There is additional evidence to suggest that *M. croceipes* might orient to even lower GLV release rates than tested here: The cross-sectional area of an odor plume increases and the concentration of volatiles in that plume decreases with distance from the odor source. In our tests, *M. croceipes* were released 100 cm downwind, where the concentration of test volatile was relatively low. When wasps were released much closer to the odor source (15 cm distant), where odor concentrations were greater, wasps oriented much better (Table 1). This is an important point because in the field *M. croceipes* hunt by flying slowly 5–10 cm downwind from plants. At such a close range, the wasps should be able to detect very low levels of GLVs, perhaps lower than we have tested here.

In our tests, we used individual GLVs, but in nature, a caterpillar feeding on a plant would produce a complex blend of volatiles (Whitman and Eller, 1990; Turlings et al., 1990). A survey of previous literature (Drost et al., 1986, 1988; Eller et al., 1988; Prevost and Lewis, 1990) shows that when *M. croceipes* wasps were tested in wind tunnels to the full complement of plant and caterpillar odors, 45–90% of the wasps made successful orientation flights. This compares favorably with the highest responses (60–70%) recorded from our trials using individual compounds. Because both the sensitivities and behavioral responses of animals to odor blends may exceed the sum of component thresholds and responses (Laska et al., 1990), we suspect that combinations of two or more individual GLVs might elicit greater responses from the wasps.

Information about the sensory and neural mechanisms of the wasps' response to GLVs can be derived from the various GLV dose–response curves. All eight curves were fairly similar in shape, suggesting a similar stimulus–response mechanism. Generally, the height of the curve was proportional to its length;

compounds that elicited high responses were also active over a greater range. For each GLV, there was usually one concentration that produced a maximum flight response. Above or below that release rate, the orientation rate dropped. The decreased flight responses that were observed at low release rates probably occurred because GLV concentrations were insufficient to reach sensory or neural thresholds. Decreases in flight response at high release rates were possibly due to stimulus overload; as wasps approached the odor source, the GLV concentration increased to a point where it became repellent. This was shown by the fact that, when exposed to high GLV release rates, wasps often oriented well when far from the odor source, but turned sharply away when within 5–20 cm of the source. It should be noted, however, that such high release rates are artificial and would seldom occur in nature.

When the dose–response curves are plotted on numerical, instead of semi-log scales, the left-hand sides of the curves are very steep, and the maximum responses lie close to the low dose thresholds, suggesting that the maximum responses of the wasps have evolved to occur near their low sensory thresholds.

The dose–response curves reported here (Figure 1) clearly show that the response of *M. croceipes* wasps to GLVs varies with the dose. This underscores the great importance of always examining dose effects when investigating semiochemical interactions. Failure to consider dose effects when comparing semiochemicals could easily lead to erroneous conclusions about their absolute or relative activities.

Many authors have suggested that carnivorous natural enemies use plant chemicals to locate their herbivorous hosts (Whitman, 1988a,b; Ding et al., 1989; Navasero and Elzen, 1989; Sheehan and Shelton, 1989; Dicke et al., 1990a; Martin et al., 1990; McAuslane et al., 1991; Turlings et al., 1991a,b). Others have hypothesized that certain plant volatiles may have evolved to serve a tritrophic communicative function (i.e., plants release natural enemy attractive substances in direct response to herbivore attack) (Whitman 1988a,b; Dicke and Sabelis, 1989; Dicke et al., 1990a,b; Turlings et al., 1990, Whitman and Eller, 1990). The release of GLVs is undoubtedly advantageous for *M. croceipes* wasps because it allows the wasps to locate hosts. If it is shown that plants benefit when their attendant herbivores are destroyed by natural enemies that respond to these GLVs, then these chemicals should be regarded as plant-to-parasitoid synomones.

INHIBITORY EFFECTS OF TERPENE ALCOHOLS AND ALDEHYDES ON GROWTH OF GREEN ALGA *Chlorella pyrenoidosa*

(Received February 27, 1992; accepted May 29, 1992)

Abstract—The growth of the green alga *Chlorella pyrenoidosa* was inhibited by terpene alcohols and the terpene aldehyde citral. The strongest activity was shown by citral. Nerol, geraniol, and citronellol also showed pronounced activity. Strong inhibition was linked to acyclic terpenes containing a primary alcohol or aldehyde function. Inhibition appeared to be taking place through the vapor phase rather than by diffusion through the agar medium from the terpene-treated paper disks used in the system. Inhibition through agar diffusion was shown by certain aged samples of terpene hydrocarbons but not by recently purchased samples.

Key Words—*Chlorella pyrenoidosa*, alga, terpenes, growth inhibition.

INTRODUCTION

Terpene hydrocarbons, alcohols, aldehydes, and ketones have been reported to have antibacterial and antifungal activity (Morris, 1972; Smirnoff, 1972; Uzdennikov, 1972; Andrews et al., 1980; Mathela, 1981), and it has been suggested that terpenes in the diet may be responsible for the gut of the larvae of the Douglas fir tussock moth *Orgyia pseudotsugata* being relatively free of microflora (Andrews et al., 1980). Therefore, terpenes may have an ecological significance in certain situations involving microorganisms. Studies involving the effects of terpenes on microalgae are more limited. The use of terpene alcohols as anti-blue-green algal agents has been described in the European patent literature (Juettner, 1983).

In previous studies we have described the pronounced inhibitory effects of fungi-produced toxins (mycotoxins) on the growth of the green alga *Chlorella pyrenoidosa* (Ikawa et al., 1969, 1979, 1985; Sullivan and Ikawa, 1972). Many of the more active of these mycotoxins are terpenoids, and terpene intermediates are involved in their biosynthesis. This paper reports on an extension of this work to the simple terpenes themselves.

METHODS AND MATERIALS

Paper disks (6 mm, Difco Laboratories, Detroit, Michigan) were dipped into test solutions in ethanol, excess solution removed by touching the disks to the edge of the container (ca. 20 μl of solution was retained on the disk), and the disks placed on the surface of light yellow-green *Chlorella*-seeded agar plates (100-mm-diameter Petri plates, three disks per plate) prepared as previously described (Ikawa et al., 1985). The plates were placed under a fluorescent light at room temperature and zones of inhibition read after two days under constant illumination.

RESULTS AND DISCUSSION

The terpene hydrocarbons showed little or no inhibition at a disk concentration of 10 mg/ml (Table 1). However, it was found that samples of some of the terpenes that had been collected from various laboratories on campus and that presumably had been on the shelf for some time did show zones of growth inhibition (Table 1, footnote *d*), indicating that the older samples had probably undergone chemical changes to form inhibitory substances. These results recall those that had been observed with chlorellin, the antibacterial and autotoxic substance produced by *Chlorella*, where it was shown that chlorellin activity was due to photooxidation products of unsaturated fatty acids present in *Chlorella* (Spoehr et al., 1949).

Most of the terpene alcohols and aldehydes tested showed inhibition that was evident as a lightening or total wipe out of color in the light yellow-green *Chlorella* lawn (Table 1). That inhibition was taking place through the vapor phase rather than by diffusion through the agar was shown by observing the same results when the paper disks were placed on slightly larger Teflon disks and thus were not in direct physical contact with the agar surface. The greatest inhibition was shown by nerol, geraniol, citronellol, and citral, all of which possess the acyclic terpene structure with a primary alcohol or aldehyde function (Figure 1). Citral appeared to be the most active, showing complete plate color wipe out with three disks at 1 mg/ml. The cyclic terpene alcohols borneol and isoborneol and terpenes carrying the alcohol function at a nonterminal position

TABLE 1. INHIBITION OF *Chlorella* GROWTH BY TERPENES

[b] Disk diameter (6 mm) subtracted from the total diameter of the inhibition zone. Figures represent the mean of all disks (three per plate) run on two or more separate occasions. Standard deviations generally ran $< 10\%$ of the mean for means > 5 mm.

[c] Concentration of test solution in ethanol.

[d] Older shelf samples of these compounds that were collected from various laboratories on campus showed inhibition at 10 mg/ml.

[e] * indicates platewise lightening of the lawn color as compared to control plates. ** indicates complete wipe out of the yellow-green lawn color with three disks per plate. Similar results were obtained when disks were prevented from direct contact with the agar surface by interposing larger diameter Teflon disks between the paper disks and the agar surface.

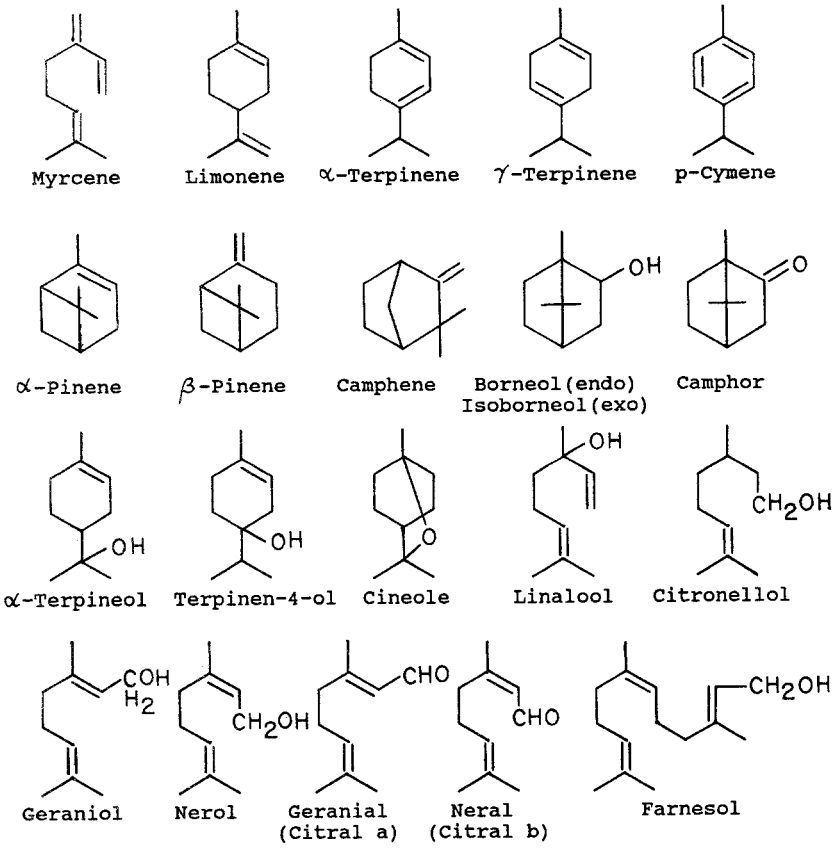

FIG. 1. Structures of terpenes tested against *Chlorella*.

(α-terpineol, terpinen-4-ol, linalool) showed less activity than the more active alcohols. The sesquiterpene alcohol farnesol showed some activity at 10 mg/ml through agar diffusion.

The leaf alcohol (*cis*-3-hexen-1-ol) and a series of related hexenols were also tested. As shown in Table 1, none of the compounds showed any activity at a concentration of 10 mg/ml.

In contrast to the activity of terpene hydrocarbons against bacteria and fungi, our results indicate that the hydrocarbons are not particularly toxic to the green alga *Chlorella*. Terpene alcohols showed activity, the highest activity being shown by acyclic compounds that carried the functional group on the terminal carbon atom. Acyclic terpene alcohols have been described as anti-blue-green algal agents, with farnesol being particularly active against *Synechococcus* (Juettner, 1983).

Lorber and Muller (1976) showed that when root tip cells of *Cucumis sativus* were exposed to the vapors of the volatile monoterpenes from the leaves of *Salvia leucophylla*, disruption of the membranes surrounding the nuclei, mitochondria, and dictyosomes took place. Disruption of the cytoplasmic membranes of *Bacillus thuringiensis* and *Saccharomyces cerevisiae* were also observed when these microorganisms were treated with α-pinene (Andrews et al., 1980). Lipophilicity appeared to be an important contributing factor in the inhibition of lettuce fruit germination by terpenes (Reynolds, 1987). In this case, the terpene alcohols, aldehydes, and ketones appeared to be active, while the more lipophilic hydrocarbons did not show inhibitory activity. In our case also, the inhibitory activity of the alcohols in contrast to the inactivity of the hydrocarbons indicated the need for a hydrophilic head and a lipophilic tail in a molecule for optimum activity. Although membrane effects may be the first actions of these compounds, these effects could, in turn, influence other cellular processes, such as respiration, photosynthesis, and protein synthesis. The trichothecenes, which are sesquiterpene alcohols, are strong inhibitors of protein synthesis (Sato and Ueno, 1977). Our previous results showed that there was good correlation between inhibition of protein synthesis and inhibition of *Chlorella* growth among the various trichothecenes (Ikawa et al., 1985). This suggests a possible link to processes beyond a primary disruption of membrane function.

(Received December 9, 1991; accepted May 29, 1992)

Abstract—Antennal olfactory responses of the parasitoid, *Microplitis croceipes* (Cresson) (Hymenoptera: Braconidae), to 29 cotton volatile compounds were measured by electroantennogram (EAG) techniques. No significant sexual differences were found in EAGs of males and females to volatiles emanating from 100-μg stimulus loads of the 29 cotton compounds. Green leaf volatiles (saturated and monounsaturated six-carbon alcohols, aldehydes, and their acetate derivatives), heptanal, and the benzene derivatives, benzaldehyde and acetophenone, elicited the largest EAGs. Monoterpenes elicited moderate EAGs with β-ocimene being the most effective monoterpene tested. Among the sesquiterpenes tested, β-bisabolol was the most effective stimulus at the 100-μg dose. Dose–response curves constructed from EAGs of females revealed a low threshold for (*Z*)-3-hexenyl acetate, a compound previously shown to be an effective attractant in wind-tunnel bioassays. Comparison of relative volatilities of the various odorants indicated differential selectivity and sensitivity of *M. croceipes* antennal receptors to them. The roles of cotton plant volatiles in host habitat location of *M. croceipes* are discussed.

Key Words—*Microplitis croceipes*, Hymenoptera, Braconidae, chemoreceptors, cotton, electroantennogram, host habitat location, plant volatiles, parasitoid, EAG.

INTRODUCTION

Microplitis croceipes (Cresson) (Hymenoptera: Braconidae) is a predominant parasitoid of two major cotton pests: the cotton bollworm [*Helicoverpa zea* (Boddie) (Lepidoptera: Noctuidae)] and the tobacco budworm [*Heliothis virescence* (F.)] in the United States (Powell and King, 1984). As an important biological control agent, *M. croceipes* has been studied extensively in recent years (Drost et al., 1986; Eller et al., 1988; Hopper and King, 1984; Lewis et al., 1988; Powell and King, 1984; Whitman and Eller, 1990). The success of the parasitic wasp in suppressing the pest population depends on its ability to locate hosts in a complex olfactory and visual environment. Understanding the mechanisms governing host-searching behavior by the wasp is critical to successful implementation of biological control programs.

Host-finding behavior in parasitoids is a hierarchy of behavioral events, which include host habitat location and host location (Vinson, 1981, 1984). Chemical cues are known to play a central role in each level of these behaviors. Electroantennograms (EAGs) to several plant volatiles by two parasitoids, *Campoletis sonorensis* (Ichneumonidae) (Baehrecke et al., 1989) and *Microplitis demolitor* (Ramachandran and Norris, 1991), have been previously reported. Numerous volatiles have been identified from the cotton plant (Chang et al., 1988; Hedin, 1976; Thompson et al., 1971). Some of these compounds play important roles in mediating host-searching behaviors in *Campoletis sonorensis* (Elzen et al., 1983, 1984; Baehrecke et al., 1989).

Behavioral responses of *M. croceipes* to volatiles from the plant–host complex have been studied by several workers (Drost et al., 1986; Eller et al., 1988; Whitman, 1988). Drost et al. (1986) showed that *M. croceipes* responded in a wind tunnel to odors by increasing the frequency of sustained and oriented flight. *M. croceipes* also showed a dose-dependent response to volatiles from its plant–host complex in an olfactometer (Eller et al., 1988). *M. croceipes* was also shown to orient in a flight tunnel to green leaf volatiles (Whitman, 1988; Whitman and Eller, 1990). No information is available on the nature of neurophysiological responses of *M. croceipes* to volatiles emanating from its plant–host complex.

The purpose of this study was to investigate neurophysiological responses of *M. croceipes* to cotton volatiles by means of electroantennograms (EAGs). Our results provide a basis for our future studies of single olfactory receptor neurons on the antenna.

METHODS AND MATERIALS

Insects. Microplitis croceipes used in this study were from a colony maintained at the USDA, ARS, Biological Control of Insects Research Lab, Columbia, Missouri. Pupae of the wasp were shipped overnight to the behavioral

physiology lab at the USDA, ARS, Boll Weevil Research Unit, Mississippi State, Mississippi, where they were kept in Petri dishes at room temperature (25 ± 1°C) until emergence. Newly emerged wasps were sexed and maintained in Petri dishes at room temperature and a light cycle of 16 hr light and 8 hr darkness. Adult wasps were provided water and honey until testing three to six days after emergence.

Odorous Stimuli. Compounds tested, their purities, and supply sources are listed in Table 1. These compounds were chosen based primarily on their presence in the cotton plant and/or in the green leaf volatile complex (Dickens, 1984). Compounds were diluted in spectrometric grade hexane, and tested for purity using a gas chromatograph (Tracor Instruments model 540, Austin, Texas). Serial dilutions of 0.001–100 $\mu g/\mu l$ were prepared for eight of the 29 compounds tested. All test solutions were kept at −4°C before and after each experiment. Solutions were allowed to reach room temperature before testing.

The odor delivery system and stimulation technique were the same as that described by Dickens (1984). Stimulus compounds diluted in hexane were delivered as 1-μl or 10-μl samples placed on No. 1 filter paper (7 × 16 mm) inserted into glass cartridges (80 mm long × 5 mm ID) and oriented toward the preparation from ca. 1.5 cm. Filtered and dried hydrocarbon-free air carried odor molecules evaporating from the filter paper over the preparation. Stimulus duration was 1.0 sec; air flow was 1 m/sec as measured by a thermistor. The atmosphere around the preparation was continuously exhausted.

Electrophysiological Recording Technique. Electroantennogram (=EAG) techniques used in this study were a modification of previous techniques and are described in detail elsewhere (Schneider, 1957; Dickens and Payne, 1977; Dickens, 1984). Ag–AgCl glass capillary microelectrodes were used. Following prepuncture with a sharpened tungsten needle, the recording electrode was inserted into the distal segment of the antenna. In the same manner, the indifferent electrode was inserted into the scape. The signal was amplified 10× by a Grass P-16 AC/DC microelectrode amplifier and viewed on a Tektronix 5111A storage oscilloscope. EAGs were recorded on graph paper by an Omniscribe recorder (Houston Instruments, Houston, Texas) for subsequent analyses and storage.

Experimental Procedure. Two series of experiments were conducted. In the first series of experiments, responses of the antennal receptors were measured by recording EAGs to 100-μg stimulus loads of each test odorant. In the second series of experiments, eight compounds were chosen based on results of the first series of experiments, and their function in host location of other parasitic wasps. Serial dilutions of each odorant were presented from the lowest to the highest dose. Because of the variation in volatility of the test compounds, only relative comparisons can be made between the stimuli.

In the first experimental series, EAGs were recorded from five wasps of

[a] A, Fisher Scientific Co., Pittsburgh, Pennsylvania; B, J.T. Baker Chem. Co., Phillipsburg, New Jersey; C, Aldrich Chem. Co., Milwaukee, Wisconsin; D. Alfred Bader Lib. Rare Chem., Milwaukee, Wisconsin; E, Pfaltz & Bauer, Inc., Stamford, Connecticut; F, ICN-K&K Laboratories, Inc., Plainview, New York; G, P.A. Hedin, USDA, ARS, Mississippi State, Mississippi; H, Sigma Chemical Co., St. Louis, Missouri.

each sex for each test compound. Only female wasps were tested for the dose–response studies for each of eight chosen compounds. In both experiments, control stimulations (1 μl or 10 μl of hexane solvent on filter paper in a cartridge) were tested three to five times in each preparation. Hexan-1-ol (100 μg on filter paper) served as a standard and was tested following every two experimental stimuli. Response to the solvent control, if any, was deducted from all responses. Responses to the standard were used to normalize all responses so that the responses from different preparations could be compared. At least 3 min were allowed between each stimulation for recovery of the EAG.

EAGs to test compounds were evaluated by measuring the maximum amplitude of depolarization elicited by a stimulus, then subtracting the amplitude of the response to the preceding control. Millivolt responses to all stimuli were converted to percentage values of the mean responses to the two nearest standards (Dickens, 1984).

Threshold was defined as the stimulus load at which the mean EAG minus the standard error was greater than the mean EAG to the lowest stimulus load tested plus the standard error. Saturation was considered to be the stimulus load at which the mean EAG plus the standard error was greater than or equal to the mean EAG minus the standard error for the next highest dose tested.

Statistical Analyses. For the first series of experiments, EAGs to 100-μg doses of the various odorants were compared for significant differences using a general linear models procedure (SAS Institute, Cary, North Carolina). Dose–response curves were evaluated by analysis of variance. Where differences were noted, comparisons were made using Duncan's new multiple-range test.

RESULTS

Mean responses of the male [-3.53 mV (SE = ± 0.14 mV)] and female [-3.81 mV (SE = ± 0.13 mV)] *M. croceipes* to the 1-hexanol standard (100 μg) were not significantly different ($P < 0.05$).

Selectivity. Although no significant differences were found in responses of male and female wasps to the various odorants, EAGs to individual compounds did differ ($P < 0.05$) (Table 2). The most effective odorants were heptanal, benzenoids (i.e., benzaldehyde and acetophenone), and green leaf volatiles (GLVs). Responses of both sexes to primary alcohols with three to 10 carbons were maximal for the six-carbon alcohol (hexan-1-ol, a GLV), and declined as the carbon chain length increased or decreased (Figure 1A). All GLVs tested elicited strong responses in both male and female wasps, but EAGs for individual GLVs did not differ significantly ($P < 0.05$) (Figure 1B). Monoterpenes were less effective than GLVs and elicited moderate responses. Among the oxygenated monoterpenes tested, linalool elicited significantly higher responses

TABLE 2. MEAN EAGS OF FIVE MALE AND FIVE FEMALE *M. croceipes* TO 100-μg STIMULUS LOAD OF SELECTED COTTON VOLATILES AND OTHER COMPOUNDS[a]

Compound	Mean EAG[b]	I_k[c]

[a] EAGs from males and females were combined since chemical * sex interaction was not significant. Numbers followed by different letters are significantly different ($P < 0.05$; Duncan's multiple-range test).
[b] EAGs are represented as percent response to the standard = hexan-1-ol (100 μg).
[c] Kovàts' indices on OV-17 column from Hedin et al. (1975). Values in brackets were extrapolated.

than either geraniol or nerol. β-Ocimene was the most effective monoterpene hydrocarbon with decreasing responses elicited by the remaining compounds of the same class: (−)-β-pinene > myrcene > (−)-limonene > (−)-α-pinene. With the exception of β-bisabolol, which elicited a moderate response, the sesquiterpenes were ineffective. Both of the alkanes tested, decane and undecane, elicited moderate responses that did not differ significantly.

Sensitivity. Dose–response curves were constructed from EAGs of female

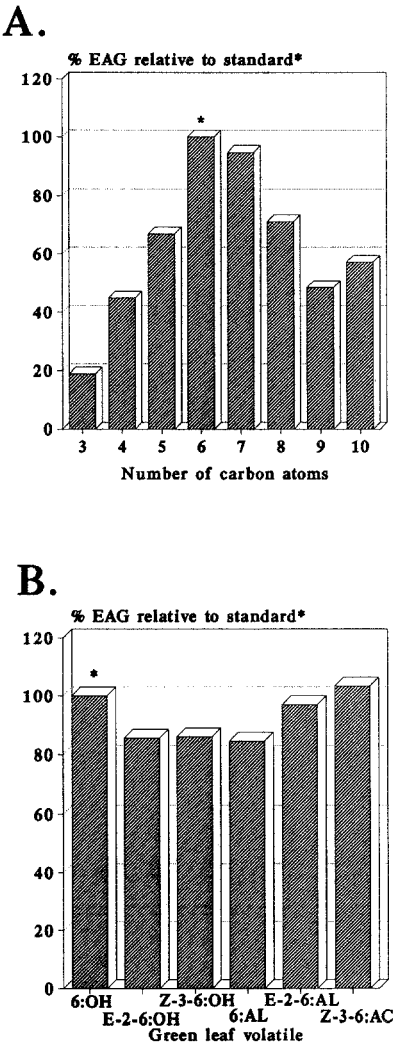

FIG. 1. Mean EAGs of *M. croceipes* (N = 10, five males and five females) to: (A) stimulus load of 100 μg of saturated primary alcohols with chain length from three to ten carbons; (B) stimulus load of 100 μg of green leaf volatile alcohols [hexan-1-ol = 6:OH, (*E*)-2-hexen-1-ol = *E*2-6:OH, (*Z*)-3-hexen-1-ol = *Z*3-6:OH), aldehydes (hexanal = 6:Al, (*E*)-2-hexenal = *E*2-6:Al], and acetate [(*Z*)-3-hexenyl acetate = *Z*3-6:Ac, N = 5 females for this compound]. See Table 2 for statistical analyses.

wasps to eight volatiles distributed among four chemical classes: monoterpenes, sesquiterpenes, green leaf volatiles, and benzene derivatives (Figure 2). Thresholds for compounds relative to those in the same class were: monoterpenes—β-ocimene (0.01 μg) > linalool (10 μg) > (−)-β-pinene (100 μg); sesquiterpenes—β-bisabolol (1 μg) = β-caryophyllene (1 μg); green leaf volatiles—(*Z*)-3-hexenyl acetate (0.01 μg) > (*E*)-2-hexenal (1 μg). Benzaldehyde had a threshold of 1.0 μg. Only β-caryophyllene clearly reached saturation at a stimulus load of 10 μg.

DISCUSSION

Characteristics of Electroantennograms. No significant sexual differences were found in EAGs to 100-μg stimulus loads among the 29 compounds tested. Similarity in antennal responses of male and female insects to plant odors was previously noted for several phytophagous pests (Fein et al., 1982; Dickens, 1984; Wellso et al., 1984; Light et al., 1988; Hansson et al., 1989). The explanation for such similarity was that males and females live in the same habitat and may share the same chemical cues to locate host plants on which to feed and mate. In contrast to phytophagous insects, female parasitic wasps use plant volatiles to locate host insects, while male wasps probably share some of the same chemical cues, possibly in conjunction with a sex pheromone (Powell and King, 1984), to locate females for mating. Differences in behavioral responses of male and female wasps to green leaf volatiles (Whitman, 1988; Whitman and Eller, 1990) may arise from sexual differences in higher-order processing of incoming peripheral olfactory information.

Both the differential EAGs recorded to 100-μg stimulus loads of the various odorants (Table 2) and the differing dose–response curves to selected odorants recorded from females (Figure 2) indicate differential selectivity and sensitivity of the antennal olfactory receptor system of *M. croceipes* for host habitat odors. Clearly the number of molecules emanating from the filter paper in the glass odor cartridge, and ultimately reaching the preparation, differs for the various odorants tested due to differing volatilities of the compounds and binding characteristics of the compounds to the filter paper. Thus, what is being compared is stimulus loading and not the number of molecules reaching the preparation. However, the observed differences in EAGs cannot be ascribed solely to differences in volatility of the various compounds. This point is illustrated by comparing Kovàts' retention indices (a measure of relative volatility) (Kovàts, 1961) for the various odorants with observed thresholds of neurons responsive to them (Table 2). Kovàts' indices previously calculated for the compounds, and threshold stimulus loads (μg) were: β-ocimene = 1210, 0.01; β-bisabolol = 1795, 1.0; β-caryophyllene = 1582, 1.0; (*E*)-2-hexenal = 965, 1.0; benzaldehyde =

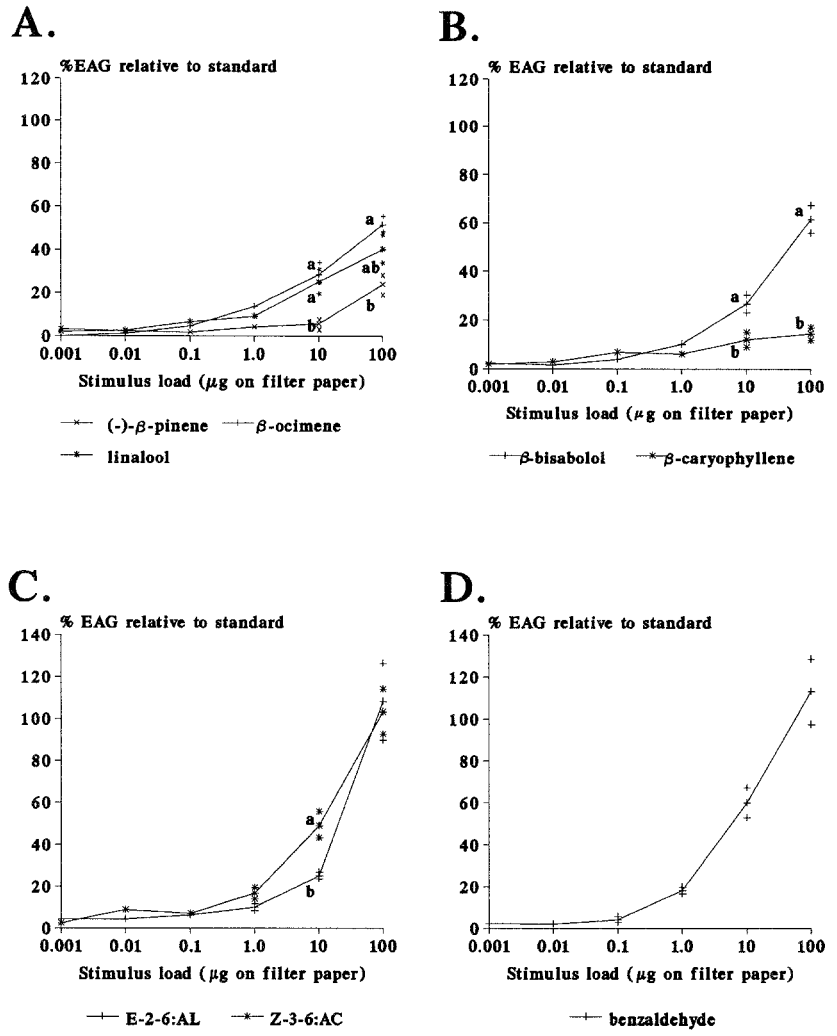

FIG. 2. Dose–response curves constructed from EAGs of female *M. croceipes* ($N = 5$) to serial stimulus loads of: (A) (−)-β-pinene, β-ocimene, and linalool; (B) β-bisabolol and β-caryophyllene; (C) (*E*)-2-hexenal and (*Z*)-3-hexenyl acetate; and (D) benzaldehyde. EAGs to different chemicals at the same dose in the same graph with different letters are significantly different ($P < 0.05$; Duncan's multiple-range test). Points above and below means represent standard errors.

1172, 1.0; and β-pinene = 1105, 100 (OV-17 column; Hedin et al., 1975). Kovàts' indices were unavailable for linalool (threshold = 0.1 μg), and (*Z*)-3-hexenyl acetate (threshold = 0.01 μg). However, geraniol, a monoterpene alcohol closely related to linalool, had a Kovàts' index = 1425 (Hedin et al., 1975). (*Z*)-3-Hexenyl acetate should be considerably less volatile than (*E*)-2-hexenal based on boiling points of compounds that are similarly related, for example, hexyl acetate (bp = 168°C) and hexanal (bp = 131°C) (boiling points from Windholz, 1983). EAGs of *M. croceipes* to alcohols and aldehydes reported here are similar to those reported previously for *M. demolitor* (Ramachandran and Norris, 1991).

Behavioral Correlations. Detection of host volatiles by phytophagous insects and their possible role in insect behavior have been the subjects of numerous studies. The most effective volatiles and the specific receptors involved in their detection have been identified in some insects by EAG and single-neuron recording techniques as well as behavioral studies (Dickens and Payne, 1977; Dickens, 1984, 1990a,b; Dickens et al., 1984; Dickens and Boldt, 1985; Guerin and Visser, 1980; Visser, 1979, 1986). In contrast, most work done on parasitic wasps is at the behavioral level (Whitman, 1988). Host location and acceptance by parasitic wasps were believed to be mediated by chemical stimuli emitting from the host and its plant (Vet et al., 1983; Vinson, 1984; Bouchard and Cloutier, 1985). For example, several sesquiterpenes, including β-bisabolol and β-caryophyllene, were identified as compounds released from cotton, which elicited behavioral responses from the parasitic ichneumonid, *Campoletis sonorensis* (Elzen et al., 1983, 1984). β-Bisabolol, which constitutes 50–60% of the volatiles emitted by maturing cotton plants (Thompson et al., 1971), elicited significantly larger EAGs in *M. croceipes* in our current study than any other sesquiterpene tested. Relatively large EAGs were generated by β-bisabolol in the boll weevil, a cotton-feeding insect, which has neurons selectively responsive to this sesquiterpene (Dickens, 1990a).

The importance of plant chemicals in host finding has been proven for several parasitic wasps including *M. croceipes* (Eller et al., 1988; Whitman, 1988; Ding et al., 1989; Navasero and Elzen, 1989). Large EAGs of *M. croceipes* females to green leaf volatiles correlate well with the previously reported behavioral studies indicating their attractiveness (Whitman, 1988; Whitman and Eller, 1990). (*Z*)-3-Hexenyl acetate was among the most effective odorants among the cotton volatile compounds tested in our current study. Acetate analogs of green leaf volatiles were among the most effective volatiles eliciting flight behavior in female *M. croceipes* (Whitman, 1988; Whitman and Eller, 1990). Insect predators and parasitoids are more attracted to damaged plants than undamaged plants (Sato, 1979; Elzen et al., 1983; Whitman, 1988; Dicke and Sabelis, 1989; Whitman and Eller, 1990). Corn seedlings release large amounts of terpenoid volatiles and (*Z*)-3-hexenyl acetate after being fed upon by cater-

pillars (Turlings et al., 1990). Both caterpillar-damaged and artificially damaged plants emit GLVs that are attractive to female *M. croceipes* (Whitman and Eller, 1990). Thus results of chemical analyses, behavioral studies, and our current neurophysiological study correlate well with reported female behavior and are indicative of chemical communication among the parasitoid, plant, and insect host. Green leaf volatiles also elicited large EAGs in *C. sonorensis*, another parasitoid associated with cotton insects (Baehrecke et al., 1989).

Similarity between parasitoids and host herbivores in responding to some host plant volatiles has been reported in several plant–herbivore–parasitoid systems (Salkeld, 1959; Camors and Payne, 1972; Guerin and Visser, 1980; Ramachandran and Norris, 1991). EAGs in response to cotton volatiles have not yet been reported for either *Heliothis virescens* or *Helicoverpa zea*, both hosts of *M. croceipes*. We suspect these hosts may use some of the same plant volatiles used by *M. croceipes* for locating host plants. In fact, one of us recently found that (Z)-3-hexenyl acetate, an attractant (Whitman, 1988; Whitman and Eller, 1990) for *M. croceipes*, and an effective EAG stimulus as reported herein, enhances the sex attractant pheromone of a host, *H. virescens* (Dickens et al., 1992).

While plant volatiles may be maladaptive in the sense of attracting herbivores, evolution of tritrophic chemical communication between plants and parasitoids is highly adaptive. More information about the olfactory responsiveness of *H. virescens* and *H. zea* is needed in order to better understand tritrophic communication among *M. croceipes*, its lepidopterous hosts, and host plant.

Acknowledgments—The authors are grateful to: D. Davis for assistance in rearing the parasitoids; E. Mattix for technical assistance; and Drs. F.J. Eller, G.J. Puterlea, D.W. Whitman, M.R. McLaughlin, J.W. Haynes, S.B. Vinson, and J.C. Schneider for comments on the manuscript. The work was conducted by Y. Li as part of the requirements for the PhD degree at the University of Missouri, Columbia.

NAIVE OPHIOPHAGUS LIZARDS RECOGNIZE AND AVOID VENOMOUS SNAKES USING CHEMICAL CUES

JOHN A. PHILLIPS* and ALLISON C. ALBERTS

Center for Reproduction of Endangered Species
Zoological Society of San Diego
Box 551, San Diego, California 92112

(Received March 9, 1992; accepted June 1, 1992)

Abstract—Monitor lizards prey on snakes. Conversely, venomous snakes prey on juvenile monitor lizards. Immediately after hatching, monitor lizards are naive to all prey items, thus correct assessment of snake prey is paramount for survival. Experiments were conducted to determine how hatchling monitor lizards (*Varanus albigularis*) with no previous exposure to snakes reacted to sympatric venomous and nonvenomous snakes. Hatchling lizards attacked harmless snakes, but avoided venomous species. Lizards readily accepted meat from skinned snakes, regardless of species. When invertebrate prey covered with skin segments from venomous snakes were restrained from moving, they were usually investigated by tongue-flicking and rejected. Unrestrained skin-covered prey, however, were generally attacked and eaten without prior evaluation by tongue-flicking. Attack was inhibited in trials in which unrestrained prey were tongue-flicked, suggesting that chemical cues contained in snake skins mediate avoidance of venomous snakes. Selection for the ability to perceive snake integumental chemicals may be especially strong in species that both consume and are consumed by snakes.

Key Words—Chemical cues, *Varanus*, snakes, lizards, monitor lizard.

INTRODUCTION

A variety of vertebrate prey react to the scent products of snakes (Weldon and Burghardt, 1979; Weldon, 1991), and certain prey use chemoreception to discriminate snakes that are their predators from those that are harmless (Weldon, 1982; Dial et al., 1989). The chemical senses also aid some predators in their

*To whom correspondence should be addressed.

0098-0331/92/1000-1775$06.50/0 © 1992 Plenum Publishing Corporation

identification of snake prey (Weldon and Schell, 1984). However, the responses by a species to chemical cues from organisms that are potentially either their predators or their prey have not been examined systematically.

As a genus, monitor lizards consume a variety of prey (King and Green, 1979; Losos and Greene, 1988) and chemoreception is extremely important in their foraging ecology (Auffenberg, 1978; Pianka, 1986; Cooper, 1989). Although invertebrates account for the majority of the natural diet, a substantial percentage of the annual caloric intake is obtained from vertebrate prey, including snakes (Shine, 1986; Branch, 1991). Conversely, as juveniles, many species of monitors are preyed upon by snakes (Shine, 1989; Shine and Slip, 1990).

The white-throated savanna monitor, *Varanus albigularis*, is a large (>5 kg) lizard that inhabits a variety of southern African habitats, including the arid savanna. In this environment, dramatic increases in vegetational growth and animal populations occur during the rainy season (Berry and Louw, 1982). As with most reptiles, hatching of snakes and monitor lizards occurs midway through the wet season (Branch, 1988). Growth of recently hatched snakes and lizards during this period is rapid, with most species amassing substantial fat deposits required for survival during the subsequent eight months of drought. Juvenile lizards and snakes are favored prey items of numerous species of birds and mammals, and lizards and snakes also prey upon one another (Branch, 1988).

Snakes that eat lizards and those that do not are likely to be visually similar at a distance, thus necessitating close-range investigation by lizards attempting to distinguish them. Because snakes are generally formidable predators, any misclassification of a predator species as prey is potentially very costly. In this study, we demonstrate the chemical discrimination of snake predators from snake prey by naive white-throated savanna monitor hatchlings.

METHODS AND MATERIALS

Five gravid female white-throated savanna monitors were caught and housed in a 50-m^2 outdoor enclosure at the Etosha Ecology Institute, Etosha National Park, in north-central Namibia. Oviposition occurred within two weeks of capture, and eggs were artificially incubated. The females were released at the site of their capture. Twenty-seven of 120 hatchlings (five or six hatchlings from each clutch) were retained in captivity; the remaining hatchlings were released in the area where their mother had been caught.

After the umbilical scar had completely sealed, the retained hatchlings were released in the outdoor enclosure. The hatchlings were exposed to human contact for 2 hr each day, and exhibited no discernible aggressive or defensive behavior to human presence in the enclosure. Hatchlings were offered daily a variety of invertebrates (grasshoppers, crickets, land snails, centipedes, scorpions) that are

known to be common prey of this species of monitor lizard (W.R. Branch, personal communication; J.A. Phillips, unpublished data). Prey items were offered with forceps individually or were placed in the enclosure en masse. Water was available ad libitum. Hatchlings were fed until satiated. All animal care was in compliance with the guidelines of the Zoological Society of San Diego Animal Care and Use Committee.

Experiment 1. At six weeks of age each hatchling (total length 220–250 mm) was offered unrestrained grasshoppers, and land snails, grasshoppers, and corn crickets restrained by forceps, on each of two occasions. Trials were begun between 1300 and 1400 hr, at which time the lizards had been actively searching for food for several hours. The sequence of tongue-flicking, aggressive and/or defensive postures, and attack and/or retreat were videotaped and analyzed for each prey item.

At seven weeks of age, hatchlings were assigned to one of three groups (nine hatchlings per group). Members of each group were individually exposed to either a whole fresh (less than 2 h old) road-killed sand snake (*Psammophis leightoni*), road-killed spitting cobra (*Naja nigricollis*), or road-killed horned adder (*Bitis caudalis*) at two-day intervals. The order of presentation of the three snakes was randomized among hatchling groups, and a total of nine different snake carcasses (three from each species) were used in the presentations. The behavioral responses of individual hatchling lizards to the road-killed snakes were videotaped and analyzed as above.

Experiment 2. At eight weeks of age, the hatchlings were assigned to one of five groups, with one to two hatchlings from each clutch represented in each group (numbers of hatchlings in each of the five groups were 5, 5, 5, 6, 6). Each member of the five groups of hatchlings was tested individually for its response to fresh road-killed sand snakes, spitting cobras, and horned adders under five treatment conditions: (I) whole snake, (II) 50-mm intact snake sections, (III) 50-mm sections of snake with the skin removed, (IV) live grasshopper covered with a coat of snake skin restrained from jumping by a pair of forceps (Figure 1), and (V) live unrestrained grasshopper covered with a coat of snake skin. The snakes used in the experiment were 700–930 mm total length. Treatments were presented to the five hatchling groups in a Latin-square design, thus the order of exposure to the five treatments differed for each group of hatchlings. Each of the three snake species was tested under each of the five treatment conditions in random order at 72- to 96-h intervals. Trials were begun between 1300 and 1400 hr.

Statistics. Repeated measures analysis of variance (ANOVA) was used to examine variation in the rate of tongue-flicking in response to invertebrate prey and venomous and nonvenomous snakes in experiment 1. In experiment 2, Latin-square ANOVA was used to compare the percentage (arcsine square-root transformed) of hatchlings in each of the five groups that attacked snakes under

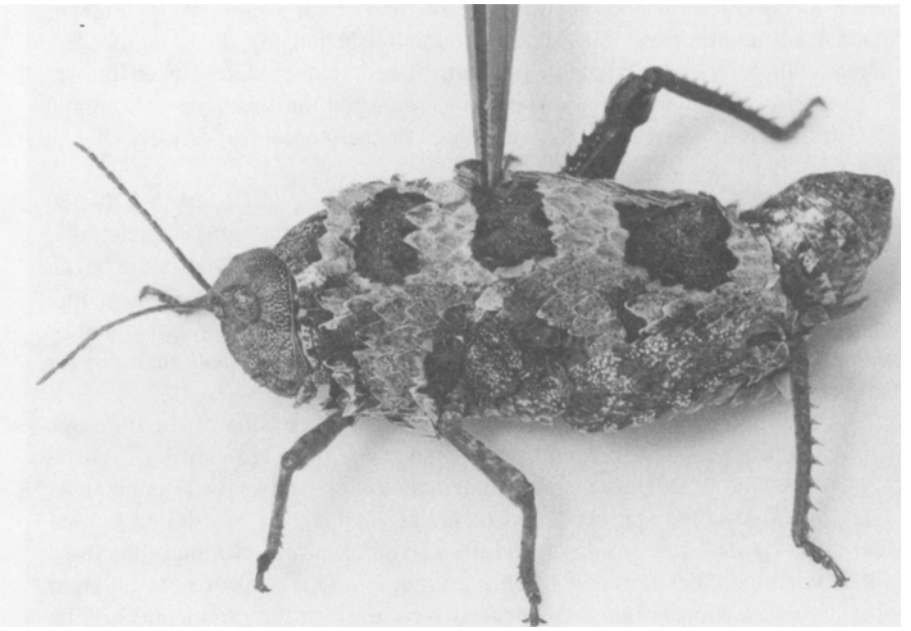

FIG. 1. Pamphagid grasshopper (approximately 50-mm body length) covered with a coat of skin from a horned adder.

the five treatment conditions. Differences in response to each of the three snake species were assessed using Fisher's protected least significant difference tests (Carmer and Swanson, 1973).

RESULTS AND DISCUSSION

In experiment 1, hatchlings exhibited tongue-flicking, a behavior that probably delivers odorants to the vomeronasal organ (Halpern, 1987), when exposed to invertebrate prey (Table 1). In most cases, two to four tongue-flicks were emitted before a prey item was attacked. However, most attacks on unrestrained grasshoppers occurred in the absence of tongue-flicking. Tongue-flicking rates were significantly lower in response to unrestrained moving grasshoppers than to the other invertebrate prey items presented ($F = 132.48$; $df = 3,53$; $P = 0.0001$), suggesting that visual cues may be more important than chemical cues in eliciting attack of moving prey. In no instance were aggressive or defensive behaviors observed in response to live invertebrate prey.

Sand snakes do not eat monitor lizards but are relatively common prey

TABLE 1. RESPONSES OF 27 HATCHLING SAVANNA MONITORS TO INVERTEBRATES AND WHOLE ROAD-KILLED SNAKES[a]

	Mean tongue flicks	Percent attack	Percent of hatchlings exhibiting defensive/ aggressive behaviors			
			Lateral	Hiss	Slap	Vent
Invertebrates						
Land snail (54)	4.33	100	0	0	0	0
Corn cricket (54)	4.35	100	0	0	0	0
Restrained grasshopper (54)	3.94	100	0	0	0	0
Unrestrained grasshopper (54)	0.18	100	0	0	0	0
Snakes						
Sand snake (27)	4.27	100	0	0	0	0
Spitting cobra (27)	4.84	22	100	93	52	100
Horned adder (27)	4.55	11	100	100	81	0

[a]Sample size in parentheses. Each invertebrate prey type was offered on two different occasions. Lateral compression of the body (lateral), hissing vocalizations (hiss), and tail slap (slap) are aggressive displays, whereas vent dragging (vent) is a territorial behavior.

items of adult savanna monitors. The stomach contents of 18 road-killed savanna monitors revealed two sand snakes, among other prey, accounting for about 10% of the total caloric value of the stomach contents (J.A. Phillips, personal observation). Sand snakes were universally attacked by hatchlings in a manner similar to invertebrate prey (Table 1). After initial attack, the hatchlings exhibited no hesitation in attempts to consume the sand snakes. No aggressive or defensive behaviors were noted in response to sand snakes.

The spitting cobra and the horned adder are highly venomous snakes that eat hatchling monitor lizards (Branch, 1988). Similar to other potential prey items, tongue-flicking by hatchling lizards occurred immediately after exposure to these two species. There was no difference in the rate of tongue-flicking in response to the three species of snakes ($F = 1.16$; $df = 2,78$; $P = 0.32$). However, in only nine of 54 cases was attack of venomous snakes observed (Table 1), and in no instance did the hatchlings attempt to consume venomous snake carcasses.

Regardless of whether snakes were attacked, all hatchlings exhibited one or more defensive and/or aggressive behaviors toward the venomous snakes (Table 1). The behavioral responses exhibited by hatchlings were specific to each of the two venomous snake species. In particular, posterior adpression (vent dragging), apparent in every encounter with the spitting cobra, was never elicited when hatchlings were exposed to horned adders. Hatchling savanna

monitors defecate at latrine sites, and when exiting these sites, often perform vent dragging (J.A. Phillips, personal observation). When other hatchlings investigate areas where vent dragging has occurred, aggressive posturing is frequently observed, suggesting that vent dragging may function in territorial marking.

In experiment 2, the hatchlings responded to whole bodies of the three snake species in a manner similar to that of experiment 1. Latin-square ANOVA revealed no effects of order of presentation ($F = 1.001$, $df = 4,12$, $P > 0.50$), no differences in response among the five hatchling groups ($F = 1.001$, $df = 4,12$, $P > 0.50$), and no differences in response across the five treatments ($F = 1.001$, $df = 4,12$, $P > 0.50$) for sand snakes (Figure 2). These results contrasted with those for the two venomous snake species. For spitting cobras, there were no effects of order of presentation ($F = 0.56$, $df = 4,12$, $P > 0.50$), no differences among hatchling groups ($F = 0.28$, $df = 4,12$, $P > 0.50$), but significant differences across treatments ($F = 6.84$, $df = 4,12$, $P < 0.01$). For horned adders, there were also no effects of order of presentation ($F = 1.62$, $df = 4,12$, $P > 0.20$), no differences among hatchling groups ($F = 0.78$ $df = 4, 12$, $P > 0.50$), but significant differences across treatments ($F = 48.10$, $df = 4,12$, $P < 0.001$).

For spitting cobras and horned adders, Fisher's protected least significant difference tests revealed that hatchlings were significantly more likely to attack skinned body sections and skin-covered unrestrained grasshoppers than whole snakes, sectioned snakes, or skin-covered restrained grasshoppers (Figure 2). Hatchlings avoided sectioned snakes and skin-covered restrained grasshoppers

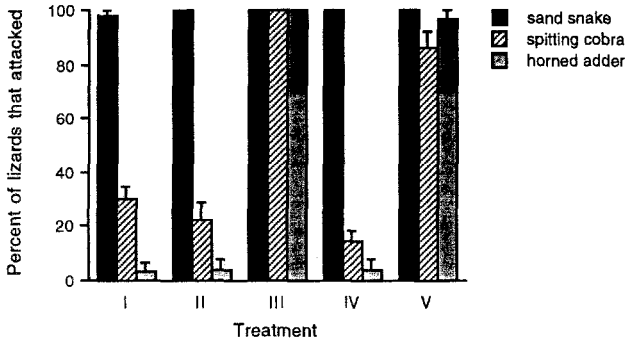

FIG. 2. Mean percentage (±SE) of hatchling savanna monitors in five groups that attacked (I) whole road-killed snakes, (II) snake sections, (III) skinned snake sections, (IV) a restrained grasshopper covered with a segment of snake skin, or (V) an unrestrained grasshopper covered with a segment of snake skin. Three snake species were presented, the sand snake, and two highly venomous species, the spitting cobra and the horned adder.

at a rate similar to that for whole snakes. Hatchlings attacked unrestrained grasshoppers covered with skin from either spitting cobras or horned adders in 49 of 54 trails. The five hatchlings that rejected skin-covered grasshoppers exhibited tongue-flicking, whereas all hatchlings that attacked grasshoppers did so without tongue-flicking. This indicates that chemical, rather than visual, cues associated with snake skins mediate avoidance of venomous snakes.

Past studies with scincid lizards have shown higher levels of tongue-flicking toward snakes that are their predators than those that are not (Cooper, 1990). Skinks are insectivorous, thus harmless snakes represent neither predator nor prey and are not expected to elicit a strong response. The lack of a difference in tongue-flicking rate to the three snake species in the present study probably reflects the fact that all of the snake species tested interact with savanna monitors. Although spitting cobras and horned adders are predators and sand snakes are prey, predator detection and foraging are both ecological contexts in which tongue-flicking occurs (Burghardt, 1970; Halpern and Kubie, 1983; Simon, 1983; Duvall et al., 1990).

Naive hatchling savanna monitors not only differentiated venomous from nonvenomous snakes in their propensity to attack them, they also reacted differently toward the two species of venomous snakes. Horned adders (Viperidae) and spitting cobras (Elapidae) possess divergent hunting strategies and chemically distinctive venoms (Visser, 1967). For these reasons, it is not unexpected that responses by their prey will differ. The tendency for some hatchlings to attack cobras and all to perform vent dragging behavior, which may be associated with aggression in savanna monitors, suggests that cobras may be less dangerous than adders, at least to these lizards. The long, stiff fangs of adders, capable of inflicting a deeper and more serious bite than those of cobras, may partially explain the differential treatment of the two predatory snake species.

The rejection of invertebrate prey bearing skins of venomous snakes and the indiscriminant acceptance of skinned snake meat suggest that savanna monitor hatchlings use skin-borne chemicals to identify snakes. That lizards having no previous experience with snakes exhibit these responses indicates that they are innate. Because snakes represent both predators and prey for savanna monitors, the ability to discriminate among them potentially functions in two different adaptive contexts. Foraging efficiency is increased when appropriate prey items are identified prior to attack, and survivorship is enhanced when potential predators are detected and avoided with minimal physical contact.

Previous experiments suggest that the movement of prey is important in the feeding behavior of reptiles (Drummond, 1985). Chemical cues also stimulate feeding behavior in snakes, and naive hatchlings recognize and attack their species-typical prey on the basis of chemical cues (Burghardt, 1966, 1968). Our results for monitor lizards indicate that visual cues associated with prey movement can override chemical cues. These visual responses may be learned, as

the tested lizards had been fed invertebrate prey since hatching. A hierarchy of cues involving multiple sensory modalities and both learned and unlearned behavior is probably used by lizards in the recognition of sympatric snake species and assessment of their relative suitability as prey.

Acknowledgments—We thank the Department of Nature Conservation of Namibia, and especially the Namibian scientists at Etosha National Park for their permission and help in carrying out this research. We are grateful to Janet Phillips for excellent technical help and to Joel Berger for useful advice on experimental design. Invaluable comments on earlier drafts of the manuscript were provided by Don Lindburg, Don Owings, and Paul Weldon. This work was supported by an NSF Conservation and Restoration Biology grant (BNS 90-00100) and the Institute of Museum Services (IC-00348-90).

(Received February 4, 1992; accepted June 2, 1992)

Abstract—Sasa (*Sasa cernua* Makino) is a very serious weed pest. Its allelopathy was studied using lettuce, wheat, timothy, and green amaranth as testing species. Cultured in the rhizosphere soil of *Sasa cernua*, the seedlings were inhibited by 42–80% compared with the controls cultured in normal soil and vermiculite. The phenolic fraction extracted with 1 M NaOH from the rhizosphere soil of *S. cernua* caused significant inhibitions on the seed germination and seedling growth of lettuce, timothy, green amaranth, and barnyard grass. *p*-Coumaric, ferulic, vanillic, and *p*-hydroxybenzoic acids and *p*-hydroxybenzaldehyde were identified as the main allelochemicals in sasa soil by HPLC and [^{1}H]NMR. Their contents in the rhizosphere soil were 5640, 1060, 860, 810 and 630 μg/100 g soil. The neutral fraction inhibited the seed germination and seedling growth of lettuce in the TLC direct bioassay. Volatile compounds released from sasa leaves also inhibited the growth of lettuce, wheat, timothy, and green amaranth grown under light, and the growth of etiolated seedlings of barley and wheat. These results confirm that *S. cernua* produces typical allelopathy through its rhizosphere soil and air space.

Key Words—Allelopathy, allelochemicals, growth inhibitors, rhizosphere soil, sasa, *Sasa cernua*, volatile compounds, phenolic compounds.

INTRODUCTION

Sasa plant is a very serious weed pest distributed widely in Japan and some other regions of Asia and Europe. In Japan, over 4300 kilohectares (kha) are

*To whom correspondence should be addressed.

0098-0331/92/1000-1785$06.50/0 © 1992 Plenum Publishing Corporation

covered with sasa. Many mountains, called "sasa mountains," are overgrown with sasa. In Hokkaido, sasa can be seen everywhere, and it covers over 3360 kha, constituting over 60% of the total forested area (Kawahara, 1979). The aggressiveness of sasa has led to serious problems in forestry and agriculture. When trees are cut, sasa grows rapidly and has made reforestation difficult.

Many studies have been made on the growth, distribution, and chemical components of sasa (Chuyen and Kato, 1982; Chuyen et al., 1982; Kawahara, 1979; Kazumori and Sakakibara, 1977; Ponomareva, 1971; Shibata et al., 1976; Suzuki et al., 1968). However, the allelopathic effects of the *Sasa* spp. have not been reported. Although in many places competing grasses grow poorly in the vicinity of a sasa community, they grow vigorously away from it, suggesting that sasa has allelopathic effects. Recently, there have been increasing reports on allelochemicals among plants (Chou and Waller, 1989; Putnam and Tang, 1986; Rice, 1984; Waller, 1987). Allelochemicals have numerous impacts on cultivated and natural ecosystems. In allelopathy between plants, allelochemicals must be transmitted from donor (emitting) plant to acceptor (affected) plant through either their rhizosphere soil or air space (volatile components).

Sasa cernua is one of the three main species of the *Sasa* genus in the Sapporo area. In this paper, the allelopathic effects of the rhizosphere soil and the volatile components of *S. cernua* were examined, the main allelochemicals in the rhizosphere soil were identified, and their possible roles discussed.

METHODS AND MATERIALS

Plant Culture Tests with Soil. Plant culture tests with soil were done using a plastic culture box set containing two 10 × 10 × 6 cm boxes. The lower box contained nutrient solution and the upper contained soil. A piece of gauze was used in each set to transport the nutrient solution in the lower box to the upper soil box by capillary force. This apparatus allowed easy replacement of the nutrient solution. Samples of rhizosphere soil (5- to 15-cm layer from soil surface) were collected in September 1990 under the pure stands of wild *S. cernua*. Two controls were used: control I was vermiculite and control II consisted of soils taken from the vicinity of the sasa community with no sasa growth or residue. Two-day-old etiolated seedlings of lettuce (*Lactuca scariola* L. var. *sativa* Bisch), wheat (*Triticum aestivum* cv. Norin No. 59), timothy (*Phleum pratense* L.), and green amaranth (*Amaranthus viridis* L.) were transplanted to the culture boxes and grown in a phytotron for 15 or 30 days, under a 14-hr light (white fluorescence, 3.8×10^3 ergs/cm^2/sec, 28°C) and 10-hr dark (20°C) cycle. Distilled water was used for irrigation during the first week and Hoagland's solution thereafter. Ten plants for each testing species were used. Each test was run in triplicate.

Volatile Components from Leaves of S. cernua. Ten germinated seedlings of each test species were planted in vermiculite in the culture boxes described above. They were placed into airtight glass containers (50 × 25 × 30 cm) with (treatment) or without (control) dried sasa leaves (dried in air at room temperature for two days, 500 g for each box). The containers were maintained in a greenhouse at 25°C with a photoperiod of 14 hr (2.0×10^3 ergs/cm^2/sec of white fluorescent light). The sasa leaves in the glass container were changed every three days. After one month, the fresh and dry weight of the plants were measured. For tests on etiolated seedlings, Petri dishes (33 mm diameter) with 15 seeds were put in the airtight glass box with (treatment) or without (control) sasa leaves for one day to allow air saturation with the volatile components, and then water was added to the dishes to let the seed germinate and grow in the dark at 25°C. The lengths of roots and aerial parts were measured after one week. Each test was repeated at least two times.

Extraction of Active Substances from Soil. The rhizosphere soil of *S. cernua* was dried in a desiccator at room temperature. The extraction procedure is shown in Figure 1.

Seed Germination Tests. Seed germination tests were done on Tokyo No. 1 filter paper in 33-mm-diameter Petri dishes with 1 ml test solution or control containing 100 ppm Tween 80. Thirty seeds were added to each dish and germinated in the dark at 25°C. Germinated seeds were counted after a certain number of hours according to plant species (see Table 1). Each test was repeated at least three times.

Seedling Growth Tests. For all the seedling growth tests, seeds were sterilized with 1% sodium hypochlorite for 5 min and washed with distilled water. Germination was carried out on filter paper moistened with distilled water in a plastic tray in dark at 25°C for 36 hr (lettuce), 48 hr (timothy, green amaranth), or 72 hr (barnyard grass, *Echinochloa crus-galli* Beauv var. *crus-galli*). Uniform seedlings with ca. 3-mm hypocotyls or coleoptiles and 5-mm roots were selected. All the growth tests were done in 33-mm-diameter Petri dishes with 1 ml test solution. For each test, five seedlings were used. The seedlings were cultured for 48 hr in the dark at 25°C. The lengths of roots and hypocotyls or coleoptiles were measured. Each test was repeated three times.

Direct Bioassay on TLC Plate. One 10-mg sample was applied on a TLC plate (6.6 × 20 cm with 0.25 mm thickness silica gel) and developed to 15 cm from the original with toluene–ethyl acetate–methanol, 5:3:2, v/v. The thickness of the TLC plate could be changed from 0.25 to 2.0 mm according to the amount of the sample size. After evaporation of the solvents in a desiccator overnight, a 3-mm-thick 0.8% agar layer was put on the TLC plate. The plates were kept in a culture box saturated with water for one night to allow the compounds to diffuse into the agar. Seeds were then sowed on the agar plate in lines and the plates placed in an airtight container and cultured in the greenhouse

at 25°C. Seed germination and seedling growth were recorded after two and five days, respectively.

Isolation and Identification of Allelochemicals in Rhizosphere Soil. The phenolic fraction was separated by HPLC (YMC-packed ODS column 10 × 300 mm) with UV detection at 254 nm. The sample was eluted with A (H_2O–

acetonitrile–acetic acid, 80:20:0.1, v/v/v) from 0 to 30 min, linear gradient to B (H_2O–acetonitrile, 9:1) from 30 to 60 min, and B from 60 to 70 min, at 2 ml/min. Purified compounds were identified by comparing their retention times and the [^{1}H]NMR spectra with those of the standard compounds.

RESULTS

Effects of Rhizosphere Soil of S. cernua *on Plant Growth.* Four testing plants (wheat, timothy, lettuce, and green amaranth) were cultured in a phytotron in the rhizosphere soil of *S. cernua* (treatment) with two controls (control I: in vermiculite; control II: in normal soil). Differences in growth could be seen after one week. The growth of wheat and timothy were inhibited by 80% and 45% after 15 days of culture, and the growth of lettuce and green amaranth were inhibited by 80% and 74% against control I after 30 days, respectively (Figure 2 and 3). All the treatments were significantly different from the two controls. In Figure 3, however, it can be seen that control II also showed a weak inhibition on lettuce, wheat, and timothy, but not on green amaranth, when compared to control I.

Effects of Extracts from Rhizosphere Soil of S. cernua *on Seed Germination and Seedling Growth.* The neutral and phenolic fractions were obtained from the rhizosphere soil of *S. cernua* (Figure 1). The phenolic fraction showed a strong inhibition on both seed germination and seedling growth of lettuce, green amaranth, timothy, and barnyard grass at 500 (pH 3.6) or 1000 (pH 3.3) ppm, although the magnitudes of the inhibitions differed according to plant species (Table 1). It had significant inhibition on both root elongation and the elongation of hypocotyl or coleoptile at 500 ppm. In the cases of timothy and barnyard grass, the inhibitions were stronger on root than on coleoptile. Seed germination was completely inhibited in lettuce and timothy, and inhibited by 90% in green amaranth at 500 ppm. Barnyard grass was less sensitive, its germination was inhibited by 30% and 45%, respectively, at 500 and 1000 ppm.

At 500 and 1000 ppm, the neutral fraction extracted with $CHCl_3$–CH_3OH–H_2O (10:5:4) did not show significant inhibition on either seed germination or seedling growth (data not shown). However, in the TLC direct bioassay, this fraction showed selective inhibition on different plant species, strongly inhibited germination and seedling growth of lettuce, but had little effect on timothy, green amaranth, and barnyard grass (Figure 4).

Identification of Main Allelochemicals in Rhizosphere Soil. The phenolic fraction was separated by HPLC. Five main inhibitory compounds, *p*-coumaric, ferulic, vanillic, and *p*-hydroxybenzoic acids and *p*-hydroxybenzaldehyde were identified. These phenolics are well-known allelochemicals (Chou and Lee, 1991; Chou and Waller, 1989; Putnam and Tang, 1986; Rice, 1984; Waller, 1987).

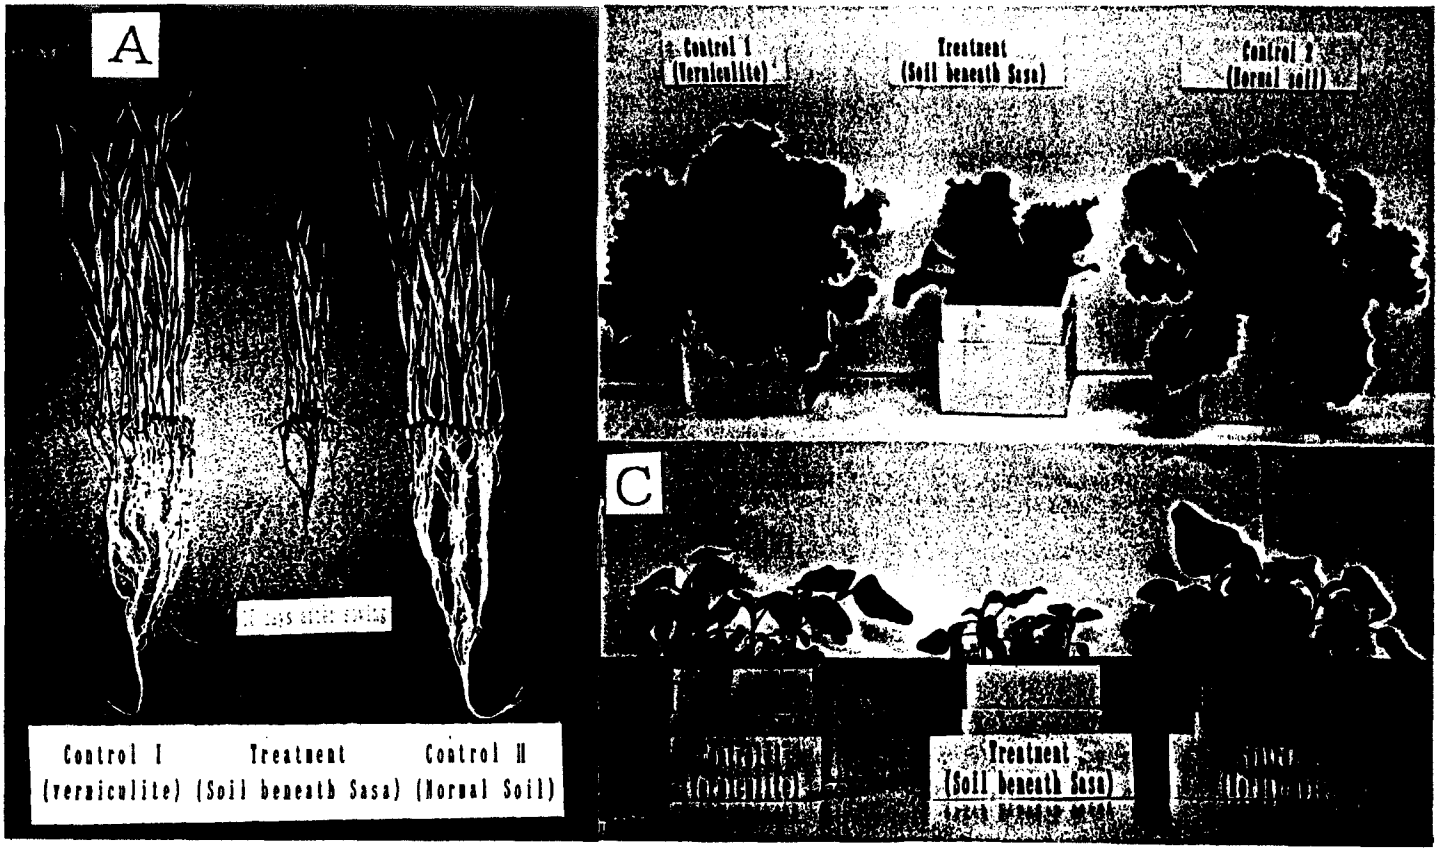

FIG. 2. Effects of rhizosphere soil of *Sasa cernua* on the growth of plants in soil assays. (A) wheat seedlings cultured for 15 days, (B) lettuce seedlings cultured for 30 days, (C) green amaranth seedlings cultured for 30 days.

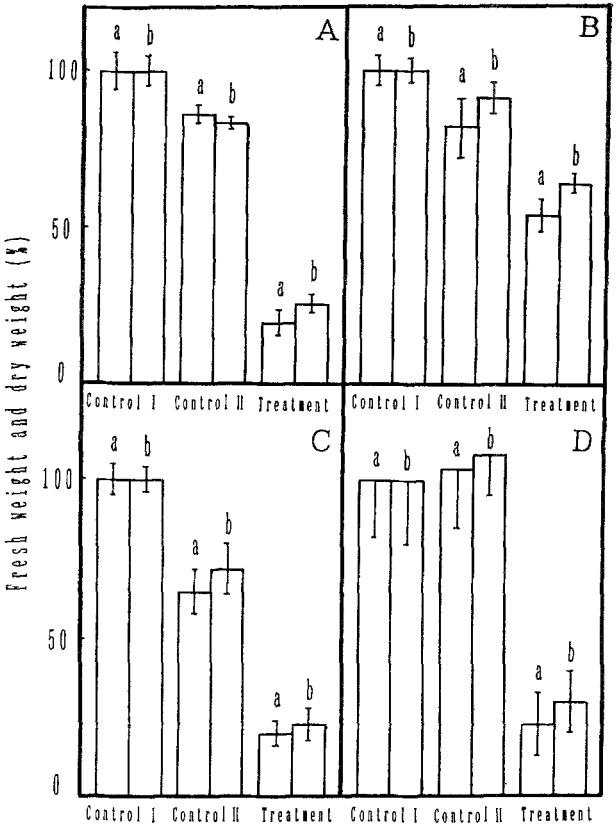

FIG. 3. Effects of rhizosphere soil of *Sasa cernua* on the fresh and dry weights of wheat (A, 15 days culture), timothy (B, 15 days culture), lettuce (C, 30 days culture), and green amaranth (D, 30 days culture). a: fresh weight, b: dry weight. Data were the means of 20 plants (two independent replicates each with 10 plants) ± SE (vertical bars).

They were reported to inhibit seed germination, root elongation, leaf expansion, photosynthesis, nutrient absorption, and the accumulation of dry matter in shoots and roots in plants (Blum and Rebbeck, 1989; Lyu et al., 1990; Rice, 1984). Contents of these five phenolic compounds in the rhizosphere soil were 5640 ± 500, 1060 ± 120, 860 ± 80, 810 ± 30 and 630 ± 90 μg/100 g soil, although the actual amounts in the soil might be higher than those detected. It was reported that phenolic allelochemicals in soil could be easily oxidized when the soil was removed from the natural status (Cast et al., 1990; Cheng, 1989).

The active substances from the neutral fraction were separated using column and thin-layer chromatography. The active substances, based on the seed

germination test of lettuce, were unstable and remain unidentified. The [^{1}H]NMR spectrum of the unpurified active fraction showed that it might consist of a series of unsaturated long-chain esters of fatty acids.

Effects of Volatile Components from Leaves of S. cernua *on Plant Growth.* Wheat, timothy, lettuce, and green amaranth cultured in greenhouse were inhibited by 30, 44, 35, and 31%, respectively, in 20 days (Figure 5). Elongation of coleoptiles and roots were inhibited by 35% and 50% in etiolated seedlings of barley and by 46% and 35% in those of wheat after one week following germination. However, these inhibitions were weak on lettuce, green amaranth, and timothy (Table 2).

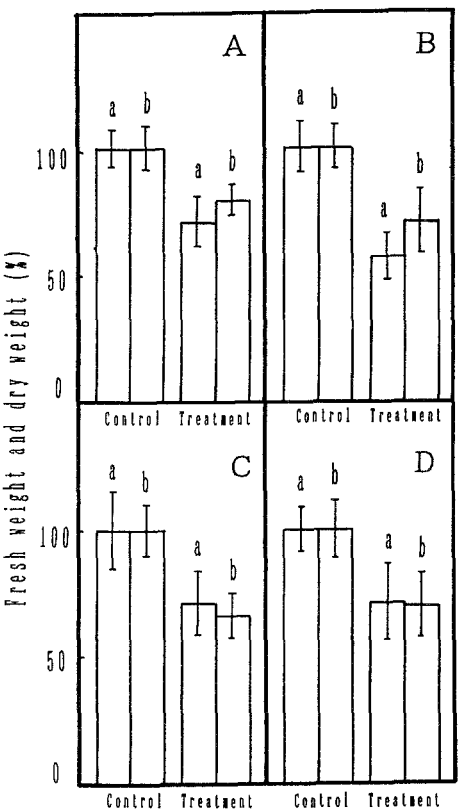

FIG. 5. Effect of volatile components released from the leaves of *S. cernua* on the fresh (a) and dry weights (b) of wheat (A), timothy (B), lettuce (C), and green amaranth (D) seedlings. Data are the means of 20 plants (two independent replicates each with 10 plants) ± SE (vertical bars).

[a] Lengths of aerial parts and roots were measured seven days after the start of treatment. Each value is the mean of 30 seedlings of three separate tests ± SE.

DISCUSSION

In the cultural tests with soil, it seems that suitable methods were important for the expression of allelopathic effect (Putnam and Tang, 1986). In the preliminary experiments, several traditional cultural methods were tested but did not yield uniform repeatable results. One problem seemed to arise from surface irrigation with water or nutrient solution. Usually, the small plants at the beginning of the experiments grew in the uppermost layer of the soil, and irrigation might dilute or wash away the allelochemicals (especially the water-soluble compounds). Nutrient conditions also affected the test results. It was reported that phenolic allelopathy may be more severe under low fertility, and raising the nutrient level can suppress some of the allelochemical effect (Einhellig, 1987). Lehmann et al. (1987) and Wang and Huang (1989) reported that inorganic ions in soil, such as Mn, Fe, Al, and Si, promoted the oxidation of phenolic allelochemicals. Inorganic irons might also affect the activities of acidic allelochemicals by salinization. Nutrient deficiencies or stresses might induce the ability for the root system to absorb substances including allelochemicals and inorganic irons from soil. In addition, nutrient deficiencies might have additive or even synergistic effects on allelopathy. In this paper, we used distilled water in the first week of the soil tests. To maintain sufficient nutrient levels for the test plants, especially for control I with vermiculite, nutrient solution

was added from the second week. The use of nutrient solution from the beginning of the tests resulted in lower inhibition (data not shown). The effects of nutrients on allelopathy should be studied further. The results on the soil tests for *S. cernua* (Figures 2 and 3) showed that this method was useful for detecting allelopathy in soil.

In the tests of the phenolic extracts from the rhizosphere soil of *S. cernua*, the low pH of the test solution might have some effect on seed germination and seedling growth. We tested the pH effect of the extracts from sasa soil and two kinds of phenolic acids (*p*-coumaric acid and *p*-hydroxybenzoic acid), which were identified in many plant soils and cultural solutions as allelochemicals (Chou and Lee, 1991; Chou and Waller, 1989; Putnam and Tang, 1986; Tang, 1986; Tang et al., 1989; Waller, 1987), on the growth of lettuce seedlings with pH 5.0 MES buffer and water solutions. The inhibitions of both the phenolic fraction from sasa soil and the phenolic acids on the growth of lettuce seedlings were lowered in the case of buffer solution compared to water solution. To obtain the same inhibition, two to five times higher concentrations were needed in the tests with the buffer solution than in those with water (data not shown). *S. cernua* might produce its allelopathy by releasing allelochemicals and lowering the pH of the soil.

In the tests for volatile components from the leaves of *S. cernua*, dried leaves were used in the airtight cultural boxes. At first, we used fresh leaves in the culture container with the petioles in cultural solution. It showed similar results (data not shown) as in the case of dried leaves. In the test with fresh leaves, however, the inhibition might be affected by the change of air components, which is difficult to control in an airtight container.

Chuyen and Kato (1982) identified 39 volatile flavor compounds in the headspace of *Sasa albo-marginata*; 1-penten-3-ol, *trans*-2-hexenal, acetaldehyde, *cis*-3-hexen-1-ol, hexanal α-terpineol etc. were the main components. Some of them had been demonstrated in residues of many plant species and shown to be toxic for plant growth as allelochemicals (Bradow and Connick 1990). Many other compounds were also toxic to plants, although their amounts were very low. Whether *S. cernua* produces the same volatile compounds is under investigation.

The dominant growth of sasa might result from many factors. The results above showed that sasa was allelopathic through its rhizosphere soil and air space. The significant allelopathic effects might be an important factor that contributes to the dominance of the landscape in Japan and some other countries.

RESPONSIVENESS OF *Pseudaletia unipuncta* (LEPIDOPTERA: NOCTUIDAE) MALES, MAINTAINED AS ADULTS UNDER DIFFERENT TEMPERATURE AND PHOTOPERIODIC CONDITIONS, TO FEMALE SEX PHEROMONE

STÉPHANE DUMONT[1] and JEREMY N. McNEIL*

(Received December 13, 1991; accepted June 8, 1992)

Abstract—Different-aged *Pseudaletia unipuncta* (Haworth) males, maintained as adults at 10 and 25°C under 16:8 and 12:12 light–dark photoperiodic regimes, were flown to a 30-μg pheromone source in a wind tunnel at 20°C. While the responsiveness of individuals reared under both photoperiodic conditions at 25°C was similar by day 5 (65–75%), response levels of younger males showed that those reared at 16:8 light–dark matured more rapidly than those under 12:12 light–dark. A significant delay in the onset of responsiveness was observed for males reared under 10°C with less than 25% of individuals responding to the pheromone, even at 25 days old. At this temperature, photoperiodic conditions had no significant effect on male receptivity. When males are transferred from 10°C to 25°C 16:8 light–dark, their level of responsiveness after five days was similar to control 5-day-old males reared at 25°C, 16:8 light–dark. These results are discussed relative to the hypothesis that this species migrates in response to seasonal cues that indicate a predictable habitat deterioration.

Key Words—*Pseudaletia unipuncta*, true armyworm, Lepidoptera, Noctuidae, male responsiveness, temperature, photoperiod, female sex pheromone, seasonal migration.

INTRODUCTION

Many environmental factors may influence daily and seasonal pheromone-mediated communication in moths: photoperiod (Fatzinger, 1973; Baker and Cardé, 1979), temperature (Cardé and Roelofs, 1973; Cardé et al., 1975; Comeau et al., 1976; Castrovillo and Cardé, 1979; Haynes and Birch, 1984), light intensity (Traynier, 1970; Kanno, 1981; Dreisig, 1986), relative humidity (Webster and Cardé, 1982), and wind velocity (Conner et al., 1985) are known to affect the time at which females produce and release the sex pheromone and/or the level of male responsiveness to it.

Saario et al. (1970) noted seasonal differences in the patterns of cabbage looper male captures in pheromone traps, with individuals being captured earlier in the day during cooler seasons than warmer ones. A rather different situation has been observed in the seasonal activity of the true armyworm *Pseudaletia unipuncta* (Haworth) (Lepidoptera: Noctuidae) where there are two distinct annual flights at Normandin, Quebec (McNeil, 1987). During the first, from May to July, the pattern of pheromone trap captures was similar to those of light traps, while in the fall flight, from August to October, very few males were attracted to pheromone traps even though they were caught in light traps.

Previous studies have shown that the age at which virgin *P. unipuncta* females initiated calling could be significantly influenced by abiotic conditions (Turgeon and McNeil, 1983; Delisle and McNeil, 1986, 1987). In this paper we examine how temperature and photoperiodic conditions during adult life influenced the responsiveness of virgin *P. unipuncta* males to a synthetic sex pheromone lure in a wind tunnel.

METHODS AND MATERIALS

Larvae of *P. unipuncta*, obtained from a laboratory colony established for less than 10 generations, were reared individually on a pinto bean diet modified after Shorey and Hale (1965). Pupae were sexed using the criteria described by Breeland (1958), and only males were kept. Both larvae and pupae were kept at 25 ± 1°C, 65 ± 5% relative humidity under a 16:8 light–dark photoperiod (750–1000 lux during photophase). Males were segregated by day of emergence in cages (20 × 20 × 30 cm) containing 8% sucrose solution and held under the appropriate temperature and photoperiodic conditions until tested.

To minimize the effect of handling close to the time of testing, males were placed in small individual wire mesh "release cages" 18–24 hr before flight tests. They were transferred to the standard test conditions of 20 ± 1°C and 65–90% relative humidity in the controlled environment chamber housing the Plexiglas wind tunnel (1 × 1 × 4 m) 1 hr before each trial. The logic behind testing males from different holding conditions at a standard condition in the

wind tunnel was to overcome potential problems associated with differences in thermoregulation and flight performance (Turgeon et al., 1983a), the release rates of the pheromone from the lure (Ioriatti et al., 1987), and dispersal of pheromone (Gaston et al., 1971) when experiments are carried out at different temperatures. The thoracic temperature of individuals transferred from 10°C conditions rapidly attained 20°C, the ambient temperature in the wind tunnel, and males were capable of flight within 2 min following the transfer. Thus, we believe that any differences observed in pheromone receptivity of males are due to major physiological changes and not to temperature shifts 1 hr prior to testing. A rubber septum loaded with 30 μg of (Z)-11-hexadecenyl acetate (Z11-16:Ac) and 0.15 μg of (Z)-11-hexadecenol (Z11-16:OH), the principal components of the female sex pheromone (Hill and Roelofs, 1980; McDonough et al., 1980), was placed on an insect pin 2.5 cm above a cork at the upwind end of the tunnel on a 30-cm-high galvanized steel stand. This concentration was chosen as it elicits a good male upwind flight under humidity conditions similar to those used in this experiment (Fitzpatrick et al., 1988). A release cage with an inactive male was placed on a 36-cm-high galvanized steel stand 230 cm downwind from the pheromone source. Once placed in the pheromone plume, the number of males exhibiting "locking on" behavior (initiation of directional flight towards the pheromone source) was scored, and for those initiating this behavior the distance flown towards the lure, the number touching the lure, and the flight speed calculated. Males not taking flight after 3 min, or those flying directly to either the walls or ceiling of the wind tunnel, were considered as nonresponsive to the pheromone. Males showing no activity during the 3-min period were nudged with a pencil to verify that each individual was capable of sustained flight. Less than 5% of males from any holding conditions were nonfliers, and these individuals were not included in the analyses. During each trial total light intensity was less than 0.17 lux, provided by diffused white light from above the tunnel and supplemented by a red point light source behind a white curtain on one side of the tunnel at the level of the release cage. Wind speed was 0.39 $\pm$ 0.02 m/sec. Males were only used once. Release cages were rinsed in acetone and dried after each test.

As the time at which females initiated calling behavior after lights out was affected by the length of the scotophase (Delisle and McNeil, 1986), an experiment was carried out to compare the receptivity of males held since emergence under 16:8 or 12:12 light–dark photoperiodic regimes at 25°C. Four- and 8-day-old males were tested in the second, fifth, and eighth hour of the 8-hr scotophase (16:8 light–dark) and in the second, fifth, eighth, and eleventh hour of the 12-hr scotophase (12:12 light–dark). Twenty males were tested at each period for each photoperiodic regime. No significant differences due to age or photoperiodic conditions were detected in the pattern of male response in the eighth hour of the scotophase, where responses ranged from 60 to 80% (χ^2 =

2.507, $df = 3$, $P = 0.4740$), so all subsequent experiments were carried out at that maximum response time.

A minimum of 20 males from each of the two photoperiodic regimes were tested at different ages: 2, 3, 4, and 5 days old at 25°C and 5, 10, 15, 20, and 25 days old at 10°C. To ensure that any differences in the response levels observed in males held at 10°C were not due to a shift in the time of maximum response (earlier in the scotophase), as noted for female calling behavior (Delisle and McNeil, 1987), 15-day-old males ($N = 9$) were also tested in the second and fifth hour of the scotophase but no response were observed at those times.

Turgeon et al. (1983a) demonstrated that the level of male response increased with an increase in pheromone concentration. Therefore, to ensure that the lack of responsiveness by males held at 10°C was not just a question of concentration, 5- and 10-day-old males, held from emergence at the two extreme conditions (10°C 12:12 light–dark or 25°C 16:8 light–dark), were tested using a 100-μg lure and compared with responses to a 30-μg concentration.

Males held at 10°C, 16:8 light–dark for 10 or 20 days were transferred to 25°C, 16:8 light–dark, held five days, and then tested to determine if males, like females (Delisle and McNeil, 1987), mature rapidly once placed under favorable conditions.

On every day that experiments were carried out, a number of 5- to 7-day-old males from the standard 25°C, 16:8 light–dark rearing conditions were also flown as a form of control to ensure that conditions on any given day were favorable for flight.

"Locking on" and touching behaviors were analyzed by contingency table (χ^2) techniques. Distance had a bimodal distribution, so a one-way nonparametric ANOVA for each effect was done (Kruskall-Wallis analysis). Speed, after transformation to its natural log, was normally distributed and had homogeneity of variance, but, since it was unbalanced, we used the GLM procedure with a type III SS (SAS Institute, 1987).

RESULTS

Short day conditions at 25°C induced a delay in the responsiveness of *P. unipuncta* male to the female sex pheromone on day 2 ($\chi^2 = 5.71$, $df = 1$, $P = 0.02$) and day 3 ($\chi^2 = 3.75$, $df = 1$, $P = 0.05$) compared with males held under long day conditions (Table 1). For example, 25% of males held under 16:8 light–dark responded on day 2 while none of the similar aged individuals at 12:12 light–dark did. Furthermore, response levels of day 3 males from 12:12 light–dark were similar to those observed for day 2 individuals held under long day conditions. However, by day 5 the responsiveness of males from both

photoperiodic conditions were comparable ($\chi^2 = 0.13$, $df = 1$, $P = 0.72$). Neither daylength ($\chi^2 = 0.04$, $df = 1$, $P = 0.84$; $F = 0.20$, $df = 1$, $P = 0.66$) nor age ($\chi^2 = 3.16$, $df = 3$, $P = 0.37$; $F = 0.67$, $df = 3$, $P = 0.58$) had any significant effect on either the distance flown or flight speed of males responding to the pheromone source (Table 1).

For males held at 10°C there was a slight age-related increase in the proportion of individuals locking on over the 25-day period (Figure 1), yet even 25-day-old males were significantly less responsive ($\chi^2 = 17.90$, $df = 1$, $P < 0.0001$) than 5- to 7-day-old males reared continuously at 25°C, 16:8 light–dark (Table 2). However, no significant photoperiodic effects ($P > 0.26$) were detected in males of any age reared at 10°C (Figure 1). As at 25°C, neither age ($\chi^2 = 3.11$, $df = 3$, $P = 0.37$; $F = 0.40$, $df = 3$, $P = 0.76$) nor photoperiodic conditions ($\chi^2 = 1.84$, $df = 1$, $P = 0.18$; $F = 0.56$, $df = 1$, $P = 0.46$) affected flight distance or speed (Table 2). An overall comparison of individuals held at 10 and 25°C, to a 100-μg cap, again demonstrated that males held at the lower temperature are significantly less responsive ($\chi^2 = 25.39$, $df = 1$, $P < 0.0001$) than those at the higher one (Table 3). As so few males held at 10°C responded, no meaningful comparisons could be made for distance flown or flight speed for individuals at the two temperatures. Furthermore, the responsiveness of males (both ages pooled) at 10°C did not increase with an increase in pheromone concentration ($\chi^2 = 2.57$, $df = 1$, $P = 0.11$) (Table 3). A similar trend was noted in the field: while an increase in pheromone concentration from 300 to 1000 μg increased trap efficiency during the summer flight (Turgeon et al., 1983b), this was not the case during the fall flight (McNeil, unpublished).

When males held at 10°C for 10 or 20 days were transferred to 25°C and

tested five days later, their level of response was not significantly different ($\chi^2 = 0.25$, $df = 2$, $P = 0.88$) from 5- to 7-day-old control males (Figure 2).

DISCUSSION

There is very clear evidence that many moth species extend their geographic range each summer and establish temporary populations in regions where climatic conditions do not permit permanent occupation. However, the fate of these populations once weather conditions deteriorate in the fall is far from clear. Rabb and Stinner (1978) suggested that they die off, while Walker (1980) proposed the possibility of a return migration, a well-documented phenomenon in a number of butterfly species.

The true armyworm occurs each year throughout much of eastern Canada (Beirne, 1971), but does not have the ability to overwinter there (Fields and McNeil, 1984; Ayre, 1985), thus providing a working system to test the return migration hypothesis. All armyworm females reared under summer conditions (25°C, 16:8 light–dark) initiate calling behavior within nine days following emergence, while only 50% of those under fall conditions (10°C, 12:12 light–dark) do so within 35 days of emergence (Delisle and McNeil, 1987). Furthermore, those that called did so at a significantly older age ($X = 21.0 \pm 1.1$ days) than those under summer conditions ($X = 5.8 \pm 0.4$ days). More than 90% of all females captured in light traps during the summer flight were mated and have mature eggs in their ovaries, in sharp contrast to the fall flight where <2% of females were mated, and the vast majority of individuals captured had immature ovaries and large fat bodies (McNeil, 1987).

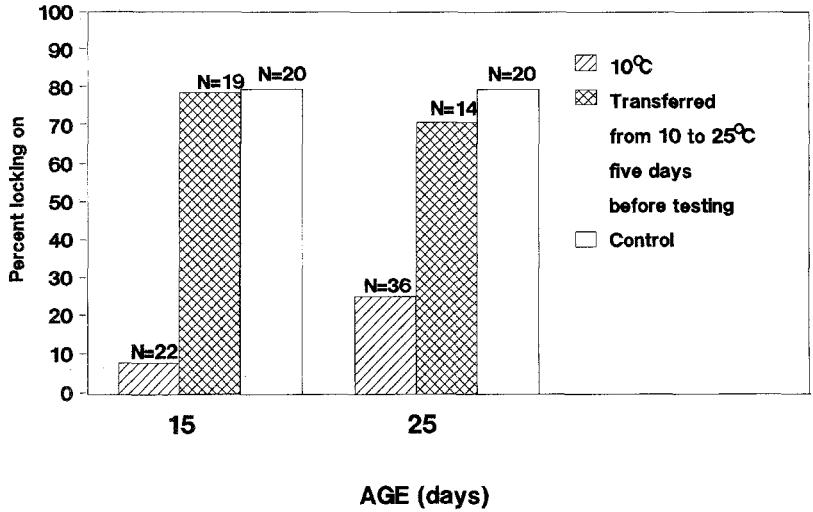

FIG. 2. Percent of *P. unipuncta males* "locking on" to the pheromone plume five days after being transferred to 25°C/16L:8D after being held for 10 or 20 days at 10°C/16L:8D. Controls were 5- to 7-day-old males reared continuously at 25°C/16L:8D. The numbers of males tested are indicated directly above the histograms.

Based on these results, McNeil (1987) hypothesized that the delay in reproduction induced by short-day, low-temperature conditions could be associated with a southward fall migration, as suggested by Johnson's "oogenesis–flight syndrome" (Johnson, 1969). Subsequently, Cusson and McNeil (1989a,b) demonstrated that the initiation of pheromone synthesis and calling behavior in the true armyworm are associated with the onset of ovarian development and that all three processes require the presence of juvenile hormone (JH). Rankin and Riddiford (1978) proposed a migration model for the milkweed bug: migration occurred when hemolymph levels of JH surpassed the "threshold for migratory flight" while remaining below the "threshold for ovarian development." Cusson et al. (1990) suggested a similar model may hold for the true armyworm as JH biosynthesis in females held for 35 days at 10°C, 12:12 light–dark was significantly lower than levels in 3-day-old individuals at 25°C, 16:8 light–dark. Furthermore, a marked increase in JH biosynthesis occurred within 24 hr of females being transferred to 25°C, 16:8 light–dark (Cusson et al., 1990).

In the summer flight, the pattern of male captures in pheromone-baited (300 μg) traps was similar to the pattern observed in light traps. However, in the fall flight, males are captured in the light traps but rarely attracted to pheromone lures (McNeil, 1987). These observations led to the suggestion that, like females, male maturation was delayed by short-day, low-temperature conditions

(McNeil, 1987). The results of the experiments reported here provide solid evidence that low temperatures do significantly delay the age at which males become responsive to pheromones and that, under certain conditions, day length may play a significant role.

True armyworm males produce JH acids (JHA) (Cusson et al., 1991), and the patterns of JHA biosynthesis parallel those of JH biosynthesis in females (Cusson et al., submitted). At 25°C, 16:8 light–dark there is a significant increase in JHA biosynthesis on the third day following emergence, coinciding with the age at which some males complete upwind flight to the lure (Table 1) and will mate with calling females (unpublish observations). However, JHA biosynthesis by males reared at 10°C, 12:12 light–dark remains low on day 5, but increases on day 10, the age at which males first show any level of response to pheromone lures (Table 2). As previously reported for females (Cusson et al., 1990), a switch from fall to summer conditions results in a significant and rapid increase in JHA biosynthesis (Cusson et al., submitted). In the present experiment, the response levels of such males are similar to controls (Figure 2).

Maturation of male accessory glands in the migratory grasshopper, *Melanoplus sanguinipes*, and the reduviid bug, *Panstrongylus megistus*, occurs following emergence and in both species is under the control of JH (Gillot and Friedel, 1976; Couche et al., 1985; Regis et al., 1985). In the armyworm, we dissected males and noted that accessory glands increase noticeably in volume over the five days following emergence at 25°C, 16:8 light–dark, while at 10°C, 12:12 light–dark there is little or no evidence of accessory gland development in the first 10 days of adult life. We therefore interpret the reduced responsiveness of males reared at 10°C in this study as a delay in sexual maturation. Thus, both sexes of the armyworm exhibit a hormonally mediated delay in the onset of mating in response to environmental cues that are reliable predictors of subsequent habitat deterioration, and this extended prereproductive period would provide a window during which long-distance migration could be undertaken.

ANTIMICROBIAL TERPENES FROM OLEORESIN OF PONDEROSA PINE TREE *Pinus ponderosa:* A DEFENSE MECHANISM AGAINST MICROBIAL INVASION

MASAKI HIMEJIMA, KENNETH R. HOBSON, TOSHIKAZU OTSUKA, DAVID L. WOOD, and ISAO KUBO*

(Received March 2, 1992; accepted June 8, 1992)

Abstract—The oleoresin of the ponderosa pine, *Pinus ponderosa* (Pinaceae) exhibited broad antimicrobial activity. In order to identify the active compounds, the oleoresin was steam distilled to give a distillate and residue. The distillate contained mainly monoterpenes and some sesquiterpenes, while the residue consisted chiefly of four structurally related diterpene acids. An antimicrobial assay with the pure compounds indicated that the monoterpenes were active primarily against fungi, but there was also some activity against gram-positive bacteria. The diterpene acids, in contrast, only exhibited activity against gram-positive bacteria. Although not all of the identified sesquiterpenes could be tested, longifolene showed activity only against gram-positive bacteria. Therefore, it appears that the oleoresin of *P. ponderosa* functions as a biochemical defense against microbial invasion.

Key Words—Antimicrobial activity, gram-positive bacteria, fungi, Pinus ponderosa, oleoresin, monoterpene, sesquiterpene, diterpene acid, defense mechanism.

INTRODUCTION

When pine trees are physically damaged or attacked by insects, they exude resins that apparently protect them from further damage. This damage is usually caused by microorganisms that may be transmitted by insects as well as by other

*To whom correspondence should be addressed.

means (Harris, 1948). Paradoxically, bark beetles are known to be attracted by pine oleoresins (Wood, 1982; Miller et al., 1986; Phillips et al., 1988). Thus, the response of bark beetles to attractants in oleoresins is a critical, initial step in the colonization of host tissues. However, as long as trees are healthy, the insects are probably expelled by resin flow before they can colonize the phloem tissue (Vité, 1961; Berryman, 1972; Wood, 1972). Often, the trees are damaged more by insect-transmitted microorganisms than by insect action itself (Raffa and Berryman, 1982; Cook and Hain, 1985; Pain and Stephen, 1987; Owen et al., 1987; Raffa and Smalley, 1988; Parmeter et al., 1989). Moreover, microorganisms may be transmitted by other means as well, since trees are continually exposed to microorganisms in the environment (Andrews et al., 1980). Therefore, we might expect that oleoresins have broad antimicrobial activity that protects the trees from these nonspecific microorganisms (Smirnoff, 1972; Morris, 1972).

This paper describes identification of the principal components in the distillate and residue of the ponderosa pine oleoresin, and their antimicrobial activities.

METHODS AND MATERIALS

General. All NMR spectra were run in $CDCl_3$ on a Nicolet spectrometer equipped with an Oxford superconducting magnet at 300 MHz for ^1H and 75 MHz for ^{13}C. Mass spectra were obtained with a Hitachi RMU 6-MG spectrometer in electron impact mode (EI-MS). UV spectra were recorded in ethanol on a Hitachi 100-80 spectrometer. IR spectra were recorded on a Perkin-Elmer 1310 spectrometer. Merck 35–70 mesh silica gel was used for column chromatography. The solvents used were of reagent or HPLC grade.

Chemicals. The xylem oleoresin was collected in vials screwed into holes bored into the stems of the ponderosa pine *P. ponderosa*, near Blodgett Research Forest (El Dorado County, California) in 1987. The oleoresin (850 g) was steam distilled for 2 hr to yield a distillate (126 g) and residue (690 g). The fractions were submitted to GC-MS analysis and R-HPLC separation, respectively. α-Pinene, β-pinene, 3-carene, and limonene were purchased from Aldrich Chemical Co. (Milwaukee, Wisconsin). Terpinolene was purchased from Glidco Organics (Jacksonville, Florida), and abietic acid was purchased from Sigma Chemical Co. (St. Louis, Missouri). Longifolene was a gift from Takasago International Corporation (Tokyo, Japan). These compounds were all used for the assay without purification. *N,N*-Dimethylformamide (DMF) was purchased from EM Science (Gibbstown, New Jersey).

Microorganisms and Media. All microorganisms used for the antimicrobial assay were purchased from American Type Culture Collection (Rockville,

Maryland). They are *Bacillus subtilis* ATCC 9372, *Brevibacterium ammoniagenes* ATCC 6872, *Staphylococcus aureus* ATCC 12598 (a methicillin-susceptible strain), *Escherichia coli* ATCC 9637, *Pseudomonas aeruginosa* ATCC 10145, *Saccharomyces cerevisiae* ATCC 7754, *Candida utilis* ATCC 9226, *Penicillium chrysogenum* ATCC 10106, *Rhizopus stolonifer* ATCC 6227b, *Aspergillus niger* ATCC 16404, and *Mucor mucedo* ATCC 20094.

The culture media for bacteria consisted of 0.8% nutrient broth (BBL), 0.5% yeast extract (Difco) and 0.1% glucose. The culture media for fungi consisted of 2.5% malt extract broth (BBL).

Cultivation of Microorganisms. The freeze-dried microorganisms were reactivated as follows. *B. subtilis*, *S. cerevisiae*, *C. utilis*, *P. chrysogenum*, *R. stolonifer*, *A. niger*, and *M. mucedo* were cultured with shaking at 30°C. *B. ammoniagenes* was cultured stationarily at 30°C, and *S. aureus*, *E. coli*, and *P. aeruginosa* were cultured stationarily at 37°C.

Antimicrobial Assay. Preliminary routine antimicrobial assay was performed by a paper disk method. The test compound was dissolved in chloroform at a concentration of 8 mg/ml, and an aliquot of 0.1 ml of the sample solution was applied to a disk with a diameter of 8 mm (Toyo disk). This disk was placed onto the agar medium, which had been previously inoculated with a test microorganism. After incubation for two days at 37°C for bacteria and 30°C for fungi, the diameter of the inhibitory zone was measured with a caliper.

Since the *P. ponderosa* oleoresin was only slightly soluble in water, the paper disk method was an inadequate method because the water-insoluble oleoresin cannot disperse into the media. Therefore, throughout this report, the assay was performed by a broth dilution method (Taniguchi and Satomura, 1972) unless otherwise specified. For the broth dilution method, the test compound was dissolved in DMF and diluted in a twofold series with DMF, and 1% of sample solution was added to the broth medium. Microorganisms were cultured in a series of tubes with the different concentrations of the test compound in the broth medium. For the assay, the four common molds, *P. chrysogenum*, *R. stolonifer*, *A. niger*, and *M. mucedo*, were cultured with shaking, and other microorganisms were cultured stationarily. After two days (five days for molds), the growth was examined as a function of turbidity (OD at 660 nm) or visually in the case of molds. The lowest concentration of the test compound in which no growth occurred was defined as the minimal inhibitory concentration (MIC). It should be noted that the concentration of DMF in each test medium was always 1%. This did not affect the growth of any of the microorganisms tested.

GC and GC-MS Analysis. Analytical gas chromatography (GC) of the distillate was performed on a Hewlett-Packard 5890 gas chromatograph equipped with a flame ionization detector (FID) and fitted with a glass capillary column (0.25 mm ID × 30 m) coated with Carbowax bonded (20 m). The carrier gas was helium at 1.5 ml/min, and the oven temperature was programmed from 50 to 230°C at 4°C/min.

GC-MS analysis was carried out on a Hitachi M-808 double-focusing instrument equipped with a Hewlett-Packard 5890 gas chromatograph. The GC conditions were identical to the above analytical GC runs. Mass spectral data were acquired and processed by a built-in computer system (M-0101) (Takasago International Corporation, Tokyo, Japan). The distillate was composed of a mixture of almost exclusively mono- and sesquiterpene hydrocarbons. Components were identified on the basis of a comparison of the GC retention time and MS fragmentation with those of the authentic samples.

R-HPLC Analysis. Recycle HPLC was performed on a JAI LC-09 (Japan Analytical Industry, Tokyo, Japan) equipped with a JAI refractive index detector and a JAI UV detector operating 235 nm. An ODS column (25 cm × 25 mm ID) was employed. The residue (19 g) was first further purified by silica-gel chromatography with *n*-hexane–ethyl acetate eluant to obtain a major fraction (14.5 g), which showed a single spot on a TLC plate. This fraction (40 mg) was injected into the R-HPLC system. The mobile phase was methanol at a flow rate of 3 ml/min. R-HPLC was repeated until four known diterpene acids were separated (Figure 1). Their UV and [^{1}H]NMR were identical with those of the authentic samples.

RESULTS AND DISCUSSION

Preliminary antimicrobial assays of *P. ponderosa* oleoresin exhibited activity against the gram-positive bacteria, *B. subtilis* and *B. ammoniagenes*, but not against the gram-negative bacteria, *E. coli* and *P. aeruginosa* up to 500 μg/ml. For the fungi, the oleoresin showed activity against *C. utilis* but not against *S.*

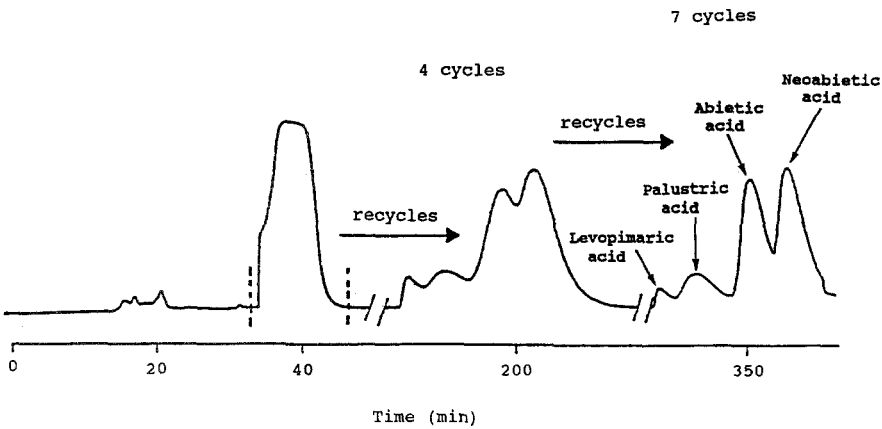

FIG. 1. Separation of diterpenoids by recycle HPLC.

cerevisiae at 10,000 ; gmg/ml (Table 1). As shown in Table 1, the distillate maintained almost the same activity as the oleoresin itself and showed additional activity against *S. cerevisiae*, but the residue lost activity against fungi. Thus, the distillate showed activity against fungi and gram-positive bacteria, while the residue exhibited activity only against gram-positive bacteria. Neither fraction showed any activity against gram-negative bacteria. It seems that the distillate and residue combine to yield the original antimicrobial activity of the oleoresin. It should be noted that none of these fractions showed any activity by the paper disk method. A possible reason for this is discussed later.

In order to identify the antimicrobial principles in both the distillate and residue, further analysis was performed. In the distillate, seven monoterpenes (α-pinene, β-pinene, 3-carene, myrcene, limonene, β-phellandrene and terpinolene), three sesquiterpenes (α-longipinene, longifolene, and germacrene D), and one phenolic compound (estragole) were identified by GC-MS analysis. This result is in general agreement with those reported earlier (Anderson et al., 1969; Smith, 1964).

On the other hand, the residue was found to be a mixture of primarily diterpene acids. The residue was first further fractionated by silica-gel column chromatography to remove the remaining volatile compounds resulting in a nondistillable fraction in 65% yield from the original oleoresin. Although this fraction showed a single spot on TLC plate, its NMR (^{1}H and ^{13}C) spectra indicated that it was still a mixture of abietic acid-type diterpenes. These structurally related diterpene acids were efficiently separated by R-HPLC (Kubo and Nakatsu, 1990). The mixture was injected into an R-HPLC system using an ODS column with the recycling carried out at intervals of about 50 min. By cycle 4 it was evident that this mixture contained four components as shown in

TABLE 1. ANTIMICROBIAL ACTIVITY OF OLEORESIN AND ITS DISTILLATE AND RESIDUE BY STEAM DISTILLATION

Microorganisms tested	Activity[a]		
	Oleoresin	Distillate	Residue

Brevibacterium ammoniagenes ATCC 6872	+	+	+
Escherichia coli ATCC 9637	−	−	−
Pseudomonas aeruginosa ATCC 10145	−	−	−
Saccharomyces cerevisiae ATCC 7754	−[b]	+	−
Candida utilis ATCC 9226	+[b]	+	−

[a] +, Active at a concentration of 500 μg/ml; −, inactive at the concentration of 500 μg/ml.
[b] The concentration was 10,000 μg/ml.

Figure 1. Each fraction was collected, and R-HPLC was repeated under the same conditions to give four pure structurally similar diterpene acids; abietic acid, levopimaric acid, neoabietic acid, and palustric acid were isolated in natural form and identified by spectroscopic studies. These diterpene acids were previously identified in the same source by various methods (Anderson et al., 1969) including GC-MS analysis after methylation with diazomethane (Fujii and Zinkel, 1984).

Various biological activities of abietic acid-type diterpenes have been reported. For example, ingestion of the hexane extract of *P. ponderosa* needles, composed chiefly of eight diterpene acids, caused reproductive failure in mice during the early stages of gestation (Kubik and Jackson, 1981). The diterpene acids from various coniferous trees are also known as antifeedants against insects (Wagner et al., 1983; Schuh and Benjamin, 1984) and aphids (Rose et al., 1981).

Among the volatile hydrocarbons identified in the distillate, α-pinene, β-pinene, 3-carene, limonene, terpinolene, and longifolene were tested for antimicrobial activity. However, we were unable to test the antimicrobial activity of several compounds for the following reasons: (1) myrcene was barely soluble in DMF, so that we could not prepare the necessary sample solution for the assay; (2) germacrene D was unstable under the sample preparation conditions for the assay; and (3) some substances were minor and available only in small quantities. None of the volatile components tested showed activity against gram-negative bacteria up to 800 μg/ml (Table 2). Most monoterpenes showed activity against fungi, especially against *S. cerevisiae*, but almost no activity against gram-positive bacteria at concentrations up to 800 μg/ml. However, longifolene, a sesquiterpene hydrocarbon identified in the distillate showed no activity against fungi but exhibited activity against gram-positive bacteria, among

TABLE 2. ANTIMICROBIAL ACTIVITY OF PRINCIPAL VOLATILE IN DISTILLATE

	MICs against microorganisms[a] tested (μg/ml)					
Volatile	Bs	Ba	Ec	Pa	Sc	Cu

Terpinolene	800	800	>800	>800	50	100
Longifolene	3.13	200	>800	>800	>800	>800

[a]Bs, *B. subtilis*; Ba, *B. ammoniagenes*; Ec, *E. coli*; Pa, *P. aeruginosa*; Sc, *S. cerevisiae*; Cu, *C. utilis*.

which *B. subtilis* was much more sensitive than *B. ammoniagenes*. These results indicate that the original activity of the distillate against fungi was due to monoterpenes and the activity against gram-positive bacteria was due to sesquiterpenes. Therefore, even among the components of the distillate, monoterpenes and sesquiterpenes may share antimicrobial activity. Interestingly, none of these antimicrobial terpenes showed any activity by the paper disk method. There are two possible explanations for this: (1) Since these volatiles are not soluble in water they might not disperse into the media, and (2) they might have been partially if not entirely evaporated from the disk when the solvent was removed from the disk under reduced pressure. However, when these volatile monoterpenes were tested against insect-transmitted fungi in a closed system with the saturated vapor, all of them exhibited fungistatic activity (Cobb et al., 1968). Therefore, we retested the five monoterpenes against four common molds, namely *P. chrysogenum* (blue-green mold), *R. stolonifer* (black bread mold), *A. niger* (black mold), and *M. mucedo* in a broth media at 800 μg/ml. Results showed that only limonene exhibited activity against *M. mucedo* with a MIC of 400 μg/ml (Table 3).

In the case of the residue, the antimicrobial activity of abietic acid was extensively studied as a representative component, because the others were rather unstable and available only in minute quantities. Abietic acid exhibited strong activity against gram-positive bacteria (Table 4), comparable to the original activity of the residue itself. Since the three other diterpene acids are structurally similar to abietic acid, and the antimicrobial activity of pure abietic acid did not increase compared with the residue itself, they might be expected to show the same activity as abietic acid. Among gram-positive bacteria tested, *S. aureus* is an important human pathogenic bacterium. Based on this activity of abietic acid, the three other purified diterpene acids were also tested against this bacterium. All four diterpene acids exhibited the same antibacterial activity against *S. aureus* at MIC of 25 μg/ml.

P. aeruginosa	>800	>800
S. cerevisiae	>800	>800
C. utilis	>800	>800

The oleoresin of *P. ponderosa* may play an important role in protecting the tree from microbial invasion. Moreover, the viscous residue, comprised almost exclusively of diterpene acids, retains the volatile antifungal monoterpene hydrocarbons. Otherwise, these volatiles would rapidly escape into the environment and have only a short duration of antimicrobial activity. For our study, oleoresin was collected from the stems of *P. ponderosa* by boring through the bark into the xylem tissue. We speculate that the role of the oleoresin in defense against microbial invasion may not be only chemical but also biological. However, we were unable to determine if any of the substances identified in the oleoresin were a result of de novo synthesis. Furthermore, the relative amounts of these compounds in the outer and inner bark may effect microbial invasion of pines.

Acknowledgments—The study was supported in part by Resional Research Project W-110 and by USDA/SEA Research Grants Program (88-37253-411; 89-37250-4588-0892). We thank Dr. H. Tsuruta, Takasago International Corporation for GC-MS measurements and providing the authentic longifolene; Mr. H. Naoki, Suntory Institute for Bioorganic Research for NMR measurements; and Dr. S.J. Seybold for critical review of the manuscript.

Abstract—Bioassay-guided isolation of bioactive natural substances requires monitoring of all fractionation and purification steps using a bioassay system. This is often a long and tedious process, especially with insect feeding bioassays. We report here a new method, based on the principle of bioautography, for a quick isolation of insect antifeedant compounds. TLC plates, after development, are coated with a thin layer of artificial diet and fed to *Spodoptera litura* larvae. The location of uneaten areas is then compared with the R_f values of the TLC spots, in order to determine rapidly the active fractions. This methods allows for a very fast determination of the most active antifeedant compounds in a complex mixture and considerably speeds up the isolation process. This new method was successfully applied in the study of antifeedant activity of several plant samples, and results are presented here for a model plant, *Skimmia japonica* (Rutaceae). Using this new method, the compounds responsible for the feeding-deterrent activity, three furanocoumarins (bergapten, xanthotoxin, and oxypeucedanin), were quickly and efficiently identified.

Key Words—Antifeedants, tobacco cutworm, *Spodoptera litura*, Lepidoptera, Noctuidae, bioautography, new bioassay, *Skimmia japonica*, Rutaceae, furanocoumarins.

INTRODUCTION

In the past decade, the increased awareness of the potential dangers of synthetic pesticides, as well as a permanent increase in pest resistance, have prompted a search for new types of compounds with pest control properties. Among other leads, compounds affecting the feeding behavior of insects have been targeted as a promising group (Klocke, 1989; Jermy, 1990), and extensive searches for antifeedants of natural origin have been conducted. Plants have been the main focus of this search, since their resistance to herbivory by insects is often attributed to the presence of secondary compounds, which are thought to function primarily to deter herbivory through a variety of mechanisms (Feeny, 1976; Smith, 1989).

The screening of plant extracts for antiherbivore activity and the isolation and purification of active compounds are often long, expensive, and tedious processes. Numerous samples or chromatographic fractions are usually evaluated against a target insect, in a sequence of feeding bioassays. These bioassays require large numbers of insects, need to be replicated several times for statistical validation, are therefore generally laborious to conduct and evaluate, and have prompted a search for alternative methods (Alkofahi et al., 1989).

We propose here an alternative method to the classical leaf-disk choice bioassay (Lewis and Van Emden, 1986; Kubo, 1991), for the isolation of antifeedants against larvae of herbivorous insects. This new method is based on bioautography, a method widely used for the isolation of antifungal or antibacterial agents from complex mixtures (Hamburger and Cordell, 1987; Rios et al., 1988). In the general method, a solution containing candidate compounds is separated on a thin-layer chromatography (TLC) plate. The plate is coated with culture medium, inoculated with microorganisms, and incubated. Active components are quickly identified by comparing the location of growth inhibition zones with the R_f values of compounds on a control plate (Figure 1A).

We have successfully adapted the concept of bioautography to the isolation of insect antifeedant compounds, using feeding on TLC plates coated with an artificial diet as an indicator of activity. We present here details of this method as well as its application to the study of a Japanese plant, *Skimmia japonica*, which was previously found to possess insect feeding-deterrent properties in a broad screening of plants from Hokkaido (Escoubas et al., In press).

Although previous work has applied this concept to the study of insect (Metcalf et al., 1980; Ferguson et al., 1983) or marine gastropod (Sakata et al., 1984) feeding stimulants, to our knowledge, this is the first application of bioautography to the study of insect antifeedant compounds.

METHODS AND MATERIALS

Insect Rearing. Spodoptera litura (Noctuidae) were reared on an artificial diet (Insecta LF, Nihon Nosan Kogyo Co.) in a controlled environment chamber at 27°C and 70% relative humidity.

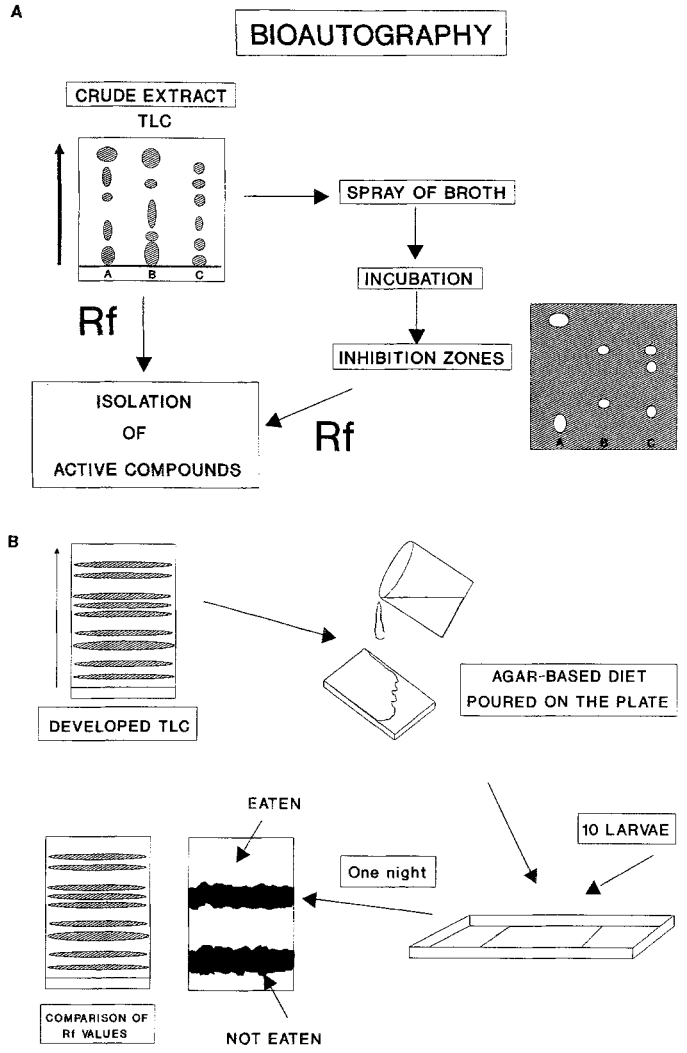

FIG. 1. (A) General principle of bioautography, as used for the identification of antibacterial or antifungal agents. (B) Application of bioautography to the identification of insect feeding-deterrent compounds.

Artificial Diet. The artificial diet used in the bioassay differs from the diet used for rearing the insects and is derived from a general-purpose insect diet (Singh, 1985). The composition is described in Table 1. The diet was prepared as follows: agar is boiled in 200 ml distilled water in a microwave oven (750 W, 1 min 30 sec). Other constituents except vitamins are added to 120 ml of distilled water and thoroughly mixed to avoid the formation of lumps. The

TABLE 1. COMPOSITION OF INSECT ARTIFICIAL DIET

Ingredients	Weight (g)
Agar	8.8
Wheat germ	12.8
Soy flour	14.8
Sucrose	12.8
Sorbic acid	0.4
α-Cellulose	1.9
Methyl *p*-hydroxybenzoate	1.9
Wesson salt mix	3.6
Vanderzant's insect vitamin mix	5.8
Distilled water	320 ml

two solutions are combined, and the vitamin mixture is added after the temperature has cooled to 55°C.

Diet Bioassay. TLC silica gel plates with fluorescent indicator (Merck Silica Gel 60 F_{254} 0.25 mm) were cut into 5 × 10-cm pieces. The sample containing candidate compounds (ca. 5 mg) is applied as a band, and the plate is developed in an appropriate solvent mixture in order to give the best possible separation. The solvent is then completely evaporated under reduced pressure in a glass desiccator. The plate is then coated with hot insect artificial diet and left to solidify for a few minutes. The diet is poured from a beaker onto a plate placed at a 45-degree angle in order to form a layer about 1–1.5 mm thick. The diet used quenches the fluorescence, making the coated plate appear dark under UV light (254 nm). For each experiment, a control plate with no sample is prepared. A second control plate developed under the same conditions, but not coated with diet, serves as reference for visualizing and measuring the R_f values of individual compounds.

Each plate is laid in a 10 × 15 × 1-cm plastic dish, lined with wet filter paper, with ten 10-day-old larvae of *Spodoptera litura* (end of fourth instar). The larvae are allowed to feed on the plate for 16–18 hr, at 27°C, in the dark, in order to avoid visual cues (Lewis and Van Emden, 1986). Under these conditions, the larvae usually consume most of the diet layer on the control plates, leaving only the underlying fluorescent silica gel. The plates are dried with a hair-dryer and then examined under UV light (254 nm) to visualize the uneaten areas. The location of these areas is compared with the R_f values of the compounds detected on a reference plate (Figure 1B). Compounds with feeding-deterrent properties produce a dark band or spot, due to quenching by the remaining diet. To evaluate the sensitivity of the method, known amounts of extracts

were applied as spots, at 2-cm intervals on TLC plates and submitted to the same protocol. The level of activity was estimated visually.

Leaf-Disk Bioassay. The dose–response activity of various pure compounds was determined. Ten sweet potato leaf disks (1 cm^2), treated with 10 μl of sample or solvent for control, were arranged alternately in 9-cm-diameter plastic Petri dishes, in three replicates. After allowing five 4-day old *Spodoptera litura* larvae to feed for one night in the dark at 27°C, leaf areas are measured using a video camera coupled with an Apple Macintosh computer. Calculation of an antifeedant index allowed for comparison of activities; an index of less than 20 indicated significant antifeedant activity (Alkofahi et al., 1989; Escoubas et al., In press) .

$$\text{Antifeedant index} = 100 \times \frac{\%T}{\%T + \%C}$$

$\%T$ = % of treated disks consumed, $\%C$ = % of control disks consumed. The index varies from 0 (total feeding-inhibition) to 100 (total feeding-stimulation).

Isolation of Skimmia japonica *Compounds. S. japonica* leaves were collected in the Nopporo Forest Park, Hokkaido, Japan, ground, and then extracted with 5% aqueous methanol for one week, at room temperature. This crude extract was subsequently partitioned between water and ethyl acetate (1 : 4). The aqueous extract was reextracted with butanol (1 : 1).

The first TLC separation of the ethyl acetate fraction was carried on silical gel TLC plates, using a chloroform–ethyl acetate mixture (8 : 2). Further separation of the active portion of the above chromatogram, obtained by preparative TLC, was achieved using a mixture of hexane–chloroform–ethyl acetate (7 : 2 : 1) and three successive developments. In all TLC separations, compounds were visualized under fluorescent light (365 nm).

Spots found to be active in the bioassays described were purified further by open-column chromatography using Silica Gel 60 (230–400 mesh). Compounds were eluted with a mixture of hexane–chloroform–ethyl acetate in various proportions (8 : 1 : 1, 7 : 2 : 1, and 6 : 3 : 1). Final purification of the compounds was done using preparative TLC, under the conditions described above. NMR data were obtained on a 270-MHz JEOL EX 270 spectrometer, and mass spectra were taken on a high-resolution JEOL JMS-DX 300 mass spectrometer.

RESULTS

Identification of antifeedants in Skimmia japonica. The first bioassay of the water, butanol, and ethyl acetate extracts of *S. japonica* was conducted without migration of the samples. When the three fractions were tested by bioautography, only the ethyl acetate extract showed activity (Figure 2A). When the bioas-

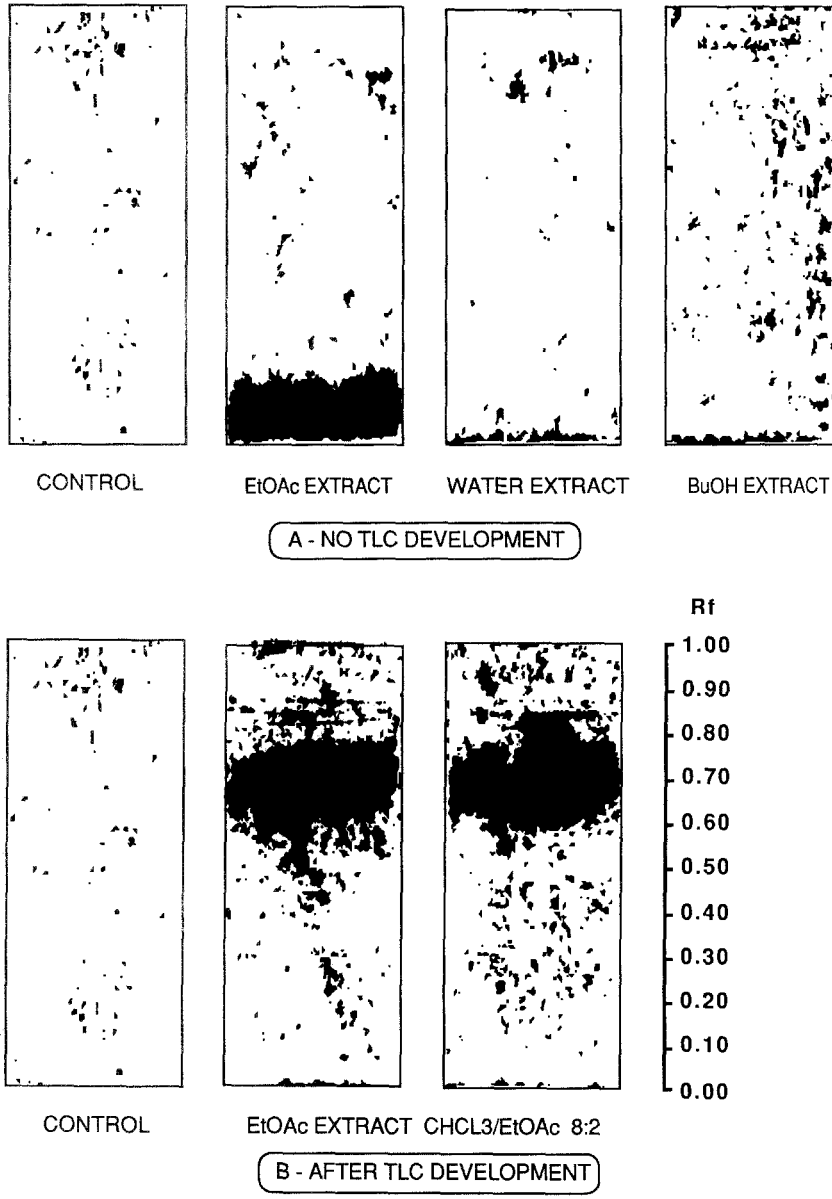

FIG. 2. Identification of *Skimmia japonica* active compounds. Actual pictures of experiments were digitized with a desktop computer scanner. White areas represent fluorescence at 254 nm, and black areas indicate quenching by the artificial diet. (A) Bioassay of the ethyl acetate, water, and butanol extracts, without development of the plates; (B) bioassay of the ethyl acetate fraction (two replicates) after development.

say of the ethyl acetate extract was repeated after development, the activity, visualized by the quenching, moved from the application point to the upper part of the plate, and was found at a R_f of 0.60–0.80. (Figure 2B). This result demonstrated that, after TLC separation, the activity of the total extract could be successfully localized in one portion of the chromatogram, with the diet being consumed in all other parts. When this band was subsequently isolated and bioassayed separately using the second solvent system, antifeedant activity appeared between R_f = 0.35 and 0.56. The active portion of the chromatogram contained four compounds (SKJ-1 to −4). No supplementary bioassay step was needed and the compounds were isolated and purified by column chromatography followed by preparative TLC.

Subsequent leaf-disk bioassay, at a concentration of 1 mg/ml (10 $\mu g/cm^2$), showed that only three of the purified compounds possessed antifeedant activity (Table 2). The structural analysis was therefore carried out only for these three compounds and showed them to be three furanocoumarins: bergapten (SKJ-1) xanthotoxin (SKJ-2), and oxypeucedanin (SKJ-3) (Figure 3). Evaluation of the dose–response activity in the leaf-disk bioassay, for the ethyl acetate fraction as well as for the pure compounds, showed that the most active antifeedant was bergapten, followed by xanthotoxin and oxypeucedanin (Figure 4).

Spectral Data. The physicochemical and spectral data for bergapten and xanthotoxin were identical in all respects with those reported previously in the literature (Razdan et al., 1987).

Bergapten (M^+ 216.0386, calc. for $C_{12}H_8O_4$, 216.0608): Recrystallization from benzene gave colorless needles, mp 186–188°C. zation from chloroform gave colorless needles, mp 146–148°C, IR (KBr, cm^{-1}) 1710, 1610. UV (MeOH) max (nm) 215, 249, 264, 299, 315. [^{1}H]NMR ($CDCl_3$) 7.76 (d, 1H, $J_{4,3}$ = 10 Hz, H-4), 7.62 (d, 1H, $J_{10,9}$ = 2 Hz, H-10), 7.35 (s, 1H, H-5), 6.81 (d, 1H, $J_{9,10}$ = 2 Hz, H-9), 6.37 (d, 1H, $J_{3,4}$ = 10 Hz, H-3), 4.30 (s, 3H, CH_3O).

Oxypeucedanin gave identical physicochemical and spectral data with those previously published (Atkinson et al., 1974) (M^+ 286.0833, calc for $C_{16}H_{14}O_5$ 286.1078). Recrystallization from chloroform gave colorless needles, mp 102–104°C. IR (KBr, cm^{-1}) 1720, 1620. UV (MeOH) max (nm) 222, 247, 270, 306. [^{1}H]NMR ($CDCl_3$) 8.20 (d, 1H, $J_{4,3}$ = 12 Hz, H-4), 7.61 (d, 1H, $J_{10,9}$ = 2 Hz, H-10), 7.20 (s, 1H, H-5), 6.95 (d, 1H, $J_{9,10}$ = 2 Hz, H-9), 6.31 (d, 1H, $J_{3,4}$ = 12 Hz, H-3), 4.61 (dd, 1H, $J_{1a',1b'}$ = 11 Hz, $J_{1a',2'}$ = 4.5 Hz,

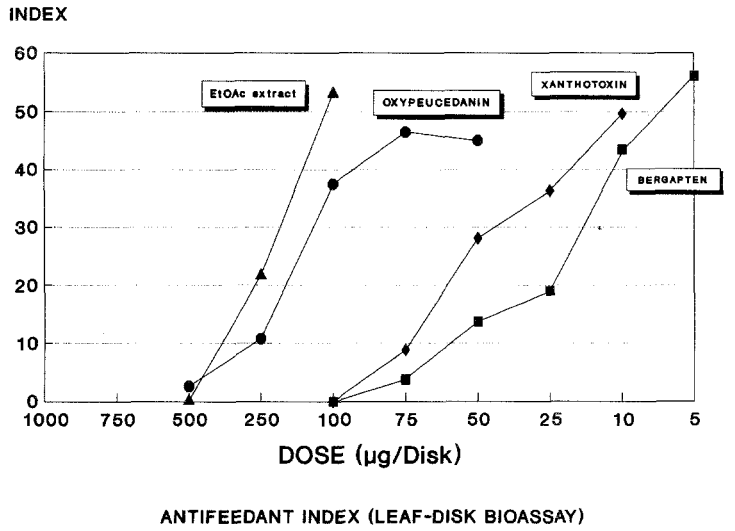

FIG. 4. Dose–response activity for the ethyl acetate fractions and the purified furanocoumarins.

H-1a′), 4.32 (dd, 1H, $J_{1b',1a'}$ = 11 Hz, $J_{1b',2'}$ = 4.5 Hz, H-1b′), 3.28 (dd, 1H, $J_{2',1a'}$ = 4.5 Hz, $J_{2',1b'}$ = 4.5 Hz, H-2′), 1.41 (s, 3H, CH_3), 1.33 (s, 3H, CH_3).

Evaluation of Sensitivity. Figure 5 summarizes the results of the comparison between the leaf-disk bioassay method and the bioautography method. The threshold of activity (index = 20) in the leaf-disk bioassay is approximately 10 $\mu g/cm^2$ (or 10 μg/disk). In the TLC bioassay, activity could be detected with a lower limit of 20 μg for spots and 50 μg for bands.

DISCUSSION

Our results show that bioautography is a quick and efficient method for the isolation of insect-active compounds from complex mixtures. In the case studied here, at least two fractionation steps and subsequent purification of the samples would have been necessary in order to isolate the active constituents using traditional leaf-disk methodology to monitor the activity. In terms of bioassays, this would have translated into several dozen individual experiments. In the example reported here, total time required to obtain the R_f values of the active compounds was only four days. This can be advantageously compared with the time usually required to monitor all fractionation steps with an insect bioassay. Hence, bioautography provides a substantial reduction in cost, time, and labor.

DETECTION OF ACTIVITY ON THE TLC PLATE BIOASSAY

FIG. 5. Comparison of the sensitivity between the leaf-disk bioassay method and the TLC bioautography method. (+ indicates visually detectable quenching under UV light. SPOT/BAND indicates mode of initial sample application).

The sensitivity study shows that there is almost no loss of information when using this new method. Good sensitivity is important, especially in the final stages of the purification, when small amounts of material are available for testing, sometimes not compatible with the concentration or replication requirements of the classical bioassays. In any event, most problems with sensitivity can easily be overcome by increasing the amount of original material extracted. With plants, the amount of material is generally not a limiting factor.

One potential drawback of bioautography would be in the case of high synergistic effects between compounds otherwise possessing weak individual activity. Their elution and separation would then result in a loss of activity. Another potential problem is the possible degradation of proteinaceous substances or evaporation of volatile compounds when coming in contact with the hot diet. Although minimized with prior cooling of the diet, this problem should be considered when the presence of such compounds is suspected. Similarly, photoactivated compounds might not be detected unless a second set of experiments in the presence of UV irradiation is conducted. It should be noted that, although dark conditions were found preferable, *Spodoptera litura* larvae can feed in the presence of light.

The difference of sensitivity observed when applying the extract as spots or as bands can easily be explained by the concentration of the sample, higher

in the case of spots, therefore avoiding a "dilution" of the antifeedant effect during the bioassay. In the most favorable case, under the experimental conditions, the sensitivity of the TLC bioassay was only two times lower than the leaf-disk bioassay. Usually, application in bands was preferred since the response is clearer than with spots. A TLC analysis conducted with an amount of 1–5 mg of dry material would therefore represent a good compromise for starting an analysis. However, since the detection of activity depends on the sample, the nature of the active constituents, and their concentration in the extract, no absolute starting dose can be defined and a higher initial concentration can be used. However, personal experience has shown that an excessive amount of material can induce wide diffusion of the compounds in the medium, thus broadening the uneaten bands and reducing the precision of the method.

As for separation conditions, any type of TLC plate can be used, since the animals do not consume the chromatographic medium. However, a rigid support such as glass is preferable for easy manipulation and to avoid deformations of the diet layer.

The most important problem associated with this technique is the transfer rate of compounds from the silica plate into the agar-based diet. This rate is presumably dependent on the hydrophilic–lipophilic character of the compounds. In the examples we have studied so far, such as aristolochic acids, triterpenoids (Escoubas et al., unpublished data), or furanocoumarins, the transfer rate was satisfactory and allowed for a clear visualization of uneaten areas. This was probably due to the ability of these compounds to partially dissolve in aqueous solvents as well as to the partial lipophilic character of the diet, which contains a certain proportion of lipids, since these compounds are rather lipid-soluble ones (Harborne, 1984). In the case of very lipophilic compounds, migration into the diet could be a problem, preventing the successful identification of active compounds. New diet formulations, with an increased lipid content, might solve this problem. It should be noted, however, that excessive diffusion of compounds in the diet would defeat the purpose of the method, by extending the uneaten area and therefore inducing an error in determining the R_f values of the active components.

The three active furanocoumarins isolated have previously been identified in other representatives of the genus *Skimmia* (Weinstein and Craig, 1971; Razdan et al., 1987). Although furanocoumarins of *Skimmia japonica* have been previously investigated (Atkinson et al., 1974; Reisch and Achenbach, 1989), and ovicidal activity against acarians described (Tanaka et al., 1985), no mention was made of their role in the plant protection against herbivorous insects.

Under our experimental conditions, we found that bergapten was a more potent antifeedant against *S. litura* than oxypeucedanin or xanthotoxin. This result complements previous work (Yajima et al., 1977; Yajima and Munakata, 1979), and once again raises the question of whether or not a high antifeedant

activity is linked to the high phototoxic activity of xanthotoxin and bergapten, as noted previously (Klocke et al., 1989). Our bioassays were conducted in darkness, thus limiting the potential influence of phototoxicity on test results. According to our results, the substitution of a methoxy group in position 8, by a 2′,3′-epoxy-3′-methylbutyloxy group, substantially decreased the antifeedant activity against *S. litura*. However, response and activity levels vary with the test insects used, and structure–activity relationships can hardly be generalized.

S. japonica defense systems against herbivores and pathogens are complex and involve compounds with both feeding deterrent and growth-inhibitory activity (Ochi et al., 1988). The presence of limonoids and furanocoumarins in the leaves and fruits provides this plant with a very high defense potential against a wide array of natural enemies. Furthermore, both phototoxic and nonphototoxic metabolites are involved, making this plant an interesting model for the study of complex defense strategies. Furanocoumarins show phototoxic, chronic, and acute toxicity as well as phagodeterrent activities in members of the Rutaceae and Umbelliferae (Luthria et al., 1989; Nitao, 1990; Zobel et al., 1991) and undoubtedly represent an important element of the plant's defense system.

CONCLUSION

Isolation of bioactive compounds from complex plant extracts is usually a very long process. To fractionate and then subfractionate crude mixtures represents a laborious chemical endeavor. Assessing the activity of all fractions is equally time- and effort-consuming, considering that only a small percentage of that effort produces a significant output because active substances can comprise only a few out of a large number of constituents. Bioautography solves these problems by considerably speeding the isolation of active compounds. In the case of antifeedants, we demonstrate here that bioautography is faster than traditional leaf-disk bioassays, with no loss of information or sensitivity.

(Received February 18, 1992; accepted June 10, 1992)

Abstract—The root exudates from *Polygonum sachalinense* in a recirculating system significantly inhibited lettuce seedling growth. The rhizomes and roots of *P. sachalinense* were extracted with 80% acetone. Bioassay of the neutral–acidic fraction on the TLC agar plate showed the inhibitory activity corresponded to the two yellow pigment bands. Two orange needles were isolated and identified as anthraquinone compounds: emodin and physcion. Both compounds exhibited inhibitory activities against the seedling growth of several testing plant species. Glucosides were isolated from *P. sachalinense* and were identified as emodin-1-*O*-β-D-glucoside and physcion-1-*O*-β-D-glucoside, respectively. On plant growth bioassay, these glucosides showed no phytotoxic activity against lettuce seedlings. The concentrations of emodin, physcion, and their glucosides from rhizome with roots, aerial parts, fallen leaves, and soil were determined. The rhizome with roots and fallen leaves contained emodin and physcion at relatively high concentrations. Emodin also occurs in the soil of this plant community with effective concentrations in the fall. The results indicate that these anthraquinones are responsible for the observed interference and are potent allelopathic substances.

Key Words—*Polygonum sachalinense*, allelopathy, allelochemicals, anthraquinone, emodin, emodin-1-*O*-D-glucoside, physcion, physcion-1-*O*-D-glucoside, root exudates.

INTRODUCTION

Chemical interactions among plants have long been recognized. Many scientists have shown that certain plants produce secondary compounds that have the

*To whom correspondence should be addressed.

0098-0331/92/1000-1833$06.50/0 © 1992 Plenum Publishing Corporation

ability to inhibit growth and germination of other plants (Rice, 1984; Harborne, 1988). The genus *Polygonum* has about 300 species and is distributed all over the world. AlSaadawi and coworkers demonstrated that *Polygonum aviculare* was allelopathic, and several phenolic compounds and long-chain fatty acids appeared to be responsible for this activity (AlSaadawi and Rice, 1982a,b; AlSaadawi et al., 1983).

P. sachalinense (Sachaline giant knotweed), or "Ohitadori" in Japanese, is a perennial grass found in Honshu and Hokkaido. Its rhizome has been used as an herbal medicine for laxative and diuretic purposes. This grass forms colonies along roadsides and river banks in gravelly soils. Judging from its ability to rapidly colonize, we hypothesize that allelopathy contributes to its aggressiveness.

This paper deals with the isolation and identification of allelochemicals in *P. sachalinense* and the evaluation of these allelochemicals in the ecosystem.

METHODS AND MATERIALS

Root Exudate Recirculating Systems. The evaluation of the effect of the root exudates as allelochemicals was carried out according to the root exudate recirculating system of Stevens and Tang (1985). Lettuce seedlings were planted in the acceptor pot, while *P. sachalinense* was grown in the donor pot. Nutrient solution (Tadano and Tanaka, 1976) from the donor pot was lifted through 8-mm-diameter glass tubing to the acceptor pot using an air pump. Nutrient levels were maintained, and pH was kept 5.5 with H_2SO_4 or NaOH. Recirculating solution was not changed during the experiment except for replenishing water and nutrient solution. After 10–14 days, the growing condition of lettuce (*Lactuca sativa* L.) seedlings was compared with that of the control growing under the same conditions without the donor plant. The experiment was carried out in a greenhouse.

Plant Materials and Extraction. Rhizomes with roots, aerial parts, and fallen leaves of *P. sachalinense* were collected at several wild places near the campus of Hokkaido Tokai University. Excavated rhizomes were rinsed with tap water and brushed lightly to remove soil, and air-dried. The rhizome (5.1 kg) and aerial part (3.8 kg) were sliced and extracted in separate containers with 80% acetone for about two months at room temperature. The extracts were filtered and concentrated under reduced pressure. In another experiment, 100 g of fallen leaves were extracted with 300 ml of ether for 24 hr, and the residues were removed by filtration.

Fractionation. The acetone extract of rhizome with roots was divided into ether-soluble and water-soluble fractions. The ether-soluble fraction was further divided into neutral, acidic, and basic fractions in an usual manner. The water-

soluble fraction was evaporated to dryness for bioassay; it did not show any significant activity against the growth of lettuce seedlings.

TLC Agar Plate Bioassay. Thin-layer chromatography was carried out on a 20 × 7-cm silica gel glass plate (Merck, Kieselgel 60 F254) 0.25 mm thick using hexane–$CHCl_3$–MeOH (4 : 10 : 1 v/v/v) as developing solvents. The chromatogram was covered with a 0.5% agar layer (2 mm), and the seeds of green amaranth (*Amaranthus viridis* L.), timothy grass (*Phleum pratense* L.), crabgrass (*Digitaria adscendens* Henr.), and Chinese cabbage (*Brassica campestris* L.) were sown in a row perpendicular to the bands on the chromatogram. The seeds were incubated in a moisture saturated growth chamber at 24–26°C with 14 hr light and 10 hr dark. After four to seven days, seed germination and plant growth were examined.

Seedling Growth Bioassay. In a 25-mm-high × 40-mm-ID glass Petri dish 10 germinated seeds were placed on 0.5% agar gel with a known concentration of the test sample. Lettuce, green amaranth, and timothy grass were used for bioassay. The assay was done in duplicate. Incubation was for seven days in a growth chamber at 24–26°C with a 14-hr light and 10-hr dark cycle. The average length of hypocotyl or leaf sheath and the longest roots of the testing plants were measured and compared with that of the control growing on 0.5% agar gel only.

Isolation and Identification of Allelochemicals. The inhibitory substances against seedling growth were fractionated by SiO_2 column chromatography using a hexane–$CHCl_3$–MeOH gradient as an eluent, and the desired products were recrystallized from hexane–$CHCl_3$ to give two orange-needle crystals. The isolated compounds were identified from IR, UV, mass, and NMR spectra.

Emodin **(1):** IR (KBr) ν_{max} 3400 (H)(OH), 1630 (C=O) cm^{-1}; UV (MeOH) λ_{max} 221, 253, 265, 289, 437 nm; [^{1}H]NMR [$(CD_3)_2CO$] δ 2.46 (3H, s, Ar-CH_3), 6.65 (1H, d, J = 2.5 Hz, H-2), 7.12 (1 H, br s, H-7), 7.24 (1H, d, J = 2.5 Hz, H-4), 7.55 (1H, br s, H-5), 12.05 (1H, s, OH), 12.18 (1H, s, OH); HR-EI-MS m/z 270.0515 ($C_{15}H_{10}O_5$).

Physcion **(2):** IR (KBr); ν_{max} 3400 (OH), 1630 (C=O) cm^{-1}; UV (MeOH) λ_{max} 223, 254, 265, 287, 434 nm; [^{1}H]NMR ($CDCl_3$) δ 2.45 (3H, s, Ar-CH_3), 3.94 (3H, s, Ar-OCH_3), 6.68 (1H, d, J = 2.5 Hz, H-2), 7.08 (1H, br s, H-7), 7.36 (1H, d, J = 2.5 Hz, H-4), 7.63 (1H, br s, H-5), 12.12 (1H, s, OH), 12.31 (1H, s, OH); HR-EI-MS m/z 284.0704 ($C_{16}H_{12}O_5$).

Isolation and Identification of Anthraquinone Glycoside. The rhizomes with roots and the aerial part of *P. sachalinense* were collected in June 1991. Immediately after cutting, they were extracted in EtOH by refluxing for 5 hr and the EtOH solution concentrated to one third of the original volume. The aqueous concentrate was extracted with ether to remove free anthraquinones and other ether-soluble constituents. $Ba(OH)_2$ solution (5%) was added to precipitate the organic acids. After filtration, the filtrate was adjusted to pH 3 and was extracted

with *n*-BuOH. The *n*-BuOH layer was separated and evaporated in vacuo to give the crude glycoside fraction, which was further fractionated by SiO_2 column chromatography using a hexane—$CHCl_3$—MeOH as an eluent to obtain anthraquinone glycosides. Rechromatography and further recrystallization from MeOH gave two glycosides as orange-needle crystals. Identification was based on the comparison of the melting point, R_f values, and spectrometric data with those in Kang and Woo (1982) and Kato and Morita (1987).

Emodin-1-*O*-β-D-glucoside **(3):** mp 193°C; IR (KBr) ν_{max} 3400 (OH), 1630 (free C=O), 1600 (chelated C=O) cm^{-1}; UV (EtOH) λ_{max} 221, 253, 265, 286, 421 nm; [^{1}H]NMR (CD_3OD) δ 2.40 (3H, s, Ar-CH_3), 4.96 (1H, d, J = 7.5 Hz, anomeric H), 7.04 (1H, br s, H-7), 7.10 (1H, d, J = 2.5 Hz, H-2), 7.32 (1H, d, J = 2.5 Hz, H-4), 7.48 (1H, br s, H-5); FAB-MS (DMSO) *m/z* (NaCl addition) 455 $(M + Na)^+$, 478 $(M + 2Na)^+$.

Physcion-1-*O*-β-D-glucoside **(4):** mp 240°C; IR (KBr); ν_{max} 3400 (OH), 1640 (free C=O), 1600 (chelated C=O) cm^{-1}; UV (MeOH) λ_{max} 226, 273, 417 nm; [^{1}H]NMR (CD_3OD) δ 2.46 (3H, s, Ar-CH_3), 3.97 (3H, s, Ar-OCH_3), 4.96 (1H, d, J = 7.5 Hz, anomeric H), 7.11 (1H, br s, H-7), 7.30 (1H, d, J = 2.5 Hz, H-2), 7.57 (1H, d, J = 2.5 Hz, H-4), 7.60 (1H, br s, H-5).

Quantitation of Anthraquinones and Anthraquinone Glycosides. Plant samples were collected at several wild places near the campus of Hokkaido Tokai University. Fresh aerial parts, rhizome with roots, and fallen leaves were extracted with 80% acetone. After concentration, the aqueous residues were extracted with ether. The ether-soluble fractions were quantitatively analyzed by HPLC (JASCO System-800) and compared with standard emodin and physcion (purchased from Funakoshi Co. Ltd.). The analytical conditions are as follows: column—YMC-Pack ODS-AM (30 cm × 10 mm ID); solvent—MeOH/H_2O (80:20, v/v); flow rate—4 ml/min, wavelength of detection—245 nm.

