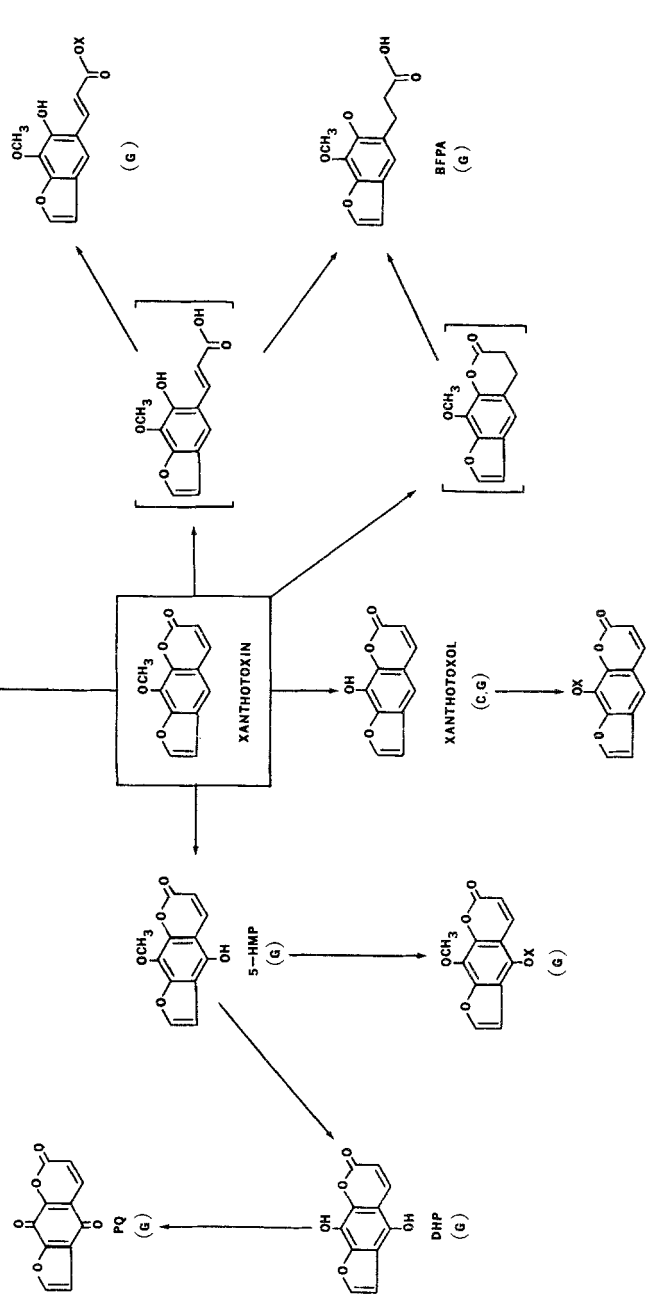

FIG. 5. Proposed pathways of xanthotoxin metabolism in laying hens and a lactating goat. Structures in brackets indicate logical intermediates leading to certain metabolites identified. Conjugating moieties are indicated by X. Letters in parentheses indicate that specific compounds were identified as xanthotoxin metabolites in the chicken (C) and/or goat (G).

oxidation products have not been definitely established; however, Kolis et al. (1979) postulated the generation of a short-lived reactive epoxide intermediate (shown in brackets, Figure 5) in the formation of these two metabolites.

In the goat, pathways for xanthotoxin metabolism include: (1) *O*-demethylation of the 8-methoxy group, (2) hydroxylation at position 5 to form 5-HMP, (3) hydrolysis of the lactone ring, (4) saturation of the lactone olefinic moiety, (5) oxidative opening of the furan ring, and (6) conjugation. At least one metabolite, 5-HMP, occurred partially as a conjugate on the evidence that its concentration was increased after hydrolysis of the urine prior to extraction. The apparent conjugation of xanthotoxin observed in these studies likely occurs after hydrolysis of the lactone ring (Kolis et al., 1979).

Low levels of unmetabolized xanthotoxin were found in the urine of the goat. Polarity considerations make it unlikely that xanthotoxin itself would be excreted in the urine; more likely these residues resulted either from low-level fecal contamination or from lactone hydrolysis followed by recyclization (Kolis et al., 1979).

The furan oxidation (HCA and HCHA) and lactone hydrolysis (BFPA) products identified in this study were also isolated in the previous goat metabolism study (Ivie et al., 1986). Although not established experimentally, formation of BFPA in the goat may be catalyzed in the rumen, a highly reductive environment (Van Soest, 1982; Ennis et al., 1989). The goat, along with the fungus *Gibberella pulicars* (Spencer et al., 1990), are apparently the only organisms thus far known to metabolize xanthotoxin by a reductive mechanism leading to BFPA.

The hydroxylation products, 5-HMP and DHP, as well as PQ, have also been identified as metabolites of xanthotoxin in rats (Mays et al., 1986) but apparently not in other species studied. We consider the identities of PQ and DHP in the goat as tentative because these metabolites were identified only by cochromatography with authentic standards using HPLC techniques and the structures were not confirmed by spectral analyses.

The present studies add to the body of knowledge on xanthotoxin metabolism in vertebrates and represent the first reported data on furanocoumarin metabolism by an avian species. We conclude that xanthotoxin is not likely to be secreted into milk at appreciable levels; thus, animals ingesting furanocoumarin-containing plants probably will not produce milk with sufficient photosensitizing residues to present significant toxicological or ecological risks. However, in eggs of xanthotoxin-treated chickens, the furanocoumarin residues were shown to consist largely of unmetabolized xanthotoxin, raising the issue that under certain circumstances, ingestion of furanocoumarin-containing plants by avian wildlife might result in toxicological consequences to developing embryos.

Because only low levels of radiocarbon residues occurred in the tissues,

eggs, and milk of the xanthotoxin-treated chickens and goat, it seems unlikely that human exposure to furanocoumarins through animal-derived foodstuffs will be appreciable or toxicologically significant.

Abstract—Responses of sawfly larvae (Hymenoptera, Diprionidae) to the flavonoid taxifolin glucoside in their host plant were studied in a laboratory experiment. Larvae of *Neodiprion sertifer* and *Diprion pini* were raised from egg hatch to cocoon spinning on two Scots pine (*Pinus sylvestris*) chemotypes, one without needle taxifolin glucoside (−) and the other containing 2–4% taxifolin glucoside (+). The (+) chemotype had somewhat lower concentrations of needle terpenoids (resin acids) than the (−) chemotype. Current-year needles had higher taxifolin glucoside concentrations than mature needles. There were no differences in survival or body size between *N. sertifer* larvae that fed on the (+) chemotype and those that fed on the (−) chemotype. Female *D. pini* larvae raised on (+) needles developed 6% more slowly than larvae fed (−) needles. The results from this study are contrary to earlier findings showing that flavonoid glucosides have strong negative effects on insect performance. Possible explanations for the different outcomes are discussed.

INTRODUCTION

Flavonoids are polyphenolic compounds found in many species of plants, where they usually occur as glycosides (Harborne, 1979). Little is known about the function of flavonoid compounds. Some (e.g., quercitrin, rutin, and maysin) are known to have deleterious effects on agricultural insects (Shaver and Lukefahr, 1969; Waiss et al., 1979; Elliger et al., 1980, 1981; Isman and Duffey, 1982; Hedin et al., 1983; Duffey et al., 1986). However, rutin has also been shown to enhance insect growth (McFarlane and Distler, 1982), and other flavonoid compounds (e.g., morin and kaempherol) act as feeding stimulants for certain insects (Hamamura et al., 1962; Nielsen et al., 1979).

Coniferous trees have a great variety of flavonoid compounds in their needles (Nieman, 1988), yet their function in the plant is poorly known. There are some indications that they confer resistance against microorganisms (Nomura and Kishida, 1978; Szweykowski and Urbaniak, 1982). Their effects on the feeding of folivorous insects have not been studied.

Two Scots pine (*Pinus sylvestris* L.) chemotypes exist with respect to one particular flavonoid, the dihydroflavonol glucoside taxifolin 3′-*O*-β-D-glucopyranoside (taxifolin glucoside) (Lundgren and Theander, 1988; Laracine-Pittet and Lebreton, 1988). One of the chemotypes lacks taxifolin glucoside, while the other can have a needle taxifolin glucoside concentration of 3–4% dry weight (Lundgren, unpublished data). The two chemotypes cooccur over large parts of Europe, and the relative frequencies in a given tree population seem to vary with climatic conditions (Laracine-Pittet and Lebreton, 1988).

These chemotypes offer an interesting opportunity to study flavonoid–insect interactions in natural plant tissue. In some cases, variation in plant phenolics may have an important influence on insect population dynamics. For example, it has been suggested that stress-induced changes in needle chemistry may trigger outbreaks of needle-eating insects (Larsson and Tenow, 1984). Environmental stress can alter phenolic glycoside concentrations in leaves of some woody plants (Larsson et al., 1986b; Bryant et al., 1987). It is not known, however, whether this also applies to flavonoids in conifers. If it can be shown that insect performance is affected by flavonoids, then it would be rewarding to investigate how needle flavonoid concentrations are influenced by environmental factors.

In this paper we report the results from an experiment in which two species of pine sawflies [*Diprion pini* L. and *Neodiprion sertifer* (Fourcroy)] were fed the two Scots pine chemotypes. Insects were raised on the two types of needles,

and responses were evaluated in terms of larval survival, developmental time, and cocoon weight.

METHODS AND MATERIALS

Study Organisms. Plant material was obtained from a 15-year-old Scots pine plantation at Hägerdal, 30 km north of Uppsala, central Sweden. Trees in this plantation had been investigated earlier with respect to variation in needle flavonoid chemistry (Lundgren unpublished data). Based on these results, trees with [(+) chemotype] and without [(−) chemotype] taxifolin glucoside and chemically related compounds (Figure 1) were selected for use. The experiment was performed in 1986 and 1987, using a different insect species each year (see below). From each study tree (N = 12 trees in 1986, N = 5 trees in 1987) one branch (three branches in 1987) was sampled from the lower half of the crown, which was immediately placed in a bucket of water and taken to the laboratory.

Larvae of *Neodiprion sertifer*, collected from an outbreak area south of Sandviken, central Sweden, were used in the 1986 experiment, and larvae of *Diprion pini* from a small outbreak at Närsholmen, Gotland, southeast Sweden, were used in the 1987 experiment. In both years, insects for the experiments were obtained by collecting pine shoots containing egg batches just prior to hatching. The shoots were taken to the laboratory and checked daily for hatched larvae. The transfer of larvae to test shoots began as soon as the first emerging larvae were observed.

Larval Performance Experiments. Sawfly larvae were raised from egg hatch to cocoon spinning on experimental shoots in an environmental chamber (18:6 light–dark photoperiod, 18°C, 70% relative humidity). Larvae were presented their preferred needle type, i.e., 1-year-old needles for *N. sertifer* and both

R=R'=OH	Ampelopsin glucoside

FIG. 1. Flavonoid glucosides present in the needles of the (+) chemotype (cf. Lundgren and Theander, 1988).

1-year-old needles (early instars) and current-year needles (late instars) for *D. pini*. Each shoot was placed in a plastic container filled with tap water. To prevent mixing of the larvae, each shoot was enclosed in a transparent plastic cylinder with a muslin cover. Larvae were given fresh shoots at weekly intervals.

At the start of the experiment newly emerged larvae or eggs just about to hatch were transferred to shoots representing each of the two types of trees. About 30 larvae were transferred to each shoot. In 1986, 12 replicates were studied (one shoot from each of 12 trees). In 1987, three shoots from each of five trees were studied (always one terminal and two lateral shoots). Larvae that had started to feed on a terminal shoot were always given terminal shoots, and larvae that had started feeding on lateral shoots were always given lateral shoots.

In order to avoid pseudoreplication, means were calculated for male and female larvae fed needles from the same tree. Thus, there were 12 independent observations in 1986 and five in 1987. Statistical analyses were performed on these mean values.

Chemical Analyses. Needles intended for chemical analyses were sampled from branches offered to the larvae in the performance experiments. In 1986, 1-year-old needles were sampled fresh from trees on June 17. In 1987, 1-year-old needles were sampled fresh from trees on July 16. After one week in the laboratory, samples were again taken from the same shoots to check whether the laboratory treatment had any effects on needle phenolic chemistry. Current-year foliage was sampled fresh from trees on July 27, 1987, and again from shoots in the laboratory on July 30. Since no effects of the laboratory treatment on phenolic chemistry were found, data were pooled in all subsequent analyses.

Phenolic compounds were analyzed by reverse phase high-performance chromatography (HPLC). In the 1986 experiment, needle extracts were treated with pectinase and the resulting aglycone mixtures were extracted with ethyl acetate and examined by HPLC. The taxifolin content was determined, and the concentration of taxifolin glucoside in the needles calculated, assuming that taxifolin glucoside is quantitatively hydrolyzed and extracted to the organic layer. Acetovanillon was used as internal standard. In 1987, the intact extractives were analyzed, and picein was used as internal standard. The internal standard (0.5 mg) was added to the needle sample (1000 mg fresh weight), and the sample was homogenized with an UltraTurrax with 2 × 5 ml of 95% ethanol (5 and 0.5 min, respectively) and with 2 × 5 ml of 80% ethanol in the same way. The combined aqueous ethanol extract was evaporated to dryness, dissolved in water (15 ml) and extracted with light petroleum (bp 40–60°C) (2 × 20 ml). In 1987 the aqueous layer was evaporated to dryness and the residue dissolved in methanol (1 ml). In 1986 the aqueous layer was treated with pectinase (0.5 ml, No. P-5146, Sigma) overnight at room temperature, acidified with three drops of 25% phosphoric acid, and extracted with ethyl acetate (3 × 10 ml). The combined ethyl acetate extract was dried with sodium sulfate and

evaporated to dryness, after which the residue was dissolved in methanol (1 ml).

The HPLC separation was performed with a Spectra Physics liquid chromatogram system with a Nova-Pak Rad-Pak C-18 column (Waters Associates). The separated components were detected with a UV detector at 280 nm. For the 1986 experiment, the mobile phase (mixture by volume of 0.01 M, pH 2.8, aqueous sodium phosphate buffer and methanol) consisted of a linear gradient from 20% to 30% methanol for 15 min, then maintained isocratically for 10 min, followed by a linear gradient to 55% methanol for 25 min and to 80% methanol for 10 min. The flow rate was 1.5 ml/min. For the 1987 experiment, the mobile phase (mixture by volume of 0.01 M, pH 2.8, aqueous sodium phosphate buffer and acetonitrile) consisted for the initial 7 min of 5% acetonitrile. The concentration of acetonitrile was increased linearly to 25% in 43 min and subsequently to 70% during 10 min. The flow rate was 1.5 ml/min.

Diterpenoids were extracted and treated according to the methods reported by Gref and Ericsson (1985). Samples were analyzed on a Varian 3700 gas chromatograph equipped with a fused silica capillary column (15 m × 0.25 mm ID) with 0.25-μm film of DB-1 (J & W Scientific). The chromatograph was equipped with a split injector and a flame ionization detector. Hydrogen was used as a carrier gas at a flow rate of 1.60 ml/min. The chromatograph was operated isothermally at 210°C or temperature programmed to increase from 160°C to 240°C at 4°/min. Peak areas, relative to the internal standard, and retention times were measured with an electronic integrator.

Total nitrogen (on a dry weight basis) was measured with a CHN-elemental analyzer (Perkin-Elmer model 2400 CHN).

RESULTS

Needle Chemistry. As expected, the two types of trees differed in their needle concentrations of taxifolin glucoside. No taxifolin glucoside was found in the (−) chemotype, whereas taxifolin glucoside made up 1.7–3.8% of the needle dry weight in the (+) chemotype (Figure 2; Table 1). In 1987, taxifolin glucoside concentrations were twice as high in current-year needles as in 1-year-old needles. Other hydrophilic UV-absorbing compounds (presumably phenolics) were not specifically quantified, but their total chromatogram peak areas were determined. Concentrations of these compounds in 1-year-old needles were higher in the (+) chemotype than in the (−) chemotype in both 1986 and 1987, i.e., 26% and 40%, respectively (Table 1). No differences were found with respect to these compounds in current-year needles.

In 1986, concentrations of total resin acids were, on average, 69% higher in the (−) chemotype compared with the (+) chemotype (Table 1). Pinifolic

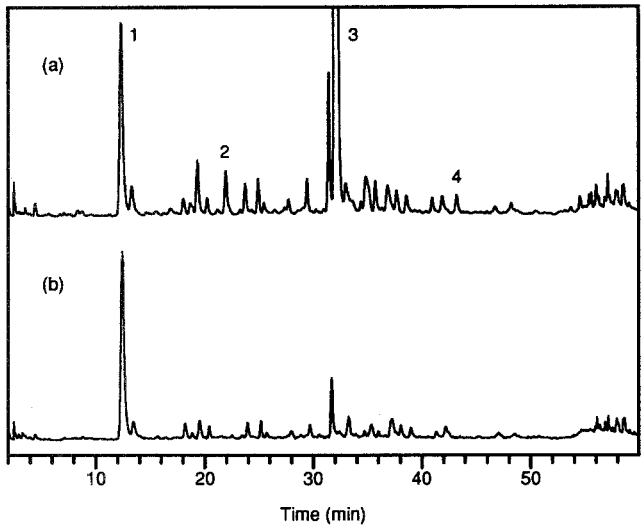

FIG. 2. HPLC separation of phenolic extractives from needles of (a) a pine tree containing taxifolin glucoside [= (+) chemotype] and (b) a pine tree lacking taxifolin glucoside [= (−) chemotype]. Peak numbers refer to (1) picein (internal standard), (2) ampelopsin glucoside, (3) taxifolin glucoside, and (4) eriodictyol glucoside (cf. Figure 1).

acid contributed most to the total resin acid content (66.5%, averaged over the two types of trees). In 1987, a subset of five trees of each type was compared. These trees were selected in a way that minimized variation in resin acid concentrations. As a result, there was much less variation in resin acid concentrations in the 1987 experiment. No differences were found in total resin acid or pinifolic acid concentrations, but there were significantly higher concentrations of 4-epiimbricatolic acid and neoabietic acid in the (+) chemotype.

There were no differences in concentrations of total nitrogen between the two types of trees (Table 1).

Larval Performance. No differences were found in survival or cocoon weight between *N. sertifer* larvae raised on the (+) chemotype and those raised on the (−) chemotype (Table 2). No detailed measurements of larval development were made. However, according to a survey made on June 27 (late cocoon spinning stage), the proportion of larvae that had spun cocoons was 79% on the (+) chemotype and 71% on the (−) chemotype.

D. pini larvae developed more slowly on the (+) chemotype (Table 2). The difference was small (6%) and significant for female larvae ($P < 0.05$), but not significant for male larvae. No effects on body size were found.

DISCUSSION

Three findings with ecological implications came out of this study: First, trees of the (+) chemotype tended to have lower concentrations of needle resin acids than those of the (−) chemotype. Second, concentrations of taxifolin glucoside in current-year needles were about twice as high as those in 1-year-old needles. Third, despite the great differences in flavonoid concentrations between the two chemotypes, differences in performance between larvae fed the (+) chemotype and those fed the (−) chemotype were surprisingly small.

In 1987, we selected trees in a way that minimized differences in resin acid content between chemotype groups in order to isolate the taxifolin glucoside effect on sawfly performance. This explains why a chemotype-related difference in resin acid concentrations was found in 1986 but not in 1987. The negative relationship between resin acid and taxifolin glucoside concentrations in 1986 is difficult to explain because these two types of substances are synthesized along completely different metabolic pathways (Goodwin and Mercher, 1983). Since both types of compounds are examples of carbon-based substances, their synthesis might have been constrained owing to limited substrate availability (e.g., Steward and Keeler, 1988).

In 1987, concentrations of taxifolin glucoside were found to be higher in young needles than in 1-year-old needles. Although this type of comparison could not be made in 1986, we were able to compare concentrations in 1-year-old needles between 1986 and 1987 and found them to be somewhat higher in 1986. This difference suggests that concentrations may vary between years, but it could also reflect within-season variation since needles were sampled at an

earlier date in 1986. Young plant tissue often has higher concentrations of secondary metabolites than mature tissue, although the reverse also occurs (Ikeda et al., 1977; Niemelä et al., 1982; Raupp and Denno, 1983). It may be adaptive for the plant to invest strongly in the defense of young tissue, which will contribute most to future growth and reproduction (e.g., McKey, 1979). Thus, it appears likely that the high concentrations of taxifolin glucoside in young needle tissue is an example of such an adaptation, since it is known that this compound has a protective function in some plant species (Nomura and Kishida, 1978).

The results of the present experiments, however, provide little support for the hypothesis that taxifolin glucoside helps to protect *P. sylvestris* against pine sawflies. It is possible, however, that the performance of *N. sertifer* larvae fed the (+) chemotype was reduced, but that this reduction was masked by the higher resin acid concentrations in the (−) chemotype, which should have also adversely affected performance (Larsson et al., 1986a).

In the *D. pini* experiment, where the two chemotype groups had similar resin acid concentrations, there was a significant difference in the larval performance of females (developmental time), but the difference was small. Developmental time was the insect trait most affected in earlier sawfly–needle quality experiments in which *N. sertifer* larval performance was related to resin acid content (Larsson et al., 1986a) and nitrogen content (Björkman et al., 1991). Thus, in response to suboptimal food quality, it appears as if, in general, sawfly larvae extend the length of their feeding period rather than accepting a reduction in body weight.

It is somewhat surprising that the great difference in taxifolin glucoside concentrations did not result in stronger effects on sawfly performance. Effects of flavonoids on other insects have been reported at much lower concentrations. For example, flavonoid concentrations of 0.1–0.4% reduced growth in *Heliothis zea*, *H. virescens*, and *Pectinophora gossypiella* (Shaver and Lukefahr, 1969). Similarly, *Heliothis zea* larval weight was reduced by about half on control medium when 0.3% (fresh weight) of rutin was added (Isman and Duffy, 1982). Pine sawflies, which are oligophagous, might be less sensitive than polyphagous insect species to variation in the composition of their preferred host plants (cf. Barbosa, 1988). Most insect species for which flavonoids have been shown to reduce performance have a broader host range than the sawflies studied here, i.e., *Heliothis zea*, *H. virescens*, *Pectinophora gossypiella*, and *Schizaphis graminae* (Shaver and Lukefahr, 1969; Waiss et al., 1979; Elliger et al., 1980, 1981; Isman and Duffey, 1982; Hedin et al., 1983; Duffey et al., 1986).

In addition, there may be differences in bioactivity between flavonoid compounds depending on their molecular structures. Elliger et al. (1980) reported that *H. zea* larvae fed an artificial diet containing 3.5 mmol/kg (=0.11% fresh weight) of dihydroquercetin (=taxifolin), the aglycone of taxifolin glucoside, grew 50% more slowly than controls. However, there are probably important

differences in the mode of action between taxifolin and the taxifolin glucoside. Flavonoids possessing a catecholic B-ring seem to be active against insects, whereas those with other substitution patterns generally are not (Elliger et al., 1980). Taxifolin has a catecholic B-ring while the 3′-*O*-glucoside is glucosylated on the B-ring, and therefore does not possess the structure that presumably is active.

Thus, as in certain other plants (e.g., Yu, 1989) the aglycone appears to be more toxic to insects than the glucoside. Free taxifolin occurs in very small concentrations in Scots pine needles (L. Lundgren, unpublished data). Many herbivorous insects are known to enzymatically cleave glycosidic bonds, releasing sugar and the aglycone (Lindroth, 1991). Further studies will be needed to determine whether such a process takes place in sawfly larvae, which would indicate that they have evolved a mechanism for tolerating taxifolin (cf. Lindroth et al., 1987). Presently, all that we can conclude is that high needle concentrations of taxifolin glucoside have a minor effect on sawfly larval performance.

Acknowledgments—We would like to thank Gunilla Lekselius and Berith Solbreck for technical assistance and Kjell Olofsson for carrying out the nitrogen analysis. Helpful comments on the manuscript were provided by Christer Björkman, Göran Nordlander, Ken Raffa, and David Tilles. Financial support for this work was provided by the Swedish Natural Science Foundation and the Swedish Council of Forestry and Agricultural Research.

(Received September 17, 1991; accepted October 28, 1991)

Abstract—Isomers of [11,12-$^3H_2$]-11-tetradecenyl acetate (57 Ci/mM) were synthesized. Behavioral assay of the two compounds using Z- and E-type European corn borer (ECB) males showed that introduction of tritons into the double bond of the pheromone caused a significant isotope effect in the E-type ECB but not in the Z-type ECB. Measurements of tritium associated with the male antennae after a 3-min exposure showed that radioactivity equivalent to 10^{-17} mol pheromone was adsorbed onto male antennae. Time-course in vivo metabolic studies with picogram amounts of compound applied topically to antennae of E- and Z-type males and Z-type females showed that they metabolized pheromone similarly but females degraded pheromone more slowly than males. Pheromone was hydrolyzed, and the only other major radiolabeled metabolite observed by combined high-pressure liquid chromatography-radiodetection was tritiated water. Capillary gas chromatography and radiomonitoring permitted detection of a trace amount of 11-tetradecenoic acid, which indicated alcohol oxidase activity is associated with the antennae. Evidence shows that clearing of pheromone from the ECB male antennae involves hydrolysis and oxidation of the alcohol to fatty acid, which in turn is degraded, probably via β-oxidation, to carbon dioxide and water.

Key Words—Lepidoptera, Pyralidae, *Ostrinia nubilalis*, European corn borer, tritiated pheromone, 11-tetradecenyl acetate, sensory biochemistry, catabolism.

INTRODUCTION

Ostensibly, the role of the catabolic enzymes in moth olfaction is to maintain chemoreceptive sensitivity to pheromone through rapid clearing of resident pheromone from antennal structures and to thereby maintain a high level of sensitivity to fresh incoming chemical signals. Radiolabeled sex pheromones have proven to be useful in the study of pheromonal catabolism in a number species of moths. The radioactive probes have expedited discovery and elucidation of esterase, epoxide hydrase, alcohol oxidase, and aldehyde dehydrogenase activities in the moths (Prestwich et al., 1989a; Tasayco and Prestwich, 1990; Ding and Prestwich, 1986). However, with the exception of studies with the polyphemus moth (*Antheraea polyphemus*) and the silk moth (*Bombyx mori*) by Kasang et al. (1989a,b), most pheromone catabolism studies have involved identification of only the first intermediary catabolic product formed after pheromone contacts the antenna. The intent of our present work was to elucidate degradative pathways and metabolites beyond the first product.

Much has been accomplished in studies of first-product metabolites of pheromones. As examples, Prestwich et al. (1989b) discovered that antennae of gypsy moth (*Lymantria dispar*) males contain epoxide hydrolase activity, which transforms the epoxide moiety of the gypsy moth pheromone to a diol, but the metabolic fate of the diol was not investigated. Tasayco and Prestwich (1990) demonstrated conversion of pheromonal aldehydes of the tobacco budworm to carboxylic acids but did not determine the fate of the acids. Ferkovich (1982) monitored hydrolysis of the cabbage looper pheromone component, (*Z*)-7-dodecenyl acetate, but the fate of the alcohol was not studied. In these examples, the research was focused upon the first step of pheromone catabolism because the first product was either known or assumed to be behaviorally inert and a simple one-step conversion presumably fulfilled the pheromone-clearance requirement for maintenance of optimal olfactory sensitivity. However, the assumption that a first product is behaviorally inert can be faulty. It is known, for instance, that such an assumption is not valid for the cabbage looper; males possess antennal chemoreceptor cells that are specifically responsive to (*Z*)-7-dodecenol (Grant and O'Connell, 1986), and the compound is a potent inhibitor of male behavior (Tumlinson et al., 1972; McLaughlin et al., 1974). Inasmuch as cabbage looper males show considerable electrophysiological and behavioral sensitivity to (*Z*)-7-dodecenol, then, provided the hypothetical role of catabolic enzymes in moth olfaction is correct, mechanisms for clearance of that compound from the chemosensory sensilla of the antennae must also exist and it is imperative to know what they may be. An analogous situation exists in case of the ECB (*Ostrinia nubilalis*). Gas chromatographic analyses of extracts of Z- and E-type ECB (Klun and Huettel, 1988) male antennae treated with 11-tetradecenyl acetate have shown that antennal esterase effectively hydrolyzes

the pheromone and that the alcohol subsequently also disappears from the antennae (Klun et al., 1991). Flight-tunnel assays with Z-type ECB males have shown that when (*Z*)-11-tetradecenol was coevaporated with its pheromone, male upwind flight response was inhibited (Schwarz et al., 1990). Thus, the alcohol formed by esterase operating on ECB pheromone is a behaviorally relevant substance, and it must necessarily be cleared from the antennal chemosensory sensilla; otherwise it could interfere with response to pheromone. We present evidence that provides insight into the metabolic fate of the alcohol in the ECB.

It is well known that compounds labeled with tritium, like all compounds containing isotopes, possess physical properties that are different from compounds composed of natural stable isotopes and these can cause what is referred to as an isotope effect (Evans, 1974). To our knowledge no one has ever attempted to ascertain what effect tritium might have upon the biological activity of an insect pheromone, despite the fact that a number of high specific activity pheromones have been prepared. Therefore, it became of interest to see if tritiated ECB pheromone might express an isotope effect at a behavioral level in the insect.

METHODS AND MATERIALS

[11,12-$^3H_2$]-11-Tetradecenyl Acetate. Preparation and purification of tritiated pheromone was conducted at the National Tritium Labeling Facility (NTLF) in Berkeley, California, where appropriate facilities exist for handling carrier-free tritium. All synthetic and purification procedures used at NTLF were developed and tested in advance at Beltsville using deuterium. The semitritiation method was patterned after that reported by Ding and Prestwich (1986). 11-Tetradecynyl acetate (0.03 mM) in 2 ml hexane was transferred to a reaction vessel fitted with a magnetic stirring bar and attached to a gas manifold system. Five milligrams of Lindlar catalyst (5% palladium on $CaCO_3$-Pb poisoned; Strem Chemicals Inc., Newburyport, Massachusetts) were placed in a glass spoon above the hexane solution. The reaction vessel was closed, the hexane solution degassed by three freeze–pump–thaw cycles with nitrogen and liquid nitrogen cooling. Tritium, desorbed from uranium, was then delivered to the evacuated reaction vessel at room temperature until its internal pressure was at atmospheric pressure. The Lindlar catalyst was added to the hexane solution, and the reaction mixture was stirred for 5 min. In model reduction reactions with deuterium, the 5-min reaction time caused reduction of one half of the alkyne; partial reduction minimized the formation of secondary products and facilitated isolation of pure product. Tritium and hexane were removed from the reaction vessel under vacuum. The residue was washed with three separate 1-ml aliquots of methanol that were successively added to the reaction mixture and

removed under reduced pressure to rid the preparation of exchangeable tritium. Toluene (2 ml) was added to the residue, and the mixture was filtered through a 0.5-μm Millex-SR filter (Millipore Corp., Bedford, Massachusetts) into a Luer-lock syringe. The toluene solution was concentrated to 0.4 ml under a nitrogen gas flow and injected onto two 25-cm × 10-mm-ID 10-μm Spherisorb silica (Phase Sep, Norwalk, Connecticut) chromatographic columns plumbed in series and eluted with toluene pumped at 4 ml/min. The chromatography was designed to resolve reduction products from unreacted alkyne. Column effluent was monitored using a solid scintillant detector cell and a refractive index detector. The reduction products were collected in ca. 8 ml toluene from 10 min to 12 min after injection. The toluene solution containing products was concentrated to 0.3 ml and injected onto a 31-cm × 10-mm-ID 20% $AgNO_3$–5-μm Spherisorb silica column eluted with toluene at 3 ml/min to obtain ca. 0.56 Ci pure *Z* isomer (T_r = 14.5 min).

Isomerization and Tritiated trans *Isomer Isolation.* One half of the purified [11,12-$^3H_2$]-(*Z*)-11-tetradecenyl acetate in 0.25 ml toluene was transferred to a 2-ml screw-cap vial and 60 μg thiophenol in 2 μl toluene and 34 μg 2,2′-azobis-(2-methylpropanenitrile)–2 μl benzene were added to the sample. The vial was closed, placed into a high-pressure containment flask and warmed at 103°C in a sand bath for 1.5 hr to cause formation of a 6:4 *E*:*Z* equilibrium mixture (Schwarz et al., 1986). Approximately 0.17 Ci pure *E* isomer (T_r = 9.9) was isolated by using argentation chromatography described previously.

The specific activities of the *Z* and *E* isomers were determined by NMR. Specific activity measurements are usually made by liquid scintillation (LS) counting of a known mass of compound, by mass spectrometry, or by determination of the [^{3}H]- and [^{1}H]NMR spectrum of a compound. The NMR technique has been used to analyze compounds such as [^{3}H]$NaBH_4$, where the other methods are not facile, and NMR is most readily applied when the level of replacement of ^{1}H by ^{3}H at specific positions in the molecule is greater than 10% (Bloxsidge et al., 1971; Altman and Thomas, 1980). In our case, the method involved integration of residual protons at the tritiated site, carbons 11 and 12 (δ = 5.5 ppm) relative to integration of protons at carbon 1 (δ = 4.0 ppm). Requisites and assumptions for use of NMR in specific activity determinations are: the compound must be chemically and radiochemically pure, the residual protons are assumed to have the same relaxation time as the internal reference protons, the proton spectrum must be sufficiently resolved to allow integration of the sites of interest, and the specific radioactivity of the compound containing one tritium per molecule is assumed to be 28.72 Ci/mM. Specific activity determinations by NMR spectroscopy are subject to an error of ±10%. (Dr. Philip Williams, NTLF personal communication). [^{1}H]- and [^{3}H]NMR spectra were recorded in deuterated benzene, on an IBM AF-300 NMR spectrometer (^{3}H at 320 MHz, ^{1}H at 300 MHz), using a ^{3}H/^{1}H 5-mm dual probe.

Samples were made to a volume of 200 μl in Teflon tubes (Wilmad, #6005), which were then placed into 5-mm glass NMR tubes having screw caps (Wilmad, 507-TR-8″). A high-quality ^{3}H band stop–^{1}H band pass filter (Cir Q-Tel Inc., FBT/20-300/3-6/50-3A/3A) was placed in the proton decoupling line of the instrument, and the observed channel had an in-line ^{1}H band stop–^{3}H band pass filter. Tritium and proton spectra were acquired over ca. 12 ppm, using a 5-sec total recycle time and excitation pulse of 3.6 μsec (^{3}H, 65°) and 2 μsec (^{1}H, 25°). All spectra were acquired at 297K with the sample spinning. Referencing of tritium chemical shifts was achieved by generation of a ghost ^{3}H tetramethylsilane (TMS) signal from internal TMS in the [^{1}H]NMR spectrum.

Glass ampoules containing approximately 100 mCi *Z* isomer or *E* isomer in 5 ml toluene were transported to Beltsville and stored at −80°C to await use. During the course of study, all tritiated compounds were repurified every four to eight weeks.

Derivatives of Tritiated Pheromone. The radiolabeled acetates were used to prepare corresponding 11,12-^{3}H alcohols and aldehydes using synthetic methods similar to those described by Ding and Prestwich (1986). [11,12-^{3}H]-(*Z*)-11-tetradecenoic acid was prepared by oxidation of aldehyde using Ag_2O as oxidizing agent (Campaigne and LeSuer, 1963). Tritiated derivatives were used in metabolic studies and as chromatographic references.

Liquid Chromatography and Radioisotope Detection. All high-pressure liquid chromatographic (HPLC) analyses or preparative purifications of compounds involving tritium were conducted using a Beckman System Gold (Beckman Instruments, Fullerton, California 92634) chromatographic system equipped with a Beckman model 171 radiochromatography detector that was fitted with either a solid scintillator (Ultra-Scint) or a liquid cell. In liquid cell applications, Beckman Ready Flow liquid scintillant was pumped at 2 ml/min and mixed with the chromatographic column effluent (1 ml/min). The solid scintillator cell was used when compounds were purified by using a 43.5-cm × 3-mm 5-μm Spherisorb silica column eluted with an appropriate mixture of hexane–ethyl acetate. The hexane–ethyl acetate was removed in a nitrogen gas flow, and the sample was taken up into heptane solution to form a stock solution whose tritium composition was quantified by liquid scintillation counting. The stock solution was then used in assays and in preparation of appropriate dilute heptane solutions.

Most analyses of the extracts of insect tissues for tritiated pheromone and its metabolites were performed using a 25-cm × 3-mm-ID column packed with 5-μm Spherisorb ODS (octadecylsilane coated silica), acetonitrile–water (85 : 15) pumped as eluant, and the liquid cell detector. Tritium detection efficiency of the liquid cell was 20% for organics and 17% for water. The minimum detection limit for tritiated pheromone was 400 dpm. The retention times of pheromone and other reference compounds in HPLC were established by using tritiated

reference compounds that we synthesized or purchased from NEN, DuPont Company, Boston, Massachusetts 02118. In instances where reference compounds were not available with a radiolabel, the HPLC effluent was monitored by using a Waters Associates model 401 differential refractometer to determine their retention characteristics relative to radiolabeled components in insect extracts.

Normal liquid scintillation (LS) counting was done by using a Beckman model LS 6000 counter and 20 ml Ecoscint LS cocktail (National Diagnostics, Manville, New Jersey 08835). Detection efficiency was 23% for tritiated water and 39% for tritiated organic compounds. Counting efficiency was verified by using external-standard tritiated NEN toluene or water calibration compounds.

Gas Chromatography and Tritium Detection. The chromatography was conducted using a Hewlett-Packard model 5880A gas chromatograph that was vented to a chemical fume hood. The instrument was fitted with a splitless injector, flame ionization detector (FID), and either a polar 60-m × 0.25-mm DB-Wax column (J & W Scientific, Folsom, California 95630) or a nonpolar 50-m × 0.32-mm Ultra 1 (cross-linked methyl silicone gum, Hewlett-Packard, Palo Alto, California 94304). The oven temperature program for both columns was 90°C for 0.4 min after injection, heating at 2°C/min to 120°C followed by heating to 175°C at 30°C/min. Hydrogen was used as carrier gas at 50 cm/sec flow. Gas flows through the FID detector were 300 ml air, 60 ml hydrogen, and 60 ml nitrogen. A detector-insert tube normally used for measurement of FID gas flows was positioned in the chimney of the detector, and the occurrence of tritiated water, formed by hydrogen-flame combustion of compounds eluting from the column, was monitored throughout each chromatographic run. FID water was collected at 1-min intervals into disposable 23-cm glass Pasteur pipets that were inserted through a 17-cm × 8-mm-ID glass sleeve cooled with Dry Ice and over the detector effluent flow tube (3.2 mm OD). The collections were made from the time of injection to 2500 (Kovats retention index) on DB-Wax and from injection to 2200 on Ultra 1. Water collected in each pipet was rinsed with Ecoscint into a LS vial and assayed in the LS counter. Tests in which picogram amounts of tritiated pheromone were injected onto the columns showed that ca. 30% of the radioactivity injected was recovered in the FID water coincident with the retention time of the compound on the column. This methodology permitted us to analyze antennal extracts for tritiated pheromone and its metabolites by capillary gas chromatography (GC). In advance of such analyses, retention time reference points were established by injecting unlabeled standard mixtures of C_7–C_{14} saturated fatty acid methyl esters, 11-tetradecenyl acetate, 11-tetradecenol, 11-tetradecenal, and methyl-11-tetradecenoate isomers onto the capillary columns.

Analyses of Pheromonal Metabolites via GC. Previous pheromone catabolism studies in several species of moths showed that pheromones were often

oxidized to carboxylic acids (Kasang et al., 1989a,b; Lonergan, 1986; Prestwich et al., 1989a; Rybczynski et al., 1989). Therefore, we conducted a specific search for fatty acid metabolites of pheromone in the ECB by conducting an experiment with a large amount of radiolabeled pheromone. A pooled chloroform extract of the antennae of Z-type male ECB was prepared by treating the antennae of each of 30 males with 123.5×10^3 dpm *Z* pheromone. After a 6-min in vivo incubation, antennae were excised into 300 μl chloroform. The combined extract was filtered, 10 μl was analyzed on the ODS HPLC to determine tritium recovery and composition of the sample, and the remainder was reacted with an excess of diazomethane in diethyl ether to convert putative fatty acids in the extracts to methyl esters. The methylated sample was reanalyzed (10 μl) on ODS, concentrated in a nitrogen gas flow to 10 μl, and chromatographed on the DB-Wax and Ultra capillary columns as described earlier to determine the retention times of radiolabeled metabolites in the extracts. This experiment was replicated twice.

Bioassay of Tritiated versus Nonradioactive Pheromone. A glass closed-system device (Figure 1) for bioassay of the pheromones was fabricated using a 65/40 standard glass joint. The tube size on the socket end was 6 cm × 40 mm ID, and it ended with 3 cm × 4 mm ID tube to which a Luer connector was cemented. The tube length on the ball end of the joint was 8.5 cm, and it was constricted and ended with a 18/9 socket joint. A sintered glass 40-mm-diam. disk drilled with 21 1-mm-diam. uniformly distributed holes was fitted

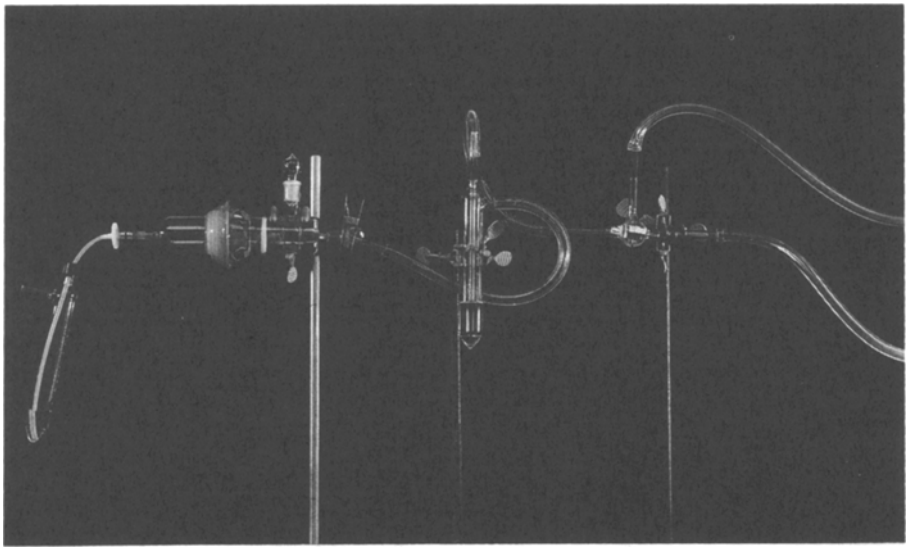

FIG. 1. Apparatus for bioassay of high specific activity tritiated sex pheromone.

across the diameter of the tube 5.4 cm from the end of the ball joint. The eventual function of the disk was to serve as a barrier between a pheromone source and moths used in the assays. A 14/20 standard taper joint and stopper was located perpendicular to the tube of the ball joint and 8.5 cm from the ball joint end. The 14/20 stopper was fitted with a nichrome wire to which an alligator clip was attached. The ball-joint half of the device was clamped to a ring stand in a fume hood. Tygon tubing was used to connect a tank of compressed breathing-quality air and a tank of CO_2 to a water-filled bubbler via a three way T valve, and the bubbler effluent was connected to a 18/9 ball joint, which was attached to the bioassay device with a pinch-type clamp. A Millex filter was loaded with 2 mg KB grade Darco activated carbon and attached to the Luer connector of the socket portion of the 65/40 joint to contain tritiated pheromone. Tritium containment was verified in advance of conducting any bioassays by passing tritiated pheromone laden air through the system for 20 min while effluent from the filter was bubbled through ethylene glycol; LS counting showed no tritium in the ethylene glycol.

In the bioassays, a 48- to 72-hr-old male moth was transferred to the socket portion of the device, and it was connected to the ball joint with a pinch-type clamp. All assays were conducted at 20–21 °C under low-intensity red light (ca. 2.5 lux) when males were in the second to fourth hour of their 8-hr scotophase. Radioactive pheromones and nonradioactive pheromones were assayed in separate but identical apparatus. Geometrically pure *Z*- (14 ng) or *E*- (12.5 ng) tritiated or an equal amount of the respective nonradioactive isomer in 1 μl heptane was applied to a 6-mm × 6-mm filter paper that was attached to the alligator clip and inserted upwind of the male and just beyond the sintered disk. Each pheromone-treated filter paper was used successively to test four to six males before it was discarded. Humidified air was delivered through the bioassay unit at 33 ml/sec, and each male was observed and exposed to stimulus for 3 min. A positive response was recorded if the male displayed precopulatory behavior (extension of genitalia, wing vibration, and clasper response) in the exposure period and a negative response was recorded if he did not display the behavior. The unit was then purged with CO_2, the anesthetized moth was removed, and the male's antennae were excised into Ecoscint for LS counting. Antennae of males exposed to nonradioactive pheromone were processed in the same way and LS counts obtained with them served as a measure of background radiation. Testing was replicated over time, each male represented a replicate, and equal numbers of males within ECB pheromonal types were tested against equal amounts of radioactive and nonradioactive pheromone. In all, the tests with Z-type and E-type males were replicated 52 and 84 times, respectively. The behavioral responses to radioactive and nonradioactive pheromones were compared, for both types of males, with a logistic analysis using the SAS CATMOD procedure (SAS, 1988). The LS counts per minute (cpm) for the two treatments within male types were compared by analysis of variance using

the SAS GLM procedure (SAS, 1988). The cpm difference observed between antennae exposed to tritiated pheromone and antennae exposed to nonradioactive pheromone represented above-background radiation, and it was converted to disintegrations per minute (dpm) by assuming that the tritium was in the form of water, a 23% LS efficiency. With a specific activity of 57 Ci/mM, 1 dpm represented 2.04 fg pheromone, and thereby the amount of radiolabeled pheromone adsorbed onto male's antennae in the 3-min exposure was calculated.

[11,12-$^3H_2$]-11-Tetradecenyl Acetate Metabolism in ECB Types. In the time-course studies of *Z* and *E* pheromone metabolism in Z- and E-type ECB males, respectively, and in the study of *Z* pheromone metabolism in Z-type females, one antenna of a CO_2-anesthetized moth (24–96 hr old) was treated with 106.5 $\times$ 10^3 dpm tritiated pheromone (ca. 220 pg) in 0.5 μl heptane using a micrometer-driven 10 μl syringe and a dissection microscope. Heptane was used as solvent because previous study showed that treatment of the antennae of moths with this solvent did not impair male behavioral sensitivity to sex pheromone (Klun et al., 1991). Following the topical treatment, the antenna was then either immediately excised (T_0) at its base into 50 μl chloroform–methanol (2:1, v/v) or the moth was enclosed in a plastic jelly cup and permitted to incubate for 3 min (T_3), 6 min (T_6), or 12 min (T_{12}). The antenna was then excised into chloroform–methanol (CM), soaked 30 min, and removed from the solvent. The volume of the extract remaining was measured by drawing all of the solvent into a 50-μl Hamilton syringe and then half the sample was analyzed by ODS HPLC. Using this technique, we monitored degradation of pheromone, formation of radiolabeled metabolites, estimated tritium recoveries, and followed changes in the proportional distribution of tritium between pheromone and its metabolites as a function of time. Mean proportions of tritium were plotted as a function of incubation time. Arbitrarily, best-fit simple linear regression equations for the data points were computed and drawn by using a personal computer with Cricket Graph software for all metabolic data. Tests were replicated 12 times in the case of E-type males and six times with the other male type and females.

[11,12-$^3H_2$]-11-Tetradecen-1-ol Metabolism. Alcohols were applied to the male ECB types using the same techniques as were used with the acetates. E-type males were treated with 128.4 $\times$ 10^3 dpm *E* isomer (287 pg) and Z-types were treated with 126.5 $\times$ 10^3 dpm *Z* isomer (258 pg). The tests were replicated six times with each type of insect.

RESULTS AND DISCUSSION

Reduction of alkyne with tritium proceeded more rapidly than it had with deuterium; no residual alkyne remained after 5 min of tritiation and significantly more saturated product was formed than had been observed in reductions using

deuterium. The yield was 13.4% tetradecyl acetate, 23.5% *E* isomer, and 63.1% *Z* isomer according to high-pressure liquid chromatography. However, the purification procedures yielded the desired pure high specific activity isomers of the ECB pheromone.

NMR spectroscopy of *E* pheromone showed a ^{1}H integrated intensity of 0.0985 at 5.5 ppm and 0.9215 at 4 ppm (protons of carbon 1). This indicated a specific activity (SA) of 51.29 Ci/mM at carbons 11 and 12. Comparison of the ^{3}H integrated intensity at 5.5 ppm (25.082) and 2 ppm (2.59) indicated that 5.29 Ci/mM was associated with carbons 10 and 13. Therefore the total estimated SA for the *E* pheromone was 56.6 Ci/mM. In the proton spectrum of the *Z* pheromone, the signal-to-noise ratio was such that an integral for residual protons at carbons 11 and 12 could not be obtained. We therefore assumed that the SA associated with those carbons was the same as observed in the *E* pheromone since it was derived from the *Z* compound. For the *Z* pheromone, the ^{3}H integrated intensity at 5.5 ppm was 20.690 and the integral at 2 ppm was 2.391, indicating 5.93 Ci/mM was associated with carbons 10 and 13. Thus, the SA estimated for the *Z* pheromone was 57.2 Ci/mM. Inasmuch as SA values for both isomers are subject to a 10% error, we concluded that the nominal SA for each isomer was 57 Ci/mM.

Results of behavioral assays with tritiated and nonradioactive pheromones showed that tritiated *Z* isomer elicited behavioral responses from Z-type males as effectively as natural pheromone. On the other hand, tests with tritiated *E* isomer showed that it was significantly less effective in evoking behavioral responses from the E-type ECB than the protonated counterpart (Table 1). Thus, incorporation of tritium into the *E* pheromone caused a significant isotope effect; the Z-type borer was deceived by our tritiated analog, but the E-type was not. Previous pheromone-structure × activity relationship studies (Schwarz et al., 1990) have proven that the olfactory systems of the E- and Z-type ECB are quite dissimilar in their organization, inasmuch as the types often responded differently to identical analogs of their pheromones. Therefore, we were not

TABLE 1. COMPARATIVE BIOLOGICAL ACTIVITY OF TRITIATED AND NATURAL EUROPEAN CORN BORER FEMALE SEX PHEROMONES IN BIOASSAYS WITH *E*- AND *Z*-TYPE MALES[a]

surprised that the two types also reacted dissimilarly to the tritiated analogs. It is not known whether the mechanistic basis for the differential responses lies at the receptor level, at the central nervous system processing level, or in a combination of the levels.

Liquid scintillation counting data from antennae exposed to airborne pheromone in the 3 min bioassays showed that the above-background count associated with antennae exposed to tritiated pheromone was 60.4 ± 12.5 dpm ($SE_{diff.}$; $P = 0.05$) and 43.4 ± 8.7 dpm ($SE_{diff.}$; $P = 0.05$) for Z- and E-type males, respectively. These data indicate that a minimum of 123 ± 25 fg pheromone was adsorbed by Z-type male antennae and 88 ± 18 fg was adsorbed by E-type males. This represents 10^{-17} mol pheromone/pair of antennae/3 min exposure for both types. The amount provides insight as to how little compound impinges on the moth's antennae when it is exposed to a physiologically relevant dose of pheromone. The amount estimated to be associated with antennae is probably an underestimation because some tritium may have been internalized and not extracted by the LS cocktail. Owing to the low energy of the tritium β emission, such radiolabel would have gone undetected.

In an earlier study with tritiated pheromone, Kasang et al. (1989) estimated that a pair of male silk moth (*Bombyx mori*) antennae adsorbed 40–400 pg pheromone (bombykol)/10 sec from a 50 ml/sec pheromone-laden airstream. This value is a 1000-fold greater than we observed to be adsorbed on ECB antennae. Although it is difficult to compare results directly, the greater amount adsorbed by the silk moth may be due, in part, to the comparatively larger size of its antennae, but it is unlikely that this can account for the 1000-fold difference in observed values.

Results of time-course metabolism studies with tritiated pheromone applied to antennae of the two types of males and Z-type females showed formation of two radiolabeled metabolites according to ODS HPLC analyses. The retention time of one metabolite was coincident with the tritiated water standard; it eluted at void volume. The other metabolite was coincident with the 11-tetradecenol and 11-tetradecenal standards on ODS. We rechromatographed an aliquot sample of the extracts on the Spherisorb silica HPLC column and found that the metabolite eluted coincident with alcohol. Gas chromatographic analyses, described subsequently, also confirmed identity of the alcohol.

Data in Figure 2A and 2B show that at T_0 (ca. 5–10 sec incubation) almost all acetate applied to the E- and Z-type ECB males was converted to alcohol. With increasing incubation time, the proportion of tritiated alcohol and acetate declined as the proportion of tritiated water increased. The rate of increase in the tritiated water proportion (slope = 4.8) was similar in the two types of ECB males, showing that catabolism proceeded at a similar rate in each type. Measurements of tritium recoveries from the male antennae in each incubation period (Figure 3) showed that they were similar in each type of male; only ca. 40%

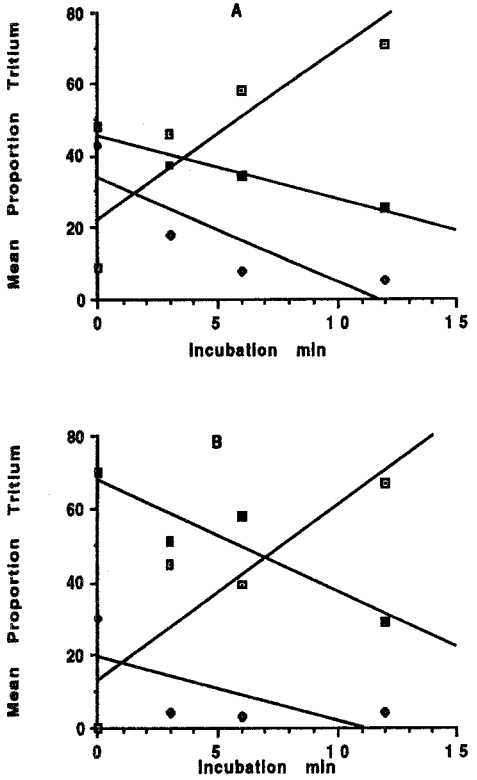

FIG. 2. Mean proportion tritium in antennal extracts of ECB as a function of incubation time. (A) E-type males; (B) Z-type males. Diamond = 11-tetradecenyl acetate Open square = water, Closed square = 11-tetradecenol.

was recovered at T_0, and by T_{12} recovery fell to ca. 15%. The radiolabel loss is attributed to evaporation and diffusion of the tritium from the antennae to the body of the insect. Data obtained from females (Figure 4) showed that females catabolized pheromone in the same manner as the males. However, the relatively slower proportional rate of increase of tritiated water in the females (slope = 2.8) indicated that the catabolism proceeded more slowly in the females than in males.

When isomers of tritiated 11-tetradecenol were applied to the male antennae and incubated 0–12 min, results showed (Figure 5) that changes in the proportion of tritium in alcohol and the proportion in water were inversely related over time. This is evidence that the alcohol serves as an immediate substrate for an aggressive oxidative process.

In our search for intermediary fatty acid metabolites of pheromone, an

average of 9×10^5 dpm were recovered (24% of total applied tritium) in the combined extracts of 30 male antennae. ODS HPLC showed that the extracts contained 81.5% tritium in the form of 11-tetradecenol and 18.5% in water. Neither acetate nor any other labeled product was detected before or after the extract was treated with diazomethane. Capillary GC analyses of the derivatized extracts on the polar and nonpolar columns consistently showed elution of tritium at retention times coincident with (Z)-11-tetradecenol, (Z)-11-tetradecenyl acetate, and methyl-(Z)-11-tetradecenoate. More than 90% of the FID-recovered tritium resided with the alcohol, 6% was in tetradecenoate, and the remainder was in acetate. Small amounts of radioactivity, barely discernible above background, were seen in early FID-effluent collections (2–4 min) where water elutes. Most of the tritiated water detected in HPLC analyses of the extracts was prob-

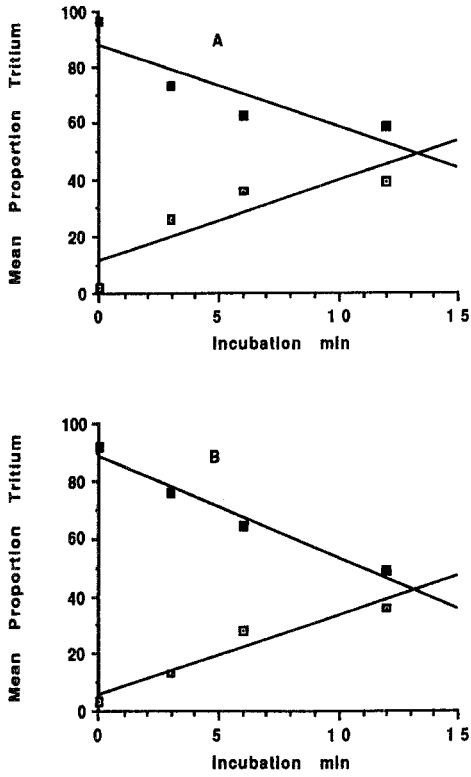

FIG. 5. Mean proportion tritiated alcohol and water in extracts of antennae of E-type (A) and Z-type (B) males treated with tritiated 11-tetradecenol and incubated in vivo for 0–12 min. Symbols: see Figure 2.

ably lost through evaporation when the extracts were concentrated for the GC analyses. Moreover, the capillary GC results proved that pheromone is converted to the corresponding fatty acid, but the size of this metabolic pool was well below detection limits in HPLC analyses of extracts from individual moths.

The data suggest two possible catabolic pathways for pheromone: the degradation may have proceeded via hydrolysis followed by direct attack upon the double bond of the alcohol to rapidly yield radiolabeled water, or by hydrolysis, conversion of the alcohol to acid and β-oxidation of the fatty acid chain. If oxidation of the double bond or ω-oxidation was a primary catabolic pathway, we should have detected a metabolite indicative of an attack upon the terminal end of the molecule. This was not the case, but having detected tetradecenoic acid, there is good evidence for oxidative attack of the functional end of the molecule. Therefore, β-oxidation is the more plausible catabolic pathway. The

free fatty acid probably represents a metabolic pool that is intermediate to transfer of the fatty acyl to coenzyme A, and the tritiated water is likely a result of rapid β-oxidation of the carbon chain in the mitochondrial matrix (Stumpf, 1969). Studies of the ultrastructural characteristics of chemosensilla (Zacharuk, 1980) have shown that mitochondria are among the most abundant organelles in cells that comprise the antennal chemosensory sensilla. A pair of male ECB antennae are known to be clothed with more than 14×10^3 chemosensory sensilla (Cornford et al., 1973), and their abundance and heavy provisions of mitochondria make them the probable site for the β-oxidation.

FILAMENTOUS NATURE OF PHEROMONE PLUMES PROTECTS INTEGRITY OF SIGNAL FROM BACKGROUND CHEMICAL NOISE IN CABBAGE LOOPER MOTH, *Trichoplusia ni*

Abstract—(Z)-7-Dodecenol failed to interrupt pheromone-mediated anemotactic responses by male cabbage looper moths, *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae) in a wind tunnel when released 5 cm crosswind on both sides of the pheromone source or 10 cm upwind of the source to create an overlapping plume downwind. Significant inhibitory effects of (Z)-7-dodecenol were observed when released with the six-component pheromone blend from the same septum or abutting septa. These results indicate that (Z)-7-dodecenol needs to be received simultaneously with the pheromone blend to inhibit the anemotactic responses of males to the sex pheromone. We suggest that this feature and the filamentous nature of pheromone plumes render pheromone signals relatively protected from background chemical noise that may originate from pheromone plumes of other insect species. Unless filaments from a pheromone signal and an inhibitor arrive simultaneously, the integrity of the signal is maintained.

Key Words—*Trichoplusia ni*, Lepidoptera, Noctuidae, sex pheromone, inhibitor, (Z)-7-dodecenol, wind tunnel, orientation.

INTRODUCTION

A male moth orienting upwind in a pheromone plume does not encounter a uniform pheromone signal, as some time-averaged models of plume structure might suggest (Wright, 1958; Bossert and Wilson, 1963; Sower et al., 1973;

*To whom correspondence should be addressed.

0098-0331/92/0300-0299$06.50/0 © 1992 Plenum Publishing Corporation

Nakamura, 1976). Rather, pheromone plumes are discontinuous in nature and are composed of many filaments (Wright, 1958; Murlis and Jones, 1981; Baker et al., 1985). In fact, the filamentous nature of pheromone plumes appears to be important in sustaining upwind flight (Baker et al., 1985). The filamentous nature of pheromone plumes may also render pheromone signals relatively protected from background chemical noise. Although the pheromone plumes of different species may overlap spatially, it is less likely that individual pheromone filaments within the overlapping plumes will mix to a great extent. The integrity of the signal may be maintained within some filaments. Thus the pheromone-mediated communication system within a species may be relatively protected if insects can sense and respond to those intact pheromone filaments without being affected by subsequent detection of filaments that contain chemical noise or contaminated pheromone signals.

This concept was tested using the cabbage looper moth, *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae). The pheromone blend of female *T. ni* consists of (Z)-7-dodecenyl acetate (Z7-12:Ac) (Berger, 1966), dodecyl acetate (12:AC), (Z)-5-dodecenyl acetate (Z5-12:Ac), 11-dodecenyl acetate (11-12:Ac), (Z)-7-tetradecenyl acetate (Z7-14:Ac), and (Z)-9-tetradecenyl acetate (Z9-14:Ac) (Bjostad et al., 1984). (Z)-7-Dodecenol (Z7-12:OH) inhibits the anemotactic responses of male *T. ni* to pheromone sources (Tumlinson et al., 1972; McLaughlin et al., 1974; Bjostad et al., 1984; Linn et al., 1984). This compound has been found in gland extracts and volatile collections from forcibly extruded pheromone glands of female *T. ni* (Bjostad et al., 1984; Haynes and Hunt, 1990), but apparently it does not play a role in the normal pheromone signal since it is not released by calling females (Haynes and Hunt, 1990). Male *T. ni* have specialized sensory receptors for Z7-12:OH (O'Connell et al., 1983; O'Connell, 1985). It is possible that responding to Z7-12:OH may play a role in preventing responses to other species. In this wind-tunnel study, we demonstrate that the inhibitor Z7-12:OH must be received simultaneously with the pheromone blend to interrupt the normal anemotactic response of the moth to the pheromone source. This finding supports the concept that pheromone signals are relatively protected from background chemical noise.

METHODS AND MATERIALS

Insects. Cabbage loopers were reared on a semisynthetic diet (Shorey and Hale, 1965). Males were separated from females as pupae. Emerged adults were removed daily and provided with 8% sugar water. Pupae and adults were kept in 3.8-liter paper cartons under 16:8 light-dark photoperiod and 27 ± 1°C.

Chemicals. All pheromone components and Z7-12:OH were of >99% purity (Pesticide Research Institute, Wageningen, The Netherlands). The pro-

portions of blend components in the six-component blend for rubber septa were as follows: 12:Ac (5%), Z5-12:Ac (10%), Z7-12:Ac (100%), 11-12:Ac (3%), Z7-14:Ac (3%), and Z9-14:Ac (2%). This blend ratio resulted in a released blend from a loaded rubber septum similar to that emitted by female *T. ni* (Hunt et al., 1990). All solutions were prepared in hexane (HPLC grade) and checked by gas chromatography (30-m Carbowax 20 M capillary column in a Hewlett-Packard 5890A gas chromatograph linked to a Hewlett-Packard 5970B mass selective detector) to ensure purity and blend ratios of pheromone components. Dilutions were made for all solutions to yield 0.2 μg/μl Z7-12:Ac or Z7-12:OH. A 50-μl aliquot of each solution (containing 10 μg Z7-12:Ac or Z7-12:OH) was added to the wide end of a rubber septum (Thomas Scientific, Swedesboro, New Jersey; 5 × 9 mm, preextracted with hexane). The loaded rubber septa were kept in a laboratory exhaust hood for 24 hr before being used in wind-tunnel flight experiments.

Test Procedures. Male *T. ni* (3 to 4 days old) were confined individually in 5-cm-diam. × 10-cm-high hardware cloth cages during the last hour of the photophase and placed in an environmental chamber under the same conditions as above. They were tested in a wind tunnel during the fifth through seventh hours of the scotophase under conditions of about 0.3 lux light intensity, 50 cm/sec wind velocity, and 27–30°C temperature.

A moth was released from the cage on a flat metal mesh surface 20 cm above the tunnel floor and 1.5 m downwind from the pheromone source, which was positioned 20 cm above the tunnel floor. Each moth was allowed about 1 min to respond after it left the cage. Behaviors of moths were scored as: wing fanning, taking flight, locking on (initiation of counter-turning), and source contact. In addition, the distance of closest approach to the pheromone source was recorded.

Experiment 1. Effects of Z 7-12:OH Released 5 cm Crosswind from Pheromone Source on Male Responses. The four treatments of this experiment included: (1) the full six-component blend, (2) the full blend and Z7-12:OH in the same septum, (3) the full blend and Z7-12:OH in different but abutting septa, and (4) the full blend with septa containing Z7-12:OH 5 cm from it across the wind line on both sides. A randomized complete-block design was used in both experiments. The rubber septa containing the pheromone blend or Z7-12:OH were fixed at the downwind edge of a 15 × 15-cm metal plate positioned 20 cm above the tunnel floor. A total of 75 males was tested for each treatment. Ryan's (1960) test was used to compare proportions of behavioral responses among treatments in both experiments.

Experiment 2. Effects of Z 7-12:OH Released 10 cm Upwind of Pheromone Source on Male Responses. The four treatments included: (1) the full blend, (2) the full blend and Z7-12:OH in the same septum, (3) the full blend and Z7-12:OH in different but abutting septa, and (4) the full blend with a Z7-12:OH

septum placed 10 cm upwind. Rubber septa corresponding to different treatments were supported with 2.5-mm-diam. copper wire 8 cm above the downwind edge of a 15 × 15-cm metal plate placed on a metal mesh surface 12 cm above the tunnel floor. In the last treatment, a rubber septum loaded with Z7–12:OH solution was supported with the copper wire 10 cm upwind of the pheromone source. For all treatments, a 15 × 15-cm metal plate was positioned further upwind with the downwind edge angled up 15° using a metal stand. The downwind edge was 1 cm above the septa level and 17 cm from pheromone sources. This created turbulence, which improved the behavioral responses to the six-component blend.

Using cigarette smoke, we demonstrated that this arrangement resulted in converging of the two smoke plumes about 10–15 cm downwind of the source. The two smoke plumes were generated 10 cm apart along the wind line at the positions of the pheromone source and Z7–12:OH as in the last treatment. The plumes appeared to completely overlap further downwind. A total of 65 male *T. ni* was tested for each treatment.

RESULTS AND DISCUSSION

Z7–12:OH reduced locking-on rates to pheromone plumes when it was released from the same septum as the pheromone or when the two septa, one containing Z7–12:OH and another with the full blend, were placed together. This resulted in significantly lower source contact rates than for the full blend (Figures 1 and 2). When released 5 cm crosswind on both sides of the pheromone source, Z7–12:OH failed to interrupt pheromone-mediated anemotactic flight. There were no significant differences in locking-on rate or source contact rate between the full blend with Z7–12:OH 5 cm crosswind and the full blend alone. The locking-on rate and upwind flight for the treatment with Z7–12:OH and the full blend from different but abutting septa were significantly higher than those for the treatment with Z7–12:OH and the full blend from the same septum, although the difference in source contact rate was not significant. For all four treatments, most moths that locked on to plumes succeeded in contacting the pheromone sources (Figure 1). Similar results were achieved in experiment 2 in which Z7–12:OH, when released 10 cm upwind of the pheromone source, failed to inhibit upwind flight of male *T. ni* (Figure 2).

The ineffectiveness of Z7–12:OH in interrupting anemotactic responses to the pheromone source by male *T. ni* when it was released only 5 cm crosswind on both sides of or 10 cm upwind of the source indicated that Z7–12:OH, as an inhibitor, must be detected simultaneously with the pheromone to influence the behavioral responses of the moth. Witzgall and Priesner (1991) drew the same conclusion based on a wind-tunnel study with *Coleophora laricella*. The

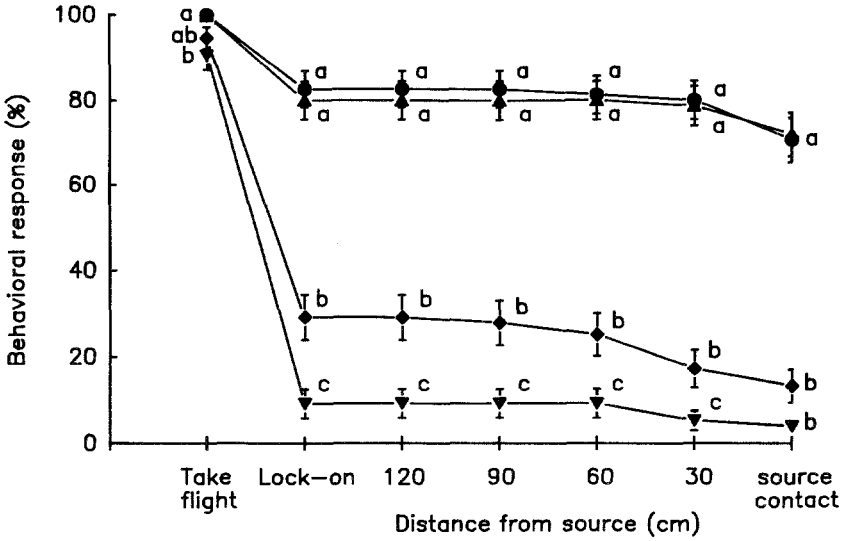

FIG. 1. Effects of Z7-12:OH released 5 cm crosswind on both sides of the pheromone source on responses of male *T. ni*. The four treatments were: (1) the full six-component blend (●), (2) the full blend and Z7-12:OH in the same septum (▼), (3) the full blend and Z7-12:OH released from different but abutting septa (♦), and (4) the full blend with Z7-12:OH septa 5 cm apart crosswind on both sides (▲). For each behavioral category, values with the same letter were not significantly different based on Ryan's multiple comparison test on proportions ($P > 0.05$) (Ryan, 1960).

inhibitor (Z)-5-decenyl acetate failed to interrupt responses of male moths to the pheromone (Z)-5-decenol when released 5 cm crosswind on one side of the pheromone source.

Several field studies support the conclusion that an inhibitor and a pheromone must be detected simultaneously to interrupt behavioral responses of moths. Z7-12:OH failed to inhibit the attractant responses by male *T. ni* when released in the proximity of a pheromone source (McLaughlin et al., 1974). Z9-12:Ac, Z9-14:Ac, or (Z,E)-9,12-tetradecadienyl acetate inhibits attractant responses of male *T. ni* to Z7-12:Ac when they were released separately within the same trap at a comparable release rate. When evaporated into the atmosphere surrounding pheromone traps, none of the three chemicals had a significant influence on the capture of male *T. ni* (Mitchell, 1976). In *Rhyacionia buoliana*, the geometrical isomer of its pheromone, (E)-9-dodecenyl acetate, inhibited attractant responses of males to the pheromone when they were released together. When dispersed around pheromone- or virgin female-baited traps, the inhibitory isomer did not suppress male orientation to the pheromone source (Daterman et

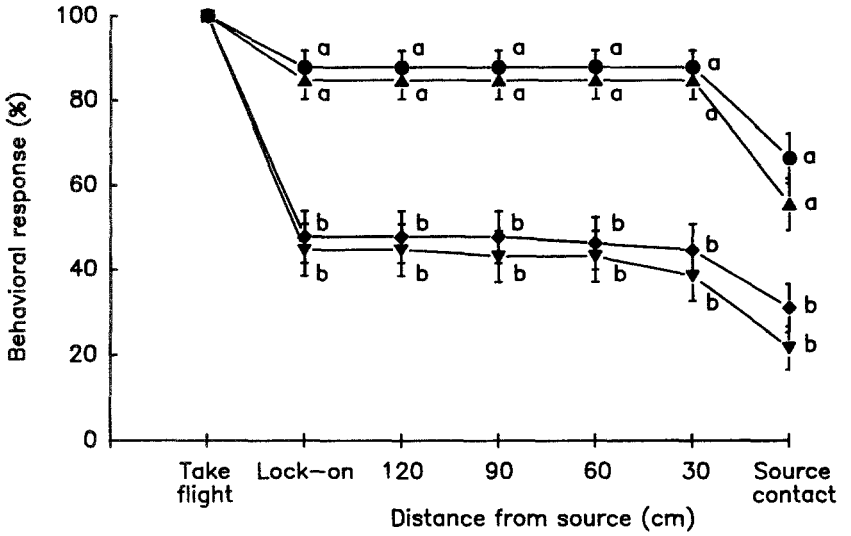

FIG. 2. Effects of Z7-12:OH released 10 cm upwind of the pheromone source on responses of male *T. ni*. The four treatments were: (1) the full blend (●), (2) the full blend and Z7-12:OH in the same septum (▼), (3) the full blend and Z7-12:OH released from different but abutting septa (♦), and (4) the full blend with Z7-12:OH septum placed 10 cm upwind (▲). Vertical lines represent standard error of means. For each behavioral category, values with the same letter were not significantly different based on Ryan's multiple comparison test on proportions ($P > 0.05$) (Ryan, 1960).

al., 1975). In *Coleophora laricella*, anemotactic flight of males towards the pheromone (Z)-5-decenol was not fully suppressed even with the same amount of the inhibitor (Z)-5-decenyl acetate placed only 2–5 cm apart. However, male responses to (Z)-5-decenol were totally suppressed when it contained only 3% (Z)-5-decenyl acetate (Priesner and Witzgall, 1984).

In the wind tunnel, plumes of Z7-12:OH and the pheromone overlapped each other as demonstrated with smoke. However, a plume is composed of many entangled filaments (Murlis and Jones, 1981; Baker et al., 1985). Although some mixing may occur between filaments containing pheromone and Z7-12:OH, respectively, especially far downwind from sources, large portions of these individual pheromone filaments may maintain their integrity. Thus, male moths may still detect intact pheromone filaments and detect Z7-12:OH filaments or Z7-12:OH-contaminated pheromone filaments sequentially as they fly upwind towards the pheromone source. Studies have revealed that moths are able to respond rapidly to individual pheromone filaments at the sensory level (Kaissling, 1986; Baker and Haynes, 1989). This suggests that a moth is able to detect closely spaced filaments of its pheromone and chemical noise as dis-

crete signals contained within individual filaments rather than as a signal which is averaged.

There is probably a threshold on the time interval within which two sequentially arriving signals would be perceived as one signal. The threshold is likely dependent in part on the speed of biochemical processes related to receiving and disposing of pheromone molecules in the insect antenna. When pheromone components are released from separated points to form an overlapping plume downwind, it is likely that some filaments may mix to such an extent that insects perceive them as a signal of the pheromone blend rather than discrete signals of individual pheromone components. This may explain the increased responses by male *T. ni* when 12:Ac was released close to *Z*7–12:Ac resulting in an overlapping plume downwind (Linn and Gaston, 1981). Our own study (unpublished) also revealed that responses to *Z*7–12:Ac by male *T. ni* were enhanced when minor pheromone components were released near *Z*7–12:Ac. As long as a complete signal is perceived within the plume, the moth will exhibit appropriate behavioral responses.

The fact that an inhibitor such as *Z*7–12:OH interrupts the response by male *T. ni* to the pheromone only if detected simultaneously protects the integrity of the pheromone signal. This mechanism may help to ensure species specificity in *T. ni* as well as other lepidopteran species. In natural habitats, it is common that many lepidopteran species have spatially overlapping distributions and temporally overlapping diurnal calling rhythms. A moth that orients upwind within a pheromone plume of its own species may encounter pheromones produced by other species. On a time-averaged scale, a pheromone plume may be contaminated by these chemical noise signals. However, a moth is likely to detect an intact and uncontaminated pheromone blend contained in individual filaments. Because individual filaments within a plume are less likely to overlap and sequential reception of chemical noise such as *Z*7–12:OH in different filaments does not interrupt normal anemotactic responses of a moth to its pheromone, pheromone signals should be relatively protected from background chemical noise.

Abstract—Chemical investigation of the secondary metabolites of the marine sponge *Aplysilla glacialis* collected at French Wells, Crooked Island, Bahamas, resulted in the isolation and characterization of four diterpenes, two sterol endoperoxides, and two methylated primary metabolites. Some of these compounds, along with crude extracts of the sponge, were investigated for their ability to deter fish predation, affect the fouling of surfaces, and inhibit the growth of marine microorganisms. The diterpene manoöl **(3)**, cholesterol endoperoxide **(4)**, and the crude nonpolar extract of *A. glacialis* were shown to deter feeding by a natural assemblage of fish predators in an in situ assay conducted at French Wells. Pure secondary metabolites and crude extracts of *A. glacialis* also were tested in a laboratory fish feeding assay employing the wrasse *Thalassoma lunare*. A mixture of sterol endoperoxides was isolated from the mucus that coats the surface of *A. glacialis* and is exuded in large quantities when the sponge is disturbed. These compounds are thereby distributed in a manner in which they can best serve a defensive role for the sponge. An in situ assay was designed to determine the effect that pure secondary metabolites and crude extracts have on the fouling of surfaces. Manoöl **(3)** and cholesterol endoperoxide **(4)** were determined to increase the rate of fouling when compared to control surfaces. 1-Methyladenine **(5)** was identified as an antimicrobial constituent of *A. glacialis* that inhibited the growth of four marine bacteria isolated from seawater samples collected at French Wells.

INTRODUCTION

Marine sponges have proven to be an extremely rich source of natural products (see reviews by Minale et al., 1976; Faulkner, 1984, 1986, 1987, 1988, 1990, 1991). Sponge secondary metabolites provide examples of many unique carbon skeletons and include compounds derived from terpenoid, amino acid, alkaloid, acetogenin, and mixed biosynthetic origins. Most of the interest in natural products from sponges has come from the desire to isolate new compounds with potential pharmaceutical applications. Sponge metabolites have been shown to possess hypotensive (Baslow, 1977), antiinflammatory (Kernan, 1988; Glaser et al., 1989), antiviral (Rinehart et al., 1981), cytotoxic (Rinehart et al., 1981; Jacobs et al., 1981), antimicrobial (Rinehart et al., 1981), antifungal (Baker and Wells, 1981), and many other potentially useful pharmacological properties (Baker and Wells, 1981; Kaul, 1982). To a much lesser extent, studies have been undertaken to determine the roles that these chemicals may play in the natural environment. Many of the reports of secondary metabolites from sponges include speculation regarding the defensive purposes of the compounds isolated, but there has been relatively little effort to experimentally determine the natural functions of sponge metabolites.

There are many ecological roles that may be played by secondary metabolites in the marine environment. Conspecific and interspecific interactions are often mediated by the presence of secondary metabolites in ways that enhance the survival of the producing organism. Most of these aspects have been discussed in recent reviews on marine chemical ecology (Bakus et al., 1986; Van Alstyne and Paul, 1989; Coll and Sammarco, 1989). Secondary metabolites may provide a competitive advantage for a sponge by deterring predation by fish or invertebrates, deterring settlement or overgrowth by other benthic organisms competing for substrate space, preventing invasion by pathogenic microorganisms, and attracting conspecific gametes.

Our continuing interest in the chemistry of sponges of the order Dendroceratida (Bobzin and Faulkner, 1989a, b, 1991a, b; Bobzin, 1990) led us to collect the pink encrusting sponge *Aplysilla glacialis* from the mangrove lagoon at French Wells, Crooked Island, Bahamas, in June 1988 and July 1989. *Aplysilla glacialis* is a cosmopolitan species that has been reported from the Caribbean, North and South America, Australia, and the Arctic Ocean (Zea, 1987). Our investigation of sponges of the order Dendroceratida was motivated by the hypothesis that the absence of siliceous spicules, which is characteristic of this

order, may be compensated by an increase in the variety and quantity of defensive secondary metabolites produced by these animals. This hypothesis originates from the observation that the loss of a physical defense mechanism, such as spicules, may be the result of an evolutionary development of an alternate, chemical defense mechanism (Faulkner and Ghiselin, 1983).

Aplysilla glacialis was found only on the prop roots of the mangrove trees that line the lagoon at French Wells in depths of 0–2 m. *Aplysilla glacialis* is rarely overgrown by the invertebrates and algae that compete for substrate space in this diverse environment, and it was never observed to be eaten by fish despite the fleshy, aspiculous nature of its tissue. In situ and laboratory assays were designed to determine whether crude extracts of *A. glacialis*, or pure secondary metabolites isolated from these extracts, were responsible for these observations. The assays employed in this work were designed to determine whether the extracts or metabolites deterred feeding by fish, affected the rate of fouling of surfaces, and inhibited the growth of marine microorganisms.

A sample of *Aplysilla glacialis* collected in British Columbia has been reported to possess a number of spongian diterpene metabolites (Tischler and Anderson, 1989; Tischler et al., 1991). Two of these diterpenes, glaciolide **(1)** and cadlinolide A **(2)**, were also isolated from the dorid nudibranch *Cadlina luteomarginata*, which was collected in the same locality. It was suggested that the glaciolide and cadlinolide A found in *C. luteomarginata* were obtained by the nudibranch from its diet, which includes *A. glacialis*. Dorid nudibranchs often sequester secondary metabolites from their sponge diets, and these compounds are widely believed to serve a defensive role for both animals. Unfortunately, no effort was made to determine whether glaciolide **(1)** and cadlinolide A **(2)** served any ecological role for the sponge and the nudibranch.

Chemical investigation of our samples of *Aplysilla glacialis* collected at French Wells, Crooked Island, Bahamas, did not result in the isolation of any of the spongian diterpenes previously reported from this species. Instead, four diterpenes, two sterol endoperoxides, and two methylated primary metabolites were isolated from the Bahamian collections made during 1988 and 1989. Crude extracts and the pure metabolites manoöl **(3)** and 5α,8α-epidioxycholest-6-en-3β-ol **(4)** ("cholesterol endoperoxide") obtained from the June 1988 collection of *A. glacialis* were assayed in San Diego Bay, California, in January 1990 to determine their effect on the fouling of surfaces in situ. Manoöl **(3)**, cholesterol endoperoxide **(4)**, and the dichloromethane-soluble portion of the fresh methanol extract of *A. glacialis* were tested for their effect on fish feeding in an in situ assay carried out at French Wells in July 1989. Crude extracts and pure secondary metabolites isolated from a sample of *A. glacialis* collected in July 1989 were tested in a laboratory fish feeding deterrence assay employing the wrasse *Thalassoma lunare*. These crude extracts and pure compounds were also screened for antimicrobial activity against nine bacterial isolates obtained from seawater

samples collected in the mangrove lagoon at French Wells in July 1989. 1-Methyladenine (**5**) was isolated as an antimicrobial metabolite from *A. glacialis* that inhibited the growth of four of the nine marine bacterial isolates screened. Several other secondary metabolites were also isolated from the collections of *A. glacialis*, but these compounds were not obtained in large enough quantity to allow testing in these assays.

METHODS AND MATERIALS

Collection of Aplysilla glacialis. The pink encrusting sponge *A. glacialis* was collected by hand at a depth of 0–2 m from the mangrove prop roots in the lagoon at French Wells, Crooked Island, Bahamas (Lat. 22°42'N, Long. 74°23'W) in June 1988 (sample 88-275) and July 1989 (samples 89-150B and 89-150C). Numerous individuals were combined in each of these collections. The samples were either stored frozen (−10°C) or directly extracted in methanol.

Extraction and Chromatography of Aplysilla glacialis. The sponge (sample 88-275) was stored frozen for approximately six months and then freeze-dried. The lyophilized sponge tissue (54.4 g) was successively extracted with hexane (1 × 600 ml), hexane–dichloromethane (1:1, 2 × 800 ml), dichloromethane (4 × 600 ml), ethyl acetate (1 × 600 ml), and methanol (4 × 600 ml). The hexane and dichloromethane extracts were combined to yield a crude nonpolar extract (1.9 g, 3.5% dry weight) that was separated by flash chromatography on silica[2] (column size 39 × 4 cm) using a solvent gradient from hexane–ethyl acetate (9:1) to ethyl acetate to elute the mixture. A fraction (42 mg) that eluted with hexane–ethyl acetate (4:1) was purified by HPLC on μ-Partisil in hexane–diethyl ether (4:1) to yield manoöl (**3**, 21.0 mg, 0.039% dry weight). Manoöl (**3**) was identified by comparison of the [^{13}C]NMR data with published values (Buckwalter et al., 1975). A second fraction (157 mg) that eluted with hexane–ethyl acetate (2:3) was separated by HPLC on μ-Partisil in hexane–ethyl acetate (1:1) to yield two nearly pure sterol endoperoxides[3] along with a mixture of several other sterol endoperoxides. Both of the nearly pure fractions (34 and 35 mg) were purified by HPLC on μ-Partisil in hexane–ethyl acetate (1:1) to yield 5α,8α-epidioxy-24ξ-ethylcholest-6-en-3β-ol (**6**, 33.8 mg, 0.062% dry weight) ("24-ethylcholesterol endoperoxide") and 5α,8α-epidioxycholest-6-en-3β-ol (**4**, 33.2 mg, 0.061% dry weight) (cholesterol endoperoxide), respectively. These two compounds were identified by their characteristic [^{1}H]NMR resonances and

[2]Kieselgel 60, 230–400 mesh (Gallade Chemical, Escondido, California) was used for all silica flash chromatography separations (Still et al., 1978).

[3]We define the term "sterol endoperoxide" as any compound possessing a tetracyclic sterol skeleton (cf. cholesterol) and an endoperoxide bridge between carbons 5 and 8.

fragments in the low-resolution mass spectrum (Gunatilaka et al., 1981). The ethyl acetate and methanol extracts were combined to form a polar extract (10.3 g, 19.0% dry weight). This polar extract was triturated with dichloromethane (3 × 100 ml) to yield a polar triturate (1.2 g, 2.2% dry weight).

The second collection of *Aplysilla glacialis* (sample 89-150B, 6.5 g dry weight) was directly extracted in methanol (3 × 250 ml). The methanol extract was partitioned between dichloromethane (2 × 200 ml) and water (200 ml), the organic soluble portion dried over sodium sulfate, and the solvent removed to yield a green oil (202 mg, 4.1% dry weight) that exhibited antimicrobial activity against *Bacillus subtilis* and *Staphylococcus aureus*. This mixture was separated on Sephadex LH-20 (column size 95 × 3 cm) in dichloromethane–methanol (1:1). The active fractions were combined and separated by flash chromatography on silica (column size 17.5 × 1.7 cm) using a solvent gradient from hexane–ethyl acetate (9:1) to ethyl acetate to elute the mixture. This procedure yielded an impure sample of manoöl (**3,** 12.7 mg, 0.26% dry weight), a mixture of sterol endoperoxides (11.7 mg, 0.24% dry weight), and two fractions that appeared by [^{1}H]NMR to consist of diterpenes that had not been isolated from the previous sample (88-275) of *A. glacialis*. The least polar of these two fractions (12 mg) was separated by HPLC on μ-Partisil in hexane–diethyl ether (7:3) to yield spongia-16-one (**7,** 1.9 mg, 0.039% dry weight). Spongia-16-one (**7**) was identified by comparison on the [^{1}H]- and [^{13}C]NMR data with published values (Kernan et al., 1990). The second fraction (16 mg) was purified by HPLC on μ-Partisil in hexane–ethyl acetate (1:1) to yield atisane-3β,16α-diol (**8,** 4.1 mg, 0.083% dry weight). Atisane-3β,16α-diol (**8**) crystallized from diethyl ether–methanol and its structure was determined by single-crystal X-ray diffraction analysis.

The third collection of *Aplysilla glacialis* (sample 89-150C) was stored frozen for approximately three months and then freeze-dried. The lyophilized sponge tissue (8.8 g) was extracted successively with hexane (3 × 100 ml), dichloromethane (3 × 100 ml), ethyl acetate (3 × 100 ml), and methanol (3 × 100 ml). The hexane extract (176 mg, 2.0% dry weight) was separated by flash chromatography on silica (column size 17 × 2 cm) using a solvent gradient from hexane to hexane–ethyl acetate (3:7) to elute the mixture. This produced an impure sample of manoöl (**3,** 8.6 mg, 0.098% dry weight), a mixture of sterol endoperoxides (8.2 mg, 0.093% dry weight), and pure spongia-15α,16α-diacetate (**9,** 43.5 mg, 0.49% dry weight). The diacetate **9** was identified by comparison of the [^{1}H]- and [^{13}C]NMR data with published values (Cimino et al., 1982). The dichloromethane extract (141 mg, 1.6% dry weight) was determined by [^{1}H]NMR to contain a mixture of sterol endoperoxides and fatty acids. The ethyl acetate extract (17.1 mg, 0.19% dry weight) appeared by [^{1}H]NMR to contain mostly fatty acids.

Separation of the methanol extract of sample 89-150C was bioassay-directed

by using the antimicrobial activity against *Flavobacterium* sp. (strain H-73) in the standard disk assay (Acar, 1980). The methanol extract (1.66 g, 18.8% dry weight) was separated on Sephadex LH-20 (column size 95 × 3 cm) in methanol, the bioactive fractions combined, and the solvent removed. The resulting white solid (76 mg) was triturated with dry ethyl acetate (7 ml) and dry methanol (7 ml) to yield *N,N'*-dimethylglycine bisulfite (**10,** 9.7 mg, 0.11% dry weight) as an inactive, insoluble component of the mixture. *N,N'*-Dimethylglycine bisulfite (**10**) was identified from [^{1}H]NMR, [^{13}C]NMR, and mass spectral data. The soluble, active portion was partitioned between hexane (25 ml) and methanol (25 ml). The methanol-soluble portion retained the antimicrobial activity and was further partitioned between ethyl acetate (25 ml) and water (25 ml). The water-soluble portion was triturated with dry methanol (10 ml) to yield methanol-soluble and -insoluble fractions that both retained strong activity against *Flavobacterium* sp. The methanol-insoluble fraction was identified as pure 1-methyladenine (**5,** 3.6 mg, 0.04% dry weight), while the methanol-soluble fraction was identified as impure 1-methyladenine (45.5 mg, 0.52% dry weight). 1-Methyladenine (**5**) was identified from [^{1}H]NMR, [^{13}C]NMR, UV, and mass spectral data (Brookes and Lawley, 1960).

Extraction and Chromatography of Aplysilla glacialis *Mucus.* A solution of seawater and mucus (ca. 250 ml) that was recovered from the plastic bags in which *A. glacialis* (sample 89-150C) had been collected was separated from the sponge tissue and stored frozen (−10°C) for one week. The solution was freeze-dried, and the lyophilized residue was extracted with dry dichloromethane–methanol (1:1, 3 × 100 ml). This extract was partitioned between dichloromethane (75 ml) and water (75 ml), the organic soluble portion dried over sodium sulfate, and the solvent removed to yield a yellow oil (6.7 mg). This oil was separated on a silica Sep-pak (Waters Associates, Milford, Massachusetts) using hexane–ethyl acetate (1:1) to elute the mixture. The fractions that appeared by TLC to possess sterol endoperoxides were combined and separated by HPLC on μ-Partisil in hexane–ethyl acetate (3:2) to yield a clean mixture of sterol endoperoxides (0.69 mg, 10.3% of CH_2Cl_2 solubles). TLC and [^{1}H]NMR analyses were used to identify the mixture, but the GC-MS data were too complex to identify specific sterol endoperoxides from this mixture.

Detection of Secondary Metabolites Exuded by Aplysilla glacialis. A sample of *A. glacialis* was collected intact by cutting off a 6-in. length of mangrove prop root upon which a relatively large specimen of the sponge was growing. The sponge-encrusted root was placed in a 32-oz jar underwater to avoid air exposure and left undisturbed for approximately 24 hr. After this length of time, the root and sponge were removed and the seawater (ca. 650 ml) filtered through three (ca. 220 ml each) disposable C_{18} mini-extraction columns (6 ml HC Bakerbond spe*, J.T. Baker Inc., Phillipsburg, New Jersey). Each column then was washed successively with methanol (25 ml) and dichloromethane (25 ml), the

respective washes combined, the solvents removed, and the residues stored at 0°C. After 10 days the methanol wash was triturated with dry methanol (4 ml) and filtered through a cotton plug to yield a white solid (46.2 mg). The dichloromethane wash was dissolved in dry dichloromethane (4 ml) and filtered through a cotton plug to yield a yellow oil (5.6 mg). TLC and [^{1}H]NMR analysis of the two washes indicated that they contained mostly fatty acids and salt. None of the secondary metabolites reported from samples of *A. glacialis* were detected. This procedure was repeated and again failed to detect any of the secondary metabolites from *A. glacialis*.

Fish Feeding Deterrence Assays. In situ fish feeding deterrence assays were carried out in July 1989 in the mangrove lagoon at French Wells, Crooked Island, Bahamas, in the same locations where *Aplysilla glacialis* was found. The assays were carried out in a manner similar to that previously described (Harvell et al., 1988; Pawlik and Fenical, 1989). Artificial fish food strips (5 × 1 × 0.5 cm) were prepared from a mixture of carrageenan agar (Gelcarin FF 961L, FMC Corp., Philadelphia, Pennsylvania), water, and a homogenate of tuna to make the food palatable to fish. The tuna homogenate was prepared from canned chunk light tuna packed in oil (6.5 oz) and water (250 ml). Batches of 10 food strips were prepared by stirring the carrageenan agar (4.0 ml) and tuna homogenate (10 ml) into water (40 ml) and heating the mixture to boiling. Dichloromethane solutions (1.5 ml) of manoöl **(3)**, cholesterol endoperoxide **(4)**, or the dichloromethane-soluble portion of the crude methanol extract of *A. glacialis* were then stirred into this mixture to prepare experimental samples with a concentration of 1.6% dry weight (0.37% wet weight) of the pure metabolites or a "natural concentration" (see below) of the dichloromethane extract. Control strips were prepared by adding an equal volume of dichloromethane to the food preparation. The hot, fluid agar mixture was then poured into a plastic mold (10 × 5 × 0.5 cm) crossed by five lengths (40 cm) of cotton string. After the mixture cooled and solidified, ten strips were sliced to size (5 × 1 × 0.5 cm), leaving lengths of string (15 cm) free from one end to be used to secure the strips to a substrate.

The manoöl **(3)** that was used in the in situ feeding assay was obtained from a commercial source (Aldrich Chemical Co., Inc., Milwaukee, Wisconsin), while cholesterol endoperoxide **(4)** was prepared by singlet oxygen addition to 7-dehydrocholesterol obtained from Aldrich. 7-Dehydrocholesterol (5.1 g) was dissolved in absolute ethanol (600 ml) and oxygen gas bubbled through the solution. A solution of 10% eosin in absolute ethanol (20 ml) was added as a photosensitizer, and the reaction mixture was irradiated with a 500-W tungsten lamp. The reaction mixture was stirred and refluxed for 5.0 hr, whereupon more 10% eosin in ethanol solution (20 ml) was added and the reaction was continued for an additional 7.5 hr. The solvent was removed and the reaction mixture was separated by flash chromatography on silica (column size 34 × 4.5 cm) using

a solvent gradient from hexane–ethyl acetate (4:1) to ethyl acetate to elute the material. Cholesterol endoperoxide (**4**, 1.77 g, 35% yield) was crystallized (MeOH, mp 149–152°C) from the fractions that eluted in hexane–ethyl acetate (3:7 and 1:4).

The dichloromethane-soluble portion of the crude methanol extract was prepared by extracting a volume of *Aplysilla glacialis* tissue that was equal to the volume of the fish food preparation used in the assay, therefore providing the experimental samples with a volumetric concentration of extract equal to that found in the sponge. A portion (ca. 80 ml) of *A. glacialis* tissue (sample 89-150B) was extracted with methanol (150 ml) for 24 hr. The methanol extract was partitioned between dichloromethane (125 ml) and water (125 ml), the organic-soluble portion dried over sodium sulfate, and the solvent removed to obtain a yellow oil. Half of this material was dissolved in dichloromethane (1.5 ml) and added to the fish food preparation as described above.

Control and experimental food strips were deployed in pairs using the string to tie them directly to the mangrove prop roots (0 to −2 m) at various locations in the lagoon at French Wells where *Aplysilla glacialis* was found. The strips were retrieved after 2–8 hr depending on the predator pressure at each time and place of deployment. Each strip was then measured to determine the amount consumed by estimating the percentage of the area of each 5 × 1 × 0.5 cm strip that had been eaten. The two-tailed Wilcoxon paired-sample test (Zar, 1984) was used to analyze the assay results after first excluding pairs where both the experimental and control samples had been either completely consumed or not eaten at all.

Laboratory fish feeding assays were carried out in a similar manner to that described for the determination of the feeding deterrent properties of metabolites isolated from the intertidal limpet *Collisella limatula* (Pawlik et al., 1986). The assay animals, a group of nine wrasses (*Thalassoma lunare*), were kept in separate cubicles in flowing seawater aquaria. *Thalassoma lunare*, an Indo-Pacific species, was used due to the unavailability of an endemic Caribbean species. Freeze-dried krill (4–10 mg, *Euphausia pacifica*, Aqua-Stock Inc., Bayonne, New Jersey) were weighed and then injected with solutions of crude extracts or pure secondary metabolites from *Aplysilla glacialis* to produce experimental food samples of the appropriate concentration. Control food samples were prepared by only injecting the corresponding solvent into the krill. The solvents were then evaporated using a stream of nitrogen. Experimental and control food samples were fed in pairs to each fish individually, randomly alternating the order of control and experimental samples. A sample was determined to be rejected if the fish repeatedly (three times) took the food particle into its mouth and regurgitated it.

Extracts of *Aplysilla glacialis* (sample 89-150C) were used in the laboratory fish feeding assay. The hexane, dichloromethane, and ethyl acetate extracts of

A. glacialis were assayed at a concentration of 100 μg extract/mg krill, while the methanol extract was assayed at a concentration of 200 μg extract/mg krill. The pure secondary metabolites manoöl **(3)**, cholesterol endoperoxide **(4)**, and spongia-15α,16α-diacetate **(9)** were assayed at a concentration of 50 μg metabolite/mg krill. The results from these experiments were analyzed using the G test for independence (Sokal and Rohlf, 1969).

In Situ Fouling Assay. The fouling assay design employed unglazed ceramic plates (2 × 2 in. surface area 55.6 cm^2) that were coated with crude extracts or pure metabolites from *Aplysilla glacialis* (sample 88-275) by immersing the plates in a solution of a known concentration of the extract or compound for approximately 1 min. The semiporous plates were found to absorb approximately 0.3 ml of solvent in this length of time, thereby providing an estimate of the surface concentration achieved by this method. Sample plates were back-extracted to verify the exact surface concentration of each extract or pure metabolite assayed. Control plates were prepared by immersing the plate in solvent only. The plates were then suspended in the water column by hanging them from wooden dowels (36 in. long × 1/2 in. diam.) with Dacron fishing line (50 lb test, 24 in.) tied through holes (1/16 in.) that had been drilled in the plates. The dowels were suspended at a depth of about 3 ft, leaving the plates at a depth of approximately 5 ft. Each experiment consisted of a group of five experimental plates and one control plate hung in random order 6 in. apart along the wooden dowel.

Plates were immersed in solutions of manoöl (**3,** 50 mg/ml dichloromethane), cholesterol endoperoxide (**4,** 40 mg/ml dichloromethane), the nonpolar extract (22 mg/ml dichloromethane), polar extract (133 mg/ml methanol), and the polar triturate (55 mg/ml dichloromethane) of *Aplysilla glacialis* (sample 88-275) to produce surface concentrations of 241, 203, 199, 585, and 300 $\mu g/cm^2$, respectively. Surface concentrations were checked by back-extracting (3 × 20 ml) sample plates with their respective solvent to determine the amount of material that had been adsorbed to the plate. Sample plates were also back-extracted (3 × 20 ml) with their respective solvent after being left in beakers of sterile, filtered seawater (120 ml) for approximately 24 hr in order to determine the extent to which the compounds were desorbed off of the plate's surface when immersed in water. Manoöl (**3,** 89.5% recovery) and cholesterol endoperoxide (**4,** 94.1% recovery) were only slightly affected by immersion in seawater, while the nonpolar extract (13% recovery), polar extract (3% recovery), and polar triturate (21% recovery) were substantially desorbed off of the plate's surface over this period of time. The manoöl **(3)** used in this assay was obtained from a commercial source (Aldrich Chemical Co., Inc., Milwaukee, Wisconsin), while cholesterol endoperoxide **(4)** was prepared by singlet oxygen addition to 7-dehydrocholesterol (see above).

Nineteen experiments were deployed under a boat dock at Coronado Cays

in southwest San Diego Bay in January 1990. Ten experiments were retrieved after a period of two weeks, while the remaining nine experiments were retrieved after five weeks. The plates were preserved by rinsing them in sterile, filtered seawater and then stored individually in plastic Petri dishes (9 cm diam.) at −10°C until analyzed.

The plates were analyzed for total adsorbed protein using the bicinchoninic acid (BCA) protein assay (Pierce, Rockford, Illinois) (Smith et al., 1985) to provide an indication of the total biomass that was present on each plate. Each plate was ultrasonically agitated (0.5 hr) in a solution of 1.0 M sodium hydroxide (10 ml) to desorb the particulate matter from the plate surface. The protein from each plate was then extracted by heating the plate in this solution for half an hour at 80°C in a water bath. This technique was similar to that used to extract protein from plankton and seawater samples for quantitative analysis (Mayzaud and Martin, 1975; Barlow and Swart, 1981). After adjusting the volume back to 10 ml with distilled water, the solutions were centrifuged (15 min), and an aliquot (1.00 ml) of each of the sodium hydroxide extracts was neutralized with 1.0 M hydrochloric acid (1.00 ml). An aliquot (0.20 ml) of each neutralized assay solution was mixed with the BCA working reagent (4.00 ml) and the solutions incubated for 30 min in a water bath at 60°C. Each sample was prepared in duplicate. After the samples were cooled to room temperature, the absorbance at 562 nm of each solution was recorded against a reagent blank prepared in 1.0 M sodium chloride. A standard curve was constructed from standards (5, 10, 25, 50, and 100 μg/ml) of bovine serum albumin (BSA) prepared in 1.0 M sodium chloride in order to obtain the concentration of protein in each of the experimental samples. The two-tailed Wilcoxon paired-sample test (Zar, 1984) was used to analyze the assay results.

RESULTS

Nonpolar Secondary Metabolites from Aplysilla glacialis. Chemical investigation of *A. glacialis* collected from the mangrove lagoon at French Wells, Crooked Island, Bahamas, in 1988–1989 has resulted in the isolation and characterization of a variety of nonpolar secondary metabolites (Scheme 1 and 2). Different samples of *A. glacialis* were found to possess different mixtures of secondary metabolites (Table 1). *Aplysilla glacialis* (sample 88-275) collected in June 1988 was found to possess the labdane diterpene manoöl **(3),** 5α,8α-epidioxycholest-6-en-3β-ol **(4,** "cholesterol endoperoxide"), and 5α,8α-epidioxy-24ξ-ethylcholest-6-en-3β-ol **(6,** "24-ethylcholesterol endoperoxide"), along with a mixture of several other sterol endoperoxides that were not separated. Manoöl **(3)** has been isolated from numerous terrestrial sources, but this is the first report of manoöl from a marine source. Cholesterol endoperoxide **(4)**

and 24-ethylcholesterol endoperoxide **(6)** have been reported from a variety of marine sources and appear to be especially common in sponges (Gunatilaka et al., 1981).

A second collection of *Aplysilla glacialis* (sample 89-150B) was made in July 1989 from the same location in the Bahamas as the collection of the previous year. Separation of the dichloromethane-soluble portion of the crude methanol extract of the sponge yielded a sample of impure manoöl **(3)**, a mixture of sterol endoperoxides, and two diterpenes, spongia-16-one **(7)** and atisane-3β,16α-diol **(8)**, not found in the previous collection of *A. glacialis*. Spongia-16-one **(7)** has been reported recently from the dendroceratid sponge *Dictyodendrilla cavernosa* (Kernan et al., 1990), while atisane-3β,16α-diol **(8)** had been isolated previously

from the sponge *Tedania ignis* collected in the Caribbean Sea (Schmitz et al., 1983).

A third sample of *Aplysilla glacialis* (sample 89-150C) was collected from the same location in July 1989 and stored frozen for three months. The hexane extract of the lyophilized sponge tissue was separated to yield impure manoöl **(3)**, a mixture of sterol endoperoxides, and pure spongia-15α,16α-diacetate **(9)**. Spongia-15α,16α-diacetate **(9)** had been reported previously from *Spongia officinalis* collected in the Mediterranean Sea (Cimino et al., 1982).

was recovered from the plastic bags in which *A. glacialis* (sample 89-150C) was collected. Chemical investigation of this mucus yielded a mixture of sterol endoperoxides. TLC and [^{1}H]NMR analyses were used to identify the mixture, but the GC-MS data were too complex to identify specific sterol endoperoxides from this mixture. Experiments were conducted in order to determine whether any of the nonpolar secondary metabolites isolated from the tissue of *Aplysilla glacialis* might be actively exuded directly into the water column. These experiments failed to detect the secondary metabolites isolated from *A. glacialis* in the water around the sponge.

Fish Feeding Deterrents from Aplysilla glacialis. In situ fish feeding assays were carried out in the lagoon at French Wells, Crooked Island, Bahamas, in July 1989. The results (Figure 1) show that the pure secondary metabolites manoöl (**3**) and cholesterol endoperoxide (**4**) deter fish feeding by a natural assemblage of fish predators at a concentration of 1.6% dry weight (0.37% wet weight). Although these concentrations are approximately 10 times higher than was found in the sponge tissue, the dichloromethane-soluble portion of the crude methanol extract of *A. glacialis* (sample 89-150B) also was found to deter fish feeding when assayed at a natural volumetric concentration (Figure 1). Chemical investigation of the dichloromethane-soluble portion of the crude methanol extract of *A. glacialis* (sample 89-150B) revealed that this collection contained a mixture of sterol endoperoxides, manoöl (**3**), spongia-16-one (**7**), and atisane-3β,16α-diol (**8**). Spongia-16-one (**7**) and atisane-3β,16α-diol (**8**) were unavailable for testing in their pure form.

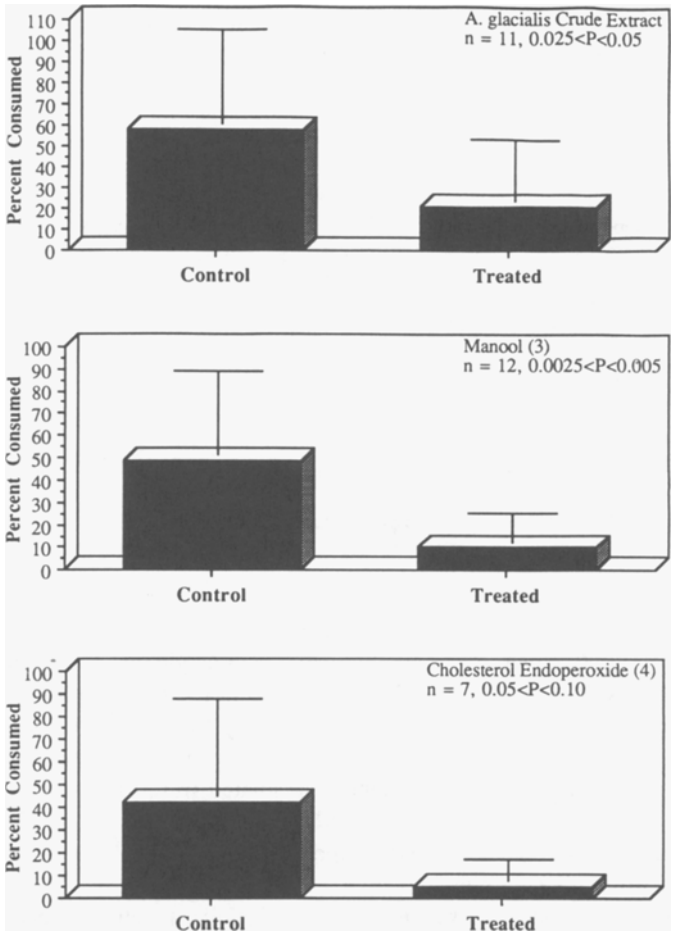

FIG. 1. In situ fish feeding deterrence assay results for manoöl (**3,** 1.6% dry weight), cholesterol endoperoxide (**4,** 1.6% dry weight), and the dichloromethane soluble portion of the crude methanol extract of *Aplysilla glacialis* ("natural concentration"—see text). Error bars indicate one standard deviation from the mean, n = number of experiments, P = significance value calculated using the two-tailed Wilcoxon paired-sample test.

Additional fish feeding assays were carried out in aquaria using a group of nine wrasses as the assay animals. *Thalassoma lunare*, an Indo-Pacific species, was used due to the unavailability of an endemic Caribbean species. The hexane, dichloromethane, and ethyl acetate extracts of *Aplysilla glacialis* (sample 89-150C) were assayed at a concentration of 100 μg extract/mg krill, while the methanol extract was assayed at a concentration of 200 μg extract/mg krill. Each

of the crude extracts appeared to exhibit a deterrent effect on the feeding of *Thalassoma lunare* at these concentrations, although the methanol extract was the only extract assayed in enough replicates to achieve favorable significance values (Table 2). Manoöl **(3)**, spongia-15α,16α-diacetate **(9)**, and a mixture of sterol endoperoxides were isolated from the hexane extract of this collection of *A. glacialis*, while *N,N'*-dimethylglycine bisulfite **(10)** and 1-methyladenine **(5)** were isolated from the methanol extract. The dichloromethane extract was determined by [^{1}H]NMR to contain a mixture of sterol endoperoxides and fatty acids, while the ethyl acetate extract appeared by [^{1}H]NMR to contain mostly fatty acids. The pure secondary metabolites manoöl **(3)**, cholesterol endoperoxide **(4)**, and spongia-15α,16α-diacetate **(9)** were assayed at a concentration of 50 μg metabolite/mg krill. None of these pure compounds had an appreciable effect on the feeding of *Thalassoma lunare* (Table 2). *N,N'*-Dimethylglycine bisulfite **(10)** and 1-methyladenine **(5)** were not available for testing in this assay.

Effect of Secondary Metabolites of Aplysilla glacialis *on Surface Fouling.* An in situ assay was carried out to determine the effect of manoöl **(3)** and cholesterol endoperoxide **(4)** on the fouling of surfaces at a concentration of 241 and 203 μg/cm^2, respectively. Ten experiments were deployed for a period of two weeks in southwest San Diego Bay in January 1990. After this period of

[a]Assay organism: *Thalassoma lunare*. Significance values were calculated using the G test of independence.

time, visual inspection of the plates indicated that the surfaces were very sparsely settled by invertebrate larvae but were quite heavily colonized by bacteria, fungi, diatoms, and other unicellular algae. Therefore, the fouling of the plates was not assessed by visual inspection, but by a technique that would provide an index of the total biomass that had settled on the plates. The plates were analyzed for total adsorbed protein using the bicinchoninic acid (BCA) protein assay (Smith et al., 1985) to provide an indication of the total biomass that was present on each plate. The results indicate that manoöl **(3)** and, to a less significant extent, cholesterol endoperoxide **(4)** enhanced the rate of fouling when compared to the control plates (Figure 2).

The results obtained for the experiments that used the crude extracts of *Aplysilla glacialis* were discarded due to the loss of material from the plates' surface upon immersion in seawater. The results for the experiments that were allowed to remain submerged for five weeks were also discarded due to uncertainties in the stability and solubility of the materials over this period of time.

Antimicrobial Activity of Secondary Metabolites and Crude Extracts of Aplysilla glacialis. Nine pure bacteria cultures were isolated from seawater samples collected in the lagoon at French Wells, Crooked Island, Bahamas, in July 1989. These seawater isolates were used for antimicrobial screening of the crude extracts and pure compounds from *A. glacialis*. The hexane, dichloromethane, ethyl acetate, and methanol extracts of *Aplysilla glacialis* (sample 89-150C) were assayed against the nine bacterial isolates in the standard disk assay at a concentration of 250 μg/disk. The hexane and dichloromethane extracts were inactive at this concentration against all nine of the bacterial isolates

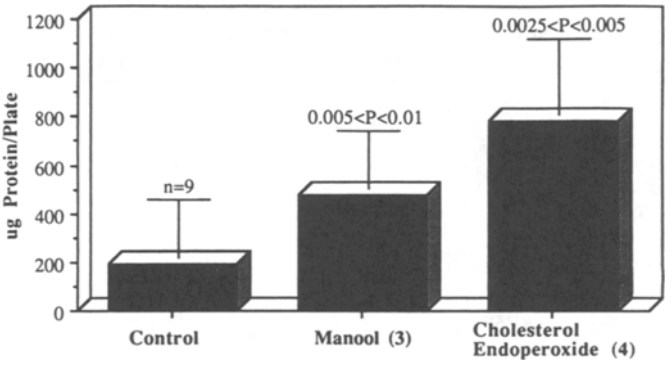

FIG. 2. In situ fouling assay results for manoöl (**3**, 241 μg/cm^2) and cholesterol endoperoxide (**4**, 203 μg/cm^2). Assay conducted for two weeks in southwest San Diego Bay, California, in January 1990. Error bars indicate one standard deviation from the mean, n = number of experiments, P = significance value calculated using the two-tailed Wilcoxon paired-sample test.

screened. The ethyl acetate extract showed slight activity (8- to 10-mm zone of growth inhibition) against *Vibrio* sp. (strain H-46), *Acinetobacter* sp. (strain H-60), and *Flavobacterium* sp. (strain H-73), while the methanol extract showed strong activity (17- to 21-mm zone of growth inhibition) against these three isolates in addition to slight activity against another *Vibrio* sp. (strain H-12). The active, methanol extract of *Aplysilla glacialis* was separated using the activity against *Flavobacterium* sp. (strain H-73) to guide the isolation process. This yielded *N,N'*-dimethylglycine bisulfite **(10)** as an inactive component of the mixture and 1-methyladenine **(5)** as an active component. 1-Methyladenine inhibited the growth (11-mm zone) of *Flavobacterium* sp. (strain H-73) at a concentration of 50 μg/disk.

DISCUSSION

Chemistry of Aplysilla glacialis. Chemical investigation of *Aplysilla glacialis* from French Wells, Crooked Island, Bahamas, revealed that different collections of the sponge contained different mixtures of nonpolar secondary metabolites (Table 1). Manoöl **(3)** and sterol endoperoxides were isolated from each of the three collections of *A. glacialis* made in June 1988 and July 1989, while the diterpenes, spongia-16-one **(7),** atisane-3β,16α-diol **(8),** and spongia-15α,16α-diacetate **(9),** were each isolated from only one of these collections. These differences may be due to the different procedures that were used in the storage, extraction, and isolation of each of the samples, although the high concentration of spongia-15α,16α-diacetate in sample 89-150C (0.49% dry weight) makes it appear unlikely that this compound could have gone undetected in the other collections. Alternatively, there may be a high degree of variability in the secondary metabolism of sponges in the French Wells population of *A. glacialis* or the species may be affected by unknown spatial, temporal, and environmental factors. The reports of several different spongian diterpene metabolites that were isolated from *A. glacialis* collected in British Columbia (Tischler and Anderson, 1989; Tischler et al., 1991) indicate that the secondary metabolism of *A. glacialis* does exhibit a high degree of variability. These compounds, exemplified by glaciolide **(1)** and cadlinolide A **(2),** would have been detected by the isolation procedure used in this work. Despite this, we believe that it would be premature to speculate as to which one of these possibilities has led to the observed differences in the chemistry of *A. glacialis*.

We observed that *Aplysilla glacialis* exudes a mucus that is distributed as a thin film over the exterior of the sponge surface and that large quantities of this mucus are exuded when the sponge is handled or disturbed. The presence of sterol endoperoxides in the mucus of *A. glacialis* provides circumstantial evidence for the hypothesis that these compounds serve a defensive role. By

distributing these compounds in the mucus, the sponge deploys them in a manner in which they could most effectively deter predation, overgrowth, or invasion by pathogens. The use of mucus exudates containing secondary metabolites is quite common in the defensive strategy of marine animals, especially among the opisthobranchs (Faulkner and Ghiselin, 1983). The secondary metabolites isolated from the mucus of the sponge *Siphonodictyon coralliphagum* were proposed to be responsible for the zones of dead coral polyps adjacent to this burrowing species (Sullivan, 1985).

The isolation of sterol endoperoxides from the mucus of *Aplysilla glacialis* suggested that these compounds may also be actively exuded by the sponge into the surrounding water. The exudation of secondary metabolites by a sponge has been demonstrated in one case (Walker et al., 1985). This type of allelochemical defense strategy has also been observed in soft corals (Coll et al., 1982). The negative results from our field experiments do not eliminate the possibility that *A. glacialis* actively exudes its secondary metabolites into the surrounding environment, but it is apparent that when left undisturbed *A. glacialis* does not exude large quantities of compounds. Experiments with the sponge *Aplysina fistularis* indicated that this species exuded secondary metabolites at a rate of 10^{-3}–10^{-4} μg/min/g dry weight of sponge (Walker et al., 1985). If *A. glacialis* exuded its metabolites at a similar rate, our experiments would have retrieved a quantity of metabolites well below the detection limits of TLC and [^{1}H]NMR.

Chemical Ecology of Aplysilla glacialis. Our field observations of *Aplysilla glacialis* indicated that this sponge was rarely eaten by fish, despite the fleshy, aspiculous nature of its tissue. This observation suggested that *A. glacialis* may be protected by a chemical defense provided by its secondary metabolites. There have been no reports in the literature of fish predation on dendroceratid sponges, but the absence of spicules in sponges of this order may be responsible for this observation because most of the studies of sponge predation by fishes have analyzed the gut contents of fishes for spicules in order to determine the species of sponges consumed (Randall and Hartman, 1968). Alternatively, the abundance of secondary metabolites that is common in dendroceratid sponges may provide this group with a very effective chemical defense against fish predation.

The lagoon at French Wells, Crooked Island, Bahamas, is populated by yellowtail snappers (*Ocyurus chrysurus*), angelfishes (*Pomacanthus* spp. and *Holacanthus* spp.), grunts (unidentified species), bluehead wrasses (*Thalassoma bifasciatum*), foureye butterflyfishes (*Chaetodon capistratus*), juvenile barracudas (*Sphyraena barracuda*), and numerous schools of unidentified juvenile fishes. Of these fish species, only angelfishes are known to prefer sponges as a major component of their diet (Randall and Hartman, 1968), although butterflyfishes have also been identified as occasional spongivores (Dawson et al., 1955). Bluehead wrasses are omnivores that may include sponges in their diverse

diet, while grunts, snappers, and barracudas are carnivores that probably do not normally include sponges in their diet.

The results from the in situ fish feeding assay conducted at French Wells show that the pure secondary metabolites manoöl **(3)** and cholesterol endoperoxide **(4)** deter fish feeding by a natural assemblage of fish predators at a concentration of 1.6% dry weight (0.37% wet weight) (Figure 1). This dry weight concentration is approximately an order of magnitude higher than that found in samples of *Aplysilla glacialis*, but the identification of sterol endoperoxides in the mucus of *A. glacialis* indicates that these compounds may be present at much higher concentrations at the sponge surface where they would be encountered by potential fish predators. This argument may not be applied to manoöl **(3)**, but the high degree of significance of these data (Figure 1) indicates that this compound may be deterrent at lower concentrations. In support of this hypothesis, the dichloromethane-soluble portion of the crude methanol extract of *A. glacialis* (sample 89-150B), from which manoöl **(3)**, spongia-16-one **(7)**, atisane-3β,16α-diol **(8)**, and sterol endoperoxides were isolated, was shown to deter fish feeding in situ when assayed at a natural volumetric concentration (Figure 1). Pure spongia-16-one **(7)** and atisane-3β,16α-diol **(8)** were not tested due to lack of material. These results provide the first data on the effect of sponge extracts and pure secondary metabolites on fish feeding in situ at a location where the sponge species naturally occurs.

The results from the laboratory fish feeding assay show that the crude methanol extract of *Aplysilla glacialis* (sample 89-150C) deterred feeding by *Thalassoma lunare* (Table 2). The other crude extracts also appear to deter feeding by *T. lunare*, but the limited number of replicates for these experiments resulted in poor significance values (Table 2). Manoöl **(3)**, spongia-15α,16α-diacetate **(9)**, and a mixture of sterol endoperoxides were isolated from the hexane extract of this collection of *A. glacialis*, while *N,N'*-dimethylglycine bisulfite **(10)** and 1-methyladenine **(5)** were isolated from the methanol extract. Pure samples of manoöl **(3)**, cholesterol endoperoxide **(4)**, and spongia-15α,16α-diacetate **(9)** did not have an appreciable effect on the feeding of *Thalassoma lunare* at a concentration of 50 μg/mg (Table 2). *N,N'*-Dimethylglycine bisulfite **(10)** and 1-methyladenine **(5)** were not available for testing in this assay due to lack of material. The lack of a deterrent effect of the pure secondary metabolites may be an indication that these compounds must be present together, or present with some unknown component(s) of the crude extract, to elicit a strong negative response. Unfortunately, mixtures of the pure metabolites were unavailable for testing the hypothesis that the metabolites act synergistically to deter fish predation.

We observed that *Aplysilla glacialis* was rarely overgrown by other invertebrates or algae and hypothesized that the secondary metabolites of *A. glacialis*

may prevent fouling of the sponge's surface. The benthic environment in the lagoon at French Wells, Crooked Island, Bahamas, is a diverse and abundant habitat. The sea grass *Thallassia testudinum* carpets the sand–sediment bottom wherever the depth is less than 15 ft. Several species of tunicates, hydroids, green algae, and brown algae are found at French Wells, while 23 species of sponges have been collected from this lagoon (Bobzin and Faulkner, unpublished data). Although many of these organisms co-occurred with *A. glacialis* on the mangrove prop roots, none of them were observed to overgrow this sponge. In fact, it was often found that *A. glacialis* would overgrow adjacent benthic species.

An in situ assay was designed to determine the effect of manoöl **(3)**, cholesterol endoperoxide **(4)**, and crude extracts of *Aplysilla glacialis* on the fouling of surfaces. The results from the two week experiment carried out in San Diego Bay, California, indicate that manoöl **(3)** and, to a less significant extent, cholesterol endoperoxide **(4)** enhance the rate of fouling when compared to control plates (Figure 2). The results for the crude extracts of *A. glacialis* were discarded due to the interference of components in these chemical mixtures with the BCA assay used to quantify the results and due to the inherent water solubility of these extracts, which allowed most of the plate coatings to be desorbed in a short period of time. The results for the five week experiment were also discarded due to the loss of compounds and extracts off of the plates after this period of time.

These results indicate that manoöl **(3)** and cholesterol endoperoxide **(4)** most likely serve no role in the maintenance of the unfouled surface of *Aplysilla glacialis*. The observation that these metabolites actually enhance the rate of fouling may be simply due to the organic nature of the coatings that are applied to the experimental plates. The organic material may provide a nutritional source for bacteria and thereby increase the rate of colonization by bacteria, which is believed to be the first step in the succession of fouling (O'Neill and Wilcox, 1971). This point illuminates one of the shortcomings in the experimental design of the control plates. These plates should have possessed an equivalent organic coating similar to that of the experimental plates, thus providing the control plates with similar organic content and surface wettability characteristics. Despite these shortcomings, we believe that a truly deterrent metabolite would have overcome these factors.

There have been few investigations into the antifouling role of marine secondary metabolites. Relevant in situ assays to determine the effect of secondary metabolites on fouling have been difficult to design (Bakus et al., 1983). Therefore, most investigations have employed pure cultures of a fouling species to determine the effect of secondary metabolites in laboratory experiments (Thompson et al., 1985; Rittschof et al., 1985; Targett et al., 1983). Our experimental design provides a quick and easy, albeit crude, method for deter-

mining the effect that pure nonpolar secondary metabolites have on surface fouling in situ. Although we acknowledge that the experimental design requires some refinements, we found that the BCA assay technique was a very quick and accurate method for quantifying the results from such an experiment.

The secondary metabolites produced by *Aplysilla glacialis* may also serve to protect the sponge from invasion by pathogenic marine microorganisms that the sponge filters out of the water while feeding. 1-Methyladenine **(5)** was identified as the antimicrobial constituent of *A. glacialis* (sample 89-150C) responsible for the growth inhibition of two strains of *Vibrio* sp., a *Flavobacterium* sp., and an *Acinetobacter* sp. These potentially pathogenic bacteria were isolated from seawater samples collected from within the lagoon at French Wells and would therefore presumably come into contact with *A. glacialis* in the natural environment. The antimicrobial activity of 1-methyladenine **(5)** may also be useful to *A. glacialis* as an aid to feeding by causing the agglutination of bacteria in the incurrent canals of the sponge (Bergquist and Bedford, 1978), in addition to a defense against invasion by pathogenic microorganisms.

The field of sponge chemical ecology has received relatively little attention when one considers the amount of effort that has been invested in the isolation and characterization of the secondary metabolites produced by sponges. We have investigated several aspects of the chemical ecology of *Aplysilla glacialis* in an effort to determine whether the secondary metabolites produced by this sponge may serve ecologically relevant functions for the animal. Our results show that *A. glacialis* produces compounds, most notably manoöl **(3)** and cholesterol endoperoxide **(4)**, that deter predation by fish in situ. A mixture of sterol endoperoxides, which are also believed to deter fish predation, were also isolated from the mucus which is exuded by *A. glacialis*. The distribution of these compounds in this mucus layer that coats the exterior of the sponge allows them to be deployed in a manner in which they could most effectively deter an attack by a fish predator. Although the results from the surface fouling experiments indicated that the compounds tested had no role in the maintenance of the unfouled surface of *A. glacialis*, the exudation of mucus may provide a physical means of continuously renewing the sponge surface, thereby sloughing off any growth that may start on the sponge. Another compound, 1-methyladenine **(5)**, was found to inhibit the growth of several strains of marine bacteria, although the ecological purpose for this antimicrobial activity was not determined. It is quite apparent that *A. glacialis* employs a variety of strategies, both physical and chemical, to enhance its survival, and that the chemical aspect consists of more than one compound.

Acknowledgments—The authors would like to thank Ms. Mary Kay Harper, Mrs. Barbara Potts, Mr. Ron Iverson, and Dr. Denise Manker for help in collecting specimens and running assays. Ms. Karin Björkman isolated and identified the marine bacteria strains used in our antimicrobial assays and assisted in the construction and deployment of the fouling deterrence experiments.

Dr. Jon Clardy conducted the single-crystal X-ray diffraction analysis used to identify atisane-3β,16α-diol **(8)**. Dr. Rita Colwell kindly provided us the opportunity to participate on research cruises in June 1988 and July 1989 aboard the *R/V Columbus Iselin* (University of Miami). These cruises were funded by a research grant from the National Science Foundation (BSR-84-01397) to Dr. Rita Colwell, University of Maryland. This research was supported by grants from the California Sea Grant College Program (R/MP-46) and the National Science Foundation (CHE89-10821) to D.J.F.

(Received June 20, 1991; accepted October 28, 1991)

Abstract—The alfalfa seed chalcid (ASC), *Bruchophagus roddi*, is a monophagous pest of alfalfa that parasitizes developing seeds. To further understand the olfactory basis of host-plant recognition by ASCs, we recorded electroantennograms (EAGs) from females and males to 39 volatiles from both alfalfa and red clover. The chemoreceptive sensitivity of ASCs was selective for certain general classes of compounds, defined by their carbon-chain length (C_6 and C_8), structure (aliphatics and phenolics), isomerism, and/or functional group (acetates, ketones, and alcohols). The compounds that elicited the largest EAGs were ranked as follows: (Z)-3-hexenyl acetate > hexyl acetate ≥ acetophenone ≥ octan-3-one ≥ methyl salicylate > octan-3-ol > oct-1-en-3-one > oct-1-en-3-ol ≥ (*E*)-β-ocimene ≥ (*Z*)- and (*E*)-3-hexen-1-ols. Over half the test compounds elicited significantly different responses between the sexes, and female antennal responses exceeded those of males for twice the number of these volatiles. Relationships of the tested volatiles to host-plant composition, EAG responses, and ASC behaviors showed no consistent correlations. However, nearly all of the host-plant volatiles known to stimulate behavioral activity also elicited moderate to potent EAG responses.

INTRODUCTION

The alfalfa seed chalcid, *Bruchophagus roddi* (Gussakovsky) is a monophagous pest of alfalfa (*Medicago sativa* L.). Alfalfa seed chalcids (ASC) will oviposit only in alfalfa seed pods and not in pods of red clover (*Trifolium pratense* L.) or other sympatric forage legumes (Strong, 1962). When ASC females were exposed to the odors of alfalfa and red clover (either whole plant parts or extracts) in a flight-tunnel bioassay arena, they flew to, landed on, and explored targets emanating alfalfa but not red clover odors (Kamm and Buttery, 1986a; Kamm, 1989). Moreover, when female ASCs were exposed to individual volatile components of alfalfa, they oriented to, alighted on, and explored targets impregnated with certain specific components, some of which also stimulated oviposition (Kamm and Buttery, 1983, 1986b).

More than half the volatile components in the odors of alfalfa and red clover are common to both species (Kami, 1978, 1983; Buttery and Kamm, 1980; Buttery et al., 1982, 1984; Srinivas, 1986) (Table 1). Hence, host-plant recognition based on olfaction by ASCs is a complex task of both sensory reception and integration. An array of relationships between plant volatile production by these two legumes and associated chalcid behaviors have been identified for ASC females (Kamm and Buttery, 1983, 1986b) (Table 1). Certain plant-specific volatiles have chalcid species-specific semiochemical activity (Kamm and Buttery, 1986a,b).

To further understand the olfactory basis of host-plant detection, we determined the chemoreceptive responsiveness and sensitivity of antennae of female and male ASCs, by recording the electroantennogram (EAG) responses to both alfalfa and red clover volatiles. The EAG responses of ASCs were then correlated to the composition of the plant emissions and the behaviors evoked by these volatiles, as determined in previous laboratory bioassays.

METHODS AND MATERIALS

Insects. Test insects emerged in the laboratory from infested alfalfa seeds from Ontario, Oregon, as previously described (Kamm and Buttery, 1983). Chalcids were collected on the day of emergence and put into vials (95 × 24 mm) segregated by gender, provisioned with 10% sucrose water solution, and exposed to a photoperiod regime of 16 hr light–8 hr dark, at 24°C for 48–72 hr before a test.

Olfactory Stimuli. Table 1 lists the 40 test compounds (36 legume volatiles

[a]The headspace volatiles in the atmosphere associated with the plant's intact leaves, flowers, and pods were adsorbed on Tenax substrates, extracted in back-washes of ether, concentrated, and then identified by comparisons of the complete mass spectrum and Kovats' GLC retention index of authentic samples, followed by GLC/FID integrative analysis of the percent relative occurrence in the trapped plant-odor; alfalfa analysis (Buttery et al., 1982) and Red clover analysis (Buttery et al., 1984).

[b]Kamm and Buttery (1983, 1986a, b).

[c]Retention index on a nonpolar DB-1 column (a bonded, cross-linked polymethylsiloxane coated fused-silica capillary column); this retention index is an approximate reflection of the volatility of a component relative to a scale of normal saturated, aliphatic hydrocarbons, where the assigned values are: e.g., butane = 400, pentane = 500, hexane = 600, etc.

[d]Compounds fully indented were found only in red clover analyses.

[e]Compounds not indented were found only in alfalfa analyses.

[f]Compounds partially indented were found in analyses of both plant species.

[g]Blank spaces represent the compound having not been found or tested.

[h]NR: no response elicited behaviorally by the compound.

[i]For the alfalfa composition analysis the 2- and 3-isomers of methylbutanol were not distinguished.

[j]The EAG responses reported for α-copaene are an average of those recorded to separate samples of the (+) and (−) enantiomers.

and four analog compounds), their presence in different plant parts of the two legume species, and the type and threshold of behavioral responses of females when exposed to individual compounds in laboratory bioassays. Test chemicals were either obtained from commercial sources, synthesized, or isolated from plant extracts. All compounds were repurified by preparative gas chromotography separation and their identities verified by mass and infrared spectrometries. Purity was >95% for all compounds except the sesquiterpenes. The sesquiterpenes are not commercially available and therefore were separated from hop oils (Buttery et al., 1982) with the following purities: α-copaene (>81%), caryophyllene (>85%), (*E*)-β-farnesene (>93%), and γ-muurolene (>80%).

Test compounds were dissolved in spectrometric grade hexane to form volume-to-volume dilutions resulting in 10% and 1% solutions of compounds. For nine of the compounds the dilution series were taken to the 0.0001% or 0.00001% levels. For each test, 1 μl of a compound solution was pipetted onto a 1 × 2-cm piece of folded glass-fiber, Whatman No. 1 filter paper. For the 10% and 1% solutions approximately 100 μg and 10 μg, respectively, of test compound were placed on separate filter-paper odor sources. For the dose–response tests the dilution series spanned from 100 μg to 1 ng of test compound on the filter papers. Due to insufficient amounts of octan-3-ol and oct-1-en-3-one, their dilution series had to span from 10 μg to 0.1 ng. After the solvent was allowed to evaporate for 10 sec, the filter paper was inserted into a glass "test cartridge" (a disposable Pasteur pipet), which was then immediately attached to the test odorant delivery system. Each test cartridge (including the control and standard, see following) was prepared just prior to its testing, tested, and then discarded. Compounds were tested in random order for each chalcid replication. All solutions were stored at −50°C.

Electrophysiological Recording Technique. The electroantennogram procedure utilized glass capillary Ag–AgCl electrodes filled with insect saline, as described by Light et al. (1988). Test insects were immobilized by imbedding their dorsal side into low-melting-point wax affixed to one end of brass rod (3 × 100 mm). Antennae were secured with a strand of aramid fiber (Kevlar, DuPont DeNemours Co., Wilmington, Delaware). Under 128× microscope magnification, the brass rod mount was then positioned for ease of insertion of the recording electrode into the distal antennal tip. The indifferent electrode was inserted into the frons near the base of the scape. The signal was amplified 1000× by a microelectrode amplifier (P-16, Grass Instruments, Inc., Quincy, Massachusetts) and viewed on a digital storage oscilloscope (310, Nicolet Instruments, Inc., Madison, Wisconsin). EAG deflections were measured directly from the screen image and stored on floppy diskettes for later retrieval.

Odor Delivery. The odor delivery system was similar to that previously described (Light et al., 1988). Briefly, charcoal-filtered and humidified compressed air, delivered via Teflon tubing, was continuously passed over the

antenna at the rate of 1 liter/min through a disposable (pipet tip) nozzle positioned 1 cm from the antenna. Activation of a three-way solenoid valve diverted the purified air through a test cartridge where the evaporated volatiles were purged by the airflow and carried onto the antenna. The duration of an odor stimulation was 1.0 sec, as controlled by a precision time-delay relay circuit.

Experimental Procedure. The following experiments were conducted on ASC antennae: (1) 39–40 different volatiles at 10-μg dose, (2) 29 of those volatiles at 100 μg dose, and (3) nine of the volatiles (determined to be the most potent in the 10-μg experiment and/or prior behavioral bioassays) over a six-decade step series of doses. All three experiments were conducted on females, while only the two set-dose experiments were conducted on males. At least 3 min elapsed between stimulations to allow for adequate receptor recovery of ASC antennae. In the dose–response experiments compounds were randomly chosen for testing and then test doses for each compound were presented sequentially from lowest to highest. Different cohorts of individual chalcids were used for the three separate experiments. Each experiment was replicated on five different individuals per sex.

