For catalyzed reduction, an aliquot of enriched kairomone was evaporated to dryness and resuspended in 2 ml of methanol. For platinum-catalyzed reduction with hydrogen, 100 mg of PtO_2 was added, and the solution was stirred for 6 hr under hydrogen. Reduction with $NaBH_4$ was performed by adding 100 mg of the hydride to the resuspended sample, which was then gently stirred for 6 hr in a sealed microvial. After reduction with either Pt/H_2 or $NaBH_4$, the catalyst was removed by centrifugation; the supernatant was evaporated to dryness and resuspended in ultrapure water.

Kairomone enriched by C18-SPE from 20 ml of holding water was subjected to reversed-phase HPLC on a 250-mm × 4.6-mm column packed with Biosil (C18, 5 μm, Biorad) by a linear gradient of ultrapure water and methanol (0 min: 0%; 3 min: 0%; 28 min: 100%; 36 min: 100% methanol) at a flow

rate of 1 mL/min. Fractions of 4 ml were collected, evaporated, and tested for biological activity.

RESULTS

Lipophilic Nature of Kairomone. Aliquots of holding water from *Leucaspius delineatus* were adjusted to pH values ranging from 0 to 12 with equal increments of 1 pH unit and extracted with diethyl ether. In all treatments activity remained in the aqueous layer, indicating low lipophilicity of the cue at any pH. Despite its low lipophilicity, the activity could be enriched quantitatively from water by lipophilic sorbents (Table 1). There was complete removal of activity by nonpolar sorbents and full recovery from the sorbents could be achieved by eluting with methanol. The phenyl cartridge, which more selectively interacts with aromatic molecules, showed retention abilities similar to those of the C18 and the C8 cartridges, so that an aromatic chemical nature of the cue can not be excluded. Subsequently we used C18 cartridges as the standard method to enrich the DVM-inducing activity from holding water of fish.

Interactions with Ion Exchange Resins. The hydrophilicity of the kairomone exuded from *Leucaspius delineatus* might be due to polar ionic or nonionic groups. In order to test for ionic groups, enriched activity from *L. delineatus* was passed through different ion exchange cartridges at different pH values. The

kairomone was not retained by the cation-exchange resin at acidic or neutral pH values (Table 2). Hence no cationic groups are present in the cue. The cue was removed by a weak anion-exchange resin (Table 2). The pH values in the 2.5–7.5 range did not influence the interaction with the weak anion exchanger (Table 2), which indicates that it is not a carboxyl group that makes the kairomone an anion.

In order to investigate the nature of the interactions of the kairomone with the strong anion exchanger, an activity-loaded strong anion exchanger was sequentially developed with methanol and increasing salinity (Table 3). Lipophilic adsorption of the kairomone to the polypropylene wall of the cartridge would have resulted in an active methanol fraction, but only the 0.5 M NaCl eluate was active, indicating that the retention of the cue was due to its anionic character.

Chemical Derivatization. Characterization of functional groups essential for activity was attempted by chemical derivatization prior to biotesting. C18-SPE-enriched kairomone from *Leucaspius delineatus* was not destroyed by saponification (Table 4), which excludes esters as an essential constituent of the biological activity. Activity was inactivated by base-catalyzed acetylation (Table 4), but full biological activity was recovered after subsequent saponification. Thus the cue was not damaged by the chemical procedure itself, but a functional group that could be acetylated was essential for biological activity. To gain further information about the functional group, agents that more specifically

acetylated primary and secondary amino groups were tested. No loss of activity was found after derivatization with fluorescamine, *o*-phthaldialdehyde, or FMOC, which showed that the loss of activity after unspecific acetylation was not due to an amino group.

Neither reduction with Pt/H_2 nor with $NaBH_4$ resulted in reduced activity (Table 4). Thus, neither a carbonyl group nor olefinic double bonds are essential for biological activity.

Chemical Comparison of Kairomones from Different Cyprinid Species. When the kairomone released by *Leucaspius delineatus* was compared chemically with those of two different cyprinid species (*Carassius carrassius* and *Rutilus rutilus*), no differences were found (Table 5) with regard to retention by C18-SPE, anion exchanger, and reversible inactivation by acetylation. When an aliquot of C18-enriched kairomone from the three cyprinid species was subjected to HPLC on a linear water–methanol gradient and fractions were tested for induction of DVM, activity was confined to the same fraction in all three cases (Figure 1). The activity of the active HPLC fraction matched that of the aliquot prior to HPLC, indicating that total activity was recovered.

DISCUSSION

Many species of planktivorous fish are known to exude a chemical cue inducing DVM in *Daphnia*. First attempts to chemically characterize the kairomone released by *Leucaspius delineatus* showed that it is a water-soluble, low-molecular-weight compound (< 500 daltons), which is stable to extreme pH and temperature (Loose et al., 1993). On the basis of those results we devised a method for enriching the kairomone from the holding water of fish by solid-phase extraction (SPE). The cue was quantitatively removed from the holding water of fish by SPE, both with weakly (phenyl, C8) and with strongly lipophilic (C18) resins. Nevertheless hydrophilic groups are present in the kairomone rendering it not extractable by diethyl ether at any pH.

An anionic side group, which is not a carboxyl group, contributes to the

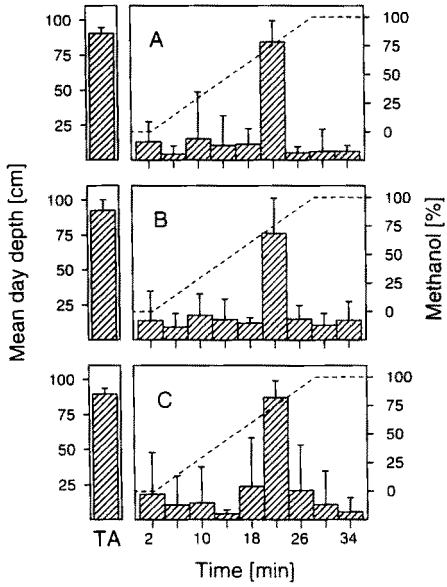

FIG. 1. Reversed-phase HPLC of enriched kairomones from different cyprinid fish species. Bars indicate biological activity (error bars: 95% CI, $N = 5$). The broken line indicates the methanol gradient. TA: total activity prior to HPLC. Fractionation of TA from A: *Leucaspius delineatus*, B: *Carassius carassius*, C: *Rutilus rutilus*. HPLC of kairomones from the three species yields one active fraction with identical retention times. Main activity of the HPLC matches total activity.

hydrophilic character of the cue. Additional nonionic hydrophilic groups are part of the kairomone, as can be concluded from the reversible inactivation by acetylation, indicating the presence of hydroxyl, amino, or thiol groups (Knapp, 1979) that are essential for activity. The presence of amino groups is ruled out since agents selectively blocking primary and secondary amino groups did not inactivate the cue. These findings are supported by the lack of interactions with a strong cation exchange resin at neutral and acidic pH, as would be expected for a protonated amino group. Hence, it is probably a hydroxyl group that is essential for activity. As a nonionic group, it also contributes under in situ conditions of pH 8–10 to the hydrophilic character of the kairomone.

The kairomone released by *Leucaspius delineatus* is of low-molecular weight and intermediate lipophilicity and can be reversibly inactivated by acetylation. Amino groups are not part of the molecule, and neither olefinic and ester bonds nor aldehyde and keto groups are essential for biological activity. The nonvolatile, anionic nature of the DVM-inducing chemical released by

L. delineatus ensures that the cue spreads fast and lingers in the epilimnion. This characteristic is adequate for signaling the activity of planktivorous fish, which usually forage throughout the whole epilimnion and are continuously active over a period of months (Ringelberg et al., 1991).

Water-soluble kairomones of low volatility have been found in other aquatic predator–prey systems as well: predatory rotifers release kairomones acting on other rotifers (Gilbert, 1966), *Chaoborus* releases a kairomone that acts on *Daphnia* (Tollrian and von Elert, 1994), and ciliates respond to kairomones from turbellarian flatworms (Kuhlmann, 1994), predatory ciliates (Kusch and Heckmann, 1992), and rhizopods (Kusch 1993).

The release of a kairomone that induces DVM in *Daphnia* occurs in many plantivorous fish of different taxa (for a review see Larsson and Dodson, 1993), indicating that DVM is not a predator-specific defense mechanism. This unspecificity of DVM leads to the question: is it the same kairomone in different species that induces the response? We chemically compared the kairomones of three different cyprinid species. No differences were found, when the kairomone of *Leucaspius delineatus* was compared with those of *Carassius carassius* and *Rutilus rutilus* by using both chemical characterization and HPLC. However, due to the steep gradient of the HPLC, it is possible that the kairomones behave chromatographically similarly, but are chemically different. However, the data presented suggest that the investigated cues are chemically similar, if not identical. As all planktivorous fish represent a risk of predation to *Daphnia*, a common rather than a species-specific cue should be preferred as an indicator of the overall risk of predation. No evidence for the involvement of more than one cue in the induction of DVM in *Daphnia* has been found.

(Received July 31, 1995; accepted December 11, 1995)

Abstract—Two polyoxygenated fatty acids with antifungal activity have been isolated from aerial parts of *Aeollanthus parvifolius* (Labiatae) using bioassay-guided isolation procedures. Spectroscopic analysis was used to identify the compounds as (*Z*)-4ξ,9ξ-diacetoxy-6ξ,7ξ-epoxy-5ξ-hydroxy-8-oxododeca-2-enoic acid and (*Z*)-4ξ,6ξ,7ξ,9ξ-tetraacetoxy-5ξ-hydroxy-8-oxododeca-2-enoic acid. Both of these compounds inhibited spore germination of *Cladosporium cucumerinum*. Minimum inhibitory doses were 1 μg and 5 μg, respectively, but only the former inhibited germination of *Aspergillus niger* at a dose of 5 μg. Neither compound exhibited antibacterial activity. (*Z*)-4ξ,9ξ-Diacetoxy-6ξ,7ξ-epoxy-5ξ-hydroxy-8-oxododeca-2-enoic acid reduced the hyphal growth of *Pythium ultimum*. The mode of action was not resolved but did not involve either the disruption of the cell wall membrane or the inhibition of extracellular enzymes. Application of (*Z*)-4ξ,6ξ,7ξ,9ξ-tetraacetoxy-5ξ-hydroxy-8-oxododeca-2-enoic acid to seedling plants did not give any protection against fungal attack, and indeed the compound appeared to be phytotoxic.

Key Words—*Aeollanthus parvifolius*, Labiatae, polyoxygenated fatty acids, antifungal activity, *Cladosporium cucumerinum*, *Aspergillus niger*, *Pythium ultimum*.

INTRODUCTION

The genus *Aeollanthus* Mart. ex Spreng (Labiatae) consists of over 100 species and occurs throughout Africa (Ryding, 1986). *Aeollanthus parvifolius* Benth. is

*To whom correspondence should be addressed.

0098-0331/96/0500-0897$09.50/0 © 1996 Plenum Publishing Corporation

a subshrub, sometimes tiny and almost herbaceous, which grows on rocks or shallow soil at altitudes of 0–1300 m in parts of Transvaal, Natal, Swaziland, and southern parts of Mozambique (Ryding, 1986). This species was selected for study based on results obtained from random screening of several species of the Labiatae, when the chloroform extract was found to display appreciable antifungal activity. The compounds responsible for activity were identified as novel (*Z*)-dodeca-2-enoic acid derivatives, more highly oxygenated than those found previously in another species of *Aeollanthus* (Dellar et al., 1996). Attempts were made to determine the mode of action of the two new fatty acids against some plant pathogenic fungi.

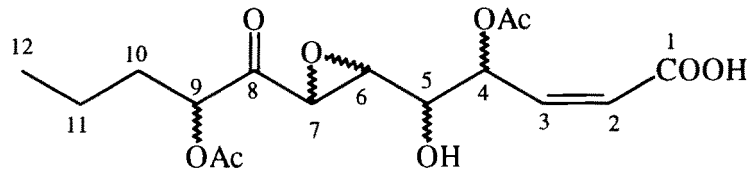
METHODS AND MATERIALS

Aeollanthus parvifolius was obtained from The Living Collection at The Royal Botanic Garden, Edinburgh, where a voucher specimen is deposited. The material used in this study was propagated in glasshouses at Strathclyde University.

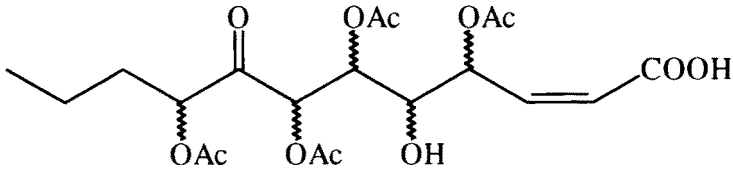
Determination of Antifungal Activity. Fresh plants were lyophilized and powdered to yield 60 g of dry plant material, which was then extracted in chloroform followed by methanol at room temperature for 72 hr, yielding 5 g and 3.6 g of dry extract, respectively. Both extracts were subjected to vacuum liquid chromatography (VLC) (Pelletier et al., 1986) and the resulting fractions were investigated for antifungal activity using direct bioautography on silica gel TLC plates with *Cladosporium cucumerinum* (IMI 299104) as the test organism (Homans and Fuchs, 1970). Antifungal activity was observed in the chloroform extract in fractions eluted from the VLC column with 35–60% petroleum ether in ethyl acetate.

Isolation of Antifungal Compounds. Direct bioautography of the active fractions on silica gel using hexane–ethyl acetate (1 : 1) as the developing solvent revealed two fungitoxic bands at R_f 0.22 and 0.45. Purification was achieved with centrifugal thin-layer chromatography (Marston and Hostettmann, 1991) using an isocratic elution system of hexane–ethyl acetate (3 : 2). Compounds **1** and **2** (Figure 1) were isolated in yields of 43.5 mg and 400 mg, corresponding to R_f values of 0.45 and 0.22, respectively.

Identification of Isolated Compounds. (*Z*)-4ξ,9ξ-Diacetoxy-6ξ,7ξ-epoxy-5ξ-hydroxy-8-oxododeca-2-enoic acid (**1**) is an oil, giving a red-brown spot when sprayed with 1% vanillin in concentrated sulfuric acid and heated to 100°C for 5–10 min. $[\alpha]_D$ = +7.1° (*c* 0.14, MeOH). IR γ_{max} (KBr) cm^{-1}: 3422, 2964, 1741, 1374, 1221, 1198, 1096, 1044, 953, 826. UV λ_{max} (MeOH) nm: 272, 202. For NMR, see Table 1. HR-FAB-MS *m/z*: 363 $(M\text{-}H_2O+Na)^+$. (*Z*)-4ξ,6ξ,7ξ,9ξ-Tetraacetoxy-5ξ-hydroxy-8-oxododeca-2-enoic acid (**2**) is an



1



2

FIG. 1. Compounds **1** and **2**.

oil, giving a red–brown spot when sprayed with 1% vanillin in concentrated sulfuric acid and heated to 100°C for 5–10 min. $[\alpha]_D$ +147.8° (*c* 1.84, MeOH). IR γ_{max} (KBr) cm^{-1}: 3442, 2962, 1751, 1374, 1222, 1094, 1033, 949, 826, 757. UV λ_{max} (MeOH) nm: 332, 272, 212. For NMR, see Table 1. HR-FAB-MS *m/z*: 465 $(M\text{-}H_2O+Na)^+$.

Determination of Minimum Inhibitory Dose (MID) and Minimum Inhibitory Concentration (MIC). The MID required to prevent fungal spore germination was determined using direct bioautography with *C. cucumerinum* and *Aspergillus niger* (IMI 17454) as test organisms. This was undertaken as previously described for *C. cucumerinum* (Homans and Fuchs, 1970), while for *A. niger* a sporing colony was resuspended in sterile saline (20 ml) and a 100-μl aliquot was added to 10 ml of molten malt extract agar. This *A. niger*-seeded medium was sprayed thinly and evenly over a silica gel plate previously impregnated with the test compounds at a range of concentrations, together with amphoteracin-B as a control. The plates were incubated at 25°C for 48 hr. The lowest dose at which no sporulation was observed was determined as the MID.

The antibacterial MIC value was assessed using the broth dilution method (Rios et al., 1988), with *Bacillus subtilis* (NCTC 8326) (4×10^{13} CFU/ml), *Staphylococcus aureus* (NCTC) 6751 (9×10^{13} CFU/ml), *Pseudomonas aeruginosa* (NCTC 6750) (9×10^{13} CFU/ml), *Erwinia carotovora* (IMI 347390) (4×10^9 CFU/ml), *Pseudomonas syringae* (IMI 349170) (4×10^9 CFU/ml),

and *Streptomyces scabies* (IMI 349428) (3×10^8 CFU/ml) as the test organisms. The former three species were incubated at 37°C and the remainder at 25°C. Test compounds were dissolved in methanol and added in 10-μl aliquots to each well in a 96-well microtiter plate giving a final concentration range of 0.01–100 μg/ml. Chloramphenicol in the same concentration range was used as the positive control and 10 μl methanol alone as negative control. Results were recorded after 24 hr.

Investigation of Reduction of Radial Hyphal Growth in Response to Test Compounds. Test compounds were added in 1-μl aliquots of methanol to 10-ml batches of molten malt extract agar to give final concentrations of 5, 10, 25, 50, and 100 μg/ml. Methanol-only and agar-only negative controls were performed in parallel, as were positive controls using griseofulvin, at a dose of 10 μg/ml. The agar was allowed to solidify in 9-cm Petri dishes, and each plate was inoculated at the center with 6-mm fungal plugs taken from the margins of actively growing colonies of either *Pythium ultimum* (IMI 30827) or *Thaneto-*

phorus cucumeris (IMI 303152). Plates were incubated for 48–72 hr at 25°C and radial growth for each test was recorded by taking the average diameter from four measurements.

Investigation of Effect of Compounds on Hyphal Morphology. Test compounds were dissolved in methanol and added in 1-μl aliquots to 1-ml portions of molten malt extract agar, to given final concentrations of 10, 25, 50, and 100 μg/ml. Each batch was then applied to a sterilized glass slide as an even layer and placed in a Petri dish with damp filter paper (7 cm ID). A 6-mm plug taken from cultures of *P. ultimum* or *T. cucumeris* was placed onto the center of each slide. Dishes were covered and incubated at 25°C for 18–48 hr. Hyphae were examined with light microscopy for changes in hyphal morphology, such as abnormal growth patterns or lysis of hyphal tips and were compared with methanol-only and agar-only negative controls. Staining of cells with Evan's blue stain (0.05% in distilled water) was used to indicate cell membrane dysfunction (Smith, 1982).

Determination of Effect of Test Compounds on Extracellular Enzymes. The method described by Barth and Bridge (1989) was used to detect whether the antifungal activity of test compounds was due to the inhibition of β-glucosidase, which is released as an extracellular enzyme into the culture media. The substrate used was 4-methylumbelliferyl-β-D-glucoside (4MUGlu) (Sigma) prepared according to Barth and Bridge (1989). Malt extract broth (100 ml) was added to conical flasks (250 ml) and autoclaved. Test compounds dissolved in 100-μl aliquots of methanol were added to give a final concentration of 50 μg/ml. Negative controls consisted of broth and methanol alone and broth alone. Each flask was subsequently inoculated with 2 × 6-mm disks taken from the leading edge of an actively growing vegetative culture of *P. ultimum*. Flasks without the addition of fungi were run as further controls. Each flask was sealed with a plug of cotton wool and placed in a shaker–incubator at 25°C (100 rpm) for five days. Cultures were vacuum filtered and allowed to air dry for 24 hr, after which each fungal mass was recorded. Culture filtrates were assayed for enzyme activity as follows. Substrate (50 μl) was added to culture medium (50 μl) in a microtiter well. Each test was performed in triplicate. Plates were then incubated at 37°C for 4 hr. To examine whether reduction of enzyme activity was due to direct enzyme inhibition by the test compounds, culture filtrate taken from the fungus-only flask was assayed as above, but with the direct addition of the test compound at final concentrations of 25, 50, and 100 μg/ml.

After incubation, 50 μl of saturated sodium bicarbonate solution was added to each well in order to enhance fluorescence of any 4-methyl umbelliferone (4MU) released (O'Brien and Colwell, 1987). Fluorescence was measured at excitation and emission wavelengths of 377 and 447 nm, respectively. Readings were compared with a standard curve prepared using recrystallized 4MU dissolved in methanol over a concentration range of 0.01–10 μM.

Investigation of In Vivo Activity of Test Compounds. Compounds were investigated for in vivo activity using a plant/pathogen test system of cucumber seedlings (Mr. Fotheringills Ridge Perfection) and *Cladosporium cucumerinum*. Test solutions were prepared in acetone–water (1 : 1) to give a final concentration of 100 μg/ml and seedlings at the two-cotyledon stage were sprayed until runoff. Control plants were sprayed with acetone–water (1 : 1) solution only, 1% malt extract broth only, or remained untreated. After allowing leaves to dry, half the seedlings subjected to each test were sprayed until runoff with a spore suspension of *C. cucumerinum* in 1% malt extract broth (2.5×10^6 spores/ml) (Emmatty, 1974). All seedlings were covered with polythene for 48 hr at approximately 18°C, after which the plastic was removed and plants were grown under normal glasshouse conditions. The subsequent onset of disease was monitored.

RESULTS

Identification of Compounds 1 and 2. Compounds **1** and **2** showed similar spectral features, which were analogous to those observed previously for polyoxygenated fatty acids isolated from another species of *Aeollanthus* (Dellar et al., 1996). The FT-IR spectra of both indicated carbonyl and hydroxyl functional groups. The ^1H and ^{13}C NMR spectra of **1** (Table 1) revealed the presence of a dodecanoic acid, with one double bond and two acetoxyl substituents. A FAB-MS spectrum obtained for **1** failed to show a molecular ion, but a major fragment at *m/z* 363 was identified as due to $(M\text{-}H_2O+Na)^+$, indicating a molecular weight of 358 ($C_{16}H_{22}O_9$). Based on the coupling constant of the olefinic protons (J = 9.8 Hz), the double bond was determined to have *cis* stereochemistry. A comprehensive study using two-dimensional (2-D) NMR techniques was undertaken applying methods described previously by Quader et al. (1991). Direct H-C couplings were established on the basis of HC-COBI-dec experiments, while the 2-D ^1H-^1H COSY-45 spectrum allowed the assignment of ^2J and ^3J homonuclear correlations, and long-range hetronuclear couplings were determined by the HMBC technique (Table 2). These observations established the position of the double bond at C-2/C-3, placed the acetoxyl substituents at C-4 and C-9, and the carbonyl at C-8. The presence of a terminal propyl group (C-10 to C-12) required that C-5 to C-7 be oxygenated. The C-5 carbon had to be assigned the ^{13}C resonance at 73.9 ppm because of long-range coupling to the olefinic H-3 (Table 2) leaving C-6 and C-7 represented by the signals at 54.9 and 55.2 ppm. Of the remaining two oxygens to be assigned to C-5 through C-7, C-5 must carry a hydroxyl while the more shielded C-6 and C-7 carbons must share an epoxide. Thus compound **1** can be assigned the structure (*Z*)-4ξ,9ξ-diacetoxy-6ξ,7ξ-epoxy-5ξ-hydroxy-8-oxododeca-2-enoic acid.

Compound **2** was clearly similar to **1** but showed two additional acetoxyl

9-OCOMe		170.8		170.0

substituents, which, using the same NMR techniques (Tables 1 and 2), must be placed at positions C-6 and C-7, therefore replacing the epoxide moiety present in **1**. The *cis* configuration (J = 9.7 Hz) at C-2 and C-3 was maintained. The FAB-MS spectrum obtained for **2** failed to show the parent ion corresponding to $C_{20}H_{28}O_{12}$ (MW 460), but the m/z 465 $(M\text{-}H_2O+Na)^+$ was present. Compound **2** was therefore identified as (Z)-4ξ,6ξ,7ξ,9ξtetraacetoxy-5ξ-hydroxy-8-oxododeca-2-enoic acid.

Minimum Inhibitory Dose of 1 and 2. The two compounds were able to prevent spore germination of *Cladosporium cucumerinum* at 1 μg and 5 μg, respectively, with activity persisting for 40 hr. Only compound **1**, however, was able to inhibit germination of *Aspergillus niger* at a dose of 5 μg, with activity again persisting for 40 hr (Table 3).

Antibacterial Activity of 1 and 2. Neither compound was able to inhibit growth of any of the bacterial species selected for this assay. They were tested to a maximum concentration of 100 μg/ml.

Inhibition of Fungal Radial Growth by 1 and 2. Regression analysis allowed ID_{50} values (the concentrations at which fungal growth was inhibited by 50% in comparison to the methanol control) to be determined after 24 hr. Compound **1** gave ID_{50} values of 24.9 μg/ml and 179.2 μg/ml against *P. ultimum* and *T. cucumeris*, respectively, while **2** was less effective, with ID_{50} values of 232.2 μg/ml and 728.2 μg/ml, respectively.

Effect of 1 and 2 on Fungal Morphology. After 22 hr, **1** caused hyphal shrinkage and curling of *P. ultimum* at concentrations of 10–25 μg/ml in comparison with negative controls, while concentrations of 50–100 μg/ml inhibited vegetative growth almost completely. However, after 44 hr, inhibition was to some degree overcome at all concentrations. Normal growth of *T. cucumeris*

TABLE 3. MINIMUM INHIBITORY DOSE OF COMPOUNDS **1** AND **2** AGAINST *Cladosporium cucumerinum* AND *Aspergillus niger*

	Minimum inhibitory dose (μg)		
Time (hr)	**1**	**2**	Amphoteracin B
C. cucumerinum			
40	1	5	<0.5
88	1	25	<0.5
264	5	>100	<0.5
A. niger			
40	5	>100	<0.5
80	10	>100	<0.5
264	10	>100	<0.5

was also disrupted at 50–100 μg/ml after 22 hr, but no inhibition was observed after 44 hr. Compound **2** caused little growth disruption of *T. cucumeris*, but *P. ultimum* did show some signs of abnormal growth up to 22 hr, after which no inhibition was observed. Abnormal hyphae failed to take up Evan's blue stain, indicating that membranes were able to function normally.

Inhibition of Fungal Extracellular Enzymes by Compound 1. Regression analysis of fluorescence vs. 4MU concentration gave the equation $y = 1.795x + 29.751$ ($r^2 = 0.99$), which was used to calculate the release of 4MU in the enzyme assay. Compound **1** reduced release of β-D-glucosidase by 92%, while fungal biomass was reduced by 74% at a concentration of 50 μg/ml. When the cell-free culture medium obtained by filtration of fungi was incubated with compound **1** no inhibition of enzyme activity was observed. Therefore, the reduction of enzyme activity does not appear to be due to the direct action of **1.**

In Vivo Activity of Compound 1. Uninoculated seedlings treated with compound **1** remained healthy, as did plantlets treated with broth, or water and acetone alone, with and without subsequent inoculation. Only those plantlets treated with **1** prior to inoculation developed signs of disease, with 20% dying within nine days and 55% within 15 days.

DISCUSSION

Both compounds **1** and **2** are previously unreported. Results obtained from all the in vitro assays against various fungal organisms indicate compound **1** to be the more fungitoxic. In the agar dilution assay, fungal hyphal growth was able to attain the maximum allowed on a 9-cm Petri dish; therefore, the effects of **1** and **2** would appear to be fungistatic rather than fungicidal. Biological activity has been reported for compounds with similar structures from a number of other sources (Bowers et al., 1986; Masui et al., 1989: Kuwahara et al., 1992; Namai et al., 1993). A study of structure–activity relationships of various fatty acids against *Pyricularia oryzae* (Mori et al., 1987) revealed that a free monocarboxyl, a chain length of C-10 to C-13 and an α,β-unsaturated carboxylic acid moiety was necessary for any activity. Both **1** and **2** satisfy these criteria. The addition of an epoxide group in **1** seems likely to be the important factor for its enhanced activity.

Intuitively, it would seem probable that the manufacture of these compounds forms a useful chemical defense against fungal pathogens in *A. parvifolius*. However, an attempt to use pure compound **1** to protect cucumber seedlings against the attack of fungal pathogens was not successful; in fact, pretreatment of the seedlings with this compound appeared to enhance the infection process, resulting in a higher mortality rate for treated seedlings than for the controls. Similar compounds have been reported to have cytotoxic activity

(Kuwahara et al., 1992; Namai et al., 1993), which may account for the reduced success of treated seedlings. *Aeollanthus* species probably sequester these potentially toxic compounds in trichomes present on the leaf surface, thereby isolating them from general metabolism, but at the same time leaving them available for rapid release in order to fight pathogen invasion.

Acknowledgments—J.D. thanks the BBSRC for the award of a scholarship. We thank the Royal Botanic Garden, Edinburgh, for the supply of plant material. NMR spectra were run at the University of Strathclyde NMR Laboratory. FAB-MS were obtained from Dr. J. Ballantyne, University College, Swansea.

REPELLENCY OF ORAL EXUDATE TO EASTERN AND WESTERN SPRUCE BUDWORM LARVAE (LEPIDOPTERA: TORTRICIDAE)

L. M. POIRIER* and J. H. BORDEN

(Received May 16, 1995; accepted December 31, 1995)

Abstract—A two-choice feeding bioassay was used to investigate the intraspecific repellency of the larval oral exudate of eastern and western spruce budworms, *Choristoneura fumiferana* (Clem.) and *C. occidentalis* Free., respectively. Results of the bioassay indicated that feeding behavior on artificial diet-drop feeding stations was modified in the presence of exudate, with feeding stations treated with conspecific exudate being avoided when an untreated station was available 3 cm away. Feeding was suppressed when a single, exudate-treated station was provided, or when the treated and untreated stations were separated by only 1 cm. The repellent effect functioned both inter- and intraspecifically. When induced to produce exudate, *C. occidentalis* larvae were not immediately repelled by either their own or other individuals' exudate. However, 24 hr after induction, test larvae were repelled by exudate from either source. In both species, larval oral exudate probably functions to repel conspecific competitors.

Key Words—*Choristoneura fumiferana*, *Choristoneura occidentalis*, spruce budworm, oral exudate, regurgitant.

INTRODUCTION

Many insects release oral secretions when they are disturbed or handled (Davies and McCauley, 1970; Corbet, 1971; Eisner et al., 1974). Such secretions are an important defense against predators and parasites (Eisner et al., 1974). However, they may also play a role in intraspecific interactions, mediating optimal

larval density in a habitat in a concentration-dependent manner (Corbet, 1971). Recent evidence (Poirier and Borden, 1995) has shown that oral exudate from larvae of eastern and western spruce budworms, *Choristoneura fumiferana* (Clem.) and *Choristoneura occidentalis* Free., respectively, may act as an epideictic (spacing) pheromone (Prokopy, 1981). Larvae produced the exudate during intraspecific encounters, and experimental exposure to exudate caused an increase in the proportion of larvae dispersing from established feeding sites (Poirier and Borden, 1995). In the field, generally only one larva is found in each tree bud (L. E. Maclauchlan, British Columbia Ministry of Forests, Kamloops Region, personal communication).

In order for the intraspecific repellency of larval oral exudate to be investigated further, an effective laboratory bioassay procedure was required. Our first objective, therefore, was to develop such a bioassay. Subsequent objectives were to determine the specificity of the exudate between the two *Choristoneura* species and to determine whether an individual larva could "recognize" whether exudate came from itself or another larva.

METHODS AND MATERIALS

Insects. Second-instar, diapausing larvae of *C. fumiferana* and *C. occidentalis* were obtained from the Forest Pest Management Institute, Canadian Forest Service, Sault Ste. Marie, Ontario. These insects were reared in the laboratory at approximately 24°C and 60% relative humidity. Photoperiod was maintained at 16L:8D. Larvae were reared on an agar-based, artificial spruce budworm diet (Bio-Serv Inc., Frenchtown, New Jersey) in 30-ml disposable vials. Two larvae were kept in each vial. Some *C. occidentalis* larvae were reared on cut branches of Douglas fir, *Pseudotsuga menziesii* (Mirb.) Franco, collected in Burnaby, British Columbia.

Bioassay Development. To test the repellent effect of larval oral exudate, two drops of molten artifical diet (approximately 0.5 cm in diameter) were placed in the bottom of a 100 × 15-mm disposable Petri dish and allowed to solidify. In all bioassays, the Petri dishes were inverted so that the diet feeding stations were on the "ceiling" of the Petri dish chamber.

In experiments 1 and 2, the two feeding stations were placed in each dish with 3 cm between their centers. In experiments 3 and 4, the two feeding stations were separated by only 1 cm. Each dish for experiments 5 and 6 contained a single feeding station, placed at the center of the chamber. Oral exudate was collected from artificial diet-reared larvae by touching their heads with a 5-μl micropipet (Poirier and Borden, 1995). As much exudate as could be collected from two larvae was used to cover one of the two feeding stations in each dish

in experiments 1–4, and the single stations in experiments 5 and 6. Separate dishes, with one station treated with 5 μl of distilled water, served as controls.

A conspecific artificial-diet-reared third to fifth instar, (*C. fumiferana* in experiments 1, 3, and 5, and *C. occidentalis* in experiments 2, 4, and 6) was then placed on moist filter paper on the floor of each chamber and exposed to the feeding stations by placing the roof on the chamber. Test larvae that produced exudate while being transferred to the chamber were not used in the experiments. The larvae were left for 24 hr under the above rearing conditions, and their final positions were then recorded. Any evidence of feeding or establishment on a particular station, such as feeding cavities, deposited silk, silk feeding tunnels, or frass, was recorded. Larvae that did not establish on a feeding station were included in the sample, unless they had molted or pupated over the 24-hr test period. Larvae were, therefore, categorized as not feeding, feeding on the untreated station, or feeding on the treated station.

Each experiment consisted of 20 experimental and 20 control replicates. The numbers of larvae in the three categories were compared between experimental and control dishes using Fisher's exact test, $\alpha = 0.05$, for a 2×3 contingency table, due to the small sample size (Steel and Torrie, 1980; Schlotzhauer and Littell, 1987).

Interspecific Repellency. Artificial-diet-reared third to fifth instars of *C. fumiferana* (experiment 7) and *C. occidentalis* (experiment 8) were tested in Petri dish bioassays as described in experiment 1. Exudate from two larvae of one species was used to treat one of the stations in each dish. Larvae of the other species were then used as test insects. Control dishes were also set up, with one station treated with 5 μl of distilled water. There were 20 experimental and 20 control dishes for each species. Test larvae were left in the dishes for 24 hr, and the results were assessed and analyzed as in experiment 1.

Self-Recognition. Bioassay dishes for experiment 9 were constructed as dscribed in experiment 1, except that the filter paper was omitted and the dishes were not inverted. Both exudate donors and test insects were third to fifth instars of *C. occidentalis* that had been reared on artificial diet. Dishes were divided among four treatments. In the control treatment, one station in each dish was treated with 2 μl of distilled water, and the test larva was not induced to produce exudate prior to the start of the experiment. In the first experimental treatment, one station was treated with 2 μl of conspecific exudate, and the test larva was not induced. Test larvae were induced to produce exudate in experimental treatments 2 and 3; one station in each dish received 2 μl of exudate, which was produced by either the test larva (treatment 2) or another, conspecific larva (treatment 3). Test larvae were placed in all dishes immediately following treatment of the feeding stations. Each of the four treatments was replicated 40 times.

This experiment was repeated (experiment 10) with dishes that had been treated and left on a bench for 24 hr before test larvae were introduced. Test larvae were selected and, where appropriate, induced at the time of treatment and placed in individual vials of artificial diet for 24 hr, then placed in the bioassay dishes. Each of the four treatments was replicated 40 times. All test larvae from experiments 5 and 6 were left in the bioassay dishes for 24 hr. The results were then assessed and analyzed as for experiment 1.

Experiments 9 and 10 were repeated (experiments 11 and 12) using third- to fifth-instar *C. occidentalis* larvae that had been reared on foliage. Test larvae in experiment 12 were placed on small twigs of current-year Douglas fir foliage and held in individual vials for 24 hr before being placed in the bioassay dishes. For both experiments 11 and 12, each treatment was replicated 40 times. Test larvae were left in the bioassay dishes for 24 hr, and the results were then assessed and analyzed as for experiment 1.

RESULTS

Bioassay Development. When the two feeding stations were separated by 3 cm (experiments 1 and 2), the numbers of larvae in the three categories (not feeding, feeding on the untreated station, or feeding on the treated station) were significantly different between experimental and control dishes for both *C. fumiferana* and *C. occidentalis* (Figure 1). In experimental dishes, most larvae fed on the untreated stations, while in the control dishes there were approximately equal numbers feeding on the water-treated stations and the untreated stations.

When the two feeding stations were separated by 1 cm in experiments 3 and 4, the numbers of larvae in the three categories were again significantly different between the experimental and control dishes for both species (Figure 2). As in experiment 1, very few larvae fed on the exudate-treated station. However, 50% and 75% of *C. fumiferana* and *C. occidentalis*, respectively, did not feed at all on either station in the experimental dishes. Feeding on untreated and water-treated stations in control dishes was relatively equal.

When only one feeding station treated with conspecific oral exudate was available (experiments 5 and 6), 65% and 90% of *C. fumiferana* and *C. occidentalis*, respectively, did not feed (Figure 3). Approximately 90% of all larvae of both species fed on the water-treated station in control dishes (Figure 3).

Interspecific Repellency. The results of experiments 7 and 8 (Figure 4) were very similar to those of experiments 1 and 2 (Figure 1), indicating reciprocal activity of larval oral exudate between the two *Choristoneura* species. The effect of *C. fumiferana* exudate on *C. occidentalis* larvae was particularly strong; no *C. occidentalis* larvae fed on diet stations treated with *C. fumiferana* exudate, and 45% did not feed at all.

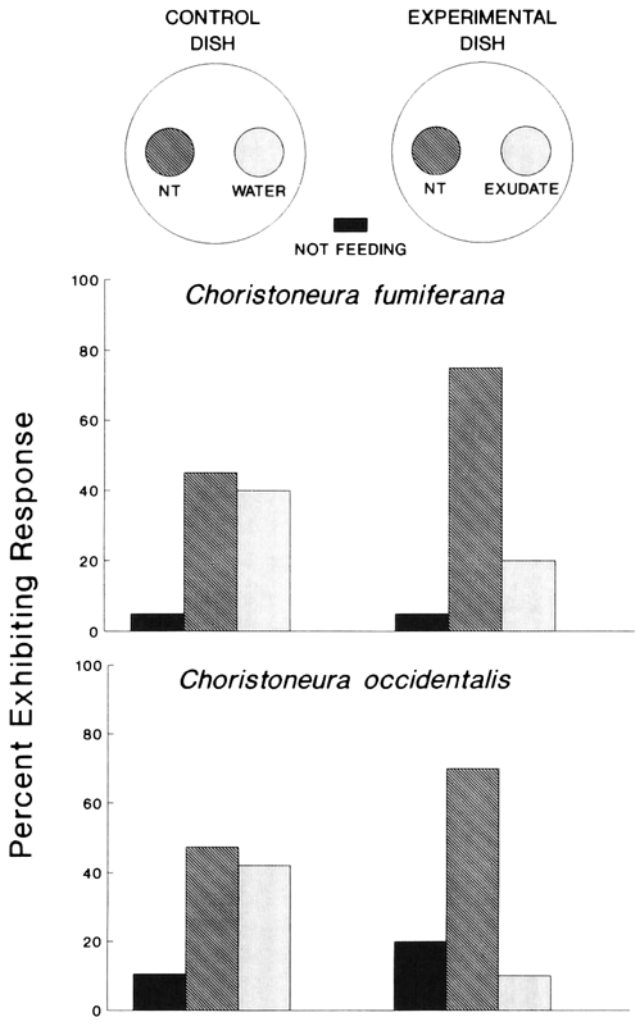

FIG. 1. Percentage of *C. fumiferana* (experiment 1) or *C. occidentalis* (experiment 2) larvae not feeding or feeding on one of two diet stations with centers separated by 3 cm. Circular schematic diagrams indicate placement of diet stations (magnified in size) in Petri dishes, with shading of treatment corresponding to the percent response bars below. The control dish (left) contains an untreated diet station (NT) paired with one treated with distilled water. The experimental dish (right) contains an untreated diet station (NT) paired with one treated with conspecific larval oral exudate. $N = 20$. For both species, control and experimental distributions are significantly different, Fisher's exact test, $P = 0.034$ and $P = 0.029$, respectively.

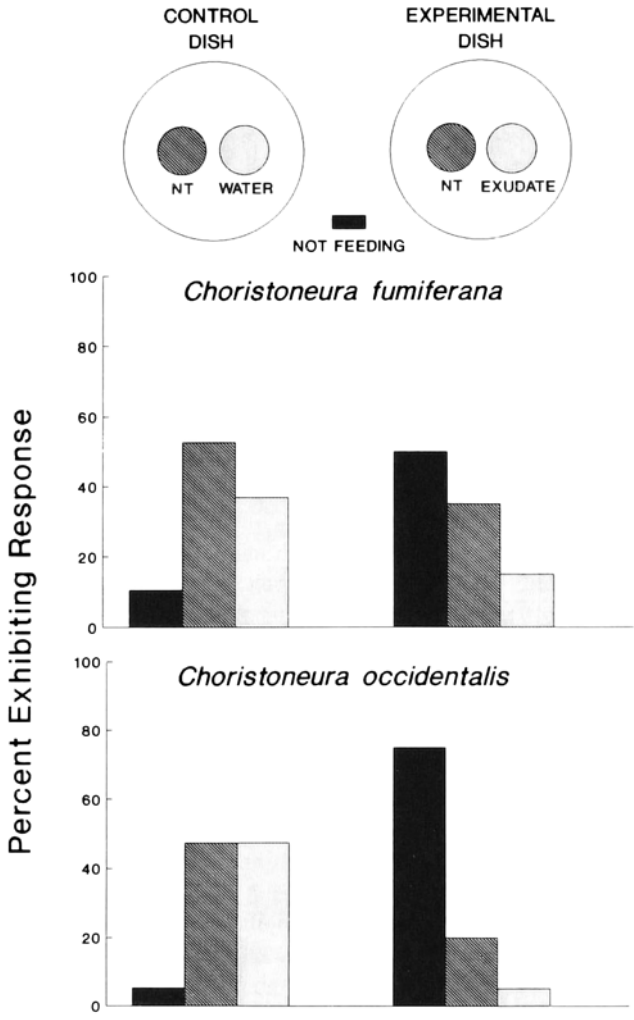

FIG. 2. Percentage of *C. fumiferana* (experiment 3) or *C. occidentalis* (Experiment 4) larvae not feeding or feeding on one of two diet stations with centers separated by 1 cm. Circular schematic diagrams indicate placement of diet stations (magnified in size) in Petri dishes, with shading of treatment corresponding to the percent response bars below. The control dish (left) contains an untreated diet station (NT) paired with one treated with distilled water. The experimental dish (right) contains an untreated diet station (NT) paired with one treated with conspecific larval oral exudate. $N = 20$. For both species, control and experimental distributions are significantly different, Fisher's Exact Test, $P = 0.026$ and $P < 0.0001$, respectively.

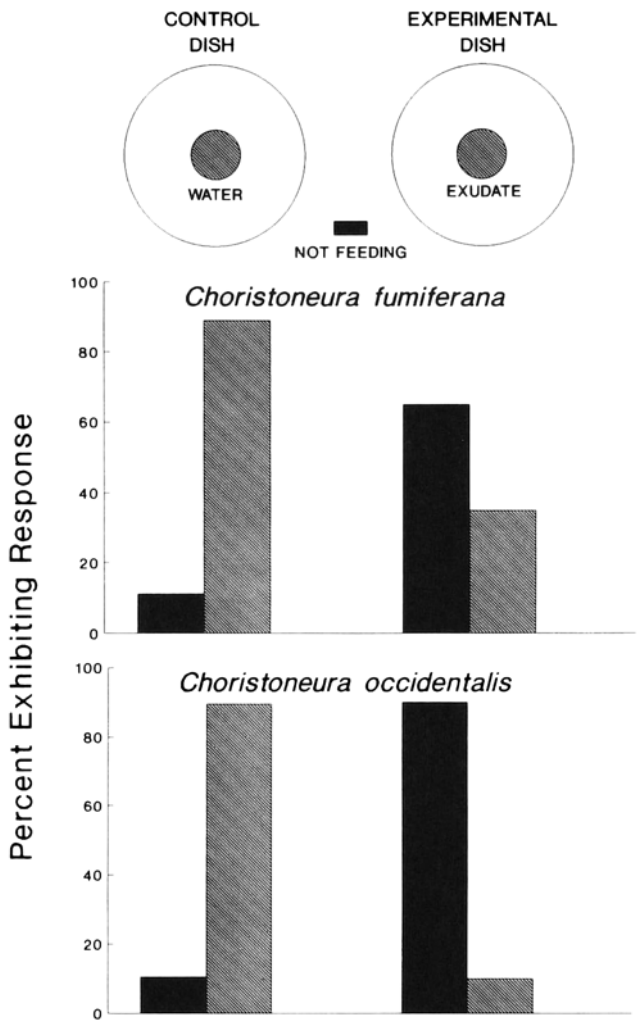

FIG. 3. Percentage of *C. fumiferana* (experiment 5) or *C. occidentalis* (experiment 6) larvae not feeding or feeding on single diet stations. Circular schematic diagrams indicate placement of diet stations (magnified in size) in Petri dishes, with shading of treatment corresponding to the percent response bars below. The control dish (left) contains diet station treated with distilled water. The experimental dish (right) contains diet station treated with conspecific larval oral exudate. $N = 20$. For both species, control and experimental distributions are significantly different, Fisher's exact test, $P < 0.001$ and $P < 0.0001$, respectively.

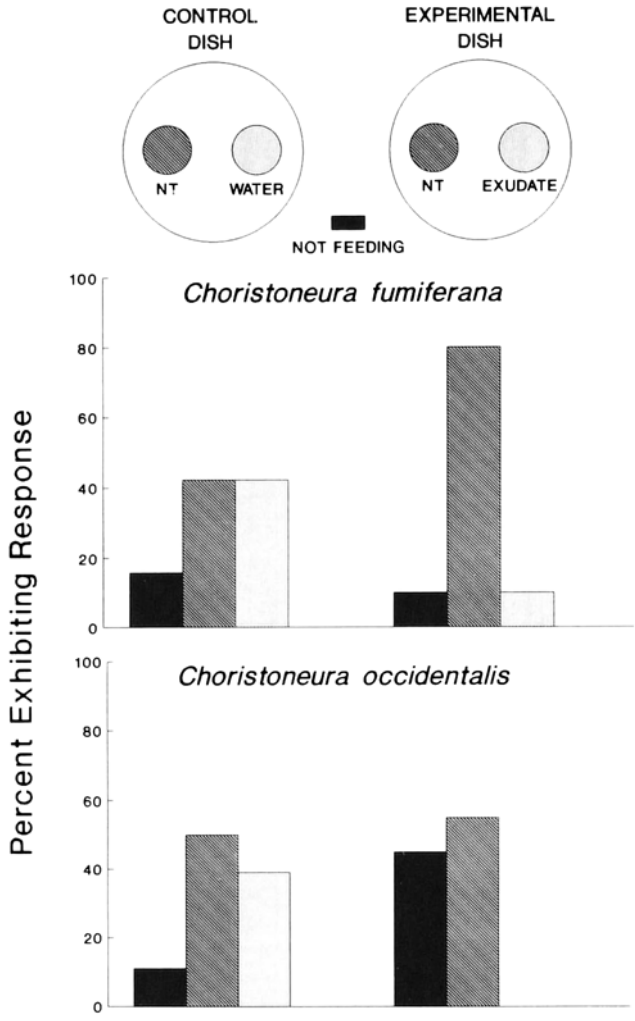

FIG. 4. Percentage of *C. fumiferana* (experiment 7) or *C. occidentalis* (experiment 8) larvae not feeding or feeding on one of two diet stations with centers separated by 3 cm. Circular schematic diagrams indicate placement of diet stations (magnified in size) in Petri dishes, with shading of treatment corresponding to the percent response bars below. The control dish (left) contains an untreated diet station (NT) paired with one treated with distilled water. The experimental dish (right) contains an untreated diet station (NT) paired with one treated with larval oral exudate from the other species. $N = 20$. For both species, control and experimental distributions are significantly different, Fisher's exact test, $P = 0.042$ and $P < 0.003$, respectively.

Self-Recognition. In experiment 9 (Figure 5), the numbers of artificial-diet-reared larvae in the three categories were significantly different from the control dishes in only one case: when one station was treated with oral exudate from another larva, and the test larva had not been induced to produce exudate, most test larvae fed on the untreated station. There was no significant difference between the treatment groups that used induced test larvae and the control groups, whether the exudate was from the test larva (Figure 5, experimental dish 2) or another larva (experimental dish 3). However, in experiment 10, when larvae were placed in the dishes 24 hr after the stations were treated, all experimental treatments caused significant rejection of the treated feeding stations. Both induced and uninduced larvae fed on the untreated station most frequently, whether the exudate was from the test larva or not.

Results with foliage-reared larvae in experiment 11 and 12 (Figure 6) were similar to those for diet-reared larvae (Figure 5).

DISCUSSION

The significant inhibition of feeding on diet stations treated with conspecific oral exudate when experimental and control stations were separated by 3 cm (Figure 1), indicates that the oral exudate acts as a feeding deterrent. The inhibition of feeding on both treated and untreated stations when the stations were 1 cm apart (Figure 2), suggests that the larval oral exudate also acts as a volatile repellent. The power of the repellency and feeding deterrency is demonstrated by the high numbers of non-feeding larvae when they were presented with no choice other than a treated diet station (Figure 3). However, these experiments used relatively large quantities of exudate, approximately 4–5 larval equivalents per treated station (Poirier and Borden, 1995), and the response may be correspondingly greater than might be expected under normal field conditions. Moreover, larvae were kept in a small chamber throughout the experiment and were not given the opportunity to disperse away from the exudate. Dispersal has already been shown to be a common larval response to an encounter with exudate (Poirier and Borden, 1995).

Both *C. fumiferana* and *C. occidentalis* larvae were repelled by exudate from larvae of the other species. Thus, the components in the exudate may be the same for both species. However, particularly if the exudate is a regurgitant (Poirier and Borden, 1995), this reciprocal activity may not be evident under field conditions, in which larvae of the two species are found on different host trees and are allopatric (Harvey, 1985).

Immediately after being induced to produce oral exudate, larvae apparently enter a refractory phase, during which they are unable to respond to their own or other individuals' exudate (Figure 5). After 24 hr, however, induced larvae had recovered their ability to discriminate. The lack of response may be due to

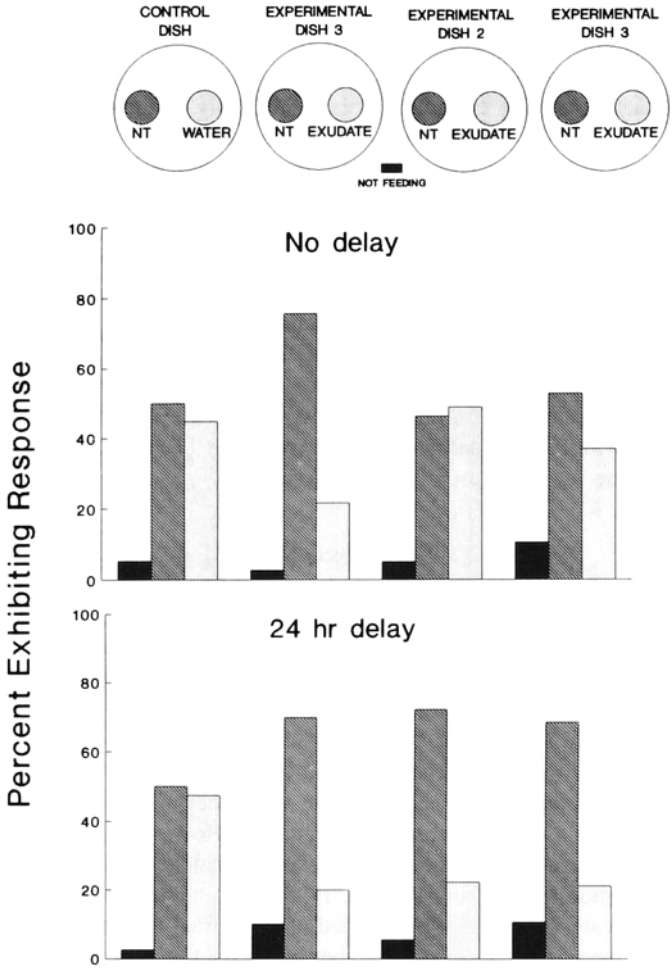

FIG. 5. Percentage of artificial diet-reared *C. occidentalis* larvae not feeding or feeding on one of two diet stations with centers separated by 3 cm, either 0 (experiment 9) or 24 hr (experiment 10) after treatment of stations and induction of exudate production. Circular schematic diagrams indicate placement of diet stations (magnified in size) in Petri dishes, with shading of treatment corresponding to the percent response bars below. The control dish (left) contains an untreated diet station (NT) paired with one treated with distilled water. The experimental dishes (right) each contain an untreated diet station (NT) paired with one treated with conspecific larval oral exudate. In dish 1, exudate was from another individual (test larva not induced to produce exudate). In dish 2, exudate was from the test larva (test larva induced). In dish 3, exudate was from another individual (test larva induced). $N = 40$. With no delay in introduction of test larva, only the distribution in dish 1 is significantly different from the control, Fisher's exact test, $P = 0.047$. Following a 24-hr delay, all experimental distributions are significantly different from the control, $P = 0.024$, $P = 0.048$, and $P = 0.035$, respectively.

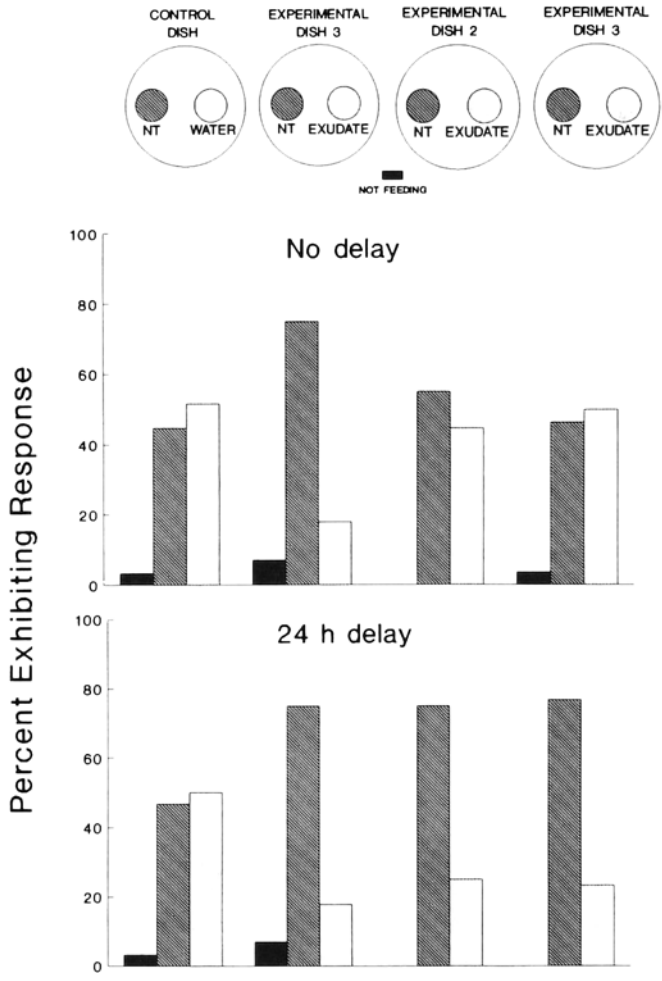

FIG. 6. Percentage of foliage-reared *C. occidentalis* larvae not feeding or feeding on one of two diet stations with centers separated by 3 cm, either 0 (experiment 11) or 24 hr (experiment 12) after treatment of stations and induction of exudate production. Circular schematic diagrams indicate placement of diet stations (magnified in size) in Petri dishes, with shading of treatment corresponding to the percent response bars below. The control dish (left) contains an untreated diet station (NT) paired with one treated with distilled water. The experimental dishes (right) each contain an untreated diet station (NT) paired with one treated with conspecific larval oral exudate. In dish 1, exudate was from another individual (test larva not induced to produce exudate). In dish 2, exudate was from the test larva (test larva induced). In dish 3, exudate was from another individual (test larva induced). $N = 40$. With no delay in introduction of test larva, only the distribution in dish 1 is significantly different from the control, Fisher's exact test, $P = 0.032$. Following a 24-hr delay, all experimental distributions are significantly different from the control, $P = 0.025$, $P = 0.043$, and $P = 0.033$, respectively.

proprioception of the partially empty gut. Such a mechanism would enable larvae to use exudate to repel competitors from valuable resources, such as silken feeding tunnels (Berenbaum et al., 1993), without repelling themselves. Under field conditions, a refractory period of 24 hr may be sufficient for most of the active components in the exudate to volatilize, degrade, or be washed away. However, in the laboratory, some larvae that had been induced to produce exudate in or at the mouths of their own feeding tunnels abandoned the tunnels 6–8 hr later (Poirier and Borden, 1995). This dispersal may reflect a natural response in which the persistent occurrence of exudate (whether self- or otherwise produced) could signal an overpopulated habitat.

Many avenues of investigation remain to be explored. These include determination of the role of natural host foliage in the production and potency of the exudate, the persistence and chemical nature of the exudate, and evaluation of the potential utility of the exudate or its components in the management of spruce budworms.

Abstract—Cotton, *Gossypium hirsutum* L., has been shown to exhibit systemic induced resistance to arthropods under certain conditions. We conducted experiments to determine the effects of previous feeding of *Spodoptera exigua* Hübner and *Spodoptera littoralis* (Boisd.) larvae on feeding behavior, growth, and survival of larvae subsequently feeding on cotton. In one feeding choice test, *S. exigua* larvae preferred young leaves from undamaged control plants to undamaged young leaves from a previously damaged plant. Feeding deterrence was noticeable after only 6 hr of initial feeding damage by larvae, and there was almost complete deterrence after 30 and 54 hr of continuous feeding. In a second feeding choice test, *S. littoralis* larvae fed more on mature leaves from undamaged control plants than on undamaged mature leaves from previously damaged plants. In no-choice tests, third instars of *S. littoralis* fed undamaged young leaves from damaged plants did not gain weight and died by the seventh day, whereas larvae fed young leaves from undamaged control plants gained weight and pupated within 11 days. Sixth instars of *S. littoralis* fed either old damaged leaves, old undamaged leaves, or young undamaged leaves all from previously damaged plants gained weight slowly and took more than 12 days to pupate, whereas larvae fed young leaves from undamaged plants gained weight rapidly and pupated within five days of the beginning of the experiment.

INTRODUCTION

Plants have evolved many traits, both physical and chemical, that protect them from damage by herbivores. Resistance may be either constitutive, when resistance factors are present regardless of injury, or induced. Induced resistance is the qualitative or quantitative enhancement of a plant's defense mechanism in response to physical or chemical extrinsic stimuli, such as herbivory, pathogen infection, or mechanical injury (Kogan and Paxton, 1983). Induced responses to injury may be localized (i.e., restricted to a small area around the actual site of damage), or systemic, where a signal produced at the damaged site is transported throughout the plant causing effects at sites distant from the initial injury. While much is known about constitutive plant resistance to arthropods, relatively less is known about induced resistance, especially systemic induction of resistance. This emerging area of plant-insect interactions is gaining considerable interest (Karban and Myers, 1989; Tallamy and Raupp, 1991; Schultz, 1993).

Cultivated cotton, *Gossypium hirsutum* L., has been studied intensively for resistance to important arthropod pests such as corn earworm, *Helicoverpa zea* Boddie; tobacco budworm, *Heliothis virescens* (F.); boll weevil, *Anthonomus grandis* Boheman; spider mites; and other pests (Niles, 1980). Constitutive factors contributing to resistance to lepidopterous pests include morphological traits, such as foliar form, color, and pilosity (reviewed in Niles, 1980), and the presence of allelochemicals, such as sesquiterpenes (Stipanovic et al., 1986), terpenoid aldehydes (Stipanovic et al., 1986; Hedin et al., 1992), condensed tannins, and flavonoids (reviewed in Hedin et al., 1983).

Localized induction of resistance to *Spodoptera littoralis* Boisd. was found in cotton leaves that experienced artificial wounding (Croxford et al., 1989). Larvae avoided feeding at the edge of the wound and in a halo surrounding the damaged site. The degree of avoidance increased up to seven days after damage and decreased with distance up to 1 cm from the wound. Systemic resistance in cotton to spider mites, *Tetranychus urticae* Koch, was induced by feeding damage on the cotyledons (Karban and Carey, 1984). Mite-exposed plants were less suitable for mite population increase than plants never exposed to mites. In addition, female mites showed a slight preference for unexposed plants over previously exposed plants in choice situations (Harrison and Karban, 1986). Beet armyworm, *Spodoptera exigua* Hübner, had a lower probability of survival from second instar to pupation on cotton plants previously exposed to mites but did not orient towards nor consume more of the foliage from unexposed plants than from previously exposed plants (Karban, 1988).

In general, studies to date on herbivore-induced resistance have produced variable results, and the effects on herbivore performance observed have often been slight (Fowler and Lawton, 1985). In the experiments reported here, we used cotton and two lepidopterous herbivores, *S. exigua* and *S. littoralis*, to determine the subsequent palatability and suitability for development of foliage from plants previously damaged by larval feeding. In particular, we wanted to determine whether systemic feeding deterrence could be induced by previous larval feeding and how quickly such a response would be noted. Secondly, would both young and mature leaves be similarly affected? Finally, would plant response to previous feeding influence both larval feeding choice and survival?

METHODS AND MATERIALS

Plants. Cotton plants (var. DPL 90) were grown in 16-cm-diameter pots filled with a mixture of potting soil and vermiculite (3 : 1) in either a greenhouse or an environmental chamber. The greenhouse was illuminated with natural light, and conditions were ambient for Florida summer (14L : 10D light cycle, 85 ± 10% relative humidity, and 30 ± 10°C). Environmental chamber conditions mimicked conditions in the Florida greenhouse (14L : 10D light cycle, 30/20°C, 75/90% relative humidity (day/night), and ca. 360 μmol photons/sec/m^2 at 400–700 nm). Plants were watered as necessary and fertilized once a week with a complete liquid fertilizer (5-1-4 with micronutrients). Plants used in experiments were at the six- to eight-true-leaf stage (one month to six weeks after planting).

Insects. Spodoptera exigua larvae were reared on an artificial diet, based on pinto beans, according to established methods (King and Leppla, 1984). *Spodoptera littoralis* larvae were reared on a potato-based artificial diet (Hinks and Byers, 1976). Larvae were starved for 24 hr prior to all experiments to ensure immediate feeding during bioassays. Larvae were used once in a bioassay and then discarded.

Feeding Choice Bioassays. Two feeding choice experiments were conducted. The first was designed to determine whether feeding by third instars on mature cotton leaves would deter subsequent feeding on young developing leaves. The second was designed to determine whether feeding on mature foliage would deter subsequent feeding on already mature fully developed cotton leaves.

In the first bioassay, two third instars of *S. exigua* were confined on each of the two oldest true leaves of cotton plants (Figure 1A). Larvae were confined in cages made from a modified Petri dish. Each half of the Petri dish was provided with a ventilation hole covered with gauze material. A styrofoam ring cushioned each side of the cage where it touched the leaf. The two sides of the cage were held together with hair clips, and the cage was held horizontal by wooden sticks placed in the soil.

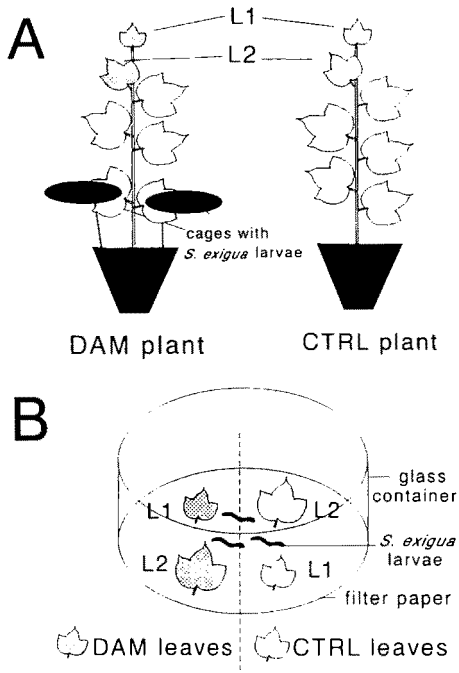

FIG. 1. (A) Experimental set-up for induction of feeding deterrents in cotton by third instars of *S. exigua*. The youngest leaves, leaf 1 (L1) and leaf 2 (L2), were cut from the damaged (DAM) and control (CTRL) plants after the oldest leaves had been exposed to larvae feeding for either 6, 30, or 54 hr. (B) Larvae were allowed to choose among leaves from control and damaged plants in a 19-cm-diameter glass arena and their consumption was measured after 18 and 24 hr.

Larvae were introduced into the cages at 11:00 hr and were replaced daily with starved third instars for up to three days. The two youngest leaves (L1 and L2, Figure 1A) were cut from one plant after 6 hr of continuous feeding, from a second plant after 30 hr of feeding, and from a third plant after 54 hr of feeding. The L1 and L2 leaves cut from the larvae-damaged plant (DAM) were paired with two leaves matched for size, age, and position within the plant from an undamaged control plant (CTRL). Preliminary experiments indicated that attaching Petri-dish cages to leaves without larvae had no effect on subsequent larval feeding preference. The four leaves were placed in a glass arena (10 cm high × 19 cm outside diameter) with three third instars placed in the center (Figure 1B). Leaf area was determined by tracing the outline of a photocopy of each leaf with a graphic digitizer (model 2200, Jandel Scientific, Sausalito,

California) before the experiment began, after 18 hr of feeding, and after 24 hr of feeding. Each time, the leaves were carefully examined for small amounts of damage that were then marked on the photocopy. The experiment was replicated five times.

In the second bioassay to determine whether mature, already fully developed leaves would be affected by larval feeding, two third instars of *S. littoralis* were caged on the oldest true leaf of five cotton plants. Larvae were removed after being allowed to feed overnight (ca. 16 hr), and plants were placed, along with undamaged control plants, in an environmental chamber for five days. After this time, the leaf immediately above the damaged leaf was caged with a leaf from the control plant matched for size, age, and position within the plant. Two third instars were added to this cage and allowed to feed overnight. After 16 hr, the leaves were cut off the plants and the area consumed was measured.

Larval Growth and Development in No-Choice Feeding Bioassays. Feeding damage in experimental plants was produced by caging one egg mass of *S. littoralis* on each of the two oldest leaves of a cotton plant (Figure 2A). When 10–20 eggs had hatched, the remaining eggs were removed and larvae were allowed to feed. After five days, all larvae were removed and the damaged plants, as well as undamaged control plants, were placed in an environmental chamber.

In the first no-choice experiment, 10 days after the larvae that caused the initial damage had been removed, young leaves that had developed after the initial damage were removed from the plant. Two third instars were placed in each of eight 9-cm-diameter Petri dishes, four containing an undamaged leaf from a previously damaged plant and four containing a leaf from a undamaged control plant. Each day fresh leaves of the same type were added, and larvae were weighed until they commenced wandering prior to pupation or died.

In a second no-choice experiment, leaves were taken from damaged and control plants 12 days after the larvae that caused the initial damage were removed. One of four types of leaves was presented to a sixth instar in a Petri dish: (1) old damaged leaves (OD) or (2) old nondamaged leaves (OND), both from damaged plants; (3) young nondamaged leaves (YND) that developed on damaged plants after the initial feeding damage occurred; or (4) young nondamaged leaves from nondamaged control plants (CTRL) (Figure 2B). Nine replicates of the four leaf types were set up. Leaves were replaced daily and larvae were weighed until they died or commenced wandering in search of pupation sites.

Statistical Analyses. For choice tests, the amount of foliage eaten from control or damaged cotton plants was expressed as a proportion of total leaf area consumed within the choice arena. Data were analyzed by analysis of variance. For no-choice tests, significant differences in larval weights were tested by paired t tests or Tukey's studentized range tests after analysis of variance,

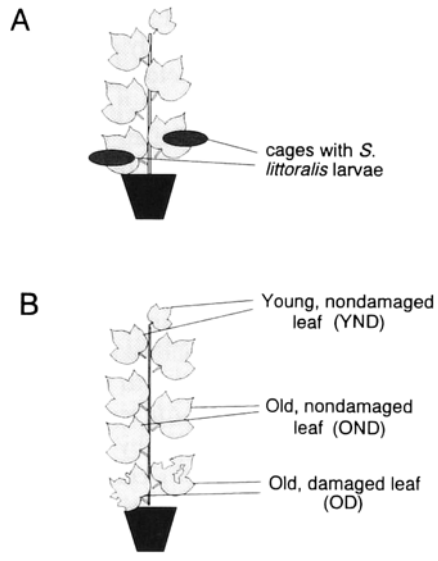

FIG. 2. (A) Experimental set-up for induction of feeding deterrents in cotton by first instars of *S. littoralis*. Initial damage was produced by caging one egg mass on each of the two oldest leaves. After eggs had hatched, larvae were allowed to feed for five days and were then removed. (B) Larval feeding response and growth were determined 10 or 12 days after larvae were removed. Larvae were presented either old, damaged leaves (OD), old, nondamaged leaves (OND), or young, nondamaged leaves (YND) from previously damaged plants, or young, nondamaged leaves from undamaged control plants (CTRL).

using a significance level of 5%. All analyses were performed with SYSTAT (Systat Inc., Evanston, Illinois).

RESULTS

Feeding Choice Bioassays. In the first bioassay, feeding by third instars of *S. exigua* on mature cotton leaves deterred feeding by subsequent larvae on young developing leaves, indicating systemic induction of feeding deterrents in developing leaves. At least 50% of the area of each type of leaf remained in all replicates of the experiment. Therefore, leaf consumption was expressed as the percentage of total leaf area eaten in a replicate for each combination of leaf age and treatment (Table 1).

Treatment contributed significantly to the variation in percentage consumption of foliage for all durations of initial feeding damage and at both

TABLE 1. LEAF AREA CONSUMED AFTER 18 AND 24 HOURS FROM YOUNGEST (L1) AND SECOND YOUNGEST (L2) LEAVES OF UNDAMAGED COTTON PLANTS (CTRL) AND PLANTS PREVIOUSLY DAMAGED BY 6, 30, AND 54 HOURS OF FEEDING BY THIRD INSTARS OF *S. Exigua* CONFINED ON TWO OLDEST LEAVES (DAM)

Duration of initial feeding damage (hr)	Treatment	18 hr feeding		24 hr feeding	
		L1	L2	L1	L2
Percentage of total leaf area consumed (mean ± SEM)					
6	DAM	1.38 ± 0.88	30.68 ± 10.65	3.90 ± 3.36	32.99 ± 7.54
	CTRL	7.36 ± 5.25	60.58 ± 8.29	8.67 ± 5.38	54.46 ± 7.65
30	DAM	0.10 ± 0.06	16.58 ± 9.39	0.46 ± 0.12	12.64 ± 4.83
	CTRL	5.05 ± 1.78	78.27 ± 10.42	4.91 ± 2.00	81.99 ± 5.75
54	DAM	0.84 ± 0.84	2.21 ± 2.21	0.64 ± 0.60	2.38 ± 2.09
	CTRL	13.55 ± 8.05	83.4 ± 8.38	13.68 ± 6.72	83.30 ± 6.61
Leaf area consumed (mm^2) (mean ± SEM)					
6	DAM	14 ± 6	454 ± 183	51 ± 39	787 ± 207
	CTRL	154 ± 126	999 ± 242	248 ± 192	1353 ± 309
30	DAM	2 ± 1	124 ± 43	7 ± 2	252 ± 154
	CTRL	57 ± 25	1176 ± 322	74 ± 27	1581 ± 338
54	DAM	3 ± 3	7 ± 7	4 ± 4	17 ± 13
	CTRL	178 ± 137	933 ± 233	227 ± 127	1313 ± 296

observation periods (18 or 24 hr) (Table 2). As little as 6 hr of feeding damage inflicted by third instars of *S. exigua* caused subsequent larvae to consume a significantly smaller percentage of foliage from previously damaged plants than from control plants (Table 1) ($P = 0.025$ at 18 hr and $P = 0.052$ at 24 hr; Table 2). Young leaves from plants experiencing 30 and 54 hr of feeding injury were significantly less preferred than leaves from control plants (Tables 1 and 2). The duration of initial feeding damage significantly influenced percentage consumption of both control ($F = 4.54$; $df = 1,16$; $P = 0.049$) and damaged leaves ($F = 6.19$; $df = 1,16$; $P = 0.024$) measured after 24 hr of larval feeding. As duration of initial feeding injury increased (from 6 to 54 hr) leaves from previously damaged plants contributed less to the total consumption, while leaves from control plants contributed correspondingly more (Table 1).

Leaf age (the youngest leaf, L1, or the second youngest leaf, L2) was a significant source of variation for all combinations (Table 2). Larvae always consumed smaller amounts of the youngest leaves (L1), regardless of whether they were from control or previously damaged plants (Table 1). There was also a significant interaction between leaf age and treatment for all time periods except for feeding injury of 6 hr (Table 2). This can be explained by the observation that while L2 leaves from control plants were very much more palatable

TABLE 2. ANALYSIS OF VARIANCE OF PERCENTAGE OF LEAF AREA CONSUMED BY THIRD INSTARS OF *S. Exigua* IN 18 OR 24 HOURS IN CHOICE TESTS AFTER INITIAL FEEDING DURATION OF 6, 30, OR 54 HOURS

[a] Youngest (L1) or second youngest (L2) leaf.
[b] Undamaged control (CTRL) or previously damaged (DAM) plants.

than L2 leaves from damaged plants, L1 leaves from control plants were not much more palatable than these youngest leaves from damaged plants (Table 1). The youngest leaves appeared to be inherently protected against herbivore attack.

Results from the second bioassay indicated that previous feeding damage by third instars of *S. littoralis* induced production of feeding deterrents in already mature, nondamaged leaves (the leaf immediately above the damaged leaf). When *S. littoralis* larvae were confined with still-attached leaves from damaged and undamaged plants, 99.1 ± 0.9% (mean ± SD, $N = 5$) of the leaf area consumed was from the control rather than the previously damaged plant.

Larval Growth and Development in No-Choice Feeding Bioassays. Third instars of *S. littoralis* confined with young undamaged leaves from a previously damaged cotton plant or with young undamaged leaves from a control plant differed significantly in weight gain and survival over the nine-day course of the experiment (Figure 3). Larvae presented with undamaged foliage from a previously damaged plant refused to feed and did not gain weight. All eight larvae died by day 7 with seven, five, and one larva remaining alive on days 4, 5, and 6, respectively. On the other hand, larvae fed leaves from a control plant gained weight almost exponentially after day 5. These larvae survived to day 9 of the experiment, when they left the foliage in search of pupation sites. Larvae in the two treatments weighed the same at the start of the experiment, but larvae fed control foliage weighed significantly more than larvae fed induced foliage on days 1–6 (two-tailed t test, $\alpha = 0.05$).

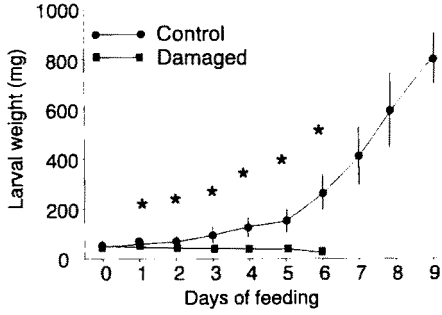

FIG. 3. Average weight (±1 SD, $N = 8$) of *S. littoralis* larvae confined in Petri dishes as third instars with young, undamaged leaves from either a damaged cotton plant (damaged, ■) or an undamaged control plant (control, ●). Larvae were weighed daily until they left the foliage in search of pupation sites (day 10 for larvae fed control leaves) or they died (day 7 for larvae fed leaves from previously damaged plants). *Significant difference in larval weight (two-tailed t test, $\alpha = 0.05$).

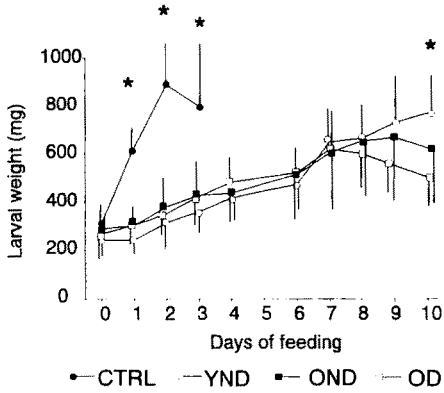

FIG. 4. Average weight (±1 SD, $N = 9$) of *S. littoralis* larvae confined in Petri dishes as sixth instars with either old, damaged leaves (OD, □), old, nondamaged leaves (OND, ■), or young, nondamaged leaves (YND, ○) from previously damaged plants, or young, nondamaged leaves from undamaged control plants (CTRL, ●). Larvae were weighed daily until they left the foliage in search of pupation sites (day 4 for larvae confined with undamaged control leaves and day 11 for all others). *Significant difference in larval weights among the four leaf types (Tukey's studentized range test, $\alpha = 0.05$).

Sixth instars of *S. littoralis* presented with one of three types of leaves from previously damaged cotton plants (YND, OND, or OD, Figure 2B) or with leaves from undamaged plants (CTRL) all attempted to feed; however, weight gain and survival differed significantly among the treatments (Figure 4). Larvae fed young foliage from control plants gained weight significantly faster than larvae fed foliage from previously damaged plants (Tukey's studentized range test, $\alpha = 0.05$) and left the foliage in search of pupation sites by day 4 of the experiment. Larval weight did not differ significantly among the other three treatments until day 10, when larvae fed young undamaged foliage from the previously damaged plant (YND) weighed more than larvae fed the old damaged leaves from the damaged plant (OD) (Figure 4). After 10 days, the induced plants were severely depleted of foliage. Therefore, remaining larvae had to be fed noninduced foliage and, as a consequence, survival to pupation and emergence could not be calculated. However, all but two of the larvae fed induced foliage for 10 days eventually pupated and produced normal-looking moths (one larva fed OD foliage died on day 6 and one larva fed OND foliage died on day 8).

DISCUSSION

Systemic induction of antifeedants in response to insect herbivory was first discovered in tomato and potato (Green and Ryan, 1972). Since then research

into systemic responses to herbivory has increased dramatically. Research efforts can be divided into those addressing annual or herbaceous perennial plants such as tomato, soybean, cucurbits, tobacco, and cotton, and studies on trees such as birch, alder, oak, willow, conifers, quaking aspen, and poplar (reviewed in Tallamy and Raupp, 1991). Differences in the defensive strategies of these two groups are to be expected because of their differing "apparency" to enemies (Feeny, 1977). Most of the accounts of rapid, systemic, induced responses to insect herbivores occur in annual plants.

In our experiments, larvae of two *Spodoptera* species fed more on foliage from undamaged cotton plants than on undamaged foliage from plants previously fed upon by larvae. In contrast, Karban (1988) found that *S. exigua* larvae did not consume more foliage from undamaged cotton plants than foliage from plants exposed to mites at the cotyledonary stage when given a choice. Female mites, however, were observed to choose foliage from unexposed plants over foliage from previously mite-exposed plants for feeding and oviposition (Harrison and Karban, 1986). They suggested that the mites made this choice without contacting the plant or feeding, and instead relied on olfactory cues. While we know that volatiles produced systemically from undamaged leaves of herbivore-damaged cotton plants differ from volatiles released from undamaged plants (Röse et al., unpublished data), we do not know whether volatile signals influenced the feeding choices of *S. exigua* or *S. littoralis*.

In studies by other researchers, *S. littoralis* avoided the immediate area around a disk punched in cotton and soybean leaves, indicating some localized antifeedant (Croxford et al., 1989). The soybean looper, *Pseudoplusia includens* (Walker), and *Epilachna varivestis* Mulsant, the Mexican bean beetle, fed preferentially on disks cut from foliage of uninjured soybean rather than on disks from undamaged foliage of plants previously fed on by soybean looper (Lin and Kogan, 1990). *Trichoplusia ni* (Hübner) consumed more low-alkaloid content tobacco leaves than high-alkaloid content leaves (Baldwin, 1991) when alkaloids had been induced by mechanical damage. *S. littoralis* fed more on tomato leaves from undamaged plants than on damaged or undamaged leaves from a previously wounded plant (Edwards et al., 1985).

Results from the preceding experiments indicate that many herbivores are capable of choosing to feed on noninduced foliage rather than on induced foliage. For mobile insects, such as lepidopterous larvae, avoidance behavior in response to antifeedants may result in mortality in the field due to increased encounters with predators, pathogens, or parasitoids; falling off the plant; or expenditure of energy searching for suitable feeding sites rather than feeding. The relationship between laboratory bioassays and population effects in the field is not often explored, however (Fowler and Lawton, 1985; Karban, 1991b).

In our experiments, feeding by two third instars of *S. exigua* on the two oldest cotton leaves produced pronounced systemic feeding deterrency in the two youngest leaves in as little as 6 hr (Table 1). The factor responsible for

deterrence was somehow translocated upwards and its effects were observed at least three nodes higher than the location where initial damage occurred. No research to date has addressed the speed of onset of systemic induction in cotton other than that of Karban and Carey (1984), who found that feeding by mites produced noticeable effects within 14 days of initial feeding damage. In tomato, however, *S. littoralis* fed significantly less on leaves cut with scissors than on control leaves within 8 hr of injury. The same was true of the leaf adjacent to the wounded leaf 24 hr after damage (Edwards et al., 1985). Green and Ryan (1972) found that within 1 hr of artificial wounding in tomato, sufficient signal has been transported that leaves adjacent to the injured leaves were induced and contained elevated levels of proteinase inhibitors. Thus the speed of onset of systemic induction in our experiments with cotton is similar to that found by other researchers for tomato.

In our studies, we observed reduced feeding by larvae in choice tests involving both young, still-developing leaves and fully mature leaves. Similarly, larvae feeding on either mature leaves or young leaves from induced plants in no-choice situations both gained weight slowly. Presumably, fewer primary metabolites are being directed towards the mature leaves and more to the developing leaves; however, the signal still travels to the mature leaves and induces feeding deterrents or growth inhibitors. The distribution of induced responses within plants has not been studied in much detail (Karban and Myers, 1989) and will be addressed in future research.

The detrimental effects to larvae of feeding on foliage from previously damaged plants were significant and pronounced in our experiments. Third instars of *S. littoralis* refused to feed on foliage from induced plants. Larvae lost weight during the experiment and all died by day 7, whereas larvae fed foliage from undamaged plants gained weight rapidly and pupated successfully. Sixth instars confined on induced foliage during their period of almost exponential weight gain also gained weight significantly more slowly than those larvae confined on young foliage from control plants. Larvae fed either damaged old leaves, undamaged old leaves, or young leaves, all from previously damaged plants, did not differ significantly in weight until the last day of the experiment (day 10, Figure 4), when larvae fed young leaves weighed more than larvae fed either type of old leaves.

In general, herbivores that feed on artificially wounded or herbivore-damaged plants often exhibit reduced population growth, survival, growth rates, adult weight, and adult fecundity (reviewed in Karban, 1987) compared to herbivores feeding on undamaged plants. For example, *S. exigua* reared on foliage from mite-exposed cotton plants had a lower probability of surviving from second instars to pupation and reduced expected life-spans compared to larvae fed control plants (Karban, 1988). Population growth of *T. urticae* on previously mite-exposed cotton plants was about half that on unexposed plants (Karban and

Carey, 1984). Localized induced resistance in a wild cotton, *Gossypium australe*, led to decreased survival of the leafminer, *Bucculatrix gossypii*, on leaves previously damaged by leafminers (Karban, 1991a). The detrimental effects on herbivores observed in these experiments are slight compared to results of our studies.

Many questions arise from these experiments, and this model system should provide fertile ground for further research. It is not known whether the induced response we observed was chemical or physical in nature. Known antixenotic and antibiotic allelochemicals conferring constitutive resistance to herbivores of cotton may be inducible, and this should be investigated. Similarly, is the induction of feeding deterrents related to the induction of volatiles in cotton? In corn seedlings, mechanical damage alone does not induce systemic production of volatile sesquiterpenes (Turlings et al., 1990). Larval feeding damage or application of larval regurgitant to mechanical damage is necessary for induction of volatiles. Comparative studies on the effects of mechanical damage versus larval feeding damage on feeding deterrents in cotton will address this issue. Finally, cotton leaves were not sterilized prior to the experiments, so it is possible that phylloplane microbes elicited the responses observed rather than insect-related factors (Benedict and Chang, 1991). Few experiments, in fact, separate these two factors (Schultz, 1993). Well-designed experiments could shed light on the interesting phenomenon of systemic induced resistance in cotton.

USE OF A COMPARATIVE APPROACH TO IDENTIFY ALLELOPATHIC POTENTIAL AND RELATIONSHIP BETWEEN ALLELOPATHY BIOASSAYS AND "COMPETITION" EXPERIMENTS FOR TEN GRASSLAND AND PLANT SPECIES

D. A. WARDLE,* K. S. NICHOLSON, and A. RAHMAN

AgResearch, Ruakura Agricultural Research Centre

(Received May 15, 1995; accepted January 1, 1996)

Abstract—Various allelopathy bioassays were used to evaluate the allelopathic potential of 10 grassland forage species against a common test (phytometer) species, *Carduus nutans* L. Aqueous extracts did not influence *C. nutans* germination, although radicle elongation was often severely inhibited. *C. nutans* was strongly affected by shoot, but not root, leachates. Decomposing ground tissue had mixed effects, and often stimulated shoot production of *C. nutans*. Calculation of R^2 (coefficient of determination) values between these results, and the results of previous experiments investigating the effects of the same 10 species on *C. nutans* emergence and development in field plots and glasshouse competition experiments frequently revealed strong, statistically significant relationships. Our results therefore provide correlative evidence for the importance of allelopathy in field conditions.

Key Words—Allelopathy, bioassay, *Carduus nutans* L., comparative approach, correlative evidence, forage plant, grassland, phytometer.

INTRODUCTION

Allelopathy has frequently been suggested as an important factor in regulating the structure of plant communities (McPherson et al., 1971; Rice, 1984; Rutherford and Powrie, 1993; Smith and Martin, 1994) and growth rate of plants in

*To whom correspondence should be addressed.

field conditions (Dias, 1991; Li et al., 1992; Nakahisa et al., 1993). However, many researchers have criticized the notion that allelopathic agents are active or important under field conditions, mainly because of perceived flaws in the methodologies (principally bioassays) used for evaluating allelopathy (Harper, 1977; Keeley, 1988) and because of the failure of one study (Stowe, 1979) to detect a statistically significant relationship between the bioassay results for a range of species and the spatial patterning of the same species in the field.

Comparative approaches to plant ecology often have been utilized successfully for testing hypotheses relating to factors influencing plant growth and structuring plant communities (Gaudet and Keddy, 1988; Grime et al., 1988; Shipley and Peters, 1990; Keddy et al., 1994). Such approaches involve selecting a number of plant species (with each species representing a single independent data point), and investigating whether a statistically significant relationship (usually a correlation) exists between two or more variables measured for the whole range of species tested. Although correlation does not mean causation, predictive comparative approaches can enable prediction of factors important in regulating a wide spectrum of species in a given community (Peters, 1991).

The comparative approach has considerable potential in testing the allelopathy hypothesis. Such a test would involve quantifying the relative allelopathic effect of a range of donor species against a common receiver species (= phytometer; Gaudet and Keddy, 1988) and determining whether these effects were correlated with the relative effects of the same donor species against the receiver species in field (or glasshouse) interference experiments. In previous studies we have reported the relative effects of 10 grassland forage plant species against the seedling emergence, growth, and development of a single test species (the pasture weed *Carduus nutans* L. or nodding thistle) in both field experiments (Wardle et al., 1995) and glasshouse competition experiments (Wardle et al., 1992b). The purposes of the present study were to utilize various conventional bioassay techniques to determine the potential allelopathic effects of the same 10 species on *C. nutans* and to employ the comparative approach to elucidate whether significant relationships could be established between the results of these bioassays and the results of Wardle et al. (1992b, 1995).

METHODS AND MATERIALS

The donor species used for this study are all used as forage species in New Zealand pastures, and included six grasses [*Dactylis glomerata* L. (cocksfoot), *Phalaris aquatica* L. (phalaris), *Bromus wildenowii* L. (prairie grass), *Lolium perenne* L. (perennial ryegrass), *Festuca arundinacea* Schreb. (tall fescue), and *Holcus lanata* L. (yorkshire fog)] and four legumes [*Medicago sativa* L.

(lucerne), *Trifolium pratense* L. (red clover), *T. subterraneum* L. (subterranean clover), and *T. repens* L. (white clover)]. Seedlings of donor species were raised from commercially available seed sources. Seeds for the receiver species, *C. nutans*, were collected from pastures in the Waikato district of New Zealand [area described in detail by Wardle et al. (1995)], during the summer of 1990–1991. Four bioassays were used to evaluate the effects of each of the 10 species on *C. nutans*: aqueous extract bioassays, leaf leachate bioassays, root leachate bioassays, and decomposing tissue bioassays.

Tissue Preparation. To provide tissues for the allelopathy bioassays, polystyrene trays, 50 × 30 × 9 cm deep were filled up to 1 cm depth with a 1 : 1 mixture of soil and pumice, as described by Wardle et al. (1992b). The soil was a Vitric hapludand (Horotiu sandy loam; pH 5.7; organic C 9.1%); the pumice was included to ease the separation of roots. These trays were sown with seeds of each of the 10 species (eight trays per species) at the recommended field sowing rate for each species [rates given by Wardle et al. (1992b)]. Following establishment, the swards were left in glasshouse conditions (temperature range: 10–25°C; day–night light ratio 12 : 12) and amended approximately every two weeks with an appropriate nutrient solution (Smith et al., 1983). After 90 days all the above-ground and below-ground tissue produced by each species was harvested.

Aqueous Extract Bioassay. This was conducted according to Wardle et al. (1992a). Subsamples of the shoot and root tissues of each species were air-dried and ground to 0.5 mm using a Wiley mill, mixed with deionized water at a concentration of 5% (w/v), and stirred vigorously at room temperature for 20 min. The mixture was filtered by passing it twice through cheesecloth and then through Whatman No. 1 filter paper. For each tissue, two solutions, 2% and 5% w/v, of tissue were prepared. These concentrations are within the range normally used for bioassays of this type (Stowe, 1979; Hegazy et al., 1990). To assess the allelopathic effect of each solution, 10 replicate 9-cm-diameter Petri dishes were set up and germination tests performed as described by Wardle et al. (1992a). Two pieces of Whatman No. 1 filter paper (9 cm diameter) were added to each dish, to which was added 5 ml of aqueous extract and 20 seeds of *C. nutans*. Controls consisted of 10 Petri dishes containing deionized water in place of the extract. Osmotically adjusted controls were not used (cf. Wardle et al., 1992a) because *C. nutans* is not responsive to osmotic potentials of the extracts. The total number of seeds that germinated for each Petri dish was determined daily for 21 days and seeds were removed upon germination so as to prevent radicles and cotyledons of germinated seeds from interfering with germination of other seeds. Total percent germination for each Petri dish was determined for the whole 21-day period, as well as the speed of germination index, *S*, of Khandakar and Bradbeer (1983) as described by Ahmed and Wardle (1994). This index ranges from 100 (if all seeds germinate on the first day

following set-up) to 0 (if no seeds germinate by the end of the experiment). Assessments of allelopathic effects of these extracts on *C. nutans* radicle elongation were also made, as described by Wardle et al. (1993). Seeds of *C. nutans* were pregerminated on moistened filtered paper, and upon germination were placed in Petri dishes (three seeds per dish) with 5 ml of each of the solutions described above and five replicate dishes per extract. Corresponding controls consisted of deionized water in place of the extract. After 10 days, the length of each radicle was measured.

Aqueous Leaf Leachate Bioassay. This bioassay was performed for each donor species as described by Wardle et al. (1993), based on the approach of McPherson et al. (1971) and Stowe (1979). This involved placing 1.5 kg (fresh weight) shoot tissue on a 1-m-diameter sieve (holes = 4 mm) and spraying it with a fine mist of deionized water for approximately 15 min, until 200 ml of leachate was obtained. The effect of each leachate on percent germination, speed of germination, and radicle elongation of *C. nutans* was evaluated exactly as for the aqueous extract bioassay.