Soil samples were collected in November 1990 from the center of a *P. sachalinense* community near the campus of Hokkaido Tokai University at the depth of about 10 cm. Litter was removed as completely as possible by sieving and the soil was dried at room temperature overnight. A 500-g soil sample was stirred in 2 liters of acetone–1 N HCl (2:1, v/v) for 1 hr at 50°C and further treated with ultrasonic energy for 1 min. After leaving overnight at room temperature, it was filtered. The filtrate was evaporated to remove acetone and extracted three times with ether. The ether extract was evaporated in vacuo and fractionated by SiO_2 column chromatography. The contents of emodin and physcion were determined by HPLC. The amounts of anthraquinone glycosides were determined by weighing the isolated crystals of emodin-1-*O*-β-D-glucoside and physcion-1-*O*-β-D-glucoside.

Spectrometers. IR spectra were recorded on a JASCO IR-810 as KBr disk for crystals. UV spectra were recorded on a Hitachi U-3210 spectrophotometer. NMR spectra were measured on a Bruker AM-400 (400 MHz) spectrometer

using TMS as an internal standard. Mass spectra were recorded using JEOL JMS-DX303HF GC-MS spectrometer.

RESULTS AND DISCUSSION

The root exudates from *P. sachalinense* showed an inhibition on lettuce seedling growth using the recirculating system. It is well known that organic compounds are exuded from healthy undamaged plant roots (Rovira, 1969), and we expect that allelochemicals or their precursors are present in the plant tissue and also released from the rhizome and roots.

From the results of the TLC agar plate bioassay, growth inhibitory activity was shown in the two bands of yellow pigments against green amaranth and timothy grass on the chromatogram of the neutral–acid fraction (Figure 1). Two corresponding orange needles were isolated and identified as anthraquinone compounds: emodin **(1)** and physcion **(2)** (Figure 2).

Emodin and physcion exhibited inhibitory activities against the seedling growth of several test species (Figure 3). Emodin inhibited root and hypocotyl or leaf sheath growth over 100 ppm (3.7×10^{-4} M). It severely inhibited the growth of lettuce seedlings at 50 ppm (1.85×10^{-4} M). Physcion was less active and inhibited root and hypocotyl growth at 200 ppm (7.0×10^{-4} M).

The presence of anthraquinone glucosides was expected since they are common for transportation and storage and are less toxic in the plant. As a result, two glucosides were isolated from both the rhizome and aerial part of *P.*

sachalinense and identified as emodin-1-*O*-β-D-glucoside **(3)** and physcion-1-*O*-β-D-glucoside **(4)** (Figure 2). In plant growth bioassay, both emodin and physcion glucosides showed no phytotoxicity at 200 ppm against lettuce seedlings.

The concentrations of emodin and physcion, and their glucosides in the rhizome, aerial part, fallen leaves, and soil were quantitatively determined. Contents of emodin and physcion in the fresh rhizome were ca. 158 and 32 mg/kg fresh weight, and in the aerial part, ca. 72 and 22 mg/kg fresh weight, respectively. Large amounts of anthraquinones were still detected in dry fallen leaves more than four months after defoliation: emodin, 213 mg/kg dry weight; physcion, 180 mg/kg dry weight. In addition, contents of emodin and physcion in the soil were 55 and 30 mg/kg dry weight, respectively; these concentrations

are enough to inhibit plant seedlings. These facts indicate that the anthraquinones are very stable in the ecosystem.

Allelopathic substances are released from plants in four ways (Tukey, 1969): (1) Litter of leaves and stems decomposes by physical or biological processes and the substance is released. (2) The active substance is released to the soil from the root directly by exudation or through the decay of dead roots. (3) Volatile material is vaporized from plants and acts on other plants through the air. (4) Rain and fog drips transfer toxic compounds from leaves to the soil.

We consider that the first two items above are associated with the allelopathy of *P. sachalinense*. It has anthraquinone glucosides in the plant tissue. We propose that either these glucosides or the aglycons are released from the rhizome. The glucosides are then decomposed to active forms—emodin and physcion—and subsequently exhibit plant growth inhibitory activities against other plant species. To confirm this hypothesis, isolating glucosides and aglycons from the root exudate solution is currently under investigation. Furthermore, anthraquinones exuded from the fallen leaves of *P. sachalinense* accumulate on the soil surface and affects early seedling growth of nearby plants of the community.

There are reports about antimicrobial activities of emodin and physcion (Podojil et al., 1978; Anke et al., 1980; Kitanaka and Takido, 1986). Some antimicrobial activity by emodin and physcion may directly or indirectly affect the growth of other plants. Rice (1964, 1984) and AlSaadawi et al. (1983) pointed out that some weeds produce allelopathic chemicals that inhibited soil bacteria and changed the soil environment to their own advantage. While these anthraquinone compounds are potent allelopathic substances, the question of the extent of their impact against the flora in *P. sachalinense* is yet to be fully evaluated.

Acknowledgments—We wish to thank Mr. A. Sato (Hokkaido Tokai University) for NMR and mass spectral measurements.

(Received March 27, 1992; accepted June 11, 1992)

Abstract—In an earlier study we documented attraction of the specialist parasitoid *Macrocentrus grandii* Goidanich to odors of corn, potato, and snap bean. In the present study the chemical bases of the parasitoid's attraction to these food plants of its European corn borer host were compared. Volatile compounds from corn leaves were isolated using Tenax and identified by capillary gas chromatographic–mass spectrometry. Twenty-one compounds including aldehydes, ketones, alcohols, esters, and sesquiterpenes were present in corn. These were separated into fractions by column chromatography on Florisil. Wind-tunnel bioassays of the fractions indicated that *M. grandii* was attracted to fractions containing nonpolar and slightly polar compounds including sesquiterpenes, aldehydes, a ketone, and esters. More polar compounds in corn, like alcohols, were not attractive. Attraction to potato odor was based on the presence of the same classes of compounds that were attractive in corn, but more polar compounds were involved in attraction to snap bean odor. This study indicated that only some compounds in each of the three odor complexes tested were attractive. It also documented that different compounds were involved in attraction of *M. grandii* to different plant odors.

INTRODUCTION

Parasitoids of phytophagous insects use olfactory cues for host location. In long-range orientation, volatile cues emanating from plants are used for locating habitats where hosts are likely to be present. Some parasitoids, however, are attracted to odors of only certain food plants of their hosts (Shahjahan, 1974; Elzen et al., 1983; Ding et al., 1989b; Navasero and Elzen, 1989; Martin et al., 1990). This is likely to affect the range of plants on which their hosts are parasitized. If the searching behavior of a parasitoid in the field can be increased by application of attractive plant odors, then this strategy can be incorporated in biological control programs for retaining a parasitoid in a habitat or introducing it to a less preferred habitat.

For their efficient use in biological control programs, attractive plant compounds need to be identified. Plant odors contain numerous compounds of which only some may be critical for parasitoid attraction. Plant compounds involved in interactions between plants and parasitoids are termed synomones (allelochemicals that mediate mutually beneficial interactions, Nordlund and Lewis, 1976). In several studies (Read et al., 1970; Camors and Payne, 1972; Elzen et al., 1984; Sugimoto et al., 1988; Turlings et al., 1991) plant synomones involved in habitat location behavior of parasitoids were identified. However, the chemical basis of a parasitoid's differential response to several food plants of its host has not been analyzed.

Macrocentrus grandii Goidanich (Hymenoptera: Braconidae) is a specialist parasitoid that was introduced into the United States for biological control of European corn borer, *Ostrinia nubilalis* (Hübner) (Lepidoptera: Pyralidae) in corn (Parker, 1931). While *M. grandii* is established in several U.S. regions (Clausen, 1956; Peairs and Lilly, 1975; Lewis, 1982) parasitism levels in corn have been low. According to Parker (1931), the inefficiency of this parasitoid is due to the limited ability of the female to locate corn borers. The European corn borer is polyphagous but *M. grandii* locates it only in certain habitats. In an earlier study (Udayagiri, 1991) *M. grandii* exhibited different olfactory responses to food plants of its host. It was attracted to volatiles of corn, potato, and snap bean but not to those of pepper and soybean. It may be possible to increase searching behavior of female *M. grandii* by providing chemical stimuli attractive to the parasitoid. If specific volatile plant compounds critical for attraction are identified and synthesized, they might be used for increasing host-location efficiency of *M. grandii*. It may also be possible to use plant synomones for introducing *M. grandii* to less attractive habitats.

In the present study, we examined the chemical basis of habitat location

behavior in *M. grandii*. We were interested in (1) identifying constituents of corn odor that are responsible for long-range attraction by *M. grandii* and (2) determining whether attraction to other plant odors was based on the presence of similar or different volatile compounds than those found to be attractive in corn.

METHODS AND MATERIALS

Plant Material. Corn (Jubilee), potato (Reddale), and snap bean (Strike) were raised during the summer of 1990 at the Minnesota Agricultural Experimental Station, University of Minnesota, in St. Paul, Minnesota. Normal cultivation practices were used but no pesticides were applied.

Insects. European corn borer larvae were maintained on an artificial diet (Guthrie et al., 1971), and *M. grandii* were reared on European corn borer larvae as described by Ding et al. (1989a). Adult parasitoids were transferred on the day of emergence to Plexiglas/aluminum cages 30 × 30 × 45 cm with nylon netting on three sides, provided with honey and water, and maintained at 23°C and 70–80% relative humidity under a 18:6 light–dark photoperiod. Experiments were conducted 4–6 hr into the photophase. One-week-old, mated, naive (with no previous oviposition experience or exposure to larval frass or foliage) *M. grandii* females were used for bioassays.

Isolation of Plant Volatiles. Leaves were collected from corn, potato, and snap bean plants 40–50 days from planting date. In separate collections, volatile compounds were isolated from the leaves using the Tenax trapping method described by Buttery and Ling (1984). Whole leaves (500 g) were placed in a 20-liter flask connected to a Tenax trap. The trap consisted of a Pyrex tube (15 cm long and 1.5 cm diameter) packed with 2 g of Tenax. Collection of volatiles from the atmosphere around the leaves was continued for 12 hrs. Volatiles were eluted from the trap with 10 ml pentane. Each collection provided 600 g hr of volatiles [(500 g × 12 hr) ÷ 10 ml solvent where 1 g hr = volatiles from 1 g of plant material aerated for 1 hr and eluted with 1 ml solvent]. Plant extracts were stored at −70°C until used.

Identification of Plant Volatiles. Volatile compounds in corn extract were identified by gas chromatographic–mass spectral analysis. Identities were confirmed by comparison of gas chromatographic and mass spectral data with those of standards obtained from commercial sources.

Extracts of corn volatiles in pentane were separated with a J & W 30-m × 0.53-mm-ID DB-wax fused silica capillary column with 1 μm film thickness on a Hewlett-Packard 5890A gas chromatograph equipped with a flame ionization detector and coupled to a HP 3392A integrator. The gas chromatographic unit was temperature programmed from 40°C to 200°C at 5°C/min with a 2-min

initial delay. The carrier gas was helium at a linear velocity of 47 cm/sec at 150°C. For each extract, 1 μl of each sample (= 0.6 g hr) was injected in the splitless mode.

Equivalent chain length (ECL) (Miwa, 1963) for each corn compound was calculated by running internal and external standards. Two alkanes, dodecane (C-12) and eicosane (C-20), were added as internal standards to the extract of corn volatiles. A mixture of external standards was prepared by combining equal quantities of nine consecutive alkanes from dodecane to eicosane. The mixture of external standards and the corn extract containing the internal standards were chromatographed and the retention time (on the gas chromatograph column) of each compound was recorded. The chromatogram of corn extract with the internal standards was superimposed over the chromatogram of the external standard based on the two internal standard alkanes and ECLs were determined by comparison of the retention time of each corn compound with those of the alkanes.

Mass spectral data were obtained from a Kratos MS 25 gas chromatograph–mass spectrometer. Samples were injected in the splitless mode through the same J & W DB-wax column and the samples were fractionated using the temperature program listed above. The electron ionization energy was 70 eV. Mass spectral data were compared with mass spectra of standards obtained from commercial sources and with mass spectra published by McLafferty and Stauffer (1989).

Compounds in the corn extract were considered to be identified if their mass spectral and gas chromatographic retention data were consistent with those of standards obtained from commercial sources run on the same instruments. Standards used (purity given in parentheses) were: hexanal (99%), (*E*)-2-hexenal (99%), 2-heptanone (98%), hexanol (98%), and (Z)-3-hexen-1-ol (98%) from Aldrich Chemical Company, Inc., Milwaukee, Wisconsin; cyclosativene (>99%) from Fluka Chemical Corp., Ronkonkoma, New York; β-caryophyllene (84%) from Pfaltz & Bauer, Inc., Waterbury, Connecticut; and (Z)-3-hexen-1-yl acetate (approximately 98%) from Sigma Chemical Company, St. Louis, Missouri.

Separation of Plant Volatiles. Compounds in volatile extracts of corn, potato, and snap bean were separated by column chromatography on Florisil. Florisil (2 g) was added to a Pyrex tube to create a 2 × 5-cm column. A small plug of glasswool was placed at the bottom to support Florisil and a narrow layer of anhydrous sodium sulfate (0.2 g) was placed above Florisil for absorption of water.

Volatile extracts from three collections (= 1800 g hr) were combined and concentrated to 0.5 ml under nitrogen. The concentrated material was loaded onto the Florisil column and the column was eluted consecutively with 3 ml (= one void volume of the column) of solvents of increasing polarity. The solvents used were pentane (P) + ether (E) in the following combinations: 100%

P, 97.5% P + 2.5% E, 95% P + 5% E, 92.5% P + 7.5% E, 90% P + 10% E, 80% P + 20% E, 50% P + 50% E and 100% E followed by acetone and methanol. Solvents used were of analytical quality. Ten fractions (each containing 3 ml of solvent) were collected and 1 μl of each fraction was injected on the gas chromatograph to determine evidence of plant compounds. Fractions that contained visible quantities (>1 ng) of plant compounds were retained and stored at $-70°C$.

Bioassay of Plant Volatiles after Separation. Fractions that contained plant compounds were bioassayed for behavioral activity by presenting them in separate tests in the wind tunnel olfactometer as described by Udayagiri (1991). Aliquots of each fraction (200 μl) were tested and the response of 10 naive *M. grandii* was determined. When a particular fraction was bioassayed, the solvent used for eluting the fraction was used as the control. Each bioassay was replicated five times.

Statistical Analysis. Categorical data from bioassays for each Florisil fraction were analyzed by constructing contingency tables and fitting log linear models (Fienberg, 1989). Goodness-of-fit for each model was determined by examining the log likelihood ratio chi-squared statistic [$= G^2 = 2\Sigma$ (observed No.) $\times$ log (observed No. $\div$ expected No.)] (Fienberg, 1989). Model selection was done as described by Sakamoto and Akaike (1978) using AIC (Akaike Information Criterion), where AIC $= G^2 - 2\,df +$ No. of cells in the contingency table. Models with low G^2 and large degrees of freedom that resulted in low AIC and $P > 0.05$ were considered to provide a good fit. The effect of a specific variable was determined by estimation of ΔG^2 values for nested models. High ΔG^2 values with low degrees of freedom and $P < 0.05$ were considered to be indicative of strong effects. The Bonferroni method (Devore and Peck, 1986) was adopted for multiple comparisons between treatments in each bioassay and P values were obtained by comparison of estimated values with values from a standard z table. Each Florisil fraction was assayed independently and hence comparisons were not made across fractions. G^2 and Bonferroni critical values were obtained using the 'S' package (Becker et al., 1988) on the UNIX system.

RESULTS

Identification of Plant Volatiles. Table 1 lists the 21 volatile compounds isolated from leaves of corn. These included aldehydes, ketones, alcohols, esters, and sesquiterpenes. Hexanal, (*E*)-2-hexenal, 2-heptanone, (*Z*)-3-hexen-1-yl acetate, hexanol, (*Z*)-3-hexen-1-ol, cyclosativene, and β-caryophyllene were identified by comparing the spectrum of the mass of each compound against that of a synthetic standard. ECLs of these compounds matched those of standards run on the same gas chromatographic column. Mass spectra of (*Z*)-3-

[a] Major fragmentation ion values (*m/z*) over 40 in descending order of intensity.
[b] Equivalent chain length, which indicates the affinity of a compound on a DB-wax gas chromatographic column relative to that of standard alkanes.
[c] No authentic sample was available; identification based on published spectra (McLafferty and Stauffer, 1989).

hexenal, (*E*)-4-hepten-2-one, 2-heptanol acetate, (*E*)-4-hepten-2-ol, ylangene, α-humulene and δ-cadinene matched published spectra (McLafferty and Stauffer, 1989) of the same compounds, but commercial standards of these compounds were not available for confirmation of the identities. Mass spectral data indicated the presence of six additional sesquiterpenes.

Separation of Plant Volatiles. Gas chromatographic analysis indicated that visible quantities (>1 ng) of several compounds were present in each of the three plant extracts. During column chromatography 10 fractions were collected

for each plant extract. However, only fractions 1, 4, 5, and 7 contained visible quantities (>1 ng) of compounds based on gas chromatographic analysis.

The volatile profile of whole-corn extract prior to Florisil separation was compared with the profile of each Florisil fraction of corn on the gas chromatograph. Identities of compounds in each Florisil fraction are listed in Table 2.

Bioassay of Plant Volatiles after Separation. For analyzing results of the bioassays, 2 (No. of choices) $\times$ 5 (No. of replications) contingency tables with a total of 10 cells were set up. Model selection based on lowest AIC values indicated that, for all bioassays, the model that provided the best fit was the model that considered the effects of choice between the fraction containing plant odor and the control.

Corn. The effects of preference were significant for fraction 1 with $\Delta G^2 = 37.99$ at $df = 1$ and $P < 0.001$ and for fraction 4 with $\Delta G^2 = 13.55$ at $df = 1$ and $P < 0.001$. There were more landings on wicks containing fraction 1 and fraction 4 compared to control wicks (Figure 1). Based on the Bonferroni comparison approach, these differences in the number of landings were significant for fraction 1 with $z = 4.71$ and $P < 0.001$ and for fraction 4 with $z = 2.86$ and $P = 0.004$.

TABLE 2. SEPARATION OF COMPOUNDS IN VOLATILE EXTRACT OF CORN USING COLUMN CHROMATOGRAPHY ON FLORISIL

Fraction	Compounds eluted
1 (eluted with pentane)	(+)-cyclosativene
	ylangene
	β-caryophyllene
	α-humulene
	δ-cadinene
	6 unidentified sesquiterpenes
4 (eluted with 92.5% pentane + 7.5% ether)	hexanal
	(*Z*)-3-hexenal
	2-heptanol acetate
	(*Z*)-3-hexen-1-yl acetate[a]
5 (eluted with 90% pentane + 10% ether)	(*E*)-2-hexenal
	2-heptanone[b]
	(*E*)-4-hepten-2-one
7 (eluted with 50% pentane + 50% ether)	(*E*)-4-hepten-2-ol
	hexanol
	(*Z*)-3-hexen-1-ol

[a] Minor quantity eluted in fraction 5.
[b] Minor quantity eluted in fraction 4.

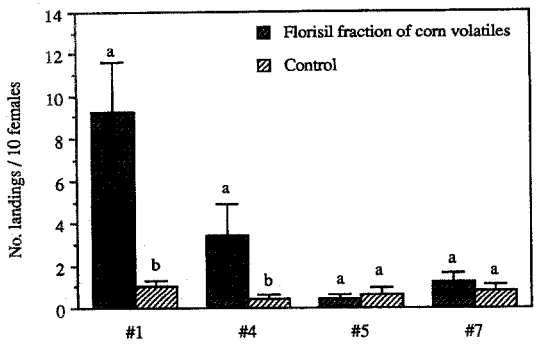

FIG. 1. Response of *Macrocentrus grandii* females to Florisil fractions of corn volatiles. Number of females tested in each assay was 50. Treatments with different letters within the same fraction are significantly different ($P < 0.05$). Comparisons cannot be made across fractions since each fraction was bioassayed in a separate test.

In bioassays that tested the activities of fractions 5 and 7, the effects of preference were not significant. For fraction 5 $\Delta G^2 = 0.2$ at $df = 1$ and $P = 0.65$ and for fraction 7 $\Delta G^2 = 0.4$ at $df = 1$ and $P = 0.53$. The difference between the number of landings on the wick containing fraction 5 and on the control wick was not statistically significant ($z = 0.44$; $P = 0.66$). Similarly, there was no significant difference between the number of landings on wicks containing fraction 7 and the control ($z = 0.63$; $P = 0.53$) (Figure 1).

Potato. The effects of preference were significant for fraction 1 where $\Delta G^2 = 19.81$ at $df = 1$ and $P < 0.001$ and for fraction 4 where $\Delta G^2 = 5.01$ at $df = 1$ and $P = 0.03$. Based on the Bonferroni comparison approach, these differences were significant for fraction 1 ($z = 3.72$; $P < 0.001$) and for fraction 4 ($z = 2.12$; $P = 0.03$) (Figure 2).

In assays that tested the effects of fractions 5 and 7, the effects of preference were not significant. For fraction 5 $\Delta G^2 = 2.32$ at $df = 1$ and $P = 0.13$ and for fraction 7 $\Delta G^2 = 2.84$ at $df = 1$ and $P = 0.09$. The difference between the number of landings between the wick containing fraction 5 and the control wick was not statistically significant ($z = 1.49$; $P = 0.14$) (Figure 2). There was also no significant difference between the number of landings on wicks containing fraction 7 and the control ($z = 1.64$; $P = 0.1$).

Snap Bean. The effects of preference were not significant for fraction 1 with $\Delta G^2 = 2.65$ at $df = 1$ and $P = 0.1$ and fraction 4 with $\Delta G^2 = 0.29$ at $df = 1$ and $P = 0.59$. There were no significant differences in the numbers of landings on control wicks and wicks containing fraction 1 ($z = 1.55$; $P = 0.12$) and fraction 4 ($z = 0.53$; $P = 0.59$) (Figure 3).

The effects of preference were significant for fraction 5 where $\Delta G^2 = 10.13$ at $df = 1$ and $P = 0.0014$ and fraction 7 where $\Delta G^2 = 10.13$ at $df =$

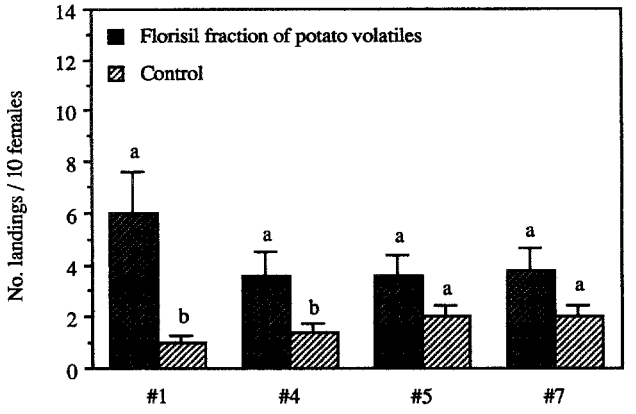

FIG. 2. Response of *Macrocentrus grandii* females to Florisil fractions of potato volatiles. Number of females tested in each assay was 50. Treatments with different letters within the same fraction are significantly different ($P < 0.05$). Comparisons cannot be made across fractions since each fraction was bioassayed in a separate test.

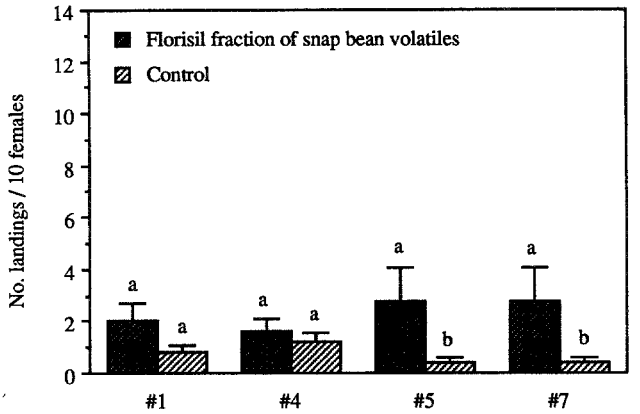

FIG. 3. Response of *Macrocentrus grandii* females to Florisil fractions of snap bean volatiles. Number of females tested in each assay was 50. Treatments with different letters within the same fraction are significantly different ($P < 0.05$). Comparisons cannot be made across fractions since each fraction was bioassayed in a separate test.

1 and $P = 0.0014$ (Figure 3). The difference between the landings on the wick containing fraction 5 with the landings on the control wick was significant ($z = 2.6$; $P = 0.009$). The difference in number of landings containing fraction 7 compared to the control was also significant ($z = 2.57$; $P = 0.01$).

DISCUSSION

Plant odors contain numerous compounds including many that are common among different plants and some that are unique to a plant. Common compounds include green-leaf volatiles, which are six-carbon alcohols, aldehydes, and esters present in varying ratios in different plant species (Visser et al., 1979; Dickens, 1989; Whitman and Eller, 1990). In earlier studies, compounds known to be present in plants were obtained from commercial sources and parasitoid attraction to these compounds was tested. Read et al. (1970) observed that the parasitoid *Diaretiella brassicae* was attracted to allyl isothiocyanate present in cruciferous plants, while Camors and Payne (1972) determined that parasitoids of bark beetles were attracted to α-pinene present in pines. However, a parasitoid could be attracted to more than one compound present in an attractive plant odor. Whitman and Eller (1990) and Ramachandran and Norris (1991) observed that parasitoids were attracted to several green-leaf volatiles obtained from commercial sources. They did not study attraction of these parasitoids to compounds that are unique to specific food plants of their hosts. For a parasitoid, a particular blend of commonly occurring and unique compounds may be critical for attraction. Hence analysis of plant synomones that play a role in plant–parasitoid interactions requires systematic isolation, identification, separation and bioassay of plant compounds.

In the present study, a systematic approach to analyzing plant synomones involved in habitat location behavior of *M. grandii* was attempted by initial isolation and identification of corn volatiles. The isolated volatile extract of corn appeared to contain at least 21 compounds that included six-and seven-carbon compounds and sesquiterpenes. Sesquiterpenes are 15-carbon compounds that are fragrant and present in the essential oils of several plants. Eleven sesquiterpenes were present in corn, of which the identities of five were established. The mass spectra of the remaining sesquiterpenes are very similar to spectra of several sesquiterpenes, but other sophisticated techniques will be required to establish their identities. Sesquiterpenes were present in minor quantities ($< 2\%$) except for β-caryophyllene (18%) and cyclosativene (27.7%). The six-carbon alcohols, esters, and aldehydes identified in corn are green-leaf volatiles common in plants. These compounds were present in varying amounts ranging from 1.0% to 12.4%. Ketones present in corn included 4-hepten-2-one (2.9%), which is unique to corn (Buttery and Ling, 1984), and 2-heptanone (6.9%).

Techniques used for collection and isolation of corn volatiles in the present study were similar to those used by Buttery and Ling (1984). They reported the presence of 24 compounds from leaves of Bonanza and Stylepak cultivars of corn that included 13 compounds that we obtained from Jubilee. In addition they obtained 2-methyl-2-pentanal, (*E*)-2-nonenal, myrcene, limonene, linalool, α- and β-copaene, (*E*)-β-farnesene, α-muurolene, methyl salicylate, and an

unidentified sesquiterpene. These compounds may have been present in Jubilee in low quantities. However, they did not find 2-heptanol acetate and α-humulene (also known as α-caryophyllene), which we obtained from Jubilee. We also obtained 11 sesquiterpenes, whereas they reported nine in their extracts. These differences in volatile profiles could be because different cultivars were used.

Our results differ from those of Turlings et al. (1991), who reported that significant quantities of volatiles were obtained only when corn plants were damaged by insects. They obtained (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*-3-hexen-1-ol, and (*Z*)-3-hexen-1-yl acetate from corn seedlings of Ioana cultivar only after the plants were damaged by beet armyworm larvae. However, we found these compounds in corn plants that were not damaged by insects. Concentrations of these compounds in the present study were similar to those reported by Turlings et al. (1991), except for (*Z*)-3-hexen-1-yl-acetate, of which they obtained 12–20%. (*E*)-Nerolidol, α-*trans*-bergamotene, (*E*)-β-farnesene, linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene reported from Ioana were not observed in Jubilee in the present study. These compounds may be specific to the cultivar or age of plants used by Turlings et al. (1991). Alternatively, they may be insect-induced compounds. However, linalool and (*E*)-β-farnesene were also reported by Buttery and Ling (1984) from plants undamaged by insects.

Column separation on Florisil provided a simple method of separating compounds into groups based on their polarity. All 11 sesquiterpenes were collected in fraction 1, which was eluted with pentane. Esters were collected in fraction 4 eluted with 92.5% P + 7.5% E, aldehydes and ketones were eluted with 92.5% P + 7.5% E or 90% P + 10% E and collected in fractions 4 and 5, while alcohols were eluted with 50% P + 50% E and collected in fraction 7 (Table 2). Adequate separation was achieved for all compounds except (*Z*)-3-hexen-1-yl acetate and 2-heptanone. (*Z*)-3-Hexen-1-yl acetate was collected in fraction 4 but minor quantities of the ester were also present in fraction 5. The ketone 2-heptanone was eluted with 90% P + 10% E with minor quantities in the fraction eluted with 92.5% P + 7.5% E.

Wind-tunnel bioassays of the Florisil fractions made it was possible to identify components of corn odor that are critical for attraction of *M. grandii*. Fraction 1, which contained nonpolar compounds, elicited the greatest response. Few or all of the 11 sesquiterpenes present in this fraction may be critical for attraction of *M. grandii* to corn odor. Fraction 4 was also attractive while fractions 5 and 7 were not. Fraction 4 contained five compounds of which 2-heptanone and (*Z*)-3-hexen-1-yl acetate may not be attractive, since these were also present in fraction 5, which did not elicit positive responses in *M. grandii*. However, the concentration of a compound could be critical for attraction of a parasitoid, and these compounds may attract *M. grandii* at concentrations present in fraction 4. The compounds 2-hexenal and 4-hepten-2-one, which were present

in fraction 5 do not appear to be attractive to *M. grandii*. Alcohols present in fraction 7 were also not attractive.

More than one fraction was attractive, indicating that more than one class of compounds can elicit oriented flight behavior in *M. grandii*. The fraction containing sesquiterpenes was most attractive, which suggests that the compounds present in this fraction may play a major role in parasitoid attraction to corn plants. Further separation is required to determine whether all compounds in this fraction are attractive to *M. grandii*.

Turlings et al. (1991) used a similar approach and identified 11 compounds in corn damaged by beet armyworm. They documented that a blend of synthetic versions of these 11 compounds was attractive to the parasitoid *Cotesia marginiventris*. However, their study did not indicate whether all 11 compounds were essential for parasitoid attraction. In the present study, certain components of plant odor were not involved in parasitoid attraction. Elzen et al. (1984) observed that, in a Petri dish Y-tube bioassay, the parasitoid *Campoletis sonorensis* was attracted to five of six sesquiterpenes isolated from cotton. In a study by Sugimoto et al. (1988), ether-soluble components of volatiles of *Ranunculus glaber* were attractive to the parasitoid *Dapsilarthra rufiventris* in a Y-tube olfactometer. No information on flight responses to plant compounds were reported in these studies. The present study is the first to document positive flight responses of a parasitoid to isolated fractions of plant odor.

Parasitoids of polyphagous hosts are likely to be attracted to several food plants of their host. In a previous study, we documented that, besides corn, *M. grandii* was attracted to volatiles of potato and snap bean. Attraction to these plants could be based on the presence of compounds similar to those attractive in corn, or different compounds could be involved. The attraction to snap bean could be because the same attractive compounds were present in low concentrations, or attraction to snap bean could be based on different compounds that are less attractive to *M. grandii*.

In the present study, separation by column chromatography indicated that extracts of potato and snap bean contain volatiles that belong to the same four classes of compounds as those present in the volatile extract of corn. When potato fractions were bioassayed, *M. grandii* was attracted to fractions 1 and 4. Compounds in these fractions were not identified. However, based on column chromatography of corn, these fractions are likely to contain nonpolar and slightly polar compounds, respectively. These classes of compounds in corn were also attractive. This suggests that attraction to potato and corn are based on similar compounds. Fractions 5 and 7, which were not attractive in corn, were also not attractive in potato. When snap bean fractions were bioassayed, *M. grandii* responded positively to the more polar fractions 5 and 7 but not to fractions 1 and 4. Attraction to snap bean odor appears to be based on classes of compounds different from those responsible for attraction to corn or potato odor.

Preliminary gas chromatographic–mass spectral analysis (data not included) indicates the presence of several sesquiterpenes in potato extract. These are likely to have been eluted in fraction 1, which was attractive to *M. grandii*. This suggests that sesquiterpenes are responsible for attraction to potato odor. Snap bean extract did not appear to contain sesquiterpenes in significant amounts. This would explain lack of attraction to fraction 1 of snap bean. Detailed analysis of compounds in fractions 1 and 4 of potato and fractions 5 and 7 of snap bean are required to determine the identity of compounds in these plants responsible for attraction by *M. grandii*.

CONCLUSIONS

Parasitoids exhibit diverse responses to plants based on the chemical composition of plant odor. In an earlier study, we provided evidence that *M. grandii* exhibits differential flight response to odor of food plants of its European corn borer host. Whereas it exhibits positive responses to odors of corn, potato, and snap bean, its response to pepper is neutral and its response to soybean is slightly negative.

The present study documents that attractive components of corn, potato, and snap bean odors are extractable with pentane and can be isolated using Tenax. For each attractive extract, more than one fraction elicited positive responses, indicating that attraction is not based on a single attractive compound. An interesting result was that among attractive plants, different classes of compounds were responsible for eliciting positive responses in *M. grandii*. This indicates that location of food plants of its host is a complex process where foraging parasitoids select and respond to diverse classes of plant compounds. Plant odors thus influence attraction of a parasitoid to a particular plant where hosts are likely to be present.

Information on the chemical basis of a parasitoid's attraction to plant odors may be used for manipulation of its behavior toward increasing its efficiency in the field. While European corn borer is polyphagous, *M. grandii* has not been reported parasitizing it in diverse habitats. Absence of attractive compounds in certain plant odors could be the basis for lack of attraction to a plant despite the presence of hosts. Chemical cues for orientation of *M. grandii* are absent in pepper and soybean, and European corn borers are likely to escape parasitism when present in these plants. However, other plants that are not hosts of European corn borers may possess compounds that are critical for attraction of *M. grandii* from a distance. Intercropping these plants with pepper and soybean may increase parasitism of European corn borers in these habitats. Alternatively, attractive plant extracts may be useful in increasing parasitoid efficiency. In studies by Altieri et al. (1982) and Nordlund et al. (1985) application of plant

extracts in the field resulted in increased parasitism. By provision of attractive plant compounds, it may be possible to introduce *M. grandii* to less attractive habitats like those of pepper and soybean.

Acknowledgments—We are grateful to Bill Miller and to two anonymous reviewers for critical review of the manuscript. Kinley Larntz assisted with statistical analysis while Tom Krick, Dave Baloga, and LeEtta Jarvis helped with identification of compounds. Paul Swedenborg provided invaluable assistance, and Rebecca Melton maintained the insect colonies. The research was conducted by S.U. as part of the requirements for a PhD degree. It was supported by funds from the Minnesota Agricultural Experiment Station, University of Minnesota, and a Doctoral Dissertation Fellowship from the Graduate School to S.U. Paper #19778, Scientific Journal Series, Minnesota Agricultural Experiment Station, University of Minnesota, St. Paul, Minnesota 55108.

INHIBITION OF SCOTS PINE SEEDLING ESTABLISHMENT BY *Empetrum hermaphroditum*

MARIE-CHARLOTTE NILSSON* and OLLE ZACKRISSON

Swedish University of Agricultural Sciences
Faculty of Forestry, Department of Forest Vegetation Ecology
S-901 83 Umeå, Sweden

(Received March 2, 1992; accepted June 11, 1992)

Abstract—Poor establishment and reduced seedling growth of Scots pine (*Pinus silvestris* L.) in northern Sweden is related to an allelopathic inhibition by the dwarf shrub *Empetrum hermaphroditum* Hagerup. Indoor bioassays with green and brown leaves of *Empetrum* have strong negative effects on rooting ability, radicle elongation, and growth of Scots pine seedlings. Bioassays with soil samples show that phytotoxic substances leached from *Empetrum* foliage accumulate in the soil. Field experiments reveal that chemical inhibition by *Empetrum*, causing high mortality and slow growth of pine seedlings, can be reduced by adding activated carbon to the soil.

Key Words—Allelopathy, *Pinus silvestris*, *Empetrum hermaphroditum*, succession, regeneration failures, soil toxicity, activated carbon, forest fires.

INTRODUCTION

Empetrum hermaphroditum Hagerup is a 5- to 15-cm-high evergreen dwarf shrub forming extensive clones in postfire successions on acid mor humus soils with high C/N ratios in northern Scandinavia (Haapasaari, 1988; Odell and Drakenberg, 1991). Regeneration of Scots pine (*Pinus silvestris* L.) from seed trees and from planting operations on clear-cut areas dominated by *Empetrum* have often been unsuccessful (Arnborg, 1943; Malmström, 1949; Sarvas, 1950; Ebeling, 1979; Hagner, 1984). Traditional interpretations of these regeneration problems and slow growth have focused mostly on harsh climate, unfavorable soils, and dense plant cover. Recently, the possibility of chemical inhibition by *Empetrum* has been suggested (Zackrisson and Nilsson, 1992). *Empetrum* leaves

were found to possess glands that are responsible for the production of water-soluble toxins easily leached out by rain. Chemical identification revealed that 3-methoxy-5,3′-dihydroxy, dihydrostilbene, or batatasin III (B-III) is one substance in water extracts of *Empetrum* that strongly inhibits seed germination under controlled indoor conditions (Odén et al., 1992). In this paper we have assessed the allelopathic potential of *Empetrum* on early seedling growth of Scots pine in both field experiments and indoor bioassays.

METHODS AND MATERIALS

Green leaves of living *Empetrum* were collected during late autumn at Rovågern (63°50′N), air-dried at 20°C, and stored at −18°C before use in the bioassays. A stock 5% solution of aqueous extract was prepared by soaking 50 g of dry green leaves in 1 liter of distilled water while slowly stirring for 48 hr. One leaf is about 3 × 7 mm and has a dry weight of 0.4 mg. The extract was filtered (Munktell No. 3 filter paper) to yield a clear, yellowish brown solution with a characteristic odor. The solution had an osmotic potential of 43 mmol/kg and a pH of 4.2. Scots pine seeds (Skaholma, 66°99′N, half-sib seeds with a viability of 92%) were used in all experiments, unless otherwise noted.

Analysis of Data

Variation among treatments was tested with analysis of variance or Student's t test. Tukey's multiple a posteriori range test and the least significant difference (LSD) (Sokal and Rohlf, 1981) were used to determine significant ($P \leq 0.05$) differences between treatments.

Experiment 1. Bioassays of Aqueous Leaf Extracts

Method 1. Empetrum extract (2 ml of 5% solution) was placed into 50-mm-diameter Petri dishes lined with a sheet of filter paper (Munktell No. 3). In seven replicate dishes for each treatment, seven seeds with a pregerminated radicle of 1 mm were exposed to the extract or to distilled water controls for 7, 19, 25, 48, 72, or 240 hr, and then rinsed in distilled water and transferred to Petri dishes lined with filter paper and containing 2 ml of distilled water. Petri dishes were maintained in a growth chamber under 20 hr illumination at 20°C. The length of the radicle and, later, total seedling length (root plus hypocotyl) were measured daily with a digital ruler.

Method 2. Scots pine seeds were germinated on moist, oven-sterilized (130°C, 12 hr) industrial quartz sand (Silversand 90) in the greenhouse. After 12 days, one seedling was transferred to each of 80 0.1-liter plastic pots containing sterile sand watered to field capacity, and placed in the greenhouse under

18 hr illumination and alternating temperatures of 20°C (day) and 15°C (night). All pots were watered every second day with a complete nutrient solution (5 mg NH_4-N/liter) recommended by Ingestad (1979). Twenty days after transfer, 4 ml of three concentrations (5%, 2.5%, and 1.25%) of aqueous extracts of *Empetrum* or distilled water was given twice a week. Seedling height, measured to the longest primary or secondary needle, and mortality were recorded at the start of the treatments and every fifth day thereafter. At harvest after 46 days of treatment, sand was rinsed off the roots, seedlings were dried at 70°C for 72 hr, dry weights of shoots and roots were determined separately, and root growth characteristics were recorded. All extracts were kept at 2°C during the experiment. Each treatment was replicated 20 times.

Experiment 2. Bioassays of Empetrum *Leaves*

Method 1. Scots pine seeds were germinated on industrial quartz sand watered to field capacity with distilled water in 10 90-mm-diameter 0.7-liter plastic pots. When seedlings reached 10 mm in height, they were thinned to 20 seedlings per pot. Then, 3.0 g of air-dried green leaves of *Empetrum* was added to five pots and 3.0 g of dry commercial greenhouse peat (unlimed, unfertilized and finely ground) was added to five pots as a control. Pots were misted several times a day with tapwater to maintain a high moisture level. On days 4, 7, 11, 14, and 17, seedling height and mortality were recorded. After 17 days of treatment, sand was rinsed off the roots, the seedlings were dried at 70°C for 72 hr, and the main root length and dry weights of shoots and roots were determined.

Method 2. Scots pine seeds were pregerminated in distilled water. When a radicle of 1 mm emerged, 10 seeds were carefully transferred, without changing their orientation, onto each of five replicate 0.7-liter pots containing moistened quartz sand and either 0.48, 0.12, 0.06 g or no dry green leaves and 3 g peat on the surface. Plastic bags allowing airflow were placed over the pots to maintain the moisture level. When the radicle penetrated the substrate and the hypocotyl grew above the substrate, the seedling was considered rooted.

Method 3. Green leaves and brown leaves, still connected to the three-year shoots, were removed and air-dried at 20°C. Ten Scots pine seeds, pregerminated in distilled water with a radicle of 1 mm length, were transferred to 60-mm-diameter 0.15-liter plastic pots half-filled with sterile quartz sand and 2 g of one of the following substrates on top: (1) green leaves, (2) brown leaves, (3) a control of soaked green leaves, (4) a control of soaked brown leaves and (5) peat. "Soaked" leaves were 25 g leaves in 1 liter of distilled water, repeatedly changed during eight days, to detoxify the leaves, yet maintain physical similarity in surface structure of the seed beds. As this experiment was intended to simulate leaves and litter exposed to natural wet conditions (heavy rainfall or

snow meltwater), the leaves and peat were soaked in 10 ml of distilled water for 48 hr before transfer to the pots. Ten replicates of each treatment were sealed with parafilm to maintain uniform moisture and placed in a climate chamber at 20°C and with 20 hr illumination. The numbers of rooted seedlings and seedling mortality were recorded daily for five days, after which the experiment was terminated and total length of seedlings (root plus hypocotyl) was measured.

Experiment 3. Bioassay of Freshly Collected Soil

To investigate the accumulation of phytotoxins in soils, six replicate soil samples were taken beneath a homogeneous clone of *Empetrum* at the Akkanålke field site (lat 65°40′N) in May, August, and October 1990, May and July 1991, and in May 1992. There were no trees, or ground layer of mosses or lichens at the sampling site. The sampling in May 1991 and May 1992 coincides with recent snow melt on frozen soil, but in May 1990 the frozen soil had thawed during unseasonably warm weather. Each sample included a complete humus soil profile plus the uppermost mineral soil (A00–A2) (Rieger, 1983). A similar fine-textured leached moraine soil (A2 horizon), where plant cover and humus had been removed three years earlier, was sampled nearby as a control. Soil samples were transferred to plastic bags and immediately transported at 2°C to the laboratory, where each sample was separated into A00 (litter), A1 (humus), and A2 (leached mineral soil) portions. The uppermost 0.5 cm of each layer was transferred to 50-mm-diameter Petri dishes. Industrial quartz sand was used as an additional control substrate in the bioassay. Fifty aspen (*Populus tremula* L.) seeds were sown on the soil in each dish because aspen germinates more quickly than pine, and a quick germination response is needed when diminishing levels of toxins are expected in samples brought indoors. The dishes were sealed with parafilm and placed in a growth chamber. Seed germination was recorded for seven days. Six replicates per treatment were used.

Experiment 4. Field Experiment

Three field sites on acid mor humus soils with cover dominated by *Empetrum* were selected at Akkanålke (65°40′N, 700 m asl), Kiutisvaara (67°30′N, 300 m asl), and Salmisjärvi (68°15′N, 430 m asl) in northern Sweden. At each site 40 level plots (0.75 × 0.75 m) were selected where *Empetrum* cover was about 80% and no mosses, lichens, or trees were present. On 20 randomly chosen plots, 280 g of fine-powdered (pro analysi) activated carbon (Labasco) was added (Zackrisson and Nilsson, 1992). In the central part of each plot, 100 seeds of Scots pine were sown in a 60 × 60-cm plastic exclosure with 10 mm mesh, at Akkanålke and Kiutisvaara in May 1988 and at Salmisjärvi in May 1989. Additional amounts of activated carbon were applied in the springs of 1988 (140 g/plot), 1989 (70 g/plot), and 1990 (45 g/plot). Germination, and

the survival and the stage of development of emerged seedlings were counted two to four times a year during 1988–1991. Seedling height to the apical bud was measured in September 1991.

Experiment 5. Bioassays of Activated Carbon

Method 1. To determine the effect of activated carbon on seed germination of Scots pine, 20 g of industrial quartz sand or 2.5 g of well-decomposed humus were added to 10 50-mm-diameter Petri dishes. One gram of fine-powdered activated carbon was added to five dishes, each filled with sand and humus. Each dish was watered to field capacity with distilled water and 50 Scots pine seeds were sown. When radicles reached seed length, they were counted as germinated and removed from the dishes daily until there was no further germination.

Method 2. Ten Scots pine seeds germinating on wet industrial quartz sand in the greenhouse were transferred when seedlings reached 10 mm length into each of 10 plastic pots filled with wet sand. Five grams of activated carbon (equivalent to field applications) was added to the sand surface of five pots. Shoot heights of the seedlings were measured every third day until termination at day 28, when shoot height and main root length were measured.

RESULTS

Experiment 1

Growth of germinating seedlings exposed to the 5% aqueous extract of *Empetrum* was significantly inhibited compared to controls exposed to distilled water (Figure 1). Degree of inhibition increased with time of exposure. Although exposed seedlings grew, inhibition after exposure was persistent and growth as a percent of control continued to decline. Seedlings continuously exposed or exposed 48 hr or 72 hr almost stopped growing—an indication of severe physiological damage. In addition, *Empetrum* aqueous extract significantly decreased growth of pine seedlings when application of extracts was initiated after depletion of the cotyledonary reserves (Table 1). As *Empetrum* extract concentration increased, mean dry weight of seedlings and elongation of roots decreased. In the 5% treatment, seedlings started to lose turgor after six days of treatment, and mortality reached 10% at day 22 of treatment, 40% at day 31, and 100% by day 46. Other treatments exhibited little mortality. Seedlings exposed to *Empetrum* extract had dark, discolored primary roots and strongly reduced side roots, chiefly occurring near the pot bottoms. The abnormalities appeared to be related to extract concentration.

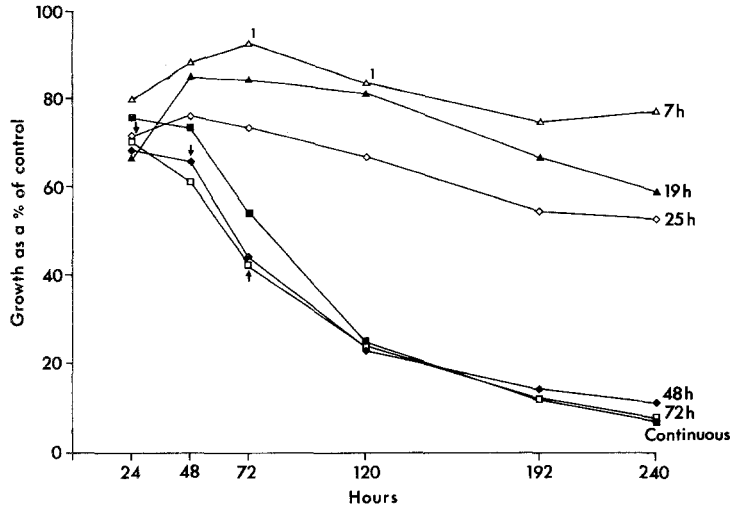

FIG. 1. Radicle growth as a percent of controls of Scots pine germinating seedlings exposed to 5% aqueous extract of *Empetrum* leaves for different times. All growth reductions are statistically different from controls except for the dots marked with "one." Arrows indicate when exposure to *Empetrum* ended.

TABLE 1. MEAN AND ± SE FOR SCOTS PINE SEEDLINGS AFTER 46 DAYS OF EXPOSURE TO DIFFERENT CONCENTRATIONS OF AQUEOUS LEAF EXTRACT OF *Empetrum* OR DISTILLED WATER CONTROLS[a]

	Empetrum treatment			
	1.25%	2.50%	5%	Control
Shoot height (mm)	44.4 ± 1.5a	41.1 ± 1.8a	41.8 ± 1.2a	46.4 ± 1.2a
Shoot weight (mg)	13.8 ± 0.8a	13.2 ± 0.7a	7.3 ± 0.4b	19.5 ± 1.0c
Root weight (mg)	15.6 ± 1.9a	10.0 ± 0.9b	2.6 ± 0.2c	20.1 ± 2.2d
Shoot-root ratio	1.2a	1.5a	3.2b	1.1a
Total weight (mg)	29.4 ± 2.4a	23.2 ± 1.4b	9.8 ± 0.4c	39.6 ± 3.1d
Main root length (mm)	110.8 ± 7.6a	102.9 ± 23.3a	56.6 ± 2.6b	121.2 ± 8.0a
Mortality (% of control)	5	0	100	0

[a] Values are means of 20 seedlings. Values in a row followed by the different letters are significantly different at $P \leq 0.05$ in Tukey's multiple range test.

TABLE 2. MEAN AND ± SE OF DRY WEIGHT OF SHOOTS AND ROOTS, SHOOT LENGTHS, ROOT LENGTHS, AND MORTALITY OF SCOTS PINE SEEDLINGS GROWN IN CONTACT WITH 3.0 GRAMS OF GREEN LEAVES OF *Empetrum* OR PEAT (CONTROL)[a]

	Treatment	
	Empetrum	Control
Shoot weight (mg)	129.6 ± 2.2[b]	229.8 ± 4.5
Root weight (mg)	30.4 ± 7.4[b]	72.0 ± 1.2
Shoot–root ratio	4.7 ± 0.5	3.2 ± 0.1
Shoot length (mm)	31.8 ± 0.7[b]	35.0 ± 0.5
Main root length (mm)	44.8 ± 2.9[b]	88.5 ± 1.8
Mortality (%)	57.6[b]	12.8

[b] Significantly different from control at $P \leq 0.05$.

Experiment 2

In the first bioassay of *Empetrum* leaves, seedlings grown with air dried green *Empetrum* leaves had significantly higher mortality (58%) than the control (13%) (Table 2). Surviving seedlings in the *Empetrum* treatment had dry weights of shoots and roots and lengths of main roots about half those in the control (Table 2). Differences in shoot length were less exaggerated. A higher shoot–root ratio was also observed for *Empetrum* treated seedlings. Seedlings in the *Empetrum* treatment had dark-colored, dwarfed root systems whereas control seedlings were light-colored and healthy.

In the second bioassay of *Empetrum* leaves, rooting of pregerminated Scots pine seeds was inversely related to leaf weights in pots even after one day of treatment (Figure 2). In the 0.48-g treatment most radicles were stunted and died before rooting. Convergence of the treated seedlings over time is due to mortality. Variation in number of rooted seedlings is explained by mortality and delayed rooting.

In the third bioassay of *Empetrum* leaves, rooting of germinating Scots pine seedlings was shown to be severely affected by green leaves of *Empetrum* (Figure 3). Brown leaves also strongly inhibited the rooting. Soaked green and brown leaves revealed lower inhibition than the respective unsoaked leaves, although all treatments caused statistically significant growth reductions compared to the control. Mortality of germlings was 100% in the green leaf treatment, but they grew in the other treatments.

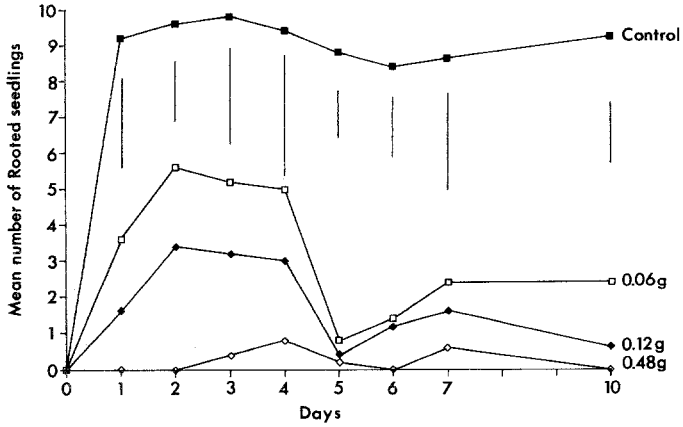

FIG. 2. Rooting ability of pregerminated Scots pine seeds grown in pots with different quantities of green leaves of *Empetrum* or peat (control). Vertical bars give the least significant differences (LSD) among treatments.

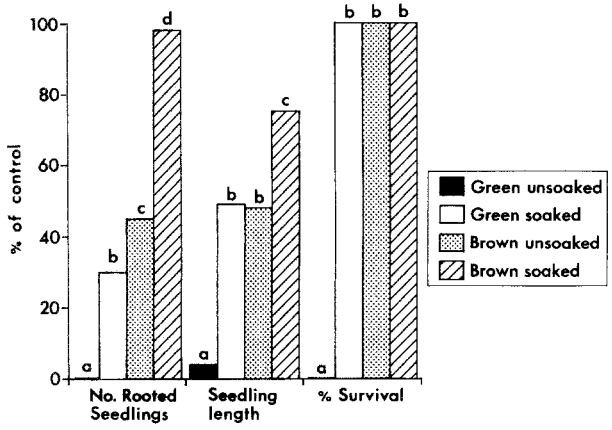

FIG. 3. Rooting ability and seedling length (root plus hypocotyl) of pregerminated Scots pine seeds grown in contact with soaked and unsoaked green and brown leaves of *Empetrum* during five days of treatment. Bars topped with the same letter do not differ significantly in Tukey's multiple-range test.

Experiment 3

Seed germination of aspen on different layers (A00, A1, A2) of *Empetrum* mor humus showed that inhibition was strongest during May 1991 and May 1992, and generally increased with depth in the soil profile from the litter layer

(A00) to the leached mineral soil (A2) (Figure 4). The mineral soil (A2) sampled from the soil uncovered with humus and the industrial quartz sand (data not shown) had no inhibitory effect on seed germination.

Experiment 4

A significantly smaller number of Scots pine seeds germinated and fewer seedlings became established in untreated *Empetrum* vegetation compared with the activated carbon-treated vegetation at all three field sites (Table 3). Ger-

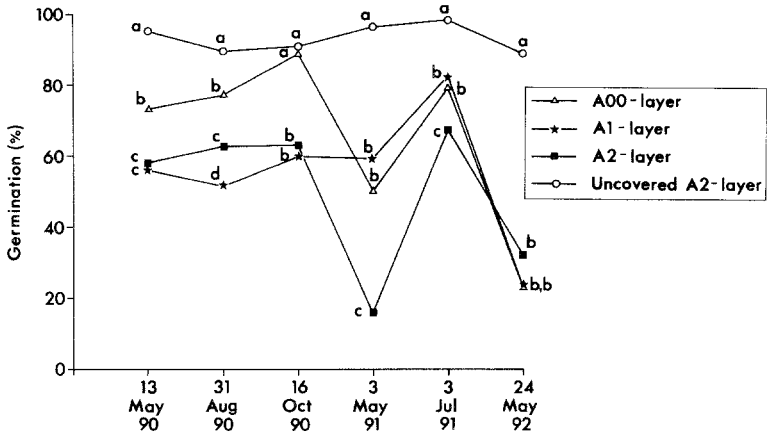

FIG. 4. Seed germination of aspen in soil collected at different depths and at different times in natural *Empetrum* vegetation. Means on the same date followed by the same letters do not differ in Tukey's multiple-range test.

TABLE 3. SEED GERMINATION, SURVIVAL, AND GROWTH OF 2000 SCOTS PINE PER PLOT IN UNTREATED AND ACTIVATED (A) CARBON-TREATED *Empetrum* VEGETATION AT THREE FIELD SITES IN INTERIOR NORTHERN SWEDEN, 1988–1991[a]

Site	Treatment	Germination observed (%)	Surviving in September 1991 (%)	Seedling height (mm) in September 1991 (Mean ± SE)
Akkanålke	Untreated	36.6[a]	11.4	39.7 ± 0.4[a]
	A carbon	52.2	15.0	45.7 ± 0.7
Kiutisvaara	Untreated	21.3[a]	3.1[a]	36.3 ± 1.0[a]
	A carbon	35.9	12.4	39.6 ± 0.7
Salmisjärvi	Untreated	11.0[a]	1.0[a]	43.9 ± 1.4
	A carbon	45.3	6.8	49.1 ± 1.0

[a]Significantly different from plots treated with activated carbon at $P \leq 0.05$ level.

mination was also delayed and seedlings grew more slowly in the untreated plots compared to the carbon-treated plots during the first season (data not shown). Seedling survival and seedling height were significantly higher in activated carbon-treated plots at the end of the experiment. Seedling density was compared to seedling height in order to check for interspecific competition in the plots, but no correlations were found.

Experiment 5

Activated carbon alone did not have any positive effect on seed germination. No differences in seed germination were evident between seeds grown in humus (96.8%), sand (96.8%), humus treated with carbon (99.2%), or sand treated with carbon (99.6%). There were also no differences in the rate of germination among the treatments (data not shown). For seedlings in pots, shoot height did not show any significant differences when grown in sand (39.1 $\pm$ 0.7 mm) or in sand treated with activated carbon (36.7 $\pm$ 0.7 mm). Main root lengths were 38.5 $\pm$ 1.4 mm and 39.2 $\pm$ 1.4 mm, respectively.

DISCUSSION

Indoor bioassays showed strongly increased mortality and reduced growth of Scots pine seedlings when grown in pots together with green or brown leaves of *Empetrum*, or when watered with different dosages of aqueous leaf extracts. Water-soluble phytotoxins may be leached from leaves of *Empetrum* and taken up by the developing radicle and primary roots, leading to stagnant growth and high mortality. The different results of growth and rooting ability between germinating seedlings grown in contact with soaked and unsoaked leaves could not be attributed to physical dissimilarities of the seed bed. Soaked leaves are probably less inhibitory than unsoaked leaves because allelochemicals were leached from the former during soaking. Soaking, however, did not totally reduce the inhibitory effect, indicating that all toxins are not easily washed away despite repeated soaking in large quantities of water. Compared to green leaves, brown leaves were also less inhibitory to rooting ability.

When a seed lands on the upper soil surface in an *Empetrum*-dominated microhabitat, it comes in direct contact with newly fallen toxic litter and is exposed to phytotoxins released from the green foliage of *Empetrum* by rain and snowmelt water. During the imbibition process, the seeds absorb water, and if the water contains toxins from *Empetrum*, the germination will be delayed or totally inhibited, depending on the toxin concentrations (Zackrisson and Nilsson, 1992). Before rooting occurs, the early radicle may be exposed in the same way. In this paper we have shown that very short exposure times of germinating seedlings to aqueous leaf extracts of *Empetrum* have a persistent inhibitory effect

on radicle growth. Osmotic pressure or pH in extracts are not responsible for the observed inhibition (unpublished data).

Our field data provide empirical evidence of a possible allelopathic inhibition by *Empetrum* on Scots pine. The treatments used in the field studies were designed to subject pine seeds and seedlings to the interference of *Empetrum*, without removing competitive influence, and to reveal possible allelopathic effects. Pine responded to this treatment by displaying significantly better establishment and growth when the phytotoxins were removed by activated carbon. The activated carbon will adsorb inhibiting substances produced by leaves and litter leached into the soil. The reduction in germination and lower seedling shoot growth is certainly due to chemical inhibition as the experimental design ruled out the possibilities that conditions of illumination, root competition, humidity, and nutritional conditions of the soil could differ between the two treatments. There is no reason to assume that seed or seedling predation would differ between the treatments. The activated carbon in itself does not contribute to any positive effects, as shown in our indoor bioassays.

Similarly, Eliasson (1959) showed that activated carbon, when present in a nutrient solution, did not stimulate the growth of wheat roots. Low amounts of activated carbon effectively detoxify aqueous extracts of *Empetrum* (Zackrisson and Nilsson, 1992). Smaller amounts than presently used in the field experiment are preferable in future studies, as an excess of carbon may retard growth of seedlings by blackening the photosynthetic tissues. Activated carbon can only be expected to detoxify substances originating from leaves and litter leaching into the soil. Toxins accumulated in the soil by *Empetrum* before the experiment started or through the decomposition process cannot be reduced by activated carbon on the surface. It was also found that germination and seedling growth were delayed in the untreated plots during the first growing season. This delay in growth probably also contributes to the lower total shoot height found after three (Salmisjärvi) and four growing periods (Akkanålke and Kiutisvaara). Indoor experiments with pine seeds also show that germination is delayed when exposed to low amounts of extracts (Zackrisson and Nilsson, 1992). Slow seedling growth in the first season (data not shown) may also cause a delay in the winter hardening process, giving rise to the increased mortality demonstrated in the untreated plots. Allelopathy could also cause seedlings to suffer from reduced mycorrhizal infection (Olsen et al., 1971; Brown and Mikola, 1974; Rose et al., 1983, Perry and Choquette, 1987; Coté and Thibault, 1988), which may inhibit the seedling's ability to compete for nutrients. No seedlings were harvested in our field experiments and conclusions could not be drawn about the below-ground effects of inhibition on pine root development. In the greenhouse experiment, however, we noted a greater negative impact of *Empetrum* on root growth than on shoot growth. Restricted root growth may result in mortality of seedlings due to desiccation. Desiccation interpreted in a wide sense is one of

the major causes of mortality registered during periods with spring and summer droughts.

The snowmelt water contains biologically inhibiting levels of toxins produced by *Empetrum* through the natural soaking of green vegetative parts and litter (Zackrisson and Nilsson, 1992). The accumulation of toxins in soil may be greatest during early spring when the snow has just melted, and ground ice still persists deep into the soil, preventing the snowmelt water from draining into the ground. The microbial detoxification in this situation is probably slow because of the low soil temperatures and anaerobic conditions. After the snow has melted away, the soil may remain frozen for weeks, as in May 1991 and 1992, when the toxicity level at all soil depths studied was high. In other years, such as May 1990, with hardly any frozen soil and rapid snowmelt (statistics from the Swedish Meteorological Institute), the water drained quickly into the soil and the threshold situation with persistently high toxin levels in the soil was probably very short. As pointed out by Jalal and Read (1983), Yoder-Williams and Parker (1987), Cast et al. (1990), and Molina et al. (1991), allelopathy could be operative in a specific environment only for a short period of the growing season or under specific environmental conditions. The most profound effects of pine seedling mortality are registered during the spring.

Allelopathic interference is one likely explanation of conifer seed regeneration failures found in *Empetrum*-dominated vegetation in northern Sweden. There are reasons to suspect that the substances leached from *Empetrum* could also affect more long-term growth of pine saplings. Martinsson (unpublished data) has shown that young coniferous forest stands established on *Empetrum*-dominated clear-cuts were less productive than nearby prescribed burned areas of the same age on sites previously influenced by *Empetrum*. *Empetrum* is fire sensitive and normally does not resprout vegetatively after burning. *Empetrum* is a slow seed recolonizer, and thus seldom reaches a dominance in the postfire forest floor vegetation before crown closure. After cutting without burning, *Empetrum* expands vegetatively and can form a dense field layer vegetation. In virgin pine stands, fire return intervals normally were short (Zackrisson, 1977, 1981), and *Empetrum* seldom reached the distribution and densities found today due to fire protection. Fire elimination will therefore indirectly contribute to the regeneration failures attributed to expansion of *Empetrum* vegetation.

Whether allelopathy is the major factor responsible for the regeneration problems described cannot be fully concluded from this study. However, regeneration failures and reduced growth under allelopathic influence of *Empetrum* may exacerbate an already stressful boreal environment. Although other environmental factors may contribute to regeneration failure, our study indicates allelopathy by *Empetrum* may be an important factor.

Acknowledgments—This project was funded by The Swedish Council of Forestry and Agricultural Research. We thank Anders Jäderlund, Gisela Norberg, and Anita Wennström for skillful field and laboratory assistance. We also owe Stephen B. Horsley many thanks for valuable methodological discussions over the years.

(Received December 20, 1991; accepted June 15, 1992)

Abstract—An earlier study of population genetics of an estuarine amphipod provided evidence from genomic DNA analysis for a habitat-specific race of amphipods within the species *Eogammarus confervicolus*. In some estuaries of the northeast Pacific, this race of amphipods exists sympatrically with other members of the species. Here we present evidence for a race-specific pheromone that appears to be the consequence of differential metabolism of the algae (*Fucus distichus* and *Pelvetia fastigiata*) characteristic of the habitat occupied by this race. The race-specific pheromone identified in this study is a subtle modification of an already existing communication system: females of the habitat-specific race produce the pheromone characteristic of the species as a whole but have an ability not shared by other females of the species to modify this pheromone when raised on the algal substrate characteristic of their habitat. Only males of this race make a distinction between the more specific pheromone and the species pheromone. The formation of hybrids (conceived and raised on the algal substrate) between members of the habitat-specific race and the other members of the species disrupted the ability to produce and distinguish the race-specific pheromone; hybrids still produced a pheromone, but it was indistinguishable from that produced by the species as a whole. Behavioral assays and the results of reciprocal, interpopulation crosses indicated pheromone response in males had evolved with production; males however, did not have to be raised on the algal substrate to respond to the alternate pheromone. No evidence for maternal effects or sex linkage were

detected in the results of the crosses; more specific indications of the genetics underlying pheromone production were not evident.

Key Words—*Eogammarus confervicolus*, crustacean pheromone, mate choice, ecological genetics, amphipod, estuarine crustacean, sympatric population subdivision, race formation.

INTRODUCTION

Information on the origin of ethological isolating mechanisms is important to an understanding of the speciation process. Differences in sex pheromone communication systems between closely related species, or within a species, are an example of such an ethological isolating mechanism. The manner in which chemical communication channels differentiate is thus of intrinsic interest. Relatively little is known about the genetics and evolution of invertebrate sex pheromone communication systems. Most of the information that is available comes from insect species (e.g., tussock moth: Grant et al., 1975; *Drosophila melanogaster:* Averhoff and Richardson, 1976; budworm moths: Sanders et al., 1977; sulfur butterfly: Grula and Taylor, 1979; European corn borer: Klun and Maini, 1979; Klun and Huettel, 1988). Although crustaceans are known to produce sex pheromones, there is little or no information on genetics and evolution of pheromones in this class of arthropods (see Dunham, 1978, for review). Sex pheromones in insects are thought to be important reproductive isolating mechanisms (see Cardé, 1986, for a review), and there are cases where pheromone polymorphisms have been implicated in sympatric diversification or at least in the maintenance of sympatric subdivided population structure (e.g., Sturgeon and Mitton, 1986; Klun and Huettel, 1988). Population polymorphisms have not been demonstrated in crustacean pheromones but there are well-documented cases in certain insect species (e.g., European corn borer, *Ostrinia nubilalis:* Klun and Maini, 1979; Roelofs, et al., 1987; Klun and Huettel, 1988; Pena et al., 1988; Bengtsson and Lofstedt, 1990). Behavioral assays suggesting species-specific differences in amphipod sex pheromones have been reported (Borowsky, 1985). Although the role of pheromone communication systems in speciation remains largely speculative, there is little doubt that pheromone differences are effective premating isolating mechanisms in many insect species and, thus, the development of a new chemical communication pathway in any species clearly has the potential to contribute to the speciation process.

Stanhope and Levings (1985), in a study of population dynamics of a gammarid amphipod, *Eogammarus confervicolus*, found that populations occupying three distinct habitat types (characterized by three distinct substrate types) within the same estuary had size frequency distributions that suggested they were not experiencing any significant interhabitat immigration and emmigration.

Two of the populations were separated by only 200 m of intertidal mud flat, the third by a distance of about 1.5 km. Gammarid amphipods are highly vagile marine organisms (e.g., Fincham, 1972; Kolding, 1981; Miller, 1984), and thus these populations can satisfactorily be considered sympatric. The population dynamics data (Stanhope and Levings, 1985), concomitant with direct behavioral observations, indicate that animals mate and reproduce within their respective environment types (i.e., periods where most individuals are engaged in amplexus, or pair formation, are followed by high juvenile numbers in size frequency distributions). More recently, Stanhope (1989) has provided evidence from genomic DNA analysis that the amphipods comprising one of these populations are members of a distinct race within the species *E. confervicolus;* although this race has a clearly distinct genotype, it is not as divergent as the only other taxonomically recognized species in this genus (*Eogammarus oclari*). Interpopulation and interracial hybrids can be readily formed in the laboratory (Stanhope, 1989). As part of a larger study designed to determine the factors responsible for maintaining the distinct character of these sympatric groups, we have undertaken a behavioral and ecological genetic study of mate choice in this amphipod species. The results provide evidence for a race-specific pheromone that appears to be the consequence of differential metabolism of the algae characteristic of the habitat occupied by this race.

METHODS AND MATERIALS

Species Description. Eogammarus confervicolus is the most abundant and widely distributed gammarid amphipod on the North American Pacific coast (Bousfield, 1979). It occurs intertidally and in the shallow subtidal regions of estuaries and protected shores that have brackish waters, among sedge, under various species of algae, woody debris, or stones. Its salinity tolerance is 5–25 parts per thousand (ppt); optimum is 5–10 ppt (Sharp, 1980). Gammarid amphipods graze on epiphytic fungi, bacteria, diatoms, and various macrophytes (Hargrave, 1970; Kostalos and Seymour, 1976; Sutcliffe et al., 1981), and there are many examples of marine, estuarine, and lotic amphipods exhibiting substrate preferences (e.g., Fenchel and Kolding, 1979; Stoner, 1980; Kneib, 1982; Williams and Moore, 1986; DeWitt, 1987). Many of these studies suggest that the choice is based on food preference (e.g., Williams and Moore, 1986; DeWitt, 1987).

Populations and Their Habitats. Three habitat types were included in this investigation: woody debris, a particular type of *Fucus distichus* community, and embankments along the perimeter of *Carex lyngbyei* marshes.

Logs have been stored in estuaries in British Columbia (and throughout the northeast Pacific) for 75–100 years. In areas where log booms ground at low

tide, the result is a mud flat devoid of macrophytes with accumulations of bark fragments in depressions along the surface. *Eogammarus confervicolus* can be found among such wood debris. Such areas are commonly about 2.0 m above mean low water.

The second principal habitat type was a mixture of two brown algae: *Fucus distichus* and *Pelvetia fastigiata* (hereinafter termed *Fucus*) overlying soft dark black mud smelling of hydrogen sulfide. The amphipods were found within the algal mixture and at the mud surface. This algal community usually occurs as relatively small patches (rarely exceeding 1 ha) in estuaries or quiet, brackish water bays at about 3.5 m above mean low water.

Many estuaries of the northeast Pacific possess deltas covered predominately with *Carex lyngbyei*. The perimeter of such a marsh is an embankment over which hangs a mat composed of sand, clay, and *C. lyngbyei* rhizomes (hereinafter termed bank) at about 2.0 m above mean low water. *Eogammarus confervicolus* can be found on the underside of this mat, mixed with the rhizomes of the marsh plant.

One of each of these habitat types exists in the Squamish River estuary, British Columbia. (Figure 1). Wood debris and *Fucus* habitats in the Squamish estuary are separated by only 200 m of mud flat, whereas the distance between bank and wood debris habitats is approximately 1.5 km, with a variety of physical obstructions in the middle of the estuary. The area of the *Fucus* habitat in the Squamish estuary is approximately 5000 m^2; the wood debris habitat exists over an area approximately 10 times the size of the *Fucus* habitat. Bank habitat exists along the perimeter of the central and east deltas as well as along the sides of the many channels running through both deltas.

The *Fucus* population in the Squamish estuary is univoltine and the other two are bivoltine. The bivoltine populations are reproductively synchronous, and the adult members of all three populations are reproductively active in the spring and summer months (Stanhope and Levings, 1985).

In order to test whether the trends observed in mate choice involving the Squamish *Fucus* population reflected a unique situation in this estuary or was a characteristic more broadly representative of this race, we investigated pheromone production and response in several other geographically proximal and removed *Fucus* populations. Two additional populations were sampled: a population in Howe Sound (southern British Columbia coast), about 4 km south of Squamish (i.e., the Squamish estuary is at the north end of Howe Sound, see Figure 1) and a population in an estuary in the Queen Charlotte Islands, approximately 750 km north of Squamish.

Mate Choice. Mate choice experiments were performed using a Y-tube apparatus designed by Borowsky (1984) for choice tests in another amphipod species (diagramed in Figure 2). The base of the Y was connected to a 2-liter bottle (termed by Borowsky the departure bottle) by plastic tubing (2 cm ID);

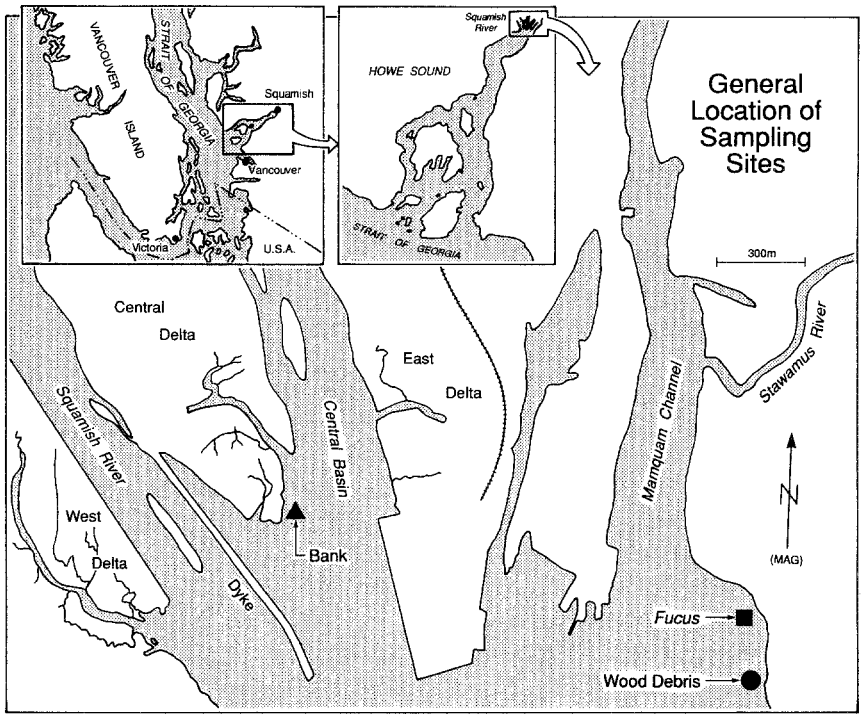

FIG. 1. Location and map of the Squamish estuary, showing the major physical features and the position of the three principal habitat types.

each of the arms of the Y were similarly connected to two additional 2-liter bottles (arrival bottles). The base and the arms of the Y were 25 cm long. Two further bottles (test chambers) were supported on a shelf slightly above the arrival bottles with plastic tubing stretching from an opening at their base into the mouths of the arrival bottles. Amphipods (30 individuals) whose secretions were to be tested were placed in these test chambers. The test chambers had fine mesh screen covering the opening at their base preventing amphipods from traveling through the tubing into the arrival bottles. Water at 10ppt and 10°C was passed into the test chambers "washing" the amphipods; their secretions thus traveled into the arrival bottles, on through the arms of the Y, into the base of the Y and finally into the departure bottle. A slight current was thus created in the direction of test chamber to departure bottle. Before each experiment, the appropriate individuals were placed in the test chambers and water was allowed to flow through the system for several hours. Water flow was then turned off, and the males concerned with a particular test were placed in the departure bottles. The top of this bottle was then covered with a fine mesh screen to

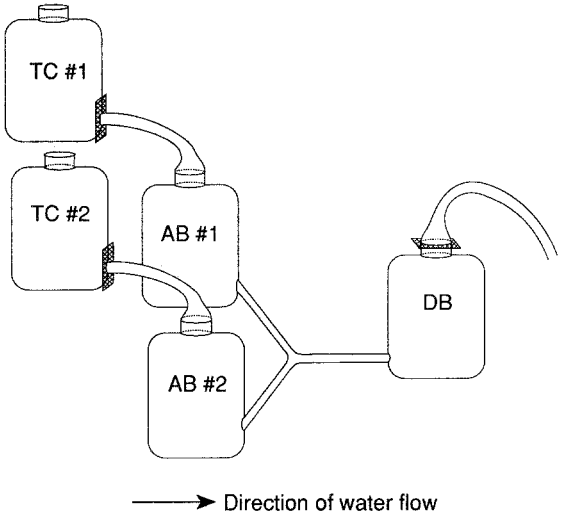

FIG. 2. Mate choice apparatus employed to test for differences in secretions of amphipods from the various populations, crosses, and manipulations. TC = test chamber; AB = arrival bottle; DB = departure bottle.

prevent males from escaping the system. A slight water current was then reapplied. Males could travel freely between the departure bottle and two arrival bottles. Five hours later, the number of males in each arrival bottle as well as those left in the departure bottle were noted. Thirty males were used for each replicate; the same individuals (male or female) were never used more than once. Chi-square was used in analysis and, since there was a single degree of freedom, Yates' correction for continuity was employed (i.e., absolute value of each deviation of observed frequency from expected frequency was reduced by 0.5) (Zar, 1974). To test whether individual replicates of particular experiments were homogeneous, we performed a heterogeneity chi-square analysis for each experiment (Zar, 1974). In those experiments where the replicates were judged homogeneous, the numbers were pooled in the final calculation of chi-square. The entire apparatus was disassembled and thoroughly washed between tests.

The first series of experiments were designed to test whether there was any preference of males for females from each of the three Squamish populations. The results of these tests led to some follow up experiments, designed to test whether the substrate on which the females were raised had any effect on male choice; in other words, could a particular pattern of mate choice be induced by environment? These reciprocal transplant experiments were performed in a series of laboratory 50-liter aquaria, each containing one of the three representative substrate types. The wood debris habitat simulation was simply a mixture of

wood chips overlying the sand–mud typical of that habitat. Bank substrate consisted of a layer of sand, several pieces of the rhizome mat, with additional bunches of entangled *Carex rhizomes*. *Fucus* substrate consisted of the algal mixture overlying a sand–mud mixture, without H_2S mud (i.e., H_2S mud eventually fouled the aquarium water). Aquarium water was kept well aerated and at 10°C and 10ppt. Water and substrate were changed regularly. Test animals for these transplant experiments were the offspring of wild-caught mating pairs. Amphipods in amplexus were collected from each of the respective locations and placed in the various laboratory transplant situations (including several control situations in which amphipods were raised in the laboratory simulation of their native habitat type); the offspring of these individuals, upon reaching reproductive maturity (first appearance in amplexus), were those used in the mate choice experiments.

Tests were then performed using amphipods from the other *Fucus* populations to see if the pattern observed for the *Fucus* Squamish population was unique to Squamish or was common to the race. Several tests were then performed on F_1s and F_2s of some select interpopulation hybrids. Parents for these crosses came from separating mating pairs in the respective estuarine habitats, or from laboratory maintained stocks. Stocks were maintained in a series of 50- or 200-liter aquaria, with the substrate type from which they arose. All crosses were established using approximately 50 pairs and were conducted in laboratory aquaria containing *Fucus* substrate (minus the H_2S mud). Females were held separately for a few weeks prior to crossing, in order to avoid any possible confusion due to an earlier fertilization. Hybrids were not only conceived but raised on *Fucus* substrate. Animals placed in test chambers were, for all the experiments, obtained by separating pairs joined in amplexus, whether they came from a laboratory culture or directly from the estuary. Most experiments had three replicates, each using different amphipods.

RESULTS

Sexually receptive females from all three Squamish populations produced some form of waterborne male attractant (Table 1); in controls without animals in the test chambers, most males never left the departure bottle (they were in the departure bottle at the end of the trial period and periodic checks of the apparatus indicated their presence throughout the test) and when only one chamber contained females, males were found in the arrival bottle fed from that chamber. Males did not produce an attractant.

Males from the Squamish bank and wood debris habitats were unable to make a distinction in the attractant produced by females arising from any of the three Squamish populations (Table 2, experiments 1–6). *Fucus* males, on the

[a]FSQ, BKSQ, and WDSQ refer to the Squamish *Fucus*, bank, and wood debris populations, respectively. Chi-square was calculated employing Yates' correction for continuity (because $df = 1$) except in those experiments where most amphipods were still in the departure bottle at the end of the trial period; in those particular situations the null hypothesis was: males were evenly distributed among the three possible chambers (i.e., two arrival bottles and the departure bottle) and thus $df = 2$. Replicates were judged homogeneous and thus pooled values are presented. N/A = not available; $***P < 0.0001$.

other hand, made distinct choices in favor of females from *Fucus* over any other females (Table 2, experiments 8 and 9) but would respond to females from the other two locations when not offered a choice (Table 2 experiments 7 and 10).

Males from the Squamish *Fucus* population showed no preference for Squamish *Fucus* females when the latter were raised on alternate substrates (Table 3, experiments 1, 2, 6, and 7); the females still produced an attractant, but the males did not distinguish it from that of the females native to the substrate upon which the amphipods had been raised (Table 3, experiments 1 and 2). *Fucus* males exercised a strong preference for native *Fucus* females over *Fucus* females raised on both bank and wood debris substrates (Table 3, experiments 6 and 7). These results suggest that the genotype of Squamish *Fucus* females alone is not solely responsible for the production of *Fucus* female pheromone. On the other hand, raising bank and wood debris females on *Fucus* substrate was not sufficient to induce their choice by *Fucus* males (Table 3, experiments 4 and 5). This, in turn, suggests that it is not simply the *Fucus* substrate that causes females to produce *Fucus* female pheromone. *Fucus* substrate alone did not appear to act as an attractant (Table 3, experiment 10), and *Fucus* females raised on wood debris substrate and then placed in the test chamber with *Fucus* substrate were indistinguishable from wood debris females (Table 3, experiment

[a] FSQ, BKSQ and WDSQ refer to the Squamish *Fucus*, bank, and wood debris populations respectively. Replicates are listed individually when they were judged to be heterogeneous, otherwise pooled values are presented. *$0.01 < P < 0.05$, ***$P < 0.0001$, ns = not significant.

11). Males collected directly from the *Fucus* habitat in the Squamish estuary and offered a choice of females raised in the laboratory-simulated *Fucus* habitat and females collected directly from the estuary made no distinction (Table 3, experiment 3), suggesting the laboratory habitats were accurately simulating the factor(s) responsible for differences in mate choice. Thus, both the *Fucus* genotype and the *Fucus* environment combined are necessary to induce the production of *Fucus* female pheromone. The response of *Fucus* males to the pheromone produced by *Fucus* females was independent of the substrate upon which the males were raised (Table 3, experiments 8 and 9).

Mate choice tests involving *E. confervicolus* from other *Fucus* populations along the British Columbia coast suggested that populations occupying *Fucus* habitats were producing a common pheromone (Table 4, experiments 1–7). Like the Squamish *Fucus* population, the two other *Fucus* populations only produced this specific pheromone when raised on *Fucus* substrate (Table 4, experiments 8–11). When raised on wood debris substrate, they still produced a pheromone, but it was indistinguishable from that produced by wood debris females (Table 4, experiments 9 and 11).

The ability to produce and distinguish the *Fucus* pheromone was disrupted

in wood debris–*Fucus* interpopulation hybrids. F_1 and F_2 females of crosses between wood debris and *Fucus* (with the reminder that all such animals were raised on *Fucus* substrate) produced an attractant that *Fucus* males were not able to distinguish from that produced by wood debris females (Table 5, experiments 1–4). Wood debris males were attracted similarly to the substances produced by both groups of test individuals (Table 5, experiments 5 and 6). Hybrid males did not exercise any choice between wood debris or *Fucus* females (Table 5, experiments 7–10) as well as between hybrid and wood debris females (Table 5, experiments 11 and 12). In contrast, the formation of *Fucus–Fucus* interpopulation hybrids appeared to have no effect on either production or perception of the pheromone (Table 5, experiments 13–23). The frequency of choice was similar in all reciprocal crosses (contingency chi-square values were not significant for any pairwise comparison), indicating the differences in pheromone production were not due to maternal effects.

DISCUSSION

A central topic in speciation theory is the study of the evolution of reproductive isolating mechanisms (White, 1978). An important and as yet unresolved question is whether the primary role in initiating speciation is a premating or postmating isolating mechanism. Results of our investigations of differentiated populations of *E. confervicolus* suggest that isolation in this gammaridean amphipod may result from premating mechanisms. Our array of choice test results indicates that the *Fucus* amphipods are a distinct race within the species *E. confervicolus* and have an ability to produce a modified pheromone (or alternate blend of pheromones) through the metabolism of *Fucus*, *Pelvetia*, or something associated with the algae. This ability is not shared by other non-*Fucus* populations and is disrupted when interpopulation hybrids are formed between *Fucus* and non-*Fucus* groups, indicating a genetic basis. *Fucus–Fucus* interpopulation hybrids did not disrupt *Fucus* pheromone production or response. F_1 and F_2 progeny in this study were produced by simply combining in the same aquaria

[a]Males are listed first in each cross, i.e., WDSQ-FSQ(F_1) refers to the F_1 of a cross in which the male parent came from the wood debris Squamish population and the female parent from the *Fucus* Squamish population. FQC = the Queen Charlotte *Fucus* population. Replicates are listed individually when they were judged to be heterogeneous, otherwise pooled values are presented. *$0.01 < P < 0.05$, ***$P < 0.0001$, ns = not significant.

males and females from the respective populations. Stanhope (1989) found no evidence for differences in mating success (percentage of matings that produced offspring) in interpopulation crosses involving these same populations (both parental and F_1 crosses). Thus, a postmating isolating mechanism such as gametic incompatibility or zygote mortality does not appear to exist. Starch gel electrophoresis of 15 enzymes indicated that almost all loci were fixed for the same allele in the six sampled populations (BKSQ, WDSQ, FSQ, FHS, a wood debris

population on Vancouver Island, and a bank population in the Fraser River estuary near Vancouver). Mannose-6-phosphate isomerase and glucose-6-phosphate isomerase were the only detectable polymorphisms; however, *Mpi* and *Gpi* allele frequencies were not significantly heterogenous among all six sites (J.H. McDonald, Department of Ecology and Evolutionary Biology, Princeton University, Princeton, New Jersey 08544; Stanhope, unpublished data). In other words, starch gel electrophoresis of several enzymes did not reveal the fixed allelic differences between locations that would indicate hidden species were present. A more fine-tuned analysis, however, using genomic DNA RFLPs (restriction fragment length polymorphisms) of nine populations (three of each habitat type included in this study) and the only other species in this genus (*Eogammarus oclari*), has indicated that the three *Fucus* populations are a distinct phylogenetic group from the bank and wood debris populations (Stanhope, 1989). They are, however, much more similar to other *E. confervicolus* than to *E. oclari*. The fact that *Fucus–Fucus* interpopulation hybrids still produced the *Fucus* pheromone, and *Fucus*–wood debris hybrids did not, is further corroborating evidence that amphipods residing in *Fucus* substrate comprise a distinct genotype. In some additional tests of ours, two other clearly distinguishable and taxonomically recognized species of gammarid amphipod (*Lagunogammarus setosus* and *Rammellogammarus* sp.) both produced their own pheromone that was only recognized by males of that species (Stanhope, unpublished data), suggesting there is a distinct species specificity to pheromone production and response in gammarid amphipods.

Thus, it appears that *Fucus* amphipods are a distinct evolutionary line within the species *E. confervicolus* that have not developed any marked postmating isolating mechanisms but have evolved an unusual diet-modified sex pheromone. It appears that they produce the pheromone characteristic of the species as a whole but have an ability not shared by other members of the species to modify this pheromone when raised on *Fucus* substrate. We are aware of no other example of a diet-modified pheromone in crustaceans, but there are examples of insect chemical attractants that are blends of insect pheromone and host-tree volatiles (Bedard et al., 1969, 1980); the host-tree volatile is released when it is attacked. Our example differs from these, however, in that the "host" in our case provides an ingredient(s) that is transformed by the members of the race that occupy that habitat into a more specific pheromone. It is not simply a blend of algal chemical and amphipod pheromone, since a combination of amphipods (raised on wood debris substrate) and algae did not elicit the same response. The resulting surmise is that it is a metabolic by-product of the amphipods feeding on algal substrate (or possibly related epiphytes) that either functions as part of a blend or subtly alters the structure of the general pheromone.

Although no crustacean sex pheromone has been completely chemically characterized, Borowsky et al. (1987) present evidence that the amphipod *Micro-*

deutopus gryllotalpa produces a polar attractant that the authors hypothesize is an amino acid or charged organic conjugate. Perhaps the sex pheromone produced by *E. confervicolus* is a peptide that includes a prosthetic group which, in *Fucus* amphipods, either can be replaced or an additional one included, when the diet is changed. Borowsky et al. also found algae could be important in the chemical communication of their species; the intertidal alga *Ulva lactuca* inhibited the male response to receptive female secretions. Amphipods are known to make dramatically different food choices in response to structurally similar algal metabolic compounds (Hay et al., 1987). These findings emphasize the key role algae play in structuring marine intertidal communities through chemical communication channels.

Whatever the precise nature of the difference in pheromone between the *Fucus* race and the other populations, it is likely a contributing factor to reproductive isolation in this group. The close proximity of the wood debris and *Fucus* populations (separated by only 200 m of intertidal mud flat) means it is very likely that individuals from these two groups will encounter each other. At least some portion of the population enters the water column with the flooding tide; we know this from both personal observation and from data that indicate *E. confervicolus* is a major food organism for juvenile salmonids in the Squamish estuary (Goodman and Vroom, 1972; Levy and Levings, 1978). There is also information available indicating that gammarid amphipods are highly vagile aquatic invertebrates (Fincham, 1972; Kolding, 1981; Miller, 1984). Although our bioassay ran for 5 hr [(approximately the same time as in Borowsky's original experiment involving this choice test apparatus (Borowsky, 1984)], many of the amphipods made their choice within the first few minutes, with the rest of the individuals responding gradually over the course of the next several hours. Thus, there is reason to believe the *Fucus*-specific attractant will be, at least at high tide, a contributing factor towards assortative mating. Although it is not an aggregation pheromone per se, it may also have an effect as a "habitat homing" mechanism. As already mentioned, our DNA analysis (Stanhope, 1989) clearly indicates the three *Fucus* populations comprise a distinct race. This race has so far only been identified within *Fucus* habitats. These habitats are often represented by very small patches (FSQ and FHS, for example). The *Fucus*-specific pheromone may be an important factor in maintaining this habitat-based segregation by identifying (at least to males) the location of these relatively small environments.

Unfortunately, the results of the crosses do not provide much specific information on the genetics underlying pheromone production. They do indicate, however, that there was no evidence for maternal effects or sex linkage. Evidence for sex-linked pheromone production has been reported for several insect species (e.g., Sanders et al., 1977; Grula and Taylor, 1979). Pheromone response in *Fucus* males evolved with production; males responded preferentially to the

Fucus pheromone, and this ability was disrupted in interpopulation hybrids. The only apparent difference in production and response was that males did not have to be raised on *Fucus* substrate to respond to the *Fucus* pheromone. A more precise description of the genetic mechanisms underlying production and response may depend on chemical characterization of the different pheromones in order to score the phenotypes more accurately.

Borowsky and Borowsky (1987) have broken down the nature of reproductive stimuli in a gammaridean amphipod (*Gammarus palustris*) into several stages and suggest that a contact pheromone may be an important component in pair formation. We have no information to suggest whether a similar system exists in *E. confervicolus*. It raises, however, the intriguing question of whether different pheromone systems (contact vs. waterborne) would evolve together. Clearly, the situation in *E. confervicolus* is a subtle modification of an already existing communication system. Would we expect a similar modification in a contact pheromone and, if so, what would be the underlying genetic mechanism?

The modeling results of Diehl and Bush (1989) and Rice (1984) and the recent experimental work of Rice and Salt (1990) suggest that considerable sympatric population divergence (and in fact significant progress towards sympatric speciation) can occur if mate choice is closely coupled with habitat preference. Our case provides an unusual example of such a coupling, in that the production of the specific pheromone responsible for distinctions in mate choice is dependent on a key feature of the habitat.

Acknowledgments—We thank Dr. C.D. Levings and the West Vancouver Laboratory for their generous provision of aquarium facilities. J. Brown, F. Juanes, and B. Leighton offered much helpful advice. M. Stanhope was supported by a G.R.E.A.T. award from the British Columbia Science Council.

(Received February 13, 1992; accepted June 15, 1992)

Abstract—The inhibition of ATP synthesis, proton uptake, and electron transport (basal, phosphorylating, and uncoupled) from water to methylviologen by zaluzanin C indicates that it acts as an electron transport inhibitor. Uncoupled photosystem I electron transport rate was not affected by zaluzanin C; however, uncoupled photosystem II electron flow from water to 2,3,5,6-tetramethyl phenylenediamine and from water to silicomolybdate was inhibited, but electron transport from diphenylcarbazide to silicomolybdate was not affected. We conclude that the site of inhibition by zaluzanin C is located at the oxygen evolution level.

Key Words—Zaluzanin C, *Zaluzania triloba*, chloroplast, oxygen evolution, inhibition, Hill reaction, photosystem I, photosystem II.

INTRODUCTION

Sesquiterpene lactones are characteristic constituents of Compositae, although investigations of other families (e.g., Magnoliacea and Umbelliferae) indicate that they occur sporadically (Dalvi et al., 1971, see reference herein). These secondary constituents are primarily classified on the basis of their hydrocarbon skeleton as germacranolides, guaianolides, eudesmanolides, pseudoguaianol-

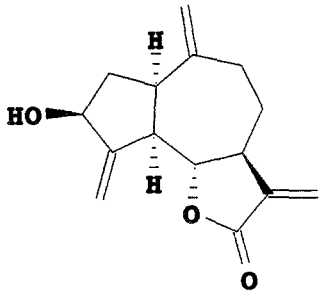
*To whom correspondence should be addressed.

0098-0331/92/1100-1891$06.50/0 © 1992 Plenum Publishing Corporation

ides, eremophilanolides, and xanthanolides (Rodríguez, 1977 and Rodríguez et al., 1976).

Some sesquiterpene lactones have shown the following biological properties: they produce allergic contact dermatitis in humans; they have poisoning properties in livestock; they are insect feeding deterrents and microbial growth inhibitors; they have cytotoxic and tumor-inhibiting properties: they are plant growth inhibitors; and they have antibiotic properties (Dalvi et al., 1971; Garcidueñas et at., 1972; and see reference therein). It appears that the biological activity of sesquiterpene lactones depends on several structural characteristics: (1) lipophilicity; (2) exocyclic double bonds conjugated to γ lactone; (3) β unsubstituted cyclopentenone ring in pseudoguaianolides; (4) type of sesquiterpene lactone; (5) presence of functional groups, such as epoxide, hydroxyl, chlorohydrin; and (6) stereochemistry (Rodríguez, 1977 and Rodríguez et al., 1976 and see reference therein).

The sesquiterpene lactones with phytotoxic properties are vernolepin, an eudesmanolide that inhibits the extension growth of wheat coleoptile sections; parthenin, a pseudoguaianolide that inhibits the germination of *Phaseolus vulgaris* and affects the development of adventitious roots; and alantolactone and isoalantolactone, two eudesmanolides that greatly enhance the rate of respiration of *Chlorella pyrenoidosa* and inhibit the growth of the cell. Lactones isolate from the leaves of *Artemisia* (arbusalin, adiilin, desacetoxymatricarin, and viscidulin-B and -C) were found to inhibit the germination of three grasses (Kanchan, 1975; Lee et al., 1971). *Ambrosia cumanensis* was inhibited by several sesquiterpene lactones (Amo and Anaya, 1978). The ecological role in plants of zaluzanin C, a guaianolide, is not known, but it probably behaves as an allelochemical agent, interfering with the metabolism of other organisms. The purpose of this research is to study the effect of zaluzanin C (Figure 1) on energy metabolism in photosynthesis and to localize its target(s) of action. Zaluzanin



zaluzanin C

FIG. 1. Structure of zaluzanin C.

C was isolated from *Zaluzania triloba* from Hidalgo State, Mexico. The identification of zaluzanin C was made by comparison with its spectroscopic data reported in the literature (Romo de Vivar et al., 1967). Our results show that zaluzanin C inhibits photosystem II at the level of oxygen evolution. This fact suggests that zaluzanin C could interfere with the growth of photosynthetic organisms.

METHODS AND MATERIALS

Zaluzanin C was obtained from aerial parts of *Zaluzania triloba* and dried after successive chromatographic separations on silica-gel columns from the hexane and acetone extracts using eluent gradients of hexane-ethyl acetate as reported by Romo de Vivar et al. (1967). It was later dissolved in dimethylsulfoxide. Chloroplast thylakoids were isolated from marked spinach leaves (*Spinacea oleracea* L.) as described earlier (Lotina-Hennsen et al., 1987a; and suspended, unless indicated, in 100 mM sorbitol, 5 mM $MgCl_2$, 40 mM KCl and buffered with 30 mM Na^+ Tricine at pH 8.0; 0.05 mM methylviologen was added as an electron acceptor for the Hill reaction (water to methylviologen); KCN (1 mM) was added to inhibit catalase activity. Chlorophyll quantification (Strain et al., 1971), photosynthetic noncyclic electron transport from water to methylviologen (Lotina-Hennsen et al., 1991; Peña-Valdivia et al., 1991), proton uptake (Dilley, 1972), and ATP systhesis (Peña-Valdivia et al., 1991) were determined as described in the literature. Photosystem I and photosystem II (Lotina-Hennsen et al., 1991; Peña-Valdivia et al., 1991), electron transport from water to silicomolybdate (Giaquinta and Dilley, 1975), and diphenylcarbazide (DCP) to dichlorophenol-indophenol (DCIP) (Vernon and Shaw, 1969) were measured as reported. All reaction mixtures were illuminated with actinic light of a projector lamp (GAF 2660) and were passed through a 5-cm filter of a 1% $CuSO_4$ solution.

RESULTS AND DISCUSSIONS

Photosynthetic phosphorylation associated with the methylviologen reduction in spinach thylakoid was partially inhibited by zaluzanin C in concentrations up to 6.8 mM (Figure 2A), the I_{50} (concentration producing 50% inhibition) was 4.6 mM. The light-dependent proton uptake was 100% inhibited at 6.6 mM zaluzanin C concentration (Figure 2B, I_{50} was 4.2 mM); however, ATP synthesis was only 60% inhibited.

The light-dependent systhesis of ATP, phosphorylation, and proton uptake by illuminated thylakoids such as zaluzanin C may be inhibited in one of three ways:

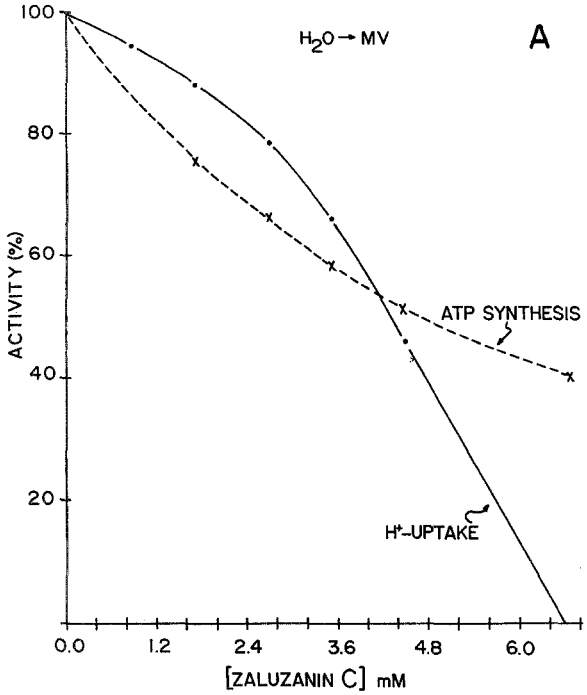


FIG. 2. (A) Effect of increasing concentrations of zaluzanin C on the inhibition of photophosphorylation and proton uptake from water to methylviologen. Proton uptake was measured as a pH rise between 8.0 and 8.1 as described by Dilley (1972) using a combination microelectrode connected to a Corning potentiomenter with expanded scale. The pH changes were recorded (Gilson recorder). After the illumination period H^+ ions produced were quantified by titration with a standard solution 0.01 N HCl. Control value for proton uptake (expressed in μeq H^+/hr/mg Chl) was 11.7. Photophosphorylation was measured as in proton uptake conditions in the presence of 1 mM ADP and 3 mM K^+ phosphate. Each cuvette contained 20 μg chlorophyll per milliliter in 100 mM Kcl, 5 mM $MgCl_2$, and 1 mM Na^+ tricine, pH 8.0; 0.05 mM methylviologen was added as electron acceptor; reaction time: 1 min; aerobic conditions; saturating white light. Control valve for ATP synthesis (expressed in μmol/hr/mg Chl) was 276. (B) Noncyclic electron transport from water to methylviologen (basal electron transport) as a function of zaluzanin C concentrations, was determined with an oxygraph YSI model 5300. Each cuvette contained 20 μg chlorophyll per milliliter in the reaction medium as in (A) except that Na^+ tricine concentration was changed to 15 mM; reaction time: 1 min, aerobic conditions; saturating white light. Other conditions are as described in Methods and Materials. Phosphorylating electron transport was measured as basal electron transport and 1 mM ADP and 3 mM KH_2PO_4 were added. Uncoupled electron transport was measured as basal electron transport and 3 mM NH_4Cl was added. Control values for basal, phosphorylating, and uncoupled electron transport rate (expressed in μeq/hr/mg Chl) were 217, 608, and 837 respectively.

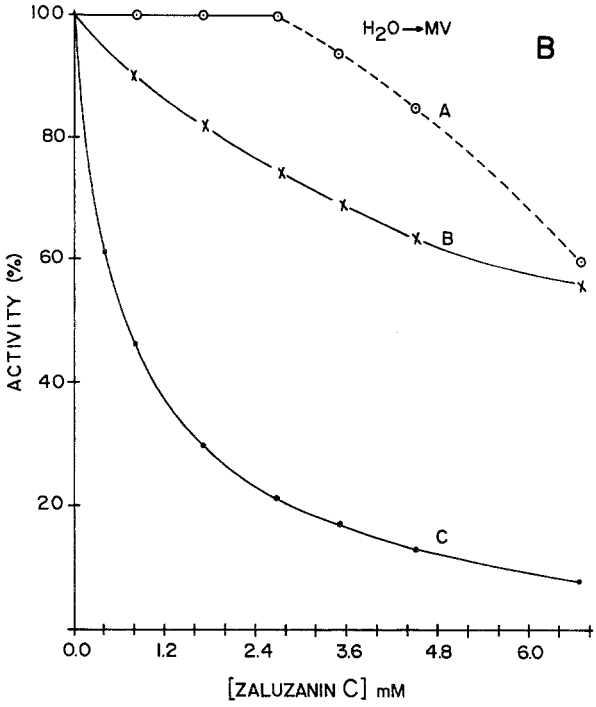

FIG. 2. Continued

TABLE 1. EFFECT OF ZALUZANIN C ON UNCOUPLED PHOTOSYSTEM I ELECTRON TRANSPORT FROM DAD TO MV[a]

Compound	Addition (mM)	H_2O to DAD (μeq/hr/mg Chl)	DPC to DCIP (μeq/hr/mg Chl)
Control	none	1200	118
Zaluzanin C	1.9	1185	117
	2.6	1207	120
	3.5	1201	119
	4.4	1193	118
	6.6	1203	118

[a] Reaction mixture as described in Figure 2A; concentrations—DAD 100 μM, $K_3[Fe(CN)_6]$ 200 mM, DCMU 10 μM, Na_4Cl 3 mM, chloroplast 20 μg Chl. Uncoupled electron transport from DPC to DCIP determined from Tris-treated chloroplasts, reaction mixture as for the photosystem I measurement except that $K_3[Fe(CN)_6]$ and DCMU were omitted and 200 μM DPC was added. Electron flow from DPC to DCIP was measured spectrophotometrically in the resuspended medium.

1. Blocking the electron transport. Reagents that block the electron transport also inhibit ATP systhesis because the generation of the transmembrane electrochemical gradients, the driving force for ATP synthesis, is dependent upon the electron flow.

2. Uncoupling ATP systhesis from the electron transport. Chemicals that increase the proton permeability of thylakoid membranes uncouple phosphorylation from electron flow. Uncoupling agents inhibit ATP synthesis by decreasing the proton gradient, but allow electron transport to occur at high rates.

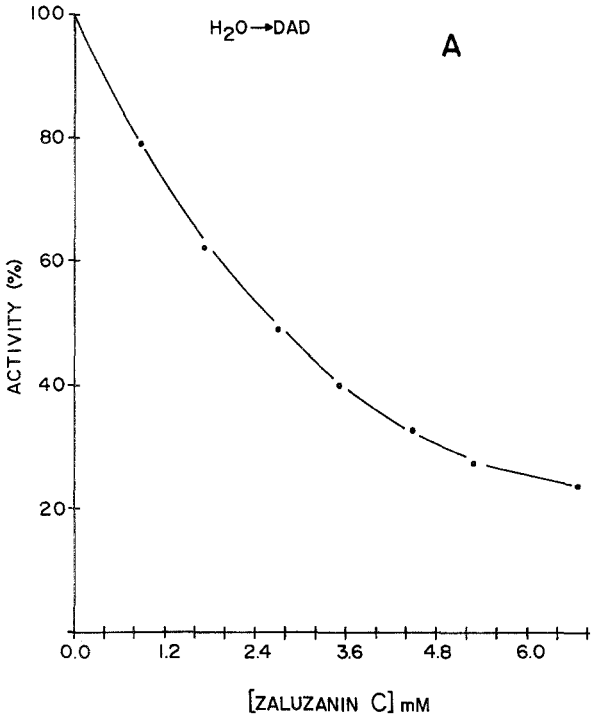

FIG. 3. (A) Effect of increasing concentrations of zaluzanin C on uncoupled photosystem II electron transport from water to DAD. The composition of the reaction mixture is similar to Figure 2B except that in photosystem II the following reagents were added: 0.1 mM DAD, 3 mM $K_3Fe(CN)_6$, and 1 mM DBMIB; methylviologen was omitted. Control valve for uncoupled photosystem II electron transport (expressed in μeq/hr/mg Chl) was 1305. (B) Effect of increasing concentrations of zaluzanin C on uncoupled electron transport from water to silicomolybdate. The composition of the reaction mixture is similar to Figure 2B, except that the following reagents were added: 200 μM Na^+ silicomolybdate and 10 μM DCMU; MV was omitted. Control valve for electron transport rate from water to silicomilybdate (expressed in μeq/hr/mg Chl) was 112.

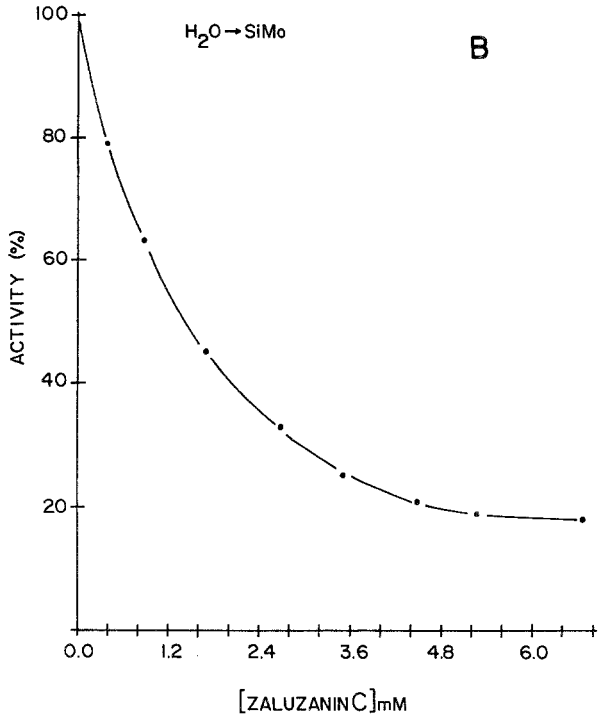

FIG. 3. Continued

3. Blocking the phosphorylation reaction itself (energy transfer inhibitors). In contrast to the other mechanisms, direct inhibitors of photophosphorylation block phosphorylation and the portion of electron transport that is a consequence of proton efflux linked to phosphorylation.

In order to obtain further information, we studied the effect of zaluzanin C on photosynthetic electron transport. Figure 2B shows that basal, phosphorylating, and uncoupled electron transport rates from water to methylviologen were inhibited as zaluzanin C concentrations increased up to concentrations similar to those affecting ATP synthesis and proton uptake (compare Figure 2B with 2A). These results indicate that zaluzanin C behaves as a typical electron transport inhibitor (process 1), since it inhibited uncoupled electron transport and phosphorylation, as well as proton uptake. Taking into account that uncoupled electron transport (I_{50} was 0.7 mM) was severely inhibited compared to the basal and phosphorylating electron rate, these data suggest that zaluzanin C binds to the target of an enzyme that suffers conformational changes when the membrane is energized and shields the zaluzanin's site.

In order to localize the inhibition site of zaluzanin C, photosystems I and

TABLE 2. EFFECT OF DIFFERENT COMPOUNDS IN REACTION OF WATER OXIDATION ENZYMES COMPLEX AS REPORTED IN LITERATURE[a]

Compound	Concentration (mM)	Oxygen evolution inhibition (%)
Ammonia (1)[a]	10	100
Methylamine (1)	100	100
Hydroxylamine (2)	1	100
Tris-washing (3)	800	60–80
DCMU (4)	0.2	80

Z^{2+} (11)	4.0	100

[a](1) Izawa and Good, 1972; (2) Joliot, 1966; (3) Yamashita and Butler, 1968; (4) Renger, 1973; (5) Singh and Singh, 1987; (6) Lotina-Hennsen et al., 1991; (7) Lotina-Hennsen et al., 1987b; (8) data from this work; (9) ANT2p = (2-(3-chloro-4-trifluoromethyl)amilino-3,5-dinitrothiophene); Packham and Robert, 1986; (10) Giaquinta et al., 1974; (11) Tripathy and Mohanty, 1980.

II were measured in the presence of this chemical. The activity of photosystem I from 2,3,5,6-tetramethyl-p-phenylandiamine (DAD) was not affected by this compound (Table 1). However, zaluzanin C inhibited coupled photosystem II electron transport from H_2O to DAD; the I_{50} was 2.7 mM (Figure 3A). Electron transport from water to silicomolybdate was inhibited by zaluzanin C with I_{50} 1.4 mM (Figure 3B). The concentration of zaluzanin C is low because silimolybdate destroys the coupling capacity of PSII (Giaquinta et al., 1974).

To determine the site of electron transport inhibition between water and Q_A by zaluzanin C, electron flows were measured from DPC to DCIP. The results show that this span of electron transport was not affected by zaluzanin C (Table 1). Therefore, this result indicates that zaluzanin C inhibits the Hill reaction by acting between H_2O to P680.

The water-splitting enzyme system is a key event in photosynthesis. It is known to be far more labile (with ammonia, methylamine, hydroxylamine, etc.) than the photosystem II trapping center; therefore, various inhibitors and treatments are effective in selectively blocking or destroying the water oxidation step (Izawa and Good, 1972; see references therein). Table 2 shows that the concentration of each compound needed to inhibit water oxidation varies widely. The structure of these compounds also varies greatly. Thus, these data indicate that these compounds inhibit the enzyme at different sites and with different

mechanisms of action. It is important to note that the only natural product that inhibits oxygen evolution as zaluzanin C does is cacalol (Lotina-Hennsen et al., 1991). The I_{50} of zaluzanin C (0.8 mm) is in the average range of various inhibitors at the same target.

As far as we know, there are eudesmanolides that greatly enhance the rate of respiration of *Chlorella pyrenoidosa*, but the effect of sesquiterpertene lactones on photosynthesis is unknown. This is the first time that zaluzanin C is reported as an inhibitor at this target (at the level of oxygen evolution). This result is similar to that found for cacalol (Lotina-Hennsen et al., 1991). How significant the effect of zaluzanin C is in the normal growth pattern of the plant has yet to be determined.

(Received December 12, 1991; accepted June 17, 1992)

Abstract—A multicomponent sex pheromone in *Macrocentrus grandii* Goidanich (Hymenoptera: Braconidae) was demonstrated using wind-tunnel and field bioassays. In wind-tunnel bioassays, three Florisil fractions from female wasps (hexane, 5%, and 50% ether in hexane) and one from male wasps (50% ether in hexane) were attractive to males. The hexane and 5% ether in hexane fractions each elicited similar male behavioral responses. These included upwind anemotaxis, casting, landing on the source, wing fanning, and mating attempts between males. The 50% ether in hexane fraction, whether male- or female-derived, initiated a strong flight response by males but few landings on the source. In addition, the 50% ether in hexane fraction was found to synergize strongly the hexane fraction. All females tested in the wind tunnel gave no responses to male- or female-derived extracts. Field tests generally supported the wind-tunnel results, although no field attraction was observed for the 5% ether in hexane fraction.

INTRODUCTION

The integration of natural enemies with other means of control in pest management programs is receiving increased attention (Chiang and Palmer, 1978; Lewis, 1982; Greany et al., 1984; Tumlinson, 1988). An understanding of the chemical ecology of these natural enemies is an important part of the integration and enhancement of beneficial insects in these programs. This may include the iden-

tification and evaluation of parasitoid pheromones, which could provide a means for assessing parasitoid activity and density and for predicting rates of host parasitism (Lewis et al., 1971; Robacker et al., 1976; Greany et al., 1984; Morse and Kulman, 1985).

Eller et al. (1984) reviewed the contributions citing sex pheromones in parasitic Hymenoptera. Additional investigations have been made in the families Braconidae (Weseloh, 1977, 1980; Vinson, 1978; Tagawa and Kitano, 1981; Tagawa, 1983; Powell and King, 1984; Jones, 1989), Pteromalidae (Assem et al., 1981), Ichneumonidae (Rotheray, 1981) Eulophidae (Takahashi and Sugai, 1982; Qui et al. 1984; Gonzalez et al., 1985), Trichogrammatidae (Pintureau and Toonders, 1983), and Aphidiidae (Singh and Sinha, 1982; Powell and Zhang, 1983). These works present behavioral evidence for the existence of a sex pheromone in over 35 species and in 10 families of parasitic Hymenoptera by using live wasps, body parts or fluids, and/or solvent extracts of these elements as sources of attraction.

The isolation, identification, and field bioassay of a parasitoid's sex pheromone has been described for only one species. Eller et al. (1984) identified and field tested synthetic ethyl (Z)-9-hexadecenoate, a sex pheromone from *Syndipnus rubiginosus* Walley (Ichneumonidae). Later, Morse and Kulman (1985), using sex pheromone traps, studied the relationship between catches of *S. rubiginosus* and its host *Pikonema alaskensis* (Rohwer), the yellowheaded spruce sawfly, and subsequent sawfly-caused defoliation. They found a significant relationship between defoliation and trap catches (host and parasitoid) and suggested such information could provide a pest manager with information on the natural control and the growth phase of a pest population.

Macrocentrus grandii Goidanich is an introduced larval parasitoid of the European corn borer, *Ostrinia nubilalis* (Hübner). *M. grandii* was imported from France and the Orient as early as 1926, and today, throughout much of its range, it is in good synchrony with the peak abundance of its favored larval host stages (Winnie and Chiang, 1984). Despite this synchrony, rates of parasitism in many areas have generally been poor ($<1\%$) except for periodic and localized high parasitism rates (9–56%) (Andreadis, 1980, 1982; Burbutis et al., 1981; Lewis, 1982). Why these fluctuations in parasitism rates have occurred is unclear, but factors such as pesticide usage, susceptibility to pathogens, and low host density have been proposed (Andreadis, 1982; Chiang, 1978; Lewis, 1982).

An understanding of *M. grandii's* courtship behavior and knowledge of its sex pheromone could lead to enhanced efficacy of this beneficial parasitoid. The purpose of this investigation was to document and define the role of pheromones in the sexual behavior of *M. grandii*. The study was prompted by observations in the laboratory that the presence of female-associated chemicals elicited attraction and wing fanning by males.

METHODS AND MATERIALS

Insect Material. M. grandii and *O. nubilalis* were reared according to Ding et al. (1989) and Guthrie et al. (1971), respectively. Voucher specimens have been placed in the University of Minnesota insect museum.

Pheromone Collection and Purification. To collect pheromone(s) associated with courtship behavior, whole-body extracts of male and female virgin wasps (one to three days after pupal emergence) were made by soaking wasps (sexes separate) in hexane for several days. After soaking, the hexane extract was drawn off, reduced under nitrogen, and fractionated by column chromatography on Florisil (2.5% water by weight). The column was eluted consecutively with aliquots of hexane, then 2.5, 5.0, 7.5, 10.0, and 50.0% ether in hexane (hereafter labeled 2.5E, 5E, 7.5E, 10E, and 50E), ether, acetone, and methanol. The volume of each eluant was about twice the void volume of the column. Fractions were capped under nitrogen and stored at -70°C until used for bioassay.

Laboratory Bioassay. Pheromone bioassays were conducted indoors in a rectangular fish tank (31 × 42 × 92 cm) modified to function as a wind-tunnel. The wind-tunnel was screened on each end and was all glass elsewhere. Air was circulated through the wind-tunnel by a fan at the downwind end that pulled air through the wind-tunnel at ca. 0.25 m/sec. The bioassay arena was held in a walk-in environmental chamber in which 16:8 hr, light–dark, 25°C constant temperature, and 80–90% relative humidity were maintained. Air, drawn by the fan through the tunnel, was subsequently exhausted out of the environmental chamber. A bank of four 40-W fluorescent lights, 5 cm above the wind tunnel, ran parallel with the length of the tank. About 150–200 male or female wasps were used for a bioassay. Chemical extract preparations were placed on 4-cm watch-glass plates. After the solvent had evaporated, each plate was attached to a Boston clip and each clip with its plate was then slipped onto a wire hook. The hooks were positioned in the upwind end of the tunnel 21 cm or 10.5 cm apart (distance apart depended on whether we were bioassaying two or three treatments) and 15 cm above the wind-tunnel floor. All chemical preparations were tested at the rate of 1/3 of a male or female equivalent (ME or FE). All chemical preparations were used for only one test, with the exception of the experiment testing the activity of three Florisil fractions over 24 hr. In this experiment, the initial chemical treatments were the same treatments bioassayed at 15 min, 1 hr, and 24 hr, and with the same male wasps. Live virgin wasps (male or female), when bioassayed, were placed in 4×2-cm screen cylinders and positioned likewise in the upwind end of the tunnel.

Observed behavior included upwind flight, casting, landing on the source, wing fanning, and mating attempts between males. Visits at the source were usually brief, and the bioassay was quantified by recording the total number of

wasps landing on each plate during a 1-min period. Since the wasps were not trapped, the same wasp could land more than once and/or land on more than one treatment. All replicates were run usually with untested male or female wasps in the wind-tunnel. For pairwise comparisons, data were analyzed by a one-sided paired t test. Chemical positions were exchanged for each replicate. Three-way comparisons were considered a randomized complete block design with each bioassay labeled a block. Chemical preparations were positioned randomly for each bioassay. Data were transformed ($\sqrt{x + 1}$) to stabilize variance and tested for homogeneity with Levene's test. An analysis of variance (ANOVA) was then applied (degrees of freedom for error = 4) with mean separations by Fisher's (protected) least significant difference (PLSD), $\alpha \leq 0.05$ (Steel and Torrie, 1980).

Field Bioassay. Field bioassays were conducted within a University of Minnesota test plot of hybrid field corn. An area of no less than 52 rows × 75 hills was chosen and all experiments were run in a randomized complete block design with rows of corn as blocks. Treatments were 10 hills apart, blocks 10 rows apart, and traps (Pherocon 1C) were secured to the corn stalk 1.0–1.5m above ground. Block rows were always a minimum of 10 rows from the field border. Chemical extract preparations were placed on 4-cm watch-glass plates centered inside the trap bottom. Live virgin wasps (male or female) were placed with honey and water in 4 × 2-cm screen cylinders that were centered under the top of each trap. However, even with the provision of honey and water, many of the wasps within the cylinders were dead by the end of the experiment (24 hr).

Because of low and variable natural populations of *M. grandii*, laboratory-reared males were released into the test plots to ensure adequate densities. Males were used for all field bioassays, and they were released from emergence cups into the plots immediately after extracts were placed into the traps. They were released along each fifth row in between blocks, and the number of cups per row and their distance apart varied and was dependent upon male availability. In three separate field tests, ca. 1100, 2000, or 3000 males were released. Males were also released five rows outside the experimental area. All field experiments were begun in the early afternoon. Field data was transformed to $\sqrt{x + 1}$ to stabilize variance and tested for homogeneity with Levene's test. Treatments in which all replicates had zero captures were not included in the analysis. An ANOVA was applied with mean separations by PLSD, $\alpha \leq 0.05$.

RESULTS

Laboratory Bioassay. Evaluation of male *M. grandii* response to female-derived Florisil fractions indicated that the hexane, 5E, and 50E fractions contained attractive chemicals as measured by landing at the source (Table 1,

[a] 150–200 males 1–5 days old were tested.
[b] Each treatment plate was paired with a control. The female treatments utilize female wasps and extracts, the male treatments utilize male wasps and extracts. (WE) implies wasp equivalent.
[c] Six replications with each replicate using a new group of untested males; counts represent the mean number of male wasps landing on each plate during a 1-min interval; * and ** imply significant differences from control at the $\alpha \leq 0.05$ and $\alpha \leq 0.01$ levels (one-sided paired t test).

Female/Control). The hexane and 5E fractions elicited similar quantitative activity as the virgin female or to its hexane extract. The hexane and 5E fractions, the female hexane extract, and the virgin female also elicited qualitatively similar male behaviors in the wind-tunnel. These responses included flight initiation, upwind anemotaxis, casting, landing on the source, walking, wing fanning, and mating attempts between males.

The 50E fraction elicited a very different response. Although there was a very strong upwind anemotaxis, landings on the watch-glass were few. Males also were observed to land on the floor of the wind-tunnel directly under the 50E treatment watch-glass; this was a behavior not observed frequently with the other Florisil fractions.

In the evaluation of male wasp response to male-derived Florisil fractions, significant landing responses were observed with the hexane extract and the Florisil hexane fraction (Table 1, Male/Control). Again no significant landing response was observed with the 50E fraction, but it elicited a very strong upwind anemotaxis response, as observed by males responding to the female-derived 50E fraction. In addition, the male hexane extract gave similar flight responses

and landings under the watch-glass as the male- or female-derived 50E fractions. The male-derived hexane Florisil fraction was active, but there was no strong flight response. However, the few males attracted to the plate exhibited landing and wing-fanning behaviors. Whether this attraction to the male-derived hexane fraction is significant in nature seems doubtful because it is very weak compared to the male response to female-derived material.

Evaluation of female wasp response in the wind-tunnel to male- or female-derived extracts or Florisil fractions of these extracts ($N = 6$; identical to the Florisil fractions in Table 1) elicited no observable behavioral response.

To test for synergism, combinations of the fractions were presented to males. A significant increase in landing response was observed when the female-derived hexane and male- or female-derived 50E fractions were combined (Table 2; tests 1 and 2). No other fraction or combination of male- or female-derived fractions, when compared to these fractions, was as attractive (Table 2; tests 8–12). In fact, the previously "very attractive" female-derived hexane or 5E fractions gave a minimal response when tested along with the hexane plus 50E combination (Tables 1 and 2; tests 1, 2, and 8). The combined female-derived hexane and male- or female-derived 50E fractions generally "dominated" the bioassay arena at 1/3 male or female equivalent. In contrast, combining the 50E fraction (male- or female-derived) with the female-derived 5E fraction appeared to reduce attraction to the 5E fraction (Table 2; test 5 and 6). Combining the female-derived hexane and 5E fractions also provided a significantly more attractive source than either of the fractions alone (Table 2; test 7). However, combining the female-derived hexane and 5E fractions was not as attractive as a combination of the hexane and 50E (Table 2; test 9).

The three active female-derived Florisil fractions—hexane, 5E, and 50E—were tested for their activity over time (Table 3). Only the hexane fraction and hexane plus 50E fractions elicited male attractancy behavior after the initial bioassay. After 15 min, the 5E fraction was nearly inactive and the 50E fraction no longer elicited upwind anemotaxis. After the initial bioassay, the hexane plus 50E fraction's activity also dropped to a level comparable to the hexane fraction only. The activity of the hexane fraction remained quite active even 24 hr later.

Field Bioassay. When female-derived Florisil fractions were individually field tested, only the hexane fraction was highly attractive (Table 4). This activity was similar to that elicited by female-derived hexane extract and virgin females (Tables 4–6).

The 5E fraction (which in the wind-tunnel was highly attractive) was unattractive in the field bioassay (Tables 1 and 4). Results of the wind-tunnel bioassay had indicated that attraction to the 5E fraction was short-lived (Table 3; test 1). Therefore, attempts were made to increase the attraction time of the 5E fraction by increasing its concentration and/or combining it with other fractions or release-rate retardants. However, all efforts to demonstrate field activity with the 5E fraction were unsuccessful.

[a] Unless noted with the letter M, which implies male-derived, Florisil fractions are female-derived.
[b] Three replications with each replicate using a new group of 150–200 untested males 1–5 days old; counts represent the mean number of males landing on each plate during a 1-min test. In each test, column means followed by different letters are significantly different (PLSD, $\alpha \leq 0.05$).

Field testing of the 50E fraction demonstrated very low trap catches (Table 4). This was not surprising since the wind-tunnel bioassays also had demonstrated infrequent landing behavior and short-lived activity for the 50E fraction (Tables 1 and 3). To increase the attraction period of the 50E fraction, its concentration was increased to two or three times the dosage of the other fractions in subsequent tests. The change in concentration did appear to increase the 50E trap catch. In addition, when the 50E fraction was combined with the

[c] Florisil hexane fractions are 10 female wasp equivalents, 50E fractions are 20 male wasp equivalents.

hexane Florisil fraction, catches increased synergistically (Table 5). This observation was similar to that observed in the wind-tunnel. All other fractions bioassayed individually or in conjunction with other fractions were not significantly active in the field.

When the male-derived 50E fraction was field tested with the female-derived

hexane fraction, activity analogous to that found with a mix of the female-derived hexane and 50E fractions was observed (Table 6). This result was comparable to that observed in the wind-tunnel. Tests also showed that virgin males were attractive to males (Table 6). This attractancy was similar to that of virgin females or a mix of the males and females. The attractancy of traps baited with virgin males plus the female-derived hexane fraction was not significantly different from the female-derived hexane fraction only. However, the death of many of the live wasps in the live bait treatments leaves these results unclear.

DISCUSSION

Both the wind-tunnel and field studies support the view that *M. grandii* has a multicomponent sex pheromone. The combination of the Florisil hexane fraction with the male- or female-derived 50E fraction was the most attractive source. The 50E fraction elicits a strong flight response in male wasps, and the hexane fraction elicits flight, landing, and mating behaviors. Together these components appear to comprise a potent sex pheromone with long-range attraction, landing, and mating behavior.

The function of the 5E fraction in this scenario is unexplained. It appeared very attractive in wind-tunnel bioassays, whether bioassayed alone on in conjunction with the female-derived Florisil hexane fraction. However, the attractiveness of the 5E fraction decreased when combined with the 50E fraction and the 5E fraction was not attractive in the field. This latter result may be due to the field procedures, since release of males into the test site took several minutes after the extracts were applied, and ephemeral extracts could lose much of their attractiveness during this time.

The Florisil separation indicated the likelihood of at least three different chemicals contributing to pheromone activity. The hexane fraction would contain nonpolar compounds (i.e., hydrocarbons), the 5E fraction would contain moderately polar compounds (i.e., ketones, aldehydes, or esters), and the 50E fraction would contain chemicals similar in polarity to the primary alcohol. In addition, the fact that the hexane fraction was attractive 24 hr later indicated the chemical(s) responsible for its attractiveness were either quite abundant, slow to vaporize, and/or a product of a continually occurring chemical reaction (e.g., photo oxidation). The active component(s) of the 5E and 50E fractions were very volatile and/or unstable because their activity diminished significantly in 15 min.

The wind-tunnel and field data also demonstrated that males, with the male-derived 50E fraction eliciting qualitatively identical male responses as the female-derived 50E fraction, may be "chemically" active in the mate finding scenario. Lewis et al. (1971) observed the behavior of males attracting males with *Car-*

diochiles nigriceps and postulated male flight aggregation with subsequent response to females that fly into the area. They had observed groups of males flying through the field. Although we have not observed *M. grandii* flying freely in the field, these data indicate that male aggregation may play a role in the behavior of *M. grandii*.

Identification and clarification of the roles of these behavioral components for *M. grandii* is the subject of subsequent papers.

(Received December 12, 1991; accepted June 17, 1992)

Abstract—(*Z*)-4-Tridecenal was identified as a sex pheromone component of *Macrocentrus grandii*, a larval parasitoid of the European corn borer. The aldehyde was found to be a common air oxidation product from a series of (*Z,Z*)-9,13-dienes of 27–33, 35, 37, 39, and 41 carbon atoms in female wasps. Synthetic (*Z*)-4-tridecenal and (*Z,Z*)-9,13-heptacosdiene each elicited flight initiation, upwind anemotaxis, casting, landing on the source, walking, wing fanning, and copulatory attempts by male wasps in a wind-tunnel. Field studies demonstrated that both compounds are synergized by a more polar component. Synthetic (*E*)-4-tridecenal was not attractive.

Key Words—Pheromone, hydrocarbon, diene, (*Z*)-4-tridecenal, oxidation, Hymenoptera, Braconidae, *Macrocentrus grandii*, parasitoid.

INTRODUCTION

Macrocentrus grandii Goidanich is a larval parasitoid of the European corn borer, *Ostrinia nubilalis* (Hübner). In a previous report we described evidence of a female-produced multicomponent sex pheromone for *M. grandii* (Swedenborg and Jones, 1992). These components occurred in the hexane, 5% ether in hexane (5E), and 50% ether in hexane (50E) fractions eluted from Florisil. In this paper we report the isolation, identification, and synthesis of two pheromone components originating from the hexane and 5E fractions. In addition,

*To whom correspondence should be addressed.

we report evidence for a second pheromone component occurring in the 5E fraction.

METHODS AND MATERIALS

Wasps, Extracts, and Florisil Fractions. *M. grandii* and *O. nubilalis* were reared according to Ding et al. (1989) and Guthrie et al. (1971), respectively. Handling, extraction, and initial purification of the extracts using Florisil were as described by Swedenborg and Jones (1992). Voucher specimens have been placed in the University of Minnesota insect museum.

Chromatography. Open-column argentation chromatography was conducted using a 9-in. Pasteur capillary pipet packed with 5 cm of 20% silver nitrate on silica gel (60/200 mesh). The column (void volume ca. 1 ml) was eluted first with 2 ml hexane, followed by 2 ml of 10% ether in hexane. The sample was the original Florisil hexane fraction (Swedenborg and Jones, 1992). Similar chromatography was conducted using Florisil (2.5% water by weight). This column was eluted consecutively with aliquots of hexane then 2.5, 5.0, 7.5, 10.0, and 50.0% ether in hexane, ether, acetone, and methanol. The samples were the products of diene oxidation and chemical syntheses. All fractions were capped under nitrogen and stored at −70°C until used for bioassay or analysis.

High-pressure liquid chromatography (HPLC) was done isocratically with a Waters Associates M6000A pump and a R401 differential refractometer detector. Columns used were a Serva 250-mm × 4.6-mm-ID Servachrome silica gel column coated in situ with 20% silver nitrate, as described by Heath and Sonnet (1980), and an Altex 300-mm × 8-mm-ID μ-Spherogel 50 Å size-exclusion column. Samples on the Serva Column were eluted with 25% toluene in hexane (hydrocarbon analysis) or 100% toluene (aldehyde analysis) at 2.0 ml/min. Samples on the Altex column (aldehyde analysis) were eluted with 25% ether in hexane at 1.0 ml/min.

Gas chromatography (GC) was performed with Hewlett Packard 5830A and 5890A instruments, both equipped with flame ionization detectors. The 5830A was modified to contain an effluent splitter and thermal gradient collector (similar to that described by Brownlee and Silverstein, 1968). Columns used were: glass columns, 1.9 m × 2 mm or 4 mm ID packed with 3% Dexsil 300 on 80/100 Gas Chrom Q for hydrocarbon and aldehyde analysis, collection, and hydrocarbon equivalent chain length (ECL) determination; a bonded fused silica column, Supelco Supelcowax 10, 30 m × 0.53 mm ID, for aldehyde analysis and collection; a bonded fused silica capillary column, J & W DB-1, 30 m × 0.32 mm ID, for hydrocarbon and aldehyde analysis; and a fused silica capillary column, Quadrex SLP-Silar-10C 50 m × 0.25 mm ID, for aldehyde double bond configuration. Key GC temperature programs are noted with results.

Spectroscopy. Coupled gas chromatography–mass spectroscopy (GC-MS) was carried out with either an LKB-9000 instrument using a 0.6-m × 2-mm-ID 3% Dexsil 300 column and electron ionization energy of 20 eV or 70 eV, or a Kratos MS25 instrument using a J & W DB-1 15-m × 0.53-mm-ID column.

The Fourier-transform infrared (FT-IR) spectrum was taken with a Nicolet 170SX spectrometer. The IR spectrum was run with ca. 2 mg of the HPLC-purified diene material held between two KBr 25-mm × 4-mm disks. Bands were reported in wave numbers (cm^{-1}).

Chemical Tests. Ozonolysis was done as described by Beroza and Bierl (1967). Samples (0.1–2 μg of diene material) were ozonized in 20 μl of carbon disulfide for 2 min at −70°C. The ozonides were then reduced with triphenylphosphine to aldehydes. Subsequently, ozonized samples were run on the GC or GC-MS to identify reaction products.

For molecular sieve tests, samples (1–2 μg of diene material) were evaporated under nitrogen then resolubilized in isooctane containing activated 5 Å molecular sieve pellets to separate branched from straight-chain compounds (Hutchins and Martin, 1968). Control samples included the dienes but no molecular sieve pellets. Twenty-four hours later the sample solutions were analyzed by GC for changes in diene concentration.

For diene oxidation tests, six samples (20 μg each) of natural and synthetic (Z,Z)-9,13-heptacosadiene, after purification by Florisil, HPLC, and GC, were solubilized in hexane and placed on 6-cm watch-glass plates. Three replicates of each source were placed on the lab bench under fluorescent ceiling lights and three were placed in an ultra-low freezer −70°C. After 24 h, the watch-glass plates were each rinsed with 1 ml hexane. Each replicate was then chromatographed through a Florisil column (to separate dienes from diene oxidation products) followed by GC or GC-MS to look at reaction products and bioassayed for activity. In addition, a similar oxidation was performed with 200 μg of the entire diene series.

Synthesis of (Z,Z)-*9,13-Heptacosadiene.* Diene synthesis was guided by the procedure of Sonnet (1974) utilizing a Wittig condensation with the cosolvent, dimethyl sulfoxide. A procedural change involved the preparation of the alkyltriphenylphosphonium salt from 1,4-dibromobutane, which, upon simultaneous addition of nonanal and tetradecanal, provided for double-bond formation on each end of the four-carbon precursor (Bartelt et al., 1986). Following synthesis, the dienes were separated from polar by-products on Florisil and 9,13-heptacosadiene was separated from the nonpolar symmetrical by-products of 9,13-docosadiene and 14,18-dotriacontadiene using gas chromatography. HPLC, using a silver nitrate-coated silica gel column, eluted with 25% toluene in hexane, was used to provide geometrical purity of the synthetic dienes (Bartelt et al., 1982). All starting chemicals were obtained from Aldrich Chemical Co. Inc., Milwaukee, Wisconsin, and used without further purification.

Synthesis of (Z)-*4-Tridecenal and* (E)-*4-Tridecenal.* (Z)-4-Tridecenyl acetate and (*E*)-4-tridecenyl acetate were purchased from Bedoukian Research, Inc., Danbury, Connecticut. The isomers were base hydrolyzed to their respective alcohols using KOH in 95% aqueous ethanol. Following hydrolysis, the ethanol was distilled off, and the sample was diluted with methylene chloride and dried over 4 Å molecular sieves. Without further purification, the alcohols were oxidized with chromium trioxide and pyridinium chloride to provide (*Z*)-4-tridecenal and (*E*)-4-tridecenal (Svirskaya et al., 1980). Following synthesis, the aldehydes were purified using Florisil, HPLC, and GC.

Laboratory and Field Bioassay. Bioassays were conducted as described by Swedenborg and Jones (1992). For the laboratory bioassay a wind-tunnel was utilized with treatments on 4-cm watch-glass plates at the upwind end of the tunnel. About 150–200 males were used for a bioassay. Male behaviors in the bioassay included flight initiation, upwind anemotaxis, casting, landing on the source, walking, wing fanning, and mating attempts between males. Visits at the source were usually brief, and the bioassay was quantified by recording the total number of males landing on each plate during a 1-min period. Open column silver nitrate fractions were tested at 1/3 female equivalent (FE), HPLC fractions were tested at 5 FE, and GC fractions were tested at 1/3 FE (HPLC purified dienes) or 5 FE (diene oxidation products and HPLC purified 5E). All synthetic and female-derived dienes were tested at a 100-ng dosage (the total diene material extracted from one female using hexane is ca. 9 μg), and all sources of 4-tridecenal were tested at a 17-pg dosage [the total (Z)-4-tridecenal extracted from one female using hexane is ca. 50 pg]. For pairwise comparisons, data were analyzed by a one-sided paired *t* test. Chemical positions were exchanged for each replicate. Three-way comparisons were considered a randomized complete block design with each bioassay being a block. Data were transformed ($\sqrt{x + 1}$) to stabilize variance and tested for homogeneity with Levene's test. An analysis of variance (ANOVA) was then applied (degrees of freedom for error = 4) with mean separations by Fisher's (protected) least significant difference (PLSD), $\alpha \leq 0.05$ (Steel and Torrie, 1980).

In two separate field tests ca. 1200 and 800 laboratory-reared males were released into a test plot of hybrid field corn. Traps (Pherocon 1C) were secured to the corn stalk 1.0–1.5 m above ground. Chemical extract preparations were placed on 4-cm watch-glass plates centered inside the trap bottom. A Hercon polymer-bonded slow-release wafer formulation (0.15 mg isomer/cm^2) of (Z)-4-tridecenal and (*E*)-4-tridecenal was used at target release dosages of 50 ng/hr each for test 1 (release rates not verified). The 50E fraction was applied at 15 FE for test 1 and 20 FE for test 2. Synthetic (Z,Z)-9,13-heptacosadiene was applied at 20 FE or 180 μg diene for test 2. Each test was initiated near midday and run for 24 hr. Wasps were released immediately after the treatments were applied. Field data were transformed ($\sqrt{x + 1}$) to stabilize variance and tested

for homogeneity with Levene's test. An ANOVA was applied with mean separations by PLSD, $\alpha \leq 0.05$.

RESULTS

Female-Derived Florisil Hexane Fraction. Bioassays of the Florisil hexane fraction were consistently active in laboratory and field studies (Swedenborg and Jones, 1992). This fraction (475 FE) was concentrated to 100 μl and chromatographed on a pipet column of 20% silver nitrate on silica gel to separate paraffins from olefins. The active fraction was the 10% ether in hexane fraction, which contained the olefins (Table 1; test 1). The olefin fraction was comparable in activity to the original Florisil hexane fraction (Table 1; test 2), and activity was not improved by addition of the hexane- or paraffin-containing fraction (Table 1; test 3).

Subsequently, the olefin fraction was chromatographed using HPLC on a silver nitrate-coated silica gel column eluted with 25% toluene in hexane to separate monoenes from dienes (Figure 1). Bioassay activity coincided with fractions 5–9. GC and/or GC-MS analysis of the HPLC fractions identified the

FIG. 1. HPLC chromatogram using a Serva ServaChrom silica gel column coated in situ with silver nitrate. Sample represents 425 FE from the olefin fraction. Fractions were collected every 2 ml. The data represent the mean landing response of male *M. grandii* to each HPLC fraction in a laboratory wind-tunnel during a 1-min interval. Each treatment plate was paired with a solvent-only control; control plates paired with HPLC fractions 1 and 5–10 hand zero landings, plates 2–4 had 0.2 mean landings. 150–200 males 1–5 days old were tested; five replications with each replicate representing a new group of untested males; all HPLC fractions were bioassayed at 5 FE; * and ** imply significant differences from controls at the $\alpha \leq 0.05$ and $\alpha \leq 0.01$ levels (one-sided paired t test).

presence of monoenes in fractions 2 and 3 and dienes in fractions 5–9. The analysis demonstrated that dienes of longer chain length eluted slightly ahead of shorter-chain dienes on the silver nitrate-coated column. Therefore, each fraction did not contain the same mixture of dienes as the original olefin fraction. An identical analysis using male hydrocarbons demonstrated a virtual absence of dienes in male wasps with monoenes representing over 99% of the olefin component, whereas monoenes represented 39% of the olefin component in female wasps. In both male and female wasps saturated hydrocarbons represented ca. 20% of the total hydrocarbon component. Fraction 7 contained the bulk of the active HPLC peak. GC analysis showed fraction 7 over three times more concentrated with diene material than fractions 6 or 8. The reduced behavioral response to fraction 7 may have been due to an imbalance in the diene mixture and/or to pheromone overload in this fraction.

The active HPLC fractions (5–9) were combined and chromatographed on a 3% Dexsil 300 column (Figure 2). The peaks were collected separately and bioassayed at 1/3 FE. GC fractions 2–12 were significantly attractive. Male activity increased with greater peak area. The ECLs for the active diene peaks were 0.41–0.50 units less than the corresponding *n*-alkane (Table 2). The ECL

FIG. 2. GC chromatogram of the HPLC purified dienes using a 3% Dexsil 300 1.9-m × 4-mm column. The GC temperature program used was an initial temperature of 240°C for 1.0 min followed by a 3°C/min increase to 325°C and held at 325°C for 10 min. The carrier was nitrogen at 70 ml/min. The data represent the mean landing response of male *M. grandii* to each GC fraction in a laboratory wind-tunnel during a 1-min interval. Each treatment plate was paired with a solvent-only control; all control plates paired with the GC fractions had zero landings. 150–200 males 1–5 days old were tested; four replications with each replicate representing a new group of untested males; all GC fractions were bioassayed at 1/3 FE; * and ** imply significant differences from controls at the $\alpha \leq 0.05$ and $\alpha \leq 0.01$ levels (one-sided paired t test).

fractional part increased with increasing chain length as predicted by the model set forth by Bartelt et al. (1986).

Mass spectra of the GC peaks were similar in appearance with a discernible molecular ion and an absence of the intense odd mass peaks indicative of branching. Experiments with 5 Å molecular sieve pellets also indicated an absence of branching. Molecular ions were consistent with hydrocarbons of 27–33, 35, 37, 39, and 41 carbon atoms; each with two degrees of unsaturation (Table 2). The mass spectrum for the peak in GC fraction 6 is shown in Figure 3A.

Double-bond positions were determined by ozonolysis of the dienes. GC retention times or GC-MS of the aldehydes (products of diene ozonolysis) were compared to those of standard aldehydes. For each unsaturated hydrocarbon,

[a] Fractions are those collected by GC and bioassayed (Figure 2).
[b] Peak equivalent chain length (ECL) based on a coinjection of *n*-alkane standards *n*-24–40. The column used was a glass column 1.9 × 2 mm ID packed with 3% Dexsil 300. The GC temperature program was 180°C for 1 min followed by a 3°C min increase to 325°C and held at 325°C for 10 min. The carrier was nitrogen at 20 ml/min.
[c] GC-MS molecular weight determinations.
[d] Carbon number based on molecular weight and/or ECL determinations.
[e] Ozonolysis fragments were determined by GC retention times based on aldehyde standards or GC-MS.
[f] Double-bond positions were hypothesized from the ozonolysis fragments.
[g] Peak amount is the percent of total 9,13-dienes.

nonanal was found, and tetradecanal–eicosanal, docosanal, tetracosanal, hexacosanal, and octacosanal were found for dienes of 27–33, 35, 37, 39, and 41 carbon atoms respectively (Table 2). Butanedial (possibly unstable) was not found, but the double-bond positions could be hypothesized from the data as 9,13 for all dienes.

To determine the configurations of the double bonds, an FT-IR spectrum was obtained for HPLC purified diene material. Typical hydrocarbon bands were found at 2924, 2855, 1466, 1380, and 723 cm^{-1}. A peak at 3007 cm^{-1} (olefinic C—H stretch) indicated the presence of double bonds. Peaks at 1655 cm^{-1} (C=C stretch) and 1400 cm^{-1} (olefinic C—H in-plane bending) indicated the *Z* configuration. The lack of a peak at ca. 970 cm^{-1} (olefinic C—H out-of-plane bending) indicated the absence of the *E* configuration. Therefore, the geometrical configuration for the diene material was determined to be *Z,Z* and the tentative structure determination was complete as a series of (Z,Z)-9,13-dienes.

(Z,Z)-9,13-Heptacosadiene was synthesized and purified by Florisil, GC, and HPLC. Mass spectra and FT-IR spectra of the synthetic were identical to the female-derived (Z,Z)-9,13-heptacosadiene. Synthetic and female-derived

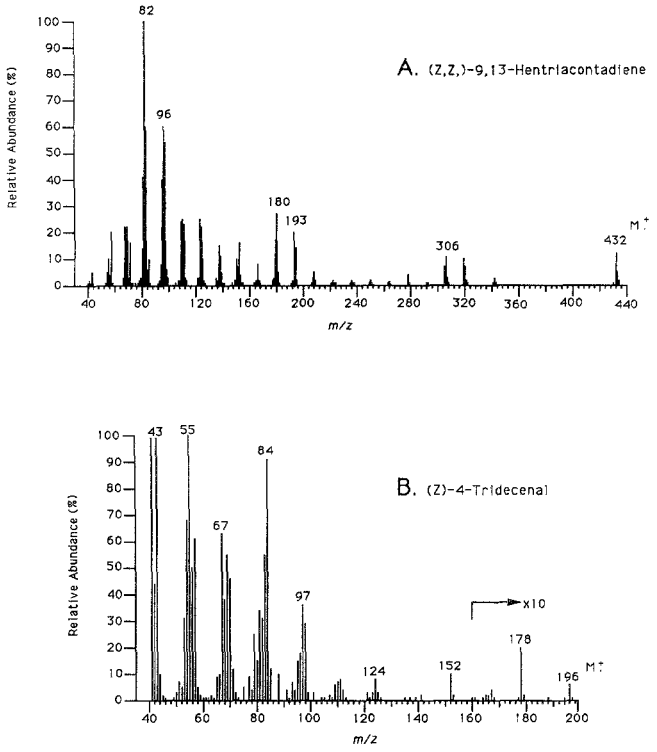

FIG. 3. (A) Electron impact (70 eV) mass spectrum of the GC peak in fraction 6, Figure 2, (Z,Z)-9,13-hentriacontadiene. A member of the homologous series of (Z,Z)-9,13-dienes in female *M. grandii*. (B) Electron impact (70 eV) mass spectrum of (Z)-4-tridecenal. An oxidation product of any member of the female-derived (Z,Z)-9,13-diene series.