Interspersed between every fifth test odor stimulation were "control" stimulations (odor cartridges with filter papers impregnated with 1 μl of hexane solvent) and "standard" stimulations [odor cartridges with filter papers impregnated with 1 μl of a 1% solution of hexyl acetate (a 10-μg dose)]. For each individual chalcid, EAG responses were evaluated by measuring the maximum amplitude of the negative polarity deflection ($-$mV) elicited by each test volatile stimulation, minus the amplitude of the response to the accompanying solvent control. Then these "control-corrected" $-$mV responses to the test volatiles were converted for each individual to percentage values of the response to the accompanying 10-μg hexyl acetate standard. This normalization of each response to a percentage of a standard response permits comparison of responses within and between preparations (Payne, 1975).

Data Analysis. For the two set-dose experiments, statistical differences between the evoked EAG responses to the ensemble of legume volatiles were evaluated by ANOVA followed by Duncan's multiple-range test. Certain large differences between means were evaluated by paired t test statistics for the dose–response data. Statistical differences between the sexes in their EAG response magnitudes for a set volatile at a set test dose were evaluated by t test statistics.

Analysis of antennal sensitivity for the nine dose–response test compounds was based on three dose–EAG response curve parameters: threshold dose, maximum response, and the slope of the curve over its dynamic response phase (Light, 1983). The "threshold dose" is defined as the interpolated dose of a test compound that elicited an EAG response that just exceeded the average response to control stimulations (delineated by the horizontal zero lines in Figure 3 below). The "maximum EAG response" was elicited usually to the highest

(100 μg) dose of compound tested. The curve slope was calculated for the exponential "dynamic response phase" of each curve, when the rate of change in response is the greatest (i.e., steepest slope). Thus, higher antennal sensitivity to a compound is represented by lower threshold, greater slope, and greater maximum percent response values.

RESULTS

Antennal Responses to Control and Standard

The mean $-$mV responses of both female and male antennae to the solvent control stimulations were < -0.20 mV and uniform. The mean $-$mV responses to the standard stimulations (10 μg hexyl acetate) for both sexes were of a moderate magnitude. No significant difference in EAGs to standard was found between males ($X = -0.84$ mV $\pm$ 0.02 SEM, $N = 10$) and females ($X = -0.80$ mV $\pm$ 0.02 SEM, $N = 15$). However, a great degree of sexual dimorphism in response to many of the 38 legume volatiles was evident, with significant differences between the sexes found in response to 58% of the volatiles tested at the two set-doses.

Antennal Responsiveness

Limitations in Comparative Analyses. Most test volatiles in Table 1 and Figures 1 and 2 are arranged by increasing molecular weight and GC retention index (nonpolar capillary column). The relative volatility of these compounds is generally correlated to these two physical property indexes. Thus, the relative number of molecules of a test volatile delivered to the antennae in these EAG tests varied tremendously over the full range of volatiles tested, from the three- and four-carbon aliphatic compounds to the 15-carbon sesquiterpenes.

Therefore, we have limited direct comparisons in EAG responsiveness to subsets of compounds, each subset comprised of compounds possessing a common narrow range in volatility, as delineated in Table 2 by a common capital letter following the retention time index values. Thus, EAGs to volatiles in the subsets at the extremes of volatility (i.e., the $\leq C_5$ volatiles and the sesquiterpenes) can be compared validly only with members of their subset. The EAGs elicited by the C_6 acetates (e.g., the experimental standard) can be compared to C_7–C_8 volatiles, monoterpenes, and most aromatic volatiles. However, valid relative comparisons in potency of EAGs are possible between compounds in different volatility subsets, if the compound with a lower volatility (i.e., far fewer numbers of molecules per stimulation puff) elicited EAG responses of equal or greater magnitude than those elicited by the compound with a higher volatility (i.e., far greater numbers of molecules per stimulation puff). One may

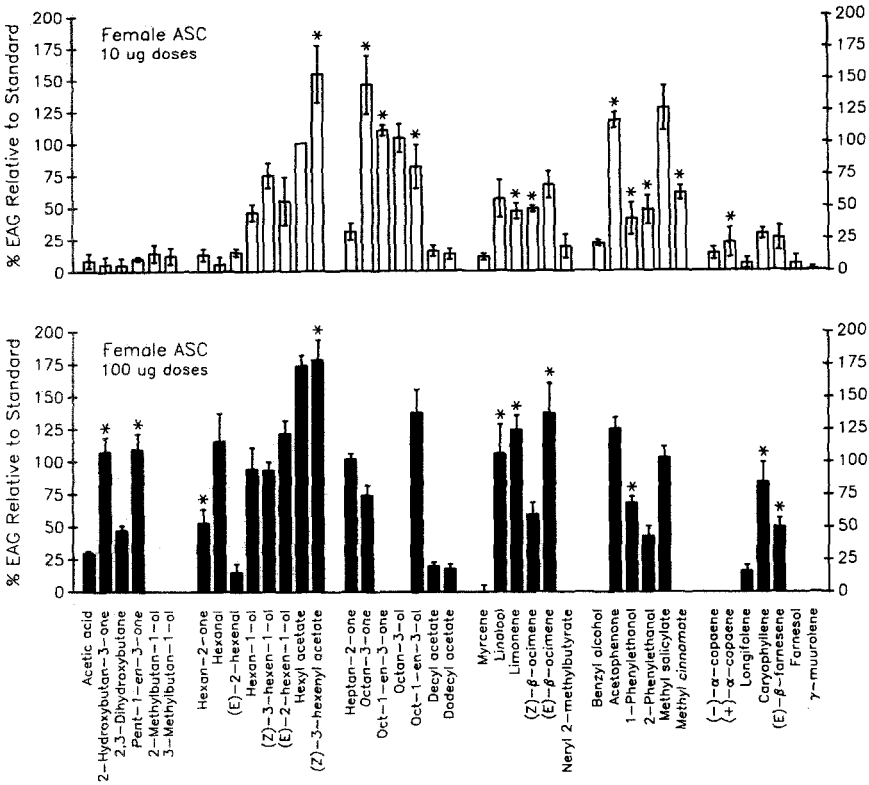

FIG. 1. Mean EAGs (±SEM, $N = 5$) of female alfalfa seed chalcids to alfalfa and red clover volatiles at 10 μg and 100 μg doses. A 100% response is approx. −0.80 mV. Asterisks identify compounds that elicited significantly larger EAGs ($P < 0.05$) from females than males.

then conclude that the less volatile compound is a superior EAG stimulant (e.g., higher transductory affinity of acceptor sites, greater degree and/or numbers of receptors and/or acceptors depolarized or "excited", etc.) than the more volatile compound, because the EAG magnitude per molecule delivered was proportionately far greater.

Legume Volatiles. With these analysis limitations considered, EAG recordings for both sexes show C_6 acetates, phenolic ketone compounds, and C_8 secondary ketones and alcohols (Table 1, Figures 1 and 2) elicited the largest EAGs. The compounds found to elicit the largest EAGs (i.e., >100% of standard) may be ranked as follows: (Z)-3-hexenyl acetate > hexyl acetate ≥ acetophenone ≥ octan-3-one ≥ methyl salicylate > octan-3-ol > oct-1-en-3-one. The compounds that elicited EAGs of moderate magnitudes

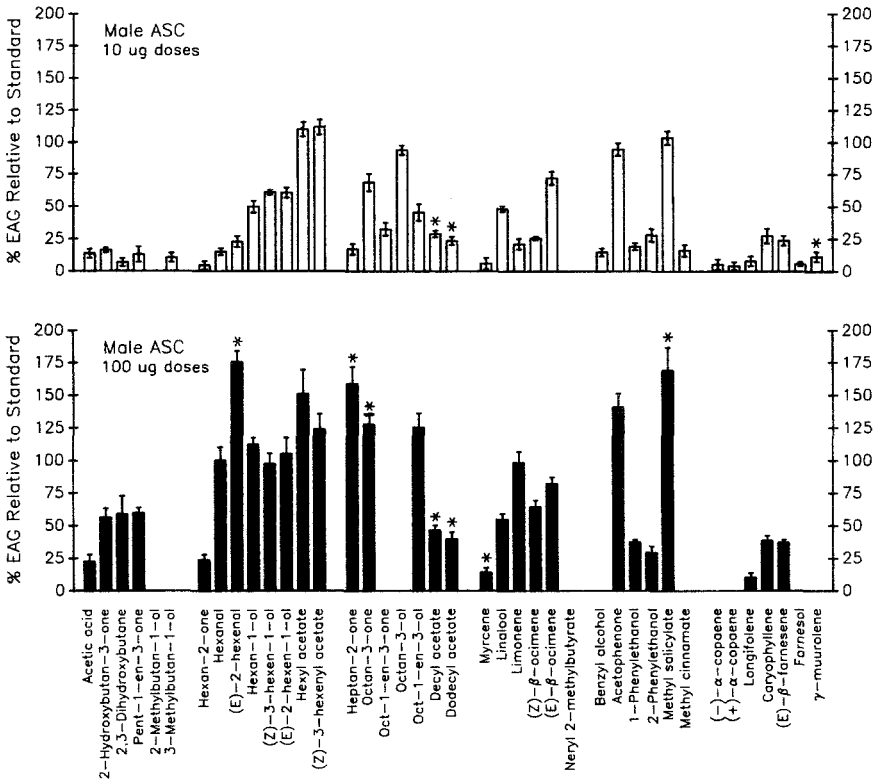

FIG. 2. Mean EAGs (±SEM, $N = 5$) of male alfalfa seed chalcids to alfalfa and red clover volatiles at 10-μg and 100-μg doses. A 100% response is approx. −0.84 mV. Asterisks identify compounds that elicited significantly larger EAGs ($P < 0.05$) from males than females.

(i.e., 50–100% of standard) were: oct-1-en-3-ol ≥ (*E*)-β-ocimene ≥ (Z)-3- and (*E*)-2-hexen-1-ols. These rankings reflect both set-dose experiments (10 and 100 μg) for both females and males (Table 1). However, males varied from females in the order of compound ranking, in that male antennae appear to be relatively less responsive to the C_8 secondary ketones and alcohols than to the C_6 alcohols (Table 1).

Sexual Dimorphism. Analysis of EAG responsiveness to the two set-dose presentations reveals that 58% of the test compounds elicited responses that varied significantly between the sexes (Figures 1 and 2). Further, female antennal responsiveness exceeded that of males for twice the number of volatiles found to elicit sexual dimorphic responses. For the 38 compounds tested in the 10-μg dose experiments, EAG responses by females significantly exceed those

TABLE 2. SENSITIVITY PARAMETERS[a] FOR ANTENNAE OF FEMALE ALFALFA SEED CHALIDS DERIVED FROM DOSE VS. MEAN EAG RESPONSE CURVES (FIGURE 3)

Compound	Threshold $\log_{10}$ dose (μg)	Maximum response (% of response to standard) (100-μg doses)	Dynamic response phase slope [% EAG response/ $\log_{10}$ dose (μg) step][b]
(Z)-3-Hexen-1-ol	−0.5	101.5	57.7
Hexyl Acetate	−1.4	152.5	48.8
(Z)-3-Hexenyl Acetate	−2.2	162.1	86.1
Octan-3-one	< −3.0	140.2	77.9
Oct-1-en-3-one	≤ −4.0	(> 108.4)[c]	76.6
Octan-3-ol	−3.2	(> 104.9)	82.3
Oct-1-en-3-ol	−1.6	134.1	78.2:55.8[d]
Acetophenone	−2.8	138.4	65.9
Methyl Salicylate	−2.6	117.5	59.4

[a] See Materials and Methods for definitions of parameters.
[b] The dose-step interval over which slope was determined was the segment between 1-μg and 10-μg doses for all but one compound (see [d]).
[c] Percent response values in parentheses were to 10-μg dose stimulations.
[d] For this compound the slope values are for the dose-step intervals of 0.1 to 1.0 μg: an average over two $\log_{10}$ steps, 0.1 μg to 10 μg.

of males for 15 compounds (four compounds $P < 0.01$ and 11 compounds $P < 0.05$), while male responses exceed those of females for six compounds ($P < 0.05$) (Figures 1 and 2). Similarly, for the 29 compounds tested in the 100-μg dose experiments, female EAGs exceed those of males for 11 compounds (for seven, $P < 0.01$; remainder, $P < 0.05$) and the opposite was observed for seven compounds (for four, $P < 0.01$; remainder, $P < 0.05$). The compounds that selectively evoked larger EAGs from females than males can be ranked (from highest to lowest degree of sex difference) as: oct-1-en-3-one, octan-3-one, methyl cinnamate, (Z)-3-hexenyl acetate, oct-1-en-3-ol, (Z)- and (E)-β-ocimenes, limonene, acetophenone, caryophyllene, 3-methylbutan-1-ol, pent-1-en-3-one, 1-phenylethanol, hexan-2-one, linalool, 2-phenylethanol, (+)-α-copaene, and (E)-β-farnesene. The rank of compounds that evoked larger EAGs from males than females (but primarily at the higher 100-μg dose; Table 1) was: (E)-2-hexenal, methyl salicylate, heptan-2-one, octan-3-one, decyl acetate, dodecyl acetate, γ-muurolene, and myrcene.

Relative Responsiveness of Structural Analogues

Positional Isomers. Antennal responsiveness of female ASCs was greater for the three-than the two-position methylbutanols (100-μg doses) (Figure 1, Table 1), but for the hexen-1-ols, the (E)-2- geometric isomer elicited larger

EAGs from females than the (*Z*)-3- isomer (100-μg doses). Both sexes were significantly more responsive to the (*E*)- than the (*Z*)-β-ocimene geometric isomer or its positional isomer, myrcene. Antennal responsiveness of ASCs was greater for 1-phenylethanol than 2-phenylethanol (100-μg doses).

Carbon-Chain-Length Analogs. Both sexes of ASCs were more responsive to the C_8 and C_7 saturated ketones than to the C_6 analog (Figures 1 and 2, Table 1). Similarly, the C_8 monounsaturated ketone elicited significantly greater EAGs than the C_5 analog. Hexyl acetate was a more potent EAG stimulant than either decyl or dodecyl acetates. 2-Phenylethanol, with its two-carbon side chain, elicited significantly larger EAGs than benzyl alcohol, with its single-carbon moiety.

Saturation vs. Unsaturation Analogs. Antennal responsiveness of females was greater for hexanal than (*E*)-2-hexenal at the 100-μg dose level, while the opposite was observed for males (Figures 1 and 2, Table 1). Antennal responsiveness was only slightly greater for both the (*E*)-2- and the (*Z*)-3-hexen-1-ols than hexan-1-ol. Only female antennae were significantly more responsive to (*Z*)-3-hexenyl acetate than hexyl acetate. Both sexes were more responsive to the C_8 saturated ketone, octan-3-one, than its unsaturated analog, oct-1-en-3-one. Similarly, octan-3-ol elicited significantly larger EAGs than oct-1-en-3-ol but just for males.

Functional-Group Analogs. Antennal responsiveness to the four functional-group moieties associated with the saturated and unsaturated six-carbon compounds tested increased in the order of their listing (by generally decreasing volatility) in Table 1. Thus, the least volatile compounds, the C_6 acetates, elicited significantly greater EAGs than the increasingly more volatile C_6 alcohols, aldehydes, and ketone tested (Figures 1 and 2, Table 1). Antennal responsiveness was greatest for (*Z*)-3-hexenyl acetate followed by (*Z*)-3-hexen-1-ol, (*E*)-2-hexen-1-ol, and (*E*)-2-hexenal, and similarly was greatest for hexyl acetate followed by hexan-1-ol and hexanal. However, EAGs of females were significantly greater for C_8 ketones than for C_8 alcohols, while the opposite was observed for males at the 10-μg dose. Both sexes were significantly more responsive to the ketone, acetophenone, than to its alcohol analog, 1-phenylethanol. Methyl salicylate (with its additional alcohol moiety) elicited significantly larger EAGs than methyl cinnamate (with its two-carbon longer side chain). The hydrocarbon, myrcene, was a far less potent EAG stimulant than its alcohol analog, linalool; conversely, (*E*)-β-farnesene was a more potent EAG stimulant than its alcohol analog, farnesol.

Antennal Sensitivity

Relative Sensitivity to Legume Volatiles. Pertinent to the analysis of antennal sensitivity to specific compounds are three parameters (threshold dose, maximum response, and the slope of the dynamic response phase; Table 2) that are

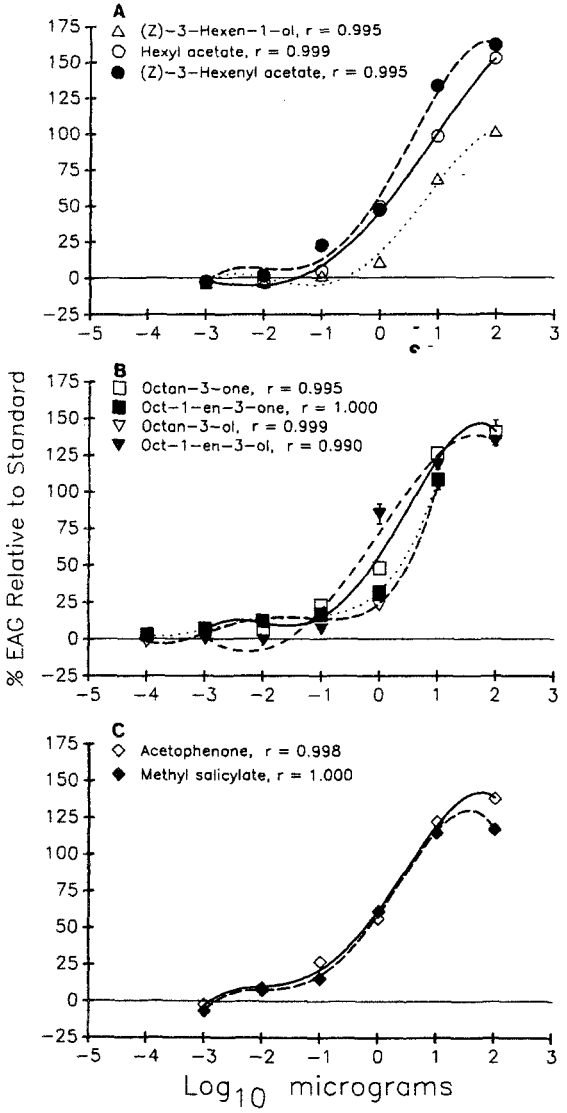

FIG. 3. Dose-EAG curves of female alfalfa seed chalcids to nine compounds found to be potent EAG elicitors: (A) six-carbon alcohol and acetates, (B) eight-carbon ketones and alcohols, and (C) phenolic ketones. Points are means of recordings from five females and vertical lines are ±SEM.

derived from the dose–EAG response curve data (Figure 3). The dose–response curves for the nine compounds tested on female ASC antennae were all sigmoidal (Figure 3), but varied in their threshold, slope, and maximum height values (Table 2). The lowest threshold doses observed were in response to oct-1-en-3-one, octan-3-ol, and octan-3-one. The largest EAG response maxima were to 100 μg stimulations by (*Z*)-3-hexenyl acetate, hexyl acetate, octan-3-one, and acetophenone. The greatest or steepest slopes of the EAG response curves were attained by doses of (*Z*)-3-hexenyl acetate, octan-3-ol, oct-1-en-3-ol, octan-3-one, oct-1-en-3-one, and acetophenone. Combining the analyses of these three sensitivity parameters, the tested compounds may then be ranked as to female ASC antennal sensitivity in the following order: oct-1-en-3-one $\geq$ octan-3-one $\geq$ (*Z*)-3-hexenyl acetate $\geq$ octan-3-ol $\geq$ oct-1-en-3-ol $\geq$ acetophenone $>$ hexyl acetate $\geq$ methyl salicylate $>$ (*Z*)-3-hexen-1-ol.

Sensitivity to Six-Carbon Compounds. Female antennae were more sensitive to (*Z*)-3-hexenyl acetate than the saturated C_6 acetate followed by the (*Z*)-3-alcohol, as evidenced by significantly higher mean response values (except at the 1-μg dose), greater response rates (steeper curve slope), and lower threshold values.

DISCUSSION

Antennal Chemoreceptive Sensitivity

The EAG is thought to be the summational expression of generator potentials of many simultaneously stimulated receptor cells with potentially different acceptor specificities and/or affinities (Boeckh et al., 1965). The amplitude of the EAG deflection has been interpreted to be a measure of the relative number of acceptors responding to an odor stimulus (Payne, 1975). Because both the position of the electrodes and the presentation of the odor stimuli spanned the entire length of the antennae, the EAGs recorded should reflect the overall population size of chemoreceptors and/or acceptors present. Thus, the EAG results reported here for alfalfa seed chalcids suggest significant differences in size of antennal receptor and/or acceptor populations for the various alfalfa hostplant and nonhost-plant (red clover) volatiles examined. In general, both female and male ASCs possess antennal chemoreceptive sensitivities that were keen, dynamic, and selective to certain specific compounds and to certain classes of compounds, defined by their carbon-chain length, structure, isomerism, and/or functional group (Table 1). The antennae of ASCs are stimulated to a greater extent and thus possess larger populations of responsive receptors and/or acceptors for constituents of three (of the seven) structural classes of compounds investigated: (1) the six-carbon acetates, primary alcohols, and aldehydes; (2)

the eight-carbon, three-position ketones and secondary alcohols; and (3) the aromatic methyl ketones and methyl esters.

ASC Sexual Dimorphism. There appear to be significant differences between the ASC sexes in the size of their receptor and/or acceptor populations responsive to a majority (58% overall) of the alfalfa and legume volatiles tested. Overall, the receptivity of female ASCs significantly exceeded that of males for 18 of the 38 tested compounds, while the reverse was observed for just eight of the 38 compounds (Figures 1 and 2, Table 1). Furthermore, the dominance of female receptivity to legume volatiles over that of males is evident for: (1) six of the top 10 EAG stimulants (for males > females, 1/10) (Figure 3), (2) six of the 14 demonstrated behavioral attractants (for males > females, 3/14) (Table 1), and (3) four of the six demonstrated ovipositional stimulants (for males > females, 1/6) (Table 1).

The observed sexual dimorphism in antennal receptivity to volatiles of host- and nonhost-plant odors might be a consequence of either (1) chromosomal genetics or (2) natural selection. First, because male–female sex determination in Hymenoptera is due to a haploid–diploid chromosomal endowment, the apparent sexual dimorphism in antennal receptivity to volatiles of host- and nonhost-plant odors might be an expression of the different genotypes of the sexes, potentially creating differences in numbers of receptors. We suggest the second possibility, that this dimorphism in reception reflects differences between the sexes in perception of these compounds that has evolved through the selective advantage of the use of these olfactory cues in the survival requisites of host finding, food foraging, and oviposition.

Both sexes share some of these survival requisites and roles that are reflected in some common searching and foraging behaviors. Because ASCs are monophagous, host finding is selective and critical; however, they forage for nectar on host and nonhost plants. The primarily floral volatiles from alfalfa are: (*E*)-β-ocimene, 3-methylbutanol, decyl and dodecyl acetates, and methyl salicylate; those from red clover are: acetophenone, methyl cinnamate, (*E*)-2-hexenal, 2-hydroxybutan-3-one, and 2,3-dihydroxybutane (Table 1). None of these alfalfa floral volatiles were attractive or stimulatory to females in laboratory behavioral bioassays (Kamm and Buttery, 1983, 1986a,b). Because methyl salicylate was a potent elicitor of EAGs, we suspect it could have an impact on behavior but was overlooked in previous bioassays (Kamm and Buttery, 1983, 1986a,b).

The obvious specialization and diversification between the sexes is in their reproductive physiology and behavior. Since mating and oviposition of ASCs are restricted to their alfalfa host plant, one might assume that alfalfa odors that are indicative of the phenological quality or suitability of pods and/or seeds for exploitation might influence the selection by female ASCs of not just oviposition sites (Kamm and Buttery, 1986b; Kamm, 1989) but also calling and/or mating sites and/or release of pheromone (Riddiford and Williams, 1967; Riddiford,

1967; Raina, 1988). Similarly, because females call and release pheromone in the immediate context of host kairomones, the perception of these two distinct semiochemical odors may have coevolved in chemical communication to the degree that alfalfa odors might influence, enhance, or synergize the attractiveness of the female-released pheromone to orienting males. Such enhancement or synergism of the attractiveness of pheromones by plant volatiles has been observed for a number of insect species (e.g., Dickens et al., 1990; Light, unpublished).

Green Leaf Volatiles. The saturated and unsaturated [(*E*)-2- and (*Z*)-3-] C_6 acetates, alcohols, and aldehydes are the most common class of botanical volatiles, having been termed the general "green leaf volatiles" (GLVs). The GLVs are ubiquitous in the plant kingdom and are produced from the general oxidative breakdown of simple fatty acids (Buttery, 1981; Tressel et al., 1981; Schreier, 1984; Visser et al., 1979). Plant species and their plant parts differ in composition (occurrence and ratio) of these GLV compounds (Visser et al., 1979; Buttery, 1981; Van Straten and Maarse, 1983). (*Z*)-3-Hexenyl acetate and (*Z*)-3-hexen-1-ol are the dominant contributors to the odors of many forage legumes, especially alfalfa (Kami, 1978, 1983; Buttery and Kamm, 1980; Buttery et al., 1982, 1984; Srinivas, 1986) (Table 1). These two particular GLVs were potent EAG stimulants and were moderate to low in potency in eliciting behavioral responses (Figure 4), and they should be included in future behavioral tests with various chalcid species.

Because the GLVs, in particular the C_6 acetates, were found to be very potent EAG stimulants, we conclude that ASC antennae possess large populations of receptor and/or acceptors responsive to these compounds. Furthermore, this substantial olfactory receptor and/or acceptor endowment suggests a selective detection and perception of the GLVs by ASCs. Similarly, the GLVs have been found to be potent EAG and receptor cell stimulants for a great number of diverse insects (see Light et al., 1988; Visser, 1983, 1986), e.g. *Ceratitis capitata* (Light et al., 1988), *Dacus dorsalis* (Light and Jang, 1987), *Anthonomus grandis* (Dickens, 1984), *Leptinotarsa decemlineata* (Visser, 1979), and *Trirhabda bacharides* (Dickens and Boldt, 1985).

Antennal Responsiveness of Other Hymenoptera. Half the legume compounds tested here have also been the subject of electrophysiological investigations on other species of Hymenoptera from diverse families and resource ecologies—from ichneumonid parasitoids, nyssonine wasps, horntail wood wasps, to eusocial hymenopteran ants and bees. Many of these compounds have been tested on the eusocial Hymenoptera because of their importance to chemical communication, having been identified as pheromones or constituents and/or products of various glands (anal, cephalic, Dufour's, mandibular, poison, and/or sting) (Wheeler and Duffield, 1988). Single-cell electrophysiological recordings on both an ant species, *Lasius fuliginosus* (Dumpert, 1972), and *Apis*

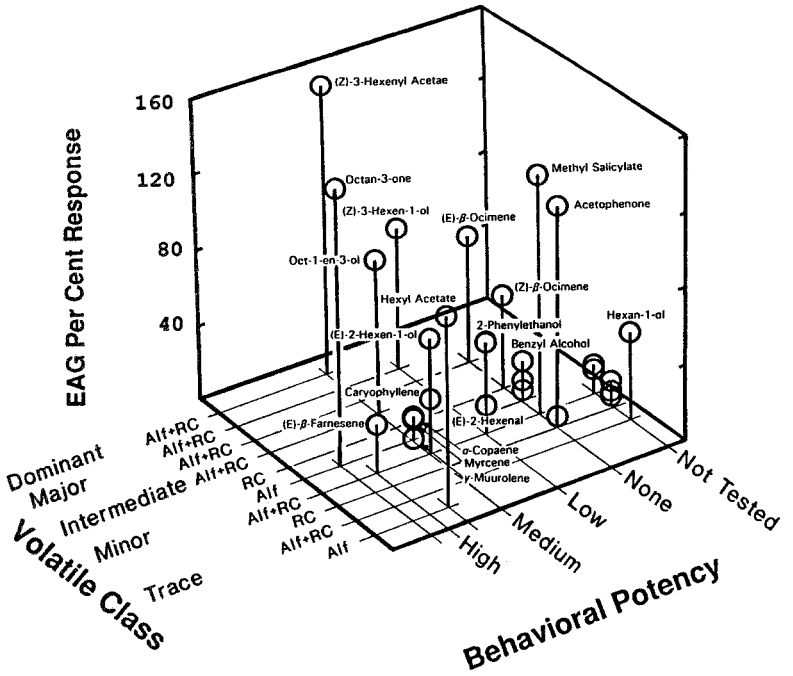

FIG. 4. Relationship of the tested volatiles to their: evoked EAGs by female ASCs, behavioral potency classification for female ASCs, and contribution classification to the odor composition of alfalfa, red clover, or both legumes. The EAG data are the mean percent response relative to standard for 10-μg doses of volatiles. Behavioral potency classification is based on threshold doses (TD): "high" potency (TD $\geq$ 0.025 μg), "medium" potency (TD $\geq$ 2.5 μg), and "low" potency (TD $>$ 25.0 μg). Contribution classification or "volatile class" for the odor constituents of leaves and/or pods is delineated as: "dominant" ($>$30% of odor), "major" ($>$10%), "intermediate" ($>$5%), "minor" ($>$1%), and "trace" ($<$1%). " Alf," "RC," and "RC+Alf" designate the presence of those volatiles in alfalfa, red clover, or both odors.

mellifera (Lacher, 1964; Vareschi, 1971) have established that the sensitivity to many of these compounds is based on the antennae being endowed with an array of different "generalist" cell types, each possessing a rather narrow specificity for certain structural, chain-length, and functional-group classes of compounds. The presence of an array of generalist cell types might also occur for ASCs.

Plant Odor Composition, Chemoreceptivity, and Behavior

No correlations were found between either the specific occurrence and concentration of a plant volatile and ASC behavior (Table 1 and Figure 4). ASCs were highly receptive to the dominant odorants of alfalfa, (Z)-3-hexenyl

acetate and (*Z*)-3-hexen-1-ol, but these compounds individually elicited only medium and low potency (respectively) overall behavioral responses (low attractancy, but moderate arrestment and ovipositional stimulation) (Table 1 and Figure 4). However, the three compounds that were most potent behaviorally (volatiles that elicited significant levels of behavior at the lowest threshold doses) were merely minor or trace odor constituents of either alfalfa or red clover. For example, octan-3-one and hexyl acetate are minor and trace components of alfalfa odor, but they are potent elicitors of both EAG responses and behavioral attraction, arrestment, and oviposition responses. In contrast, (*E*)-β-farnesene is a minor to trace component of both alfalfa and red clover odors and low in EAG potency, but it is second overall to octan-3-one as a very potent elicitor of ASC behavioral attraction and a potent elicitor of oviposition.

Nearly all of the plant components that were behaviorally active elicited moderate [e.g., (*E*)-2- and (*Z*)-3-hexen-1-ols and oct-1-en-3-ol] to potent [e.g., (*Z*)-3-hexenyl acetate, octan-3-one and hexyl acetate] EAGs. Three exceptions are minor constituents of alfalfa odors that are relatively impotent as EAG stimulants. Two of these volatiles, α-copaene and γ-muurolene, are minor components of alfalfa pod odor and are moderately potent in eliciting close-range flight and pedestrian orientation, while γ-muurolene inhibits oviposition (Table 1) (Kamm and Buttery, 1983, 1986b). Myrcene (a minor component of both alfalfa flower and leaf odors) also elicited a very low EAG response but was a very potent stimulant for oviposition but not flight. These behaviors were observed only when females were in contact with the host (or an evaporative substrate, i.e., filter paper) (Kamm and Buttery, 1983, 1986b). Considering both the low antennal olfactory responses and the low volatility of these compounds, female ASCs may detect these semiochemicals with contact chemoreceptors on the tarsi, ovipositor, or tip of antennae (Kamm and Buttery, 1986b). Chalcids constantly tap plant surfaces with the tips of their antennae in a manner suggesting both a chemo- and mechanoreceptive evaluation of substrates.

The detection and recognition of host from nonhost plant is crucial for seed chalcids, and thus both the presence of host species-specific volatiles and their selected activity as kairomones and allomones is expected. The seed chalcids might follow sequential perceptual assessments and behavioral responses to olfactory information in their immediate environment. The activation of flight orientation by ASCs might be elicited by general volatiles of clover-related legume species, but the maintenance of the anemotaxis (i.e., the flight to or arrival on the target plant) might require the discrimination of alfalfa-specific volatiles. Moreover, ASCs might be initially attracted to legume kairomones, but this attraction might be repelled (inhibited or interrupted) by allomonal nonhost volatiles. However, we doubt that nonhost components can confound host finding because chalcids readily identify their hosts from nonhosts in mixed stands in nature. Finally, close-range orientation and alightment might be elicited by alfalfa volatiles followed by contact host-assessment and either stimu-

lation or inhibition and/or interruption of oviposition. The odorants in common between alfalfa and red clover can be segregated into four classes based on behavioral response of female ASCs: (1) volatiles that elicited no responses [(*E*)-β-ocimene and methyl salicylate], (2) volatiles that elicited only flight orientations (attraction) [oct-1-en-3-ol and (*E*)-2-hexenal], (3) volatiles that elicited flight and pedestrian orientations [(*E*)-2-hexen-1-ol and (*Z*)-3-hexen-1-ol], and (4) volatiles that elicited both of these orientations and oviposition [(*Z*)-3-hexenyl acetate, (*E*)-β-farnesene and caryophyllene] (Table 1, Figure 4). Some of these compounds common to both legumes, for which ASCs have a keen chemoreceptivity and which elicit orientation behavior, are believed to be involved in initial host (or legume) finding; then the alfalfa-specific volatiles with demonstrated behavioral impact [hexyl acetate, γ-muurolene, α-copaene, and myrcene (Table 1)] are perhaps close-range cues that females use for host identification and/or discrimination. Conversely, ASC antennae were keenly sensitive to acetophenone (a red clover-specific volatile) and thus it might be a distinguishing cue for identification of nonhost legumes. Without sensitivity to such nonhost compounds, ASC females could expend considerable time and energy maladaptively responding to compounds present in both legumes. Appropriate flight bioassays are now required to identify the specific behaviors (initiation of flight, orientation, landing, and assessment of the source) elicited by specific host and nonhost volatiles when presented individually and in various binary and multicomponent combinations, as was accomplished using plant parts (Kamm, 1989). Information herein will provide insight into how chalcids perceive and use olfactory cues to exploit their host plant.

Acknowledgments—Special thanks to Mr. W.E. Gavin for rearing the insects and conducting the electroantennograms. We thank Drs. Judith Eash and Bruce Campbell for valuable comments on the manuscript.

(Received July 18, 1991; accepted October 28, 1991)

Abstract—Females of the European grapevine moth (*Lobesia botrana* Den. et Schiff.) usually deposit isolated eggs on flowers and berries of the grapevine (*Vitis vinifera* L.). We have investigated whether an epideictic pheromone could be present on the egg surface to explain this spacing behavior. About 21,000 eggs of *L. botrana* were washed in cold methanol, and the biological activity was tested in a two-choice bioassay offering treated and nontreated areas. Different dilutions of the extract were tested in methanol, which was inactive alone. At the dose of four egg equivalents per microliter of extract, the number of eggs laid by the *L. botrana* females was reduced by as much as 57% on the treated areas compared to nontreated areas. A longer-term suppression of oviposition (at least 24 hr) following an exposure to the extract occurred for two doses (0.6 and 4.0 eggs/μl) of egg extract. Our results strongly suggest the occurrence of an oviposition-deterring pheromone (ODP) on the eggs of *L. botrana*. The ecological value of these results is discussed.

Key Words—Pheromone, oviposition-deterring pheromone, oviposition, *Lobesia botrana*, Lepidoptera, Tortricidae.

INTRODUCTION

The study of insect oviposition behavior in response to plant semiochemicals has been a focus of numerous studies (Renwick and Radke, 1987; Schöni et al., 1987; Thompson and Pellmyr, 1990). However, little is known about the role

and the nature of conspecific host-marking chemicals that mediate the oviposition behavior of females. Host-marking has been reported in insect parasitoids (van Lenteren, 1981) and in more than 30 phytophagous species (Anderson, 1986; Roitberg and Prokopy, 1987). The biological activity of epideictic pheromones extracted from Lepidoptera eggs has been reported in only a few species (Rothschild and Schoonhoven, 1977; Klijnstra, 1986; Schoonhoven et al., 1990; Thiéry and Le Quéré, 1991).

Lobesia botrana Den. et Schiff. (European grapevine moth, EGM) is a polyphagous insect *stricto sensu* that develops on a range of host plants that belong to different families (Stoeva, 1982). The oviposition behavior depends on the adult generation in the year and on the available plants (Bovey, 1966; Stoeva, 1982). Females usually lay isolated eggs on flower buds (first flight), immature (second flight), and matured grapes (third flight). This suggests that egg marking might exist and that it might influence the oviposition site selection and egg dispersion in this insect.

This paper reports on the mediation of the egg laying by *L. botrana* in response to conspecific semiochemicals extracted from the egg surface.

METHODS AND MATERIALS

Biological Material and Extraction. The insects originated from a stock culture annually infused with wild insects (INRA, Bordeaux, France) reared on a semisynthetic diet under controlled conditions (16:8 light–dark; 22 ± 1°C; 65 ± 5% relative humidity). Females were allowed to oviposit inside precleaned glass tubing (1 cm diam.) 48 hr after mating. Two females were placed in each tube for 24 hr, then the tubes were replaced for an additional 24 hr period. A total of 21,363 eggs laid by 386 females were collected. Each tube was rinsed with 2 ml of purified methanol (purity >99.99%). Scales were removed from the extract by filtration on a Millipore filter (type GW, 0.22 μm). The total extract was then reconcentrated under a flow of nitrogen (U quality), which was previously purified by a Tenax trap. Three dilutions expressed in egg equivalent (ee) per microliter were obtained: 4 ee, 0.6 ee, and 0 ee (pure solvent).

Bioassay. The bioassay consisted of a two-way choice. The oviposition arena was a Plexiglas tube (ID 6.5 cm, length 13.6 cm) in which females could oviposit on a sheet of cardboard (10.7 × 13.6 cm) (Figure 1A). The cardboard covered the upper half of the inside oviposition arena, and the other half was covered with white tissue to avoid oviposition (females are able to lay the eggs only on smooth surface). To test the different dilutions, 32 drops of 5 μl each were deposited on the oviposition substrate. In order to make equidistant circles approximating the size of small berries, we applied on the oviposition substrate a Plexiglas mask to limit marking to the circles on the substrate (Figure 1B).

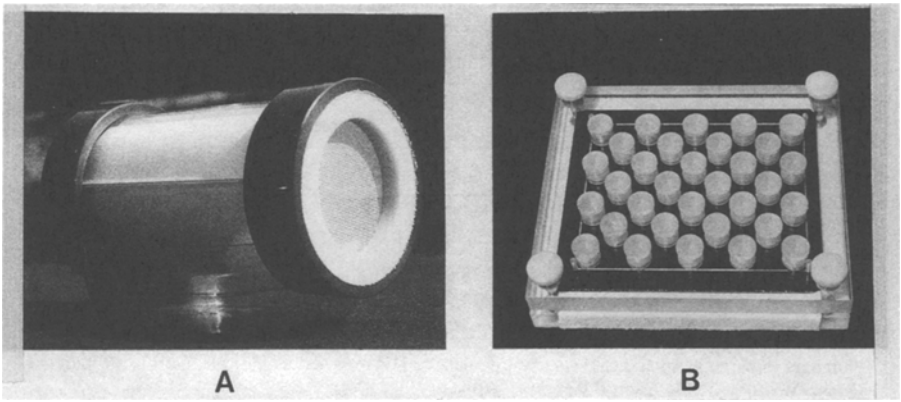

FIG. 1. (A) Oviposition arena used with *Lobesia botrana*; (B) Plexiglas mask with 32 holes (1.1 cm diam.) used to deposit the extract. Each hole is covered with a cap pierced in its center for insertion of the syringe needle.

Circles were 1.1 cm diameter (centers 2.1 cm apart). Ten females per replicate were placed for one night inside the arena. The number and the position of the eggs were then recorded. The ovipositing status of the females was determined by placing them separately in glass tubing 24 hr after the exposure to the various treatments and observing whether or not they oviposited. The number of eggs laid by each female was then counted.

At least 10 groups of females were used for each treatment. A deterrence index (DI) was calculated according to the area ratio between the untreated and treated area (B area $= 3 \times A$ area), DI $= [(3A - B)/(3A + B)] \times 100$, where A is the total number of eggs laid on the treated areas and B on the untreated area for all the replicates. The number of eggs laid by females 24 hr after exposure to the egg extract was also noted.

RESULTS AND DISCUSSION

The mean of the ratio of the number of eggs per ovipositing female during the exposure to the egg extract was not significantly affected by the various treatments. This mean varied from 38.91 ± 7.98 (methanol) to 41.2 ± 4.84 (4 eggs/μl dose). These differences were not statistically significant (Mann-Whitney U test) (Table 1).

The oviposition preferences are reported in Table 2. In the blank experiment (cardboard without solvent), females deposited about 1/4 of their eggs on the area corresponding to the position of the deposits of solvent or extract. The value of DI (0.06%) indicates no preference between these two areas, and the

TABLE 2. EFFECT OF EXPOSURE OF *Lobesia botrana* FEMALES TO DIFFERENT CONCENTRATIONS OF CONSPECIFIC EGG EXTRACTS[a]

	Treatments			
	Blank	Methanol	0.6 egg/μl	4 eggs/μl
Replicates	10	16	11	10
Treated area (36.17 cm^2)	80,30 (11,61)	78,38 (21,85)	69,73 (26,59)	36,50 (10,71)
Untreated area (109.35 cm^2)	240,60 (34,16)	232,06 (65,67)	286 (102,44)	331,00 (87,37)
DI (%)	0.06	0.65	−15.51	−50.28
Statistical analysis	(a)	(a)	(b)	(c)

[a]Numbers in parentheses represent standard deviations. Differences letters indicate statistical differences on egg numbers (χ^2 analysis, $P < 0.01$). The deterrence index (DI) varies from +100% in case of maximal stimulation to −100% in case of maximal deterrency, the 0% value indicates no preference.

deterrency index obtained in the methanol treatment (DI = 0.65%) was very similar to that for the blank (χ^2). The observation that methanol does not affect oviposition is consistent with that on other Lepidoptera (Dittrick et al., 1983; Klijnstra, 1986; Thiéry and Le Quére, 1990). At the dose of 20 egg equivalents (ee) per circle (4 ee/μl), females strongly preferred to oviposit on the untreated areas (χ^2, $P < 0.001$) (DI = −50.28%). The observed deterrency was apparently dose dependent, as the deterrence index obtained with the 0.6 ee/μl dilution (DI = −15.51%) was significantly higher to that obtained with solvent (χ^2, $P < 0.01$), but lower than that obtained with the dose of 4 ee/μl (χ^2, $P < 0.001$).

We never obtained total suppression of oviposition in any replicate. The maximum reduction obtained with the highest dose was 57% (DI) (i.e., 309 eggs deposited on the untreated area vs. 28 eggs on the treated area; control methanol: 169 vs. 61 eggs). This observation is consistent with experiments reported on other lepidopteran species in which total deterrency was never observed (Schoonhoven, 1990; Thiéry and Le Quéré, 1990). In *L. botrana*, we can observe a slight but insignificant increase in the mean number of eggs laid by females with the higher dose of egg extract (Mann Whitney U test) (Table 1). Klijnstra and Schoonhoven (1987) observed that, after contacting ODP, *Pieris brassicae* increased its dispersal activity. This might influence the number of eggs laid by females. The presence of egg extract on the substrate might also lure the females, providing them with chemical information that corresponds to a "better quality substrate" because it releases egglike signals. The slight increase we have observed at the high dose needs confirmation by further observation. In such a two-choice bioassay, the effect of *L. botrana* ODP is interpreted as discrimination enhancing more than oviposition suppressing.

The mean number of eggs laid by *L. botrana* females was depressed 24 hr after exposure to the dose of 0.6 ee/μl (Mann-Whitney U test, $P < 0.02$) and to the dose of 4 ee/μl (Mann-Whitney U test, $P < 0.002$), although no statistical differences were observed between these two doses (Table 1). This effect was not observed in either the blank or the methanol treatment, where no statistical differences were observed between the two consecutive days of oviposition (Mann-Whitney U test) (Table 1). These results suggest a persistent effect of the deterrency in *L. botrana*. The mechanism underlying this reduction in the number of eggs laid after exposure to the ODP is not yet understood. We lack data to conclude whether peripheral saturation of the neuroreceptors, integrative processing, or motor control of egg deposition are involved in this suppression. The ecological significance of a lasting effect of the ODP exposure is still unknown. The effect we observed needs to be checked over longer periods and has to be confirmed with single female observations instead of grouped females.

In Europe, *L. botrana* is considered one of the major pests of vineyards (Bovey, 1966). ODP could be useful in future integrated pest management tactics against this insect. However, insect control programs utilizing ODP will need additional study of chemical identification, learning capacities of females, polymorphism of ODP production, and perception by females.

Acknowledgments—The Plexiglas mask and the oviposition device were built in the Cooperative "Moravsky Zizkov," Czechoslovakia. We thank Veronique Pronier, INRA, Bordeaux, France, for supplying insects. J. Alan A. Renwick, Boyce Thompson Institute, Ithaca, New York; Frank G. Zalom, University of California, Davis; and Louis Schoonhoven, Department of Entomology, Wageningen, The Netherlands, carefully edited the manuscript.

MAJOR ANTITERMITIC COMPONENTS OF THE HEARTWOOD OF SOUTHERN CATALPA

C.A. McDANIEL

Forestry Sciences Laboratory, USDA-Forest Service
Box 2008 GMF
Gulfport, Mississippi 39505

(Received August 28, 1991; accepted October 28, 1991)

Abstract—The heartwood of southern catalpa, *Catalpa bignonioides* Walt., is resistant to attack by the eastern subterranean termite *Reticulitermes flavipes* (Kollar), but extraction with a ternary solvent mixture of acetone-hexane-water (54:44:2) by volume removed the antitermitic characteristics from the heartwood. Four compounds comprised approximately 98% of the antitermitic fraction of the extract: the sesquiterpene alcohol, catalponol (67%); its epimer, epicatalponol (5%); a structurally related ketone, catalponone (1%); and the phthalide, catalpalactone (25%). Pure compounds were isolated by semipreparative scale reversed-phase HPLC and identified by GC-MS and UV spectroscopy. The structure of catalponol was further confirmed by the formation of derivatives. Bioassays indicated that catalponol had the greatest toxicity in cellulose pad tests, but in tests using vacuum impregnation of these compounds into termite-susceptible wood blocks at levels approximating those found in catalpa heartwood, catalpalactone exhibited the highest antitermitic activity.

Key Words—*Catalpa bignonioides*, Isoptera, *Reticulitermes flavipes*, termite, sesquiterpenoids, wood extractives, catalponol, epicatalponol, catalponone, catalpalactone, antitermitic activity.

INTRODUCTION

Southern catalpa, *Catalpa bignonioides* Walt., is well known for its durability and has long been used for fence posts. Our studies on conifers (McDaniel, 1989; McDaniel et al., 1989), a recent study on bald cypress by Scheffrahn (1989), and previous studies by Carter and coworkers (Carter, 1976, 1979; Carter and Dell, 1981; Carter and Smythe, 1972, 1974; Carter et al., 1978) have all indicated that antitermitic properties of heartwoods are related to the

amount and chemical characteristics of the extractable material contained in the heartwood. Except for the identification of catalpalactone (Inouye et al., 1967), little work has been done on the chemical nature of *C. bignonioides* extractives, but Carter and Beal (1982) did show that an acetone extract of *C. bignonioides* heartwood protected susceptible southern pine sapwood from subterranean termite attack in a one-year field test.

Extensive studies on the biosynthetic pathways of naphthoquinone congeners have led to the identification of the extractives of a similar species, *C. ovata* G. Don. (Inoue et al., 1980; Inouye et al., 1965, 1967, 1971, 1975a,b, 1981; Shingu et al., 1971; Ueda et al., 1980), which is native to Japan and is known as "kisasage."

In this study, the extractive components of *C. bignonioides* were found to be nearly identical to those of *C. ovata*. The major components were isolated and the antitermitic properties of these components were investigated.

METHODS AND MATERIALS

Preparation of Test Material. Heartwood boards were cut from two *C. bignonioides* trees: one felled in the Harrison Experimental Forest in southern Mississippi, the other in Copiah County in central Mississippi. The boards were oven-dried overnight at 50°C, after which shavings were made with a jointer and then ground in a Wiley mill. A 500-g portion of freshly milled wood was extracted six times with 1000-ml volumes of a ternary solvent mixture of acetone–hexane–water (AHW) that was 54:44:2 by volume. The extract was vacuum filtered and the solvent removed from the extracted components in vacuo at 40°C. Residual water was removed by azeotroping with ethanol in vacuo at 50°C.

Separation of Extractive Components. The extracted material was stirred for 2 hr with 200 ml of toluene and then vacuum filtered again. The beige-colored insoluble portion was washed four times with 10-ml portions of toluene and the filtrates were combined.

The toluene solvent was removed in vacuo at 50°C, and 100 ml of acetonitrile were added. A white gelatinous precipitate formed and was removed by vacuum filtration. The dark yellow–brown filtrate was placed in a freezer at −10°C for one week. Crude yellow crystals that formed during this time were then removed by vacuum filtration, and subsequent recrystallization from methanol yielded white crystals.

The components of the acetonitrile filtrate were further separated by semi-preparative, reversed-phase high-performance liquid chromatography (HPLC)

with a Perkin-Elmer 3B Liquid Chromatograph[1] and a Whatmann M-9 ODS-3 column. The solvent employed was a 1:1 (v/v) mixture of acetonitrile–water at a flow rate of 2.5 ml/min. The eluant was monitored with a Hewlett-Packard 1037A refractive index detector and a Hewlett-Packard 3392A recording integrator. HPLC fractions were collected, and the volumes were increased twofold by the addition of distilled water and then partitioned with methylene chloride. The methylene chloride extract was dried over anhydrous sodium sulfate, and the solvent removed in vacuo.

Analysis of Components. The extractive components were identified with a Hewlett-Packard 5890A gas chromatograph (GC) coupled to a 5970 Mass Selective Detector, which is a quadrupole mass spectrometer (MS) that uses 70-eV electron-impact ionization. The system is interfaced to a HP 9000-216 computer and a 9133 disk drive. The column employed was a 30-m × 0.25-mm-ID DB-5 (J&W Scientific, Folsom, California) fused silica capillary column. The carrier gas was ultrapure helium at a head pressure of 105 kPa. The oven temperature was programmed from 50°C to 150°C at 25°C/min, and then to 285°C at 5°C/min. The injection port temperature was 250°C and the transfer line was 280°C.

The components were quantified with a Shimadzu 6AM gas chromatograph and a flame ionization detector (FID) interfaced to a Hewlett-Packard 3392A integrator. The column employed was a 30-m × 0.53-mm Megabore DB-1 (J&W Scientific), with ultrapure nitrogen as the carrier gas at a flow rate of 7 ml/min. The oven temperature was programmed from 150°C to 325°C at 5°C/min. The injection port and detector temperatures were 285°C.

Ultraviolet (UV) spectra were obtained using a Perkin-Elmer Hitachi 200 spectrophotometer with ethanol as the solvent.

Bioassays. Bioassays were performed using workers beyond the third instar from field-collected colonies of the subterranean termite *Reticulitermes flavipes* (Kollar). The colonies were collected in the Desoto National Forest in southern Mississippi.

Preliminary tests were performed by dissolving the material in acetone and applying 1.0-ml aliquots of the solutions to cellulose pads (ca. 0.5 g, 47 mm diameter, Gelmann Instrument Company) at concentrations of 2500 μg/ml, 1,250 μg/ml, 500 μg/ml, and 250 μg/ml. The solvent was allowed to evaporate, the pads were moistened with 1.0-ml portions of distilled water and placed in cylindrical plastic test chambers that measured 4.0-cm high by 5.3-cm in diameter, and 25 *R. flavipes* workers were added to each container. Pads treated with 1.0-ml volumes of acetone served as controls, and all tests were run in triplicate.

[1] Mention of a company, trade name, or commercial products is for identification purposes only and does not imply endorsement by the USDA.

The condition of the termites was observed at 24 hr, 48 hr, 72 hr, one week, and then twice a week for the duration of the four-week test.

Further bioassays were performed to assess the wood-protectant qualities of the extractive components. The test material was dissolved in acetone (or, in one case, tetrahydrofuran) and vacuum-impregnated into sapwood blocks of sweetgum, *Liquidambar styraciflua* L., according to ASTM methodology (Anon., 1976), at concentrations approximating that of the material in catalpa heartwood.

The control blocks were prepared by treating them with acetone only. They were weighed, vacuum-impregnated with acetone, and then weighed again. The mean uptake of acetone in the controls was used to estimate the concentrations of the extract materials necessary to prepare wood at given concentrations.

Two protocols were used in the laboratory tests: no-choice tests and choice tests. In no-choice tests, a mixture of sand–vermiculite–water (1:1:0.4) by volume (Haverty, 1979) was placed into a cylindrical plastic test chamber as described above. The treated blocks were oven-dried for 3 hr at 50°C, cooled for 30 min, and weighed to the nearest 0.01 g. They were then placed into the test chambers with the sand–vermiculite–water mixture completely covering them. Then 100 *R. flavipes* workers were added to each test chamber and tops were placed on the chambers. The choice test was similar to the no-choice test except that two chambers connected by a 10-cm × 0.5-cm-ID polypropylene foraging tube were employed in the former. An untreated block was buried in one chamber and a treated block in the other. The 100 *R. flavipes* workers were then placed into the chamber with the treated block, and tops were placed on both chambers.

In both the choice and no-choice protocols all treatments were run in triplicate, and blocks treated with solvent alone served as controls.

After four weeks the test chambers were dismantled and the surviving termites were counted. The blocks were cleaned with a small brush, dried as before, and the weight loss determined. The physical condition of each block was examined and assigned a rating based on both weight loss and physical condition (Table 1).

RESULTS AND DISCUSSION

The initial separations yielded a toluene-insoluble brown solid, an acetonitrile-insoluble material, and an acetonitrile-soluble fraction. A total ion chromatogram of the acetonitrile-soluble material is shown in Figure 1. Identifications of the major components of this mixture, quantified by FID detector response, and their Kovats' indices are shown in Table 2. Relevant UV and MS data of these major components are presented in Table 3. In general, they are in excel-

[a]All UV spectra were run in ethanol solvent.

lent agreement with data on these compounds obtained from *C. ovata* (Inouye et al., 1971, 1975b). The identifications of catalponol, epicatalponol, catalponone, and deoxylapachone were further substantiated by the isomerization of catalponol to epicatalponol with NaOH, the oxidation of catalponol to catalponone with Jones reagent, and the oxidation of catalponol to deoxylapachone with manganese dioxide (Inouye et al., 1975a). Additional amounts of epica-

talponol and catalponone were generated by these methods as needed for bioassays.

The HPLC chromatogram of the acetonitrile-soluble extract is shown in Figure 2. The major compounds from Table 2 were isolated in >95% purity for bioassays.

The results of the bioassays on cellulose pads are shown in Table 4. The most active termiticidal components were catalponone and catalponol; epicatalponol was somewhat less active. Catalpalactone was less termiticidal than the above compounds, but it did have moderate activity at higher concentrations. The toluene-insoluble fraction showed no toxicity toward *R. flavipes*, even at the highest concentration. The acetonitrile-insoluble material turned brown during vacuum filtration and became only slightly soluble in acetone. It was not tested on the cellulose pads because the evidence suggested that changes were taking place in the material and it was no longer a heartwood component, but was an artifact instead. This material was, however, tested later in the vacuum impregnation tests.

The results of the choice and no-choice vacuum-impregnation bioassays are presented in Tables 5 and 6. These tests indicated that the primary antiter-

mitic compounds in *C. bignonioides* are the most abundant compounds in the acetonitrile-soluble extract fraction, catalponol and catalpalactone. When they were placed into susceptible wood at levels approximating those found in the heartwood of *C. bignonioides*, both of these compounds imparted antitermitic qualities that were comparable to those of the heartwood itself.

TABLE 5. NO-CHOICE TEST OF *Catalpa bignonioides* HEARTWOOD AND HEARTWOOD EXTRACTIVES[a]

Test material	Concentration (%)	Termite survival (%)	Damage rating
Catalponone	0.02	79	2.0

ELECTROANTENNOGRAM RESPONSES OF SYNTHETIC PERIPLANONE-A AND PERIPLANONE-B IN THE AMERICAN COCKROACH

H.T. YANG, C.H. WANG,[1] R. KOU, and Y.S. CHOW*

Institute of Zoology, Academia Sinica

(Received May 13, 1991; accepted October 30, 1991)

Abstract—The electroantennogram responses of synthetic (−)-periplanone-B (PB) and (−)-periplanone-A (PA) were evaluated by using the antennae of the unmated male American cockroach *Periplaneta americana* L. The threshold concentrations of the pheromone activities for the two chemicals were similar. Neither a synergistic nor an inhibitory response was noted, and only an additive effect was detected when PA and PB were applied as a mixture.

Key Words—American cockroach, *Periplaneta americana*, sex pheromone, EAG response, periplanone-A, periplanone-B, Orthoptera, Blattidae.

INTRODUCTION

Nishino and coworkers have extensively studied EAG responses of sex pheromones (SP) and their mimics (SPM) in the American cockroach and other *Periplaneta* spp. In 1979, Nishino and Takayanagi showed that the middle region of male antenna was the most strongly stimulated by SPM. The male–female index of EAG responses was a good indicator for the response of sexually active components (Nishino and Kimura, 1981; Nishino and Takayanagi, 1981). Nishino et al. (1983) isolated the SP of the American roach, periplanone-A (PA) and periplanone-B (PB), from female feces and soiled filter paper, and the quantities of PA and PB were estimated to be 6.8 and 1.5 μg, respectively. Nishino and Kuwabara (1983) evaluated the threshold dose of PA and PB. In

the EAG response, both pheromones induced significant responses from the male antennae at 1×10^{-4} μg. By applying a differential saturation EAG technique (DS-EAG), Nishino and Manabe (1983, 1984) showed that there were two types of SP receptors specifically responsible for PA and PB in their experiment. Additionally, Manabe and Nishino (1985) studied the affinity and intrinsic activity of the stimulants to the PB receptor and categorized those chemicals into four types. Nishino and Usui (1985) dealt with the comparative olfactory sensitivity of *Periplaneta* cockroaches to general odors. Nishino et al. (1988) further found that the ratio of PA and PB in the feces and soiled filter paper was 8:5. Recently, Okada et al. (1991) evaluated the biological activities of synthetic periplanone analogs, including four candidates of PA by behavioral and EAG assays and suggested that Hauptmann's PA is a natural PA produced from female cockroaches.

In 1990, Okada et al. (1990a) showed that the activity of synthetic PB was two orders of magnitude lower than that of PA, and the mixtures of PA and PB (PA + PB) elicited only a simple additive effect in the sexual response of the American cockroach when a special behavioral bioassay was used. In this study, the authors used standard EAG techniques to investigate the olfactory responses of *P. americana* to synthetic PB, Hauptmann's PA, and PA + PB to see if there is a synergism or inhibition when PA and PB are used together.

METHODS AND MATERIALS

Insects. Unmated male cockroaches (3–4 months old) from the Institute of Zoology colonies were selected and kept in a room that was isolated from females and female odor. Water and commercial dry dog food were provided ad libitum. Room temperature was 26 ± 2°C and relative humidity was 55 ± 5%. The light regime was a 16:8 light–dark photocycle, with the dark phase beginning at 8:00 A.M. The insects were chosen on the basis of behavioral sex responses when stimulated by the pipet method with 10^{-2} μg PB (Chow and Wang, 1981).

Pheromone Sources. Synthetic pure crystalline compounds of PB and Hauptmann's PA were kindly provided by Dr. Kenji Mori. Gas chromatography–mass spectrometry analysis of the compounds showed that both compounds were chromatographically pure and had the same mass spectra as reported for PA (Kuwahara and Mori, 1990) and for PB (Talman et al., 1978). The GC-MS system consists of a Varian 3400 GC coupled with a Finnigan MAT Incos 50. A 30-m DB-5 fused silica capillary column was used for the analysis and elution was programmed from 50°C (hold for 5 min), then 50°C to 280°C with a heating rate of 2°C/min (carrier gas: helium). The injector temperature was set at 200°C, and the ion source temperature at 180°C. PA eluted at 23:46 and

with mass fragmentation of *m/z* 41(65), 55(32), 65(24), 77(55), 79(45), 91(100), 105(53), 117(40), 131(28), 147(20), 159(28), 171(10), 189(10), 202(8). Compound PB eluted at 25:32 and with mass fragmentation of *m/ z* 41(70), 55(40), 69(30), 77(70), 91(100), 105(43), 117(25), 131(22), 145(20), 159(20), 175(10), 187(20), 204(8), 248(1).

EAG Recording. PA and PB were tested on excised male antennae that were snipped off at the pedical; 1 mm of the distal tip was cut off. The EAG recording system used was based on the early methods used by Chow et al. (1980) and Nishino and Takayanagi (1979). PA and PB were diluted hexane and applied to a 1-cm^2 filter paper at doses of 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 10^0, 10^1, 10^2 μg; the solvent was allowed to evaporate for 5 minutes. Twenty-five combinations of PA and PB were made from 10^{-3}, 10^{-2}, 10^{-1}, 10^0, 10^1 μg (see Figure 2 below). Preparation of 8:5 mixtures of PA and PB (Nishino et al., 1988) at doses of 10^{-5}, 10^{-4}, and 10^{-3} μg were completed. Stimulation with air alone and hexane alone (10 μl) were applied as check samples. The needles and stimulation syringes were only used once. Routinely, tests were repeated at 3-min intervals. An antenna was tested by PA, then PB at the same dose, or was tested by PB, then PA. In tests of single PA and PB samples, each antenna was used for eight pairs of tests from the lowest to the highest dose. In tests of PA + PB, each antenna was used for eight tests. During the testing period, the temperature of the EAG room was controlled at 21 $\pm$ 1°C. The EAG response was preamplified by an amplifier (100×/1000×) and analyzed with a V1000 video, 4035 digital storage oscilloscope and ES1000 recorder (Gould Co. Ltd.).

Analytical Method. Calculation of the expected value of PA + PB was adapted from the method described in Okada et al. (1990a), except that EAG measurements were used in place of the total activity counts per minute for their behavioral assays. The observed data of PA and PA + PB were plotted according to the patterns described by Ariens et al. (1964a,b; cited in Manabe and Nishino, 1985) in order to get the relationship between PA, PB, and their antennal receptors.

RESULTS

Neat samples of both of PA and PB elicit a negative EAG response on excised male antennae of the American cockroach. The effect of the increasing amount of PA and PB on EAG amplitudes is summarized and illustrated in Figure 1. There was no significant difference in EAG amplitude to be detected between 10^{-5} μg PA (or PB) and the control. The threshold quantity is approximately 10^{-4} μg. The doses of PA and PB that elicited maximal EAG response were about 10^2 μg. Generally, the EAG amplitude elicited by lower doses of

PB was somewhat greater than that of PA, whereas the reverse situation was observed when higher doses of PA were used. A linear increase of the range of PA activity, from 10^{-3} to 10^{1} μg, was noted to be similar to that of PB. The EAG amplitude for each dosage of PA and PB could be related to the log of the pheromone amount to give two regression equations (Figure 1): $Y_{PA} = 1.005 + 0.249 \log_{10} (X_{PA})$ (for PA, $R^2 = 0.929$, interval 10^{-3} to 10^{1} μg) and $Y_{PB} = 0.962 + 0.224 \log_{10} (X_{PB})$ (for PB, $R^2 = 0.889$, interval 10^{-3} to 10^{1} μg). The regression slope of PA was larger than that of PB.

To estimate the effects of addition of PA to PB on the male cockroach antennae, the EAG response was detected using samples with 25 combinations

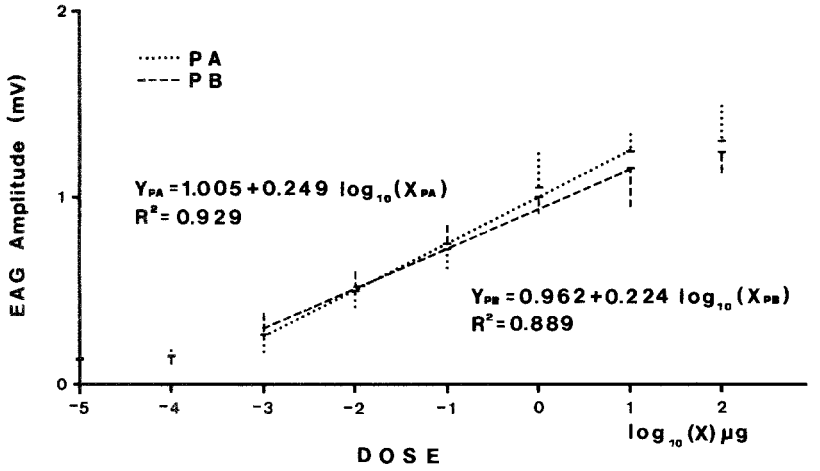

FIG. 1. Regression lines of dose–response for PA and PB. Data used in the calculation are the EAG amplitude of each dose. The vertical bar indicates the standard error of the mean.

TABLE 1. EAG AMPLITUDES (mV) OF UNMATED MALE AMERICAN COCKROACH TREATED WITH PA, PA + PB, AND PB

Dose (μg)	EAG amplitude (mV)		
	PA	PA + PB (8:5)	PB
10^{-5}	0.13 ± 0.03	0.13 ± 0.03	0.13 ± 0.04
10^{-4}	0.15 ± 0.04	0.14 ± 0.04	0.14 ± 0.04
10^{-3}	0.27 ± 0.08	0.27 ± 0.07	0.27 ± 0.11

as well as the 8:5 blend of PA and PB. Table 1 shows the comparative results among PA, PA + PB, and PB at doses of 10^{-5}, 10^{-4}, and 10^{-3} μg. Figure 2 shows the observed EAG amplitudes for the mixed samples of PA and PB. The samples were compared with those expected, which were calculated by the above regression equations for PA and PB.

The study indicated that no significant difference existed in the comparison of PA, PA + PB, and PB, between the observed and the expected EAG ampli-

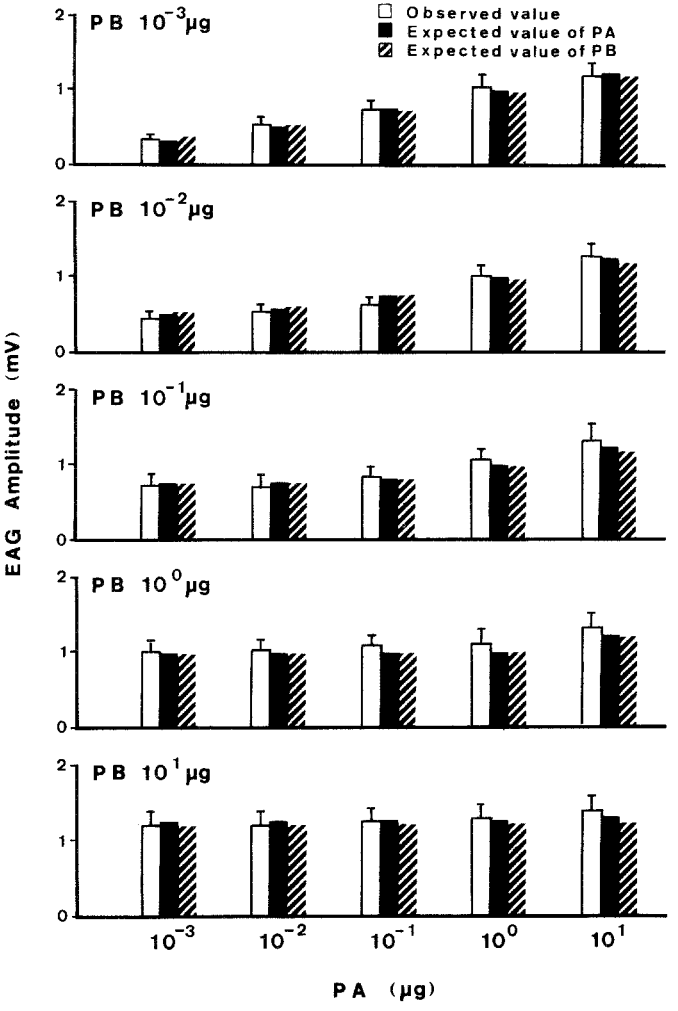

FIG. 2. EAG response of male *P. americana* antennae to the mixture of PA and PB. The vertical bar indicates the standard error of the mean.

tudes of the mixtures by Student's t test (significant level 5%) (Steel and Torrie, 1980). There was no particular ratio of the mixture of PA and PB that suppressed or reinforced the EAG amplitude. The addition of PA and PB elicited only an integrated total response.

In light of Ariens' theory that different receptors for different chemical drugs was considered, our curve of the dose of PA + PB vs EAG response is shown in Figure 3. The curves revealed that when different quantities (10^{-1}, 10^{0}, 10^{1} μg) of PB were added to PA, there is an increase on EAG response, while at higher concentrations the response approaches the maximal values.

DISCUSSION

In these studies with synthetic PB and Hauptmann's PA, the results were the same as those obtained by Nishino and Kuwabara (1983), but different from those obtained by Okada et al. (1991). This difference might be explained as resulting from different pheromone application systems, since in Okada's experiment the test solution was applied directly to the inner side of a disposable glass pipet, while in the experiments of Nishino and Kuwabara (1983) and our experiments, the test solution was impregnated on a filter paper. The filter paper can absorb the test chemicals in large quantities, so a higher dosage of the test chemicals is needed to obtain similar EAG response.

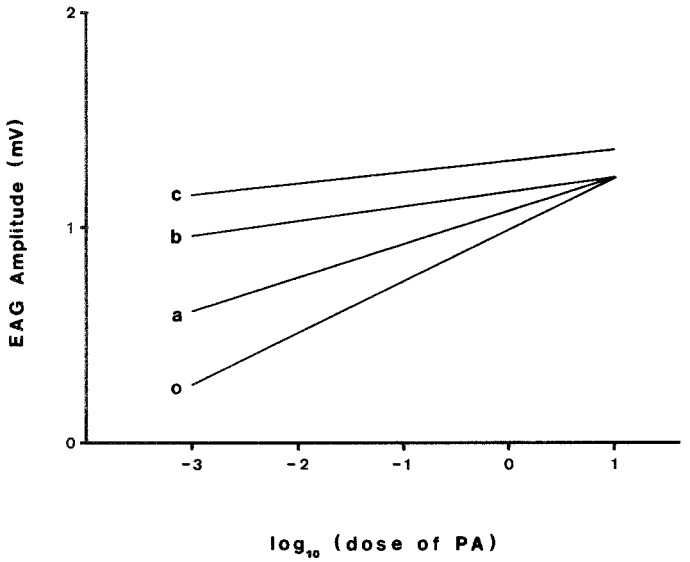

FIG. 3. Dose–EAG response curves of PA alone (o) and mixtures of PA with 10^{-1} (a), 10^{0} (b) and 10^{1} (c) μg PB.

The EAG response in this study was determined by lower doses of PB as being larger than that of PA, whereas higher doses of PA gave greater responses than those of PB. This phenomenon was also shown by Nishino and Kuwabara (1983); this supports the data of Seelinger (1985) that PB was responsible for long-distance attraction and PA was responsible for short-distance attraction.

According to the result from Sass (1983), PA and PB were detected by different individual olfactory cells. Nishino and Manabe (1983, 1984) and Nishino et al. (1988) also showed that there were two types of receptors specifically responsible for PA and PB by applying the DS-EAG technique. Moreover, in molecular pharmacology, Ariens et al. (1964a,b) determined that when drugs A and B occupy their own receptors, the curves of the addition of different quantities of drug B to drug A were categorized as pattern 3 (cited in Manabe and Nishino, 1985). In the EAG studies, the curves (Figure 3) produced by PA + PB coincided with the pattern 3. Thus this study confirms that the specificities of the receptors for PA and PB are different using the filter paper method for analysis.

Acknowledgments—Financial support by the Bureau of Environmental Sanitation and Toxic Substances Control, Environmental Protection Administration, Executive Yuan, Taipei, Taiwan, is appreciated. The authors wish to thank Prof. Kenji Mori of Tokyo University for supplying pure crystalline synthetic periplanone-B and Hauptmann's periplanone-A, Dr. W.L. Roelofs for kindly supplying an EAG amplifier (100×/1000×), and Dr. George R. Waller for critical reading of the manuscript.

Peoria, Illinois 61604

(Received August 22, 1991; accepted October 31, 1991)

Abstract—Males of *Carpophilus hemipterus* (L.), the dried-fruit beetle, (Coleoptera: Nitidulidae) were found to emit nine all-*E* tetraene and one all-*E* triene hydrocarbons in addition to two pheromonally active tetraenes that had been reported previously. The previously known compounds are (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene **(1)** and (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-undecatetraene **(2)**. The new tetraenes were all related to structure **1** by having one additional carbon at either one or two of the following four locations: at carbon 1 of the chain, at carbon 10 of the chain, at the 5-alkyl branch, or at the 7-alkyl branch. (Structure **2** also fits within this pattern.) The triene in *C. hemipterus* is (2*E*,4*E*,6*E*)-5-ethyl-3-methyl-2,4,6-nonatriene. Also identified from volatile collections from the beetles were the 2*Z* and 4*Z* isomers of **1.** All structures were proven by synthesis, with NMR and mass spectral data for the compounds provided. Two of the newly discovered compounds, (2*E*,4*E*,6*E*,8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-decatetraene and (2*E*,4*E*,6*E*,8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-undecatetraene, were quite active in the wind-tunnel bioassay, but others, such as (2*E*,4*E*,6*E*,8*E*)-5-ethyl-3,7-dimethyl-2,4,6,8-decatetraene and (2*E*,4*E*,6*E*,8*E*)-4,6,8-trimethyl-2,4,6,8-undecatetraene were not. Structure–activity relationships are explored among the natural compounds and additional, synthetic analogs, which were never detected from the beetles. Some of these analogs, such as (2*E*,4*E*,6*E*,8*E*)-3,5-dimethyl-7-propyl-2,4,6,8-undecatetraene, were quite active in the bioassay. The biosynthesis of the beetle-derived compounds is discussed. A single biosynthetic scheme that lacks complete enzyme specificity at four specific steps could account for the

*To whom correspondence should be addressed.

entire series of compounds found in the beetles and their relative proportions. The definition of "pheromone" is discussed in relation to these hydrocarbons.

Key Words—Pheromone, aggregation, hydrocarbon, tetraene, triene, NMR, mass spectra, dried-fruit beetle, *Carpophilus hemipterus*, Coleoptera, Nitidulidae.

INTRODUCTION

The dried-fruit beetle *Carpophilus hemipterus* (L.) (Coleoptera: Nitidulidae) has a male-produced aggregation pheromone that was found to include two unusual tetraene hydrocarbons (Figure 1 below, structures **1** and **2**) (Bartelt et al., 1990a). In that earlier paper, the existence of at least eight additional male-specific hydrocarbons was reported, but no chemical structures or information about pheromonal activity was presented. The male-specific hydrocarbons of *C. hemipterus* have been studied further, and additional structures are reported here.

These compounds were identified by mass spectrometry (MS), gas chromatography (GC), and high-performance liquid chromatography (HPLC). The minute amounts of the natural chemicals from the beetles precluded the use of additional spectral methods. However, structure assignment was possible using only these techniques as long as appropriate model compounds were available for comparison. A key problem then, became one of choosing the correct model structures for synthesis. Such choices were difficult at first because interpretation of the limited analytical data for the natural compounds was ambiguous. However, the first identifications did suggest a biosynthetic model for the *C. hemipterus* hydrocarbons, similar to those proposed for *C. lugubris* and *C. freemani* (Bartelt et al., 1991, 1990b). The model was found to have great predictive value and became very useful in guiding the later hydrocarbon syntheses. NMR spectroscopy was used to verify that synthesis of the intended structures had been achieved, and the NMR and mass spectral characteristics of the synthetic tetraenes are summarized in the paper.

The large series of synthetic compounds gave us the opportunity to explore relationships between structure and pheromonal activity, and these bioassay results are also presented.

METHODS AND MATERIALS

Beetles and Volatile Collections. The beetle culture, originally from the Fresno area of California, was maintained on an artificial, pinto-bean diet (Dowd, 1987) or on a modified diet in which additional brewer's yeast was substituted for the pinto beans. Volatiles were collected from feeding beetles as previously described (Bartelt et al., 1990a). Approximately 50,000 beetle-days of volatiles

were available for analysis for this study. Silica gel and $AgNO_3$ HPLC were used to obtain the unsaturated hydrocarbons from these samples. Three separate preparations were analyzed for the additional male-specific compounds; two of these were separated into fractions by $AgNO_3$ HPLC before detailed analysis, and the other was examined without prior HPLC fractionation.

Identification of Male-Derived Hydrocarbons. Initial study was directed at the male-specific compounds for which GC retention indices and mass spectra had been obtained previously but for which structures were still undetermined (Bartelt et al., 1990a). It was known that many of these compounds could be separated from each other by applying both $AgNO_3$ and size-exclusion HPLC (Bartelt et al., 1990a). The initial effort was to isolate as many of these as possible for hydrogenation followed by GC-MS analysis. The resulting additional information, along with knowledge of pheromones in related species, allowed structures to be suggested, but the beetle-derived compounds were considered "identified" only when a synthetic standard was found that matched the natural one by all available criteria (GC retention, HPLC retention, mass spectrum, and when possible, GC retentions and mass spectra of hydrogenation products). Later on, the natural samples were examined further by GC-MS for still other tetraenes that had not been detected earlier (Bartelt et al., 1990a) but that were predicted to be present by a biosynthetic model. As before, structure identification of the additional compounds entailed matching the properties with authentic standards, although for these, too little material was available for the hydrogenation experiment.

Synthetic Compounds. The compounds used in this research are shown in Figure 1. The following chemicals were prepared in the course of this work: (2*E*,4*E*,6*E*,8*E*)-5-ethyl-3,7-dimethyl-2,4,6,8-decatetraene **(4)**, (2*E*,4*E*,6*E*,8*E*)-4,6,8-trimethyl-2,4,6,8-undecatetraene **(5)**, (3*E*,5*E*,7*E*,9*E*)-4,6,8-trimethyl-3,5,7,9-dodecatetraene **(8)**, (2*E*,4*E*,6*E*,8*E*)-5,7-diethyl-3-methyl-2,4,6,8-decatetraene **(9)**, (2*E*,4*E*,6*E*,8*E*)-4-ethyl-6,8-dimethyl-2,4,6,8-undecatetraene **(10)**, (2*E*,4*E*,6*E*,8*E*)-6-ethyl-4,8-dimethyl-2,4,6,8-undecatetraene **(11)**, (2*Z*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene **(13)**, (2*E*,4*Z*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene **(14)**, (2*E*,4*E*,6*E*,8*Z*)-3,5,7-trimethyl-2,4,6,8-decatetraene **(16)**, (2*E*,4*E*,6*E*,8*E*)-3-ethyl-5,7-dimethyl-2,4,6,8-decatetraene **(18)**, (2*E*,4*E*,6*E*,8*E*)-3,5-dimethyl-2,4,6,8-decatetraene **(19)**, (2*E*,4*E*,6*E*,8*E*)-3,5-dimethyl-2,4,6,8-undecatetraene **(20)**, (2*E*,4*E*,6*E*,8*E*)-3,5-dimethyl-7-propyl-2,4,6,8-decatetraene **(21)**, (2*E*,4*E*,6*E*,8*E*)-3,5-dimethyl-7-propyl-2,4,6,8-undecatetraene **(22)**, and (4*E*,6*E*,8*E*)-2,3,5,7-tetramethyl-2,4,6,8-decatetraene **(26)**. Other compounds were available from earlier research: (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene **(1)**, (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-undecatetraene **(2)**, (2*E*,4*E*,6*Z*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene **(15)**, and (2*E*,4*E*,6*Z*,8*E*)-3,5,7-trimethyl-2,4,6,8-undecatetraene **(17)** (Bartelt et al., 1990a); (2*E*,4*E*,6*E*,8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-undecatet-

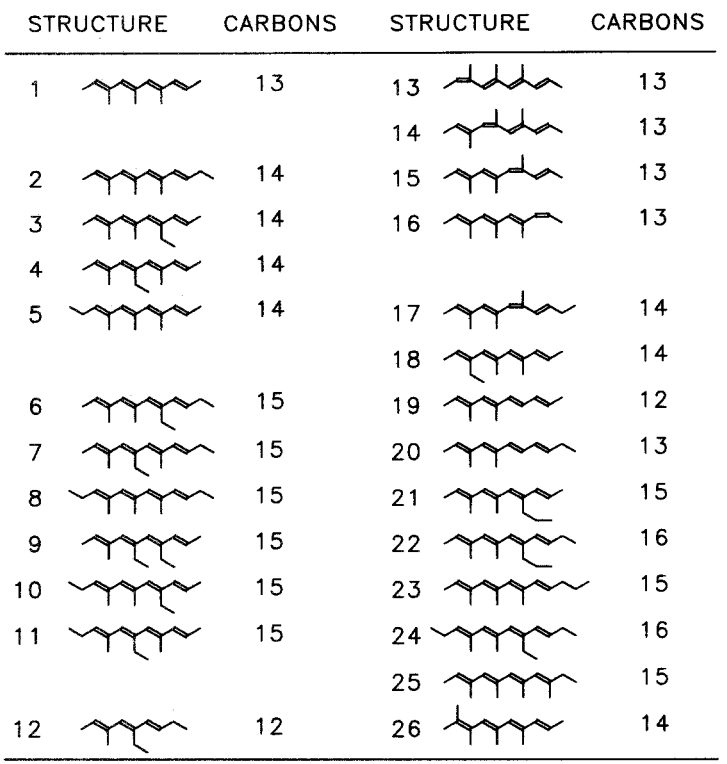

FIG. 1. Structures, structure numbers, and numbers of carbons for the compounds used in this research.

raene **(6)**, (2*E*,4*E*,6*E*,8*E*)-5-ethyl-3,7-dimethyl-2,4,6,8-undecatetraene **(7)**, (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-dodecatetraene **(23)**, and (2*E*,4*E*,6*E*,8*E*)-3,5,7,9-tetramethyl-2,4,6,8-undecatetraene **(25)** (Bartelt et al., 1991); (2*E*,4*E*,6*E*,8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-decatetraene **(3)** (Bartelt et al., 1990c); and (2*E*,4*E*,6*E*)-5-ethyl-3-methyl-2,4,6-nonatriene **(12)** and (3*E*,5*E*,7*E*,9*E*)-8-ethyl-4,6-dimethyl-3,5,7,9-dodecatetraene **(24)** (Bartelt et al., 1990b).

Hydrocarbon syntheses generally followed methods described previously (Bartelt et al., 1990a,c). The conjugated double bond systems were built up using Wittig-Horner and Wittig reactions. The propyl side chains of **21** and **22** were introduced during a Wittig-Horner olefination step by alkylating the phosphonate anion from triethyl 2-phosphonoacetate with propyl iodide (Boutagy and Thomas, 1974). The resulting reagent was then treated with a second equivalent of base and allowed to react with the aldehyde substrate in the usual way.

These syntheses also afforded structures **19** and **20** because the alkylation with propyl iodide was incomplete.

Two mono-*Z* isomers of **1**, structures **13** and **14**, were obtained in usable amounts from a synthesis of **1** in which NaOEt in EtOH was employed as the base–solvent system for the Wittig Horner reactions. [Less of the *Z* isomers were produced when BuLi and THF were the base and solvent (Bartelt et al., 1990c)].

The synthetic compounds were purified by passage through open columns of silica gel with hexane, followed by HPLC on a $AgNO_3$-coated silica column. Purities of compounds were 90–99% by capillary GC, except for **3, 9, 17,** and **23,** which were between 83% and 88%. Impurities were generally small amounts of *Z* isomers. An aliquot of each purified synthetic compound was diluted to 1.3 ng/10 μl with hexane for bioassays. NMR spectra were obtained to verify structures of the purified compounds; the solvent was deuterobenzene. Proton shifts were assigned by analogy to previously assigned compounds in the series and by double irradiation and COSY experiments. Nuclear Overhauser experiments were conducted with the *Z* isomers, **13** and **14,** to determine configurations at the trisubstituted double bonds. Mass spectra were also obtained for all synthetic compounds. GC retention indices (I) relative to *n*-alkanes were determined on a 15-m × 0.25-mm-ID DB-1 capillary column with 1.0-μm film thickness (J & W Scientific, Folsom, California); the temperature program was 100–200°C at 10°/min, and linear interpolation was used (Poole and Schuette, 1984, p. 25). Instrumentation was as described previously (Bartelt et al., 1990a).

Bioassays with Synthetic Hydrocarbons. The wind-tunnel bioassays were conducted as described by Bartelt et al. (1990a). The wind tunnel contained ca. 500–1000 beetles, and ca. 50–100 were in flight at any time during bioassays. Two treatment preparations to be compared were applied to pieces of filter paper, and these were hung side by side in the upwind end of the wind tunnel. Each test lasted 3 min, and the numbers of beetles alighting on the pieces of filter paper were recorded. The synthetic hydrocarbons were tested for activity both with and without adding a "host-type" coattractant to the bioassay treatments. The series of experiments are summarized in Table 1. In experiment 1, compounds **1–26** were evaluated versus controls. Every fourth test, the synthetic pheromone blend (SPB) was tested versus a control to ensure that the beetles in the wind tunnel remained responsive. (SPB included the following structures and amounts per dose: **1,** 1000 pg; **2,** 135 pg; **3,** 76 pg; **4,** 39 pg; **5,** 64 pg; and **6,** 29 pg. SPB was the best approximation to the actual male-specific hydrocarbon blend midway through the project, and it was used as a standard for the bioassay comparisons.) Additional experiments (2–8) were conducted to evaluate some compounds more extensively. These were all run as balanced incomplete block experiments with two treatments per block (two treatments in the wind tunnel during each test). Experiment 2 explored the effect of (conceptually)

TABLE 1. SUMMARY OF BIOASSAY EXPERIMENTS CONDUCTED WITH SYNTHETIC HYDROCARBONS

Experiment	Description[a]	Treatments[b]	N^c
1	Evaluation vs. control	**1–26,** SPB, control	≥4
2	Effect of adding "extra carbon" to **1**	**1, 2–5, 18, 26,** SPB, control	8
3	Activity of *Z* isomers of **1**	**1, 13–16,** SPB, control	12
4	Size of alkyl group at 7 position on 10-carbon chain	**1, 19, 3, 21,** SPB, control	10
5	Size of alkyl group at 7 position on 11-carbon chain	**2, 20, 6, 22,** SPB, control	20
6	SPB vs. natural pheromone	Male-derived HCs, SPB, control	16
7	Effect of adding **14** to SPB	SPB + **14,** SPB, control	16
8	SPB vs. mix of **1** and **2**	**1** + **2,** SPB, control	24
9	Evaluation with coattractant, constant dose (1.3 ng)	**1–26** + PA, SPB + PA, PA	≥8
10	Evaluation with coattractant, "natural" dose (ca. 1 male equivalent)	**1–7** + PA, SPB + PA, PA	8

[a] All tests in experiment 1 were versus controls (see text). In experiments 2–8 a balanced incomplete block design was used (treatments tested in pairs in all possible ways). In experiments 9 and 10, a balanced incomplete block experiment was run for *each* hydrocarbon; the treatments were hydrocarbon + PA, SPB + PA, and PA alone.

[b] SPB = synthetic pheromone blend, 1.3 ng dose (ca. 1 beetle equivalent); see text for composition; PA = propyl acetate, 10% solution in mineral oil, 20 μl/test. In most cases, the dose of each compound was 1.3 ng. In experiment 6, the total dose of male-derived tetraenes was 1.3 ng. In experiment 7, the dose of 14 was 400 pg; in experiment 8, the doses of **1** and **2** were 1000 and 130 pg, respectively.

[c] Number of replications for each hydrocarbon treatment in the experiment. In experiments 1, 9, and 10, the treatments, SPB, SPB + PA, PA, and control were replicated many more times; see text.

placing an additional carbon on various positions of structure **1.** Experiment 3 compared the mono-*Z* isomers of **1.** Experiments 4 and 5 examined the effect of alkyl substituent size at position 7 in 10- and 11-carbon chains. SPB was also compared to the natural pheromone (experiment 6), to a mixture of SPB + **14** (experiment 7), and to a mixture of just **1** and **2** (experiment 8). For experiments 9 and 10, each hydrocarbon [alongside propyl acetate (PA) on the same filter paper] was tested in a balanced incomplete block experiment with PA alone and with SPB plus PA. For experiments 1–6 and 9, the hydrocarbon dose was always 1.3 ng; in experiments 7 and 8, component mixtures had slightly different total doses; and in experiment 10, the "natural" dose was used (ca. 1 beetle equivalent) (see Table 1).

Wind-tunnel responses to combinations of pheromone and coattractants

such as propyl acetate are greater than to either attractant alone (Bartelt et al., 1990a; Dowd and Bartelt, 1991). Nevertheless, meaningful counts (e.g., >10 per 3-min test) can be obtained to the pheromone alone if the beetles are allowed to "warm up" for a sufficient period of time before testing and if they are not exposed to treatments containing the host volatiles during the experiments. Tests without the coattractant (experiments 1–8) are the most sensitive in that the blank filter paper controls receive consistently low numbers of visits (almost always ≤ 1 per test). However, if the compounds were active only in the presence of a coattractant, then their activity could be overlooked. The additional experiments (9 and 10) explored this possibility. Because the control for these latter experiments, PA by itself, is an attractant in its own right, responses to it were more variable, and the effect of the test compound over and above PA was more difficult to detect. Taken together, experiments with both types of controls were expected to provide a fairly comprehensive view of activity in the compounds.

Statistical Analysis. The bioassay data were analyzed by categorical methods (Fienberg, 1977). Initially, the data set for each of experiments 1–8 was analyzed separately. A parameter was fitted for each treatment and for the total number of responders for each 3-min test. Because only two of the experimental treatments were compared in any given test, the overall contingency table was of the incomplete type, and the model of quasiindependence was applied (Fienberg, 1977). For all eight experiments the model fitted well ($P > 0.05$, chi-square test using the likelihood ratio statistic, G^2), indicating that the data were well-behaved for this sort of analysis. Because there was no evidence for interactions involving replications in these experiments, the data sets were collapsed (summed) over the replications of each two-treatment comparison to give simpler data sets for subsequent calculations. All eight experiments were then combined into one overall quasiindependence model. By combining all of the data into one model, all information about each treatment was used, and the most powerful statistical tests for differences among treatments could be obtained. Conditional chi-square tests (analogous to t tests in ANOVA) were used to detect these differences. Comparisons to the control were usually of greatest interest.

The quasiindependence model for experiments 1–8 did not quite fit ($G^2 = 129$ with 87 df). The 0.95 percentage point of the chi square distribution with 87 df is 110. Nevertheless, it did account for almost all of the variability among treatments; when the parameters for differences among treatments were removed from the model, G^2 became very large (3096, with 119 df). This very simple model was believed adequate to give reasonable conditional tests for differences among treatments and reasonable descriptions of treatment effects relative to the controls and SPB. The lack of fit of the model was due almost entirely to slightly different relationships between controls and SPB in experiment 1 versus experiments 2–8. In experiment 1, the control counts were 1.1% of SPB, whereas in

experiments 2–8, they were 3.3% of SPB. When an extra parameter was included in the model for the controls of experiment 1, G^2 was decreased to 110 (86 *df*).

For experiments 9 and 10, a separate categorical analysis was run for each treatment. In these experiments, each treatment was linked only to SPB + PA and to PA, and there was nothing to be gained by combining the data into one large model.

With categorical analysis, relationships among the treatments are often expressed as ratios of fitted values. For this study two were of particular interest: the ratio between a test compound and the control (*t/c*) and the ratio between SPB and the control (*spb/c*). The effect of each test compound was summarized for presentation by combining these values into a measure of relative activity. Relative activity = $100 \times [(t/c - 1)/(spb/c - 1)]$, and it expresses the effect of a compound as a percentage of the activity of SPB, correcting for controls. (Recall that for experiments 9 and 10, the "control" was PA.)

RESULTS AND DISCUSSION

Identification of Novel 14-Carbon Tetraenes from Males. Hydrogenation following isolation was successful for three previously unidentified 14-carbon compounds (I = 14.22, 14.28, and 14.63) (Bartelt et al., 1990a). The GC and mass spectral data for the 14-carbon compounds are given in Table 2. Multiple GC peaks after hydrogenation were due to the creation of asymmetric centers; the mass spectra for these peaks were always nearly identical. These data indicated that the carbon skeletons were distinctly different from each other and from the previously identified 14-carbon tetraene **2.** The molecular weights of all three new compounds increased by 8 after hydrogenation (from 190 to 198). Therefore, each had four double bonds (if no triple bonds) but no rings.

The compound with I = 14.63 produced a readily interpreted MS fragmentation pattern after hydrogenation. Enhanced fragments at *m/z* 71, 113, and 155 suggested a 4,6,8-trimethylundecane carbon skeleton. Structure **5** was chosen as a synthetic target for the natural tetraene by analogy to the previously identified **1** and **2** with regard to the positions and configurations of double bonds. Synthetic **5** matched the natural compound in every way, both before and after hydrogenation. (The carbon skeleton of **5** has symmetry about carbon 6 after hydrogenation; thus only three distinct diastereoisomers can be produced, in a 2:1:1 ratio. Formation of three asymmetric centers during hydrogenation normally results in four possible diastereoisomers.)

Mass spectrometry of the hydrogenated tetraenes with I = 14.22 and 14.28 was less informative. The dominant fragment was the *m/z* 169 (M-29) peak in these spectra. While loss of an ethyl group was evident, the positions of the alkyl group(s) were not obvious. A similar situation was encountered previously

TABLE 2. ANALYSIS OF FOUR MALE-DERIVED 14-CARBON TETRAENES BY HYDROGENATION, GC, AND MASS SPECTROMETRY; COMPARISON TO TETRADECANE

with the 15-carbon pheromone of *C. lugubris* (Bartelt et al., 1991). The usual rules for interpreting the mass spectra of methyl branched hydrocarbons (Nelson, 1978) do not apply clearly to ethyl-branched hydrocarbons because the loss of the ethyl group so dominates the spectrum. The compound at I = 14.28 before hydrogenation produced a relatively intense (12%) key spectral peak at *m/z* 83 (Table 3). By analogy to the *C. lugubris* pheromone, the compound was believed to be the 7-ethyl tetraene **3.** The compound at I = 14.22 produced only a small *m/z* 83 peak but a large (57%) *m/z* 69 peak, suggesting it to be either the 5-ethyl tetraene **4** or the 3-ethyl tetraene **18.** However, the 3-ethyl isomer **(18)** would have only two asymmetric centers after hydrogenation and therefore could not

produce more than two GC peaks. (The natural compound produced four.) Thus the initial synthetic targets were **3** and **4,** and they matched the natural tetraenes in every way. The fragment ions expected to be enhanced, if the "rules" for methyl-branched hydrocarbons are followed, are noted in Table 2. Many of these for structures **3** and **4** were not especially large. Even though the spectra were not readily rationalized, the fragmentation patterns and GC retentions after hydrogenation did provide diagnostic "fingerprints" for the carbon skeletons, as long as authentic standards were available for comparison.

15-Carbon Tetraenes. A 15-carbon compound with molecular weight 204 and I = 15.15, probably another tetraene, was reported previously from male *C. hemipterus* (Bartelt et al., 1990a). Fortuitously, this compound matched perfectly the GC retention and mass spectrum of the pheromone of *C. lugubris* (Bartelt et al., 1991), and structure **6** is concluded to be a component of the emission from male *C. hemipterus* as well. A search for additional 15-carbon tetraenes was motivated by the biosynthetic argument detailed below. The additional 15-carbon tetraenes **7–11** were synthesized as standards. With the GC retentions, HPLC retentions, and mass spectra of the synthetic standards as guides, the volatile collections from male beetles were examined carefully by GC-MS, and compounds **7, 8, 10,** and **11** were clearly detected. A compound was also present from the beetles with all the correct chromatographic properties to be **9,** but too little material was available for a definitive mass spectrum. The major peaks (*m/z* 105, 119, 133, 147, 175, and 204) were in the proper ratios, but smaller peaks were lost in background noise.

In the volatile collections from both male and female beetles, there were a number of additional compounds with molecular weight 204. Many of these were probably sesquiterpenes originating in the artificial diet. The compounds appearing with both sexes had large mass spectral fragments at one or more of *m/z* 69, 91, 93, 133, 147, and 161, but the 175 peaks were always very small. Tetraenes **6–11** all have intense *m/z* 175 fragments in the mass spectra, and this series is not evident in volatiles from females. The amount of the "sesquiterpenes" in the samples varied considerably, and the GC peak at I = 14.91 reported by Bartelt et al. (1990a) now appears to have been one of these. By GC, it was not resolved from the smaller amount of tetraene **11** at I = 14.95, but the selected-ion chromatogram for *m/z* 175 clearly indicated that the tetraene was hidden in the tail of the GC peak. The male-specific peaks with molecular weights of 204 and large *m/z* 175 fragments were always present and in very similar ratios in the samples examined.

Z *Isomers.* The two male-derived 13-carbon compounds at I = 12.44 and 13.08 (Bartelt et al., 1990a) were concluded to have the same carbon skeleton as **1,** based on analysis after hydrogenation. Thus the compounds differed from **1** only in double bond position or configuration. The compound with I = 12.44 has not yet been identified, but the more abundant one (I = 13.08) clearly

matched structure **14,** by GC retention, HPLC retention, mass spectrum, and by the peculiar GC peak shape (see Figure 5 below). Furthermore, the beetle-derived peak at I = 13.39 matched structure **13** by GC retention, HPLC retention, and mass spectrum. Thus both the 2*Z* and 4*Z* isomers of **1** were concluded to be present in the volatile collections from the beetles; however, the 6*Z* and 8*Z* isomers were not detected.

Just as *Z* isomers of major component **1** were present in small amounts in the volatile collections, *Z* isomers of the less abundant 14- and 15-carbon tetraenes also appeared to be present at correspondingly lower levels. Careful GC-MS revealed a large number of these in minute amounts, but the structures remain undetermined. In general, the *Z* isomers have identical mass spectra to those of the all-*E* isomers, elute well before the corresponding all-*E* isomers by GC and, as long as the *Z* double bond is trisubstituted, by $AgNO_3$ HPLC as well.

Apparently, isomerization of double-bond configuration can occur fairly readily. For example, when all-*E* **1** is applied to a rubber septum and the released volatiles analyzed, mono-*Z* **14** is invariably present (typically 10–50% the amount of **1**). Other examples of isomerization are given below, where gas chromatography of standards is discussed. It is unknown whether the beetles actually release *Z* isomers or whether their presence is due solely to isomerization of the all-*E* tetraenes during volatile collections and subsequent handling. Because the amount of *Z* isomers detected in samples varied considerably and because the freshest samples tended to have less, the latter explanation is favored.

Other Structures. One additional compound, triene **12,** was identified from male *C. hemipterus*, by HPLC, GC, and MS. This compound is of special interest because it is the major pheromone component of *C. freemani* (Bartelt et al., 1990b). This compound was overlooked originally (Bartelt et al., 1990a) because it elutes from the $AgNO_3$ column before the pheromonally active compounds. None of the other structures **(15–26)** in Figure 1 were detected from the beetles. The abundances of compounds **1–14** in volatile collections from beetles are summarized in Figure 3 (below).

Biosynthesis. Proposed biosynthetic schemes were published previously for the pheromones of *C. lugubris* (Bartelt et al., 1991) and *C. freemani* (Bartelt et al., 1990b). A similar scheme can account well for the hydrocarbons of *C. hemipterus* (Figure 2). Under this scheme, the carbon skeletons are built up in cyclic fashion, through a series of elongation, reduction, and dehydration steps. At some point after the final acylation, a decarboxylation occurs, and the free hydrocarbon is released. A methyl branch is introduced if the second, third, or fourth acyl unit is propionate. Correspondingly, butyrate addition leads to ethyl branches.

Although 12 different carbon skeletons are produced by male *C. hemipterus*, it is suggested that there are not 12 different biosynthetic pathways. Instead,

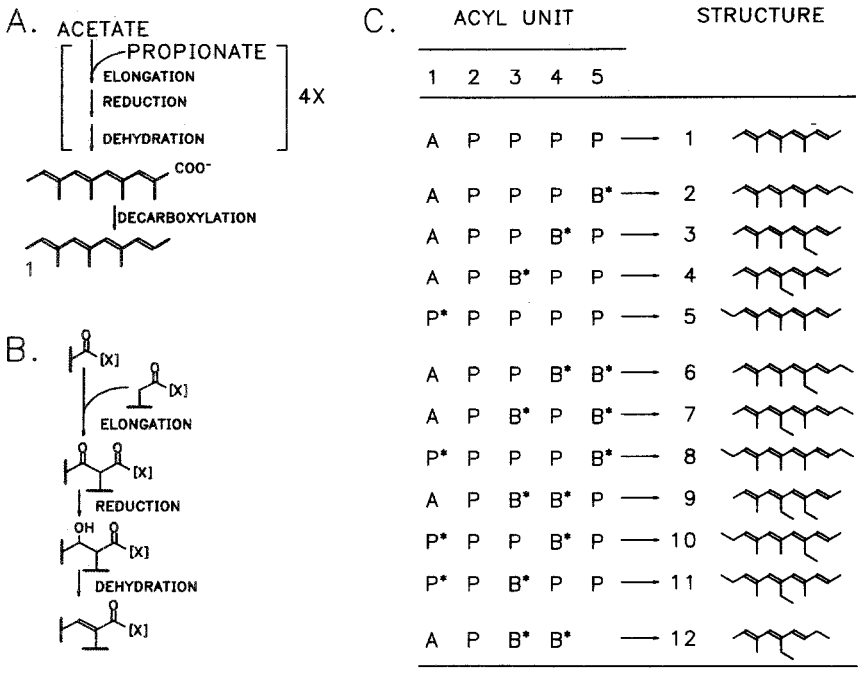

FIG. 2. Proposed biosynthetic scheme for the male-specific hydrocarbons of *C. hemipterus*. The biosynthesis of **1** is summarized in (A). The details of the elongation, reduction, and dehydration steps are given in (B); [X] is an acyl carrier such as coenzyme A. The acyl units needed to form **1–12** are shown in (C). A = acetate, P = propionate, and B = butyrate; points of deviation from the "usual" biosynthetic route (that of **1**) indicated by (*).

all of these could be produced by just one pathway. If **1** is the usual biosynthetic product (suggested by its abundance), then **2–5** would each result from one biosynthetic "mistake" (e.g., lack of rigorous enzyme specificity during the elongation step). These four points of deviation from the usual route are indicated in Figure 2. The six 15-carbon tetraenes **6–11** would result if two of these mistakes occurred in one compound. There are six ways of combining the four possibilities two at a time, and there was evidence for all six of the structures in the beetles. If the mistakes occurred independently, then one would expect compounds with two of them to be far less abundant than those with only one, and this is just the pattern seen in the beetles. Triene **12** would result from the biosynthetic sequence leading to **9** if chain termination occurred after the fourth acyl addition rather than after the fifth. Apparently, two successive butyrate units tend to lead to chain termination, regardless of the chain length when the second one is added. This could explain the relatively small amount of **9.**

Tetraenes with 16 carbons, such as **24,** would result if three mistakes occurred during biosynthesis. These were never detected, but in line with the model, the occurrence of three of these independent events in one molecule would be even less likely, and the apparent absence of these compounds is not surprising. If a greater amount of beetle-derived material were available for careful analysis, they might well be detected. Of the other compounds in Figure 1, **18–20** could easily be rationalized from acetate, propionate, and butyrate units, but they were not detected from the beetles. Compounds **21–23** could be rationalized if valerate units were used to account for the propyl branches and the long chain terminus in **23,** but again, there was no evidence for these. Compounds **25** and **26** cannot be constructed from acetate, propionate, and butyrate units as outlined in Figure 2.

Bioassays. The results of the bioassay experiments are summarized in Figure 3. Significant differences between the treatments and the control at the 0.05, 0.01, and 0.001 levels are indicated by one, two, and three asterisks, respec-

FIG. 3. Bioassay activity for 26 individual hydrocarbons. In experiments 1–5, the compounds were tested at 1.3 ng per dose, without a coattractant; in experiment 9, at 1.3 ng per dose, with propyl acetate (PA) as a coattractant; and in experiment 10, at doses as in the abundance column (in pg), with PA added. Activity is expressed relative to the standard synthetic pheromone blend, corrected for controls (see text). Significant differences from the controls at the 0.05, 0.01, and 0.001 levels denoted by *, **, and ***, respectively (conditional G^2 tests). Abundances of the compounds in the beetles are summarized, as the approximate number of picograms per male; ND, not detected.

tively (conditional G^2 tests). The beetles were ready to respond during all of these experiments because 1.3 ng of SPB was always clearly different from controls. Overall means for SPB and control were 24.5 and 0.4, respectively, in experiments 1–8. The overall means for SPB + PA and PA were 17.4 and 1.0 for experiment 9 and 18.0 and 0.6 for experiment 10.

Most striking was that of the 11 all-*E* tetraenes found in *C. hemipterus*, only five (**1–3, 6,** and **8**) ever showed significant activity relative to controls. Compounds **2, 3,** and **6** were active in experiment 10 even in doses of well under 1 ng. In general, the results when the hydrocarbons were tested in conjunction with PA (experiments 9 and 10) paralleled those when no PA was present (experiments 1–8), but the results for **8** were unusual in that significant activity was seen only in the presence of PA. Compounds **4, 5, 7,** and **9–11** were never significantly active, nor was triene **12.**

All four of the mono-*Z* isomers of **1 (13–16)** showed significant activity, with **16** being the most active and **13,** the least. Only **13** and **14** were ever detected from the beetles. Given the instability of **14** especially, it is unclear whether the responses were to **14** itself or if partial isomerization to **1** occurred during the bioassay. The results for **14** are as one might expect from a lower dose of **1.** By GC at least, compound **16** is more stable, and it is believed to be active in its own right.

Compounds **1** and **2,** the most active tetraenes at natural doses, were not significantly different from SPB when combined in natural proportions (experiment 8, **1** + **2** was 87% of SPB). The male-derived hydrocarbons were also equivalent to SPB (95% as active as SPB, experiment 6). Adding **14,** a relatively abundant constituent of the volatile collections from beetles, to SPB did not significantly enhance the activity of SPB (combination was 112% of SPB, experiment 7). Compounds **1** and **2** are clearly major pheromone components, as concluded earlier (Bartelt et al., 1990a). Compounds **3** and **6** are also potentially important under natural conditions. The other natural compounds **4** and **5** and **7–14** would appear to have, at best, very subtle roles under natural conditions.

Of the other model compounds not found in the volatile collections, **22** was strikingly active, and five others, **17, 18, 21, 23,** and **26,** had significant activity under some conditions.

Structure–Activity Relationships. Several generalizations can be made about structure–activity relationships: (1) An ethyl group as the middle alkyl branch (e.g., the 5-ethyl group in **4**) renders the compound inactive. (2) The right-hand terminal alkyl group (as drawn in Figure 3) can be methyl, ethyl, or propyl and the compound still have activity; the ethyl group seems most consistent with high activity, however. (3) The right-hand alkyl branch (e.g., the 7 position in **1**) can be methyl, ethyl, or propyl and the compound still be active, but having only a hydrogen in that position (**19** and **20**) renders the compound inactive. (4) The left-hand terminal alkyl group (as drawn in Figure 3) should be methyl for

maximal activity, although there was some evidence of activity with ethyl (i.e., **8**). Because structure **8** is analogous to **2** and because **2** is, perhaps, the most active of the tetraenes, the high activity with PA of **8** relative to **5, 10,** and **11** is not surprising. (5) The left-hand alkyl branch should be methyl, but the one example with an ethyl group at that location **(18)** did have slight activity. (6) Alkyl groups in other locations (e.g., **25** and **26**) greatly reduce activity.

The Pheromone of C. hemipterus. It is debatable whether the entire male-specific series of compounds should be called a pheromone. We suggest the situation is as modeled in Figure 4. There is a set of compounds produced only by male beetles, and there is another set of compounds to which the pheromone receptors can respond. It is only the intersection of these two sets that should be considered as the pheromone. Inaccurate biosynthesis could nicely account for the variety of structures encountered in *C. hemipterus*, and it may be incorrect to assume that each compound has biological function merely because it is there. The pheromone receptors do detect the major tetraene **1** and minor tetraenes **2, 3,** and **6** very well, but other structures in the series seem to be unused. These structures could be retained in the emission from *C. hemipterus* as long as they pose no selective disadvantage. On a weight basis, the inactive compounds account for a very small proportion of the male-specific emission, thus their production would not be especially wasteful energetically.

At present, we believe the pheromone of *C. hemipterus* to include **1, 2, 3,** and **6.** Whether other compounds for which activity has not yet been demonstrated should be included must await careful field testing of mixtures of components.

The inactive compounds from the beetles could serve as a pool of new pheromones during speciation. If pheromone receptors evolved to detect these

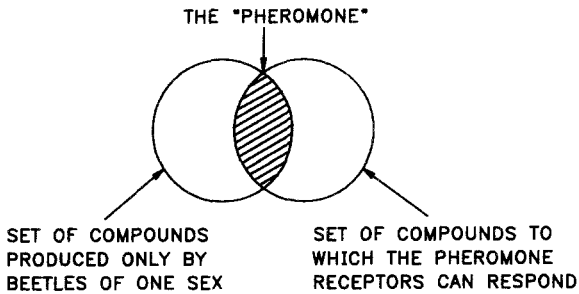

FIG. 4. Relationship of the male-specific hydrocarbons of *C. hemipterus* to the functional aggregation pheromone. As presently understood, not all of the male-specific hydrocarbons are pheromonally active, and the beetles do respond to some pheromone analogs that they do not produce. The intersection of these sets represents the pheromone blend that serves for communication under natural conditions.

compounds, then they could become biosynthetically enhanced through natural selection, and the new species could then develop a very different pheromone profile from the parent species. It is interesting that **12,** which is apparently inactive in *C. hemipterus*, is the major pheromone component in *C. freemani* and that **6,** which is active in *C. hemipterus* but is only a minor portion of the pheromone blend, is nevertheless the major pheromone component of *C. lugubris* and is an important minor component in *C. freemani*.

Gas Chromatography of Standards. Retention indices (I) relative to *n*-alkanes are given in Tables 2 and 3 and Figure 5 for the tetraenes. Triene **12** has an index of I = 12.24. While the all-*E* tetraenes always produced sharp GC peaks, some of the *Z* isomers did not. Examples are shown in Figure 5. The isomers with "internal" *Z* double bonds (**14** and **15**) produced distorted GC peaks, probably due to thermal rearrangement or other degradation, while those with a *Z* double bond at either end (**13** and **16**) generated sharp peaks. The GC peak of compound **14** rose slowly at the leading edge, then dropped off sharply. Compound **15** showed an initial sharp peak at I = 12.06, a second sharp peak at I = 13.26, and a broad hump between them. If the injector temperature was set at 250°C, only the peak at 12.06 was seen for **15;** with the injector at 100°C, no I = 12.06 peak appeared. If the sample was run on a thinner film (0.25 μm vs. 1.0 μm) column, which allowed the compound to elute at a cooler temperature (115°C vs. 160°C), only the I = 13.26 peak was evident; thus I = 13.26 most likely represented the unchanged compound. Compound **14** also chromatographed as a single, sharp peak on the thin-film column. The chromatogram for **17** (not shown) had a similar appearance to **15,** but I = 14.06 (Bartelt et al., 1990a). Of greatest importance to this study was that the diagnostic peak shape for some of these standards aided in the identification of compounds in volatile collections.

All of the *Z* isomers could be prepared in essentially pure form by $AgNO_3$ HPLC, but after storage for several months in a freezer (which was true of the samples used as examples for this figure), analysis by GC revealed additional peaks (e.g., I = 13.39, 13.83). These apparently corresponded to partial isomerization to **13** and **1,** respectively. Isomerization of **1** to **13** and **14** was also observed, although not in the sample shown in Figure 5.

Mass Spectra of Standards. The mass spectra of 20 all-*E* tetraenes are summarized in Table 3. Examples of whole spectra appeared previously (Bartelt et al., 1990a,b, 1991), but the data for these are shown here also for comparative purposes. The molecular ions were prominent (27–95% of base peak), and the masses, *m/z* 77, 91, 105, 119, 133, and 147, were very evident in all spectra (14–100% of base peak). Structural correlations were not obvious in the intensities of these peaks, but the series served as fingerprints for the structures.

Certain features of the spectra did give specific structural information, however. The most intense of the M-15, M-29, and M-43 peaks usually indi-

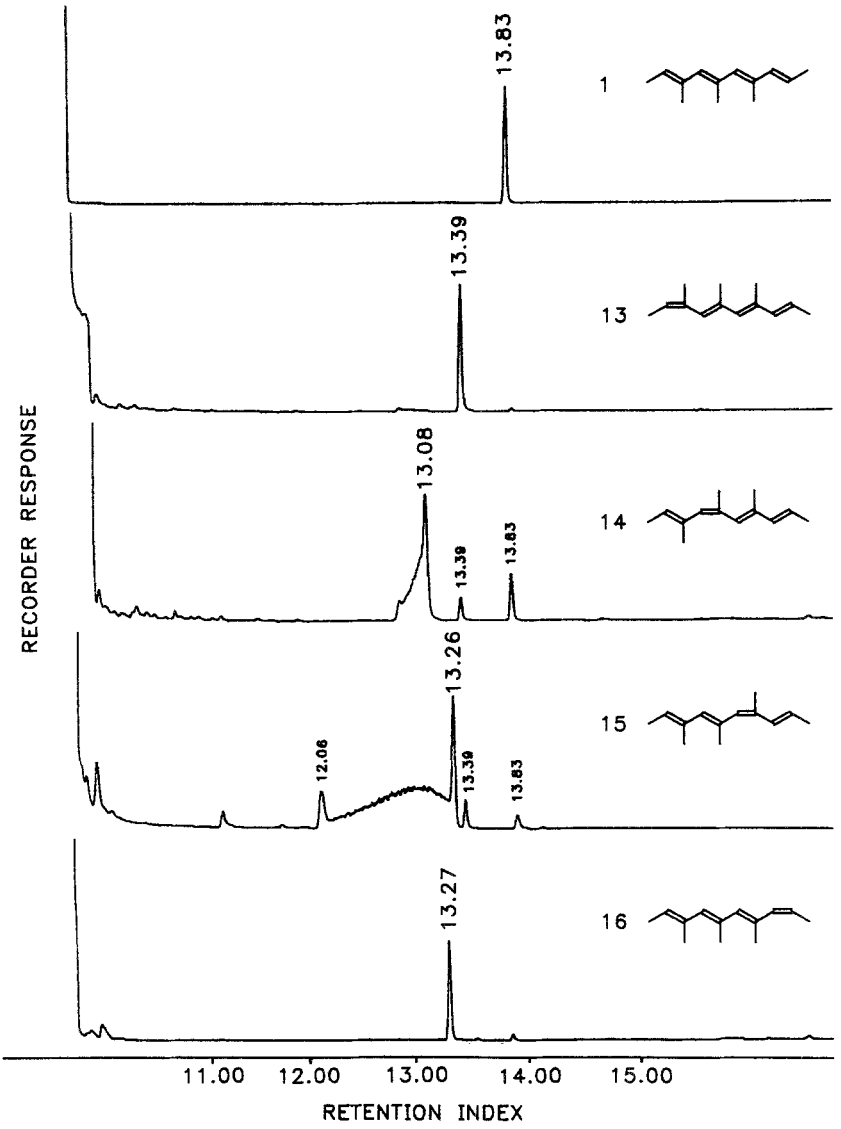

FIG. 5. Gas chromatograms of five geometrical isomers of 3,5,7-trimethyl-2,4,6,8-decatetraene. GC conditions: 15-m × 0.25-mm-ID DB-1 capillary column (1.0-μm film thickness), programmed from 100°C at 10°/min; injector temperature 170°C. Retention indices relative to *n*-alkanes; 14.00 corresponds to a retention time of 6.31 min.

TABLE 3. GC RETENTION AND MASS SPECTRAL FRAGMENTATION DATA FOR 20 ALL *E*-TETRAENES[a]

[a] GC retention index relative to *n*-alkanes; abundances of MS ions expressed as percentage of base peak.
[b] Expected to be enhanced because of fragmentation through third double bond; see text.
[c] Expected to be enhanced; represents loss of largest alkyl group attached to the tetraene system. See text.
[d] Base peak was *m/z* 41.
[e] Peak at *m/z* 111 had intensity of 4%; no other compounds had detectable 111 peak.
[f] Peak at *m/z* 203 had intensity of 10% in **22** and 15% in **24**; no other compounds had 203 peak.

cated the largest alkyl group attached anywhere on the conjugated tetraene system, either at an end or as a side chain. Thus in **1** and **19,** a methyl was the largest alkyl group, but in **2** and **7** it was an ethyl, and in **21** and **23,** a propyl, and the corresponding fragments were relatively intense (Table 3). This generalization did not work well for **18** or **19,** however. For **19,** the large M-43 peak corresponded to *m/z* 119; because *m/z* 119 was intense in all of the compounds, it was not diagnostic for a propyl group. For the higher molecular weight compounds, this complication did not arise.

A second spectral feature involved the peaks in the C_nH_{2n-1} series, *m/z* 69, 83, 97, and 111. As noted previously (Bartelt et al., 1991), cleavage through the double bond at the 6 position in structure **6,** accompanied by hydrogen migration, corresponded to an enhanced *m/z* 97 peak, and cleavage through the analogous double bond in other structures led to enhancement of other fragments in this series. The fragments expected to be enhanced are marked in Table 3. Within each column, the marked fragments are relatively intense except with the dialkyl tetraenes **19** and **20,** for which the pattern fails. Apparently, unless there is an alkyl group at this double bond, the characteristic cleavage is not observed.

The mass spectra for the mono-*Z* tetraenes **13–17** appeared identical to the respective all-*E* isomers, **1** and **2.** The mass spectrum for triene **12** was presented elsewhere (Bartelt et al., 1990b).

NMR Spectra for Synthetic Standards. The NMR data for the standards are presented in Figures 6–9. The proton shift assignments for the all-*E* tetraenes are presented in Figure 6. The shifts for the mono-*Z* 13-carbon tetraenes related to **1** are shown in Figure 7. The data for **1, 2, 3, 6, 15,** and **24** (Bartelt et al., 1990a–c; 1991) are reproduced in these figures to facilitate comparison. The NMR data for triene **12** and tetraene **17** appear elsewhere (Bartelt et al., 1990a,b).

The proton splitting patterns were usually simple, and most could be interpreted by first order rules, although this was complicated by overlapping signals in some compounds. The coupling constants are summarized in Figure 8 for the trialkyl, all-*E* tetraenes. The large coupling (15.4–15.7 Hz) between H_D and H_E was consistent with the *E* configuration for the double bond (Silverstein et al., 1981, p. 235). In the one compound with a disubstituted double bond in the *Z* configuration **(16),** the coupling constant was 11.6 Hz. Slight long-range coupling (J = 0.5 Hz) was sometimes observed between pairs of signals not noted in Figure 8, such as between H_C and H_D. Such interactions led to line broadening but not usually to distinct splitting, and these were not included in the figure. The splittings between R_4 and H_C and between R_3 and H_B were larger (ca. 1.2–1.4 Hz) when R was methyl but were <1 Hz when R was ethyl or propyl. Configuration at the trisubstituted double bonds did not affect these coupling constants.

The spectra of four compounds **(19–22)** had second-order features. Figure

FIG. 8. NMR coupling constants observed in the trialkyl all-*E* tetraenes.

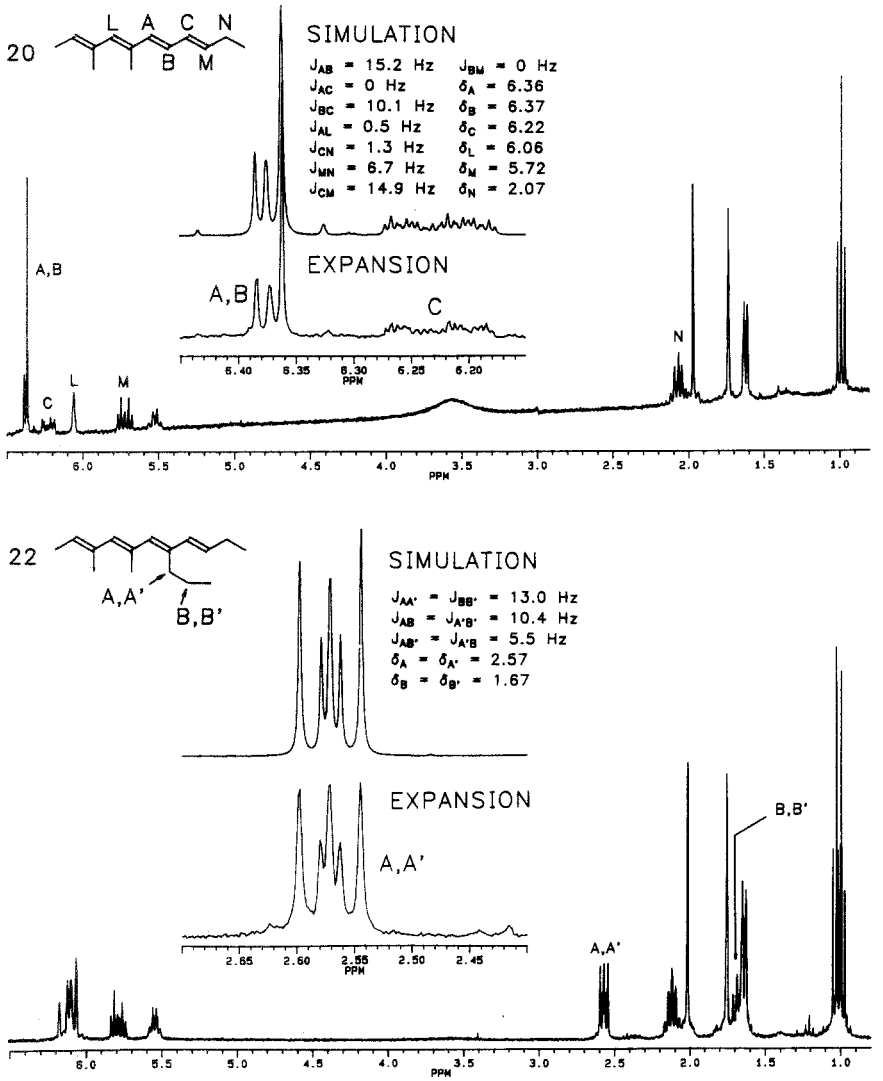

FIG. 9. NMR spectra of two tetraenes not interpretable by first-order rules. Insets show expansion of the regions with second-order character and computer simulations of these regions, based on the listed coupling constants and shifts.

9 shows examples of these. In the dialkyl tetraene **20** (Figure 9, upper), the signals at δ 6.36, 6.37, and 6.22 had ABC character, with additional splitting and line broadening by the protons at δ 5.72, 2.07, and 6.06. Through simulation, it became apparent that the coupling constant between the protons at δ 6.36 and 6.37 was $J = 15.2$ Hz, which supported the *E* configuration for this double bond. Other estimated coupling constants are given in the figure. In **22** (Figure 9, lower), the methylene protons of the propyl side chain produced an unusual multiplet. This was apparently due to hindered rotation about the bond between methylene groups in the side chain. Computer simulation of these methylenes as an AA′BB′ system accounted for the appearance of the signal. The BB′ portion is partially obscured by a methyl signal, making its features difficult to see. Although these spectra were fairly complex, they did support the postulated structures.

For the 13-carbon tetraenes, **13** and **14,** NOE experiments were used to determine the configurations at the trisubstituted double bonds (Figure 7). Each olefinic proton on a trisubstituted double bond was observed for enhancement when the methyl group sharing the same double bond was irradiated. In each compound only one such enhancement was observed; thus each had exactly one trisubstituted *Z* double bond. The locations of the *Z* double bonds were known because all proton shifts had been assigned in the structures. Enhancements of protons *not* on the same double bond as the irradiated methyl group were also observed (Figure 7) and gave some information about the conformations of these compounds in solution. The four double bonds are probably not coplanar as drawn in the figure. Molecular models and molecular mechanics calculations suggest that certain nonplanar conformations would be less strained. For example, in **13** and **14,** the double bond in the 4 position probably lies in a plane nearly perpendicular to those of the 2 and 6 double bonds. NOE data for **1** and **15** (Bartelt et al., 1990a) are also included in Figure 7 for comparison.

Acknowledgments—The assistance of D.G. Carlson, K.L. Smith, C.M. Weber, and B.W. Zilkowski is gratefully acknowledged. We also thank J.W. Hagemann of this laboratory for doing the molecular mechanics calculations for structures **13** and **14;** Chem X molecular modeling software, developed and distributed by Chemical Design, Ltd., Oxford, England, was used for this purpose.

(Received June 19, 1991; accepted October 31, 1991)

Abstract—Analysis of ovipositor washings from virgin female *Helicoverpa assulta* (Guenée) (Lepidoptera: Noctuidae) from Korea by gas chromatography (GC) linked to electroantennography and GC linked to mass spectrometry resulted in the identification of nine compounds, hexadecanal, (Z)-9-hexadecenal, (Z)-11-hexadecenal, hexadecyl acetate, (Z)-9-hexadecenyl acetate, (Z)-11-hexadecenyl acetate, hexadecan-1-ol, (Z)-9-hexadecen-1-ol, and (Z)-11-hexadecen-1-ol. However, ovipositor washings from females from Thailand contained mainly the 16-carbon aldehydes with very small amounts of (Z)-9-hexadecenyl acetate. Field tests conducted in Korea, China, and Thai-

land indicated that a binary blend of (Z)-9-hexadecenal and (Z)-11-hexadecenal was sufficient for attraction, although the most attractive ratio of compounds varied with location. In Korea a 20:1 blend of compounds was the most attractive, while in Thailand a 7.5:1 blend was most attractive. In China both blends of hexadecenal isomers were equally attractive. Addition of the hexadecenyl acetates to the 20:1 blend of hexadecenals in the ratio of 1:3.3 increased the trap catch of male *H. assulta* compared to lures containing the aldehydes alone in Korea but reduced trap catch in China. Addition of the hexadecenyl acetates to the 7.5:1 blend of hexadecenals had no significant effect on trap catch in Thailand or China compared to the aldehydes alone. The addition of the 16-carbon alcohols to the aldehydes had a significantly inhibitory effect in all three countries, suggesting they are not pheromone components. Taken together these results indicate that *H. assulta* is polymorphic with at least two populations responding to different sex pheromones.

Key Words—*Helicoverpa assulta*, *Heliothis*, Lepidoptera, Noctuidae, hexadecanal, (Z)-9-hexadecenal, (Z)-11-hexadecenal, hexadecyl acetate, (Z)-9-hexadecenyl acetate, (Z)-11-hexadecenyl acetate, hexadecan-1-ol, (Z)-9-hexadecen-1-ol, (Z)-11-hexadecen-1-ol, sex pheromone.

INTRODUCTION

The Oriental tobacco budworm, *Helicoverpa assulta* (Guenée) is found throughout the Far East, Africa, and Australasia, where it is a pest of such crops as peppers (Cho and Boo, 1988) and tobacco and onions (Hill, 1983). Control of this pest in the larval stages with insecticides is particularly difficult because of its habit of feeding within the fruits of host plants, and these difficulties have been further aggravated by the increasing resistance of larvae to the insecticides currently used for its control (Lee and Boo, 1985). In order to achieve effective control strategies, there is a need for a sensitive, species-specific monitoring system. An attractive bait based on the sex pheromone of the species would fit this requirement and have the added advantage that traps based on such a lure are highly mobile and cheap to operate, requirements that are particularly important to pest monitoring systems when utilized in developing countries (Beevor et al., 1983).

The present study describes our efforts to identify components of the female sex pheromone and develop a species-specific lure for monitoring *H. assulta* by conducting field trials of the compounds identified in Korea, China, and Thailand.

METHODS AND MATERIALS

Insect Material. Larvae were collected in the Suwon area of Korea and reared on either tobacco leaves or an artificial diet (Kim et al., 1984). Pupae were sexed and dispatched by air to England. On arrival they were separated

into single sex groups of 10–15 individuals and placed in Perspex containers (30 × 15 × 15 cm) with access to 10% sucrose solution and tissue paper in vertical strips to allow them to expand their wings on emergence (Cho and Boo, 1988). The containers were placed in an environmental cabinet maintained at 25°C and 60% humidity during the reversed 12-hr light period and 22°C and 60% humidity in the 12-hr dark period. In Thailand, insects were reared on artificial diet (Kim et al., 1984) and maintained on a 12-hr: 12-hr light–dark cycle.

Pheromone Collection. Pheromone gland washings were prepared in England from Korean insects using hexane and 0- to 2-day-old females 4–6 hr and 10 hr into the scotophase as described by Sower et al. (1973). In Thailand gland extracts were prepared 10 hr into the scotophase (10 glands/sample) and dispatched to Israel for chemical analysis.

Gas Chromatography (GC). GC analyses of pheromone gland extracts made from Korean insects were conducted on a Carlo Erba Mega series 5300 instrument fitted with two Grob split/splitless injectors (200°C) and flame ionization detector (FID) (220°C). Fused silica capillary columns (25 m × 0.32 mm ID) were used throughout the study, coated with either nonpolar CP Sil 5CB (chemically bonded methylsilicone; Chrompack) or polar CP Wax 52CB (chemically bonded Carbowax 20 M equivalent; Chrompack). The carrier gas was helium with an inlet pressure of 0.4 kg/cm^2. All injections were made with the split valve closed for 40 sec onto a column held at 70°C for 2 min then temperature programmed at 20°C/min to 120°C, and then at 4°C/min to 210°C.

GC analyses of Thai pheromone gland extracts were conducted on a Varian 3700 instrument equipped with a FID detector, splitless injector system, and polar fused silica capillary column (30 m × 0.25 mm ID) coated with DB-225 (chemically bonded cyanosilicone; J & W). Samples were injected onto the analytical column, held at 60°C for 2 min, and then temperature programmed to 150°C at 10°C/min. The purge valve was opened 1 min after injection, and the inlet pressure of the helium carrier gas was 1.0 kg/cm^2.

Retention times of compounds identified in the ovipositor washings are summarized in Table 1 and quoted as equivalent chain lengths (ECLs) relative to the retention times of straight-chain acetates; thus, for example, tetradecyl acetate = 14.00 (Christie, 1988; Harris and Habgood, 1966).

Electroantennography (EAG). Linked GC-EAG analyses were carried out essentially as described by Cork et al. (1990) by splitting half of the analytical column effluent to the FID detector and the other half to a silanized glass reservoir in the GC oven. Column effluent was expelled from the reservoir at 17-sec intervals for 3-sec with a stream of nitrogen (250 cm^3/min) into a constant stream of nitrogen (250 cm^3/min) over the EAG preparation. The series of EAG responses generated were then compared to identify those that were significantly above background responses in order to determine the presence of electrophysiologically active compounds.

TABLE 1. GC RETENTION TIMES AND RELATIVE COMPOSITION OF EAG-ACTIVE COMPOUNDS IDENTIFIED IN PHEROMONE GLAND WASHINGS OF *H. assulta* FROM KOREA

	Retention times (ECL)[a]				Composition[b] normalised to Z9-16:Ald

Mass Spectrometry (MS). Electron impact (EI) and chemical ionization (CI) mass spectra with isobutane as reagent gas were obtained on a Finnigan MAT Ion Trap Detector, model 700, under continuous ion monitoring between *m/z* 30–250 at 220°C for EI-MS and *m/z* 60–300 at 200°C for CI-MS as described by Cork et al. (1991). EI mass spectra of dimethyl disulfide (DMDS) adducts were obtained in the multiple ion detection (MID) mode on a Finnigan 5100 EI machine at 70 eV, coupled to a Super Incos data system and interfaced with a Finnigan MAT 9610 GC. Samples were injected onto a fused silica capillary column (30 m × 0.25 mm ID) with low-polarity SE 54 (chemically bonded phenylmethylsilicone; J & W) held at 60°C for 4 min and then temperature programmed at 20°C/min to 230°C. The injector was operated in the splitless mode with the purge valve opened 0.5 min after injection. The inlet pressure of the helium carrier gas was maintained at 0.7 kg/cm^2.

Synthetic Chemicals. Monounsaturated acetates, alcohols,and aldehydes were obtained by standard Wittig and acetylenic coupling reactions (Henrick, 1977) or purchased from Shin Etsu Chemical Co. (Tokyo, Japan). Compounds used for field testing were further purified by argentation chromatography (Houx

et al., 1974) to give material at least 99.9% isomerically and chemically pure by GC analysis.

Microreactions. Dimethyl disulfide derivatives were prepared essentially as described by Buser et al. (1983) and Dunkelblum et al. (1985).

Field Trials. Field trials in China were conducted in Hunan province in tobacco and hot-pepper fields using water traps (Campion et al., 1974). Related trials in Korea were conducted in hot-pepper fields using cone traps (Hartstack et al., 1979), while those in Thailand were conducted in tobacco fields with sleeve traps (Dunkelblum and Kehat, 1989; Neumark and Teich, 1980). In Korea and China treatments were placed out in randomized complete blocks with at least 20 m between treatments in a block and 100 m between blocks. The position of treatments within a block was rotated in a clockwise direction daily when trap catches were recorded and insects discarded. Female moths tested in Korea were provided with sugar solution and changed daily. In Thailand traps were rotated and trap catches counted once or twice a week.

Pheromone dispensers were white rubber septa (Aldrich, catalog No. Z10,072-2) impregnated with 0.1 ml of hexane solution containing the synthetic pheromone blend and an equivalent weight of 2,6-di-*tert*-butyl-4-methylphenol as antioxidant.

The results were statistically analyzed by analysis of variance (ANOVA) after combining catches for each treatment and transforming them to log $(x + 1)$. If differences in treatment means were significant at the 5% level or lower, then they were ranked by Duncan's multiple-range test (DMRT) (Duncan, 1955).

RESULTS

Structure Determination. GC-EAG analyses of extracts prepared from insects collected in Korea using typically 0.1 pheromone gland equivalents on a nonpolar CP Sil 5CB column under temperature programmed conditions indicated three regions of EAG activity significantly above background. GC retention times of compounds eluting in these regions were consistent with those of saturated and monounsaturated 16-carbon, straight-chain aldehydes, alcohols, and acetates, respectively (Table 1).