Root Leachate Bioassay. This bioassay was performed basically as described by Ahmed and Wardle (1994). Six replicate pots (15 cm diameter × 12 cm deep) were prepared for each donor species by filling them with a 1 : 1 mixture of Horotiu silt loam soil and pumice, and sowing them with seeds of that species at the recommended sowing rate (Wardle et al., 1992b). Another six pots, filled with the soil–pumice mix but left unplanted, were set up to serve as controls. All pots were then left in glasshouse conditions as described above, and trimmed every two to three weeks to 5 cm height (to simulate grazing removal in the field; Wardle et al., 1994). After 90 days a further 66 pots were prepared, each filled with the same soil–pumice mix, and planted with 15 *C. nutans* seeds. Each *C. nutans* (receiver) pot was linked with one donor pot (so as to maintain statistical independence). Every seven days for a further 98 days, 650 ml of deionized water was added to the soil surface of each donor pot. Over the following 2 hr, 250 ml of the water that came out of the bottom of each donor pot was collected and added to the soil surface of the corresponding receiver pot. The total number of *C. nutans* seedlings that emerged in each receiver pot was counted approximately every two days for the first three weeks and approximately every five days thereafter until the end of the experiment, so as to determine the total percent seedling emergence and speed of emergence index, E (calculated the same as the speed of germination index, S). Thirty-eight days after setting up the receiver pots, the total number of *C. nutans* seedlings was thinned to one per pot, to reduce the potential for intraspecific interference (Wardle et al., 1993). At the end of the experiment, the *C. nutans* plant present in each pot was harvested and the total above-ground and below-ground biomass dry weight, and shoot–root ratio was determined following oven drying (80°C;

24 hr). The entire experiment was performed in glasshouse conditions as described above.

Decomposing Tissue Bioassay. This bioassay was performed as described by Wardle et al., (1993). For each donor species, air-dried root and shoot tissue was ground to 0.5 mm using a Wiley mill and mixed with the soil–pumice mixture described above, at each of two concentrations: 0.2% and 0.8% w/w. The concentrations used correspond with the quantities of forage plant tissues present in managed pastures (Wardle et al., 1993). Two types of controls were also used. The first consisted of pumice + soil, without amendments. The second consisted of peat moss mixed with the pumice + soil at concentrations of 0.2% and 0.8%. The rationale behind this second control is that soil organic matter levels are enhanced following addition of plant tissue (resulting in plant responses being attributable to factors other than allelopathy), and the addition of a supposedly inert medium (peat moss) in place of plant tissue is presumed to correct for changes in organic matter without inducing allelopathic effects (Stowe, 1979; Shafer and Garrison, 1986). Six replicate pots (each 15 cm diameter × 12 cm deep) were filled with soil from each tissue type × concentration combination. Fifteen seeds of *C. nutans* were planted in each pot and the total percent seedling emergence and speed of emergence determined as described for the root leachate bioassay. Pots were maintained in glasshouse conditions as described above and amended with an appropriate nutrient solution (Smith et al., 1983). After 36 days the total number of *C. nutans* seedlings in each pot was thinned to one. The experiment was then left for a further 59 days, after which the oven-dry shoot and root weight and shoot–root ratio of each seedling was determined.

Data Analysis. Data for each bioassay were calculated as treatment value divided by control value, so as to aid comparisons between bioassays (Wardle et al., 1993; Ahmed and Wardle, 1994). These data were analyzed using analysis of variance testing for donor species effects on *C. nutans*, followed by Tukey's honestly significant difference test at $P = 0.05$.

Coefficients of determination (R^2) values were calculated in order to evaluate the relationships between the allelopathy bioassay results and the results of the studies of Wardle et al. (1992b, 1995), who investigated the nature of interference of the 10 forage species on seedling emergence, growth, and development of *C. nutans*. Because of the large number of variables measured for the 10 species (especially in terms of the allelopathy bioassays), if all possible combinations between variables were tested it would be expected that a number of R^2 values would emerge as being statistically significant simply due to chance (or type 1 error). To help overcome this problem and to reduce the number of variables in the data set, the data were simplified by using principal components analysis (PCA) to identify principal components that summarized the maximal

variation present across the 10 species for each of the four bioassays (see Wardle and Parkinson, 1990). For example, the six variables relating to the aqueous extracts (germination, speed of germination, and radicle elongation data for each of the 2% and 5% concentrations of extract) were all simplified to one variable, namely the principal component maximizing variation between donor species. Only the first principal component (explaining the greatest variation) was used from each of the four bioassay types, since preliminary analysis revealed that lower-order principal components were unimportant in explaining observed trends. A fifth allelopathy variable was also used, namely the principal component explaining the maximal variation in a previous study aimed at evaluating the effects of residual soil toxicity of each of the 10 donor species against *C. nutans* (Wardle et al., 1991) (hereafter referred to as the residual soil bioassay). R^2 analysis was used to elucidate the relationship between each of the five principal components, and the effects of swards of each of the 10 forage species on *C. nutans* seedling emergence, growth rate, mortality, and flowering intensity in the field [data from Wardle et al. (1995)] and on *C. nutans* seedling emergence and growth rate in glasshouse competition experiments [data from Wardle et al. (1992b)].

In a previous study, Wardle et al. (1993) determined the response of the same 10 forage species to the allelopathic potential of *C. nutans* tissues. To determine whether any relationship exists between the allelopathic effect of these 10 species (present study) and their response to allelopathic effects of another species [i.e., whether there exists an allelopathic equivalent of the competitive hierarchy (Panetta and Randall, 1993) of plants], R^2 analysis was performed between each of the five principal components described above and the principal components derived from data presented by Wardle et al. (1993). The analyses included principal components summarizing forage plant response to *C. nutans* aqueous extracts, *C. nutans* shoot leachates, and *C. nutans* decomposing tissues.

RESULTS AND DISCUSSION

Bioassay Data. The aqueous extract bioassays showed that total germination and speed of germination of *C. nutans* was generally unresponsive to forage plant tissues at the 2% concentration (Table 1). However, shoot extracts of several species at the 5% concentration inhibited these variables, while root extracts for five of the six grasses significantly enhanced *C. nutans* speed of germination. Radicle elongation had a stronger (and consistently negative) response to shoot and root extracts, supporting other studies that suggest that radicle elongation bioassays are considerably more sensitive than those based on germination (Rice, 1984; Leather and Einhellig, 1986). Since this bioassay is most widely used to evaluate whether water-soluble inhibitors are released

from dried plant material (Stowe, 1979), it would appear from this bioassay that establishment of seedlings from germinated seeds is likely to be generally negatively affected by the forage species studied.

The aqueous shoot leachates of grasses did not exert strong effects on germination or radicle growth of *C. nutans* (Table 2) except for *L. perenne*, which caused a significant decrease in radicle elongation. However, all four legume species induced a statistically significant stimulation of *C. nutans* speed of germination, and *T. subterraneum* induced a significant decline in *C. nutans* radicle elongation. Since this bioassay is indicative of possible effects of rainfall

passing through the leaves of forage plants and reaching target plants situated beneath them (McPherson et al. 1971), it appears unlikely that this mechanism is consistent with suppression of *C. nutans* seedlings by forage species in the field.

There were no significant effects of root leachates on *C. nutans* seedling emergence (Table 3), probably indicative of the high variability of the data. However, both shoot growth and root growth of *C. nutans* were significantly influenced by most of the forage species, with the strongest effects being shown by *P. aquatica*, *L. perenne*, *H. lanata*, and *F. arundinacea*. Nutrient analysis of selected leachates from the donor pots demonstrated that the ammonium, nitrate, and phosphate concentrations did not differ between species (data not shown), so the differential levels of inhibition induced by different species appears to be due to allelopathic, not nutrient depletion effects. For five of the 10 donor species, there was also a significant reduction of *C. nutans* shoot–root ratio, indicating that shoot growth is more susceptible to root leachate toxicity than is root growth. Although this finding is inconsistent with some previous studies (Wardle et al., 1993; Nilsson, 1994), allelopathy involves a wide range of compounds, all of which affect target plants in different ways, so perhaps differences between the results from different studies are not surprising.

The decomposing shoot and root tissues of the donor species did not significantly alter *C. nutans* seedling emergence or rate of emergence (Table 4). However, statistically significant stimulations of *C. nutans* root growth (relative

to the unamended controls) were caused by shoot tissues of *D. glomerata* (0.2% concentration), *P. aquatica* (0.2% and 0.8%), *B. wildenowii* (0.2%), *F. arundinacea* (0.2%), and *H. lanata* (0.2 and 0.8%), and by root tissues of *P. aquatica* (0.8%) and *F. arundinacea* (0.8%). However, none of these stimulations were statistically significant when compared with the peat moss-amended control. This suggests that the stimulation of shoot growth may not have been due to allelopathic growth stimulation (Rice, 1986) but rather due to the improvement of soil quality due to organic matter enrichment. Amendment of soil by these tissues could conceivably increase plant growth through enhancing microbial mineralization of plant-available nutrients and enhancing turnover of the soil microbial biomass (Singh et al., 1989; Wardle, 1992).

The bioassay results in combination suggest that different forage plant species may differ in relation to their effects on *C. nutans* establishment. These effects are, however, not consistent across bioassays, probably because aqueous extract and leachate bioassays assess the potential of material to release soluble compounds over a comparatively short period, while decomposition-based bioassays evaluate longer-term processes that affect plant growth and may involve soil microorganisms.

Correlative Evidence for Allelopathy. The coefficients of determination (R^2) values between the principal component scores for the 10 forage plant species (based on principal components summarizing the data for each of Tables 1–4) and the effects of the same 10 species on *C. nutans* in field plots were often

very highly significant (Table 5). This result provides strong support for the likelihood of allelopathy occurring in the field experiment of Wardle et al. (1995), in that over 50% of the variation in *C. nutans* seedling mortality (i.e., those *C. nutans* plants that died before flowering) and the proportion of *C. nutans* plants that flowered as annuals (i.e., those that reached sufficient size in their first year to flower rather than persist as biennials) in field plots could be explained by each of the four bioassays. Further, the decomposing tissue

TABLE 5. COEFFICIENTS OF DETERMINATION (R^2) FOR RELATIONSHIPS BETWEEN PRINCIPAL COMPONENTS SUMMARIZING DATA FOR ALLELOPATHY BIOASSAYS OF TEN FORAGE SPECIES AGAINST *Carduus nutans* AND RESPONSE OF *C. nutans* TO SAME 10 SPECIES IN FIELD PLOTS AND GLASSHOUSE COMPETITION EXPERIMENTS

bioassay also explained over 80% of the variation in capitula number produced per *C. nutans* plant across the 10 sward types in the field, suggesting that allelopathy is important in regulating the final size that *C. nutans* plants reach when they flower and, hence, their potential reproductive fitness (or output). Essentially, the same pattern was observed when the results of the four bioassays were compared with the effects of the same 10 species on *C. nutans* in glasshouse competition experiments [data from Wardle et al. (1992b)]—*C. nutans* shoot weight, root weight, plant diameter, and seedling emergence all showed a consistent relationship with each of the four principal components. The principal component summarizing the results of the soil toxicity bioassay study of Wardle et al. (1991) did not, however, show strong relationships with either the field or glasshouse competition experiments.

It should be noted that for two of the bioassays (aqueous extract and decomposing tissue), some donor species stimulated *C. nutans*, while the same species inhibited *C. nutans* in the studies of Wardle et al. (1992b, 1995). However, in competition experiments, both allelopathy and resource competition can occur simultaneously (see Nilsson, 1994), and it could be expected that resource competition by forage species suppresses *C. nutans* growth, so that the overall effect of forage species on *C. nutans* would be considerably more negative than would be predicted by an allelopathy bioassay.

One of the principal criticisms of the allelopathy hypothesis is the supposed failure of bioassay results to correlate with those of field studies or observations [interestingly, the same demands are not usually made for experiments testing for resource competition; see discussion by Williamson, (1990)]. Moreover, the failure of Stowe (1979) to detect a statistical relationship between allelopathy bioassays for seven species and the field patterning of the same seven species is often used as evidence against the allelopathy hypothesis (see, e.g., Keeley, 1988). Our results differed from those of Stowe (1979) in that we were able to detect a statistical relationship; however, this may be due to important differences between the two studies. In our study, the experimental field plots consisted of comparatively pure swards of each of the 10 species, enabling allelopathic compounds of only one species to dominate in each plot. It is therefore possible that this accumulation of allelopathic components can be simulated in a bioassay if an appropriate concentration of tissue is used. Stowe's field site, in contrast, consisted of a diverse range of species, and it is unlikely that any one species would ever reach sufficient dominance for its allelochemicals to dominate subsequent interactions. We propose that effective and consistent allelopathic inhibition of one species by another is more likely to occur in communities of low species richness where the nature of the soil biochemistry is likely to be determined by a dominant plant species. Christensen and Muller (1975) detected a statistically significant relationship between the differential response of 10 herbaceous species to the chaparral shrub *Adenostema fasciculata*

H.&A. in field conditions and their response to the allelopathy bioassays of *A. fasciculata*. Their experiment also supports our hypothesis, since individual *A. fasciculata* shrubs would be much larger than individuals of the other species present and would therefore be more likely to have a dominating effect on the soil biochemical composition. We are aware that correlation does not mean causation, but we believe that our results help to refute one of the main criticisms of allelopathy bioassays—that their results do not correlate well with observed vegetation patterns.

Comparison of Effects and Responses. The results of our study can also be used, via a comparative approach, to test hypotheses relating to whether species that are more allelopathic are also those that are less sensitive to allelopathic effects of other species. Values of R^2 for allelopathic effects against *C. nutans* vs. allelopathic response to *C. nutans* across the 10 forage species revealed weak and inconsistent relationships (Table 6). In studies of plant competition, it has often been demonstrated that effect and response are inversely correlated (Goldberg and Fleetwood, 1987; Miller and Werner, 1987; Panetta and Randall, 1993) and that a competitive hierarchy therefore exists. No such relationship was detected in the present study, meaning that the two components of allelopathy (effect and response) are unrelated and that there is little evidence for an allelopathic hierarchy. If such a hierarchy does not exist, it could be expected that wherever allelopathy is important in field conditions, species spatial patterning would be much less predictable than in circumstances where competition is important.

Implications for Biological Control. One of the most promising applications

TABLE 6. COEFFICIENTS OF DETERMINATION (R^2) FOR RELATIONSHIPS BETWEEN PRINCIPAL COMPONENTS SUMMARIZING BIOASSAY DATA FOR ALLELOPATHIC EFFECTS OF 10 FORAGE SPECIES AGAINST *Carduus nutans* AND RESPONSE OF SAME 10 SPECIES TO ALLELOPATHIC EFFECTS OF *C. nutans*[a]

of allelopathy is for biological control of weeds (Altieri and Doll, 1978; Lovett, 1990). Our phytometer species, *C. nutans*, is a serious weed in many temperate regions, including New Zealand (Popay and Medd, 1990), where it aggressively competes with forage plants and reduces potential production available for livestock (Thompson et al., 1987). In our previous field study (Wardle et al., 1995) we demonstrated that interference from forage species was extremely important in regulating *C. nutans* population density, growth rate, and reproductive output of individual plants. The present study has provided evidence, through the use of a comparative approach, that this inhibition has an allelopathic basis and that forage species and cultivars with strong allelopathic effects may have a considerable and largely unrealized potential in the management of problematic weed species such as *C. nutans*.

Abstract—Males of a giant danaine butterfly, *Idea leuconoe*, display hairpencils during courtship. The females were visually attracted to and olfactorily arrested by an artificial butterfly model to which male hairpencil extracts were added. The hairpencil extracts contained a complex mixture of volatiles, including pyrrolizidine alkaloid (PA) derivatives (danaidone, viridifloric β-lactone), aromatics (phenol, *p*-cresol, benzoic acid), terpenoids (geranyl methyl thioether, (*E*,*E*)-farnesol), a series of γ-lactones (6-hydroxy-4-undecanolides and its homologs), hydrocarbons [(*Z*)-9-tricosene, etc.], and several compounds with higher molecular weight. A mixture of the major volatiles applied to a butterfly dummy strongly elicited an abdomen-curling acceptance posture in females. Viridifloric β-lactone and danaidone induced significant electroantennogram responses on the female's antennae, suggesting their principal role together with other hairpencil components as a sex pheromone to seduce females. *I. leuconoe* males seem to acquire the precursor for both of the PA fragments from the host plant, *Parsonsia laevigata* (Apocynaceae), during the larval stage; thereby they do not show pharmacophagous behavior towards PA-containing plants during the adult stage. However, males are pharmacophagously attracted to and feed on a number of simple phenolic compounds in a manner similar to other danaine species towards PAs. Wild

males sequester one of the phagostimulants, (−)-mellein, in the hairpencils in varying quantities. Phenolic compounds incorporated in the hairpencils may act primarily as warning odors linked with the defensive PAs present in the body tissues.

Key Words—Lepidoptera, Danainae, *Idea leuconoe*, hairpencil, pheromone, *Parsonsia laevigata*, pyrrolizidine alkaloid, mellein, defense.

INTRODUCTION

A giant danaine butterfly, *Idea leuconoe* Erichson, is found in coastal habitats from the Malay Peninsula to Java, the Philippines, Taiwan, and the Ryukyu Islands (Okinawa, Japan) (Ackery and Vane-Wright, 1984). The larvae feed exclusively on *Parsonsia laevigata* Alston (Apocynaceae) in the Ryukyus. The host plant contains a series of pyrrolizidine alkaloids (PAs) (Abe and Yamauchi, 1987; Abe et al., 1990, 1991), and the imago stores large quantities of the sequestered alkaloid components in its body tissues (3 mg/insect, as *N*-oxide forms) (Nishida et al., 1991, Kim et al., 1994). Thus, unlike most other danaines, the adult males do not seek PAs.

The abdominal hairpencils of *I. leuconoe* males are composed of a pair of large brushes (approximately 15 mm when fully elongated) and a pair of small brushes (approx. 2 mm as the bundle), each independently housed in its own sheath (Figure 1). The male everts the hairpencils during courtship while hovering above a female, thus disseminating volatile chemicals from the hairpencils. The large bundles of the hairpencils occasionally touch the female's antennae or a part of the body, and then the female accepts him and copulation occurs. The hairpencil components were suggested to play a decisive role as a male sex pheromone, as has been shown in the queen butterfly, *Danaus gilippus* (Pliske and Eisner, 1969).

Upon predatory attacks, the males also display hairpencils, disseminating a phenol-like odor. This suggests a secondary function of the hairpencil volatiles as repellents or as an aposematic odor in conjunction with the PAs sequestered in the body. Although *I. leuconoe* males do not show affinity to PAs, they are strongly attracted to some phenolic substances (Nishida et al., 1990), which implies a pharmacophagous association different from all other danaine species.

We report here on the identification of the hairpencil components and their biological roles as a sex pheromone and possibly as an allomone in this danaine species.

METHODS AND MATERIALS

Instruments. Gas chromatography (GC) -electron impact mass spectra (EI-MS) for the volatile components were obtained with a Hitachi M-80 mass

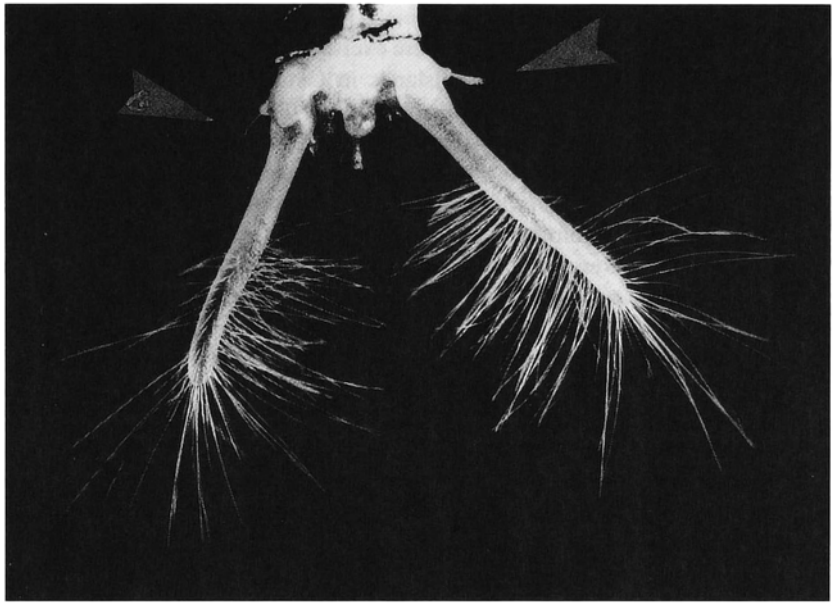

FIG. 1. Extruded hairpencils of *Idea leuconoe* male. A small pair of hairpencils (arrows) are situated on the sheath of a large pair.

spectrometer (70 eV) connected to a GC column (24-m × 0.25-mm fused silica column coated with cross-linked methyl silicone HP-1, 0.33-μm film thickness, helium as carrier gas) programmed from 80°C (approximately 2 min holding) to 240°C at a rate of 10°C/min unless otherwise mentioned. Less volatile substances were analyzed by a GC-MS system (VG 70/250 S mass spectrometer coupled to a Hewlett-Packard HP 5890A gas chromatograph using a CP-Sil-8-CB (30-m × 0.32-mm, 0.25-μm film thickness, Chrompack fused silica column with hydrogen as carrier gas and different temperature programs). High-resolution mass spectra were obtained with the same system. Chemical ionization (CI) -MS measurements were done with isobutane under similar GC conditions using a Shimadzu GC-MS QP1000EX. A chiral GC column (CP-Cyclodextrin B-2,3,6-M-19, Chrompack, 25 m × 0.25 mm, 0.25-μm film thickness, 150°C isothermal, helium) was used for determination of the absolute configuration of mellein. GC-FT-infrared (IR) spectra were obtained with a Shimadzu IRG-8000 spectrometer connected to a capillary column (30 m × 0.53 mm CBJ 17-W30-100, 1.0-μm film thickness, with helium as carrier). The ^{1}H NMR (90 MHz) and ^{13}C NMR (22.5 MHz) spectra were recorded with a Jeol JNM FX-90Q spectrometer with TMS as an internal standard.

Extraction of I. leuconoe *Hairpencil Volatiles.* Hairpencils (large and small pairs of the bundles combined) were excised from 40 males collected from field sites in Ishigaki and Iriomote islands in Okinawa Prefecture at various seasons and were extracted with ethanol (40 ml). The residue was reextracted twice with 4 ml chloroform–ethanol (1 : 1), and the combined extracts were evaporated at 25°C (20 mm Hg) to yield an oily material (53 mg). This extract was partitioned between chloroform (10 ml) and water (5 ml), the water phase extracted again with chloroform, and the combined chloroform layers dried over anhydrous Na_2SO_4. Removal of the solvent by evaporation under reduced pressure gave a yellow oil (11.5 mg), which was chromatographed on a silica gel column (0.5 g, Wako gel C-200) into 18 fractions eluting in sequence with a mixture of increasing concentrations of methyl acetate (%) in hexane (v/v, 5 ml each) as follows: fractions 1 (0%), 2 (1%), 3 (2%), 4 (3%), 5 (4%), 6 (5%), 7 (7%), 8 (9%), 9 (12%), 10 (15%), 11 (20%), 12 (25%), 13 (32%), 14 (40%), 15 (50%), 16 (60%), 17 (72%), 18 (100%).

Isolation of Compounds ***4*** *and* ***11.*** Fractions 9 and 10 were combined and subjected to preparative HPLC (Nucleosil 100-5, 8 mm ID × 300 mm). Fractions were eluted with 20% methyl acetate in hexane at a flow rate of 2 ml/min and monitored with a refractive index detector (Knauer Differential Refractometer). Compounds **4** and **11** were found at retention times (R_t) of 13.0 min and 13.2 min, respectively. Both compounds were purified further using the same HPLC column eluted with 8% methyl acetate + 6% acetone in hexane. Compound **11** was isolated at R_t = 15.1 min (yield, approx. 0.5 mg), and compound **4** was isolated at R_t = 16.6 min (yield, approx. 0.2 mg).

Quantifications of Hairpencil Volatiles. The hairpencil complex was excised from laboratory-reared males that were raised on *Parsonsia laevigata* and fed with sucrose solution during the adult stage and kept in small cages, at 22–25°C and 16 : 8 light–dark photoperiod. The hairpencil complex was excised at 5, 10, 15, 20, and 30 days after emergence, and individually extracted with ethanol (0.5 ml/male). Portions of supernatants of the crude extracts after grinding and ultrasonication were subjected to GC analyses. Excised hairpencils from wild males were processed in a similar manner. GC quantification of volatiles was done on an HP 5790A gas chromatograph with the same HP-1 column and conditions as those employed for the GC-MS analysis. Comparison of the FID intensities with those of the standard samples of known concentrations was performed using an HP 3390A reporting integrator (Hewlett Packard).

Behavioral Bioassay. Virgin females of *I. leuconone* (two to four weeks after adult eclosion) were released in a greenhouse (approx. 50 m^3) where the host plant and some nectar sources (host flowers and sucrose solution) were supplied. A butterfly dummy was made with a sheet of paper (Ricopy PPC paper type 6200, Ricoh) by copying the intact wings of an *I. leuconoe* male with a

copying machine and the dummy glued on a small piece of plastic plate connected to a glass rod; a thin piece of filter paper disk (Advantec Toyo 4A, 21 mm diameter) was attached to the end of the rod where the everted hairpencils would be situated (see Figure 6A below). When the model was moved manually by waving the rod as though the butterfly were flying, the patrolling virgin female usually approached regardless of the presence or absence of the hairpencil chemicals. Within a 1-m range of the model, individual females approaching randomly were scored for touching, landing, and eventual abdomen-curling on the model during a test period of 15 sec.

Feeding Bioassay of Mellein. The pharmacophagous acquisition of mellein was examined using a pure sample of (−)-mellein isolated from a fungus, *Lasiodiplodia theobromae* (provided by Dr. H. Nago) (Matsumoto and Nago, 1994). Laboratory-reared males (25 days old) were allowed to feed on 60 μg of the compound for about 1 hr. Thereafter they were given sucrose solution daily, and the hairpencil complex was removed five days after feeding on (−)-mellein and processed in the same manner as described above for GC quantifications.

Electroantennogram (EAG) Recording. EAG responses were recorded from antennae of 10- to 14-day-old adults of both sexes. An antenna was excised at its base and mounted upward on a plastic plate that was placed in Ringer's solution (Roelofs and Comeau, 1971). An AgCl-coated Ag plate was used as the indifferent electrode. The recording electrode consisted of a glass capillary filled with Ringer's solution (Pt wire inserted) and was brought into contact with the distal end of the excised antenna. This preparation was connected to a DPZ-115 input probe coupled with a DPA-100 amplifier (Dia Medical System), which was interfaced to a NEC PC-9801m microcomputer. EAGs were visualized on a CRT and measured as the maximum amplitude of depolarization elicited by a stimulus. An odor puff of 2 ml was mixed with a humidified airstream blowing continuously over the antenna at a rate of 350 ml/min through 6-mm-ID glass tubing, which terminated 1 cm from the antennal preparation. A test compound dissolved in dichloromethane was adsorbed on a piece of filter paper (5 × 30 mm). After evaporating the solvent at room temperature, the filter paper was placed in a sample cartridge (6 mm ID × 50 mm), and puffed into the airstream. Each chemical was tested at two doses (0.1 and 1.0 μg) on 10–14 male antennae and 10–11 female antennae, each of which originated from a different butterfly. All tests were repeated five times for each antenna. Since the antennal responses decreased in amplitude over time and the interindividual variation in absolute response to a stimulus was considerable, standards (10 μg of 1-hexanol) and blanks were included before and after each test chemical. The responses were averaged and expressed as percentages of the response to the standard.

RESULTS

Identification of Hairpencil Volatiles

Small and large bundles of hairpencils excised from sexually mature indoor males of *I. leuconoe* were analyzed separately by means of GC-MS as shown in Figure 2A and 2B. The chromatograms exhibited a series of volatile substances numbered from **1** to **16.** Although the quantities of the volatiles in the small hairpencils were extremely low compared to the larger ones (e.g., less than one thirtieth of compound **15** contained in the small ones), both shared the same compounds in different ratios. Figure 2C shows the hairpencil volatiles from males captured in Iriomote Island (large and small bundles combined). The profile was very similar to that of indoor males, but most of the males contained compound **8,** which was absent in the indoor males. Figure 3 shows mass spectra of the hairpencil components (**2, 4, 6, 7, 8,** and **10**). The hairpencil volatiles appeared to contain a variety of compounds belonging to several different classes. In order to facilitate the structural elucidation of unknown compounds, some of the components were isolated in pure forms from hairpencil extracts of outdoor males by column chromatography and preparative HPLC. Each component was characterized by spectrometric analyses and also by syntheses, if necessary, as described below.

Simple Aromatics (1, 3, 5). Compounds **1** and **3** were found to be responsible for the characteristic strong odor of the hairpencils. Compound **1** (EI-MS: *m/z* 94, 66, 65, 39) and compound **3** (EI-MS: *m/z* 108, 107, 79, 77, 51) were identified as phenol and *p*-cresol, respectively, while compound **5** proved to be benzoic acid (EI-MS: *m/z* 122, 105, 77), by comparing their gas chromatographic and mass spectroscopic data with the authentic samples.

β-Lactones (2 and 4). Compound **4** was isolated by column chromatography (fractions 9 and 10). The EI-MS (Figure 3) showed prominent ions at *m/z* 100, 85, 57 and 43, while the CI-MS exhibited ions at *m/z* (%) 145 (M+H, 40), 127 (54), 117 (100) and 101 (60). The ^{1}H NMR spectrum of compound **4** indicated the presence of an isopropyl group (δ2.27, 1H, septet, J = 6.8 Hz; 1.16, 3H, doublet, J = 7 Hz; 0.98, 3H, doublet, J = 6.6 Hz) and a secondary methyl group (δ1.54, 3H, doublet, J = 6.5 Hz) coupled with a methine proton

FIG. 2. Gas chromatograms of volatiles in the extracts of *Idea leuconoe* male hairpencils. (A) Small pair of hairpencils from indoor males. (B) Large pair of hairpencils from indoor male. (C) Hairpencil complex (large and small pairs combined) of wild males captured at Iriomote Island. Chromatograms were done on a capillary HP-1 column (24 m × 0.25 mm, programmed from 80 to 240°C, 10°C/min) with a total ion monitor (*m/z* 33–330).

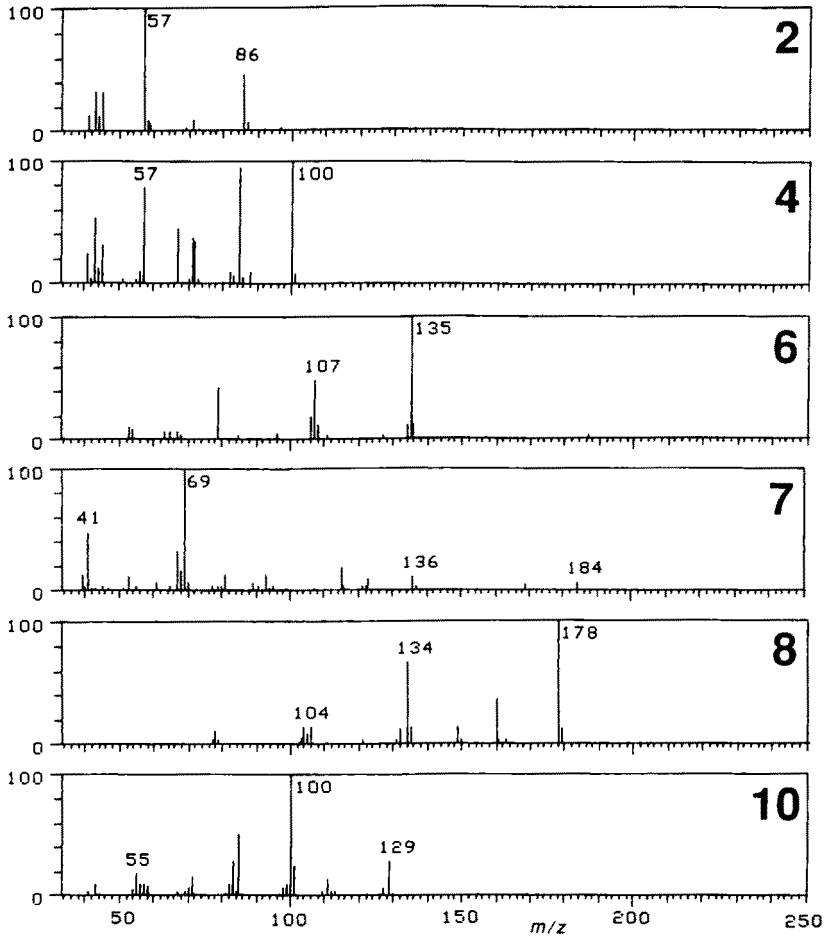

FIG. 3. Mass spectra of compounds **2**, **4**, **6**, **7**, **8**, and **10** (EI-MS, 70 eV).

(δ4.62, 1H, quartet, J = 6.5 Hz), the spectral pattern of which was similar to that of a necic acid fragment, either viridifloric acid or trachelanthic acid (Nishida et al., 1991). These data suggested a β-lactone structure for compound **4.** The FT-IR spectrum of **4** gave a strong absorption at 1850 cm^{-1}, which is characteristic of a carbonyl stretching band of a β-lactone (Figure 4). Conclusive evidence was obtained by an unequivocal synthesis of the corresponding β-lactones both from (−)-viridifloric acid and (+)-trachelanthic acid by cyclization with methansulfonyl chloride (Schulz and Nishida, 1996). The spectral

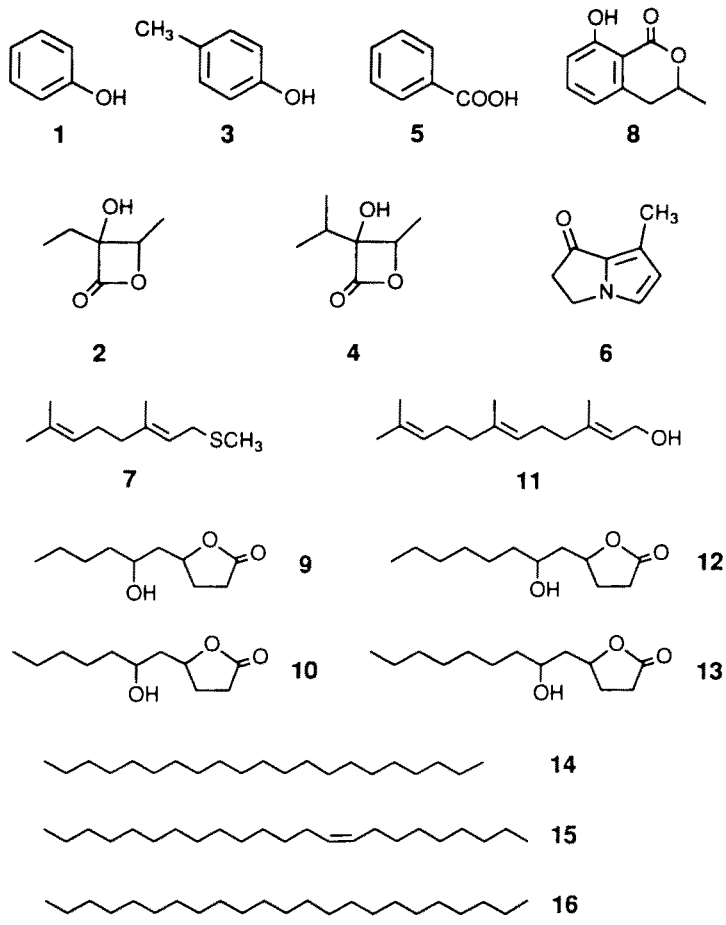

FIG. 4. Hairpencil volatiles of *Idea leuconoe* male. **1:** Phenol, **2:** 2-hydroxy-2-ethyl-3-butanolide, **3:** *p*-cresol, **4:** 2-hydroxy-2-(1-methylethyl)-3-butanolide (viridifloric β-lactone), **5:** benzoic acid, **6:** danaidone, **7:** geranyl methyl thioether, **8:** (−)-mellein, **9:** 6-hydroxy-4-decanolide, **10:** 6-hydroxy-4-undecanolide, **11:** (*E*,*E*)-farnesol **12:** 6-hydroxy-4-dodecanolide, **13:** 6-hydroxy-4-tridecanolide, **14:** heneicosane **15:** (*Z*)-9-tricosene **16:** tricosane.

(EI-MS, ^{1}H-NMR) and chromatographic (GC) data of compound **4** coincided with the β-lactone derived from viridifloric acid. Thus compound **4** was determined as viridifloric β-lactone [(2*RS*,3*RS*)-2-hydroxy-2-(1-methylethyl)-3-butanolide]. Since *I. leuconoe* incorporate (+)-lycopsamine *N*-oxide, which

contains the (−)-viridifloric acid moiety, from its host *P. laevigata*, the β-lactone is assumed to possess the same 2*S*,3*S* configuration.

Compound **2** was deduced to be a nor-derivative of β-lactone **4** (2-hydroxy-2-ethyl-3-butanolide) (Figure 4), because its mass spectrum showed ions at *m/z* 131 (M+H) in the CI-MS and at *m/z* 86 (M-CO_2) in the EI-MS (Figure 3). This was also supported by the evidence that ideamine A *N*-oxide (a nor-analog of lycopsamine *N*-oxide possessing a 2-ethyl-2,3-dihydroxy moiety) is one of the major PAs sequestered by the imago (Nishida et al., 1991).

Danaidone (6). The presence of danaidone (**6**) (found predominantly in column chromatographic fraction 13) was confirmed by its diagnostic GC-MS behavior (Figure 3) in comparison with a synthetic sample.

Terpenoids (7 and 11). The molecular formula of compound **7** was determined to be $C_{11}H_{20}S$ by GC-HRMS (M^+: obs. 184.1286, calc. 184.1289). Compound **7** gave a mass-spectrometric fragmentation pattern with some similarity to geraniol (Figure 3) and characteristic sulfur-containing ions at *m/z* 45, 61 and 115, suggesting a methyl thioether structure of a monoterpene. Geranyl methyl thioether was prepared by reaction of geranyl chloride with sodium thiomethanoate (Schulz and Nishida, 1996). The gas chromatographic and mass spectroscopic data of the thioether completely coincided with that of **7**. Thus, **7** was assigned to be (*E*)-3,7-dimethyl-2,6-octadienyl methyl thioether (Figure 4).

Compound **11** was identified as (*E*,*E*)-farnesol by comparison with an authentic sample (Aldrich Chemical Co.); no other geometrical isomers were present in the hairpencil extracts. MS: *m/z* (%) 222 (4), 204 (1), 136 (16), 93 (27), 81 (42), 69 (100), 41 (18). ^{1}H NMR ($CDCl_3$): δ5.40 (1H, broad triplet, J = 6.5 Hz), 5.10 (2H, multiplet), 4.13 (2H, doublet, J = 6.8 Hz), 2.05 (8H, multiplet), 1.67 (6H, broad singlet), 1.60 (6H, broad singlet).

Mellein (8). This compound was recovered from fractions 6 and 7 of the column chromatography and identified as mellein from its diagnostic GC-MS data (Figure 3) and ^{1}H NMR spectrum. ^{1}H NMR ($CDCl_3$) δ11.02 (1H, singlet), 7.40 (1H, double doublet, J = 8.4, 7.5 Hz), 6.88 (1H, doublet, J = 8.4 Hz), 6.67 (1H, doublet, J = 7.5 Hz), 4.72 (1H, sextet, J = 6.6 Hz), 2.92 (2H, doublet, J = 7.0 Hz), 1.52 (3H, doublet, J = 6.2 Hz). The absolute configuration of **8** was determined to be (−)-*R* by comparing its GC-retention time (R_t = 16.52 min) on a chiral column with optically active samples of mellein [(−)-*R*: R_t = 16.52, (+)-*S*: R_t = 16.68 min].

γ-Lactones (9, 10, 12, 13). The column chromatographic fractions 14 and 15 were found to consist of four homologous compounds, **9, 10, 12,** and **13,** all of which gave a characteristic mass spectrometric fragmentation pattern with three prominent peaks at *m/z* 129 (highest mass fragment), 100 (base peak), and 85 (Figure 3). Molecular weights of compounds **10** and **12** were determined to be 200 and 214, respectively, from their CI mass spectra [**10,** *m/z* (%) 201

(65), 183 (100), 165 (53); **12**, *m/z* (%) 215 (48), 197 (77), 179 (51)]. FT-IR spectra of **10**, **12**, and **13** exhibited strong bands at 1810 cm^{-1}, suggesting the presence of a γ-lactone moiety in these compounds. The ^1H and ^{13}C NMR spectra of fractions 14 and 15 (as a mixture of **9**, **10**, **12**, and **13**) confirmed the presence of a γ-lactone moiety with a hydroxy group on the side chain. The ^1H NMR spectrum ($CDCl_3$) of the homologous mixture gave signals at δ4.80 (1H, multiplet), 3.89 (1H, multiplet), and 0.89 (3H, virtually coupled triplet, J = 5.5 Hz). The highly splitting coupling pattern arising from the lactone ring protons in the range of 1.8–2.7 ppm resembled the pattern observed in that of γ-nonalactone. The ^{13}C NMR spectrum ($CDCl_3$) of the mixture gave 11 major signals arising mainly from compound **10** at 176.93, 78.17, 68.64, 43.29, 38.14, 31.80, 28.88, 28.60, 25.19, 22.64, and 14.03 ppm. The hydroxy group was assigned to be attached to C-6, since the prominent peaks at *m/z* 129 and 100 in the EI-MS (Figure 3) can be explained by cleavage at the side of the carbinol group. Thus, compounds **9**, **10**, **12**, and **13** were characterized as 6-hydroxy-4-decanolide, 6-hydroxy-4-undecanolide, 6-hydroxy-4-dodecanolide, and 6-hydroxy-4-tridecanolide, respectively. This structural assignment was confirmed by synthesis of racemic 6-hydroxy-4-undecanolide. The absolute configuration of the natural compound **12** could be established to be 4*S*,6*S* by stereoselective synthesis and chiral gas chromatography (Schulz and Nishida, 1996).

*Hydrocarbons (**14**, **15**, **16**).* Compounds **14**, **15**, and **16** were eluted in fraction 1 from column chromatography. Compounds **14** and **16** were identified as heneicosane and tricosane, respectively. Compound **15** [^{13}C NMR ($CDCl_3$) 129.91, 31.91, 29.69, 29.36, 27.25, 25.62, 24.97, 22.70, 14.09] was identified as (*Z*)-9-tricosene by dimethyldisulfide (DMDS) derivatization (Francis and Veland, 1981) of the hydrocarbon mixture (fraction 1) and direct comparison of the adduct with those of authentic samples of (*E*)- and (*Z*)-9-tricosene. DMDS derivative of **15**: MS *m/z* (%): 416 (M^+, 8), 243 ($C_{11}H_{28}SCH_3$, 89), 173 ($C_9H_{18}SCH_3$, 100). Besides these compounds, small amounts of the following straight-chain hydrocarbons were also detected: nonadecane, nonadecene, 7- and 9-heneicosene, 7-, 8-, and 9-docosene, tricosadiene, tetracosane, 7- and 9-tetracosene, pentacosane, 7- and 9-pentacosene, hexacosane, and heptacosane.

Higher Boiling-Point Compounds. Besides the volatile compounds eluting before tricosane on our GC column, several other lipidic components could be identified by their characteristic mass spectra and comparison with selected synthetic samples. They consisted mainly of straight-chain ketones, secondary alcohols, 2,5-dialkyltetrahydrofurans (Schulz et al., 1993), and steroids. The ketones form regioisomeric mixtures of C_{21}, C_{23}, C_{24}, and C_{25} compounds, for example 2-, 3-, 4-, 5-, 6-, 7-, 9-, or 10-pentacosanone. Corresponding secondary alcohols as unsaturated compounds were also present. The tetrahydrofurans occur as *trans* and *cis* isomers with chain lengths between C_{27} and C_{33}. Most prominent was 2-hexadecyl-5-nonyltetrahydrofuran, accompanied by 14 other tetrahydrofurans.

Cholesterol, ergosterol, sitosterol, and α-tocopherol were also detected in small quantities. Full details of the identified lipids will be given elsewhere (Schulz and Nishida, 1996). However, it has not been confirmed whether these compounds originate exclusively from the hairpencil organs, or whether they are also present on the cuticle and/or blood of the butterflies.

Figure 4 summarizes the structures of the volatile components (**1–16**) characterized from hairpencil extracts of *I. leuconoe* males.

Changes in Contents of Hairpencil Volatiles during Aging

The contents of hairpencil volatiles of indoor-raised *I. leuconoe* males were roughly quantified by GC. Figure 5 shows the mean contents of compounds **4, 6, 10,** and **15** from the hairpencil complex (small and large bundles combined) by age (5, 10, 15, 20, and 30 days after adult emergence). The hairpencils from 5-day-old males contained volatiles in trace amounts, although the extruded hairpencils possessed a faint phenol-like odor. The mean contents (±SE) of the major volatiles at the 20th day were as follows: **4:** 6.3 ± 0.7, **6:** 1.0 ± 0.3, **7:** 1.0 ± 0.1, **10:** 14.6 ± 2.0, **11:** 6.8 ± 1.2, **15:** 23.1 ± 3.4 μg/male (N = 5). The amounts of other hairpencil volatiles also increased more or less proportionally with age, although the quantities varied individually.

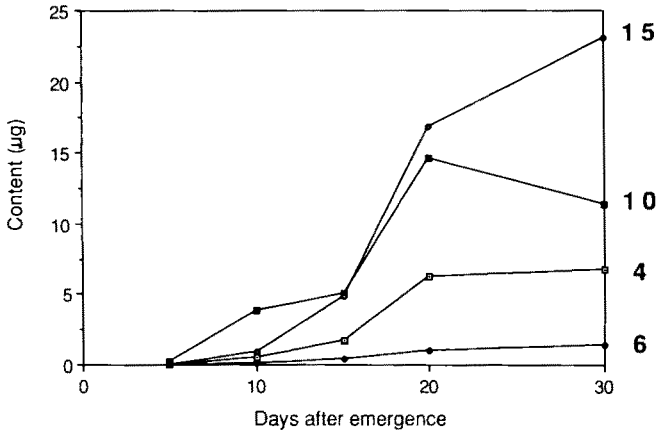

FIG. 5. Mean contents of viridifloric β-lactone (**4**), danaidone (**6**), 6-hydroxy-4-undecanolide (**10**), and (*Z*)-9-tricosene (**15**) in the hairpencil complex of *Idea leuconoe* males by age (N = 5).

TABLE 1. MEAN CONTENTS OF MELLEIN IN HAIRPENCIL COMPLEX OF LABORATORY MALES OF *Idea leuconoe* UNFED AND FED WITH MELLEIN AND OF OUTDOOR MALES

Males analyzed	Mellein content (± SE μg/male)	*N*
Unfed[a]	0	5
Fed with mellein[a]	8.9 ± 2.2	6
Wild (May 1990)[b]	4.2 ± 1.2	19
Wild (November 1991)[b]	4.3 ± 1.8	6

[a]Indoor males (30 days old, five days after treatment with mellein).
[b]Males captured at field sites in Iriomote Island.

Incorporation of Mellein (8) in Hairpencils

Males of *I. leuconoe* showed strong affinity to one of the hairpencil components, mellein, and ingested the compound by dissolving it with saliva. Most of the males quickly extended their proboscis as soon as the sample was brought near them, and they continued to feed for more than 30 min. Mellein was incorporated in the hairpencil complex as shown in Table 1. GC profiles of the hairpencil extracts in mellein-fed males were very similar to those in some of the males captured at field sites, although the quantities of the compounds varied individually. Mellein was scantily detected (0–0.02 μg/male) in the small pair of hairpencils, while a larger portion was accumulated in the large pair, sometimes over 15 μg/male.

Pheromonal Effect of Hairpencil Volatiles towards Females

In the mating sequence of *I. leuconoe*, males usually chase flying females and repeatedly display hairpencils in the female's vicinity, most frequently hovering above the female's head. In response to the hairpencil display, a receptive female lands on a nearby plant leaf, closes her wings, and curls her abdomen downward, which seems to be a typical acceptance posture of the female. Copulation takes place immediately afterwards.

Some of the females displayed the same abdomen-curling behavior when exposed to excised hairpencils or a piece of filter paper impregnated with crude extracts of hairpencils from mature males (0.1 male equivalent/paper disk). If the hairpencil extract was supplied together with a paper model of the butterfly, the females responded more effectively to the volatiles, particularly when the model was "fluttering," as shown in Figure 6A. Moreover, the receptive virgin

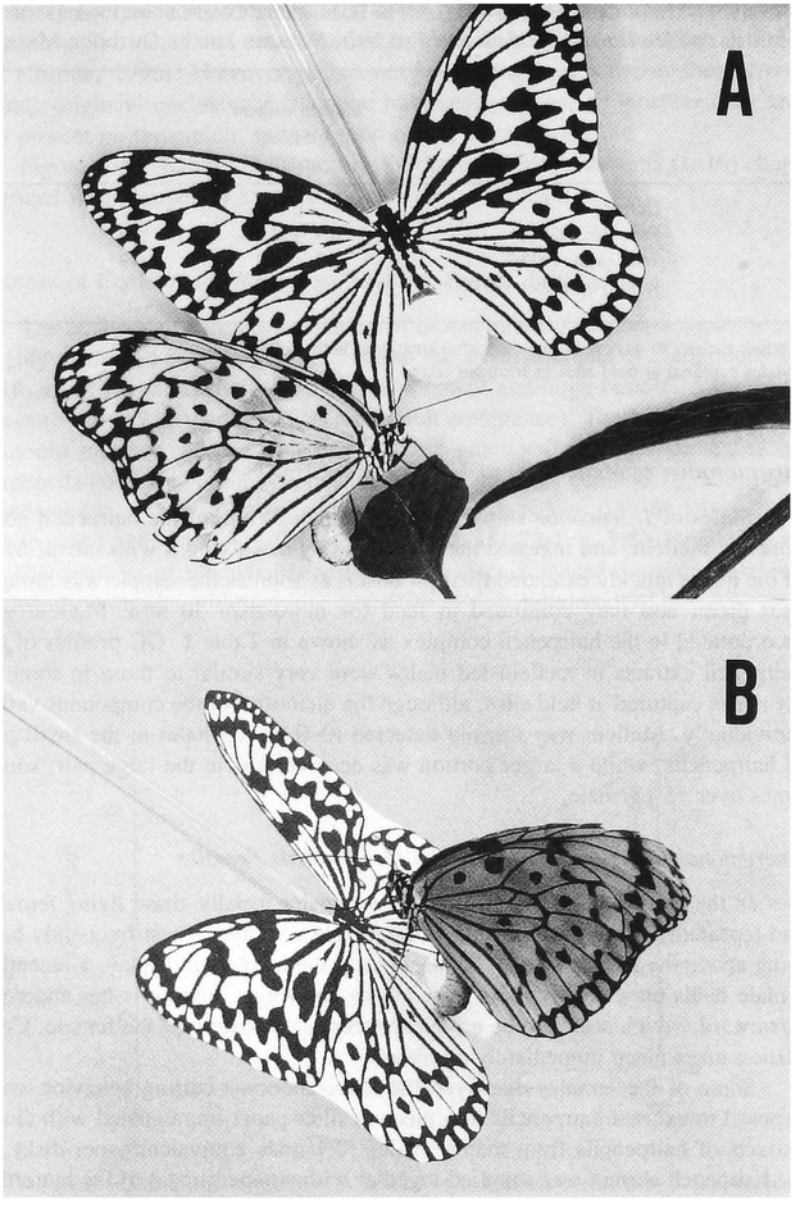

FIG. 6. (A) *Idea leuconoe* female in acceptance posture, visually and chemically stimulated by a paper model of a male with a paper disk impregnated with the hairpencil extract. The female is strongly arrested, exposing the tip of her abdomen from the

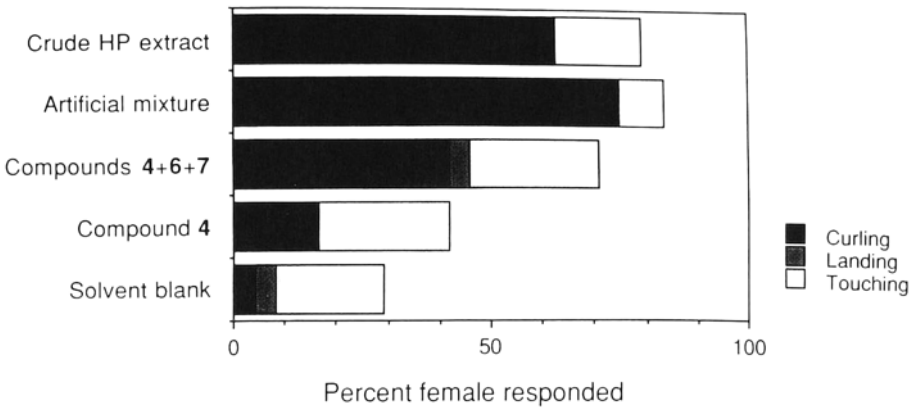

FIG. 7. Behavioral responses of *Idea leuconoe* females to hairpencil (HP) extract and blends of compounds isolated from males. Crude HP extract: 0.1 male equivalent/disk. Artificial mixture (compounds **1** + **3** + **4** + **5** + **6** + **7** + **9** + **10** + **11** + **12** + **13** + **15**): approx. 0.1 male equivalent/disk. Compounds 4 + **6** + **7**: 5.0:0.5:0.5 μg dose. Compound **4:** 5.0 μg dose. Female approaches to a butterfly model plus chemical samples were scored for touching the model (light gray), landing on the model (dark gray), and abdomen-curling behavior (black) (N = 24 for each treatment).

female (2–4 weeks old) actively chased the fluttering model, and landed on the model wings with abdomen-curling posture, sometimes firmly pushing the tip of her abdomen toward the sample paper disk (Figure 6B).

Figure 7 shows behavioral responses of virgin females to the crude hairpencil extract and hairpencil components tested with the fluttering-paper model by the method shown in Figure 6B. Crude HP extract at a dose of 0.1 male equivalent/dummy was sufficient to attract and arrest females on the dummy. An artificial mixture of compounds **1, 3–13,** and **15** induced abdomen-curling response to the same level as that of the crude extract (response not significantly different from the crude extract, chi-square 2 × 2 test of independence with Yates' correction, $P > 0.05$). A mixture of **4, 6,** and **7** also exhibited activity to some extent (response significantly different from solvent blank, $P < 0.01$), but the abdomen-curling activity of compound **4** alone was not significantly different from the solvent blank at $P = 0.05$.

hindwings. (B) The female landed on the paper model plus paper disk treated with an artificial blend of hairpencil components (**1** + **3** + **4** + **5** + **6** + **7** + **9** + **10** + **11** + **12** + **13** + **15**), curling her abdomen.

EAG Responses to Hairpencil Components

EAG responses of *I. leuconoe* males and females to some of the hairpencil volatiles are shown in Figure 8 [a mixture of hydroxy-γ-lactones (**9** + **10** + **12** + **13**) used for the test was obtained from chromatographic fractions 14 and 15]. Average EAG amplitudes differed by a factor of 3 between the least and most stimulating compounds. Although stronger responses were evoked at a higher dosage (1.0 μg), the dose-response relation appeared not to be strong. However, relative responses of female and male antennae to viridifloric β-lactone (53.3–83.6%) and danaidone (54.8–90.5%) were higher than those to the other hairpencil components (25.8–55.6%), and female-to-male ratios of

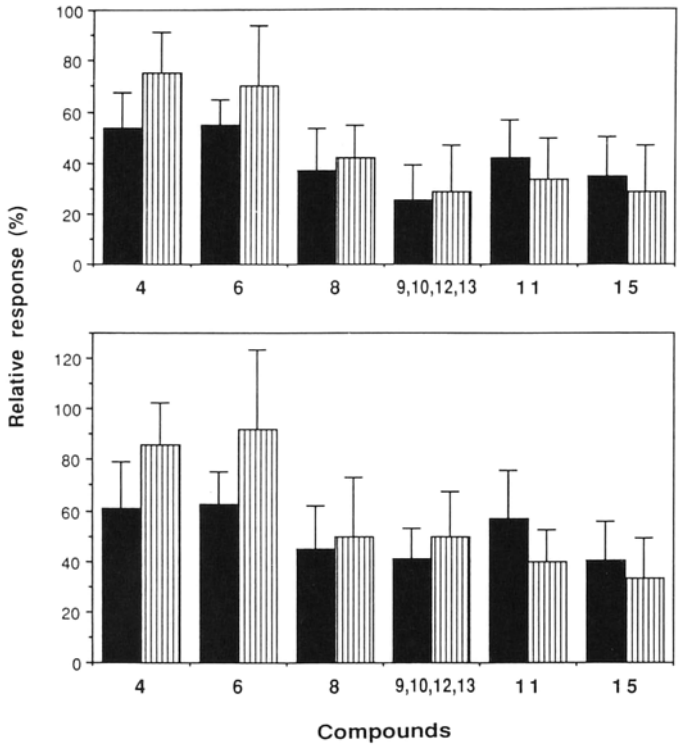

FIG. 8. Relative EAG responses of males (black) and females (striped) to hairpencil components: viridifloric β-lactone (**4**), danaidone (**6**), mellein (**8**), a mixture of 6-hydroxy-4-alkanolides (**9** + **10** + **12** + **13**), (*E*,*E*)-farnesol (**11**), and (*Z*)-9-tricosene (**15**). Relative values to the response for standard 1-hexanol at the same dosages are given. Upper: 0.1-μg dose, lower: 1.0-μg dose.

responses to viridifloric β-lactone (1.4) and danaidone (1.3–1.5) were somewhat larger than to the others (0.7–1.2).

DISCUSSION

Similar to other danaine species (Brower et al., 1965; Pliske and Eisner, 1968; Ackery and Vane-Wright, 1984), the courtship behavior of *Idea leuconoe* consists of a complex behavioral sequence with some variations. In a typical interaction, a male displays hairpencils in aerial pursuit of a female. A receptive female alights on available herbage nearby. The male hovers above her and repeatedly extrudes and retracts his hairpencils in front of her. The female assumes a rigid posture with her wings closed and the abdomen curved downward below the hind wings. This posture, which is assumed to be an acceptance response, evidently facilitates copulation. The male alights laterally and eventually copulates.

It has been shown here that the hairpencil volatiles of *I. leuconoe* males elicit a typical acceptance posture in the females when supplied together with the butterfly dummy. The male hairpencil pheromone is composed of a complex mixture. A visual cue as well as the olfactory signal appeared to be involved in induction of female acceptance. Preliminary experiments showed that an air current together with the crude hairpencil extract (0.1 male equivalent on a piece of filter paper per 5-ml air puff) induced a proboscis-extending response in caged virgin females, sometimes accompanied by the abdomen-curling response even without visual cues. During actual courtship, some of the females occasionally uncoil their proboscis halfway in response to a male's hairpencil display prior to abdomen-curling; the same behavior can also be seen toward the model scented with hairpencil extract. The proboscis-extending behavior may be associated with the aphrodisiac response of the female.

After an aerial pursuit by a male, a young virgin female (e.g., one week after emergence) lands on herbage and either passively accepts the hairpencilling male for mating or rejects him by an evasive posture with her wings open. Such young females seldom chased males under greenhouse conditions. However, 2-week-old or older virgin females positively pursued males. Then the females quickly landed on neighboring plant leaves and curled their abdomens, apparently inviting a male. The landing and abdomen-curling behavior on the butterfly dummy looked as though it was a positive copulatory attempt by the female, but this behavior may be a mere arrested reaction when no nearby herbage is available within 1 m from the dummy.

I. leuconoe adults survive for several months (three to five months under laboratory condition at 25 ± 3°C). According to indoor observations, the day of the first mating occurred a few weeks after adult emergence both in males

and females, and most of the males and females mated several times during their lives. The date of the first mating and the mating frequency varied greatly by individual [the mean first mating was 45 days in males (N = 139), and 27 days in females (N = 129) at Kashihara City Insectarium (August 1993–July 1994) (H. Morishima et al., personal communication). The behavioral change in females and relatively slow production of the hairpencil volatiles in males (Figure 5) appeared to be more or less consistent with their sexual maturation.

The hairpencil volatiles of *I. leuconoe* males consist of a complex mixture of several classes of compounds, including simple aromatics (**1, 3, 5**), two β-lactones (**2, 4**), danaidone (**6**), acyclic mono- and sesquiterpenes (**7, 11**), a series of new hydroxy-γ-lactones (**9, 10, 12, 13**), and several straight-chain aliphatic compounds (**14, 15, 16** and higher boiling-point components). Although the contribution of each individual component has not been determined, a blend of the compounds was found to be responsible for seducing females.

Danaidone acts as an aphrodisiac pheromone for *Danaus gilippus* females and is transferred to the female's antennae by means of cuticular particles (pheromone transfer particles) through direct contact with the hairpencils. The particles are glued to the antennae by a terpenoid diol (Pliske and Eisner, 1969). *I. leuconoe* males, which do not appear to possess pheromone transfer particles, usually hover and evert hairpencils above the females, and brush them against a female's antennae and head. The female responded positively even without direct contact to the crude hairpencil extracts. Thus, the hairpencil components are transmitted primarily through air. Nevertheless, the intensity or duration of the pheromonal signal may be enhanced by applying a solution of the pheromone components directly onto the antennae of the female. It seems likely that the high boiling-point ketones, alcohols, and hydrocarbons may function as such a solvent.

Danaidone appears to be one of the important factors of the pheromone blend in *I. leuconoe*. This compound has been identified from a number of danaine species, including the genera *Danaus*, *Amauris*, and *Parantica* (Meinwald et al., 1966, 1969; Edgar and Culvenor, 1975; Edgar, 1982; Petty et al. 1977; Komae et al., 1982; Schulz et al., 1988, 1993; Francke et al., 1989). Precursors for danaidone are acquired by adults while pharmacophagously feeding on PA-containing plants in most of those danaine species (Edgar et al. 1973; Schneider et al., 1975). In contrast, *I. leuconoe* obtains a series of PAs from its own host during the larval stage (Nishida et al., 1991). Thus, the males are likely to convert a portion of the alkaloids to danaidone without pharmacophagous foraging during the adult stage. Interestingly, Abe and Yamauchi (1987) isolated a (−)-viridifloric ester of 1-hydroxymethyl-5,6-dihydropyrrolizin-7-one (parsonine) from stems of the host *P. laevigata*, the necine moiety of which structurally resembles danaidone (1-methyl-5,6-dihydropyrrolizin-7-one). However, the actual precursor(s) of danaidone in *I. leuconone* are not known.

β-Lactones **2** and **4** seem to originate from the other skeletal portion of PA moieties, the necic acids. They are cyclization products of norviridifloric (2-ethyl-2,3-hydroxybutanoic) and viridifloric acids, which correspond to the esterifying acid moieties of ideamine A and lycopsamine, respectively, major PA components sequestered by *I. leuconoe* (Nishida et al., 1991). The β-lactone ring is unique as a sex pheromone. The related ithomiine butterflies use a γ-lactone, ithomiolide A, as pheromone, which is also derived from viridifloric acid (Edgar et al., 1976; Schulz, 1992). β-Lactone **4** and danaidone gave potent EAG responses, in which the antennal signals in females were significantly higher than those in males, providing additional support for the essential contribution of these PA fragments to the pheromone system studied.

Geranyl methyl thioether (**7**) is also a novel compound, although several oxygenated monoterpenic compounds have been characterized from hairpencils of danaine species (Schulz et al., 1988, 1993; Francke et al., 1989). The sulfur-containing monoterpene seems to be a rare example as a component of glandular secretions in insects. The sesquiterpene (*E,E*)-farnesol (**11**) has been identified from some danaine species in the genus *Amauris* (Schulz et al., 1993). A bis-homomonoterpene diol, (*E,E*)-3,7-dimethyldeca-2,6-dien-1,10-diol from the hairpencil of *D. gilippus* acts as a glue for the pheromone transfer particles (Meinwald et al., 1969). (*E,E*)-Farnesol may function as an olfactory cue, since the distinct floral fragrance of hairpencil extracts after evaporation of phenols is mainly due to this compound. It is noted that a relatively higher proportion of **11** was present in the small pair of the hairpencils (Figure 2A). The only other compound described so far from another *Idea* species, *I. iasonia*, is the cyclic bisnorsesquiterpene dihydroactinidiolide (Francke et al., 1989), which is absent in the species investigated by us.

Among a series of 6-hydroxy-γ-lactones (**9, 10, 12, 13**) characterized from *I. leuconoe* hairpencils, the C_{11} analog **10** was found to be the most abundant. These compounds are new natural products and may be biosynthesized by the insects.

Several long-chain hydrocarbons (**14, 15, 16,** and others) were present in the hairpencil extract, in which (*Z*)-9-tricosene (**15**) was the major component. They were accompanied by several other less volatile aliphatic compounds, including a series of alkanones, secondary alcohols, and 2,5-dialkylated tetrahydrofuran derivatives. Considering their abundance in the hairpencils, these compounds may act as solvents to regulate vaporization of highly volatile pheromone components in the hairpencil organs. In addition they function to transmit a set of the volatile pheromone onto the female's antennae through direct contact during brushing as discussed above. The oxygenated molecules may be needed to enhance the solubility of polar components.

Although hairpencil components are essential for induction of female acceptance, males deprived of hairpencil organs (large and small bundles both)

can occasionally mate under insectary conditions. Interestingly, such hairpencil-ectomized males were persistently chased by normal males, and sometimes normal males displayed hairpencils to the dissected males (more than 20 cases of homosexual hairpencilling behavior were observed exclusively from the normal males to the hairpencil-ectomized males) (Nishida, unpublished data). This suggests a secondary pheromonal function of hairpencil components for male–male recognition. The double hairpencil structure is a characteristic of the genus *Idea* (Ackery and Vane-Wright, 1984). The small pair of the hairpencil organs may be involved in the male–male interaction, although it is not currently possible to be sure whether they actually display the small hairpencils during homosexual rejection. The behavioral effect of the hairpencil volatiles toward males is now under investigation.

Males of *I. leuconoe* quickly evert their hairpencils to full length as soon as they are captured in the field, disseminating a characteristic smell of phenol (**1**) and *p*-cresol (**3**). Since the butterfly contains considerable amounts of defensive PAs, these odoriferous compounds seem to act as a warning signal in conjunction with the aposematically yellow-colored hairpencils. The male twists the abdomen to stroke the long-forked hairpencil bundles toward the objects. Simple phenolics have been identified from defensive gland secretions in various arthropods, and the initial phenolic note has been suggested to serve as a highly distinctive early-warning system (Blum, 1981). Phenol and *p*-cresol tested alone did not affect the behavior of *I. leuconoe* females, and their role in the pheromone system remains unknown.

Besides the endogenous volatiles, wild males store an additional component, mellein (**8**), in varying quantities in the hairpencils. The male shows a strong affinity to mellein and selectively accumulates the intact compound within their hairpencil organ (predominantly in the large pairs). A high proportion of the male population in Iriomote Island contained substantial quantities of mellein (over 70% of males examined in May 1990 and November 1991; see Table 1), which implied an ecological role of this compound in nature. The indoor males can mate without access to mellein, and our preliminary bioassay did not give any behavioral evidence of mellein in the courtship sequence.

Mellein is a known fungal metabolite, especially in endophytic species (Yubata and Sumiki, 1933; Arakawa et al., 1969; Aldridge et al., 1971; Matsumoto and Nago, 1994). Nago and Matsumoto (1994) isolated a mellein-producing fungus, *Lasiodiplodia theobromae*, from the body surface of the *I. leuconoe* males captured in Iriomote Island. They suggested a possible ecological significance of mellein in a fungus–butterfly association, in which *I. leuconoe* males potentially act as vectors to transmit fungus spores. So far, no other source for mellein in the natural habitat is known. Mellein is also one of the male hairpencil pheromone components of the Oriental fruit moth, *Grapholitha molesta* (Baker et al., 1981; Nishida et al., 1982), and mellein apparently func-

tioned as a male–male pheromone to repel other males (Nishida et al., 1985). Mellein was also shown to be the male wing gland pheromone of the bumblebee wax moth, *Aphomia sociella*. A mellein-producing fungus, *Aspergillus ochraceus*, in the host nests was suggested as a source (Kunesch and Zagatti, 1987). Mellein has also been found in the secretions of many ant species (Brand et al., 1973; Attygalle et al., 1989; Lloyd et al., 1989; Bestmann et al., 1992).

In addition to mellein a number of other phenolic substances act as potent attractants as well as phagostimulants for *I. leuconoe* males. Males are strongly attracted by certain kinds of hair pomades and cosmetics in an insectary, and methyl *p*-hyroxybenzoate (a preservative) was characterized as the active principle (Nishida et al., 1990). Methyl salicylate was another potent attractant, while the isomer, methyl *m*-hydoxybenzoate, was inactive (Nishida et al., 1990). 2-Hydroxy-4-methoxyacetophenone (paeonol) in the plant *Exacum affine* was also reported as an *I. leuconoe* male attractant (Matsumoto, 1994). Not only these exogenous carbonylated phenols but also endogenous phenols **1** and **3** elicit the feeding response in males (Nishida, unpublished). The males that ingested **1** and **3** accumulated additional quantities of the compounds in the hairpencils. Methyl salicylate, *p*-nitrophenol, *o*-cresol, thiophenol, and an isomer of chloromethylphenols were also detected in hairpencil extracts from a number of males captured in the field (Nishida, unpublished data), although their outdoor sources are unknown.

Endogenous phenol and *p*-cresol seem to act primarily as a warning sign against predators. The pharmacophagous behavior of the males towards a variety of phenolic substances and sequestration of those miscellaneous compounds in the hairpencils are very likely to be associated with the defense mechanism of this poisonous butterfly. Since phenols **1** and **3** are highly volatile and the quantities in the hairpencils are always extremely low, these compounds may quickly evaporate during continuous hairpencilling at courtship. The males could intensify the aposematic odor of hairpencils by acquiring additional amounts of volatile phenols by pharmacophagous foraging from certain sources. Mellein may be one such substance, although its sensory activity to predators has not been examined. A methoxy derivative of mellein (8-hydroxy-6-methoxy-3-methyl-3,4-dihydroisocoumarin) is a bitter principle of deteriorating carrots (Sondheimer, 1957). (−)-Mellein tastes bitter as well (Nishida, unpublished data). It might act as a gustatory cue to deter predators.

Male *Idea* butterflies never seek PAs, probably because they already possess substantial quantities from their larval host, *Parsonsia laevigata*. Portions of sequestered PAs seem to be processed into the necine base and necic acid fragments by males, which utilize them as sex pheromones. Nevertheless, the males show pharmacophagous activity towards phenolics and accumulate the compounds in the hairpencils, while most other danaine species exhibit pharmacophagy towards PAs. Although the overall meaning of this behavior by *I.*

leuconoe is not fully understood, the two different types of pharmacophagy may originate in similar adaptive mechanisms in the danaine species (Edgar et al., 1974; Boppré, 1978, 1990).

Among the 12 species of the genus *Idea*, at least two, including *I. leuconoe*, feed on *Parsonsia*, a genus known to contain PAs (Edgar and Culvenor, 1975; Abe et al., 1990, 1991), while others are recorded either from other Apocynaceae or from Asclepiadaceae (Ackery and Vane-Wright, 1984). Several other danaine and ithomiine species also utilize Parsonsieae as the larval host (Edgar, 1984); a primitive ithomiine butterfly, *Tithorea harmonia*, has been shown to incorporate PAs from the Parsonsieae plant, *Prestonia acutifolia*, during the larval stage (Trigo and Brown, 1990). In addition to *Parsonsia*, two asclepiad plants, *Cynanchum formosanum* and *Tylophora hispida*, were recorded as the larval food plant of *I. leuconoe* (Ackery and Vane-Wright, 1984); the presence of PAs in these plants is not known. It has been suggested that the ancestral food plants of the Danainae contained PAs, and the insects retained the ability to acquire PAs through pharmacophagy even after they shifted to other plants (Edgar et al., 1974; Edgar, 1984). It is of great interest to study further the life history of the primitive genus *Idea*, because it might provide a clue for understanding the evolution of pharmacopagous behavior in the subfamily Danainae.

Acknowledgments—A part of the work was conducted at the Tropical Biosphere Research Center, the University of the Ryukyus; we are indebted to Drs. K. Kinjo, O. Iwahashi, S. Azuma, and K. Minato of the university for sampling of the wild specimens and valuable suggestions on *Idea leuconoe*. We thank Mr. H. Ohmura of Hiroshima University for EAG recordings. We are grateful to the staff of Kashihara City Insectarium for useful information on the life history of *I. leuconoe*. We thank Drs. J. Takabayashi and R. Yamaoka for CI-MS measurements. Optically active samples of mellein were prepared and kindly provided by Mr. Y. Kawabata and Dr. T. Ueno of Kyoto University. We also thank Drs. H. Nago, Setouchi College; W. Francke, University of Hamburg; and M. Boppré, University of Freiburg, for useful comments and discussions. This work was partly supported by a Grant-in-Aid for Scientific Research (No. 05453165) from the Ministry of Education, Science and Culture of Japan, and Chemical Materials Research and Development Foundation.

(Received July 14, 1995; accepted January 3, 1996)

Abstract—Laboratory and greenhouse bioassays were used to test for inhibitory effects of senescent and decomposed leaves and aqueous extract from bilberry (*Vaccinium myrtillus* L.) against seed germination and seedling growth of aspen (*Populus tremula* L.), birch (*Betula pendula* Roth.), Scots pine (*Pinus sylvestris* L.), and Norway spruce [*Picea abies* (L.) Karst.]. Aqueous extracts from bilberry leaves were inhibitory to aspen seed germination and seedling growth and also induced root damage and growth abnormalities. Addition of activated carbon removed the inhibitory effects of extracts. Senescent leaves reduced pine and spruce seed germination, but rinsing of seeds reversed this inhibition. Senescent leaves were more inhibitory than decomposed leaf litter, suggesting that the inhibitory compounds in bilberry leaves are relatively soluble and released at early stages during decomposition. Spruce was generally less negatively affected by litter and aqueous extracts than the other tested species. This study indicates that chemical effects of bilberry litter have the potential to inhibit tree seedling recruitment, but these effects were not consistently strong. Phytotoxicity is unlikely to be of critical importance in determining success for spruce seedling establishment.

Key Words—*Vaccinium myrtillus*, regeneration failure, seed germination, seedling establishment, activated carbon, germination inhibitors, phenolic compounds, *Populus tremula*, *Pinus sylvestris*, *Picea abies*, *Betula pendula*.

INTRODUCTION

Bilberry (*Vaccinium myrtillus* L.) is a dominant component of ground vegetation in Eurasian boreal forest biomes (Walter and Breckle, 1989; Havas and Kubin, 1983). When found in dense clonal monospecific stands, bilberry can interfere negatively with tree recruitment, and these effects can be severe (Sarvas, 1950; Sirén, 1955; Pellissier, 1994). Several possible explanations for failure in seed germination and seedling establishment have been proposed, including resource competition, chemical interference, and humus accumulation (Tirén, 1949; Lehto, 1969; André et al., 1987; Pellisier, 1993, 1994; Kuuluvainen, 1994). Seedlings of deciduous and coniferous trees are seldom observed in monospecific bilberry sites (Arnborg, 1943; Sirén, 1955), and it is therefore reasonable to expect that litter interferes with tree establishment. The large amounts of senescent and decomposing leaves of bilberry found in dense stands could potentially interfere with seed germination and growth of tree seedlings through both physical and chemical interactions. The aim of our study was to test this hypothesis by using senescent and decomposed bilberry leaf-litter in a series of germination and root growth bioassays with pioneer and late successional boreal trees as target species.

METHODS AND MATERIALS

Collection of Senescent Bilberry Leaves. Bilberry leaves were sampled in October 1990 during senescence while they were still attached to shoots. The site used for litter collection was a late successional mixed pine–spruce forest of *Vaccinium myrtillus* type (*sensu* Arnborg, 1990), near Umeå in northern Sweden (63°50′N, 20°22′E). The leaves were air-dried on plastic trays at 20°C until no further weight loss was recorded and then stored in a deep freezer (−18°C) until the experiment started.

Seed Source. Seeds of the following four tree species were used in bioassays: aspen (*Populus tremula* L.) seeds from a natural stand (Ålidhem 63°50′N) with a viability of 96%; Scots pine (*Pinus sylvestris* L.) half-sib plantation seeds (Skaholma 66°90′N), with a viability of 96%; Norway spruce [*Picea abies* (L.) Karst.] half-sib plantation seeds (Lillpite 65°00′N), with a viability of 98%; and birch (*Betula pendula* Roth.) seeds from a natural stand (Mattismyran 66°03′N) with a viability of 42%.

Bioassays with Aqueous Extracts. This experiment was performed to test the effect of aqueous extracts of senescent bilberry leaves on seed germination and radicle growth. Extracts were prepared by soaking 12.5 g of dried leaves in 100 ml distilled water with slow continual stirring for 48 hr at 20°C. The solution was then passed through a filter paper (Munktell No. 3) and the extract

was frozen and stored at −18°C until used. This represents the 12.5% extract, and from this, extracts of 10%, 7.5%, 5.0% and 2.5% were prepared. Two milliliters of each water extract were added to 50-mm-diameter Petri dishes containing one sheet of filter paper (Munktell No. 3) and 50 seeds of either aspen, Scots pine, or Norway spruce. An additional treatment was set up in which 0.5 g of finely powdered activated carbon (Labasco) was added to Petri dishes with 2 ml of 10% extract (and containing 50 seeds of aspen). The carbon was expected to detoxify the extract. Distilled water was used as a control. All treatments were replicated five times. The total number of germinated seeds was counted daily for all species until there was no further germination. Aspen root necroses and abnormal seedlings (i.e., those growing in a prostrate manner) were recorded seven days after sowing. Root length was measured for 10 randomly chosen seedlings per Petri dish at the end of the experiment.

Measurements of pH and osmotic effects were made to eliminate the possibility that these might influence observed trends. The osmotic pressure of the 10% bilberry water extract, measured using a vapor pressure osmometer (Wescor 5500), was 84 mmol/kg, while the pH of the extract was 4.3. Germination tests with polyethylene glycol showed that the lowest molality required to cause negative effects on germination of aspen, Scots pine, and Norway spruce seeds was 154 mmol/kg, 146 mmol/kg, and 130 mmol/kg, respectively, which means that the osmotic potential of our solutions was too low to cause inhibition of our test species.

Bioassays with Senescent Bilberry Leaves. An experiment was set up to test for possible inhibitory effects of bilberry leaves against germination of aspen, Norway spruce, Scots pine, and birch. To each of twenty-seven 50-mm-diameter Petri dishes, 0.5 g of air-dried leaves and 8 ml of distilled water were added, and this was left to incubate for 48 hr at 20°C. To five of the Petri dishes, later to be sown with aspen seeds, 0.5 g of finely powdered activated carbon (Labasco) were added after 44 hr. The Petri dishes were sealed with Parafilm during the incubation. Petri dishes with 10 filter-papers and 8 ml distilled water were used as controls. After incubation one sheet of filter paper (Munktell No. 3) was placed on top of the material used in the different treatments and 50 seeds of aspen, Norway spruce, Scots pine, or birch were sown. Five replicates were used for aspen and birch, and six replicates for Scots pine and Norway spruce. The test was run in a greenhouse with a temperature of 20°C and a day–night light ratio of 17:7. Seed germination was measured daily, 7 days for aspen and 21 days for Norway spruce, Scots pine, and birch.

To investigate whether Scots pine, Norway spruce, and birch seeds that had not germinated at the end of the test were nonviable or only quiescent, a water cleaning treatment was performed. The seeds were moved to new Petri dishes containing 20 ml distilled water, and after 3 hr they were rinsed in running tap water for 15 sec. The seeds were then placed in a clean Petri dishes, each

containing one filter paper and 2 ml distilled water. The Petri dishes were placed in the greenhouse, and total seed germination was measured after 17 days.

Bioassays with Senescent and Decomposed Bilberry Leaves. An experiment was set up to compare rooting ability and root growth of pregerminated Norway spruce and Scots pine seeds in senescent and decomposed bilberry leaves. Decomposed bilberry leaves were prepared by placing 21 g air-dried leaves in nylon-net litterbags on the ground under snow in bilberry-dominated vegetation in January 1991. In May the same year, the litterbags were collected and the leaves dried at room temperature (20°C) for 60 hr. The loss of weight after decomposition was 15% compared to senescent leaves.

A corresponding treatment was set up in which senescent leaves were repeatedly soaked in distilled water. It was assumed that soaking removes possible toxicity of the leaves but that the leaves have the same physical structure as unsoaked leaves. The soaked leaves were prepared in the following way. One hundred grams of dried bilberry senescent leaves were added to 1000 ml of distilled water and stirred for 8 hr. The extracts were decanted and another 1000 ml of distilled water was added, stirred at 8 hours, with the soaking process repeated 21 times in seven days. The leaves were then dried on plastic trays at 20°C.

Subsamples of 1.5 g dried leaf material and unlimed, unfertilized commercial peat, which served as control, were put in 50-mm Petri dishes, each filled with 10 ml distilled water. All Petri dishes were sealed with Parafilm and incubated in 20°C for 48 hr, so that all samples had the same moisture conditions at the start of the experiment. Pots (100 ml) were then half filled with sand (Silversand 90), and distilled water was added to saturation. The incubated leaves and peat were then placed on the sand surface and 10 pregerminated Scots pine and Norway spruce seeds, each with a radicle length of 1 mm, were placed on top of peat or leaves in each of the pots. All pots were covered with Parafilm and placed in a greenhouse at 20°C and with a day–night light ratio of 17:7. Pots were sprayed with distilled water daily. There were six replicates of each treatment for each species. The total numbers of rooted seedlings per treatment were counted daily for six days. A seedling was considered to be rooted when the radicle had penetrated the organic substrate and the cotyledons grew so that there was no contact with the organic substrate. The length (root plus hypocotyle) of each seedling was measured six days after the test had started.

RESULTS

Effects of Bilberry Aqueous Extract. Aspen seed germination was significantly reduced by all extracts compared to the distilled water control and the activated carbon treatment (Figure 1). The germination rates in the distilled

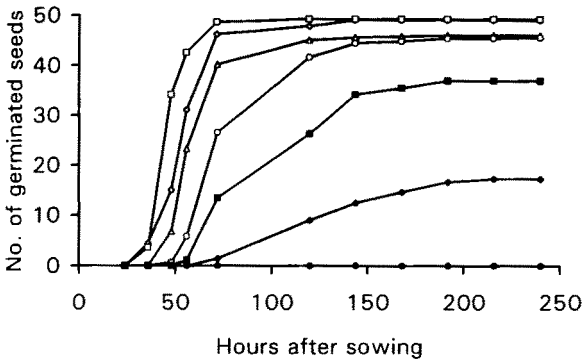

FIG. 1. Seed germination of aspen (*Populus tremula*) exposed to aqueous extract of bilberry (*Vaccinium myrtillus*) senescent leaves. Treatments: □, 10% extract treated with activated carbon; ◇, distilled water control; △, 2.5% extract, ▽, 5.0% extract; ■, 7.5% extract; ◆, 10.0% extract; and ●, 12.5% extract. See Table 1 for statistical analysis. $N = 5$.

water control and the activated carbon treatments were not significantly different (Table 1). Initiation of germination was delayed in all extract treatments when compared with germination in the distilled water control. In all extract concentrations, the root length of aspen was significantly reduced compared to the activated carbon treatment (Figure 2). Root length was reduced by 71% in the most diluted extract and by 97% in the 10% extract compared to the activated carbon treatment.

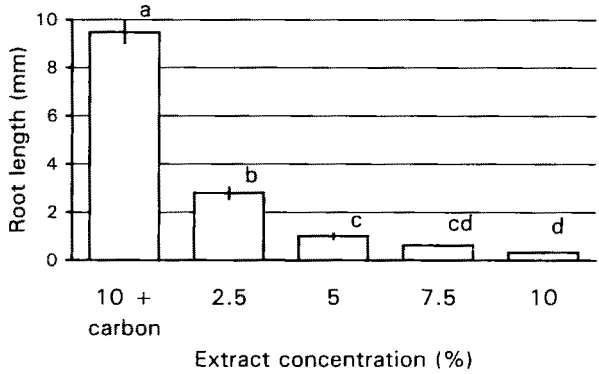

FIG. 2. Root length of aspen (*Populus tremula*) exposed to aqueous extracts of bilberry (*Vaccinium myrtillus*) senescent leaves and extract treated with activated carbon. Vertical line = standard error. Treatments with the same letter do not differ significantly in Tukey's multiple range test at $P \leq 0.05$.

Aspen roots in all extract treatments were necrotic, while those in the distilled water control and activated carbon treatments were fresh and normal in color (Table 2). All aspen seedlings in the 10% extract had abnormal prostrate growth forms (Table 2), while 49% of the seedlings had abnormal prostrate growth form in the most diluted solution. Seed germination of Scots pine and Norway spruce were also affected by the extracts, but less so than aspen. Scots pine germination was slightly (but not significantly) reduced in the 10% extract compared to the control (Table 3). Norway spruce germination was inhibited only by the 12.5% extract compared to the control (Table 3).

Effects of Bilberry Senescent Leaves. Bilberry senescent leaves had significantly inhibitory effects on seed germination of Scots pine, Norway spruce, and birch when compared to the distilled water control (Table 4). Bilberry leaves delayed the start of germination by seven days for Scots pine and 10 days for Norway spruce and birch. After the seeds exposed to the leaves had been rinsed in water, germination increased from 24% to 93% for Scots pine and from 22% to 79% for Norway spruce (Table 4). Rinsing caused Scots pine germination to increase to the level of the control. Birch germination did not increase significantly after rinsing.

Seven days after sowing, the total germination of aspen was 80% in treatments with senescent bilberry leaves and 97% in the activated carbon treatment

TABLE 4. SCOTS PINE (*Pinus sylvestris*), NORWAY SPRUCE (*Picea abies*), AND BIRCH (*Betula pendula*) SEED GERMINATION IN SENESCENT BILBERRY (*Vaccinium myrtillus*) LEAVES AND DISTILLED WATER CONTROL AFTER 21 DAYS[a]

Treatments with the same letter do not differ significantly in Tukey's multiple range test at $P \leq 0.05$, $N = 5$.

when compared to the distilled water control (Figure 3). None of the treatments differed significantly from the distilled water control.

Effects of Senescent and Decomposed Leaves on Root Development. The proportion of rooted Scots pine and Norway spruce seedlings was significantly reduced by both senescent and decomposed bilberry leaves compared to controls with peat and soaked leaves (Figure 4a and b). Senescent leaves were more inhibitory than decomposed leaves. Root growth was also significantly inhibited by senescent and decomposed bilberry leaves when compared to soaked bilberry leaves and peat (Figure 5a and b). The effects of the senescent leaves were the strongest, and these reduced root growth by 79% for pine and by 67% for spruce when compared to peat. Treatments with senescent bilberry leaves resulted in 17% mortality of Scots pine and 13% mortality of Norway spruce seedlings. No mortality occurred in treatments consisting of decomposed leaves, soaked leaves, or peat.

DISCUSSION

Bilberry litter has the potential to inhibit tree seedling establishment of the tested species, although these effects were weak for Norway spruce. Seed germination, growth, and root condition of aspen were negatively affected by even the most diluted extracts. Neither the pH nor the osmotic pressure of the bilberry

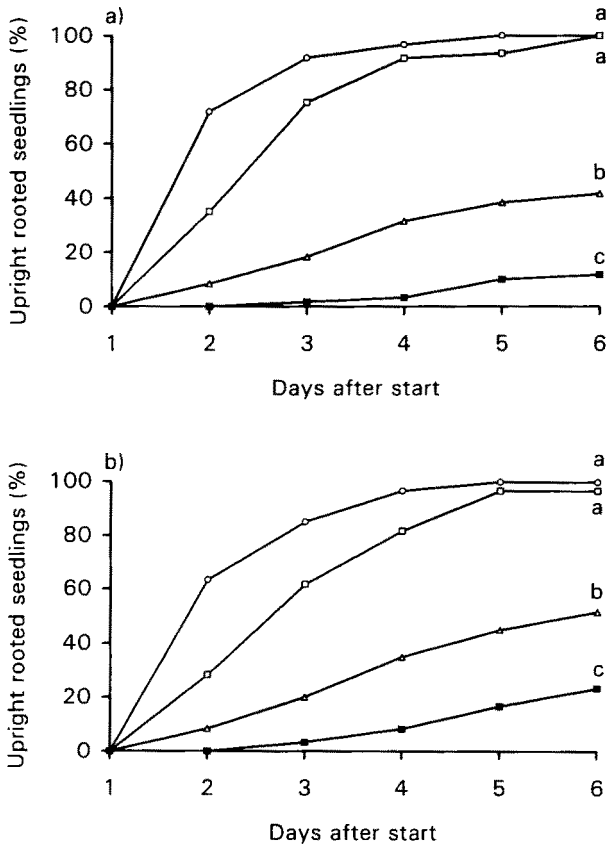

FIG. 4. Proportion of upright rooted (a) Scots pine (*Pinus sylvestris*) and (b) Norway spruce (*Picea abies*) seedlings in senescent and decomposed bilberry (*Vaccinium myrtillus*) leaves. Control = peat and soaked bilberry leaves. ■, senescent leaves; △, decomposed leaves; □, soaked leaves; ○, peat. water extract are likely to be responsible for the observed negative effects on seed germination we observed (Nilsson, 1992; Rikala and Jozetek, 1990).

The production and mode of action of phytotoxins present in senescent litter remains unknown. Our bioassays suggest that the inhibitory compounds are water soluble and released from senescent leaves during early decomposition. It is also possible that microorganisms could mediate transformation of compounds, causing inhibition both during the extraction process and later when the

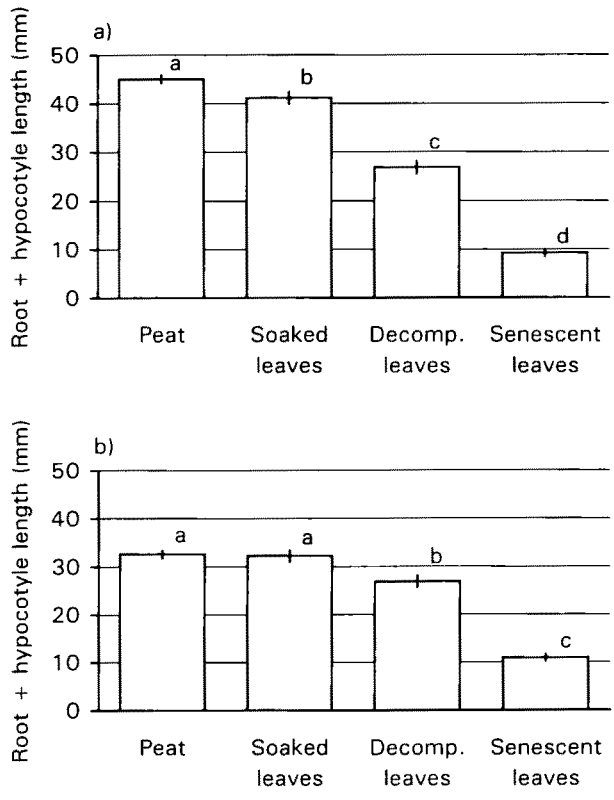

FIG. 5. Root and hypocotyle length of (a) Scots pine (*Pinus sylvestris*) and (b) Norway spruce (*Picea abies*) seedlings in senescent and decomposed bilberry (*Vaccinium myrtillus*) leaves. Control = peat and soaked bilberry leaves. Vertical line = standard error. Treatments with the same letter do not differ significantly in Tukey's multiple range test at $P \leq 0.05$.

water extracts were used in different bioassays. However the sterilization of extracts prepared from senescent leaves by 0.45-μm and 0.22-μm sterile filtration did not alter the degree of inhibition observed (data not shown).

Rinsing of exposed pine and spruce seeds removed the negative effects of water-soluble compounds extracted from bilberry litter. The results of the litterbag study with decomposing senescent leaves also indicates that when the litter produced in the autumn is allowed to decompose under subnival conditions during winter, between 34 and 74% of the inhibitory effect is lost. We interpret this to mean that natural rinsing of coniferous seeds and water-soluble compounds from bilberry litter by snowmelt and rain during normal field conditions

may reduce most of the inhibitory effects found in senescent litter. In experiments with *Empetrum hermaphroditum*, another dominant boreal species that forms clonal mats, Zackrisson and Nilsson (1992) found that the toxic compounds leached from leaf glands and absorbed by seeds could not be removed by washing exposed seeds. They also concluded that toxins were quickly absorbed by seeds and caused seed mortality before germination. The low seed mortality and radicle growth inhibition found in Scots pine and Norway spruce seedlings in our study indicates that the phytotoxic effects by bilberry litter are relatively limited, especially in comparison with results obtained in similar experiments with *Empetrum hermaphroditum* (Nilsson and Zackrisson, 1992).

The slower germination rate and radicle growth for seeds present in senescent leaves compared to that of the control treatments can be important for successful natural establishment of all species, but especially those with microbiotic seeds such as aspen. During the dry conditions prevailing in spring, the effect can be severe as radicle and whole seedlings are susceptible to drought and the litter may be more difficult to penetrate. Quick radicle penetration of litter and humus, which accelerates the opportunity of the seedlings with low nutrient resources to reach moist soil, can strongly reduce the susceptibility to water deficit under dry conditions (Grime and Curtis, 1976).