(Z,Z)-9,13-heptacosadiene were bioassayed on equal weight bases, 100 ng, and the two were found comparable (Table 3; test 1). In addition, 100 ng of 27-carbon synthetic and 100 ng (1/30 FE) of HPLC-purified female-derived dienes, which contained the entire diene series in the female, were bioassayed (Table 3; test 2). These results were equivalent, demonstrating that the dienes may substitute for one another. A by-product of the synthesis was (Z,Z)-9,13-docosadiene. This symmetrical diene was not found in *M. grandii*; however, since it was a member of the homologous series of 9,13 dienes, it was bioassayed and found to be as attractive as the female-derived dienes (Table 3; test 3).

Female-Derived Florisil 5E Fraction. This fraction produced a similar qualitative response in bioassays as the original Florisil hexane fraction; however, the length of time the 5E fraction remained active was shorter (less than 15 min

TABLE 3. LANDING RESPONSES OF MALE *M. grandii* TO FEMALE-DERIVED AND SYNTHETIC (Z,Z)-9,13-HEPTACOSADIENE, AND SYNTHETIC (Z,Z)-9,13-DOCOSADIENE IN LABORATORY WIND-TUNNEL

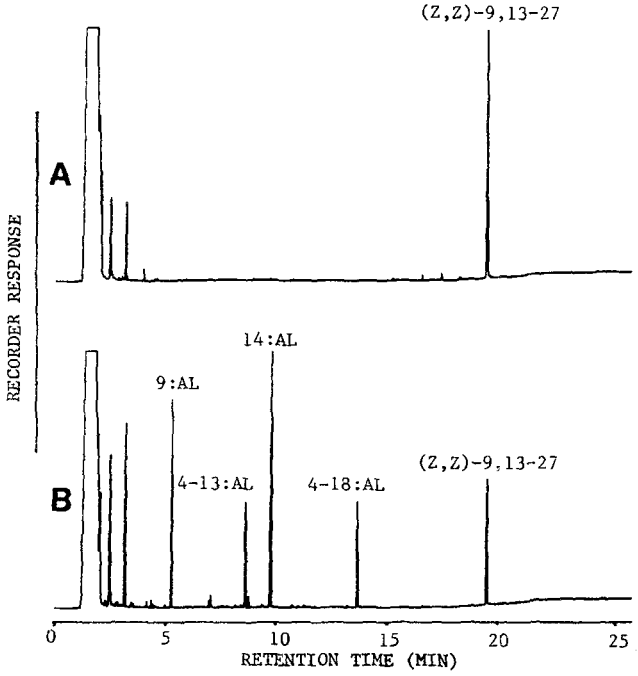
[a] 150–200 males 1–5 days old were tested. Three replications with each replicate using a new group of untested males; counts represent the mean number of wasps landing on each plate during a 1-min interval; all diene fractions contain 100 ng diene material; in each test column means followed by different letters are significantly different (PLSD, $\alpha \leq 0.05$).

versus at least 24 hr for the hydrocarbon fraction) and the activity of the 5E fraction was generally reduced when combined with the 50E fraction (Swedenborg and Jones, 1992). Our initial effort in identifying the active component(s) in the 5E fraction was to look at oxidation products of the (Z,Z)-9,13-dienes. Previously, in this laboratory, cuticular dienes of *Pikonema alaskensis* (Rohwer), the yellowheaded spruce sawfly were demonstrated to oxidatively decompose to yield a pheromonally active aldehyde (Bartelt and Jones, 1983). An aldehyde would elute in the 5E fraction using the ether in hexane elution gradient on Florisil. During oxidative degradation, due to their homologous nature, each (Z,Z)-9,13-diene would be expected to produce nonanal, 4-tridecenal, butanedial, and two unique aldehydes. The analogous bioassay activity of all the dienes and their continuous activity over time may be due to a common oxidation product. To verify this hypothesis, we exposed synthetic and female-derived (Z,Z)-9,13-heptacosadiene to the fluorescent ceiling lights above our lab bench at room temperature. As a control, a like number were placed in the dark inside an ultra-low temperature freezer. After 24 hr, the samples were resolubilized in hexane and chromatographed on the GC. Four major oxidation products were found for the synthetic and female-derived "benchtop" (Z,Z)-9,13-heptacosadiene samples (Figure 4B). In addition, over 70% of the original diene material



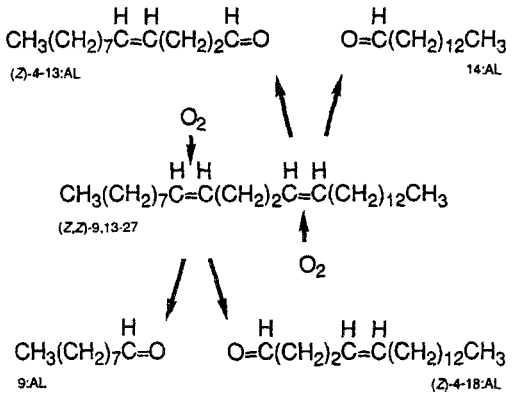


FIG. 4. Top: GC chromatograms using a DB-1 column of (Z,Z)-9,13-heptacosadiene after a 24-hr period in the freezer (A) or exposed on the benchtop (B). The four major oxidation products were nonanal (9:Al), (Z)-4-tridecenal (4-13:Al), tetradecenal (14:Al), and (Z)-4-octadecenal (4-18:Al). The GC temperature program used was at an initial temperature of 40°C for 0.5 min followed by a 20°C/min increase to 150°C, a subsequent programming of 10°C/min to 300°C and held at 300°C for 5 min. The carrier was helium at a linear velocity of 35 cm/sec (150°C). Below, the expected aldehyde cleavage fragments from double-bond oxidation of (Z,Z)-9,13-heptocosadiene.

(20 μg) was gone from these watch-glass plates. However, there was no evidence of oxidation for the samples placed in the −70°C freezer, and the diene material recovered from the freezer plates was greater than 95% (Figure 4A).

The diene oxidation products from the benchtop samples were separated from the remaining dienes by Florisil and the four major products eluted in the 5E fraction. They were identified by GC-MS as a saturated 9-carbon aldehyde, a monounsaturated 13-carbon aldehyde, a saturated 14-carbon aldehyde, and a monounsaturated 18-carbon aldehyde (Figure 4B). Each of the four oxidation products was GC collected and bioassayed. Only the 13-carbon peak was active. The mass spectrum of the active 13-carbon peak verified it as a monounsaturated aldehyde with a discernible molecular ion at 196 and a significant M−18 (loss of water) (Figure 3B). Ozonolysis revealed the double bond to be in the 4 position.

The diene oxidation products obtained from oxidation of 200 μg of the complete diene series were similar to that of (*Z*,*Z*)-9,13-heptacosadiene except additional aldehydes were found due to the increased chain length of the other dienes. Bioassays of the diene oxidation products demonstrated that only the 13-carbon peak (Table 4, fraction 7) was active.

Configuration of the female-derived active oxidation product 4-tridecenal was determined to be 100% *Z*, based on its identical retention time to that of synthetic (*Z*)-4-tridecenal on a Silar-10C capillary column. There was no chromatographic evidence of the *E* isomer as a product of oxidation.

In laboratory bioassay, all sources of 4-tridecenal were bioassayed using 17 pg, the amount of *Z* isomer determined to exist in 1/3 FE of the 5E fraction. Bioassays determined female-derived (*Z*)-4-tridecenal (collected via watch-glass diene oxidation) and synthetic (*Z*)-4-tridecenal elicited comparable activity (Table 5; test 1). Laboratory bioassays of the synthetic *Z* and *E* isomers also demonstrated the *E* isomer was inactive and, when the *E* isomer was added to the *Z* isomer, there was no inhibition or synergism (Table 5; tests 2 and 3). Additionally, the synthetic *Z* isomer and the 5E fraction bioassayed equivalent (Table 5; test 5).

A chemical analysis of the 5E fraction was performed to further verify the oxidation hypothesis and to check for additional biologically active components in the 5E fraction. HPLC analysis was conducted with 200 FE of the 5E fraction on Servachrome (silver nitrate coated) and Spherogel columns (Figures 5 and 6). A broad biologically active region was demonstrated on both columns; however, specific peaks could not be associated with the activities. An HPLC analysis of standard (*Z*)-4-tridecenal on each column using identical chromatographic conditions demonstrated (*Z*)-4-tridecenal would elute predominantly in the two most attractive fractions of either column. A subsequent GC collection using Supelcowax 10 and 3% Dexsil 300 columns was conducted with 100 FE of the combined active HPLC fractions from either column and compared with the

[a] 150–200 males 1–5 days old were tested.

[b] Each source was collected on the same GC column (Supelcowax 10, 15 m × 0.53 mm ID) and under the same GC conditions. The GC temperature program was an initial temperature of 100°C for 1 min followed by a 10°C min increase to 250°C and held at 250°C for 10 min. Fractions were collected at minute intervals.

[c] Each treatment plate was paired with a solvent-only control; Six replications with each replicate generally using a new group of untested males; counts represent the mean number of wasps landing on each plate during a 1-min interval; all GC fractions were bioassayed at 5 FE except the diene oxidation product source, which was based on the amount of (Z)-4-tridecenal in fraction 7 ($AgNO_3$ source) as determined by GC and normalized to this concentration; * and ** imply significant differences from controls at the $\alpha \leq 0.05$ and $\alpha \leq 0.01$ levels (one-sided paired *t* test). All control plates averaged less than one landing, most were zero.

[d] Diene oxidation products were the products of diene oxidation from the complete series of *M. grandii* female dienes (200 μg) previously purified utilizing argentation chromatography. Diene oxidation products were separated from the dienes using open column chromatography with Florisil support. The Florisil 5E fraction represented the oxidation products source utilized for GC collection.

[e] The Spherogel and $AgNO_3$ sources (their source was the original 5E fraction) represent the active HPLC fractions from these respective columns. The HPLC active fractions were combined, concentrated, and injected (100 FE) on the GC for collection.

diene oxidation products from the complete female diene series. The data from the Supelcowax 10 column is shown in Table 4. Fraction 7 and, where significant, fractions 8 and 9 were active due to the presence of (Z)-4-tridecenal in all three sources. Using capillary GC retention times, the presence of (Z)-4-tridecenal was demonstrated in these fractions. In addition, fraction 14 demonstrated biological activity for both HPLC sources and additional active frac-

Female-derived 5E fraction (1/3 FE)	32.2a
Control	0.0b

[a] 150–200 males 1–5 days old were tested. Three replications with each replicate using a new group of untested males; counts represent the mean number of wasps landing on each plate during a 1-min interval; all sources of the *E* and *Z* isomers were tested at 17-pg dosages, the amount of *Z* isomer found in 1/3 FE of the 5E fraction; in each test column means followed by different letters are significantly different (PLSD, $\alpha \leq 0.05$).

tions (15–20) were observed for the Spherogel source. Fraction 14 eluted with the retention of a 26- to 27-carbon hydrocarbon or a 20- to 21-carbon aldehyde on the Supelcowax 10 column. Qualitatively, the active fractions 14–20 demonstrated identical biological activity as (*Z*)-4-tridecenal. This included upwind anemotaxis, casting, landing, wing fanning, and mating attempts between males. Similar findings of activity, additional to (*Z*)-4-tridecenal, were observed for the Dexsil column. The source and nature of this component(s) is unknown. However, we believe it is not a hydrocarbon oxidation product produced by the method that yields (*Z*)-4-tridecenal. There was no evidence of biological activity in fraction 14 in the diene oxidation products collection. Additionally, female monoenes were previously demonstrated as inactive.

In field bioassays (*Z*)-4-tridecenal or (*Z,Z*)-9,13-heptacosadiene, when combined with the 50E fraction, were the most attractive treatments (Table 6, tests 1 and 2). No other fraction or combination of fractions was as attractive as these two combinations. In addition, (*E*)-4-tridecenal demonstrated no activity alone or in combination with the 50E fraction. Trap catch observations were

FIG. 5. HPLC chromatogram using a Serva ServaChrom silica gel column coated in situ with silver nitrate. Sample represents 200 FE from the original 5E fraction. Fractions were collected every 1 ml. The data represent the mean landing response of male *M. grandii* to each HPLC fraction in a laboratory wind-tunnel during a 1-min interval. Each treatment plate was paired with a solvent only control; all control plates paired with the HPLC fractions had zero landings. 150-200 males 1–5 days old were tested; six replications with each replicate representing a new group of untested males; all HPLC fractions were bioassayed at 5 FE; ** implies significant differences from controls at the $\alpha \leq 0.01$ levels (one-sided paired t test).

made for both tests. During the first ca. 30 min after each test began, many male wasps were observed actively searching near the traps treated with the combined attractive fractions [(Z)-4-tridecenal or (Z,Z)-9,13-heptacosadiene with the 50E fraction], while few if any were observed around any of the other treatments. It also appeared that many more wasps were searching near the attractive traps than were eventually captured. However, following this initial period, few wasps were observed near even the most attractive traps. Perhaps the ephemeral activity of the 50E component (Swedenborg and Jones, 1992) (Table 3) reduced the synergistic attraction to a very short period after which these treatments were no more attractive than the controlled release treatments of the aldehyde or diene.

DISCUSSION

Large cuticular hydrocarbons that elicit sex pheromone behaviors have been described for a number of species. The works by Howard and Blomquist (1982), Blomquist and Dillwith (1985), and Lockey (1988) provide reviews. Most infor-

FIG. 6. HPLC chromatogram using an Altex Spherogel 50 Å size exclusion column. Sample represents 200 FE from the original 5E fraction. Fractions were collected every 1 ml. The data represent the mean landing response of male *M. grandii* to each HPLC fraction in a laboratory wind-tunnel during a 1-min interval. Each treatment plate was paired with a solvent only control; all control plates paired with the HPLC fractions had zero landings. 150–200 males 1–5 days old were tested; six replications with each replicate representing a new group of untested males; all HPLC fractions were bioassayed at 5 FE; ** implies significant differences from controls at the $\alpha \leq 0.01$ levels (one-sided paired t test).

mation concerns the Diptera, where cuticular olefins and methylalkanes have been demonstrated to be short-range attractants or contact pheromones (e.g., Carlson et al., 1971; Sonnet et al., 1979; Uebel et al., 1978). Long-range attraction due to large cuticular hydrocarbons (greater than 25 carbons) has not been demonstrated clearly. In the Hymenoptera, a series of (Z,Z)-9,19-dienes (28–37 carbon atoms) for *Pikonema alaskensis* (Rohwer), the yellow-headed spruce sawfly, were found to elicit long-range attraction in laboratory wind tunnel and field studies (Bartelt et al., 1982). However, Bartelt and Jones (1983) later proposed and documented an alternative hypothesis that the (Z,Z)-9,19-dienes were oxidizing and a common oxidation product, (Z)-10-nonadecenal, was responsible for the pheromonal activity of the dienes. This work also demonstrated that oxidation of the dienes and consequent production of active (Z)-10-nonadecenal occurred in the absence of the insect.

We propose that (Z)-4-tridecenal is a primary sex pheromone of *M. grandii* and, like the sawfly, a homologous series of dienes are apparently precursors to this component. Diene oxidation occurs on the cuticle or isolated from the cuticle to produce the pheromone aldehydes. It is not known whether these insects have a controlling mechanism for this oxidation. There is evidence that

TABLE 6. RESPONSE OF MALE *Macrocentrus grandii* TO *E* AND *Z* ISOMERS OF 4-TRIDECENAL AND FEMALE-DERIVED 50% ETHER IN HEXANE FRACTION IN CORN FIELD

[a] In each test column means followed by different letters are significantly different (PLSD, $\alpha \leq 0.05$).

[b] (*E*)-4-Tridecenal and (*Z*)-4-tridecenal were released via a Hercon polymer-bonded show-release wafer at a target dosage of 50 ng/hr. The 50E fraction was released at 15 FE per trap. Approximately 1200 laboratory-reared males were released for this field bioassay.

[c] Synthetic (Z,Z)-9,13-heptacosadiene was applied at 180 μg/trap. The 50E fraction was released at 20 FE/trap. Approximately 800 laboratory-reared males were released for this field bioassay.

in certain insects olefin oxidation is inhibited. Atkinson et al. (1973) demonstrated that (Z,Z)-6,9-heptacosdiene (the major hydrocarbon component of *Periplaneta americana* L.) was stable when undisturbed on the cuticle. However, the (Z,Z)-6,9-diene oxidatively decomposed very readily when isolated from the cuticle. In our diene oxidation studies, the (Z,Z)-9,13-dienes decomposed rapidly when isolated from the wasp [greater than 70% of 20 μg of (Z,Z)-9,13-heptacosadiene were decomposed or evaporated within 24 hr]. Inhibition of diene oxidation by other cuticular chemicals may occur in *M. grandii* and *P. alaskensis*. Atkinson et al. (1973) reported that polyhydric phenols, extractable from cuticle, would inhibit diene oxidation when isolated. However, inhibition does not necessarily mean control of pheromone release. In the case of *M. grandii* we have observed females to mate only once; however, they remain attractive to males long after mating. This indicates a pheromone is still being released.

If the production of (Z)-4-tridecenal from cuticular olefins is an uncontrolled event as it appears to be, it is possible that this system represents an early to intermediate stage for sex pheromone evolution. Once any sexual dimorphism in olefin quality occurs, for whatever reason, the stage is set for males to become rapidly selected for their ability to detect any odor differences. Subsequently, those males that best detect this difference and those females that produce more of the unique odor will be favored for selection. Over time and continuous selection, some part of the female integument would specialize in the production of the subject chemical, thus producing a pheromone gland. It is possible that the elaborate system seen in Lepidoptera began with males taking advantage of a serendipitous event in female cuticle composition.

M. grandii (Braconidae) and *P. alaskensis* (Tenthredinidae) are phylogenetically very distant. However, both species have apparently evolved a very similar mechanism for release of sex pheromone. With the ubiquitous nature of hydrocarbons in insects and with the frequent occurrence of the olefin component, this mechanism may be repeated often.

In addition to the (Z,Z)-9,13-dienes and (Z)-4-tridecenal, the pheromone blend for *M. grandii* includes the previously demonstrated 50E fraction and at least one additional component in the 5E fraction. The 50E fraction was previously found to synergize the Florisil hexane fraction (Swedenborg and Jones, 1992) and in this study synergized (Z)-4-tridecenal and (Z,Z)-9,13-heptacosdiene in field bioassays. The identification of the 50E component is the subject of a future paper. The unidentified component of the 5E fraction elicited similar bioassays as the (Z,Z)-9,13-dienes and (Z)-4-tridecenal. Whether it is related to these compounds and/or responsible for the reduced attraction of the 5E fraction when combined with the 50E fraction (Swedenborg and Jones, 1992) or additional behaviors remains to be clarified.

Acknowledgments—The authors wish to thank T.P. Krick for assistance with mass spectral determinations and R.J. Bartelt for helpful comments throughout this study. We are grateful to J.A. Verdoorn, W.J. Hall, T. Apreala, and T.F. Czeck for their technical assistance and two anonymous reviewers who made helpful comments on the manuscript. Funding for this project was provided by the Legislative Commission on Minnesota Resources. ASSESSMENT OF ALLELOPATHIC POTENTIAL IN *Artemisia princeps* var. *orientalis* RESIDUES

KYEONG WON YUN and BONG-SEOP KIL*

Department of Biology Education
Wonkwang University
Iri, 570-749, Republic of Korea

(Received October 28, 1991; accepted June 17, 1992)

Abstract—Field and laboratory studies were conducted to examine the differential phytotoxicity of residues of *Artemisia princeps* var. *orientalis* (wormwood) using various plants as test species. Seedling elongation and dry weights of receptor plants were inversely proportional to the concentration and incubation time of dry leaves of *A. princeps* var. *orientalis* in vermiculite. In seedling growth tests with abandoned field soils (control) and soil underneath wormwood plants (test), the elongation, dry weight, and caloric content of seedlings grown in the soil from under wormwood plants were severely inhibited, thereby suggesting that certain growth inhibitors were released from wormwood and the inhibitor remained in the soil.

Key Words—*Artemisia princeps* var. *orientalis*, allelopathy, growth inhibition, wormwood residues.

INTRODUCTION

Allelopathic chemicals are released from plant tissue in a variety of ways, including exudation of volatile chemicals from living plant parts (Muller et al., 1964; Heisey and Delwiche, 1984); exudation of water-soluble toxins from belowground parts (AlSaadawi et al., 1986); leaching of water-soluble chemicals from aboveground parts in response to the action of rain, fog, or dew (Al-Naib and Rice, 1971; Kumari and Kohli, 1987); and release of toxic chemicals from nonliving plant parts through leaching of toxins from litter, sloughed root cells, or tissues decomposed by microorganisms (Patrick and Koch, 1958; Goel et al., 1989).

Virtually all parts of plants have been bioassayed, and the inhibitors were found in their organs (Horsley, 1977). Rice (1984) recognized that low concentrations of allelopathic substances may be stimulatory or nontoxic, but higher concentrations of the same substances are quite inhibitory.

Many plant residues have been reported to inhibit growth of plants (Rice, 1984). The degree of inhibition appears to depend on such factors as the test plants; quantity, placement, and weathering of residues; nutrient status of the soil; microbial activity and other soil parameters (Mason-Sedum et al., 1986). The objective of this research was to determine the allelopathic potential of *Artemisia princeps* var. *orientalis* residues.

METHODS AND MATERIALS.

Donor and Receptor Plants. For the study of allelopathic potential of *Artemisia princeps* var. *orientalis* (Pampan.) Hara (wormwood), the donor plant, ten receptor plants were selected. The receptor species included; *Lactuca sativa* L., *Achyranthes japonica* (Miq.) Nakai, *Artemisia princeps* var. *orientalis*, *Oenothera odorata* Jacq., *Plantago asiatica* L., *Zoysia japonica* Steud., *Echinochloa crus-galli* (L.) Beauv., *Hordeum vulgare* var. *hexastichon* Aschers., *Chrysanthemum boreale* Makino, and *Artemisia rubripes* Nakai.

Plant Residues Test. Powdered air-dried fresh leaves were added to vermiculite at various concentrations, and the mixture was put in plastic pots (12 cm). Vermiculite without the powder was used as the control pot. Seeds of receptor plants were sown separately in these pots and, six weeks after sowing, receptor plants were harvested and their lengths and dry weights measured.

Incubation Treatment of Vermiculite and Powder Mixture. Powdered air-dried fresh leaves (5 g) were added to vermiculite (100 g) and then 100 ml of Hoagland's solution (Hoagland and Arnon, 1950) was added to the mixture. These final mixtures were allowed to decompose at 30°C (in the dark) for three, six, and nine days, respectively. The treated vermiculite mixture was put into plastic pots, and then seeds of test plants were sown. Vermiculite without powdered leaves was used in control pots. Hoagland's solution (30 ml) was supplied to each pot every two days. Four weeks after sowing, all plants were harvested and elongation and dry weights determined. This procedure was a slight modification of the method of de Jong and Klinkhamer (1985) and Mason-Sedum and Jessop (1988).

Field Soil Test. To determine whether allelopathic compounds were released from wormwood plants into soil, soil samples were collected from an abandoned field in which wormwood plants were growing. Soil for the control set was collected from a field without wormwood. The soil was screened with a sieve (mesh, 2.0 mm), and seeds of receptor plants were sown in plastic pots con-

taining the soils. When germination was completed and small plants were thinned out, the largest 10 seedlings were grown for four to five weeks.

The results were taken by measuring the total length of each seedling and the dry weight. After the samples were oven-dried at 80°C and reached constant weight, the dry weight of the seedlings was measured and the caloric content was determined by using a calorimeter (Shimadzu, CA-4). All bioassays consisted of four replications, and each experiment was repeated four times. Relative elongation ratio and relative calorie ratio were calculated as suggested by Rho and Kil (1986).

$$\text{Relative elongation ratio (RER)} = \frac{\text{Mean length of tested plant}}{\text{Mean length of control}} \times 100$$

$$\text{Relative calorie ratio (RCR)} = \frac{\text{Calorie of tested plant}}{\text{Calorie of control}} \times 100$$

RESULTS

Effect of Residues on Seedling Growth. Elongation and increase in dry weight of *Achyranthes japonica* were inhibited by addition of powdered wormwood leaves to vermiculite (Table 1). The dry weight was more strongly inhibited than was elongation. The dry weight was only 43.7% of the control in the 10-g powder treatment.

Effect of Incubation Time on Phytotoxicity of Residues. It is evident from Figure 1 that there were significant changes in length of the receptor plants treated with incubated wormwood leaf. The growth of all receptor plants was significantly decreased in accordance with increased incubation time (three, six, and nine days).

TABLE 1. THE DECREASE OF ELONGATION AND DRY WEIGHT OF *Achyranthes japonica* BY ADDITION OF DIFFERENT AMOUNTS OF WORMWOOD LEAF TO VERMICULITE[a]

Amount of dry leaf (g/100 g vermiculite)	Plant growth	
	Elongation (mm)	Dry weight (mg)
0.0	345.5a	327.0a
0.2	308.9ab	232.0b
1.0	276.0bc	182.0b
5.0	246.9c	182.0b
10.0	241.5c	143.0b

[a]Values in a column having the same letters are not significantly different at the 5% level by Duncan's multiple-range test.

The dry weight and caloric content of receptor plants were also strongly decreased by the decomposed wormwood leaf. The order of the inhibitory effect by chemical substances from the wormwood residues was caloric content > dry weight > elongation. Among the receptor plants *A. princeps* var. *orientalis* itself was inhibited most severely (Table 2, Figure 2).

Seedling Growth of Receptor Species in Wormwood Field Soil. Seedling length of receptor plants in abandoned field soil with wormwood plants is graphically shown in Figure 3. *L. sativa* was inhibited severely to 36.8% of RER. *A. japonica*, *O. odorata*, *P. asiatica*, and *A. princeps* var. *orientalis* grew comparatively well in wormwood field soil. This difference may be attributed to differences in species sensitivity to wormwood residues in field soil.

In contrast to seedling lengths, the dry weights of receptor plants, except *P. asiatica* and *A. princeps* var. *orientalis*, were found to be reduced. RWR of

A. rubripes and *Z. japonica* were less than 43.5% and 68.7% of control, respectively (Figure 4).

DISCUSSION

Incorporating wormwood leaf powder into vermiculite in which test plants were planted showed that elongation and dry weight were progressively decreased with increasing concentrations of wormwood leaf powder. Irons and Burnside

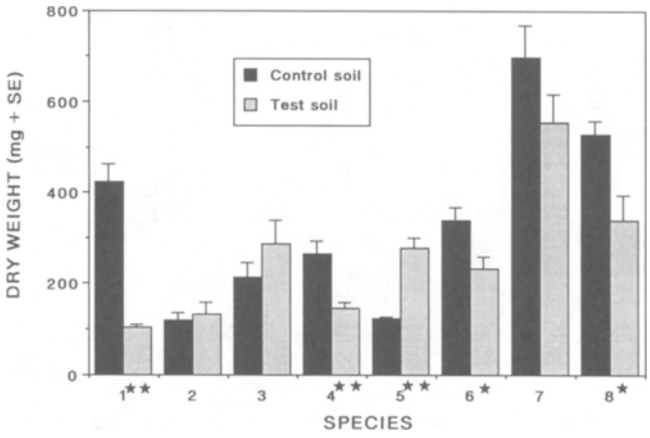

FIG. 4. Seedling dry weight of receptor plants tested in soils from underneath wormwood plants. Keys to species as in Figure 3. Bar is standard error. Student's t test: *significantly different, $P \leq 0.05$; **$P \leq 0.01$.

(1982) reported that 2% or greater amounts of ground, mature sunflower leaves mixed into the soil significantly reduced emergence, height, fresh weight, and dry weight of the tested plants. It was reported that incorporation of dried shoot or root residues of lantana into the soil significantly reduced milkweedvine growth compared with growth in control soil (Achhireddy and Singh, 1984). White et al. (1989) reported that cotton and pitted morning glory emergence and dry weight were decreased approximately 60–80% when these plants were grown under greenhouse conditions in the presence of increasing amounts of field-grown crimson clover or hairy vetch debris incorporated into the soil medium, while corn dry weight was increased 20–75% when legume debris was placed on the soil surface.

It was found that increasing the incubation time of wormwood leaf decreased elongation, dry weight, and caloric content of receptor plants. Patrick and Koch (1958) noted that substances possessing phytotoxic properties may be formed during the decomposition of plant residues in the soil; Al-Naib and Rice (1971) found that decaying sycamore leaves significantly reduced seed germination and seedling growth of all test species. Kuo et al. (1981) pointed out that the aqueous extraction of decomposing Chinese cabbage leaves completely inhibited mungbean seed emergence. Phytotoxicity of Chinese cabbage was caused by substances produced by decomposing Chinese cabbage leaves or microorganisms associated with the decomposition rather than by microorganisms becoming pathogenic agents for the following mungbean crop. The fact that the increase in growth inhibition of tested plants with incubation time may have been due to a release of inhibitory substances from decomposing plant tissue or to the

formation of toxic substances by microorganisms associated with the decomposing leaves was discussed by Barnes and Putnam (1983) and Harrison and Peterson (1986). Thus, it is likely that the allelopathic effect of the wormwood plants was partly due to this interaction between residues and microorganisms.

Field soil collected under the wormwood plants significantly reduced or somewhat promoted growth of the test plants. These results are in agreement or disagreement with following results: soil collected from some plant fields exhibited phytotoxity by reducing growth (Al-Naib and Rice, 1971; AlSaadawi and AlRubeaa, 1985; Inam et al., 1989) and soil from below some test plants did not inhibit germination and growth of the test species (Fadayomi and Oyebade, 1984; Goel and Sareen, 1986).

The current study demonstrates phytotoxicity of wormwood residues in soil.

ISOTHIOCYANATES AS ALLEOPATHIC COMPOUNDS FROM *Rorippa indica* Hiern. (Cruciferae) ROOTS

A. YAMANE, J. FUJIKURA, H. OGAWA, and J. MIZUTANI*

Department of Agricultural Chemistry
Faculty of Agriculture
Hokkaido University
Kita-ku, Sapporo 060, Japan

(Received November 25, 1991; accepted June 17, 1992)

Abstract—The ethyl acetate extracts of *Rorippa indica* Hiern. contained hirsutin, arabin, camelinin, and three novel ω-methylsulfonylalkyl isothiocyanates (n = 8, 9, and 10). These compounds severely inhibited lettuce (*Lactuca sativa*) hypocotyl and root growth at 0.1 mM or above. The precursor glucosinolates of hirsutin, arabin, and camelinin were isolated. Presence of the three ω-methylsulfonylalkylglucosinolates, along with other glucosinolates in the roots were verified by the isolation and identification of their desulfo-derivatives. Using the continuous root exudate trapping apparatus and GC-MS, hirsutin and the three ω-methlylsulfonylalkyl isothiocyanates were detected in the root exudates of *R. indica*, suggesting that these isothiocyanates are the primary candidate of allelopathic compounds contributing to the aggressiveness of this cruciferous weed.

Key Words—Allelopathy, root exudates, hirsutin, glucohirsutin, arabin, glucoarabin, camelinin, glucocamelinin, ω-methylsulfonylalkyl isothiocyanates, *Rorippa indica*, cruciferae.

INTRODUCTION

Rorippa indica Hiern. (Inugarashi in Japanese, Cruciferae) is a common perennial weed in the fields and pastures of Japan. The weed has the ability to propagate through its vegetative organs such as roots or stems (Ito et al., 1989). As the weed exists in very dense and practically pure stands, this suggests that the species may produce substances that are allelopathic to other surrounding plants.

*To whom correspondence should be addressed.

0098-0331/92/1100-1941$06.50/0 © 1992 Plenum Publishing Corporation

Recently, we reported that *Rorippa sylvestris* contained 8-methyl sulfinyloctyl isothiocyanate (hirsutin) as a major inhibitory principle in the roots and that the compound inhibited the growth of lettuce (Kawabata et al., 1989). The content of glucohirsutin and deoxyglucohirsutin in the root increased during both the vegetative and the reproductive growing stages. Isothiocyanates in cruciferous plants are thought to play an important role as inhibitors of plant growth, in addition to their antimicrobial activity (Harborne, 1988). These sulfur-containing compounds are usually found in macerated tissues owing to the mixing of the precursor glucosinolates with the hydrolytic enzyme thioglucosidase (Olsen and Sørensen, 1981). The most frequent fate of the unstable aglycones generated by initial hydrolysis is to undergo spontaneous rearrangement via either a proton-independent Lossen rearrangement concerted with a loss of sulfate to yield an isothiocyanate, or a competing proton-dependent desulfation to yield a nitrile (McGregor et al., 1983).

Tang and Takenaka (1983) reported that for 2-month-old trees (*Carica papaya* L.), the rate of benzyl isothiocyanate released from the root system was 2–3 μg/tree/day in the continuous root exudate trapping system. Interestingly, Tang (1971) pointed out that herbicidal secondary metabolites are released from the undisturbed plant root system.

As many studies of allelopathic interactions in germination and growth have only dealt with plant extracts or leachate from soils, it is usually difficult to assign the active principle in plant–plant interactions. For this reason, we applied the continuous root exudate trapping system according to Tang and Young (1982) to the exploration and identification of the constituents in the root exudates of *R. indica* which inhibit the growth of lettuce.

METHODS AND MATERIALS

Plant Collection and Extraction. Roots (2.4 kg, fresh weight) of *R. indica* were collected on the campus of Hokkaido University in July 1989 and were extracted with EtOAc for one month at room temperature. The extract was evaporated under reduced pressure, and the aqueous concentrate was fractionated into acidic and neutral fractions in the usual way.

Bioassay of Inhibitory Activities against Lettuce. We examined the activity of each extract, chromatographic fractions, and isolated compounds by a lettuce seed germination bioassay. An appropriate amount of the sample was dissolved in 0.5 ml of acetone, and the solution was poured into a 6-cm-diam. Petri dish with two sheets of filter paper (No. 3, 5.5 cm, Toyo Roshi Co., Ltd.) placed at the bottom. The acetone was evaporated, and 2 ml of Tween-80 aqueous solution (100 ppm) was poured into each Petri dish. The dishes were covered and kept in the dark for 24 hr at room temp. Lettuce seeds (30 seeds per dish)

were placed on the filter paper and then incubated at 23°C in the dark. Germination percentages were recorded after 24 hr. A control containing only the Tween-80 aqueous solution was included in each experiment. All experiments were duplicated.

For those isolated compounds with significant biological activities, a lettuce hypocotyl and radicle growth bioassay was also used. A sample was dissolved in 150 μl acetone and poured into the 15-ml hot 0.35% agar solution in a Petri dish. The agar solution was cooled, and 20 lettuce seedlings (24 hr after germination) were placed in each dish. The dishes were covered and kept in a growth chamber for one week at 23°C under a 12-hr light–dark cycle. The hypocotyl and radicle lengths for each seedling were measured to the nearest millimeter. The mean length was determined for 20 seedlings (two replications). A control without the sample was included in each experiment.

Fractionation of EtOAc Extract. The neutral fraction inhibited the lettuce seed germination by 90% at 500 ppm and was subjected to silica gel column chromatography using $CHCl_3$–MeOH as eluents. The $CHCl_3$–MeOH (99.5:0.5) and the $CHCl_3$–MeOH (99:1) eluates inhibited lettuce seed germination by 97% and 100% at 500 ppm, respectively. Both fractions were further purified by HPLC using a Megapak Sil C18T, 5 μm, 10 × 250 mm (Gaskuro Kogyo). The UV detector measured absorbance at 254 nm. The eluent system was MeOH–H_2O–CH_3CN (60:25:15) at a flow rate of 4 ml/min. By HPLC, the former eluate was divided into three fractions, and from each fraction, compounds 1, 2, and 3 (37.8, 868, and 44.1 mg) were isolated, respectively. From the latter eluate, three compounds, i.e., compounds 4 (0.2 mg), 5 (42.5 mg), and 6 (6.6 mg) were isolated.

Preparation and Isolation of Desulfoglucosinolates. Fresh roots of *R. indica* were collected on the campus of Hokkaido University in June 1989. The roots (55.7 g) were added slowly to 100 ml of boiling 80% ethanol, and boiled further for 15 min at boiling point. After having been cooled and then homogenized, the resulting suspension was filtered through filter paper. The ethanol was removed by rotary evaporation at 35°C. After transferring the aqueous solution to an Erlenmeyer flask, 5 ml of 0.3 M barium and lead acetate solution were added. The solution was centrifuged (5×10^3 rpm, 5°C, 10 min) and the supernatant was augmented to 50 ml, applied to DEAE-Sephadex A-25, and desulfated with aryl sulfatase (Sigma, H-1), as described by Ishii et al. (1988). Desulfoglucosinolates were obtained after an overnight reaction with sulfatase at ambient temperature (Figure 1). Nine desulfoglucosinolates (7–15) were separated on an HPLC column (Unisil Q C_{18}, 7.6 × 300 mm) (Figure 2). The column was eluted (2.5 ml/min, UV detection; 227.5 nm) with H_2O–CH_3CN (3:2).

Detection of Allelopathic Compounds in R. indica *Root Exudates.* Whole *R. indica* plants were collected on the campus of Hokkaido University and were

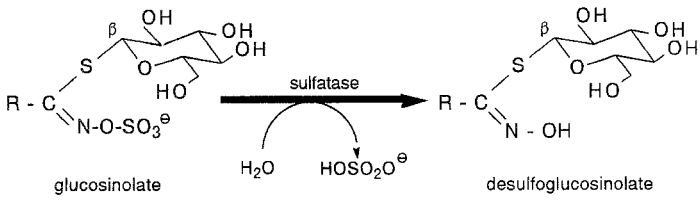

FIG. 1. Preparation to desulfoglucosinolate from glucosinolate.

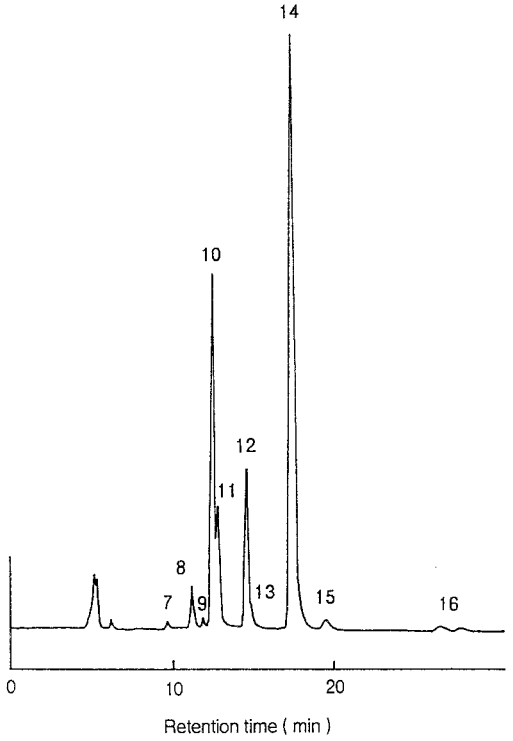

FIG. 2. HPLC separation of desulfoglucosinolates from *R. indica* root. Column: Unisil Q C_{18}, 7.6 × 300 mm, 5 μm; mobile phase: H_2O–CH_3CN (3:2), 2.5 ml/min; UV detection: 227.5 nm

then transplanted into the continuous root exudate trapping system similar to that devised by Tang and Young (1982). The pots were irrigated with a circulating nutrient solution (Tadano and Tanaka, 1976) at a rate of ca. 1 liter/hr. It was necessary to replace the nutrient solution every five days to obtain the best growth.

The plants were ca. 150 mm tall with healthy and proliferous root systems, and collection of root exudates commenced 10 days after transplanting. Prior to the collection, the pots were washed by leaching with 2 liters of distilled water to rinse off accumulated residues, after which a column containing 15 ml of cleaned XAD-4 resin was attached to the pot, fresh nutrient solution was circulated at 1 liter/hr for 48 hr. The charged column was detached from the pot, and then washed with 100 ml of distilled water followed by elution with 100 ml of acetone. The eluate was concentrated to ca. 10 ml at 40°C using a rotary evaporator, and the resultant solution was extracted twice with 10 ml of ether. The combined organic extracts were dried with anhydrous Na_2SO_4 and concentrated to ca. 500 μl for GC analysis.

Chemical Analysis. GC analysis was performed on a Hitachi Gas Chromatograph 263-30, with an OV-1 capillary column (25 m × 0.35 mm ID). The column temperature was programmed from 100°C to 300°C at 4°C/min. GC-mass spectrometry was conducted using a JEOL DX-300 GC-MS system with a 25 m OV-1 column. EI-MS and FD (FI)-MS determinations were carried out, respectively, on a JEOL DX-300 and JEOL JMS-01SG-2. ^{1}H-NMR and ^{13}C-NMR spectra were recorded on a BRUKER AM-500 instrument at 500 MHz and 125 MHz, respectively, with TMS as an internal standard. Infrared spectra were obtained using a Hitachi model 285, and UV spectra were recorded on a Hitachi model U-3210 spectrophotometer.

RESULTS

Isothiocyanates from EtOAc Extracts. The bioassay results revealed that the neutral fraction of the EtOAc extracts remarkably inhibited lettuce seed germination. Silica gel column chromatography, preparative TLC, and subsequent HPLC of these fractions, based on the lettuce seed germination bioassay, resulted in the isolation of inhibitors **1–6**.

The MS of compound **1** [FD-MS *m/z* (%): 249 (M^+, 100)] suggested a hirsutin-related structure. The presence of an isothiocyanate group in **1** was confirmed by the IR spectrum (ν −N=C=S at 2170 and 2100 cm^{-1}), and the absorption at 1290, 1270, 1250, and 1130 cm^{-1} suggested the presence of a sulfonyl moiety. The ^{1}H-NMR spectrum indicated an ω-methylsulfonylalkyl isothiocyanate. From the physiochemical data shown in Table 1, compound **1** was assigned to the structure of 8-methylsulfonyloctyl isothiocyanate (Figure 3).

The MS of **2** [FD-MS *m/z* (%): 263 (M^+, 100)] and **3** [FD-MS *m/z* (%): 277 (M^+, 100)] suggested homologs of 1. From the physicochemical data shown in Table 1, compounds **2** and **3** were assigned to the structures of 9-methylsulfonylnonyl isothiocyanate and 10-methylsulfonyldecyl isothiocyanate, respectively (Figure 3).

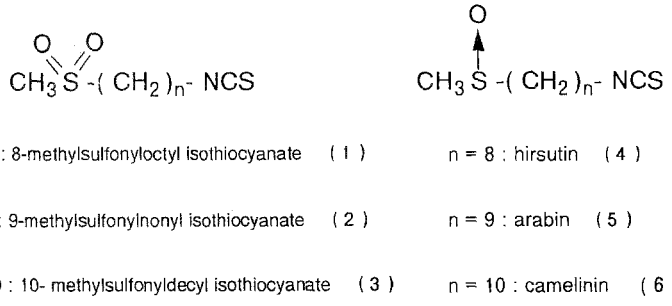

FIG. 3. Chemical structures of isothiocyanates; the allelochemical candidates referred to the text.

The MS of **4** (buff-colored oil) suggested hirsutin that we had isolated from the root of yellow fieldcress (*R. sylvestris*, Kirehainugarashi in Japanese) (Kawabata et al., 1989), and its optical rotation was $[\alpha]_D^{23} = -50°$ ($c = 0.145$, MeOH). The ^{1}H-NMR, IR, and UV spectra of **4** were identical with those of hirsutin (Figure 3).

The MS of **5** and **6** suggested homologs of **4**. Compound **5** has optical rotation $[\alpha]_D^{23} = -51°$ ($c = 0.153$, MeOH), and the ^{1}H-NMR, IR, and UV spectra of compound **5** were assigned to the structure of 9-methylsulfinylnonyl isothiocyanate (arabin) (Figure 3). Compound **6** has optical rotation $[\alpha]_D^{23} = -55°$ ($c = 0.003$, MeOH) and its ^{1}H-NMR, IR, and UV spectra were assigned to the structure of 10-methylsulfinyldecyl isothiocyanate (camelinin) (Figure 3).

Inhibitory Activities against Lettuce. Hirsutin (Kawabata et al., 1989), arabin, camelinin and ω-methylsulfonylalkyl isothiocyanates ($n = 8$ and 9) inhibited seed germination at 0.5 mM by 100, 88, 9, 100, and 58%, respectively. On the other hand, 10-methylsulfonyldecyl isothiocyanate had no effect upon seed germination (Table 2). All compounds inhibited root and hypocotyl elongations of lettuce seedling at 0.4 mM (Table 3). In particular, 9-methylsulfonylnonyl isothiocyanate showed a remarkable inhibitory activity and reduced the hypocotyl and radicle elongations of lettuce seedling at 0.2 mM by 63 and 76%, respectively. Even at 0.1 mM (26 ppm), it inhibited the hypocotyl elongation of lettuce seedlings by more than 30%. As a reference compound to clarify the activity of 9-methylsulfonylnonyl isothiocyanate, juglone was used. Although the tendencies of inhibition for lettuce seedling growth differed for the compounds, it could be concluded that the inhibitory activity of 9-methylsulfonylnonyl isothiocyanate was as half strong as that of juglone.

Physicochemical Properties of Isolated Desulfoglucosinolates (DS-GSLs). The main DS-GSLs extracted from the *R. indica* root were further purified on HPLC, and nine DS-GSLs were isolated (**7–15**) (Figure 2). All the DS-GSLs were identified by FD-MS and ^{1}H-NMR spectra as follows.

[a]Elongations (percent of control) for a particular compound. Means within column followed by the same letters are not significantly different at the 0.05 level according to Duncan's multiple-range test.

Compound **7** (0.2 mg): 8-methylsulfinyloctyldesulfoglucosinolate (DS-glucohirsutin); compound **8** (1.1 mg): 9-methylsulfinylnonyldesulfoglucosinolate (DS-glucoarabin); compound **9** (0.5 mg): 8-methylsulfonyloctyldesulfoglucosinolate; compound **10** (2.4 mg): desulfoglucobrassicin, compound **11** (0.8 mg): 4-methoxydesulfoglucobrassicin; compound **12** (5.6 mg): 9-methylsulfonylnonyldesulfoglucosinolate; compound **13** (0.1 mg): 10-methylsulfinyldecyldesulfoglucosinolate (DS-glucocamelinin); compound **14** (5.4 mg): 1-me-

thoxydesulfoglucobrassicin; and compound **15** (0.7 mg): 10-methylsulfonyldecyldesulfoglucosinolate.

The anomeric proton doublets of **7–15** (H-1′) were observed in the ^{1}H-NMR, and these signals indicated a β-linked glucoside structure, by comparison with prepared desulfosinigrin (J = 9.8 Hz).

The FD-MS of the lowest polar fraction **16** (colorless oil, 0.2 mg) indicated a mixture of three homologous compounds (M^+ 397, M^+ 411, and M^+ 425) and suggested the structures of 8-methylthiooctyldesulfoglucosinolate, 9-methylthiononyldesulfoglucosinolate, and 10-methylthiodecyldesulfoglucosinolate, respectively.

Candidates of Allelopathic Compounds in R. indica *Root Exudates.* The hydrophobic substances in the recirculating solution inhibited lettuce seed germination by 85% at 200 ppm and also reduced the hypocotyl and root elongations of lettuce seedling at 100 ppm by 35% and 7%, respectively. Even at 10 ppm, it affected the growth of lettuce seedling hypocotyl.

The chromatogram of root exudates obtained from GC equipped with FID showed more than 50 peaks, and the retention time of the isolated standard compounds and GC-MS revealed the presence of **1** (t_R 17 min 24 sec), **2** (t_R 18 min 39 sec), **3** (t_R 19 min 42 sec), and **4** (t_R 15 min 48 sec). 8-Methylsulfonyloctyl isothiocyanate (**1**), MS *m/z* (%): 249(M^+, 0.1), 216 (8), 170 (50), 115 (36), 81 (17), 69 (79), 55 (100); 9-methylsulfonylnonyl isothiocyanate (**2**), MS *m/z* (%): 263 (M^+, 2), 230 (16), 184 (5), 115 (13), 81 (26), 69 (51), 55 (100); 10-methylsulfonyldecyl isothiocyanate (**3**), MS *m/z* (%): 277 (M^+, 0.2), 244 (15), 198 (3), 115 (78), 69 (35), 55 (100); 8-methylsulfinyloctyl isothiocyanate (**4**), MS *m/z* (%): 233 (M^+, 1), 216 (11), 170 (23), 69 (53), 55 (90). The other phytotoxic isothiocyanates that we isolated may exist in the root exudates at lower concentrations.

DISCUSSION

The isolation of compounds from *R. indica* root extracts revealed not only the presence of phytotoxic isothiocyanates, hirsutin, arabin, and camelinin that had been reported previously for the essential oil (Kjaer and Christensen, 1958; Kjaer and Gmelin, 1956; Kjaer et al., 1956) but also novel ω-methylsulfonylalkyl isothiocyanates (n = 8, 9, and 10). This is the first report of their occurrence as major phytotoxic isothiocyanates in *R. indica*.

The data in Table 2 clearly demonstrate a close relationship between chemical structure and inhibitory activity. The inhibition rate of lettuce seed germination by ω-methyl-sulfinyl (and sulfonyl) alkyl isothiocyanates (n = 8, 9, and 10) was gradually decreased as the values of n increased. However, this hypothesis was not applicable for the inhibition of lettuce seedling growth by ω-meth-

ylsulfonylalkyl isothiocyanate (n = 8, 9, and 10) (Table 3). The difference may be attributed to the differences in the mode of action between the inhibition of lettuce seed germination and the inhibition of lettuce seedling growth (Einhellig, 1986).

In order to elucidate how these isothiocyanates are generated, we needed to isolate their precursor glucosinolates. Kjaer et al. reported that they have isolated glucohirsutin, glucoarabin, and glucocamelinin in addition to an extremely small amount of deoxyglucohirsutin, deoxyglucoarabin, and deoxyglucocamelinin as desulfoglucosinolate (Kjaer et al., 1956; Kjaer and Christensen, 1957, 1958; Kjaer and Gmelin, 1956), but no one has previously shown that these compounds are also present in *R. indica*. We have found, for the first time, that ω-methylsulfonylalkylglucosinolates (n = 8, 9, and 10) isolated for desulfoglucosinolate are naturally occurring glucosinolates. Although the indole glucosinolates glucobrassicin, 4-methoxyglucobrassicin, and 1-methoxyglucobrassicin represent a significant proportion of the total glucosinolate content of cruciferous vegetables (Fenwick et al., 1983; Truscott et al., 1982), while Virtanen (1965) has demonstrated that, following the rupture of the cells of plant material, indole glucosinolate is hydrolyzed by the endogenous enzyme myrosinase to a number of compounds, including indolyl nitrile in acidic condition or thiocyanate ion and indolyl alcohol in neutral condition, it is still necessary to investigate the mechanism of these chemodynamics and the role of those compounds in *R. indica*.

Chisholm (1972) has reported that in *Cheiranthus kewensis* DL-methionine-2-^{14}C and DL-homomethionine-2-^{14}C were incorporated into 3-methylthiopropylglucosinolate and 3-methylsulfinylpropylglucosinolate; these results suggested the following sequence of biochemical reactions: methionine → homomethionine → 3-methylthiopropylglucosinolate → 3-methylsulfinylpropylglucosinolate. This result suggests that, in *R. indica*, the oxidation of ω-methylthioalkylglucosinolate into ω-methylsulfinylalkylglucosinolate and of ω-methylsulfinylalkylglucosinolate to ω-methylsulfonylalkylglucosinolate may also be performed by enzymatic oxidation, since isothiocyanates are usually found in macerated tissues owing to the mixing of glucosinolates and the hydrolytic enzyme thioglucosidase (Olsen and Sørensen, 1981). We therefore consider that ω-methyl-sulfonyl (and sulfinyl) alkylglucosinolates (n = 8, 9, and 10) are the precursors of phytotoxic ω-methyl-sulfonyl (and sulfinyl) alkyl isothiocyanates (n = 8, 9, and 10).

Because many studies of allelopathic interactions on plant seed germination and growth have only dealt with crude plant extracts or leached compounds from soils, it is difficult to assign the active principle in plant–plant interactions. For this reason we used the continuous root exudate trapping method. Tang and Takenaka (1982) reported that in 2-month-old trees of *Carica papaya* L., benzyl isothiocyanate was released from the undisturbed plant root system. Our study

has revealed that the inhibitory activity of hydrophobic exudates from *R. indica* roots upon lettuce seed germination and lettuce seedling growth may be caused by phytotoxic isothiocyanates including ω-methylsulfonylalkyl isothiocyanates (n = 8, 9, and 10) and hirsutin. Einhellig (1987) reported that allelopathic inhibition of germination and plant growth typically occurred as a result of the joint action of several allelochemicals. In the same way, isothiocyanates may interact in an additive or synergistic manner. Owing to their low water solubility, ω-methyl-sulfonyl (and sulfinyl) alkyl isothiocyanates released from the root surface will diffuse slowly into the soil solution, resulting in a concentration gradient at the root–soil interface. The continuous release of ω-methyl-sulfonyl (and sulfinyl) alkyl isothiocyanate from normal growing *R. indica* roots would suggest that this metabolite plays an important active role in the rhizospheric ecosystem.

Our investigation clearly shows that several isothiocyanates are potent phytotoxins to lettuce seed and lettuce seedling. Furthermore, these isothiocyanates appear to be allelochemical compounds in plant–plant interactions.

Acknowledgments—We wish to thank Dr. J. Kawabata and Mrs. E. Fukushi for ^{1}H-NMR and ^{13}C-NMR spectral measurements; we are also grateful to Mr. K. Watanabe and Mrs. Y. Sugiyama for mass spectral measurements.

(Received March 17, 1992; accepted June 18, 1992)

Abstract—Young *Cinchona ledgeriana* plants contain two types of alkaloid: indole alkaloids in the leaves and quinoline alkaloids in the root. From *Cinchona* leaves, a crude alkaloid extract was made, containing the cinchophylline type of indole alkaloids and a small amount of 5-methoxytryptamine. The leaf alkaloid extract exerted a strong detrimental effect on the growth of larvae of the polyphagous beet armyworm, *Spodoptera exigua* (Lepidoptera). Feeding of larvae on an artificial diet containing the leaf alkaloids at the same concentrations as those found in the plant resulted in significant growth reduction, retardation in development, and mortality of the larvae. Cinchophyllines are composed of 5-methoxytryptamine coupled to a corynantheal unit. When incorporated into the artificial diet, 5-methoxytryptamine alone had no effect on the *S. exigua* larvae. Corynantheal, however, had a strong detrimental effect on growth of the larvae, its effect being comparable to that of the leaf alkaloid extract. In contrast to the indole-type leaf alkaloids, the quinoline-type *Cinchona* root alkaloids did not affect growth and development of the larvae. These results suggest that the indole-type alkaloids, which in *Cinchona* plants are present at the highest concentrations in the young, vulnerable leaflets, are involved in the chemical defense of the plant against herbivorous insects.

Key Words—Chemical defense, *Cinchona*, indole alkaloids, leaf alkaloids, Lepidoptera, Noctuidae, quinoline alkaloids, root alkaloids, *Spodoptera exigua*.

INTRODUCTION

Alkaloids are present in an enormous range of chemical structures in about 20% of the higher plant families. These secondary plant compounds often have a feeding-inhibitory or toxic activity towards herbivores (Janzen et al., 1977; Devitt and Philogène, 1980; Clay and Cheplick, 1989; Harborne, 1989). *Cinchona ledgeriana* Moens (fam. Rubiaceae) is indigenous to South America, and this species produces a variety of alkaloids, including the well-known antimalarial agent quinine (McHale, 1986). In young *C. ledgeriana* plants the various types of alkaloids are present in different organs: indole cinchophylline alkaloids in the aerial parts, and quinoline alkaloids in the roots (Aerts et al., 1991a).

All *Cinchona* alkaloids are ultimately derived from the common precursor alkaloid, strictosidine (Nagakura et al., 1979). Strictosidine is formed in a reaction catalyzed by the enzyme strictosidine synthase (Scott et al., 1977; Stöckigt and Zenk, 1977). In a previous study it was shown that in 6-month-old *C. ledgeriana* plants, the highest strictosidine synthase activity of the plant is present in the young, expanding leaflets (Aerts et al., 1991a). Indeed, the highest alkaloid content of the plant is also found in the young leaflets, in which the cinchophylline concentration is about 15 mM (15 nmol/mg fresh weight). In old leaves the cinchophylline concentration is five times lower than in young leaflets (Aerts et al., 1991a). Much lower strictosidine synthase activity than in the young leaflets is found in the roots of young *C. ledgeriana* plants, where quinoline alkaloids are present in concentrations of about 6 mM (Aerts et al., 1991a).

The high content of cinchophyllines in the young, nutrient-rich leaflets of *Cinchona* plants, and the striking difference in content between young leaflets and old leaves, may point to a protective role of the cinchophylline alkaloids against herbivores. In a number of cases, plants have been shown to express an explicit defense strategy in the timing and localization of alkaloid accumulation. The alkaloids produced by *Coffea arabica* L., for instance, have a deterrent or lethal effect on insect larvae (Janzen et al., 1977; Usher et al., 1988). Furthermore, during leaf development in coffee plants, the highest alkaloid content is present in the young, soft leaflets at the moment they emerge from their protective stipules (Frischknecht et al., 1986). Likewise, the alkaloid halostachine deters feeding by *Locusta*. In rye grass (*Lolium perenne* L.), a high concentration of halostachine is present in young, vulnerable seedlings just after germination, and the concentration decreases as the plant matures. Accordingly, the

meal size taken by *Locusta* nymphs from rye grass seedlings is much smaller than from mature leaves of the same species (Bernays and Chapman, 1976).

Here, we set out to investigate the possible protective role of *Cinchona* cinchophylline alkaloids. To this end, the alkaloids were incorporated into an artificial diet, and the effects were monitored on growth of larvae of the polyphagous beet armyworm *Spodoptera exigua* (Hübner) (Lepidoptera, Noctuidae).

METHODS AND MATERIALS

Extraction and Quantification of Leaf Alkaloids. Twenty-one of the youngest leaves (22.8 g) were collected from several *Cinchona ledgeriana* Moens plants. The leaves were cut in pieces and frozen in liquid nitrogen. The plant material was ground in a mortar and extracted twice with methanol. After evaporation of the methanol, the alkaloids were taken up in 2% H_2SO_4 and, after alkalinization with NH_4OH, were extracted three times in chloroform. The procedure was repeated once more: the chloroform extract was extracted three times with 2% H_2SO_4, and, after alkalinization of the aqueous extract, the alkaloids were again extracted three times in chloroform. The chloroform extract was filtered, dried over Na_2SO_4, and taken to dryness.

Identification and quantification of the alkaloids was by means of reference compounds and a HPLC system coupled to a photodiode array detector as described previously (Aerts et al., 1991a). In addition, identification was also by TLC as described previously (Aerts et al., 1991a,b). The crude extract contained the 3α,17β-, 3α,17α-, and 3β,17α-cinchophyllines (cf. Mulder-Krieger et al., 1982; Keene et al., 1983), as well as 7% 5-methoxytryptamine.

Other Alkaloids Used. The other alkaloids used were from commercial sources or gifts: 5-methoxytryptamine (Sigma); cinchonine, cinchonidine, quinine, and quinidine (a kind gift of ACF Chemiefarma); corynantheal (a kind gift of Dr. G. Massiot, Reims); emetine (gift).

Feeding Studies. An artificial diet was prepared as follows: 3 g agar was dissolved in 88.5 ml water and, after boiling, 14.5 g cornmeal, 3.5 g ground wheat germ, and 4 g brewer's yeast were added and mixed for 2 min. When the mixture had cooled to 60°C, vitamin C (0.5 g), benzoic acid (0.16 g), methyl *p*-hydroxybenzoate (0.13 g) and Aureomycin (8 mg) were added, and the complete diet was mixed for 3 min and further cooled. The alkaloids, dissolved either in water or in 96% ethanol, were thoroughly mixed into the artificial diet. Controls were provided by diets treated with solvent, i.e., water or 96% ethanol, only. After evaporation of the ethanol, the diets were offered to newly hatched *Spodoptera exigua* (Hübner) larvae. For each condition, 30–45 larvae, divided over four to six separate dishes, were used and were kept on the diet in the dark at 26–27°C. Every two to three days, the larvae received freshly

prepared artificial diet with alkaloid added. After six days, the mortality and average weight of the surviving larvae were determined. The average weight of the larvae was expressed as a percentage of the average weight of larvae kept on control diet (= 0 nM alkaloid, 100% growth).

To check for sensitivity of the larvae towards changes in ionic strength, larvae were also kept on artificial diet containing 15 mM NaCl. The NaCl had no effect on the growth of the larvae. The HPLC pattern and absorption spectra of the leaf alkaloids were unchanged after four days in the artificial diet, indicating no breakdown of the alkaloids.

Injection Studies. Fifth-instar larvae of *S. exigua* were mildly anesthetized with CO_2 and injected into the hemolymph with 1-μl volumes of solutions of the leaf alkaloids in 96% ethanol. Injections were performed by means of micropipets made with a Narishige Micropipette Puller. For each dose, 17 larvae were injected; controls were injected with 96% ethanol only. After injection with the highest dose (80 μg), the yellowish colored alkaloid solution could be clearly observed inside the larvae. The larvae were subsequently kept individually on artificial diet (see Feeding Studies) in the dark at 26–27°C. Seven days after injection, the pupae were transferred to containers with sawdust at the bottom. The pupae were kept in a 12 : 12 hr light–dark regime at 25–26°C. After emergence, the adults were offered a 10% honey solution.

RESULTS AND DISCUSSION

An extract of *Cinchona* leaf alkaloids was incorporated into an artificial diet in a concentration range similar to that found in *Cinchona* plants. The modified diet was offered to newly hatched *Spodoptera exigua* larvae, and the effects on growth of the larvae were monitored (see Methods and Materials). The leaf alkaloids exerted a strong detrimental effect on growth of the larvae (Figure 1, circles). At concentrations similar to those present in young leaflets of *Cinchona* plants (15 mM; in Figure 1 indicated with an arrow), the growth of the larvae was reduced to about 10% of that of controls. At a concentration of 5 mM, the growth of the larvae was approximately reduced by half. Concomitant with growth reduction, retardation in development was observed. At the highest concentration of leaf alkaloids used (15 mM), most of the larvae were still in their first instar after six days, whereas controls were already in their second or third instar.

Besides effects on growth and development of the larvae, the leaf alkaloids also caused high mortality: 41% of the larvae did not survive a six-day period on a diet with a concentration of alkaloid such as was present in young *Cinchona* leaflets (Table 1). In preliminary experiments, *Cinchona* leaf alkaloids were found to have comparable detrimental effects on larvae of *Biston betularia* L. and *Trichoplusia ni* (Hübner) as on the *Spodoptera exigua* larvae (not shown).

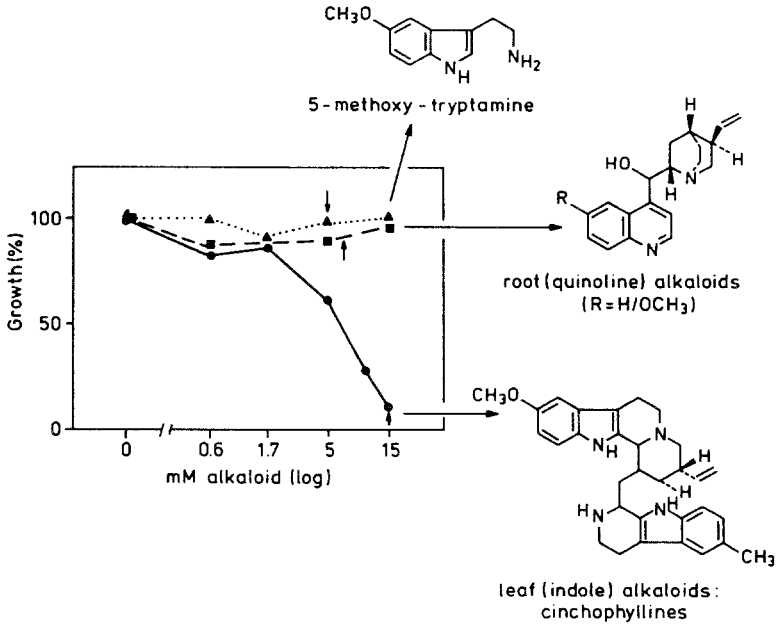

FIG. 1. Effects of the various alkaloids present in young *Cinchona ledgeriana* plants on the growth of larvae of the polyphagous insect *Spodoptera exigua* (Noctuidae, Lepidoptera). Newly hatched larvae were offered an artificial diet with the alkaloids added at several concentrations. After six days, the average weight of the surviving larvae was determined. Growth (=weight) of the larvae is expressed as a percentage of that of control larvae (= 0 mM alkaloid; see Methods and Materials). Arrows indicate the highest concentrations of the alkaloids such as found in 6-month-old *C. ledgeriana* plants.

Emetine	97

[a]Cinchonine, cinchonidine, quinine, and quinidine (1:1:1:1)

To distinguish between effects of cinchophylline alkaloids and 5-methoxytryptamine, which were both present in the leaf extract (see Methods and Materials), the effect of 5-methoxytryptamine alone on growth and mortality of *Spodoptera exigua* larvae was investigated (Figure 1, triangles; Table 1). 5-Methoxytryptamine alone had no effect on the larvae, either at the concentration such as present in *Cinchona* plants (in Figure 1 indicated with an arrow) or at higher concentrations. This indicates that the effect of the leaf-alkaloid extract was due to the cinchophylline alkaloids.

In young *Cinchona* plants, 5-methoxytryptamine is present in plant parts that are rich in cinchophyllines (Aerts et al., 1991a) and these may very well be involved in the synthesis of cinchophyllines, since 5-methoxytryptamine constitutes part of the cinchophylline molecule (Figure 1, structures). The other part of the cinchophylline molecule consists of a corynantheal unit (Figures 1 and 2, structures). Because 5-methoxytryptamine alone did not influence growth of the larvae, the effect of corynantheal on the larvae was investigated and was shown to have a detrimental effect on growth of the larvae, in a manner similar to the leaf alkaloids (Figure 2, circles; cf. Figure 1). At the highest concentration used (15 mM), corynantheal reduced growth of the larvae to about 15% of that untreated controls, and at a concentration of 5 mM, growth was reduced by approximately half. Again, concomitant with growth reduction, both retardation in molting and mortality of the larvae were observed (Table 1).

These results may indicate that in cinchophylline molecules the corynan-

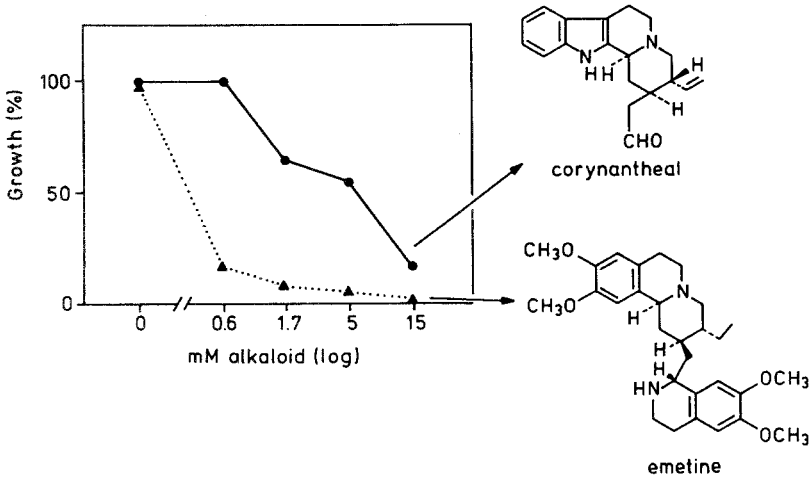

FIG. 2. Effects on the growth of *S. exigua* larvae of the corynantheal moiety of cinchophylline alkaloids from *Cinchona* and the alkaloid emetine from *Cephaëlis*. For experimental details, see legend to Figure 1.

theal moiety is the active site exerting the detrimental effects on the larvae. Alternatively, the detrimental effect of corynantheal may be related to the aldehyde group present in this molecule (Figure 2). This aldehydic function may also explain the coupling of corynantheal to 5-methoxytryptamine in the plant.

The quinoline-type alkaloids found in the underground parts of young *C. ledgeriana* plants were also tested for their effect on growth of *S. exigua* larvae. Intriguingly, in contrast to the indole-type leaf alkaloids, the quinoline-type root alkaloids did not affect growth of the larvae (Figure 1, Table 1).

Emetine is an alkaloid from *Cephaëlis ipecacuanha* and, like *Cinchona* is a member of the Rubiaceae family and has medicinal and amebicidal properties (Hughes and Genest, 1973; Keene et al., 1986). Because the mode of biosynthesis of emetine is closely related to that of cinchophylline alkaloids (Hegnauer, 1973; Verpoorte et al., 1985), and the chemical structures of emetine and cinchophylline alkaloids have features in common (Figure 1 and 2, structures), the effect of emetine was tested, and it turned out to have strong detrimental effects on the growth of the larvae (Figure 2, Table 1).

In general, the protective effect of secondary compounds in plant tissues can be due to their toxicity, to their feeding deterrence, or to a combination of the two. To study the possible toxicity of the *Cinchona* leaf alkaloids directly, known amounts of the alkaloids were injected into the hemolymph of final-instar *S. exigua* larvae (see Methods and Materials). Figure 3 shows that seven days after injection, the percentage of larvae that became pupae was unchanged at all amounts injected, as compared to controls injected with carrier only. The

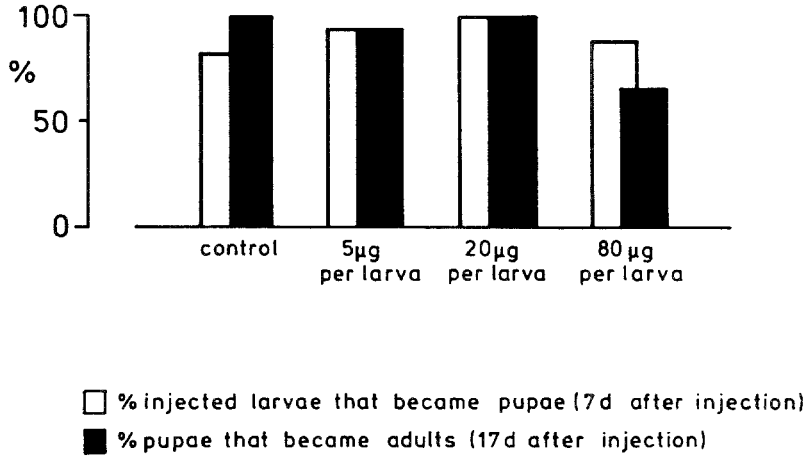

FIG. 3. Development of *S. exigua* final-instar larvae after injection into the hemolymph of increasing doses of *Cinchona* leaf alkaloids. For each condition, 17 larvae were injected. Controls were injected with carrier only.

percentage of pupae that subsequently became adults 17 days after injection declined only at the highest amount injected (80 μg) (Figure 3). Under all conditions, the adults produced eggs from which larvae hatched. Thus, acute, pronounced toxic effects of the *Cinchona* leaf alkaloids were not observed at the amounts injected.

The largest amount injected (80 μg) corresponds to a dose of about 0.4–0.8 mg/g of body weight. For comparison, in leaves of *Encelia asperifolia* and *E. actoni*, the toxic sesquiterpene lactone encelin is present in concentrations roughly corresponding to those of alkaloids in *Cinchona* leaves (Srivastava et al., 1990). However, encelin caused 60% mortality within two days when final-instar *Spodoptera littoralis* larvae were injected into the hemolymph with a dose of only about 0.1 mg/g of body weight (Srivastava et al., 1990). Likewise, when fifth-instar *Locusta migratoria* and *Schistocerca gregaria* larvae were injected into the hemolymph with the triterpenoid azadirachtin or the alkaloids nicotine or tomatine, the doses at which 50% mortality occurred within 24 hr were estimated at 0.08–0.16 mg/g for azadirachtin, 0.6–0.8 mg/g for nicotine, and 0.1–0.7 mg/g for tomatine (Cottee et al., 1988). Compared to these natural compounds, which are present in plants in comparable (nicotine, tomatine) or lower (azadirachtin) concentrations as the *Cinchona* leaf alkaloids, the latter show very low toxicity. How, exactly, the leaf alkaloids exert their detrimental effects on the larvae is at present unknown.

We have shown that *Cinchona* leaf alkaloids, when introduced into an artificial diet at concentrations such as present in the plant, exert detrimental and lethal effects on larvae of *S. exigua*. As has been stated before (Harborne, 1989), if secondary compounds play a protective role in the plant, then the timing and localization of accumulation of these compounds can be expected to reflect a defense strategy. Indeed, the highest concentration of leaf alkaloids in *Cinchona* plants has been shown to be present in the vulnerable, young expanding leaflets (Aerts et al., 1991a). These results suggest that the leaf alkaloids play a role in the chemical defense of the plant against phytophagous insects.

Evidence suggests that the *Cinchona* leaf alkaloids have, in fact, multiple defensive functions, since the alkaloids were shown to have amebicidal and antimicrobial activities as well (Keene et al., 1986; Caron et al., 1988). More secondary compounds synthesized by *Cinchona* may be involved in the chemical defense of the plant, since the anthraquinones produced by *Cinchona* also have antimicrobial activity, and a role of the anthraquinones as phytoalexins has been suggested (Verpoorte et al., 1985; Wijnsma et al., 1985). Finally, with respect to the root alkaloids of young *Cinchona* plants, which did not affect the *S. exigua* larvae, it is interesting to note that these alkaloids have been shown to have antigastropodan activity (Aerts et al., 1991b).

Acknowledgments—We wish to thank Dr. V. De Luca for helpful discussions and critical reading of the manuscript.

FOLIAR CHEMICALS OF WHEAT AND RELATED GRASSES INFLUENCING OVIPOSITION BY HESSIAN FLY, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae)

(Received April 2, 1992; accepted June 24, 1992)

Abstract—More than twice the number of mated female Hessian flies, *Mayetiola destructor* (Say) entered a zone within 1 cm of a paper strip treated with one plant equivalent (PE) of a chloroform extract of wheat foliar waxes compared to a strip treated with solvent only; females also stayed six times longer and laid 10 times more eggs on the strip treated with the wheat extract. Column chromatographic fractionation of the wheat extract and application of these fractions onto filter paper strips showed four fractions elicited significant numbers of eggs to be laid. Single, binary, and tertiary combinations of three of these fractions (two of the four fractions apparently contained similar compounds) were tested. The greatest numbers of eggs were laid on strips treated with the tertiary combination or the binary combination containing the two most active fractions (3 and 6); three times the number of eggs were laid on strips treated with this binary combination than the sum of eggs laid on strips treated with these two fractions separately. A comparison of grasses and their extracts showed female Hessian flies laid greater numbers of eggs on wheat or rye than on barley or oat. Fractionated barley and oat extracts were tested for activity as for wheat, and a similar pattern was observed, i.e., the greatest numbers of eggs were laid on fractions 3 and 6. Dose–response tests, using these two fractions of wheat, barley, or oat showed the same threshold of activity for fraction 3 for all three extracts, i.e., 2 PE. In contrast, fraction 6 of wheat was active at the lowest dosage tested, 0.25 PE, while the same fraction of either barley or oat was not active until tested at a dosage of 2 PE. It appears that (at least) two chemicals in the foliar

waxes of these grasses influence ovipositional behavior of female Hessian flies. Furthermore, given the similar foliar chemistry of these grasses and the strong synergistic interaction between fractions 3 and 6 shown for wheat extract, it is likely that the ovipositional preferences exhibited by female Hessian flies towards these grasses may be explained by quantitative differences in the amount(s) of the active chemical(s) in their respective fraction 6 (most polar fraction tested).

Key Words—Hessian fly, *Mayetiola destructor*, Diptera, Cecidomyiidae, oviposition stimulants, wheat, rye, barley, oat.

INTRODUCTION

The Hessian fly, *Mayetiola destructor* (Say), is one of the most destructive insect pests of wheat, *Triticum aestivum* L. The Hessian fly is found in most of the major wheat-growing areas in the Northern Hemisphere, as well as in New Zealand in the Southern hemisphere (Hatchett, 1986). In the United States, it is found in all the major wheat-growing areas from the Atlantic coast to the Great Plains and in the coastal areas of California, Oregon, and Washington (Gallun et al., 1975; Morrill and Nelson, 1976; Pike and Antonelli, 1981).

Although wheat is the best known host of the Hessian fly, Hessian fly larvae feed and survive on other grasses in the tribe Triticeae, such as barley (*Hordeum vulgare* L.) and rye (*Secale cereale* L.) (McColloch, 1923; Jones, 1938; Stokes, 1957). In contrast, oat, *Avena sativa* L. (tribe Aveneae), does not support growth of Hessian fly larvae (Morrill, 1982). The mobility of Hessian fly larvae is, however, limited to movement down the leaf from the site where the egg is laid to feeding sites near the crown of the plant. Consequently it is the adult female, by ovipositing, that determines which plant the larva feeds upon.

Recently some of the factors influencing host-plant selection by the female Hessian fly have been studied. Using a surrogate wheat leaf, Harris and Rose (1990) found that female Hessian flies were strongly influenced by chemical, visual, and tactile cues in their choice of an oviposition site. Chemicals extracted from the surface of wheat foliage were found to stimulate female oviposition such that significant increases in the number of eggs were laid on surrogate leaves when treated with levels as low as 0.01 plant equivalents (PE).

We have further investigated the role of foliar chemicals that elicit female Hessian flies to oviposit. We had four objectives in this work: (1) to determine the effects of wheat foliar chemicals on behaviors of mated female Hessian flies preceding and succeeding landing, (2) to determine whether there was more than one chemical in the wheat extract that influenced oviposition by female Hessian flies, (3) to determine whether female Hessian flies exhibited ovipositional preferences towards different grasses, and (4) if females exhibited preferences

towards the various grasses, to determine whether these preferences were due to differences in foliar chemicals of the grasses, and if so, whether these differences were qualitative or quantitative.

METHODS AND MATERIALS

Insects. Hessian flies were from a laboratory culture originally collected from wheat fields in Ellis County, Kansas, in 1986. Although the Great Plains biotype is predominant in Ellis County, other biotypes are present (biotypes A and B, Dr. J. Hatchett, personal communication) and consequently may have been used in experiments. The laboratory colony was reared on the susceptible wheat cultivar Newton in the two- to three-leaf stage. Single, mated females were placed in cages (10 cm diam. × 30 cm height) containing 20 plants and allowed to oviposit; adults emerged from the wheat plants approximately 30 days later and were harvested for use in the experiments reported here.

Mated females for the experiments were obtained from a cage containing 20–100 each of newly emerged males and females. Virgin females could be easily distinguished from mated females by their distended ovipositors; females were usually mated within 15 min of being placed with males.

Grasses and Their Foliar Extracts. Plants of wheat (cultivar Newton), oat (cultivar Don 6), barley (cultivar Kanby) and rye were grown outdoors in September 1989 either in pots (10 cm diam.) or in field plots at Tuttle Creek Research Farm (Manhattan, Kansas). Plants were grown to the three- to four-leaf stage and then either used intact or the leaves were cut at the base of the plant and extracts of their foliar waxes prepared by dipping them in cold (0°C) chloroform for 60 sec according to the method of Bianchi and Figini (1986). Crude extracts were concentrated to 1 PE/30 μl by rotary evaporation at 40°C and stored in glass vials at −15°C.

The concentrated, foliar extract of 500 plants of each grass (each extract containing ca. 30–100 mg of wax) was fractionated on a column (24 cm length × 1.2 cm diam.) containing 12 g of silica gel G (Woelm Pharma, Eschwege, Germany), using mixtures of hexane and diethyl ether according to Kate (1972, p. 404): 45 ml hexane (yielding fraction 1), 95 ml hexane–diethyl ether (99 : 1 v/v) (fraction 2), 60 ml hexane–diethyl ether (95 : 5) (fraction 3), 75 ml hexane–diethyl ether (92 : 8) (fraction 4), 115 ml hexane–diethyl ether (85 : 15) (fraction 5) and 45 ml diethyl ether (fraction 6). Each of the fractions was concentrated, using a rotary evaporator, to 1 PE/30 μl as for the mother solution.

Thin-Layer Chromatography. Extracts and fractions were analyzed by thin-layer chromatography (TLC) using 10 cm (width) × 20 cm (length), 250-μm silica gel-coated glass plates (Fisher Scientific). The various extracts and fractions were applied to the origin of the plates and the plates developed using a

mixture of chloroform–1% ethanol (Tulloch and Hoffman, 1971). After the plates were developed, they were sprayed with rhodamine G (Sigma Chemicals, St. Louis, Missouri). The spots were visualized under 254 nm ultraviolet light. The R_f values of the various spots from the extracts and fractions were compared with R_f values of mixtures of C_{22}–C_{32} alkanes and alcohols, hentriacontane-14,16-dione, 8-hydroxyhentriacontane-14,16-dione, and a mixture of C_{44}–C_{52} esters run on plates under the same conditions.

Behaviors Preceding and Succeeding Landing. At 0800 hr, virgin females ($N = 20$) that had eclosed between 0600 and 0700 hr were placed in cages with males ($N = 20$) and allowed 10 min to mate. At 1100 hr, the mated females were transferred to an arena (18 cm height × 10 cm diam. transparent acrylic walls, a screen top, and moist soil on the floor) containing two filter paper strips (0.5 × 10 cm), one yellow (treated with a vegetable dye, McCormick and Co., Baltimore, Maryland) and treated with 1 PE (in 100 μl) of a chloroform extract of wheat leaves, and the other yellow and treated with 100 μl of chloroform. The strips were placed 4 cm apart and 2 cm away from the arena walls and were held in position by metal clips placed in the soil.

The observer recorded for 20 min: (1) the number of females entering the 1-cm zone surrounding each strip, and (2) the number of females landing on the strips. A landing was scored when all six legs of a female contacted a strip, and the female's wings were folded over her abdomen. At the end of the observation period the numbers of eggs laid on each strip were counted. The test was replicated 10 times with 10 different groups of females.

In tests quantifying the behaviors of female Hessian flies after landing (see Harris and Rose, 1989, for detailed descriptions of behaviors), the observer waited for the first female to land on either of the two treatments (yellow filter paper with or without wheat extract) and then recorded (using a tape recorder) the following events or behaviors for that female: (1) time from landing to flight; (2) the frequency of antennation (antennae brought into contact with or within ca. 1 mm of the filter paper), arching (abdomen arched so that ovipositor touches filter paper), and sitting (abdomen straightened and held parallel to the filter paper); (3) percent of total time on the filter paper that was spent in the arching posture; and (4) the numbers of eggs laid by the female before flying off the strip. After this first observation, the same data were recorded for the next females landing on the other strip, using the same group of mated females. These paired observations were made using 12 different groups of females so that, in all, 12 females were observed both on chloroform-treated and wheat extract-treated yellow strips. Since a randomized complete block design was used in both sets of observations, the data were analyzed by a two-way ANOVA.

These tests were conducted in a climate-controlled room (22.5 ± 0.5°C, and 60–70% relative humidity) under a light intensity of 290 μW/cm^2 [generated using six full-spectrum fluorescent tubes, (Verilux Inc., Greenwich, Connecti-

cut) and measured using a United Detector Technology Model 61 Radiometer (Hawthorne, California)].

Bioassays. Egg-laying responses to the grasses, wheat, rye, barley, and oat [three- to four-leaf stage, 10 plants of each, transplanted into pots (37 cm diam.) with a cage top (18 cm height × 37 cm diam.) transparent acrylic walls, a screened top, and moist soil on the floor] were compared. At 1000 hr, 20–30 mated females were introduced into the cage. Females were removed 6 hr later, and the numbers of eggs laid on the four different grass species were recorded.

For the experiments comparing egg-laying responses to plant foliar extracts and fractions of extracts, extracts or chloroform were applied in appropriate volumes to yellow filter paper strips (10 × 0.5 cm), and the solvent was left to evaporate for 60 min before the paper strips were placed in cages (cages consisted of a transparent acrylic cylinder, 10 cm diam. × 10 cm height, with a screened top, placed over a 10 cm diam. pot containing moist soil). Filter paper strips were held upright (long axis) by small metal clips placed in soil and were placed to maximize the distance between adjacent strips and also the cage walls. Five to 15 mated females were introduced into each pot at 1000 hr. The pots were arranged randomly in an illuminated Percival model E-54B plant growth chamber (22 ± 1°C, 60–80% relative humidity). At 1400 hr, the number of eggs laid on each of the strips was recorded. In experiments with more than six treatments, the same procedures were used except the strips were presented to females in a larger cage (18 cm diam. × 21 cm height).

The experimental design for each of these experiments was a randomized complete block. Data were subjected to Bartlett's test for homogeneity of variances, transformed (square root or log) if heteroscedastic, and analyzed by a two-way ANOVA. Means of treatments were compared using Fisher's protected least significant difference tests. Unless otherwise stated, all statistical differences are reported to $P < 0.01$. In the experiment using the factorial design, the interactions between the different fractions were tested using a general linear models procedure (SAS Institute, 1988).

RESULTS

Behaviors Preceding and Succeeding Landing. Over twice as many females entered the 1-cm zone around the strip treated with wheat extract as entered the 1-cm zone around the chloroform-treated (blank) strip (significantly greater, $P < 0.001$). Upon entering the 1-cm zones, females typically changed to a hovering type of flight in front of the filter paper strip before they landed or flew out of the zone. Of these females, 33% and 77% went on to land on filter papers treated with chloroform or a chloroform extract of wheat, respectively. Wheat extract continued to influence female behavior after landing. Females that landed

on the wheat extract-treated filter paper strip laid twice as many eggs as females that landed on the blank strip (Table 1).

The influence of wheat extract on behaviors after landing on a surface was examined in greater detail by recording the behaviors of individual females on wheat extract and blank yellow filter paper strips (Table 2). Females spent a larger portion of their time arching on wheat extract-treated strips but exhibited higher frequencies of antennation and sitting on blank strips. Overall, females spent ca. 6.8 times longer on wheat extract-treated strips than on the blank strips. The greater mean time and percentage of time spent arching on the strips treated with wheat extract corresponded with a significantly higher ($P < 0.001$) mean number of eggs laid on these strips compared to the blank strips.

Activity of Fractions of Wheat Extract. Using the egg-count bioassay, the six fractions of the wheat extract (each at 4 PE) were tested for their ability to

TABLE 1. COMPARISON OF BEHAVIORS PRECEDING AND SUCCEEDING LANDING OF MATED FEMALE HESSIAN FLIES TO FILTER PAPER STRIPS TREATED WITH SOLVENT (CHLOROFORM) OR 1 PLANT EQUIVALENT (PE) OF WHEAT EXTRACT[a]

Treatment	Total encounters	Landed (%)	Eggs (*N*/landing)
Solvent blank	63.2	33	0.6
Wheat extract (1PE)	134.1	77	1.2
F value	12.91	80.52	7.99
Significance	$P < 0.001$	$P < 0.001$	$P < 0.05$

[a] Total encounters refers to the number of females flying into a 1 cm zone (2 cm diam) surrounding filter paper strips. Landed (%) refers to the number of females flying into the 1-cm zone that went on to land on the filter paper strip. Data derived from 10 replicates; statistical comparison was made by a two-way ANOVA.

TABLE 2. COMPARISON OF BEHAVIORS EXHIBITED BY MATED FEMALE HESSIAN FLIES ON FILTER PAPER STRIPS TREATED WITH SOLVENT OR 1 PLANT EQUIVALENT OF WHEAT EXTRACT[a]

		Frequency (events/10 sec)				
Treatment	Time arch (%)	Anten	Arch	Sit	Total time	Eggs (*N*)
Solvent blank	64	18.4	2.47	0.89	8.9	0.3
Wheat extract	87	4.5	0.28	0.19	60.9	3.6
F value	5.34	17.75	4.9	5.38	35.48	48.1
Significance	$P < 0.05$	$P < 0.001$	NS	$P < 0.05$	$P < 0.001$	$P < 0.001$

[a] For a description of the behaviors arching (Arch), antennation (Anten), and sitting (Sit), see text. Data derived from observations of 10 females each for blank and wheat extract.

stimulate oviposition by female Hessian flies. Females laid significantly more eggs on strips treated with fractions 3, 5, and 6, than on the blank strips (Figure 1). Females also laid more than twice as many eggs on fraction 1 (mean of 40.7/strip) than on the blank strips (mean of 15.7/strip; significantly different at $P < 0.05$). In a separate experiment testing only fraction 1 (at 4 PE) versus the blank, the mean number of eggs laid on strips treated with fraction 1 (103.2/strip) was significantly greater ($P < 0.001$) than the mean number of eggs laid on the blank strips (40.6/strip).

Silica gel TLC of the four active fractions of the wheat extract showed that these fractions contained compounds with R_f values corresponding to the following standards: hydrocarbons (fraction 1), esters (fraction 3), and alcohols (fractions 5 and 6).

Single Fractions versus Blends of Fractions of Wheat Extract. Using a factorial design, the relative activities of single, binary, and tertiary combinations of fractions 1, 3, and 6, at dosages of 1 PE, were determined (Figure 2). At this lower dosage, only fractions 3 and 6 (of the single fractions) exhibited significant activity relative to the blank. Strips treated with the binary combinations containing fraction 1 did not have significantly greater numbers of eggs laid on them than the corresponding unitary fractions, 3 or 6. However, strips treated with the binary combination of fractions 3 and 6 had over three times the number of eggs laid on them (mean of 198) than the combined sum of eggs laid on fraction 3 (mean of 23) and fraction 6 (mean of 42). The greatest number of eggs was laid on strips treated with the tertiary combination, although this was not significantly different from the number laid on the binary combination

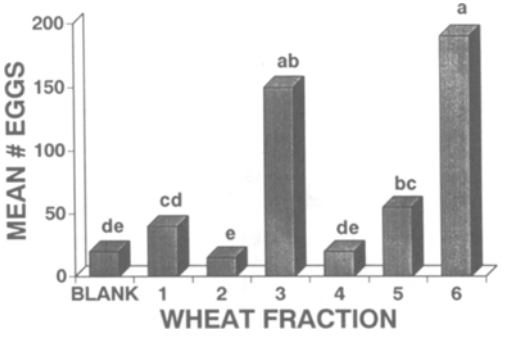

FIG. 1. Mean number of eggs laid by mated female Hessian flies on six different fractions (each at a dosage of 4 PE on filter paper strips) of wheat foliar extract; filter paper strips treated with chloroform were used as the blank. See text for details of silica gel column fractionation. Means with different letters are statistically different at $P < 0.01$ (ANOVA and Fisher's protected least significant difference test). The means were derived from three replicates.

of fractions 3 and 6. Analysis of the data showed a significant interaction between fractions 3 and 6 ($F = 22.3$, $P < 0.0001$), and no other significant interactions.

A Comparison of Egg-Laying Responses to Various Grasses and Their Extracts. The relative number of eggs laid on plants of wheat, rye, barley, and oat by female Hessian flies was determined (Figure 3). There were no significant differences in numbers of eggs laid on wheat and rye, but significantly fewer eggs were laid on both barley and oat.

Chloroform extracts of wheat, rye, barley, and oat plants on filter paper strips were similarly compared. The pattern of egg-laying on the filter paper strips treated with the different extracts showed a similar, but slightly different,

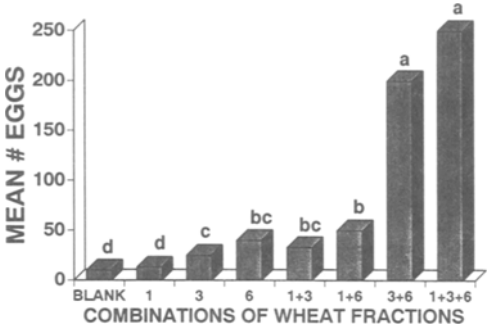

FIG. 2. Mean number of eggs laid by mated female Hessian flies on unitary, binary, and tertiary mixtures (each at a dosage of 4 PE) of three fractions of wheat extract; filter paper strips treated with chloroform were used as the blank. See text for details of silica gel column fractionation. Means with different letters are statistically different at $P < 0.01$ (ANOVA and Fisher's protected least significant difference test). The means were derived from three replicates.

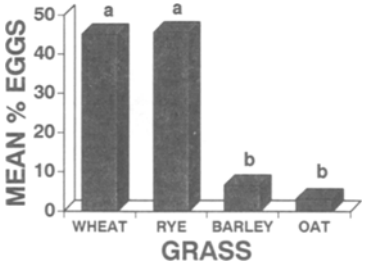

FIG. 3. A comparison of the percentage of eggs laid by mated females Hessian flies on plants, in the two- to three-leaf stage, of wheat, rye, barley, and oat. Means with different letters are statistically different at $P < 0.01$ (ANOVA and Fisher's protected least significant difference test). The means were derived from three replicates.

pattern to that on the grasses themselves; there was no significant difference between the numbers of eggs laid on rye and barley, and there was a significant difference between the numbers of eggs laid on barley and on oat (Figure 4). All the filter paper strips treated with extracts from the various grasses had significantly greater numbers of eggs laid on them than the blank strips.

Comparative Activity of Fractions of Extracts of Different Grasses. The chloroform extracts of barley and oat were fractionated by silica gel G column chromatography into six fractions, as for wheat, and each of the resulting fractions tested at 4 PE. A pattern of activity similar to that for wheat was observed for the six fractions of both barley and oat (Figure 5), with females laying the greatest number of eggs on strips treated with fractions 3 and 6. In the case of barley, strips treated with fraction 1 also had a significantly greater number of eggs laid on them than the blank strips.

Silica gel G TLC analysis of fractions 1, 3, and 6 of both barley and oat showed compounds with the same R_f values as for wheat, i.e., hydrocarbons (fraction 1), esters (fraction 3), and alcohols (fraction 6).

Dose–Response Relationships of Active Fractions of Extracts of Grasses. In order to determine whether the extracts of wheat, barley, and oat had different activities for eliciting oviposition in their respective fractions 3 and 6, different dosages of these fractions were applied to the filter paper strips and presented along with a blank in separate bioassays. The threshold of activity for fraction 3 was the same for all of the extracts (Figure 6); only at a dosage of 2 PE did females lay significantly more eggs on these strips than on the blank strips. However, for strips treated with fraction 6, the dose-response pattern for wheat differed from those for barley or oat (Figure 7). Females laid significantly more eggs on strips treated with fraction 6 of wheat extract, even at the lowest dosage

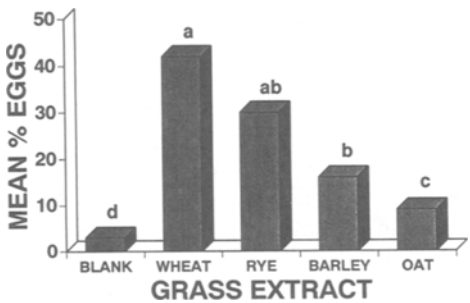

FIG. 4. A comparison of the percentage of eggs laid by mated female Hessian flies on filter paper strips treated with foliar extracts of wheat, rye, barley, and oat; filter papers strips treated with chloroform were used as the blank. Means with different letters are statistically different at $P < 0.01$ (ANOVA and Fisher's protected least significant difference test). The means were derived from three replicates.

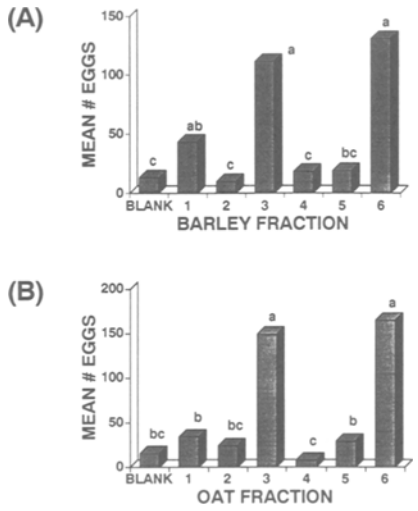

FIG. 5. Mean number of eggs laid by mated female Hessian flies on six different fractions (each at a dosage of four plant equivalents) of (A) barley and (B) oat foliar extract; filter paper strips treated with chloroform were used as the blank. See text for details of silica gel column fractionation. Means with different letters are statistically different at $P < 0.01$ (ANOVA and Fisher's protected least significant difference test). The means were derived from three replicates.

tested of 0.25 PE, than on the blank strips. In contrast, for fraction 6 of both barley and oat, females did not lay significantly greater numbers of eggs on strips treated with dosages up to 1 PE, compared to the blank strips. Only at a dosage of 2 PE did strips treated with fraction 6 of barley and oat have significantly more eggs laid on them than the blank strips.

DISCUSSION

Previously it had been shown (Harris and Rose, 1990) that at least three sensory inputs influence host finding and acceptance by female Hessian flies, namely, visual, tactile, and chemical. In this study we have investigated the chemical inputs in greater detail.

Chemicals present in the chloroform extract of the foliar waxes of wheat leaves clearly exert a major influence on the behaviors exhibited by mated female Hessian flies before and after landing. Over twice as many females entered the 1-cm zone surrounding the wheat extract-treated filter paper strip, suggesting that female Hessian flies are able to perceive, presumably through the olfactory modality, the wheat extract, at least from distances of 1 cm. Foliar chemicals

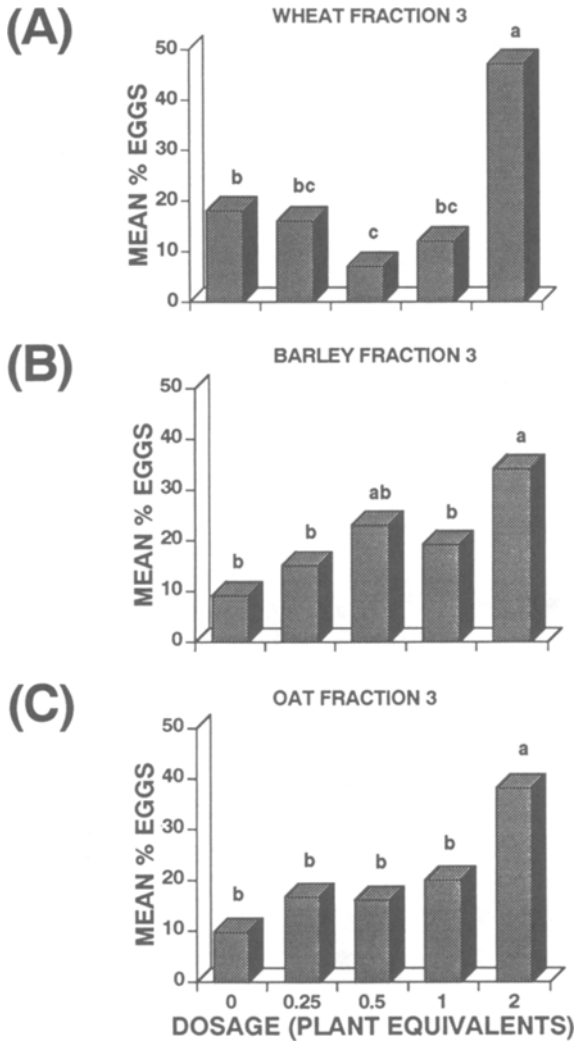

FIG. 6. Dose-response tests of the number of eggs laid by mated female Hessian flies on filter paper strips treated with different dosages of fraction 3 (see text for details of silica gel fractionation) of foliar extract of (A) wheat, (B) barley, and (C) oat; filter paper strips treated with chloroform were used as the blank. Means with different letters are statistically different at $P < 0.01$ (ANOVA and Fisher's protected least significant difference test). The means were derived from three replicates.

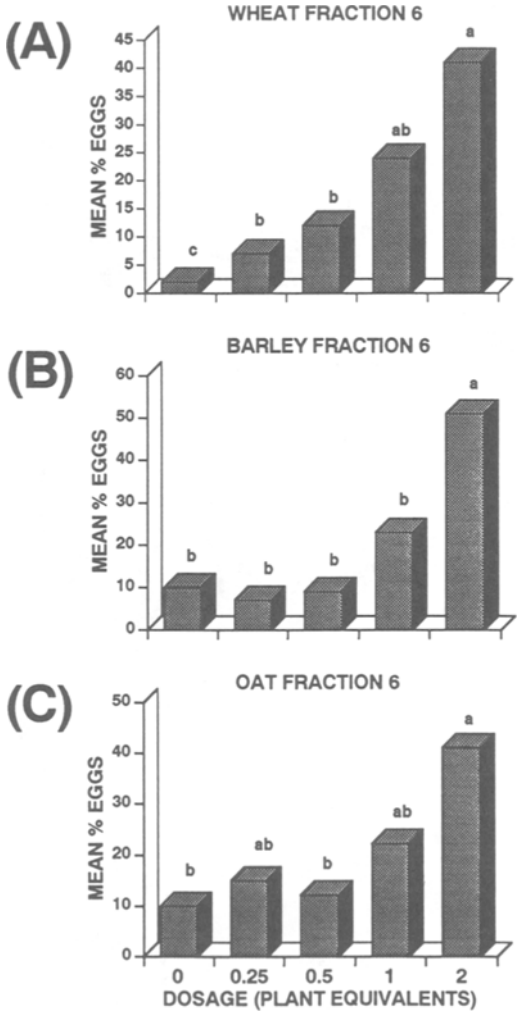

FIG. 7. Dose–response tests of the number of eggs laid by mated female Hessian flies on filter paper strips treated with different dosages of fraction 6 (see text for details of silica gel fractionation) of foliar extract of (A) wheat, (B) barley, and (C) oat; filter paper strips treated with chloroform were used as the blank. Means with different letters are statistically different at $P < 0.01$ (ANOVA and Fisher's protected least significant difference test). The means were derived from three replicates.

also influenced females after they had landed on the filter paper strips, with females staying six times longer and laying 10 times more eggs on strips treated with wheat extract as opposed to only solvent.

Subsequent experiments testing various fractions of the wheat extract (see below) indicate that there is more than one chemical that exerts an influence on the number of eggs laid on wheat. We do not know whether different chemicals in the extract elicit the distinct behaviors preceding and succeeding landing, or whether these behaviors are influenced by the same chemical(s). However, clearly at least one chemical in the wheat extract must be volatile enough to elicit orientation of females in flight, while the same or another chemical(s) must be relatively unvolatile, such that females may perceive it (them) on the surface of the plant. It has been suggested that volatile chemicals in wheat leaves, including low-molecular-weight alcohols, aldehydes, and esters, as well as some sesquiterpenes, may be attractants for some insects (Buttery et al., 1985). It is worth noting that our method for concentrating the extract would largely remove the more volatile chemicals present in the initial extract of the wheat foliage.

The stimulatory chemicals in the wheat extract were investigated by fractionating the extract and presenting single fractions to mated females. Of the six fractions, four, when placed on filter paper strips, showed some ability to stimulate oviposition by females. However, one of these fractions (fraction 1) only elicited a significant level of oviposition when presented at a relatively high dosage (4 PE) and did not significantly increase the number of eggs laid when added to the other active fractions (see below), while another of these fractions (fraction 5) appeared to contain the same class of compounds as the subsequent fraction (fraction 6). Thus, conservatively, we can state that there are two compounds in wheat foliar waxes that, at natural levels, appear to stimulate oviposition by female Hessian flies. However, it is possible that there may be more than two compounds that stimulate oviposition by female Hessian flies. For example, the two active fractions may each contain more than one active compound or fraction 5 may contain an additional, unique active compound.

While the compounds in the two (most) active fractions of wheat extract, when presented by themselves, elicited oviposition by females, it appears that, in their natural context, their effect on female Hessian flies is synergistic. That is, when presented together they elicit a significantly greater ovipositional response from females than the sum of the responses they elicit when presented separately. Such a synergistic effect on different chemicals on stimulating oviposition has been noted in other insects. For example, the addition of up to five other compounds synergizes the effects of the most stimulatory chemical (i.e., that with the lowest activity threshold), a polyacetylene falcarindiol, on oviposition by female carrot flies (Städler and Buser, 1984).

While Hessian flies are best know as pests of wheat, females also oviposit

on other grass species (McColloch, 1923; Jones, 1938; Stokes, 1957). In our experiments, females showed an order of preference to the various grasses of wheat $\approx$ rye $>$ barley $\approx$ oat. This order of preference appears to be mediated for the most part by the foliar chemistry of the grasses; when filter paper strips were treated with extracts of each grass, the order of preference was similar to that of the grasses themselves, i.e., wheat $\geq$ rye $\geq$ barley $>$ oat. The inclusion of a chloroform control in this experiment also revealed that all the grasses contained behaviorally significant amounts of stimulatory chemicals in their foliar waxes.

Column chromatographic fractionation of the foliar extracts of barley and oat separated each of these extracts into six fractions, at least two of which, when applied to filter paper strips, elicited female Hessian flies to lay significant numbers of eggs. Extracts of wheat, barley, and oat appear to have these same active fractions in common. To explain the greater activity of the wheat extract over those of barley and oat, we surmised that the wheat extract must contain greater activity in either or both of these two fractions. The dose–response experiment showed that fraction 3 elicited significant oviposition by female Hessian flies at a threshold of 2 PE for all three grass extracts. In contrast, fraction 6 of wheat elicited oviposition by female Hessian flies at a dosage as low as 0.25 PE, while for the extracts of barley and oat, fraction 6 did not elicit significant oviposition until at a dosage of 2 PE. Therefore, the greater activity of wheat extract (and to a large extent that of the grass itself) to elicit oviposition by female Hessian flies, over those of the other grasses, is due to the greater activity of the compound(s) in its fraction 6.

There are two possible explanations for this observation. First, the grasses have qualitative differences in their respective fraction 6, i.e., wheat contains a different and more powerful ovipositional stimulant than does barley or oat. The second explanation is that there are quantitative differences in the chemicals in their respective fraction 6, i.e., wheat (and probably rye) contains more of a particular ovipositional stimulant(s) than does barley or oat. We believe, given the similarities between the epicuticular wax chemistry of the grasses (see below), the dose–response results of fraction 6, and the powerful synergistic interaction between fractions 3 and 6 shown in wheat extract, that the latter explanation is more likely. In further support of this is the activity of fraction 5 in wheat, this fraction apparently containing more of the same or similar types of chemicals as fraction 6. Clearly, only identification of the oviposition-stimulating chemicals and their quantification in the different grasses will equivocally establish (or disestablish) this postulate.

The chemistry of the epicuticular waxes of a number of grasses in the tribe Triticeae (family Poaceae) has been studied extensively (Tulloch et al., 1980; Bianchi and Figini, 1986). The principal classes of compounds include long-chain hydrocarbons, alcohols, free fatty acids, esters, aldehydes, and β-diketones

and hydroxy-β-diketones. Most of the compounds within the classes are homologous, differing in series of two carbons, with the exceptions of the β-diketones and hydroxy-β-diketones, which are usually hentriacontane-14,16-dione and 8-, 9-, or 25-hydroxyhentriacontane-14,16-dione, respectively. The observed differences in epicuticular wax content between the different species or varieties of grasses are usually in the relative proportions of the classes or homologs or in the presence or absence of different isomers of a particular chemical. For example, spring wheat, *Triticum aestivum* L., varieties Selkirk and Manitou, differ in their relative proportions of unsaturated esters, free fatty acids, and β-diketones, while the hydroxy-β-diketone fraction in these varieties consists of a mixture of the 8- and 9-isomers, as opposed to the 25-isomer found in Durum wheat, *Triticum durum* Destf. (Tulloch and Hoffman, 1973). The identity of the chemicals that elicit oviposition by female Hessian flies is as yet unknown. TLC data indicated that fractions 3 and 6 contained large quantities of esters and alcohols, respectively. While compounds of these classes may be the actual oviposition stimulants, the crudeness of the techniques employed here does not preclude other classes of chemicals that either coelute with these classes or exist as trace (and undetected) components within these fractions as the actual oviposition stimulants.

Identification and quantification of the chemicals in the various grasses that elicit the behaviors and behavioral differences outlined in this paper will allow us greater insight into the chemical mechanisms involved in host selection be female Hessian flies.

Acknowledgments—We thank Susan Rose and Paul Malsch for conducting or assistance with some of the experiments, and Dr. Ralph Howard for use of his laboratory facilities. We are also grateful to Dr. Jack Dillwith for his generous gift of standard hydrocarbons, esters, and alcohols. This work was funded in part by USDA Competitive Grant 87-CRCR-1-2412 (to M.O.H.).

(Received February 7, 1992; accepted June 26, 1992)

Abstract—Ferulic acid was tested for its effect on the growth of root and shoot, fresh and dry weights, and hydrolytic enzyme activities of germinating maize seeds. The results showed that root growth was inhibited more than shoot growth. A significant reduction in the activities of hydrolytic enzymes was also observed, which reflects a mechanism of action for the natural growth inhibitors, which may include other phenolic compounds.

Key Words—Allelopathy, ferulic acid, amylase, maltase, invertase, acid protease, acid phosphatase, *Zea mays*, growth, root, shoot.

INTRODUCTION

Allelopathy in agriculture is receiving considerable attention because of the allelochemicals that reduce the yields of crop plants due to phytotoxicity. This phenomenon is explored in the biological control of pests, diseases, and as a source of natural chemicals to solve other problems that arise in conventional agricultural crops. A number of potential growth inhibitory organic compounds are released into the environment in appreciable quantities via root exudates, leaf leachates, roots and other degrading plant residues, which include a wide range of phenolic acids such as *p*-hydroxybenzoic, *p*-hydroxycinnamic, ferulic, vanillic, and salicylic acids; alkaloids; and terpenoids (Glass, 1975a; Rice, 1987). Among the phenolic acids identified as allelochemicals, ferulic acid is a common one in leaf leachates and other degrading plant parts (Glass, 1975a; Rice, 1984).

Several phenolic acids are known to modify growth and development of plants, including germination and early seedling growth (Al-Quadan et al., 1981; Boya et al., 1990; Chen and Klessig, 1991; Glass, 1973, 1975a,b; Holappa and Blum, 1991; Hoover et al., 1977; Kabi et al., 1981; Lyu and Blum, 1990; Lyu et al., 1990; McClure et al., 1977; Sharma et al., 1990; Sharma and Singh, 1987; Tayal and Sharma, 1985). However, the details of the biochemical mechanism through which a particular compound exerts a toxic effect on the growth of the plants are not known. One of the early events of seedling growth involves the mobilization of reserve food material, which supplies the required nutrients for the developing embryo and various other physiological processes.

Therefore, the aim of this work was to study the effect of ferulic acid on the early growth of maize seedlings by analyzing the activities of hydrolytic enzymes, viz., amylase, maltase, invertase, acid protease, and acid phosphatase. Any inhibition or promotion of activity of these enzymes will have a concomitantly major role in the early phase of the seedling growth. Ferulic acid was chosen as an allelochemical for our study because of its wide distribution and its toxicity to a variety of plant species.

METHODS AND MATERIALS

Maize seeds (*Zea mays* cv. Ganga-5) were purchased from the local market, surface sterilized with 5% sodium hypochlorite solution for 15 min, and washed with distilled water three times. The sterile seeds were soaked in water for 12 hr and placed on filter paper disks (9 × 9 cm) in polypropylene boxes (9 × 9 cm, inner dimensions). The seeds were treated with 10-ml solutions of 1–5 mM ferulic acid (Sigma Chemical Co., St. Louis, Missouri) for eight days using distilled water as the control. The seedlings grown in the light were used to determine the root and shoot length and fresh and dry weight.

Ferulic acid-treated seeds and distilled water controls grown in the dark (to exclude any light and photosynthetic effects on enzymes) were used for enzyme assays. On the specified days, the shoot and root portions of the germinated seedlings were removed, leaving behind the seed proper. Seed tissue (1 g), washed with water, was homogenized at 4°C in 5 ml of extraction buffer, viz., 50 mM sodium acetate buffer containing 20 mM calcium chloride, pH 4.8, for amylase; 50 mM sodium acetate buffer, pH 5.0, for maltase and invertase; 100 mM sodium acetate buffer, pH 5.0, containing 20 mM magnesium chloride for acid phosphatase; and 0.1 M acetate buffer containing 10 mM mercaptoethonol for proteases. The extract was centrifuged at 10,000*g* for 20 min, and the supernatant was used to determine enzyme activity. For day zero the 12-hr soaked seeds ground in the homogenization buffer. All the experiments were repeated six times.

Enzyme Assays. Amylase (E.C. 3.2.1.1) activity was determined by a modified method (Anonymous, 1979). Incubation of 1 ml of the reaction mixture containing 2 mg of amylopectin and 25 μl of enzyme extract in 50 mM acetate buffer with 20 mM calcium chloride, pH 4.8, in test tubes was carried out at 37°C for 10 min. One milliliter of dinitrosalicylic acid (Miller, 1959) was added to terminate the reaction and then placed in a boiling water bath for 5 min. The tubes were then cooled to room temperature, 2 ml of double-distilled water added, and absorbance was measured at 540 nm. Maltose was used as the standard (50–500 μg) reducing sugar. One unit of amylase activity was defined as the quantity of protein that liberates 1 μmol of reducing sugar.

Maltase (E.C. 3.2.1.20) activity was measured by the method of Yamasaki and Suzuki (1980). The reaction mixture, containing 0.1 ml of 0.1% maltose, 0.35 ml of 50 mM acetate buffer, pH 5.0, and 50 μl of enzyme extract in a final volume of 0.5 ml, was incubated at 37°C for 1 hr. The reaction was stopped by keeping the tubes in a boiling water bath for 5 min. The amount of glucose formed was determined using the arsenomolybdate reagent (Nelson et al., 1944). Maltase activity was represented as micromoles of glucose equivalents released per milligram of protein per hour.

Invertase (E.C. 3.2.1.26) activity was measured by the method of Billet et al. (1977): 1 ml of reaction mixture containing 100 mM sucrose, 50 μl enzyme extract in 100 mM acetate buffer, pH 5.0, was incubated at 35°C for 1 hr. The reaction was terminated by keeping the tubes for 5 min in a boiling water bath and the released glucose was measured using arsenomolybdate reagent (Nelson, 1944). Invertase activity was expressed as micromoles of glucose equivalents released per milligram of protein per hour.

Acid protease (E.C. 3.4.11.2) activity in the seeds was measured by the method of Mathur et al. (1988): 2 ml of assay mixture contained 100 μl of enzyme extract, 0.5 ml of 1% casein, and 0.1 M acetate buffer containing 10 mM mercaptoethonol, pH 5. The mixture was incubated for 1 hr at 40°C, and the reaction was stopped by adding 2 ml of 10% trichloroacetic acid, and the precipitated protein was removed by centrifugation. The supernatant was used for the estimation of amino acids by the method of Rosen (1957) using ninhydrin. Protease activity is expressed in micromoles of amino acids formed per hour per gram of fresh weight of tissue, using a standard curve for L-leucine.

Acid phosphatase (E.C. 3.1.3.2) activity in the seeds was measured by the method of Shinishi and Kato (1979). The reaction mixture, containing 0.1 M acetate buffer, pH 5, 20 mM magnesium chloride, 50 μl of enzyme extract, and 0.5 mM *p*-nitrophenylphosphate in a total volume of 1 ml, was incubated for 10 min at 30°C. The reaction was terminated by adding 2 ml of 1 N sodium hydroxide. The absorbance was measured at 400 nm. One unit of enzyme activity was defined as the amount of protein that liberates 1 μmol of *p*-nitrophenol per minute. A molar extinction coefficient of 18,000 is used in the calculations.

RESULTS

The germination bioassays indicate that ferulic acid (FA) suppressed the length of shoot (30–75%) and root (50–80%) (Figure 1A). Reduction in fresh weight of roots (38–78%) and shoots (35–60%) was also observed (Figure 1B). The dry weight was also decreased (roots 15–75%, and shoots 35–60%) (Figure 1B). The length, fresh weight, and dry weight of shoots and roots drastically decreased up to 2 mM FA treatment; thereafter, the reduction was not very steep with 3, 4, and 5 mM FA treatment.

Effect of Ferulic Acid on Activities of Hydrolytic Enzymes. Amylase activity increases gradually and reaches a maximum on the sixth day in control seeds. The 2 mM FA treatment had slightly inhibited the amylase activity on day 2 (4.5%), which was not significant. However, in other treatments, FA stimulated the activity up to 28%. FA after four days of treatment inhibited the activity by 10–22%. Significant reduction in the amylase activity was observed on days six and eight after FA treatment. Amylase activity was decreased by 30–50% and 18–45% on days six and eight, respectively (Table 1).

In the control seeds, maltase activity showed a biphasic increase on days 2 and 6. The maltase activity increased with 2 mM and 3 mM FA two days

after treatment by 6–8%. Its activity was further stimulated by 3 mM and 4 mM FA treatment to 16–33% on the fourth day. However, 5 mM FA inhibited activity by 58% on the fourth day. All concentrations of FA treatment inhibited activity on the sixth day (15–53%) and the eighth day (35–42%) (Table 2).

In untreated seeds, invertase activity was constant, with a slight rise in activity on the fourth day of germination that was not significant. FA at 1 mM and 2 mM two days after treatment increased activity by about 18%, and 5 mM FA decreased the activity by 33%. On the fourth day, 2 mM and 3 mM FA-treated seeds showed stimulation in invertase activity of 28% and 16%, respectively. However, 4 mM and 5 mM FA-treated seeds did not show significant change in activity compared to the control. By the sixth day, inhibition in invertase activity was prominent (16–42%), and its activity was suppressed by 19–47% with all FA treatments on the eighth day (Table 3).

In the control seeds, protease activity reached its peak on the sixth day. On treatment with FA (1–5 mM), 9–35% stimulation in activity was observed on day 2. However, there was a significant reduction in activity in FA-treated seeds at four, six and eight days. FA treatment after four days resulted in significant reduction in the activity by 19–57%. Similarly, after six and eight days, drastic inhibition in the activity (40–70% and 38–61%, respectively) was observed in FA-treated seeds (Table 4).

Phosphatase activity in untreated seeds was maximal (85 units) on the sixth day. On the second day only 1 mM and 2 mM FA treatments slightly stimulated

its activity (4–15%) and 3–5 mM FA inhibited activity (10–27%). On the fourth day, except in 1 mM FA-treated seeds, there was a linear inhibition in the activity of acid phosphatase with 2–5 mM FA (13–30%). Drastic inhibition in the activity was observed with all the FA treatments on days six and eight (17–44% and 23–48%, respectively) (Table 5).

DISCUSSION

The results on the growth of the FA-treated maize seedlings show a considerable reduction in the growth, which conformed with the previous reports (Blum et al., 1984; Blum and Dalton, 1985; Einhellig and Rasmussen, 1979). In mature maize seeds, starch is the important reserve food material. The degradation of this to glucose via the amylolytic pathway involves three principal enzymes, i.e., amylase, maltase, and invertase (Nomura et al., 1969).

As can be seen in Table 1, the reduction in amylase activity by the action of FA will lead to a reduction in the production of maltose. As maltose is the substrate for maltase, the reduction in maltose levels may lead to alteration in the levels of maltase during germination. FA treatment resulted in the inhibition of both amylase and maltase, which would result in a reduced supply of glucose from the starch via the amylolytic pathway, which may influence several physiological processes, including the respiration, growth, and development of the

seedling. Similar changes in amylase activity were observed with other phenolic compounds such as coumarin and tannic acid (Jacobson and Corcoran, 1977; Kabi et al., 1981). The initial rise in maltase activity in FA-treated seeds might be due to the supply of the maltose produced in the initial stages of germination.

Sucrose is the main transportable sugar from endosperm to the embryonic tissue. The breakdown of sucrose into glucose and fructose is mediated by invertase. Suppression in the activity of invertase by FA treatment only at later stages of germination suggests further interference of FA with carbohydrate metabolism.

At the early stages of seed germination, the supply of smaller peptides and amino acids that are essential for a variety of metabolic processes are produced by the action of proteases on the reserve proteins. FA inhibited the protease activity, and the effect will obviously reflect on the growth and development of seedlings. Compared to carbohydrate metabolism, the protein degradation is conspicuously affected at the early stages of germination (Table 4).

The reserve phosphates in the seeds are mobilized through phosphatases. Interference in phosphate metabolism due to FA may further bring about deleterious changes in the growth of the plants, as phosphorus is involved in various energy-dependent and energy-mediated processes, such as ATPases, and cell components such as phospholipid and nucleotide synthesis, respiration, etc. (Beweley and Black, 1985).

The results obtained in the present study support the hypothesis that FA,

through its deleterious effect on the activities of amylase, maltase, protease, and phosphatase, might interfere with carbohydrate, protein, and phosphate mobilization during germination, exerting a direct or indirect influence on various physiological and biochemical processes such as respiration and nitrogen and carbohydrate metabolism, etc. The synergistic effects of the inhibition of these hydrolytic enzymes might account for the reduction in growth of the maize seedlings that has been observed with FA treatment in this investigation.

(Received April 20, 1992; accepted June 29, 1992)

Abstract—It has been shown previously that sulfur volatiles produced by *Allium* plants affect the behavior of their specialist phytophages and of their specialist entomophages. The action of these compounds in protecting the leek moth *Acrolepiopsis assectella* against generalist entomophages was studied in comparison to the proposed original defensive role of these compounds against generalist herbivorous insects. Two ants species, *Formica selysi* and *F. fusca*, were used as generalist predators. Six behavioral criteria of the predatory behavior of the ants were studied in presence of the last-instar caterpillars (C_5). C_5 reared on artificial diets with or without leek components were tested, as well as C_5 soaked in frass of leek-reared caterpillars or disulfide solutions. In addition, the response of the ants to pure chemicals found in leek was studied using honey solutions with or without sulfur compounds. The sulfur allelochemicals of *Allium* plants have a negative action on predatory ants. Interestingly, the nonvolatile precursors of sulfur volatiles of *Allium* plants seem to have a protective role for their phytophagous insects against generalist entomophages.

Key Words—Ants, defense, phytophage, predation, sulfur allelochemicals, *Allium*, *Formica fusca*, *Formica selysi*, Hymenoptera, Formicidae, *Acrolepiopsis assectella*, Lepidoptera, Acrolepiidae.

INTRODUCTION

Plants of the genus *Allium* produce sulfur amino acids, *S*-alk(en)yl-L-cysteine sulfoxides, precursors of thiosulfinates and volatile alkyl disulfides (Auger et

*To whom correspondence should be addressed.

0098-0331/92/1100-1991$06.50/0 © 1992 Plenum Publishing Corporation

al., 1989a), which are given off when the leaves are broken (Virtanen, 1965). These volatile compounds are perceived by the specialist phytophagous insect *Acrolepiopsis assectella* (Hyponomeutoïdea), attracting adults and caterpillars, while precursors of these volatiles are phagostimulant for them (Lecomte et al., 1987; Al Rouz and Thibout, 1988, 1989). The disulfides are very abundant in the frass and are also perceived by the specialist parasitoid *Diadromus pulchellus* (Ichneumonidae), where they modify locomotor behavior and favor the search for host chrysalids (Lecomte and Thibout, 1984; Thibout et al., 1988; Auger et al., 1989b). The primary defensive role of allelochemical compounds put forth in certain hypotheses (Fraenkel, 1959; Rosenthal, 1988) has thus been diverted by some specialist insects to their benefit, regardless of the trophic level. Even though one of the raisons d'être of these allelochemicals is a protective role, particularly against insects, the phytophagous insect that has successfully diverted them should, in turn, also be able to be protected from generalist entomophagous species. This has, in fact, been described in several cases (Aplin et al., 1975; Pasteels et al., 1988; Belofsky et al., 1989; Nishida and Fukami, 1989), but it is perhaps general in phytophagous insects feeding on allelochemical-rich plants.

We thus sought a repulsive or potentially deterrent action of *Allium* allelochemicals, more particularly those of the leek *A. porrum*, on the predatory activity of ants when encountering leek moth caterpillars. These hymenopterans were chosen because a large number of species are generalist predators (Finnegan, 1974), whose role in maintaining insect populations is well known (Sterling et al., 1979). In addition, they had been used previously to test various allelochemicals (Eisner et al., 1980; Godzinska, 1986; Bowers and Larin, 1989). Furthermore, one of us had witnessed the attack on *A. assectella* chrysalids by ants, of which several species are often observed on leeks during the summer.

METHODS AND MATERIALS

Phytophagous Insect. Caterpillars from the last instar (C_5) were obtained from three sources. The first was on the host plant, leeks (C_5 L). Photoperiod was 18:6 hr light–dark with a synchronous 25°C/18°C thermoperiod, with relative humidity varying from 50% to 70%. The second was on artificial medium, according to the technique of Arnault (1979) in 14:10 hr light–dark at constant 25°C and 70% relative humidity. The medium contained about 10% (dry weight) powdered leek leaves (C_5 M+L). The third source was identical to the second except that the medium contained no constituent from the host plant (C_5 M). Strain L was renewed every summer from caterpillars gathered in leek fields. Strain M+L has been raised in the laboratory for the past 15 years at about one generation per month. Strain M is formed from M+L neonatal caterpillars whenever necessary.

Predators. Formica selysi (Bondroit) and *F. fusca* (L.) (Formicidae) were used. Colonies were maintained in the same conditions as C_5 L in artificial ant nests composed of a cylindrical tube (5 cm × 8 cm in diameter) in darkness at high relative humidity. An 80-cm-long, 0.5-cm-diameter tube connected the nest to a 12 × 18-cm foraging area, open to air and containing water. During experimental periods, the colonies were given honey water and cut *Tenebrio molitor* larvae once a week. Colonies were composed of 300–400 ants.

Preliminary Experiments. Preliminary experiments were carried out with ten *F. fusca* or *F. selysi* removed from the foraging area of the colonies. They were placed in a 7-cm-diameter Petri dish containing one *A. assectella* C_5 L (10 replicates) and one C_5 of *Ephestia kuehniella* (10 replicates) or *Plodia interpunctella* (five replicates). The latter two Lepidoptera were raised on wheat flour and on corn flour + glycerol, respectively, in 18:6 hr light–dark and 25°C/18°C. These two species were chosen because they have nearly the same size as *A. assectella* (C_5 length = 1 cm) and because they do not eat leek. All observations were made in photophase at 25°C and lasted for 1 hr. The last observation was made 24 hr later. Results obtained with this type of experiment led to a modification in the procedure.

Behavior of Ants in Presence of A. assectella *C_5 of Different Food Origins.* One leek moth C_5 was deposited in the foraging area of an ant colony, and the behavior of the ants present in the area was observed for 30 min. Thirty minutes after the end of the observation period, a second C_5 of a different food origin was deposited and also observed for 30 min. The following behavioral criteria were noted: (1) time before the first attack, (2) time during which C_5 remained in the foraging area, (3) time required to transport the C_5 into the tube leading to the nest, (4) number of C_5 brought into the nest, (5) number of ants in contact with the C_5 every 30 sec, and (6) relative frequency of antennal cleaning among the ants. Three categories were distinguished for the last criterion: 0 = no cleaning, + = several cleanings, ++ = numerous and frequent cleanings.

With *F. selysi*, an initial experiment compared their behavior in the presence of C_5 M and C_5 M+L and a second in the presence of C_5 L and C_5 M+L. In the case of *F. fusca*, three groups of C_5 M were compared, immersed 10 min before the experiments in: (1) an extract of frass (C_5 F, 0.25 g/ml of 10% methanol), (2) 0.1% dipropyl disulfide (DSP_2) in 10% methanol (C_5 D), and (3) in 10% methanol alone. In the morning and afternoon, two or three observations were made, alternating the C_5 of different origins.

Behavior of Ants in Presence of Honey with Sulfur Chemicals. The last type of experiment was used to test the repulsive or deterrent action of precursor amino acids and volatile disulfides towards the ants. A control drop of honey (5% in water) was deposited in the foraging area of the *F. fusca* colony. A second drop of honey was diluted in either an aqueous solution of DSP_2 at 10^{-3} (solution D, five replicates) or an aqueous solution of *S*-propyl cysteine sulfoxide

(PCSO) at 10^{-3} (solution P, eight replicates) and placed at 2 cm from the control. The latter compound is a sulfur amino acid produced by leeks and the precursor of DSP_2. The quantity of precursor in one fresh *Allium* is about 10^{-3} (Lancaster et al., 1984). The number of ants in contact with each drop of honey was noted every 30 sec.

Statistical analyses were carried out with χ^2 or the t test for comparing means two by two.

RESULTS

Preliminary Experiments. The preliminary experiments provided data on the number of attacks on the C_5 during the hour of observation and the number of C_5 eaten by the ants 24 hr after the beginning of the experiment (Table 1). Despite the small number of data, the C_5 of *A. assectella* raised on leeks were attacked less and eaten less frequently by both species of the ants used than the C_5 of the other two Lepidoptera (Table 1). The eaten C_5 distribution of the three moth species is not statistically homogeneous whatever the predatory ant, *F. fusca* ($\chi^2 = 14.856$; $df = 4$) or *F. selysi* ($\chi^2 = 10.059$; $df = 4$). An analogous result was also obtained comparing the *F. fusca* attacks on the three moth C^5 ($\chi^2 = 8.944$; $df = 2$), but the differences are not significant for *F. selysi* attacks ($\chi^2 = 3.860$; $df = 2$).

Owing to the behavioral differences in the C_5 of the different prey species—more rapid movements by *E. kuehniella*, agility in climbing the vertical walls by *P. interpunctella*—and, above all, the hard integument of these two species, the results of these experiments were used to define experimental conditions and to choose the behavioral criteria used in subsequent experiments.

TABLE 1. PRELIMINARY OBSERVATIONS ON PREDATION OF THREE MOTH SPECIES BY *F. fusca* AND *F. selysi*[a]

			Attack		Eaten C_5 (%)		
		C_5 (N)	Weak	High	0	0–50	>50
F. fusca	*A. assectella*	10	8	2	4	5	1
	E. kuehniella	10	4	6	0	1	9
	P. interpunctella	5	0	5	0	2	3
F. selysi	*A. assectella*	10	5	5	2	6	2
	E. kuehniella	10	3	7	1	2	7
	P. interpunctella	5	0	5	0	0	5

[a] Caterpillars can be weakly or highly attacked and can be highly (% > 50), partly (0 < % < 50) or not (% = 0) eaten.

Behavior of F. selysi *in Presence of C_5 M or C_5 M+L.* Both types of *A. assectella* C_5 were successively placed in the foraging area 1 hr apart. The analysis had to take the presentation order into account, since it could have modified the behavior of the ants due to experience. This order was systematically inverted in each replicate. One C_5 M was added first (C_5 M1) in one experiment, followed by a C_5 M+L (C_5 M+L2), while in the following series a C_5 M+L was added first (C_5 M+L1), followed by a C_5 M2.

Comparing the results with C_5 M1 and M2 showed no difference, regardless of the behavioral criterion chosen (Table 2), and the data were thus pooled. The same was true for C_5 M+L1 and M+L2, where only the mean number of ants in contact with the C_5 per 30 sec was higher with C_5 M+L1 than with C_5 M+L2 (Table 2).

Once the data were pooled, the comparison of ants with C_5 M or C_5 M+L showed significant differences for all the criteria observed, except for the time required by the ants to attack the C_5. The times spent by C_5 in the foraging area or that of transport of C_5 to the tube were all longer with C_5 M+L. Whereas all the C_5 M were taken into the nest, only a small number of C_5 M+L was taken in. In this context, we often observed a forager trying to advance to the nest with a C_5 M+L, while another ant recently emerged from the nest was pulling it back to the foraging area. The number of ants paying attention to the C_5 M+L in the area was lower than that of ants interested in C_5 M. Finally, antennal cleanings in ants with C_5 M were infrequent and were manifested by only a few insects, while they were very frequent in a large number of ants when they were in presence of C_5 M+L (Table 2).

Behavior of F. selysi *in the Presence of C_5 M+L or C_5 L.* As above, there was no difference between the C_5 placed in the foraging area first and those placed second. Both types of C_5 were thus similar (Table 3). With the exception of the time taken for the ants to attack the C_5 being higher with C_5 L than with C_5 M+L, there was no significant difference in the behavior of the ants in the presence of C_5 L and that of the ants in the presence of C_5 M+L, regardless of the criterion used (Table 3).

In addition, data obtained with C_5 M+L in the previous experiment (Table 2) are very similar to those obtained here with the C_5 M+L (Table 3). Even though statistical comparison was impossible because both experiments were not done at the same time, it is clearly seen (Table 3) that only the number of C_5 M+L brought into the nest varied from one experiment to the other.

Behavior of F. fusca *in the Presence of C_5 M, C_5 F, or C_5 D.* In contrast to the prior two experiments, the order of C_5 presentation was not taken into account, since the number of combinations was excessive. There was a very high similarity between the behavior of the ants in presence of C_5 F and of C_5 D (Table 4). In contrast, the ants behaved very differently with C_5 M, and the data (Table 4) are reminiscent of those in Table 2. Only the mean number of ants in contact with the C_5 every 30 sec was the same in the three cases.

[a]For further information refer to Table 2.

Although the data in Tables 3 and 4 cannot be compared statistically, there are certain similarities and occasionally differences in the behavior of the ants in the presence of C_5 L or C_5 M+L and those in the presence of C_5 F or C_5 D. The time before the first attack, the time spent in the area, the mean number of ants in contact with the C_5, or the frequency of antennal cleanings are similar with the four types of C_5. The transport times in the tube, however, were much lower with C_5 F and C_5 D, while the numbers of C_5 brought into the nest were lower with C_5 L and C_5 M+L. The effects of frass and of DSP_2 are apparently less persistent.

Behavior of F. fusca *in Presence of Honey with* DSP_2 *or PCSO.* A honey solution became less attractive and phagostimulating for the ants when DSP_2 was added (Figure 1). In five experiments done at irregular time intervals, more ants were counted on pure honey than on honey with DSP_2 in four cases. Among a total of 1369 ants observed eating, 61.8% were on pure honey in 30 min ($P < 0.05$), and this percentage was even higher in 15 min at 65.1% for 764 ants ($P < 0.001$).

When PCSO was added to the honey, the results were comparable to those obtained with DSP_2. Among 610 ants observed during eating, 68.0% were on pure honey ($P < 0.001$). The observations in this experiment were carried out at more regular intervals than in the preceding one, and so changes in responses were analyzed as a function of time (Figure 2). Initial observations strongly suggested that *F. fusca* did not initially differentiate between the two food sources, but they gradually "learned" to recognize PCSO and avoid it, particularly if two observations were separated only by a few hours.

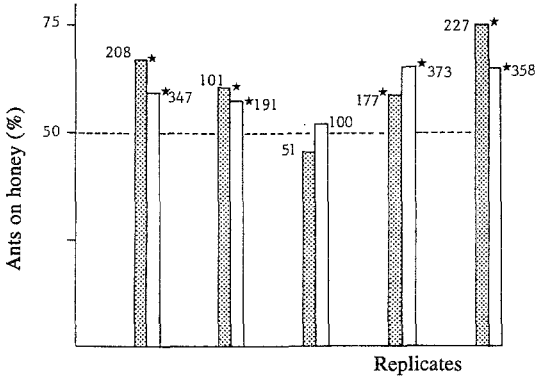

FIG. 1. Percentage of *F. fusca* feeding on pure honey in comparison to the total number of ants feeding (pure honey + honey + DSP_2). The asterisks indicate that the percentage is 50% different in $P = 0.05$ (χ^2). The numbers indicate the total number of ants. Gray columns: observations during 15 min, open columns: observations during 30 min.

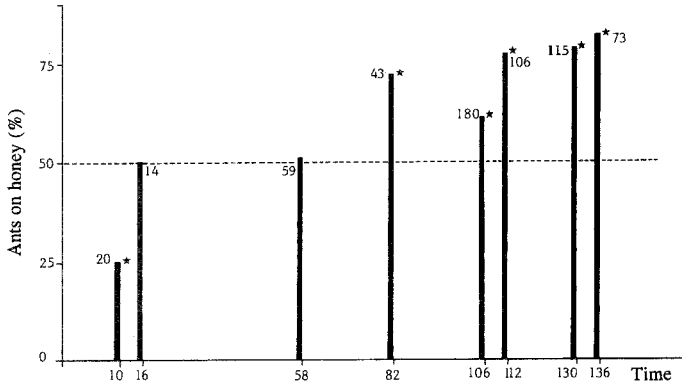

FIG. 2. Percentage according to time (in hours) of *F. fusca* feeding on pure honey in comparison to the total number of ants feeding (pure honey + honey + PCSO). See further explanations in Figure 1 legend.

DISCUSSION

A comparison between the two predatory species used would seem to indicate that *F. selysi* and *F. fusca* show a very similar predatory behavior, because the data in presence of C_5 M are analogous (Tables 2 and 4). On the other hand, in the experiments with honey, *F. fusca* changes its behavior over time, whereas *F. selysi* does not. As a large number of publications have shown, ants can modify their behavior as a function of acquired experience (Alloway, 1972; Bowers and Larin, 1989; Godzinska and Lenoir, 1990; Hölldobler and Wilson, 1990). When replicates are conducted at relatively short times, *F. fusca* seems to "learn" to avoid PCSO.

As shown previously, the predatory behavior of ants differs in the presence of C_5 M and C_5 M+L or C_5 L. Compounds arising from the host plant, the leek in this case, are thus perceived by the ants and lower their predatory efficiency by increasing the times of attack and decreasing the number of C_5 brought into the nest.

In preliminary experiments, the ants manifested a preference for caterpillars that had not been exposed to *Allium* compounds. Comparison with results obtained with C_5 D or C_5 F and C_5 M+L or C_5 L indicates that the values of behavioral criteria observed at the beginning of the experiment are relatively similar—time before the first attack, time spent in the hunting area—while the values of behavioral criteria observed at the end of the experiment are different—transport time in the tube, number of C_5 brought into the nest. Predatory behavior is thus more intense at the end of the experiment in the presence of C_5 F and D, while it is lower in the presence of C_5 L and M+L. The DSP_2 present

on the C_5 F and C_5 D could be responsible for this behavioral difference. This compound is volatile and its concentration on the surface of the C_5 automatically decreases with time. The volatility of leek constituents that disturb ant attacks must thus be low or nonexistent, and they may be precursor sulfur amino acids. This hypothesis is apparently confirmed by the results obtained when studying the feeding behavior of ants in the presence of honey. The phagostimulating power of honey was decreased by the presence of nonvolatile PCSO and also by DSP_2, but in this case the effect was more pronounced in the first quarter hour.

If PCSO is indeed the (or one of the) compound(s) in the leek that disturbs predation exerted by the two ant species, it would be interesting to elucidate the metabolism of these precursors in *A. assectella* caterpillars and determine if they are present in the cuticle, hemolymph, fat body, or only in the digestive tube. Are there sequestration phenomena involved (Duffey, 1980) or is there just a simple contamination by contact?

This example of the protection of a phytophagous insect against predation, even if in the present case it is a phytophagous species already specialized, tends to reinforce the hypothesis of Bernays and coworkers, according to which generalist predators would cause a selection pressure tending to limit the diversity of plant hosts among their phytophagous prey (Bernays, 1988, 1989; Bernays and Cornelius, 1989). Individuals eating plants that are the richest in allelochemical compounds would be those undergoing the lowest selection pressure by the generalist predators. This phenomenon would be all the more interesting in *A. assectella* since it was relatively unpredictable. Caterpillars are well protected physically since they develop in mines they dig in the parenchyma of host plant leaves.

Chemical protection related to the host plant towards generalist predators in this phytophagous species could nevertheless have an effect during the search for a metamorphosing site and while the cocoon is being spun.

Acknowledgments—The authors thank Professor A. Lenoir, as well as Mr. G. Leroux and Doctor F. Berton for their helpful advice and for furnishing the ants. They also thank Professor J.C. Biémont who assisted them with the statistical analyses of the results and, finally, Mr. J.C. Landré for his technical assistance.

(Received September 9, 1991; accepted June 15, 1992)

Abstract—Three components of the male yellowfin Baikal sculpin pheromonal signal have been isolated from urine by diethyl ether extraction, thin-layer chromatography (TLC), and high-performance liquid chromatography (HPLC). Using mass spectrometry, we have identified two of them as testosterone (T) and 11β-hydroxytestosterone (11HT). These steroids are synthesized in testes during full spermatogenesis, and they are excreted in male urine with milt. The third component is not a steroid. It is more likely to be a polyene alcohol (farnesol). 2*Z*,6*E*-Farnesol possesses behavioral activity.

Key Words—Teleost fish, yellowfin Baikal sculpin, Cottocomephorus grewingki, sex pheromones, testosterone, 11β-hydroxytestosterone, farnesol.

INTRODUCTION

Identification (or close characterization) of male pheromone has been reported for three teleost species: black goby (Colombo et al., 1989), zebrafish (Van den Hurk et al., 1987), and African catfish (Resink et al., 1989). In all cases the proposed pheromones are steroid glucuronides from the testes or seminal vesicles. Nonsteroids were not studied.

The yellowfin Baikal sculpin has a developed system of chemical communication that determines a complex of reproductive behaviors. It includes the

preparation of a "nest" by the male, territory guarding, attracting partners, stimulation of maturation, and care of the young. The source of the male sex pheromones is a spawning male's urine (U). Introduction of aqueous urine solution (1×10^{-8}, vol. %) into a Y-maze aquarium with spawning females elicited the whole complex of stereotype elements of sexual behavior (Dmitrieva and Ostroumov, 1986).

Thus the presence of a male pheromonal signal, which determines female sexual behavior, sexual dimorphism, and organ source of the male sex pheromones make the yellowfin Baikal sculpin an ideal model for identification of sex pheromones. Our strategy to identify the pheromones was based on fractionation of the mixture containing signal substances; isolation of fractions preserving behavioral activity, with subsequent substance identification.

METHODS AND MATERIALS

Spawning fish were caught in the South Baikal and brought to the Irkutsk University Biostation (Bay Bolshie Koty, Lake Baikal). Fish were put into 600-liter pools with a constant inflow of running lake water. After a two-day acclimatization period, the urinary bladder was isolated from males and its contents were collected in ampules and frozen. The urine (0.1–1 ml) was taken from each individual and a total of 430 ml was collected from fish.

Separation. Silica gel plates (5 × 20 cm) with a 0.25-mm layer of sorbent (Merck) were used for TLC. HPLC was carried out on a microanalytical chromatograph, Milichrom (USSR), with 62 × 2-mm column (Nucleosil C_{-18}, 5 μm, Macherey Nagel). Detection was carried out at 220, 250, and 280 nm. All solvents and chemicals were of analytical grade.

Isolation of C_{19} Steroids from Testes. The spawning male testes (16 g) were homogenized on ice with (3 × 50 ml) of ethanol–diethyl ether mixture (3:1, v/v). The combined homogenates were centrifuged. Supernatant was evaporated in vacuum at 30°C. The residue was dissolved in 30 ml of water. Steroids from the water–ethanol solution were extracted by ethyl acetate (3 × 60 ml). The combined extracts were washed with 50 ml of 0.1 N NaOH and 50 ml of water during 2 min and evaporated. Then the residue was dissolved in 10 ml of 70% methanol. The purification from lipids was carried out by cold precipitation at −20°C during 24 hr. Methylene chloride (CH_2Cl_2) was then added (4 × 50 ml) to the extract of the free steroids from the water–methanol solution. The combined extracts were evaporated and subjected to HPLC.

Mass Spectrometry. Finnigan MAT-4615 mass spectrometer with a data processing system (Incos-2000) was used. The ionization potential was 70 eV. The reagent with chemical ionization was NH_3. Input port temperature was 40°C and was increased 1.5 min after input to 250°C for the 2.5.6 component and

to 500°C for 2.7.3 and 2.7.4 components. The temperature of the ionization chamber was 150°C.

Bioassays. The behavioral activity of the fractions was studied using spawning females during the light period after two days of adaptation. A two-choice preference test tank (40 liter; rate of flow: 2–3 liters/min) was used. Lake water was used in the tanks, and the temperature corresponded to the current lake temperature. The aqueous fractions (100 ml, 1×10^{-8} mg/liter) were added to one of the two compartments of tanks, and the behavior was observed during 30 min. This included the whole complex of stereotypical elements of female sexual behavior: female "testing motion" (periodic wide opening of mouth, rotating movements of thoracic fins and turning towards a stimuli source); attracting towards a stimuli compartment; "courting dance" (snakelike body movements in the opposite direction, head bending towards to bottom); movements imitating entering a "nest" (head bending towards to bottom and short fast movements forward with short standstills); imitation of a pose of laying oocytes (female attempt to turn upside down). We put these elements in the scale of criteria of sexual behavior of females (Dmitrieva et al., 1988). The procedure and results of behavioral testing were described in detail in our previous articles (Dmitrieva and Ostroumov, 1986; Dmitrieva et al., 1988, 1991; Katsel, 1990).

RESULTS AND DISCUSSION

We carried out the progressive isolation of the pheromonal signal from the urine of the male yellowfin Baikal sculpin using the procedures outlined in Figure 1. The first stage included urine fractionation by consecutive extraction with a series of organic solvents: hexane, diethyl ether, chloroform, and ethyl acetate. The extracts were dried in vacuum, diluted in water, and tested for behavioral activity. The pheromonal signal was present in fractions 2 and 3 (Figure 1). In the second stage, active fractions were studied by TLC using benzene–chloroform (1:2, v/v). Sulfuric acid, 10% solution of phosphomolybdic acid in ethanol, saturated $SbCl_3$ solution in chloroform, iodine vapor, and UV light (250 nm) were used for detection. We found that fractions 2 and 3 contained multiple components. To find out which component possessed behavioral activity, chromatograms were divided into zones as described in an earlier paper (Dmitrieva et al., 1988). The substances were eluted from the plates using methanol, dried, diluted in the water to the same concentration as in the previous fractionation stage, and bioassayed. It was established that zones 2.5 and 2.7 in fraction 2 and the same zones in fraction 3, containing substances with $R_f = 0.35$ and 0.04, as well as starting components possessed behavioral activity (Dmitrieva et al., 1988). In the third stage, the isolated zones 2.5 and

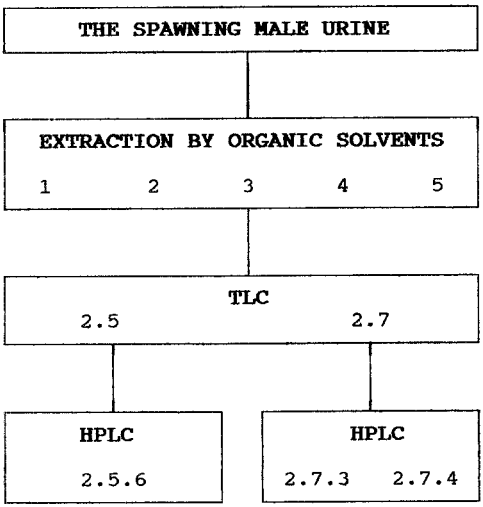

FIG. 1. Diagram of isolation of male sex pheromones. Fractions: 1, hexane; 2, diethyl ether; 3, chloroform; 4, ethyl acetate; 5, water residue.