Analysis of the 16-carbon aldehyde region by EI-MS indicated the presence of three compounds (Figure 1). The compounds had MS consistent with synthetic hexadecanal and two hexadecenal isomers. CI-MS of the compounds confirmed these results, with significant M + 1 ions at *m/z* 241 and 239 for hexadecanal and the two hexadecenal isomers, respectively, and significant M − 1 and M + 1 − 18 ions associated with the hexadecenal isomers at *m/z* 237 and *m/z* 221, respectively. Comparison of GC retention times of the 16-carbon aldehydes with synthetic analogues on polar and nonpolar phases under iso-

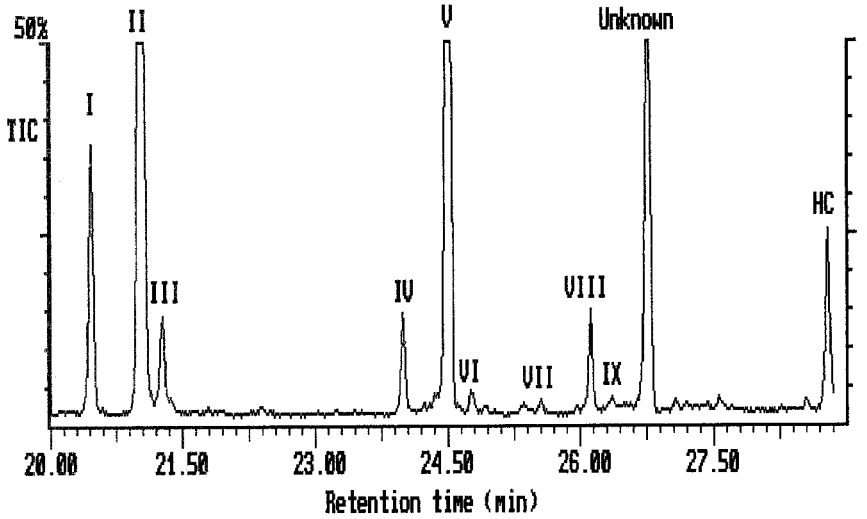

FIG. 1. Total ion chromatogram in EI mode, *m/z* 30–250, of 0.2 equivalents of *H. assulta* ovipositor extract prepared from insects reared in Korea and chromatographed on a polar GC column. The mass spectra and GC retention times of the labeled compounds corresponded with I, 16:Ald; II, Z9–16:Ald; III, Z11–16:Ald; IV, 16:Ac; V, Z9–16:Ac; VI, Z11–16:Ac; VII, 16:OH; VIII, Z9–16:OH; IX, Z11–16:OH; Unknown, unidentified compound; and HC, saturated straight-chain hydrocarbon.

thermal conditions (Cork et al., 1988) confirmed the presence of hexadecanal (16:Ald), (Z)-9-hexadecenal (Z9–16:Ald) and (Z)-11-hexadecenal (Z11–16:Ald) in the approximate ratio of 3.5:13.3:1 for pooled extracts prepared between 4 and 6 hr into the scotophase. In a related study of 10 individual female ovipositor extracts prepared 10 hr into the scotophase, the average ratio of 16:Ald, Z9–16:Ald, and Z11–16:Ald was 4:23:1. Extracts prepared 4–6 hr into the scotophase contained on average 150 ng/female equivalent of Z9–16:Ald, whereas ovipositor extracts prepared 10 hr into the scotophase contained on average 60 ng of Z9–16:Ald, but this varied from 4 to 180 ng.

Similarly three 16-carbon alcohols were observed by EI-MS (Figure 1) that had the same GC retention times on a polar column (Table 1) and mass spectra as hexadecan-1-ol (16:OH), (Z)-9-hexadecen-1-ol (Z9–16:OH), and (Z)-11-hexadecen-1-ol (Z11–16:OH). The alcohols were present in amounts approximately 2% of the corresponding aldehydes in extracts prepared 4–6 hr into the scotophase, but this increased to an average of 55% in extracts prepared 10 hr into the scotophase. Only the most abundant alcohol, Z9–16:OH, could be confirmed on both GC phases and by CI-MS with M + 1 ions at *m/z* 241.

EAG activity elicited by compounds eluting in the 16-carbon acetate region was shown by EI-MS to be associated with three compounds that had characteristic ions at *m/z* 61 $(CH_3COOH_2)^+$ and M−60 ions at *m/z* 224 and 222, indicative of hexadecyl acetate (16:Ac) and two hexadecenyl acetate isomers, respectively. CI-MS was only able to confirm the major hexadecenyl acetate with M+1 ions at 283 and M−60 ions at *m/z* 222. The GC retention times of these compounds on polar and nonpolar GC columns were consistent with those of 16:Ac, (Z)-9-hexadecenyl acetate (Z9-16:Ac), and (Z)-11-hexadecenyl acetate (Z11-16:Ac) (Table 1). The amount of Z9-16:Ac relative to Z9-16:Ald was found to be approximately 26% in extracts prepared 4–6 hr into the scotophase, but this increased dramatically to an average of 232% in extracts prepared 10 hr into the scotophase, although there was considerable variation between ovipositor extracts prepared from individual female moths of from 20% to 600%.

There was no evidence from GC-EAG or GC-MS analyses for the presence of any tetradecenal isomers that are observed in the sex pheromones of some Heliothidinae (Dunkelblum and Kehat, 1989; Klun et al., 1980a).

Ovipositor washings from insects collected in Thailand were analyzed by capillary GC and by GC-MS after conversion to the dimethyl disulfide adducts (Buser et al., 1983; Dunkelblum et al., 1985). The latter analyses confirmed the presence of Z9-16:Ald and Z11-16:Ald with characteristic retention times and ions at *m/z* 145, 187, and 332 (M^+) for Z9-16:Ald, and 117, 215, and 332 (M^+) for Z11-16:Ald. The average ratio of 16:Ald, Z9-16:Ald, and Z11-16:Ald was 1.5:5:1, respectively, and pheromone yields were 1–5 ng per female. Small amounts of Z9-16:Ac were detected in some extracts, but the alcohols were never observed.

Field Tests. Preliminary field trials were conducted in China, Korea, and Thailand with different ratios of Z9-16:Ald and Z11-16:Ald. Different results were obtained at each location. In Korea the most attractive blend tested was the 20:1 ratio of components, in Thailand the 7.5:1 ratio of compounds was the most attractive, and in China there was no significant difference in catches with lures containing either the 50:1 or 5:1 ratio of hexadecenal isomers, although the 1:1 ratio of hexadecenal isomers was significantly less attractive (Table 2). In Korea, the 20:1 blend of hexadecenal isomers was shown to be significantly more attractive to male moths than two virgin females in field trials (Table 2).

The 20:1 blend of Z9-16:Ald and Z11-16:Ald was then tested in China and Korea at different loadings and in both instances the highest catch was obtained with the highest loading tested, 5000 μg, although differences between catches for each treatment were not significant in the trial conducted in China (Table 3). A 7.5:1 blend of compounds was tested in China and Thailand with

the same result (Table 4). Lures with 1000 μg or more of the 20:1 ratio of hexadecenal isomers were found to be significantly more attractive than two female moths in Korea (Table 3).

The effect on attractiveness of adding Z9-16:OH, Z9-16:Ac, and Z11-16:Ac to a 20:1 blend of Z9-16:Ald and Z11-16:Ald was tested in China and Korea (Table 5). The compounds were added at levels comparable to those found in ovipositor extracts prepared 4–6 hr into the scotophase, when the highest levels of mating were observed in Korea (Kim and Boo, 1986). At both locations Z9-16:OH was found to reduce trap catch significantly when added at 2% of Z9-16:Ald. However, the effect of adding a 20:1 blend of Z9-16:Ac and Z11-16:Ac to an equivalent blend of Z9-16:Ald and Z11-16:Ald in the ratio of 1:3.3 was to increase trap catch significantly in Korea, but reduce trap catch significantly in China. In a related experiment in China and Thailand with a 7.5:1 ratio of Z9-16:Ald and Z11-16:Ald, the addition of the related alcohols in the same isomeric ratio reduced trap catch significantly, while the addition of the related acetates had no statistically significant effect on trap catch (Table 6).

DISCUSSION

The female sex pheromones of Heliothidinae moths characterized so far are blends of saturated and monounsaturated 14-carbon aldehydes, 16-carbon aldehydes, 16-carbon acetates, and 16-carbon alcohols (Table 7). The EAG-

active compounds identified in ovipositor washings of *H. assulta* moths collected in Korea and Thailand were similar 16-carbon aldehydes, acetates, and alcohols, but the relative abundances of the compounds differed both in comparison with other species and between the populations studied.

In all other *Helicoverpa* and *Heliothis* pheromones characterized, the major component is Z11-16:Ald, but Z9-16:Ald was the most abundant hexadecenal isomer found in ovipositor washings from *H. assulta* obtained from Korea and Thailand with Z11-16:Ald detected as a minor component (Table 1). Significant differences in the ratio of Z9-16:Ald to Z11-16:Ald were found in ovipositor washings prepared from insects obtained from Korea and Thailand, and this could not be attributed to differences in sampling protocols as samples were prepared by the same method (Sower et al., 1973) and in the same time period

in the scotophase. Extracts were prepared at times when calling behavior or mating had been observed, notably 4–6 hr into the scotophase for Korean insects (Kim and Boo, 1986) and 10 hr for Thai insects. Extracts prepared from Thai insects at earlier periods in the scotophase contained no detectable quantities of pheromone.

Ovipositor washings made from Korean insects also contained significant amounts of hexadecenyl acetates and hexadecen-1-ols, and again the (Z)-9 isomer predominated over the (Z)-11 isomer. The relative abundance of Z9–16:Ald, Z9–16:Ac, and Z9–16:OH changed from 1:0.3:0.02 in extracts prepared from females 4–6 hr into the scotophase to 1:2.5:0.55 in extracts prepared 10 hr into the scotophase (Table 1). This is in line with similar observations by Heath et al. (1991) working with the (Z)-11 isomers from *H. subflexa* ovipositor washings. In contrast, ovipositor washings prepared from Thai insects 10 hr into the scotophase contained only trace amounts of Z9–16:Ac and the hexadecen-1-ols were not detected.

In view of the large differences in ratios of EAG-active compounds found in the ovipositor washings of female *H. assulta*, it was not possible to define the natural blend of EAG-active compounds that would elicit the optimal mate-finding response from receptive male moths without either collecting volatiles released from calling female moths or field testing different blends of the compounds identified. In this instance the latter course of action was taken.

Field tests in Korea, China, and Thailand showed male *H. assulta* moths were attracted by blends of the two hexadecenal isomers alone in which Z9–16:Ald predominated, but the optimum ratio varied with the location and reflected differences in the ratios found in the ovipositor washings. The most attractive blend of Z9–16:Ald and Z11–16:Ald tested in Thailand was 7.5:1, while 20:1 was significantly more attractive in Korea. In China there was no difference in attractiveness with blends containing between a 50:1 and 5:1 ratio of Z9–16:Ald and Z11–16:Ald although the 1:1 blend was significantly less attractive. Taken together the laboratory and field data suggest there may be two populations of *H. assulta* and that both were present in the Hunan province of China when the field tests were conducted.

Addition of corresponding blends of the two hexadecenyl acetates to the optimum blend of aldehydes increased attractiveness in Korea (Table 5) but did not significantly affect attractiveness in Thailand (Table 6). Addition of the hexadecenyl acetates to a 20:1 blend of Z9–16:Ald and Z11–16:Ald significantly decreased attractiveness in China (Table 5), but addition of the acetates to a 7.5:1 blend had no significant effect on trap catches (Table 6). These results provide further evidence for the existence of different populations of *H. assulta*. However, addition of Z9–16:OH to blends of the hexadecenal isomers with or without the hexadecenyl acetate isomers at a level of only 2% of the Z9–16:Ald dramatically reduced trap catches in China, Korea, and Thailand (Tables 5 and

6), suggesting that the alcohol found in ovipositor washings might have been a pheromone precursor (Teal and Tumlinson, 1986).

This study has provided another example of the way in which related species achieve species specificity by varying the relative amounts of a limited range of related chemicals in their sex pheromones (Kaae et al., 1973). In India *H. assulta* coexists with both *H. armigera* and *H. peltigera*. *H. armigera* is attracted by mixtures of Z11-16:Ald with 1-10% Z9-16:Ald (Kehat et al., 1980), in agreement with relative amounts of pheromone components found in analyses of ovipositor washings (Nesbitt et al., 1979, 1980). Ten potential pheromone components were detected in female ovipositor washings from *H. peltigera* by Dunkelblum and Kehat (1989), with Z11-16:Ald, Z11-16:OH, and Z9-14:Ald the most abundant components. Laboratory and field tests showed Z9-16:Ald was not necessary for attraction of this species, and a 2:1 mixture of Z11-16:Ald and Z9-14:Ald attracted male *H. peltigera* moths and only a few male *H. armigera*. Addition of Z11-16:OH further reduced the attractiveness to *H. armigera* without affecting attraction of *H. peltigera*. Presumably male *H. assulta* moths would not be attracted to *H. armigera* female moths because of the relative amounts of Z11-16:Ald and Z9-16:Ald, nor would they be attracted to *H. peltigera* female moths because of the virtual absence of Z9-16:Ald and the presence of Z11-16:OH. The Z9-14:Ald is vital for attraction of *H. peltigera* and reduces attractiveness to *H. armigera*, but it was not detected in ovipositor washings from *H. assulta* and its effect on the behavior of this species was not tested.

In Australia, *H. assulta* is sympatric with both *H. armigera* and the native budworm, *H. punctiger*. Rothschild et al. (1982) showed that a 20:20:1 mixture of Z11-16:Ald, Z11-16:Ac, and Z9-14:Ald provided an attractive lure for male *H. punctiger* moths, again in line with analyses of ovipositor washings from virgin female moths. Cross-attraction with *H. armigera* would not be expected because of the absence of Z9-16:Ald and the presence of Z9-14:Ald in the *H. punctiger* pheromone, while male *H. assulta* moths would not be attracted because of the absence of Z9-16:Ald.

From this work, the best blends recommended for monitoring *H. assulta* are a 20:1 mixture of Z9-16:Ald and Z11-16:Ald with 30% of a corresponding mixture of Z9-16:Ac and Z11-16:Ac in Korea and a 7.5:1 mixture of the two aldehydes with 30% of the corresponding acetates in Thailand. In China the situation is complicated by the apparent mixing of these populations and, until insect material is analyzed from China, only the blend recommended for Thailand should be used. Pheromone polymorphism involving different ratios of pheromone components has been observed previously in a number of lepidopterous species (e.g., Guerin et al., 1984; Bailey et al., 1986; Löfstedt et al., 1986; Löfstedt, 1990), but whether the different populations can be described as different species will depend, in part, on the degree of homogeneity of the

pheromone blends produced by each population and the degree of cross-attractiveness of the pheromones (Foster and Roelofs, 1987). Although this study provides evidence for the possible existence of at least two separate populations of *H. assulta*, confirmation will have to await further analyses of the pheromone produced by insects collected in different regions and further field testing of the different blends. Obviously, this is particularly important if pheromone lures are to be used for reliable monitoring of *H. assulta* in different areas.

Acknowledgments—Research conducted in Israel and Thailand was supported by grant C5-020 from the U.S.-Israel Co-operative Development Research (CDR) Program. In Korea the research was supported by grants from the Korea Science and Engineering Foundation (862-1503-007-2).

Abstract—(*E,Z*)-3,13-Octadecadienyl acetate **(1a)** and (*E,Z*)-3,13-octadecadien-1-ol **(2a)** were identified from the sex pheromone gland of the virgin female mulberry clearwing moth *Paradoxecia pieli* L., by GC analysis, EAG, SCR survey, and field bioassay. One female equivalent contained 250 ng of **1a** and 30 ng of **2a.** In the field tests, 100 μg of synthetic **1a** was attractive to male moths of the species.

Key Words—Insect sex pheromone, mulberry clearwing moth, Lepidoptera, Sesiidae, *Paradoxecia pieli* L. (*E,Z*)-3,13-octadecadien-yl acetate, (*E,Z*)-3,13-octadecadien-1-ol, single cell recording, EAG.

INTRODUCTION

The mulberry clearwing moth, *Paradoxecia pieli* L. (Sesiidae), is distributed in Jiang Su, Zhe Jiang, Si Chuan and Gui Zhou provinces in China. The larvae

	1c *Z,Z*		**2c** *Z,Z*
	1d *E,E*		**2d** *E,E*

[a] *E,Z* describes the *E* form of configuration at Δ3 and the *Z* form at Δ13. Similar meanings apply to *Z,E*, *Z,Z* and *E,E*.

damage mulberry trees by making holes in the twigs. In the most severe situations, 30% of the twigs and leaf sprouts could be killed. The larvae and nymphs remain inside the twigs, therefore, it is difficult to kill this insect by spraying with insecticides. Because the insect has only one generation each year, it may be possible to use a mass-trapping technique with insect sex pheromone as a control.

The sex pheromone of Sesiidae has been identified as 3,13-octadecadien-1-ol, or its acetate, with few exceptions (Zhang et al., 1986). In our previous reports, the major sex pheromones of the poplar twig clearwing moth, *Paranthrene tabaniformis* Rott, (Zhang et al., 1986); the poplar pole clearwing moth, *Sphecia siningensis* Hsu (Guo et al., 1990a); and the vine tree borer, *Paranthrene regalis* Bulter, (Guo et al., 1990b) were identified as (*E,Z*)-3,13-octadecadien-1-ol **(2a)**, (*Z,Z*)-3,13-octadecadien-1-ol **(2c)**, and (*E,Z*)-3,13-octadecadien-1-ol **(2a)**,[5] respectively (Table 1). Here we report the identification of the sex pheromone of the mulberry clearwing moth.

METHODS AND MATERIALS

Pheromone Collection. Twigs in which either nymphs or the last instar larvae were located were removed from mulberry trees in Ru Guo County in late May, and they were stored in the laboratory under normal conditions. Care was taken to keep adequate humidity by occasionally watering some pieces of cotton placed adjacent to the twigs. Adults were sexed immediately upon emergence. The ovipositors of 1- to 2-day-old virgin female moths (altogether 25 virgin females were collected for use) were removed and dipped in acetyl acetate.

[5] (*E,Z*)-3,13-Octadecadien-1-ol and its Z,Z-isomer were abbreviated as (*E,Z*)-3,13–18:OH and (*Z,Z*)-3,13–18:OH, respectively. Similar abbreviations were used for other OH isomers and their acetate isomers.

The extract was then filtered over glass wool and the clean filtrate was concentrated, sealed in a glass tube (ID 1.0 mm), and stored in a freezer until needed for EAG survey, GC analysis, and field tests. The antennae of 1- to 2-day-old unmated male moths were cut off according to the published paper for EAG bioassays (Roelofs et al., 1971).

GC Analysis. GC 102 instrument (Shanghai Analytical Instrument Factory) was employed for GC analysis under two conditions: condition A—glass column 5 m × 3 mm ID, packed with 3% OV-1 on 80–100 mesh Gas Chrom Q, column temperature 210°C; condition B—glass column 5 m × 3 mm ID, packed with 5% DEGS on 80–100 mesh Gas Chrom Q column temperature 180°C.

Single Cell Recording (SCR). The electrophysiological recording technique used was essentially the same as that applied by Kaissling and Thorson (1980). Each antenna was cut off from a male moth that had emerged two days before. One capillary (about 10 μm diameter) was placed over the end of the sensillum trichodeum olfactory hair where the tip had been removed to record the potential and nerve impulses of the receptor cell. The stimulus source was a piece of filter paper treated with 0.01 μg of the test compound. In our case, this was the minimum amount used for SCR so that the effect of possible impurity isomers could be diminished.

Field Bioassays. Field tests have been conducted since 1985 in Jiang Su Province during the adult flight season. Water traps were placed on the ground; each trap was made from a large bowl (25 cm diam.) filled with water and a lure. The lure was fastened with a piece of wire and placed in the middle of the bowl 3 cm above the water surface. Each lure was charged with either 100 μg or 200 μg of the synthetic chemical using rolled filter paper or polyethylene hollow tubes as dispensers. The crude extract was also employed as the natural lure for comparison under the same conditions.

Chemicals. All geometric isomers of 3,13-octadecadien-1-ol **(2a–d)** and their acetates **(1a–d)** were synthesized at purities of over 95% as previously reported by Zhang et al. (1985). Satisfactory spectroscopic data (IR, [^{1}H]NMR, MS) were obtained with all the above compounds.

RESULTS AND DISCUSSION

EAG Survey. Among the eight compounds (**1a–d** and **2a–d**) tested using the EAG survey technique on the mulberry clearwing moth, (*E,Z*)-3,13-18:OAc **(1a)** gave the highest response, and (*E,Z*)-3,13-18:OH **(2a)** exhibited the next highest in comparison with the untreated control. The EAG responses and calculated response index are shown in Table 2. The results indicate that the pheromone system might consist of several components with (*E,Z*)-3,13-18:OAc **(1a)** as the major component.

Field Bioassays. The eight compounds (**1a–d** and **2a–d**) were bioassayed individually in the field (Table 3). Only (*E,Z*)-3,13–18:OAc (**1a**) caught significant numbers of male moths; the other seven compounds (**1b–d** and **2a–d**) were not active during five days of testing in 1985. The preliminary test also showed that the addition of either (*Z,Z*)-3,13–18:OAc (**1c**) or (*E,Z*)-3,13–18:OH (**2a**) to (*E,Z*)-3,13–18:OAc (**1a**) gave no obvious increase in the number of male moths captured. Therefore, only (**1a**) was used in the subsequent tests.

GC Analysis. The crude washing from female sex gland (0.4–1 FE) was performed on GC on either column A (nonpolar column) or column B (polar column). For comparison, four synthetic acetates (**1a–d**) and their corresponding alcohols (**2a–d**) were performed on GC under the same conditions. There were

two diagnostic peaks from the crude washing that appeared on column A with retention times of 11.3 min (peak I) and 16.0 min (peak II), respectively, and two peaks on column B with retention times at of 15.2 min and 18.9 min. The retention times for **2a–d** under the same conditions were 11.3 min on column A and 18.9, 20.0, 20.9, and 18.1 min on column B. For **1a–d,** the retention time were 16.0 min on column A and 15.2, 15.0, 15.8, and 14.6 min on column B (see Table 4). Thus the above data showed that the natural sex pheromone consisted of **2a,** which appeared on GC as peak I, and **1a,** as peak II (Table 4).

Calculation of the peak areas on GC with the standard compounds revealed that 1 FE contained 30 ng (peak I) and 250 ng (peak II). Therefore, 250 ng of **1a** and 30 ng of **2a** was obtained from the crude washings of the female's sex pheromone gland.

In Figure 1, receptor potentials and nerve impulses were recorded from an olfactory hair on the male moth antenna of *Paradoxecia pieli*. Each cell is activated by only one pheromone component (distinguishable by the amplitude of the nerve impulses). The stimuli were (*E*,*Z*)-3,13–18:OAc (Figure 1A) and (*Z*,*Z*)-3,13–18:OAc (Figure 1B). Each response is AC- and DC-amplified (upper and lower trace, respectively).

The single cell recording (Figure 1) from the mulberry clearwing moth indicated that each sensilla trichodeum contained two receptor cells. The nerve impulses came from receptor cells that could be distinguished from each other by their amplitudes. One type of receptor cell producing the larger spikes was

TABLE 4. RETENTION TIME OBTAINED FROM NATURAL SEX PHEROMONE AND FROM SYNTHETIC CHEMICALS **1a–d** AND **2a–d**

Samples		Retention time (min)	
		Condition A	Condition B
(*E*,*Z*)-3,13–18:OAc **(1a)**		16.0	15.2
(*Z*,*E*)-3,13–18:OAc **(1b)**		16.0	15.0
(*Z*,*Z*)-3,13–18:OAc **(1c)**		16.0	15.8
(*E*,*E*)-3,13–18:OAc **(1d)**		16.0	14.6
(*E*,*Z*)-3,13–18:OH **(2a)**		11.3	18.9
(*Z*,*E*)-3,13–18:OH **(2b)**		11.3	20.0
(*Z*,*Z*)-3,13–18:OH **(2c)**		11.3	20.9

Natural sex pheromone	Peak I	11.3	18.9
	Peak II	16.0	15.2

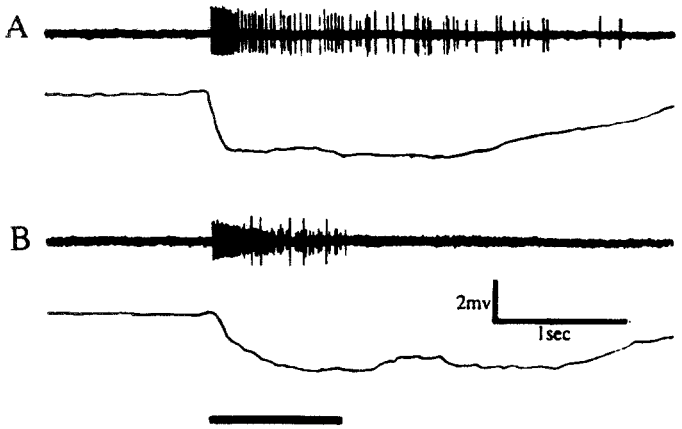

FIG. 1. Single cell recording.

sensitive to (*E*,*Z*)-3,13-18:OAc **(1a)** (Figure 1A); the other, producing smaller spikes, was reactive to (*Z*,*Z*)-3,13-18:OAc **(1c)** (Figure 1B). Each type of cell was specifically responsive and sensitive to a particular pheromone component. In general, the nerve impulses could be recorded by dosages of 0.01 μg.

The cells also responded to (*E*,*Z*)-3,13-18:OH **(2a)** and (*Z*,*Z*)-3,13-18:OH **(2c)** but exhibited lower responses than those to (*E*,*Z*)-3,13-18:OAc **(1a)** and (*Z*,*Z*)-3,13-18:OAc **(1c).** No response was observed to (*Z*,*E*)-3,13-18:OAc **(1b),** (*E*,*E*)-3,13-18:OAc **(1d),** (*Z*,*E*)-3,13-18:OH **(2b),** and (*E*,*E*)-3,13-18:OH **(2d).**

CONCLUSION

The data obtained from GC analysis field bioassays, EAG survey, and SCR strongly suggest that (*E*,*Z*)-3,13-18:OAc **(1a)** is the major sex pheromone component of the mulberry clearwing moth, *Paradoxecia pieli* L., and that (*E*,*Z*)-3,13-18:OH **(2a)** also was found in the pheromone gland. **1a** and **2a** averaged 250 ng and 30 ng, respectively, in each of the sex pheromone glands (1 FE). In the field test, only **1a** was attractive to male moths. This compound has been used for monitoring populations of this insect since 1985. The addition of **2a** to **1a** did not increase significantly captures of male mulberry clearwing moths. The behavioral function of **2a** has not yet been established. SCR investigation showed clearly that each sensilla trichodeum contained two kinds of receptor cells. One kind responded to (*E*,*Z*)-3,13-18:OAc **(1a)** and produced the larger spikes; the other was sensitive to (*Z*,*Z*)-3,13-18:OAc **(1c)** and released the smaller spikes. Further work is needed to understand the reason for the receptor

cells' response to (Z,Z)-3,13-18:OAc **(1c)**, which was not found in the sex pheromone gland.

(Received September 16, 1991; accepted November 4, 1991)

Abstract—The olfactory receptor neurons in basiconic sensilla on the antennae of *Utetheisa ornatrix*, which, in females, had earlier been shown to be responsive to stimulation with hydroxydanaidal (HD), are here shown to be responsive to volatile substances in samples of pyrrolizidine alkaloids (PAs). These latter substances are secondary plant metabolites present in the host plant of the larvae. Their sequestration during larval life serves to protect all life stages from predation. In males, the PAs also provide precursors for the production of the male pheromone, HD. In females, basiconic receptor neurons begin to respond to stimulus cartridges containing 1 ng of (*R*)-(−)-hydroxydanaidal, 100 ng of its isomer, (*S*)-(+)-hydroxydanaidal, and to volatiles emanating from 10 μg of the alkaloids monocrotaline and heliotrine. Receptor neurons in males are generally responsive to the same array of substances but with reduced sensitivity. The dietary background of the adult moths with respect to prior ingestion of PAs does not influence the response capabilities of basiconic receptor neurons to HD or to the volatile components of PAs. Earlier studies in another arctiid (*Rhodogastria*), had indicated that trace amounts of HD are present in PAs, presumably as their hydrolysis product. Thus we assume that, under natural conditions, HD may be an active component of the volatiles from PAs and may serve as both a male pheromone and a kairomone. Sensitivity to HD could thereby provide information about the location and PA content of potential mates and food plants. Mechanisms that may have resulted in the evolution of a signaling system with these properties are discussed.

INTRODUCTION

Pyrrolizidine alkaloids (PAs) play a central role in the natural history of a number of insects including *Utetheisa ornatrix* (Linnaeus). Female moths of this species oviposit exclusively on host plants of *Crotalaria* spp. (Leguminosae; cf. Eisner and Meinwald, 1987). These plants are known to be protected from general herbivory by their content of poisonous PAs (Mattocks, 1968). *Utetheisa* larvae compete for and ingest preferentially those portions of the plant that contain elevated amounts of PAs. The alkaloids thus sequestered are carried forward into the adults and the eggs of the next generation. At each of these stages, the sequestered alkaloids protect the animal from predation (cf. Eisner and Meinwald, 1987). The PAs ingested as larvae also influence the sexual life of these moths, especially males, where these chemicals provide the precursors for the production of hydroxydanaidal (HD), the male pheromone (Conner et al., 1981, 1990). In the absence of sequestered alkaloid, males fail to produce their pheromone and are less acceptable to females. The amount of HD produced by the male pheromone gland is directly proportional to the alkaloid content of the male (Conner et al., 1990). Thus, the amount of HD released from the male coremata could offer the female a direct measure of each male's sequestered alkaloid (cf. Conner et al., 1981) and an indirect measure of the prospective alkaloid gift to be obtained in the transfer of the spermatophore (Dussourd et al., 1988). Female *Utetheisa* moths possess a specialized antennal olfactory receptor neuron in basiconic sensilla responsive to the volatiles from nanogram amounts of HD (Grant et al., 1989).

In addition to its role as an actively synthesized male pheromone, HD may also modulate other communicative functions in certain insects. For example, hydrolysis of the alkaloid monocrotaline results in the production of trace amounts of HD, which can serve as a more volatile marker for the presence of PAs in plants and animals. In a series of electrophysiological and thin-layer chromatographic experiments (Bogner, 1987; Bogner and Boppré, 1989), traces of HD were reported in alkaloid sources that were stimulative in certain PA-pharmacophagous Lepidoptera such as *Rhodogastria* (Arctiidae), *Euchromia* (Ctenuchiidae), and *Danaus* (subfamily, Danainae). These species find sources of PAs attractive over long distances but do not appear to possess olfactory receptor neurons specifically responsive to stimulation with small doses (1 μg) of alkaloid (Bogner and Boppré, 1989). However, these species do possess specific olfactory receptor neurons that respond to the volatiles from sources containing large

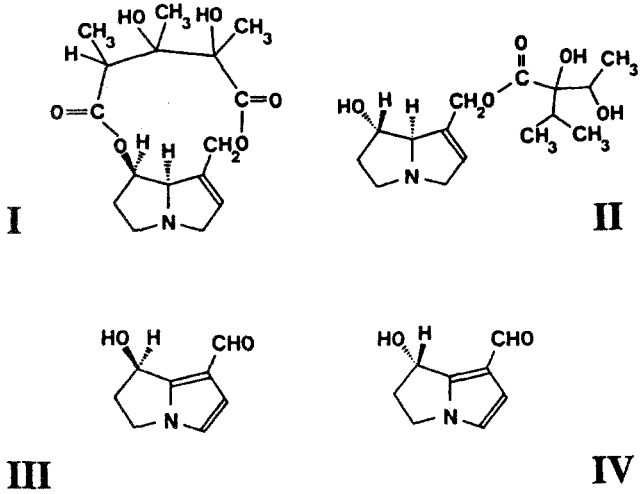
doses (10 μg) of PAs and to authentic samples of HD (10 ng) even though there is no evidence, in these species, for an HD-based male pheromone system (Boppré, 1990). Thus, it was postulated that these species are able to detect and locate sources of alkaloids by virtue of their ability to detect small amounts of the more volatile HD that may normally be present in natural sources of PAs.

Hydroxydanaidal may thus fulfill multiple functions in the life of *Utetheisa*. In addition to its direct role as a male pheromone and, thereby, an indicator of an adult male's alkaloid load, HD may also serve as a volatile marker for the presence of PAs in plants and other organisms. Consequently, we decided to expand on the concepts developed for *Rhodogastria* (Bogner and Boppré, 1989; Boppré, 1990), by using the demonstrated sensitivity of olfactory receptor neurons in female *Utetheisa* sensilla basiconica to stimulation with HD, as a bioassay for the potential presence of HD in alkaloids. Specifically, we asked four questions: (1) Do these receptor neurons respond to the volatiles emanating from mg doses of alkaloids? (2) If so, does this sensitivity depend on the moth's dietary background of ingested alkaloid? (3) How sensitive are these receptor neurons to the two stereoisomers of HD? and (4) Do male *Utetheisa* have a comparable sensitivity to the volatile components of PAs?

METHODS AND MATERIALS

Animals. The animals used in the present investigation were from a laboratory culture of *Utetheisa ornatrix*, established with stock taken from Highlands County, Florida. Voucher specimens (lot 1154) are deposited in the Cornell University insect collection. The moths were reared on two diets: (1) a pinto bean (PB) diet devoid of pyrrolizidine alkaloids (Miller et al., 1976), and (2) a modified PB diet containing 10% (by weight) dried, ground *Crotalaria spectabilis* seeds (CS diet). *C. spectabilis*, one of the principal food-plants of *Utetheisa* in the southeastern United States, contains the pyrrolizidine alkaloid monocrotaline, largely in its seeds (Johnson et al., 1985).

Stimuli. The stimuli evaluated included the volatiles swept out of odor cartridges containing: the PAs—monocrotaline (I), heliotrine (II), and monocrotaline-*N*-oxide; and the male pheromones—danaidone and the two stereoisomers of hydroxydanaidal, (*R*)-(−)-hydroxydanaidal (III), and (*S*)-(+)-hydroxydanaidal (IV) (Scheme 1). All of the stimuli were obtained from sources detailed by Bogner and Boppré, (1989). Heliotrine is not reported in either of the primary food plants of *Utetheisa* in the United States (*C. spectabilis*, *C. mucronata*) but is known to be present in other plant sources (Mattocks, 1968). All samples were diluted in spectrophotometric grade methylene chloride except for monocrotaline-*N*-oxide, which was dissolved in glass-distilled water. Aliquots of these solutions (5–50 μl) were pipetted onto filter-paper strips housed



SCHEME 1. Formula of the stimuli: monocrotaline (I); heliotrine (II); (*R*)-(−)-hydroxydanaidal (III); and (*S*)-(+)-hydroxydanaidal (IV).

in small odor cartridges (Grant et al., 1989). Control cartridges contained equivalent amounts of the appropriate solvent. The purity of individual stimuli was preserved by sealing the odor cartridges between experiments and storing them in individual glass vials held at 4°C in an opaque container purged with dry N_2 to retard oxidation and hydrolysis. Stimuli were brought to room temperature (22°C) several hours before use. The stimulus quantities stated herein indicate the total amount of material loaded into the odor cartridges and not the amounts that actually reach the olfactory receptor neurons.

Stimulation. A purge stream of purified air continuously bathed the preparation between stimulations. During stimulation, this purge stream was diverted away from the preparation and a stream of dry, O_2-free N_2 was directed through the stimulus cartridge and over the preparation. The outlets of the purge stream and the stimulus cartridge were positioned on opposite sides of the antenna, with the outlet of the stimulus cartridge approximately 6 mm from the antenna. The timing of the stimulus was controlled by computer, which simultaneously activated Teflon solenoid valves in both the purge and stimulus streams.

Recording. The procedures for electrode manufacture, as well as signal amplification, discrimination and storage, have been described previously (Grant et al., 1988, 1989). Briefly, adult animals (2–6 days old) were immobilized with wax and fixed to the stage of a microscope so that an electrolytically sharpened tungsten microelectrode (indifferent electrode) could be inserted into the lumen of a flagellar subsegment near the tip of the antenna. A second microelectrode (recording electrode) was then inserted at the base of a single

sensillum on a more proximal subsegment. Electrical signals were amplified and sent to an oscilloscope and to a microcomputer for data acquisition, analysis, and storage (O'Connell et al., 1973). Twenty seconds of neural activity were recorded for each stimulus presentation, including 10 sec of prestimulus activity, 2 sec of activity during the stimulus pulse, and 8 sec of poststimulus activity. Response values are expressed here as the rate of impulse activity (impulses per second) during the 2-sec stimulus pulse. Whenever mean response values are given, the standard error of the mean is also reported (mean $\pm$ SEM). Interstimulus periods typically ranged from 3 to 10 min, depending on the intensity of the preceding response. When multiple doses of a compound were evaluated, they were always presented in order of increasing concentration.

RESULTS

Extracellular recordings from basiconic sensilla on the antennae of both sexes usually (55%, $N = 66$) revealed the electrical activity of two receptor neurons. As demonstrated earlier, the neuron producing the smaller-amplitude action potential (the B neuron) fired infrequently, failed to respond to any of the stimuli evaluated, and therefore was not considered further in this analysis (Grant et al., 1989). This series of recordings was obtained from 23 basiconic receptor neurons sampled from each of 10 males and 13 females. Seven of the animals of each sex were raised on CS diet, the remainder on PB diet. The average spontaneous activity of the neuron producing the larger amplitude action potential (the A neuron) was 2.9 $\pm$ 0.8 impulses/sec (mean $\pm$ SEM) in females (Figure 1A) and 1.2 $\pm$ 0.4 in males. These values are comparable to those reported earlier in females (Grant et al., 1989).

The A receptor neuron is responsive to the volatiles from small amounts ($\geq$ 1 ng) of the active (*R*)-(−) isomer of HD (Figure 1D and F), larger amounts ($\geq$ 100 ng) of the (*S*)-(+) isomer (Figure 1E), and to those emanating from stimulus cartridges containing elevated doses ($\geq$ 1 μg) of the alkaloids monocrotaline and heliotrine (Figure 1B and C). The average dose–response functions for receptor neurons stimulated with the volatile components of the two alkaloids are shown in Figure 2 for females (Figure 2A) and males (Figure 2B). The average response threshold for these alkaloids was ~1 μg for females and ~10 μg for males. The volatile stimuli from cartridges containing monocrotaline were more effective than those from cartridges containing heliotrine. For example, in females, cartridges containing 1 mg monocrotaline elicited an average of 28.2 $\pm$ 2.2 impulses/sec whereas a cartridge containing 1 mg of heliotrine elicited an average of 12.8 $\pm$ 2.1 impulses/sec. These data also indicate that male receptor neurons are slightly less responsive to these stimuli (e.g., 1 mg of monocrotaline = 21.0 $\pm$ 3.2, and 1 mg of heliotrine = 6.3 $\pm$ 1.7 impulses/

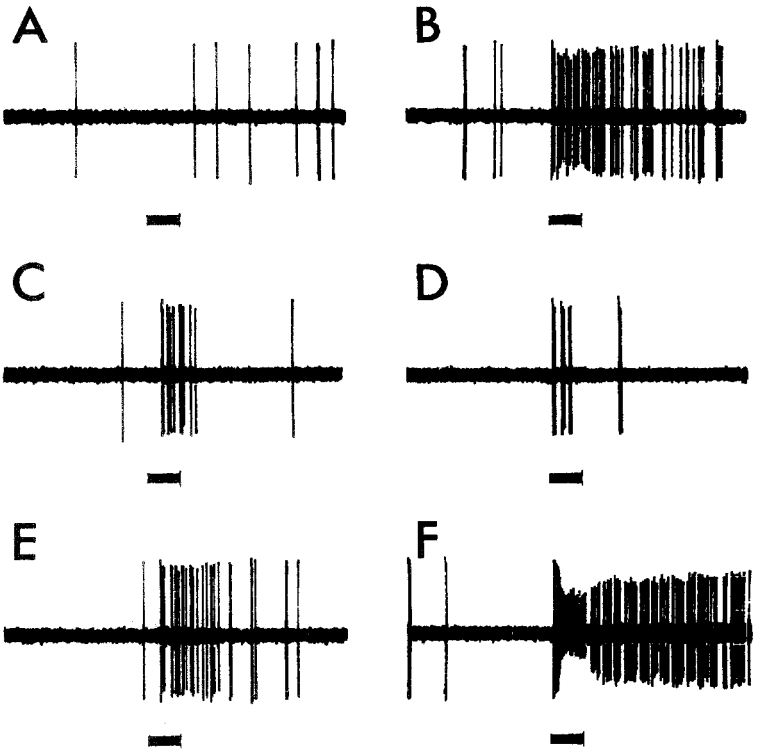


FIG. 1. Extracellular recordings from an antennal basiconic receptor neuron of a female *Utetheisa ornatrix* raised on alkaloid free diet. Each trace represents ~20 sec of electrical activity. The responses illustrated were elicited by odor cartridges containing: a solvent control (A); 1 mg monocrotaline (B); 1 mg heliotrine (C); 10 ng (*R*)-(−)-hydroxydanaidal (D); 1 μg (*S*)-(+)-hydroxydanaidal (E); and 1 μg (*R*)-(−)-hydroxydanaidal (F). The stimulus markers under each trace indicated the timing and duration of the 2-sec stimulus pulse.

sec) than are those of females. This sexual dimorphism extends to other substances including (*R*)-(−)-HD (100 ng = 15.8 ± 2.2 in males vs. 28.6 ± 3.5 impulses/sec in females) and (*S*)-(+)-HD (10 μg = 18.1 ± 2.1 in males vs. 30.2 ± 2.7 impulses/sec in females). The average responses of female receptor neurons to large amounts (1 mg) of monocrotaline-*N*-oxide, a precursor of HD, were slight (8.2 ± 3.4 impulses/sec), as was the average response (7.5 ± 2.5 impulses/sec) elicited by stimulation with a cartridge containing 1 μg of danaidone, a male pheromone of another species that is chemically similar to HD (Boppré, 1986).

The dietary background of adults did not reliably alter the responses of

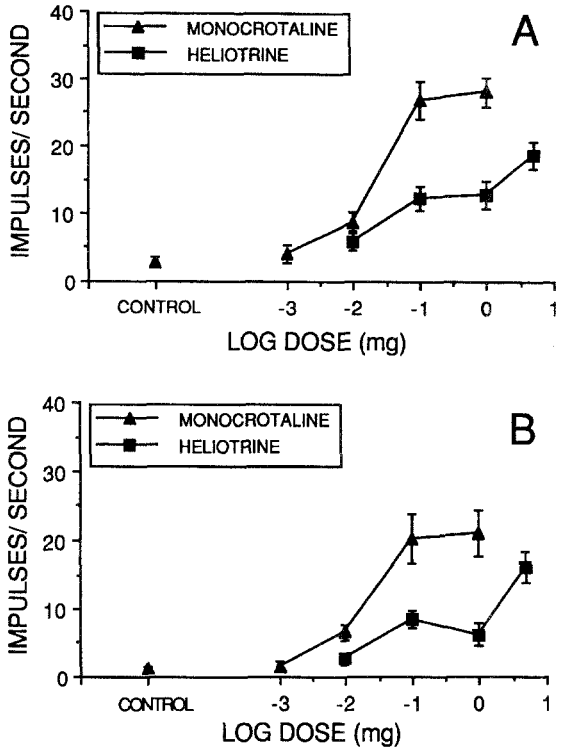

FIG. 2. Mean dose–response functions (±SEM) of antennal basiconic receptor neurons of female (A) and male (B) *Utetheisa* to stimulation with the volatiles from cartridges containing the indicated amounts of monocrotaline or heliotrine.

basiconic receptor neurons to the volatiles from PAs. Figure 3 contrasts the average dose–response function elicited by cartridges containing various doses of monocrotaline in adult females whose larvae had fed on a PA-free diet with those obtained from females whose larvae had fed on a diet containing PAs. For example, stimulation with a cartridge containing 10 μg monocrotaline elicited an average of 7.2 $\pm$ 2.4 impulses/sec in animals raised on CS diet vs. 10.8 $\pm$ 1.2 impulses/sec in those raised on PB diet. Similar data were also observed in response to stimulation with the volatiles from cartridges containing heliotrine (10 μg heliotrine = 5.1 $\pm$ 1.9 with CS diet vs. 6.9 $\pm$ 1.3 impulses/sec with PB diet). Over the range of doses and substances evaluated, systematic differences were not observed in the responses of animals, raised on diets with or without sequestered PAs, to stimulation with cartridges containing alkaloids. Similar results had been obtained earlier during an evaluation of female basiconic receptor neurons' sensitivity to stimulation with HD (Grant et al., 1989).

The differential sensitivity of basiconic receptor neurons to PAs illustrated in Figure 2 suggests that a comparable difference in sensitivity should be observed to the two isomers of HD that are the likely by-products of the hydrolysis of the alkaloids. Figure 4 details the average dose–response functions of female receptor neurons to stimulation with cartridges containing various doses of (*R*)-(−)-HD and (*S*)-(+)-HD. As expected from earlier studies, the average response threshold for (*R*)-(−)-HD was ~1 ng (3.3 ± 0.8 impulses/sec). The compa-

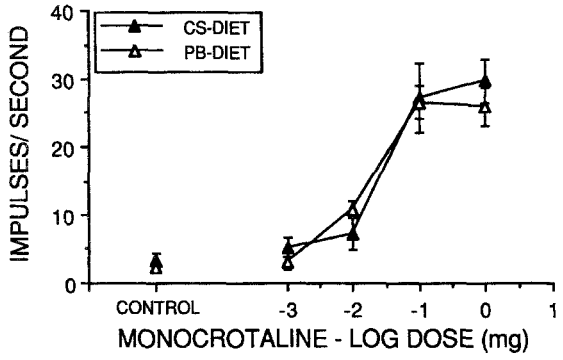

FIG. 3. Mean dose–response functions (±SEM) of antennal basiconic receptor neurons of female *Utetheisa* to stimulation with the volatiles from cartridges containing the indicated amounts of monocrotaline. The responses of adults that had been raised on larval diets containing alkaloid (CS-diet) are contrasted with those raised on alkaloid-free diet (PB-diet).

rable threshold for (*S*)-(+)-HD was about two orders of magnitude higher (100 ng = 7.0 ± 2.4 impulses/sec).

DISCUSSION

The olfactory receptor neurons of basiconic sensilla on the antennae of female *Utetheisa ornatrix*, which had earlier been shown to be responsive to the male-produced pheromone HD (Grant et al., 1989), are also responsive to the volatiles emanating from cartridges dosed with PAs. The most parsimonious explanation for this observation involves the earlier demonstration (Bogner and Boppré, 1989) that HD is a volatile trace component in samples of PAs. Alkaloids are thought to contain, as a natural breakdown product, trace amounts of HD which, in turn, functions as the volatile signal for the presence of PAs. The (*R*)-(−)-enantiomer of HD is thought to be the active volatile component in samples of monocrotaline and the (*S*)-(+)-enantiomer is thought to result from the hydrolysis of samples of heliotrine with the appropriate configuration at the C-7 position. Thus, it was suggested that those receptor neurons, which appeared to be responsive to pyrrolizidine alkaloids in *Rhodogastria* were, in fact, responsive to the trace amounts of HD found in the PA samples, even though HD is not a natural component of the male pheromone system in this animal (Bogner and Boppré, 1989; Boppré, 1990).

This hypothesis was approached here with quantitative electrophysiological techniques using an animal (*Utetheisa ornatrix*) that has a male pheromone system involving male production and female sensitivity to HD and that engages in a vigorous competition for sources of PAs. The findings detailed in Figures 2A and 4 reveal that there are rather large differences in the absolute amounts of each material required to elicit a specified level of activity in female receptor neurons. For example, an average response of 15 impulses/sec would be expected from stimulation with cartridges containing approximately 10 ng of (*R*)-(−)-HD; 1 μg of (*S*)-(+)-HD; 20 μg of monocrotaline; and 2 mg of heliotrine. Thus, there is roughly a 2000-fold difference in the sensitivity of these receptor neurons to stimulation with each of the parent alkaloids when compared to the responses elicited by their hydrolytic by-products. There is also roughly a 100-fold difference in the sensitivity of these receptor neurons to stimulation with either the two isomers of HD (Figure 4) or with the two alkaloids (Figure 2A). These observations are all consistent with the hypothesis that these receptor neurons are differentially responsive to the two isomers of HD and that the two PAs each contain ~0.05% of the expected isomer of HD. A comparison of the semilogarithmic plots of the average dose–response functions observed in female receptor neurons shows comparable slopes to these materials and thus lends support to the notion that the PA samples contain isomers of HD. The slopes

for the two isomers of HD (Figure 4) were; (*R*)-(−)-HD = 12.2 impulses/sec/log dose (mg), and (*S*)-(+)-HD = 12.2 impulses/sec/log dose (mg). The slope of the function for monocrotaline (Figure 2A) was comparable [11.3 impulses/sec/log dose (mg)] to the slopes for the two HD isomers, consistent with the suggestion that the active material released from the alkaloid samples is HD. In contrast, the slope of the heliotrine dose–response function was considerably less [4.6 impulses/sec/log dose (mg)]. This latter fact may suggest that heliotrine naturally contains other substances that are less effective stimuli for these receptor neurons. It is also possible that the rate of release of active material from the heliotrine cartridge was reduced by one or another of the materials contained in the sample. This latter explanation may also account for the observation that the dose–response functions for the alkaloids (Figure 2A) are sigmoidal, with smaller increases in activity at elevated doses. In this case, it may be that the surface area available in the cartridge for stimulus release may be exhausted at alkaloid loads above ~1 mg.

An equally likely variant of these arguments, which will account for the observed pattern of sensitivity, involves the fact that danaidone, monocrotaline-*N*-oxide, and all four of the compounds detailed in Scheme 1 share nearly identical amino-alcohol moieties. This leaves open the possibility that all of the responses observed in basiconic receptor neurons actually reflect the differential avidity of a common odor binding site for the several variants of this common functional group (Eisner, personal communication). Resolution of these various alternatives awaits the development of biophysical and biochemical techniques with sufficient sensitivity and resolution to provide a direct evaluation of the odor binding events initiated by these stimuli at the dendritic membrane of basiconic receptor neurons.

The alkaloid content of the larval diet does not influence the sensitivity of the adult receptor neurons in females to stimulation with HD (Grant et al., 1989) or with the volatiles from cartridges containing PAs (Figure 3). A similar conclusion can be reached in evaluating the responses, observed in males raised on either diet, to stimulation with cartridges containing PAs (data not shown). This lack of a dependence on alkaloid in the diet ensures that both male and female adults have basiconic receptor neurons whose capabilities provide the ability to detect the volatile signals associated with PAs. HD thus, may fulfill a dual function in *Utetheisa*. On the one hand, it is an actively produced male pheromone and, on the other, a volatile signal that may act as a kairomone indicating the presence and location of desirable secondary plant substances. The differential sensitivity of basiconic receptor neurons to these materials (~2000-fold) also provides an amplification mechanism that allows receptor neurons responsive to the volatiles from nanogram amounts of HD to provide information on sources containing milligram amounts of relatively nonvolatile PAs. Pheromone-sensitive receptor neurons are normally housed in trichoid sensilla (Cuperus,

1985), whereas receptor neurons sensitive to other odors are normally housed in basiconic sensilla (Kaissling, 1971). Therefore, a receptor neuron responsive to a male pheromone (HD) in female basiconic sensilla is unusual at first glance (Grant et al., 1989). However, this location may be explicable in an evolutionary context, since the same stimulatory substance functions as a potential kairomone to mark the presence and location of PAs, which, in turn, are important substances in the natural history of the animal. In females, HD has a dual importance both as a volatile marker for PAs in host plants and as a sexual signal for selecting males with large amounts of PAs. Even though adult male *Utetheisa* do not appear to imbibe PAs (Eisner and Meinwald, 1987) or to engage in lek-building (c.f. Boppré, 1986), males could gain a competitive advantage with the ability to detect the volatile signals associated with locales containing PAs, simply because of the greater likelihood of encountering females.

The general utility of PAs and the importance of the volatile signals associated with them may suggest a common link in the evolution of the pheromone production and perceptual systems in this animal. For example, HD may have initially signaled the presence of PAs in plants and males could have begun to synthesize and emit this material from the alkaloid they sequestered, allowing those females with sensitivity to HD to determine both the location of food plants containing PAs and the location and relative fitness of males seeking mates. Moreover, the relative differences observed in the sensitivity of male and female receptor neurons suggests that there are differences in the selective pressures brought to bear on the sexes. In general, this evolutionary supposition is supported by the observations that: (1) male *Utetheisa* receptor neurons are responsive to their own pheromone; (2) these receptor neurons are found in basiconic sensilla instead of in trichoid sensilla where "typical" pheromone receptor neurons are normally expected; and (3) the receptor neurons may function as a potential kairomone detector with a reasonable degree of stereospecificity and an absolute sensitivity for only a selected subset of the available volatile by-products of PAs.

If HD actually functions as a kairomone for *Utetheisa ornatrix*, one may wonder how the disparate messages conveyed by this substance are encoded. Apparently HD could stem from male androconical brushes or any plant containing large amounts of PAs (Boppré, 1990). In other species these two "messages" are unambiguously signaled by two different chemicals and are received by two different receptor neuron types (e.g., *Danainae*, Bogner and Boppré, 1989). It is unlikely, in any species, that the complex behaviors triggered by mating partners and food sources are dependent on a single set or modality of sensory inputs, although baiting experiments of others (Krasnoff and Dussourd, 1989) with HD-containing coremata suggest that there are certain similarities in both courtship and host-plant selection behaviors in other species. However, we have no real evidence or explanation for a segregation of these behaviors in

nature. At this time we cannot fully explain why *Utetheisa* should have come to rely on only one sensory receptor neuron for all of these important odor-guided behaviors. We do see these observations as a promising step in the exploration of the mechanisms responsible for the evolution of the receptor neuron specificities currently seen in *Arctiidae*.

(Received May 24, 1991; accepted November 4, 1991)

Abstract—A multicomponent pheromone produced by male cabbage looper moths that is attractive to female moths in a flight tunnel bioassay was isolated and identified. Based on analyses of hairpencil extracts of male cabbage loopers and volatiles emitted by males, the pheromone has been identified as a blend consisting of (*S*)-(+)-linalool, *p*-cresol, and *m*-cresol. The chirality of the major component, (*S*)-(+)-linalool, is important for behavioral response of females. These pheromonal compounds were also identified as volatiles released by males when males were exposed to the principal pheromone component of female cabbage loopers, (*Z*)-7-dodecen-1-ol acetate. The amount of male pheromone released was increased significantly when males were exposed to a combination of (*Z*)-7-dodecen-1-ol acetate and the odor from cabbage. Neither linalool nor the cresols were detected in volatiles from cabbage or from males exposed to cabbage odor.

Key Words—Male-produced pheromone, cabbage looper, *Trichoplusia ni*, Lepidoptera, Noctuidae, female attractant, linalool, *p*-cresol, *m*-cresol, enantiomers.

INTRODUCTION

Considerable research has been focused on female-produced sex pheromones of lepidopteran insects. The number of female sex attractants reported in the literature is in excess of 1700 (Mayer and McLaughlin, 1990). Male-produced sex attractants are less common in insects (Thornhill and Alcock, 1983) and unusual in Lepidoptera. In a review of male pheromones in Lepidoptera, Birch

*To whom correspondence should be addressed.

and Hefetz (1987) listed six species in which female attraction to male pheromones is known. There are now four reports of female flight attraction responses to males: the arctiids *Estigmene acrea* (Drury) (Willis and Birch, 1982) and possibly *Creatonotos transiens* (Walker) and *C. ganges* (L.) (Wunderer et al., 1986) and the cabbage looper *Trichoplusia ni* (Hübner) (Landolt and Heath, 1990). Female behavior often associated with the release of male-produced pheromones includes mate acceptance and occurs only at close range (Birch 1974).

Male cabbage loopers produce volatile compounds that may influence female behavior in attraction and courtship interactions. An electrophysiological response of female cabbage loopers to material extracted from male hairpencils was reported by Grant (1970). In subsequent investigations Grant (1971) and Grant and Brady (1973) speculated on the possible function of chemicals associated with hairpencils and brushes of the male cabbage looper. Jacobson et al. (1976) reported the identification of 2-phenylethanol in male cabbage looper hairpencils and a wing flutter response by females to hairpencil extracts and to 2-phenylethanol. These findings were contradicted by Hagan and Brady (1981), who were unable to find 2-phenylethanol in male cabbage loopers. Gothilf and Shorey (1976), however, were unable to demonstrate a male scent brush role in mating success of this species.

Based on reports of female catches in traps baited with female sex pheromone (Mitchell et al., 1972; Creighton et al., 1973; Birch, 1977), Birch (1977) suggested that females may have responded to chemicals released by males at the trap rather than to the female pheromone used as the trap lure. Recently, Landolt and Heath (1989, 1990) demonstrated attraction of unmated females to live males, extracts of males, and extracts of male hairpencils in flight-tunnel experiments.

We report here the isolation and identification of a multicomponent male cabbage looper pheromone attractive to females in a flight-tunnel bioassay. The release of these identified pheromone components by males exposed to female sex pheromone also was demonstrated, and the release rate and ratio of pheromone components from stimulated males were determined.

MATERIALS AND METHODS

Insects and Bioassays. All moths used were reared as larvae on artificial diet according to the procedures reported by Guy et al. (1985). Pupae were sorted by sex and placed in 22 × 22 × 22-cm aluminum and fiberglass screen cages. Cages of pupae and emerged moths were held in environmental chambers on a 14:10 light–dark cycle, at 25 ± 1°C and 60 ± 10% relative humidity. Pupae were transferred daily to new cages, providing emerged moths of discrete

age groups. Moths were held with cups of a sugar–honey solution on cotton as food.

Bioassays were conducted during the fifth to seventh hour of the 10-hr scotophase in a Plexiglas flight tunnel constructed as a 1 × 1 × 2-m box, with air drawn through by a fan at 0.22 m/sec. Lures were hung from a wire loop near the center of the upwind end of the tunnel and moths were released singly from a 20-ml polystyrene vial with a screen bottom and open top hung horizontally from a clamp on a ring stand near the center of the downwind end of the flight tunnel. Observations were aided by overhead red lights at <1 footcandles. Virgin female moths 4–6 days old were placed in the flight tunnel chamber 1–3 hr before bioassays to allow adjustment to the conditions in the chamber. All bioassays consisted of a 2-min observation period following the release of a single moth. Test material was applied to 5.5-cm-diam. filter papers and was air dried in the tunnel for 60 sec before testing. Generally, five moths were tested sequentially per test sample. Responses scored included flight, anemotactic (upwind) flight, plume tracking (zig-zagging upwind flight within the apparent odor plume), and contact. Five females were also released sequentially to solvent treated filter paper at the upwind end and observed for 2 min each, as controls.

Hairpencil Extracts and Collection of Volatiles. Extracts of male hairpencils were prepared by removing the terminal large paired abdominal hairpencils with forceps and placing them in a vial of hexane. Hairpencils from 50 males were accumulated in 2 ml of hexane. The hexane extract was pipetted to a clean vial after 20 min and concentrated when necessary under a stream of N_2.

A modified push–pull system (Landolt and Heath, 1987) was used to collect volatiles emitted by 3- to 6-day-old males. A schematic of the system is shown

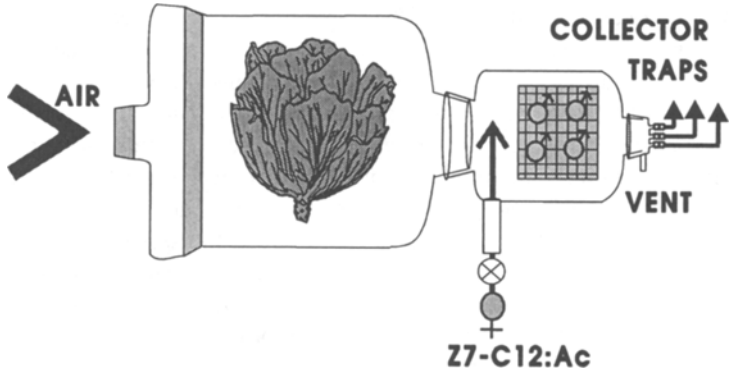

FIG. 1. Schematic of system used to collect volatiles from male cabbage loopers, suspected male stimulants, and combination of males and stimulants.

in Figure 1. Briefly, compressed air, purified by passing through two charcoal filters, was separated into two airstreams. One of these streams was saturated with water by passage through a water-filled gas dispersion cylinder. The two airstreams were recombined to provide an adjusted relative humidity of 60–65%. This purified and humidified air was introduced into a glass chamber(s) that contained a frit near the upwind end of the chamber and provided a laminar airflow. Volatiles were collected on one of three collector traps positioned at the downwind end of the chambers, any one of which could be selected for volatile collection. Vent flow was monitored with a meter from a vent in the chamber, and the vent flow was maintained at 2% of the airflow through the filter. Airflow was maintained at 1 liter/min with a slight positive pressure (+0.2 cm H_2O) established in the glass chamber(s). Pressure drop in the chamber(s) due to the collector trap was reduced to near zero by the use of vacuum downwind of the collector filter. This system was used to collect volatiles from males exposed to airflow passed over a cabbage plant, from males exposed to airflow containing (*Z*)-7 dodecen-1-ol acetate (Z7–12 : Ac), from males exposed to airflow passed over a cabbage plant and Z7–12 : Ac, from airflow over cabbage plants, and from airflow containing Z7–12 : Ac released from a rubber septum loaded with 10 μg of the acetate.

Collections were made using a 10-cm-OD × 30-cm-long glass chamber, which held the cabbage, or a 5-cm-OD × 30-cm-long chamber, which contained five moths. The smaller chamber contained a port that permitted the introduction of Z7–12 : Ac upwind of the males, via ground glass joints, and the chamber that housed the cabbage could be coupled in series with the chamber containing the insects.

Volatiles were collected on traps using Super-Q as the adsorbent. Super-Q traps were prepared by packing ca. 20 mg of the adsorbent in 4-cm-long × 4.0-mm-ID glass tubes resulting in a bed length of 5 mm. Two stainless-steel frits were used to contain the adsorbent. The Super-Q traps were cleaned by Soxhlet extraction with methylene chloride for 24 hr prior to use. Volatiles collected on the traps were eluted with 200 μl of methylene chloride and then 50 ng of tridecan-1-ol acetate was added as internal standard for subsequent analyses.

Isolation and Analysis of Pheromone. Capillary gas chromatography was done using a retention gap column prior to the capillary column. This system permitted the injection of samples without concentration in 5–100 μl of solvent. A combination of three fused silica columns connected in series using Glassseal connectors (Supelco Inc., Bellefonte, Pennsylvania) were used. The primary deactivated fused silica column, 8 cm × 0.5 mm ID, was connected between the injector and the retention gap column. This primary column permitted the use of 0.4-mm-OD stainless-steel needles with a septum injector. Selection of retention gap columns for use with the analytical column was determined by the

phase ratio of both columns (Grob, 1982; Murphy, 1989). For the purpose of this investigation the retention gap columns were 10-m × 0.25-mm-ID silane deactivated fused silica (Quadrex, New Haven, Connecticut). Analytical columns used for analyses were a 50-m × 0.25-mm-ID Supelcowax 10 (bonded Carbowax), a 50-m × 0.25-mm-ID bonded BP-1 and a 25-m × 0.25-mm Chirasil-val (Chrompak, Raritan, New Jersey). A 15-m × 0.53-mm-ID, 1.0-μm film Carbowax fused silica column (Quadrex) was used for micropreparative purification of hairpencil extracts, extracts of coriander seeds, and candidate synthetics.

Gas chromatographic analyses were conducted with a Hewlett-Packard model 5890 gas chromatograph, equipped with cool-on column capillary injector (septum injector) and flame ionization detector. Helium was used as the carrier gas at a linear flow of 18 cm/sec. The temperature program was isothermal at 60°C for 2 min, and then programmed at 20°/min to 160°C. The chromatographic data were stored and analyzed in a Nelson 4000 data system.

Initial micropreparative purification of hairpencil extracts on the 0.53-mm-ID capillary column resulted in the collection of three large fractions. Fraction 1 included the collection of compounds having an equivalent chain length unit (ECLU) (Swaboda, 1962) of heptan-1-ol acetate (ECLU = 700) to compounds eluting before nonan-1-ol acetate (ECLU = 900) (material collected from 6 to 14 min during GC run). Fraction 2 included compounds having an ECLU of 900–1400 (material collected from 18.2 to 20 min during GC run), and fraction 3 included compounds within the range of 1400–1800 (material collected from 20.2 to 30 min during GC run). Effluent from the column was split, with 2% of the effluent routed to the FID detector and 98% of the effluent collected in a cooled, 30-cm glass capillary tube. The capillary was contained in a temperature gradient collector similar to that described by Brownlee and Silverstein (1968) and liquid nitrogen was used to cool the capillary. Collected fractions were washed from the capillary using 200 μl of 1 : 1 hexane–ether. Fractions that were used in identifications were analyzed on the analytical columns described to ensure that the peak contained only one component. This same analytical method was used to further purify fractions of natural extracts, synthetics, and linalool from coriander seeds.

Identification of Male Pheromone. Mass spectra of active natural compounds and candidate compounds were obtained using the BP-1 column, operated as described above, coupled to a Nermag model R1010 mass spectrometer in either electron impact (EI-MS) or chemical ionization (CI-MS) mode. The reagent gas used for CI was either methane or isobutane. Vapor-phase infrared spectra were obtained with a Nicolet 20SXC GC-FTIR spectrometer. Samples were introduced to the FTIR spectrometer via a BP-1 column connected to the Hewlett-Packard model 5890 gas chromatograph equipped with cool-on column

capillary injector. Nuclear magnetic resonance spectra (^1H) were obtained with a Nicolet NT-300 (300 MHz) Fourier transform spectrometer using either $CDCl_3$ or C_6D_6 as the solvent and tetramethyl silane as an internal reference.

Reagents and Derivatization. The chirality of linalool (3,7-dimethyl-1,6-octadien-3-ol) was determined by formation of the diastereomeric 1-phenylethyl-urethanes with 1-phenylethyl-isocyanate (PEI) (Fluka Chemical Corp., Ronkonkoma, New York) diastereomers according to the method of Gaydou and Randriamiharisda (1987). The (*R*)-(+)- and (*S*)-(−)-PEI were used without purification. Approximately 200 ng of linalool isolated from male hairpencils, coriander, or synthetic racemic or (*R*)-(−)-linalool was dissolved in 20 μl of methylene chloride, to which approximately 1 μg of the (*R*)-(+)-PEI was added. After heating at 100°C for 1 hr, the sample was concentrated with dry N_2. The sample was redissolved in HPLC grade methanol (J.T. Baker) containing 100 ng of *n*-tetradecanol as the internal standard for GC analysis.

Racemic (Aldrich Chemical Corp., Milwaukee, Wisconsin) and (*R*)-(−)-linalool (K&K Laboratories, Cleveland, Ohio) were purified using preparative GC. (*S*)-(+)-linalool was obtained from coriander seeds (Harris Seeds, Rochester, New York). Seeds were crushed and then soaked in GC-grade methylene chloride over night. The concentrated residue was filtered and purified by preparative GC. Ortho-, meta-, and paracresol were purchased from Aldrich Chemicals and purified by preparative GC prior to use. Linalool from coriander seed and synthetic compounds used for bioassays were >98% purity based on GC analyses.

Synthetic pheromone components and blends were tested, using flight tunnel bioassays, for attractiveness to unmated female cabbage loopers and were compared to hairpencil extracts and solvent blanks. All materials tested were applied to 5.5-cm-diam. filter paper at dosages of 5 male equivalents (ca. 122.5 ng of linalool, 25.5 ng of *p*-cresol, and 3.5 ng of *m*-cresol) in hexane. A comparison (at amounts equal to 5 male equivalents) was conducted of attraction to: (1) racemic linalool, *p*-cresol, and *m*-cresol; (2) (*R*)-(−)-linalool, *p*-cresol, and *m*-cresol; (3) (*S*)-(+)-linalool, *p*-cresol, and *m*-cresol; and (4) hairpencil extracts from five males. Fifty females were tested per treatment, as 10 sets of five. Using a randomized complete block design, a complete treatment comparison of five females tested per treatment, covering all five treatments, was conducted per day for 10 days to provide the data set. In a second test, the following treatments were similarly compared: hexane (200 μl); *p*-cresol and *m*-cresol at 25.5 and 3.5 ng per aliquot; (*R*)-(−)-linalool at 122.5 ng per aliquot; the complete identified blend of (*R*)-(−)-linalool, *p*-cresol, and *m*-cresol at 122.5, 25.5, and 3.5 ng, respectively; and hairpencil extracts from five males.

Odors from cabbage plants, *Brassica oleraceae* (L), and Z7–12 : Ac loaded at 10 μg on rubber septa were tested as stimulants to elicit pheromone release from male cabbage loopers. Cabbage plants were grown in a greenhouse and

were 8–12 weeks old, 20–25 cm wide and 15–20 cm tall when used, with no head development. The Z7–12:Ac was purchased from Aldrich Chemicals and purified (>98% purity) prior to use by $AgNO_3$ high-performance liquid chromatography (Heath and Sonnet, 1980). Volatiles from males without stimuli, males exposed to cabbage odor, males exposed to Z7–12:Ac released from a rubber septum, and a combination of Z7–12:Ac and cabbage odor were collected and analyzed. Additionally, volatiles from the septum containing Z7–12:Ac and cabbage were analyzed.

Data on female bioassay response to fractions, isolates, synthetic, and linalool from coriander were subjected to ANOVA after arcsin transformation, with significant differences between treatment response means determined by Student's *t* test (Steel and Torrie, 1960) or Duncan's new multiple-range test (Duncan, 1955).

RESULTS

Response of female cabbage loopers in the flight tunnel to fraction 1 (material collected from 6 to 14 min during GC run), fraction 2 (material collected from 18.2 to 20 min during GC run), fraction 3 (material collected from 20.2 to 30 min during GC run), and combined fractions collected from the GC of male hairpencil extracts indicated that no loss in activity had occurred during chromatography (Table 1). Further testing of combinations of fractions indicated

that all activity was accounted for by fractions 1 and 3 (Table 1), containing three peaks eluting with equivalent chain lengths (Swaboda, 1962) of 838.50, 1434.77, and 1439.61 (designated A, B, and C in Figure 2). Chemical ionization mass spectra of peak A, in which methane was used as the reagent gas, established that the molecular weight of this compound was 154 with diagnostic ions at *m/e* 153 (M − 1) and 155 (M + 1). Diagnostic ions at *m/e* 135 (M + 1 − 18) suggested the loss of water from the parent molecule. Electron impact did not provide an ion indicative of the molecular weight of the compound. Based on this information, peak A was proposed to be a 10-carbon alcohol containing two degrees of unsaturation. Further analysis by infrared spectroscopy indicated an alcohol stretch at 3636 cm^{-1}, and a terminal methylene characterized by $C{=}CH_2$ stretch at 3090 cm^{-1}. Proton NMR spectra with decoupling experiments on ca. 4 μg of material provided the information for the identification of the compound as linalool based on the following spectral data: [^{1}H]NMR (C_6D_6) δ1.28 (s, 3 H), 1.51–1.65 (m, 3H), 1.68 (s, 3H), 1.96–2.11 (m, 2H), 5.07 (dd, 1H J = 1.9, 11.2 Hz), 5.08–5.17 (m, 1H), 5.21 (dd, 1H, J = 1.9, 16.9 Hz),

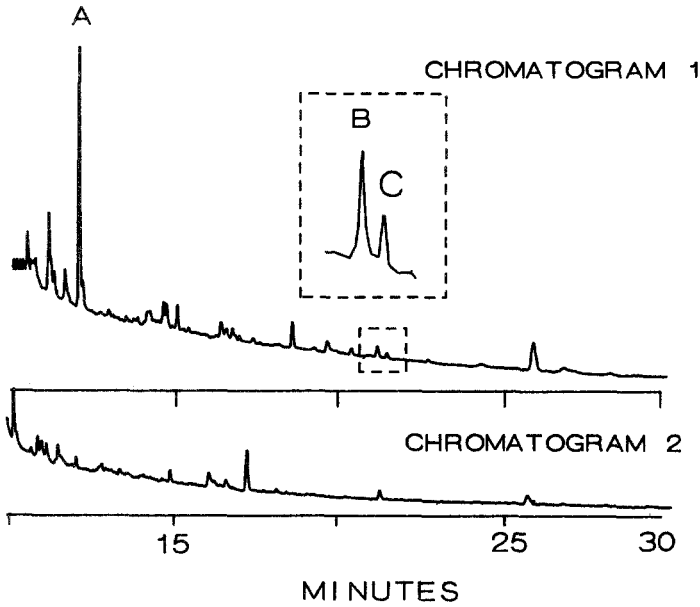

FIG. 2. Chromatograms of volatiles collected from males in the presence of Z7-12:Ac and cabbage odor (chromatogram 1) and volatiles from males in the presence of cabbage (chromatogram 2). Peak identification is A = linalool, B = *p*-cresol, and C = *m*-cresol. Gas chromatograph analysis was done on a 50-m × 0.25-mm-ID Supelcowax 10 column.

5.92 (dd, 1H, J = 11.2, 16.9 Hz). These data are in agreement with that reported for linalool by Ohwa et al. (1986).

Preliminary experiments using (*R*)-(+)- and (*S*)-(−)-1-phenylethyl isocyanate as the derivitizing agent indicated that the (*R*)-(+)-urethane derivative was enantiomerically more pure (97%) and provided greater separation factor then the (*S*)-(−) derivative. Thus, the chirality of isolated linalool was determined by formation of the (*R*)-(+)-1-phenylethyl urethane diastereomer of the natural linalool and comparison of its retention time with the linalool diastereomers of known configuration. The products were chromatographed on a Chiralsil-val column and coeluted with the diastereomer formed with the linalool obtained from coriander seeds, previously reported as (*S*)-(+)-linalool (Cornforth et al., 1962; Ohloff and Klein, 1962). The elution time of the diastereomer formed with the linalool from male hairpencils was 14.2 min compared with 14.2 min for the (*S*,*R*) diastereomer and 16.3 min for the (*R*,*R*) diastereomer.

Electron impact mass spectra of the smaller active peaks (B and C in Figure 2) found in the hairpencil extracts gave identical spectra. The molecular weight of these compounds were 108 with diagnostic ions at *m/e* 108 (M^+) and 107 ($M^+ - 1$). Diagnostic ions at *m/e* 90 ($M^+ - 18$) suggested the loss of water from the parent molecule. A computer search of the National Institute of Standards and Technology mass spectral library resulted in a significant match with the spectra of cresol. Confirmation of the identity of these two compounds was obtained by comparison of vapor-phase IR spectra of the natural product with synthetic material and GC retention time comparisons. Based on these analyses, compounds B and C were identified as para- and meta-cresol, respectively.

The average amount of (*S*)-(+)-linalool, *p*-cresol, and *m*-cresol found in male hairpencils was 24.5, 5.1, and 0.7 ng for each compound, respectively (Table 2). Wind-tunnel bioassays of the synthetic cresols and (*S*)-(+)-linalool obtained from coriander seeds resulted in comparable female response when compared to the hairpencil extracts (Table 3). Synthetic blends prepared using (*R*)-(−)-linalool and racemic linalool in combination with *p*- and *m*-cresols were significantly less attractive. In a comparison of a blend of the three components—(*S*)-(+)-linalool, *p*-cresol, and *m*-cresol—and hairpencil extracts, (*S*)-(+)-linalool alone and *p*- and *m*-cresol were significantly less attractive than the complete blend or extracts.

Having identified pheromonal components from male hairpencils that elicited positive behavioral responses of females, we investigated the emission of these compounds from males. Results of the GC analysis of the volatiles collected are shown in Table 2. The identified male-produced pheromonal components were found only in volatiles collected from males exposed to Z7-12:Ac. In a previous study (Landolt and Heath, 1990) we showed that males exposed to cabbage odor were much more attractive to females than were males alone or cabbage alone. Similar results were obtained with males exposed to

Z7-12:Ac, which were much more attractive to females than were unexposed males. We were unable to detect the presence of linalool or cresols in volatiles from males, cabbage, or males placed in the odor of cabbage (Table 2 and Figure 2). There was, however, an increase in the amount of pheromonal components released by males exposed to both cabbage and Z7-12:Ac compared

to males exposed to Z7-12:Ac alone (Table 2). It was also noted that less pheromonal material was obtained from volatiles collected from these stimulated males than was found in analyzed hairpencil extracts. This difference in amount is due to the experimental design. It is important to note however, that the active materials isolated from male hairpencils were emitted from stimulated males.

DISCUSSION

Our results demonstrate that unmated female cabbage looper moths are attracted to a blend of three components identified in the terminal genital hairpencils of conspecific males. Linalool, the major component of the pheromone blend, is ubiquitous in plants and is often the major component of essential oils (Masada, 1976). It occurs in both the dextrorotatory [(*S*)-(+)-linalool or coriandrol] and levorotatory [(*R*)-(−)-linalool or licerol] forms. Additionally, linalool has been reported as a chemical component involved in the attraction of many other insects. For example, it is reported as a component of the attractant of the carrot fly larva, *Psila rosae* (Ryan and Guerin, 1982), a component of a female attractant of the spined soldier bug, *Podisus maculiventris* (Aldrich et al., 1984), and a component of a synthetic blend that attracts eastern yellowjackets, *Vespula maculifrons* (Aldrich et al., 1986). The effect of the chirality of linalool on the response of the carrot fly larvae, spined soldier bug, and eastern yellowjackets has not been reported. The chirality of linalool is of significance to the behavioral response of female cabbage loopers to the male pheromone.

In addition to linalool, two cresols were found as components in the pheromonal blend attractive to female cabbage loopers. *p*-Cresol has been reported as a component of female pheromone of two hard ticks, *Rhipicephalus appendicalatus* and *R. pulchellus* (Wood et al., 1975) and as a component of an oviposition attractant of the tree-hole mosquito, *Aedes triseriatus* (Bentley et al., 1981). Bioassays conducted with the cresols were based on the ratio found either in hairpencil extracts or as collected volatiles. Studies are currently being conducted to determine the importance of the ratio of these components to the response of females to blends containing altered ratios.

We have also demonstrated that, in addition to the identification of (*S*)-(+)-linalool, *p*-cresol, and *m*-cresol in male hairpencils, these compounds are released by males when males are exposed to Z7-12:Ac, and the amount of pheromone released was increased when males were exposed to Z7-12:Ac and the odor from cabbage. Neither linalool nor the cresols were evident in volatiles from cabbage or unstimulated males in the presence of cabbage odor. This suggests that either these compounds are not responsible for previously reported female attraction to cabbage and increased attraction of females to males on cabbage or that they occur in amounts not detectable with the analytical methods employed in these experiments.

Although male pheromone in the cabbage looper may function as an aphrodisiac or have some other courtship role, under the conditions of our studies the hairpencil blend of (*S*)-(+)-linalool and *p*- and *m*-cresols attracts unmated females. Field studies will be required to fully determine the potential use of these compounds as a female attractant. Captures of female cabbage loopers in traps baited with *Z*7–12 : Ac reported by Mitchell et al. (1972), Creighton et al. (1973), and Birch (1977) may have been due to female attraction to (*S*)-(+)-linalool, *p*-cresol, and *m*-cresol in male hairpencils displayed at or in the traps.

ELEVATION IN TONGUE-FLICK RATE AFTER BITING PREY IN THE BROAD-HEADED SKINK, *Eumeces laticeps*

WILLIAM E. COOPER, JR.[1]

Department of Biological Sciences
Indiana University
Purdue University at Fort Wayne
Fort Wayne, Indiana 46805

(Received September 3, 1991; accepted November 6, 1991)

Abstract—A postbite elevation in tongue-flicking (PETF) rate occurs in adult male broad-headed skinks, *Eumeces laticeps*. Males having bitten neonatal mice showed significantly higher tongue-flicking rates in the 2 min following experimental removal of the prey than did males in several control conditions. In a second experiment designed to separate the effects of tactile and chemical stimulation of the oral cavity during biting, males tongue-flicked at significantly higher rates in response to swabs bearing surface chemicals from neonatal mice than to identical swabs lacking the surface chemicals. These findings agree with previous data showing that PETF and searching movements occur in those families of lizards that can detect prey chemicals and use the tongue to do so during active foraging. The occurrence of PETF and putative searching movements supports the interpretation that PETF represents an attempt to relocate lost prey by chemosensory means. PETF was much briefer in *E. laticeps* than in many snakes and in a representative species from another lizard family and was not detectable after the first minute. This brevity is consistent with the prediction that PETF should be brief in squamates that feed on prey not likely to be located by scent-trailing.

Key Words—Prey chemicals, tongue-flicking, feeding behavior, Sauria, Scincidae, *Eumeces laticeps*.

INTRODUCTION

Reliance on chemical cues sampled by tongue-flicking has been established in the broad-headed skink, *Eumeces laticeps*, for various ecologically important

functions. Pheromonal communication is highly developed in this species, allowing discrimination of conspecific lizards from heterospecific congeners (Cooper and Vitt, 1986a,b; 1987a,b; Cooper and Garstka, 1987), recognition of sex (Cooper and Vitt, 1984a,b, 1987c, 1989) and reproductive condition (Cooper et al., 1986), and location of reproductively active females by scent-trailing males (Cooper and Vitt, 1986c). Other important functions of tongue-flicking are detection and selective response to ophidian predators (Cooper and Vitt, 1990) and responses to prey.

Broad-headed skinks may rely heavily on the chemical senses in searching for cryptic prey (Vitt and Cooper, 1986). They are capable of detecting and responding selectively to integumentary prey chemicals (Cooper and Vitt, 1989). In comparison with responses to control chemicals, adult male *E. laticeps* that are presented with prey chemicals tongue-flick at higher rates. They are also more likely to bite cotton swabs on which the chemicals are presented than control swabs (Cooper and Vitt, 1989, 1990).

In this paper I report further investigation of chemosensory behavior related to feeding in *E. laticeps*, focusing on tongue-flicking behavior after prey has been bitten and then removed from the lizard's mouth by the experimenter. Following similar removal of bitten prey from the mouth, the tongue-flicking rate increased for variable durations in several species of nonvenomous squamate reptiles (e.g., Cooper 1989a, 1991a,b, 1992a,b; Cooper et al., 1989).

The increase is the poststrike elevation in tongue-flicking (PETF) (Cooper, 1991a, 1992b). In the species studied, PETF is accompanied by locomotion interpreted as searching movements (Cooper, 1989b, 1991a,b, 1992a,b; Cooper et al., 1989). In venomous snakes the increased tongue-flicking rate and searching movements are called strike-induced chemosensory searching (SICS), which normally occurs following voluntary release of envenomated prey (Chiszar and Scudder, 1980; O'Connell et al., 1985).

Release usually occurs during predatory attacks on large, potentially dangerous prey (Radcliffe et al., 1980). Upon releasing the prey, a venomous snake may remain motionless for a brief interval and then begin tongue-flicking at a high rate that may not return to the prestrike baseline level for an extended period, sometimes more than 2 hr if the prey has not been relocated (Chiszar and Scudder, 1980; Chiszar et al., 1982). While tongue-flicking, the snake locates and follows the chemical trail to the prey after the prey has been rendered harmless (Chiszar and Scudder, 1980).

Lacking venom to subdue their prey, nonvenomous snakes and lizards do not voluntarily release prey and thus do not exhibit the strike–release–trail strategy of many venomous snakes (Chiszar and Scudder, 1980; Chiszar et al., 1985). PETF in lizards combined with apparent searching movements appears to be SICS without voluntary release or scent-trailing, which has not been possible in the experimental paradigm used to detect PETF.

The hypothesis that SICS in lizards and nonvenomous snakes is an attempt to use chemical cues to relocate lost prey predicts that PETF should occur in a wide variety of nonvenomous squamates that use the tongue–vomeronasal system during foraging. This applies to several families of active foragers, including Scincidae, that are capable of prey chemical discrimination based on lingually sampled stimuli (e.g., Cooper, 1990a, 1992b). Thus, I predicted that PETF and searching movements would occur in *E. laticeps* following forcible removal of prey. An additional prediction was that chemical cues induce greater PETF than can be attributed to oral tactile stimulation from the prey while the lizard bites. Finally, because broad-headed skinks feed primarily on cryptic invertebrate prey that is likely to be discovered and consumed on the spot rather than scent-trailed, it was predicted that the duration of PETF would be brief.

METHODS AND MATERIALS

Subjects and Maintenance. Sixteen adult male *E. laticeps* were captured on Kiawah Island and Seabrook Island, Charleston County, South Carolina, in May 1987. They were housed at the Savannah River Ecology Laboratory (SREL) in a building having translucent walls and were exposed to the natural light cycle of the region. A retractable roof was opened on warm, sunny days to allow natural insolation. During the study, the maximum daytime temperature was maintained in the low thirties Celsius by heat lamps. Because tongue-flicking rates in lizards vary with temperature (Cooper and Vitt, 1986d; Van Damme et al., 1990), it is necessary to control temperature in experiments using numbers of tongue-flicks as a response variable. In *E. laticeps* the tongue-flicking rate in response to pheromones is maximal near 30°C. After being maintained for over a year before the experiments began, the skinks were habituated to laboratory conditions and to the close proximity of a human being. Each lizard was housed individually in a 49 × 49 × 32-cm glass terrarium containing a water bowl, a wooden shelter board, a sand substrate, and a removable wire screen top. The skinks were fed crickets to satiation three times per week and neonatal mice several times prior to the experiments. Water was continuously available.

The skinks were transported to Auburn University at Montgomery (AUM) in early September 1988, where they were housed for several more months prior to further testing. Lizards were housed and fed as at SREL, with the exception that cage dimensions were 50 × 31 × 27 cm. At AUM, indirect natural light was supplemented by fluorescent lighting on a 14:10 light–dark cycle. Air temperatures varied from 22 to 31°C. Even at low air temperatures, undercage heaters allowed the lizards to thermoregulate.

Poststrike Elevation in Tongue-Flick Rate. The effect of biting prey on tongue-flicking rate was assessed by counting tongue-flicks emitted in two con-

secutive minutes in four experimental conditions. In the strike condition a neonatal mouse held in forceps was positioned just above the substrate 10 cm anterior to a lizard's snout. When the lizard bit the mouse, the experimenter removed the mouse from the lizard's mouth as gently as possible and began to count tongue-flicks immediately. The pull condition was similar until the lizard approached, tongue-flicked, and prepared to bite the mouse. At that time the experimenter withdrew the mouse with one hand, simultaneously moved the lizard a short distance with the other hand to simulate removal of prey in the strike condition, and began counting tongue-flicks upon releasing the lizard. In the sight condition, the experimenter held a mouse in forceps at the far side of the cage in clear view of the lizard. The mouse was removed after a maximum of 10 sec if the lizard did not approach or, to prevent the lizard from tongue-flicking the mouse, as soon as the lizard approached. The forceps condition was identical to the sight condition except that the forceps were empty. In the sight and forceps conditions, counts of tongue-flicks began simultaneously with removal of the experimental stimuli.

The strike condition is necessary to observe the effects of biting on tongue-flicking because *E. laticeps* does not release prey such as mice voluntarily prior to swallowing. However, because the experimental removal of prey from a lizard's mouth requires contact between the lizard and the experimenter's hand, aspects of the lizard's behavior other than tongue-flicking may be affected. The pull condition is a control for effects of handling in the strike condition. The crucial difference between the strike and pull conditions is that chemical and possibly other cues associated with biting are limited to the strike condition. The effect of seeing the prey on tongue-flicking rate is assessed by the sight condition. The forceps condition reveals tongue-flicking rates expected in the experimental milieu. The experimental procedures and interpretation of results are discussed in greater detail in Cooper et al. (1989) and Cooper (1989a).

Each lizard was tested in all four experimental conditions in a randomized blocks (repeated measures) design. The sequence of presentation of experimental conditions was randomized. Each lizard was tested once per day. Hunger was equalized over trials by testing two days after feeding to satiation. Thirteen lizards were tested from 1200 to 1400 hr EST in late August 1988. Air temperatures 1 cm above the substrate were 31.1 $\pm$ 0.8 SD in the strike condition, 31.0 $\pm$ 0.8 in the pull condition, 31.2 $\pm$ 0.9 in the sight condition, and 31.3 $\pm$ 1.3 in the forceps condition.

For the entire 2 min, significances of differences in numbers of tongue-flicks emitted among conditions were tested by nonparametric Friedman two-way analysis of variance (Siegel, 1956). Parametric analysis of variance could not be used because variances were unequal among conditions and the distributions of tongue-flicks were nonnormal in the forceps and mouse conditions due to frequent zero values. After determination that the main condition effect

was significant, individual comparisons between pairs of conditions were made using procedures described in Hollander and Wolfe (1973). Additional sign, Wilcoxon (Siegel, 1956), and paired t tests (Winer, 1962) were conducted to examine the difference between the strike and pull conditions. Significance tests were conducted with $\alpha = 0.05$ and were two-tailed for main effects and one-tailed for directional individual comparisons unless otherwise stated.

Control for Tactile Oral Cues. In a study of garter snakes, an additional control for the effects of tactile stimuli during biting was used to show that the chemical cues received during biting produced PETF (Cooper et al., 1989). To test the possibility that PETF in broad-headed skinks is a response to tactile cues received during biting rather than to chemical stimuli, a second experiment was conducted at SREL on 1 September 1988. To begin a trial, the experimenter grasped a skink, inserted a cotton-tipped applicator in its mouth (most individuals readily bit it), removed the applicator, returned the skink to its home cage, and counted its tongue-flicks for 2 min. The two experimental conditions consisted of presenting applicators (1) dipped in deionized water and (2) dipped in deionized water and then rubbed on the skin of a neonatal mouse to impart prey chemicals.

Sixteen lizards were tested in both conditions in counterbalanced sequence with an intertrial interval of approximately 1 hr. Air temperatures were 31.1 $\pm$ 1.0°C SD in the mouse condition and 31.2 $\pm$ 1.1°C SD in the water condition. Prior to analysis of the experimental effects, the tenability of the assumption of homogeneity of variance was examined by a Hartley's F_{max} test. Significance of the difference between condition means was assessed by a t test for correlated samples.

Duration of PETF. A preliminary examination of the duration of PETF was made by recording tongue flicks performed by seven skinks for five consecutive minutes in the strike and pull conditions. This study was conducted at AUM on 22–23 March 1989 at 27.4 and 27.0°C room temperature, respectively (only one measurement was taken each day). Significance of the difference between conditions was determined by Wilcoxon signed-ranks matched pairs tests for each minute. The criterion for presence of PETF in a particular minute was a significantly greater number of tongue-flicks in the strike condition than in the pull condition. One-tailed tests with $\alpha = 0.05$ were used because the prediction was directional.

A different approach to determining the duration of effects of biting prey on tongue-flicking was conducted at AUM on 20 February and 3 March 1989 at an air temperature of 29.5 $\pm$ 0.2°C SD. Numbers of tongue-flicks were recorded each minute for six individuals for a 5-min baseline interval. At the end of the baseline period, the lizard was allowed to bite a neonatal mouse, which was removed from the lizard's mouth as in the strike condition. Following removal of the mouse, tongue-flicks were recorded for 10 min or until the lizard

failed to emit any tongue-flicks for five consecutive minutes, whichever came first. The significance of elevation in tongue-flicking rate for each minute after biting was assessed by a binomial test of the numbers of individuals emitting more tongue-flicks during the experimental interval than the mean number of tongue-flicks per minute in the baseline period.

RESULTS

PETF. Substantial numbers of tongue-flicks occurred only in the strike and pull conditions, only two individuals responding in each of the other conditions. By far the highest mean tongue-flicking rates occurred in the strike condition (Table 1). The main condition effect was highly significant ($\chi_r^2 = 28.59$, $df = 3$, $P < 0.001$). Individual comparisons revealed no difference between the sight and forceps conditions ($P > 0.10$). Significant differences were found between the forceps and pull conditions ($P < 0.001$), the sight and pull conditions ($P < 0.01$), the forceps and strike conditions ($P < 0.001$), and the sight and strike conditions ($P < 0.001$).

Using the extremely conservative procedure (Hollander and Wolfe, 1973) for individual comparisons, the large difference between the strike and pull conditions is not significant ($P < 0.09$). However, because this comparison was planned as the single critical one for establishment of PETF, because the response rates in these two conditions were over an order of magnitude greater than in the forceps and sight conditions, and because the distributions in the sight and forceps conditions differed drastically from those in the strike and pull conditions, additional statistical tests of the significance of the mean difference between the strike and pull groups were conducted. Results of sign and Wilcoxon signed-ranks matched-pairs tests both revealed significance ($P = 0.01$ and $T = 10.5$, $P < 0.01$, respectively, one-tailed). Variances in the strike and pull conditions were homogeneous ($F_{max} = 2.63$; $df = 2,12$; $P > 0.05$), allowing a t test for correlated samples, which corroborated the findings of the two previous tests ($t = 2.52$, $df = 12$, $P < 0.025$).

The highest numbers of tongue-flicks were emitted by individuals that

TABLE 1. MEANS, STANDARD ERRORS (SE) AND RANGES OF NUMBERS OF TONGUE-FLICKS BY *Eumeces laticeps* IN 2 MIN IN FOUR EXPERIMENTAL CONDITIONS

Statistic	Strike	Pull	Sight	Forceps
Mean	52.2	22.8	1.8	0.8
SE	10.2	6.3	6.1	0.4
Range	8–108	1–55	0–22	0–9

moved about the cages or attempted to burrow in the sand. The individuals that had the three highest tongue-flicking rates in the pull condition burrowed persistently and were clearly not foraging, whereas the locomotion of lizards in the strike condition was consistent with searching for food. No quantitative data are available, but skinks burrowed less in the strike condition than in the pull condition and no burrowing occurred in the sight and forceps conditions. Individuals that did not tongue-flick at all in the sight and forceps conditions tended to remain motionless.

Tactile Oral Cues. Skinks tongue-flicked at fairly high rates in both conditions and exhibited consistently higher rates in trials with applicators bearing integumentary chemicals from mice than with applicators immersed only in water. Lizards performed 52.6 $\pm$ 1.2 SE (range 19–97) tongue-flicks in the mouse condition and 34.8 $\pm$ 1.0 SE in the water condition. Variances were homogeneous ($F_{max} = 1.81$; $df = 2, 15$; $P > 0.05$) and significantly more tongue-flicks were emitted in the mouse condition than in the water condition ($t = 2.55$, $df = 15$, $P < 0.02$, one-tailed).

Duration of PETF. Tongue-flick rates were much higher in the strike condition than in the pull condition during the first minute. Thereafter, the mean tongue-flicking rate was only slightly higher in the strike condition than in the pull condition until the fifth minute, when the rates were nearly identical (Figure 1). The only significant difference occurred in the first minute (Wilcoxon $T = 0.016$, one-tailed); for the remaining minutes, $T = 11$, 8, 11, and 7, respectively ($P > 0.10$).

During each of the first 3 min after biting a mouse, the tongue-flicking rate of all six lizards was elevated above baseline (binomial $P = 0.016$, one-tailed for each minute). Thereafter, tongue-flicking was above the mean baseline rate for four of six individuals in minute 4, three in minute 5, one in minute 6 and two in minute 7 ($P > 0.10$ each). No lizard tongue-flicked in minutes 8–10.

DISCUSSION

PETF, SICS, and Their Duration. The significantly greater tongue-flicking rate in the strike condition than in the pull, sight, and forceps conditions demonstrates the existence of PETF in *E. laticeps*. The similarity of tongue-flicking rates in the sight and forceps conditions suggests that seeing the mouse briefly did not induce an increase in tongue-flicking rate above the baseline rate for the experimental setting. On the other hand, the opportunity to approach the prey (sometimes while tongue-flicking) combined with handling of the lizard by the experimenter induced a substantial increase in tongue-flicking rate, as indicated by the significantly higher tongue-flicking rate in the pull condition than in the sight and forceps conditions. As in water snakes of the genus *Nerodia*, handling

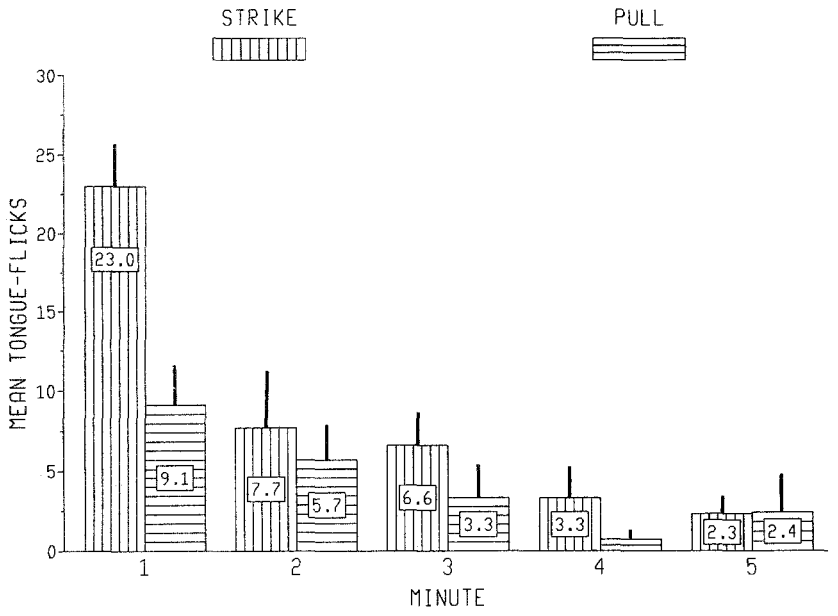

FIG. 1. Vertical bars represent the mean number of tongue-flicks emitted by adult male *Eumeces laticeps* in five successive minutes in two experimental conditions. Vertical lines above the bars represent 1 SE.

alone is followed by an increase in the tongue-flicking rate (Scudder and Burghardt, 1983).

The excess in tongue-flicking rate in the strike condition over that in the pull condition presumably represents a specific response to cues associated with biting, which could be tactile or chemical. Further evidence demonstrating the effectiveness of oral chemical stimuli is that the tongue-flick rates of lizards stimulated on the oral epithelia by moistened cotton swabs bearing prey chemicals were greater than when the swabs bore water alone. A similar effect has been reported in garter snakes (Cooper et al., 1989).

Tactile cues associated with biting prey appear to be less effective than chemical cues in eliciting elevated tongue-flicking, but they may stimulate some increase. Tongue-flicking rates were nearly identical in the strike condition and following oral stimulation by swabs bearing prey chemicals, suggesting that the combined effects of tactile and chemical stimulation to the mouth were the same in the two experiments. That the rate of tongue-flicking was somewhat higher among lizards picked up by the experimenter and stimulated by swabs bearing water only than in the pull condition suggests (1) that being held and having a swab inserted in the mouth may be more stressful than treatment in the pull

condition or (2) that biting the prey may stimulate an increase in tongue-flicking due to oral tactile stimuli independent of chemical stimuli. However, this apparent difference might or might not be significant in a planned experimental test.

The greater effectiveness of chemosensory cues than tactile cues in eliciting PETF raises the question of the degree of increase in tongue-flicking rate that can be induced by tongue-flicking prey in the absence of mechanical stimuli occurring during biting and by tongue-flicking prey chemicals on a substrate. There was some opportunity to tongue-flick prey in the pull condition, which may account at least in part for the greater tongue-flicking rate in that condition than in the sight and forceps conditions. Because movement and tongue-flicking are correlated in lizards (Burghardt et al., 1986), chemical stimulation alone might induce both PETF and searching movement, i.e., SICS. Nevertheless, the variability of relationships between locomotion and tongue-flicks directed to air and substrates in different experimental settings (Burghardt et al., 1986) emphasizes the necessity for careful experimentation. From this perspective, another possibility ignored heretofore is that approach during the pull condition increases the likelihood of subsequent movement and therefore of tongue-flicking. This could explain at least some of the differences between the pull condition and the other control conditions.

SICS appears to be present in *E. laticeps* because, in addition to their demonstrated PETF, males in the strike condition moved more frequently than they did in the other conditions. This interpretation is strengthened by the qualitative differences in movements in the strike and pull conditions, the movements in the strike condition alone resembling searching movements.

The duration of PETF as determined by comparisons of tongue-flicking rates in the strike and pull conditions is only 1 min. Such comparisons are very important for determination of the duration of PETF demonstrated by the experimental methods used here because the pull condition itself induces an increase above baseline rates. When the tongue-flicking rates in the strike condition are compared with baseline rates for undisturbed lizards, the apparent duration may be much longer. In this study, the duration of increased tongue-flicking was 3 min for the comparison between baseline and poststrike rates, with an indication that it might extend a few minutes longer if a larger sample size were tested.

Because the experimental method used to determine the duration of PETF in this and my previous related studies (Cooper, 1991a,b, 1992a,b) is based on comparison of tongue-flicking rates in the strike conditions with those in the pull condition, the durations reported are not directly comparable with those reported by Chiszar and his colleagues in a long series of papers on venomous snakes (e.g., see references above and Radcliffe et al., 1986). Indeed, although these studies have established beyond doubt the importance of chemical cues in the SICS and scent-trailing of prey by venomous snakes that release prey voluntarily after envenomation, it would be of interest to know how great a portion

of the duration of SICS relative to undisturbed baseline conditions in venomous species is attributable to tactile cues imparted while striking and releasing prey. A recent study shows that SICS occurs after striking in rattlesnakes and water moccasins having ligated and severed venom ducts; this finding eliminates stimuli arising from injection of venom as necessary antecedents of PETF (Chiszar et al., 1991). However, potentially important roles of other mechanical stimulations during the process of strike and release by venomous snakes remain to be investigated.

Comparative Data for Nonvenomous Squamates. PETF and apparent SICS have been documented in three nonvenomous species of snakes representing two families: Colubridae (Cooper et al., 1989) and Pythonidae (Cooper, 1992a); and in four species from four families of lizards: Cordylidae (Cooper, 1992c), Lacertidae (Cooper, 1991), Scincidae (this study), and Varanidae (Cooper, 1989a, 1992b). All of these squamates are also capable of detecting prey chemicals and discriminating them from control chemicals (Burghardt, 1970, 1973; papers just cited and references therein). Nonvenomous snakes use the tongue to locate prey while foraging (Burghardt, 1970). Among the lizards, all are known to be active foragers, except the cordylid, for which the foraging mode is uncertain. All available data are consistent with the hypothesis that PETF (and SICS) in lizards and nonvenomous snakes constitute use of the tongue in the attempt to relocate by chemosensory means prey that has escaped recently.

Little is known regarding the importance of foraging mode in lizards to the existence and duration of PETF and SICS, but it may be predicted that PETF and SICS are reduced or do not occur in lizards incapable of discriminating prey chemicals from control substances and in those that do not use the tongue to detect chemical prey cues during foraging. So far as is known, families of active foragers do so use the tongue and discriminate prey from nonprey chemicals (e.g., Evans, 1961; Nicoletto, 1985; Cooper, 1990a). On the contrary, insectivorous lizards that are strict ambush or sit-and-wait foragers do not discriminate chemical prey cues or tongue-flick frequently while foraging (Curio and Mobius, 1978; Cooper, 1989b, 1990b). It thus may be predicted that PETF and SICS are reduced or absent in insectivorous agamids, polychrids, and phrynosomatids.

The duration of PETF varies considerably among the few lizards studied. It is quite brief in three species of fairly small, primarily insectivorous lizards, the lacertid *Podarcis muralis* (1 min; Cooper, 1991a), the scincid *E. laticeps* (1 min; this paper), and the cordylid *Gerrhosaurus nigrolineatus* (2 min; Cooper, 1992b), despite differences in the openness of foraging habitats and methods of locating food. The scincid, for example, forages more often under forest litter for hidden prey (Vitt and Cooper, 1986) in less open habitats than the other two species. The duration of PETF is much greater in *Varanus exanthematicus*, at least 25 min (Cooper, 1992a). Although *V. exanthematicus* preys primarily on invertebrates, the occasional large vertebrate prey item may be energetically

important. Highly mobile vertebrates such as small mammals seem much more likely than insects to be located by scent-trailing. Furthermore, several other varanids, most notably *V. komodoensis*, regularly consume vertebrates and appear to locate them by scent-trailing (Auffenberg, 1981). Thus, the relatively long interval of PETF in *V. exanthematicus* might reflect a current selective regime, a historical one in which the ancestral varanids specialized in vertebrates, or both. Because snakes are believed to have evolved from varanid lizards or their predecessors (McDowell, 1972; Schwenk, 1989), the long-lasting PETF of the varanid strengthens the hypothesis that the highly developed SICS of snakes is an elaboration of the ancestral condition in lizards (Cooper et al., 1989).

(Received July 29, 1991; accepted November 13, 1991)

Abstract—DIMBOA (2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one), a secondary metabolite found in cereal extracts, confers resistance in wheat to aphids. Its effect on beneficial organisms was tested on larvae of the aphid predator *Eriopis connexa* Germar. Larvae were fed until pupation on artificial diets to which different concentrations of DIMBOA (2–200 μg/g diet) were added, as well as on aphids that had been feeding on wheat seedlings with different DIMBOA levels (140–440 μg/g fresh tissue). In diets, the effect of DIMBOA was greatest on survival of third-instar larvae and on the duration of the second and fourth instars. When aphids were provided as food, those that had fed on a wheat cultivar with an intermediate DIMBOA level led to a significantly longer larval duration in the predator than did those that fed on either low or high DIMBOA cultivars. Shortest predator development times were obtained with aphid prey that had fed on high DIMBOA seedlings. Higher DIMBOA levels in the plant appear to reduce aphid feeding rates (and rates of DIMBOA ingestion), decreasing aphid survival and minimizing the effect of the toxin on the predator.

Key Words—Wheat, hydroxamic acids, DIMBOA, plant resistance, cereal aphids, Homoptera, Aphididae, aphid predators, *Eriopis connexa*, Coleoptera, Coccinellidae, tritrophic interactions.

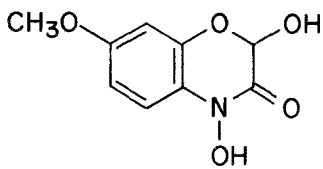
INTRODUCTION

The most prevalent cereal aphids in Chile are *Metopolophium dirhodum* (Walk.), *Sitobion avenae* (Fab.), *Schizaphis graminum* (Rond.), and *Rhopalosiphum padi* (L.) (Ramírez, 1990). Although an array of natural enemies, which includes predators, parasitoids, and pathogens limit their populations to a great extent (Zúñiga, 1987), aphids constitute a potential problem due to their ability to transmit virus diseases, such as the barley yellow dwarf virus (BYDV) (Herrera and Quiroz, 1988). *Eriopis connexa* Germar (Coccinellidae) is one of the most important aphid predators in Chile because of its high populations in spring and summer, wide range of prey, and predatory efficiency (Macfarlane, 1985).

DIMBOA (2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one), the main hydroxamic acid (Hx) present in wheat extracts (Niemeyer, 1988a), has been associated with resistance of the plant to aphids through antibiosis (Argandoña et al., 1980; Bohidar et al., 1986; Thackray et al., 1990; Wratten et al., 1991) and feeding deterrency (Argandoña et al., 1983; Niemeyer et al., 1989b; Givovich and Niemeyer, 1991).

Biological control and host-plant resistance are often compatible and even complementary (Emden and Wratten, 1991), as has been found to be the case of resistance in varieties of barley and sorghum that complemented the activity of the parasitoid *Lysiphlebus testaceipes* Cresson (Starks et al., 1972). However, variations in host plants may have dramatic effects on biological control agents. Thus, prey confined to resistant host plants may represent a low-quality food for predators and parasitoids, affecting their biology (Bergman and Tingey, 1979). Secondary metabolites in the plants may be the cause of detrimental effects on organisms at the third trophic level, as is the case of α-tomatine, an alkaloid in *Solanum* and *Lycopersicon* species, that is toxic to the endoparasitoid *Hyposoter exiguae* (Viereck), which takes up the compound through its host *Heliothis zea* (Boddie) (Campbell and Duffey, 1979). Nicotine, an alkaloid from *Nicotiana* species confers plant resistance to *Manduca sexta* L. but has negative effects on the parasitoids *Hyposoter annulipes* (Cresson) and *Cotesia congregata* (Say) developing on *M. sexta* larvae reared in nicotine-containing diets (Thorpe and Barbosa, 1986; Barbosa et al., 1986). Plant secondary metabolites might



DIMBOA

SCHEME 1.

confer resistance in the herbivore towards the predator, as is the case of *Macrosiphon albifrons*, an aphid that is protected from attack by *Carabus problematicus* by quinolizidine alkaloids ingested from its lupin host plants (Wink and Römer, 1986).

An increase in Hx levels in wheat, proposed as a mechanism to enhance resistance towards aphids (Niemeyer, 1988b; Copaja et al., 1991a,b; Wratten et al., 1991), could affect beneficial organisms. Hence, the effect of DIMBOA on the development of *E. connexa* was examined.

METHODS AND MATERIALS

A mass rearing technique and an artificial diet for *Eriopis connexa* were developed; the direct effect of DIMBOA was studied by adding the compound in different concentrations to the diet; finally, larvae were fed aphids reared on wheat lines containing different DIMBOA levels.

Mass Rearing of E. connexa. Rearing was started with 25 pairs of coccinellids collected in fields near the laboratory. Beetles were fed on the aphid *R. padi* reared on oat seedlings in a room maintained at 21°C with a 10°C range, 50% relative humidity with a 10% range and a 16:8 light–dark photoregime.

All stages of the predator were maintained separately in plastic containers of 12 cm diameter and 7.5 cm height fitted with a cover with fine holes. Adults were confined at a density of five to eight pairs per container. Aphids on oat leaves were placed as food on a sheet of paper towel inside the container. Egg groups were collected daily and maintained separately in containers. Larvae were also fed with aphids from oats; these aphids were offered as soon as egg hatch occurred. The fourth instars were supplied with a sheet of paper towel for pupation. The mean number of aphids provided daily per larva from first to fourth instar were 10, 25, 20, and 15, respectively. Pupae were collected daily and were placed on a sheet of paper towel inside a container. Adults that had emerged within the same 24-hr period were sexed and maintained in pairs in the containers.

Artificial Diet for E. connexa. Diets were based on those developed for coccinellids using liver and meat extracts (Herrera, 1960; Atallah and Newson, 1966; Ferran and Laforge, 1975) and were tested by rearing first-instar larvae in 5.5-cm-diam. Petri dishes, each larva receiving 0.5 g diet every two or four days. Table 1 shows the best formulation of those tested.

Pollen with polyvitamins and wheat germ were pulverized separately with a mortar and pestle. These constituents were mixed with sorbic acid, ascorbic acid, and vitamin E, and then bee honey was added. This mixture was blended for 30 sec with liver in 50 ml water in a domestic blender. Agar was dissolved in 50 ml water at 80°C and cooled down before being mixed into the previous

Vitamin E	0.4
Water	100.0

mixture for 1 min. The homogeneous dough of semisolid texture obtained was dispensed to sterilized containers and stored at 6°C.

The diet was tested with 10 first-instar larvae and was renewed every two days. For comparison, 14 first-instar larvae were reared individually with natural diet using *R. padi* nymphs ad libitum as food.

Effect of DIMBOA in Artificial Diets on Development of E. connexa. First-instar larvae of *E. connexa* were reared on artificial diet containing DIMBOA, isolated from ethereal extracts of *Zea mays* cv. T129s, as previously described (Queirolo et al., 1983). This compound was incorporated to the diet at the required concentration in 50 ml of water before adding the agar suspension. The latter was cooled down before use in order to minimize decomposition of DIMBOA. Analysis of the diet after four days at room temperature revealed that at least 85% of DIMBOA remained in it. Experiments were carried out in a completely randomized design with six treatments and two replicates. Treatments consisted of five DIMBOA concentrations in artificial diet plus a control without DIMBOA. Concentrations tested were 0, 2, 5, 10, 50, and 200 μg DIMBOA/g diet. Each replicate consisted of 10 recently hatched larvae of *E. connexa* maintained separately in 5.5-cm-diam. Petri dishes. The diet (0.5 g) was renewed every four days for the first and second instars and every two days for the third and fourth instars. The Petri dishes were sealed with Parafilm to keep larvae from escaping and diet from drying. Larval mortality, duration of each instar, pupal mortality, pupal duration, weight of pupae, and time to reach adulthood were evaluated.

Study of E. connexa *Larvae Fed on Aphids Reared on DIMBOA-Containing Wheat Lines.* Three wheat lines with different contents of the compound were chosen (Millaleu: 140 μg DIMBOA/g fresh tissue, Nobo: 270 μg, and Maiten: 440 μg). Oats were used as a control without DIMBOA. Aphids (*R. padi*) were

allowed to feed on the plants for 24 hr. They were placed within a clip cage located in the middle third of the leaf of a wheat seedling in the one-leaf stage, the stage at which DIMBOA was analyzed. One first-instar larva of *E. connexa* was placed inside each Petri dish with a piece of wet filter paper and allowed to develop to the adult stage. Aphids were removed from the plants and placed inside the Petri dish ad libitum for the larvae. For each wheat cultivar and the oat control there were 10 replicates. Survival of larvae, number of aphids eaten per larva, and the duration of each larval developmental stage were determined. The larvae employed were obtained from eggs laid by field-collected females that had been kept together with males for two weeks under the rearing conditions described above.

Plant Material and Hydroxamic Acid Analysis. Wheat seedlings used were in the one-leaf stage (G.S. 11) (Zadoks et al., 1974). Hydroxamic acids were analyzed by reverse-phase high-performance liquid chromatography, as previously described (Niemeyer et al., 1989a).

RESULTS

Mass Rearing of E. connexa. This technique was developed in order to obtain uniform individuals in high quantities for laboratory assays. Mating was frequent and occurred from early adulthood up to just before death. Females began oviposition on average 16.5 days after reaching adulthood, and the oviposition frequency was every three to four days. Eggs were laid in groups, usually on the surface of paper towel, each batch comprising about 25 eggs. Individuals older than three months laid a higher proportion of infertile than fertile eggs. Eggs were collected daily by cutting the paper around the batch; they hatched five days later.

Larvae were voracious, consuming on average 54, 39, 55, and 72 nymphs of *R. padi* in first, second, third and fourth instars, respectively. Development times for each stage are given in Table 2. The pupal stage lasted 5.4 days and the sex ratio was 1:1. These adults consumed 15–20 aphids per day. The life cycle was completed in 44 days.

Artificial Diet for E. connexa. The rearing of *E. connexa* under laboratory conditions is relatively easy and cheap with aphids as food. However, experiments in which the effect of a given compound is being investigated demand the use of an artificial diet for rearing. Table 2 shows comparative data on larval and pupal development of *E. connexa* on natural and artificial diets. Larvae were reared on artificial diets from first instar to adulthood. Molting was normal, with no mortality recorded. However, the larval developmental period was different from that observed with natural diet, and adults, although being as large as the controls, were whitish in color, possibly due to a lack of appropriate pigments in the diet.

Effect of DIMBOA in Artificial Diet on Development of E. connexa. Table 3 shows the effect of DIMBOA in an artificial diet on the development and survival of larvae of *E. connexa*. Survival was not significantly affected by DIMBOA, with the exception of that of the third-instar larva. In this case, progressively lower survival was obtained with diets with higher DIMBOA concentrations.

The durations of instars two and four were significantly increased by higher DIMBOA concentrations in the diet, albeit only at the highest concentration in the latter instar.

Table 4 shows the overall effect of DIMBOA on larval development and survival and also the effect on pupae and adults obtained from treated larvae. While an increase in time to reach adulthood seems apparent at the lowest

concentration of DIMBOA tested, the effect was statistically significant only for the highest concentration of DIMBOA. This concentration also decreased larval survival but had no effect on pupal survival nor on adult emergence.

Effect of Aphids Reared on DIMBOA-Containing Wheat Lines on E. connexa *Larvae.* The development time of *E. connexa* larvae differed significantly depending on the wheat cultivar on which their aphid prey had fed, the duration being longer in the case of the cultivar with an intermediate level of DIMBOA. Pupal developmental time was not affected by the level of DIMBOA in the wheat cultivar. Larval survival was lower with aphids that had fed on the wheat cultivar with the intermediate DIMBOA level (Table 5); aphid consumption was also lower in this cultivar (Table 6).

DISCUSSION

DIMBOA has been shown to be a feeding deterrent towards aphids. Thus, survival of aphids feeding on diets (Argandoña et al., 1983; Niemeyer et al., 1989b) or on wheat plants (Niemeyer et al., 1989b) differing in DIMBOA level showed a biphasic behavior: in the lower DIMBOA range survival was inversely correlated with DIMBOA concentrations while at the higher end survival was positively correlated with DIMBOA concentrations. Dual choice tests showed that aphids preferentially settled on leaves of wheat seedlings containing lower DIMBOA levels (Givovich and Niemeyer, 1991). Finally, electronic monitoring of aphid feeding behavior showed that fewer aphids reached the phloem, and those that did took longer to reach it in seedlings with higher DIMBOA levels

than in those with lower ones (Givovich and Niemeyer, 1991). Hence, it appears that below a given DIMBOA level, the aphid ingests the compound, while above this level DIMBOA deters the aphid from feeding, leading to higher short-term survival rates.

An aphid feeding for 24 hr on a wheat seedling will accumulate DIMBOA in concentrations on the order of 1 μg/g aphid (Niemeyer et al., 1989b). Longer feeding times, as may occur under field conditions, should not radically affect this estimation since: (1) DIMBOA levels in the plant decrease as the plant develops (Argandoña et al., 1981), thus exposing the aphid to lower DIMBOA levels when feeding; (2) the instability of DIMBOA in aqueous solutions (Niemeyer et al., 1982) will hinder its accumulation; and (3) metabolization of

DIMBOA by the insect may occur, as has been shown in the case of a lepidopteran (Campos et al., 1989), which would also hinder its accumulation.

The lowest concentration of DIMBOA in diets tested on *E. connexa* is comparable with that expected in aphid bodies (Niemeyer et al., 1989b). This concentration led to a detectable, albeit not significant, increase of larval and pupal time periods of *E. connexa* with respect to control diet (Tables 3 and 4). When the predator fed on aphids, development times were also altered, being longest when the aphid prey had fed on the cultivar that had an intermediate DIMBOA level. An explanation of this finding is that these aphids were more deleterious to the predator. This is supported by the facts that: (1) two other cereal aphid species, *M. dirhodum* and *S. avenae*, feeding on wheat seedlings with intermediate DIMBOA levels accumulated the most DIMBOA in their bodies (Niemeyer et al., 1989b), and (2) *R. padi* feeding on wheat seedlings with intermediate DIMBOA levels accumulated the most DIMBOA (in glucosylated form) in their honeydew (Givovich et al., 1992). Alternatively, longer development times may have resulted from larvae ingesting fewer aphids (Table 6), which would still suggest that the compound in the plant was acting on the third trophic level, in this case through feeding deterrency. The fact that the development time of the predator significantly decreased when it fed on aphids from wheat seedlings containing high DIMBOA levels with respect to those containing low DIMBOA levels suggests that an increase in DIMBOA concentration in the plant, useful for aphid resistance, could result in the additional benefit of minimizing the effect of the toxin on the predator. This is a subtle and hitherto unreported mechanism in a tritrophic interaction between plant, herbivore, and predator (see Emden and Wratten, 1991).

Acknowledgments—The authors wish to express their gratitude to Miss Lucía Muñoz for able technical assistance and to Dr. S.D. Wratten for helpful comments on the manuscript. Financial support by International Program in the Chemical Sciences (IPICS), Agency for International Development, and FONDECYT are gratefully acknowledged. A.M. is indebted to IPICS for a fellowship to visit the laboratory in Chile.

EFFECTS OF COLORADO POTATO BEETLE AND POTATO LEAFHOPPER ON AMINO ACID PROFILE OF POTATO FOLIAGE

E.S. TOMLIN[1] and M.K. SEARS*

Department of Environmental Biology
University of Guelph
Guelph, Ontario, Canada N1G 2W1

(Received September 9, 1991; accepted November 15, 1991)

Abstract—Feeding by Colorado potato beetles and artificial defoliation had a minor effect on the profile of amino acids in potato foliage, whereas feeding by potato leafhoppers caused an increase in about one half of the amino acids measured.

Key Words—Amino acids, *Solanum tuberosum*, *Leptinotarsa decemlineata*, Coleoptera, Chrysomelidae, *Empoasca fabae*, Homoptera, Cicadellidae, feeding damage.

INTRODUCTION

Two herbivores may be considered competitors if their feeding behavior reduces the relative nutritional quality of their common host plant (Kareiva, 1982). This is the probable mechanism through which the Colorado potato beetle (*Leptinotarsa decemlineata* Say) (Coleoptera: Chrysomelidae) and the potato leafhopper (*Empoasca fabae* Harris) (Homoptera: Cicadellidae) compete on potato (*Solanum tuberosum* L.) (Tomlin and Sears, in preparation). The effect of feeding damage caused by potato beetles and potato leafhoppers on the levels of certain nutrients, such as individual amino acids, in potato foliage is poorly

documented. Changes in concentrations of amino acids in damaged plants that might lead to altered protein synthesis or production of secondary compounds was investigated.

Potato beetles have chemoreceptors specific to amino acids such as alanine, serine, proline, and γ-aminobutyric acid (GABA) (Mitchell and Schoonhoven, 1974; Hare, 1983). Pea aphids, which feed in a similar manner to leafhoppers, are also sensitive to certain amino acids (Srivastava et al., 1983). Alanine and GABA are feeding stimulants for *Acyrthosiphon pisum*, while asparagine and aspartic acid, cysteine, cystine, glutamine, glycine, proline, serine, and tyrosine are inhibitory. A negative correlation that occurs between populations of potato beetles and potato leafhoppers in the field (Tomlin, 1991) may be caused by perceived differences in the amino acid profile of potato plants or by a change in foliar nitrogen metabolism that could be indicated by a change in the profile of amino acids. Potato beetles fed on plants damaged by potato leafhoppers exhibited reduced growth and survival (Tomlin and Sears, in preparation). Jansson and Smilowitz (1985) found that the growth and development of field populations of potato beetles were negatively correlated with the concentration of total foliar nitrogen, but they did not measure the levels of free amino acids.

The objectives of this study were: (1) to determine the effect of feeding by both the Colorado potato beetle and the potato leafhopper on the profile of amino acids in potato leaves, and (2) to compare the effect of artificial defoliation with defoliation caused by potato beetles, and the effect of drought stress with damage caused by potato leafhoppers.

METHODS AND MATERIALS

Measurement of Several Factors Affecting Amino Acid Profile of Potato Foliage

Feeding by Colorado Potato Beetle and Potato Leafhopper. Pieces of potato seed (cv. Kennebec) consisting of a single eye were planted in plastic pots (10 cm diam.) in a greenhouse. Each pot, containing a 5-week-old single haulm, was covered with a cylindrical Plexiglas cage, and assigned randomly to treatment groups in a randomized complete-block design. Treatments placed on the plants consisted of 0, 1, 2, or 5 first instar beetles for 10 days or 0, 5, 10, or 20 potato leafhopper adults for 20 days replicated 10 times for beetle larvae and five times for potato leafhoppers. The cages were held in a growth room at 22–27°C and 16:8 light–dark photoperiod. Samples of tissue were removed for analysis of amino acids at the end of the period of infestation. Because leafhoppers remove fluids as they feed, the percent moisture of the leaf tissue was compared between the treatments.

Artificial Defoliation. Thirty potato plants (cv. Kennebec, 5 weeks old) were placed at 22–27°C and 16:8 light–dark. To simulate the feeding behavior of the Colorado potato beetle, scissors were used to remove either 0, 25, or 50% of a leaflet. On the first day, the appropriate amount of tissue was cut from the top three leaves of each plant, on the second day from the next three leaves, and so on until there were no leaves left to cut (five days). This cutting pattern imitated the way potato beetles defoliate potato plants. Ten replicates of each treatment were used. Tissue samples were removed for analysis of amino acids at the end of five days.

Drought Stress. The effect of drought stress on the profile of amino acids in potato foliage was measured on 5-week-old potato plants (cv. Norchip) grown in a greenhouse where natural light was supplemented with sodium vapor lamps and the temperature ranged from 15°C (night) to 28°C (day). The variety Norchip was used because Kennebec seed was unavailable. Five plants were given 100 ml water/day, five 50 ml water/day and five were never watered. This experiment was arranged in a completely randomized design on a 1-m^2 area of bench surrounded by other potato plants. Randomization was necessary to account for variation in light intensity, temperature, and humidity. After two weeks, samples of tissue were removed for analysis of amino acids.

Sample Preparation and Analysis

Tissue samples were removed from plants with a standard single-hole punch at the end of each experiment and frozen at −70°C. Representative samples were obtained from between the major veins by punching one disk of tissue (0.28 cm^2) from every leaflet.

Tissue samples were thawed to room temperature. A subsample of 0.2 g wet weight was homogenized in ice-cold 10% sulfosalicylic acid containing 0.0003 N norleucine as the internal amino acid standard. Samples were pureed using an OMNI 2000 hand-held homogenizer in 5-ml centrifuge tubes embedded in crushed ice. The homogenate was centrifuged in 1.5-ml microfuge tubes in a bench-top centrifuge at 14000 *g* for 30 min. The supernatant was removed and stored frozen at −70°C for analysis. The samples were rendered volatile by preparing the *N*-heptaflourobutyral isobutyl derivatives according to the method of Lindqvist and Mäenpää (1982).

Samples were analyzed by gas–liquid chromatography (Hewlett Packard 5890, Avondale, Pennsylvania) by use of electron-capture detection with an HP 19091A-112, 5% phenylmethyl silicone-fused silica capillary column (25 m × 0.31 mm ID). A 50:1 sample splitter was used at the injection port (250°C) with a carrier gas flow rate of 1.4 ml/min and a detector temperature of 300°C. The initial phase of the oven temperature program was 100°C for 5 min. The temperature was then increased by 4°C/min to 280°C, which was maintained

for 10 min. Asparagine and aspartic acid, and glutamine and glutamic acid, were not separated, and they are reported as the sums of the two. Arginine was too volatile to identify reliably and was excluded from analyses.

Statistical Analysis

The amount of each amino acid in the samples was expressed as micromoles of amino acid per gram wet weight of sample for comparisons. Quantities were transformed by square roots to normalize the variance.

For each source of stress that was investigated, it was determined if the treatment groups differed with respect to the amount of amino acid using both univariate analysis of variance (ANOVA) and multivariate analysis of variance (MANOVA) (SAS Institute, 1988). The number of variables was reduced to leave enough degrees of freedom to estimate the error terms using stepwise discriminant analysis (STEPDISC) (SAS Institute, 1988). A canonical discriminant analysis (CANDISC) (SAS Institute, 1988) described the patterns of variation in amino acids among the treatment groups.

RESULTS AND DISCUSSION

Feeding by the Colorado potato beetle affected the amount of amino acids in potato foliage (Wilks' λ: $F = 2.85$; $df = 12,254.28$; $P = 0.0011$) (Figure 1). Feeding by beetles caused an increase in the amount of asparagine/aspartic acid and leucine, and a decrease in the amount of valine and histidine. The decrease in the amount of valine was the most important difference between the treatment groups because it had the highest canonical coefficient. Although multivariate methods showed that a change in several amino acids separated the degrees of defoliation by beetles, only the amount of histidine varied individually. These results appear contradictory, but multivariate methods can reveal differences among treatment groups not indicated by univariate methods if the variables are correlated (Tabachnick and Fidell, 1983). If all of the statistical data are considered, it can be concluded that defoliation by beetles does affect the profile of amino acids in potato foliage in a minor way.

Feeding by potato leafhoppers affected the amounts of amino acids in potato leaves (Wilks' λ: $F = 1.69$; $df = 15,66.65$; $P = 0.0329$) by causing an increase in the amounts of half of the amino acids (Figure 1). The increase in the amount of threonine was the most important difference between the treatment groups. There was no difference in the percent moisture of the leaves between the treatments ($F = 0.15$; $df = 3$; $P = 0.8609$), indicating that the changes in levels of amino acids were not an artifact of using wet weights. Schroeder et al. (1988) found that only the amount of proline (micromoles per gram of dry

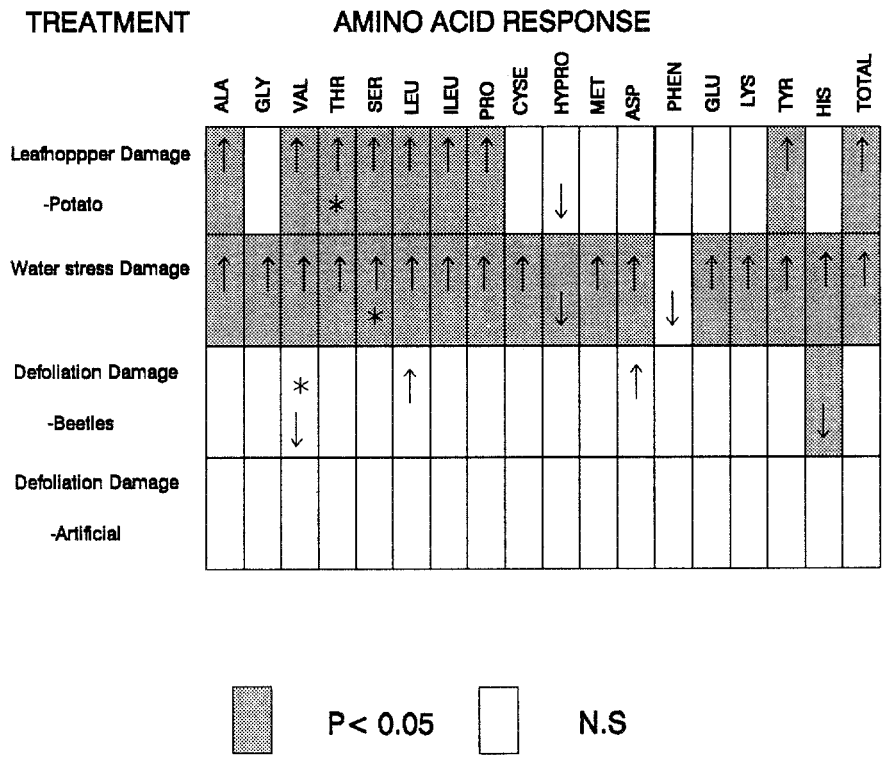

FIG. 1. A comparison of patterns of amino acid variation among the different experiments. A significant P value indicates that the amino acid increased or decreased as the level of damage increased for each type of treatment applied. ↑ or ↓ indicates whether the amount of amino acid increased or decreased based on canonical discriminant analysis and univariate means. * indicates amino acid chosen as the most important in separating the treatment groups by canonical discriminant analysis.

tissue) increased in response to feeding by leafhoppers in alfalfa and that the levels of crude protein decreased.

Different degrees of artificial defoliation had no effect on the amounts of amino acids in the leaves (Wilks' λ: $F = 1.00$; $df = 36,50$; $P = 0.4889$), and there was no significant variation in the amounts of any individual amino acids (Figure 1). Defoliation by potato beetles differs from artificial defoliation because feeding by beetles has a slight effect on the amino acid profile of the foliage, perhaps caused by salivary enzymes.

Drought stress significantly affected the amounts of amino acids in potato leaves (Wilks' λ: $F = 25.18$; $df = 4,62$; $P < 0.0001$). The treatments that received 50 and 100 ml water/day differed from the treatment that did not receive

water. The amounts of all amino acids increased except for hydroxy-L-proline and phenylalanine, which decreased in amount in response to drought stress (Figure 1). The most important factor in the separation of the treatment groups was the increase in the amount of serine. Because the percent moisture of the leaf tissue was not compared between the treatments, the increase in the amounts of amino acids could be a result of water loss from the leaf tissue, although the amounts of two amino acids did decrease.

The effect of drought stress on the profile of amino acids in different plants is well documented. Fukutoku and Yamada (1981) found that the amounts (micromoles per gram of dry weight) of isoleucine, leucine, valine, phenylalanine, glutamine, and histidine increased in drought-stressed soybean leaves. Proline and asparagine only accumulated under severe stress. Similarly, Sano and Kawashima (1982) found that the concentrations of most amino acids (micromoles per gram of fresh weight) increased while the concentrations of a few decreased in wilting tobacco leaves. Proline increased most dramatically. Hsiao (1973) and Waldren and Teare (1974) also found that the amount of proline increased in sorghum and soybean in response to severe drought stress. These results are similar to those found in this study where the concentrations of most amino acids, including proline, increased in response to drought stress.

Most authors cite an increase in the amount of proline in foliage as a symptom of stress. In this study, the amount of proline was found to increase in response to both drought stress and feeding by leafhoppers. Reinbothe and Miersch (1985) suggest that accumulated proline plays an important role in the balance of cell metabolism during stress. Proline is formed by de novo synthesis from both glutamate and arginine and may serve as a storage compound for reduced carbon and nitrogen (Hsiao, 1973; Boggess et al., 1976; Boggess and Stewart, 1976; Wrench et al., 1977). Levitt (1972) suggested that proline may act as an NH_3 storage compound and that other amino acids are converted to proline, which may accumulate without causing injury.

Increased amounts of amino acids other than proline may be caused by degradation of proteins. Levitt (1972) found that the rate of incorporation of ^{14}C-labeled serine into protein decreased and the transfer into other free amino acids increased in response to drought stress. Fukutoku and Yamada (1981b) observed an increase in amounts of amino acids usually found in the proteins of drought-stressed plants, indicating that degradation of proteins occurred.

In summary, damage caused by both leafhoppers and drought stress produce similar, although not identical, reactions in plants. This suggests that both types of damage could affect similar physiological processes, although comparisons using dry rather than wet weights of tissue should be done. Leafhoppers may cause hydrolysis of certain proteins in xylem and phloem cells with specific enzymes in their saliva, whereas drought stress may cause a more general and widespread degradation of protein through changes in membrane properties of

the cells (Cooke et al., 1980). Feeding by potato beetles had more effect than artificial defoliation on the amounts of amino acids possibly caused by salivary enzymes.

Acknowledgments—We would sincerely like to thank Margaret Carter for her invaluable technical assistance and advice with the gas chromatographic analyses. We would also like to thank the National Science and Engineering Research Council of Canada and the Ontario Ministry of Agriculture and Food for their support of this project. The data presented here are in partial fulfillment of the MSc degree for the senior author.

(Received August 15, 1991; accepted November 13, 1991)

Abstract—The defensive spray of a single female of the rare carabid beetle, *Helluomorphoides clairvillei* (subfamily Carabinae, supertribe Lebiitae, tribe Helluonini), was found to contain a mixture of compounds, including carboxylic acids (formic, acetic), aliphatic esters (principally nonyl acetate), and hydrocarbons (principally decane). In a single series of discharges, the beetle ejected a total of about 1% of its body weight as formic acid (1.1 mg). Our findings demonstrate that characterization of secretory components from even minimal samples of secretion should be possible in many cases.

Key Words—Coleoptera, Carabidae, beetles, *Helluomorphoides clairvillei*, defensive secretion, formic acid, acetates, formates, hydrocarbons.

INTRODUCTION

Information is now available on the chemistry of the defensive secretion of over 300 species of carabid beetles (Blum, 1981; Weatherston and Percy, 1978; Dettner, 1987). While early characterizations had been restricted largely to major components of the mixtures, improved instrumentation, particularly capillary gas chromatography, has made possible the characterization of minor components, even from very small samples of material. We here report on the composition of the defensive spray of a rare carabid beetle, *Helluomorphoides clairvillei*, that was available to us as a single specimen only. Some years ago,

we investigated the secretions of two other species of *Helluomorphoides* and characterized only formic acid and nonyl acetate (Eisner et al., 1968). In *H. clairvillei* we were able to detect 26 components.