In all of our experiments, Norway spruce seeds and seedlings were less affected by bilberry litter and water extracts than were the other tree species. Norway spruce is a late successional climax species (Sirén, 1955; Havas and Kubin, 1983) and can be expected to be more tolerant of inhibitory effects from phytotoxic compounds than early successional species. However, it is also tempting to speculate that the lower level of inhibition found in spruce is an effect of coevolution between spruce and bilberry, since these two widespread boreal species may have coexisted in distinctive plant communities at least since the end of the Tertiary period (Walter and Breckle, 1989; Tallis, 1991). The deciduous broad leafed tree, *Populus tremula*, was more strongly inhibited by water extracts of senescent bilberry leaves than were the two coniferous species. *Betula pendula* seed germination in litter was relatively high, but rinsing had a much lesser revitalizing effect on these seeds than on the coniferous seeds following exposure to inhibitory compounds. Our interpretation is that the two boreal deciduous species we tested are more sensitive to litter of bilberry at the seedling stage than are coniferous species. Both aspen and birch are pioneer species that naturally colonize by seed in early successions after fire or other disturbances (Zackrisson, 1985; Grime et al., 1988). Fire has played an evolutionary important role in the maintenance of most boreal forest ecosystems dominated by bilberry (Sirén, 1955; Kuusela, 1990). Fire return intervals of less than 100 years have been determined for Norway spruce–bilberry forest types (Zackrisson, 1977). Nutritional changes (increased cation concentration and higher pH) caused by combustion of bilberry litter and organic soil following

fire (Viro, 1974; Pietikäinen and Fritze, 1995) can facilitate the establishment of pioneer deciduous trees such as aspen and birch. Species diversity also increases substantially in early postfire succession on previous bilberry sites (Schimmel, 1993). We postulate that this is not only a question of nutritional release, but also an effect of reduction of bilberry litter and humus that cause inhibitory effects on seedling establishment of early succesional species. In any ecosystem in which fire is a common element, one of its functions could be the destruction or deactivation of phenolics and other phytotoxic compounds found in litter and soil.

Addition of pure activated carbon in our bioassays resulted in significantly higher seed germination and seedling growth of aspen. These results support previous studies (e.g, Zackrisson and Nilsson, 1992; Mahall and Callaway, 1992; Yambe et al., 1992; Nilsson, 1994) and suggest that the activated carbon adsorbed inhibitory substances and deactivated them. The technique of using activated carbon to detoxify inhibitors therefore enables us to separate phytotoxic and nonphytotoxic effects. There is no reason to suppose that the carbon powder is itself a stimulatory factor in our experiments since distilled water amended with activated carbon did not cause stimulation of seed germination (Eliasson, 1959; Zackrisson and Nilsson, 1992).

It has previously been shown by Gallet and Lebreton (1995) that bilberry contains a range of phenolics including tannins, caffeic acid, *p*-coumaric acid, and flavonoids. Many of these also have been detected in high amounts in litter leachates from bilberry. These are all compounds with documented inhibitory effects on seed germination and seedling growth (Rice, 1984; Blum et al., 1984, 1985; Einhellig, 1987). Most of the phenolic compounds identified in bilberry have also been detected in soil (Blum and Rice, 1969; Whitehead et al., 1983; Kuiters and Danneman, 1987). Even if many of the phenolic compounds present are found only in low amounts in litter and soil, they can have an additive or synergistic effects on seed germination and growth (Rasmussen and Einhellig, 1977; Williams and Hoagland, 1982; Blum et al., 1985, 1989; Einhellig, 1987; Lyu et al., 1990; Lehman et al., 1994).

Our results provide evidence that phytotoxic effect of bilberry can be important in inhibiting seedling recruitment. However, these effects are not necessarily strong, and decomposing leaves do not appear to have a significant role in suppressing conifer tree seedling establishment. Our results also showed that the tree species we considered did not respond equally, and in particular spruce was less sensitive than the others.

(Received May 15, 1995; accepted January 5, 1996)

Abstract—The chemical composition of the secretions of the metapleural glands of workers and soldiers of two *Atta* species, *Atta sexdens rubropilosa* and *A. cephalotes*, and workers of *Acromyrmex octospinosus*, has been studied. As indicated by infrared spectrometry and confirmed by the ninhydrin test, the secretions contain chiefly proteins. Of the volatile acidic portion, which is present as ionized salts, phenylacetic acid is the major component in workers and soldiers of *A. s. rubropilosa* and *A. cephalotes*. Both *Atta* species also contain 3-hydroxydecanoic acid and its homolog as minor components together with indoleacetic acid. While there are qualitative similarities in the acidic composition in the secretions of *A. s. rubropilosa* and *A. cephalotes*, they differ quantitatively. The secretion of *Acromyrmex octospinosus* contains 3-hydroxydecanoic and indoleacetic acids, but lacks phenylacetic acid. The bactericidal and fungicidal actions of the three major substances have been confirmed.

Key Words—*Atta sexdens rubropilosa*, *Atta cephalotes*, *Acromyrmex octospinosus*, metapleural glands, phenylacetic acid, Formicidae.

INTRODUCTION

The metapleural glands of ants are located in the metathorax, where they open on either side through a permanently open duct adjacent to the hindleg coxae. The duct is internally connected with a large sclerotized bulla or reservoir, into which open the numerous secretory cells by means of their accompanying duct cells (Hölldobler and Engel-Siegel, 1984; Schoeters and Billen, 1993). Some functions, such as production of nestmate recognition substances, territorial-marking pheromones, protection against microorganisms (Maschwitz et al., 1970), and pollen germination inhibition (Sanderson and Wright, 1989) have been attributed to the secretion from these glands.

Work carried out some 20 years ago on the secretion from two myrmicine ants, using large amounts of insect material, identified phenylacetic acid (**1**) and indoleacetic acid (**3**) as components of the secretion of *Atta sexdens* and *A. s. rubropilosa* (Maschwitz et al., 1970; Schildknecht and Koob, 1970). Schildknecht (1976), using the metathoracic extracts of 40 ants, later identified three further components in the secretion of *A. s. rubropilosa*, namely 3-hydroxyhexanoic, 3-hydroxyoctanoic and 3-hydroxydecanoic acids. No further work was recorded on metapleural glands until recently, when three further reports appeared.

Attygalle et al. (1989) showed that the myrmicine species *Crematogaster deformis* has hypertrophied metapleural glands that contain 3-propyl and 3-pentylphenol, 5-propyl- and 5-pentylresorcinol and a related coumarin. Beattie et al. (1994) extended the claim for antibacterial action of the metapleural secretion to the Australian ant *Myrmecia gulosa*. Knapp et al. (1994) at the same conference, however, drew attention to the antifungal activity of the mandibular gland secretion of attine ants, while Jaffé et al. (1994) described the metapleural secretion of a large number of ant species as being composed largely of fatty acids. In the leaf-cutting species *Atta laevigata*, *Acromyrmex subterraneus*, and *A. landolti*, the major component was palmitic acid. They reviewed the claim for antimicrobial activity (Jaffé et al., 1994).

Independently, we have carried out studies to confirm the work of Schildknecht (1976), which up to this time had not been reexamined in the intervening two decades. Our objective was to work only with pure metapleural secretion and to avoid any contamination with other tissue or secretions. We have shown that the metapleural secretions of three attine species contain acidic compounds, as described by Schildknecht (1976), and the composition varies with species. The secretion also contains proteins. Microbiological tests confirm the activity of the secretion and synthetic substances against some bacteria and fungi.

METHODS AND MATERIALS

Colonies of *Atta sexdens rubropilosa* Forel, *A. cephalotes*, (L.) and *Acromyrmex octospinosus* (Reich.), from Vicosa and other locations in Brazil and Trinidad were maintained in laboratories at Leuven, Würzburg, or Exeter. Secretions from the metapleural glands of workers and soldiers of the two *Atta* species and workers of *A. octospinosus* were collected in fine glass capillaries (50–70 μm diameter) as described below. These capillaries were placed in large soft glass capillaries (1.8 $\pm$ 0.2 mm $\times$ 20 $\pm$ 5 mm), which had been first sealed at one end (Morgan, 1990). The larger capillaries were then completely sealed and transported to Keele for analysis.

To collect secretion, a system was devised that required a 10-μl syringe mounted in an expanded polystyrene block. The 50 to 70-μm capillary was drawn from a larger capillary in a flame, and the larger end was attached to the microliter syringe needle with a silicone tubing connection. The capillary was held steady in another small polystyrene block. The wall of the bulla of the metapleural gland was pierced with a fine insect-mounting pin, the ant was then held so the fine tip of the capillary are inserted into the hole in the bulla (Figure 1) and the secretion withdrawn into the capillary by gently raising the plunger of the syringe. With practice, this could be done routinely for a number of ants, collecting secretion from the paired metapleural glands in one capillary.

The infrared spectrum of the secretion of *A. sexdens rubropilosa* major workers was recorded with a FTIR Brucker microscope attached to a Brucker IFS 48 Fourier Transform infrared spectrometer. For the ninhydrin test, the section from one metapleural gland of each species was placed on filter paper and sprayed with 0.1% ninhydrin reagent (Merck) and heated to 110°C. Approximately equal quantities of hemolymph from each species were tested similarly.

The chemical analyses of these secretions were carried out by gas chromatography–mass spectrometry (GC-MS) with a solid-sampling technique (Morgan and Wadhams (1972). Preliminary analyses were made by directly crushing the sealed capillaries in the heated injection zone of the gas chromatograph and separating the components on a polar phase capillary column (polyethylene glycol, 12 m $\times$ 0.20 mm ID $\times$ 0.25-μm film thickness). This method did not give very satisfactory results for the very small quantities of acidic secretion. We had to modify the technique by opening each capillary at the tip, converting the acids to their methyl esters by adding a solution of diazomethane in ether (50 μl), and blowing off the ether with a stream of nitrogen, then resealing the capillary and using the solid-sampling method. These methyl esters were then analyzed on a column with a nonpolar phase (dimethylsiloxane, 12 m $\times$ 0.22 mm ID $\times$ 0.25-μm film thickness). The oven was programmed from 30°C at

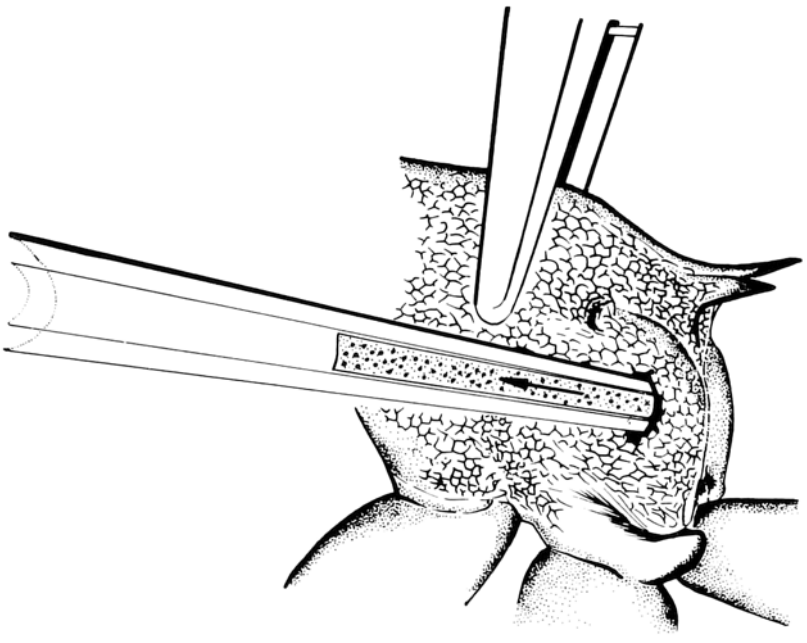

FIG. 1. Method for removing metapleural gland secretion from an ant. After perforating the reservoir cuticle with an insect pin, the capillary was inserted into the opening. The ant was held with fine forceps. Arrow indicates secretion transport inside the capillary.

8°C/min to 250°C and helium was used as the carrier gas at 1 ml/min. The split vent was closed before crushing the sample and reopened 30 sec later. The chemical substances separated were identified by interpretation of the mass spectra of their methyl esters and confirmed by comparison of retention time and mass spectrum with synthetic standards. The analyses were carried on at least two colonies of each species, using at least 10 individual specimens for each colony caste. The methyl esters of phenylacetic and indoleacetic acids were prepared by esterification of their corresponding acids with diazomethane, and the methyl esters of the 3-hydroxy acids were obtained via a Reformatsky reaction. These compounds were used as external standards for quantification of the components, and for microbial assays.

Preparation of Methyl 3-Hydroxy Esters. Methyl 3-hydroxy esters were prepared from a mixture of methyl bromoacetate (2 ml, 20 mmol, Fluka) and either hexanal, octanal, or decanal (20 mmol, Aldrich) dissolved in a mixture of dry toluene and ether (4 : 1). The solution was added dropwise to zinc powder

(2 g, 20 mmol) and the mixture was refluxed for 1.5 hr, giving the zinc alkoxide of the hydroxy-ester. This was treated with a solution of sulfuric acid (10%), followed by aqueous sodium carbonate (10%). The product was extracted with diethyl ether (50 ml) and the solvent layer was dried ($CaSO_4$), filtered, and the solvent removed by rotatory evaporation to yield the methyl esters of 3-hydroxyhexanoic, -octanoic, -decanoic and -dodecanoic acids, respectively. The yield in each reaction was approximately 60%.

Microbiological Tests. To test for the inhibition of spore germination by metapleural gland secretion of *A. s. rubropilosa* the following fungi were used: *Botrytis cinerea*, *Pyricularia oryzae*, *Trichoderma viride*, and *Venturia inaequalis*. The spores were stored in a refrigerator and subjected to heat-shock immediately before use to induce germination. Spore suspension (10 μl) was transferred into sterile potato dextrose bouillon (2.4%) with glucose (1%) (10 ml, diluted 1 : 2) containing tetracycline (final concentration 0.05%). An aliquot of this suspension (80 μl) was placed in a microliter plate either with (experimental) or without (control) metapleural gland secretion (1–2 μl) and maintained at 25°C for 33 hr. The samples were observed by light scattering in a spectrophotometer at 595 nm.

For antibacterial tests, the following species were used: *Bacillus cereus* (6923, numbers in the Difco catalogue), *Bacillus sphaericus* (7134), *Pseudomonas fluorescens* (1794), and *Pseudomonas putida* (2257). The bacterial were grown on Muelder-Hinton agar (Difco). To inoculated Petri dishes were added either metapleural gland secretion (1 μl) or an aqueous suspension of the synthetic acids in distilled water (1 : 1) (1 μl).

RESULTS

The milky white secretion from the metapleural glands can be collected in a fine glass capillary as reported by Schildknecht (1976), but can be collected more easily by first piercing the bulla (Figure 1) and then inserting the capillary into the orifice. We first examined a droplet of the secretion of *A. s. rubropilosa* with the aid of a microscope and a Fourier transform infrared spectrometer. The spectrum showed very broad OH and possibly NH absorption with a sharp maximum at 3287 cm^{-1} and a secondary maximum at 3086 cm^{-1}. There was no carboxylic acid C=O absorption near 1700 cm^{-1}. There were two strong bands at 1655 cm^{-1} and 1626 cm^{-1}, which we attributed to amide I and II, and a broad absorption at 1549 cm^{-1}, which can be attributed to ionized carboxylate (COO^-) (Figure 2). We concluded that the spectrum showed chiefly the characteristics of a concentrated peptide or protein solution. This was confirmed for each species using the ninhydrin test for protein, which gave clear positive tests.

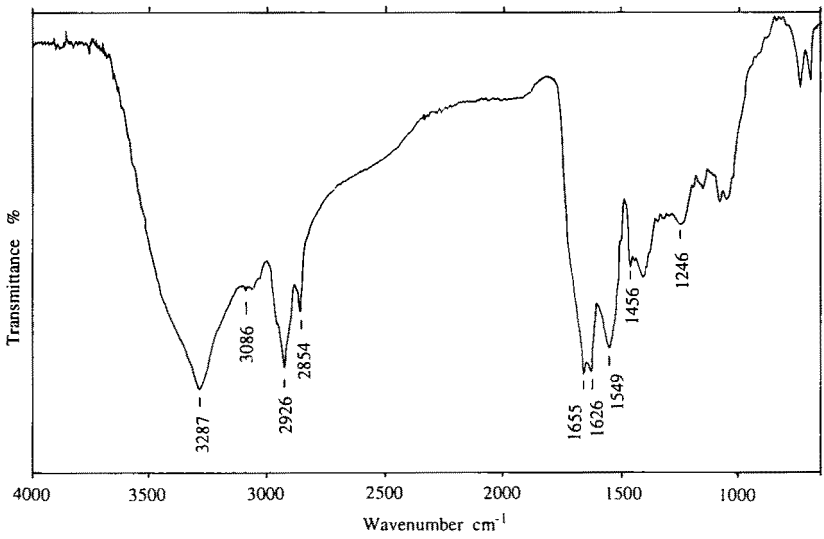

FIG. 2. Infrared spectrum of the total metapleural gland secretion obtained from a major worker of *Atta sexdens rubropilosa*.

For comparison, the same quantity of hemolymph from an ant gave a weaker reaction.

Phenylacetic acid (Figure 3, **1**) was identified in the secretion of *A. s. rubropilosa* on a polar phase capillary gas chromatography column. However, converting the free acids into their corresponding methyl esters with diazomethane showed the presence of other acids in the secretions (Figure 4). The second most important constituent was 3-hydroxydecanoic acid. The exact composition varied with the individual, as indicated by the large standard deviations in Table 1. The soldiers showed a greater proportion of phenylacetic acid than the workers, but no more secretion. There were no differences found between colonies. Schildknecht and Koob (1970) found on average 1.4 μg of phenylacetic acid per insect. We found a mean of 0.54 μg per major worker, and 0.82 μg per soldier. The difference may suggest incomplete removal of secretion by our method.

In *A. cephalotes*, phenylacetic acid and indole acetic acid were the major substances (Figure 5). Again there were differences in composition between soldiers and workers, the soldiers having more secretion than we found in the workers. The secretion of *A. cephalotes* contained traces of the odorous compound skatole (**4**), which was not detected in *A. s. rubropilosa*, while the 3-hydroxy acids were undetected in workers.

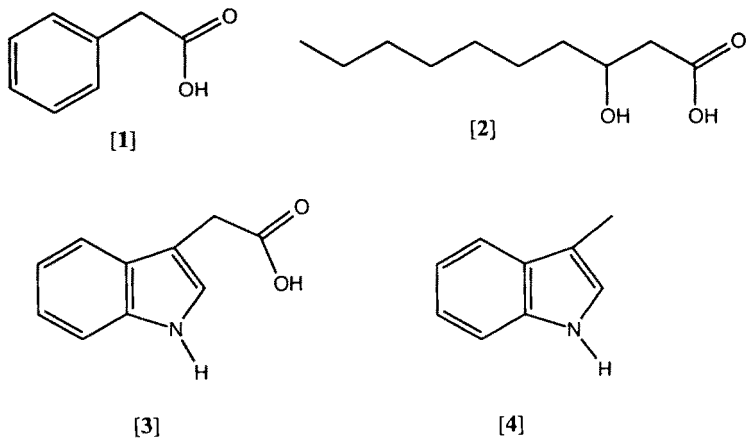

FIG. 3. Structures of the compounds found in the metapleural glands: **1:** phenylacetic acid; **2:** 3-hydroxydecanoic acid; **3:** indoleacetic acid; **4:** skatole.

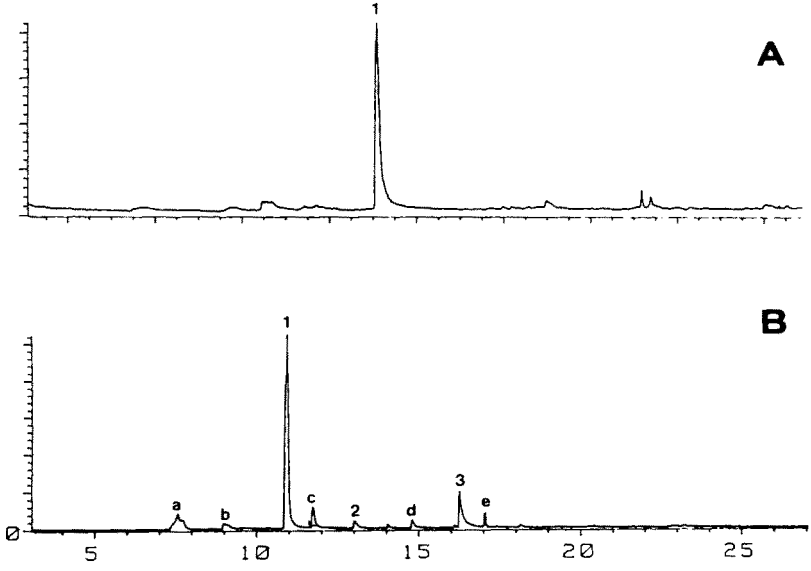

FIG. 4. Total ion chromatogram of the volatile acids (as their methyl esters) from the metapleural glands of *Atta sexdens rubropilosa*. (A) From a major worker: (B) from a soldier caste. Peaks a–e are impurities introduced with the diazomethane solution.

TABLE 1. CHEMICAL COMPOSITION OF VOLATILES IN METAPLEURAL GLAND SECRETION OF *Atta sexdens rubropilosa* WORKERS AND SOLDIERS (N = 12)

Compound number in Figure 4	Compound[a]	Mean proportion (% ± SD)	
		Workers	Soldiers
1	Phenylacetic acid	57.3 ± 24.5	86.5 ± 13.4
2	3-Hydroxyoctanoic acid	t	
3	3-Hydroxydecanoic acid	35.9 ± 24.9	12.0 ± 12.6
4	3-Hydroxydodecanoic acid	6.85 ± 5.6	1.5 ± 3.2
	Indoleacetic acid	t	t
Mean total amount (μg)		0.95 ± 1.2	0.95 ± 1.4

[a]The compounds were identified as their methyl esters after derivatization with diazomethane.

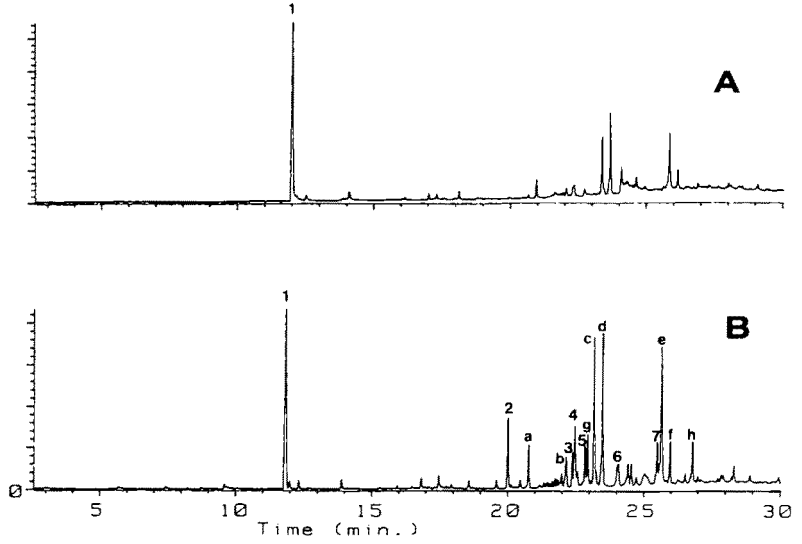

FIG. 5. Total ion chromatogram obtained after treatment with diazomethane of the volatile part of the metapleural gland secretion of *Atta cephalotes*. (A) Major workers, (B) soldier. For numbered peaks, see Table 2. Peaks a–f are fatty acid esters ranging from C_{12} to C_{18} that were found to be contaminants in the diazomethane solution and peaks g and h are hexadecane and octadecane, respectively.

The metapleural gland secretions of *A. octospinosus* were characterized by the presence of 3-hydroxydecanoic acid (**2**) and indoleacetic acid (**3**) and by the absence of phenylacetic acid (Figure 6). Again no colony differences were found.

In tests on the phytopathogens, *Botrytis cinerea* showed germination and hyphal growth in both the experimental and control conditions. *Pyricularia oryzae* showed abundant mycelial growth in both control and experimental conditions, while *Trichoderma viride* showed strong mycelial growth in the control, but no germination in the experimental conditions. *Venturia inaequalis* showed only slight reduction of spore germination in the presence of the metapleural gland secretion.

For antibacterial tests, the secretion of minor, medium, and major workers of *A. s. rubropilosa* was placed on an agar plate together with phenylacetic acid, 3-hydroxydecanoic acid, and indoleacetic acid. The metapleural gland secretion showed strong growth inhibition against *Bacillus sphaericus* and *Pseudomonas putida* and a weaker effect against *B. cereus* and *P. fluorescens* (Figure 7). It showed little effect against *E. coli* and *S. aureus*. Phenylacetic acid in the pure state was inhibitory towards all six species, and 3-hydroxydecanoic acid was inhibitory towards all but *S. aureus*. Indoleacetic acid, which tended to diffuse into the agar and gave larger, more diffuse spots, was strongly inhibitory

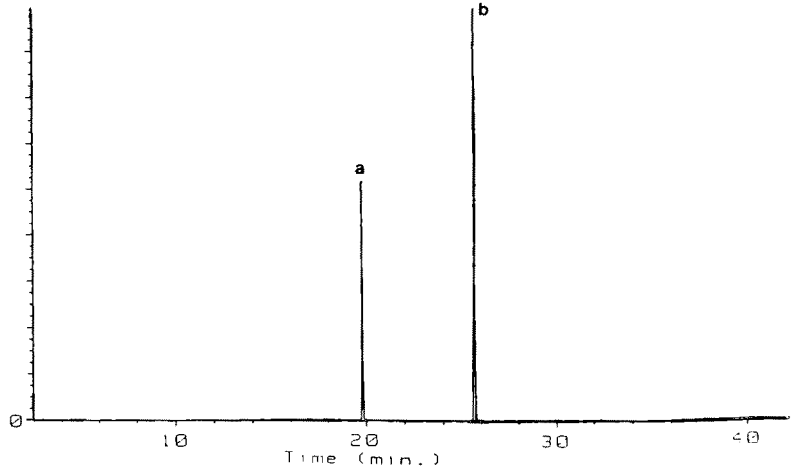

FIG. 6. Ion chromatogram of *m/z* 103 for the metapleural gland secretion of an *Acromyrmex octospinosus* worker, after treatment with diazomethane. Peak a, 3-hydroxydecanoic acid; b, indoleacetic acid (as their methyl esters). The amount of secretion was very small and the peaks did not show up well in a total ion chromatogram.

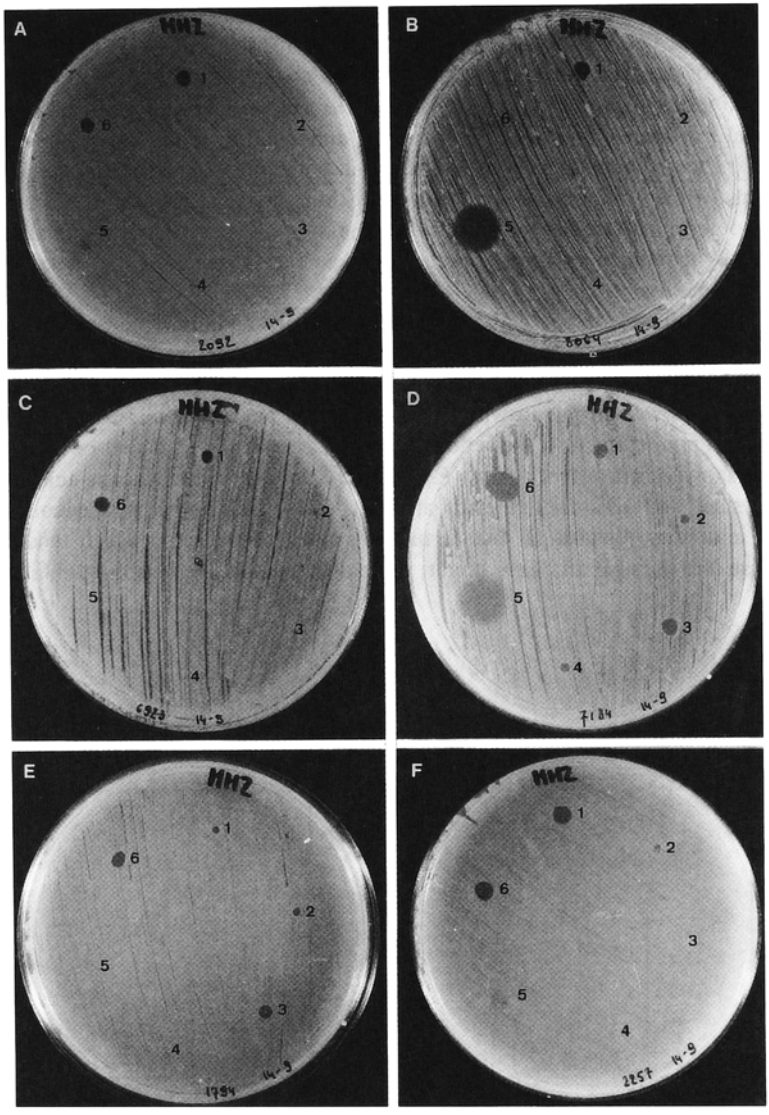

FIG. 7. Results of inhibition of bacterial growth. An emulsion of phenylacetic acid and distilled water, 1 : 1 (1); 1 μl metapleural gland secretion of *A. s. rubropilosa* major (2); medium (3) and minor (4) workers were placed on the agar plates (MHZ) together with indoleacetic acid and water 1 : 1 (5); and 3-hydroxydecanoic acid and water 1 : 1 (6). (A) *Escherichia coli*; (B) *Staphylococcus aureus*, (C) *Bacillus cereus*; (D) *Bacillus sphaericus*, (E) *Psuedomonas fluorescens*, (F) *Pseudomonas putida*.

toward *S. aureus* and *B. sphaericus*, weakly inhibitory towards *P. putida* and *E. coli*, and showed no effect against *B. cereus* and *P. fluorescens*.

DISCUSSION

The metapleural gland secretion of the three species of attine ant examined here is a milky white substance, and is thus an emulsion, not a solution. The secretion is readily seen through the thin cuticle of minor and medium workers of *A. s. rubropilosa*, so that individuals with full reservoirs can be identified, but it is not visible through the more opaque cuticle of major workers and soldiers.

The infrared spectrum of the secretion of *A. s. rubropilosa* was not at all like that of a mixture of carboxylic acids. There was no evidence of carboxylic acid C=O absorption of phenylacetic acid (at 1697 cm^{-1}) or of the 3-hydroxydecanoic acid (at 1730 cm^{-1}). It showed strong OH absorption, typical of associated hydroxy groups, which could be a concentrated aqueous solution. It showed a sharp maximum at 3287 cm^{-1}, typical of secondary amides, and two very strong bands at 1655 cm^{-1} and 1626 cm^{-1}, which could be attributed to amide I and II bands of peptides or proteins. The broad band at 1549 cm^{-1} can be correlated with ionized carboxyl. We concluded that the secretion was an aqueous emulsion of protein and the ionized form of the carboxylic acids. The secretion gave a strong, positive ninhydrin test for protein, stronger than that of hemolymph. Schoeters and Billen (1993) have already described the glandular endoplasmic reticulum in the secretory cells of the metapleural gland, which suggests considerable protein-synthesizing ability. The remainder of the study concentrated on the volatile part of the secretion.

Carboxylic acids are not ideal compounds for gas chromatography because they are very polar and small quantities can be lost through adsorption on surfaces in the instrument. Initially, we showed that phenylacetic acid was present in the secretion of *A. s. rubropilosa*. It gave a clear peak when the whole secretion was chromatographed on a polar column, but no other substances were visible. Thereafter, we converted all carboxylic acids to their less polar methyl esters by treating the secretion on a microscale with diazomethane solution. Minor peaks were then visible, which from their mass spectra and coincidence of retention times were identified as the compounds listed in Tables 1 and 2. While Schildknecht and Koob (1970), Maschwitz et al. (1970), and Schildknecht (1976) apparently were unaware of the presence of protein in the secretion, we confirmed the report of Schildknecht (1976) that the major volatile and acidic substances in *A. s. rubropilosa* were phenylacetic acid followed by 3-hydroxydecanoic acid, which we synthesized for comparison. However, where Schildknecht found the C_6, C_8, and C_{10} β-hydroxyacids, we found the C_8, C_{10}, and

[a]The compounds were identified as their methyl esters after derivatization with diazomethane.

C_{12} β-hydroxy acids. The mean composition of the large workers' and soldiers' secretions were different, but because of the wide individual variations, it is not clear if this difference is important.

Microbiological tests showed that the antibacterial action of the secretion can be ascribed to the volatile acid portion. However, as pointed out by Hölldobler and Engel-Siegel (1984), the presence of an antiseptic effect in the secretion does not necessarily mean that the primary function of the gland is antisepsis. The work of Van den Broeck (1993) and Knapp (1994) showed that there are powerful antiseptic effects in the mandibular glands of attine ants.

According to Diehl-Fleig and Valim-Labres (1993), isolation of *Aspergillus* spp., *Mucor* spp., and *Penicillium* spp. from *Atta sexdens piriventris* and *Acromyrmex heyeri* workers shows that mandibular and metapleural gland secretions are not fungicidal to at least some species. These results are also supported by the fact that one can find fungus ants with *Beauveria bassiana* (entomopathogen) (Diehl-Fleig et al., 1992) and *Metarhizium anisopliae*. Thus, it seems that the ants cannot avoid the occurrence of alien fungi.

In preliminary tests, Van den Broeck (1993) found that the Atta garden fungus (*Attamyces* sp.) did not inhibit germination of *Trichoderma hamatum* spores. *T. hamatum* and *T. viride* are mycotoxic fungi. We, therefore, concluded there was no natural protection against pathogenic fungi in the fungus garden, and included *T. viride* in our tests. Strong hyphal growth of *T. viride* was

observed in the control, but no growth at all occurred in the experiment. This indicated that the metapleural substances could provide protection for *Attamyces* from pathogens. Powell and Stradling (1986) have already shown that the metapleural gland secretion had only a minor influence on the growth of *Attamyces*.

The metapleural gland secretion of *A. cephalotes* workers contains phenylacetic acid, and the secretions from the soldiers contain four β-hydroxy acids (C_{10}, C_{12}, C_{14}, and C_{16}). In addition, the soldiers contained two unidentified compounds, which after conversion to methylesters, had mass spectra that showed a base peak of m/z 103 and fragmentation patterns similar to unsaturated hydrocarbons. This is characteristic of methyl β-hydroxyesters. We therefore concluded that these are from unsaturated β-hydroxy acids. Skatole, not detected in *A. s. rubropilosa*, was also present in *A. cephalotes* and is probably responsible for the distinct odor of the secretion.

The secretion of *Acromyrmex octospinosus* workers was more difficult to collect and different from that of the two *Atta* species. By searching the mass spectra, 3-hydroxydecanoic acid and indoleacetic acid were identified and confirmed by selective ion monitoring. *A. octospinosus* secretion did not contain phenylacetic acid. It is noteworthy that Schildknecht and Koob (1970) also recorded that *Acromyrmex subterraneus* lacked phenylacetic acid. Indoleacetic acid (a heteroauxin) is well known as a plant growth hormone.

It is clear that these leaf-cutting ants possess a metapleural gland secretion that contains, in part, volatile acids that have antibacterial action. They could protect the ant fungus garden from other fungi, which, like *Trichoderma viride*, produce mycotoxins. The earlier work of Maschwitz et al. (1970) and Schildknecht (1976) are confirmed to that extent. However, the gas chromatography, powerful as it is, is not the solution to all analytical problems, and it cannot detect peptides and proteins. To obtain a solution in an organic solvent and to analyze the volatile components of that solution may be to overlook other substances. Unless the secretion is homogeneous and the components identified can account for the full mass of the secretion, such results must be treated with caution. The metapleural gland secretions of these ants require further investigation before we know their full composition and function.

Acknowledgments—We thank B. Hölldobler for providing some of the ant material.

Abstract—The presence of a stable radical species in both fresh straw and that which had been submerged in aerated water for up to six months has been demonstrated using electron paramagnetic (spin) resonance (EPR or ESR) spectroscopy. A radical signal was associated also with material shown to contain straw lignin markers, which was leached from the rotting straw into surrounding water. Fresh straw treated with strong alkali to remove phenolics did not show a radical signal. The possible effect of a dissolved stable free radical is discussed in relation to the antagonistic effect of rotting straw on algal and cyanobacterial growth in water to which straw has been added as a nuisance algal control agent.

Key Words—Electron paramagnetic resonance, electron spin resonance, stable free radical semiquinone radical, aquatic decomposition, soluble lignin, algal control.

INTRODUCTION

A free radical is simply any species that contains one or more unpaired electrons. The resulting paramagnetism of radicals can be detected using electron paramagnetic resonance (EPR) spectroscopy, providing that the radical persists for long enough to permit analysis. While highly reactive free radicals currently are receiving unprecedented attention (Halliwell et al., 1995), possibly because they

are implicated in the aging process and a range of human diseases, few studies have been directed towards the effect of radicals that are long-lived.

Remarkably stable organic free radicals have been detected in biological polymeric material including lignin, tannin, and melanin (Tolin and Steelink, 1966; Senesi et al., 1987). A stable free radical is present in senescent plant material and its occurrence is possibly ubiquitous in plants (Hendry et al., 1994). Atherton et al. (1993) postulated that the radical is derived from a quinone, although its provenance is unclear. It is likely that radicals in biopolymers are protected by entrapment within the macromolecule (Steelink, 1966) and, as biopolymers are generally recalcitrant in the natural environment, little consideration has been given to the possible reactivity of such radical sites.

Lignin, of course, is recognized as one of the most recalcitrant fractions of plants. However, it has been reported previously that portions of the lignin macromolecule are solubilized following microbial degradation of lignocellulosic substrates under laboratory conditions (Nordkvist et al., 1989; Suzuki et al., 1990) including barley straw (Zimmerman and Broda, 1989; Kivaisi et al., 1990). Dissolved macromolecular material was recovered from aqueous solution either by acid (Crawford et al., 1983) or solvent (Suzuki et al., 1989) precipitation; the soluble lignin material was shown to be of medium molecular weight (Crawford et al., 1983). We have confirmed, using pyrolysis gas chromatography–mass spectrometry (GC-MS), the presence of lignin markers in macromolecular material recovered by ethanol precipitation from solution in the water containing barley straw rotting under natural conditions (Pillinger, 1993; Pillinger and Gilmour, unpublished data).

Our aims here are twofold: (1) to confirm that barley straw, and in particular the lignin fraction, shows an EPR spectrum characteristic of an organic free radical, and (2) to determine whether the free radical is transferred to the aqueous environment in association with macromolecular lignin solubilized during microbial degradation.

METHODS AND MATERIALS

Barley, *Hordeum vulgare*, straw was obtained from a local farm and stored in a dry barn. About 2 g dry wt straw to each liter of aged tap water was subjected to decomposition under water either in a tank of well-aerated water as described previously (Pillinger et al., 1994) or in a shallow experimental pond (ca. 1000-liter capacity). In the latter case, straw (ca. 60 g dry wt) was contained in mesh bags suspended just below the surface to maximize natural aeration. The straw appeared to retain structural integrity for at least six months, although it often became discolored due mainly to fungal infection. Rotted straw for the studies reported here was harvested from either the tank or pond. Unrot-

ted straw was subjected to alkali treatment by immersion in 1 M NaOH overnight followed by thorough rinsing. Details of the various straw samples and treatments are summarized in Table 1.

A precipitate, which included polyphenolic material (soluble lignin), was prepared from either the culture medium or from pond water in which straw had soaked. The solution was passed through a glass fiber filter (1.2-μm pore size) and typically a 50-ml aliquot was added slowly to a fivefold excess of 99% ethanol (Suzuki et al., 1989). The precipitate was recovered by centrifugation and dried under nitrogen.

A preliminary and rapid method to screen for the presence of radical sites is afforded by X-band EPR spectroscopy. A single broad signal is indicative of a radical site, but in order to resolve the signal further, Q-band EPR spectroscopy, which provides higher resolution of radical signals due to higher spectrometer frequency, is required. X-band EPR spectra were recorded on a Varian E109 spectrometer operating with a klystron tuned to ~9 GHz. In X-band, a modulation amplitude of 0.2 mT, significantly less than the observed radical line width, was used. The Q-band EPR spectra were recorded on a Varian E112 spectrometer at ~35 GHz using a modulation amplitude of 0.5 mT, again not greater than the line width of the EPR signals. All EPR spectra were obtained at room temperature.

Internodal sections only of straw were used for EPR spectroscopy. Fresh straw and alkali-treated samples were analyzed without additional treatment. A

TABLE 1. DESCRIPTION OF SAMPLES

Sample	Preparation of sample prior to EPR spectroscopy
1. Unrotted straw	Barn-stored straw removed to laboratory and stored at room temperature
2. Rotted straw (tank)	Straw soaked in laboratory tank for six months, sample removed, soaked in algal culture medium for two weeks at room temperature
3. Rotted straw (tank)	As for sample 2, but straw air dried for further seven days at room temperature
4. Rotted straw (pond)	Straw soaked in pond for two months, straw sample removed and soaked in same pond water for two weeks at room temperature
5. Alkali-treated straw	Unrotted straw (sample 1) immersed in 1 M NaOH overnight
6. Soluble lignin from aqueous solution containing sample of 2.	Precipitate prepared from the algal culture medium in which sample 2 was soaked
7. Soluble lignin from aqueous solution containing sample of 4.	Precipitate prepared from pond water in which sample 4 was soaked

sample of rotted straw (250 mg) was soaked further in 250 ml algal culture medium at pH 8 (historically used in experiments designed to test the algal toxicity of rotted straw) (Pillinger et al., 1994) or pond water (250 ml) for two weeks prior to analysis. The sole purpose of the additional period of laboratory incubation of naturally decomposed straw from the pond was to concentrate the straw leachate in the aqueous phase for subsequent preparation of sufficient soluble lignin fraction for analysis; tank-rotted straw was treated similarly for comparison. Initially any wet straw samples were blotted dry; such drying proved adequate for X-band spectroscopy, although subsequent measurements (and Q-band spectroscopy) were carried out on samples that had been air dried in the laboratory. Straw, approximately 6 mg/cm vertical depth of cavity, was inserted into a 3-mm quartz EPR tube; no attempt was made to relate the strength of radical signal with the amount of sample scanned. During each batch of analyses, a spectrum of the standard, diphenylpicrylhydrazine (DPPH), was recorded. The values of g, which characterize the EPR signals, are calculated relative to the known g value for DPPH. An uncertainty in the estimation of the g value arises due to the signal-to-noise ratio and lack of symmetry of the signal and due to overlapping signals particularly in the Q-band spectra. In order to take account of such uncertainity, g values are quoted as falling within a specified range.

RESULTS

Under the operating conditions of field sweep and signal-to-noise ratio, the g value for the X-band signals are quoted to within ± 0.0005 (Table 2). Similar values for the Q-band spectra are quoted in Table 3. Repeated scanning (typically three times) of each X-band spectrum prior to the recording showed that the reproducibility of any one spectrum was within the range that the spectroscopic analysis imposes on the g values. Likewise, replicate subsamples ($N = 3$) of pond-rotted straw analyzed sequentially and samples of tank-rotted straw ($N = 3$) analyzed at different times during a three-month period had g values in the stated range. The data quoted below, therefore, represent the values of g obtained on individual representative samples. The significant features of the data are, first, the presence or absence of a signal and, second, those parameters that indicate the presence of an organic free radical (a g value close to 2 and the shape and line width of the signal).

Qualitative X-band electron paramagnetic resonance spectroscopy indicated that a radical was present in each of the samples studied, with the exception of the straw that had been delignified by alkali treatment (Table 2). The radical was similar in the samples analyzed both in terms of the g value and line shape and width (ca. 0.5 ± 0.05 mT) and was close to the free-spin value ($g \sim 2$)

TABLE 2. DESCRIPTION OF X-BAND EPR SIGNAL RECORDED FOR VARIOUS STRAW SAMPLES

[a] See Table 1.
[b] See Figure 2.
[c] The g values for signals a and c were estimated from the peak turnover (maximum) and for signal b from the inflection point. Uncertainties in g values are about ± 0.0005 for peaks a and c and ± 0.0002 for peak b.
[d] Relative strength within a spectrum; quantitative comparison between samples was not made.

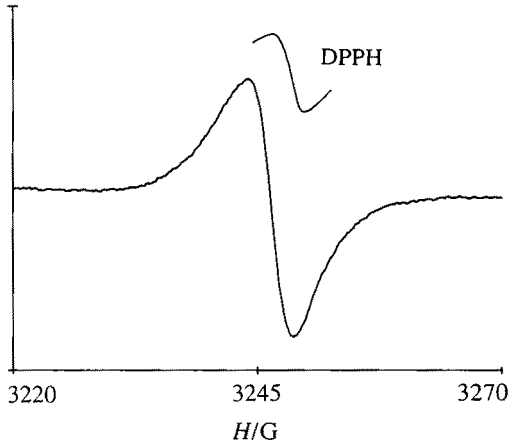

FIG. 1. X-band EPR spectrum of pond-rotted straw. The X-band EPR spectrum (9.1 GHz) shown was recorded on an air-dried sample of pond-rotted straw (sample 4, Tables 1 and 2). DPPH standard included in the sample cavity, shown as insert spectra overlap.

expected for an organic free radical. The X-band EPR spectrum of pond-rotted straw is shown in Figure 1.

A further examination of some of the samples by Q-band EPR spectroscopy established that power saturation occurred in the range of 10–20 dB, confirming the radical nature of the signal. The Q-band spectra were more informative than the X-band ones and revealed that, although the material was broadly similar in all cases, different radical signals with differing intensities were present (Table 3). Thus, fresh straw had two major signals, one with a g value of 2.0046 (Table 3, signal a), which was some five times greater in intensity than the other (c) with a g value of 2.0019. The radical signals a and c were present in both of the rotted straw samples, but in addition, a further signal b with an intermediate g value of 2.0033 was present. In the spectrum of the pond-rotted straw, this signal was the most intense of the three signals. The Q-band EPR spectra of unrotted and pond-rotted straw are shown in Figure 2. The spectrum of the latter sample clearly shows the presence of an additional signal (b) of intermediate g value. The soluble lignin preparation showed a spectrum that was essentially the same as that of the fresh straw, both in terms of g values and relative intensity of the radical signals a and c. No signal corresponding to b was observed in the soluble lignin preparation. We conclude that signal b derives from a different radical site than signals a and c. Signals a and c, however, could result from different sites or anisotropy of one site.

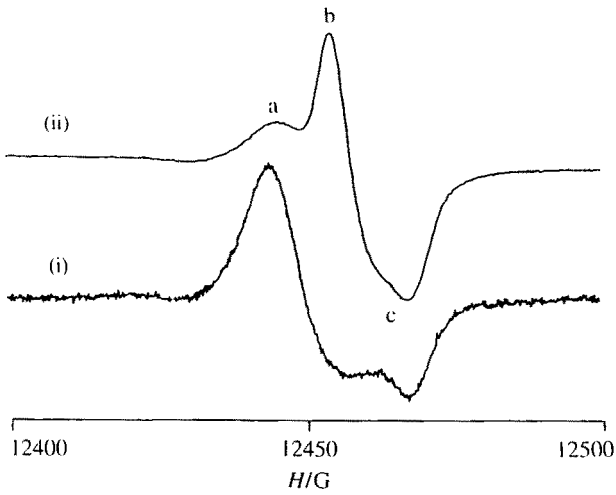

FIG. 2. Q-band EPR spectrum of (i) unrotted straw and (ii) pond-rotted straw. The Q-band EPR spectrum (35 GHz) shown was recorded on (i) unrotted straw (sample 1, Tables 1 and 3) and an air-dried sample of pond-rotted straw (sample 4, Tables 1 and 3). Microwave power 20 dB. The signals arising from the straw labeled a, b, and c are discussed in the text and g values provided in Table 3. A weak feature barely evident at the low-field side (approx. 1243 mT) of the radical signals is one of six hyperfine lines due to manganese.

DISCUSSION

We discuss here the presence of a persistent free radical in unrotted straw, decomposing straw, and in the macromolecular material recovered from the water in which straw was decomposing and suggest that our data indicate that the radical is associated with the lignin fraction of the straw. The role of microorganisms associated with rotting straw in the overall EPR signal is considered. Finally, we speculate on the significance of our findings to the observed selective antibiotic effects of water in which straw is rotting and to questions of water quality in general.

Our data extend the range of plant materials reported to contain stable radicals by showing the presence of a radical that gave a broad signal (X-band EPR) with a g value of 2.004 in an agricultural sample of barley straw. The major radical signal obtained on the same material with Q-band EPR spectroscopy had a g value of 2.0046. This value is consistent with the radical being of the semiquinone type, in which g values occur in the range 2.0038–2.0047

(Saiz-Jimenez and Shafizadeh, 1985). Whether the radical we detected in the unrotted straw is similar to that reported as being ubiquitous in senescent plant material (Hendry et al., 1994) has yet to be determined. The radical was detected at room temperature without recourse to grinding the sample, suggesting that it is inherently stable in natural straw and not a result of physical disruption that can induce a radical signal (Ludwig, 1971; Partidge et al., 1993).

Even when straw had undergone aquatic decomposition for up to six months, a radical persisted in association with the straw. Under such conditions microbial lignolytic activity was minimal, as evidenced by the intact appearance of the straw. Furthermore, alkali treatment of the unrotted straw, designed to solubilize lignin (Jackson, 1977), left the straw without an EPR signal. We suggest, therefore, that the radical we detected in straw is within the polyphenol lignin fraction, which typically comprises some 15% by weight of straw. The high syringyl content of barley straw lignin (Boon, 1989) may support the presence of radical sites in this material. Steelink (1966), for example, showed that syringyl (dimethoxy-substituted) lignin contained more free radicals than guaiacyl (monomethoxy) lignin. The X-band spectral data indicate that the radical of fresh straw was similar to that of the rotted straw. However, the additional information provided by Q-band spectra suggested that while the radical sites seen in fresh straw survive aquatic decomposition, an additional signal (b) was present in rotted straw.

Not only was a radical detected in rotted straw, but the material known to contain solubilized lignin components, which leached naturally into the surrounding water, also demonstrated a radical signal. The radical in the dried soluble lignin preparation was stable at room temperature for at least eight weeks. While X-band EPR spectroscopy indicated that the radical was indistinguishable from that of the rotted straw from which it was derived, Q-band spectra of the two samples indicated dissimilarities. Indeed, the EPR spectrum of the soluble lignin material was similar to that of the fresh straw prior to rotting, further indicating a polyphenolic origin for the radical population observed in the unrotted straw. The soluble lignin preparation did not show the additional signal demonstrated in the rotted straw samples. Whatever component accounted for the additional radical site in the straw following decomposition either: (1) did not solubilize into the surrounding water, (2) was unstable in solution, or (3) was not precipitated within the macromolecular lignin complex. Possibly, it remained in the ethanolic phase, which was discarded.

We suggest two possible explanations for the additional radical signal associated with rotted straw. First, the radical may result from the presence of fungal decomposers that can contain compounds (e.g., melanins) that have an indigenous population of stable free radicals. Our preliminary evidence from the X-band EPR spectra (data not shown) of mycelium of two pigmented fungi, a *Fusarium* species and *Alternaria alternata*, a dematiaceous hyphomycete, does

indeed support this suggestion. Further experiments in which natural isolates are grown under defined conditions are needed to produce samples for detailed spectroscopy. Species of *Fusarium* and black-pigmented fungi are common isolates from rotting straw (Pillinger et al., 1992). It is interesting that Peng et al. (1992) showed that the presence of a fungal contaminant of either *Fusarium* or *Alternaria* increased the free radical signal of grain substrate, but they did not consider that the increase may be due directly to the presence of fungal material. Secondly, while fungi may contribute radical signal b, it is also possible that this additional radical signal in rotted straw may be produced indirectly by fungal or other biological action on the lignin itself enhancing (Steelink, 1966) or generating a radical. Experiments are planned to distinguish between the possible provenances of the radical b.

The free radical signature of lignin is clearly remarkably stable, possibly protected in the polymeric matrix. However, the potential reactivity of the radical-containing lignin fraction when dissolved in water is unknown. While the radical site may remain protected even when the macromolecular material is in solution, it is possible that breakdown of the macromolecule will expose the radical site(s). Indeed Everall and Lees (1996) recently detected low-molecular-weight phenolic materials in water in the vicinity of submerged straw. The fate of the additional radical site associated with the rotted straw is also unknown.

It is now accepted that barley straw rotting in well-oxygenated water prevents algal growth. The use of straw is exploited widely to control nuisance algae (Ridge and Barrett, 1992) and cyanobacteria (Newman and Barrett, 1993) in fresh water, including potable supply reservoirs (Barrett et al., 1996). The oxidized polyphenolic content of straw has been implicated in the observed toxicity to algae (Pillinger et al., 1994), and syringyl lignin appears to be more toxic than guaiacyl lignin (Pillinger et al., 1995). Peng et al. (1992) postulated that a stable free radical dissolved in drinking water containing a high concentration of fulvic acids was one of the major causes of Kashin-Beck disease. We have yet to determine whether the observed toxicity of rotting straw towards algae can be attributed in any way to damage from radicals derived from straw polyphenolics.

CONCLUSIONS

We suggest the importance of our observations is that a radical was detected after recovery from aqueous solution and that the signal was associated with a material derived from naturally decomposing plant litter. An additional radical not observed in fresh straw was associated with the decomposing straw. Whether radicals associated with the lignin fraction of plant litter are available to effect damage to aquatic organisms or to organisms ingesting contaminated water has yet to be determined.

(Received September 20, 1995; accepted January 6, 1996)

Abstract—Essential oils from coniferous trees contain secondary metabolites that act as feeding deterrents for a number of herbivorous mammals. We investigated effects of pine needle oil on feeding and other behaviors of herbivorous plains pocket gophers. In experiment 1, pocket gophers were offered sweet potato from single feeding stations placed in home cages of individually housed animals. Stations contained either a scent dispenser with pine needle oil or mineral oil. Subjects removed significantly less food from stations scented with pine needle oil. Experiment 2 was performed to investigate neophobic responses to odors. *d*-Pulegone, presented under conditions identical to those used in experiment 1, did not reduce food removal compared to mineral oil. In experiment 3 pocket gophers were observed in a maze consisting of a start box connected to two goal boxes by tunnels. One goal was scented with pine needle oil, the second with mineral oil. Subjects entered goals scented with pine needle oil significantly less frequently than goals scented with mineral oil and spent less time there. They performed all recorded behaviors at lower frequencies while located in pine-scented goals. In experiment 4 animals were introduced into a maze consisting of a start box from which two soil-packed tunnels could be entered. Embedded in the soil of one tunnel was a barrier of electrical cable that had been soaked in pine needle oil, the second tunnel contained a barrier of cable soaked in mineral oil. Pocket gophers gnawed

significantly less insulation from cable treated with pine needle oil than from cable treated with mineral oil. Our results show that constituents in pine needle oil are aversive to plains pocket gophers. Under natural conditions they may function as feeding deterrents. Some of the compounds may be suitable repellents for control of pocket gopher damage.

Key Words—Pocket gophers, avoidance behavior, feeding deterrents, plant secondary metabolites, pine needle oil.

INTRODUCTION

Plants produce a great variety of secondary metabolites such as phenolics, alkaloids, and terpenoids that act as defense against herbivores (Harborne, 1991; Haslam, 1988; Langenheim, 1994). Many of these compounds are toxic, and herbivorous mammals have evolved physiological mechanisms to protect themselves from this toxicity (Freeland and Janzen, 1974; McArthur et al., 1991). They also possess behavioral mechanisms to avoid ingestion of some plants or parts of plants, and these mechanisms often are based on chemosensory detection of secondary metabolites. Snowshoe hares (*Lepus americanus*), for example, are highly selective feeders. Their avoidance of buds and catkins of Alaskan green alder (*Alnus crispa*) is mediated by two phenolic compounds, pinosylvin and pinosylvin methyl ether (Bryant et al., 1983; Clausen et al., 1986). Mixtures of phenolic secondary compounds in some structures and growth stages of balsam popular (*Populus balsamifera*) cause avoidance by the same species (Reichardt et al., 1990a). Snowshoe hares also avoid winter apical birch (*Betula* spp.) twigs containing phenolic glycosides (Iason and Palo, 1991; Sunnerheim et al., 1988), juvenile growth stages of winter-dormant paper birch (*Betula resinifera*) bearing papyriferic acid (Reichardt et al., 1984), as well as food sources with germacrone, a terpene from Labrador tea (*Ledum groenlandicum*) (Reichardt et al., 1990b).

Essential oils from conifers also contain secondary metabolites, mostly terpenoids and phenols, that act as feeding deterrents for snowshoe hare (Sinclair et al., 1988), meadow vole (*Microtus pennsylvanicus*) (Roy and Bergeron, 1990), moose (*Alces alces*) (Sunnheim-Sjoberg, 1992; Sunnheim-Sjoberg and Hamalaien, 1992), red deer (*Cervus elaphus*) (Elliott and Loudon, 1987), and mule deer (*Odocoileus hemionus columbianus*) (Schwartz et al., 1980). Industrial pine oil, a by-product of the wood pulp industry, has shown some promise as a feeding deterrent for snowshoe hare and Townsend's vole (*Microtus townsendii*) (Bell and Harestad, 1987).

Responses of pocket gophers to secondary plant metabolites have not been studied in any detail. For *Thomomys*, however, Radwan et al. (1982) showed that ponderosa pine (*Pinus ponderosa*) seedlings from some geographic areas

are protected against attack, while other seedlings are heavily damaged. Different parts of the same seedling are also discriminated during feeding. Preferences are negatively correlated to stem oils, indicating that some terpenoid constituents of conifer oils are able to protect trees from gopher attacks, and therefore are potential feeding repellents.

In the present study the effects of pine needle oil and of *d*-pulegone on feeding and other behaviors of plains pocket gophers (*Geomys bursarius*) were assessed. Pocket gophers are generalist herbivores that forage mostly underground by excavating tunnels to reach food plants. These rodents cause problems by gnawing through underground cable they encounter while digging. Moreover, they are serious pests in agricultural and reforestation areas (Chase et al., 1982). Species of the genus *Thomomys*, in particular, hinder conifer reforestation by clipping roots and girdling trunks (Burton and Black, 1978; Gottfried and Patton, 1984; Radwan et al., 1982) and are also a persistent problem in orchards (Sullivan et al., 1987). Plains pocket gophers inhibit establishment of red oak (*Quercus rubra*) and white pine (*Pinus strobus*) (Huntly and Inouye, 1988) and can damage Christmas tree plantations (Hegdal, personal communication).

METHODS AND MATERIALS

Subjects. Twenty-four adult plains pocket gophers, 15 females and 9 males, served as subjects. Eighteen had been trapped near San Antonio, Texas, and six were born in the laboratory to females that were pregnant when caught. All animals were individually housed in stainless steel cages (60 × 50 cm, 22 cm high), containing aspen chips, pieces of plastic pipe (15 cm long, inner diameter 8 cm), and cardboard boxes for nesting. Purina Guinea Pig Chow, Mazur Omnivore A pellets, and a mixture of rolled oats, sunflower seeds, and peanuts were fed ad libitum and were available during all experiments. Dandelion, kale, and crab apple branches were given occasionally. The animal room was kept at approximately 21°C; light and dark phases were adjusted to reflect seasonal changes in hours of day light in Philadelphia (14L:10D in July; 10L:14D in December).

Stimulus Material. Pine needle oil was purchased from the Penn Herb Co., Philadelphia, Pennsylvania (Siberian Pine Needle Oil, catalog no. 549). A partial analysis of the oil, performed in our laboratory, showed α-pinene, β-pinene, and myrcine to be among its constituents (Wager-Pagé et al., 1996). *d*-Pulegone was obtained from International Flavors and Fragrances. Light white mineral oil NF (Lannett Co., Philadelphia, Pennsylvania) served as a control stimulus.

Experiment 1. The effect of pine needle oil on retrieval and consumption of preferred food was assessed in single-choice tests. Ten wild-born and six captive-born animals served as subjects. During each test a scented feeding

station containing 10 g of diced sweet potato was placed into the subject's home cage for 1 hr. The amount of sweet potato remaining in the feeding station at the end of the trial was used as a measure of pine needle oil repellency.

Each feeding station consisted of a plastic tunnel (25 cm long, 8 cm ID) that was sealed at one end by inserting a 6-cm-deep stainless steep cup. The cup contained the sweet potato and a scent dispenser attached to the cup above the food. Tunnels were placed parallel to the front walls of the home cages and were kept from rolling by securing them with a clean brick.

Stimulus fluids (100 μl) were applied to filter paper, 3 × 9 cm, folded into 3-cm^2 pads. Papers were placed into plastic mesh capsules (HistoPrep, Fisher Scientific; 25 × 6 mm). These scent dispensers allowed the animals to smell but not to contact the stimuli and prevented contamination of the food with odorants. The volume of 100 μl resulted in a moderately strong scent that could be detected easily by the human observer at the end of the trials.

Different sets of tunnels and cups were used with mineral and pine needle oil to avoid cross-contamination. All testing equipment was machine washed at 82°C and thoroughly rinsed with clean water between trials. Scent dispensers were discarded after each trial.

Subjects were tested once with each stimulus on different days. Only eight individuals per day were tested, four receiving pine needle oil and four receiving mineral oil. The order of stimulus presentation was counterbalanced across subjects. The experiment was conducted during November. All trials were given between 14:00 and 16:00 hr. This time lies within the species' activity period under natural conditions (Benedix, 1994).

Results were evaluated in a two-factor analysis of variance (ANOVA). The independent factor was groups (two levels: wild-caught and laboratory-born individuals). The dependent factor was stimulus type (two levels: pine needle oil and mineral oil). Tukey post-hoc tests (Winer, 1962) were used to isolate differences among mean grams of food taken.

Experiment 2. To assess the possibility that responses to pine needle oil were the result of neophobia, responses to a novel odor were tested in eight wild-caught pocket gophers that had never experienced the odor and that were not included in any of the experiments with pine needle oil. *d*-Pulegone, a bird repellent (Mason, 1990) with a potent mint scent (for humans) was used. Mineral oil served as a control. The experiment was performed in July. Testing procedures were identical to those used in experiment 1. Results were evaluated by paired *t* test.

Experiment 3. The effects of pine needle oil on the behavior of pocket gophers in a maze apparatus were investigated using the 16 animals tested in experiment 1. The maze consisted of an opaque plastic start box (30 × 20 cm, 14 cm high) covered with a clear Plexiglas lid. The start box was connected to two clear plastic goal boxes (28 × 28 cm, 12 cm high) via tunnels. Each tunnel

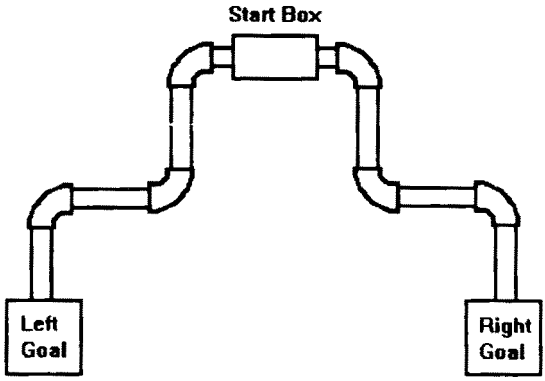

FIG. 1. The maze used in experiment 3.

consisted of three 25-cm-long secretions of translucent PVC tubing (5 cm ID) connected with 90° elbows (Figure 1). The start box was ventilated by connecting a hose attached to an opening in the lid of the box to the air exhaust of the test room.

Each goal box contained 200 ml of fresh aspen bedding and an aluminum plate (5 cm wide, 10 cm long, 4 mm thick). A HistoPrep scent dispenser containing a 3 × 9-cm strip of folded filter paper was taped to each plate to prevent the subjects from removing the dispensers from the goal box. Three cubes (2 × 2 × 2 cm) of sweet potato were placed on each plate in front of the scent dispenser.

To habituate the animals to the maze and to test for the presence of side preferences, each subject was given one trial in the clean maze, with both goal boxes containing empty scent dispensers. Following this trial, each gopher was given two trials in which the dispenser in one goal box contained 100 μl pine needle oil and the dispenser in the second goal box 100 μl mineral oil. To avoid cross-contamination, one goal box was dedicated to use with pine needle oil, the other with mineral oil. Their left–right positions were counterbalanced across subjects and replications. Between trials, equipment was washed with detergent, rinsed in water, and then soaked in 70% ethanol for several minutes.

Trials were 10 min long, divided into 60 intervals of 10 sec, indicated by an audible timer signal. At each 10-sec signal, an observer noted the location of the animal as being in the start box, the left or right tunnel system, or the left or right goal box. Behaviors were scored as Hansen frequencies (Altmann and Wagner, 1970) per 10-sec interval. For each interval the subject received a score of 1 for each of the behaviors defined below, if this pattern was displayed. The following behaviors were recorded as Hansen frequencies: (1) enter

left/right goal box, (2) dig in the litter of the left/right goal box, (3) eat in left/right goal box, (4) carry food from left/right goal box, and (5) groom self in left/right goal box.

Subjects were tested between 14:00 and 16:00 hr and were only removed from their home cages when they were active. Gophers were transferred to the maze in a plastic tube and released into the start box. The 10-min trial began with the first 10-sec interval after the subject left the start box. The experiment was conducted between December and March.

For results obtained during habituation trials, differences between the subjects' location in the left and right side of the maze and between behaviors performed in these locations were compared by paired *t* test. Paired *t* tests were also used to analyze location and behavior scores recorded during experimental trials.

Experiment 4. The effects of pine needle oil on cable gnawing were investigated. Trials were performed in a maze where subjects encountered electrical cable embedded in soil. The weight of material removed from the cable in the course of an 18-hr trial was taken as a measure of the effectiveness of the pine needle oil as a repellent in this context.

The maze consisted of a linear arrangement of a start box (60 × 40 cm, 40 cm high) from which two 45-cm-long tunnels (15 cm ID) were accessible. Each tunnel was sealed at one end and completely filled with soil. It contained a barrier of three electrical cables, set in a frame and embedded in the soil 35 cm from the tunnel entry. Copper conductor cable with PVC insulation and jacket (12 mm wide, 7 mm thick) was used. The frame was made from plastic pipe (10 cm long, 12 cm ID) that fitted inside the tunnel. Three 14-cm-long pieces of cable were inserted into holes in the pipe and secured by bending them on the outside of the frame. The wires crossed each other and formed a netlike barrier that blocked the gopher's progress as it dug along the tunnel.

Twelve of the animals used in experiments 1 and 3 were each given four trials in the maze. During the first two trials, cables were untreated. During the third and fourth trials, one tunnel contained cables that had been immersed in pine needle oil for six days. The second contained cables that had soaked in mineral oil for six days. During trials with scented cable, one of the tunnels and frames was used only with pine needle oil, the other only with mineral oil. The left–right positions of the tunnels containing mineral and pine needle oils were counterbalanced across subjects and replications.

Trials were conducted overnight. Prior to each trial, the electrical cable was weighed, inserted into the frames, and embedded in fresh, commercially obtained top soil. Soaked cables were completely dried before weighing. The start box was supplied with standard diet and a small apple.

Each subject was removed from its home cage at 16:00 hr and placed into the start box of the maze. At 10:00 hr the following day, the animal was returned

to its home cage. The cables were then weighed and discarded together with the used soil. Between trials, equipment was washed in a commercial cage washer at 82°C and thoroughly rinsed with clean water. Experiment 4 was performed in July and August.

Differences among weights of the material removed from the cables under unscented and scented conditions were analyzed in a two-factor ANOVA for repeated measures. Factors were conditions (two levels: clean maze and scented maze) and stimulus type (two levels: mineral oil and pine needle oil). For the latter factor, gnawing of mineral-oil-soaked wire was compared with gnawing of wire soaked in pine oil. Tukey post-hoc tests (Winer, 1962) were used to isolate differences among means.

RESULTS

Experiment 1. ANOVA revealed a significant difference between stimulus types ($F = 72.9$; 1,13 *df*; $P < 0.00001$) but no interaction between groups and stimulus types. Tukey tests showed that wild-caught as well as laboratory-born pocket gophers retrieved much less food from stations scented with pine needle oil than from stations scented with mineral oil (Figure 2).

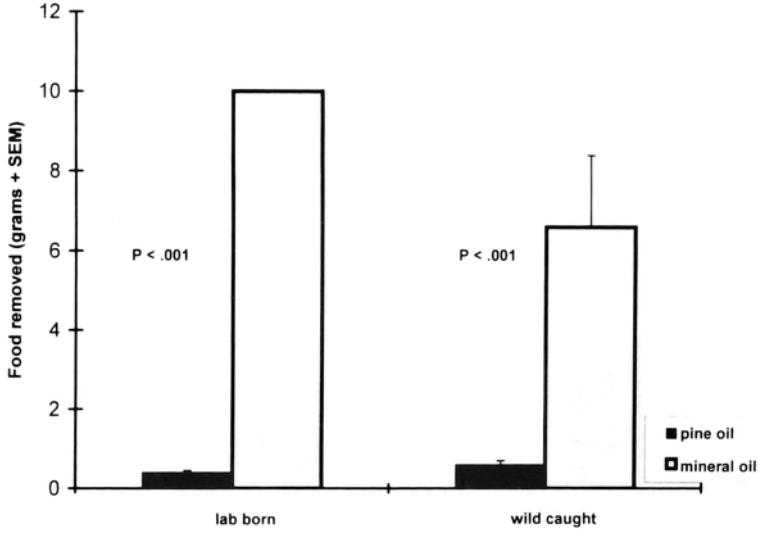

FIG. 2. Mean amount of sweet potato (SEM) removed by laboratory and wild born pocket gophers in experiment 1 from feeding stations scented with pine needle oil or mineral oil.

Experiment 2. Pulegone had no effect on food retrieval. The animals removed an average of 3.1 g (SEM 1.1 and 1.2, respectively) of food from each feeding station.

Experiment 3. The pocket gophers did not exhibit locational or behavioral side preferences during trials in the unscented maze. However, for experimental trials, *t* tests revealed significant differences between location scores in the pine needle oil scented and mineral oil scented parts of the maze and between scores for all behaviors performed in these locations (Figures 3 and 4). There were no differences in the scores obtained for being located in any of the three tunnels leading to the pine and mineral oil scented goal boxes. However, subjects entered pine needle oil scented goals significantly less frequently than mineral oil scented goals, and they were less frequently located there.

All behaviors were performed at significantly lower levels in the goal containing pine needle oil (Figure 4). Eating was particularly strongly affected, with only two of the 16 animals, one male and one female, eating while inside the pine needle oil scented goal, as compared to 12 of 16 animals eating while inside the control goal.

Experiment 4. ANOVA revealed a significant difference between stimulus types ($F = 8.0$; 1,11 *df*; $P < 0.016$) and a significant interaction between conditions and stimulus types ($F = 8.8$; 1,11 *df*; $P < 0.012$). The analysis was

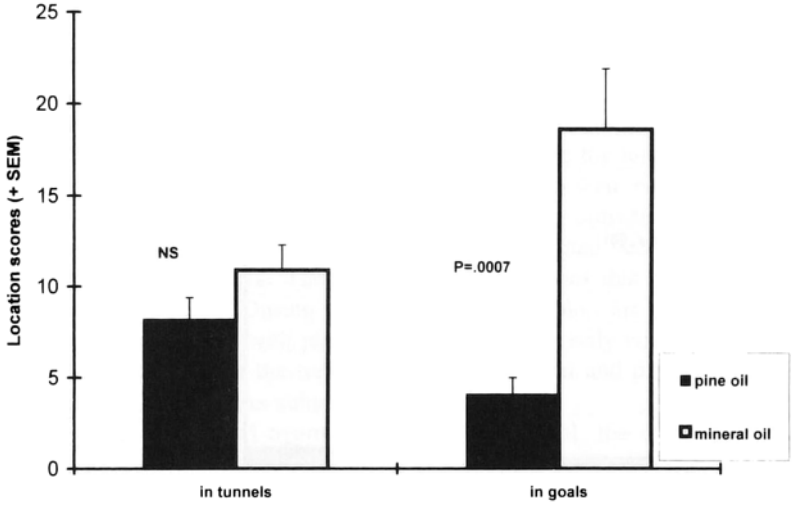

FIG. 3. Mean (+SEM) scores obtained by pocket gophers in experiment 3 for locations in tunnels leading to each goal box and in goal boxes scented with pine needle or mineral oil. NS, no significant difference.

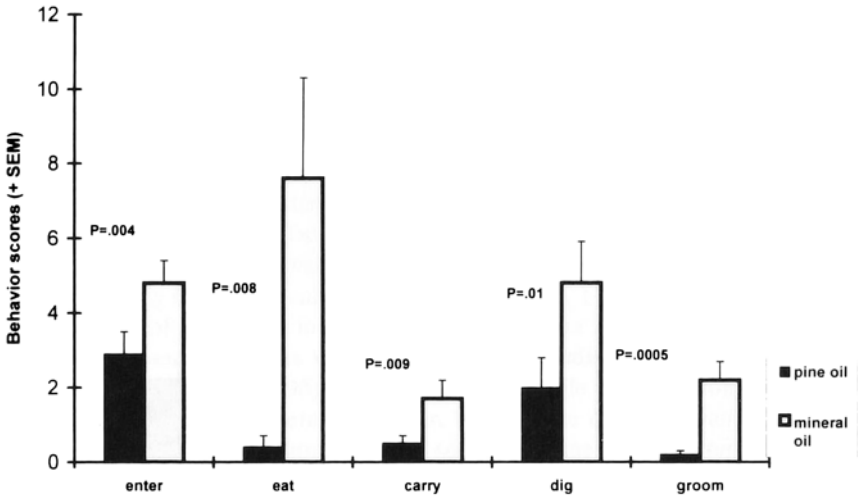

FIG. 4. Mean (+SEM) behavior scores obtained by pocket gophers in experiment 3 for entering goal boxes scented with pine needle or mineral oil and for digging, eating, carrying food, and grooming in these locations.

interpreted in terms of the interaction. During habituation trials with unscented electrical cable, no side preferences were displayed. About equal amounts of material were removed from the cables in each tunnel (Figure 5). Impregnating cable in one of the tunnels with pine needle oil did not reduce the overall amount of material removed from both tunnels, but shifted gnawing activity from pine needle oil impregnated material to that impregnated with mineral oil. Tukey tests showed that subjects removed significantly less material from wire scented with pine needle oil than that scented with mineral oil or from clean wire (Figure 5).

DISCUSSION

For the plains pocket gopher, pine needle oil is an aversive stimulus that influences behavior in a variety of contexts. Food caching was significantly reduced, as was consumption. Pine needle oil also caused area avoidance. In the maze, pocket gophers entered pine-scented chambers less frequently than chambers scented with mineral oil. All behaviors were performed less frequently in the presence of pine scent, perhaps as a result of spending less time there. Similar results were obtained in a more recent study with northern pocket gophers (*Thomomys talpoides*) that were tested in a maze comparable to that used in

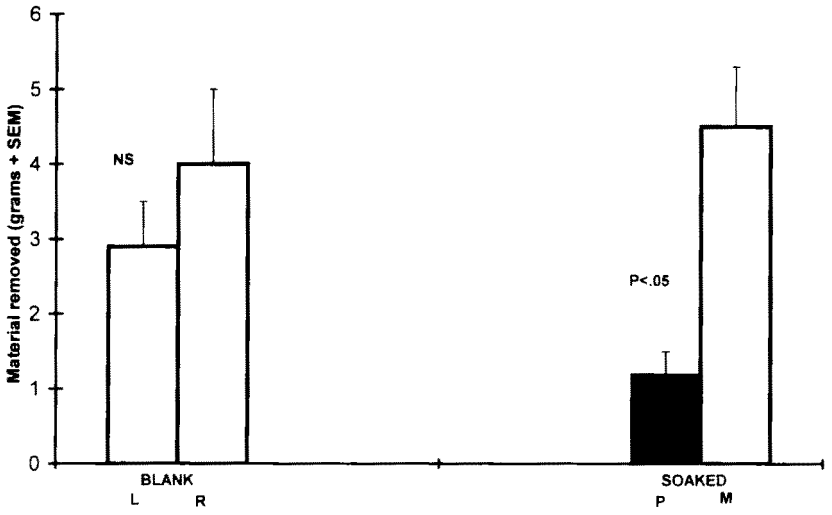

FIG. 5. Mean (+SEM) weight of material removed in experiment 4 from clean cable and from cable soaked in pine needle oil or mineral oil.

experiment 3 (Epple et al., 1996). In experiment 4, pine needle oil significantly reduced damage to soil embedded cable.

In the present study, individuals born in the laboratory and never before exposed to pine needle oil responded as strongly as wild-caught animals, about whose previous experiences with this oil or any of its components we have no information. Thus, it appears that one or several constituents of the pine oil are innately aversive to plains pocket gophers. The indifference of the animals to pulegone, a compound that is very odoriferous for the human nose, shows that this aversion is not based on neophobia. Moreover, there was no habituation to pine needle oil across experiments involving the same subjects.

In experiment 4, the pocket gophers contacted the pine needle oil soaked cable during chewing, and the stimulus could have influenced behavior via olfaction, the trigeminal system, which mediates irritation, other nasal chemosensory systems, or taste. In experiments 1 and 3, however, stimuli were enclosed in plastic capsules, and the animals could only perceive volatile cues. Although nasal trigeminal chemoreception could have been involved, the animals showed no behavioral indication of irritation, and it appears likely that avoidance was mediated, at least in part, by olfaction. Olfaction also appeared to be involved in mediating responses of northern pocket gophers to pine needle oil (Epple et al., 1996). Secondary plant metabolites are feeding deterrents for several mammalian herbivores (Iason and Palo, 1991; Langenheim, 1994; Reichardt et al.,

1984, 1990a,b; Roy and Bergeron, 1990; Sinclair et al., 1988; Sunnerheim-Sjoberg and Hamalainen, 1992). Some of these species avoid deterrents on the basis of olfactory cues alone. Snowshoe hares and Townsend's voles avoid feeding from sources associated with the scent of pine oil extracted from pulp waste (Bell and Harestad, 1987). Snowshoe hares also avoid feeding on conifer seedlings to which odor dispensers with pinosylvin, a phenolic compound from Alaskan green alder (Clausen et al., 1986), have been attached (Sullivan et al., 1992). The odors of crushed foliage from lodgepole pine (*Pinus contorta*) and Sitka spruce (*Picea sitchensis*) and of some of their monoterpene constituents inhibit feeding in red deer calves (Elliott and Loudon, 1987). Mule deer respond to the odors of juniper oil in selecting food (Schwartz et al., 1980).

The present results as well as those of our studies with northern pocket gophers (Epple et al., 1996) suggest that pine needle oil is a strong repellent for pocket gophers in general. However, the possible role the essential oil and its constituents play in controlling food selection in these species remains to be elucidated. It is likely that the animals responded to the pine needle oil because it contains compounds that act as feeding deterrents under natural conditions. Grasses constitute the most important part of the yearly diet of plains pocket gophers, although succulent forbs are preferred in spring and summer (Behrend and Tester, 1988; Benedix, 1993; Luce et al., 1980; Myers and Vaughan, 1964). Grasses and forbs do not contain essential oils, and grazers have less well-developed detoxification mechanisms than browsers and may depend more on avoidance (McArthur et al., 1991). However, plains pocket gophers consume roots of white pine and red oak (Huntly and Inouye, 1988), and under snow cover also eat above-ground parts of pine trees in Christmas tree plantations (Hegdal, personal communication). Northern pocker gophers contribute heavily to seedling mortality in fir plantations (Gottfried and Patton, 1984; Radwan et al., 1982). It is likely, therefore, that both species encounter essential oils from conifers during foraging.

Essential oils from conifers are chemically complex, being predominantly composed of monoterpene hydrocarbons (Langenheim, 1994; Radwan et al., 1982). There are differences in the composition of oils among different conifer species, different populations of the same species, individual trees, and different parts of the same plant, and animals respond to such differences (Langenheim, 1994). In the only study on pocket gophers known to us, feeding preferences of *Thomomys* (species not given) for ponderosa pine seedlings were negatively correlated to the β-pinene plus sabinene component of stem oils but positively correlated to the total terpene yield of root oils. Leaf oils, on the other hand, showed no correlation with feeding preference (Radwan et al., 1982).

In conclusion, the strong avoidance of odors from the pine needle oil used in this study suggests that compounds from this essential oil are ecologically significant for *Geomys bursarius* and might make very promising feeding repel-

lents for other species of pocket gophers as well. Moreover, the use of pine needle oil constituents in reducing gnawing damage to underground cable should be considered. However, studies on isolation and identification of active compounds from the brand of oil used in the present experiments are needed before its use as a repellent can be explored.

Acknowledgments—The studies were supported through Cooperative Agreement Number 95-7407-0040-CA between The Denver Wildlife Research Center and The Monell Chemical Senses Center.

(Received April 10, 1995; accepted January 7, 1996)

Abstract—An interpretation is given of a number of observations on the chemiotropic behavior of *Bactrocera oleae* in connection with olive maceration water and the fly's return to the olive groves after the first summer rains. To this end, the headspace of both maceration water and leaf leaching water, simulating rainfall, were examined. In both cases, the presence of ammonia, which is generally known to attract fruit flies (Diptera, Tephritidae), was detected and, for the first time, in addition to other compounds that are inert for the fly, the presence of styrene was also detected. This aromatic hydrocarbon was found to be a strong attractant. It is shown that both ammonia and styrene are products of the metabolism of microbial flora present on the olive and leaf surface.

Key Words—*Olea europaea*, attractants, *Bactrocera oleae*, Diptera, Tephritidae, olive maceration water, olive leaf leachate, microbial metabolites, styrene, ammonia.

INTRODUCTION

Despite the gradual increase in our knowledge of the complex relation between the olive fly, *Bactrocera oleae* (B. oleae), and the host plant (*Olea europaea*) the causes of the following chemiotropic behaviors are still unknown: (1) drowning of numerous females in the maceration water during the process of sweet-

*To whom correspondence should be addressed.

0098-0331/96/0500-1027$09.50/0 © 1996 Plenum Publishing Corporation

ening olives for food purposes (Vita and Cirio, 1980); and (2) large-scale return of the fly to olive groves after the first abundant summer rains (Girolami et al., 1982). It is reasonable to postulate the presence of attractants in both the maceration water and on rain-soaked leaves, particularly in warm weather. As part of our on-going work on the interaction between *B. oleae* and the olive tree (Scarpati et al., 1993; Lo Scalzo et al., 1994), we report here the results of research leading to the identification of chemical substances responsible for attraction of flies to olive maceration water and to rain-soaked leaves.

METHODS AND MATERIALS

General Experimental Materials

Olive leaves or olives (Frantoio or Leccino cultivars) were collected from July to November in the Lazio region of Italy. Ammonia was determined by the colorimetric test Merckoquant (Merck, Cod. 10024). Aldrich GC purity samples were used for laboratory bioassays. The systems used for the analysis of the volatile compounds were described in previous publications (Scarpati et al., 1993; Lo Scalzo et al., 1994).

Preparation of Olive Maceration Water for Determination of Attractancy, Headspace Volatiles, and Ammonia

One kilogram of olives was soaked in 1 liter of H_2O and allowed to stand at room temperature for 8–10 days. The decanted maceration water solution (MW) was used for the reported determinations. The same procedure was used for the preparation of maceration water in which microbial growth was inhibited by adding 1 g of streptomycin per liter of H_2O (MWS).

Preparation of Leaf Leachate Water for Determination of Attractancy and Ammonia Release

One kilogram of freshly cut olive branches was placed in a stoppered vessel and shaken constantly for 15 min with 200 ml of H_2O. The decanted leaf leachate solution (LW) was used for the reported determinations. The same procedure was used to produce leaf leachate water in which microbial growth was inhibited by adding 200 mg of streptomycin (LWS).

Preparation in the Field of Enriched Leaf Leachate Water for Headspace Volatile Analysis

One liter of distilled water was sprayed for about 5 min on a leafy branch about 1 m long that had not been cut from the tree. The water dripping off the

branch, simulating rainfall, was collected in a large vessel placed underneath, and then it was sprayed on the same branch twice more. The same solution was used repeatedly on nine different branches, thus allowing about 0.5 liter of enriched leachate water to be obtained.

Chemical Investigations

The headspace volatiles from MW, MWS, and enriched leaf leachate water were trapped and analyzed with the following methods described by Scarpati et al. (1993). Water solutions were stripped with pure nitrogen for 15–120 min at a flow rate of 50 ml/min. Adsorption of the volatiles at the exit of the container was performed with a Supelco Carbotrap 300, 115 mm × 4 mm ID. All connections were made with steel–glass or glass–glass contacts secured with Teflon pipes. The adsorbed components were desorbed by heating the Carbotrap with a Supelco Thermal Desorption Unit (TDU, model 850) under a helium flow and analyzed with a GC-MS (HP 5890/HP 5971 A) system linked with a data processor (HP 59970 MS Chemstation). The GC column was a capillary Supelco SPB-1 (1% methyl-phenylsilicone), 30 m × 0.2 mm ID, film thickness 0.2 μm.

In order to identify and determine the less volatile compounds, such as 2-phenylethanol, which were not well represented in the headsapce volatiles, 500 ml of MW were partioned for 8 hr with a *n*-pentane–methylene chloride solution 6:4, in a continuous liquid–liquid extractor. The final MW extract in *n*-pentane–methylene chloride was concentrated to a small volume through a Vigreux column for GC analysis.

Ammonia determinations were carried out on MW, MWS, LW, and LWS, after a paper filtration with the colorimetric method (Merckoquant, Cod. 10024).

Laboratory Bioassays

Bioassays described by Scarpati et al. (1993), were conducted under laboratory conditions of 21–25°C and 40–50% relative humidity. Adult olive fruit flies from groves in the Lazio region were transferred to Plexiglas cages (20 × 20 × 20 cm) and fed a diet consisting of a mixture of sugar (33%), soy flour (33%), and yeast hydrolysate (33%). A rearing procedure was adopted using fruits of the Itrana olive cultivars, available until April. The insects were transferred to cages 10 days after eclosion and subjected to the tests, during which water was constantly available but food was removed in order to avoid interference.

Two different bioassays were done in order to ascertain the effect of the sample on the behavior of gravid females of *B. oleae*.

Attractancy. In a Plexiglas cage (20 × 20 × 20 cm) containing gravid females (25 individuals), two 5-cm-ID Petri dishes were placed as far apart as possible. They contained 15 ml of test solution of a pure chemical or water

(blank). Every 30 min positions of the dishes were switched to eliminate position effects. An insect visiting a container was trapped in the dish containing test solution or water. Testing was carried out before sunset for 150 min, and the trapped individuals were counted.

Oviposition. The oviposition test, conducted in a Plexiglas cage (20 × 20 × 20 cm), was based upon the ability of three gravid females to oviposit on six natural fruits resting at the top of six test tubes (6 cm × 1.2 cm ID), three of which contained water (blank) and three filled to within 2.5 cm of the rim with test solution. An olive was placed on the rim of each test tube in such a way that volatiles evaporating from the solution came into contact with the fly (Figure 1). Six hours later, before sunset, oviposition punctures were counted, and the ratio between the total number of oviposition punctures on the three olives exposed to the test sample and the three exposed only to water was determined. The response index was defined as the mean value of the ratios resulting from ten bioassays.

Tests of attractancy and oviposition were conducted on MW, WMS, LW, LWS, and single synthetic chemicals identified in the headspace volatiles from olive MW, and/or leaf-enriched leachate water. All the pure chemicals used for

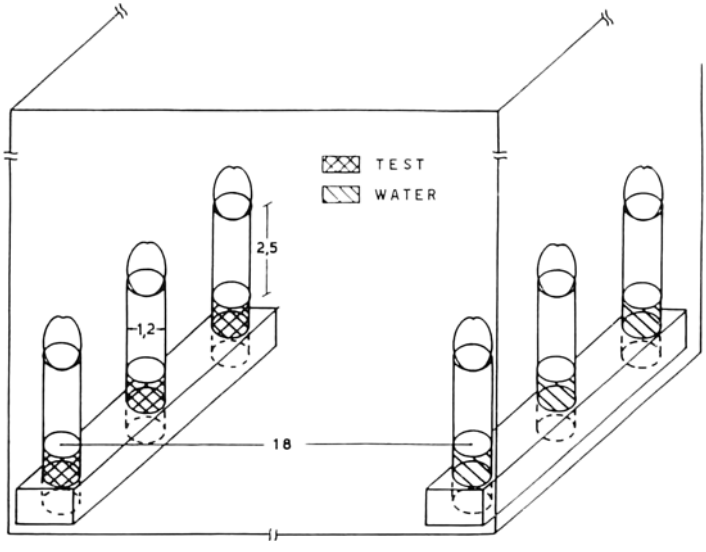

FIG. 1. Setup used in oviposition test with three gravid females and six olives; three test tubes contain chemicals and three water. All sizes are expressed in centimeters. Results are reported in Figure 4.

bioassays were bought from Aldrich (GC purity). They were dissolved or suspended in distilled water at a concentration of 5–20 ppm.

RESULTS AND DISCUSSION

Chemical Investigations. All the compounds identified are reported in Table 1. From MW headspace volatiles we identified the following, in order of decreasing GC peak area: styrene, **1**; *n*-pentanol, **2**, ethyl acetate, **3**; nonanal, **4**; 2-phenyl-ethanol, **5**; and, in smaller amounts, limonene, **6**; α-pinene, **7**; and β-pinene, **8**. Compounds **4**, **6**, **7**, and **8** had already been identified by us in the headspace volatiles from olives themselves. A stripping time of 15 min was sufficent to collect all the styrene because of its high volatility, but complete stripping of the other components required 2 hr.

Gas-chromatographic examination of the MW extract with methylene chloride–pentane indicated that 2-phenyl-ethanol is present in quantities four times greater than styrene. Styrene was not detectable in the headspace volatiles of MWS.

Compounds **1**, **5**, and **4**, in decreasing order, and small amounts of **6**; **7**; *p*-cimene, **9**; and *n*-octane, **10** were found in the headspace of the leaf-enriched leachate water. Compounds **6**, **7**, **9**, and **10** had already been identified by us in headspace volatiles from leaves themselves.

Ammonia is a generic attractant for many insects (Bateman and Morton, 1981) and is present in MW at concentrations of 80–150 ppm. Its content

decreases to 10–15 ppm in MWS, suggesting that it is largely produced from microbial fermentation.

Ammonia determination in LW prepared at different time intervals after the last rainfall indicates that values are fairly constant before rainfall (20–25 ppm), decrease immediately after rainfall, and then reach a maximum about 6–10 days later (55–60 ppm). The presence of streptomycin inhibits NH_3 formation also in LWS.

Attractancy Test. The MW was highly attractive (Scarpati et al., 1993), and MW was thus adopted as a positive control in the bioassays. The present results confirmed again the attractancy of MW. On dilution of MW with H_2O, the activity decreased, and the lower threshold occurred at a dilution of 1:4. MWS was completely devoid of activity. In order to demonstrate that the cancellation of activity was not due to a repulsive effect related to the addition of streptomycin, the attractancy of MW diluted with MWS 1:1 was compared with the attractancy of MW diluted with H_2O 1:1, and very similar responses were obtained. LW also was active, while LWS proved to be inactive. These results are shown in Figure 2.

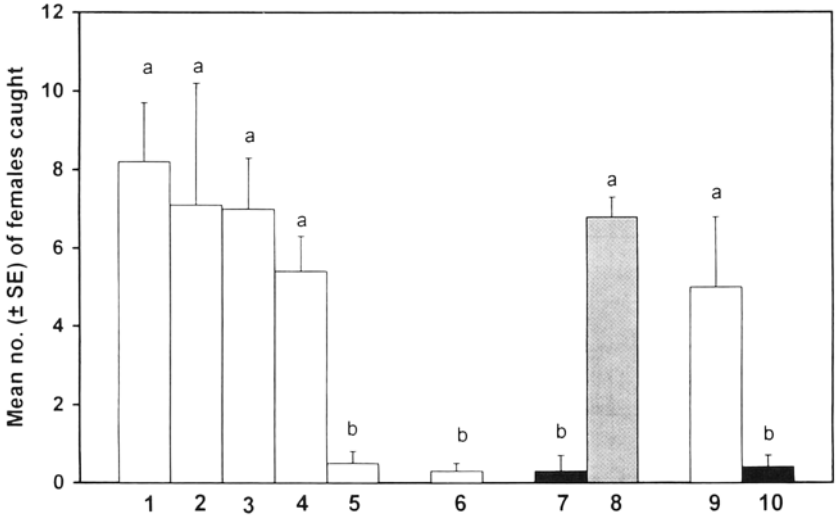

FIG. 2. Attractiveness to *B. oleae* females of MW, MWS, LW, and LWS in an olfactory attractancy bioassay. Replicate numbers are given in parentheses. Error bars represent standard error. Significant differences ($P < 0.05$) within each graph are indicated by different lowercase letters, as indicated by Duncan's (1955) multiple range test. **1,** absolute MW (30); **2,** MW–H_2O 1:1 (10); **3,** MW–H_2O 1:2 (10); **4,** MW–H_2O 1:3 (10); **5,** MW–H_2O 1:4 (10); **6,** H_2O (50); **7,** MWS (8); **8,** MW–MWS 1:1 (9); **9,** LW (8); **10,** LWS (8).