2.7 were analyzed by HPLC. Zone 2.5 was fractionated in a linear gradient of methanol in water (40–100%); time of gradient formation = 12 min, elution rate = 100 μl/min. Eight components were discovered, which were bioassayed as in previous stages. We found that component 2.5.6 (retention time: 13 min 45 sec) had pheromonal activity (Katsel, 1990). This component has also been found in fraction 3, but in much lower concentration. Zone 2.7 was fractionated in a linear gradient of acetonitrile in water (30–100%); time of gradient formation = 14 min; elution rate = 100 μl/min. As a result, seven components were separated and bioassayed. Two components, 2.7.3 and 2.7.4 had pheromonal activity (retention times: 6 min 08 sec and 6 min 50 sec, respectively) (Katsel), 1990).

It should be pointed out that female behavioral reactions to the three isolated components were different. After introduction of the 2.5.6 component, the latent period of reaction did not exceed 5 min. The latent periods of 2.7.3 and 2.7.4 components were longer (more than 10 min); the elements of a courting dance and the imitation of entering the nest were observed. At the end of these reactions, a considerable increase in female activity was noted. Only females that had ovulated showed these reactions. Females that had not ovulated did not demonstrate the elements of sexual behavior in response to components 2.7.3 and 2.7.4. We observed the same female behavioral reactions in response to some Δ^4-3-keto C_{19} steroids (Dmitrieva et al., 1991). The effect of the 2.5.6 component consisted mostly of attracting females to the compartment with a

stimulus. The same bioassay results were obtained with both ovulating and unovulating females. We also studied the effect of isolated components on ovary maturation (Katsel, 1990; Dmitrieva et al., 1991). We found that the 2.7.3 component induced almost 100% maturation of the females.

In the process of isolating components 2.7.3 and 2.7.4, we supposed that these substances might be products of spermatogenesis, since they were isolated only from the urine of males with mature testes. During this period there was a precipitate in the urine that contained spermatogenic cells (Dmitrieva et al., 1988). Further, one can assume that these are nonconjugated steroids since they were extracted by a nonpolar solvent—diethyl ether. The fraction of steroid conjugates (glucuronides and sulfates) that were isolated from urine did not possess behavioral activity in our bioassay (Katsel, 1990). The results of fish sex pheromone studies indicated that steroid hormones and their metabolites can function as sex pheromones (review: Stacey et al., 1987). HPLC analysis in the presence of C_{19} and C_{21} steroids indicated that 2.7.3 retention time coincides with 11HT and 2.7.4 coincides with T. We registered mass spectra of isolated

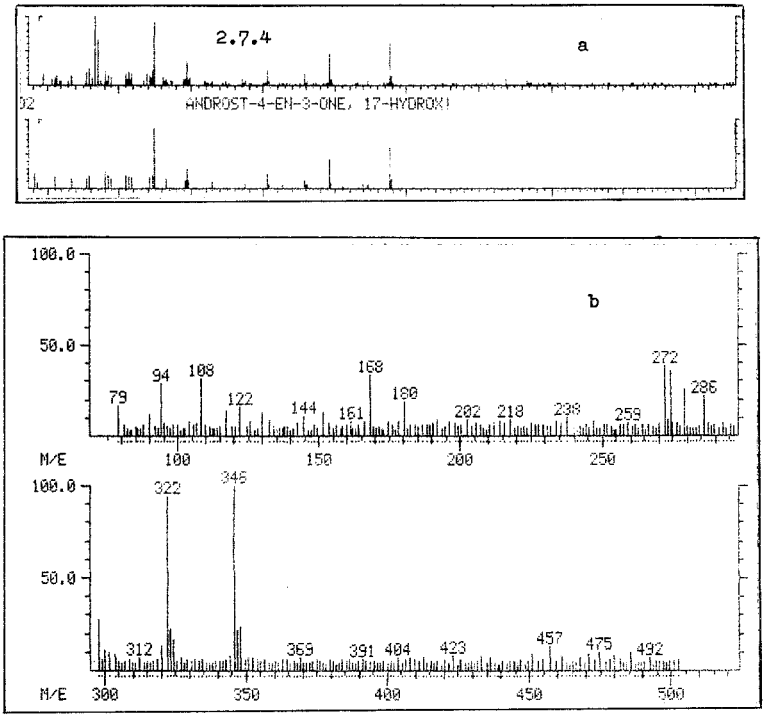

FIG. 2. Mass spectra of electron ionization of 2.7.4 and T (a), and chemical ionization of 2.7.3 (b).

compounds. The mass spectrum of electron ionization of 2.7.4 corresponded to T (Figure 2a). In the chemical ionization mass spectrum of 2.7.3, the ammonium adduct ion $(M+NH_3)^+$ m/z 322 was discovered, which indicates a molecular weight of 304 (Figure 2b). 11HT has the same mass. There is also a peak at m/z 346. The reconstruction of the curve of change of total ion current according to the given ions indicated that these are different compounds. At present, a study of the chemical structure of a component that has ion m/z 346 is being carried out.

It is possible that these steroids get into the urine with the seminal liquid. The aqueous extracts of mature testes homogenates elicited sexual behavior in females that had ovulated (Dmitrieva and Ostroumov, 1986). We isolated C_{19} steroids from the testes of the males during the spawning period. As a result, it was found that 11HT and T were contained in the testes during the final stage of spermatogenesis.

The calculation of identified steroids concentration in male urine according to mole response showed that 11HT concentration is approximately 9×10^{-8} M and T is 1×10^{-9} M. These data correspond to the data on T concentration in sea lamprey urine (Adams et al., 1987).

As for component 2.5.6, we surmised that this compound is not a steroid. In terms of fragmentation as a whole the electron ionization mäss spectrum of 2.5.6 (Figure 3) may be attributed to the spectrum of olefins. However the m/z 256 and 284 ions which are in the spectrum and may be molecular ions, do not correlate with masses of olefins. Calculation of mass numbers suggests that it

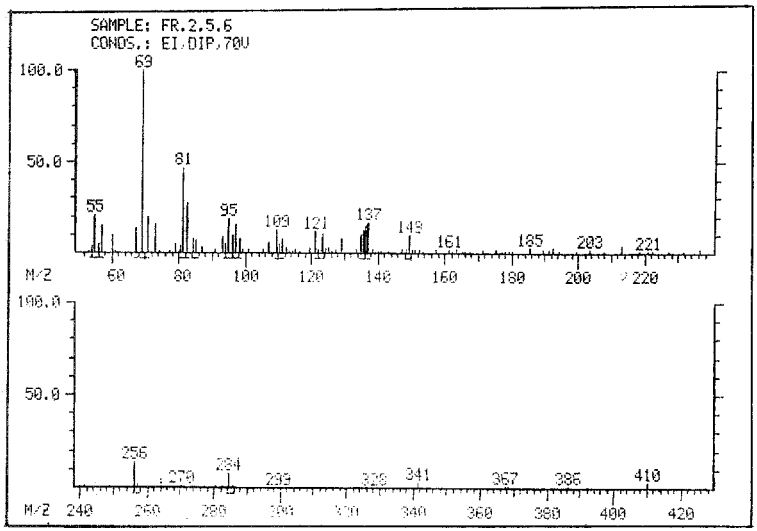

FIG. 3. Mass spectrum of electron ionization of 2.5.6.

is an oxygen-containing compound. Palmitic and stearic acids were found in fraction 2.5.6 using gas chromatography–mass spectrometry. These acids have masses corresponding to ions *m/z* 256 and 284. Solutions of these acids did not possess pheromonal activity (Katsel, 1990). The library search of the spectrum of Figure 3 indicates that it may be a polyene alcohol—farnesol (2*Z*,6*E*), M^+ 222. The molecular ion $(M+H)^+$ 223 demonstrated here using chemical ionization, superimposes on the known molecular ion of farnesol (Katsel, 1990). Farnesol and its derivatives have been reported as pheromones in insects (Regev and Cone, 1973) and mammals (Wheeler et al., 1982; Novotny et al., 1990). It is likely that farnesol is a key compound in the synthesis of steroid hormones. We conducted behavioral testing of steroisomers of farnesol (Katsel, 1990). Only 2*Z*, 6*E*-farnesol possessed pheromonal activity at 1×10^{-8} M. The identification of farnesol in the male urine is presently proceeding.

We found 2.5.6 in male urine at the beginning of the spawning period when steroid pheromones were absent. Excreting polyene alcohol with urine may be a signal to females that have not ovulated of the presence of males. This pheromone provokes the attraction of females that have not ovulated to nests where males are located. The attracted females do not enter nests. They remain on the periphery. Probably at that moment primer pheromones of the partners provoke a synchronization of their maturation. We have not yet identified the female sex pheromone. However, it was discovered that a primer pheromone—11HT excreted by the male at the final stage of spermatogenesis—initiated the maturation of oocytes (Dmitrieva et al., 1991). In addition, 11HT and T elicited sexual behavior of females that had ovulated, which we characterize as the phase of "sexual activation" (Katsel, 1990). The female's behavioral reaction are completed on entering the nests and spawning.

(Received September 3, 1991; accepted June 29, 1992)

Abstract—Prior electrophoretic and morphological studies have identified two closely related, economically important tephritid flies, *R. mendax* (Curran) and *R. pomonella* (Walsh), which infest the fruits of ericaceous and rosaceous plants, respectively. Further studies also have shown consistent differences among these species in their ovipositional preferences for apples and highbush blueberries and have determined that their ovipositional behavior is elicited by extracts obtained from these fruits. In this paper we report the results of an experiment that tested whether these species show distinct electroantennogram (EAG) responses to a large array of compounds present in gas chromatograph-fractionated pentane extracts of apples and highbush blueberries. *R. mendax* and *R. pomonella* flies were found to have significant differences in their antennal sensitivity to 11 blueberry and nine apple extract peaks, which correspond to 24.4% of all blueberry and 25.0% of all apple peaks that elicited a measurable EAG response from either species. Interspecific differences in peripheral sensitivity were more pronounced for blueberry than apple extract; *R. pomonella* flies were most sensitive to blueberry compounds with low retention times, whereas *R. mendax* flies responded to blueberry compounds with a broader range of retention times. Both species were most sensitive to apple peaks with high retention times. The retention times of most apple and blueberry peaks that elicited EAG responses from *R. mendax* and *R. pomonella* flies were different from the retention times of seven attractant fruit esters that were previously identified by Fein et al. (1982). The identification of these unknown apple and blueberry compounds could lead to the

discovery of new chemical cues that mediate the host-plant preferences of these sibling species.

Key Words—Electroantennogram, GC splitter, *Rhagoletis pomonella*, *Rhagoletis mendax*, Diptera, Tephritidae, sibling species, antennal sensitivity differences, host odor compounds, host-plant recognition, speciation.

INTRODUCTION

Many phytophagous insects utilize odor perception to find and recognize host plants that are suitable for feeding, mating, and oviposition (e.g., see Guerin and Städler, 1982; Miller and Strickler, 1984; Visser, 1986). Prior studies have investigated this aspect of host-plant selection for several tephritid fruit flies and oftentimes found that volatile compounds that emanate from the fruits of their host plants are effective attractants that can also stimulate ovipositional behavior (e.g., Pritchard, 1969; Prokopy et al., 1973; Fein et al., 1982; Reissig et al., 1982; Levinson and Haisch, 1983; Metcalf et al., 1983; Averill et al., 1988; Bierbaum and Bush, 1990b). Although prior studies have shown that fruit volatiles influence the host selection behavior of several tephritid species, there are few studies that have examined whether closely related species have evolved distinct behavioral and chemosensory responses to host-related chemical cues. Recent comparative studies have, however, begun to test whether two closely related, economically important species, *R. mendax* (Curran) and *R. pomonella* (Walsh), have evolved divergent chemosensory and ovipositional responses to host-associated fruit chemical cues (Diehl and Prokopy, 1986; Bierbaum and Bush, 1990b; Frey and Bush, 1990).

These sibling species occur sympatrically over much of eastern and central North America where *R. pomonella* infests rosaceous plants (primarily apples, *Malus pumila* Miller = *Pyrus malus* L., and hawthorns, *Crataegus* spp.), and *R. mendax* infests ericaceous plants (primarily highbush, *Vaccinium corymbosum* L., and lowbush blueberries, e.g., *V. angustifolium* Ait.). In addition to species-specific alleles at several electrophoretic loci (Berlocher, 1980; Feder et al., 1989), they can be distinguished by differences in adult and pupal size (Bush, 1966; Bierbaum and Bush, 1990a). Prior field and laboratory studies have also found that *R. mendax* and *R. pomonella* flies show consistent differences in their ovipositional responses to apples and highbush blueberries (Diehl and Prokopy, 1986; Bierbaum and Bush, 1987, 1990a), as well as apple-treated versus blueberry-treated artificial fruits [see the results of the experiment reported by Bierbaum and Bush (1990b) in which artificial fruits were treated with pentane-extracted apple and blueberry compounds, and the experiment reported by Diehl and Prokopy (1986) in which compounds were rubbed off the surface of apple and blueberry fruits with a cotton swab, then rubbed onto the surface of

an artificial fruit]. The results of both studies indicate that the ovipositional responses of *R. mendax* and *R. pomonella* flies to apple-treated and blueberry-treated artificial fruits parallel their ovipositional responses to apples and blueberries. Furthermore, Bierbaum and Bush (1990b) found that the addition of apple esters to waxy artificial fruits increased the number of eggs that were laid in the fruits by *R. pomonella* flies. In summary, prior studies have shown that fruit compounds are one of the plant cues that mediate the ovipositional preferences of *R. mendax* and *R. pomonella* flies.

Prior laboratory and field studies have also shown that volatile apple esters are effective attractants for *R. pomonella* flies (Fein et al., 1982; Reissig et al., 1982; Averill et al., 1988). Fein et al. (1982) initially identified a blend of seven apple esters that increased the number of *R. pomonella* flies that alighted on odor sources at the upwind end of a wind tunnel. Moreover, they observed that the electroantennogram (EAG) responses of *R. pomonella* flies to specific GC fractions of apple extracts were correlated with the "attractiveness" of the extract fractions in their wind-tunnel bioassays (i.e., the extract fractions that attracted the most flies to the upwind end of a wind tunnel also elicited the largest EAG responses from olfactory chemoreceptors on their antennae). Subsequently, Frey and Bush (1990) found differences among *R. mendax* and *R. pomonella* flies in their EAG responses to crude, unfractionated, pentane extracts of apples and highbush blueberries, as well as a few identified fruit volatiles. The results of their experiment indicate that the antennal sensitivity of both species is selectively adapted to odors that are associated with the fruits of their respective host plants.

Additional experiments using purified, fractionated fruit extracts and identified fruit compounds could help pinpoint plant chemical cues that mediate the distinct host-plant preferences of these sibling species and also test whether their olfactory chemoreceptors show a high degree of specificity in their responses to host-related volatiles. To address this latter objective, we measured the EAG responses of *R. mendax* and *R. pomonella* flies to a large array of compounds present in GC-fractionated pentane extracts of apples and blueberries. Specifically, we analyzed the antennal sensitivity of both species to compounds present in apple and blueberry extracts by injecting the extracts onto a capillary GC column that had its outlet split between a flame ionization detector and an electroantennogram apparatus, which recorded the EAG responses of individual flies to each peak in the fractionated fruit extract. The following questions were addressed in our study: (1) What is the antennal sensitivity of each species in response to the full spectrum of compounds found in the GC-fractionated host and nonhost fruit extracts? (2) Are there differences among *R. mendax* and *R. pomonella* flies in their EAG responses to individual apple or blueberry peaks, and, if so, which extract peaks elicit the largest interspecific response differences? (3) Do any of the extract peaks that elicit significant EAG responses

from *R. mendax* and *R. pomonella* flies have retention times that differ from the retention times of the esters identified by Fein et al. (1982)?

METHODS AND MATERIAL

Mature (5- to 11-day-old) *R. mendax* and *R. pomonella* females were used in the electroantennogram bioassays. Recordings were made from seven *R. pomonella* and eight *R. mendax* flies exposed to apple extract, and six *R. pomonella* and five *R. mendax* flies exposed to blueberry extract. *R. pomonella* flies were reared from pupae that were obtained from an abandoned apple orchard near Hart, Michigan, and *R. mendax* flies were reared from pupae that were obtained from an abandoned highbush blueberry orchard near Sawyer, Michigan. After the pupae were collected, they were kept in moist vermiculite at 4°C for five months, then incubated in a 25°C chamber with 16:8 hr light–dark photoperiod until the adults emerged.

Whole-fruit extracts were obtained from Bluehaven blueberries and McIntosh apples by the methods described in detail in Bierbaum and Bush (1990b). The following paragraphs describe additional extract purification procedures and gas chromatography–electroantennographic detector (GC-EAD) methods that were used in the present study. In our initial fruit extractions, methanol, methylene chloride, and pentane were used as solvents. However, methanol and methylene chloride removed less extract material from the fruits than pentane, and the cuticular wax residues that were obtained by submerging fruits in pentane had a stronger fruity odor than those obtained using methanol and methylene chloride. Therefore, reagent-grade *n*-pentane (98% minimum purity, Columbus Chemical Industries, Columbus, Wisconsin) was chosen as the solvent for the fruit extractions. To increase its purity prior to the extractions, the pentane was distilled on a fractional distillation column at 36°C.

Several weeks prior to the start of the extractions, we used nylon-mesh bags to cover fruit-bearing branches of McIntosh apple trees and Bluehaven blueberry bushes in an abandoned orchard in East Lansing, Michigan. These protected the fruits from insect infestation without using pesticides. After the fruits had ripened, they were harvested and brought into the laboratory approximately 40 min before the start of the extractions. Thirty-two McIntosh apples and 785 Bluehaven blueberries were than placed in separate glass beakers and submerged in pentane (apples: 1940 ml; blueberries; 320 ml) for 60 min. The fruits were removed from the beakers and the remaining apple and blueberry extracts were each concentrated to a volume of 25 ml by distilling off excess pentane under a vacuum at 30°C. The concentrated fruit extracts were then stored at −70°C until the GC-EAD recordings.

Cuticular waxes and other undissolved solids in the extracts were removed

by centrifugation in a microcentrifuge for 15 min at 12,400 rpm. This produced a bilayer consisting of a lower layer of undissolved solids and an upper layer of pentane extract. This upper layer was centrifuged for another 15 min to remove the remaining undissolved solids. This produced the clear upper layer of pentane extract used in the experiment.

At the start of each recording session, 1 μl of either blueberry or apple extract solution was injected into a model 3700 Varian gas chromatograph equipped with a 25-m × 0.32-mm-ID OV-1 capillary column (methyl silicone, film thickness 1.05 μm; Quadrex Corp., New Haven, Connecticut). This volume of extract contained either ca. 3% of the total dissolved extract from a single blueberry or ca. 0.1% of the extract from a single apple. Helium was used as the carrier gas at a linear velocity of 24 cm/sec (at 100°C) and the GC oven underwent the following temperature-programmed changes after each sample injection: 40°C for the first 5 min, followed by an increase of 5°C/min up to a maximum of 205°C.

The end of the capillary column was divided into two pieces by a TEE-splitter (Valco Instruments Co., Houston, Texas), which enabled 50% of the effluent extract material to pass into the flame ionization detector (FID) and 50% to pass to an electroantennographic detector (EAD) mounted on top of the GC. The EAD apparatus consisted of a 10-cm-long × 1-mm-ID piece of L-shaped glass tubing that carried the column effluent to an antennal preparation, which was mounted as described in Frey and Bush (1990). The separated fruit compounds were delivered to the fly's antennae and the FID by adding purified compressed air through valves mounted after the TEE-splitter. This compressed air swept the separated fruit compounds off the end of the capillary column, into the L-shaped glass delivery tube and over the fly's antennae at a rate of 300 ml/min. Although there may have been some band-broadening of the eluting compounds due to the use of an unheated glass delivery tube, the use of the compressed air minimized this problem. The outputs from the EAD and FID were stored on a Zenith microcomputer. During the recordings, we observed small time delays between a given FID peak and a fly's corresponding EAG response, which were adjusted for by using the fly's response to the solvent peak (pentane).

In preliminary runs using the above-described conditions, we assessed the retention time (R_t) of several reference esters: hexyl acetate (15.8 min), hexyl propanoate (18.9 min), hexyl butanoate (21.5 min), and hexyl octanoate (31.6 min). From these data, the R_t of the hydrocarbons missing in this series can be interpolated: hexyl pentanoate (23.8 min), hexyl hexanoate (26.4 min), and hexyl heptanoate (29.1 min). Hexyl acetate, hexyl propanoate, and hexyl butanoate are three of the seven Fein blend esters. In addition to these, we also ran the other Fein blend esters: (*E*)-2-hexen-1-yl acetate had the same R_t as hexyl acetate (15.9 min) and butyl hexanoate the same as hexyl butanoate (21.6 min).

Butyl-2-methyl butanoate ran off at 16.8 min and propyl hexanoate at 18.6 min. Finally, we also ran three esters with shorter R_t's: methyl pentanoate (9.0 min), ethyl pentanoate (10.3 min), butyl butanoate (15.5 min).

Since we did not detect clear EAG responses in the second half of our 40-min GC runs, we used the first 20 min of each run for our data analysis. The EAG responses to the GC effluent were quantified as follows: For the EAG responses to the apple extract, the amplitudes of each individual fly were measured, averaged within each species, and then standardized relative to the EAG responses to the extract peak with an R_t of 6.62 min, which elicited the largest average amplitude EAG response from both species [1.06 $\pm$ 0.49 mV (average $\pm$ standard deviation) for *R. mendax* flies and 1.31 $\pm$ 0.53 mV for *R. pomonella* flies]. The same procedure was used for the EAG responses to the blueberry extract where the extract peak with an R_t of 6.55 min was used for standardization of the other peaks. This peak elicited the largest average EAG response from *R. pomonella* flies (1.46 $\pm$ 0.80 mV) and the second largest mean response from *R. mendax* flies (0.96 $\pm$ 0.56 mV). The EAG responses of both species to this blueberry peak were similar to the 6.62-min apple peak; however, it is not known whether these apple and blueberry peaks contained the same compound(s). Differences among species in their EAG responses to single extract fractions were analyzed by Mann-Whitney U tests.

RESULTS

The Fein blend esters elicited clear EAG signals from the flies' antennae with a signal-to-noise ratio of between 10 and 18 for all compounds. Specifically, we recorded a response of 2.00 mV to propyl hexanoate at 10^{-3} dilution (v/v) in pentane, the same compound at 10^{-4} gave a response of 1.44 mV, butyl hexanoate at 10^{-4} gave a response of 1.28 mV, hexyl propanoate at 10^{-4} one of 0.83 mV, butyl-2-methyl butanoate at 10^{-4} one of 0.76 mV, and hexyl acetate at 10^{-3} one of 0.66 mV and at 10^{-4} one of 0.28 mV. Our data allowed estimating the content of hexyl acetate in the apple crude extract to be about 4 $\times$ 10^{-4} μl/μl injected crude extract.

We detected distinct differences in the number of apple versus blueberry FID peaks within two separate ranges of retention times. Blueberry extract contained more large-amplitude peaks than apple extract from 1 to 5 min R_t, and vice versa from 5 to 10 min R_t (Figure 1A, B). Both extracts contained few large-amplitude peaks between 11 and 15 min R_t, and both contained an abundance of peaks with retention times greater than 15 min. In summary, our results show that the composition of apple and blueberry extracts differed most for peaks with retention times between 1 and 10 min. However, these differences among the extracts may be largely due to differences in the quantity of specific

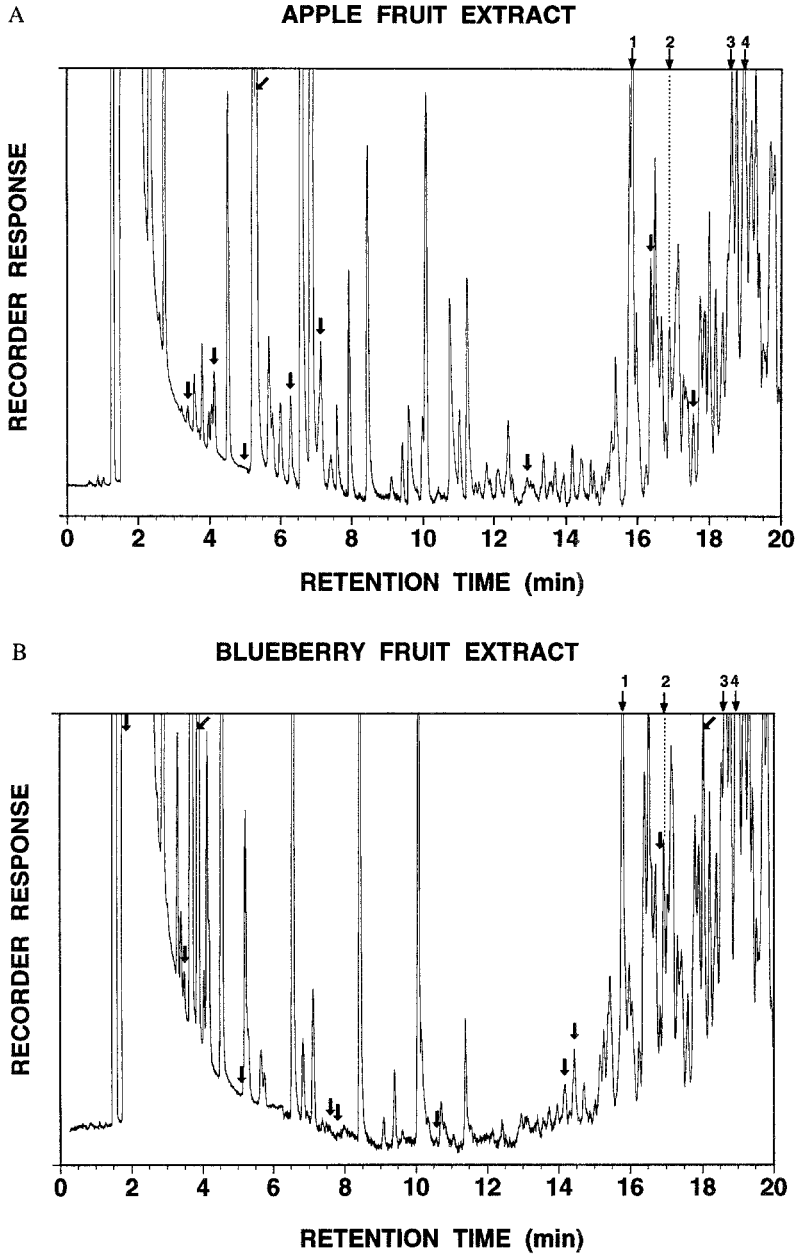

FIG. 1. Gas chromatogram of (A) apple fruit extract and (B) blueberry fruit extract. Compounds eliciting EAG responses with significant interspecific indifferences are marked by an arrow. Peaks marked by numbered arrows correspond to the retention times of the Fein blend esters: (1) hexyl acetate and (*E*)-2-hexen-1-yl acetate, (2) butyl-2-methyl butanoate, (3) propyl hexanoate, (4) hexyl propanoate.

compounds, rather than the complete presence or absence of compounds, since traces of almost every major peak found in one extract were also found in the other.

The results of our electroantennogram recordings indicate that blueberry fruit extract elicited 43 EAG response peaks above threshold level from *R. pomonella* flies and 45 EAG peaks from *R. mendax* flies, whereas apple fruit extract elicited 30 EAG peaks from *R. pomonella* flies and 33 EAG peaks from *R. mendax* flies (Table 1 and 2). Interspecific differences in the relative amplitude of these EAG responses were significant at the $P < 0.05$ level for 11 responses to blueberry extract and nine responses to apple extract (Figures 2A, B). The data in Tables 1 and 2 also indicate that differences in the peripheral sensitivity of *R. mendax* and *R. pomonella* flies were more pronounced for blueberry extract than apple extract. This is indicated by the approximately twofold greater sum of EAG amplitude differences among *R. mendax* and *R. pomonella* flies responding to blueberry extract compared to apple extract (see summations at the bottom of Tables 1 and 2). Furthermore, the 10 largest-amplitude EAG responses of *R. mendax* and *R. pomonella* flies were more similar for apple extract than blueberry extract; eight of their 10 largest responses corresponded to the same apple extract peaks (Table 1), whereas only four of their 10 largest responses corresponded to the same blueberry peaks (Table 2).

Several differences were found among *R. mendax* and *R. pomonella* flies in their EAG responses to blueberry compounds with retention times less than 6 min. *R. pomonella* flies were very sensitive to these compounds (seven of their 10 largest EAG responses corresponded to blueberry peaks with retention times less than 6 min, whereas only one of these responses corresponded to a blueberry peak with a retention time greater than 8 min; see Table 2). In contrast, the 10 largest-amplitude EAG responses of *R. mendax* flies corresponded to blueberry peaks with a broader range of retention times. Only three of these responses corresponded to blueberry peaks with retention times less than 6 min, whereas four of them corresponded to blueberry peaks with retention times greater than 8 min (Table 2). Lastly, both *R. mendax* and *R. pomonella* flies had more large-amplitude responses to apple peaks than blueberry peaks with high retention times (i.e., peaks with retention times greater than 6 min; see Tables 1 and 2).

DISCUSSION

Our results indicate that there are significant interspecific differences in the antennal sensitivity of *R. mendax* and *R. pomonella* flies to 11 blueberry and nine apple extract peaks. Currently, we do not know the structure of these compounds, but their identification is in progress.

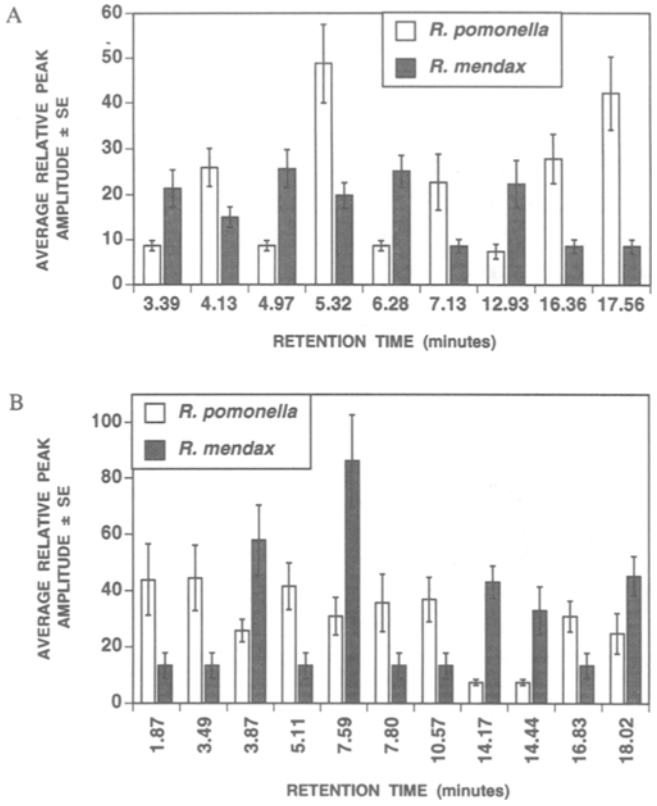

FIG. 2. Significant interspecific differences in antennal sensitivity to (A) apple extract compounds and (B) blueberry extract compounds ($P < 0.05$).

Several of the above threshold EAG responses were elicited by compounds with the same retention time as some Fein blend compounds, which, under the GC conditions used in our study, showed retention times between 15.8 and 21.5 min (e.g., in the apple extract hexyl acetate and hexyl propanoate and in the blueberry extract hexyl acetate, butyl-2-methyl butanoate, and propyl hexanoate; see Tables 1 and 2). Some of the GC peaks corresponding to the retention times of the Fein blend esters did not elicit EAG responses, probably because of low concentration in the extracts. However, there are cases where the GC trace showed a peak at a position where one of these esters was expected to elute but no EAG response was recorded. This may be caused by two reasons: (1) there may be two different compounds eluting at the same R_t, the concentration of the ester expected to elicit an EAG response being too low, or (2) the fly's

antenna may still be in the recovery period of a response to a compound running off just before the relevant ester and may therefore not be able to respond.

The results of our study indicate, however, that 87% of the apple peaks and 77% of the blueberry peaks that elicited measurable EAG responses from either *R. mendax* or *R. pomonella* flies have retention times that are smaller than those of the seven esters identified by Fein et al. (1982). Similarly, 94% of the apple peaks and 78% of the blueberry peaks that elicited EAG responses from *R. mendax* flies had smaller retention times than any of the Fein blend esters. Moreover, the majority of the largest-amplitude EAG responses of both species were to apple and blueberry peaks with retention times less than those of the Fein blend compounds (see Tables 1 and 2). The identification of these unknown apple and blueberry compounds could lead to the discovery of new chemical cues that mediate the host selection behavior of *R. mendax* and *R. pomonella* flies. For example, the addition of identified compounds to artificial fruits with suitable visual and size characteristics (Prokopy and Bush, 1973; Papaj and Prokopy, 1986; Bierbaum and Bush, 1990b) could lead to the discovery of new chemical cues that either elicit or deter oviposition.

In designing such bioassays, it is important to realize that the actual differences in host odor recognition between *R. mendax* and *R. pomonella* flies may be even more pronounced than indicated by the results of our EAG measurements. The transmission of peripheral information to the central nervous system (CNS) can be divided into two different modes (Visser and De Jong, 1988): (1) a large number of relatively unspecific generalist receptors may transmit their signals across many fibers of olfactory neurons to the CNS (i.e., across-fiber patterning), and (2) a low number of specialist receptors, each of which responds exclusively to a single compound in the blend, may transmit their signals via labeled lines directly to the CNS. If a small number of highly specific receptor cells project their signals via labeled lines into the CNS, a significant behavioral response may be elicited although no EAG response can be detected. Therefore, future attempts to identify plant compounds that elicit behavioral responses from *R. mendax* and *R. pomonella* flies should also include fruit volatiles that do not evoke measurable EAG responses from these flies.

Lastly, the results in Tables 1 and 2 indicate that there were significant differences among 25.0% of all *R. mendax* and *R. pomonella* responses to apple extract peaks and 24.4% of their EAG responses to blueberry peaks. Therefore, approximately 75% of their EAG responses to either apple or blueberry peaks were not measurably different. This result is consistent with the findings of van der Pers (1981), who recorded the EAG responses of seven closely related ermine moth species to 57 plant volatiles. Six of these species are associated with distinct principal host plants, and olfactory cues appear to play an important role in their selection of host plants. He observed that all of the compounds elicited a measurable EAG response from all of the species and that the EAG

response spectra of each of the seven species were very similar (i.e., less than 10% of the plant compounds elicited significantly different EAG responses from different species). The results of van der Pers (1981), as well as our results for *R. mendax* and *R. pomonella* flies, suggest that the olfactory receptors of some closely related oligophagous and monophagous insects are specifically tuned to only a small percentage of the plant compounds they detect. A similar pattern of responses was found among olfaction-deficient mutants of *Drosophila* whose antennal sensitivity is specifically affected by some odor compounds, but not others (Venard and Pichon, 1984). Furthermore, several studies on *Drosophila* flies indicate that genetic changes at only one or a few genes can affect their peripheral sensitivity to odor compounds (e.g., Falk and Atidia, 1975; Venard and Pichon, 1984; Arora et al., 1987; Lilly and Carlson, 1989). These results suggest that genetic changes at relatively few loci could influence an insect's peripheral sensitivity to key plant compounds, which may be sufficient to trigger changes in host preference. In host-specific parasitic organisms that mate on their host, such changes may result in a genetically based shift onto a new host when there are very low levels of gene flow among the host-associated populations. Thus, genetically based changes in the perception of plant odors may have played a significant role in mediating the host shifts of *Rhagoletis* fruit flies (Bush, 1975).

Acknowledgments—We thank M. Harris, J. Miller, R. Pax., E. Städler and H.-P. Buser for helpful discussions on various aspects of this research, and we are grateful to M. Case, P. Roessingh, and R. Baur for their comments on an earlier draft of our manuscript. We also thank J. Ross and H. Tran for their technical assistance with collecting fruit extracts, and J. Miller for the use of his gas chromatograph. (1*S*,2*R*,4*S*,5*S*)-ANGELICOIDENOL-2-*O*-β-D-GLUCOPYRANOSIDE—A MOOSE DETERRENT COMPOUND IN SCOTS PINE (*Pinus sylvestris* L.)

KERSTIN SUNNERHEIM-SJÖBERG

Department of Chemistry
Swedish University of Agricultural Sciences
P.O. Box 7015

(Received January 23, 1992; accepted June 29, 1992)

Abstract—Hydrophilic extracts of Scots pine (*Pinus sylvestris* L.) twigs have been investigated for palatability to moose in feeding experiments. The predominant repellent effect was observed from the 2-*O*-β-D-glucopyranoside of the monoterpene (1*S*,2*R*,4*S*,5*S*)-angelicoidenol. Of other isolated and tested substances, only taxifolin-3′-*O*-β-D-glucopyranoside had a deterring effect. One fraction—containing mainly aliphatic compounds—also had a strong effect, but the effect was lost after further fractionation. Tannin-containing fractions had no effect. Angelicoidenol glucoside has not previously been reported from *P. sylvestris*. The results are discussed in view of phenols as defense compounds.

Key Words—Phenols, monoterpenes, glycosides, chemical defense, feeding experiments, moose browsing, *Alces alces*, Scots pine, *Pinus sylvestris* L., angelicoidenol glucoside, taxifolin glucoside.

INTRODUCTION

Phenols are considered to act as defense substances in plants against herbivory (Palo, 1984; Harborne, 1985; Haslam 1988). On this basis, many investigations have been made to elucidate the relations between food choice and phenols. One of the earlier studies was made by Feeny (1970), who studied caterpillar feeding behavior in relation to tannin content in oak leaves and found that leaves rich in tannins were consumed less. Tannins—quantified by protein-precipitating ability of plant extracts—had various effects on protein availability to moose (Robbins et al., 1987). Another study by Häggman and Rousi (1985) showed

0098-0331/92/1100-2025$06.50/0 © 1992 Plenum Publishing Corporation

that the total phenolic content in Scots pine was negatively correlated to browsing by mountain hare (*Lepus timidus* L.). None of these investigations included isolation of single substances, so the compound(s) causing the effect is(are) still unknown. However, Bryant et al. (1983) and Clausen et al. (1986) have shown that the phenolic compound pinosylvin and its monomethyl ether—both isolated from green alder (*Alnus crispa*)—are highly repellent to snow-shoe hare (*L. americanus*).

In a previous study (Sunnerheim et al., 1988), the effect of birch twig extractives on digestibility in vitro in goat rumen liquor was studied. It was shown that platyphylloside [5-hydroxy-1,7-bis-(4-hydroxyphenyl)-heptan-3-one-5-*O*-β-D-glucoside] was the most effective compound for reducing digestibility, while other fractions—including those containing tannins—showed minor effects.

A few investigations of terpenes have also been performed for effect on food selection by moose. For instance, Danell et al. (1990) found that there is a negative correlation between the presence of the diterpene pinifolic acid and moose browsing of Scots pine. However, Löyttiniemi and Hiltonen (1978) as well as Löyttiniemi (1981) and Niemelä and Danell (1988) found no correlation between the total amount of ether extractives of Scots pine and moose browsing.

Moose (*Alces alces* L.) feed to a great extent on Scots pine (*P. sylvestris*), (Ahlén, 1968; 1975; Cederlund et al., 1980). However, some individual pine trees are preferred over other, apparently equal, pines in the same clump (Haukioja, 1983; Danell et al., 1990). This fact indicates that pines are provided with a chemical defense varying in strength between individuals.

The aim of the present work was to investigate the chemical defense in pine by testing extracts and isolated substances for their palatability to moose in feeding experiments.

In a parallel study, the palatability of pine individuals as a function of phenolic composition is studied by means of multivariate data analysis (Sunnerheim-Sjöberg and Hämäläinen, 1992).

METHODS AND MATERIALS

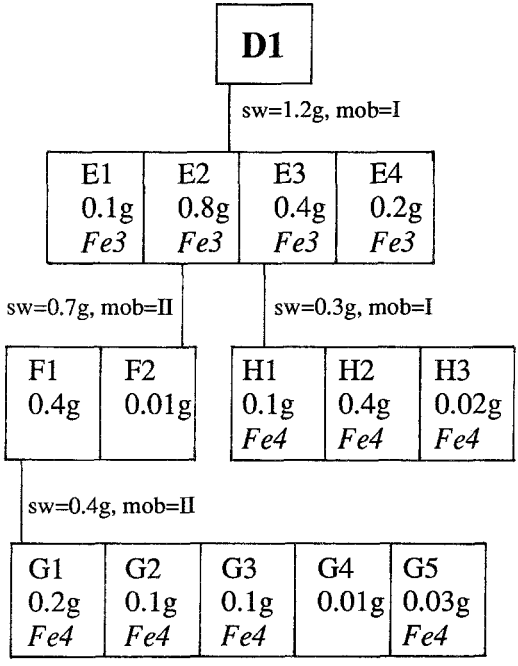
Plant Material. Twigs from unbrowsed Scots pines (*P. sylvestris*) were collected in winter outside Umeå in coastal northern Sweden. The twigs were stored at −20°C or used directly. Twigs from birch (*Betula pendula*) were collected in winter in Uppsala, Sweden. The birch twigs were used without storage.

Extraction. Frozen pine twigs (including needles) <5 mm diameter (5.6 kg) and cut in pieces were extracted in a homogenizer with a total of 10 liters 95% ethanol followed by 10 liters 80% aqueous ethanol. The extracts were filtered, and the ethanol was evaporated. The remaining aqueous phase was

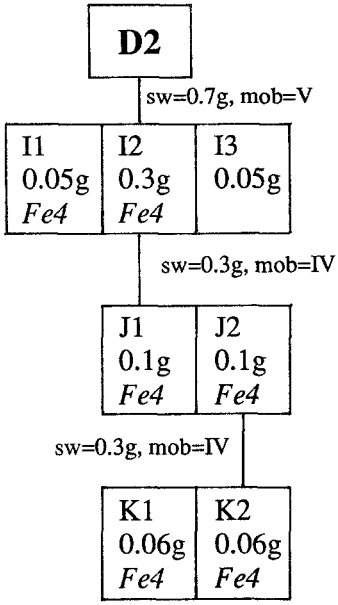
diluted with water to 2.0 liters and extracted with 3 × 2.0 liters petroleum ether (bp 40–60°C) (P) followed by 3 × 2.0 liters ethyl acetate (E). The organic phases were dried over anhydrous sodium sulfate and evaporated. Evaporations were performed at reduced pressure below 40°C. The remaining water extract (W) was lyophilized. The three extracts (W, 203 g; E, 112g; P, 142 g) were tested in feeding experiment 1 (Fe1).

Fresh pine twigs (3.0 kg fresh weight) were extracted as above for further fractionations.

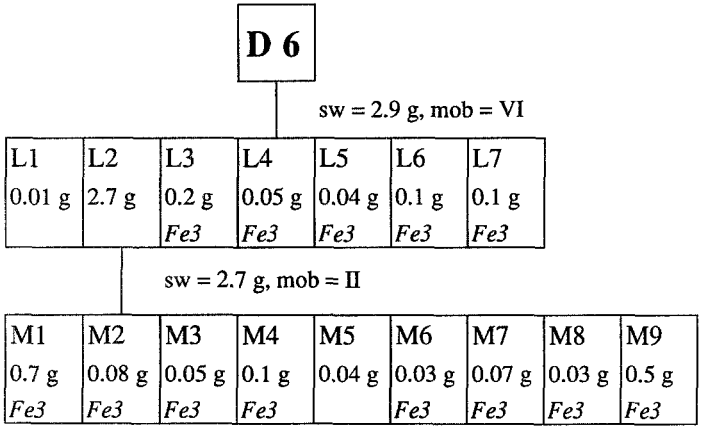
Fractionation of Extracts. The ethyl acetate extract (30 g) was chromatographed on a Sephadex LH-20 column (9 × 30 cm). Water, 30%, 60% and 95% aqueous ethanol, and finally acetone (3 liters of each) were used as eluents. The fractions were examined by TLC. Nine fractions were collected: (D1) 2.73 g, (D2) 1.46 g, (D3) 4.04 g, (D4) 3.02 g, (D5) 3.27 g, (D6) 3.73 g, (D7) 2.68 g, (D8) 1.38 g, (D9) 4.10 g. Parts of D1–D9 were tested in feeding experiment 2 (Fe2). The remaining parts of fractions D1, D2, and D6 were rechromatographed on silica gel columns to E–H, I–K, and L–M, respectively according to Schemes 1–3. Weights of extracts and fractions might include solvent residues.



SCHEME 1. Subfractions of D1. sw = sample weight, mob = mobile phase, *Fen* = fraction tested in feeding experiment *n*.



SCHEME 2. Subfractions of D2. sw = sample weight, mob = mobile phase, *Fe4* = fraction tested in feeding experiment 4.



SCHEME 3. Subfractions of D6. sw = sample weight, mob = mobile phase, *Fe3* = fraction tested in feeding experiment 3.

Subfractionations. Liquid chromatography (LC) was performed on a silica gel (Riedel-de-Haen, 0.032–0.064 mm) column (2 × 50 cm). Thin-layer chromatography (TLC) was performed on Merck HF-254 silica gel plates. The following eluents were used for TLC and for LC (silica gel): (I) chloroform–butanone–methanol–acetic acid (10:7:4:2, v/v); (II) chloroform–methanol–water (80:15:1, v/v); (III) chloroform–methanol–water (120:15:1, v/v); (IV) chloroform–methanol–water (40:15:1, v/v); (V) ethyl acetate–95% ethanol–acetic acid (9:2:1, v/v); and (VI) ethyl acetate–95% ethanol–acetic acid (18:2:1, v/v).

The TLC plates were inspected under UV light at 254 nm. Spray reagents used were: (i) diazotized sulfanilic acid (Fluka AG, CH 9470) in 10% aqueous sodium carbonate, followed by 50% sulfuric acid (v/v) (phenols); (ii) vanillin in 18% hydrochloric acid (catechin derivatives); (iii) 50% sulfuric acid, followed by heating at 100°C for about 1 min (organic compounds in general).

High-performance liquid chromatography (HPLC) was performed using an analytical column (Chrompack CP-TM-spher C18, 4.6 × 250 mm). Mobile phases were linear gradients of water with increasing amounts of methanol with constant concentration of 1% formic acid. Detection was made with a UV detector at 280 nm.

Spectroscopy. ^{1}H and ^{13}C NMR spectra were recorded at 400 MHz and 101 MHz, respectively. A Varian VXR-400 spectrometer was used. Chemical shifts (δ) are given relative to tetramethyl-silane (TMS) as internal reference. Mass spectra were recorded at 70 eV with a Finnigan 4000 spectrometer using a direct insertion probe. Chemical ionization was performed using NH_3 as the reactant gas.

Reference Substances. Shikimic acid was commercially available. Taxifolin-3′-*O*-β-D-glucopyranoside was available at our laboratory (Lundgren, 1987; Lundgren and Theander, 1988).

Isolated Substances. (1*S*,2*R*,4*S*,5*S*)-(−)-Angelicoidenol-2-*O*-β-D-glucopyranoside (A, Figure 1) was isolated from fraction K2, 63 mg (Scheme 2).

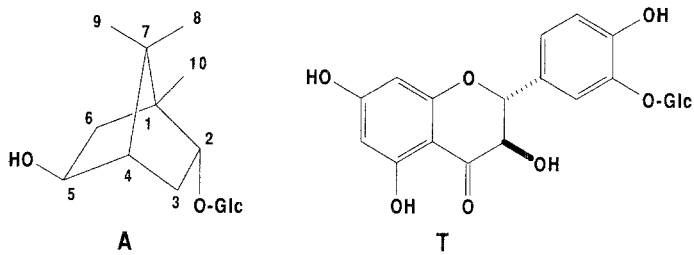


FIG. 1. Isolated substances with deterrent effect. (1*S*,2*R*,4*S*,5*S*)-(−)-Angelicoidenol-2*O*-β-D-glucopyranoside (A) and taxifolin-3′-*O*-β-D-glucopyranoside (T).

TLC; Eluent I: R_f = 0.34, color with spray (iii): greyish violet. ^{1}H NMR and ^{13}C NMR data—both in pyridine-d_5—were in accordance with those published by Inoshiri et al. (1988). ^{1}H NMR (CD_3OD) (δ): 0.85 (3H, s, CH_3-8), 0.92 (3H, s, CH_3-10), 1.01 (1H, dd, $J_{2\beta}$ = 3.0; $J_{3\beta}$ = 13.4 Hz, H-3α), 1.08 (3H, s, CH_3-9), 1.31 (1H, d (broad), $J_{6\alpha}$ = 13.2 Hz, H-6β), 1.69 (1H, d, $J_{3\beta}$ = 5.4 Hz, H-4α), 2.18 (1H, ddd, $J_{2\beta}$ = 9.3 Hz, H-3β), 2.44 (1H, dd, $J_{5\alpha}$ = 8.0 Hz, H-6α), 3.14 (1H, t, $J_{1'}$ = 7.9 Hz, H-2′), 3.18–3.26 [1H, m (broad), H-5′], 3.27–3.36 (2H, hidden, H-3′ and H-4′), 3.66 (1H, dd, $J_{5'}$ = 11.7; $J_{6'}$ = 5.6 Hz, H-6′), 3.85 (2H, m, H-6′ and H-5α), 4.05 (1H, d, H-2β), 4.21 (1H, d, H-1′). 2D NMR was run with standard methods. The structure was verified with COSY, long-range COSY, C,H-COSY and NOESY. $[\alpha]_D$ = −23.8° ± 3° (c = 0.65 in MeOH); ($[\alpha]_D$ = −26.3° [c 1.04 in MeOH], Inoshiri, 1988). EI-MS m/z (relative intensity): 170(4.3), 153(26.8), 152(20.4), 137(28.1), 135(19.4), 108(100), CI-MS: 350 $[M+NH_4]^+$.

Angelicoidenol and glucose were obtained by enzymatic hydrolysis: A (10 mg) was incubated in 2 ml of water with 1 mg of pectinase (Sigma Chemical Co. No. P4625). After 20 hr at room temperature in the dark, the solution was extracted with 2 × 2 ml ethyl acetate. The organic phase was dried over anhydrous sodium sulfate and evaporated to dryness. The residue was identified as angelicoidenol by ^{1}H NMR spectroscopy in pyridine-d_5, the spectrum being in accordance with literature data, (Mahmood et al., 1983; Gunawardana and Cordella, 1988). ^{1}H NMR (CD_3OD) (δ): 0.77 (1H, dd, $J_{2\beta}$ = 3.2 Hz, $J_{3\beta}$ = 13.7 Hz, H-3α), 0.85 (3H, s, CH_3-8), 0.87 (3H, s, CH_3-10), 1.08 (3H, s, CH_3-9), 1.32 (1H, d(broad), $J_{6\alpha}$ = 13.3 Hz, H-6β), 1.67 (1H, d, $J_{3\beta}$ = 5.2 Hz, H-4α), 2.25 (1H, ddd, $J_{2\beta}$ = 9.8 Hz, H-3β), 2,32 (1H, dd, $J_{5\alpha}$ = 7.9 Hz, H-6α), 3.80 (1H, dd, $J_{6\beta}$ = 3.4 Hz, H-5α), 3.84 (1H, ddd, $J_{6\beta}$ = 2.0 Hz, H-2β). NMR and TLC data were in accordance with a synthetic sample prepared according to Marquet and Gabard (1967).

Glucose was identified by gas chromatography as trimethylsilyl derivative (Sweeley et al., 1963).

Taxifolin-3′-*O*-β-D-glucopyranoside (T, Figure 1), was isolated from fraction M9, 540 mg (Scheme 3) and was identified by ^{1}H NMR spectroscopy and co-TLC and co-HPLC with an authentic sample.

Feeding Experiments. Birch twigs were treated with pine twig extractives dissolved in 95% ethanol. The birch twigs were placed in a beaker, and the extract was evenly distributed over the twigs with a Pasteur pipet. To n g dry matter (DM) of birch twigs, extract from approximately 3.5 × n g (DM) of pine twigs was added. The control birch twigs (C) were treated with 95% ethanol.

In feeding experiments 1–4 (Fe1–Fe4), artificial trees were constructed from nine treated birch twigs and a rod with nine holes for the twigs. The trees—one tree per extract in each test—were planted in the snow in a pasture for moose

in a zoological park in Lycksele, Sweden. After about 1-hr the amount consumed was determined.

In feeding experiment 5 (Fe5), the test animal was fed by hand—one bunch of treated twigs and one control were offered simultaneously.

The number of test animals was: Fe1, varied between three and five in each test; Fe2, test 2 : 1—two adult bulls, two cows and three calves, Test 2 : 2—two adult bulls, one cow and three calves; Fe3, one adult cow in both tests; Fe4, one adult bull; and Fe5, one adult bull.

Quantification of consumption was as follows: normalized consumption = r_i/r_c, where relative consumption (r) = biomass removed/biomass available; r_i = relative consumption of sample i = $(b_i - a_i)/b_i$, where b_i = weight of birch twigs of artificial tree i before test, a_i = weight of birch twigs of artificial tree i after test, r_c = relative consumption of the control is defined analogously.

RESULTS AND DISCUSSION

Water, Ethyl Acetate, and Petroleum Ether Extracts. The three pine extracts (water, ethyl acetate, and petroleum ether) and one control were used in Fe1. Eleven tests were performed with four artificial trees in each test (Figure 2).

The water extract did not markedly affect the palatability of the twigs. The twigs were browsed more than 80% in 10 of the 11 experiments. The water phase contained mainly carbohydrates and hydrophilic glycosides. Glucose, fructose, and sucrose together constitute about 7% of the dry matter of pine needles (Popoff and Theander, 1976).

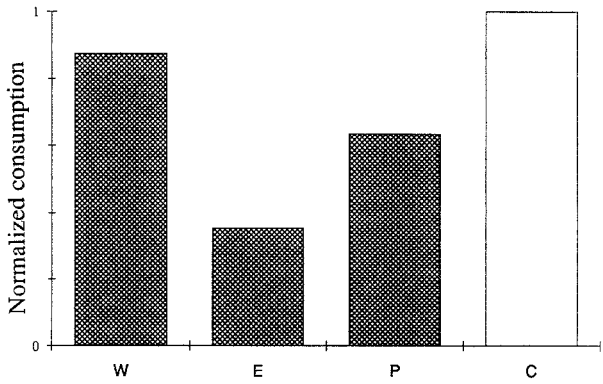

FIG. 2. Results from feeding experiment 1 (Fe1). Normalized consumption (means, $N = 11$) for test twigs treated with water (W), ethyl acetate (E), or petroleum ether (P) extract. Standard deviations: W, 0.29; E, 0.35; P, 0.29. Untreated twigs were used as control (C).

Browsing was least on twigs treated with ethyl acetate extract. In eight of the 11 experiments the sample twigs were consumed less than 50%. Ethyl acetate extract of Scots pine have been shown to contain compounds of intermediate hydrophilicity, such as glycosides—both phenolic and non phenolic—as well as aglycones (Popoff and Theander, 1975, 1976, 1977; Lundgren et al., 1982; Andersson and Lundgren 1988; Lundgren and Theander, 1988). To a lesser extent hydrophilic compounds, such as shikimic acid, are also extracted by ethyl acetate.

The petroleum ether phase of pine needles contains the most lipophilic compounds, such as chlorophyll and terpenoids. The content of the diterpene pinifolic acid is 1–2% of DM in pine needles (Enzell and Theander, 1962; Danell et al., 1990). As the concentration of pinifolic acid has been shown to be negatively correlated to moose browsing (Danell et al., 1990), the presence of this compound might be part of the explanation to the moderately but clear deterrent effect of the petroleum ether extract.

The most active fraction, the ethyl acetate extract, was further fractionated to D1–D9 as described above.

Fractions from Ethyl Acetate Extract. The nine fractions, D1–D9 (originating from Sephadex LH-20 chromatography of the ethyl acetate phase), and one control (C) were tested in each of two tests (Fe2). Figure 3 shows the mean value of results from tests 2:1 and 2:2. Fractions D1 and D2 were most deterrent in both tests. According to ^{1}H NMR spectroscopy and TLC, fraction D1 contained mostly sugars, several other aliphatic and small amounts of phenolic compounds. Fraction D2 was dominated by sugars and two other aliphatic compounds.

According to Popoff and Theander (1977) fractions D3–D6 were expected to contain several phenolic glycosides. This was confirmed by ^{1}H NMR spectroscopy and TLC. D6 was slightly deterrent in both tests, and D4 in one test. Twigs treated with fractions D3 and D5 showed no repellent activity (Figure 3).

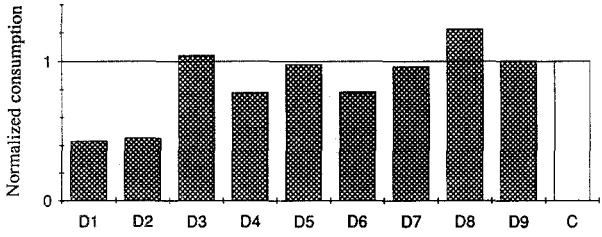

FIG. 3. Results from feeding experiment 2 (Fe2). Normalized consumption for test twigs treated with fractions D1–D9. Untreated twigs were used as control (C). Mean of two tests.

Fractions D7–D9 contained several phenolic compounds, such as catechin and probably also oligomers of catechin, i.e., condensed tannins (Proanthocyanidins) (Haslam, 1988). It has also been stated by Gupta and Haslam (1981) that needles of Scots pine are rich sources of proanthocyanidins. Catechin derivatives are easily detected with vanillin/hydrochloric acid and are assumed to have the ability to complex with proteins (including enzymes), leading to astringent taste and digestibility-reducing properties (Haslam, 1988). However, these fractions containing condensed tannins were not repellent to moose.

Fractions D1, D2, and D6 were further fractionated on silica gel columns as described as above.

Subfractions from D1. The strong effect of fraction D1 was lost after two fractionations (Scheme 1). Apart from the uncertainties in the feeding experiments there might be several explanations to this: (1) Synergistic effects might be caused by two or more compounds, which after a chromatographic procedure occur in different subfractions. (2) Active substance(s) might be divided into several fractions leading to a decrease in concentration. (3) Chemical reactions can occur, e.g., oxidation, during the work-up procedures and tests. (4) Active compounds might also be completely retained on the silica gel column.

Subfractions from D2: Isolation and Test of (1S,2R,4S,5S)-(−)-Angelicoidenol-2-O-β-D-glucopyranoside. The two main compounds of the deterrent fraction D2 were obtained after three subfractionations (Scheme 2). K1 was pure shikimic acid, identified with ^{1}H NMR spectroscopy. K2 was angelicoidenol glucoside A.

Fractions I1, I3, J1, K1, and K2 were tested in a feeding experiment (Fe4) in each of two tests. Unfortunately, the moose was not interested in feeding trials in the second test. Figure 4 shows results from test 1.

(−)-Angelicoidenol-2-*O*-β-D-glucopyranoside was the most deterrent sub-

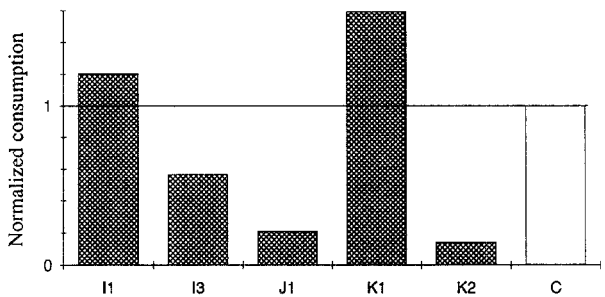

FIG. 4. Results from feeding experiment 4 (Fe4). Normalized consumption for test twigs treated with fractions I1, I3, J1, K1, and K2 (A). Untreated twigs were used as control (C).

stance tested. In test 1, the birch twigs treated with A were eaten only 17% compared to the control.

The palatable fraction I1 lacked A, while fraction I3 and J1, both eaten less than the control in the first test, contained A among other substances. Since shikimic acid (fraction K1) was the most palatable substance tested, this compound could be excluded as a cause of the deterrent effects of the extracts containing both compounds. Thus, angelicoidenol glucoside might be responsible for the repellent effect.

Even the water extract, tested in feeding experiment 1 (Figure 2), contained A in small amounts, but the taste might have been masked by the high sugar content.

Many phenols, glycosidically bound as well as free, have been isolated from pine (Norin, 1972; Popoff and Theander, 1975; 1976; 1977; Niemann, 1979; Lundgren et al., 1982; Niemann and Van Genderen, 1980; Theander, 1982; Theander and Lundgren, 1989). Terpenes also have been intensively studied, and a great number have been isolated (Norin, 1972; Enzell and Theander, 1962; Gref, 1981, 1987; Dev, 1989). However, glycosides of terpenes seem not to occur so frequently in pine species.

(1*S*,2*R*,4*S*,5*S*)-(−)-Angelicoidenol-2-*O*-β-D-glucoside has, to my knowledge, never been isolated from pine and is reported only once in the literature (Inoshiri et al., 1988). The aglycone angelicoidenol has four chiral centers, but, due to the bridgehead, can only occur in eight isomeric forms. However, only (1*S*,2*R*,4*S*,5*S*)-(−)-angelicoidenol and its enantiomer—glycosidically bound or as the free aglycone—have, to my knowledge, been found in nature. The 2-*O*-β-D-glucopyranosides of the two enantiomeric angelicoidenols were isolated from *Berchemia racemosa* by Inoshiri et al. (1988). [They call the two compounds (+)- and (−)-angelicoidenol-2-*O*-β-D-glucopyranoside, respectively, although both isomers have negative specific rotation.] The 2-*O*-β-D-glucoside of (1*R*,2*S*,4*R*,5*R*)-(+)-angelicoidenol (amomumoside) isolated from ginger (*Amomum xanthoides*) by Fujioka et al. (1988) was found to have sedative properties.

(1*S*,2*R*,4*S*,5*S*)-(−)-Angelicoidenol has been named by Mahmood et al. (1983), who isolated it from the Himalayan herb *Pleurospermeum angelicoides*. Gunawardana and Cordell (1988) found the same compound, here called (−)-5-*exo*-hydroxyborneol, in the Australian plant *Hedycarya angustifolia*.

This compound has also been formed by synthetic (Marquet and Gabard, 1967; Allen et al., 1979) and microbiological hydroxylation of borneol (Allen et al., 1979).

Based upon comparison with ^{1}H and ^{13}C NMR spectroscopy and optical rotation data from previous studies (Mahmood et al., 1983; Fujioka et al., 1988; Inoshiri et al. 1988), A was deduced to have the absolute configuration 1*S*,2*R*,4*S*,5*S*.

Subfractions from D6: Isolation and Test of Taxifolin-3'-O-β-D-Glucopyranoside. Subfractions—all containing phenols—from the slightly deterrent D6 were tested in feeding experiment 3 (Fe3). No strong deterrent effects were shown.

Naringenin glycosides are frequently occurring in the plant kingdom. Naringin (naringenin-7-*O*-β-neohesperidose) is responsible for the bitter taste of grapefruit, but, e.g., naringenin-7-[β-D-glucosyl (1→2) β-D-galactoside] is tasteless to man (Kamiya et al., 1974). Therefore it was of interest to test fraction M7 in a feeding experiment. ^{1}H NMR spectroscopy of this fraction showed that the main component was a 7-*O*-glucoside (probably the β-D-glucoside) of naringenin. Identification was made by comparison with the ^{1}H NMR spectrum of naringenin-7-*O*-β-D-glucopyranoside isolated from spruce needles (Lundgren, personal communication). Glucose was identified as described above. This fraction was only slightly deterrent, so the naringenin-7-*O*-glucoside is probably not too unpalatable to moose.

Fraction M9 was pure taxifolin-3'-*O*-β-D-glucopyranoside (T), which was shown to be slightly deterrent (Fe3). Twigs prepared with T were eaten 80% compared to the control. Taxifolin glucoside is a well-known flavonoid in conifers (Lundgren and Theander, 1988; Strack et al., 1989). In some clones of Scots pine, T is the main phenolic compound with a concentration of about 3% of needle DM, while it is absent in other clones (Sunnerheim-Sjöberg et al., 1992). The facts that (1) the concentration of T was shown to be correlated to moose browsing in the models in the multivariate study (Sunnerheim-Sjöberg and Hämäläinen, 1992), (2) T is the main phenolic compound in some of the pine individuals, and (3) T is shown to be genetically controlled (Sunnerheim-Sjöberg et al., 1992), made it of special interest to investigate the palatability of this compound.

Test of Angelicoidenol and Taxifolin Glucosides. Different concentrations of (−)-angelicoidenol-2-*O*-β-D-glucopyranoside and taxifolin-3'-*O*-β-D-glucopyranoside (both compounds obtained from additional isolations) were tested in simple two-choice feeding trials (sample and control, Fe5).

Three concentrations (A1–A3) of A were tested in Fe5 (Figure 5): A1; two samples, conc. 0.05% of DM; A2; one sample, conc. 0.15% of DM; and A3; two samples, conc. 0.25% of DM.

Even at the lowest concentration of A, the moose ate less from twigs treated with A compared to control twigs. The moose ate 29% and 79%, respectively, in the two tests and expectorated some. Higher concentrations caused complete aversion of the prepared twigs.

In Fe3 T was tested in a concentration of about 0.1% of dry matter. In this experiment (Fe5) three concentrations (T1–T3) of T were tested (Figure 5). T1; two samples, conc. 0.14% of DM; T2; two samples, conc. 2.8% of DM; and T3; one sample, conc. 5.5% of DM.

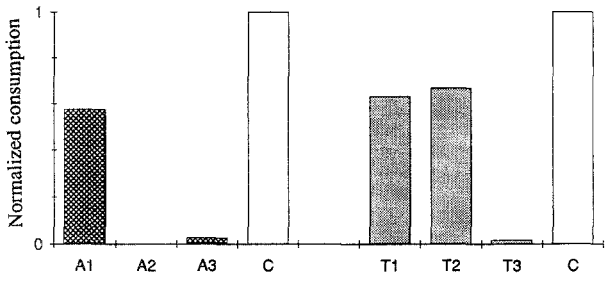

FIG. 5. Results from feeding experiment 5 (Fe5). Normalized consumption of twigs treated with different concentrations of A and T.

T was only slightly deterrent. In the lowest concentration, the twigs treated with T were eaten 55–100% compared to the control. At medium concentration (T2), the consumption was 44–100%. This concentration corresponds to the natural concentration in pines of high-T-chemotype (3% DM). However, if the concentration of T was doubled (T3), the moose expectorated the twigs after tasting.

The deterrent fraction D1 discussed earlier did not contain angelicoidenol glucoside or taxifolin glucoside.

Advantages and Disadvantages with Feeding Experiments. The large amount of sample required for a feeding experiment sets limits to the number of experiments. Here, some of the extracts were tested in only two trials, which, of course, can not be regarded as statistically significant. In some cases the moose had no interest in the artificial trees, so the test was of no value. However, the deterrent effect of angelicoidenol glucoside seems to be unequivocal: All the fractions from the ethyl acetate phase that contained A were avoided by the moose in the feeding experiments. These extracts were tested in 21 tests, and in 16 of these, the twigs were eaten less than 50% as compared to the control. Concerning food choice among the samples: in 18 of these 21 tests, the moose ate least from twigs prepared with extracts containing A, and in the remaining three tests, these twigs were chosen second to last. Only one extract containing A, the water extract (W) in Fe1 was not deterrent. However, this fraction also contained substantial amounts of sugars.

One advantage of feeding experiments in studying chemical defense is that food choice is a more direct measurement compared to quantities such as digestibility effects or toxicity. However, the normal diet of captured moose is not the same as for wild-living ones, which might influence the food choice.

Phenols as Chemical Defense Substances? Phenols—particularly tannins—have long been considered to be involved in the chemical defense of plants against herbivores (Feeny, 1970, 1976; Haslam, 1988). This work shows, how-

ever, that many of the phenol-containing fractions were not repellent. Moreover, the only fractions that might have contained condensed tannins, the vanillin-positive, were not deterrent. On the contrary, the most predominant effect was connected with a monoterpene glycoside and with fractions that almost lacked phenols. In another study (Sunnerheim-Sjöberg and Hämäläinen, 1992) 55 compounds absorbing at 280 nm, i.e., including phenols but not angelicoidenol glucoside, were analyzed. None of these compounds alone could explain the moose food choice among individual pines. However, there were significant correlations between the phenol pattern in Scots pine needles and moose food choice. Taxifolin glucoside was shown to be an important substance for food choice, although a high concentration of T was not sufficient for unpalatability of a pine individual. In view of the many observations of phenols as herbivore-deterring factors and the results above, one can conclude that, if there is a chemical defense in pine against moose browsing based upon phenols, it is of a complex nature. However, twigs prepared with extracts containing the monoterpene angelicoidenol glucoside were unpalatable to the moose tested. Thus, A might be an important part of the chemical defense of pine.

Acknowledgments—I thank Mr. Rolf Andersson for recording the NMR spectra, Dr. Lennart Lundgren for providing reference samples, and Prof. Olof Theander for valuable discussions. Prof. Kjell Danell is thanked for supplying me with personnel resources and plant material. Mr. Åke Nordström and Mr. Ola Gärdemalm are thanked for performing the feeding experiments. Financial support from SJFR is gratefully acknowledged.

(Received March 31, 1992; accepted June 29, 1992)

Abstract—Capping of worker *Apis mellifera* cells is elicited by four fatty acid methyl esters (Methyl palmitate, methyl oleate, methyl linoleate, and methyl linolenate) that are present on the surface of the worker and drone larvae only a few hours before the cell is closed. The amount of the pheromone reaches its maximum value when the cell has just been capped, at 8.5 and at 10.25 days of age, respectively, for worker and drone larvae. Thereafter, the amount of the pheromone decreases to its initial level. These data suggest that the esters also have a role in the capping of the drone cells, the temporal signal allowing the worker bees to recognize the age of the larvae and then to do the appropriate behavior. Two pheromonal components, methyl palmitate and methyl linolenate, and the inactive ethyl palmitate are kairomones attractive to *Varroa* females. Their secretion by the larvae follows the same pattern of development as the pheromonal signal. The longer and greater kairomonal signal in drone larvae, compared to worker secretion, could explain the preference of *Varroa* towards drone brood.

INTRODUCTION

Honey bee (*Apis mellifera*) brood is reared in wax cells throughout its development. After hatching, the larva is fed by adult bees, which thereafter close the cell with a wax cap, a process called capping behavior. The behavior differs between worker and drone brood, because cap shape and cell size is different for these two kinds of larvae. Pupation occurs under shelter of the cap, and at about 21 and 24 days after egg laying, respectively, in workers and drones, the adult bee emerges from its cell.

Four fatty acid methyl esters [methyl palmitate (MP), methyl oleate (MO), methyl linoleate (ML), and methyl linolenate (MLN)] trigger the capping of the worker cells by the adult bees (Le Conte et al., 1990). These compounds are secreted by the worker larvae a few hours before the cell is closed and are present in great amounts on the larval surface during the capping period. They disappear during the following days (Trouiller et al., 1991). The temporal secretion of the brood pheromones seems to allow the adult workers to perform the capping behavior at the appropriate period. The six other methyl and ethyl esters present in the worker larvae [methyl stearate (MS), ethyl palmitate (EP), ethyl stearate (ES), ethyl oleate (EO), ethyl linoleate (EL), and ethyl linolenate (ELN)] do not induce capping behavior.

Two of the pheromonal compounds, MP and MLN, and the inactive EP, are kairomones attractive to *Varroa jacobsoni* (Le Conte et al., 1989). *Varroa* is responsible for a virulent, almost worldwide, parasitism of *Apis mellifera* (Ritter, 1981; Arnold, 1990). Adult *Varroa* feed on the hemolymph of the adult and immature bees, and their development is associated with bee brood. To reproduce, the *Varroa* female enters a cell containing a larva before it is capped (Grobov, 1977). After the closing of the cell, the *Varroa* females lays eggs and its offspring grow at the expense of the bee pupa. Later on, the mature acarians emerge from the cell with the adult bee. *Varroa* females prefer to infest drone brood rather than worker brood, when they are both present in the colony (Grobov, 1977; Sulimanovic, 1982; Tewarson, 1983; Schulz, 1984; Fuchs, 1990). As with the pheromonal compounds, the worker *Apis mellifera* brood only secrete the kairomonal compounds a few hours before the cell is closed (Trouiller et al., 1991). It is only during this period that *Varroa* enters the cell (Ifantidis, 1988; Boot et al., 1990; Wieting and Ferenz, 1991).

In this paper, we investigated the quantitative and qualitative variations in the secretion of the esters by drone larvae in order to attempt to explain the

differences in *Varroa* infestation and in the capping behavior of drone and worker brood. The data obtained from the drone brood were compared with those obtained in a previous study in worker brood (Trouiller et al., 1991).

METHODS AND MATERIALS

Biological Material

Rate of Development of Drone Brood. A queen (*Apis mellifera ligustica*) was allowed to lay during a short period (3 hr) on a comb set up with drone cells, isolated from the colony with a queen excluder (May 1991). Thereafter, the queen was excluded from the frame, which was left in the colony. From the sixth day, 20 larvae, chosen randomly, were removed every 12 or 24 hrs, the mean weight of the individuals and the form of the larvae and of their cells were noted. The size of the young larvae (between 7 and 8.5 days) was estimated in the cell. For larvae at their maximum development (between 9.5 and 10.25 days), the main criterion was the formation of the wax cap (no cap, capping in progress, and end of the capping). At subsequent ages (between 11.5 and 15 days), we noted the stage of the insect (traces of the larval cocoon, prepupa, and white eyed pupa). Using these data, we chose a series of stages of development that were easily distinguishable, and we assigned to them a mean age obtained from the growth curves and the other criteria (form of the cap and stage of the insect).

Comparison between Drone and Worker Brood. In order to compare the chemical data from the drone brood with that obtained from worker brood in 1990 (Trouiller et al., 1991), we also established a growth curve for the worker brood. To get this curve, we used the same protocol as described above: we placed a comb with worker cells in the same colony during the period that the drones were being reared.

Sample of Drone Brood. We took larvae from the same colony and reared during the same period. A queen (*Apis mellifera ligustica*) was allowed to lay for 24 hr on a comb set up with drone cells according to the same protocol described before. Seven days later, we took brood samples according to the criteria we had established from the growth curves. We used one or two samples of each stage, each sample consisting of 15–30 g of brood.

Chemical Analysis

The insects were taken intact from their cells and their cuticle extracted twice with *n*-pentane and thereafter once with dichloromethane. Each extract was shaken for 15 min. We used 2 ml of solvent per gram of insects for each of the three extractions of each sample; the three extracts were combined and

concentrated under a purified nitrogen flow. Then the residue was solubilized in 1 ml of pentane.

Each sample was fractionated on a silica gel column (Merck, 230–400 mesh) of 0.5 cm I.D. and 20 cm length. The silica gel was first washed with dichloromethane and dried at 60°C under vacuum. The first fraction, containing cuticular hydrocarbons (characterization by GC-MS), was obtained by passing 6 ml of pentane through the column; thereafter a second fraction containing the esters was obtained using 6 ml of dichloromethane.

Because of the presence of great amounts of di- and triglycerides, the second fraction was purified with HPLC. We used a Waters 6000 pump equipped with a Waters U6K injector and a refractometer detector (Erma ERC 7510). A mixture of *n*-heptane and ethyl acetate (95:5), with a flow of 1 ml/min was passed through a silica column (Interchrom 250, diameter 4.6 mm, intersphere 5 μm). The samples were recovered between 190 and 420 sec, dried under a nitrogen flow, and solubilized in *n*-hexane.

The esters were quantified by GC (Carlo Erba 6000 equipped with a on-column injector and a flame ionization detector) with a Carbowax capillary column (SGE, length 50 m, internal diameter 0.32 mm, film thickness 0.5 μm). We used hydrogen as carrier gas at a pressure of 40 kPa. The oven temperature was programmed from 55°C to 230°C at 7°C/min and held at 230°C for 20 min.

The amounts of total esters (TE) were determined by the use of 10 standard curves obtained by injection of quantities of external standard esters ranging from 0.01 to 1 μg for each of the 10 esters quantified: methyl palmitate (MP), ethyl palmitate (EP), methyl stearate (MS), ethyl stearate (ES), methyl oleate (MO), ethyl oleate (EO), methyl linoleate (ML), ethyl linoleate (EL), methyl linolenate (MLN), and ethyl linolenate (ELN).

Compounds were identified according to their retention times and molecular fragmentation by GC-MS, and we compared the mass spectra of the compounds present in the extract with those of reference esters (Sigma). The GC apparatus was a Varian 3400 equipped with a split–splitless injector. We used the same column and temperature program. The MS was an Incos 50 (Finnigan). Analysis was performed with positive ionization, at a 0.015 torr pressure and the electromultiplier was set at 70 eV.

RESULTS

Rate of Development of Drone and Worker Larvae. Between 6 and 8 days of age, drone and worker larvae had the same rate of growth. The worker cells were capped between 8 and 9.25 days; half of the cells were capped at 8.5 days (mean capping age). The mean capping age for workers, observed during this

experiment, differed to some extent from that observed by us in the summer of 1990. Accordingly, we reduced by 12 hr the mean age of capping assigned to the 1990 worker larvae.

When capped, the worker larvae stopped growing and reached a mean weight of 161 mg. The growth of drone larvae continued after 8 days until the cells were capped, which occurred between 9.5 and 11 days of age; the mean capping age was 10.25 days. At this time, the drone larvae weighed 410 mg, 2.5 times heavier than workers. The mean ages of spinning larvae, prepupae, and white-eyed pupae were, respectively 11.5, 13, and 15 days for drones, and 9.5, 11, and 12.5 days for workers.

Amounts of Esters in Drone Larvae. At 7 and 8.5 days of age, total esters (TE) were present at 10 and 60 ng per drone larva, respectively (Figure 1). When the cell is capped (10.25 days), there are 1850 ng of TE per larva; thereafter, the amount of TE decreases until only 40 ng are present in the white-eyed pupae (15 days).

The esters attractive to *Varroa* (VE: MP, EP, and MLN) and those eliciting the capping of the worker cells (CEW: MP, MO, ML, and MLN) follow the same quantitative pattern (Figure 1), with a peak of 955 ng for VE and 845 ng for CEW (10.25 days).

Between 8.5 and 10.25 days, the secretion of the esters by drone brood does not have the same amplitude for each ester (Figure 2). The amounts of the methyl and ethyl esters of the palmitic and linolenic acids increase strongly, and the proportions of the total esters also increase. The amounts of the esters

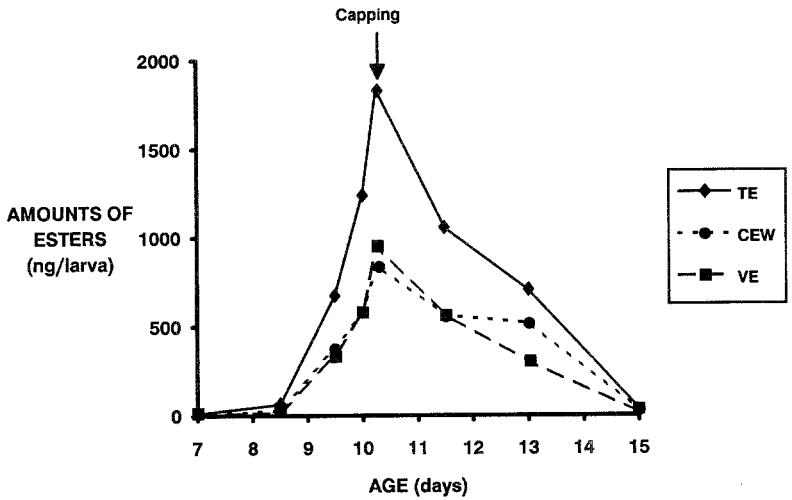

FIG. 1. Amounts of esters in drone brood of different ages. TE: total ester; CEW: esters eliciting the capping of worker cells, VE: esters attractive to the *Varroa* mite.

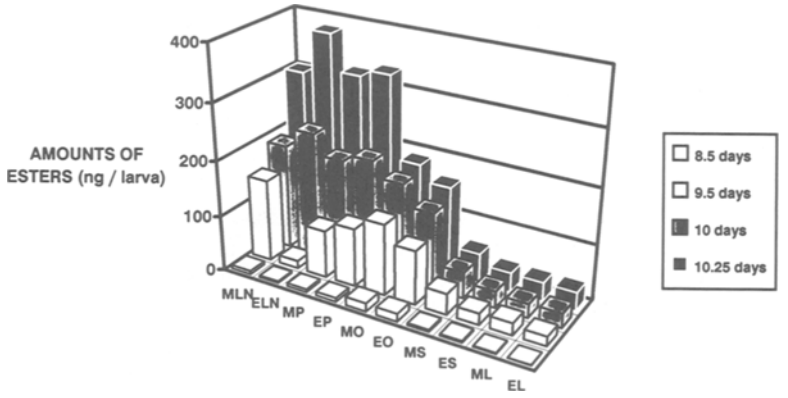

FIG. 2. Ester secretion in drone larvae 8.5 to 10.25 days of age during the capping period.

of oleic acid increase, but their relative amounts decrease; those of the stearic and linoleic acid esters show little increase.

To ensure that the ester secretion increase was not due simply to the increase of larval weight, we expressed the amounts of secretion per gram of larvae. The amounts per gram follow a similar pattern of change to that shown in Figure 1. Between 8.5 and 10.25 days, VE increased from 90 to 2600 ng/g of larva, and CEW from 140 to 2300 ng/g, an increase of 29 and 16 times, respectively.

Comparison between Drone and Worker Secretions. The quantification of esters in workers has been published (Trouiller et al., 1991), and the ages of the worker brood observed in the summer of 1990 have been modified to reflect the growth curve obtained in 1991.

The pheromonal signal of drone and worker broods has many similarities (Figure 3). As in worker brood, the ester secretion changes during the development of the insects. In both sexes, the amounts of esters reached their maximum just after the cells were capped and then decreased. On the other hand, the duration of the chemical signal is shorter in the worker brood; it began after 7.5 days of age and reached its maximum at 8.5 days, while in the drone brood the signal only appeared after 8.5 days of age and reached its maximum 40 hr later, at 10.25 days.

In both sexes, the amounts of esters were not directly proportional to the weight of the larvae. This is clear for 8.5-day-old larvae; in workers (151 mg larvae) there were 280 ng of CEW, while in drones (200 mg larvae) there were only 28 ng. The amounts of esters per gram of larvae reach a maximum value during capping. This signal is due to an intensified secretion of esters during the period before the capping.

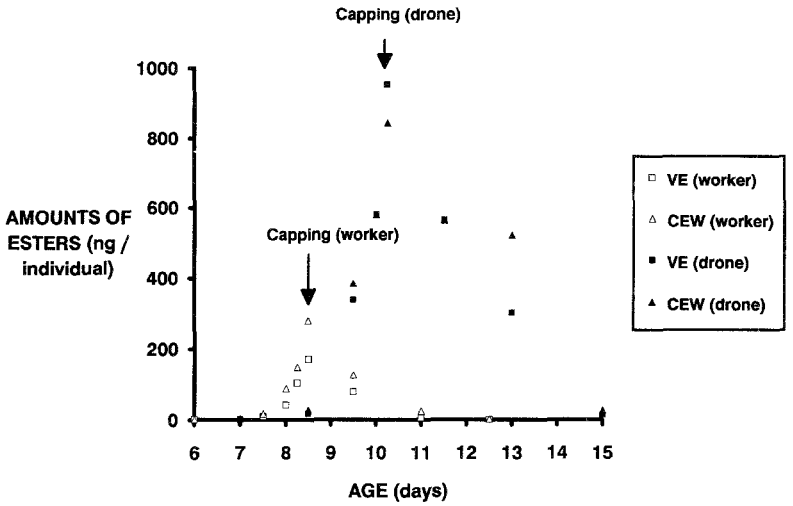

FIG. 3. Drone and worker secretion as a function of age. VE: esters attractive to the *Varroa* mite; CEW: esters eliciting the capping of worker cells.

The drone's pheromonal signal is more abundant than the worker's. During capping, there were 950 ng VE per drone larva while there were 170 ng in workers, 5.6 times more. At a maximum, there were 840 ng of brood pheromones per drone larva, whereas workers contained only one third as much (280 ng). Thus, the difference between the two sexes is much greater for the kairomones attractive to *Varroa*.

The day before capping, the increase in the secretion of esters was different between drone and worker larvae. In drones, the greatest increase of secretion was that of methyl and ethyl esters of palmitic and linolenic acids (MP, EP, MLN, and ELN, Figure 2). In the worker brood, the methyl esters were emphasized (MP, MS, MO, and MLN) (Trouiller et al., 1991).

During capping, the relative amounts of the esters are different between drone and worker broods (Figure 4). In drones, for each fatty acid, the methyl and ethyl esters were present in equal amounts, while there was about twice as much of the methyl esters than ethyl esters in workers. The most abundant compounds in drones were the esters of palmitic, linolenic, and oleic acids. In workers, MLN and MO were also major compounds, the corresponding ethyl esters being present in smaller amounts; MS was also a major ester, while in drones it was present in low amounts. Some major compounds, like EP, EO, and ELN in drones, and MS in workers, were inactive in eliciting capping behavior.

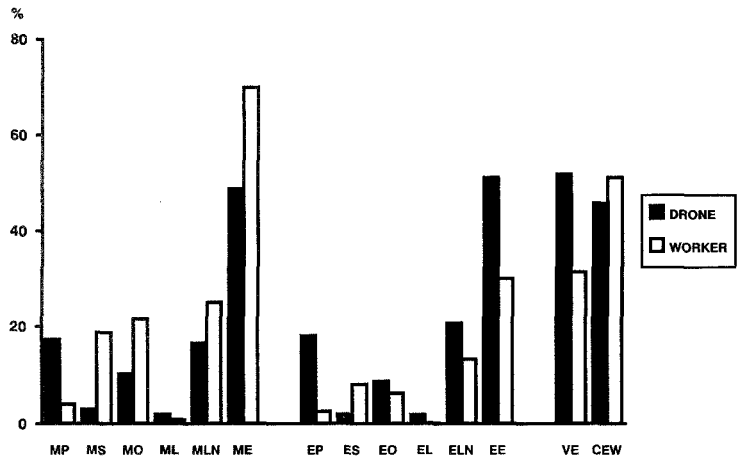

FIG. 4. Comparative percentage of esters in relation to total esters in worker and drone larvae at the end of capping: ME: methyl esters; EE: ethyl esters; VE: esters attractive to the *Varroa* mite; CEW: esters eliciting the capping of worker cells.

DISCUSSION

Kairomonal Secretion and Varroa jacobsoni *Infestation.* To reproduce, the female mites leave the adult bees and enter cells containing bee larvae. Several studies have shown that larvae, even when isolated from the colony, are attractive to *Varroa* females (Rosenkranz et al., 1984; Issa et al., 1986; Fuchs and Müller, 1988; Otten and Fuchs, 1988; Le Conte et al., 1989; Fuchs, 1990). It has been shown using a behavioral bioassay, that, in the experimental conditions used, the three kairomonal compounds completely mimic the attractive signal emitted by the larvae, because the esters are as attractive as living larvae (Le Conte, 1990).

In a colony, the mites invade only the cells that contain last-instar larvae, when these larvae occupy almost all the cell width (Grobov, 1977). After the *Varroa* has entered a cell, it becomes immersed in the brood food at the bottom of the cell and stays there until the food is totally eaten by the larva a few hours after capping. The invasion of the brood (L5) has two advantages for *Varroa*, it allows it to limit the immobilization period in the larval food and the size of the larva protects the acarian from adult bees, which cannot remove the mite at this stage.

The age-dependent attractiveness of the larvae has been analyzed with different bioassays. The young 5- to 6-day larvae (L3–L4 stages) and the white-eyed pupae are much less attractive than L5 larvae, both in the worker and drone broods (Rosenkranz et al., 1984; Fuchs and Müller, 1988; Le Conte,

1990). When comparing these observations with our data, it seems that a correlation exists between the amounts of kairomones present on the larvae and the attractiveness of the brood. The L5 worker and drone larvae, which are the most attractive towards *Varroa*, contain the greatest amounts of kairomones. However, the greater attraction of pupae to young larvae (Fuchs and Müller, 1988) is not correlated with the ester concentration, because the kairomones are present in the same amounts in the two stages. We can make the assumption that other chemical compounds could be present in pupae and could allow the acarians to be directed towards the bee pupa, after the invasion of the cell, to ensure its feeding.

The *Varroa* infestation rate of the brood has been studied inside the colony. Ifantidis (1988) observed that the infestation rate was a function of the larval weight; he showed that the invasion begins when worker larvae weight 100–125 mg and drone larvae 200–250 mg. According to our data, these larval weights correspond to the releasing of the kairomonal secretion at eight days in workers and at nine days in drones.

The time of the infestation has also been precisely determined relative to capping time. The infestation of the worker brood begins 20–27 hr before their cells are capped and 36–40 hr before in drones (Boot et al., 1990, Wieting and Ferenz, 1991). The beginning of brood infestation is correlated with the period at which the release of esters in larvae begins to increase strongly. The data concerning the entrance rate of the mite in relation to the age of the brood is variable (Boot et al., 1990; Wieting and Ferenz, 1991), and hence it is not possible to compare entrance rate with the amount of kairomones.

When both worker and drone broods are present, the drones are more infested than workers by the mite. In different races of *Apis mellifera*, the infestation rate of drone brood is five to nine times higher than in workers (Sulimanovic et al., 1982; Schulz, 1984; Issa et al., 1986; Fuchs, 1990). The drone preference is advantageous to *Varroa* because the rate of reproduction is greater in drone brood; this is related to the longer postcapping period (about 12 days in worker versus 15 days in drones), and higher fecundity (Schulz, 1984). Behavioral studies showed that L5 drone larvae were more attractive than worker L5 larvae (Rosenkranz et al., 1984; Issa et al., 1986; Otten and Fuchs, 1988; Le Conte, 1990). These observations are supported by our present data. During the capping, the amounts of attractive esters are 5.6 times higher in drone larvae. Moreover, the chemical signal, before the cell is capped, lasts longer in drone larvae (two days versus one day in workers) (Figure 3). The lesser attractiveness of worker brood could also be due to the fact that the most attractive compounds, MP and EP, are present in low amounts, whereas the less attractive MLN is the major kairomonal compound (Le Conte, 1990). In drone brood, MP and EP constitute the most abundant kairomones.

Compounds of low volatility, still unidentified, could also be active in the

recognition of the larva. It has been shown for another acarian bee parasite, *Acarapis woodi*, that cuticular hydrocarbons may be involved in host recognition (Phelan et al., 1991).

If chemical stimuli, according to the bioassays, seem to explain the recognition of the larva by *Varroa*, in the colony other factors could also play an important role in the location and choice of its host. Several experiments have demonstrated the importance of the different size and shape of the cells in the mite attraction (Message and Gonçalves, 1983; Camazine, 1986; De Ruijter, 1986).

According to our data, it seems that the kairomonal esters are used by *Varroa* to locate bee larvae of both sexes. The use of the temporal pheromonal secretion by *Varroa* seems to be a specific adaptation to the strategy of infestation by the mite, which allows it to choose an appropriate host and to invade it at the right time.

Brood Pheromone Secretion. To allow for normal development of the brood, the nurse bees perform behaviors adapted to the age, sex, and caste of the brood: nutrition (Townsend and Shuel, 1962; Haydak, 1970; Dietz, 1972; Rembold et al., 1974), capping behavior, sometimes removal of a part of the brood (Woyke, 1977; Free and Winder, 1983), and incubation behavior (Koeniger, 1978). Among the factors that elicit these behaviors, the chemical stimuli secreted by the brood should be important and allow for the recognition of the sex, age, and caste of the larvae. Free (1987) put forward the hypothesis that "a relatively involatile pheromone present on the body surface of brood is the primary brood recognition signal" and that, in addition, other pheromones like a capping pheromone could exist. The first bee brood pheromone, which elicits the incubation of the pupae, has been identified as the glyceryl-1,2-dioleate-3-palmitate (Koeniger and Veith, 1983). This pheromone is present in greater amounts in drone and queen larvae than in workers (Koeniger and Veith, 1984). This can be associated with the fact that, by using a bioassay, the larvae of the first two castes are preferentially incubated compared to worker larvae (Koeniger, 1978). However, no correlation between the ages of the larvae, the amounts of the pheromone, and the different incubation behaviors of the nurse bees has been demonstrated.

The wax cap that covers the cell that contains a drone larva is raised and domelike, whereas it is flat when the cell contains a worker larva. This aspect of the cap seems to be determined by the sex of the larva, because in dequeened colonies, when the laying workers deposit drone eggs in worker cells, the cap is domelike. The cells are also different between the two sexes, the diameter and the length of the drone cells are greater than those of worker cells. The caps are built by adult workers at each reproductive cycle, and are destroyed by the emerging adult bees, whereas the cells are used numerous times.

The recognition of the sex of the drone larva by the adult bees could be

mediated by a chemical factor. It seems, however, that the drone pheromonal signal is not the same as the worker signal (CEW), because when drone larvae are 9.5 days old, one day before the capping of the cell, the amounts of CEW are 1.5 times higher than the maximum pheromonal amounts that elicit capping of worker larvae cells. Qualitative and quantitative differences in the pheromonal signal composition could exist between the two sexes. The existence of the intensive secretion of esters before capping suggests that some of them could play a role in eliciting the capping of drone cells; for example three ethyl esters (EP, EO, and ELN) are inactive for the capping of the worker cells (Le Conte et al., 1990). Other semiochemicals than the 10 esters analyzed could be involved in the capping of the cells containing a drone larva.

The importance of mechanical stimuli is demonstrated by the fact that when pure esters are placed on the bottom of a cell, capping is not elicited (Le Conte and Trouiller, unpublished data). Both the presence of the mass of a lure and the chemical factor are necessary for eliciting capping behavior. Furthermore, the importance of both mechanical and chemical stimuli has been shown in the incubation behavior of the brood by adult bees (Koeniger, 1978; Koeniger and Veith, 1983). Mechanical stimuli linked to the larvae, such as the distance from the larva to the surface of the cell, could be of importance in eliciting the domed cap in drone cells (Buchner, 1953; Gontarski, 1954).

(Received February 24, 1992; accepted July 1, 1992)

Abstract—Since several species of predatory ants show some kind of repulsion towards the first-instar larvae (FIL) of *Diaprepes abbreviatus* L., the predatory behavior of *Solenopsis geminata* (F.), a common ant in the citrus groves in Guadeloupe, was studied. Different extracts of larvae were disposed on egg masses of *D. abbreviatus* and presented as prey to the ants, both in the field and in the laboratory. The ants are repelled by the FIL extracts. The allelochemicals involved are produced in large amounts, from 5 to 20 ng per larva. Physiochemical analyses have led to the identification of two sesquiterpenes of molecular weight 218 and 234, secreted in the respective proportions of 65 and 35%.

Key Words—*Diaprepes abbreviatus*, Coleoptera, Curculionidae, defensive secretion, *Solenopsis geminata*, Hymenoptera, Formicidae, sesquiterpenes, 5-methyl-8-isopropenyl-3, 4,4a,5,6,7,8,8a- octahydro-2-naphthalene carboxy aldehyde.

INTRODUCTION

Diaprepes abbreviatus, commonly known as the rootstalk borer weevil, is an important pest of citrus and sugarcane in the Caribbean basin. This species has a broad host range, including fruit, vegetables, and ornamentals (Martorell, 1945; Wolcott, 1948; Woodruff, 1968) but the main problem concerns citrus groves and nurseries, especially in Florida (Schroeder and Beavers, 1977), Puerto Rico (Woodruff, 1964), and the French West Indies (Mauléon and Mademba-Sy, 1988).

The adult weevils feed on the young foliage and deposit their eggs in masses between mature leaves, which are held together with an adhesive secretion. After hatching, first-instar larvae drop and burrow into the soil where they spend all their larval stages. Larvae feed on roots, causing severe damage. After pupation, the adults emerge from the soil.

Among the natural enemies, several species of predatory ants can play a role. Egg mass predation in the trees by *Monomorium floricola* Jerdon, *M. ebinium* Forel, *Pheidolle fallax* Forel, and *Ectatomma ruidum* Roger is reported (Buren and Whitcomb, 1977).

In Florida and Puerto Rico, ants are the dominant predators on first-instar larvae (Richman et al., 1983); the major ant species involved are *Tetramorium similum* Roger, *Pheidolle dentata* Mayr, and *P. floridana* Emery in Florida and *P. fallax* and *Tetramorium bicarinatum* (Nylander) in Puerto Rico. In a qualitative evaluation of ants as predators on *Diaprepes* species in the French West Indies, Jaffé et al. (1991) report predation of egg masses, larvae, and adults by several species of ants, but in most cases, ants showed some kind of repulsion towards the first-instar larvae. In the literature, there is no report of such a phenomenon. In this study, we tested this repellency, using first-instar larvae or egg masses treated with first-instar larvae extracts and presenting it as prey to a common ant of Guadeloupe: *Solenopsis geminata* (F.). This species is an important predator in citrus groves (Jaffé et al., 1991). The aim of the present work is to determine whether there is any chemical basis for repellency. Gas chromatography, mass spectrometry, nuclear magnetic resonance, and infrared spectrometry were used for the detection and identification of the chemicals involved.

METHODS AND MATERIAL

Insects. Fragments of ant colonies were collected in the field by digging up a nest and placing the soil containing large numbers of ants into boxes whose sides were coated with Fluon. The ants were separated from the soil by allowing water to slowly drip into the box and providing them with several wire bridges over which they could escape into a second Fluon-coated box containing the

nest. The nests consisted of plaster of Paris in standard Petri dishes, with a centrally positioned tube to permit the nest to be artificially moistened, and then covered with red plastic to simulate darkness. The ants were fed on larvae of the greater wax moth, *Galleria mellonella*.

The weevil species *Diaprepes abbreviatus* was collected in Guadeloupe and maintained in the laboratory at 26 ± 3°C, in large plastic cages. Adults were fed on young citrus foliage, and females oviposited readily between pieces of sulfurized paper stapled to a leaf, as well as between leaves. Egg masses were collected daily and placed in eclosion boxes. On hatching, the neonates drop through the gauze into a vial. They were collected daily, and some were placed in plastic vials with medium (supplied by Dr. W. J. Schroeder, USDA, Orlando, Florida) for rearing while others were utilized for extracts. The larvae used for extracts were kept in clean plastic vials with a piece of moistened paper towel to prevent dehydration and removed when required.

Preparation of Extracts. These were made by washing with hexane. For eggs, the number in a mass on sulfurized paper was counted and the paper cut to the smallest size possible. Larvae were counted and collected in a Pasteur pipet. Extracts were made from first-instar larvae up to 7 days old and also second instar larvae up to 30 days old. The eggs or larvae were placed in a Pasteur pipet that had a small plug of glass wool inserted. A volume of 500 μl was allowed to pass through the pipet and collected in a glass vial. After concentration under argon, extracts were stored at −18°C.

Field Bioassay. Before developing a laboratory bioassay, we simply observed the behavioral response of the ants near their nest on the soil of a citrus grove in Guadeloupe. Egg masses of *D. abbreviatus* were available to ants on the soil. Test and control stimuli consisted of 10 μl of first-instar larvae (FIL) extract at 1 L1 equivalent/μl (1 L1E/μl), 10 μl of second instar extract (1 L2E/μl), and 10 μl of hexane, respectively, applied to masses of approximately 10 eggs. Each stimulus was tested with 30 ants. The assays were conducted between 9:00 and 10:00 AM. When an ant came in contact with an egg mass, its behavior was recorded.

Laboratory Bioassay. A box containing the artificial nest of *S. geminata* was connected to a smaller box, containing the usual food of the ants, by three glass tubes (Figure 1). The stimulus (egg mass or larva) was placed in the central tube and when an ant entered this tube, the entrances were closed, using pieces of wrapped Parafilm as plugs. The ant was observed for a period of 5 min, and its behavioral response when it came in contact with the larva or egg mass noted. After 5 min, the plugs were removed and the ant was allowed to leave. This was repeated 20 times for each nest with the same test stimulus, and the glass tube and the stimulus were replaced each five replicates. An egg mass of 10 eggs or one larva was used for each test. For the tests that utilized extracts, 10 μl of a solution (concentration: 1 larva equivalent per microliter) were placed

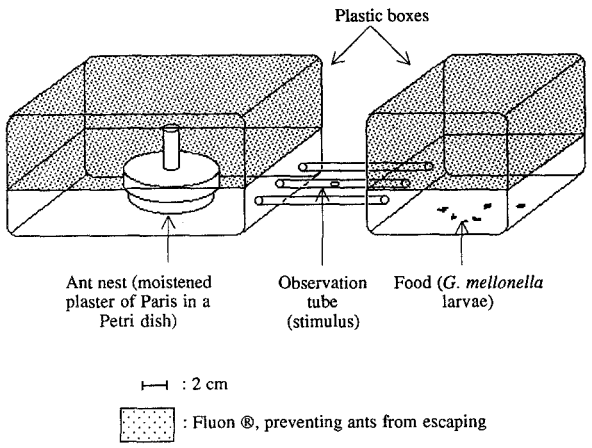

FIG. 1. Laboratory bioassay.

on the egg mass. Controls using 10 μl of pure hexane were also included. The following stimuli were tested: 5-day-old eggs, 5-day-old eggs treated with hexane, 5-day-old eggs treated with either a 0.5- or 5-day-old FIL extract and FIL of 0.5, 1, 2, 3, 4, and 5 days old. For statistical analysis, chi-square tests were carried out using the system STATITCF computer package for microcomputers.

Another laboratory bioassay was developed to test the activity of the two compounds (A1 and A2) isolated from the FIL extracts. One microliter of the tested solution was disposed on a piece of Bristol paper (1 × 1 cm), washed with a Soxhlet system. The exact place of the stimulus was delimited by a spot made with a pen. After a mechanical excitation of the ant nest, the piece of paper was placed on the Petri dish and the number of ants coming in contact with the source was recorded during 90 sec. The following stimulations were applied to four ant nests: compound A1 at 10, 100, 500 ng; compound A2 at 10, 100, 500 ng; a mixture of A1 (10 ng) and A2 (10 ng); and a mixture of A1 (100 ng) and A2 (100 ng) and a 12-hr-old FIL extract (10 L1E). The control consisted of 1 μl of *n*-hexane, and seven repetitions were made for each stimulus. For statistical analysis, the non-parametric U test of Mann and Whitney was used.

Chemical Analyses. Gas chromatography (GC) was performed with a HP 5890 Hewlett Packard chromatograph equipped with a Ross injector system fitted with a 25-m × 0.32-mm-ID CPSil8CB, WCOT; column temperature: 180°C (carrier gas: helium at 1 kg/cm^2). Gas chromatography–mass spectrometry (GC-MS) was carried out with a Nermag R-10-10C quadrupole mass spectrometer (electron impact at 70 eV) coupled with a Girdel 32 gas chromatograph equipped with a Ross injector. The system was fitted with a fused

silica capillary column (25 m WCOT CPSil5CB, 0.32 mm ID, Chrompack, Middleburg, The Netherlands). The column temperature was 200°C, using helium as carrier gas at 1 kg/cm^2. Chemical ionization–mass spectrometric data were obtained using ammonia as reactant gas at 92.5 eV.

To determine the number of unsaturations in the molecules, catalytic microhydrogenation was done, using PtO_2 in methanol.

Micropreparative capillary gas chromatography was performed on a Girdel 300 (Malosse, 1990) fitted with a wide-bore fused-silica capillary column (5 m WCOT HP-1, 0.53 mm ID, 160°C, Hewlett-Packard). The carrier gas was helium at 0.3 kg/cm^2. The split system was a Y glass tube (Chrompack) with capillaries giving a split ratio of 85:15. The different fractions were collected in 18-cm × 0.8-mm-ID glass capillaries and cooled with a mixture of acetone and Dry Ice.

Nuclear magnetic resonance (NMR) spectra were recorded with a Bruker 600 MHz spectrometer. Samples separated by micropreparative GC were rinsed from collection tubes with C_6D_6 (99.93% CEA, France). After analysis, the different fractions were used to test their activity on ants.

Gas chromatography-infrared (GC-FTIR) was carried out with a IFS-85 Bruker coupled to a HRGC 5160 Carlo Erba chromatograph (on-column injector) fitted with a fused-silica capillary column 30 m WCOT DB-5, 0.32 mm ID, heated from 30 to 170°C (10°C/min) and from 170 to 220°C (5°C/min), with helium as carrier gas. The light pipe was heated at 220°C.

RESULTS

Field Bioassay. Three kinds of behavior were observed when ants came in contact with the egg mass. First, predation of eggs: the ant stops, antennates the egg mass, and picks off an egg with its mandibles with a few seconds and carries it away. Secondly, repulsion: the ant avoids the egg mass or, after a short period of antennation (less than 2 sec), it quickly moves away from the egg mass, then stops and cleans its antennae with its forelegs. At last, indifferent behavior: the ant arrives close to the eggs but continues without stopping or antennating.

Table 1 shows that in most cases, ants refused the egg mass treated with FIL extract (1 L1E/egg). In contrast, when exposed to solvent control or to the 1 L2E/egg extract, ants always accepted eggs as prey after antennation. The proportion of indifferent behavior is less significant for the treated eggs. That means that a close contact is not necessary, indicating a relative volatility of the chemicals involved in this host–prey relationship.

Laboratory Bioassay. Figure 2 shows clearly the significant results of the tests. Eggs treated with FIL extracts (FIL of ages less than 12 hrs or 5 days)

TABLE 1. PREDATORY RESPONSE OF *Solenopsis geminata* TO LARVAL EXTRACTS OF *Diaprepes abbreviatus* DISPOSED ON EGG MASSES, AT PHYSIOLOGICAL DOSES

Treatment[a]	Acceptance of eggs	Indifferent behavior	Repulsion
Solvent (a)	15	13	2
L1 extract (b) (1 L1E/egg[b])	2	5	23
L2 extract (a) (1 L2E/egg)	14	15	1

[a] Treatments followed by the same letter do not differ significantly (χ^2 test, $P < 0.05$).
[b] One first-instar larva equivalent per egg.

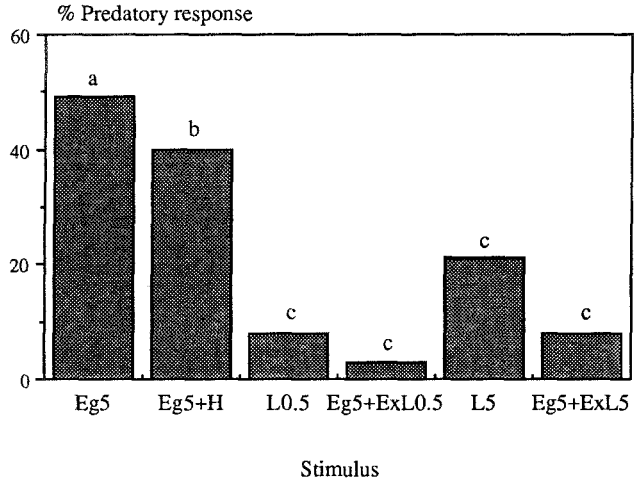

FIG. 2. Degree of predation by *Solenopsis geminata* upon *Diaprepes abbreviatus*. Results based upon the means of tests with 20 ants per nest, with three different nests per stimulus. Eg5: 5-day-old eggs; Eg5+H: 5-day-old eggs + hexane; L0.5: 0.5-day-old first-instar larvae; Eg5+ExL0.5: 5-day-old eggs + extract of larvae 0.5 days old; L5: first-instar larvae 5 days old; Eg5+ExL5: 5-day-old eggs + extract of larvae 5 days old. Histogram bars with the same letter are not significantly different (χ^2 test, $P < 0.05$).

are less preyed upon than untreated eggs or eggs with hexane. Similarly, 0.5-day-old and 5-day-old first-instar larvae are preyed upon less than eggs. This confirms that first-instar larvae produce a chemical repellent that is active immediately after hatching.

There is a significant difference between the responses of ants to 5-day-old eggs and 5-day-old eggs treated with hexane. Hexane appears to make eggs less attractive. In the majority of the tests, predation seems slightly less on eggs +

larval extracts than on larvae of the corresponding age. It is possible that hexane dissolves phagostimulant compounds present at the surface of the chorions.

Figure 3 shows the evolution of the predatory response with the age of the larvae used for the tests or for the extracts. In both cases, we can see that direct predation is low (less than 30%) at any age. Repulsion varied from 30% to 70%. Indifferent behavior decreases with the age of the larvae. It can tentatively be stated that predation increases with larval age, but there is no clear pattern for repulsive behavior.

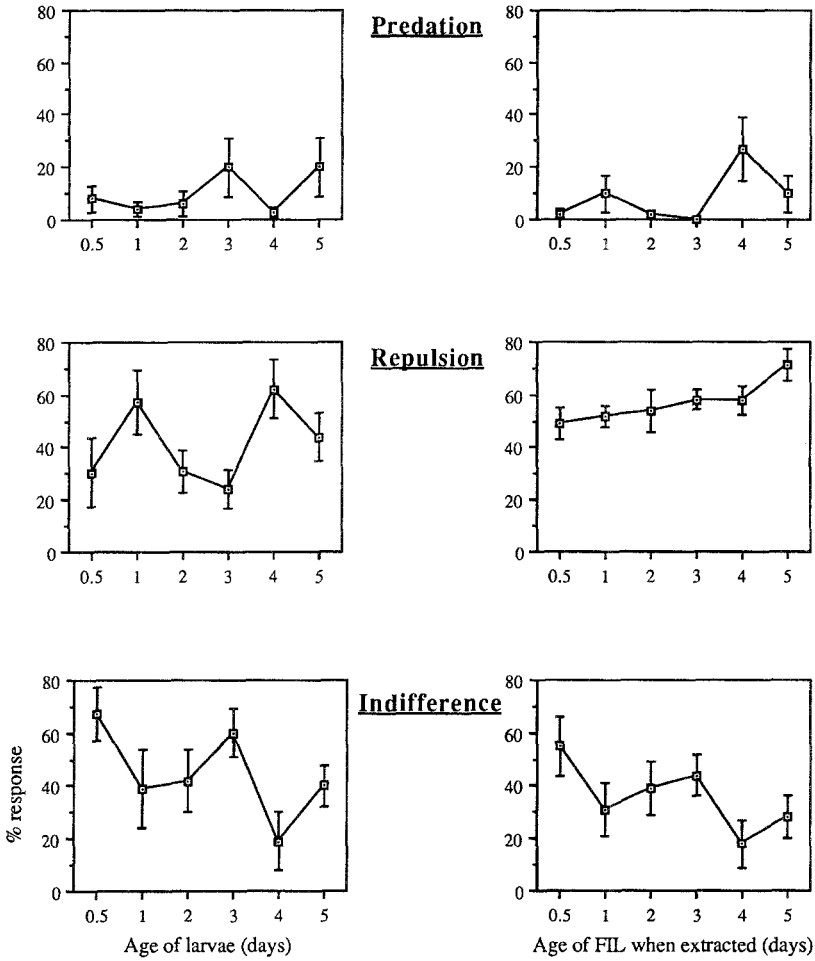

FIG. 3. Mean (±SEM) behavioral response of *S. geminata* towards *D. abbreviatus* first-instar larvae of different ages and egg masses treated with extracts of first instar larvae of different ages. An average of 170 ants were observed for each test.

The results with isolated compounds A1 and A2 are represented in Figure 4. A1 and A2 had no repellent activity at the dose of 10 ng. However, at 100 and 500 ng, their respective activities were significantly different from the control at the 5% level. The repellent activity of the whole extract was not different from the activities of each compound. The mixture of the two compounds was no more active than the compounds alone.

Chemical Analyses. Chromatograms of the *D. abbreviatus* first-instar larvae extracts showed the existence of two main peaks: A1 (65%) and A2 (35%) (Figure 5), which are nearly absent in the second-instar larvae and egg extract chromatograms. In addition to these specific compounds present in FIL extracts, hydrocarbons and saturated and unsaturated hexadecanoic acids were detected in all extracts.

According to the quantitative GC results, concentration of the repellent appears to decrease with the time, being at its highest in neonates and apparently absent from larvae after about four days (Figure 6). The results of the tests with *S. geminata* show some consistency with this result.

Micropreparative capillary GC led to the isolation of ca. 150 μg of compound A1 and 50 μg of compound A2 from 5000 first-instar larvae. The low resolution GC-EI-MS spectrum of A1 shows ions at *m/z* (% of relative abundance): 218 (M+, 38), 203 (29), 200 (5), 187 (52), 175 (21), 161 (13), 148

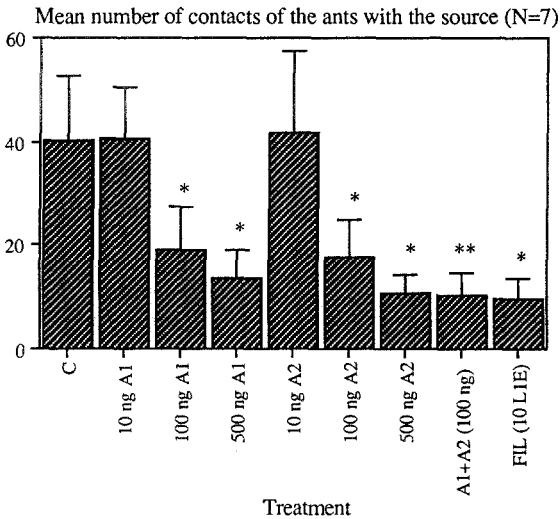

FIG. 4. Repellent activity of diaprepal A1 and A2 on *Solenopsis geminata*. C: control (1 μl of hexane); FIL (10 L1E): 1 μl of 12-hr-old FIL extract, corresponding to 10 FIL. Bars with asterisk are significantly different from the control, Mann and Whitney test (*$P < 0.05$, **$P < 0.01$).

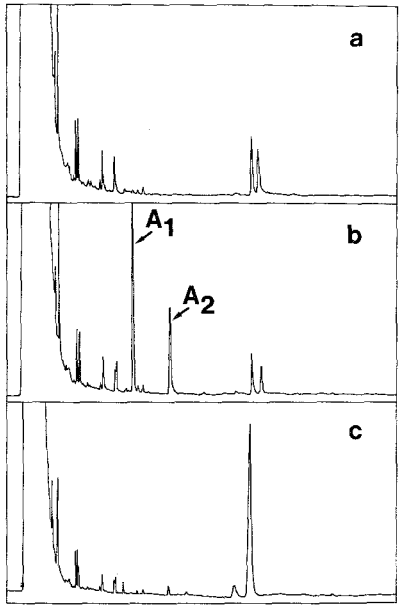

FIG. 5. Chromatograms of *Diaprepes abbreviatus* extracts: (a) egg extract; (b) first-instar larvae extract; (c) second-instar larvae extract. (HP 5890 chromatograph equipped with a Ross injector, system fitted with a 25-m × 0.32-mm-ID (CPSil8CB); column temperature: 180°C; carrier gas: helium at 1 kg/cm^2).

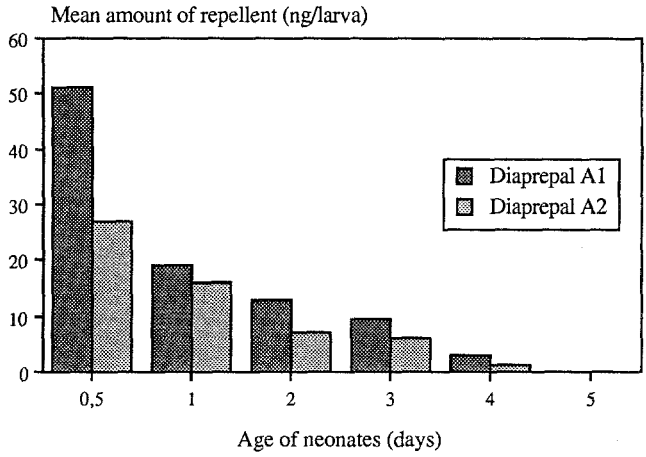

FIG. 6. Mean amounts of repellent extracted from *Diaprepes abbreviatus* first-instar larvae, at different ages.

(18), 147 (18), 133 (11), 119 (13), 107 (39), 91 (46), 79 (100), 67 (93), 55 (56), and 41 (73). GC (NH_4) CI-MS spectrum giving ions at *m/z* 236 ($(M+NH_4)+$, 31), 219 (MH+, 100), 201 ($(MH-H_2O)+$, 5), and 187 (4) confirmed the molecular formula as $C_{15}H_{22}O$ (HRMS calculated for $C_{15}H_{22}O$: 218,1658, found: 218,1658).

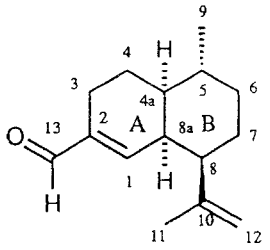
Catalytic microhydrogenation gave ions at *m/z* 222 (M+, 2), 204 (24), 191 (2), 179 (80), 161 (100), 119 (11), 109 (11), 105 (22), 95 (15), 81 (49), 69 (54), 55 (48), and 41 (56), indicating the occurrence of two unsaturations. The oxygen function was assigned to an aldehyde group regarding data from GC-FTIR showing absorption at 2800, 2708, 1705, and 1381 cm^{-1}. GC-EI-MS (loss of 43 amu) and GC-FTIR (absorption at 897 cm^{-1}) also confirmed the presence of an isoprenyl group. We proposed for the structure of compound A1, called diaprepal A1, a monounsaturated naphthane skeleton with three substituents: an aldehyde group, a methyl group, and an isoprenyl group. The final structure has been determined by ^1H NMR spectrometry (600 MHz). One-dimensional (1D) extensive decoupling and 2D COSY experiments led us to propose the structure represented on Figure 7.

Stereochemistry of the *cis* decalinic system is surmised from the observation of a small coupling constant between H-4a and H-8a (J = 3 Hz). Determination of the equatorial position on the B ring of the methyl and of the isoprenyl group is provided by measurements of characteristic *trans* diaxial coupling constants between H-5 and H-6α, H-5 and H-4a, and between H-7β and H-8. (9, 11, and 11.5 Hz, respectively). Proton H-8a is in an equatorial position in ring B, according to the coupling constant between H-8 and H-8a (J = 2 Hz). Location of the double bond (α to the ring junction) is obtained by observation of two ^5J coupling constants characteristic of the cyclohexene ring between H-8a and both H-3 (J = 6 and 3 Hz), the latter being in an allylic position according to their geminal coupling constant (J = 21 Hz) and coupled with both H-4. No coupling constant is detected between H-8a and H-1 owing to a dihedral angle of 90° between the two bonds H-8a—C-8a and H-1—C-1 (Figure 8a).

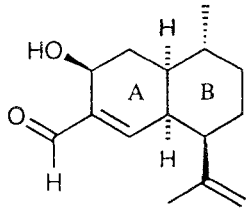
^1H chemical shifts (δ ppm): 1.12 (m, H-5); 1.2 (m, H-6α); 1.68 (m, H-6β); 1.69 (m, H-7β); 1.00 (bt, H-7α); 1.27 (dt, H-4a); 2.07 (bd, H-8); 2.65 (bs, H-8a); 2.22 (tm, H-3α); 2.57 (bdd, H-3β); 2.00 (dm, H-4α); 1.4 (tdd, H-4β); 6.55 (bs, H-1); 5.22 (s), 4.95 (s) (2H, H-12); 9.55 (s, H-13); 0.95 (d, 3H, H-9); 1.85 (bs, 3H, H-11).

Coupling constants were: $J_{4a,5}$ = 11 Hz; $J_{5,6\alpha}$ = 9 Hz; $J_{6\alpha,6\beta}$ = 10.5 Hz; $J_{6\alpha,7\beta}$ = 10 Hz; $J_{7\alpha,7\beta}$ = 12 Hz; $J_{7\beta,8}$ = 11.5 Hz; $J_{8,8a}$ = 2Hz; $J_{8a,3\alpha}$ = 3Hz; $J_{8a,3\beta}$ = 6 Hz; $J_{3\alpha,3\beta}$ = 21 Hz; $J_{3\alpha,4\beta}$ = 11 Hz; $J_{3\beta,4\beta}$ = 6 Hz; $J_{4a,4\beta}$ = 2 Hz; $J_{4a,4\alpha}$ = 3Hz; $J_{4\alpha,4\beta}$ = 15 Hz.

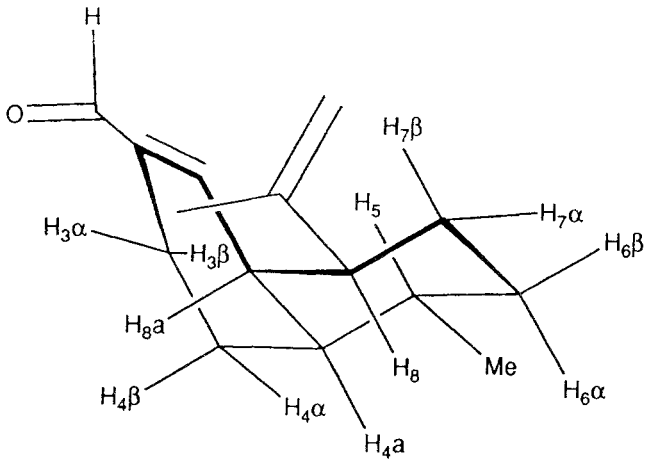
The GC-EI-MS spectrum of the minor compound (A2) gives ions at *m/z* 234 (M+. 14), 219 (3), 216 (55), 205 (14), 201 (25), 191 (14), 187 (43), 173 (27), 159 (25), 146 (38), 131 (26), 119 (14), 107 (39), 91 (62), 79 (87), 68



Diaprepal A_1



Diaprepal A_2



*

FIG. 7. Diaprepal A1 and A2 from first instar-larvae of *Diaprepes abbreviatus* (*spatial representation of A1).

(90), 67 (100), 55 (88), 41 (84), and GC (NH_4) CI-MS, ions at *m/z* 252 [(M+NH_4+), 27], 235 (MH+, 27), 234 (M+, 46), 217 [(MH−H_2O)+, 100], 199{[(MH−H_2O)−H_2O]+,4} and 187 (4).

In agreement with these data, compound A2 has $C_{15}H_{22}O_2$ as its molecular formula. The second oxygen function was assigned as a hydroxy group. The GC-FTIR spectrum exhibiting absorptions at 3595 cm^{-1} and 1026 cm^{-1}. Lowering of absorption at 3595 cm^{-1} and also at 1695 cm^{-1} (compared to 1705 cm^{-1} for compound A1) indicates an intramolecular hydrogen bond between the hydroxy and the carbonyl group.

Close spectral NMR data of A1 and A2 led us to propose for compound A2 the same structure as diaprepal A1 with an additional hydroxy group at C-3 as represented in Figure 7. Owing to the fact that H-8a is in an equatorial position in the B ring and that H-3 on the carbon bearing the hydroxy group H-bonded to the aldehyde function has a coupling constant with only one proton H-4, the β position of the hydroxy group seems to be the more suitable (Figure 8b).

^{1}H chemical shifts (400 MHz, C_6D_6) δ (ppm) were as follows: 9.15 (s, H-13); 6.37 (s, H-1); 5.03 (s), 4.76 (s) (H-12); 4.48 (d, H-3); 2.3 (dd, H-4β); 2.27 (m, H-8a); 1.61 (s, H-11); 1.12 (s, H-9); and 0.82–2.1 (m, 8H, H-6, H-7, H-5, H-4α, H-4β).

Coupling constants were: $J_{3,4\alpha}$ = 5.8 Hz; $J_{4\alpha,4\beta}$ = 11 Hz; $J_{4\beta,4a}$ = 3 Hz.

DISCUSSION

In this study, we report for the first time the presence of a defensive secretion produced by a curculionid larva: the first-instar larvae of a citrus root weevil, *Diaprepes abbreviatus*, produce semiochemicals that have a repellent effect upon an important predator in citrus groves, *Solenopsis geminata*. The repellency reduces predation by about 40%. These allomonal compounds are not detected

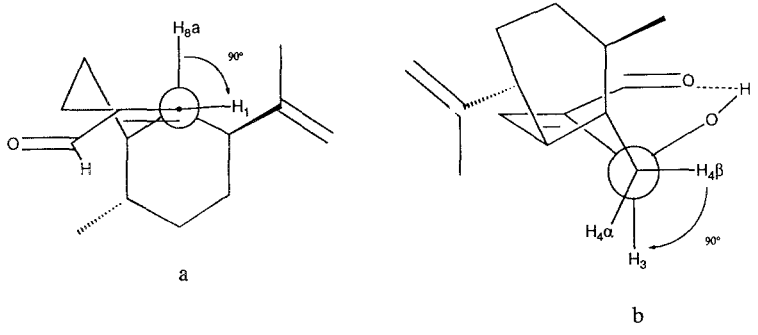


FIG. 8. Spatial representation of diaprepal A1 (a) and A2 (b).

in the second instars, nor in the egg masses. In the citrus trees, egg masses are stuck between two leaves, and they are not easily preyed upon by ants. When they drop on the soil, the neonates are very vulnerable, and their secretions allow them to be protected against their main predators.

For *D. abbreviatus*, the secretion has been identified as a mixture of two bicyclic sesquiterpenes aldehydes, in the proportion 65% and 35%. They have not been identified previously and we call them diaprepal A1 and A2. Sesquiterpenes are very frequent in plants and insects, and they can have different functions, such as alarm pheromones in aphids (Blum, 1969) or sex pheromones in Pentatomidae (Baker et al., 1987). Moreover, caryophyllene and caryophyllene epoxyde (terpenoids produced by neotropical plants) are known to be deterrent to leafcutter ants (Howard et al., 1989). Tricyclic sesquiterpenes (zizanal and epizizanal) (Jain et al., 1982) and sesquiterpene aldehydes (cadinenal, dehydroxycadinenal) (Plavkan, 1985, in Davidson et al., 1990), present in the essential oil of *Vetiveria zizanoides*, have potent topical irritant activity on cockroaches and flies.

It would be interesting to extend the investigation by testing for the same or related repellents in other *Diaprepes* species or in other curculionids. The repellent appears to be effective against the predator as long as necessary under natural conditions, because, as already mentioned, the neonates generally remain on the soil surface and are subject to predation by ant species for less than 3 hr. In these species, all living stages are relatively protected against predators, except the young emerging adults on which natural regulation by predatory ants seem to be more effective than on neonates.

Acknowledgments—We wish to thank P.H. Lambert (Institut de Recherches Servier) for HR-EI-MS analyses and J.L. Lequéré and E. Sémon (Institut National de la Recherche Agronomique, Laboratoire des Arômes) for GC-FTIR measurements.

BEHAVIORAL RESPONSES TO OWN AND OTHER SPECIES' SCENT MARKS IN *Lemur fulvus* AND *Lemur macaco*

ISABELLE FORNASIERI and JEAN-JACQUES ROEDER*

Laboratoire de Psychophysiologie

(Received April 2, 1992; accepted July 3, 1992)

Abstract—Behavioral responses (duration and frequencies of sniffing, scent-marking activity) were studied in one captive group each of *L. fulvus* and *L. macaco* when confronted with their own and other species' scent marks. Both species showed less interest in neutral objects or objects carrying their own group's odor than odors from an unfamiliar group of the same species or from another lemur species. The persistence of scent marks was also investigated. *L. fulvus* scent appeared to possess greater longevity than *L. macaco* scent. Olfactory long-term memory was analyzed in *L. fulvus*. The results showed that familiar rejected group members could be discriminated from an unfamiliar conspecific through odor cues 10 months after their eviction from the group.

Key Words—Olfactory discrimination, scent marking, Primates, *Lemur fulvus*, *Lemur macaco*, olfactory memory, persistence of marks.

INTRODUCTION

Lemurs are particularly important for the understanding of the evolution of communicatory systems in primates and more generally in mammals. They have conserved a number of primitive behavioral characteristics, one of which is their ability to communicate through olfactory cues, especially scent marks (Jolly, 1966; Tattersall, 1982). *Lemur macaco* and *Lemur fulvus* live in multimale, multifemale groups (number of individuals per group: 6–18; Petter et al., 1977;

*To whom correspondence should be addressed.

0098-0331/92/1100-2069$06.50/0 © 1992 Plenum Publishing Corporation

Tattersall, 1977). They have well developed visual and acoustic systems for communicating, but scent marking has retained an important role: in both species, adult individuals of both sexes perform anogenital marking, allomarking being only performed by males.

Surprisingly, only a few studies have addressed the information content of scent marks in *Lemur* species (Schilling, 1979). In *L. fulvus*, it has been shown that adults can discriminate individuals by scents (Harrington, 1976) and that males can discriminate males' scent marks from those of females (Harrington, 1974, 1977). However, the same studies failed to show evidence of subspecific discrimination or of male discrimination of estrous vs. anestrous females by scent only. To our knowledge, no such studies have been carried out in *Lemur macaco*. In *Lemur fulvus*, the studies were done using individual odors. In both species, several adult individuals often deposit their secretions on the same places in the environment. It seems likely therefore that under natural conditions, the animals are confronted with a mixture of individual scent marks.

In a long-term correlational study in these two species we did not find a significant change in scent-marking frequencies during the breeding season, or a direct relation between scent marking and emitted aggression (Fornasieri and Roeder, 1993). The results suggested that qualitative rather than quantitative changes in scent might play a role in social and reproductive processes, by transmitting information about the emitter. In order to test this hypothesis, we assessed the informative content of scent marks by recording behavioral responses towards various scent marks. The specific aims of this comparative study were to investigate discrimination between conspecific and heterospecific group odors in *L. macaco* and in *L. fulvus*, to study the persistence of scent marks in the two species, and to investigate the possibility of olfactory long-term memory in *L. fulvus*.

METHODS AND MATERIALS

The subjects were two groups of *L. macaco macaco* and *L. fulvus mayottensis* formed from unrelated wild-born adults and their offspring born in captivity. The *L. macaco* group contained one adult male (Q), two adult females (P, R), and their offspring (three males: pe, ro, and ram, which were 24, 18 and 7 months old, respectively, at the start of the experiments). The *L. fulvus* group contained two adult males (B, M), five adult females (H, R, V, P, F), one young male (fo), and one young female (he), 12 and 24 months old, respectively. The animals were individually identified using differences in coat color and condition and by distinctive features such as tail shape or facial scars. Each group was housed at the Centre de Primatologie de l'Université Louis Pasteur (Strasbourg, France) in a spacious indoor–outdoor cage (indoors: 4.90 × 2.10

× 2.60 m, outdoors: 3.00 × 2.90 × 2.60 m) furnished with three trunks providing aerial walkways, and two wooden boxes attached to the walls of the indoor area for use as resting sites. Food (commercial primate pellets) and water were available ad libitum, and fresh fruits and vegetables were provided twice per week.

During the study, two *L. fulvus* females (P, F) were removed from the group following persistent serious targeting aggression (see Vick and Pereira, 1980); they were housed temporarily in individual cages under the same conditions. Another captive group of each species, housed under similar conditions at the Laboratoire d'Embryologie de la Faculté de Médecine de Strasbourg was used as a scent donor. The *L. macaco macaco* donor group consisted of one adult male and two adult females, and the *L. fulvus mayottensis* donor group contained one adult male and one adult female. A conspecific was considered "unfamiliar" for the receiver group if it had never had any direct olfactory contact with the group before the experiment.

Experiment 1: Conspecific and Heterospecific Discrimination. In both groups, the reaction of each individual to conspecific and heterospecific scent marks was observed. Olfactory stimuli were collected on plastic boxes (10 × 10 × 10 cm) placed in the donors' cage 8–15 days before the test session. Concurrent observations were done to confirm that the donors scent marked the boxes. A mark mainly consisted of secretion of the anogenital area (skin glands), but urine and feces could also come in contact with the boxes. After removal from the donor's cage, the latency until scent marks were presented to the subjects never exceeded eight days. In each group, daily sessions were given on 20 successive days. During each session, each group was presented successively with four types of olfactory stimuli in random order: control unscented boxes, familiar conspecific scent (the group's own scent), unfamiliar conspecific scent (the scent of an unfamiliar conspecific group) and heterospecific scent (*L. macaco* scent for *L. fulvus* and vice versa). Two successive presentations during the same session were separated by a 5-min interval. During each test, the box was placed on the cage floor for a 15-min period, previous observations having shown that the animals were no longer interested after this period. Between each session, new boxes were used or previously used boxes were cleaned with alcohol and always served for collecting the same odors. All sessions occurred outside the females' estrous period.

For each individual, the frequency and duration of sniffing the box and frequency of marking on the box were recorded. The occurrence of scent marking elsewhere in the cage was also noted. The durations of sniffing and marking frequencies in the different conditions were compared using a Mann-Whitney U test. Sniffing duration and frequency were always strongly positively correlated, therefore analysis only used the duration measure.

In the *L. fulvus* group, the two subordinate females, P and F, were not

included in the analysis due to their infrequent response to the stimulus boxes, which did not allow statistical analysis. Similarly, young individuals were included in statistical analysis only when their response rates were sufficiently high, as they generally showed reduced interest towards the stimulus boxes compared to adults. During the overall experiment period, some juvenile individuals began to perform scent marking and therefore are or are not represented on the figures.

Experiment 2: Persistence of Scent Marks. The persistence of scent marks was investigated by recording the discriminatory responses to scent marks of differing ages. Each individual's responses towards an unfamiliar group's scent marks were compared to those directed towards the group's own scent marks of the same age. Scent marks were collected according to the usual procedure (boxes staying eight days in the donors' cage) and were stored in contact with air until the test. A series of 10 trials was conducted for each age. A trial consisted of the simultaneous presentation of the two stimuli (own group marks/ unfamiliar group marks). The same behavioral measures as above were recorded. In the *L. fulvus* group, a single series of tests was conducted using 3-month-old scent marks. In the *L. macaco* group, three series were conducted using 3-month, 5-week, and 15-day-old marks, respectively. All the series were done outside the breeding season. For statistical analyses we used the Wilcoxon *T* test.

Experiment 3: Olfactory Long-Term Memory. In this experiment, the possibility of olfactory memorization of familiar rejected groups members' scent marks was investigated in *L. fulvus*. Two females (P, F), which had been members of the group since its formation (four years earlier), were removed from it due to persistent and violent targeting aggression and served as scent donors. Two different females were used as donors for unfamiliar scent marks. All the donor females were isolated and housed under the same conditions, receiving the same diet. Scent marks were collected on plastic boxes introduced in the donors' cage several days before the test and removed just before the beginning of a test. Discrimination between fresh scent marks of one of the previously rejected females and scent marks from an unknown female was tested in the group. Four series of 20 tests were conducted with the scent from each of the rejected females. Each test consisted of the simultaneous presentation of the two stimuli (familiar vs. unfamiliar). These four series were carried out during three testing periods: 1–6 months, 8–10 months and 10–12 months from the date of the donors' removal from her group. The measures recorded were the same as in the preceding experiments. The second testing period was the only one during which females were receptive. No test was conducted on days when copulation was observed. Statistical analysis used the Wilcoxon *T* test.

RESULTS

Experiment 1. In both species, sniffing durations were significantly higher when investigating scents from unfamiliar conspecifics and from a heterospecific group than when investigating the control stimulus (Figure 1a and 2a). The only

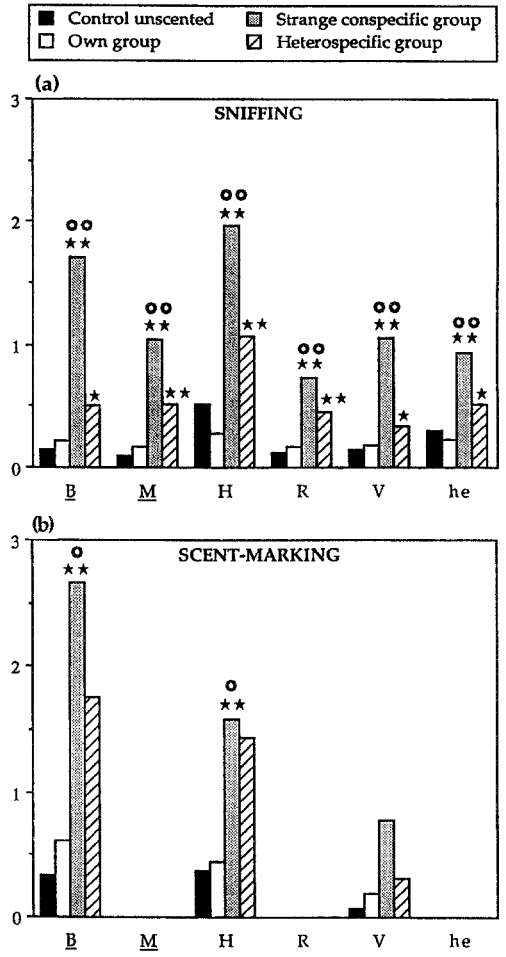

FIG. 1. Olfactory discrimination by *L. fulvus* individuals of various stimuli of conspecific and heterospecific origin: (a) mean sniffing duration (in minutes) and (b) mean scent-marking frequency (Mann-Whitney U test: comparisons with control ★:$P < 0.05$, ★★: $P < 0.01$, comparison familiar conspecific/strange conspecific: ✪: $P < 0.05$, ✪✪: $P < 0.01$). Male subjects are underlined.

exception was the male *L. macaco* (Q), who did not show more interest towards heterospecific scent marks compared to the control. In all cases, the duration of sniffing the group's own odor was not statistically different from that sniffing the control. Both species showed significantly more interest in unfamiliar conspecific group odors than in their own group odors. The comparison between unfamiliar conspecific and heterospecific scent marks showed that in *L. fulvus*, three individuals were significantly more interested in the former (Mann-Whit-

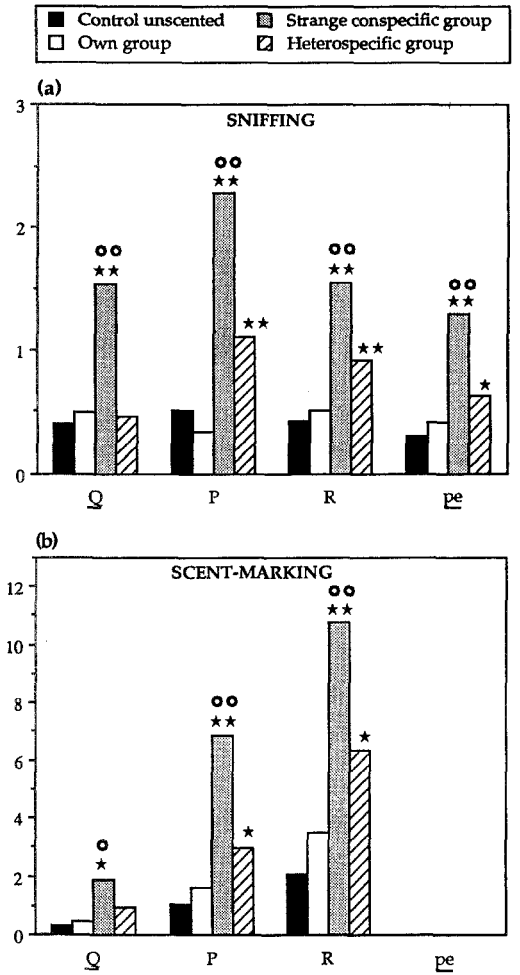

FIG. 2. Olfactory discrimination by *L. macaco* individuals of various stimuli of conspecific and heterospecific origin: (a) mean sniffing duration (in minutes) and (b) mean scent-marking frequency (Mann-Whitney U test: comparisons with control ★:$P < 0.05$, ★★: $P < 0.01$, comparison familiar conspecific/strange conspecific: ⭘: $P < 0.05$, ⭘⭘: $P < 0.01$). Male subjects are underlined.

ney B: n1 = 18, n2 = 17, U = 38; H: n1 = 19, n2 = 18, U = 74.5; V: n1 = 18, n2 = 13, U = 35; $P < 0.01$ in all cases). In *L. macaco*, this difference was statistically significant for all adult individuals (P: n1 = 17, n2 = 20, U = 65, $P < 0.01$; Q: n1 = 16, n2 = 17, U = 21, $P < 0.01$; R: n1 = 19, n2 = 17, U = 88, $P < 0.05$).

Marking responses were less clear, with important individual differences (Figures 1b and 2b). Two of the five adult *L. fulvus*, one male (M) and one female (R), never marked the boxes during the tests (the juvenile female did not yet perform anogenital marking at this test period). When scent marking did occur, it paralleled the sniffing response. Thus, the boxes most frequently marked were, in decreasing order, the unfamiliar conspecific stimulus then the heterospecific stimulus with no difference between the group's odor condition and the control. Three *L. fulvus* performed more scent marking on the box scented by unfamiliar conspecifics compared to all other conditions. This difference was statistically significant for two of them compared to control and to their own group's odor (Figure 1b). The difference was not statistically significant when comparing scent marking with unfamiliar conspecifics and heterospecific scents (B: n1 = 18, n2 = 16, U = 103; H: n1 = 19, n2 = 18, U = 152; V: n1 = 18, n2 = 13, U = 88; ns in all cases).

All *L. macaco* adults performed scent marking on the boxes. In this group, marking responses also paralleled sniffing responses (Figure 2b). A comparison between unfamiliar conspecific and heterospecific scents revealed a significant difference in only one female (R: n1 = 19, n2 = 17, U = 88, $P < 0.05$). No change in marking activity in the cage was observed in either species during the tests compared to their scent marking rates determined from regular observations done outside the test periods.

Experiment 2. In the *L. fulvus* group, the 3-month-old scent of the unfamiliar conspecific group still elicited more sniffing and marking than the group's own scent, although responses were weaker than with fresh marks. The difference in sniffing responses towards the two stimuli was statistically significant for each adult subject (Figure 3a,b). Scent marking responses gave a less clear picture, a significant difference emerging only in one individual (female H, Figure 3b).

In the *L. macaco* group, sniffing duration in response to the group's own 3-month-old scent marks did not differ from that obtained with unfamiliar conspecific scent marks. Five-week-old scent marks elicited no olfactory discrimination, sniffing responses appearing inconsistent (Figure 4c). Finally, only the third test series using 15-day-old scent marks resulted in significant discriminatory responses by some individuals: in three animals (Q, P, R), the unfamiliar group's scent marks were sniffed for significantly longer than the group's own marks; one individual (a juvenile male) showed more interest towards his group's scent marks than towards those of the unfamiliar group (Figure 4b). Such differences were not apparent when considering the mean marking frequencies.

Experiment 3. Surprisingly, the most important sniffing response was elicited by the familiar female's scent marks. During the first test period, all individual responses showed the same tendency. The difference for the whole group was statistically significant and persisted over the second period (Table 1). After

one year, the difference in sniffing duration between the familiar and unfamiliar stimulus was no longer statistically significant for the group.

In general, the time course of marking responses paralleled that of sniffing responses: the familiar stimulus was scent marked significantly more frequently than the control stimulus up to a period of 10 months (first and second test period), but not after this time (due to low response rates, the juvenile male was dropped from the statistical analysis) (Table 2). Marking responses showed large individual variations. In particular, two adult females scent marked frequently during some test series but did not scent mark at all during others (at 6 and 10 months), although they sniffed the boxes. This temporary absence of scent marking extended to the entire cage environment. One adult male showed consistently low scent-marking rates on the boxes and at other marking sites, in parallel with a generally low response level. The juvenile male (fo) showed particularly variable sniffing and marking responses during these tests: he did not contact the boxes in more than 50% of tests, and what responses he did show were weaker than in adults. No significant differences were found for fo.

DISCUSSION

In both species, several individuals deposited their scent marks at the same location. Therefore, a receiver must analyze not only an individual mark but a mixture of different individual odoriferous substances.

Our results clearly demonstrate the possibility of conspecific and heterospecific discrimination based on odor cues in *L macaco* and *L. fulvus*. All

individuals in the two groups were able to differentiate not only between the scent of the other species but also that of an unfamiliar group of their own species, and their own group's odor. Over marking does not appear to have any effect on the behavioral response of the observed subjects as animals do not react differently to control objects and objects carrying their own group's odors. These results suggest that both species can recognize scent marks as being those of their own group, as the animals responded less to these than to marks of any other origin. It seems likely that in *L. macaco*, as demonstrated in *L. fulvus* and *L. catta* (Mertl, 1975; Harrington, 1976, 1977; Dugmore et al., 1984), other individual scent marks (e.g., a familiar vs. an unfamiliar conspecific) could be discriminated. Such studies remain to be conducted. Similar discriminatory abilities have been demonstrated in several other primate species (Epple, 1985; Epple and Smith, 1985), suggesting that the information content of scent marks or urine does not differ greatly between lemurs and other species.

In the present experiments, discrimination might have been related to differences in quantities of scent produced by the different groups. However, under natural conditions animals are not confronted with neatly quantified samples of scent. Instead, they must obtain specific information from a mixture of scents. It would be interesting to investigate whether species that are largely dependent on olfactory cues are able to discriminate one particular scent mark combined with others.

The low sniffing and marking rates observed towards control objects and a group's own scent marks suggest that scent marks may have a role in familiarizing the animals with their physical environment (Eisenberg and Kleiman, 1972). This interpretation is reinforced by the finding that striking increases in scent marking occur in unfamiliar environments (Fornasieri and Roeder, 1993). However, the function of scent marking in the maintenance of intra- and intergroup social relationships has not been well studied in the species used here. How such discriminatory abilities act under natural conditions to maintain intergroup spatial distribution and perhaps prevent hybridization remains to be studied.

Our results showed differences between *L. fulvus* and *L. macaco* in the persistence of scent marks. In *L. fulvus*, olfactory discrimination of 3-month-old unfamiliar conspecific vs. familiar scent marks occurred. In *L. macaco*, discrimination persisted until only 15 days after the collection of scent marks. The diminished olfactory response in *L. macaco* may be related to the lesser development of the anogenital glandular field (Rumpler and Oddou, 1970) and less frequent anogenital marking compared to *L. fulvus* (Koenders, 1990). Personal observations over a two-year period have also shown that the mean marking rate in *L. macaco* is low compared to that of *L. fulvus* except over some restricted and occasional periods (Fornasieri and Roeder, 1992). Our results are

in accordance with Koender's hypothesis (1990) that *L. macaco* should show a greater tendency towards the development of visual communication at the expense of olfactory cues than *L. fulvus*. The scent mark stimuli were stored indoors. It is not known whether persistence would be the same for scent marks deposited in the natural environment and therefore exposed to climatic conditions. However, the biological significance of such differences in scent mark persistence in free-living populations remains to be investigated.