METHODS AND MATERIALS

The single female beetle (120.5 mg, 18 mm body length) was collected near Lake Placid, Highlands County, Florida, and maintained in the laboratory on water and freshly cut mealworms. The specimen is now deposited under lot label 1206 (T. Eisner) in the Cornell University insect collection.

Collection of Secretion. To obtain secretion for analysis, the beetle was induced to spray by pinching its legs with forceps while it was confined in a small vial. Two individual milkings were obtained in which the beetle was caused to eject several times in succession into vials (cold ether was added as solvent). After a period of three weeks, in which the beetle was kept undisturbed, it was again milked, but this time by being caused to spray only once into each of four vials, to which 100 μl of cold ether was then added.

Chemicals. Heptyl, octyl, nonyl, decyl, undecyl, and dodecyl acetates were purchased from Sigma Chemical Co. The formates were synthesized by heating the corresponding alcohols with 88% formic acid. The propionates and butyrates were made from the corresponding alcohols and acid anhydrides.

Derivatization. Pentafluorobenzyl esters of carboxylic acids and dimethyldisulfide (DMDS) derivatives of unsaturated compounds were prepared as previously described (Attygalle and Morgan, 1986).

Analytical Procedures. Gas chromatography was performed on a Hewlett-Packard (HP) 5890 instrument equipped with a splitless injector, a flame ionization detector (FID), and a HP 3396A integrator. The following 25-m $\times$ 0.22-mm fused-silica columns were used: DB-1; DB-Wax; Superox-FA.

Infrared and mass spectra were obtained with a HP 5890 gas chromatograph linked in series to a HP 5965A IR detector and a HP 5970 mass selective detector (MSD). Analyses were performed using a 25-m $\times$ 0.32-mm fused-silica column coated with SE-54. Mass spectra were also obtained on a HP 5890 gas chromatograph linked to a Finnigan ion trap detector (ITD).

For quantitative determinations of acidic components (ion-trap detection) and nonacidic components (flame-ionization detection), the external standards were, respectively, formic acid (Mallinckrodt) and decyl acetate (Sigma Chemical Co.).

RESULTS

The pungent odor of formic acid was easily recognized when the beetle was "milked." However, analytical determination of formic acid without prior derivatization is not entirely straightforward. Thus, the flame-ionization detector

(FID) most frequently used in GC hardly responds to formic acid. The ion-trap detector (ITD), on the other hand, is able to detect picogram amounts of underivatized formic acid. Using the ITD in conjunction with the Superox-FA capillary column, we were able to identify and quantify formic acid in the beetle's spray. A small amount of acetic acid was also detected. The presence of acetic acid was confirmed by conversion to its pentafluorobenzyl ester and observation of the mass spectrum of this derivative [*m/z* (%), 240(M^+, 11), 181(46), 161(16), 43(100)]. The mass spectrum and retention time of the ester corresponded to those obtained with an authentic sample of pentafluorobenzyl acetate. Table 1 shows the amount of formic and acetic acid present in the four consecutive discharges of the beetle. The total formic acid in the ejections amounted to 1.1 mg, or ca. 1% of the body mass of the beetle.

Figure 1 shows an FID gas chromatogram depicting the nonacidic components of the defensive secretion. Table 2 lists the compounds identified, together with the analytical data supporting the identifications. The proposed structures are based on the mass spectra obtained by GC-MS. In addition, the identifications of the major components were supported by infrared spectra obtained by GC-FTIR. Gas-phase FTIR spectra proved particularly helpful in recognizing acetate, formate, and hydrocarbon peaks. Thus, the absorption for carbonyl groups appeared characteristically at 1761–1762 cm^{-1} in the gas-phase FTIR spectra of the octyl, nonyl, decyl, and undecyl acetates, whereas that of formates appeared at 1740–1748 cm^{-1} (Table 2). A search for the ions *m/z* 61, 75, and 89 in the acquired mass spectral data, corresponding to the protonated carboxylic acids, readily identified those chromatographic peaks representing acetates, propionates, and butyrates, respectively. Although the signal for protonated formic acid at *m/z* 47 in the spectra of formates is not as strong as those of corresponding protonated acids in the spectra of other esters, it is highly characteristic and therefore analytically useful. The identifications of all the saturated ester peaks were confirmed by comparisons with authentic samples.

TABLE 1. MASS OF ACIDIC AND NONACIDIC COMPONENTS IN FOUR CONSECUTIVE DISCHARGES OF *H. clairvillei*

	Mass discharged [μg (% of total)]			
	1st spray	2nd spray	3rd spray	4th spray
HCOOH	44 (28)	201 (49)	853 (60)	35 (45)
CH_3COOH	2 (1)	5 (1)	15 (1)	1 (1)
Nonacidic components	112 (71)	205 (50)	564 (39)	41 (54)
Total	158	411	1432	77

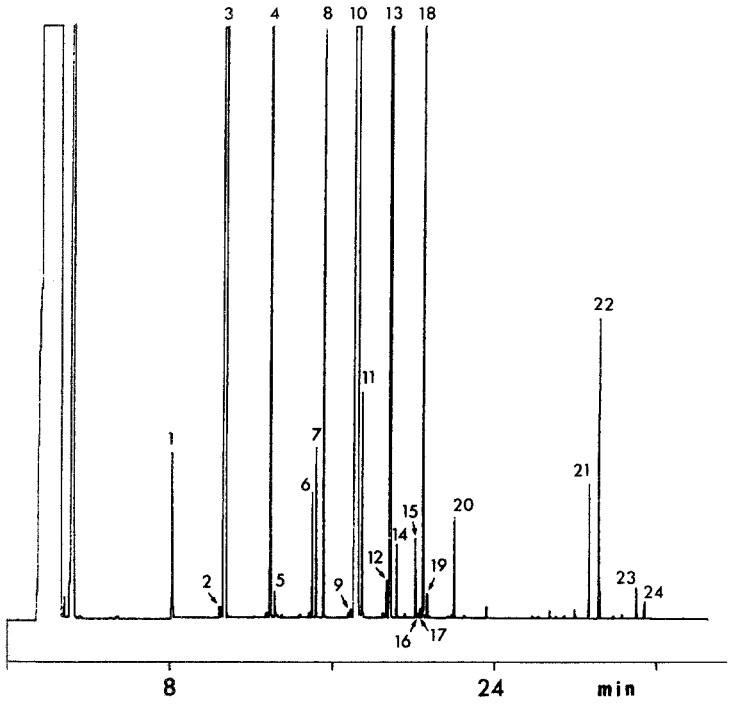

FIG. 1. FID gas chromatogram of *H. clairvillei* defensive secretion obtained on a 25-m × 0.22-mm fused-silica capillary coated with DB-5 (40°C for 4 min, then to 260°C at 8°C/min). Refer to Table 2 for peak identifications.

The double-bond positions of the unsaturated compounds, 1- and 3-decene, 3-nonen-1-yl acetate, and 4-undecen-1-yl acetate were determined by the DMDS derivatization method (Buser et al., 1983; Francis and Veland, 1981). The relevant mass spectral data are shown in Table 3. The mass spectrum of the DMDS derivative of the nonenyl acetate showed a molecular ion at *m/z* 278, and two intense ions at *m/z* 131 and 87, arising from a cleavage between the vicinal thiomethyl groups. The ion at *m/z* 131 represents $CH_3-(CH_2)_4-CH=S^+CH_3$, which arises from the distal end of the molecule, whereas the ion *m/z* 87 is from the functional-group-bearing end of the molecule after loss of acetic acid. Hence, the parent compound was identified as 3-nonen-1-yl acetate. Similarly, 4-undecen-1-yl acetate was identified on the basis of its derivative's characteristic mass spectrum (*m/z* 306, 145, and 101). Furthermore, after DMDS derivatization, two other chromatographic peaks representing a pair of isomers with molecular weight 234 were observed. These two peaks were identified as DMDS derivatives of 1-decene and 3-decene on the basis of their

TABLE 3. MASS SPECTRA OF DMDS DERIVATIVES OF UNSATURATED COMPOUNDS IN *H. clairvillei* DEFENSIVE SECRETION

Compound	Mass spectrum of DMDS derivative (*m/z*, %)
3-Nonen-1-yl acetate	278(M^+,35), 131(70), 87(54), 83(47), 61(66), 55(53), 43(100)
4-Undecen-1-yl acetate	306(M^+,54), 199(4), 145(90), 101(65), 97(41), 61(70), 55(74), 43(100)
1-Decene	234(M^+,38), 187(13), 173(100), 117(27), 83(38), 69(46), 61(96)
3-Decene	234(M^+,48), 145(100), 89(62), 59(82)

mass spectra (Table 3). The decenes are trace constituents in the secretion (0.05% combined). The capability of locating the double-bond positions in such minor constituents exemplifies the efficacy of the DMDS procedure as a potent microchemical method.

The beetle was dissected when it died. Its two defensive glands were identical in appearance to those depicted for other species of *Helluomorphoides* (Eisner et al., 1968).

DISCUSSION

Although aliphatic hydrocarbons are commonly found in arthropod defensive secretions, these hydrocarbons usually contain an odd number of carbon atoms; those with an even number are found only as trace constituents (Blum, 1981). Since hydrocarbons are considered to originate from decarboxylation of fatty acids, this distribution pattern generally reflects that of the fatty acids (Jackson and Blomquist, 1976). In this respect, the secretion of *H. clairvillei* is atypical in that the hydrocarbons show a Gaussian-like distribution with decane as the major representative (Table 2). Interestingly, a similar pattern is seen with the acetate esters in this secretion, with nonyl acetate as the major component.

Several high-molecular-weight hydrocarbons were also observed in this secretion (Figure 1). The four major constituents were identified as heneicosane, tricosane, 9-methylheneicosane, and 9-methyltricosane. However, the identification of the two branched hydrocarbons, based solely on mass spectral data, should be considered tentative since synthetic standards were not available for comparison.

We identified four formates in the secretion (Table 2). A wide variety of

formate esters have been found in the exocrine products of animals (Kuwahara et al., 1975, 1982; Weatherston et al., 1986). As in the present case, these formates are often found together with formic acid (Burger et al., 1981; Francke et al., 1985; Bagneres, 1991). To the best of our knowledge, the only formates known from carabid beetles are nonyl formate (Moore and Wallbank, 1968) and decyl formate (Moore, 1979; Kanehisa and Kawazu, 1985).

The total mass of secretory components recovered in the consecutive discharges of the beetle was not constant, indicating that there was variability in the amount of secretion ejected per discharge. There was also variability in the ratio of components in these sprayings. We attribute the latter variability, in part, to variable evaporative loss of formic acid from the samples during the collection procedure (the inevitable time-delay between milking of the beetle in the vial and addition of solvent to the vial was not kept constant). It is also possible that the two glands, which most probably did not contain the secretory components in the same ratios, and which could both have discharged in the sprayings, contributed unequally to the ejections. A further possibility (for which we have no direct evidence) is that the secretion is a coarsely distributed two-phase system rather than a one-phase system. If so, glandular output could be expected to be variable, even from consecutive discharges of the same gland.

Although the secretion of *H. clairvillei* here described is the most complex carabid defensive secretion reported so far, we do not believe such complexity to be exceptional. Nor is the production of a mixture of formic acid and a variety of lipophilic congeners in itself novel. In fact, the defensive use of a low-molecular-weight acid along with less polar compounds that help the acid penetrate an opponent's "armor" appears to have evolved independently several times (Eisner et al., 1961; 1972; Löfqvist, 1976; Moore and Wallbank, 1968; Moore, 1979; Weatherston et al., 1979). Nevertheless, it is worth noting that a combination of chromatographic, spectroscopic, and derivatization procedures has served to characterize a secretion consisting of over two dozen compounds obtained from the spray of a single insect, including compounds that constitute less than 0.05% of the mixture. In an entirely different context, a recent meticulous examination of the sexual pheromones of a brown alga led the authors to discover "a degree of elaboration not known before in algae," and they point out that "progress in analytical methods will make it necessary to re-evaluate earlier work, since at least some of the brown algal pheromone systems may be more complicated than was previously believed in respect to bouquet composition, relative biological activities, and enantiomer composition" (Müller et al., 1990). For chemotaxonomic purposes alone, analyses providing a high degree of chemical resolution are clearly more useful than those revealing only major components. Beyond this, the analysis of compounds from single specimens permits the examination of both quantitative and qualitative chemical differences between one individual and another. With pooled samples, a wealth of

potentially important information on variations of chemistry with sex, age, diet, season, geographical source, etc., is lost. For studies in chemical ecology, in contrast to explorations of "natural products" chemistry, analysis at the individual level would seem to offer special opportunities.

Acknowledgments—This work was supported by NIH grants AI 12020 and AI 02908. We thank Mark Deyrup, Archbold Biological Station, Lake Placid, Florida, for collecting the beetle, and our colleague Richard Hoebeke for identifying it.

Abstract—The effects of glandular trichome/methyl ketone (2-tridecanone and 2-undecanone) -based insect resistance in the wild tomato, *Lycopersicon hirsutum* f. *glabratum* C.H. Mull, accession PI 134417, on *Archytas marmoratus* (Townsend) and *Eucelatoria bryani* (Sabrosky) (Diptera: Tachinidae), both parasitoids of *Helicoverpa* (=*Heliothis*) *zea* (Boddie) (Lepidoptera: Noctuidae), were investigated in the laboratory. *A. marmoratus* deposits larvae (planidia) on the foliage of its host's food plant; planidia attach to passing hosts, penetrate the cuticle, and develop in the host pupae. *E. bryani* larviposits directly into its host; its larvae develop in the host larva. *A. marmoratus* planidia are killed by glandular trichomes of PI 134417 and also by trichomes of hybrid lines with no methyl ketones. The methyl ketones are toxic to planidia, but at least part of the effect is due to other factors, possibly physical entanglement. Both species can be affected indirectly by methyl ketones in the diet of the host. 2-Undecanone reduces the percentage of *A. marmoratus* larvae that reach pupation. This effect is evidently due to premature death and desiccation of the host pupa caused by 2-undecanone. 2-Tridecanone in host diets had no effect on *A. marmoratus*. In *E. bryani*, 2-tridecanone in the diet of the host reduced the number of parasitoids yielded by each parasitized host,

although not the overall percentage of hosts parasitized. 2-Undecanone in the diet of the host had no effect on *E. bryani*.

Key Words—Parasitism, *Archytas marmoratus*, *Eucelatoria bryani*, Diptera, Tachinidae, tomato, *Lycopersicon hirsutum*, glandular trichomes, *Helicoverpa zea*, Lepidoptera, Noctuidae, trilevel interaction, 2-undecanone, 2-tridecanone.

INTRODUCTION

Host-plant resistance and biological control by parasitoids and predators are important tactics in many integrated pest management systems. These tactics are often cited as being compatible in that they combine the density-independent effects of host-plant resistance with the density-dependent effects of biological control (Bergman and Tingey, 1979; Duffey and Bloem, 1986). However, the same plant characteristics that condition resistance to a pest may also adversely affect beneficial insects, resulting in incompatibility of these tactics (Bergman and Tingey, 1979; Duffey and Bloem, 1986; Duffey et al., 1986; Obrycki, 1986; Price, 1986; van Emden, 1986). These adverse effects can be divided into the broad categories: (1) direct effects, usually resulting from contact between the parasitoid or predator and the host plant, in which the herbivore may not necessarily be involved; and (2) indirect effects, in which the herbivore is altered in some way that renders it less suitable as a host or prey.

In the literature on interactions between host-plant resistance and insect parasitoids and predators, few broad patterns are evident. Perhaps the most apparent pattern is the impediment of small natural enemies by plant trichomes. Glandular trichomes may entrap these insects, while nonglandular trichomes may impede their movement (reviewed by Obrycki, 1986). Otherwise, it would be difficult to predict how a given host-plant resistance characteristic might affect a given species of natural enemy. We hypothesize that one reason for the variation in these interactions is variation in the life histories of parasitoids and predators. The study reported herein was undertaken as a part of our effort to test this hypothesis by comparing the response to an insect-resistance factor by two species of parasitoids with different life histories.

The parasitoids selected for this study were two species of tachinid flies (Diptera), both of which attack the tomato fruitworm, *Helicoverpa* (=*Heliothis*) *zea* (Boddie) (Lepidoptera: Noctuidae): *Archytas marmoratus* (Townsend) and *Eucelatoria bryani* Sabrosky. *A. marmoratus* larviposits minute live maggots, or planidia, on its host's food plant. Planidia attach themselves to passing hosts and penetrate the cuticle. The parasitoid undergoes only limited development until the host pupates, when it develops rapidly and emerges from the host pupa as an adult (Hughes, 1975). No more than one fly emerges from a single host. *E. bryani*, in contrast, larviposits directly into its host. Its larvae develop rapidly,

killing the host larva after a few days. Mature larvae emerge from the dead host larva to pupate. A single host often yields several parasitoids, occasionally as many as 20 (Jackson et al., 1969; Bryan et al., 1972). The larvae of *A. marmoratus*, therefore, come into direct contact with the host's food plant, whereas those of *E. bryani* do not, as dead hosts would typically fall off the host plant. Hosts inside tomato fruit might not fall off, but fruit do not contain the resistance mechanisms examined in this study.

The host-plant resistance examined in this study was the methyl ketone (2-tridecanone and 2-undecanone)/glandular trichome-based resistance of the wild tomato, *Lycopersicon hirsutum* f. *glabratum* C.H. Mull, accession PI 134417. 2-Tridecanone, the 13-carbon methyl ketone, occurs in type VI (Luckwill, 1943) glandular trichomes on the foliage and is largely responsible for resistance to several insect pests of tomato, including the tobacco hornworm, *Manduca sexta* (L.) and Colorado potato beetle, *Leptinotarsa decemlineata* (Say), (Kennedy and Henderson, 1978; Kennedy and Yamamoto, 1979; Williams et al., 1980; Kennedy and Sorenson, 1985; Kennedy et al., 1985; Kennedy, 1986; Kennedy and Farrar, 1987). Neonate larvae of these insects typically die soon after being placed on resistant foliage. 2-Tridecanone confers a limited degree of resistance to *H. zea* as well; however, most of the resistance to *H. zea* is conferred by as yet undetermined factors in leaf tissues other than the trichomes (Farrar and Kennedy, 1987a). 2-Undecanone, the 11-carbon methyl ketone, also occurs in PI 134417 type VI trichomes, but is less abundant and less acutely toxic to neonate *H. zea* than 2-tridecanone (Dimock et al., 1982). However, in combination, 2-undecanone and 2-tridecanone are synergistic in their toxicity to several insects, including *H. zea* (Farrar and Kennedy, 1987b, 1988; Lin et al., 1987). 2-Undecanone, at levels commonly found in PI 134417 foliage, also causes extensive mortality of *H. zea* in the pupal stage if ingested by the fifth-instar larva (Farrar and Kennedy, 1987b, 1988).

In recent studies, the methyl ketone/glandular trichome-based resistance of PI 134417 has been shown to inhibit several species of insect parasitoids. These species include *Campoletis sonorensis* (Cameron) (Hymenoptera: Ichneumonidae), a larval parasitoid of *H. zea* (Kauffman and Kennedy, 1989a,c; Farrar and Kennedy, unpublished data), *Trichogramma* spp. (Hymenoptera: Trichogrammatidae) egg parasitoids of *H. zea* and *M. sexta* (Kauffman and Kennedy, 1989b; Kashyap et al., 1991), and *Telenomus sphingis* (Ashmead) (Hymenoptera: Scelionidae), an egg parasitoid of *M. sexta* (Kashyap et al., 1991; Farrar and Kennedy, 1991). Farrar and Kennedy (unpublished data) also found reduced activity of an array of parasitoids on *M. sexta*-resistant plants in the field in North Carolina. That study did not include the tachinids studied here, as, in North Carolina, *E. bryani* does not occur naturally and *A. marmoratus* is not seen in high numbers until late in the growing season (Hughes and Rabb, 1976).

The study reported herein was designed to evaluate the effects of methyl

ketone/glandular trichome-based resistance of PI 134417 on *A. marmoratus* and *E. bryani* and to determine whether any differences between the two species were related to differences in their life histories.

METHODS AND MATERIALS

All insects were obtained from colonies maintained at North Carolina State University. Hosts [*H. zea* and *H. virescens* (F.)] were maintained on corn–soya–milk (CSM) diet (Burton, 1970). *A. marmoratus* was maintained on *H. zea* according to Hughes (1975) and Gross and Johnson (1985). *E. bryani* was maintained on *H. virescens* according to Bryan et al. (1969, 1972). All experiments, however, were done using *H. zea* as the host for both species.

All tomato plants were grown in a greenhouse using a commercial soil mix (Metro Mix 220) and were fertilized weekly (Peter's Professional 20-20-20 at 2.8 g/plant). Daily photoperiod was supplemented to 16 hr with metal halide lamps. The following plant lines were included in the study: PI 134417, the susceptible *L. esculentum* Mill. cultivar Better Boy, the F_1 hybrid (*L. esculentum* × PI 134417), and BC-2, a selection from an F_1 backcross family (F_1 × PI 134417). F_1 foliage has a density of type VI trichomes intermediate between those of PI 134417 and Better Boy, but no detectable methyl ketones (Kauffman and Kennedy, 1989b). BC-2 usually has a moderately high density of type VI trichomes and intermediate levels of methyl ketones (Kauffman and Kennedy, 1989b). The *L. esculentum* cultivar Walter was used to make the crosses since Better Boy, a hybrid cultivar, does not cross readily with PI 134417. Lepidopterous larvae respond similarly to Walter and Better Boy, and neither cultivar contains detectable levels of methyl ketones (Farrar and Kennedy, unpublished data).

A. marmoratus *Experiments.* Because *A. marmoratus* planidia spend a period of time on the surface of the host's food plant, experiments were conducted to evaluate the effects of the methyl ketones and/or glandular trichomes of PI 134417 on mortality of planidia on this foliage.

Planidia were picked up with a fine brush from the larviposition substrate (filter paper) and dropped onto foliage from a height of ca. 1 cm by flicking them off the brush with a second brush. In experiments using filter paper instead of foliage (see below), handling in this manner resulted in ca. 7% mortality of planidia. Care was taken not to touch the leaf with the brushes and thereby rupture trichome tips. Twenty-five to 35 planidia, constituting one observation, were placed on each leaflet. The petioles of the leaves were placed in flasks of water. The leaves were held at 25 ± 2°C for 24 hr, at which time the planidia were scored as alive or dead. Planidia that showed vigorous movement when gently prodded with a fine bristle were scored as alive, those that did not were

scored as dead. Ten replications of each plant line were done. Percentage mortality was calculated, normalized by arcsine $\sqrt{\%}$ transformation, and subjected to analysis of variance (ANOVA). Means were separated by the least significant difference (LSD) test.

To verify that effects seen in the above experiment (see below) were due to the glandular trichomes, the experiment was repeated including foliage from which the exudate of the glandular trichomes had been removed. Trichome exudate was removed by gently wiping the foliage, first with a dry cotton ball, then with a cotton ball saturated with a 0.1% aqueous solution of Triton X-155 (a nonphytotoxic emulsifying agent), then rinsing it, first in 0.1% Triton, then in clean water. Although it cannot be said with certainty that this method removes 100% of the trichome exudate, results of previously published studies (e.g., Farrar and Kennedy 1987a; Kennedy and Farrar, 1987) are consistent with removal of the vast majority of the exudate. Furthermore, microscopic examination of this foliage revealed no intact trichomes. This experiment was otherwise similar to the above experiment, except that BC-2 was omitted, since mortality on it was similar to that on PI 134417.

Every two weeks during the tests involving foliage, the density of type VI trichomes was measured for each plant line. In addition, the levels of 2-tridecanone and 2-undecanone were measured for the plant lines known to possess them, BC-2 and PI 134417. The other lines, F_1 and Better Boy, previously have been shown to possess no detectable levels of methyl ketones (Kauffman and Kennedy, 1989b; Farrar and Kennedy, unpublished). Four leaflets were collected for each sample. From each leaflet, a 5.8-mm-diam. disk was cut with a cork borer and type VI trichomes on one surface of each disk were counted. For PI 134417 and BC-2, 300 type VI trichome tips were collected with glass microcapillary tubes from each leaflet (total of 1200 tips per plant line). Counts and collections were done on the adaxial surface of two of the leaflets and from the abaxial surface of the other two leaflets. The samples were analyzed using a Hewlett-Packard 5880 gas chromatograph with a 15-m Durabond DB5 temperature-program analysis (100°C for 1 min, then to 275°C at 5°C/min, and held at 275°C for 5 min). 2-Tetradecanone (Wiley Organics, 4654 Kenny Rd., Columbus, Ohio 43220) was used as an internal standard. These data were used to calculate the concentration of 2-tridecanone and 2-undecanone in PI 134417 as weight per square centimeter of foliage.

To evaluate the toxicity of the methyl ketones, LC_{50} values (the concentration needed to kill 50% of the test insects) were determined for 2-tridecanone and 2-undecanone for *A. marmoratus* planidia. Standard solutions of a range of concentrations of purified ketones (2-tridecanone: Fluka Chemical Corp., Hauppauge, New York 11788; 2-undecanone: Pfaltz and Bauer, Inc., Stamford, Connecticut 06902) were prepared in acetone. Solutions were pipetted onto filter paper at a rate of 21 $\mu l/cm^2$ and the acetone allowed to evaporate. Rates of

0.21–1.05 $\mu g/cm^2$ and 1.05–15.12 $\mu g/cm^2$ were used for 2-tridecanone and 2-undecanone, respectively. Controls, treated with acetone only, were included in all tests. Filter papers were placed in the lids of inverted 5.5-cm disposable plastic Petri dishes and moistened with four drops of water per filter paper disk. Twenty-five to 30 planidia were dropped onto each filter paper disk as above. Dishes were sealed with Parafilm and held at 27°C for 24 hr, at which time the planidia were scored as dead or alive, as above. The data were adjusted for mortality in the controls (ca. 7%) using Abbott's (1925) formula, and probit analysis was used to calculate LC_{50} values.

H. zea larvae developing on tomato plants with methyl ketone-based resistance to *M. sexta* ingest methyl ketones during at least part of the larval stage. Therefore, there is the potential for indirect, or host-mediated, effects on the parasitoids. Experiments were conducted in which parasitoids were reared on *H. zea* larvae, which were in turn reared throughout the larval stage on diets containing 2-tridecanone and/or 2-undecanone. Diet (CSM) (Burton, 1970) was prepared in batches of 4.0 liters using a commercial blender. To make different treatments, 500 ml of warm (ca. 45°C) liquid diet was poured into a 1-liter blender. Measured amounts of the ketones were added and blended into the diet for a minimum of 1 min at high speed. Both ketones are liquids at 45°C. Diet was poured into 30-ml plastic cups (ca. 10 ml/cup) in which the larvae were reared. Control (untreated) diet was poured directly into cups. In all tests, concentrations of 0.3% and 0.06% (wet weight) were used for 2-tridecanone and 2-undecanone, respectively. These concentrations are representative of those found in PI 134417 foliage. *H. zea* shows some mortality in the early larval stage on diet with these concentrations of 2-tridecanone or 2-tridecanone plus 2-undecanone ($\bar{x}$ = 15 and 27%, respectively; Farrar and Kennedy, 1987b), but sufficient numbers of larvae can be reared on these diets.

To test for indirect effects on *A. marmoratus*, *H. zea* larvae were reared through the fifth instar on one of four diets: 2-tridecanone (0.3%), 2-undecanone (0.06%), 2-tridecanone plus 2-undecanone (0.3 + 0.06%), and control (untreated). Larvae were held at 27°C under a 16:8 light–dark photoperiod. On the first or second day of the fifth larval instar, using a small brush, three planidia were placed on the dorsal surface of each larva. Larvae were held until pupation on their respective diets. Uneaten diet was then removed from the cups. In *Helicoverpa* pupae parasitized by *A. marmoratus*, parasitoid larvae typically form respiratory funnels that are visible around the host's wing pads (Hughes, 1975). Pupae showing respiratory funnels were therefore classified as parasitized; those without, as unparasitized. Pupae were held through death, fly emergence, or moth emergence. Pupae that were classified as parasitized but that did not yield flies were dissected to determine if dead parasitoids were present. Thirty *H. zea* larvae per replicate were reared on each treatment, and the experiment was replicated three times. The following variables were calculated and

analyzed by chi-square tests: percentage parasitized pupae, percentage of total pupae yielding flies, percentage of parasitized pupae yielding flies, and percentage of dead parasitized pupae containing visible dead parasitoids. Developmental time from host pupation to fly emergence was analyzed by ANOVA with the LSD test to separate means.

The above experiment indicated that emergence of flies from parasitized hosts reared on diets with 2-undecanone was reduced (see below). 2-Undecanone causes extensive mortality of *H. zea* pupae (Farrar and Kennedy, 1987a, 1988). Therefore, we hypothesized that this reduction in fly emergence was due to death and desiccation of the host before the parasitoid could complete development. An experiment was thus conducted in which parasitized *H. zea* pupae were held at high or low relative humidity and fly emergence recorded. Larvae were reared on diet with 2-undecanone (0.06%) or control diet and infested with planidia as above (50 *H. zea* larvae per treatment). Unparasitized controls of both dietary treatments were also included. At pupation, pupae of each dietary treatment were randomly divided into two groups of 20–25 pupae. For the treatments that received planidia, only pupae with visible respiratory funnels were retained; other pupae were discarded. One group of pupae was placed in a 15-cm Petri dish lined with moist filter paper, covered with a plastic lid, and sealed with Parafilm (high relative humidity treatment). The other group was placed in a similar Petri dish but with dry filter paper and a screen wire lid (low relative humidity treatment). All Petri dishes were held in an environmental chamber at 27°C, 30% relative humidity, and a 16:8 light–dark photoperiod. After seven days, the plastic lids of the high relative humidity dishes were replaced with screen wire lids. (Preliminary tests indicated that high relative humidity for the entire developmental period reduced emergence of both adult flies and moths). Three replications were done. The percentage of *H. zea* pupae in which the parasitoid reached pupation, the percentage of *H. zea* pupae yielding flies, and the percentage of parasitoid puparia yielding adult flies were calculated. These variables were analyzed by chi-square tests for differences between dietary treatments within relative humidity treatments and for differences between relative humidity treatments within dietary treatments. The unparasitized controls were analyzed similarly for differences in percentage moth emergence.

E. bryani *Experiments.* A similar experiment was conducted to evaluate indirect effects on *E. bryani*. In this case, however, it was not possible to infest each larva with a constant number of parasitoids as it was with *A. marmoratus*, since *E. bryani* larviposits directly into its host. To equalize exposure to the parasitoids, ten fifth-instar larvae reared on each treatment were placed in a single cage (44 × 44 × 44-cm wire-screen cage with a cloth sleeve) with 25–30 flies for 3 hr. To separate larvae from different dietary treatments after exposure, each larva was marked with a felt tip pen. Marks were made on the

anterior, posterior, left middle or right middle portions of the thorax–abdomen. Preliminary tests indicated no effect of marking on parasitism or larval survival. Dietary treatments included 2-tridecanone (0.3%), 2-undecanone (0.06%), 2-tridecanone plus 2-undecanone (0.3 + 0.06%), and control (untreated). Thirty larvae were reared through the fifth instar on each diet. They were exposed to flies in three groups of 10 larvae per treatment on the first or second day of the fifth instar. Larvae were returned to the diet on which they were reared and held through host pupation or death. Uneaten diet was then removed, so that parasitoid larvae would not contact it upon emergence from the host. Parasitoid puparia were held for adult emergence. Three replications (over time, with different flies each time) were performed. Percentage of hosts parasitized (data pooled across replicates) was calculated and analyzed by chi-square tests. Numbers of puparia and flies per host (not including hosts which pupated), percentage of puparia yielding adult flies, and time to fly emergence were subjected to ANOVA with the LSD test to separate means.

RESULTS AND DISCUSSION

A. marmoratus *Experiments.* Plant line significantly affected the mortality of *A. marmoratus* planidia on foliage ($F = 65.83$, treatment $df = 3$, error $df = 33$, $P \leq 0.0001$). Mortality was high on PI 134417 and BC-2 and intermediate on F_1 (Table 1, Test 1). In the second experiment, there was a highly significant interaction between plant line and the presence or absence of trichome exudate ($F = 20.69$, interaction $df = 2$, error $df = 25$, $P \leq 0.0001$). Among treatments with intact trichomes, plant line again significantly affected mortality ($F = 43.30$, treatment $df = 2$, error $df = 25$, $P \leq 0.0001$), although mortality was higher on all lines than in the first experiment. In contrast, among treatments without trichome exudate, rates of mortality were almost identical on all plant lines, with no significant differences ($F = 0.07$, treatment $df = 2$, error $df = 26$, $P = 0.9333$). Within plant lines, there was a significant effect of trichome exudate removal for PI 134417 ($F = 154.58$, treatment $df = 1$, error $df = 16$, $P \leq 0.0001$) and for F_1 ($F = 72.13$, treatment $df = 1$, error $df = 16$, $P \leq 0.0001$), but not for Better Boy ($F = 1.86$, treatment $df = 1$, error $df = 17$, $P = 0.1900$). These results indicate that the glandular trichomes of PI 134417 cause mortality of *A. marmoratus* planidia. The trichomes of F_1 also caused mortality, but at lower levels. There appeared to be some mortality due to trichomes on Better Boy as well in the second experiment, although this effect was not significant.

Levels of methyl ketones, as measured by gas chromatography, were low, but within the range reported by Kauffman and Kennedy (1989b) (Table 1). Levels in BC-2 were higher than expected and similar to those in PI 134417. Numbers of trichomes per unit area were within the expected range.

TABLE 1. TRICHOME DENSITY, METHYL KETONE CONTENT, AND MORTALITY OF *A. marmoratus* PLANIDIA ON FOLIAGE OF *M. sexta*-RESISTANT AND -SUSCEPTIBLE TOMATOES

Plant line	Trichome density (#/mm^2)	2-Tridecanone (μg/cm^2)	2-Undecanone (μg/cm^2)	Mortality (%)[a] Test 1 Trichomes present N	Test 1 Trichomes present Mean	Test 2[b] Trichomes present N	Test 2[b] Trichomes present Mean	Test 2[b] Trichomes absent N	Test 2[b] Trichomes absent Mean

[a] Means separation within columns by LSD; means with the same capital letter are not significantly different ($P > 0.05$).
[b] In test 2 only, means separation within rows by F test; means with the same lower case letter are not significantly different ($P > 0.05$).

In tests with purified chemicals, probit analysis yielded LC_{50} values of 0.676 μg/cm^2 (95% fiducial limits: 0.635–0.718 μg/cm^2) for 2-tridecanone and 8.914 μg/cm^2 (95% fiducial limits: 8.239–9.672 μg/cm^2) for 2-undecanone. These data indicate that levels of 2-tridecanone, at least, in PI 134417 and BC-2 foliage were sufficient to kill *A. marmoratus* planidia. However, elevated levels of mortality were also seen on F_1, which has an intermediate density of trichomes, but no methyl ketones (Kauffman and Kennedy 1989b, Farrar and Kennedy, unpublished). Therefore, factors in the trichomes other than, or in addition to, methyl ketones must be involved in planidial mortality. Physical entanglement of planidia in trichome exudate may be involved. Because PI 134417 and BC-2 represent both increased densities of trichomes and the presence of methyl ketones, it is not possible to separate these effects using data collected in this study. However, given that 2-tridecanone is highly toxic to the planidia, it is likely that both physical and chemical factors are involved.

Rearing *A. marmoratus* on *H. zea* fed diets with methyl ketones indicated an indirect, or host-mediated, effect of 2-undecanone, but not of 2-tridecanone. At the time of host pupation, there were no significant differences ($P > 0.05$) between treatments in percentage parasitized pupae (i.e., the percentage with visible respiratory tunnels) (Table 2). However, the number of hosts yielding

[a] Parasitized *H. zea* pupae were those that had visible respiratory funnels of *A. marmoratus* under or around the wing pads.
[b] Means separation for each variable by chi square; means with the same letter are not significantly different ($P > 0.05$).
[c] Only one dead parasitized host pupa in this treatment.
[d] Means separation for this variable by LSD; means with the same letter are not significantly different ($P > 0.05$).

adult flies, expressed either as a percentage of total hosts or as a percentage of parasitized hosts, was significantly ($P \leq 0.05$) reduced on treatments with 2-undecanone. There was no difference between diet with 2-undecanone only and that with both 2-undecanone and 2-tridecanone. Of the pupae reared on these two diet treatments, nearly all parasitized pupae that did not yield adult flies contained dead parasitoid larvae. There was no significant treatment effect on developmental time of those flies that reached the adult stage ($F = 2.30$, treatment $df = 3$, error $df = 139$, $P = 0.0796$). Although this probability value (0.0796) suggests a trend, developmental time on 2-tridecanone plus 2-undecanone, which could be expected to be the most toxic treatment, differed from that on the control by only 0.1 day in this case. In hosts reared on diets con-

taining 0.06% 2-undecanone, ca. 50% of *A. marmoratus* die between host pupation and parasitoid emergence. There were, however, no indications of any effects of any treatments on mortality of parasitoids between penetration of the host and host pupation.

Holding parasitized pupae at different relative humidities strongly influenced the effects of 2-undecanone on *A. marmoratus*. At low relative humidity (ca. 30%), 2-undecanone significantly decreased the percentage of hosts yielding fly puparia relative to the control ($\chi^2 = 9.5033$, $df = 1$, $P = 0.0021$) (Table 3); this effect is consistent with that in the above experiment. However, at high relative humidity (ca. 100%), 2-undecanone did not affect on the percentage of hosts yielding fly puparia ($\chi^2 = 0.0393$, $df = 1$, $P = 0.8429$). In puparia that were produced at low humidity, 2-undecanone did not affect the percentage yielding adult flies ($\chi^2 = 0.1886$, $df = 1$, $P = 0.6641$). However, at high relative humidity the percentage of puparia yielding flies was significantly higher for parasitoids from hosts reared on 2-undecanone ($\chi^2 = 9.8718$, $df = 1$, $P = 0.0017$). Differences in puparial numbers are reflected in the percentages of parasitized hosts yielding adult flies: this percentage was significantly lower on the 2-undecanone treatment of low relative humidity ($\chi^2 = 7.0528$, $df = 1$, $P = 0.0079$), but significantly higher on this treatment at high relative humidity ($\chi^2 = 7.2473$, $df = 1$, $P = 0.0069$). The percentage of unparasitized *H. zea* pupae yielding moths was significantly lower on diet with 2-undecanone at both high and low relative humidity, with no evidence of any effect of relative humidity; these results are consistent with those of Farrar and Kennedy (1987b, 1988).

The lack of an effect of 2-undecanone on the percentage of parasitized hosts yielding puparia at high relative humidity, in contrast to the pronounced effect of 2-undecanone at low relative humidity, supports our hypothesis that 2-undecanone affects *A. marmoratus* through premature death and desiccation of the host. The lack of an effect of 2-undecanone on the percentage of puparia yielding adult flies, at least at low relative humidity, shows that the effect is not a pupal toxicity effect like that which affects *H. zea*. We have no satisfactory explanation for the higher percentage of puparia yielding flies on the 2-undecanone treatment at high relative humidity. This percentage was, however, lower for both dietary treatments at high relative humidity than at low relative humidity. The high relative humidity treatments were held at ca. 100% relative humidity for seven days. Preliminary tests indicated that maintaining the level of relative humidity through the entire pupal period resulted in extensive mortality both of *A. marmoratus* and of unparasitized *H. zea*. In the first experiment with methyl ketone-treated diet, the developmental time of *A. marmoratus* on hosts reared on diet with 2-undecanone was slightly, although not significantly ($P > 0.05$), longer than on control hosts (Table 2). A slight developmental delay could have resulted in puparia from hosts reared on 2-undecanone passing the stage susceptible to excessive moisture after the seventh day, when they were allowed to dry out.

TABLE 3. EFFECTS OF 2-UNDECANONE (0.06%) IN HOST DIET ON EMERGENCE OF *A. marmoratus* ADULTS FROM PARASITIZED *H. zea* PUPAE, AND ON MOTH EMERGENCE FROM UNPARASITIZED PUPAE AT HIGH AND LOW RELATIVE HUMIDITY

[a] Parasitized pupae were those that had visible respiratory funnels of *A. marmoratus* under or around the wing pads.

In the field, *H. zea* pupates in the soil. The effect of 2-undecanone on *A. marmoratus* in the field would therefore probably depend on soil moisture. *A. marmoratus* might be killed under dry conditions but not under higher moisture conditions.

E. bryani *Experiments.* Results of the test for indirect effects on *E. bryani* differed markedly from those of the *A. marmoratus* experiments. 2-Undecanone had no significant effect on any parameter that was measured for *E. bryani* (Table 4). In contrast, 2-tridecanone, which had no effect on *A. marmoratus*, caused a decrease in the number of puparia per host for those hosts that yielded puparia. This effect did not, however, result in any significant differences in percentage parasitism (the percentage of hosts yielding one or more puparia). The percentage of puparia yielding adult flies was not affected ($F = 1.00$, treatment $df = 3$, error $df = 15$, $P = 0.4208$), nor was developmental time ($F = 0.01$, treatment $df = 3$, error $df = 910$, $P = 0.9994$).

Several ways exist in which the number of *E. bryani* puparia obtained from apparently parasitized host larvae is reduced. One way is superparasitism, in which there are more parasitoid larvae in the host than can develop on available

TABLE 4. RATES OF PARASITISM, SURVIVAL, AND DEVELOPMENT OF *E. bryani* ON *H. zea* REARED ON DIETS WITH OR WITHOUT METHYL KETONES

food. In this case, which is seen regularly in colony maintenance, the host dies within a few days after exposure to the flies and has the same general appearance as other parasitized hosts, but it yields no puparia. However, in the experiment only three larvae died prior to pupation but yielded no parasitoids. All of these larvae were reared on diet with 2-tridecanone. None were seen in the treatment that received both 2-tridecanone and 2-undecanone and that showed a similar reduction in the number of puparia per host. Therefore, it is unlikely that superparasitism was a factor in the effect of 2-tridecanone. Superparasitism would also require increased larviposition, which would not be expected in hosts reared on 2-tridecanone. Several other factors could be involved, however, including: reduction in the number of flies larvipositing in each host, reduction in the number of larvae inserted by each fly into each host, and mortality of parasitoid larvae in the host. However, our experimental design did not allow us to determine which of these factors was operating.

The methyl ketone/glandular trichome-based insect resistance of PI 134417 clearly adversely affects both *A. marmoratus* and *E. bryani*. These effects are different for each species, however, and at least a portion of these differences is apparently related to differences in life histories of the two tachinid species. *A. marmoratus* planidia are killed by the foliar trichomes. *E. bryani* larvae are not directly affected by foliar trichomes since they are deposited directly into the host. 2-Undecanone indirectly affects *A. marmoratus*, evidently by killing its host before the parasitoid can complete development. *E. bryani* escapes any such effects by completing development before the host pupates. Unlike *A. marmoratus*, *E. bryani* larvae are apparently susceptible to indirect effects of 2-tridecanone. This difference may be due to differential susceptibility to the toxic effects of 2-tridecanone, rather than any differences in life histories.

Previous studies have shown that variation in life histories and/or physical characteristics can also influence the effects of methyl ketone/glandular trichome-based resistance on other parasitoid species. Kashyap et al. (1991) found that the egg parasitoids *Telenomus sphingis* and *Trichogramma pretiosum* Riley both became entangled in trichome exudate. However, *T. sphingis*, the larger of the two species, can free itself through prolonged grooming, while *T. pretiosum* cannot free itself and eventually dies. In *Campoletis sonorensis*, rates of parasitism are reduced on PI 134417 (Farrar and Kennedy, unpublished data). Since *C. sonorensis* oviposits directly into its host, similar to *E. bryani*, this effect is not obviously related to the life history of *C. sonorensis*. However, *C. sonorensis* larvae emerge from the host on the foliage of the hosts' food plant, and, on PI 134417, are killed by the trichomes (Kauffman and Kennedy, 1989a,c). Species of parasitoids that do not emerge from the host on the foliage would avoid these effects.

In conclusion, the life history of a parasitoid can influence whether and how the parasitoid may be affected by a given host-plant resistance factor.

Variation in life histories, thus, may be one reason for the lack of general patterns in such interactions reported in the literature. It is therefore important to consider the life history of the insect when studying these interactions. So doing will increase the understanding of the nature of these interactions and better enable us to integrate biological control and host-plant resistance in pest-management systems.

Abstract—Whole-body extracts of the termite, *Coptotermes formosanus* Shiraki served for examining the presence of trail pheromone precursor(s). Three trail pheromone precursor candidates, identified as dodecatrienyl stearate, dodecatrienyl oleate, and dodecatrienyl linoleate, were isolated using various chromatographic methods in conjunction with bioassay and by capillary GC-MS analyses.

Key Words—Subterranean termite, *Coptotermes formosanus*, Rhinotermitidae, Isoptera, trail pheromone precursor, dodecatrienyl fatty acid esters.

INTRODUCTION

Only (*Z*,*Z*,*E*)-3,6,8-dodecatrien-1-ol (DTE-OH) has been identified as a trail pheromone of rhinotermitid termites. This compound was isolated from wood decayed by a brown rot fungus, *Gloeophyllum trabeum* (Matsumura et al., 1968, 1969) and proved identical with a trail pheromone of workers of *Reticulitermes virginicus* (Banks) on the basis of the biological activity (Tai et al., 1969).

We recently isolated the trail pheromone from other two rhinotermitid ter-

mites, *Reticulitermes speratus* (Kolbe) (Tokoro et al., 1991) and *Coptotermes formosanus* Shiraki (Tokoro et al., 1989), and identified it as DTE-OH (Yamaoka et al., 1987; Tokoro et al., 1992a). Heterogeneric isolations suggest that DTE-OH may be a trail pheromone common to the family Rhinotermitidae.

Because the amount of the trail pheromone per individual was extraordinarily small (i.e., a worker termite could produce a 1.5-m long secretion of effective trail of the pheromone), we hypothesized that the pheromone might be stored in the termite body in the form of a precursor. Whole-body extracts of *R. speratus* workers were subjected to various chemical isolation procedures and bioassays to examine the presence of trail pheromone precursor (Tokoro et al., 1990). Fractions that mainly contained fatty acid esters were obtained from hexane extracts by means of silica-gel column chromatography. Trail-following activity of the fractions was activated by alkaline hydrolysis, while the original fractions did not show any conspicuous activity. Bioassay showed that the activity of hydrolyzed product was approximately 20 times higher than the original hexane extract. This suggests that the precursor candidate could be stored in termite bodies as an esterified form. Chemical analyses revealed that the complete structure of the hydrolyzed product was identical to DTE-OH (Tokoro et al., 1990).

Whole-body extracts of *C. formosanus* were also examined for the presence of a trail pheromone precursor. The hydrolyzed substance of several fractions prepared by silica-gel column chromatography showed high trail-following activity and was identified as DTE-OH (Tokoro et al., 1992b). The findings suggest that the trail pheromone of *C. formosanus* could be stored as with *R. speratus*.

The main purpose of the present investigation was to isolate and to identify the trail pheromone precursors of *C. formosanus*.

METHODS AND MATERIALS

Insects. Colonies of *C. formosanus* were collected in the city of Wakayama, Japan, and kept in the laboratory (Uji city) for about seven years with Japanese red pine (*Pinus densiflora* Sieb. et Zucc.) as food source at 28 ± 2°C and ca. 80% relative humidity. Only undifferentiated pseudergates (workers) of *C. formosanus*, ca. 938 g and ca. 310,000 in number, were selected for the present experiment.

Chemicals. Synthetic (*Z,Z,E*)-3,6,8-dodecatrien-1-ol (DTE-OH) (Ikeda et al., 1984) was supplied by Dr. H. Yamamoto (Nagoya University, Japan). Standard dodecanoic fatty acid esters were prepared by an esterification reaction with *p*-toluenesulfonic acid as catalyst and purified by high-performance liquid chromatography (HPLC). All other reagents were purchased from Nacalai Tesque Inc. (NTI; Kyoto, Japan).

Confirmation of Precursor Candidate. Since precursor candidates would not always show trail-following activity, existence of precursor candidates during the purification procedures was examined after alkaline hydrolysis of isolates followed by termite bioassay. The trail-following activity was estimated by a modified open-field bioassay. When three or more of the nine workers followed the 15-cm trail treated with 2 μl test solution, the sample was designated positive. Tenfold dilution series and more highly diluted solutions of each sample were employed to determine the "minimum effective worker equivalent (MEWE)" [worker equivalent (WE)/15-cm trail]. Strength of trail-following activity was evaluated by MEWE. Details of the methods of hydrolysis and bioassay were described previously (Tokoro et al., 1989, 1990, 1991).

Extraction. The worker termites (ca. 938 g) had been fed with moistened filter paper as food source for about five days before extraction so that the existing intestinal materials were completely replaced with filter paper. The termites were then soaked in *n*-hexane (ca. 300 ml per 20,000 worker termites) for about 10 days without homogenization at $-20°C$.

Isolation. The hexane extracts were prepared by filtration and concentration by a rotary vacuum evaporator to obtain a yellowish crude lipid (ca. 71 g). A large portion of this crude lipid (ca. 68 g and ca. 300,000 worker equivalent) was first fractionated by silica-gel column chromatography with *n*-hexane (Hx)–ethyl acetate (EtOAc) and methyl alcohol (MeOH) eluants, and the cycle repeated once again (Figure 1).

The active fractions, from silica-gel column chromatography above, were further fractionated by HPLC with diethyl ether (Er)/Hx eluants (HPLC 1: 2.5% Er/Hx; HPLC 2: 0.5% Er/Hx; both flow rates were 1.0 ml/min). The HPLC was a model LC-9A (Shimadzu, Kyoto, Japan) pump connected in series to a model SPD-6AV (Shimadzu) UV-VIS spectrophotometric detector and to a model ERC-7511 (Erma, Tokyo, Japan) refractive index (RI) detector. The analytical column used was a Cosmosil 5SL (silica-gel, 25 cm $\times$ 4.6 cm ID, particle size 5 μm; NTI) with a Cosmosil 10SL (5 cm $\times$ 4.6 cm ID) guard column. The conjugated double bond of the active substance was detected by UV-VIS detector at 234 nm and additionally by the RI detector and fractionated at each peak for bioassay.

The final purification step was carried out by capillary gas chromatography (GC), which was conducted with a model GC-15A (Shimadzu), equipped with an FID detector. A fused silica wide-bore capillary column was a CBP1-W12-300 (12 m $\times$ 0.53 mm ID, Shimadzu) coated with methyl silicone (coating width: 3 μm). Analytical conditions were as follows: the oven temperature was kept at 180°C for the first minute and then raised at 20°C/min to 320°C and finally maintained at 320°C for 10 min; injection temperature was 320°C and detector temperature 350°C; the carrier gas was helium at a velocity of approximately 60 cm/sec. The outlet gas was fractionated for each peak, and the trail

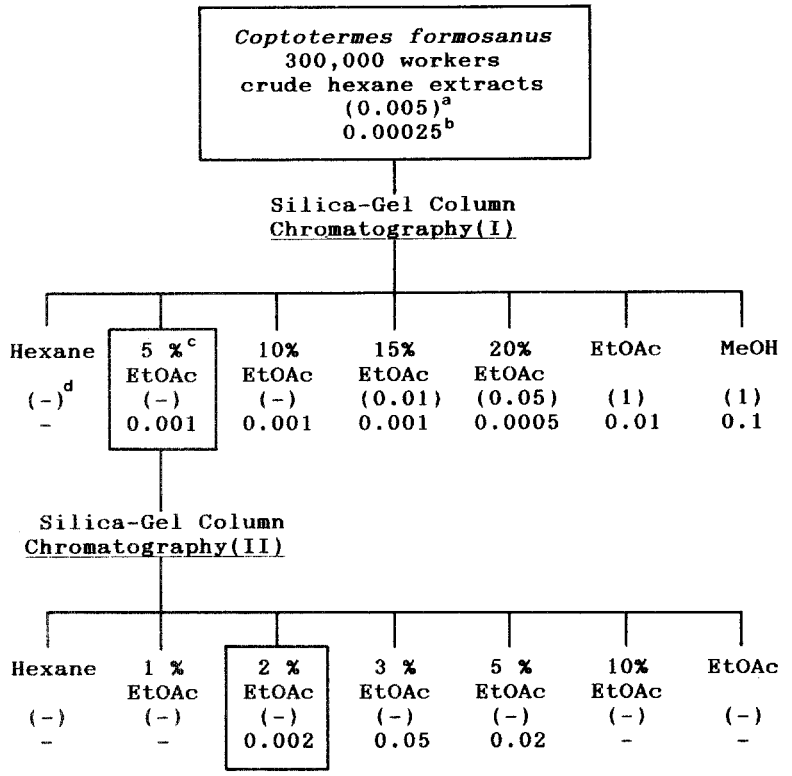

FIG. 1. Results of silica-gel column chromatography of the crude hexane extracts from *C. formosanus*. [a]The values in parentheses are the trail-following activity before hydrolysis. The activity was estimated by a modified open-field bioassay (Tokoro et al., 1991). When three or more of nine workers followed the 15-cm trail, the sample was designated positive. Tenfold dilution series and more highly diluted solutions of each sample were employed to determine the minimum effective worker equivalent (MEWE) (worker-equivalent/15-cm trail). [b]The values are the trail-following activity as MEWE (WE/15-cm trail) after alkaline (2% KOH/MeOH) hydrolysis. [c]Percentage by volume of ethyl acetate (EtOAc)/*n*-hexane (Hx) as eluants. [d]The signs indicate no trail following response or insufficient response (i.e., the estimated value was more than 10 WE/15-cm trail) for trail-following before (in parentheses) and after alkaline hydrolysis.

following activity after hydrolysis was determined. To obtain GC fractions for analysis, a glass tube cooled with Dry Ice in the middle portion was indirectly connected to the metal head of the FID detector with a Teflon tube. The glass tube was rapidly rinsed with diethyl ether to extract the effluent for the later evaluation of trail-following activity.

The active GC peak was analyzed by a capillary gas chromatograph–mass

spectrometer (GC-MS). The GC-MS was a model 5970 gas chromatograph (Hewlett-Packard (HP), combined with a model M-80B (Hitachi, Ibaraki, Japan) mass spectrometer equipped with a model 0101 on-line data system (Hitachi). A cross-linked methyl silicone fused silica capillary column (12.5 m × 0.2 mm ID, 0.2 μm, (HP) was used. The conditions were as follows: oven temperature of GC increased at a rate of 15°C/min over the range of 200°C (1 min) to 300°C (10 min); injection temperature was 300°C; and the carrier gas was helium at a velocity of approximately 60 cm/sec. The ion source temperature was 300°C, and the ionization voltage was 70 eV.

RESULTS AND DISCUSSION

Bioassay results of trail-following activity of the crude hexane extracts after hydrolysis indicated that a 0.00025 WE extract induced trail-following behavior over a 15-cm trail: the MEWE was identified as 0.00025 WE/15-cm trail. The activity was about 20 times higher than that of extract before hydrolysis (0.005 WE/15-cm trail) by MEWE. However, the mechanism of secretion of the pheromone (MacFarlane, 1983) was not clear in *C. formosanus*, since the hexane extract before hydrolysis indicated that a 0.005 WE extract induced trail-following over a 15-cm trail, and a 1 WE extract could induce a 30-m-long effective trail; a worker termite could produce a 30-m effective trail. While 0.00025 WE of the hydrolyzed hexane extract induced trail-following over a 15-cm trail, a worker termite could produce a 600-m effective trail. Therefore, there might be an appreciable quantity of trail pheromone stock as an esterified form in a *C. formosanus* worker body. If the termites produced the esterified pheromone by themselves, the storage system seemed to become more efficient. The results of a preliminary experiment clearly indicated that both pheromone and precursor candidates were stored in a sternal gland, as described elsewhere (Tokoro et al., 1992b).

Bioassay results on the hexane extracts after silica-gel column chromatographies are shown in Figure 1. The native trail pheromone was eluted mainly in the 20% EtOAc/Hx fraction, and the result was similar to that of a previous report (Tokoro et al., 1989). Active trail-following behavior was produced by several fractions after hydrolysis in this experiment (Tokoro et al., 1992b), although as for *R. speratus*, the fractions eluted with 5–10% EtOAc/Hx were activated (Tokoro et al., 1990). In the case of *C. formosanus*, the component of the fractions eluted with 5–10% EtOAc/Hx was activated by alkaline hydrolysis, and the component of the fractions that contained the native active substance was also activated. Each hydrolyzed product from the activated fractions was identical to DTE-OH (Tokoro et al., 1992b).

The active 5% EtOAc/Hx fraction was selected for further isolation. This

fraction contained the fatty-acid esters, including a vast quantity of triglycerides. The active component of the fraction was eluted with 2% EtOAc/Hx by the secondary silica-gel column chromatography (Figure 1).

The precursor candidates from the 2% EtOAc/Hx fraction were eluted by HPLC 1 in a peak at a retention time (R_t) of around 3 min. It seemed that the retention time of the precursor candidates was earlier than that of the triglycerides contained in the same fraction. On the secondary HPLC preparation (HPLC 2), the precursor candidates were eluted in peaks 1 (R_t 38–43 min) and 2 (R_t 47–53 min). The retention time of peak 1 was longer than that of lauryl laurate (R_t 22.3 min), and a little shorter than lauryl acetate (R_t 48.5 min). The retention time of peak 2 was close to that of lauryl acetate. Subsequently, both of the fractions were analyzed by capillary GC.

The GC retention times of the precursor candidates from both fractions (peaks 1 and 2) were about 10.5 min (peaks a and b, respectively). This retention time was a little longer than that of lauryl stearate (R_t 10.2), which had the same carbon number as the alcohol moiety of DTE-OH. The acid moiety of the precursor candidate, consequently, is expected to have 18 carbons if the precursor candidate is a stearate ester. However, the half-height width of peak a indicated that it consisted of multiple compounds.

Capillary GC-MS data of peaks a and b are shown in Figures 2 and 3. The components of peak a were separated into two component peaks by the total ion chromatogram (TIC) (peaks X and Y in Figure 2A). The electron impact (EI) mass spectrum of the peak X (scan 361; Figure 2B) showed a molecular ion at m/z 446 (ca. 6%). It also showed a diagnostic base peak ion at m/z 162 (M−284), which came from McLafferty rearrangement, that is, elimination of the fatty acid moiety of the esterified pheromone, as in the case of the DTE-acetate (Yamaoka et al., 1987). The prominent diagnostic fragment ions of DTE-OH, m/z 91, 105, 119, and 133 were observed (Tokoro et al., 1989). The present analysis indicated that the component of peak X corresponded to dodecatrienyl stearate.

The mass spectrum of the peak Y (scan 346; Figure 2C) showed a molecular ion at m/z 444 (ca. 1.4%) and a diagnostic base peak ion at m/z 162 (M−282) derived from McLafferty rearrangement, along with prominent diagnostic fragment ions of DTE-OH. These data indicated that peak Y was dodecatrienyl oleate.

The mass spectrum of peak Z (scan 353; Figure 3), which corresponded to peak b of the capillary GC chromatogram,showed a molecular ion at m/z 442 (ca. 1.6%) and a diagnostic base peak ion m/z 162 (M−280) and also prominent characteristic fragment ions of DTE-OH at m/z 91, 105, 119, and 133 were observed. These data indicated that the component of peak Z corresponded to dodecatrienyl linoleate.

Finally, stearic acid ester of DTE-OH (DTE-stearate), oleic acid ester of

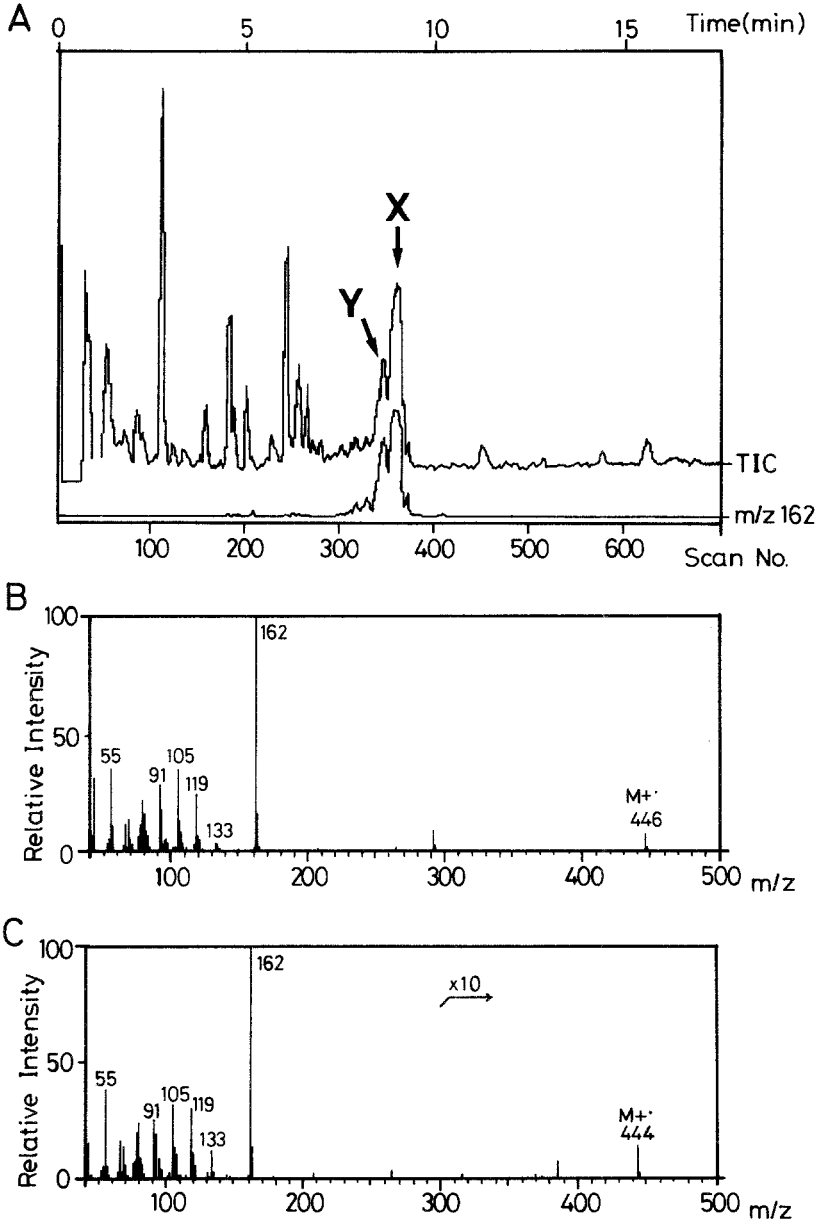

FIG. 2. Results of capillary GC-MS analyses. Total ion chromatogram (TIC) and mass chromatogram (*m/z* 162) of the active fraction (A). The arrows indicate the active peaks: scan 361 (peak X) and scan 346 (peak Y). Also shown are mass spectra of peaks X (B) and Y (C).

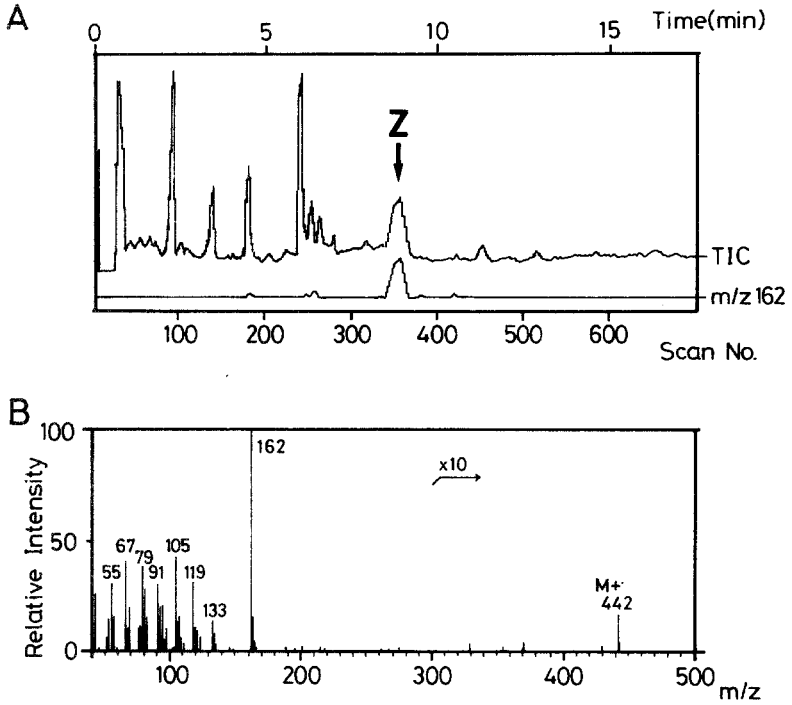

FIG. 3. Results of capillary GC-MS analysis. Total ion chromatogram (TIC) and mass chromatogram (*m/z* 162) of the active fraction (A). The arrow indicates the active peak: scan 353 (peak Z). Also shown is the mass spectrum of peak Z (B).

DTE-OH (DTE-oleate), and linoleic acid ester of DTE-OH (DTE-linoleate) were synthesized and subjected to capillary GC and capillary GC-MS analyses. The analyses demonstrated that the three peaks (X, Y, Z) were identical with the three compounds, respectively.

Thus, the precursors are stored as fatty acid esters in the *C. formosanus* bodies. Amounts of the isolated precursor candidates per individual worker termite estimated from GC analysis were ca. 100 pg for the DTE-stearate, ca. 25 pg for the DTE-oleate, and ca. 25 pg for the DTE-linoleate, approximately three times larger than that of the native pheromone isolated in a previous experiment (ca. 50 pg). Results of the bioassays after isolation indicated that the isolation procedure caused a decrease in activity (from 0.002 to 0.005 WE/15-cm trail) of the 2% EtOAc/Hx fraction (Figure 1). This may be due not only to unavoidable loss during the isolation but also dispersion of other active minor components esterified with DTE-OH.

It is still necessary to prove whether these candidates are true precursors

of the trail pheromone by other methodologies such as a tracer technique. If the precursor candidates are biosynthesized by *C. formosanus* themselves, the resultant decreased volatility would be advantageous for a longer storage. Yamaoka et al. (1985) demonstrated that the sex pheromone (bombykol) of the silkworm, *Bombyx mori*, was inactivated as bombykol linolenate bound to protein in the hemolymph. It is therefore possible that the precursor candidates bind with protein. Although further investigation is needed in order to account for the significance of esterification of the termite pheromone, it may be related to the transportation of the pheromone in the bodies if the precursors bind a protein. Therefore, it is of interest to determine the organ for biosynthesizing those precursor candidates, since the storing organ of those was already determined as the sternal gland (Tokoro et al., 1992b).

Based on the results of the first silica-gel column chromatography, it seems possible that there exist other kinds of precursor candidates of the trail pheromone in the hexane extracts, as described elsewhere (Tokoro et al., 1992b). It is necessary to demonstrate the existence of other precursor candidates and entirely reveal the supplementary system of the trail pheromone.

Acknowledgments—We greatly appreciate the generous gift of (*Z,Z,E*)-3,6,8-dodecatrien-1-ol from Prof. H. Yamamoto, Nagoya University. We thank Dr. K. Tsunoda, Kyoto University, for his comments and advice while preparing this manuscript.

Book Review

Chemical Signals in Vertebrates 5. D.W. Macdonald, D. Müller-Schwarze, and S.E. Natynczuk. Oxford, U.K.: Oxford University Press, 1990. £55.00, 659 pp.

This book is yet another excellent contribution on chemical signals and vertebrate biology arising from the series of Chemical Signals in Vertebrates Conferences. The fifth conference was held in August 1988 at the Department of Zoology, University of Oxford, Oxford, United Kingdom.

This meeting was arranged to synthesize current technical and experimental progress, from an interdisciplinary perspective, in unraveling the fascinating but complex world of chemical signals in vertebrate biology. The book is divided into six sections: semiochemistry, neurophysiology and anatomy, reproduction and primers, social behavior, predators and prey, and applications.

The first section presents contributions ranging from Albone's general discussion of mammalian semiochemistry and the need for interdisciplinary collaboration of chemists and biologists to the specific dynamic solvent effect sampling technique described by Apps. Novotny et al. discuss the advantages of using current leads in rodent olfactory communication to acquire more general information on mammalian olfaction. Three papers discuss human olfactory communication, particularly the role of 16-androstene steroids and related compounds. A very interesting article on identification and practical use of host odor attractants for tse tse flies is given by Hall. This paper would have been more appropriate in the section on applications.

The second section has an elegant study by Keverne and Kaba, who discuss a neural mechanism for olfactory learning in mammals, with respect to pregnancy block in the mouse. A paper by Cocke and Thiessen outlines evidence that a chemical signal can induce significant alterations in the immune system in laboratory mice. This study provides considerable insight into the underlying mechanism of the actual process linking stress with immune suppression in rodents. Additional studies on physiological relationships to chemical signals include alarm pheromones in ostariophysan fishes and amniotic fluids in sheep. Reports on the anatomy of the vomeronasal organ of the prairie vole and Asian elephant reflects the breadth of interest in olfactory systems in mammals. This pattern is further supported by an introductory study of white eye secretion in mountain beaver and the evolutionary development of posterolateral gland development in microtine rodents.

0098-0331/92/0300-0529$06.50/0 © 1992 Plenum Publishing Corporation

Section three includes excellent review papers on pheromonal contraception, male preferences for females of different reproductive conditions, fetal olfaction, responses of human neonates to odors of lactating females, and hormonal pheromones in goldfish. An interesting investigation of reproduction in meadow voles by Storey concluded that chemical cues were not sufficient for male-induced pregnancy disruption. This result contrasts with earlier work, which reported that chemical and physical cues were equally effective in the pine vole. Werner and Clarke discuss the relationship of olfactory signals to sexual development in field voles and the potential role in population regulation. The effects of female urinal and vaginal chemical signals in gerbils and hamsters, respectively, on male behavior are discussed in two additional papers. Individual recognition via body odor or chemical fingerprint in the reproductive behavior of mammals and its relationship to the major histocompatibility complex (MHC) is discussed by Brown et al. This intriguing subject is further discussed by Beauchamp et al. with respect to genetic determination of individual mouse odor and its relevance to individual and kin recognition. Additional contributions include the effects of mouse urine on development and behavior and the relationship of dominance status to the Bruce effect in house mice. With respect to large mammals, Marchinton et al. report on the behavioral components of scent marking in white-tailed deer.

The fourth section covers chemical signals and social behavior in a wide range of vertebrate species. Gosling reviews the role of scent marking of resource holders with respect to alternative mechanisms for advertising the costs of competition. An interesting study on an olfactory mechanism for female choice and residency assessment in the European rabbit is reported by Engel. Differential responses of farm cats to conspecific urine from different sources and the significance to group discrimination is discussed by Passanisi and Macdonald. Three papers report on various aspects of urine or scent marking in wolves and arctic foxes, including relationship to social status, reproductive state, and territorial demarcation. Primate social behavior is represented by studies of conspecific chemical signals in ringtailed lemurs, possibly related to the pattern of female dominance, and the scent marking behavior of wild marmosets having different functions depending on glandular origin.

Spatial distribution, territoriality, and scent marking are discussed for aardwolfs, European moles, pikas, and snakes. Social behavior and scent marking is reported for captive Virginia opossums. The complex network of olfactory communication in wild house mouse populations reported by Hurst suggests that mice urine-mark their physical environment both for their own orientation and to communicate chemically with each other. Aldhous reports on the role of olfactory cues in kin discrimination by mice. Sandnabba discusses the differences between aggressive and nonaggressive male mice in odor signals and

marking behavior, concluding that differences reduce fighting between potential rivals and communicate the aggressive status of a male to the female. Papers on conspecific odors in the rat and the semiochemical sources sampled by rats during social behavior complete this section.

The fifth section includes a comprehensive review of the responses of vertebrates to chemicals from predators by Weldon. Burghardt selectively reviews prey recognition and foraging in vertebrates with respect to diversity, ontogeny, and information transfer and uses snakes to demonstrate the complex interactions of prey cue recognition with various factors. Chemosensory orientation by eastern garter snakes with earthworm castings playing a major role in prey location is discussed by Gillingham et al. Cooper reviews the distribution and use of chemical cues in feeding among squamate families. Duvall and Chiszar describe a series of elegant experiments on the chemical ecology of vernal migration of prairie rattlesnakes. This combination of parallel field and laboratory analyses has yielded considerable insight into the dynamics of chemical foraging for prey by rattlesnakes. The ecological significance of identification of snake predators by eublepharid lizards is discussed by Dial. Robinson describes the avoidance responses of *Apodemus* and *Clethrionomys*, and the suppressed feeding behavior of European rabbits, to a synthetic anal-gland constituent from mink. These results are discussed in light of similar responses between predator-based odors and small mammal prey. Doving provides an intriguing assessment of chemical signals and migrating salmon, with particular emphasis on the importance of olfaction in selecting the appropriate layers of water to direct migration.

The sixth section, on applications, includes a comprehensive review of animal and plant odors for managing vertebrates by Müller-Schwarze. This discussion includes application of chemical signals to animal husbandry, biological pest control, wildlife management, and population monitoring. Abbott et al. report on the chemistry and behavior of a natural deer repellent from lion dung. Their short-term results on repellent efficacy are encouraging. However, their claim that this is the first multidisciplinary study in development of a predator-based repellent is clearly not true as there are several other interdisciplinary groups that have conducted research in this field. Signoret reports on the complex role of chemical communication in reproductive and social behaviors of domestic ungulates. A two-part sequence based on olfaction and sample contact is described by Rivard and Klemm for bull response to estrous pheromone in cattle. Sommerville et al. report on a dog discrimination bioassay for compounds in human sweat and a potential relationship to genotype. Bradshaw et al. discuss the potential use of anal sac volatiles from domestic dogs.

The editors should be congratulated on the considerable effort expended to organize and produce this excellent volume of papers. A suggestion for future volumes might be the addition of an abstract or summary in each paper as

required in contributions to scientific journals. I highly recommend this book for those working in this exciting and rapidly progressing field.

THE RESPONSE OF MOUNTAIN PINE BEETLE (*Dendroctonus ponderosae*) TO LODGEPOLE PINE TREES BAITED WITH VERBENONE AND *exo*-BREVICOMIN

T.L. SHORE,[1,*] L. SAFRANYIK,[1] and B.S. LINDGREN[2]

(Received August 2, 1991; accepted November 19, 1991)

Abstract—*exo*-brevicomin, a multifunctional pheromone of the mountain pine beetle, *Dendroctonus ponderosae*, was tested at release rates of 0.5 and 2.5 mg/day alone and in combination with the antiaggregation pheromone verbenone against unbaited controls. Significantly more lodgepole pine *Pinus contorta* var. *latifolia* trees were attacked, and at higher densities, with both release rates of *exo*-brevicomin than with all other treatments. Verbenone significantly reduced the response of mountain pine beetles to *exo*-brevicomin. Verbenone alone did not reduce the number of trees attacked by mountain pine beetle or the attack density when compared to the unbaited controls.

Key Words—*Dendroctonus ponderosae*, mountain pine beetle, Coleoptera, Scolytidae, pheromone, antiaggregation, verbenone, *exo*-brevicomin.

INTRODUCTION

The mountain pine beetle, *Dendroctonus ponderosae* Hopk., is currently the most destructive insect pest of mature forests in western North America (Gibson, 1989; Van Sickle, 1989). Commercially available aggregation semiochemicals are used to attract and concentrate mountain pine beetle populations into trees that are scheduled for subsequent direct control treatment (Borden and Lacey, 1985; McMullen et al., 1986). These aggregation semiochemicals include *trans*-verbenol, a pheromone produced by the female beetle that attracts mainly males (Pitman et al., 1968; Pitman, 1971; Conn et al., 1983; Borden et al., 1983),

*To whom correspondence should be addressed.

exo-brevicomin, a pheromone produced by the male beetle that attracts mainly females (Rudinsky et al., 1974; Conn et al., 1983), and the monoterpene myrcene, a kairomone that synergizes the insects response to their aggregation pheromones (Billings et al., 1976; Conn et al., 1983; Borden et al., 1983).

In recent years research on the mountain pine beetle has focused on antiaggregation pheromones. Verbenone (4,6,6-trimethylbicyclo[3.1.1]hept-3-en-2-one) has been identified in a number of beetles in the family Scolytidae and found to have antiaggregative properties. These species include *D. frontalis* Zimm., *D. brevicomis* LeC. (Renwick, 1967; Renwick and Vité, 1970; Hughes and Pitman, 1970; Payne et al., 1978; Bedard et al., 1980), *D. adjunctus* Bland. (Livingston et al., 1983), *Ips typographus* (L.) (Bakke, 1981; Schlyter et al., 1988), *I. paraconconfusus* Lanier (Byers and Wood, 1980), and *Tomicus piniperda* L. (Schlyter et al., 1988; Byers et al., 1989). In the mountain pine beetle, verbenone was identified in hindguts of emergent and feeding females (Pitman et al., 1969) and trapped in air passed over male–female pairs (Rudinsky et al., 1974).

Verbenone inhibited the response of mountain pine beetle to traps baited with attractants in field tests (Ryker and Yandell, 1983; Borden et al., 1987; Schmitz and McGregor, 1990). Lodgepole pine stands baited with verbenone alone or with verbenone and attractant bait had lower percentages of mass-attacked trees than blocks baited with attractants alone or unbaited blocks, although differences were not always statistically significant (Amman et al., 1989; Lindgren et al., 1989). In ponderosa pine, *P. ponderosae* Lawson, no significant difference in number of attacked trees was found between 2.5-acre plots treated with four densities of verbenone capsules and untreated plots. It was noted that some of the pine trees to which the verbenone capsules were attached were attacked by the mountain pine beetle (Bentz et al., 1989).

Although *exo*-brevicomin (*exo*-7-ethyl-5-methyl-6,8-dioxabiclyo[3.2.1]-octane) (Silverstein et al., 1968) has been found to be an aggregation pheromone for the mountain pine beetle, there is evidence that it has a multifunctional role in the insect's chemical ecology; at low release rates it induces an aggregative response and at high release rates it induces an antiaggregative response (Rudinsky et al., 1974). Experiments testing various release rates of *exo*-brevicomin as a pheromone for the mountain pine beetle on traps and trees with and without other attractants can generally be summarized as follows: at release rates of 0.04 mg/day and lower, no response by mountain pine beetle was found (Libbey et al., 1985); at 0.05 mg/day an aggregative response was found (Conn et al., 1983; Borden et al., 1987); rates of 4.0, 5.0, 10.0, and 12.0 mg/day resulted in antiaggregative responses (Ryker and Rudinsky, 1982; Libbey et al., 1985; Borden et al., 1987). At release rates between 0.05 and 4.0, results have not been as consistent. Lodgepole pine trees baited with *exo*-brevicomin released at 0.2 mg/day were more frequently attacked than unbaited trees, but the attraction

did not extend to the other pines within a radius of 10 m of the baited tree (Borden et al., 1990). Lodgepole pine trees baited with other semiochemicals plus *exo*-brevicomin released at 0.37 or 1.26 mg/day initially experienced higher attack densities than trees baited with the other semiochemicals alone, but final attack densities were not significantly different (Borden et al., 1983). McKnight (1979) found an antiaggregative response to *exo*-brevicomin released at 0.53 mg/day on western white pine, *P. monticola* Dougl., but on lodgepole pine he found no significant response at release rates from 0.53 to 2.28 mg/day in one experiment, while in a second experiment, also on lodgepole pine, there was a significant increase in the percentage of trees killed by the mountain pine beetle for the treatment including *exo*-brevicomin released at 0.53 mg/day. Borden et al. (1987) found an intermediate response between aggregation and antiaggregation when *exo*-brevicomin released at 0.5 mg/day was added to baited funnel traps.

endo- and *exo*-Brevicomin were tested in combination with verbenone as aggregation inhibitors for *D. frontalis*, and the brevicomin isomers and brevicomin–verbenone combination resulted in lower landing trap catches than verbenone alone (Richerson and Payne, 1979). Watterson et al. (1981) reduced *D. frontalis* emergent population density with a combination of *exo*- and *endo*-brevicomin and verbenone.

In 1989 we established an experiment with the following objectives: (1) to test the multifunctional role of *exo*-brevicomin and further refine the release rate that differentiates aggregative and antiaggregative responses; (2) to examine the response of the mountain pine beetle to combinations of the antiaggregative pheromone verbenone and the multifunctional pheromone *exo*-brevicomin; (3) to determine if individual trees can be protected from the mountain pine beetle by treatment with verbenone; and (4) to determine if trees in the immediate vicinity (5 m radius) of verbenone-baited trees can be protected from the mountain pine beetle.

METHODS AND MATERIALS

Lodgepole pine trees were baited with one of six treatments at each of 28 replications just east of Penticton, British Columbia, in late June 1989, prior to the main beetle flight period in late July–August. The six treatments were: (1) verbenone—released from a bubble cap at approximately 10 mg/day; (2) *exo*-brevicomin (high)—released from a 250-μl polyethylene Eppendorf tube at approximately 2.5 mg/day; (3) *exo*-brevicomin (low)—released from a 6-cm-long solid PVC release device (Flex Lure) at approximately 0.5 mg/day; (4) verbenone plus *exo*-brevicomin (high); (5) verbenone plus *exo*-brevicomin (low); and (6) unbaited control. Verbenone had optical purity of 84% and chemical

purity of 98%, *exo*-brevicomin was racemic with a chemical purity of 97% and 2% *endo*-brevicomin. All chemicals and release devices were supplied by Phero Tech Inc., Delta, British Columbia, Canada.

Baited trees were selected as larger diameter lodgepole pine with a mean diameter at breast height of 23.3 cm (±0.3 SE) and were spaced approximately 20 m apart. Baits were assigned randomly within each replication and stapled on the north side at a height of approximately 2 m on each tree. The replications ranged from 50 m to several kilometers apart and were in an area of active mountain pine beetle infestation. The locations of each replication were selected where the majority of trees were still alive but were of sufficient age and diameter to be susceptible to beetle attack (Safranyik et al., 1974). To verify that randomization had resulted in a similar number of unattacked lodgepole pine trees of suitable diameter for the mountain pine beetle to attack (Safranyik et al., 1974) in each treatment, an analysis of variance was conducted. The mean number of unattacked lodgepole pine 10 cm and larger was not significantly different among treatments ($F = 0.18$, $P = 0.97$).

In late September, following the beetle flight, baited trees and all trees within a radius of 5 m of each baited tree were checked for mountain pine beetle attacks. Tree species, diameter at breast height, and total number of attacks were recorded. If the number of attacks was too high to count, it was estimated using the method of Safranyik (1988) based on tree diameter, the attack height, and attack density in two 15-cm × 15-cm bark samples taken on opposite sides of the tree at breast height. The experiment was analyzed as a randomized block using the general linear models procedure in SAS (SAS Institute, Inc., 1985). Differences among means were tested using Duncan's multiple-range test. Data on number of attacks per baited tree and total attacks within a 5-m radius of the baited tree were transformed to $\log10(x + 1)$ prior to analysis.

A separate analysis was conducted on "mass-attacked" trees. Trees were classified as attacked (having one or more mountain pine beetle attacks on them) or mass attacked (having more than 31.3 attacks/m^2 at breast height); the attacked category included mass-attacked trees. Mass-attacked trees have been defined as those having more than five attacks in a 0.16-m^2 sample area at breast height (31.3/m^2), which is a beetle density sufficient to be lethal to the host tree (Lindgren et al., 1989).

RESULTS

Trees baited with both high and low release rates of *exo*-brevicomin were attacked more frequently than all other treatments (Table 1). There was no significant difference in the number of attacked trees between the two release rates of *exo*-brevicomin. The addition of verbenone significantly reduced the

TABLE 1. MEAN NUMBERS (SE) OF ATTACKED OR MASS-ATTACKED BAITED TREES FOR SIX SEMIOCHEMICAL TREATMENTS REPLICATED 28 TIMES

Treatment[a]	Attacked trees[b]	Mass-attacked trees[c]
exo-B. high	0.89a (0.06)	0.82a (0.07)
exo-B. low	0.86a (0.07)	0.68a (0.09)
Verb. + *exo*-B. high	0.39b (0.09)	0.11bc (0.06)
Verb. + *exo*-B. low	0.29bc (0.09)	0.21b (0.08)
Unbaited	0.18bc (0.07)	0.14bc (0.07)
Verbenone	0.10c (0.06)	0.00c (0.00)

[a] *exo*-B. = *exo*-brevicomin, high = 2.5 mg/day, low = 0.5 mg/day, Verb. = verbenone 10 mg/day.
[b] Means within a column followed by the same letter are not significantly different, ANOVA attacked $F_{5,135} = 21.0$, $P < 0.0001$; mass attacked $F_{5,135} = 25.5$, $P < 0.0001$; Duncan's test on means, $P = 0.05$.

response of mountain pine beetle to *exo*-brevicomin so that it was not statistically different from the response to the unbaited (control) trees. The verbenone-baited trees were attacked less often than the unbaited trees but the difference was not statistically significant (Table 1). The treatment effect for mean number of mass-attacked trees was very similar to that for mean number of attacked trees except the position of the two verbenone plus *exo*-brevicomin treatments was reversed. None of the trees baited with verbenone was mass attacked (Table 1).

The mean numbers of trees attacked within a 5-m radius of the trees baited with *exo*-brevicomin were significantly higher than those of the other treatments (Table 2). There was no significant difference between the means of the two *exo*-brevicomin treatments. There also was no significant difference between the verbenone plus high *exo*-brevicomin treatment and the verbenone treatment, as was found for baited trees alone (Table 2). The numbers of trees that were mass attacked within 5 m of the baited trees showed the same treatment effects as for trees receiving any attack (Table 2).

The treatments had a similar effect on the number of mountain pine beetle attacks on baited trees as they did on the number of trees attacked. Trees baited with either high or low *exo*-brevicomin had significantly higher attack densities than trees in any of the other treatments (Table 3). Verbenone significantly reduced the attack density on trees baited with *exo*-brevicomin so that they were not statistically different from the unbaited trees. The attack density on the trees baited with verbenone was slightly lower but not significantly different from the control (Table 3).

The total number of attacks within a 5-m radius of baited trees reflected the same treatment preferences by the beetles as for the baited trees except that

Treatment[a]	Baited trees only[b]	Trees in 5-m plot
exo-B. high	291.0a (35.2)	587.2a (110.7)
exo-B. low	178.9a (33.6)	524.7a (92.5)
Verb. + *exo*-B. high	90.6b (45.9)	194.8b (87.6)
Verb. + *exo*-B. low	61.0b (29.7)	182.4b (76.7)
Unbaited	40.2b (20.7)	88.6b (37.9)
Verbenone	29.5b (29.5)	158.1b (73.2)

[a] *exo*-B. = *exo*-brevicomin, high = 2.5 mg/day, low = 0.5 mg/day, Verb. = verbenone 10 mg/day.
[b] Means within a column followed by the same letter are not significantly different, ANOVA baited tree $F_{5,135} = 27.2$, $P < 0.0001$; 5-m plot $F_{5,135} = 17.9$, $P < 0.0001$; Duncan's test on means, $P = 0.05$. Data transformed to $\log10(x + 1)$ for analysis.

trees in the unbaited treatment had fewer attacks than those near the verbenone treatment, but the difference was not statistically significant (Table 3).

DISCUSSION

exo-Brevicomin was attractive to mountain pine beetle at both release rates. Based on previous work by Borden et al. (1987) we expected some antiaggregative response at 2.5 mg/day. However, with the exception of one experiment

in which *exo*-brevicomin was released on western white pine (McKnight, 1979), the antiaggregative effects of *exo*-brevicomin have been demonstrated on traps, not live trees. In trees, any successful attacks by the beetles bring the complication of additional semiochemicals being released. If our release rates of *exo*-brevicomin were sufficient to induce an antiaggregative response from the mountain pine beetle, we would have expected a reduction in the number of attacks on the baited trees and an increase in attacks on the surrounding trees. It appears, however, that a release rate of 2.5 mg/day is too low to induce an antiaggregative response on live trees because even the baited trees were heavily attacked.

Our results clearly show that verbenone reduced the response of mountain pine beetle to trees baited with *exo*-brevicomin. Verbenone influenced not only the attack on the baited trees but on the trees within a 5-m radius of the baited tree. This supports results of previous studies using traps in which the response of mountain pine beetle to aggregation pheromones was reduced with the addition of verbenone (Ryker and Yandell, 1983; Borden et al., 1987; Schmitz and McGregor, 1990).

Our results provide some insight regarding the potential for protecting individual trees or small groups of trees with verbenone. The effect of verbenone on the mountain pine beetle cannot be described as repellent because the verbenone treatment did not result in significantly fewer attacked trees or lower attack densities on either the baited trees or trees within a 5-m radius of the baited trees when compared to the unbaited treatment. The effect was more that of neutralizing or masking the attractiveness of the aggregation pheromone *exo*-brevicomin to the mountain pine beetle.

Treating trees with verbenone would not appear to make the trees any less attractive to the beetle than an unbaited tree. It may, however, make them (and the trees within a 5-m radius) less attractive than a recently attacked tree and thereby reduce mass attack, hence tree mortality, in a treated stand. These results support previous findings that verbenone reduces the number of mass-attacked trees in stands (Amman et al., 1989; Lindgren et al., 1989). In our study no trees baited with verbenone were mass attacked.

Acknowledgments—We appreciate the technical assistance of R.E. Betts and D.A. Linton in establishing and assessing this experiment. Research supported in part by Science Council of British Columbia grant 28 to B.S.L.

(Received October 7, 1991; accepted November 19, 1991)

Abstract—We have developed and tested a technique to microencapsulate terpene compounds by forming gelatin-walled microcapsules around the terpene essential oils. Eight terpenes that are common constituents of Douglas fir (*Pseudotsuga menziesii*) oleoresin were encapsulated, including five monoterpenes (α-pinene, β-pinene, camphene, myrcene, and limonene) and three oxygenated monoterpenes (bornyl acetate, linalool, and β-citronellol). The encapsulated terpenes were mixed into artificial diets to determine the effects they had on western spruce budworm (*Choristoneura occidentalis*) survival and reproduction, using a three-generation bioassay. We describe the technique and present data from preliminary bioassays with seven of the terpenes to demonstrate that *C. occidentalis* larvae would consume diets fortified with microencapsulated terpenes. The technique is useful because it helps to reduce the rate at which terpenes volatilize from the diets and it "packages" the terpenes in a manner more closely resembling the way they are present in the resin canals of plant foliage. Many scientists investigating the biological importance of terpenes in mediating plant–herbivore interactions may find that microencapsulated terpenes are useful in both laboratory diet studies and field and greenhouse experiments with plant material.

Key Words—Artificial diets, *Choristoneura occidentalis*, Lepidoptera, Tortricidae, Douglas fir, microencapsulated terpenes, monoterpenes, multiple generation bioassay, nutritional ecology, oxygenated monoterpenes, *Pseudotsuga menziesii*, western spruce budworm.

INTRODUCTION

Defensive compounds, or allelochemicals, in host plants have been widely implicated as important traits influencing the plant's suitability as food for insect herbivores (Feeny, 1976; Rhoades and Cates, 1976; Rosenthal and Janzen, 1979; Hedin, 1983; Rhoades, 1983; Strong et al., 1984; Coley et al., 1985; Green and Hedin, 1986; Mattson et al., 1988). Several lines of evidence suggest terpenes are the most likely defensive chemicals in Douglas fir [*Pseudotsuga menziesii* (Mirb.) Franco (Coniferales: Pinaceae)] against the western spruce budworm [*Choristoneura occidentalis* Freeman (Lepidoptera: Tortricidae)] (Redak, 1982; Cates et al., 1983a,b, 1987; Perry and Pitman, 1983; Redak and Cates, 1984; Cates, 1985; Shepherd, 1985; Wagner and Tinus, 1985; Cates and Redak, 1986, 1988; Campbell, 1987; Hermann, 1987; Wulf and Cates, 1987; Wagner et al., 1989, 1990; Cates and Zou, 1990). *C. occidentalis* is a major defoliator of coniferous forests in western North America (Fellin and Dewey, 1982; Fellin et al., 1983; Harris et al., 1985; Sanders, et al., 1985; Wulf and Cates, 1987).

However, in order to evaluate the role of terpenes as potential resistance mechanisms in Douglas fir against western spruce budworm attack, we need to know which specific terpenes have the most significant effects on budworm survival and reproduction. This involves determining the response curves of the budworm to selected terpenes that occur in Douglas fir foliage to identify the minimum and maximum concentrations tolerated. Furthermore, we must know how different compounds in host foliage, such as various terpenes and/or nutrients, interact to influence the plant's suitability as food for the budworm (House, 1961; Mattson and Scriber, 1987).

Clancy (1991a) has developed a multiple generation bioassay to define the "nutritional niche" of *C. occidentalis*. Insects are reared for three successive generations on artificial diets that have prescribed levels of various host-plant nutrients or allelochemicals. Empirical data thus generated are used to estimate population growth and fitness, expressed as the number of F_1, F_2, and F_3 offspring produced. This provides a very complete evaluation of the effects that individual compounds (or combinations) have on budworm performance, and thus furnishes an indication of the biological significance of various natural products contained in plant tissue.

We wanted to develop a method that would enable terpenes to be incorporated into artificial diets to determine the effects of various terpenes on western spruce budworm fitness, using Clancy's (1991a) multiple generation bioassay. Two methods have been used in the past to add terpenes to lepidopteran artificial diets. Cates et al. (1987), Cates and Zou (1990), and Mattson et al. (1991) merely added purified terpene compounds to diets while they were being mixed in a blender. Another method, used by Isman and Rodriguez (1984), Rossiter et al. (1986), and Gunasena et al. (1988), involves dissolving the terpene and coating the solution onto a cellulose powder by evaporating the solvent, and then using the treated cellulose in the diet.

Several limitations are associated with adding terpenes to diets using these methods. First, the terpenes are not "packaged" the way they are in plant tissues. Terpene compounds are not evenly distributed throughout conifer needles; they are restricted to the resin canals. Second, all monoterpenes and many sesquiterpenes are volatile and evaporate into the air, especially at higher temperatures (Kramer and Kozlowski, 1979). Thus, diets prepared as described above will lose part of their terpene content over time through volatilization. Cates and Zou (1990) and Cates et al. (1987) compensated for this by mixing new diets every two or 10 days, respectively. Other researchers have just accepted the decline over time in the terpene content of the diets they are testing, or they have used a bioassay that only measures effects on performance for a short period (i.e., insects are fed the treatment diets for one instar versus the whole larval period). Additionally, the vapor pressure of the terpene in the container holding the diet and insects is too high when the terpene is not encapsulated.

We have developed and tested a technique that alleviates these problems by microencapsulating the terpene compounds with gelatin and then mixing the microcapsules of terpene into the diet. This is one of the techniques described by Usher et al. (1989) for dosing insects with compounds that normally deter feeding. We believe that many scientists investigating the biological importance of terpenes in mediating plant–herbivore interactions may find that microencapsulated terpenes are useful in experimentation.

The objectives of the studies reported here were to: (1) determine if various terpenes could be microencapsulated and incorporated into artificial diets; (2) establish if microencapsulation helped to reduce terpene volatilization from diets; (3) ascertain if dietary nitrogen was substantially increased by the addition of the microcapsules, since gelatin is a protein; and (4) conduct preliminary bioassays with seven of the eight terpenes we microencapsulated to demonstrate that *C. occidentalis* larvae would consume diets fortified with microencapsulated terpenes and show that this technique can be used to determine the effects of terpenes on budworm fitness. The results from subsequent, replicated bioassays with all eight microencapsulated terpenes will be reported separately (Karen M. Clancy, unpublished data).

METHODS AND MATERIALS

Microencapsulation of Terpenes and Incorporation into Diets. There are at least 30 different terpene compounds that occur in Douglas fir foliage (Cates and Redak, 1988; Wagner et al., 1989). A subset of eight was selected for evaluation of their biological importance to the budworm based on the following criteria: (1) quantitative abundance in Douglas fir foliage—we chose compounds that were typically present in concentrations of at least 20 μg/g dry mass of foliage; (2) indications from the literature that variation in foliar concentration of the terpene is associated with budworm defoliation, seasonal feeding patterns, survival, or growth; (3) availability of the terpene from chemical supply companies; and (4) formulation considerations—some of the terpenes we were interested in could not be microencapsulated successfully (e.g., camphor and anethole), and it was necessary to add isopropyl myristate (i.e., myristic acid, a C_{14} saturated essential fatty acid) to the camphene to microencapsulate it effectively. The problems encountered with encapsulating some of the terpenes are probably related to the physical properties of the compounds (e.g., solubility and surface tension). There were several other potentially interesting terpenes, such as caryophyllene, longifolene, and tricyclene, that we did not use because the quantity required for microencapsulation (at least 120 g) was too expensive.

The eight terpenes selected and the diet concentrations we tested were: α-pinene, β-pinene, camphene, and bornyl acetate at 100, 500, and 1500 ppm fresh mass, plus myrcene, limonene, linalool, and β-citronellol at 50, 150, and 500 ppm fresh mass in diets with 84.5% moisture. The concentrations were based on the reported ranges for the terpenes in Douglas fir foliage from trees in Arizona and Colorado (Wagner et al., 1989; Clancy, 1991b; Karen M. Clancy, unpublished data). Although there are many other terpenes that could also be important allelochemicals for the western spruce budworm, these eight provided a good start for investigating how the quantity and composition of oleoresin affects budworm performance.

The encapsulation process involved forming gelatin-walled microcapsules around the terpene essential oils by complex coacervation (Usher et al., 1989). Coacervates of gelatin and gum arabic were induced to deposit around the oil droplets in an emulsion, and the gelatin was set by cooling and chemical cross-linking with glutaraldehyde to harden the shell. The capsules were packaged as a water slurry. Diameters of the capsules ranged from about 30 to 80 μm, which corresponds well with the diameters of resin canals in Douglas fir needles (28–105 μm; Karen E. Burr and Karen M. Clancy, unpublished data).

The various microcapsule slurries were mixed into batches of warm, liquid artificial diet using an electric handheld whisk (i.e., a cooking appliance for mixing thick liquids). The diets were then poured into pans to cool and cut into cubes or were poured into 30-ml plastic cups. We did not observe any settling

of the microcapsules in the liquid diet; it appeared to be viscous enough to keep the small capsules suspended until the diet cooled and solidified. We also tried mixing the capsules into diets with a blender, but it was clear that many of the capsules ruptured. The experimental base diet to which the microencapsulated terpenes were added contained 1.25% nitrogen, 10.9% sugars, 84.5% moisture, and concentrations of most minerals that did not deviate substantially from the composition of Douglas fir foliage (Clancy, 1991a).

Samples of the diets were analyzed for terpene content by capillary column gas chromatograph (see Wagner et al., 1989, for details about the analysis). The terpenes were extracted from the diets using the following procedure: For the initial extraction, a 200-ml plastic cup about half full of diet cubes (about 35–65 g fresh mass of diet material) was brought to the Analytical Services Laboratory at Northern Arizona University within 24 hr of preparation. The diet cubes were weighed and placed in a flask with approximately 200 ml of chromatography-grade hexane, covered, and refrigerated (4°C) overnight. The following morning the flask was put in an ultrasonic bath for 10 min to rupture the microcapsules and release the terpene (We are not convinced this step was effective because subsequent extraction of terpenes from the microcapsule slurries indicated that terpene recovery was greater with longer extraction times. This implies the capsules were not ruptured in the ultrasonic bath. Thus, this step could probably be eliminated). The sample was then poured into a blender, and the volume was increased to 250 ml by adding more hexane. The diet–hexane matrix was blended at slow speed for 2–4 min to obtain a homogeneous slurry, then it was blended for 5 min at high speed to rupture the capsules. After blending, an aliquot was transferred to a 25-ml vial and stored in a freezer at −10°C. For the gas chromatography analysis, a 5-ml aliquot was removed, spiked with an internal standard, and filtered through a 0.45-μm membrane for analysis. The terpene concentration was calculated based on the fresh mass of the diet.

Terpene Volatilization from Diets. One of the advantages of adding microencapsulated terpenes to diets should be to slow the rate at which the terpenes evaporate into the air. We tested this by comparing terpene degradation over time for diets fortified with regular versus microencapsulated β-pinene. Four cups of diet cubes from both the regular and microencapsulated diets were analyzed separately for β-pinene content when the diets were initially prepared and after the diets had been incubated at 25°C for two and four weeks. The moisture content of the diets was determined at each sample time to enable us to convert the fresh mass concentrations to dry mass and thus eliminate variation due to moisture loss (the diets dry out over time). The data were analyzed with ANOVA to determine if β-pinene concentrations changed over time. Furthermore, when bioassays were conducted with the different microencapsulated terpenes, we quantified the dry mass terpene content of the diets when the

experiments were initiated and after the P_1 budworm larvae had fed on the diets for 35–39 days and were ready to be transferred to fresh diets.

Effect of Gelatin Microcapsules on Dietary Nitrogen. The gelatin material used to encapsulate the terpenes is a protein that could be utilized by the insects as a source of nitrogen. Although we suspected it was unlikely that the small amount of microcapsule material added would substantially change the N content of the diet, we conducted a study to test this possibility. We made 11-cup batches of the experimental base diet (see Clancy, 1991a, for recipe) with 0, 0.25, 1.00, 5.00, 20.00, and 50.00 ml of microencapsulated β-pinene added. This was representative of the amounts of the various microcapsule slurries that were used in the experiments (1.00–30.00 ml in the original recipes, 0.24–19.30 ml in the revised recipes). Four randomly selected cups of diet cubes from each batch were oven-dried (70°C) and analyzed separately for total Kjeldahl N (colorimetrically). The data were analyzed with ANOVA to determine if N content changed detectably with the addition of various amounts of microcapsules.

Effects of Microencapsulated Terpenes on Budworm Fitness. We determined the effects that various terpene compounds had on *C. occidentalis* survival and reproduction by rearing larvae for three consecutive generations on diets with different levels of the terpenes. The bioassay technique is described in detail in Clancy (1991a). The P_1 generation of the experiments started with egg masses from a laboratory colony of nondiapausing western spruce budworm. Survival rates were determined for all life stages, including survival from early to late instars, late instars to pupal stage, and pupal to adult stage. These measures were multiplied to estimate cohort survival to the adult stage. Egg masses produced by the adult moths were incubated to determine viability ($\geq 50\%$ of the eggs in the mass hatched). The bioassay for each treatment and generation started with 10 egg masses that usually produced 200–300 first-instar larvae. Up to 150 randomly selected late-instar larvae were transferred to fresh diets to complete development. Fifty to 120 larvae pupated and produced about 40–100 moths, which laid a total of 25–75 egg masses. Pupae were weighed and the average female pupal masses for each treatment and generation were used to predict female fecundity or the number of oocytes in the adult moth (Wagner et al., 1987).

The following population growth model was used to obtain a composite measure of how different levels of the terpenes affected budworm performance:

$$\begin{aligned}\text{number of } F_1 \text{ larvae} = {} & (\text{number of } P_1 \text{ larvae}) \\ & \times (P_1 \text{ percentage cohort survival to adult stage}) \\ & \times (P_1 \ \bar{X} \text{ female fecundity}) \\ & \times (F_1 \text{ percentage egg masses with viable eggs})\end{aligned}$$

The numbers of F_2 and F_3 larvae were calculated with data for the appropriate generation. The model estimated the number of first instars alive at the beginning of the F_1, F_2, and F_3 generations, assuming all the treatments had equal populations at the beginning of the P_1 generation (i.e., we assumed that all treatments started with a single P_1 larva).

RESULTS

Microencapsulation of Terpenes and Incorporation into Diets. Our initial assumption was that all the slurries of various microencapsulated terpenes would contain about the same amount of active ingredient. Consequently, standard recipes were developed for the different concentrations we wanted to test and experimental bioassays were started. However, analysis of the diets showed that except for myrcene, the terpene concentrations achieved were far from the targets, which were selected based on data from host trees. Levels of myrcene were within 4% of the target concentrations. For the remaining seven terpenes, variation from the target concentrations ranged from 13% to 455% ($\bar{X}$ = 185%, SD = 159%, N = 21). Nonetheless, the bioassays initiated with these original terpene formulations were completed to ensure that this technique could be used to determine the effects of terpenes on budworm fitness, and the results are reported here.

Subsequent analysis of the terpene microcapsule slurries indicated the active ingredient (by weight) ranged from 1.3% to 14.3% among different terpenes and between different batches of the same terpene. The diet recipes were revised by adjusting the amount of microcapsule slurry added, based on the percent active ingredient. Furthermore, test batches with an intermediate target concentration were made with each terpene and analyzed to compare the terpene concentration expected to the concentration achieved; additional adjustments to the recipes were made based on these results. New bioassay experiments were started once we were confident we could formulate diets with the desired levels of the various terpenes; results from replicated bioassays using the revised formulations plus the original myrcene formulation will be reported separately (Karen M. Clancy, unpublished data). The revised terpene formulations produced diets much closer to the target concentrations; the average deviation from the targets was 17% (SD = 14%, range 0–49%, N = 47). Furthermore, analysis of two separate batches of the same recipe demonstrated that the terpene concentrations achieved were duplicated within 20% on average (SD = 12%, range 2–44%, N = 23).

Terpene Volatilization from Diets. Diets with microencapsulated β-pinene maintained their terpene content over time better than diets with regular β-pinene (Table 1). The microencapsulated β-pinene diets lost (on average) 21% of their terpene content over four weeks (P = 0.138), whereas the regular β-pinene

TABLE 1. TERPENE DEGRADATION OVER TIME FOR DIETS FORTIFIED WITH MICROENCAPSULATED VERSUS REGULAR β-PINENE

Time at 25°C (weeks)	$\bar{X} \pm$ SE β-pinene concentration (ppm dry mass) ($N = 4$)	P value from ANOVA for changes in β-pinene concentration over time ($df = 2, 9$; $n = 12$)
Microencapsulated diets		0.138
0	4460 ± 420.5	
2	4233 ± 92.67	
4	3529 ± 314.1

0	1534 ± 147.2	
2	960.3 ± 56.77	
4	713.8 ± 58.08	

diets lost 53% ($P = 0.006$). Although the decline in terpene concentration for the microencapsulated diets was not statistically detectable, these diets were much more variable regarding losses. This is probably because the microcapsules did not get as evenly distributed throughout the diet when they were whisked in as the regular terpenes did when they were blended in (although we did not notice any sticking or clumping due to whisking). Consequently, the power of the statistical test to detect real differences among the sample times was much lower for the microencapsulated diets compared to the regular diets.

Another potential caveat in interpreting the results in Table 1 relates to the different initial β-pinene concentrations achieved in the two diets. This was not intentional, but resulted from imprecise knowledge of the relationship between amounts of terpenes added and the resulting concentration in the diet. It is possible that the different initial terpene levels tested could influence the loss rates observed. Finally, it is likely that the lipids, phospholipids, and salts in the diet may alter the gelatin properties over time (E.A. Bernays, personal communication); this could account for the greater loss in microencapsulated β-pinene during weeks 2 through 4, than during the first two weeks.

Diets augmented with microencapsulated monoterpenes generally lost less of their terpene content over time than diets with oxygenated monoterpenes (Figures 1 and 2; data are for the revised terpene formulations). For the most part, there was some loss in concentrations of the monoterpenes α-pinene, β-pinene, camphene, myrcene, and limonene over a 35- to 39-day period, but the decline in concentrations of the oxygenated monoterpenes bornyl acetate, linalool, and β-citronellol over equivalent periods was much greater. We attribute the apparent increase in α-pinene over time to uneven distribution of the

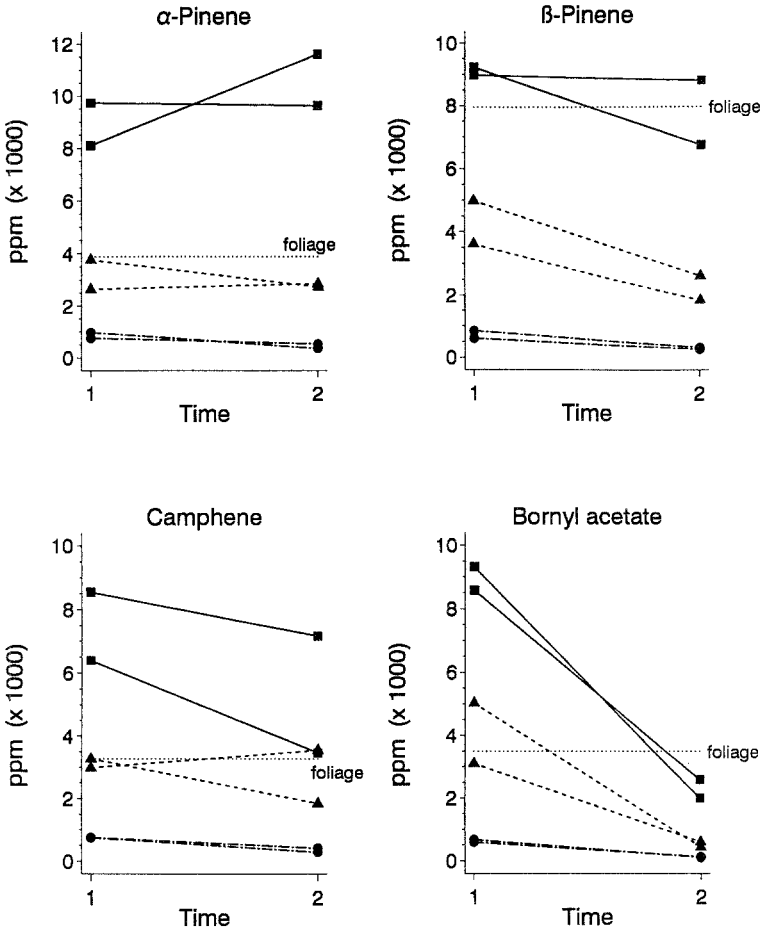

FIG. 1. Concentrations (ppm dry mass) of microencapsulated α-pinene, β-pinene, camphene, and bornyl acetate in experimental diets when they were initially prepared (time = 1) and after they had been incubated at 25°C for 35–39 days (time = 2; $\bar{X}$ = 36.5 days, SD = 1.23). Three levels of each terpene were tested: ■——■ = high target (9677 ppm); ▲----▲ = intermediate target (3226 ppm); ●–·–·–● = low target (645 ppm); these are equivalent to 1500, 500, and 100 ppm fresh mass for diets with 84.5% moisture. Each experiment was repeated twice. The dotted line labeled "foliage" shows the highest concentration of the terpene found in Douglas fir foliage to provide a reference point.

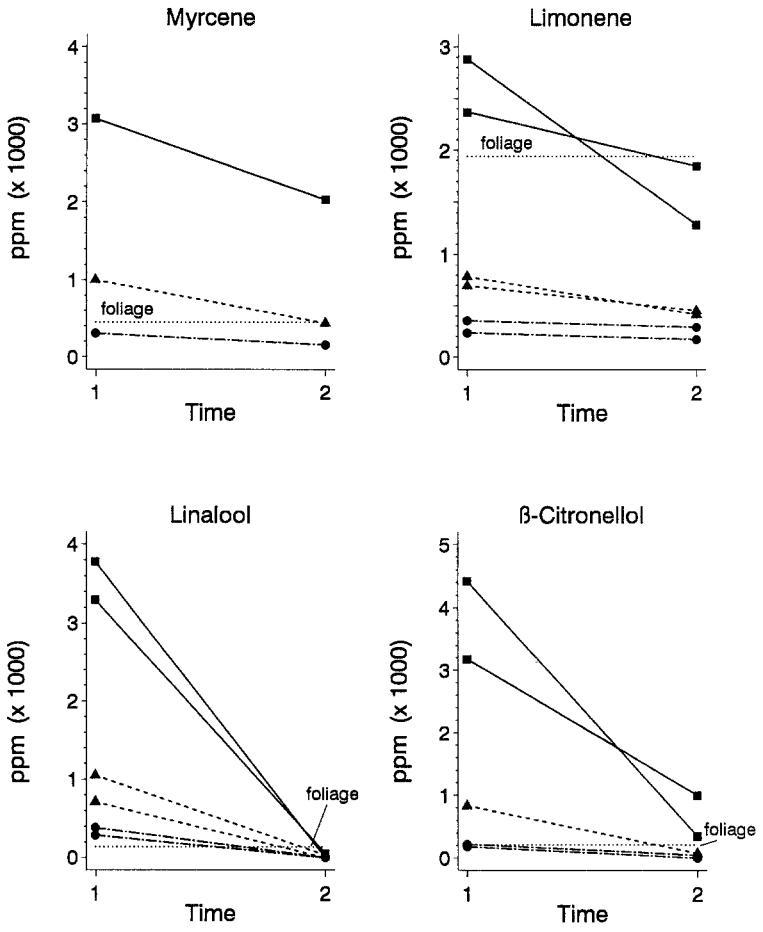

FIG. 2. As for Figure 1, but for microencapsulated myrcene (a single replication is shown), limonene, linalool, and β-citronellol. The high, medium, and low targets were 3226, 968, and 323 ppm, respectively, equivalent to 500, 150, and 50 ppm fresh mass for diets with 84.5% moisture.

microcapsules in the diet, plus possible errors in measuring dietary moisture content; we do not think the increase is significant.

Effects of Gelatin Microcapsules on Dietary N. The addition of microcapsules in amounts representative of those used in experiments did not cause a detectable increase in dietary N content ($P = 0.198$; Table 2). Although the diets with 50 ml of microencapsulated terpene appeared to have about 6% more N than the other diets (1.40% compared to 1.32%), the revised diet recipes

TABLE 2. NITROGEN CONCENTRATION FOR DIETS WITH VARIOUS AMOUNTS OF MICROENCAPSULATED β-PINENE ADDED

Amount of β-pinene added to diet (ml)	$\bar{X}$ ± SE nitrogen concentration (% dry mass) (N = 4)[a]
0	1.34 ± 0.0359
0.25	1.29 ± 0.0118
1.00	1.32 ± 0.0318
5.00	1.34 ± 0.0417
20.00	1.30 ± 0.0442
50.00	1.40 ± 0.0095

[a]The N levels were not different among the diets (P = 0.198; df = 5, 18; N = 24; P for Bartlett's test for homogeneity of variances = 0.142), indicating the gelatin in the microcapsules did not change the dietary N content.

contained about 20 ml of microencapsulated terpene at most. Thus, we conclude that such small amounts of the gelatin microcapsules added to the diets are unlikely to result in an increase in N that is biologically meaningful to the budworm.

The average N content of the experimental base diet was 1.25% (SD = 0.062, N = 68) (Clancy, 1991a). The test diets listed in Table 2 had an average N level of 1.33% (SD = 0.041, N = 6), which was higher than we expected based on past analyses, but not unreasonable considering normal batch-to-batch variation.

Effects of Microencapsulated Terpenes on Budworm Fitness. Data from the preliminary bioassays conducted with the original terpene formulations are presented in Figures 3–6. The higher concentrations tested generally far exceeded the upper limit reported for Douglas fir foliage, particularly for β-citronellol and linalool. Although the results are preliminary, they indicate that even very high concentrations of the monoterpenes β-pinene, α-pinene (Figure 3), and limonene (Figure 4) had very little effect on budworm population growth, but higher concentrations of camphene (Figure 5) had definite deleterious effects. Low concentrations of the oxygenated monoterpene bornyl acetate appeared to improve budworm fitness slightly, whereas high concentrations reduced fitness and very high concentrations (far exceeding levels in foliage) were clearly toxic (Figure 5). Likewise, extremely high concentrations of the other oxygenated monoterpenes, β-citronellol (Figure 4) and linalool (Figure 6), were deadly. Intermediate concentrations of β-citronellol had more severe impacts on the budworm than comparable levels of linalool.

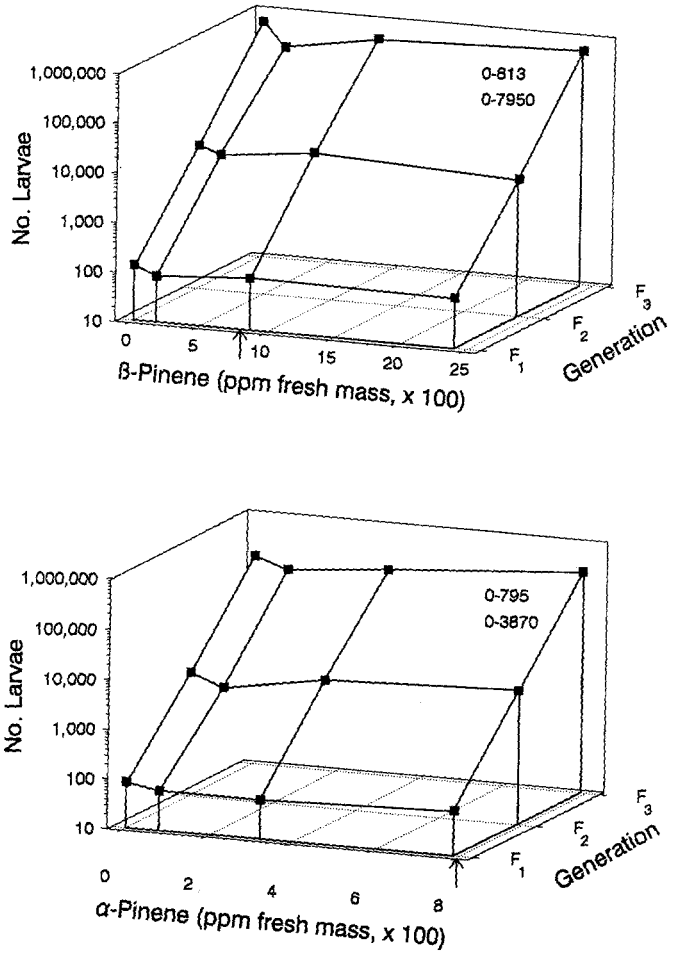

FIG. 3. Estimated western spruce budworm population growth (number of first instars alive at the beginning of the F_1, F_2, and F_3 generations) for diets with different levels of the monoterpenes β-pinene (top) and α-pinene (bottom), assuming all populations were equal at the beginning of the P_1 generation. See text for model of population growth used to calculate estimates. The numbers in the upper right corner list the range of terpene concentrations observed in foliage from Douglas fir trees in Arizona and Colorado; top numbers = ppm fresh mass, bottom numbers = ppm dry mass, and the arrows on the x axes indicate the highest fresh mass concentration.

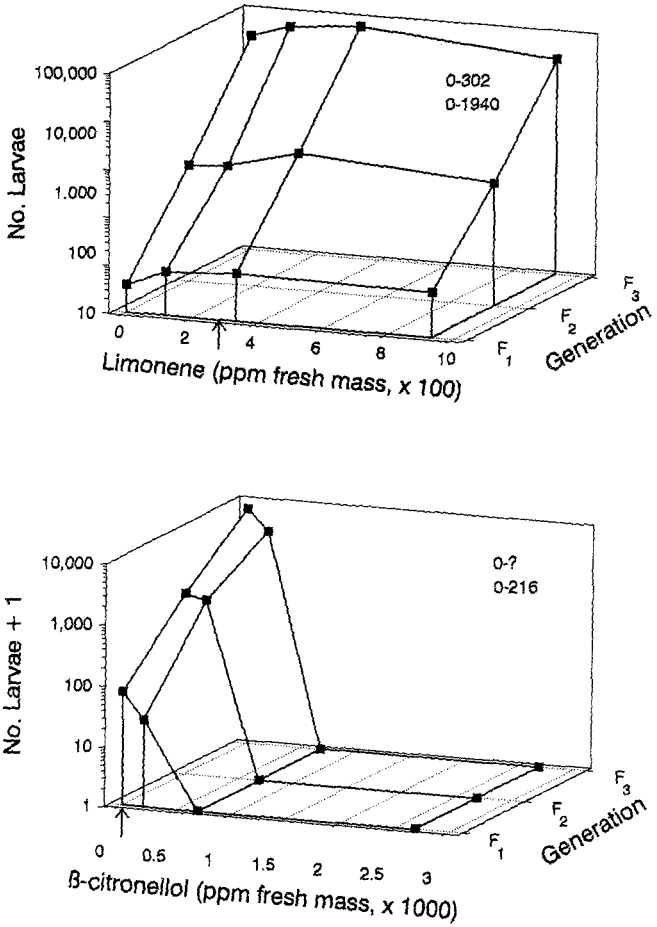

FIG. 4. As for Figure 3, but for the monoterpene limonene (top) and the oxygenated monoterpene β-citronellol (bottom).

DISCUSSION

Terpene compounds can be microencapsulated and mixed into lepidopteran artificial diets to determine the effects of terpenes on insect herbivore performance. This technique is useful because it packages the terpenes in a manner more closely resembling plant foliage and it reduces their volatilization rate from artificial diets. Although terpenes in conifer needles are not enclosed in protein shells, they are compartmentalized in resin canals rather than being distributed throughout the needle tissue. Preliminary bioassay experiments with diets containing seven terpenes that are common constituents of Douglas fir

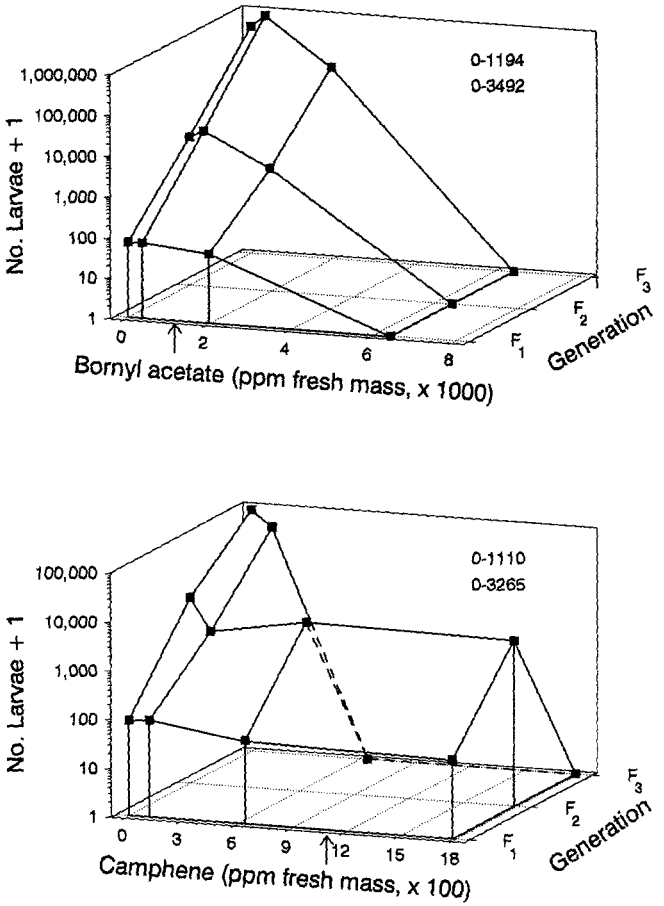

FIG. 5. As for Figure 3, but for the oxygenated monoterpene bornyl acetate (top) and the monoterpene camphene (bottom).

oleoresin indicated that even very high concentrations of β-pinene, α-pinene, and limonene had very little effect on western spruce budworm fitness, whereas relatively high levels of camphene, bornyl acetate, β-citronellol, and linalool had definite deleterious effects on budworm population growth.

Volatilization of terpene essential oils from diets is reduced because the terpene content of the microcapsules is not released until a larva bites the capsule open or ingests the capsule. Studies by Usher et al. (1989) have established that the gelatin microcapsule walls are broken down very rapidly after ingestion by armyworms [*Pseudaletia unipuncta* (Haworth) (Lepidoptera: Noctuidae)] and

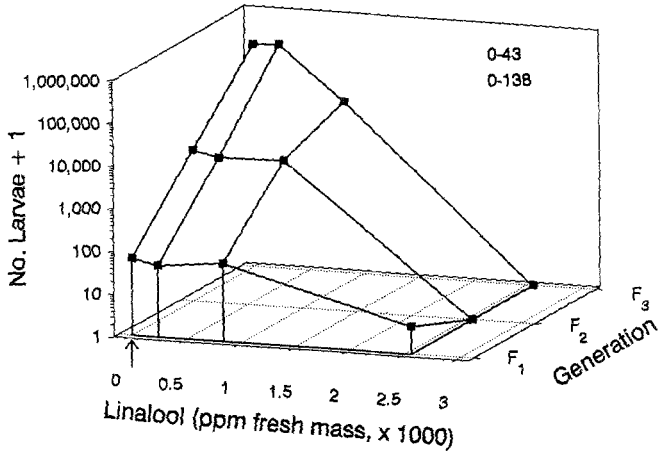

FIG. 6. As for Figure 3, but for the oxygenated monoterpene linalool.

grasshoppers [*Schistocerca americana* (Drury) (Orthoptera: Acrididae)], permitting release of the encapsulated compound in the gut.

Microencapsulation appeared to reduce volatilization of the monoterpenes tested more than the oxygenated monoterpenes (Figures 1 and 2). Our explanation for this is that the monoterpenes tended to encapsulate more efficiently than the oxygenated monoterpenes because they are less polar and thus less soluble in water. The encapsulation efficiency relates to the percentage of terpene compound residing within the microcapsule as opposed to being left to the exterior aqueous phase. In other words, a greater percentage of the oxygenated monoterpenes was unencapsulated in the aqueous phase. The unencapsulated terpene would tend to volatilize fairly rapidly (Table 1); we believe this accounts for the greater loss of terpene content in oxygenated monoterpene diets over time. In the future, it should be possible to compensate for solubility and achieve equal encapsulation efficiencies for all terpene compounds.

We predict that microencapsulated terpenes may have many useful applications not only in laboratory diet studies but also in field and greenhouse experiments with plant material. Materials can be added to the microcapsule slurry to adhere the capsules to surfaces. Thus, microencapsulated terpenes could be coated onto the surfaces of needles, leaves, twigs, etc., to provide plant material that is enhanced with particular terpene compounds or combinations. Usher et al. (1989, p. 121) pointed out that "Microcapsules adhering to leaf surfaces could be a relatively realistic dosing technique for plant secondary compounds, many of which are superficial or compartmentalized in leaves in nature."

There are some disadvantages associated with this technique: (1) not all

terpenes can be microencapsulated successfully; (2) the microencapsulation process requires a minimum of 120 g of terpene material; (3) the amount of active ingredient in the microcapsule slurry was quite variable among different batches because each compound has a different solubility in water, thus requiring more preliminary formulation work to produce the desired terpene concentrations; and (4) there is undoubtedly a less even distribution of the capsules whisked into the diet than if liquid terpenes were blended in. In spite of these limitations, we believe the technique is a much better way to incorporate terpenes into artificial diets than to merely blend terpenes into diets or to coat terpenes onto cellulose powder.

Acknowledgments—We thank E.A. Bernays, R.G. Kelsey, R.A. Redak, and two anonymous reviewers for comments on the manuscript. Suggestions from R.A. Redak and R.W. Tinus contributed to the development of the technique. We are grateful to D.P. Huebner and J.K. Itami for assistance with the experiments and to D.P. Huebner for help in preparing the figures. The western spruce budworm colony that provided the experimental animals was started with egg masses obtained from the Insect Production Unit of the Forest Pest Management Institute, Forestry Canada, in Sault Ste. Marie, Ontario.

Abstract—Ultraviolet irradiation of mulberry leaves caused a reduced feeding response in *Bombyx mori* larvae (ca. 22% reduction in consumption as compared with control). Sucrose content of the foliage decreased after exposure to UV irradiation (0.5 mW/cm^2) for 1 hr. Electrophysiological responses of the sensilla styloconica-I to sucrose concentration (ca. 0–80 mg/g) showed a reduced response to UV-irradiated foliage when compared with the control. From feeding, gustatory, and electrophysiological responses, as well as the measurement of sucrose contents of the leaves, we concluded that the reduced feeding response to UV-irradiated leaves is due to the reduced sucrose content of the mulberry leaves, thus reducing pleogostimulatory levels.

Key Words—UV irradiation, *Bombyx mori*, Lepidoptera, Bombycidae, mulberry leaf, sucrose, electrophysiology, sensilla responses.

INTRODUCTION

The mulberry, *Morus alba* (Moraceae), is the sole food plant for the silkworm, *Bombyx mori*, throughout its range. In the presence of laboratory ultraviolet (UV) irradiation, we found that *B. mori* larvae reduce their consumption rates

(Yazawa et al., 1991a,b). It is well known that phytophagous insects reduce consumption rates of host plants in the presence of UV radiation (Berenbaum, 1978; Zangerl and Berenbaum, 1987). Zangerl and Berenbaum (1987) found that UV irradiation induces the biothynthesis of the furanocoumarin xanthotoxin, an antifeedant, in plants of the families Rutaceae and Umbelliferae. We also found changes in coumarin level in relation to UV radiation (Yazawa et al., 1991a,b) and UV radiation induced changes in sucrose content of mulberry leaves.

METHODS AND MATERIALS

Insects. Bombyx mori (N 601 × C601) were reared on an artificial diet containing chlorella (Yakuruto Co., Ltd., Tokyo). Male last-instar larvae were used in the feeding and electrophysiological experiments.

UV Radiation Sources and Levels. UV light (15W; National Electric Co., Ltd., Japan) levels of 0.2–0.6 mW/cm^2 for 1–60 min were applied to the picked plant leaves, *Morus alba.*

Feeding Response. The larvae used in the feeding experiment were newly molted fourth-instar larvae within several hours after ecdysis. The larvae were simply fed irradiated foliage for 1 hr. Six larvae were used in the experiments. The relative consumption rate of irradiated foliage and body weight were calculated by subtracting initial weight from body weight 1 hr after initiation of the feeding period.

Measurements of Sucrose Content. Two analytical methods for measurement of carbohydrates were employed. Method I (Figure 1) was used for getting precise data per one leaf or milligram of leaf; method II was used for obtaining a rapid estimate. The latter method consisted of directly extracting irradiated foliage with 80% hot EtOH (3 × 100 ml) and evaporating to dryness, after which 2 ml distilled water were added.

HPLC Analysis of Carbohydrates. Carbohydrate analysis was performed with high-performance liquid chromatography (HPLC) (Shimadzu LC-6A) with an IR detector. The column type was Shim-pack CLC-NH2 (Shimadzu Co. Ltd.) and was eluted with 70% acetonitrile at a flow rate of 1 ml/min. Authentic sucrose was also injected as a standard carbohydrate in the same manner.

Electrophysiological Response. The electrophysiological methods used in the experiments were the same as described previously (Ishikawa, 1963; Hirao and Arai, 1991). A head–thorax was amputated at the middle part of the thorax and secured with clay to a silver plate, which was used as the indifferent electrode. A glass capillary, which served as the stimulating–recording electrode, was applied externally over the tip of the hair. A silver wire inserted into the

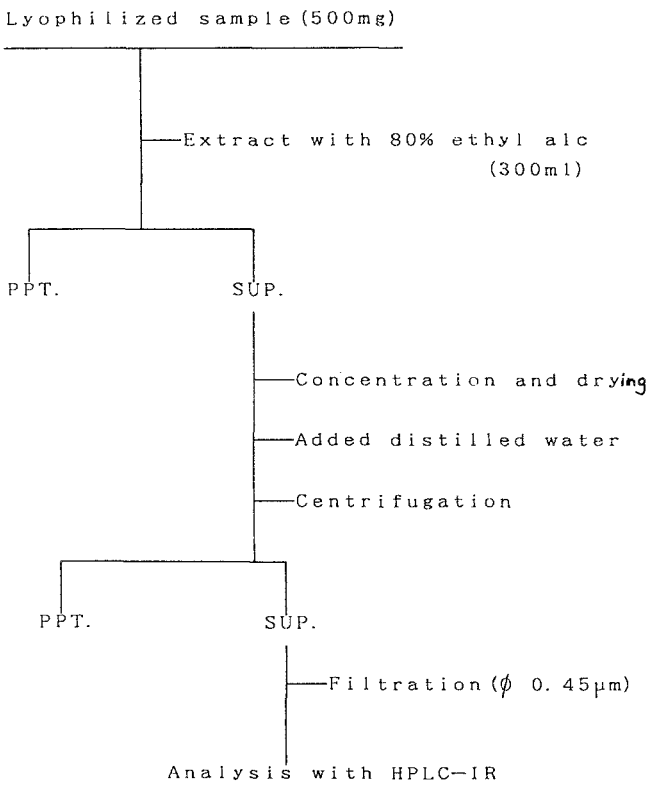

FIG. 1. Analytical methods of sucrose content of the mulberry leaves.

capillary was connected with a high-input impedance, cathode-follower preamplifier, followed by the main amplifier and oscilloscope. Recordings from sensilla styloconica-I and -II were carried out for 1 sec after 1 sec from the stimuli.

RESULTS

Feeding Response. As shown in Figure 2, the larvae consumed more non-treated mulberry leaves than UV-treated leaves. Exposure of more than 0.4 mW/cm^2 UV radiation for 1 min caused a reduction in body weight. With UV radiation for 30 min at more than 0.5 mW/cm^2, final body weight was reduced relative to initial body weight.

Sucrose Contents in Mulberry Leaves with Reference to UV Radiation. Typical chromatograms of sugar standards, as well as sugars obtained from

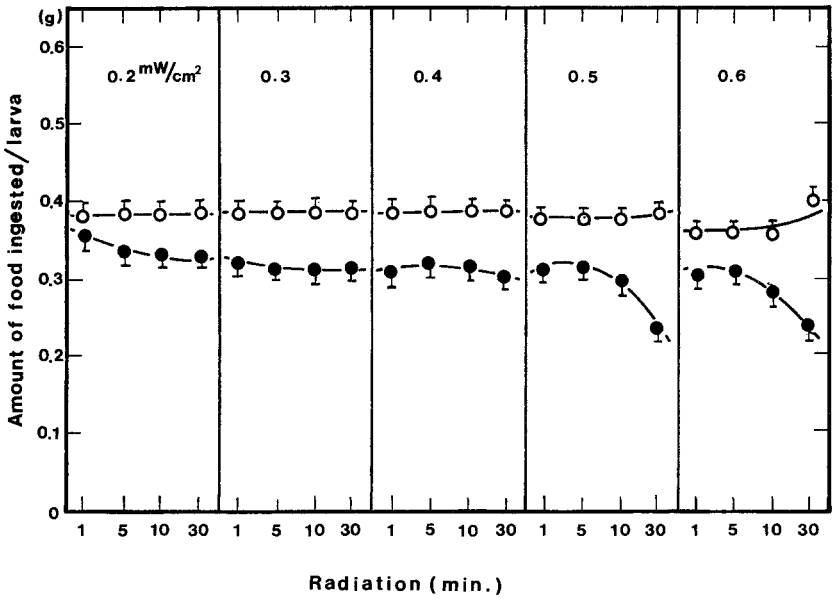

FIG. 2. Feeding response of *Bombyx mori* offered UV-irradiated leaves. Open and filled circles show amount of food ingested in the absence and presence of UV irradiation, respectively.

extracts from irradiated and nonirradiated leaves, are illustrated in Figure 3A–C, respectively. As shown in Figure 3B and C, four sugars (sucrose, glucose, maltose and fructose), were detected in the extraction with method II. After UV radiation (0.5 mW/cm^2) of the leaves, the sucrose peak became smaller (Figure 3B) compared to that of control (Figure 3C).

With UV treatment (0.5 mW/cm^2) for 0.5 hr on the mulberry leaves, total sugar content was reduced ca. 49% compared with the control (Figure 4A). Sucrose, glucose, maltose, and fructose were detected in the presence and absence of UV. In the presence of UV, the level of glucose, maltose, and fructose was not changed; only sucrose content was reduced when UV radiation was applied for 10 or 30 min (Figure 4A). Among total sugars, the sucrose content of the mulberry leaves was also reduced in proportion to UV intensity (Figure 4B). In the case of analytical method I, levels of sucrose per leaf (Figure 4B) were similar to those measured by analytical method II (Figure 4B). Analytical method I is more suitable for sucrose analysis, because it is conventional and produces reliable results.