The single pure compounds identified in the headspace volatiles from MW and enriched leaf leachate were bioassayed with female *B. oleae*. Only styrene was highly attractive, while **2, 3,** and **4,** and its probable metabolic precursor, **5,** were inactive. Compounds **6–10** had been found previously to be inactive or weakly active. Attractancy peaked in water mixtures containing 10–15 ppm styrene, while it decreased strongly in mixtures containing 5 or 20 ppm styrene. Attractancy of styrene to *B. oleae* males was tested at concentrations of 10 and 15 ppm, and it was found to be practically inactive. Figure 3 gives a comparison of the activities of styrene, ethylbenzene, and toluene, which had shown significant activity in previous research (Scarpati et al., 1993).

Oviposition Test. All results of the oviposition test are shown in Figure 4. Styrene proved to be highly active in the oviposition assay, although it was not possible to ascertain whether the increased oviposition was due solely to a true stimulus of oviposition or only to olfactory attractancy (Figure 3). The other components from MW headspace, i.e., **2, 3, 4,** and **5,** were inactive in this test.

α-Pinene (**7**) had previously been found to act as a specific oviposition stimulus, but it proved only weakly active in the attractancy test. The comparison between **7** and **1** in the oviposition test showed that styrene is much more

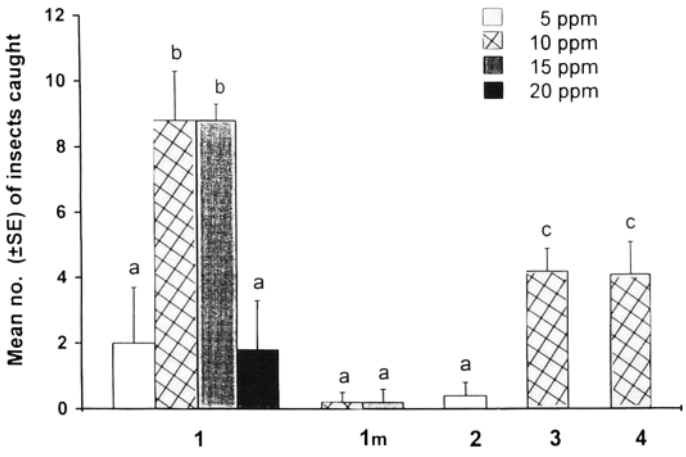

FIG. 3. Attractiveness to *B. oleae* females of styrene, toluene, and ethylbenzene in an olfactory attractancy bioassay at reported concentration in H_2O. Only styrene was assayed on males. Replicate numbers are given in parentheses. Error bars represent standard error. Significant differences ($P < 0.05$) within each graph are indicated by different lowercase letters, as indicated by Duncan's (1955) multiple range test. **1,** styrene on females (10); **1m,** styrene on males (10); **2,** H_2O (30); **3,** ethylbenzene (10); **4,** toluene (10).

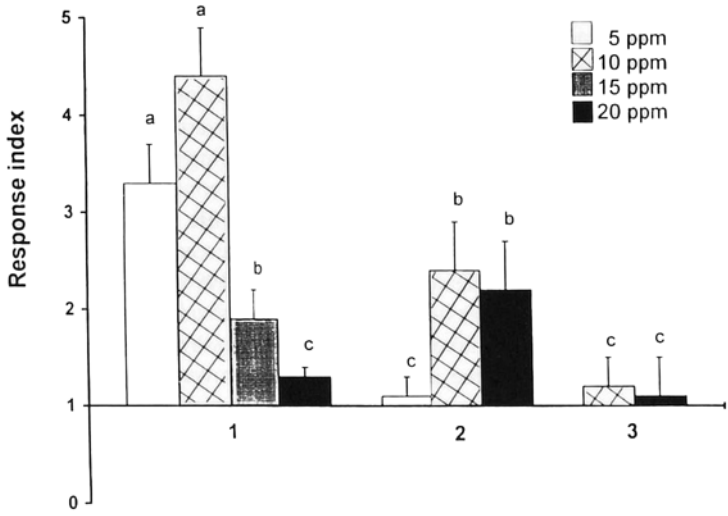

FIG. 4. The ratio between the total number of ovipositions of *B. oleae* on three olives exposed with the test sample and three exposed only with water was determined for each bioassay. The response index was defined as the mean value of the ratios from 10 bioassays. Replicate numbers are given in parentheses. Error bars represent standard error. Significant differences ($P < 0.05$) within each graph are indicated by different lowercase letters, as indicated by Duncan's (1955) multiple range test. **1,** styrene (10); **2,** α-pinene (10); **3,** ethylbenzene (10).

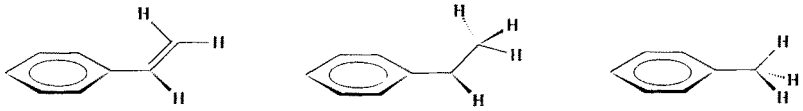
active than α-pinene at a concentration of 5 ppm, while the gap narrows at a concentration of 10 ppm. At 20 ppm, the activity of styrene decreases, while that of α-pinene remains constant.

CONCLUSIONS

Styrene, identified in MW and in leaf-enriched leachate was unexpectedly found to be highly attractive to the *B. oleae* female. Styrene is accompanied by 2-phenyl-ethanol, which was inactive and is likely the precursor of styrene.

Previously (Scarpati et al., 1993) we found that several components of the headspace volatiles from leaves and olives, i.e., ethylbenzene and toluene, exerted significant olfactory attractancy. Styrene has a structure related to such compounds, but conjugation with the aromatic ring of the vinyl group, which flattens the molecule, may produce a better steric interaction with the insect's receptor (Figure 5) (Metcalf, 1990).



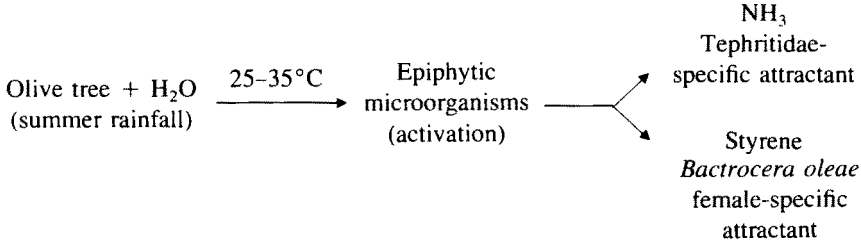
1 **ethylbenzene** **toluene**

FIG. 5. Tridimensional structures of styrene **1**, ethylbenzene, and toluene.

We have never found **1** or **5** in headspace volatiles from whole olives or leaves themselves. It is likely that, like ammonia, these compounds do not come from the plant's metabolism but from epiphytic microrganisms. These microrganisms have adapted to the surface of *Olea europaea* fruits and leaves (Ercolani, 1991), which are protected by a wax layer of triterpenic acids. The microrganisms are activated by the water (Richardson and Dowding, 1988), especially at relatively high summer temperatures. When microbial activity was inhibited by the addition of streptomycin to MW or LW, styrene was absent and ammonia was reduced to a minimum.

Both styrene and 2-phenyl-ethanol may be produced from the same intermediate, phenylacetaldehyde, a known breakdown product of phenylalanine. Styrene can also be a product of decarboxylation of cinnamic acid (Manitto, 1981).

The return of flies to the olive groves after the first summer rain may, in our opinion, occur according to the following pattern:



It is clear that in the coevolution of *B. oleae* with its host plant, the microbial populations living in symbiosis with the plant played an important role. The identification of a strong female attractant, styrene, together with the previous discovery of a strong repellent, (*E*)-2-hexenal (Scarpati et al., 1993; Lo Scalzo et al., 1994), provide a promising base for future field control of the *B. oleae* female, the scourge of olive oil production in the Mediterranean area.

(Received June 2, 1995; accepted January 9, 1996)

Abstract—Gas chromatographic analysis of the volatile terpenes of the wood oleoresin of maritime pines showed that the relative proportions of terpenes within the same tree did not vary according to sampling height and date. Pruning and tree vigor did not affect terpene profiles, but oleoresin composition varied widely from tree to tree. The trees attacked by *Dioryctria sylvestrella* contained a significantly higher percentage of limonene, longipinene, and copaene, and a discriminant analysis, using the relative percentage of six terpenes, significantly separated infested and uninfested trees. The olfactory sensitivity of adult moths to a series of 20 volatile chemicals, including maritime pine oleoresin components, was evaluated with the electroantennogram method. Both sexes were sensitive to monoterpenes, oxygenated terpenoid compounds, and oleoresin samples. The use of terpenes as host attractants and biochemical markers for resistance to *D. sylvestrella* is discussed.

Key Words—Pine tree, *Pinus pinaster*, Lepidoptera, *Dioryctria sylvestrella*, oleoresin, terpenes, host selection, resistance marker.

INTRODUCTION

The European stem borer, *Dioryctria sylvestrella* Ratz., is one of the major pests of maritime pines in Europe. This oligophagous insect is restricted to the genus *Pinus* in Eurasia (Speight and Speechly, 1982; Menassieu et al., 1989) with occasional damage to *Picea* spp. (Menassieu, personal communication). Larvae tunnel through the bark into the phloem where they feed from July to October and March to May. If larvae succeed in girdling the stem, the tree may suffer from interruption of sap flow, resulting in a decrease of the annual increment or in the malformation of the trunk and increasing the risk of windbreak (Baronio and Butturini, 1988). Foraging larvae cause resin pockets, which render the timber worthless, particularly for peeling and sawing. For the last 10 years, major infestations of *D. sylvestrella* have developed in southwestern France (Menassieu et al., 1989; Jactel et al., 1994), a region that contains the largest unit of managed forest in Europe (1.2 million ha). The high cost of the intensive management of this maritime pine forest makes it necessary to prevent stems borers from reducing the volume and the quality of the forest products grown. The impossibility of chemical control because the insect is hidden under the bark more than 11 months each year and the uncertainty of biological controls led us to promote changes in silviculture practices and to develop pest-resistant trees. Both of these two strategies are based on the same principle: the reduction of tree attractiveness.

Early work (Jactel et al., 1994, 1995) demonstrated that the infestation rate of *D. sylvestrella* increases with the severity of pruning and with the vigor of maritime pine trees, i.e., with two factors closely linked to intensive pine forest management. Planting at low densities and fertilizing were developed to favor fast growth. Tree pruning, the removal of live branches, is used to reduce the incidence of knots and to increase the proportion of clear lumber in the logs. It was hypothesized that primary attraction, mediated by components of the oleoresin exuding from the pruning wounds or bark cracks, might attract insect to host trees. Our studies suggest that the olfactory system of *D. sylvestrella* females is tuned to volatiles from the constitutive oleoresin, among which terpenes or their derivatives may play a major role in the attraction. Terpenes affect the behavior of a variety of insects (reviewed by Speight and Wainhouse, 1989), including several *Dioryctria* species (Hanula et al., 1985). Moreover, infestation rates of forest insects (Smith, 1966; Annila and Hiltunen, 1977; Rappaport et al., 1995) or variations in tree resistance (Hanover and Furniss, 1966; Wright et al., 1975; Sturgeon, 1979; Charles et al., 1980; Bridgen and Hanover, 1980) have been related to terpene ratios in oleoresin or volatile extracts.

Due to low natural densities and lack of mass rearing, few adult moths were available for laboratory experiment. This made the use of behavioral tests too difficult for studying the attractiveness of terpenes. It seemed more conve-

nient to base our investigations on epidemiological data by comparing the terpene composition of oleoresin between attacked and unattacked trees. Before attacks could be related to individual attractiveness, five precautions had to be taken. First, oleoresin was sampled before *D. sylvestrella* attack. Second, oleoresin was collected from the trunk of maritime pine trees, because the resin involved in tree attractiveness seemed to be that exuding from pruning wounds (Jactel et al., 1994, 1995). This resin is synthesized in the wood (secondary) tissues and stored in resin ducts (Pauly, 1962; Bernard-Dagan, 1968) as opposed to the resin located in cortical (primary) tissues (Baradat and Marpeau-Bezard, 1988). Third, the within-tree variability of the terpene composition had to be determined as a function of sampling height and date. Fourth, since more vigorous trees and pruning are known to increase the risk of attack, it had to be verified whether these physiological changes modify the terpene composition (i.e., the nature of the attractive signal) or only the rate of release (i.e., the emission pattern of the attractive signal). Terpenes whose proportion significantly differ between attacked and unattacked trees might serve as biochemical markers for resistance to *D. sylvestrella*. In a fifth step, we had to determine whether these terpenes act as host attractants themselves. We thus compared, by electroantennography (EAG) recordings, the detection abilities of the European stem-borer moth towards several terpenes and volatiles that commonly occur in pine trees.

METHODS AND MATERIALS

Oleoresin Sampling. Oleoresin samples were taken from 55 twelve-year-old pine trees (*Pinus pinaster* Ait.), unattacked by *D. sylvestrella*: 25 trees were randomly chosen from one pure stand and 30 from a second pure stand grown on damp heaths in the Landes de Gascogne (southwestern France) where the sensitivity of pruned maritime pines has been studied in relation to tree vigor and date of pruning (Jactel et al., 1995). Forty-three trees were pruned at different dates, and 12 remained unpruned until June 1993 at the start of the insect attack period (Table 1). The latter 12 trees (control trees) were pruned in June 1994 in order to study the short-term effects of pruning on the terpene profile. Pruning consisted of the removal of all branches except the upper (younger) four whorls, about 5 m above ground level, which is the usual practice for maritime pine in France. Due to the spacing of trees (almost 2 m) and the number of large branches, pruning is needed to reduce the incidence of knots in saw timber. In October 1993, the diameter at breast height (at 1.3 m above the ground) and the presence of *D. sylvestrella* attacks were recorded on all 55 trees.

A sampling method was developed to collect sufficient wood resin. Holes

TABLE 1. SAMPLE SIZE OF FIVE TREATMENTS APPLIED TO 55 TREES SAMPLED FOR WOOD RESIN COMPOSITION AND *Dioryctria sylvestrella* ATTACK

Tree treatment	Number of trees		
	Stand 1	Stand 2	Total
Pruned in August 1992	4	3	7
Pruned in November 1992	4	4	8
Pruned in February 1993	6	8	14
Pruned in May 1993	6	8	14
Unpruned (control)	5	7	12
Total	25	30	55

were bored with a drill, along an oblique line, through the sapwood, in the vicinity of a branch insertion point. One end of a plastic tube was introduced into the hole and the other side was cellotaped to a glass vial. Oleoresin flowing out of the holes was collected for 24 hr. The vial samples were then placed in a nitrogen atmosphere in Dry Ice, and stored in the laboratory at −30°C until analysis (Delorme and Lieutier, 1990). In each pine stem, constitutive oleoresin was sampled at two levels. One hole was bored near the branch insertion of the 3-year-old internode, where the highest number of *D. sylvestrella* attacks are located (Jactel et al., 1994), and the second hole was bored in the 5-year-old internode, the upper whorl from which live branches were removed in pruned trees and where *D. sylvestrella* attacks also occur. In control trees, oleoresin was sampled seven times at the same two levels: in August 1992, November 1992, February 1993, May 1993, June 1993, and in June 1994 before and after pruning (14 samples per control tree). In pruned trees, oleoresin was sampled once near the pruning wounds the day after pruning and at the two heights defined above in June 1993 (three samples per pruned tree).

Gas Chromatographic Analyses. Only mono- and sesquiterpenes were studied. Approximately 1 ml of resin was solubilized in 1.5 ml of pentane. Pentane solutions of the terpenes were purified by column chromatography on SDS silica 70–230 mesh (8 ml) in a glass column (20 cm long × 1 cm ID). Terpenes were eluted by a pentane–ether solution (30 ml, 98:2), and sodium sulfate (0.5 ml) was added to eliminate water from the resin extract. The purified extract was concentrated by evaporation under moderate vacuum and analyzed by FID-GC (Delsi Intersmat IGC-120, temperature program. 60°C to 280°C at 6°C/min, splitless (injector 200°C, detector 290°C) on a 25-m × 0.25-mm-ID Chrompack CPSIL 5 column (N_2, 0.4 ml/min, 1 μl sample). The components had been previously identified by infrared and mass Spectrometry and by comparing their

retention times with those of authentic samples (Pauly et al., 1973). The relative percentages of mono- and sesquiterpenes were calculated from the summation of all recorded terpene peaks.

Electroantennography. D. sylvestrella chrysalids were collected from attacked pine trees near the INRA Forestry Centre (Gazinet, France) in May–June 1994. Adults emerged in the laboratory and were maintained in containers at 20°C under natural light. Three- to 6-day-old moths of both sexes were used for electrophysiological recordings. Electroantennograms (EAG) were recorded from 6 males and 11 females with a classical electrophysiological set-up (Gabel et al., 1992). Head antenna preparations were stimulated with a series of volatile compounds delivered for 2 sec (2 ml/sec) in a continuous airflow (4 ml/sec; humidified, compressed air). A variable time interval (30 sec to 2 min.) enabled the antenna to recover from previous stimulation. All chemicals were diluted in paraffin oil (10^{-2} v/v) and deposited on filter paper (5 μl on 2 cm^2) inside a disposable Pasteur pipet. A standard stimulus, hexanol, was delivered every four stimulations. Hexanol was chosen as a standard because it is a general green leaf volatile (Visser, 1986). Chemical compounds (GC purity) were either purchased from commercial sources or prepared from natural maritime pine oleoresin. The series of 20 compounds tested included mono- and sesquiterpenes, terpenic acetates, terpenic alcohols, total oleoresins, and paraffin oil and blank (empty pipet) as controls (listed in Figure 3 below).

Electrical signals were continuously recorded and analyzed on a PC-compatible microcomputer using a custom-designed program (Marion-Poll and Tobin, 1991; Marion-Poll and Thiéry, 1995). EAG responses were expressed relative to the response of the standard stimulus (hexanol).

Statistical Analyses. All statistical analyses were carried out with SAS Software (SAS Institute Inc., 1987). Analyses of variance (*t* test or GLM) of percentage variables were computed with the arcsin $\sqrt{x}$ transformation (Dagnelie, 1973). Mean differences were tested using Scheffé's multiple range test.

RESULTS

Within-Tree and Intertree Variations in Terpene Composition. Thirteen terpenes exhibited relative proportions higher than 0.05%, and were used throughout the study. In order of increasing retention time, there were six monoterpenes: α-pinene, camphene, β-pinene, myrcene, limonene, terpinolene; and seven sesquiterpenes: longipinene, copaene, cubebene, longifolene, β-caryophyllene, α-humulene and germacrene. The α- and β-pinenes averaged 90% of the total amount of terpenes and the sesquiterpenes almost 5%. The relative proportions of terpenes determined by gas chromatography were accurate since the standard error varied from 0.4% for α-pinene, the major com-

ponent (60%), to 0.003% for copaene and germacrene, the minor components (0.1%).

The variances of the relative proportions of the 13 terpenes in the 12 unpruned trees were analyzed according to sampling date (five dates in 1993, one date in 1994 before pruning, $df = 5$), sampling height (3- and 5-year-old internodes, $df = 1$), and the interaction between these factors ($N = 144$). None of the factors nor their interaction induced any significant differences ($P > 0.05$). The terpene composition of the oleoresin did not vary with sampling height in the part of the stem where *D. sylvestrella* attacks are located. Only minor changes were recorded in the relative proportion of terpenes during the same year and between two successive years (Figure 1). In June 1994, the control trees were sampled before and 48 hr after pruning, at both heights. There were no significant differences for any of the 13 terpenes between the relative proportion before and shortly after pruning (t test, $N = 12$, $P > 0.05$). Likewise, the 43 pruned trees were sampled in the 5-year-old internode 48 hr after pruning and in June 1993. There were no significant differences for any of the 13 terpenes between the relative proportion just after pruning and 1–10 months after pruning (t test, $N = 7$ to $N = 14$, $P > 0.05$).

The percentage of each terpene showed a wide intertree variability. The 12 unpruned trees and the 43 pruned trees differed significantly from each other in all components of their terpenes composition ($N = 12$ and $N = 3$, respectively; $P < 0.001$). For both pruned and unpruned trees, the coefficient of variation of the terpenes proportions was 1.2- to 7.5-fold more important between trees than within trees (Table 2). Simple correlation coefficients of each terpene proportion with the diameter at breast height were computed for all 55 trees. Terpene proportions were never significantly correlated with tree diameter ($N = 55$, $P > 0.05$).

Terpene Composition and Susceptibility to D. sylvestrella *Attack.* Since pruning did not induce any change in terpene composition, the 12 unpruned trees and the 43 pruned trees were pooled for this analysis. Thirty-three trees were attacked and 22 were uninfected. Wood resins did not differ qualitatively between attacked and unattacked trees, since both types of tree produced the same typical chromatogram of the same 13 terpenes. However, some differences in relative percentage of terpenes were significant (Figure 2). Trees that had been attacked exhibited significantly more limonene ($P < 0.04$), longipinene ($P < 0.03$), and copaene ($P < 0.03$) and less camphene ($P < 0.004$) than unattacked trees. The ratio of limonene plus longipinene plus copaene to camphene differed even more significantly between attacked and unattacked trees ($P < 0.003$). Discriminant analyses were performed to determine whether the whole terpene composition could separate the two classes of trees. The best discriminant analysis was obtained with the combination of six variables: the proportion of β-pinene, camphene, myrcene, limonene, terpinolene, and ger-

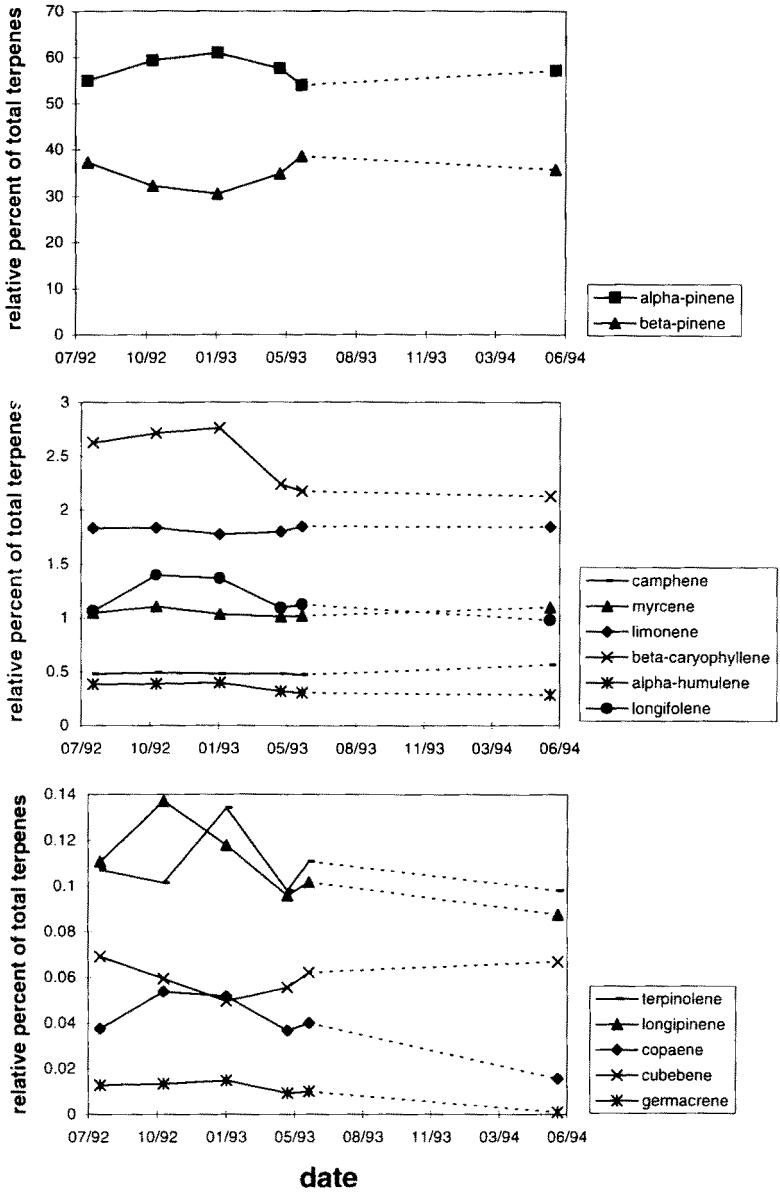

FIG. 1. Changes in the relative percentage of terpenes in the wood resin of maritime pines over the course of two years (12 trees).

TABLE 2. WITHIN AND INTERTREE COEFFICIENT OF VARIATION (CV) OF RELATIVE PROPORTION OF 13 TERPENES PRESENT IN MARITIME PINE WOOD RESIN

[a] API, α-pinene; CAM, camphene; BPI, β-pinene; MYR, myrcene; LIM, limonene; TPL, terpinolene; LGP, longipinene; COP, copaene; CUB, cubebene; LGF, longifolene; BCA, β-caryophyllene; AHU, α-humulene; GER, germacrene.

[b] Control trees: within tree CV is calculated as the mean (N = 12 trees) of the CV of the proportion of terpenes in each tree (N = 12, two heights, six dates). Intertree CV is calculated as the CV (N = 12 trees) of the mean proportion of terpenes in each tree (N = 12, two heights, six dates).

[c] Pruned trees: Within tree CV is calculated as the mean (N = 43 trees) of the CV of the proportion of terpenes in each tree (N = 3, two heights, two dates). Intertree CV is calculated as the CV (N = 43 trees) of the mean proportion of terpenes in each tree (N = 3, two heights, two dates).

macrene. Wilk's lambda statistic showed a highly significant difference between the means of attacked and unattacked trees ($F = 3.19$, $P = 0.007$). The resubstitution using linear discriminant function produced an error count estimate of 28% for the attack (18.2% for misclassified attacked trees and 37.9% for misclassified unattacked trees).

Electrophysiological Response of D. sylvestrella *to Terpenoid Compounds.* All compounds elicited EAG responses within 20–140% of the hexanol standard EAG responses of both sexes were compared with a t test. Eight compounds elicited significantly higher responses in females: α-pinene ($P < 0.02$), camphene ($P < 0.003$), β-pinene ($P < 0.02$), myrcene ($P < 0.04$), δ3-carene ($P < 0.02$), limonene ($P < 0.04$), longifolene ($P < 0.03$), β-caryophyllene ($P < 0.002$). Although differences in mean EAG response to the 21 compounds were tested separately, their patterns were the same in males and females (Figure 3). The most stimulating substances were pine tree resins, 4-terpineol, linalool, and neryl acetate. Medium stimuli were given by the monoterpenes and geraniol. Sesquiterpenes, terpenyl acetate, and nerolidol did not induce any response that was significantly different from those elicited by the blank and the paraffin oil.

DISCUSSION

Terpene Variations in Constitutive Oleoresin. The terpene composition of the sampled resin, with pinenes representing almost 90% of the total amount,

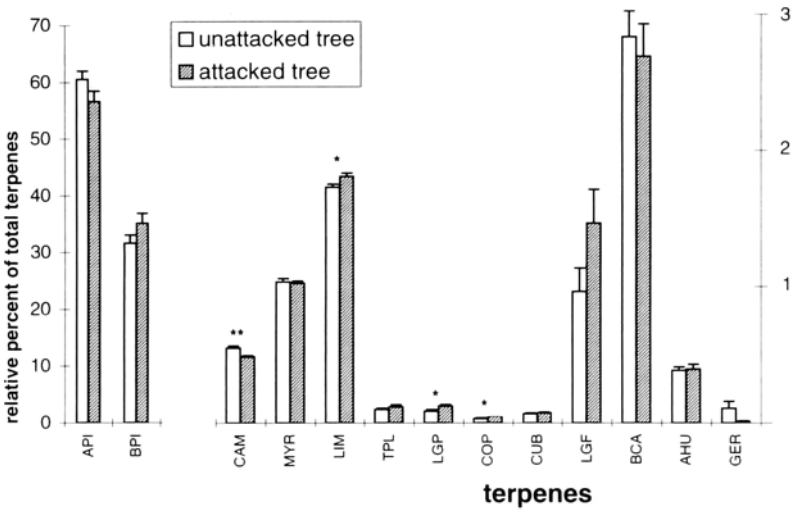

FIG. 2. Comparison of mean (± standard deviation) terpene profiles of wood resin in attacked and unattacked maritime pine trees. One or two stars above a pair of bars indicate a significant or highly significant difference between the mean relative percentage of terpene in attacked and unattacked tree. API: α-pinene, BPI: β-pinene, CAM: camphene, MYR: myrcene, LIM: limonene, TPL: terpinolene, LGP: longipinene, COP: copaene, CUB: cubebene, LGF: longifolene, BCA: β-caryophyllene, AHU: α-humulene, and GER: germacrene.

was very similar to the composition of the secondary resin already described in maritime pine (Bernard-Dagan, 1968; Baradat and Marpeau-Bezard, 1988). Collecting resin from holes bored through the sapwood may thus provide a convenient method for assessing the chemical composition of the oleoresin flowing out of the pruning wounds, which are particularly damaging to the secondary tissues. Our data suggest that pruning has neither short-term nor long-term effects on the terpene composition of the resin. However, it has been reported that mechanical injuries increase the resin content of pine tissues, due to the induced defense reaction (Berryman, 1972; Christiansen and Hornvendt, 1983; Lieutier et al., 1989). In pruning wounds, the resin exuding from several resin ducts might mix with the resin of the induced reaction, but it has been demonstrated that the terpene composition of the neosynthesised resin is very similar to that of wood resin (Cheniclet, 1987; Baradat and Marpeau-Bezard, 1988). The mixture of resins exuding from pruning wounds would thus be of the secondary type. Therefore, if terpenes in exuding resins were involved in the host attraction of *D. sylvestrella* they can be profitably studied in the secondary resin known as wood resin.

The terpene composition of wood resin did not vary significantly within

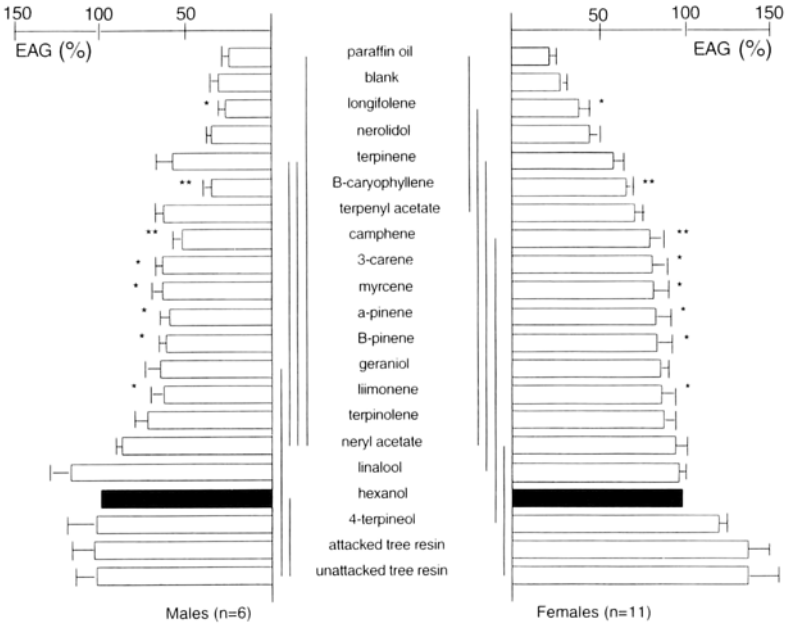

FIG. 3. Male and female *Dioryctria sylvestrella* EAG responses relative to the standard (hexanol). Bars represent the EAG relative amplitude (mean ± standard deviation). Stars indicate a highly significant difference between male and female EAGs. Two substances joined by the same vertical line (Scheffé's multiple range test) do not elicit a significantly different EAG response (lines at the left for males, at the right for females).

the same trunk, which supports previous findings that there is no variation in the wood resin composition according to the sampling height (Bernard-Dagan, 1968; Bernard-Dagan et al., 1971; Baradat and Marpeau-Bezard, 1988). Likewise, in *Pinus pinaster* (Bernard-Dagan et al., 1971), *Pinus monticola* Dougl. (Hanover and Furniss, 1966), or *Picea glauca* (Moench) Voss. (von Rudloff, 1972) the relative proportions of monoterpenes in individual trees change only slightly between seasons in shoot or stem tissues. In wood tissues, the terpene composition of the resin stabilized towards the fifth year of growth (Baradat et al., 1972; Schmitt et al., 1988). Consequently, collecting only one wood resin sample anywhere in the trunk and at anytime provides a convenient way of assessing the terpene profile of a single tree.

The 55 pine trees sampled in this study differed significantly with respect to the relative proportion of each of the 13 terpenes detected in the constitutive resin. This pattern of wide intertree variability in terpene composition has been noticed in the resin of many conifers, including *P. pinaster* (Bernard-Dagan,

1968), *Pinus muriatica* D. (Mirov et al., 1966), *P. contorta* (Pauly and von Rudloff, 1971), *Pinus ponderosa* (Zavarin et al., 1971), and *Picea abies* L. Karst (Schönwitz et al., 1987). In agreement with Douglas fir studies by Hanover and Furniss (1966), we found no significant correlation between the relative percentage of terpenes and tree diameter. As a rule, this intertree variability probably mainly results from genetic control (Hanover, 1966; Mirov et al., 1966; Squillace et al., 1980; Baradat and Marpeau-Bezard, 1988). The terpenes of wood resin are stable in time and space within the same stem, variable between trees, and under genetic control. Thus they possess all the attributes that would make them biochemical markers for selecting genetic resistance to *D. sylvestrella*.

Terpenes as Biochemical Markers for Resistance to D. sylvestrella. For terpenes to be used as biochemical markers for tree resistance, they have to be consistently related to the intensity of damage. The percentage of cones infected by *Pissodes validirostris* is significantly correlated with the α-pinene extracted from needles (Annila and Hiltunen, 1977), and the attack rates of *Megastigmus spermotrophus* Wachtl increase significantly with limonene and terpinolene levels in *Pseudotsuga menziesii* Mirb. cones (Rappaport et al., 1995). Wright et al. (1975) related the resistance of southern Scots pine varieties to *Dioryctria zimmermanni* (Grote) to low levels of δ 3-carene and terpinolene. In this study, Maritime pine sensitivity to *D. sylvestrella* was significantly correlated with high level of limonene, longipinene, and copaene and low levels of camphene in wood resin. Ratios of four terpenes and discriminant analysis, involving six different terpenes, further improved the significance of the differences between attacked and unattacked pine trees. This result seems to be consistent with the way polyphagous insects perceive host plants, which is believed to be based on mixtures or ratios of common volatiles rather than specific molecules (Visser, 1986; Marion-Poll and Thiéry, 1995).

The behavioral role of the wood resin terpenes has not yet been established in *D. sylvestrella*, but the physiological sensitivity of the species was assessed by EAG. As a rule, the EAGs from females were greater in amplitude (relative to the standard) than those of males. Since sexual dimorphism in the number of head antenna receptors may exist, further anatomical observations are needed to interpret these differences. Sesquiterpenes did not induce significant electrophysiological response, but monoterpenes were stimulating and oxygenated monoterpenes (alcohols and acetates) were even more effective. It is noteworthy that the amplitude of adult moth responses increased with the relative volatility of the tested compounds. Marion-Poll and Thiéry (1995) found the same order in *M. spermotrophus*, but this might be due to a technical artifact. Because head antenna preparations were stimulated by volatile compounds via a series of constant air volumes, the number of molecules that reach the antennal receptors was directly proportional to compound volatility. Hence, the more volatile compounds may be more stimulative.

The maximum response was elicited by the odors of complete wood resins. These extracts might contain a great number of unknown and untested stimulating compounds. The amplitude of the overall response may have been higher merely because of the additive effects of the various components. Moreover, no particular signal compound seemed to be distinguishable from the others by an especially high amplitude of response. These observations suggest that the olfactory system of *D. sylvestrella* is tuned to perceiving attractant mixtures or ratios of commonly occurring pine volatiles rather than to detecting specific compounds. These perception features could then explain why ratios of terpenes and discriminant analysis improved the significance of differences between infested and uninfested trees.

In conclusion, this study pointed out that monoterpenes of the wood resin may provide suitable markers in indirect selection programs for *D. sylvestrella* resistance in maritime pine, provided that heritability of the terpene profile can be demonstrated. In order to improve our understanding of host tree selection and to evaluate the potential use of behavior-modifying chemicals in pest management, headspace volatiles analyses and behavioral experiments should be developed to determine the most effective host attractants. Our data suggest that particular attention should be paid to monoterpenes and oxygenated terpenoid compounds.

(Received June 12, 1995; accepted January 12, 1996)

Abstract—The giant springtail, *Tetrodontophora bielanensis* (Waga), is characterized by integumental openings (pseudocells) from which small droplets of a sticky defensive fluid are secreted after molestation. The secretion originates initially from secretory cells below the pseudocellae; subsequent irritations result in release of hemolymph, which was identified by both chemical and microscopical methods as well as by scanning electron microscopy. Bioassays with topically treated ground beetles *Nebria brevicollis* showed that the pseudocellular fluid evokes a total disorientation and cleansing behavior of the beetle. The main constituents were identified as the following pyridopyrazines: 2,3-dimethoxypyrido[2,3-b]pyrazine (**1**), 3-isopropyl-2-methoxypyrido[2,3-b]pyrazine (**2**), and 2-methoxy-4*H*-pyrido[2,3-b]pyrazine-3-one (**3**). These alkaloids are mainly present in the pseudocellar fluids of female and male springtails but are absent in their food or feces. Minor amounts are found in the hemolymph of adults, while larvae contain traces of **2** only. All compounds were synthesized and tested for activity. In natural concentrations, the synthetic alkaloids elicited the same effects from the ground beetles as the pseudocellar fluid.

Key Words—Chemical defense, alkaloids, pyridopyrazines; Collembola, *Tetrodontophora bielanensis*, pseudocells, cleansing behavior, disorientation, 2,3-dimethoxypyrido[2,3-b]pyrazine, 3-isopropyl-2-methoxypyrido[2,3-b]pyrazine, 2-methoxy-4*H*-pyrido[2,3-b]pyrazine-3-one.

INTRODUCTION

Apterygote insects represent an ecologically important group of mainly soil-, bark-, litter-, and moss-inhabiting arthropods that occur in a wide range of moist environments. With maximal densities of 53,000 individuals m^2, springtails (Collembola) in particular are often exceedingly abundant and are among the most important consumers in many soil ecosystems. Springtails and other apterygotes also represent important and readily available prey for many predatory mites, spiders, beetles, bugs, or hymenopteran species. According to the primitive character of this large group of mainly entognathous hexapods, apterygote insects were recently considered to be devoid of chemical defenses (Berenbaum and Seigler 1992). However, a careful literature survey amply reveals that chemical defense is widespread in both ento- and ectognathous hexapods. The weakly sclerotized Protura contain voluminous abdominal defensive glands and, like staphylinid beetles, can bend their abdominal tips toward the aggressor to emit an acidic sticky gland material (Berlese, 1909; Francois and Dallai, 1986). When molested springtails escape from potential predators by suddenly releasing their furca, which is held under tension beneath the abdomen, thus propelling themselves through the air. Many species of the eyeless soil-inhabiting Onychiuridae have lost their jumping ability for escape and instead may release sticky droplets of unknown chemical composition from small integumental openings called pseudocells (Hale and Smith, 1966; Koncek, 1924). These pseudocellar fluids may mechanically repel predators by contaminating their body and appendages. In *Onychiurus* species these fluids exhibit paralyzing activities on predatory mites (Karg, 1961) and effectively repel other springtails and millipedes (Simon, 1961). Aromatic alkaloids, 2,3-dimethoxypyrido[2,3-b]pyrazine (**1**) and 3-isopropyl-2-methoxypyrido[2,3-b]pyrazine (**2**), were identified in the extracts of whole *Tetrodontophora bielanensis* (Budesinsky et al., 1986). Since it has not yet been clarified whether the pseudocellar fluid of onychiuran Collembola represents a true secretion or simply hemolymph, we want to report here on the origin and depletion of these droplets in the giant (length 5–9 mm) collembolan species *Tetrodontophora bielanensis* (Waga). Moreover, unambiguous structural assignments of biologically active constituents of this fluid will be presented as well as bioassays using pseudocellar fluids and synthetic compounds in order to demonstrate the defensive activity of the constituents.

METHODS AND MATERIALS

Individuals (630) of the giant collembolan species *Tetrodontophora bielanensis* (Waga) were collected and sieved either from a beech-forest litter of the Czech Elbsandsteingebirge near Hrensko (altitude 250 m) or from litter of a pine–beech forest near Cierny Balog (Tatra, Slovakia; altitude 900 m). In the

laboratory most of the specimens were frozen or kept alive in small plastic boxes supplied with moistened plaster bottoms and soil (constant temperature control 12°C; light–dark 8:16). The springtails were fed with dried dog food and granulated pollen.

Whole specimens or dissected body parts of *T. bielanensis* were transfered to Gisin's fixation mixture (Gisin, 1960), dehydrated in a graded series of acetone, critical-point dried with carbon dioxide, and sputter coated with gold. Scanning electron microscopy (SEM) was carried out by using a Cambridge Stereoscan 90. For examination of the cuticular parts, fragments of *T. bielanensis* were previously treated with 5% potassium hydroxide for 24 hr.

Tiny droplets of pseudocellar fluid were secreted after slight molestations of springtails with a forceps, and the droplets were collected with microcapillaries. In order to obtain hemolymph, the collophore of previously frozen springtails was dissected and hemolymph samples were taken with a microcapillary. Collected fluids were used for microscopical examination (photomicroscope Olympus BH-2), Wright-staining (Clark, 1973), electrophoresis, GC-MS examination, and bioassays. One microliter of pseudocellar fluid or hemolymph of *T. bielanensis* was employed for each electrophoretic separation. For native disk PAGE the sample was mixed with 20 μl buffer (10 mM Tris HCl, 1 mM EDTA, 0.01% bromophenolblue), centrifuged at 13,000*g* for 30 min, and the supernatant diluted with buffer to give a sample–buffer ratio of 1:80 prior to electrophoresis. Electrophoresis was carried out at 10°C using the PhastSystem and PhastGel Gradient 8-25 (both Pharmacia). The gel was developed by silver staining (method 3 according to PhastGel Silver Kit instruction manual). For SDS disk PAGE samples were mixed with SDS-buffer (2.5% SDS, 5% mercaptoethanol), heated for 5 min at 80°C, centrifuged, diluted with SDS buffer, separated, and stained as above.

The ^{1}H and ^{13}C NMR spectra were obtained with Bruker WM 400 and AC 250P instruments with TMS as an internal standard. Mass spectra (70 eV) were obtained with a VG 70/250 S mass spectrometer coupled to a Hewlett-Packard HP 5890 A gas chromatograph. Gas chromatography was carried out with a Carlo-Erba Fractovap 2101 instrument equipped with a flame ionization detector and on-column injection. Separations were performed using a 30-m DB-5 (0.32 mm internal diameter (ID), thickness of decoding film (d_f) = 0.25 μm) fused silica column with hydrogen as the carrier gas. Melting points (uncorrected) were measured with an Ernst Leitz instrument. Column and thin-layer chromatography were performed on silica gel (70-230 mesh, Merck).

Syntheses of Pyridopyrazines 1–3

*1H,4H-pyrido[2,3-b]pyrazine-2,3-dione (**B**).* This alkaloid was prepared from 2,3-diaminopyridine (**A**) according to the method of Winterfield and Wildersohn (1970).

2,3-Dichloro-pyrido[2,3-b]pyrazine (E). A mixture of 320 mg (2 mmol) **B**, 1 ml $POCl_3$, and 200 mg triethyl amine was heated under reflux for 2.5 hr. The mixture was treated with ice water, neutralized with aq. NaOH solution and extracted with chloroform. After drying over $MgSO_4$ and removal of the solvent, the product was purified by column chromatography (silica) to yield 320 mg (80%) of the pure product. mp: 149°C [Lit. 144–145°C (Winterfeld and Wildersohn, 1970)]. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.79 (dd, 1H, H-7, $J_{6,7}$ = 4.2 Hz, $J_{7,8}$ = 8.4 Hz), 8.42 (dd, 1H, H-8, $J_{6,8}$ = 1.8 Hz), 9.29 (dd, 1H, H-6). ^{13}C NMR (62.9 MHz, $CDCl_3$): δ = 126.29 (C-7), 130.18 (C-8a), 137.20 (C-8), 146.50 (C-4a), 148.75 (C-3), 154.13 (C-2), 154.92 (C-6).

2,3-Dimethoxy-pyrido[2,3-b]pyrazine (1): A mixture of 800 mg **E** and 5 ml 2 M sodium methoxide solution was heated under reflux for 1 hr. After cooling, the mixture was treated with water and extracted three times with chloroform. The combined organic phases were dried over $MgSO_4$ and the solvent removed. Column chromatography (silica, ethyl acetate–methanol 1 : 1) yielded the pure alkaloid **1** in 53% yield (400 mg). mp: 125°C. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 4.18 (s, 3H, CH_3), 4.26 (s, 3H, CH_3), 7.48 (dd, 1H, H-7, $J_{6,7}$ = 4.4 Hz, $J_{7,8}$ = 8.0 Hz), 8.15 (dd, 1H, H-8, $J_{6,8}$ = 1.8 Hz), 8.78 (dd, 1H, H-6). ^{13}C NMR (62.9 MHz, $CDCl_3$): δ = 54.76 (q, CH_3, J = 147.8 Hz), 55.10 (q, CH_3, J = 147.8 Hz), 122.31 (C-7, J = 165.0 Hz, J = 9.0 Hz), 132.06 (C-8a, J = 8.6 Hz), 135.07 (C-8, J = 164.0 Hz, J = 6.4 Hz), 147.89 (C-4a, J = 13.0 Hz, J = 5.2 Hz), 149.06 (C-6, J = 179.3 Hz, J = 9.0 Hz, J = 3.3 Hz), 150.39 (C-3, J = 3.8 Hz), 152.39 (C-2, J = 3.8 Hz). The mass spectrum and formula for compound **1** are presented in Figure 5 below.

3-Isopropyl-1H-pyrido[2,3-b]pyrazine-2-one (F). A mixture of 1 g (9.3 mmol) **A** and 2 g (10.4 mmol) methyl 3-methyl-2-oxobutyrate (3 : 1 mixture with diethyl oxalate) (Weinstock et al., 1981) were heated under nitrogen for 1 hr to 100°C. After cooling, the residue was washed successively with pentane, chloroform and ethanol. A mixture of the regioisomeric ketones 3-isopropyl-1*H*-pyrido[2,3-b]pyrazine-2-one (**F**) and 2-isopropyl-4*H*-pyrido[2,3-b]pyrazine-3-one (**G**) was present in the chloroform and ethanol phases; the insoluble residue represents the dione **B.** After combining the chloroform and ethanol phases and removing the solvents, the ketones were separated by column chromatography (silica, 0.5% NH_4OH, ethyl acetate). 3-Isopropyl-1*H*-pyrido[2,3-b]pyrazine-2-one (**F**) R_f = 0.09 (ether), mp: 254–256°C, yield: 540 mg (31%). ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.37 (d, 6H CH_3, J = 6,8 Hz), 3.70 (sept, 1H, CH), 7.46 (dd, 1H, H-7, $J_{6,7}$ = 4.6 Hz, $J_{7,8}$ = 8.4 Hz), 7.75 (dd, 1H, H-8, $J_{6,8}$ = 1.6 Hz), 8.67 (dd, 1H, H-6), 12.5 (bs, 1H, NH). MS (70 eV): m/z(%) = 39 (18), 64 (14), 65 (17), 78 (6), 91 (12), 92 (12), 93 (12), 119 (13), 120 (14), 133 (10), 146 (100), 160 (27), 161 (50), 174 (78), 189 (62, M^+).

2-Isopropyl-4*H*-pyrido[2,3-b]pyrazine-3-one (**G**) R_f = 0.67 (ether), mp: 193–194°C, yield: 720 mg (41%). ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.34 (d, 6H, CH_3, J = 6,8 Hz), 3.64 (sept, 1H, CH), 7.33 (dd, 1H, H-7, $J_{6,7}$ = 4.8 Hz, $J_{7,8}$ = 8.0 Hz), 8.17 (dd, 1H, H-8, $J_{6,8}$ = 1.6 Hz), 8.59 (dd, 1H, H-6), 12.5 (bs, 1H, NH). MS (70 eV): m/z(%) = 39 (18), 64 (10), 66 (12), 78 (8), 93 (14), 120 (22), 133 (8), 146 (100), 161 (87), 174 (58), 189 (75, M^+).

3-Isopropyl-2-methoxy-pyrido[2,3-b]pyrazine (2). As described above in the synthesis of **1,** the ketone **F** was converted into 2-chloro-3-isopropyl-pyrido[2,3-b]pyrazine [**H,** 85% yield; ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.49 (d, 6H, CH_3, J = 6,6 Hz), 3.77 (sept, 1H, CH), 7.89 (dd, 1H, H-7, $J_{6,7}$ = 4.4 Hz, $J_{7,8}$ = 8.4 Hz), 8.56 (dd, 1H, H-8, $J_{6,8}$ = 1.6 Hz), 9.26 (dd, 1H, H-6)], which was subsequently converted to **2.** ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.41 (d, 6H, CH_3, J = 6.8 Hz), 3.55 (sept, 1H, CH), 4.14 (s, 3H, CH_3), 7.54 (dd, 1H, H-7, $J_{6,7}$ = 4.4 Hz, $J_{7,8}$ = 8.2 Hz), 8.16 (dd, 1H, H-8, $J_{6,8}$ = 1.8 Hz), 8.87 (dd, 1H, H-6). ^{13}C NMR (62.9 MHz, $CDCl_3$): δ = 20.30 (2 CH_3), 30.78 (CH), 54.14 (OCH_3), 124.16 (C-7), 134.41 (C-8a), 135.51 (C-8), 148.57 (C-4a), 149.29 (C-6), 156.13 (C-2), 159.43 (C-3). The mass spectrum (70 eV) and formula for compound **2** are presented in Figure 5 below.

2-Methoxy-4H-pyrido[2,3-b]pyrazine-3-one (3). A mixture of 1 g (9.1 mmol) **A,** 1.85 g (18.3 mmol) triethyl amine, 1.56 g (8.3 mmol) methyl 2,2-dichloro-2-methoxyacetate and 20 ml absolute toluene was heated under nitrogen to 100°C. After 1 hr the cooled mixture was filtrated and the residue subsequently washed with chloroform and water. The brownish residue contained a 9:1 mixture of the two regioisomers 2-methoxy-4*H*-pyrido[2,3-b]pyrazine-3-one (**I** = **3**) and 3-methoxy-1*H*-pyrido[2,3-b]pyrazine-2-one (**II**), which were separated by column chromatography (silica, methanol–triethyl amine, 99:1). The products were insoluble in most organic solvents with the exception of DMSO and pyridine. Structural assignments of the products was achieved by the use of ^{1}H, ^{13}C NMR coupling obtained with gated-decoupled ^{13}C NMR-spectra (see below). 2-Methoxy-4*H*-pyrido[2,3-b]pyrazine-3-one (**3**) yield: 420 mg, 34%. ^{1}H NMR (400 MHz, [D_5]-pyridine): δ = 4.02 (s, 3H CH_3), 7.19 (dd, 1H, H-7, $J_{6,7}$ = 5.0 Hz, $J_{7,8}$ = 8.0 Hz), 7.97 (dd, 1H, H-8, $J_{6,8}$ = 1.6 Hz), 8.50 (dd, 1H, H-6). ^{13}C NMR (100 MHz, [D_5]-pyridine): δ = 54.65 (OCH_3), 119.58 (C-7), 126.79 (C-8a), 134.08 (C-8), 144.32 (C-4a), 146.69 (C-6), 152.81 (C-2), 156.64 (C-3). The mass spectrum of compound **3** is shown in Figure 5 below. 3-Methoxy-1*H*-pyrido[2,3-b]pyrazine-2-one (**II**) yield: 50 mg, 4%. ^{1}H NMR (400 MHz, [D_5]-pyridine): δ = 4.09 (s, 3H, CH_3), 7.28 (dd, 1H, H-7, $J_{6,7}$ = 4.6 Hz, $J_{7,8}$ = 8.0 Hz), 7.70 (dd, 1H, H-8, $J_{6,8}$ = 1.6 Hz), 8.63 (dd, 1H, H-6).

1,4-Dimethyl-1H,4H-pyrido[2,3-b]pyrazine-2,3-dione (C). To a solution of 100 mg (0.63 mmol) **B** in 20 ml absolute DMSO were added 40 mg (1.66 mmol) sodium hydride. A whitish precipitate was formed with hydrogen release.

After the gas formation had ceased, 200 mg (1.4 mmol) methyl iodide were added. The precipitate dissolved, and the solution became reddish. The reaction mixture was then treated with 30 ml brine. After extraction with methylene chloride the combined organic phases were dried with $MgSO_4$. The residue obtained by filtration and removal of the solvent was subjected to column chromatography to yield 60 mg (50%) of a pure product (silica, ethyl acetate/0.5% NH_4OH). ^1H NMR (400 MHz, $CDCl_3$): δ = 3.67 (s, 3H, CH_3), 3.77 (s, 3H, CH_3), 7.28 (dd, 1H, H-7, $J_{6,7}$ = 4.2 Hz, $J_{7,8}$ = 8.0 Hz), 7.59 (dd, 1H, H-8, $J_{6,8}$ = 1.6 Hz), 8.30 (dd, 1H, H-6). ^{13}C NMR (100 MHz, $CDCl_3$): δ = 28.33 (q, NCH_3, J = 143.0 Hz), 29.21 (q, NCH_3, J = 140.8 Hz), 119.04 (C-7, J = 166.0 Hz, J = 9.0 Hz), 121.56 (C-8, J = 164.1 Hz, J = 6.7 Hz, J = 1.0 Hz), 123.39 (m, C-8a), 138.63 (m, C-4a), 142.16 (C-6, J = 182.2 Hz, J = 7.6 Hz, J = 2.9 Hz), 153.33 (C-2), 154.50 (C-3). MS (70 eV): m/z (%) = 52 (12), 66 (8), 78 (15), 91 (9), 107 (8), 119 (6), 120 (12), 135 (8), 134 (82), 148 (12), 162 (28), 163 (22), 191 (100, M^+).

2-Methoxy-4-methyl-4H-pyrido[2,3-b]pyrazine-3-one (D). The *N*-methylated ketone **D** was obtained from **3** in an identical synthesis as described for **C**. Yield 63%. ^1H NMR (400 MHz, $CDCl_3$): δ = 3.85 (s, 3H, CH_3), 4.15 (s, 3H, CH_3), 7.26 (dd, 1H, H-7, $J_{6,7}$ = 4.2 Hz, $J_{7,8}$ = 8.0 Hz), 7.92 (dd, 1H, H-8, $J_{6,8}$ = 1.6 Hz), 8.43 (dd, 1H, H-6). ^{13}C NMR (100 MHz, $CDCl_3$): δ = 28.17 (q, NCH_3, J = 142.8 Hz), 54.90 (q, NCH_3, J = 147.8 Hz), 119.73 (C-7, J = 164.0 Hz, J = 8.6 Hz), 126.76 (C-8a, J = 7.6 Hz), 134.54 (C-8, J = 163.0 Hz, J = 7.0 Hz), 143.17 (m, C-4a), 145.97 (C-6, J = 179.1 Hz, J = 7.6 Hz, J = 2.4 Hz), 152.02 (C-3), 154.77 (C-2). MS (70 eV): m/z(%) = 52 (11), 64 (14), 78 (12), 91 (28), 105 (8), 119 (28), 120 (23), 132 (14), 133 (10), 134 (14), 148 (29), 162 (55), 176 (17), 191 (100, M^+).

2-Quinoxalinole in acetone was used as an internal standard to quantify the total amount of pyridopyrazines in pseudocellar fluids and hemolymph samples (6 samples each) of three specimens of *T. bielanensis* by GC. The presence/absence and semiquantitative determination of the three pyridopyrazines within various compartments, feces, and food of *T. bielanensis* was tested by GC-MS (four samples in each case). Percentage of total peak areas of the pyridopyrazines (total ion chromatogram) reflect their proportion either within the hemolymph or pseudocellar fluids of females, males and larvae.

In order to test the biological significance of *T. bielanensis* pseudocellar fluid on natural predators, interactions of *Nebria brevicollis* ground beetles and the giant springtails were observed and analyzed qualitatively and quantitatively using a videocamera (JVC, GX-N8E). Single individuals of each species were placed within a light-exposed 6 × 6 plastic arena (moistened calcium sulfate bottom) and 20 interactions were recorded qualitatively by using a Panasonic NV-180EG recorder. Quantitation of deterrency was measured by placing 1 μl of pseudocellar fluid (*T. bielanensis*), hemolymph (*T. bielanensis*), or hemo-

lymph of darkling beetle, *Tenebrio molitor* (control), respectively at the mandible underside of a *N. brevicollis* beetle. Of the various behavioral reactions of topically treated ground beetles (10 specimens per tested fluid), disorientation behavior, cleansing behavior, and elytral movements were selected and quantified for 10 min after application of test fluids. The duration of a particular behavior was expressed as a percentage of the observation time with 10 min of video monitoring equal to 100%.

In the same way the percentage of time spent in cleansing behavior and disorientation was measured from mixed groups of carabid beetles (four specimens of *Nebria brevicollis*, three specimens of *Pterostichus oblongopunctatus*) within 10 min after having been topically treated with 1 μl of test fluids of authentic pyridopyrazines. Solutions (0.05, 0.1, and 0.5 M) of 2-methoxy-4*H*-pyrido[2,3-b]pyrazine-3-one, 2,3-dimethoxypyrido[2,3-b]pyrazine, and 3-isopropyl-2-methoxypyrido[2,3-b]pyrazine in DMSO were used.

RESULTS

Origin and Depletion of Droplets of T. bielanensis

After a slight mechanical molestation with forceps, specimens of *T. bielanensis* release sticky whitish droplets from integumental openings called pseudocells (Figure 1A,B). Compared to these pseudocellar fluids, hemolymph samples show a slight violet to whitish coloration. Pseudocellar droplets appear especially at the rear border of the tergites. A careful examination of this springtail species reveals the presence of numerous pseudocells on both its dorsal and ventral sclerites. The total number of dorsal pseudocells is 48, and they are located at antennal bases (three per half) and rear borders of the head (2), thoracic (3 × 2), and abdominal tergites (5 × 2; 1 × 3; Figure 1A,B). The 36 ventral pseudocells are associated with head, coxae, collophore, and abdominal sternites. Numbers and arrangement of pseudocells represent taxonomically important species-specific characters in onychophoran springtails.

The integument and pseudocells of *T. bielanensis* are surrounded by macrotubercles (Figure 2g–i), which are composed of numerous apically fused microtubercles (Figure 2a,b). Pseudocells show an oval shape (diameter about 20 μm; Figure 2a,e) and represent integumental depressions. Externally they are marked by 15–20 longitudinally interrupted ribs that are arranged on the surface of a longitudinally divided cap, also seen from the interior view (Figure 2e). Obviously the external ribs are composed of several fused microtubercles (Figure 2b). SEM examination of shedded old *T. bielanensis* cuticles revealed that the complete pseudocell is molted (deformated caps and surrounding macrotubercles).

Both cap halves and ribs do not survive treatment with 5% potassium

hydroxide, which also destroys integumental macrotubercles (Figure 2c). Macerated pseudocells only are left as oval-shaped stable rings (Figure 2c–e), which serve as an entrenchment zone for the two cap halves in nonmacerated pseudocells. Specimens of *T. bielanensis* that were killed on Dry Ice exhibited pseudocells with a complete opening sequence (Figure 2a,f–i). At first the two cap halves broke longitudinally (Figure 2f), then pseudocellar fluid was squeezed out and both cap halves were pressed outward (Figure 2g). Later pseudocellar droplets may cover not only the external pseudocell area (Figure 2h) but are

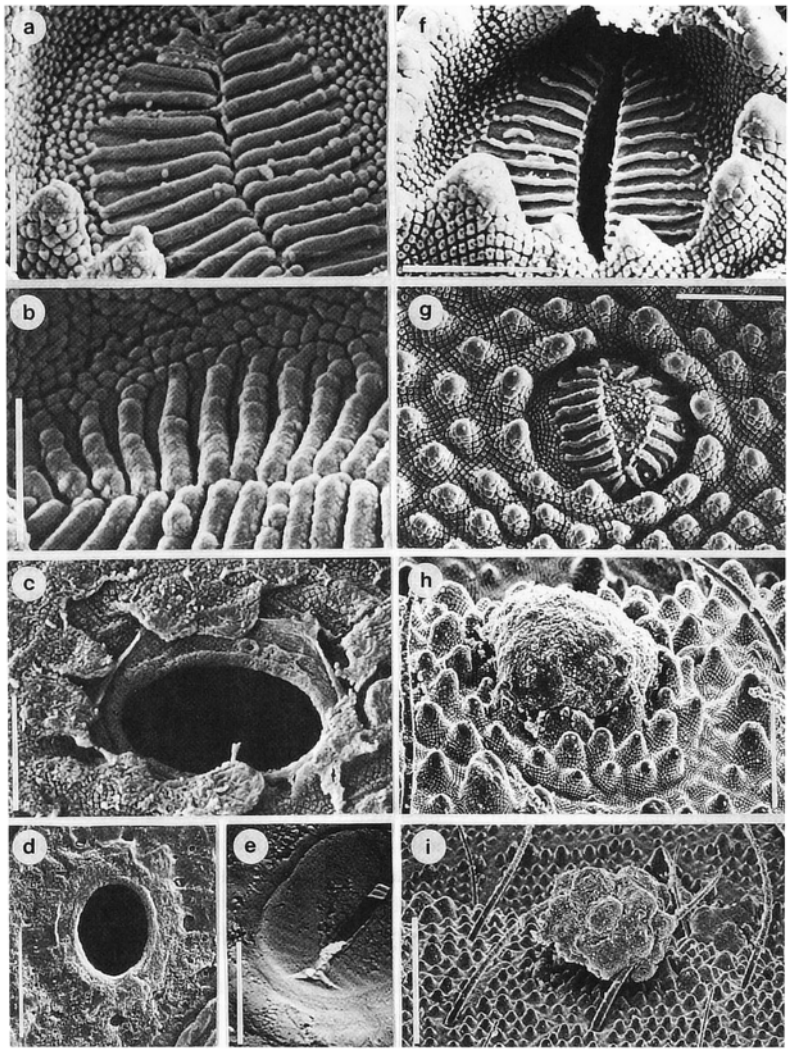

FIG. 2. SEM views of *T. bielanensis* pseudocells (a–i). Oval-shaped pseudocells are externally surrounded by microtubercles which fuse to produce 15–20 longitudinally interrupted ribs arranged on the surface of a longitudinally divided cap (a,b). External (c) and internal (d,e) view of a pseudocell without (e) and after (c,d) treatment with 5% KOH. Macerated pseudocells only remain as oval-shaped stable rings (c,d), which serve as an entrenchment zone for the two cap halves in nonmacerated pseudocells (e). Opening sequence (a,f–i) of a pseudocell (external view) with longitudinally breaking (f) and outward pressing (g) of cap halves and squeezing of pseudocellar secretion (h). Residue of previously squeezed pseudocellar droplets remain adhering at setae and macrotubercles of the collembolan integument (i).

even found side by side along the rear border of a sclerite. The remains of previously squeezed pseudocellar droplets may be found as amorphous material adhering to setae and macrotubercles of the collembolan integument (Figure 2i).

A microscopic investigation of hemolymph samples and pseudocellar fluid shows remarkable differences. Freshly collected pseudocellar fluid contains various prohemocytes (Figure 1D; ph: 7 μm diameter) and several irregular shaped coagulocytes (co: 20 μm diameter), which may quickly burst and thereby release clouded, threadlike filaments (Figure 1D, th). In contrast, hemolymph samples are characterized by many ellipsoid urate crystals (Figure 1E, ur: 2–5 μm diameter), lipid droplets, prohemocytes, and a few hemocytes (he) including coagulocytes. After repeated mechanical molestations, pseudocellar fluid contains urate crystals whereas coagulocytes are almost missing. This observation favors the idea that the composition of initially squeezed pseudocellar fluid differs from hemolymph samples. Only after repeated molestations do pseudocells seemingly exude droplets of hemolymph.

In order to test this hypothesis, peptide patterns of originally squeezed pseudocellar fluids were electrophoretically compared with collophore hemolymph droplets (Figure 3). Native disk PAGE exhibits about six common peptides (51, 68, 230, 240, 430, 770 kDa) in both fluids, whereas several peptides are exclusively present in one type of fluid only (Hemolymph: 85, 125, 190, 285, 290, 350, 510, 630 kDa; pseudocellar fluid: 66, 127, 560, 680 kDa). SDS disk PAGE results in nine common peptides (18, 23, 33, 42, 44, 48, 54, 58, 115). However, pseudocellar fluid (13.5, 16, 25, 68, 70, 77, 127, 135, 145) and hemolymph (22, 38, 39, 65, 73) exclusively contain five to nine peptides, which underlines the different composition of the two collembolan fluids. We conclude, therefore, that the initially emitted pseudocellar fluid represents a secretion distinctly different from hemolymph; removing this secretion with a piece of filter paper and subsequent molestation of the *Tetrodontophora* specimen results in emission of tiny hemolymph droplets through the pseudocellar orifice.

Chemical Constituents

A GC-MS investigation of the pseudocellar fluid revealed the presence of three alkaloids and common C_{16} and C_{18} fatty acids (Figure 4). According to their mass spectra, two of the alkaloids were identified as 2,3-dimethoxypyrido[2,3-b]pyrazine (**1**) and 3-isopropyl-2-methoxypyrido[2,3-b]pyrazine (**2**), both of which had been previously isolated from whole body extracts of *T. bielanensis* (Budesinsky et al., 1986). The third, previously unknown alkaloid, exhibited the mass spectrum shown in Figure 5 with a molecular ion at m/z = 177 (14 mass units less than **1**). A high-resolution mass spectrum proved its composition to be $C_8H_7N_3O_2$.

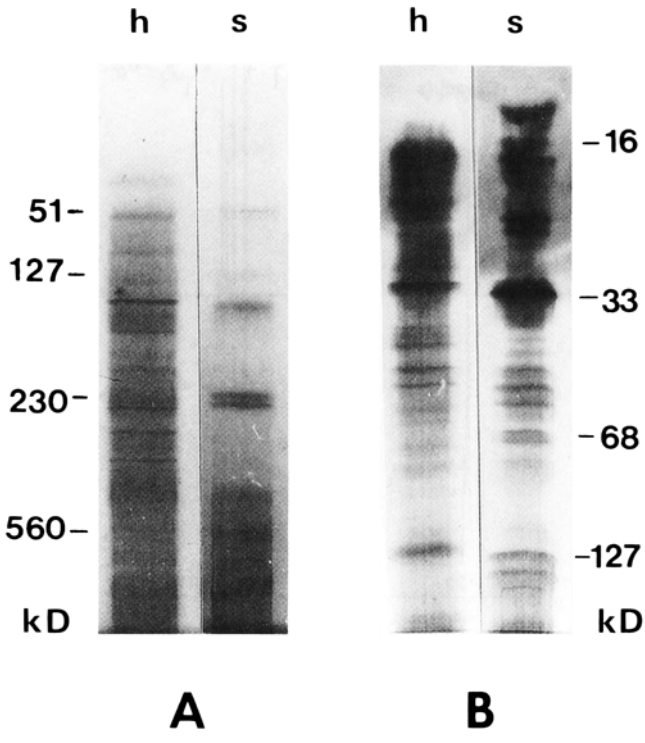

FIG. 3. Native disk PAGE (A) and SDS-PAGE (B) of *Tetrodontophora bielanensis* hemolymph samples (h) and pseudocellar fluid (s). Dilution of each body fluid 1:80 (applied volume 1 μl). Inserted molecular masses of proteins were determined by using high- (A) and low-molecular-weight reference proteins.

Apart from the singlets of the methoxy groups of **1** and **2**, the ^{1}H NMR spectrum of the pseudocellar fluid showed an additional singlet at 4.06 ppm that could also be attributed to a methoxy group. This led to the conclusion that the unknown alkaloid was a demethylated analog of **1**. To elucidate the position of the remaining methoxy group in **3** and to prove its structure, a synthesis of the two possible methoxypyrido[2,3-b]pyrazinones was carried out. According to the method of Anschütz (1906) for the synthesis of imidates, ethyl dichloromethoxyacetate was heated with 2,3-diaminopyridine (**A**) in the presence of triethyl amine in toluene. The product proved to be a 9:1 mixture of the two regioisomers **I** and **II** of methoxypyrido[2,3-b]pyrazinone, of which the major compound **I** was identical with the unknown natural product **3**. Structural assignment of the synthetic products was achieved by use of gated-decoupled ^{13}C

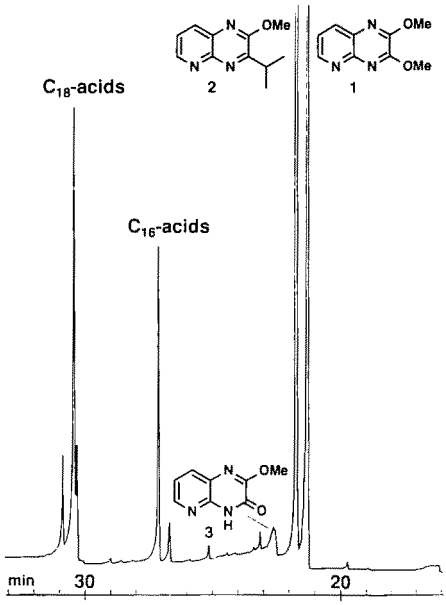

FIG. 4. Gas chromatogram of pseudocellar fluid from *Tetrodontophora bielanensis*, 30-m DB-5, temperature programmed from 60°C to 300°C at 5°C/min, on-column injection.

NMR spectroscopy of *N*-methylated compounds. These derivatives were obtained by reaction of NaH/DMSO/MeI with **I** or 1*H*,4*H*-pyrido[2,3-b]pyrazine-2,3-dione [**B**, obtained by reaction of 2,3-diaminopyridine (**A**) with diethyl oxalate according to the procedure of Weinstock et al. (1981)]. The bridging C atoms are found between 123 and 133 ppm for C-8a and 140 and 150 ppm for C-4a in the ^{13}C NMR spectra of pyrido[2,3-b]pyrazines synthesized by us and other authors (Nagel et al., 1979). The signal for C-4a in the dimethoxy compound **1** shows a quartet with $J_{C,H}$ = 5 and 11 Hz while C-8a is a doublet with $J_{C,H}$ = 8 Hz (see Figure 6A). On the other hand, the C-4a and C-8a signals of 1,4-dimethyl-1*H*,4*H*-pyrido[2,3-b]pyrazine-2,3-dione (**C**) are degenerated to broad multiplets due to coupling to the H-atoms of the *N*-methyl groups (see Figure 6C).

By *N*-methylation of **I** the derivative **D** is obtained, and its spectrum shows signals of C-8a as a doublet with J = 8 Hz and of C-4a a broad multiplet (see Figure 6B). This reveals that C-4a is coupling to the *N*-methyl group, which is thus located at N-4. Therefore, the alkaloid **I** is 2-methoxy-4*H*-pyrido[2,3-b]pyrazine-3-one, the natural alkaloid **3.** This is in accordance with the finding of **I** as the main product in the synthesis, since the more nucleophilic 2-amino

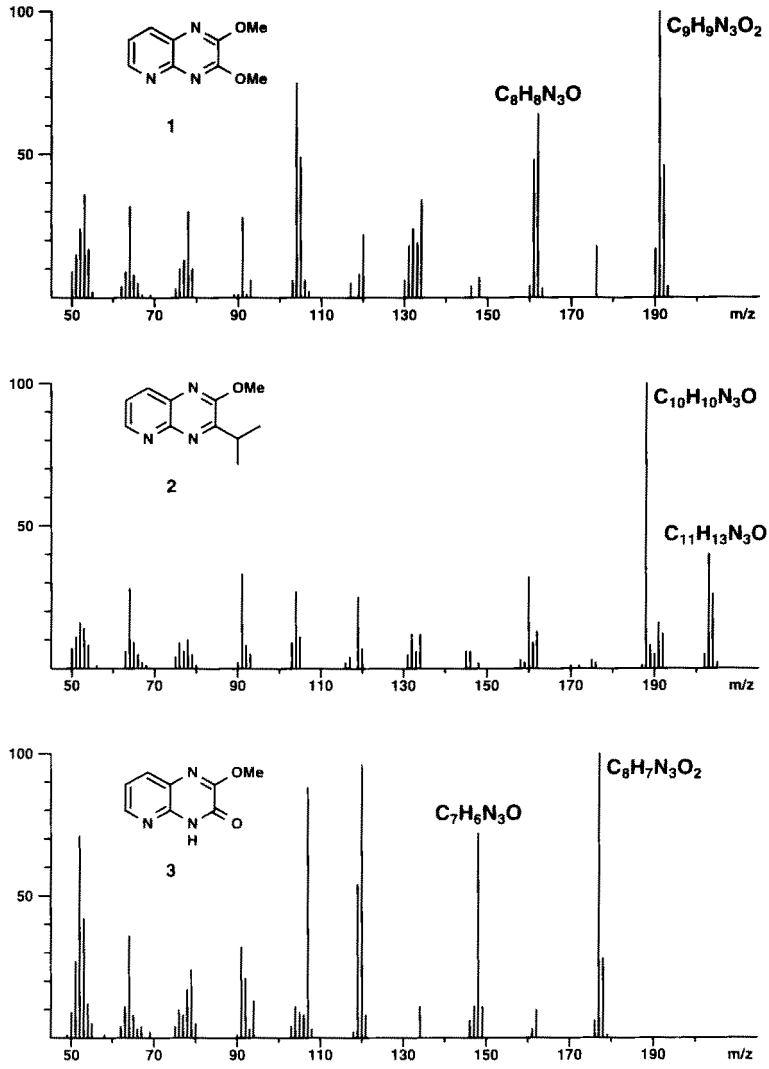

FIG. 5. Mass spectra of the pyridopyrazines **1**, **2**, and **3**.

group of 2,3-diaminopyridine reacts preferentially with the more reactive dichloromethoxymethyl group of the condensing acetate. For bioassays, the two alkaloids **1** and **2** were prepared for the first time starting from 2,3-diaminopyridine (**A**, see Figure 7). Condensation with diethyl oxalate yields the dione **B**, which could not be selectively *O*-methylated using diazomethane, trimethyl-

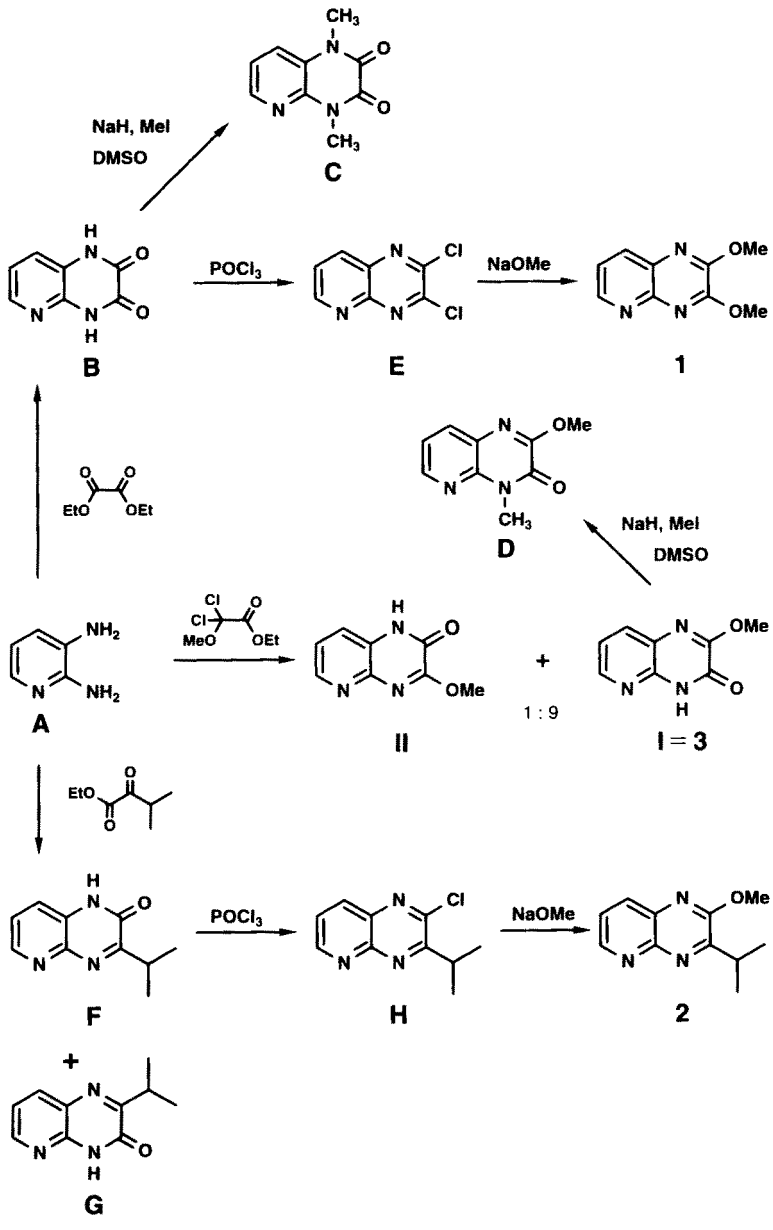

FIG. 7. Synthesis of the pyridopyrazines **1**, **2**, **3**, **C**, and **D**.

oxonium tetrafluoroborate, or Ag_2O/MeI. The results of the methylations are similar to those obtained by Cheeseman in the methylation of hydroxyquinoxalines (Cheeseman, 1955). Instead, chlorination with $POCl_3$ to the dichloride **E** followed by nucleophilic displacement with sodium methoxide yielded the alkaloid **1.** In a similar reaction, methyl 3-methyl-2-oxobutyrate (Weinstock et al., 1981) was condensed with **A** to yield a mixture of 3-isopropyl-1*H*-pyrido[2,3-b]pyrazine-2-one (**F**) and 2-isopropyl-4*H*-pyrido[2,3-b]pyrazine-3-one (**G**), which were separated by column chromatography. Chlorination of **F** to **H** and reaction with sodium methoxide yielded the desired alkaloid **2.** The spectral data of **1** and **2** were identical to the values reported by Budesinsky et al. (1986).

The total concentration of the three pyridopyrazines in adult specimens is about 0.1 mol/liter within pseudocellar fluid and up to 0.05 mol/liter in hemolymph samples. 2,3-Dimethoxypyrido[2,3-b]pyrazine (**1**), 3-isopropyl-2-methoxypyrido[2,3-b]pyrazine (**2**), and 2-methoxy-4*H*-pyrido[2,3-b]pyrazine-3-one (**3**) could be found within pseudocellar fluids and hemolymph samples of both males and females of *T. bielanensis* (Table 1). Pseudocellar secretions of the springtail larvae contain approximately equal amounts of **1** and **2;** the 3-isopropyl-2-methoxy-derivative represents the only pyridopyrazine of the larval hemolymph. Minor amounts of **1** and **2** are also present in the guts of both sexes, the ovaries and the male fat body; however, neither feces nor food of *T. bielanensis* contain even traces of these alkaloids.

Biological Significance of Reflex Bleeding

The target animals, *Nebria brevicollis*, are nocturnal polyphagous carabids that clearly prefer springtails as prey (Pollet and Desender, 1988). When there was a contact of *T. bielanensis* with antennae of the carabid beetle, the beetle's forelegs jerked forward and the springtail showed curling behavior (Figure 1C). If the beetle tried to grasp the springtail with its mandibles, *T. bielanensis* exuded a droplet from a pseudocell. Aggressive behavior of *Nebria* was immediately interrupted, and the carabid beetle tried to clean its mandibles. In cleansing behavior the mandibles are spread out and dug into the ground (Carrel and Eisner, 1974). The beetles further showed uncoordinated movements, fell on their back (disorientation), and usually secreted a clear fluid from their mouth. After a contact with pseudocellar fluid, the beetles usually extended their legs, slightly lifted their abdomens, and spread their elytra (elytra movement). A second attack of the carabid beetle was never observed.

Topical treatment of carabid mandibles and quantitative analyses of subsequent disorientation, cleansing behavior, and elytral movement revealed distinctly different results depending on the kind of fluids used in the experiment (Figure 8). Cleansing behavior was observed with all three test fluids but was only significantly increased ($P < 0.01$, nonparametric STP test; Sokal and

Rohlf, 1981) if pseudocellar fluid had been topically applied previously on mandibles of the ground beetle. Disorientation of carabid beetles resulted after contact with pseudocellar fluid only, whereas elytral movement was observed exclusively after testing of pseudocellar fluid and *T. bielanensis* hemolymph (Figure 8). Distinct cleansing behavior was especially released after a topical application of 1 μl of 0.5 M DMSO solutions of **3** and **1** and even a 0.1 M DMSO solution of **2**. As compared to the DMSO solvent, which did not harm the beetles, strong disorientation could be observed only if 0.5, 0.1, and 0.05 M solutions of **2** were applied. Both cleansing behavior and disorientation of carabids increased with increasing concentrations of the three authentic pyridopyrazines (see Discussion). The pronounced activity of **2** (Table 1) is interesting in three respects: (1) Compound **2** quantitatively represents the main pyrazine in pseudocellar fluids and hemolymph of males and females of *T. bielanensis*. (2) It constitutes the only pyridopyrazine in the hemolymph samples

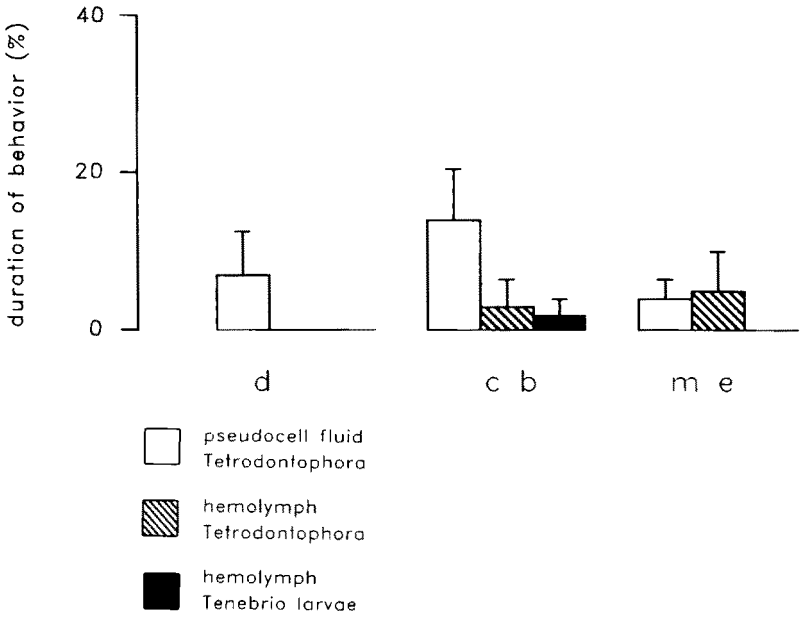

FIG. 8. Percentage duration of disorientation (d), cleansing behavior (cb), and elytral movements (me) of carabid beetles *Nebria brevicollis* within 10 min after having been topically treated with 1 μl test fluids. Pseudocellar fluid (light bar) and hemolymph of *T. bielanensis* (shaded bar) as well as hemolymph of *T. molitor* (black bar; controls) were used for tests. Ten carabid beetle specimens were used per test fluid (95% confidence values are denoted). Hemolymph samples of both *Tetrodontophora* and *Tenebrio* caused no disorientation behavior.

of the *Tetrodontophora* larvae. (3) The total concentration of the three pyridopyrazines in adult specimens amounts to about 0.1 mol/liter within pseudocellar fluids and up to 0.05 mol/liter in hemolymph samples.

DISCUSSION

Origin and Depletion of Pseudocellar Droplets of T. bielanensis

Several springtail species devoid of pseudocells show reflex bleeding behavior after nonspecific irritations such as mechanical contact or vibration (Paclt, 1956). Reflex bleeding at soft integumental areas usually is connected to rolling-up behavior and seems to be due to an increase in internal body pressure. Pseudocells are seemingly restricted to Tullbergiinae, and Pachytullbergiinae, Onychiurinae, and Tetrodontophorinae and probably represent an

advanced condition as compared to reflex bleeding. The primitive type of pseudocells is externally located at the trochanters of legs of *Onychiurus* species and is not distinctly differentiated from the surrounding integument. Furthermore, it is considerably smaller and shows no circular ring as observed in *T. bielanensis* (Rusek, 1984). The normal advanced type of pseudocell, however, is enlarged and corresponds to pseudocells of *T. bielanensis* or *Onychiurus armatus* (Rusek and Weyda, 1981). Depending on the species, the number, distribution, and external gross and fine structure of advanced springtail pseudocells may vary considerably (Hale and Smith, 1966; Rusek and Weyda, 1981). Morphologically there is a remarkable congruency between pseudocells of *T. bielanensis* and *Onychiurus armatus* that becomes evident after SEM and TEM studies (this paper; Rusek and Weyda, 1981). Pseudocellar caps are epicuticular structures that do not survive KOH maceration. On the contrary, the KOH-resistant stable pseudocellar ring represents a part of the endocuticle. One to several secretory cells are distinctly associated with the pseudocell. These cells adhere at the interior border of pseudocellar caps and are distally floating within hemolymph. The secretory cells of *O. armatus* contain many voluminous secretory vesicles (Rusek and Weyda, 1981), which clearly indicates that pseudocells are secretory structures par excellence. After slight molestation, rupture of the epicuticular caps occurs, which simultaneously destroys the secretory cells and liberates their contents. Subsequent irritations result in liberation of hemolymph (reflex bleeding) through the pseudocellar ring. Whether the closure of the longitudinal pseudocellar slit after molestation is due to elasticity of certain structures of the pseudocell is not yet clear. However, the suggestion of Koncek (1924), that secretory cells under the pseudocell would be brushed aside during its opening and hemolymph-outflow may be rejected.

As was shown by native disk PAGE, hemolymph samples contain more exclusive peptides as compared to pseudocellar secretion. However, SDS-PAGE produced more exclusive peptides in the pseudocellar secretion as compared to hemolymph samples. Due to the decreased pore diameter of PhastGel gradient 8-25 after SDS treatment, high-molecular-weight plasma proteins probably cannot diffuse into the gel, which may be responsible for this effect. Special peptides of pseudocellar secretions probably originate primarily from pseudocell coagulocytes and may principally represent clotting proteins, toxic peptides, or enzymes involved in pyridopyrazine biosynthesis. However, clotting proteins should be also present in hemolymph samples because coagulocytes are also present. Moreover, bioassays with authentic pyridopyrazines produced similar effects as the crude pseudocellar secretion. Therefore, the presence of toxic proteins within the pseudocellar coagulocytes seems unlikely.

The distribution of the three pyridopyrazines in different compartments of *T. bielanensis* (Table 1) cannot reveal structures or tissues where these unusual compounds are synthesized. However, it seems possible that pyridopyrazines are

synthesized within secretory cells located below the pseudocells. From there pyridopyrazines might be transfered into hemolymph and subsequently distributed interiorly within the body of *T. bielanensis*. Three arguments would favor this suggestion: As compared to hemolymph, the highest total amounts of pyridopyrazines are found in pseudocellar fluids (1). The complete series of pyridopyrazines is only present in the pseudocellar fluid, not in other compartments of larvae or adults (2). If the 3-isopropyl-2-methoxy-derivative **2** should represent the precursor for **1** and **3,** it is remarkable that the percentage of **2** decreases from pseudocellar fluid to hemolymph (3, Table 1). On the other hand, it may not be excluded that one or two pyridopyrazines might also be synthesized somewhere in the interior body of the springtail and then subsequently enriched within the pseudocellar secretory cells.

Biologically Active Constituents

Budesinsky et al. (1986) isolated **1** and **2** from total body extracts of 7300 *T. bielanensis*. Both pyridopyrazines and the newly identified compound **3** have been isolated for the first time from their natural glandular sources. Comparable nitrogen-containing aromatic heterocycles from arthropods contain either fewer [e.g., methyl-8-hydroxyquinoline-2-carboxylate; 1-methyl-2-quinolone; glomerin; homoglomerin (Dettner 1987, Numata and Ibuka, 1987)] or more nitrogen atoms [various pteridines (Numata and Ibuka, 1987)]. The biosynthetic pathway leading to the pyridopyrazines is unknown. Our HPLC analyses of body extracts of males and females of *T. bielanensis* showed that this species contained considerable amounts of uric acid, the granules of which are also found in hemolymph samples. This is reasonable since Collembola have no Malpighian tubules as excretory organs (Feustel, 1958). Uric acid therefore, might be an available pool for nitrogen-containing compounds in all collembolan species.

Intermediates for the biosynthesis of pyridopyrazines are unknown, although purines (and uric acid) might serve as precursors for related pteridines. Nevertheless, we regard **2** to be the precursor of the other two pyridopyrazines. An oxidative degradation of the isopropyl side chain would produce **3,** which could be methylated to produce **1.** This pathway is supported in three respects: The pyridopyrazine **2** is the only compound of this type present in the larval hemolymph, which supports the suggestion that larvae may exhibit more primitive characteristics than the adults (Table 1). At the same time this compound shows the maximal deterrent activity as compared to the two other analogs (Figure 9). In addition, **3** as the final product of the biogenetic sequence could not be detected in various body compartments (Table 1). A precursor for the pyridopyrazine **2** might be valine or its amide, as was suggested for the biosynthesis of 3-alkyl-2,6-dimethylpyrazines in ants (Numata and Ibuka, 1987).

Synthetic derivatives of pyrido[2,3-b]pyrazines, which have also been named 1,4,5-triazanaphthalenes or 5-azaquinoxalines, are well known as anti-

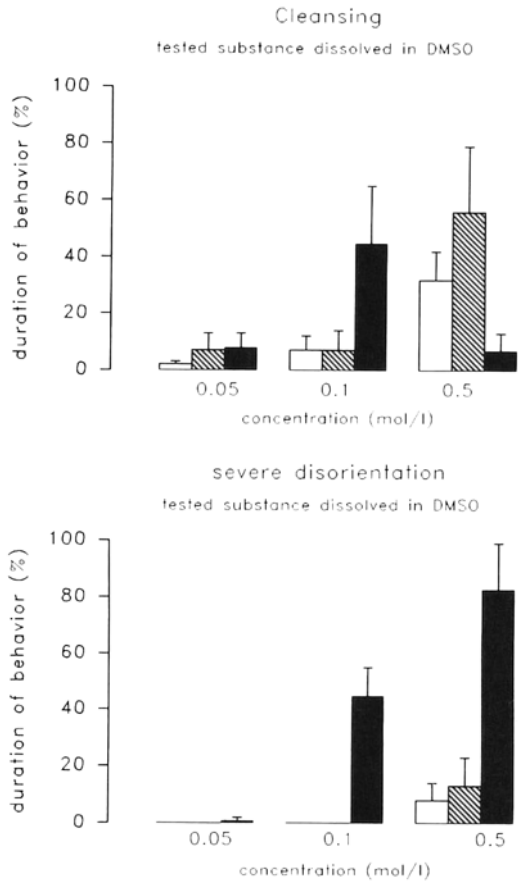

FIG. 9. Percentages duration of cleansing behavior (above) and disorientation (below) of mixed groups of carabid beetles (*Nebria brevicollis*, *Pterostichus oblongopunctatus*) within 10 min after having been topically treated with 1 μl of test fluids. Test fluids were 0.05, 0.1, and 0.5 M solutions of authentic 2-methoxy-4*H*-pyrido[2,3-b]pyrazine-3-one (light bar), 2,3-dimethoxypyrido[2,3-b]pyrazine (shaded bar), and 3-isopropyl-2-methoxypyrido[2,3-b]pyrazine (black bar) dissolved in DMSO. With each test fluid seven carabid beetles (four specimens of *N. b.* and three specimens of *P. o.*) were used (95% confidence values are noted).

metabolites and folic acid antagonists. Whereas various 8-substituted amino derivatives of pyrido[2,3-b]pyrazines show antibacterial activities, a number of 3,6-diamino-derivatives exhibits antiviral, diuretic, and antiinflammatory properties (Cheeseman and Cookson, 1979). Our results clearly show that these unique pyrazines are not directly derived from food. They must be synthesized

within internal tissues of Collembola. The distribution pattern may indicate that coagulocytes contribute to the complete set of pyridopyrazines present, because **3** is exclusively found within this compartment.