In contrast to the results of the above-described experiments, the animals showed more interest towards the marks of previously known conspecifics than towards totally unknown conspecifics. They discriminated the scent marks of a rejected group member from those of an unfamiliar conspecific up to 10 months after the stimulus animal's removal from the group. Our results do not demonstrate that this discriminative ability was lost after this time, but the recorded behavioral responses no longer made this ability apparent. In comparison, similar studies have shown that such "long-term memory" lasts eight days in some rodents (Cheal et al., 1982) and 17 weeks in some carnivores (Roeder, 1983). Our results also argue for the possibility of individual recognition in *L. fulvus* through olfactory cues and that such cues may play an important role in the maintenance of their social organization, which appears to be characterized by frequent migration from one social group to another (Tattersall, 1977).

In general, scent marking responses were less consistent than sniffing responses, and showed larger intra- and interindividual variability. Some individual differences were related to social status. For example, the consistently low-marking adult male *L. fulvus* was subordinate to the other adult male and showed relatively low scent-marking rates at all times (Fornasieri and Roeder, 1993). Although the females usually showed quite high marking rates, the absence of marking responses during some experimental sessions occurred in parallel with a virtual absence of scent marking during the regular behavioral observations at the same time.

In olfaction-dependent species, the informative content of scent marks is traditionally assessed through discrimination tests. It is another problem to know how the animals use the information transmitted by olfactory cues. Are they able to discriminate one particular scent mixed with several others? Do they memorize (and if so, for how long) individual scent marks belonging to conspecifics with which they have had previous social experience? Responding to such questions will increase our understanding of the animals' olfactory language.

Acknowledgments—This study was carried out at the Centre de Primatologie of Université Louis Pasteur (Strasbourg). We are very grateful to Dr. J.R. Anderson for valuable comments and for correcting the English.

(Received January 9, 1992; accepted July 6, 1992).

Abstract—Ergosta-5,7,24(28)-trien-3β-ol (trienol) **6** was isolated from the intracellular symbiotes (symbiotic microorganisms) of the planthoppers, *Nilaparvata lugens* and *Laodelphax striatellus*. The steroidogenic end product of the symbiotes was found to depend on the environmental conditions, i.e., although trienol **6** was produced under symbiotic conditions, ergosterol **4** was formed in aerobic culture. When the normal diet was replaced by a steroid-deficient artificial one, the ratio of 24-methylenecholesterol **5** to total insect sterols was significantly increased. The above study offers further corroborating evidence for our assumption that the host insects require 24-methylenecholesterol **5** as an alternate source for cholesterol **1** under certain environmental conditions. In our previous biotransformation experiments, 24-methylenecholesterol **5** was shown to be an immediate precursor of cholesterol **1.** However, the complexity of the insects' vital functions hindered all subsequent attempted transformations into cholesterol **1** of sitosterol **2,** trienol **6,** and ergosterol **4,** under injection conditions.

Key Words—Ergosta-5,7,24(28)-trien-3β-ol, trienol, intracellular symbiotes, steroidogenesis, planthoppers, *Nilaparvata lugens*, *Laodelphax striatellus*, Homoptera, Fulgoridae, steroid-deficient diet.

INTRODUCTION

Insects cannot biosynthesize steroids (Clayton, 1964), which are essential membrane components and the precursors of molting hormone ecdysteroids. Therefore insects' steroid requirement is usually met by dietary sterols, such as cholesterol **(1)** and/or phytosterols. The senita cactus fly *Drosophila pachea* (Heed and Kirscher, 1965) and ambrosia beetle *Xyleborus ferrugineus* (Chu et al., 1970) are exceptional in requiring sterols with a 7-ene or a 5,7-diene system for metamorphosis to adults. Phytophagous insects are generally capable of dealkylating the side chains of phytosterols (Svoboda and Thompson, 1985; Ikekawa, 1985), such as sitosterol **(2),** stigmasterol, and campesterol to produce cholesterol via desmosterol **(3).** On the other hand, some homopterous insects, exemplified by planthoppers, may rely on their obligatory intracellular symbiotes in addition to their diet as a steroidal source. For example, the brown planthopper (*Nilaparvata lugens* Stål) and the small brown planthopper (*Laodelphax striatellus* Fallén), which host yeastlike symbiotes (Nasu, 1965), can live on an artificial diet without sterols. In these insects, the symbiotes are transmitted from the mycetocytes in the host's fat body through the ovary to the next host generation (Noda, 1977).

Previously, we reported that the yeastlike symbiotes (*Candida* sp.) Nl-1 and Nl-2 from *N. lugens*, and Ls-1 and Ls-2 from *L. striatellus* synthesize sterols to meet the host's need (Eya et al., 1989). The yeastlike symbiotes produced ergosterol **(4)** as the sole product when cultured. A comparative study of the steroids present in the cultured symbiotes, the normal and aposymbiotic insects, and dietary rice plants (*Oriza sativa* L. Koshihikari) led to the hypothesis that ergosterol is the key steroid provided to the host insects and is converted by the host via 24-methylenecholesterol **(5)** to cholesterol **1.** The biotransformation of injected 24-methylenecholesterol-(23,23,25-d_3, **5**-d_3) into cholesterol-d_3 by *N. lugens* supported this hypothesis (Eya et al., 1989).

We report here subsequent findings to further clarify previous results. Ergosta-5,7,24(28)-trien-3β-ol (trienol) **(6)** has now been isolated and identified as the major sterol component of the symbiotes, which were separated from the host insects by Percoll density gradient centrifugation; this also showed that our previous identification of ergosterol **4** in the host insects required revision. Namely, careful reinvestigation of mass spectra with the aid of capillary GC-MS revealed that the compound previously identified as ergosterol **4** in the host insects was in fact trienol **6,** a precursor of ergosterol in fungi, including *Saccharomyces cerevisiae* (Barton et al., 1972) and *Phycomyces blakesleeanus* (Goulston and Mercer, 1969). As yet we have not been able to secure direct evidence for the conversion of trienol **6** into cholesterol **1** via 24-methylenecholesterol **5**; all attempts to transform trienol **6** (symbiote origin), ergosterol **4** (feasible symbiote origin), and sitosterol **2** (plant origin) into cholesterol **1** by

injection were hindered by the complexity of the insects' vital functions. However, 24-methylenecholesterol **5** was shown to be a readily acceptable intermediate in cholesterol **1** synthesis (Eya et al., 1989).

Incubation of the symbiotes, separated from their host by centrifugation, with the cell culture medium MGM-448 without fetal bovine serum (Mitsuhashi, 1984) at 28°C for 4 hr, did not change trienol content and produced no additional sterols. In addition, sterols will not be released into the medium in measurable quantities. Incubation of insect homogenate, at 28°C for 3 hr, with culture medium containing trienol **6**-d_7 did not induce deuterium incorporation into any other sterols. Thus, the requirement for symbiote sterol by *N. lugens* was reinvestigated by administration of a steroid-deficient artificial diet, as an easier alternative to ingestion of labeled phytosterol by hard-to-obtain aposymbiotic insects. When third-instar *N. lugens* were switched from a normal diet to a steroid-deficient artificial one, growth and molting were slightly disrupted, and the ratio of 24-methylenecholesterol **5** to total sterols was significantly increased. The present study offers further corroborating evidence for our assumption that the host insects require 24-methylenecholesterol as an alternate source for cholesterol under certain environmental conditions.

METHODS AND MATERIALS

Chemicals and Supplies. 24-Methylenecholesterol was a gift from Professors John Blunt and Murrary H.G. Munro, University of Canterbury, Christchurch, New Zealand. Other chemicals were obtained from the following commercial suppliers: 2-bromopropane-(d_7), MSD Isotopes; cholesterol, Nakarai Chemicals; desmosterol, Steraloids; Emulgen 913, Kao Co.; ergosterol, Wako Pure Chemical Industries; lanosterol, Nacalai Tesque; Percoll, Pharmacia LKB, Sweden; β-sitosterol and 3β-hydroxy-Δ^5-cholenic acid, Tokyo Kasei Kogyo. Other reagents were obtained from Nacalai Tesque or Wako Pure Chemical Industries. Thin-layer chromatography R_f values refer to elution of Merck silica gel 60 F254 plates of 0.25-mm layer thickness with ether–hexane 1 : 1. Flash chromatography was performed with Merck 230–400 mesh silica gel. Cell culture medium MGM-448 without fetal bovine serum was prepared according to the procedure outlined previously by Mitsuhashi (1984).

Insects and Dietary Plants. The insects *N. lugens* and *L. striatellus* were collected at Shimane Prefecture in Japan. The insects were reared on seedlings of their dietary plant, *Oriza sativa* L. in plastic cages at 25°C under photoperiodic conditions of 16 : 8 hr light–dark for successive generations.

Steroid-Deficient Artificial Diet. N. lugens were reared on their dietary plant up to the third instar and then switched over a steroid-deficient artificial diet (Mitsuhashi and Koyama, 1971) for one week. Within one week, the insects

reared on rice seedlings reached the fifth instar; however, growth of the experimental insects was restricted to the fourth instar.

Symbiotes. The yeastlike symbiotes were separated from the host insects according to the method of Noda and Omura (1991). Adults and nymphs (8 g) were homogenized with 80 ml of 0.85% brine, and the insect debris was removed by filtration through cotton cloth. The pellet obtained after centrifugation (5 min at 100*g*) was purified by repetition of the suspension and centrifugation steps. The suspension of the final pellet in 0.85% brine was treated with four times its volume of Percoll. The mixture was ultracentrifuged at 85,000*g* for 40 min on a Beckman Type 70 Ti angle rotor. The upper insect lipid and the lower symbiote fractions were lyophilized.

Fractionation of Sterols. Throughout the experiments involving the insects *N. lugens* and *L. striatellus* and their yeastlike symbiotes, exposure to light was minimized by use of aluminum foil. The procedure for sterol fractionation of insect and symbiote samples was essentially the same as that reported previously (Eya et al., 1989). In a typical experiment, ca. 200 insects were ground with a pestle and then homogenized by a Teflon homogenizer with chloroform–methanol (2 : 1, 5 ml) under ice cooling. After sonication for 30 min, the homogenate was centrifuged at 3000 rpm for 5 min. The supernatant was removed, and the solid residue was extracted in the same fashion again with fresh solvent (5 ml). The combined supernatants were concentrated to dryness. The residue was stirred magnetically with 2 M aq. potassium hydroxide (1 ml), methanol (1 ml), and tetrahydrofuran (1 ml) at reflux under a nitrogen atmosphere. The mixture was acidified with 0.2 M aq. hydrogen chloride (10 ml), and extracted with three portions of methylene chloride. The usual treatment of the combined organic extracts afforded 26.3 mg of light brown semisolid residue, which contained free sterols and fatty acids. After esterification of fatty acids with diazomethane–ether, the sterol fraction (0.1 mg) was separated by flash chromatography (10 × 150-mm column, ether–hexane 6 : 4) and chromatographed on HPLC [Cosmosil $5C_{18}$ column (Nacalai Tesque), 4.6 × 250 mm, methanol–water 95 : 5, flow rate 1 ml/min].

GC-MS of Sterols. The sterol fraction (0.1 mg) was treated with hexamethyldisilazane (100 μl) and chlorotrimethylsilane (50 μl) in pyridine (250 μl) for 30 min at room temperature under nitrogen. The reaction mixture was cooled to 0°C, diluted with pentane, and water was added. The aqueous layer was extracted twice with pentane to yield TMS-derivatized sterols, which were analyzed by GC-MS (Hewlett-Packard 5710 chromatograph connected to a Hitachi M-80 mass spectrometer). A 50-m Hewlett-Packard HP-5 cross-linked 5% phenyl methyl silicone gum phase column (0.2 mm ID) was employed. Other GC settings were as follows: column flow rate 0.4 ml/min, split ratio between 10 : 1 and 30 : 1, injector and auxiliary heater 250°C, column temperature program 200–290°C at 2°C/min. Mass spectrometer settings for sterol identification

were as follows: ionization voltage 70 eV, source slit 500 μm, collector slit 150 μm, scanning rate m/z 60–600 in 1.08 sec, rescan duration 1 sec, sampling time 25 μsec, multiplier 1500 V. The following mass spectrometer settings were employed for measurement of isotopic abundance ratios (MID mode): ionization voltage 70 eV, source slit 600 μm, collector slit 300 μm, scanning rate m/z 0–2000 in 128 sec, rescan duration 10 sec, sampling time 100 μsec, multiplier 1500 V. TMS sterols (R = TMS in **1, 2** and **4–6**) were identified from their mass spectra and by coinjection whenever authentic samples were available.

Preparation of Authentic Ergosta-5,7,24(28)-trien-3β-ol **6.** A $\Delta^{7,8}$ double bond was introduced into 24-methylenecholesterol: (1) benzoyl chloride, pyridine; (2) *N*-bromosuccinimide, azoisobutyronitrile (AIBN), CCl_4, reflux; (3) $(MeO)_3P$, CH_3CN; (4) 2% aq. KOH, MeOH, THF.

Synthesis of Labeled Sterols. Scheme 1 outlines the synthesis of ergosta-5,7,24(28)-trien-3β-ol-(25,26,27,d_7) (**6**-d_7, upper sequence) together with 23,23,25-d_3 (**6**-d_3, lower sequence). Grignard coupling of tetrahydropyranyl aldehyde (I) (Eya et al., 1989) with heptadeutero isopropyl magnesium bromide [from 2-bromopropane-(d_7)] in ether gave (II) (81%), which was oxidized to ketosteroid (III) (PCC, CH_2Cl_2, 81%). The THP protecting group was replaced by benzoyl (1. 1 N HCl-MeOH; 2. benzoyl chloride in pyridine) to afford (IV). Introduction of the Δ_7 double bond and the 24-methylene group of **6**-d_7 was accomplished according to the procedures that Fryberg et al. (1973) reported for the nondeuterated material. Compound **6**-d_7 was identified by the usual spectroscopic methods. Compound **6**-d_3 was obtained by deuteration of the intermediate (iv, X = Y = Z:H) four times in a solution of methanol-d_1 and 1% K_2CO_3 in D_2O for 20 min at 70°C. The deuterium incorporation was greater than 99% based on mass spectroscopy [overall yield, 4% from (i)].

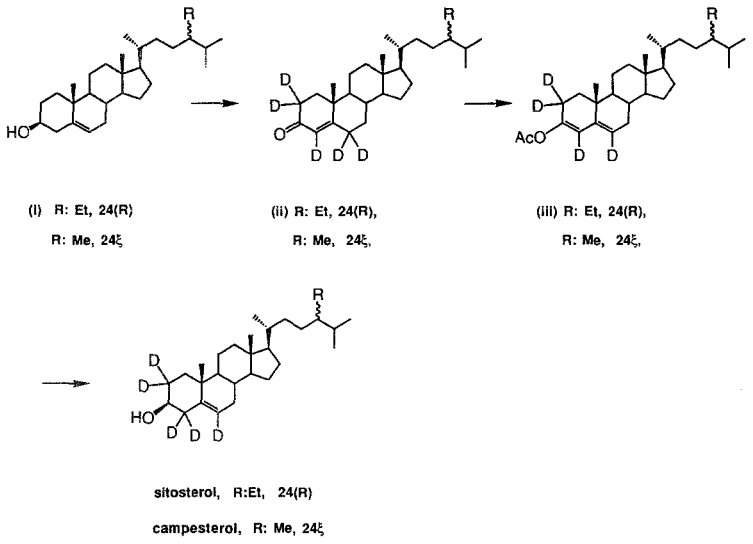
SCHEME 1. Synthesis of ergosta-5,7,24(28)-triene-3β-ol-d_7 and -d_3 (**6**-d_7 and **6**-d_3).

For the preparation of sitosterol-(2,4,6-d_5, **2**-d_5) in Scheme 2, we adapted and improved upon Greunke and Craig's (1979) synthesis of cholesterol-(2,4,6-d_5) (**1**-d_5) to give the side-chain alkylated variant in greater isotopic purity and yield (> 90% d_5, 38% yield from sitost-4-en-3-one vs. 68% d_5, 18% yield for **1**-d_5 from cholest-4-en-3-one). A mixture of 4-en-3-ones (R = Et and Me), obtained in one step (Dow et al., 1983) from commercially available sitosterol (i: R = Et (R) 61%, R = Me (ξ) 39%), was exchanged with five portions of MeOD at reflux in the presence of NaOMe (Dufourc et al., 1984) to afford the corresponding mixture of (ii: R = Et and Me) in 84% yield and > 90% isotopic purity. Lithiation with Ph_3CLi (from PhLi and Ph_3CH, DME, r.t.), followed by injection of acetic anhydride, gave the thermodynamically favored heteroannular 3,5-dien-3-ol acetates (iii: R = Et and Me) in 70% yield. Sodium borohydride reduction (NaOD, D_2O, dioxane, 33°C; Barton et al., 1971), followed by reverse-phase HPLC separation gave pure sitosterol **2**-d_5 in 39% yield (63% based on pure iii-d_4, R = Et). Campesterol-(2,4,6-d_5) was also isolated in 27% yield (69% based on pure iii-d_4, R = Me). Structures were confirmed by spectroscopic and HPLC comparison with authentic, nondeuterated samples. Mass spectroscopic measurements showed that **2**-d_5 was > 90% isotopically pure.

RESULTS

Ergosta-5,7,24(28)-trien-3β-ol **6**. From the symbiotes separated from 8 g of *N. lugens* (see above), the sterol fraction (2.1 mg) was trimethylsilylated and analyzed by GC-MS as described above. After desilylation (2 M aq. KOH-



SCHEME 2. Synthesis of sitosterol-d_5 and campesterol-d_5.

MeOH-THF, each 1 ml), the major sterol (1 mg, 85% of the total sterol content) was purified by HPLC. Its ^{1}H NMR spectrum indicated the structure to be ergosta-5,7,24(28)-trien-3β-ol **6,** which was confirmed by comparison with an authentic sample prepared as described above. ^{1}H NMR ($CDCl_3$, 360 MHz) δ: 0.63 (s, 3 H, 18-H), 0.94 (s, 3 H, 19-H), 0.98 (d, J = 6.3, 3 H, 21-H), 1.03 (d, J = 7, 6 H, 26-H and 27-H), 1.10–2.53 (m, 23 H, CH_2 × 9 and CH × 5), 3.64 (m, $W_{1/2}$ = 22.7 Hz, 1 H, 3-H), 4.67 (br s, 1 H, 28-H_a), 4.72 (br s, 1 H, 28-H_b), 5.39 (m, $W_{1/2}$ = 11.2 Hz, 1 H, 7-H), 5.58 (m, $W_{1/2}$ = 10.8 Hz, 1 H, 6-H); ^{13}C NMR ($CDCl_3$, 75.5 MHz) δ: 11.83 (C-18), 16.31 (C-19), 18.85 (C-21), 21.13 (C-11), 21.88 and 22.01 (C-26 and C-27), 23.05 (C-15), 28.09 (C-16), 31.04 (C-23), 32.02 (C-2), 33.83 (C-25), 34.63 (C-22), 36.12 (C-20), 37.03 (C-10), 38.39 (C-1), 39.21 (C-12), 40.81 (C-4), 42.97 (C-13), 46.25 (C-9), 54.50 (C-14), 55.76 (C-17), 70.48 (C-3), 105.98 (C-28), 116.31 (C-7), 119.60 (C-6), 139.78 (C-5), 141.35 (C-8), 156.82 (C-24); EI-MS *m/z* (relative intensity) 396 (M^+, 100, $C_{28}H_{44}O$, calculated for 396.3392, found 396.3417), 381 (M − CH_3, 5), 378 (M − H_2O, 7), 363 (M − CH_3 − H_2O, 72), 337 (M − C_3H_7O, 32), 312 (M − C_6H_{12}, 4), 294 (M − C_6H_{12} − H_2O, 5), 279 (M − C_6H_{12} − H_2O − CH_3, 4), 271 (M − side chain, 7), 269 (M − side chain − 2H, 5), 253 (M − side chain − H_2O, 12), 251 (M − side chain − 2H − H_2O, 8).

Sterols in Whole Insects Reared on Rice Plant. The three major sterols, cholesterol **1,** 24-methylenecholesterol **5,** and trienol **6,** were found in different relative amounts in both *N. lugens* and *L. striatellus*. Neither species contained more than a trace of ergosterol **4,** save one exceptional sample of *N. lugens*. Small amounts of sitosterol **2** and desmosterol **3** were found in some *N. lugens* samples. Episterol **(7)** was tentatively identified in both insect species, on the basis of the mass spectrum of the TMS ether derivative.

Sterols in Symbiote and Insect Lipid Fractions. The symbiote and insect lipid fractions were separated from whole *N. lugens* or *L. striatellus* by density gradient centrifugation. The lipid fraction from each insect species displayed approximately the same sterol composition as the corresponding whole insects. In each symbiote fraction, trienol **6** occurred as the only major sterol together with small amounts of cholesterol **1,** 24-methylenecholesterol **5,** and lanosterol **(8).** Trace amounts of ergosterol **4** were tentatively identified in some samples. Tentative identifications were made for episterol **7,** 4α-methyl-5α-ergosta-8,24(28)-dien-3β-ol **(9),** 14α-methyl-5α-ergosta-8,24(28)-dien-3β-ol **(10),** 24-methylene-24,25-dihydrolanosterol **(11),** and 4,4-dimethyl-5α-ergosta-8,24(28)-dien-3β-ol **(12)** on the basis of mass spectroscopic evidence. All sterol constituents of symbiotes from the two insect species were essentially the same.

Sterols in Whole Insects Reared on Artificial Diet. N. lugens insects that had been administered a steroid-deficient diet for one week contained the same major steroid constituents as control insects, i.e., cholesterol **1,** 24-methylene-

cholesterol **5**, and trienol **6**, according to GC-MS measurements of the TMS ether derivatives. However, the artificially fed insects contained more than three times the amount of **5**, relative to total sterols, than the control insects.

DISCUSSION

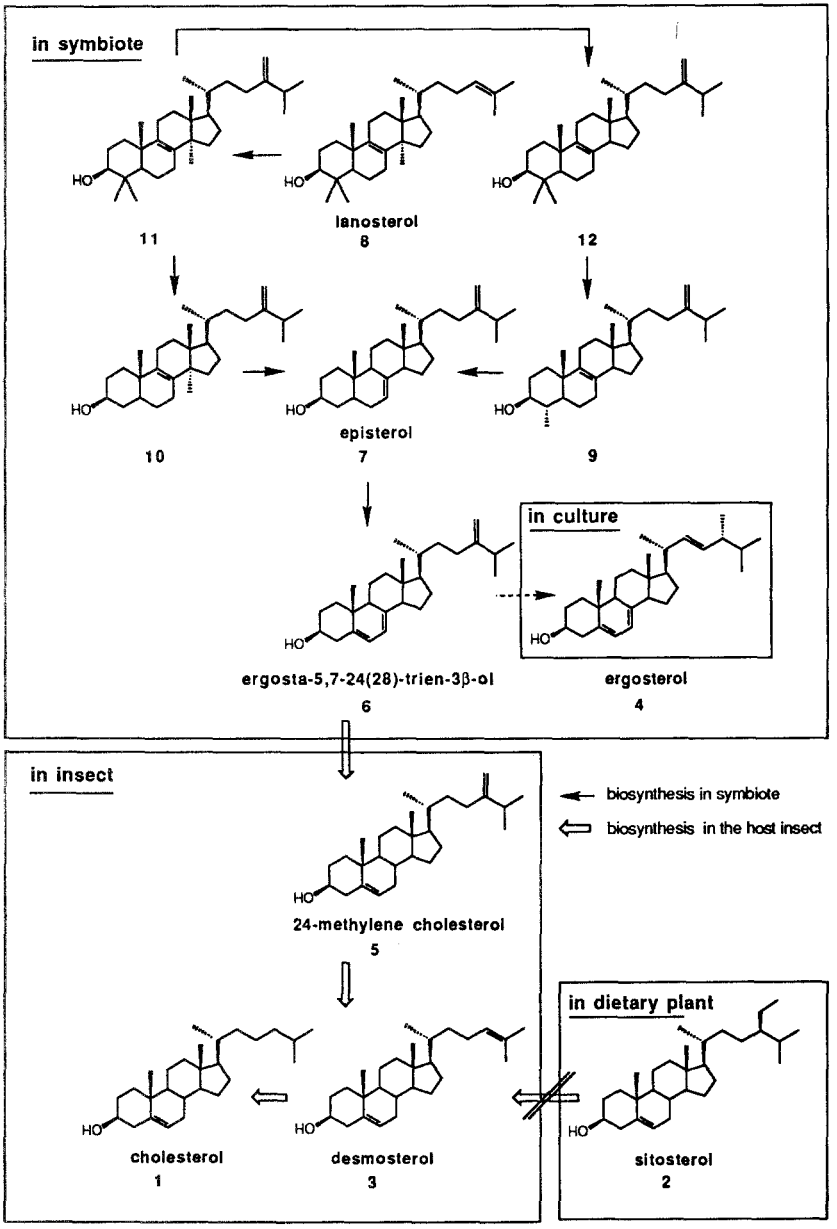
Isolation and identification of trienol **6** from the symbiotes separated by centrifugation prompted us to reinvestigate our previous results (Eya et al., 1989). Our present experiments revealed that trienol **6** was incorrectly assigned as ergosterol **4** in our previous report, although the characterization of ergosterol in cultures of Nl-1, Nl-2, Ls-1, and Ls-2 was correct. Ergosterol **4** was the single major sterol in the culture, but trienol **6** was the only sterol found in substantial quantities in both the symbiote and insect fractions separated by density gradient centrifugation. It has now become clear that the similarity in the mass spectra of the two compounds led us to erroneously conclude that the two were identical. The EI mass spectra of TMS-trienol (TMS-**6**) and TMS-ergosterol (TMS-**4**) were almost indistinguishable except for the generation of low-intensity *m/z* 294 and *m/z* 279 peaks by the former, but not by the latter. The *m/z* peak was attributed to loss of C_6H_{12} from the side chain in a McLafferty fragmentation and loss of Me_3SiOH. Loss of an additional CH_3 radical from *m/z* 294 provided *m/z* 279. Now, trienol appears to be the key compound supplied by the symbiote to the host insect. This hypothesis is supported by our previous heat-treatment experiment, in which removal of the yeastlike symbiotes from *N. lugens* led to the complete disappearance of **6** (not **4**), as well as to a 10-fold reduction in total sterol content, due to restriction of the insect growth (Eya et al., 1989). A dramatic decrease in 24-methylenecholesterol **5** as well as trienol **6** in aposymbiotic insects suggested that these compounds are essential to the development of host insects. The occurrence of a large amount of 24-methylenecholesterol **5** and a small amount of desmosterol **3** in the normal insect lipid fraction indicated that consumption of **5** is the rate-determining steroidogenic step in the host insects.

The co-occurrence of sterols **6–12** in the yeastlike symbiotes strongly suggests that the symbiotes in the host insects methylenate primarily at the stage of lanosterol **8.** In this respect, the yeastlike symbiotes are similar to *Phycomyces blakesleeanus*, *Agaricus campestris* (Goulston et al., 1975), *Mucor pusillus* (Mercer and Carrier, 1976), and *Neurospora crassa* (Renaud et al., 1978), among others, but different from *S. cerevisiae* (Barton et al., 1972). In the latter, elimination of the *gem*-dimethyl groups at C-4 occurs before introduction of the methylene group at C-24. In *Candida albicans*, preliminary evidence suggests that C-24 methylation can occur at either the demethyl sterol or the lanosterol stage (Shimokawa et al., 1986; Cannon and Kerridge, 1988).

Interestingly, the symbiotes Nl-1, Nl-2, Ls-1 and Ls-2 produced only ergosterol as their end product under aerobic culture conditions (Eya et al., 1989). In contrast, reduction of the $\Delta^{24(28)}$ double bond and introduction of the Δ^{22} double bond are both inhibited in the symbiotic environment of these microorganisms. The disabling of these two conversions in the symbiotic environment could result from active inhibition by the host insect, or from changes in the concentrations of cofactors required for these conversions (e.g., oxygen, see Osumi et al., 1978). It is also possible that the symbiotes isolated from the eggs of *N. lugens* and *L. striatellus* underwent mutation under the artificial culture conditions to produce ergosterol.

Ergosterol **4** has been suggested to be a growth factor for *S. cerevisiae* (Pinto et al., 1983). If **4** serves the same function in these yeastlike symbiotes, severe curtailment by the host insect of **4** biosynthesis in the symbiotes may allow the insect to control the growth rate of its guest, to the mutual benefit of host and guest. The relatively high concentrations of 24-methylenecholesterol **5** in *N. lugens* and *L. striatellus* are peculiar among insects, as noted previously (Noda et al., 1979). A need by the host insects for an extremely efficient Δ^7-reductase to allow successful competition with the symbiotes for limited supplies of trienol **6** could at least partially account for the unusual buildup of **5** in the insect tissues.

In order to clarify the origin of cholesterol via 24-methylenecholesterol in the host insects, biotransformations of the deuterated precursors (**6, 4, 2**) were examined. The carrier for injection was selected according to the solubility of the compound to be injected. Insects were injected with **6**-d_7 suspended in 20% aqueous glycerol containing 0.2% Emulgen 913 as the carrier, or in olive oil containing 0.2% Emulgen 913, in which **6**-d_7 had slightly greater solubility. The insects that were injected with the latter suspension were maintained for 28 hr and 96 hr before sacrifice. The sterol fraction was separated, TMS-derivatized, and analyzed by capillary GC-MS in multiple ion detection (MID) mode (selected ion monitoring). No deuterated 24-methylenecholesterol and/or cholesterol was detected. Another deutero compound, **6**-d_3, which had improved solubility, was prepared and injected in a similar manner. The result was the same as before. Insects injected similarly with **4**-d_2 and retained for 25 hr and 70 hr also afforded no conversion. However, the observation of a dramatic reduction of trienol **6** and 24-methylenecholesterol **5** in the aposymbiotic insects, and an increase of **5** in the insects reared on a steroid-deficient diet, strongly suggested the involvement of symbiote-derived **6** in cholesterol biosynthesis of the symbiotic insects. The ability of the insects to biotransform the major sterol of their dietary plant was also tested. Insects injected with sitosterol-2,4,6-d_5 (**2**-d_5) dissolved in either olive oil or 0.2% Emulgen 913 in 20% aqueous glycerol were allowed to live for three days before sterol extraction and analysis. Biotransformation of sitosterol into cholesterol and/or desmosterol was not observed under these conditions.



SCHEME 3. Proposed steroidogenesis in *N. lugens* hosting symbiotes.

In conclusion, all injection experiments with deuterated trienol **6**, ergosterol **4**, and sitosterol **2** failed to yield deuterated cholesterol **1**; only 24-methylenecholesterol **5** was biotransformed into cholesterol **1**. The present study may suggest that there are specific mechanisms in situ for transportation of the essential compounds; sitosterol **2** can be transformed by an ingestive route, whereupon cholesterol was the only excreted sterol. Administration of a steroid-deficient diet provided an alternate proof that 24-methylenecholesterol **5** originates from the symbiotes. Thus, Scheme 3 illustrates the proposed steroidogenesis in the symbiotic insects.

Abstract—Bare zones around shrubs in the Florida scrub indicate the possibility of allelopathy by shrubs controlling the distribution of grasses invading from adjacent sandhills. The allelochemical, hydrocinnamic acid, has been identified as a breakdown product of ceratiolin, which is released from the shrub *Ceratiola ericoides*. Here, hydrocinnamic acid (HCA) was shown to have a strongly inhibitory effect on shoot and root biomass of the grass *Schizachyrium scoparium* in greenhouse bioassays lasting 4.5 months. Linear increases in the concentration of HCA from 0 to 200 ppm, applied biweekly, resulted in exponential decreases in root and shoot biomass at harvest. Plants grown at 200 ppm HCA had root and shoot biomasses 13% and 17% of controls, respectively. Concurrent investigation of reduced nutrient levels indicated greater inhibition by HCA in a reduced nitrogen (N) treatment and in a reduced potassium (K) treatment relative to HCA inhibition in the full nutrient treatment. The negative slopes of the regressions of log of biomass on HCA concentration were steepest in the reduced N and reduced K treatments. Root and shoot biomasses in reduced N treatments were 20–43% and 24–34% less than the respective biomasses in the full nutrient treatment. Comparable reductions in the reduced K treatment were as much as 19% and 10% for root and shoot biomasses, respectively. The effects of HCA in a reduced phosphorus (P) treatment and in a reduced P and K treatment were not significantly different from the effects of HCA in the full nutrient treatment. Extraction of the soils at harvest indicated no buildup of HCA at the end of the experiment. The sensitivity of *Schizachyrium scoparium* to HCA

in general and increased sensitivity under low N and low K solutions may be important in the Florida scrub community where levels of N and K are known to be low.

Key Words—Allelopathy, *Schizachyrium scoparium*, *Ceratiola ericoides*, hydrocinnamic acid, nitrogen, phosphorus, potassium, fire, sand pine scrub, sandhill.

INTRODUCTION

Two distinct vegetative communities coexist on the upland dry sandy soils of Florida, the sandhill and the sand pine scrub. The sandhill is an open woodland with longleaf pine (*Pinus palustris* Mill.) and slash pine (*Pinus elliotti* Engelm.) towering over a savannah dominated by little bluestem [*Schizachyrium scoparium* (Michx.) Nash] and wire grass (*Aristida stricta* Michx.). The scrub is dominated by sand pine [*Pinus clausa* (Chapm. ex Engelm.) Vassey ex Sarg.] with an understory of rosemary (*Ceratiola ericoides* Michx.) (Empetraceae) and scrub oaks, but little herbaceous ground cover. One notable difference in the selective regimes of the two communities is the frequency of lightning-originated fires. Surface fires are common in the sandhill, typically occurring every three to eight years (Christensen, 1988). The sand pine scrub has more intense crown fires every 20–50 years (Richardson and Williamson, 1988; Williamson, 1990). Webber (1935) called the scrub a "fire fighting machine," as fires sweeping through the sandhills are often extinguished at the scrub ecotone due to changes in fuel availability. In the absence of fire in the sandhills, scrub species will invade; thus, different fire regimes are necessary for the existence of the two communities (Veno, 1976).

An examination of soils in both regions has revealed few differences in physical and chemical soil characteristics to a depth of 5 m, indicating a uniform substrate across vegetative boundaries (Kalisz and Stone, 1984). The differences in soil color or organic matter that are sometimes observed may be induced by the vegetation types. There is little evidence to support the early hypothesis that the abrupt boundary is caused by differences in soils, with the scrub community being characterized by nutrient-poor soils relative to the sandhill (Laessle, 1958; Christensen, 1981).

In addition to fire regime, allelopathy may have a large role in establishing and maintaining the boundaries (Richardson and Williamson, 1988; Weidenhamer and Romeo, 1989; Williamson et al., 1991). The scrub shrubs release chemicals that may inhibit the growth of the sandhill grasses and pines that provide fuel for fires that would kill the shrubs. *Ceratiola ericoides* is one shrub that has been implicated in allelopathic interactions (Fischer et al., 1988). Ceratiolin, a novel dihydrochalcone, is washed from the leaves and decaying litter by rainwater (Tanrisever et al., 1987). Although allelopathically inactive, the

compound decomposes in aqueous solution to form hydrocinnamic acid (HCA), which is highly phytotoxic in Petri dish bioassays to native sandhill grasses, including little blustem, *Schizachyrium scoparium* (Michx.) Nash (Fischer et al., 1988; Williamson et al., 1991).

We present here an investigation of the effects of HCA on growth of *S. scoparium* in greenhouse bioassays conducted in pots with sand as a substrate and under natural light regimes. These studies differ from earlier bioassays of leaf washes and mists and of pure HCA on seeds and seedlings in Petri dishes in the dark (Tanrisever et al., 1987; Fischer et al., 1988). In addition, reduced nutrient levels were used to test for interactions between nutrient reduction and inhibition by HCA. Allelopathy involving phenolic compounds has been suggested to be more important in soils of lower fertility, and in some cases reduced nutrient levels have increased allelopathic effects (Glass, 1976; Stowe and Osborn, 1980). Adsorption of potassium and phosphate is decreased by many phenolic acids identified as allelopathic inhibitors (Glass, 1973, 1974; Harper and Balke, 1981). Scrub soils are known to be low in some soil nutrients, notably potassium, calcium, and nitrogen (Kalisz and Stone, 1984; Richardson, 1958), so toxic effects of phenolic allelochemicals may be intensified. We applied HCA with nutrient solutions at both low concentrations and higher concentrations designed to overcome any nutrient limitation present.

METHODS AND MATERIALS

Schizachyrium scoparium was used as the test species for bioassays of both the phytotoxicity of hydrocinnamic acid in aqueous concentrations of 0 to 200 ppm and the influences of nutrient reduction. Thirty seeds were planted at a depth of 1 cm in sand in plastic pots 10 cm^2 × 7.5 cm high. Each pot was filled 5 cm deep with Easy Blast blasting sand, a river sand washed extensively to remove organic matter and free nutrients. The bottom of each pot was lined with a fiberglass screen covered with 1 cm of pea gravel to allow free drainage without soil loss.

The pots were placed in a completely randomized block design in a shaded greenhouse receiving 55% of full sunlight as measured with a Li-Cor model LI-185B Quantum/Radiometer/Photometer. Initially, pots were watered twice a week with 90 ml of tapwater. To deter fungal growth, Captan, 2.5 ml/liter of solution, was added to the water when the seeds were planted and again after five weeks. After two weeks, seedlings were thinned to one plant per pot. Two weeks later the sand surface was covered with a 1-cm layer of black gravel to deter surface algal growth, and the nutrient–HCA treatments were initiated. On Mondays and Fridays pots received 90 ml of one of five levels of HCA and one of five nutrient treatments. Ten replicates of each combination were used.

To preclude the accumulation of toxic levels of nutrient salts, pots were flushed on Wednesday with tapwater from a hose until water ran both through and over the pot top.

HCA was applied at concentrations of 0, 25, 50, 100, and 200 ppm. Five nutrient solutions, prepared according to Stowe and Osborn (1980), were used: full nutrient solution (F), reduced nitrogen (N), reduced potassium (K), reduced phosphorus (P), and reduced potassium and phosphorus (KP). The full nutrient solution contained 81 ppm N, 9 ppm P, and 78 ppm K. Other nutrient concentrations were held constant, as in Bradshaw et al. (1964). The reduced concentration of a nutrient was 1/9 the concentration in the full solution. In the reduced KP solution, both nutrients were reduced to 1/9 the full concentration. As concentrations of sulfate in the reduced K and reduced KP solutions decreased, sodium sulfate was added proportionally to maintain a constant sulfate concentration. Solutions were prepared with deionized water and were adjusted to pH 5.5 using NaOH and HCl.

Plants were harvested 4.5 months after planting. The pots were overturned and the plants gently rinsed in tap water until soil particles were freed from the roots. Each plant was divided into shoot and root components, the tissues were oven dried for 48 hr at 60°C, and dry weights were obtained. Shoot weights included living biomass and total biomass, the latter including dead leaves attached to the plant at the time of harvest. Data were then $\log_{10}$ transformed and analyzed by regression analysis using SAS (SAS Institute, 1985) to determine the effect of HCA and nutrient treatments.

Soil samples were taken from each full nutrient solution–HCA combination in order to determine the concentration of HCA at the time of harvest. The soil was extracted into water and analyzed using HPLC according to the methods of Jordan (1990). Identity of HCA was confirmed by comparing UV spectra and retention times to standards. A Hewlett Packard 1090 Liquid Chromatograph equipped with a diode array detector and auto injector was used with detection at 257 nm, and a C-18 reverse-phase column, 10 μm Carbosphere (250 mm $\times$ 4.6 mm ID, Phenomenex, Palo Alto, California). A two-solvent system of (A) methanol and acetic acid (99.5:0.5) and (B) double-distilled deionized water and acetic acid (99.5:0.5) was used, with a gradient of 50% (A) to 100% (A) in 17 min.

RESULTS

As the HCA concentration increased from 25 to 200 ppm, the overall mean shoot and root dry weights of *S. scoparium* decreased (Figure 1). Biomass reduction, clearly visible at harvest, was greater in the roots than in the shoots (Figure 2). In 200 ppm HCA, root biomass was reduced to 13% of the control,

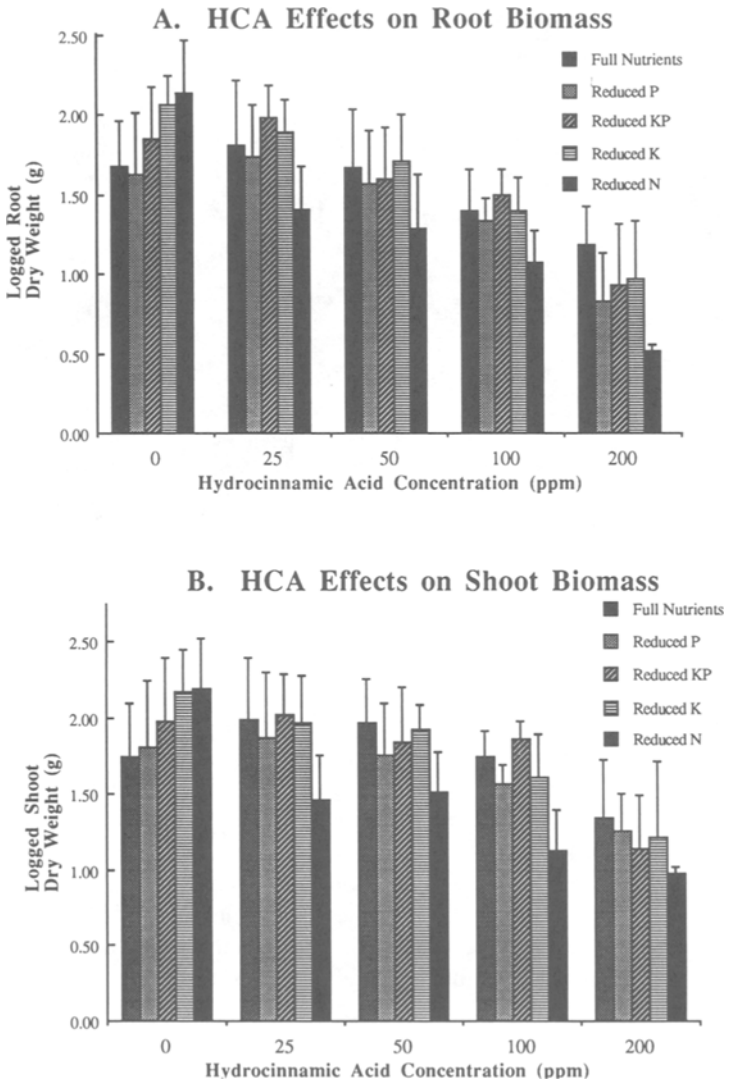

FIG. 1. Dry biomass of roots (A) and living shoots (B) at harvest of *Schizachyrium scoparium* after 4.5 months of growth exposed to 0, 25, 50, 100, and 200 ppm HCA in full nutrient (F), reduced phosphorus (P), reduced phosphorus and potassium (KP), reduced potassium (K), and reduced nitrogen (N). Data are means $\pm$ 1 SD.

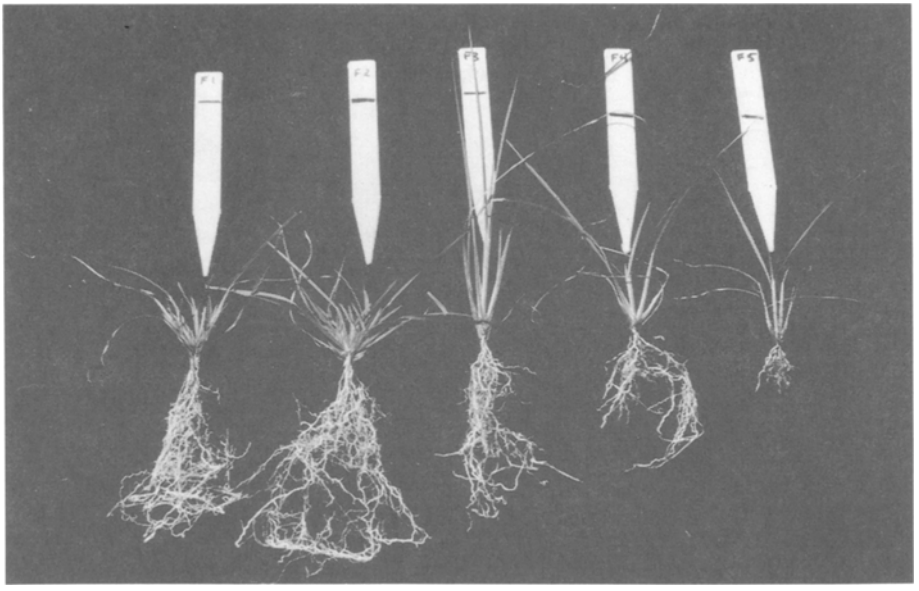

FIG. 2. Representative *Schizachyrium scoparium* plants at harvest, from the full nutrient treatment and HCA concentrations of 0, 25, 50, 100, and 200 ppm, labeled F1–F5, left to right.

living shoot biomass to 17% of the control, and total shoot biomass to 24% of the control. Linear regressions of the log of root, living shoot, and total shoot biomasses on HCA concentration were statistically significant for all nutrient treatments ($P \leq 0.05$) (Table 1). Therefore, as HCA concentration increased linearly, biomass at harvest decreased exponentially.

Reduced nutrient treatments had variable effects (Figure 1). A covariance model tested for differences in slope of the dependent variable, biomass, on the covariate, HCA concentration, with nutrient treatment as the class variable and a nutrient–HCA interaction term, where significance of the latter indicated different slopes. The slopes for both reduced N and reduced K were significantly different from the slope for the full nutrient solution for both root and living shoot biomasses (Table 1). For HCA concentrations from 25 to 200 ppm, reduced N produced root biomass from 20% to 43% of the control, living shoot biomass from 24% to 34% of the control, and total shoot biomass from 33% to 46% of the control. However, at 0 ppm HCA, reduced N exhibited an increase over the control of 27%, 26%, and 19%, for root, living shoot, and total shoot biomasses, respectively. Effects of reduced K were less pronounced than reduced

TABLE 1. RESULTS OF REGRESSIONS OF ROOT AND LIVING SHOOT BIOMASS OF *Schizachyrium scoparium* ON HCA CONCENTRATION INDIVIDUALLY FOR FIVE NUTRIENT TREATMENTS: FULL NUTRIENT (F), REDUCED PHOSPHORUS (P), REDUCED PHOSPHORUS AND POTASSIUM (KP), REDUCED POTASSIUM (K), AND REDUCED NITROGEN (N)[a]

	Slope	Intercept	R^2	P
Root biomass				
Full nutrients	−0.136	1.94	0.27	0.002
Reduced P	−0.183	1.97	0.36	0.0001
Reduced KP	−0.245	2.31	0.52	0.0001
Reduced K	−0.267*	2.40	0.72	0.0002
Reduced N	−0.326**	2.26	0.62	0.0001
Living shoot biomass				
Full nutrients	−0.09	2.02	0.10	0.05
Reduced P	−0.132	2.05	0.21	0.005
Reduced KP	−0.198	2.37	0.35	0.0007
Reduced K	−0.228*	2.43	0.51	0.0001
Reduced N	−0.269*	2.22	0.50	0.001

[a] Regression parameters are slope and intercept with the associated R^2 and probability of significance. Slopes significantly different from the full nutrient treatment are indicated by * if $p \leq 0.05$ and by ** if $p \leq 0.01$.

N and resulted in root and living shoot biomasses ranging from 82% to 123%, and 90% to 125%, respectively, of the full nutrient treatments (Figure 1).

The slope of the reduced KP treatment approached a statistically significant difference from the slope of the full nutrient treatment for root biomass ($P = 0.08$), living shoot biomass ($P = 0.13$), and total shoot biomass ($P = 0.16$) (Table 1). The slope of reduced P treatment was not different from the slope of the full nutrient treatment for root biomass ($P = 0.43$), living shoot biomass ($P = 0.54$), and total shoot biomass ($P = 0.63$). As the slopes of the reduced KP and reduced P treatments were not different from the slope of the full nutrient treatment, a second test for differences in intercepts (at HCA = 0 ppm) was performed, but it also yielded no significant differences ($P \geq 0.05$). Finally, comparisons between reduced KP versus reduced K and reduced KP versus reduced P treatment were also conducted to compare the double nutrient reduction with the single nutrient reductions, but no differences were found in slopes or intercepts.

Analysis of soil samples taken from pots at time of harvest revealed only trace concentrations of HCA in some samples, and no acetophenone. The concentrations of HCA found were several orders of magnitude lower than concentrations applied, and followed no apparent trend relative to application dosage.

DISCUSSION

Past studies of hydrocinnamic acid in Petri dish bioassays showed inhibition of germination and radicle elongation of *Schizachyrium scoparium* at levels of 63 ppm (Fischer et al., 1988). Leaf and litter washes of *Ceratiola* were also inhibitory to germination and radicle growth of *Schizachyrium scoparium* and other grasses in Petri dish bioassays at concentrations lower than 60 ppm (Tanrisever 1987, Williamson et al., 1991). The effect produced from both fresh foliage and litter was subject to seasonal variation (Richardson and Williamson, 1988). Studies of whole plants were deemed necessary to investigate the effects on growth over longer periods of time.

In this study the whole plants subjected to HCA treatments showed exceptionally strong inhibitory effects (Figure 1). At 200 ppm, roots were reduced to 13% of controls and live shoots were 17% of controls. At 25 ppm, the lowest concentration applied, roots were reduced to 82% of controls and live shoots to 78% of controls. These effects were achieved under greenhouse conditions that simulated natural conditions. The plants were grown in sand and the treatments were applied twice weekly. These pulses of application simulate the way natural doses are carried into the soil by sporadic rainfall leaching ceratiolin from leaves and litter of *Ceratiola*. HCA has been found in concentrations of 15–418 ppm in soil near *Ceratiola* (Jordan, 1990).

Previous studies have shown that the rate of formation of HCA from *Ceratiola* is greater than the rate of degradation of HCA into acetophenone (Jordan, 1990). This allows HCA to persist in the soil despite rapid decomposition when continuously resupplied. When nonsterile soil is spiked with HCA only once, recovery is 36% after 30 hr (Jordan, 1990). However, when HCA is spiked every other day and extracted 48 hr after the fifth addition, the amount extracted is 75% greater than an individual spike (Jordan, 1990). HCA in soil is known to degrade microbially into acetophenone (Jordan, 1990), a compound that also has allelopathic activity in Petri dish bioassays (Obee, unpublished data). The microbial degradation is rapid and stimulated by higher temperatures. Leaf washes of *Ceratiola* showed the most activity during summer months (Richardson and Williamson, 1988). This is likely due to both increased degradation during the hotter summer months and increased production caused by higher metabolic rates.

Soil samples were taken at the time of harvest from the HCA–nutrient experiment to determine whether HCA had accumulated in our pots at levels greater than those applied. Results showed that the samples contained only trace amounts of HCA in some pots and no acetophenone, a toxic degradation product of HCA. Since significant accumulation was not detected, the three- to four-day period between the biweekly applications may have been sufficient time for the breakdown of HCA. As the soil HCA was monitored only at the end of the

experiment, it is still possible that sporadic accumulation occurred at other times during the 4.5 months.

Reduced nutrient solutions were applied to test for nutrient stress and for interactive effects between nutrient stress and HCA. In each nutrient treatment increasing concentrations of HCA from 0 to 200 ppm caused decreases in plant biomass (Figure 1). Regression analysis showed that the effects of HCA did vary consistently according to nutrient treatments (Table 1): HCA had the strongest effect with reduced N, and successively milder effects with reduced K, reduced KP, reduced P, and finally the full nutrient treatment. The reduced N and reduced K treatments resulted in decreases in plant biomass that were significantly different from the HCA effect in the full nutrient treatment, whereas HCA effects in reduced P and reduced KP treatments were not significantly different from HCA effects in the full nutrient treatment. The Florida soils where *Schizachyrium scoparium* proliferates are considered nutrient poor (Christensen, 1988) and have low levels of K and N (Kalisz and Stone, 1984; Richardson, 1985), but an adequate level of P (Kalisz and Stone, 1984).

Since *Schizachyrium* grows on nutrient poor soils, it may be expected to be tolerant of reduced nutrient conditions. Here the inhibition of growth due to reduced nutrients was less severe, although significant for nitrogen and potassium, than the inhibition due to HCA. With reduced nitrogen or potassium, the allelopathic effects of HCA on *Schizachyrium* are intensified. This effect is similar to results of Stowe and Osborn (1980), who found that low nutrients combined with phenolics caused significant inhibition of barley not seen with phenolics alone. Einhellig (1989) found no evidence that more favorable phosphorus levels would overcome the allelopathic effects of ferulic acid on grain sorghum. In this case of phosphorus reductions the grain sorghum had the same insensitivity as the native *Schizachyrium*. Although here a native and agricultural species are shown to have similar reactions, comparisons should always be made with caution, as agricultural species are often more susceptible to nutrient limitation than native species.

Higher concentrations of HCA had a significant effect on mean dry weights (Figure 1). This effect, intensified by nutrient reduction, may be important where grasses grow near the shrub *Ceratiola*, the source of ceratiolin and its degradation product, HCA. In nutrient poor soils, grasses may be unable to colonize near the shrub where HCA concentrations reach inhibitory or toxic levels in the soil. This interaction between HCA, low nutrients, and the grasses may account for bare zones in the *Ceratiola* "balds," near pure stands of the shrub, and at some ecotones between sandhill and scrub where the latter is dominated by *Ceratiola*. Other environmental factors, notably high temperature and low soil moisture, may also increase the phytotoxicity of HCA (Einhellig and Eckrich, 1984; Einhellig, 1989). The well-drained sands of the Southeastern Coastal Plain have soil surface temperatures in excess of 50°C on sunny days (Richardson,

1985), and moisture stress is a significant factor in the dry season and during pauses in summer rains. The low plant densities in the scrub may also contribute to the enhanced effectiveness of allelochemicals such as HCA. The density of seeds and germinating seedlings has been shown to have a major impact on the magnitude of phytotoxic effects (Weidenhamer et al., 1987). Herbivory, which has been suggested as an explanation for bare zones around shrubs in the California chaparral (Bartholomew, 1970), may be a factor in the scrub. However, individual *Ceratiola* plants that are too small to harbor rodents also exhibit "halos" when colonizing disturbed scrub areas (Williamson, 1990). Where colonizing shrubs are sufficiently aggregated or grow sufficiently large to harbor rodents, both herbivory and allelopathy may contribute to a lack of plant growth around shrubs.

Abstract—Yellowfin tuna enhance their hunting success in the vast pelagic environment by using their sense of smell to detect intact (uninjured) prey that are beyond visual range. However, the olfactory cues that tuna use would normally face huge and rapid dilution in the open ocean. We demonstrate that these prey odors are complexed within biologically derived lipid structures that probably delay the dilution of the amino acids to subthreshold concentrations and provide persistent arousal and search cues for the tuna. This may be the first demonstration of an extracorporeal biological function for liposomes. Tuna may also form "chemical search images" to maximize feeding efficiency. We demonstrate that the amino acid profiles of various prey species are consistent over time and between schools, which makes the formation of search images feasible.

Key Words—yellowfin tuna, *Thunnus albacares*, amino acid profiles, liposomes, olfaction, search image, lipid complexes.

INTRODUCTION

Yellowfin tuna, *Thunnus albacares*, feed primarily on schooling prey that are patchily distributed in a huge ecosystem and that are consequently difficult to detect even in clear pelagic waters. Captive tuna respond to the odors of intact prey organisms (Atema et al., 1980), and, in the wild, arousal to food beyond visual range is probably mediated by olfactory detection of excretory and mucal slough-off compounds produced by the schools of prey. Aqueous rinses of the surfaces of tuna prey organisms contain complexes of lipids and amino acids, the latter being chemosensory feeding stimuli for a wide range of fish species including tuna (Bardach and Villars, 1974; Atema, 1980; Atema et al., 1980; Hara, 1982; Olsén et al., 1986).

Maximum energetic advantage (i.e., energy expended in hunting versus caloric value of the food consumed) may be obtained by use of a "chemical search image" shaped by recent feeding success on locally or seasonally abundant food types, and there is evidence that tuna respond preferentially to the odors of recently consumed prey species (Atema et al., 1980). However, for a chemical search image to be effective, the amino acid profile of a particular prey type must remain constant over time and be qualitatively similar between different schools of the same species. Furthermore, to provide arousal and, possibly, chemotactic cues, the prey odors must stay above detection thresholds even in the face of the immense dilutions possible in the open ocean. Detection thresholds for yellowfin tuna are around 5×10^{-6} g/liter for squid rinse (Yost, 1988) and estimated as 1×10^{-11} M for single amino acids (Atema et al., 1980). However, this estimate was extrapolated from minimum detectable amino acid concentrations in complex prey stimuli and is in the range of background concentrations found in ocean water (Carr and Derby, 1986).

There were two principal objectives of the current study: first, determine whether the amino acid profiles of tuna prey species were consistent over time and between schools, and second, because our previous attempts to separate prey rinses into discrete molecular weight fractions were consistently confounded by the presence of small-molecular-weight compounds in the supposedly pure large-molecular-weight fractions, investigate the possibility that amino acids were being entrained in the lipid components of the prey rinses.

METHODS AND MATERIALS

Rinses of the following prey were analyzed: (1) Hawaiian mackerel—"opelu" (*Decapturus macarellus*), (2) Hawaiian anchovy—"nehu" (*Stolephorus purpureus*), (3) bigeye scad—"akule" (*Selar crumenopthalmus*), and squid (*Loligo sp.*). Specimens were collected live from fishermen, from the wild, or from a local wholesale fish auction. In all cases, contact with possible contam-

inants was nonexistent or minimal. For the fish species, rinses were obtained through gentle washing of fresh dead whole prey in an agitating bath of either fresh- or saltwater for about 20 min. Washing was always terminated before any rupturing of the gills occurred. Squid rinses were obtained in the same way from previously frozen specimens. The rinses were filtered, and analyses were performed on both the fresh and lyophilized product.

Amino acid content of the rinses was determined by ion-exchange chromatography using a Beckman autoanalyzer with ninhydrin postcolumn derivatization. The lipophilic components of the prey rinses were Soxhlet-extracted using dry methylene chloride or chloroform. These extracts were then analyzed with high-performance thin-layer chromatography (HPTLC). The quantities of the various lypophilic compounds were ascertained using enzymatic methods of analysis (Anon., 1987).

Opelu rinses were prepared for electron and fluorescence microscopy by filtering the prey rinse through a Whatman No. 1 paper, followed by centrifugation at 5000 rpm for 20 min. For fluorescence microscopy, 2-ml aliquots of rinse were mixed with equal volumes of the derivitizing agent *o*-phthalaldehyde (Pickering Labs., Mountain View, California), which is specific for primary amine-bearing compounds (Chen et al., 1979) and which was prepared by dissolving 80 mg in 10 ml of 100 mM borate buffer, pH 9.4, and adding 100 μl of β-mercaptoethanol. One drop of derivatized prey rinse was viewed under UV illumination (340 nm) and observed through a 4-nm narrow band-pass filter. The image was captured with a video attachment interfaced with an IBM XT computer. Samples of opelu rinse for electron microscopy were stained with either phosphotungstic acid or uranyl acetate, both 2% in seawater. To ensure that the lipid vesicles were not an artifact of the centrifugation procedure, a sample of crude, filtered opelu rinse was scanned for the presence of liposomes.

Fluorescence spectroscopy was conducted on fresh opelu rinse diluted 1:20 with filtered seawater and excited with UV light at 280 nm. The intrinsic fluorescent properties of tryptophan (Trp) allowed us to utilize this amino acid as a probe to determine the location of amino acids occurring in the prey rinses. Fluorescence-quenching studies were conducted by adding increasing concentrations of potassium iodide to the prey rinse and measuring the degree of quenching with a multifrequency phase fluorometer (Alcala et al., 1985). Prey rinses were also analyzed with ^{1}H NMR techniques in which the emission spectra of Trp in opelu rinse was compared with the spectra of free Trp in deuterated seawater.

Behavioral bioassays, which quantify the responses of captive tuna to the presentation of dilute chemical stimuli, were conducted as described by Atema et al. (1980). A small school of tuna (three to five animals) was tested daily and their responses quantified by an observer who did not know the nature of the stimulus. Responses were ranked on a scale of 0 to 9, with 0 being no

response and 9 a very strong behavioral response. The fish were fed to satiation on the day before testing to minimize variations in response intensity due to hunger motivation. The stimuli were presented in a quasirandomized sequence with trials separated by about 1 hr. Responses to the whole squid rinse served as a measure of the tuna's responsiveness on each day and allowed evaluation of the relative efficacy of the test stimuli.

Four types of stimuli were used: (1) pure lipids produced from soybean lecithin (0.9 g/500 ml starting concentration); (2) reconstituted squid amino acid profile (0.5 g/500 ml); (3) reconstituted amino acid profile (0.5 g) plus soybean liposomes (0.9 g/500 ml); and (4) a control stimulus of lyophilized whole squid rinse (0.5 g/500 ml). The lipids and lipid–amino acid mixtures were sonicated for approx. 15 min to promote the formation of lipid complexes in the form of liposomes (Naoi et al., 1977; Klein et al., 1971).

RESULTS

The amino acid profiles proved to be species specific and consistent across replicate samples of each species taken over a period in excess of two years (Figure 1). In addition to these physiological amino acids (i.e., those occurring naturally in proteins), taurine was also found in the rinses of all prey species and was incorporated into the artificial amino acid mixtures. Microscopic examination using ultraviolet (UV) illumination of fresh rinses combined with the derivatizing reagent *o*-phthalaldehyde revealed that fluorescence was localized within the lipid structures and absent from the background medium, thereby verifying that amino acids were sequestered in the lipid domain.

The emission spectra of prey rinses excited at 280 nm demonstrated a Trp fluorescence that was blue-shifted by up to 30 nm compared with the emission maximum of 355 nm observed for Trp in pure seawater, indicating that Trp was complexed within the lipid structures. Quenching of this Trp fluorescence with potassium iodide resulted in Stern-Volmer plots (Lehrer, 1971), which indicate that the Trp associated with the liposomes was substantially shielded relative to Trp free in solution (Figure 2). The fluorescence lifetime of Trp in liposomes was also found to be heterogeneous and lengthened (average = 3.6 nsec) compared to Trp free in solution (average = 2.9 nsec), which supports the conclusion that Trp is associated with lipid matrices in the prey rinses.

Further indication of lipid–amino acid complexation was acquired from ^{1}H NMR examination of the rinses. Spectra of Trp in the presence of liposomes formed both with lipid extracts from the prey fish rinses and from standard lipid mixtures showed chemical shift and line broadening when compared with spectra of free Trp in deuterated seawater.

Examination of rinses under the electron microscope revealed classic mul-

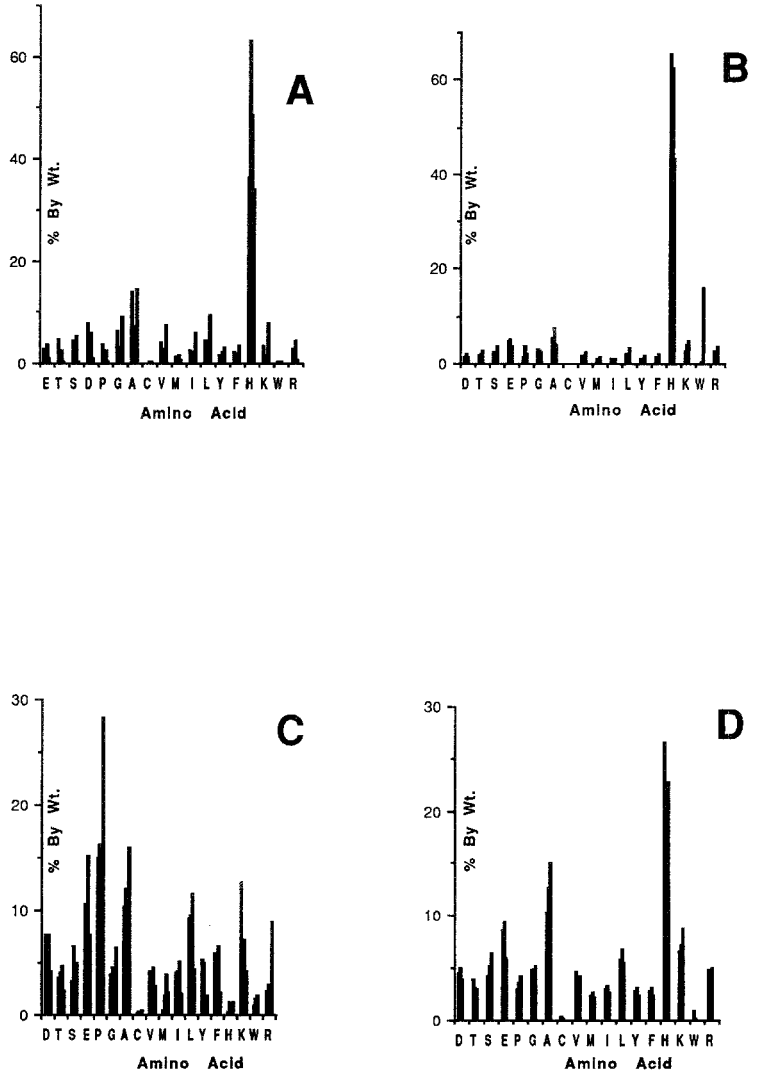

FIG. 1. Amino acid profiles of the aqueous rinses of four tuna prey species. (A) Opelu: profiles of rinses from four schools acquired over a period of two years. (B) Akule: profiles of rinses from three samples collected over two years. (C) Squid: four profiles of rinses sampled over two years. (D) Nehu: profiles of samples from three separate schools of fish taken from Kaneohe Bay, Oahu, Hawaii, over a period of approximately three years. Amino acids are as follows: A, alanine; C, cysteine; D, apartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; P, proline; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

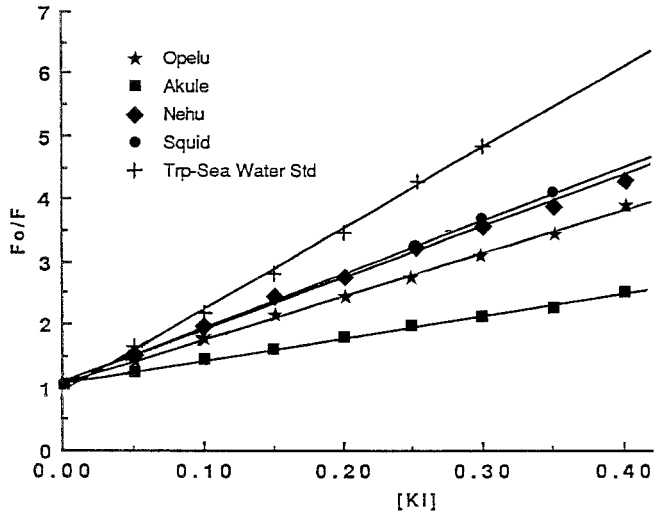

FIG. 2. Stern-Volmer iodide quenching plots of the rinses of four tuna prey species and plain sea water. F_0 = fluorescence intensity of Trp in the rinse in the absence of quencher; F = Trp fluorescence intensity with quencher. The flatter slope of F_0/F for the prey rinses relative to Trp free in solution indicates that Trp is occluded to varying degrees within lipid matrices in the rinses of each species.

tilamellar onion-skin structures, which are usually associated with the formation of liposomes (Figure 3). These structures were observed in both the centrifuged and crude opelu rinses.

HPTLC analysis of the extracts revealed the presence, in all species, of cholesteryl esters, cholesterol, free fatty acids, glycero-fatty acid triesters, and phospholipids.

The behavioral response intensities of captive tuna to the various stimuli are shown in Table 1. Kolmogorov-Smirnov chi-square approximation analysis of the behavioral data indicated that response intensities to the reconstituted squid amino acid profile and to the same profile complexed with soybean lipids were not significantly different. They were both significantly better stimuli than the lipids alone, but evoked significantly weaker responses than the squid odor control. The average response to the amino acid–liposome mixture was 62% as strong as responses to the unaltered squid odor.

DISCUSSION

The specificity and constancy of the amino acid profiles among schools of the same species, in some cases over periods in excess of two years, supports the concept of chemical search images as a viable foraging technique for tuna.

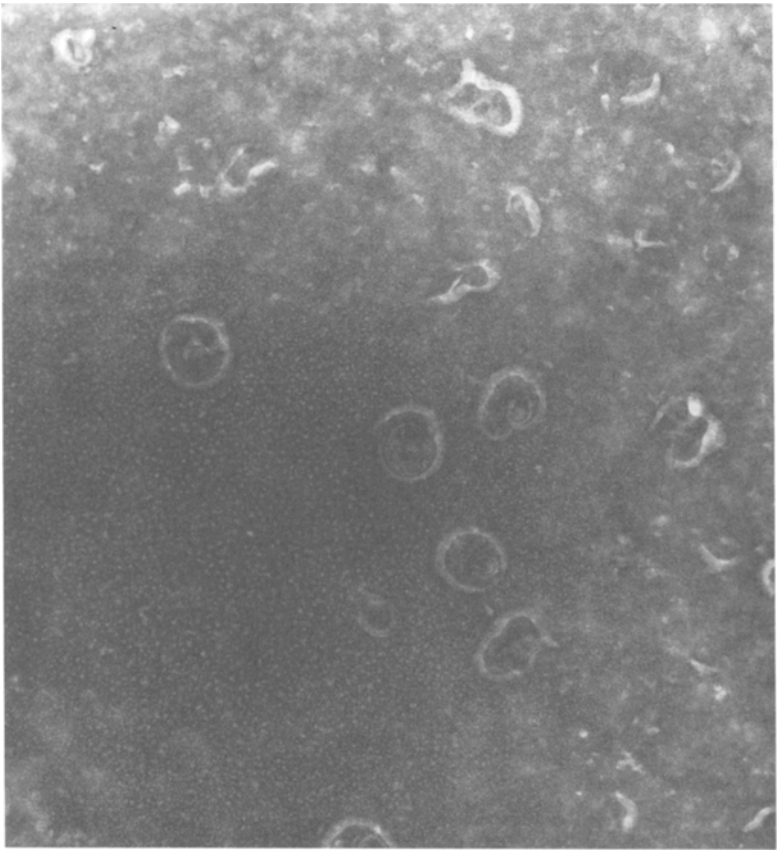

FIG. 3. Transmission electron micrograph of opelu seawater rinse at 127,500×. Lipid vesicles display the classic onion-skin structure of liposomes.

TABLE 1. BEHAVIORAL RESPONSE INTENSITIES TO OLFACTORY STIMULI

Stimulus type	Average response intensity (SD)	Number of trials
Soy bean liposomes	0.8 (0.8)	9
Amino acid mixture	3.0 (1.6)	7
Soy liposomes plus amino acid mixture	4.4 (0.5)	9
Whole squid (control)	7.1 (1.0)	11

These chemical search images may heighten appetitive feeding behavior in response to the odors of previously consumed prey (Atema et al., 1980) and thereby improve foraging efficiency. Even without a learned response to a particular prey species, the predictable nature of the prey odors could facilitate innate responses to specific food types. The qualitatively similar profiles of opelu and akule perhaps reflect the fact that they are both in the family Carangidae.

Amino acids appear to be routinely bound into a variety of biogenic lipid structures. The presence of tryptophan fluorescence in the liposomes, and its absence in the background medium, suggests that a large portion of amino acids emanating from prey are incorporated into lipid complexes. The HPTLC results indicate that lipid compounds suitable for liposome formation are present in the prey rinses. The rate of efflux of a particular amino acid from lipid vesicles is determined by the size and complexity of the lipid structure, the type of lipids from which the liposome is constructed, pH, and temperature (Klein et al., 1971; Naoi et al., 1977). Therefore, the time course of amino acid elution from liposomes in the open ocean will be variable, but it is probable that the lipid complexation significantly delays the dilution of prey odors to subthreshold levels.

The similar behavioral response intensities to the free amino acids and to the amino acid–liposome mixture indicate that lipid complexation does not significantly alter the biological potency of prey amino acid profiles. The reconstituted amino acid–lipid mixtures were not as effective as the whole rinse, but this is consistent with results from tuna and other species, which indicate that, although amino acids are important components of prey odors, there are other compounds present in the natural stimuli that contribute to their total effectiveness (Carr and Derby, 1986; Atema et al., 1980; Holland, 1978; Carr and Chaney, 1976). Diminution of maximum stimulus strength is probably less important to a passing school of tuna than the prolonged suprathreshold dwell time induced by lipid complexation of the amino acids. This would improve the chances of the tuna detecting the presence of food beyond visual range and possibly provide orientation cues for subsequent food search behavior.

Even though the amino acid profiles were temporally and spatially consistent and may permit olfactory recognition of the type of prey, lipid complexation may modify the profile detected by the predator because different amino acids elute from liposomes at different rates (Klein et al., 1971). Thus, the perceived prey profiles may well be constant, but somewhat modified, from those determined by our methods of analysis. This could explain why amino acid profiles constructed from ninhydrin-based analyses do not match the biological potency of the original natural stimulus. We believe this is the first demonstration of biogenic liposomes mediating interspecific interactions and that lipid structures may have a widespread role in the semiochemistry of aquatic chemoreception.

Abstract—The structural analog of amino acid L-arginine, L-canavanine (2-amino-4-guanidinooxybutyric acid), is found in 26 cultivars of alfalfa. Its concentration ranges from 6 to 16 mg/g of dry seeds. Canavanine represented more than 70% of the total soluble nitrogen in seeds. Practically all of the canavanine was stored in the cotyledons. Comparison is made of the canavanine content in the cultivars Verko and Europa harvested in different years. During sprouting, 29% of the guanidinooxy compound was translocated into the hypocotyl and radicle in 24 hr. In this early stage of seedling development, the level of the nonprotein amino acid, canavanine, increased threefold whereas the protein amino acid, arginine, as well as asparagine increased 11- and 35-fold, respectively. Two-day-old seedlings are capable of synthesizing canavanine derived from canaline up to 25%. Contrary to this finding in seedlings grown in the time range of 24 days, the guanidino compounds canavanine and arginine were metabolized rapidly, whereas asparagine increased. Furthermore, the toxic canavanine got into the environment of swelled seeds or into the rhizosphere of young seedlings and increased in the milieu to concentrations at 3–57 μM. In a biotest, this inhibited the growth of a tomato cell suspension culture as well as the growth of cabbage radicle.

Key Words—Canavanine, arginine, asparagine, amino acids, root exudates, growth inhibition, alfalfa, *Medicago sativa*.

INTRODUCTION

The nonprotein amino acid canavanine (2-amino-4-guanidinooxybutyric acid) is a structural analog of L-arginine (2-amino-5-guanidinovaleric acid) and its metabolic antagonist (Rosenthal, 1977a, 1991; Natelson, 1985a; Lavin, 1986). This toxic compound is stored in the seeds of many leguminous plants (Rosenthal, 1977a; Lavin, 1986). During the imbibition and germination of seeds the nitrogen-rich canavanine is mobilized and degraded, resulting in the formation of aminooxy acid canaline and urea (Töpfer et al., 1970; Bell et al., 1978; Downum et al., 1983; Rosenthal, 1990). Contrary to this finding, canavanine increased in the first days of cultivation of the sword bean, *Canavalia gladiata* (Jaqu.) DC (Fujihara et al., 1986) and alfalfa, *Medicago sativa* L. (Kasai and Sakamura, 1986). In seedlings of *Medicago sativa* L. (Miersch et al., 1988) and *Canavalia ensiformis* (L.) DC (Rosenthal, 1972) the toxic amino acid canavanine was localized in roots, leaves, and stems. Obviously, distinct canavanine-free (or very low) stages of growth periods can be detected in the life cycle of *Medicago* (Miersch et al., 1988), whereas *Canavalia* is a canavanine-containing legume during the whole growing time (Rosenthal, 1977b; Fujihara et al., 1986).

In this paper, some experiments are carried out to clear up the following points: (1) the distribution of canavanine in seeds as well as in the developing seedlings of alfalfa, and (2) the secretion of canavanine into root space and the growth inhibition of receptor plants.

METHODS AND MATERIALS

Seed Material and Cultivation of Alfalfa. Seeds of alfalfa (*Medicago sativa* L.) were gifts of various institutions (see Table 1). The seeds were germinated and the seedlings were cultivated under sterile as well as nonsterile conditions according to Gorski et al. (1991).

Biotests. The influence of canavanine was measured on cell growth of tomato suspension culture (*Lycopersicon esculentum* MILL., cv. Lukullus) described earlier (Grancharov et al., 1985). The experiment was started by inoculation of cells and application of filter-sterilized solution of canavanine at concentrations of 10^{-3}–10^{-6} M.

The inhibition of radicle growth of cabbage (*Brassica oleracea* L.) was estimated during a period of seven days at 20°C and 6000 lux. For example, 40 seeds of cabbage (control) and 40 seeds of cabbage and 40 or 80 seeds of alfalfa were placed on a paper disk in Petri dishes of 8 cm diameter saturated with 5 ml of water. After seven days, the radicle length of the cabbage was measured.

Statistical Analysis. The data were analyzed statistically according to Weber

(1986) by variance (*F* test), comparison of average root length (Student's *t* test) and homogeneity (chi-square test).

Canavanine Analysis. This amino acid was quantified by colorimetric estimation with pentacyanoammoniumferrate (Fearon and Bell, 1955) with respect to results obtained by other groups (Rosenthal and Dahlman, 1982; Natelson,

1985a; Brune et al., 1988). The standard deviation was determined to be 15% at 5 μg/ml and 2% at 70 μg/ml sample.

Small amounts of canavanine were verified by TLC analysis of dansylated canavanine on polyamide sheets (Woods and Wang, 1967). The detection limit was found to be 10^{-12} M canavanine.

Amino Acid Analysis. Aliquots of extracts were subjected to amino acid analysis using an amino acid autoanalyzer (type AAA 881, Microtechna, Prague, CSFR) according to the method of Spackman et al. (1951). In general, the standard deviation was measured to 8–10%. The calculation of the amide asparagine and glutamine was based on the estimation of aspartic and glutamic acid before and after hydrolysis with 6 N NCl for 1 hr at 80°C. After that, the samples were evaporated in vacuo to dryness and the residues dissolved in 0.01 N HCl. In this case, the standard deviation was measured to 15–20%.

Extraction Procedure. Plant material (100 mg to 2 g) was dried at 80°C for 4 hr, powdered, and then extracted three times with 10 ml of a mixture containing 50% aqueous ethanol, 0.4 N with respect to H_2SO_4. Seeds and cotyledons were shaken three times with 20 ml diethyl ether to remove lipids. After that, neutralization of the extracts was carried out by the addition of 2 N NaOH. If protein was precipitated, the extracts were centrifuged at 2000*g* for 10 min, and the supernatant as well as the aqueous milieu of the paper disks or sandy beds was fractionated by cation exchange chromatography on Dowex 50 WX8 (NH_4^+), 100–200 mesh, according to Rosenthal (1977c). The resin-bound canavanine was eluated by 50% aqueous ethanol, 0.35 N with respect to NH_4OH. All eluates were evaporated to dryness in vacuo below 40°C, and the residues obtained were dissolved in 1–2 ml of double-distilled water.

For measuring amino acids by an automatical analyzer, the same extraction procedure was used except: (1) the cation exchange resin used was changed to Dowex 50 WX8 (H^+), 100–200 mesh, (2) the resin-bound amino acids were eluated by 2 N NH_4OH in 50% aqueous ethanol, and (3) the residues were dissolved in 4 ml 0.01 N HCl.

Feeding Experiments. Seedlings of alfalfa were grown under nonsterile conditions in Petri dishes on paper disks for two days as described above. Then, 10 seedlings were fed through the roots with one of the following compounds, [U−^{3}H]canaline, [6−^{3}H]glucose and [6−^{14}C]glucose, dissolved in 500 μl double-distilled water in a time range up to 20 hr at 20°C and 4000 Lux. After the feeding time, the seedlings were harvested and canavanine isolated as described under "Extraction procedure" above. Further purification of canavanine was obtained by TLC on silica gel with the mobile phase ethanol–25% NH_4OH 77:23 (v/v) as well as electrophoresis on cellulose sheets (Takahara et al., 1978). The canavanine area from chromatograms or pherograms was localized and scraped off directly into scintillation vials containing toluene–PPO–POPOP scintillator. To determine the uptake of canaline, aliquots of the feeding solution

were also added to scintillation vials. The radioactivity was measured in a Packard-Tricarb-Scintillation Spectrometer, model 3380.

Chemicals. [U−^{3}H]Canaline (specific activity: 346 MBq/mmol) was obtained by enzymatical degradation of Wilzbach-tritiated canavanine sulfate (Zentralinstitut für Kernforschung, Dresden, Germany) using liver arginase according to Rosenthal (1973). The isolation and purification procedure was described by Miersch (1967). [6−^{3}H]Glucose (specific activity: 6.73 GBq/mmol) and [6−^{14}C]glucose (specific activity: 1.98 GBq/mmol) were supplied by UVVVR, Prague, CSFR, and Radiochemical Centre, Amersham, England, respectively. All other chemicals are commercial products from Germany.

RESULTS AND DISCUSSION

Canavanine Level in Alfalfa Seeds and Seedlings. Values of canavanine obtained ranged from 5.7 to 16 mg/g dry seeds for 26 European varieties of alfalfa (Table 1). Furthermore, the amount of this toxic amino acid depends on the origin as well as the year of collection, as demonstrated with the cultivars Verko and Europa (Table 1). These quantitations are in agreement with experimental findings of Tschiersch (1961), Natelson (1985b), and our earlier data (Miersch et al., 1988, 1990). In particular the amount of canavanine obtained from different samples of the cultivar Weevlchek can be variable and ranged from 1.4 to 2% (Natelson, 1985a).

It can be shown that nearly the whole amount of canavanine was stored in the cotyledons, while this toxic compound was found to be 0.6% in the testa (Table 2). In the testa of *Canavalia ensiformis* (L.) DC seeds, the guanidinooxy compound was only measured to 0.3%.

Besides canavanine, mainly histidine reacts with pentacyanoammonium-

TABLE 2. DISTRIBUTION OF CANAVANINE IN SEEDS OF ALFALFA (*Medicago sativa* CV. VERKO)

[b] In dry seeds the term means embryo and cotyledons.

ferrate (PCAF), yielding a pink complex (Rosenthal and Dahlman, 1982). This colorimetric method is more sensitive (eightfold) for the guanidinooxy compound (Natelson, 1985a, Brune et al., 1988) than histidine. Since the relative error of the PCAF reaction was measured for 5 μg and 70 μg/ml sample at 15% and 2%, respectively, the amount of histidine in biological samples is unimportant if the ratio of histidine to canavanine does not exceed 1:20 (Table 3). Additionally, a practical control of canavanine analysis was made by reducing the guanidinooxy compound using gaseous hydrogen on palladium oxide (Natelson and Bratton, 1984).

In young seedlings, the canavanine accumulation and degradation in relation to growth condition are shown in Figure 1. The catabolism and exudation of canavanine depends on the nutritional situation of growing seedlings (Figure 1C,D). In alfalfa plants cultivated under sterile conditions for 65 days, no canavanine was detectable using PCAF reagent (Miersch et al., 1988). This increase of the toxic amino acid during development of young seedlings (Figure 1, Table 3) is not explained by remobilization of a canavanine-containing compound because we could not find, e.g., higher levels of canavanylpeptides or canavaninosuccinic acid in seeds or seedlings. Feeding experiments have shown that lucerne seedlings cultivated for two days are capable of incorporating 24% of [^{3}H]canaline into canavanine in 12 hr (Table 4). The nonspecific incorporation of [6$-^3$H]- or [6$-^{14}$C]glucose is low (0.2%) under the same experimental conditions. Therefore, the incorporation of [^{3}H]canaline into canavanine was discussed via ureidohomoserine and canavanylsuccinate (Rosenthal, 1972). Besides [^{3}H]canavanine, a second ^{3}H-labeled compound was detected that was not homoserine. This unknown compound could be isoxazolidone, resulting from deamination, decarboxylation, and ring closure of canaline (Sugii et al., 1981).

The chromatographic separation of the main amino acids in extracts of mature seeds and seedlings is illustrated in Table 3. Extremely high levels of canavanine were measured in the seeds and far exceeded those of arginine and asparagine. Canavanine and arginine represented about 70% and 13%, respectively, which is in agreement with findings of *Canavalia* (Rosenthal, 1977b; Fujihara et al., 1986). The canavanine and arginine content increased during seedling development up to 29% and 23%, respectively, whereas asparagine and proline were enriched to 23% and 18%, respectively. Whereas canavanine was catabolized nearly completely, depending on cultural conditions (Figure 1), this amide is present for a long time in the lucerne plant (Bickoff et al., 1972; Girousse et al., 1991). During seedling growth, alfalfa represented a guanidino compound nitrogen-storage plant, which changed to an amide-nitrogen type. Proline accumulation that was observed can be also an auxiliary nitrogen storage in older plants or the result of environmental stresses (Nover et al., 1989).

Canavanine Exudation and Growth Inhibition. During the swelling of seeds

[a] Year of collection: 1987. Germination, cultivation of seedlings, and standard deviations are described in Methods and Materials: weight of seedlings is shown in Figure 1. Abbreviation used: SH = shoots, S = seeds, R = roots, E = exudates, + = trace, – = not determined.

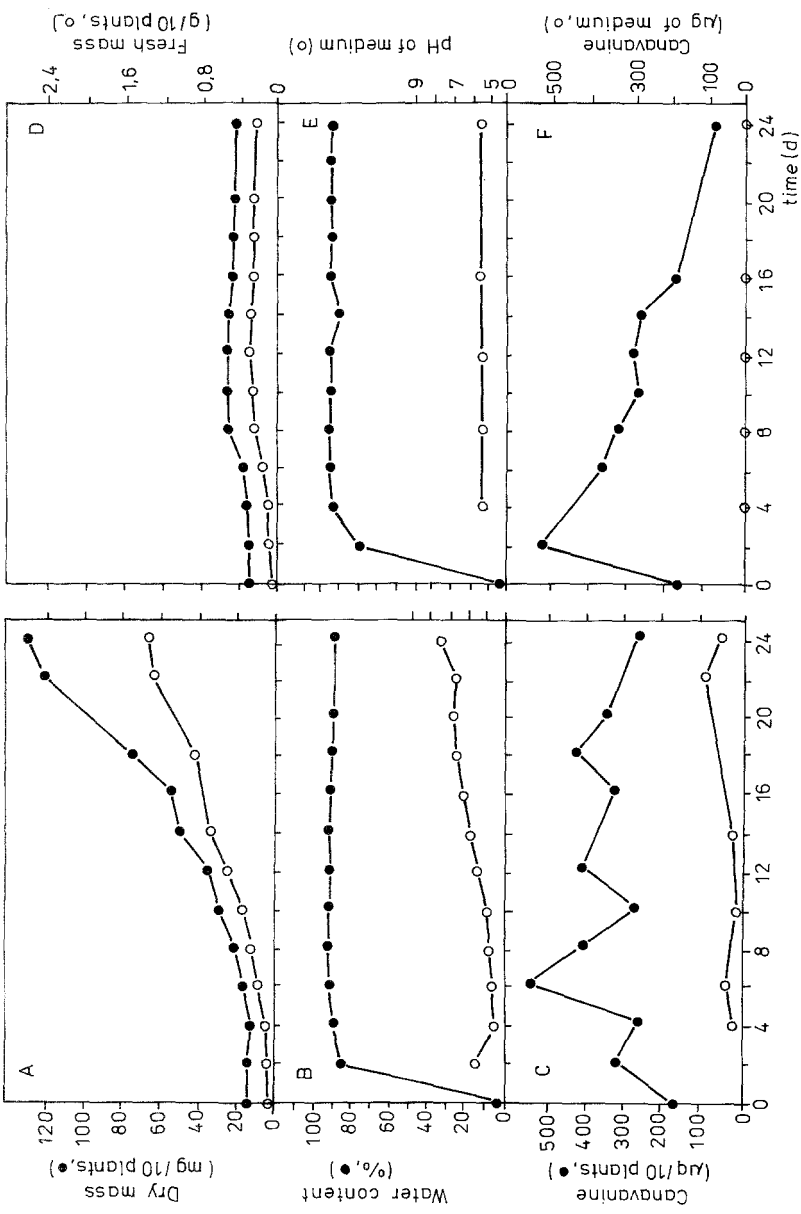

FIG. 1. Growth conditions and canavanine levels in seedlings and root exudations of alfalfa (*Medicago sativa* L. cv. Verko). Growth (A, D), water content, pH of medium (B, E), and canavanine levels as well as root exudates (C, F) of seedlings cultured in nutrition solution (A–C) or water (D, F).

and growth of seedlings, the storage compound was mobilized and released into the rhizosphere. Around seeds soaked in water, canavanine was found to be up to 8% of total amino acids or 13% of total canavanine in paper disks, but from roots of young seedlings this compound was released in nutrient solutions at a rate of about 1% of the total amount of amino acids (Table 3). The fluctuation of amino acids in root exudates of alfalfa (Richter, 1967) was also measured for canavanine, which ranged from 4% to 18% of total canavanine (Figure 1D, Table 3). This compound increased in the soil under experimental conditions to

such concentrations (Table 5) as to inhibit the growth of receptor plants. From experimental data, we could calculate a concentration of canavanine of 3–57 μM in the aqueous milieu of sandy bed or paper disks; 500 seedlings of alfalfa cultivated for four days under sterile conditions formed a concentration of canavanine of about 26 μM in the aqueous milieu of the sandy bed (Table 5). In the presence of microorganisms, the concentration of canavanine increased only to 8 μM (Table 5). With nonsterile conditions, no canavanine exudate was detected from roots of seedlings cultivated on water for 24 days (Figure 1F). Because canavanine at the 10 μM level inhibited the growth of tomato cells by 35% at the fourth day (Figure 2), we assume an allelochemical influence of canavanine on other plants surrounding the imbibed as well as germinated seeds. We also found growth inhibition in experiments with cabbage (*Brassica oleracea* L.) during seedling growth of seven days. In this case, the radicle length was significantly decreased to 51% and 81%, depending on the amount of alfalfa seedlings present (Table 6), and decreased to 41% by using 50 μM canavanine. Because canavanine was found in the solution, the sand, or on the paper disk, these inhibitory effects seem to be caused by canavanine or some other substances rather than by saponins (Gorski et al., 1991). Further experiments are in progress to demonstrate the release of root exudates by alfalfa grown under sterile as well as field conditions.

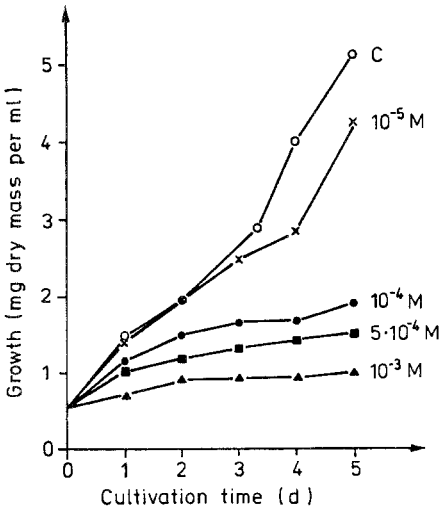

FIG. 2. Growth inhibition of cell suspension culture of tomato (*Lycopersicon esculentum* MILL. cv. Lukullus) by various concentrations of canavanine. Standard deviations were covered by symbols.

(Received April 20, 1992; accepted July 13, 1992)

Abstract—Foraging in trees by the Argentine ant, *Iridomyrmex humilis* (Mayr), was disrupted by a variety of synthetic chemicals, with the most effective chemical being farnesol. Testing of substrates for presentation of the disruptant chemicals gave some success with rubber or Tygon tubing, although best results were obtained through incorporation of the material into Stikem, which was then banded around tree trunks. Amounts of farnesol used for effective, long residual ant control were between 0.8 and 2 g per tree.

Key Words—Argentine ants, *Iridomyrmex humilis*, Hymenoptera, Formicidae, semiochemicals, ant repellents, farnesol.

INTRODUCTION

Ants are highly organized social insects whose communication with others of their species and with their environment is mediated largely through behaviorally

active chemicals (Hölldobler and Wilson, 1990). Some of the chemicals cause repellency or inhibition of ongoing behavior. For example, an alarm pheromone released from an ant that is injured or attacked may cause a variety of specific behaviors, including repellency, among nearby sister workers.

The alarm pheromones of some ants have received considerable study. An example is the genus *Atta*, in which the mandibular glands contain a rich medley of chemicals, many presumably functioning as alarm pheromone components. The discovery of citral in the mandibular glands of *Atta sexdens* dates back to Butenandt et al. (1959). Blum et al. (1968) later found nerol and geraniol in the mandibular glands of *Atta* species. The content of these glands was further studied by Schildknecht (1976), who found β-pinene, citral, farnesol, and 14 other compounds.

Another example of a chemical medley constituting ant alarm pheromones was identified by Lloyd et al. (1989), who found methyl salicylate to be a principal alarm pheromone component produced by workers of several species of honey ants, *Myrmecocystus* spp. A number of terpenoids found in the workers, including neral, geranial, citronellol, and limonene, presumably also possess ant alarm-pheromone activity.

The various species of *Formica*, when alarmed, spray mixtures of formic acid and Dufour's gland secretion toward the enemy, with the mixtures serving simultaneously as defensive substances and alarm pheromones (Maschwitz, 1964). In some genera of ants, alarm pheromones may originate simultaneously from as many as three different glandular sites, serving both a defensive and an alarm function (Hölldobler, 1977).

It is of interest that, although workers of the Argentine ant, *Iridomyrmex humilis* (Mayr), the species which serves as the object of the present study, contain many volatile chemicals, including a number of terpenoid compounds, such as iridomyrmecin, which have insecticidal properties (Cavill and Houghton, 1974), there is apparently no alarm pheromone reaction exhibited by workers of this species to their crushed sisters (Key et al., 1981).

Chemical-structure–biological-activity relationships have been investigated for alarm pheromone components and related chemicals for several ant species. Blum et al. (1966) tested a series of 49 ketones related to one of the natural alarm pheromone chemicals (2-heptanone) on *Iridomyrmex pruinosus*. The more the structure was varied from that of 2-heptanone in terms of numbers of carbon atoms or position of functional groups, the lower the activity of alarm behavior elicited by the chemicals. A similar result was obtained by Regnier and Wilson (1968) for *Acanthomyops claviger*; they found alkanes between 10 and 13 carbons in length elicited good alarm response (the natural alarm pheromone of this species is an 11-carbon alkane). Enantiomeric specificity of antennal receptor response to alarm pheromones has been demonstrated for *Atta texana* and *A. cephalotes* (Riley et al., 1974) and for *Pogonomyrmex barbatus* (Benthuysen and Blum, 1974).

Many behavior-inhibiting or repellent chemicals are kairomones, which are released by members of other species and ward off ants. Honda (1983) demonstrated a defensive potential against ants of the secretion of the larval osmeteria of papilionid caterpillars; they determined the active principal to be α-pinene. Scheffrahn et al. (1983) reported on a mix of six sesquiterpene hydrocarbons that is secreted onto the head surface of the North American termite, *Amitermes wheeleri*; a defensive function was proposed for the mixture, due to the avoidance behavior seen in foraging Argentine ants. A Nearctic desert termite, *Amitermes minimus*, produces 4,11-epoxy-*cis*-eudesmane, which was found to be repellent to the ant, *Crematogaster californica* (Scheffrahn et al., 1984a).

The ant, *Forelius foetidus*, secretes 2-heptanone which, when used singly, functions as an alarm pheromone. It also secretes *cis, trans*-iridodial, which, when mixed with 2-heptanone, elicits defensive behavior in *F. foetidus* and repellent behavior in two other ants, *Solenopsis maniosa* and *Crematogaster californica* (Scheffrahn et al., 1984b).

Ants prey on the brood of tropical social wasps (Jeanne, 1975; Post and Jeanne, 1981). The wasps' defenses include application of repellent substances to the nest support. One of the active components in the defensive secretion of *Polistes fuscatus* is methyl palmitate. Ants of several species are reluctant to cross barriers of methyl palmitate, or its methyl ester homolog, methyl myristate (Post and Jeanne, 1981; Post et al., 1984; Henderson and Jeanne, 1989).

Kistner and Blum (1971) found that staphylinid beetles of the genus *Pella* mingle with workers of the ant, *Lasius spathepus*, from which they take food and dead ants. They are generally tolerated by the ants, but, if attacked, they release citronellal, which has a dispersal-inducing effect. Huth and Dettner (1990) examined the abdominal gland secretions of 13 staphylinid species and found them to contain a rapidly polymerizing iridoid dialdehyde, as well as α-pinene, neral, geranial, nerol, and citronellol; the role of these chemicals presumably is to inhibit aggression and cause dispersal of ants.

Some secondary plant chemicals are potent ant repellents, and the occurrence of such compounds is widespread in nature. Various terpenoid chemicals are the most important chemical factors in determining plant deterrency to leaf-cutting ants (Hubbell et al., 1983, 1984; Howard, 1987; Howard et al., 1988, 1989; Bueno et al., 1990).

Ants must be considered as serious pests of a number of agricultural crops. The action of the ants is often indirect, in that they tend homopterous honeydew-producing insects such as aphids, soft scales, and mealybugs. Through their transporting of these homopterous insects to new growth on the plants, and through their role in warding off potential parasites and predators, ants may create situations where the tended insects assume serious pest status, whereas, in the absence of the ants, the insects would often be regulated through the action of beneficial predatory and parasitic species.

It is surprising that, with so much fundamental research having been conducted to elucidate the many naturally occurring compounds that repel or otherwise inhibit the activities of ants, these chemicals have received essentially no attention as possible agents for pest management. The research discussed here was initiated to investigate the degree of disruption of Argentine ant trail-following on the trunks of citrus trees that could be obtained through the use of a variety of behaviorally active chemicals, including many of those mentioned above.

METHODS AND MATERIALS

The research was conducted in a planting of young, nonbearing lemon trees at the Limoneira Company Ranch, Santa Paula, Ventura County, California. Trees were about 2 m high, and stem diameter ranged from 3 to 5 cm at 10 cm above the soil surface. The trees were heavily infested with a variety of honeydew-producing Homoptera, and the Argentine ants made trails from their nests in the ground, up the trunks to the vicinities of the insects they were tending.

A double layer of duct tape was wrapped around the trunks of trees, at about 10 cm above the soil surface. Candidate chemicals tested for disrupting ant trail following were placed on specified lengths of cotton twine or Tygon or rubber tubing, which were then wrapped two or three times around the tree trunk, over the duct tape. The tape was intended to protect the tree trunks from possible phytotoxic effects of the tested chemicals. Under most circumstances, the twine or tubing was held in position by staples driven through the duct tape and into the tree trunk. An exception to this procedure occurred in the case of Stikem or Tree Tanglefoot-impregnated cotton twine, the ends of which were tucked under the loops of twine wrapped around the trunk.

Chemicals tested were obtained from a commercial supplier (Aldrich). They are listed in Tables 1–5 below. When a given chemical was tested in conjunction with a carrier of sticky material (Stikem Special, Seabright Enterprises, Emeryville, California; Tree Tanglefoot, The Tanglefoot Company, Grand Rapids, Michigan) the sticky material was first thinned through heating; the specified amount of sticky material was then mixed with the candidate chemical; finally, this sticky material–chemical mixture was placed in a glass jar containing a specified length of Puritan cotton garden twine and was continuously agitated until essentially all of the mixture was incorporated in and on the twine.

Efficacy of disruption of ant trail following and foraging was evaluated on specified days following placement of the chemical-impregnated twine or tubing around tree trunks, by counts of the numbers of ants walking across the twine or tubing during a 2-min interval. Ants were counted without regard to whether they were proceeding up or down the trunk. Untreated control counts were made of ants crossing over a band of untreated twine around control tree trunks.

RESULTS AND DISCUSSION

Nineteen chemicals were tested for efficacy through the inoculation of 1 g of each onto 30-cm lengths of cotton twine, which were then wrapped around the trunks of test trees (Table 1). Each tree was regarded as a plot, and treatments were replicated three times in a randomized complete-block design. Counts of ants passing over the test twine were made on the sixth day following application. It was evident that farnesol had a high degree of ant repellent activity, with several other chemicals (methyl eugenol, β-citronellol, and bornyl acetate) also possessing good activity. A difficulty in interpreting these results is apparent in that it is not clear whether a lack of activity of a chemical after six days of exposure in the field is due to that chemical having an inherent low level of

[a] Lengths of (30 cm) cotton twine permeated with 1 g of candidate chemical were wrapped around tree trunks 10 cm above the soil surface; 1991.

[b] Each treatment chemical was replicated three times in a randomized complete-block design. Counts of ants crossing the barriers in 2 min were transformed to $\ln(X + 1)$ for ANOVA. Duncan's multiple-range test was performed on transformed means. Means in the same column followed by a common letter are not significantly (5% probability) different. Means presented here are transformed back to the original scale.

activity, or to the chemical having volatilized, oxidized, or otherwise become unavailable to the ants.

Testing conducted to evaluate the efficacy of methyl eugenol incorporated into Tygon tubing of three different sizes or into one size of rubber tubing, and of citral incorporated only into the rubber tubing, is summarized in Table 2. Through occasional agitation over a 24-hr period, approximately 1:1 incorporation of the chemicals into the Tygon or rubber was accomplished. Based on the efficacy of both chemicals on rubber tubing, methyl eugenol was seen to be more active in disrupting the foraging of Argentine ants than was citral. However, even at the heaviest application of methyl eugenol in Tygon, at about 13 g per tree, complete deterrence of foraging by ants was only seen for about one week.

Some of the better candidate chemicals found through earlier testing were mixed as either 10 or 40% solutions in Stikem, which was then incorporated at the rate of 2 g formulated material into 50-cm lengths of cotton twine (Table 3). The treated lengths of twine were placed around tree trunks as described above. Complete disruption of ant foraging for seven days after application was seen with the 40% farnesol treatment (giving 0.8 g farnesol per tree). By three

days after application, and continuing through 14 days, farnesol is seen to be more active as a disruptant than methyl eugenol, citral, or β-citronellol, although, as discussed earlier, this comparison may be confounded by differing rates of volatilization or degradation of the tested chemicals.

Farnesol and Stikem were tested at higher rates (Table 4). A farnesol-Stikem mixture was placed at 2 g of each material onto 50-cm lengths of cotton twine wrapped around tree trunks. Also tested were 30-cm lengths of rubber tubing, each containing 3 g farnesol. Farnesol alone, at 2 g per twine per tree, provided effective (over 90%) disruption of foraging by ants for about four weeks; rubber tubing containing 3 g farnesol per tree provided effective disruption for about seven weeks; and 2 g of farnesol in 2 g of Stikem provided effective disruption for 17 weeks (the last recorded reading).

Additional chemicals were tested as mixtures in Stikem (2 g of chemical in 2 g of Stikem) (Table 5). These were compared for efficacy with a farnesol-Stikem mix. Also tested were a farnesol–Tree Tanglefoot mix, Tree Tanglefoot alone, and Stikem alone. No significant difference is seen between Stikem and Tree Tanglefoot alone in disrupting ant foraging. Both materials were penetrated

almost immediately (within seven days) by significant numbers of foraging ants. However, farnesol mixed with Tree Tanglefoot gave effective disruption of foraging for seven weeks, and farnesol mixed with Stikem gave effective disruption for about 14 weeks. None of the other tested materials gave ant foraging disruption comparable to that provided by farnesol.

These experiments have shown that foraging in trees by the Argentine ant can be disrupted by a variety of synthetic chemicals. The most effective chemical found to date is farnesol, although an extensive, systematic search for disruptants has not been undertaken. Our evaluation of substrates for presentation of the disruptant chemicals had indicated some success with rubber or Tygon tubing, although best results to date have been obtained through incorporation of the material into Stikem-impregnated cotton twine, which was then banded around tree trunks. Presumably, the Stikem decreases the rate of volatilization and/or degradation of the chemicals. The use of chemical plus Stikem has some appeal, because Stikem is presently used to prevent certain insects from climbing tree trunks; farnesol apparently greatly extends the effective life of Stikem. Amounts of farnesol used to afford effective ant control were between 0.8 and 2 g per tree. These amounts should be subject to reduction through determining single chemicals or mixtures of chemicals that possess higher levels of activity than farnesol and determining more effective substrates for presentation of the materials in the field. Antioxidants also may prove useful in prolonging the activity of the most promising materials.

Book Review

Chemical Communication: The Language of Pheromones. William C. Agosta. New York: Scientific American Library, 1992. 179 pp.

Chemical ecology has come of age. Professor Agosta, head of the Laboratory of Organic Chemistry at Rockefeller University is the perfect author to present the field to a larger audience. He works on the cutting edge of the field himself and combines an amazing breadth of biological and chemical knowledge with the clear, enticing style of a good journalist. This superbly written book moves along like a fast-paced video. It brings together members of the diverse discipline of chemical ecology. Laid out taxonomically, in seven chapters, the book features the key players in a vivid history of discovery.

Dr. Agosta highlights some landmark research, such as the identification of the first bark beetle pheromone by R.M. Silverstein and D.L. Wood. The golden hamster's mating pheromones, studied in Dr. Agosta's laboratory, are covered in detail: Among other facets, only 200 molecules of dimethyl disulfide suffice to attract the male to a female odor source!

Pheromones can signal established fecundity. David Crews found that the female red-sided garter snake makes a pheromone from vitellogenin. The liver sends vitellogenin not only to the ovary for eggs, but also to the skin. Here it remains until the following year to form a pheromone that exudes through the skin. Thus, this year's amount of pheromone signals to a male last year's number of eggs. A male chooses a large female with a high level of pheromone and thus many eggs.

The chemical language of insects can be complex: ants use 10–20 different signals to coordinate their colony, most of them chemical (E.O. Wilson, B. Hölldobler). The honeybee uses more than 30 chemical signals. In invertebrates, odor–response relationships are more direct, "hardwired" than in vertebrates. In Agosta's example, three pinched sea slugs will all recoil and secrete their alarm pheromone. Pinch three dogs and you can expect all kinds of responses.

Other complexities challenge the investigator. Simple stimulus–response relationships between one compound and a specific behavior are only one of many ways to code information. Pheromones often are mixtures of compounds. In garter snakes, the male recognition pheromone contains squalene, which is absent in females, but other compounds enhance the effect of squalene. In the golden hamster, one compound, dimethyl disulfide, accounts for 60% of the attractive power of vaginal secretion, but full activity requires most or all of the

0098-0331/92/1100-2143$06.50/0 © 1992 Plenum Publishing Corporation

other volatiles (A.G. Singer, R.J. O'Connell, and W.C. Agosta). Several pheromones can control behavior sequentially. For instance, the mating behavior of certain ticks is guided by three pheromones. First, dichlorophenol from the female attracts the male. Then, cholesteryl oleate (from blood diet) induces the male to mount the female. Finally, a mixture of fatty acids with 14, 16, 18, and 20 carbon atoms from the digestive tract of the female facilitates actual copulation. In goldfish, a steroidal sex pheromone from the female stimulates milt production in the male. After that, a prostaglandin attracts the male.

We have been weaned from the notion that pheromones have to be unique compounds. Common, even ubiquitous compounds, can still be pheromones. Brown algae use several hydrocarbons; the soybean cyst nematode, vanillic acid; mites, 2-hydroxy-6-methylbenzaldehyde; and garter snakes, squalene. Furthermore, the same or closely related compounds crop up in vastly different species: prostaglandins as hatching pheromone in barnacles and as sex attractant and hormone in goldfish. *exo*-Brevicomin is found in the aggregation pheromone of bark beetles and dehydro-*exo*-brevicomin in male mouse urine. Finally, two related animal species may use the very same mixture of compounds. The dog ticks *Dermacentor variabilis* and *D. andersoni* share the same mixture of fatty acids as copulatory pheromone, but *D. andersoni* females have 12 times as much pheromone as *D. variabilis*.

Pheromones may derive from the diet, either directly or via precursors. The western pine beetle *Dendroctonus brevicomis* uses myrcene from ponderosa pine directly as a constituent of its aggregation pheromone. Female ticks take up cholesteryl oleate with their blood meal. This compound signals to the male that a host is available. The male then mounts the female. The male bark beetle *Ips paraconfusus*, aided by gut bacteria, converts myrcene into ipsenol and ipsdienol; α-pinene is converted into *cis*-verbenol. These together form the aggregation pheromone. The male queen butterfly's danaidone is a pyrrolizidine alkaloid, made from ingested plant alkaloids. The male stores 80% of the toxic alkaloids in his reproductive accessory glands and transfers them to the female during copulation. The female in turn incorporates these compounds into her eggs, where they deter predators.

From hormone to pheromone or vice versa? How certain animals use chemical signals may shed some light on the evolution of their communication system. In the goldfish, a steroidal hormone first serves as hormone to stimulate egg production and later as a pheromone that stimulates milt production in males, as mentioned above. Likewise, a prostaglandin as hormone stimulates spawning and as pheromone attracts the male. Another "hormone-to-pheromone" is testosterone when it serves as sex attractant in the urine of the male sea lamprey. Conversely, as unicellular organisms evolved into metazoa, they may have incorporated their original intercellular, interorganismal pheromones into their tissues as hormones for now internal use.

Practical applications of pheromones have scored some spectacular successes. One is the treatment of California cotton fields with gossyplure, the female pink bollworm's sex attractant, to disrupt mating. The other is monitoring the populations of pest insects such as bark beetles or the medfly over vast areas by attracting them to sticky traps scented with sex or aggregation pheromones. At the same time, Dr. Agosta clearly points out how biological, political, and commercial factors limit the applications of pheromones.

Tantilizing leads abound in this still-young field. Examples: (1) the female pheromone in urine of the economically important common blue crab has not been identified yet. (2) Little is known about pheromones in spiders. (3) The dog pheromones are still elusive.

To produce this slender volume that ranges over a broad area of chemical ecology, many topics are inevitably omitted. Thus, Agosta does not use the term "priming pheromones," although he discusses priming effects in goldfish and house mice. He discusses geometric isomers but does not mention enantiomers at all. Another minor point: Amphibia also have a vomeronasal organ.

The illustrations are superb. It is here that the only (merely minor) typos and inconsistencies occur. The final editing of the figure captions probably was beyond the control of the author. The index is much too short. One cannot find Bruce effect, pregnancy block, or priming pheromones, or many other topics discussed in the text. A very clear glossary will be most helpful to the unitiated. In all, I highly recommend this excellent book. It is very worthwhile for specialist and lay reader alike, and real fun to read.

Book Review

Microbial Mediation of Plant–Herbivore Interactions. P. Barbosa, V.A. Krischik, and C.G. Jones (eds.). New York: John Wiley & Sons, 1991. $98.00 hardcover, 530 pp. + xiii.

The study of plant–herbivore interactions in a bitrophic context had been qualified as too narrow a view in 1980 by Price and coworkers. This influences many researchers to include the third trophic level, represented by predators and parasitoids of herbivores. The study of three-trophic-level interactions involving macroorganisms had flourished since the stimulating paper of Price et al. (1980) and has yielded a wealth of information on a wide variety of phenomena. However, most of the information is still rather idiosyncratic. This should not surprise anyone, because it is difficult to find patterns in systems in which both direct and indirect interactions occur. It is very important that facts are gathered, but it is as important to incorporate the facts into theory. Recently, attempts have been made to predict patterns instead of merely "collecting stamps" in macroorganismal tritrophic interactions (Price, 1991a, Hunter et al., 1992; Vet and Dicke, 1992). No one will be surprised that, apart from macroorganisms such as parasitoids and predators, microorganisms also affect plant–herbivore interactions. However, these usually invisible organisms have received much less interest in tritrophic studies of plant–herbivore interactions than macroorganisms. Yet, unraveling the influence of microorganisms on interactions between plants and herbivores may reveal that characteristics imputed to macroorganisms in fact reflect activities of microorganisms. The book *Microbial Mediation of Plant–Herbivore Interactions* seems to be a logical step in the development of integrated knowledge on microorganisms as mediators of herbivore–plant interactions. Previous steps were chapters in books with a wider scope: Jones (1984) in the book *A New Ecology. Novel Approaches to Interactive Systems*, edited by Price, Slobodchikoff, and Gaud; and Berenbaum (1988) and Dicke (1988) in the book *Novel Aspects of Insect–Plant Interactions*, edited by Barbosa and Letourneau. The present book runs the risk of being accused of making plant–herbivore interactions more difficult to understand than they already are, but its appearance is more likely to stimulate many researchers to unravel phenomena not yet understood.

Microbial Mediation of Plant–Herbivore Interactions deals with an enormously varied scope of effects of microorganisms. The book has five parts: an integrative prologue, and four parts on plant mutualists, plant pathogens, insect

0098-0331/92/1100-2147$06.50/0 © 1992 Plenum Publishing Corporation

mutualists, and insect pathogens, respectively. Thus, the book has the potential of being a manual of collected stamps, where the readers cannot see the wood for the trees. However, two of the editors, C.G. Jones and V.A. Krischik, provide a framework that gives a firm structure to the book. This is done in the first chapter by Jones, and also in the introductions to the different parts of the book by Krischik and Jones. In the first chapter, Jones stresses the importance of determining overall effects on performance of the insect to deduce the general ecological importance and evolutionary role of microorganisms. He subsequently develops an approach based on net effects to provide the book with a framework. In doing so, Jones hypothesizes on major selection pressures on plants, herbivores, and microorganisms. The value of his approach is evident from the sometimes counterintuitive predictions. Thus, this chapter is of great importance to the value of the book: the relatively limited knowledge of microorganisms as mediators of plant–herbivore interactions is presented in a conceptual framework that will stimulate future research to investigate the predictions made. In fact, this first chapter can be read as an excellent synopsis of the complete volume.

Despite this good framework, the main body of the book has chapters that are of varying interest, and the book could certainly have been less voluminous without losing essential information. The length of the chapters is rather variable (14–42 pages), with the longer chapters not always being the best ones.

The second part of the book (Plant Mutualists) is by far the longest one 270 pages). It contains chapters on the effect of symbiotic nitrogen-fixing bacteria, mycorrhizae, endophytes, and phylloplane microorganisms. The chapters by N.D. Johnson and B.L. Bentley (N_2-fixing bacteria) and by C.G. Jones and F.T. Last (ectomycorrhizae) are firmly based on the plant defense theory as developed by Coley et al. (1985) in which plant resources are the basis of plant defense. These are interesting chapters that strengthen my feeling that plant physiologists should be more involved in the study of plant–herbivore interactions. The chapters by K. Clay (endophytes) and by G.C. Carroll (plant-mutualistic fungi as antagonists of insects) are informative reviews and place plant defense in a tritrophic context involving microorganisms. The chapter by J.H. Benedict et al. points to interesting phenomena on the phylloplane, where the microflora may influence the production of plant volatiles that affect herbivore behavior. Despite some very exciting chapters, it is my feeling that this part of the book could have easily been shortened. For example, the chapter by Jones and Last had many repetitions; chapters 5 and 6 (by S.C. Rabatin and B.R. Stinner and by E.R. Ingham and R. Molina, respectively) have considerable overlap while chapter 4 (J.C. Moore et al.) is much more superficial in nature than several other chapters in this part of the book and lacks a clear message.

Part three, on plant pathogens, has a very exciting chapter by V.A. Krischik on specific or generalized plant defense. She points to the general nature of

plant defense that is effective against both plant pathogens and herbivores. The effects of this generalized defense on insect pathogens through sequestration may imply that plant defense aimed directly at herbivores has a boomerang effect through the effects on herbivore pathogens. It is interesting that defensive characteristics of plants that affect the behavior of natural enemies of herbivores through attracting these members of the third trophic level appear to be highly specific (Vet and Dicke, 1992). It seems that the specificity vs. generalized nature of plant defense is a topic that will appear in many future investigations of multitrophic level interactions.

Currently there is much interest in the effects of plant stress and plant vigor on herbivore performance (e.g., Price, 1991b; Mopper and Whitham, 1992). This issue is the topic of the chapter by P. Barbosa on plant pathogens and nonvector herbivores. However, it is remarkable to see that most literature cited in this chapter was published between 1960 and 1980, while relatively few citations are made to literature of the past decade. This is again a chapter (the longest of the book) that could have easily been shortened.

Part four, on insect mutualists, contains a very interesting and well-written chapter by R.A.I. Drew and A.C. Lloyd on the various aspects of the role of bacteria in the ecology of tephritid fruit flies. The chapter on symbiont-mediated detoxification in insect herbivores by P.F. Dowd provides food for thought about the potential abilities of insect herbivores to adapt to secondary plant chemicals. This adaptation may be much quicker than generally thought if, in fact, the detoxification is accomplished by symbiotic microorganisms.

Part five, on insect pathogens, has only two chapters; the one by J.C. Schultz and S.T. Keating on host-plant-mediated interactions between the gypsy moth and a baculovirus is among the best chapters of the book. These authors present both mechanistic data as well as the consequences for population dynamics, viral evolution, and gypsy moth evolution. This chapter again shows that a good understanding of interactions between different trophic levels may yield unanticipated effects: the influence of leaf chemistry on herbivores and their population dynamics may be far greater via an interaction with herbivore pathogens than by acting directly on the insect itself.

This book will be an eye-opener to many researchers who investigate plant–herbivore interactions. It will certainly stimulate those researchers to be alert for effects of microorganisms on herbivores, on plants, and especially on the interactions between the two. However, ideally it should also stimulate cooperation among entomologists, microbiologists, phytophatologists. In fact, it is striking that this book is dominated by entomologist authors. Yet, when seen in the development of the field of microorganisms as mediators of insect–plant interactions and given the stimulating contribution of the majority of this book to this development, I am certain that we will hear more exciting facts and theories. The information presented in this book is not only of interest for those

who study the interactions among plants, herbivores, and microorganisms; the book is worthwhile reading for all those interested in plant–herbivore interactions in general. In fact, there seem to be several parallels between patterns presented in this volume and patterns in tritrophic interactions involving macroorganisms exclusively. Comparing patterns in microorganismally mediated herbivore–plant interactions and macroorganismally mediated herbivore–plant interactions will be a fruitful effort that will contribute to our understanding of systems that comprise more than two interacting organisms.

Announcement

PHEROMONE TECHNOLOGY IN EUROPE AND THE DEVELOPING COUNTRIES

The International Organization for Biological and Integrated Control of Noxious Animals and Plants—West Palearctic Regional Section will hold a meeting at the Natural Resources Institute, Chatham, England, on May 10, 1993. Topics will include: basic technologies in pheromone research and development, case studies of pheromone application, and general issues such as mechanisms for multinational collaborations, problems of registration of pheromones, etc. For further information write to: OILB Pheromone Meeting, Peter Beevor or Lawrence McVeigh, Natural Resources Institute, Central Avenue, Chatham Maritime, Chatham, Kent, ME4 4TB, England; Phone: (44) 634 880088; FAX: (44) 634 880066/77.

Abstract—Pheromone traps baited with (+)-disparlure, *cis*-7,8-epoxy-2-methyocta-decane, captured males of *Lymantria dispar*, *L. monacha*, and *L. mathura* in northeastern People's Republic of China. *L. dispar* responded to the addition of olefin to (+)-disparlure-baited traps in a negative dose–response manner. Observations on site and seasonal capture of *L. dispar* and *L. mathura* are discussed.

Key Words—*Lymantria dispar*, gypsy moth, *Lymantria mathura*, Lepidoptera, Lymantriidae, pheromone, disparlure, *cis*-7,8-epoxy-2-methyocta-decane.

INTRODUCTION

Under a 1982 scientific agreement between the Chinese Academy of Forestry and the U.S. Department of Agriculture, Wallner et al. (1984) tested the attrac-

*To whom correspondence should be addressed.
[1]Lepidoptera: Lymantriidae.

tiveness of (+)-disparlure and its olefin precursor to gypsy moth, *Lymantria dispar* L., in two widely separated sites in the People's Republic of China (PRC). Their results indicated that the male response of Chinese gypsy moth was similar to that of North American gypsy moth, although there were significant differences between sites in male responses to the olefin precursor. During these 1982 tests no other lymantriid species were captured, although *L. mathura* (L.) had been observed feeding in one site (Dunhua) and *L. monacha* (L.) was known to be native to the area. *L. mathura* has not been reported as being attracted to (+)-disparlure and its analogs, whereas *L. monacha* has (Kovalev et al., 1980; Klimetzek et al., 1976; Vité et al., 1976; Schneider et al., 1974).

In 1983, under the same scientific agreement, a team of U.S. and PRC scientists traveled to Heilongjiang Province, in northeastern People's Republic of China, to investigate the natural enemy complex, biology, and behavior of the gypsy moth, *L. dispar*, and to continue the pheromone investigations initiated in 1982 (Wallner et al., 1984). We report here on a further test to clarify the effect of the olefin component and (+)-disparlure on capture of *L. dispar* in northeastern China, and on attempts to detect populations of *L. mathura* and *L. monacha* using (+)-disparlure baited traps.

METHODS AND MATERIALS

U.S. Department of Agriculture 3.8-liter milk carton pheromone traps (Schwalbe, 1981) were used in all tests. Traps were placed in six forest sites at the Provincial Forest Production Farm, Mengjiagang, Hunan County, Heilongjiang Province, PRC, in 1983. Gypsy moth larvae were collected in these sites three to four weeks prior to trap placement.

To determine the relative attractiveness of (+)- and (±)-disparlure and its *cis* olefin precursor [2-methyl-Z-7-octadecane], 36 traps were hung on July 21 in a 12-year-old *Larix* sp. plantation. The traps were arrayed in a complete randomized design with 15 m between each trap. Traps were hung from wood lathing nailed to tree trunks so that they were 0.6 m from the tree and 2 m above the ground. This test included seven disparlure/olefin treatments: 0.1 mg (+)-disparlure; 0.1 mg (+)-disparlure with 0.001 mg olefin; 0.1 mg (+)-disparlure with 0.01 mg olefin; 0.1 mg (+)-disparlure with 0.1 mg olefin; 0.1 mg (±)-disparlure; 0.1 mg (−)-disparlure; and 0.1 mg olefin. Each treatment was replicated five times. One unbaited trap completed the 36-trap design. Each trap contained a Vapona pesticide strip. The solutions of disparlure-related compounds were provided by B.A. Leonhardt, U.S. Department of Agriculture, Beltsville, Maryland. They were transported from the United States to the PRC in sealed ampules. In the Mengjiagang Biological Control Laboratory, the given amounts of each treatment were applied, each in 100μl of hexane, to cotton

wicks (1 cm long × 1 cm diam.) on the day they were placed in the field; the wicks remained in place throughout the experiment. Fresh disposable rubber gloves were used while baiting traps for each treatment.

To survey for lymantriid species in other sites in Mengjiagang, single traps were hung in five wooded sites where gypsy moth larvae previously had been collected (July 6–15). The five sites were 1–16 km apart and had the following composition: site 1, mixed second growth of *Q. mongolica*, *Betula*, *Corylus*, *Ulmus*, and *Tilia*; site 2, mixed second growth of *Q. mongolica*, *Corylus*, *Betula*, and *Malus*; site 3, mixed *Q. mongolica*, *Betula*, and *Salix* adjacent to a small *Larix* plantation; site 4, primarily *Q. mongolica* forest, with trees ca. 12.7 cm DBH; site 5, *Larix* spp. plantation, containing 18- to 20-year-old trees with a DBH of ca. 17 cm. Traps were hung (July 20–21) from branches of *Quercus mongolica* or *Larix* spp. Each trap contained a Hercon 4 × 25-mm PVC laminate wick with an inner polymer layer containing 0.5 mg (+)-disparlure (Paszek, 1984) and a 3 × 3× 0.03-cm piece of Vapona pesticide 7 (dichlorvos).

All traps were inspected at six- to seven-day intervals beginning on July 25 and ending September 8. On each visit, moths were collected and placed in containers labeled by trap number and date and returned to the laboratory for identification.

RESULTS

Table 1 and Figure 1 summarize the test to determine the relative attractancy of (+)-disparlure and olefin. *L. dispar* was found in 20 different traps representing all treatments except those baited with (−)-disparlure, olefin, or the unbaited trap. Traps containing only the (+)-disparlure had 44.2% of the 120 gypsy moths captured. With the addition of olefin, moth captures declined; traps with (+)-disparlure and 0.001 mg, 0.01 mg, and 0.1 mg olefin, respectively captured 29.2%, 11.7%, and 12.5% of all gypsy moths found in the 36-trap array. Seasonally, 84% of the 120 *L. dispar* trapped were caught in the two-week period of August 4–17. No moths were captured after August 24; traps were removed September 2.

A total of 1043 *L. dispar* were captured in the single traps baited with a Hercon (+)-disparlure dispenser; 333, 181, 154, 254, and 142 in the five sites, respectively. Peak capture (57%) of *L. dispar* in all five traps occurred August 11–17. The last *L. dispar* trapped ($N = 12$) occurred August 25–September 3. Traps were removed September 8.

Populations of *L. mathura* were detected in five of the six trap sites. The *L. monacha* were captured in site 5 during the second week of trapping; the trap also contained five *L. dispar*. *L. mathura* ($N = 23$) was captured in sites 1, 2, 3, 5, and 6. Ten were found in eight traps in the (+)-disparlure–olefin

TABLE 1. NUMBER OF *L. dispar* CAPTURED DURING 1983 IN PHEROMONE TRAPS BAITED WITH DISPARLURE ENANTIOMERS AND OLEFIN PRECURSOR, MENGJIAGANG, HUNAN COUNTY, HEILONGJIANG PROVINCE, PEOPLE'S REPUBLIC OF CHINA

Treatments/traps[a]	Traps (*N*)	*L. dispar* (*mathura*)					
		1	2	3	4	5	Total
1. 0.1 mg (+)-disparlure	5	9	0 (1)	26	9 (1)	9 (1)	53 (3)
2. 0.1 mg (+)-disparlure, 0.1 mg olefin	5	5	1	3 (1)	2	4 (2)	15 (3)
3. 0.1 mg (+)-disparlure, 0.01 mg olefin	4	3	4	3	4 (1)	lost	14 (1)
4. 0.1 mg (+)-disparlure, 0.001 mg olefin	5	4	3 (1)	4 (2)	3	21	35 (3)
5. 0.1 mg (±)-disparlure	5	0	0	1	0	2	3

[a] Traps were arrayed in complete randomized design with 15 m between each trap. Trap 5, treatment 3, was missing after first trap week. No lymantriids were caught in traps containing 0.1 mg (−)-disparlure, 0.1 mg olefin, or in the unbaited trap.

experiment; these traps contained either (+)-disparlure or (+)-disparlure and olefin. Seasonally, 20 *L. mathura* were caught in the first week of trapping (July 29–August 3), the other three were captured the following week, when the first *L. dispar* were captured. No *L. mathura* were found in traps with *L. dispar*.

DISCUSSION

Trap catches of *L. dispar* in (+)-disparlure- and olefin-baited traps in Mengjiagang, People's Republic of China, indicate a dose–response effect in which trap catch decreases as olefin concentration increases. This supports and further defines the response of *L. dispar* to disparlure-related compounds in northeastern China reported by Wallner et al. (1984). The response to the addition of olefin to (+)-disparlure-baited traps appears to be similar to the effect of the olefin on the attractancy of (±)-disparlure (racemic)-baited traps to North American gypsy moth (Cardé et al., 1973). They reported that when sticky "sectar" traps (model XC-26; 3M Company) were baited with both racemic disparlure and olefin, low concentrations of olefin suppressed attraction and higher concentrations "effectively inhibited attraction." In a subsequent study, Cardé et al. (1975) described olefin as having a dual effect depending on the "context of presentation"; when presented together with racemic disparlure, suppression of attraction occurs; when olefin is presented around any attraction source, an increase in searching occurs. The milieu of presentation of attractant

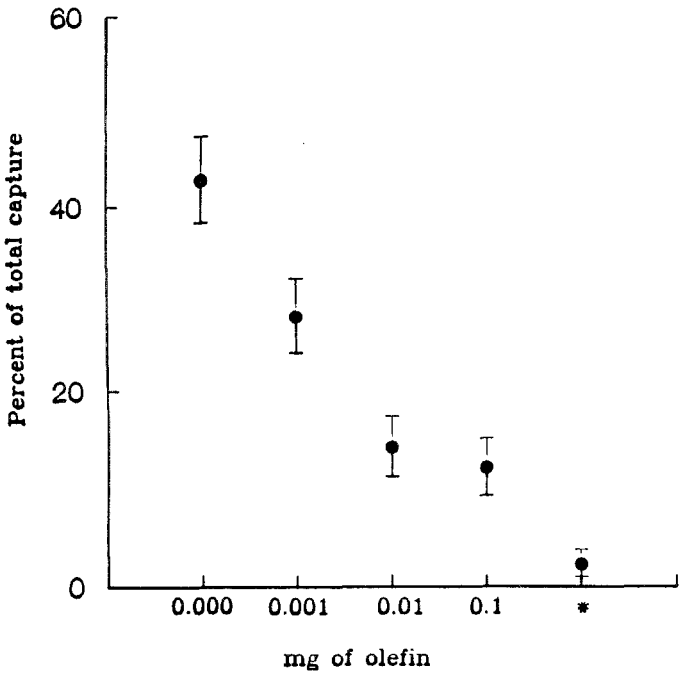

FIG. 1. The influence of olefin on trap capture of *Lymantria dispar* L.* (±)-Disparlure (0.1 mg).

and olefin in our study was random, and since searching behavior was not observed, the effect of olefin on searching cannot be addressed. However, suppression of attraction to individual traps containing both (+)-disparlure and olefin is apparent.

Only 120 moths were caught in the 36-trap array, with 53 of these found in traps baited with (+)-disparlure. In the five survey traps baited with Hercon (+)-disparlure dispensers, 1043 *L. dispar* were captured; each trap had more than the total caught in the test area. The difference in the emission rate of (+)-disparlure between cotton and Hercon PVC laminate wicks likely accounts for the disparity in captures. The apparent low emission rate of cotton wicks may also help explain the low capture of adults reported by Wallner et al. (1984); only 43 males were captured, but the 2500+ late-instar gypsy moth larvae collected in the same area suggests that population density in the predominantly oak forest was greater than moth capture indicated.

In our 1983 investigations in Mengjiagang, larval density was very low. In approximately 400 man hours of searching for and collecting *L. dispar* larvae, only 594 *L. dispar* and 1 *L. mathura* (on *Quercus* sp.) were collected. Larval

collections were made in all six sites in which traps were hung, but 71% were collected in the three *Larix* sp. plantations, sites 3 and 5, and the disparlure–olefin test site. Traps in these sites had the lowest seasonal capture of *L. dispar*. The success in finding larvae in *Larix* plantations may reflect the ease in finding them under bark flaps as compared to searching in the mixed hardwood areas with many other kinds of larval resting sites. The time spent searching in each of the six sites was approximately the same, but searching under bark flaps on *Larix* trees planted in rows, with sparse undergrowth, made our efforts more efficient and productive.

This is the first reported capture of *L. mathura* in disparlure-baited traps. However, the low number of *L. mathura* captured prevents definite statements on their relative attractancy to disparlure and olefin, or on other aspects of flight behavior. Our results do provide information that may be useful in designing other trapping experiments for evaluating *L. mathura*'s response to attractants and/or its seasonal and temporal flight periodicity. In contrast to the relatively low (35% of total) capture of *L. dispar* in *Larix* plantations, 78% of *L. mathura* were trapped in these sites, so trapping site may be important. This may be why the previous investigation (Wallner et al., 1984) was not successful in trapping this species: their traps were placed in predominantly hardwood areas. The low number and seasonal timing of *L. mathura* captures suggests that late July/early August was the latter part of its flight period and that traps probably should be arrayed earlier. Finally, although only one *L. mathura* larva was found, adult males were captured in five of the six trapping sites and in 12 of the 24 traps containing (+)-disparlure, so it is likely that this lymantriid species can be detected at relatively low population densities using the milk-carton trap and an appropriate attractant, perhaps (+)-disparlure.

Acknowledgments—We thank Joseph S. Elkinton and Victor C. Mastro for critical review of the original manuscript; Ring Cardé for a later version; Gerald S. Walton for statistical review; and the Ministry of Forestry, People's Republic of China and the USDA Office of International Cooperation and Development for providing support for this study.

(Received March 23, 1992; accepted July 23, 1992)

Abstract—The poison gland, which is the source of the trail pheromone in *Daceton armigerum*, contains a mixture of dimethylpyrazine, trimethylpyrazine and 3-ethyl-2,5-dimethylpyrazine in approximately equal proportions, similar to that of the ant *Manica rubida*. The cross-activity in trail-following tests with several other species can thus be explained. The Dufour gland of *D. armigerum* contains a mixture of 26 identified hydrocarbons, chiefly 9-tricosene, tricosane, and 9-pentacosene. It also contains very small amounts of two sesquiterpene aldehydes, tetramorine-2 and tetramorine-3, already known in other myrmicine Dufour glands. No volatile substances were detected in the pygidial gland.

Key Words—Ants, Hymenoptera, Formicidae, poison gland, Dufour gland, alkylpyrazines, tetramorine, trail following.

INTRODUCTION

The neotropical ant *Daceton armigerum* (Latreille), the only species in this myrmicine genus, is strictly arboreal and has been considered the most primitive species of the tribe Dacetini (Brown and Wilson, 1959). The division of labor

within a *Daceton* colony has been studied by Wilson (1962) and more recently Hölldobler et al. (1990) concluded a behavioral analysis of chemical communication signals from exocrine glands of *D. armigerum* workers. These latter authors demonstrated that workers were recruited to foraging trails when termite food was provided for them, and they observed workers extending their stings at irregular intervals. In further tests, they showed that the trail-following response came from the poison gland and to a lesser extent from a sternal gland.

These results were different from those of Blum and Portocarrero (1966), who failed to demonstrate trail-following in *D. armigerum*, but found that three attine ant species could follow trails drawn with *D. armigerum* poison gland secretion. Wilson (1962) found that *Solenopsis invicta* followed trails of *D. armigerum* Dufour gland secretions. Hölldobler et al. (1990) confirmed these interspecific responses by showing that *Atta cephalotes* workers followed *D. armigerum* poison gland secretions but ignored their Dufour gland secretions, while *Solenopsis invicta* workers ignored *D. armigerum* poison gland secretions but followed those of Dufour glands, although the species always had a preference for their own trails. *Daceton*, however, did not follow the other species' trails. *Daceton* workers clearly perceived their Dufour gland secretion, but did not follow trails of it, nor were they more than mildly attracted to it.

In order to learn more about the secretions of *D. armigerum*, we have made a chemical examination of the pygidial, poison, and Dufour glands of workers. The results given here explain the unusual interspecific effect in trail-following tests with the other species described above.

METHODS AND MATERIALS

A sample of workers from a colony of *Daceton armigerum* collected in 1988 at Imataca Forest Reserve, Venezuela, were dissected as described by Morgan (1990), and either the Dufour glands or the whole poison apparatus (including both glands) were sealed in glass capillary tubes (approx. 1.5 × 0.2 cm.) and sent to Keele where they were stored in a refrigerator for analysis.

The sealed samples of glands were subjected to gas chromatography by crushing them in a solid sampling device (Morgan and Wadhams, 1972), which transferred the volatile material directly to the chromatography column, which in turn was linked to a mass spectrometer. Gas chromatography was carried out as described by Bagnères et al. (1991). For analysis of Dufour and pygidial glands, the sample was heated for 3 min in the injection area (220°C) before crushing. The oven temperature was initially 120°C and increased at 5°C/min to 270°C. For the poison glands, the injection area was maintained at 140°C. The oven temperature was initially at 35°C for 2.5 min and then increased at 5°C/min. For the early samples, it was continued to 270°C, but for later samples, it was stopped at 150°C, when all the compounds of interest had eluted.

For location of double bonds in alkenes, a sealed capillary containing 10 Dufour glands was crushed in a small tissue grinder made from glass tubing and a glass rod, and the hydrocarbons extracted with hexane (70 μl), of which 50 μl was transferred to a Keele Microreactor (Attygalle and Morgan, 1986). The solution was treated with iodine and dimethyl disulfide as described by Bagnères et al. (1991) to obtain the mass spectra of dimethylthioether derivatives of the alkenes.

RESULTS

The poison glands of *D. armigerum* contain very small amounts of low mass, volatile compounds, readily identified from their mass spectra and retention times (cf. Jackson et al., 1990a) as 2,5-dimethylpyrazine (DMP), trimethylpyrazine (TMP), and 3-ethyl-2,5-dimethylpyrazine (EDMP). The amounts were very small (of the order of 1 ng each per gland) and very variable. The least detectable amount with any reliability is 1 ng for each of these compounds. In only six of 10 samples were all three compounds visible, and sometimes the EDMP was present in smaller quantity than the other two. No higher mass compounds were observed, as expected for an aqueous protein venom.

The Dufour glands of *D. armigerum* contain chiefly a mixture of linear alkanes and alkenes, with tricosene and pentacosene the major ones (Table 1). By the methylthioether method, these were shown to be 9-tricosene (strong ions at *m/z* 173 and 243) and 9-pentacosene (characteristic ions at *m/z* 173 and 271). Traces of two separate isomers of heneicosene and of three isomers of heptacosene were evident from the gas chromatogram (Figure 1). These, no doubt, corresponded to isomers with the double bond at different positions in the chain, but there was too little for them to be seen in the methylthioether chromatograms. Two methyl-branched pentacosanes were also present. Also detected were very small amounts ($< 1\%$ of total) of the sesquiterpenoid aldehydes tetramorine-2 and tetramorine-3 (Ali et al., 1987).

The examination of the pygidial glands did not reveal the presence of any volatile substances by gas chromatography.

DISCUSSION

The behavioral work with *D. armigerum* (Hölldobler et al., 1990) was carried out with a large queenright colony. This was apparently a crucial factor for simulating natural conditions in the laboratory and for designing the appropriate bioassays during which the ants could be tested in foraging motivation. Unfortunately, we failed twice to obtain another queenright colony of *D. armigerum*. Myrmecologists are well aware that it is quite difficult to collect entire

colonies of this species. We were therefore unable to bioassay the chemical compounds for their pheromone function. Nevertheless, we feel it is important to report our chemical results, because *Daceton* is a phylogenetically very interesting species within the subfamily Myrmicinae. Although a wealth of chemical data exist about other myrmicine species, this is the first chemical analysis of exocrine gland secretions for any dacetine ant. Furthermore, the findings given here also explain the unusual interspecific effects in trail-following tests with the other species described above.

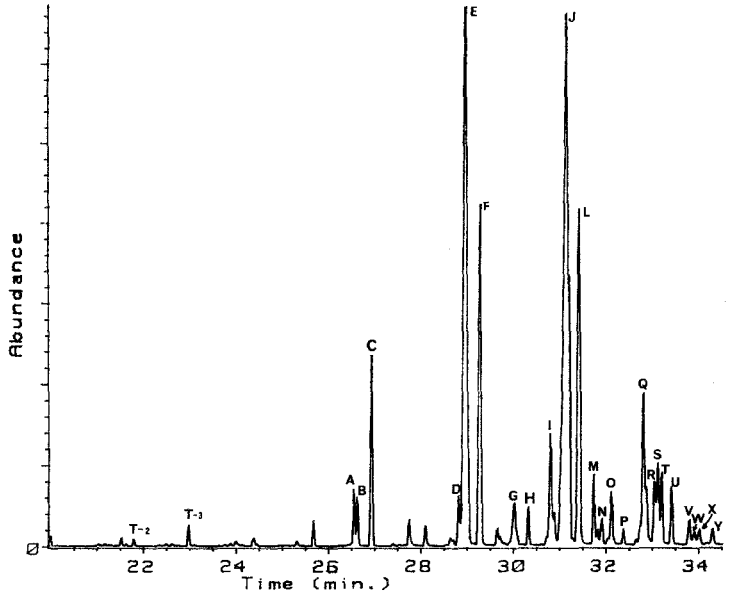

FIG. 1. Gas chromatogram of the Dufour gland contents of a single worker of *D. armigerum*.

The discovery of a mixture of simple alkylpyrazines in the venom gland of *D. armigerum* is not surprising, since these compounds, and EDMP in particular, have been identified as the trail pheromone in a number of species of myrmicine ants (Attygalle and Morgan, 1985). The venom gland of *Manica rubida* contains these same three pyrazines, although in behavioral tests, only EDMP was found to be active (Attygalle et al., 1985, 1986). These three substances were also found in *Tetramorium caespitum* venom glands (Attygalle and Morgan, 1983), where initially DMP and EDMP were found to act synergistically and later TMP was also found to have activity (Attygalle et al., 1986). A mixture of indole with traces of alkylpyrazines were shown to provide the pheromone in *Tetramorium meridionale* (Jackson et al., 1990a). We hope to carry out behavioral tests with these substances when next a colony of *D. armigerum* becomes available.

The trail pheromone of *Atta cephalotes* has been shown to be methyl 4-methylpyrrole-2-carboxylate (M4MPC) (Riley et al., 1974), but Robinson et al. (1974) have demonstrated cross-activity between *A. cephalotes* and *A. sexdens* in which EDMP is the trail pheromone (Cross et al., 1979; Evershed and Morgan, 1983), and Evershed and Morgan (1983) have shown that *A. cephalotes* venom glands contain both the pyrrole and EDMP. This alone can explain the observation that *A. cephalotes* workers will follow a trail of *D. armigerum*

venom gland secretions. Moreover, in just one of the 10 specimens of *D. armigerum* venom gland analyzed, we also detected M4MPC in quantity comparable to the pyrazines that were also present. We have no explanation for this isolated result. The exact blend of pyrazines must be critical in *D. armigerum* since its workers did not follow trails of *Atta cephalotes* or *T. caespitum*. In all cases where EDMP and M4MPC have been detected in poison glands they have been in the range of 1–5 ng. See, for example, Evershed and Morgan (1983) where an average of 1.1 ng of M4MPC per worker poison gland in *A. cephalotes* was reported.

The ability of *Solenopsis invicta* to follow trails of Dufour gland secretions of *D. armigerum* cannot be explained yet. Although sesquiterpenes have been found in *S. invicta* and they provide the trail pheromone of that species (Vander Meer, 1986), they are different in structure from the tetramorines reported here. The tetramorines were first discovered in the Dufour glands of *Tetramorium caespitum* and *T. impurum* (Billen et al., 1986) and later found also in *Leptothorax acervorum* and *Leptothorax nylanderi* (Ali et al., 1987; Jackson, 1991). We now know that these compounds are homologs of 2,3-dihydrofarnesal ($C_{15}H_{26}O$), which can be regarded as tetramorine-0. Tetramorine-1 ($C_{16}H_{28}O$), tetramorine-2 ($C_{17}H_{30}O$), and tetramorine-3 ($C_{16}H_{32}O$) have, respectively, one, two, and three extra CH_2 groups added to dihydrofarnesal but their exact position is yet to be determined.

The main constituents of the Dufour gland are a mixture of linear alkanes and alkenes, with 9-tricosene and 9-pentacosene the major components. There are small amounts of methyl-branched alkanes also present. These are commonly found in formicine ants, but up to now have only been found among harvester ants (*Messor* and *Pogonomyrmex*) in myrmicines (Ali et al., 1989). It is possible that the linear hydrocarbons act as a solvent and "keeper" for the more volatile and odorous tetramorines.

There have been few reports of the identification of volatile substances in the pygidial glands of ants, other than the iridoid-containing anal pygidial glands of the Dolichoderinae. Isogeraniol, *m*-hydroxybenzaldehyde, and two C_{17} hydrocarbons were identified in the pygidial glands of *Rhytidoponera metallica* (Meinwald et al., 1983), and we have found a variety of volatile substances recently in the pygidial glands of the Australian ants *Nothomyrmecia macrops* (Billen et al., 1988) and *Myrmecia nigriceps* (Jackson et al., 1990b). Attygalle et al. (1988) have identified (3*R*,4*S*)-4-methyl-3-heptanol in the pygidial gland of *Leptogenys diminuta*, where it functions as a trail pheromone. We were unable to identify any volatile substances in the pygidial glands of *D. armigerum* in the present work and are unable at present to account for the behavioral response to this gland described by Hölldobler et al. (1990).

(Received January 7, 1992; accepted June 10, 1992)

Abstract—The major component (>90% of volatiles) of the male rectal glandular extract of the nonpest species *Bactrocera visenda* (Hardy) is 3-methyl-2-butenyl acetate, with minor components being the isomeric 3-methyl-3-butenyl acetate, the homologous esters, 3-methyl-2-butenyl propanoate and 3-methyl-2-butenyl formate, along with 3-methyl-2-buten-1-ol, 3-methyl-2-butenal, and 3-methylbutyl acetate. None of these compounds has been identified previously from a *Bactrocera* species, supporting the view that *Bactrocera visenda* is taxonomically distant from other *Bactrocera* species identified from the Australian mainland. This collection of compounds adds to the known types utilized by dipteran species and emphasizes their extensive biosynthetic capability.

Key Words—*Bactrocera visenda*, Diptera, Tephritidae, fruit fly, 3-methyl-2-butenyl acetate.

INTRODUCTION

Within the identified species of fruit flies, a significant number are destructive pests of many forms of horticulture, and methods of monitoring and control are

*To whom correspondence should be addressed.

being sought that are based on the chemical cues that regulate phases of fruit fly biology (Drew et al., 1982). In this connection, the volatile compounds secreted and released from male rectal glands have been studied extensively and shown to be behavior-mediating in certain cases. On the other hand, many species are not of pest status, but study is still warranted to define the considerable biosynthetic capability exhibited by these insects (Blomquist et al., 1987; Blum, 1981; Bradshaw, 1985), as well as to delineate taxonomic features (Perkins et al., 1990a). In previous reports, we described studies of male rectal glands secretions from species that fall into each of these pests (Kitching et al., 1989) and nonpest categories (Perkins et al., 1990b; Krohn et al., 1991). *Bactrocera* (*Polistomimetes*) *visenda* (Hardy) is a medium-sized species (Drew, 1989) that is taxonomically very different from all other species identified from mainland Australia, but does resemble *Bactrocera mesonotochra* (Drew, 1989), a species localized in Morobe Province in Papua New Guinea. In view of this taxonomic isolation, it appeared that the chemistry of the male rectal gland secretion would be of interest, as previous studies (Perkins et al., 1990a) had shown that the gland contents can provide significant chemical taxonomic information. *Bactrocera visenda* is widespread in southern coastal areas of Papua New Guinea, northeastern coastal areas of Queensland, and the Torres Strait islands. It infests only native rain-forest hosts such as the "mangosteen" (*Garcinia warrenii* and *Garcinia gibbsiae*). In this report we describe the identification of the volatile chemical constituents of the male rectal gland, which are unlike the constituents of any other fruit fly species examined.

METHODS AND MATERIALS

Bactrocera visenda specimens were bred out in the laboratory at the Department of Primary Industries, Indooroopilly, Queensland, from infested mangosteen fruit (*Garcinia warrenii* and *Garcinia gibbsiae*) obtained from the rainforests of North Queensland.