Electrophysiological Response to Partially Purified Samples. Since the level of glucose and fructose did not change in the presence of UV, only sucrose, which shows high activity with sensilla styloconica-I (Ss-I), was checked elec-

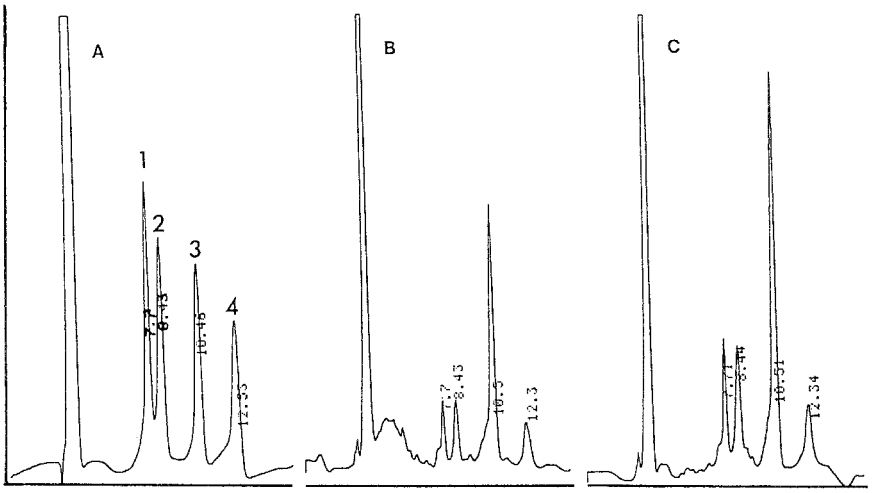

FIG. 3. The HPLC pattern of sugar analysis of the standard compounds (A), UV-exposed leaves (B), and control leaves (C). Ordinate: response; abscissa: retention time (min). 1, fructose; 2, glucose; 3, sucrose; 4, maltose.

trophysiologically. Electrophysiological response from Ss-I showed many impulses discharged in both the partially purified sample and the 1/10 dilution sample of the nonirradiated foliage, as compared with samples of irradiated foliage (Figure 5B and E). The number of impulses from Ss-II does not change with the presence and absence of UV. Figure 6 shows the relationship between actually detected sucrose concentrations and the number of impulses discharged from Ss-I. The number of impulses increased with increasing sucrose concentrations.

DISCUSSION

By our experimental methods, sucrose, glucose, fructose, and maltose were detected in mulberry leaves. There are other reports on the sucrose content of the mulberry leaf (Yazawa and Yamashita, 1974), since it is well known that the taste receptors of sensilla styloconica-I (Ss-I) and -II (Ss-II) in the larvae of *Bombyx mori* play important roles in feeding behavior. Hirao and Arai (1991) and Yazawa et al. (1991a,b) reported on the relation between sucrose and palatability of mulberry to *B. mori*, and they recorded impulses of the sugar receptor of Ss-I to *Morus alba* leaf extracts.

As shown in Figure 6, the number of impulses from Ss-I increased with increasing sucrose content of the leaves. The 25–33% decrease in sucrose con-

centrations in the UV-treated foliage might account for the reduced feeding response. From the results of recording Ss-II (bitter sense) (Ishikawa, 1966; Hirao and Arai, 1991), we assume that bitter tasting substances are not synthesized in the mulberry leaves in the presence of UV radiation. Maltose analyzed from the mulberry leaves produced a similar response pattern to that of sucrose with respect to the Ls (sucrose) receptor on the Ss-I, but response of the receptor to maltose is low compared with sucrose (Ishikawa, 1963). In the present experiments, the Li (inositol) receptor, the activity of which is specifically high with respect to inositol, discharged many impulses in response to the sample of UV-treated and nontreated mulberry leaves. Mulberry leaves contain polyhydric

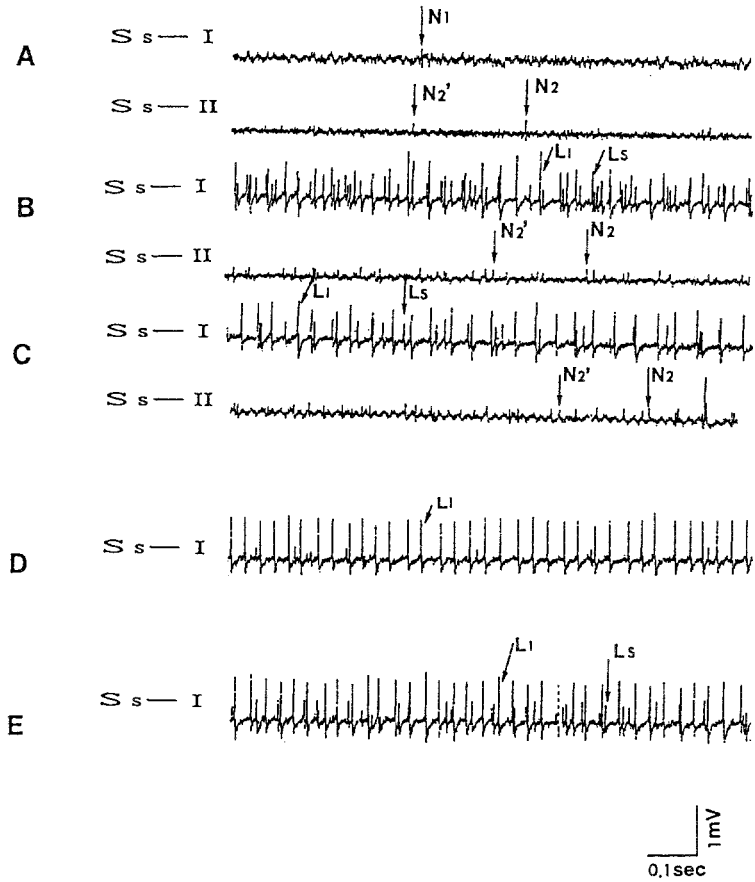

FIG. 5. The impulses discharged from Ss-I and Ss-II. (A) Response of 5 mM NaCl solution from Ss-I and -II; (B) response of control sample from Ss-I and -II; (C) response of sample with UV-treated leaves from Ss-I and -II; (D) response of sample with UV-treated leaves from Ss-I; (E) response of control sample from the Ss-I. alcohols, such as inositol (Naito and Hamamura, 1961). Therefore we must investigate the relationship between actual inositol content of mulberry leaves and the Li receptor activity.

The mechanism by which UV radiation affects the sucrose content of the leaf is not clear. Among four sugars in the leaves, only sucrose was reduced in the presence of UV; therefore, we presume that sucrose degradation is not induced by UV radiation. Probably, synthesis of sucrose was blocked through

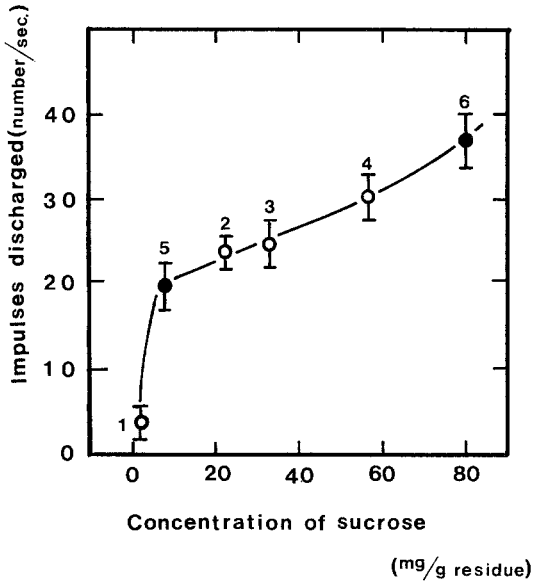

FIG. 6. The relationship between sucrose doses actually detected from the leaves and the number of impulses discharged. damage to the chloroplasts by UV irradiation. A similar reduction of sucrose contents by UV-B irradiation was previously reported by Takeuchi et al. (1989). Considering the role of sucrose as a phagostimulant, understanding the mechanism of sucrose reduction is of importance.

(Received October 4, 1991; accepted November 25, 1991)

Abstract—The fate of the tomato foliar phenolic, chlorogenic acid, in the digestive systems of Colorado potato beetle *Leptinotarsa decemlineata* (Coleoptera: Chrysomelidae) and *Helicoverpa zea* (Lepidoptera: Noctuidae) is compared. In larval *H. zea* and other lepidopteran species previously examined, approximately 35–50% of the ingested chlorogenic acid was oxidized in the digestive system by foliar phenolic oxidases (i.e., polyphenol oxidase and peroxidase) from the tomato plant. The oxidized form of chlorogenic acid, chlorogenoquinone, is a potent alkylator of dietary protein and can exert a strong antinutritive effect upon larvae through chemical degradation of essential amino acids. In contrast, in *L. decemlineata* less than 4% of the ingested dose of chlorogenic acid was bound to protein. In vitro experiments to determine the influence of pH on covalent binding of chlorogenic acid to protein showed that 30–45% less chlorogenic acid bound to protein at pHs representative of the beetle midgut (pH 5.5–6.5) than at a pH representing the lepidopteran midgut (pH 8.5). At an acidic pH, considerably more of the alkylatable functional groups of amino acids ($-NH_2$, $-SH$) are in the nonreactive, protonated state. Hence, polyphenol oxidases are unlikely to have significant antinutritive effects against the Colorado potato beetle and may not be a useful biochemical source of resistance against this insect. The influence of feeding by larval Colorado potato beetle on foliar polyphenol oxidase activity in tomato foliage and its possible significance to interspecific competition is also considered.

phenol oxidase, peroxidase, chlorogenic acid, *Lycopersicon esculentum*, tomato, host-plant resistance, midgut pH.

INTRODUCTION

Feeding by the Colorado potato beetle, *Leptinotarsa decemlineata*, is normally restricted to solanaceous plants including potato, tomato, and eggplant (Hsiao, 1974, 1978; Hare, 1990). Because of the considerable damage this insect may cause to these crops, substantial efforts have been made to develop host-plant resistance to the beetle; however, commercially acceptable varieties have not been released (Hare, 1990). Several phytochemicals have been specifically implicated in resistance to the Colorado potato beetle (CPB), including steroidal glycoalkaloids (Hare, 1983, 1987; but see Barbour and Kennedy, 1991), methyl ketones (Kennedy and Sorenson, 1985) and the sesquiterpene, zingiberine (Carter et al., 1989). Although CPB causes a massive induction of serine protease inhibitors in tomato leaves during feeding (Green and Ryan, 1972), the beetle is insensitive to their adverse effects (Wolfson and Murdock, 1987) because it relies not upon serine proteases such as trypsin and chymotrypsin, but instead upon the thiol proteases, cathepsins B and H, for protein digestion (Murdock et al., 1987; Thie and Houseman, 1990).

Another important component of chemical defense in solanaceous plants is the enzymic oxidation of phenolics. In the wild potato species, *Solanum berthaultii*, type A glandular trichomes containing polyphenol oxidase are essential for resistance against CPB (Neal et al., 1989; Tingey, 1991). Moreover, type B trichomes containing sucrose esters increase the expression of resistance in the presence of type A trichomes (Neal et al., 1989; Pelletier and Smilowitz, 1990; Tingey, 1991). A significant amount of the total leaf polyphenol oxidase is associated with the chloroplast in potato and tomato. The majority of the work on phenolic oxidation in potato has focused on the entrapping properties of trichomes; little work has been done on the potential antinutritive properties of oxidized phenolics as a basis of resistance to CPB. Carter (1987) reported that resistance to CPB in tomato species was not associated with total foliar phenolic oxidation.

Our paper compares the ability of an antinutritive plant defense (i.e., polyphenol oxidase) to operate against two insects, CPB and *Helicoverpa* (=*Heliothis*) *zea*, with distinctly different gut physiologies, the former having an acidic midgut and the latter an alkaline midgut. In the highly polyphagous lepidopteran species, *H. zea* and *Spodoptera exigua*, phenolic oxidation exerts a strong antinutritive effect against larvae (Felton et al., 1989a,b). When larvae disrupt plant cellular compartments during feeding, the enzyme polyphenol oxidase mixes with phenolic substrates such as chlorogenic acid, leading to the rapid formation of orthoquinones (Felton et al., 1989a). The quinones readily

alkylate dietary protein, resulting in a substantial decline in the nutritive quality of the protein (Felton et al., 1989a,b; Duffey and Felton, 1989, 1991). The lepidopteran species tend to feed on fruiting structures, where polyphenol oxidase activity is markedly lower than in foliage, thereby avoiding a significant impact of phenolic oxidation upon food quality (Felton et al., 1989a). In contrast, CPB feeds primarily on foliage and hence is potentially exposed to high levels of phenolic oxidation products.

We report here an assessment of the potential for polyphenol oxidase to operate as an antinutritive source of resistance to CPB. The role of midgut pH in mediating the impact of phenolic oxidation on food quality is also considered.

METHODS AND MATERIALS

Insects and Plants. Eggs of CPB were obtained from a colony maintained on potato in the laboratory of Dr. George Kennedy, North Carolina State University. Emerging larvae were reared in environmental chambers on tomato, *Lycopersicon esculentum* (var. Castlemart) for one generation before experiments were begun. Eggs of *H. zea* were obtained from the Bioenvironmental Insect Control Laboratory, USDA (Stoneville, Mississippi). Plants used for feeding and induction assays were grown following Broadway et al. (1986).

Chemicals and Isotopes. Tritiated chlorogenic acid was prepared by tritium exchange by Research Products International Corp. (Gif-sur-Yvette, France) and purified using thin-layer chromatography conforming to Isman and Duffey (1983). The specific activity of the purified [^{3}H]chlorogenic acid was 153 mCi/mmol.

Enzyme Assays. Preparation of leaf tissue for enzyme analysis has been described previously (Felton and Duffey, 1990). Peroxidase and polyphenol oxidase activities were measured following Ryan et al. (1982) using guaiacol and chlorogenic acid as substrates, respectively. Leaf protein was measured using Coomassie blue G-250 dye following Jones et al. (1989).

Metabolism of Chlorogenic Acid in Larval Digestive System. Two-microliter aliquots of [^{3}H]chlorogenic acid containing ca. 205,000 dpm (ca. 215 ng) in 50% aqueous methanol were applied to the surfaces of tomato leaflets weighing ca. 50 mg. After the aqueous methanol evaporated, fourth-instar CPB or fifth-instar *H. zea* larvae that had been starved for 12 hr were placed on individual leaflets containing the radioisotope. Larvae completely ingesting the leaflet within 6 hr were used in the assay. Feces were collected as described (Felton et al., 1989a) from nine larvae per species and pooled in groups of three larvae for each replicate. A total of three replicates per species was analyzed by two-dimensional thin-layer chromatography (2% formic acid followed by *n*-butanol–ethanol–2% NH_4OH at 6:1:3 on cellulose) followed by liquid scintillation

counting for radioactivity associated with free chlorogenic acid, protein-bound chlorogenic acid, and polymeric chlorogenic acid (Felton et al., 1989a).

Oxidative Enzymes in Larval Midgut. To determine the presence of phenolic oxidizing enzyme activity in the beetle digestive system, five newly molted fourth-instar larvae were placed on an undamaged six- to seven-leaf stage tomato plant. Larvae were removed after 24 hr and held on ice for 30 min. Midguts were removed, and each midgut, containing lumen contents, was mechanically homogenized in ice-cold 1.15% KCl for 30 sec. Samples were centrifuged at 10,000*g* for 20 min; the supernatant was used immediately as the enzyme source for peroxidase and polyphenol oxidase. One leaflet was excised with a razor blade from each leaf of the tomato plant and assayed for peroxidase and polyphenol oxidase activities as described above. The experiment was replicated five times. Protein concentration was quantified using Coomassie brilliant blue G-250 following Jones et al. (1989).

Determination of pH in Larval Digestive System. Twenty fourth-instar CPB and 20 fifth-instar *H. zea* were placed individually in Petri dishes containing two tomato leaflets excised from six-leaf stage tomato plants. After 24 hr, regurgitate was individually collected from 10 larvae of each species for pH determination. Midgut luminal fluid was individually collected from the remaining 10 larvae per species following dissection of the digestive tract. The pH of the regurgitate and midgut fluid was determined with short-range pH paper.

Influence of pH on Polyphenol Oxidase and on Covalent Binding of Chlorogenic Acid to Protein. To determine the influence of pH on polyphenol oxidase activity and the subsequent binding of chlorogenic acid to protein, tomato polyphenol oxidase was partially purified by ammonium sulfate fractionation to a specific activity of 2300 units/mg protein (Felton and Duffey, 1991a). One unit of activity equals a change in OD_{470} of 0.001/min with chlorogenic acid as a substrate. A 1-ml solution containing 20 mg bovine serum albumin and 3.0 μmol chlorogenic acid was incubated with 30 μg polyphenol oxidase in 0.1 M sodium phosphate buffer at pH 5.5, 6.5, 7.5, or 8.5 for 60 min. Three replicates were performed at each pH. The polyphenol oxidase activity for each pH level was determined from 10-μl aliquots performed in triplicate (Ryan et al., 1982). Control treatments for each pH were treated identically except chlorogenic acid was omitted.

The solutions were then dialyzed (12,000 mol wt cutoff) at 1–4°C against 8 M urea for 24 hr to remove noncovalently bound chlorogenic acid (Barbeau and Kinsella, 1983), followed by dialysis against distilled H_2O for 24 hr, and finally desalted in a PD-10 Sephadex G-25M column (Pharmacia LKB, Uppsala, Sweden) according to the manufacturer's suggestions. The amount of chlorogenic acid covalently bound to the protein was determined from a standard curve using a SLM-Aminco 3000 Array spectrophotometer following Broadway et al.

(1986). The small amount of background absorbance in the respective control treatments was subtracted from each test protein.

Effect of Colorado Potato Beetle Feeding on Leaf Phenolic Oxidases. To determine the effect of CPB larval feeding on polyphenol oxidase activity, tomato plants (var. Castlemart) were grown in the greenhouse in fine mesh cages to exclude unwanted insects. When plants reached the six- to seven-leaf stage, one fourth-instar larva was placed on each plant on the lowest true leaf. No effort was made to restrict larval feeding to a particular leaf position. Control plants were treated identically throughout with the exception of not being infested with beetle larvae. Seven plants per treatment were maintained in the cages during the experiment. After seven days, plants were transported to the laboratory where six leaflets (one terminal leaflet per leaf) per plant were removed for analyses. Leaflets included both damaged and undamaged samples. Leaflets for each replicate plant were pooled, homogenized, and assayed in triplicate for polyphenol oxidase and peroxidase as described above.

RESULTS

Metabolism of Chlorogenic Acid in Larval Digestive System. The majority of excreted chlorogenic acid in the CPB was not covalently bound to protein but remained in unbound, monomeric form (Table 1). Less than 4% of excreted chlorogenic acid was covalently bound to protein and/or amino acids, but a significant amount (ca. 16%) of excreted chlorogenic acid was polymerized. In contrast, considerably more excreted chlorogenic acid was bound to protein and/or amino acids in larval *H. zea*: nearly 35% was covalently bound, and approximately 14% was polymerized. Polymerized chlorogenic acid remained at or

TABLE 1. FATE OF EXCRETED [^{3}H]-CHLOROGENIC ACID IN FECES OF COLORADO POTATO BEETLE *Leptinotarsa decemlineata* AND TOMATO FRUITWORM *Helicoverpa zea* LARVAE

Chemical	Percent of total excreted radioactivity[a]	
	CPB	*H. zea*
Chlorogenic acid (unbound)	82.9 (±12.2) A	34.1 (±7.5) B
Chlorogenic acid–protein conjugate	3.5 (±0.9) A	34.8 (±7.6) B
Chlorogenic acid (polymer)	16.3 (±4.4) A	13.7 (±2.6) A

near the origin in the TLC systems tested. Chlorogenic acid chemically oxidized with 0.1 N NaOH or with ferrous sulfate at pH 8.0 behaved similarly.

Oxidative Enzymes in Larval Midgut. Substantial polyphenol oxidase activity was present in the midgut contents in CPB larvae feeding on tomato foliage (Table 2). Activity was approximately 36% of that found in tomato foliage used as the food source. It is unknown if the midgut contains endogenous polyphenol oxidase or is merely derived from ingested foliage; nevertheless, ingested polyphenol oxidase activity is reduced in the gut of CPB. Peroxidase activity in the midgut contents was nearly 12× in excess of that present in ingested leaflets (Table 2). The enriched peroxidative activity of the midgut with respect to the food plant implies the presence of endogenous peroxidase.

pH of Larval Digestive System. The pH of the CPB regurgitate ranged from 5.5 to 6.0, whereas the regurgitate from *H. zea* was 7.0–7.4. The beetle's midgut fluid was acidic at pH 6.0–6.5, but the caterpillar's midgut was alkaline, ranging from 8.0 to 8.7.

Influence of pH on Polyphenol Oxidase Activity and Covalent Binding of Chlorogenic Acid to Protein. Both polyphenol oxidase from tomato foliage and covalent binding of chlorogenic acid to protein were significantly affected by pH (Figure 1). Optimal oxidase activity occurred at pH 6.5 within the pH range of the beetle midgut lumen, but at pH 8.5, representative of the lepidopteran midgut, polyphenol oxidase activity was nearly 50% less. However, maximal covalent binding was observed at the alkaline pH 8.5. At pHs occurring in the digestive system of CPB (i.e., 5.5–6.5), ca. 25–40% less covalent binding occurred than at pH 8.5 (Figure 1).

Effect of Colorado Potato Beetle Feeding on Leaf Phenolic Oxidases. Feeding by CPB for 48 hr on tomato foliage did not significantly ($P > 0.05$) affect foliar peroxidase activity (Figure 2). However, polyphenol oxidase activity in foliage increased by 92% when feeding damage by CPB occurred (Figure 2; $P < 0.01$).

TABLE 2. PHENOLIC OXIDIZING ENZYMES[a] IN TOMATO FOLIAGE AND MIDGUT OF COLORADO POTATO BEETLE

Source	Polyphenol oxidase	Peroxidase

[b] Midgut measurements made with midgut wall and lumen contents.

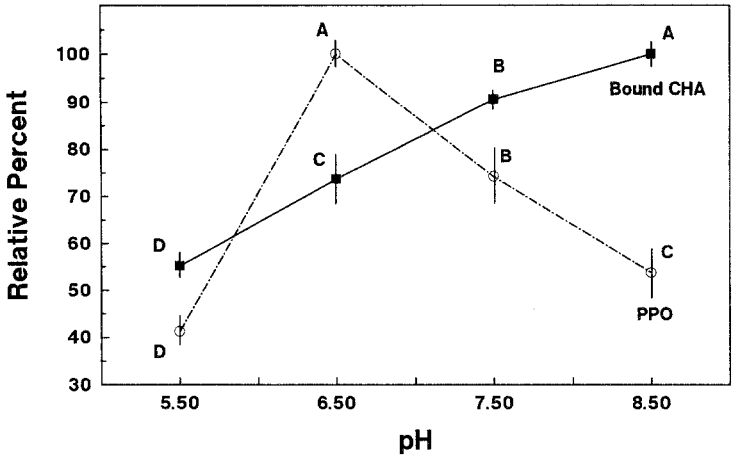

FIG. 1. Influence of pH on tomato foliar polyphenol oxidase (PPO) activity and on the covalent binding of chlorogenic acid (CHA) to protein. Each point represents the mean of three replicates. Error bars indicate 95% confidence limits. Means on each line not followed by the same letter are significantly different at $P < 0.05$ by 95% confidence limits. The absolute values for 100% relative polyphenol oxidase activity and 100% covalent binding are respectively, 2300 units/mg protein/min and 144.4 nmol chlorogenic acid bound/mg protein.

DISCUSSION

The fate of the foliar phenolic, chlorogenic acid, in the digestive system of the Colorado potato beetle was strikingly different from its fate in lepidopteran species (Felton et al., 1989a; Felton and Duffey, 1991a). In the Colorado potato beetle, the majority of ingested chlorogenic acid remained unoxidized in the beetle's digestive system (ca. 80%); however, a substantial amount (16%) was oxidatively polymerized. A small amount of chlorogenic acid (<4%) was covalently bound to amino acids and/or proteins in the beetle digestive system. In contrast, in the lepidopteran species *H. zea*, *Spodoptera exigua*, *Manduca sexta*, and *Trichoplusia ni*, approximately 35–50% of excreted chlorogenic acid was covalently bound to protein or amino acids (Felton et al., 1989a; Felton and Duffey, 1991a, unpublished data).

The differences in phenolic–protein binding among these insects are largely explicable by differences in midgut pH. The midgut luminal pH in the lepidopteran species was moderately to highly alkaline (i.e., pH 8.0–11.0; Felton et al., 1989a; Felton and Duffey, 1991a; Dow, 1984), but the pH of the digestive fluids of the beetle was mildly acidic (i.e., pH 5.5–6.5; see also Wolfson and Murdock, 1987). In an acidic midgut, chlorogenic acid is less likely to be covalently bound to amino acids and proteins for two reasons. First, the nonen-

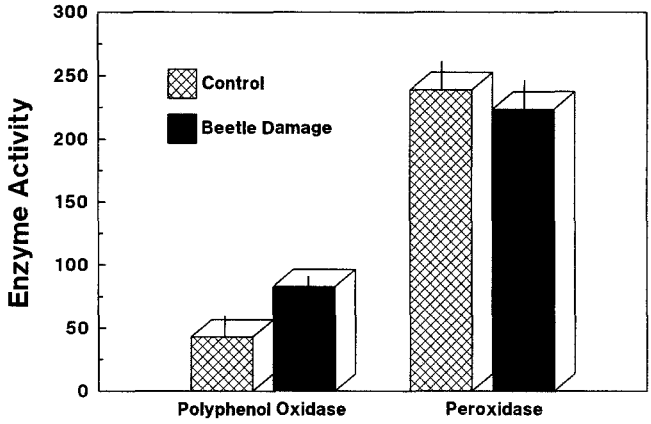

FIG. 2. Effect of foliar feeding by Colorado potato beetle larvae on activities of tomato polyphenol oxidase and peroxidase. Enzyme activity expressed in units of change in OD_{470}/min/gm foliage with guaiacol as substrate for peroxidase and chlorogenic acid as substrate for polyphenol oxidase. Controls represent undamaged plants. Error bars indicate 95% confidence limits. Each treatment was replicated seven times. Activities of enzymes were determined after seven days feeding by one fourth-instar larva. Polyphenol oxidase activity was significantly higher ($P < 0.01$) in plants damaged by beetle larvae. No significant differences were observed in peroxidase activity.

zymic oxidation (i.e., autooxidation) of chlorogenic acid is minimized at acidic pH (Barbeau and Kinsella, 1983; Cilliers and Singleton, 1989). Second, the chemical reactivity of the nucleophilic functional groups of amino acids (−SH and −NH or $-NH_2$) is strongly influenced by pH. In alkaline conditions, many amino acid side chains are unprotonated and, consequently, more prone to nucleophilic attack by electrophiles (e.g., quinones, epoxides); on the other hand in acidic pH (<6.5), the side chains become protonated and hence less susceptible to alkylation (Pierpoint, 1983; Barbeau and Kinsella, 1983). For instance, the pK_as of the reactive −SH, −NH, and $-NH_2$ groups of cysteine, histidine, and lysine, are respectively 8.1, 8.8, and 9.0. Consequently, at acidic pH, few of these groups are unprotonated and the oxidative polymerization of phenolics is favored, thereby minimizing the antinutritive effects of phenolics on protein. The phenolic polymer of chlorogenic acid possesses negligible toxicity to lepidopteran species (Felton et al., 1989a); however, its toxicity to CPB has not been determined.

The oxidative polymerization of phenolics by insect peroxidase and phenol oxidases has been hypothesized to be a detoxicative process in certain insects (e.g., aphids; Peng and Miles, 1988). It is conceivable that in insect species possessing an acidic midgut, peroxidase and polyphenol oxidase activities (Table

2) contribute to detoxification of chlorogenic acid. However, it must also be noted that the midgut of the CPB presumably possesses a negative oxidation potential because of the necessity for thiol digestive proteases to be in a reducing environment (Murdock et al., 1987; Thie and Houseman, 1990). A reducing environment minimizes phenolic oxidation (Appel and Martin, 1990) and may partially account for our observations that substantially less total phenolic oxidation (i.e., polymer formation and protein-bound phenolic) occurs in CPB compared to the lepidopteran species, despite the fact that foliar polyphenol oxidases in tomato are highly active at the pH of the CPB midgut (Felton et al., 1989a).

The relatively large differences in the pH of the digestive system between the leaf-feeding beetle, CPB (mildly acidic, ca. 5.5–6.5), and the leaf-feeding lepidopterans, *Manduca sexta* and *Trichoplusia ni* (highly alkaline, >9.5) may represent two divergent physiological mechanisms for tolerating phenolics and their oxidation products. We have hypothesized that, although quinones are more reactive with amino acids in the highly alkaline midgut, the alkalinity would allow for greater solubilization of plant protein, thus compensating for any nutritional loss in essential amino acids due to conjugation of phenolics with amino acids (Felton and Duffey, 1991a). This appends the earlier interpretation of gut alkalinity as an adaptive mechanism to circumvent tannin toxicity through inhibition of hydrogen bond complexation (Berenbaum, 1980). Alternatively, an acidic midgut impedes the covalent conjugation of amino acids with the electrophilic quinones, thus preventing the loss of essential amino acids. Therefore, it follows that insects with mildly alkaline digestive systems (i.e., pH 8–9; *H. zea* and *Spodoptera exigua*) are predicted to be most susceptible to the antinutritive effects of phenolic oxidation. Hence, we predict that host-plant resistance based upon the antinutritive properties of polyphenol oxidase will not be particularly effective against insects possessing acidic midguts (e.g., many beetles and grasshoppers).

The ability of an acidic midgut to inhibit phenolic-protein covalent interactions cannot fully account for the unexpectedly small amount of phenolic–protein conjugate observed in feces of the CPB (i.e., <4%; Table 1) as compared to the 55% observed in vitro (Figure 1). We are aware that there are other physiological and/or biochemical properties of the CPB digestive system that probably contribute to minimizing phenolic–protein binding and/or phenolic toxicity. In fact, a host of other mechanisms are known to be involved in detoxifying phenolics in herbivorous insects; the sheer number of detoxification mechanisms implicates phenolics as important chemical mediators in plant–herbivore associations. These mechanisms involve a combination of physiological, biochemical, and chemical processes (Table 3). For instance, phenolics may be maintained in their reduced state via quinone reductase, which was reported in several lepidopterans including *H. zea* (Yu, 1987; Felton and Duffey, 1992).

TABLE 3. SUMMARY OF PHYSIOLOGICAL AND BIOCHEMICAL MECHANISMS OF INSECT HERBIVORES FOR TOLERATING TOXICITY FROM PHENOLICS AND QUINONES

Mechanism	Author and citation
Enzymatic mechanisms	
Quinone reductase	Yu (1987), Felton and Duffey (1992)
Ascorbate reducing enzymes	Felton and Duffey (1992)
Superoxide dismutase	Ahmad and Pardini (1990)
Catalase	Ahmad and Pardini (1990), Pritsos et al. (1988), Felton and Duffey, (1991b)
Glutathione transferase	Weinhold et al., (1990)
Esterases	Lindroth and Hemming (1990)
Reduced β-glucosidase activity	Lindroth (1988)
Glutathione reductase	Ahmad and Pardini (1990), Pritsos et al. (1988), Felton and Duffey (1992)
Nonenzymatic mechanisms	
Reducing conditions in gut	Appel and Martin (1990)
Gut surfactants	Felton and Duffey (1991a)
Alkaline midgut	Felton and Duffey (1991a)
Acidic midgut	This investigation
Ascorbic acid	Felton and Duffey (1992)
Glutathione	unpublished data

The widely occurring antioxidant enzymes catalase, superoxide dismutase, and glutathione reductase have received considerable attention as protective mechanisms against oxidative damage by phenolics (e.g., Ahmad and Pardini, 1990; Pritsos et al., 1988; Felton and Duffey, 1991b). Glutathione transferases can facilitate the conjugation and elimination of phenolic oxidation products (Weinhold et al., 1990). Lindroth (1988) reported on the role of diminished β-glucosidase activity in Lepidoptera as an adaptation to minimize the enzymatic conversion of phenolic glycosides to the more toxic aglycone. Moreover, esterases are also important in the detoxification of some phenolics (Lindroth and Hemming, 1990).

Reducing agents such as ascorbate and glutathione may provide additional protection by reducing oxidized phenolics (i.e., quinones). We have also proposed that ascorbate functions in an enzymatic reducing system utilizing the enzymes ascorbate free radical reductase and dehydroascorbate reductase to maintain the redox properties of ascorbate (Felton and Duffey, 1992). The reducing conditions found in the midgut of *Manduca sexta* were also postulated to be a protective mechanism against phenolic oxidation (Appel and Martin, 1990). Gut surfactants, such as lysolecithin, may directly inhibit polyphenol oxidase activity (Felton and Duffey, 1991a). Furthermore, the metal-binding protein,

ferritin, in the midgut of Lepidoptera may sequester iron and prevent its participation as a catalyst in phenolic autooxidation (Nichol and Locke, 1989).

If CPB successfully avoids the antinutritive or toxic effects of phenolic oxidation as contended, then the induction or amplification of polyphenol oxidase activity by CPB feeding (Table 2) would seem to have limited defensive value against CPB. This may be analogous to the induction of serine protease inhibitors by CPB damage, which do not target the digestive processes of CPB (Ryan et al., 1986; Wolfson and Murdock, 1987). The induction of these defenses, however, may indirectly alter interspecific competition. The fitness of other herbivores, which are susceptible to protease inhibitors and/or phenolic oxidation (e.g., *H. zea*; Felton et al., 1989a,b), may be compromised when utilizing host plants previously or concurrently damaged by CPB. This form of competition mediated through host-plant chemistry may be comparable to the induction of cucurbitacins in *Cucurbita* reported by Tallamy and Krischik (1989), wherein the cucurbitacins were effective defenses against generalist herbivores but were ineffective against specialist herbivores because these chemicals acted as feeding stimulants. Damage caused by early-season leaf-chewing guilds in *Quercus emoryi* affected the performance of a late-season, leaf-mining guild via chemical interferences (Faeth, 1986). Furthermore, interspecific competition between spider mites and a vascular wilt fungus in cotton is presumably chemically mediated (Karban et al., 1987). Karban and English-Loeb (1990) also showed that a "vaccination" of Willamette spider mites on grapevines prevented large population densities of Pacific spider mites from occurring. Our data provide further evidence to support the contention that the future emphasis in insect–plant interactions should be on interactive networks of species rather than simply upon species pairs.

Acknowledgments—The authors are grateful to Dr. George G. Kennedy for supplying CPB eggs. The assistance of Mr. C. Summers was especially appreciated. We thank Drs. R. Karban, J. Ruberson, D.T. Johnson, and Mr. M. Stout for their helpful criticism of the manuscript. We acknowledge the USDA for support via grants (89-37250-4639) and (89-34195-4378). This manuscript was approved by the Director of the Arkansas Agricultural Experiment Station.

COMPUTER TRACKING AS A BEHAVIORAL GC DETECTOR: NEMATODE RESPONSES TO VAPOR OF HOST ROOTS

MARK E. McCALLUM and DAVID B. DUSENBERY*

(Received October 25, 1991; accepted December 2, 1991)

Abstract—A computer tracking system previously developed for studying the behavioral responses of nematodes to volatile stimuli was modified so that the effluent of a gas chromatograph passed over the nematodes while their behavior was analyzed. Since the behavior of several hundred nematodes can be analyzed simultaneously, this technique has the potential to provide a sensitive assay for behaviorally active fractions from the GC. This potential was tested with infective juveniles of the root-knot nematode *Meloidogyne incognita* and vapor from the roots of host tomato plants. Direct injection of 1 ml of vapor led to reproducible responses at times corresponding to nitrogen plus oxygen elution and to carbon dioxide elution. Experiments with pure gases demonstrated responses to oxygen and to carbon dioxide. Attempts were made to find less volatile and less active components by pulling large volumes of vapor through a trap of Tenax GC and subsequently eluting them onto the GC. This approach did not lead to the detection of other activities. We conclude that, other than carbon dioxide, there are no volatile stimuli released from host roots in effective quantities.

Key Words—Root-knot nematode, *Meloidogyne incognita*, root vapor, bioassay, gas chromatography, chemotaxis, tomato, carbon dioxide, oxygen.

INTRODUCTION

We have previously developed a technique that permits the rapid acquisition of behavioral information on a group of animals (Dusenbery, 1985a). This technique employs a video camera interfaced to a microcomputer and a program

*To whom correspondence should be addressed.

0098-0331/92/0400-0585$06.50/0 © 1992 Plenum Publishing Corporation

that keeps track of the position of up to several hundred individuals simultaneously. The technique was developed to study the responses of nematodes to volatile stimuli that were carried in a stream of air flowing over them (Dusenbery, 1985b; Pline and Dusenbery, 1987). In this paper, we report on experiments in which this system was connected to a gas chromatograph (GC) so that the effluent of the GC was carried in the airstream over the nematodes. This technique is analogous to the use of insect antennae for monitoring GC effluents (Moorhouse et al., 1969; Arn et al., 1975). The system was used to look for volatile stimuli that plant-parasitic nematodes might employ to locate the roots of host plants.

Nematodes are economically important pests in agriculture, and identification of the stimuli they use to move to the roots of host plants might provide better ways of controlling them (Dusenbery, 1987b). However, relatively little information is available on the mechanisms by which they locate host plants. The common assumption is that chemotaxis to chemicals released by the roots plays an important role (Steiner, 1925; Prot, 1980). One of the most widespread nematode pests is the root-knot nematode *Meloidogyne incognita*. This investigation is part of a series on the sensory behavior of infective juveniles of this species (Diez and Dusenbery, 1989a,b; Dusenbery, 1987a, 1988a–c, 1989; Goode and Dusenbery, 1985; Pline and Dusenbery, 1987; Pline et al., 1988).

METHODS AND MATERIALS

Nematodes and Host Plants. The nematodes were grown on tomato plants (Rutgers cultivar) as previously described (Goode and Dusenbery, 1985; Diez and Dusenbery, 1989b). Plants used for a source of chemical stimuli were similar tomato plants that had grown six to eight weeks.

Computer Tracking System. The computer tracking system was similar to that previously described (Pline and Dusenbery, 1987; Dusenbery, 1992). An IBM XT contained an Imaging Technology video camera interface and to it was added a MetraByte DASCON-1 multifunction board that contains a four-channel, 12-bit analog to digital (A/D) converter that was used to obtain a record of the GC oven temperature and signal from the GC detector.

Gas Chromatograph. The GC was an HP 5890. For some experiments it was fitted with a cryogenic cooler for the oven. The column was 1/8-in. stainless steel, 6 ft long, and packed with Tenax GC. This large-bore column was used to increase the flow rate and amount of material eluted. The response of the nematodes was not sufficiently fast that the brief peaks characteristic of higher-resolution columns were expected to be advantageous. To further broaden the peaks to match the response of the nematodes, the rate of flow was reduced to about 0.1 ml/sec (helium). When natural samples were studied, the oven tem-

perature was increased after injection in order to maintain approximately constant peak width across a broad range of retention times. In order to separate oxygen and nitrogen from carbon dioxide, the temperature program was started at about 3°C.

A thermal conductivity detector (TCD) was used in order not to destroy the chemicals eluting from the column. The effluent of the detector was injected into the center of a parallel flow of hydrated air, which was 10 times larger in volume flow rate than the effluent flow of the column (Figure 1). This combined flow was carried through 157 cm of 0.06-cm internal diameter Teflon tubing to the chamber containing the nematodes. Within this length of tubing lateral diffusion should be sufficient to provide good mixing. In some experiments, a splitter was used to bypass the TCD in case biologically active chemicals were altered in the hot detector, but no evidence of alteration was found.

Traps. Traps for volatile chemicals were made from 5 cm of 1/8-in. stainless steel tubing fitted with a stainless steel frit at each end and filled with 28 mg of Tenax GC. Before use the trap was purged by passing helium at 7 ml/min at a temperature of 290°C overnight. The trap was loaded by pulling air through it at a rate of about 1 ml/min for several hours. The trap was then immediately connected at the head of the GC column (Mieure and Dietrich, 1973) and flow and a temperature program started.

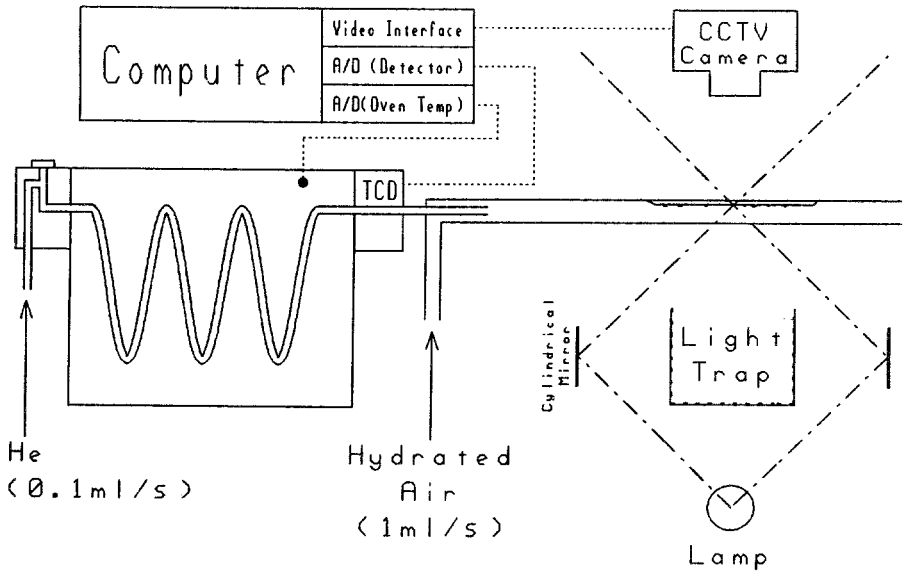

FIG. 1. Schematic diagram of the system. The nematodes are located on the right, under the camera.

RESULTS

The simplest experiments involved the direct injection of a sample of root vapor into the GC. In most experiments, a 1-ml sample was taken with a gas-tight syringe from a plastic bag in which the roots of a tomato plant and 100 ml of water had been sealed for 24 hr (Figure 2). With these samples, three TCD peaks were apparent. The first contained both O_2 and N_2, the second CO_2, and the third H_2O. The average rate of movement of the nematodes usually showed several peaks that appeared to be above background, but not much. Repetition of the experiment revealed that the only reproducible responses were those that lagged slightly behind the first and second TCD peaks. Carbon dioxide is known to be a powerful stimulus under these conditions (Pline and Dusenbery, 1987), and the nematodes respond to it when CO_2 is injected into the GC (data not shown). This accounts for the second response peak.

In order to identify which gases were responsible for the first response peak, samples of the pure gases were injected onto the GC (Figure 3). Nitrogen produced no responses. Oxygen usually produced a clear response peak that lagged slightly the TCD peak. This supports the reasonable hypothesis that oxygen was the stimulus for the first response peak from root vapor samples.

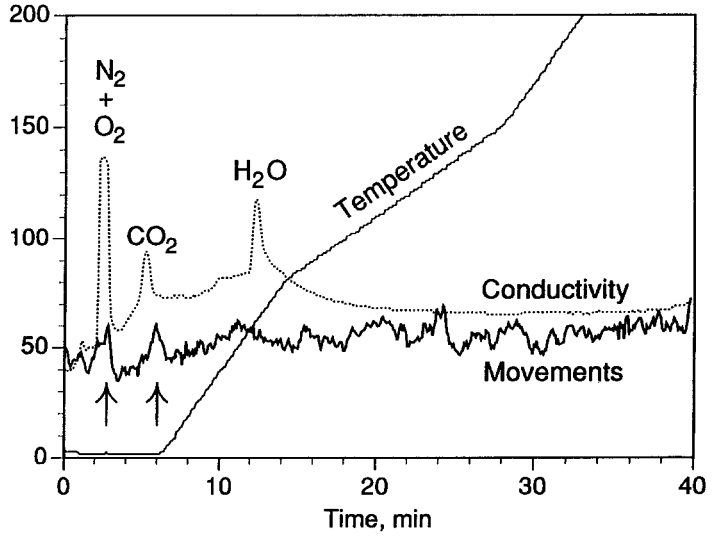

FIG. 2. Direct injection of root vapor into GC. A 1-ml sample was injected at time zero. The plot shows the oven temperature, the relative output of the TCD, and the average rate of movement of the nematodes. The latter has been smoothed with a running average of three samples. The two arrows indicate the response peaks that were found to be reproducible in repeated experiments.

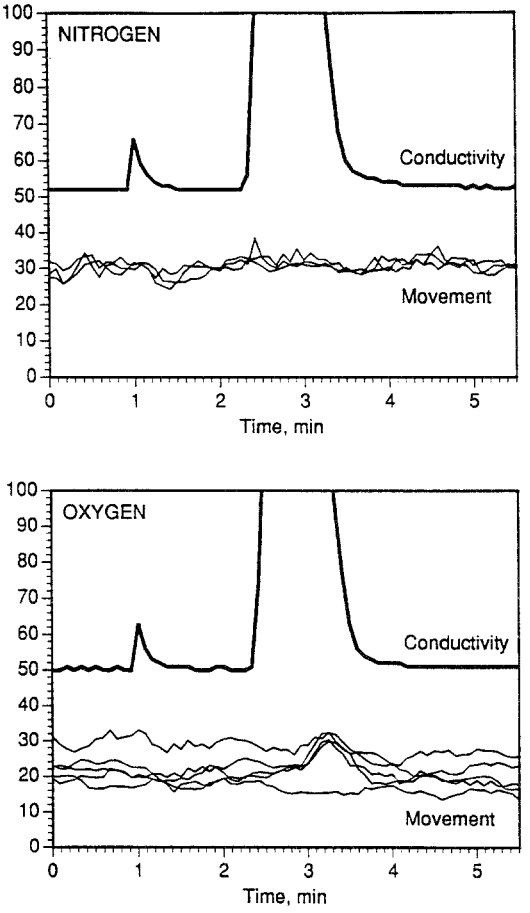

FIG. 3. Responses to pure gases. The upper graph is for the injection of 1 ml of nitrogen; the lower is for oxygen. The column temperature was a constant 0°C. The heavy lines show the output of the TCD. The thin lines show typical responses in repeated experiments. No response is apparent for the three repeats of nitrogen injection. Among the five repeats of oxygen injection, three show very clear responses, one is probable, and one shows no evidence of a response. This variability is typical of what was found in experiments not shown.

Direct injection resulted in a significant dilution ($\approx$50-fold) of the chemicals in the sample. Consequently, there remained a possibility that there were other constituents in the vapor that were diluted to below threshold in the apparatus. In order to search for these, approximately 10 liters of air were pulled through a Tenax GC trap, which can be assumed to trap most chemicals of

interest (e.g., Buttery and Ling, 1984; Sakaki et al., 1984). The trap was then attached at the head of the GC column and trapped chemicals eluted during the programmed temperature increase.

Figure 4 shows typical results for a root vapor sample and a control in which only ambient air was pulled through the trap. For both samples, the thermal conductivity detector shows a large peak of water eluting around 5 min (and atypically broad). The only other peaks detected are several eluting at 30–45 min and present only in the root vapor sample. These peaks occur at a time when 6- to 10-carbon *n*-alkanes would elute. In both samples, the nematode

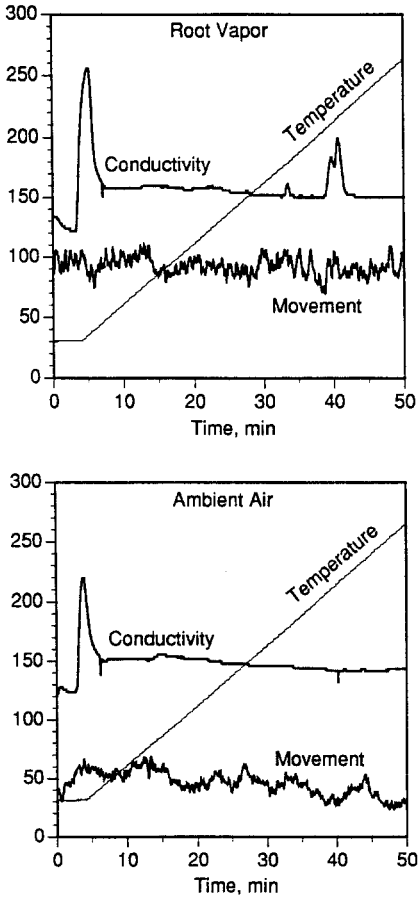

Fig. 4. Eluting Tenax traps on the GC. Typical results for traps that had been charged with root vapor (above) or ambient air (below). The large TCD peak at about 5 min is due to water eluting from the GC.

movements show no clear responses and none of the possible responses were reproduced in repeated experiments.

In other experiments (not shown), samples were obtained by inserting a tube into the center of a 15-cm pot containing a tomato plant and pulling out a sample of the airspace from the undisturbed roots and soil. This type of sampling did not lead to the discovery of any additional stimuli.

DISCUSSION

These results demonstrate that computer tracking has the potential to act as a useful detector of behaviorally active chemicals as they elute from a gas chromatograph. The technique could presumably be adapted to work with a wide range of other kinds of animals.

The results further indicate that there are not any strong volatile stimuli released by the roots of host plants other than carbon dioxide, which was previously shown to be a powerful stimulus to this (Pline and Dusenbery, 1987) and other (Klingler, 1961) nematodes. There is clear evidence from other work (Diez and Dusenbery, 1989b) that there exist nonvolatile repellents released by the roots. It is possible that unstable volatile compounds are released but decompose before detection with our methods. However, it is doubtful that any such chemicals could persist long enough in the soil to act very far from the roots. Roots absorb oxygen and experiments not shown suggest the nematodes are attracted to oxygen. Consequently, the response to oxygen should hinder host finding if it plays any significant role.

(Received August 19, 1991; accepted December 2, 1991)

Abstract—Four limonoids were evaluated by a no-choice bioassay method as termite antifeedants using *Reticulitermes speratus* Kolbe. Obacunone showed the highest degree of antifeeding potency (PC_{95} = 1133 ppm w/w), followed by nomilin (PC_{95} = 4475 ppm), azadirachtin (PC_{95} = 65,293 ppm), and limonin (with PC_{95} estimates beyond the bioassay limits), which was the least potent. None of the four limonoids exhibited any evidence of acute toxicity towards *R. speratus*, although termites fed on obacunone and nomilin at concentrations higher than their PC_{95} estimates tend to die faster than those in the unfed treatment. Obacunone and nomilin also showed a drastic antifeedant consumption (AC) reduction effect at concentrations higher than 510 and 1360 ppm, respectively. With azadirachtin and limonin, such an effect was not observed. The present data suggest that both obacunone and nomilin have an absolute antifeeding activity towards *R. speratus*.

INTRODUCTION

Substances currently used as wood preservatives, such as arsenic oxide–metal salt mixtures, pentachlorophenol, coal tar creosote, and soil-borne termiticides, are broad-spectrum toxicants. Although they have provided effective control against termites, their extensive and sometimes indiscriminate use has led to serious social and environmental repercussions. Tough legal restrictions have been imposed on their sale and use, and some have been removed from the market (Anonymous, 1986). This has prompted researchers to identify alternative antitermite compounds that are selective and more acceptable environmentally.

A number of new synthetic chemicals, particularly those with delayed toxicity, have been evaluated as baited insecticides against termites (Jones, 1984; Su et al., 1985, 1987; Scheffrahn and Su, 1987; Su and Scheffrahn, 1988; Logan and Abood, 1990). However, one of the chemicals, hydramethylnon, could not successfully control *Coptotermes formosanus* Shiraki in a field trial (Su et al., 1982).

Natural products have also been scrutinized for the same purpose. Work is still scarce, but several extracts of hardwoods are already known to be active (Carter and Mauldin, 1981; Carter et al., 1983). Our present interest on natural products is focused on limonoids, a group of bitter tetranortriterpenoids found predominantly in Meliaceae and Rutaceae plants (Klocke and Kubo, 1982), one of the most promising groups of the natural products for insect control (Klocke et al., 1989; Champagne et al., 1989). Recently, Rutaceae limonoids (obacunone, nomilin, and limonin), which are known to be active against several insect pests (Klocke and Kubo, 1982; Randall and Bentley, 1986; Randall et al., 1987; Champagne et al., 1989), were observed to have potential as antifeedants against termites (Kawaguchi et al., 1989; Serit et al., 1991). Although work on the pesticidal properties of Meliaceae limonoids are voluminous, their antitermite activity has remained largely unknown.

Among the Meliaceae limonoids, azadirachtin is the most suitable candidate for this study. Azadirachtin was first identified as a potent feeding deterrent for the desert locust, *Schistocerca gregaria* (Butterworth and Morgan, 1868, 1971), and has subsequently been reported to have antifeeding activity against nearly 200 species of insects (Jacobson, 1986; Saxena, 1989). In fact, Kubo and Klocke (1982) considered azadirachtin to be one of the most potent insect control agents isolated from botanical sources. In view of the potential future role of limonoids in termite control and the present scarcity of biological data related to their antitermite activity, we compared the antifeeding potency of azadirachtin, oba-

cunone, nomilin, and limonin using *Reticulitermes speratus* Kolbe, a termite of economic importance in Japan.

METHODS AND MATERIALS

Termite. The *R. speratus* colony used in this study was collected in Mie Prefecture, Japan, and maintained in well-humidified chambers at 23°C. The termites used were at least at their third instar (pseudergates), based on their relative sizes. Their weights were determined from a random sample of 50 such individuals as 1.85 ± 0.02 mg (mean ± SE).

Limonoids. The four limonoids are shown in Figure 1. Rutaceae limonoids (i.e., obacunone, nomilin, and limonin) were purified from *Citrus natsudaidai* seeds, as previously described (Serit et al., 1991), while the Meliaceae limonoid (azadirachtin A) was obtained from Daicel Chemical Industries Ltd., Himeji City, Japan, as 98% pure.

No-Choice Bioassay Method. The bottom of transparent plastic cups (6 cm rim diam., 4.5 cm bottom diam., and 3.5 cm height) was layered with 6 g of

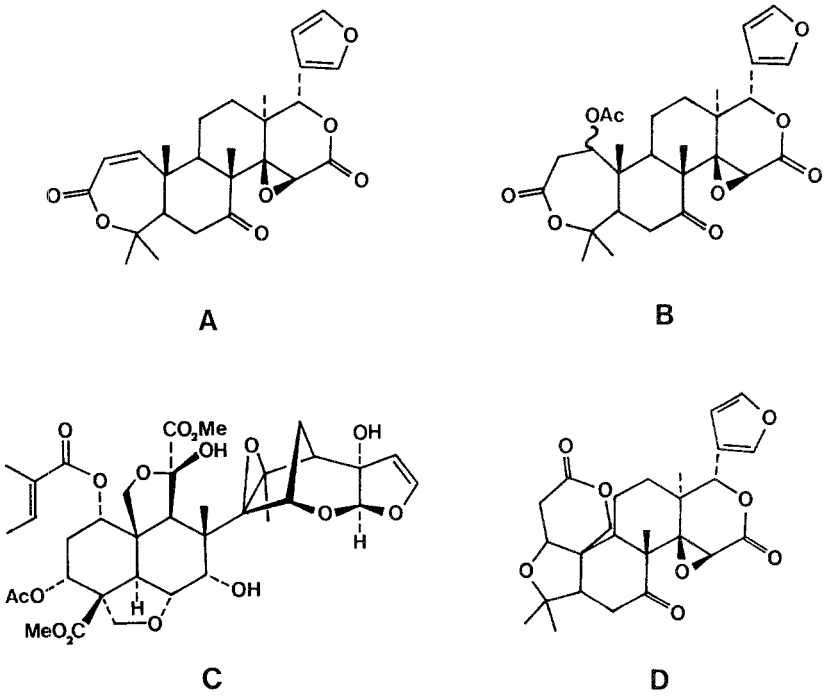

FIG. 1. Structures of obacunone (A), nomilin (B), azadirachtin (C), and limonin (D).

sea sand (Nacalai Tesque Inc., Kyoto, Japan), and moistened with 400 μl of microfiltered water. The sand was subsequently remoistened with 200 μl of water every 10 days during the bioassay.

Paper disks (Toyo Roshi Kaisha Ltd., Tokyo, Japan; 8 mm diam. and 1.5 mm thickness) were oven-dried (40°C, 48 hr). The required amount of each limonoid in 60 μl of an appropriate solvent (i.e., methanol for azadirachtin, and acetone for obacunone, nomilin, and limonin) was applied to the oven-dried paper disks; control and blank disks received only the solvent. Concentration ranges were as follows: azadirachtin, 680–13,600 ppm; obacunone, 340–1700 ppm; nomilin, 680–10,200 ppm; and limonin, 1700–68,000 ppm. The disks were desiccated (room temperature, 48 hr), individually weighed (initial weight, IW), and placed on the sand with 20 termites, except for the control disks (no termites). In order to check *R. speratus* survival under complete starvation, each bioassay was run with an unfed treatment. Survival in each cup was recorded every five days for 25 days. On day 25, disks were collected, oven-dried (40°C, 48 hr), desiccated (room temperature, 48 hr), and individually weighed (final weight, FW). Each bioassay was conducted in three sequential runs of five replicates each.

Calculation and Data Analysis. Despite the drying and desiccation, the control disks were still observed to increase by an average of 1.38% in weight as a result of the water addition during the bioassay. Therefore, a correction procedure was necessary. Disk weight loss, which was the estimate of the amount of food consumed (C), was calculated as $IW_s - [(FW_s \times IW_c)/FW_c]$, where subscript c indicates control disks, and subscript s the treated and blank disks.

Percentage feeding reduction (% FR) was calculated as $(1 - C_t/C_b) \times 100\%$, where subscripts b and t indicate blank and treated disks, respectively. The data were analyzed using probit analysis (Finney, 1971) to estimate the 50% and 90% protection concentrations (or PC_{50} and PC_{95}, respectively) for each limonoid, but comparison of their antifeeding potency was based on their PC_{95} estimates, as suggested by Klocke and Kubo (1982).

Amount of limonoid lost per disk at each concentration was used as the estimate the antifeedant consumption (AC). Assuming an even distribution, AC was calculated as $(C_t/IW_t) \times$ concentration (Lewis and van Emden, 1986). The means were compared using a Student's t test for unpaired data.

RESULTS

Antifeeding Potency. After 25 days, termites consumed a mean ± SE of 19.36 ± 0.82 mg of the blank disks (initial weight = 29.41 ± 0.69 mg). At the highest concentrations tested, azadirachtin (13,600 ppm) and limonin (68,000 ppm, maximum disk capacity for limonin) could only induce an average feeding

reduction of 80.70 and 50.40%, respectively. On the other hand, it required only 850 ppm of obacunone or 3400 ppm of nomilin to reduce feeding by 89.20 and 89.84%, respectively.

The most potent antifeedant against *R. speratus* was obacunone (PC_{95} = 1133 ppm), followed in decreasing order of potency by nomilin (PC_{95} = 4475 ppm), and azadirachtin (PC_{95} = 65,293 ppm); limonin, with PC_{95} estimates beyond the bioassay limits, was the least potent (Table 1). Regression slopes were steep for obacunone (5.33) and nomilin (3.21), but gradual for azadirachtin (1.11) and limonin (0.48).

Effect on Survival. Unfed termites reached an average survival of 0.3% on day 25, compared with 95.0% survival in the blank treatment (Table 2). At their highest concentrations tested, azadirachtin and limonin could only reduce survival on day 25 to 40.3 and 56.7%, respectively. With obacunone and nomilin, it required only 1190 and 4250 ppm, respectively, to cause a survival similar (i.e., 0.5 and 0.7%, respectively) to those of the unfed treatment. The result also shows that none of the four limonoids exhibited any evidence of acute toxicity, although *R. speratus* fed on obacunone or nomilin at concentrations higher than their PC_{95} (or higher than 1190 and 4250 ppm, respectively) had a tendency to die faster than the unfed termites.

Antifeedant Consumption. For potent antifeedants such as obacunone and nomilin, maximum antifeedant consumptions (ACs) were observed at 510 ppm (6.97 $\pm$ 0.69 μg) and 1360 ppm (13.87 $\pm$ 0.70 μg), respectively (Figure 2A and B). At higher concentrations, obacunone (510–850 ppm) and nomilin (1360–3400 ppm) had a drastic reduction effect on ACs. Further increase in obacunone

[a] Only six concentrations are presented in this study.
[b] Averages of 15 replicates in three sequential runs of five each.

and nomilin concentrations caused ACs to fluctuate between 0.30 ± 0.20 and 2.04 ± 0.61 μg (for obacunone) and 4.36 ± 0.70 and 6.86 ± 0.82 μg (for nomilin).

In contrast, for the weak termite antifeedants, azadirachtin and limonin, maximum ACs were not observed at any of the concentrations tested. In fact, their ACs increased steadily from 7.71 ± 0.39 μg at 680 ppm to 56.85 ± 3.01 μg at 13,600 ppm for azadirachtin, and from 27.44 ± 0.75 μg at 1700 ppm to 666.62 ± 11.39 μg at 68,000 ppm for limonin (Figure 2C and D).

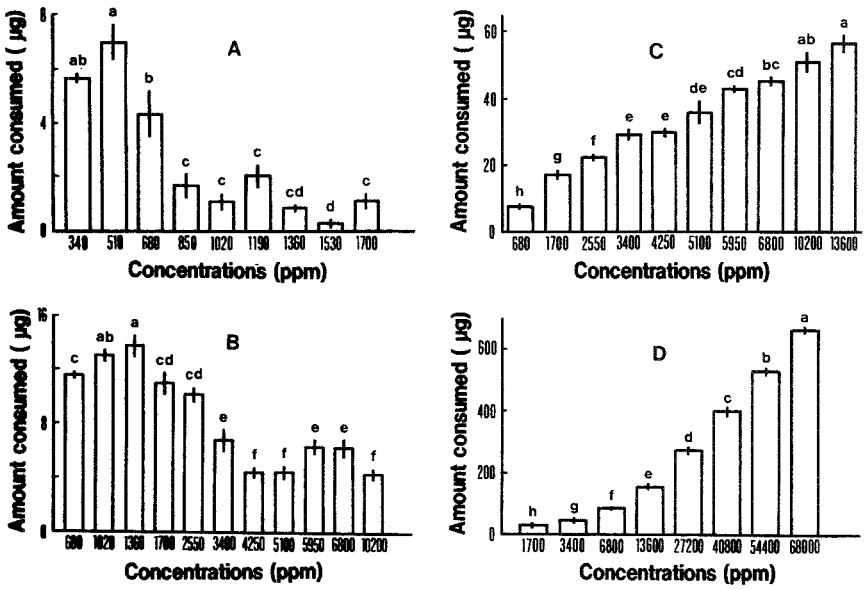

FIG. 2. Antifeedant consumption curves for obacunone (A), nomilin (B), azadirachtin (C), and limonin (D): means ± SE (vertical lines) with at least one similar letter are not significantly different at $P < 0.05$.

DISCUSSION

Unlike the usual pest insect control programs, the main goal of termite control is to protect specific properties (Spear, 1970). This is where antifeedants could effectively be used to provide selective protection.

When dealing with termites infesting building structures and furniture, frequent treatments would not only be expensive but impractical. If antifeedants are to be used, those with absolute activity are preferable as they would ensure a more lasting protection. One efficient way to identify such antifeedants is to expose them to insects until starvation, and the insects should remain deterred if their activity is absolute (Klocke et al., 1989). Based on this criterion, the antifeeding activity of obacunone and nomilin against *R. speratus* seems to be more absolute than relative. This was clearly evident from their effect on *R. speratus* survival (Table 2). Azadirachtin and limonin, at the concentration ranges tested, appeared to act as relative antifeedants, in which starving termites started to feed on the treated disks and survived.

There are at least seven isomeric azadirachtins available from natural sources, of which azadirachtin A is the most common (Rembold, 1989). Although azadirachtin has been reported potent as an antifeedant against nearly

200 insect species (Jacobson, 1986; Saxena, 1989), it was earlier reported to have no effect on feeding and survival of the termite *R. santonensis* and to be only moderately active against *Pieris brassicae* larvae (Butterworth and Morgan, 1971). The present finding also shows that azadirachtin (as represented by azadirachtin A) could only exhibit a weak antifeeding potency against *R. speratus* and apparently no acute toxicity. Based on their PC_{95} ratios, obacunone and nomilin were, respectively, about 58- and 15-fold more potent than azadirachtin. There is still insufficient evidence to infer a structure–activity relationship, but modifications of the A-ring and its side chains from the simple structures in obacunone and nomilin to those in azadirachtin and limonin might have been a cause of the activity loss.

Azadirachtin, obacunone, and nomilin were equally potent as antifeedants against *Heliothis zea* (PC_{95} = 6 μg/disk), but differed against *Spodoptera frugiperda*, with azadirachtin sixfold stronger. However, azadirachtin was toxic to both insects (less than 10 ppm), while obacunone and nomilin were not toxic at concentrations up to 2500 ppm (Klocke and Kubo, 1982). Obacunone and nomilin had been observed to be inactive against *Peridroma saucia* at 0.5 μmol/g diet (Champagne et al., 1989). Limonin, which has only been reported active (96% feeding reduction = 100 μg/disk) against *Leptinotarsa decemlineata* (Randall et al., 1987), is generally considered a weak antifeedant (Klocke and Kubo, 1982; Randall et al., 1986).

It has been emphasized that neem products such as azadirachtin-enriched pesticides (Koul et al., 1990) have a relatively short residual effect of about five to seven days under tropical conditions (Schmutterer, 1988, 1990). This poor stability of azadirachtin and its apparent lack of absolute antifeeding activity against termites are presently thought to be the main factors reducing its antifeeding activity in this long-term bioassay system, and thus limiting its practicality in termite control.

AC curves showed at least two major differences between the potent (Figure 2A and B) and weak antifeedants (Figure 2C and D). First, maximum ACs for obacunone and nomilin were observed at concentrations corresponding to 50% feeding reduction or PC_{50} (Table 1 and Figure 2). PC_{50} for azadirachtin and limonin were, respectively, 2157 and 41,791 ppm, but maximum ACs were not observed at these concentrations. Secondly, ACs for obacunone and nomilin dropped sharply at concentrations higher than 510 and 1360 ppm, respectively, indicating that feeding in this instance was affected by the limonoid concentrations rather than by the total amounts consumed. At concentrations higher than the corresponding 90% feeding reduction (i.e., obacunone > 850 ppm or nomilin > 3400 ppm), ACs fluctuated but at lower levels. In contrast, within the concentration ranges tested, ACs for azadirachtin and limonin increased with concentration, which might be characteristic of weak or relative antifeedants. As feeding was still observed at 300 μg/disk (or approximately 10,200 ppm) of

obacunone (Serit et al., 1991), initial feeding seems necessary for the antifeedants to later affect feeding.

Among the four limonoids tested, only obacunone and nomilin exhibit potential for use as antifeedants against termites. There are at least three advantages of using obacunone and nomilin in termite control. First, Rutaceae limonoids are readily available in large quantity as the unwanted by-products of the citrus processing industry. For instance, a theoretical calculation indicates the potential availability of natural limonoids extracted strictly from grapefruit seeds to be over 300 metric tons per annum (Klocke and Kubo, 1982). Meliaceae limonoids, such as azadirachtin, on the other hand, are both limited in abundance and too complicated for large-scale synthesis. At its effective concentrations, azadirachtin may be impractical for use against termites. Limonin is not at all practical. Second, obacunone and nomilin have yet another desirable effect on termites in that when consumed at high concentrations they could appreciably effect the survival of the termite intestinal microflora, resulting in a faster rate of mortality (Serit et al., 1991). Third, obacunone and nomilin are not toxic, even to termites. They are apparently harmless to humans as they are also present in citrus juices, peels, and seeds (Maier et al., 1977).

We have virtually relied upon toxic chlorinated hydrocarbon for the control of subterranean termites. Antifeedants that could effectively be used to protect selected properties will fit well into any integrated pest management system for termites. More importantly, their use will gradually reduce our dependence on the toxic chemicals, and thus offers a real hope for a new generation of insect control chemicals that will not pollute our environment, poison our food, or harm nonpest species (Ley and Toogood, 1990). The present activity and safety of obacunone and nomilin therefore warrant further investigation of Rutaceae limonoids as antifeedants against termites.

Abstract—Using traps baited with natural and synthetic onion volatiles, we examined the effects of different habitats and mating on the olfactory behavior of laboratory-reared and wild onion flies. Rankings of olfactory treatments as host-finding stimuli for females were dependent on their mating status and the habitat in which they were foraging. In habitats devoid of hosts, traps baited with individual alkyl sulfides were as effective as 4-day-old chopped onions and more effective than 1-day-old onions in eliciting host-finding behavior in laboratory-reared unmated females (LUF) and laboratory-reared mated females (LMF). However, upwind dispersal and percent recapture were always significantly greater in LUF. In one experiment, Pr_2S_2 was 19 times more attractive to LMF in a fallow field, as than it was in an onion field. Reduced effectiveness of alkyl sulfides as host-finding stimuli in onion fields probably results in part because they are less findable, but more importantly because of a change in searching behavior after females have mated. Evidence to support the latter contention is that traps baited with alkyl sulfides and onions were equally findable by unmated females in both habitats. The behavior of LMF was identical to that of wild females, whereas the behavior of LUF was identical to wild males. The hypothesis that olfactory host-finding behavior in onion flies is modified by the resource level was upheld. Alkyl sulfides appear to be the primary, and possibly the only, chemical effectors of host-finding at the patch level of resource distribution, whereas the complex blend emitted by aged, chopped, or damaged onions appears to be acting at the final level of host-finding, while egg-laying females are moving between adjacent hosts in search of an optimal oviposition site.

Key Words—*Delia antiqua*, Diptera, Anthomyiidae, onion fly, onion maggot, host finding, olfactory behavior, resource distribution.

INTRODUCTION

While foraging for oviposition sites, herbivorous insects may encounter host-plant resources in a hierarchical sequence: habitat, patch, and resource item (Hassel and Southwood, 1978). This hierarchy of resource levels probably selects for a hierarchical host-selection response pattern, especially with regard to the sorts of stimuli and sensory systems insects use to recognize resources (Prokopy, 1986; Harris and Miller, 1988).

Insects that use olfaction to locate host plants will likely encounter variations in the quantity and quality of chemical information as a function of resource level. For example, plant odor concentrations may range from minute when the insect is several meters downwind of the source, to high when the insect alights on the plant. Likewise, while plant odors are usually released as complex blends, the number of constituents that an insect might detect simultaneously should decrease as a function of downwind distance from the source (Visser, 1986), especially if the chemical mixture is composed of different classes of compounds with different molecular weights. Thus, perceived plant odor composition might be expected to vary at different levels of resource distribution.

The anthomyiid fly, *Delia antiqua* (Meigen), is an oligophagous herbivore that infests a small number of domesticated *Allium* spp. (Perron et al., 1958, 1960). The olfactory basis for host recognition and oviposition by female onion flies after alighting on or near a plant was shown to depend on the presence of propylthiol chemicals specific to plants in the *Allium* genus (Bernhard, 1970; Vernon et al., 1978). However, whether they were tested at optimal release rates (Dindonis and Miller, 1981a) or as simple mixtures (Vernon et al., 1981), alkyl sulfides such as *n*-dipropyl disulfide (Pr_2S_2) have never proven to be potent baits for onion flies in onion fields (Miller et al., 1984). Consequently, the most effective host-finding stimulus for the female onion fly is thought to be a "complex blend" of volatiles commonly emitted by aged, microbially and/or insect-infested onions (Ikeshoji et al., 1980; Dindonis and Miller, 1981b; Vernon et al., 1981; Hausmann and Miller, 1989). To date, the hypothesis that this complex blend of volatiles is the most effective host-finding stimulus for onion flies at all levels of resource distribution has not been tested experimentally.

Contrary to the above findings, synthetic Pr_2S_2 has proved to be a potent host-finding stimulant for laboratory-reared onion flies foraging in habitats devoid of host plants (Judd and Borden, 1988, 1989). Pr_2S_2 induces significant upwind dispersal in unmated, but not mated female onion flies located at least 100 m downwind, and on average ca. 65% of the released insects were recaptured with

Pr_2S_2 baits. Apparent differences in the response of onion flies to Pr_2S_2 while foraging in and outside onion fields may be evidence that resource level, mating, and/or laboratory rearing influence olfactory behavior of onion flies seeking ovipositional hosts, either individually or collectively.

We tested four hypotheses with regard to olfactory behavior of female onion flies: (1) individual propylthiol compounds are as effective host-finding stimuli as aged, microbially infested onions; (2) olfactory responses are independent of mating status; (3) olfactory responses are independent of habitat; and (4) the olfactory behavior of laboratory-reared onion flies is equivalent to wild onion flies.

METHODS AND MATERIALS

Experimental Insects. Natural populations of onion flies are very low or at least very transient outside commercial onion fields (Martinson et al., 1989), therefore it is very difficult to examine the behavior of wild onion flies in different habitats. For that reason, and in order to control the sex, age, mating status, and hunger of onion flies responding to host-plant volatiles, all studies were conducted with laboratory-reared and released flies. When these studies were conducted, our culture of flies had been reared on onion in the laboratory for three years. However, simultaneous comparisons of the behavior of laboratory-reared and wild onion flies allowed us to test for effects of laboratory culturing on behavior.

Rearing and release of onion flies were as described by Judd and Borden (1988). Larvae were reared on onions and stored as pupae until required for experiments. Emergent adults were maintained at 22°C under a 16:8 hr light–dark photoperiod, in an environmental chamber where they fed ad libitum on Ticheler's (1971) diet. At least 24 hr before being released flies were dusted lightly with one of several colored fluorescent powders (DayGlo Color Corp., Cleveland, Ohio).

Experiment 1: Trap Catches with Different Host-Plant Olfactory Stimuli. Trap catches provide a relative measure of the effectiveness of different olfactory baits as host-finding stimuli (Dindonis and Miller, 1981a). Therefore, five *Allium*-related baits were compared as host-finding stimuli: 1- and 4-day-old, chopped onion tissue and three synthetic, but naturally occurring, alkyl sulfides (Pierce et al., 1978), Pr_2S_2, methyl-propyl-disulfide ($MPrS_2$) and propenyl-propyl-disulfide ($PPrS_2$).

Onions of an unknown cultivar were chopped (mean particle weight ca. 100 mg) and 100 g was placed 2 cm deep into plastic Petri dishes (2 cm high × 9 cm diameter). Lids were placed over the Petri dishes to reduce desiccation, and they were held at 22°C and 65% relative humidity in an environmental

chamber for either one or four days until required for testing. Pr_2S_2 was purchased (Eastman Kodak, Rochester, New York, 98% pure by gas chromatography) and $MPrS_2$ and $PPrS_2$ were synthesized as described by Pierce et al. (1978). Each alkyl sulfide was suspended in paraffin oil (1% by volume) and dispensed individually into plastic Petri dishes (25 mm high × 60 mm diameter) in 5-ml aliquots. Dishes containing sulfides were set inside 9-cm-diameter Petri dishes.

All 9-cm Petri dishes holding baits were placed in the center of 20 × 20-cm white, horizontal, sticky traps to capture alighting flies (Judd and Borden, 1988). In order to allow volatile emission and prevent entry of flies into baits, 9-cm Petri dish lids were supported ca. 5 mm above all baits on three nails, which also held the sticky square in position. An unbaited 9-cm Petri dish and lid on a white, sticky trap served as a control to measure visual responses to traps.

To ensure that released insects were distributed homogeneously, equal numbers of flies were released from 49 equally spaced, intersecting points of a 60 × 60 m grid. Six replicates of the six treatments (unbaited control, Pr_2S_2, $MPrS_2$, $PPrS_2$, and 1- and 4-day-old chopped onion) were arranged within the 60 × 60-m release area using a 6 × 6 Latin-square randomization (Cochran and Cox, 1957), with rows and traps within rows 10 m apart. This experimental design ensured that each trap was surrounded by four groups of released flies, each at a distance of ca. 7 m. Baits were placed in traps ca. 1 hr before release of flies at 2000–2200 hr Pacific daylight time (PDT). This experiment was concluded after 24 hr.

Experiment 2: Upwind Dispersal in Response to Host-Plant Olfactory Stimuli. In the previous experiment, trap catches were employed as a measure of the "effectiveness" of olfactory stimuli in eliciting host-finding behavior. However, trap catches reveal very little about the underlying behavioral mechanisms that the captured insects used to find the volatile source (Kennedy, 1978). For example, trap catches do not reveal whether onion flies are stimulated to fly towards the trap from some distance or are simply arrested after randomly encountering the trap.

A circular trapping design (Judd and Borden, 1988, 1989), in which onion flies are released from the center of a circular array of traps, provides information on the direction of movement before capture. Used in conjunction with continuous wind measurement, this circular design can be used to assess the effectiveness of different olfactory stimuli in eliciting upwind dispersal and long-range host finding in released onion flies.

Two treatments, 4-day-old chopped onion tissue and Pr_2S_2, both as previously described,were compared for their ability to elicit upwind dispersal in female onion flies. A third, unbaited control treatment served to measure dis-

persal in the absence of olfactory stimuli and visual response to traps. Individual treatments were compared in three separate but simultaneous circular releases. Each treatment circle (10 m radius) consisted of eight traps, one in each major and minor cardinal direction. Individual trap circles were set 50–100 m apart. Treatment baits and flies were placed in the field between 2000 and 2200 hr PDT. This experiment was concluded at 1200 hr PDT the following day. Wind direction was measured continuously throughout this experiment with a SIAP mechanical anemometer (Judd and Borden, 1988).

Influence of Resource Level on Olfactory Behavior. Searching for onions in a fallow field is considered equivalent to searching at the habitat level of resource distribution, while searching for individual onions in an onion field is probably equivalent to within-patch search (Judd and Borden, 1988; Harris and Miller, 1988). To test the hypothesis (Judd and Borden, 1988, 1989) that response to host-plant olfactory stimuli is dependent on resource level, we conducted experiments 1 and 2 (as described above) in two sites simultaneously: a 5-ha fallow, bare-soil field and a 0.5-ha field of 10- to 25-cm high onions (var. Autumn Spice). A significant treatment × site interaction would indicate that olfactory behavior is dependent on resource level.

Influence of Mating on Olfactory Behavior. Female onion flies reach reproductive maturity at ca. 8–10 days of age and will not usually oviposit until they have mated (Theunisson, 1976). As a result, mated, gravid females are probably more stimulated to oviposit than similarly aged unmated females. To test the hypothesis (Judd and Borden, 1988) that olfactory behavior of female onion flies is dependent of their mating status, we released both mated and unmated, 10-day-old, gravid females simultaneously in each habitat, in both experiments 1 and 2 described above. In experiment 1 (grid-type release) we released 245 unmated and 343 mated females in the fallow field, and 490 females of each type in the onion field. In experiment 2 (circular release) we released 50 females of each mating status from the center of each treatment circle in each habitat. A significant treatment × fly interaction in these experiments would indicate that mating influences olfactory behavior.

Statistical Analyses. To make valid comparisons between the response of mated and unmated females or laboratory-reared females and wild flies, we had to convert all trap-catch data to percentages (treatment catch/total catch on all treatments), because actual trap catches reflect differences in population size as well as behavior. Transforming catches to percentages serves to rank treatments within a fly class, which allows us to compare across fly classes independent of differences in the population size of each class of flies. Percentages were transformed (arcsine $\sqrt{p}$), and analyzed by an ANOVA appropriate for Latin squares (Cochran and Cox, 1957). Treatment means were compared using the Student-

Newman-Keuls (SNK) multiple-range test (Zar, 1984). Factorial ANOVAs (treatment, habitat, fly class) were used to test for the effects of olfactory stimuli, resource level, mating, and laboratory-rearing on olfactory behavior.

In experiment 2, contingency tables and χ^2 tests were used to test the hypotheses that trap catches with different olfactory treatments were independent of resource level and mating, and to test for differences in the behavior of laboratory-reared and wild onion flies. Directional-flight data from experiment 2 (circular release) were analyzed using a Rayleigh test (Batschelet, 1981; Judd and Borden, 1988).

RESULTS

Trap Catches with Different Host-Plant Olfactory Stimuli. The response of laboratory-reared unmated and mated females to olfactory baits in fallow versus onion fields was analyzed with a three-way factorial ANOVA (treatment, fly class, habitat). This analysis revealed a significant treatment effect ($F_{5,120} = 16.93$, $P < 0.001$). However, treatment rankings are dependent on mating status and habitat, as the treatment × fly class ($F_{5,120} = 3.75$) and treatment × habitat ($F_{5,120} = 5.70$) interactions were both highly significant ($P < 0.005$). Therefore, statements about the effectiveness of various olfactory baits as host-finding stimuli must be restricted to a particular fly class or habitat.

The ranking of olfactory baits as host-finding stimuli for unmated and mated females in the fallow field was very similar. Traps baited with individual sulfides caught as many unmated and mated flies as did 4-day-old onion and more than 1-day-old onion (Table 1). However, there was a marked change in the behavior of mated females across habitats. For example, unmated females were equally responsive to Pr_2S_2, $MPrS_2$, and 4-day-old onion in both habitats, whereas mated females exhibited a significant response to 4-day-old onion over all of the alkyl sulfides tested in the onion field (Table 1). Comparing mean percent catches with Pr_2S_2 and 4-day-old onion baits across rows in Table 1 clearly illustrates how the relative responsiveness of mated females to alkyl sulfides is reduced by about threefold in onion fields, while their responsiveness to 4-day-old onion is increased by about twofold.

The olfactory response of laboratory-reared unmated and mated females (LUF and LMF, respectively) and wild female (WF) and male (WM) onion flies in an onion field (Table 2) was compared using a two-way ANOVA (treatment, fly class). This analysis revealed a significant treatment effect ($F_{5,110} = 21.06$, $P < 0.0001$), but a nonsignificant ($F_{3,110} = 0.001$, $P > 0.05$) fly effect. The fly × treatment interaction was also not significant ($F_{15,110} = 1.62$, $P = 0.079$). However, data in Table 2 indicate some differences and similarities in behavior based on mating status and sex. For example, while LMF and WF

TABLE 1. MEAN PERCENTAGE OF LABORATORY-REARED UNMATED AND MATED FEMALE (LUF, LMF) ONION FLIES RECAPTURED ON TRAPS BAITED WITH INDIVIDUAL, SYNTHETIC DISULFIDES OR AGED CHOPPED ONION IN DIFFERENT HABITATS (SIX REPLICATES/TREATMENT)

Treatments	LUF[a]		LMF[a]

Recaptured (%, n/N)[b]	70_1	53_2	74_1	28_3

[a] Percentages within a column = means of number recaptured per treatment and replicate divided by total number recaptured (n). Column means followed by the same letter or row means subscripted by the same number are not significantly different (SNK test, $\alpha = 0.05$).

[b] Percentages within this row subscripted by the same letter are not significantly different ($\alpha = 0.05$) using a modified SNK test for independent binomial data (Zar, 1984).

TABLE 2. MEAN PERCENTAGE OF LABORATORY-REARED AND WILD ONION FLIES CAPTURED ON TRAPS BAITED WITH INDIVIDUAL, SYNTHETIC DISULFIDES OR AGED CHOPPED ONION IN AN ONION FIELD (SIX REPLICATES/TREATMENT)

Treatment	Mean percentage capture[a]			
	LUF	LMF	WF	WM
Methyl-propyl-disulfide	4.0ab	1.3b	1.6b	2.7ab
Propenyl-propyl-disulfide	2.2bc	2.2b	1.8b	2.4ab
Dipropyl-disulfide	$3.3ab_1$	$0.9b_2$	$1.8b_2$	$2.9ab_1$
4-day-old onion	$5.4a_2$	$8.9a_1$	$7.1a_1$	$5.3a_2$
1-day-old onion	1.6bc	2.8b	3.5b	1.7b
Unbaited control	0.8c	0.5b	0.8b	1.5b
Total catch (n)	258	137	140	118

[a] Laboratory-reared unmated females (LUF), laboratory-reared mated females (LMF), wild females (WF), and wild males (WM). Percentages within a column = means of number caught per treatment and replicate divided by total number caught (n). Column means followed by the same letter or row means subscripted by the same number are not significantly different (SNK test, $\alpha = 0.05$).

rank olfactory stimuli identically, both behave differently than LUF or WM (Table 2). LMF and WF were most responsive to 4-day-old onion, while LUF and WM discriminated very little between 4-day-old onion and alkyl sulfides (Table 2). These differences and similarities are seen most clearly when mean responses to 4-day-old onion and Pr_2S_2 are compared within rows across columns of Table 2.

Trap Catches with Host-Plant Olfactory Stimuli in Circular Arrays. As in the previous experiment (Table 1), the olfactory behavior of LUF and LMF was similar in a fallow field but significantly different in the onion field when the circular trapping array was employed (Table 3). LMF were equally responsive to onion and Pr_2S_2 baits in the fallow field (38 vs 38%), but aged-onion baits were 18-fold more attractive than Pr_2S_2 baits in the onion field (36 vs 2%). Comparing female recapture within a habitat clearly indicates that LUF are more likely to be caught on traps baited with real and artificial host odors than are LMF, especially when a circular trapping arrangement is used, thus corroborating findings of Judd and Borden (1988).

Upwind Dispersal in Response to Host-Plant Olfactory Stimuli. As in all previous experiments of this type (Judd and Borden, 1988, 1989), dispersal of LUF in fallow fields was significantly directional in the presence of host-plant odor and nondirectional in its absence (Table 3). Pr_2S_2 and 4-day-old onion

TABLE 3. COMPARISON OF PERCENT RECAPTURE, MEAN FLIGHT DIRECTION, AND FLIGHT DIRECTEDNESS OF LABORATORY-REARED FEMALE ONION FLIES EXPOSED TO DIFFERENT OLFACTORY STIMULI IN FALLOW FIELD (FF) AND ONION FIELD (OF)

Treatment	Mating status	Percent recapture[a]		Directedness of flight ($\bar{R}$)[b]		Mean flight direction ($\bar{\phi}$)[c]	
		FF	OF	FF	OF	FF	OF
4-day-old onion	unmated	$68a_1$	$64a_1$	0.33*	0.58**	22°	97°
	mated	$38b_1$	$36b_1$	0.29 NS	0.36 NS	38°	167°

	mated	$14a_1$	$2b_1$	0.14 NS	NC	182°	NC

[a] Paired percentages within a column followed by different letters or within a row subscripted by different numbers are significantly different ($P < 0.05$) by a χ^2 test on actual counts.
[b] Statistical significance of $\bar{R}$ (Rayleigh test [Batschelet, 1981]) indicated by: NS = $P > 0.05$; * = $P < 0.05$; ** = $P < 0.005$. NC indicates values not calculated due to small sample size.
[c] Mean wind direction was 37°.

treatments elicited similar mean dispersal directions ($\bar{\phi}$) and directedness ($\bar{R}$), indicating similar effectiveness as host-finding stimuli. Random dispersal of LMF in the presence of Pr_2S_2 (Table 3) is consistent with our previous studies (Judd and Borden, 1988); however, lack of directed dispersal by LMF exposed to 4-day-old onion baits is demonstrated for the first time (Table 3).

Although dispersal of onion flies within onion fields was directional, it appeared to be independent of trap-released volatiles because dispersal by LUF was significantly directional even in the unbaited control treatment (Table 3). The mean dispersal directions for LUF tended to be crosswind to upwind (Table 3). Conversely, dispersal by LMF in the circle of 4-day-old onion baits was not significantly directional and the mean direction of dispersal was slightly downwind (Table 3). Unfortunately, directional statistics could not be calculated for dispersal of LMF in the Pr_2S_2 and unbaited control treatment circles, as recapture rates were too low.

Catches of Laboratory-Reared and Wild Onion Flies in Circular Assays. The total relative catch of LUF, LMF, WF, and WM on 4-day-old onion, Pr_2S_2, and unbaited traps for the circular experiment conducted in the onion field were compared using contingency tables and χ^2 tests. A 3 × 4 contingency table (three treatments, four fly classes) was highly significant ($\chi^2 = 37.79$, $df = 6$, $P < 0.001$), indicating that responses to olfactory treatments were dependent on fly class. Table 4 summarizes the results of all possible pairwise comparisons using 2 × 3 contingency tables. The experimentwise error rate for these com-

TABLE 4. NUMBER AND PERCENTAGE OF LABORATORY-REARED AND WILD ONION FLIES CAUGHT ON TRAPS ARRANGED IN CIRCULAR ARRAYS IN ONION FIELD

Treatment	Number (and percentage) of flies of each type caught/treatment[a]				Contingency tables tested[b]	Statistical significance level[c]
	LUF	LMF	WF	WM		
4-day-old onion	32	18	172	39	LUF vs LMF	0.025
	(54.2)	(90)	(75.1)	(46.9)	LUF vs WF	0.005
Dipropyl-disulfide	16	1	43	23	LUF vs WM	NS
	(27.1)	(5)	(18.8)	(27.7)	LMF vs WF	NS
Unbaited control	11	1	14	21	LMF vs WM	0.005
	(18.7)	(5)	(6.1)	(25.4)	WF vs WM	0.001

[a] Percentages in a column = numbers caught per treatment divided by total number caught on all treatments. LUF = laboratory-reared unmated females; LMF = laboratory-reared mated females; WF = wild females; WM = wild males.

[b] 2 × 3 contingency tables (two fly classes × three treatments) tested the hypothesis that response to treatments was independent of fly classification.

[c] Significance of χ^2 statistic for contingency tables: NS = $P > 0.05$.

parisons was held below 5% by adjusting alpha of individual comparisons. These analyses corroborated previous observations (Table 2) that LMF behave the same as WF, but different from LUF and WM, while LUF behave the same as WM.

DISCUSSION

Despite ample evidence that plant-odor blends mediate host selection, most available data are related to behaviors that occur after an insect has found the resource, e.g., amounts of foliage eaten or numbers of eggs laid. Very little direct evidence bears on the role of odor mixtures in distant host-plant location (May and Ahmad, 1983), and even less about the effects of resource level on insects' response to host-plant olfactory stimuli (Prokopy, 1986; Bell, 1990).

The view that a complex odor blend associated with damaged onions is the most effective olfactory stimulus for onion flies seeking ovipositional hosts has arisen out of research conducted in agricultural crops (Dindonis and Miller, 1980a, 1981b; Ishikawa et al., 1981; Vernon et al., 1981; Miller et al., 1984). To a host-seeking onion fly, onion fields probably represent the patch level of resource distribution (Judd and Borden, 1988; Harris and Miller, 1988). Our results indicate that olfactory behavior of onion flies, like visual behavior (Judd and Borden, 1991), is quite different when they are foraging for patches of onions as opposed to individual host plants in a patch of onions. Thus, discussion of host-finding behavior of onion flies should consider resource levels.

Whether the "effectiveness" of olfactory treatments as host-finding stimuli is based on rates of recapture or stimulation of upwind dispersal, when tested in a fallow field, individual alkyl sulfides were as effective as the complex blend of alkyl sulfides, aldehydes, and alcohols emitted by 4-day-old onion (Ikeshoji et al., 1980; Vernon et al., 1981). In contrast, the complex odor blend from damaged onions was clearly the most effective host-finding stimulus in onion fields, but only for mated, gravid, and presumably ovipositing females.

These results do not necessarily disprove the hypothesis that a complex blend of volatiles is the most effective host-finding stimulus for onion flies foraging outside onion fields, because a valid comparison of various volatiles as host-finding stimuli requires that each be tested at an optimal concentration and release rate. As the concentrations and release rates of volatiles from the 4-day-old onion tissue are unknown and variable, we cannot say categorically that a complex, aged-onion blend would not be a superior host-finding stimulus to Pr_2S_2 if it were released at higher concentrations. In fact, Miller et al. (1984) showed that catches of onion flies increased with increasing amounts of aged onion. However, the latter results should be interpreted with caution as increased catches with larger baits may simply reflect traps that are sampling a larger area

and population. Hence, increased catches with a higher release-rate bait does not identify a bait that is inherently more attractive unless the populations and active spaces are controlled to the extent they were in our experiments. A true test of the complex blend hypothesis (Dindonis and Miller, 1981b) must await identification of the active constituents of the aged-onion odor blend, as previously identified chemicals (Ikeshoji et al., 1980; Ishikawa et al., 1983) have not proven themselves to be as effective as aged onion (Miller et al., 1984; Hausmann and Miller, 1989).

In spite of the caveat above, what remains important from the perspective of this paper is that an amount of aged onion that was more effective than alkyl sulfides in an onion field was not more effective in a fallow field. Our results indicate that a simple, but distinctive chemical signal such as Pr_2S_2, even when released at a relatively low rate (6–9 μg/min) , acted as effectively as a complex odor signal when onion flies were foraging outside an onion patch. Additionally, our finding that each synthetic disulfide bait caught more onion flies than freshly chopped onion outside an onion field, combined with the observation that freshly cut onion emits almost exclusively alkyl disulfides (Vernon et al., 1981), suggests that the release rate of alkyl disulfides may be more important than the complexity of the signal when onion flies are foraging at the habitat level of resource distribution. One might infer from these results that the probability of an onion fly locating a new patch of onions is dependent on patch size or density, rather than the quality of individual host plants within the patch. In contrast, assessment of host-plant quality after finding a patch likely depends on more complex chemical signals, hence, the strong response of ovipositing females to 4-day-old onion in an onion field.

The question of why mated females are more responsive to aged-onion baits than alkyl sulfides at the patch level of foraging has both proximate and ultimate answers. One proximate explanation may be that alkyl sulfide baits are simply less findable in an onion field. Note that the proportion of mated females recaptured with Pr_2S_2 decreased substantially in the onion field. It was this reduction in response to Pr_2S_2 by mated females, more than an increase in response to aged onion that produced the significant treatment differences in nearly all statistical tests performed. The low release rate from sulfide baits, relative to the concentration of natural sulfides surrounding many thousand of plants, may make sulfide baits indiscernible, i.e., their plumes may be masked in the same way insects' pheromones may be masked in a crop permeated with pheromone. Likewise, onion flies somewhat habituated by natural sulfides in an onion field may be less likely to respond to a point source of sulfides. Yet, if these were the only explanations, why did LUF appear capable of finding the alkyl sulfides in both habitats?

An alternative proximate explanation for the different olfactory response pattern in onion fields may be that compounds from aged-onion baits are inter-

acting with volatiles released from onions growing in the field in a way that enhances mated female response. The fact that traps releasing specific host-plant volatiles often capture more insects when placed in a crop of host plants, as opposed to a fallow field, is sometimes cited as evidence that mixtures of volatiles are the most effective host-finding stimuli for phytophagous insects (Geurin et al., 1983). The inference is that volatiles tested in the host crop are synergyzed by crop-released volatiles to provide a superior stimulus (Finch, 1980). If chemical interaction of this type were responsible for enhancing mated female response to aged-onion odor in an onion field, we would expect the ratio of female recaptures with onion-baited traps in the onion field and the fallow field to be greater than 1 : 1. In fact, the ratios for both unmated and mated females' response to aged onion in different habitats were 1 : 1. Therefore, chemical synergysm of this type does not seem adequate to explain our results.

The most probable ultimate cause for the response of mated females to odor from damaged onions in an onion field is that this odor identifies host plants that may maximize a female's reproductive success and decrease developmental time of her offspring (Gorlenko et al., 1956; Zurlini and Robinson, 1978; Schneider et al., 1983). Such behavior would be consistent with predictions from optimal foraging models (Pyke et al., 1977; Jaenike, 1978) that suggest the most suitable resources should always be consumed when encountered and, hence, responded to when detected. Likewise, the fact that unmated females do not oviposit may explain in part why they are less discriminating than ovipositing females. Our results support the hypothesis (Judd and Borden, 1991) that the olfactory behavior of females, in particular their ranking of host stimuli, changes as a function of mating status and resource level.

How ovipositing females might locate these optimal resources while foraging among individual onion plants is not entirely clear from our studies. It has been suggested that onion flies respond anemotactically to damaged onions from several meters downwind (Dindonis and Miller, 1980b), independent of reproductive development (Miller and Strickler, 1984). While unmated females clearly disperse upwind in response to simple synthetic and complex natural host-plant chemical signals, we were unable to find any evidence of anemotactic responses by mated females in fallow areas or onion fields, in this or previous studies (Judd and Borden, 1988). Another interesting observation from these studies was that recapture of mated females was always significantly less than that of unmated females regardless of the type of olfactory stimulus involved. These differences were most apparent in the circular trapping arrays. Perhaps the mode of search used by females changes with mating status. Movement of unmated females may be more free ranging and directional than that of mated females, allowing them to locate upwind baits more easily in the experimental setting we have employed. As movement by mated females appears to be random with respect to the mean wind direction, perhaps odor from decomposing onions

influences behavior at short-range, by arresting movement through increased turning or stimulating landing.

Although complex blends can increase the host-finding responses in several species, including the Colorado potato beetle, *Leptinotarsa decemlineata* L., apple maggot, *Rhagoletis pomonella* (Walsh), and carrot rust fly, *Psila rosae* (F.), to our knowledge the role of, or necessity for, complex blends in distant host-plant patch-finding has not been demonstrated for any oligophagous species (Visser and Avé, 1978; Fein et al., 1982; Geurin et al., 1983). It seems predictable, however, that when olfaction is an important component of distant host-plant recognition, insects will utilize a simple, but distinctive chemical message. In some cases this chemical message may also be the predominant host volatile (Miller and Borden, 1990). This prediction seems likely in light of the fact that the integrity of a complex chemical signal may not be maintained several meters downwind in a mixed plant community (Wilson, 1968; Visser, 1986). Of course the validity of this hypothesis will depend on the chemical class, structure, and molecular weight of those chemicals making up the blend. The more diverse these chemicals are, the more likely this hypothesis will hold true. In the case of onion fly, it remains to be shown exactly what chemicals are responsible for the response to damaged onions.

Our results support the hypothesis that the predominant propylthiol volatiles from onions, such as Pr_2S_2, are probably the primary chemical effectors of long-range host finding at the patch level of resource distribution for onion flies. The complex odor blend associated with damaged onions appears to be acting at the final level of the host-finding sequence, when egg-laying females are moving between adjacent host plants in search of an optimal oviposition site.

Hypothetical Optimal Host-Finding Strategy for Onion Flies. It is now possible to construct a plausible sequence of events for an optimal host-finding strategy in *D. antiqua* (Judd, 1986). For onion flies that do not locate onions by chance during random dispersal after emergence (Martinson et al., 1989), long-range host finding of new patches (fields) of onions probably occurs through the detection and upwind response to volatile host alkyl sulfides (Judd and Borden, 1988, 1989). Visual stimuli come into play at short range and are probably used to delineate patch boundaries when flies approach the source of olfactory stimuli (Judd and Borden, 1991). Once a female onion fly crosses the boundary into a patch of onions, as she would on the border of an onion field, she must locate individual plants on which to lay her eggs. Healthy onions are often the site of oviposition early in the season; however, if some plants are already mechanically damaged, diseased, or infested with insects, location of these plants would be enhanced by the release of metabolites resulting from microbial degradation of onion tissue (Miller et al., 1984). Within a patch, damaged or decomposing onions are probably located through odor-mediated

arrestment or landing responses rather than long-range directed movements. Near this odor source (ca. 1 m), the decision to alight on a potential host will be determined by the size, shape, and spectral reflectance of the stem (Harris and Miller, 1988; Judd and Borden, 1991).

Acknowledgments—We thank the B.C. Ministry of Forestry and G. Sprangers for making field sites available to us, A.D. Wynne for his technical assistance, and H.D. Pierce, Department of Chemistry, Simon Fraser University, for synthesizing the sulfide compounds. This research was completed while the senior author was on educational leave from Agriculture Canada, Harrow, Ontario, and supported in part by Natural Sciences and Engineering Research Council, Canada, Operating Grant A3881, and Undergraduate Scholarship to A.D. Wynne.

(Received November 26, 1990; accepted December 13, 1991)

Abstract—Experiments conducted in the laboratory tested the hypotheses that aggregated oviposition by onion maggot flies, *Delia antiqua* (Meigen), is caused by stimuli associated with ovipositing females, newly laid eggs, or both. Using a paired oviposition station bioassay that eliminated visual stimuli associated with the treatment under study, 67% of the eggs laid by caged females were in response to the odor of females already ovipositing on an onion slice, as opposed to 33% of the eggs laid in response to an onion slice alone. When newly laid eggs were transferred to onion slices and held for either 24 or 48 hr before being bioassayed against similarly aged untreated onions, 74% and 97% of the eggs were laid at the egg-treated onion stations, respectively. Similar results were achieved when an aqueous wash of newly laid eggs was applied to the onion slice. When the egg wash was processed through a bacterial filter or when eggs were present but not in contact with onions, all response was eliminated. These results implicate microorganisms transmitted on the egg surface in creating an attraction for ovipositing females. Heptane extracts of ovipositor tips from mated, ovipositing females induced 72% of the test females to oviposit near points at which extracts were applied to the oviposition station floor. A behavioral sequence for an optimal host-selection strategy is hypothesized, whereby host-seeking female onion flies respond to host-derived alkyl sulfides at long range and metabolic by-products of microbially infested hosts and visual cues at short range (ca. 1 m), with final selection of oviposition sites potentially reinforced by contact with an aggregation pheromone released or left on the substrate by ovipositing females.

INTRODUCTION

Insects may lay eggs in different patterns, from highly dispersed to highly aggregated. Presumably, the distribution pattern of the eggs imparts some selective advantage to the individuals that use it (Stamp, 1980). For example, solitary eggs may escape predation or parasitism or may afford the resultant larvae exclusive access to a limited resource. Conversely, laying eggs in groups or masses may reduce desiccation, facilitate parental care, help overcome resistant hosts, or allow optimal use of a host with a patchy distribution. Thus, there is apparently some optimal density of eggs per unit of resource that insects can actively regulate by altering oviposition behavior (Peters and Barbosa, 1977; Prokopy, 1981).

Variable oviposition patterns occur in the dipteran family Anthomyiidae. For example, a montane *Delia* sp. lays solitary eggs, or at the most, two eggs, in the ovaries of *Polymonium foliosissimum* Gray, and employs an epideictic (marking) pheromone (Prokopy, 1981) to deter further oviposition at the original oviposition site (Zimmerman, 1979, 1980, 1982). Similarly, the sorghum shootfly, *Atherigona soccata* Rondani, usually lays one egg per sorghum plant (Ogwaro, 1978) and deposits a water-soluble marking pheromone with the glue used to cement eggs to leaves (Raina, 1981). A forest nursery pest, *Delia anthracina* (Czerny), lays from one to three eggs on cones of spruces, a behavior consistent with the limited carrying capacity of the cones and the ability of a single larva to consume about 55% of the potential seeds in a cone (Hedlin, 1973).

In contrast to these cases of solitary oviposition, there is growing evidence that the onion maggot, *Delia antiqua* (Meigen), lays its eggs in a highly aggregated manner. Using egg traps to monitor oviposition patterns in the field, Loosjes (1976) harvested hundreds of eggs, representing the oviposition of several females in individual traps. Robinson and Zurlini (1979) observed "social facilitation" of oviposition in mass-rearing cages, and Harris and Miller (1983) found that female *D. antiqua* tended to oviposit on treatments where other females were already ovipositing. Likewise, in a two-choice bioassay, with identical olfactory stimuli, Vernon (1979) found oviposition to be characteristically aggregated at one stimulus or the other. We have often observed female *D. antiqua* ovipositing in groups around a single oviposition station, while equivalent stations remain unoccupied. As they probe the substrate, many females in these groups are observed dragging their extended ovipositors, in a behavior

consistent with the deposition of a pheromone (Figure 1). Pheromone-mediated group oviposition has been demonstrated in several insect genera, including *Andrena* and *Trogoderma* (Brossut, 1975), *Schistocerca* (Norris, 1963), *Musca* (Bay and Pitts, 1977), and *Lucilia* (Barton Browne, 1958; Barton Browne et al., 1969).

Our objectives were to investigate three hypotheses that could explain the group oviposition behavior of *D. antiqua* and consequent aggregation of newly laid eggs, as seen in the laboratory: (1) there is a "female factor," e.g., a pheromone released by ovipositing females, that causes other gravid females to aggregate in the same location; (2) there is an "egg factor," e.g., a volatile semiochemical associated with newly laid eggs, either produced by the eggs themselves or by associated microorganisms that promotes aggregation; or (3) aggregation is induced by a combination of female and egg factors.

METHODS AND MATERIALS

Design and Experimental Use of Oviposition Station Bioassay. Experiments were conducted with an oviposition station bioassay (Vernon et al., 1977), modified so that all possible contact with a host- or insect-associated stimulus

FIG. 1. Female *D. antiqua* in typical ovipositor-dragging posture, suggesting potential for deposition of a pheromone.

was eliminated. This was done by locating such stimuli above a wire-mesh screen barrier, set 5 cm above the floor of the station arena inside an inverted cup (Figure 2). Although potential auditory stimuli were not altogether eliminated if live insects were enclosed in the upper half of this apparatus, it was designed to eliminate visual and tactile cues associated with the treatment flies while focusing primarily on olfactory stimuli.

All experiments were conducted with a laboratory colony of onion flies that was started in 1978 and infused in 1982 with several thousand flies obtained from Agriculture Canada laboratory in London, Ontario (Harris et al., 1984). As assays were conducted over several years, these studies were conducted with flies that had been reared on onion for one to four years in our laboratory (Judd and Borden, 1988). In each experiment, a replicate consisted of 15 females and five males allowed to move freely, ingest food and water, mate, and oviposit within a 25 × 25 × 45-cm, wooden-frame cage with screened walls and top, and Plexiglas front. Water and food (Ticheler, 1971) were available ad libitum throughout each experiment. Two paired oviposition stations were randomly assigned to positions diagonally separated by 10 cm on the floor of each cage. All test flies were between 14 and 28 days old and had previously oviposited on a sliced onion. In each replicate, females were given 24 hr at 22°C and 60% relative humidity under a 16:8 hr light–dark photoregime to oviposit at the station of choice except where noted below. Stations were then removed and the eggs counted.

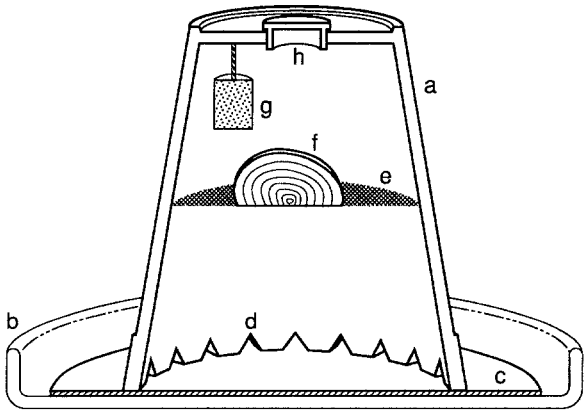

FIG. 2. Cut-away diagram of oviposition station (Vernon et al., 1977) modified to enclose hidden stimuli above screen within inverted 250 ml styrofoam cup, while permitting odors to be released through oviposition grooves around rim of cup. (a) inverted cup, (b) Petri dish, (c) filter paper, (d) oviposition apertures, (e) wire screen, (f) onion slice, (g) moist cotton wick, and (h) removable snap cap.

In all experiments, an onion slice was a common stimulus in both the treatment and control stations. The stimulus or treatment of main interest was then superimposed on the background onion stimulus in one of the stations.

Experiments with Adult Flies as Stimuli. Three preliminary experiments were conducted to test conclusively whether aggregated oviposition by *D. antiqua* occurs and to implicate whether or not it is mediated by semiochemicals.

The treatment stimuli, consisting of 10 mated, ovipositing females (experiment 1), 10 virgin females (experiment 2), and 10 virgin males (experiment 3) were placed above the screen in the upper half of one of the oviposition stations. Mated females had been exposed to males for seven days and were confirmed to have mated by dissection of spermathecae from a subsample of females. There were 20 replicates in experiment 1, and 10 in experiments 2 and 3. Mated females confined within the oviposition station (experiment 1) were free to oviposit above the screen and usually did so on the onion. Occasionally a few eggs would fall through the screen, but these could be identified because they were near the center of the filter paper where responding flies outside the inverted cup could not have reached.

Experiments with Eggs as Stimuli. The previous experiments did not separate stimuli associated with either the flies or their eggs. Therefore, three experiments (experiments 4–6) tested the hypothesis that there is an egg-associated stimulus that promotes aggregated oviposition by *D. antiqua*. Three hundred newly laid *D. antiqua* eggs collected within 24 hr of oviposition were the experimental stimulus in all three experiments. In experiment 4, eggs were placed on the center of the filter paper floor under the inverted cup (Figure 2). Thus, eggs were separated from both the onion slice and the ovipositing females outside the station. In experiments 5 and 6 eggs were placed directly on the onion slice for periods of 24 and 48 hr, respectively, before being tested. There were six replicates in experiment 4, and 10 in experiments 5 and 6.

Experiments with Egg Wash Water as Stimulus. If aggregated oviposition is induced by factors associated with *D. antiqua* eggs, these factors may be biotic (e.g., microbes on the egg surface) or abiotic (e.g., chemicals on the egg surface). Two experiments were designed to discriminate between these two hypotheses.

To collect eggs for this experiment, a special oviposition station was constructed out of glass, which in turn was wrapped in aluminum foil and autoclaved. A sterile wax wick loaded with 1 μl of dipropyl disulfide (Vernon et al., 1977) was placed inside the sterilized glass oviposition station, and the entire apparatus was placed in a rearing cage with several hundred gravid females. Several hundred 1-day-old eggs were harvested from beneath this glass oviposition station by gently washing eggs attached to the inside lip of the inverted cup with 50 ml of autoclaved, distilled water. Eggs adhering to the filter paper under the glass cup were removed with a sterile brush. The eggs and wash water

were agitated gently for ca. 5 min. Half of the resulting egg wash water was passed through a 20-μm Millipore filter (Millipore Corp., Bedford, Massachusetts) to remove all free-living microorganisms. This entire egg collection procedure was performed in a laminar airflow hood to minimize external contamination.

In experiment 7, ovipositing females were given a paired choice between oviposition stations baited with an onion slice over which 10 μl of unfiltered egg wash water was pipetted and a similar onion slice treated with 10 μl of autoclaved, distilled water. In experiment 8, paired onion slices were treated with either 10 μl of filtered egg wash water or 10 μl of autoclaved, distilled water. Experiments 7 and 8 were replicated 10 times.

Experiment with Ovipositor Extract. A final experiment tested the hypothesis that aggregated oviposition was stimulated by a pheromone produced in the ovipositor and released during oviposition. Extruded ovipositor tips, comprising three to four distal segments, were excised from mated, gravid females that had begun to oviposit. Ten ovipositors were immediately immersed in 25 μl of heptane held on ice. Four sites on the filter paper ca. 5 mm outside the apertures in the rim of the inverted oviposition cup (Figure 2), were spotted with 2.5-μl aliquots of extract, each containing one female ovipositor tip equivalent. In this way ovipositing females could contact the extract, just as they would contact a pheromone deposited onto a substrate during or after oviposition (Figure 1). Each control station received an equivalent amount of solvent. After 1 hr, the number of females ovipositing on each treatment was recorded and the eggs counted. This experiment was replicated 12 times.

We limited this assay to 1 hr because we had observed that when an oviposition station became crowded as female aggregations formed, an occasional female would wander to the adjacent station and the presence of the onion stimulus would often cause them to oviposit. This secondary oviposition often caused another aggregation to form, which, if left to run several hours, might obscure initial treatment differences.

Statistical Analyses. In all experiments, the numbers of eggs laid or females ovipositing per treatment were converted to percentages of the total number of eggs laid or females ovipositing on both treatments. Percentages were transformed (arcsine $\sqrt{p}$) and compared using paired t tests (Zar, 1984).

RESULTS AND DISCUSSION

Experiments with Adult Flies as Stimuli. The first three experiments demonstrated conclusively that only odors associated with mated, ovipositing females induced aggregated oviposition by *D. antiqua* (Table 1). Sixty-seven percent of the eggs laid in experiment 1 were at oviposition stations containing mated

TABLE 1. OVIPOSITION RESPONSE BY *D. antiqua* FEMALES IN 8 EXPERIMENTS WHEN EXPOSED TO CHOICE OF OVIPOSITION STATIONS WITH HIDDEN STIMULI OFFERING ODOR OF ONION ALONE (CONTROL IN ALL 8 EXPERIMENTS), OR ONION TREATED IN VARIOUS WAYS

Type of stimuli and exp. no.	No. of replicates	Treatment superimposed on onion odor[a]	Mean (± SE) percentage of eggs laid per stimulus[b]	
			Treatment plus onion	Onion alone
Flies				
1	20	10 mated females	66.8 ± 4.3a	33.2 ± 4.3b
2	10	10 virgin females	49.6 ± 11.2a	50.4 ± 11.2a
3	10	10 males	35.1 ± 9.3a	64.9 ± 9.3a
Eggs				
4	6	300 eggs on paper	40.1 ± 11.4a	59.1 ± 11.4a
5	10	300 eggs on onion 24 hr	73.6 ± 13.9a	26.4 ± 13.4b
6	10	300 eggs on onion 48 hr	96.6 ± 2.3a	3.4 ± 2.3b
Egg wash water				
7	10	10 μl unfiltered	77.7 ± 7.6a	22.3 ± 7.6b
8	10	10 μl filtered	41.9 ± 5.8a	58.1 ± 5.8a

[a] Times for eggs on onions refer to time when the bioassay began.
[b] Means within a row followed by different letters are significantly different ($P < 0.05$), paired t test.

females ovipositing on onion. Neither nonovipositing, virgin females (experiment 2) nor males (experiment 3) induced aggregations (Table 1). These results uphold the hypothesis that aggregated oviposition is induced by an olfactory stimulus associated with egg-laying females. However, they do not discriminate between possible egg or fly factors.

Experiments with Eggs as Stimuli. When eggs were present but not in contact with the onion slice (experiment 4), there was no induced aggregation (Table 1). However, when eggs were in contact with onion slices for 24 hr before being assayed (experiment 5), oviposition became markedly aggregated at stations containing this stimulus (Table 1). Aggregation was even more intense when eggs had been in contact with onions for 48 hr (experiment 6, Table 1). Because none of the eggs placed on the onion slices had hatched, even after 48 hr, the induced aggregation could not have been caused by larval activity. Similarly, because eggs kept separated from onion were unable to induce aggregation, any stimulus directly associated with the odor of eggs or an accessory product coating their surface can be ruled out.

However, if some factor on the eggs, either biotic or abiotic, were able to break down the onion tissue when eggs were in direct contact with it, the induced

aggregation might then have been caused by an odor released by contaminated onion tissue, or by active biotic factors on that tissue, or both. The activity of microorganisms would be consistent with numerous reports of microbially induced attraction and oviposition of *D. antiqua* (Ikeshoji et al., 1980; Hough et al., 1981; Miller et al., 1984; Hausmann and Miller, 1989a,b). The next series of experiments was designed to discriminate between possible biotic and abiotic factors on the eggs by separating from the eggs any microorganisms that were resident on their surface.

Experiments with Egg Wash Water as Stimulus. Filtering an aqueous egg wash through a bacterial filter (experiment 8) completely eliminated the aggregated oviposition induced by onion slices treated with unfiltered egg wash (experiment 7, Table 1). As the filtered egg wash water would contain no microorganisms, but would contain any water-soluble chemicals associated with the eggs, biotic, not abiotic, factors are implicated as the agents of increased oviposition when eggs contact onions.

Microorganisms have been implicated several times in enhancing attraction of *D. antiqua* to onions, and several species of bacteria have been isolated from either *D. antiqua* adults or infested onions (Gorlenko et al., 1956; Ikeshoji et al., 1980; Hough et al., 1982; Miller et al., 1984; Hausmann and Miller, 1989a). Microbe-infected nonhosts (e.g., potato) are only marginally more attractive than uninfected nonhosts to *D. antiqua* (Hausmann and Miller, 1989a). Thus, an interaction between bacteria and onions enhances attraction. The likely basis for this interaction is the release of a metabolite not found or present in very small amounts in noninfected onions. Several compounds, including ethyl acetate, tetramethylpyrazine and *n*-heptanal (Ikeshoji et al., 1980); 2-phenylethanol (Ishikawa et al., 1983); and *n*-valeric acid (Ishikawa et al., 1984), have been implicated in this enhanced attraction. However, none appears to account for the greatly increased activity associated with microbial infection. While a mixture of 2-phenylethanol and *n*-valeric acid was up to five times more attractive than decomposing onion pulp (Ishikawa et al., 1984), the onion pulp was preincubated at 25°C for eight days, and Miller et al. (1984) found a sharp decline in the attractiveness of chopped onion after four days. Therefore, a classical isolation and identification procedure (Silverstein, 1970) will probably be required to yield the most active constituents.

Merez (1984) concluded that *D. antiqua* deposits eggs lacking bacteria, whereas Gorlenko et al. (1956) reported isolating *Erwinia carotovora* from all lifestages of *D. antiqua*, including eggs. It is interesting that Hausmann and Miller (1989a) reported that onion tissue inoculated with *E. carotovora* var. *carotovora* was more attractive and stimulated more oviposition than axenic onion tissue or onion tissue inoculated with other bacteria. However, the work of Schneider et al. (1983) has clearly established that onion maggots are capable of developing on onion tissue in the absence of microbes and, thus, onion

maggot larvae can function as true herbivores. Therefore, the important questions with regard to the role of microbes in onion fly biology are: do onion maggots ever feed on onion in the absence of bacteria under natural conditions, and if they do not, then what benefit do the bacteria provide?

The answer to the first question is probably that most larvae feed in the presence of bacteria because larvae will inoculate the onion as they begin to feed or bacteria in the soil will inadvertently enter through feeding sites, but certainly some may not be exposed to bacteria. The answer to the second question is that bacterial contaminants of onion may predispose healthy onions to more successful attack by *D. antiqua* (Hausmann and Miller, 1989b), provide or make available certain nutrients that enhance larval survival (Eymann and Friend, 1985), and they may be responsible for the decrease in development time when *D. antiqua* feeds on decomposing onion (Gorlenko et al., 1956; Schneider et al., 1983; Zurlini and Robinson, 1978).

Although an association between onion flies and bacteria is not necessarily requisite (sensu Schneider et al., 1983) and association between *E. carotovora*, onion maggot eggs, and onions infested with onion maggot larvae may be coincidental, it seems plausible that microbes transmitted from female *D. antiqua* to eggs and larvae might have a greater probability of finding their way into damaged onion tissue at the exclusion of other bacteria. Such an association would be similar to the relationship between scolytid beetles and microorganisms that subdue resistant hosts and/or provide nutrients for invading beetles (Whitney, 1982).

We do not know how newly hatched *D. antiqua* larvae might acquire microorganisms from the egg surface, but it is possible that they either ingest the spent chorion after hatching or acquire microorganisms through mechanical contact. In either case, it may not be necessary that eggs come directly in contact with onions in nature. Positive proof of trans-ovum transmission and induced attraction mechanisms would demand isolation and identification of microorganisms, not from infected host plants, but from gravid females and newly laid eggs, and inoculation of uninfected onion tissue with pure microbial cultures. Hough et al. (1982) have shown that a mixture of several microbial species from male and female onion flies is capable of enhancing oviposition when it is placed on onion tissue. Possibly, many species of microbes can fulfill this role, and it will be of interest to establish the range of species isolated from different onion maggot populations.

Experiment with Ovipositor Extract. When females seeking an oviposition site were given a choice of substrates treated with either a heptane extract of ovipositors or a control substrate treated with heptane only, 72% chose the extract-treated substrate (Figure 3). This choice was reflected almost identically in the percentages of eggs laid at the two stations. This induced aggregation (Figure 3) could not have been due to microbial activity, because any microbes

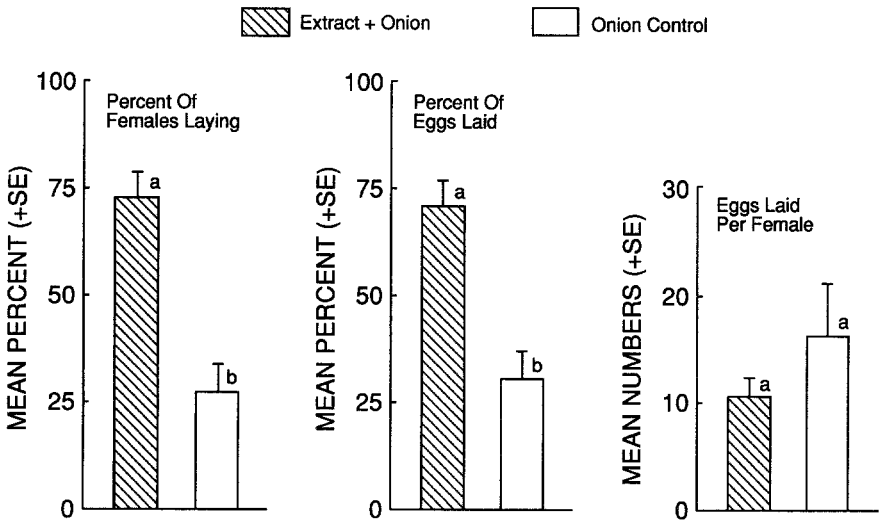

FIG. 3. Oviposition responses in 1 hr by *D. antiqua* females offered a choice of an experimental oviposition station in which the substrate at the sites of oviposition was treated with a heptane extract of ovipositors from egg-laying females, or a control station in which the substrate was treated with heptane only ($N = 12$). Paired bars superscripted by different letters are significantly different, paired t test, $P < 0.05$.

would have been killed in the heptane solvent, and contact of microbes with onion was precluded (Table 1). In a further experiment (data not shown), extracts of virgin females did not stimulate aggregated oviposition.

Oviposition, Marking, or Aggregation Pheromone? Our data uphold the hypothesis that a female factor, a pheromone, is in part responsible for the group oviposition observed in *D. antiqua* under laboratory conditions. The ovipositor extract is probably not an oviposition stimulant in the strictest definition (although more oviposition bouts could be generated), because once females made a choice, they each apparently laid the same number of eggs, regardless of the station they chose (Figure 3).

It is possible that the female-produced pheromone extracted from *D. antiqua* is similar to the marking pheromones found in other anthomyiids (Zimmerman, 1979, 1980, 1982; Raina, 1981). In each of these species, females deposit a pheromone on the host during oviposition, and they search each new host, presumably for the presence of pheromone, before making a decision not to oviposit on already infested hosts. Similar searching behavior could readily precede a positive decision by *D. antiqua* to oviposit if a pheromone were being deposited on onion stems during or after oviposition. While we have extracted a pheromone from egg-laying females, attempts to isolate the same pheromone

from substrates onto which *D. antiqua* had oviposited were unsuccessful (G.J.R. Judd, unpublished data). Therefore, we have no evidence that the chemical we have extracted is actually being deposited on the substrate during oviposition.

When the ovipositor extract was superimposed upon an oviposition stimulant, it induced females to form groups while laying eggs. However, these results do not necessarily prove that such a pheromone evolved as an oviposition aggregation pheromone. Aggregations of both males and virgin females might also have been induced had we tested them. A pheromone that induces aggregations of both sexes has been extracted from the cuticular lipids of female *L. cuprina* (Emmens, 1981).

Group Oviposition and Implications for Ovipositional Bioassays. Laboratory studies examining oviposition in the onion fly often report (Harris and Miller, 1983, 1984) that treatment variances are heterogenous. This heterogeneity is undoubtedly due in large part to group oviposition (Harris and Miller, 1983). While our results provide ample explanation for this variance, and heteroscedastic variance presents problems for statistical analysis (Zar, 1984), group oviposition and the mechanisms causing it have more important implications for the interpretation of group ovipositional bioassays, including our own.

While eggs laid on a treatment by the first female are the result of that treatment's stimulatory capacity, subsequent eggs are possibly laid in response to deposition of microbes and pheromone by "pioneer" females. Because the effects of bacterial contaminants are stronger than the effects of the "aggregation pheromone," assays running 24 hr or longer, in which females or bacteria carried by females can potentially contact onion tissue, will be particularly sensitive to a grouping effect. However, deposition of a pheromone, even an ephemeral one having perhaps 30–60 min activity, would be expected to influence subsequent oviposition to some extent. As each ovipositing female deposits more pheromone, the running time for activity of the pheromone would be reset to zero and oviposition of each subsequent female might be affected for at least an additional 30–60 min period. In this way the influence of the pheromone could be extended throughout an assay running several hours. Therefore, the egg-laying behaviors of all females, except the very first one, may not be independent of one another. A lack of independence would invalidate many statistical tests (Zar, 1984). At the very least, differences between treatments may be magnified by grouping, making certain treatments appear more stimulatory than they might otherwise. We acknowledge that our own experiments are subject to these same grouping effects. For example, the activity of the "pheromone extract" we applied to an oviposition station is probably magnified by the deposition of pheromone from the responding females, and deposition of a pheromone might have increased oviposition at stations baited with microbially infested onion tissue.

Based on our findings, we recommend caution in evaluating group ovipo-

sition assays and suggest that at the very least a comparison should be made between the results from group and single female assays. While certainly not the only solution, ovipositional bioassays with individual flies and replacement of treatments after each oviposition bout would eliminate the problems we have highlighted. Replacement of the treatment between oviposition bouts is recommended to reduce the effect a female might have on her own subsequent behavior.

Natural Implications of Aggregated Oviposition. Extrapolating field behavior of animals from laboratory observations is always difficult. Undoubtedly our two-choice bioassay procedure with stimuli in close proximity provides an experimental setting that maximizes detection of differences between treatments. The obvious shortcoming of this approach is that the importance of a stimulus could be overestimated because the magnitude of the difference is often equated with biological significance. By the same token, the biological significance of an insect's behavior or an observed phenomenon, particularly among agricultural pests, may not always appear relevant if we mistakenly believe that the behavior necessarily evolved in the current agricultural context. These considerations should be kept in mind when evaluating the importance of onion flies as a source of microbes in decomposing onion or an aggregation pheromone as it relates to field situations.

Insects may achieve a selective advantage by aggregating in areas that, among other things, provide food, shelter, or the opportunity to mate and reproduce (Borden, 1985). Egg clustering may also increase the survival of eggs and reduce desiccation in dry environments by decreasing the amount of egg surface exposed to ambient conditions (Stamp, 1980). In their natural habitats, many *Allium* species grow in dry conditions and have very patchy distributions (Stearn, 1944a,b); any onion fly able to find this unevenly distributed resource efficiently would gain a considerable selective advantage. Moreover, if the potential resource were resistant to infestation, as are healthy, mature, wild or cultivated *Allium* spp. (Loosjes, 1976; Zurlini and Robinson, 1978; Finch and Eckenrode, 1985; Hausmann and Miller, 1989b), an advantage would be imparted by exploiting the activity of conspecifics to increase resource suitability, e.g., through preconditioning by previous maggot feeding and the activity of associated microorganisms (Hausmann and Miller, 1989b). Response to microbially infested onions might in itself produce aggregations of egg-laying females (Judd and Borden, 1992) or at very least increase chance encounters under low population densities, as these hosts represent optimal oviposition sites (Zurlini and Robinson, 1978).

A behavioral sequence for an optimal host-selection strategy is hypothesized (Judd, 1986), whereby host-seeking female onion flies respond to host-derived alkyl sulfides at long range (Judd and Borden, 1989) and metabolic by-products of microbially infested hosts and visual cues at short range (ca. 1 m)

(Judd and Borden, 1991). Once located, oviposition at these optimal sites is induced by alkyl disulfides (Vernon et al., 1977), synergized by visual stimuli (Harris and Miller, 1983, 1984) and microbially produced metabolites (Hausmann and Miller, 1989a,b), and perhaps reinforced, if only ephemerally, by the detection of and response to an aggregation pheromone.

(Received August 22, 1991; accepted December 11, 1991)

Abstract—Methyl-substituted analogs of (*Z*)-5-decenyl acetate, a pheromone component of the turnip moth, *Agrotis segetum*, have been synthesized and studied by electrophysiological single-sensillum recordings and molecular mechanics calculations [MM2(85)]. The analogs are monomethyl substituted in the 2, 3, 4, and 5 positions and geminally dimethyl substituted in the 2, 3, and 4 positions. The methyl groups have been employed as space probes to study the degree of steric complementarity between the acetate-substituted alkyl chain of the pheromone component and its receptor. The electrophysiological activities, interpreted in terms of a receptor interaction model, indicate significant steric repulsive interactions between the introduced methyl groups and the receptor. This implies a high degree of complementarity between the acetate-substituted alkyl chain of the natural pheromone component and its receptor.

Key Words—Lepidoptera, Noctuidae, *Agrotis segetum*, (*Z*)-5-decenyl acetate, pheromone analog, methyl substitution, structure–activity, single-sensillum recordings, receptor interaction, conformational analysis, molecular mechanics.

INTRODUCTION

Moth sex pheromone components interact with their receptors in a highly selective way (Priesner, 1979). Furthermore, the very small amount of substrate needed to activate the receptors demonstrates that the natural pheromone component has an extremely high affinity for the receptor tuned to this component. These characteristics of the receptor suggest a high complementarity between the natural substrate and the receptor cavity. The degree of complementarity between the pheromone component and its receptor can be studied by introducing space-demanding substituents to various positions of the parent molecule and investigating the effects of such substituents on the biological activity.

In a previous structure–activity study we systematically introduced alkyl groups to the terminal chain of (*Z*)-5-decenyl acetate (**1,** Figure 1), a pheromone component of the turnip moth, *Agrotis segetum*, and studied the electrophysiological single-cell responses of these analogs (Jönsson et al., 1991). By introducing alkyl substituents as space probes, we were able to characterize the degree of complementarity between the substrate and its receptor with respect to the terminal (nonpolar) chain of **1.** We concluded that there is a very high degree of complementarity between the receptor and the terminal chain of the pheromone component **1.**

In the present study, we have further systematically varied the structure of **1,** this time in the chain between the double bond and the acetate group, by introducing methyl groups in the 2, 3, 4, and 5 positions and geminal dimethyl groups in the 2, 3, and 4 positions. The compounds studied are shown in Figure 1. These compounds were synthesized, and the receptor responses were determined by the electrophysiological single-sensillum (single-cell) technique.

Previous studies on alkyl-substituted pheromone components have concentrated on substitutions in the terminal alkyl chain (Priesner et al., 1977; Bestmann et al., 1979, 1980; Schwarz et al., 1989; Jönsson et al., 1991). To our knowledge, alkyl derivatives of moth sex pheromone components of the monoene acetate type, substituted in the chain connecting the acetate group and the double bond, have not been previously studied.

The main aim of the present study is to characterize the degree of complementarity between the acetate-substituted alkyl chain of the pheromone component and the receptor by using methyl groups at various positions along the chain as probes for repulsive steric interactions with the receptor. In conjunction with our previous study (Jönsson et al., 1991), the results of such a study should make it possible to obtain a detailed picture of the degree of complementarity between the entire alkyl part of the pheromone component and its receptor.

A repulsive interaction between the introduced substituent and the receptor will show up as a decrease of the electrophysiological activity. However, an observed activity decrease may also be due to a high conformational energy

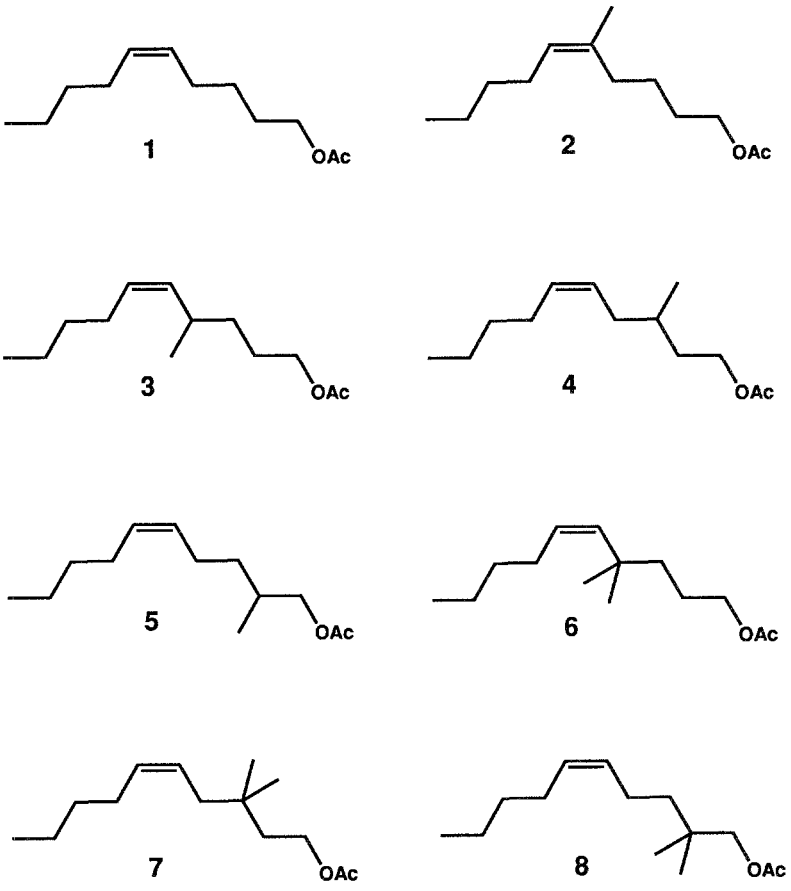

FIG. 1. Compounds studied.

required by the analog to acquire its biologically active conformation. In order to separate these effects, we have, as in our previous work (Jönsson et al., 1991), calculated conformational energies by the molecular mechanics method MM2(85) and used our previously developed receptor interaction model (Liljefors et al., 1987) to calculate the required conformational energies.

METHODS AND MATERIALS

Synthesis. All reagents were obtained from commercial suppliers and were used without further purification. Diethyl ether and tetrahydrofuran (THF) were distilled from dark blue solutions of sodium benzophenone radical anion. *N,N'*-

Dimethyl-*N,N'*-propylene urea (DMPU) was used as cosolvent as a substitute for the carcinogenic HMPA. It was stored under argon over 4A molecular sieves. The crude pheromone products were purified by flash chromatography with TLC–silica gel 60H and with petroleum ether–ethyl acetate (20:1) as eluent. Geometric isomers were separated by argentation chromatography (Houx et al., 1974). All products were further purified by preparative GLC using a 6-m × 4-mm 15% OV-351 column and/or by high-performance liquid chromatography (HPLC) using a semipreparative straight-phase column (Kromasil, particle size 10 μm, 250 × 10 mm ID) and a differential refractometer as monitor.

Analytical GLC was carried out on a Varian 3400 capillary GLC fitted with a DB-Wax or a OV-240-OH column. The purity of the isolated final products was >99% and no trace (<0.05%) of the natural pheromone component **1** could be detected. [^{1}H]- and [^{13}C]NMR spectra were recorded in $CDCl_3$ solution on a Varian XL-300 or a Jeol JNM-PMX60 spectrometer. Chemical shifts (δ) are given downfield relative to TMS. The $CHCl_3$ signal was used as an internal reference (7.26 ppm). High-resolution mass spectra were obtained using a Jeol JMS-SX 102 spectrometer.

The synthetic schemes for the preparation of compounds **2–8** are shown in Schemes 1–6.