Biological Significance of Reflex Bleeding

By comparing results from Figure 9, it is evident that biological activity of the three pyridopyrazines increases with lipophilicity. The significant decrease of cleansing behavior after application of a 1-μl droplet of a 0.5 M solution of 3-isopropyl-2-methoxypyrido[2,3-b]pyrazine on a beetle mandible is a consequence of the fact that these beetles were disorientated during almost the whole observation period. Cleansing behavior, which was expected to be increase after treatment with a 0.5 M solution, decreased at the expense of a strong disorientation behavior. Another preliminary experiment demonstrated that the three compounds with different biological activities might also act synergistically in the laboratory and in the field. When 1 μl of a DMSO solution (0.1 M in total pyridopyrazines: mixture of **1, 2,** and **3** in a ratio of 3 : 3 : 1) was applied topically to a mandible of a carabid beetle, the duration of cleansing behavior and disorientation was comparable to 1 μl of a pure 0.1 M solution of the most active compound **2.** This synergism indicates that compounds **1** and **3,** with weaker activities when tested alone, exhibit increased biological activities when tested together with **2.**

Many possibilities exist for springtails to avoid contacts with predators or to escape after being discovered. Primary defenses may include slow movements or cryptic colorations (Bauer and Pfeifer, 1991). Secondary defenses of springtails are their jumping ability, the presence of integumental hairs and scales, and a fast unpredictable stampede (Bauer and Pfeifer, 1991). In the first case, after a mechanical stimulation, Collembola escape from a predator by jumping away within a few milliseconds. The second defensive mechanism is also effective, since such scales and hairs (present in only few families of Collembola) are easily removed and are always found sticking to the mouth parts of arthropods that feed on springtails (Bauer and Pfeifer, 1991).

Concerning the secondary defenses, especially chemical defenses, all important mechanisms as observed in other insects are also found in springtail species. Southeast Asian and Pacific species of the genera *Piroides* and *Corynephora* (Dicyrtomidae) show warning coloration and have a clublike defensive gland located dorsally at the abdominal tip (Greenslade and Suhardjone, 1992; Bauer, personal communication). Many springtail species, especially the eyeless soil-inhabiting Onychiuridae, do not have jumping ability and instead may release defensive compounds from pseudocells or toxic hemolymph chemicals by reflex bleeding (Paclt, 1956). It is probable that these insects may represent a rich source of biologically active new defensive compounds. This is supported by

observations of Weinreich (1968) and Bauer and Pfeifer (1991), who observed hunting behavior of the springtail-feeding rove beetle, *Stenus comma*, which has a protrusible labium to catch collembolan prey. This visually orienting beetle ignores certain collembolan species of a genera *Folsomia*, *Xenyella*, and *Tomocerus* and never feeds on *Onychiurus armatus* or *Podura aquatica*. Since *Podura aquatica* neither possesses pseudocells nor shows reflex bleeding, the presence of internal toxins or epicuticular deterrents might be suggested. Specimens of *Podura aquatica* were caught in 75% of all attacks by *Stenus comma*, but 88% of the seized collembolans were released within a few seconds and about 50% of them survived the attack (Bauer and Pfeifer, 1991). After these interactions, the beetles cleaned their mouthparts and rubbed them in the soil.

In other Collembola the use of alarm pheromones, which may act even across families, has been described (Purrington et al., 1991). The chemical nature of these alarm compounds has not been elucidated, but pseudocellar compounds and hemolymph toxins such as the pyridopyrazines may play a role in alarm behavior. The smell of *Tetrodontophora bielanensis* strongly resembles the smell of toxic coccinellid beetles that exhibit reflex bleeding (unpublished observation). Some 2-methoxy-3-alkylpyrazines have been described as warning odors (Moore et al., 1990; Dettner and Liepert, 1994). Whether *T. bielanensis* contains similar odor signals remains to be clarified, but synthetic alkaloids **1–3** are almost odorless.

Book Review

Bombardier Beetles and Fever Trees, A Close-Up Look at Chemical Warfare and Signals in Animals and Plants. William Agosta. New York: Helix Books, Addison-Wesley Publishing Company, 1996. US $25, Canada $34. ISBN 0-201-62658-6

This is a very entertaining and excellent introduction to the broad field of chemical ecology. Although the author does not include a preface in which he might have told us to whom he was writing, it appears that the book is written for a general audience. The word "pheromone" occurs in the book, but such words as "semiochemical," "allomone," and "kairomone" are not used. Professional scientists working in chemical ecology will find it interesting reading and, as I did, will probably find that it broadens one's perspective on the range of interactions in chemical ecology. The book does not go into experimental details or theory in chemical ecology, and there is no emphasis on chemistry, except to mention some chemicals by name. Examples are chosen from many groups, including plankton, bacteria, fungi, higher plants, nematodes, insects, and a variety of vertebrates, including mammals and humans to illustrate diversity in chemical ecology. The book contains nine chapters, and 16 black and white half-tone illustrations. The author concludes the book with a short "Note to the Reader" explaining the basis of scientific classification and units of measurement. There is an index.

Chapter 1, "Nature's Storehouse of Chemicals," introduces the universality of chemicals and chemical ecology in the lives of all organisms. The author attempts to dispel the phobia that some have of anything chemical by offering examples of beneficial chemicals in our foods that may provide anticancer protection, and vitamins that are essential for good health.

Chapter 2, "Chemical Defenses in the Plant World," provides interesting examples of the many plant–animal, particularly plant–insect, interactions with examples drawn from the *Diabrotica*–curcurbitacin story, *Larrea* spp. (creosote bushes), and some insects that feed with impunity upon them, light-activated plant defensive chemicals such as hypericin, and plant-produced compounds such as paper factor, phytoecdysones, and precocenes, that alter hormonal control of growth and development in insects. The chapter ends with a section entitled "Can Plants Call for Help?" with examples of plant–plant interactions induced by various insect and mite attacks.

0098-0331/96/0500-1075$09.50/0 © 1996 Plenum Publishing Corporation

Chapter 3, "How Animals Use Chemical Warfare," deals mainly with defensive chemical ecology, including toxic chemicals in the cuticle of insects and skin of frogs, special glandular secretions, and nematocysts of cnidarians. The interesting, but little understood, process of self-anointing common in some vertebrates is described. As the title of the book promises, the story of bombardier beetles that can aim and spray a hot mix of chemicals at an attacker receives good coverage. One section deals with how humans cope with some natural toxins, including avoiding the puffer fish toxin when it is used as food, and important uses of its toxin in neurophysiological studies. Agosta points out that tetrodotoxin is not produced by the fish, but comes from bacteria in the fish. The author admonishes us that we need to protect our natural environmental resources, which are likely to hold many yet to be discovered treasures.

Chapter 4, "Warfare in Simple Organisms," deals with bacteria and fungi, and examples show how these are important to agriculture and human medicine. Penicillin, aflatoxin, BT pesticides, avermectin and its slightly modified derivative, ivermectin, are described. Merck's development of avermectin and ivermectin, and the potential for these in management of river blindness in several parts of the world make a fascinating story.

Chapter 5, "Medicines and Drugs from Plants," introduces folk medicines and drugs that we get directly from plants or from derivatives of plant chemicals, such as aspirin. The fever tree referred to in the book title is the Peruvian *Chinchona* tree that yields quinine; the scourge of malaria and its treatment with quinine and derived drugs are discussed at some length. This chapter contains a few pages on mood-altering drugs, such as those from coca plants, peyote plants, psilocybin from certain mushrooms, and cannabis, and a page or two on the possible use of healing plants by chimpanzees. The author ends this chapter with emphasis on how important it is to preserve the great diversity of plants and other organisms that still exist, but which we are losing very rapidly at present, and to investigate them for substances useful to humans.

Chapter 6, "Chemicals and Lifestyles," describes how chemicals play a vital role in the life of all organisms, with examples drawn from fireflies, fish, and other organisms with antifreeze in their systems; natural adhesives produced by numerous organisms; and products such as silk. Several pages are devoted to discussion of camouflage and warning colors, display colors for attracting mates, and mimicry.

Chapter 7, "Chemical Messages within the Family," describes the early demonstration of a moth pheromone by Fabre, who attracted numerous male moths to his open window with a caged female emperor moth, and the first pheromone identified, bombykol, by Adolph Butenandt. Other pheromonal roles are explored, including pheromones in vertebrates and the vertebrate vomeronasal system involved in detecting pheromonal chemicals. The author discusses possible pheromones in plants, some practical applications of pheromones, and

concludes the chapter with a brief presentation of documented and potential human pheromones.

Chapter 8, "Chemical Messages to the Wider World," concerns messages between hunters and their prey. It was fascinating to learn that some fungi secrete attractants that lure nematodes and perhaps other small organisms into entangling sticky filaments, where they will be digested as food for the fungus. Human applications of chemical ecology in pest control and in breeding parasite- and disease-resistant plants are given.

Chapter 9, "Making use of Nature's Molecules," reinforces Chapter 1 by summarizing the universal occurrence of chemicals in the life of all living organisms and presents a challenge to scientists to discover the nature of these chemicals and the role(s) they play in the life of those organisms. The author points out that ". . . scientists have searched for chemicals in only a few thousand of the approximately 1,400,000 known living species." Perhaps several million species and their chemical ecology relationships still wait to be discovered. Some known groups of organisms have barely been touched, and Agosta promises surprises and interesting stories for many generations of scientists, if we carefully manage and preserve what we still have. The potential for current gene technology to aid in the search for useful products from the natural world is briefly mentioned in this very short chapter.

Bombardier Beetles and Fever Trees has a handsome jacket cover, is attractively printed, and is written in a lively style. Its modest price makes this 224-page book available to a wide audience, and it will provide entertaining reading for amateur naturalists and professionals alike. It will be a useful book to introduce chemical ecology and nature's diversity to undergraduate students interested in biology, environmental issues, nature, and conservation. It should be available in high school, college, and university libraries. Readers of papers in the Journal of Chemical Ecology will find it light, but entertaining and lively reading.

PHORETIC EGG PARASITOID, *Telenomus euproctidis* (HYMENOPTERA: SCELIONIDAE), USES SEX PHEROMONE OF TUSSOCK MOTH *Euproctis taiwana* (LEPIDOPTERA: LYMANTRIIDAE) AS A KAIROMONE

NORIO ARAKAKI,[1,*] SADAO WAKAMURA, and TETSUYA YASUDA

(Received September 11, 1995; accepted January 27, 1996)

Abstract—The phoretic egg parasitoid, *Telenomus euproctidis* Wilcox (Hymenoptera: Scelionidae) was found more frequently on virgin than on mated female moths of *Euproctis taiwana* (Shiraki) (Lepidoptera: Lymantriidae), when virgin and mated moths were exposed concurrently in the field for 24 hr. A synthetic component of the moth's sex pheromone, (Z)-16-methyl-9-heptadecenyl isobutyrate, attracted both the wasp, *T. euproctidis*, and male *E. taiwana*. These findings suggest that *T. euproctidis* uses the sex pheromone of the female moth, *E. taiwana*, as a kairomone to locate a host female moth and through her the host eggs.

Key Words—*Telenomus euproctidis*, kairomone, sex pheromone, phoresy, *Euproctis taiwana*.

INTRODUCTION

Several species of *Telenomus* egg parasitoids (Hymenoptera: Scelionidae) have developed a special phoretic relationship with the adults of their host species (Clausen, 1972, 1976). Phoresy has been observed in *T. euproctidis* Wilcox (=*Telenomus* sp. cf. *euproctidis*), a parasitoid of the eggs of the tussock moth, *Euproctis taiwana* (Lepidoptera: Lymantriidae), in Okinawa, Japan (Arakaki, 1990). All of the observed female parasitoids were associated with the long anal tufts of adult female moths. As soon as the moth began to lay the first egg-

mass, the parasitoids left the moth and attacked the host eggs. However, the question of how this parasitoid locates its phoretic host remains unsolved.

It is known that several larval parasitoids use herbivore-induced plant odors associated with their hosts as olfactory cues to locate host larvae (e.g., McCall et al., 1993; Mattiacci et al., 1994; Turlings et al., 1990). However, egg parasitoids basically have a problem in locating their host because (1) the host egg does not feed and, therefore, does not yield herbivore-induced plant odors and (2) noninduced plant odors are not a reliable indicator of host presence. Thus, information that is present for many other parasitoids is not available to egg parasitoids. One possibility is that egg parasitoids might rely upon detectable information from virgin host females, the mothers of their future hosts.

Some nonphoretic egg parasitoids are known to use the female sex pheromones of several lepidopterous species in location of eggs that serve as their hosts (Lewis, 1982; Nordlund et al., 1983; Noldus and van Lenteren, 1985). There has been only one report that the phoretic egg parasitoid, *Telenomus* n. sp., uses a host pheromone in long-range host location (Aldrich et al., 1984). The phoretic association of *T. euproctidis* with *E. taiwana* female moths whose eggs are parasitized by the parasitoid suggests that sex pheromone might be the cue used by the parasitoid to locate the adult female.

Two compounds have been identified as sex pheromone components in *E. taiwana*. These compounds are (*Z*)-16-methyl-9-heptadecenyl isobutyrate (16Me-Z9-17:iBu) and 16-methylheptadecyl isobutyrate (16Me-17:iBu) (Yasuda et al., 1995). In this paper, we test a hypothesis that the phoretic egg parasitoid, *T. euproctidis*, uses the moth sex pheromone as a primary cue for host location.

METHODS AND MATERIALS

Insects. The moths we used in the study originated from individuals collected from a wild population in a cabbage field at Naha, Okinawa, Japan, in 1994. They were maintained for about eight generations in the laboratory at 25 ± 0.5°C under a 16:8-hr light–dark photoperiod. Larvae were reared on a commercially available artificial diet for some lepidopterous larvae (Insecta LF; Nihon Nosan Kogyo Co. Ltd., Kanagawa, Japan). In order to reduce allergic reactions in those working with this moth, we removed the urticating bristles attached to the cocoons by dissolving the cocoons in 1% sodium hypochloride solution for about 10 min and then washing the pupae in tap water.

Attraction and Phoresy of Parasitoids on Intact Virgin and Mated Female Moths. Field experiments were conducted at Okinawa Prefectural Agricultural Experiment Station, Naha, Okinawa, in May 1994. Treatments consisted of either plastic cups containing a single virgin female ($N = 8$ replicates), or plastic cups containing a single 3-day-old mated female (=control: $N = 8$ replicates).

Each 120-ml cup with a moth had 2.5- × 1.5-cm windows cut at opposite sides, and the windows were covered with 3-mm mesh plastic netting. The netting allowed the moth's pheromone to diffuse into the air surrounding the cup. The mesh size also allowed attracted parasitoids to enter the cup. These cups with moths were then placed on the branches of hedge plants such as hibiscus at 5-m intervals, 1.2 m above the ground at around 11:00 hr. After a 24-hr exposure in the field, the cups with moths were placed in plastic bags, one cup to a bag, returned to the laboratory, and placed in a freezer for 1 hr to kill the moth and any parasitoids. The anal tufts of the moths were inspected for parasitoids by using a dissecting microscope, and the parasitoids per moth were counted and recorded.

Response of Parasitoid to Synthetic Sex Pheromone. Five treatments using different components or mixtures of components of a synthetic pheromone for *E. taiwana* and a control were placed in the field at Okinawa Prefectural Agricultural Experiment Station.

The dose and blend of synthetic pheromone components for attraction of *E. taiwana* were determined in a previous experiment (Yasuda et al., 1995). The treatments consisted of (1) 300 μg of 16Me-Z9-17:iBu, (2) 100 μg of 16Me-17:iBu, and (3) a blend of 300 μg of 16-Me-Z9-17:iBu and 100 μg of 16-Me-17:iBu. Chemicals were dissolved in hexane, and the solution was added to a 2- × 5-cm piece of filter paper (Toyo No. 2). The filter paper was then placed 3 cm above a sticky plate in a trap (SE type; Sankei Chemical Co., Kagosima, Japan). Controls consisted of a piece of filter paper treated with solvent only, and three caged virgin *E. taiwana* female (1–3 days old), which were placed in a sticky trap. Treatments were replicated three times (=3 traps per treatment), and the traps were set out at 5-m intervals, 1 m above the ground.

In trial 1 the traps were set out about 18:00 hr on April 24 and collected on May 4, 1995, but baits and trap locations were not changed. The second experiment was conducted from May 22 to 24, during which time the baits and sticky plates were changed to fresh ones at about 18:00 hr each day. Trap locations were exchanged systematically to cancel the possible effect of trap position on trap catches. The numbers of *E. taiwana* males and the numbers and sex of *T. euproctidis* caught on the sticky plates were counted with the aid of a dissecting microscope.

RESULTS

Attraction and Phoresy of Parasitoids on Intact Virgin and Mated Female Moths. A total of 36 *T. euproctidis* were found in the anal tuft of virgin females, but only six were found on the mated females (Table 1). This difference was

statistically significant ($P < 0.05$, Wilcoxon's signed-rank test). All parasitoids found on the moths were female.

Response of Parasitoids to Synthetic Sex Pheromone. Large numbers of *T. euproctidis* were caught in traps baited with synthetic sex pheromone for *E. taiwana*, 16Me-Z9-17:iBu alone, and in the blend of 16Me-Z9-17:iBu with 16Me-17:iBu, but significantly fewer were attracted to 16Me-17:iBu alone and to a blank trap (Figure 1). Traps baited with virgin female *E. taiwana* also captured a large number of *T. euproctidis*. All the captured parasitoids were female. Similar results were observed in the total number of *E. taiwana* males captured; many *E. taiwana* males were caught with 16Me-Z9-17:iBu alone, with the blend tested, and with virgin females, but none was caught with 16Me-17:iBu alone or a blank trap. The total number of parasitoids caught was greater in trial 1 than in trial 2.

DISCUSSION

Some species of egg parasitoids are known to use the sex pheromone of the female moth to locate their host. Lewis (1982) first implicated volatile chemicals emanating from the abdominal tips of virgin female moths of *Heliothis zea* (Boddie) as a kairomone for *Trichogramma* spp. A synthetic sex pheromone blend of *H. zea* increased rates of parasitization of *H. zea* eggs by *Trichogramma*

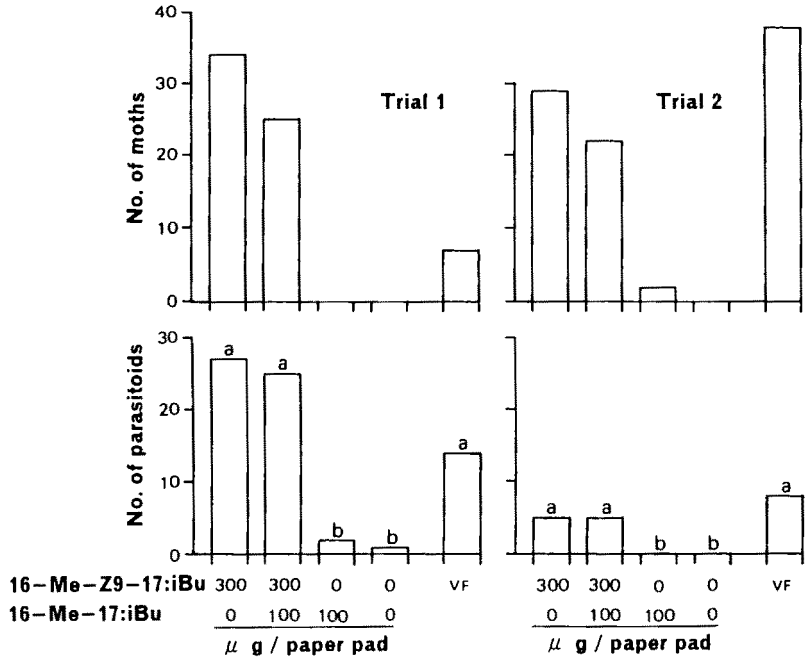

FIG. 1. Total trap catches of *T. euproctidis* (bottom) and male *E. taiwana* (top) with synthetic sex pheromone components, 16Me-Z9-17:iBu, 16Me-17:iBu, or a blend of 16Me-Z9-17:iBu and 16Me-17:iBu (1995, Okinawa). Data were transformed to $\sqrt{(x + 0.5)}$ and submitted to analysis of variance. Means followed by the same letter are not significantly different at the 5% level by Tukey's test. VF: three virgin female moths (1-3 days old).

spp. in greenhouse and field experiments. A similar finding was reported for the egg parasitoid, *Telenomus remus* Nixon; females showed increased rates of parasitization in the presence of volatile substances from the abdominal tips of *Spodoptera frugiperda* (J. E. Smith) or two compounds of the sex pheromone of this moth (Nordlund et al., 1983). In both these cases, however, the calling site of the female moth is not necessarily its oviposition site. A response, however, by these egg parasitoids to the host pheromone likely increases the possibility of their locating habitats in which the female moths have recently oviposited or are actively ovipositing eggs. In phoretic egg parasitoids, the link between parasitoid response to the adult pheromone and finding of the host eggs seems to be much tighter than in nonphoretic egg species.

Virgin female *E. taiwana* exposed in the field attracted significantly more female *T. euproctidis* than mated ones (Table 1). This suggests that the egg

parasitoids were attracted to the sex pheromone emitted by virgin female moths. Nevertheless, a small number of parasitoids was also attracted to mated moths. This may be due to sex pheromone adsorbed on the abdominal scale hairs as she calls. Because the sex pheromone is a high-molecular-weight, but volatile, pheromone, it may continue to attract egg parasitoids after the female moth has mated.

Two compounds were isolated and identified from abdominal tips of female *E. taiwana*: 16Me-Z9-17 : iBu, and 16Me-17 : iBu (Yasuda et al., 1995). Many *T. euproctidis* were attracted to 16Me-Z9-17 : iBu alone or a blend of 16Me-Z9 : iBu and 16Me-17 : iBu, but they were not attracted to 16Me-17 : iBu alone. These results showed that 16Me-Z9-17 : iBu is essential to attract the phoretic egg parasitoid. Male moths were attracted also by 300 μg of 16Me-Z9-17 : iBu alone or a blend of 300 μg of 16Me-Z9-17 : iBu and 100 μg of 16Me-17 : iBu, but no males were caught with 100 μg of 16Me-17 : iBu alone.

More parasitoids were caught in trial 1 than in trial 2. The traps in trial 1 may have attracted more individuals than those in trial 2 because trapping occurred in trial 1 over a longer period of time.

These experiments support the hypothesis that the phoretic egg parasitoid, *T. euproctidis*, uses the sex pheromone of the moth, *E. taiwana*, as a kairomone to locate the female moth, and through her the host eggs.

(Received July 26, 1995; accepted January 28, 1996)

Abstract—The major component of the sex pheromone of female *Spodoptera littoralis*, (*Z*,*E*)-9,11-tetradecadienyl acetate (**1**), elicited all steps of the male behavioral sequence, i.e., wing fanning and taking flight, oriented upwind flight and arrival to the middle of the tunnel, close approach and contact with the source. The activity was equivalent to that elicited by virgin females. In the range of doses tested, the dosage of **1** had no significant effect on the number of source contacts. Male response was significantly affected by light intensity, being optimum at 3 lux. Activity of the minor components (*Z*)-9-tetradecenyl acetate (**2**), (*E*)-11-tetradecenyl acetate (**3**), tetradecyl acetate (**4**), (*Z*)-11-tetradecenyl acetate (**5**), and (*Z*,*E*)-9,12-tetradecadienyl acetate (**6**) was significantly lower than that of the major component when assayed individually. In multicomponent blends compound **4** appeared to strongly decrease the number of males arrested at the source, the effect being particularly important when compound **5** was present in the blend. Results of single sensillum experiments confirmed the existence of two main physiologically distinct sensillar types. The most common type of sensilla contained a neuron that responded specifically to compound **1**. A second type of sensilla, located laterally on the ventral sensory surface, contained two receptor neurons responding to compound **6** and to (*Z*)-9-tetradecenol. Among short sensilla, one hair responded to compound **4** and could represent a minor sensillar type. No sensory neuron was found to detect the other minor pheromone compounds **2**, **3**, and **5**.

Key Words—Wind tunnel, behavior, single sensillum recording, *Spodoptera littoralis*, Lepidoptera, Noctuidae, Egyptian armyworm.

INTRODUCTION

Wind tunnels have been widely used as a reliable technique to study the orientation mechanisms of flying insects to their sex pheromones (Miller and Roelofs, 1978; Cardé, 1984; Mafra-Neto and Cardé, 1994), as well as for evaluation of the mating disruption process (Sanders, 1982) and inhibition induced by specific synthetic compounds (Preiss and Priesner, 1988).

The sex pheromone of the Egyptian armyworm *Spodoptera littoralis*, an important pest of cotton and vegetable crops in Europe, Asia, and Africa, was first identified by Nesbitt et al. (1973) as a mixture of (*Z*,*E*)-9,11-tetradecadienyl acetate (**1**), (*Z*)-9-tetradecenyl acetate (**2**), (*E*)-11-tetradecenyl acetate (**3**), and tetradecyl acetate (**4**) (Figure 1). The pheromone composition, however, varies with the origin of the strain analyzed. Thus, while Dunkelblum et al. (1982) in Israel reported that the sex pheromone complex was a mixture of **1** (33%), **2** (46%), **3** (9%), (*Z*)-11-tetradecenyl acetate (**5**) (7%), (*Z*,*Z*)-9,11-tetradecadienyl acetate (4%), and (*Z*,*E*)-9,12-tetradecadienyl acetate (**6**) (0.5–1%), Tamaki and Yushima (1974) found that abdominal tip extracts from Kenyan insects contained a mixture of only **1** and **6**. Different compositions were also found by Campion et al. (1980) from calling virgin females of Crete, Israel, and Egypt. Thus, whereas volatiles of virgin females from Egypt contained much larger amounts of compounds **4** and **2** + **3** than **1**, the Israeli strain showed compounds **4** and **5** as the major components, and the Cretan stock produced only saturated acetate **4**. The small number of insects available, however, made the results of this study of limited value. In previous studies carried out on our laboratory strain, Martínez et al. (1990) found that the pheromone gland contained a mixture of compounds **1–5** in the ratio 66:12:11:2:9, respectively. The estimated amounts

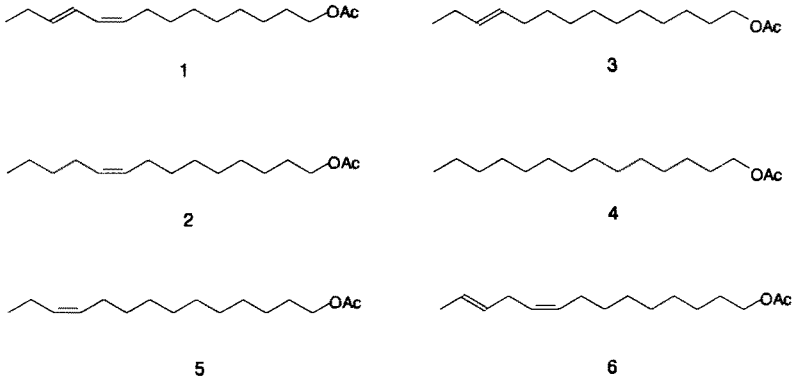

FIG. 1. Structures of compounds **1–6** tested.

of these compounds per female were ca. 40, 7, 7, 1, and 6 ng, respectively. The difference in composition of the pheromone of our strain relative to others led us to study the behavioral activity induced by each component found in the gland alone and in blends with the major compound **1.**

Although field tests are the definitive experiments to assess pheromonal activity (Ridgway et al., 1990), behavioral assays to determine male response to pheromone components in comparison with virgin females are also beneficial for gaining insight into the communication system of the species (Baker and Cardé, 1984; Löfstedt et al., 1985; Linn et al., 1987). In this regard, only one report describing minor component effects on male behavior of Egyptian and Cretan origins has been found in the literature (Haines, 1983). In this paper we report behavioral activity of components **1–5** found in the female gland of our strain, alone and in blends with the major compound **1.** Activity of diene **6,** absent in our population but present in others (see above), and comparison of the activity of the major component and the natural blend with that of virgin females is also presented. Single sensillum experiments (Kaissling, 1979) were also conducted in order to establish the existence of specific receptor cells for the pheromone components found in the gland.

METHODS AND MATERIALS

Insects. Insects were obtained from a laboratory colony taken from the Station de Zoologie (INRA, Montfavet, France) and reared in our laboratory on a slightly modified artificial diet from the one previously reported (Poitout et al., 1972). Modifications include replacement of aureomycin chlorohydrate by Wesson salt mixture (1%, Sigma) and addition of 0.08% of 35% aq. formaldehyde. Pupae were sexed, placed in groups of 20–25 in 20- × 20-cm plastic boxes, and maintained in a climatic chamber on a 16L:8D regime at 25 ± 1°C with 60–70% relative humidity until emergence. Adults were separated daily by age and provided with 10% sucrose solution.

Chemicals. Compounds **1–3** were obtained from Sigma Chem. Co. (St. Louis, Missouri) and their purity (>95%) was checked by GLC on a SPB-5 fused silica capillary column. Stereochemical purity of **1** was *Z,E*:*E,E* 96:4. Compounds **4** and **5** were prepared by acetylation of tetradecyl alcohol and (*Z*)-11-tetradecenol (Sigma), respectively, with acetyl chloride 99%+ (Aldrich Chemie, Steinheim, Germany) followed by purification by column chromatography to assess a >98% purity by GLC analysis. Just prior to the experiments, solutions were prepared by dissolving the compounds in 100 μl of nanograde hexane. The required volume to achieve the test doses (1–1000 μg) was applied to a 1.5- × 1-cm cotton wick and the solvent evaporated. The wicks were discarded after use.

Wind Tunnel. The tests were performed in a glass wind tunnel 180 cm long, 55 cm wide, and 50 cm high. The frame of the tunnel was made of aluminum and access was gained by two sliding doors, each one covering one half of the tunnel. The air was pushed through by a centrifugal fan and pulled out of the building with the aid of an exhaust blower. The fan and blower worked simultaneously and their action was carefully regulated by a potentiometer to avoid undesired turbulence in the moving air. Turbulence was controlled through a SO_3-containing airflow tester (Drägerwerk Aktiengesellschaft, Germany). The airstream was purified through a 2-cm-thick glass wool bed and conducted through two consecutive nylon screens to smooth the airflow and get a laminar regime through the tunnel. A 58-W red fluorescent light located 16 cm above the tunnel provided the required illumination. Light intensity was adjusted to 3–10 lux by covering the top of the tunnel with red cellophane paper strips. A white board containing irregular-shaped, dark brown spots was placed on the floor of the tunnel since striped patterns may induce unexpected effects on the orientation of flying insects (David, 1982). The airspeed was 45–55 cm/sec, the temperature of the experiment room was 22 $\pm$ 1°C, and the relative humidity 60 $\pm$ 5%. The wind tunnel was thoroughly cleansed with acetone before every change of formulation.

Bioassays. Newly emerged moths were separated from the remaining pupae twice a day and placed into 31- $\times$ 12- $\times$ 21-cm plastic boxes. Only insects on their first and second scotophase were tested since they had shown maximum EAG responses in comparison to older insects (Murgó and Guerrero, unpublished data). At the onset of the scotophase, males were distributed in groups of five individuals, placed in Petri dishes, and maintained in the dark for 3 hr. They were then allowed to acclimate to the tunnel conditions for 60 min and utilized only once. The males were taken from their containers, placed over a filter paper on a stainless steel jack at 130 cm downwind from the source, and allowed 5 min to respond. When virgin females were used as the pheromone source, five individuals (10–35 hr old) were placed in 6.5- $\times$ 4 $\times$ 3-cm stainless steel cages of 0.2- $\times$ 0.2-cm mesh and suspended about 18 cm from the top and 40 cm from the upwind end of the tunnel. Males were introduced into the tunnel only after the virgin females had adopted the calling position. To study the effect of synthetic chemicals, cotton wicks containing the compounds were hung on the same holders. The experiments were carried out 3–6 hr into the scotophase since female calling behavior reaches its maximum 3–9 hr into the dark period (Dunkelblum et al., 1987). Responses of 15–20 males were recorded per day of experiment with a minimum of two replicates per formulation.

Males were scored according to the following behavior: wing fanning and taking flight, arrival at the middle of the tunnel (65 cm), close approach to the lure (ca. 10 cm), and contact with the source. In the tests with individual compounds, latency, i.e., delay in time spent by males to leave the filter paper,

was also considered. Only those males arrested at the source for a minimum period of 5 sec were recorded as source contacts. The effect of a specific formulation was calculated as the number of males showing a particular behavior in comparison with the total number of insects released. The results were analyzed for significance using a chi-square 2 × 2 test of independence (Sokal and Rohlf, 1969).

Electrophysiology. Single sensillum recordings (SSRs) were performed on whole insect preparations according to the standard tip recording technique (Kaissling and Thorson, 1980). Glass electrodes were filled with sensillar saline for the recording electrode and with hemolymph saline for the reference electrode. After cutting the more distal segments, the tip of the antenna was covered with the hemolymph saline. The tips of several sensilla were cut off using sharpened forceps, and the recording electrode was slipped over the cut end of one hair. The SSR responses were filtered (150–5000 Hz) and amplified (×1000). The recordings were stored on a PC-AT microcomputer via a DASH 16 analog-to-digital conversion board. Acquisition and analysis of the recordings were performed by programs we developed in Asyst (McMillan Software Co.). Records were plotted with Awave, a software developed by F. Marion-Poll in Visual C++.

In addition to pheromone components **1–6,** other pheromone analogs were also tested on several trichoid sensilla, i.e., dodecyl acetate, (*Z*)-7-dodecenyl acetate, (*Z*)-9-dodecenyl acetate, and (*Z*)-9-tetradecenol, in a randomized order. The olfactory stimulations were achieved by blowing a puff of air (0.5 liters/min) of 1 sec duration through a Pasteur pipet containing a filter paper, on which 0.1, 0.5, or 5 μg of the test compound diluted in 1 μl of hexane had been deposited. The antenna was continuously flushed with humidified air (1.0 liter/min, 100% relative humidity). Receptor neurons tuned to compound **4** were searched for in olfactory hairs sampled among all different morphological classes and locations of sensilla trichodea. In addition, the activity of binary mixtures **1** + **4** were compared to that displayed by the individual compounds alone in order to check for a possible interaction of these two components at the receptor cell level.

RESULTS

Male Response to Major Component 1. The effect of dosage of major component **1** on male behavioral response is shown in Figure 2. In the range of doses tested (1–1000 μg), dosage had no significant effect on the number of males displaying every stage of the courtship sequence. In contrast, light intensity exerted a clear effect on male responses to major component **1,** particularly at moderate dose (Figure 3). Thus, when 1, 3, and 10 lux were tested, males

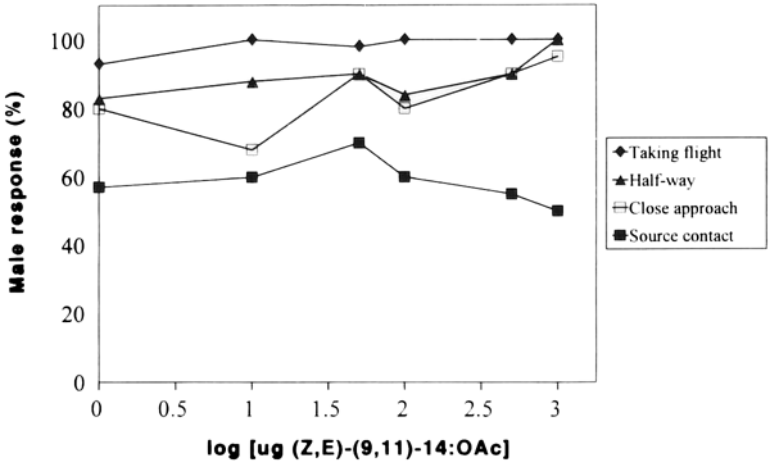

FIG. 2. Percentage of *Spodoptera littoralis* males exhibiting all types of behavior in response to various doses of (*Z*,*E*)-9,11-tetradecadienyl acetate (**1**) in wind tunnel at an airspeed of 45 cm/sec and 3 lux of light intensity.

displayed highest responses at 3 lux and significantly higher responses at 50- to 100-μg doses than those elicited with other illuminations. The effect was dose-dependent, the difference in number of males contacting the source under the three light intensities was higher at higher concentrations.

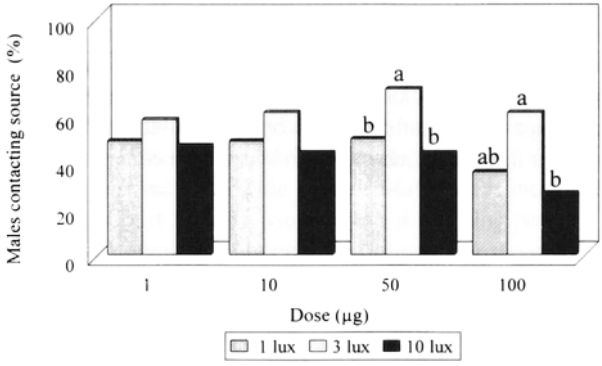

FIG. 3. Percentage of *Spodoptera littoralis* males contacting the source in response to several doses of (*Z*,*E*)-9,11-tetradecadienyl acetate (**1**) under different light intensities. Bars topped by different letters within a dose are significantly different at $P < 0.05$ (chi-square 2 × 2 test).

Male Response to the Minor Components 2–6. The minor components **2–5,** found in our strain, as well as diene **6** found in some strains, were assayed individually at several concentrations (100–1000 μg). Little activity was generally elicited at any of the doses tested, the activity being significantly lower than that displayed by the major component **1** ($P < 0.05$) (Figure 4). Lack of response was evident at the earliest stages of behavior, i.e., wing fanning and higher latency (> 120 sec) in comparison with insects responding to major component **1** (60–100 sec). In most cases the number of source contacts was negligible, so activity was evaluated in terms of number of males performing close approach. At the 100-μg dosage, compound **2** was the most active minor component ($P < 0.05$). It was able to induce landing of 35% of males at that concentration. Compound **3** was also active, the effect being higher at increasing concentrations, although activity was not significant relative to the other minor components. Compounds **4** and **5,** in turn, were only able to elicit close approach to the source in 20–30% of males, whereas compound **6** showed moderate attractivity only at 1000 μg.

Male Response to Binary Mixtures. The effects induced by binary mixtures of **1** with minor components **2–6** in a similar ratio to that found in the pheromone gland were also studied. Cotton wicks were loaded with previously prepared

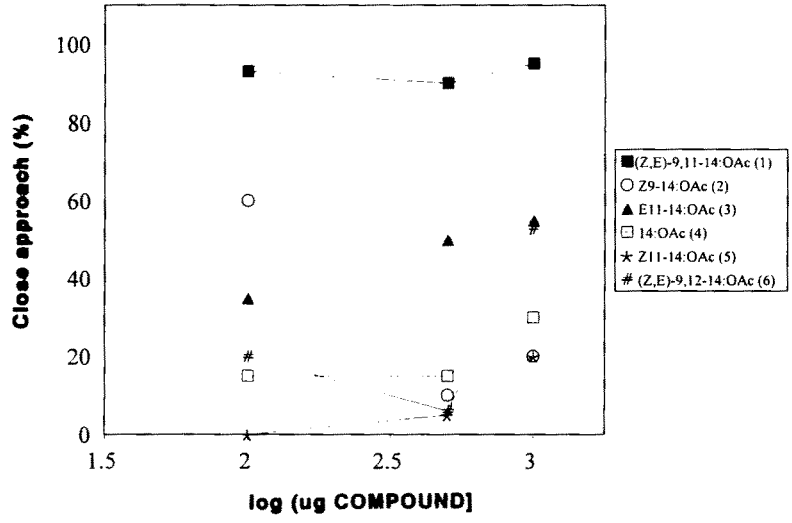

FIG. 4. Percentage of *Spodoptera littoralis* males performing close approach behavior in response to various doses of Z9–14:OAc (**2**), *E*11–14:OAc (**3**), 14:OAc (**4**), Z11–14:OAc (**5**), and (*Z,E*)-9,12–14:OAc (**6**) in wind tunnel. Responses to (*Z,E*)-9,11-tetradecadienyl acetate (**1**) are given for comparison.

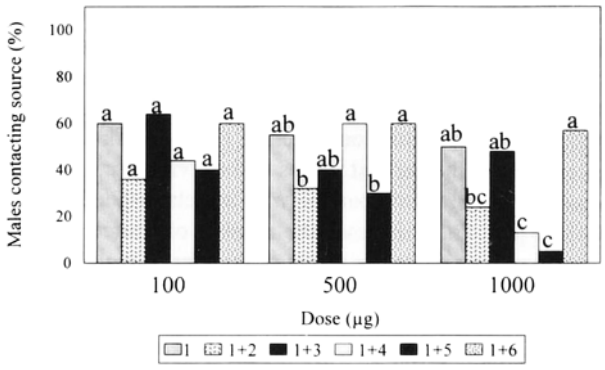

FIG. 5. Percentage of *Spodoptera littoralis* males contacting the source in response to binary mixtures of (*Z*,*E*)-9,11-tetradecadienyl acetate (**1**) with *Z*9-14:OAc (**2**), *E*11-14:OAc (**3**), 14:OAc (**4**), *Z*11-14:OAc (**5**), and (*Z*,*E*)-9,12-14:OAc (**6**) at different doses. Bars bearing different letters within a dose are significantly different at $P < 0.05$ (chi-square 2 × 2 test).

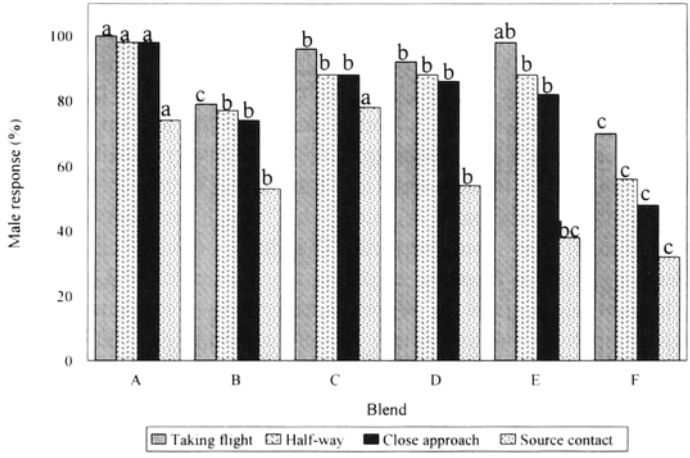
mixtures of 100, 500, and 1000 μg of **1** and the corresponding amount of the minor compounds (Figure 5).

In general, these binary blends did not increase the number of source contacts elicited by compound **1.** Differences in activity between the major component and mixtures increased with the concentration, being significant ($P < 0.05$) at the highest doses (500–1000 μg). Among the binary mixtures, formulation **1** + **3** was the most active, but the number of source contacts was very similar to that displayed by compound **1** alone. A slightly lower effect was elicited by mixture **1** + **2,** with activity being independent of the concentration assayed. The effect of the dosage was particularly evident when blends **1** + **4** and **1** + **5** were tested at 1000 μg, wherein both mixtures elicited a notable inhibition of landing response. The effect was significant ($P < 0.05$) relative to the one displayed by the major compound alone. Compound **6** was completely ineffective when mixed with **1** at every dosage tested, in comparison with the activity induced by the major component alone.

Male Response to Multicomponent Blends. In order to compare the response to synthetic pheromone blends with that elicited by virgin females, several multiple combinations of compounds **1–5** were assayed in similar ratios to the one found in the gland. Six blends, A–F, were prepared by adding the corresponding amounts of components **2–5** to 1000 μg of the major component **1.** The final formulations were the following: A: **1** + **2** + **3,** 75:13:12; B: **1** + **2** + **3** + **4,** 66:12:11:11; C: **1** + **2** + **3** + **5,** 67:12:11:9; D: **1** + **2** + **3** + **4** + **5,** 67:12:11:0.5:9; E: **1** + **2** + **3** + **4** + **5,** 66:12:11:2:9; F: **1** + **2** + **3** + **4** + **5,** 61:8:10:10:11.

Formulation E, which mimicked the natural pheromone blend, was, surprisingly, one of the less effective blends, with only 38% of males landing at the source (Figure 6). Formulation A, in contrast, was the most active, with 74% of males contacting the lure. Blend C was also very effective in eliciting complete flights to the source, and although the number of males taking flight and approaching the source was lower than with blend A ($P < 0.05$), there was no significant difference in the number of source contacts. Activity of formulation C was not significantly higher than that of virgin females, but induced a significantly higher number of male arrests at the source than compound **1** alone ($P < 0.05$, Figure 7). Addition of **4** to blend A (formulation B) significantly decreased male response. This effect was confirmed when the same compound was added to formulation C to make blend E. In this case, however, only the number of contacts with the source was significantly diminished. The same effect was noticed with formulation D, containing only 0.5% of compound **4.** The difference in behavior elicited relative to blend C was also significant ($P < 0.05$). Furthermore, formulation B, containing 11% of compound **4,** significantly reduced the number of males displaying all types of behavior in comparison with blend A. The inhibitory effect induced by **4** can be also noticed in



A: 1 + 2 + 3 (75:13:12)
B: 1 + 2 + 3 + 4 (66:12:11:11)
C: 1 + 2 + 3 + 5 (67:12:11:9)
D: 1 + 2 + 3 + 4 + 5 (67:12:11:0.5:9)
E: 1 + 2 + 3 + 4 + 5 (66:12:11:2:9)
F: 1 + 2 + 3 + 4 + 5 (61:8:10:10:11)

FIG. 6. Percentage of *Spodoptera littoralis* males exhibiting all types of behavior in response to multicomponent mixtures of (*Z*,*E*)-9,11-tetradecadienyl acetate (**1**) with *Z*9-14:OAc (**2**), *E*11-14:OAc (**3**), 14:OAc (**4**), and *Z*11-14:OAc (**5**). Values corresponding to the same type of behavior have been compared and bars topped by different letters are significantly different at $P < 0.05$ (chi-square 2 × 2 test).

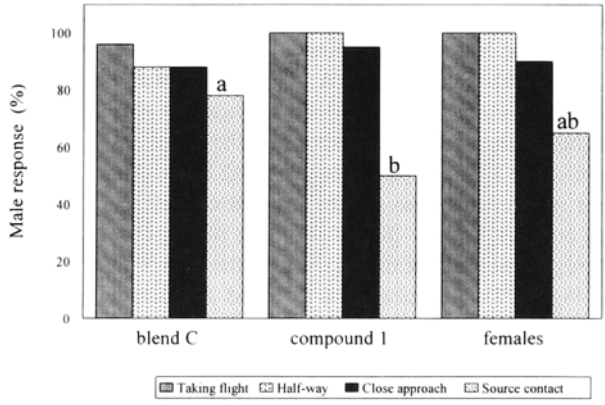


FIG. 7. Comparison of male responses to blend C, major compound **1**, and virgin females. Bars topped by different letters are significantly different at $P < 0.05$ (chi-square 2 × 2 test).

formulation F, wherein the number of males performing all behaviors was also significantly lower ($P < 0.05$) in comparison to those responding to blend C (Figure 6).

Single Sensillum Recordings. The activity of more than 100 long and 100 short sensilla trichodea chosen at random in the proximal half of the antenna was recorded. When the amplitude of their action potentials could be clearly distinguished from each other, A and B designate the sensory neurons firing action potentials of high and low amplitude, respectively. Most short and long trichoid sensilla housed a large-spike cell responding only to compound **1** (Figure 8a). In some of these hairs, a second cell, which fired action potentials of smaller amplitude, was also observed. The firing activity, however, did not significantly increase in response to pheromone compounds. Long sensilla trichodea, located laterally on the ventral sensory side of the antenna, housed A cells responding to compound **6** and B cells responding to (*Z*)-9-tetradecenol (Figure 8b,c). No response to **4,** even at 5 μg, was recorded from these two sensillar types. However, one short sensillum trichodeum showed a different cell response pattern. Its firing activity consisted of a single class of action potential amplitude. This sensillum neither responded to compounds **1, 6,** and (*Z*)-9-tetradecenol at 500 ng and 5 μg doses nor to compound **4** (500 ng), but stimulations with 5 μg of the latter component elicited significant responses (Figure 8d). Despite extensive efforts, no other hair displaying the same type of response could be found. Numerous short sensilla did not respond to any of the pheromone molecules assayed.

Sixteen sensilla from three males containing a receptor neuron tuned to

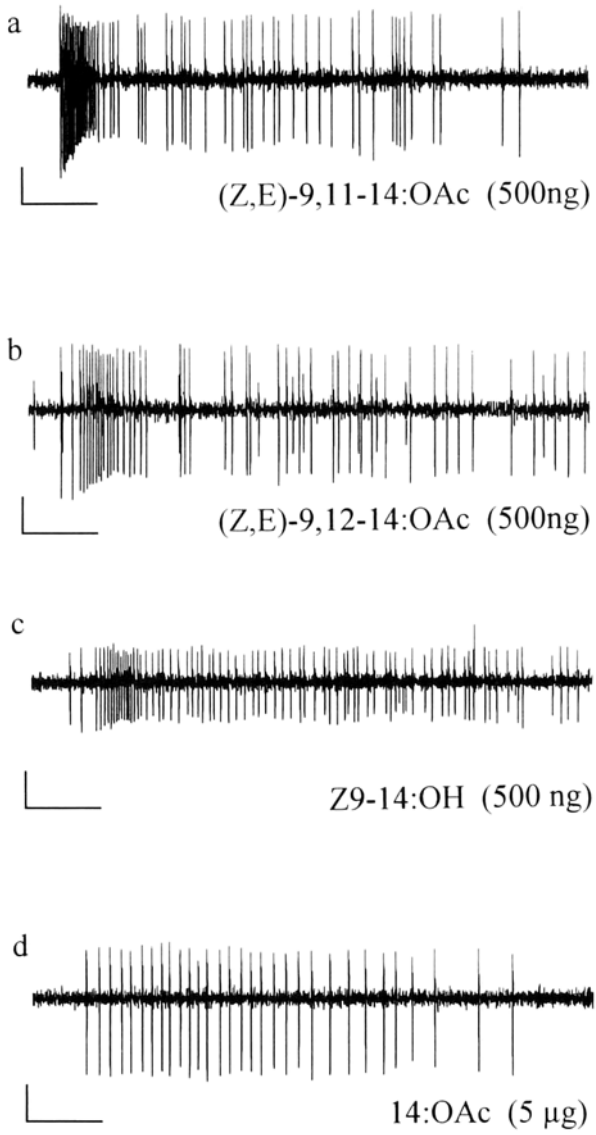

FIG. 8. Single sensillum recordings from the three types of sensilla trichodea: (a) from a sensillum responding to (*Z,E*)-9,11-tetradecadienyl acetate (**1**); (b) and (c) from a sensillum responding to (*Z,E*)-9,11-tetradecadienyl acetate (**1**) (A cell), and to *Z*9–14:OH (B cell); and (d) from a sensillum responding to 14:OAc (**4**). Scale bars: 200 msec, 0.5 mV. Stimulation duration: 1 sec.

compound **1** were subjected to compounds **1** (100 ng), **4** (10, 100 ng), and mixtures of **1** + **4** (100 + 10 ng, 100 + 100 ng). Compound **4** alone was inactive but when mixed with compound **1**, it slightly increased the firing frequency by 2–5 spikes/sec, but the difference was not significant (data not shown).

DISCUSSION

Our results show that in our strain, major compound **1**, whose presence in the gland accounts, on average, for 66% of the total amount of pheromone components, is able to produce alone all steps of the behavioral sequence in males. The activity is similar to that displayed by virgin females. The response level is clearly dependent on light intensity, particularly at 50 μg dosage and higher. Wind velocity had practically no significant effect at speeds ranging from 45 to 80 cm/sec, whereas at 40 cm/sec only 25% of males initiated upwind flight towards the source (data not shown). This is in agreement with the experiments of Haines (1983) on other strains.

Low loadings (1 μg) of the major component are sufficient to promote all behaviors of the mate-finding sequence, but higher doses do not impair the ability of males to orient. Many insects respond to low amounts of chemicals in their flight orientation behavior, i.e., *Mamestra suasa* (Frérot et al., 1989), *Grapholita molesta* (Linn and Roelofs, 1983; Linn et al., 1988), *Agrotis segetum* (Löfstedt et al., 1985), *Laspeyresia pomonella* (Preiss and Priesner, 1988), *Lymantria dispar* (Charlton et al., 1993), or *S. litura* (Kawasaki, 1986), among others. The high attractivity of **1** had been previously noticed in the field by Kehat et al. (1976), who found that 1 mg of the chemical was equivalent in effectiveness to a trap baited with virgin females.

In general, little activity was displayed by the minor components when assayed individually, the lack of response being evident at the earliest steps of the behavioral sequence. However, compounds **2** and **3** evoked source contacts in 20–30% of males at 100 μg and 500 or 1000 μg, respectively (data not shown). Compound **2** was found to be encoded by a specific receptor by Priesner (1979), but we did not find a specific receptor cell for **2.** In the field, compounds **2** and **5** behaved as inhibitors of the male activation response induced by compound **1** (Campion et al., 1980), although Kehat et al. (1976) found that addition of small amounts of **5** to the "pure" major component **1** in the Israeli strain markedly enhanced the activity of the diene. Acetate **6,** whose presence in other strains appeared essential for a maximum trap catch in the field (Kehat et al., 1976; Dunkelblum et al., 1982), elicited activation and orientation to the plume only at high doses but failed to induce close approach to the source.

Binary mixtures of the minor components with major compound **1** did not significantly increase the number of males responding in comparison with com-

pound **1** alone. There was, however, a significant inhibitory effect in the number of contacts elicited by compounds **4** and **5** at high dosage (1000 μg). The effect induced by **4** is in agreement with the results of Haines (1983) on a Cretan population, wherein addition of ≥ 10% of **4** significantly reduced the percentage of males responding. The same mixture, however, did not elicit any appreciable effect on the Egyptian strain. These results suggest that minor components **4** and **5** exert their arrestment activity at a close distance to the source and at relatively high atmospheric concentrations, in a similar way to the activity shown by dodecyl acetate in *Trichoplusia ni* (Linn and Gaston, 1981).

The effect exerted by compound **4** was confirmed when multiple component blends B–F were assayed. Comparison of formulations D and E with C clearly shows an inhibition effect in the number of males arrested at the source, the presence of only 0.5% of **4** being enough to induce a significant decrease of source contacts. The effect was dose-dependent, the highest inhibition of response being elicited by composition F containing 10% of the minor component. The effect was specially remarkable when compound **5** was also present in the pheromone composition (compare formulations B and F). Compound **4** appears, therefore, to be a close-range inhibitor, but depending on the presence and concentration of **5**, it may also inhibit other behaviors, such as wing fanning, orientation to the plume, and close approach to the source.

The most active formulations were A and C, the latter inducing slightly lower activation and orientation to the plume but with similar numbers of males arrested at the source. Compound **5**, present in formulation C, appears, therefore, to be a behaviorally neutral minor component. The high activity elicited by blends A and C, analogous to that of virgin females, and the inhibition shown by compound **4** suggest that perhaps females do not release this minor component. Despite extensive effort, we have been unable to detect saturated acetate **4** in aeration experiments of female volatiles.

The presence of compound **4** in the pheromone gland induced us to look for a specific receptor cell and to study its peripheral detection by male antennae. Single sensillum recordings confirmed the existence of two main physiological types of sensilla trichodea on the male antenna, as previously described by Ljungberg et al. (1993). Thus, despite differences in the composition of their sex pheromones, the two populations show the same sensillar organization. In addition, among short hairs, one different sensillum responded to saturated acetate **4**. No sensillum of the same type was, however, recorded in further experiments, which can be interpreted in two ways. Either hairs of this type are present in very low numbers on the antenna, as is the case for the (*Z*)-9-tetradecenyl acetate receptor cell in *Agrotis segetum* (Löfstedt et al., 1982), or the hairs responding to the inhibitor may have been undersampled due to their location or size. Considering the very weak EAG activity of compound **4** (Nes-

bitt et al., 1973; Ljungberg et al., 1993), the former possibility seems more likely. Responses from this sensillum were recorded only to 5 μg of compound **4**, ten times higher than the dose required for eliciting activity on the other two sensillar types. This high threshold may be due to the absence of tuning of this sensillum to the minor component, or it may originate from the experimental conditions, which include cutting the tip of the sensilla and covering its distal part. On a short hair, this may result in a considerable diminution of the sensory zone in contact with the stimulating pheromone molecules.

In summary, the major component **1** is a very effective attractant for the Spanish strain of *Spodoptera littoralis* males in behavioral studies, its activity being equivalent to that elicited by virgin females. Among the minor components present in the gland and in multicomponent blends, compound **5** is behaviorally neutral, while **4** appears to be a close-range inhibitor of arrestant behavior.

Acknowledgments—We thank CICYT (PB 93-0158 and AGF 92-0178) for financial support and Kenogard S.A. for a predoctoral fellowship to C. Q. Exchange visits to both laboratories have been possible through PICASSO Program No. 172B.

(Received May 12, 1995; accepted January 29, 1996)

Abstract—(*Z,E*)-9,11-tetradecadienal (*Z*9,*E*11-14:Ald; 11%), (*Z,E*)-9,11,13-tetradecatrienal (*Z*9,*E*11, 13-14:Ald; 67%), (*Z,E*)-9,11-tetradecadienyl acetate (*Z*9,*E*11-14:Ac, 5.5%), and (*Z,E*)-9,11,13-tetradecatrienyl acetate (*Z*9,*E*11,13-14:Ac; 16.5%) were identified in the extracts of female pheromone glands of *Stenoma cecropia* (Lepidoptera: Elachistidae). From electroantennograms and single sensillum recordings, receptors to *Z*9,*E*11,13-14:Ald and *Z*9,*E*11-14:Ald were found on male antenna. Behavioral data were obtained from olfactometric tests in the laboratory and field trapping experiments in Colombia. It appeared that a blend of *Z*9,*E*11,13-14:Ald (83%) and *Z*9,*E*11-14:Ald (17%) was attractive to males. These aldehydes are assumed to be components of the sex pheromone of *S. cecropia*, whereas the acetates found in gland extracts might be precursors of the pheromone.

Key Words—Lepidoptera, Elachistidae, *Stenoma cecropia*, sex pheromone, identification, electroantennography, single sensillum recording, field trapping (*Z,E*)-9,11-tetradecadienal, (*Z,E*)-9,11,13-tetradecatrienal.

INTRODUCTION

The moth *Stenoma cecropia* Meyrick belongs to a neotropical subfamily (Stenominae) of the Gelechioidea. These moths were considered as Oecophoridae by

*To whom correspondence should be addressed.

Hodges (1974). More recently, Minet revisited the taxonomic status of Stenominae and included them in the family Elachistidae on the basis of the abdominal articulation of the nymph (Minet, 1989). The adults of *S. cecropia* look like colorful tortricids, but the larvae live in fixed bags and feed on several forest trees, including the leaflets of Palmaceae. In oil palm plantations of central Colombia, the populations of this insect can reach huge levels, and the threshold for insecticidal treatment is 80 larvae per leaf (Genty, 1978). Severe defoliations by this insect may decrease the yield of oil palm trees by as much as 15–20%. We undertook the identification of the sex pheromone of *S. cecropia* to provide a useful tool for monitoring the populations of the moth.

The chemical aspects relating to the synthesis of pheromone components have been partly published (Ramiandrasoa and Tellier, 1990; Tellier and Descoins, 1990). We present here the full identification study together with biological data.

METHODS AND MATERIALS

Insects

Preliminary trials to send live insects to France were very unsatisfactory, because 90% of the larvae or pupae died. It was thus decided in 1987 to extract the pheromone in central Colombia by using a field laboratory in a 9000-ha plantation (San Alberto, Cesar). The pupae were collected daily in their bags and sexed in the laboratory. Half the pupae and emerging adults were then kept under natural conditions (temperature varying between 28 and 40°C, 100% relative humidity, and daylight from 06:30 to 18:30 hr). The other half of the insects were kept in a room under similar conditions except that light was provided from 04:30 to 16:30 hr.

The insects used for olfactometric tests, electroantennographic (EAG) recordings, and single-sensillum recordings were collected as young pupae in the field and brought back to France courtesy of traveling colleagues. They were sexed and kept at 27°C with 75% relative humidity under a 12–12 hr photoperiod until emergence of the adults. The male moths used in these laboratory studies were 1 or 2 days old.

Pheromone Extraction

As shown by observation of traps baited with virgin females, the period of sexual activity of *S. cecropia* begins half an hour before dusk and lasts 2 hrs. In San Alberto, the pheromone was extracted between 18:30 and 20:30 hr (insects under natural photoperiod) or between 16:30 and 18:30 hr (insects under shifted light regime).

The last three abdominal segments of 1 or 2-day old virgin females were clipped and soaked for 12 hr in 1 ml hexane (Carlo Erba Codex Depurato) at −5°C. The extract then was filtered through glass wool, reduced to ca. 100 μl under a N_2 flow and kept at −30°C until used. Three extracts of, respectively, 684, 759, and 557 female abdominal tips were made using this method from February 27 to March 18, 1987.

Pheromone Analysis

The sex pheromone extracts were analyzed by gas chromatography (GC) and gas chromatography–mass spectrometry (GC-MS). GC analyses were performed on a Hewlett-Packard 5890 chromatograph with flame ionization detector (FID) and a Ross injector heated at 240°C, equipped either with a polar column (30-m WCOT CPSil-88 CB, 0.22 mm ID; Chrompack, Middleburg, The Netherlands) operated isothermally at 180°C, or with a nonpolar column (25-m WCOT CPSil-5 CB, 0.22 mm ID; Chrompack) heated from 160 to 220°C at 5°C/min. GC-MS was performed on a Girdel 32 gas chromatograph linked to a Nermag R 10-10C quadrupole mass spectrometer controlled by a SIDAR data acquisition system. The chromatograph was fitted with a fused silica capillary column (25-m WCOT CPSil-5 CB, 0.22 mm ID; Chrompack) and operated isothermally at 180°C. Mass spectra were obtained by electron impact (EI) at 70 eV scanning from 40 to 350 amu, and by chemical ionization (CI) at 92.5 eV with ammonia (NH_3) and isobutane (i-C_4H_{10}) as the reactant gas. Pheromone compounds were identified by comparing their GC retention times and mass spectra with those of chemicals synthesized in the laboratory (see below).

Synthesis of Chemicals

We report herein the synthesis of (*Z*,*E*)-9,11,13-tetradecatrien-1-al. For some years, several laboratories have been interested in synthesis of 1,3,5-undecatrienes (Näf et al., 1975; Ratovelomanana and Linstrumelle, 1987; Andreini et al., 1987), which are reported to have odors highly appreciated in perfumery. The need for regio- and stereochemically pure compounds for biological tests is well recognized. A number of stereoselective methods (Ratovelomanana and Linstrumelle, 1987; Andreini et al., 1987) for obtaining these nonfunctionalized trienes have been described. In our case the approach that has given the best results was based upon the method of Rossi (Andreini et al., 1987), which involved two sequential palladium-catalyzed cross-coupling reactions. A first coupling between a molar excess of commercial *E*/*Z* 1,2-dibromoethylene and adequate alkynylzinc bromides led to (*E*)-1-bromo-1-en-3-yne derivatives with a high stereoisomeric purity, since (*E*)-1,2-dibromoethylene reacts preferentially when it is blended with the *Z* stereoisomer. These intermediate bromoenynes were then coupled with vinylzinc bromide to afford the

corresponding 1,(*E*)-3-dien-5-ynes. The latter were allowed to undergo a *Z* stereoselective reduction to give 1,(*E*)-3,(*Z*)-5-trienes. The actual steps for synthesizing the desired trienal are shown in Figure 1. ^1H and ^{13}C NMR spectra were recorded on a Bruker AC 200 spectrometer [$CDCl_3$; δ(ppm) from TMS, *J* (Hz)]. Infrared spectra were measured on a Perkin-Elmer 397 spectrometer [neat, γ cm^{-1})]. Stereoisomeric purity of all products was determined by gas chromatographic analyses performed on a model 2900 Carlo Erba instrument equipped with silica capillary polar column (25-m WCOT FFAP 0.32 ID, H_2 carrier gas flow 25 ml/min, 1.2 b).

(E)-1-Terbutoxy-12-bromo-9-dodecyn-11-ene. To a solution of 1-terbutoxy-9-decyne (Tellier and Descoins, 1990) [10.5 g (0.05 mol) in 25 ml Et_2O and 25 ml THF] at 0°C were added 31 ml (0.05 mol) of 1.6 M *n*-BuLi in hexane. After 30 min at 20°C, alkynyl lithium was obtained. To this reagent was added at 0°C an anhydrous $ZnBr_2$ solution [12.4 g (0.055 mol)/50 ml THF]. The stirred mixture was warmed to 20°C for 30 min; then at 0°C were added successively solutions of $Pd(PPh_3)_4$ (3%) [1.7 g (1.5 mmol)/20 ml THF] and 46.5 g (0.25 mol) of *E/Z* (40/60) 1,2-dibromoethylene. The reaction mixture was allowed to warm to room temperature for 16 hr and then hydrolyzed by H_2SO_4 solution (1 N). After extraction with ether and evaporation of the solvent, the crude mixture was passed through a small silica gel column in order to remove the palladium catalyst (eluting with cyclohexane). The solvents were evaporated and the residue distilled to afford 7.9 g of bromoynene (50% yield); *E* purity ≥ 99%; bp, 120°C/0.1 Torr; *m/z*: 299, 301 (M-15); IR: 2250, 1200; ^1H NMR: 1.18 (s, 9H), 1.33 (m, 12H), 2.22 (m, 2H), 3.32 (t, 2H), 6.13 (dt, H^{11}), 6.56 (d, H^{12}) $J_{H^{11}/H^{12}}$ = 14, $J_{H^8/H^{11}}$ = 2; ^{13}C NMR: 19.5, 61.6, 72.3, 77.3, 93.2, 116.8, 118.1. Anal. calcd. for $C_{16}H_{27}BrO$: C, 60.95; H, 8.63. Found: C, 61.20; H, 8.77.

(E)-1-Acetoxy-12-bromo-9-dodecyn-11-ene. Ac_2O, 4.7 ml (0.05 mol), and 0.4 g (2.5 mmol) of $FeCl_3$ were successively added to a solution of 7.9 g (0.025

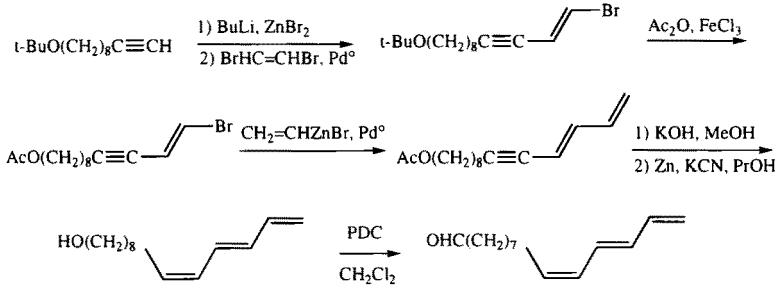

FIG. 1. Synthesis of (*Z,E*)-9,11,13-tetradecatrien-1-al.

mol) *t*-butyl ether in Et_2O (50 ml). The stirred solution was left at room temperature overnight. A saturated aqueous solution of Na_2HPO_4 (50 ml) was added and the mixture was stirred for 1 hr. The solid precipitate was removed by filtration. After extraction with ether and evaporation of the solvent, 6.9 g of acetoxybromoynene were obtained (92% crude yield); *E* purity (99%); *m/z*: 221 (M-80); IR: 2250, 1740; ^{1}H NMR: 1.2–1.7 (m, 12H), 2.03 (s, 3H), 2.25 (m, 2H), 4.04 (t, 2H), 6.16 (dt, H^{11}), 6.57 (d, H^{12}) $J_{H^{11}H^{12}}$ = 14, $J_{H^8/H^{11}}$ = 2; ^{13}C NMR: 19.4, 64.45, 77.4, 93.1, 116.9, 118.1, 170.6.

(E)-1-Acetoxy-11,13-tetradecadien-9-yne. A solution of $ZnBr_2$ [24.8 g (0.11 mol)/100 ml THF] was added to a 1 M THF solution of vinyl magnesium bromide (100 ml, 0.1 mol) cooled at 0°C. The reaction mixture was stirred at 20°C for 30 min, and after cooling to 0°C, 0.7 g (0.6 mmol) of $Pd(PPh_3)_4$ in THF (20 ml) followed by 6 g (0.02 mol) of bromoynene were added. The stirred mixture was allowed to warm to room temperature for 12 hr and then hydrolyzed by H_2SO_4 solution (1 N). After extraction with ether and evaporation of the solvent the crude mixture was passed through a small packed silica gel column (eluting with cyclohexane). The solvent was evaporated and the residue distilled to afford 3.7 g of acetoxydienyne (75% yield); *E* purity (96%); bp 115°C/0.1 Torr; *m/z*: 248 (M^+, 3%), 91 (100%); IR: 2250, 1740, 1620, 1245, 1000, 940, 905, 840, 745, 720, 700; ^{1}H NMR: 1.33 (m, 12H), 2.02 (s, 3H), 2.30 (m, 2H), 4.04 (t, 2H), 5.09 (dd, H^{14}), 5.21 (dd, $H^{14'}$), 5.59 (d, H^{11}), 6.25 (dd, H^{12}), 6.45 (ddd, H^{13}) $J_{H^{13}/H^{14'}}$ = 16.5, $J_{H^{11}/H^{12}}$ = 14.4, $J_{H^{12}/H^{13}}$ = 9.9, $J_{H^{13}/H^{14}}$ = 9, $J_{H^{14}/H^{14'}}$ = 2; ^{13}C NMR: 64.5, 79.6, 93.4, 112.7, 118.4, 136.4, 140.9, 171. Anal. calcd. for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74. Found: C, 77.33; H, 9.62.

(E)-11,13-Tetradecadien-9-yn-1-ol. This product was prepared by saponification of the corresponding acetate with 2 N KOH in MeOH; Crude yield (98%); *E* purity (96%); *m/z*: 206 (M^+, 4%), 91 (100%); IR: 3350, 2200, 1620, 1580, 1000, 940, 905, 840, 740, 695; ^{1}H NMR: 1.34 (m, 12H), 2.32 (m, 2H), 3.0 (m, 1H), 3.57 (t, 2H), 5.08 (dd, H^{14}), 5.20 (dd, $H^{14'}$), 5.58 (d, H^{11}), 6.24 (dd, H^{12}), 6.45 (ddd, H^{13}) $J_{H^{13}/H^{14'}}$ = 16.5, $J_{H^{11}/H^{12}}$ = 14.4, $J_{H^{12}/H^{13}}$ = 10.8, $J_{H^{13}/H^{14}}$ = 9, $J_{H^{14}/H^{14'}}$ = 2. ^{13}C NMR: 62.5, 79.6, 93.5, 112.7, 118.4, 136.3, 140.8.

(Z,E)-9,11,13-Tetradecatrien-1-ol. A mixture of dienynol (2.9 g, 0.014 mol), 1-propanol–water (1/1) (600 ml), zinc powder (200 g), and potassium cyanide (10.4 g, 0.16 mol) was stirred at room temperature for 24 hr under argon in the dark. The reaction product was filtered through celite, and the filtrate was extracted with Et_2O. After evaporation of the solvent, 2.6 g of trienol were obtained (90% crude yield); *ZE* purity (98%); *m/z*: 208 (M^+, 11%), IR: 3340, 1620, 1570, 1000, 935, 895, 740, 720, 695; ^{1}H NMR: 1.33 (m, 12H), 1.99 (m, 1H), 2.16 (m, 2H), 3.60 (t, 2H), 5.07 (dd, H^{14}), 5.20 (dd, $H^{14'}$), 5.46 (dt, H^9), 6.00 (ddt, H^{10}), 6.19 (dd, H^{12}), 6.41 (ddd, H^{13}), 6.51 (dd, H^{11}) $J_{H^{13}/H^{14'}}$ = 16.8, $J_{H^{11}/H^{12}}$ = 14.6, $J_{H^9/H^{10}}$ = 11, $J_{H^{10}/H^{11}}$ = 10.6, $J_{H^{12}/H^{13}}$ = 10.6,

$J_{H^{13}/H^{14}} = 10$, $J_{H^8/H^9} = 7.7$, $J_{H^{14}/H^{14'}} = 2$, $J_{H^8/H^{10}} = 1.5$; ^{13}C NMR: 62.4, 116.6, 128.4, 128.6, 132.9, 133.2, 137.2. Anal. calcd. for $C_{14}H_{24}O$: C, 80.71; H, 11.61. Found: C, 80.94; H, 11.45.

(Z,E)-1-Acetoxy-9,11,13-tetradecatriene. Ac_2O, 1.4 ml (15 mmol), was added to a stirred mixture of 1 g (5 mmol) of alcohol and 1.2 ml of pyridine. Stirring was maintained for 3 hr at room temperature, and the mixture was poured on crushed ice. After extraction with ether and evaporation of the solvent, 1.1 g of acetate were obtained (90% crude yield); *ZE* purity (98%); *m/z*: 250 (M^+, 10%), 79 (100%); IR: 1745, 1235; ^1H NMR: 1.32 (m, 12H), 2.02 (s, 3H), 2.16 (m, 2H), 4.04 (t, 2H). Data of the double-bond system are the same as those of trienol. ^{13}C NMR: 64.6, 116.85, 128.7, 128.8, 133.2, 133.3, 137.4, 170.8. Anal. calcd. for $C_{16}H_{26}O_2$: C, 76.75; H, 10.47. Found: C, 76.50; H, 10.36.

(Z,E)-9,11,13-Tetradecatrien-1-al. To a solution of alcohol, 1 g (5 mmol) in CH_2Cl_2 (20 ml), was added 5.6 g (15 mmol) of PDC (pyridinium dichromate). The reaction mixture was stirred at room temperature for 8 hr, mixed with Et_2O, and filtered through a small column packed with Florisil to give, after evaporation of solvents, the desired compound, 0.9 g (90% crude yield); *ZE* purity (98%); *m/z*: 206 (M^+, 6%), 70 (100%); IR: 2700, 1720; ^1H NMR: 1.31 (m, 10H), 2.15 (m, 2H), 2.40 (td, 2H), 9.72 (t, 1H) ($J = 1.75$). Data of the double-bond system are identical to those of trienol. ^{13}C NMR: 43.8, 116.7, 128.5, 128.6, 133.0, 133.15, 137.2, 203.3. Anal. calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75. Found: C, 81.71; H, 10.91.

Other Chemicals. The dienic compounds and (*Z*)-9,11-tetradecenyn-1-al (Z9,Yne11-14:Ald) were prepared as described in Ramiandrasoa and Tellier (1990). The other geometric isomers of trienic compounds, used in the identification work, were synthesized as described in Tellier et al. (1991) and Tellier (1991).

Electrophysiology

Electroantennograms were recorded on male *S. cecropia* secured in a styrofoam block. After a few antennal segments had been snipped off, the distal end of one antenna was inserted into the tip of the recording electrode. The neutral electrode was implanted in the neck of the insect. Both electrodes were glass capillaries filled with Roeder's saline (NaCl: 9.0 g/liter; KCl: 0.2 g/liter; glucose: 4.36 g/liter). Electrodes were connected to a WPI preamplifier through chloridized silver wires. The filtered signal (DC to 300 Hz) was fed into an oscilloscope and monitored directly on the screen.

To stimulate the antenna, air was puffed (0.5 sec; 1.5 liters/min) onto the antenna through a glass cartridge containing a piece of filter paper impregnated with 500 ng of synthetic compound. Ten compounds were tested, including

those found in gland extracts of female *S. cecropia*, and a number of analogs. All were synthesized in the laboratory, with an isomeric purity better than 98%. The response profiles to synthetic compounds were recorded on 10 males (five replicates only for the trienic aldehyde, acetate, and alcohol that had not been synthesized at the beginning of the EAG screening).

Single sensillum recordings were carried out on excised antennae, using the tip recording technique (Kaissling and Thorson, 1980; Lucas and Renou, 1989). The base of the antenna was inserted in a glass microelectrode filled with hemolymph saline (Kaissling and Thorson, 1980). The tip of a few sensilla trichodea were cut off with sharpened forceps, and the recording electrode, filled with receptor lymph saline, was slipped over the cut end of a single hair. The action potentials were filtered (150–5000 Hz), amplified ($\times 1000$), and recorded on an audio tape recorder (Revox B77). The recordings were then played back and digitized, with a 10-kHz conversion rate, by an A/D converter board (Dash 16 of Metrabyte) integrated in a PC microcomputer. The responses were analyzed using a specific program written in Asyst (Macmillan Software Company) language (Lucas and Renou, 1989).

The outlet of a Y-shaped glass tube was positioned 2 cm from the antenna, and a flow of humidified pure air (1.5 liters/min) was continuously blown over the antenna through one of the lateral branches. The stimulation cartridge consisted of a Pasteur pipet containing a piece of filter paper (0.5 cm^2) on which hexane extracts or hexane solutions of compounds were deposited. This cartridge was introduced in the main branch of the Y tube. Stimulation was achieved by blowing a puff of air (0.5 sec; 0.5 liters/min) through the cartridge. The same compounds as those used for EAG were assayed on 14 sensilla trichodea belonging to six different male moths.

Olfactometric Tests

The availability of tens of living pupae in the spring of 1989 enabled us to develop a laboratory-based bioassay of pheromones. As we had insufficient time to check the optimum conditions for wind-tunnel tests, we chose a dynamic, linear olfactometer (Sower et al., 1973; Zagatti et al., 1987), consisting of a glass tube (70 cm long, 3.5 cm diameter). Air was humidified by bubbling into water and heated to 25°C, then flowed into the tube at 1.5 liters/min. The olfactometer was situated in a room heated at 25°C and lighted by three incandescent red bulbs (40 W each).

The test started just at the beginning of the scotophase and lasted 1 hr. Eight virgin males (1 or 2 days old) were placed at the downwind end of the tube. Then the blend of synthetic compounds to be tested was deposited (1 μl) on a glass applicator at the upwind end of the tube. The males were scored during 3 min according to whether they exhibited any of the following behavior

patterns: (1) wing fanning, (2) orientation toward the source by walking through one half of the olfactometer length, and (3) contact with the source of attractant with or without copulation attempts. These behavior patterns always occurred in this order in a hierarchical sequence. Each male was tested only once, and 112 males were tested in 14 sets.

To test synthetic attractants, the compounds were diluted in hexane (Carlo Erba Analyticals RPE) and the blends were prepared to obtain the doses (in 1 μl hexane) shown in Table 1. These six blends were qualitatively the same as those used during the 1989 field trapping experiment in San Alberto (Table 2). In addition, the effect of natural pheromone was assayed by clipping off the pheromone glands of two calling females and crushing them immediately to be tested on the glass applicator.

The results were analyzed by a 7 $\times$ 2 chi-square test for global heterogeneity ($P < 0.05$), and then all blends or female glands were compared pairwise using a 2 $\times$ 2 chi-square test. As this method multiplies the degrees of freedom, the threshold of significance for the pairwise comparisons was fixed at $P < 0.01$, although the overall significance of the test was $P < 0.05$. The last step of the behavioral sequence (contacts with source) was not analyzed, due to a small number of responses.

Field Trapping

The first field-trapping experiments were conducted in August–October 1989 in San Alberto (estate of Indupalma S.A.). In the first part of this experiment, the efficiency of pheromone trapping was studied by using traps baited with virgin females. A trap containing two virgin females was hung 1.5 m above the ground on a palm tree. This palm tree was examined every week to check the number of living pupae on leaf number 17 and the number of eggs on 10 leaflets of leaf number 17. This is a standard method for monitoring populations of *S. cecropia* (Genty et al., 1978). Three traps were used simultaneously and the palm trees containing them subsequently sampled. The traps were made from plastic cans (1 gallon vol) from which two windows (10 $\times$ 5 cm) were cut. A small wire mesh cage was hung inside the trap in front of the windows, and the bottom of the trap was filled with water and detergent. Two 1-day old virgin females were held in the cages and replaced every two days. The trap catches were recorded every day.

The second part of this experiment was conducted simultaneously to compare the attractancy of synthetic chemicals. These chemicals were synthesized in the laboratory with an isomeric purity greater than 98%. Six blends were compared (Table 2). All tested blends were diluted in 1 ml hexane and loaded on methanol extracted rubber septa (SNL, Paris, France). The trap design was the same as in the virgin female trapping experiment, except that the pheromone

dispensers were hung inside the trap in front of the windows. The trap catches were recorded daily for one month, with three replicates of each blend. The pheromone dispensers were changed once, 18 days after the beginning of the experiment.

A second trapping campaign was scheduled in June 1992 in Tumaco (Nariño, south of Colombia) in a 3500-ha plantation (estate of Palmas de Tumaco Ltda.). Synthetic chemicals, dispenser, and trap design were the same as in San Alberto. Seven blends were compared (Table 3) with three replicates in a completely randomized block design. The trap catches were recorded daily for two weeks.

The results were submitted to one-way (San Alberto) or two-way (Tumaco) analysis of variance on data transformed by $\sqrt{(x + 0.5)}$ to reach homoscedasticity. The means were then compared by Newman-Keuls test with $P < 0.05$ (Dagnélie, 1975). As some traps caught both males and females, the differences between male and female catches were compared using Wilcoxon's randomization test for matched pairs (Siegel, 1956).

RESULTS

Pheromone Idenification

GC-MS analyses of the 557, 684, and 759 female gland extracts revealed the same chromatographic pattern. In addition to saturated and unsaturated hydrocarbons and fatty acids, GC-MS data (in electron impact mode) indicated

two 14-carbon aldehydes, one of them diunsaturated [*m/z* 41, 55, 67 (100%), 82, 95, 105, 208 ($M^+\cdot$; confirmed by CI-NH_3 with ions at *m/z* 209 and 226)] and the other triunsaturated [*m/z* 41, 55, 67, 79 (100%), 80, 91, 107, 206 ($M^+\cdot$; ions at *m/z* 207 and 224 in CI-NH_3)]. The corresponding 14-carbon acetates were also identified [one of them was diunsaturated with ions at *m/z* 43, 55, 67 (100%), 79, 82, 93, 110, 121, 192 (M-CH_3COOH) and 252 ($M^+\cdot$; ions at *m/z* 253 and 270 in CI-NH_3) and the other triunsaturated with ions at *m/z* 43, 55, 67, 79 (100%), 80, 91, 105, 119, and 250 ($M^+\cdot$; ions at *m/z* 251 and 268 in CI-NH_3)]. The diunsaturated aldehyde was identified by chemical ionization analysis using isobutane to determine the position of the double bonds (Einhorn et al., 1985). The mass spectrum exhibited various molecular species: $M^+\cdot$ (*m/z* 208, 22%), $(M + C_4H_9)^+$ (*m/z* 265, 4%), MH^+ (*m/z* 209, 91%), $(MH\text{-}H_2O)^+$ (*m/z* 191, 39%), and revealed the presence of abundant ions at *m/z* 71 (33%), 169 (100%), and 151 (60%), which were clearly related to a 9,11 position of the diethylenic system. The stereochemistry was assigned to (*Z,E*)-9,11 by comparison of the GC retention times with standards. Data on the trienic system were completely lacking at the beginning of our work. The mass spectrum could be assigned either to a triene or to a triple bond, Δ9,Yne11-enyne. The triene hypothesis of a conjugated system with a terminal double bond was suggested by comparing the mass spectrum of the natural product with spectra of several chemicals sharing the same trienic motif, already prepared in our laboratory as reaction intermediates during studies on moth pheromones. Finally, all possible isomers of (Δ,Δ)-9,11,13 and Δ9,Yne11 14-carbon aldehydes and acetates were synthesized, and comparison of GC retention times and mass spectra proved that the natural products were (*Z,E*)-9,11,13-tetradecatrienal and (*Z,E*)-9,11,13-tetradecatrienyl acetate. The extracts of pheromone glands of *S. cecropia* contained: (*Z,E*)-9,11-tetradecadienal (*Z*9,*E*11-14:Ald; 11%), (*Z,E*)-9,11,13-tetradecatrienal (*Z*9,*E*11,13-14:Ald; 67%), (*Z,E*)-9,11-tetradecadienyl acetate (*Z*9,*E*11-14:Ac; 5.5%) and (*Z,E*)-9,11,13-tetradecatrienyl acetate (*Z*9,*E*11,13-14:Ac, 16.5%).

Electrophysiology

The EAG screening demonstrated that the two aldehydes found in the female gland extracts were active on the antenna of male *S. cecropia* (Figure 2). The most active compound was the triene aldehyde, *Z*9,*E*11,13-14:Ald, which elicited an EAG response of 1.9 ± 0.7 mV (mean ± 95% confidence interval). The dienic aldehyde, *Z*9,*E*11-14:Ald, also elicited high-amplitude EAG (1.5 ± 0.5 mV). Responses to other compounds assayed, and in particular to the two acetates identified in the gland extracts, were all inferior to 0.7 mV.

The activity of 14 sensilla trichodea was recorded from six different males in response to 10 pheromone compounds and pheromone analogs. Sensilla trichodea could be separated into four different groups based on the response profiles of their sensory neurons (Figure 2). Sensilla 1–6 presented a firing

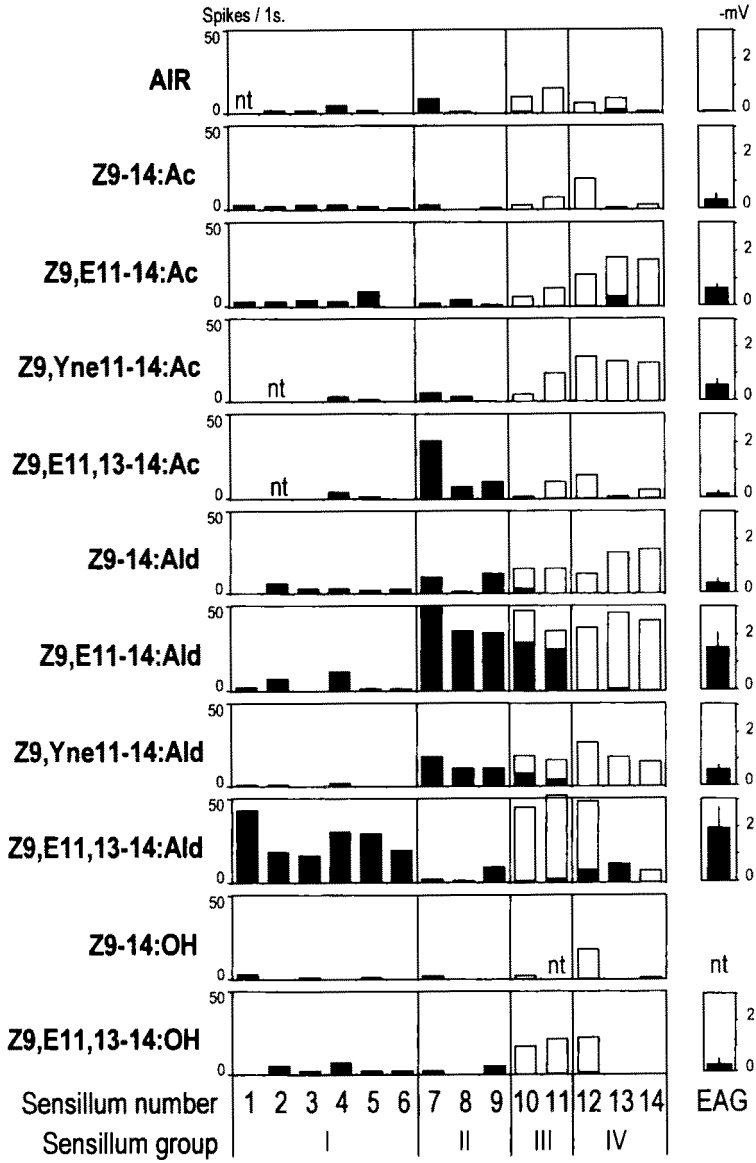

FIG. 2. Electroantennograms (EAG) and single sensillum recordings obtained from male *Stenoma cecropia* antennae stimulated by synthetic compounds. EAG are expressed as the mean (in millivolts) of 5–10 replicates. The vertical bars represent the 95% confidence interval of the mean. The single sensillum recordings were obtained from 14 sensilla trichodea belonging to six different male moths. Black bars: A cell activity; open bars: B cell activity (groups III and IV). Name of compounds were abridged as follows: Z9-, geometry and position of the double bond; Yne11-, triple bond; -14, chain length; OH, Ald, Ac, alcohol, aldehyde, and acetate, respectively; nt: compound not tested.

activity consisting of a single amplitude class of action potentials. Their firing activity was stimulated by Z9,E11,13-14:Ald. Responses to other compounds were not significant when compared to the air control. A second group, sensilla 7-9, presented a single class of action potentials and responded to the other EAG-active compound, Z9,E11-14:Ald. These sensilla were less specific than group I sensilla since they also weakly responded to Z9,E11,13-14:Ac and to Z9,Yne11-14:Ald. The firing activity of group III (sensilla 10 and 11) and group IV (sensilla 12-14) clearly consisted of two amplitude classes of action potentials, indicating the presence of at least two receptor neurons. In groups III and IV, the cells firing high-amplitude action potentials, up to 3 mV, are referred to as the A cells. Action potentials emitted by the other cells, referred to as B cells, were much smaller (50% of the amplitude of A cell action potentials). In group III sensilla, A cells clearly responded to Z9,E11-14:Ald and B cells to Z9,E11,13-14:Ald. The response profiles of sensilla from group IV were characterized by strong responses from B cells to Z9,E11-14:Ald and to a lesser exent to Z9,E11-14:Ac, Z9,Yne11-14:Ac, Z9-14:Ald and Z9,Yne11-14:Ald. In two out three of these sensilla, A cells responded weakly to Z9,E11,13-14:Ald.

Olfactometric Tests

The results are shown in Table 1. It appeared that two glands of virgin females were able to evoke wing fanning and orientation toward the odor source in male moths. The percentage of moths making contact with the source was very low (18.8%). Two blends of synthetic compounds evoked the same responses by virgin males as did female glands: a blend of Z9,E11-14:Ald, Z9,E11,13-14:Ald, Z9,E11-14:Ac, and Z9,E11,13-14:Ac and a blend of Z9,E11-14:Ald and Z9,E11,13-14:Ald.

Field Trapping

The results of the first trapping experiment (Figure 3) showed that the population levels were very high. The number of living pupae per leaf reached 30 at the beginning of the experiment. The emergence of adults, as shown by the decrease of pupa counts, occurred during the first days of September. By this time the number of unhatched eggs had increased and reached a maximum on September 8. These data suggest that the population of sexually active females was at its highest between September 3 and September 15, 1989.

The attractiveness of virgin females as bait was not correlated with these data. The number of males caught in traps was very small during the first two weeks of September, started increasing as late as September 18, and reached a maximum of 37 males/day/trap on September 20. The three female traps also

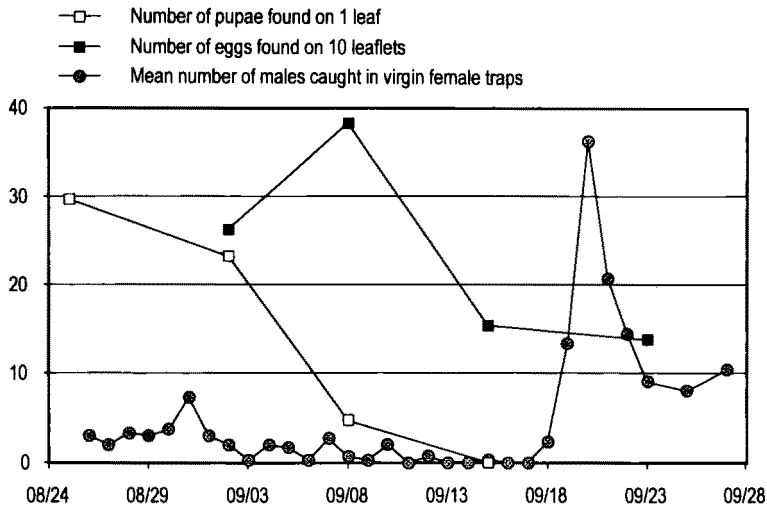

FIG. 3. Chronological catches of *Stenoma cecropia* males obtained with traps baited with two virgin females (mean of three traps) from September 25 to October 27, 1989 (San Alberto, central Colombia). The population levels were estimated by counting living pupae on leaf number 17 and counting unhatched eggs on 10 leaflets (of leaf number 17) on the trees from which the traps were hung (mean of three counts). The scale of the *y* axis is the same for the three curves.

caught females regularly throughout the month the experiment lasted, with an average of 0.25 females/day/trap.