Gland Secretion Analysis and Identification. Sexually mature adult male flies were chilled briefly (0°C) and their rectal glands were excised and stored in spectrograde pentane, as described previously (Kitching et al., 1989). Combined GC-MS examinations were performed using Hewlett-Packard HP5970 MSD, Finnigan Mat 1020 and double-focusing VG 70-750SE instruments with polar (BP21, FFAP) and nonpolar columns (DB5). Proton magnetic resonance spectra were recorded at 400 MHz (FT mode) on JEOL JNM-GX400 and Bruker WP400 spectrometers. Deuterochloroform was employed as solvent and chemical shifts (δ values) are relative to residual chloroform at δ 7.24. ^{13}C NMR spectra were recorded at 100 MHz utilizing $CDCl_3$ as solvent, and chemical shifts are relative to the central component of the $CDCl_3$ triplet at 77.00 ppm.

Synthesis of Glandular Components. 3-Methyl-2-buten-1-ol **(5),** 3-methyl-2-butenal **(6),** methylbutylacetate **(7),** and 3-methyl-3-buten-1-ol were obtained from the Aldrich Chemical Company and exhibited NMR and mass spectra in agreement with the structures. Compounds **1, 2, 3,** and **4** have been characterized previously (Babin et al., 1980; Aljancic-Solaja et al., 1987; Nazarov et al., 1952).

3-Methyl-2-butenyl Acetate (1). A stirred solution of 3-methyl-2-buten-1-ol **(5)** (1 g) in dry pyridine (20 ml) at 0°C was treated with acetyl chloride (0.94 g), and after about 12 hr was poured into ice–water and then extracted thoroughly with ether. The ether layer was washed with dilute HCl, $NaHCO_3$ solution, and water. The dried ($MgSO_4$) ether solution was concentrated under reduced pressure and the ester purified by flash chromatography (hexane) to provide **1** (0.89, 54%). ^{13}C NMR ($CDCl_3$): 170.96, 138.92, 118.54, 61.27, 25.64, 20.90, 17.87. ^1H NMR ($CDCl_3$): 1.66 (s, 3H), 1.71 (s, 3H), 1.99 (s, 3H), 4.51 (d, 2H, J = 7 Hz), 5.29 (t, 1H, J = 7 Hz). These ^1H NMR data are in excellent agreement with that reported (Babin et al., 1980). Mass spectrum: 128 ($M^{+\cdot}$, 0.4), 86 (7), 85 (4), 71 (15), 69 (21), 68 (49), 67 (36), 53 (20), 43 (100), 41 (54), 39 (24).

3-Methyl-3-butenyl Acetate (2). 3-Methyl-3-buten-1-ol was treated with acetyl chloride as described above in the preparation of **1.** Flash chromatography followed by preparative gas chromatography afforded a pure sample of **2.** ^{13}C NMR ($CDCl_3$): 171.04, 141.67, 112.16, 62.64, 36.65, 22.44, 20.92. ^1H NMR ($CDCl_3$): 1.73 (s, 3H), 2.01 (s, 3H), 2.31 (t, 2H, J = 7 Hz), 4.15 (t, 2H, J = 7 Hz), 4.71 (br s, 1H), 4.78 (br s, 1H). These ^1H NMR data agree well with that reported (Aljancic-Solaja et al., 1987). Mass spectrum: 128 ($M^{+\cdot}$, 0), 73 (2), 69 (4), 68 (52), 67 (31), 53 (10), 43 (100), 41 (12), 39 (15), such data being in agreement with a reported mass spectrum (Aljancic-Solaja et al., 1987).

3-Methyl-2-butenyl Propanoate (3). Treatment of alcohol **5** with propanoyl chloride, in the manner described for acquiring **1**, provided the propanoate **3**. [Lit. bp 162–164°/710 mm (Nazarov et al., 1952)]. ^{13}C NMR ($CDCl_3$): 174.33, 138.67, 118.65, 61.09, 27.45, 25.59, 17.81, 8.98. ^1H NMR ($CDCl_3$): 1.07 (t, 3H, J = 7.6 Hz), 1.64 (s, 3H), 1.69 (s, 3H), 2.25 (q, 2H, J = 7.6 Hz), 4.50 (d, 2H, J = 7 Hz), 5.27 (br t, 1H). Mass spectrum: 142 ($M^{+\cdot}$, 1), 114 (1), 100 (3), 85 (5), 71 (3), 69 (42), 68 (58), 67 (41), 57 (100), 53 (16), 41 (71), 39 (22).

3-Methyl-2-butenyl Formate (4). ^{13}C NMR ($CDCl_3$): 161:13, 139.91, 117.89, 60.74, 25.65, 17.93. ^1H NMR ($CDCl_3$): 1.70 (s, 3H), 1.75 (s, 3H), 4.64 (d, 2H, J = 7 Hz), 5.34 (br t, J = 7 Hz), 8.04 (s, 1H). These ^1H NMR data are in agreement with literature values (Babin et al., 1980). Mass spectrum: 114 ($M^{+\cdot}$, 1), 85 (9), 83 (1), 71 (38), 69 (31), 68 (59), 67 (50), 53 (36), 43 (28), 41 (100), 39 (56), such data being in agreement with that reported (Babin et al., 1980).

3-Methyl-2-butenal ***(6).*** Oxidation of 3-methyl-3-buten-1-ol with pyridinium chlorochromate provided **6,** identical with the commercially available material. Distillation [bp 135°, lit. 133°/730 mm (Pauling et al., 1976)] followed by careful preparative gas chromatography yielded **6.** ^{13}C NMR ($CDCl_3$): 190.96, 160.50, 128.03, 27.12, 18.80. ^1H NMR ($CDCl_3$): 1.92 (s, 3H), 2.11 (s, 3H), 5.82 (d, 1H, J = 8 Hz), 9.89 (d, 1H, J = 8 Hz). These ^1H NMR data are in agreement with literature values (Pauling et al., 1976). Mass spectrum: 84 ($M^{+\cdot}$, 100), 83 (48), 69 (6), 65 (2), 55 (82), 53 (18), 41 (76), 39 (80).

RESULTS AND DISCUSSION

Combined GC-MS examination of a pentane extract of approximately 20 rectal glands from *Bactrocera visenda* males showed the presence of one dominant component (>90% of volatiles), four minor components (each 1–2%), and a number of trace components (<1%) (Figure 1).

A library mass spectra search tentatively identified the major component as 3-methyl-2-butenyl acetate **(1),** and this was confirmed by synthesis and

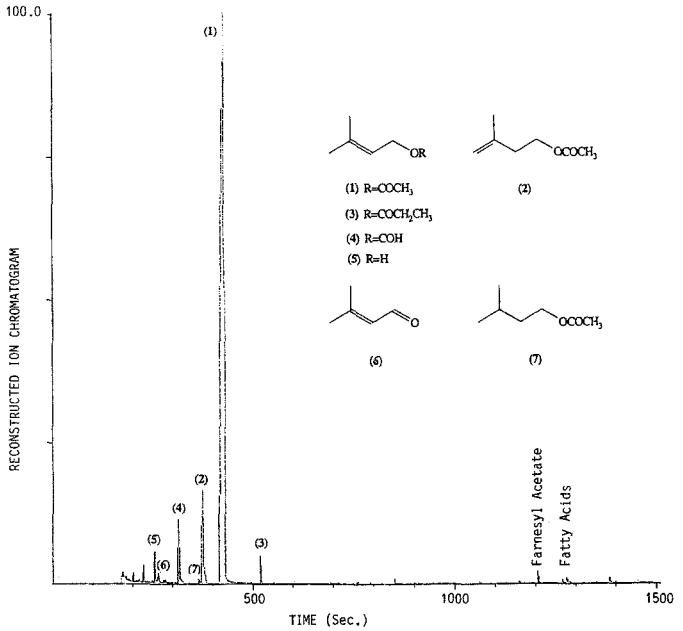

FIG. 1. Gas chromatograph of rectal gland extract form adult male *Bactrocera (Polistomimetes) visenda* (Hardy). *Column and conditions:* 30-m DB5 capillary column (J&W). Temperature programmed, 40°C, 2 min then 10°/min to 260°C.

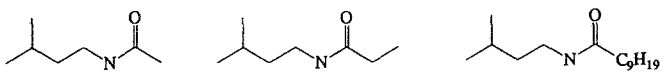
coinjection of the authentic sample with the *B. visenda* extract. Three of the minor gland components showed significant mass spectral similarities with that of **1,** with ions at 53 (C_4H_5), 67 (C_5H_8), and 69 (C_5H_9) being important in this regard. GC-MS comparisons with authentic compounds enabled the identification of these components as the isomeric acetate, 3-methyl-3-butenyl acetate **(2),** and two other esters of **1,** 3-methyl-2-butenyl propanoate **(3)** and 3-methyl-2-butenyl formate **(4).** The fourth minor component showed a mass spectral library match with 3-methyl-2-buten-1-ol **(5),** and the assignment was confirmed upon examination of a commercial sample of the alcohol and coinjection with the gland extract.

An unsaturated C_5-aldehyde was deduced as the most likely structure of one of the trace components based on mass spectral interpretation. 3-Methyl-2-butenal **(6)** proved to be identical with the natural component (coinjection and GC-MS). An additional trace component was identified as 3-methylbutyl acetate **(7)** on the basis of library matching and coinjection of an authentic sample. A number of less volatile trace components were tentatively identified and included farnesyl acetate and C_{16} saturated and unsaturated acids.

Some of these compounds are known as components of the aroma of certain fruits with, for example, **1, 2** and **5** in pepino and other fruits (Shiota et al., 1988) and **1, 2, 5,** and **7** as minor headspace constituents of intact tree-ripened nectarines (Takeoka et al., 1988). α,β-Unsaturated aldehyde **6** is a volatile constituent of commercial proteinaceous baits for fruit flies (Morton and Bateman, 1981).

With respect to insect derivation, compounds **1, 2** and **7** have been identified (Jang et al., 1989) as minor or trace headspace components from the odor of calling male Mediterranean fruit flies (*Ceratitis capitata*). Compounds **2** and **7** have also been identified from the venom of the European hornet (Wheeler et al., 1983), while **7** is an important component of the alarm pheromone of honeybee workers (Morse et al., 1967; Blum et al., 1978). Long-chain fatty acid esters of **5** are present in the Dufour's gland of halictid bees (Duffield et al., 1981, 1982). Interestingly, aza-analogs of **7** are also known from insects (Figure 2); **8** is the alarm pheromone of the wasp, *Vespula squamosa* (Heath and Landolt, 1988) and was also found in *Dacus cucurbitae* (Baker et al., 1982; Perkins et al., 1990b). The same compound and related amides, including the corresponding propanamide **9,** were found in the rectal glands of *Dacus tryoni*



(8) (9) (10)

FIG. 2. Aza-analogues of **7** found in other insect species.

and *Dacus neohumeralis* (Bellas and Fletcher, 1979). Other volatiles showing a 1-aza-4-methylpentyl substructure, such as **10**, are known from ponerine ants (Fales et al., 1984). To the best of our knowledge, and propyl ester **(3)** and formate **(4)** have not been identified previously from a natural source.

The biosynthetic routes to volatile short-chain compounds present in insect species are unclear, but those with branched structures may be derived from isoprenoid units or amino acids (Blomquist et al., 1987; Bradshaw, 1985; Blum, 1981). In this regard, Attygalle et al. (1991) have demonstrated recently that $^2H_8$-L-valine is incorporated with high efficiency into methacrylic and isobutyric acids in the defensive gland of a carabid beetle, *Scarites subterranous* and that the isotope distribution pattern is consistent with the saturated acid being the precursor of the unsaturated analog.

Male rectal glands from other *Bacterocera* species generally contain amides (Bellas and Fletcher, 1979) and/or C_9–C_{13} spiroacetals, ketoalcohols, or diols (Kitching et al., 1989; Krohn et al., 1991; Perkins et al., 1990a,b). Thus the identification of the C_5 alcohols, esters, and aldehydes **(1–7)** in *B. visenda* supports the conclusion that this species is taxonomically quite distinct from other Australian species, and examination of *B. mesonotochra* (Drew, 1989) would be worthwhile from this point of view. In addition, the characterization of these compounds indicates a very diverse biosynthetic capability for Dipteran species (Tumlinson, 1989). Although no assessment of the biological activity of these components has been undertaken, it would be surprising if they lacked a role in the communication system of the species.

Acknowledgments—The authors are grateful to Ms. Marlene Elson-Harris and Mr. Edie Hamacek of the Department of Primary Industries, Indooroopilly, Queensland, for collecting the infested fruit and rearing the flies.

PERFORMANCE CHARACTERISTICS OF A COMMERCIAL CONTROLLED-RELEASE DISPENSER OF SEX PHEROMONE FOR CONTROL OF CODLING MOTH (*Cydia pomonella*) BY MATING DISRUPTION

L.M. McDONOUGH,* W.C. ALLER, and A.L. KNIGHT

USDA, Agricultural Research Service
3706 W. Nob Hill Blvd.

(Received June 8, 1992; accepted July 27, 1992)

Abstract—Performance characteristics of polyethylene tube dispensers containing a mixture of (*E*,*E*)-8,10-dodecadien-1-ol **(1),** dodecan-1-ol **(2),** and tetradecan-1-ol **(3)** were evaluated for suitability as a mating disruptant for codling moth control. The rate of loss of pheromone component from a dispenser at any time was found to be described by the equation:

$$-dP/dt = (k_1k_2 + k_d)P$$

where P is the amount of pheromone component in the dispenser well; t is time; k_1 is the ratio of the amount dissolved in the dispenser wall to the amount in the dispenser well; k_2 is the ratio of the evaporation rate to the amount dissolved in the dispenser wall; k_d is the rate constant for chemical decomposition. The evaporation rate, E, of a pheromone component at any time was given by:

$$E = k_1k_2P$$

For all three components during the first three weeks, k_1 decreased from ca. 0.25 to ca. 0.10 and was approximately constant thereafter. The decrease of k_1 with time may have been caused by weather-induced cross-linking of the polyethylene. Over time k_2 was constant and was $1.27 \pm 0.26 \times 10^{-3}$/hr for **1,** $1.96 \pm 0.33 \times 10^{-3}$/hr for **2,** and $0.31 \pm 0.05 \times 10^{-3}$/hr for **3.** The k_d was zero for **2** and **3** and 6.96×10^{-4} for **1.** After 150 days in an orchard in 1991, 95% of **1** was lost from the dispensers (61% of the loss was by chemical decomposition and 39% by evaporation). The heat summation units in a Yakima valley orchard during 1991 were 4.7% above the average for the 1980–1991 period, while during 1990 they were the highest for this

*To whom correspondence should be addressed.

period (26% above average). After the first three weeks of dispenser aging, the regression line half-lives for **1** for 1990 and 1991 were 31.0 and 35.1 days, respectively. The difference in temperature between 1990 and 1991 did not affect the half-life of **1** very much because so much of the loss was from photochemically induced decomposition. Based on an estimate of the required minimum evaporation rate for mating disruption of 2 mg/ha-hr and a half-life of 35 days for **1**, 2345 dispensers/ha would be required for one application per season; 944 dispensers/ha for two applications per season; and 734 dispensers/ha for three applications per season. If a different emission rate of **1** is required for reliable mating disruption, then the number of dispensers required would be changed proportionately.

Key Words—Sex pheromone, codling moth, *Cydia pomonella*, Lepidoptera, Tortricidae, Olethreutinae, controlled release, mating disruption, dodecan-1-ol, tetradecan-1-ol, (*E*,*E*)-8,10-dodecadien-1-ol.

INTRODUCTION

Since the early 1970s, the principle of insect control by application of sex pheromones to the host crop has been demonstrated numerous times (Roelofs, 1979). In the last few years this technique has become more practical, and renewed interest has developed (Charmillot, 1990; Rice and Kirsch, 1990; Kirsch, 1988).

Controlled-release dispensers are critical to the development of practical control programs. Commercial dispensers that have shown promise in some context and for which release characteristics have been studied, include microcapsules (Campion et al., 1981), Hercon Environmental Co. dispensers (Leonhardt and Moreno, 1982), Conrel Corp. hollow fibers (Weatherston et al., 1985a,b) and other types (Kraan and Ebbers, 1990).

Recently, the Biocontrol Ltd. dispenser has shown promise in commercial applications. This dispenser consists of a hollow plastic tube sealed at both ends and filled with pheromone. Imbedded longitudinally in the plastic wall is a wire so that the dispenser can be manually tied to a stem of crop foliage. This dispenser is used in Australia and the United States for control of the Oriental fruit moth (Rice and Kirsch, 1990), in Japan for control of a tea-tortrix complex (Ogawa, 1990), and extensively in management of pink bollworm (Baker et al., 1990).

Biocontrol Ltd. is also exploring the use of their dispenser for the sex pheromone of the codling moth. Their formulation consists of a mixture of (*E*,*E*)-8,10-dodecadien-1-ol (*E*8,*E*10–12:OH), dodecan-1-ol (12:OH), and tetradecan-1-ol (14:OH) stabilized with vitamin E. In a study of the evaporation rate characteristics of an earlier dispenser of these components, Brown et al. (1992) showed that the evaporation rate could be empirically correlated with a

combination of degree-hours and temperature during the summer of 1989 in the Yakima valley.

Weatherston (1990) suggested that pheromone release from the Biocontrol dispenser follows first order kinetics. The experience of Brown et al. (1992) with the codling moth formulation suggested a more complex situation with this pheromone. Our study was undertaken to identify factors controlling the loss mechanism of the codling moth formulation from this dispenser. The results indicate that the dispenser does follow first-order kinetics, but weathering of the dispenser and decomposition of 8,10–12:OH are modifying factors.

METHODS AND MATERIALS

Dispensers. The dispensers were obtained from Biocontrol Ltd., Davis, California. The dispensers were ca. 20 cm long and 1 × 3 mm in diameter, and the total weight of components in the dispensers was about 195 mg. Some of the liquid from one of the dispensers was weighed and made to a concentration of 12.27 μg/ml in heptane. External standards were used for gas chromatographic analysis (DB-WAX capillary column), which indicated a total pheromone titer of 11.48 μg/ml (93.6%); 58.8% 8,10–12:OH; 29.5% 12:OH; 5.3% 14:OH. According to the company, 5% vitamin E is added as a stabilizer (Phillip Kirsch, personal communication), which therefore accounts for most of the remaining 6.4%.

In 1991 and 1990, the dispensers were tied to apple tree branches on April 22 in a commercial orchard located 20 km from Yakima. Dispensers were placed in the upper third of the canopy of 15-year-old red delicious apple trees. At appropriate time intervals, three dispensers were individually collected, placed in plastic seal-top bags, and stored in a freezer.

Determination of Evaporation Rates. Dispensers were removed from the freezer and allowed to equilibrate at room temperature (ca. 22°C) for 24 hr. Then, immediately prior to determination of the evaporation rates, the lengths of the liquid wells were measured. The evaporation rates were determined by the method of McDonough et al. (1989), except 50-ml syringes were used for the dispenser chamber and silica gel Sep-Pak cartridges (Millipore Corp., Marlborough, Massachusetts) were used for collecting evaporated pheromone. Prior to insertion of a dispenser into the syringe, it was bent around a small beaker and the ends were crimped so that only a small part of the dispenser touched the side of the syringe wall. The dispensers were placed within 3 mm of the end of the syringe. The flow rate of nitrogen was 16.2 cm/sec (6 liters/min), and the temperature was 20°C in 1991 and 22.5°C in 1990.

Determination of Contents of Dispenser Liquid Well. The 1991 dispensers 0, 16, 36, and 86 days old were weighed. Then a hole was made in each end

of the dispenser and the contents drained into a 125-ml flask. The dispensers were cut laterally into two pieces, cotton wads were twice pushed through the dispensers with straightened paper clips, and both wads and clips added to the flask. The dichloromethane solution was decanted from the cotton wads and paper clips. The flask contents were then extracted three times with dichloromethane. Dichloromethane was removed from the pooled solution with a rotary evaporator, and the residue was weighted. The initial liquid well contents of the dispensers were 154 ± 3.5 mg.

Determination of Titer of Pheromone Components in Dispenser Wall. After the well contents were removed, the 1991 dispensers were each placed into 125-ml flasks containing 50 ml dichloromethane. The contents were shaken for 1 hr with a mechanical shaker. The extracts were poured into another flask, and the original flask was rinsed three times with dichloromethane. The extraction and rinsing procedures were repeated two more times. The combined extracts were partially evaporated to a volume of about 75 ml; 75 ml heptane was added, and the solution was again evaporated to a volume of 75 ml and made to an appropriate volume for gas chromatographic analysis. The dispensers were allowed to dry overnight and then weighed so the total weight of components dissolved in the plastic wall could be determined. The weight of nonpheromone extractable constituents of the plastic wall were constant over time at 13.3 ± 2.2 mg/dispenser.

Control Experiments. Controls were run for all analytical procedures. Recoveries were typically 90–100%, and no corrections were applied to analytical data.

Mathematical Relationships. If the evaporative loss from the dispenser were first order, then (assuming evaporation was the only loss process) the evaporation rate (E) of a pheromone component at any time would be:

$$E = -dP/dt = kP \tag{1}$$

where P is the amount of the pheromone component in the liquid well, t is time, and k is a proportionality constant (the ratio of the evaporation rate of a component to the amount of that component in the liquid well).

The process of evaporation involves two steps: the solution of the components of the well into the plastic wall and the evaporation out of the wall. In order to evaluate these processes separately, new constants can be defined: k_1 is the ratio of the amount of pheromone in the plastic wall to that in the liquid well, and k_2 is the ratio of the evaporation rate to the amount in the plastic wall. It follows that $k_1k_2 = k$.

If a first-order chemical decomposition were to occur concurrently with the first-order evaporative loss, then $k = k_1k_2 + k_d$, where k_d is the rate constant for chemical decomposition. Note that when decomposition occurs, the rate of

loss ($-dP/dt$) is no longer equal to the evaporation rate, E, which is still equal to k_1k_2P.

The integral form of the equation for a first order loss is:

$$\ln\left(\frac{P_0}{P}\right) = kt \text{ or } \ln\left(\frac{k_1k_2P_0}{k_1k_2P}\right) = kt$$

which is equivalent to

$$\ln\left(\frac{E_0}{E}\right) = kt \tag{2}$$

Where P_0 is the amount of pheromone when $t = 0$ and E_0 is the evaporation rate when $t = 0$. Therefore, plots of ln P versus time and ln E versus time will give parallel straight lines with a slope of $-k$.

Statistical Calculations. Regression lines and 95% confidence limits were calculated with NCSS 5.03 Software (Hintze, 1991).

RESULTS

Change in Evaporation Rate with Time Versus Loss of Dispenser Content with Time. Figure 1 shows a plot of logarithm of dispenser content in terms of both length of liquid well (millimeters) and weight of liquid well content (mil-

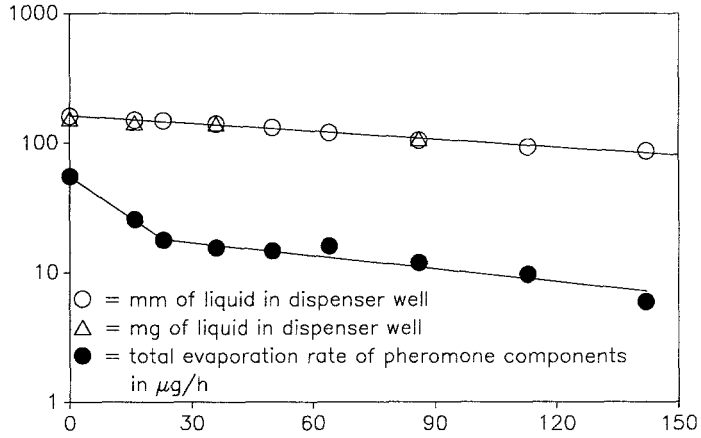

FIG. 1. Loss of dispenser well contents as measured by well length and weight of well components vs. time, and loss of evaporation rate, E (total of all components) vs. time during 1991. Ordinate numbers represent logarithm of titer in millimeters and milligrams, and logarithm E in micrograms per hour. Abscissa numbers are days.

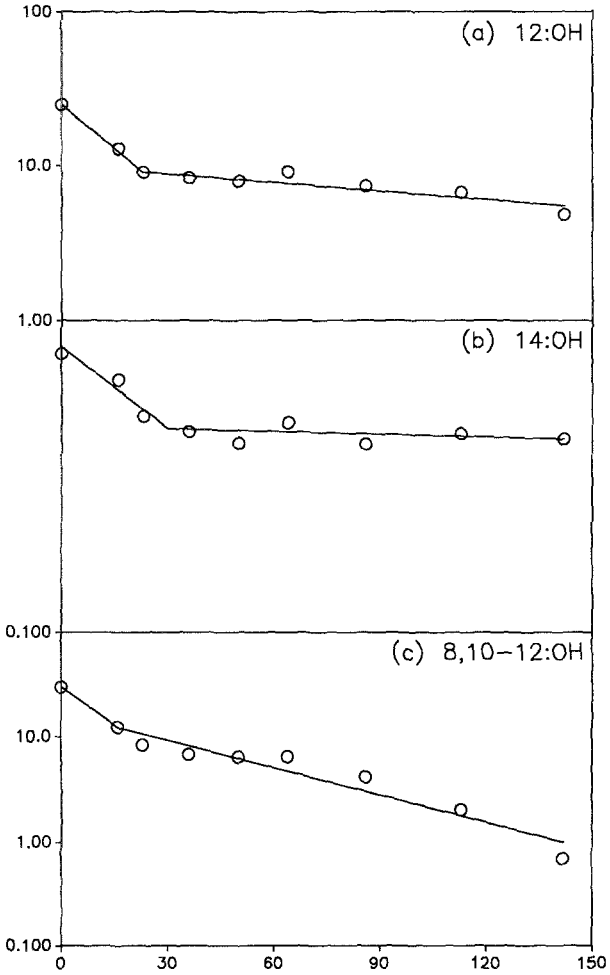

FIG. 2. Logarithm of evaporation rate, E (μg/hr), versus time (days) for 1991 dispensers for each pheromone component.

ligrams) with time (days) compared to the logarithm of total evaporation rate (micrograms per hour) of all three components with time during 1991. The slope of the line for logarithm of liquid well content (millimeters) corresponded to a half-life of 148.5 days (R^2 = 0.987). The slope for the first leg of the line for logarithm of evaporation rate corresponded to a half-life of 14.2 days (R^2 = 0.9997) and for the second leg, to a half-life of 81.3 days (R^2 = 0.910). Therefore, these lines are not parallel as would be required for a simple first-order process.

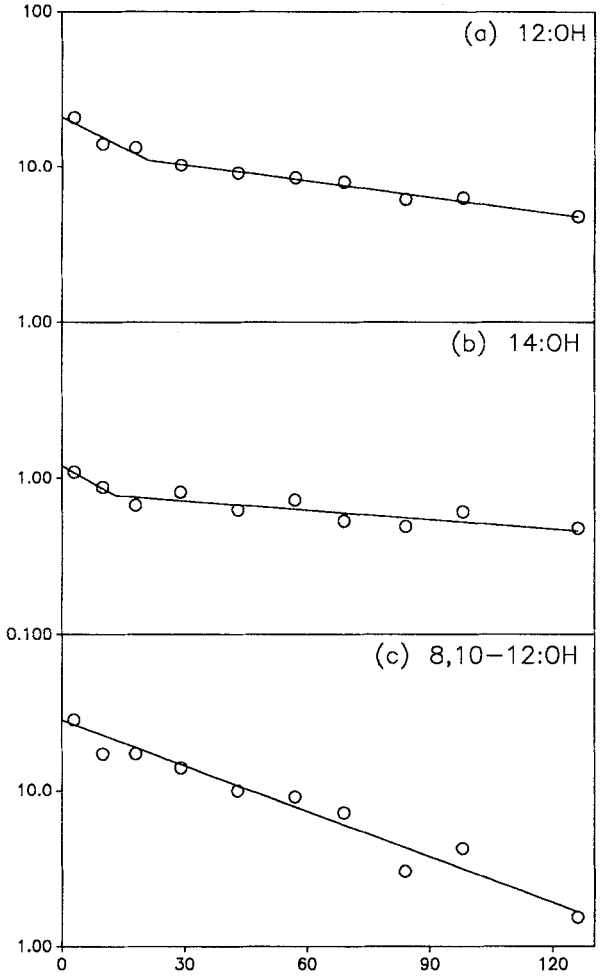

FIG. 3. Logarithm of evaporation rate, E (μg/hr), versus time (days) for 1990 dispensers for each pheromone component.

Change in Evaporation Rates of Individual Components with Time. Figure 2a–c shows plots of logarithm E versus time for each pheromone component in the 1991 dispensers. Each curve shows a faster loss during the first three weeks followed by a slower loss. The pattern is the same as that shown for the composite in Figure 1. Figure 3a–c shows the same plots for the 1990 dispensers. Again, for 12:OH and 14:OH the usual pattern is evident: a fast loss of E during the first three weeks followed by a slower loss. The pattern is not clear for 8,10–12:OH because of its fast loss after three weeks. Comparison of losses

TABLE 1. RATIO (k_2) OF EVAPORATION RATE TO TITER IN DISPENSER WALL[a]

Age (days)	$k_2 \times 10^3$ (SE)			k_2(12:OH)/ k_2(14:OH)	k_2(12:OH)/ k_2(8, 10–12:OH)
	12:OH	14:OH	8, 10–12:OH		
0	2.22 (0.37)	0.33 (0.03)	1.51 (0.22)	6.62	1.47
16	1.95 (0.40)	0.32 (0.05)	1.18 (0.27)	6.01	1.65
36	1.74 (0.19)	0.28 (0.07)	1.02 (0.14)	6.28	1.71
86	1.85 (0.22)	0.29 (0.03)	1.28 (0.16)	6.49	1.45
Overall average	1.96 (0.33)	0.31 (0.05)	1.27 (0.26)	6.37 (0.64)	1.56 (0.14)

[a]On day 0 there were 4 replications; on other days there were 3.

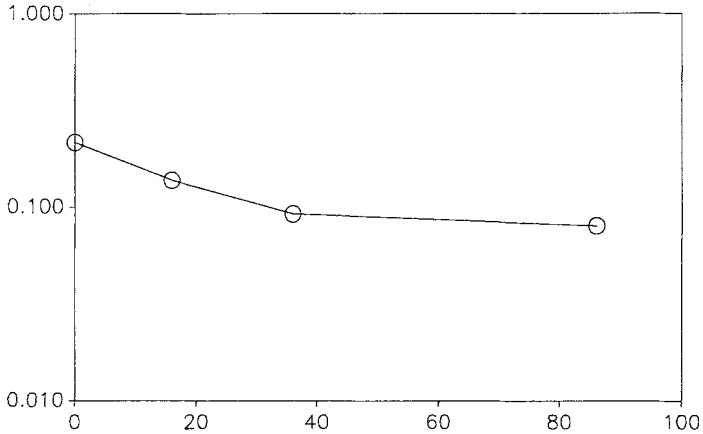

FIG. 4. Logarithm of k_1 (ratio of titer of pheromone components in plastic wall to the weight in dispenser well) versus time (days) for 1991 dispensers.

of each compound during the first three weeks (first three data points) shows that they are about the same. In terms of half-life, the values are: 12:OH, 23.7 days; 14:OH, 21.5 days; 8,10–12:OH, 21.7 days. The similarity of these values indicates that the slopes of the first leg of these curves were being dictated by a factor other than volatility.

Change in k_2 *Values with Time.* The k_2 values for each pheromone component in the 1991 dispensers were evaluated at four different dates from 0 to 86 days in the field and are summarized in Table 1. For each compound the k_2 values are constant across dates within $\pm 20\%$ of the averages. A regression analysis of the k_2 values versus time indicates slightly negative slopes with low correlation coefficients. Values of slopes and R^2 values for each compound are: 12:OH, −0.0039, 0.156; 14:OH, −0.0006, 0.189; 8,10–12:OH, −0.0020,

0.065. These data show that the evaporation rate of each pheromone component is proportional to the concentration of that pheromone component in the plastic wall.

Change in k_1 *Values with Time.* The k_1 values (total titer of pheromone components in the plastic wall: weight of total well contents) for 1991 dispensers are given in Figure 4. The values were not constant but decreased by a factor of about 2.5. In Figure 1, E values decreased by a factor of 3.1 during the first three weeks. Therefore, most of the fast decrease in E values shown in Figure 1 can be explained by changing k_1 values. Evaporative loss and chemical decomposition would also contribute to loss in evaporation rate during the first three weeks.

DISCUSSION

Evaluation of Steps in Evaporative Release. For the 1991 dispensers, Figure 1 shows that the change in evaporation rate, E, with time does not parallel the change in pheromone content with time. Figure 2 shows that the pattern of evaporation rate changes in Figure 1 applies to each individual component, and this pattern also exists for the 1990 dispensers (Figure 3).

The discrepancy between change of pheromone content and change of evaporation rates cannot be explained by variation in k_2, since k_2 values were virtually constant for each component. The k_1 values (Figure 4), however, decreased by a factor of 2.5, closely paralleling the changes in E values. Since k_1 values represent the partitioning of the components between the well and the wall, k_1 values could change because of changes in either medium. Oxidation of vitamin E or 8,10–12:OH would increase the polarity of the well contents (Ideses and Shani, 1988). Because pheromone components are of moderate polarity, higher polarity of well contents would probably not favor increased solubility of the components in the well over the wall. More probable is a decrease in the solubility of the components in the wall. Perhaps the combined effect of oxygen and sunlight caused cross-linking of the polyethylene (Smith et al., 1977). Cross-linking would decrease the solubility of the components (Smith et al., 1977).

Amount of 8,10–12:OH Lost by Chemical Decomposition. The ratio of k_2 values for 12:OH/8,10–12:OH (Table 1) was 1.56 ± 0.14. Based on data from rubber septa where the $t_{1/2}$ of 8,10–12:OH is 26.5 days at room temperature (Maitlen et al., 1976) and the $t_{1/2}$ of 12:OH at 20°C is 17.5 (McDonough, 1991), the ratio of rate constants (inverse of $t_{1/2}$ values) is 1.51. Moreover, the ratio of k_2 values for dispensers for 12:OH/14:OH is 6.37 ± 0.64 compared to 7.50 for rubber septa (McDonough, 1991). Therefore, ratios of evaporation rate constants from these polyethylene dispensers are similar to those from rub-

ber septa. This is reasonable because both polyethylene and rubber are hydrocarbons and therefore of very similar polarity. The ratio of k_2 values shows that 12:OH is more volatile and would be expected to be lost faster than 8,10–12:OH from these dispensers, but because 8,10–12:OH was lost faster, concurrent chemical degradation of 8,10–12:OH must have been occurring.

The percent of 8,10–12:OH lost by chemical decomposition in the 1991 dispensers can be estimated by comparing the theoretical loss curve based on evaporation as the only loss process to the observed loss from a combination of evaporation and decomposition. The changes of ln E values versus time for 12:OH and 8,10–12:OH are shown in Figure 2a and c. Because k_2 values are constant and k_1 values are approximately constant after the third week, the second leg of each curve can be analyzed in terms of equation 2:

$$\ln E = -kt + \ln E_0$$

E_0 is the value of E that would be obtained by extrapolating the regression line to time zero. For t in hours and E in micrograms per hour, the regression lines are: for 12:OH:

$$\ln E = -0.0001939t + \ln 10.43 \quad (3)$$

$R^2 = 0.67$ and the 95% confidence limits of k were -0.000260 to -0.000128; for 8,10–12:OH:

$$\ln E = -0.0008225t + \ln 16.47 \quad (4)$$

$R^2 = 0.89$ and the 95% confidence limits of k were 0.000964 to 0.000681. In the absence of chemical decomposition $k = k_1k_2$, and therefore the value of k for 12:OH from the regression equation 3 can be compared with k_1 and k_2 for 12:OH obtained from Figure 4 and Table 1. From Table 1 the value of k_2 is 1.96×10^{-3} compared to a value of k from the regression equation 3 of 1.94×10^{-4}. Therefore, k_1 should be about 0.1, which is a reasonable value based on the data of Figure 4. Because these two methods of estimating k agree, 12:OH must have been lost from the dispensers exclusively by evaporation.

Therefore, a value of $k_1 = 0.1$ can be used as an approximation for 8,10–12:OH, also. Then, since k_2 for 8,10–12:OH $= 1.27 \times 10^{-3}$ (Table 1) and if evaporation were the only loss process, k for 8,10–12:OH would be $k_1k_2 = 1.27 \times 10^{-4}$. When this value of k was substituted in place of the experimentally determined k in the regression equation 4 for 8,10–12:OH (keeping the same E_0 value), the calculated theoretical value of E after 150 days (3600 hr) was found to be 10.43 μg/hr compared to the observed value of 0.85 μg/hr (equation 4). Since the evaporation rate is proportional to the amount of material remaining in the well, the difference between observed and theoretical final evaporation rates is a measure of the amount lost because of decomposition. Therefore, the percentage of 8,10–12:OH lost by decomposition was 100(10.43

$- 0.85)/(16.47 - 0.85) = 61$. This is an approximate value because the value of k_1 was approximate. However, the result is not very sensitive to the value of k_1. For example, for k_1 values of 0.09 and 0.11, the percent decomposition would be 64.5 and 58.2, respectively.

Comparison of 1991 and 1990 Dispensers. Heat summation units for the period 1980–1991, except for 1982, and from April 1 to September 30 each year were calculated with lower and upper thresholds of 10°C and 31.1°C. The 11-year average was 26,131 ± 3179 deg-hr. In 1991 there were 27,347 deg-hr, and in 1990 there were 32,280 deg-hr.

Evaporation rate data from 1990 and 1991 dispensers allows us to compare data from a fairly average year, 1991 (with heat summation units 4.7% above average), with 1990, the hottest year of this 11-year period (with heat summation units 26% above average). Plots of logarithm E versus time for the 1991 and 1990 dispensers for each component are shown in Figures 2a–c and 3a–c, respectively. The second leg of the 1990 curves shows faster losses than in 1991. The half-lives in days and 95% confidence limits for each compound for 1991 and 1990 (Figures 2 and 3) were: 12:OH, 149 (111–226) and 89.1 (74.2–112); 8,10–12:OH, 35.1 (30.0–42.4) and 31.0 (23.3–46.5); 14:OH, 812 (282–infinity) and 148 (78–1456). The values of E for 14:OH were small and changed slowly with time. Consequently, its half-life values are imprecise. Half-life values for 12:OH were 40% smaller in 1990 compared to 1991, but only 12% smaller for 8,10–12:OH. The main factor in the loss curve for 8,10–12:OH is chemical decomposition. The rate of decomposition is mainly determined by the presence of oxygen and sunlight (Ideses and Shani, 1988) and is not affected very much by temperature; therefore the overall half-life should not be expected to show as large a percentage decrease as does the half-life for 12:OH. Because of the similarity of half-lives of 8,10–12:OH for these two dissimilar years, calculations based on the 1991 data should be broadly applicable to other seasons.

Efficiency of Dispensers. The minimum evaporation rate of *E*8,*E*10–12:OH needed for control of codling moth is not known with the desired precision. The value of the minimum needed evaporation rate will probably vary with moth population, size of trees, and other environmental factors. Charmillot (1990) estimated the value at 10–40 mg/ha-hr, Hathaway et al. (1979) estimated the value at 15 mg/ha-hr, and Cardé et al. (1978) estimated the value at 2 mg/ha-hr. If a value is assumed, equation 4 can be used to determine the number of dispensers needed for various application protocols.

Assuming a minimum needed evaporation rate of 2 mg/ha-hr and one application per season (150 days), the needed number of dispensers is this rate divided by the rate per dispenser on day 150 (2000 μg/ha-hr ÷ 0.853 μg/dispenser-hr) which is 2345 dispensers/ha-season. Fewer dispensers would be needed if more applications were made. If two applications were used per season, the second

application would only have to be enough to replace the amount lost by the time of the second application. After 75 days (from equation 4), the evaporation rate per dispenser is 3.75 μg/hr. The first application would require 533 dispensers (2000/3.75). After 75 days, the evaporation rate of *E*8,*E*10–12:OH had decreased by 77.2% [100 × (16.47 − 3.75)/16.47], and therefore the second application would require 411 (533 × 0.772) for a total of 944 dispensers/ha-season. Similarly, three applications per season would require 326 + 204 + 204 (total: 734) dispensers/ha-season. Clearly, two or three applications are much more efficient than one. If the minimum required evaporation rate is different from 2 mg/ha-hr, the number of required dispensers for each application protocol would be changed in direct proportion.

Acknowledgments—We thank the Washington State Tree Fruit Research Commission for a research grant to partially support this work, Pacific Biocontrol Ltd. for supplying the dispensers, and Patrick Ward for technical assistance.

(Received May 13, 1992; accepted July 30, 1992)

Abstract—The primary objective of this research was to determine if soil extracts could be used directly in bioassays for the detection of allelopathic activity. Here we describe: (1) a way to estimate levels of allelopathic compounds in soil; (2) how pH, solute potential, and/or ion content of extracts may modify the action of allelopathic compounds on germination and radicle and hypocotyl length of crimson clover (*Trifolium incarnatum* L.) and ivy-leaved morning glory (*Ipomoea hederacea* L. Jacquin.); and (3) how biological activity of soil extracts may be determined. A water-autoclave extraction procedure was chosen over the immediate-water and 5-hr EDTA extraction procedures, because the autoclave procedure was effective in extracting solution and reversibly bound ferulic acid as well as phenolic acids from wheat debris. The resulting soil extracts were used directly in germination bioassays. A mixture of phenolic acids similar to that obtained from wheat-no-till soils did not affect germination of clover or morning glory and radicle and hypocotyl length of morning glory. The mixture did, however, reduce radicle and hypocotyl length of clover. Individual phenolic acids also did not inhibit germination, but did reduce radicle and hypocotyl length of both species. 6-MBOA (6-methoxy-2,3-benzoxazolinone), a conversion product of 2-*o*-glu-

cosyl-7-methoxy-1,4-benzoxazin-3-one, a hydroxamic acid in living wheat plants, inhibited germination and radicle and hypocotyl length of clover and morning glory. 6-MBOA, however, was not detected in wheat debris, stubble, or soil extracts. Total phenolic acids (FC) in extracts were determined with Folin and Ciocalteu's phenol reagent. Levels of FC in wheat-conventional-till soil extracts were not related to germination or radicle and hypocotyl length of either species. Levels of FC in wheat-no-till soil extracts were also not related to germination of clover or morning glory, but were inversely related to radicle and hypocotyl length of clover and morning glory. FC values, solute potential, and acidity of wheat-no-till soil extracts appeared to be independent (additive) in action on clover radicle and hypocotyl length. Radicle and hypocotyl length of clover was inversely related to increasing FC and solute potential and directly related to decreasing acidity. Biological activity of extracts was determined best from slopes of radicle and hypocotyl length obtained from bioassays of extract dilutions. Thus, data derived from the water-autoclave extraction procedure, FC analysis, and slope analysis for extract activity in conjunction with data on extract pH and solute potential can be used to estimate allelopathic activity of wheat-no-till soils

Key Words—Cover crops, wheat, *Triticum aestivum*, soybean, *Glycine max*, soil extracts, germination bioassays, phenolic acids, hydroxamic acids, allelopathy, slope analysis, ivy-leaved morning glory, *Ipomoea hederacea*, crimson clover, *Trifolium incarnatum*.

INTRODUCTION

As growers in the United States implement the conservation requirements of the 1985 and 1990 Food Security Acts, many will turn to conservation or no-till agriculture (Worsham, 1990). Understanding how conservation tillage will impact crop production and sustainability of various crop management systems is therefore of considerable interest to U.S. farmers. Although many benefits are cited for no-tillage (i.e., control of soil erosion, soil water retention, reduced use of fossil fuel, etc.), reductions in crop yield and a perceived increased use of herbicides (potential for weed resistance, pollution, etc.) continue to be concerns. The development of effective management options using plant residues could, however, minimize the negative impacts on crop yield and lead to early weed control and a reduction in the use of preemergence herbicides (Worsham, 1991a,b).

Inhibition of weed germination and seedling growth by small grain mulches may be due to: (1) the physical barriers and shading associated with the residues (Worsham, 1989), (2) the immobilization of nitrogen (Broadbent and Tyler, 1962; Kimber, 1973), (3) a reduction in soil disturbance (Worsham, 1989), and/or (4) allelopathic compounds (Chou and Patrick, 1976; Liebl and Worsham, 1983; Shilling et al., 1985, 1986a,b; Barnes et al., 1986; Waller et al., 1987).

Potential allelopathic compounds that have been identified in living and

decomposing tissue of small grains include phenolic acids (Chou and Patrick, 1976; Liebl and Worsham, 1983; Barnes et al., 1986; Blum et al., 1991), organic acids (Patrick, 1971; Chou and Patrick, 1976; Lynch, 1977; Tang and Waiss, 1978; Shilling et al., 1985), hydroxamic acids and related compounds (Willard and Penner, 1976; Niemeyer et al., 1989; Nair et al., 1990), and volatiles (Buttery et al., 1985; Bradow, 1991). The presence of such inhibitors in living and decomposing plant tissue does not, however, always translate into actual allelopathic activity, since the level of inhibition observed for a given weed or crop species depends upon: (1) the sensitivity of the species, (2) an adequate rate of release of inhibitors, (3) the activity and strengths of various "sinks" (i.e., clays, organic matter, microbes, seeds, roots) for inhibitors within the soil, and (4) environmental factors (i.e., temperature, soil nutrition, soil pH, etc.). These observations have led researchers to use soil extracts and various chromatographic techniques to identify and quantify potential inhibitors in soils. The identified potential inhibitors, usually in pure form, have then been tested for toxicity (Rice, 1984). Soil solutions, however, contain a complex mixture of inorganic and organic ions and/or molecules that affect the action of any given organic molecule in solution. The use of soil extracts to simulate the soil solution might thus be more meaningful in determining allelopathic potential. The primary objective of this research was, therefore, to determine if soil extracts could be used directly in bioassays for the detection of allelopathic activity.

We have chosen wheat (*Triticum aestivum* L. Coker 916) –soybean (*Glycine max* L. Merill Deltapine) no-till and conventional-till systems (Cecil and Appling gravelly sandy loam) for exploratory studies. The focus was primarily on phenolic acids and secondarily on 6-methoxy-2,3-benzoxazolinone, a conversion product of 2-*o*-glucosyl-7-methoxy-1,4-benzoxazin-3-one, a hydroxamic acid found in living wheat plants.

METHODS AND MATERIALS

Soil Extraction Procedures. Samples from A_1 and B_1 horizons (from the same pedon) of a Cecil (Typic Kanhaludults, clayey, kaolinitic, thermic) soil from the Piedmont of North Carolina were air-dried, sieved (0.25 mm), and characterized (Dalton et al., 1987). Air-dried soil was stored at room temperature in a laboratory until used. One gram of soil was placed in a 15-ml glass centrifuge tube, capped (Bacti-Capall, Sherwood Medical Industries), and autoclaved three times (15 min at 1.2 kg/cm^2 and 121°C) at three-day intervals. One milliliter of filter-sterilized (0.2-μm membrane filter) ferulic acid (1000 μg/ml), adjusted to pH 5 with NaOH, was added to each tube aseptically. The soil–ferulic acid mixtures were incubated at 24°C in a dark and high relative humidity environment. After 70 days, half the test tubes received 0.5 ml of filtered (What-

man No. 42) soil extract obtained from the appropriate Cecil soil material and 0.5 ml double-strength Hoagland's solution (Hoagland and Arnon, 1950) (pH 5). This reinfected the soil with microorganisms. The other half received 0.5 ml filter-sterilized soil extract and 0.5 ml filter-sterilized double-strength Hoagland's solution.

Soil extracts (300 ml of water per 150 g soil material) for reinfestation were obtained from soil–sand mixtures (1 : 2 soil–sand by weight) that had been treated with 5 ml of a phenolic acid mixture (1230 μg/ml; composition of the seven phenolic acid mixtures is described subsequently) and 30 ml of double-strength Hoagland's solution and incubated in the dark at 30°C for three days (Blum and Shafer, 1988). Thirty days after reinfestation, soil samples were extracted. Three extraction procedures were used: (1) immediate water extraction, (2) water-autoclave extraction (45 min) (Blum et al., 1991), and (3) EDTA extraction (0.5 M EDTA adjusted to pH 8, 5 hr extraction time) (Dalton et al., 1987). The final solution volume in each tube was approximately 4 ml. Actual water content was determined gravimetrically on a subset of test tubes (105°C). Tubes were centrifuged for 10 min at 12,100*g*. The resulting supernatants were filter-sterilized (0.2 μm membrane filters) and injected into an HPLC to quantify extracted ferulic acid (Blum et al., 1991).

Field Soil Samples and Extracts. Soil samples (0–2.5 cm depth) were obtained from soybean plots of a low-input sustainable agriculture (LISA) study located 5 km south of North Carolina State University campus. Soybean plots selected included plots with wheat (*Triticum aestivum* L. Coker 916) stubble (no-till), plots in which the wheat stubble had been tilled into the soil, and plots without wheat. Detailed information on the field plots used has been described by Blum et al. (1991). Soil [Cecil and Appling gravelly sandy loam (Typic Kanhaludults)] samples covering a range of treatments, harvests, and soil depths were chosen from 371 samples collected during July–October, 1989, and 72 samples collected during June–November, 1990. Upon collection, soil samples were sieved (3-mm sieve), placed into plastic bags, and stored at −20°C. Soil samples to be extracted were thawed overnight at 10°C. Water content was determined gravimetrically on 10–15 g of soil (105°C).

To obtain extracts, 50–75 g of soil, depending on the experiment, was placed in a 500-ml Erlenmeyer flask with 100 ml deionized water. Changes in the amount of soil extracted per milliliter of water were made to adjust the baseline concentrations of the extracts. Loosely capped flasks were autoclaved for 45 min, removed from the autoclave, and cooled to room temperature over 20–30 min. The slurry in the flask was centrifuged for 10 min at 27,200*g*, and the resulting supernatant was filtered (Whatman No. 42). Except for the final bioassay experiment, filtered supernatants were adjusted with NaOH or HCl to pH 5 (extract 1) or adjusted to pH 2 with HCl, centrifuged for 10 min at 27,200*g* to remove humic acid, and then adjusted to pH 5 with NaOH (extract 2).

Determination of phenolic acid content in extracts is described below. Freezing point depression of extracts was determined with a Osmette Precision Osmometer (Precision Systems Inc., Natick, Massachusetts). No-till soils for final soil extract bioassay were also analyzed for nitrate, ammonium (Cataldo et al., 1974), phosphorus (Taussky and Shorr, 1953), and potassium (atomic absorption spectroscopy).

Solute Potentials of Extracts. Data from Lang (1967) for sodium chloride (20°C) and a model from Steuter (1981) for polyethylene glycol (PEG) 6000 in conjunction with freezing point depression data were used to estimate the solute potential of salt and PEG solutions. This was done only to identify the range of solute potentials of extracts. Regressions for bioassays, to determine the relationship between soil extract solute potential and seed response, were based on freezing point depression values (milliosmoles, mosmol).

Phenolic Acid Determinations. Five milliliters of ferulic acid (standard phenolic acid) solutions (pH 5) or extracts 1 or 2 (0.5 ml) plus 4.5 ml deionized water were mixed with 0.75 ml of 1.9 M Na_2CO_3 and 0.25 ml Folin and Ciocalteu's phenol reagent. This mixture was incubated in the dark at room temperature for at least 1 hr before absorption at 750 nm was measured (Box, 1983; Blum et al., 1991). This procedure will be referred to subsequently as the FC method. Units of total phenolic acid are in micrograms ferulic acid equivalents per gram of soil or milliliter of soil extract. Individual phenolic acids were determined by HPLC analysis (Blum et al., 1991). Folin and Ciocalteu's phenol reagent and phenolic acids, with the exception of sinapic acid, were purchased from Sigma Chemical Company (St. Louis, Missouri). Sinapic acid was purchased from Aldrich Chemical Company (Milwaukee, Wisconsin).

6-MBOA Determinations. Folin and Ciocalteu's phenol reagent also reacted with 6-methoxy-2,3-benzoxazolinone (6-MBOA). 6-MBOA was purchased from Sigma Chemical Company. The amount of 6-MBOA dissolved in water (pH 5) could be estimated by the FC method and the following equation: μg 6-MBOA $= -1.427 + (98.341 * \text{ABS})$, $R^2 = 0.998$, $P \leq 0.0001$, where ABS = the optical density at 750 nm. The HPLC procedure used to detect and quantify phenolic acids was also used for 6-MBOA. 6-MBOA was detected and quantified, however, at 290 nm instead of 254 nm. 6-MBOA concentrations before and after autoclaving procedures were essentially identical. Since 6-MBOA and *p*-coumaric acid have very similar HPLC retention times, thin-layer chromatography of extracts was also used to confirm the absence or presence of 6-MBOA.

Germination Studies. Twenty crimson clover seeds (*Trifolium incarnatum* L. Jacquin. Tibbee; Funk Seeds International, Bloomington, Illinois) inoculated with *Rhizobium* (Nitragin Co., Milwaukee, Wisconsin) or 10 ivy-leaved morning glory seeds (*Ipomoea hederacea* L.; F&J Seed Service, Woodstock, Illinois) were placed in 9-cm-diameter petri dishes containing Whatman No. 1 filter paper and 5 ml of a solution to be tested. Petri dishes were incubated at 30°C for 48

hr before germination, and the total length of the radicle and hypocotyl were determined.

The following solutions were tested for inhibitory effects: (1) soil extracts adjusted to pH 5, unless otherwise stated; (2) PEG 6000 solutions (pH 5) ranging from 0 (distilled water) to 10%; (3) Hoagland's solution (pH 5) ranging from 0 strength (distilled water) to double-strength; (4) a phenolic acid mixture (12, 11, 17, 12, 33, 10, and 5% of the *p*-hydroxybenzoic, caffeic, vanillic, syringic, *p*-coumaric, ferulic, and sinapic acids, respectively; at total concentrations of 0–394 μg/ml; initial solution pH was 5) with various concentrations of PEG or strengths of Hoagland's solution; (5) individual phenolic acids (caffeic, ferulic, *p*-coumaric, *p*-hydroxybenzoic, vanillic, sinapic, or syringic) or 6-MBOA solutions ranging from 0 to 2 mM (pH 5); or (6) 6-MBOA (0–1 mM) with various concentrations of PEG or various strengths of Hoagland's solution. Molecular weights of phenolic acids and 6-MBOA ranged from 138.1 for *p*-hydroxybenzoic acid to 224.2 for sinapic acid. The proportions of the phenolic acids in the mixture were based on the average values for soil extracts (extract 2) from wheat–no-till plots (Blum et al., 1991). Hoagland's solution of various strengths and PEG solutions of various concentrations were used to generate different solute potentials.

General Data Analyses. Data were analyzed by analysis of variance, regressions (PROC GLM), and response surface (PROC RSREG) analysis (SAS Institute Inc., 1988). An alpha value of 0.05 was used in all instances.

Analysis for Final Soil Extract Bioassay. Experimental details for preliminary bioassays, which varied somewhat from the final soil extract bioassay, are given in the results section. Each of the 33 soil extracts from no-till plots was tested at full-, half-, quarter-, and zero-strength using three subsamples of each extract. All extracts showed a trend towards a greater inhibition at higher concentrations. For the data from each extract, the simple linear regression of clover germination (and, separately, of radicle and hypocotyl lengths) on extract strength (0, 0.25×, 0.5×, 1×) was obtained using a common intercept. The resulting slope for an extract served as a measure of its biological activity (e.g., ability to inhibit germination or radicle and hypocotyl length); the steeper the slope, the higher the activity. For completeness, an overall test for quadratic effects was run and found to be not significant. Thus, the use of simple linear slopes was deemed to be adequate. The slopes were used as input (dependent variable) to a further analysis.

Other characteristics of the extracts were also obtained including pH, FC value, freezing point depression, NO_3^-, NH_4^+, K, and P. Model-building tools such as stepwise regressions (SAS PROC LEAPS) and response surface analysis (SAS PROC RSREG) were used to determine which combinations of these characteristics best accounted for the variability in slopes. The resulting regression model related the extract slopes to the measured characteristics of the extracts.

RESULTS

Soil Extraction Procedures. One hundred days after the addition of 1000 μg/g ferulic acid; water, water-autoclave, and EDTA procedures recovered 28, 32, and 37%, respectively, from sterile Cecil A_1, and 17, 30, 52% from sterile Cecil B_1 soil materials, respectively (Table 1). For soils reinfested with microorganisms, recovery was reduced to less than 2%.

Seventy-two and 83% of the ferulic acid added to sterile Cecil A_1 and B_1 soil materials, respectively, could not be recovered by the water-extraction procedure after 100 days (Table 2). Ferulic acid has been shown to be both reversibly and nonreversibly fixed in Cecil soils (Dalton et al., 1987). Six and 16% of the sorbed ferulic acid was recovered from Cecil A_1 and B_1 soil materials, respectively, by the water-autoclave procedure and 13 and 43% by the EDTA procedure. More than 96% of the sorbed ferulic acid recovered from sterile soil by the EDTA procedure was absent in soil extracts from reinfested soils. This was also true for the sorbed ferulic acid recovered from Cecil B_1 soil material by the water-autoclave procedure. Only 55%, however, of the sorbed ferulic acid recovered from the Cecil A_1 soil material by the water-autoclave procedure was accessible to microbes. The Cecil A_1 and B_1 soil material contained 37 and 2 g organic matter/kg, respectively (Dalton et al., 1987). This suggested that at least part of the sorbed ferulic acid recovered by the water-autoclave procedure came from the organic matter in the soil.

The EDTA procedure recovered 2–2.6 times more sorbed ferulic acid than the water-autoclave procedure. EDTA soil extracts, however, could not be used directly for germination bioassays, because clover and morning glory seeds (our bioassay species) would not germinate in the presence of these extracts. In

TABLE 1. RECOVERY OF ADDED FERULIC ACID FROM CECIL SOIL MATERIAL BY THREE EXTRACTION PROCEDURES

Soil and horizon	Microorganisms[a]	Solution pH just before extraction[b]	Recovery (μg/g ± standard error)		
			Water	Autoclave	EDTA
Cecil A_1	Absent	5.0	277 ± 3	322 ± 10	373 ± 19
	Present	7.4	0 ± 0	20 ± 4	4 ± 0.4
Cecil B_1	Absent	4.6	167 ± 12	304 ± 9	524 ± 6
	Present	5.2	0 ± 0	4 ± 0.4	0.4 ± 0.2

[a] Soil materials were reinfested with microbes 70 days after addition of ferulic acid; extracts of soil were made 30 days after reinfestation; three replicates.

[b] Because of the small volume, solutions from five test tubes were combined for pH measurements. Initial pH values of soils were 5.5 and 5.0 for Cecil A_1 and B_1, respectively.

TABLE 2. ESTIMATES OF FERULIC ACID ADDED TO CECIL SOIL MATERIAL SORBED IN SOIL AFTER 100 DAYS RECOVERED BY AUTOCLAVE AND EDTA PROCEDURES, AND AVAILABLE TO SOIL MICROBES

	Ferulic acid (μg/g)				
		Autoclave procedure		EDTA procedure	
Soil and horizon	Sorbed in soil[a]	Recovered[b]	Utilized by microbes[c]	Recovered[b]	Utilized by microbes[c]
Cecil A_1	723 (72%)[d]	45 (6%)[e]	25 (55%)[f]	96 (13%)[e]	92 (96%)[f]
Cecil B_1	833 (83%)	137 (16%)	133 (97%)	357 (43%)	357 (100%)

[a] Ferulic acid, 1000 μg, was added to 1 g of soil material. Sorbed in soil = amount not recovered by water extraction from sterile soil materials.
[b] For sterile soils. The difference in recovery between the water and autoclave or EDTA procedures.
[c] Difference between sorbed recovered by autoclave or EDTA procedures from sterile soils and soils reinfested with microbes.
[d] Percentage of 1000 μg initially added.
[e] Percentage of sorbed amount that was recovered.
[f] Percentage of recovered amount that was utilized by microbes.

addition, Folin and Ciocalteu's phenol reagent was reduced by EDTA immediately upon contact, thus EDTA soil extracts could not be used to estimate total phenolic acid equivalents in soil extracts. The EDTA extraction procedure also was very ineffective in extracting phenolic acids from plant debris. The EDTA extraction procedure extracted no detectable phenolic acids (HPLC analysis) from ground (60 mesh) wheat stubble (500 mg/100 ml), whereas extracts from the water-autoclave procedure contained 11 distinct peaks (HPLC analysis). Concentrations for ferulic, vanillic, *p*-coumaric, and *p*-hydroxybenzoic were 33, 22, 1034, and 47 μg/g dry weight, respectively. The water-autoclave procedure was, therefore, used in all subsequent studies.

Preliminary Bioassays of Soil Extracts. In an experiment using 1989 soil samples, the phytotoxicity of various concentrations of soil extract (0, 10, 20, 40, 80%) was determined. Data for germination (radicle emergence), mean radicle and hypocotyl length based on all seeds in a Petri dish (RAD), and mean radicle and hypocotyl length based on germinated seeds in a Petri dish (ARAD) of crimson clover were regressed against dilutions of extracts used (see "Analysis for Final Soil Extract Bioassay" in Methods and Materials section for details). Significant slopes for all individual extracts were linear. Six, 50, and 62% of the slopes for extract 1 (crude extract) and 38, 94, and 100% of the slopes for extract 2 (humic acid removed) were significantly greater than zero for germination, RAD, and ARAD, respectively. Thus the removal of humic acid by acidification and subsequent adjustment to pH 5 with NaOH apparently

changed the toxicity of the organic compounds in extract 2 and/or the solute potential of the solution. We suspect it was primarily the solute potential, since the milliosmole values (determined by freezing point depression) of extracts 1 and 2 were 1.25 ± 0.58 and 38.5 ± 2.40, respectively, and the removal of humic acid resulted in only minor changes in the free phenolic acid concentrations in the extract (Blum et al., 1991).

When slopes representing the activity of each extract for germination, RAD or ARAD, were regressed against the FC (total phenolic acid expressed as ferulic acid equivalents) and the milliosmole values of the original extract, only the extract 2 slopes were significantly greater than zero. An analysis based directly on germination, RAD, and ARAD values (not slopes) and FC and milliosmole values of the original extract (no extract dilutions were included in the analysis) resulted in F values that were 50% smaller than the F values from the slope (activity) analysis.

The pellet of humic acid produced by acidification of extract 1 was redissolved in the original volume from which it was recovered by adjusting the water solution to pH 5 with NaOH. The resulting solutions were tested against clover seeds. No significant effects on germination or radicle and hypocotyl length were observed.

For the experiments just discussed, each 0.42 ± 0.005 g of soil was extracted with 1 ml of water (2.35 ml/g). For the following experiment, 0.67 ± 0.005 g (wheat–conventional till) and 0.65 ± 0.006 g (wheat–no till) of soil were extracted with 1 ml of water (1.49 and 1.65 ml/g). These changes were made to adjust the baseline concentrations of the extracts. Extract 1 solutions of 1990 soils from wheat–no-till plots (extract dilutions were not included in this experiment) inhibited RAD and ARAD of clover and ARAD of morning glory (Table 3). The importance of FC and/or milliosmole values in determining RAD and ARAD responses depended on which of these variables was first placed in the response surface analyses (Table 3). This suggested that a colinearity existed between FC values and solute potential of the extract solutions. Extract 1 solutions of 1990 soils from conventional wheat–tilled plots did not affect germination or radicle and hypocotyl length of clover or morning glory.

Solute Potentials of Extracts. Modeling of NaCl solution freezing point depression values with solute potentials from Lang (1967) resulted in the following equation: J/kg of NaCl solution $= -2.133 \times 10^{-5} - (2.0924 \times 10^{-6} \times \text{mosmol}) - [1.3706 \times 10^{-9} \times (\text{mosmol})^2]$; $P \leq 0.0001$; $R^2 = 0.99$. Modeling of freezing point depression values for PEG 6000 with solute potential values generated from the PEG 6000 model of Steuter (1981) resulted in the following equation: J/kg of PEG $= 3.843 \times 10^{-6} - (1.426 \times 10^{-6} \times \text{mosmol})$; $P \leq 0.0001$; $R^2 = 0.99$. J/kg and mosmol in both equations represents joules per kilogram and milliosmoles, respectively.

Applying these equations, we found that NaCl (representing Hoagland's

[a] Analysis run twice using different order of sources.
[b] RAD = sum of radicle and hypocotyl lengths (millimeters) in a Petri dish divided by the number of seeds in the dish (seeds per Petri dish: 20 for clover and 10 for morning glory); ARAD = sum of radicle and hypocotyl lengths in a Petri dish divided by the number of germinated seeds in the dish.
[c] FC values (estimated phenolic acid values) ranged from 49 to 174 μg/ml ferulic acid equivalents. Milliosmole values ranged from 8 to 24. These values do not describe the factor space because they are not entirely independent.
[d] Values in parentheses are *P* values; if no *P* values are given then $P > 0.05$.

solution) and PEG solutions of 20 mosmol, for example, would equal -6.4×10^{-5} J/kg (−0.064 MPa) and -2.6×10^{-5} J/kg (−0.026 MPa), respectively. The solute potential of a 20 mosmol NaCl solution was thus 2.46 more negative in value than a 20 mosmol PEG solution. The J/kg values for 80 mosmol NaCl and PEG solutions were -2.0×10^{-4} (−0.20 MPa) and -1.1×10^{-4} (−0.11 MPa), respectively. In this case the NaCl solution was 1.82 times more negative than the PEG solution.

PEG and PEG–Phenolic Acid Mixtures. As the milliosmoles of the PEG solutions increased, germination, RAD, and ARAD declined (Table 4; Figure 1). A solution of 20 mosmol, for example, reduced clover germination, RAD and ARAD by 0, 13, and 5%, respectively. Morning glory germination, RAD, and ARAD were reduced 28, 44, and 36%, respectively.

As the milliosmoles of the PEG solutions increased, the effects of the phenolic acid mixture declined for RAD and ARAD of clover (Table 5; Figure 2). RAD and ARAD of morning glory were not affected by the concentrations

R^2	0.61	0.61
P	0.0001	0.0001

[a] Milliosmole values for PEG solutions ranged from 0 (distilled water) to 90. Phenolic acid mixtures ranged from 0 to 393.6 μg/ml of solution. Mixtures were composed of 15% *p*-hydroxybenzoic, 10% caffeic, 17% vanillic, 10% syringic, 35% *p*-coumaric, 9% ferulic and 4% sinapic; 5 replicates.

[b] RAD = sum of radicles and hypocotyl lengths (millimeters) in a Petri dish divided by the number of seeds in the dish (20 seeds); ARAD = sum of radicles and hypocotyl lengths in a Petri dish divided by the number of germinated seeds in the dish.

of the phenolic acid mixture used. The phenolic acid mixture consisted of seven phenolic acids proportioned to that observed for soils from no-till wheat–soybean plots (see Table 5 for composition) (Blum et al., 1991). Germination of both species was not altered by the concentrations of the phenolic acid mixture used. The increasing milliosmoles of the PEG solution did, however, reduce germination of both species as noted earlier (Table 4; Figure 1).

Hoagland's, Hoagland's–Phenolic Acid Mixtures. Clover germination, RAD, and ARAD were reduced with increasing strength of Hoagland's solution (Table 6; Figure 3). A solution of 20 mosmol reduced clover germination, RAD, and ARAD by 64, 71, and 35%, respectively. Morning glory germination was not affected by the zero to double-strength Hoagland's solutions. RAD and ARAD values of morning glory increased and then decreased (Table 6; Figure 3) as the strength of Hoagland's solution increased.

Since morning glory germination and radicle and hypocotyl length were not affected by the concentrations of the phenolic acid mixtures used, only clover seeds were treated with concentrations of the phenolic acid mixture in various strength of Hoagland's solution. Germination of clover was not affected significantly by the concentrations of the phenolic acid mixture. The effects of zero (distilled water) to double-strength Hoagland's solution on RAD and ARAD

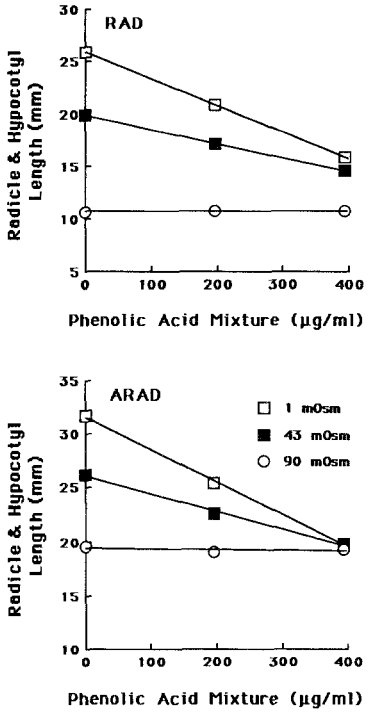

FIG. 2. Modification of the effects of a phenolic acid mixture on radicle and hypocotyl length (RAD, ARAD) of clover by PEG 6000 solutions with different freezing point depressions (milliosmoles). Lines derived from models in Table 5.

were independent of the effects of the phenolic acid mixture, i.e., the effects were additive (Table 7; Figure 4).

Individual Phenolic Acids. None of the seven phenolic acids (0–2 mM; *p*-hydroxybenzoic, vanillic, caffeic, syringic, *p*-coumaric, ferulic, or sinapic) tested affected germination of clover or morning glory (data not shown). Clover RAD and ARAD were reduced by the cinnamic acid derivatives ferulic acid and *p*-coumaric acid and the benzoic acid derivatives *p*-hydroxybenzoic acid and vanillic acid (Table 8; Figure 5). RAD of morning glory was reduced only by *p*-hydroxybenzoic acid and ARAD of morning glory was reduced only by *p*-coumaric acid (Table 8; Figure 6). ARAD of clover, for example, was reduced 26, 11, 10, and 5% by 0.5 mM *p*-coumaric, ferulic, vanillic, and *p*-hydroxybenzoic acids, respectively. ARAD of morning glory was reduced 7% by 0.5 mM *p*-coumaric acid.

6-MBOA, PEG- or Hoagland's-6-MBOA Mixtures. Germination, RAD, and ARAD of both species were reduced by 6-MBOA (Table 9; Figure 7). For

TABLE 6. PARTIAL REGRESSION COEFFICIENTS, R^2, AND P VALUES FOR GERMINATION AND RADICLE AND HYPOCOTYL LENGTH OF CLOVER AND MORNING GLORY SEEDS GERMINATED IN VARIOUS STRENGTHS OF HOAGLAND'S SOLUTION[a]

Variable[b]	Intercept	Linear	Quadratic	R^2	P
Clover					
GERM	0.5999	−0.0231	0.0002	0.69	0.0001
RAD	10.8237	−0.4946	0.0054	0.72	0.0001
ARAD	19.0369	−0.4040	0.0034	0.55	0.0001
Morning-glory					
RAD	32.4311	1.1830	−0.0163	0.23	0.031
ARAD	44.3235	1.2762	−0.0189	0.33	0.005

[a] Milliosmoles of the various strengths of Hoagland's solution ranged from 0 to 61; 5 replicates.
[b] GERM = germination; RAD = sum of radicle and hypocotyl lengths (millimeters) in a Petri dish divided by the number of seeds in the dish (seeds per Petri dish: 20 for clover and 10 for morning glory); ARAD = sum of radicle and hypocotyl lengths in a Petri dish divided by the number of germinated seeds in the dish.

example, a 0.5 mM 6-MBOA solution reduced clover germination, RAD, and ARAD values by 24–28%. Morning glory germination, RAD, and ARAD were reduced 14, 23, and 22%, respectively.

As the milliosmoles of the PEG solutions increased, the effects of 6-MBOA on clover germination and clover and morning glory RAD values declined (Table 10; Figures 8 and 9). The effects of mixtures of PEG and 6-MBOA on clover and morning glory ARAD were independent, i.e., the effects were additive.

As the milliosmoles of the various Hoagland's solutions increased, the effects of 6-MBOA on germination and RAD values of clover declined (Table 11). The various strengths of Hoagland's solution did not alter clover ARAD or morning glory RAD and ARAD values. Germination of morning glory was also not affected by 0–1 mM 6-MBOA.

Final Bioassay of Extracts. A subset of 1990 wheat–no-till soil samples was extracted by the water-autoclave procedure. The 33 soil samples chosen represented a cross section of the soil samples collected. Soil extract (extract 1) characteristics were as follows: pH 5.7 ± 0.058, freezing point depression 11.35 ± 0.757 mosmol, FC 121.94 ± 4.26 μg/ml ferulic acid equivalents, NO_3^- 6.016 ± 0.878 μg/ml, NH_4^+ 5.27 ± 0.1267 μg/ml, K 109.72 ± 5.496 μg/ml, and P 17.81 ± 0.951 μg/ml (number of extracts = 33). Since each milliliter of extract represented 0.60 ± 0.01 g soil, 1.68 ml of extract represented 1 g of soil. Five milliliters of extract or diluted extract were used in each Petri dish, thus the extract in each dish represented ≤3 g of soil or ≤0.15 g per crimson

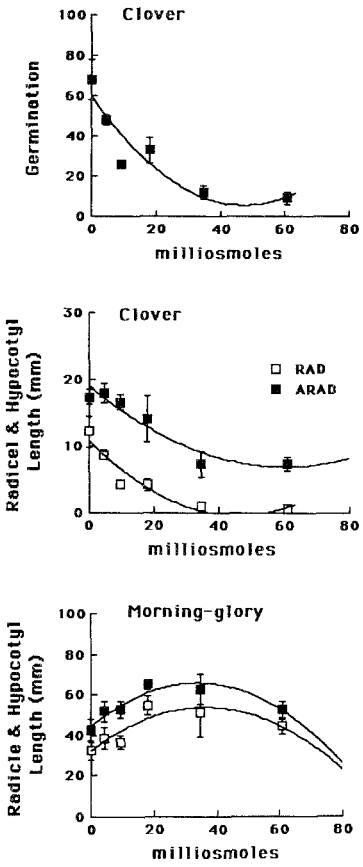

FIG. 3. Effects of Hoagland's solutions with different freezing point depressions (milliosmoles) on germination and radicle and hypocotyl length (RAD, ARAD) of clover and/or morning glory. Means ± standard errors.

clover seed (20 seeds per dish). See "Analysis for Final Soil Extract Bioassay" in Methods and Materials section for additional details.

The phytotoxicity of various dilutions of extract (0, 0.25×, 0.5×, and 1× strength) was determined on clover seeds. Sixty-three, 97, and 100% of the slopes were significantly greater than zero for clover germination, RAD and ARAD, respectively. Slopes were regressed against FC (μg/ml ferulic acid equivalents); milliosmoles; concentrations (μg/ml) of K, P, NO_3^- and NH_4^+, and pH of original soil extracts. PROC LEAPS, PROC RSREG, and PROC GLM procedures of SAS were used to identify the significant independent variables and to generate models (Tables 12 and 13; Figure 10). Partial regres-

R^2	0.37	0.19
P	0.0001	0.0001

[a] Milliosmole values for the various strengths of Hoagland's solution ranged from 0 (distilled water) to 61. Phenolic acid mixture ranged from 0 to 393.6 μg/ml of solution. See Table 3 for composition of the phenolic acid mixture; 5 replicates.

[b] RAD = sum of radicles and hypocotyl lengths (millimeters) in a Petri dish divided by the number of seeds in the dish (20 seeds); ARAD = sum of radicles and hypocotyl lengths in a Petri dish divided by the number of germinated seed in the dish.

sion coefficients for FC values, milliosmoles, and pH were significant for clover RAD slopes, but only the partial regression coefficient for FC values was significant for clover ARAD slopes.

Clover RAD slopes, representing extract activity, became more negative with increasing FC values (linear), milliosmole values (concave), and pH values (linear). The more negative the slope, the more inhibitory the factor. The relationship of FC, milliosmoles, and acidity on clover RAD were independent, i.e., the effects were additive.

A separate analysis based on actual clover germination, RAD, and ARAD values (not slopes) and undiluted extracts confirmed the earlier observation (based on F values) that slope analysis was a more powerful tool in detecting the significant extract characteristics and their effects on germination and radicle and hypocotyl length.

DISCUSSION

An effective protocol for the identification of a functional allelopathic cover crop should provide: (1) an estimate, preferably a single integrated value, of the levels of active compounds in the soil; (2) an estimate of the biological activity of the observed action fraction; and (3) an estimate of how physical and chemical soil factors (e.g., pH, water potential, fertility, etc.) may moderate the effects of this active fraction. In addition, the relationship between the cover crop and crop performance must also ultimately be determined.

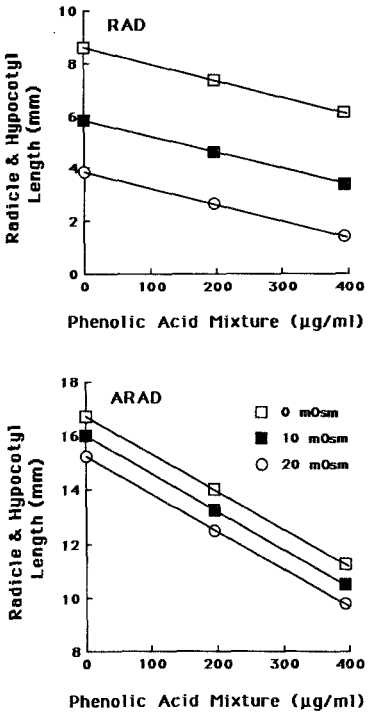

FIG. 4. Modification of the effects of a phenolic acid mixture on radicle and hypocotyl length (RAD, ARAD) of clover by Hoagland's solutions with different freezing point depressions (milliosmoles). Lines derived from models in Table 7.

Estimating Levels of Active Compounds in Soil. All productive agricultural soils contain a large number of organic substances, many of which can affect germination and growth of weeds and crops. Experience and the literature, however, suggest that certain types of compounds are more likely than others to inhibit germination and growth. In wheat systems, these include phenolic acids (Chou and Patrick, 1976; Liebl and Worsham, 1983; Barnes et al., 1986; Blum et al., 1991), organic acids (Patrick, 1971; Chou and Patrick, 1976; Lynch, 1977; Tang and Waiss, 1978; Shilling et al., 1985), hydroxamic acids and related compounds (Willard and Penner, 1976; Niemeyer et al., 1989; Nair et al., 1990), and volatiles (Buttery et al., 1985; Bradow, 1991).

Based on the recovery of ferulic acid, a phenolic acid, from sterile and nonsterile Cecil soils (Tables 1 and 2), water (immediate) and EDTA (0.5 M; pH 8; 5-hr extraction) extractions will provide a reasonable and adequate estimate of the active fraction of free or readily exchangeable phenolic acids in soils, but not phenolic acids in plant debris and/or soil organic matter. The

immediate water extraction will provide an estimate of phenolic acid concentrations in soil solution, and the difference in the recovery of phenolic acid concentrations by the water and EDTA extraction will provide an estimate of that which is immediately available to go into soil solution. EDTA extracts of soil, which contain soil solution and reversibly bound phenolic acids, however, could not be used directly in germination bioassays, because 0.5 M, pH 8 EDTA solutions completely inhibited clover and morning glory germination. Longer-term soil extractions with water, to recover at least some of the reversibly bound phenolic acids in soils, could not be used because microbes utilize phenolic acids as a carbon source during the extraction period (Blum and Shafer, 1988). We therefore chose to use the water-autoclave procedure. This procedure is rapid, eliminates microbial activity in the extract, and changes extract acidity within acceptable limits (soil pH 6.5 $\pm$ 0.06, extract pH 5.6 $\pm$ 0.05, $N = 72$). Adjustments of extracts to a common pH were not desirable due to the variations this generated in solute potential for soil extracts. Soil extracts produced by the water-autoclave procedure were thus used directly in germination bioassays.

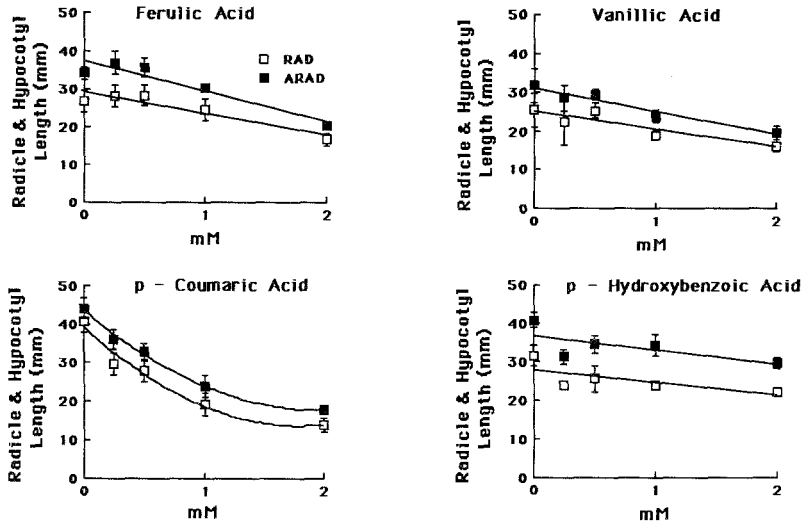

FIG. 5. Effects of individual phenolic acids on radicle and hypocotyl length (RAD, ARAD) of clover. Means ± standard errors.

Identification and quantification of individual phenolic acids in soil extracts by HPLC analysis were very time-consuming (approximately 1 hr per sample); so a rapid means of estimating phenolic acid content was required. An estimate of total phenolic acid, expressed as ferulic acid equivalents, in soil extracts was obtained by the use of Folin and Ciocalteu's phenol reagent (FC method). The resulting values were correlated ($r \geq 0.95$ for 1989 data and $r \geq 0.85$ for 1990 data) with the sum of seven phenolic acid concentrations in water-autoclave extracts as determined by HPLC analysis (Blum et al., 1991). Average values estimated by the FC procedure were 16.75 (1989) and 18 (1990) times greater than those determined by HPLC analysis. The phenol reagent used in the FC procedure was immediately reduced by EDTA, and thus EDTA extracts of soil could not be used to estimate total phenolic acid as ferulic acid equivalents. The phenol reagent is also reduced by a number of other organic and inorganic substances (Box, 1983) including 6-MBOA. 6-MBOA, however, was not detected by HPLC analysis or thin-layer chromatography in any of the wheat debris and soil extracts. This does not, however, preclude the presence of other hydroxamic acids or related products. Hydroxamic acids are constitutive secondary metabolites in several grasses (Zuniga et al., 1983), including wheat, maize, and rye (Willard and Penner, 1976). Wheat contains primarily 2-*o*-glucosyl-7-methoxy-1,4-benzoxazin-3-one (DIMBOA glucoside) (Willard and Penner, 1976; Nair et al., 1990). Upon cell injury, this glucoside is hydrolyzed and spontaneously converted to 6-MBOA. Since DIMBOA does not appear

to be released by living wheat plants (Argandona et al., 1987; Perez and Ormeno-Nunez, 1991), we assumed that injury of tissue with associated conversion to 6-MBOA was required. 6-MBOA was, however, not detected in soil or wheat debris extracts.

Potential Soil Extract Characteristics and Germination Bioassays. Germination and radicle and hypocotyl growth of weed and crop seeds are affected by many physical and chemical characteristics of soil extracts, such as pH, solute potential, nutrient content, and organic matter content. Effects of soil extracts on seed germination and radicle and hypocotyl length thus are not the exclusive property of allelopathic agents present in the extract, but are a product of all such factors acting independently or in concert with each other.

Crimson clover and ivy-leaved morning glory were used as bioassay species to characterize the role of some of these factors and their interactions. Crimson clover was chosen because of frequently poor early fall stands of clover seeded into our wheat–no-till soybean plots. Ivy-leaved morning glory was chosen

[a] Milliosmole values for PEG solutions ranged from 0 (distilled water) to 84; 6-MBOA ranged from 0 to 0.87 mM; 5 replicates.

[b] GERM = germination; RAD = sum of radicles and hypocotyl lengths (millimeters) in Petri dish divided by number of seeds in dish (seeds per Petri dish: 20 for clover and 10 for morning glory); ARAD = sum of radicle and hypocotyl lengths in a Petri dish divided by the number of germinated seeds in dish.

because it is a noxious weed, and because Liebl and Worsham (1983) reported a significant reduction in morning glory in field studies involving wheat mulch.

Germination (i.e., radicle emergence) of clover and morning glory was not affected by the seven individual phenolic acids (0–2 mM) tested. Clover radicle and hypocotyl length was inhibited more than morning glory radicle and hypocotyl length by individual phenolic acids. A mixture of phenolic acids that simulated the composition of phenolic acids in wheat–no-till soil extracts inhibited radicle and hypocotyl length of clover but not of morning glory. Crimson clover thus became our primary bioassay species.

Although experiments with seven individual phenolic acids, 6-MBOA, and a mixture of phenolic acids that simulated wheat–no-till extracts were included in these studies, the effects of complex mixtures of organic compounds on germination and radicle and hypocotyl length were not addressed directly. Since FC values of soil extracts represent the Folin and Ciocalteu's phenol reagent-reactive portion of such organic complexes, identifying the composition of these reactive organic complexes would appear to be an important area for future study. Attempts to understand the effects of simple mixtures of phenolic acids on germination and plant growth have been made by a number of researchers (Rasmussen and Einhellig, 1977; Williams and Hoagland, 1982; Blum et al., 1984, 1985, 1989; Einhellig, 1987; Gerig and Blum, 1991), but these represent

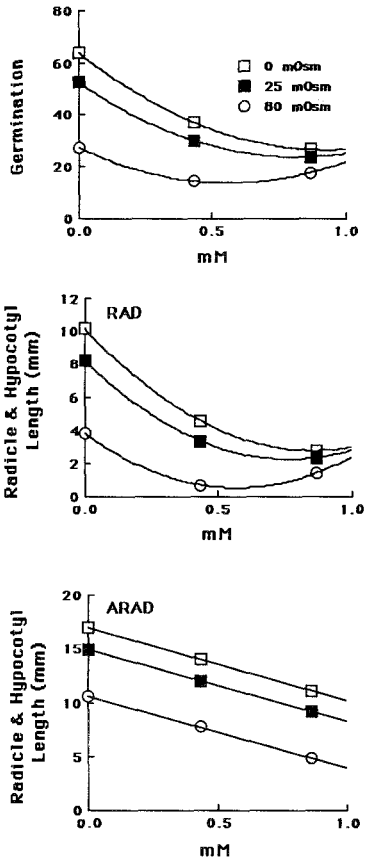

FIG. 8. Modification of the effects of 6-MBOA on germination and radicle and hypocotyl length (RAD, ARAD) of clover by PEG 6000 solutions with different freezing point depressions (milliosmoles). Lines derived from models in Table 10.

only a first step in understanding the role of complex organic mixtures in allelopathic interactions. Apparently, concentrations of individual phenolic acids in mixtures required for a given growth inhibition decline as the number of phenolic acids in a mixture increases (Gerig and Blum, 1991).

The effects of extract acidity on germination and radicle and hypocotyl length were also not determined in this study, but Blum et al. (1984, 1985) noted that effects of phenolic acids on radicle and seedling growth of some crop species were greater under acidic conditions than under neutral conditions. Changes in the acidity of phenolic acid solutions did not, however, result in any detectable modification of ladino clover (*Trifolium repens* L. Tillman) radicle length.

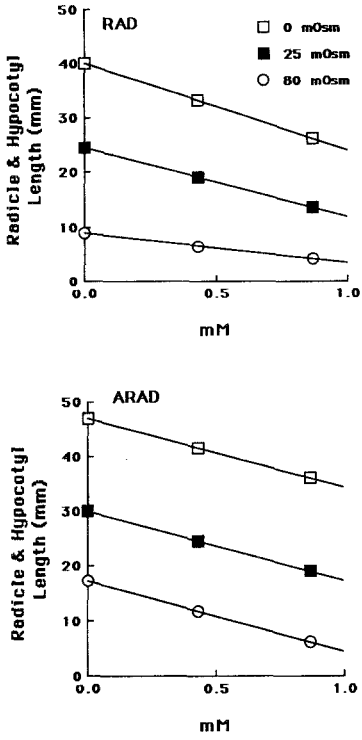

FIG. 9. Modification of the effects of 6-MBOA on radicle and hypocotyl length (RAD, ARAD) of morning glory by PEG 6000 solutions with different freezing point depressions (milliosmoles). Lines derived from models in Table 10.

The response of crimson clover and/or ivy-leaved morning glory seeds to PEG and Hoagland's solutions were substantially different. For example, PEG and Hoagland's solutions with freezing point depressions of 20 mosmol reduced clover RAD 13 and 71%, respectively. Morning glory RAD was reduced 44% by PEG and stimulated 52% by the Hoagland's solution. In addition, inhibition of clover RAD by the phenolic acid mixture declined as the milliosmoles for the different PEG concentrations was increased, whereas the inhibition of the phenolic acid mixture on clover RAD was independent of the milliosmoles for the different strengths of Hoagland's solution. These observations suggest the possibility of a series of complex interactions among clover or morning glory seeds, nutrient ions, and solute potentials of soil extracts. These differences in response may have been due to the nature of the osmoticum (i.e., organic vs. inorganic, nonionic vs. ionic) and/or the biological activity of the PEG molecules and/or the ions in the Hoagland's solution as perceived by the two species.

TABLE 11. PARTIAL REGRESSION COEFFICIENTS, R^2, AND P VALUES FOR GERMINATION AND RADICLE AND HYPOCOTYL LENGTH OF CLOVER AND MORNING GLORY SEEDS GERMINATED IN VARIOUS CONCENTRATIONS OF 6-MBOA AND VARIOUS STRENGTHS OF HOAGLAND'S SOLUTION[a]

[a] Analysis run several times using different order of sources.
[b] RAD = sum of radicle and hypocotyl lengths (millimeters) in a Petri dish divided by the number of seeds in the dish (20 seeds).
[c] FC values ranged (estimated phenolic acid values) from 67 to 162 μg/ml ferulic acid equivalents; milliosmole values ranged from 2.8 to 18.6; pH values ranged from 4.9 to 6.4. These values do not describe the factor space because they are not entirely independent.
[d] Values in parentheses are *P* values; if no *P* values are given, then $P > 0.05$.

The solute potential of a NaCl solution (simulation of the Hoagland's solution) at 20 mosmol was 2.46 times more negative than a 20 mosmol PEG solution.

In summary, these observations suggest that before allelopathic effects of soil or plant extracts can be identified, the action of other physical and chemical properties (e.g., pH, solute potential, nutrient ion content, etc.) of the extracts and the interactions among such properties and allelopathic agents must be identified for any given bioassay species. One way of identifying potential active properties of extract solutions is to apply regression procedures to biological responses and extract characteristics.

Final Soil Extract Bioassay. In an attempt to estimate the activity of soils, extracts from soils were tested at various dilutions. Germination and radicle and hypocotyl length of clover were then regressed against the dilutions of these extracts. The resulting slopes, which represented activity of these extracts, were

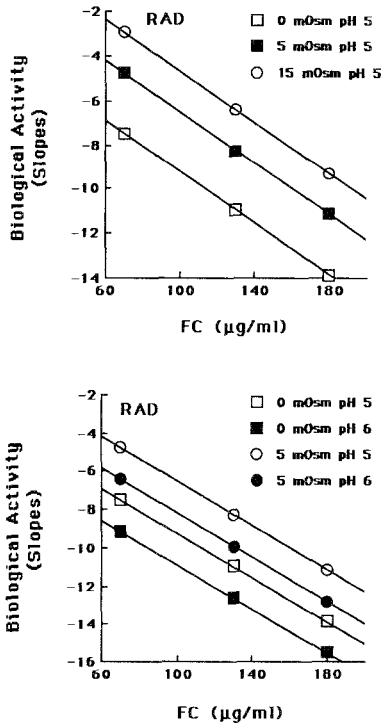

FIG. 10. Activity (slopes) versus FC (micrograms per gram ferulic acid equivalents), freezing point depression (milliosmoles), and pH in wheat–no-till soil extracts on radicle and hypocotyl length (RAD) of clover. The more negative the slope the greater the inhibition of radicle and hypocotyl length. Lines derived from models in Table 12.

then regressed against various characteristics of the extracts, including FC values, pH, freezing point depression, and ion content. This approach appeared to be a useful technique for the identification of the role and potential importance of allelopathic agents in soils.

We chose to estimate primarily the role of phenolic acids and secondarily 6-MBOA, in wheat–no-till and conventional till systems because numerous researchers have suggested that these were the important allelopathic compounds in wheat systems (see Rice, 1984; also see Introduction). Since 6-MBOA was not detected, the FC method was used primarily to estimate phenolic acid content in extracts (Box, 1983; Blum et al., 1991, also see Methods and Materials). Since the effects of allelopathic compounds are concentration-dependent, the amount of soil extracted per unit of water is important. Average dry weights of soil extracted for preliminary bioassay experiments by 1 ml water for 1989 and 1990 and the final 1990 soil extract bioassay were 0.42, 0.65 and 0.67 (no till

and conventional till), and 0.60 g, respectively. Petri dishes with undiluted extracts (5 ml) thus contained extracts derived from 2.10, 3.25 and 3.35, and 3 g of soil. Mean FC values (micrograms of ferulic acid equivalents per milliliter), and minimum and maximum values were as follows: (1) 1989 preliminary experiment, crude extracts—44, 19, and 70 (extracts with humic acid removed were approximately 10% lower); (2) 1990 preliminary experiment, wheat–conventional till—88, 40, and 154; wheat–no till—119, 49, and 174; and (3) 1990 final experiment, wheat–no-till—121, 67, and 162.

No significant FC trends for germination of both clover and morning glory seeds were observed for the 1989 and 1990 soil extracts. However, trends for FC values of extracts from wheat–no-till soils were observed for radicle and hypocotyl length of both species and slopes of radicle and hypocotyl length for clover; slopes for morning glory were not determined. The amount of soil extracted per unit of water for 1989 soil samples and for 1990 wheat–conventional-till soil samples resulted in FC concentration gradients that were too low for detectable trends by clover or morning glory.

Slopes for clover RAD (mean radicle and hypocotyl length based on all seeds in a Petri dish) became more negative with increasing FC, milliosmoles, and pH values; the more negative the slope, the more inhibitory the factor. Other soil extract characteristics such as NO_3^-, NH_4^+, K, and P were not found to make a significant contribution in characterizing the RAD response. The relationships of increasing soil extract FC, milliosmoles, and acidity on clover RAD were independent; i.e., the "effects" were additive.

Extract FC relationships for clover RAD were consistent with the effects observed with individual or the mixture of phenolic acids. The independent and additive actions of extract FC and solute potentials (represented here by milliosmoles) on clover RAD were consistent with the results observed for the phenolic acid mixture–Hoagland's solution experiment, but not for the phenolic acid mixture–PEG experiment. We suspect that the solute potentials produced by various dilutions of Hoagland's solutions more closely mimic solute potentials of soil extracts than the solute potentials produced by various dilutions of PEG. The effects of 6-MBOA on clover germination and the interactions between 6-MBOA and milliosmoles of Hoagland's solutions on clover RAD were not consistent with the activity of the soil extracts. The importance of other hydroxamic acids and other phytotoxins present in the extracts are presently unknown.

As the extract acidity increased, the toxicity (the slope) associated with FC decreased. We do not know how phenolic acid solutions with different pH values may affect radicle and hypocotyl length of crimson clover, but the effects of phenolic acids on radicle length of another clover species (*Trifolium repens* cv. Tillman) were not modified by solution pH (Blum et al., 1984). We do know, however, that the higher the acidity of the soil at the time of extraction, the lower the amount of phenolic acid recovered from soil (Dalton et al., 1983).

Furthermore, the lowest recovery of phenolic acids from soils occurs with acidic extractants when compared to neutral or basic extractants (Whitehead et al., 1981). We suspect that these may explain the relationships noted for extract pH, especially since soils were extracted with water, and thereby the initial soil pH and the extractant pH were determinants of the soil sample.

Trends for clover ARAD (mean radicle and hypocotyl length based on germinated seeds in a Petri dish) were noted only for FC values of the extract. ARAD values represent growth of active seeds, while RAD values represent growth associated with all seeds in a population. The lower R^2 values for ARAD, when compared to RAD, most likely were a result of genetic variation associates with clover seed lots. For example a few insensitive seeds within a Petri dish affected ARAD values much more than RAD values.

Summary. The water-autoclave procedure in conjunction with the FC method can provide a single estimate of the level of available phenolic acids in wheat–no-till and conventional till soil samples. The use of appropriate species and slope analyses of extracts should provide a measure of biological activity. The resulting slopes may be regressed against appropriate characteristics of the extract, such as solute potential, pH, etc., to study their relationships to biological activity. Thus soil extracts may be used directly to identify potential allelopathic activity in wheat soils.

Acknowledgments—The authors wish to thank Drs. W.S. Chilton, R.C. Fites, and S.R. Shafer for review of this manuscript and Martha Brewster for her technical assistance in the field and the laboratory. This research was partially supported by the Southern Region Low-Input Sustainable Agricultural Research and Extension Program of USDA, and the North Carolina Agricultural Research Service.

(Received January 21, 1992; accepted August 3, 1992)

Abstract—House mice (*Mus musculus*) living in outdoor enclosures were tested for urinary chemical cue preferences using odor-baited traps. In the first experiment, with only volatile cues available, odors from conspecific males and females of various age classes and reproductive conditions were tested; no preferences were exhibited. In the second experiment mice had both nonvolatile and volatile cues available from the same sources as in experiment I. All age and sex class and female reproductive condition groups exhibited odor cue preferences except juvenile females. There were no specific odor cue preferences exhibited by any of the responder types with regard to odors from juvenile females. In the third and fifth experiments, mice were presented with nonvolatile plus volatile or only volatile urine odor cues, respectively, from four genera, *Mus*, *Peromyscus*, *Microtus*, and *Homo*. Mice of all age classes and both sexes preferred *Mus musculus* odor, were neutral toward *Microtus ochrogaster* odor, and avoided odors from *Peromyscus leucopus* and *Homo sapiens*; these patterns were the same regardless of whether only volatile or both volatile and nonvolatile cues were presented. The fourth and sixth experiments involved testing volatile cues only and volatile cues plus nonvolatile cues from human sweat or feces from dogs, cats, or shrews. Mice avoided the human sweat and feces from cats and shrews, but were neutral toward the odor of dog feces. There were effects on whether mice were trapped in the interior of the enclosure or on the perimeter for some odors tested in these six experiments. The findings provide insights regarding possible functions of odor cues in the behavioral ecology of house mice. Odor-baiting traps can be an effective tool with respect to testing some, but not all questions pertaining to olfactory cues and house mouse social biology.

INTRODUCTION

Olfactory cues play key roles in the behavioral biology of many rodent species (Vandenbergh, 1983a; Albone, 1984; Bronson, 1989), and house mice (*Mus musculus*) in particular (Bronson, 1979; Drickamer, 1986; Vandenbergh and Coppola, 1986). For house mice, odor cues may affect reproductive condition and puberty (e.g., Vandenbergh, 1983b; Drickamer, 1986), recognition of deme membership, age, sex, and reproductive condition (e.g., Bowers and Alexander, 1967; Cox, 1989), mate selection (e.g., Yamazaki et al., 1976; Lenington and Egid, 1985), and urine marking (e.g., Bronson, 1976; Hurst, 1987, 1989, 1990a–c). Similar functions have been reported for olfactory communication in other rodent taxa, including *Peromyscus* (e.g., Doty, 1972) and *Microtus* (e.g., Ferguson et al., 1986). In particular, Doty (1972) reported that female *Peromyscus maniculatus bairdi*, given a choice between odors from males of two species, their own and *P. leucopus noveboracensis*, preferred the homospecific odor when they were in estrus, but exhibited no preference when they were in diestrus.

Recently, Hurst (1990a–c) used laboratory enclosures to study responses by house mice to urine marks made by conspecifics. Dominant and subordinate males use urine marks to orient toward their own territory and away from territories of other males (Hurst, 1990a). Rates of investigation of urine marks and of countermarking indicate that odor communication between females is significant; females mark at high rates to signify their dominant breeding status (Hurst, 1990b). Dominant males countermark all types of female urine (Hurst, 1990c); this is in agreement with an earlier report concerning investigation of olfactory cues by males (Drickamer, 1989). Lastly, Hurst (1990c) reported that although countermarking responses by females were more variable than those for males, females did mark more frequently in response to males not from their own territory than when presented with urine marks from the home territory.

The behavior of many rodents is difficult to study under natural conditions because (1) many are nocturnal and/or (2) they are small and live in habitats where observation is limited or impossible. Odor-baiting of traps has been employed with some success in assessing the significance and possible functions of olfactory cues in rodent behavioral and social biology. Soiled traps are entered more frequently than clean traps by a variety of rodents, including *Microtus townsendii*, *M. agrestis*, *Apodemus sylvaticus*, *A. flavicollis*, and *Clethrionomys*

glareolus (Boonstra and Krebs, 1976; Stoddart, 1982; Gurnell and Little, 1992). *P. leucopus* preferred traps baited with odors from conspecifics of the opposite sex (Mazdzer et al., 1976), confirming a laboratory study of Doty (1973) on the same species. Daly et al. (1978) noted that there were seasonal differences in the tendency of *Peromyscus maniculatus gambelli* to enter traps containing conspecific odors. In a similar study, California voles (*Microtus californicus*) exhibited strong preferences for conspecific odors (Heske, 1987). Daly et al. (1980) showed that for *P. m. gambelli*, traps baited with conspecific odors were preferred by mice in reproductive condition, but mice not in reproductive condition preferred neutral, unbaited traps. In the same study, Daly et al. (1980) reported interspecific responsiveness to rodents in reproductive condition for deer mice, *Perognathus fallax*, and *Dipodomys merriami*. Drickamer (1984) found that *Peromyscus leucopus noveboracensis* and *P. maniculatus gracilis* avoided heterospecific odors and preferred homospecific odors, and also, within each species, there was a strong preference for heterosexual odors.

To our knowledge, while behavioral interactions of house mice and other species have been studied by trapping (Caldwell, 1964; Quandagno, 1968), no one has employed the odor-baiting technique to explore house mouse social behavior or interspecific reactions under natural or seminatural conditions. Rowe (1970) reported that wild stock house mice tested in small laboratory arenas responded differentially to live traps soiled by odors from mice of the opposite sex. Intraspecific odor cues may be important to mice in terms of a number of functions including finding mates, approaching or avoiding conspecifics, individual or deme recognition, and possible interspecific interactions and predator avoidance. Certainly the results of investigations by Hurst (1990a–c), Bronson (1976), Davies and Bellamy (1974), and others indicate that odor cues play key functional roles in the lives of house mice living in commensal situations. Are odor cues significant signals for house mice living under more feral conditions in field enclosures?

The three rodent species (house mice, *Peromyscus leucopus*, and *Microtus ochrogaster*) chosen for investigation in some of these experiments are sympatric over a broad range of the central United States (Hall, 1981). These species exhibit some degree of habitat overlap, either with pairs present in the same location or all three being caught in the same fields in some regions (Linduska, 1950; Whitaker, 1967; Drickamer, unpublished data from southern Illinois). Where interspecific relations involving voles, deer mice, and house mice have been examined in more detail, on species may dominate with the other going to extinction (e.g., *Mus musculus* and *Peromyscus polionotus*) (Caldwell, 1964; Caldwell and Gentry, 1965); one species may increase more rapidly than the other (e.g., *Mus musculus* and *Microtus californicus*) (Quadagno, 1968); or there may be the appearance of general coexistence with numbers for the different species varying slightly over time, but exhibiting no particular directional

patterns (Whitaker, 1967). For most reports of interspecific competition involving these genera and species of rodents, there are no reported observations of actual contact interactions or fighting behavior. The competition between the species must be indirect. While there may be some visual contact, it seems probable that there would be considerable communication via olfactory signals. It is thus of some interest to know whether odor cues may mediate some interactions between house mice, white-footed deer mice, and prairie voles.

Olfactory cues may also be important to rodents in terms of detecting the presence of and avoiding contact with potential predators. Several investigators (Eadie, 1952; Barbehenn, 1958; Fulk, 1972) have shown that activity and spatial relations in voles of several species are influenced by the presence of shrews (*Blarina brevicauda*). The shrews can prey upon the voles and thus we would expect voles to avoid them. Other predators, e.g., foxes and weasels (Madison et al., 1984) also affect the activity and spatial distribution of voles. It seems likely that house mice would also respond to the presence of predators by shifting either their activity and/or their use of space. Olfactory cues could play a significant role in the ability of the mice to detect the presence of potential predators.

To determine the manner in which olfactory cues influence house mouse behavior under natural conditions, we tested the following questions using free-living house mice maintained in outdoor enclosures: (1) Do male and female mice of different age and sex classes exhibit particular preferences for volatile and/or nonvolatile urinary cues from conspecifics of various age and sex classes? (2) Do house mice exhibit differential responses to volatile and/or nonvolatile odor cues from their own species, *Peromyscus leucopus*, *Microtus ochrogaster*, or *Homo sapiens*? (3) Do house mice exhibit differential responses to volatile and/or nonvolatile odor cues from potential predators?

METHODS AND MATERIALS

Enclosures. Eight 0.1-ha enclosures located in an abandoned horse pasture were used for these experiments (see Drickamer and Mikesic, 1990, for full description of the enclosures and their construction). Each enclosure measures 25 × 40 m, has wire mesh and aluminum side walls, and contains four symmetrically placed 2-m-diameter structures, called "mouse cities" (King, 1983), made of 2-m-high aluminum affixed to wooden posts. These mouse cities have a plywood roof, two entrances on opposite sides just above ground level, nesting cavities in cinder blocks located in the interior, and are supplied weekly with food and water. We mowed a 1.5-m strip around the interior perimeter of each enclosure and around each mouse city approximately once each month; in all other areas of each enclosure we allowed the vegetation to grow uncut, attaining

heights of 1–1.5 m. Each enclosure contained a 6 × 9 trapping grid with 5-m intervals between trap stations. The trapping grid thus had 26 trap stations located along the walls of each enclosure and seven rows of four traps each, for a total of 28, in the interior.

Start-Up Procedures. We initiated the enclosure populations with second- and third-generation stock from wild mice originally captured at Little Egypt Grain Co. (Crab Orchard National Wildlife Refuge, Williamson County, Illinois). The pens were started on April 1, 1990, and April 7, 1991, by placing groups of four females and one male into each mouse city (total of four males and 16 females into each enclosure). All eight enclosures were used in 1990 and four enclosures were used in 1991. Starter mice were all 110–160 days of age at the time the enclosures were stocked, and they had been held in unisexual groups of 3–5/cage since weaning at 25–30 days of age. One week prior to placement in the enclosures, mice were housed with one male and four females together. At this time we weighed each mouse to the nearest 0.5 g with a Pesola scale, checked its reproductive condition, and gave it a unique toe-clip ear-punch number. During the first week in the enclosures, mice were restricted to living inside the mouse city where they were placed. We then opened the cities, checked for the presence of the mice, and removed the rubber stoppers from the entrances so that mice had free access to the entire enclosure. Populations were allowed to grow freely for 30 weeks. The first three experiments commenced nine weeks after the pens were started, in early June 1990, and continued for 20 consecutive weeks, until early October. The fourth through sixth experiments were conducted between June and October 1991. The procedures and results are presented in the order in which the experiments were conducted.

Experiment I: Volatile Cues from Conspecifics. The initial experiment was designed to explore the responses of house mice to volatile urine odor cues from various age and sex classes of conspecifics. Eight different urine odor sources were used: adult males, juvenile males, adult estrous females, adult nonestrous females, adult pregnant females, adult lactating females, adult grouped females, and adult juvenile females. Juvenile males were ≤ 15 g body mass and did not have scrotal testes. Juvenile females were ≤ 13 g body mass and had not attained vaginal introitus. Adult males and females were ≥ 100 days of age; males were scrotal and female reproductive condition varied according to the treatment, although all had experienced first vaginal estrus. Grouped females were housed 5–6/cage; all others were housed individually, with their litters, or with a mate. We collected urine using metabolism cages (Maryland Plastics Corp.) with wild stock mice housed in the laboratory colony maintained at 22 $\pm$ 2°C and 50–80% relative humidity with overhead fluorescent lights on from 0800 to 2200 hr. Designated mice were placed in metabolism cages between 1200 and 1300 hours. We provided them with water, but not food, and removed them approximately 20 hr later at 0800 hr. The apparatus was then cleaned thoroughly.

Urine was collected fresh from at least 20 different subjects for each source type. It was pooled, diluted with 3 parts water to 1 part urine, placed in labeled 2-ml vials, and stored in a freezer at −20°C until used in the field enclosures. Freezing does not influence most urinary chemosignals (Drickamer, 1982; Drickamer and Mikesic, 1990) and urinary chemosignals are effective in very small doses (Drickamer, 1984).

The experimental design involved eight enclosures, eight urine odor sources, and eight weeks of testing. A complete Latin-square design was employed with each urine odor treatment occurring in each enclosure for one week. In each pen, 20 of the interior grid stations were used for the experimental test; these stations were the four traps in each of five of the seven rows. The same trap locations were used in each enclosure. Two Sherman live traps (9 × 10 × 25 cm long) were placed at each of these 20 locations; all other locations had a single Sherman live trap. One of each pair of traps was designated as a control trap, and the other as an odorized trap. Thus, there were 74 traps in each enclosure, 26 along the perimeter walls and 48 in the interior, 40 at stations with pairs, and 8 as individual traps. Every live trap was placed inside a half-gallon waxed milk carton, providing additional insulation and protection against the elements. Each week the traps and cartons designated for a particular odor source were rotated to the next designated pen.

Our procedures for control traps in this and subsequent experiments should be explained in detail. All traps were removed from the field, cleaned thoroughly with soap and water, and returned to the field in new, previously unused milk cartons after experiments II, III, IV, and V. The only time this procedure was not followed was between the first two experiments and in that instance we deliberately wanted to have the same set of traps used for both tests. Since all traps, control and experimental traps at the 20 designation stations in each grid, as well as all other traps could acquire some odors at or near their entrances from the passage of other mice, we have made the general assumption that control traps represent a baseline with accumulated odors possible near the entrance. This is then contrasted with odorized traps that have the same possible accumulation of incidental odors near the entrance plus the designated odor that we have supplied. Incidentally, this assumption would be true for all other previous studies of the effects of residual odors as detailed in the Introduction even to the point that within the same night mice could pause outside any trap long enough to deposit some odor, but without entering, although possibly influencing the selection of a trap to enter by any other mouse encountering that trap on that or subsequent nights. We should also note that under our field conditions, house mice did not leave visible urine marks or collections of feces on the traps, or the milk cartons in which the traps were placed, like those described by Hurst and Berreen (1985) for mice living in poultry houses.

The odors were supplied to the traps by placing 0.5 (±0.1) cc of a urine–

water mixture on a cotton square (2.5 × 2.5 × 0.3 cm thick; Ancare Corp.). The urine–water mixture was obtained by thawing appropriate vials from the freezer and mixing the solution with 3 parts water, thus making the final dilution 9 parts water to 1 part urine. The mixture was applied to the cotton square using a hypodermic syringe; different syringes were used for each urine source. Cotton squares were taken to the enclosures and placed into the traps as described below. Since the cotton squares were placed to the rear of the trap, on the treadle, only volatile cues from the odor source would be available to a mouse approaching the entrance of the trap. To obtain more stimulus, including non-volatile odor cues, the mouse was required to go to the rear of the trap.

We live-trapped on two days each week; traps were opened and baited between 1600 and 1800 hr on Tuesday and Thursday afternoons and checked and closed between 0600 and 0800 the next morning. On Tuesday afternoons, we collected all odorized traps and shifted them to the next designated pen in the design. Cotton squares from the previous week were removed and fresh ones were placed in the traps and odorized, then traps were distributed to appropriate stations in the "new" enclosure. All nonodorized traps (including control and perimeter traps) contained a clean cotton square. All traps in each enclosure were opened and baited with a pinch of rolled oats. When a mouse was caught in a control or odorized trap, that trap was removed to the laboratory for thorough cleaning. A clean trap with either a clean cotton square or one with appropriate urine odor was put in its place. On Thursdays we replaced all traps where captures had occurred during the previous trapping session and opened and baited all traps. Also on Thursdays, the cotton square in each odorized trap was refreshed with 0.2 cc of the appropriate urine–water mixture, made up as described previously and placed on the cotton in the traps using the same series of hypodermic syringes.

For each mouse that was captured, we recorded its sex, body mass, and reproductive condition. For males, reproductive condition was recorded as scrotal or nonscrotal. For females, if the vagina was open (all postpubertal female house mice generally have the vagina open continuously), we did a vaginal lavage with a pipet and approximately 0.2 cc of water. The wet-mount vaginal smears were examined in the field with a light microscope to determine the proportion of cornified cells in the smear. Females were classified as estrus (90% or more of the cells in the smear being cornified epithelial cells) or nonestrus (all other combinations of epithelial cells and leukocytes). Pregnancy and lactation were judged by body mass, condition of the nipples, and gentle palpation of the abdomen.

We analyzed the trapping results to determine whether there were any differential responses to the various odors, any differential responses by mice of particular age or sex classes, and any effects on capture rates in the interior versus perimeter locations. Chi-square tests (Sokal and Rohlf, 1981) were used with $\alpha = 0.05$.

Experiment II: Nonvolatile and Volatile Cues from Conspecifics. The second experiment was designed to test responses to both nonvolatile and volatile conspecific urine odor cues. The urine collection procedures, experimental design, field procedures, and analyses were identical to those used in experiment I except that the method of applying the urine to the cotton and traps was altered. Instead of a syringe to place the urine on the cotton square, we employed plastic spray bottles, of the type used for watering house plants. Urine was applied to the cotton square already in the trap and to the open trap door, thus putting odor(s) at the entrance to the trap as well as on the cotton, which was in the rear of the trap, on the treadle. Thus, in contrast to experiment I, mice could obtain either nonvolatile or volatile cues without entering the trap. Separate spray bottles were used for each urine odor type. The concentration of the urine sprayed into the traps was approximately the same as that used for experiment I; 12 cc of the urine–water mixture was obtained from thawed vials and was mixed with 35–40 cc of water, creating an overall dilution of about 1 part urine to 9–10 parts water. The amount of spraying used for each odorized trap in this experiment resulted in the use of the same initial amount of water and urine mixture (0.5 ± 0.1 cc) per trap as in experiment I. We then refreshed each trap entrance and cotton in the odorized traps with ca. 0.2 cc of the appropriate urine–water mixture at the time the traps were opened and baited on Thursday.

The odorized cotton squares in the traps were not changed each week when traps were shifted between pens, except, as noted earlier, when a trap caught a mouse. In the latter case, we always replaced the trap and cotton for the next trapping session.

Experiment III: Nonvolatile and Volatile Cues from Heterospecific Rodents and Human Urine. The third experiment was designed to test the responses of the mice to volatile plus nonvolatile odors from conspecifics and from three other species. Prior to the start of this experiment, all traps were removed to the laboratory and cleaned thoroughly to remove any residual odors from previous experiment; new milk cartons were placed at all stations when the clean traps were replaced into the enclosures. For this test, there were four urine odor sources consisting of pooled urine from males and females of four species: *Mus musculus*, *Peromyscus leucopus*, *Microtus ochrogaster*, and *Homo sapiens*. All but the human urine were collected in the same manner as described previously for experiment I. Mice and voles used for urine collection were first- or second-generation wild stocks being held in colonies in the laboratory (six males and six females—all adults—were used for each species). Human urine was collected from two adult males. As before, all urine was pooled, diluted with 3 parts water to 1 part urine and frozen in 2-ml vials. The experimental design involved four urine sources, four weeks, and all eight enclosures; each urine type was placed into two enclosures in each week. The four urine sources were rotated through the eight pens in four weeks. In all other respects, the design, proce-

dures, and analyses were like those for experiment II, including the fact that urine was sprayed onto the cotton and front door of designated traps and these odorized traps were not changed, except when a mouse was captured. Both odorized and control traps were exchanged for fresh traps when a mouse was captured.

Experiment IV: Volatile Cues from Potential Predators and Human Sweat. The fourth experiment involved testing volatile odors only from potential predators. Four enclosures were used; each of four treatments was tested in each enclosure on two separate occasions. Four odor bait types were rotated through the four enclosures over a four-week period and then the process was repeated for an additional four weeks. The four odor sources consisted of (1) human sweat, collected from an adult male *Homo sapiens*, (2) a homogenate of fecal material obtained from an adult male dog (*Canis familiaris*) mixed with water, (3) a homogenate of fecal material obtained from an adult male and an adult female cat (*Felis domesticus*) mixed with water, and (4) a homogenate of fecal material obtained from two short-tailed shrews (*Blarina brevicauda*) of unknown sex, mixed with water. The homogenates were prepared and frozen in 2-ml vials until used. Procedures for providing the odor baits to the traps on cotton squares and the trapping scheme were identical to experiment I. All traps and milk cartons were clean at the start of this experiment.

Experiment V: Volatile Cues from Heterospecifics and Human Urine. In this experiment we tested the effects of using only volatile odor cues from the four species used for experiment III, *Mus musculus*, *Microtus ochrogaster*, *Peromyscus leucopus*, and *Homo sapiens*. The design was similar to experiment IV, with four enclosures each tested twice in an eight-week period. The procedures for providing the cotton squares with odors and the trapping scheme were identical to those in experiment I.

Experiment VI: Nonvolatile and Volatile Cues from Potential Predators and Human Sweat. The final experiment involved testing responses to volatile plus nonvolatile odor cues from the potential predators tested in experiment IV. The design involved only four weeks and a single placement of each odor type into each of four enclosures. The methods used for odor-baiting the traps followed those for experiment II and all other procedures were as in experiment I.

Assumptions. We examined several assumptions inherent in the experimental methods just described to ensure the validity of the results. The number of misfired traps, those that were closed on a trap-check monitoring but did not contain mice, could be a problem if there were a large number of them. Furthermore, traps that had the mechanism set such that the trap would not fire, even with a mouse inside, could lead to loss of information. Across the eight enclosures and over the 20 weeks of testing there were 592 traps open each session for two sessions each week (74 traps/enclosure), providing a total of

23,680 trap nights in 1990. For 1991, there were four enclosures used for 20 weeks of testing with two trapping sessions each week and 296 traps open for each session, giving a total of 11,840 trap nights (74 traps/enclosure). There were, per trapping session, on average, less than five misfires and less than four traps that likely would not close if a mouse had entered. Both of these values are less than 1% of the available traps. (We should note that each time either problem was detected, the trap was adjusted or replaced as necessary.) Thus, it would appear that neither of these issues caused any measurable bias in our data.

A second issue is that some mice may get caught on both nights in a given week. Concerning the independence of these data points, we ascertained whether such occurrences comprised a significant percentage of the total captures and whether, when mice were caught twice in the same week, they were captured at different types of traps. Recaptures could be in the same type of trap, e.g., odorized (first capture)–odorized (second capture), control–control, nonexperimental–nonexperimental, or some combination of different sources, e.g., odorized–control, etc. The rate of recaptures varied from 10% to 19% across the six experiments (Table 1). This might be cause for some concern. However, of the various total recaptures within experiments, only very small proportions (<2%) were mice caught twice in the same type of trap (Table 1). Thus, we feel justified in using each capture as an independent event for our analyses.

A third issue concerns whether mice coming to grid stations with two traps, one control and one odorized, faced the problem of having both traps already closed, containing mice. If this problem arose at a high proportion of traps, we

TABLE 1. TOTAL CAPTURES BY EXPERIMENT AND TESTS OF ASSUMPTIONS ASSOCIATED WITH ODOR-BAITING EXPERIMENTAL PROCEDURES

	Experiment					
	I	II	III	IV	V	VI
Duration (weeks)	8	8	4	8	8	4
No. enclosures used	8	8	8	4	4	4
Total captures	586	667	315	423	296	169
Recaptures in same week (%)	113 (19%)	90 (14%)	31 (10%)	47 (11%)	34 (8%)	24 (14%)
Recaptures at the same bait type (%)	14 (2%)	7 (1%)	3 (1%)	8 (2%)	8 (2%)	65 (4%)
Two captures at same grid station on same night (%)	32 (5%)	26 (4%)	11 (4%)	11 (3%)	9 (2%)	4 (2%)

would lose information and also possibly create a bias in the data set, particularly at the stations that were part of the experimental test. Fortunately, the rates of pairs of captures, with both traps at a station closed were only 2–5% (i.e., only one station of the 20 experimental stations in each enclosure had both traps closed on a given trapping night), not of significant magnitude to bias results.

RESULTS

Experiment I: Volatile Cues from Conspecifics. For the 586 captures in this experiment, there were no significant differences in the numbers of mice captured with the various odor types present in the enclosures: $\chi^2 = 4.74$, $df = 7$; $P > 0.20$ (Table 2). We first analyzed the data with respect to the eight odor types used as attractants with expected captures based upon a 50:50 distribution between odor and control. There were no significant preferences for any of the eight test odors using volatile cues only (Table 2). With a contingency test, there also were no significant effects when considering captures in perimeter versus interior traps ($\chi^2 = 3.97$; $df = 7$; $P > 0.20$; Table 2). However, when capture data were analyzed using the numbers of trap stations (28 interior and 26 perimeter) to generate expected values, significantly more captures occurred in interior traps ($\chi^2 = 365.49$; $df = 7$; $P < 0.001$). In this test and subsequent tests of this type, we have assumed that because there were such low rates of double captures at those stations with two traps (see Assumptions), the use of all 28 interior stations as if they contained a single trap is justified and does not introduce any undue bias into the analyses. There was no significant effect (χ^2

[a] Expected values in parentheses are from the chi-square contingency analyses—see Results.

= 0.01; $df = 1$; $P > 0.20$) involving age (young and adult) versus treatment (odor and control). There also was no significant effect ($\chi^2 = 0.98$; $df = 1$; $P > 0.20$) with sex versus treatment (odor and control).

We also analyzed the data according to the seven possible responder types—the different age and sex classes and reproductive conditions of mice that could enter the traps (Table 3). Because mice of different age and sex classes were present in the pens in differing numbers, we calculated expected values for total captures in each responder category by using available data regarding the composition of each enclosure population each week. For adult females, the four categories were combined because the reproductive condition of the female is not determined until capture and using that information to generate expected values would be circular. The mean numbers of each responder type that occurred in each of the enclosures during the eight weeks of this experiment were averaged to obtain a grand mean for all enclosures. These means were, in turn, used to generate expected values as proportions of the total number of captures. This same procedure was carried out for each of the other five experiments; when the duration of an experiment was only four weeks, we used a similar procedure, but computed the grand mean based on the enclosure means calculated for just those four weeks. Using expected values computed in this manner resulted in a significant difference in the proportional rate of capture for mice in the seven responder categories ($\chi^2 = 11.50$; $df = 6$; $P < 0.01$; Table 3). More adult females (all reproductive conditions combined) than expected were captured and fewer adult males, juvenile males, or juvenile females were caught than expected. Using expected values based on a 50:50 distribution between odor and control traps, only one of seven analyses, that for pregnant females, was significant; pregnant females preferred odorized traps over control traps (Table 3). For pregnant females, entry into odorized traps was not differentially distributed in favor of any particular odor type.

When data for responders were analyzed for location of capture using a contingency test, there was no significant effect ($\chi^2 = 5.82$; $df = 6$; $P > 0.20$; Table 3). When expected values were based on the numbers of interior vs. perimeter trap stations, significantly more mice were caught in interior than perimeter traps ($\chi^2 = 383.38$; $df = 6$; $P < 0.001$; Table 3).

Experiment II: Nonvolatile and Volatile Cues from Conspecifics. For the 687 captures in this experiment, there were no significant differences in the numbers of mice captured with the various odor types present in the enclosures: $\chi^2 = 8.34$; $df = 7$; $P > 0.20$ (Table 4). Again, we first analyzed the data with respect to the eight odor types. For seven of the eight odors there was a significant effect when both volatile and nonvolatile cues were available (Table 4); in each case more mice than expected were captured in odorized traps and fewer in control traps. With a contingency chi-square test, there was no significant differential capture of animals in the interior versus the perimeter with any of

TABLE 3. CAPTURES ACCORDING TO RESPONDER TYPES: TOTAL CAPTURES, ODOR VS. CONTROL, AND CAPTURES BY LOCATION WITH VOLATILE CUES ONLY IN TRAPS—CONSPECIFIC ODORS (EXPERIMENT I)

		Treatment				Trap location	
Responder type	Total	Odor	Control	χ^2	P	Interior	Perimeter
Adult male	129 (146)[a]	51	62	0.74	NS	122 (119.1)[b]	7 (9.9)

TABLE 4. TOTAL CAPTURES, CAPTURES BY ODOR SOURCE TYPES, AND CAPTURES BY TRAP LOCATION WITH NONOVOLATILE AND VOLATILE ODORS IN TRAPS—CONSPECIFIC ODORS (EXPERIMENT II)

Urine Odor Source	Total captures	Treatment		χ^2	P	Trap location	
		Odor	Control			Interior	Perimeter
Adult male	87	45	18	11.57	<0.001	72 (69.7)[a]	15 (17.3)
Juvenile male	84	39	21	5.40	<0.025	74 (67.3)	10 (16.3)
Nonestrous female	93	43	18	10.25	<0.005	75 (74.5)	18 (18.5)
Estrous female	70	32	13	8.02	<0.025	51 (56.0)	19 (14.0)
Grouped females	88	39	22	5.92	<0.025	74 (70.5)	14 (17.5)
Pregnant female	78	31	12	8.40	<0.001	60 (62.4)	18 (15.6)
Lactating female	77	34	14	8.33	<0.005	57 (61.6)	20 (15.4)
Juvenile female	84	28	22	0.72	NS	74 (67.3)	19 (17.9)

[a]Expected values in parentheses are from the chi-square contingency analyses—see Results.

the odor types as baits, $\chi^2 = 8.92$; $df = 7$; $P > 0.20$ (Table 4). However, using numbers of trap stations to generate expected values did produce a significant result; mice were captured more frequently than expected in the interior traps and less frequently in perimeter traps ($\chi^2 = 209.71$; $df = 7$; $P < 0.001$; Table 4). There was a significant interaction of age and treatment (Table 5; $\chi^2 = 4.82$; $df = 1$; $P < 0.01$); more adults and fewer young than expected were caught at odor-baited traps and fewer adults and more young than expected were caught in control traps. There was no significant effect considering sex vs. treatment (odor and control) ($\chi^2 = 0.49$; $df = 1$; $P > 0.20$).

When we analyzed overall captures according to the seven possible responder types using the method described in experiment I for generating proportional expected values, there were no significant differences in capture rates for the various categories ($\chi^2 = 7.04$; $df = 3$; $0.01 > P > 0.05$; Table 6). Using expected values based on a 50:50 capture rate for odorized and control traps, five of the seven responder types preferred odor-baited traps; only lactating females and juvenile females failed to exhibit significant preferences. Within each responder type, the binomial test (Siegel, 1956) was used to analyze the distribution of responses to the various odors used as baits. Adult male mice exhibited significant ($P < 0.05$) responses in favor of traps containing odors from adult males, pregnant females, and lactating females. Juvenile males were caught more than expected only in traps containing the odor of nonestrous females. Nonestrous females entered the odorized trap more than the control trap when the attractant odor was from juvenile males. Estrous females exhibited a significant choice of odorized traps with respect to both estrous female urine and urine from lactating females. Finally, pregnant females chose odorized traps over controls when the urine was from pregnant females. No other tests were significant.

Considering location of capture (perimeter vs. interior) for all seven responder types, there was no significant effect ($\chi^2 = 12.84$; $df = 6$; $0.05 <$

TABLE 5. INTERACTION OF AGE (YOUNG AND ADULT) VERSUS EXPERIMENTAL TREATMENT (ODOR AND CONTROL) WITH BOTH NONVOLATILE AND VOLATILE ODOR CUES PRESENT IN TRAPS (EXPERIMENT II)[a]

	Age	
Treatment	Young	Adult
Odor	119 (129.6)	172 (161.4)
Control	73 (62.4)	67 (77.6)

[a] Expected values from a chi-square contingency analysis are shown in parentheses.

$P < 0.10$; Table 7). When these same data were subjected to a chi-square analysis with the expected values generated based upon the numbers of trap stations, then significantly more mice were caught in the interior than on the perimeter, $\chi^2 = 186.15$; $df = 6$; $P < 0.001$ (Table 6).

Experiment III: Nonvolatile and Volatile Cues from Heterospecific Rodents and Human Urine. For the 315 captures in this experiment, there were significant differences in the numbers of house mice captured with the various odor types present in the enclosures ($\chi^2 = 11.43$; $df = 3$; $P < 0.001$; Table 7); fewer mice than expected were captured when *M. ochrogaster* odor was used and more than expected were captured when the homospecific odor was in the traps. For three of the four odor types there were significant effects with regard

		Treatment				Trap location	
Responder type	Total	Odor	Control	χ^2	P	Interior	Perimeter
Adult male	178 (187)[a]	70	32	14.16	<0.001	133 (139.6)[b]	45 (38.4)
Juvenile male	135 (124)	67	39	7.40	<0.01	116 (105.9)	19 (29.1)
Nonestrous female	93 (203)	42	15	12.79	<0.001	73 (72.9)	20 (20.1)
Estrous female	69	30	11	8.80	<0.005	51 (54.1)	18 (14.9)
Pregnant female	33	17	4	8.05	<0.005	29 (25.9)	4 (7.1)
Lactating female	29	13	5	3.56	NS	26 (22.7)	3 (6.9)
Juvenile female	130 (153)	52	34	3.77	NS	95 (101.9)	35 (28.1)

[a] Proportionalized expected values (see text) in parentheses—single expected value for adult females includes all four categories of adult females.
[b] Expected values in parentheses are from the chi-square contingency analyses.

TABLE 7. TOTAL CAPTURES, CAPTURES BY ODOR SOURCE TYPES, AND CAPTURES BY TRAP LOCATION WITH VARIOUS SPECIES ODORS IN TRAPS (EXPERIMENT III)

		Treatment				Trap location	
Urine odor source	Total captures	Odor	Control	χ^2	P	Interior	Perimeter
Microtus ochrogaster	59	19	19	0.00	NS	45 (30.7)[a]	14 (28.3)
Homo sapiens	80	11	26	6.08	<0.025	47 (41.6)	33 (38.4)
Peromyscus leucopus	75	12	26	5.16	<0.025	55 (39.0)	20 (36.0)
Mus musculus	101	49	18	14.34	<0.001	80 (52.5)	21 (48.5)

[a] Values in parentheses are from the chi-square contingency analyses—see Results.

to the odor treatment (Table 7). Fewer captures than expected occurred in the odorized traps when either *H. sapiens* or *P. leucopus* odor was used as bait and more than expected were captured when *M. musculus* odor was used to odorize the traps. There was no significant effect for urine from *M. ochrogaster*.

For capture locations, testing interior versus perimeter, both the contingency test ($\chi^2 = 10.21$; $df = 3$; $P < 0.01$) and the test using numbers of trap stations to generate expected values ($\chi^2 = 59.01$; $df = 3$; $P < 0.001$) were significant (Table 7). A greater number of mice were captured at perimeter traps when *H. sapiens* odor was used as the bait than with the other three bait-odor treatments. For the *M. musculus*, *M. ochrogaster*, and *P. leucopus* odors, the general pattern seen in early tests—more mice caught in the interior traps—prevailed.

There was no significant effect ($\chi^2 = 3.27$; $df = 1$; $0.05 < P < 0.10$) when the data were analyzed with a contingency table involving age (young and adult) versus treatment (odor and control). A contingency test also revealed no significant effect ($\chi^2 = 0.05$; $df = 1$; $P > 0.20$) for sex (male and female) versus treatment (odor and control).

With respect to the seven possible responder types, there were no significant differences in the overall capture rates ($\chi^2 = 6.30$; $df = 3$; $P > 0.10$; Table 8). Where there were sufficient data to conduct tests (Table 8), there were no significant odor versus control effects for any responder types.

When we considered bait-odor type and analyzed capture locations in terms of interior versus perimeter traps, both the contingency test ($\chi^2 = 17.62$; $df = 3$; $P < 0.01$) and the test using numbers of trap stations to generate expected

TABLE 8. CAPTURES ACCORDING TO RESPONDER TYPES: TOTAL CAPTURES, ODOR VS. CONTROL, AND CAPTURES BY LOCATION WITH VARIOUS SPECIES ODORS IN TRAPS (EXPERIMENT III)

		Treatment				Trap location	
Responder type	Total	Odor	Control	χ^2	P	Interior	Perimeter
Adult male	87 (77)[a]	18	15	0.27	NS	48 (61.3)[b]	39 (25.7)
Juvenile male	54 (44)	13	18	0.81	NS	37 (38.1)	17 (15.9)
Nonestrous female	67 (131)	23	23	0.00	NS	54 (47.2)	13 (19.8)
Estrous female	13	4	3			9 (9.2)	4 (3.8)
Pregnant female	11	4	4			8 (7.8)	3 (3.2)
Lactating female	24	11	5	2.50	NS	21 (16.9)	3 (7.1)
Juvenile female	56 (63)	14	23	2.19	NS	43 (39.5)	13 (16.5)

[a] Proportionalized expected values (see text) in parentheses—single expected value for adult females includes all four categories of adult females.

[b] Expected values in parentheses are from the chi-square contingency analyses.

values ($\chi^2 = 54.58$; $df = 3$; $P < 0.001$) were significant (Table 8). The contingency test indicated that adult males were trapped more often than expected at the perimeter, whereas nonestrous females and lactating females were trapped more often than expected at interior stations; the other responder types did not differ significantly from expected values. Basing the expected values on the numbers of trap stations, all of the responder types except adult males were caught more often than expected at the interior stations; adult males were caught about equally at both locations (Table 8).

Experiment IV: Volatile Cues from Potential Predators and Human Sweat. For the 423 captures in this experiment, there were no significant differences with respect to the total numbers of mice captured with each of the four types of odor sources in the enclosures ($\chi^2 = 2.98$; $df = 3$; $P > 0.20$). When we analyzed the data with respect to odor versus control capture frequencies within each odor-bait type, using a prediction of equal rates of capture at the two types of traps, there were significant differences for all but the dog odor (Table 9). A contingency test ($\chi^2 = 9.25$; $df = 3$; $P < 0.005$) revealed significant differential captures at the perimeter versus the interior traps (Table 9). More mice than expected were caught at the interior traps when the bait odor was from a dog and fewer than expected were caught at interior stations when the bait odor was from shrews. Using the numbers of trap stations to generate the expected values for analyzing interior versus perimeter stations, we found that for human sweat, cat fecal odor, and shrew fecal odor, there were significantly more mice caught on the perimeter than expected ($\chi^2 = 48.63$; $df = 3$; $P < 0.001$; Table 9); only for the dog fecal odor was there no significant deviation from the expected pattern. There were no significant differences when the data were analyzed for age (young and adult) versus treatment (odor and control) ($\chi^2 = 1.62$; $df = 1$; $P > 0.20$) or when the data were analyzed for sex (male and female) versus treatment (odor and control) ($\chi^2 = 2.35$; $df = 1$; $P > 0.20$).

TABLE 9. TOTAL CAPTURES, CAPTURES BY ODOR SOURCE TYPES, AND CAPTURES BY TRAP LOCATION WITH VOLATILE ODOR CUES ONLY FROM POTENTIAL PREDATORS IN TRAPS (EXPERIMENT IV)

Odor source	Total captures	Treatment		χ^2	P	Trap location	
		Odor	Control			Interior	Perimeter
Dog (*Canis familiaris*)	109	18	29	2.57	NS	52 (39.9)[a]	57 (69.1)
Human sweat (*Homo sapiens*)	106	5	23	11.57	<0.001	37 (33.8)	69 (67.2)
Cat (*Felis musculus*)	114	9	29	10.53	<0.005	40 (41.8)	74 (72.2)
Shrew (*Blarina brevicauda*)	94	3	19	11.64	<0.001	26 (34.4)	68 (59.6)

[a] Expected values in parentheses are from the chi-square contingency analyses—see Results.

When we analyzed the data according to the possible responder types, there were significant differences from the proportionalized expected values ($\chi^2 = 16.60$; $df = 3$; $P < 0.001$; Table 10). Fewer females and more adult males and juvenile males and females were caught than expected. For four of the seven responder types there were significant deviations from a 50:50 expected ratio between control and odorized traps (Table 10).

When the data for capture location were analyzed with a contingency test, no significant deviations from the expected values were recorded ($\chi^2 = 0.61$; $df = 6$; $P > 0.20$). However, when the same data were examined using the numbers of interior and perimeter trap stations to generate the expected values, the test was significant ($\chi^2 = 40.37$; $df = 6$; $P < 0.001$; Table 10). Many more mice of each responder type were caught at perimeter stations than expected.

Experiment V: Volatile Cues from Heterospecifics and Human Urine. For the 429 captures in this experiment, there were no significant differences in the numbers of house mice captured with the various odor types present in the enclosures ($\chi^2 = 2.10$; $df = 3$; $P > 0.20$; Table 11). When we analyzed the data with respect to the odor versus control capture frequencies within each odor-bait type, using a prediction of equal rates of capture at the two types of traps, there were significant differences for all but urine from *Microtus ochrogaster* (Table 11). A contingency test ($\chi^2 = 49.39$; $df = 3$; $P < 0.001$) revealed significant differential captures at perimeter versus interior traps (Table 11). More mice than expected were caught at the interior traps when the bait odor was from voles and fewer than expected were caught at interior stations when

TABLE 11. TOTAL CAPTURES, CAPTURES BY ODOR SOURCE TYPES, AND CAPTURES BY TRAP LOCATION WITH VOLATILE CUES ONLY FROM VARIOUS SPECIES IN TRAPS (EXPERIMENT V)

Urine odor source	Total captures	Treatment		χ^2	P	Trap location	
		Odor	Control			Interior	Perimeter
Microtus ochrogaster	104	35	33	0.06	NS	89 (75.4)[a]	15 (28.6)
Homo sapiens	117	25	55	11.25	<0.001	57 (84.8)	60 (32.2)
Peromyscus leucopus	111	33	51	3.86	<0.05	83 (80.5)	28 (30.5)
Mus musculus	97	42	20	7.81	<0.01	82 (70.3)	15 (26.7)

[a]Expected values in parentheses are from the chi-square contingency analyses—see Results.

the bait odor was human urine. Using the numbers of trap stations to generate the expected values for analyzing interior versus perimeter stations, we found a significant effect ($\chi^2 = 114.33$; $df = 3$; $P < 0.001$; Table 11); more mice than expected were caught at interior traps for *Microtus*, *Peromyscus*, and *Mus* urine, and capture frequencies were close to expected values when human urine was the bait-odor source in the enclosure. There were no significant differences when the data were analyzed for age (young and adult) versus treatment (odor and control) ($\chi^2 = 2.43$; $df = 1$; $P > 0.20$) or when the data were analyzed for sex (male and female) versus treatment (odor and control) ($\chi^2 = 0.95$; $df = 1$; $P > 0.20$).

When we analyzed the data according to the possible responder types, there were no significant differences from the proportionalized expected values ($\chi^2 = 6.01$; $df = 3$; $P > 0.10$; Table 12). There were no significant deviations from a 50:50 expected ratio between control and odorized traps for any of the responder types (Table 12).

When the data for capture location were analyzed with a contingency test, no significant deviations from expected values were recorded ($\chi^2 = 1.16$; $df = 6$; $P > 0.20$; Table 12). However, when the same data were examined using the numbers of interior and perimeter trap stations to generate the expected values, the test was significant ($\chi^2 = 73.10$; $df = 6$; $P < 0.001$; Table 12). More mice of each responder type were caught at interior stations than expected.

Experiment VI: Nonvolatile and Volatile Cues from Potential Predators and Human Sweat. For the 169 captures in this experiment, there were significant differences in the numbers of house mice captured with the various odor types present in the enclosures ($\chi^2 = 15.18$; $df = 3$; $P > 0.001$; Table 13). More mice were captured when the bait odor was from dogs and fewer than expected were captured overall when the bait odor was from cats. When we analyzed the data with respect to the odor versus control capture frequencies

Lactating female	14	3	11	4.57	<0.05	7 (8.2)	7 (5.8)
Juvenile female	18 (29)	4	14	5.56	<0.025	11 (10.4)	7 (7.6)

[a] Proportionalized expected values (see text) in parentheses—single expected value for adult females includes all four categories of adult females.
[b] Expected values in parentheses are from the chi-square contingency analyses.

13); more mice than expected were caught at interior traps for human sweat and shrew; fewer than expected were caught at interior traps with cat odor, and capture frequencies were close to expected values when dog was the bait-odor source in the enclosure. There were no significant differences when the data were analyzed for age (young and adult) versus treatment (odor and control) ($\chi^2 = 1.63$; $df = 1$; $P > 0.20$) or when the data were analyzed for sex (male and female) versus treatment (odor and control) ($\chi^2 = 3.18$; $df = 1$; $0.05 < P < 0.10$).

When we analyzed the data according to the possible responder types, there were significant differences from the proportionalized expected values ($\chi^2 = 9.18$; $df = 3$; $P < 0.05$; Table 14). Adult males and females were captured at about the expected rates, but juvenile males were caught more often than expected and juvenile females less often. There were significant deviations from a 50:50 expected ratio between control and odorized traps for all of the responder types (Table 12).

When the data for capture location were analyzed with a contingency test, no significant deviations from expected values were recorded ($\chi^2 = 1.61$; $df = 6$; $P > 0.20$; Table 14). When these data were examined using the numbers of interior and perimeter trap stations to generate the expected values, the test also was significant ($\chi^2 = 73.10$; $df = 6$; $P < 0.001$; Table 14).

DISCUSSION

The foregoing experiments support several general conclusions: (1) House mice respond to conspecific odor cues when both volatile and nonvolatile odors are present, but not when only volatile cues are available. (2) There is some

discrimination of specific age and sex classes and of reproductive condition based on odor cues, particularly by adult mice. (3) House mice reacted differently to heterospecific odors from deer mice and prairie voles, although, when given the opportunity, they displayed a strong preference toward their own species odor. (4) House mice avoided odors from cat and shrew feces, but not dog feces. (5) House mice avoided odors from human urine, but not human sweat. Because of the large number of statistical tests that we conducted and in order to avoid possible type I errors, we have confined our conclusions to the general and consistent patterns observed within and across the six experiments.

Conspecific Odors. The lack of any recorded preferences in experiment I, followed by the consistent preferences exhibited in experiment II suggests strongly that the mice can distinguish conspecific odors, but not based on volatile odors. They apparently must be able to obtain direct contact with the odor substance in order to make discriminations and exhibit preferences. This finding suggests involvement of the vomeronasal organ and is in agreement with earlier reports concerning vomeronasal reception of many chemosignals that affect house mouse social and reproductive biology (Keverne, 1979; Johns, 1980; Drickamer and Assmann, 1981; Lepri et al., 1985).

The present finding of a general preference for conspecific odor over control traps without odor is reminiscent of the earlier work on voles by Boonstra and Krebs (1976), in which traps that had become soiled by previous captures were more likely to catch additional animals than clean traps. We conclude that house mice, like other rodents tested (*Peromyscus*, Mazdzer et al., 1976; Daly et al., 1980; and *Microtus*, Heske, 1987), will make use of urinary odor cues placed in live traps.

How specific are these odor cue preferences and how much detailed information are the mice obtaining from the urine? In the second experiment, adult mice were more likely to exhibit specific preferences than young mice. In general, we did not detect any particular patterns with respect to particular odor cue preferences by specific responder types. Three responder types exhibited significant preferences for urine of their own age or sex class and reproductive condition: adult males, estrous females, and pregnant females. This suggests the ability for specific recognition of a mouse's own condition, possibly by some sort of matching mechanism, but additional information would be needed to confirm this. It is also not clear why mice should differentially prefer urine from their own age or sex class and reproductive condition. Juvenile males and nonestrous females exhibited reciprocal preferences for the opposite urine odor. Again, there is no clear rationale concerning why this should occur. Adult males also preferred the urine odor of pregnant and lactating females, but, interestingly, they were not attracted to estrous or nonestrous females. If the odor-baiting technique proves useful, then, in conjunction with other techniques, e.g., DNA fingerprinting, a number of additional questions can be tested involving members of the same deme, neighbors and strangers, kin recognition, and mate finding.

In the first two experiments, significantly more mice were trapped at stations in the interior of the enclosures than on the perimeter. We attribute this result to the presence of the 1.5-m mowed strip of grass around the inside walls of each enclosure; these strips were removed approximately once each month. If mice had been trapped more often than expected along the walls, this would be good evidence for the effect of whatever urine odor was used to bait traps in the interior having a repelling effect on the mice.

Heterospecific Odors. With respect to interspecific interactions, we recorded more house mouse captures at odor-baited traps with conspecific urine than for any of the other treatments. This result is not surprising in light of the findings from the first two experiments. However, house mice avoided urine from *P. leucopus*. For deer mice, the effect was only one of avoidance; mice entered control traps more often than odor-baited traps. There was no effect on overall activity as measured by the captures in the interior versus those on the perimeter of the enclosures. This result is in accord with two previous field studies on interspecific interactions involving house mice and deer mice (Caldwell, 1964; Caldwell and Gentry, 1965). *P. polionotus* were generally able to outcompete house mice in an old field setting and in a one-acre enclosure. In contrast, King (1957) reported that house mice were more aggressive toward and dominant over *P. maniculatus*. To our knowledge, no one has yet studied the direct interactions of house mice and *P. leucopus* in a field setting. One of us (L.C.D.) has unpublished laboratory data in which *P. leucopus* were dominant to *M. musculus*. Those laboratory data and earlier field studies would suggest a prediction that house mice would avoid *P. leucopus* odors in the enclosures; this is what we observed.

In the third experiment, the house mice were caught less frequently when *M. ochrogaster* odor was present as a bait. We do not know exactly to what to attribute this finding, particularly since there was no effect on the location of mouse captures with regard to the interior versus perimeter trap sites in the enclosures with *M. ochrogaster* urine odor as bait. The picture is further complicated by the fact that no preference was exhibited between odor-baited and control traps for *M. ochrogaster* urine. Based upon previous work involving *M. musculus* and *Microtus* spp. (Lidicker, 1966; DeLong, 1966; Quadagno, 1968), we might have expected a clearer reaction from the house mice. In the previous studies of interactions between *Microtus* and *Mus*, voles generally displaced house mice. Further work will be necessary to more completely delineate the effects of urine odors from *M. ochrogaster* on house mouse behavior.