(Z)-*5-Decenyl Acetate* ***(1).*** This compound was prepared as previously described (Olsson et al., 1983).

5-Methyl-(Z)-5-decenyl Acetate ***(2).*** 5-Methyl-(Z)-5-decenol was prepared according to Gardette et al. (1985) from ω-magnesium-protected 4-hydroxybutyl magnesium chloride (30 mmol). The crude alcohol was dissolved in dry pyridine (7.5 ml) and acetic anhydride (5 ml) and the mixture was stirred for 4 hr at room temperature. It was then poured into water and extracted with pentane,

washed with 1 M HCl, and $NaHCO_3$, and finally dried over $MgSO_4$. The solvents were removed and the crude product purified by flash chromatography to give 3.5 g (55% yield) of the trisubstituted olefin. A small amount of disubstituted olefin deriving from acetylene contaminated propyne was carefully removed in the final purification. Analysis by GLC (column DB-Wax 100–215°C at 2°C/min) revealed that the final product contains 0.8% of the *E* isomer. δ_H (300 MHz) 0.88 (t, 3H, CH_3CH_2), 1.23–1.33 (m, 4H, CH_3CH_2, $CH_2CC=$), 1.36–1.48 (m, 2H, $=CCCH_2$), 1.55–1.65 (m, 2H, CH_2CO), 1.65–1.67 (m, 3H, $=CCH_3$), 1.92–2.08 (m, 4H, $CH_2C=$), 2.03 (s, 3H, $COCH_3$), 4.06 (t, 2H, CH_2O), 5.10–5.17 (m, 1H, CH=C); δ_C (75.4 MHz) 14.0, 21.0, 22.4, 23.3, 24.3, 27.5, 28.4, 31.2, 32.3, 64.5, 125.9, 134.5, 171.2; high resolution CI mass spectrum, for $C_{13}H_{25}O_2$ ($M+H^+$), calcd. 213.1854, found 213.1855.

2-Methyl-4-pentenol ***(9).*** 2-Methyl-4-pentenoic acid (11.4 g, 0.1 mol), freshly prepared according to Ställberg-Stenhagen (1946), was dissolved in ether (100 ml) and slowly added to a stirred slurry of lithium aluminum hydride (6.9 g, 0.18 mol) in ether (500 ml) at −10°C and stirred overnight at room temperature. The mixture was then cooled to −20°C and the excess hydride was destroyed (7 ml H_2O), 7 ml 15% NaOH, 21 ml H_2O). The resulting white slurry was filtered and the solution dried and concentrated to give a colorless liquid (10.0 g). The purity was 90% by GLC. δ_H(60 MHz) 0.9 (d, 3H, CH_3), 1.2–2.3 (m, 3H, CH, CH_2), 2.5 (s, 1H, OH), 3.5 (d, 2H, CH_2O), 4.8–6.2 (m, 3H, $CH_2=CH$).

2-Methyl-4-pentenyl Bromide ***(10).*** 2-Methyl-4-pentenol **(9)** (10 g, 0.1 mol) was dissolved in dry pyridine (20 ml) at 0°C. *p*-Toluenesulphonyl chloride (22.9 g, 0.12 mol) was added and the mixture stirred for 6 hr. It was then poured into dilute HCl and ice, extracted with ether and washed with water and $NaHCO_3$. The extract was dried, concentrated, and the residual oil dissolved in acetone (200 ml) with anhydrous lithium bromide (13 g, 0.15 mol). The mixture was refluxed (16 hr), poured into water, and extracted with pentane. The extracts were washed with water, dried ($MgSO_4$), and concentrated to give a colorless oil (12.1 g, 74%), which was employed for the synthesis of **3,** described below, without further purification.

4-Methyl-(Z)-5-decenyl Acetate ***(3).*** 2-Methyl-4-pentenyl bromide **(10)** was treated with triphenylphosphine (19.4 g, 74 mmol) and sodium iodide (27 g, 180 mmol) in acetonitrile (100 ml) under reflux (72 hr). The main part of the solvent was removed by rotary evaporation, CH_2Cl_2 (25 ml) was added and the residual slurry filtered. The solution was treated with ether and a semisolid oil precipitated. The supernatant solution was removed and the residual solvents removed under reduced pressure to give 31.0 g of a sticky product. NMR spectrum showed signals at 7.3 and 7.8 ppm, indicating unreacted triphenylphosphine (attempts to purify the product by crystallization were not successful).

The crude phosphonium salt (11.8 g, 25 mmol) and dry THF (50 ml) was cooled to 0°C under nitrogen. *n*-Butyllithium (25 mmol) was injected, and the resulting dark red solution was stirred for 1 hr. It was then cooled to −72°C, DMPU (8 ml) was added, and after 15 min freshly distilled valeraldehyde (2.7 ml, 25 mmol). The mixture was stirred for 1 hr and then for another 1 hr without external cooling. Water was added and the solution was extracted with pentane, dried, concentrated, and chromatographed (silica gel, pentane as eluant) to give 1.25 g of the alkadiene (33% yield from the bromide). δ_H (60 MHz) 0.8–1.1 (m, 6H, CH_3), 1.2–1.5 (m, 4H, CH_2), 1.6–2.2 (m, 5H, allylic), 4.8–5.5 (m, 5H, vinylic).

The diene (8.2 mmol) was dissolved in THF (10 ml) and cooled in an ice bath under nitrogen. 9-Borabicyclo[3.3.1]nonane (9-BBN, 16.4 ml, 0.5 M in THF) was injected, the solution stirred at room temperature overnight, and then recooled. A mixture of 3 N NaOH (2.8 ml) and 30% H_2O_2 (3.3 ml) was added dropwise, stirred for 60 min at 35°C, water (10 ml) was added, and the mixture extracted with ether. The ether phase was washed (H_2O), dried ($MgSO_4$), and concentrated. The crude product was acetylated and purified as described for compound **2** to give 1.23 g (70% yield). Analysis of the product by GLC indicated the presence of 4.9% of the *E* isomer, which was removed by argentation column chromatography to give the final product. δ_H (300 MHz) 0.89 (t, 3H, $\mathbf{CH_3}CH_2$), 0.94 (d, 3H, $\mathbf{CH_3}CH$), 1.14–1.42 (m, 6H, $CH_3\mathbf{CH_2}$, CH_2CC=, =$CCCH_2$), 1.48–1.69 (m, 2H, CH_2CO), 1.92–2.11 (m, 2H, CH_2C=), 2.04 (s, 3H, $COCH_3$), 2.36–2.51 (m, 1H, =CCH) 4.03 (t, 2H, CH_2O), 5.09 (m, 1H, J = 10.9 Hz, =$\mathbf{CH}$CH), 5.32 (m, 1H, J = 10.9 Hz, $CH_2\mathbf{CH}$=); δ_C (75.4 MHz) 14.0, 21.0, 21.4, 22.3, 26.7, 27.2, 31.4, 32.1, 33.6, 64.7, 129.0, 135.5, 171.2; high resolution CI mass spectrum, for $C_{13}H_{25}O_2$ ($M+H^+$), calcd. 213.1854, found 213.1853.

(Z)-2-Heptenyl Bromide (11). (Z)-2-Heptenol was prepared according to Alexakis et al. (1980) from butyllithium (244 ml, 2 M in hexane, 0.5 mol). The crude alcohol was diluted with ether (425 ml), pyridine (5.8 ml) was added, then PBr_3 (19 ml, 0.2 mol), dropwise. After stirring overnight, the mixture was poured into ice water, washed with $NaHCO_3$ and water, and then dried over Na_2SO_4. Fractional distillation afforded pure **11** (48.7 g, 55% yield): bp 62–65°C/14 mm. δ_H (60 MHz) 0.9 (t, 3H, CH_3), 1.1–1.7 (m, 4H, CH_2), 1.9–2.3 (m, 2H, CH_2C=), 4.0 (d, 2H, CH_2Br), 5.3–5.9 (m, 2H, CH=CH).

3-Methyl-(Z)-5-decenyl Acetate (4). 2-Methyl-(Z)-4-nonenoic acid (**12**) was prepared by a modification of a method of Pfeffer et al. (1972). To a stirred solution of diisopropylamine (13.5 ml, 0.1 mol) in dry THF (70 ml) at −5°C under nitrogen was added *n*-butyllithium in hexane (48.5 ml 2 M, 0.1 mol) and after 10 min propionic acid (2.6 ml, 35 mmol). DMPU (4.8 ml, 40 mmol) was added to the milky white solution and the temperature allowed to rise to room temperature. After 30 min of stirring, the cloudy solution was cooled to 0°C

and (Z)-2-heptenyl bromide **(11)** (6.2 g, 35 mmol) added rapidly. The reaction mixture was stirred for 2 hr at room temperature and then neutralized with ice cold 10% HCl. The aqueous layer was extracted with hexane, and the combined organic phases washed with 10% HCl, water, and dried (Na_2SO_4). Removal of the solvent yielded the crude acid **12,** which was reduced with lithium aluminum hydride as described above for **9,** chromatographed (silica gel, petroleum ether–ether 6:1) to give pure 2-methyl-(Z)-4-nonenol (1.75 g, 32%). TLC: R_f 0.17 (hexane–ethyl acetate 10:1); δ_H (60 MHz) 3.5 (d, 2H, CH_2O).

p-Toluenesulphonyl chloride (2.6 g, 14 mmol) was added to a stirred ice-cooled solution of 2-methyl-(Z)-4-nonenol (11.2 mmol) in dry pyridine (6 ml) and stirred for 4 hr. It was then poured into dilute HCl and ice, extracted with ether, and washed with water and $NaHCO_3$. The ether solution was dried ($MgSO_4$) and concentrated in vacuo to give the crude tosylate quantitatively. TLC: R_f 0.36 (hexane–ethyl acetate 10:1).

This was dissolved in DMSO (12 ml) and NaCN (1 g) was added. The mixture was stirred and heated at 60°C overnight, poured into ice-water, and extracted with ether. The ether extract was washed with water and brine, dried ($MgSO_4$), and concentrated to give the nitrile. TLC: R_f 0.47 (hexane–ethyl acetate 10:1); δ_H (60 MHz) 2.3 (d, 2H, CH_2CN).

A solution of the crude nitrile and NaOH (8 g) in 60% ethanol (35 ml) was heated under reflux for 30 hr. The mixture was stripped from ethanol by rotary evaporation, diluted with water, and acidified with HCl and thereafter extracted with ether. The ether solution was washed with water and brine, dried, and concentrated to give the acid. TLC: R_f 0.06 (hexane–ethyl acetate 10:1).

The crude acid was then reduced with lithium aluminum hydride as for **9** to give 3-methyl-(Z)-5-decenol [TLC: R_f 0.17 (hexane–ethyl acetate 10:1); δ_H (60 MHz) 3.5 (t, 2H, CH_2O)], which was acetylated as described for **2** to give the final product in an overall yield of 69% from 2-methyl-(Z)-4-nonenol. δ_H (300 MHz) 0.89 (t, 3H, CH_3CH_2), 0.91 (d, 3H, $=CCCCH_3$), 1.28–1.49 (m, 5H, CH_3CH_2, $CH_2CC=$, $=CCCH$), 1.55–1.75 (m, 2H, CH_2CO), 1.87–2.09 (m, 4H, $CH_2C=$), 2.04 (s, 3H, $COCH_3$), 4.03–4.17 (m, 2H, CH_2O), 5.29–5.47 (m, 2H, J = 11.0 Hz, $CH=C$); δ_C (75.4 MHz) 14.0, 19.4, 21.0, 22.4, 27.0, 30.5, 31.9, 34.3, 35.1, 63.0, 127.5, 131.3, 171.2 high resolution CI mass spectrum, for $C_{13}H_{25}O_2$ ($M+H^+$), calcd. 213.1854, found 213.1849.

2-Methyl-(Z)-5-decenyl Acetate ***(5).*** (Z)-3-Octenyl bromide was prepared from lithium (Z)-dihexenyl cuprate (0.12 mol) and ethylene oxide (12.5 ml, 0.25 mol) to furnish (Z)-3-octenol (Alexakis et al., 1980), which was converted to the bromide in the same manner as described for the preparation of **11.** Distillation afforded 21.5 g, 45% yield; bp 72–79°C/14 mm. δ_H (60 MHz) 0.9 (t, 3H, CH_3), 1.1–1.7 (m, 4H, CH_2), 1.9–2.7 (m, 4H, $CH_2C=$), 3.2 (d, 2H, CH_2Br), 5.0–5.7 (m, 2H, $CH=CH$).

Alkylation of ethyl methylmalonate (6.0 ml, 35 mmol) using sodium, dry

ethanol, and the prepared (Z)-3-octenyl bromide, with subsequent hydrolysis and decarboxylation, was carried out as described for compound **9.** The prepared acid was then reduced with lithium aluminum hydride and acetylated to yield the final product (2.6 g, 35%). δ_H (300 MHz) 0.89 (t, 3H, CH_3CH_2), 0.93 (d, 3H, CH_3CCO), 1.12–1.48 (m, 6H, CH_3CH_2, $CH_2CC=$, $=CCCH_2$), 1.73–1.87 (m, 1H, CHCO), 1.98–2.12 (m, 4H, $CH_2C=$), 2.05 (s, 3H, $COCH_3$), 3.83–3.98 (m, 2H, CH_2O), 5.27–5.41 (m, 2H, J = 10.8 Hz, CH=C); δ_C (75.4 MHz) 14.0, 16.7, 20.9, 22.3, 24.5, 26.9, 31.9, 32.1, 33.4, 69.3, 129.2, 130.3, 171.2; high resolution CI mass spectrum, for $C_{13}H_{25}O_2$ ($M+H^+$), calcd. 213.1854, found 213.1849.

4,4-Dimethyl-(Z)-5-decenyl Acetate ***(6).*** Neat 3-methyl-2-butenal (3.9 ml, 40 mmol) was injected into a solution of lithium (Z)-dihexenyl cuprate (25 mmol) at −72°C. To this reaction mixture after 30 min of stirring at −50°C, was successively added trimethyl silyl chloride (15 ml, 116 mmol), triethylamine (17.8 ml, 128 mmol), and DMPU (6.3 ml, 52 mmol) (Chuit et al., 1981). The temperature was allowed to rise to 0°C and 4% HCl was added to neutralize the mixture. The ether solution was washed with sat. $NaHCO_3$, NaCl, dried ($MgSO_4$), concentrated, and distilled to give 4.5 g of a colorless oil (47% yield); bp 105–120°C/14 mm. This product was dissolved in THF (30 ml) and added to a solution of oxalic acid (1 g) in water (30 ml). The mixture was stirred 1 hr at room temperature. The aqueous layer was extracted once with ether and the combined organic phases were washed with $NaHCO_3$ and dried. The solvent was evaporated and the residue chromatographed (silica gel, petroleum ether–ethyl acetate 20:1) to furnish 1.95 g (62%) of the pure aldehyde. According to the previously described reaction sequence for compound **4,** the aldehyde was reduced with $LiAlH_4$ to the alcohol, tosylated, and converted to the nitrile; then hydrolyzed, reduced, and acetylated to give 1.8 g of **6.** Overall yield from the aldehyde 72%. δ_H (300 MHz) 0.90 (t, 3H, CH_3CH_2), 1.09 (s, 6H, $=CCCH_3$), 1.29–1.41 (m, 6H, CH_3CH_2, $CH_2CC=$, $=CCCH_2$), 1.58–1.64 (m, 2H, CH_2CO), 2.04 (s, 3H, $COCH_3$), 2.10–2.17 (m, 2H, $CH_2C=$), 4.03 (t, 2H, CH_2O), 5.14–5.26 (m, 2H, J = 12.1 Hz, CH=C); δ_C (75.4 MHz) 14.0, 21.0, 22.4, 24.3, 28.1, 29.0, 32.4, 36.0, 40.0, 65.3, 130.1, 137.7, 171.2; high resolution CI mass spectrum, for $C_{14}H_{27}O_2$ ($M+H^+$), calcd. 227.2011, found 227.1999.

3,3-Dimethyl-(Z)-5-decenyl Acetate ***(7).*** This compound was prepared via the same sequence of reactions as described for compound **4.** Addition of isobutyric acid in place of propionic acid to lithium diisopropylamide resulted in a clear homogeneous solution, which was warmed at 50°C for 2 hr before alkylation. No DMPU was added as cosolvent. 2,2-Dimethyl-(Z)-4-nonenoic acid was obtained in 72% yield. Due to steric hindrance of the neopentyl system, the displacement of tosylate by cyanide required extended reaction time (24 hr) and increased temperature (120–130°C). Overall yield from (Z)-4-nonenoic acid

was 42%. δ_H (300 MHz) 0.89 (t, 3H, CH_3CH_2), 0.91 (s, 6H, $=CCCCH_3$), 1.25–1.37 (m, 4H, CH_3CH_2, $CH_2CC=$), 1.54–1.62 (m, 2H, CH_2CO), 1.95–2.04 (m, 4H, $CH_2C=$), 2.03 (s, 3H, $COCH_3$), 4.11 (t, 2H, CH_2O), 5.34–5.51 (m, 2H, J = 11.1 Hz, CH=C); δ_C (75.4 MHz) 14.0, 21.1, 22.4, 27.0, 31.8, 32.9, 39.5, 39.6, 61.9, 125.4, 132.1, 171.2; high resolution CI mass spectrum, for $C_{14}H_{27}O_2$ ($M+H^+$), calcd. 227.2011, found 227.2016.

2,2-Dimethyl-(Z)-5-decenyl Acetate ***(8).*** Following the method described above for the preparation of **7,** the dilithio anion of isobutyric acid (0.14 mol) was alkylated with allyl bromide to give 17.6 g as residue. The crude acid was reduced with lithium aluminum hydride to furnish 13.7 g (86% yield) of the alcohol (purity 88% by GLC). The crude alcohol was thereafter dissolved in ether (100 ml) containing *p*-toluenesulfonyl chloride (0.1 g), and dihydropyran (18 ml, 0.2 mol) was added dropwise to the solution. The mixture was stirred overnight, then washed with K_2CO_3, dried over K_2CO_3, and concentrated. Distillation of the residue in base-washed equipment afforded 18.9 g product, bp 54–62°C/1 mm. The protected alkenol (5.0 g, 25 mmol) was oxidized with 9-BBN as described for compound **3.** It was then oxidized using pyridinium chlorochromate (10.8 g, 50 mmol) buffered with NaOAc (10.6 g) to give 2.5 g of pure aldehyde **13** (47% from the alkenol).

Triphenylphosphine (26.2 g, 0.1 mol) and pentyl bromide (13.7 ml, 0.11 mol) in acetonitrile (100 ml) were heated under reflux for 30 hr. The main part of the solvent was removed by rotary evaporation and dry ether was slowly added to the mixture. The precipitated white crystals were collected on a filter, washed with dry ether, and dried in vacuo over P_2O_5 to give 41.3 g of the phosphonium salt. Part of this (4.13 g, 10 mmol) was treated with *n*-butyllithium and thereafter with the aldehyde **13** in a Wittig condensation reaction as described for compound **3.** The crude product was thereafter acetylated with a mixture of acetic acid and acetyl chloride at 50°C overnight. It was then poured into icewater, extracted with pentane, and washed with $NaHCO_3$. The solvent was concentrated and flash chromatographed to give 1.3 g (63%) of the product, which was purified by argentation column chromatography to give an isomerically pure final product. δ_H (300 MHz) 0.90 (t, 3H, CH_3CH_2), 0.92 (s, 6H, CH_3CCO), 1.26–1.35 (m, 6H, CH_3CH_2, $CH_2CC=$, $=CCCH_2$), 1.94–2.06 (m, 4H, $CH_2C=$), 2.06 (s, 3H, $COCH_3$), 3.80 (s, 2H, CH_2O), 5.27–5.39 (m, 2H, J = 10.8 Hz, CH=C); δ_C (75.4 MHz) 14.0, 20.9, 21.8, 22.3, 24.2, 26.7, 26.8, 31.9, 33.7, 39.1, 72.4, 129.7, 129.9, 171.2; high resolution CI mass spectrum, for $C_{14}H_{27}O_2$ ($M+H^+$), calcd. 227.2011, found 227.2021.

Electrophysiology. Electrophysiological activities were determined by the single sensillum (single-cell) technique (Kaissling, 1974). Olfactory receptor cells specifically tuned to (Z)-5-decenyl acetate **(1)** are present in antennal sensilla type SW1 of *Agrotis segetum* (Hallberg, 1981; Löfstedt et al., 1982, van der Pers and Löfstedt, 1983). The method used was modified according to van

der Pers and Den Otter (1978) and has been described previously (Liljefors et al., 1987; Bengtsson et al., 1990). Dose–response curves were constructed using five different stimulus amounts. The amounts used for the pheromone component **1** were 10^{-4}–1 μg and for the analogs 10^{-3}–100 μg, in decadic steps. For each stimulus amount, 10 replicates were recorded and the mean value of the number of action potentials generated during 1 sec from the onset of stimulation was calculated and employed in the construction of the dose–response curves. Errors are expressed as standard errors of mean (SEM). The electrophysiological activity of each compound in relation to that of **1** is expressed as the reciprocal of the relative quantities required to elicit the same response from the receptor cell as the natural pheromone component **1.**

Corrections for differences in volatility have been made using relative vapor pressures, as previously described (Liljefors et al., 1985; Bengtsson et al., 1990). The correction factors for compounds **2–8** are based on vapor pressure data for saturated hydrocarbons (pentane–tridecane) and their methyl substituted analogs (Weast, 1971). The correction factors used are 2.2 for the monomethyl analogs and 4.6 for the dimethyl analogs.

Molecular Mechanics Calculations. The calculations of energy-minimized geometries and conformational energies were done using the molecular mechanics program MM2(85) developed by Allinger and coworkers (Burkert and Allinger, 1982). Starting structures for MM2(85) were obtained from the molecular modeling system MIMIC (Liljefors, 1983; von der Lieth et al., 1984).

RESULTS

Chemicals. The methyl substituted pheromone analogs **2–8** were prepared by the sequences of reactions shown in Schemes 1–6. The trisubstituted olefin analog **2** (Scheme 1) was obtained by carbocupration of propyne, followed by alkylation of the intermediate alkenyl cuprate, a method reported to give very high isomeric purity (Gardette et al., 1985) and this was also found in our case. The olefin analogs **4–7** were prepared analogously from carbocupration of acetylene to form olefinic intermediates and products with excellent isomeric purity. The α-dimethyl-substituted analog **6** (α with respect to the double bond) was thus prepared by conjugate addition of the intermediate alkenyl cuprate to 3-methyl-2-butenal and subsequent chain elongation and acetylation (Scheme 5). The β-substituted analogs **4** and **7** were obtained by treating the alkenyl cuprate with formaldehyde (Scheme 3). This allylic alcohol precursor was transformed to the corresponding bromide and reacted with the dianions of propionic acid and isobutyric acid, respectively. The alkylated products were chain elongated and acetylated similarly to compound **6.** Due to elimination of the homoallyllic system, the use of the corresponding reaction sequence to introduce a

methyl group in the γ-position was less successful. An attempt to prepare compound **5** by malonic ester synthesis furnished the mono-substituted analog in acceptable yield (Scheme 4). Compounds **3** (Scheme 2) and **8** (Scheme 6) were prepared by Wittig reactions in THF with DMPU as cosolvent. GLC analysis of the products showed the presence of 7–10% of the *E* isomers, which were removed by argentation chromatography.

Receptor Cell Responses. Electrophysiological single-cell activities for compounds **1–8** are shown in Figure 2. The relative activities shown in Figure 2 include corrections for differences in volatility (see Methods and Materials).

All methyl-substituted analogs display a significantly reduced activity compared to the activity of the natural pheromone component **1.** However, depending on the position of the introduced methyl substituent(s), the decrease in activity differs.

Methyl substitution in the 5 position at the double bond (compound **2**) reduces the electrophysiological activity by a factor of 600 compared to that of **1.** Monomethyl or dimethyl substitution in the 4-position, (compounds **3** and **6**) gives virtually inactive compounds. In position 3 (compound **4**), monomethyl substitution leads to a moderate drop of activity by a factor of 22, which makes this compound the most active one of the analogs in the present series. However, geminal dimethyl substitution in this position (compound **7**) reduces the activity considerably. Compound **7** is 1100 times less active than the natural component

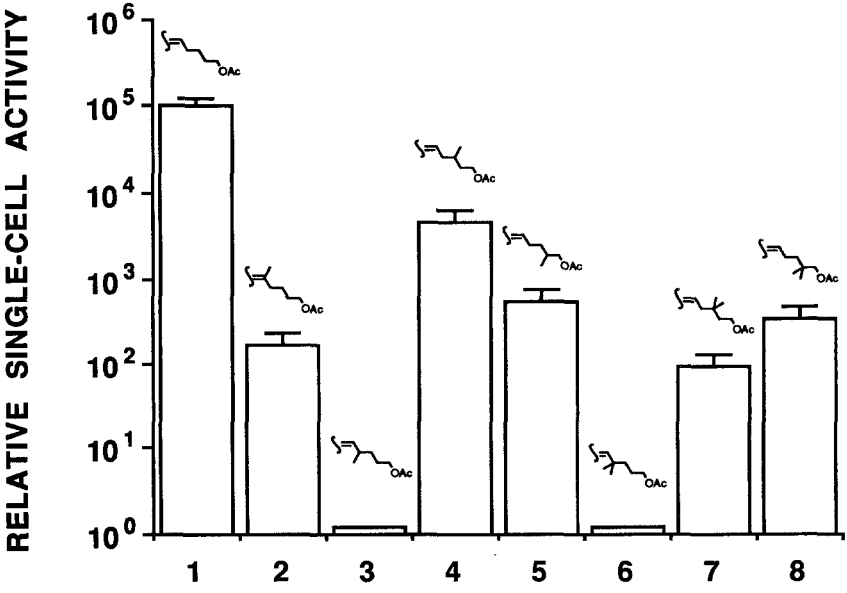

FIG. 2. Relative single-cell activities (+SEM) for compounds **1–8.**

1. In contrast to the large activity difference between monomethyl and dimethyl substitution in position 3, the corresponding substitutions in position 2 give very similar electrophysiological activities. Compounds **5** and **8** are less active than **1** by a factor of 180 and 288, respectively.

Comparing the effects on the electrophysiological activity of mono- and dimethyl substitution in positions 2 and 3, monomethyl substitution in position 3 leads to the more active compound **(4),** while the 2-dimethyl substituted compound **8** is more active than the 3-dimethyl substituted one **(7).**

Conformational Energies. The calculated thermodynamically most stable conformers of compounds **2–8** are shown in Figure 3. These are the lowest-energy conformers found by energy minimizations [MM2(85)] of a large number of trial conformers for each compound. With the exception of compound **6,** attractive van der Waals (dispersion) forces between the terminal alkyl chain and the acetate-substituted chain of the pheromone analogs stabilize a "coiled" conformer in which the two chains are in an essentially parallel arrangement.

In our previous conformational analysis of the pheromone component **1,** we found two *cis*-oid and one *trans*-oid conformation with all-anti alkyl chains to be the thermodynamically preferred conformations of this compound (Liljefors et al., 1987). One of these conformers correspond to the deduced biologically active conformation of **1** shown in Figure 4. As the type of "coiled" lowest-energy conformation found for most of the methyl-substituted compounds studied in the present work (Figure 3) was not included in our previous conformational analysis of **1,** we have reinvestigated the conformational properties of **1,** including conformers of the "coiled" type. In spite of two gauche arrangements about adjacent bonds in **1** (C-2—C-3 and C-3—C-4), we also found that for **1,** the "coiled" type of conformer was lower in energy than any of the conformers we have found previously. This conformer of **1,** shown in Figure 3, is calculated to be 1.1 kcal/mol lower in energy than the *cis*-oid and *trans*-oid conformers described above. In order to investigate if this finding requires revision of our previous structure–activity analysis of analogs of **1,** we have recalculated all previously reported conformational energies. The result of this revised conformational analysis is that all previously obtained structure–activity results are virtually unchanged by the inclusion of conformers of the "coiled" type. In particular, the correlation obtained between conformational energies and electrophysiological activities (Liljefors et al., 1987; Bengtsson et al., 1987) is still valid with an energy of ca. 2 kcal/mol, corresponding to a decrease of the electrophysiological activity by a factor of 10. The conformational energies reported in our study on alkyl substitution in the terminal chain of **1** (Jönsson et al., 1991) are also essentially unaffected by the inclusion of "coiled" conformers. It should be noted that the "coiled" conformer of **1** is not a likely candidate for the biologically active conformation. As described above, the "coiled" conformer has gauche arrangements about the C-2—C-3 and

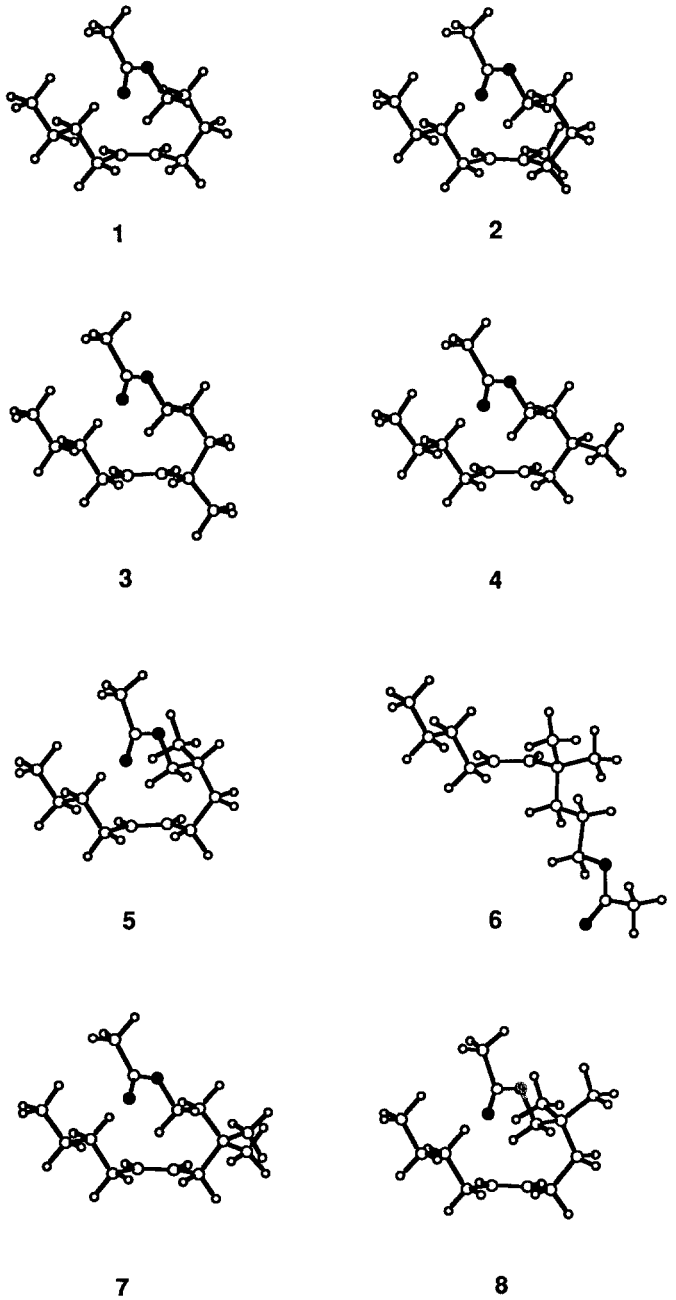

FIG. 3. Calculated [MM2(85)] lowest energy conformers for compounds **1–8.**

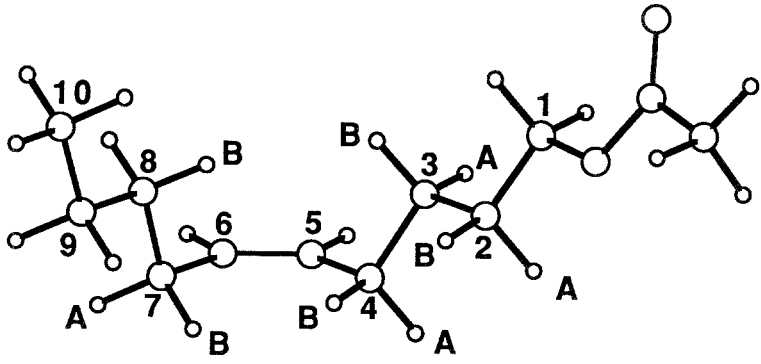

FIG. 4. The proposed biologically active conformation of compound **1** and the possible methyl group directions in methyl-substituted analogs of **1**.

C-3—C-4 bonds, which is not compatible with the quite high activities of (*Z*)-5,(*E*)-2 and (*Z*)-5,(*E*)-3 analogs of **1**, in which the corresponding bonds are locked in an anti arrangement (Bengtsson et al., 1987).

In order to calculate the energy required for each of compounds **2–8** to acquire the biologically active conformation, according to our receptor interaction model (Liljefors et al., 1987), a second series of calculations was performed in which each methyl-substituted molecule was superimposed on the proposed biologically active conformation of **1** (Figure 4) and energy minimized. During the minimization, the positions of the acetate group and the terminal methyl group were held fixed at the positions of the corresponding parts of **1**, while the double bond of the analogs was allowed to move in a plane containing the double bond of **1**. A more detailed description of the computational procedure is given by Liljefors et al. (1987). For each compound, the difference between the energy calculated in this way and the energy of the thermodynamically preferred conformer yields the energy required by an analog in order to optimally mimic the biologically active conformation of **1**. The calculated energies correspond to internal energies or entalphies. We assume that the entropic factor is similar for the different compounds in the present series.

The calculated energies required by each compound to acquire its biologically active conformation (in relation to the energy required by the natural component **1**), are shown in Table 1. For compound **2**, rearrangement of the compound from its thermodynamically preferred conformation to the biologically active one, as described above, is calculated to require only a small amount of energy, 0.2 kcal/mol in excess of the energy required by **1**.

A methyl substituent in positions 2, 3, and 4 (compounds **3–5**) may adopt two different directions, denoted A and B in Figure 4. In the B direction, the substituent is oriented towards the terminal chain and may suffer from repulsive

TABLE 1. CALCULATED CONFORMATIONAL ENERGY DIFFERENCES (kcal/mol) BETWEEN PROPOSED BIOLOGICALLY ACTIVE CONFORMATION AND LOWEST ENERGY CONFORMATION OF COMPOUNDS **1–8**[a]

Compound	A	A + B	B
1		0.0[b]	
2		0.2	
3	1.0		5.0
4	1.7		1.5
5	1.3		1.0
6		3.2	
7		2.4	
8		0.2	

[a]The energy values are given in relation to that of **1**. A and B denote alkyl group directions according to Figure 4. The energies may be used to estimate the expected decrease in the electrophysiological response due to a "pure" conformational effect by using the relation that ca. 2 kcal/mol corresponds to a decrease in the response by a factor of 10 (Liljefors et al., 1987; Bengtsson et al., 1987).
[b]The A/B designation is not applicable in this case.

steric interactions with this chain, while in the A direction it is directed away from the terminal chain. Monosubstitution in the A and B directions corresponds to different enantiomers. A relatively small energy is calculated for a 4-methyl substituent (compound **3**) in the A direction (1.0 kcal/mol, Table 1), while in the biologically active conformation of the compound with a methyl group in the B direction causes severe repulsive interactions with the terminal alkyl segment leading to a high energy to acquire this conformation (5.0 kcal/mol, Table 1). This repulsive interaction is less pronounced in positions 3 and 2. A methyl group in these positions (compounds **4** and **5**) gives similar calculated energies (1.0–1.7 kcal/mol) irrespective of its direction. Geminal dimethyl substitution in the 4, 3, and 2 positions results in a successive decrease of the calculated energy, 3.2, 2.4, and 0.2 kcal/mol, respectively.

DISCUSSION

Methyl substitution of the pheromone component **1** changes the hydrophobicity, shape, and conformational properties of the parent compound. The increased hydrophobic character of the methyl substituted analogs is expected to give a higher affinity to a nonpolar receptor cavity. Due to the additive nature of this physicochemical property, the hydrophobic effects can be predicted to be essentially identical for all monomethyl analogs and for all dimethyl analogs (Leo et al., 1971; Hansch and Leo, 1979). The increased molecular size due to

the methyl substituent may cause steric interference between the analog and a complementary receptor site and consequently a decrease in the biological activity due to repulsive steric interactions. This effect may give information on the dimension of different parts of the receptor cavity. A methyl substituent may also alter the conformation of the molecule and affect the energy required to bring an analog into the biologically active conformation. In terms of our conformational energy model (Liljefors et al., 1987; Bengtsson et al., 1987), an increase of this energy by ca. 2 kcal/mol corresponds to a decrease of the electrophysiological activity by a factor of 10. We have used this model to investigate if a decrease in the observed activity may be due to unfavorable conformational energies or to steric repulsive interactions with the receptor.

A methyl group in the 5 position, compound **2,** decreases the electrophysiological activity by a factor of 600 compared to the natural substrate **1** (Figure 2). This activity decrease may be compared to that due to the corresponding substitution in the other double bond position, position 6, which results in an activity drop of only 10 times (Jönsson et al., 1991). The calculated conformational energies for both these analogs to acquire the active conformation are small (Table 1) (Jönsson et al., 1991). This implies that the observed activity decrease is most probably caused by steric repulsive interactions between the methyl substituent and the receptor. The steric repulsions are clearly more pronounced in the 5 position than in the 6 position. These results demonstrate a high complementarity, in particular at position 6, between the "backside" of the *Z* double bond of natural substrate and the receptor.

Geminal dimethyl substitution in the 4 position (compound **6**) results in complete inactivity (Figure 2), which was previously also found for geminal dimethyl substitution in the 7 position (Jönsson et al., 1991). Although the conformational energy required to bring compound **6** into its active conformation is 3.2 kcal/mol higher than is required by **1** (Table 1), the main reason for the inactivity of **6** is concluded to be repulsive steric interactions with the receptor. It is clear that the extra volumes produced by the methyl groups of **6,** as well as the methyl groups in the 7-dimethyl compound (Jönsson et al., 1991) are detrimental to a productive receptor interaction. It is likely that at least some of these methyl groups at each of the positions interfere with the interaction between the *Z* double bond and its receptor site. Monomethyl substitution in the 4-position (compound **3**) gives an essentially inactive compound, which should be compared to the moderate activity decrease by a factor of 45 due to a methyl group in the analogous 7 position (Jönsson et al., 1991). The calculated conformational energy penalty for a methyl group in the A direction is low (Table 1), but it is significantly higher (5.0 kcal/mol) for a methyl group in the B direction. The high calculated energy for a B substituent partly explains the low activity, but probably repulsive interactions are involved as well. The low calculated energy for an A-oriented substituent clearly indicates that an A substituent destructively

interacts with the receptor. An investigation of the pure enantiomers of compound **3** is necessary for a final analysis. However, it is clear that the steric requirements of the receptor cavity are even more strict in the area corresponding to position 4 of the substrate than in the area corresponding to the other allylic position (position 7). The discussion above and our previous study (Jönsson et al., 1991) lead to the prediction that while one of the enantiomers of the 7-methyl compound may be significantly more active than the other, both enantiomers of 4-methyl-substituted **1** should be essentially inactive.

In the 3 position, geminal dimethyl substitution (compound **7**) reduces the biological activity considerably, 1100 times, compared to 95 times for the same substitution in the corresponding position in the terminal chain, position 8 (Jönsson et al., 1991). The calculated conformational energy for **7** is 2.4 kcal/mol (Table 1). In terms of our model, this corresponds to an activity decrease by approximately a factor of 10, due to the conformational effect. This indicates that there is substantial repulsion between the methyl group and the receptor in at least one of the A and B directions of **7** (Figure 4). Monomethyl substitution in the 3 position (compound **4**), decreases the activity only 22 times, which is similar to the activity decrease by a factor of 45 due to a methyl group in the 8 position (Jönsson et al., 1991). The two possible methyl group directions of **4** give very similar conformational energies (Table 1). Considering the low activity of the dimethyl-substituted compound **7** and the quite high activity of the monomethyl-substituted compound **4,** this implies that in the 3 position only one of the substituent directions, A or B, sterically interferes with the receptor. Since the B direction is "shielded" by the terminal alkyl chain (Figure 4), the destructive methyl group position is most probably the A position.

Dimethyl substitution in the 2 position (compound **8**) causes a reduction of the electrophysiological activity, compared to that of **1,** by a factor of 288 (Figure 2). The calculated conformational energy effect on the activity is negligible (Table 1). The corresponding monomethyl-substituted compound **5** displays an activity that is only slightly higher than that of compound **8** (Figure 2). The calculated conformational energy penalties for **5** are low for both substituent directions (Table 1) and should not cause a significant reduction of the activity. The observed activity decreases for compounds **5** and **8,** and the calculated low conformational energy effects indicate that there are repulsive steric interactions with the receptor in at least one of the A and B directions. A study of the enantiomers of **5** is required for a final analysis. Methyl substituents in the 2 position may interfere with binding sites for the ester oxygen of the acetate group. It has been shown that the presence of this oxygen atom is necessary for a productive receptor interaction (Liljefors et al., 1984).

Since the observed activity of **5** is lower than that of **4** (Figure 2) and since the calculated conformational energy penalties are almost identical for these compounds (Table 1), the combined repulsive interactions in the A and B direc-

tions are more pronounced for a methyl substituent in the 2 position than in the 3 position. This would be expected to result in the 3,3-dimethyl compound **7** being more active than the corresponding 2,2-dimethyl-substituted compound **8.** However, this is not the case. Compound **8** is found to be somewhat more active than compound **7** (Figure 2). This observation may be explained by the 2.2 kcal/mol higher conformational energy penalty for **7** than for **8,** which counteracts the less severe repulsions with the receptor for compound **7.**

CONCLUSIONS

In a previous paper (Jönsson et al., 1991), we concluded that there is a high steric complementarity between the receptor and the terminal alkyl part (n-chain) of the pheromone component **1.** The receptor tuned to this compound clearly does not tolerate the extra bulk of a methyl group in positions 6–9 of the natural substrate. The study reported above shows that a methyl substituent in at least one of the A and B directions (Figure 4) in position 2–4, in the alkyl chain connecting the *Z* double bond and the acetate group (m-chain), causes repulsive steric interactions with the receptor. This indicates that there is a high degree of steric complementarity also between the receptor and the acetate-substituted alkyl chain of **1.** It is noteworthy that geminal dimethyl substitution in the m-chain leads to a higher decrease of the electrophysiological activity than dimethyl substitution in the corresponding positions (with respect to the double bond) in the n-chain.

Methyl substitution at either double bond position causes repulsive steric interactions with the receptor. The activity decrease is most pronounced in the 5 position, to which the m-chain is connected.

Our studies on methyl-substituted analogs of **1** indicate that the entire hydrocarbon part of the compound interacts with the receptor in a highly complementary way. This finding rationalizes the very high selectivity of the pheromone component receptor. Furthermore, the high complementarity implies that all methylene units in the pheromone are involved in the binding of the pheromone component and thus contribute to the affinity of the molecule. This rationalizes the observed high affinity of the pheromone component for its receptor.

MULTIVARIATE STUDY OF MOOSE BROWSING IN RELATION TO PHENOL PATTERN IN PINE NEEDLES

KERSTIN SUNNERHEIM-SJÖBERG* and MARKKU HÄMÄLÄINEN

Department of Chemistry
Swedish University of Agricultural Sciences
Box 7016
S-750 07 Uppsala, Sweden

(Received July 31, 1991; accepted December 12, 1991)

Abstract—Extracts of needles from Scots pine, *Pinus sylvestris* L., grown on fertile (A) or poor (B) soil, and from lodgepole pine, *P. contorta* Doug. (C), have been analyzed with HPLC and UV detection. By application of multivariate analysis, the phenol pattern was shown to vary between species and between habitats. Within groups A and B, moose food choice was highly correlated to phenol pattern. Concentrations of most of the analyzed compounds were internally correlated. Information related to pine growth rate could also be extracted from the phenolic pattern for A, B, and C. Moose food choice was not correlated to pine growth rate.

Key Words—Phenols, moose browsing, *Alces alces*, multivariate analysis, chemical defense, pine, *Pinus sylvestris* L., *P. contorta* Doug., herbivory.

INTRODUCTION

Trees of the genus *Pinus* are an important food source for moose, *Alces alces*. Moose exhibit both species and individual tree preferences. Preferential browsing of pines growing side by side by moose has been reported. Some individual trees were completely destroyed, whereas others were untouched (Haukioja et al., 1983; Danell et al., 1990).

Evidence suggests that plants have a chemical defense against herbivores (Feeny, 1976; Bryant and Kuropat, 1980; Bryant et al., 1984). The relationship between moose browsing and chemical characteristics of pine trees has hardly been studied. Löyttyniemi and Hiltonen (1978) and Löyttyniemi (1981) found

no correlation between moose browsing and contents of monoterpenes or nutrients. Niemelä and Danell (1988), investigating a number of morphological and chemical parameters (including weight of the ether-soluble fraction, fiber, ash, metals and nitrogen content), found the amount of available twig biomass, but not the chemical parameters, to be correlated to moose browsing.

Recently, Danell et al. (1990) studied the correlation between moose browsing and individual terpenes from Scots pine needles. They found a negative correlation between pinifolic acid content and consumption. A similar repellency was observed with another compound, angelicoidenol-2-*O*-β-D-glucoside, isolated from Scots pine (Sunnerheim-Sjöberg, 1991).

Plant phenols possess defense functions against herbivores (Feeny, 1976; Harborne, 1985; Rhodes, 1985; Haslam, 1988). Tannins and total phenol concentration have been intensively studied with regard to these aspects, and several authors have reported correlations with feeding behavior (Häggman and Rousi, 1985; Marks et al., 1988). However, the mechanism for defense is not understood and, in all probability, the role of phenols in plant defense is a complex one (Harborne, 1985).

Several naturally occurring phenolic compounds have been reported to act as defensive substances against herbivores. For example, the phenolic stilbene pinosylvin and its monomethyl ether—both isolated from green alder (*Alnus crispa*)—are highly repellent to snowshoe-hares (*Lepus americanus*) (Bryant et al., 1983; Clausen et al., 1986). Platyphylloside [5-hydroxy-1,7-bis-(4-hydroxyphenyl)heptan-3-one-5-*O*-D-glucoside], isolated from silver birch (*Betula pendula*) was shown to reduce digestibility in vitro in goat rumen liquor, suggesting a defensive role for this phenol against ruminants (Sunnerheim et al., 1988). A more general discussion of phenols as defense substances in birch, willow, and poplar has been presented by Palo (1984).

The aim of this work was to investigate whether there are significant correlations between the phenol pattern in pine needles and moose browsing on pine. Needle extracts from pines exposed to moose living in the wild have been studied using high-performance liquid chromatography (HPLC) with UV detection. Previous reports from our research group (Popoff and Theander, 1975, 1976, 1977; Theander, 1982; Lundgren et al., 1982; Lundgren, 1987) have shown that the vast majority of pine needle constituents analyzed by this method are phenolic glycosides. Since chemical defense might result from a combination of several compounds, and since the chromatographic patterns from pine needles are complex, multivariate analysis was used. This method offers the possibility of analyzing large amounts of data. The plant material used is the same as in the investigation of Niemelä and Danell (1988).

In view of the role of phenols as growth regulators (Kefeli and Kutacek, 1976, 1979; Jacobs and Rubery, 1988) and the findings that soil nutritional factors affect phenol content (Barry and Manley, 1986; Briggs, 1990), the phenol

data in this investigation were also examined to see if phenol pattern was correlated with pine growth rate.

METHODS AND MATERIALS

Plant Material

Two Scots pine (*Pinus sylvestris*) phenotypes from fertile (A) and poor (B) soils, with low and high productivity, respectively, and lodgepole pine (*Pinus contorta*) (C) from an intermediate habitat were used. The pines were all growing in stands with no overstory, outside Umeå in coastal northern Sweden (around 63°45′N, 20°0′E). Fifty unbrowsed, 2-m-high, single-stemmed pines of each type were cut, and morphological data of each tree were noted. The trees were cut in late autumn, when the ground was frozen.

From each of the test pines, twig samples (twig diameter < 6 mm) were cut and stored at -20°C before extraction.

The trees were then exposed to wild-living moose: three pines, one of each type, were placed at each of 50 stations. The pines were inserted into the ground and appeared similar to growing trees.

For a more detailed description of the plant material, including the various growth parameters and the determination of moose consumption, see Niemelä and Danell (1988).

Extraction

Needles (0.50 g) were extracted in a mixer (Ultra-turrax) with 2×5.0 ml 95% aqueous ethanol for 2 and 0.5 min, respectively. The same procedure was repeated but with 80% aqueous ethanol. The combined extracts were glass-filtered and evaporated to dryness. Water (5.0 ml) was added, and the solution was extracted with 3×5.0 ml petroleum ether. The aqueous phase was centrifuged and the supernatant was transferred to a measuring flask. Water was added to 5.00 ml. The extracts were stored at -20°C before HPLC analysis.

Chemical Analysis

HPLC was performed on a Spectra Physics SP 8100 HPLC system equipped with a SP 8840 variable UV detector and using an analytical column (Chrompack CP-TM-spher C18, 4.6 mm $\times$ 250 mm). Mobile phase: 0–50 min, 10–80% aqueous methanol; 50–60 min, 80% aqueous methanol. Flow rate 1.5 ml/min. Oven temperature: 40°C. Detection wavelength: 280 nm. Chromatographic data, measured as peak areas, were automatically transferred to a computer. All samples were prepared and analyzed in random order to minimize systematic errors.

Statistical Analysis

Principal component analysis (PCA) (Wold et al., 1984; Jolliffe, 1986) was performed to study the main tendencies of systematic variation between the species and phenotypes. The relations between the block of dependent variables (growth rate and moose consumption) and independent variables (chromatographic data) were studied using the method of partial least-squares regression (PLSR) (Geladi and Kowalski, 1986; Martens and Naes, 1989) on latent variables.

Input Data: Independent variables. The "phenol patterns" are described by the automatically integrated chromatographic peaks from substances absorbing UV light of 280 nm.

Input Data: Dependent Variables. Relative consumption is: (biomass removed − biomass left on ground)/(available biomass). Consumption choice is: (relative consumption from one tree)/(total relative consumption at the test station). Growth rate was estimated by dividing the height of the tree by its age. For further details about the plant material and the moose browsing data, see Niemelä and Danell (1988).

The number of objects in the PLSR consumption models: A, 33 objects; B, 30 objects; C, 24 objects; and in the growth rate models: A, 45 objects; B, 39 objects; C, 24 objects.

Principal Component Analysis (PCA). PCA is used for reduction of the dimensionality of a data set, which consists of a large number of intercorrelated variables, while retaining as much as possible of the original variation as a new set of variables, the principal components. These are uncorrelated, and ordered so that the first few components retain most of the variation present in all of the original variables.

PCA is here used for an overview of the data set and for the identification of subgroups. If subgroups are present, better calibrations are sometimes obtained with separate models for each group.

Partial Least-Squares Regression (PLSR). In PLSR the linear relation between dependent variable(s) and the set of independent variables is calculated. [For example: consumption choice = f(phenolic pattern) (Geladi and Kowalski, 1986; Martens and Naes, 1989).]

Terms and Definitions

The data within brackets refer to a particular example; namely areas of chromatographic peaks from extracts of Scots pine needles in relation to consumption choice.

Variables. Measured quantities (here: areas of 55 chromatographic peaks give 55 variables). Each variable represents one dimension in a multidimensional space.

Objects. Each object represents one point in a multidimensional space. (Here: 33 pine individuals).

Principal Component 1 (PC1). A line of best fit to the points in the multidimensional space (here: a straight line passing as close as possible to all the 33 experimental points in 55 dimensions).

Principal Component 2 (PC2). A new line—orthogonal to PC1 and least-squares adapted to the residuals (here: the residuals are the distances from each of the 33 points to PC1 expressed as coordinates of the 55 variables).

PLSR Factor. The orthogonal two-dimensional coordinate system that describes the relation between the dependent (here: consumption choice) and the independent variables (here: chromatographic data). The PLSR factors have similar functions for PLSR as principal components have for PCA.

Validation

Prediction Model. For each object, the dependent variable, y_{pred}, (here: consumption choice) is calculated (from its chromatographic data) based on a PLSR model (Martens and Naes, 1989, Chapter 3, p. 5).

Standard Error of Prediction (SEP).

$$SEP = \sqrt{\frac{\sum (y_{\text{pred}} - y_{\text{obs}})^2}{n}}$$

where y_{pred} = from PLSR model predicted value, y_{obs} = the corresponding observed value, and n = number of predicted objects. For PCA and PLSR calculations, the SIRIUS software was used (Kvalheim and Karstang, 1988).

Cross Validation (CV). The principal component/PLSR factor is calculated for some of the objects and the rest is predicted by the model. This is repeated for all objects (Wold et al., 1987; Martens and Naes, 1989).

Cross-Validation Ratio (CVr). Ratio between predicted and present residual standard deviation. CV ratio < 1 is a criterion for a significant principal component/PLSR factor.

RESULTS AND DISCUSSION

Chromatographic Pattern and Principal Component Analysis

Typical chromatograms from the HPLC analysis are given in Figure 1. The principal component analysis showed that the phenol pattern in *P. contorta* differed significantly from *P. sylvestris* (Figure 2). Component one (PC1) mainly separated the two species, while PC2 mainly separated the two habitats of *P. sylvestris*. Differentiation of the two species could be made by visual inspection of the chromatograms (Figure 1). PCA applied to the samples of Scots pine

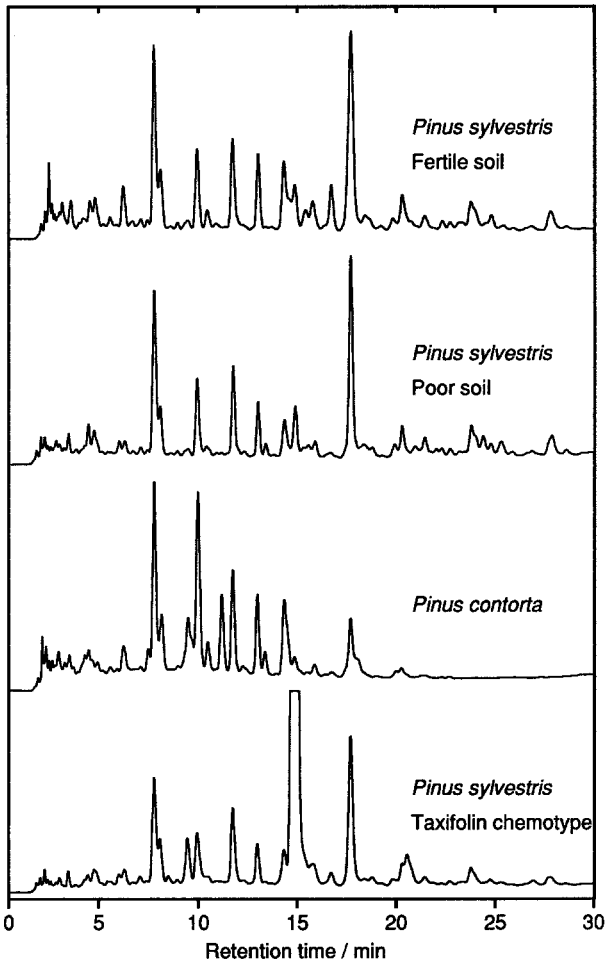

FIG. 1. Representative chromatograms of extracts from *P. sylvestris* in fertile soil (A), *P. sylvestris* in poor soil (B), *P. contorta* (C), and from a high-taxifolin chemotype of *P. sylvestris*.

showed that the major variation in phenol composition was related to the contrast between phenotypes (Figure 3). These divisions indicated that the three subgroups should be analyzed separately in the following PLSR-model calculations.

Among Scots pines, some clones (seven of 49 for A and five of 49 for B) contain taxifolin-3′-*O*-β-D-glucoside in high concentration—3% of needle dry matter—and other clones lack this compound (Sunnerheim-Sjöberg et al., 1991). Figure 1 shows an example of a chromatogram from a taxifolin-glucoside-rich

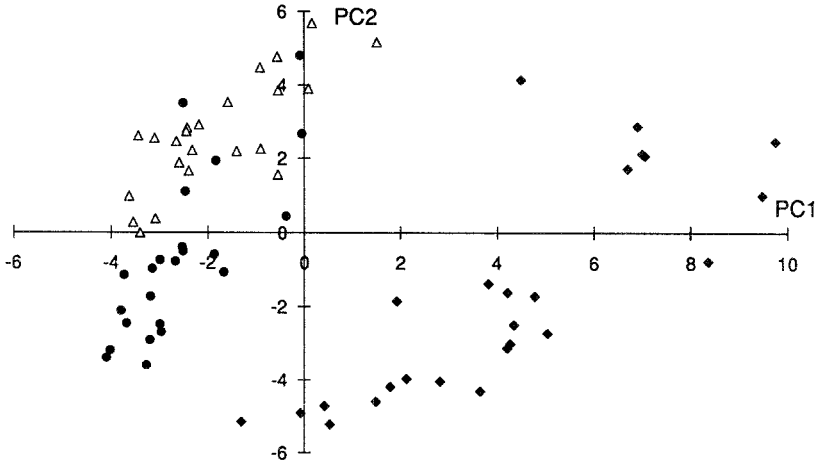

FIG. 2. PCA of A, B, and C, two principal components. Objects: Δ = *Pinus sylvestris*, fertile soil (A); • = *P. sylvestris*, poor soil (B); ♦ = *P. contorta* (C).

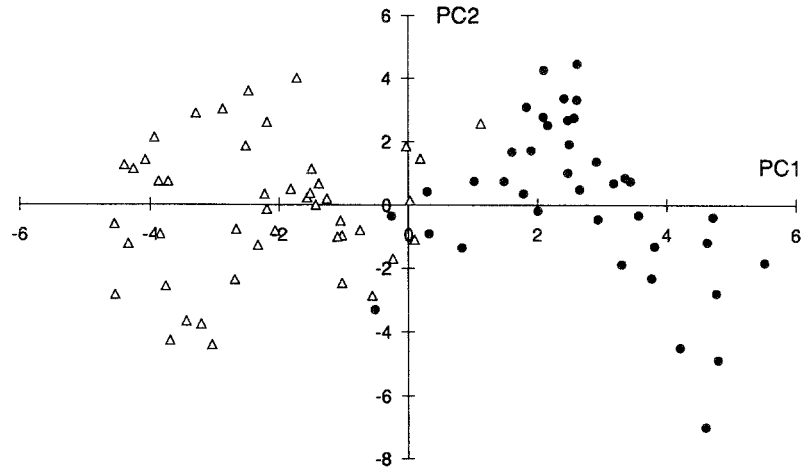

FIG. 3. PCA of A and B, two principal components. Objects: Δ = *Pinus sylvestris*, fertile soil (A); • = *P. sylvestris*, poor soil (B).

pine. The large peak corresponding to taxifolin-glucoside hides some adjacent peaks, leading to a decrease in information from these variables. However, exclusion of the taxifolin-glucoside-rich pines from the PLSR models had only a minor influence on the predictions. The other peaks in the chromatograms were not identified. The areas of 47 of 55 chromatographic peaks were internally

correlated, i.e., the peak areas were dependent on other peak areas in the chromatogram.

Partial Least-Squares Regression Models

Relative Consumption. Since available biomass differed between A, B, and C (203, 158, and 134 g dry matter/tree, respectively), relative consumption (consumption/biomass available) was used as the dependent variable in the PLSR models. Relative consumption was correlated with the chromatographic pattern for A. One significant factor was obtained. Figure 4 shows how a PLSR model predicted the relative consumption for A. Observed relative consumption ranged from 10 to 98% and SEP was 17% (Table 1). Trees from stations where all three trees were browsed by moose were included in the model, resulting in 33 objects. When the unbrowsed trees were also included in the model, the explained variance decreased. This indicated that the moose had to taste the twig—odor was not sufficient—to determine palatability. No significant correlations were found for B and C.

Consumption Choice. If one pine at a station was intensively browsed, the other trees were also heavily browsed (Niemelä and Danell, 1988). Consumption differences might be affected by the surroundings; topography and vegetation

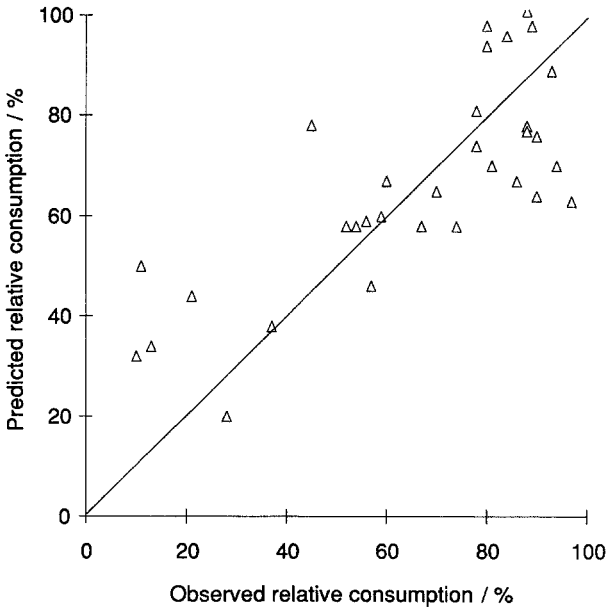

FIG. 4. Predicted versus observed relative consumption for *P. sylvestris*, fertile soil (A); one-factor model.

TABLE 1. VALIDATION RESULTS FROM PLSR MODELS WITH CHROMATOGRAPHIC DATA AS INDEPENDENT VARIABLES AND DIFFERENT DEPENDENT VARIABLES[a]

Dependent variable	Indep. variable	Factor 1		Factor 2		Factor 3		SEP	Figure
		CVr	EV	CVr	EV	CVr	EV		
Relative consumption	A_{Ph}	0.93	56%					17%	4
Consumption choice	A_{Ph}	0.97	55%	0.94	78%			4.5%	5
Consumption choice	B_{Ph}	0.98	35%	0.97	48%	0.99	62%	4.6%	6

[a] A_{Ph} and B_{Ph} are phenol composition for *Pinus sylvestris* fertile and poor soils, respectively, and EV is the explained variance.

are not identical at all stations and the number of moose were not identical. Moreover, the moose might have been more hungry at some stations than others. Therefore, "consumption choice" was probably a more relevant variable than "relative consumption" for quantifying feeding behavior. If "consumption choice" was used as a dependent variable, significant models were obtained for both Scots pine phenotypes. Observed consumption choice varied from 6 to 48% for A and from 16 to 55% for B. Standard errors of predictions were 4.5 and 4.6%, respectively, and explained variances were 78 and 62% for A and B, respectively, indicating that phenol composition was very well correlated to food choice (Figures 5 and 6, Table 1).

Two PLSR-factors were obtained for A and three for B, which might point to several independent defense systems. A PLSR model including both Scots pine habitats was not significant, which might point to different chemical defenses in trees from soils of different nutritional status or differences in phenol pattern due to pine growth rate overrode the variation in consumption choice.

The age of the trees from fertile soil varied from 6 to 8 years. For B, pines older than 11 and younger than 9 years were excluded from the model, leaving 30 objects in the model. When all ages, 8–15 years, were included, the models were not significant. Since trees of 2 m height were selected, the older trees among the pines investigated had a slower growth rate. Growth rate is correlated to phenol pattern (see below), and this interference on the consumption choice models is reduced by studying a more narrow range of ages. Thus, within an area, and among pines of similar growth rate, moose food choice was well predicted by the PLSR models based on the chemical composition of the needles.

For *P. contorta*, no significant PLSR model was obtained with consumption choice as the dependent variable. The variations in age (7–12 years), growth

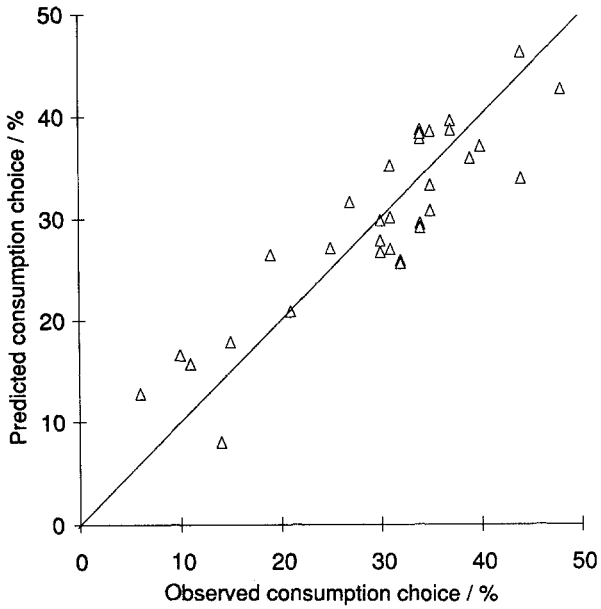

FIG. 5. Predicted versus observed consumption choice for *P. sylvestris*, fertile soil (A); two-factor model.

rate, and phenol composition (Figure 2) were larger compared to *P. sylvestris* and might account for the lack of correlation.

Are Phenols Repellents?

None of the 55 variables alone could be held responsible for the moose food choice. Only one variable was correlated to consumption choice (CV ratio 0.90), but the relation was valid only for fertile soil phenotypes and the explained variance was low (22%). However, the composition of the phenolic compounds in the needles was strongly correlated with moose food choice. The models show only correlations and tell us nothing about phenols as repellents. Phenols might lack effect and may only be markers for active compounds not detected here, or they may be active in combination with other compounds—both phenolic and nonphenolic. Nevertheless, the model can predict moose food choice from the phenol data.

Pine Growth Rate. Figure 3 shows that different soil fertilities could be distinguished by means of the phenol composition in the pine needles. This observation supports the theories of Bryant et al. (1983) and Coley et al. (1985) that the evolutionary response to resource limitation is an inherently slow growth and that the composition of secondary compounds differs between plants in

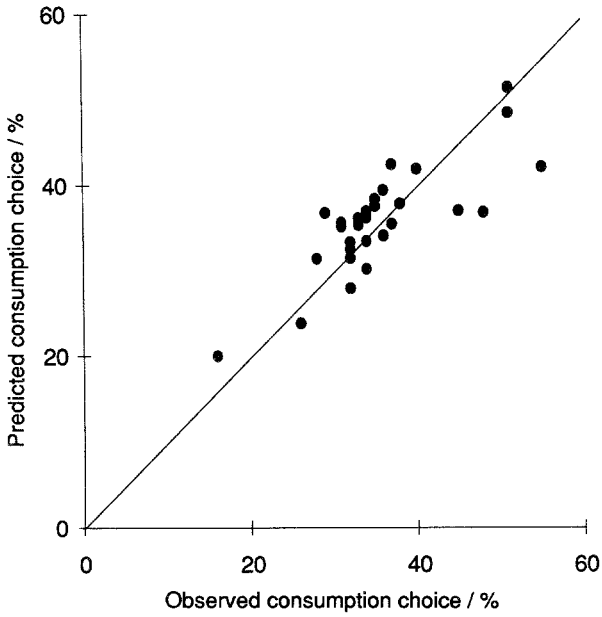

FIG. 6. Predicted versus observed consumption choice for *P. sylvestris*, poor soil (B); three-factor model.

different habitats. It might also reflect an effect of soil nutritional status on phenol content (Rhodes, 1985; Barry and Manley, 1986; Briggs, 1990).

However, even within the three stands, A, B, and C, pine growth rate was correlated to phenol pattern. These results support the findings that certain phenols are growth regulators (Kefeli and Kutacek, 1976, 1979; Jacobs and Rubery, 1988; Kuiters, 1989). The models used 34–51% of the variance in the phenol pattern to explain growth rate, giving a standard error of prediction of 1.6–3 cm/year. Thus, the phenol composition in the needles was less correlated to pine growth rate than to twig consumption by moose, but the consumption choice models were only valid for pines of similar growth rate.

Consumption versus Growth Rate

Bryant and Kuropat (1980) and Danell and Huss-Danell (1985) noted a correlation between plant growth rate and herbivore preference for different species. The present investigation of browsing preference for individual trees of the same species showed no such correlation. Neither relative consumption nor consumption choice was correlated to pine growth rate, although both consumption and growth rate were correlated to phenolic pattern. The variables

important for the different models were not identical; i.e., the growth rate and the consumption models were influenced by different phenols.

CONCLUSIONS

- Moose food choice was related to the phenol composition of the needles of Scots pine among pines of similar growth rate.
- Palatability was probably determined by a complex covariation of a number of compounds in the needles.
- Food choice was not correlated to pine growth rate.
- Within the same location, pine growth rate was correlated to phenol pattern for both Scots and lodgepole pines.
- The phenol composition of the needles was different for trees of different species and for trees from soils of different fertilities.
- Concentrations of most of the individual phenols were internally correlated.

Acknowledgments—We thank Prof. Kjell Danell, Umeå, for supplying the plant material and all available data on the trees and moose browsing, and Karin Engström for performing the extractions and the HPLC analyses. We also thank SJFR for financial support.

(Received September 3, 1991; accepted December 16, 1991)

Abstract—A phagostimulant, 6,10,14-trimethylpentadecan-2-one (phytone), was isolated and identified from Bermuda grass, *Cynodon dactylon* (L.). The phagostimulant activity of this isoprenoid ketone was established from bioassays of fall armyworm larvae, *Spodoptera frugiperda* (J.E. Smith). Larvae displayed increased body mass accumulation as well as preference to diet supplemented with this molecule. Neonate larvae fed diet supplemented with chromatographic isolates of phytone-containing fractions from six Bermuda grass cultivars showed a 10–40% increase in body mass accumulation as compared with controls. This variation in larval body mass accumulation seems attributable to a differential concentration of phytone in the cultivars, which ranged from 0.5 to 43 ppm. Additionally, first-instar larvae responded preferentially to diet pellets topically treated with phytone in concentrations as low as 0.1 ppm.

Key Words—Allelochemistry, Bermuda grass, *Cynodon dactylon*, phagostimulant, *Spodoptera frugiperda*, Lepidoptera, Noctuidae, fall armyworm, 6,10,14-trimethylpentadecan-2-one.

INTRODUCTION

Host selection by phytophagous insects is mediated principally by secondary plant metabolites (Fraenkel, 1959; Thorsteinson, 1960). Both larval and adult insect herbivores are known to be responsive to a variety of plant chemical stimuli (Visser, 1986). Phagostimulants and deterrents are thought to provide

*To whom correspondence should be addressed.

the bulk of information that govern choice of food plant and host suitability (Dethier, 1947; Schoonhoven, 1968). Given the crucial role of these molecules in modifying insect behavior and physiology, manipulation of crop plants with defined allelochemic profiles has been recognized as affording a promising mode of insect pest management (Smith, 1990). This approach seems inherently plausible with crops of low economic returns such as forages (Bernays and Barbehenn, 1987).

A major perennial source of nutritious forage is Bermuda grass, *Cynodon dactylon* (L.), which enjoys a cosmopolitan distribution with 4 million ha under cultivation in the United States alone. One of its major insect herbivores, the fall armyworm, *Spodoptera frugiperda* (J.E. Smith), has systematically eroded the value of this crop over the last decade (Mitchell, 1979; Sparks, 1979; Hogg et al., 1982; Johnson, 1987). In addition, given the fall armyworm's migratory behavior, Bermuda grass serves as an important reservoir for population outbreaks in grain crops such as corn. In an effort to develop resistant cultivars, conventional breeding programs and tissue-culture-derived lines have yielded several Bermuda grass variants to which fall armyworm has shown variable feeding preference (Lueck et al., 1968; Lynch et al., 1983; Quisenberry and Wilson, 1985; Jamjanya and Quisenberry, 1988; Croughan and Quisenberry, 1989). Additional studies (Quisenberry et al., 1988) have implicated allelochemics such as feeding deterrents and/or phagostimulants as the basis of fall armyworm variable response to Bermuda grass cultivars.

Phagostimulants have been implicated in insect host plant preference and suitability (Soni and Finch, 1979; Saxena and Prabha, 1975; Jones and Coaker, 1978; Mori, 1982; Stadler and Buser, 1984; Blust and Hopkins, 1987). Their relationship to resistance to insect herbivory has been implicated in several studies (Guerren and Ryan, 1984; Khan et al., 1987). In this study, we report the isolation and identification of 6,10,14-trimethylpentadecan-2-one as a Bermuda grass phagostimulant and the quantitative variability in six cultivars and somaclones.

METHODS AND MATERIALS

Chemicals. All chemicals used in these experiments were of the highest purity commercially available, particularly distilled-in-glass solvents (Burdick and Jackson Co.).

Insect Culture. Fall armyworm (rice strain; Pashley, 1986) was cultured on a modified meridic diet (Quisenberry and Whitford, 1988) according to procedures by Perkins (1979) at 27.6 $\pm$ 0.5°C, 16:8-hr photoperiod, >50% relative humidity.

Phagostimulant Isolation Protocols. Six Bermuda grass cultivars were

selected for this experiment on the basis of differential feeding responses observed with the fall armyworm (Quisenberry and Wilson, 1985; Jamjanya and Quisenberry, 1988; Croughan and Quisenberry, 1989). These included Grazer, Tifton 78, Alicia, OSU 71 × 6-7, and two Brazos somaclones regenerated from tissue-culture-derived lines (R1 and R2). The grasses were oven dried (60°C) and milled (Wiley Mill, with a 1-mm sieve) prior to extraction. Crude extracts were obtained by sequential Soxhlet extraction with hexane, ether, and methanol typically with 40 g of each grass. Based on preliminary observations that suggested phagostimulant activity in the ether crude extract, this fraction was concentrated and the active component isolated by a bioassay-guided fractionation scheme. Initially, the crude extract was separated by adsorption silica gel (180 g) flash column chromatography (Still et al., 1978). The following solvents were used: hexane, a gradient (10–100% in 10% increments of CH_2Cl_2) of CH_2Cl_2–hexane, EtOAc, and MeOH. An active phagostimulatory fraction collected at 50% CH_2Cl_2 was separated into several components by reverse-phase preparative thin-layer and high-pressure liquid chromatography (RPTLC and HPLC). RPTLC was carried out on 1000 μm, 20 × 20 cm, Whatman PLKC 18F plates with MeOH. The active fraction was isolated at $R_f = 0.44$ and further purified by HPLC (Waters Delta Prep HPLC). HPLC was performed on a Waters 100 Å Delta Pak C-18 preparative column with a solvent flow rate of 80 ml/min (210 psi) monitored at 254 nm. Phagostimulant activity was observed to a peak $R_t = 2.3$ min. All fractions were concentrated under reduced pressure with a rotary evaporator.

Fractions from each cultivar were subjected to analyses by gas chromatography (GC) with flame ionization detectors (Waters Dimension 1 gas chromatograph). The conditions for GC analyses with a 30-m DB-5 megabore capillary column included a temperature program of 40°C/1 min, 20°C/min to 285°C (hold) with a He flow rate of 6 ml/min at a detector sensitivity of 16×10^{-12}. All samples were additionally analyzed on a more polar capillary column (DB-225) to confirm sample separation and identity.

The active HPLC isolate was subjected to GC-mass spectrometry (70 eV, Hewlett Packard 5890 Series 2 mass spectrometer) for structural identification. The mass fragmentation pattern was indicative of a saturated ketone (*m/e* 58, C_3H_6O) and was unambiguously identical to published spectra of 6,10,14-trimethylpentadecan-2-one (Ikan et al., 1973).

An authentic sample of this material was prepared by oxidative cleavage of 3,7,11,15-tetramethyl-2-hexadecen-1-ol with $NaIO_4/KMnO_4$ (Lemieux and von Rudloff, 1955). Phytone was purified by phase separation of the acidified product into ether, which was then concentrated and separated by flash silica gel 60 column chromatography using a CH_2Cl_2–hexane gradient. Phytone was eluted at 50% CH_2Cl_2–hexane, 60% yield (TLC $R_f = 0.7$, silica gel with 10% EtOAc–CH_2Cl_2). The structure was confirmed through GC-MS, which yielded

an identical spectra to that published as well as that found in Bermuda grass. In addition, capillary GC of coinjected active isolate from Bermuda grass and synthetic phytone yielded a single peak at 13.00 min. Final identification of this molecule was based on the identity of authentic samples with unknowns both in terms of GC retention times and MS fragmentation patterns.

Bioassays. Fractionated material from each cultivar, HPLC isolate, or synthetic phytone were adsorbed onto cellulose followed by solvent removal under reduced pressure with a rotary evaporator. Solvent-treated cellulose served as the control. The treated cellulose was then mixed into the modified meridic diet to effect a final concentration equivalent to a gram of tissue extracted for silica gel column and HPLC fractions. Phytone was impregnated onto cellulose to effect a final concentration of 1 and 10 ppm in the diet. A larva was incubated in a polystyrene cup (29.7 ml) with 1.5 g of diet and each treatment had 16 replicates. Bioassays were conducted with freshly eclosed fall armyworm larvae (1 mg initial weight) at 26.7 $\pm$ 0.5°C, 16:8-hr photoperiod, >50% relative humidity. Larvae were weighed subsequently at four, six, and eight days post-treatment.

Choice Tests. First-instar fall armyworm larvae were tested for their response to phytone in a choice assay at concentrations of 0.01, 1, and 10 ppm. The assay consisted of placing diet pellets with and without phytone equidistant from each other in a divided Petri plate (15 $\times$ 1.5 cm) and releasing a larva in the center of the dish. Pellets without phytone were solvent-treated and served as controls. The plates were sealed with parafilm and incubated under identical conditions as described for bioassays. Twenty replicates were tested simultaneously for each treatment. The larvae were then observed as to their feeding preference at 48 hr.

Statistics. Bioassay data were analyzed as a randomized block design using PC-SAS (SAS Institute, 1985). Significant treatment means were separated using Duncan's multiple-range test (Duncan, 1955). Choice test data were analyzed using Student's *t* test (Steel and Torrie, 1980).

RESULTS

Silica gel adsorption chromatography of crude Soxhlet-extracted Bermuda grass cultivars yielded a fraction (50% CH_2Cl_2–hexane) that stimulated a significant increase in fall armyworm larval body weight accumulation (Table 1). However, there were significant differences observed in response among the cultivars and somaclones tested. Larval weight accumulation for established cultivars Grazer, Tifton 78, Alicia, and OSU 71 $\times$ 6-7 displayed a 30–40% increase in comparison to somaclones derived from Brazos (10–15%) by day 8.

Further fractionation of this active phagostimulatory isolate from Grazer

by preparative reverse-phase TLC and HPLC yielded a single peak that induced a 33% increased larval weight accumulation (Table 1). This response was identical to larvae fed diet treated with synthetic phytone. Capillary GLC analyses of the active silica gel fractions from each cultivar with respect to the molecule identified from the HPLC isolate (phytone) revealed a variability of the concentration of the molecule ranging from 0.15 to 43 ppm (Table 2, Figure 1).

[a]Means within a column followed by the same letter are not significantly different ($P = 0.05$, $df = 144$, Duncan's multiple-range test) (Duncan, 1955).
[b]HPLC isolate of phytone was at 1 ppm of diet.

TABLE 2. CONCENTRATIONS OF PHAGOSTIMULANT PHYTONE IN BERMUDA GRASS CULTIVARS AND SOMACLONES

Bermuda grass cv.	Phytone concentration (ppm)[a]
Grazer	43
Tifton 78	25
OSU 71 × 6-7	3
Alicia	1.5
Brazos R1	0.3
Brazos R2	0.15

[a]Concentration of phytone was determined for each Bermuda grass cultivar and somaclone using fatty acid ester standards. Phytone was identified from each cultivar by its identity of GLC R_t values and mass spectral fragmentation pattern with an authentic sample.

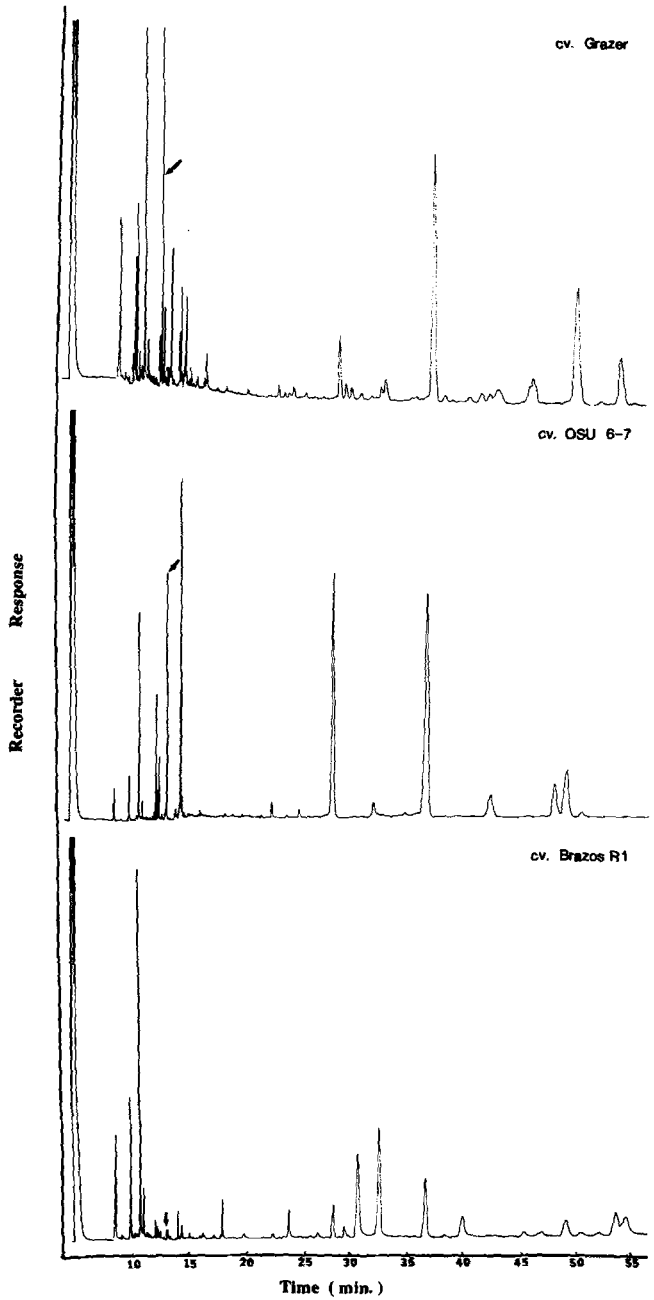

FIG. 1. Capillary GLC analyses of phagostimulant flash column adsorption chromatography fraction from three Bermuda grass variants. Variability in the concentration of phytone (R_t = 13.00 min, indicated by arrows) from equivalent masses of sample (50 mg).

GC-MS of the phagostimulant isolate indicated a long-chain saturated ketone with an *m/e* of 268 (Figure 2). The mass spectral pattern of this molecule was identical to 6,10,14-trimethylpentadecan-2-one (phytone) (Ikan et al., 1973). Oxidative cleavage of the allylic alcohol [3,7,11,15-tetramethyl-2-hexadecen-1-ol (phytol)] yielded an authentic preparation of phytone with an identical mass spectra and GC retention time (13.00 min) in comparison with the phagostimulant isolate from Bermuda grass.

Bioassays of fall armyworm larvae in choice tests elicited a preferential

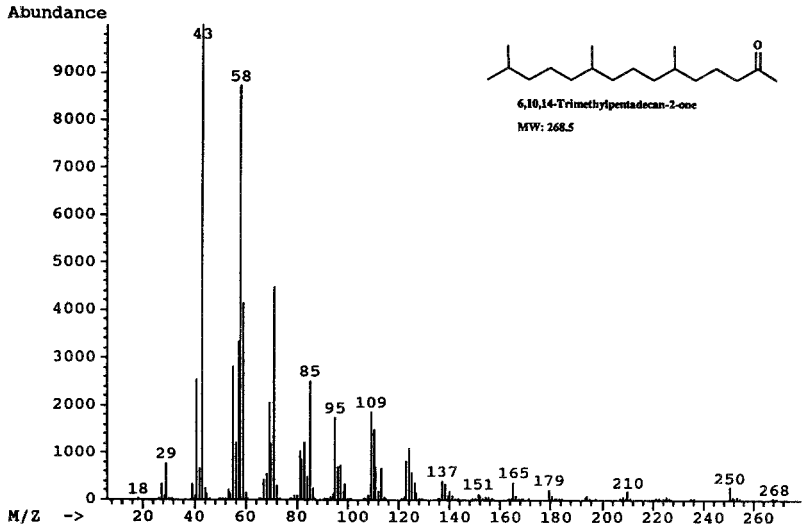

FIG. 2. Electron impact mass spectra of the fall armyworm phagostimulant, phytone, isolated from Bermuda grass.

TABLE 3. RESPONSE OF FALL ARMYWORM FIRST-INSTAR LARVAE IN CHOICE ASSAY WITH BERMUDA GRASS PHAGOSTIMULANT, PHYTONE

Phytone conc. (ppm)	Larvae (%)[a]	
	Treated	Untreated
0.01	75a	25b
0.1	90a	10b
1.0	90a	10b

[a] Phytone was applied topically to diet pellets and larvae were monitored 48 hr postreatment. Means within a row followed by the same letter are not significantly different ($P = 0.01$, $df = 19$, Student's t test) (Steel and Torrie, 1980.)

response from diet pellets treated topically with phytone (Table 3). That is, larvae consistently preferred diet to which phytone was topically applied.

DISCUSSION

A phagostimulant, 6,10,14-trimethylpentadecan-2-one, was isolated and identified from Bermuda grass. This molecule, at concentrations as low as 1 ppm, was found to influence larval food choice as well as larval growth patterns, responses typical of phagostimulants (Mori, 1982). Indeed, choice assays with and without this ketone indicate a preference for the former by the fall armyworm larvae. In addition, meridic diet supplemented with a fraction from six Bermuda grass variants containing phytone at variable concentrations led to significant gain in larval weights that was cultivar dependent. Brazos somaclones, with phytone concentrations less than 1 ppm, stimulated larval weight gains that were not significantly different from controls. Cultivars such as Grazer, Tifton 78, Alicia, and OSU 71 × 6-7, with phytone concentrations ranging from 1.5 to 43 ppm, did display significant weight gain increases. Given the fact that these body mass increases among the cultivars were not significantly different, it would seem that phagostimulation of fall armyworm larvae by phytone is more of a threshold effect. That is, an optimal concentration of 1 ppm is sufficient to stimulate an excess larval feeding response, although larvae are capable of detecting phytone in concentrations as low as 0.01 ppm in choice tests.

While these studies support the idea that phytone in Bermuda grass influences host selection and suitability by fall armyworm, the degree of resistance seems driven by a quantitative variation of this phagostimulant with respect to feeding deterrents. Bioassays of total and fractionated extracts from several Bermuda grass variants by Quisenberry et al. (1988) suggest the occurrence of allelochemics with variable antibiotic properties to fall armyworm (Mohamed and Quisenberry, unpublished data). Our results are consistent with current thought on the relationship of different of secondary plant metabolites and their the final feeding response of insect herbivores. That is, host choice by insects is determined by a balance of chemosensory information from negative and positive stimuli (Jermy, 1966; Schoonhoven, 1968; Dethier, 1982).

Phytone has been documented previously in marine algae (Rao and Pullaiah, 1982) and lavender oil (Kaiser and Lamparsky, 1983). This ketone also was reported as a major component of the male crab, *Carcinus maenas*, androgenic glands, functioning as an inhibitor of ovarian vitellogenesis (Ferezou et al., 1976).

The occurrence of a somewhat volatile phagostimulant in fall armyworm preferred host, Bermuda grass, may account for the highly mobile nature of this insect. It is possible that migration patterns of both adult and larval stages may

be influenced by phytone. Volatile phagostimulants have been proposed for use in crop management schemes, a notable success is the control of corn rootworms (*Diabrotica barberi* Smith & Lawrence and *D. undecimpunctata howardi* Barber) with curcurbacitin baits treated with insecticides (Gould, 1991). In this vein, phytone may be potentially useful in a trap crop, as a general attractant, or a synergist to fall armyworm sex pheromone.

Acknowledgments—We would like to acknowledge the technical assistance of Bobbie Watson, Mindy Berteau, Stephanie Warner, Jamie Gautreau, Reginald Thompson, and Mark Muegge. Bermuda grass somaclones were provided by Suzan Croughan, Rice Research Station, Crowley, Louisiana. We thank Drs. J.B. Graves, T.J. Riley, R.N. Story, and F.S. Guillot for their critical reviews. This manuscript is approved for publication by the Director of the Louisiana Agricultural Experiment Station as manuscript 91-17-5407.

(Received August 19, 1991; accepted December 18, 1991)

Abstract—Both the neutral and acidic fractions of the acetone extract of yellow fieldcress (Kireha-inugarashi, *Rorippa sylvestris* Besser) inhibited lettuce seed germination. Salicylic, *p*-hydroxybenzoic, vanillic, and syringic acid were identified in the acidic fraction. In the neutral fraction, hirsutin (8-methylsulfinyloctyl isothiocyanate), 4-methoxyindole-3-acetonitrile, and pyrocatechol were identified. Bioassay using a root exudate recirculating system showed *R. sylvestris* during flowering inhibited the lettuce seedling growth. Hirsutin (13 μg/plant/day) and pyrocatechol (9.3 μg/plant/day) were the major compounds released into the rhizosphere. Several combinations of pyrocatechol, *p*-hydroxybenzoic acid, vanillic acid, and hirsutin reduced lettuce seedling growth. These compounds seemed to be allelochemicals.

Key Words—Allelopathy, *Rorippa sylvestris*, weeds, salicylic acid, *p*-hydroxybenzoic acid, vanillic acid, syringic acid, hirsutin, 4-methoxyindole-3-acetonitrile, pyrocatechol, root exudate.

INTRODUCTION

A cruciferous weed species, *Rorippa sylvestris* Besser (yellow fieldcress, Kireha-inugarashi in Japanese) has been naturalized in Hokkaido since the 1950s and is considered to be one of the worst weeds in wet fields and pastures (Morita, 1981). The weed has strong propagative power and invades the territories of other plant species. It may be allelopathic against neighboring plants.

R. sylvestris contains hirsutin in the roots, which inhibits lettuce growth (Kawabata et al., 1989). Isothiocyanates in cruciferous plants play an important role as inhibitors of plant growth in addition to their antimicrobial activity (Harborne, 1988). These sulfur-containing compounds are usually found in macerated tissues due to mixing of the precursor glucosinolates and the hydrolytic enzyme thioglucosidase (Olsen and Sørensen, 1981).

Allelopathic inhibition of seed germination and plant growth typically occurs by the joint action of several allelochemicals. Additive or synergistic effects have been reported with combinations of monoterpenes, organic acids, and several classes of phenolic compounds (Einhellig, 1987; Williams and Hoagland, 1982).

Many studies of possible allelopathic effects on germination and growth have been dealt with using crude plant extracts or soil leachates, which make it difficult to discern the active principle in plant–plant interactions. For this reason, we used a bioassay with a root exudate recirculating system to explore the inhibitory constituents in the rhizosphere of *R. sylvestris* against lettuce growth. Inhibitory activities of pure compounds, singly and in combination, against lettuce seedling growth were also tested.

METHODS AND MATERIALS

Plant Collection and Extraction. Fresh roots of *Rorippa sylvestris* Besser (yellow fieldcress) were collected on the Hokkaido University campus in August 1988. The fresh roots (5.4 kg) were extracted with acetone for one month at room temperature. The filtered extract was concentrated under reduced pressure, and the aqueous concentrate was acidified with HCl (1 N), followed by extraction with ethyl acetate. The ethyl acetate extract was further divided into an acidic and a neutral fraction. From the aqueous residue, a basic fraction was obtained in the usual way. The basic fraction did not show any significant activity against lettuce.

Bioassay of Inhibitory Activity against Lettuce. A lettuce (*Lactuca sativa* L.) seed germination bioassay was used to examine the inhibitory activity of each extract, chromatographic fraction, or isolated compound. An appropriate amount of each of the samples was dissolved in 0.5 ml of acetone, and the solution was poured into a 6-cm Petri dish with two sheets of filter paper (No. 3, 5.5 cm, Toyo Roshi Co., Ltd.) placed on the bottom. Acetone was evaporated and 2 ml of water containing 100 ppm (w/v) Tween-80 was poured into the Petri dish. The dishes were covered and kept in the dark for 24 hr at room temperature to allow samples to dissolve completely and avoid light reaction. Thirty lettuce seeds were placed on the filter paper and incubated at 23°C in the dark. Germination percentages were recorded after 24 hr incubation. A

control with water containing 100 ppm (w/v) Tween-80 was included in each experiment. Each experiment was duplicated.

A lettuce seedling growth bioassay was used to determine the activity of the isolated compounds. The compound was dissolved in 150 μl of acetone and mixed into 15 ml of hot agar solution (0.35% w/v) in a Petri dish. The agar solution was cooled and 20 germinated lettuce seedlings (24 hr after germination) were placed in each dish. The dishes were covered and kept in a growth chamber (23°C, 12 hr dark and 12 hr light). The hypocotyl and root lengths for each seedling were measured at the end of one week. Mean hypocotyl and root lengths were determined for 20 seedlings (two replications). A control was included in each experiment.

Fractionation and Identification of Acetone Extract. The acidic fraction was subjected to silica gel column chromatography using hexane, ethyl acetate, and methanol as eluents. The hexane–ethyl acetate (1:1, v/v) eluate inhibited lettuce seed germination by 79% at 200 ppm (w/v). Further purification of this fraction by silicagel preparative thin-layer chromatography (TLC) using chloroform–methanol (2:1, v/v) as a mobile phase yielded compound I. Compound I was characterized by EI-MS, [^{1}H]NMR, and IR spectra, which were identical with those of authentic salicylic acid.

The hexane–ethyl acetate (2:3,v/v) eluate inhibited lettuce seed germination by 32% at 200 ppm (w/v). Compounds II, III, and IV were isolated from this eluate by silica gel preparative TLC. Compound II had a mp of 220–221°C and EI-MS, [^{1}H]NMR, UV, and IR spectra that were identical with those of authentic *p*-hydroxybenzoic acid. Compound III had a mp of 215°C and EI-MS, [^{1}H]NMR, UV, and IR spectra that were identical with those of authentic vanillic acid. Compound IV (colorless needles, 2.0 mg) had EI-MS, [^{1}H]NMR, and IR spectra that were identical with those of authentic syringic acid.

The neutral fraction including phenolics, which contained hirsutin (compound VII) (Kawabata et al., 1989), inhibited lettuce seed germination by 90% at 1000 ppm. Compound V (buff-colored needles, 45.9 mg) was isolated by silica gel preparative TLC (R_f = 0.78, developed with $CHCl_3$–MeOH, 20:1, v/v) and had a mp of 143°C. FD-MS *m/z*: 186 (M^+, 100%), EI-HR-MS *m/z*: M^+, 186.0797 ($C_{11}H_{10}N_2O$ requires 186.0793); EI-MS *m/z* (%): 186 (M^+, 90), 171 (100), 155 (8), 143 (13), 130 (4), 116 (13), 101 (4), 89 (12), 75 (4), 63 (7), 51 (4). The [^{1}H]NMR, [^{13}C]NMR, UV, and IR spectra were identical with those of authentic 4-methoxyindole-3-acetonitrile. Compound VI (colorless needles, 9.7 mg) was also isolated by silica gel preparative TLC (R_f = 0.46, developed with $CHCl_3$–MeOH, 10:1, v/v) and had a mp of 103.5°C. Compound VI had FD-MS, EI-MS, [^{1}H]NMR, UV, and IR spectra, which were identical with those of authentic pyrocatechol.

Bioassay Using Root Exudate Recirculating System. A bioassay using a root exudate recirculating system was performed following the method of

Stevens and Tang (1985). Donor pots containing *R. sylvestris* and acceptor pots containing lettuce seedlings were made from 1-gal brown glass bottles with the bottoms cut off. Both donor and acceptor pots contained coarse grade silica sand as the medium, with a 10-cm layer of small rock (2 cm size) under the sand. The sand in acceptor pots was topped with 1 cm of vermiculite to maintain moisture. Nutrient solution (Tadano and Tanaka, 1976) from the donor pot was lifted through 8-mm-diameter glass tubing to the acceptor pot using an air pump. Containers and glass tubings were wrapped with aluminum foil to exclude light. The solution was circulated at a rate of about 0.8 liters/hr. In the resin control pot, hydrophobic allelochemical compounds were removed from the recirculating solution using an XAD-4 column (18 × 120-mm glass column packed with 10 g Amberlite XAD-4 polymeric adsorbent resin). Treatments consisted of *R. sylvestris* as a donor species, *R. sylvestris* with a column containing XAD-4 (resin control), and a donor pot without the weeds (pot control). *R. sylvestris* plants (fresh weight ca. 50 g) were established in donor pots, and 30 lettuce seedlings (24 hr after germination) were planted in acceptor pots. Nutrient levels were maintained, and pH kept at 5.5 with H_2SO_4. Recirculating solution was not changed during the experiment except for replenishing water and nutrient solution. Lettuce seedlings were removed 14 days after beginning the bioassay, and plant heights, root lengths, and fresh weights of aerial parts and subterranean parts (two replications) were determined.

Quantification of Allelochemical Candidates in Recirculating Solution. Hydrophobic substances (100 μg) trapped with XAD-4 resin were eluted with acetone. Residual water was removed azeotropically by several additions of methanol. After 200 μl of pyridine and 100 μl of *N,O*-bis(trimethylsilyl)acetamide were added to the sample, the glass tube containing the reaction mixture was sealed with a polyethylene stopper and heated in an oil-bath at 80°C for 30 min (Schulz and Herrmann, 1980). 1-Octanol (15 μl) was then added to the sample as an internal standard and the trimethylsilylated sample was analyzed with gas chromatography [1.5% Silicone OV-17 on Uniport HP (80–100 mesh), 1 m].

Hirsutin was determined by adding 50 μl of methylene chloride and 3 ml of 20% ammoniacal ethanol (1 part concentrated NH_4OH and 4 parts anhydrous ethanol) to a portion (1 mg) of the total substances trapped with XAD-4 resin and heating the mixture for 2 hr at 50°C in a water bath (Wetter and Young, 1976). After cooling, the optical density was measured at 230, 259, and 304 nm (λ_{max} values of hirsutin–phenylthiourea). The blank was 50 μl of methylene chloride in 3 ml of 20% ammoniacal ethanol. On TLC chromatogram, hirsutin was found to be only one isothiocyanate.

Bioassay of Combined Compounds. Six combinations of two compounds (pyrocatechol plus *p*-hydroxybenzoic acid, pyrocatechol plus vanillic acid, pyrocatechol plus hirsutin, *p*-hydroxybenzoic acid plus vanillic acid,

p-hydroxybenzoic acid plus hirsutin, and vanillic acid plus hirsutin) with the concentration of each component 0.9×10^{-4} M, four combinations of three compounds (pyrocatechol plus *p*-hydroxybenzoic acid plus vanillic acid, pyrocatechol plus *p*-hydroxybenzoic acid plus hirsutin, pyrocatechol plus vanillic acid plus hirsutin, and *p*-hydroxybenzoic acid plus vanillic acid plus hirsutin) with the concentration of each component 0.6×10^{-4} M, and all compounds combined (pyrocatechol plus *p*-hydroxybenzoic acid plus vanillic acid plus hirsutin) with the concentration of each component 0.45×10^{-4} M were tested to determine their effects on lettuce seed germination. This total concentration (1.8×10^{-4} M) used in the bioassay represents a reasonable biological test level for the comparison of naturally occurring phytotoxic chemicals.

Analysis of Data. Differences among means were calculated using Duncan's multiple range test at the 5% level of probability. This allowed the effect of each compound, combined compounds, and the recirculating solution, including substances trapped with XAD-4 resin, to be examined.

RESULTS AND DISCUSSION

Both the neutral and acidic fractions of the acetone extracts inhibited lettuce seed germination (data not shown). Salicylic, *p*-hydroxybenzoic, vanillic, and syringic acid were isolated from the acidic fraction (Figure 1). At 200 ppm,

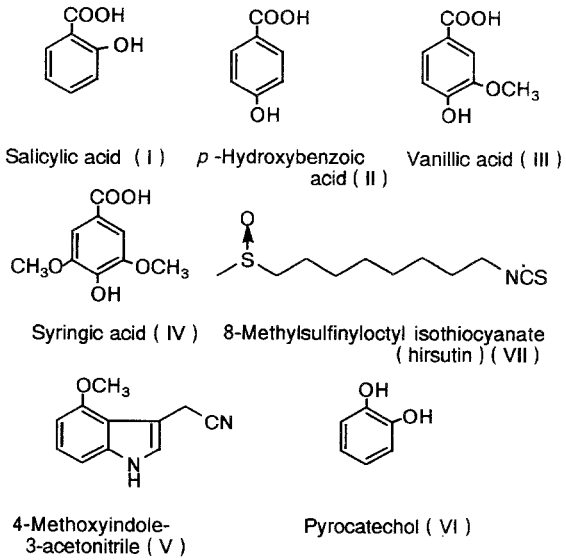

FIG. 1. Chemical structures of allelochemical candidates in the text.

these phenolic acids inhibited germination at 100, 100, 93, and 57%, respectively. Many phenolic compounds are inhibitory to seed germination or plant growth (Kuiters, 1989). In some instances, these compounds affect fundamental plant processes such as hormonal balance, protein synthesis, photosynthesis, chlorophyll production, plant–water relations and membrane permeability (Einhellig, 1986).

In addition to hirsutin, 4-methoxyindole-3-acetonitrile and pyrocatechol were isolated from the neutral fraction (Figure 1). 4-Methoxyindole-3-acetonitrile and pyrocatechol inhibited the germination at 200 ppm (w/v) by 12% and 100%, respectively. 4-Methoxyindole-3-acetonitrile had been isolated from the clubroots of Chinese cabbage (*Brassica pekinensis*) (Nomoto and Tamura, 1970), but this is the first report of this compound in *R. sylvestris*.

We have examined the effect of removing the hydrophobic substances using XAD-4 resin from the root exudates of *R. sylvestris* on lettuce seedling growth. Differences between the resin control and the pot control (no *R. sylvestris*) were presumed to be the results of inhibition by hydrophilic root exudates, while differences between the resin control and *R. sylvestris* were presumed to be caused by hydrophobic root exudates. Differences between *R. sylvestris* and the pot control represent the total allelopathic effect.

Root exudates inhibited lettuce seedling growth in June, July and August (Table 1). These were the flowering stages of *R. sylvestris*. However, for March

and November bioassays, lettuce seedling growth was not inhibited (Table 1). These periods were the vegetative growing stages of *R. sylvestris*. Aerial parts of the lettuce plant were more sensitive than the subterranean parts to the inhibition (Table 1). These responses were probably caused by the accumulation of toxic root exudates, as nutrient solution was not changed during the experiments.

Hydrophobic root exudates (XAD-4 versus control) inhibited growth of acceptor lettuce seedlings in the July and August bioassays (Table 1). The rate of hirsutin, pyrocatechol, vanillic acid, and *p*-hydroxybenzoic acid released from *R. sylvestris* roots in July and August was 13.0, 9.3, 1.1, and 0.7 μg/plant/day, respectively (data not shown). Recently, we (Mizutani and Yamane, 1991) reported that the content of precursor glucosinolates (glucohirsutin and deoxyglucohirsutin) increased during the vegetative growing stage and the flowering stage of *R. sylvestris*, suggesting that the content of glucosinolates may relate to the content of hydrophobic root exudate (hirsutin) and the bioassay results on this report. Deoxyhirsutin, which has no activity against lettuce, is another possible isothiocyanate, but we could not detect deoxyhirsutin in the hydrophobic root exudate.

Tang and Takenaka (1983) reported that for 2-month-old *Carica papaya* L. the rate of benzyl isothiocyanate release from the root system was 2–3 μg/tree/day in a continuous root exudate trapping system. This herbicidal secondary metabolite was released from the undisturbed plant root system.

Einhellig (1987) reported that allelopathic inhibition of germination and plant growth typically occurs from the joint action of several allelochemicals. Thus, the potential impact of an allelochemical on plant growth should be evaluated with regard to both the presence of associated allelopathic compounds and the influence of other chemical and physical conditions in the environment.

Several combinations of pyrocatechol, *p*-hydroxybenzoic acid, vanillic acid, and hirsutin reduced lettuce seedling growth (Table 2). Pyrocatechol plus *p*-hydroxybenzoicacid, pyrocatechol plus vanillic acid, pyrocatechol plus hirsutin, and *p*-hydroxybenzoic acid plus hirsutin significantly reduced lettuce hypocotyl elongation. From the combination effect (total inhibition rate of the single test divided by constituent number of combination), pyrocatechol plus *p*-hydroxybenzoic acid significantly reduced hypocotyl elongation, while the other combinations produced slight or insignificant effects.

On the other hand, several combinations showed significant effects on root elongation of lettuce seedlings. The combinations of pyrocatechol plus *p*-hydroxybenzoic acid and pyrocatechol plus vanillic acid, pyrocatechol plus *p*-hydroxybenzoic acid plus vanillic acid, and the combination of all four compounds increased root elongation. Among these, the combination of pyrocatechol plus *p*-hydroxybenzoic acid at 230% over the control was the most

effective. These data suggest an auxin effect observed in the lettuce root growth bioassay at low concentrations of phytotoxic compounds (Manners and Galitz, 1985).

Our investigation clearly shows several phenolic compounds and hirsutin to be potent phytotoxins to developing lettuce seedlings and suggests that these compounds are allelochemical compounds in plant–plant interactions.

Acknowledgments—We wish to thank Mrs. Y. Misu for [^{1}H]NMR and [^{13}C]NMR spectral measurements, and we are also grateful to Mr. K. Watanabe and Mrs. Y. Sugiyama for mass spectral measurements.

Abstract—The European grapevine moth (EGVM), *Lobesia botrana*, is a major pest of grapes in Europe. Females are attracted to a nonhost plant: tansy (*Tanacetum vulgare* L.), which is a common weed in Slovakian vineyards. A steam distillate extract of tansy flowers was analyzed by means of a GC-EAG technique to screen constituents detected by the olfactory receptors of EGVM females. From more than 200 GC peaks, nine peaks corresponding to monoterpenoids released an EAG response in more than 70% of the females (N = 15): *p*-cymene, *d*-limonene, α-thujene, α-thujone, β-thujone, thujyl alcohol, terpinene-4-ol, (*Z*)-verbenol, and piperitone. The steam distillate of tansy as well as a synthetic blend of identified compounds released consistent attraction in a field cage. The use of nonhost plants and host plant odors in integrated pest management is discussed.

Key Words—*Lobesia botrana*, *Vitis vinifera*, *Tanacetum vulgare*, tansy,

INTRODUCTION

The role of host plant odors mediating different behaviors has received much attention for monophagous and polyphagous insects. It has been suggested that host-specific molecules as well as more commonly occurring compounds are used by phytophagous insects to identify their host plants (Finch, 1980; Visser, 1986; Masson and Mustaparta, 1990).

The European grapevine moth (EGVM), *Lobesiabotrana* Den. et Schiff., represents one of the most important pests of vineyards in Europe. This insect is considered a polyphagous insect restricted to a narrow range of plants belonging to different families (Stoeva, 1982). Olfaction seems to play an important role in its colonization patterns. The attraction of adults has been observed in response to fermented wine and fruit odors (Feytaud and Bos, 1914; Roussel and Vonderheyden, 1964). In nature, EGVM females are strongly attracted to tansy, *Tanacetum vulgare* L. (Gabel, 1992). This attraction appears to be sexually selective, since males are seldom observed on this plant, and has been attributed to volatiles emitted by the flowers (Gabel et al., 1991). Tansy is not considered to be a host plant of the EGVM nor a rendezvous site for mating (Gabel, 1992).

Tansy is a wild species of Compositae growing in temperate regions. In Slovakian vineyards, the absence of herbicide usage favors the natural occurrence of this plant within vineyard rows and at the borders. More than 30 chemotypes of tansy have been reported worldwide according to the major constituents belonging to monoterpenes and sesquiterpenes (Nano et al., 1979; Holopainen et al., 1987).

In this paper, we report on the detection of tansy flower volatiles by EGVM females and the attractiveness of a reduced mixture of these volatiles. We also discuss the potential use of tansy and nonhost plant odors in integrated control programs.

METHODS AND MATERIALS

Plant Extract. Flowers of tansy (without the pedicel) were collected along vineyard borders and stored at $-15°C$. Tansy flowers were steam distilled using a distillation–extraction device modified after Likens and Nickerson (Pharmacopea Bohemoslovaca, 1987). Flowers (440 g) were extracted in 1 liter of

distilled water. The solvent-free fraction corresponding to the first 2 hr of distillation was collected and used for the experiments.

Insect Material. A laboratory strain of EGVM from INRA Pont-de-la-Maye, annually infused with wild insects from Bordeaux vineyards (France), was reared on a semisynthetic diet under controlled conditions (16:8 hr light–dark; 22°C ± 1°C; 60% relative humidity). Two-day-old, mated females were used for electrophysiological recordings.

Gas Chromatography–Electroantennography Coupling. A gas chromatograph (GC) was equipped with an on-column injector, a 5-m-long deactivated fused silica megabore precolumn, a 30-m-long fused silica megabore DB-5 column (5% phenyl-, 95% methyl-pyloxane), a deactivated Y-shaped fused silica outlet splitter heated at a constant temperature (250°C), and a flame ionization detector (FID) (split ratio = $\frac{2}{3}$ towards the antenna) (see Thiéry et al., 1990, for details). The carrier gas was helium. The temperature was raised linearly at 5°C/min from 40°C up to 250°C. Molecules eluted from the column were blown into a humidified stream of purified air: air speed = 20 cm/sec, flow diameter = 0.8 cm. The relative concentration of each constituent was expressed as a percentage of the sum of all the peaks after subtraction of the solvent peak area.

Electroantennograms (EAG) were recorded from 15 females. Isolated heads of EGVM were mounted between the recording electrode covering the tip of the antenna and the indifferent electrode inserted in the clypeus. EAG and GC signals were stored on a microcomputer using custom software. GC peaks that elicited an EAG response in more than four individuals were subsequently chemically identified.

Identification. Identification of chemicals was performed by GC–mass spectrometry (GC: HP 5890II; MS: HP5971A). Identifications were based on electron impact ionization (EI, 70 eV). The mass spectra obtained were compared to spectra from the NBS Database and confirmed by injection of standard chemicals when available.

Bioassay. The attractiveness of the steam distillate and of a blend of the chemicals identified through the GC-EAG analysis were tested in a field cage with an artificial population of EGVM. A row of vine grapes (Cabernet Sauvignon cultivar) was covered under a tunnel made of P17 tissue (polypropylene, 0.17 mm thickness, SODOCA S.A.R.L., France) (length = 12 m, height = 2.5 m, width = 3 m). Five traps designed for EGVM females (Gabel, 1990) were used: one control, two baited with tansy extract, and two baited with the synthetic blend. The traps were placed evenly within the row, 1 m above the ground. Exchangeable trapping plates were coated with Bird Tanglefoot glue (Tanglefoot Co., Michigan). Males (N = 738) and mated females (N = 592) were released in the cage. The number of insects recaptured was counted each morning during five consecutive days. The odors were released from a glass

TABLE 1. MOLECULES RELEASING EAG IN MORE THAN 11 OF 15 *Lobesia botrana* FEMALES[a]

Molecule	Amount (%)	EAG response (in mV ± SD)
p-Cymene	0.27	0.16 ± 0.05
d-Limonene	0.03	0.19 ± 0.08
α-Thujene	0.28	0.20 ± 0.08
α-Thujone	1.05	0.33 ± 0.16
β-Thujone	78.34	0.67 ± 0.28
Thujyl alcohol	0.64	
Terpinen-4-ol	0.75	0.29 ± 0.07
(*Z*)-Verbenol	4.33	0.30 ± 0.10
Piperitone	6.35	0.25 ± 0.10

[a]Identifications by GC-MS (electron impact ionization), mass spectra compared to reference spectra (NBS Database) and confirmed by injection of standards.

tube (1 cm diam.) filled with either the extract of tansy (1 ml) or a blend of monoterpenes (1 ml) in the proportions expressed in Table 1. The monoterpenes used in the synthetic blend were of GC standard quality: *p*-cymene, thujyl alcohol, piperitone, terpinen-4-ol (INRA, Dijon, France), *d*-limonene and (*Z*)-verbenol (Fluka), isomers of thujone (Pharmaceutical Faculty, Bratislava, CSFR). α-Thujene was not available.

RESULTS AND DISCUSSION

Steam distillation of tansy flowers yielded an extract in which over 200 peaks were detected by the GC analysis. The GC-EAG method was used as a screening procedure to locate the most active fractions and compounds of this complex blend. Only 24 GC peaks released measurable EAG responses in 27% of the females. Nine peaks elicited responses in 70% of the females (Figure 1). These peaks are monoterpenes: *p*-cymene, *d*-limonene, α-thujene, α-thujone, a blend of β-thujone and thujyl alcohol, terpinen-4-ol, (*Z*)-verbenol, and piperitone.

EAG responses closely matched the corresponding GC peaks (Figure 1). This relationship was true for the major peak (β-thujone) where the EAG response was maintained until end of the peak tail (Figure 1). Responses were observed during the release of thujyl alcohol, which occurred while the antenna was still recovering from the stimulation of β-thujone. Improved separation or classical EAG studies are needed to confirm if thujyl alcohol stimulates the olfactory receptors of EGVM females. Both major and minor compounds released EAG

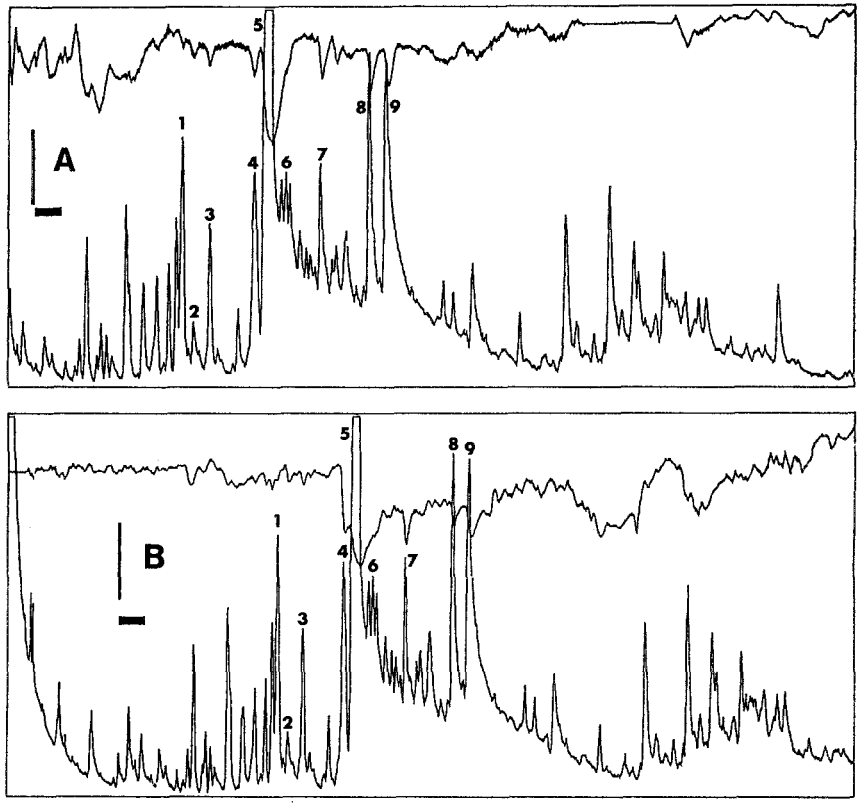

FIG. 1. GC-EAG recordings of two females of *Lobesia botrana* in response to tansy extract. Upper trace = EAG, lower trace = FID signal. 1 = *p*-cymene, 2 = *d*-limonene, 3 = α-thujene, 4 = α-thujone, 5 = β-thujone, 6 = thujylalcohol, 7 = terpinen-4-ol, 8 = (Z)-verbenol, 9 = piperitone. Horizontal bar = 100 sec; vertical bars—A: 1 mV, B: 2 mV.

responses in EGVM females (Table 1). The detection of chemicals at low concentrations within plant extracts suggests an important biological activity of these substances.

The biological activity of eight of the nine monoterpenes [*p*-cymene, *d*-limonene, α-thujone, a blend of β-thujone and thujyl alcohol, terpinen-4-ol, (Z)-verbenol, and piperitone] identified in the tansy flowers were compared to the steam distillate (Figure 2). A total of 28.4% of the released females were recaptured in the traps (2.6% in the control, 15.5% with the steam distillate, and 10.3% with the synthetic blend). Low temperature (13.5°C) and high wind speed (15 m/sec) reduced the effectiveness of the traps during the first night. We assumed that tansy odors were effective only against females. For this reason

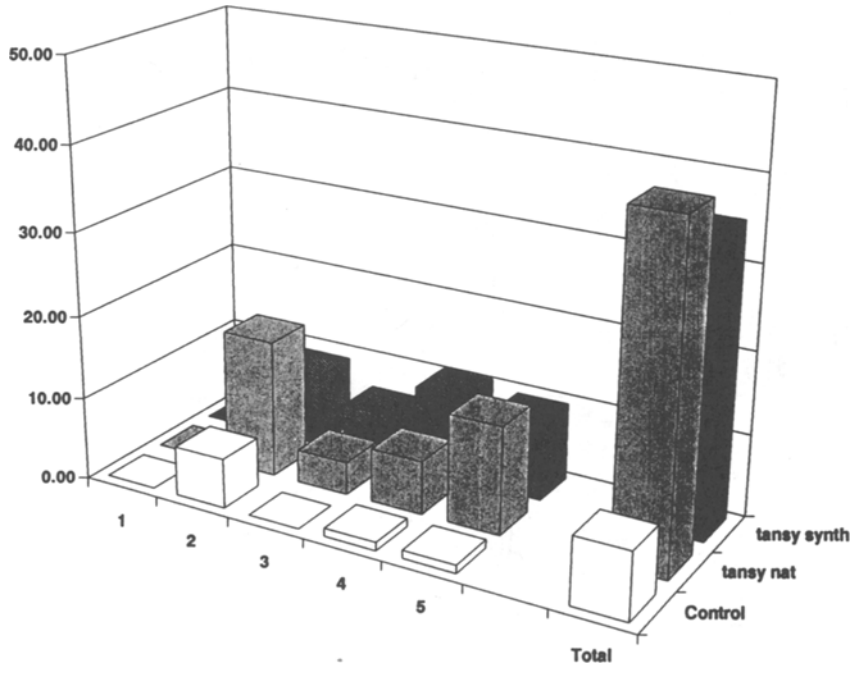

FIG. 2. Daily number of *Lobesia botrana* females caught in two different odorant traps (5 days): white bars = control, grey bars = tansy steam distillate, striped bars = synthetic blend.

we have used a type of trap especially designed to catch females (Gabel, 1990). However, males (22%) were also recaptured, possibly attracted by sexual pheromones emitted from the trapped females (Gabel and Stockel, 1988). Catching females with tansy extracts confirmed previous reports on the attractiveness of natural populations of EGVM females by tansy plants (Gabel, 1992). At the concentration used, our synthetic blend was almost as attractive as the steam distillate. α-Thujene was lacking in the synthetic blend used. The role of this chemical as well as different concentrations of the reduced blend have now to be tested.

Terpenic compounds have been tested as possible trapping agents against EGVM by Stellwaag and Götz (1937), but their results were inconclusive mainly for methodological reasons. Except for thujone, most of the monoterpenes used in our trapping experiments are present in flower or leaf extracts of grapevines (Schreier et al., 1976). These data suggest that such molecules are involved in olfactory recognition of plants by EGVM females.

Other volatile compounds, such as general green leaf volatiles, might con-

tribute to the olfactory recognition in the EGVM. Chemical analysis of various grapevine cultivars reported that green odor volatiles were emitted from leaves and immature grapes [e.g., 1-hexanol, (*E*)-2-hexen-1-ol, (*Z*)-3-hexen-1-ol, (*E*)-2-hexenal] (Kepner and Webb, 1956; Wildenradt et al., 1975; Schreier et al., 1976; Shimizu and Watanabe, 1981). Such chemicals are produced at low concentration in Compositae flowers (Rudlof, 1963; Etiévant et al., 1984; Flath et al., 1985; Souleles and Stamatakou, 1991). In our experiments, we could not demonstrate whether the females detect these substances. Other distillation methods should be used to extract and concentrate such chemicals.

The attraction of EGVM females towards a nonhost plant on which oviposition and feeding was never observed raises an exciting ecological question. Olfactory detection of major terpenoids of tansy suggests that females might search for tansy-specific chemicals. However, the exact role of tansy in the biology of EGVM is not yet understood. Tansy flowers and nectar might provide a food source needed by females for egg maturation (Stoeva, 1982). Tansy has long been used for various pharmaceutical and toxicological purposes (Chandler et al., 1982; Dembitskii et al., 1984). It is therefore possible that the occurrence of females on tansy flowers is related to pharmacophagy as demonstrated in the Lepidoptera (Boppré, 1984).

Nonhost plant odors can interfere with the perception of the particular blend used by an herbivore and modify its orientation (Thiéry and Visser, 1986, 1987). Tansy has been reported to alter colonizing patterns of different insect species. Observations made on the flea beetle, *Phyllotreta cruciferae*, indicated that tansy inhibits adult colonization (Latheef and Ortiz, 1984). Essential oils of tansy have also been proposed as repellents against aphids in orchards (Dembitskii et al., 1984) and Colorado potato beetle (Schearer, 1984). In the cabbage worm, *Pieris rapae*, tansy increases the number of eggs laid on crop plants, whereas in the cabbage looper, *Trichoplusia ni*, the effect was the reverse (Latheef and Ortiz, 1983). In the case of EGVM, the odor produced by tansy could be used to (1) interfere with the orientation of females to their host, (2) lure females outside the vineyards, (3) monitor the population dynamics, or (4) directly control the population by mass trapping. The reduced blend of monoterpenes that evoked significant electrophysiological and behavioral activity for the EGVM, must now be tested for its behavior-evoking activity in larger scale experiments in vineyards.

Acknowledgments—The authors are grateful to Roger Roerich, INRA Bordeaux, France, for supplying insects, and to Jean Luc Le Quéré, Laboratoire INRA de Recherches sur les Arômes, Dijon, France for providing pure standards. We thank Frank Zalom, University of California, Davis, for linguistic assistance. Bruno Gabel was supported by a grant from the French Ministry of Foreign Affairs (MRI). The trapping experiments were made at the Service of Plant Protection (S.P.V.) Carcassonne, France.

(Received August 19, 1991; accepted December 23, 1991)

Abstract—Femoral gland secretions were collected from 21 captive adult male green iguanas (*Iguana iguana*) in Orotina, Costa Rica, and San Diego, California, during the breeding (November) and nonbreeding (March) seasons. Lipids were extracted with methylene chloride, weighed, separated by thin-layer chromatography, and analyzed by gas chromatography–mass spectrometry. Free and esterified C_{14}–C_{26} fatty acids, 5β-cholestan-3α-ol (epicoprostanol), cholest-5-en-3β-ol (cholesterol), cholest-5-en-24-methyl-3β-ol (campesterol), cholesta-5,22-dien-24b-ethyl-3β-ol (stigmasterol), cholesta-8,24(5α)-dien-4,4,14α-trimethyl-3β-ol (lanosterol), cholest-5-en-24-ethyl-3β-ol (β-sitosterol), and two uncharacterized sterols were indicated. lipids were recovered from femoral gland secretions obtained during the breeding than the nonbreeding months, indicating that secretion deposits may be more detectable during the mating season.

Key Words—Femoral glands, lipids, fatty acids, sterols, pheromones, *Iguana iguana*.

INTRODUCTION

Femoral glands are secretory structures located on the ventral surface of the hindlegs of many lizards (Cole, 1966). These glands are most active during the breeding season and usually are better developed in males than in females. Femoral gland secretions, which contain lipids and proteins (Gasc et al., 1969; Weldon et al., 1990; Alberts, 1990, 1991), elicit increased tongue-flicking in iguanid lizards (Duvall, 1986; Alberts, 1989), and may function in conspecific recognition and home-range marking (Alberts, 1992). The location of the glands on the underside of the hindlegs probably facilitates deposition of secretions onto the substrate during locomotion (Fergusson et al., 1985).

A number of studies indicate that femoral gland activity is modulated by androgenic hormones. In several lizard families, increased femoral gland size and productivity are positively associated with testicular activity (Regamey, 1935; Atland, 1941; Van Wyk, 1990), whereas castration results in glandular atrophy (Matthey, 1929; Regamey, 1932; Padoa, 1933). Fergusson et al. (1985) demonstrated that exogenous testosterone stimulates femoral gland activity in the ornate dragon, *Amphibolurus fordi*. In male green iguanas, *Iguana iguana*, femoral gland productivity is positively correlated with endogenous plasma testosterone levels throughout the year (Alberts et al., 1992). Regulation of secretory activity by androgens is commonly observed in mammalian scent glands known to produce pheromones (Ebling, 1977).

The green iguana is a large lizard inhabiting trees along rivers and streams in neotropical lowland forests. In the wild, large dominant males defend territories, usually occupied by several females and subordinate males (Dugan, 1982; Rodda, 1992). Courtship begins at the end of the rainy season in October and November and is followed by mating at the beginning of the dry season (Rand and Greene, 1982). The presence of a well-developed olfactory epithelium and vomeronasal organ (Gabe and Saint Girons, 1976; Schwenk, 1992) indicates that green iguanas probably detect volatile and nonvolatile chemicals. Tongue-flicking, which could deliver odorants to the vomeronasal organ or facilitate gustatory reception, occurs at a high frequency in both wild and captive green iguanas (Burghardt et al., 1986).

Adult male iguanas possess prominent femoral glands, while those of females are greatly reduced (Lazell, 1973; Rodda, 1991). Behavioral and phys-

iological studies with captive green iguanas indicate that femoral gland secretions may play an important role in establishing and maintaining dominance relationships among males during the breeding season (Alberts et al., 1992). We report here on seasonal differences in the lipid composition of femoral gland secretions in male green iguanas. In addition, we examine individual variation in lipid composition among males.

METHODS AND MATERIALS

Femoral gland secretions were collected from 15 adult male green iguanas at the Fundacion Pro Iguana Verde in Orotina, Costa Rica, in November 1989 and March 1990 and from six adult male green iguanas in a captive colony at the Zoological Society of San Diego, California, in December 1989. The Costa Rica iguanas originally came from a wild population in Panama and the San Diego iguanas from a wild population in Belize. Samples were obtained by applying gentle manual pressure around the openings of four femoral pores (Figure 1) and removing secretion plugs with small forceps. Samples were placed in glass vials containing several milliliters of methylene chloride. Secretion plugs were macerated with a metal spatula, filtered to remove insoluble components, and dried under N_2. The lipid residue was allowed to desiccate

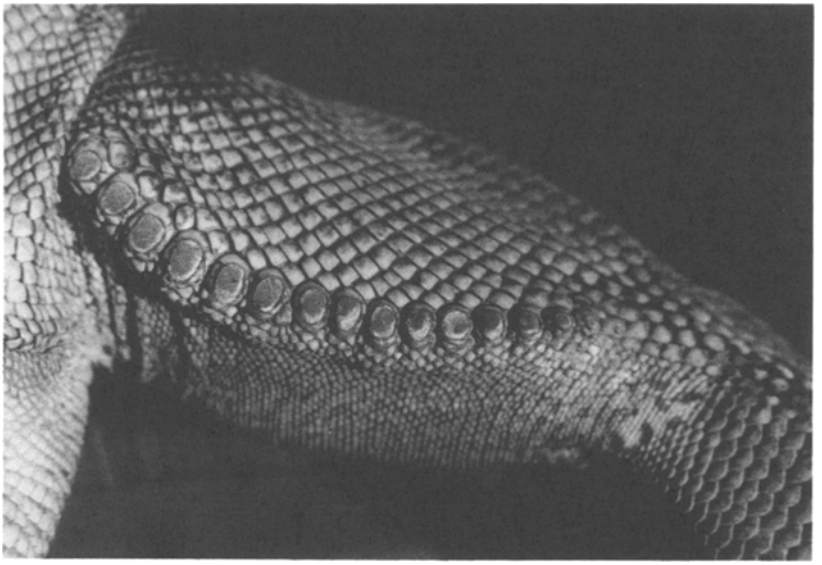

FIG. 1. A row of femoral glands on the ventral surface of the hindleg of an adult male green iguana. The diameter of the largest femoral pore is approximately 4.5 mm.

overnight, and then was weighed and redissolved in hexane. All samples were stored at −80°C. Samples collected from the 15 males in the Costa Rica colony were pooled for each of the two collections.

Aliquots of each pooled sample from the breeding and nonbreeding seasons (400 μg each) were applied to 0.25-mm preparative thin-layer chromatography (TLC) plates of silica gel 60G and resolved by successive development in hexane, toluene, and hexane–diethyl ether–acetic acid (80:20:2, v/v). Mixed nonpolar lipid standards (Nu-Chek-Prep, Elysian, Minnesota) were developed in an adjacent lane. Fractions from the region to which each of the five lipid standards migrated (cholesterol, R_f 0.25; oleic acid, R_f 0.43; triolein, R_f 0.60; methyl oleate, R_f 0.70; cholesteryl oleate, R_f 0.83) were eluted from each plate with diethyl ether. The six samples from the San Diego colony were not fractionated by TLC due to the limited material available from individual males.

All fractions eluted from TLC plates, except the sterol fraction, were converted to methyl esters by transesterification prior to analysis by gas chromatography–mass spectrometry (GC-MS) (Long et al., 1988). The sterol and steryl ester fractions were converted to trimethylsilyl derivatives by adding 200 μl Tri-Sil silylating agent (Pierce, Rockford, Illinois) and allowing them to equilibrate at room temperature for at least 30 min. The unfractionated pooled secretions from Costa Rica and the six individual samples from San Diego were transesterified and then trimethylsilylated prior to GC-MS analysis. Two microliters of each sample were injected into a Hewlett-Packard model 5995C GC-MS system with ultrapure helium as the carrier gas (DB-5 column, 30:1 split injection). The temperature program for the column was: T_{initial} = 180°C/1.0 min, programmed at 5°C/min, T_{final} = 350°C/0 min.

The mass spectrum of each compound evident on the gas chromatograms was obtained. The retention index of each compound was calculated based on retention time relative to that of the normal hydrocarbon series C_{15}–C_{25}, C_{28}, C_{32}, C_{36}. Lipids were identified by comparison of retention indices and mass spectra of derivatives with those of authentic standards and published data in the National Bureau of Standards mass spectral data base.

RESULTS AND DISCUSSION

Our results confirm the presence of a diversity of lipids in the femoral gland secretions of male green iguanas (Weldon et al., 1990), and document several previously unreported compounds (Table 1). Saturated C_{14}–C_{26} and unsaturated C_{16}–C_{24} fatty acids were identified. Hexadecanoic acid was the most abundant fatty acid, followed by C_{20}, C_{18} and its unsaturated homologs, and C_{22}. Saturated C_{15}–C_{25} fatty acids were detected in trace amounts. A series of eight sterols was also evident, six of which were identified: 5β-cholestan-3α-ol (epicoprostanol),

Tetracosenoic acid	394	2700	0.67	0.78
Tetracosanoic acid	396	2730	2.67	2.72
Pentacosanoic acid	410	2829	0.15	<0.01
Hexacosanoic acid	424	2934	0.30	0.44
Epicoprostanol	388	3098	2.33	1.38
Unknown sterol I	384	3160	1.28	1.42
Cholesterol	386	3192	6.54	8.39
Unknown sterol II	402	3201	0.83	0.94
Campesterol	400	3305	7.41	6.08
Stigmasterol	412	3332	1.25	0.86
Lanosterol	426	3393	11.06	17.24
β-Sitosterol	414	3408	1.11	1.08

cholest-5-en-3β-ol (cholesterol), cholest-5-en-24-methyl-3β-ol (campesterol), cholesta-5,22-dien-24b-ethyl-3β-ol (stigmasterol), cholesta-8,24(5α)-dien-4,4,14α-trimethyl-3β-ol (lanosterol), and cholest-5-en-24-ethyl-3β-ol (β-sitosterol). Unknown sterol I (retention index = 3160) had a molecular weight two mass units less than cholesterol, and its mass spectrum shared many characteristics with that of cholesterol. This suggests that it is similar in structure to cholesterol but contains an additional unsaturation site. Unknown sterol II (retention index 3201) exhibited a structure similar to and a molecular weight 14 mass units greater than epicoprostanol, suggesting that it differs from epicoprostanol by possessing an additional methyl group.

The most abundant sterol in the secretions during both the breeding and nonbreeding seasons was lanosterol, followed by cholesterol and campesterol. The remaining five sterols were detected at much lower concentrations. Some of these sterols may be dietary in origin. Like many iguanine lizards, green iguanas are herbivorous throughout their lives (Van Devender, 1982). Campesterol, stigmasterol, β-sitosterol, and their respective esters, which together represented approximately 10% of total lipids by weight, typically occur in plants (Goodwin, 1985).

Seasonal variation in the lipid composition of green iguana femoral gland secretions was evident. During the breeding season, the mean percentage by weight of lipids in the secretions (35.10% $\pm$ 0.016) significantly exceeded that during the nonbreeding season (13.40% $\pm$ 0.007; Paired t test = 13.23, df = 14, P = 0.0001, arcsine square-root transformation). Although the overall relative abundances of fatty acid components showed little variation between the breeding and nonbreeding seasons (Table 1), there was considerable variation in the proportion of these acids in different lipid classes (Table 2). Most of the unsaturated acids in the free fatty acid, methyl ester, and triglyceride fractions occurred at a higher concentration during the breeding than the nonbreeding

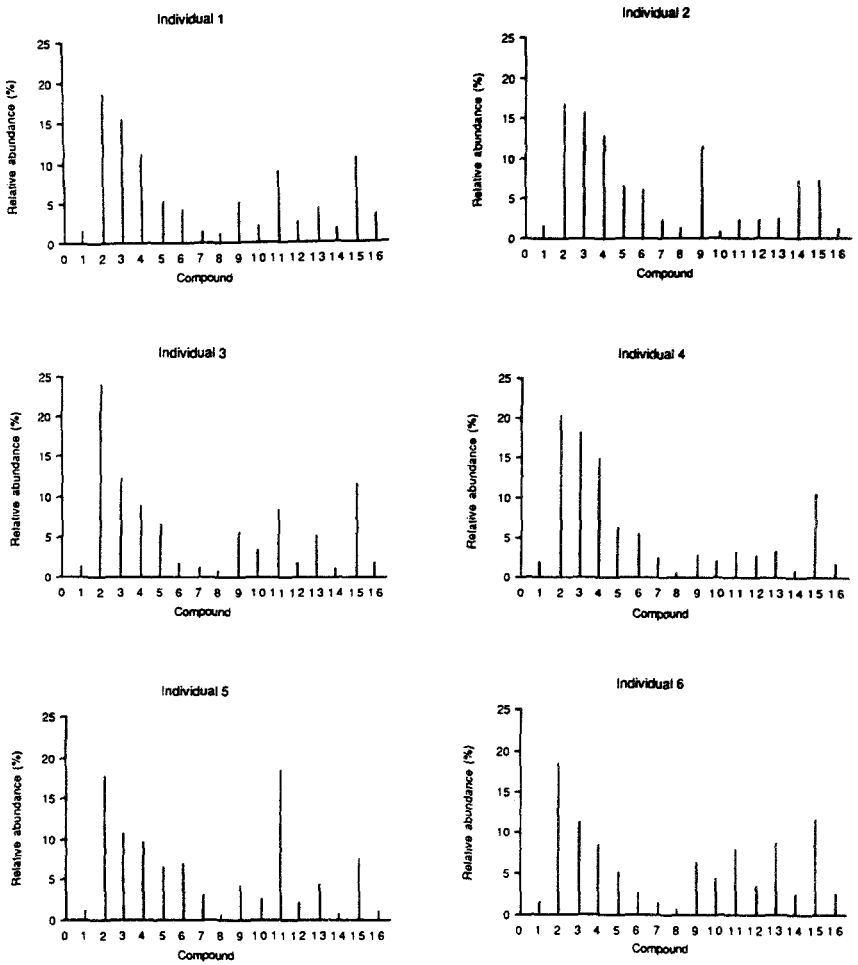

FIG. 2. Relative abundances of the following lipid compounds in the femoral gland secretions of six adult male green iguanas: 1 = tetradecanoic acid, 2 = hexadecanoic acid, 3 = octadecanoic acid, 4 = octadecenoic acid, 5 = octadecadienoic acid, 6 = eicosanoic acid, 7 = docosanoic acid, 8 = tetracosanoic acid, 9 = epicoprostanol, 10 = unknown sterol I, 11 = cholesterol, 12 = unknown sterol II, 13 = campesterol, 14 = stigmasterol, 15 = lanosterol, 16 = β-sitosterol.

season. Both the increased lipid content and greater unsaturation evident during the breeding season probably increase the volatility of femoral gland deposits. Higher volatility of secretions during the mating period may enhance the detectability of the secretions at the time of year when they are presumed to have their greatest utility.