The other part of this experiment was carried out at the same time and in the same habitat as virgin female trapping. It consisted of a comparison between different synthetic pheromone blends. The results (Table 2) showed that all traps caught female moths (average of 0.2 female/trap/day), with no significant differences between blends. Male and female catches in the same trap were significantly different when the traps were baited with blend SC5 (*Z*9,*E*11–14 : Ald, 50 μg, and *Z*9,*E*11,13–14 : Ald, 250 μg) or virgin females ($P = 0.031$). Blend SC5 caught significantly more males than the other blends but catches with this blend were five times lower than those obtained using the virgin females as bait.

The second trapping campaign was conducted in 1992 with a low *S. cecropia* population level that did not exceed one larva per leaf. Mono- or polyunsaturated aldehydes were tested along with the best blend of the 1989 experiment (SC5). The results (Table 3) showed that only males were caught. Blend SC11 caught four times more males than SC5 (Table 3). It consisted of the same blend of *Z*9,*E*11–14 : Ald and *Z*9,*E*11,13–14 : Ald at a load four times higher than

SC5. When tested separately (SC7 and SC8, Table 3) these aldehydes were not attractive.

DISCUSSION

Sex Pheromone of Stenoma cecropia

Four compounds were identified in the sex pheromone gland extracts of *Stenoma cecropia* females: a dienic and a trienic aldehyde, and the corresponding acetates. The electrophysiological study gave evidence for specific receptors to the aldehydes only. The olfactometric tests showed a similar level of response to female glands and to a blend containing the four synthetic compounds in a ratio close to that of female extracts. However, removal of the two acetates did not alter the response of males. In field-trapping experiments, blends containing the dienic and trienic aldehydes attracted males, whereas a four-component blend, which included the acetates, did not.

From these biological data it can be concluded that (*Z*,*E*)-9,11,13-tetradecatrienal and (*Z*,*E*)-9,11-tetradecadienal are components of the sex pheromone of *Stenoma cecropia*. The corresponding acetates do not seem to be involved in the pheromone communication system. They are probably precursors of the aldehydes in a way similar to the biosynthetic pathway described in *Choristoneura fumiferana*. In this tortricid moth, the pheromone components (*E*- and *Z*-11-tetradecenal) are biosynthesized de novo via Δ-11-tetradecen-1-ol and Δ-11-tetradecen-1-ol acetate. The amounts of Δ-11-tetradecen-1-ol acetate in female glands of *C. fumiferana* vary during the daily cycle as this acetate is used as a storage precursor of the pheromone and converted into the corresponding aldehyde just before pheromone emission (Morse and Meighen, 1984, 1986).

Traps baited with the best attractants in the present work caught fewer insects than traps baited with virgin females. This may mean that at least one component of the pheromone of *S. cecropia* remains unknown.

(*Z*,*E*)-9,11,13-Tetradecatrienal has been identified as a pheromone component of the carob moth *Ectomyelois ceratoniae* (Baker et al., 1989), which belongs to the family Pyralidae, a family not closely related to Elachistidae. This compound was also identified in another *Stenoma* species, *Stenoma decora*, a major pest of cocoa in Brazil (D. R. Hall, personal communication).

The phylogenetic relationships between families of the Gelechioidea remain puzzling. Minet (1989) included in the Elachistidae several genera formerly thought to belong to the Oecophoridae. Some of them are listed in a recent review of sex attractants (Arn et al., 1992): *Ethmia* spp. (Elachistidae: Ethminae), *Depressaria olerella* and *Agonopterix* spp. (Elachistidae: Depressariinae). None of them use aldehydes as sex attractants. Instead they use monoenic acetates or alcohols with chain lengths of 10–14 carbons. Thus, the chemotaxonomy

of sex pheromones does not seem to be promising for clarifying the status of this group.

Influence of Insect Density

The results of the field-trapping experiments raised questions about the influence of the population density on the effectiveness of sexual trapping. During the 1989 season, the population levels were very high. It can be seen in Figure 3 that the maximum number of sexually active females occurred between September 3 and September 15. The number of males caught during this period by the virgin female traps was very small (33 out of a total catch of 458). It began to increase after September 18, at a time when few females were likely to be unmated and calling for males.

It is generally admitted that catches in traps baited with synthetic attractants are not correlated with insect population levels at the highest levels of density (Cardé, 1979). To our knowledge, this has not been reported for traps baited with virgin females. These are expected to be very attractive, because the calling period of the caged females lasts 1 or 2 hr whereas the "free" females stop calling as soon as they mate. The lack of male catches during the early part of our experiment with *S. cecropia* suggests that the insects used other mate-searching systems than pheromone orientation when density was high. The movements of many moths in the vicinity of the traps may explain the number of drowned females (Table 2). It may also result in sexual encounters and subsequent matings.

The monitoring of pest populations with pheromones has now become a routine technique for plant protection in temperate countries. It is not yet widespread in the tropics (Zagatti, 1993), where different pest characteristics may result in a different approach to pest management programs.

Acknowledgments—This work was accomplished through the financial and technical support of Indupalma S.A. We are pleased to thank Dr. E. Andrade, general manager, and Ing. Manoloin Avila for field assistance. Palmas de Tumaco Ltda. helped us finish the work, and we are indebted to Drs. F. Bernal and F. Rodriguez. D. (Received July 26, 1995; accepted January 29, 1996)

Abstract—*Pluchea lanceolata*, an allelopathic perennial weed, has an extensive deep root and rhizome system. The objective of the present study was to determine the allelopathic potential of well water collected from weed-infested cultivated fields. Results indicate that well water recovered from *P. lanceolata*-infested cultivated fields inhibited the shoot growth of pea, chick pea, mustard, and wheat under greenhouse conditions. Two phenolic compounds, phenol and phloroglucinol, were isolated and identified from collected well water using UV spectroscopy. The allelopathic potential of the aqueous extract of the two compounds was determined by growth experiments with 10^{-4} M solutions of the compounds. As a consequence of repeated irrigation with well water from *P. lanceolata*-infested fields, higher levels of phenolics can accumulate in the soil, which may contribue to increased interference to crop plants. The present study is of significance since it cautions on the use of well water for irrigating cultivated fields infested with the perennial allelopathic weed (*P. lanceolata*) with dense subterranean systems and emphasizes the importance of controlling such weeds in cultivated fields.

Key Words—*pluchea lanceolata*, allelopathy, weed, phenol, phloroglucinol, well water.

INTRODUCTION

Pluchea lanceolata (DC) C. B. Clarke (Asteraceae) is a perennial weed of semiarid regions of India (Inderjit and Dakshini, 1990). *P. lanceolata* achieves its success by inhibiting the growth and establishment of crop plants through water-soluble phenolics released to the soil (Inderjit and Dakshini, 1990, 1992b).

*To whom correspondence should be addressed.

Farmers plow the above-ground parts of the weed while preparing fields for cultivation, and irrigation results in leaching of water-soluble phenolics into the soil (Inderjit and Dakshini, 1994b, 1996). The extensive subterranean roots and rhizomes (up to 80 ft deep) leach water-soluble phenolics to the soil (Inderjit and Dakshini, 1994c). Growth of *P. lanceolata* results in availability of water-soluble phenolics throughout the year. A flavonone (hesperidin), a dihydroflavonol (taxifolin 3-arabinoside), a flavonol (quercitrin), an isoflavonoid (formononetin 7-*O*-glucoside), and other phenolics, such as chlorogenic acid, phloroglucinol, and simple phenol, isolated from *P. lanceolata*-infested cultivated soils are potent allelochemicals (Inderjit and Dakshini, 1991, 1992a, 1994c, 1995a).

Irrigation of cultivated fields with well water is a common practice in northern India. Because of the extensive and deep root and rhizome system of *P. lanceolata* and its potential to leach water-soluble phenolics, we hypothesized that phenolics released by the weed may percolate through the soil profile to groundwater level. Thus with each irrigation, the weed not only cycles phenolics but the concentration of phenolics may also increase. The establishment of the relationship between the phenolics released by *P. lanceolata* and phytotoxicity of well water in the field should be of practical value in demonstrating strategies to control the weed's effect on crops. The objectives of the present study were: (1) to study the allelopathic potential of well water collected from fields infested with *P. lanceolata*; (2) to isolate, identify, and quantify the phenolic constituents responsible for the observed allelopathic potential; and (3) to test the allelopathic potential of isolated phenolic compounds.

METHODS AND MATERIALS

The cultivated fields, infested with the weed *P. lanceolata*, were irrigated with water from deep wells (50–75 ft) installed in the fields for 20–25 years (28°38′N, 77°12′E). Each well is a lined shaft sunk in the fields, and serves approximately 1 *ha* of cultivated land. The fields had been infested with the weed for 20 years. Water from three wells installed in these fields was collected in glass containers (Borosil) and refrigerated at 20°C. Additionally, well water from fields not infested with *P. lanceolata* was also collected and served as the controls. No *P. lanceolata* occurred in control fields based upon observations that revealed no *P. lanceolata* visible above the ground, and no roots or rhizomes of *P. lanceolata* were observed after digging the soils up to 4 ft depth.

Both weed-infested and weed-free cultivated fields had been subjected to similar agricultural practices. The surface texture of the soil was sandy loam (coarse sand, 6%; fine sand, 74%; silt, 9% and clay, 11%). The main crops cultivated in this region are radish (*Raphanus sativus*), wheat (*Triticum aesti-*

vum), mustard (*Brassica juncea*), chick pea (*Cicer arietinum*), and tomato (*Lycopersicon esculentum*). Common weeds in these areas are Mexican pricklepoppy (*Argemone mexicana*), common lambsquarters (*Chenopodium album*), field bindweed (*Convolvulus arvensis*), white sweetclover (*Melilotus alba*), calotrope (*Calotropis procera*), onionweed (*Asphodelus tenuifolius*), and sowthistle (*Sonchus arvensis*). The climate of this region is semiarid with a marked hot and dry summer (May–June, temperature 25–45°C), a dry and cold winter (December through mid-February, temperature 4–20°C), and the rainfall (July–September) is moderately low for India (600–1200 mm).

Cultivated fields were heavily infested with *P. lanceolata* (density, 15.9 $\pm$ 4.1 plants/m^2). The pH of the well water (7.7) from weed-infested fields ($N = 26$) was significantly ($P < 0.01$) lower than that of well water from weed-free cultivated fields (8.4).

Evaluation of Well Water for Allelopathic Response. The experiments were designed to study the effect of well water on the growth and establishment of crop plants. Ten seeds of radish (var. pusa chetaki), mustard (var. CV PR45), wheat (var. HD-2923), chick pea (var. H-208), tomato (var. pusa ruby), and turnip (*Brassica rapa* var. purple white top) were sown 2.5 cm deep in clay pots (1500 cm^3) filled with sandy loam soil. The soil had the following characteristics: pH, 7.87 $\pm$ 0.37; electrical conductivity, 231.5 $\pm$ 26.6 μmho/cm; organic matter, 5.54 $\pm$ 1.4 g/kg; organic nitrogen, 38 $\pm$ 7.4 mg/100 g; phosphate, 7.9 $\pm$ 3.2 mg/100 g; Ca, 910 $\pm$ 98.7 mg/100 g; Na, 23.7 $\pm$ 9.88 mg/100 g; Mg, 28.03 $\pm$ 4.08 mg/100 g; K, 33.8 $\pm$ 10.1 mg/100 g; and Zn, 0.300 $\pm$ 0.130 mg/100 g. These pots were kept in an experimental garden of the Department of Botany, University of Delhi. The pots were irrigated daily with 500 ml of well water from weed-infested fields (identified as treatments) or with well water from weed-free fields (identified as controls). A random block design was replicated three times (Panse and Sukhatme, 1967). The average day–night temperature was 25/14°C with average light conditions of 403 $\mu E/m^2/sec$. The emergence of the plumule from the soil by the end of the sixth day after sowing was the criterion for germination. Thereafter, the shoot length was recorded for three weeks. Data were analyzed through ANOVA.

Isolation, Identification and Quantification of Allelopathic Substances. Two liters of well water from weed-infested and weed-free fields were concentrated under vacuum and residues were extracted with 10 ml of methanol. These extracts were chromatographed on Whatman No. 3 (46 $\times$ 57 cm) paper and developed through descending chromatography using butanol–acetic acid–water (BAW, 4:1:5, upper phase) according to Harborne (1973). The developed chromatograms were scanned under UV prior to and after NH_3 treatment and the bands marked.

Each band was eluted in methanol, loaded again separately on Whatman No. 3, washed with distilled water (DW), and finally extracted with methanol.

Care was taken to avoid loss of the compounds during washing and elution. To confirm the purity of these compounds, each compound was spotted on Whatman No. 1 chromatographic paper and run in four solvents: DW, BAW, 15% acetic acid, and forestal (conc. HCl–acetic acid–water, 3:30:10 by volume) (Harborne, 1973). After confirming the purity of the compounds, each was eluted in methanol for spectral analysis, acid hydrolysis, and acid–base shifts (NaOH, $AlCl_3$, $AlCl_3$-HCl, NaOAc, NaOAc-H_3BO_3), if any, of the parent as well as the hydrolyzed fractions (Harborne, 1973; Van Sumare, 1989). To finally confirm the identification, isolated compounds were cochromatographed with authentic reference compounds and their spectral data matched. Two compounds, phenol and phloroglucinol, were quantified with reference to authentic reference compounds (Sigma, St. Louis, Missouri).

Allelopathic Effect of Compounds. Growth experiments were performed to determine the allelopathic potential of the two isolated compounds. The authentic reference compounds were initially dissolved in methanol, dried under vacuum, and then dissolved in water to a final concentration of 10^{-4} M, which is the lowest recommended effective concentration of allelochemicals used to assess phytotoxicity (Inderjit et al., 1995; Rice, 1984; Williams and Hoagland, 1982). The seeds of commonly grown cultivated crops such as radish (var. pusa chetaki), mustard (var. CV PR45), and tomato (pusa ruby) were selected for growth experiments. Fifty seeds (in triplicate) of the respective crop plants were placed on Whatman No. 1 filter paper moistened with 70 ml of 10^{-4} M solutions, with DW as control and placed in 15-cm-diameter Petri dishes. To maintain uniform moisture status in the Petri dishes, a cotton pad soaked in DW or compounds was placed below the filter paper. Root and shoot lengths were recorded every 24 hr for six days, but seedling lengths recorded on the sixth day are presented in the present study. The experiments were conducted at 25 ± 4°C; 373 μE/m^2/sec fluorescent light with a 16/8 light–dark period. The experiments were completely randomized and replicated three times. Data were pooled and analyzed through ANOVA.

RESULTS

Among the seeds tested, only germination of mustard was affected by well water from *P. lanceolata*-infested fields (Table 1). Compared to irrigation with well water from weed-free fields, shoot growth of mustard (31.7%), pea (61.5%), chick pea (36.7%), and wheat (26.9%) was reduced in plants irrigated with well water from weed-infested field (Table 1).

Two bands appeared on chromatograms loaded with well water from weed-infested fields, while no bands were detected on chromatograms loaded with extracts of well water from weed-free fields. These bands were identified as

TABLE 1. RESPONSE OF CROP PLANTS TO WELL WATER FROM *Pluchea lanceolata*-INFESTED CULTIVATED FIELDS

Crop plants	Response relative to control[a]	
	Germination (%)[b]	Shoot length (%)[c]
Wheat	93	−26.9[d]
Pea	50	−61.5[d]
Chick pea	109	−36.7[d]
Mustard	50[d]	−31.7[d]
Radish	96	+1.65
Turnip	107	−7.9

[d]Treatment means are different from control at $*P < 0.05$.

phenol and phlorglucinol through UV spectral studies (Table 2). The concentration of phloroglucinol in well water was 6.8 ± 0.60 mg/liter, while that of phenol was 2.7 ± 0.21 mg/liter (Table 2).

At a concentration of 10^{-4} M, phloroglucinol significantly ($P < 0.05$) inhibited shoot growth of mustard and tomato, while radish was not affected (Table 3). Phenol significantly ($P < 0.05$) inhibited the root growth of mustard and radish, but tomato was not affected (Table 3). Comparatively, shoot growth was more sensitive to phloroglucinol, while root growth was more sensitive to phenol.

DISCUSSION

The presence of phenol and phloroglucinol in well water and the inhibitory effects of well water from weed-infested fields and of phloroglucinol and phenol on crop plants demonstrate the allelopathic potential of well water from *P. lanceolata*-infested cultivated fields. Growth responses of seeds watered with well water from *P. lanceolata*-infested fields and responses of seeds subjected to two phenolic compounds (Table 3) varied with the seeds tested. Presently, even though the causes of such variation can not be explained, it is likely due to differences in seed size, seed permeability, differential uptake, and metabolism (Williams and Hoagland, 1982), thus leading to allelochemical selectivity.

Inderjit and Dakshini (1994c) isolated phenol and phloroglucinol from *P. lanceolata* roots and its associated soils. Since the weed has subterranean roots and rhizomes up to 80 ft in depth and irrigation in cultivated fields is frequent,

leaching of these compounds to groundwater levels is very likely. Inderjit and Dakshini (1994c) reported the concentration of phenol and phloroglucinol in aqueous leachates from *P. lanceolata* roots as 46.5 and 25.5 mg/liter, respectively. While these compounds were not detected from *P. lanceolata*-free cultivated soils, their concentration in *P. lanceolata*-infested soils varied from 5 $\times$ 10^{-3} to 10^{-6} M under field conditions (Inderjit and Dakshini, unpublished data). It is difficult to determine the exact bioactive concentrations of these compounds in soils under field conditions, because the compounds have been determined through the input of leaf leachates, root exudates, decomposing and leaching from plant parts, sorption to seeds and roots, fixation by soil components, and microbial activity (Blum and Shafer, 1988; Cheng, 1995; Dalton et al., 1983; Haider and Martin, 1975; Rice, 1984). Because of the uneven distribution of aboveground and subterranean parts of *P. lanceolata*, the concentration of these two compounds depends on the amount of roots and incorporated leaves present in soil pockets (Liebl and Worsham, 1983). Each irrigation probably contributes to additional leaching of chemicals. Even low concentrations of allelochemicals may significantly influence plant growth (Muller, 1966). Total phenolics of soil were higher in weed-infested cultivated fields (Inderjit and Dakshini, 1994a; 1996). This may be partly the result of frequent irrigation of cultivated fields with well water containing phenolics.

Flavonoids such as quercetin and quercitrin from *P. lanceolata* leaves, and hesperidin, taxifolin 3-arabinoside, formononetin 7-*O*-glucoside, and quercitrin from *P. lanceolata*-infested soils have been reported (Inderjit and Dakshini, 1991, 1992a, 1994c, 1995a). Flavonoids are known to degrade physically, chemically, and/or microbially in the soils yielding simple phenols and phloroglucinol (Chang et al., 1969; Henderson, 1956; Padron et al., 1960; Rice,

1984; Tanrisever et al., 1987). *P. lanceolata* has the potential to contribute phenol and phloroglucinol either through direct leaching or through degradation of flavonoids contributed to the soil by the weed. Although data on length of time phenol and phloroglucinol persist in soil or well water is essential to finally establish their allelopathic potential, it could be argued that the maintenance and periodic replenishment of these compounds in well water from *P. lanceolata*-infested fields is due to the perennial and evergreen nature of the weed. The allelopathic activity of phloroglucinol and phenol are well documented (Inderjit et al., 1995; Rice, 1984, Waller, 1987); however, the presence of phenol and phloroglucinol in well water from an allelopathic weed is demonstrated for the first time.

The lower pH of well water from weed-infested cultivated fields could be due to the presence of phenolics contributed by the plant (Dalton et al., 1983). The present study offers a reasonable explanation for the growth responses of crop plants to well water. Involvement of other factors such as nutrients and soil characteristics were minimized since the same soils were used in both control and treatments. Moisture stress was eliminated through watering each pot daily with well water from weed-infested (treatments) and weed-free cultivated field (controls). Repeated irrigation of cultivated fields with phenolic-loaded well water will not only degrade the quality of groundwater with time, but such a practice could result in making the fields unsuitable for cultivation. The present study is of significance since it serves as a caution on the use of well water for irrigating drawn from fields infested with the perennial allelopathic weed *P. lanceolata*. The results further emphasize the importance of controlling such weeds in cultivated fields.

(Received September 16, 1994; accepted January 30, 1996)

Abstract—Although within-plant variation in the nutrient and allelochemical composition of phloem sap has been invoked to explain patterns of host use by phloem-feeding insects, little is known about within-plant variation in phloem chemistry. Here I describe a new technique in which I use the green peach aphid, *Myzus persicae* Sulz., to investigate within-plant variation in the concentrations of chemicals in the phloem sap of black mustard, *Brassica nigra* (L.) Koch (Cruciferae). Relationships between the concentrations of chemicals in aphid diets and honeydew were established using honeydew from aphids fed on artificial diets with known concentrations of amino acids, sucrose, and sinigrin. These relationships were applied to honeydew from aphids fed on different aged leaves of black mustard to estimate the concentrations of the chemicals in phloem sap. Sinigrin concentration was estimated to be high (>10 mM) in phloem sap in young leaves, calling into question the prevailing opinion that phloem sap contains only low concentrations of allelochemicals. High concentrations may function as defenses against sap-feeding herbivores. Within-plant variation in phloem sap composition was high: (1) young leaves had high concentrations of nutrients (216 mM amino acids, 26% sugar) and sinigrin (>10 mM); (2) mature and presenescent leaves had lower concentrations of nutrients (77–83 mM amino acids, 19–20% sugar) and low concentrations of sinigrin (1–2 mM); and (3) senescing leaves had high concentrations of nutrients (199 mM amino acids, 25% sugar) and low concentrations of sinigrin (3 mM).

Key Words—*Myzus persicae*, *Brassica nigra*, phloem sap, glucosinolates, sinigrin, herbivore distributions, plant defense.

INTRODUCTION

Extensive variation in the nutrient and allelochemical composition of foliage has been documented within individual plants, and this variation has been proposed to explain spatial and temporal patterns of host use by leaf-chewing insects (e.g., Feeny, 1970; Mattson, 1980; Denno and McClure, 1983). Similar arguments have been made to explain host use by phloem-feeding insects (van Emden, 1972; Dixon, 1976; Wink et al., 1982; Whitham, 1983; Wink and Römer, 1986), but almost no information is available about within-plant variability in the chemistry of phloem sap. Phloem sap contains two macronutrients, amino acids and sugars (usually sucrose). Although concentrations of these chemicals in phloem sap have been measured in many plants (e.g., Becker, 1973; and cited in Ziegler, 1975; Zimmerman and Ziegler, 1975), their variability within individual plants has been investigated in only two species: *Salix acutifolia* (Mittler, 1958) and *Lupinus albus* (Pate et al., 1979). Similarly, the presence of allelochemicals in phloem sap is now firmly established (Molyneux et al., 1990; Montllor, 1991). However, within-plant variability in the concentrations of these chemicals in phloem sap has been assessed in only one species, *Lupinus consentinii* (Wink et al., 1982).

A major obstacle to examining within-plant variability in the chemical composition of phloem sap has been the difficulty of obtaining phloem sap in sufficient quantity and purity for chemical analysis. For example, the method that probably yields the purest samples, the severed-stylet technique (Kennedy and Mittler, 1953), suffers from three potentially serious drawbacks (Fisher and Frame, 1984). First, not all plant species exude phloem sap through severed homopteran stylets. Second, even among those species that do, yields are generally small, especially from herbaceous plants. Third, exudation rates can vary greatly depending on tissue age. This last drawback is especially serious, for if parts of a plant cannot be sampled, within-plant variability cannot be meaningfully assessed.

Here I present a new technique for estimating the composition of phloem sap from aphid honeydew. This technique is used to examine the exposure of the green peach aphid, *Myzus persicae* Sulz., to nutrients and allelochemicals in phloem sap of different aged leaves of black mustard, *Brassica nigra* (L.) Koch (Cruciferae). The green peach aphid is a polyphagous herbivore that feeds on phloem sap (Pollard, 1973; but see van Emdem et al., 1969), and black mustard is one of the aphid's host plants. The phloem sap of crucifers contains amino acids (Pate, 1973) and glucosinolates (Weber et al., 1986), a class of sulfur-containing allelochemicals. Natural populations of the aphid on crucifers occur mainly on the lower, senescing leaves of the plants (van Emden et al., 1969), and it has been hypothesized that this pattern results from within-plant

differences in the nutrient and allelochemical composition of phloem sap (van Emden, 1972).

METHODS AND MATERIALS

Aphids. Two clones of the green peach aphid were used. One was initiated from a single asexually reproducing female (virginopara) obtained from a greenhouse population feeding on tree tomato (*Cyphomandra crassicaulis*, Solanaceae) at the University of Michigan Matthaei Botanical Gardens. The clone was maintained for two years in the laboratory on radish seedlings (var. Red Devil B, Ferry-Morse Seed Co., Modesto, California) at room temperature under long day conditions (18L:6D). Voucher specimens are deposited at the Illinois State Natural History Survey, Champaign, Illinois. A second clone was obtained from a laboratory culture at the University of California at Berkeley, where it had been maintained for many years on radish (T. E. Mittler, personal communication.)

Honeydew Collection from Aphids Fed on Artificial Diets. I used chemically defined liquid diets developed for the green peach aphid (Kunkel, 1977; diet a) modified for a three-way factorial design with two levels of the amino acid mixture (61 and 122 mM), two levels of sucrose (10% and 20%), and three levels of sinigrin (Sigma) (0, 5, and 10 mM). These amino acid and sucrose concentrations were within the range of values recorded in the phloem sap of herbaceous plants (Barlow and Randolph, 1978; Fukumorita and Chino, 1982; Chino et al., 1986; Hayashi and Chino, 1986; Fisher and Gifford, 1986). Because no data on sinigrin concentrations in phloem sap were available, sinigrin concentrations were based on assays of tissue homogenates of black mustard (Feeny and Rosenberry, 1982). Sinigrin was the only glucosinolate in the present study to be detected by GLC in the honeydew of aphids feeding on black mustard (S. Merritt, unpublished data). This experiment was conducted using the University of Michigan clone.

I conducted a subsequent experiment to extend the range of amino acid concentrations present in the diet. This second experiment used the University of California clone because the University of Michigan clone was no longer available. The experiment was a one-way design with three levels of the amino acid mixture (92, 184, and 276 mM) and constant levels of sucrose (15%) and sinigrin (0%).

Diets were prepared according to Kunkel (1977), filtered (0.45 μm) into sterile plastic vials under a laminar-flow hood, and stored at $-60°C$ until needed. All diets were used within 14 days of mixing.

Diets were offered in Parafilm sachets consisting of about 0.2 ml of diet

sandwiched between two layers of stretched Parafilm (Mittler and Dadd, 1964). To minimize microbial contamination, sachets were prepared according to published procedures (Kunkel, 1977) with two modifications. First, sachets were prepared under a laminar-flow hood with diets dispensed from sterile glass pipets. Second, the Parafilm was not surface sterilized. Instead, only the paper-covered side of the Parafilm was allowed to contact the diet (i.e., form the inside of the sachet).

Aphids were reared in cages in an incubator (21°C, 16L:8D) for five days. Cages were made from 3-cm segments of acrylic tubing (3.81 cm OD, 3.18 cm ID) covered with a Parafilm sachet on the top and plastic cap on the bottom. Aphids fed upside down by piercing the Parafilm membrane and imbibing the liquid diet. Aphids were transferred to cages with fresh sachets every three days.

Each cage was started with five adult aphids that were allowed to feed and reproduce for five days, after which honeydew collection began. To collect honeydew, the bottom of each cage was removed, and the cage was nested in a 50-ml polypropylene beaker containing about 20 ml of technical grade (94%) 1-hexadecene (mp, 4°C; bp, 274°C) (Aldrich). Honeydew excreted by the aphids fell into the 1-hexadecene in the beaker and accumulated below the surface, which prevented honeydew evaporation so that solute concentrations could be measured. Honeydew from each cage was removed daily with a plastic micropipet tip, pooled with honeydew collected previously from the same cage, and stored under 1-hexadecene at −60°C until chemical analysis. About 0.1–0.2 ml of honeydew was recovered from each cage in six days of collection.

Honeydew Collection from Aphids Fed on Black Mustard. Black mustard plants were grown from seed (obtained from V & J Seed Farms, Woodstock, Illinois) under natural light from December to March in a greenhouse at the University of Michigan Matthaei Botanical Gardens. Plants were grown individually in 20.3-cm pots in potting soil (Fison's Sunshine Mix No. 4), watered daily, and fertilized every two weeks. After the plants had bolted, aphids were placed on leaves of four developmental stages on each plant: (1) young actively growing leaves; (2) mature leaves (dark green); (3) presenescent leaves (light green); and (4) senescent leaves (yellow-green to yellow). To collect honeydew, a plastic cup containing 1-hexadecene was positioned under each aphid-infested leaf. Each cup was supported by an acrylic ring that was attached to a ring stand by a steel rod. Honeydew from each leaf was collected as described above, pooled with honeydew collected previously from the same leaf, and stored under 1-hexadecene at −20°C until chemical analysis. About 0.2–0.3 ml of honeydew was recovered from each leaf in seven days of collection.

Chemical Analysis of Honeydew. The amino acid concentration in honeydew was measured colorimetrically (Coleman Junior Spectrophotometer, model 6C; or Sequoia-Turner, model 340) by the ninhydrin method (Spies, 1957). Concentrations were expressed in asparagine equivalents because asparagine was

the dominant amino acid in the artificial diets (Kunkel, 1977) and is often present in high concentration relative to other amino acids in the phloem sap of herbaceous plants (e.g., Pate et al., 1974; Barlow and Randolph, 1978; Fukumorita and Chino, 1982; Wink and Witte, 1984; Hayashi and Chino, 1986).

The sugar concentration in honeydew was measured colorimetrically (Coleman Junior Spectrophotometer, model 6C) by the phenol–sulfuric acid method (Hodge and Hofreiter, 1962). Sugar concentrations were expressed in sucrose equivalents because sucrose was the sugar in the artificial diets (Kunkel, 1977) and is the dominant carbohydrate in the phloem sap of herbaceous plants (e.g., Pate et al., 1974; Barlow and Randolph, 1978; Fukumorita and Chino, 1982; Hayashi and Chino, 1986), including crucifers (Pate, 1973).

Glucosinolate concentrations in honeydew were measured by gas chromatography (GC) of isothiocyanate hydrolysis products following the procedures of Rodman (1978) and Blau and Hanscom (1986). Phosphate buffer, ascorbate, and myrosinase were prepared according to Rodman (1978). Measured honeydew samples (0.025–0.125 ml) were placed into 1/2-dram shell vials along with phosphate buffer (0.450 ml), ascorbate solution (0.020 ml), myrosinase extract (0.010 ml), and methylene chloride (0.500 ml), which contained 0.01% *n*-undecane as an internal standard. Vials were capped and shaken gently at room temperature for 12 hr, after which the methylene chloride phase, without concentration, was subjected to analysis on a Hewlett-Packard 5890 gas chromatograph furnished with a 30-m column coated with a 100% methyl polysiloxane stationary phase. Both injector and FID temperatures were 250°C. Oven temperature was maintained at 90°C for 1 min and then increased at 50°C/min. Glucosinolates were identified and quantified by comparing retention times and peak areas with standards. Identifications were confirmed by GC-MS. Up to 75 samples per day were analyzed following this procedure.

Mean extraction efficiency of sinigrin standards was 80.6% (SD = 10.9%, $N = 35$). To avoid underestimating sinigrin concentrations in honeydew, estimates were based on a standard curve.

Statistical Analysis. All statistical analyses were done using SYSTAT (Wilkinson, 1990). Stepwise multiple linear regression was performed on various combinations of the independent variables (i.e., concentrations of chemicals in the honeydew), both transformed and untransformed, to generate equations for estimating concentrations of amino acids, sugar, and sinigrin in artificial diets from concentrations of these chemicals in aphid honeydew. These regressions are for predictive purposes only and are not meant to characterize mechanistic relationships. Ideally, a range of concentrations of diet components should be used to reliably characterize the relationship between aphid diets and honeydew. However, because the experiment was a factorial design, only two or three levels of diet components were feasible. As a result, some precision will be lost when estimating the concentrations of chemicals in phloem sap using these

equations. Furthermore, estimated concentration of sinigrin in young leaves was far higher than the highest diet concentration used to generate the equations; therefore, the highest diet concentration is presented as a conservative estimate of the concentration present, assuming a monotonically increasing relationship.

Estimated concentrations of amino acids in phloem sap were log transformed to obtain homogeneous variances, after which pairwise comparisons were made using a Tukey HSD test. Variances in the estimated concentrations of sugars in phloem sap could not be made homogeneous, so pairwise comparisons were made using Mann-Whitney U tests with alpha adjusted to 0.008 (0.05/6) for multiple comparisons.

Pairwise comparisons of means for estimated levels of sinigrin were tested using two-sample t tests when both values were within the range of diet concentrations used to generate the equations. When one of the values has higher than the highest diet concentration used, comparisons were done using one-sample t tests with the highest diet concentration (10 mM) used as the known mean. Estimated concentrations of sinigrin in the phloem sap of mature, presenescent, and senescing leaves were log $(X + 1)$ transformed to satisfy the assumptions of normality and homogeneity of variance. Alpha was adjusted to 0.008 (0.05/6) for multiple comparisons.

RESULTS

To estimate the composition of diets from the composition of honeydew, the following equations were generated relating the concentrations of amino acids (AA), sugar (SU), and sinigrin (SI) measured in the honeydew (h) of aphids fed on artificial diets (hAA, hSU, hSI, respectively) with the dietary (d) concentrations of these chemicals (dAA, dSU, dSI) (Table 1). In the parentheses below each equation is the range of concentrations in the diet component over which these equations apply and the proportion of the variance in the diet component explained by the equations (i.e., r^2).

$$dAA\ [\text{mM}] = 24.6 + 28.3\ (hAA\ [\text{mM}])^{1/2}$$

(range: 61–276 mM; $r^2 = 0.968$)

$$dSU\ [\%] = -4.05 + 4.59\ (hSU\ [\%])^{1/2} + 1.81\ (hAA\ [\text{mM}])^{1/2}$$

(range: 10–20%; $r^2 = 0.961$)

$$dSI\ [\text{mM}] = 0.438 + 0.405\ (hSI\ [\text{mM}])\ (hSU\ [\text{mM}])^{1/2}$$

(range: 0–10 mM; $r^2 = 0.940$)

TABLE 1. CONCENTRATIONS OF AMINO ACIDS, SUGARS, AND SINIGRIN IN HONEYDEW FROM APHIDS FED ON ARTIFICIAL DIETS

Diet concentration			Honeydew concentration (mean ± SEM)[a]

TABLE 3. ESTIMATED CONCENTRATIONS OF AMINO ACIDS, SUGARS, AND SINIGRIN IN PHLOEM SAP OF BLACK MUSTARD

Leaf age	Estimated Honeydew Concentration (mean and 95% CI)[a]			
	Amino acids (mM)[b]	Sugars (%)[c]	Sinigrin (mM)[d]	N
Young	215.7a (167.5–277.8)	25.8a (23.0–28.6)	>10.00a	9
Mature	83.4b (71.3–97.6)	19.8b (19.0–20.5)	1.66bc (1.13–2.32)	10
Presenescent	77.0b (69.1–85.9)	19.2b (18.4–20.0)	0.96c (0.58–1.43)	10
Senescing	198.5a (148.6–265.3)	25.1a (22.6–27.5)	3.02b (1.75–4.88)	10

[a] Means in a column followed by different letters differ at $P < 0.05$.
[b] Asparagine equivalents back-transformed from log (X).
[c] Sucrose equivalents.
[d] Back-transformed from log ($X + 1$). Estimates for sinigrin in young leaves were far higher than the highest diet concentration used to generate the equations; therefore, the highest diet concentration is presented as a conservative estimate of the concentration present, assuming a monotonically increasing relationship.

Applying these equations to the concentrations of chemicals measured in honeydew of aphids fed on black mustard (Table 2) gave estimates of the concentrations of chemicals in phloem sap (Table 3). Phloem sap in young and senescing leaves contained higher amino acid and sugar concentrations than phloem sap in mature and presenescent leaves. A high concentration of sinigrin occurred only in phloem sap in young leaves. Although the concentration of sinigrin was slightly higher in phloem sap in senescing leaves than in mature and presenescent leaves, sinigrin concentrations in these leaves were far lower than those in young leaves.

Based on the nutrient and allelochemical profile of their phloem sap, leaves of black mustard fell into three classes: (1) young leaves with high concentrations of nutrients and sinigrin, (2) mature and presenescent leaves with low concentrations of nutrients and sinigrin, and (3) sensecing leaves with high concentrations of nutrients and low concentrations of sinigrin.

DISCUSSION

The conclusions of this study rest on the reliability of the estimate of phloem sap composition. Two lines of evidence suggest that the estimates are reasonable. First, the artificial diet experiment shows that diet composition can

be accurately estimated from honeydew composition. Indeed, the regressions explained 94% or more of the variance in diet concentrations of amino acids, sucrose, and sinigrin. Second, the estimates in the present study compare favorably with values obtained in other studies. The estimated concentrations of amino acids in the phloem sap of black mustard (77–216 mM) (Table 3) are similar to those measured in the phloem sap of a variety of herbaceous plant species (112–1600 mM) (Barlow and Randolph, 1978; Fukumorita and Chino, 1982; Pate et al., 1984; Fisher and Gifford, 1986; Weibull, 1988). Similarly, estimated sugar concentrations (19.1–25.8%) (Table 3) fall within the range recorded in herbaceous plants (4.3–30.8%) (e.g., Pate, 1973; Pate et al., 1974; Fukumorita and Chino, 1982; Fisher and Gifford, 1986; Ohshima et al., 1990). However, feeding by aphids has been shown to enhance the translocation of sugars into infested leaves, and thus it is possible that these estimates are high (Way and Cammell, 1970).

Nevertheless, there remains some concern about the accuracy of the estimates of phloem sap composition both because the equations are based on very few levels of diet components and because some estimates fall far outside the range of concentrations over which the equations apply. In addition, the estimation procedure is sensitive to the presence of nontarget compounds that give positive reactions with the assays. This latter consideration is unlikely to be important for sinigrin because of the high specificity of the GC test for this chemical. However, the ninhydrin and phenol–sulfuric acid assays are not as specific, and it is known that phloem sap contains a number of chemicals that give positive reactions with each (e.g., nonprotein amino acids, nucleotides for ninhydrin assay; flavonoids, phenolics, complex carbohydrates for phenol–sulfuric assay). The estimation procedure assumes the presence of insignificant amounts of these interfering chemicals, and estimates will be inflated depending on the levels of these chemicals in the phloem sap and their metabolism in the gut of aphids.

It is generally believed that phloem sap contains only low concentrations of allelochemicals (Mullin, 1986; Dreyer and Campbell, 1987; Klingauf, 1987a; Brattsten, 1988). However, the estimates in this study of the concentrations of sinigrin in phloem sap in young leaves (>10.00 mM, i.e., >0.416% fresh weight) are as high as those measured in foliage of black mustard (0.165–0.632% fresh weight) (Feeny and Rosenberry, 1982). Indeed, the sinigrin concentration in phloem sap in young leaves might be even higher because the highest diet concentration is presented as a conservative estimate of the concentration present. Thus, the present study adds to the growing body of evidence documenting high concentrations of allelochemicals in phloem sap (Wink et al., 1982; Wink and Witte, 1984) and in related vascular exudates (Treutter et al., 1985; Niemeyer, 1988; Peng and Miles, 1991).

The assumption that allelochemicals occur at low concentrations in phloem

sap has led many authors to conclude that phloem-borne allelochemicals do not act as defenses against sap-feeders (Mullin, 1986; Dreyer and Campbell, 1987; Klingauf, 1987a; Brattsten, 1988). However, the presence of high allelochemical concentrations indicates that this conclusion needs to be reconsidered. Furthermore, the occurrence of within-plant variability in allelochemical concentrations in phloem sap suggests that some plant parts may be better defended than others. For example, the high sinigrin concentration in young leaves implies that they will be better defended against nonadapted sap-feeding herbivores than will mature, presenescent, or senescent leaves. Similar within-plant variability was also documented in a species of lupine, *Lupinus consentinii*, in which it was found that phloem sap from fruits contained over three times the alkaloid concentration as phloem sap in stems (Wink et al., 1982). These data support the hypothesis that young leaves should be better defended against herbivores because they have higher relative fitness value to the plant than do mature, presenescent, and senescing leaves (McKey, 1979; Rhoades, 1979).

Nutrient concentrations in phloem sap also varied within plants. Young and senescent leaves of black mustard contained higher amino nitrogen and sugar than did mature and presenescent leaves (Table 3). Similar patterns have been reported for nitrogen in phloem sap. Phloem sap in young and senescing foliage of *Salix acutifolia* contains about three times the nitrogen as phloem sap of mature foliage (Mittler, 1958). Likewise, phloem exudate from growing tissue (stem tops, developing fruits) of *Lupinus albus* contains about 1.7 times the amino nitrogen as exudate from mature leaves (Pate et al., 1979). Moreover, as mature leaves senesce, amino nitrogen content increases 1.7 times (Pate et al. 1979). This pattern of high amino nitrogen concentration in phloem in senescing leaves probably arises from the breakdown of leaf proteins and subsequent translocation back to the plant of the resulting amino acid components prior to leaf abscission (Stoddart and Thomas, 1982). Pate et al. (1979) also examined within-plant variation in sucrose concentrations. In contrast to the present study, concentrations in exudate from growing tissue of *Lupinus albus* were lower (0.7–0.8 times) than in exudate from mature leaves.

The within-plant variability in phloem sap composition documented here may affect the performance and feeding preferences of sap-feeding herbivores. Numerous studies have shown that variation in dietary concentrations of amino acids and sucrose affects aphid growth, survival, and reproduction (reviewed in Klingauf, 1987a). Allelochemicals too can alter food quality for aphids, acting as arrestants, deterrents, or phagostimulants (see references in Klingauf, 1987b; Risebrow and Dixon, 1987; Montllor, 1991). In plants, variability in these chemicals will make some feeding sites more suitable than others. For example, by feeding on senescing leaves of black mustard, a phloem-feeding insect would simultaneously maximize its nutrient intake and minimize its exposure to sinigrin. This explanation appears to account for the occurrence of highest densities

of the green peach aphid on senescing leaves of crucifers (van Emden et al. 1969). Within-plant variation in phloem chemistry may similarly explain some of the patterns of host use seen in other phloem-feeding insects (Dixon, 1976; Wink et al. 1982; Whitham, 1983; Wink and Römer, 1986).

Acknowledgments—I thank T. Mittler for providing a clone of aphids and D. Voegtlin for identifying them. I also thank C. Bach, G. Estabrook, H. Kirkpatrick, M. Martin, B. Rathcke, and one anonymous reviewer for insightful criticism of this manuscript, and P. Knochel for the use of the gas chromatograph. Partial funding for this research was provided by a Sigma Xi Grant-in-Aid-of-Research and by the University of Michigan Rackham School of Graduate Studies.

(Received October 16, 1995; accepted February 2, 1996)

Abstract—Tall larkspur (*Delphinium* spp.) is a serious toxic plant problem on western U.S. ranges. The major toxins in tall larkspur are methyllycaconitine (MLA) and 14-deacetylnudicauline (14-DAN); the sum of both is termed the toxic alkaloid concentration. Toxic alkaloids comprise about 20–50% of the total alkaloid concentration in tall larkspur. Toxic and total alkaloid concentration generally declines with maturity, whereas cattle and sheep consumption of larkspur typically increases with plant maturity. We hypothesized that cattle and sheep consumption of tall larkspur was negatively related to higher concentrations of total or toxic alkaloid. We compared consumption of several collections of dried, ground larkspur and fresh larkspur in a series of trials. In another trial, a crude alkaloid fraction was extracted with ethanol, added to alfalfa hay, and consumption compared to untreated alfalfa hay, alcohol-treated hay, and the essentially alkaloid-free plant residue. In all cases we correlated amounts eaten with total and toxic alkaloid concentration. A grazing trial was also conducted to relate larkspur consumption over time to alkaloid concentrations. Total alkaloid concentrations in dried, whole-plant collections ranged from 9.3 to 38.8 mg/g of dry weight, whereas toxic alkaloid concentrations varied from 0.0 to 7.1 mg/g. In one pen trial, cattle preferred a larkspur collection ($P < 0.01$) that contained no toxic alkaloids but had a high total alkaloid concentration (39 mg/g). There was no correlation ($P > 0.05$), however, between concentrations of total or toxic alkaloids and amount of dry plant consumed in this or any other trial. Conversely, sheep consumption tended to be negatively influenced by total and toxic alkaloid concentration ($P \leq 0.08$). In the trials with extract, cattle preferred the alcohol-treated hay and rejected the alkaloid-free residue ($P < 0.01$), whereas the alkaloid-

treated hay was of intermediate acceptability. Cattle preferred the alkaloid-treated hay over the alkaloid-free residue, indicating that alkaloids did not deter consumption. Conversely, the alkaloid-treated hay was less preferred than either untreated or alcohol-treated hay, suggesting a negative effect on acceptability. There was no correlation between alkaloid concentration and amount of treated feed eaten. In field trials, the amount of composited, fresh leaves or flowers eaten by cattle was influenced by plant part ($P = 0.04$), but was not related ($P > 0.05$) to alkaloid concentration. Cattle preferred leaves over flowers when offered individual plants differing in phenological stage and/or amount of shade, but alkaloid concentration was not related to consumption. We conclude that knowledge of the concentration of total or toxic alkaloid in tall larkspur will give little or no indication of plant acceptability to cattle. Even though accurate predictions can be made about the potential toxicity of larkspur based on the concentration of toxic alkaloids, predictions about consumption must be based primarily on plant phenology.

Key Words—Plant toxins, palatability, diterpenoid alkaloids, methyllycaconitine, *Delphinium* spp.

INTRODUCTION

Tall larkspur (*Delphinium* spp.) is a serious toxic plant problem on western U.S. ranges. Cattle grazing summer ranges sometimes consume large quantities (>30% of diets) of tall larkspur (Pfister et al., 1988a,b) and are often fatally poisoned as a result. Death losses average 5% and may exceed 15% each year on grazing allotments where larkspur is prevalent.

The major toxins in tall larkspur are the diterpenoid alkaloids methyllycaconitine (MLA) and 14-deacetylnudicauline (14-DAN) (Manner et al., 1993). Collectively, these two alkaloids account for about 90% of the toxicity of tall larkspur (Manners and Panter, unpublished data, 1995). These toxins block acetylcholine receptors in the central and peripheral nervous systems, resulting in muscular paralysis and eventually death (Dobelis et al., 1993). Tall larkspur contains other diterpenoid alkaloids in varying quantities (e.g., deltaline), but these other alkaloids are relatively nontoxic (Manners et al., 1993). Thus, in examining the alkaloid concentration of MLA and 14-DAN, the sum of these two toxic alkaloids (MLA + 14-DAN) are termed the toxic alkaloid concentration, and the combined concentration of all alkaloids are the total alkaloids.

The toxic and total alkaloid concentration in leaves generally declines as plants mature (Ralphs et al. 1988; Pfister et al., 1994a), whereas cattle and sheep consumption usually increases with plant maturity (Pfister et al., 1988a,b; Pfister and Manners, 1991, 1995; Ralphs et al., 1991; Ralphs and Olsen, 1992). Based on this inverse relationship, we hypothesized that toxic or total alkaloid concentration negatively influences the acceptability of tall larkspur to cattle and sheep. Our objective in this study was to test this hypothesis using both dried and fresh tall larkspur plant in a series of pen and field trials.

METHODS AND MATERIALS

Cattle Trials

Dried Plant Pen Trials (Trials 1 and 2). Entire tall larkspur plants (*Delphinium barbeyi* and *D. occidentale*) were harvested at various phenological stages (Table 1), air-dried at 25°C, ground to pass a 2-mm screen in a Wiley mill, and stored in sealed plastic bags at 16°C until use. Larkspur alkaloids are stable indefinitely under these conditions. In trial 1, we used ground larkspur collected during 1989, whereas in trial 2 we used ground larkspur collected over a four-year period. We ground the larkspur in order to offer homogenous plant material to subjects and to ensure that subjects could not select for specific plant parts. In both trials, larkspur material was collected at different stages of maturity and/or locations in order to maximize potential differences in alkaloid concentration, since immature larkspur generally contains the highest concentration of total and toxic alkaloids. Ground plant material was subsampled for alkaloid analysis in trials 1 and 2. We hypothesized that immature larkspur would be less acceptable to cattle than mature plant because of a higher alkaloid concentration.

Four yearling Hereford × Angus heifers (290 kg) were used during the spring of 1992 to evaluate the acceptability of the ground larkspur. Animals were group fed ground (2-mm screen) alfalfa hay for 21 days to habituate them to ground feed. Cattle were individually trained in the test procedure for four days. Each subject was given several opportunities to eat small amounts (about 100 g) of rolled barley, and later ground alfalfa, from four feed pans evenly spaced along the fence on one side of the pen. The 36- × 18- × 15-cm (length × width × depth) test pans were placed in specially constructed frames that hooked into the fence in the animal's pen. Animals had free access to all pans for 5 min. The subjects quickly learned to move from pan to pan, eating the small amount of feed in each pan. During testing, animals were fasted until mid-morning when they were tested; they were fed their basal ration of alfalfa hay at midday.

We determined in pilot tests that cattle could consume about 300–500 g of ground alfalfa hay during 5-min test periods. In the test procedure, about 500 g of larkspur material was weighed into each pan, and after an overnight fast, individual animals were offered all four choices simultaneously in the pans for 5 min. Each day the larkspur collections were allocated to a different position in the pen, and each test was run for either three or four consecutive days. Cattle must ingest 8–11 mg of toxic alkaloids per kilogram body weight within a couple of hours for subclinical toxicosis to occur (Pfister et al., 1994b), and animals did not eat enough larkspur to approach this toxic threshold.

Multiple 4 × 4 Latin squares were used initially to assess preference for four different larkspur collections (Borman et al., 1991). Each animal in a pen

TABLE 1. LARKSPUR SPECIES OR FEED TYPE, PHENOLOGICAL STAGE, HARVEST DATE, LOCATION OF PLANT COLLECTION, AND PHYSICAL FORM OFFERED TO CATTLE OR SHEEP DURING ACCEPTABILITY TRIALS.

Species or feed	Phenological stage	Harvest date	Location	Form offered
Trial 1: Cattle and sheep				
Delphinium occidentale	vegetative	6/21/1989	Oakley, ID	air-dried, ground
Delphinium occidentale	flower	7/18/1989	Oakley, ID	air-dried, ground
Delphinium barbeyi	vegetative	7/1/1989	Manti, UT	air-dried, ground
Delphinium barbeyi	flower	8/15/1989	Manti, UT	air-dried, ground
Trial 2				
Delphinium barbeyi	pod	8/25/1986	Manti, UT	air-dried, ground
Delphinium barbeyi	flower	8/12/1987	Manti, UT	air-dried, ground
Delphinium barbeyi	vegetative	7/6/1989	Manti, UT	air-dried, ground
Delphinium barbeyi	flower	8/5/1990	Manti, UT	air-dried, ground
Trial 3				
D. barbeyi extracted residue[a]	flower	7/93	Manti, UT	air-dried, ground
D. barbeyi crude extract[b]	flower	7/93	Manti, UT	mixed with ground hay
Alfalfa + EtOH[c]				air-dried, ground hay
Alfalfa untreated				air-dried, ground hay

Trial 4				
Delphinium barbeyi	full flower[d]	7/16/92	Yampa, CO	fresh, composited flowers
Delphinium barbeyi	early flower[e]	7/16/92	Yampa, CO	fresh, composited leaves
Delphinium barbeyi	early flower	7/16/92	Yampa, CO	fresh, composited flowers
Delphinium barbeyi	full flower	7/16/92	Yampa, CO	fresh, composited leaves
Trial 5				
D. barbeyi plant 1	full flower	7/17/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 2	early flower	7/17/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 3	full flower	7/17/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 4	early flower	7/17/92	Yampa, CO	fresh, cut stalks
Trial 6				
D. barbeyi plant 1	full flower (shaded)	8/7/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 2	full flower (shaded)	8/7/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 3	full flower (no shade)	8/7/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 4	full flower (no shade)	8/7/92	Yampa, CO	fresh, cut stalks
Trial 7				
D. barbeyi plant 1	full pod[f] (no shade)	8/19/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 2	full pod (shaded)	8/19/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 3	early pod[g] (shaded)	8/19/92	Yampa, CO	fresh, cut stalks
D. barbeyi plant 4	full pod (no shade)	8/19/92	Yampa, CO	fresh, cut stalks

[a] Larkspur plant residue was the material remaining after extraction with ethanol
[b] Crude extract was extracted, tar-like material; the extract was mixed with ground alfalfa hay
[c] Ethanol was mixed with ground alfalfa hay, then hay was air-dried.
[d] Flowering racemes fully elongated; sepals fully opened and conspicuous
[e] Flowering racemes fully elongated; sepals closed- not visible or inconspicuous
[f] Pods fully developed
[g] Pods partially formed; some flower parts visible

constituted a complete Latin square, with factors: animal (i.e., square), four positions within the pen, four days, and four different larkspur collections (Table 1). After the initial 4 × 4 Latin square was completed for trial 1, the plant material with the highest ranking (i.e., most acceptable) was eliminated, and the test was repeated using three randomly selected animals in a 3 × 3 Latin square; this elimination and retesting procedure was not done during trial 2. We retested to determine if acceptability of the remaining choices was consistent with previous trials.

Larkspur Extract Trial (Trial 3). This trial with ground plant tissue was conducted to assess the acceptability of tall larkspur with the alkaloid fraction removed and to determine if this extracted crude fraction was acceptable when added to alfalfa hay. We hypothesized that cattle would accept the alkaloid-free tall larkspur residue and that cattle would not accept the alfalfa hay when mixed with the crude alkaloid-rich extract. Tall larkspur (*D. barbeyi*) plants were collected during August 1993 near Manti, Utah, on the Wasatch Plateau at about 3000 m elevation, dried at 20°C, and ground to pass a 2-mm screen. Plant material (3.3 kg air-dry weight) was exhaustively extracted with 95% ethanol (EtOH) for four days using a large Soxhlet apparatus to remove all alkaloid compounds. The solvent was removed from the crude alkaloid extract in a rotary evaporator. The tarlike crude alkaloid extract was reconstituted with saline at 3.25 ml/g of extract. The crude extract was evenly applied to 3.3 kg of ground (2-mm screen) alfalfa hay, and air-dried at 20°C for four days. This trial had two controls: untreated, ground (2-mm screen) alfalfa hay and ground alfalfa hay treated with 95% EtOH at 0.75 ml/g of hay. The EtOH was evenly mixed with the hay until all the hay was moist, then the EtOH hay was allowed to dry for four days at 20°C. The extracted larkspur plant residue and crude plant extract containing larkspur alkaloids were subsampled for alkaloid analysis.

The same testing protocol was followed in this trial as in the preceding cattle trials. The four test animals were 3-year-old cows (Hereford × Angus cross; 470 kg); animals were not naive to larkspur, and they were habituated to the procedure before testing.

Fresh Plant Trials (Trials 4–7). Because dried, ground larkspur is not the physical form encountered by grazing cattle, we also conducted acceptability trials using fresh plant material. As with the previous trials, we harvested tall larkspur plants at different phenological stages and/or grown in full or partial sunlight; the intent in all plant collections was to simultaneously offer plants with potential differences in total and total toxic alkaloid concentrations. It was not possible to determine the alkaloid concentration of fresh plants before trials began; hence, we selected plants based on two assumptions: (1) plants grown in full sunlight have higher concentrations of total alkaloids compared to larkspur grown in partial shade (Pfister et al., 1988a), and (2) toxic and total alkaloid concentrations will be lower in mature compared to less mature plants. We

hypothesized that leaves or flowers from mature larkspur, with lower alkaloid concentrations, would be more acceptable to cattle compared to immature plant material; and, furthermore, that larkspur at the same growth stage grown in partial shade, with presumably lower alkaloid concentrations, would be more acceptable to cattle compared to larkspur grown in full sunlight.

Trials with freshly harvested tall larkspur (*D. barbeyi*) were conducted during July and August 1992 near Yampa, Colorado, using composite plant collections (trial 4, Table 1) or individual plants (trials 5–7, Table 1). The design for trials 4–7 was a 4 × 4 Latin square with each animal comprising a separate square.

Four yearling Hereford × Angus heifers (320 kg) were used as test animals. A portable corral was constructed adjacent to a larkspur-infested site at 2866 m elevation and a 5- × 8-m pen used for these trials. Animals were gentle and habituated to the test procedure before testing began. Testing was done individually in the morning, with cattle grazing during the remainder of the day.

Composite collections of larkspur leaves and flowers were tested as fresh material (trial 4, Table 1). Numerous (i.e., > 15) plants in the same phenological stage were stripped of leaves and flowers on the morning of the first test. Sufficient material was collected to last for all tests. The material was offered in feed pans in different pen locations as noted above. All four choices were offered simultaneously in this and subsequent trials. Between tests on the subsequent three days, the composited collections were sprinkled with water and stored in plastic bags at 10°C. On the last test day the material was not visibly wilted.

In Trials 5–7, individual larkspur plants were cut at ground level and preserved for the remainder of the trials (Table 1). Multiple stalks from the same plant were bound into a single sheaf near the bottom using cord. Plants were offered to cattle after securing them to the pen fence. When not being offered to cattle, individual plants were kept fresh and turgid by placing them under a shaded canopy with the bottom portion of each plant immersed in water. At this high mountain elevation, daytime temperatures are sufficiently cool that wilting did not occur. Each day individual animals were released into a test pen and allowed 5-min access to larkspur. The number of bites by plant part (leaf, stem, or reproductive parts) from each plant was recorded by a single observer. Each day plants were rotated to a new position.

Subsamples (10 g) of fresh flowers and leaves in trial 4 were frozen, freeze-dried, and ground through a 2-mm screen. Alkaloid concentration was determined for individual plants in trials 5, 6, and 7 by harvesting leaves and reproductive parts (i.e., flowers or pods) from two randomly selected stems immediately after the plant was cut; these samples were immediately frozen, then later freeze-dried and ground (2-mm screen) for analysis. The alkaloid concentration of leaves harvested from one or more stems is representative of leaves from the whole-plant (Manners and Pfister, unpublished data).

Lamb Trial

Sheep are not often intoxicated by tall larkspur because they are much less susceptible to the toxic alkaloids. Sheep are sometimes used to graze a pasture before cattle to reduce subsequent larkspur availability to cattle by trampling or consumption (Ralphs et al., 1991). Grazing trials with sheep have shown that sheep are reluctant to eat immature tall larkspur, but will eat mature larkspur (Ralphs et al., 1991, Ralphs and Olsen, 1992); thus, we hypothesized that alkaloid concentration was inversely related to acceptability to sheep. To test this hypothesis, four 6-month-old weaned male lambs were offered ground *D. barbeyi* or *D. occidentale* collected in the vegetative or flower stage (Table 1). We used the same material in this trial as in cattle trial 1. Sheep were naive to larkspur. Lambs were habituated to consuming 1.5 kg/day of ground alfalfa for 21 days. As in the cattle trials (described above), sheep were tested first in a 4 × 4 Latin square, then tested in a 3 × 3 Latin square trial with the most acceptable feed removed. At the end of the 3 × 3 trial, we removed the most acceptable feed, and conducted another trial using a 2 × 2 crossover design with four sheep, two feeds, and two positions over two days.

Cattle Field Grazing Trial

Grazing cattle select leaves from some tall larkspur plants and avoid others; furthermore during some years cattle select large amounts of tall larkspur, whereas during other years cattle may totally ignore larspur in the same location (Pfister et al., 1988a,b; Pfister and Manners, 1991, 1995). We hypothesized that these selection patterns are at least partially mediated by alkaloid concentrations; we predicted that highly selected plant samples would have lower alkaloid concentrations than plants in the general population. We also predicted that consumption of tall larkspur by grazing cattle would show an inverse relationship to total or toxic alkaloid concentration.

Six 1-year-old heifers (302 kg) were grazed from July 15 to August 26, 1992, on a tall larkspur-infested range at 2866 m elevation near Yampa, Colorado. The 8-ha pasture was enclosed with electric fence, and the cattle were allowed to freely graze from 07:00 to 19:00 hr each day. Cattle were not naive to tall larkspur, as they had grazed on similar tall larkspur-infested pastures the previous summer. Tall larkspur was in the early flower stage (i.e., reproductive racemes elongated, but flowers not open) when the trial began. At the end of the trial, all tall larkspur plants were in the pod stage, and some plants were senescing.

Cattle diets were determined using a bite-count procedure (Pfister et al., 1988a,b) on the seven dates that plant samples were collected for alkaloid analysis. Individual subjects were observed for 5-min periods in a predetermined order during all daylight hours when cattle were actively grazing; at the end of

the 5-min observation period the observer would observe the next animal in the sequence. We recorded bites of tall larkspur plant parts (flower, pod, or leaf), grasses, other forbs, shrubs, and monkshood (*Aconitum columbianum*). We defined an individual bite as a single cropping motion, always indicated by a head jerk, often acompanied by a visible sweep of the tongue, independent of chewing motions.

Tall larkspur leaves and reproductive parts from >20 plants were collected on seven dates to determine alkaloid concentration as larkspur matured. In addition, on three other occasions cattle were observed eating unusually large amounts of tall larkspur (i.e., >50% of diet for >1 hr), and remaining leaves from several partially consumed plants were collected and designated "palatable larkspur samples." Plant samples were composited, frozen at −20°C, freeze-dried, and ground to pass a 2-mm screen.

Plant Alkaloid Analysis

HPLC Toxic Alkaloid Analysis. One gram of ground, air-dried plant material was extracted in a Soxhlet apparatus with 80% EtOH. Further details of the HPLC procedure are given in Manners and Pfister (1993). Norditerpenoid alkaloids were detected by UV absorbance at 200 and 280 nm.

Total Alkaloid Analysis. Plant samples (100 mg) were weighed into a test tube and extracted with a mixture of $CHCl_3$ (4 ml) and 1 N HCl (4 ml) by mechanical rotation for 45 min. After centrifugation, the aqueous extract was removed and saved, and the plant material was extracted a second time with 1 N HCl (2 ml) for 5 min. The two aqueous extracts were combined and made alkaline with concentrated NH_4OH to pH 9. The samples were then extracted with $CHCl_3$ (2×), and the $CHCl_3$ solution was separated and filtered through Na_2SO_4. The solvent was removed by evaporation at 70°C under a stream of nitrogen. Carbon disulfide (2.0 ml) was added and the samples analyzed by FT-IR spectroscopy for total alkaloids using a quantitative partial least-squares model based on gravimetric analyses of the identically prepared total alkaloid fraction from a set of standard samples (D. Gardner, unpublished data, 1995).

Statistical Analysis

The statistical model for the Latin square trials was: intake = animal in pen (i.e., squares), position in pen, day in pen, larkspur collection or plant (i.e., treatment), error. The protected LSD procedure was used to compare treatment means after a significant F test ($P < 0.05$). Although there were confounding factors (e.g., years and phenology in trial 2; amount of shade in trials 6 and 7), we consider this to be trivial in the analysis because the independent variable of interest was alkaloid concentration. We determined Pearson correlation coefficients (r) relating alkaloid concentrations to: (1) amount eaten (grams) in trials

1–3 (dried, ground material); (2) amount eaten (grams) in trial 4 (composite fresh material); and (3) total bites of leaves, flowers, and pods from individual plants in trials 5–7, with these three trials grouped together for the correlation analysis.

Bite count data from the grazing trial were transformed using an arcsin-square root transformation. The grazing trial was analyzed using ANOVA procedures, with individual animals as blocks and sampling dates as treatments. The GLM procedure of SAS (1987) was used for data analysis. No statistical analysis was possible on corresponding alkaloid concentrations for each date, as composite samples were used and no measure of the variance was available.

RESULTS

Cattle Pen Trials

No differences in consumption due to plant collection were found in trial 1 ($P = 0.13$), although cattle did consume numerically more of the late season *D. barbeyi* and less of the early-season *D. barbeyi* (Table 2). Thus, we rejected the hypothesis that cattle would consume significantly more of the mature larkspur with a lower alkaloid concentration. When the late-season *D. barbeyi* was removed as a choice and the test rerun as a 3 × 3 Latin square, no differences in consumption were noted ($P = 0.79$) (Table 2). There was no relationship ($P > 0.05$) between total or toxic alkaloid concentrations and the amount of plant eaten (Table 3). There were significant correlations among the specific alkaloid concentrations, with the exception of 14-DAN.

In trial 2, cattle preferred the 1986 *D. barbeyi* collection ($P < 0.01$) over the other plant collections (Table 4). This collection was unusual in that it had no detectable toxic alkaloid concentration, but it did have a high concentration of total alkaloid. Thus, we rejected the hypothesis that total alkaloid concentration negatively influences consumption, but this trial suggested that toxic alkaloid concentration may influence acceptability. There was no correlation ($P > 0.05$), however, between concentrations of total or toxic alkaloids and amount of dry plant consumed in trial 2 (Table 5).

Cattle preferred both EtOH-treated hay and untreated hay during trial 3 (Table 4). The alkaloid-treated hay was of intermediate acceptability, whereas the alkaloid-free residue was rejected. During the 3 × 3 trial, when the EtOH-treated hay was withdrawn, the ranking remained the same, with cattle preferring untreated alfalfa, consuming moderate amounts of the alkaloid-treated hay, and rejecting the residue (Table 4). We rejected the hypothesis that cattle would preferentially accept the alkaloid-free residue over the alfalfa hay treated with the crude alkaloid extract. We could not reject the hypothesis of alkaloid influences because the alkaloid-treated hay was less preferred than either control

TABLE 2. TOTAL CONSUMPTION DURING TRIAL 1 OF DIFFERENT LARKSPUR COLLECTIONS (WHOLE PLANT), OFFERED AS AIR-DRIED, GROUND MATERIAL TO CATTLE AND SHEEP, AND CONCENTRATION OF METHYLLYCACONITINE (MLA), 14-DEACETYLNUDICAULINE (14-DAN), TOXIC ALKALOID, AND TOTAL ALKALOID IN PLANT MATERIAL

food. There was, however, no correlation ($P > 0.05$) between any alkaloid concentration and amount consumed (Table 5), but there were significant relationships among all the alkaloid components.

When fresh leaves and flowers were offered to cattle during trial 4, cattle rejected flowers and ate mostly leaves from plants in the full-flower stage ($P = 0.04$) (Table 4). The MLA concentration of the various composite collections varied greatly, but the range of total alkaloid concentrations was relatively small among the four collections. There was a biologically noteworthy, but statistically insignificant, negative relationship between amount of fresh plant eaten and total alkaloid concentration ($r = -0.74$, $P = 0.26$) (Table 5). Unlike the other trials, the only significant correlation among alkaloid concentrations in this trial was between MLA and toxic alkaloids (Table 5).

There were no differences ($P > 0.1$) in acceptability of individual plants in trials 5, 6, or 7 (Table 6). In trials 5 and 6, cattle ate no flowers, but cattle did take some bites of pods during trial 7 (Table 6). There was no correlation between alkaloid concentration and bites taken of plant material (Table 7). In general, all alkaloidal components were significantly correlated with one another. Taking trials 5–7 together, we rejected the hypothesis that mature larkspur would be more acceptable than less mature plant because of lower alkaloid concentrations. We were also unable to detect any significant impact from shade or full sun on amount of leaf material eaten by cattle.

[a]See Table 1.

Sheep Trials

Sheep displayed a distinct preference for the late-season plant material in all three tests. In the 4 × 4 test, they preferred the late-season *D. barbeyi* ($P < 0.01$) over the other three choices (Table 2). In the three-choice test, they also preferred the late season *D. occidentale* ($P = 0.05$) compared to *D. barbeyi* and *D. occidentale* collected in the vegetative stage (Table 2). When only two plant collections were compared in the 2 × 2 crossover tests, lambs showed no preference between *D. barbeyi* and *D. occidentale* in the vegetative stage. Thus, we accepted the hypothesis that total and/or toxic alkaloid concentration negatively influences sheep preference for tall larkspur. There was a strong tendency for sheep preferences to be negatively correlated with total and toxic alkaloid concentrations and to MLA concentration (Table 3). Both MLA and toxic alkaloid concentrations were related to each other and to total alkaloid concentration, but 14-DAN concentration was not related to the other alkaloid components (Table 3).

Cattle Grazing Trial

Cattle consumed 7 ± 2.5% of their overall diet as larkspur during the seven sampling dates. Larkspur consumption differed by dates, as cattle ate little larkspur during July, but increased larkspur consumption during mid- to late August (Figure 1). Most (>90%) of the larkspur consumed was leaves, with flowers and pods being selected only occasionally (data not shown). The concentration of toxic alkaloid in leaves declined slightly in late July and early August, but then increased slightly in mid- to late August (Figure 1). Total alkaloid concentration in leaves peaked in mid-July, decreased during July and much of August, but then increased in late August (Figure 1). On the three occasions (July 19, August 23 and 24) when cattle greatly increased leaf consumption during or just after storms, the toxic and total alkaloid concentration in leaves from preferred plants was 5.8 and 7.6, 1.8 and 5.4, and 2.3 and 6.0 mg/g, respectively, for the three dates. One of these samples contained a substantial amount (>5 mg/g) of toxic alkaloids, and two samples contained low to moderate (~2 mg/g) amounts of toxic alkaloids, and provided circumstantial evidence that toxic alkaloid concentration was not a major factor in selection of tall larkspur by grazing cattle. The leaf concentration of total alkaloids was in the range for most tall larkspur samples collected from this area and did not provide evidence for either avoidance or preference.

DISCUSSION

Our study indicates that concentrations of total or toxic alkaloid in tall larkspur generally have little or no influence on acceptability of tall larkspur to

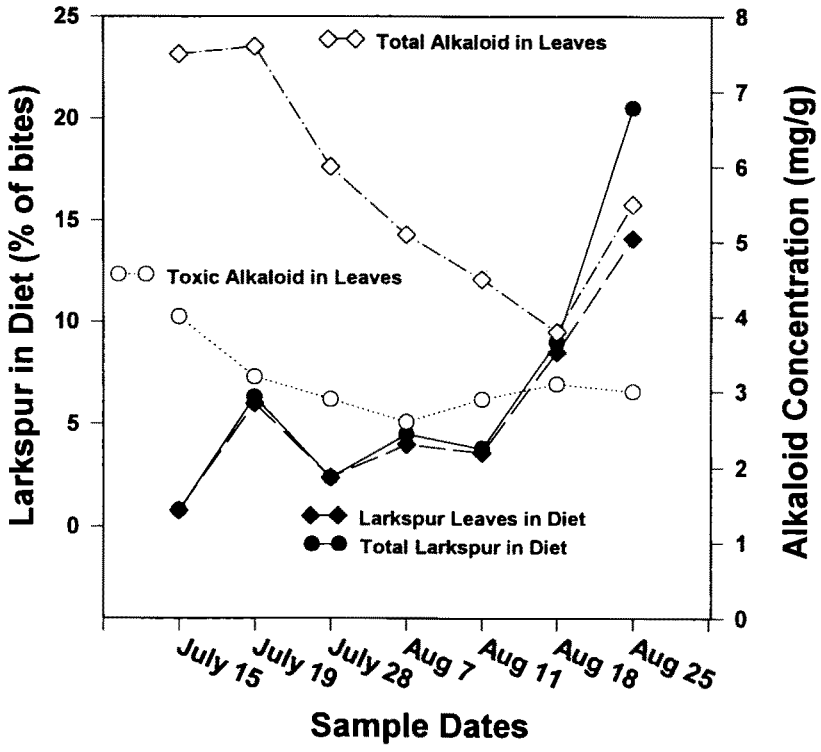

FIG. 1. Mean amounts of tall larkspur in diets of cattle (percentage of bites: leaves and total larkspur) and concentration (mg/g dry weight) of toxic alkaloids and total alkaloids in leaves sampled when cattle diets were determined during a grazing study near Yampa, Colorado, during summer, 1992.

cattle. The pen trials showed few or no relationships between alkaloid concentration (toxic or total) and amounts eaten by cattle, and the field grazing trial also indicated that toxic or total alkaloid concentrations in larkspur do not negatively influence consumption patterns. One collection of *D. barbeyi* from Utah contained no toxic alkaloids, yet had a total alkaloid concentration of nearly 39 mg/g. Cattle preferred this atypical plant collection during pen trials, thus providing strong circumstantial evidence that a high total alkaloid concentration is not deterrent to cattle. Conversely, this result indicates that very low toxic alkaloid concentrations may influence acceptability. Yet, we found no correlation in this or any other trial between toxic alkaloid concentration and amount eaten; further, other collections with lower toxic alkaloid concentrations (<2.0 mg/g) were not differentially accepted by cattle. We cannot explain the increase

in total alkaloids in leaves in late August during the grazing trial, but it seems doubtful that cattle increased larkspur consumption in response to this upswing in total alkaloid concentration. Our results are based primarily on correlation; hence, we can suggest causative factors but cannot be definitive about the interpretation. Plant factors other than alkaloids may have influenced our results (Reichardt et al., 1987).

There is disagreement on whether the taste of alkaloids affects palatability. Alkaloids apparently taste bitter to humans (DuPont et al., 1994) and livestock (Laycock, 1978), and bitterness may (Bate-Smith, 1972) or may not (Robinson, 1979; Glendinning, 1994) be universally repellent. Some classes of alkaloids apparently do not have a bitter taste (Molyneux and Ralphs, 1992). The alkaloid concentration of some toxic plants (e.g., *Phalaris* spp., *Lupinus* spp., *Senecio* spp.) is inversely related to palatability or may deter grazing (Ralphs and Olsen, 1987). Other alkaloid-containing toxic plants such as *Oxytropis* spp. and *Astragalus* spp., however, apparently do not show this relationship (Ralphs and Olsen, 1987).

Cattle did not eat enough larkspur in any trial for toxicosis to influence results. Nonetheless, aversive postingestive feedback may limit intake of specific foods (Provenza, 1995), and we have shown that larkspur ingestion by cattle above a toxic threshold is regulated by postingestive consequences (Pfister et al., 1990). Larkspur alkaloidal extracts can cause food aversions (Olsen and Ralphs, 1986), but cattle must consume about 9–11 mg of toxic alkaloids per kilogram of body weight for subclinical toxicosis to influence intake (Pfister et al., 1994b).

For reasons that are unclear, cattle in the pen and grazing trials near Yampa ate few or no flowers or pods. We have noted this same propensity in other grazing trials in this region during three other summers (Pfister, unpublished data). This is in contrast to cattle consumption patterns in Utah, where grazing trials have shown that cattle prefer larkspur pods from mature plants (Pfister et al., 1988a,b). We are presently unable to account for these differences in acceptability.

During trial 3 using alkaloid extract, cattle preferred the larkspur extract on alfalfa hay over the alkaloid-free residue, indicating that alkaloids did not deter consumption. Conversely, the extract-treated hay was less preferred than either untreated or EtOH-treated hay, suggesting a deleterious effect on acceptability. We recognize that extraction may remove many cellular constituents (e.g., some free sugars); however, 95% ethanol extraction only removes a small proportion of the major fructosans (Smith, 1969, 1973). It is possible that cattle selected the alkaloid-treated hay because of carbohydrates that were simultaneously extracted. Alternatively, it is possible that some very nonpolar constituents (e.g., terpenoids) were left in the residue, and acted as feeding deterrents to cattle.

In contrast to cattle, sheep consumption was negatively influenced by concentrations of total alkaloid and MLA in tall larkspur. Sheep apparently have a lower rejection threshold for bitter flavors than do cattle (Goatcher and Church, 1970), and this may account for their negative response to total alkaloid concentration in larkspur. Grazing sheep before cattle in tall larkspur-infested pastures has had limited success (Ralphs et al., 1991) because of the difficulty in getting sheep to eat larkspur before the plant is relatively mature. Our results suggest that higher concentrations of total alkaloid, or MLA, often found in immature larkspur, may be deterrent to sheep.

Arnold and Hill (1972) noted that the total alkaloid concentration of *Phalaris* spp. was more important to palatability than were individual alkaloids. Similarly, we found little indication that individual alkaloids influence cattle consumption; however, MLA concentration was negatively correlated with sheep consumption. Since MLA and total alkaloid concentration were also highly correlated, our sheep trials give no clear indication of the relative importance of total versus MLA alkaloid concentration.

At times there was not a strong correlation between concentrations of total and toxic alkaloids (or MLA concentration). Concentration of MLA was always related to toxic alkaloid concentration, since MLA comprises most of the toxic fraction, but MLA concentration was sometimes not related to amounts of 14-DAN. With plant material collected near Yampa, Colorado (trials 4–7), toxic alkaloid concentration was variable, whereas total alkaloid concentration was relatively low, with ratios of toxic to total alkaloid concentration varying from 0.3 to 0.75. Collections of tall larkspur from either Utah or Idaho (trials 1 and 2) had toxic/total ratios of about 0.2 or less. The extracted residue (trial 3) also did not have any toxic alkaloids, but had a small amount of total alkaloid left after extraction.

Even though we collected both shaded and unshaded larkspur plant for comparisons in trials 6 and 7, no distinct trend emerged for alkaloid concentration as leaves from both shaded and unshaded plants had total alkaloid concentrations averaging about 4 mg/g and toxic alkaloid concentrations averaging about 2 mg/g. The alkaloid concentrations in flowers also did not show clear differences due to shading. We have previously found that grazing cattle prefer to graze shaded larkspur plants over plants growing in sun (Pfister et al., 1988a), but that trend was not evident in this study.

Overall, this study indicates that knowledge of the concentration of total or toxic alkaloid in tall larkspur will not give any clear indication of whether cattle are likely to ingest the plant or not. We can make accurate predictions about the toxicity of tall larkspur based on the concentration of toxic alkaloids, but this information will only provide the livestock producer with the risk of toxicity assuming some level of consumption. Predicted consumption by cattle must necessarily be based on an understanding of other factors, such as plant

phenology (Pfister et al., 1988a,b), or weather patterns (Ralphs et al., 1994), but not plant toxicity.

(Received August 22, 1995; accepted February 14, 1996)

Abstract—Mating in the aphid parasitoid *Praon volucre* is mediated by a female-produced sex pheromone, which laboratory behavioral studies suggest is released from the abdomen. Gas chromatography coupled with electrophysiological and behavioral assays on males showed one area of activity in an air entrainment sample of virgin females. However, levels of pheromone production are very low and this has so far precluded its identification.

Key Words—Hymenoptera, aphid, parasitoid, sex, pheromone, GC, EAG, behavior.

INTRODUCTION

Praon volucre Haliday (Hymenoptera, Braconidae) is a generalist parasitoid attacking several species of aphid (Homoptera, Aphididae) and has been used in biological control programs since the late 1950s (Stary, 1970). More recently, it has been shown that *P. volucre* females are attracted by aphid sex pheromones, and this innate response may be utilized to manipulate *Praon* populations in the field with a view to improving aphid control (Powell et al., 1993; Lilley et al., 1994). However, to develop an integrated strategy for aphid management, there is a need for accurate monitoring systems for both aphids and their natural enemies. Parasitoid sex pheromones can provide a method of assessing natural

or released populations of these beneficial insects (Brodeur and McNeil, 1994). Laboratory and field studies have supplied evidence for sex pheromone production in virgin female *P. volucre* (Decker et al., 1993) and preliminary studies on chemical identification are reported here.

METHODS AND MATERIALS

Insects. P. volucre were maintained on a clone of the English grain aphid, *Sitobion avenae* (Fab.), reared on oats, *Avena sativa* L. (Poaceae), at 18°C with a 16L : 8D hr photoperiod. Parasitoid mummies (pupal stage) were collected from culture cages and isolated in corked glass tubes. After emergence, mummies were removed from the tubes and the parasitoids sexed and provided with an aqueous solution of honey.

Pheromone Collection—Crude Extracts. Males and virgin females (1–2 days old) were anaesthetized by chilling and then extracted in diethyl ether for 1 hr. Preliminary experiments indicated that the age of the females (1, 2, or 3 days old) did not affect the activity of the extracts. To determine the location of pheromone production, 1-day-old virgin females were dissected, and the head, thorax (including the wings and legs) and abdomen were extracted separately with ether.

Pheromone Collection—Air Entrainment. Twenty virgin females (1–3 days old) were placed in a glass culture vessel (Quickfit FV range, 1 liter) and air, dried and purified by passage through activated 5 Å molecular sieve and charcoal, was drawn at 1 liter/min through the vessel. Volatiles were entrained over a 24-hr period onto Porapak Q that had been purified by washing with diethyl ether (5 ml) and heating for 12 hr at 150°C under a stream of nitrogen. Collected volatiles were desorbed from the Porapak by elution with freshly distilled diethyl ether. The resulting extract was concentrated under a stream of nitrogen and stored in sealed glass ampoules at −20°C.

Electrophysiology. Electroantennogram (EAG) recordings from 1-day-old male parasitoids were made using Ag–AgCl glass electrodes filled with saline solution [composition as in Maddrell (1969) but without the glucose]. The insect was anesthetized by chilling, and the head was excised and mounted on the indifferent electrode. The tip of the recording electrode was removed so that its inside diameter was just wide enough to accept the uncut terminal process of the antenna. The signals were passed through a high impedance amplifier (UN-03b, Syntech) and displayed on an oscilloscope.

Coupled Gas Chromatography (GC)–Electrophysiology. The coupled GC-electrophysiology system, in which the antennal preparation is directly coupled to the capillary column GC, has been described previously (Wadhams, 1990). Separation of the air entrainment sample was achieved on an AI 93 GC equipped

with a cold on-column injector and a flame ionization detector (FID). The column (30 m × 0.53 mm ID, HP-1) was maintained at 40°C for 2 min and then programmed at 10°/min to 250°C. The carrier gas was hydrogen. The outputs from the EAG amplifier and the FID were monitored simultaneously on a chart recorder.

Coupled GC-Behavioral Assay. The effluent from the GC column was split equally between the FID and a transfer line, the end of which was inserted through a hole into a tube connected to a glass chamber containing a single 1-day-old *P. volucre* male. An airstream (600 ml/min) carried the effluent to the insect. The insect and the chart recorder monitoring the signal from the FID of the GC were simultaneously video recorded. Wing-fanning responses were converted into bins that were cumulated over 15 sec and marked onto the GC trace to provide response profiles. Individual records were time-synchronized on the injection time. Elution times of the compounds in the five analyses were reproducible, so that all records could be cumulated without further processing. The test sample and GC conditions were the same as for the coupled GC-EAG.

Olfactometry. The behavioral responses of males were observed in a Pettersson olfactometer (diameter 10 cm) having a weak airstream (600 ml/min) directed towards the center from each of four side arms (Pettersson, 1970). The test stimulus was placed at the end of one of the arms. Treatments were: (1) 1-day-old virgin females, (2) 1-day-old males, (3) the crude extract of virgin females (0.1 female equivalents) and (4) the air entrainment sample of virgin females (5 female-hour equivalents). The olfactometer was placed in a darkened room and illuminated from the top. A 1-day-old naive male *P. volucre* was allowed to enter the chamber through a hole (4 mm) in the center of the olfactometer floor. The time spent in each olfactometer arm and the first choice made by the insect were recorded by means of the computer program OLFA 1.0 (Nazzi, 1995). The experiments lasted 15 min, and the olfactometer was rotated through 90° every minute. After each experiment, the olfactometer was thoroughly washed in 1% aqueous anionic detergent (Teepol) and rinsed with water. The experiments were carried out between 11:00 and 14:00 hr and replicated a minimum of seven times.

Wing-Fanning Bioassay. In previous studies, male wing fanning was a key behavioral component of the mating sequence in aphid parasitoids (Stary, 1970) and its occurrence provides strong evidence for the presence of a sex pheromone (Askari and Alishah, 1979; Decker et al., 1993; McNeil and Brodeur, 1995). Consequently, the wing-fanning bioassay was used to confirm the presence of a sex pheromone and to determine the source of pheromone production. The test sample (5 μl) was applied to a strip of filter paper (Whatman No. 1; ca. 0.5 × 2.0 cm), which was inserted, after evaporation of the solvent, into a glass tube (0.8 × 3.0 cm) containing a 1-day-old naive male parasitoid. The wing fannings that occurred immediately after introduction of the stimulus and

over the next 60 sec were recorded. Treatments were: (1) the crude extracts of males and virgin females (0.1 insect equivalents), (2) extracts of female head, thorax, and abdomen, and (3) the air entrainment sample of virgin females (5 female-hour equivalents).

Statistical Analysis of Data. The times spent in the treated and control arms of the olfactometer were analyzed using a paired t test. The number of insects that chose the treated arm first, out of the total number of males tested, was compared with the figure expected in the case of a binomial distribution. The results of the wing-fanning bioassay were analyzed, when necessary, with the Fisher exact solution test.

RESULTS AND DISCUSSION

In the olfactometer, males showed significant responses to live virgin females in terms of first choice (Table 1) and total time spent in the treatment arm (Table 2). Crude whole body extracts of virgin females (0.1 insect equivalents) and the air entrainment sample from virgin females (5 female-hour equivalents) were also attractive to males (Tables 1 and 2). No response was observed to live males.

In the wing-fanning bioassay, the whole-body extracts of virgin females and the air entrainment sample elicited responses from over 80% of the males tested, but no response was obtained to the male extract (Table 3). The wing-fanning bioassay was also used to determine the site of pheromone production. Of the 15 males tested, 13 responded strongly to the extract of female abdomens, but the head extract showed no activity. The thorax extract was weakly active, with three of 15 males responding; this may be due to contamination of the wings, which are normally folded above the abdomen. In addition, the marked

Air entrainment (5 female hr equiv)	9	6	<0.01

NS = not significantly different from control at $P = 0.05$.

TABLE 2. RESPONSE OF *Praon volucre* NAIVE MALES TO DIFFERENT STIMULI IN OLFACTOMETER: MEAN TIME SPENT IN TREATED OR CONTROL ARMS

Stimulus	Males tested (*N*)	Mean time (min ± SE) spent in		Probability
		treated	control	
Control (ether)	7	2.3 ± 1.7	1.4 ± 0.6	NS
Live male	8	3.7 ± 1.7	2.6 ± 0.7	NS
Live virgin female	9	6.7 ± 1.1	1.1 ± 0.5	<0.01
Crude extract (0.1 female equiv)	11	6.0 ± 1.9	1.2 ± 0.5	<0.05
Air entrainment (5 female hr equiv)	9	6.8 ± 1.8	1.2 ± 0.4	<0.05

NS = not significantly different from control at $P = 0.05$.

grooming behavior of parasitoids could play a role in spreading pheromone over other parts of the body. Thus, pheromone production, as with *Diaeretiella rapae* (Askari and Alishah, 1979) and *Aphidius nigripes* (McNeil and Brodeur, 1995), appears to be associated with the female abdomen.

EAG responses from male antennae were recorded to groups of 10 live virgin females (0.26 ± 0.02 mV; $N = 5$) and to 50 female-hour equivalents of the air entrainment sample (0.5 mV), suggesting that this sample is a realistic reflection of the level of volatiles produced by the females. Coupled GC-EAG showed only one major area of activity, corresponding to a minor component in the sample (Figure 1). The activity of this component was confirmed using the coupled GC-behavioral assay: three of the five males tested showed wing-fanning responses in the area associated with the electrophysiologically active peak (Figure 1). One of the three and one other male showed wing-fanning behavior in two areas at shorter GC retention times, but these were not associated with electrophysiological activity.

TABLE 3. RESPONSE OF *Praon volucre* NAIVE MALES TO DIFFERENT STIMULI IN WING-FANNING BIOASSAY

Stimulus	Males tested (*N*)	Males responding (*N*)
Control (ether)	48	0
Crude extract (0.1 male equiv)	30	0
Crude extract (0.1 female equiv)	48	40
Air entrainment (5 female hr equiv)	48	42

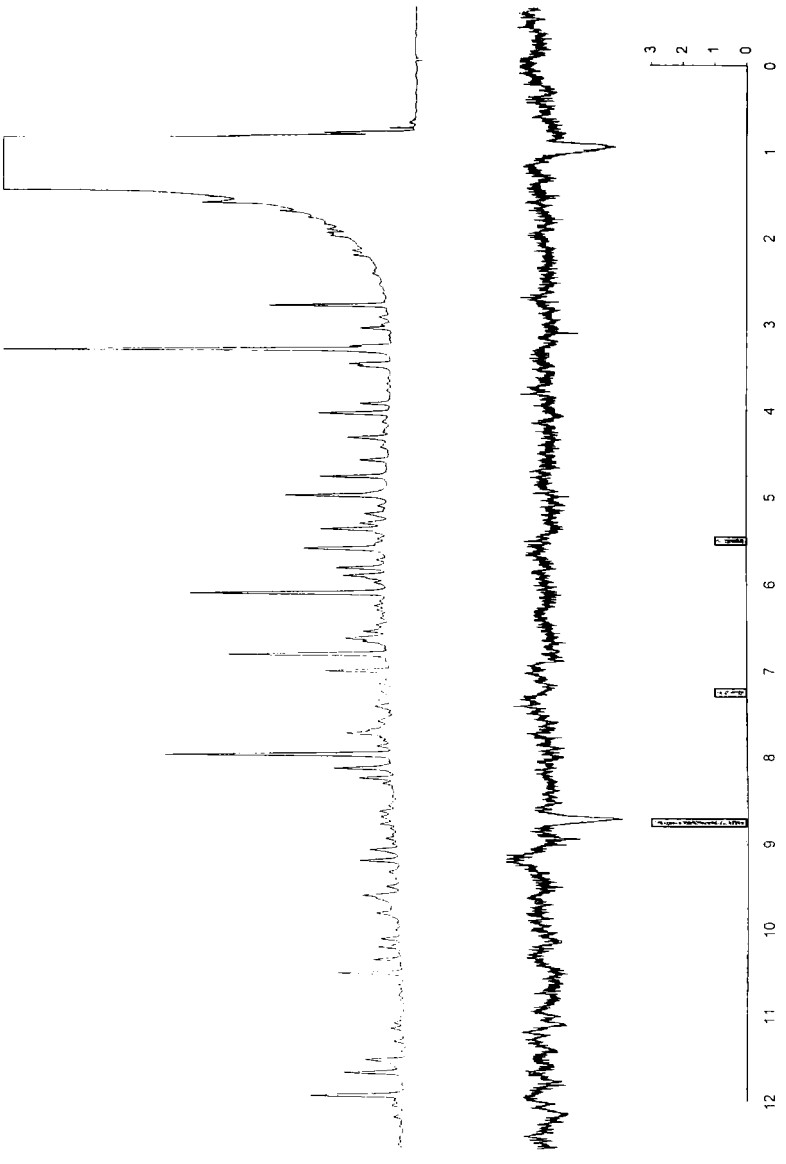

FIG. 1. *Praon volucre* males: coupled GC-EAG and GC-behavioral assay with the air entrainment sample of virgin females (50 female-hour equivalents). Upper trace: GC of volatiles from virgin females. Middle trace: EAG response of one male. Lower trace: behavioral responses; vertical axis shows number of males, out of five tested, exhibiting wing-fanning activity

This study has confirmed a female sex pheromone for *P. volucre*, although the amount of pheromone produced is very small. Approximate quantifications from the GC peak area of the air entrainment sample suggest that pheromone production is of the order of only picograms per hour. The similarity between the EAG responses of males to live virgin females and to the entrainment sample suggests that this is not an experimental artifact. Although males are shown to be highly sensitive to the pheromone, with as little as 5 female-hour equivalents eliciting a response in the olfactometer and 10 virgin females per trap attracting males in the field (Decker et al., 1993), the paucity of pheromone has so far precluded its identification.

SENSITIVITY OF *Lemna* BIOASSAY INTERACTS WITH STOCK-CULTURE PERIOD

OLAF CHRISTEN* and CHRISTIANE THEUER

Institute of Crop Science and Plant Breeding
University of Kiel, Olshausenstr. 40
24118 Kiel, Germany

(Received April 10, 1995, accepted February 19, 1996)

Abstract—The effect of stock-culture period on the sensitivity of the *Lemna* bioassay to four different phenolic substances was evaluated in this study. The sensitivity of the bioassay interacted with the stock-culture period of either 11, 14, or 18 days. After a seven-day test *p*-hydroxybenzoic acid (HBA), vanillic acid (VA), *trans*-cinnamic acid (CA), and ferulic acid (FA) with a concentration of 0.05 mM significantly reduced the number of fronds and the dry weight compared with the untreated control when the stock-culture period had been exactly 14 days. The sensitivity after the shorter (11 days) or longer (18 days) stock-culture period was reduced, and the differences in the dry weight to the untreated control were not significant after a stock culture period of 18 days. The two higher concentrations (0.1 and 0.25 mM) showed stronger inhibition. A comparison of the inhibition at 0.05 mM revealed that the stock-culture period affected the relative toxicity of the four phenolic substances. Since the pH increased in the stock-culture flasks during the 18-day period from 6.25 to 7.9, we hypothesize that differences in the *Lemna* assay can be at least partly attributed to a pH effect, possibly in combination with a relative nutrient deficiency. We recommend a standardization of the stock-culture period to 14 days to improve the sensitivity of the *Lemna* bioassay.