Predator Odors. Although there were some differences based on whether volatile only or volatile and nonvolatile cues were available, house mice avoided cat fecal odors and, to a lesser degree, shrew fecal odors. Cat odor and shrew odor also resulted in some shift in the activity of the mice; more were captured near the perimeter of the pens when these odors were presented in the traps in

the interior. These data on cats and particularly on shrews indicate, in a preliminary way, that house mice, like voles (Eadie, 1952; Barbehenn, 1958; Fulk, 1972) respond to odors from *Blarina* by avoiding them, both in terms of immediate choices of where to go, measured by negative responses to odor-baited traps, and in terms of general use of space, measured by their shift to the perimeter of the pens. In none of these tests did the mice avoid the odor of dog feces. We do not have a sound explanation for this apparent deviation from what we would have predicted based on the logic that dogs (canids), like cats (felids), represent potential predatory threats for the mice.

Human Odors. With human urine, there was both an avoidance of odor-baited traps relative to control traps and a general effect on activity. With human urine, the mice were caught more often on the perimeter than expected, suggesting that they shifted a significant proportion of their daily activity to the perimeter of the enclosure, even with the presence of the 1.5-m strip of mowed grass. The mice exhibited no differential response to human sweat odors, either in terms of their frequency of capture at odor- versus control-baited traps or with regard to interior versus perimeter trap stations. It is puzzling why house mice should avoid one odor source and not the other. House mice have lived in the presence of *H. sapiens* for many thousands of years and thus should be accustomed to any of the variety of odors from humans. It is also not clear that humans represent a threat of predation to house mice, yet something of this sort must be the source of the observed pattern of activity. It is possible that the mice are habituated to the odor of human sweat and thus failed to react to it in the same manner that they reacted to human urine. This habituation may come about because we leave sweat odors on virtually all traps as we work with them in the summer heat in southern Illinois. Hence, the mice have regularly encountered the sweat-odor cues, but not those from human urine.

Acknowledgments—We thank Heather Rice, Lynn Gillie, Ami Sessions Robinson, John Petzing, and Susan T. Meiers for assistance with data collection; George A. Feldhamer for helpful discussions and for reading an earlier version of the manuscript; and Patricia A. Gowaty and Lynn Gillie for providing helpful comments on a draft of the manuscript. Charles Paine provided advice regarding statistical procedures. This research was supported, in part, by funds supplied by the College of Science and by the Office of Research Development and Administration at Southern Illinois University at Carbondale.

ODORS AS CUES FOR ORIENTATION TO MOTHERS BY WEANLING VIRGINIA OPOSSUMS

(Received May 12, 1992; accepted August 5, 1992)

Abstract—Three experiments were conducted to investigate whether whole-body and pouch odors facilitate social cohesion between young Virginia opossums and their mothers just prior to weaning. In experiment 1, young oriented toward plastic buckets containing their mothers, directing significantly higher levels of investigative behavior and more distress vocalizations toward them than toward buckets containing unrelated lactating females. In experiment 2, young oriented toward and investigated empty buckets containing whole-body odors of their mothers more than empty buckets containing odors of other females. Similarly, more investigative behavior was directed toward plastic bucket lids containing pouch odors from subjects' mothers than toward pouch odors from unrelated females in experiment 3. These results suggest that social odors help young didelphid marsupials maintain contact with their mothers, as in other mammals, and that whole-body and pouch gland odors are important chemical signals in this nongregarious species.

Key Words—*Didelphis virginiana*, Didephidae, maternal–young recognition, maternal odors, pouch glands, Virginia opossum.

INTRODUCTION

The importance of odors in facilitating maternal–young recognition and the orientation of dependent offspring to mothers has been established for a wide range of mammalian species (for reviews, see Stoddart, 1980; Brown and Macdonald, 1985). Scent glands are common in the New World marsupial family

Didelphidae, as in other mammalian groups, and olfaction has been suggested to function as a primary modality for social communication in this group (McManus, 1970; Gardner, 1982). While there is a growing body of evidence of the importance of scent gland secretions and other chemical signals in didelphid reproduction and behavior (Boggs, 1969; Fadem, 1989; Fadem and Cole, 1985; Fadem and Schwartz, 1986; Holmes, 1987, 1990, 1992; Holmes Meisner, 1986), the role of olfactory cues in opossum social systems is generally not well understood. This is particularly true for odors that may facilitate social cohesion, including the maintenance of contact between mothers and offspring.

Virginia opossums are born after 12–13 days gestation and complete their postnatal development in the mother's pouch, where they remain firmly attached to nipples for 45–50 days (Reynolds, 1952). They are carried in the pouch until about day 80, after which the mother either leaves them in the den or carries them on her back while foraging (Eisenberg, 1975; Gillette, 1980; Reynolds, 1952; Seidensticker et al., 1987; Wright, 1989). During the period between detachment from the nipples and complete weaning, mothers and young use vocalizations to maintain social contact when they become separated: mothers emit a click, which sounds like a lip smack, and young produce a birdlike distress call (McManus, 1970; Reynolds, 1952). Mothers often respond to vocalizations of their offspring by approaching and allowing them to climb onto the body or into the pouch.

In the period between parturition and weaning, the skin of the maternal pouch produces a brownish orange, musky exudate, suggesting the development of specialized apocrine or sebaceous scent glands (Reynolds, 1952; and personal observation). By the time young have their eyes open and begin to move around the nest on their own, these secretions have become copious enough to coat their fur and discolor it (personal observation). Although odorous pouch secretions have been described briefly in other marsupials (Russell, 1984, 1985), and olfactory cues have been suggested to aid marsupial neonates in their climb to the pouch at birth (Hartman, 1928; Sharman and Calaby, 1964), the possible role of pouch gland scents in mediating interactions between *Didelphis* mothers and young in later development has never been investigated experimentally.

Young opossums begin to show an interest in solid food after about day 85 but are not completely weaned until between 96 and 108 days (Reynolds, 1952; Seidensticker, 1987; Wright, 1989). Although captive young of about 85 days of age may wander away from their mothers for brief periods, they often show signs of distress, including vocalizations, if separated long enough to become hungry (personal observation). In the wild, some young may continue denning with the mother or littermates for up to 120 days, after which they become independent and largely solitary (Wright, 1989; personal observation).

To explore the potential role of maternal odors in maintaining contact between young opossums approaching weaning and their mothers, I conducted

a series of pairwise choice experiments. The first was designated to determine if young oriented to restrained mothers when mothers were presented in combination with restrained unrelated lactating females in the absence of any physical solicitation of contact on the part of "stimulus" females. In the second, I tested whether young oriented toward whole-body odors of mothers when they were presented in combination with those of unrelated lactating females. The third experiment was performed to determine whether mothers' pouch odors alone elicited more orientation and investigative behavior by young than did pouch odors of unrelated females.

METHODS AND MATERIALS

Subjects and Test Setting. Experiments were conducted over a three-day period in early September, after the end of the 1991 breeding season (opossums breed from January to August), during the animals' most active nocturnal period (dusk to 2400 hr EST) (Holmes, 1991; McManus, 1971). The test arena consisted of a clean galvanized metal cattle watering tank (1.52 m diameter and 0.6 m deep), with a 3-cm-deep layer of clean pine shavings on the bottom. Testing took place in a quiet, well-ventilated room under diffuse fluorescent light.

Subjects were 17 young (10 females, 7 males) between 85 and 95 days of age from three litters (one of five, one of four, and one of eight young). Their ages had been determined earlier as pouch young (between 30 and 50 days of age) to an accuracy of one week using standard developmental landmarks for this species (Gardner, 1982; Hartman, 1923; Reynolds, 1952). The mothers of these three litters were used as stimulus females and odor donors; all were unrelated and had been live-trapped during their first breeding year in South Carolina or Georgia. All mothers had been captive for at least two months and housed individually with their litters in adjacent outdoor kennels. Olfactory and social contact were possible between animals in adjacent kennels. Subjects and stimulus females were accustomed to the presence of humans, but had not been handled except as required for routine care. Diet consisted of dry dog food supplemented with vitamin E, liver, eggs, vegetables, and fruit, and water was supplied ad libitum.

All 17 subjects and all three stimulus females were used in each of the three experiments. Young were removed from their mothers' nestboxes 9–10 hr before each test session, placed in clean 1.89-liter plastic buckets with their littermates, and deprived of food and water until testing was completed. Before beginning a test session, all subjects were combined in a single bucket and allowed to acclimate for 20 min. Subjects were tested in random order by selecting them "blindly" from this communal bucket (all were eartagged for

individual identification, but could not be identified except by very close inspection of tags). To further reduce the potential for observer bias, I performed all observations myself, but had another person code the labels for stimulus females and odors and select appropriate coded, paired combinations of stimulus females or odors for each test session. I did not decode these until testing was finished for each night.

Experiment 1. The three stimulus females were removed from their nestboxes several hours before testing and placed gently in separate clean 1.89-liter plastic buckets with lids, with 1-cm holes drilled at 3-cm intervals into both buckets and lids. A coded, preassigned pair of stimulus females—the subject's mother and one of the two unrelated lactating females—were placed 1 m apart in the test arena in their respective buckets. Each trial consisted of a 5-min test period that began when the subject was placed in the center of the test arena between the two stimulus buckets.

Young had ample space to move around the perimeter of the test arena and ignore both stimulus buckets, or to approach and actively investigate either at will. Only behaviors performed directly on or in the immediate vicinity of one of the buckets was recorded. This protocol made it very unlikely that avoidance of one stimulus object could be confused with attraction to the other. Responses to stimulus objects in each 5-min trial were quantified using a "one-zero" score (Bernstein, 1991; Rhine and Flanigan, 1978), consisting of the number of 5-sec intervals during the test period in which the subject performed a specified orientation or investigative behavior at least once. In experiment 1, behavior patterns that were scored included approaching within 5 cm of the stimulus bucket and sniffing, biting, licking, or otherwise contacting it. I scored vocalizations emitted by the young in the vicinity of a bucket in the same way.

When alarmed, adult opossums exude a distinctive smelly secretion from their anal glands (Gardner, 1982), therefore I handled stimulus females as little as possible and did not remove them or clean stimulus buckets between trials in experiments 1 or 2. However, the unrelated female used for each subject, as well as the position of the two stimulus females in the test arena in each trial, was alternated in a random fashion among tests for each evening. The pine shavings lining the floor of the tank were stirred up thoroughly between trials, thereby randomly redistributing any olfactory cues left on them by the subjects.

Experiment 2. The protocol outlined above was repeated in experiments 2 and 3, but each of the latter tests involved an alteration of the two stimulus objects used. In experiment 2, I used empty buckets that had been occupied for 4 hr by one of the three stimulus females and still contained any odors they had deposited during this time (probably including urine, saliva, vaginal and pouch secretions, as well as other body odors). Buckets were placed in the test arena on their sides without lids (rather than upright, as in experiment 1), and subjects were free to climb on or into either bucket. The behavior patterns scored in

experiment 1 were expanded to include these. As in experiment 1, buckets were not cleaned between trials in order to preserve the odors they contained, but their positions were randomized among trials.

Since the possible confounding influence of subjects' investigation of stimulus buckets on responses of subsequent subjects was not readily controlled, I addressed this possible source of error statistically (see Analysis section below).

Experiment 3. Pouch odors were collected from each of the three stimulus females by thoroughly swabbing the inside of the empty pouch with clean, dry tissues, which were then sealed in clean plastic bags until testing (approximately 4 hr). I attempted to collect only pouch secretions, to avoid picking up saliva, vaginal or anal gland secretions, and to alarm females as little as possible during this procedure. Secretions collected from pouches in this manner had a distinct odor, but I could not detect them visually. Immediately before testing, each of the tissues carrying a pouch odor was unfolded and sandwiched between two plastic bucket lids (30 cm in diameter with 30 2-cm holes drilled in each) stacked on top of one another. Lids were cleaned thoroughly with 70% alcohol before loading them with odors and between trials. I wore disposable plastic gloves when handling all odors and stimulus objects. and took care not to mix odors from different females. During testing, lids containing odors collected from the appropriate females were placed flat in the test arena in the same positions as were the buckets used in the first two experiments. The same observational protocol was used as in experiments 1 and 2, but behavior patterns scored were expanded to include walking on the lids as an additional form of orientation or investigative behavior.

Analysis. One-tailed Wilcoxon paired-samples tests (median tests) (Zar, 1984) were performed on data from each of the three experiments to test the hypothesis that subjects would orient or display higher levels of investigative behavior toward odors of their mothers than toward those of unrelated females. For experiments 1 and 2, the variance in each subject's response attributable to investigation by previous subjects was examined by regressing the differences between investigation scores directed toward the two buckets in each trial on the cumulative differences between responses to those buckets by subjects run previously (simple linear regression) (Zar, 1984).

RESULTS

All subjects thoroughly explored the entire test arena, and they approached a stimulus object in the first 20 sec in 42 (82%) of the 51 trials. In experiment 1, young directed higher levels of investigative behavior toward the bucket containing their mothers in 15 of 17 trials; one failed to investigate either stimulus bucket and was excluded from the analysis. Median scores for behavior

(i.e., number of 5-sec intervals during the test period in which one or more of the specified behaviors occurred) directed by the remaining 16 subjects toward mothers and unrelated lactating females were 32.0 and 3.0, respectively, and were significantly different ($T_{(\text{one-tailed})} = 5.5$, $N = 16$, $P < 0.0001$); means and standard deviations are shown in Figure 1. Vocalizations were directed toward the bucket containing the mother by six of 17 young and never toward the bucket containing the unrelated female. Medians for vocalizations toward mothers and nonmothers were 2.5 and 0, respectively, and were also significantly different ($T_{(\text{one-tailed})} = 0$, $N = 6$, $P = 0.025$). Stimulus females emitted no vocalizations that were audible to me during testing.

In experiment 2, 15 of 17 subjects oriented and directed more investigative behavior toward whole-body odors of mothers than those of unrelated females. Median scores were 12.0 and 6.0, respectively, for maternal and nonmaternal odors and were significantly different ($T_{(\text{one-tailed})} = 6$, $N = 16$, $P < 0.0005$; means in Figure 1). One subject failed to investigate either bucket. Similarly, in experiment 3, young investigated objects containing pouch odors alone from mothers significantly more than those containing odors from unrelated females. Of the 17 subjects, 12 investigated lids containing mothers' pouch odors more than those containing the odor of an unrelated female; medians were 11.0 and 9.0, respectively ($T_{(\text{one-tailed})} = 36.5$, $N = 17$, $P < 0.05$; means in Figure 1).

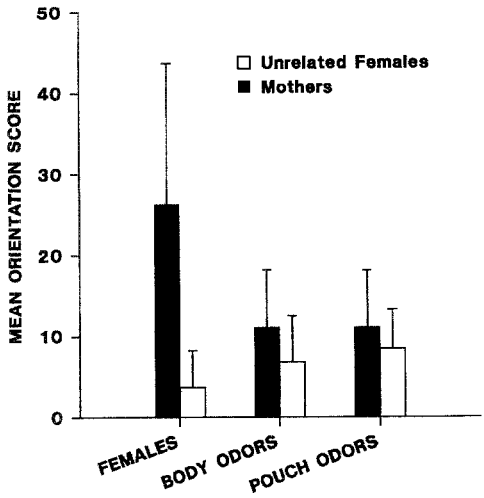

FIG 1. Responses of weanling opossums to odors of mothers and unrelated lactating females. Orientation scores consist of the number of 5-sec intervals in the 5-min test period (one-zero score) in which subjects engaged in specified investigative behaviors on or in the immediate vicinity of the stimulus object. Bars represent standard deviations. See text for details of experimental methods.

Neither young nor adult females vocalized audibly in experiments 2 or 3. The variance in investigative behavior explained (i.e., potentially confounded) by previous subjects' investigation of each bucket was nonsignificant in both experiments ($R^2 = 0.21$, $P = 0.08$ and $R^2 = 0.006$, $P = 0.78$ for experiments 1 and 2, respectively). This indicates that subjects were responding primarily to odors of stimulus females and not those deposited by subjects tested previously.

DISCUSSION

Weanling opossums consistently oriented toward and investigated odors of their mothers when odors were presented with those of unrelated lactating females. Subjects actively investigated their own mothers' odors in preference to those of strange females, rather than demonstrating an avoidance of unrelated females. This study did not employ odor "blanks" (clean, empty stimulus buckets or lids), hence I cannot conclude that young responded to odors of unrelated females differently than they might have to novel stimulus objects. Nonetheless, young clearly can discriminate their mothers from other lactating females using whole-body odors, and pouch odors alone contain sufficient chemical information to enable young to discriminate their mothers from other females. These results indicate that maternal odors, including pouch odors, have the potential to facilitate contact during the period preceding dispersal by juvenile opossums. It is not clear, however, if the enhanced production of pouch secretions during late postnatal development actually represents a specialized chemical mechanism for promoting contact between mothers and young. Whether pouch secretions are more effective cues for maternal recognition than odors from other specific body areas also remains to be investigated.

While the adaptive value of chemical cues for orientation to mothers by young opossums still suckling and denning with the mother is obvious, it is unknown how often young at this developmental stage may actually encounter and need to discriminate odors of unrelated lactating females in the wild. Recent radiotracking data show that home ranges of adult female *Didelphis* overlap (Fitch and Shirer, 1970; Gillette, 1980; Ryser, 1990; Sunquist et al., 1987), and observations of female captives generally have shown a greater capacity for social tolerance than was earlier suspected for this "solitary" species (Holmes, 1987, 1991). Adult females are more philopatric than males, and often disperse little from maternal home ranges; hence related as well as unrelated females with their litters may encounter one another on contiguous ranges. Since opossums are nongregarious, however, and usually live less than two years in the wild (Sunquist et al., 1987; Austad, 1992), olfactory recognition of individual conspecifics may be of minimal importance in the social structure of adults.

In sum, these findings corroborate past work indicating the importance of

chemocommunication in didelphid opossums, a group in which social behavior remains largely unexplored, and suggests that affiliative behaviors are better developed in this group than previously thought.

Acknowledgments—E. Berg, M. Newman, and J.H.K. Pechmann coded stimulus objects and tests, and J.H.K. Pechmann helped with experimental design. R. Borgella, K.E. Fischer, M.G. Heagler, J.H.K. Pechmann and several anonymous reviewers made valuable comments on the manuscript. P. Dixon provided advice about regression analysis. (Received May 18, 1992; accepted August 5, 1992)

Abstract—In *Nauphoeta cinerea*, male calling behavior is associated with sex pheromone release by the sternal glands. The male pheromone that attracts females from a distance is a mixture of 2-methylthiazolidine and 4-ethylguaiacol. It is active at very low concentrations, 0.05 and 0.01 ng, respectively. Two other compounds, 3-hydroxy-2-butanone and 2-methyl-2-thiazoline, act at close range, keeping the female in the vicinity of the male. The function of the volatile pheromone and those of previously described contact pheromones are discussed in regard to their possible involvement in the establishment of male dominant–subordinate relationships.

Key Words—Cockroach, Dictyoptera, Blattaria, *Nauphoeta*, 2-methylthiazolidine, 4-ethylguaiacol, male sex pheromone, calling behavior.

INTRODUCTION

Studies on the biology of the cockroach *Nauphoeta cinerea* have taken several approaches. Since Kramer (1964) described aggressiveness in males, about 20 papers have been devoted to the dominant–subordinate relationship and hier-

archy (see Schal and Bell, 1983; Moore 1990b). In the same way, after Roth and Dateo (1966) demonstrated the existence of a male sex pheromone, Menon (1981) and Sreng (1984, 1985) studied the morphology of the exocrine glands involved in the production of this pheromone. Takahashi and Fukui (1980, 1983) and Sreng (1983, 1991) identified several compounds specific to the males that trigger different sequences of sexual behavior. Our aim was to study this hierarchy and its relationship to male sex pheromone titer and release, using as a basis the chemical data from Sreng (1991). We came to the conclusion that the methodology employed for extraction was unsatisfactory, leading to questionable results on the quantification and biological activity of the three compounds identified as the sex pheromone (3-hydroxy-2-butanone, 2-methylthiazolidine, and 4-ethylguaiacol), even though their presence and activity are indisputable. It was then necessary to reinvestigate the composition of the male sex pheromone, before investigating its possible function in agonistic behavior and a dominance hierarchy.

METHODS AND MATERIALS

Insects. Colonies of *N. cinerea* were reared in glass aquaria (40 × 25 × 25 cm) maintained at a constant temperature of 26± 2°C and 70% relative humidity with a 12 : 12 dark–light photoperiod. Insects had free access to dry dog food and water.

Adults used for bioassays were isolated from colonies at adult ecdysis (dates were recorded). Males and females were kept in separate plastic boxes (9 × 6 × 2 cm); males were kept alone and the females in groups (5 insects/box) until tested.

Preparation of Extracts. For GC analysis and quantification of the pheromonal components, five pooled samples of 10 adult males were taken at random in colonies at the third hour of the dark period. Sternal glands (sternites 3–7) and tergal glands (tergites 2–8) were dissected with microscissors and forceps. Glands, separated from adjacent tissues (hemolymph, fat body) with a paper towel, were transferred to a vial of double-distilled methylene chloride (4 ml/sternal or tergal gland) and allowed to soak for 3 hr at ambient temperature. Phenylethanol internal standard was added (200 ng/sternal or tergal gland). The pooled extracts (200 ml) were concentrated to a small volume ($\approx$300 μl) by the method of Kuderna-Danish (Perry, 1961) and kept in a deep freezer at −20°C.

For GC-MS analysis, two pooled samples (130 sternal and 130 tergal glands) were prepared with the same procedure as above, but without internal standard.

For a comparative GC analysis of the sternites of males, females, and last-instar males (L7) and female nymphs (L8), we used the same extraction procedure as above, using for each category three pooled samples of five insects.

Chemical Analysis. Gas chromatographic analyses were carried out with a Packard 437 gas chromatograph fitted with a split–splitless injector and a flame-ionization detector. The capillary column used was a Chrompack CP-Wax 58CB column (25 m × 0.25 mm ID, film thickness 0.22 μm) with temperature programming from 50°C to 220°C at 2°C/min. Injector and detector temperatures were, respectively, 270°C and 290°C. Helium was used as the carrier gas at a flow rate of 2 ml/min. The GC traces were recorded and integrated with a Shimadzu CR-4A integrator.

Gas chromatographic–mass spectrometric analyses were carried out with a Nermag R 10-10-C quadrupole mass spectrometer coupled to a Girdel 31 gas chromatograph fitted with a split–splitless injector and the same capillary column as above. The GC conditions were the same as described above. The column was directly connected to the ion source of the spectrometer through a heated transfer line maintained at 260°C. Electron impact mass spectra were obtained at 70 eV.

Identifications were made by comparison of the mass spectra of unknowns to those of the EPA-NIH mass spectral data base (Heller and Milne, 1980) and the mass spectra from the library of the Laboratoire de Recherches sur les Arômes de l'I.N.R.A. (Dijon).

Compounds 3-hydroxy-2-butanone (acetoin), (2*R*,3*R*)-butanediol, and (2*S*,3*S*)-butanediol were purchased from Pfaltz & Bauer; 4-methylphenol (*p*-cresol), 4-ethylphenol, and thiazolidine from Aldrich-chemie; 2-piperidone and phenylethanol (internal standard) from Fluka; acetic acid, propanoic acid, butanoic acid, octanoic acid, and nonanoic acid from Polyscience Corp.; guaiacol, 4-ethylguaiacol (4-ethyl-2-methoxyphenol), and 2-methyl-2-thiazoline from Interchim. 2-Methylthiazolidine was synthesized according to the procedure described by Sheehan et al. (1956).

Correct identification was confirmed if the GC characteristics and mass spectrum of the unknown compound were the same as those of the reference compound analyzed under the same conditions on a CP Wax 58 CB column. Identification was also confirmed by coinjection of glandular extracts and pure compounds. All chemicals were >98% pure as determined by capillary GC analysis and were used without further purification for bioassays.

Observations: Sexual Behavior, Reactions of Virgin Females toward Different Chemical Stimuli. Observations were made in glass aquaria (20 × 20 × 15 cm) between the second and sixth hour of darkness under a dim red light. The virgin males and females used (isolated in separate boxes since the imaginal molt) were 12 days old. Sexual behavior was observed until mating occurred on ten pairs. Pure chemicals, identified as male-specific compounds, were presented to virgin females on pieces of filter paper (see below) and the reactions of the females were recorded.

Bioassays (Y-Maze Olfactometer). Olfactory stimuli were tested on virgin

females (12 ± 4 days old) in an Y-maze olfactometer. The olfactometer was a glass tube (2 cm ID) with a 40-cm-long common arm (A), splitting into two 30-cm-long choice arms, B and C (the angle between B and C was 70°). The samples tested were living insects or filter papers (1 × 2 cm, folded in V) impregnated with the stimuli source. Samples were placed at the ends of arms B or C in a box (9 × 6 × 5 cm). An airstream (10 ml/min, controlled by flowmeters) flowed through the boxes and the arms B and C to convey the chemical stimuli through the common arm A to the "starting box" containing the test insect. Each insect was used once. The sample was changed after each insect was tested. We compared the time of discovery of the arm B and of the arm C (time taken by the insect to go to intersection and chose either arm B or C) by Wilcoxon's test of differences between two matched samples. The time of each test was 5 min. We recorded the first choice made. If the insect did not respond in 5 min, the test was terminated.

Each of the 10 virgin females to be tested was kept in a separate adaptation box (6 × 9 × 5 cm) for at least 1 hr before each test. Each box could be connected with the common branch A. Boxes had a screen door that could be raised to allow the female to enter the common arm at the starting point. Ten virgin females were used for each test. All tests were conducted in a dark room, under photographic red light between the second and the sixth hour of the scotophase.

Different chemical stimuli were tested: 1 μl CH_2CL_2 (solvent/control); extracts corresponding to: 10^{-6}, 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2} male sternal gland equivalents; 1, 10, 100, and 1000 ng of 3-hydroxy-2-butanone and thiazolidine; 1, 10, and 100 ng of 2-methyl-2-thiazoline, (2*R*,3*R*)-butanediol, (2*S*,3*S*)-butanediol, and a racemic mixture of (2,3)-butanediol; 0.05, 1, 10, 100, and 1000 ng of 2-methylthiazolidine; 0.01, 0.1, 1, 10, 100, and 1000 ng of 4-ethylguaiacol; different mixtures of 3-hydroxy-2-butanone, 2-methylthiazolidine, 4-ethylguaiacol (100:0.05:0.01; 100:5:1; 100:100:1; 100:100:20; 0:0.005:0.001; 0:0.05:0.01; 0:0.5:0.1; 0:5:1; 0:50:10 ng).

Virgin females were given the choice between the stimuli (extracts or chemicals) and the airstream alone. Ten virgin females were given the choice between three living males and mixtures of pure chemicals. The olfactometer was cleaned with methylene chloride after each test.

We recorded and compared the time spent by the females before entering branch A or B of the olfactometer by Wilcoxon's test. The time of each test was 5 min. If the insect did not respond in 5 min, the test was terminated.

RESULTS

The chromatogram shown in Figure 1 is representative of male sternal gland extracts revealing the presence of more than 30 compounds, with major ones being peaks 1, 4, 8, 9, 18, and 22, From the 31 compounds studied, 23 were

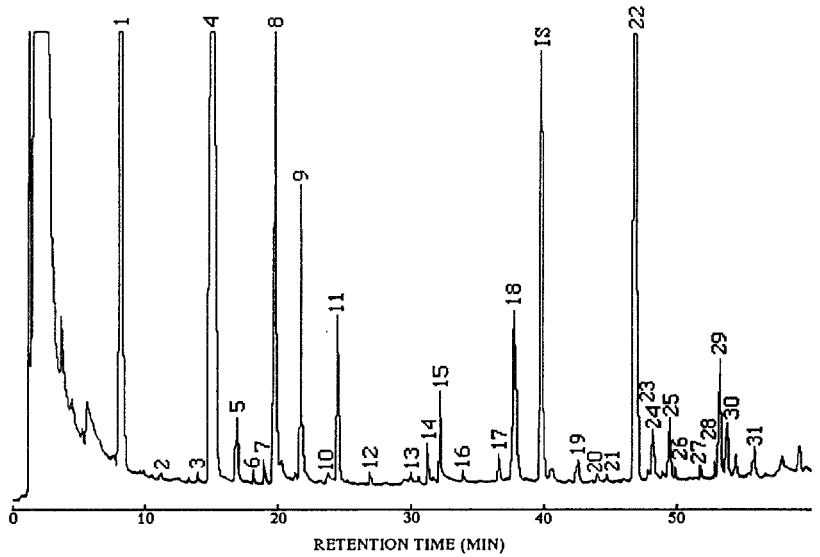

FIG. 1. Capillary gas chromatogram of the sternal gland secretion from males of *Nauphoeta cinerea*. Conditions: CP-Wax 58 CB fused silica column (25 m × 0.25 mm ID); temperature 50–220°C (2°C/min); carrier gas, helium at flow rate of 2 ml/min. Compounds are listed below with their molecular weight (MW) and the relative abundance of the eight main peaks [*m/z* (%)] observed on their EI mass spectrum.

[a]The data are means of five pools (10 males/pool) ± SE expressed in nanograms of given compounds per male (ng/M). M: male-specific compounds; traces: less than 10 ng.

identified (listed in the legend of Figure 1). The identifications of two further compounds, the two butylthiopiperidines need confirmation. Six compounds remain unidentified; three of them are specific to males (Table 1). Compound 19 is only present in trace amount. Compounds 16 and 18 are present in noticeable amounts; 18 always represents more than 2% of the secretion. Compounds 16 and 18 display identical mass spectra (legend of Figure 1) and are probably isomers. Apart from 2-ethylthiazolidine and 2-butylthiazolidine, which are present in trace amounts, all other compounds specific to males are also major peaks: peak 1, 2-hydroxy-3-butanone; peak 4, 2-methylthiazolidine; peak 5, thiazolidine; peak 8, (2*R**,3*R**)-butanediol; peak 9, (2*R**,3*S**)-butanediol, and peak 22, 4-ethylguaiacol.

From 31 studied compounds, 19 were also found in females and larvae. From the 12 male-specific compounds found in the sternal gland extracts, only four were also found in the tergal gland extracts: 2-hydroxy-3-butanone, 2-methylthiazolidine, and the two isomers of butanediol. Table 1 shows that 2-methylthiazolidine is as abundant in sternal glands (36%) as in tergal glands (30%). Whereas their relative percentages are similar in the sternal and tergal secretions, that of 3-hydroxy-2-butanone is less than half as abundant in the tergal secretions. The two isomers of butanediol, on the other hand, were three times more abundant in tergal secretions.

The amount of each compound and its relative percentage in the sternal gland secretion varied widely between individuals. These individual variations are so significant that even the use of pooled samples instead of individuals did not eliminate them. The quantitative analysis of five pooled samples (10 males/sample) of sternal glands extracts showed that the amounts of the five main compounds vary from 4300 ng to 9300 ng for 3-hydroxy-2-butanone, 2200 to 7000 ng for 2-methylthiazolidine, 370 to 1130 ng for (2*R**,3*R**)-butanediol, 300 to 600 ng for (2*R**,3*S**)-butanediol, and 300 to 970 ng for 4-ethylguaiacol.

Bioassays. The biological activity of male sternal gland extracts was tested at different concentrations, from 10^{-6} sternal gland equivalents (St. Eq.) to 1 St. Eq. (Table 2). The male-specific compounds were tested separately or in mixture [3-hydroxy-2-butanone, 2-methyl-2-thiazoline, 2-methylthiazolidine, thiazolidine, (2,3)-butanediol, (2*R*,3*R*)-butanediol, (2*S*,3*S*)-butanediol, 4-ethylguaiacol, and mixtures of 3-hydroxy-2-butanone, 2-methylthiazolidine, and 4-ethylguaiacol].

Male sternal gland extract attracted receptive females with a dose of 10^{-5} St. Eq. (80% of positive responses). For 10^{-4} St. Eq. or more, 100% of the females respond positively.

Preliminary tests showed that only some of the male-specific compounds elicited responses from the females, including 3-hydroxy-2-butanone, 2-methyl-2-thiazoline, 2-methylthiazolidine, thiazolidine, the two enantiomers of butanediol, and 4-ethylguaiacol.

[a] Virgin females ($N = 10$) were given a choice between an airstream and an odor stimulus (extracts or pure chemicals). Time: time spent by a female before entering the branch A or B of the olfactometer (mean ± SE). Eight different stimuli were tested: a, 1 µl CH_2Cl_2 (solvent/control); b, 10^{-6}, 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 1 male sternal gland extract equivalents (St.Ext. 10^{-x} Eq.); c, 1, 10, 100, 1000 ng of 3-hydroxy-2-butanone (3H2B); d, 1, 10, 100 ng of 2-methyl-2-thiazoline (2M2T); e, 0.05, 1, 10, 100, 1000 ng of 2-methylthiazolidine (2MT); f, 0.01, 0.1, 1, 10, 100, 1000 ng of 4-ethylguaiacol (4EG); g, different mixtures of 3H2B/2MT/4EG (100/0.05/0.01; 100/5/1; 100/100/1; 100/100/20; 0/0.005/0.001; 0/0.05/0.01; 0/0.5/0.1; 0/5/1; 0/50/10 ng); h, 3 males vs 3H2B/2MT/4EG (0/0.5/0.01).

[b] Percentage of females first chosing the branch with the airstream.

[c] Percentage of females first chosing the branch with the stimulus.

[d] NS: $P > 0.05$; $*P < 0.05$; $**P < 0.01$.

All of our attempts to trap the compounds 16 and 18 by semipreparative GC failed; very likely, these compounds decomposed during collection because the two trapped peaks resulted in several small peaks when reinjected in the GC.

Eight pure compounds were tested on mature females at different concentrations. Thiazolidine and (2,3)-butanediol (racemic mixture or pure *R,R* or *S,S* forms) did not attract females from a distance. These two compounds were tested at 1, 10, 100, and 1000 ng; females remained in the test box or did not significantly chose arms B or C.

3-Hydroxy-2-butanone attracted virgin females only at high concentrations. With 100 ng, 90% of the females were attracted. At a concentration of 1000 ng, the females avoided the arm of the olfactometer containing this stimulus.

2-Methyl-2-thiazoline, present in trace amount in the sternal glands (< 10 ng), attracted 60% of the females at a concentration of 100 ng, a concentration that was never found in the gland.

2-Methylthiazolidine at a concentration of 1 ng or 10 ng attracted 90% of the females, and 100% at a concentration of 100 ng. Beyond this concentration, the females were neither attracted nor repelled.

4-Ethylguaiacol attracted 100% of the females at a concentration of 1 ng, but the percentage of responding females decreased as the concentration increased (80% at 10 ng, 60% at 100 ng).

From these tests on pure compounds, it appeared that only 2-methylthiazolidine and 4-ethylguaiacol were consistently attractive alone at a concentration of 1 ng. When tested together, the amount necessary to obtain 100% attraction of females dramatically decreased: 0.05 ng and 0.01 ng, respectively. Amounts ten times lower (0.005 ng and 0.001 ng) still attracted 70% of the females even though the attractiveness was not statistically significant. This mixture remained attractive in a broad range of concentrations, since at concentrations of 50 ng and 10 ng, respectively, 100% of the females were still attracted.

These results are consistent with the fact that crude extracts from the sternal glands, at a concentration of 10^{-4} St. Eq., could attract 100% of the females. Of all the male-specific compounds, 2-methylthiazolidine and 4-ethylguaiacol are the only two that considering their threshold of activity and their relative abundance in the glands, could match this test.

The addition of 100 ng of 3-hydroxy-2-butanone (concentration at which this compound is active) to different mixtures of 2-methylthiazolidine and 4-ethylguaiacol did not change to their attractiveness.

When tested on virgin females at short range (20 cm), most of the male-specific compounds [2-hydroxy-3-butanone, 2-methyl-2-thiazoline, 2-methylthiazolidine, thiazolidine, (2*R*,3*R*)-butanediol, (2*S*,3*S*)-butanediol, 4-ethylguaiacol] elicited searching behavior and, when the impregnated paper was contacted, palpation. Whatever the compound tested, the attention of the female

was always very brief, the chemical stimulus triggering an exploration of the area and search for a male. The quantification of the time spent near the paper was not significant as compared to the blank.

Of these seven male-specific compounds, only two are very attractive at a distance and at very low thresholds—2-methylthiazolidine and 4-ethylguaiacol—and they constitute the two components of the volatile sex pheromone.

3-Hydroxy-2-butanone and 2-methyl-2-thiazoline are attractive at a distance only when they are used at high concentrations, but under natural conditions, where they are emitted in "normal" amounts, they probably act as close-range attractants, sexual stimulants, or arrestants, increasing the excitation of the female and preventing her from leaving the area near the male.

DISCUSSION

The most obvious sequence of the sexual behavior of *N. cinerea* is the wing raising posture of the males, and when Roth and Dateo (1966) demonstrated the existence of a male sex pheromone, they correlated its emission with this very characteristic behavior. Sreng (1979) demonstrated that the male sex pheromone was produced by the sternal glands and described the calling posture associated with its emission. Using more than 2000 virgin males, two compounds, 3-hydroxy-2-butanone and 2-methylthiazolidine, were identified, both being long-range attractants for females (Sreng, 1983; Brossut and Sreng, 1985). Recently, it was reported (Sreng, 1991) that the sex pheromone is a mixture of three compounds, 3-hydroxy-2-butanone, 2-methylthiazolidine, and 4-ethyl-2-methoxyphenol (4-ethylguaiacol) in a ratio of 4:4:1 (2700 ng). However, the inadequate amount of solvent used (100 μl) allowed only a limited extraction, leading to subsequent inaccuracy in quantification. The calling posture can last 2 hr or more, with many short interruptions. A constant emission in microgram amounts, as suggested by Sreng (1991), would imply tremendous biosynthetic activity. On the contrary, the thresholds estimated from the present match this extended pheromone release behavior. Study of the diel periodicity of male sex pheromone titer and release throughout adult life (Sirugue, 1992) demonstrated that the amounts of each compound in the secretion change during the life of the male, and that the wide variations noticed by Sreng (1991) are not due to the "presence of hierarchies" but a diel pattern in pheromone biosynthesis. 2-Methylthiazolidine and 4-ethylguaiacol are actively synthesized during the scotophase, while the amount of 3-hydroxy-2-butanone synthesized progressively falls during the scotophase, which fits with our results on their biological activity (Sirugue et al., unpublished data; Sirugue, 1992).

Nitrogen-containing compounds are fairly common in vertebrate and insect semiochemicals (Wheeler, 1977; Blum, 1981), but sulfur-containing compounds

are unusual in insects (mandibular glands of fire ants, Longhurst et al., 1980; pygidial glands of aquatic beetles, Dettner and Schwinger, 1980). 4-Ethylguaiacol is very common in plants (tea-plant, Yamanishi et al., 1970; tobacco-plant, Irvine and Saxby, 1969; rhubarb, Frattini et al., 1976), and less in insects where it has been reported (with other closely related compounds) as an attractant for the northern corn rootworm, *Diabrotica barberi* (MacGovern and Ladd, 1981). 3-Hydroxy-2-butanone is found in many plants (*Helianthus annuus*, Etievant et al. 1984; *Vitis rotundifolia* Welch et al., 1982; *Carica papaya*, *Psidium guajava*, Idstein and Schreier, 1985a,b) and in red clover, *Trifolium pratense*, where it is one of the volatiles that attract the beetle *Hylastinus obscurus* (Kamm and Buttery, 1984; Kamm et al., 1984).

We have no real indication of the origin of the main compounds found in the sternal secretions. 3-Hydroxy-2-butanone and butanediol may be simultaneously produced by fermentation of glucose by bacteria and fungi (MacFaddin, 1980; Gottshalk, 1986). In the sternal glands, where it assumes no obvious function, butanediol may be a precursor of 3-hydroxy-2-butanone.

Biosynthesis of volatile semiochemicals in insects remains, in many cases, very perplexing. In arctiid moths, the methyl-branched hydrocarbon sex pheromone is biosynthesized from leucine via methyl-branched fatty acids, but these fatty acids were detected in small amounts or were absent in the pheromone gland (Charlton and Roelofs, 1991). This suggests that once "initiated, biosynthesis of the pheromone proceeds rapidly with little or no accumulation of intermediates and/or that the pheromone is biosynthesized elsewhere in the insect and transported to the gland" (Charlton and Roelofs, 1991). Such a process would explain why the only compounds found in abundance in the sternal glands of *N. cinerea* are the components of the sex pheromone.

During courtship, male *N. cinerea* display two successive very characteristic postures, the first being a calling posture when the long-range sex pheromone is emitted (Sreng, 1979; Sirugue, 1992), and the second, after antennal contact with a female, being the wing-raising posture in which the tergal glands are exposed (Roth and Willis, 1952). Usually, as soon as the male adopts the wing-raising posture, the female climbs on its back, "feeding" on the tergal secretions while the male grasps the female's genitalia. We observed that if the female fails to respond to the wing raising, even if she is in contact with the male, the male adopts the calling posture again, then switches again to the wing-raising posture and so on. This behavior demonstrates that the sternal secretions, basically used at long range, can also act at short range. The tergal secretions (aphrodisiacs) are complex mixtures (Brossut et al., 1975) in which the volatile compounds represent only a few percent of the mixture. In *N. cinerea*, in terms of the two components of the long-range pheromone, only 2-methylthiazolidine is still present in detectable amounts, but at a concentration 50 times less than

in the sternal glands. 4-Ethylguaiacol is present in trace amounts. 3-Hydroxy-2-butanone is 150 times less abundant than in the sternal glands. When emitted by the tergal glands, these compounds could enhance the attraction of the aphrodisiac and promote the female climbing on the male's back.

Females of *Leucophaea maderae* are not attracted by males of *N. cinerea*. The volatile male sex pheromone of *L. maderae*, attractive at a distance, is 3-hydroxy-2-butanone. Two other compounds, senecioic and (*E*)-2-octenoic acids, act as short range arrestants (Sirugue, 1992). These three main compounds are also found in the tergal secretions and, in contrast with *N. cinerea*, are present in large amounts, the pheromone 3-hydroxy-2-butanone being only 10 times less abundant than in the sternal glands.

Aggressive behavior, dominant–subordinate relationships, hierarchy, and territoriality have been extensively studied in male *N. cinerea* (Ewing, 1972, 1973; Ewing and Ewing, 1973; Bell et al., 1979; Bell and Gorton, 1978, Breed at al., 1980). The use of olfactory cues in discrimination among individuals has been suggested in the establishment of male dominance hierarchies and in the choice of a male by females (Smith and Breed, 1982; Schal and Bell, 1983; Moore, 1988, 1989, 1990a; Sreng, 1991). Our data (Sirugue, 1992) clearly show that the presence of dominant males inhibits the calling posture in subordinate males, which results in the accumulation of great amounts of pheromone in the latter. Until now, we have failed to demonstrate the existence of chemicals specific to dominant or subordinate males.

N. cinerea presents a rather complex sexual behavior with its series of sequences. The first is the emission of a volatile sex pheromone, which promotes the encounter of the sexes. The following recognized sequences are controlled by chemical signals perceived through contact chemoreception. The female sex pheromone of *Blattella germanica*, consisting of four methylketones, is one example of these contact sex pheromones (Nishida et al., 1976; Schal et al., 1990). A similar pheromone, eliciting male wing-raising posture, was studied in *N. cinerea* by Takahashi and Fukui (1980), but the hydrocarbon fraction isolated was also present in females. We are reinvestigating its composition. In this species, several contact pheromones are involved in social interactions. The "nauphoetin" [octadecyl (*Z*)-9-tetracosenoate] described by Fukui and Takahashi (1983) as an intermale recognition pheromone is not connected with aggressive behavior. Our current research indicates the existence of another contact pheromone that triggers male agonistic behavior through antennal contact.

Acknowledgments—We thank Dr. Jocelyn G. Millar for valuable discussions and comments on the manuscript and Dr. F.X. Webster for his help in the synthesis of 2-methylthiazolidine.

(Received June 17, 1992; accepted August 5, 1992)

Abstract—A two-choice chamber was used to determine if three-spine sticklebacks could distinguish between water conditioned by a displaying male and water conditioned by a male that was active but not displaying. Both nonterritorial males and gravid females appeared to recognize which male was displaying; i.e., males and females were more likely to bite or bump the substrate in front of a chamber receiving water from a displaying male. Nonterritorial males were more likely to enter the chamber receiving water from a male that was not displaying; gravid females entered the chamber that received water from the displaying male more often than males but not more often than expected by chance. The aggressive displays of male sticklebacks may have both visual and chemical components; alternatively, the fish may have been capable of detecting chemical by-products associated with different rates of physical activity.

Key Words—Chemical signals, aggression, three-spine sticklebacks, *Gasterosteus aculeatus*, communication.

INTRODUCTION

A major goal of research in animal communication is to determine how and why signals influence perceivers. One of the first steps in determining how displays work is to examine the way in which they engage a perceiver's sensory

system. Displays often influence more than one of the perceiver's senses at the same time; for example, many signals include both visual and acoustic components. However, relatively little effort has been directed toward determining whether vertebrates use chemical cues in concert with the visual or acoustic components of their displays.

Determining how signals influence a perceiver's sensory system and its behavior is particularly crucial for species that are used frequently in studies of behavior. The elaborate displays of three-spine sticklebacks (*Gasterosteus aculeatus*) have held the attention of ethologists for decades (Tinbergen, 1951; Assem, 1967; Wootton, 1976, 1984); however, studies of nonvisual signals in sticklebacks are rare.

Many studies of chemical signals in fish have neglected to consider whether cues from passive donors differ from those released by donors that are actively courting or behaving aggressively, even though such differences might influence the way in which the cues affect perceivers (Colyer and Jenkins, 1976). Researchers also have neglected to evaluate how the same chemical cues influence both sexes.

Here we determine whether nonterritorial males and gravid females: (1) detect differences between water conditioned by a territorial male that is displaying and water conditioned by a male that is not displaying, and (2) prefer to approach water from a displaying male or water from a nondisplaying male in a two-choice chamber.

METHODS AND MATERIALS

Sticklebacks were seined from Priest Creek, Quebec (45°48′N, 75°43′W) in the late spring. Males and females were kept in separate tanks and fed brine shrimp and blood worms twice a day. All subjects had bred at least once in the laboratory. Fish were maintained on a 8:16-hr light–dark cycle and 16°C for one month before being shifted to a 16:8-hr cycle; we did this to synchronize subjects that had experienced different lighting conditions.

The test apparatus consisted of four tanks (Figure 1). The top tank (51 × 26 × 30 cm high) fed water through plastic tubes (4 mm in diameter) into two lower "stimulus" tanks (30 × 16 × 21 cm high). These tanks had a mirror mounted on one end wall and a cover plate that could be raised and lowered to expose or hide the mirror (Figure 1).

A second pair of tubes connected the stimulus tanks to a "choice" tank (77 × 32 × 31 cm high). This tank contained a U-shaped partition that rested flat against the bottom of the tank. The partition left a 10-cm-wide opening between the central compartment and each side compartment; subjects were free to swim through the opening.

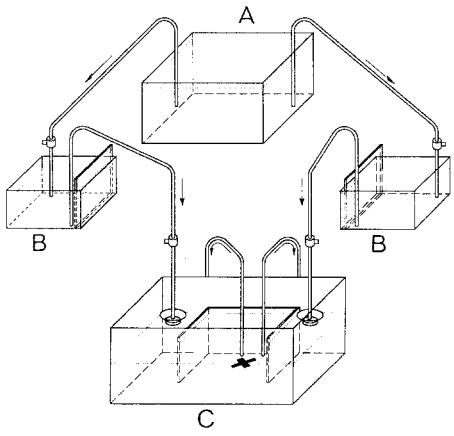

FIG. 1. Experimental apparatus used to determine whether nonterritorial males and gravid females distinguished between water from displaying and nondisplaying males. X marks the spot where the test fish was introduced. A, reservoir of aged water; B, stimulus tanks with mirror covers and mirrors mounted on inner walls; C, test tank with U-shaped partition. The arrows show the direction of water flow through the apparatus.

Behind each arm of the partition, a tube from one of the stimulus tanks poured water over a plastic mesh, which broke the flow of water so that it dripped into the side compartments (Figure 1). This severed any acoustic link that a continuous flow of water might create between tanks (Crapon de Caprona and Ryan, 1990).

A third pair of tubes, mounted along the back wall of the partition, provided an outflow. To ensure that the flow patterns on each side of the tank were identical, we carefully measured the position of the partition arms and connecting tubes so that they were perfectly symmetrical within the tank. The tubes on each side of the apparatus were cut to the same length. Plastic valves were used to set the water flow on each side; we used a graduated cylinder to ensure that water flow through each tube was exactly 80 ml/min. The flow of water was checked regularly.

At the beginning of each test, the tubes were clasped and a "stimulus male" was placed into each of the stimulus tanks. These males occupied territories prior to the tests and were capable of "creeping through" their nests (i.e., this behavior signifies a complete nest; see Wootton, 1976) in the presence of gravid females. Stimulus males were held in isolation prior to the experiments.

After a 30-min settling period, the cover plate in one stimulus tank (selected randomly) was raised to expose the mirror; the cover plate in the other tank was jiggled but not removed. Both stimulus males remained active during most of

their time in the tanks; occasionally, the males' activities were punctuated with brief periods of hovering or resting. Males that were exposed to the mirror displayed (using "head downs" and "charges"; see Wootton, 1976) and bit at their mirror image; the other males swam and bumped the walls of their tank but rarely displayed.

After 10 min, the tubes were unclasped. One minute later, a dip-net was used to place the test fish in front of the outflow tubes (Figure 1). From behind a blind, the observer recorded: (1) the direction(s) in which the fish bumped or bit the substrate; (2) which side of the tank the fish entered first (hereafter called "approached"); and (3) the time elapsed before the fish left the central compartment.

Tests ended when the fish passed either arm of the partition; the mirror cover was then replaced. After removing the test fish, the water in the choice tank was drained and the tank refilled with clean water. We only partially drained the stimulus tanks (the stimulus males were not removed), and then allowed water to flow through them for 15 min before filling them again and starting the next test with a new fish. This time the opposite stimulus fish was exposed to the mirror; this process was continued until we had tested 10 individuals.

The next day we ran the experiment again, using the same test fish but switching stimulus fish between tanks. We did this to determine if we could reverse the pattern of results recorded on the previous day and to assess how the previous day's experience influenced the choices made by males and females.

The experiment consisted of 10 two-day trials; each trial consisted of 20 tests (10 on the first day and 10 on the second). Trials were one week apart. In five trials we tested 10 gravid females; in the other five trials we tested 10 nonterritorial males (note, however, that two of the males died before the last trial). A new pair of stimulus males was used in each trial. We also ran a control trial on nine males and nine females to determine how the fish responded to tests in the absence of stimulus fish.

Replicated tests of goodness of fit (Sokal and Rohlf, 1981) were used to determine whether: (1) males or females were more likely to bump or bite the substrate in front of the partition that separated them from the water of a displaying male, and (2) males or females were more likely to approach the water from a displaying male.

RESULTS

After each subject entered the choice tank, it remained motionless for 5–15 sec before exploring the central compartment. During this time, subjects often bit at or bumped the substrate near each partition. Because individual bumps and bites occurred in rapid succession, we simply recorded whether the animal bumped or bit to the right, left, or to both sides of the choice chamber.

Bumps and bites were directed toward the base of the partition arms (which were not sealed to the tank floor) or one of the two openings. We did not include cases where a test fish bumped or bit the substrate as it entered one of the two side chambers. Only one of nine females and two of nine males bumped or bit the substrate when no stimulus fish were present in the apparatus; during actual trials, the activities were more common. Gravid females bit or bumped the substrate during more tests than males [round 1: females 78.0% (39 of 50 tests), males 45.8% (22 of 48 tests); round 2: females 82.0% (41 of 50 tests), males 52.1% (25 of 48 tests); $\chi^2 > 9.90$, $df = 1$, $P < 0.005$].

During the first round, males were more likely than females to bump or bite toward only one side of the arena [females 36.0% (14 of the 39 cases), males 90.9% (20 of the 22 cases); $\chi^2 = 17.3$, $df = 1$, $P < 0.001$]; this was not the case during the second round [females 43.9% (18 of 41 cases), males 56.0% (14 of 25 cases); $\chi^2 = 0.9$, $df = 1$, NS].

Males that bumped or bit toward only one side of the chamber were most likely to direct their activities toward water from the displaying male (Table 1). However, a test of heterogeneity indicated variation between trials in round 1 ($G_H = 11.5$, $df = 4$, $P < 0.05$); this was mainly the result of the last trial (i.e., the only trial where more males displayed toward the covered-mirror side). Data from trials in the second round and all other rounds listed below were homogeneous ($G_H < 5.7$, $df = 4$, NS).

Females that bit or bumped toward only one side of the chamber were also more likely to direct the activity toward water from the displaying male; however, the difference was only significant during the second round (Table 1).

Males were most likely to enter the side compartment receiving water from the nondisplaying animal; this trend was significant during the first round but not the second (Table 1).

TABLE 1. NUMBER OF INDIVIDUALS APPROACHING OR BITING TOWARD WATER FROM DISPLAYING AND NONDISPLAYING MALES IN TWO-CHOICE CHAMBER

		Nonterritorial males			Gravid females		
Activity	Round	Male displaying	Male not displaying	G_P[a]	Male displaying	Male not displaying	G_P[a]
Bump/Bite	1	17	3	10.8***	8	5	1.2,NS
	2	11	3	4.9*	14	4	5.9*
Approach	1	13	35	10.5**	30	20	2.0,NS
	2	19	29	2.1,NS	28	22	0.7.NS

[a] $*P < 0.05$; $**P < 0.01$; $***P < 0.001$; NS, not significant.

Gravid females approached water from the displaying animal more often than males (round 1: $\chi^2 = 10.8$, $df = 1$, $P < 0.001$; round 2: $\chi^2 = 2.6$, $df = 1$, NS) but not significantly more often than expected by chance (Table 1).

In the control situation, fish left the central chamber in less than a minute ($X \pm$ SE: males 27.56 sec $\pm$ 10.38; females 52.00 sec $\pm$ 19.28). In the experimental situation, males and females took much longer to leave the central chamber (males 160.5 sec $\pm$ 18.28; females 133.3 sec $\pm$ 10.70; Wilcoxon-Mann-Whitney tests, $P < 0.01$). In neither case did one sex take significantly longer than the other to leave the central chamber (Wilcoxon-Mann-Whitney tests, NS). In the experimental situation, there were no major differences in the time taken to enter either side of the choice tank (males: mirror 126.7 sec $\pm$ 14.0, other 177.4 sec $\pm$ 26.3; females: mirror 127.0 sec $\pm$ 13.9, other 141.0 sec $\pm$ 16.9; Wilcoxon-Mann-Whitney tests, NS).

DISCUSSION

Chemical cue(s) from displaying male sticklebacks were detected by nonterritorial males and gravid females. Nonterritorial males avoided water conditioned by displaying males; gravid females approached the water more often than males but not more often than expected by chance (ca. 10%). Both males and females were most likely to bite or bump in the direction of water from the displaying male.

The bites and bumps performed by test fish were very similar to the "head down" threats used by male sticklebacks defending territories. The test fish would orient toward a partition, lower its snout, and drawback along the substrate. We observed the same type of behavior when fish were exposed to territorial males behind a glass partition; gravid females often attempted to engage in courtship activities with such males shortly after bumping or biting the substrate (Waas, unpublished observation). The activities are probably best considered displacement behaviors, reflecting a state of internal conflict (Sevenster, 1961).

Tests of heterogeneity showed that a similar proportion of animals bumped and/or bit toward or approached water conditioned by displaying males in all five trials; this suggested that animals did not habituate to the test apparatus between trials. By swapping stimulus males between tanks on the second day of each trial, we found that we could reverse the sequence of results obtained on the first day. However, fewer animals distinguished between the two stimuli, suggesting that the fish habituated to the conditions when tested on subsequent days with the same two stimulus males.

Only two other studies have determined how chemicals emitted by a displaying fish influence the behavior of conspecifics. Colyer and Jenkins (1976)

found that *Betta splendens* males placed in water conditioned by displaying males "air gulped" (an act associated with arousal; Simpson, 1968) more often than males in water conditioned by nondisplaying fish. However, work by Ingersoll et al. (1976) on the same species showed no difference. Neither of these studies examined the responses of females.

The chemicals released by male sticklebacks may constitute a signal similar to birdsong. However, females did not approach water from the displaying male more often than expected by chance. Females may not use chemical cues in mate choice. Alternatively, females may have chosen between males on the basis of chemical cues that were not influenced by whether the individual was displaying; i.e., the cues emitted by displaying males may make them more obvious but not more attractive. Furthermore, some females may not have been motivationally or physiologically ready for courtship even though they appeared gravid.

Male sticklebacks prefer to nest near other males (Assem, 1967). Thus, we may have expected males to be attracted to, instead of repelled by, cues from displaying males. However, a signal's effect may depend on the context in which it is performed. For example, a songbird's call may repel birds that trespass on their territory but attract more distant animals searching for breeding areas. In our study, chemical cues were released by an unseen, nearby male; thus, the test males may have perceived themselves as trespassers and avoided the displaying animal. This does not negate the possibility that males approach cues from distant males when searching for breeding areas.

Finally, it is possible that the chemical cues detected by males and females were a simple by-product of metabolic processes (e.g., associated with movement during displays); for example, Sevenster (1961; see also van Iersel, 1953) found that male sticklebacks exposed to brief CO_2 baths performed fewer sexual and more aggressive activities than males exposed to tap water. Perceivers may be using cues that are not "actively conveyed" by the donor (Liley, 1982). In some cases, the cues may be precursors of true pheromones; for example, it has been suggested that sexual pheromones in fish evolved from excreted hormones and their metabolites (Doving, 1976; Colombo et al., 1982).

Sticklebacks have been described as having a very limited ability for chemosensory perception (e.g., Bardach and Todd, 1970; Wootton, 1976). The present study and other recent work (e.g., van Havre and FitzGerald, 1988; FitzGerald and van Havre, 1987 suggests that this may not be the case. Despite their small olfactory epithelium (which has only two folds; Teichmann, 1959), sticklebacks detect and react to chemical cues associated with their visually elaborate displays.

ALLELOPATHIC SUBSTANCES AND INTERACTIONS OF *Delonix regia* (BOJ) RAF[1]

CHANG-HUNG CHOU* and LIH-LING LEU

Institute of Botany
Academia Sinica
Taipei, Taiwan 115, Republic of China

(Received April 13, 1992; Accepted August 10, 1992)

Abstract—A unique pattern of weed exclusion was found under the canopy of *Delonix regia*, which was planted in many places as an ornamental tree in the south of Taiwan. A quadrat method was employed to examine the botanical composition between the area underneath *D. regia* and its adjacent control grassland. The number of species and coverage of understory species were significantly lower in the area of the *D. regia* than that of the grassland, indicating the growth of understory species was suppressed by *D. regia*. A series of aqueous extracts of leaves, flowers, and twigs of *D. regia* were bioassayed against three species to determine their phytotoxicity, and the results showed highest inhibition in the flowers. A water-culture experiment indicated the aqueous extract of flowers of *D. regia* on two local understory species (*Isachne nipponensis* and *Centella asiatica*) inhibited growth of both species by more than 70%. The phytotoxicities of fallen leaves and flowers of *D. regia* were not significantly affected by temperature. When the plant material was subjected to temperatures above 70°C, however, phytotoxicity was decreased, indicating that the allelopathic nature of *D. regia* could easily be decomposed by fire. By means of paper, thin-layer, and high-performance liquid chromatography, and UV–visible spectrophotometry, responsible phytotoxins present in leaves, flowers, and twigs of *D. regia* were identified as 4-hydroxybenzoic, chlorogenic, 3,4-dihydroxybenzoic, gallic, 3,4-dihydroxycinnamic, 3,5-dinitrobenzoic, and L-azetidine-2-carboxylic acids, and 3,4-dihydroxybenzaldehyde. The findings of bioassays and the number and amount of responsible allelopathic compounds found in *D. regia* are well correlated, thus permitting the conclusion that the exclusion of understory plants under the canopy of *D. regia* trees was due primarily to the allelopathic

effect of the fallen flower, leaves, and twigs of the *D. regia*. A possible mechanism of action is discussed.

Key Words—*Delonix regia*, ornamental tree, allelopathy, phytotoxic phenolics, L-azetidine-2-carboxylic acid, understory species, mechanism of action.

INTRODUCTION

Delonix regia (Boj.) Raf., a deciduous tropical tree distributed in the Philippines, Indonesia, Africa, and many other parts of the world, was introduced to Taiwan many centuries ago as an ornamental tree. The trees were planted along roadsides and at school campuses and parks in the south of Taiwan. A relatively thick mat of fallen flowers, leaves, seed pods, and twigs of *D. regia* is found under the canopy of *D. regia*, but understory plants are almost entirely lacking. The unique pattern of the bare area underneath the trees has been observed by the senior author for several decades, yet the mechanism of formation of the pattern has not been studied. In the past, systematic and pathologic investigations of *D. regia* were carried out (Ather and Mahmood, 1980; Gill and Husaini, 1982; Ghouse and Hashmi, 1977; Hodges and Tenorio, 1984). Biochemical ecological studies of the plant were scant, with Sung and Fowden (1969) isolating azetidine-2-carboxylic acid from seedlings of *D. regia*, which would interfere with the biosynthesis of proline. The physiological and ecological significance of L-azetidine-2-carboxylic acid and its related natural products have not been well understood, although much allelopathic research of leguminous plants has been carried out in many parts of the world (Chou and Waller, 1980, 1989; Chou and Kuo, 1986; Chou, 1992; Rice, 1984; Waller, 1987.) This study was thus aimed at elucidating the allelopathic interaction of the understory species with *D. regia* and the mechanism thereof.

METHODS AND MATERIALS

Study Site. Delonix regia was planted in many places in the southern parts of Taiwan. When the trees bloom in the summer, they are beautiful in appearance. The present study sites were selected from the campuses of the Taiwan Livestock Research Institute and the National Cheng Kung University (NCKU), at Tainan, Taiwan. Adjacent to the *Delonix regia* trees, a control grass area was also selected for comparison. The physical environments for the two study areas were not significantly different.

Field Measurements. The botanical composition of understory species under *D. regia* and the controlled grass area was investigated by using a quadrat method, 2 × 2 m each; coverage and presence of each species present in the two plantations was measured. Ten quadrats were used along a transection of

D. regia trees and in the grassland. All of the species appearing in the quadrats were identified. The measurements were done quarterly for two years (1990–1992), in order to determine seasonal succession.

Materials. Plant materials, including leaves, flowers, and twigs, were collected from each study site. Some of the samples were air-dried at room temperature, and the remainder were stored at −5°C prior to use. Under the canopy of *D. regia*, litter was collected from the surface of the ground (designated as A_{00}); soil beneath the litter at a depth of 0–5 cm from the soil surface (designated as A_0), and rhizosphere soil (A_1) at depths of 5–10 cm in 34 × 34-cm sections were also sampled in each quadrat. The soils were air-dried and screened through a 2-mm sieve to remove all visible plant residue. After preparation, plant and soil samples were used for bioassay, chemical extraction, and identification of some components.

Preparation of Aqueous Extracts of D. regia *Leaves, Flowers, Twigs, and Soil.* A series of aqueous extracts of air-dried leaves, flowers, and twigs was separately prepared by adding 2, 4, 6, 8 and 10 g to 198, 196, 194, 192, and 190 ml of distilled water, respectively, shaking the mixture for 2 hr, and then subjecting to vacuum filtration. Another series of extracts was prepared by adding 1 g of air-dried plant material to 99 ml dichloromethane, shaking for 2 hr, after which the CH_2Cl_2-soluble extract was collected; the plant residue was dried at room temperature (15–20°C). The same procedure was used in preparing the methanol extraction. To the dry residues from the dichloromethane and methanol, 99 ml distilled water was added to prepare the extracts. Soil extracts were prepared by shaking 150 g of each soil with 500 ml distilled water for 2 hr and centrifuging the mixture at 3000 rpm (2369 *g*). All plant and soil extracts were stored at −5°C before bioassay.

Bioassay Techniques. Two bioassay techniques were employed to determine the phytotoxicity of the leaf, flower, twig, and soil extracts. A modified sponge bioassay described by Chou and Young (1975) and a modified chromatographic bioassay described by Chou and Chung (1974) were employed using test seeds as follows: *Lactuca sativa* Linn. (lettuce), *Medicago sativa* Linn. (alfalfa), *Brassica chinensis* Linn. (Chinese cabbage), *Ageratum conyzoides*, *Isachnne nipponensis*, and *Centella asiatica*. Some of these test plants were also found to occur in the experimental sites. Distilled water served as a control for the bioassays. Tests and controls were set up in triplicate.

The authentic compounds, azetidine-2-carboxylic acid, and phenolic acids were prepared in a series of aqueous solutions, 10, 20, 40, 80, 160, 320 and 500 ppm for bioassay, using the same technique as described to determine phytotoxicity. The radicle growth of seeds was recorded 72 hr after incubation at 25°C in an incubator. The bioassay data were subjected to statistical analysis using Student's *t* test and Duncan's multiple range test (Gomez and Gomez, 1976).

Temperature Treatment on Plant Materials of D. regia. In order to determine the effect of temperature on the phytotoxic nature of leaves, flowers, and twigs of the plant, these materials were treated at temperatures of 37°C, 70°C, and 110°C, respectively. The samples were then extracted with distilled water, using the same techniques as described earlier. The 1% aqueous extracts were bioassayed against lettuce seeds.

Greenhouse Experiments Using Pots. Young seedlings of *Ageratum conzoides* transplanted from the field into pots were allowed to grow to 10 cm height. The seedlings then were separately watered with 1%, 2%, or 3% aqueous extracts from the flowers of *D. regia* using tap water as a control. The seedling growth of *A. conzoides* as affected by the test solutions was compared daily until the fifteenth day after treatment.

Water Culture. Three stolon cuttings (about 15 cm long, cut between two young nodes) of each tested plant (*Centella asiatica* and *Isachne nipponensis*) were used and grown in a 15-cm glass tube (3 cm internal diameter) containing either distilled water as a control or aqueous extracts of *D. regia* plant parts. Each treatment was run in triplicate, and the tubes were placed in an incubator at 25°C for seven days; then the root length of each plant was measured (Leu, 1991).

Quantitative Determination of Allelopathic Substances. The allelopathic substances present in the aqueous extracts of the *D. regia* plant parts were obtained by using extraction and purification techniques as described by Chou and Yao (1983) and Leu (1991). The phytotoxins from the *D. regia* rhizosphere soil were obtained using extraction techniques developed by Wang et al. (1967a) and Tang (1986). Compounds were identified by paper chromatography (Wang et al., 1967b) and a high-performance liquid chromatograph (HPLC), using an LDC/Milton Roy ConstaMetric 3000, SpectroMonitor 3000, flow rate of 1 ml/min, wavelengths at 254 nm and 280 nm, a column of Lichrospher 100 RP-18 (250 mm, 4 mm ID), and using the solvent methanol–distilled water–glacial acetic acid (30:70:1, v/v/v). The amount of L-azetidine-2-carboxylic acid was determined by techniques described by Leu (1991): an aliquot of ninhydrin solution and the isolated compound were mixed, then determined by a UV–visible spectrophotometer at OD 570 nm, and the same technique was used to compare the authentic standard compound for reference material.

RESULTS

Botanical Composition in Study Sites of D. regia. The area under the canopy of *D. regia* trees lacks understory plants (Figure 1A), but outside the canopy there is luxuriant growth of weeds (Figure 1B). The floristic composition in the

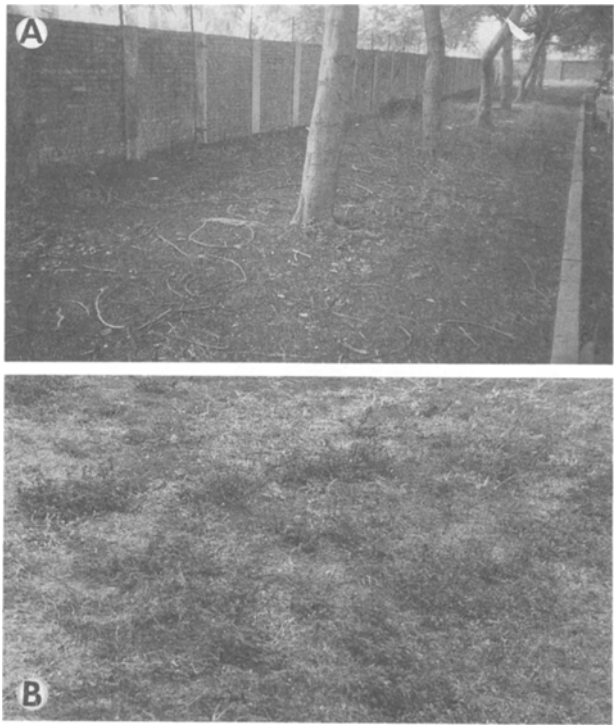

FIG. 1. A pattern of vegetation difference of understory plants shown on the tree of *Delonix regia* floor (A) and the adjacent grassland control (B) at the campus of the National Cheng Kung University, Tainan, Taiwan.

D. regia understory at the NCKU site included 29 species, while in the adjacent area of grassland control there were 38 species (Table 1). Of them, *Alysicarpus vaginalis*, *Borreria medium*, *Cyperus rotundus*, *Desmodium renifolium*, *Gnaphalium purpureum*, *Indigofera trifoliata*, *Ipomoea acuminata*, *Mimosa pudica*, *Oxalis corymbosa*, *Phyla nodifolia*, *Sida rhombifolia*, *Sporobolus hirta*, and *Zoysia* sp. were the most abundant in the control site. These species were either absent or less abundant on the floor of the *D. regia* tree site (Table 1), showing that the coverage of the plants at each site was significantly different.

Although climatic changes that occurred during the four seasons were not distinctly different, summer and winter seasons were different enough that there was variation in botanical composition. There was a significantly different number of species affected by seasons, being sharply decreased from spring to winter; significant differences of the number of species also was observed in the areas of control and the *D. regia* sites. The amount of coverage of understory

[b] – indicates the species absent.

species was drastically lower on the *D. regia* plot than in the control site (Figure 2), indicating that both physical competition and biological interaction of allelopathy could possibly be involved. However, most of the species appearing on the ground under *D. regia* were neither light sensitive nor light tolerant (Chou and Yang, 1982; Chou and Kuo, 1986). Since the two study sites were situated close together, their physical properties, such as soil characteristics, moisture, and texture were approximately the same. Thus, the relatively bare ground with little survival of weeds was probably not due to physical competition among species.

Phytotoxic Effects of Aqueous Extracts of Delonix regia *Plant Parts.* Aqueous solutions comprised of 1%, 2%, 3%, 4%, 5%, of flowers, leaves, and twigs of *D. regia* were bioassayed against three test plants, namely alfalfa (*Medicago sativa*), lettuce (*Lactuca sativa*), and Chinese cabbage (*Brassica chinensis*). Radicle growth of lettuce and Chinese cabbage was most significantly inhibited by the extracts, while the growth of alfalfa was inhibited to a lesser extent (Figure 3). Among the extracts, the phytotoxicity was remarkably higher in the flowers than in the others, ranging from 20% to 80% inhibition for the 1% extract and from 25% to 90% for the 5% extract. The degree of inhibition increased with an increase of concentration of the extracted plant material.

The increasing inhibition of the extracts upon the tested plant material might be caused by an osmotic and/or pH effect. The extracts were analyzed for osmotic concentration using a Fiske osmometer. The osmotic concentrations of 3% extracts of leaves, flowers, and twigs were all below 50 mosmol (Table 2). Neutral solutions, such as polyethylene glycol, sucrose or manitol solution,

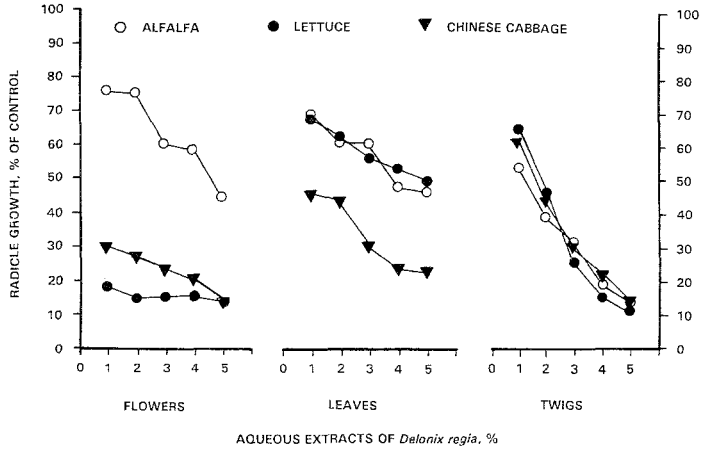

FIG. 3. The effects of aqueous extracts of flowers, twigs, and leaves of *D. regia* using a series of concentrations on the radicle growth of alfalfa, lettuce, and Chinese cabbage.

TABLE 2. COMPARISON OF OSMOTIC CONCENTRATION AND pH OF AQUEOUS EXTRACTS OF FLOWERS, LEAVES, AND TWIGS OF *D. regia* COLLECTED IN 1990–1992

Concentration (%)	Osmotic concentration (mosmol/kg)			pH		
	Flower	Leaf	Twig	Flower	Leaf	Twig
1	16	12	12	4.47	6.08	6.19
2	31	22	30	4.43	6.16	6.15
3	48	33	45	4.37	6.19	6.08
4	67	42	62	4.34	6.19	6.04
5	83	52	72	4.32	6.28	6.04

cause less than 25% osmotic inhibition in the lettuce bioassay at or below 50 mosmol (Chou and Young, 1974). In the present study, the lowest pHs of the extracts ranged from 4.32 to 4.47, which should give about 20% inhibition if neutral solutions adjusted to the same pH and osmotic concentration were employed (Chou and Young, 1974). This degree of inhibition is here called "osmotic and pH inhibition." Thus, if the inhibition yielded by *D. regia* is above 50%, the inhibition after subtracting 20% osmotic and pH inhibition will still be 30%. Thus, the inhibition is due naturally to phytotoxic inhibition. In the present study, the inhibition of plant extracts was significantly higher than 50%, which means that the inhibitory effects of aqueous extracts of flowers,

leaves, and twigs are due to the phytotoxic compounds present in the extracts, and the effects of osmolality of pH can be neglected. The degree of inhibition is shown to be in the order: flower > leaves > twig.

To ascertain if the growth inhibitors were hydrophilic or hydrophobic, the leaves, flowers, and twigs were extracted with dichloromethane and methanol. The aqueous solutions were bioassayed against lettuce and the results obtained are shown in Figure 4. The findings indicated that the water extract that followed the CH_2Cl_2 extraction exhibited nearly the same degree of inhibition (Figure 4B) as the original water extract (Figure 4A), while the aqueous extract that followed after methanol extraction showed only a little inhibition (Figure 4C). It was concluded that the inhibitor was hydrophilic in nature.

Leachability of Phytotoxins from Plant Parts and Soil of D. regia. A 5% aqueous extract of flowers, leaves, twigs, and soils of *D. regia* was obtained. The first extract was designated as extract I, and excluded the soil; the residues were then reextracted with water twice and designated as extracts II and III. All extracts were bioassayed against lettuce to compare their phytotoxicities. The results shown in Figure 5 indicated that most of the phytotoxic substances are

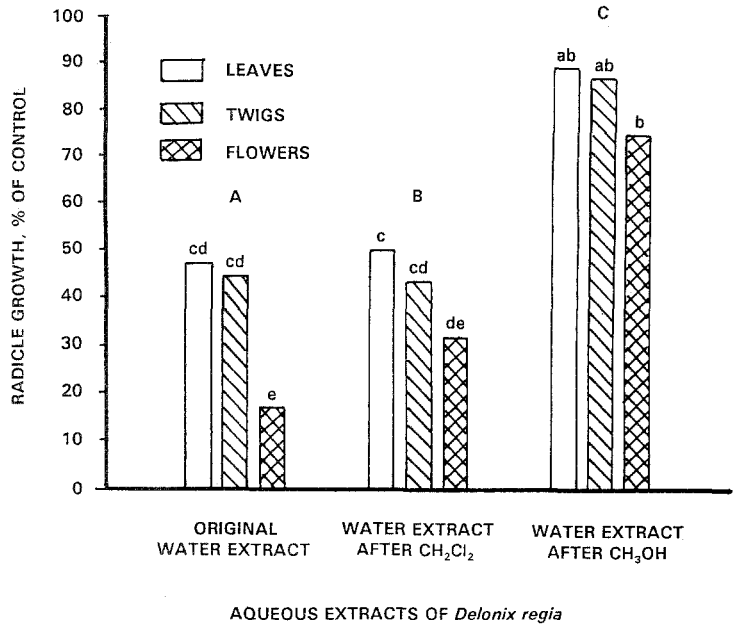

FIG. 4. A comparison of phytotoxicity of 1% aqueous extracts of plant parts of *D. regia*. The aqueous extracts were obtained: (A) by the original water extract, (B) after extraction with dichloromethane, and (C) after extraction with methanol. Effects are on the radicle growth of *Brassica campestris* L.

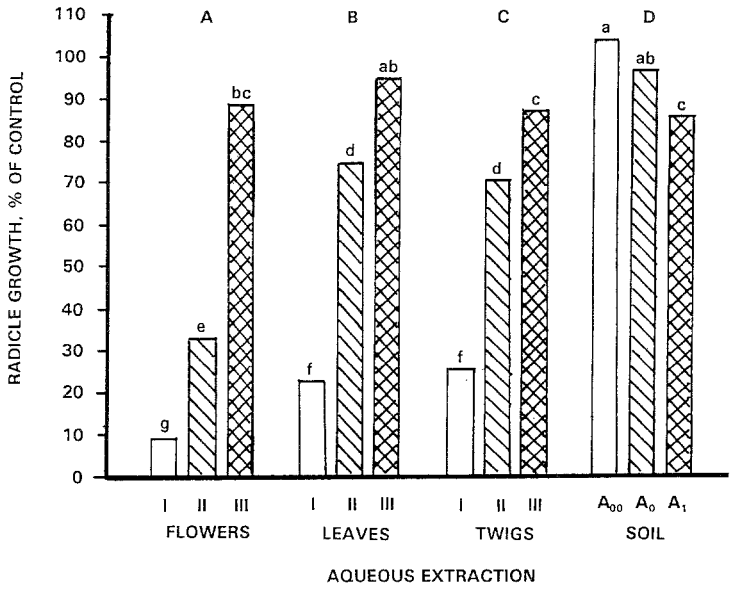

FIG. 5. The effects of aqueous extracts of plants of *D. regia* and its soil on the radicle growth of lettuce. The plant extracts were obtained by sequential extraction: 5% aqueous extracts of flowers, leaves, and twigs of *D. regia* were obtained (I), the residues were extracted with water twice and designated as extracts II and III. The soil was collected from different depths of the soil profile; the litter collected from the soil surface is designated as A_{00}, soil collected beneath the litter layer of surface soil to a depth of 0–5 cm is designated as A_0, and the soil collected beneath A_0 layer to 10 cm depth is designated A_1.

present in extracts I and II, and little toxicity remains in extract III. This finding suggests that the leachability of allelopathic substances in plant parts of *D. regia* is high.

Regarding the bioassay of soil extracts, A_{00} (litter on ground), A_0 (soil beneath litter at depth 0–5 cm), and A_1 (rhizosphere soil at depth 5–10 cm), the results show that A_{00} revealed stimulation, while soil A_0 exhibited neither stimulation nor inhibition, and soil A_1 had an inhibitory effect (Figure 5). The findings indicated that the allelopathic substances could be water soluble and leached out from the litter through the soil surface and down to the deep soil by rainfall.

Effects of Temperature on Phytotoxicity of Plant Parts of D. regia. During the summer in Tainan, the surface soil temperature may go up to 40–50°C. The plant material exposed to such temperatures may be deleteriously affected,

resulting in denaturation of chemical constituents that lead to a change of phytotoxic properties. The bioassay results of aqueous extracts of leaves, flowers, and twigs treated by temperatures of 37°C, 70°C, and 110°C are given in Figure 6. It shows that about 60% phytotoxicity remains in the leaves, flowers, and twigs at 37°C, but the toxicity in twigs is greatly reduced at 70°C and lost at 110°C for leaves and twigs. Nevertheless, 60% of the toxicity was still retained in the flowers treated at 110°C, suggesting that phytotoxic constituents present in the plant parts of *D. regia* are different.

Inhibitory Effect of Aqueous Extracts of D. regia *Flowers on Plant Growth in Pot.* Since most inhibitory agents acting upon the growth of understory species of *D. regia* were due to dropping flowers, a further investigation was undertaken to determine the effect of the extract on the growth of *Ageratum conyzoides*. One percent, 2%, and 3% extracts of the flower of *D. regia* were used on 10-cm-high seedlings of *A. conyzoides* that were transplanted into pots in the greenhouse; the results are shown in Table 3. When the *A. conyzoides* were watered with tap water (control) and the 1% extract of flowers, they grew well during a period of 15 days. However, the plants grew quite poorly when they were watered with 2% or 3% flower extract. The plants began to show chlorosis at the seventh day with 2% extract and at the third day with 3% extract. The plants began to wilt at the ninth day with 2% extract and the seventh day with

3% extract, suggesting that the leachate of *D. regia* flowers could significantly suppress the growth of understory species.

In addition to that, water culture experiments were employed to assist in gaining an understanding of the response of *Isachne nipponensis* and *Centella asiatica* to the flower extracts. Both species were commonly found in the university campus, but the latter species was occasionally found in the control site and was absent under the canopy of *D. regia* trees. In the 1% extract experiment, the root growth of both plants was severely retarded and the inhibition was 65% for *I. nipponensis* and 73% for *C. asiatica* as compared to the distilled water control. In the 2% extract, the inhibition increased up to 82% for the former and 100% for the latter species. Moreover, when the extract concentration was increased to 3%, the inhibition went up tremendously to about 100% for both species (Figure 7). The findings suggested that the low percentage of both species under the canopy of *D. regia* was apparently due to the allelopathic interaction of the species.

Identity of Allelopathic Substances in D. regia. The responsible allelopathic substances present in aqueous extracts of flowers, leaves, and twigs of *Delonix regia* were identified by paper chromatography and quantitatively estimated by HPLC, using standard compounds. The compounds identified were chlorogenic, 4-hydroxybenzoic, 3,4-dihydroxybenzoic, gallic, 3,4-dihydroxycinnamic, 3,5-dinitrobenzoic, L-azetidine-2-carboxylic acids and 3,4-dihydroxybenzaldehyde (Table 4). Of them, chlorogenic acid and 3,4-dihydroxybenzaldehyde were absent in leaf; L-azetidine-2-carboxylic acid was not found in twigs; and four compounds, 4-hydoxybenzoic, 3,4-dihydroxycinnamic, 3,5-dinitrobenzoic, and L-azetidine-2-carboxylic acids were missing in the flowers (Table 4).

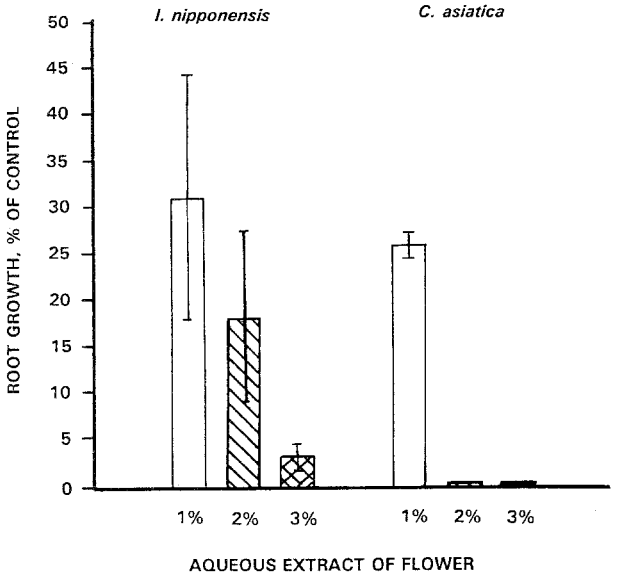

FIG. 7. Comparison of phytotoxic effect on a series of aqueous extracts, 1%, 2% and 3%, of *D. regia* on the seedling growth of *I. nipponensis* and *C. asiatica*. The experiment was conducted in water culture by using extracts as tests; tap water served as a control.

Chromatographic Bioassay of Compounds Isolated from Leaf, Flower, and Twig of D. regia. By using a chromatographic bioassay as described by Chou and Chung (1974), spots appearing on paper chromatograms developed in 2% acetic acid were cut and bioassayed against lettuce seeds. The same chromatographic paper without spotting with extract was used as control. The bioassay results for chromatographic segments according to R_f values showed both stimulation and inhibition (Table 5). The chromatograms from flowers and twigs showed higher inhibition than leaves, indicating that most allelopathic compounds were released from these two parts.

To further confirm the allelopathic properties of the compounds isolated, chlorogenic, L-azetidine-2-carboxylic, gallic, 4-hydroxybenzoic, 3,4-dihydroxybenzoic, 3,4-dihydroxycinnamic, and 3,5-dinitrozenzoic acids and 3,4-dihydroxybenzaldehyde prepared in a series of concentrations of aqueous solutions (10, 20, 40, 80, 160, 320, and 500 ppm) were bioassayed with lettuce seeds. The bioassay results are given in Figure 8 and indicate that the significant inhibition above 30% of the control was shown at 10 ppm. The inhibition increased when the concentration of compounds increased. Most of these compounds have been confirmed to be allelopathic by many scientists (Chou and Lin, 1976; Chou and Muller, 1972; Chou and Lee, 1991; Tang, 1986; Waller,

1987). L-azetidine-2-carboxylic acid was first reported to be an allelochemical compound.

DISCUSSION

A unique pattern of weed exclusion under the canopy of *Delonix regia* has been found in the tropical areas of Taiwan. In autumn, the flowers of *D. regia* trees blossom and a substantial numbers of flowers, leaves, twigs, and pods fall to the ground. These fallen plant parts could play an important role in establishing the unique pattern. On the other hand, competition for physical factors, such as light, soil moisture, and nutrients between weeds and *D. regia* could not be ruled out from the interaction, and some attention in examining these and other pertinent factors should be carefully investigated. The competition for light was not important between trees of *D. regia* and its understory species because the light intensity measured under the canopy of *D. regia* was sufficient for the growth of understory species; in addition, the soil moisture and nutrient contents were much higher in the soil of *D. regia* (Leu, 1991), reflecting that the physical competition for light, soil moisture, and nutrients were not significant between the *D. regia* and its understory species. Moreover, the relatively bare ground underneath *D. regia* was not due to mammal activities, because the

area has been fenced (Figure 1A) since the university was established and was taken care of by the university gardeners.

However, the gardeners regularly collected and burned the litter (photos shown in Leu, 1991). In the burn area under the *D. regia* trees, there is an apparent lack of weeds appearing for up to a year. Chou (1973) indicated that burning does not completely denature the phytotoxins present in the soil layer below 5 cm deep of the California chaparral, such as *Arctostaphylos glandulosa* var. *zacaensis*. McPherson and Muller (1969) indicated that the removal of *Adenostoma fasciculatum* in the chaparral vegetation of southern California resulted in luxuriant growth of weeds, which appeared in the first year following the fire. Some of the allelopathic compounds could be decomposed and lose their phytotoxic activity when the temperatures rise to 110°C and higher by surface fires. This suggests that different allelopathic constituents have different responses to the fire. Chou further examined the plantation of *D. regia* on the campus of the Taiwan Livestock Research Institute and found that a substantial number of weeds appeared under the canopy of *D. regia* trees one year after the trees were removed (Chou, 1989 personal observation). The finding suggested that the removal of the toxic source from *D. regia* resulted in reappearance of weeds in the site.

The accumulation of litter, leachates, and metabolites formed from biodegradation were found to be allelopathic agents suppressing the growth of plants under the canopy of *D. regia* trees. The present bioassay findings strongly support the allelopathic hypothesis for the unique pattern of weed exclusion. Aqueous extracts of the *D. regia* plant parts revealed significant phytotoxicity, with the flowers of the plants exhibiting the highest inhibition of tested plant parts. It was found that the phytotoxins present in *D. regia* were water soluble and thus were leached by rain. Consequently, a continuous supply of fallen leaves, twigs, pods, and flowers ensures that allelopathic compounds are constantly provided to suppress the growth of understory species.

In the present study, eight phytotoxins were identified. Of them, L-azetidine-2-carboxylic acid was first reported here as an allelopathic substance. We found that the aqueous extract of flowers of *D. regia* caused the highest phytotoxicity among extracts of plant parts; however, only four phenolics were present and four were missing in flowers, suggesting that other important water-borne phytotoxin(s) should be identified. Casinovi et al. (1983) and Heisey (1990a,b) indicated that most Simarubaceae plants possess water-borne phytotoxins that are methanol-soluble quassinoids.

In conclusion, our results suggest that the exclusion of plants under the canopy of *Delonix regia* was due primarily to allelopathic interaction. Some of the responsible allelopathic substances were identified; however, some other phytotoxins, such as anthocyanins, flavonoids, or quassinoids which may be present in plant parts of *D. regia*, need to be positively identified before the mechanism of action can be established.

(Received May 11, 1992; accepted August 10, 1992)

Abstract—Five doses of lanierone (2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one) were tested with one dose of enantiomerically pure [99.4% (4*R*)-(−)] ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) for activity as an aggregation pheromone of *Ips pini* (Say) in California. The response of *I. pini* to 1 mg/day ipsdienol + 20 μg/day lanierone was significantly greater than the response to ipsdienol alone, but the response pattern did not demonstrate a clear dose–response relationship. The response to the highest dose of lanierone (2 mg/day) was significantly lower than the response to ipsdienol alone. Ipsdienol attracted significantly more *I. pini* than a male-infested log. Lanierone did not alter the percentage of male *I. pini* responding to ipsdienol alone. Neither sex of *I. pini* or *Dendroctonus brevicomis* LeConte from California produced detectable amounts of lanierone, but myrcene-aerated male *D. brevicomis* produced 97.8%-(4*S*)-(+)-ipsdienol. The black-bellied clerid, *Enoclerus lecontei* (Wolcott) (Coleoptera: Cleridae) was attracted to lanierone when released with ipsdienol. Neither compound was attractive when released

alone, proving synergism for the kairomone of this predator. Lanierone did not influence the response of the predators *Temnochila chlorodia* (Mannerheim) (Coleoptera: Trogositidae) and *Enoclerus sphegeus* (F.) (Coleoptera: Cleridae), which were attracted to all treatments containing ipsdienol. *Tomicobia tibialis* Ashmead (Hymenoptera: Pteromalidae) responded in significantly greater numbers to the male-infested log than it did to ipsdienol or ipsdienol + 20 μg/day lanierone.

Key Words—Coleoptera, Scolytidae, Cleridae, Trogositidae, Pteromalidae, *Ips pini*, *Dendroctonus brevicomis*, *Enoclerus lecontei*, *Enoclerus sphegeus*, *Temnochila chlorodia*, *Tomicobia tibialis*, ipsdienol, lanierone, aggregation pheromone, kairomone.

INTRODUCTION

Ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) was identified as the aggregation pheromone of the pine engraver beetle, *Ips pini* (Say) (Coleoptera: Scolytidae), from populations in California (Birch et al., 1980) and New York (Stewart, 1975; Lanier et al., 1980). Prior to the identification of ipsdienol from *I. pini*, populations from California, Idaho, and New York were known to respond preferentially to their regionally specific pheromones (Lanier, 1972; Lanier et al., 1972), yet populations from California (and Arizona) and Ontario were shown to be interfertile (Lanier, 1972). In lab and field tests in California, (4*R*)-(−)-ipsdienol [95% (−)-lab, 97.8% (−)-field] was found to be attractive to *I. pini* while the (4*S*)-(+)-enantiomer [87% (+)-lab, 94.1% (+)-field], which was inactive alone, interrupted the response to (−)-ipsdienol (Birch et al., 1980). In contrast, in New York, Lanier et al. (1980) found the maximum response to racemic ipsdienol and demonstrated synergism between the two enantiomers [91% (−) and 80% (+)] in a field bioassay. Raffa and Klepzig (1989) provided additional evidence that eastern populations of *I. pini* prefer intermediate enantiomeric blends of ipsdienol when they showed maximum trap catches to 50% (−) and 25% (−) in two separate field studies in Wisconsin. The high activity of (−)-ipsdienol in western populations was further documented in one population in southeastern British Columbia [98% (−)-ipsdienol, Miller, 1990] and in another population in California [99.9% (−)-ipsdienol, Seybold et al., 1992d]. Miller (1990) also demonstrated a preferential response to the racemate by three other populations in southern British Columbia. In a study of production of ipsdienol by individual *I. pini*, Miller et al. (1989) found that inter- and intrapopulational variation of enantiomeric composition of ipsdienol ranged from 91% (−) in California and 89% (−) in southeastern British Columbia to 43% (−) in New York and 34% (−) in southwestern British Columbia.

Recently Teale and Lanier (1991) found considerable variability in the

response of a New York population to ipsdienol; in spring and early summer this compound had no activity. Subsequent investigations with the New York population resulted in the identification of lanierone (2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one), which was shown to act as a synergist with synthetic racemic ipsdienol in the lab and in the field (Teale et al., 1991).

In the present study we investigated a California population of *I. pini* for the presence (or absence) and activity of lanierone to determine whether lanierone is a factor in the interpopulational specificity observed by Lanier et al. (1972). Because we have found that the black-bellied clerid, *Enoclerus lecontei* (Wolcott) (Coleoptera: Cleridae), is attracted to ipsdienol and lanierone and since *E. lecontei* is the principal predator of the western pine beetle, *Dendroctonus brevicomis* LeConte (Person, 1940), we also investigated a California population of *D. brevicomis* for the presence or absence of lanierone.

METHODS AND MATERIALS

Laboratory Studies. For analysis of lanierone production, *I. pini* were collected on June 13, 1991 in ponderosa pine, *Pinus ponderosa* Laws., and Jeffrey pine, *Pinus jeffreyi*, Grev. & Balf. logging debris from area I of the field study site. For analysis of lanierone and ipsdienol production, *D. brevicomis* were collected on September 20, 1991 in a recently cut stem of *P. ponderosa* and by flight-trapping. The collection site was the University of California Blodgett Experimental Forest (El Dorado County, California). Insects were allowed to emerge from the infested material and stored at 4°C until utilized (Browne, 1972). Volatiles were collected separately from male and female *I. pini* and *D. brevicomis* by introducing the insects individually into freshly cut logs of *P. ponderosa*. *I. pini* males (741) and females (636) were introduced into the logs through holes drilled through the outer bark, secured in the artificial tunnels by screening, and allowed to feed in the phloem for 24 hr. After this feeding period, the logs (one set of three, 8–13 cm diameter × 28 cm length, for each sex) were placed into 19-liter silylated glass carboys (Sylon CT, Supelco Inc., Bellefonte, Pennsylvania) and aerated for 168 hr (July 12–19, 1991) with charcoal-filtered air (4 liters/min). Volatiles from each carboy were trapped on 15 g Porapak Q (50/80 mesh) (Supelco Co., Bellefonte, Pennsylvania) (Byrne et al., 1975) held in 25-cm × 2.4-cm (ID) glass columns. Each Porapak sample was extracted with 350 ml pentane. The same procedure was used with *D. brevicomis* males (166) and females (267), which were aerated October 15–22, 1991 (one set of two, 8- to 11-cm-diameter × 28-cm-length logs for each sex).

Flight-trapped and newly emerged *D. brevicomis* of each sex were introduced into freshly cut *P. ponderosa* logs, allowed to feed for 48 hr, and recovered

alive from the logs. Mid- and hindgut tissue was removed from fed and unfed insects and extracted for 2 hr in 200 μl pentane with 5% ethyl acetate for analysis of lanierone production. *D. brevicomis* of each sex were also placed on glass wool in tightly sealed 19-liter glass carboys and incubated for 18 hr at room temperature with or without 200 μl β-myrcene (Byers, 1982). Mid- and hindgut tissue from these insects as well as from insects recovered from the Porapak Q aeration was removed and extracted for 24 hr in 200 μl diethyl ether for analysis of ipsdienol enantiomeric composition. Total guts dissected for ipsdienol analysis were as follows: unfed, no myrcene: 31 males, 44 females; unfed, myrcene: 78 males, 60 females; fed: 31 males; 37 females.

The Porapak extracts of the *I. pini* and *D. brevicomis* male and female aerations were analyzed for lanierone by GC-MS using multiple ion detection (*m/z* 109, 124, 137, 152) in a Finnigan model 4500 fitted with a 30-m SPB-1 capillary column (Supelco, Inc., Bellefonte, Pennsylvania), with the injection temperature set at 250°C. The samples were run at 70 eV and the detection level for lanierone was ~0.5 ng. Porapak extracts of *D. brevicomis* male and female aerations were analyzed for ipsdienol by fractionation on HPLC (Seybold et al., 1992b,c). These fractions were assayed by GC for detection of ipsdienol (conditions below). The crude male *D. brevicomis* Porapak extract was also analyzed for the presence of ipsdienol by GC-MS using the conditions described above. Diethyl ether gut extracts of *D. brevicomis* were dried on sodium sulfate and filtered through sodium sulfate and glass wool before concentration to 20 μl. Concentrated crude extracts were analyzed for ipsdienol enantiomeric composition by direct injection on capillary GC [Shimadzu GC-9A; column: 50 m Cydex-B (50 m × 0.22 mm ID × 0.25 μm film), SGE Inc., Austin, Texas; He carrier gas; flow rate: 1.4 ml/min (2.7 kg/cm^2), linear velocity: 24.2 cm/sec, column temperature: 110°C isothermal, injector and detector temperatures: 250°C]. The presence of each enantiomer of ipsdienol on GC was verified by coinjection with authentic enantiopure (+)- and (−)-ipsdienol (Seybold et al., 1992a,c).

Residue analysis of ipsdienol in membrane release devices was carried out by Consep Membranes Inc. (Bend, Oregon) using capillary GC. For analysis, each lure was cut into 1-cm strips and extracted in 10 ml acetone with 1 mg/ml hexadecane as internal standard. An aliquot of each extract (2 μl) was analyzed by capillary GC [column: HP-5 (25 m × 0.2 mm ID × 0.33 μm film); He carrier gas; flow rate: 1 ml/min, linear velocity: 26.1 cm/sec; temperature program: 140°C for 5 min followed by 20°C/min to 220°C and held for 8 min; injection temperature: 250°C; and detector temperature: 300°C]. Under these conditions, ipsdienol had a retention time of ~3.8 min and hexadecane had a retention time of ~9.5 min.

Field Studies. A field study to determine the flight response of *I. pini* and associated fauna to varying doses of lanierone released with a standard dose of

ipsdienol was conducted between July 26 and August 3, 1991, in a recently thinned stand of *P. ponderosa* and *P. jeffreyi* located near Jelly Spring, Lassen County, California (19 km east of Hat Creek, Shasta County, California). This site is located 70 km southeast of that utilized by Birch et al. (1980) and Lanier et al. (1972) for *I. pini* pheromone isolation and field testing. The 13-km^2 site was divided into three test areas, each separated by at least 2 km. Area I was located in the $SE\frac{1}{4}$ $NE\frac{1}{2}$ S26 T34N R6E, area II was located in the $SW\frac{1}{4}$ S23 T34N R6E, and area III was located in the $NE\frac{1}{4}$ S15 and $NW\frac{1}{4}$ S14 T34N R6E. In each area, eight-unit funnel traps (Pherotech Inc., Delta, British Columbia) (Lindgren, 1983) and associated treatments were randomly assigned to positions located at least 100 m apart to minimize treatment interactions. This was a randomized block design, in which a block consisted of nine trap positions in a test area and a single day's trap catch. There were 24 blocks in the study (eight days at each of three test areas). Each day, the funnel traps were emptied, rebaited, and rerandomized between 7:30 and 11:30 AM. The treatments in the study were: (1) blank trap, (2) *P. jeffreyi* log infested with 20 male *I. pini*, (3) synthetic ipsdienol (1 mg/day), (4) synthetic lanierone (20 μg/day), (5) ipsdienol (1 mg/day) + lanierone (0.1 μg/day), (6) ipsdienol (1 mg/day) + lanierone (1 μg/day), (7) ipsdienol (1 mg/day) + lanierone (20 μg/day), (8) ipsdienol (1 mg/day) + lanierone (100 μg/day), and (9) ipsdienol (1 mg/day) + lanierone (2 mg/day). Ipsdienol (neat) was released from membrane lures (Consep Membranes, Inc.), and lanierone (in hexane) was released from capped, 2.5-ml polyethylene vials (Kartell, Fisher Scientific). Each ipsdienol membrane lure was allowed to elute 1 mg for 24 hr, and then replaced with a fresh lure. The initial amount of racemic ipsdienol loaded in the device was 7.93 mg. The load was delivered volumetrically based on the specific gravity of pure ipsdienol (0.9) and adjusted for the chemical purity of the synthetic ipsdienol. Prior laboratory analysis[6] had shown that these lures release an average of 1.39 mg/day over a four-day period, 1.31 mg/day over a five-day period, and 1.02 mg/day over a seven-day period (conditions: 25°C $\pm$ 1°C, wind speed 0.3 m/sec, and relative humidity 20–30%). The daily release rate of ipsdienol during the study was determined from residue analysis of the used membrane lures. Each polyethylene vial was charged with a 100-μl or 200-μl hexane solution of lanierone in concentrations calibrated to give the desired release rates [100 μl of 250 μg/ml for 0.1 μg/day; 100 μl of 500 μg/ml for 1 μg/day; 100 μl of 1 mg/ml for 20 μg/day (two vials); 100 μl of 10 mg/ml for 100 μg/day; and 200 μl of 50 mg/ml for 2 mg/day (two vials)]. The male-infested logs ($\sim$10 cm diameter $\times$ 12 cm length) were incubated for 36 hr prior to placement in the test and dissected following the test to determine how many males constructed feeding galleries. Throughout the course of the study, the mean maximum temperature

[6]Data on file at Consep Membranes Inc., Bend, Oregon.

on the site was 32.7°C and the mean minimum temperature was 8.9°C with a range of 4.4°C to 36.1°C.

Because hexane was used as a solvent for lanierone, a second study was conducted to determine if the presence of hexane alone would influence the response of *I. pini* and associated fauna to ipsdienol. This test was conducted on July 31, 1991 near area I of the lanierone dose study. The two treatments were ipsdienol (1 mg/day) and ipsdienol (1 mg/day) + hexane (100 μl/day = 66 mg/day). Release devices were identical to those used in the lanierone dose study. Each treatment was replicated nine times. Because lanierone is a solid at room temperature, the effect of neat lanierone on the response of *I. pini* to ipsdienol could not be tested.

Chemicals. (−)-Ipsdienol [99.39% ± 0.02% (−), 97.86% ± 0.61% chemical purity, mean of 10 injections ± SE] used in field studies was purchased from Pherotech Inc. Technical grade β-myrcene was purchased from Aldrich Chemical Co., Inc., Milwaukee, Wisconsin. Lanierone was synthesized in Syracuse (Teale et al., 1991). All solvents were HPLC grade.

Statistical Analysis. Data from tests 1 and 2 were analyzed using a nonparametric randomized blocks procedure with aligned ranks to test for equality of all treatments (Lehmann, 1975, Chapter 6, pp. 270–273). Because we knew at the outset that our trap-catch data would not be normally distributed (trap catches are integer data), we chose to use this nonparametric analysis. Data were aligned by subtraction of the mean catch in each block. Selected pairwise comparisons of treatments were performed using the Wilcoxon signed-rank test (Lehmann, 1975, Chapter 3, pp. 123–132) and the Bonferroni method was used for pairwise comparisons to control overall error rate (procedurewise $\alpha = 0.05$). Where results of tests are represented with an inequality sign, this indicates a one-sided test. Comparisons frequently involved the treatment ipsdienol (1 mg/day) + lanierone (20 μg/day), because this represents an approximation of the ratio in which the two compounds occur in New York populations of *I. pini* (Teale et al., 1991). In some cases, we performed one-sided pairwise comparisons in order to determine whether our data showed the same trends as reported for this insect in eastern North America (Teale et al., 1991). Regression analyses of percentage of male *I. pini* and the number of *E. lecontei* responding on the logarithm of lanierone concentration were performed as described in Draper and Smith (1981, Chapter 1, pp. 8–33). In the regression analysis, a log $[Y + 1]$ transformation was performed on the number of *E. lecontei*. An analysis of equality of proportions of male *I. pini* caught for all treatments as well as pairwise comparisons of proportions of males caught for selected pairs of treatments were performed using Pearson's goodness-of-fit test. The Bonferroni method was also used to control overall error rate for these pairwise comparisons (procedurewise $\alpha = 0.05$).

RESULTS

Laboratory Studies. The multiple ion detection mass spectra (*m/z* 109, 124, 137, 152) of the *I. pini* male and female aerations revealed ipsdienol and no detectable level of lanierone in the male extract, but neither compound in the female extract. Lanierone and ipsdienol were not detected in gut extracts from fed or unfed male or female *D. brevicomis*. Neither compound was detected in Porapak Q aeration extracts from male or female *D. brevicomis*. However, ipsdienol was present in gut extracts from male (but not female) insects that had been aerated with myrcene. The enantiomeric composition of the ipsdienol present in males was 97.79 ± 0.04% (+) (mean of five injections ± SE).

Laboratory residue analysis of used membrane lures from the field study (Table 1) showed that the mean daily release rate of ipsdienol throughout the course of the study was 2.56 ± 0.26 mg (grand mean of differences between day 0 and other days, nine measurements). This estimate of release rate should be viewed as a maximum estimate. The lures analyzed for day 0 of the study were not taken in the field at the time that the test was begun and then shipped for analysis. Rather, they were prepared in Berkeley and shipped to Bend for analysis. Thus, these devices had representative expected loads for day 0 and were prepared using the same equipment and materials as the other devices, but were not treated identically.

Field Studies. With the exception of one dose (2 mg/day), the lanierone dose study shows that *I. pini* responds in larger numbers to the combination of ipsdienol and lanierone than it does to ipsdienol alone (Figure 1). The response

TABLE 1. QUANTITY OF IPSDIENOL REMAINING IN MEMBRANE LURES FIELD TESTED 19 km EAST OF HAT CREEK, CALIFORNIA, JULY 26–AUGUST 3, 1991

Day of study	Ipsdienol (mg) (mean ± SE)	Lures analyzed (*N*)	Field temperature (°C) (minimum–maximum)
0	7.77 ± 0.05	12

[a] Hexane test.

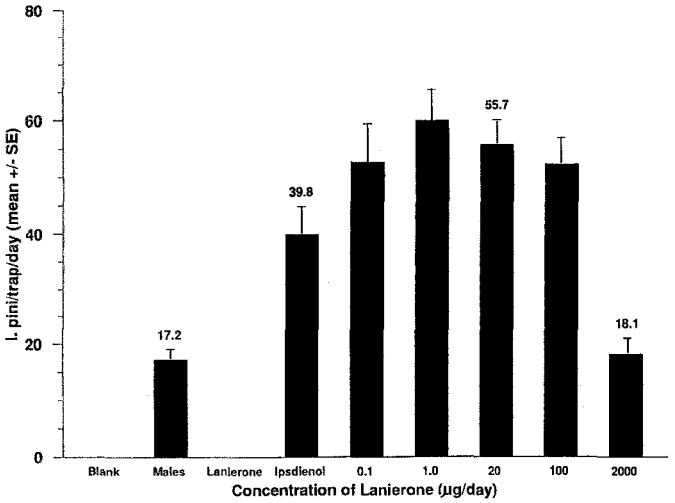

FIG. 1. The effect of varying the release rate of lanierone with a constant release rate [1 mg/day, 99.4% (−)] of ipsdienol on the mean number of *Ips pini* trapped 19 km east of Hat Creek, California, July 26–August 3, 1991. Male-infested logs, ipsdienol alone (1 mg/day), lanierone alone (20 µg/day), and blank traps served as controls. Treatment means (per trap per day) given above bars represent treatments involved in pairwise comparisons. The following pairwise comparisons were tested:

Comparison	Type of test	Significant
H_O: Ipsdienol ≥ ipsdienol + 20 µg lanierone H_A: Ipsdienol ≤ ipsdienol + 20 µg lanierone	One-sided	Yes ($P = 0.0055$)
H_O: Ipsdienol ≤ ipsdienol + 2 mg lanierone H_A: Ipsdienol ≥ ipsdienol + 2 mg lanierone	One-sided	Yes ($P = 0.0004$)
H_O: Ipsdienol ≤ male-infested log H_A: Ipsdienol ≥ male-infested log	One-sided	Yes ($P = 0.0003$)

The test for equality of all treatments was significant ($P < 0.0001$). The pairwise comparisons were analyzed using the Wilcoxon signed-rank test and the Bonferroni method was used to control for overall error rate (procedurewise $\alpha = 0.05$).

of *I. pini* to ipsdienol + lanierone (20 µg/day) was significantly greater than the response to ipsdienol alone. The response of *I. pini* to the combination of ipsdienol and the highest dose of lanierone (2 mg/day) was significantly lower than the response to ipsdienol alone. In a third significant comparison, the response of *I. pini* to ipsdienol alone was more than twice the response to the male-infested log.

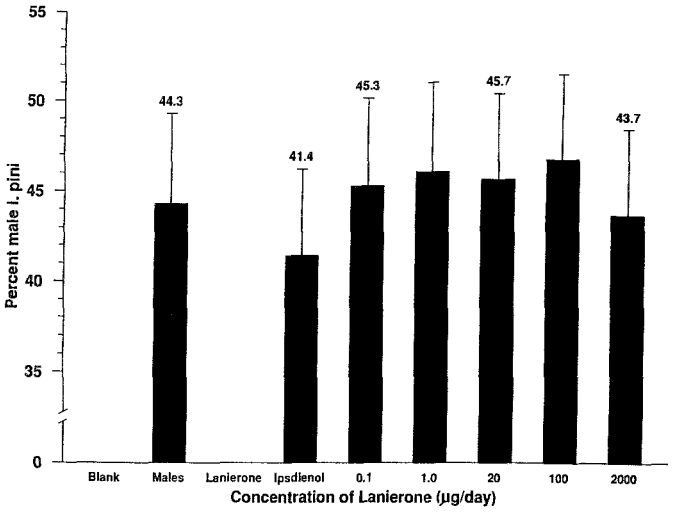

FIG. 2. The effect of varying the release rate of lanierone with a constant release rate [1 mg/day, 99.4% (−)] of ipsdienol on the percentage of male *Ips pini* trapped 19 km east of Hat Creek, California, July 26–August 3, 1991. Male infested logs, ipsdienol alone (1 mg/day), lanierone alone (20 µg/day), and blank traps served as controls. Treatment means (per trap per day) given above bars represent treatments involved in pairwise comparisons. The following pairwise comparisons were tested:

Comparison	Type of test	Significant
H_O: Ipsdienol = male-infested log H_A: Ipsdienol ≠ male-infested log	Two-sided	No ($P = 0.3209$)
H_O: Ipsdienol ≥ ipsdienol + 20 µg lanierone H_A: Ipsdienol ≤ ipsdienol + 20 µg lanierone	One-sided	No ($P = 0.0202$)
H_O: Ipsdienol + 20 µg lanierone ≥ male-infested log H_A: Ipsdienol + 20 µg lanierone < male-infested log	One-sided	No ($P = 0.6942$)
H_O: Ipsdienol + 2 mg lanierone ≤ ipsdienol + 0.1 µg lanierone H_A: Ipsdienol + 2 mg lanierone > ipsdienol + 0.1 µg lanierone	One-sided	No ($P = 0.7242$)

The test for equality of all treatments was not significant ($P = 0.2400$). The pairwise comparisons were analyzed using the Pearson's goodness-of-fit test and the Bonferroni method was used to control for overall error rate (procedurewise $\alpha = 0.05$).

The proportion of male *I. pini* responding was not influenced by the presence of lanierone (Figure 2). Regression analysis of percentage of males on logarithm of concentration of lanierone [log (mg)] did not fit the model [R^2 = 0.0026, $Y = -0.37$ (log X) + 45.17 (where Y = percentage of males trapped and X = mg lanierone), slope not significantly different from 0, $P = 0.58$, $\alpha = 0.05$]. The percentage of male *I. pini* responding to the male-infested log (44.3%) was not significantly different from the percentage of male *I. pini* responding to (−)-ipsdienol (41.4%) (Figure 2). The addition of lanierone at 20 μg/day did not cause a significant increase in the percentage of male *I. pini* responding to ipsdienol (45.7% vs. 41.4%) and the addition of 2 mg/day lanierone did not cause a significant increase over 0.1 μg/day lanierone (43.7% vs. 45.3%). There was no significant difference between the responses of *I. pini* to ipsdienol and to ipsdienol + hexane (mean response to ipsdienol ± SE: 44.5 ± 9.5; mean response to ipsdienol + hexane ± SE: 48.3 ± 10.2; two-sided Wilcoxon signed-rank test, $P = 0.9528$).

Insect predators and parasitoids of *I. pini* responded to various treatments in these studies. The proportion of each sex of these associates responding was not determined. None of these insects appeared to be attracted to lanierone alone. However, some were attracted to ipsdienol alone, and one, *Enoclerus lecontei*, responded to the combination of these compounds. In selected paired comparisons, the responses of the predators *Temnochila chlorodia* (Mannerheim) (Coleoptera: Trogositidae) and *Enoclerus sphegeus* (F.) (Coleoptera: Cleridae) to ipsdienol + lanierone (20 μg/day) did not differ significantly from their responses to ipsdienol alone (Figures 3 and 4). The responses of both species to ipsdienol alone were significantly greater than they were to an unbaited trap. This study indicated a significant difference between the responses of *T. chlorodia* to ipsdienol and to the male-infested log (Figure 3). In this case, ipsdienol was more attractive than the male-infested log. The response of *E. sphegeus* to ipsdienol was not significantly different from the response to the male-infested log (Figure 4).

E. lecontei exhibited a clear dose-dependent response to lanierone when delivered with ipsdienol (Figure 5). The response of this predator to ipsdienol + lanierone (20 μg/day) did not differ significantly from its response to the male-infested log, while the response to ipsdienol + lanierone (20 μg/day) was significantly greater than it was to a blank trap. The catch at traps baited with ipsdienol alone was not significantly different from the response to the blank trap. Although we could not analyze the comparison between the response to the blank trap and the response to lanierone (in hexane) alone, no *E. lecontei* were trapped coming to either treatment (Figure 5). The estimated slope in the regression analysis for *E. lecontei* was significant [$R^2 = 0.52$, log $(Y + 1) = 0.17$ (log$X$) + 0.69 (where Y = trap catch and X = mg lanierone), slope significantly different from 0, t test, $P = 0.0001$, $\alpha = 0.05$].

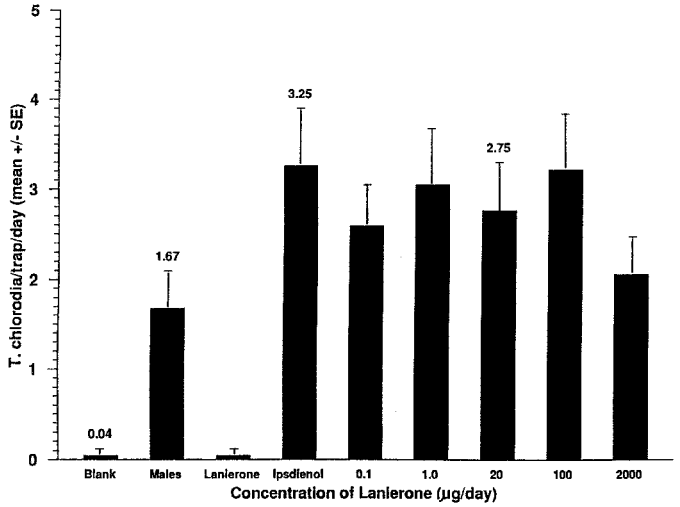

FIG. 3. The effect of varying the release rate of lanierone with a constant release rate [1 mg/day, 99.4% (−)] of ipsdienol on the mean number of *Temnochila chlorodia* trapped 19 km east of Hat Creek, California, July 26–August 3, 1991. *Ips pini* male-infested logs, ipsdienol alone (1 mg/day), lanierone alone (20 µg/day), and blank traps served as controls. Treatment means (per trap per day) given above bars represent treatments involved in pairwise comparisons. The following pairwise comparisons were tested:

Comparison	Type of test	Significant
H_O: Ipsdienol ≤ blank H_A: Ipsdienol > blank	One-sided	Yes ($P < 0.0001$)
H_O: Ipsdienol = male-infested log H_A: Ipsdienol ≠ male-infested log	Two-sided	Yes ($P = 0.0026$)
H_O: Ipsdienol = ipsdienol + 20 µg lanierone H_A: Ipsdienol ≠ ipsdienol + 20 µg lanierone	Two-sided	No ($P = 0.3830$)

The test for equality of all treatments was significant ($P < 0.0001$). The pairwise comparisons were analyzed using the Wilcoxon signed-rank test and the Bonferroni method was used to control for overall error rate (procedurewise $\alpha = 0.05$).

A mean of 2.4 *Tomicobia tibialis* Ashmead (Hymenoptera: Pteromalidae) (Figure 6) were trapped at male-infested logs each day while a mean of less than 0.2 *T. tibialis* were trapped at lanierone, ipsdienol, or the combination of these compounds. The response to the male-infested log was significantly greater than it was to the blank trap, to ipsdienol, or to ipsdienol + lanierone (20 µg/day).

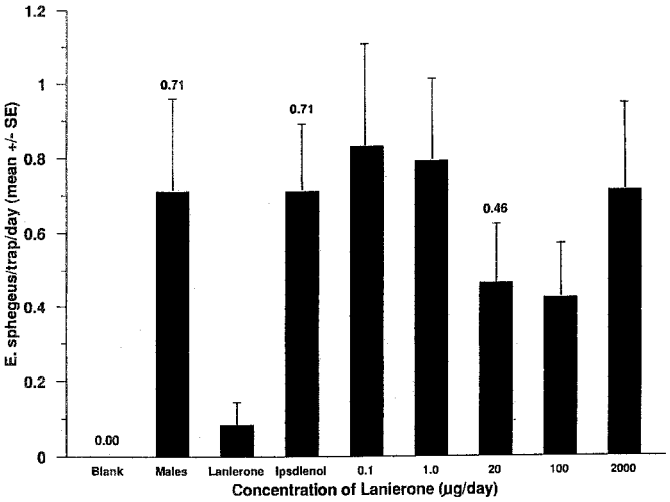

FIG. 4. The effect of varying the release rate of lanierone with a constant release rate [1 mg/day, 99.4% (−)] of ipsdienol on the mean number of *Enoclerus sphegeus* trapped 19 km east of Hat Creek, California, July 26–August 3, 1991. *I. pini* male-infested logs, ipsdienol alone (1 mg/day), lanierone alone (20 μg/day), and blank traps served as controls. Treatment means (per trap per day) given above bars represent treatments involved in pairwise comparisons. The following pairwise comparisons were tested:

Comparison	Type of test	Significant
H_O: Ipsdienol $\leq$ blank H_A: Ipsdienol $\geq$ blank	One-sided	Yes (P = 0.0005)
H_O: Ipsdienol = male-infested log H_A: Ipsdienol $\neq$ male-infested log	Two-sided	No (P = 0.8557)
H_O: Ipsdienol = ipsdienol + 20 μg lanierone H_A: Ipsdienol $\neq$ ipsdienol + 20 μg lanierone	Two-sided	No (P = 0.2775)

The test for equality of all treatments was significant (P = 0.0010). The pairwise comparisons were analyzed using the Wilcoxon signed-rank test and the Bonferroni method was used to control for overall error rate (procedurewise α = 0.05).

A total of 40 *Pityogenes carinulatus* (LeConte) (Coleoptera: Scolytidae) were trapped during the study and 38 of the specimens responded to treatments involving lanierone and ipsdienol. The test for equality of all treatments was significant (P = 0.002) for *P. carinulatus* and the response to ipsdienol + 0.1 μg/day lanierone (0.33 insects/trap/day) was significantly greater than the response to the blank trap (0 insects/trap/day)(P = 0.0072).

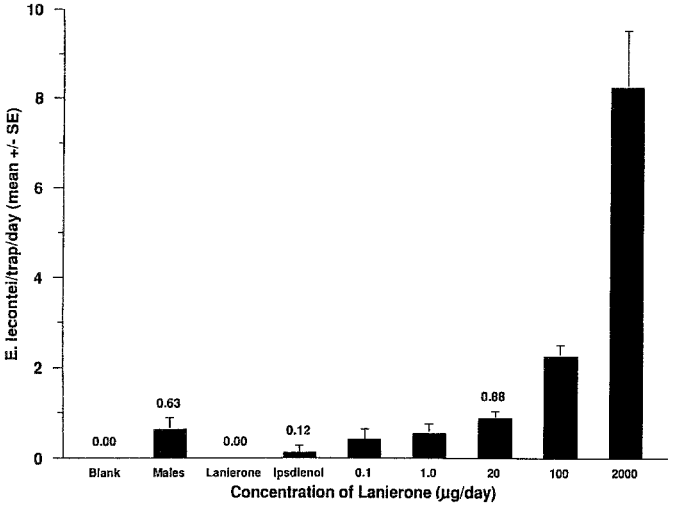

FIG. 5. The effect of varying the release rate of lanierone with a constant release rate [1 mg/day, 99.4% (−)] of ipsdienol on the mean number of *Enoclerus lecontei* trapped 19 km east of Hat Creek, California, July 26–August 3, 1991. *I. pini* male-infested logs, ipsdienol alone (1 mg/day), lanierone alone (20 µg/day), and blank traps served as controls. Treatment means (per trap per day) given above bars represent treatments involved in pairwise comparisons. The following pairwise comparisons were tested:

Comparison	Type of test	Significant
H_O: Ipsdienol = blank H_A: Ipsdienol ≠ blank	Two-sided	No ($P = 0.0833$)
H_O: Lanierone = blank H_A: Lanierone ≠ blank	Two-sided	Could not test
H_O: Ipsdienol + 20 µg lanierone ≤ blank H_A: Ipsdienol + 20 µg lanierone ≥ blank	One-sided	Yes ($P < 0.0001$)
H_O: Ipsdienol + 20 µg lanierone = male-infested log H_A: Ipsdienol + 20 µg lanierone ≠ male-infested log	Two-sided	No ($P = 0.1786$)

The test for equality of all treatments was significant ($P < 0.0001$). The pairwise comparisons were analyzed using the Wilcoxon signed-rank test and the Bonferroni method was used to control for overall error rate (procedurewise $\alpha = 0.05$).

The predators *Enoclerus barri* Knull (Coleoptera: Cleridae) and *Othnius* spp. (Coleoptera: Othniidae), and the associates *Lasconotus subcostulatus* Kraus (Coleoptera: Colydiidae), *Corticeus* spp. (Coleoptera: Tenebrionidae), *Dendroctonus valens* LeConte (Coleoptera: Scolytidae), *Pityophthorus jeffreyi* Blackman (Coleoptera: Scolytidae), *Aulonium* spp. (Coleoptera: Colydiidae),

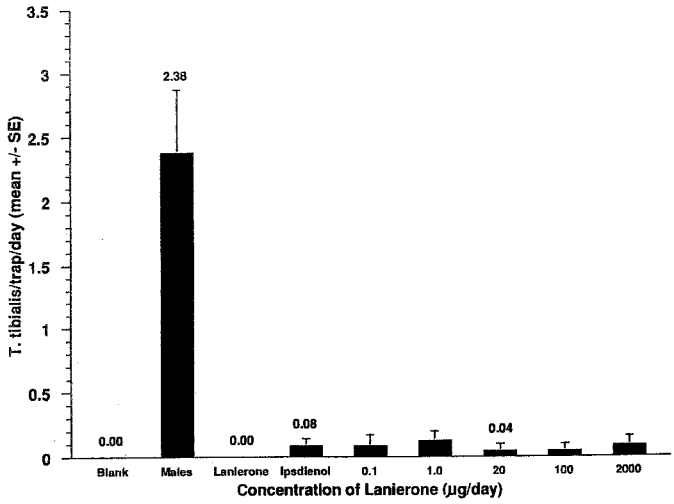

FIG. 6. The effect of varying the release rate of lanierone with a constant release rate [1 mg/day, 99.4% (−)] of ipsdienol on the mean number of *Tomicobia tibialis* trapped 19 km east of Hat Creek, California, July 26–August 3, 1991. *Ips pini* male-infested logs, ipsdienol alone (1 mg/day), lanierone alone (20 µg/day), and blank traps served as controls. Treatment means (per trap per day) given above bars represent treatments involved in pairwise comparisons. The following pairwise comparisons were tested:

Comparison	Type of test	Significant
H_O: Male-infested log ≤ blank H_A: Male-infested log ≥ blank	One-sided	Yes ($P < 0.0001$)
H_O: Male-infested log ≤ ipsdienol H_A: Male-infested log ≥ ipsdienol	One-sided	Yes ($P < 0.0001$)
H_O: Male-infested log ≤ ipsdienol + 20 µg lanierone H_A: Male-infested log ≥ ipsdienol + 20 µg lanierone	One-sided	Yes ($P < 0.0001$)

The test for equality of all treatments was significant ($P < 0.0001$). The pairwise comparisons were analyzed using the Wilcoxon signed-rank test and the Bonferroni method was used to control for overall error rate (procedurewise $\alpha = 0.05$).

Lyctocoris spp. (Hemiptera: Anthocoridae), and *Cylistix* spp. (Coleoptera: Histeridae) were trapped only in small numbers, and thus conclusions cannot be drawn about their responses to ipsdienol or lanierone.

Dissection of the 24 male-infested logs used in this study revealed that a mean of 18.04 (range 15–20) males had constructed feeding galleries in each of these logs.

DISCUSSION

The California population of *I. pini* that we studied behaves differently than the New York population in several ways. Ipsdienol elicits a proportionately higher level of response from California *I. pini* than a male-infested log (Figure 1). However, New York *I. pini*, in both lab and field studies, responds in significantly greater numbers to male-produced volatiles or a male-infested log than it does to ipsdienol (Teale et al., 1991). Teale et al. (1991) used a field-study dose of ipsdienol (10 mg for a six-day test period) similar to that used in California (2.6 mg/day). Birch et al. (1980) discovered the importance of the (−)-enantiomer of ipsdienol to the field attraction of this California population of *I. pini*. Response of *I. pini* to 99.4% (−)-synthetic ipsdienol in our study may exceed the response to the male-infested log because of the higher release rate from the devices or because the optical purity of the synthetic compound exceeds that of a log infested with 20 male *I. pini* [mean 98.2% (−), range 96.6–98.9% (−), 12 replicates]. The dose of (−)-ipsdienol released in 24 hr from these male-infested logs ranges from 0.7 to 1.9 mg/day (Seybold et al., 1992d).

In California, *I. pini* responds to ipsdienol at levels comparable to its response to a male-infested log from May through August (Seybold et al., 1992d), while in New York *I. pini* responds to ipsdienol in greater numbers (although still lower than to the male-infested log) only after the beginning of August (Teale and Lanier, 1991). Similarly, in Wisconsin, Raffa (1991) reported trapping the most beetles late in the season, but the level of response relative to male-produced attractants was not tested. Nonetheless, in two of three years where the flight behavior of *I. pini* was studied from spring through fall, Raffa (1991) demonstrated a response to ipsdienol in April and May. Wisconsin and New York populations are similar because they produce and respond to similar enantiomeric blends of ipsdienol (Seybold et al., unpublished; Raffa and Klepzig, 1989; Teale, 1990).

Another difference between California and New York populations is that the response of California *I. pini* to increasing doses of lanierone in the presence of ipsdienol does not demonstrate the clear dose-dependent response elicited from New York *I. pini* (Figure 1 and Teale et al., 1991). In addition, the percentage of male *I. pini* responding in California to the male-infested log is not significantly different from the percentage of male *I. pini* responding to (−)-ipsdienol alone. Adding lanierone to ipsdienol does not affect the proportion of males responding in California. In two different field studies, Birch et al. (1980) also found that the male to female sex ratio of *I. pini* responding to (−)-ipsdienol was not different from the sex ratio of *I. pini* responding to a male-infested log. However, in New York, Teale et al. (1991) have found a positive relationship between the percentage of males in the responding population and the quantity

of lanierone added to a fixed amount of ipsdienol. They also found that the percentage of male responders was highest (48%) to the male-infested log. In California, the percentage of males responding to the male-infested log (44.3%) was not significantly greater than the percentage of males responding to ipsdienol and 20 μg/day lanierone (45.7%).

There is a considerable difference between the enantiomeric composition of ipsdienol produced by New York and California populations of *I. pini*. Birch et al. (1980) isolated ipsdienol from benzene extracts (Young et al., 1973) of California *I. pini* male-produced frass, as well as from volatiles condensed in a liquid nitrogen trap. The enantiomeric composition of the ipsdienol from this isolation was not determined, but Stewart (1975) found that California *I. pini* produce (−)-ipsdienol, and Miller et al. (1989) obtained a mean of 91% (−) from a population collected near Hat Creek, California. Lanier et al. (1980) reported the isolation of ipsdienol from male New York *I. pini* by trapping volatiles on Porapak Q. Earlier, the enantiomeric composition of this ipsdienol had been found to be 35% (−) (Stewart, 1975). Miller et al. (1989) measured a mean of 43% (−) from a population collected in New York. The isolations by Birch et al. (1980) and Lanier et al. (1980) were both guided by lab and field assays.

In addition to the differences in the stereochemistry of ipsdienol, we have found that a California population of *I. pini* does not produce detectable levels of lanierone. Based on the smallest detectable peak in the GC (FID) trace, lanierone production would have to be much less than 0.002% of the amount of ipsdienol produced by male *I. pini* in California. This is one-hundredth of the amount of lanierone (0.2%, relative to ipsdienol) produced by *I. pini* in New York (Teale et al., 1991). The absence of lanierone in this California population of *I. pini* and its presence in New York populations may be related to differences in the hosts (*P. ponderosa* vs. *Pinus resinosa* Ait.) from which volatiles were collected. Since Teale et al. (1991) did not find lanierone in Porapak extracts from female New York *I. pini* in *P. resinosa*, it is unlikely that lanierone is present in the host itself. However, precursors for biosynthesis of lanierone may be present in *P. resinosa*, but not in *P. ponderosa*. It should be noted that the host species does not appear to affect ipsdienol production (including enantiomeric composition), which was unchanged when males from New York populations reared in *P. resinosa* were allowed to feed in *P. ponderosa* (Seybold et al., unpublished).

Besides the interfertility of eastern (Ontario) and western (California and Arizona) populations of *I. pini* (Lanier, 1972), there are also some similarities in the flight behavior of western (California) and eastern (New York) populations. Neither responds to lanierone alone, and both appear to be inhibited at high lanierone concentrations [10 mg for a six-day test[7] period for eastern pop-

[7]Log[mg] doses in Teale et al. (1991) Figure 11 should read left to right, −3, −2, −1, 0, and 1.

ulations (Teale et al., 1991) and 2 mg/day for western populations (this study)]. Although western populations of *I. pini* do not produce detectable amounts of lanierone, the ipsdienol-elicited flight response of *I. pini* in California can be increased by its presence. This latter result would seem to suggest a relictual behavioral link between the eastern and western forms of *I. pini*.

Much remains to be learned about the evolutionary history of the pheromone variants of *I. pini* [formerly *I. oregonis* (Eichhoff) = western and *I. pini* (Say) = eastern; Hopping, 1964]. Based on glacial history and production and response profiles of enantiomeric blends of ipsdienol, Miller (1990) suggested that eastern populations of *I. pini* originated from a southeastern refugium in the Appalachian Mountains, that eastern-like populations currently in British Columbia originated from a southwestern refugium, and that western populations in British Columbia derived from populations similar to those presently in northern California. However, there are other possible explanations for the origin of the pheromone types noted in British Columbia. These include introduction from eastern localities (J.W.A. Volney, personal communication); blending of eastern and western forms originating from eastern and western glacial refugia, respectively (D.E. Bright, personal communication); and post-Pleistocene colonization from the Beringia (= Yukon) refugium (D.E. Bright, personal communication).

It is possible that an eastern population of *I. pini* was introduced and established in British Columbia. Movement of insects in logs, timbers, and rough-wood crates by human transport is a well-known current problem (Ciesla, 1988), but it has probably also occurred during the past century. For example, there is an endemic population of *I. calligraphus calligraphus* in central California that probably originated from the southeastern United States and was present at least by 1914 (Herbert, 1916, Wood and Stark, 1968, and Lanier et al., 1991).

The eastern form of *I. pini* may have moved naturally into northwestern Canada from a southeastern refugium (Matthews, 1979) or from midcontinental refugia (Critchfield, 1985) by following the post-Pleistocene migration of jack pine, *Pinus banksiana* Lamb. *P. banksiana* is a rapidly colonizing species that invaded western Canada during the last 10,000 years where it occurs in a hybridization zone with *P. contorta latifolia* in northern Alberta and the southern Yukon Territory (Critchfield, 1957, 1985). *P. contorta* appears to have experienced a more sedentary post-Pleistocene colonization pattern, originating from refugia south of the Cordilleran glacial ice mass and, perhaps, in the Yukon (Critchfield, 1985). This zone of host hybridization prompts the question whether eastern and western forms of *I. pini* also form a zone of sympatry in this region. The rapid migration of *P. banksiana* through Canada suggests that the eastern form of *I. pini* may have become established in British Columbia in *P. contorta latifolia* prior to or contemporaneously with the advent of the western form,

which may have also utilized *P. ponderosa*, *P. contorta murrayana*, or *P. contorta contorta* as its refugial hosts. Ross (1955) also noted the transcontinental distribution of *P. banksiana* as a major factor in the evolution of the *Neodiprion* sawflies. Despite the continuity of genetic variation in *P. banksiana* across Canada, it is possible that it also occupied one or more western refugia during the Pleistocene (Critchfield, 1985). Similarly, host islands of *P. contorta* may have been available for *I. pini* in ice-free corridors between the Cordilleran and Laurentide ice sheets (Critchfield, 1985).

Miller (1990) discounted Beringia as a source of present-day *I. pini* in British Columbia based on the meager and highly localized modern-times collection record of *I. pini* in coastal southeastern Alaska (Wood, 1982). However, in addition to indications that the host, *P. contorta*, may have been in a Yukon refugium (Critchfield, 1985), there is one record of *I. pini* from interior Alaska (Bright, 1976). Moreover current distribution does not always reflect historical distribution [e.g., the scolytid, *Carphoborus andersoni* Swaine, occurs only in northern Alberta, the Northwest Territories, and Alaska, but fossils indicate its former presence in Minnesota, New York, and Ontario between 10,000 and 70,000 years ago (Bright, 1976; Wood, 1982; D.E. Bright, personal communication)].

Gahan (1938) and Reid (1957) documented the association of the solitary parasitoid wasp *T. tibialis* with *I. pini*. *T. tibialis* has also been shown to respond to logs infested with male California five-spined ips, *Ips paraconfusus* Lanier (Bedard, 1965) and to logs infested with male and not female *I. pini* (Rice, 1968). In a field study in California, Lanier et al. (1972) demonstrated that *T. tibialis* preferred California and Idaho male *I. pini*-infested logs over New York male *I. pini*-infested logs. In our study we have found that *T. tibialis* responded to logs infested with male *I. pini*, but not to ipsdienol, lanierone, or any combination of these compounds. This indicates that the kairomone that attracts *T. tibialis* to *I. pini* probably involves other chemicals, although it may include ipsdienol, which is produced by males of both *I. paraconfusus* and *I. pini* (Silverstein et al., 1966; Birch et al., 1980). In the present study, *T. tibialis* was often observed and collected from the white surface of the top of the funnel traps beneath the male-infested logs, but it was never observed or collected from this surface or near the release devices on traps baited with synthetic chemicals. Nonchemical behavioral stimuli associated with the presence of male frass, the pine log, and the attracted live bark beetles may also have contributed to the arrestment of *T. tibialis* on the surface of traps baited with male-infested logs.

In contrast to its influence on *I. pini*, lanierone had no effect on the responses of *T. chlorodia* or *E. sphegeus* to ipsdienol. As with California *I. pini*, the response of these predators to the male-infested log appears to be fully explained by their response to ipsdienol. Despite many prior studies of bark beetle pheromones where *T. chlorodia* has been shown to respond to various natural and

synthetic substrates, it has never been found to respond to ipsdienol alone [*D. brevicomis*-infested log (Vité and Gara, 1962); male *I. paraconfusus*-infested log (Vité and Gara, 1962; Rice, 1969); synthetic *exo*-brevicomin (Bedard et al., 1969, 1980; Vité and Pitman, 1969); synthetic ipsenol and male *I. pini*-infested log (Furniss and Livingston, 1979); and mixture of ipsenol, ipsdienol, and *cis*-verbenol (Wood et al., 1968; Wood, 1970)].

The red-bellied clerid, *E. sphegeus*, is a principal predator of the mountain pine beetle, *Dendroctonus ponderosae* Hopkins (Struble, 1942), and also preys on *Ips* spp. (Furniss and Carolin, 1977). Furniss and Livingston (1979) reported low numbers of *E. sphegeus* responding in Idaho to synthetic ipsenol and combined with logs infested with male *I. pini*, while Miller and Borden (1990) presented clear evidence from British Columbia that *E. sphegeus* is attracted to synthetic, racemic ipsdienol. In California we have confirmed the response of *E. sphegeus* to ipsdienol and further demonstrated that *E. sphegeus* will respond to almost optically pure (99.4%) (−)-ipsdienol.

The black-bellied clerid, *E. lecontei*, is the principal predator of *D. brevicomis* (Person, 1940) and is known to aggregate rapidly on trees freshly attacked by *D. brevicomis* (Stephen and Dahlsten, 1976). It also preys on *Ips* spp. (Furniss and Carolin, 1977). Vité and Gara (1962) reported attraction of *E. lecontei* to *P. ponderosa* logs infested with any of five species of scolytids, including *I. paraconfusus* and *D. brevicomis*. Wood et al. (1968) and Wood (1970) trapped *E. lecontei* responding to *P. ponderosa* logs infested with male *I. paraconfusus* and to various mixtures of synthetic ipsenol, ipsdienol, and *cis*-verbenol. Lanier et al. (1972), Birch and Wood (1975), and Furniss and Livingston (1979) have reported response of *E. lecontei* to natural aggregation pheromones produced by male *I. pini*. *E. lecontei* responded in a dose-dependent fashion to synthetic, racemic ipsdienol (Miller and Borden, 1990). In that study the pine monoterpene, β-phellendrene, had no effect on the response of *E. lecontei*.

In our study, *E. lecontei* did not respond to one release rate of 99.4% (−)-ipsdienol or lanierone individually above control levels; however, together the two compounds represent a synergistic kairomone for a significant bark beetle natural enemy. This pattern of activity is similar to that discovered for *I. paraconfusus*, where three terpene alcohols, including ipsdienol, were inactive individually, but together they elicited the attractant response (Silverstein et al., 1966; Wood et al., 1968). The dose-dependent response (Figure 5) stands in contrast to the response of *I. pini* (Figure 1) to these two compounds, and to the results obtained by Miller and Borden (1990) in British Columbia. Indeed, *E. lecontei* in California responds to the ipsdienol–lanierone combination as *I. pini* does in New York (Teale et al., 1991). It would be interesting to determine the response pattern for *E. lecontei* to increasing doses or variable enantiomeric compositions of ipsdienol in the presence of a fixed dose of lanierone.

Lanier et al. (1972) found that *E. lecontei* in California and Idaho exhibited

a strong preference for logs infested with male *I. pini* from New York over those infested with males from California and Idaho. The strong response of *E. lecontei* to lanierone and ipsdienol, which are both produced by New York *I. pini*, and the absence or very low amounts of lanierone in California *I. pini* in this study are sufficient to explain the preference observed by Lanier et al. (1972). In this study, the lower response of *E. lecontei* to ipsdienol alone than to the male-infested log (Figure 5) may indicate the release of additional kairomonal compounds from the male-infested log.

The strong response of *E. lecontei* to lanierone + ipsdienol may have evolved because of a close association between *E. lecontei* and eastern populations of *I. pini*, for which lanierone plays a major role in aggregation (Teale et al., 1991). The current distribution of *E. lecontei* is reported to range eastward from the Pacific coast to Ontario and Michigan (Person, 1940; Papp, 1960), and *I. pini* is the principal bark beetle attacking pines in northeastern and north central North America. In contrast, *E. sphegeus* and *T. chlorodia*, neither of which discriminated between the combination of lanierone + ipsdienol and ipsdienol alone, have entirely western distributions (Person, 1940; Barron, 1971). *T. chlorodia* is replaced by the closely related *T. virescens* (F.) and *T. acuta* LeConte in eastern and southern North America (Barron, 1971).

Another possibility is that the strong response of *E. lecontei* to lanierone + ipsdienol in western North America may have evolved in response to production of lanierone and ipsdienol by a western ancestral form of *I. pini* that resembled its present-day eastern counterpart in this trait. Selection pressure exerted by *E. lecontei* on *I. pini* may have resulted in the loss or reduction of the biosynthetic capacity for lanierone production and a reduced response to lanierone and ipsdienol by the present population of *I. pini* in California relative to other populations in North America. Miller et al. (unpublished) have found that the relative increase in response of California *I. pini* to lanierone and ipsdienol compared to ipsdienol alone is the lowest of six populations tested in North America. It has been suggested that selection pressure by the predaceous clerid *Thanasimus dubius* (F.) results in a shift in response to the enantiomers of ipsdienol by populations of *I. pini* in north-central North America (Raffa and Klepzig, 1989; Herms et al., 1991). In the same fashion, Payne et al. (1984) suggested that selection pressure by *T. dubius* on *D. frontalis* may result in a production–response shift in the enantiomeric composition of frontalin.

Alternatively, *E. lecontei* may have evolved a strong kairomonal response to ipsdienol and lanierone because these compounds are produced by other prey species in western North America. Male *D. brevicomis* have been reported to produce (+)-ipsdienol (Byers, 1982), and this compound was present in the extracts of hindgut tissue from males that were collected live from a pheromone-baited tree (Byers et al., 1984). In the latter study, the amount of ipsdienol was maximal when the males were exposed to elevated levels of oleoresin exuded

by the attacked tree (day 2, 80 ng/male). Ipsdienol remained detectable later in the colonization process (days 8 and 11, 5 and 7 ng/male, respectively). The high, but slightly delayed response of *E. lecontei* to an aggregation of *D. brevicomis* (Byers et al., 1984) may be explained by lanierone production in either or both sexes of *D. brevicomis* several days after arrival on the tree. This would also explain the increase in response of *E. lecontei* when a *D. brevicomis*-infested log is added to a male *I. paraconfusus* log (Byers and Wood, 1980). Therefore, we hypothesized the presence of lanierone in *D. brevicomis*, but did not detect it. It is possible that lanierone is produced by *D. brevicomis* when both sexes are together in the standing tree or that it is produced by *E. lecontei* itself as an aggregation pheromone component whose activity is dependent on ipsdienol, a bark beetle-produced synergist.

We have shown for the first time that the enantiomeric composition of ipsdienol produced by male *D. brevicomis* is 97.8% (+), which is slightly greater than that produced by the cohabiting *I. paraconfusus* from the same locality (Seybold et al., 1992b,c). This enantiomeric composition of ipsdienol may limit aggregations of *D. brevicomis*. Byers (1982) has shown that racemic ipsdienol interrupts response of *D. brevicomis* to synthetic aggregation pheromones. However, various enantiomeric blends of ipsdienol remain to be tested against the natural pheromone produced in trees under attack by *D. brevicomis*. This enantiomeric composition of ipsdienol would also interrupt aggregations of *I. pini* in areas where *I. pini* and *D. brevicomis* co-occur in *P. ponderosa* (e.g., eastern California, Oregon, Washington, Idaho, and southeastern British Columbia). The absence of male-produced ipsdienol in gut extracts of fed and unfed insects, as well as in the extract from the Porapak Q aeration may be a result of low myrcene content in the *P. ponderosa* logs used to feed *D. brevicomis* males. Byers et al. (1984) observed the correlation of ipsdienol production in male *D. brevicomis* with oleoresin exudation from *P. ponderosa* and myrcene is present in *P. ponderosa* oleoresin.

Kohnle and Vité (1984) have classified the prey location strategies of bark beetle predators as generalist or specialist based on the number of kairomones used for prey location. Several members of the Trogositidae, including *T. chlorodia*, were grouped among the specialists (one kairomone), while members of the Cleridae were grouped among the generalists (several kairomones). However, we have demonstrated that, in addition to *exo*-brevicomin, *T. chlorodia* also responds to ipsdienol, which is produced by at least 21 species of *Ips* in North America (Seybold et al., 1992b) and by male *D. brevicomis* (Byers, 1982). *E. lecontei* and *E. sphegeus*, the principal predators of *D. brevicomis* and *D. ponderosae*, respectively, also respond to ipsdienol + lanierone and ipsdienol, respectively. In contrast to species-specific aggregation pheromones of their prey, these bark beetle predators have evolved the capacity to recognize multiple kairomone signals that are important components of the aggregation

pheromone of different prey species. Vité and Gara (1962) observed the response of these three predators to five scolytid species. The ability to locate aggregations of several bark beetle species occurring throughout its geographic range increases the size of the possible food base for the predator and thus increases the probability of survival and reproduction.

The strong response of *E. lecontei* to ipsdienol and lanierone released at 2 mg/day and the inhibition of *I. pini* response at this dose suggest a novel control strategy using behavioral chemicals. Nascent aggregations of *I. pini* could be treated with a proportionately high dose of lanierone compared to ipsdienol, which would minimize further bark beetle aggregation while recruiting additional predators. Together with lanierone, the use of (+)-ipsdienol, a strong inhibitor for *I. pini* (Seybold et al., 1992d) and possibly for *D. brevicomis* (Byers, 1982), may also decrease the probability of further bark beetle aggregation.

Acknowledgments—We dedicate this study to the memory of the late Gerald N. Lanier, a pioneer in insect chemical ecology, who devoted much of his scientific career to unravelling the pheromone biology of *Ips pini*. We would like to thank P. Shea, USDA Forest Service, Davis, California, for providing the facilities for the field portion of our study and J. Tupy, N. Lewis, and J. Davis for field and laboratory assistance. J. Tupy critically reviewed the manuscript. J. Gillespie, M. Banfield, D. Bestwick, E. Christensen, and K. Hayes of Consep Membrane, Inc., Bend, Oregon, carried out the formulation and analysis of ipsdienol. We thank D. Bright for stimulating and helpful discussions regarding the evolution of *I. pini* and for identifying scolytid associates of *I. pini*. C. Jordan, Department of Entomological Sciences, University of California at Berkeley, provided assistance with preparation of graphics. This research was supported by the University of California at Berkeley, National Science Foundation Dissertation Improvement Grant BSR-8914625 to S.J.S. and D.L.W., and USDA-CSRS Grant 8802317 to F.X.W.