Little individual variation was detected in the relative abundances of fatty acid components (Figure 2). The same eight acids were present in similar relative concentrations for the six individuals examined. Slightly more variation was evident among the sterol components, but cholesterol and lanosterol generally were the most abundant of these compounds. These results contrast with those reported for some mammals, in which individual variation in the lipid composition of glandular secretions, especially in fatty acid components, has been demonstrated and is hypothesized to function in individual recognition (e.g., Gorman, 1976).

Weldon et al. (1990) failed to detect differences in the femoral gland lipids of juvenile and adult male green iguanas, suggesting a lack of ontogenetic variability in lipid composition. Significant variation in the lipid composition of male and female secretions was not detected in the two lizards in which it has been examined, *Dipsosaurus dorsalis* (Alberts, 1990) and *Amphibolurus fordi* (Cogger, 1978). These studies suggest that, at least for these species, insufficient intraspecific variation exists for femoral gland lipids to permit individual recognition.

Results for femoral gland lipids of iguanas differ from those for femoral gland proteins, which exhibit individual variation, but no detectable seasonal variation (Alberts, Phillips, and Werner, unpublished data). It is possible that the lipids in green iguana femoral gland secretions permit initial detection of secretion deposits in the environment through the release of volatile compounds. After secretion deposits are localized, low volatility proteins may provide more information on the status and identity of the signaler. Secretions from more individuals need to be examined, and behavioral tests conducted to determine the degree to which chemical variation in different secretion components is perceived and utilized in social behavior.

Acknowledgments—We thank Yara Cerrud and Armando Batista of the Fundacion Pro Iguana Verde in Costa Rica and Nancy Pratt and John Phillips of the San Diego Zoo for help in collecting femoral gland secretions, and Daisy Rey for logistical support. FORMONONETIN 7-*O*-GLUCOSIDE (ONONIN), AN ADDITIONAL GROWTH INHIBITOR IN SOILS ASSOCIATED WITH THE WEED, *Pluchea lanceolata* (DC) C.B. CLARKE (ASTERACEAE)

INDERJIT and K.M.M. DAKSHINI*

Department of Botany
University of Delhi
Delhi 110007, India

(Received October 7, 1991; accepted December 23, 1991)

Abstract—Formononetin 7-*O*-glucoside (ononin), an isoflavonoid, was isolated from the soils of cultivated areas associated with the perennial weed, *Pluchea lanceolata*. Aqueous solutions of this compound inhibited significantly root and shoot growth of mustard at 1×10^{-4} M, 5×10^{-4} M, and 1×10^{-3}M. The level of inhibition was similar to that of hesperidin and taxifolin 3-arabinoside, as reported earlier. The potential allelopathic effect of this compound under field conditions is discussed.

Key Words—Allelopathy, Asteraceae, formononetin 7-*O*-glucoside, *Pluchea lanceolata*, weed.

INTRODUCTION

Our earlier observations established the presence of potential toxins in *Pluchea lanceolata* (DC) C.B. Clarke (Inderjit and Dakshini, 1990) and in its associated soils (Inderjit and Dakshini, 1991). Here, we describe a new potential toxin, the isoflavonoid, formononetin 7-*O*-glucoside (ononin) in soils associated with the weed. To learn whether or not this compound, like hesperidin and taxifolin 3-arabinoside reported earlier (Inderjit and Dakshini, 1991), was toxic, formononetin was tested against mustard seeds.

METHODS AND MATERIALS

Soils next to and away from (as control) the weed *Pluchea lanceolata* were collected from cultivated fields around the metropolitan city of Delhi. These soils, sandy loam, were air-dried at room temperature (25 ± 5°C), sieved (2 mm sieve), and stored in paper bags for 16 weeks prior to chemical analysis (Allen, 1989), identification, and characterization of phenolic constituents (Harborne, 1973). The chemical characteristics of associated soils were as follows: pH = 7.72 ± 0.23; electrical conductivity = 146.35 ± 76.15 μmho/cm; exchangeable PO_4 = 3.50 ± 2.06 (mg/100 g); Zn = 0.106 ± 0.093 (mg/100 g); Na = 63.6 ± 34.5 (mg/100 g); K = 21.32 ± 15.17 (mg/100 g); Mg = 23.32 ± 15.17 (mg/100g); Ca = 146.02 ± 138 (mg/100 g).

Extraction, Purification, and Identification of Phenolic Compounds. Twenty grams of soil was shaken for 1 hr with 100 ml of double-distilled water (DDW) at room temperature (25 ± 5°C). The soil extracts were then filtered and evaporated to dryness under vacuum. The residues were dissolved in 10 ml of methanol and chromatographed (Whatman No. 3, 46 × 57 cm), one dimension in butanol–acetic acid–water (BAW, 4:1:5, upper phase) following Harborne (1973). The developed chromatograms were then scanned under UV($-NH_3$) and UV($+NH_3$) and bands marked. Each of these bands was eluted in 10 ml of methanol, concentrated under vacuum, and again chromatographed on Whatman No. 3 in four solvent systems: BAW, DDW, 15% acetic acid, and forestal (conc. HCl–acetic acid–water, 3:30:10). After confirming the purity of these compounds, each was again concentrated and chromatographed on Whatman No. 3 and washed repeatedly with DDW through descending chromatography. Finally, these compounds were eluted from chromatograms with methanol and used for spectral analysis, acid hydrolysis, and acid–base shifts (NaOH, $AlCl_3$, $AlCl_3$–HCl, NaOAc, NaOAc–H_3BO_3) of parent as well as hydrolyzed fractions. R_f (×100) values (Whatman No. 1) and fluorescence (UV, UV+NH_3) of compounds in the four solvents were recorded. The aqueous layer of the hydrolyzed fraction was used for identification of the sugar moiety (Harborne, 1973). Additionally, the aglycone portion was cochromatographed with the authentic samples and the spectral data matched with that of authentic compounds (Mabry et al., 1970).

Mass Spectroscopy. Mass spectral value of the isolated compound was analyzed through a mass spectrometer (Jeol JMX 303), operated at an accelerator voltage of 3 kV and an ion source temperature at 280°C with scan speed of 100 m/e/sec.

Seed Germination and Growth Experiments. To evaluate the allelopathic potential of the isolated compound, germination and growth experiments were performed with various concentrations of aqueous solutions of the compound. *Brassica juncea* cv. PR 45, a common cultivated crop, was selected to assess

the allelopathic potential of the compound. Fifty seeds ($N = 3$) were sown in 15-cm-diam Petri plates on one layer of filter paper (Whatman No. 1), placed on a cotton pad, moistened with 60 ml of DDW (as control), or test solutions ranging from 1×10^{-4} M to 1×10^{-3} M (S1, S2, and S3). Germination percentages were calculated when no further germination occurred. Root and shoot length were recorded on the sixth day.

RESULTS AND DISCUSSION

The analysis resulted in the extraction of six compounds. Of these, two were common to the control as well as the weed-associated soils. Three of these compounds were taxifolin 3-arabinoside and hesperidin (Inderjit and Dakshini, 1991) and a phenolic acid. The fluorescence, R_f ($\times 100$) values, and absorption spectral data (Table 1); mass spectra showing presence of parent ion at 286.26; as well as glucose as sugar moiety confirm that a fourth compound isolated from associated soils of the weed *Pluchea lanceloata* is formononetin 7-*O*-glucoside (ononin).

Percent seed germination of mustard was not affected significantly by any of the formononetin test solutions (Table 2). However, root and shoot length were inhibited significantly ($P < 0.01$) by all concentrations except root length with S1 (Table 2). An increase in percent inhibition in root length by 18.11% and in shoot by 15.99% was recorded in S3 as compared to S1, showing that inhibition was concentration-dependent.

Formononetin 7-*O*-glucoside (ononin) has been reported in root extracts of *Baptisia australis*, *Glycyrrhiza uralensis*, *Hedysarum polybotrys*, *Ononis spinosa*, and *Trifolium pratense* and in leaves of *Cicer arietinum*, *Glycine max*, and *Trifolium polyphyllum* (Dewick, 1988). However, their availability in the soil and their allelopathic potential have not been determined. Chang et al. (1969) reported the presence of an isoflavonoid in red clover, but its presence in red clover-infested soils was not observed. They found that red clover soil sickness was due to various phenolic acids that were degradation products of isoflavonoids. However, in the present investigation the isoflavonoid formononetin 7-*O*-glucoside detected from the weed-infested soils remained persistent in saline–alkaline soils. Further, it remained stable after being stored for four months, thus suggesting that it is more potent allelopathically by itself as compared to its degraded constituents. The persistence of the isoflavonoid in the soil could be due to its antimicrobial activities (Kramer et al., 1984). However, whether formononetin 7-*O*-glucoside also possesses such characteristics and thus maintains toxic potential, needs further investigation. The mechanism(s) whereby isoflavonoid formononetin 7-*O*-glucoside interferes with the seedling growth of mustard is not clear. However, several suggestions on the effects of isoflavonoids

on physiological processes have been suggested by Koeppe and Miller (1974), Lang and Racker (1974), and Rice (1984). The fact that this isoflavonoid is released into the soil and inhibits the seedling growth of mustard shows that it is a potent allelopathic compound. Furthermore, its rapid leaching with water and persistence in the soil during storage ensure its presence in the soil prior to the sowing of seeds in the fields. The significance of such a release is relevant since this weed is perennial and maintains continuous availability of the compound along with the other allelochemicals. The present study not only establishes the allelopathic potential of the isoflavonoid formononetin 7-*O*-glucoside but also of the weed *Pluchea lanceolata* as it maintains a pool of not only formononetin, but also hesperidin and taxifolin (Inderjit and Dakshini, 1991) as three potential allelochemicals in the soil around its root zone.

Acknowledgments—We thank Professor M.R. Parthsarathy, Department of Chemistry, University of Delhi, for his help in identification of the compound. The financial assistance to one of us (Inderjit) from University Grants Commission (U.G.C.) and Council of Scientific and Industrial Research (C.S.I.R.) India, is gratefully acknowledged. We wish to thank Professor M.A.K. Lodhi, Missouri, and an anonymous reviewer for their valuable comments to improve the manuscript.

TANNIC ACID INHIBITION OF AMINO ACID AND SUGAR ABSORPTION BY MOUSE AND VOLE INTESTINE: TESTS FOLLOWING ACUTE AND SUBCHRONIC EXPOSURE

WILLIAM H. KARASOV,* MICHAEL W. MEYER, and BRUCE W. DARKEN

Department of Wildlife Ecology
University of Wisconsin
Madison, Wisconsin 53706

(Received July 22, 1991; accepted December 30, 1991)

Abstract—The acute effects of tannin (tannic acid; TA) on nutrient absorption were studied by measuring sugar and amino acid uptake across the brush border (luminal membrane) of intact intestine in the presence and absence of TA. Incubation of tissue for 4–9 min in TA solution (1 mg/ml) caused a reduction in passive influx of L-glucose in voles and mice and a reduction in carrier-mediated influx of D-glucose and total influx of L-proline in mice, but not voles. In subchronic experiments, mice and voles were fed for 7–14 days a diet with 4% TA, but there was no significant effect on intestinal brush border uptake of L-glucose, D-glucose, or L-proline (or three other amino acids tested in voles). In a synthesis of our study with others in the literature, three inferences are made from the patterns of effects across solutes, time scales of exposure, and species. First, the transport inhibitory effects following acute exposure are probably mediated by two processes: increased resistance to passive flux across an effective unstirred layer juxtaposed to the brush border membrane, perhaps due to tannin–mucin binding, and reduced Na^+-coupled nutrient uptake across the intestinal brush border. Second, there is a species sensitivity difference in TA's effect on the second process. Third, the negative effects observed at the acute time scale in vitro do not necessarily occur in animals eating TA subchronically because little TA reaches the luminal membrane, or if it does its effects are quickly reversed when the tissue is removed and washed with solution free of TA.

INTRODUCTION

Several plant secondary metabolites (PSMs) exhibit characteristics in vitro that suggest important effects on nutrient absorption in vivo. For example, lectins bind specific sugar residues located on the surface of cells, which can cause histological damage (Pusztai, 1979a,b) and impair food digestion (Banwell et al., 1983) and nutrient absorption (Jaffe and Camejo, 1961).

Tannins and phenolics are among the most widespread of the PSMs. Because they complex with natural polymers (for review, see Bernays et al., 1989), it has been suggested that they can act directly on gut enzymes and possibly tan the luminal membrane, thereby blocking nutrient absorption (Swain, 1979). Ingestion of certain varieties of the field bean (*Vicia faba*) containing polyphenolics is associated with reduced sugar and amino acid absorption in chickens (Santidrian et al., 1981). Extracts from the field bean containing polyphenolics reduced D-glucose absorption in vivo in rat ileum (Motilva et al., 1983).

The hydrolyzable tannin, tannic acid, has been the most studied polyphenolic. In rats it was found to erode the mucosal lining of the gastrointestinal tract (Mitjavila et al., 1977) and inhibit enterocyte metabolism (Mitjavila et al., 1968). In isolated rat brush border membrane, tannic acid inhibits sucrase activity (Welsch et al., 1989a) and D-glucose transport (Welsch et al., 1989b).

In this study, we tested for effects of acute and subchronic exposure of tannic acid on intestinal nutrient absorption in laboratory mice and a wild herbivore, the prairie vole (*Microtus ochragaster*). We chose tannic acid because it is an effective protein-binding agent (Bernays et al., 1989) and is more inhibitory to glucose transport than other phenolics that have been tested (Welsch et al., 1989b). We were interested in four issues.

First, we wondered whether the past findings of reduced glucose absorption in response to acute exposure to tannins applied under in vivo conditions. No studies in mammals (to our knowledge) have tested for effects of subchronic ingestion of dietary tannic acid on intestinal absorption, which is the most natural manner of exposure of the enterocytes to a secondary metabolite.

Second, we were interested in tannic acid's possible effects on amino acid absorption. This is practically unstudied even though tannins are known to reduce apparent protein digestion in some cases (Mole and Waterman, 1987).

Third, intestinal nutrient uptake into enterocytes occurs across several barriers by several processes, and we sought to determine which barriers and processes were affected by tannic acid. The barriers are either an unstirred water layer or the mucous coat (Smithson et al., 1981), which are juxtaposed to the

intestinal brush border membrane barrier. The processes include passive and carrier-mediated transport, the latter sometimes Na^+-dependent (hence active). To discriminate among these barriers and processes we used several solutes as probes (see below).

Finally, we considered it important to test another species besides laboratory rats or mice. The generality of tannic acid effects is uncertain, and other studies have documented traits in some animals that ameliorate the potential effects of tannins in the gut (e.g., high gut pH, presence of surfactants, secretion of parotid proteins; reviewed in Bernays et al., 1989).

METHODS AND MATERIALS

Animals. Prairie voles (*Microtus ochrogaster*) were obtained from an outbred colony maintained at the University of Illinois, Urbana. The original stock for the colony was live-trapped in nearby oldfield habitats. Laboratory mice (*Mus musculus*) 8–10 weeks old, were obtained from Sprague-Dawley, Indianapolis, Indiana. Both species were housed in plastic shoebox cages, maintained on a 15:9 hr light–dark regime at 21 ± 2°C, and fed and watered ad libitum. Mice and voles in the acute studies ate standard rodent chow (Purina Formulab), supplemented with alfalfa pellets (Purina Lab Rabbit Chow) in the case of the voles. The tannic acid content of these diets was negligible (unpublished observations). In subchronic studies, both species were fed ad libitum experimental diets with or without tannic acid (TA) (and lacking other PSMs that might be in rodent or rabbit pellets) for 7–14 days. Seven days is adequate for mice to acclimate to TA-containing diets (Freeland et al., 1985).

Experimental Diets. The experimental diets (Table 1) were based on formulations designed specifically for voles (Lindroth et al., 1984), but they were also satisfactory for mice if the fiber content was lowered (personal observation). Therefore, fiber level was set at 15% (Table 1), although in one study with voles it was 40%.

The level of TA incorporated into the diet, 4% (Sigma Chemical Co., St. Louis, Missouri), was chosen because it was enough to cause reduced apparent digestive efficiency but not so much as to cause mass loss and thus nonspecific decline in intestinal structure and function. At 4% there was no significant decrease in daily food intake of either species and both species ate enough to maintain body mass (personal observation; below), whereas at 6% TA mass gain was reduced in voles (Lindroth and Batzli, 1984). Furthermore, apparent protein digestibility was reduced at 4% TA in the mice (Meyer, 1989) and somewhere between 3% and 6% in the voles (Lindroth and Batzli, 1984). The added TA displaced an equal volume of sucrose and corn starch.

TABLE 1. COMPOSITION OF SYNTHETIC DIETS

Component	Components (g/kg diet)
Casein[a]	115.0
DL-Methionine[a]	5.0
Corn starch[a]	252.4
Sucrose[a]	207.0
Fiber[b]	150.0
Corn oil[a]	72.2
Vitamin[a,c]	16.6
Mineral mix[a,d]	16.6
$CaCO_3$[e]	9.4
$Ca(H_2PO_4)_2 \cdot H_2O$[d]	5.8
Tannic acid[d,f]	***

[b] Purified cellulose (solka-floc).
[c] Vitamin mix catalog No. 40060.
[d] Rodent mineral mix catalog No. 79055; custom mineral mix for lagomorphs = 11.94 g $KHCO_3$, 8.55 g K_2HPO_4, 5.0 g NaCl, 3.32 g MgO, 0.9 g $FEC_6H_5O_7$, 0.1 g $MnSO_4 \cdot H_2O$, 0.06 g $ZnCO_3$, 0.04 g $CuSO_4$, 0.004 g $CoCl_2 \cdot 6H_2O$, 0.004 g KIO_3.
[e] Ingredients from Sigma Chemical, St. Louis, Missouri.
[f] In experimental diets, tannic acid (40 g/kg) replaced equal mass of sucrose.

Uptake Measurements. In both mice and voles we measured the uptake of two sugars (L-glucose and D-glucose) that have different utility in discriminating changes in nutrient transport processes. We considered L-glucose at trace concentration a probe for changes in epithelium that affect primarily passive transport (Karasov and Diamond, 1983). These might include change in surface area, permeability of the brush border membrane (bbm) to hydrophilic organic solutes, and resistance of the mucous or unstirred layer adjacent to the membrane to passive solute flux. The mucous/unstirred layer and the brush border membrane constitute two series resistances to solute uptake (see Karasov and Diamond, 1983, and references therein).

We considered D-glucose at saturating concentration a probe for changes in epithelium that affect either the stereospecific glucose transporter or the electrochemical gradient that energizes the Na-coupled transport. This is so for two reasons: (1) because our technique for measuring D-glucose uptake, using L-glucose as a simultaneous marker for adherent glucose and passive glucose uptake (Karasov and Diamond, 1983), yields a measure of the mediated, stereospecific transport of glucose, and (2) because when the membrane transporters are saturated the membrane becomes the primary resistance to glucose uptake and the relative importance of the mucous/unstirred layer diminishes (Karasov and Diamond, 1983).

We also measured the total uptake of L-proline (Pro) in both mice and voles, and three additional solutes [L-leucine (Leu), L-lysine (Lys), and L-aspartate (Asp)] in voles. These four amino acids are transported by the four Na^+-dependent amino acid transporters in vertebrate intestinal brush border membrane (Karasov, 1988). Total uptake of amino acids includes carrier-mediated and nonmediated (passive) pathways. In some cases the uptake of the amino acids was partitioned into its Na-dependent and Na-independent components using Na-free solutions (below).

The preparation for measuring solute uptake across the brush border (not transepithelial flux) was an excised, everted sleeve of intestine 1-cm long, cut from the proximal, middle, and distal small intestine, and secured to a rod with the intestinal mucosa pointing outwards (Karasov and Diamond, 1983). Measurements were begun around noon to reduce effects of any diurnal rhythm in uptake. Rodents were anesthetized (ca. 0.1 ml sodium pentabarbital) and the small intestine isolated and perfused with ice cold Ringer solution. Solution composition (in mM) was 128 NaCl, 20 $NaHCO_3$, 4.7 KCl, 2.5 $CaCl_2$, 1.2 KH_2PO_4, and 1.2 $MgSO_4$, gassed with 5% CO_2–95% O_2 to yield pH 7.3–7.4, osmolarity 290 mosm.

In experiments testing for an effect of acute exposure, TA was added at a concentration of 1 mg/ml (i.e., 0.1%) because this concentration has been shown to reduce glucose uptake in isolated bbm vesicles (Welsch et al., 1989b) and in perfused intestine (Mitjavila et al., 1970) and because higher concentrations are difficult to solubilize (personal observation). In comparison, during the subchronic feeding trials actual luminal concentration was probably ≤ 8 mg TA/ml because the diet concentration was 40 mg TA/g food and the ratio of food to water in the intestinal lumen was 0.201 ± 0.031 g/ml ($N = 4$) (hence $40 \times 0.201 = 8$). The actual luminal TA concentration, however, may be lower due to the hydrolysis of TA to gallic acid and glucose in the acidic stomach or binding to dietary or endogenous protein (below). In these acute experiments 10 mM HEPES was used as the buffer, and KOH was added to yield a final pH of 7.4. In the control solutions (also buffered with HEPES and KOH), mannitol (ca. 10 mM) was added instead of TA and both solutions had a final osmotic pressure of 290 mosm.

Sleeves were kept in ice cold mammalian Ringer bubbled with 5% CO_2–95% O_2 until an uptake measurement was made. After a preincubation for 5 min in Ringer at 37°C with or without 0.1% TA, the sleeve was incubated for 1–4 min at 37°C in a stirred (1200 rpm) solution containing radioactive tracers with or without 0.1% TA. In those solutions that contained 0.1% TA, bubbling with O_2 probably favored oxidation of TA; a color change to yellow was observed. However, in rats both oxidized and reduced forms of TA inhibit D-glucose transport to the same extent (Welsch et al., 1989b).

Incubation times to yield unidirectional uptake rates were chosen as 1 min

for D-glucose, 4 min for L-glucose, and 2 min for amino acids (L-proline, Pro; L-leucine, Leu; L-lysine, Lys; L-aspartate, Asp) based on our previous studies with mice (Karasov and Diamond, 1983) and results of validation experiments with voles described in the Appendix.

In studies of passive uptake of L-[1-^{3}H[N]]glucose (New England Nuclear), [*carboxyl*-^{14}C]inulin (ICN) was used to correct for L-glucose in adherent fluid. In studies of carrier-mediated uptake of D-[6-^{3}H]glucose (20–40 Ci/mmol; Amersham), L-[1-^{14}C]glucose (30–40 mCi/mmol; Amersham) at trace concentration was used to correct simultaneously for D-glucose in adherent fluid and for D-glucose taken up passively. In studies of total uptake (i.e., sum of carrier-mediated and passive uptake) of L-[2,3-^{3}H]Pro (American Radiolable), L-[4,5-^{3}H]Leu (ICN), L-[G-^{3}H]Lys (ICN) and L-[2,3-^{3}H]Asp (ICN), [*carboxyl*-^{14}C]inulin (ICN) was used to correct for amino acid in fluid adhering to the tissue.

Following incubations, tissues were rinsed or blotted (Karasov and Diamond, 1983), and 1-cm lengths of tissue were removed from the rods for weighing, solubilization, and scintillation counting (Karasov and Diamond, 1983). Other details about measurement of uptake in voles are provided in the Appendix.

Carrier-mediated D-glucose uptake was measured at 50 mM, a saturating concentration in vertebrate intestine studied with the everted sleeve preparation (Karasov, 1988). Uptake at 25 mM Pro was measured in mice because at this concentration the Pro uptake is 75% Na^+-dependent and nearly maximal (the transporter is nearly saturated; Karasov et al., 1986). This concentration was also used in voles, but because Na^+-dependence was lower (below), we also used a concentration of 0.01 mM Pro at which more of the uptake was Na^+-dependent. Pro uptake kinetics had not previously been characterized in voles, and so this was studied in the voles also.

Morphometric Measurements. To test for changes in intestinal gross morphology that may have resulted from TA diet, we measured three intestinal parameters in all rodents: (1) intestinal length (to the nearest 0.5 cm) from pylorus to the ileal–cecal junction, (2) intestinal wet mass per centimeter ($\pm$0.1 mg), and (3) proportion that mass of scraped mucosa bears to mass of whole intestinal thickness, measured by cutting a 2-cm piece of intestine and scraping off the mucosa with a glass slide and determining its dry mass ($\pm$0.1 mg) and that of the remaining tissue. We report most nutrient uptake rates normalized to 1-cm length of intestine, which we consider physiologically most meaningful. However, for studying treatment effects on uptake rates using adjacent tissues from within an animal, we also normalized uptake rates to milligrams of wet mass as recommended by Karasov (1988). To estimate the summed uptake rate of the entire length of the small intestine for each solute, we interpolated rates

linearly between successive positions along the intestine and then summed over the small intestine length.

Statistical Analysis and Presentation of Data. Results are given as means ± SE (N = number of rodents unless indicated otherwise). For comparisons of single measures between control and experimental tissues from within individual voles, paired t tests were performed. For comparisons of single measures between voles, Student's t test was used. Simultaneous tests for effects of intestinal position on parameters within voles, and diet effects on parameters between voles, were determined by a repeated measures ANOVA followed by Tukey's honest significant difference (HSD) test. A one-tailed test was used for testing the a priori hypothesis that incubation in the presence of TA reduces nutrient uptake. The $P < 0.05$ level was considered significant.

For fitting uptake rates to kinetic models to derive kinetic parameters, and for comparing kinetics of uptake rates in different diet groups, we used the procedures recommended by Motulsky and Ransmas (1987). Kinetic models included: (1) simple diffusion; $J = P[S]$ where J = uptake, $[S]$ = substrate concentration, P = permeability coefficient; and (2) diffusion plus one mediated system; $J = P[S] + J_{max}[S]/(K_m + [S])$ where J_{max} = maximal uptake rate, K_m = the transport constant such that $K_m = [S]$ when $J = J_{max}/2$.

RESULTS

Tests for Acute Effects of 0.1% Tannic Acid Solution on Nutrient Uptake

Exposure of mouse intestinal sleeves to 0.1% TA solution caused reduction of total Pro uptake and passive and carrier-mediated glucose uptake (Table 2). Reductions were greater and statistically significant when 1- or 2-min uptake incubations in the presence of TA were preceded by 5-min preincubations in the presence of TA. This suggests a time dependence to the uptake inhibition by TA in mice.

In contrast, in voles total Pro uptake and carrier-mediated D-glucose uptake were not significantly reduced but appeared to increase (Table 2). As in mice, however, passive glucose uptake, measured with L-glucose, was significantly lower in tissues exposed to TA.

We were concerned that the ca. 40% reductions in L-glucose uptake in both species might be artifacts of the overestimation of adherent L-[1-^{14}C]glucose due either to inulin–TA–membrane binding or inulin influx across disrupted membranes, rather than to decreased L-glucose uptake per se. Thus, we also compared inulin and L-glucose spaces, which are simply the amount of radioactivity per unit tissue, normalized to the amount in the incubation solution and

TABLE 2. ACUTE EFFECT OF TANNIC ACID (TA, 1 mg/ml) ON SOLUTE UPTAKE IN VITRO BY MIDINTESTINE[a]

[a]Values are means ± SE (N = number of tissues for control, and number of paired comparisons in other cases). Within each row, values that are significantly different from their respective controls are signified with asterisks. Paired t test; *$P < 0.05$; **$P < 0.025$; ***$P < 0.01$; ****$P < 0.001$.

[b]Signifies an *a priori* test, hence one-tailed. Control tissues were adjacent sleeves from the same animals, and comparisons were made of uptake when normalized to both tissue mass and tissue length. Uptake of L-glucose was measured at tracer concentration and normalized to a concentration of 1 mM.

thus having units of microliters per centimeter (Karasov and Diamond, 1983). L-Glucose space of tissues incubated in the presence of TA did appear to be lower (voles, $P = 0.009$; mice, $P = 0.135$; paired comparisons among adjacent tissues within individuals) whereas inulin space in the same tissues was similar in voles ($P = 0.35$) and nonsignificantly higher in mice ($P = 0.115$). Thus, in mice, but not in voles, this artifact might have occurred and contributed to a seemingly larger decrease in L-glucose uptake than actually occurred.

Tests for Effect of Subchronic Intake of 4% Tannic Acid Diet on Body Mass and Gut Structure

Body mass was not significantly different between mice fed TA and control diets (respectively, 22.9 ± 1.6 g vs. 25.7 ± 2.0, $N = 7$ in each case; $P > 0.3$) nor between voles fed the two diets (respectively, 35.3 ± 1.8 g vs. 35.5 ± 1.6, $N = 15$ in each case; $P > 0.9$). Small intestine length also did not

differ significantly with diet in either mice (respectively, 41 ± 1 cm vs. 41 ± 1; $P > 0.8$) or voles (respectively, 28.1 ± 0.6 cm vs. 27.1 ± 0.7; $P = 0.28$). In both species, diet had no significant effect on intestinal mass at any of the three positions tested nor on the percent of intestine mass that was mucosa (Figure 1).

Tests for Effect of Subchronic Intake of 4% Tannic Acid Diet on Nutrient Uptake in Mice

There was no significant effect of diet on either Pro or D-glucose uptake at any position in the small intestine of mice (Figure 2), or summed uptake over the entire length of small intestine for either Pro ($P > 0.5$) or D-glucose ($P = 0.28$). L-Glucose uptake normalized to 1 mM also did not differ significantly between control mice (0.38 ± 0.09 nmol/min/cm, $N = 6$) and TA mice (0.36 ± 0.06, $N = 6$) ($P > 0.8$). Thus, in contrast to the findings in the acute

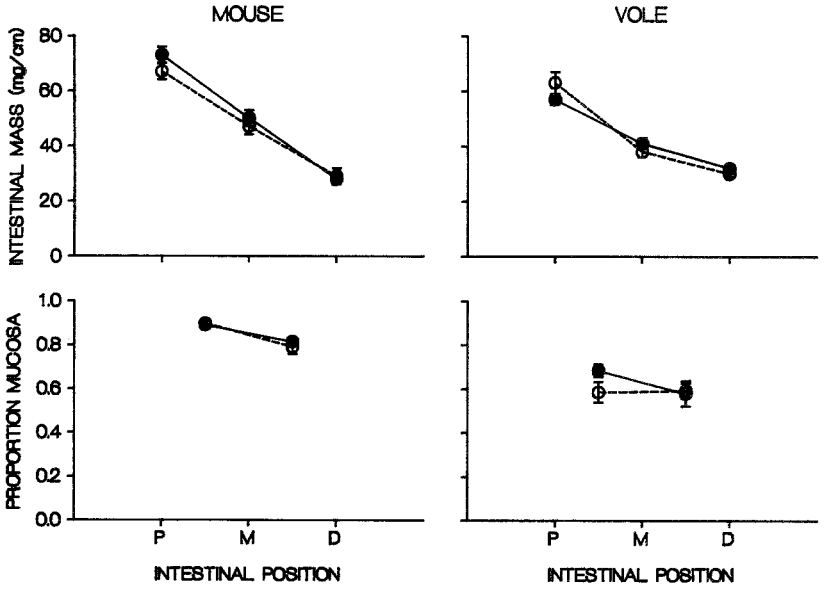

FIG. 1. Intestine wet mass per centimeter (top figures) and proportion of that mass that was mucosa (bottom figures) in mice (left) and voles (right) fed control diet (open symbols) or tannic acid diet (closed symbols). In mice the effect of diet was not significant for either gut mass per centimeter ($P > 0.4$; repeated measures ANOVA) or the proportion of the mass that was mucosa ($P > 0.6$). In voles also the effect of diet was not significant for either gut mass per centimeter ($P > 0.9$) or mucosa mass ($P > 0.4$). In both species gut mass decreased significantly in the distal direction ($P < 0.001$ in both cases), as did mucosa mass in mice ($P < 0.001$) but not voles ($P = 0.17$).

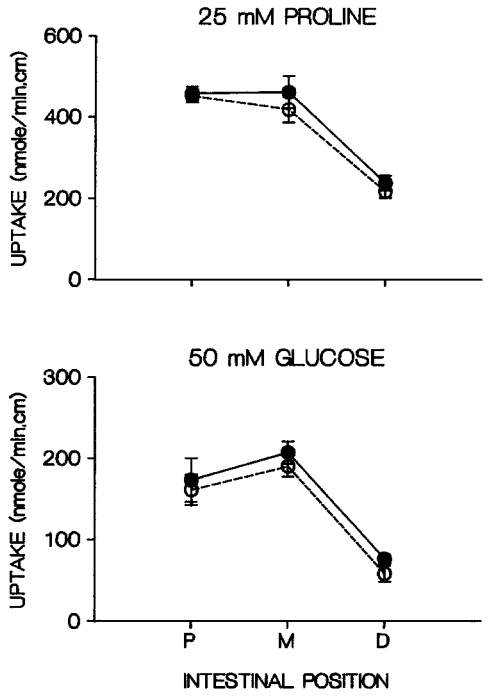

FIG. 2. Total uptake of L-proline per centimeter (top) and carrier-mediated D-glucose uptake (bottom) at three intestinal positions in mice fed control diet (open symbols) or tannic acid diet (closed symbols). P, proximal; M, mid; D, distal. Values are means ± SE ($N = 7$ in each case). Diet had no significant effect on uptake of either L-proline or D-glucose ($P > 0.4$ in each case; repeated measures ANOVA).

experiments, subchronic exposure to TA had no significant effect on passive or mediated uptake of sugar or total uptake of Pro in mice.

Tests for Effect of Subchronic Intake of 4% Tannic Acid Diet on Nutrient Uptake in Voles

Kinetics of Pro Uptake in Midgut. There was no significant effect of diet on Na^+-independent Pro uptake ($F_{2,62} = 0.10$, $P > 0.3$; Figure 3) or total uptake measured in the presence of Na^+ ($F_{2,62} = 1.184$, $P > 0.25$; Figure 3). Na^+-independent uptake was no better fit to a model of diffusion plus carrier-mediated uptake than to a simple diffusion (i.e., linear) model ($F_{2,27} = 0.45$, $P > 0.3$). Therefore, we took the slope derived from the data of both diet groups, 2.7 ± 0.3 μl/min/cm ($N = 11$ voles), as a measure of the apparent passive permeability coefficient (P*) to Pro. Uptake in the presence of Na^+ was better fit to a model of nonsaturable (i.e., passive) plus a carrier-mediated pro-

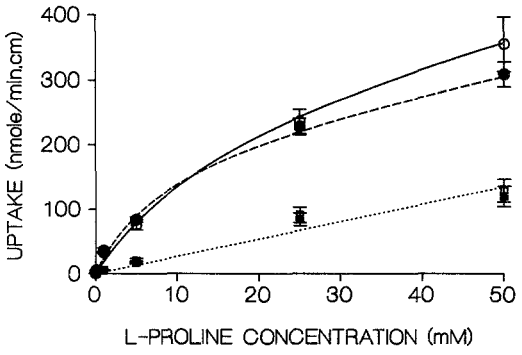

FIG. 3. Total uptake (± SE) of L-proline in the absence (squares) and presence (circles) of Na^+, as a function of concentration in midgut of voles fed for 14 days the control diet (open; $N = 7$ voles) or the tannic acid diet (closed; $N = 7$ voles). Line of dots is linear least-squares fit of Na^+-independent uptake. Solid and dashed curves are nonlinear least-squares fits of uptake in the presence of Na^+ to the equation: uptake = P* × concn + ([J_{max} × concn]/K_m^* + concn]), where P* is the slope of the Na^+-independent line. There was no significant effect of diet (see text). Fitted kinetic parameters for the control voles were P* = 2.5 ± 0.2 μl/min/cm, J_{max} = 212 ± 15 nmol/min/cm, K_m^* = 8.7 ± 2.1 mM; for tannic acid voles, P* = 2.7 ± 0.2 μl/min/cm, J_{max} = 302 ± 59, K_m^* = 18 ± 10.

cess than to one of simple diffusion alone ($F_{1,64} = 45.5$, $P < 0.001$) and could not be computer fit to a model with two carrier-mediated processes. When kinetics of Pro uptake were evaluated for each individual vole and then compared by diet, there was still no significant diet effect on P* ($P > 0.7$), J_{max} ($P = 0.14$), or apparent K_m ($P = 0.12$).

Amino Acid Uptake as a Function of Intestinal Position (Experiments with 40% Solka Floc Diet). There was no significant effect of diet on total Pro uptake at any region of the intestine (Figures 4A and B) whether measured at 25 mM ($P = 0.647$, repeated measures ANOVA) or 0.01 mM ($P = 0.513$) (Figure 4). Neither was there a significant effect on summed Pro uptake at 25 mM ($P > 0.5$). The proportion of total Pro uptake that was Na^+-independent at 0.01 mM was 33.8 ± 7.2% in control voles and 28.5 ± 8.7% in TA voles ($P > 0.5$).

Total uptake of 0.01 mM Leu also was not significantly affected by diet at any intestinal position ($P > 0.5$; Figure 4C). Lys uptake at 0.01 mM in midgut of control voles (545 ± 74 pmol/cm/min, $N = 8$) and TA voles (613 ± 73, $N = 8$) did not differ significantly ($P > 0.5$). Asp uptake at 0.01 mM also did not differ significantly ($P > 0.5$) in control voles (329 ± 50 pmol/cm/min, $N = 8$) and TA voles (379 ± 61, $N = 8$).

Glucose Uptake. Carrier-mediated D-glucose uptake was measured in voles fed diet with and without TA for seven days (Figure 4D). Repeated-measures

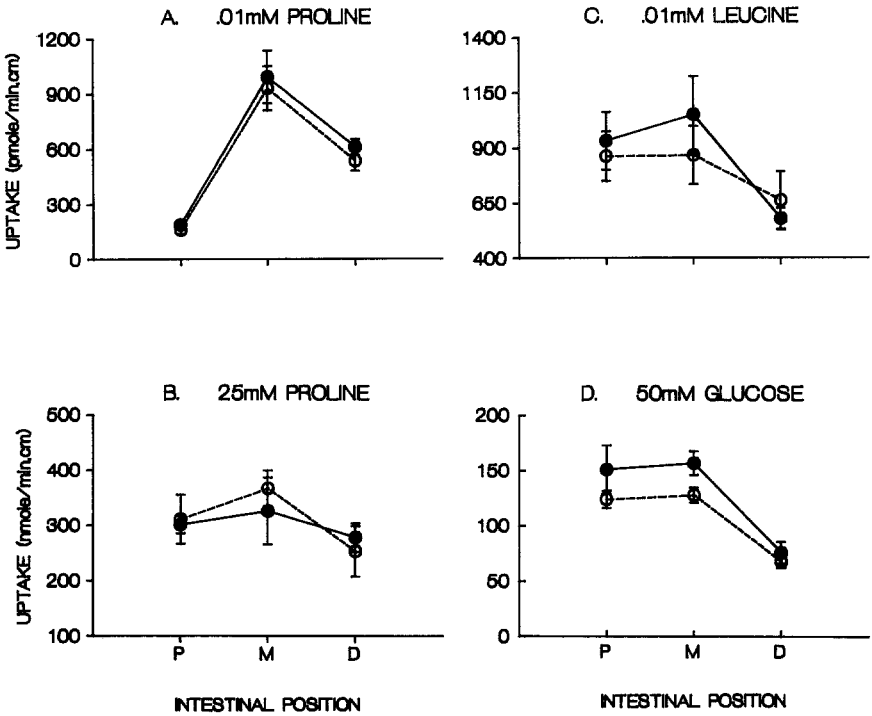

FIG. 4. Total uptake of L-proline per centimeter at 0.01 mM (A) and 25 mM (B), total uptake of L-leucine at 0.01 mM (C), and carrier-mediated D-glucose uptake (D) at three intestinal positions in voles fed control diet (open symbols) or tannic acid diet (closed symbols) seven days. P, proximal; M, mid; D, distal. Values are means $\pm$ SE ($N \geq 5$ voles in each case, with the exception of controls in B where $N = 4$). See text for statistical comparisons.

ANOVA indicated that the former group had significantly higher uptake ($P = 0.049$), but comparisons (Tukey) at each position were not significant for the proximal ($P = 0.265$), middle ($P = 0.055$), and distal ($P = 0.589$) intestine. Summed D-glucose uptake was 23% higher in TA-fed voles (3.88 ± 0.63 μmol/min, $N = 6$) than in controls (3.15 ± 0.15, $N = 6$) ($P = 0.034$) even though intestinal lengths were similar (respectively, 28.6 ± 0.5 cm vs. 28.2 ± 0.9; $P > 0.5$). In the midgut, L-glucose uptake, normalized to 1 mM, did not differ significantly between control voles (1.12 ± 0.10 μl/min/cm, $N = 6$) and TA voles (1.22 ± 0.06, $N = 6$) ($P > 0.4$).

Overall, in voles (as in mice) subchronic exposure to TA had no significant effect on total uptake of amino acids. Carrier-mediated glucose uptake was significantly higher in TA fed voles, but passive glucose uptake was unaltered.

DISCUSSION

Our study indicates a species dependence in the sensitivity of intestinal nutrient absorption to acute exposure to TA. Furthermore, even in a species acutely sensitive (e.g., mice), there are not necessarily parallel decreases in amino acid and sugar absorption in response to subchronic TA exposure, at least at the dietary concentration used in this study. Indeed, the only hint of an effect from subchronic exposure was in the opposite direction—a possible increase in carrier-mediated glucose uptake by vole intestine (Figure 4D).

In the following discussion we attempt to synthesize our results with others in the literature. We first consider the observed acute effects in relation to possible mechanisms of action. Then, we discuss the relation between responses at the acute and subchronic time scales, especially in relation to the broader nutritional picture.

Acute Effects of Tannic Acid on Intestinal Nutrient Absorption. In mice, D-glucose absorption was decreased following exposure to 0.1% TA, whether measured in vivo in intestine perfused with TA (Mitjavila et al., 1970) or in vitro in intact intestine (this study; Table 3). Additionally, mouse intestine

TABLE 3. EFFECTS OF TANNIC ACID ON INTESTINAL NUTRIENT ABSORPTION

absorption rates of methionine (Met) and butyrate were reduced when measured in vivo (Mitjavila et al., 1970), and Pro and L-glucose uptake by intact intestine was reduced (this study; Table 3). At first glance, this uniform pattern across solutes suggests a nonspecific effect of TA, perhaps tanning of either the luminal membrane (Swain, 1979) or of mucin (composed of mucoproteins, glycoproteins, and glycolipids) in the adjacent mucous coat (Mitjavila et al., 1968), hence partially blocking nutrient absorption across either an effective unstirred layer or the brush border membrane (bbm).

Other observations indicate that different, more specific mechanisms are involved. First, in both voles and rats changes in D-glucose (or Pro) uptake were not paralleled by changes in L-glucose uptake (Table 3). Second, in our experiments, which were performed using a saturating concentration of D-glucose as a probe and L-glucose as a marker simultaneously, the significant decrease in stereospecific glucose uptake (Table 2) indicates an effect in addition to that measured solely with L-glucose, an effect on the stereospecific glucose transporter or the electrochemical gradient that energizes the Na^+-coupled transport. Because Pro uptake was also decreased in the mice and is highly (ca. 75%) Na^+-dependent, we suspect an effect on the electrochemical gradient rather than a very specific effect on the glucose transporter.

There is also other evidence suggesting that in rats a more specific effect of TA is on Na^+-coupled transport of sugar and amino acids. Studies with brush border membrane vesicles (bbmv) indicated that uptake of D-glucose was reduced following exposure to TA, but because L-glucose transport was not altered, a change in bbm permeability to passive glucose flux was probably not the cause. Instead, measurements under conditions of Na^+ equilibrium suggested that TA may reduce glucose uptake by altering the Na^+ electrochemical gradient (Welsch et al., 1989b). Welsch et al. (1989b) suggested that the Na^+ gradient might be dissipated by membrane Na permeability changes, but it is also possible that basolateral extrusion of Na (which sets up the gradient) might be inhibited, as suggested by decreased respiration of enterocytes (Mitjavila et al., 1968, 1977) and inhibition of Na,K-ATPase at the basolateral membrane (Lacombe et al., 1976).

There is another aspect of the data on mouse intestine that seems consistent with the hypothesis that, in mice, an effect of TA is reduction of Na^+-coupled transport of nutrients. Within the in vivo study (Mitjavila et al., 1970), and in our in vitro study, glucose absorption was inhibited by TA to a greater extent than was amino acid absorption, and butyrate absorption was inhibited least. This order coincides with the extent to which their absorption is Na^+-dependent. In mouse intestine D-glucose absorption is at least 75% Na^+-dependent (Karasov and Diamond, 1983), Pro and Met absorption are 33–67% Na-dependent at the concentrations tested (Karasov et al., 1986), and butyrate absorption is probably primarily passive (hence, Na^+-independent).

Thus, the most unifying mechanistic explanation of the negative impact of acute TA exposure on intestinal nutrient absorption (Table 3) is that there are two effects. One involves inhibition of passive flux, and it is most apparent in measurement of flux of solutes whose transport is primarily passive (such as L-glucose, butyrate). Because it was not observed in the rat bbmv preparation, which lacks the mucous coat (Smithson et al., 1981), it probably involves an increase in resistance to solute flux due to fixation of TA by mucin (Mitjavila et al., 1968). The other effect involves inhibition of Na^+-coupled transport, which is most apparent in measurement of flux of solutes whose transport includes this pathway (such as D-glucose, amino acids). Both effects appear to occur rapidly following exposure of intestine to TA, because all of the acute effects documented in Table 3 occurred following exposures of ≤ 30 min.

The reason why the apparent effect on Na-coupled transport is not observed in vole intestine is unknown. One interesting idea is that a higher level of mucin, and hence a greater TA fixation capacity, might act as a protective barrier against the toxic effect of TA on enterocytes. Studies with bbmv (e.g., Welsch et al., 1989b) can help discriminate between hypotheses involving extracellular and membrane events.

Relationship between Effects of Acute and Subchronic Exposure to Tannic Acid. Whatever the explanation for reduced nutrient absorption following acute exposure to TA, it is remarkable that subchronic ingestion of TA had no significant effect on nutrient absorption in mice or voles (Figures 2–4). The answer to this paradox may be that little TA reaches the luminal membrane, or that if it does, its effects are quickly reversed when the tissue is washed with solution free of TA.

Factors that could minimize contact between ingested TA and the intestinal luminal membrane include acid hydrolysis to glucose and gallic acid, and preintestinal binding into insoluble protein–tannin complexes. Some TA might be hydrolyzed in the acid environment of the stomach (although we do not know of any tests of this), and the gallic acid moiety appears to have a negligible effect on glucose absorption (Welsch et al., 1989b) or fecal N excretion (Glick and Joslyn, 1970). The parotid glands of mice increase in mass by 700% after four days on tannin-containing diets (Freeland et al., 1985) and secrete copious quantities of proline-rich proteins with a strong binding affinity for tannins (Mehansho et al., 1983, 1985). Whether this occurs in voles is unknown, but the fact that they cannot subsist on quebracho tannin diet (Lindroth and Batzli, 1984; Meyer, 1989) whereas mice can (Freeland et al., 1985; Meyer, 1989) suggests that they lack this parotid adaptation or some other protective trait.

It is also possible that even if TA reaches the luminal membrane and elicits its toxic effects, those effects are quickly reversed once the TA is flushed away when the tissue is washed with solution free of TA (or by a TA-free meal in vivo). In this regard it is instructive to note that when rat intestine was perfused

with TA, the inhibition of absorption of glucose, Met, and butyrate was reversed following perfusion with tannin-free solution (Mitjavila et al., 1970).

Overview. The effects of TA and other tannins on intestinal nutrient absorption, and on digestion in general, appear to us complex. This is partly because our results and analysis indicate that when tannins interact with intestinal tissue they may reduce nutrient uptake by enterocytes by at least two mechanisms—binding with mucin, which may reduce passive flux across an effective unstirred layer juxtaposed to the brush border membrane, and toxic effects on enterocyte function, which reduces Na^+-coupled nutrient transport across the brush border membrane.

Whether these effects actually occur in vivo may depend on the amount of tannin reaching the luminal membrane. This amount may be reduced by pregastric binding into insoluble complexes, gastric hydrolysis, and intestinal hypersecretion of mucin. Thus, effects on digestion at the whole-animal level are not easily predicted from studies conducted at the in vitro level.

Finally, an added complication is that there appear to be notable differences between species in physiological response to tannins at the tissue and whole-animal level. Mouse intestinal tissue appears to be more sensitive to TA than vole intestine. Chickens may be even more sensitive to TA than either mice or voles, because ingestion of TA-containing diet is associated with reduced intestinal sugar absorption and reduced growth (Marzo et al., 1987).

These species differences in TA and tannin effects on nutrient absorption and nutrition preclude broad generalizations about nutritional or ecological effects of tannins, but they do offer a comparative approach for the study of the mechanisms of action of tannins at the cellular, tissue, and whole-animal level.

APPENDIX: SELECTION OF INCUBATION TIME

We previously found that 2-min and 1-min incubations yielded measures of unidirectional uptake of amino acids and glucose, respectively, in mice (Karasov and Diamond, 1983; Karasov et al., 1986). We performed the following tests to verify whether this was also the case for voles.

We incubated tissues for various times in Ringer solution containing tracer inulin and Pro or Leu (50 mM) and determined tissue uptake after blotting the tissue. Adjacent tissues from the same voles were incubated to minimize interindividual variation; one piece incubated for 2 min was a control and the adjacent piece was incubated for 1 or 4 min.

Pro uptake proved to vary linearly with time to at least 2 min, as evidenced by uptakes at 2 min that were 1.78 ± 0.11 times uptakes at 1 min ($N = 6$ pairs of tissues; not significantly different from expected value of 2.0, $t_5 = 2.0$, $P > 0.1$). Uptakes at 4 min, however, were significantly less than double the

uptakes at 2 min (ratio = 1.74 ± 0.1, $N = 6$ pairs of tissues, $t_5 = 2.6$, $P < 0.05$). A smaller number of comparisons for Leu uptake suggested a similar pattern for that solute: ratio 2 min/1 min = 1.763 ± 0.16 ($N = 3$, $P > 0.2$ for difference from 2.0); ratio 4 min/2 min = 1.43 ± 0.13 ($N = 4$, $P < 0.025$ for difference from 2.0). Inulin space, which was used to correct measured amino acid uptake for amino acid in the adherent fluid, was similar at 1 min (0.36 ± 0.02 μl/mg, $N = 7$ tissues), 2 min (0.39 ± 0.02, $N = 8$), and 4 min (0.40 ± 0.02, $N = 8$). Thus, the inulin space had equilibrated by 1 min.

For D-glucose, 1 -min incubations apparently underestimated unidirectional uptake because uptake for tissues incubated for 1 min were 1.634 ± 0.063 times uptakes at 0.5 min ($N = 6$ pairs of tissues, $t_5 = 5.81$, $P < 0.005$ for difference from 2.0). Uptakes at 2 min were 1.655 ± 0.147 times uptakes at 1 min ($N = 7$, $t_6 = 2.347$, $P = 0.06$).

Acknowledgments—This research was funded by a grant from the College of Agriculture and Life Sciences, University of Wisconsin-Madison and NSF BSR8452089. We would like to thank Dr. George Batzli for his generous contribution of voles used in this experiment, and Dr. Wally Jakubas for useful comments on the manuscript. Chris Richards, Chris Zurich, Ismael Ozanne, Steve Yu, and Dale Cooper assisted in care of rodents.

(Received October 3, 1991; accepted January 6, 1992)

Abstract—Substitution of nine hydrogens by nine fluorines in the butyl terminus of (Z)-7-dodecenyl acetate, the major component of the pheromone blend of the cabbage looper, *Trichoplusia ni* (Lepidoptera: Noctuidae), produces a highly volatile analog that is significantly less active as a replacement for the natural pheromone component, either alone or substituted in the six-component pheromone blend of this species. When 9,9,10,10,11,11,12,12,12-nonafluoro-(Z)-7-dodecenyl acetate (nf-Z7-12:OAc) was tested in a wind tunnel as a single component or as part of the six-component blend, males exhibited preflight activation, but they did not orient in the pheromone plume and fly upwind over a five-decade range of doses at levels comparable with those of the natural component and blend. Addition of large amounts of nf-Z7-12:OAc to the optimal dose of the natural blend also did not effect flight arrestment as when increased amounts of Z7-12:OAc were added. The nonafluoro (nf) analog of (Z)-9-tetradecenyl acetate, a minor component in the *T. ni* blend, did not affect male behavior when substituted in the six-component blend, and substitution of both nf analogs in the natural blend produced the same results as observed for blends containing nf-Z7-12:OAc. The lack of an effect with substitution of nf-Z9-14:OAc is discussed in relation to the reported redundancy in the action of minor components in *T. ni*.

INTRODUCTION

Partial substitution of fluorine for hydrogen in pheromone components can lead to analogs with varying amounts of activity on pheromone perception by male moths. For example, three different modifications of the major component of the European grape berry moth *Eupoecilia ambiguella* pheromone, Z9–12 : OAc, were examined in field-trapping and flight-tunnel assays. An allylic difluoro analog was as attractive as the parent compound, but the trifluoromethyl and the pentafluoroethyl analogs were inactive by themselves. When large amounts of pentafluoroethyl analog were added to the main component, Z9–12 : OAc, it appeared to mimic the effect of dodecyl acetate in increasing trap catch (Rauscher et al., 1984; Sun and Prestwich, 1990; Bengtsson et al., 1990). A variety of perfluoroalkyl analogs have been examined using single-cell and electroantennogram methods with *Heliothis zea* (Z9–14 : Al and Z11–16 : Al), the southwestern corn borer *Diatraea grandiosella* (Z9–16 : Al and Z11–16 : Al), and with the cabbage looper *Trichoplusia ni* (Z9–14 : OAc and Z7–12 : OAc). In each of the analogs, the alkyl chain on the alkene was replaced by a completely fluorinated alkyl chain of the same length (Prestwich et al., 1990). In each of the three insect sensory systems, the perfluoroalkyl-containing pheromone analogs were recognized by the same cell that responded to the parent alkyl compound; however, an analog concentration 1000–10,000 times higher was required for equal output.

Orientation of male moths to the natural pheromone blend, to partial blends, and to single components has been extensively evaluated for *T. ni* (Linn et al., 1984, 1985). Moreover, many fundamental studies on the electrophysiology of pheromone perception by single olfactory sensilla have been performed with *T. ni* (Prestwich et al., 1990; see Todd et al., 1991). For these reasons, we chose to compare the effects of the electrophysiologically active nonafluoro-Z9–14 : OAc (nf-Z9–14 : OAc) and nf-Z7–12 : OAc analogs of the natural components on moth behavior.

METHODS AND MATERIALS

Insects. Moths were obtained from a laboratory colony maintained for the past two years from field-collected pupae in Geneva, New York. The moths were reared on a semisynthetic medium (Shorey and Hale, 1965), on a 16 : 8 hr light–dark photoperiod at 25°C, 50–60% relative humidity, unless otherwise

noted. Males were separated from females as pupae. Adult males were segregated daily by age, provided with 5% sugar water, and kept under similar conditions to those during rearing.

Chemicals. The *T. ni* sex pheromone is a six-component mixture comprised of 12:OAc (6.8%), Z5–12:OAc (7.6), Z7–12:OAc (100), 11–12:OAc (2.3), Z7–14:OAc (0.9), and Z9–14:OAc (0.6) (Bjostad et al., 1984). A standard solution of this blend was prepared in hexane and checked on capillary GLC (45-m Carbowax 20 M column) to ensure chemical purity of individual compounds (>99%), with a detection limit of 0.1%. Three similar solutions were prepared at the same time: one with the nf-Z7–12:OAc substituted for Z7–12:OAc, one with nf-Z9–14:OAc instead of Z9–14:OAc, and one with both analogs instead of the parent compounds. In addition, standards of Z7–12:OAc and nf-Z7–12:OAc were prepared. The nonafluoro analogs (Figure 1) were synthesized as described previously (Prestwich et al., 1990). Materials were purified on silica gel and evaporatively distilled prior to use. Capillary GLC (DB-5, 0.21 mm × 30 m) verified 99.9% homogeneity for materials for bioassay.

Dilution series of the four blends, the Z7–12:OAc, and nf-Z7–12:OAc solutions were then prepared and were applied in 100-μl amounts to red rubber septa (5 × 9 mm, A.H. Thomas Company) to achieve the desired doses.

Procedure for Testing Insects. The flight behavior of individual males was observed in the flight tunnel of Miller and Roelofs (1978). General flight-tunnel conditions were 0.3 lux scotophase, 50–55 cm/sec air velocity, 23°C, 40–70% relative humidity. Males of the appropriate age (3–4 days old) were taken to the room housing the flight tunnel 2 hr prior to onset of scotophase, placed individually in 10 × 5-cm screen cages provided with a water-soaked dental wick, and then onto a platform adjacent to the tunnel under the same light intensity and temperature as experienced in the tunnel itself, to acclimate to

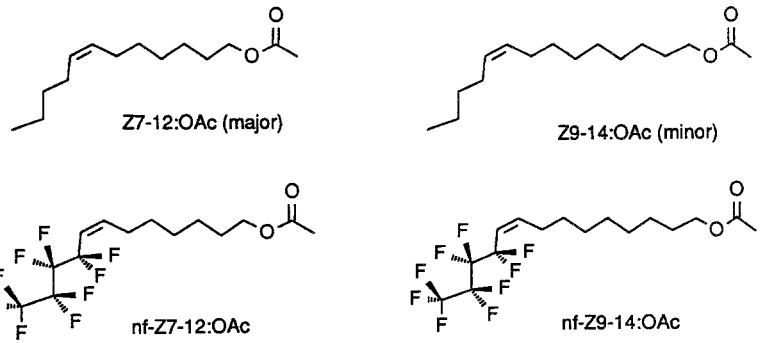

FIG. 1. Structures of major and minor pheromone components and their nf analogs.

tunnel conditions. Response to pheromone was observed by placing the cage containing a male in the odor stream at a distance of 1.5-m downwind from the source. Males were allowed 60 sec to respond and were scored for three key behaviors typically exhibited in the flight tunnel: taking flight, initiation of upwind flight, and source contact (Linn et al., 1984). In addition to the behaviors themselves, the time taken to execute each behavior was recorded, using a mini-computer. Males were tested once and then discarded.

Males were first tested to a dose-series of the Z7–12:OAc and nf-Z7–12:OAc components alone. Each test day 10 different males were tested at each of five doses (0.01, 0.1, 1, 10, and 100 μg), with replicates run until 50 males were tested with each compound–dose combination. Males were then tested with the four blend combinations. Each test day five different males were tested with each blend at the five doses indicated above. Replicates were run until 50 males were tested with each blend–dose combination. Finally, males were tested with a series of 10-μg sources of the natural blend containing excess amounts of either Z7–12:OAc or the nf-Z7–12:OAc component. Each test day 10 males were tested with each of eight combinations (see Figure 5), with replicates run until 50 males were tested with each treatment. For all tests, comparisons were made at each dose between the natural component or blend and the nonafluoro-containing analogs or blends, using the method of adjusted significance levels for proportions (Ryan, 1960).

RESULTS AND DISCUSSION

The number of source contacts following upwind flight over a 1.5-m distance by male *T. ni* to Z7–12:OAc alone, the natural six-component blend, nf-Z7–12:OAc, and blends with the substituted nf analogs are shown in Figure 2. Several features are noteworthy. First, the dose–response curve for the natural blend peaks at a lower loading than does Z7–12:OAc alone. This result was expected based on previous flight-tunnel studies with *T. ni*. In two studies (Linn et al., 1984, 1985) it was shown that response thresholds for the natural six-component blend are significantly lower than for the major component alone.

Second, with nf-Z7–12:OAc, either alone or as a substitute for Z7–12:OAc in the blend, males did not fly upwind and did not make source contact over a series of doses at which Z7–12:OAc or the six-component blend elicited responses for this species. This lack of response also was not entirely unexpected based on the results of electrophysiological measurements. In a previous study with *T. ni* (Prestwich et al., 1990) it was shown that single sensilla responded in a dose-dependent and analog-specific fashion to nf-Z7–12:OAc and nf-Z7–12:OH. However, in these single-sensilla studies there was a significant shift in the dose–response curve with these compounds, with a threshold at 10 μg

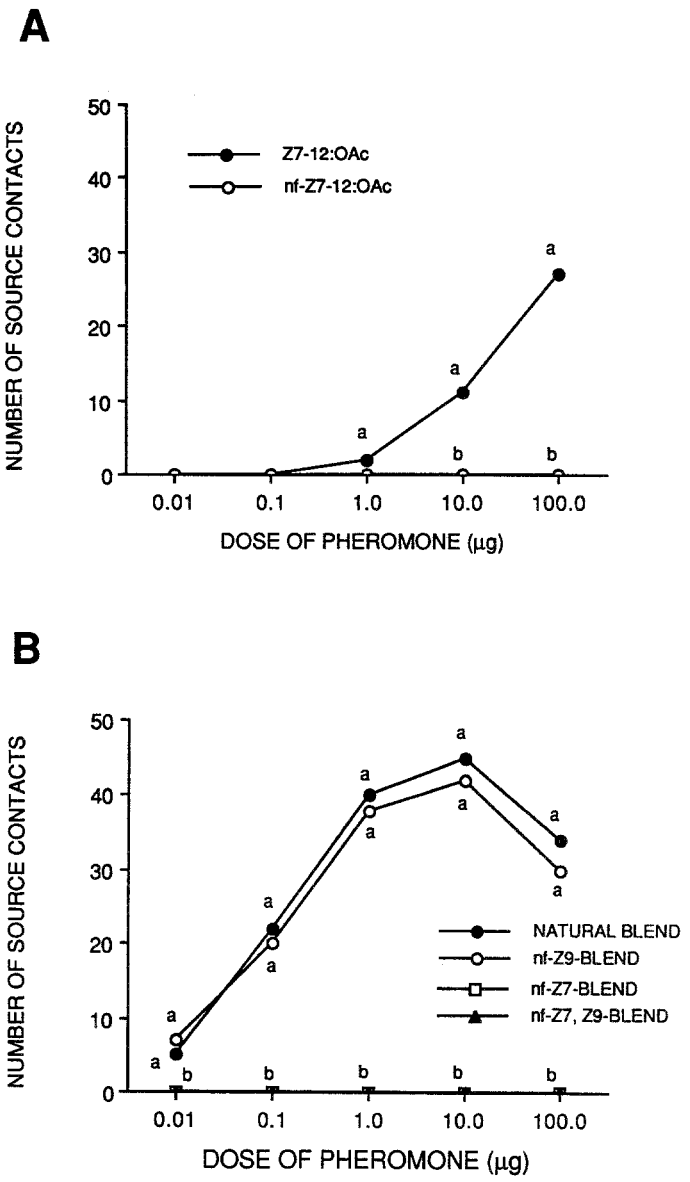

FIG. 2. Number of source contacts by male *T. ni* to a dose series of the Z7–12:OAc or the nf-Z7–12:OAc component alone (A) and to the natural blend or blends containing substituted nf-Z9–14:OAc, nf-Z7–12:OAc, or both nf-analogs (B). $N = 50$ for each source and dose combination. Small letters indicate significant differences ($P < 0.05$) between treatments at any given dose, according to the method for adjusted significance levels (Ryan, 1960).

for the nf-Z7–12:OAc component compared with 0.02 μg for Z7–12:OAc. Thus, one interpretation is that the nf-Z7–12:OAc component results in a weaker interaction with receptor sites for Z7–12:OAc, requiring greater amounts of the material for a given level of neural stimulation to occur.

Third, substitution of the nf analog of Z9–14:OAc, a minor component, to the six-component blend, also had no effect on male response, and once again this was expected on the basis of previous studies. In Prestwich et al. (1990), electrophysiological measurements showed that, as with the nf-Z7–12:OAc component, sensillum cells specific for Z9–14:OAc responded to the nf analog, but at a significantly higher dose–response range. Since there is such a small amount of this component in the blend to begin with, a weaker interaction with the nf-Z9–14:OAc component would render it almost undetectable when present at normal levels that elicit maximal response from males. This would suggest that substitution of nf-Z9–14:OAc in the blend effectively results in males being exposed to a five-component blend, a situation that with many other species would result in a lowered response to pheromone. However, in Linn et al. (1984) it was reported that, whereas the major component Z7–12:OAc was required in the blend for any male response to occur, the minor components could be selectively removed from the blend without affecting maximal response to the blend. This redundancy has been supported recently by electrophysiological studies at the antennal level by Todd et al. (1991). Of particular interest with respect to the present study was the observation by Linn et al. (1984) that, whereas the Z7- and Z9–14:OAc components could be selectively removed without affecting behavior, removal of both compounds resulted in a four-component blend with significantly lower activity. Thus we would expect no effect on male response levels by removal of Z9–14:OAc, such as in the present case with substitution of the much weaker nf-Z9–14:OAc, but we would predict that substitution of both nf-Z7- and nf-Z9–14:OAc in the blend would result in a significant decrease in upwind flights and source contacts.

The data presented in Figure 2 are for source contact, the terminal behavior in the response sequence observed in the flight tunnel. To establish whether there was any effect of the nf analogs on male response, more detailed behavioral profiles for the 1-, 10-, and 100-μg doses from Figure 2 are shown in Figure 3. With the single components (Figure 3A) or the blends (Figure 3B) there was an increase in the number of males taking flight with increased dose, although there were no significant differences in the number of males taking flight to the nf-containing vs. natural treatments at the two higher dose levels. The values for taking flight to treatments containing substituted nf analogs were significantly greater than spontaneous levels of flight activity observed, indicating that males were able to detect the treatments containing the nf-Z7–12:OAc. However, at all three doses, although there was an increase in the number of males flying upwind and making source contact to the sources containing Z7–12:OAc alone

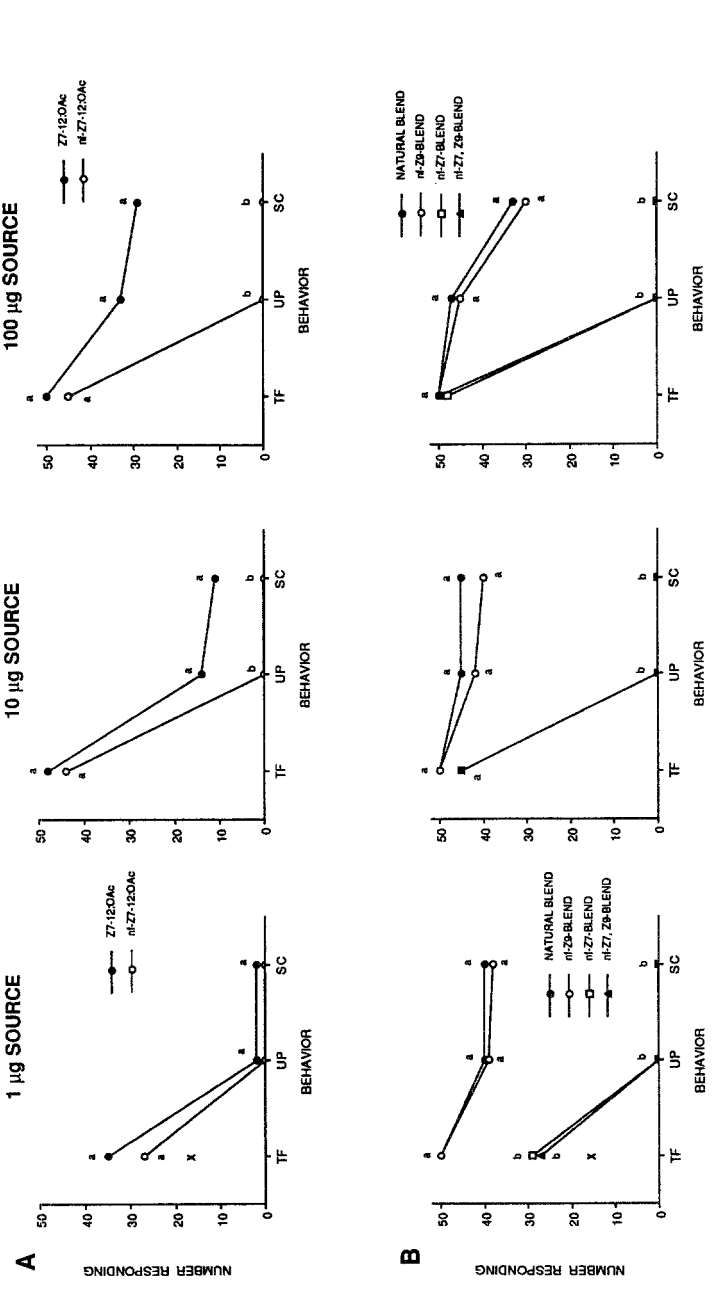

FIG. 3. Number of male *T. ni* exhibiting three behaviors in the upwind flight sequence (TF = taking flight, UP = upwind flight, SC = source contact) to the 1-, 10-, and 100-μg sources of *Z*7–12 : OAc or nf-*Z*7–12 : OAc alone (A) and to the natural blend or blends containing nf-*Z*9–14 : OAc, nf-*Z*7–12 : OAc, or both nf analogs (B). $N = 50$ for each source and dose combination. Small letters indicate significant differences ($P < 0.05$) between treatments at any given dose, according to the method for adjusted significance levels (Ryan, 1960). The X mark for TF at 1 μg indicates the level of nonpheromone stimulated spontaneous flight.

or the natural blend, these behaviors did not occur with substitution of the nf-Z7–12:OAc analog. In fact, in no case did a male attempt to orient in the odor plume to a treatment when substituting nf-Z7–12:OAc for the natural compound.

We also noted that, whereas there was no difference in the number of males taking flight to natural vs. nf-containing treatments, there was a marked difference in the temporal aspects of the response pattern, with males responding to nf-containing sources taking significantly longer to do so compared with the natural components or blends (data are shown in for the 1-μg source in Figure 4). This phenomenon of an increased latency to response, as well as an increased level of pre-upwind-flight activities, has also been observed for the flight-tunnel responses of the European grape berry moth to a perfluoroethyl analog of Z9–12:OAc (Bengtsson et al., 1990).

The above results taken together suggest that the nf-Z7–12:OAc compound has an extremely weak interaction with receptor sites for Z7–12:OAc, resulting in a weaker stimulus discharge of the antennal neurons. That this is the case, as opposed to an hypothesis that the nf analog blocks sensory processing, is demonstrated by the last two experiments on arrestment and habituation. Figure 5 shows that addition of 10 μg of Z7–12:OAc to the source containing 10 μg of the blend did not affect male behavior, but when 100 or 1000 μg of Z7–12:OAc was added, male response decreased. This is as expected from the dose–response curve in Figure 1 showing that with a 100-μg source of the natural blend, male source contacts decreased as a result of increased levels of arrested

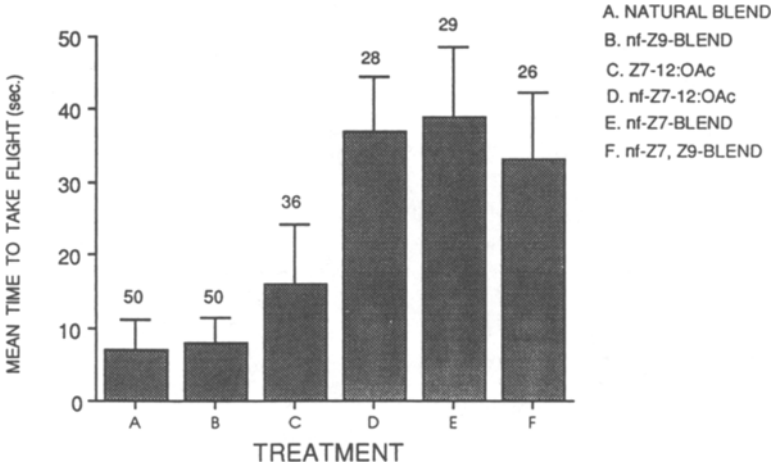

FIG. 4. Time taken for male *T. ni* to take flight to the series of 1-μg sources. Values are means $\pm$ SD, with *N* for each treatment indicated above each bar.

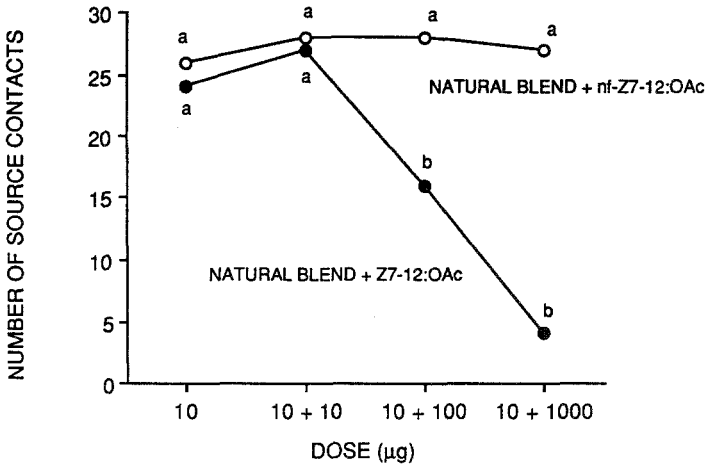

FIG. 5. Number of source contacts by male *T. ni* to a 10-μg dose of the natural blend, with added amounts (10, 100, or 1000 μg) of nf-Z7–12:OAc or Z7–12:OAc. $N = 50$ for each source and dose combination. Small letters indicate significant differences ($P < 0.05$) between treatments at any given dose, according to the method for adjusted significance levels (Ryan, 1960).

upwind flight to this high dose (see Figure 3B, 100 μg; also Baker, 1985). However, addition of 1–1000 μg nf-Z7–12:OAc to the natural 10-μg blend source did not have an affect on male response to the 10-μg source. Once again, these data support the hypothesis that the nf-Z7–12:OAc compound is significantly less active as a replacement for the natural pheromone component.

In an experiment relating to habituation, males were first exposed to a 100-μg source of nf-Z7–12:OAc alone for 2 min. During this time they were not allowed to initiate flight from the release cage. They were then removed from the odor stream in the tunnel and retested with a 10-μg source of the blend 3 min later. A control group that was not exposed to nf-Z7–12:OAc was also tested. With the 100-μg nf-Z7–12:OAc source all of the males tested ($N = 25$) became active in their release cages and exhibited sustained activity over the 2-min period. When tested with the natural 10-μg blend source 3 min later, however, 25 males activated, 25 took flight, and 23 reached the source. Of the control group, 25 activated and took flight, with 21 reaching the source. These results confirm that although males appear able to detect the presence of nf-Z7–12:OAc, as evidenced by their activity during the 2-min exposure, the analog does not affect male perception of the natural pheromone signal. The results of our experiments support the notion that nf-Z7–12:OAc in *T. ni* is more "slippery" in its interaction with antennal receptor sites compared with the natural

components (Prestwich et al., 1990; Prestwich, 1991) and had no effect on male behavior when added to the natural pheromone blend.

Synergism, here meaning an increase in trap capture, had been reported previously by Bengtsson et al. (1990) in field responses of the European grapeberry moth to lures containing a fixed amount of Z9–12:OAc and increasing doses of the perfluoroethyl analog, 11,11,12,12,12,-pentafluoro-Z9–12:OAc (pf-Z9–12:OAc). pf-Z9–12:OAc alone elicited no upwind flight or source contacts with the lure; only activation of preflight activities was noted. In addition, this compound was inactive in the field. However, when added to 100 μg Z9–12:OAc, quantities of 100, 500, and 2000 μg pf-Z9–12:OAc effected trap catch increases of two-, four-, and sevenfold. Interestingly, this effect on trap capture with Z9–12:OAc also occurs when 12:OAc is added (a fivefold increase in amount of 12:OAc added to Z9–12:OAc increases trap catch by a factor of 2–7; Rauscher et al., 1984), which suggests the possibility that the pentafluoroethyl analog is mimicking the effect of the saturated compound.

Both behavioral and electrophysiological results with perfluorinated analogs of moth pheromone components appear to support the importance of the hydrophobicity of the terminal alkyl group in pheromone-receptor protein interactions (Prestwich, 1991). When terminal butyl or hexyl groups were replaced with perfluoro groups, male antennal olfactory receptor neurons from four moth species (*T. ni*, *H. zea*, *D. grandiosella*, and *Agrotis segetum*) showed 100- to 10,000-fold lower activities relative to the parent compounds (Prestwich et al., 1990; Wu et al., 1991). Negligible poststimulus firing was also observed. With respect to effects on behavior, in *E. ambiguella*, pf-Z9–12:OAc was inactive when tested alone, but increased trap catches when added to the natural pheromone component. However, in the case of *T. ni* and *A. segetum*, when nf-Z7–12:OAc (*T. ni*) or nf-Z5–10:OAc (*A. segetum*) were substituted in the six- and three-component pheromone blends, male response was the same as that observed to respective blends missing the Z7–12:OAc or Z5–10:OAc components. In the case of *T. ni*, this resulted in no upwind flights, whereas in *A. segetum* upwind flight levels and source contacts were significantly reduced, but not eliminated, since males in this species are able to fly upwind to the remaining two-component blend of Z7–12:OAc and Z9–14:OAc.

Overall, the replacement of terminal alkyl groups with perfluoroalkyl groups in these pheromone components produced compounds with increased volatility, displaced electrophysiological dose–response profiles, and significantly lowered biological activity (Prestwich et al., 1990). Because of diminished receptor cell sensitivity, it has been proposed that the binding of the fluorinated analogs to putative receptors is reduced as a result of a less favorable interaction between the hydrophobic protein binding site and the more rigid and more polar lipophobic perfluoroalkyl moiety (Prestwich, 1991). In contrast to reports for lepidopteran pheromone systems, however, the Rothamsted group has observed that

a heptadecafluoro compound, in which the *n*-octyl group in a mosquito oviposition attractant pheromone was replaced by a perfluorooctyl group, retained high biological activity in the field and in the laboratory (Dawson et al., 1990).

The current model of pheromone perception (see Prestwich, 1991) implicates at least three types of proteins that recognize and bind to the pheromone molecules (Vogt et al., 1990; Breer et al., 1990). Thus, the ultimate electrical signal produced by the pheromone–sensillum interaction is potentially modulated by three protein–ligand interactions: pheromone–PBP (pheromone binding protein), pheromone–SE (sensillar enzyme), and pheromone–RP (receptor protein). At each level, the perfluoroalkyl components may compete with pheromone molecules for the binding sites. This complex interplay allows for rapid signal transduction and stimulus degradation, and varying fluorinated analogs can affect these equilibria differently.

Abstract—The diel periodicity of sex pheromone titer from pheromone glands of female *Lymantria dispar* is described. On the day of emergence (day 0), pheromone titer was generally low; means ranged from 1 to 4 ng *cis*-7,8-epoxy-2-methyloctadecane during photophase and gradually increased to 8.4 ng over the course of scotophase. For day-1, -2, and -3 females, the diel fluctuations of titer were more pronounced. Lowest titers (5–9 ng) occurred 0–4 hr after lights-on, and peak titers (19–32 ng) were found 0–4 hr before lights-off. Comparison of the average daily titer among the different age groups (data pooled over six time points at 4-hr intervals) indicated that significantly less pheromone was extracted from glands of day-0 (4.5 ng) than day-1 (12.4 ng), day-2 (15.4 ng), or day-3 females (13.5 ng). No significant differences were found among the three older ages. Females *in copula* exhibited a rapid reduction in titer within the first 0.5 hr of mating initiation (7.6 ng vs. 19.5 ng from virgin females of similar age). After the second 0.5 hr, the reduction in titer was not nearly as marked, falling only to 4.5 ng. Twenty-four hours after mating, titer fell below the limits of detection (0.5 ng). All extracts from pheromone glands of virgin or mated females contained <1.0 ng of the putative pheromone precursor, 2-methyl-*cis*-7-octadecene.

Key Words—*Lymantria dispar*, Lepidoptera, Lymantriidae, pheromone gland titer, diel periodicity, age effect, mating effect, *cis*-7,8-epoxy-2-methyloctadecane, 2-methyl-*cis*-7-octadecene.

INTRODUCTION

In the female gypsy moth, *Lymantria dispar* (L.), the rate of pheromone emission from naturally calling females exhibits a characteristic diel periodicity (Charlton and Cardé, 1982). At 24°C, pheromone release rates were at their lowest during the interval shortly before and after lights-on. During photophase, emissions gradually increased, peaked during late photophase–early scotophase, then decreased over the course of scotophase. This pattern, however, was not mirrored by the periodicity of calling behavior. At 24°C, the percent female calling fell to its lowest (45%) during the interval shortly before and after lights-on; at all other times, 100% of the females exhibited calling behavior (Charlton and Cardé, 1982). To understand how emission rates fluctuate during periods when there are no overt changes in the level of calling, a description of the diel periodicity of pheromone titer in the gland is necessary.

Other factors, such as age and mating, also influence pheromone production. Early field studies demonstrated that traps baited with gland extracts from newly eclosed gypsy moth females caught few males, whereas those baited with gland extracts from older females caught large numbers (Collins and Potts, 1932). Quantification of disparlure at 4 hr after lights-on has shown that the titer of pheromone increased with age, peaked four days after the day of emergence, and then fell back to low levels in females six days after the day of emergence (Giebultowicz et al., 1990). After a single mating, gypsy moth females ceased to call, and generally failed to attract additional males before ovipositing a single large egg mass (Doane, 1968). Traps baited with mated females (Forbush and Fernald, 1896; Cardé et al., 1973) or with extracts from mated female abdominal tips (Collins and Potts, 1932) also caught few males compared to traps baited with virgin females. Direct analysis of pheromone titer by GLC has shown that 24 hr after mating pheromone titer declined to very low levels and remained low for the next several days (Giebultowicz et al., 1990).

To further understand the biology of pheromone production in *L. dispar*, we report on the diel periodicity of the titer of the sex pheromone, *cis*-7,8-epoxy-2-methyloctadecane, as well as for the presumed pheromone precursor, 2-methyl-*cis*-7-octadecene. We also show how age affects the average daily pheromone titer and evaluate the short-term changes that occur in pheromone titer after mating.

METHODS AND MATERIALS

Moths. Gypsy moth egg masses from the New Jersey standard strain were supplied by the USDA-APHIS Methods Center, Otis Air National Guard Base, Massachusetts. Larvae were reared on a modified wheat germ diet (Bell et al., 1981) in an environmental chamber held at 24 ± 2°C, 50% relative humidity,

16 hr:8 hr light–dark cycle. Under these conditions, development to adult eclosion required approximately 6.5 weeks. Eclosion was strictly diurnal with 24.8% of the females emerging 0–4 hr after lights-on, 50.4% 4–8 hr after lights-on, 23.6% 8–12 hr after lights-on, and 1.2% 12–16 hr after lights-on. These values concur with previous reports of eclosion periodicity (ODell, 1978; Ma et al., 1982). Adult females were held in paper containers (110 mm diam. × 80 mm tall) with transparent plastic lids. The age in days was based on the age in hours from the time of eclosion. Day 0 refers to females 0–24 hr old; day 1, 24–48 hr old; day 2, 48–72 hr old; and day 3, 72–96 hr old.

Gland Extractions and Calling Behavior Observations. The female gypsy moth pheromone, commonly referred to as disparlure, has been identified as (7*R*,8*S*)-*cis*-epoxy-2-methyloctadecane (Bierl et al., 1970; Iwaki et al., 1974; Hansen, 1984). To assess glandular titers of the pheromone and the putative precursor, 2-methyl-*cis*-7-octadecene, the abdominal tip, which included sclerite IX, the pheromone gland (Hollander et al., 1982), and part of sclerite VIII, was excised from individual females and extracted in 150 μl hexane for 1 hr in a conical glass tube. A known amount (25 ng) of internal standard, *cis*-9,10-epoxy-eicosane, was added to the hexane immediately before the gland was extracted. Each tube was placed in a vial containing a reservoir of 100 μl hexane. Vial caps were Teflon-lined and samples were stored at −15°C until analysis.

Efficiency of pheromone extraction was determined by extracting the same gland ($N = 5$) sequentially for 1 min, 1 hr, and 24 hr. For each extraction period, the gland was immersed in 150 μl hexane with 25 ng of the internal standard. Gland transfers between tubes were done with a hooked insect pin. The first extraction period (1 min) yielded 83.2% (±2.6 SD) of the total extractable pheromone with the remaining 16.8% (±2.6 SD) of the pheromone obtained in the next extraction period (1 hr). Extraction of the same glands for an additional 24 hr failed to yield any more pheromone (<0.5 ng) and sporadically contained extraneous compounds that interfered with reliable quantification of pheromone. Therefore, 1 hr was chosen for the length of gland extractions.

To establish the diel periodicity of titer, gland extractions were performed every 4 hr beginning at lights-on for day-0, -1, -2, and day-3 females. Adult females were held in paper containers in groups of five, and observations of female calling behavior were made immediately (within 10 min) before the pheromone glands were excised and extracted. A female was scored positively for calling according to the criteria reported by Tang et al. (1987). All extractions and calling behavior observations were made under the same light and temperature conditions as the rearing regime. During scotophase, illumination was provided by a flashlight covered with a Kodak red filter. Determinations were not made for day-4 females or older since a female's average life-span is only six days (equivalent to our day-5 females) (Forbush and Fernald, 1896).

The effect of age on pheromone titer was evaluated by comparing the

average daily pheromone titer of day-0, -1, -2, and day-3 females. The average daily titer for each female age was calculated by combining the data from the six extraction times at 4-hr intervals beginning at lights-on.

To evaluate the influence of mating on pheromone titer, individual males (24–48 hr old) were placed with individual calling females (48–52 hr old) 8 hr after lights-on, and each male–female pair was housed in separate paper containers (110 mm diam. × 80 mm tall) with transparent plastic lids. This time, 8 hr after lights-on was chosen since it fell within the period (1100–1500 hr) of maximal male attraction to females (Cardé et al., 1974) and because it occurs just before the period of peak pheromone titer in day-2 females. Mating ensued within a few minutes, and those pairs that were not forcibly separated remained in copula for 58.7 min (±13.3 SD). This length of time agrees well with previous reports of copulation duration (Forbush and Fernald, 1896; Doane, 1968; Loerch and Cameron, 1984). Pheromone titers were determined immediately before copulation, and 0.5, 1.0, and 24 hr after mating initiation. Forcible separation of the mating pairs was necessary for all the 0.5-hr pheromone titer determinations and for one of the 1-hr determinations.

Sample Analysis. FID-GLC analysis was used to quantify amounts of pheromone present in ovipositor extracts. Samples were concentrated to ca. 0.8 μl under filtered N_2 and injected on a 2-m × 2-mm-ID glass column packed with SP-2100 (3% loading on 100/120 Supelcoport; N_2 carrier flow 30 ml/min). Peaks were identified by retention time comparison with synthetic compounds, and areas were quantified using an HP-3390 integrator. Under isothermal operation at 175°C, the olefin, disparlure, and the internal standard eluted at 4.4, 8.3, and 13.6 min, respectively. The lower analytical limit of the system was ca. 0.5 ng. Mass spectral analysis was performed on a few samples to confirm the identities of disparlure and the olefin in the gland extracts.

RESULTS

The effect of time of day on female pheromone titer is shown in Figure 1. Despite the inherent variability found in the data, daily trends were observable. On the day of emergence (day 0), pheromone titers were generally low during photophase (mean titers ranged from 1 to 4 ng), then gradually increased to 8.4 ng during the latter half of scotophase. For day-1 females, the lowest titer (5.1 ng) was found 4 hr after the onset of photophase, and the peak titer (19.0 ng) was observed at lights-off. For day-2 and day-3 females, the lowest titers occurred at lights-on (7.4 ng and 5.3 ng, respectively), and the peak titers were found 4 hr before lights-off (22.7 ng and 26.0 ng, respectively). Excluding the day of emergence, it appeared that daily pheromone titer in the gypsy moth did exhibit a patterned fluctuation. The diel periodicity of titer was characterized by low

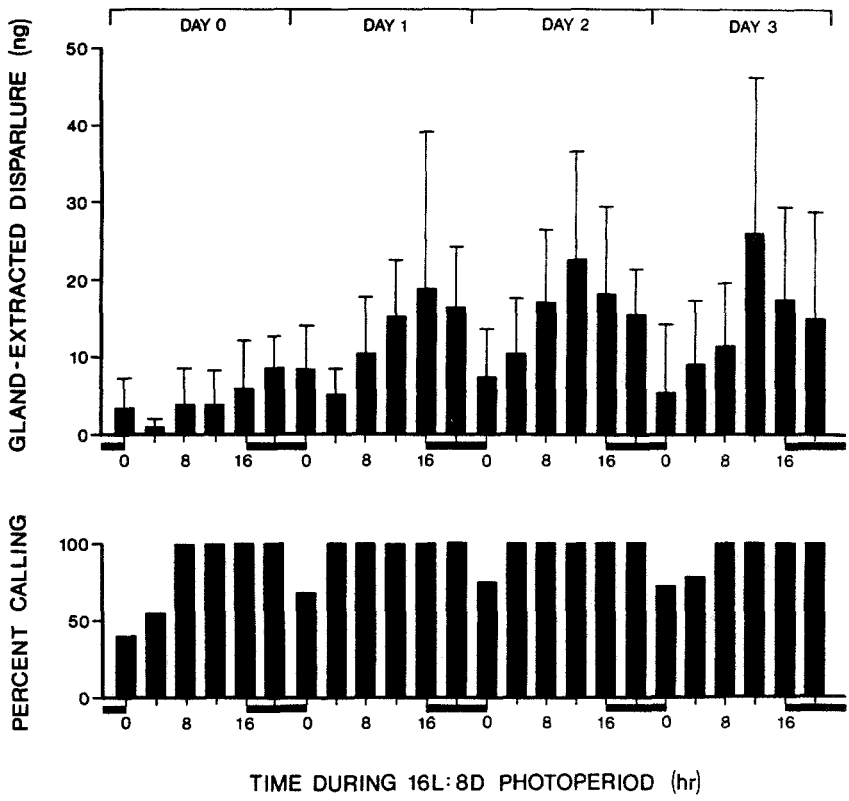

FIG. 1. Diel periodicity of sex pheromone titer (upper graph) and percent female calling immediately before each pheromone extraction time (lower graph). Mean values for each extraction period were obtained from 8 to 12 females, and vertical bars denote standard deviations from the mean. Glands were extracted individually for 1 hr in 150 μl hexane containing 25 ng internal standard, and analyzed by GLC-FID. Day 0 refers to females 0–24 hr old, day 1 to females 24–48 hr old, etc. Scotophase is indicated by dark horizontal bars.

titers at or just after the onset of photophase and peak titers at or just before the onset of scotophase.

Values for pheromone titer and percent female calling were also obtained for females within 0.5 hr of eclosion, while the wings were still undergoing expansion and hardening (data not graphed). For all these females, the pheromone titers were below the limits of detection (<0.5 ng), and none had initiated calling ($N = 5$). During this period, the ovipositor was protruded with the pheromone gland partially exposed, but there was not the rhythmic protrusion and retraction of the ovipositor that is characteristic of calling (Tang et al.,

1987). By 2–3 hr after the time of eclosion, pheromone titer increased to 1.2 ng ± 0.7 (SD, $N = 5$), and three of the five females had already initiated calling behavior.

Comparison of the diel periodicity curves for calling and pheromone titer (Figure 1) showed that females called almost continuously and that periods of 100% calling were often not indicative of periods of maximal pheromone titer. Typically, titer began to rise with the onset of 100% female calling. Once the peak titer was reached, titer began to decrease while calling activity continued at the 100% level. Periods of lowest calling activity, however, were either coincident or within 4 hr of the time of lowest pheromone titer. For example, on day 0 and day 1, lowest percent female calling was observed at lights-on, and lowest pheromone titer was observed 4 hr after lights-on. On day 2 and day 3, the period of lowest titer occurred at lights-on and coincided with the period of lowest calling activity.

The influence of age on the average daily pheromone titer is shown in Table 1. Day-0 females had significantly less pheromone in the gland (4.5 ng) than day-1 (12.4 ng), day-2 (15.4 ng), or day-3 females (13.5 ng). The average daily titer of the older three age groups, however, showed no significant differences.

Following copulation, a rapid decline in pheromone titer was observed (Table 2). Titer from females 0.5 hr after mating initiation was 7.6 ng compared to 19.5 ng from virgin females of similar age. The initial rapid rate of pheromone decrease, however, did not continue during the following 0.5 hr. Pheromone titer from these females (i.e., 1.0 hr after mating initiation) only fell an additional 3.1 ng to 4.5 ng. By 24 hr, titer from mated females had fallen below the limits of detection (0.5 ng). In addition, these latter females each laid large

TABLE 1. EFFECT OF FEMALE AGE ON AVERAGE DAILY PHEROMONE TITER[a]

Female age[b]	N	Pheromone titer (ng/gland) mean (SD)[c]
Day 0	60	4.5 a (4.7)
Day 1	59	12.4 b (11.1)
Day 2	60	15.4 b (10.7)
Day 3	60	13.5 b (13.3)

[a] Glands were extracted individually in 150 μl hexane containing 25 ng internal standard, and analyzed by GLC-FID.

[b] Day 0 refers to females 0–24 hr old, day 1 to females 24–48 hr old, etc.

[c] Means followed by different letters were significantly different ($P < 0.05$) by the Student-Newman-Keuls multiple-range test after square root transformation of the data.

TABLE 2. EFFECT OF MATING ON PHEROMONE TITER[a]

Female status[b]	N	Time of extraction after mating initiation (hr)	Pheromone (ng/gland) mean (SD)[c]
Virgin	23		19.5 a (12.8)
Mated	8	0.5	7.6 b (4.8)
	10	1.0	4.5 b (3.2)
	7	24.0	<0.5 c (0.7)

[a] Female glands were extracted individually in 150 μl hexane containing 25 ng internal standard, and analyzed by GLC-FID.

[b] Single males (24–48 hr old) were placed with individual calling females (48–52 hr old) 8 hr after lights-on. Glands from virgin females were extracted immediately, otherwise mating ensued within a few minutes, and glands were extracted at the times indicated. Forcible separation of mating pairs was necessary for all of the 0.5-hr determinations and for one of the 1-hr determinations.

[c] Means followed by different letters were significantly different ($P < 0.05$) by the Student-Newman-Keuls multiple-range test after logarithmic transformation of the data.

discrete egg masses by the time of pheromone extraction. Two females, however, were observed to mate normally but did not exhibit the decline in titer 24 hr later. They deposited partial egg masses with the majority of the eggs retained. Pheromone titers from these two females (8.9 ng and 26.1 ng) were not included in the data of Table 2.

Titer of the putative pheromone precursor, 2-methyl-*cis*-7-octadecene, from individual virgin or mated female gland extracts never exceeded 1.0 ng, and was typically below the limits of detection (0.5 ng).

DISCUSSION

The diel periodicity of sex pheromone titer in the gypsy moth was characterized by low titers at or just after the onset of photophase and peak titers at or just before the onset of scotophase. A similar pattern also has been observed for the diel periodicity of pheromone emissions; pheromone release rates from calling females were lowest just after the onset of photophase and highest just before the onset of scotophase (Charlton and Cardé, 1982). Since females call continuously except at lights-on, it appears that the amount of pheromone emitted relates directly to the amount of pheromone present in and/or on the gland. When pheromone titer was at its peak (19–32 ng), peak emission rates of 14–15 ng/hr (Charlton and Cardé, 1982; Tang et al., 1987) were observed, and 100% of the females called; when pheromone titer was at its lowest (5–9 ng), lowest emission rates (2–5 ng/hr) were recorded (Charlton and Cardé, 1982),

and percent female calling was also at its lowest (40–60%; Charlton and Cardé, 1982).

Other species that exhibit congruence between pheromone titer and emission periodicities from calling females include *Heliothis subflexa* and *H. virescens*. For both of these species, peak titers of the major pheromone component, (*Z*)-11-hexadecenal, were exhibited during periods of peak emissions and peak percent female calling, and lowest titers were found during periods of lowest emissions and lowest percent female calling (Heath et al., 1991). Quantifying pheromone release rates from *H. virescens* glands that were forcibly extruded, Pope et al. (1982) also concluded that the amount of pheromone emitted was dependent on the amount of pheromone in and/or on the gland.

In certain other moth species, an asynchronous relationship between pheromone emission and titer periodicities has been observed. In *Trichoplusia ni*, peak titer of the major pheromone component, (*Z*)-7-dodecenyl acetate, in and/or on the gland occurred at lights-off and always preceded the peak in pheromone emissions, which occurred 2–4 hr later (emission data was from forcibly extruded glands) (Hunt and Haynes, 1990). Furthermore, the peak in pheromone emission rate was observed when percent female calling was on the rise, and lowest pheromone titers were observed during periods of maximal percent female calling (Hunt and Haynes, 1990). Data from naturally calling females also indicated that during the period the pheromone gland was everted, pheromone release declined exponentially, with highest emission rates observed during the first 5 min of gland eversion (Bjostad et al., 1980). In *Holomelina lamae*, similar trends also have been noted. Quantities of the major pheromone component, 2-methylheptadecane, released from calling females were highest just after the onset of calling, and emission rates decreased as calling continued (Schal et al., 1987). Titer was also observed to decrease suddenly with the onset of female calling (Schal and Cardé, 1986).

By comparing the rates of pheromone release with the rates of pheromone biosynthesis, explanations can be proposed to account for the different relationships observed. For example, in the gypsy moth, *H. subflexa*, or *H. virescens*, the concurrent rise and fall in titer and emission periodicities would be possible if the rate of pheromone emission were always less than, but varied in proportion with the rate of pheromone biosynthesis. In *T. ni* or *H. lamae*, pheromone emission rates would have to exceed rates of pheromone biosynthesis to account for the observed periodicities. The latter hypothesis has also been proposed by Ono et al. (1990) to explain the asynchronous relationship observed for periodicities of calling and pheromone titer in the potato tuber moth. Data describing the *in vivo* rates of pheromone biosynthesis at different times of the day should determine the validity of these hypotheses.

In addition to quantifying the amount of disparlure in virgin and mated female gland extracts, we also examined the levels of the olefin, 2-methyl-*cis*-

7-octadecene. The olefin has been interpreted as an intermediate in the biosynthetic pathway of disparlure (Kasang et al., 1974) and is an inhibitor of male attraction to disparlure (Cardé et al., 1973). The levels of olefin found in our 1-hr gland extracts were always <1.0 ng and often fell below the limits of detection (0.5 ng). Previous reports (Bierl et al., 1972) have suggested that gland titers of the olefin exceeded disparlure titers because, during the course of isolating and identifying disparlure, it was found that epoxidation of active fractions containing both the olefin and disparlure led to a 10-fold increase in male activity. However, Bierl et al. (1970) reported that they extracted 78,000 female abdominal tips and that half this extract contained ca. 15 μg of the olefin (purification losses were not reported), or 0.4 ng per female, which is similar to what we found.

Our results showed that gypsy moth pheromone titers were influenced by age. The average daily titer was low on the day of eclosion (day 0), increased on day 1, and then remained unchanged on day 2 and day 3. This differs from the effects of age reported by Giebultowicz et al. (1990), who found that titer was low on the day of eclosion, increased until reaching a peak in 5-day-old females (equivalent to our day-4 females), and then declined over the next two days. Experimental differences can be held partially accountable. We determined the effects of age on the average daily titer, i.e., an average that was calculated from the titers obtained from six time points taken every 4 hr, whereas Giebultowicz et al. (1990) determined the effects of age on the mean titer obtained from one time point 4 hr after lights-on, which our data indicated fell during the period of minimal titer. Direct comparison of titers obtained at 4 hr after lights-on shows that for days 0, 1, and 2, the two sets of data are comparable. For day-3 females, however, the pheromone titer observed by Giebultowicz et al. (1990) at 4 hr after lights-on was 33 ng, as opposed to 10 ng found in our data for the same time. In a later paper, Giebultowicz et al. (1991) reported titers from virgin day-2 females of 5–6 ng for glands taken 10–12 hr after lights-on. In our data, 10–12 hr after lights-on corresponded to the period of peak titer, which we found to be 23 ng in day-2 females. Since insect rearing conditions and diet were basically the same in our experiments and those of Giebultowicz et al. (1990, 1991), differences in the data could be due to differences in insect handling and gland extraction techniques or to the insects themselves.

Mating in the gypsy moth precipitated a rapid decline in pheromone titer that was evident within 0.5 hr of mating initiation while females were still *in copula* (virgin female titer was 19.5 ng versus 7.6 ng from females that were mated for 0.5 hr). After the second 0.5 hr, the reduction in titer was not nearly as marked, falling only to 4.5 ng, and by 24 hr, pheromone titer was below the limits of detection (0.5 ng). These data suggest that two separate physiological mechanisms were involved in controlling the decline in titer after mating. This is consistent with the hypothesis of Giebultowicz et al. (1991) that the transition

from a virgin to a mated state is under two-step regulation. Giebultowicz et al. (1991) found that mechanical disturbance of the bursa copulatrix by insertion of the male genitalia during mating resulted in a transient suppression of calling behavior and a transient decline in pheromone titer. Permanent suppression of calling and pheromone production, however, only occurred when sperm was present in the spermatheca (Giebultowicz et al., 1991). In the brown-banded cockroach, termination of calling behavior in mated females was also found to be under a similar two-step regulation, i.e., placement of the spermatophore in the bursa caused an immediate cessation of calling, and continued suppression of calling was caused by the presence of sperm in the spermatheca (Smith and Schal, 1990). Insufficient sperm in the spermatheca may also explain why two of the gypsy moth females that we observed to mate normally did not exhibit a decline in pheromone titer 24 hr later (8.9 ng and 26.1 ng), nor did they deposit complete egg masses.

The nervous system appears to play a major role in the reproductive behavior of the female gypsy moth. In virgin females, calling behavior, pheromone production, and pheromone emission all depend on the CNS acting through the ventral nerve cord (Hollander and Yin, 1982; Tang et al., 1987) without any apparent endocrine or neuroendocrine involvement (Hollander and Yin, 1985; Tang et al., 1987; Raina et al., 1989). Neural innervation during mechanical disturbance of the bursa was also essential to effect the transition from a virgin to a mated state (Giebultowicz et al., 1991). Although it is still not clear whether sperm in the spermatheca is detected neurally or chemically, mechano-like sensilla in the spermatheca of *Plodia interpunctella* have been observed (Lum and Arbogast, 1980). It seems plausible, therefore, that during the transition from a virgin to a mated state, the CNS of female gypsy moths could be under neural inhibition induced by sensory feedback from the bursa and the spermatheca, thereby suppressing calling behavior, pheromone release, and pheromone production.

Acknowledgments—The authors thank Drs. C.P. Schwalbe and R.A. Bell, and the gypsy moth rearing unit at the USDA-APHIS Methods Center, Otis ANGB, Massachusetts for supplying the insect eggs, and Drs. R.P. Webster and C. Schal for suggestions during the course of the research. Abstract—Volatile chemicals emanating from the different developmental stages of *Ostrinia nubilalis* Hübner (Lepidoptera, Pyralidae) increase the mobility of *Trichogramma brassicae* Bezdenko (Hymenoptera, Trichogrammatidae) in a linear airflow olfactometer. In this paper, we have demonstrated that airborne chemicals from egg masses and virgin females during calling activity stimulate an intensive search behavior by *Trichogramma* females. On the other hand, emanations from mated females with extruded abdominal tips do not incite the parasitoid's movement. For the moment we cannot elucidate, with these bioassays, the real role of these kairomones as attractants, guides, stimulants, or retainers.

Key Words—*Trichogramma brassicae*, Hymenoptera, Trichogrammatidae, kairomone, pheromone, *Ostrinia nubilalis*, Lepidoptera, Pyralidae, biological control, European corn borer, parasitoid.

INTRODUCTION

The process of host selection by a parasitoid was described by Vinson (1985) as seven successive steps: habitat preference, potential host community location, host location, host examination, ovipositor probing, ovipositor drilling, and

*To whom correspondence should be addressed.

0098-0331/92/0500-0761$06.50/0 © 1992 Plenum Publishing Corporation

oviposition. The success of each step depends on many environmental and host factors that involve both chemical and physical cues, indicating that the process is not absolutely random. Chemicals appear to be major stimuli in the host selection process. Their importance is noted at each step of the process. Physical factors start to play a more important role beginning with the host examination step (Vinson, 1985). Such semiochemicals are called kairomones (Brown et al., 1970) and have a role in host-seeking, recognition, and oviposition behaviors.

Allelochemical sources involved in the host selection process are varied. Considering all the host–parasitoid couples investigated, kairomones can be produced by different host developmental stages. Eggs are the target of oophagous parasitoids and can be a direct source of kairomones. For example, the eggs of several Noctuidae species are attractive for several *Trichogramma* spp. females (Nordlund et al., 1977a, 1981; Ferreira et al., 1979; Ferreira-Anunciada and Pintureau, 1981; Gross et al., 1981; Bourarach and Hawlitzky, 1984). Surface chemical compounds of *Ostrinia nubilalis* egg masses are attractive for *T. brassicae* [synonymy with *T. maidis* (Pintureau, 1990) confused with *T. evanescens*] and stimulate their probing behavior (Renou et al., 1989). Noldus and van Lenteren (1985b) have shown that cabbage leaves treated with extracts of *Pieris brassicae* eggs are explored for a longer time by *T. evanescens* females than control leaves. This stage is also a source of kairomone for other oophagous (Strand and Vinson, 1982b, 1983a,b; Bin and Vinson, 1985) and egg-larval parasitoid species (Kainoh et al., 1982; Strand and Vinson, 1982a). Egg chemicals appear to act by short-range attraction and/or by contact (Renou et al., 1989). While the parasitoid already stands within a host community, such chemical cues might intervene at location and examination levels.

The kairomonal activity of eggs may be associated with an oviposition-deterring pheromone that could act by contact (Nordlund et al., 1977b; Prokopy and Webster, 1978; Noldus and van Lenteren, 1985b). Components released at the time of oviposition could interact with those of the eggs. Thus, colleterial glands (Ferreira et al., 1979) and accessory glands (Nordlund et al., 1977b, 1987) are active in the behavior of several *Trichogramma* species. For different larval parasitoid species, host larval instar and their products are a source of semiochemicals (Weseloh, 1974; Wilson et al., 1974; Gross et al., 1975; Thompson et al., 1983). Moreover, the presence of adults, particularly females, may stimulate the parasitoid's searching behavior. In oophagous insects, it was thus shown that *T. evanescens* females explored a longer time on cabbage leaves on which *Mamestra brassicae* adults have stayed than on control leaves (Smits, 1982). *Spodoptera littoralis* and *Helicoverpa armigera* females (Lepidoptera, Noctuidae) elicit behavioral responses for two Trichogrammatidae species, *Trichogrammatoidea lutea* and *Trichogramma rhenana* (Bourarach and Hawlitzky, 1984). On the other hand, oophagous and egg-larval parasitoids can be attracted by the host's sex pheromone (Noldus and van Lenteren, 1985a; Noldus et al.,

1988; Isidoro and Bin, 1988). Lewis et al. (1982) and Nordlund et al. (1983) have shown that volatile chemicals released from host abdominal tips and excretions stimulate the parasitoid's searching behavior. Moreover, these chemicals increase parasitism in the field. Likewise, this activity is found in the synthetic sex pheromone of *Heliothis zea* and *Spodoptera frugiperda*.

Scales lost by *H. zea* females at the time of oviposition have also been shown to be a source of kairomones (Lewis et al., 1971, 1972, 1975a,b; Jones et al., 1973). Such kairomones act by contact (Beevers et al., 1981), not by olfaction. Several contact kairomones have been identified for other host–parasitoid couples such as *Heliothis zea–T. pretiosum* (Gueldner et al., 1984), *Mamestra brassicae–T. evanescens* (Smits, 1982), *Pieris brassicae* and *P. rapae* for *T. evanescens* (Noldus and van Lenteren, 1985b) and also for *O. nubilalis–T. nubilale* (Shu and Jones, 1989; Shu et al., 1990). Moth scales are also a stimulus for predators (Lewis et al., 1977). Such scale-contained semiochemicals induce an arrestment response of parasitoids that is expressed by an increased klinokinesis, thus involving an increased searching behavior of parasitoid on treated areas.

In the past few years, efforts have been made in France by INRA, in association with a private company, UNCAA (Union Nationale des Coopératives Agricoles d'Approvisionnement), to elaborate and develop biological control measures against the European corn borer (ECB) *Ostrinia nubilalis* Hübner (Lepidoptera, Pyralidae) by using an oophagous insect, *Trichogramma brassicae* Bezdenko (Hymenoptera, Trichogrammatidae). In this paper we report studies on the source of volatile chemical cues used by *T. brassicae* to locate their host *O. nubilalis*, particularly in view of a possible application of semiochemicals to enhance the efficiency of parasitoids in biological control programs. We have examined the responses of *T. brassicae* to egg masses, to virgin females in different situations linked to their pheromonal cycle, and to mated females of the host, *O. nubilalis*.

METHODS AND MATERIALS

Parasitoids

A *T. brassicae* strain was used. These wasps were taken from an industrial culture, originating from material collected yearly on *O. nubilalis* egg masses in the field by UNCAA.

The parasitoids were reared on eggs of the Mediterranean flour moth, *Ephestia kuehniella* Zeller (Lepidoptera, Pyralidae) and held in diapause to await field utilization. We used *Trichogramma* from the first generation after diapause. Adult wasps were maintained on honey, in glass tubes at 25 $\pm$ 1°C, with 70% relative humidity, and a photoperiod of 16:8 hr light–dark. For these experi-

ments, only 48-hr-old mated female wasps were used (Smits, 1982); these females had no previous oviposition experience.

Moths

Adult *O. nubilalis* were reared on an artificial diet according to a modified procedure of Poitout and Bues (1970), held at 25 ± 1°C, 80% relative humidity, and a 16:8 hr light–dark photoperiod. They have been laboratory reared for a maximum of eight generations. Each year, the strain was renewed by collecting wild larvae in autumn, near Houdan (Yvelines, France).

Odor Source

Host Egg Masses. Host egg masses less than 24 hr old were provided from laboratory cultures. The oviposition substrate consisted of wax paper covering the open top of the cage containing the adults. These egg masses were easily collected by brushing off the wax paper. An increasing number of egg masses (1, 3, and 5 egg masses of medium-size, 15–20 eggs) was used to determine whether there was a concentration threshold for parasitoid females.

Virgin Female Host Adults. Stock colony pupae were collected, sexed, and separated. They were placed under a 16:8 hr light–dark photoperiod with two different times of photoperiod initiation: (1) lights on at 6 AM, or (2) lights on at 4 PM to facilitate daytime experiments. In addition, a continuous photophase to inhibit normal sex pheromone synthesis was used (Skopik et al., 1981; Subchev, 1983). Relative humidity is a critical condition; thus, it was held constant at 90–100%. In all experiments, females were 3-day-old virgins when pheromonal emission was observed to be maximum (personal observations).

In the first experiment, moths were used in the third scotophase after emergence and during their calling activity (the last 2 hr of scotophase). During this period, extrusion of the abdominal tip continued for several hours. For these experiments, female abdominal tips were extruded artificially by pressure with tweezers to allow continual sex pheromone emission, even in the light. Pheromone emission was demonstrated by the characteristic behavior of males.

Mated Female Host Adults. One female and two males (all 2 days old) were placed in a 110-mm-diam. × 80-mm-high plastic container with a layer of filter paper and placed in a climate room at 25 ± 1°C, 90–100% relative humidity, and a 16:8 hr light–dark photoperiod. Mating occurred during the first night and egg laying during the following one. After each test, the females were dissected in order to verify the presence of the spermatophore (Drecktrah and Brindley, 1967; Showers et al., 1974).

Bioassays

Bioassays were performed in a linear airflow olfactometer (Renou et al., 1989) (Figure 1). Ten *Trichogramma* females were introduced through the entry tube downwind of the odor source. The test insects were exposed to odors from different developmental host stages and to control air. A new sample odor source was used for each replication. The airflow was regulated and measured by flowmeters at 1.8 liters/hr. For each test, we calculated a moving index minute by minute (Renou et al., 1989). The different experiments consisted of series of at least 30 observations. When testing egg masses, we used a brush to place them inside the glass tube, and experiments were conducted for 15 min. For adults, the test odor source contained one female in a glass vial for 20 min.

Statistical Analysis

Student's *t* test was used for statistical comparisons between treatment and control. We calculated the difference between means every minute, at a significance level of 95%; significant differences are indicated by an asterisk in Figure 2.

RESULTS

Odor Source: Egg Masses

We wanted to determine whether volatile chemicals emanating from this target stage have an effect on parasitoid behavior. When examining female *Trichogramma* movement, we observed enhanced parasitoid mobility in the presence of three egg masses in comparison with the control (Figure 2, treatment B); no difference in mobility was observed in the presence of one and five egg masses (Figure 2, treatments A and C).

Odor Source: Virgin Females

We examined the responses of *Trichogramma* females exposed to emanations of *O. nubilalis* calling virgin females during the last 2 hr of scotophase. The test odor source was then constituted by sex pheromone blend and female-related odors. The results for calling virgin females (Figure 2, treatment D) show a significant difference from those for controls after 6 min. The *Trichogramma* came more quickly to the area around the odor source than in the control tube.

Virgin females were then tested before their calling period during scotophase to determine whether the responses shown in the preceding test were due to factors associated with calling behavior in interspecific relationships. This

FIG. 2. Responses of *Trichogramma brassicae* to different treatments with host odor sources in the linear olfactometer. min1 to min20: the numbers represent the moving index calculated each minute in the olfactometer; O = odor test; C = control test; * = significant difference between the odor test and the control. The odor sources are (A) one egg mass; (B) three egg masses; (C) five egg masses; (D) host virgin females in calling activity; (E) virgin females in scotophase just before the calling period without extruded pheromonal gland; (F) virgin females in photophase with extruded pheromonal gland; (G) virgin females in photophase without extruded pheromonal gland; (H) virgin females reared under continuous photophase with extruded pheromonal gland; (I) virgin females reared under continuous photophase without extruded pheromonal gland; (J) mated females before their first oviposition without extruded abdominal tips; (K) mated female before their first oviposition with extruded abdominal tips; (L) mated females after their first oviposition without extruded abdominal tips; (M) mated females after their first oviposition with extruded abdominal tips.

test consisted of exposing the parasitoids to emanations from virgin females during the scotophase, immediately before the onset of calling activity and without extrusion of the pheromonal gland, in order to determine whether the volatile chemicals shown in the first test were due to passive diffusion through the pheromonal gland. The results (Figure 2, treatment E) showed no significant difference over 20 min.

In the third experiment, parasitoids were exposed to virgin females of *O. nubilalis* during the photophase (after eight of the 16 hr of light), some with extruded abdominal tips and others without. The emanations from virgin females with extruded pheromonal gland increased movement of the *Trichogramma*; a significant difference was found between treatment and control (Figure 2, treatment F), whereas virgin noncalling female odors do not induce any particular behavior in the parasitoids compared to the control (Figure 2, treatment G).

The previous tests suggested that substances involved in increased parasitoid movement are related to the synthesis of the female sex pheromonal blend. To examine this phenomenon further, female pupae were reared under continuous light until their utilization three days after emergence. The absence of photoperiodicity disturbs the synthesis of sex pheromones, making females ineffective in attracting males (personal observation).

Light-exposed *O. nubilalis* females with and without extruded abdominal tips showed no significant differences between the treatments and the control (Figure 2, treatments H and I).

Odor Source: Mated Females

A male may transmit substances other than the reproductive spermatophore during mating. This may have an effect on the behavior of the parasitoids, and this hypothesis may also apply to females which, in laying their first eggs, release substances that may then stimulate the search behavior of the parasitoids. In both cases, we followed the same procedure as in the tests described above, i.e., with and without extrusion of the abdominal tip. All experiments were carried out in the middle (after 8 hr) of the light period (of 16 hr).

Emanations from mated females before their first oviposition, without extruded abdominal tips, cause a slight modification in *Trichogramma* activity (Figure 2, treatment J). The difference from the controls was only significant during the first few minutes (minutes 3–5) of a 20-min test. In contrast to the other tests, *Trichogramma* females were less responsive to mated females with an extruded abdominal tip, suggesting some sort of restraint (Figure 2, treatment K).

The response of female *Trichogramma* to host females tested after their first oviposition, with and without extrusion of their abdominal tips, caused no modification in the movement of the parasitoids (Figure 2, treatments L and

M). It thus appears that females loose the above-described properties once they have laid their eggs.

DISCUSSION

It is known that many insects exhibit positive anemotropism. The tendency to walk upwind in the control ("unscented") current suggests that *Trichogramma*, too, follow this rule. The volatile compounds emanating from the egg masses induce a modification in search behavior of *Trichogramma*, as Renou et al. (1989) demonstrated using extracts. However, these seem to be very concentration-sensitive. Under our experimental design, the parasitoids responded significantly only to the emanations from a group of three egg masses. It appears that the emanations from a single egg mass are not sufficient to lead to an increase in the movement activity of *Trichogramma*, which may be included under parasitoid search behavior. On the other hand, it appears that the emanations from five egg masses were too strong, suggesting that this concentration, perhaps by saturating the olfactory receptors, inhibits the behavioral response. Thus, these parasitoids probably have a minimum and maximum concentration threshold, which may explain the lack of response obtained by Kaiser et al. (1989), who presented 50 egg masses to the parasitoids.

There is a particular event in the life of female moths, namely the calling activity, which permits sexual recognition. It has already been shown that sex pheromones are kairomones for other species of *Trichogramma* (Lewis et al., 1982; Noldus et al., 1988). With regard to the adult stage of the host, comparison of the 1st and 2nd experiments confirms that virgin females liberate a kairomone by extrusion of their pheromonal gland. Thus, there exists a mixture of one or more molecules responsible for activating the displacement activity of *Trichogramma*. A similar mechanism has been demonstrated for *Trichogramma pretiosum* moving to the sex pheromone emitted by *Heliothis zea*, which it parasitizes (Noldus et al., 1988). Likewise, females in photophase (third experiment) induce an increase in oriented movement by *Trichogramma* when the abdominal tip is extruded. The behavioral response is less marked than for the emanations from a calling virgin, which would suggest that the molecule(s) is(are) in the process of being synthesized during photophase.

The fourth experiment suggests that, because of the 16:8 hr light–dark photoperiod, these kairomonal molecules are synthesized in the gland with the sex pheromone. Abnormal conditions, such as continuous photophase (Subchev, 1983, 1985), disturb the normal synthesis of the sex pheromone, making it ineffectual on the behavior of the males of their species and also on that of their parasitoids.

We have thus demonstrated a kairomone that is synthesized during pho-

tophase up until its liberation during the last 2 hr of scotophase. This kairomone is synthesized along with the sex pheromone of which it is a part, but which does not play any role in attracting the male since the synthetic pheromone does not modify the search behavior of *Trichogramma* [Kaiser et al., 1989; and Renou, who tested four different doses of synthetic pheromone: 1, 10, 100, and 1000 ng (personal communication)].

In addition, emanations from mated females without extruded pheromonal gland cause a slight activation of parasitoid movement, whereas mobility drops once the abdominal tip is extruded. In that case, the *Trichogramma* appear to be restrained and are not stimulated to move upwind toward the odor source. It is necessary to observe the oviposition behavior of the corn borer to interpret this phenomenon. This will be examined in the future. We may assume that after laying its first egg mass, the female may liberate an inhibitory substance around the deposited eggs. While deterring the female *Trichogramma*, these chemical signals, combined with those that attract, may favor parasitism through a better exploration of the substrate. This negative signal has been shown only in mated females, and they seem to loose these kairomonal properties after laying their first egg masses.

Acknowledgments—We thank A. Berthier and C. Brachet for technical assistance.

(Received October 28, 1991; accepted January 16, 1992)

Abstract—Two applications of isolates of *Paecilomyces marquandii* from suppressive chinampa soils or P. lilacinus from Peru, fungi that parasitize nematode eggs, generally gave better control of tomato root-knot due to *Meloidogyne incognita* than did a single application. The effects on root galling by each of the *Paecilomyces* isolates varied between experiments; however, the ovicidal potential of the three isolates did not differ significantly. Proteins specific for each of the isolates were demonstrated by SDS gel electrophoresis. The results indicate that *P. marquandii* is one of the natural soil organisms that contribute to nematode suppression in the chinampa agricultural soils.

Key Words—Nematode suppressive soil, *Paecilomyces marquandii*, *P. lilacinus*, *Meloidogyne incognita*, biological control.

INTRODUCTION

Paecilomyces lilacinus, a fungus parasite of nematode eggs, has been extensively investigated as a plant nematode biological control agent. Jatala (1985) reviewed studies that found consistent and efficient control of root-knot nematode (*Meloidogyne* spp.) on many crops by a strain of *P. lilacinus* from the International Potato Center (IPC), Peru. Cabanillas et al. (1989) tested 13 iso-

lates of *P. lilacinus* including the IPC isolate against *M. incognita* on tomato and concluded that mixtures of isolates gave the best control. In contrast, *P. lilacinus* did not effectively suppress *M. incognita* in 20 naturally infested tomato fields in California (Gaspard et al., 1990a,b). No control was obtained in studies of the IPC *P. lilacinus* isolate against *M. javanica* on tobacco in microplots (Hewlett et al., 1988). These studies represent a cross section of the many investigations that have yielded conflicting results on the efficacy of *P. lilacinus* in controlling plant nematodes.

Recently, the natural suppression of root pathogenic fungi (Lumsden et al., 1987) and of plant parasitic nematodes (Zuckerman et al., 1989) in the chinampa agricultural soils of central Mexico has been reported. The latter study involved the isolation and characterization of microbes that displayed antinematodal properties but did not include an assay for ovicidal fungi. Further examination of the chinampa soil revealed the widespread presence of another species of *Paecilomyces*, *P. marquandii*. *P. marquandii* has been reported from eggs of *Heterodera glycines* (Carris and Glawe, 1989), but to our knowledge the potential of this fungus as a nematode biocontrol agent has not been studied.

A primary objective of the current work was to examine the chinampa soils for the presence of nematophagous fungi, thereby adding to the characterization of nematode suppressiveness displayed by these soils.

This paper reports on studies of two isolates of *P. marquandii* from these soils and includes comparison of these cultures with the IPC isolate of *P. lilacinus*.

METHODS AND MATERIALS

Organisms. The nematode species for these trials was *Meloidogyne incognita* Race 3 and the tomato variety was *Lycopersicon esculentum* cv. Rutgers. The *P. lilacinus* culture originated from the IPC, Peru, and was obtained directly from Dr. N. Acosta, University of Puerto Rico, Mayaguez, Puerto Rico. The *P. marquandii* isolates, designated PM 1 and PM 2, were recovered from 50% of 20 samples taken from each of two locations of chinampa soil near Mexico City, D.F. Fungus cultures were maintained on potato dextrose agar at 25°C.

Greenhouse Trials. The experiments reported here consisted of three greenhouse trials, which encompassed 90 pots. For each trial, 2- to 3-week-old tomato seedlings grown in steam-sterilized potting soil were transferred individually to 5-in. pots containing one part sterilized soil to one part sand (1 kg/pot).

For experiments 1 and 2, fungus isolates were grown on steam-sterilized bran, sterilized for 20 min on two consecutive days. *Paecilomyces* spp. were grown for seven days on potato dextrose agar (PDA) at 25°C in the dark. Plates were flooded with sterile distilled water and scraped with a spatula to obtain a

spore suspension. Each 25 g of bran was inoculated with 1 ml of a 1×10^6 spores/ml suspension and incubated at 25°C in the dark for 10 days. To determine initial inoculum densities, 1 g of infested bran was shaken vigorously in 100 ml of sterile water and a dilution series to 10^{-10} prepared. One milliliter of each dilution was added to chitin–rose bengal agar (Godoy et al., 1982), the plates incubated for seven days at 25°C in the dark, and colonies counted. Controls for these experiments were sterilized bran inoculated with sterile water. Each treatment was replicated five times.

Where *Paecilomyces* spp. were applied as a drench (Experiments 2 and 3), the inoculum was grown on potato dextrose broth (PDB) (23 g/liter). Each flask containing 50 ml of media was inoculated with a 5-mm plug of fungus and incubated at room temperature for 10 days on a rotary shaker. Each pot received 50 ml of fungus culture and controls received 50 ml of PDB. Each treatment was replicated five times.

Seven days following the initial application of *Paecilomyces* spp., 5000–10,000 *M. incognita* eggs extracted and collected by the method of Hussey and Barker (1973) were added to each pot where appropriate. Greenhouse temperatures were between 24°C and 30°C. The duration of each experiment was 49 days.

One day prior to harvest of each experiment, a 5-mm soil core was taken from those pots that had received *Paecilomyces*. A 1-g subsample was added to 100 ml of sterile water and stirred vigorously for 10 min. One-milliliter aliquots were withdrawn while the suspension was stirring, added to Petri plates, and covered with liquefied chitin–rose bengal agar. Each plate was swirled to distribute the soil suspension, sealed with parafilm, and incubated at 25°C in the dark. Each combination was replicated three times.

Data were recorded on fresh and dry weights of the plants, and galling was assessed using a gall index as follows: 1 = 0–25% of roots galled; 2 = 25–50% galled; 3 = 50–75% galled; 4 = 75–100% galled. Data were also taken on the number of galls per root system. The data were analyzed by ANOVA supplemented by paired *t* tests.

Protein Analyses. To determine if the two *P. merquandii* isolates could be differentiated, proteins from the three fungus isolates were compared by SDS gel electrophoresis. The isolates were first grown in shake culture in potato dextrose broth for seven days at room temperature (22–25°C). Preparation of samples proceeded in the cold. Each culture was processed by passage through Whatman No. 1 filter paper, washed three times with distilled water containing 1 mm phenylmethylsulfonyl fluoride (PMSF), an equal volume of distilled water–PMSF added, and the resultant mixture processed in a Waring blender. This mixture was then passed through a Kontes "mini-bomb" cell disruption chamber using nitrogen at 100 kg/cm^2. The resultant homogenate was centrifuged at 38,720 *g* for 10 min at 4°C, the supernatant removed, 10% mercaptoethanol–

SDS added, and the sample stored frozen prior to electrophoresis. The procedure was replicated three times.

Proteins were separated by SDS gel electrophoresis on 7.5% polyacrylamide gels using a Hoefer Scientific SE600 vertical slab unit with discontinuous buffer, based on the method of Laemmli (1970). Molecular weight markers (1450–480,000) were purchased from Schwarz/Mann Biotech (Cleveland, Ohio 44128). Gels were stained with silver nitrate (Merril et al., 1980). The procedures were modifications of those described by Coles et al. (1989) and were repeated until reproducible protein spectra were attained for each isolate.

Culture Studies. In studies to compare the cultural characteristics of the three isolates, fungus cultures were grown at 25°C on potato dextrose agar. A sterilized cork borer was used to obtain uniform 5-mm fungus plugs to initiate cultures. Colony diameters were measured every two to three days and differences in colony appearance recorded.

RESULTS

Greenhouse Trials. A single application of each of the isolates gave little control of tomato root-knot (Table 1). The three trials in which the pathogenicity of the three *Paecilomyces* isolates to *M. incognita* eggs were compared gave

TABLE 1. EFFECTS OF SINGLE APPLICATION OF *Paecilomyces marquandii* ISOLATES AND *P. lilacinus* ON ROOT-KNOT OF TOMATO[a]

Treatment	Fresh weight (g/plant)		Gall index[b]	Control (%)[c]
	Top	Root		
Untreated control (25 g bran)	88.8 ± 11.1	19.5 ± 2.6		
Infested control (25 g bran)	86.5 ± 6.6	19.0 ± 1.2	2.0 ± 1.1	
PL + Mi	94.4 ± 14.6	20.1 ± 2.9	3.0 ± 0.71	
PM 1 + Mi	82.3 ± 11.2	17.1 ± 2.6	2.2 ± 0.71	15
PM 2 + Mi	88.8 ± 10.7	18.5 ± 2.1	2.0 ± 1.3	8
PM 1 + PM 2 + Mi	92.1 ± 10.4	18.9 ± 1.3	2.4 ± 1.6	
PM 1 + PL + Mi	94.2 ± 19.4	18.8 ± 3.7	2.7 ± 2.4	
PM 2 + PL + Mi	96.8 ± 10.6	20.7 ± 2.8	3.0 ± 0.71	

[a] Each treatment replicated five times. The data presented are the average of five replications ± the standard error. Fungus inoculum was added to each pot in 25 g bran. Inoculum density was 5000 *M. incognita* eggs/plant. There were no significant differences in plant weight or gall index. PL = *Paecilomyces lilacinus*; PM 1 = *Paecilomyces marquandii* isolate 1; PM 2 = *P. marquandii* isolate 2; Mi = *Meloidogyne incognita*.

[b] Gall index: 1 = 0–25% roots galled; 2 = 26–50%; 3 = 51–75%; 4 = 76–100%.

[c] Control (%) = 100 − (galls/treatment/galls/infested control).

variable results (Tables 2 and 3). Where intense root-knot pressure existed, significant reductions in galling generally occurred (Table 3). Tables 2 and 3 show variations in the efficacy of PM 2, specifically 50.3% control in one trial and 10.0% control in the second. However, a consistent trend was observed when data on the reduction of galling for all trials was averaged. These figures show a reduction in galling of 40% by the IPC *Paecilomyces*, 39% by PM 1

TABLE 2. EFFECTS OF TWO APPLICATIONS OF *Paecilomyces marquandii* ISOLATES AND *P. lilacinus* ON ROOT-KNOT OF TOMATO[a]

Treatment	Fresh weight (g/plant)		Gall index[b]	Control (%)[c]
	Top	Root		
Untreated control (25 g bran)	74.8 ± 13.67	14.6 ± 3.1		
Infested control (25 g bran)	68.0 ± 10.16	17.4 ± 1.3	1.6 ± 0.55	
PL + Mi	69.7 ± 16.25	15.3 ± 2.6	1.2 ± 0.45	31.5

[c]Control (%), see Table 1.

TABLE 3. TRIAL TO EVALUATE EFFECTS OF TWO DRENCH APPLICATIONS OF *Paecilomyces* ON ROOT-KNOT OF TOMATO[a]

Treatment	Fresh weight (g/plant)		Gall index[b]	Control (%)[c]
	Top	Root		
Untreated control (+50 ml PDB)	38.6 ± 4.0	6.7 ± 0.81		
Infested control (+50 ml PDB)	39.3 ± 4.7	6.7 ± 0.86	4.0 ± 0.89a	
PL + Mi	39.4 ± 9.1	7.0 ± 2.4	3.4 ± 0.89b	34.0
PM 1 + Mi	37.1 ± 7.1	6.5 ± 1.5	3.0 ± 0.71b	31.0
PM 2 + Mi	43.7 ± 9.1	7.1 ± 1.5	4.0 ± 0.71a	10.0

[a]Each treatment replicated five times. The data are presented as in Table 1. Gall indices followed by different letters are significantly different at the 5% level. Two applications each of 50 ml drench. Inoculum density was 10,000 eggs/pot.
[b]Gall index and abbreviations, see Table 1. Data followed by different letters differ significantly at the $P < 0.05$ level.
[c]Control (%), see Table 1.

and 36% by PM 2. We therefore conclude that these three isolates do not differ in pathogenicity to *M. incognita* eggs. All *Paecilomyces* isolates were successfully reisolated from treated soil after seven weeks (Table 4).

Plant growth was generally slightly better where the fungus–bran combinations were used. However, these differences were neither consistent nor statistically significant when compared to growth of the uninfected controls to which bran was added.

Culture Studies. The *P. marquandii* isolates each initially developed as white surface mycelium, with the underside of the culture exhibiting a bright, diffusible yellow pigment. Bright, purple spores were formed at 10–14 days. Growth rates of the isolates were significantly different, with *P. lilacinus* growing faster than the *P. marquandii* strains.

Under the same conditions, *P. lilacinus* formed a white surface mycelium with the underside of the culture tan to light brown. Brown to light purple spores formed on the leading edge of the mycelium at 10–14 days. *P. lilacinus* grew about twice as fast as did the two *P. marquandii* isolates.

Protein Analyses. The three isolates were differentiated on the basis of their protein spectra. The salient differences, shown on a representative gel, were four proteins (Figure 1C, protein cluster around second arrow from the top in high concentrations, which ranged from 166 to 250 kDa) present in *P. lilacinus* but not in *P. marquandii* isolates. PM 2 displayed a 470-kDa protein (Figure 1B indicated by second arrow from the top) at high concentration that was not present in PM 1. Two proteins (6 and 10 kDa, Figure 1B) present at lower concentrations in PM 2 were absent from PM 1. Several proteins common to *P. lilacinus* and PM 2 were not observed from PM 1 (e.g., 10-and 48-kDa proteins, Figure 1B,C).

DISCUSSION

Chinampa agricultural soils contain endemic populations of microorganisms that reduce population levels of plant-parasitic nematodes and decrease damage from these plant pests. In previous studies (Zuckerman et al., 1989), the level of nematode suppression was estimated at approximately 80%. The initial screen of chinampa soil in our laboratory yielded three fungal and six bacterial isolates that exhibited antinematodal activity (Zuckerman et al., 1989). Several additional microbes with similar properties were isolated in subsequent studies of suppressive soils (Zuckerman, Dicklow, and Marban-Mendoza, unpublished data).

In the current study, control by two applications of *Paecilomyces* averaged 30–40%. Based on these results, we estimate that root-knot control by *P. marquandii* in the field would reach 10–15%, since higher levels of control are

TABLE 4. INITIAL AND FINAL DENSITIES OF THREE *Paecilomyces* ISOLATES

Isolates	Initial inoculum density (CFU/g)[a]	Inoculum density at seven weeks (CFU/g soil)
P. lilacinus	1×10^8	1.96×10^3
P. marquandii isolate 1	9.9×10^9	1.18×10^3
P. marquandii isolate 2	5.2×10^{10}	1.12×10^3

[a] CFU = colony-forming units.