Key Words—*Lemna minor*, duckweed, bioassay, sensitivity, phenols, stock-culture period, pH.

INTRODUCTION

Duckweeds (*Lemna* spp.) are small floating angiosperms common to a wide range of rivers and lakes all over the world (Hillman, 1961). Beside its use in

*To whom correspondence should be addressed.

the field of water purification, various *Lemna* species have gained broad acceptance for bioassays in ecological and allelopathy research due to their easy handling as well as their sensitivity to a wide range of toxic substances. *Lemna* species such as *L. minor*, *L. obscura*, and *L. gibba* are extremely sensitive to various phenolic substances (Einhellig et al., 1985; Ramirez Toro et al., 1988), different pesticides (Lockhart et al., 1983, 1989; Cowgill et al., 1989; Cooley and Foy, 1992; Grossmann et al., 1992), alkaloids (Wink and Twardowski, 1992), quinones (Einhellig and Souza, 1992; Hejl et al., 1993), heavy metals (Jenner and Janssen-Mommen, 1993), mycotoxins (Vesonder et al., 1992), as well as mixtures with unknown chemicals from soil extracts, plants, or leachates from polluted sediments, etc. (e.g., Jenner and Janssen-Mommen, 1989; May and Ash, 1990; Elakovich and Wooten, 1991; Clement and Bouvet, 1993).

The most common measurement of such phytotoxic activity has been the number of *Lemna* fronds after a period of growth, but individual dry weight, growth rate, or changes in the chlorophyll content have also been determined regularly (Einhellig et al., 1985, Wink and Twardowski, 1992). Chen and Leather (1990) quantified effects on chlorophyll content per frond in *L. minor* and the anthocyanin content in *L. obscura* as part of their investigation of the phytotoxicity of the sesquiterpene lactone artemisinin. In order to gain insight into the physiological action of suspected phytotoxic substances, variables such as photosynthesis and respiration (Stiles et al., 1994) or protein synthesis (Cooley and Foy, 1992) have been monitored.

Despite proposals of Leather and Einhellig (1988), the protocols in experiments using the *Lemna* bioassay often vary considerably. This makes comparisons of results extremely difficult with respect to the toxicity of various compounds. In most protocols, the particular *Lemna* plant is chosen based on the developmental stage, i.e., three or four frond colonies. The preculture period has been documented only in a few cases where *Lemna* species were the bioassay. Clement and Bouvet (1993) mention that in their experiments the preculture period lasted exactly 14 days; however, no details were given as to why this period was originally chosen. In preliminary experiments with the *Lemna* bioassay following Einhellig et al. (1985), we experienced unexpected results. Since no known cause could explain them and most papers do not provide information about the preculture period, we investigated the interaction between the preculture period of *Lemna minor* and its sensitivity in a bioassay.

We present results of experiments evaluating the interaction between phytotoxic effects of various phenolic substances and the preculture period of *L. minor*. We used phenolic substances in this experiment, since extensive research has identified the chemical nature of allelochemicals associated with plant-soil-microbial systems as being mainly phenolic substances (Siqueira et al., 1991).

METHODS AND MATERIALS

Culture Conditions. Axenic cultures of duckweed, *Lemna minor* strain 5, were grown in autoclaved, cotton-closed 100-ml Erlenmeyer flasks with 50 ml of E medium (Cleland, 1979). The stock cultures were maintained for either 11, 14, or 18 days in an environmental growth chamber at 28°C under constant cool white light (170 $\mu E/m^2/sec$).

Bioassay. The bioassay was performed according to the methods described previously by Einhellig et al. (1985). All procedures were performed on a clean bench with aseptic techniques. Fresh E medium was prepared for each bioassay. E medium (1.5 ml) was dispensed into each well of a sterile 24-well tissue culture plate with a sterile pipet. Phenolic substances dissolved in 99% methanol were applied by dispersing 5 μl with a Eppendorf Varipette 4710 into each well with two complete tissue culture plates for each phenolic compound, i.e., 12 replicates in different wells, which were arranged randomly on the plates.

Concentrations of 0.05 mM, 0.1, and 0.25 mM of *p*-hydroxybenzoic acid (HBA), vanillic acid (VA), *trans*-cinnamic acid (CA), or ferulic acid (FA) were tested. The control received also 5 μl of methanol, giving a total of 24 tissue culture plates (576 separate wells) for the entire experiment. *Lemna* colonies at the three-frond developmental stage were transferred by a flamed culture loop into each well. The culture plates were covered and placed in an environmental growth chamber with conditions given above. The plates were arranged randomly, and their position in the growth chamber was changed twice every day to minimize effects of light, temperature, and/or relative humidity differences. In order to allow for better gas exchange and reduce evaporation of culture medium, the lids of the culture plates were lifted every day for 5 min on the clean bench.

Harvest. After exactly seven days, *L. minor* was carefully removed from each well of the culture plate and placed into water for a frond count. The fronds were then air dried for two days, and the dry weight was determined on a balance accurate to 0.01 mg.

Data Analysis. The comparisons between treatments were analyzed using a general linear model (GLM).

RESULTS

L. minor was more sensitive to the two hydroxybenzoic acids *p*-hydroxybenzoic acid (HBA) and vanillic acid (VA), than to the cinnamic acids *trans*-cinnamic acid (CA) and ferulic acid (FA) (Figure 1). The application of *trans*-cinnamic acid was most inhibitory and caused bleaching at 0.1 mM and death

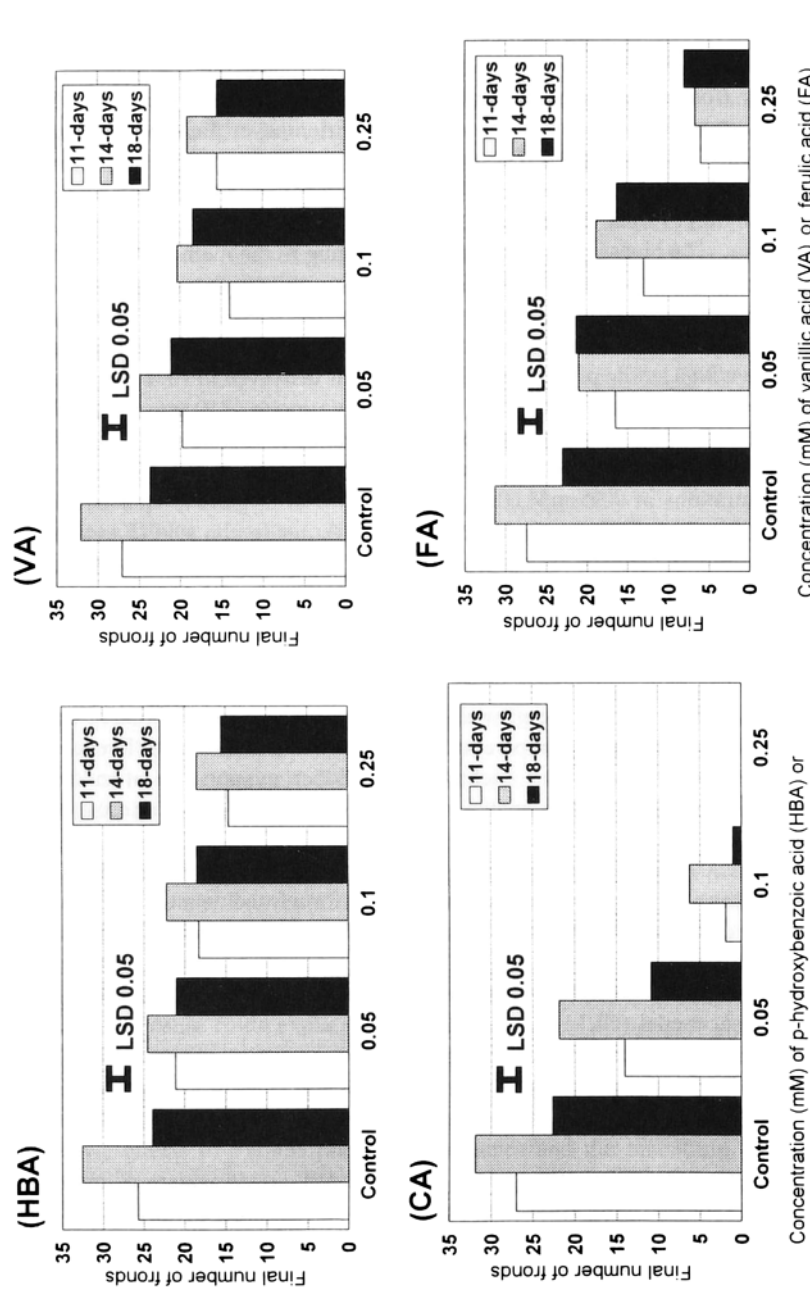

FIG. 1. Effect of stock-culture period of 11, 14, or 18 days and *p*-hydroxybenzoic acid (HBA), vanillic acid (VA), *trans*-cinnamic acid (CA), or ferulic acid (FA) on the final frond number of *L. minor* grown for seven days in tissue culture wells.

of *L. minor* at 0.25 mM. Regardless of the concentration of the test solution, in all but two cases *L. minor* produced the largest number of fronds after a stock-culture period of 14 days (Figure 1). Differences in results among the four phenolic compounds tested were inconsistent in relation to stock-culture periods of 11 or 18 days.

After a seven-day exposure period, the number of fronds from *L. minor* was significantly reduced by all four phenolic substances at 0.05 mM when the stock-culture period was 14 days.

The dry weight of *L. minor* as influenced by the phenolic substances was similar (Figure 2). Each phenolic compound caused a significant reduction in dry weight at a concentration of 0.05 mM after a 14-day stock-culture period. However, the differences were smaller between the response at 0.05 mM compared with the higher concentrations of 0.1 or 0.25 mM in reduction in the number of *L. minor* fronds, suggesting that the latter is more suitable for such comparisons. As noted for the number of fronds, the dry weight of *L. minor* interacted with the stock-culture period. However, in contrast to the results shown for the frond numbers, the plant weight was in most cases larger after a stock-culture period of 11 days. The only exceptions were the control treatments. Significant differences between the control treatments and the 0.05 mM concentration of the different phenols occurred only after a stock-culture period of 11 or 14 days.

A comparison of the mean squares and the F values of the analysis of variance for the number of fronds and the dry weight of *L. minor* reveals the significant effect of the stock-culture period as well as the two- and three-way interactions of the stock-culture period with the other factors tested in this experiment (Table 1).

Although the differences seemed to be small, a direct comparison of the number of fronds and the dry weight responses of *L. minor* exposed to the four phenolic substances at the lowest concentration of 0.05 mM showed an interaction with the stock-culture period. These results demonstrate the importance of interactions with the stock-culture period at low concentrations of a phytotoxic substance (Tables 2 and 3).

L. minor produced nearly the same numbers of fronds per tissue culture well at a concentration of 0.05 mM *p*-hydroxybenzoic acid (HBA) regardless of whether the stock-culture period lasted 11 or 18 days. The response towards ferulic acid (FA) was clearly modified, however, and the number of fronds was 23% lower after a stock-culture period of only 11 days compared with 18 days. The largest relative differences in sensitivity at 0.05 mM in relation to the stock-culture period occurred in the case of *trans*-cinnamic acid (CA), for dry weight and number of fronds at all three stock-culture periods (Tables 2 and 3). Different rankings of the toxicity of the four phenolic substances occurred at the

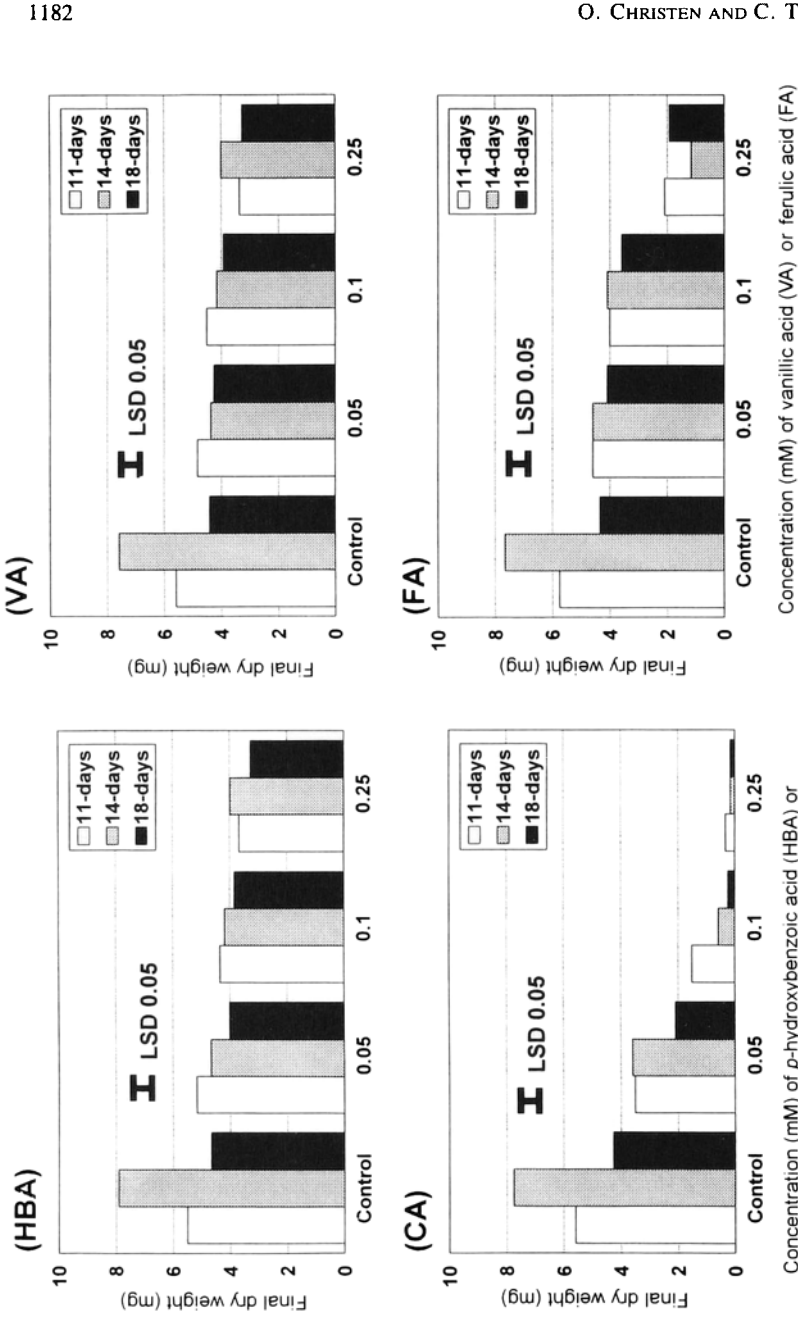

FIG. 2. Effect of stock-culture period of 11, 14, or 18 days and *p*-hydroxybenzoic acid (HBA), vanillic acid (VA), *trans*-cinnamic acid (CA), or ferulic acid (FA) on the final dry weight (mg) of *L. minor* grown for seven days in tissue culture wells.

TABLE 1. ANALYSIS OF VARIANCE FOR NUMBER OF FRONDS AND FINAL DRY WEIGHT OF *L. minor* IN TISSUE CULTURE WELLS

Source	*df*	No. of Fronds		Final dry weight (mg)	
		Mean square	*F* value	Mean square	*F* value
Phenol (P)	3	3042.7	460.5[a]	140.1	5053.1
Concentration (C)	3	8163.5	1235.5	342.0	12329.7

concentration of 0.05 mM. Such a modification of the inhibition of the growth or development of *L. minor* by the stock-culture period occurred at all tested concentrations. The relative differences, however, were smaller and, therefore, in the cases of 0.1 or 0.25 mM did not cause a variation in the ranking of the four substances according to their toxicity.

TABLE 2. EFFECT OF STOCK-CULTURE PERIOD AND FOUR DIFFERENT PHENOLICS ON FINAL FROND NUMBER OF *L. minor* GROWN FOR SEVEN DAYS IN TISSUE CULTURE WELLS[a]

Stock-culture period (days)	Phenolic (0.05 mM)[b]

DISCUSSION

The *Lemna* bioassay has proved to be a powerful tool to monitor the biological activity of a large range of potentially phytotoxic substances. Following the protocol given by Einhellig et al. (1985), it is possible to evaluate and compare the toxicity of extremely small samples of test solution.

All four phenolics used in our experiment could be detected at a concentration as low as 0.05 mM. In contrast, Einhellig et al. (1985) reported a threshold of 0.25 mM for ferulic acid in *L. minor*, and Ramirez Toro et al. (1988), using *L. gibba*, again established a threshold for ferulic acid of 0.75 mM. The results of our experiment demonstrate that the reason for such a difference in the sensitivity of the *Lemna* bioassay might be differences in the stock-culture period.

The reason for such a strong negative effect of the long stock-culture period of 18 days on the sensitivity of the bioassay might be the increase in the pH of the stock solution over time. We have monitored the pH in the different treatments and measured pH at 6.25 after 11 days, 6.89 after 14 days, and 7.90 after 18 days. Einhellig et al. (1985) report no growth reduction when the pH of the medium was in the range between 4.0 and 6.0. Therefore an effect of pH 7.90 of the stock-culture solution on the sensitivity of the *Lemna* bioassay seems possible, even when the pH in the solution for the bioassay period was adjusted to 4.6. A second factor that we did not control in our experiment might have been a relative nutrient deficiency in the stock-culture flask after the long stock-culture period of 18 days. This hypothesis concurs with results from Cowgill et al. (1989), who compared the effect of a herbicide on *L. minor* for either seven or 14 days. They report less sensitivity for the shorter bioassay

period and attribute this to nutrient deficiencies in the longer experiment. Such a prolonged effect of various stock-culture periods with different pH and/or nutrient status might be explained by possible changes in the hormonal balance of the *Lemna* plants. As Thorsteinsson and Eliasson (1990) demonstrated in experiments with *L. gibba*, the reason might be changes in the cytokinin levels, which respond slowly to an improved nutritional situation. However, the reason for the described effects remains open to discussion until more detailed physiological studies have been conducted.

An explanation for the reduced sensitivity of the *Lemna* bioassay after an 11-day stock-culture period is less obvious, since differences of the pH in the stock-culture solution and/or nutrient deficiencies are not the explanation. We argue that after an 11-day stock-culture period, *Lemna* plants are less sensitive because they have not reached the developmental stage to separate so easily in different new rosettes. This hypothesis is confirmed by the observation that the average dry weight per frond was 0.26 mg for *Lemna* plants after an 11-days stock-culture period, whereas it was only 0.18 or 0.19 mg after 14 or 18 days, respectively. Whether this explanation is sufficient requires further developmental studies.

CONCLUSION

Our results demonstrate that a standardization to 14 days for the stock-culture period before using the *Lemna* bioassay greatly enhances its sensitivity and makes it possible to detect even smaller concentrations of phytotoxic substances. Additionally, in order to ensure comparability of results of the *Lemna* bioassay among different experiments, a strict standardization of the stock-culture period and/or monitoring of the pH in the stock-culture solution is desirable. We recommend a 14-day stock-culture period. This would be a further step to improve the *Lemna* bioassay for the field of allelopathic research and make it possible to employ it for the detection of potential phytotoxic substances at extremely small concentrations.

Acknowledgments—The authors wish to thank Dr. Gerald Leather, USDA, Frederick, Maryland, for advice on the *Lemna* bioassay and for supplying the cultures of *L. minor*. This project was supported by the Deutsche Forschungsgemeinschaft.

CHEMOECOLOGICAL ROLE OF MAMMALIAN URINE IN HOST LOCATION BY TSETSE, *Glossina* spp. (DIPTERA: GLOSSINIDAE)

L. CHUKA MADUBUNYI,* A. HASSANALI, W. OUMA, D. NYARANGO and J. KABII

The International Center of Insect Physiology and Ecology (ICIPE)
P.O. Box 30772, Nairobi, Kenya

(Received August 15, 1995; accepted February 19, 1996)

Abstract—Trap catch size was used to investigate whether *Glossina pallidipes* and *G. longipennis* could distinguish between the urine of the African buffalo, cattle, and waterbuck at Nguruman in southwest Kenya. NG2G traps baited with aged urine of these bovids caught significantly more of each tsetse than did the controls. The mean catch of either tsetse species in traps baited with aged urine of buffalo and cattle (tsetse hosts) and waterbuck (a nonhost) did not differ significantly. Aged urine from both tsetse hosts (buffalo and cattle) and the nonhost (waterbuck) was found to contain 4-cresol and 3-*n*-propylphenol in about the same ratio. However, the aged urine from other tsetse hosts (bushpig and warthog) lacked 3-*n*-propylphenol. Cattle urine had to be aged outside the soil to produce statistically significant increases in the trap catch of *G. pallidipes*. Furthermore, patches of soil on which fresh urine of cattle was deposited, and in which it was aged, failed to effect a significant increase in the trap catch of either *G. austeni*, *G. brevipalpis*, or *G. pallidipes* as Gazi, southeast Kenya. The likelihood of tsetse either differentiating its hosts from nonhosts or locating favored hosts by the urine scent appears remote under natural conditions. It is more likely that the chemical signals critical for host location by the tsetse emanate from skin glands rather than volatilize from the urine of mammals.

Key Words—Tsetse, *Glossina*, host location, mammalian urine, phenols, attraction, nonhosts.

INTRODUCTION

Ecosystems in which tsetse flies thrive necessarily also support various species of mammals, including hosts and nonhosts of tsetse. Every two to five days of their adult lives, tsetse must locate hosts from which to suck blood (Jackson, 1954; Glasgow, 1963; Randolph and Rogers, 1978; Madubunyi, 1989) or else incur reproductive loss through aborted pregnancies and protracted interlarval periods (Saunders, 1960, 1972) and/or perish from starvation. In nature, female tsetse are not always able to produce enough offspring to ensure survival of the species (Jordan, 1986). Precisely timed and adequately sized blood intake by the female during each 10-day pregnancy cycle is imperative for the production of each viable offspring (Mellanby, 1937) and indispensable for maintaining net population growth of tsetse. Timely location of mammalian hosts at the crucial moments of the trophic cycle is thus fundamental to the survival of tsetse species.

Most mammals maintain their respective identities, social structures, reproductive behavior, community cohesion, etc., through visual, auditory, tactile, and olfactory communication systems. Olfactory communication encompasses generation of chemical signals by a presumptive sender and their transmission (generally as airborne volatiles) to a presumptive receiver, who responds appropriately to them (Eisenberg and Kleiman, 1972). These chemical signals are by-products of metabolism, found in the excretory products (e.g., urine, feces, sweat and breath), or glandular secretions and exudations of mammals.

The ability to intercept the chemical signals with which the hosts exchange vital intraspecific information would confer major selective advantage to a genus of obligate blood-sucking arthropods such as *Glossina* Weidemann. By suggesting that *G. pallidipes* Austen uses its olfactory sense to locate hosts, Fuller and Mossop (1929) implied that tsetse has such ability. Lloyd (1935) further confirmed that *G. swynnertoni* Austen could perceive airborne volatiles from Zebu cattle (*Bos* spp.) that were not within sight and at a distance of 23 m. Bax (1937) later reported that the scent of ox manure was unattractive to *G. swynnertoni*. Chorley (1948) subsequently showed, however, that the scent of a mixture of cattle dung and urine was attractive to *G. pallidipes*. Owaga (1984, 1985) later found urine of the African buffalo [*Syncerus caffer* (Sparrman)] to be a potent olfactory attractant for *G. pallidipes* and enhanced its potency by aging it for three weeks or longer.

The attraction of certain tsetse species, e.g., *G. pallidipes* and *G. morsitans* Westwood, to buffalo and cattle urine is attributable to their phenolic constituents. In the most attractive fraction of buffalo urine, Hassanali et al. (1986) identified seven phenols. Field subtraction bioassays revealed that the synergistic action of only two components (4-cresol and 3-*n*-propylphenol) was responsible for increased trap catches of *G. pallidipes* in Kenya (Owaga et al., 1988). In a similarly attractive fraction of cattle urine, Bursell et al. (1988) identified eight

phenols; the previously mentioned phenols (4-cresol and 3-*n*-propylphenol) were again essential for the fraction's attractiveness of *G. pallidipes* and *G. morsitans* in Zimbabwe (Vale et al., 1988). Of these two essential phenols, 3-*n*-propylphenol was critical for the attraction of tsetse to aged urine of buffalo and cattle (Owaga et al., 1988; Vale et al., 1988).

Tsetse locates stationary hosts through odor-regulated anemotaxis, with visual attraction becoming important at close range (Vale, 1974, 1977). Approximately 90% of both *G. pallidipes* and *G. morsitans* that come to a host are attracted by its odor (Vale, 1974; Vale and Hall, 1985). In nature, the extent of host-urine odor involvement in this process in not clear. Nevertheless, Brightwell et al. (1991) and Saini et al. (1993) have suggested that phenols from cattle urine mediate in tsetse host location behavior.

Most mammals, unless purposely confined, do not remain at the location where they have urinated and/or defecated. The latter activities usually occur after the animals have watered or while they are grazing. Some favorite tsetse hosts, e.g., the bushpig [*Potamochoerus porcus* (Linnaeus)], even use latrines, i.e., established dung piles to which they walk deliberately to defecate (Kingdon, 1982, p. 208). Furthermore, once deposited in the soil, urine is subject to microbial degradation. The implications of these for tsetse trapping technology, which targets host-seeking individuals, prompted us to evaluate the ecological relevance of mammalian urine in host location by tsetse. The tsetse catch of traps baited with urine of selected bovid hosts and a nonhost as well as the effect of soil on the attractiveness of cattle urine to tsetse were compared in typical tsetse-inhabited ecosystems. The phenolic constituents of urine from selected wild mammalian tsetse hosts and a nonhost also were compared in laboratory studies.

METHODS AND MATERIALS

Urine Sources. Wild mammalian hosts and nonhosts of tsetse were chosen from results of tsetse bloodmeal analyses published by Weitz (1963) and Snow et al. (1988). The choice was further narrowed by accessibility of the animal for urine collection. The hosts selected were the African buffalo, bushpig, warthog [*Phacochoerus aethiopicus* (Pallas)], and domestic cattle; the nonhost was waterbuck [*Kobus defessa* group (Ogilby)]. The buffalo, cattle, and waterbuck were in captivity and fed a zero-grazing diet of hay and concentrates. The bushpig and warthog free-ranged in the wild. Urine was collected either as these animals urinated naturally (buffalo, cattle, and waterbuck) or from their urinary bladders excised upon slaughter (bushpig and warthog). Subsequent handling of the urine depended on the requirements of the experiments (see below).

Field Sites. Field studies were done at the Olkeramatian Group Ranch at Nguruman (1°50′S, 36°05′E) in Rift Valley Province, and the Gongoni Forestry

Reserve at Gazi (4°25′S, 39°28′E) in Coast Province, Kenya. Olkeramatian Ranch is within a typical semiarid agropastoral ecosystem infested with *G. longipennis* Corti and *G. pallidipes*. The experimental sites were located along the thicketed fringes of the Ewaso Ngiro River, to the northwest of the tsetse suppression zone of Dransfield et al. (1990). Gongoni Forestry Reserve is within the rainforest zone of the south Kenya coast, whose salient ecological features Snow et al. (1988) described. Like most of the zone, the forestry reserve is infested with *G. austeni* Newstead, *G. brevipalpis* Newstead, and *G. pallidipes*. The experimental sites were in the interior biotope of the forest's southern portion, which adjoins the Msambweni Development Corporation Farm at Gazi. Both field sites are designated protected wildlife areas and each has an ample assortment of mammalian fauna.

Effect of Urine of Selected Hosts and Nonhost on Trap Catch of Tsetse. All experiments were carried out during the cool dry season (July–September) at Nguruman, using NG2G traps (Brightwell et al., 1991) baited with buffalo, cattle, or waterbuck urine aged for four weeks in the laboratory, following the procedure of Owaga (1985). The traps were placed at least 300 m apart.

The aged urine (200 ml) of each mammal was placed in a 250-ml glass jar dispenser with a mouth measuring 5.5 cm in diameter. Acetone (25 ml) was put into 200-ml glass dispensers, each of which had a 3-mm hole in its lid. The treatments consisted of traps baited with dispensers of urine and acetone placed beside each other at ground level, approximately 30 cm behind the trap entrance. The controls consisted of traps baited with acetone only.

Treatments and controls were deployed in a 4 × 4 Latin square replicated three times at two sublocations. There was a bait-free interval of four days between treatments. On the second day following positioning of odor baits, the traps were emptied to record the sex and number of each tsetse species caught.

Effect of Soil Substrate on Attractiveness of Cattle Urine to Tsetse. Experiments were conducted during the hot dry season (January–March) at the Gongoni Forestry Reserve using the NG2G trap. For this series of experiments, urine was obtained from Zebu cattle maintained under free grazing at Gazi. Large glass containers (one liter capacity, 15 cm deep) filled with soil dug up from Gongoni Forest or 250-ml glass jars without soil were used to dispense the urine odor. In the first experiment, 200 ml of fresh urine was poured into each dispenser and immediately used as bait for the traps. In the second experiment, the dispensers were left in the forest for three days after adding fresh urine before being used to bait traps from the fourth day. The treatment bait consisted of both urine and acetone; the control consisted of acetone alone.

Treatments were deployed in a 3 × 3 Latin square replicated three times at two sublocations that were ca. 500 m apart. The traps were emptied after 24 hr to record the sex and number of tsetse caught.

Extraction of Urine from Selected Hosts and Nonhost of Tsetse. Aged (3- to 6-week-old) urine samples (≈ 100 ml) of buffalo, bushpig, cattle, warthog, and waterbuck, respectively, were extracted twice with dichloromethane (20 ml × 2). The combined organic extract of each was dried over sodium sulfate, filtered, and concentrated in vacuo at 35°C. The residues were dissolved in dichloromethane (1 ml) and stored at −20°C.

Analysis of Urine Extracts. Urine extracts were analyzed on an HP 5890 gas chromatograph equipped with a flame ionization detector (FID) and an HP fused-silica capillary column (Carbowax 20 M, 50 m × 0.2 mm ID × 0.2 μm). The carrier gas was nitrogen at a flow rate of 0.62 ml/min. The GC oven temperature program consisted of an initial ramp of 100–180°C at 3°C/min, followed by a ramp from 180 to 230°C at 10°C/min. Chromatographic peaks were integrated on an HP 3393A integrator. The GC-MS analyses of urine extracts and synthetic standard compounds were conducted on a VG Masslab 12-250 mass spectrometer (EI mode, 70 eV; filament emission current 100 μA; source temperature 180°C; tuning standard PFTBA; GC interface temperature 220°C) coupled to an HP 5790 gas chromatograph under the same GC conditions as above.

Statistical Analysis. Trap catches were transformed to log $(n + 1)$ before being subjected to analysis of variance (ANOVA). If differences between the catch of female and male tsetse were negligible, the data for both sexes were pooled. When the treatment effect on trap catch was significant, differences between the treatment means were scrutinized for statistical significance at $P < 0.05$ by the Student-Newman-Keuls (SNK) test.

RESULTS

Effect of Host and Nonhost Urine on Trap Catch of Tsetse at Nguruman. Traps baited with the aged urine of buffalo, cattle, or waterbuck (treatments) caught significantly more *G. pallidipes* ($P < 0.001$) and *G. longipennis* ($P < 0.001$) than unbaited traps (controls). The source of the urine seemed to have affected the mean trap catch of *G. longipennis* but not that of *G. pallidipes* (Table 1). Nevertheless, the mean catch of either tsetse species in traps baited with the urine of buffalo and cattle (tsetse hosts) and waterbuck (a nonhost of tsetse) did not differ significantly.

Effect of Soil Substrate on Attractiveness of Cattle Urine to Tsetse in Gongoni Forest. Baiting traps with fresh cattle urine increased the catch of *G. pallidipes* and *G. brevipalpis* but tended to depress that of *G. austeni* (Table 2). The traps baited with fresh cattle urine in containers without soil caught only ~1.2 and ~1.3 times more *G. brevipalpis* and *G. pallidipes*, respectively, than those baited with fresh urine in soil-filled containers. Because of the low num-

TABLE 1. EFFECT OF AGED URINE OF SELECTED MAMMALS ON NG2G TRAP CATCH OF TSETSE AT NGURUMAN, RIFT VALLEY PROVINCE, KENYA[a]

Urine source	Catch/trap (mean ± SE)	
	Glossina longipennis	*Glossina pallidipes*
Buffalo	90 ± 18a	148 ± 34a
Cattle	52 ± 8a	120 ± 22a
Waterbuck	74 ± 11a	123 ± 33a
Control (no urine)	15 ± 4b	43 ± 12b

[a]ANOVA and SNK test for significant difference between treatment means were performed on log $(n + 1)$-transformed pooled trap-catch data. Means followed by the same letter are not significantly different ($P > 0.05$). Urine was aged for four weeks at the diurnal temperatures prevailing in the laboratory (22–25°C).

bers of *G. austeni* and *G. brevipalpis* caught, differences in their trap catch size were not subjected to statistical analysis. However, for *G. pallidipes*, whose catch sizes were statistically analyzable, the difference was not significant ($P > 0.05$).

The traps baited with cattle urine aged for three days in containers without soil caught almost twice as many *G. austeni*, *G. brevipalpis*, and *G. pallidipes* as those baited with urine aged in soil-filled containers. The latter did not attract significantly more tsetse than the unbaited control (Table 2). Again, low catch

TABLE 2. EFFECT OF AGING SUBSTRATE ON ATTRACTIVENESS OF CATTLE URINE TO TSETSE AT GAZI, COAST PROVINCE, KENYA[a]

Urine type/aging substrate	Catch/trap (mean ± SE)		
	G. austeni	*G. brevipalpis*	*G. pallidipes*
Fresh urine in container			
Without soil	0.5 ± 0.2	3.4 ± 1.0	27.1 ± 8.4
Filled with soil	1.0 ± 0.3	2.7 ± 1.0	20.4 ± 4.9
Control (acetone only)	1.2 ± 0.4	2.4 ± 0.5	18.3 ± 3.8
Urine aged in container			
Without soil	1.9 ± 0.7	2.5 ± 0.4	45.6 ± 4.2a
Filled with soil	1.0 ± 0.3	1.4 ± 0.4	19.2 ± 5.1b
Control (acetone only)	1.0 ± 0.5	2.3 ± 0.6	20.3 ± 7.7b

[a]ANOVA and, where applicable, SNK test for significant different between treatment means were performed on log $(n + 1)$-transformed pooled trap-catch data. Means in each column are not significantly different ($P > 0.05$) if followed by the same or no letter. The aging of urine lasted three days at diurnal temperatures inside Gongoni Forest (24–34°C).

excluded *G. austeni* and *G. brevipalpis* from statistical evaluation of these differences. However, for *G. pallidipes*, the substrate in which the cattle urine was aged had a statistically significant effect on the trap catch ($P < 0.01$). The urine was significantly more attractive when aged in a container without soil ($P < 0.05$).

Phenolic Constituents of Urine from Selected Hosts and a Nonhost of Tsetse. Aged urine of waterbuck contained both 4-cresol and 3-*n*-propylphenol (Figure 1A) in about the same ratio (~ 11 : 1) as that of buffalo (Figure 1B). The presence of 4-cresol and 3-*n*-propylphenol was confirmed by GC-MS analysis: 4-cresol, *m/z* (relative intensity) at 108 (86), 107 (100), 90 (12), 79 (25), 77 (80), 63 (10), 53 (15), 51 (20), 39 (18), 27 (20); 3-*n*-propylphenol, *m/z* (relative intensity) at 136 (39), 121 (15), 108 (52), 107 (100), 91 (8), 77 (30), 65 (7), 51

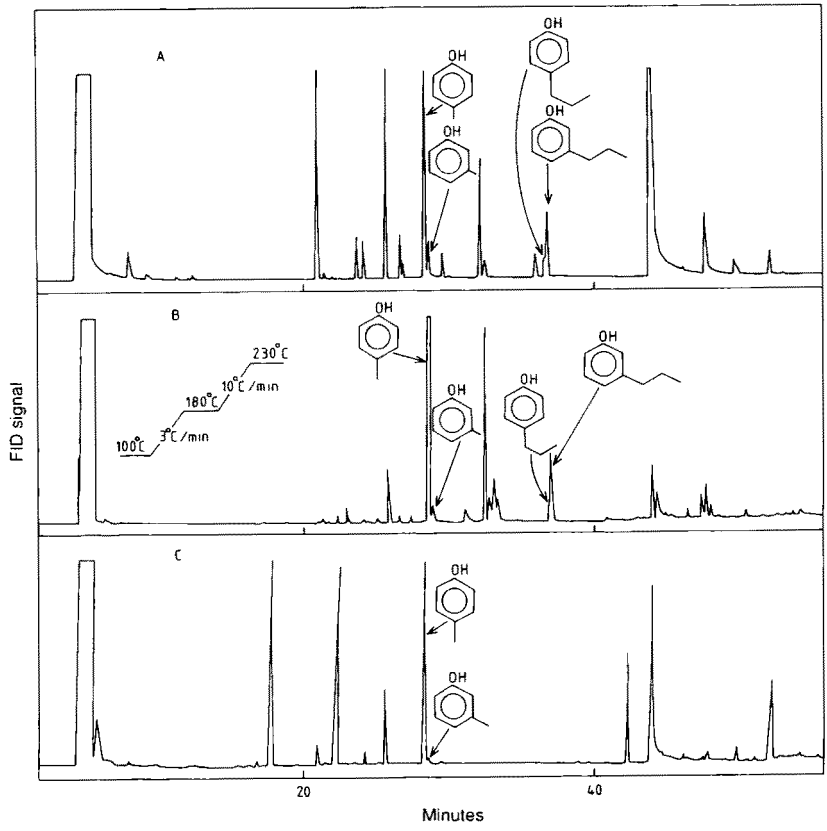

FIG. 1. Gas chromatograms of dichloromethane extracts of aged urine samples of the waterbuck (A), African buffalo (B), and warthog (C) showing the presence of 4-cresol in all the three but 3-*n*-propylphenol in only (A) and (B).

(9), 39 (18). These were identical to those of authentic synthetic standards (see also Hassanali et al., 1986). Aged urine of the warthog also contained 4-cresol but no observable amounts of 3-*n*-propylphenol (Figure 1C). Bushpig urine contained 4-cresol also, although in smaller amounts; in this case, 3-*n*-propylphenol was not observed.

DISCUSSION

The number of tsetse attracted by an odor-baited trap depends on the trap's collective olfactory and visual attractiveness to various tsetse species. The proportion of attracted flies caught depends on the trap's ensnaring efficiency. An attractive odor, applied as bait, would primarily enhance the number of tsetse attracted to the trap. By using tsetse traps of the same design for treatment and control, variability in trap catch due to the inherent efficiency of the trap design is reduced. The size of a baited trap's catch should reflect, therefore, the potency of the candidate tsetse attractant.

Aged urine of buffalo, cattle, and waterbuck, significantly increased the NG2G trap catch of the two tsetse species at Nguruman. The aged urine of tested hosts attracted *G. pallidipes* at about the same level. Aged cattle urine was apparently less attractive to *G. longipennis* than aged urine of either the buffalo or waterbuck. The chemoecological basis of these differences in the response of *G. pallidipes* and *G. longipennis* is not immediately clear, given the remarkable similarity in the phenolic composition of aged urine from all three bovids. Earlier studies, also at Nguruman, found similar differences in the effect of buffalo and cattle urine on trap catch to be statistically significant for *G. pallidipes* (Owaga, 1985) but not significant for *G. pallidipes* (Dransfield et al., 1986) and *G. longipennis* (Kyorku et al., 1990). Nevertheless, in our study, neither tsetse species showed evidence of having distinguished between traps baited with the urine of buffalo and cattle (hosts) and waterbuck (a nonhost). It is doubtful, therefore, that either species differentiates between these animals in nature solely from the scent of their aged urine.

The level of increase in the trap catch of *G. pallidipes* ($\times 1.8$) realized with fresh cattle urine in the Gongoni forest was relatively lower than that achieved with aged cattle urine at the same location ($\times 2.4$) or at Nguruman ($\times 2.8$). Significantly, according to Okech and Hassanali (1990), fresh buffalo urine has virtually no phenolic components. This is probably also true of fresh cattle urine. Since the attractiveness of aged buffalo or cattle urine to *G. pallidipes* depends on their phenolic constituents, the observed relative unattractiveness of fresh cattle urine is consistent with its probable chemical profile. It is thus improbable that urine attracts tsetse as wild animals pass it out, let alone attracting the flies to their hosts' locations.

The microbial invasion of fresh buffalo urine stored in an unsterilized container at room temperature for 16 days caused the formation and gradual accumulation of the phenols that attract tsetse (Okech and Hassanali, 1990). This study confirms that conversion of containerized fresh cattle urine into a tsetse attractant happens in as short an interval as three days under field conditions. It further shows that the substrate in which urine is aged greatly affects its transformation into a potent tsetse attractant. Thus, only when aged in a glass container, without soil, did the odor of cattle urine become sufficiently attractive to cause overall increases in the trap catch of tsetse. The outcome of aging urine in glass containers without soil is of debatable ecological relevance since, in nature, animals urinate on the ground.

A major advantage that chemical signals have over visual and auditory ones is that they can persist for some time without their sender being present (Eisenberg and Kleiman, 1972). In this study, however, cattle urine aged in soil-filled containers failed to increase significantly the trap catch of even *G. pallidipes*. This suggests that, under natural conditions, if the urine phenols essential for attraction of *G. pallidipes* happen to be produced, they do not persist. Therefore, cattle urine is an unlikely host-habitat chemical cue for this and probably other tsetse species.

By deterring microbial invasion of fresh urine through sterilization, Okech and Hassanali (1990) prevented buffalo urine from becoming attractive to tsetse. Although rich in microbial fauna and flora, soil may lack microbes that can hydrolyze the glucuronates and sulfates in fresh urine into the free phenols that make fermented bovid urine attractive to tsetse. Alternatively, the soil microflora may comprise organisms that produce these phenols and others that break them down rapidly as they are formed. Regardless of the mechanism, however, patches of soil wetted with fresh urine of cattle failed to produce significant increases in the mean trap catch of tsetse. Therefore, urine passed by moving animals is not likely to attract host-seeking tsetse to their hosts' immediate or subsequent locations.

Urinating on a social partner's body or transferring urine from one part of an animal's body to another is normal in the olfactory communication behavior of some mammalian species (Steiniger, 1950; Müller-Schwarze, 1971). In addition, the sweat glands of some mammals excrete, onto the skin surface, chemicals that are also found in their urine (Breazile, 1971). The action of microbial flora of the skin, or both urine and sweat, contributes to the total kairomonal mixture that gives an animal its body odor. For cattle, this mixture comprises all the phenols found in aged urine of buffalo or cattle and several other compounds (Saini et al., 1993). The latter are suspected of being more important to tsetse for host location and identification than the urine-derived phenols. The influence of these additional compounds may explain why the sebum of cattle significantly increased trap catches of *G. m. morsitans* (Warnes, 1990), whereas

aged urine of cattle did not (Vale et al., 1986, 1988). For the bushpig and warthog, however, it is unlikely that 3-*n*-propylphenol from urine or sweat will be among the kairomonal constituents of body odor. Bursell et al. (1988) did not find 3-*n*-propylphenol in aged domestic pig urine; neither was it found in the aged urine of the bushpig or the warthog in the present study. Therefore, pigskin wash should contain no more than trace amounts of the 3-*n*-propylphenol, which is critical for the attractiveness of aged mammalian urine to *G. pallidipes* (Owaga et al., 1988; Vale et al., 1988). Nevertheless, pigskin extract reportedly doubled and even quintupled the catch of *G. pallidipes* (Vanderplank, 1944; Persoons, 1965, 1966, 1967), suggesting that other volatile components are involved in the attraction of this tsetse. Accordingly, the presence of urine as a contaminant on the mammalian skin might be of little or no significance in attracting tsetse to hosts.

Cattle and buffalo, whose aged urine increased the trap catch of all the tsetse species in our study, are acknowledged hosts of many tsetse species (Weitz, 1963). However, *G. pallidipes* and *G. morsitans* are indifferent to the scent of aged urine of the warthog (Owaga, 1984) and the domestic pig (Bursell et al., 1988), which are also hosts of both tsetse species. In fact, Torr (1994) classified the urine of warthog as repellent to tsetse. These results seem to reflect the absence of biologically significant amounts of 3-*n*-propylphenol in aged urine of some favorite hosts of the tsetse (e.g., the domestic pig, bushpig and warthog). The scent of urine is thus of doubtful ecological relevance in the location and selection of hosts by tsetse.

In this study, *G. pallidipes* was attracted equally to the aged urine of waterbuck (a nonhost) and buffalo (a favorite host) in the field. Positive response by this tsetse species to the odor of fermented mammalian urine, therefore, does not necessarily signify a response to olfactory stimuli from a host. Perhaps this is why traps baited with aged urine of cattle caught fewer *G. pallidipes* that were foraging for a bloodmeal than those that were not (Madubunyi, 1995). A successful bout of host-seeking by tsetse ends in bloodsucking, during which it may pick up and/or transmit trypanosomes, an epidemiologically critical behavior common to all species of tsetse. It makes them all equally vulnerable to trapping and makes odor-baited traps potentially powerful tools for reducing trypanosomiasis transmission. Results obtained during this study suggest that achieving this goal would require odor-baits from a source other than mammalian urine.

Adsorbent-trapped skin volatiles of different mammalian hosts of tsetse contain a rich blend of chemicals (Hassanali, unpublished). These may include those kairomones suspected to be more potent than cattle urine phenols for host location (Saini et al., 1993) or the attraction of tsetse that are strictly foraging for a bloodmeal (Madubunyi, 1995). Skin-based constituents of body odor are chiefly secretions and exudations of glands that are part and parcel of mammalian dermatography. These are more likely than urine to possess species- or strain-

specific qualities by means of which a tsetse can make olfactory distinctions between its hosts and nonhosts or between potential hosts. The skin of their mammalian hosts is thus a promising source to prospect for kairomones that are critical for the location of hosts by each tsetse species.

Acknowledgments—We thank Reordan O. Olubayo of The Veterinary Department, Kabete, Kenya, for facilitating access to the African buffalo and waterbuck urine; Adedapo Odulaja for statistical assistance; and Slawomir A. Lux for helpful critique of our manuscript. We also thank the ICIPE Director General for permission to publish. This work was funded by the United Nations Development Programme (UNDP) under Project GLO/90/006/A/01/42.

(Received July 5, 1995; accepted Feburary 20, 1996)

Abstract—Solvent extracts of individual pheromone glands were prepared from female *Helicoverpa assulta* (Guenée) at 2-hr intervals throughout the scotophase. The amounts of female sex pheromone components, (Z)-9-hexadecenal, (Z)-11-hexadecenal, (Z)-9-hexadecenyl acetate, and (Z)-11-hexadecenyl acetate, in the extracts were determined by gas chromatographic analysis. Although females called from early scotophase (2 hr) until late scotophase (6 hr) the quantity of extracted pheromone remained high at 8 hr, the end of the scotophase. More than 70% of the pheromone gland extracts contained sex pheromone components regardless of whether the donor females had been called or resting. Pheromone components were absent from gland extracts prepared at the onset of the scotophase. The quantity of (Z)-9-hexadecenal and (Z)-11-hexadecenal increased rapidly to reach a maximum of approximately 260 and 30 ng/female, respectively, that was maintained for up to 8 hr, the duration of the scotophase. The quantity of (Z)-9-hexadecenyl acetate and (Z)-11-hexadecenyl acetate increased continuously during the scotophase to peak at 600 and 30 ng/female, respectively, 8 hr into the scotophase. At the end of scotophase the quantity of all pheromone components decreased significantly.

INTRODUCTION

Oriental tobacco budworm, *Helicoverpa assulta* (Guenée) (Lepidoptera: Noctuidae), is widely distributed throughout Asia, Oceania, and Africa. Sugie et al. (1991) identified hexadecanal, (Z)-9-hexadecenal (Z9-16:Al), (Z)-11-hexadecenal (Z11-16:Al) and (Z)-9-hexadecenyl acetate (Z9-16:Ac) as female sex pheromone components of *H. assulta* in Japan. However, mixtures of Z9-16:Al, Z11-16:Al, Z9-16:Ac, and (Z)-11-hexadecenyl acetate (Z11-16:Ac) caught the highest number of males in Korea, China, and Thailand, although the optimal ratio of compounds varied by country. Such intraspecific variation has been reported from a number of species (Arn et al., 1983; Haynes and Hunt, 1990; Löfstedt, 1990; Clearwater et al., 1991; Tòth et al., 1992), and it has been suggested that pheromone component ratio is genetically controlled in some lepidopteran species (Collins and Cardé, 1985; Haynes and Hunt, 1990; Hunt and Haynes, 1990). In contrast, the ratio of two sex pheromone components of *Phthorimaea operculella* was influenced by rearing temperature (Ono, 1993).

The two hexadecenyl acetates, Z9-16:Ac and Z11-16:Ac, were also found to elicit significantly different behavioral responses from male *H. assulta* in Korea (Cork et al., 1992; Park et al., 1994), China, Thailand (Cork et al., 1992), and Japan (Sugie et al., 1991). In Korea and Japan the hexadecenyl acetate isomers increased trap catches, while in China they both increased and decreased trap catch depending on season; in Thailand they had no significant effect on male trap catches.

Sex pheromone production and release in moths is dependent on both exogenous (photoperiod, temperature) and endogenous (neural, hormonal) factors (Baker and Cardé, 1979; Raina, 1988; Kou, 1992). The calling and mating activities of *H. assulta* were found (Kim and Boo, 1986; Cho and Boo, 1988) to have a circadian periodicity, with a peak in mating activity between 1 and 2 hr into the scotophase. Many Lepidoptera exhibit a similar diel periodicity in calling (McNeil, 1991; Giebultowicz et al., 1992) that has frequently been related to changes in pheromone titer, as reported for *H. zea* (Boddie) (Raina et al., 1986), *Pseudaletia unipunctata* (Haworth) (Delisle and McNeil, 1987), *Spodoptera littoralis* (Boisduval) (Martinez and Camps, 1988), *Spodoptera frugiperda* (J. E. Smith) (Ramaswamy et al., 1988), *Helicoverpa armigera* (Hübner) (Rafaeli and Soroker, 1989), *Heliothis virescens* (F.) (Mbata and Ramaswamy, 1990), *P. operculella* (Zeller) (Ono et al., 1990), and *H. assulta* (Kamimura and Tatsuki, 1994).

The effectiveness of sex pheromones for monitoring or control of insect pests may depend on the relative attractiveness of the synthetic sex pheromone compared to that of naturally produced pheromone. Therefore, an understanding of the temporal and spatial variability in sex pheromone composition of a species may have significant implications for a pheromone-based pest management strat-

egy. This study was conducted to investigate the periodicity of sex pheromone biosynthesis and composition in a population of the oriental tobacco budworm.

METHODS AND MATERIALS

Insects. Larvae of *H. assulta* were collected from hot pepper fields in Suwon, Korea, and reared individually on an artificial diet (Park, 1991). The colony was maintained at 25 ± 1°C for successive generations under a light–dark cycle of 16L:8D. Pupae were collected daily, sexed, and kept individually in Perspex containers (5 cm high × 3 cm diam.) under the same environmental conditions.

Observation of Calling Behavior and Pheromone Extraction. Adult virgin female *H. assulta*, 1–2 days old, were placed individually in plastic containers ($N = 37$) 2 hr before the onset of the scotophase. Two-minute observations were made of each female during each ensuing 2-h interval until 2 hr after the scotophase. Females were classified as either calling or resting. Calling females extruded their abdominal tips and displayed wing fanning over the entire period of observation, while resting females displayed negligible movement with wings and antennae folded (Cho and Boo, 1988).

Pheromone extracts were prepared at the end of each 2-hr observation period from virgin females classified as either calling or resting. Pheromone glands were excised by anesthetizing adult females with CO_2 and pressing the abdominal tip lightly to evert the ovipositor and the pheromone gland, a complete ring of glandular epithelium between the 8th and 9th abdominal segments (Moon et al., 1986). The gland and exposed abdominal tip were excised with microscissors into a microvial containing 10 μl hexane and 100 ng (*Z*)-9-tetradecenyl acetate as an internal standard, held for 30 sec, and then removed. The effect of prolonged extraction was tested by removing a 5-μl aliquot from the extract 30 sec after immersing the abdominal tip, adding a further 10 μl of hexane, without internal standard, to the vial, and taking a second extract after 300 sec had elapsed. Extracts were transferred to 10 μl glass capillary tubes, sealed, and stored at < -20°C.

Gas Chromatography (GC). Individual gland extracts were analyzed on a polar fused-silica capillary column (CBP-20, 25 m × 0.2 mm ID) in a Shimadzu model 14A GC equipped with a Grob split–splitless injector (210°C) and a flame ionization detector (210°C) with nitrogen carrier gas (2.0 kg/cm^2). Analyses were conducted with 1-μl aliquots injected onto the column held isothermally at 180°C.

Statistical Analysis. The results were statistically analysed by chi-square tests, Student's *t* test, or analysis of variance (ANOVA). If significant differences were found by ANOVA ($P = 0.05$), the means were ranked by Duncan's multiple-range test (DMRT).

RESULTS

Female *H. assulta* showed typical calling behavior (Cho and Boo, 1988) only during the scotophase. High incidence of calling behavior (80%) occurred within 2 hr of the onset of the scotophase and lasted up to 6 hr into the scotophase at essentially the same level (Figure 1). Two hours before the end of the scotophase, the level of calling decreased to about 30%, and none was observed in the photophase. Insects that were not calling showed typical resting behavior.

The percentages of gland extracts produced from calling and resting females during the scotophase that contained sex pheromone components were not significantly different (κ^2 test, $P > 0.05$), at 71 and 80%, respectively. Sixty-seven percent of resting females examined 2 hr after the end of the scotophase contained detectable amounts (>5 ng) of sex pheromone components. No sex pheromone components (<5 ng) were detected from gland extracts prepared within 2 hr of the onset of the next scotophase.

The quantity of the two major components of the female sex pheromone, Z9-16:Al and Z11-16:Al, reached an average of 189 and 23 ng/female, respectively, within 2 hr after the onset of the scotophase; thereafter the quantities remained statistically the same (Table 1). Two hours after the scotophase ended,

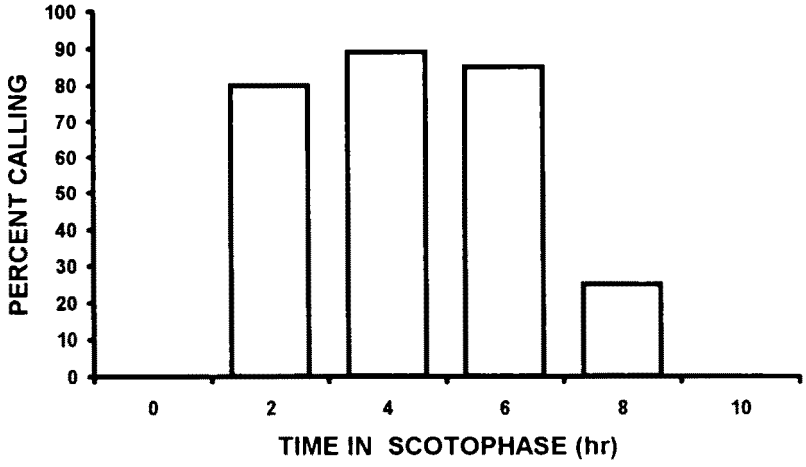

FIG. 1. The percentage of Korean female *H. assulta* calling during the scotophase under 16L:8D photoperiod at 25°C. Observations commenced 2 hr before the onset of the scotophase and terminated 2 hr after the end of the scotophase. Each female was maintained individually in a transparent polystyrene container ($N = 37$); 0 hr means 5 min before the onset, and 8 hr means 5 min before the end of scotophase. No calling was observed 2 hr before the onset of scotophase.

TABLE 1. AMOUNT OF EACH PHEROMONE COMPONENT IN FEMALE *H. assulta* GLAND EXTRACTS EXTRACTED BEFORE, DURING, AND AFTER SCOTOPHASE

Sampling time	Amount (ng) of extracted compound (average ± SE, $N = 8$)[a]			
	Z9-16:Al	Z11-16:Al	Z9-16:Ac	Z11-16:Ac
5 min before onset of scotophase	0a	0a	0a	0a
Within scotophase				
2 hr	189 ± 125bc	23 ± 14b	70 ± 70b	6 ± 6b
4 hr	260 ± 79c	30 ± 15b	122 ± 48b	9 ± 5b
6 hr	238 ± 108bc	27 ± 18b	344 ± 77c	25 ± 12b
7 hr 55 min	261 ± 83c	21 ± 10b	614 ± 262c	32 ± 20b
2 hr after scotophase	57 ± 14b	4 ± 4a	143 ± 83b	6 ± 4b

[a]Data within a column analyzed by ANOVA; means followed by different letters are significantly different at $P < 0.05$ by Duncan's multiple-range test.

the amount of each hexadecenal isomer declined significantly to 22 and 19%, respectively, of the levels 5 min before the end of the scotophase.

In contrast, the two hexadecenyl acetate isomers, Z9-16:Ac and Z11-16:Ac, increased continuously in quantity during the scotophase, statistically significantly for Z9-16:Ac (Table 1). The quantities peaked at 614 and 32 ng/female for Z9-16:Ac and Z11-16:Ac, respectively, and rapidly decreased within 2 hr after the scotophase to reach 23 and 19% of the respective levels just before the end of the scotophase.

The ratios of the amount per female of Z9-16:Al to Z11-16:Al and that of Z9-16:Ac to Z11-16:Ac were relatively constant throughout the scotophase, and averaged 14.6 ± 1 and 17.2 ± 1.5, respectively. The ratio between the ratios (aldehyde-acetate) was also relatively constant, averaging 0.83 ± 0.05. However, the ratios of each hexadecenyl acetate isomer to the homologous hexadecenal isomer changed significantly during the scotophase, rising from 0.37 and 0.26 at 2 hr into the scotophase to 2.35 and 1.52 just before the end of the scotophase for Z9-16:Ac/Z9-16:Al and Z11-16:Ac/Z11-16:Al, respectively (Figure 2). These changes were primarily due to the increased amounts of the hexadecenyl acetate isomers observed over the course of the scotophase and not to a decrease in the quantity of hexadecenal isomers.

Increasing the extraction time from 30 and 300 sex had no effect on the amount of Z9-16:Al and Z11-16:Al extracted (t test, $P > 0.05$), but significantly increased the amounts of Z9-16:Ac and Z11-16:Ac extracted by 38.9 ($P < 0.01$) and 23.4% ($P < 0.05$), respectively.

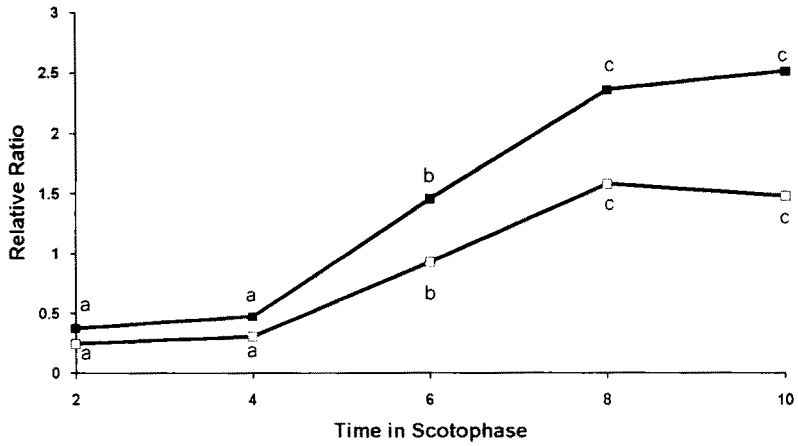

FIG. 2. Changes in the relative ratio of Z9- (solid square) and Z11-16:Ac (open square) to homologous hexadecenal isomers at different times in the scotophase in gland extracts of female *H. assulta* (16L:8D photoperiod). Values in a line with different letters are significantly different, $P < 0.05$.

DISCUSSION

The duration of calling observed in this study, from 2–6 hr into the scotophase (Figure 1), is similar to that found previously with insects of Korean (Kim and Boo, 1986; Cho and Boo, 1988) and Japanese origin (Kamimura and Tatsuki, 1993, 1994), although it contrasts with that observed for *H. assulta* from Thailand (E. Dunkelblum, personal communication), where calling was not observed until 10 h into the scotophase.

The continued high levels of extractable hexadecenal isomers (Table 1), even after calling activity declined (Figure 1), is in contrast to the findings of Kamimura and Tatsuki (1994), who found that the quantity of Z9-16:Al in gland extracts declined significantly as calling activity decreased. Since pheromone glands would be retracted when females are not calling, only enzymatic degradation could account for pheromone loss during this period. Because quantities of the hexadecenal isomers in the gland extracts did not decline during this period (Table 1), we propose that different mechanisms must control calling behavior and pheromone degradation. This hypothesis is supported by our finding that the amounts of pheromone components were independent of the behavioral status of female *H. assulta* throughout the scotophase (Table 1, Figure 2), a result that is consistent with the suggestion that calling and pheromone production are activated by different systems (Kamimura and Tatsuki, 1994).

The highly significant reduction in the pheromone content of gland extracts after the onset of the photophase (Table 1) suggests that the compounds were enzymatically degraded since loss through release would again be highly unlikely in the absence of calling. Whether this degradation is endogenously controlled by a circadian rhythm or is induced by exogenous stimuli, e.g., the presence of light, is unclear.

The absence of pheromone in gland extracts prepared 2 hr before the onset of the scotophase is in contrast to the results of Kamimura and Tatsuki (1993), who found that up to 20 ng/female of Z9–16:Al was present in Japanese *H. assulta* during the photophase.

The relative amounts of pheromone components in pheromone glands at different times through the scotophase is known to vary widely in the Heliothidinae. In *Helicoverpa zea* the quantity of pheromone components in gland extracts increased gradually after the onset of the scotophase to a maximum between 4 and 6 hr into the scotophase and then gradually declined (Heath et al., 1991). In contrast, pheromone content in *H. virescens* peaked between 8 and 10 hr into the scotophase (Heath et al., 1991). However, in both cases peak pheromone levels and calling activity coincided.

Cork et al. (1992) reported that the ratio of Z9–16:Ac to Z9–16:Al in pheromone gland extracts of female *H. assulta* from Korea increased dramatically between 4–6 and 10 hr into the scotophase from 0.26 to 2.32, respectively, in agreement with our finding of an increase of 0.37 to 2.35 between 2 and 8 hr into the scotophase. In contrast, Sugie et al. (1991) showed that the ratio of Z9–16:Ac to Z9–16:Al in Japanese females was 0.15 at the mid-scotophase. This result was subsequently confirmed by Kamimura and Tatsuki (1994), who also suggested that the relative amounts of each of the minor pheromone components remained constant despite daily fluctuations in the absolute amount of pheromone. In fact, their results do show a relative increase in the ratio of Z9–16:Ac to Z9–16:Al towards the end of the scotophase, but the change is more a reflection of a decrease in Z9–16:Al content rather than an increase in the amount of Z9–16:Ac. The reasons for the differences between the Korean and Japanese populations of *H. assulta* are unknown, but since a trap bait comprising a 3:1 ratio of the hexadecenal to hexadecenyl acetate isomers was more attractive than the hexadecenal isomers alone in Korea (Cork et al., 1992) the hexadecenyl acetates in Korea at least are behaviorally active. In related work, Heath et al. (1991) were able to show similar temporal changes in the relative proportions of alcohols to acetates and acetates to aldehydes in *Heliothis subflexa*, although in the related *H. virescens* these differences were not observed.

The increase in amounts of Z9–16:Ac and Z11–16:Ac recovered after a 10-fold increase in extraction time suggests at least some of the acetates were present inside the pheromone glands. The amounts of Z9–16:Al and Z11–16:Al recovered were not affected by extraction time, suggesting that they were only

present on the cuticular surface of the gland or are biosynthesized at or near the cuticular surface, as suggested by Teal and Tumlinson (1986) for the related *H. zea* and *H. virescens*. However, unlike *H. zea* and *H. virescens*, the presumed precursor alcohols could be synthesized from the corresponding hexadecenyl acetates that are present in the pheromone glands during the scotophase in significant quantities.

In conclusion we have shown that, in contrast to Japanese female *H. assulta*, Korean moths produce large quantities of the hexadecenyl acetate isomers, Z9–16:Ac and Z11–16:Ac, and that the relative ratios of the hexadecenal to hexadecenyl acetates vary significantly over the scotophase but are independent of the behavioral status of the females. These hexadecenyl acetates elicit a behavioral response from Korean *H. assulta*, but in China they had either no effect or reduced trap catches, depending on the time of year they were field tested (Cork et al., 1992). Thus their presence and bioactivity may define, in part, the basis for differences between geographically separated populations of *H. assulta*.

(Received August 7, 1995; accepted February 28, 1996)

Abstract—The presence of pheromones produced by larvae of *Glossina morsitans morsitans* and *G. m. centralis*, respectively, which attract gravid females and result in aggregation of pupae, is confirmed. Behavioral experiments indicated that females preferred to larviposit over moist sand conditioned by previously allowing larvae to pupariate in it. Similar results were obtained with filter papers contaminated with the prepupariation excretions of larvae and with volatiles collected from larvae prior to pupariation. *n*-Pentadecane and *n*-dodecane were identified as the dominant electrophysiologically active components of the larviposition pheromones of *G. m. morsitans* and *G. m. centralis*, respectively, by GC-EAD and GC-MS analysis of the trapped larval volatiles. Both identified compounds were shown to significantly attract gravid females to larviposition sites in laboratory behavioral assays.

Key Words—*Glossina morsitans morsitans*, *Glossina morsitans centralis*, tsetse flies, Diptera, Glossinidae, larviposition, pheromone.

INTRODUCTION

Tsetse flies (Diptera: Glossinidae: *Glossina*) mature their offspring in utero, giving birth to mature larvae that burrow into the soil and pupariate. Just before pupariation, larvae release an anal exudate that coats the larval cuticle (King-

horn, 1912; Lamborn, 1915; Fiske, 1920; Nash et al., 1976; Rowcliffe and Finlayson, 1981; Zdarek and Denlinger, 1991). In preliminary experiments undertaken by Leonard and Saini (1993), it was shown that semiochemicals from the prepupariation excretions of larvae of *G. morsitans morsitans* Westwood and *G. moristans centralis* Machado attract gravid females and result in aggregation of puparia.

In the present studies, in which we used new, larger, two-choice behavioral chambers, we reconfirmed that the anal exudate of larvae of *G. m. morsitans* and *G. m. centralis* contains pheromones that attract conspecific gravid females. Similar results were obtained with solvent extracts of larvae and with volatiles collected from larvae prior to pupariation. We report the identification of the major components of the larviposition pheromones of *G. m. morsitans* and *G. m. centralis*, respectively.

METHODS AND MATERIALS

Rearing

G. m. centralis and *G. m. morsitans* females were reared in the ICIPE rearing facility at 25°C ± 2°C, 70 ± 5% relative humidity, and a 12 L:12 D photocycle. Females were mated three days after eclosion and blood-fed on rabbits three times a week. Flies in the first cycle of parturition were used for all experiments.

Conditioning of Sand

Six cages, each containing 20 gravid female *G. m. centralis* or *G. m. morsitans*, were placed over a tray of sand previously extracted with solvents and heat sterilized at 100°C for 24 hr. At parturition, larvae burrowed through the mesh bottoms of the cages, dropped into the sand, and pupariated. Flies larviposited over a four-day period, after which puparia were removed by sifting, with a recovery of 80 pupae.

Behavioral Assays

Experiment 1. In previous experiments (Leonard and Saini, 1993) flies were held in standard tsetse rearing cages (19.5 × 7 × 6 cm), and in choice experiments the conditioned or control sand covered only 30% of the surface of the tsetse cages. Many larvae were deposited in the middle region. In the present work, new, larger, two-choice larviposition chambers 60 × 60 × 60 cm were constructed. Three sides of these chambers were covered with nylon mesh. The back was of metal and the front was covered with a removable glass door. One of the sides had a port from which flies easily could be introduced. The floor

was divided into two equal halves by disposable trays 59 × 59 × 1 cm each containing 750 g of sterilized or contaminated sand moistened with 75 ml of distilled water. The sand was conditioned by heat sterilization as above. A total of 305 *G. m. morsitans* and 268 *G. m. centralis* gravid females that were 18 days old were released in 13 replicates, and the number of pupae deposited in each tray counted at the end of each test, which ran for 96 hr. All behavioral assays were undertaken at 25°C ± 2°C, 60 ± 5% relative humidity, and a 12 L:12 D photocycle.

Experiment 2. In the next series of experiments, freshly deposited third instars were removed from the tsetse insectary and placed in four Petri dishes, each containing a 9-cm-diameter filter paper. Each dish contained 20 larvae. Some of the anal secretions produced by the larvae 1–2 hr prior to pupariation were absorbed by the filter paper in the Petri dishes, and these impregnated filter papers were subsequently used in bioassays. Four such impregnated papers were randomly placed in one tray of the large larviposition chambers and covered with 750 g of sterilized sand moistened with 75 ml of distilled water. The other tray, containing four similar plain filter papers covered with moistened sterilized sand, served as a control. A total of 335 gravid *G. m. morsitans* in nine replicates and 431 *G. m. centralis* in 12 replicates, all 18 days old, were offered the choice of control or larval-material-impregnated papers for larviposition, and the number of pupae deposited in each tray was counted at the end of each 96-hr testing period.

Experiment 3: Collection of Volatiles from Larvae. Volatiles were collected from freshly deposited third instars by placing them in a short glass tube. The inlet was plugged with activated glass wool (to adsorb contaminants from incoming air and to prevent larvae from escaping), while the outlet contained a short column of activated charcoal and another plug of glass wool as the adsorbent materials. Glass wool was activated by heating at 100°C for 24 hr. Filtered air was passed over 50 larvae for 2 hr at a constant flow rate of 15 ml/min. The adsorbents were then washed with 10 ml each of hexane and dichloromethane in succession, the extracts pooled, and the volume reduced to 100 μl by blowing a slow stream of filtered nitrogen. Collection of volatiles was repeated on four sets of larvae (50/set) in a similar fashion and all the trapped volatiles pooled. From the total volume collected, 160 μl of trapped volatiles (from 40 larvae) was kept for GC and GC-MS analysis. The remaining 240 μl was diluted with hexane to 2 ml and used for behavioral bioassays.

Behavioral Assays with Collected Volatiles

Four filter papers (9 cm diam.) were each impregnated with 250 μl of the volatile collection in hexane (equivalent to 20 larvae/filter paper), randomly placed in one tray of the larviposition chambers, and covered with 750 g of

moistened sterilized sand (moistened with 75 ml of distilled water). The control side had four filter papers, each impregnated with 250 μl of hexane and covered with 750 gm of moistened sterilized sand. Gravid 18-day-old flies, totaling 120 each of *G. m. morsitans* and *G. m. centralis* in four replicates, were offered the above choices and the number of pupae deposited in each tray counted at the end of each 96-hr testing period.

Analysis of Volatiles

Aliquots (2 μl) of the extracts were analyzed by gas chromatography (GC) and by gas chromatography–mass spectrometry (GC-MS). GC analyses were performed on a Hewlett-Packard (HP) 5890 Series II gas chromatograph equipped with a flame ionization detector (FID), an HP capillary column (methyl silicone, 50 m × 0.2 mm ID × 0.32 μm film thickness) using nitrogen as the carrier gas at a flow rate of 0.8 ml/min. GC conditions were optimized to allow adequate resolution of all candidate electrophysiologically active peaks. For the analysis of *G. m. morsitans* larval volatiles, the oven temperature was initially isothermal at 60°C (5 min) and then programmed to 190°C at 3°C/min and finally to 240°C at 5°C/min; for that of *G. m. centralis*, after an isothermal period at 60°C (5 min), the oven temperature was programmed to 240°C at 5°C/min. Chromatographic peaks were integrated by an HP 3396 integrator. GC-MS analyses were carried out on a VG Masslab 12-250 mass spectrometer (EI, 70 eV) coupled to an HP 5740 series A gas chromatograph.

Coupled gas chromatography–electroantennography (GC-EAD) was performed employing the same GC conditions as above. The column effluent was split 1 : 1 into two 50-cm-long deactivated fused silica columns, one connected to the FID and the other to an antenna of the appropriate gravid female. A make-up gas (40 ml/min) was added just before the split point to accelerate the effluent through the deactivated columns. The effluents were driven from the chromatograph through a transfer line maintained at 150°C by a THC-3 temperature control unit (Syntech) and into a moistened airstream (4.0 ml/sec, 90% relative humidity, 25°C) and focused on the antennal preparation via a stainless steel tube (5 mm ID). The return time constant was set at 2 sec. FID and EAD signals were monitored synchronously with a program on a GC-EAD interface (Syntech) card installed in a PC (Harvard Professional Computer, American Megatrends Inc.). The antennae for EAD recordings were prepared as described earlier (Leonard and Saini, 1993; Saini and Hassanali, 1991).

Responses of Gravid Females to Major Components of Larviposition Pheromones

Responses of gravid *G. m. morsitans* and *G. m. centralis* to the major components of their respective larviposition pheromones were determined in

two-choice behavioral bioassays similar to those conducted with volatiles collected from larvae (Experiment 3). Four filter papers (9 cm diam.) were impregnated with 10, 20, 40, 80, 160, or 320 larval equivalents of *n*-pentadecane or *n*-dodecane (major component of *G. m. centralis* larviposition pheromone). The dilutions of the compounds were made with paraffin oil to effect a gradual release of the compounds. The treated filter papers were randomly placed in one tray of the larviposition chambers and covered with 750 g of sterilized sand moistened with 75 ml of distilled water. The control side had four filter papers impregnated with an equivalent amount of paraffin oil and covered with 750 g of moistened sterilized sand. The number of 18-day-old gravid females of *G. m. morsitans* or *G. m. centralis* released per dose and the number of replicates are indicated in Tables 2 and 3 below. The number of pupae deposited in each tray were counted at the end of each 96-hr testing period.

RESULTS

Choice Tests

Results of the behavioral bioassays in the two-choice behavior cages (experiments 1–3) clearly showed that gravid *G. m. centralis* and *G. m. morsitans* females preferred to larviposit in sand conditioned with previous larvipositions (Table 1). Similar preference was shown by gravid females to filter papers contaminated with anal secretions and by volatiles collected from larvae prior

to pupariation (Table 1). Larval volatiles elicited the strongest larviposition response, 75% in the case of *G. m. morsitans* and 83% in *G. m. centralis*.

Analysis of Volatiles

Gas chromatographic analysis of trapped volatiles from larvae of the two tsetse species were different qualitatively and quantitatively (Figures 1 and 2). Repeated GC-EAD analyses on separate collections from *G. m. morsitans* consistently gave an EAD signal corresponding to a major peak and four weaker signals corresponding to blends of minor components (Figure 1). GC-MS analysis of the volatiles allowed the characterization of the major peak as *n*-pentadecane, *m/z* (rel. intensity) at 57 (100), 43 (90), 71 (65), 85 (45), 99 (18), 212 (18), 113 (6). This was confirmed by coinjection studies and analysis of authentic samples by GC-EAD. Similar analyses with collections from *G. m. centralis* (Figure 2) showed three sets of EAD signals, two corresponding to blends of minor components, and one to a major component identified as *n*-dodecane and confirmed by comparison (GC-EAD, GC) with an authentic sample, *m/z* (rel. intensity) 57 (100), 43 (98), 71 (60), 85 (40), 170 (15), 98 (10). In both sets of analyses, the minor EAD active components could not be clearly separated and located. Identification of these components will be done by micropreparation of blends corresponding to these regions followed by rechromatography under different sets of conditions.

were not significantly different from controls. *G. m. centralis* showed significant responses at 93.6-, 187.2-, and 374.4-μg doses of *n*-dodecane (Table 3). At lower doses (23.4 and 46.8 μg) and doses higher than 374.4 μg, the responses were not significantly different from controls.

DISCUSSION

Experiments undertaken by Leonard and Saini (1993) confirmed the results of Nash et al. (1976) that gravid female *G. m. morsitans* preferred to larviposit in sand in which larvae had pupariated previously. Results of the current experiments clearly show that filter papers contaminated with the anal exudate of larvae and, in particular, volatiles collected from larvae of *G. m. morsitans* and *G. m. centralis* prior to pupariation were attractive to respective gravid females and resulted in aggregation of corresponding puparia.

The major electrophysiologically active compounds in the larval volatiles of *G. m. morsitans* and *G. m. centralis* were identified as *n*-pentadecane and *n*-dodecane, respectively. Both these compounds caused selection by gravid females for larviposition comparable to the larval volatiles. However, the role(s) of the unidentified electrophysiologically active compounds remains to be elucidated. The dose–response results obtained for *G. m. centralis* pheromone, unlike the response of *G. m. morsitans*, showed that larviposition became less discriminatory at high doses (Table 3). We attribute this effect to higher volatility of *n*-dodecane (rather than due to an intrinsic loss of activity at high concentrations) than that of *n*-pentadecane. It may be that at high doses increasing amounts of volatile hydrocarbon diffused within the entire behavior bioassay arena, thus blurring differences between the treated and control sides.

The known sex pheromones of *Glossina* species are all saturated hydrocarbons associated with their cuticular waxes. The finding that the dominant behaviorally active components of larviposition pheromones of *G. m. morsitans* and *G. m. centralis* are also saturated hydrocarbons, albeit of lower molecular weights, suggests a general pattern for the selection of this class of compounds as signals in intraspecific communication by tsetse flies. Studies on the larviposition pheromones of other species will help to establish the validity of this generalization. Other insects that also use simple hydrocarbons in intraspecific communication include the astigmatid mite *Caloglyphus rodriguezi* (Mori et al., 1995), the red wood ant *Formica lugubris* (Walter et al., 1993), and the gregarious cockroach *Blaberus craniifer* (Brossut et al., 1974).

Since both the identified compounds are fairly volatile, they could attract gravid females from a distance to larviposition sites. At close range, the physical nature of the larviposition sites and the microclimatic conditions, such as humidity, may be important in the selection of suitable larviposition sites. In this regard, the previous work of Leonard and Saini (1993) suggests that gravid females are most responsive to larval semiochemicals when the differential between soil moisture and ambient humidity is large. Whether the larviposition pheromones function solely as a cue to aggregate gravid females or also as a stimulus for larviposition is still not clear. Further behavioral work is needed to fully understand the selection of larviposition sites before the larviposition pheromones can be exploited to either increase the efficiency of existing odor-baited traps and targets by attracting more gravid females or in concentrating gravid females and pupae in areas where pathogens or other biological control agents could cause high mortality.

Acknowledgments—We are grateful to the staff of the tsetse rearing unit for regular supply of insects. This work was supported by funds from the United Nations Development Programme (UNDP) to whom we are grateful.

(Received June 22, 1995; accepted February 29, 1996)

Abstract—A number of 15-carbon alkaloids have been identified in venom extracts of four Puerto Rican species of ants in the genus *Solenopsis* (*Diplorhoptrum*). Workers of a species from El Verde produced the *cis* and *trans* isomers of 2-methyl-6-nonylpiperidine with the latter isomer predominating. The same compounds were identified in queens of a species from Río Grande, but in this species no alkaloids were detected in worker extracts. Workers of a *Diplorhoptrum* species collected on Mona Island produced primarily a *trans*-2-methyl-6-(*Z*-4-nonenyl)piperidine, **3**, with smaller amounts of the *cis* isomer, whereas the major compound found in the queens of the same species on Mona Island was (5*Z*,9*Z*)-3-hexyl-5-methylindolizidine, identical with the alkaloid produced by queens of a species collected on Cabo Rojo. Surprisingly, workers of the Cabo Rojo species produced (5*Z*,9*Z*)- and (5*E*,9*E*)-3-butyl-5-propylindolizidine (**4** and **5**, respectively) reported earlier as the 223AB indolizidines from skins of dendrobatid frogs. The possible significance of the qualitative and quantitative differences in the venom alkaloids synthesized by queens and workers is discussed as is the possibility that ants containing such

alkaloids may serve as a dietary source for the skin alkaloids used by certain frogs in chemical defense.

Key Words—Venom, alkaloids, *Solenopsis*, Puerto Rico.

INTRODUCTION

A variety of saturated-ring nitrogen heterocycles have been identified in the venoms of ant species in the myrmicine genera *Monomorium* and *Solenopsis* (Jones et al., 1982a,b). The 3,5-dialkylindolizidines are one of the earliest reported structural classes of these compounds (Ritter et al., 1973). When they have been found with other structural types of ant venom alkaloids, their concomitants have been 2,5-dialkylpyrrolidines and 3,5-dialkylpyrrolizidines in *Monomorium* species (Ritter and Persoons, 1975; Jones et al., 1990a) and 2,6-dialkylpiperidines in *Solenopsis* species (Jones et al., 1984). The 3,5-dialkylindolizidines are often found among the skin alkaloids of dendrobatid frogs and occasionally occur in other amphibians while 2,5-disubstituted pyrrolidines, 3,5-disubstituted pyrrolizidines, and 2,6-disubstituted piperidines have also been reported as amphibian skin alkaloids (Daly et al., 1993).

The genus *Solenopsis* includes many minute species that are currently placed in a "subgenus" *Diplorhoptrum*, a large, worldwide group (Bolton, 1987) to which the species of the present study belong. In addition, in the past some "subgenera" (e.g., *Diphlorhoptrum*) have been elevated to the status of a genus, but they are now usually recognized as a synonym of *Solenopsis* (Ettershank, 1966). Here we use the name *Diplorhoptrum* as a matter of convenience without implying that it is a valid taxonomic entity.

In this report, the alkaloidal venom components of four collections of *Diplorhoptrum* spp. from Puerto Rico are described. Three of these collections, in which different castes were obtained, show conspicuous differences between alkaloids found in workers and in queens. In these collections 3,5-dialkylindolizidines and/or 2,6-dialkylpiperidines were detected, and of the former, the major alkaloid from the workers of one collection was found to be the indolizidine **223AB** (**5**) (Figure 1 below), first reported in dendrobatid frogs (Spande et al., 1981). While a number of alkaloids previously detected in ants have been found in amphibians, this is the first report of an alkaloid previously detected in amphibians, now being found in ants.

METHODS AND MATERIALS

Chemical Analyses

Gas chromatographic analyses and mass spectra were obtained using an LKB-2091 GC-MS, a Finnigan ITMS, or a Finnigan ion-trap model 800, all

equipped with 25-m × 0.32-mm-ID HP-5 fused-silica columns. The first two instruments used Hewlett-Packard 5890 gas chromatographs programmed from 60 to 250°C at 10°/min. The model 800 ion trap was interfaced with a Varian gas chromatograph model 3400 programmed from 100 to 280°C at 10°/min after a 1-min delay. FT-IR spectra were obtained using a Hewlett-Packard model 5965B detector (narrow band, 4000–750 cm^{-1}, resolution 8 cm^{-1}) interfaced with a Hewlett-Packard 5890 gas chromatograph fitted also with an HP-5 column programmed 100–280°C at 10°C/min after a 1-min delay. Data were analyzed with the 59970 IRD ChemStation. FT-IR spectra of neat liquids were obtained using a Perkin-Elmer series 1600 FT-IR instrument. High-resolution mass spectrometry (HRMS) used a JEOL SX102 instrument fitted with a 15-m × 0.20-mm HP-5 column.

Ants. Ants were collected in the areas (A–D) indicated in Table 1 below, and extracts were immediately prepared in glass vials containing methylene chloride. Voucher specimens of all samples were deposited in the collection of the Los Angeles County Museum of Natural History, Los Angeles, California. Each vial represented a different colony, and extracts of whole bodies were analyzed directly and individually. While the milking of stingers has demonstrated the venom glands to be the source of alkaloids detected in ants of the genera *Solenopsis* (cf. Brand et al., 1972; MacConnell et al., 1971) and *Monomorium* (unpublished work of Blum and Jones), the small size of the Puerto Rican *Diplorhoptrum* ants made this impractical. The alkaloid components of the extracts can be distinguished easily from the lipid components by their mass

spectra, which generally have odd-mass molecular ions and even-mass fragments (for alkaloids with one nitrogen).

Based on the similarity of their size with ants of the genus *Monomorium* (cf. Jones et al., 1982b), we estimate very roughly that each *Diplorhoptrum* worker released, at most, 0.1–1.0 μg alkaloid.

Hydrogenation of Extract C. A slow stream of hydrogen was bubbled through a small portion of this extract in methanol in the presence of PtO_2 for 2–3 min.

Synthesis of Piperidines ***2a*** *and* ***2b***

*2-[3-(6-Methyl-2-pyridyl)propyl]-1,3-dioxolane (**6**).* A solution of 2,6-lutidine anion obtained from 6.4 g (60 mmol) of lutidine in 100 ml of diethyl ether and 38 ml of 1.6 M *n*-butyllithium in hexanes at 0°C was treated with a solution containing 7 ml of 2-(2-bromoethyl)-1,3-dioxolane in 30 ml of diethyl ether. After 0.5 hr, the mixture was poured into water and extracted with ether. The ether solution was dried over anhydrous K_2CO_3, and after filtration, the more volatile components were removed in vacuo to provide 9 g of an oil that was greater than 80% compound **6** by GC. IR data (neat) were 3054, 2948, 2874, 2769, 1590, 1574, 1457, 1410, 1373, 1135, 1097, 1034, 939, 817, 790 cm^{-1}; GC retention time was 9.1 min; MS *m/z* (relative intensity, percent, Finnigan model 800 ion trap mass detector): 208 (M + 1, 10), 162(13), 134(18), 107(100), 73(38). Compound **6** was accompanied by ca. 10% of a material of retention time 17.7 min; MS *m/z* 308 (M + 1, 100), 164(22), 162(17), 147(22), 134(15), 132(10), 107(22), 99(10), 73(32), which very likely was a bis-substituted lutidine. HRMS, calculated for $C_{12}H_{17}NO_2$: 207.1255; observed, 207.1258.

*2-Methyl-6-(Z,4-nonenyl)pyridine (**7**).* A mixture containing 6 g of dioxolane **6,** 50 ml of acetone, 50 ml of methanol, and 100 ml of water was carefully acidified with concentrated HCl to ca. pH 2 and stirred for 1.5 hr at room temperature. The mixture was neutralized with solid $NaHCO_3$, and most of the solvents were removed in vacuo. The mixture was extracted with diethyl ether, and the ether extracts were dried over anhydrous $MgSO_4$. Distillation provided 3.5 g of 4-(6-methyl-2-pyridyl)butanal, bp 64–67° (0.05 mm Hg); IR(neat) 3062, 2927, 2823, 2719, 1721, 1590, 1575, 1456, 791 cm^{-1}; GC retention time 5.6 min; MS *m/z* 164 (M + 1, 65), 146(3), 134(13), 120(5), 107(100), 65(8). HRMS, calculated for $C_{10}H_{13}NO$: 163.0094; observed, 163.0098. A mixture of 2.5 g (6 mmol) of *n*-pentyltriphenylphosphonium bromide in 25 ml of THF was cooled to 0°C and treated with 2.4 ml of 2.5 M *n*-butyllithium in hexanes. After 3 hr, a solution containing 1 g (6 mmol) of 4-(6-methyl-2-pyridyl)butanal in 5 ml of THF was added, and the mixture was stirred overnight. Following the addition of 50 ml of hexane and 25 ml of diethyl ether, the mixture was filtered through a Florisil pad and the solvent was removed in

vacuo. Redissolution and filtration was repeated to provide 1.25 g of crude **7** that was nearly 90% pure by GC analysis. IR(neat) 3067, 3005, 2943, 2923, 2861, 1656(w), 1591, 1578, 1456, 790 cm^{-1}; GC retention time 13.9 min; MS *m/z* 218 (M + 1, 12), 202(8), 132(8), 120(10), 107(100). HRMS, calculated for $C_{15}H_{23}N$: 217.1825; observed, 217.1819.

2-Methyl-6-(Z,4-nonenyl)piperidine (2). The procedure of Jones et al. (1990b) was applied to the preparation of **2.** A small portion (about 20 mg) of the Wittig product **7** in 1.0 ml of absolute ethanol in a 3-ml test tube was heated to 95°C in an oil bath and small chips of sodium metal added over a period of approximately 1 hr, adding fresh ethanol as necessary. On cooling to room temperature, the resulting solid was allowed to stand capped overnight at room temperature; then water was added and the solution stirred in a hot water bath under a stream of nitrogen to remove excess ethanol. The aqueous layer was extracted four times with small portions of ethyl acetate. These extracts were combined, dried (Na_2SO_4), and the solvent was evaporated. The residue was dissolved in 2.0 ml ethanol, the pH adjusted to 6 (checked with narrow range pH paper) with 10–15 drops of 0.5 N HCl, and a small portion (about 5 mg) of $NaCNBH_3$ (Aldrich) was added, followed by another, 1 hr later, as the originally turbid solution became clear. A third portion of $NaCNBH_3$ was added 2 hr later. The solution was stirred for 18 hr and then acidified with 0.5 N HCl until the evolution of gas ceased. The solution was evaporated under a nitrogen stream, made alkaline with 2 N KOH, and extracted four times with small portions of ethyl acetate. After drying, GC-MS showed two closely eluting peaks at 9.0 min and 9.4 min (3.2 : 1.0, respectively) with the same mass and infrared spectra as reported for the isomeric mixture **2a** and **2b,** respectively. HRMS calculated for $C_{15}H_{29}N$: 223.2293; observed, 223.2305.

RESULTS

Examination of the methylene chloride extracts of four collections (A–D) of *Diplorhoptrum* species from Puerto Rico revealed the presence of 2,6-dialkylpiperidines and 3,5-dialkylindolizidines **1–5** (Table 1, Figure 1), whose structures and stereochemistry were assigned by comparison with authentic samples and/or by spectroscopic methods.

Collection A. An extract from workers collected at El Verde, PR, contained *cis* and *trans*-2-methyl-6-nonylpiperidine (**1**) in ca. a 1 : 8 ratio, characterized by nearly identical mass spectra but differing gas chromatographic retention times, which can be compared to those of authentic samples prepared in earlier studies (MacConnell et al., 1974; Jones et al., 1982a,b; Blum et al., 1985). The occurrence of piperidines and the preponderance of the *trans* stereoisomer is typical of other *Solenopsis* species (Brand et al., 1972).

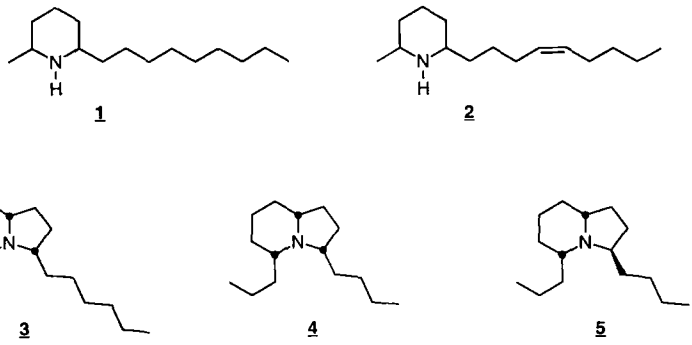

FIG. 1. Piperidines and indolizidines found in *Solenopsis* (*Diplorhoptrum*) species from Puerto Rico.

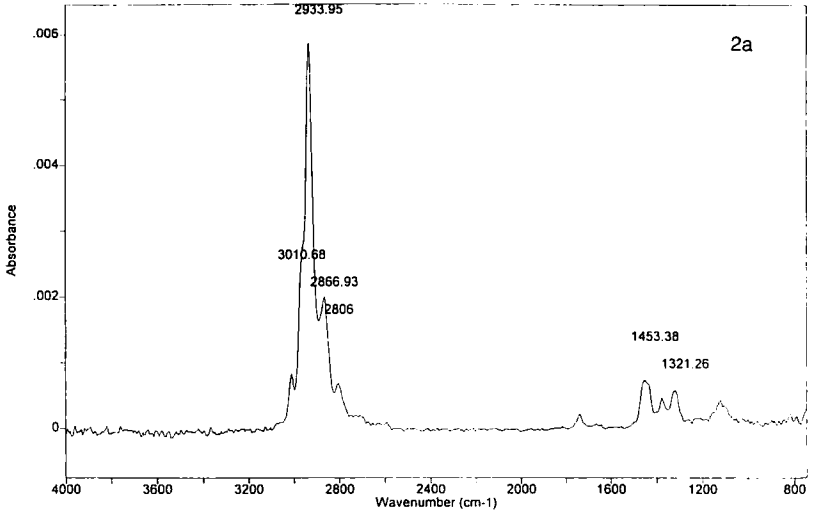
Collection B. An extract from workers collected at Río Grande, Puerto Rico, contained no alkaloids. The queens, however, contained the same alkaloids as above, *cis*- and *trans*-2-methyl-6-nonylpiperidine (**1**), but in ca. a 6:1 ratio. Additional confirmation that the major isomer was of the less commonly occurring ant alkaloid class of *cis* piperidines was provided by its FT-IR spectrum, which showed weak Bohlmann bands at 2803 and ca. 2730 cm^{-1} and was identical to that of a synthetic sample. These Bohlmann bands are absent in *trans* piperidines (Garraffo et al., 1994).