(Received March 23, 1992; accepted August 10, 1992)

Abstract—The behavioral and electrophysiological activity of a mimic [(*Z*,*E*)-7,9,11-dodecatrienyl formate] of the major sex pheromone component [(*Z*,*E*)-9,11,13-tetradecatrienal] of carob moth was assessed. Wind-tunnel bioassays demonstrated that the formate was as effective as natural gland extracts, and significantly more effective than the trienal alone or than the trienal blended with two minor pheromone components, in evoking source contact. Dispensers containing the formate were as effective as trienal-containing blend lures in attracting males when placed at the same dosage in traps in date gardens. Single-cell recordings showed that at least two olfactory neurons, differentiated by spike amplitude, are located in the long trichoid hairs on male carob moth antennae. Dose–response relationships indicated that puffs from cartridges loaded with at least 0.1 μg of the formate or of the trienal were necessary to elicit spiking by either the small- or the large-spiking cell within a sensillum. Cross-adaptation studies demonstrated that both compounds stimulated the same large-spiking cell. The frequencies of spikes evoked from the large cell when stimulated by emissions from 0.1-μg, 1-μg, or 10-μg cartridges of either the formate or the trienal were not significantly different, suggesting that the formate is an effective mimic of the trienal at the antennal receptor cell level.

Key Words—Lepidoptera, Pyralidae, sex pheromone, (*Z*,*E*)-9,11,13-tetradecatrienal, mimic, (*Z*,*E*)-7,9,11-dodecatrienyl formate, wind tunnel, attractant, electrophysiology, receptor cell.

INTRODUCTION

In the desert valleys of southern California, the carob moth, *Ectomyelois ceratoniae* (Zeller), is a serious pest of dates (Warner, 1988). If its range in this state expands northward towards the Central valley, economically important nut crops such as almonds and pistachios may be threatened, as the carob moth is a pest of these crops in other parts of the world (Dhouibi, 1982; Gothilf, 1984). In an effort to detect and monitor carob moth populations in southern California date gardens, synthetic lures placed in traps have been used with some success (Baker et al., 1991). The carob moth sex pheromone consists of a blend of three unsaturated aldehydes isolated and identified from female gland extracts (Baker et al., 1989b, 1991): (*Z,E*)-9,11,13-tetradecatrienal (trienal), (*Z,E*)-9,11-tetradecadienal (dienal), and (*Z*)-9-tetradecenal (monoenal). All three compounds evoked EAG activity from male antennae, and the major trienal component elicited upwind flight by males in the wind tunnel, with either minor component improving flight response when blended with the trienal (Baker et al., 1991). An 8:1:1 (trienal–dienal–monoenal) synthetic blend, approximating the ratio found in female gland extracts, was as effective as the natural gland extract in eliciting upwind flight and source contact (Baker et al., 1991).

In the field, Baker et al. (1991) demonstrated that the 8:1:1 blend loaded into a polyethylene Beem capsule, and placed unsealed in a Pherocon 1C trap captured significant numbers of carob moth males, although the numbers were low when compared to those trapped by live females. They suggested that this discrepancy might be due to decomposition of the trienal by oxidation and/or photodegradation under field conditions; without the trienal, attraction to the synthetic lure was negligible. Similar degradation problems have been reported for two other recently identified conjugated triene pheromones, 10*E*,12*E*,14*Z*-hexadecatrienal, a pheromone component of *Manduca sexta* (L.) (Doolittle et al., 1990), and 10*E*,12*E*,14*Z*-hexadecatrienyl acetate, a pheromone component of the mulberry pyralid, *Glyphodes pyloalis* Walker (Honda et al., 1990).

The likelihood of decomposition of the carob moth trienal in the field over periods of days or weeks prompted us to examine a potentially more stable mimic of this component that would successfully attract males when placed in traps. In the present study, we report the results of wind-tunnel bioassays and field-trapping studies that compare the attractiveness of (*Z,E*)-7,9,11-dodecatrienyl formate (formate) with that of the trienal. A formate compound was chosen as the trienal mimic because Mitchell et al. (1975) suggested that formates may be more stable under field conditions than unsaturated aldehyde pheromones, and because formates have been shown to disrupt mating communication in some moth species whose pheromones consist of blends of aldehydes (Mitchell et al., 1975, 1976). We also describe the single-cell responses of male carob moth olfactory neurons to the three sex pheromone components,

and to the formate, in order to determine if the formate is an effective mimic of the trienal at the antennal receptor cell level.

METHODS AND MATERIALS

Chemical Synthesis. The monoenal and dienal were prepared from the corresponding alcohols (available from Aldrich Chemical Co.) by oxidation with pyridinium dichromate molecular sieve (Herscovici et al., 1982) and by Swern oxidation (Mancuso et al., 1978). The crude products were purified by HPLC (RP-18; low-pressure gradient; methanol–water) or by flash chromatography on silica gel (5% ether in hexane) followed by Kugelrohr distillation (0.1 mm Hg, oven temperature 100°C). Syntheses of the trienal have been published elsewhere (Baker et al., 1989b, Millar, 1990). The triene formate was synthesized as described below (Figure 1).

Proton NMR spectra ($CDCl_3$) were recorded on a GE-300 NMR spectrometer at 300 MHz. Infrared spectra were recorded from films of neat compounds on NaCl plates with a Perkin-Elmer 727 spectrometer. Unit resolution mass spectra (electron impact at 70 eV) were recorded with a Hewlett-Packard (Avondale, Pennsylvania) 5970 mass selective detector interfaced to an H-P 5890 capillary GC. An HP-1 capillary column (20 m × 0.2 mm, Hewlett-Packard) was used. Routine GC runs were made on an H-P 5890 GC fitted with a DB-5 column (20 m × 0.32 mm, J & W Scientific, Folsom, California). Flash chromatography was run with 230–400 mesh silica gel (Aldrich Chemical Co.). Unless otherwise specified, reaction work-up solutions were dried over anhyd. Na_2SO_4 and concentrated under partial vacuum (ca. 100 mm Hg) on a rotary evaporator.

(1E)-1-Chloro-dec-1-en-3-yn-10-ol ***(3).*** 7-Octyn-1-ol **(2)** was prepared from 3-octyn-1-ol **(1)** in 84% yield by the modified acetylene zipper reaction (Abrams and Shaw, 1988). A dry 2-liter 3-neck flask was loaded with bis(triphenylphosphine)palladium(II) chloride and CuI (1 g each) and flushed

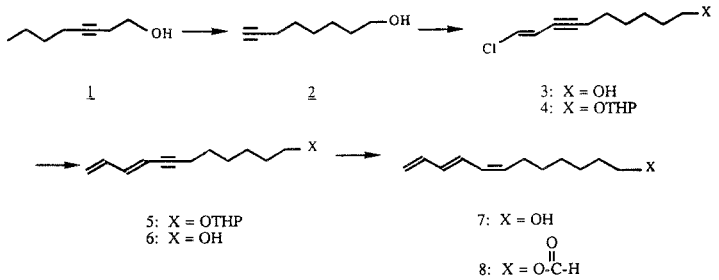

FIG. 1. Synthetic route to (*Z,E*)-7,9,11-dodecatrienyl formate.

with Ar. Alkynol **(2)** (20 g, 159 mmol), freshly distilled *trans*-1,2-dichloroethylene (31 g, 356 mmol), and THF (200 ml) were added to the reaction flask via a 5-cm column of 3 Å activated molecular sieve. To the stirred mixture were added dropwise 40 ml of diisopropylamine (distilled from CaH_2), and the initially pale yellow solution rapidly turned brown, then black. The mixture was stirred overnight at room temperature, after which time the reaction was ca. 50% complete. A further 1 g each of CuI and bis(triphenylphosphine)-palladium(II) chloride was added, and stirring was continued until the reaction was complete (4 hr). Hexane (400 ml) was then added, and the mixture was stirred a further 10 min before filtering with suction. The filtrate was extracted with saturated aqueous NH_4Cl (3 × 100 ml), dried, and passed through a column of coarse silica gel (70–230 mesh), eluting with 40% EtOAc in hexane. The eluate was concentrated and distilled, bp 100°C (0.03 mm Hg), yielding 25.2 g (85%) of chloroalcohol **(3)**. NMR δ: 6.43 (d, 1H, J = 13.7 Hz, H1), 5.92 (dt, 1H, J = 13.5, 2.2 Hz, H2), 3.64 (m, 2H, H10), 2.30 (td, 2H, J = 6.8, 2.2 Hz, H5), 1.5–1.65 (m, 4H, H6,9), 1.35–1.48 (m, 4H, H7,8), 1.22 (br. s, 1H, OH). IR cm^{-1}: 3360 (s, br.), 3100 (w), 3050 (w), 2965 (s), 2880 (s), 2250 (m), 1590 (m), 1240 (m), 1065 (m), 930 (s), 860 (m), MS *m/z*: 151 (2, $M-Cl)^+$, 114 (72), 112 (52), 105 (45), 91 (84), 79 (100), 77 (57), 65 (55), 51 (37), 41 (99).

(9E)-Dodeca-9,11-dien-7-yn-1-ol ***(6)***. Chloroalcohol **(3)** was protected as the THP ether by treatment with dihydropyran (18 ml) and a few crystals of *p*-toluenesulfonic acid in ether overnight. The mixture was worked up by extraction with sat. aq. $NaHCO_3$ and brine, drying, concentration, and removal of solvent traces under vacuum. The protected alcohol **(4)** gave one spot on TLC (5% EtOAc in hexane) and was used without further purification.

Tetrakis(triphenylphosphine)palladium(0) and chloride **(4)** (36.92 g, 134 mmol) were added to 300 ml of degassed toluene under Ar. The mixture was cooled in an ice-bath while vinyl magnesium bromide (150 ml of a 1 M solution in THF) was added dropwise over 1 hr. The mixture was warmed to room temperature with stirring overnight. [Caution: the starting material and product were indistinguishable by TLC (5% EtOAc in hexane)]. The reaction mixture was poured into hexane (500 ml), extracted thoroughly with 2 M NH_4Cl and brine, dried, and concentrated. The residue was dissolved in MeOH (100 ml), 100 mg of *p*-toluenesulfonic acid was added, and the mixture was stirred at room temperature until transetherification was complete (36 hr). $NaHCO_3$ (2 g) was added, and the mixture was concentrated on a rotary evaporator. The residue was partitioned between water and hexane (200 ml each). The hexane layer was washed with brine, dried, and partially fractionated by passage through a 2.5-cm × 20-cm column of silica gel, eluting with 40% EtOAc in hexane, and cutting ca. 300-ml fractions. The fraction containing the purified product was concentrated and pumped under vacuum, giving dienynol **(6)** as a gold oil. NMR

δ: 6.51 (dd, 1H, J = 15.3, 10.8 Hz, H10), 6.35 (overlapped ddd, 1H, J = 16.7, 10.7, 9.8 Hz, H11), 5.62 (dt, 1H, J = 15.3, 2.0 Hz, H9), 5.26 (br. d, 1H, J = 16.3 Hz, H12 *cis*), 5.13 (d, 1H, J = 9.8 Hz, H12-*trans*), 3.65 (t, 2H, J = 6.5 Hz, H1), 2.32 (td, 2H, J = 6.7, 2.1 Hz, H6), 1.63–1.5 (m, 4H, H2,5), 1.5–1.32 (m, 4H, H3,4), 1.25 (br. s, 1H, OH). IR cm^{-1}: 3360 (s, br), 3110 (w), 3050 (w), 3025 (w), 2965 (s), 2880 (s), 2245 (m), 1630 (m), 1065 (s), 1040 (m), 1010 (s), 950 (m), 915 (m), 855 (m). MS *m/z*: 178 (2, M^+), 163 (1), 131 (4), 117 (19), 106 (27), 105 (25), 91 (100), 79 (46), 78 (37), 77 (32), 65 (42), 41 (45).

(7Z,9E,11)-Dodecatrien-1-yl formate ***(8).*** Zinc granules (30 mesh, 100 g) were washed with 200 ml of 0.1 M HCl for 20 min under Ar. The acid was pipetted off, and the cleaned zinc was rinsed twice with distilled water. THF–water (80:20, 500 ml) was added, followed by a solution of dienynol **(6)** (13.35 g, 75 mmol) in 50 ml THF. The mixture was stirred vigorously under Ar for five days, then filtered, and the THF removed by rotary evaporation. The residue was extracted with hexane, the hexane layer backwashed with brine, dried, and concentrated, yielding 13.6 g of trienol **(7)** as a yellow oil. This oil was used without further purification.

Formic acetic anhydride was freshly prepared by addition of formic acid (20 ml of 96%) to 40 ml of acetic anhydride at 0°C. When the addition was complete, the mixture was slowly warmed to 50°C, held at this temperature for 20 min, then cooled to room temperature, and used immediately.

The mixed anhydride (30 ml) was added dropwise to a solution of trienol **(7)** (13.6 g, 75 mmol) and pyridine (30 ml) in ether (250 ml) at 0°C. The mixture was warmed to room temperature overnight, then cooled to 0°C, and 125 ml of sat. aq. $NaHCO_3$ were added cautiously (effervescence!) The layers were separated, the ether layer was extracted again with aq. $NaHCO_3$ and brine, then dried and concentrated, yielding 14.2 g of crude product **(8)**. A portion (4 g) was purified by flash chromatography on silica gel (5 cm × 25 cm, 5% ether in hexane), yielding 2.47 g of purified product, which was contaminated with 4% of an unidentified isomer. The purified product showed signs of rapid degradation, with the formation of insoluble white deposits on the rims of the collection tubes. Consequently, the rest of the crude material was purified by rapid Kugelrohr distillation (oven temperature 110°C, 0.07 mm Hg). The distillate (8.79 g from 10.2 g of crude material) was immediately diluted to a concentration of 50 mg/ml with hexane, butylated hydroxytoluene (BHT) was added as an antioxidant (50 mg/g formate), and the solutions were flushed with Ar before storing in brown glass bottles at −20°C. Formate solutions prepared this way could be stored for several months with negligible deterioration. NMR δ: 8.06 (br. s, 1H, Formate H), 6.49 (dd, 1H, J = 14.8, 11.3 Hz, H9 or 10), 6.41 (dt, 1H, J = 16.8, 10.3 Hz, H11), 6.21 (dd, 1H, J = 14.8, 10.7 Hz, H10 or 9), 6.05 (br. t, 1H, J = 11.0 Hz, H8), 5.47 (dt, 1H, J = 10.7, 7.7

Hz, H7), 5.22 (d, 1H, J = 16.6 Hz, H12-*trans*), 5.08 (d, 1H, J = 10.2 Hz, H12-*cis*), 4.17 (td, 2H, J = 6.6, 0.5 Hz, H1), 2.20 (m, 2H, H2), 1.67 (m, 2H, H6), 1.5–1.3 (m, 6H, H3-5). ^{13}C NMR δ: 25.68, 27.72, 28.44, 28.73, 29.43, 64.02, 117.00, 128.49, 128.54, 133.06, 133.15, 137.17, 161.18. IR cm^{-1}: 3110 (w), 3040 (m), 2965 (s), 2880 (s), 1725 (s), 1625 (m), 1585 (m), 1475 (m), 1190 (s), 1015 (s), 950 (m), 910 (m). MS *m/z*: 208 (21, M^+), 133 (4), 119 (5), 105 (12), 93 (39), 91 (64), 80 (84), 79 (100), 77 (64), 65 (16), 41 (42).

Wind-Tunnel Bioassays. Moths were obtained from laboratory cultures started from individuals collected in 1985 from infested dates near Indio in the Coachella Valley of Riverside County, California. Larvae were reared on a honey and wheat-bran diet in 1-gallon jars (Warner, 1988). Pupae were segregated by sex, and adults emerged on a 14 : 10 hr light–dark photoperiod regime.

Bioassays were conducted in a 3.5 × 1.0 × 1.0-m wind tunnel described in detail in Kuenen and Baker (1982). Two- to four-day-old males were loaded singly into screen cages (4 cm long × 3 cm diameter) during the photophase and each cage was covered with a Petri dish lid. Cages with males were placed in an environmental chamber until being transferred to the wind tunnel 1 hr before bioassays in order to acclimate males to the wind-tunnel conditions (24–26°C, 0.3 lux, 30–70% relative humidity, 0.5 m/sec wind velocity). Bioassays were conducted 4–6 hr into the scotophase, the optimal sexual activity period for carob moth (Vetter, Tatevossian, and Baker, unpublished data). Two 8 : 1 : 1 blend ratios were used, representing 40 ng trienal, 5 ng dienal, and 5 ng monoenal (referred to as the trienal blend), or 40 ng formate, 5 ng dienal, and 5 ng monoenal, respectively, with the formate replacing the trienal (referred to as the formate blend). The trienal and the formate also were each tested alone at 40 ng. Solutions were checked on GC to confirm that the ratio and concentration of each treatment were correct. When freshly prepared, the trienal was >98% stereoisomerically pure by capillary GC (DB-5). However, the trienal was contaminated with 2–5% of a rearrangement product that coeluted with the trienal on silica gel flash chromatography or HPLC. The formate was >92% pure by capillary GC, and was contaminated with an uncharacterized impurity, also apparently due to rearrangement. A control consisted of 5 female equivalents (FE) obtained from excised pheromone glands according to methods described in Baker et al. (1991). For both the treatment and the control, 10 μl of a diluted solution prepared in hexane was delivered onto a 5-cm-diameter filter-paper disk (Whatman No. 1) affixed to a 6-cm-long metal clip that was stuck in a cork base. The cork wire holder for each disk was placed on a 15 × 15-cm sheet-metal platform 15 cm above the tunnel floor, and 30 cm from the tunnel's upwind end. After completing bioassays, clips were cleaned with acetone and air-dried overnight.

Males were released from their cages 1 m from the odor source. A cage

containing a male was placed on the metal platform in the plume until the male took flight or until 1 min elapsed. If males did not fly, they were checked for flight ability by forcibly dislodging them from the cage. Forty flight-capable males were tested for each treatment and for the control. Males were scored for: (1) locking onto the plume and progressing upwind, (2) flying to within 50 cm of the source, and (3) contacting the source. Tests were conducted using a randomized, complete-block design so that all treatments were presented on a given day. The numbers of moths performing each behavior were compared by using a χ^2 2 $\times$ 2 test of independence with Yates' correction (Steel and Torrie, 1960). Statistical significance was determined at the 0.05 level.

Field-Trapping Studies. Two field studies were conducted in Deglet Noor date gardens located in the Coachella Valley in Indio or in Oasis, California, to determine the attractancy of the formate compared to that of the three-component aldehyde blend of carob moth. One study was conducted from late August through late September, 1990. Four different lures were placed in separate Pheroocon 1C traps (Zoecon Corp., Palo Alto, California), and the traps were positioned in the date palm canopy, which was ca. 18 m above ground level, by using a rope and pulley system. Lures consisted of black, chopped, Celcon hollow fibers (1.5 cm $\times$ 0.02 cm ID) (Scentry Inc., Buckeye, Arizona) that were heat-sealed at one end and then vacuum-filled with either an 8:1:1 blend of the trienal–dienal–monoenal (three fibers), or with the formate (three and 10 fibers). Both the aldehyde blend and the formate were diluted by 90% with an inert diluent, methyl tridecanoate, before the fibers were filled. Fibers also were filled with neat formate (three fibers). Fibers were stuck into a 2-cm polyurethane foam cube and affixed to the bottom of a trap. Treatments were placed in a row in each of three replicates in a randomized, complete-block design. There were two trees separating treatments in each block and 10 trees between blocks. Traps were checked every three to four days, the males removed, and the traps rerandomized within blocks. Trap bottoms were replaced when they became too soiled or dusty. Trap counts were transformed using $(x + 0.5)^{1/2}$ before being subjected to analysis of variance (ANOVA). Treatment means were separated at the 0.05 level of significance using Tukey's HSD Studentized range test (Steel and Torrie, 1960).

Because this field study (as well as two others containing live females) seemed to indicate a significant interference with male capture even to females, and hence a general disruptive effect whenever a grid of more than a few traps was used, another field comparison was made between a single trap containing the synthetic lure (either trienal blend or formate), and a trap containing live females. This study was conducted in three Deglet Noor date gardens from mid-July through mid-August of 1990 and 1991. Both the aldehyde blend and the formate were diluted by 90% with methyl tridecanoate, and three fibers were filled as previously described and stuck into a 2-cm polyurethane foam cube

that was affixed to the bottom of a Pherocon 1C trap. Five 1- to 3-day-old virgin female carob moths were placed in a screen cage in a separate Pherocon 1C trap as a control. A 2-dram glass vial containing a water-saturated dental wick was placed inside the screen cage to provide a water source for females. Traps were placed in the date palm canopy, which varied between 2 and 15 m above ground level, depending on the garden, by using a rope and pulley system. In 1990, a trienal blend-baited trap was placed in a date palm in each of the three date gardens, with a female-baited trap placed 5–10 trees away (ca. 30-m spread). In 1991, a formate-baited trap was placed in the same date palm in each garden as the previous year, with a female-baited trap also placed in the same tree as the trap from the previous year. The number of males caught in female-baited or in treatment-baited traps was recorded every three to four days. In both years, traps with females were rebaited twice a week, and fiber traps were rebaited once every two weeks. The trap catches of female-baited or of treatment-baited traps from each date garden were combined to obtain the mean ($\pm$SD) number of males captured per trap for each year. Trap catches from treatment-baited traps, either trienal blend-baited or formate-baited, and from female-baited traps were totaled within each garden, and the ratio between the number of males captured in a treatment-baited trap and in a female-baited trap was computed for each of the three date gardens. These six ratios were compared using ANOVA with the two chemical treatments blocked by date garden site. Statistical significance was determined at the 0.05 level.

Single-Cell Recordings and Stimulation. Recordings from olfactory antennal neurons of 1- to 3-day-old male carob moths were obtained by using a cut-sensillum technique (Kaissling, 1974; Van der Pers and Den Otter, 1978) that has been used on several other species of Lepidoptera (Baker et al., 1989a; Hansson et al., 1987, 1990; Löfstedt et al., 1990; Todd et al., 1992). An antenna was cut from the head, and its base placed in a micropipet (50 μl FISHERbrand disposable micropipets) that was filled with Beadle-Ephrussi Ringer solution (Ephrussi and Beadle, 1936), and grounded with an Ag–AgCl wire. Using a Leitz stereo microscope at 320× magnification, a single sensillum trichodeum was positioned over the blade of a vertically oriented, stationary glass knife by using a micromanipulator. The tip of the hair was then cut using a second glass knife whose edge was brought down over the vertical knife edge by means of a Leitz joy-stick type micromanipulator. The cut end of the hair was immediately contacted with a saline-filled Ag–AgCl pipet recording microelectrode. To prevent evaporation of the saline, a 10% aqueous solution of polyvinylpyrrolidone (Sigma Chemical Co., St. Louis, Missouri) was added to the saline (1 : 10 parts by volume), and the tip of the recording microelectrode was coated with a thin film of petroleum jelly. Recordings of both the AC and DC components of the signal were amplified on a Hansson model 103 amplifier, and stored on VCR tape using a Vetter model 420F four-channel FM recorder. Responses were

displayed and printed using a Gould model 1604 (DSO) digital oscilloscope/printer.

The antenna was continuously bathed in a stream of purified, humidified air (10 ml/sec) that passed through a 17-cm-long glass tube (8 mm ID) whose outlet was positioned 2 cm from the antennal preparation. For each of the three sex pheromone components and the formate, 10 μl of a diluted solution prepared in hexane was pipetted onto a filter-paper strip held in a glass Pasteur pipet cartridge (15 cm long). Stimulus doses ranged from 10^{-3} to 10^{1} μg/cartridge in $\log_{10}$ steps. Solutions were checked by GC to confirm that the amounts of respective compounds at a particular concentration were equal. Prior to exposure to any of the test compounds, the spontaneous activities of the receptor cell(s) within a sensillum were monitored for 60 sec. Cells were exposed to 30 msec puffs (Roelofs and Comeau, 1969) of each compound in random order, beginning with the 10^{-3}-μg cartridges and working upward to the 10-μg cartridges, by manually injecting a 2-ml puff into the airstream through a hole in the glass tube 15 cm from the outlet. Interstimulus intervals ranged between 30 and 60 sec, or until the background firing approximated that observed prior to stimulus presentation. When action potentials (spikes) were elicited by a compound, their frequency was determined for 0.2 sec following the commencement of excitation, and peak-to-peak amplitude values (mV) of the bimodal spikes were obtained during this period. The spike frequencies of individual receptor cells that were excited by each dosage of the trienal and of the formate were compared using Student's t test at the 0.05 significance level.

Cross-Adaptation Studies. Preliminary recordings indicated that the trienal and the formate consistently stimulated a large-spiking cell within each sensillum. Therefore, cross-adaptation studies were conducted to determine if the spiking activity could be attributed to the same cell or to different cells that produced similar-sized spikes (Kaissling et al., 1989). Recordings were made from the cells within 15 sensilla using four antennae of 1- to 3-day-old male carob moths as previously described. A 1-μg filter-paper-loaded cartridge of the trienal and of the formate provided the stimulus sources. To deliver a uniform stimulus with a well-defined onset and offset, a stimulus flow controller (model SFC-2, Syntech Inc., Hilversum, The Netherlands) that has been described in detail by Vickers and Baker (1992) was used. The stimulus valve was open for 0.5 sec, and two interstimulus intervals, i.e., the time between the end of the first stimulus and the beginning of the second stimulus, were used, either 0.1 sec or 1 sec. The stimulus regime consisted of the following four stimulus pairs presented at both interstimulus intervals: (1) trienal–trienal; (2) formate–formate; (3) trienal–formate; and (4) formate–trienal. Between 30 and 60 sec elapsed between exposure of the preparation to each stimulus pair.

Scanning Electron Micrographs. Antennae from newly emerged males were used for scanning electron micrographs. For fixation, antennae were placed in

2% glutaraldehyde (in cacodylate buffer, pH 7.4). Postfixation involved placing the antennae in a 2% solution of osmium tetroxide for 24 hr, followed by dehydration to 100% EtOH. Glacial acetic acid was added to each dehydration step to maintain the natural size and shape of the antenna. Specimens were critical-point dried, mounted on stubs and coated under vacuum with 60:40 gold–palladium. Specimens were examined and micrographs prepared at 15 kV accelerating voltage, using 55 P/N film on a JEOL JSM-C35 SEM located in the Department of Nematology, University of California, Riverside.

RESULTS

Wind-Tunnel Bioassays. The 8:1:1 blend containing either the trienal or the formate, or either compound alone, was as effective as 5 FE of gland extract in eliciting upwind flight in male carob moths (Table 1). Similarly, all blends were equivalent to 5 FE of gland extract in causing males to fly to within 50 cm of the source ($P > 0.05$, χ^2 2 × 2 test of independence) (Table 1). The formate alone was significantly better than either the trienal alone or than the 8:1:1 trienal or formate blends in eliciting close approach to the source ($P < 0.05$, χ^2 2 × 2 test of independence) (Table 1). The formate alone also caused significantly more males to complete upwind flight and contact the source compared to either the trienal blend or to the trienal alone ($P < 0.05$, χ^2 2 × 2 test of independence). Both the formate alone and the formate-containing blend were as effective as the natural extract in evoking source contact (Table 1).

TABLE 1. PERCENTAGES OF MALE CAROB MOTHS FLYING IN WIND TUNNEL IN RESPONSE TO 8:1:1 BLEND OF TRIENAL, DIENAL, AND MONOENAL, OR OF FORMATE, DIENAL, AND MONOENAL, OR TO TRIENAL OR FORMATE ALONE (8:0:0), COMPARED TO 5 FE OF GLAND EXTRACT[a]

	(%) Males responding to blend ratios				
	trienal		formate		
Behavior	8:0:0	8:1:1	8:0:0	8:1:1	Gland extract, 5 FE
Upwind flight	50 a[b]	65 a	70 a	63 a	53 a
Flight to within 50 cm of the source	38 b	38 b	65 a	38 b	43 ab
Source contact	18 b	18 b	45 a	25 ab	40 a

[a] Source loading on filter paper was 40 ng of trienal or formate in 10 μl of hexane. $N = 40$ flight-capable males.

[b] Percentages in a row followed by the same letter are not significantly different at the 0.05 level according to a χ^2 2 × 2 test of independence with Yates' correction.

Field-Trapping Studies. In the field study comparing the attractancy of the four synthetic lures to male carob moths, traps containing the three-fiber diluted formate lure captured as many males (2.6 ± 3.8, mean ± SD) per three- to four-day trapping period as those containing the three-fiber diluted trienal blend lure (0.7 ± 1.2, mean ± SD) ($P > 0.05$, Tukey's test). Thus the formate was at least as active as the trienal blend in attracting males in the field. The 10-fiber diluted formate lure attracted significantly more males to traps (6.3 ± 6.8, mean ± SD) than the three-fiber neat formate lure (1.7 ± 2.2, mean ± SD), or the three-fiber diluted trienal blend lure (0.7 ± 1.2, mean ± SD) ($P < 0.05$, Tukey's test), but a similar number of males as the three-fiber diluted formate lure (2.6 ± 3.8, mean ± SD). There were no statistically significant differences between the mean numbers of males caught per trap for all the other treatment comparisons ($P > 0.05$, Tukey's test).

In the other field study, the female-baited traps caught significantly more males (42 ± 34.4, mean ± SD, $N = 33$) than the trienal blend-baited traps (3.7 ± 4.6, mean ± SD, $N = 33$) when placed in a date palm canopy ($P < 0.001$, Student's t test). Similarly, female-baited traps captured significantly more males (67.2 ± 36.5, mean ± SD, $N = 31$) than the formate-baited traps (16 ± 10.9, mean ± SD, $N = 30$) ($P < 0.01$, Student's t test). However, the formate was a significantly better lure relative to females than the trienal-containing blend, since the formate-to-female trap capture ratio (0.25 ± 0.07, mean ± SD) was significantly larger than the trienal-to-female trap capture ratio (0.07 ± 0.05, mean ± SD) ($P < 0.01$, ANOVA). Thus, the formate-baited traps caught 3–4 times as many male carob moths as the trienal-blend containing traps, relative to live-female traps.

Single-Cell Recordings and Stimulation. Single-cell recordings were obtained from 56 sensilla using 10 male antennae. The longer, curved trichoid hairs located on the ventral aspect of the antenna, and irregularly distributed over the surface of a subsegment, were easily accessible to cutting compared to the shorter, straighter hairs located closer to the dorsal scaled surface (Figure 2). Recordings from these longer trichoid sensilla showed that two spike sizes could be easily distinguished; there was a larger impulse of 13.6 ± 3.9 mV (mean ± SD), and a smaller impulse of 6.9 ± 0.8 mV (mean ± SD). The spike amplitude values obtained from cells responding to emissions from 10-μg cartridges of the dienal, trienal, and formate were not included in these mean values because the spike amplitudes of both cells were noticeably reduced by exposure to this dosage. Although transmission electron microscopy of male carob moth antennae has not yet been performed to confirm the number of receptor cells within the longer trichoid hairs, the two different spike amplitudes that we consistently observed indicate that at least two receptor cells are present, which we will refer to as the large and the small cell, respectively, even though at this point it would be possible for more cells of identical spike sizes to be present.

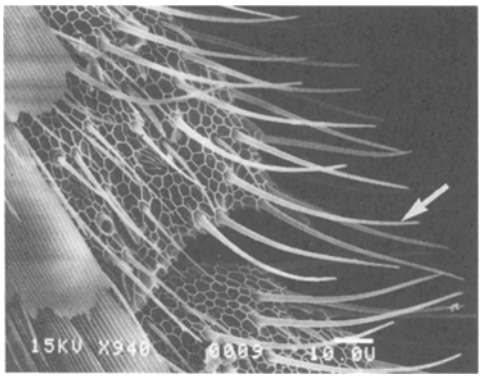

FIG. 2. Scanning electron micrograph of the middle subsegments (30–40) of the male carob moth antenna, showing the long trichoid hairs (see arrow) that were cut to obtain single-cell recordings.

In all but two of the sensilla, background firing by one or both receptor cells was observed prior to stimulus presentation. In 34 of the sensilla, both cells fired spontaneously. The background activity was 0.3 ± 0.1 spikes/sec (mean ± SD) for the smaller-spiking cell, recorded from 43 sensilla, and 0.5 ± 0.1 spikes/sec (mean ± SD) for the larger-spiking cell, recorded from 45 sensilla.

Dose–response curves indicated that puffs from cartridges loaded with less than 0.1 μg of a pheromone component or of the formate did not elicit spiking activity from either the large cell (Figure 3A) or the small cell (Figure 3B). A few of the sensilla sampled contained a cell or cells that were excited by puffs from 0.1-μg cartridges of the dienal, trienal, and formate, but not by the monoenal (Table 2). All three compounds stimulated the larger-spiking cell within a sensillum (Figure 4), although the smaller cell also was excitable in some sensilla (Table 2). There was no significant difference between the spike frequencies of the large-spiking cell when exposed to puffs from 0.1-μg cartridges of the trienal or of the formate ($P > 0.05$, Student's t test) (Figure 3A). A statistical comparison between the number of spikes evoked by the small cell when exposed to emissions from 0.1-μg cartridges of the trienal or of the formate could not be made because only one of the sensilla we sampled contained a small cell excited by the formate (Table 2).

The numbers of sensilla with receptor cells responding to puffs of the dienal, trienal, and formate increased most dramatically between the 0.1-μg and 1-μg dosages (Table 2). The first receptor cell responses to the monoenal also were recorded at the 1-μg dosage (Figure 3A), although the number of sensilla that we sampled that contained such cells was low (Table 2). The monoenal

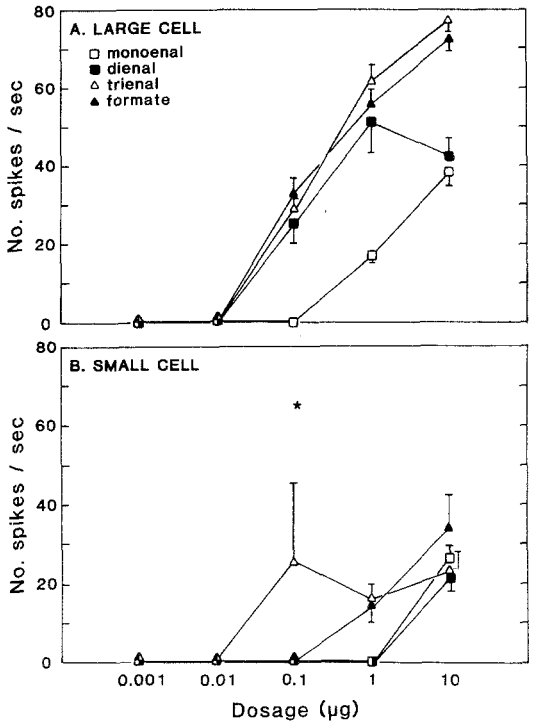

FIG. 3. Mean (± SE) dose-response relationship of the spiking activity of a large cell (A) and a small cell (B) in male carob moth antennal sensilla in response to puffs from cartridges loaded with graded amounts of one of the three sex pheromone components (monoenal, dienal, and trienal) or the trienal mimic (formate). Fifty-six sensilla were sampled. For the small-cell responses (B) at the 0.1-μg dosage, note the asterisk, which represents the spiking activity evoked by exposure to the dienal (65 spikes/sec, $N = 1$) and to the formate (65 spikes/sec, $N = 1$); no spiking activity was recorded from the small cell in the other 55 sensilla sampled.

typically stimulated the larger-spiking cell within a sensillum (Figure 4). The spike frequencies elicited by both the large and the small cell when exposed to puffs from 1-μg cartridges of the trienal were not significantly greater than those evoked by exposure to the formate ($P > 0.05$, Student's t test) (Figure 3A and 3B).

Exposure to puffs from 10-μg cartridges of the trienal or of the formate elicited single-cell responses from nearly all the sensilla sampled (Table 2). The spike frequencies of the small and the large cells when exposed to puffs from 10-μg cartridges of the trienal were not significantly different from those evoked by exposure to the formate (Student's t test, $P > 0.05$) (Figure 3A and 3B).

TABLE 2. PERCENTAGE OF SENSILLA ON MALE CAROB MOTH ANTENNAE WITH RECEPTOR CELL(S) RESPONDING TO EMISSIONS FROM CARTRIDGES LOADED WITH VARIOUS DOSAGES OF MONOENAL, DIENAL, AND TRIENAL (SEX PHEROMONE COMPONENTS), AND OF FORMATE (TRIENAL MIMIC)[a]

	Percentage of sensilla with a responding receptor cell									
	0.001 μg		0.01 μg		.1 μg		1 μg		10 μg	
Compound	SM	L	SM	L	SM	L	SM	L	SM	L
Monoenal	0	0	0	0	0	0	0	3.6	8.9	28.6
Dienal	0	0	0	0	1.8	3.6	0	12.5	33.9	67.9
Trienal	0	0	0	0	3.6	12.5	21.4	69.6	32.1	96.4
Formate	0	0	0	0	1.8	12.5	17.9	67.9	19.6	89.3

[a] A total of 56 sensilla was sampled. SM = small cell, L = large cell.

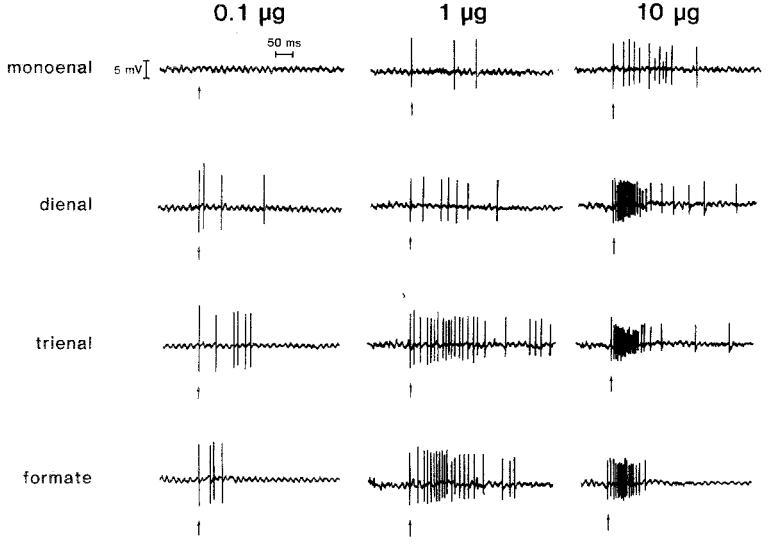

FIG. 4. Typical single-cell responses of male carob moth antennal cells to emissions from 0.1-μg, 1-μg, and 10-μg cartridges of the monoenal, dienal, and trienal (sex pheromone components) and of the formate (trienal mimic). Arrows represent stimulus presentation. Note the spikes (2) produced by the smaller-spiking cell interspersed among the large spikes for 10 μg of monoenal.

Puffs from 10-μg cartridges of the dienal, trienal, and formate appear to overdrive the larger-spiking receptor cell, as suggested by the reduced interspike intervals and diminished spike amplitudes immediately following stimulus presentation (Figure 4). However, the spike amplitude of the large cell was not diminished by exposure to puffs from 10-μg cartridges of the monoenal (Figure 4). We also noted increased spiking activity from the small cell within a sensillum after puffs from 10-μg cartridges of each compound, compared to the lower dosages (Figure 3B).

Cross-Adaptation Studies. The single-cell responses of a large-spiking neuron located within the antennal sensilla of male carob moths showed that this neuron could be partially adapted by exposure to the trienal–trienal pair, with a 0.1-sec interstimulus interval (Figure 5A). A large-spiking cell was similarly partially adapted by exposure to the formate–formate pair at a 0.1-sec interstimulus interval (Figure 5E). For both the trienal–trienal (Figure 5C) and the formate–formate (Figure 5G) stimulus pairs, the large cell was capable of becoming markedly more disadapted after a 1-sec interstimulus interval because the second stimulus of each pair evoked action potential bursts that were nearly as high in frequency as those to the first stimulus of the pair. Exposing the neuron to the trienal–formate or to the formate–trienal pairs resulted in a similar pattern of responses as those evoked by the homogeneous pairs, whether it was for the 0.1-sec interstimulus interval (Figures 5B and 5F) or for the 1-sec interstimulus interval (Figures 5D and 5H). Initial exposure to the trienal seems to adapt the large cell more completely to the second puff in the stimulus pair, regardless of whether it is the formate or the trienal (Figure 5A–D), compared to when initial exposure is to the formate (Figure 5E–H).

DISCUSSION

If a mating disruptant is to be developed against the carob moth, it would be helpful to extend the field life of the blend of aldehydes identified by Baker et al. (1989b, 1991) or to develop a more stable mimic. The first step in developing a more stable mimic is ensuring that its ability to attract males is as good as the identified pheromone components. In this initial assessment of the activity of a potential trienal pheromone mimic, our results indicate that (*Z*,*E*)-7,9,11-dodecatrienyl formate is an effective replacement for (*Z*,*E*)-9,11,13-tetradecatrienal, the major sex pheromone component of the carob moth. We do not know why the formate seems to be as effective as, or more effective than, the blend of the trienal plus two other aldehydes in attracting carob moth males in the wind tunnel and in the field. However, the greater activity of a mimic compared to the natural pheromone is not unprecedented. Mimics have been found in other studies that are more active in attracting males than the natural

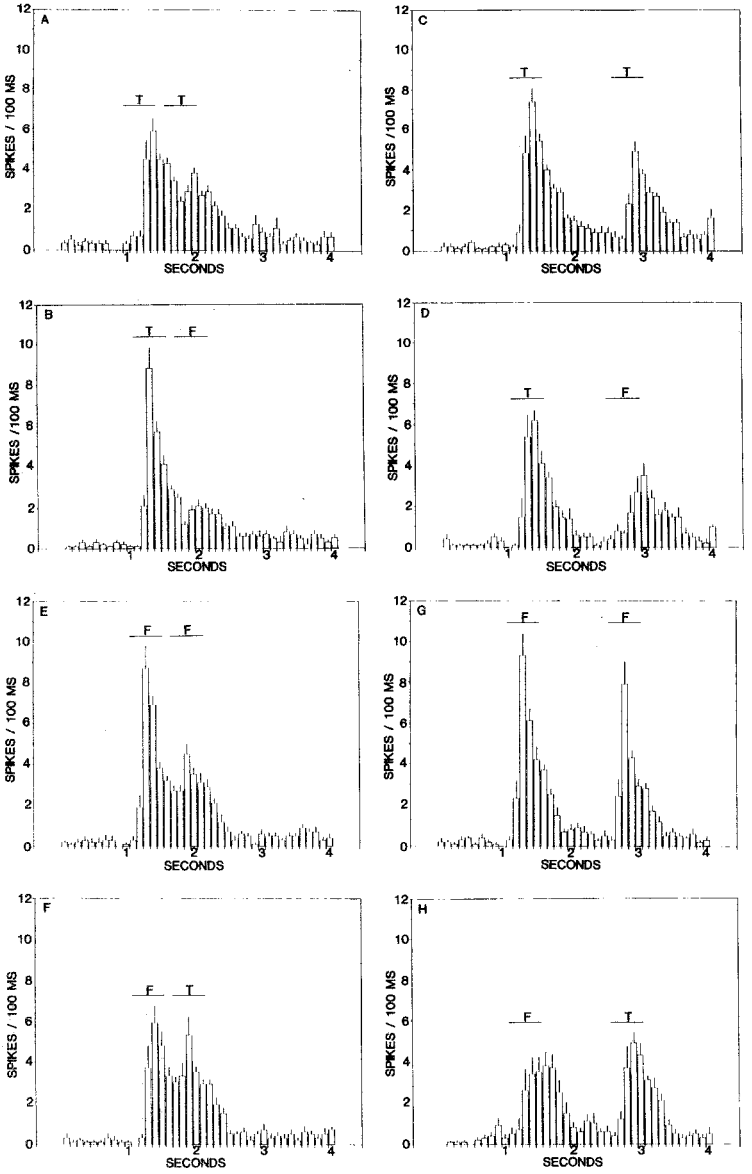

FIG. 5. Histograms showing the spike frequency (mean ± SE) of the large-spiking neuron to four stimulus pairs (T = trienal, F = formate) during cross-adaptation studies. Each histogram shows a 1-sec prestimulus period, followed by a 3-sec period during which two 0.5-sec long stimulus puffs are directed over the sensillum. Horizontal lines above the bars indicate that the stimulus valve is open, and odor molecules are entering the airstream that is passing over the antennal preparation. Interstimulus intervals are 0.1 sec and 1 sec. Recordings are continued for at least 1 sec after the end of the second stimulus.

pheromone component blend (Cardé and Roelofs, 1977) or that are more active than the natural components in stimulating antennal receptor cells (Löfstedt et al., 1990). The formate is as active on the same antennal receptor cells as the trienal; therefore, the mimic appears to be at least as active as the major pheromone component at both the neurophysiological and the behavioral levels.

Mitchell et al. (1975, 1976) showed that formate esters could act as mimics of aldehyde pheromones by demonstrating their disruptive effects on mating in species of *Heliothis*. Similarly, Landolt et al. (1982) showed that several diene formates, mimics of the dienal major pheromone component of the navel orangeworm, *Amyelois transitella* (Walker), dispensed in female-baited traps in almond orchards, reduced the number of males captured relative to untreated controls. Our study differs from these previous studies in that our initial goal has been to determine the attractancy of the formate as a trienal pheromone mimic, rather than first determining its disruptive capabilities. Compounds that are the best attractants singly or in blends have been shown to be the most efficacious disruptants of mating (Roelofs and Cardé, 1977; Minks and Cardé, 1988; Cardé, 1990). Also in our study, we have implicated the site at which the formate acts to mimic the aldehyde as being at the receptor cell level, something that most other studies, except for Grant et al. (1989), have heretofore not done.

Mitchell et al. (1975) suggested that replacing the aldehyde functional group of a pheromone with a formate ester enhances stability, so formate esters may be successful mimics of unsaturated aldehyde pheromones because of their increased field life relative to these aldehydes. It is well known that aldehydes are susceptible to degradation via a number of pathways, including oxidation to form peroxides (Kobayashi et al., 1990) or carboxylic acids (Verter, 1970; Shaver and Ivie, 1982), or by the formation of trimers (Starr and Vogel, 1978; Kubisa et al., 1980; Dunkelblum et al., 1984) or polymers (Bevington, 1952), especially when catalyzed by traces of protic or Lewis acids, or by heat. Substitution of the formate group for the aldehyde eliminates these degradation pathways, and provides an analog with a potentially longer field lifetime.

However, conjugated trienes readily isomerize and polymerize at ambient temperatures or above, especially when subjected to heat and sunlight under field conditions (Doolittle et al., 1990; Honda et al., 1990; Millar, 1990). Conjugated hydrocarbons also are prone to oxidative degradation to furans (Ideses and Shani, 1988). In a similar fashion to the carob moth trienal, the pure formate analog began to polymerize over a period of several hours when left at room temperature in air. However, unlike the trienal, the formate could be stored at $-20°C$ in dilute solution (hexane) under Ar for extended periods with no noticeable degradation, conditions under which the trienal often polymerized into an intractable gel.

We do not know if our formate remains biologically active longer than the

trienal under the field conditions in the date gardens. In the field study comparing the attractancy of four synthetic lures to male carob moths, our frequent replacement of the lures every three to four days was designed to test the attractancy of fresh formate and trienal lures without the complication of potential long-term degradation. In the other field study, the fiber lures were replaced every two weeks, and the formate outperformed the trienal blend, relative to live females, in attracting males, thus suggesting that the formate may have a longer period of optimal attractivity than the aldehyde blend. The assessment of relative field longevity needs to be performed in future field studies in which traps have much longer replacement intervals.

The coupling between female-emitted sex pheromone components and the olfactory receptor cells located in male antennal sensilla is generally highly specific for moths (Baker, 1989), with one receptor type very selective for a particular component of the sex pheromone blend. Although the electrophysiological activity of a compound may be detrimentally affected by altering the double-bond position or geometry (Liljefors et al., 1985; Bengtsson et al., 1987), or by modifying functional groups (Liljefors et al., 1984), pheromone mimics can substitute for the natural pheromone component at both the neurophysiological and the behavioral levels (Löfstedt et al., 1990).

The electrophysiological activity of formates on the antennal receptors of several noctuid species was demonstrated by Priesner et al. (1975) when they showed that formate compounds could evoke moderate EAG responses when compared to natural sex pheromone components. Our single-cell recordings from male carob moth antennal neurons showed that the formate was as electrophysiologically active as the trienal in evoking action potentials. The effective concentrations of the two compounds reaching the sensilla during stimulation were likely to be very similar, based on the comparable vapor pressures of the trienal (206 MW) and the formate (208 MW). At all dosages tested, the spike frequencies elicited from receptor cells were similar for the trienal and for the formate, and cross-adaptation studies demonstrated that both compounds stimulated the same large-spiking cell. Grant et al. (1989) also found that the aldehyde major sex pheromone component of *Heliothis zea* (Boddie) and a formate mimicking this component stimulated the same large-spiking neuron, although the aldehyde elicited significantly higher spiking activity than the formate when tested at several dosages. Based on GC–single-cell analysis, Baker et al. (1991) initially concluded that the trienal was stimulating a smaller-spiking cell within a sensillum, whereas the monoenal and the dienal were stimulating the larger-spiking cell. However, the present, more detailed examination of the antennal receptor cell responses of male carob moths to various dosages of the trienal indicates this conclusion was probably in error. Excessive amounts of the trienal may have issued from the GC effluent in the GC–single-cell study by Baker et al. (1991), thus overdriving the larger-spiking cell, and causing a reduction in

spike size to that more typical of the smaller-spiking cell (Figure 4). We now conclude that the major component and its mimic stimulate the larger-spiking cell within a male carob moth antennal sensillum, as is typical of all other moth species studied to date (Grant et al., 1989; Hansson et al., 1987, 1990; Löfstedt et al., 1990). Our results indicating that initial exposure to the trienal adapted the large cell more completely to the second puff in the stimulus pair, whether it was the trienal or the formate, may be explained by slight differences in the concentration emitted from the trienal pipets compared to the formate pipets, or perhaps to subtle differences in the time courses of adaptation–disadaptation in cells exposed to the trienal compared to the synthetic mimic. Nevertheless, our conclusion is that the two compounds stimulate the same receptor neuron based on the great similarities in adaptation of the large neuron.

Our data indicate that the behavioral and electrophysiological activity of the formate is equal, if not enhanced, compared to that of the trienal blend in attracting carob moth males. Although the formate has thus far outperformed the trienal blend under field conditions, more work needs to be done to improve the efficacy of the formate lure to make it competitive with females with regard to attractancy. We do not know why the ability of the formate to attract males in the wind tunnel is as good as the female extract, yet in the field it is only a fraction as good as live females.

In general, the high activity of synthetic blends in wind tunnels has been maintained in trapping tests in the field (Baker and Linn, 1984). However, full comparisons of the activity of synthetics against females in both the wind tunnel and the field are relatively rare, and so it is difficult to say how unusual such a decline in activity is, when the lures are taken into the field. It may be that the entire effect is due to degradation under field conditions, or perhaps some other inadequacy exists with respect to missing components that is not exposed in the relatively simple environment of the wind tunnel. In wind-tunnel bioassays with *Manduca sexta* (L.), Tumlinson et al. (1989) demonstrated that a synthetic blend of aldehydes evoked the same behavioral response level from males as gland rinses or calling females. One of the aldehydes necessary for completing the behavioral sequence, i.e., locating the source and attempting copulation, was (*E*,*E*,*Z*)-10,12,14-hexadecatrienal. Although a synthetic blend containing this trienal was not tested in the field, Tumlinson et al. (1989) suggested that aliphatic conjugated trienes are very labile and will decompose in nature when placed as components in lures or other pheromone dispensers.

Acknowledgments—We thank D.H. Headrick for helping with the scanning electron micrographs; C.C. Doane of Scentry Inc., Buckeye, Arizona, for providing the fibers used in field-trapping studies; and E.R. Zaborski for statistical advice. The comments provided by two anonymous reviewers on an earlier version of this manuscript were appreciated. This research was funded by the California Date Packers Council.

(Received April 15, 1992; accepted August 12, 1992)

Abstract—Neither toxins from *Bacillus thuringiensis* Berliner nor conspecific eggs deterred oviposition by the diamondback moth, *Plutella xylostella* (L.) (Lepidoptera: Plutellidae), in laboratory choice tests. The finding that toxins did not deter oviposition by moths from a susceptible line shows that oviposition preference and larval survival were not associated in this line. Selection for larval resistance to toxins did not significantly alter oviposition preference, which rules out a strong genetic correlation between larval performance and oviposition preference. Failure of conspecific eggs to deter oviposition may not represent lack of association of preference and performance because other evidence suggests that larval performance may not be greatly affected by larval density. These results suggest that the ability of refuges to slow evolution of physiological resistance to *B. thuringiensis* toxins will not be magnified by an oviposition preference for untreated foliage.

Key Words—Oviposition preference, preference-performance correlation, egg-load assessment, resistance, toxin, *Bacillus thuringiensis*, *Plutella xylostella*, Lepidoptera, Plutellidae.

INTRODUCTION

In phytophagous insects, the relationship between oviposition preference and larval performance affects many aspects of nutritional ecology, including host

shifts and the evolution of host specialization (Slansky and Rodriguez, 1987; Thompson, 1988). This relationship also has important implications for the efficacy of plant protectants and the evolution of resistance (Gould, 1991; Caprio and Tabashnik, 1992). One might assume that host preference reflects relative larval fitness on hosts, but this is not always true (Tabashnik and Slansky, 1987; Thompson, 1988). Therefore, to understand host-plant use, one must determine whether preference and performance are associated and, more specifically, whether they are genetically correlated (Thompson, 1988; Jaenike, 1990; Via, 1990; Jaenike and Holt, 1991).

Oviposition by Lepidoptera is influenced by a variety of factors, including phytochemicals, presence of conspecific eggs, and host shape and texture (Thompson and Pellmyr, 1991). In this study, we investigated the effect of larvicidal proteins produced by the microbe *Bacillus thuringiensis* Berliner (Hofte and Whiteley, 1989) and the effect of conspecific eggs on oviposition behavior in the diamondback moth, *Plutella xylostella* (L.) (Lepidoptera: Plutellidae), a worldwide pest of cruciferous vegetables (Talekar, 1986). Oviposition in this species is stimulated by glucosinolates, the mustard oils (Gupta and Thorsteinson, 1960; Reed et al., 1989), and can be deterred by other phytochemicals (Dover, 1985; Tabashnik, 1985).

We addressed three questions concerning oviposition behavior of the diamondback moth. First, do *B. thuringiensis* toxins deter oviposition in susceptible moths? Given the fact that survival of susceptible larvae is reduced in the presence of *B. thuringiensis* toxins, susceptible females should be deterred from ovipositing on leaves laden with toxins if oviposition preference and larval performance are associated. In field populations, adults encounter toxins on plants sprayed with commercial formulations containing toxins. The recent incorporation of toxin-coding genes from *B. thuringiensis* into genomes of several crop plants, and the planned commercial use of these genetically engineered plants (Gasser and Fraley, 1989; Boulter et al., 1990), means that field populations of insects will eventually be exposed to *B. thuringiensis* toxins produced by plant tissue. For both the current and anticipated field situation, one can view the toxins from *B. thuringiensis* as analogous to phytochemicals that could have deterrent effects on oviposition.

Second, we asked whether selection for increased larval survival on a diet including toxins would change the preference of ovipositing females as a correlated response. We addressed this question by determining whether moths derived from a field population resistant to *B. thuringiensis* (Tabashnik et al., 1990), and selected for a higher level of resistance in the laboratory (Tabashnik et al., 1991; Groeters et al., 1992), differed in their oviposition preference from susceptible moths. If so, performance and preference would be genetically correlated.

Third, do conspecific eggs deter further oviposition, as in another crucifer-

feeding lepidopteran, *Pieris brassicae*, (Rothschild and Schoonhoven, 1977; Klijnstra, 1986), and some other Lepidoptera (Thompson and Pellmyr, 1991)? Egg-load assessment is most common in species for which resource competition is likely, and so is consistent with an association of preference and performance (Thompson and Pellmyr, 1991). Diamondback moth populations appear to be regulated primarily by natural enemies, host nutrient status, and weather rather than resource competition (Harcourt, 1986). Therefore, failure to find an oviposition deterrent effect of conspecific eggs in the diamondback moth might be consistent with a positive association between preference and performance based on egg loads.

MATERIALS METHODS

Effect of Toxin on Oviposition. Oviposition preference was tested in females from a resistant (NO-QA) and a susceptible (NO-Q) line, both derived originally from diamondback moths sampled at a watercress farm near Pearl City, Oahu, Hawaii. Four generations of selection for resistance to *B. thuringiensis* resulted in a greater than 1000-fold difference in median lethal concentration (LC_{50}) between NO-QA and NO-Q (Groeters et al., 1992; selection procedures described in Tabashnik et al., 1991). The moths used in this study were the F_1 offspring of moths used to measure the aforementioned difference in resistance between lines. Although the resistant line had not undergone selection during the previous generation, the difference in resistance between the lines is unlikely to have declined dramatically over that time.

Larvae were raised on cabbage plants (C-G Cross, Takii and Company, Kyoto, Japan) in cylindrical cages made of acetate sheets. They were maintained at 28°C and 14:10 hr light–dark photoperiod. Upon adult eclosion, pairs of adults were placed into inverted Petri dishes (100 mm diam.). Food was provided by a 30-mm piece of dental wick saturated with 10% sucrose solution. Two cabbage leaf disks (20 mm diam.) served as potential oviposition sites. They were placed about 30 mm part, each on a strip of filter paper saturated with water to keep them turgid. One disk had been dipped for 5 sec in a distilled water dilution of the HD-1 strain of *B. thuringiensis* subsp. *kurstaki* (Dipel 2X; Abbott Laboratories, North Chicago, Illinois) at the recommended field rate of 0.0256 mg AI/ml. In bioassays of third-instar larvae from the previous generation, this concentration caused greater than 90% mortality in the susceptible NO-Q line and less than 1% mortality in the resistant NO-QA line at 120 hr after treatment. The other disk was dipped for 5 sec in distilled water. Following treatment, disks were air dried for 2 hr at about 23°C before being placed into cages. Most moths began ovipositing on the first night following adult eclosion. Leaf disks were collected the following morning, even if no oviposition had

occurred, and replaced with a fresh pair of disks. This procedure was repeated until we had obtained eggs laid on two separate days from each pair. Adult moths were maintained at 28°C and 14:10 hr light–dark photoperiod. Oviposition data were gathered from 37 susceptible females and 22 resistant females.

Oviposition preference was tested using randomized complete block models similar to the model employed by Jaenike and Grimaldi (1983). To test for an effect of toxins on oviposition preference of susceptible moths, we used a model that included a main effect of leaf dip and female as a block effect. A difference between susceptible and resistant moths for oviposition preference was tested with a model that included main effects for line and leaf dip, and female nested within line as a block effect. A significant line × treatment interaction would indicate that the lines differed in oviposition preference. Individual variation for preference would be indicated by a significant treatment × female interaction. Analyses were performed by the general linear models procedure of SAS (SAS Institute, 1985).

Effect of Conspecific Eggs on Oviposition. "Treated" leaf disks were obtained by placing 10 disks (20 mm diam.) and 50 two-day-old adult moths into a Petri dish (150 mm diam.) that was placed into a light-proof box at 28°C. Darkness in the box stimulated oviposition, and after 1–9 hr leaf disks with eggs on them were removed from the Petri dish. The number of eggs on each disk (its egg load) was recorded. One treated (with eggs) and one untreated (without eggs) disk were then placed into a Petri dish (100 mm diam.), 30 mm apart, along with a single female moth. A small slit made in the side signified the treated leaf disk. Females were maintained at 28°C and 14:10 hr light–dark photoperiod. Leaf disks were collected in the morning; eggs were laid the previous evening. We counted the total number of eggs laid on each disk and obtained the number laid over the course of the evening on the treated disk by subtracting the egg load for that disk. Varying the time females were allowed to oviposit on treated disks yielded a range in egg loads. The experiment was repeated three times with low, moderate, and high egg loads. In the replicate with a low egg load, a laboratory stock founded with individuals from Leeward, Oahu (LAB-L), was used. In the other two replicates, females from LAB-P, a stock founded with individuals from Pulehu, Maui, were tested. Data for each egg load level were analyzed using a t test for paired comparisons. The entire data set was analyzed by analysis of variance with main effects for egg load level (low, moderated, high) and conspecific eggs (eggs present or absent), and female nested within egg load level as a block effect.

Power Analysis. In all statistical analyses, the probability of type I error (α) was set at 0.05. Upon failure to reject a null hypothesis, we performed a power analysis to determine the detectable effect size in the experiment (Rotenberry and Wiens, 1985; Cohen, 1988). The detectable effect size is the smallest difference in a dependent variable that would be likely to result in rejection of

the null hypothesis, given the sample size (N), α, and the desired probability of type II error (β). The magnitude of the detectable effect size relative to an effect postulated to be reasonable for the biological phenomenon being investigated indicates whether or not power sufficient to detect the biological effect was present in an experiment. β was set at 0.05 to equal α. This allowed application of the same probability standard to a conclusion from a negative result (failure to reject the null hypothesis) as from a positive result (rejection of the null hypothesis).

RESULTS

B. thuringiensis toxins did not deter oviposition by susceptible diamondback moths. Susceptible moths laid 32.2 ± 2.90 (mean ± SE) eggs on leaf disks dipped in water and 32.1 ± 2.7 eggs on disks dipped in toxins. The difference was not significant (Table 1). Failure to find an effect of toxins on oviposition was not due to lack of power. The power of the F test for an effect of leaf dip is equivalent to the power of a paired t test. The detectable effect size for a paired t test with $N = 37$, $\beta = 0.05$ and $S = 33.3$ (standard deviation of the difference in number of eggs laid on the two types of leaf disk) is 18.6. The mean number of eggs laid on a disk was 32. Thus, we had sufficient power to detect even a weak deterrent effect, say nine fewer eggs than the mean on disks treated with *B. thuringiensis* and nine more eggs on control disks for a total difference of 18 eggs, a value equivalent to the detectable effect size. It can be concluded with a probability of less than 0.05 of being incorrect that *B. thuringiensis* toxins did not act as an oviposition deterrent.

Moths selected for resistance to *B. thuringiensis* toxins laid more eggs on leaf disks dipped in toxins (30.3 ± 3.4) than on disks dipped in water (22.5 ± 3.4), but the difference in preference compared with susceptible moths was not significant (effect of line × leaf dip interaction in Table 2). This suggests that preference and performance are not strongly genetically correlated. The power

of the F test for line × leaf dip interaction is equivalent to the power of a two-group t test (susceptible versus resistant lines) on the difference in number of eggs laid on the two types of leaf disks (Green, 1989). The detectable effect size for this t test, using an average N of 29 with $\beta = 0.05$ and $S = 29.7$ is 26 eggs. Because this effect is large, we cannot exclude the possibility of a weak genetic correlation between preference and performance. The leaf dip × female interaction was not significant (Table 2), which reflects an overall lack of variation in preference among individual females.

Conspecific eggs on leaf disks did not deter oviposition. For all three egg load levels, the number of eggs laid on disks without eggs was greater than the number laid on disks with eggs, but for no level was the difference significant (Table 3). Despite the tendency for fewer eggs to be laid on disks with conspecific eggs at each of the egg load levels, analysis of variance of the entire data set also indicated that the effect of conspecific eggs was not significant, either as a main effect ($F = 1.34$; $df = 1, 66$; $P = 0.25$) or through interaction with egg load level ($F = 0.10$; $df = 2, 66$; $P = 0.90$). The detectable effect sizes

were about 10–12 eggs (Table 3). If the level of a deterrent effect corresponded to the number of eggs already on a leaf disk, then the power to detect an effect in the "low" replicate may have been insufficient because there was only an average of 3.5 eggs on treated leaf disks, a value less than the detectable effect size. However, the power of the "medium" and "high" replicates to detect a deterrent effect was sufficient because the average number of eggs present initially on the treated leaf disk exceeded the detectable effect size.

DISCUSSION

The finding that toxins from *B. thuringiensis* did not deter oviposition by diamondback moths from a susceptible line shows that host preference was not positively correlated with larval performance in this line. The simplest explanation for this result is that females cannot detect the toxins. Other possibilities include lack of genetic variation in oviposition preference and lack of sufficient selection for avoidance of toxins. It has been suggested previously that oviposition on unsuitable hosts (Wiklund, 1975; Chew, 1977; Legg et al., 1986) may reflect recent associations in which the insect has not had enough time to evolve appropriate changes in behavior. In other cases, overriding effects of ecological factors, such as natural enemies, host phenology, microclimate, and foraging constraints, may cause poor correspondence between nutritional suitability and preference (Tabashnik and Slansky, 1987; Thompson, 1988).

The absence of a significant difference in preference between resistant and susceptible moths excludes a strong genetic correlation between preference and performance. However, in contrast to the lack of preference in susceptible females, resistant females laid slightly more eggs on leaf disks laden with toxins than on disks without toxins. Thus, we cannot rule out the possibility of a weak genetic correlation between preference and performance. Physiological resistance of diamondback moth larvae to *B. thuringiensis* toxins is associated with reduced fitness in the absence of toxins (Groeters et al., 1992). This type of trade-off in insect fitness on plants with and without toxins would favor host specialization; a genetic correlation between performance and preference would facilitate specialization (Via, 1990). Our results are consistent, however, with the general finding that such correlations are not common in phytophagous insects (Thompson, 1988; Jaenike and Holt, 1991).

We did not find phenotypic variation among females in oviposition preference in our laboratory lines, but intraspecific variation in preference is common in other species (Thompson and Pellmyr, 1991). The lines that we studied may have lost phenotypic and genetic variation that occurs in field populations of diamondback moth. Another important limitation of our study is that preferences for whole plants in the field may not be reflected by preferences for leaf disks in the laboratory.

In this study, the presence of conspecific eggs did not deter oviposition by diamondback moths. Although this finding might suggest that preference and performance are not associated, the diamondback moth's small size relative to its hosts and the importance of factors other than competition in regulating moth populations (Harcourt, 1986) suggest that selection for egg-load assessment is limited. Thus, our results for the diamondback moth do not contradict the principle of egg-load assessment in other Lepidoptera (Thompson and Pellmyr, 1991).

The absence of a deterrent effect of conspecific eggs has an important bearing on the test for a deterrent effect of *B. thuringiensis* toxins. A deterrent effect of conspecific eggs could have caused a uniform distribution of eggs across leaf tissue with and without toxins to be observed, suggesting lack of preference, when, in fact, the distribution was caused by a balance between a deterrent effect of toxins and a deterrent effect of previously laid eggs. The absence of a deterrent effect of conspecific eggs suggests that the failure of females to avoid ovipositing on leaf disks with *B. thuringiensis* toxins could not have been a result of the masking of a deterrent effect of toxins by an even stronger deterrent effect of conspecific eggs.

Because diamondback moths readily lay eggs on leaves treated with *B. thuringiensis* toxins, and larvae readily consume treated foliage (Schwartz et al., 1991), repeated applications of these toxins select intensely for physiological resistance (Gould, 1991). Thus, the evolution of physiological resistance to *B. thuringiensis* in diamondback moth (Ferre et al., 1991; Schwartz et al., 1991) is not surprising. Although the potential for evolution of behavioral resistance to *B. thuringiensis* toxins cannot be excluded, available evidence indicates that physiological resistance is the more likely outcome.

One of the most promising tactics for slowing evolution of resistance is to provide refuges of untreated plants (Tabashnik et al., 1991). Deterrence of oviposition by toxins would result in a disproportionately large fraction of eggs in refuges, which would enhance the ability of refuges to slow resistance development. If females do not avoid toxins, as these data suggest, the effectiveness of refuges will not be magnified by a behavioral preference for untreated foliage.

CHEMICAL SEX DISCRIMINATION IN THE CRAYFISH *Procambarus clarkii*: ROLE OF ANTENNULES

DAVID W. DUNHAM* and JIN W. OH

Department of Zoology
University of Toronto
Toronto, Ontario, Canada M5S 1A1

(Received May 5, 1992; accepted August 12, 1992)

Abstract—Chemical sex discrimination of conspecifics by male and female crayfish (*Procambarus clarkii*) was tested. Intact female subjects were more attentive in the presence of stimulus water from males than from females and showed more aggressive postures in the presence of stimulus water from females than from males. Intact males showed more aggressive postures in the presence of stimulus water from males than from females. Females and males with only one inner antennule ramus and one outer ramus performed discrimination and localization almost as well as intact subjects. Subjects with only the two inner rami or only the two outer rami were disadvantaged in either responding to the stimuli or localizing them. The relevance of this outcome to previous conflicting reports on the use of antennules in sex discrimination in crayfish is discussed.

Key Words—*Procambarus clarkii*, Crustacea, crayfish, sex discrimination, antennule, chemical communication, aggression, discrimination.

INTRODUCTION

Studies of some decapod crustaceans have demonstrated conspecific sex recognition through their response to chemical factors in water (see Dunham, 1988, for a recent review). Studies of the lobster *Homarus americanus* have focused on the mating interaction between males and females, deducing the use of chemical cues (Atema and Engstrom, 1971; Dunham, 1979; Atema and Cowan, 1986). In studies of true crabs, the emphasis has been on response to female chemical stimuli (either water from females' holding tanks or diluted females'

*To whom correspondence should be addressed.

urine) by conspecific males (Ryan, 1966; Eales, 1974; Christofferson, 1978; Gleeson, 1980). In freshwater crayfish, this type of sexual recognition has been demonstrated in male *Orconectes virilis* (Hazlett, 1985) and in both male and female *Orconectes propinquus* (Tierney and Dunham, 1984; Tierney et al., 1984). The latter proposed that the aesthetascs on the outer rami of the antennules were essential sensilla for noncontact semiochemical transduction.

Evidence for sexual recognition through the presumed use of pheromones in the crayfish *Procambarus clarkii* has also been addressed in the literature, but not without controversy. Ameyaw-Akumfi and Hazlett (1975), and Ameyaw-Akumfi (1976), reported that males could chemically discriminate males from females. Males responded in an aggressive fashion to the water from a male's tank, but in a submissive fashion to the water from a female's tank. From incomplete ablation experiments, they concluded that the inner rami of the antennules mediated this discrimination. In contrast, Itagaki and Thorp (1981) found no such discrimination by male and female *P. clarkii* in their experiments with a flow-through system. Thorp and Ammerman (1978) found no significant chemical sex discrimination in male *Procambarus acutus*, with a flow-through system. The present study was undertaken in an effort to clarify the ability of *P. clarkii* to recognize conspecific sex and to determine what role the antennules play in chemical sexual discrimination.

METHODS AND MATERIALS

The subjects, form I, intermolt male and nongravid female *P. clarkii*, were obtained from a supplier in Louisiana. They were held in large aerated plastic holding tanks for five days and then housed in individual aerated glass jars containing 4 liters of distilled water for five days before testing. They were maintained on a light cycle of 12 hr dark–12 hr light, at 18–20°C, and fed commercial fish food every second day. The experiments took place in April, May, and June 1990.

Antennule ablations were of both inner rami, both outer rami, or a cross ablation of one inner and one contralateral outer ramus (determined randomly). They were performed after anesthesia by immersion in ice water. Twenty-four hours after this procedure, the animal was used in an experiment. Intact animals were not altered in any way. Stimulus water was obtained by gently scooping out 50 ml from a jar that had held one crayfish for five days (either male or female). Stimulus water came from a different crayfish for each trial. Stimulus source crayfish were not size matched. However, tests with female *P. clarkii* from the same population showed no difference in response to unfamiliar female stimulus water ($P > 0.25$) when diluted to the following concentrations with water from their own home tank (percent by volume): 100%, 75%, 50%, and 25% (Oh and Dunham, unpublished data).

The test procedure followed was similar to that used by Rose (1986) and consisted of first placing a subject crayfish and 2 liters of its own jar water in a 20 × 36 × 22 cm (high) aquarium. After 15 min, the stimulus water (from either male or female) was placed in a 50-ml burette, which released one drop every 2–3 sec into the bubble stream above an airstone in the aquarium. The behavior of the subject animal was infrared videotaped for 15 min from an adjacent room. The aquarium and the burette were thoroughly rinsed three times with distilled water between tests. The intertest interval was 20 min. The remaining 2 liters of the subject's own jar water was then placed in the aquarium along with the animal. The subject was once again left for 15 min, and then new stimulus water, which was from a different sex crayfish than in the preceding test, was presented. This test was also videotaped for a period of 15 min. The experiments were performed at night, when the animals were most active (2100 to 0200 hr). The order of the treatments (intact, inner ablates, outer ablates, cross ablates), the order of the individual animals used in each test, and the order of the source of the stimulus water were all randomized.

Twelve males and 12 females were utilized in each of the four treatments (a total of 96 crayfish), and each animal was tested once with a male's and once with a female's stimulus water. No crayfish was used more than once for a given treatment.

The cumulative duration of the two relevant groups of behaviors exhibited by the test animals was measured with stopwatches. The first is *chelae up*, which includes the raising of the chelae from the substrate, and also the cheliped displays of meral extension and meral spread (Bruski and Dunham, 1987). This set of behaviors is indicative of the perception of a stimulus. The second group of behaviors is *attention to stimulus source*, which includes being within 2 cm of the airstone, touching the airstone with either the head or a chela, and climbing on the airstone. This set of behaviors is indicative of the perception and localization of a stimulus.

RESULTS

The median scores for the two groups of behaviors, in the four test groups of 12 crayfish each, are shown in Figures 1–4. All animals responded in each test.

The raw scores for the two groups of behaviors during the male and female stimulus water tests, within the four treatment groups, were compared using the Wilcoxon signed-rank test (Castellan and Siegel, 1988), at the 5% significance level. The raw scores for the chelae up and the attention to stimulus source behaviors were also compared across treatment groups using the Wilcoxon-Mann-Whitney test (Castellan and Siegel, 1988), at the 5% significance level.

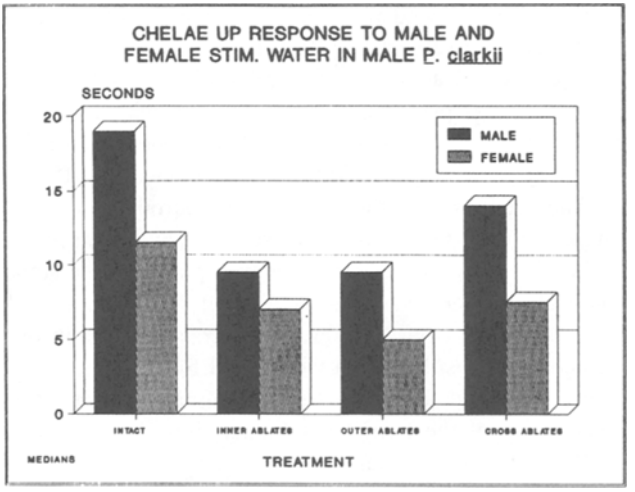

FIG. 1. Median chelae up response scores for the four groups ($N = 12$) of male crayfish *Procambarus clarkii* tested with the stimulus water from the same sex or the opposite sex conspecific. Upper, median, and lower interquartile values are given in parentheses, male stimulus test first, female stimulus test second: Intact animals (12, 19, 23; 8, 11.5, 16). Cross ablates (10, 14, 15; 4, 7.5, 9) had one inner and one outer antennule. Inner ablates (5, 9.5, 10; 5, 7, 8) had both outer antennules. Outer ablates (3, 9.5, 12; 2, 5, 6) had both inner antennules. Significance values are given in the text.

Response of Females. The intact, inner ablated (outer antennules intact) and the cross ablated (one inner and one outer ramus) female subjects displayed significantly more *chelae up* behavior in the presence of stimulus water from the same sex than in the presence of stimulus water from the opposite sex ($P = 0.007$ for intact females, $P < 0.02$ for female inner ablates, $P = 0.03$ for female cross ablates). There was no significant difference in chelae up behavior of female outer ablates in response to male versus female stimulus water ($P = 0.17$).

The female subjects differed significantly in their attention to the stimulus source. In the female trials, significantly more attention was paid to male stimulus water than to female stimulus water by the intact ($P = 0.006$), outer ablated ($P = 0.02$), and cross ablated subjects ($P = 0.01$). There was no significant difference in the attention to stimulus source by the inner ablated female subjects ($P = 0.51$).

The intact female scores for chelae up in response to both male stimulus water and female stimulus water were significantly greater than those of the inner ablates ($P < 0.03$ and $P = 0.05$, respectively). There were no significant differences between scores for the intact females and outer ablates ($P > 0.23$

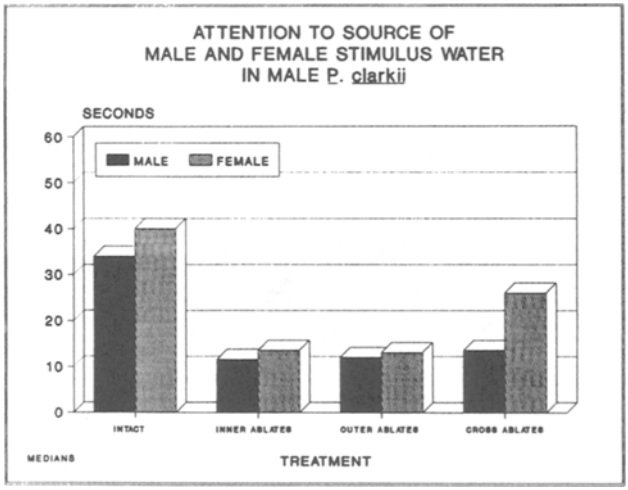

FIG. 2. Median attention to stimulus source response for the four groups ($N = 12$) of male crayfish *Procambarus clarkii* to stimulus water from the same sex or the opposite sex conspecific. Upper, median, and lower interquartile values are given in parentheses, male stimulus test first, female stimulus test second: Intact animals (19, 34, 43; 21, 40, 55). Cross ablates (8, 13.5, 18; 12, 26, 35) had one inner and one outer antennule. Inner ablates (4, 11.5, 14; 7, 13.5, 20) had both outer antennules. Outer ablates (6, 12, 17; 8, 13, 19) had both inner antennules. Significance values are given in the text.

and $P > 0.37$, respectively) or cross ablates ($P > 0.17$ and $P > 0.35$, respectively, the inner and outer ablates ($P > 0.10$ and $P > 0.09$, respectively) or cross ablates ($P > 0.06$ and $P > 0.10$, respectively), or between the outer and cross ablates ($P > 0.22$ and $P = 0.35$, respectively).

Both intact and cross ablated female subjects had significantly higher attention to the stimulus source scores, in response to male stimulus water, than those of the inner ablates ($P = 0.007$ and $P = 0.05$, respectively). There were no significant differences between the scores for intact females and outer ablates ($P > 0.13$) or cross ablates ($P > 0.49$). There were no significant differences between the scores for the outer ablates and those for the inner ($P > 0.11$) or cross ablates ($P = 0.16$).

In response to female stimulus water, the female subjects exhibited no significant differences across treatment groups in attention to the stimulus source scores. There were no significant differences in scores between the intact females and the inner, outer, and cross ablates ($P = 0.35$, $P > 0.27$, and $P > 0.22$, respectively), between the inner and the outer ($P > 0.38$) and cross ablates ($P = 0.25$), and between the outer and cross ablates ($P > 0.37$).

Response of Males. The intact, inner ablated (outer antennules intact) and

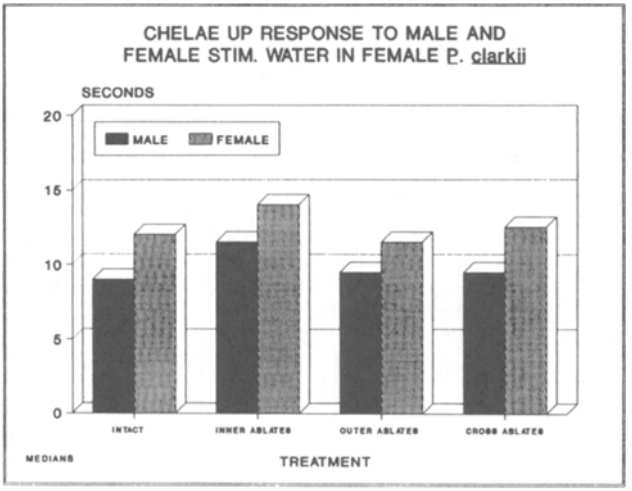

FIG. 3. Median chelae up response scores of the four groups ($N = 12$) of female crayfish *Procambarus clarkii* tested with stimulus water from male and female conspecifics. Upper, median, and lower interquartile values are given in parentheses, male stimulus test first, female stimulus test second: Intact animals (7, 11.5, 13; 11, 14, 16). Cross ablates (8, 9.5, 11; 10, 12.5, 14) had one inner and one outer antennule. Inner ablates (7, 9, 10; 10, 12, 14) had both outer antennules. Outer ablates (8, 9.5, 10; 8, 11.5, 13) had both inner antennules. Significance values are given in the text.

the cross ablated (one inner and one outer ramus) male subjects displayed significantly more chelae up behavior in the presence of stimulus water from the same sex than in the presence of stimulus water from the opposite sex ($P < 0.05$ for intact males, $P = 0.02$ for male inner ablates, $P = 0.0002$ for male cross ablates). There were no significant differences in chelae up behavior of male outer ablates in response to male versus female stimulus water ($P = 0.055$), although this difference was only marginally nonsignificant.

The male subjects did not differ significantly in their attention to the stimulus source water from males versus that from females. This result obtained in all four treatments (intact $P = 0.37$, inner ablate $P = 0.34$, outer ablate $P = 0.34$, and cross ablate $P = 0.34$).

Intact male subjects had higher chelae up scores in the presence of male stimulus water than those of the inner ablates ($P < 0.005$) and the cross ablates ($P < 0.01$), but not the outer ablates ($P = 0.055$), although the latter difference is only marginally nonsignificant. The scores of the cross ablates were significantly greater than those of the inner ablates ($P = 0.002$). There were no significant differences between the inner and outer ablates ($P > 0.08$) or the outer and cross ablates ($P > 0.12$). Intact male scores in the presence of female stimulus water were significantly greater than those of the inner ablates ($P <$

FIG. 4. Median attention to stimulus source response scores of the four groups (N = 12) of female crayfish *Procambarus clarkii* tested with the stimulus water from the same sex or the opposite sex conspecific. Upper, median, and lower interquartile values are given in parentheses, male stimulus test first, female stimulus test second: Intact animals (36, 47, 64; 21, 31, 35). Cross ablates (38, 51.5, 38; 24, 31.5, 47) had one inner and one outer antennule. Inner ablates (28, 32.5, 48; 16, 23, 42) had both outer antennules. Outer ablates (29, 44.5, 54; 17, 36, 38) had both inner antennules. Significance values are given in the text.

0.005), outer ablates ($P = 0.007$), and cross ablates ($P < 0.004$). The scores for the inner and cross ablates were significantly greater than those of the outer ablates ($P < 0.04$ and $P = 0.05$, respectively).

Attention to stimulus source scores for the intact males in the presence of the male stimulus water were significantly greater than those of the inner ablates ($P < 0.001$), outer ablates ($P < 0.001$), and cross ablates ($P = 0.006$). There were no significant differences between the inner and outer ablates, the inner and cross ablates, and the outer and cross ablates ($P > 0.31$, $P > 0.19$, and $P > 0.13$, respectively). In the presence of the female stimulus water, the scores for the intact males were significantly greater than those of the inner ($P < 0.004$), outer ($P < 0.0007$), and cross ablates ($P = 0.005$). The cross ablate scores were significantly greater than those of the outer ablates ($P < 0.02$).

DISCUSSION

Responses of Females. From the results, it is apparent that both intact and cross ablated female *Procambarus clarkii* are able to discriminate between the presence of male and female conspecifics and localize the source of stimulation

using chemical cues. The inner ablates were also able to make this discrimination, but did not localize the source of stimulation. The outer ablates did not perform chelae up behavior when demonstrating discrimination, but did differentially localize the source of male versus female stimulation.

Oh and Dunham (1991) found that female *P. clarkii* required both rami of the antennules (although not bilaterally) to clearly discriminate themselves chemically from other female conspecific and to localize the source of the stranger's water. However, their score (attention) included both chelae posture and localization of the chemical source. The present study separates these responses and shows a differential effect of outer versus inner ramus ablation on them.

Tierney and Dunham (1984) reported, after inner and outer antennule ablations, that in female crayfish *Orconectes propinquus*, the outer antennule rami were responsible for localization of the source of chemicals from opposite-sex conspecifics. They found that the inner antennule rami, while chemosensory in nature, did not play a part in conspecific localization. The contradiction between their results and those in the present study may be due to species (and generic) differences in detecting and transducing semiochemicals. Furthermore, differences in the source of stimulus water (four animals conditioned their stimulus water as opposed to one in the present study) and the type of test system used (flow-through in their study as opposed to a lentic system in the present study) may have played some unknown role in the results.

Itagaki and Thorp (1981) conclude that their female *P. clarkii* showed no evidence of chemical sex discrimination. However, their Figure 2 and Table 2 data (comparisons DE and DEF) do show sex discrimination (in chela wave) and discrimination and localization of the chemical source (time in upstream zone). Those are the only unconfounded comparisons (possible "stress pheromone" absent) that could give evidence of female sex discrimination in their design. We feel that low levels of chelae movements in isolation does not negate their value as a discriminandum here.

Responses of Males. The intact males, inner ablates, and cross ablates responded with more agonistic behavior to the male stimulus water than to the female stimulus water, demonstrating chemical discrimination based on sex. (The nonsignificant trends in median differences shown in Figures 1 and 2 suggest that additional experiments are perhaps warranted, with a larger sample of males.) The males did not demonstrate localization of the female stimulus, which may reflect a low priority for reproductive activity under the testing conditions.

Ameyaw-Akumfi and Hazlett (1975) demonstrated clear sex discrimination by male *P. clarkii* with the discriminanda of chela posture, telson posture, and feeding movements. As in the present study, they did not find a sex bias in male localization of the chemical source. Itagaki and Thorp (1981) also found no chemical source localization in male *P. clarkii*.

In the same study, Ameyaw-Akumfi and Hazlett (1975) concluded, after total antennule and inner ramus ablations with male *P. clarkii*, that chemical sexual discrimination was dependent on the presence of the inner rami of the antennules, because the above ablations resulted in loss of sex discrimination. They did not report outer ramus ablations. In the present study, the intact, inner ablated, and cross ablated male subjects discriminated between the male and female stimulus water in their chelae up scores, although not equally well. The outer ablate group score was marginally nonsignificant ($P = 0.055$). The reason for the discrepancy between our male inner ablate group performance and that from the Ameyaw-Akumfi and Hazlett (1975) study is not clear.

Tierney and Dunham (1984) reported, after inner and outer antennule ablations, that in male crayfish (*Orconectes propinquus*) the outer antennule rami were responsible for localization of the source of chemicals from opposite sex conspecifics, just as reported above for females. They found that the inner antennule rami, while chemosensory in nature, did not play a part in conspecific localization.

Itagaki and Thorp (1981) found no evidence of chemical sex discrimination or source localization in male *P. clarkii*. Thorp and Ammerman (1978) also found no evidence of chemical sex discrimination or source localization in male *Procambarus acutus*, but that could have been due to a confounding effect of "stress pheromone," as they point out.

Both Thorp and Ammerman (1978) and Itagaki and Thorp (1981) used a flow-through water system, but it is uncertain what relevance that may have had to the outcome. Much has been made of the fact that closed systems, as used by Ameyaw-Akumfi and Hazlett (1975), Rose (1986), Oh and Dunham (1991), and in the present study, probably more nearly resemble the average habitat of *P. clarkii* than does a flow-through system (Hazlett, 1985; Huner, 1988; Rose, 1984). However, given the complexity of the natural environment in which these animals interact, and the probable great variance of local concentrations of both crayfish odors and metabolite concentrations, it seems unreasonable to assume that chemical sex discrimination could occur only in a lotic or only in a lentic environment (see Hazlett, 1984; Thorp, 1984, for discussion).

Abstract—The composition of the *Autographa gamma* sex pheromone was reexamined and only (Z)-7-dodecenyl acetate and (Z)-7-dodecenol were identified by capillary GC, GC-MS, and dimethyl disulfide derivatization and subsequent GC-MS analysis. The fatty acid content of the pheromone glands was also studied, and a series of saturated and unsaturated acids was identified. However, most of the related pheromonal compounds were not detected. The male response to the pheromone components was studied in a flight tunnel and compared with the response to calling females. The best synthetic baits evoked a response similar to that observed to the virgin females, but males spent significantly more time at calling females than at the synthetic baits. The preferred synthetic baits consisted of (Z)-7-dodecenyl acetate alone or of a blend with 5% (Z)-7-dodecenol. Increasing the relative amount of the alcohol caused a gradual reduction in male response, particularly in the last steps of the courtship sequence. The addition of the minor sex pheromone components of the sympatric Plusiinae species, *Trichoplusia ni* and *Chrysodeixis chalcites*, to the *A. gamma* pheromone was also investigated in the flight tunnel. Some of these components exhibited a significantly antagonistic effect on the *A. gamma* male courtship behavior. The most potent antagonists were (Z)-5-dodecenyl acetate and (Z)-9-tetradecenyl acetate. The response of *A. gamma* and *T. ni* males to conspecific and heterospecific females was also compared in the flight tunnel. Whereas *A. gamma* males were attracted only to their conspecific females, a small percentage of *T. ni* males were also

INTRODUCTION

In many moths, and particularly in closely related species, overlapping female sex pheromone components have been found (Cardé and Baker, 1984; Baker, 1989). Most of the sex pheromones in the noctuid subfamily Plusiinae are characterized by (*Z*)-7-dodecenyl acetate (*Z*7–12 : Ac) as the main component (Arn et al., 1986), although there are a few exceptions (Heath and Landolt, 1987; Mazor et al., 1991). Despite the fact that in some locations several Plusiinae species have been trapped with *Z*7–12 : Ac (Alford and Hammond, 1982), generally speaking there is no interspecific cross-attraction between sympatric Plusiinae species under natural conditions in the field. To maintain premating and behavioral reproductive isolation among closely related moths, species-specific pheromones are utilized consisting usually of multicomponent blends containing attractive and antagonistic components (Landolt and Heath, 1987; Linn et al., 1988).

The gamma moth, *Autographa gamma*, abundant in Israel in the spring, is sympatric with *Cornutiplusia circumflexa* and *Trichoplusia ni* and sometimes with the later-appearing *Chrysodeixis chalcites* as well (Yathom and Rivnay, 1968). In the *A. gamma* sex pheromone, two components have been identified: *Z*7–12 : Ac and (*Z*)-7-dodecenol (*Z*7–12 : OH) (Dunkelblum and Gothilf, 1983; Toth et al., 1983). Field experiments indicated that lures consisting of *Z*7–12 : Ac with a low concentration of *Z*7–12 : OH were not specific to *A. gamma* males, and varying numbers of *T. ni* males were also trapped. Conversely, the six-component *T. ni* and the three-component *C. chalcites* lures were specific and never caught *A. gamma* males (Dunkelblum and Mazor, unpublished). These results prompted us to: (1) reinvestigate the composition of the *A. gamma* sex pheromone blend, and (2) study the effect of the addition of the minor *C. chalcites* and *T. ni* sex pheromone components to the *A. gamma* pheromone on the flight behavior of *A. gamma* males in a wind tunnel.

METHODS AND MATERIALS

Insects and Extracts. The colony was established from *A. gamma* moths that were captured in light traps. Larvae were reared on a modified semisynthetic diet medium (Shorey and Hale, 1965). Pupae were sexed; males were kept in

the flight-tunnel room and females in a separate room. Both rooms were maintained under the same conditions with a dark–light regime of 10:14 hr, at 26 ± 2°C and 60 ± 5% relative humidity. Adults were provided with a 10% sugar solution.

Batches of 25 pheromone glands were dissected from the ovipositors of 5- to 6-day-old females, 4 hr into scotophase, and then immersed for 15 min in hexane. The supernatant solution was pipetted into conical vials sealed with a Teflon-lined screw cap and then concentrated to the required volume by letting the samples stand in the fume hood. For quantification, 100 ng of 10-undecenyl acetate (10–11:Ac) was added as internal standard. Attempts to collect airborne pheromone from *A. gamma* virgin females, in a flow system described by Landolt and Heath (1987), failed. For the analysis of fatty acids, pheromone glands were extracted with chloroform–methanol (2:1) for 30 min and subjected to basic methanolysis with KOH in methanol, as described by Bjostad and Roelofs (1984).

Chemical Identification. Capillary GC analyses were conducted on a Carlo Erba 5300 instrument equipped with a FID detector and a splitless injector system. For pheromone analysis, a 30-m × 0.25-mm DB-5 column (J&W; Folsom, California) was kept for 2 min at 60°C and then programmed to 150°C at a rate of 10°C/min; after 21 min the temperature was raised to 200°C, at the same rate. For fatty acid methyl ester analysis, a 30-m × 0.25-mm DB-225 column (J&W) was kept for 2 min at 60°C and then programmed to 120°C at a rate of 10°C/min; after 35 min the temperature was raised at 150°C, at the same rate. The purge valve was opened 1 min after injection, and the carrier gas (helium) pressure was 1 atm (14.7 psi).

Dimethyl disulfide (DMDS) adducts were prepared from several standards (Z5–10:Ac, Z7–12:Ac, Z9–14:Ac, and Z7–12:OH) and gland extracts, as described by Dunkelblum et al. (1985). The DMDS adducts were analyzed by GC-MS on a Finnigan 5100 system, at 70 eV, coupled with a Superincos data system. A 30-m × 0.25-mm RTX 5 fused silica column (Restec; Bellefonte, Pennsylvania) was kept 2 min at 60°C and then programmed to 250°C at a rate of 20°C/min. The purge valve was opened 0.5 min after injection and the carrier gas (helium) pressure was 10 psi.

Behavioral Tests. The flight tunnel (195 × 60 × 60 cm) used in these tests was the same as described by Snir et al. (1986). The tests were conducted at a light intensity of roughly 0.5 lux with a wind speed of 0.5 m/sec, at 25 ± 2°C. All experiments were conducted with 7- to 10-day-old males during the second half of scotophase. Males were tested individually and the following behavior categories were recorded: starting flight (within 1 min), directed flight, landing, hairpencil display, and copulation attempts. The duration of source contact was recorded and males that stayed close to the bait more than 60 sec were removed from the flight tunnel. Synthetic baits were prepared by impreg-

nating rubber septa (5 × 9 mm, Arthur H. Thomas Co.), preextracted with dichloromethane in a Soxhlet apparatus, with the appropriate blends. The baits were used within 10 days after preparation. They were kept in closed vials as described by Snir et al. (1986). Individual 4- to 7-day-old virgin females (*A. gamma* or *T. ni*) were also used as baits. They were placed in cylindrical wire screen cages fitted with a plastic bottle filled with a sugar solution and plugged with a cotton wick. When needed for an experiment, a calling female was selected and introduced into the wind flight tunnel. Dispensers loaded with Z7–12:Ac and mixtures with Z7–12:OH were compared with calling females. The effect of the minor *T. ni* and *C. chalcites* pheromone components was tested by adding these compounds, in the relative ratios similar to those found in the conspecific females, to the *A. gamma* pheromone. The C_{14} acetates were added in a 10-fold amount in order to compensate approximately for their lower volatilities as compared to the C_{12} acetates (McDonough et al., 1989).

Results were analyzed by the chi-square 2 × 2 test of independence with the Yates' correction at $P < 0.05$ using the actual number of insects and are presented as percentage of response.

RESULTS

Chemical Identification. Capillary GC analysis of gland extracts indicated the presence of Z7–12:Ac and Z7–12:OH, as shown before (Dunkelblum and Gothilf, 1983). Despite the presence of additional peaks in the chromatograms, no additional pheromonal compounds could be positively identified. Maximal amounts of pheromone components, 3.4 ± 0.6 ng of Z7–12:Ac and 0.5 ± 0.3 ng of Z7–12:OH per female, were observed in 7-day-old females in the seventh hour into scotophase (Mazor and Dunkelblum, unpublished). Dimethyl disulfide (DMDS) derivatization of a gland extract and subsequent GC-MS analysis (Figure 1) confirmed the presence of these two compounds in the gland extracts with diagnostic ions of *m/e* 278, 161, 117 and 61 for Z7–12:OH/DMDS and *m/e* 320, 203, 143, 117 and 61 for Z7–12:Ac/DMDS. Monitoring the ion of *m/e* 61, characteristic of DMDS adducts (Francis and Veland, 1981), in the range between 10:Ac/DMDS and 14:Ac/DMDS, revealed no additional monounsaturated pheromonal components.

Analysis of fatty acid methyl esters, obtained by basic methanolysis of gland extracts, showed a series of C_{12}, C_{14}, C_{16}, and higher fatty acids. Considering that the same two pheromone components, albeit in an almost inverse ratio, were found also in *C. circumflexa* (Mazor et al., 1991), the fatty acid profile of pheromone glands of this Plusiinae moth was compared with that of *A. gamma* (Figure 2). The two profiles were very similar, with the same fatty acids present in both. The direct precursor of the pheromonal components, Z7–

12:Ac and Z7-12:OH, was Z7-12:Acid. Most of the other fatty acids such as Z9-14:Acid and Z11-16:Acid are probably precursors of Z7-12:Acid (Roelofs and Bjostad, 1984). The saturated fatty acids, Z9-16:Acid and the C_{18} fatty acids (not shown) are common in most gland extracts (Dunkelblum et al., 1985). The only additional uncommon acid in both Plusiinae moths was Z7-14:Acid. However, no additional pheromonal compounds derived from any observed fatty acid, except Z7-12:Acid, could be detected in both *A. gamma* and *C. circumflexa* gland extracts.

Behavioral Tests. In the first part of these tests, the male response to Z7-12:Ac and different blends of Z7-12:Ac + Z7-12:OH was compared with the response to a calling female (Table 1). Lures consisting of Z7-12:Ac alone or with 5% Z7-12:OH, evoked the same strong response as that of a virgin female. However, there was a significant difference in the duration of source contact between males reaching the synthetic bait and males responding to a calling female. Males that approached the female stayed an average 57.5 sec near the bait (most stayed more than 60 sec) and only 19.9 sec near the best synthetic bait. Increasing the relative amount of the alcohol to 50% and 100% lowered the male response but only in the last behavioral stages, and particularly in hairpencil display, copulation attempts, and duration of source contact.

The influence of the addition of the minor *T. ni* components (Bjostad et al., 1984; Dunkelblum and Mazor, unpublished) to the *A. gamma* pheromone

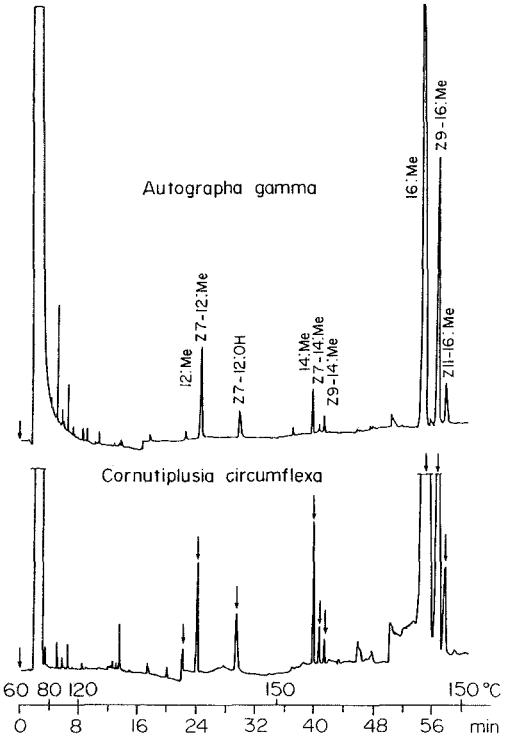

FIG. 2. Capillary GC traces of methanolized gland extracts of *Autographa gamma* (top) and *Cornutiplusia circumflexa* (bottom). The identified peaks were marked with the appropriate abbreviated formulas in the top trace and with arrows in the bottom trace.

was examined in the second part of the behavioral tests (Table 2). The blend of Z7–12 : Ac + 5% Z7–12 : OH was used as the standard *A. gamma* pheromone for these tests. Addition of either 12 : Ac or 11–12 : Ac had no effect on the flight behavior of the *A. gamma* males. Addition of Z7–14 : Ac had a moderately antagonistic effect, particularly on the three last behavioral stages. The antagonistic effect of Z9–14 : Ac was stronger and was perceived throughout the entire courtship sequence from the start of the flight to the copulation attempts. The strongest inhibitory effect was observed with the addition of Z5–12 : Ac, which reduced drastically the percentage of responding *A. gamma* males. Only 2/40 males landed on the lure consisting of the *A. gamma* pheromone + Z5–12 : Ac, as compared with 40/40 males that landed on the same lure without Z5–12 : Ac.

These behavioral tests indicate that baits containing the *T. ni* minor pheromone components can not attract *A. gamma* males. Conversely, field tests have shown that synthetic *A. gamma* baits attract both conspecific males and some

T. ni males (Dunkelblum and Mazor, unpublished). With these results in view, the response of *A. gamma* and *T. ni* males to conspecific and heterospecific females was compared in the flight tunnel (Table 3). Both *A. gamma* and *T. ni* males responded very strongly to their conspecific females, and most of them completed the whole courtship sequence. However, *A. gamma* males responded only to *A. gamma* females. On the other hand, some of the *T. ni* males were also attracted to the *A. gamma* females, with 11% of them performing the complete courtship sequence.

The influence of the addition to the *A. gamma* pheromone of the minor *C. chalcites* components, Z9–12:Ac and Z9–14:Ac, at the level present in *C. chalcites* was tested in the last part of the behavioral work (Table 4). The influence of the other two minor *C. chalcites* pheromone components, 11–12:Ac and 12:Ac (Dunkelblum et al., 1987b), was tested in the previous experiment (Table 2). The antagonistic effect of Z9–12:Ac was moderate, but it affected

all behavioral stages. Addition of a relatively large amount of Z9–14 : Ac caused an inhibitory effect similar to that of the lower amount tested before (Table 2).

DISCUSSION

Several years ago we identified Z7–12 : Ac and Z7–12 : OH in the sex pheromone gland extracts of *A. gamma* (Dunkelblum and Gothilf, 1983). The same compounds were also identified independently by Toth et al. (1983). Reexamination of the *A. gamma* gland extracts by capillary GC and by DMDS derivatization with subsequent GC-MS (Figure 1) analysis did not reveal any additional pheromonal components. An attempt to use the fatty acid content of the pheromone glands as a means to predict the presence of trace amounts of pheromonal components (Roelofs and Bjostad, 1984) did not help. Interestingly, the same fatty acid content was found also in the closely related Plusiinae moth *C. circumflexa* (Figure 2), which utilizes the same pheromone components (Z7–12 : OH and Z7–12 : Ac), albeit in an almost inverse ratio (Mazor et al., 1991). The presence of some specific fatty acids may be an indication of traces of the corresponding pheromone components, which are very difficult to identify. Furthermore, not all pheromonal components, originating from potential precursors, are indeed found in the gland extracts. For example, many specific fatty acids were identified in the gland extracts of *Choristoneura* species, but the number of detected pheromone components was much smaller (Dunkelblum et al., 1985). It seems that Z7–12 : Ac and Z7–12 : OH are, in fact, the main pheromonal components of *A. gamma*. Their amount in the pheromone gland is low. Therefore, even if other minor components were present, their detection would be very difficult. Field tests conducted several years ago indicated that the alcohol has some synergistic effect on trap catch of *A. gamma* males, but its activity was not always evident (Dunkelblum and Gothilf, 1983). However, the presence of the alcohol in the blend was important as a compound antagonistic to the sympatric *T. ni* males (Tumlinson et al., 1972; Dunkelblum and Mazor, unpublished).

The response of *A. gamma* males to lures baited with Z7–12 : Ac alone or with the acetate and 5% of Z7–12 : OH was very similar to their response to a calling female. The only difference was the duration of source contact. Males responded significantly longer close to the female than to the synthetic blend. Addition of the alcohol, at a level of 5% relative to the acetate, had no influence on the response of the males, either synergistic or antagonistic. Increasing the level of the alcohol in the binary blend resulted in a gradual decrease of male response, particularly in the last stages of the courtship sequence. The response of the males to a 1 : 1 mixture of Z7–12 : Ac and Z7–12 : OH was significantly lower in most behavioral stages, including the duration of source contact, than

their response to the standard blend containing 5% of the alcohol (Table 1). This agrees with the observation that the sympatric Plusiinae moth *C. circumflexa* utilizes the same pheromonal components as *A. gamma* but with the alcohol as the predominant component (Mazor et al., 1991). Interestingly, these two species are systematically closely related. Both genera, *Autographa* and *Cornutiplusia*, belong to the same subtribe Plusiina of the Plusiini tribe (Boisduval). On the other hand, *C. chalcites* and *T. ni*, which utilize multicomponent sex pheromones, belong to the Argyrogrammatini tribe (Kitching, 1987).

Attempts to collect airborne pheromone from *A. gamma* females were not successful, probably due to the small amounts of pheromone, and it is not certain that Z7–12:OH is actually emitted by the virgin female. However, it seems to us that the alcohol is indeed a part of the *A. gamma* sex pheromone. This view is supported by the discovery of specialist cells to Z7–12:OH in the receptor system of *A. gamma* males (Priesner, 1980).

Examination of the effect of the minor pheromone components of *T. ni* on the flight behavior of *A. gamma* males indicated that the five compounds have a different influence on the male response. Addition of 12:Ac or 11–12:Ac to the binary blend of Z7–12:Ac and Z7–12:OH had no effect on the flight behavior of the males. The three other *T. ni* minor components. Z5–12:Ac, Z7–14:Ac, and Z9–14:Ac, revealed an antagonistic influence, with Z5–12:Ac causing the most pronounced inhibitory effect (Table 2). A combination of the antagonistic components, with Z5–12:Ac in the predominant role, excludes the approach of any *A. gamma* males to a *T. ni* female. Conversely, a small percentage of *T. ni* males do fly towards a *A. gamma* female, because the specificity of the *A. gamma* sex pheromone is not high enough. Traps baited with the *A. gamma* pheromone blend of Z7–12:Ac and 5% Z7–12:OH caught some *T. ni* males in the field, but far fewer than baits containing Z7–12:Ac alone (Dunkelblum and Mazor, unpublished). The present flight experiment with live *A. gamma* and *T. ni* moths (Table 3) confirmed the ability of the *A. gamma* females to elicit the courtship sequence from a small percentage of *T. ni* males. A similar relation between the response of *T. ni* and that of *Pseudoplusia includens* males to conspecific and heterospecific pheromone blends and females was observed by Landolt and Heath (1987) and Linn et al. (1988). The percentage of *T. ni* males that approached a *P. includens* female was much higher than that of *P. includens* males flying towards a *T. ni* female. The inhibitory effect of the *T. ni* sex pheromone to *P. includens* males was similarly attributed to the antagonistic effect of Z5–12:Ac and Z9–14:Ac.

The two minor components of the *C. chalcites* sex pheromone, Z9–12:Ac and Z9–14:Ac (at a level higher than in the *T. ni* pheromone), tested in a separate experiment, both inhibited the courtship sequence of *A. gamma* males (Table 4). These results are in accord with observations from many field tests indicating that the *C. chalcites* sex pheromone blend is species-specific (Dunkelblum et al., 1987a).

Usually, species possessing a common major sex pheromone component utilize unique minor components to provide species-specific signals. Some of the minor components are part of the conspecific attractive message, whereas others may function also as antagonists to closely related sympatric species. *Autographa gamma* females seem to use a simple two-compartment blend consisting of Z7–12:Ac, the major sex pheromone component in most Plusiinae moths, and Z7–12:OH. Plusiinae males that respond, even partially, to Z7–12:Ac alone, and are not inhibited strongly by relatively small amounts of Z7–12:OH, may be attracted to a certain extent to the *A. gamma* sex pheromone blend. It seems that the Israeli *T. ni* males are less sensitive to the antagonistic effect of small amounts of Z7–12:OH (Dunkelblum and Mazor, unpublished) than the American *T. ni* males (Bjostad et al., 1984) and, therefore, they respond moderately to the *A. gamma* pheromone. Conversely, *A. gamma* males are sensitive to several Plusiinae minor sex pheromone components and their courtship behavior is inhibited strongly by some of the components emitted by the *T. ni* and *C. chalcites* females (Tables 2 and 4). The presence of specialist cells in the *A. gamma* male antenna for Z5–10:Ac, Z5–12:Ac and Z9–14:Ac (Priesner, 1980) indicates that the *A. gamma* males are able to detect these compounds despite the fact that they are not part of their conspecific sex pheromone. This phenomenon seems to be common among related species and explains the antagonistic effects we observed in the flight-tunnel experiments. The specificity of the male response results from the enhanced sensitivity to its conspecific pheromone blend and to the capability to perceive antagonistic components emitted by the closely related species.

(Received June 22, 1992; accepted August 19, 1992)

Abstract—Several Scandinavian forest insects, *Hylurgops palliatus*, *Tomicus piniperda*, and *Trypodendron domesticum* (Coleoptera: Scolytidae), *Rhizophagus ferrugineus* (Coleoptera: Rhizophagidae) and *Pollenia* spp. (Diptera: Calliphoridae) were attracted to window traps baited with ethanol and placed on Scots pine trees (*Pinus sylvestris*) in May–June, 1986. Release of ethanol at increasing relative rates of 0, 0.01, 0.1 and 1.0 (800 mg/day) from the window traps on trees in 1987 caused *H. palliatus*, *T. domesticum*, and *R. ferrugineus* to be increasingly attracted, while *T. piniperda* was equally attracted at both 0.1 and 1.0 rates. The attraction of *T. piniperda* to ethanol was weak compared to attraction to a monoterpene mix, (±)-α-pinene, (+)-3-carene, terpinolene. The terpene mix plus ethanol was significantly more attractive to *H. palliatus* than ethanol alone, but terpenes significantly reduced the attraction of *T. domesticum* to ethanol. Baiting of pipe traps with a series of short-chain alcohols (methanol to hexanol) each alone showed that ethanol was greatly preferred by *H. palliatus*, *T. domesticum*, and *R. ferrugineus* over alcohols of one more or one less carbon, while longer-chain alcohols were not attractive. However, *Glischrochilus hortensis* (Col.: Nitidulidae) was attracted only to propanol. A series of 10-fold increasing release rates of ethanol (0.0001–1.0, where 1.0 = 800 mg/day) with either a "low" or "high" release of the terpene mix had various effects on the sexes during their attraction to pipe traps and subsequent entering of holes. Release of (−)-verbenone at 0.25 mg/day had no significant effect on *H. palliatus* or *R. ferrugineus* attraction to ethanol, but the response of *T. domesticum* to ethanol was reduced. Several theories on olfactory mechanisms of host selection by *T. piniperda* are integrated and placed in ecological perspective.

INTRODUCTION

Bark beetles and associated beetles feeding on or living in trees must locate a suitable host from among the relatively few scattered widely in the forest during their dispersal from brood or hibernation sites. The host tree is restricted usually to one or a few species and in most cases the insects seek weakened, less-resistant trees, or trees that are in the initial stages of decay. Thus, it is expected that species have evolved behavioral responses to volatile host-plant chemicals that indicate the presence of a suitable host in which reproduction can occur. It is well known that ethanol, probably released by microorganisms in decaying woody tissue (Graham, 1968; Moeck, 1970; Cade et al., 1970) and stressed plants (Kimmerer and Kozlowski, 1982), is attractive to a wide variety of species of forest Coleoptera (Moeck, 1970, 1981; Kerck, 1972; Roling and Kearby, 1975; Magema et al., 1982; Montgomery and Wargo, 1983; Kohnle, 1985; Dunn et al., 1986; Klimetzek et al., 1986; Schroeder 1987, 1988; Schroeder and Eidmann, 1987; Witcosky et al., 1987; Atkinson et al., 1988; Phillips et al., 1988; Volz, 1988; Chénier and Philogène, 1989; Schroeder and Lindelöw, 1989). Similarly, various tree monoterpenes (e.g., α-pinene, myrcene, terpinolene, β-pinene) and turpentine are attractive to a large number of species (Fatzinger, 1985; Byers et al., 1985; Witcosky et al., 1987; Phillips et al., 1988; Schroeder, 1988; Chénier and Philogène, 1989; Schroeder and Lindelöw, 1989; Miller and Borden, 1990; Phillips, 1990). Synergism between ethanol and various monoterpenes (or turpentine) has also been widely reported (Nijholt and Schönherr, 1976; Kohnle, 1985; Tilles et al., 1986; Vité et al., 1986; Phillips et al., 1988; Volz, 1988; Schroeder, 1988; Chénier and Philogène, 1989; Schroeder and Lindelöw, 1989; Phillips, 1990). These compounds are not only important for primary attraction to plants but also may play a role in enhancing the bark beetles' response to aggregation pheromone (Bedard et al., 1969; Pitman et al., 1975; McLean and Borden, 1977; Borden et al., 1981; Paiva and Kiesel, 1985; Byers et al., 1988; Miller and Borden, 1990).

Bark beetle species that aggressively attack and kill living trees have been shown invariably to possess an aggregation pheromone, usually of two or more components, and are weakly, if at all, attracted by host volatiles (Byers, 1989). However, so-called "secondary" bark beetle species, those that colonize dying or decaying trees, less often use an aggregation pheromone, but generally are strongly attracted to host volatiles and ethanol (Kohnle, 1985; Klimetzek et al., 1986; Schroeder, 1988; Schroeder and Lindelöw, 1989). The pine shoot beetle, *Tomicus piniperda* (L.) (Scolytidae), sometimes kills living Scots pine (*Pinus*

sylvestris L.), but more often prefers recently fallen (still living) trees (Långström, 1984). Byers et al. (1985) used the subtractive-combination bioassay and fractionation method (Byers, 1992a) to rigorously identify the semiochemicals responsible for aggregation of *T. piniperda*. A combination of (−)-(*S*)-α-pinene, (+)-(*R*)-α-pinene, (+)-3-carene, and terpinolene, or each alone, was effective in attracting both sexes. During the isolation study, designed for detection of synergistic pheromone components, no evidence was found for beetle-produced compounds being attractive, in contrast to most bark beetles that aggregate en masse on hosts (Byers, 1989).

Following the paper of Byers et al. (1985), Vité et al. (1986) reported that ethanol plus two of the above monoterpenes (α-pinene and terpinolene) were about eight times more attractive than these terpenes to *T. piniperda*. Unfortunately, the release rates of neither the monoterpenes nor ethanol was reported. The activity of ethanol alone was also not determined. Earlier, Magema et al. (1982) had suggested ethanol is attractive to *T. piniperda*, although statistical evidence was lacking (and no release rates were given). However, the evidence of Vité et al. (1986) that ethanol could play a role in aggregation of *T. piniperda* is not in conflict with Byers et al. (1985), since the latter study used Porapak Q to collect organic volatiles, and this adsorbent is inefficient with small molecules like ethanol. In apparent contrast to the ethanol–monoterpene synergism reported by Vité et al. (1986), Klimetzek et al. (1986) tested different release rates of ethanol (24–125 mg/day) with an unreported release rate of α-pinene and terpinolene and found that the higher releases of ethanol inhibited attraction of *T. piniperda*. However, a control with ethanol alone, or terpenes alone, was not reported. Two other studies, also in seeming contrast to Vité et al. (1986), showed that ethanol at higher rates inhibited attraction of *T. piniperda* to α-pinene (Schroeder, 1988; Schroeder and Lindelöw, 1989).

Vité et al. (1986) proposed that ethanol in combination with monoterpenes are used by *T. piniperda* to locate diseased, and therefore susceptible host trees. Since chemical release rates in their study were not measured, and it is not known how much ethanol is released from diseased trees, this hypothesis remained in doubt. A way to probe the question is to assume that monoterpene releases from healthy trees are similar to diseased trees, but that ethanol releases are higher from the latter. Then, by placing ethanol on healthy trees, these trees will appear diseased and should attract more *T. piniperda*.

The objectives of the present study concerning *T. piniperda* were to determine: (1) whether ethanol is attractive when placed on standing Scots pine; (2) the relative attractiveness of ethanol, a more complete blend of monoterpenes alone, or a combination of monoterpenes with ethanol; and (3) the relative attractancy of various short-chain primary alcohols (C_1–C_6) and ethylene glycol. The attraction of other scolytids and associated fauna was also monitored. In addition, the attraction of *Hylurgops palliatus* (Gyll.) and *Trypodendron domes-*

ticum (L.), among other beetles, to ethanol alone, (−)-(*S*)-verbenone alone, or both in combination was tested. Verbenone also was tested with ethanol since the former compound is released as Scots pine logs age and has been shown to inhibit the attraction of *T. piniperda* to host volatiles (Byers et al., 1989).

METHODS AND MATERIALS

Both the window/barrier trap type (Byers et al., 1989) and the pipe trap with funnel (Bakke et al., 1983; Byers et al., 1988) were used for testing semiochemicals. The pipe trap can reveal behavioral differences between the sexes as they orient to the attractant source since the trap collects beetles in two bottles (wire screen bottoms), as they bounce off the pipe barrier into a large 33-cm-diameter funnel, and as they enter any of the 900 holes in the pipe.

Window traps of transparent plastic (17 × 35 cm high) with funnel and collection bottle were wired to Scots pine trees (about 25–35 cm DBH) at 2 m height (all experiments in a pine plantation, Sjöbo, southern Sweden). The traps on trees were spaced 90 m apart in two parallel lines 90 m apart. Ethanol was released from two open, plastic-vial dispensers per trap (total 800 mg/day) from 13 traps while 13 traps were unbaited controls. Collections of insects were done five times. The plastic vial dispensers (730 type, Kartell Inc., Italy) were made of polyethylene (0.6 cm diam. × 3 cm). Treatments were assigned at random and remained stationary during the test (April 29–May 12, 1986). A second test in 1987 (April 24–May 6) used the same traps and general methods; 11 traps/tree each were baited with either 0 (unbaited), 0.01, 0.1, or 1.0 ethanol release rates (1.0 equivalent to 800 mg/day). The diffusion-dilution method was used (Byers, 1988) to dilute ethanol with water based on mole percentages to obtain the desired rates.

A comparison of the relative attraction rates of ethanol alone (800 mg/day), the same dose plus a monoterpene mix, and the monoterpene mix alone was done using pipe traps with funnel (April 29–May 12, 1986). The monoterpene mix consisted of several monoterpenes and release rates: terpinolene (>97.3% GLC, Carl Roth KG) at 2.5 mg/day, (+)-3-carene (> 99%, $[\alpha]_D^{20} = 17°$) at 6 mg/day, and (−)-α-pinene (99%, $[\alpha]_{546}^{20} = 50°$) and (+)-α-pinene (99.5%, $[\alpha]_{546}^{20} = 57°$) each at 14 mg/day (Fluka AG). Each of the monoterpenes was placed in two plastic vial dispensers with 200 μl neat compound each, and all were placed inside the pipe. The three traps per treatments were placed 10 m apart in a line and were replicated in three areas on four dates for a total of 12 replicates. Baits were randomized after each test day.

In 1987 (April 23–May 11), two release rates of the above monoterpene mix, one at the same or "high" release rate and a "low" rate of about 3.3% that of the high rate (based on 3-cm-long tubes with an opening 3.3% that of

the dispenser above), were tested alone and in combination with a series of 10-fold increased release rates of ethanol: 0.0001, 0.001, 0.01, 0.1, and 1.0. Diffusion–dilution was again used to dilute the ethanol appropriately with water. Twelve pipe traps with funnel, six for each series, were placed in one line with traps 10 m apart. Treatments were randomized after each collection (once or twice a day) for a total of 15 replicates. In another test, eight pipe traps were baited with a series of increasing length primary alcohols (methanol, ethanol, propanol, butanol, pentanol, and hexanol) and ethylene glycol plus an unbaited trap. Exponential regression was used on vapor pressure statistics (Weast, 1971) for the primary alcohols to predict the tube opening diameters necessary to approximate the same release as the standard 1.0 ethanol rate (800 mg/day). Thus, methanol was released from one dispenser, ethanol from two, propanol from three, and butanol from seven, pentanol from 20, and hexanol from 35. For ethylene glycol, a glass container with an opening about 137 times that for methanol was used to obtain an equivalent rate of release.

The effects of verbenone on attraction of insects to ethanol was tested in 1987 (April 23–May 11) in two areas with tree traps each spaced 10 m apart in a line. The trap consisted of two window traps placed back-to-back at 1.2 m height on a metal pole. Ethanol was released at 800 mg/day from two of the traps, one of these also had two dispensers of (−)-verbenone releasing 0.25 mg/day (>99%, $[\alpha]_D^{20} = -246°$, 99.2% ee, Bedoukian). The third trap released only (−)-verbenone.

RESULTS

Window Traps Baited with Ethanol on Scots Pine Trees. Three species of bark beetle, *Tomicus piniperda*, *Hylurgops palliatus*, and *Trypodendron domesticum* were caught in the ethanol-baited window traps placed on the Scots pine trees (Table 1). The beetle *Rhizophagus ferrugineus* Payk. (Coleoptera: Rhizophagidae) and several cluster flies, *Pollenia* spp. (Diptera: Calliphoridae), were also caught only on the ethanol baited traps. Catches were relatively low in 1986 and not all of the 65 trap replicates caught insects, so use of conventional statistical tests for comparing catches was inappropriate. However, a chi-square test comparing the proportions of traps catching to those that caught none was used to compare the baits within a species between release rates. Using this method, all species above were significantly attracted to ethanol-baited traps on trees (Table 1). In 1987 a similar experiment had window traps on trees baited with either 0, 0.01, 0.1 or 1.0 ethanol equivalent (800 mg/day), and again the three bark beetle species and *R. ferrugineus* were principally caught on higher release rates of ethanol (Figure 1, Table 2). *H. palliatus* and *T. domesticum* were significantly attracted to relative rates of 0.01 ethanol and higher on the

Attraction of Forest Beetles to a Series of Primary Alcohols. In the series of increasing length primary alcohols, only methanol, ethanol, and propanol caught insects (Figure 2). There appeared to be a subtle shift in the response spectrum of the species, in which *H. palliatus* preferred ethanol but sometimes was attracted to propanol, *T. domesticum* restricted its response to ethanol, *R. ferrugineus* also preferred ethanol but would orient to methanol, while *Glis-*

chrochilus hortensis Fourcroy was caught only on propanol (Figure 2). No insects were caught on butanol, pentanol, hexanol, ethylene glycol, or in the unbaited pipe trap.

Attraction of Forest Insects to Monoterpenes and Ethanol. The catches of the above beetle species and others on pipe traps baited with either ethanol (800 mg/day), monoterpenes mix (see methods), or both are shown in Table 3.

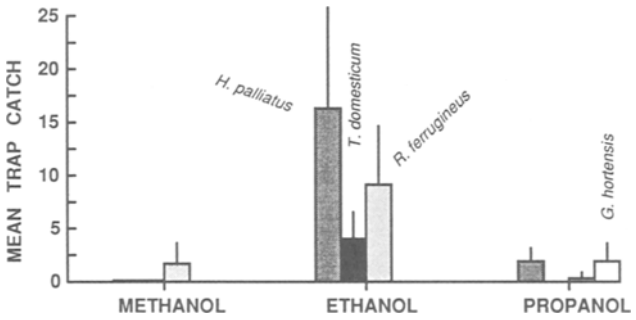

FIG. 2. Catch of *Hylurgops palliatus*, *Trypodendron domesticum*, *Rhizophagus ferrugineus*, and *Glischrochilus hortensis* attracted to pipe traps with funnel releasing either methanol, ethanol, or propanol at similar rates (about 800 mg/day; April 23–30, 1987, Sjöbo, Sweden). Bars represent 95% confidence limits ($N = 9$). Traps with either butanol, pentanol, hexanol, ethylene glycol, or unbaited caught no insects.

TABLE 3. CATCHES (MALE–FEMALE) OF VARIOUS FOREST COLEOPTERA ATTRACTED TO PIPE TRAPS WITH FUNNEL AND BAITED WITH EITHER ETHANOL (800 mg/day), MONOTERPENES (SEE TEXT), OR BOTH (APRIL 29–MAY 12, 1986, SJÖBO, SWEDEN)

	Total catch (male:female)

[a] *Hylurgops palliatus*, *Trypodendron domesticum*, *Tomicus piniperda*, *Rhizophagus ferrugineus*, *Glischrochilus quadripunctatus*, *Hylastes ater*, and *Hylobius abietis*.

Wilcoxon signed-rank tests indicated a synergism of ethanol and monoterpenes in attraction of *H. palliatus* ($P < 0.01$, $N = 10$). The attraction of *T. domesticum* to ethanol was inhibited by the monoterpenes ($P < 0.001$, $N = 12$). *T. piniperda* was not attracted to ethanol but was caught on the terpene baits ($P < 0.01$, $N = 10$).

A second test with pipe traps in 1987 attempted to determine the effect of increasing release rates of ethanol combined with two release rates of the monoterpene mix, either a "high" rate or a "low" rate (3.3% of the high rate). At the higher monoterpene release rate, the attraction of *T. piniperda* was apparently unaffected by increasing release rates of ethanol over the ranges tested (Figure 3A). However, at the lower monoterpene release rate, the attraction of *T. piniperda* increased when ethanol rates increased from 0.01 to 1.0 (Figure 3A, the 1.0 rate was significantly different from the 0.01 rate, Wilcoxon test,

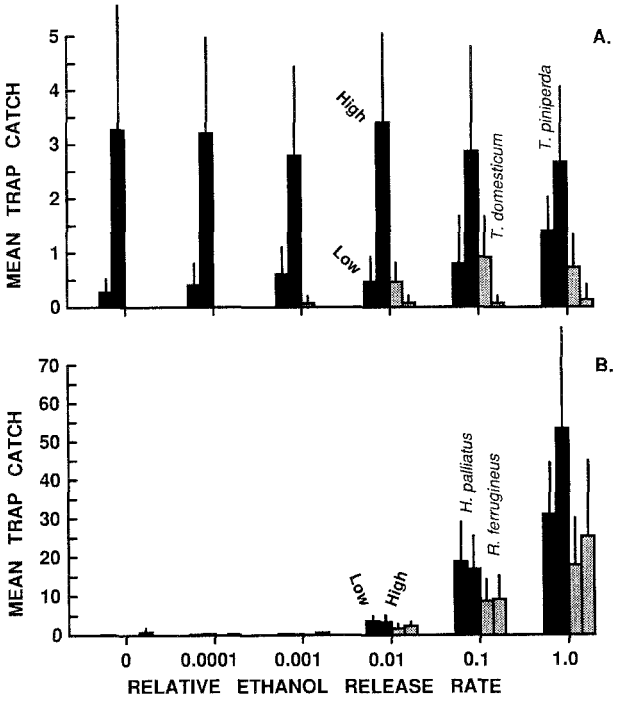

FIG. 3. (A) Catch of *Tomicus piniperda* and *Trypodendron domesticum* attracted to pipe traps with funnel releasing monoterpenes [terpinolene, (+)-3-carene, and (+)- and (−)-α-pinene] at either a "low" or "high" rate (see text) with various relative rates of ethanol (1.0 dose equivalent to 800 mg/day). (B) Catch of *Hylurgops palliatus* and *Rhizophagus ferrugineus* attracted to the same pipe traps (April 23–30, 1987, Sjöbo, Sweden). Bars represent 95% confidence limits ($N = 15$).

$N = 12$, $P < 0.05$). *T. domesticum* response increased with ethanol rates from 0.001 to 1.0 at the low monoterpene rate but remained low at the high monoterpene rate (Figure 3A), consistent with the inhibition by monoterpenes in earlier tests (Table 3). The attraction of *H. palliatus* and *R. ferrugineus* increased with ethanol rates from 0.01 to 1.0 at both the low and high monoterpene releases (Figure 3B). Although not significant, the higher rate of monoterpenes caught more *H. palliatus* at the highest ethanol release.

In the above test, beetles were collected in the outer large funnel or after they entered one of the 900 holes in the pipe. The percentage of *R. ferrugineus* entering holes was about twice as much as for *H. palliatus* at higher ethanol release rates regardless of monoterpene rate (Figure 4A). However, at the high monoterpene rate, both species increased their entering of holes as the ethanol rate was increased, but not at the low monoterpene rate (Figure 4A). At the

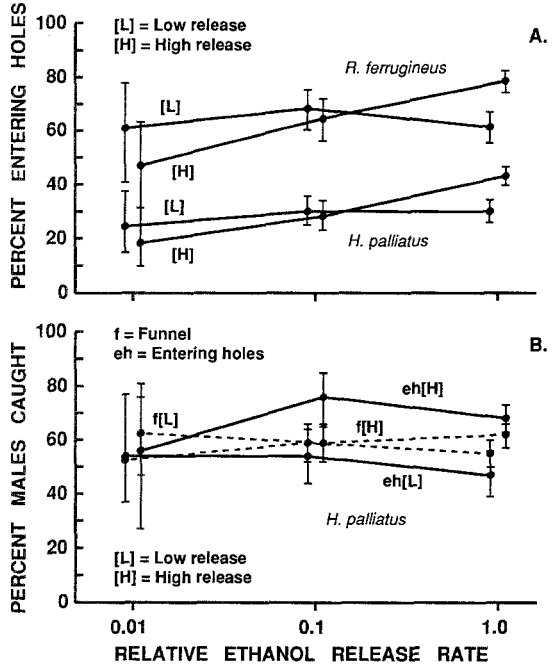

FIG. 4. (A) Percentage of *Hylurgops palliatus* and *Rhizophagus ferrugineus* entering holes in pipe traps with funnels that released monoterpenes [terpinolene, (+)-3-carene, and (+)- and (−)-α-pinene] at either "low" or "high" rates (see text) with various relative rates of ethanol (1.0 dose equivalent to 800 mg/day). (B) Male percentages of *Hylurgops palliatus* caught in the funnels or caught after entering holes in pipe traps as in Figure 4A (April 23–30, 1987, Sjöbo, Sweden). Bars with brackets represent 95% binomial confidence intervals for proportions.

higher ethanol rates (0.1 and 1.0) with monoterpenes, the percentage of males of *H. palliatus* that entered holes was significantly higher at the high monoterpene rate than at the low monoterpene rate (Figure 4B).

Effect of (−)-Verbenone on Attraction of Beetles to Ethanol. Window traps (back-to-back) baited with ethanol caught, as expected, *H. palliatus*, *T. domesticum*, and *R. ferrugineus* (Table 4). *T. piniperda* was not caught, consistent with its nonresponse to ethanol baits in Table 3. The addition of (−)-verbenone to ethanol did not decrease the attraction of *H. palliatus* but the response of *T. domesticum* was significantly reduced (Table 4). Fourteen *Rhinosimus planirostris* Fbr. (Coleoptera: Salpingidae) were caught on baits with ethanol (compared to none on verbenone). The pollen beetle, *Meligethes aeneus* Fbr.

TABLE 4. CATCH OF VARIOUS FOREST COLEOPTERA ATTRACTED TO WINDOW TRAPS (BACK-TO-BACK) BAITED WITH ETHANOL (800 mg/day), (−)-VERBENONE (0.25 mg/day), OR BOTH (APRIL 23–MAY 11, 1987, SJÖBO, SWEDEN)

Species[a]	Catch				Catch range	Percent of traps catching[b]
	Male	Female	Male proportion	95% BCL		
Ethanol						
H. palliatus	46	33	0.58	0.47–0.68	0–9	90

[a] *Hylurgops palliatus*, *Trypodendron domesticum*, *Rhizophagus ferrugineus*, *Meligethes aeneus*, and *Glischrochilus quadripunctatus*.
[b] $N = 20$ trap replicates for each treatment.
[c] Assumes equal sex ratio.
[d] Wilcoxon signed-rank tests indicated catch was different from that on ethanol alone ($P < 0.05$).

(Coleoptera: Nitidulidae), an important pest of oilseed rape (*Brassica napus*) was attracted to baits with verbenone (Table 4). No other insects were attracted to verbenone.

DISCUSSION

Primary alcohols other than ethanol have not been reported as being attractive to scolytids. However, only a few studies have tested methanol (Moeck, 1970; Montgomery and Wargo, 1983), while longer-chain alcohols were not investigated. It might be considered surprising that methanol (wood alcohol) had little activity (Figure 2). The fact that ethanol is a common by-product of glycolysis while methanol is not probably explains the evolution of the use of ethanol by forest insects. Moeck (1970) found methanol to be a minor constituent and ethanol a major constituent of extracts from Douglas-fir sapwood attractive to *Trypodendron lineatum*. Although *Tomicus piniperda* was not attracted by ethanol alone, the beetle was attracted when ethanol was placed on trees (Table 1, Figure 1) or combined with monoterpenes (Figure 3). Schroeder and Eidmann (1987) baited Scots pine trees with ethanol (1800 mg/day) and induced attacks by *T. piniperda*. Electroantennogram (EAG) responses of *T. piniperda* to a series of straight-chain alcohols indicated that the antennae respond increasingly with longer chain length, up to a maximum between pentanol and heptanol and then decrease (Lanne et al., 1987). The response spectrum can be due in part to differences in volatility. Thus, although ethanol plays a role in host selection (discussed subsequently), the EAG for ethanol is lower than for longer-chain alcohols (which probably are not involved in behavior). The attraction of the occasional crop pest *Glischrochilus hortensis* (Nitidulidae) (Alford, 1976) to propanol (Figure 2) is unusual since few insects are attracted to propanol. For example, in addition to the report here, only two nitidulid species in the genus *Carpophilus* are reported to be attracted to propanol in the Coleoptera (Lin and Phelan, 1991; Dowd and Bartelt, 1991).

Verbenone inhibited the response of *Trypodendron domesticum* but not *Hylurgops palliatus* to ethanol (Table 4). Response to ethanol by *T. domesticum* was also inhibited by the monoterpene mix, (±)-α-pinene, (+)-3-carene, and terpinolene, while the response of *H. palliatus* was enhanced (Table 3). α-Pinene has been shown earlier to inhibit *T. domesticum* response to an attractive bait of ethanol plus lineatin (Paiva and Kiesel, 1985), and Norway spruce resin or α-pinene has been shown to enhance response of *H. palliatus* to ethanol (Kohnle, 1985; Schroeder and Lindelöw, 1989). Verbenone has been shown to be increasingly released from aging Scots pine logs (Byers et al., 1989). *H. palliatus* is a "secondary" colonizing species and prefers moribund trees, hence the attraction to ethanol and insensitivity to verbenone. *T. domesticum* does not

feed in Scots pine but colonizes deciduous trees (in the study area: *Fagus sylvatica*, *Quercus* spp. *Betula* spp.) and is known to be attracted to ethanol (Magema et al., 1982; Paiva and Kiesel, 1985). Thus, conifer monoterpenes and verbenone (from decaying conifers) that are repellent would provide a mechanism for avoiding unsuitable colonization areas.

Verbenone is found in hindguts of the important pest bark beetles of the United States, *Dendroctonus frontalis* and *D. brevicomis* (Renwick and Vité, 1968), and the compound inhibited response of both beetles to their pheromone (Renwick and Vité, 1969, 1970). Verbenone from *D. brevicomis* was later shown to inhibit aggregation response of *Ips paraconfusus* to natural and synthetic pheromone (Byers and Wood, 1980), and verbenone inhibited *I. typographus* response to synthetic pheromone components (Bakke, 1981). A third genus of bark beetles was added to the list when *T. piniperda* response to the monoterpene mix above was inhibited (Byers et al., 1989). This led Byers (1989) to speculate that verbenone, as a consistent signal of microbial activity in decaying hosts, would be used by bark beetles earlier in evolution as a kairomone to avoid less suitable hosts and then subsequently serve additionally as a pheromone to reduce intraspecific competition and/or as an allomone to reduce interspecific competition. Verbenone production in beetles would coevolve in several species since the same chemical could serve as the signal for all three types of beneficial information. Recently, verbenone was found to inhibit the aggregation pheromone response of another important pest bark beetle of Europe, *Pityogenes chalcographus* (Byers, 1992b).

The attraction of *H. palliatus*, *T. domesticum*, *Glischrochilus quadripunctatus* L., and *Rhizophagus ferrugineus* to ethanol alone, with monoterpenes, and on trees (Tables 1–4, Figures 1–3) is consistent with earlier reports (Moeck, 1970; Nijholt and Schönherr, 1976; Magema et al., 1982; Kohnle, 1985; Paiva and Kiesel, 1985; Klimetzek et al., 1986; Schroeder, 1988; Volz, 1988; Schroeder and Lindelöw, 1989). The attraction of the cluster fly, *Pollenia rudis* (and related species above, Table 1), to ethanol was unexpected since this fly parasitizes earthworms (Thomson, 1973). However, it has been caught at baits with meat (Steinborn, 1981), where ethanol was probably released due to fermentation. Both sexes of *Pollenia* species may respond to ethanol, indicating food sources, but more males may have been caught due to their more extensive foraging patterns (typical of flies in Muscidae and Calliphoridae). Only one other report has proven ethanol, from fermenting sugar, attractive to pest flies in the genera *Musca*, *Muscina*, and *Fannia* (Hwang et al., 1978).

An explanation for the higher percentage of both *H. palliatus* and *R. ferrugineus* entering the holes in the pipe trap at the higher release rate of monoterpenes with the highest ethanol release is that the ratio of monoterpenes to ethanol may be closer to the natural ratio and indicates an appropriate host (Figure 4A). Host-tree compounds, monoterpenes and ethanol, elicited increased

entering rates of bark beetles *T. lineatum* and *P. chalcographus* into pipe traps baited with aggregation pheromone (Vité and Bakke, 1979; Bakke, 1983; Byers et al., 1988). The relatively large differences between the species in entering holes may not be due only to behavioral differences, but also to the fact that *H. palliatus* is easier to catch in the funnels than *R. ferrugineus*. The differences between the sexes of *H. palliatus* in entering holes at the high monoterpene release and higher ethanol releases (Figure 4B) are difficult to explain without more experiments and a deeper understanding of the biology.

The main purpose of the present experiments was to investigate the role of ethanol, in conjunction with monoterpenes, in the location of suitable hosts by *T. piniperda*. Byers et al. (1985) quantified the release rates of α-pinene, terpinolene, and 3-carene from a freshly cut log of Scots pine (28 cm $\times$ 13 cm diam.) and found them each to be about 15 mg/day (terpinolene somewhat less). Release of these amounts in the field competed favorably with a host log in attracting *T. piniperda*. Byers et al. (1985) theorized that since healthy trees were not expected to release appreciable amounts of these monoterpenes compared to broken tops and storm-felled trees where oleoresin wounds are numerous, the aggregation response to monoterpenes functioned in the beetle's recognition of both host species (other trees have less monoterpenes) and host susceptibility to colonization (wounded trees have less capacity to produce more oleoresin for defense).

Vité et al. (1986) presented evidence that ethanol enhanced the attraction of *T. piniperda* to α-pinene and terpinolene by about eight times, but as stated above chemical release rates were not given, making it difficult to replicate the results. They proposed that "contrary to" the theory of Byers et al. (1985) "we present evidence that aggregation and olfactory recognition of susceptible host material depends on the synergism between monoterpenes and ethanol." However, since ethanol release from aging Scots pine has not been quantified, there is some doubt to the validity of the theory. The two theories are not mutually exclusive, however. One way to test the hypothesis of Vité et al. (1986) would be to place ethanol baits on healthy trees as was done here (Table 1, Figure 1). The attraction of *T. piniperda* to these traps on trees (Table 1, Figure 1) supports the hypothesis. Schroeder and Eidmann (1987) also found that trees baited with ethanol (or each of the monoterpenes) were attacked by *T. piniperda*. Vité et al. (1986) did not test ethanol alone, but it has very little activity alone (Table 3, and none caught in Table 4 and Figure 2), a finding also made by Schroeder (1988) and Schroeder and Lindelöw (1989).

Klimetzek et al. (1986) "qualified" the ethanol–monoterpene synergism theory when they reported that increasing ethanol release rates from 24 to 120 mg/day reduced the response of *T. piniperda* to a mixture of racemic α-pinene and terpinolene. Since monoterpenes alone were not tested, it was not possible to confirm the synergism of ethanol and monoterpenes. In fact, the decline in

response did not support the theory that ethanol played a role in selection of susceptible hosts. Schroeder (1988) also attempted to confirm the theory of Vité et al. (1986) by increasing the release of ethanol in five steps over an even wider range from 0 to 50 g/day in combination with a 10 mg/day release of α-pinene. The attraction of *T. piniperda* linearly declined with the logarithm of ethanol release, supporting Klimetzek et al. (1986) but not Vité et al. (1986).

Schroeder and Lindelöw (1989) provided evidence that could explain the discrepancies between the above results. In their Figure 1 for *T. piniperda* it can be seen that a high release of α-pinene was most attractive to the beetle and that ethanol releases from 0 to 3 g/day had little, if any, effect on the attraction. Ethanol released at even higher rates, 120 mg/day (Klimetzek et al., 1986) or 50 g/day (Schroeder, 1988), would inhibit the response to monoterpenes. However, at a low release rate of monoterpene (2.4 or 22 mg/day), the lower releases of ethanol from 0 to 3 g/day had a synergistic effect on the weak response (Schroeder and Lindelöw, 1989). These latter results are similar to those found here (Figure 3B). Therefore, the beetle could find diseased, but physically uninjured, trees by a weak response to a synergism between low monoterpene release rates and moderate ethanol rates—the hypothesis of Vité et al. (1986). These trees would be tested occasionally by beetles and, if low in resistance, this would permit beetles to continue feeding. Resinosis and monoterpene release would elicit increased numbers joining in a mass-attack. Injured trees with wound oleoresin, and trees under attack with "pitch tubes," would have a higher monoterpene release and attract the most beetles, a scenario in line with the hypothesis of Byers et al. (1985). Trees with high ethanol release rates would indicate a tree in advanced decay and unsuitable for reproduction, thus to be avoided, as in the hypothesis of Klimetzek et al. (1986) (high monoterpenes releases would normally not occur with high ethanol rates). In addition, verbenone from decaying hosts would inhibit response to monoterpenes (Byers et al., 1989). Measurements of ethanol and monoterpene release rates from various host and nonhost substrates would be of interest and are necessary for further integration and refinement of these ecological perspectives.

Acknowledgments—Funding for the project was obtained in part from the Swedish Forest and Agricultural Research Council (SJFR). I thank colleagues and staff here in Sweden for support. The species of *Pollenia* were determined by H. Andersson, Swedish Museum of Natural History, c/o Department of Systematic Zoology, Lund University.

Herbivores: Their Interactions with Secondary Plant Metabolites—Volume 2. Ecological and Evolutionary Processes, 2nd ed. Edited by G.A. Rosenthal and M.R. Berenbaum (eds.). San Diego: Academic Press, 1992. 493 pp.

The first edition of *Herbivores: Their Interaction with Secondary Plant Metabolites*, edited by G.A. Rosenthal and D.H. Janzen, played a major role in providing a conceptual framework for studying the chemical ecology of plant–herbivore interactions. In 1979, when the first edition was published, the study of plant–herbivore interactions was in a rapid stage of growth and change, and it was inevitable that *Herbivores* would be out-of-date very quickly. A revised second edition, edited by G.A. Rosenthal and M.R. Berenbaum, has now appeared. The second edition is a two-volume set, with the first volume, *The Chemical Participants*, corresponding to Part II of the first edition, and the second volume, *Ecological and Evolutionary Processes*, corresponding to part I of the first edition. A review of Volume 1 has already appeared in this journal (Martin, Volume 18, Number 6, pp. 929–930, 1992).

Volume 2 contains 493 pages divided into twelve chapters, which compares with 350 pages divided into eight chapters in Part I of the first edition. The chapter titles in the second edition are: The Evolution of Chemical Ecology (P. Feeny), Behavioral Responses of Insects to Plant Secondary Plant Compounds (E. Städler), How Animals Perceive Secondary Plant Compounds (J.L. Frazier), Allelochemical–Nutrient Interactions in Herbivore Nutritional Ecology (F. Slansky, Jr.), Metabolic Defenses against Plant Allelochemicals (L.B. Brattsten), Third Trophic Level Influences of Plant Allelochemicals (M. Rowell-Rahier and J.M. Pasteels), Microbial Mediation of Plant–Herbivore Ecology (P.L. Phelan and B.R. Stinner), Phototoxins in Plant–Insect Interactions (J.T. Arnason, B.J.R. Philogène, and G.H.N. Towers), Woody Plant–Mammal Interactions (J.P. Bryant, P.B. Reichardt, T.P. Clausen, F.D. Provenza, and P.J. Kuropat), The Chemical Ecology of Plant–Herbivore Interactions in Marine versus Terrestrial Communities (M.E. Hay and P.D. Steinberg), Genetics of Secondary Metabolism and Herbivore Resistance in Plants (M.R. Berenbaum and A.R. Zangerl), and Evolution and Coevolution of Plants and Phytophagous Arthropods (D.J. Futuyma and M.C. Keese). The individual chapters are uniformly well written, with bibliographies that include numerous references to articles published in 1989, 1990, and 1991.

As the editors state in the Preface, Volume 2 is "more of a sequel than a

second edition—little of the subject material overlaps with the first edition." Of the 23 contributors to Volume 2 of the second edition, only one had a chapter in Part I of the first edition. Only three of the chapters in this volume have counterparts in the earlier version. Most of the new chapters in this volume fall into two broad categories: those that review the successful extension of the approaches used to study the chemical ecology of plant–insect interactions in terrestrial systems into new areas (e.g., three trophic level interactions, microbial mediation of plant–herbivore interactions, phototoxins, marine systems, and mammalian herbivory) and those that describe progress in areas that are crucial to the development of general principles that underlie plant–herbivore interactions (e.g., behavior, chemosensory physiology, the interactions of nutrients with allelochemicals, detoxification, the genetics of plant–herbivore interactions, and coevolutionary theory).

The opening chapter by Feeny falls into a category all its own. Feeny traces the roots of the various themes of contemporary research in the chemical ecology of plant–herbivore interactions (e.g., host specificity, food utilization, plant toxicity, chemical defense, and phytochemistry) to seminal papers dating from the 1800s through the first half of this century. He then recounts the explosion of the field in the 1960s and 1970s following the publication of a series of landmark papers by Dethier, Fraenkel, Gordon, Kennedy, Mittler, Self, Thorsteinson and a few others in the 1950s and early 1960s. Next he cites recent influential papers that exemplify current thinking in the field, and concludes by identifying some important issues that remain unresolved. This remarkable chapter is high-quality intellectual history, and it is fascinating reading.

It follows from Feeny's account that although the study of the influence of secondary plant metabolites on the ecology and evolution of plant–herbivore interactions may be a relatively new field, it is no longer a discipline in its infancy. It had a juvenile phase that ended sometime in the 1960s, followed by an adolescent phase that lasted about 20 years. Sometime in the 1980s it achieved maturity. The second edition of *Herbivores* reflects this maturity. The great contribution of the new edition is to present an important and vigorous subdiscipline within ecology that has both breadth and depth, and to show how the study of plant–herbivore interactions is influencing other areas of biology as much as its is being influenced by them. In revising *Herbivores*, the editors have produced an outstanding work that, for years to come, will serve both students new to the field and researchers already active in the field. Profs. Rosenthal and Berenbaum have surely done their part to "insure that the discipline continues to flourish in the next century."