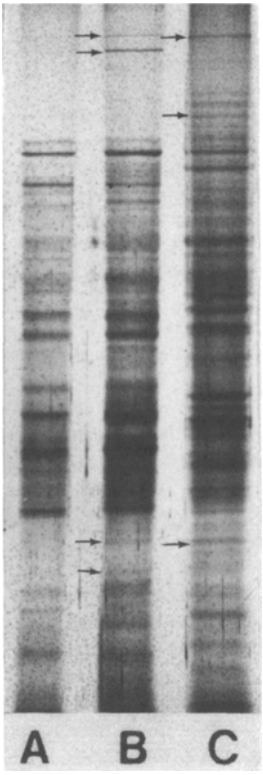

FIG. 1. Protein spectra of the (A) *Paecilomyces marquandii* isolate 1, (B) *Paecilomyces marquandii* isolate 2; and (C) *Paecilomyces* IPC isolate. Proteins specific for each isolate or common to two isolates but absent from the other as described in the text are indicated by arrows.

consistently attained in the greenhouse. Our interpretation of the current results is that *P. marquandii* plays a small, but consistent and important role as one of the natural biosphere colonists that contribute to the suppression of nematode damage in the chinampa soils.

Two applications of the *P. marquandii* isolates and the *P. lilacinus* isolate gave better root-knot control than did one application. The three isolates appeared to display equal ovicidal activity. Gel electrophoresis discriminated between *P. lilacinus* and the *P. marquandii* isolates and also showed specific differences in the two *P. marquandii* isolates. The faster growth rate of *P. lilacinus* suggests that this isolate might more readily colonize the plant rhizosphere than does *P. marquandii*.

(Received November 25, 1991; accepted January 16, 1992)

Abstract—The cuticular lipids were analyzed from individual *Polistes exclamans* workers collected from 10 nests. Surface lipids were also recovered from the paper and pedicels of these nests. Twenty-two hydrocarbons were identified in these lipid fractions. The major components of the wasp cuticular lipids were *n*-heptacosane, *n*-nonacosane, methylhentriacontane, and methyltritriacontane. Discriminant analysis of the hydrocarbon profiles of the adult wasps showed that the wasps group together according to their respective colonies. Several colonies from the same geographical location clustered more closely together than colonies from diverse locations. The nest papers and pedicels did not group with the wasps from their respective colonies, but the nest papers clustered together separately, as did the nest pedicels.

Key Words—*Polistes exclamans*, Hymenoptera, Vespidae, cuticular hydrocarbons, discriminant analysis, nest pedicel, nestmate recognition, social wasps.

INTRODUCTION

Insect cuticular hydrocarbons provide a hydrophobic barrier that protects individuals from desiccation (Blomquist and Dillwith, 1985; Hadley, 1985; Lockey, 1988). For many insect species, cuticular hydrocarbons have been shown to serve additional functions such as sex pheromones or recognition factors (Howard and Blomquist, 1982; Blomquist and Dillwith, 1985; Espelie et al., 1991).

Kin recognition cues for social insects are thought to be chemicals located in the cuticle that can be detected by other members of the colony (Wilson, 1971; Hölldobler and Michener, 1980; Fletcher and Michener, 1987). Studies with ants and termites have indicated that cuticular hydrocarbons play an important role in the process of kin recognition (Howard et al., 1982; Brill et al., 1986; Obin, 1986; Bonavita-Cougourdan et al., 1987; Vander Meer et al., 1989a; Bagnères et al., 1991). Several species of insects that are able to integrate into ant or termite colonies have cuticular hydrocarbon patterns very similar to those of their hosts (Howard et al., 1980; Vander Meer and Wojcik, 1982; Espelie and Hermann, 1988; Vander Meer et al., 1989b). These foreign insects are thought to be utilizing chemical mimicry in order to overcome normal nestmate recognition, thus supporting the possibility that cuticular hydrocarbons play a major role in kin recognition.

For several species of social wasps the nest has been clearly shown to be critical for the ontogeny of nestmate recognition ability (Shellman and Gamboa, 1982; Pfennig et al., 1983; Ryan et al., 1985; Gamboa et al., 1986; Venkataraman et al., 1988). When workers emerge, they come in contact with the nest and, with as little as 1 hr exposure to the nest, they are later able to discriminate between nestmates and nonnestmates (Pfennig et al., 1983). During the early stages of the colony development, when there are few adults on the nest, it would be especially advantageous for the emerging workers not to have to rely on the presence of the queen or workers to learn or acquire the nest odor (Gamboa et al., 1986).

Hydrocarbons have been found on the surface of the nests of several species of social wasps that are the same as those found on the cuticle of the respective wasps (Espelie and Hermann, 1988, 1990; Espelie et al., 1990). These nest paper hydrocarbons are necessary for *Polistes metricus* workers to be able to recognize their nest (Espelie et al., 1990). It has also been shown that these hydrocarbons must be on the nest in order for newly emerged *P. metricus* wasps to later recognize their nestmates (Singer and Espelie, 1992).

Although the importance of the nest for nestmate recognition has been established for several *Polistes* species, the role of cuticular and nest paper hydrocarbons has been examined only with *P. metricus*. In the present paper, we characterize the hydrocarbons extracted from the cuticle of *Polistes excla-*

mans workers and show with discriminant analysis that wasps from the same colony have a very similar profile of cuticular lipids.

METHODS AND MATERIALS

Collection. Ten colonies of *Polistes exclamans* were collected from sites in Clarke, Elbert, and Jackson counties in northeastern Georgia in June and July 1990 and immediately brought to the laboratory. Wasps were separated from their nests and frozen at −20°C. Workers were selected randomly from the wasps of each colony and extracted individually in redistilled hexane at room temperature for 60 sec (Blomquist et al., 1987). Pedicels were severed from the nest and extracted in hexane for 2 min at room temperature. Surface lipids were recovered from the nest paper by directing a stream of hexane at the outer surface of the nest and collecting the hexane in a beaker beneath the nest (Espelie et al., 1990).

Chemical Analysis. The hexane extracts were concentrated to dryness under a stream of nitrogen. The samples were resuspended in hexane (50–500 μl) and aliquots (usually 0.1–1%) were analyzed by combined gas chromatography–mass spectrometry. A Hewlett Packard 5890A gas chromatograph was equipped with a 25-m cross-linked methyl silicone capillary column with helium as the carrier gas. The oven temperature was kept at 55°C for 3 min after injection (splitless) and then the temperature was increased at a rate of 15°/min to a final temperature of 305°C. The column was connected to a Hewlett Packard 5970 mass selective detector, and mass spectra were recorded at 1.3-sec intervals at 70 eV. Data were analyzed with a Hewlett Packard Chem Station, and individual components were characterized by their mass spectra. Equivalent chain lengths were determined using standard *n*-alkanes (Sigma Chemical Co.) (Nelson, 1978; Blomquist et al., 1987), and quantitation was based upon peak areas of total ion chromatograms (Espelie and Bernays, 1989).

Discriminant Analysis. Results from the GC-MS analysis of the surface hydrocarbons from each wasp, nest paper, and nest pedicel were loaded according to percent composition onto an 84 × 22 matrix (Lotus 123). These data were transferred to a flat ASCII file on a Sun Microsystems 4/280 server running SunOS 4.0.3 (UNIX) prior to initial processing to produce submatrices and vectors representing wasps, nest paper, nest pedicels, and row/column labels, respectively. The smaller data subsets were analyzed by discriminant and hierarchical cluster analyses using the 2.2 version of the S-plus statistical software package (Statistical Sciences, Inc., 1989, 1990). Discriminant analyses were performed on the hydrocarbon profiles of the wasps only from colonies 0–9 and

on profiles of the wasps, nest papers, and nest pedicels of colonies 0–9 (Lachenbruch, 1975). Hierarchical cluster analyses, using average-linkage cluster formation on Euclidean distance between centroids of points, examined the hydrocarbon profiles of wasps, nest paper, and nest pedicels from each colony (Pielou, 1984; Becker et al., 1988). The data set was reduced from 22 to nine hydrocarbons for the analyses that included extracts of the nest papers and pedicels. The nine hydrocarbons in the reduced data set were common to the profiles of wasps, nest papers, and pedicels.

RESULTS

The cuticular hydrocarbons of *P. exclamans* workers were found by GC-MS analysis to be a mixture of *n*-alkanes, alkenes, methylalkanes, and dimethylalkanes. The major *n*-alkane was *n*-nonacosane, while the dominant methyl-branched hydrocarbons were a series of positional isomers of methylheptacosane, methylnonacosane, and methylhentriacontane (Table 1). The cuticular hydrocarbon compositions of the *Polistes exclamans* workers from the 10 nests (colonies 0–9) were very similar (Figure 1). Workers from nest 0 and nest 6 differed from one another primarily in the proportions of the methylheptacosanes and methylnonacosanes (Table 1).

The results of the GC-MS analyses of the cuticular hydrocarbons of the 50 wasps from the 10 colonies were analyzed by discriminant analysis in an effort to identify similarities between the cuticular hydrocarbon profiles of individual wasps from each nest. A plot of the first and second discriminant variables from this analysis resulted in a pattern where the five wasps from each colony clustered together in distinct groups (Figure 2). Colonies 0, 1, 2, and 3 were collected from widely separated geographic locations (>5 km). Colony 4 was collected at the same site as colony 3; the two nests were separated by 10 m. The hydrocarbon patterns for the wasps from colonies 0–4 are separated by the first discriminant variable (Figure 2). Colonies 5, 6, 7, 8, and 9 were collected from the same location and were located within 10 m of each other (>10 km from colonies 0–4). In the discriminant analysis, the hydrocarbon profiles of the workers from nests 5–9 are clustered in five groups, which are very close together. The individual wasps are clustered according to colony, but these clusters are not well separated by the first discriminant variable. The linear coefficients of the first discriminant variable are listed in Table 2. The components that were weighted most heavily in the analysis were heptacosene, *n*-heptacosane, *n*-octacosane, and dimethyltritriacontane.

The nest papers and pedicels of *P. exclamans* nests had surface hydrocarbon profiles that were very similar to those of the wasps (Table 1). However, several hydrocarbons that were minor components in the cuticular hydrocarbon profiles

of the wasps were not present in the extracts of the nest papers and pedicels. Consequently, a reduced data set (using the nine most dominant hydrocarbons) was utilized for a discriminant analysis of the hydrocarbon profiles of the wasps, nest papers, and pedicels. A plot of the first and second discriminant variables from this analysis resulted in clustering of wasps according to colony, but there was no association of the wasps with their respective nest paper or pedicel

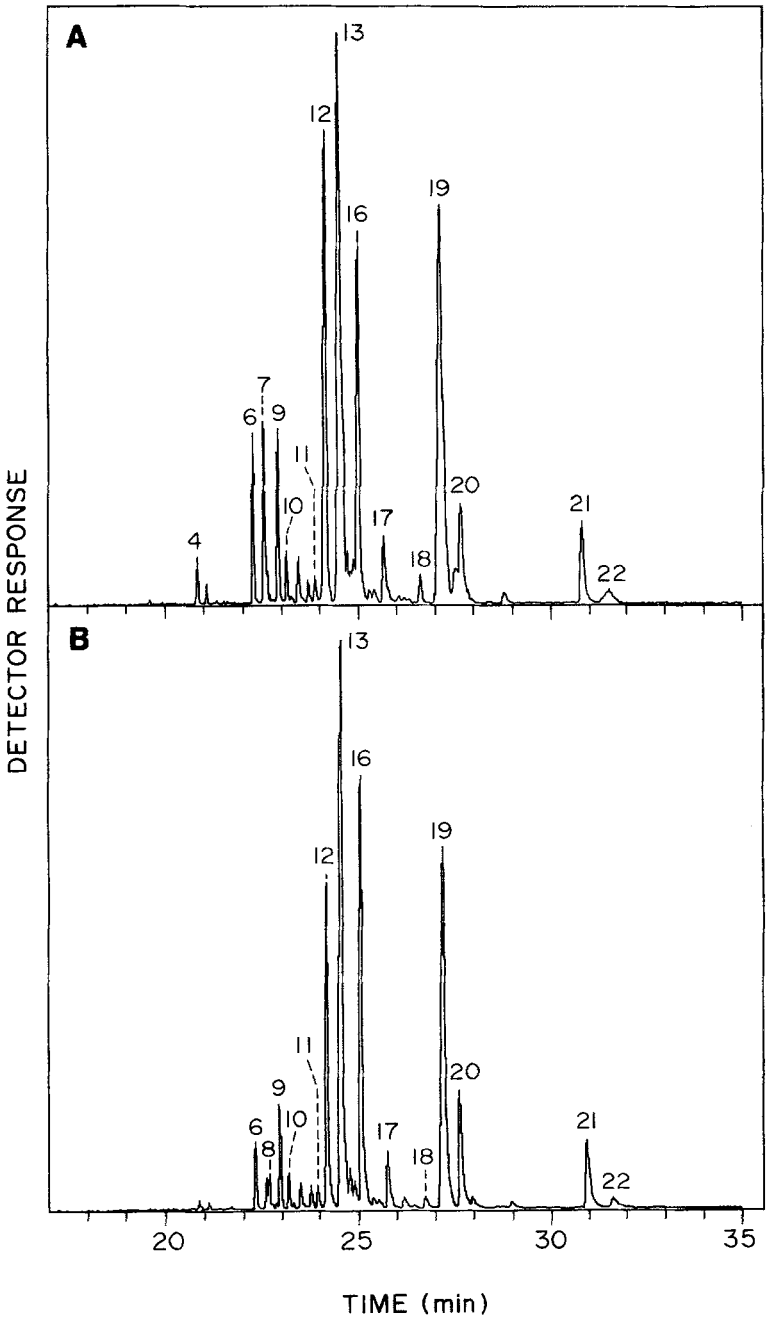

FIG. 1. Total ion chromatograms of the cuticular hydrocarbons of individual *Polistes exclamans* workers from (A) nest 0; and (B) nest 6. Numbered components are identified in Table 1.

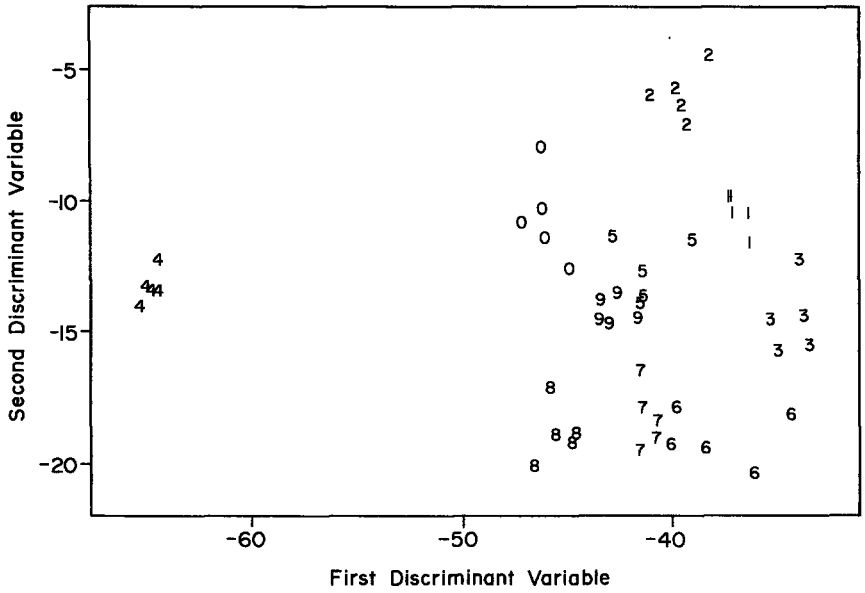

FIG. 2. Plot of the first two discriminant variables from a discriminant analysis of the cuticular hydrocarbons from workers from 10 colonies (0–9) of *Polistes exclamans*. Each number represents an individual wasp. Analysis was done on the complete data set (Table 2).

(Figure 3). The hydrocarbon profiles of the pedicels and the nest paper formed separate clusters. When nest paper profiles from two colonies plotted close to each other (e.g., 4 and 5), the hydrocarbon profiles of the nest pedicels from these two colonies did not plot close together. The hydrocarbons that were weighted most heavily in this analysis of wasps, nest paper, and nest pedicels were *n*-nonacosane and 3-methylnonacosane (Table 2).

A hierarchical cluster analysis was performed on the reduced data sets of hydrocarbon profiles for the wasps, nest papers, and nest pedicels (Figure 4). Again, most of the wasps clustered together according to colony. The nest paper and nest pedicel profiles clustered at either extreme of the dendrogram, indicating that they are very dissimilar to the wasps from their respective colonies. That is, nest paper profiles and nest pedicel profiles formed groups that were largely distinct.

DISCUSSION

The cuticular hydrocarbon composition of *P. exclamans* workers is similar to the compositions recently reported for workers of *P. annularis* (Espelie and Hermann, 1990) and *P. metricus* (Espelie et al., 1990). The major hydrocarbons

[a] Full names of components are listed in Table 1.

of *P. exclamans*, *n*-nonacosane and mid-chain methyl-branched positional isomers of methylnonacosane and methylhentriacontane (Table 1), were present in the cuticular lipids of both *P. annularis* and *P. metricus*. However, *P. annularis* and *P. metricus* workers had much higher proportions of dimethylbranched hydrocarbons (30% and 17%, respectively) than did *P. exclamans* (7%). *P. exclamans* and *P. annularis*, which are in the subgenus *Aphanilopterus*, had higher amounts of terminally methyl-branched hydrocarbons (15% and 29%, respectively) than did *P. metricus* (0.3%), which is in the subgenus *Fuscopolistes*.

Surface hydrocarbons may play an important role in nestmate recognition for *P. exclamans*. The similarity in hydrocarbon profiles of wasps within colonies (Figure 2) supports this possibility. Although the wasps from the same colony were clustered according to their hydrocarbon profiles, they did not have profiles that were similar to the hydrocarbons on the surface of their respective nests (Figure 3). It may not be necessary for a wasp to have the same surface

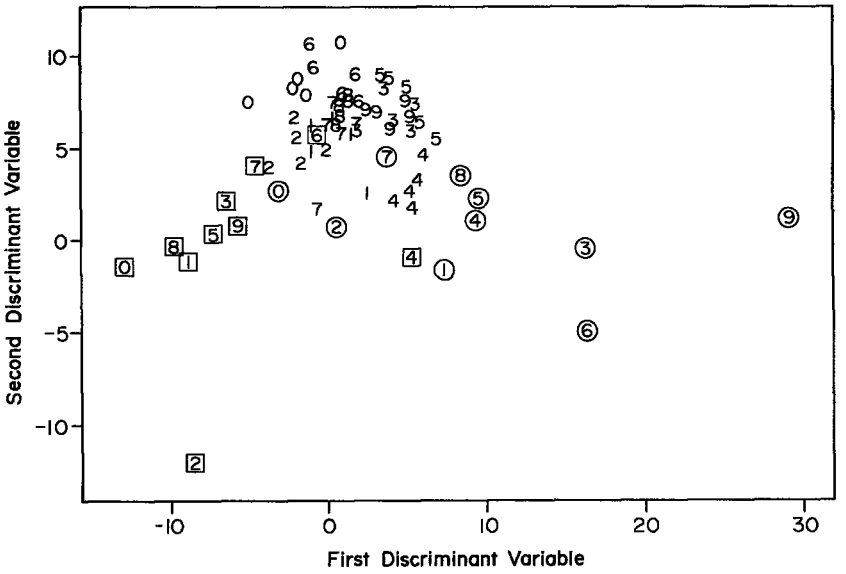

FIG. 3. Plot of the first two discriminant variables from a discriminant analysis of the hydrocarbons from workers (isolated numbers), nest paper (circles), and nest pedicel (squares) from 10 colonies (0–9) of *Polistes exclamans*. Analysis was done on the reduced data set (Table 2).

chemistry as its nest paper in order for that wasp to recognize the nest and other wasps from its colony. It is possible that the wasps, or wasps from some of the colonies, may utilize only some of the surface hydrocarbons for nest and nestmate recognition. Some wasps might recognize their nestmates primarily by the presence of the methyl-branched hydrocarbons (or the *n*-alkanes) rather than the mixture of both. With this possibility in mind, it is interesting that the cuticular lipids of the social wasps species that have been analyzed are a mixture of types of hydrocarbons, rather than merely a mixture of homologs with varying chain lengths (Espelie and Hermann, 1988, 1990; Espelie et al., 1990; Butts et al., 1991). Another possibility is that the mechanism of recognition in *P. exclamans* differs from that in *P. fuscatus* and *P. metricus*. For example, the nest may not be intimately involved in the development of recognition ability.

The similarity in the hydrocarbon profiles of the nest pedicel extracts (Figures 3 and 4) is intriguing. The hydrocarbon composition of the pedicels from 13 nests of *P. metricus* were also found to be very similar (Espelie et al., 1990). The pedicel and paper of *P. annularis* (Espelie and Himmelsbach, 1990) and *P. metricus* (Singer et al., 1992) nests have been shown to contain a protein that has a silklike amino acid composition. The pedicel has approximately six times as much protein as the nest paper. This higher protein content may cause

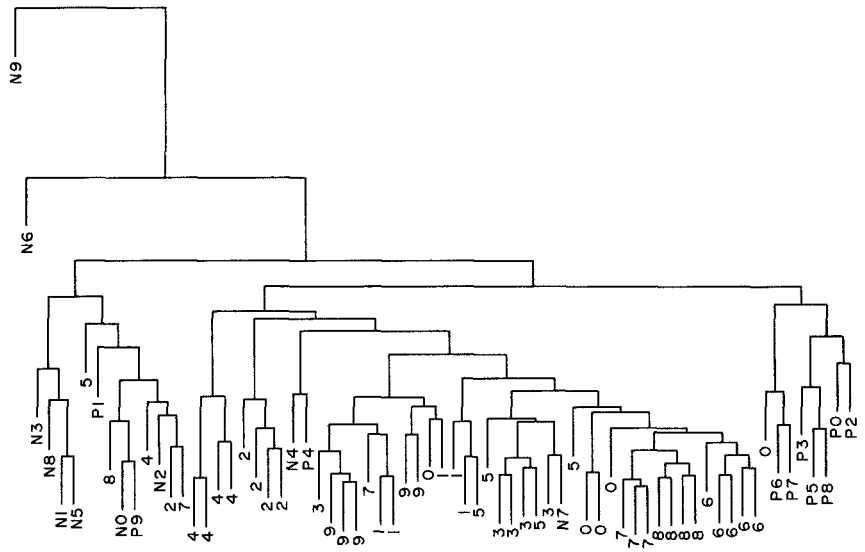

FIG. 4. Hierarchical clustering of the hydrocarbon profiles from individual workers (isolated numbers), nest paper (N), and nest pedicel (P) from 10 colonies (0–9) of *Polistes exclamans*. Analysis was done on the reduced data set (Table 2).

the selective retention of some of the surface hydrocarbons and result in the hydrocarbon profiles of the pedicel being different from those of the nest paper.

Many *Polistes* species are strongly philopatric and usually return to nest within 10 m of where their parental nests were built the previous year (Klahn, 1979; Strassmann, 1981; Reeve, 1991). Consequently, *Polistes* colonies are frequently found in aggregations. Workers are very likely to encounter members of other colonies, including related conspecifics. Willer and Hermann (1989) found that it was common for *P. exclamans* workers to switch from one nest to another at a study site that had several nests in close proximity. It was recently shown that *P. exclamans* workers are more tolerant of nonnestmates from nearby nests than they are of nonnestmates from distant nests (Pfennig, 1990). *P. exclamans* have a lower affinity for their nest than other *Polistes* species. In laboratory tests where *P. exclamans* workers were placed in a chamber with their own nest and another nest, they were found to be on their own nest 9% of the time, the other nest 3% of the time, and no nest 85% of the observed time (Singer and Espelie, unpublished results). In a similar test, the observed locations for *P. metricus* workers were 66, 3, and 31% for their own nest, the other nest, and no nest, respectively (Espelie et al., 1990). Wasps from the five colonies (5–9) that were collected from the same location in this study have similar hydrocarbon profiles (Figure 2). If variations in surface hydrocarbons

are important for kin recognition, it may be difficult for wasps with such similar profiles to discriminate between nestmates and nonnestmates from nearby nests. Behavior tests, such as those done with *P. metricus* workers (Singer and Espelie, 1992), will help to determine the role that cuticular hydrocarbons and nest paper hydrocarbons play in nestmate recognition for *P. exclamans*.

Acknowledgments—We thank Kimberly Fitzgerald for excellent technical assistance and the residents of northeastern Georgia who allowed us to collect wasp colonies from their property. This work was supported, in part, by Sigma Xi Grants-in-Aid to T.L.S. and by funds allocated by the University of Georgia Agricultural Experiment Station.

(Received June 24, 1991; accepted January 17, 1992)

Abstract—Oviposition by females of the pipevine swallowtail butterfly, *Battus philenor*, was stimulated by contact with alcoholic extracts of host foliage. D-(+)-Pinitol was isolated and identified from leaf material of one host species, *Aristolochia macrophylla* (Aristolochiaceae). In combination with chloroform-soluble components of host leaf material, this compound was comparable to the parent extract in stimulating oviposition.

Key Words—*Battus philenor*, Papilionidae, Lepidoptera, *Aristolochia macrophylla*, Aristolochiaceae, learning, D-pinitol, sequoyitol, *myo*-inositol, cyclitols, oviposition stimulant.

INTRODUCTION

Plant secondary chemicals are thought to pose both toxicological and behavioral barriers to evolutionary changes in host use by phytophagous insects (Fraenkel, 1959; Ehrlich and Raven, 1964; Feeny, 1987). Arguing that secondary chemicals represent principally behavioral barriers, Dethier (1941) and Jermy (1976,

*To whom correspondence should be addressed. Current address: Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, Arizona 85721.

1984) proposed that colonization of a novel plant by an insect species will be more probable if that plant contains compounds similar to those that the insects already use as cues in host recognition.

Dethier (1941) suggested that evolutionary shifts across plant families by swallowtail butterflies (family Papilionidae) were facilitated by essential oils shared by these families, compounds to which he found that the larvae were attracted (see also Takaishi et al., 1969; Saxena and Prabha, 1975; Khattar and Saxena, 1978). While the significance of essential oils as host-selection cues by papilionid larvae remains somewhat unclear (D.R. Papaj, K. Hale, D. Miller, and P. Feeny, unpublished), Feeny (1987) suggested that evolutionary host shifts were as likely to be regulated by the behavior of the adult female as by that of the larvae. Adult females choose the plant on which eggs will hatch and are known to oviposit "mistakenly" on nonhost plants from time to time. Plants on which mistakes are made may occasionally be incorporated into the host range of an insect population, perhaps leading eventually to the formation of new insect species (cf. Bush, 1975).

If inclusion of a given novel plant into a species' host range depends on how often eggs are mistakenly laid on the plant and if mistakes occur more frequently on plants containing chemicals similar to those that females use to select hosts than on chemically dissimilar plants, we might anticipate that related insect species will tend to exploit host species that are phytochemically, although not necessarily taxonomically, related. Exactly this pattern is observed in some taxa of butterflies (Ehrlich and Raven, 1964; Feeny et al., 1983), although little is yet known about which particular compounds are important in mediating host recognition.

Our paper is part of a broader effort by this and other laboratories to characterize the oviposition stimulants of the Papilionidae (Ichinosé and Honda, 1978; Saxena and Goyal, 1978; Feeny et al., 1983, 1988; Nishida, 1977; Ohsugi et al., 1985; Nishida et al., 1987; Nishida and Fukami, 1989; Honda, 1986, 1990). Comparative studies of different species in a family for which both larval food plants (Scriber, 1984) and systematics (Miller, 1987) are particularly well known should permit clarification of the roles played by plant chemistry in the evolution of phytophagous insects (Feeny, 1987, 1991). Here we report the isolation and identification of an oviposition stimulant for the pipevine swallowtail butterfly, *Battus philenor*, from the foliage of one of its host species, *Aristolochia macrophylla*. The pipevine swallowtail is found across much of the continental United States and Mexico (Tyler, 1975). Over its entire range, adults oviposit and larvae feed exclusively on plants in the genus *Aristolochia* in the family Aristolochiaceae (Opler and Krizek, 1984). A previous study (Papaj, 1986a) indicated that methanolic extracts of *A. macrophylla* leaves elicited oviposition by pipevine swallowtail females on artificial substrates treated with those extracts.

METHODS AND MATERIALS

Insects. Females of *B. philenor* used in bioassays comprised three types: those caught in the wild, those reared from eggs of individuals collected in the wild, and those reared from larvae collected in the wild. All adults and larvae were collected at two sites: Terrapin Mountain Overlook and Thunder Ridge Lookout, along the Blue Ridge Parkway in Jefferson County, Virginia. Individuals at these sites feed and oviposit exclusively on *A. macrophylla* (Papaj, 1986b).

Adults were stored in glassine envelopes at ca. 5–15°C until return to our laboratory at Cornell University. In the laboratory, individuals were stored in envelopes at 4°C on alternate days. On the days on which they were brought to room temperature and used in assays, they were fed a solution of 15% honey in water. All individuals were permitted to lay eggs on either *A. tagala* or *A. macrophylla* at least once every three days. Larvae collected in the field were stored at ca. 5–15°C until return to our laboratory at Cornell University where they were placed in cages located in a greenhouse. Larvae were fed mainly on cuttings of *A. macrophylla* collected from residential sites in Ithaca, New York, but also on live *A. macrophylla* and *A. tagala* plants cultured in the greenhouse. Larvae hatching from eggs laid by wild females held captive in the laboratory were reared under the same conditions.

Plants. A. macrophylla was collected from either of the general localities: (1) Jefferson County, Virginia, at various montane sites along the Blue Ridge Parkway, (2) Tompkins County, New York, at various sites in residential areas principally within the Ithaca city limits. Leaves were transported in a cooler to the laboratory at Duke or Cornell Universities, where they were extracted immediately. Representative plant specimens have been deposited in the Bailey Hortorium, Cornell University.

Bioassay Procedure. Bioassay of adult female response to plant extracts (concentrations expressed as gle, gram leaf equivalent, fresh weight) followed Feeny et al. (1988) with some modifications. A quantity (gle) of test extract was applied in a thin line across a 2.54-cm-wide strip of Whatman No. 1 cellulose. Solvent was blown off with nitrogen. The test strip was then hung in a cage and misted with water. A female was placed on the strip and permitted to walk up the strip. A positive response was recorded if the female curled her abdomen and extended her ovipositor upon tarsal contact with the treated zone. If the female did not curl her abdomen or extend her ovipositor within 15 sec, a negative response was recorded.

Females were usually pretested by placing them on damp paper in the absence of an extract or solvent. Any female that responded positively to the water blank was discarded. Similarly any female that extended her proboscis in response to the contact with a test strip (as if to drink) was also discarded. While

individuals were commonly retested in successive assays, females used in one assay were not reused for at least 30 min. Butterflies tested at shorter intervals exhibited a carry-over effect, tending to respond positively even to solvent if the response to the previous fraction had been positive.

Extraction and Fractionation of Plant Material. Leaves of *A. macrophylla*, in batches of approximately 300 g (fresh weight), were macerated in hot 95% EtOH (~2.5 liters), boiled for 5 min, and filtered. EtOH was removed from the filtrate by evaporation under reduced pressure at <40°C, and the resulting aqueous suspension was centrifuged to remove chlorophyll. The dark brown aqueous fraction (300 ml) was then extracted with $CHCl_3$ (3 × 300 ml) to yield the $CHCl_3$ fraction (Figure 1). The remaining aqueous fraction (post-$CHCl_3$ aqueous fraction) was further fractionated into the EtOAc fraction and the post-

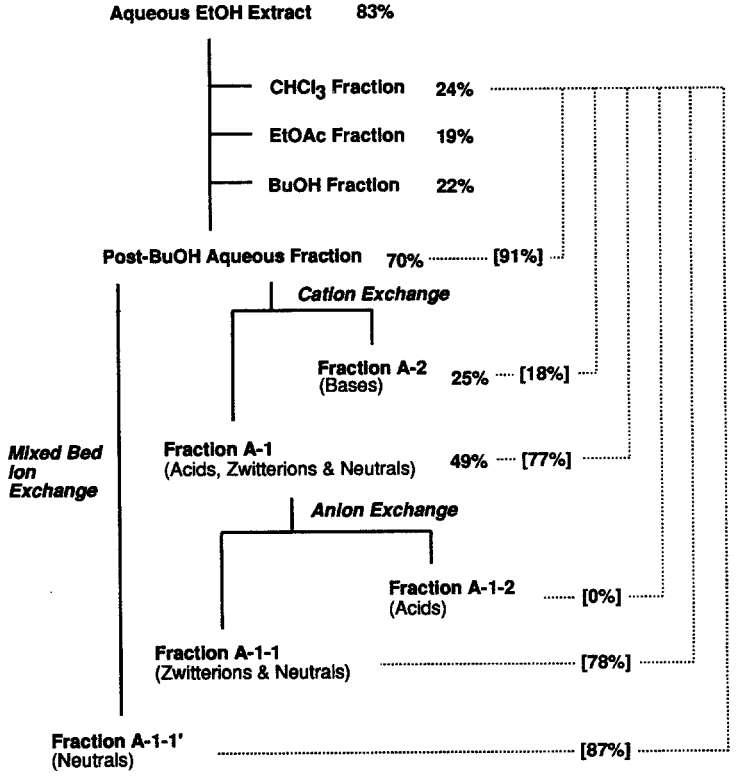

FIG. 1. Extraction scheme for isolation of oviposition stimulants for *Battus philenor* from leaves of *Aristolochia macrophylla*. Bioassay responses, as percentage of females giving a positive response, are shown for several fractions and (in brackets) combinations of fractions (see Tables 1 and 2 for relevant doses).

EtOAc fraction by extraction with EtOAc (3 × 300 ml). The post-EtOAc fraction was extracted with *n*-BuOH (3 × 300 ml) to obtain the BuOH fraction and the post-BuOH aqueous fraction (Figure 1). All the organic and aqueous fractions were concentrated under reduced pressure at <40°C. The organic fractions were evaporated to dryness and taken up in MeOH.

Instrumentation. HPLC fractionations were performed on a Waters 600 Multisolvent Delivery System equipped with a Waters model U6K LC injector, a Waters 490 Programmable Wavelength Detector, a Waters R 401 Differential Refractometer, and a Waters 730 Data Module.

Gas chromatography was carried out on a Perkin Elmer model 3920 GC, equipped with a FID detector and a glass column of 3% OV-101 (180 × 0.6 cm OD and 0.2 cm ID) supported on Chromosorb W-HP (mesh range 100–120). The flow rate of the carrier gas, N_2, was maintained at 40 ml/min. and the injector and detector temperatures at 280°C. EI mass spectra of TMSi derivatives were recorded on a Finnigan model 3300 Mass Spectrometer (70 eV) equipped with a wide-bore capillary column (Supelco) coated with SPB-1.

Analysis of Active Material. For the separation of bases from polar neutrals, acids, and zwitterions present in the post-BuOH aqueous fraction, the latter was subjected to cation exchange chromatography on Amberlite CG-50 (Sigma). The fraction (5 gle in 1.1 ml water) was loaded on a column (10 × 1.1 cm) of the resin packed in water. Two eluates (200 ml each) were collected using deionized water and 2 N HCl, respectively. The aqueous and acid eluates were concentrated by evaporation under reduced pressure to yield fractions A-1 (containing polar neutrals, acids and zwitterions) and A-2 (containing bases), respectively (Figure 1).

Further fractionation of A-1 was carried out by anion exchange chromatography. A-1 (5 gle) was applied to a column (10 × 1.1 cm) of Rexyn 203 (OH) resin (Fisher Scientific) prewashed with water (approx. 400 ml). Elution was achieved with water (100 ml), followed by 2 N HCl (100 ml). Both eluates were evaporated under reduced pressure. The aqueous fraction A-1-1 consisted of neutrals and zwitterions, whereas the second fraction A-1-2 contained acids (Figure 1).

For more rapid separation of polar neutral compounds from the post -BuOH aqueous fraction, the latter (20 gle) was passed through a column (17.5 × 1.1 cm) of Rexyn I-300 (H/OH) resin (Fisher Scientific). This mixed-bed resin is a strong cation and anion exchanger and therefore removes zwitterions and acidic and basic compounds from a mixture. The neutral compounds were eluted with water (200 ml). The aqueous fraction A-1-1′ (Figure 1) was concentrated by evaporation under reduced pressure at <40°C.

HPLC Fractionation of A-1-1′. The active fraction A-1-1′ was separated further into fractions 1–5 by HPLC on a YMC PAK-24 (25 × 1.0 cm) NH_2 partition column (YMC Inc.). The column was eluted with an isocratic system

of acetonitrile–water (75:25) at 3.0 ml/min. Separation was monitored by UV (195 and 200 nm) and RI detectors.

Preparation of Trimethyl Silyl Derivatives. HPLC fractions (each 0.4 gle in 100 μl water) were transferred to Reacti-vials (Pierce, 1 ml) and dried under a stream of N_2. The trimethyl silyl (TMSi) derivatives were prepared using Sil-Prep (Alltech Associates, 50 μl/sample). Each reaction mixture was stirred vigorously for 5 min on a Vortex mixer and then heated at ca. 120°C in a mineral oil bath for approximately 20 min with occasional shaking. The TMSi derivatives of standard samples of D-(+)-pinitol (100 μg), D-(+)-glucose (80 μg), sequoyitol (100 μg), sucrose (80 μg), and *myo*-inositol (100 μg) were prepared similarly. The sources of the standard compounds were: D-(+)-pinitol—a gift from Karen Lee Koster, Cornell University; D-(+)-glucose and *myo*-inositol—Sigma, sequoyitol—Roth; and sucrose—Empire Food Inc.

The TMSi derivatives were analyzed by GC using the following program: (1) 100°C for 4 min, (2) 100–305°C at 4°C/min, (3) hold at 305°C for 20 min.

Quantitative Analysis of A-1-1'. Fractions 1, 2, and 4 were reacted to form TMSi derivatives as above. Concentrations were determined by reference to standard GC chromatograms of TMSi derivatives of D-(+)-pinitol , sequoyitol, *myo*-inositol, and D-(+)-glucose.

Preparation of Acetyl Derivatives. Fraction 1 (0.2 gle) was dissolved in dry pyridine (100 μl) and dry acetic anhydride (100 μl) and kept overnight at room temp. The reaction mixture was diluted with ice cold water (200 μl) and evaporated to dryness. The gummy residue was taken up in water (200 μl) and extracted with $CHCl_3$ (3 × 200 μl). The $CHCl_3$ fraction was evaporated to dryness and redissolved in $CHCl_3$ (100 μl). A standard sample of D-(+)-pinitol (100 μg) was acetylated in the same manner. GC analyses of the acetates of fraction 1 and D-(+)-pinitol (2 μl each) were performed using the following program: (1) 100°C for 4 min, (2) 100–305°C at 8°C/min, (3) hold at 305°C for 5 min.

RESULTS

Ethanolic extracts of both young and mature *A. macrophylla* leaves were active in eliciting oviposition responses (Table 1), verifying earlier findings with methanolic extracts prepared in a similar manner (Papaj, 1986a). Bioassays indicated that activity was retained primarily in the aqueous layer after successive extractions with organic solvents (Table 1). Organic fractions, when bioassayed alone, were not active. The activity of the post-BuOH aqueous fraction, followed over a range of concentrations, increased steadily to a maximum at 1 gle and then decreased (Figure 2). Addition of the $CHCl_3$ fraction to the post-BuOH aqueous fraction, both at 0.1 gle, appeared to enhance activity, although the increase was not statistically significant (Table 1).

TABLE 1. CONTACT OVIPOSITION RESPONSES OF *Battus philenor* FEMALES TO EXTRACTS AND FRACTIONS OF EXTRACTS OF *Aristolochia macrophylla* LEAVES[a]

Extract	*N*	Response (%)
Young July leaves (EtOH)	30	**80**

[a] All doses were 0.1gle. All fractions from young leaf extracts. Results in boldface within a block differed significantly from respective solvent controls (χ^2 test, corrected for continuity, $P < 0.05$).
[b] Responses not statistically different from each other ($P = 0.074$).

The post-BuOH aqueous fraction was separated by weak cation-exchange chromatography into two fractions: (1) A-1, containing zwitterions and acidic and polar neutral compounds, and (2) A-2, containing basic compounds (Figure 1). When A-1 and A-2 were tested individually at 0.5 gle, activity was found only in A-1 (Table 2). The activity of A-1 appeared to be enhanced when bioassayed in combination with the $CHCl_3$ fraction while A-2 remained inactive (Table 2).

Fraction A-1 was partitioned on a weak anion-exchange resin. This procedure resulted in the separation of zwitterions and neutral compounds (fraction A-1-1), eluted with water, from acidic compounds (fraction A-1-2), eluted with HCl (Figure 1). Separate bioassays of A-1-1 and A-1-2 in combination with the $CHCl_3$ fraction indicated that activity resided solely in fraction A-1-1 (Table 2). The activity of A-1-1 could have been due to neutral compounds, zwitterions, or a combination of both. To resolve this question, a mixture of neutral compounds alone was isolated from the post-BuOH aqueous fraction by passing the latter through a mixed bed of strong cation- and anion-exchange resin. The neutral compounds were eluted with water to yield fraction A-1-1′ (Figure 1).

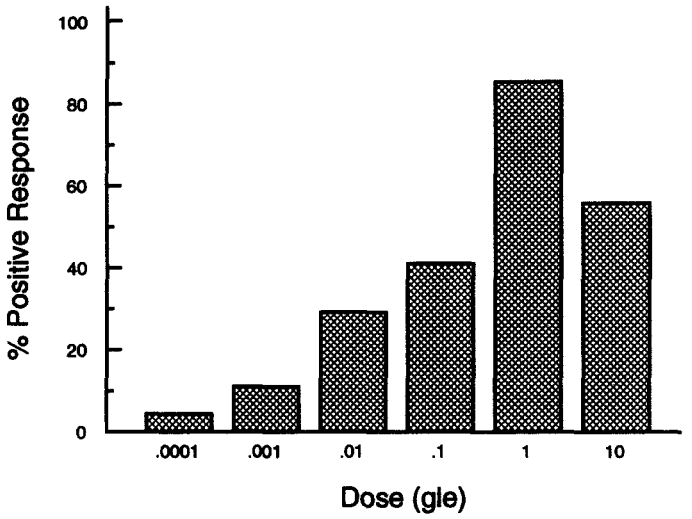

FIG. 2. Relationship of oviposition response of *Battus philenor* females to concentration of post-BuOH aqueous fraction from leaves of *Aristolochia macrophylla*. At least 15 females were tested at each concentration.

Fraction A-1-1′ alone, unlike the post-BuOH aqueous fraction, was inactive. However, when tested in combination with the $CHCl_3$ fraction, A-1-1′ was more active than the $CHCl_3$ fraction alone (Table 2). When both were tested in combination with the $CHCl_3$, A-1-1′ was as active as the post-BuOH aqueous fraction (Table 2).

Fraction A-1-1′ was separated by HPLC into five fractions, corresponding to four major peaks on the RI trace (fractions 1–4, respectively; Figure 3) and a combination of all pre- and postpeak eluents (fraction 5). When the fractions were tested in combination with the $CHCl_3$ fraction, only fraction 1 exhibited significant activity (Table 3).

Compounds present in fractions 1–4 were identified on the basis of their HPLC retention times, GC retention times, and mass spectra of their TMSi derivatives in comparison with those of standard compounds (Table 4) (Binder and Haddon, 1984; Sherman et al., 1970). Fraction 1 was identified as pinitol, fraction 2 as a mixture of sequoyitol and D-(+)-glucose, fraction 3 as sucrose, containing traces of glucose, and fraction 4 as *myo*-inositol (Figure 4). The identity of fraction 1 was confirmed by comparison of the GC retention time of its acetate with that of the penta acetate of D-(+)-pinitol (R_t = 14 min.).

Sequoyitol (0.5 gle), *myo*-inositol (0.6 gle), and D-(+)-pinitol (0.25 gle) were bioassayed in combination with the $CHCl_3$ fraction. Only D-(+)-pinitol was found to be active, evoking a 100% response (Table 3). Thus, the primary

active component of the post-BuOH aqueous fraction is D-(+)-pinitol, the activity of which is dependent on combination with one or more components of the $CHCl_3$ fraction.

DISCUSSION

D-(+)-Pinitol (5-*O*-methyl-D-*chiro*-inositol) has been reported previously by Plouvier (1956) from the leaves of three species of *Aristolochia*, including *A. macrophylla* Lam. (=*A. sipho* L'Her.; cf. Bailey, 1949). This compound is

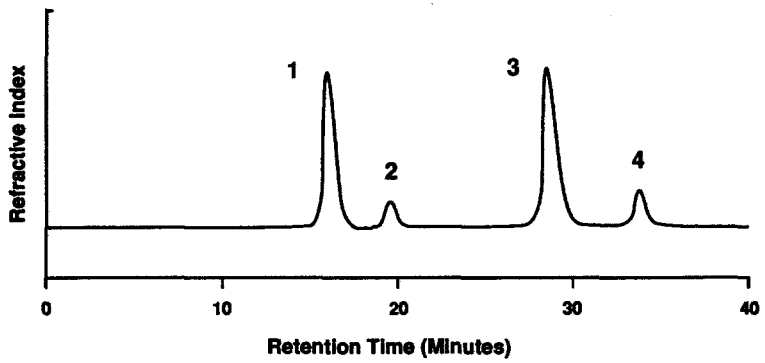

FIG. 3. HPLC trace of fraction A-1-1′, monitored with a RI detector, showing retention times of polar neutral components. Compounds were identified as follows: 1 = D-(+)-pinitol, 2 = D-(+)-glucose and sequoyitol, 3 = sucrose, 4 = *myo*-inositol.

[a]Prevalence of [M+1]$^+$ ions probably resulted from high sample pressure in the EI source (McLafferty, 1957; Silverstein et al., 1974).

one of the most widespread and abundant cyclitols in the plant kingdom (Plouvier, 1963; Kindl and Hoffmann-Ostenhof, 1966; Dittrich and Korak, 1984); however, it cannot by itself explain the extraordinary specificity to members of the genus *Aristolochia* that is characteristic of ovipositing pipevine swallowtails. Such specificity must be attributable to one or more compounds in the active chloroform fraction that interacts synergistically with D-(+)-pinitol. Nishida et al. (1987) recently identified contact oviposition stimulants for another *Aristolochia*-feeding swallowtail butterfly, *Atrophaneura alcinous* (recently reclassified as *Parides alcinous*; cf. Miller, 1987). They found that a mixture of sequoyitol (an isomer of D-(+)-pinitol) and aristolochic acids, isolated from *Aristolochia debilis*, elicited oviposition as effectively as did the parent extract. Since aristolochic acids are restricted in distribution to the family Aristolochiaceae (Mix et al., 1983; Chen and Zhu, 1987), while sequoyitol is widely distributed (Plouvier, 1963; Kindl and Hoffmann-Ostenhof, 1966), Nishida et al. (1987) attributed the oviposition specificity of *P. alcinous* females to the presence of the aristolochic acids. Current work in our laboratory suggests that aristolochic acids, which occur in the chloroform fraction of *A. macrophylla*

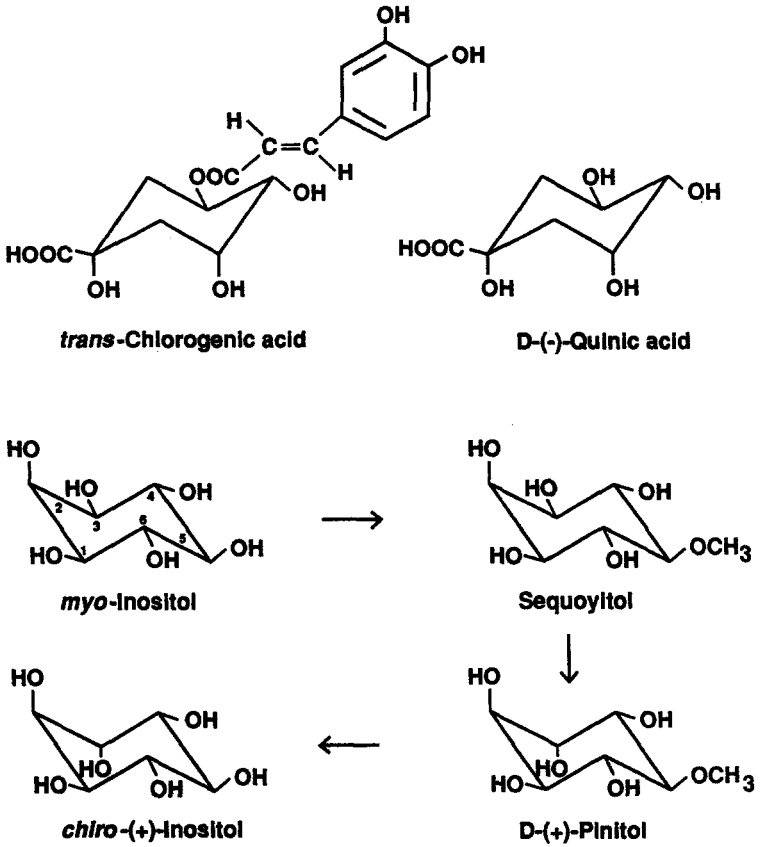

FIG. 4. Cyclitols and structurally similar compounds known to serve as larval feeding or oviposition stimulants for swallowtail butterflies. Inositol structures are portrayed in their preferred conformations. Arrows indicate typical biosynthetic relationships of D-(+)-pinitol to related inositols.

extracts, likewise contribute to host recognition by ovipositing pipevine swallowtails (K. Sachdev-Gupta, P. Feeny, and M. Carter, unpublished results).

Although we found D-(+)-pinitol to be the major methyl inositol in *A. macrophylla* leaves, traces of sequoyitol were also present. At similar doses in terms of gram leaf equivalents, sequoyitol was less stimulatory to *B. philenor* females than was D-(+)-pinitol (Table 3). While we do not yet know whether *P. alcinous* females would respond to pinitol, it is possible that these two species, representing the two subtribes (Battiti and Troiditi, respectively) of the tribe Troidini (Miller, 1987), have diverged in their relative sensitivity to the two isomers.

Inositols have frequently been shown to play a role in host recognition by insect larvae or adults. Hamamura et al. (1962) showed that *myo*-inositol, isolated from mulberry leaves, acts as a cofactor in stimulating feeding by silkworm larvae, *Bombyx mori*. More recently, both *myo*-inositol and D-pinitol, from the host plant *Lespedeza cuneata*, have been shown to act as biting stimulants (Numata et al., 1979) and arrestants (Numata et al., 1985) for larvae of the yellow butterfly, *Eurema hecabe mandarina*. Among swallowtails, (+)-*chiro*-inositol is one of several oviposition stimulants for *Papilio xuthus* (Ohsugi, et al., 1991). Curiously, while *myo*-inositol and *chiro* -inositol failed to enhance oviposition responses of a related *Citrus*-feeding species, *P. protenor*, this species responded strongly to D-(−)-quinic acid (Honda, 1990), which is similar in structure to the inositols (Figure 4). Both *P. protenor* (Honda, 1990) and *P. polyxenes* (Feeny et al., 1988) respond strongly to *trans*-chlorogenic acid, which is a cinnamic acid ester of quinic acid. The frequency with which cyclitols, or molecules of similar structure (Figure 4), have been reported as synergists in host recognition suggests that they may play a fundamental role in chemoreception, perhaps as primers for responses to other plant compounds of less general distribution. Even quite simple carbohydrates have enormous potential for encoding biological information and are implicated increasingly in cell–cell recognition (e.g., Sharon and Lis, 1989). In animal cells, at least, *myo*-inositol gives rise to a variety of inositol phosphates that play fundamental signaling roles by modifying cellular calcium dynamics in response to external stimuli (Berridge and Irvine, 1989).

A major biosynthetic pathway to D-pinitol in plants, established particularly in gymnosperms, originates from *myo*-inositol, itself formed from D-glucose-6-phosphate (Kindl and Hoffmann-Ostenhof, 1966). Methylation of *myo*-inositol to sequoyitol is followed by epimerization of sequoyitol to D-(+)-pinitol (Figure 4) (Kindl and Hoffmann-Ostenhof, 1966). Our finding of small amounts of *myo*-inositol and sequoyitol, in addition to D-(+)-pinitol, is consistent with the occurrence of this pathway in *A. macrophylla*. D- *chiro*-(+)-Inositol is a well-known demethylation product of D-(+)-pinitol (Kindl and Hoffmann-Ostenhof, 1966; Dittrich and Brandl, 1987). In several leguminous plants, D-pinitol is formed by epimerization of D-ononitol, itself arising by methylation of *myo*-inositol (Dittrich and Brandl, 1987). The frequent reports of insect responses to D-(+)-pinitol, sequoyitol, *myo*-inositol and D-*chiro*-(+)-inositol, rather than to other isomers of simple or methyl inositols, presumably reflect the widespread occurrence of these biosynthetic pathways, and hence their metabolites, in plants. The extent and significance of specificity by particular insect species for one inositol rather than another remains to be established.

The physiological or ecological functions, if any, of D-pinitol in plants remain obscure (Gardner et al., 1984). An early report of toxicity to *Heliothis zea* larvae, suggested as a cause of resistance to insects in certain soybean

varieties (Dreyer et al., 1979), was not confirmed by subsequent studies (Gardner et al., 1984). D-Pinitol is not toxic to mice (Tarazona and Sanz, 1990). Although the compound was reported as a feeding inhibitor for *H. zea* larvae (Reese et al., 1982), it had no effect on the feeding behavior of the pea aphid, *Acyrthosiphon pisum* (Campbell and Binder, 1984). On the basis of the evidence at hand, it seems unlikely that D-pinitol serves a significant defensive role against herbivores.

We close by noting that D-pinitol's impact on host selection by *B. philenor* very likely goes well beyond the stimulatory effect elicited upon tarsal contact. In addition to contact phytochemicals, *B. philenor* females also use leaf shape as a cue by which to find host plants (Rausher, 1980), orientation responses that have to be learned (Papaj, 1986a). While the stimulus modified by experience is a visual one, the experience itself is of a chemical nature: females permitted to contact nonhost plants treated with ethanolic host extracts learn the shape of the nonhost leaves (Papaj, 1986b). Contact phytochemicals thus act both as releasers for egg deposition behavior and as unconditioned stimuli (i.e., "rewards") with which previously neutral leaf-shape stimuli (i.e., conditioned stimuli) are positively associated.

We eagerly await the opportunity to examine whether contact with pinitol, alone or in combination with chloroform-soluble components, is required in order for pipevine swallowtail butterflies to learn the leaf shape of their host plant. Associative learning of visual cues upon contact with phytochemical stimuli has been reported for one other butterfly, *Pieris rapae* (Traynier, 1984, 1986, 1987). In *P. rapae*, approach-and-alighting responses to color are altered by prior contact with a single compound, sinigrin, a glucosinolate commonly found in the insect's cruciferous hosts. Sinigrin was shown previously to elicit egg deposition upon contact by female *P. rapae* (David and Gardiner, 1962; Renwick and Radke, 1983). We predict that, in contrast to Traynier's findings with *P. rapae*, at least three chemical components will be required to induce a preference for leaf shape in *B. philenor* butterflies. One of these components is likely to be D-(+)-pinitol.

Acknowledgments—We thank Mark Rausher and Maureen Carter for help with various aspects of the research, Karen Lee Koster for a sample of D-(+)-pinitol, and the National Park Service for permission to collect *B. philenor* females from the Blue Ridge Mountains, Virginia. The work was supported by NSF Research grants BSR-8516832 and BSR-8818104 to P.F.

(Received October 2, 1991; accepted January 22, 1992)

Abstract—The buckeye butterfly, *Junonia coenia* (Lepidoptera: Nymphalidae), specializes on plants that contain iridoid glycosides. To determine the fate of these compounds in larvae, pupae, and adults of this species, we reared larvae on artificial diets with and without iridoid glycosides, and on leaves of a host plant, *Plantago lanceolata* (Plantaginaceae). Quantification by gas chromatography showed that newly molted third-, fourth-, and fifth-instar larvae reared on leaves of *P. lanceolata* contained means of 5.13, 2.88, and 6.83% dry weight iridoid glycoside. In contrast, the mean iridoid glycoside concentration of actively feeding fifth-instar larvae was 0.28% dry weight, that of pupae was 0.19% dry weight iridoids, and adults contained no detectable iridoids. Feeding experiments suggested that this reduction in actively feeding larvae was due to the metabolism of iridoid glycosides. *P. lanceolata* leaves in these experiments contained a mean of 1.00% dry weight iridoid glycoside, with a 2:1 ratio of aucubin to catalpol. Calculation of iridoid consumption and utilization indices showed that larvae fed artificial diets consumed, digested, and sequestered aucubin and catalpol in similar ways. When these indices were calculated for larvae fed leaves of *P. lanceolata*, catalpol was sequestered twice as efficiently as aucubin.

Key Words—*Junonia coenia*, Lepidoptera, Nymphalidae, *Plantago lanceo-*

lata, chemical defense, evolution of unpalatability, iridoid glycosides, aucubin, catalpol, ecological chemistry, sequestration.

INTRODUCTION

Chemicals used in defense by insects may be synthesized de novo or acquired from larval or adult food resources (Blum, 1981; Brower, 1984; Brattsten, 1986). For those insects that sequester chemical defenses from larval host plants, the amount of defensive chemicals that they contain (and therefore, their protection from potential predators) is a function of plant chemical content, the insect's ability to select plants or plant parts high in useful defensive chemicals, and insect sequestrative efficiency (Brower and Brower, 1964; Bowers, 1988a). However, not all insects feeding on plant species with potential defensive compounds sequester these compounds for defense; in some cases the compounds are metabolized or excreted (Brattsten, 1979, 1986; Duffey, 1980; Blum, 1983). In addition, not all compounds that are sequestered contribute to an insect's unpalatability (Brower, 1984).

Iridoid glycosides are sequestered by insect species in four orders: Lepidoptera, Hymenoptera, Homoptera, and Coleoptera (Bowers, 1988a, 1992; Nishida and Fukami, 1989; Rimpler, 1991). The Lepidoptera have been particularly studied in this regard. For example, checkerspot butterflies of the genus *Euphydryas* may contain as much as 9% dry weight iridoid glycosides (Gardner and Stermitz, 1988), although iridoid glycoside concentration varies immensely among individuals from a single population (Gardner and Stermitz, 1988; Bowers, 1992). These butterflies are generally unpalatable to birds (Bowers, 1980, 1981; Bowers and Farley, 1990), but chemical content and degree of unpalatability may vary depending on the larval host plant (Bowers, 1980; Belofsky et al., 1989; Bowers and Farley, 1990).

The buckeye butterfly, *Junonia coenia* Hübner (Nymphalidae), specializes on plants that contain iridoid glycosides (Bowers, 1984). Two iridoid glycosides, aucubin and catalpol, that are found in many of the host plants of *J. coenia*, serve as both feeding and oviposition stimulants (Bowers, 1984; Pereyra and Bowers, 1988). Adult buckeye butterflies are palatable to gray jays, *Perisoreus canadensis* (Corvidae) (Bowers and Farley, 1990), and exhibit a pattern and coloration typical of palatable lepidopterans: the underside is quite cryptic, whereas the upperside has bright eyespots that may startle predators (Cott, 1940; Edmunds, 1974). The adults were also readily eaten by a captive big brown bat (*Eptesicus fuscus*), although the larvae were rejected (Bowers, personal observation). Buckeye larvae also appear to be unpalatable to ants (Dyer and de la Fuente, personal observation). The coloration of buckeye larvae is not easily classified as cryptic or warning: last-instar larvae are black with spines, blue and yellow spots, and an orange head. They may be quite apparent when feeding

on the host plant, but difficult to find in low vegetation (Camara, personal observation; Bowers, personal observation). Qualitative analyses of buckeye tissue by thin-layer chromatography had indicated that two iridoid glycosides, aucubin and catalpol, were present in larvae and pupae, but were absent or in undetectable amounts in the adult (Bowers and Puttick, 1986).

To determine the fate of iridoid glycosides in different life stages of *J. coenia*, we performed a series of chemical assays and a feeding experiment designed to answer the following questions: (1) What are typical host-plant iridoid glycoside concentrations to which larvae of the buckeye are exposed? (2) What happens to aucubin and catalpol in larvae, pupae, and adults?

METHODS AND MATERIALS

Study Organisms. Junonia coenia (Nymphalidae) were from a laboratory culture originally started with eggs obtained from a culture maintained at Duke University. Larvae were reared on garden- and greenhouse-grown *Plantago lanceolata* (Plantaginaceae) leaves for approximately seven generations prior to the feeding experiment in March 1988. *P. lanceolata* is commonly used as a host plant by *J. coenia* (Bowers, 1984; Scott, 1986) and contains two iridoid glycosides, aucubin and catalpol (Duff et al., 1965; Bobbitt and Segebarth, 1969).

Iridoid Glycoside Content of P. lanceolata *Leaves.* In the feeding experiments to determine nutritional and iridoid indices (described below), half of each leaf fed to the larvae was saved for iridoid glycoside analysis. The iridoid glycoside content of those leaves was used to calculate the iridoid indices and to provide a measure of the range of iridoid glycoside concentrations to which larvae were exposed in the leaf diet.

The iridoid glycoside contents (aucubin and catalpol) of plants were determined by gas chromatography using the methods of Gardner and Stermitz (1988). Using gas chromatography, we were able to detect levels as low as 0.001 mg of iridoid glycoside per sample. Phenyl-β-D-glucose was used as an internal standard. Purified aucubin was obtained from W. Berkowitz and catalpol was extracted from *Catalpa speciosa* (Bignoniaceae). Gas chromatography showed that both these compounds were at least 99% pure.

Iridoid Glycoside Content of Larvae, Pupae, and Adult J. coenia. Newly molted third- ($N = 5$ groups of five larvae), fourth- ($N = 5$ groups of two larvae) and fifth-instar larvae ($N = 16$), pupae ($N = 14$), and adults ($N = 10$) were taken from the laboratory culture maintained on *P. lanceolata* leaves to be analyzed for iridoid glycosides. Each insect was weighed on a Mettler HK60 microbalance to the nearest 0.01 mg. Because the larvae were newly molted, they had no food material in the gut. We were therefore analyzing larval iridoid

content. However, caterpillars may be attacked by potential predators while they are feeding, at which time the gut contents may also be important in determining their unpalatability and thus acceptability to predators (Brower, 1984). We therefore also analyzed actively feeding fifth-instar larvae ($N = 15$). In addition, a total of six actively feeding fifth-instar larvae were analyzed for iridoid glycoside content one, two, and three days after molting ($N = 2$ per day). Individuals were frozen for 48 hr and were then dried for at least 48 hr at 50°C. Extraction and gas chromatographic analysis were as described above for plants.

Quantification of Fate of Ingested Iridoid Glycosides in J. coenia. Because the above assays showed a dramatic decrease in levels of iridoid glycosides in actively feeding fifth-instar larvae, we designed a feeding experiment to answer the following questions: (1) What happens to iridoid glycosides in the fifth (final) instar? (2) Does presence of iridoid glycosides in the diet affect feeding and food utilization efficiency? (3) How efficiently do fifth-instar *J. coenia* larvae sequester aucubin compared to catalpol?

Newly hatched first-instar *J. coenia* larvae were transferred in groups of 20 to Petri dishes and fed a standard artificial diet (Nijhout, unpublished data) containing no iridoid glycosides or plant material, for the first four instars (approximately two weeks). Immediately after molting to the fifth instar, larvae were assigned to one of four experimental diets ($N = 15$/diet): (1) diet containing 2% dry weight catalpol (488.0 mg) (diet + CAT); (2) diet containing 2% dry weight aucubin (488.0 mg) (diet + AUC); (3) diet with no iridoids (diet); and (4) *P. lanceolata* leaves (leaves). Each newly molted fifth-instar caterpillar was weighed at the beginning of the experiment. Larvae were fed ad libitum until they were found spinning a silken pad for pupation. All food was weighed prior to feeding, and any leftover food was recovered, dried, and weighed.

Ten additional newly molted fifth-instar larvae were weighed, frozen, and dried at 50°C to constant weight in order to obtain a wet weight/dry weight conversion factor. Ten pieces of each artificial diet were separately weighed, dried at 50°C, and reweighed, in order to calculate a conversion factor to be used to determine the dry weight of diet eaten by each larva (Waldbauer, 1968).

Because individual *P. lanceolata* leaves on a given plant have variable concentrations of iridoid glycosides (Bowers, Collinge, Fajer, unpublished data), larvae on the leaves diet were fed in the following manner: individual leaves were cut down the midvein; one half was weighed and fed to the larva, and the other half was weighed and dried at 50°C for subsequent iridoid glycoside analysis. In this way, we could estimate the total amount of iridoid glycosides fed to each larva.

Larvae used in the feeding experiment were collected either when they were hanging to pupate or after they had pupated and were frozen and dried as above. All larval frass was collected from each caterpillar in the feeding experiment, dried, and weighed prior to iridoid glycoside analysis. Extraction and

quantification of iridoid glycosides from leaves, larvae, pupae, and frass were done as described above.

Standard nutritional indices were calculated for each caterpillar (Waldbauer, 1968), and the results from the iridoid glycoside analyses were then used to calculate an iridoid glycoside budget for each individual larva (see Roeske et al., 1976, for cardenolide indices). We compared the amount of iridoid glycoside ingested, the amount sequestered by the larva, the amount eliminated in the frass, and the amount lost, or metabolized. We then calculated iridoid utilization indices (Table 1), which were based on our chemical analyses and the standard nutritional indices. For the two artificial diets containing iridoids, the dry weight of diet eaten by each caterpillar was multiplied by the concentration of iridoid glycoside in the diet (2%) to yield the "iridoid ingested" (Table 1). For those larvae fed leaves, the concentrations of both aucubin and catalpol in the remaining leaf halves (i.e., those not fed to the larvae), as determined by gas chromatography, were multiplied by the dry weight eaten by each caterpillar to yield iridoid ingested (Table 1). Iridoid gained (Table 1) was the amount of iridoid present in larvae or pupae fed each of the diets (determined by gas chromatography). Iridoid in frass (Table 1) was obtained by analyzing all of the frass from each individual larva. For those larvae fed leaves, aucubin and catalpol indices were calculated separately.

Statistical Analyses. Nutritional and iridoid indices are proportions, and they were therefore transformed [arcsine (square root)] prior to analyses. Nutritional indices for larvae in the four treatments were compared by one-way ANOVA. Orthogonal contrasts compared the diet vs. diet + CAT and diet + AUC treatments, and the leaves diet vs. all artificial diets. Iridoid indices were

TABLE 1. DEFINITIONS OF AND FORMULAS USED FOR CALCULATING IRIDOID INDICES; MODIFIED FROM NUTRITIONAL INDICES OF WALDBAUER (1968)

$$\text{Relative consumption rate } (RCR_I) = \frac{\text{iridoid ingested}}{\text{mean larval weight}}$$

$$\text{Relative growth rate } (RGR_I) = \frac{\text{iridoid gained}}{\text{mean larval weight}}$$

$$\text{Approximate digestibility } (AD_I) = \frac{\text{iridoid ingested} - \text{iridoid in frass}}{\text{iridoid ingested}}$$

analyzed by one-way ANOVA first by comparing larvae fed diet + CAT to those fed diet + AUC, and second by comparing aucubin and catalpol indices for larvae fed *P. lanceolata* leaves.

RESULTS

Iridoid Glycoside Content of Plantago lanceolata. Analyses of leaves of *P. lanceolata* used in the feeding experiments ($N = 15$) showed that total iridoid glycoside content ranged from 0.69 to 1.17% dry weight ($\bar{X} = 1.00 \pm 0.04$ SE). Although variable, the concentration of aucubin ($\bar{X} = 0.66 \pm 0.03$ SE) was approximately twice that of catalpol ($\bar{X} = 0.34 \pm 0.02$ SE).

Iridoid Glycoside Content of Larvae, Pupae, and Adult J. coenia. Newly molted third-, fourth-, and fifth-instar larvae of *J. coenia* maintained on *P. lanceolata* leaves contained relatively high amounts of both aucubin and catalpol, the two iridoid glycosides present in their food plant (Table 2). We found that both the amount and the concentration of iridoid glycosides in actively feeding fifth-instar larvae were less than one sixth of that in newly molted fifth-instar larvae (Table 2). The iridoid glycoside content of pupae was about the same as that of the actively feeding larvae, although the concentration was reduced (Table 2). Adults did not contain any detectable iridoid glycosides (Table 2). Fifth-instar larvae one and two days postmolt contained no detectable iridoid glycosides ($N = 2$ for each day), but larvae collected three days after molting contained very small amounts of iridoid glycoside: 0.03 mg aucubin in one larva (0.05% dry weight) and 0.02 mg aucubin and 0.02 mg catalpol in the other (0.07% dry weight).

Quantification of Fate of Ingested Iridoid Glycosides in J. coenia. Larvae fed *P. lanceolata* leaves in the feeding experiment consumed food at a faster rate (RCR) and grew slightly faster (RGR) than those larvae fed artificial diets (Table 3). However, the leaves were less digestible than the artificial diets (AD, Table 3), probably because of their high fiber content. Larvae fed leaves were also much less efficient at converting leaf material to biomass (ECI and ECD, Table 3). There were no differences among larvae fed artificial diets in four of the five nutritional indices calculated; the one exception was that the plain artificial diet was slightly more digestible than diets containing either aucubin or catalpol (AD, Table 3).

Although fifth-instar larvae fed *P. lanceolata* leaves ingested over 3 mg iridoid glycoside,less than 2% of that was detectable in the pupae, and less than 0.1% in the frass (Table 4). Thus the drop in iridoid glycoside content of actively feeding fifth-instar larvae (Table 2) appears to be due to metabolism of the iridoid glycosides and not to their gross elimination in the frass.

There were no significant differences among larvae in the iridoid utilization

TABLE 4. FATE OF INGESTED IRIDOID GLYCOSIDES [MEAN (SE)] IN HANGING FIFTH-INSTAR LARVAE AND PUPAE OF THE BUCKEYE, *Junonia coeania*, FED ON *P. lanceolata* LEAVES ($N = 15$)

Iridoid	Amount ingested (mg)	Amount in body (mg)	Amount in frass (mg)
Aucubin	2.21(0.15)	0.03(0.01)	0.002(0.002)
Catalpol	1.13(0.08)	0.03(0.01)	none detected
Total	3.34(0.12)	0.06(0.02)	0.001(0.001)

indices on artificial diets containing aucubin or catalpol (Table 5). When the iridoid glycosides were presented to the larvae singly in artificial diets, the two compounds were consumed (RCR_I), digested (AD_I) and sequestered (ECI_I and ECD_I) in similar ways (Table 5). However, those larvae fed *P. lanceolata* leaves, which contained both aucubin and catalpol, utilized the two compounds in slightly different ways (Table 6). The relative consumption rate (RCR_I) of aucubin was significantly greater than that of catalpol (Table 6), because the *P. lanceolata* leaves fed to the larvae contained more aucubin than catalpol. There were no differences in the relative growth rates (RGR_I) of larvae for aucubin vs. catalpol. Neither of the iridoids was excreted, but there was differential sequestration of the two compounds by the *J. coenia* larvae. The larvae were

TABLE 6. IRIDOID UTILIZATION INDICES [MEAN (SE)] FOR *J. coenia* LARVAE: LARVAE FED *P. lanceolata* LEAVES

Index	Aucubin	Catalpol	*P*
RCR_I	0.009(0.000)	0.005(0.001)	<0.05
RGR_I	0.166(0.032)	0.150(0.028)	NS
ECI_I	0.019(0.003)	0.038(0.007)	<0.01
ECD_I	0.019(0.003)	0.038(0.007)	<0.01

[a]Indices were calculated for aucubin and catalpol separately. ECI_I and ECD_I were equal for each compound because none of the larvae excreted either compound.

twice as efficient at sequestering catalpol than aucubin (ECI_I and ECD_I, Table 6).

DISCUSSION

Our assays indicate that newly molted, last-instar *J. coenia* larvae contain a mean of as much as 6.8% dry weight iridoid glycosides. Iridoid glycosides, especially catalpol, appear to be responsible for the unpalatability of larvae and adults of members of the genus *Euphydryas* (Bowers and Puttick, 1986; Stermitz et al., 1986; Belofsky et al., 1989; Bowers, 1992) and are therefore likely to render buckeye larvae distasteful as well.

Unpalatable insects often have characteristics that advertise their unpalatability to potential predators. In addition to feeding on one or more plant species that contain potential defensive compounds, they are usually warningly colored, often gregarious, and may have other behaviors that enhance their apparency to potential predators (Brower, 1984). Larvae of *J. coenia* are solitary and colored black with spines and blue and yellow spots. Black is often considered a warning

color (Cott, 1940; Sillen-Tullberg, 1988; Sillen-Tullberg and Leimar, 1988), but *J. coenia* larvae may be difficult to find in the field. The coloration of this species is not easily categorized as cryptic or warning and larvae of *J. coenia* do not appear to fit the pattern of characteristics that are typical of unpalatable insects. Nonetheless, we found that these larvae contained iridoid glycoside concentrations at levels at or above those that make checkerspot butterflies unpalatable (Bowers and Farley, 1990). In addition, ants and a captive bat avoided *J. coenia* larvae, but did eat the adults (Dyer, de la Fuente, and Bowers, unpublished observations), suggesting that the presence of iridoid glycosides in buckeye larvae make them unpalatable to putative predators.

Sillen-Tullberg (1988) and Sillen-Tullberg and Leimar (1988) suggested that unpalatability may evolve before gregariousness, and such may be the case with *J. coenia*. As Sillen-Tullberg (1988, p. 303) has pointed out, warning coloration is not a necessary companion of unpalatability, and the coloration of buckeye larvae may be aposematic under some circumstances and cryptic under others (Papageorgis, 1975; Jarvi et al., 1981). Thus buckeye larvae may be unpalatable, but may not yet have evolved gregariousness.

Our chemical analyses showed that total iridoid glycoside contents of actively feeding fifth-instar larvae were one sixth that of unfed, newly molted fifth-instar larvae (decreasing from 0.87 mg in newly molted fifth instars to 0.14 mg in actively feeding fifth-instar larvae). In addition, the larvae were not excreting the intact compounds in the frass, which suggests that they were metabolizing them. For example, iridoid glycosides may be hydrolyzed by β-glucosidases in the caterpillar's gut (Spencer, 1987). Alternatively, the compounds may be bound with carrier molecules that render them inaccessible to our extraction methods (Haunerland and Bowers, 1986; Wilkinson, 1986; Wink, 1988). The loss of iridoid glycosides appears to commence with feeding in fifth-instar larvae, since actively feeding larvae at one, two, and three days after molt had low to unmeasurable amounts of iridoid glycosides. If the iridoid glycosides were attached to carrier molecules, then they were irrevocably bound or eventually degraded, because we never detected intact iridoid glycosides in adults. Since intact iridoid glycosides are known to confer unpalatability, either of these fates might result in palatable individuals.

Our results showed a dramatic decrease in iridoid glycoside content in *J. coenia* pupae compared to newly molted last-instar larvae. Chemical analyses of other insects feeding on plants containing iridoid glycosides have revealed similar patterns. For example, *Ceratomia catalpae* (Sphingidae), which feeds only on species of *Catalpa* (Bignoniaceae), has gregarious, warningly colored larvae and a cryptic adult. Larvae may contain as much as 15% dry weight iridoid glycosides, and larval hemolymph may contain 50% dry weight iridoids (Bowers, Collinge, and Lawrence, unpublished data). Pupae are relatively low

in iridoid glycosides (<0.3% dry weight) and adults are devoid of these compounds (Bowers, Collinge, and Lawrence, unpublished data).

Other species that sequester iridoid glycosides show similar patterns of a decrease in iridoid glycoside content from larva to pupa to adult. Larvae of *Euphydryas anicia*, which sequester iridoids and retain them through to the adult stage, had significantly higher concentrations (mean = 11.5% dry weight, N = 6) of iridoid glycosides than adults (mean = 2.3% dry weight, N = 6) (L'Empereur and Stermitz, 1990). Analysis of larvae, pupae, and adults of an undescribed species of *Lepipolys* (Noctuidae) showed that larvae sequester the iridoid glycoside antirrhinoside from their host plants *Maurandya antirrhiniflora* and *Antirrhinum majus* (Scrophulariaceae) (Boros et al., 1991). Larvae contain antirrhinoside in amounts ranging from 3.2% to 11.2% dry weight (N = 11), pupae contain 0–0.6% dry weight (N = 3), and adults contain no detectable antirrhinoside (N = 9) (Boros et al., 1991).

Pupal meconium of monarchs, *Danaus plexippus* (Nymphalidae) (Nishio, 1980), *E. anicia* (L'Empereur and Stermitz, 1990), *E. phaeton*, *C. catalpae*, *J. coenia* (Bowers and Puttick, 1986), two species of *Lepolys* (Noctuidae) and *Meris paradoxa* (Geometridae) contain relatively large amounts of ingested cardenolides (monarchs) or iridoids (other species). These data suggest that it may be physiologically difficult to retain the large amounts of phytochemicals in the larvae through to the pupal and adult stages (see Bowers, 1992, for a more detailed discussion).

Junonia coenia larvae were more efficient at sequestering catalpol than aucubin (Tables 2 and 6). Despite our finding that the concentration of aucubin in *P. lanceolata* was about twice that of catalpol, larvae contained approximately equal amounts of the two compounds, even in the last instar and pupa. Alternatively, *J. coenia* larvae may metabolize aucubin into catalpol. However, the gas chromatographic analyses showed only aucubin in larvae fed on artificial diets with aucubin, and only catalpol in those fed diets with catalpol, which contradicts this alternative hypothesis. Thus, catalpol appears to be more efficiently sequestered from leaves than aucubin in *J. coenia*, as has been found for *E. phaeton* (Nymphalidae) (Belofsky et al., 1989). Interestingly, catalpol appears to be responsible for the unpalatability of *Euphydryas* species (Bowers, 1980, 1988b).

Insect sequestration of defensive chemicals from host plants may involve physiologically expensive processes. For example, passage of the compounds from the gut into hemolymph and thence to the site of sequestration may require special carrier molecules (Duffey, 1980; Haunerland and Bowers, 1986; Wilkinson, 1986; Wink, 1988), as well as the construction of specialized glands or organs for storage (Duffey, 1980; Scudder et al., 1986). In addition, sequestration may require physiological or morphological adaptations for prevention of

autotoxicity to the insect (Scudder et al., 1986; Cavin and Bradley, 1988). Such a cost might be detected as a negative correlation of insect chemical content with fitness-related parameters such as size, weight, growth rate, or fecundity (Brower and Moffitt, 1974; Cohen, 1985).

Data relevant to this question are few. Cohen (1985) found a negative correlation between cardenolide concentration and adult size and weight in the monarch, *Danaus plexippus* (Nymphalidae), but no such correlation in the closely related queen, *D. gillippus*. Examination of *D. plexippus* larvae showed no evidence of any negative correlation of host-plant cardenolide content and larval weight (Erickson, 1973; Seiber et al., 1980; Cohen, 1985). In a study of chemical defense in larvae of several species of chrysomelids, daily removal of defensive secretions resulted in decreased weight gain compared to a control group, but only in some of the species tested (Rowell-Rahier and Pasteels, 1986). In another system, analysis of the data of Gardner and Stermitz (1988) on iridoid glycoside content of *Euphydryas anicia* (Nymphalidae) butterflies showed no correlation between adult weight and iridoid glycoside content for males and a positive correlation for females (Bowers, 1988a).

To evaluate the potential of a cost associated with sequestering iridoid glycosides in *J. coenia*, we compared biomass and iridoid glycoside content and concentration of newly molted fifth-instar larvae and pupae. There were significant negative correlations between biomass and iridoid glycoside concentration for both these stages (larvae: $Y = 13.263 - 0.463X$, $r^2 = 0.511$, $P < 0.002$; pupae: $Y = 0.020 - 0.007X$, $r^2 = 0.342$, $P < 0.03$); but not for biomass and iridoid glycoside content (larvae: $Y = 1.314 - 0.032X$, $r^2 = 0.170$, $P = 0.11$; pupae; $Y = 0.602 - 0.005X$, $r^2 = 0.245$, $P = 0.072$).

Indication of a physiological cost to sequestration of chemical compounds is typically revealed by a negative correlation of chemical concentration (percent dry weight) with body weight, growth rate, or fecundity (e.g., Brower and Glazier, 1975; Cohen, 1985). Alternatively, amount rather than concentration can be used to determine whether or not a cost exists. In this paper, we have presented the data in both ways, and found a significant negative relationship of larval weight with concentration (percent dry weight) in both larvae and pupae, but no significant negative relationship of body weight with chemical content (milligrams). Both amount and concentration are probably important in calculating physiological costs. One milligram of iridoid glycoside in a 10-mg caterpillar is very different from 1 mg in a 500-mg caterpillar because the concentrations are different: although the amount of biochemical machinery needed to sequester or detoxify 1 mg may be the same in caterpillars of both sizes, the proportion of the insect's total resources used may differ greatly. The best demonstration of a cost would thus be a negative correlation of both amount and concentration with body weight, fecundity, or some other performance variable related to an individual's fitness.

Acknowledgments—We greatly appreciate comments on the manuscript by L.P. Brower, E. Fajer, N. Stamp, and two anonymous reviewers. E. Fajer, J. Geary, M. Lawrence, and R. Mauricio provided laboratory assistance. F. Nijhout gave us the eggs for starting the *J. coenia* colony and the recipe for the artificial diet. W. Berkowitz generously provided the aucubin standard. This research was funded by a grant from the Whitehall Foundation.

INVESTIGATION OF SEX PHEROMONE COMPONENTS OF FEMALE ASIAN CORN BORER, *Ostrinia furnacalis* (Hübner) (LEPIDOPTERA: PYRALIDAE) IN TAIWAN

R. KOU,* H.Y. HO, H.T. YANG, Y.S. CHOW, and H.J. WU

Institute of Zoology, Academia Sinica
Nankang 11529
Taipei, Taiwan

(Received August 8, 1991; accepted January 22, 1992)

Abstract—(*E*)-12-Tetradecenyl acetate (*E*12–14:OAc), (*Z*)-12-tetradecenyl acetate (*Z*12–14:OAc), and tetradecanyl acetate (14:OAc) were extracted and identified as major chemical components from female tips of the Asian corn borer, *Ostrinia furnacalis* (Hübner) (Lepidoptera: Pyralidae) in Taiwan, with a combined wash ratio of 48:37:15 and an individual female ratio of 45:39:16. The average amount of *E*12–, *Z*12–14:OAc and 14:OAc in each female gland was 6.6 ± 4.6, 5.8 ± 3.5, and 2.4 ± 1.7 ng/female, respectively. The mixture of these three synthetic chemicals not only gave strong activities in male antennae but also could catch significantly more males than virgin females in field-trapping tests. The field test also showed no significant difference in trapping ability among the three-component Taiwan formulations, the two-component Taiwan formulation (*E*12–14:OAc and *Z*12–14:OAc, 53:47), and the Japan formulation (*Z*12–14:OAc and *E*12–14:OAc, 3:2).

Key Words—Sex pheromone, *Ostrinia furnacalis*, *E*12–14:OAc, *Z*12–14:OAc, 14:OAc.

INTRODUCTION

The Asian corn borer, *Ostrinia furnacalis* (Hübner), is a serious pest of corn in Taiwan all year around. Although the males was reported to be attracted by a large quantity of the synthetic mixture of (*Z*)-12-tetradecenyl acetate (*Z*12–14:OAc) and (*E*)-12-tetradecenyl acetate (*E*12–14:OAc) in the fields, the

attractiveness was much less than the virgin females (Chow et al., 1984). In Japan, mainland China, and the Philippines, a 3:2 (Ando et al., 1980a), 47:53 (Cheng et al., 1981), and ca. 1:1 (Klun et al., 1980) ratio of these geometric isomers (*Z* to *E*) had been reported in the Asian corn borer, respectively. The Asian corn borer might have different sex pheromone ratios in different areas of Asia. In the present study, the chemical constituents of the sex pheromone of the Asian corn borer in Taiwan were investigated, and the trapping ability of different ratios was also compared, in order to provide a better attractant for the existing mass trapping practices in corn fields.

METHODS AND MATERIALS

Insects. Female pupae of the Asian corn borer, *Ostrinia furnacalis*, used in this study were collected from the corn field in Nankang, Taipei, Taiwan. Female pupae were maintained in environmental chambers at 23–26°C under a 14:10 hr light–dark photoperiod. Emerged moths were fed with 10% aqueous sucrose solution.

Preparation of Pheromone Gland Extract. Ovipositors from 100 2- to 4-day-old virgin females were excised during the calling period in the late scotophase and immersed in 5 μl hexane per female for 10 min. The extracts were stored under 0°C for structure identification.

Chemical Analysis. Gas chromatography (GC) of the extract was performed on three capillary columns. A Shimadzu 14-A GC equipped with a flame ionization detector was used with a 30-m × 0.25-mm (ID) fused silica capillary column of Carbowax 20 M phase, a 30-m × 0.25-mm fused silica capillary column of DB-17 phase, and a 30-m × 0.25-mm fused silica capillary column of DB-225 phase. Chromatographic conditions: nitrogen carrier 0.5 kg/cm^2, column temperature was isothermal at 190°C.

Gas chromatographic–mass spectrometric (GC-MS) analysis was conducted using a Finnigan Mat Incos 50 spectrometer. The GC-MS data were obtained using a 30-m × 0.25-mm column of DB-1701 phase. The column temperature was run from 120 to 260°C at 3°C/min and held at 260°C for 5 min using helium as carrier gas. Electron impact (EI) mass spectra were collected at 70 eV with separator and source at 180°C.

The chemical components were identified by comparison of their mass spectra with those of authentic standards. Subsequently, the identification was verified by comparison of the GC retention time of the natural product to an authentic standard under the same GC condition as described above. Standards of *E*12–14:OAc and *Z*12–14:OAc were kindly supplied by Dr. J.A. Klun (USDA, Agricultural Research Service, Insect Chemical Ecology Laboratory, BARC-East, Beltsville, Maryland), and 14:OAc was purchased from Sigma Chemical Co. (St. Louis, Missouri).

Pheromone Titer Determination. For pheromone titer determination, ovipositor extracts were prepared from 15 individual 2- to 4-day-old virgin females. Each ovipositor was excised during the calling period in the late scotophase and immersed in 5 μl hexane for 10 min. The extracts were subsequently analyzed for *E*12–14:OAc, *Z*12–14:OAc and 14:OAc with the external standard method of quantitative analysis.

EAG Analysis. The procedure of EAG bioassay experiments was based on Ando et al. (1980a,b). In our preliminary test, the antennae of the male Asian corn borer were found to be rather strongly elicited by (*Z*)-11-tetradecenyl acetate (*Z*11–14:OAc), so the sensitivity of each antenna used in EAG analysis was checked by application of 10 μg *Z*11–14:OAc as standard compound. Each EAG test was replicated by the use of at least eight different antennae.

Field Trapping I. Field trapping with virgin females and synthetic chemicals [96% purity, which was synthesized and supplied by the Taiwan Agricultural Chemicals and Toxic Substances Research Institute (TACTSRI)] with the blend of *E*12–14:OAc/*Z*12–14:OAc/14:OAc = 48:37:15 (combined wash ratio) was carried out at three corn fields in Taipei, during January 1–25, 1991. One and 5 mg synthetic chemicals were dissolved in hexane and loaded in plastic tubes the day before the field test. The plastic tube was hung on the inside top of a wing-shaped sticky trap. Blank traps and traps baited with three 2- to 3-day-old virgin females per trap were used for comparison. Virgin females came from field-collected matured larvae. Females were changed and a trap record was made every two days. Traps were placed 10 m apart and 0.8–1 m above ground, and randomized nightly. A total of three replicates was made in this field test.

Field Trapping II. The ratio of *E*11–14:OAc, *Z*11–14:OAc, and 14:OAc was slightly different between the combined wash (48:37:15) (Figure 1) and individual females (45:39:16) (Table 1), and 14:OAc was reported not to be a sex pheromone in previous studies (Ando et al., 1980; Klun et al., 1980; Cheng et al., 1981). Therefore, a comparison of male field responses to the above three-component Taiwan formulations, two-component Taiwan formulation (*E*12–14:OAc/*Z*12–14:OAc = 53:47), and the Japan formulation (*Z*12–14:OAc/*E*12–14:OAc = 3:2) was carried out in the corn field during October 18–December 3, 1991, according to the above method. A trap record was made every four days.

Duncan's new multiple-range test (Steel and Torrie, 1980) was used to analyze the results.

RESULTS AND DISCUSSION

Chemical Analysis. GC analysis showed that a total of three major peaks was found in the gland extract (Figure 1). Previously reported sex pheromone components for the Asian corn borer included *E*12–14:OAc and *Z*12–14:OAc

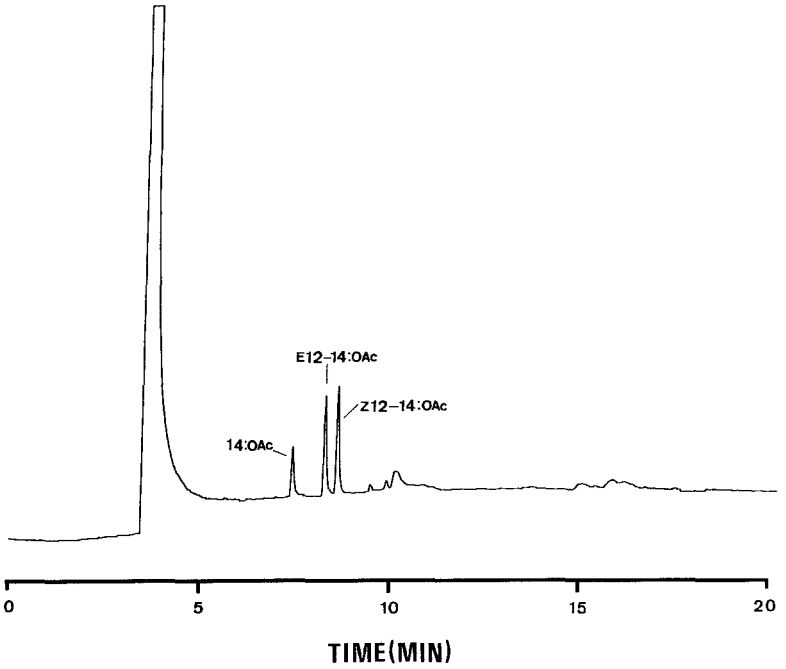

FIG. 1. Gas chromatogram of the combined wash female crude extract. The gas chromatography was performed on a 35-m × 0.25-mm Carbowax 20 M column, temperature was isothermal at 190°C.

TABLE 1. AVERAGE QUANTITY AND PERCENTAGE OF *E*12–14:OAc, *Z*12–14:OAc AND 14:OAc PRODUCED BY INDIVIDUAL 2- TO 4-DAY-OLD *Ostrinia furnacalis* VIRGIN FEMALES ($N = 15$)

Component	Mean quantity (ng/female)	Percentage
*E*12–14:OAc	6.6 ± 4.6	45
*Z*12–14:OAc	5.8 ± 3.5	39
14:OAc	2.4 ± 1.7	16

(Ando et al., 1980b; Klun et al., 1980). These two compounds and other related compounds were prepared for comparison, and it was found that synthetic *E*12–14:OAc, *Z*12–14:OAc, and 14:OAc had the same retention times (Table 2) and mass spectra as the three major peaks from ovipositors extract. The mass spectra of these three components of female tips do give a fragmentation ion at *m/z* 61, indicating that these three components are acetates. The first peak had

TABLE 2. RETENTION TIMES OF 14:OAc, *E*12–14:OAc, *Z*12–14:OAc AND PHEROMONE GLAND EXTRACT OF FEMALE *Ostrinia furnacalis* ON THREE GAS CHROMATOGRAPHIC COLUMNS

Column type	Retention time (min)			
	14:OAc	*E*12–14:OAc	*Z*12–14:OAc	Extract
Carbowax 20 M	7.49	8.32	8.64	7.47 8.30 8.62
DB-17	9.34	9.69	9.94	9.34 9.69 9.94
DB-225	11.85	12.88	13.68	11.83 12.82 13.64

a fragment ion of *m/z* 196 ($M^+ - 60$), indicating it is a 14:OAc; the second and the third peaks had a fragment ion of *m/z* 194 ($M^+ - 60$), indicating that these components are *E*12–14:OAc and *Z*12–14:OAc, respectively.

In the pooled extract, the concentration of the compounds identified as *E*12–14:OAc, *Z*12–14:OAc, and 14:OAc were determined to be in a ratio of 48:37:15, respectively, using the external standard method of quantitative analysis.

Pheromone Titer Determination. The average pheromone titer of individual 2- to 4-day-old virgin females was 14.8 ± 9.3 ng/female, with *E*12–14:OAc 6.6 ± 4.6 ng/female, *Z*12–14:OAc 5.8 ± 3.5 ng/female, and 14:OAc 2.4 ± 1.7 ng/female, with a ratio of 45:39:16 (Table 1). If we only considered *E*12–14:OAc and *Z*12–14:OAc, then the ratio between these two compounds should be 53:47. In fact, this two-component Taiwan formulation has the same blend ratio as that in the mainland China (Cheng et al., 1981). The field attractiveness of the two-component and three-component blend ratios was described in field trapping II.

EAG Analysis. The result of EAG analysis was shown in Figure 2. This assay revealed that all three singly tested compounds, 14:OAc, *E*12–14:OAc, and *Z*12–14:OAc, could elicit strong antennal responses in the male Asian corn borer, with the greatest antennal response elicited by *E*12–14:OAc and the mixture of the three compounds.

Field Trapping I. The result of field trapping of wild males with the synthetic sex pheromone (combined wash ratio, 48:37:15) and virgin females is shown in Table 3. The attractiveness of 1 mg and 5 mg synthetic compounds

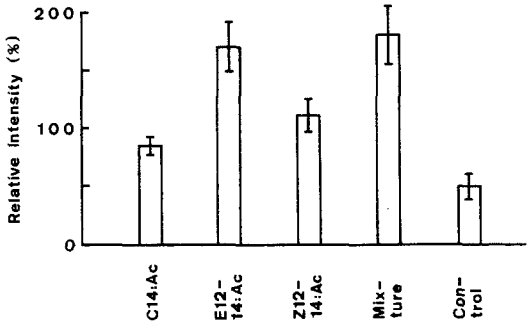

FIG. 2. EAG response of male *Ostrinia furnacalis* to 10 μg of 14:OAc, *E*12–14:OAc, Z12–14:OAc, and the mixture of *E*12–14:OAc,Z12–14:OAc, and 14:OAc (48:37:15). The response of each test chemical is expressed as percent of the response to the standard compound, 10 μg of Z11–14:OAc.

TABLE 3. MEAN NUMBER OF MALE *Ostrinia furnacalis* ATTRACTED TO SYNTHETIC SEX PHEROMONE AND VIRGIN FEMALES IN THREE CORN FIELDS DURING JANUARY 4–18, 1991[a]

*E*12-14:OAc/Z12-14:OAc/14:OAc (48:37:15)			
1 mg	5 mg	3 virgin females	Control
85.0 ± 15.1a[b]	84.0 ± 20.6a	14.0 ± 8.8b	0b

[a]The lure type was a plastic tube.
[b]Means followed by different letters are significantly different. ($P < 0.05$, Duncan's new multiple-range test).

was significantly higher than the virgin females ($P < 0.05$). There was no significant difference in the attractiveness between 1 mg and 5 mg synthetic chemicals.

Field Trapping II. No significant difference in males response was found among the three-component Taiwan formulations, the two-component Taiwan formulation, and the Japan formulation (Table 4).

The results of the present study showed that 14:OAc, although found in the gland wash of the Asian corn borer, did not enhance or suppress male responses by adding to or subtracting from trap capture with *E*/Z-12 mixture. The same results were also reported in other studies of corn borer populations in the United States (Klun and Junk, 1977) and Canada (Struble et al., 1987) and recently in the Asian corn borer (Zhao et al., 1990). On the other hand,

TABLE 4. MEAN NUMBER (MALES/TRAP/4 DAYS) OF MALE *Ostrinia furnacalis* ATTRACTED TO DIFFERENT SEX PHEROMONE BLEND RATIOS OF FORMULATION I, II, III, AND IV DURING OCTOBER 18–DECEMBER 3, 1991[a]

I	II	III	IV	Control
3.8 ± 4.3a[b]	4.4 ± 3.6a	6.0 ± 6.2a	9.0 ± 5.8a	0.0 ± 0.0b

[a]The lure type was a plastic tube. I: three-component Taiwan formulation (*E*12–14:OAc/Z12–14:OAc/14:OAc = 48:37:15, combined wash ratio). II: three-component Taiwan formulation (*E*12–14:OAc/Z12–14:OAc/14:OAc = 45:39:16, individual female ratio). III: two-component Taiwan formulation (*E*12–14:OAc/Z12–14:OAc = 53:47). IV: Japan formulation (*Z*12–14:OAc/*E*12–14:OAc = 3:2).

[b]Means followed by same letters are not significantly different. ($P < 0.05$, Duncan's new multiple-range test).

the result of male field responses to a range of pheromone ratios may suggest that the majority of males were not precisely tuned, or some behavioral morphs existed in the population, responding to different isomer ratios as in *Agrotis segetum* (Hansson et al., 1990). Therefore, individual variation in the sex pheromone system of the Asian corn borer in Taiwan should be further investigated.

Acknowledgments—We thank National Science Council, Taiwan, for financial support, Dr. J.A. Klun and TACTSRI for supplying the chemicals, and Dr. C.J. Maa for advice in field-trapping techniques.

Abstract—DIMBOA glucoside (2-O-β-D-glucopyranosyl-4-hydroxy-7-methoxy-1,4-benzoxazin-3-one), the main hydroxamic acid (Hx) in intact wheat plants, was detected in the honeydew of *Rhopalosiphum padi* feeding on seedlings of six wheat cultivars that differed in their concentration of Hx, suggesting that the chemical circulates in the phloem. Neither the aglucone (DIMBOA) nor its main breakdown product were found in any of the honeydew samples. Honeydew production by aphids caged on seedlings of the wheat cultivars and DIMBOA glucoside concentrations in the honeydew followed biphasic curves when plotted against Hx concentration, suggesting passive ingestion of the chemical from the phloem at low Hx concentrations and limited ingestion due to feeding deterrency by Hx in mesophyll cells at high Hx concentrations. The presence of plant toxins such as Hx glucosides in the phloem sap, the main ingesta of aphids, and in the mesophyll cells, has major implications for plant defense, through a feeding deterrent effect during stylet penetration, and deterrency (antixenosis) along with antibiosis during feeding.

Key Words—*Rhopalosiphum padi*, Homoptera, Aphididae, wheat, maize, DIMBOA, hydroxamic acids, aphid honeydew.

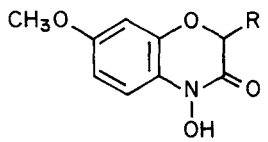
INTRODUCTION

Hydroxamic acids (Hx) are present in a number of Gramineae (Niemeyer, 1988a,b; Zuñiga et al., 1983; Copaja et al., 1991a,b; Barría et al., 1991; Niemeyer et al., 1991) including wheat. Hx exist in the intact plant as glucosides from which the more toxic aglucone is released upon disruption of the plant tissue and contact with a β-glucosidase (Hofman and Hofmanova, 1969; Cuevas et al., 1992). The most common Hx in maize and wheat tissue is 2-O-β-D-glucopyranosyl-4-hydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA glucoside) (Niemeyer, 1988a) (Scheme 1).

Hydroxamic acids are believed to play a role in the resistance of the plants to pests and diseases (Niemeyer, 1988a). Thus, a number of workers have reported negative correlations between the Hx content of maize and wheat and the performance of insect herbivores feeding on the plants. Most of the work has been concerned with the effects of Hx on the European corn borer (Klun and Robinson, 1969; Campos et al., 1989), the western corn rootworm (Xie et al., 1990), and cereal aphids (Long et al., 1977; Argandoña et al., 1980; Beck et al., 1983; Bohidar et al., 1986; Thackray et al., 1990; Givovich and Niemeyer, 1991).

The concentration of hydroxamic acids is higher in the vascular bundles than in the mesophyll (Argandoña and Corcuera, 1985; Argandoña et al., 1987). However, there is no clear evidence that Hx circulate in the phloem. Thus, although Niemeyer et al. (1989b) found DIMBOA in the bodies of aphids feeding on wheat, Molyneux et al. (1990) failed to find 6-methoxybenzoxazolin-2-one (MBOA, the main breakdown product of DIMBOA) in the honeydew of *Schizaphis graminum* feeding on wheat.

The aim of the experiments reported here was to determine whether DIMBOA and/or its glucoside could be detected in the honeydew of aphids feeding on wheat.



DIMBOA R = OH

DIMBOA glucoside R = O-β-D-glucopyranosyl

SCHEME 1.

METHODS AND MATERIALS

Determination of Hx and DIMBOA in Plant Material. High-performance liquid chromatography (HPLC) was employed for DIMBOA analysis in wheat seedlings. The method was essentially that described by Niemeyer et al. (1989a).

Determination of DIMBOA and Its Glucoside in Aphid Honeydew. Aphid honeydew was analyzed for DIMBOA glucoside, DIMBOA, and MBOA using HPLC. A standard of DIMBOA glucoside was obtained as described by Lyons et al. (1988).

Insect Material. Aphids were reared on oats (cv. Nahuen), a plant lacking Hx, in a chamber at 22°C with a 6° range.

Presence of DIMBOA Glucoside in Honeydew of R. padi. The wheat cultivars employed were chosen to contain a wide range of Hx concentrations. Experiments were carried out with seedlings at the one-leaf stage, when Hx levels are highest (Argandoña et al., 1980). Oats (cv. Nahuen) were used as a control without Hx. Twenty adult aphids were placed in a clip cage (2 cm diameter) fitted with a disk of aluminum foil at the bottom and clipped to the abaxial surface of a leaf of a wheat or oat seedling. After 36 hr, the cage was detached from the plant and the aluminum disk weighed. After washing successively with methanol and water and drying, the disk was weighed again. The difference between these measurements was attributed to honeydew produced. The methanol–water washings were concentrated to dryness, redissolved in 200 μl of water, and analyzed by HPLC. Three sets of experiments, each consisting of seven clip cages were performed.

RESULTS

Presence of DIMBOA Glucoside in Honeydew of R. padi *Feeding on Wheat.* DIMBOA glucoside was found in the honeydew of aphids caged on all six wheat cultivars. Neither aglucone nor MBOA were found in the honeydew samples analyzed (detection limit = 0.1 mmol/kg fresh weight).

DIMBOA glucoside concentrations in the honeydew of aphids feeding on wheat are shown in the lower curve of Figure 1. Rates of honeydew production are shown in relation to whole-leaf DIMBOA concentration in the upper curve of Figure 1. Honeydew production in oats, a plant lacking Hx, was 5.35 $\pm$ 0.16 μg/aphid/36 hr.

DISCUSSION

R. padi is mainly a phloem feeder (Pollard, 1973). Hydroxamic acids are known to occur in mesophyll cells of wheat plants (Argandoña et al., 1987). The present finding of DIMBOA glucoside in aphid honeydew suggests that the

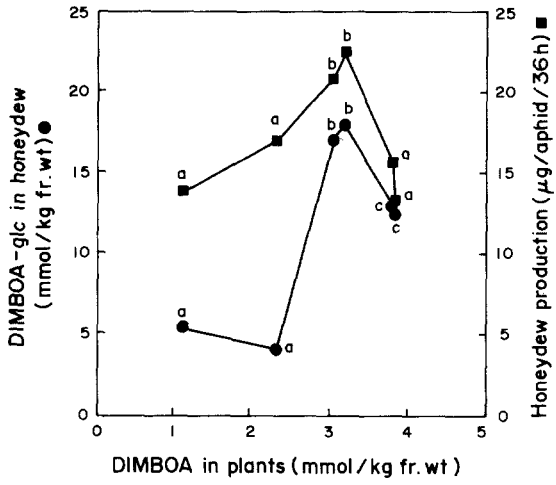


FIG. 1. Mean concentration of DIMBOA glucoside in honeydew (●) and mean honeydew production (■) of *R. padi*, as a function of DIMBOA concentration in wheat seedlings where they fed for 36 hr. Points in each curve followed by different letters are significantly different ($P < 0.01$).

chemicals are also present in wheat phloem. Further evidence for the presence of DIMBOA glucoside in phloem is provided by the failure to detect the aglucone in any of the honeydew samples: if prolonged ingestion had occurred from mesophyll cells ruptured during stylet penetration, then contact with β-glucosidase would be expected and DIMBOA should have been found in the honeydew. The lack of any DIMBOA in the samples also suggests the absence of a suitable β-glucosidase in the digestive tract of *R. padi* or the presence of efficient detoxifying glucosyltransferases. The failure of Molyneux et al. (1990) to find MBOA in the honeydew of *Schizaphis graminum* feeding on a DIMBOA-containing wheat is consistent with these results, since the glucoside does not produce the aglucone breakdown product MBOA under the conditions they used. The results are also consistent with electronic monitoring studies of aphid feeding behavior, which suggest the presence of hydroxamic acids in the phloem sap of the same wheat cultivars employed in this study, albeit in concentrations below those producing feeding deterrency (Givovich and Niemeyer, 1991).

The relationship between glucoside concentration present in honeydew and whole-leaf DIMBOA concentration in wheat followed a biphasic pattern (lower curve in Figure 1). This suggests passive ingestion from phloem sap at low leaf concentrations, and a combination of feeding deterrency, possibly during stylet penetration of the mesophyll, and ingestion from tissues with lower or non-existent Hx glucoside concentrations at high whole-leaf concentrations. Elec-

tronic monitoring of aphid feeding behavior showed that ingestion from xylem, a tissue where Hx have not been detected (Argandoña and Corcuera, 1985), increased as whole-leaf Hx concentration increased (Givovich and Niemeyer, 1991).

A biphasic curve can also be seen in the relationship between honeydew production and whole-leaf concentration of DIMBOA in the wheat cultivars (upper curve in Figure 1). The negative correlation between honeydew production and DIMBOA concentration at the high DIMBOA range may be attributed to feeding deterrency by DIMBOA. The positive correlation obtained at the low DIMBOA range may be attributed to a higher ingestion rate (and consequently, higher excretion rate) in order to compensate for the toxic effects of increasing Hx concentration of the ingesta. These effects may be related to the capacity of Hx to inhibit mitochondrial energy-linked reactions (Niemeyer et al., 1986) and digestive enzymes (Cuevas et al., 1990). Interestingly, honeydew production in oats, a plant lacking Hx, is comparable to that in the lower-DIMBOA-containing wheats.

These results suggest that Hx may be playing different roles in resistance to aphids depending on where the toxin is located in the plant. A high mesophyll concentration of Hx may provide a level of feeding deterrency during stylet penetration, while a high phloem sap concentration may also provide deterrency combined with antibiosis. Further research should determine if DIMBOA glucoside can be found directly in phloem sap.

Acknowledgments—The authors wish to express their gratitude to Miss Lucía Muñoz for able technical assistance. (Received August 5, 1991; accepted January 24, 1992)

Abstract—Cephalic extracts of two unrelated species of ants, *Leptogenys processionalis* and *Pogonomyrmex rugosus*, have been found to contain 2-phenylpropenal and 2-phenyl-2-butenal, while two other species related to the first, *L. chinensis* and *L. kitteli*, lacked either. *L. kitteli* also produced a tetrasubstituted pyrazine found previously only in two New Zealand ants in the genus *Mesoponera*. The chemical reactivity of the phenylalkenals suggests their function in repelling attack by predators.

Key Words—Phenylalkenals, *Leptogenys* spp., *Pogonomyrmex rugosus*, Hymenoptera, Formicidae, 2-phenylpropenal, 2-phenyl-2-butenal, 2,5-dimethyl-3-(1-methyl)butylpyrazine, 2,5-dimethyl-3-isopentylpyrazine, 2,5-dimethyl-3-isopentenyl-6-isopentylpyrazine, 4-methyl-3-heptanone, 5-methyl-3-hexanone, Maillard reaction, benzaldehyde, chemoreceptors, defensive allomones.

INTRODUCTION

A large variety of natural products have been identified as exocrine products of ants as abundant testimony to the biosynthetic virtuosity of these hymenopterans. Species in the subfamily Ponerinae are particularly distinctive, producing a vari-

*To whom correspondence should be addressed.

ety of pheromones and allomones belonging to diverse chemical classes (Blum, 1981). For example, ponerines generate alkyl sulfides (Casnati et al., 1967), pyrazines (Wheeler and Blum, 1973), aryl esters (Duffield and Blum, 1975), and aliphatic ketones (Duffield and Blum, 1973). These compounds are all mandibular gland products that function as either alarm pheromones, defensive allomones, or both. The already demonstrated chemical versatility of the ponerine mandibular gland makes it seem certain that analyses of additional species will yield further natural product surprises.

In the present report, we describe structures of two phenylalkenals as cephalic products of the ponerine ant *Leptogenys processionalis*. In addition, these compounds have been identified in an unrelated species, *Pogonomyrmex rugosus*, a graminivorous myrmicine that has been previously demonstrated to produce aliphatic ketones and alcohols in the mandibular glands (McGurk et al., 1966). These phenylalkenals appear to have escaped earlier detection. Two other species of *Leptogenys* were also analyzed and found to have a chemistry very different from that of *L. processionalis*. One of these species, *L. kitteli*, was distinctive in producing a tetrasubstituted pyrazine that has been detected previously only in two ponerine species of New Zealand ants in the genus *Mesoponera* (Fales et al., 1988).

METHODS AND MATERIALS

Both *L. processionalis* and *L. chinensis* were collected in Bangalore, India, and *L. kitteli* was collected in Sabah, Borneo. The harvester ant *P. rugosus* was collected in Tucson, Arizona.

Either heads or whole bodies of the *Leptogenys* species and heads of *P. rugosus* were placed in methylene chloride and the extracts sent to NIH for analysis. After concentration, these extracts were used directly for GC-MS analyses.

2-Phenylpropenal was synthesized according to established procedures (Crossland, 1981).

GC-MS was run on an LKB-2091 mass spectrometer operating at 70 eV with a source temperature of 270°C and an ionizing current of 20 μA. The GC column was a 30-m capillary coated with OV-1 methyl silicone and was programmed from 50 to 300°C at 10°C/min.

RESULTS

L. processionalis. The cephalic secretion is dominated by five compounds (Figure 1, peaks 1–5). Eluting later, and not shown on this chromatogram, are a more abundant series of fatty acids and hydrocarbons. Peaks 1, 2, and 4 were

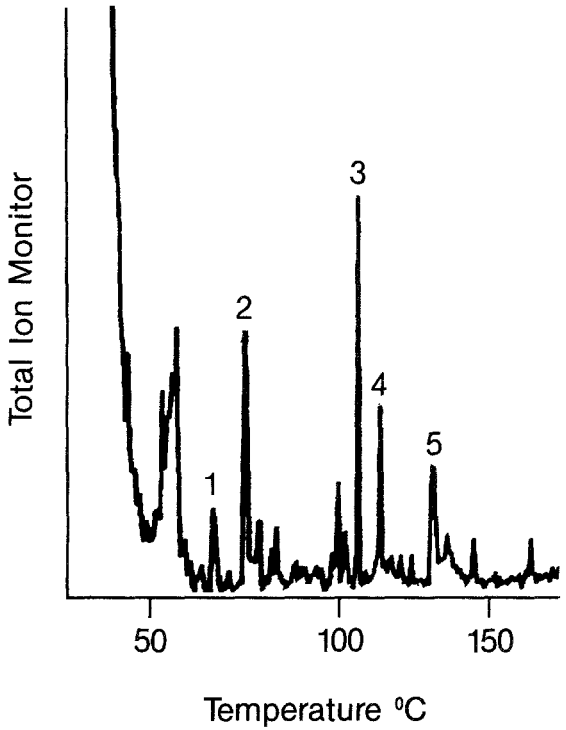

FIG. 1. Cephalic extract of *L. processionalis*. Chromatographic conditions in Methods and Materials. Peak 1: benzaldehyde, 2: phenol, 3: 2-phenylpropenal, 4: naphthalene (an artifact?), 5: 2-phenyl-2-butenal.

easily identified as benzaldehyde, phenol, and naphthalene (an artifact?) by comparison with the NIST/EPA/MSDC (1991) mass spectral data base. Peak 5 was similarly identified as 2-phenyl-2-butenal [*m/z*, (relative intensity): 146 ($M^{+}\cdot$, 77), 145 (12), 131 (9), 128 (10), 118 (17), 117 (100, $M^{+}\cdot - CHO$), 116 (24), 115 (81), 103 (9), 102 (11), 91 (54), 89 (13), 78 (17), 77 (14), 65 (13), 63 (22), 62 (9), 58 (8), 54 (8), 52 (8), 51 (22), 50 (11)]. Peak 3 showed a similar pattern shifted 14 amu lower [*m/z* (relative intensity): 132 (42, $M^{+}\cdot$), 131 (3), 104 (52), 103 (100, $M^{+}\cdot - CHO$), 102 (12), 90 (3), 78 (13), 77 (50), 76 (7), 75 (6), 74 (7), 65 (3), 63 (8), 62 (6), 61 (3), 55 (3), 54 (3), 52 (7), 51 (31), 50 (16)], and the lower homolog, 2-phenylpropenal, was a putative structure. The structure of this compound was confirmed by comparison (MS and GC retention times) with a synthetic sample prepared according to the literature (Crossland, 1981).

Since aromatic exocrine components have not been encountered frequently as cephalic natural products of ants, the blend of compounds generated by *L.*

processionalis is particularly distinctive. Benzaldehyde has been detected in a myrmicine ant in the genus *Veromessor* (Blum et al., 1969), whereas phenol has been identified in a myrmicine species in the genus *Monomorium* (Blum et al., 1985).

Extracts of bodies of the same species contained a compound tentatively identified as 2,5-dimethyl-3-(1-methyl)butylpyrazine (GC not shown) by its mass spectrum, which is identical to that described by Wheeler and Blum (1973). However, other substitution patterns on the pyrazine ring have also been detected in ants (Wheeler and Blum, 1973), and decisive assignment of the 2,5-dimethyl structure must await comparison with authentic samples (GC) or possibly GC-IR. This ant is thus provided with a component that belongs to a class of natural products characteristic of ponerine ants. Species in a diversity of ponerine genera produce pyrazines in their mandibular glands (Longhurst et al., 1978), and we assume that this is the case here as well.

L. chinensis. Cephalic extracts of this ant contained none of the aromatic constituents identified in *L. processionalis*. On the other hand, *L. chinensis* workers apparently do synthesize a pyrazine (GC not shown) that is isomeric with the one produced by *L. processionalis*. This compound, again tentatively identified by the identity of its mass spectrum with that of Wheeler and Blum (1973) as 2,5-dimethyl-3-isopentylpyrazine, is a widely occurring natural product in the mandibular gland secretions of ponerine ants (Wheeler and Blum, 1973; Brown and Moore, 1979).

L. kitteli. The cephalic secretion of this species contains a compound again tentatively identified by its mass spectrum as 2,5-dimethyl-3-isopentylpyrazine (Figure 2, peak 1), the same pyrazine produced by *L. chinensis*. However, the secretion of *L. kitteli* is distinguished by the presence of a second, unusual, tetrasubstituted pyrazine, 2,5-dimethyl-3-isopentenyl-6-isopentylpyrazine (Figure 2, peak 2). This compound, which is the major product in the exudate, has been previously identified only as a mandibular gland product in two species of New Zealand ponerine ants in the genus *Mesoponera* (Fales et al., 1988).

None of the aromatic constituents identified as cephalic products of *L. processionalis* were detected as natural products of *L. kitteli*.

Pogonomyrmex rugosus. As is the case with *L. processionalis*, the cephalic secretion of *P. rugosus* contains a diversity of aromatic constituents (Figure 3). Both species share benzaldehyde (peak 3) as well as the newly discovered phenylalkenals [peaks 5 and 6 (identified by subtraction of the spectrum of the coeluting phenylacetaldehyde)], but they differ considerably in other particulars. Thus, the exudate of *P. rugosus* is thoroughly dominated by 4-methyl-3-heptanone (Figure 3, peak 2), an ethyl ketone that is characteristic of species in this genus (McGurk et al., 1966). Traces of 5-methyl-3-hexanone (Figure 3, peak 1) were also detected, both ketones being identified through comparison with literature spectra (NIST/EPA/MSDC 1990). On the other hand, no alka-

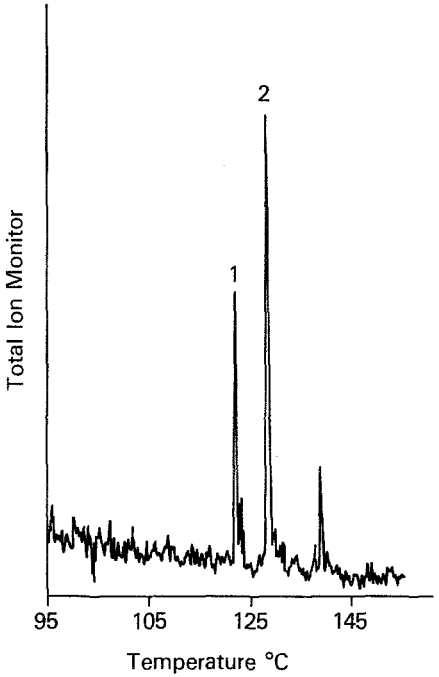

FIG. 2. Cephalic extract of *L. kitteli*. Peak 1: 2,5-dimethyl-3-isopentylpyrazine, 2: 2,5-dimethyl-3-isopentenyl-6-isopentylpyrazine.

nones were detected as cephalic products of *L. processionalis*. Similarly, constituents such as phenylacetaldehyde and phenylacetic acid (peaks 4 and 7) constitute two of the five aromatic compounds that characterize the exudate of *P. rugosus;* these compounds were not detectable as cephalic products of *L. processionalis*.

DISCUSSION

Pyrazines have been demonstrated to be characteristic mandibular gland products of species in a wide variety of ponerine genera (Wheeler and Blum, 1973; Longhurst et al., 1978; Brown and Moore, 1979). In all cases these compounds have been demonstrated to function as alarm pheromones that can attract excited workers to the source, which may be stung by these aggressive ponerines. Because of the painful stings possessed by the pyrazine-producing ponerines, it will not prove surprising if these heterocycles function as an early-warning system for predators, enabling them to avoid a thoroughly unpleasant

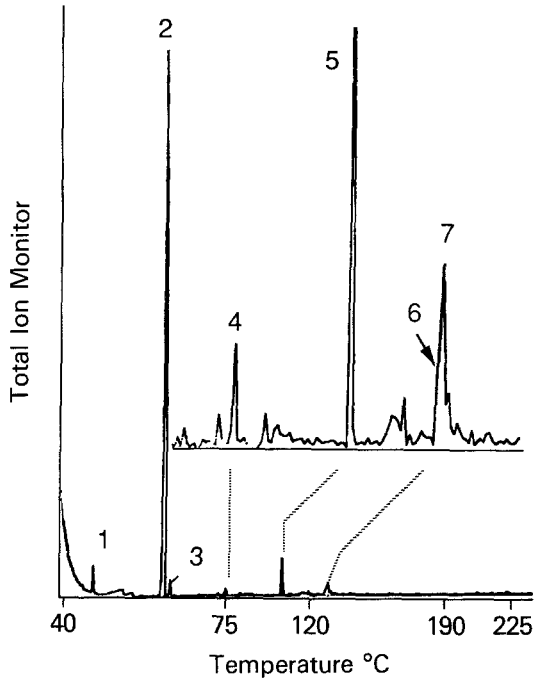

FIG. 3. Cephalic extract of *P. rugosus*. Peak 1: 5-methyl-3-hexanone, 2: 4-methyl-3-heptanone, 3: benzaldehyde, 4: phenylacetaldehyde, 5: 2-phenylpropenal, 6: 2-phenyl-2-butenal, 7: phenylacetic acid.

experience with the algogenic ponerines. The same can certainly be said for species in the myrmicine genus *Pogonomyrmex*. Rothschild (1989) have suggested that pyrazines are components of a generalized warning system in which toxic insects are easily recognized as unpalatable or dangerous prey. Furthermore, these pyrazine-producing ponerines, which share common traits such as similar appearance, exaggerated attack behavior, and painful stings, may well constitute a mimicry complex in which species in different genera may advertise their dangerous qualities with similar pyrazine signals.

The aromatic constituents generated by *L. processionalis* and *P. rugosus* in their cephalic secretions are qualitatively exceptional in terms of the exudates of ants. Aromatic aldehydes are rarely encountered as ant natural products. Even compounds such as benzaldehyde are uncommon exocrine products of ants and, for that matter, insects in general. Phenylacetic acid, a product of *P. rugosus*, has been reported to be an antibiotic produced in thoracic glands of myrmicine ants (Schildknecht and Koob, 1970).

2-Phenylpropenal has also been identified in both wings and bodies of both

sexes of an adult butterfly *Pieris rapae* (Honda and Kawatoko, 1976); its function in this insect is not known. However, the chemical reactivity of these phenylalkenals suggests that they might function as excellent defensive allomones to blunt the attacks of predators by jamming their olfactory chemoreceptors. For example, these electrophilic substances could be readily attacked by nucleophilic sites (NH and SH) in olfactory proteins, rendering a smell-oriented predator incapable of hunting with facility. It is not unlikely that the phenylalkenals, along with the other aromatic components, form part of the chemical arsenal utilized by these ants in adversarial contexts.

It has not escaped our attention that the phenylalkenals are well-known products of protein degradation (List and Freund, 1967) where they appear to derive from a Maillard reaction between glucose and phenylalanine (Baltes and Mevissen, 1988). The possibility that this reaction could take place from similar components in the injection port of the gas chromatograph was minimized by examining the extracts of *L. processionalis* after silylation with bis(trimethylsilyl)trifluoroacetamide, a reagent that should prevent such reactions by converting the intermediates to unreactive derivatives. The same phenylalkenals were, in fact, still detected along with other unidentified silylated products.

CALLING BEHAVIOR AND PHEROMONE TITER IN THE SMALLER TEA TORTRIX MOTH, *Adoxophyes* SP. (LEPIDOPTERA: TORTRICIDAE)

RONG KOU

Institute of Zoology, Academia Sinica
Nankang 11529
Taipei, Taiwan

(Received September 27, 1991; accepted January 27, 1992)

Abstract—The calling behavior and pheromone titer in the female smaller tea tortrix moth, *Adoxophyes* sp., were investigated under a 14:10-hr light–dark photoperiod. Quantitative gas chromatographic analysis of ovipositor extract for (*Z*)-11-tetradecenyl acetate (Z11–14:Ac) and (*Z*)-9-tetradecenyl acetate (Z9–14:Ac), the major pheromone components of this species, obtained on the third day postemergence, indicated that extractable amounts of sex pheromone were present throughout the period of observation. Maximal pheromone titer and calling activity was reached at 8 and 10 hr after onset of scotophase, respectively. The ratio of Z11–14:Ac to Z9–14:Ac through the 24-hr period varied significantly. The significance of the sex pheromone component ratio variation on the attraction of males was tested in a field experiment. The ratio of males trapped by the most attractive blend versus the least attractive one was 2.16.

Key Words—Calling behavior, pheromone titer, *Adoxophyes* sp., Lepidoptera, Tortricidae, (*Z*)-11-tetradecenyl acetate, (*Z*)-9-tetradecenyl acetate.

INTRODUCTION

In moths, the daily rhythm of sexual activity such as sex pheromone production and its subsequent release during the calling period usually depend upon exogenous (photoperiod, temperature) and endogenous factors (neural, hormonal) (Baker and Cardé, 1979; Hollander and Yin, 1982; Webster and Cardé, 1982; Raina et al., 1986, Raina, 1988; Tang et al., 1989). The relationship between calling behavior and pheromone titer had been precisely studied in several moth species such as *Trichoplusia ni* (Hübner) (Sower et al., 1972), *Plodia inter-*

0098-0331/92/0600-0855$06.50/0 © 1992 Plenum Publishing Corporation

punctella (Hübner), and *Ephestia cautella* (Walker) (Coffelt et al., 1978); *Platynota stultana* (Walsingham) (Webster and Cardé, 1982); and *Helicoverpa zea* (Boddie) (Raina et al., 1986).

Females of the smaller tea tortrix moth *Adoxophyes* sp. (the species is still unidentified) in Taiwan produce (Z)-11-tetradecenyl acetate (Z11–14 : Ac) and (Z)-9-tetradecenyl acetate (Z9–14 : Ac) as major constituents of its sex pheromone, and the blend ratio is 64 : 36, which is the reverse of the ratio in Japan (Kou et al., 1990). In this study, the level of female calling and the quantity and ratio of the two sex pheromone compounds in the pheromone gland of *A.* sp. are investigated at different times of day. A field-trapping experiment was also carried out to obtain an estimate of the biological significance of the pheromone ratio variation observed at different times during the calling period.

METHODS AND MATERIALS

Insects. Female pupae of the smaller tea tortrix moth used in this study were obtained from the Taiwan Tea Experiment Station, Hsinchu, Taiwan. They were maintained in environmental chambers at 23–26°C under a 14 : 10-hr light–dark photoperiod. Emerged moths were fed with 10% aqueous sucrose solution. Most adults emerged shortly after the onset of a photophase and only these were used in the tests.

Female Calling. Fifty virgin females that had called the first night after emergence were put into a 30 × 30 × 30-cm transparent plastic box. From the beginning of the third photophase, females were observed for 24 hr through the photophase and scotophase at 1-hr intervals. During photophase and scotophase, a 60-W white lamp and a 5-W red lamp were used for observation, respectively. Calling females are easily recognized by their extruded ovipositors and raised vibrating wings.

Pheromone Titer Determination. From the beginning of the third-day photophase, 10 ovipositors of the females were excised at each hour through the photophase and scotophase of that day. The ten ovipositors were then pooled in 10 μl hexane containing 0.5 μg (Z)-11-hexadecenyl acetate (Z11–16 : Ac) (internal standard). The ovipositors were soaked in the solvent for 5 min, and the extract was analyzed for Z11–14 : Ac and Z9–14 : Ac using the internal standard method of quantitative analysis (Kou et al., 1990). One microliter of the extract was injected onto a 35-m fused silica capillary column coated with 0.25-μm film of Carbowax 20 M phase; the column was installed in a Varian 3700 gas chromatograph (GC) equipped with a flame ionization detector. Chromatographic conditions were: nitrogen carrier 7.5 psi, column temperature programmed from 120°C to 200°C, at 4°C/min. The experiment was replicated three times. The ratios of the two pheromonal components were also examined

at 1-hr intervals throughout the third day. Student-Newman-Keuls' test (Steel and Torrie, 1980) was used to analyze the results.

Field Tests. The male response specificity to alternations in sex pheromone component ratios observed in female gland washes was carried out at a tea plantation in Nankang, Taipei, during May 30–August 3, 1990. Synthetic chemicals of five different blend ratios of *Z*11–14 : Ac and *Z*9–14 : Ac (58 : 42, 62 : 38, 64 : 36, 66 : 34, and 68 : 32) were prepared so as to cover most of the observed range of ratios during the calling period. One milligram of each synthetic chemical was dissolved in hexane and loaded in a plastic capsule (capsule for electron microscope, type C050, 8 mm ID × 17.8 mm, TAAB Ltd., Berkshire, England). The plastic capsule was hung on the inside top of a wing-shaped sticky trap. Traps were placed randomly, 10 m apart and 1.5 m above ground. Trap catches were monitored weekly and traps were moved weekly from one location to another during the experiment. Only one set of traps was run in this experiment. The Kruskal-Wallis one-way analysis for multiple comparisons (Siegel and Castellan, 1989) was used to analyze the field test results.

RESULTS

Female Calling. The pattern of calling behavior of the 3-day-old females observed in the present study is shown in Figure 1A. Sixteen percent of the observed females that had called at the end of the second scotophase still continued their calling at 1 hr after the onset of the third photophase, then calling percentage decreased gradually to zero at 4 hr after the onset of the third photophase. At 5 hr after the onset of scotophase, 6% of the observed females started calling, and the calling percentage increased gradually to 87% and 95% at 9 and 10 hr after scotophase, respectively.

Pheromone Titer. The pattern of change in the relative amounts of the two pheromonal compounds throughout the third day was very similar (Figure 1B and C). However, the titer of each compound differed at different times during the 24-hr period. The titers of *Z*11–14 : Ac and *Z*9–14 : Ac decreased gradually from 39.1 and 18.5 ng/female at 1 hr after photophase to 14.8 and 9.0 ng/female at 8 hr into photophase, respectively, and then increased gradually to 45.5 and 27.2 ng/female at 14 hr (the end) of the photophase, respectively. There was no significant difference in the pheromone titer of either compound during the photophase. With the onset of scotophase, *Z*11–14 : Ac and *Z*9–14 : Ac dropped abruptly to 20.4 and 14.6 ng/female at 1 hr after scotophase, respectively, then the titers of both compounds increased progressively. Maximal titers were reached at 8 hr after scotophase, with females containing 94.0 ng of *Z*11–14 : Ac and 43.3 ng of *Z*9–14 : Ac. Both titers were significantly higher than that obtained in any photophase and early scotophase preparations

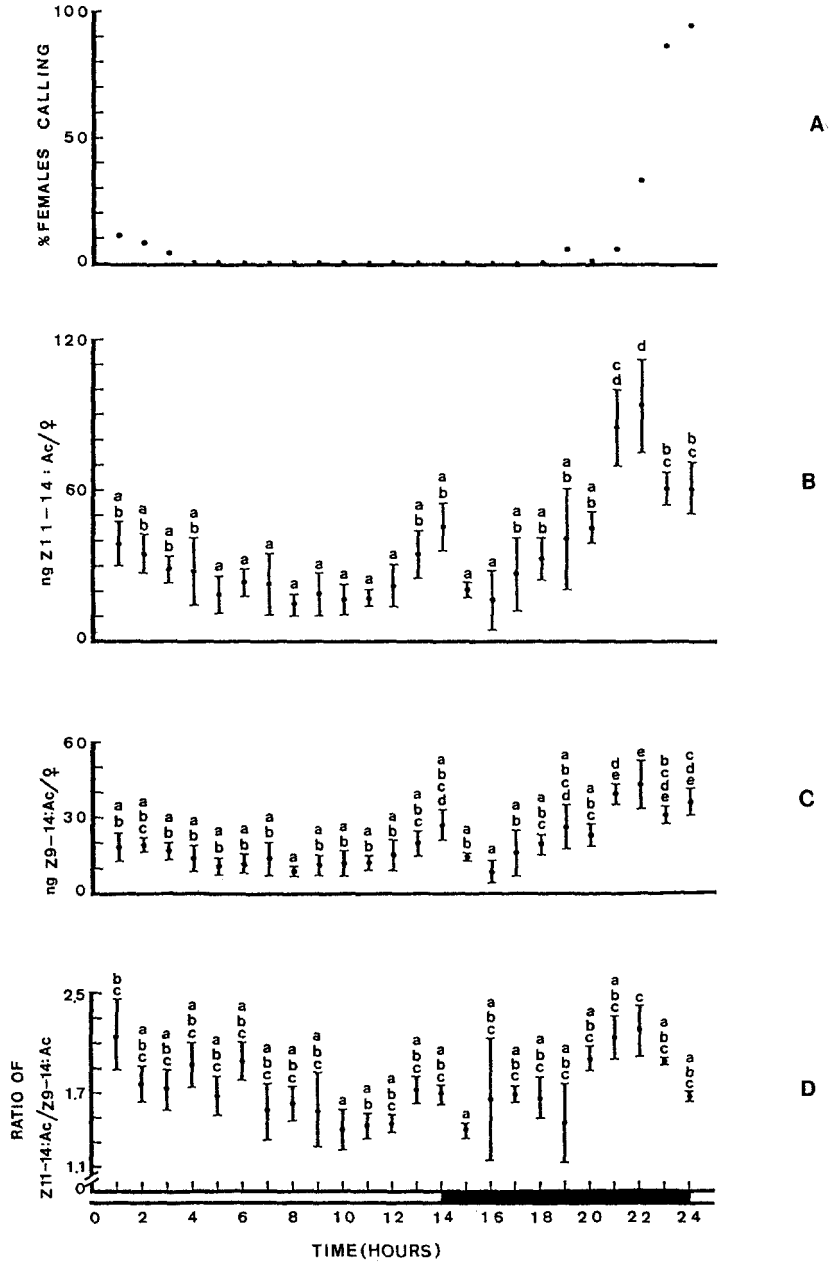

FIG. 1. (A) Periodicity of calling; (B) titer of Z11–14:Ac; (C) titer of Z9–14:Ac; and (D) ratio of Z11–14:Ac to Z9–14:Ac in the female ovipositor, throughout the third day. Shading on the abscissa denotes scotophase. Vertical bars in B, C, and D represent $\pm$SD, and means with different letters are significantly different ($P < 0.05$, Student-Newman-Keuls' test).

($P < 0.05$). The ratio of Z11–14 : Ac to Z9–14 : Ac in the sex pheromone gland was not constant through the third day, with the significantly low ratio (1.40) ($P < 0.05$) at 10 hr after photophase and 1 hr after scotophase (Figure 1D). The highest ratio (2.19) was obtained 8 hr after scotophase.

Field Test. The result of field trapping of wild males with five different blend ratios, which were observed in the gland washes during the calling period, in a tea plantation is shown in Table 1. Among the five different blend ratios, the blends of 64 : 36 (Z11–14 : Ac/Z9–14 : Ac = 1.78) and 66 : 34 (Z11–14 : Ac/Z9–14 : Ac = 1.94) were most attractive (Table 1). The ratio of the males trapped by the most attractive blend (Z11–14 : Ac/Z9–14 : Ac = 64 : 36) to the least attractive one (Z11–14 : Ac/Z9–14 : Ac = 68 : 32) was 2.16. No significant difference of attractiveness existed among the five ratios (Kruskal-Wallis analysis, $P = 0.05$).

DISCUSSION

In the smaller tea tortrix moth, the calling behavior and pheromone titer in the gland appear not to be very synchronous events under the conditions described above. Throughout the third day, the pheromone titer can be easily detected, but calling only occurred during late scotophase with some carry over into photophase. With the onset of scotophase, pheromone titers dropped abruptly, but calling behavior did not commence immediately. Maximal pheromone titer was reached at 8 hr after scotophase, in agreement with a previous observation that the sexual activity was maximized after 7–8 hr into the darkness (Tamaki et al., 1969). On the other hand, maximal calling was reached 2 hr later at 10 hr into scotophase. A same time lag between sex pheromone content and calling behavior also existed in the yellow peach moth, *Conogethes punctiferalis* (Guenée) (Konno, 1986). This time lag between calling behavior and pheromone

Blend ratio of Z11-14 : AC/Z9-14 : AC	Mean catch[a]
58 : 42	3.2 ± 3.4a
62 : 38	3.3 ± 6.2a
64 : 36	4.5 ± 8.8a
66 : 34	4.3 ± 3.2a
68 : 32	2.1 ± 1.9a

[a] Means followed by the same letter are not significantly different (ANOVA, $P > 0.05$).

titer may be explained as follows: In a natural setting, temperature rises and falls during the day and this exogenous factor certainly influences the expression of calling and perhaps the production of pheromone; a decrease in temperature early in the evening might well advance the timing of calling, perhaps thereby bringing these events into closer synchrony than now appears to be the case.

The relationship between calling and pheromone titer found in *A.* sp. was not similar to other moth species. In *Trichoplusia ni* (Hübner) (Sower et al., 1972), pheromone titer of the principal pheromone component remained relatively constant through a 24-hr period, although females called only during the scotophase. In *Plodia interpunctella* (Hübner) and *Ephesia cautella* (Walker) (Coffelt et al., 1978) and in *Helicoverpa zea* (Boddie) (Raina et al., 1986), the rhythm of pheromone titer was synchronous with calling rhythm, titer being highest during calling.