Collection C. An extract from workers collected at Mona Island, Puerto Rico, contained two components, **2a** and **2b,** in ca. a 1:4 ratio with virtually identical mass spectra: MS (*m/z*) (relative intensity), **2a** (minor): 223(M^+, 1), 222(1), 208(3), 180(5), 124(33), 111(15), 110(4), 99(7), 98(100), 96(8), 82(6), 81(8), 79(4), 70(9), 68(5), 69(27), 67(13), 56(10), 55(20); **2b** (major): 223(M^+, 2), 222(3), 208(5), 180(5), 124(15), 111(8), 99(8), 98(100), 81(4), 70(6), 69(4), 67(5), 57(8), 56(8), 55(13). The mass spectra indicated two unsaturated analogs of **1** that could be converted to a mixture of *cis*- and *trans*-**1** by catalytic hydrogenation (see Methods and Materials).

FT-IR spectra of **2a** and **2b** (Figure 2) indicated the first eluting component to be a *cis*-2,6-disubstituted piperidine and the second, its *trans* diastereomer. In addition, GC-FT-IR spectra showed a $\nu_{=CH}$ absorption at 3011 cm^{-1} and the absence of a terminal double bond as indicated by the lack of absorption at ca. 3080 ($\nu_{=CH}$ for a terminal olefin), 990 and 910 cm^{-1} ($\delta_{=CH}$ for a terminal olefin). An internal double bond of E stereochemistry was excluded by the absence of an absorption at ca. 964 cm^{-1} ($\delta_{=CH}$ for a *trans* olefin) and the presence of the 3011 cm^{-1} absorption, leaving only the possibility of an internal double bond of *Z* stereochemistry (cf. Attygalle, 1994). From the absence of



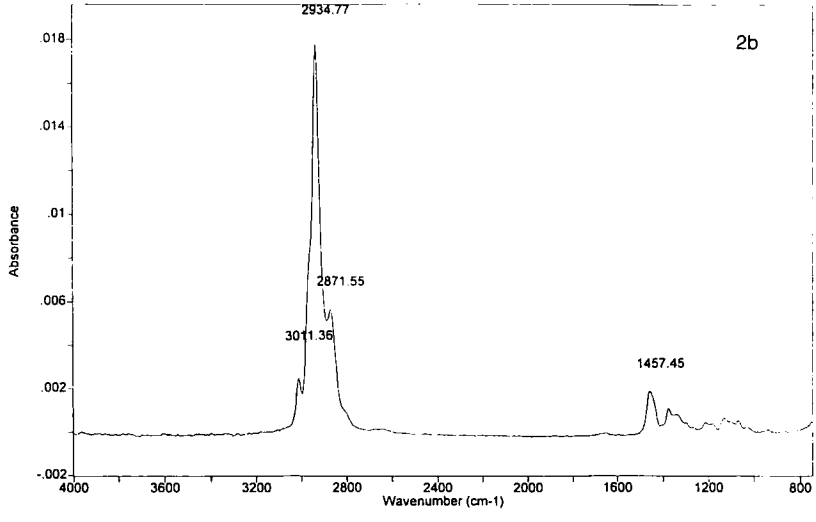


FIG. 2. GC-FT-IR spectra of the *cis*-ring piperidine **2a** and the *trans*-ring diastereomer **2b** from workers of *Diphlorhoptrum* sp. from Mona Island, Puerto Rico.

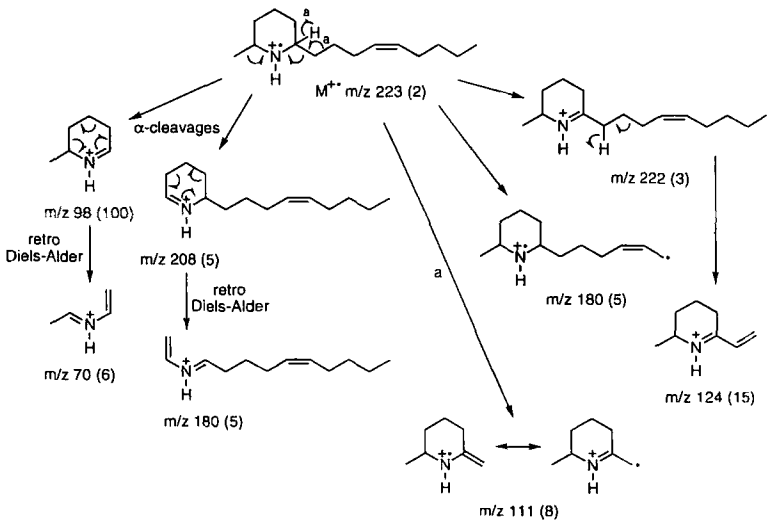
absorptions between 1600 and 1700 cm^{-1} in the infrared spectrum, the double bond in **2a/2b** was not imine or enamine unsaturation. Furthermore, vapor-phase FT-IR studies (Attygalle et al., 1994) on the position of the $\nu_{=CH}$ absorption on long-chain *Z*-monounsaturated primary acetates, excluded both Δ^{2-3} and Δ^{7-8} double bonds, since both show shifts to higher frequencies (ca. 3029 and 3022 cm^{-1}, respectively). A Δ^{3-4} position was also unlikely as their model indicated a 3018 cm^{-1} absorption for this structural class. Although the side-chain double bond in many ant venom alkaloids is in the terminal position, the loss of C_7H_{15} from the molecular ion on mass spectrometry, yielding an ion at *m/z* 124 (20%), suggested the double bond in **2a/2b** was nearer the piperidine ring and supported the structural inferences from the FT-IR spectra. Incidentally, the mass spectrum also ruled out a Δ^{1-2} position, as an *m/z* 96 base peak (with only a weak 98 peak), has been reported for pinidine [2-methyl-6-(1-propenyl)piperidine] (NIST Data Base, 1992).

We considered a Δ^{4-5} position as the most probable location of the *Z* double bond since a weak loss of C_3H_7 was seen from the molecular ion (*m/z* 223) to give a peak (5%) at *m/z* 180. Such a cleavage most probably arises from an allylic fragmentation. An analogous cleavage (M^+-heptyl, *m/z* 180) has been noted previously in dehydrosolenopsin-B, i.e., *trans*-2-methyl-6-(*Z*-4-tridecenyl)piperidine, a C_{19} homolog of **2b** from the venom of the red form of the fire ant, *Solenopsis invicta* (=*S. saevissma*) (MacConnell et al., 1971). Spectral data have been reported for the isomeric *cis*-2-methyl-6-(*Z*-4-tridecenyl)piperidine, where major fragments at *m/z* 124(20), 111(20) are also seen in addition to *m/z* 180(4) (Brand et al., 1972). In Scheme 1, we indicate probable fragmentation pathways to account for all major fragment ions observed in the mass spectra of **2a/2b.**

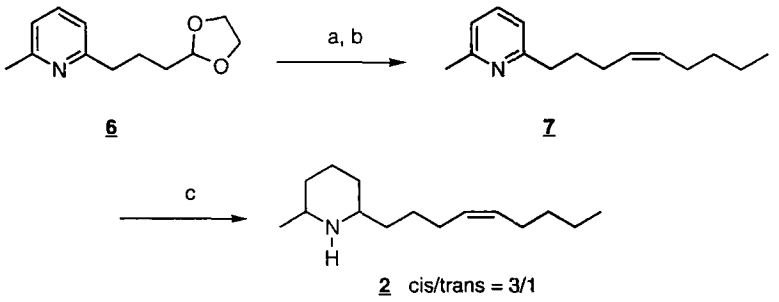
To prove this structure, the synthesis outlined in Scheme 2 was undertaken. The acetal intermediate **6** was synthesized from lutidine anion and 2-(2-bromoethyl)-1,3-dioxolane. This was deblocked to the aldehyde, which smoothly produced 2-methyl-6-(*Z*-4-nonenyl)pyridine (**7**) in a Wittig reaction (Johnson et al., 1982) with the phosphonium ylide (b) from 5-bromopentane. The olefin **7** was reduced, first with sodium in ethanol and then, after acidification to pH 6, by treatment with sodium cyanoborohydride to afford a mixture containing **2a** and **2b** (3.2:1, respectively). The GC retention times, and mass and GC-FT-IR spectra of the *cis* and *trans* disubstituted piperidines were identical in every respect to the natural alkaloids (see Methods and Materials). Coinjection on GC-MS of the synthetic mixture with the Mona Island workers' extract led to significant change in the ratio of **2a/2b** from the initial 1:4 to a 1:1.3 ratio, indicating each synthetic material to be identical in retention time to the corresponding natural material.

Along with traces of **2a/2b,** a 3-hexyl-5-methylindolizidine (**3**) was the predominant alkaloid in methylene chloride extracts from the queens of the



SCHEME 1. Proposed mass spectral fragmentations for **2b** (major isomer; *trans*-ring configuration); percentages in parentheses are electron-impact data obtained with an LKB-2091 instrument.

Mona Island collection. The mass spectrum [*m/z* 223 (M^+, 1), 222(1), 139(8), 138(100)] was the same as that reported for the compound found in the queens of an unidentified, but possibly identical, *Solenopsis species* collected in Marathon Key, Florida (Jones et al., 1984). The stereochemistry of **3** was established by examination of its FT-IR spectrum, which showed a broad range of Bohlmann bands decreasing in intensity from 2800 to 2500 cm^{-1}, which is characteristic



a) HCl/$HClO_4$, b) $Ph_3P^+C_5H_{11}$; BuLi, c) Na-EtOH; $NaCNBH_3$, pH 6

SCHEME 2. Chemical synthesis of piperidines **2a** and **2b**.

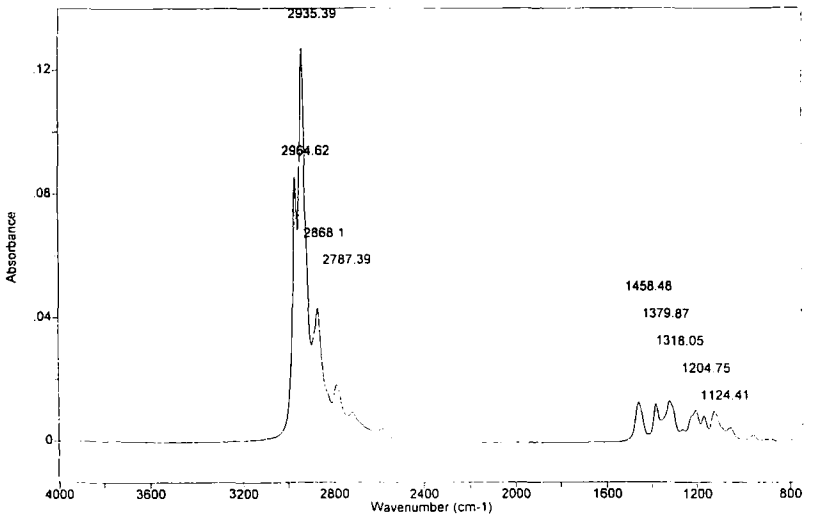


FIG. 3. GC-FT-IR spectrum of (5*Z*,9*Z*)-3-*n*-hexyl-5-methylindolizidine.

only of the 5*Z*,9*Z* isomer (Garraffo et al., 1993a). The *E*,*Z* nomenclature in the context of 3,5-disubstituted indolizidines refers to the hydrogen configurations at C-5 and C-9 with respect to that at C-3 and is either on the same molecular face (*Z*) or on the opposite face (*E*) (Sonnet et al., 1979). Compound **3** was identical with a synthetic sample of (5*Z*,9*Z*)-3-hexyl-5-methylindolizidine (Jones et al., 1984) (Figure 3). Indolizidines have been previously reported in various *Solenopsis* species (Jones et al., 1984). The Mona Island species is, at present, undescribed (Torres and Snelling, unpublished data).

Collection D. An extract from workers collected at Cabo Rojo, Puerto Rico, contained two components, **4** and **5**, in ca. 1:6 ratio, respectively, with the following mass spectra: (minor, **4**) MS *m/z*, 223(M^+, 2), 222(1), 180(30), 166(100), 124(5), 122(5); (major, **5**), MS *m/z*, 223(M^+, 4), 222(1), 180(100), 166(90), 124(7), 122(7). Extracts of two other populations of workers in the same area had ratios of these components of ca. 1:1.7 and 1:2.5. The mass and FT-IR spectra of **4** and **5** were identical to those reported for the amphibian alkaloids (5*Z*,9*Z*)-3-butyl-5-propylindolizidine and (5*E*,9*E*)-3-butyl-5-propylindolizidine, respectively (Garraffo et al., 1993a; Daly et al., 1993). Extracts from queens of the same colony contained trace amounts of **4** and **5** as well as one major component, which had mass and FT-IR spectra identical to those of **3**, the same indolizidine as found in queens from the Mona Island collection.

DISCUSSION

The alkaloids identified in this collection of *Diplorhoptrum* species from Puerto Rico may reflect the biological relationships in this group of ants. The unbranched 15-carbon skeleton of all these compounds is reminiscent of the unbranched 19-carbon alkaloid mixtures found in many New World and New Zealand *Monomorium* species (Jones et al., 1982b, 1988), where other carbon-chain lengths are not observed or are minor components. Additionally, while the presence of monocyclic alkaloids accompanying bicyclic alkaloids of the same carbon number in a particular ant venom has been reported, this is the first report of a monocyclic ant venom alkaloid (**2**) having side-chain functionality at a position that might permit the biosynthesis of a third C–N bond (in this case, by allylic activation), to yield the bicyclic alkaloid, **3**, found only in the queens. The *cis* ring diastereomer **2a**, detected as a minor component in Mona Island workers, would be the logical precursor.

Except for the queens of the Río Grande collection, where the unusual *cis*-**1** predominates, gas chromatographic retention times and FT-IR spectra show that the piperidine alkaloids **1** and **2** occur mainly as the usually encountered *trans* diastereomers with measurable amounts of *cis* diastereomers. It is noteworthy that the six-membered ring in the indolizidines **3, 4,** and **5** is *cis* disubstituted, of probable derivation from a *cis*-2,6-disubstituted piperidine, and suggesting biogenetic relationship with *Solenopsis conjurata*, whose venom contains *cis* and *trans* disubstituted piperidines along with a (5*Z*,9*Z*)-dialkylindolizidine (Jones et al., 1984).

In three of the four Puerto Rican *Diplorhoptrum* spp. for which queen and worker alkaloids have been compared (Table 1), significant differences are readily evident. Workers of the Río Grande species are extreme in not producing any detectable alkaloids in comparison with their queens. In addition, major quantitative and qualitative differences characterize the alkaloids synthesized by the Mona Island and Cabo Rojo species. Caste-specific differences in the mixtures of 2,6-dialkylpiperidines that dominate the venoms of fire ant (*Solenopsis geminata* group, sensu Trager spp.) have also been reported. For the most part, queens of these species produce a single diastereomeric pair of piperidines (*cis*- and *trans*-2-methyl-6-undecylpiperidine), whereas the workers of some species produce these and up to five pairs of *cis*/*trans* pyrrolidines (Brand et al., 1973). Since the queens are not actively involved in colony defense, their venoms may play another role. In the case of the queens of the Puerto Rican *Diplorhoptrum* spp., the presence of venom alkaloids not found in the workers strongly suggests a different function of these compounds in this caste, for example, as a pheromone or to protect the eggs from microbial infection (Vander Meer and Morel, 1994). A more systematic investigation of Puerto Rican *Diplorhoptrum* spp. is

being undertaken to determine the extent of chemical diversity in the venoms of these ants.

Most species of *Diplorhoptrum* are hypogeic, but some are known to be arboreal. An arboreal way of life may, in fact, be more common than generally realized, at least in tropical areas. Some of the species are facultative "thief ants," living in close proximity to nests of other, larger species. Often, their galleries may open into those of the larger ants. From these galleries, the *Diplorhoptrum* workers may raid the nest chambers of the other species for bits of food, but they are not above attacking the larvae and pupae of the unwilling host.

It is noteworthy that two of the four Puerto Rican *Diplorhoptrum* species studied here, the collections from Mona Island and Cabo Rojo, nest in trees, while the El Verde and Río Grande collections share the usual ground-nesting propensities of the group. An arboreal life may expose the workers to predators, such as lizards and frogs, which can readily forage on the tree and ingest large numbers of workers.

Rivero et al. (1963) found for the frog *Eleutherodactylus karlschmidti*, the most aquatic member of this genus in Puerto Rico, that most of its prey was terrestrial and 90% composed of insects. Forty-four percent of these, in turn, were comprised of dipterans, of which many were aquatic larvae. Trichopterans and hymenopterans each comprised about 15% of the insects consumed, and of the latter, most were ants. Lavigne and Drewry, who studied (1970) the prey of frogs and lizards at El Verde, found hymenopterans and dipterans to be dominant. Cintrón found (1970) a high consumption of coleopterans and hymenopterans (chiefly ants) by tree frogs of the genus *Eleutheradactylus* in palm (*Prestoea montana*) forests.

The present results are highly relevant to the proposal (Daly et al., 1994a,b) that dendrobatid frogs are sequestering, for defensive purposes, some of the venom components of dietary ants and other small arthropods. Thus, two further alkaloids (**4** and **5**), previously described only from dendrobatid frogs, have in the present paper been identified in an ant.

The indolizidine **5**, originally detected in dendrobatid frogs of the genus *Dendrobates* and named gephyrotoxin (GTX) **223AB**, has been the target of many syntheses (reviewed in Daly and Spande, 1986). It was originally thought that only the 5*E*,9*E* diastereomer occurred in dendrobatid frog skin based on the isolation of **5** from the Colombian species, *Dendrobates histrionicus* (Spande et al., 1981; Daly and Spande, 1986) while in the Panamanian species *Dendrobates speciosus* (Edwards et al., 1988) and one mantellid species from Madagascar (Garraffo et al., 1993b), only the 5*Z*,9*Z* diastereomer **4** was found. Additional work demonstrated that both **4** and **5** can also appear together in frog and toad skin extracts (Garraffo et al., 1993a; J. W. Daly, personal communication).

Dendrobatid frogs, raised in captivity on diets of fruit flies and crickets, have absolutely no skin alkaloids (Daly et al., 1992; 1994a,b) leading to the proposal that skin alkaloids are sequestered from dietary arthropods. Indeed, when fed fruit flies dusted with alkaloid-containing powder, such alkaloid-free frogs efficiently incorporated indolizidines, pyrrolizidines, and a number of other alkaloid classes (Daly et al., 1994a).

In addition, a captive-raised dendrobatid frog (*Dendrobates auratus*), when fed ants of the species *Monomorium pharaonis* (Daly et al., 1994a), incorporated the indolizidine, monomorine I, into skin. The frogs avidly ate these ants, so at least in this case the ant venom is not a deterrent to predation. These results indicate that the indolizidines **4** and **5** of the present paper should also be efficiently incorporated into dendrobatid frog skin.

At least half a dozen alkaloids of the indolizidine and pyrrolizidine classes have been found to be common to frogs and ants (Daly et al., 1993), strongly suggesting in the light of the above results that such alkaloids, when found in frog skin glands, have been sequestered from a diet containing ants. While this is not a large overlap—the total number of alkaloids detected in frog skins is over 400—it should be emphasized that only a few hundred of the many thousand species of myrmicine ants have so far been examined for alkaloids.

In Panama when captive-raised dendrobatid frogs were fed on leaf litter insects obtained through the use of Berlese funnels, some 20 alkaloids were found to have been sequestered into skin (Daly et al., 1994b). In this instance, no "ant" alkaloids were sequestered, perhaps suggesting that ants were poorly represented in the insects obtained from Berlese funnels. While the phenomenon of storing ingested alkaloids is not uncommon, having been encountered in a variety of vertebrate and invertebrate species, it may prove to be unusual in frogs, since only seven genera from four different families (Dendrobatidae, Bufonidae, Myobatrachidae, and Mantellidae) have lipophilic alkaloids with more than 80 genera examined to date. It is quite probable that this behavior reflects the presence of a transport and/or storage capacity for dietary alkaloids derived from ants or other small insects, but this has been demonstrated experimentally only for a few species of dendrobatid frogs, namely *Dendrobates auratus*, *Phyllobates bicolor*, and *Epipedobates tricolor* (Daly et al., 1994a,b).

Dendrobatid frogs are well known to include ants as a major food source (Donnelly, 1991; Toft, 1980); some dendrobatid frogs have even been referred to as "ant specialists" (Toft, 1995). *Solenopsis* species have been established by examination of stomach contents as among the food prey for frogs that are foreign to Puerto Rico (Silverstone, 1975; 1976). Ant species of the genus *Solenopsis* (*Diplorhoptrum*) related to the Puerto Rican species are sympatric with dendrobatids in Costa Rica (Jones et al., 1984) and are likely to be in other Central and South American areas as well. While the ant alkaloids have some taxonomic value, in that we have never observed collections of the same species

of ant with different alkaloids, in many cases, ants of different species do produce some of the same alkaloids, so that indolizidines **4** and **5** could very well be components of venoms of species not yet collected.

While certain ants serve as food for dendrobatid frogs, there are many that are rejected and shunned because of their bite or sting. It remains to be demonstrated, whether other classes of frog-skin alkaloids besides the 3,5-disubstituted indolizidines, **4** and **5**, will be found in ants that constitute the food of dendrobatid frogs. Dendrobatid frog skin also can contain precoccinelline, a beetle alkaloid, and a pyrrolizidine oxime closely related in structure to a millipede alkaloid (Daly et al., 1993). Indeed, such alkaloids were found in skin of dendrobatid frogs raised on leaf-litter insects in Panama (Daly et al., 1994b). Small beetles and millipedes have been documented as prey items for dendrobatid frogs and were present in the leaf litter collections.

It should be noted that almost all species of dendrobatid frogs are terrestrial. Only one of two arboreal Panamanian species contained even trace amounts of a putative ant alkaloid, in this case, alkaloid **195B**, 3-butyl-5-methylindolizidine (Daly et al., 1987). The correlation, if any, between terrestrial and arboreal ways of life of both insects and frogs in determining the skin alkaloids of the latter should be more thoroughly explored.

Acknowledgments—We are grateful to Dr. John Daly for reading this manuscript and for many valuable comments concerning the diet of dendrobatid frogs including some unpublished work. We thank Dr. Lewis Pannell of the Laboratory of Analytical Chemistry, NIDDK, NIH for the high-resolution mass spectral measurements. T.H.J. gratefully acknowledges the support of the VMI Research Committee and the VMI Chemistry Dept.

CORN VOLATILES AS ATTRACTANTS FOR NORTHERN AND WESTERN CORN ROOTWORM BEETLES (COLEOPTERA: CHRYSOMELIDAE: *Diabrotica* SPP.)[1]

LESLIE HAMMACK

USDA, ARS, Northern Grain Insects Research Laboratory

(Received September 18, 1995; accepted March 3, 1996)

Abstract—Synthetic corn volatiles and selected analogs were tested in commercial corn fields for attractiveness to feral northern (NCR, *Diabrotica barberi*) and western corn rootworm beetles (WCR, *D. virgifera virgifera*). Two new attractants, geranylacetone and α-terpineol, were identified among corn terpenes and compared at four stages in crop development with the phenylpropanoid standards cinnamyl alcohol and 4-methoxy-cinnamaldehyde, with each component at 30 mg/trap. Dose–response relationships (0.1–100 mg/trap) and efficacy of two-component blends (30 mg/component) were also examined. More beetles were captured on traps baited with (+)- than (−)-α-terpineol, but the difference was statistically significant only for WCR. Captures with geranylacetone or (+)-α-terpineol were directly proportional to the logarithm of the attractant dose. WCR females were attracted to as little as 0.1 mg of either compound. WCR males required ≥1.0 mg of (+)-α-terpineol and were not attracted to geranylacetone at any dose. NCR required ≥0.3 mg of either attractant and showed less marked response differences between the sexes than did WCR. Geranylacetone and cinnamyl alcohol were equally effective attractants, whereas (+)-α-terpineol was significantly less attractive to WCR but more attractive to NCR than was 4-methoxycinnamaldehyde. Corn terpenes and phenylpropanoid standards produced similar seasonal response patterns in that captures tended to rise in each case as the season progressed, except during silking when no compound was attractive. Mixing corn terpenes or phenylpropanoid standards synergized responses of WCR females, but (+)-α-terpineol suppressed attraction of NCR females to geranylacetone.

Key Words—Coleoptera, Chrysomelidae, *Diabrotica barberi*, *Diabrotica virgifera virgifera*, *Zea mays*, corn rootworm, host finding, monoterpene, isoprenoid, attractant, kairomone, synergism, geranylacetone, α-terpineol.

INTRODUCTION

The northern corn rootworm (NCR), *Diabrotica barberi* Smith and Lawrence, and the western corn rootworm (WCR), *D. virgifera virgifera* LeConte, are the important diabroticite pests of corn, *Zea mays* L., in the United States, where pesticide costs and crop losses from corn rootworms have been estimated to be as high as $1 billion annually (Metcalf, 1986). Several types of semiochemicals that affect adult behaviors show promise for use in corn rootworm management programs (Levine and Oloumi-Sadeghi, 1991; Sutter and Lance, 1991; Metcalf and Metcalf, 1992). Among these semiochemicals are plant kairomones or parakairomones that apparently mimic host plant odors and play a role in feeding behavior (Andersen and Metcalf, 1986; Andersen, 1987; McGovern and Ladd, 1990; Metcalf and Lampman, 1991). Most of the known kairomonal attractants for corn rootworm adults are phenylpropanoids or benzenoids. These compounds have been identified mainly from plants of the family Cucurbitaceae, which serve as hosts for many *Diabrotica* spp. Although WCR and NCR beetles aggregate on cucurbit blossoms to feed on pollen and nectar, probably reflecting their ancestral relationship with this group of plants, both species are more closely associated with grasses, corn in particular, than with cucurbits (Metcalf et al., 1980; Branson and Krysan, 1981). The association is strongest for the larval stages, which are oligophagous on the Poaceae (previously Gramineae) and feed most successfully on corn.

Unidentified corn volatiles are known to attract both WCR and NCR adults (Prystupa et al., 1988) and may function in long-range orientation of these species to corn plants for both feeding and oviposition (Prystupa et al., 1988; Seigfried and Mullin, 1990). Several compounds attractive to corn rootworm beetles and present in squash blossoms, namely indole, β-ionone, 2-phenyl-1-ethanol, and phenylacetaldehyde (Andersen and Metcalf, 1986; Andersen, 1987; Lampman and Metcalf, 1987, 1988; Lampman et al., 1987; Metcalf and Lampman, 1989), also occur in corn (Thompson et al., 1974; Flath et al., 1978; Buttery et al., 1978, 1980; Cantelo and Jacobson, 1979). Considerable additional information exists on volatiles of corn plants (Thompson et al., 1974; Flath et al., 1978; Buttery et al., 1978, 1980; Cantelo and Jacobson, 1979; Buttery and Ling, 1984; Turlings et al., 1993; Takabayashi et al., 1995), but few of these compounds have been tested for attractiveness to corn rootworm beetles.

The present study tested volatile compounds known to occur in corn, as well as selected analogs, for attractiveness to feral NCR and WCR beetles in

commercial corn fields. The study further compared two newly discovered corn terpenoid attractants [geranylacetone, an irregular terpene, and (+)-α-terpineol, a monoterpene] with existing phenylpropanoid standards [cinnamyl alcohol and 4-methoxycinnamaldehyde (Metcalf and Lampman, 1989)] at four stages in crop development, established dose–response relationships for the terpenes, and examined two-component mixtures of either the terpene or standard attractants for synergistic and inhibitory effects on beetles captures.

METHODS AND MATERIALS

Figure 1 gives the structure and purity of test compounds. α-Terpineol, (*E*)-6,10-dimethyl-5,9-undecadien-2-one (=geranylacetone), (*E*,*E*)-2,4-decadienal, limonene, and citral were obtained from Fluka Chemical Corp., Ronkonkoma, New York. 4-Methoxycinnamaldehyde was obtained from Schweizerhall Inc., South Plainfield, New Jersey, and all others were from Aldrich Chemical Co., Milwaukee, Wisconsin. The compounds were applied for testing to cotton dental rolls (3.8 cm long × 1 cm diam.) (Patterson Dental Co., Minneapolis, Minnesota) that were treated with 0.4 ml of a 1:1 mixture

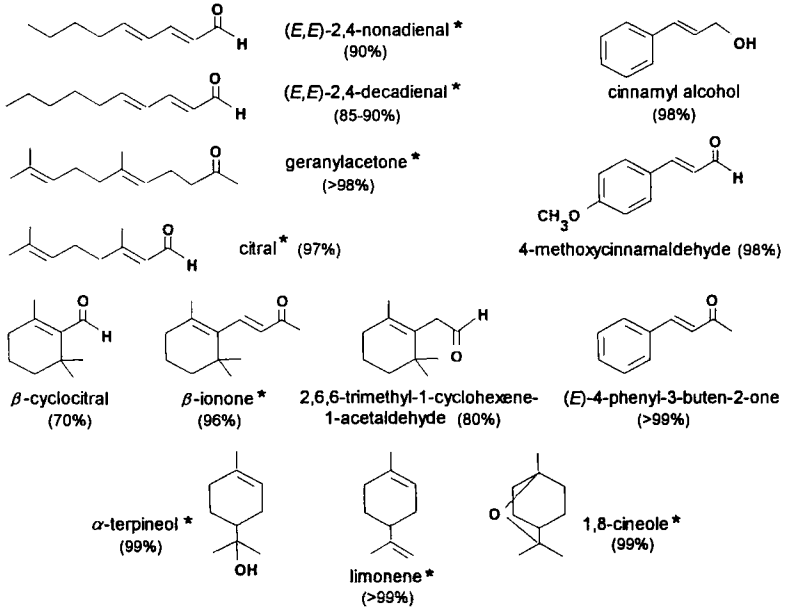

FIG. 1. Structure and purity (in parentheses) of test compounds. Asterisks indicate compounds identified from corn (see text for references).

of olive oil in hexane to sustain volatilization (Guss, 1976). The rolls were then affixed to yellow Pherocon A.M. sticky traps (Trécé Inc., Salinas, California), which were placed in 1993 or 1994 in commercial corn fields that were located in Brookings County, South Dakota, and had been in continuous corn for at least two years. Control traps were baited with dental rolls that were treated only with the oil–hexane mixture and acetone, which was used to solubilize and dilute candidate attractants. The acetone volume per trap varied among tests but was held constant among treatments within tests.

Individual candidate attractants were initially tested at a dose of 100 mg/trap, including stereoisomers of α-terpineol, which were also subsequently compared at a dose of 30 mg/trap in a test conducted August 29–31, 1994. Seasonal variation in response to the new terpenoid attractants was compared with that to the phenylpropanoid standards at a dose of 30 mg/trap by repeating tests during four stages in crop phenology (Ritchie et al., 1992): V10+ (late vegetative), R1 (silking), R3–R4 (late milk to early dough), and R4–R5 (late dough to early dent). Dose–response relationships were established for the terpenes in a test that included a series of (+)-α-terpineol and geranylacetone treatments, each ranging from 0.1 to 100 mg/trap, and a control. The effect on beetle captures of mixing attractant chemicals [geranylacetone mixed with (+)-α-terpineol and cinnamyl alcohol with 4-methoxycinnamaldehyde] was determined by dispensing 30 mg of each chemical from the same and from separate traps. When traps received both chemicals, each chemical was placed on a separate half of a dental wick that had first been treated with 0.2 ml of the 1 : 1 mixture of olive oil in hexane. Each half of the wick was then affixed separately to the trap to minimize the likelihood of chemical reactions between test compounds that were volatilized from the same trap.

Each experiment was laid out in a randomized complete block design, with six replicates in the initial screening of candidate attractants at a dose of 100 mg/trap and in the dose–response test, or eight replicates in all other tests, including comparisons repeated seasonally. Traps were wrapped around corn plants at about ear height and were separated within blocks by 30 m. Blocks were laid out within a corn row and were at least 30 m from one another and from the edge of the field. The number of NCR and WCR beetles visible per corn plant and corn developmental stage were determined during each experiment in a sample of 40 plants situated throughout the entire test area at positions in trap rows about equidistant between traps. Traps were left in the field for 48 hr, with two exceptions: cold rainy weather during the first several days of the dose–response test resulted in a six-day test period and the effect of volatilizing 4-methoxycinnamaldehyde and cinnamyl alcohol from the same trap was evaluated after a 24-hr trapping period. Traps were then returned to the laboratory, where counts were made by sex of the numbers of NCR and WCR beetles caught.

Insect captures on traps baited with single components of a two-component mixture were summed across treatments and this total compared with the sum of captures on doubly-baited and control traps to determine whether mixing attractants synergized or inhibited insect responses, i.e., produced responses significantly higher or lower than the sum of responses to individual compounds. This comparison is expressed as a ratio of interaction (ROI) = [(A + B) + Control]/[(A) + (B)], where (A) is the capture on a trap baited with compound A, (B) the capture on a trap baited with compound B, (A + B) the capture on a trap baited with both compounds, and control the capture on an unbaited trap. Captures on doubly-baited traps were increased by control captures to account for the twofold difference between one- and two-component treatments in the number of traps deployed and to avoid a possible negative or zero denominator had adjustments been made by subtraction of control captures from those on baited traps. An ROI significantly above or below or equal to 1 provided evidence for synergistic, inhibitory, or additive interactions, respectively, between test compounds.

To determine whether ROI values differed significantly from 1, a two-tailed t test for paired samples was used to test the null hypothesis of no difference between ROI numerator and denominator. Except for these t tests and the linear regression analyses described below for the dose–response test, data from each experiment were transformed as $\ln(x + 1)$ to normalize variances and were then analyzed by ANOVA. The Student-Newman-Keuls test was used to separate multiple means after a significant ANOVA. $P \leq 0.05$ was considered statistically significant. Untransformed means and standard errors are presented in the tables. For each attractant in the dose–response test, mean responses were calculated for each test dose, and the relationship between the logarithm of the attractant dose and the mean response was analyzed by linear regression. Mean responses not significantly different from control were omitted from each regression analysis, except for inclusion of that mean associated with the highest dose that failed to produce a significant response. Statistical analyses were performed with ANOVA, MEANS, and REG procedures of the SAS Institute (1988a,b).

RESULTS

The initial screening of individual candidate attractants clearly indicated an increased capture of corn rootworm adults compared with controls when traps were baited with 100 mg of geranylacetone or (+)-α-terpineol (Tables 1 and 2, respectively). Both corn rootworm species reacted to both compounds, although NCR appeared more responsive to geranylacetone than to (+)-α-terpineol, whereas WCR showed the opposite pattern. Both NCR sexes were attracted, whereas only female WCR responded above control levels. (+)-α-Terpineol

[a]Test conducted September 15–17, 1993. Mean number ± SE of northern and western corn rootworm adults counted per corn plant on September 15 was 0.4 ± 0.1 and 0.7 ± 0.2, respectively. Corn was in the dent stage (R5).

[b]Asterisks denote statistical significance at $P < 0.0001$, NS denotes $P > 0.05$ ($df = 5, 25$). Means within a column followed by the same letter do not differ by Student-Newman-Keuls test, $P > 0.05$.

attracted more of both species than did (−)-α-terpineol, although only the WCR difference in response to the stereoisomers was statistically significant (Table 2). A similar pattern occurred when the dose of (+)- and (−)-terpineol was reduced to 30 mg/trap (respectively, mean trap captures ± SE for WCR of 67.5 ± 12.8 vs. 38.6 ± 3.0 and for NCR of 27.8 ± 7.3 vs. 22.1 ± 4.3).

WCR females were also significantly, albeit weakly, attracted by β-cyclocitral (Table 1); however, purity of the test sample was low (70%), and the slight response might have been caused by unknown contaminants. As expected from an earlier study (Lampman and Metcalf, 1988), β-ionone attracted significantly more WCR females than did controls. None of the following compounds was attractive: (*E*,*E*)-2,4-nonadienal, (*E*,*E*)-2,4-decadienal, citral, 2,6,6-trimethyl-1-cyclohexene-1-acetaldehyde, (*E*)-4-phenyl-3-buten-2-one, limonene, or 1,8-cineole (Tables 1 and 2).

When beetle captures on traps baited with geranylacetone, cinnamyl alcohol, (+)-α-terpineol, and 4-methoxycinnamaldehyde were compared at four stages in crop phenology (Tables 3 and 4 for NCR and WCR, respectively), no test compound was attractive during corn silking, but NCR and WCR captures otherwise tended to increase as the season progressed, regardless of test compound, and to do so sooner in females than in males. Counts of WCR and NCR on plants also increased as the season progressed (Tables 3 and 4), although more moderately than increased captures on attractant-baited traps. The low WCR plant counts during presilking probably accounted for the low WCR captures early season.

Geranylacetone proved as attractive as cinnamyl alcohol to NCR throughout the season (Table 3), whereas (+)-α-terpineol was clearly less effective than 4-methoxycinnamaldehyde for WCR (Table 4). Geranylacetone again attracted NCR of both sexes and was moderately attractive to WCR females, but was not attractive to males late in the season when corn was in the late dough to early dent stage. (+)-α-Terpineol trapped more WCR females than did geranylacetone, but attractancy again occurred only late in the season. NCR females showed a significant, albeit weak, response to (+)-α-terpineol but not to 4-methoxycinnamaldehyde late in the season. Neither (+)-α-terpineol nor 4-methoxycinnamaldehyde attracted NCR males in this test series.

Figure 2 presents mean captures per trap of WCR and NCR as a function of the logarithm of the dose of geranylacetone or (+)-α-terpineol used to bait the traps. Mixed-sex captures are reported, except that the WCR response to geranylacetone is based only on females because WCR males failed to discriminate baited from control traps at all geranylacetone test doses, and use of mixed-sex captures would have obscured the significant relationship between geranylacetone dose and the response of WCR females. Given this stipulation, captures of both species increased with dose for both attractants and were maximum at

[a] Mean number ± SE of western corn rootworms counted per corn plant during each trapping interval was 0.03 ± 0.03, 0.4 ± 0.1, 0.9 ± 0.2, and 1.5 ± 0.2, respectively, listed in order from early- to late-season 1994 trapping interval.

[b] Asterisks denote statistical significance at $*P < 0.01$ or $**P < 0.0001$, NS denotes $P > 0.05$ ($df = 4, 28$). Means within sexes and columns followed by the same letter do not differ by Student-Newman-Keuls test, $P > 0.05$.

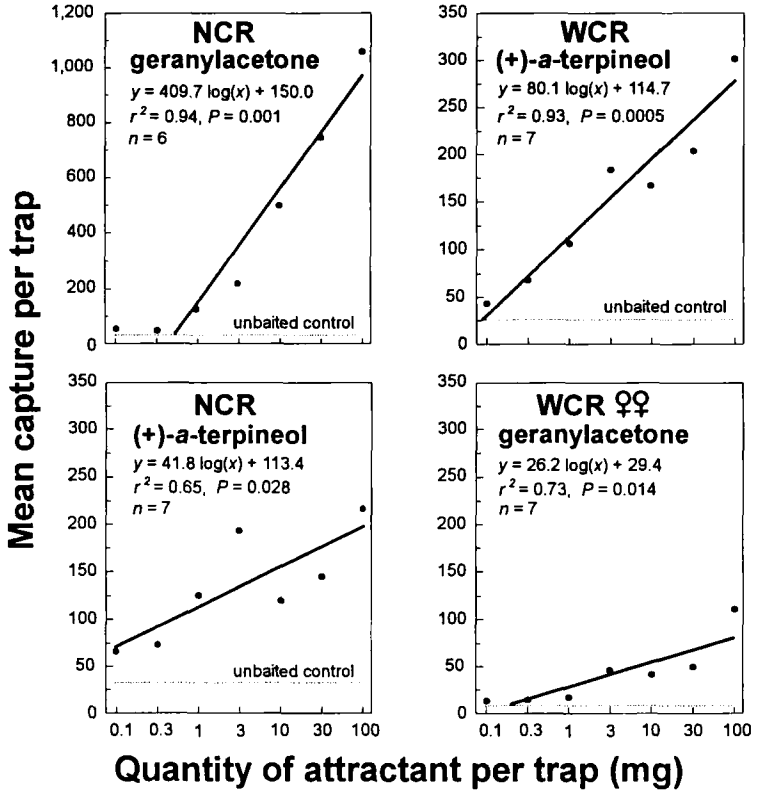

FIG. 2. Relationship between attractant dose plotted logarithmically and capture of northern (NCR) and western (WCR) corn rootworm beetles on attractant-baited traps. The six-day test ended September 6, 1994, when corn was dough to dent stage (R4–R5) and beetle counts per corn plant (mean ± SE) were 1.3 ± 0.2 for NCR and 0.6 ± 0.1 for WCR.

100 mg/trap. Attractant dose plotted logarithmically accounted for 93% or more of the variation in mean responses when NCR and WCR were tested with geranylacetone and (+)-α-terpineol, respectively. Lower R^2 values occurred when mixed-sex NCR reacted to (+)-α-terpineol (0.65) and WCR females reacted to geranylacetone (0.73). In the former case, nearly maximum captures at a dose of only 3.0 mg/trap raised the possibility of a plateau in NCR responses at the higher (+)-α-terpineol doses. The lowest dose to produce a mixed-sex response significantly higher than control was 0.3 mg/trap for NCR and WCR tested with (+)-α-terpineol, 1.0 mg/trap for NCR tested with geranylacetone,

and 3.0 mg/trap for WCR tested with geranylacetone. Detection thresholds did not vary with male, female, and mixed-sex NCR groupings, except that (+)-α-terpineol was first detected at a dose of 0.3 mg/trap by males and mixed-sex groups and at 1.0 mg/trap by females. WCR females responded at lower doses, and as little as 0.1 mg/trap of (+)-α-terpineol or geranylacetone produced captures significantly higher than those to controls. In contrast, WCR males were not attracted to (+)-α-terpineol at doses below 1.0 mg/trap and failed to respond even to 100 mg of geranylacetone. Sex also appeared to strongly influence slope (±SE) of the log dose–response lines in WCR but not NCR [for females compared with males: 61.7 ± 11.0 compared with 17.1 ± 5.0 for WCR responding to (+)-α-terpineol, 26.2 ± 7.1 and no significant male responses for WCR tested with geranylacetone, 17.7 ± 4.6 and 25.9 ± 11.1 for NCR responding to (+)-α-terpineol, and 183.2 ± 39.2 and 226.5 ± 22.6 for NCR responding to geranylacetone. These slopes differed significantly from 0, except for the 25.9 value for NCR males responding to (+)-α-terpineol ($P = 0.07$).]

When efficacy of two-component blends was compared with that of individual components of each blend through calculation of the ratio of interaction (ROI) (Table 5), only females produced ROI values that differed significantly from 1. WCR females produced ROI values that were significantly higher than 1, whether tested with geranylacetone and (+)-α-terpineol (1.71) or cinnamyl alcohol and 4-methoxycinnamaldehyde (1.57). NCR females produced a similarly elevated ROI value of 1.64 to the latter blend, but higher variability precluded statistical significance ($P = 0.27$). An ROI significantly less than one (0.81) for NCR females tested with the blend of (+)-α-terpineol and geranylacetone indicated inhibitory interaction, and (+)-α-terpineol at the 30 mg/trap dose appeared to suppress attraction to geranylacetone.

DISCUSSION

This study is the first to show geranylacetone and α-terpineol attractive to NCR and WCR beetles. These two terpenes are volatile constituents of several parts of corn plants consumed by corn rootworm adults. α-Terpineol occurs in silks (Flath et al., 1978) and geranylacetone is present in kernels and husks (Buttery et al., 1978). Adults of both corn rootworm species prefer a diet of corn pollen, fresh silks, and young kernels. These foods become scarce as corn matures and WCR increasingly utilize corn leaves, whereas NCR tend to migrate out of corn fields to feed on pollen from a variety of other plants before returning to corn for oviposition (Ludwig and Hill, 1975; Branson and Krysan, 1981; Boetel et al., 1992).

Because geranylacetone and α-terpineol were isolated from corn via vacuum steam distillation (Buttery et al., 1978; Flath et al., 1978) and this method

TABLE 5. OLFACTORY INTERACTIONS FOR NORTHERN (NCR) AND WESTERN CORN ROOTWORM (WCR) ADULTS BETWEEN CHEMICALS IN TWO-COMPONENT ATTRACTANT BLENDS DETERMINED FROM CAPTURES WHEN 30 mg OF EACH COMPONENT WERE DISPENSED FROM SAME VS. SEPARATE TRAPS[a]

[a]Tests were started August 24, 1994. Mean number ± SE of NCR and WCR per corn plant was 3.1 ± 0.5 and 1.1 ± 0.2 on August 26 (terpene test) and 5.1 ± 0.6 and 1.2 ± 0.2 on August 24 (phenylpropanoid test), respectively. Corn was in the dough stage (R4) August 24 and 26.
[b]Mean = SE; *$P < 0.05$ that ROI = 1 by a paired two-tailed t test ($df = 7$).

may detect volatile compounds not actually released from plants, the occurrence of the two terpenes in the headspace around corn plants in late vegetative and reproductive stages remains to be demonstrated. Nevertheless, the presence of these terpenes in corn distillate and their attractiveness in my tests to feral corn rootworm beetles of both sexes, especially at the lower doses used in the dose–response test, suggest that they are kairomonal feeding attractants of corn plant origin. A role in ovipositional behavior is also possible given the close association between feeding and ovipositional behaviors in diabroticite beetles, especially in WCR (Branson and Krysan, 1981).

Neither terpene is unique to corn; for example, α-terpineol and probably geranylacetone occur in sunflowers (Etievant et al., 1984), one of a number of flowering forbes that NCR use for food late in the season once corn silks have dried (Cinereski and Chiang, 1968; Krysan and Branson, 1983). α-Terpineol also occurs in evergreens and is attractive to pine beetles and several scolytid bark beetles (see Brattsten, 1983). As a group, plant terpenoids are important intermediaries in diverse insect–plant interactions and may function among other roles as feeding or oviposition deterrents, stimulants, and attractants, including herbivore-induced synomones mediating tritrophic interactions (Brattsten, 1983; Coats et al., 1991; Chou and Mullin, 1993; Dicke, 1994). Despite instances of attraction, terpenes often afford plants an effective chemical defense against herbivory (Brattsten, 1983; Coats et al., 1991).

Several groups of compounds in addition to the corn terpenoid attractants evoke positive responses from *Diabrotica* spp., even though the same groups frequently function as toxic allelochemicals in other insect–plant interactions. In this category are cucurbitacins, triterpenoid defensive compounds typically of cucurbit origin that elicit arrest and compulsive feeding in diabroticites on contact but are highly unpalatable as well as toxic to a wide variety of other organisms (Metcalf et al., 1980). Chemicals generally defending against herbivory are also represented among the compounds that attract WCR larvae toward corn roots [i.e., 6-methoxy-2-benzoxazolinone or MBOA (Bjostad and Hibbard, 1992; Hibbard et al., 1995)].

Although α-terpineol and geranylacetone are common constituents of floral odors (Knudsen et al., 1993), neither chemical was reported among volatile constituents of squash blossoms, where kairomones attractive to corn rootworm adults have so far been sought (Andersen and Metcalf, 1986, 1987; Andersen, 1987). Unlike the corn terpenoid baits, attractants of squash-blossom origin (and their many active analogs) generally contain a phenyl ring. The sole exception is β-ionone, an irregular terpene that shares the cyclohexene structure of α-terpineol and is present in steam distillates of both corn and squash (Buttery et al., 1978, 1980; Flath et al., 1978; Andersen, 1987). Geranylacetone is unique in that it lacks the six-carbon ring invariably present in other reported kairomonal or parakairomonal attractants for adult corn rootworms. Some sim-

ilarity between geranylacetone and β-ionone can be visualized by breaking the cyclohexene ring of β-ionone between the 1 and 6 positions.

Despite the structural novelty of the corn terpenes among known kairomonal attractants of corn rootworm adults, the terpenes nevertheless produced a seasonal response pattern in NCR and WCR similar to that of the phenylpropanoid standards. Captures with both groups of compounds tended to increase as the season progressed, except during corn silking when no compound was effective. Previous studies have also reported diminished or insignificant captures of corn rootworm beetles with phenylalkanoid-baited traps around the time of corn flowering, as well as a tendency for higher trap catches late season (Andersen and Metcalf, 1986; Lampman et al., 1987; Lance and Elliott, 1991; Hesler et al., 1994; Hammack and Hesler, 1995). This pattern could result from seasonal variation in beetle responsiveness to attractants or from seasonal variation in the abundance of natural food sources, most probably combined with poor competition of single-component lures with natural scents that are almost certainly complex mixtures. Preferred foods such as corn pollen and succulent silks are most abundant around the time of flowering, when single-component lures were least effective.

Sex, species, and dose all interacted to affect capture of corn rootworm adults on traps baited with the terpenoid attractants. Even though NCR captures were about five times higher with geranylacetone than with (+)-α-terpineol at the higher doses, the NCR response threshold was actually slightly lower for (+)-α-terpineol than for geranylacetone. The dose–response data suggested that NCR captures peaked at about 3 mg of (+)-α-terpineol, and this is consistent with the finding that 30 mg of (+)-α-terpineol significantly suppressed responses of NCR females to 30 mg of geranylacetone. Although captures on control traps tended to be higher for males than females, perhaps reflecting greater random movement of males at trap height, sex had little effect in NCR on slopes of dose–response lines or response thresholds to the terpenes. That was not true for WCR, and WCR females were clearly the more responsive sex, or even the only sex to respond, as in the case of geranylacetone. WCR males showed a dose-dependent response to (+)-α-terpineol in the dose–response test, but no significant male response was recorded in other tests with this compound. This discrepancy might be explained by the longer test period (six days rather than two) in the former test, perhaps combined with a test date late in the season when captures were found to be highest.

Corn volatiles known to attract diabroticite beetles are widely distributed among plants; for example, α-terpineol, geranylacetone, β-ionone, indole, and phenylacetaldehyde all occur in *Acacia* blossoms (Flath et al., 1983) and, as already noted, the first two compounds are probably present in sunflowers (Etievant et al., 1984). Thus, it is unlikely that these compounds can account for specificity of the host-finding responses of corn rootworm adults, except as constituents of a distinctive odorant blend. Several mixtures formulated from

squash-blossom volatiles are known to elicit synergistic rather than additive attraction responses from diabroticite beetles; these mixtures include VIP (equal parts by weight of veratrol, indole, and phenylacetaldehyde) for southern corn rootworms (SCR), *D. undecimpunctata howardi* Barber, and TIC [equal parts by weight of 1,2,4-trimethoxybenzene, indole, and (*E*)-cinnamaldehyde] for NCR, WCR, and SCR (Lampman and Metcalf, 1987; Metcalf et al., 1995). The present study also indicated at least modest synergism in the response of WCR females to two-component blends of corn terpenes, as well as phenylpropanoid standards, and suggested that NCR may be sensitive to ratios of attractants comprising a blend. That is, a blend of the two corn terpenes may prove more effective for NCR when (+)-α-terpineol is a considerably more minor component than geranylacetone.

Further examination of interactions among volatiles attractive to corn rootworm adults is clearly warranted, using blends that are varied both qualitatively and quantitatively. Studies aimed at defining the blend of compounds released from corn plants at stages fostering corn rootworm adult feeding and oviposition would provide a valuable framework for examining such interactions and likely yield additional behaviorally active compounds. More detailed information about the identity of corn-produced kairomones and their precise roles in host-finding, feeding, and ovipositional behaviors of diabroticite adults is needed and may lead to powerful new tools for corn rootworm management (Levine and Oloumi-Sadeghi, 1991).

Acknowledgments—Sally and Lawrence Vander Wal kindly allowed us to conduct these experiments in their corn fields. Janet K. Fergen provided invaluable technical support, with the able assistance of Lana M. Dahl, Cindi D. Hammer, and Keri L. Skroch. Thomas C. Baker (Iowa State University, Ames, Iowa), Bruce E. Hibbard (USDA-ARS, Columbia, Missouri), and Eli Levine (Illinois Natural History Survey, Champaign, Illinois) generously reviewed an earlier draft of the manuscript.

(Received March 20, 1995; accepted March 4, 1996)

Abstract—This four-year study demonstrated that low-density populations of the gypsy moth, *Lymantria dispar* (L.), were effectively suppressed by annual aerial application of 75 g of racemic disparlure per hectare formulated in plastic laminate flakes. These tests also showed that, when plots were treated with 150 g of pheromone per hectare in 1990 only and left untreated for the following three years, populations continued to be suppressed in 1991–1993 as compared with the controls. Although none of the plots were treated in 1994, population assessment continued and showed that the gypsy moth population density remained low in the plots that had been treated annually for the preceding four years. The laminate flakes released an average of 0.48 g disparlure per day per hectare from each of the two applications in 1990, and 0.72 g per day per hectare from the single application in each of the following three years (1991–1993). Only 27–40% of the applied pheromone dose was emitted during male moth flight.

Key Words—Gypsy moth, *Lymantria dispar*, disparlure, pheromone, mating disruption, laminate flakes, forest pest, aerial application.

INTRODUCTION

The gypsy moth, *Lymantria dispar* (L.), is a major pest of forests in the eastern United States, Michigan, and parts of Canada. In addition, over the last 10 years, approximately 32 isolated infestations per year have been detected and eradicated in states outside of the generally infested area (McGovern, 1994). Studies on the use of the sex attractant pheromone, (Z)-7,8-epoxy-2-methyloctadecane or disparlure (Bierl et al., 1970), for disruption of mating in low-density populations have been carried out for the past 15–20 years (Cameron, 1981). Tests of aerially applied, controlled-release formulations of disparlure conducted in the late 1970s (Webb et al., 1981) showed that gypsy moth mating was reduced by approximately 70–85% or more depending upon the population density and the applied dose (Schwalbe et al., 1979, 1983). Dose–response studies (Webb et al., 1988) showed that the degree of mating disruption increased as the amounts of disparlure in plastic laminate flakes was increased from 7.5 to 75 g/ha in aerially treated plots.

Ground applications of disparlure at rates of 5, 50, and 500 g/ha, dispensed from plastic laminate tapes in plots with high-density gypsy moth populations, resulted in 6.5, 34, and 84% decreases in mating success, respectively, as measured against controls in small plot tests (Schwalbe and Mastro, 1988). Similar studies with disparlure applied in plastic laminate tape (plastic rope) showed that doses as high as 250 g/ha were insufficient to disrupt mating in isolated, high-density populations in which pretreatment surveys showed that immature stages of gypsy moths averaged over 40 per burlap-banded tree (Webb et al., 1990). A five-year evaluation of the same technology (50 g disparlure/ha applied every other year in plastic laminate tapes) demonstrated biological activity for two seasons as measured by reduced mating success and male moth trap capture. However, these ground treatments were not effective in dampening the rate of population increase as measured by egg-mass densities over the five-year study (Kolodny-Hirsch et al., 1990). Part of the lack of efficacy was attributed to inadequate permeation of the ground-applied disruptant throughout the upper canopy of the trees. This study found a significant increase in mating success of females deployed at a height of 15 m as compared with those placed at a height of 1.5 m. These results suggest that, for mating disruption to be effective, the pheromone must be distributed vertically throughout the canopy and remain there for the duration of adult activity. An aerially applied laminate flake formulation of disparlure resulted in the deposit and adherence of the flakes throughout all strata of the canopy and yielded season-long mating disruption in Giles Country, Virginia (Leonard et al., 1992).

This paper reports the results of a five-year (1990–1994) U.S. Department of Agriculture (USDA) cooperative program within the Forest Service's Appalachian Gypsy Moth Integrated Pest Management Program (AIPM) to disrupt

mating in low-density gypsy moth populations in relatively large woodlots in Virginia. These tests compared plots aerially treated with one application of a laminated plastic flake formulation of disparlure in each of the first four years with plots treated with two applications of the flakes only in 1990 followed by no treatment in succeeding years. Efficacy and formulation release rates were determined for each treatment.

METHODS AND MATERIALS

Treatments. The test sites were isolated woodlots (each 13.8–63.9 ha, Table 1) in Rockbridge County, Virginia, in an area that was newly infested with the gypsy moth. It was considered to be part of the southern leading edge of the generally infested area. In 1989, the year prior to treatment, captures of male moths in USDA milk carton survey traps (2 km spacing) averaged 27 males/trap in the area encompassing the test plots. Nine individual woodlots, each surrounded by agricultural fields, were selected on the basis of this male moth survey data and stand composition (greater than 70% basal area oak, *Quercus* spp.). At the beginning of the study, the nearest dense gypsy moth population was approximately 20 km from any of the test plots. The woodlots were randomly assigned to one of three treatments for these mating disruption studies (Table 1). Three plots, C1, C2, and C3, were untreated controls. Three plots, 1L1, 1L2, and 1L3, were treated annually (1990–1993) with a single application of 75 g disparlure/ha just prior to initial male moth flight. The final three plots, 2L1, 2L2, and 2L3, were treated with two 75 g disparlure/ha applications only in 1990; one treatment was applied just prior to initial male moth flight and the second treatment was prior to peak flight. Treatment dates were selected based on the development of immature life stages and expected male eclosion. Monitoring of male trap catches confirmed that application dates occurred within the desired time period. For 1990 through 1993, initial treatments were applied, respectively, on June 26, 17, 30, and 23. The second treatment of pheromone to plots 2L1, 2L2, and 2L3 in 1990 was applied on July 16. All pheromone treatments were made using specialized equipment (Schwalbe et al., 1983) attached to a Cessna 206 aircraft and calibrated to deliver 75 g active ingredient (a.i.) in 405 g flakes per hectare per application. Two of the nine study plots were no longer available in 1994 due to actions by the property owners; control plot C3, defoliated by high-density gypsy moth populations in 1993, was treated with chemical insecticide and plot 1L3 was clear-cut. None of the remaining plots was treated with pheromone in 1994.

The plastic laminate flakes (1 × 3 mm) had 3-mil PVC outer layers and an inner polymer layer containing racemic disparlure (Disrupt II; Hercon Environmental Co., Emigsville, Pennsylvania). The flakes (18.5% a.i.) were pack-

aged with 4.7% diatomaceous earth to prevent clogging in the application apparatus. This mixture was blended during application with a sticker (Gelva 1990, Monsanto Corp., St. Louis, Missouri) in a 1 : 1 ratio by volume to provide adhesion to leaf surfaces.

Population Sampling Procedures. Because low-density gypsy moth populations are difficult to characterize using counts of egg masses (Wilson and Fontaine, 1978), several techniques were selected to evaluate the impacts of treatments on populations and to follow the population trends through the course of the study. These included: burlap bands for sampling abundance of immature life stages, pheromone trapping of adult males, mating success of monitor females, and wild egg mass abundance and fertility.

Immature Life Stages. Relative abundance of immature life stages (Table 1) was monitored in the plots using burlap bands (25 cm wide) fastened around host trees approximately 1.4 m above the ground (64–844 bands per plot). Sampled trees were spaced uniformly throughout the plots by selecting host trees closest to points on a 50-m grid. Burlap bands have been shown to be useful for sampling low-density gypsy moth populations (Wallner et al., 1989, 1990). Bands were checked once when gypsy moths were in the late-instar or pupal stages and a second time after adult flight when shed pupal cases and egg masses were present. Type and number of life stages were recorded at each sampling period. Egg masses were collected and held under ambient conditions for at least 30 days; following mechanical dehairing, they were inspected for evidence of embryonation.

Male Moth Trapping. USDA milk carton traps baited with the standard pheromone dispenser were used in all plots (Table 1) to monitor adult male moth flight (Schwalbe and Mastro, 1988). Generally one trap was placed every 6.2 ha (3–17 traps per plot); three traps were placed in the one plot (C2) that was smaller than 18.6 ha. All traps were monitored at least twice during the adult flight period and once after the end of male flight. In addition, one trap per plot was monitored daily to confirm that flight did not occur prior to treatment. Trap data from the control plots were used to determine the duration and peak period of male flight activity. Traps were removed from the plots or covered with plastic on the day of pheromone treatment to prevent contamination from aerially applied flakes.

Mating Success of Monitor Females. To monitor mating success, laboratory-reared females were placed in each plot because few wild females were projected to be available for sampling, particularly in the early years of the study. Normally, 30 one-day-old virgin female moths were placed in each plot three times a week. When sufficient numbers of 1-day-old females were not available, they were supplemented with 2-day-old females. In these circumstances, care was taken to uniformly distribute 1- and 2-day-old females among all plots. Females were shipped as pupae four to eight days after pupation from

increase in counts of immatures compared to the 1993 numbers (Table 2), even if the 1993 data are adjusted to exclude data from the control plot that was treated with insecticide in 1994. Such adjustment gives a mean immature density of 801 life stages/100 bands in 1993 instead of 709.

Counts of immatures under burlap bands in 1994 in the two remaining 1L plots averaged 17.6 life stages/100 bands. This appears to be a decrease in density as compared with the 1993 data (Table 2) even when the 1993 data are adjusted to remove the data for the woodlot lost to clear cutting. The adjusted mean number of life stages/100 bands in 1993 for the 1L plots is 46.4. This suggests that the gypsy moth population did not rebound in 1994, the first year that these plots were not treated with pheromone. In the three woodlots treated only in 1990 (2L), counts of immatures remained relatively low in the two years following treatment (1991 and 1992), but then increased about 10-fold in each of the next two years to a level where they were similar to those found in control plots.

Male Moth Captures. Captures of male moths in all of the plots in the first year of treatment (1990) were relatively low, but the mean male captures in the control plots (33.4 males/trap) was higher than those in either the 1L (0.0 males/trap) or 2L (0.3 males/trap) plots (Table 2). The numbers of male moths captured in the control plots were also higher in each of the following four years than the numbers captured in treated plots and increased to a mean of 1960 males/trap in 1993. In 1994, male captures in control plots (716 males/trap) were lower than the 1993 captures even if data from the control plot that was lost in 1994 (due to pesticide application) are excluded from the 1993 captures; with that adjustment, the two remaining control plots had a mean capture of 1104 males/trap in 1993.

Although gypsy moth populations adjacent to the experimental plots also had become very high, the mean number of males captured per trap in the 1L plots remained less than one per trap in each of the first four years of treatment. In 1994, the first year with no treatment, the number of males captured in the 1L plots was still very low ($\bar{X}$ = 8.5/trap) when compared with the control. Once more this suggested that the populations in the 1L plots remained suppressed, even though treatment ceased in 1993. Similarly, the numbers of males captured per trap in the 2L plots remained low ($\bar{X}$ = 0.5 males/trap) in the first year following treatment (1991), but increased each year thereafter to 534.4 males/trap in 1994 (Table 2). The data analysis showed that numbers of males captured over time differed significantly (P = 0.03) among the treatments.

Mating Success of Monitor Females. In 1990, none of 1961 monitor females recovered from the six treated plots (1L and 2L) was mated, but an average of 10.3% of the 931 females recovered from the control plots were mated. This relatively low mating success in the control plots may be attributed to low male mating pressure before and after peak male emergence. Female placements were

initiated a week prior to anticipated male flight and were continued until no males were trapped in control blocks for three consecutive days. During the two weeks of peak male flight (July 16–30, 1990), the percentage of mated monitor females in the control plots was substantially higher at 17.4% compared to 5.5% before and 4.8% after peak flight. In 1991, there was still no mating of the monitor females in the annually treated plots (1L) and only 0.2% mating (2 of 966 females) in the 2L plots. In contrast, 2.5% of the 937 females placed in the control plots in 1991 were mated, and 4.2% of those placed in the two weeks of peak male flight were mated. In 1992 and 1993, 0.7% and 0.1%, respectively, of the monitor females were mated in the 1L plots as compared with 67.7% and 52.8%, respectively, in the control plots. Data analysis for all three treatments for the first two years (1990 and 1991) showed a significant ($P = 0.004$) treatment × year interaction effect. This indicated that mating success changed differently for each of the three treatments and that these differences were significant. A separate analysis showed that mating success in the control plots over 1990–1993 was significantly ($P = 0.005$) different from that in the 1L plots. Monitor females were not placed in any plots in 1994.

Wild Egg Mass Abundance and Fertility. Analyses of numbers of fertile egg masses under burlap bands ($P = 0.0001$) and numbers of fertile egg masses discovered in surveys of 0.01-ha subplots conducted late in the year ($P = 0.007$) indicated that the density changes over time were significantly different for the three treatments.

Survey of the 0.01-ha subplots prior to treatment in the first year of the test revealed only one egg mass and that in plot C3. Numbers of fertile egg masses found under burlap bands in control plots increased over the first four years of study (Table 2). After the adult flight period in 1990, burlap bands in control plots averaged 3.5 fertile egg masses/100 bands. These numbers rose steadily for the next three years and averaged 594 fertile egg masses/100 bands in 1993. This constitutes a 170-fold increase over four years. Over the same period, the egg mass surveys in the 0.01-ha subplots indicated that an even greater increase in the fertile egg-mass density had occurred in the control plots than was indicated by the burlap-band survey. Mean numbers of fertile egg masses per hectare found in the control plots during these surveys rose from 10.1 in 1990 to a high of 3137 in 1993 (a 310-fold increase). In the control plots, 99% of all of the egg masses found in 1993 under burlap bands or in the postseason surveys were fertile. The 1994 egg mass counts from burlap-banded trees in the control plots apparently decreased even when the 1993 data are adjusted to remove data for the control plot that was lost in 1994 (adjusted 1993 mean is 443.2 egg mass/100 bands). Density estimates from sampling 0.01-ha subplots in control plots also indicated a decrease in egg mass density in 1994 (Table 2); however, when the 1993 data are adjusted to eliminate those from the lost replicate, the 1993 number of fertile egg masses per hectare becomes

2292, which is similar to the 1994 number. The contrast between this information and the 1994 decline in egg mass density indicated from the burlap band counts might suggest that, in low density populations, burlap bands are more sensitive for detecting egg masses than are the standard 0.01-ha subplot surveys. However, in high populations, the burlap bands can become saturated and the counts fail to indicate the true population level.

In plots treated annually from 1990 to 1993 with pheromone (1L), the numbers of fertile egg masses found under the burlap bands remained low throughout the years of treatment (Table 2). Although the mean number of fertile egg masses in the 1L plots was 3.9/100 bands in 1993, more egg masses (mean of 13.4/100 bands; data not shown) were actually found but only 29% of these were fertile. Postseason egg mass sampling in 0.01-ha subplots showed low numbers of fertile egg masses per hectare in 1990–1992 in the 1L plots but, in 1993, this number increased to 13.8 fertile egg masses per hectare reflecting the pressure from the surrounding high-population areas (Table 2). In 1994, the first year in which these 1L plots were not treated, the number of fertile egg masses under burlap bands and in the 0.01-ha subplots remained similar to the 1993 levels (Table 2). This assessment does not change markedly when the data for the replicate that was lost in 1994 are eliminated from the calculation of the 1993 means. The adjusted numbers of fertile egg masses are 5.3/100 bands and 18.7/ha for 1993, and these means remain comparable to the numbers obtained in 1994. As with other population measures, the fertile egg mass data suggest that the gypsy moth populations remained low in the year after the treatment was terminated.

In plots treated only in 1990 (2L), the mean number of fertile egg masses per 100 bands was very low (0.0) in the year of treatment as well as in the year following treatment (0.3), but rose thereafter (Table 2). Similarly, the mean number of fertilized egg masses per hectare found in the 0.01-ha surveys on the 2L plots were 0.0 and 0.3 in 1990 and 1991, respectively, but rose to 9.1 in 1992 and eventually to 1268 in 1994. Counts under burlap bands as well as in the 0.01-ha surveys increased approximately fourfold between 1993 and 1994 (Table 2). It appears that populations in these plots that had only been treated in 1990 were rapidly approaching densities observed in control plots.

Release Rates. Results of analyses for residual disparlure content in flakes were used to generate linear regressions of residual content with the square root of aging time (Figure 1). The rate at which disparlure was delivered by the flakes declined over the period of male moth flight (about six weeks). For each of the 1990 applications, the average release rate over the first six weeks of the test, calculated from the regression equations, was 0.94 μg/day/flake with mean rates during the first and sixth week of 2.31 and 0.49 μg/day/flake, respectively. Flakes picked from foliage gave similar values as those from spray cards (data not shown). For the 1991–1993 applications, the calculated average rate was

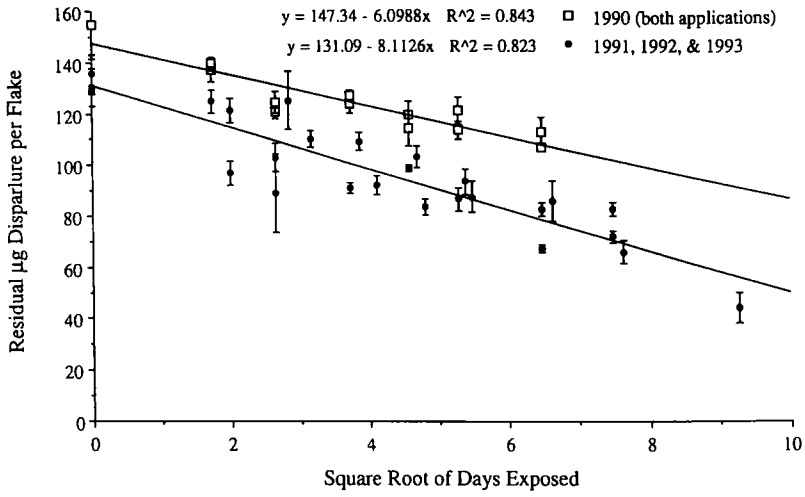

FIG. 1. Residual quantity of disparlure in flakes retrieved from spray cards in 1990–1993 field tests in Rockbridge County, Virginia. Linear regression of disparlure content with square root of time (days) exposed. Error bars show standard errors of sample means.

1.25 µg/day/flake over the first six weeks with rates during the first and sixth weeks of 3.07 and 0.53 µg/day/flake, respectively.

The release rates were used to calculate the amount of disparlure delivered per day per hectare over the course of male moth flight (Figure 2). Since the 2L plots received two applications in 1990, the additive effect is shown in Figure 2A. Each of the two 1990 applications delivered a total of 20.1 g of disparlure over the first six weeks after application for an average rate of 0.48 g/day/ha per application; this is 27% of the applied 75-g dose. The 1991–1993 applications (Figure 2B) each released 30.1 g or 40% of the applied pheromone per hectare over the first six weeks of the test for an average rate of 0.72 g/day/ha. Since male moth flight in Rockbridge County Virginia virtually ceases by the end of July, pheromone released from the flakes six weeks after mid-June application does not contribute to the treatment impact and is essentially wasted. Based on these release rates, about 60–73% of the applied pheromone in the laminate flakes was not released during moth flight in the year of application.

Analysis of flakes retrieved a year later from the 1990 application showed that 2.5 µg/flake of disparlure or about 1.8% of the original dose remained after 12 months of exposure in the field. Therefore, during moth flight in 1991, a

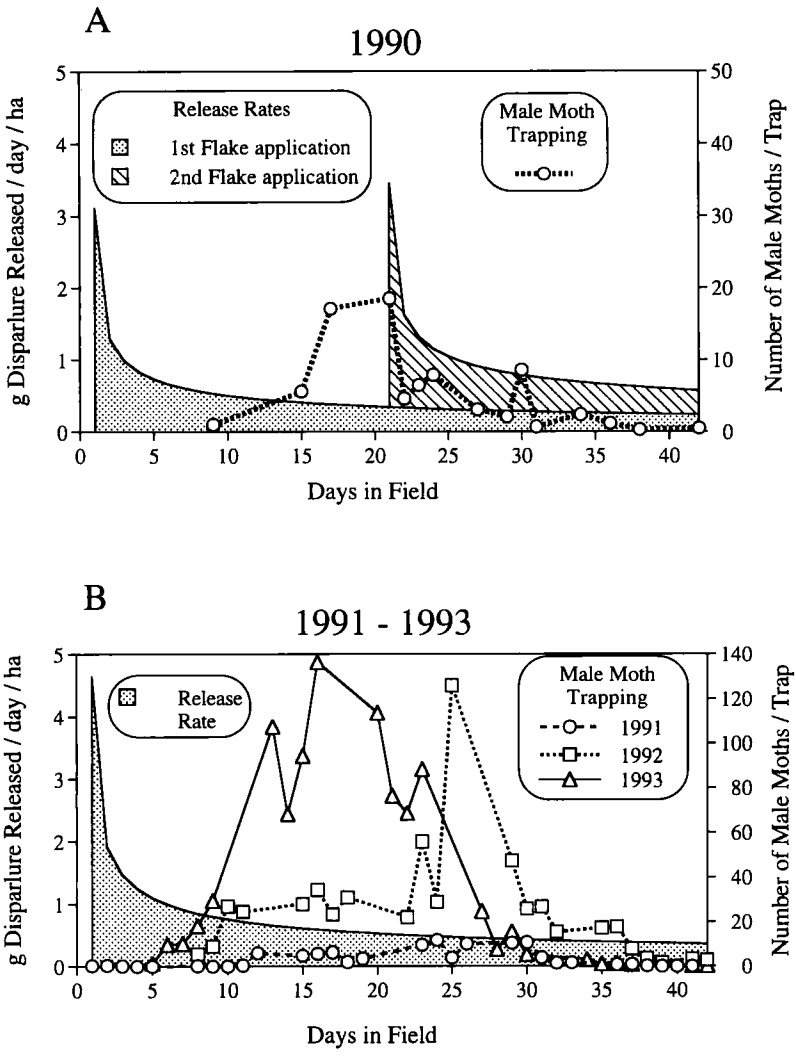

FIG. 2. Amount of disparlure delivered per day per hectare over the course of male moth flight. (A) Single and double applications in 1990. (B) Annual single applications in 1991–1993. Times of male moth flight relative to pheromone application dates are illustrated by overlayed line graphs of trap captures in control plots.

small amount of disparlure remained in the 2L plots that had been treated only in 1990.

DISCUSSION

Previous mating disruption studies with the gypsy moth have attempted to show an impact on populations only in the year of treatment. They often demonstrated that male moth captures in traps could be reduced or entirely eliminated and that mating success could be reduced, although seldom eliminated, in plots treated with pheromone. In this study, an attempt was made to study the longer-term impacts on population trends from a single treatment and from yearly treatments. The results of this study demonstrated that population densities were impacted by either type of treatment. Compared to control plots, the abundance of immature life stages and fertilized egg masses, the percentage of mating success of monitor females, and the number of trapped adult males all remained low in plots treated yearly with one application of 75 g disparlure/ha (1L plots). The reduction of monitor female and wild female mating successes indicated there was significant mating disruption in these treated plots in all four years of treatment. Although monitor females were not deployed in these plots in 1994, the year following the last pheromone treatment, the measures of population density showed that the gypsy moth populations remained suppressed.

In the 2L plots, all measures of population density were low in the year of treatment (1990) as well as in the succeeding year (1991). However, in 1992, all measures indicated an upward trend in population density. Nevertheless, it appears that the double application of pheromone in these 2L plots in 1990 resulted in populations that were lower than those in the control plots in 1992 and 1993. Meanwhile, surrounding populations and populations in control plots increased rapidly and eventually reached defoliating levels. Although the woodlots chosen for this study provide some degree of isolation from migrant males and perhaps from ballooning first-instar larvae (McManus, 1973), these plots are not totally isolated. Therefore, it is surprising (and encouraging) that the 2L plots treated only in 1990 continued to show depressed populations for one to three years as compared with the control plots.

In past studies, the absence of trap captures of males has not been equated with the absence of female mating success. It has been speculated that females are more attractive because of chemical or visual cues. Visual cues have been shown (Richerson et al., 1976; Richerson, 1977; Charlton and Cardé, 1990) to be important in male close-range orientation. However, more time is generally required for a male moth to enter a trap than to find an exposed female on a tree bole (Mastro et al., 1977). The longer the required searching time, the higher the probability that a male will discontinue the search and move on. In

this study, the monitor females were placed in a sheltered location more like native female sites in a low-density gypsy moth population. However, the shelter did not expose the females and required males to spend more time searching. While mating success of these females may have been greater if they had been exposed, it has recently been shown that mating success in low-density populations is normally low (Sharov et al., 1995).

Results of this study indicate that low-density gypsy moth populations can be substantially suppressed with annual application of 75 g disparlure/ha. It is yet to be determined what population level (as indicated by egg-mass surveys, numbers of immatures under burlap bands, or male moth trapping) can be targeted for control by the mating disruption technique. The data in this study suggest that, in the year of pheromone application in treated plots, male moth captures may be somewhat unreliable for determining the level of mating success. For example, male trap captures were low in the 1L plots in 1993 (0.6 males/trap), yet an average of 3.9 fertile egg masses/100 bands and 13.8 fertile egg masses/ha were found. Even low male captures in traps may act as a warning that a treatment did not entirely eliminate mating. Based on the four years of this study, it appears that if a pretreatment survey on 0.01-ha subplots shows less than two fertile egg masses per hectare, and if the number of immatures (larvae + pupae) per 100 burlap bands averages approximately five or less, it is highly likely that application of pheromone will effectively control female mating.

Male moths are highly mobile and attempts to relate trap captures to other measures of population density have not been successful under all conditions (Liebhold et al., 1995). Therefore, the mean numbers of immatures and fertile egg masses under burlap bands and the numbers of fertile egg masses found in late-season 0.01-ha subplot surveys were used to obtain a population index for all nine plots during the five years of this study. The sum of the means of these three population measures (immatures per 100 bands, fertile egg masses per 100 bands, and fertile egg masses per hectare) were plotted versus year (Figure 3) to indicate the population changes over time for the three treatments. From this graph, it is apparent that the single pheromone application in 1990 (2L plots) delayed the population increase by one to four years. Annual pheromone application controlled the population for three years and slowed the rate of increase thereafter.

SUMMARY

This study showed that the population represented by an average male moth capture of 27/trap in the vicinity of the test plots in 1989 was effectively controlled for at least three years by annual pheromone application until neighbor-

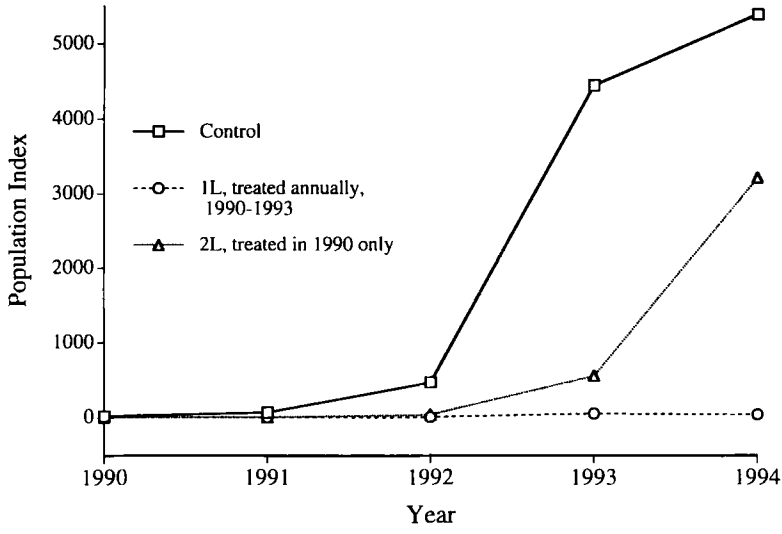

FIG. 3. Population index for all nine study plots (sum of mean number of immatures/100 bands + mean number of fertile egg masses/100 bands + mean number of fertile egg masses/ha) plotted by treatment for each of the five years of the study.

ing, uncontrolled populations exerted too high an influence. However, despite this population pressure from surrounding areas, the single application of 75 g of pheromone/per hectare significantly disrupted mating in each of the four treatment years. This study also showed that treatment with pheromone in only one year (albeit a double application) substantially suppressed the population increase as compared with the controls for three subsequent years. Thus, in properly selected populations, mating disruption with aerially applied pheromone is an effective control method.

The release profile of disparlure from the laminate flakes is characteristic of a laminated structure (Kydonieus, 1980) and has the advantage that exact timing of the application just before male flight is not critical. However, the fact that only 27–40% of the applied pheromone was released during male flight suggests that a controlled-release formulation, which more efficiently delivers its pheromone dose, would allow the total amount of applied pheromone to be reduced by perhaps a factor of two without loss of efficacy. Such a formulation would reduce treatment costs. Work is now being carried out to develop such a delivery system.

Acknowledgments—The authors wish to express their sincere appreciation and recognition for the very important contributions by Steve Talley (Gypsy Moth Coordinator for Rockbridge County,

Virginia), Gary McAninch (Virginia Department of ACS), Tim Roland (USDA-APHIS), Dee Dee Sellers and Nathan McKee (USDA-FS), Ralph Webb (USDA-ARS), and Caroline White (USDA-APHIS).

(Received May 30, 1995; accepted March 4, 1996)

Abstract—Quantitative measurement of phlorotannins (polyphenolics) in brown algae (Phaeophyta) by colorimetric assays can be confounded because: (1) most such assays also react to nonphlorotannin substances (interferences) and (2) the appropriate reference compound for such assays is not always clear, although phloroglucinol is typically used. We developed a new assay in which 2,4-dimethoxybenzaldehyde (DMBA) reacts specifically with 1,3- and 1,3,5-substituted phenols (e.g., phlorotannins) to form a colored product. This new assay, as well as eliminating the problem of measuring interferences, is inexpensive, rapid, and can be used with small sample volumes. We recommend it for all assays of phlorotannins from one or a set of closely related species where the structural types of phlorotannins present are likely to be similar among samples. It is also appropriate for broader surveys of phlorotannin levels across many species, but in this case a reference must be chosen with care. We also compared the DMBA assay to existing assays, including the Folin-Denis [both before and after the samples were mixed with polyvinylpolypyrrolidone (PVPP)] and the Prussian blue assays. PVPP was not 100% efficient (and often much less) at removing phlorotannins from solution, and its effectiveness varied among different phlorotannins. Thus, in contrast to previous studies, measuring phenolic levels in extracts before and after

treatment with PVPP will not necessarily result in an interference-free measure of phlorotannins. Based on an analysis of reactive substances in red and green algae (which do not contain phlorotannins) in the Folin-Denis and Prussian blue assays, we estimate that the average level of interferences (nonphlorotannins) in brown algae measured in these two assays is on the order of 0.5% by dry weight.

Key Words—Phlorotannins, DMBA, Folin-Denis assay, brown algae, seaweeds, phenolics, PVPP.

INTRODUCTION

Polyphenolics are one of the most common classes of secondary metabolites in terrestrial plants (Harborne, 1991; Haslam, 1989; Swain, 1979), marine angiosperms (McMillan, 1984), and macroalgae (Ragan and Glombitza, 1986; Steinberg and van Altena, 1992). They are ecologically important in both terrestrial and marine systems, deterring or inhibiting herbivores, epiphytes, pathogens, or competitors (e.g., allelopathy) (Beress et al., 1993; Bernays et al., 1989; Hay and Fenical, 1988). In particular, there is a substantial empirical and theoretical literature on the effects of polyphenolics against herbivores (Coley et al., 1985; Feeny, 1976; Steinberg, 1992; Swain, 1979). Polyphenolics can also significantly affect broad-scale ecosystem properties in both terrestrial (Schlesinger, 1991) and marine (Carlson and Mayer, 1983) systems.

Although terrestrial and marine plant polyphenolics are similar in some respects, there are some fundamental differences among the compounds. Terrestrial polyphenolics, or tannins, are polymers based on flavonoids or gallic acid (Haslam, 1989). Algal polyphenolics, or "phlorotannins" (Ragan and Glombitza 1986), which are only known from the brown algae (Phaeophyta), are restricted to polymers of phloroglucinol (1,3,5-trihydroxybenzene). Phlorotannins and terrestrial tannins vary in their linkages between monomeric units, in their size (dimers to 600,000 amu), and to some extent in the types of substitutions present (i.e., halogenation, sulfated groups) (Ragan and Glombitza, 1986).

While the abundance and ecological importance of polyphenolics in natural systems has long been recognized, the ability to quantitatively measure these compounds in plant tissue remains a complex issue (Mole and Waterman, 1987a,b; Ragan and Glombitza, 1986; Ragan and Jensen, 1977; Van Alstyne, 1995). Because the compounds are typically large, polar, and water soluble, they are difficult to measure by the standard analytical techniques used to analyze smaller nonpolar metabolites such as terpenes and acetogenins. Analysis of algal polyphenolics is further complicated by the difficulty of separating the individual compounds from the polymeric mixtures which occur naturally in vivo.

Consequently, polyphenolics have typically been analyzed in one of two

ways. The first is via various spectrophotometric procedures based on the reaction of a colored reagent with the easily oxidized phenolic functional group. The best known of these procedures is the Folin-Denis test, or variations thereof, such as the micro-Folin Denis (Arnold et al., 1995; Targett et al., 1995; Van Alstyne, 1995) or Folin-Ciocalteau (1927) tests. This assay and its variations have been used extensively in the analysis of phenolics from both marine and terrestrial plants (Ragan and Jensen, 1977; Mole and Waterman, 1987a,b; Steinberg, 1989). The second set of methods uses the ability of polyphenolics to bind to macromolecules such as proteins, thus generating a measure of "relative tanning ability" (Hagerman and Butler, 1989).

Such techniques have been very useful, but they are subject to a number of sources of error, of which two are perhaps the most significant for phlorotannins (Ragan and Glombitza, 1986; Steinberg, 1989; Van Alstyne, 1995). Firstly, because specific molecules are not analyzed, but rather total phenols or tanning ability, variation in the reactivity of structurally different polyphenolics (due to variation in size, structure, etc.) is not separable from variation in reactivity due to different amounts of compounds. Secondly, nonpolyphenolic interferences can react with the reagents used in some colorimetric assays, resulting in an overestimate of phenolic levels.

In this paper we compared three spectrophotometric assays in an attempt to assess the variation in the three assays resulting from different types of phlorotannins from marine brown algae and to determine the effect of interferences in these assays. We compared the Folin-Denis technique, used with and without polyvinylpolypyrrolidone (PVPP), a resin which binds to, and removes polyphenols in solution; the Prussian blue assay, which has been suggested to be less sensitive than the Folin-Denis assay to interfering compounds; and a new assay, which is based on the ability of 2,4-dimethoxybenzaldehyde (DMBA) to react specifically with 1,3- and 1,3,5-substituted phenols (i.e., phlorotannins), and which does not react with tannic acid containing only ortho- and parahydroxyl-substituted phenolics). We compared the color yield of these three techniques for both purified phlorotannin fractions and crude extracts from a number of brown algae. The effect of interferences on the measurement of phlorotannins was examined by measuring phenolic levels in our extracts before and after the addition of PVPP and by measuring the reactivity of extracts from red and green algae, which lack phlorotannins.

METHODS AND MATERIALS

Chemical Assays

Phenolic levels in crude extracts of brown algae and in "purified" phlorotannin fractions (see Preparation of Pure Phlorotannin Fractions, below) were

quantified by three methods. The first, the Folin-Denis procedure for measuring total phenolic content (Ragan and Jensen, 1977; Swain and Hillis, 1959), has been used extensively for measuring phlorotannins in brown algae (Ragan and Glombitza, 1986; Steinberg, 1989; Targett et al., 1992; Van Alstyne, 1995). The second, the Prussian blue assay (Price and Butler, 1977), is also well described in the literature but has not been used as extensively as the Folin-Denis procedure. Our new technique, the DMBA assay, is based on the vanillin–H_2SO_4 reaction (Butler, 1982; Butler et al., 1982; Putnam and Butler, 1985).

Folin-Denis Assay. Folin-Denis reagent was prepared by dissolving 25 g of sodium tungstate ($Na_2WO_4 \cdot 2H_2O$) and 5 g of dodecamolybdophosphoric acid ($12MoO_3 \cdot H_3PO_4 \cdot H_2O$) in 175 ml distilled water, adding 12.5 ml phosphoric acid to the solution, boiling under reflux for 2 hr, and then making up to 250.0 ml. The sample (1.0 ml) was mixed with 4.0 ml of this reagent and 8.0 ml of a saturated sodium carbonate solution and then made up to a reaction volume of 25.0 ml with distilled water. Color was allowed to develop for 5–6 hr, which allowed the precipitate that formed to settle before the absorbance was read at 725 nm.

Prussian Blue Assay. Samples were comprised of 100 μl of extract or diluted extract in 50.0 ml of distilled water in a 125 ml flask. Three milliliters of ferric ammonium sulfate (0.1 M $FeNH_4(SO_4)_2$ in 0.1 M HCl) was then added to successive samples at intervals of 1.0 minute. Exactly 20 min after the addition of ferric ammonium sulfate to each sample, 3.0 ml of potassium ferricyanide [0.008 M $K_3Fe(CN)_6$] was added. Exactly 20 min after the addition of potassium ferricyanide, the absorbance at 720 nm was read. Solvent-only blanks were included and subtracted from sample absorbances. Like Folin-Denis, Prussian blue reacts with reducing compounds such as phenols, but the phenolic group is not directly incorporated into the colored product.

DMBA Assay. Stock solutions of 2,4-dimethoxybenzaldehyde (2 g/100 ml solution) (Sigma D-3269) and of hydrochloric acid (16.0 ml concentrated hydrochloric acid per 100.0 ml solution) were prepared in glacial acetic acid. The working reagent, prepared by mixing equal volumes of these two solutions just prior to use, was kept at room temperature before starting the assay. The working reagent is slightly yellow when mixed, but becomes purple (λ_{max} = 565 nm) upon standing, so it must be prepared fresh each day. Blanks of the same volume as the sample were used in all assays because some color formation occurs in the absence of phlorotannins.

To ensure that the response was linear for each type of purified tannin, standard curves were prepared. Aliquots of each phlorotannin solution (up to 40 μg from 10 μg/μl solution) were mixed with 10 μl of DMF (*N*,*N*-dimethylformamide) and 2.5 ml of the working reagent (DMF is necessary for use in protein precipitation assays as described in Stern et al. (in press). The reaction mixtures varied in volume by 4 μl (of 2.5 ml) when testing different concentra-

tions; this was done to minimize the volume of added methanol, at the lowest level of pipetting possible (1 μl), within the range of sensitivity of the assay (10 μg). The absorbance was determined at 510 nm after exactly 60 minutes at 30°C. For fresh extracts of brown algae, 10–100 μl were used in the DMBA assay, depending on the concentration of phlorotannins.

Preparation of Pure Phlorotannin Fractions. In order to assess the variation in response of different phlorotannins in the different assays, phlorotannin fractions from six species of brown algae were prepared following the methods of Ragan and Glombitza (1986) as modified by Steinberg and van Altena (1992) and van Altena and Steinberg (1992). In brief, several kilograms of fresh seaweed were extracted in 80% methanol under nitrogen at 4°C for three days with regular mixing. The filtered extract was rotary evaporated to a small aqueous volume at 40°C. Any precipitates were then filtered and the filtrate was lyophilized, triturated with methanol several times (to remove salt), and then adsorbed onto microcrystalline cellulose. This column was eluted with toluene (to remove pigments) and then with ≈3 liters of 2:1 acetone–water. This was rotary evaporated, redissolved in water, and then freeze dried. These phlorotannin fractions contained a mixture of phlorotannin polymers and oligomers but were pure in the sense of containing 95+% phlorotannins, based on the absence of peaks in ^{13}C NMR spectra except those in the three regions typical of phlorotannins (96–106, 124–131, and 141–164 ppm) (van Altena and Steinberg, 1992).

Phlorotannins from the kelps (Order Laminariales) *Agarum cribrosum*, *Ecklonia radiata*, and *Dictyoneurum californicum*, and from the fucoids (Order Fucales) *Sargassum vestitum* and *Carpophyllum maschalocarpum* were used. High-molecular-weight phlorotannins from the fucoid *Fucus vesiculosus* were obtained from M. A. Ragan. Catechin (C1251; Sigma, St. Louis, Missouri) and phloroglucinol (1,3,5-trihydroxybenzene) (P3502; Sigma) were also tested in the assays.

Assays of Phenolic Levels in Fresh Extracts of Brown Algae. Phenolic levels in fresh methanol extracts of a variety of brown algae also were measured. Extracts were prepared by grinding fresh algal tissue (0.5–1 g) in a Sorvall Omni Mixer in 85% MeOH and storing at 4°C overnight prior to assaying for phenolic levels.

Extracts from 11 species of Australian brown algae (Phaeophyta) from four orders were measured using the DMBA and Folin-Denis assays. These included representatives of the Order Laminariales (*Ecklonia radiata*), Dictyotales (*Dilophus marginatus*, *Dictyopteris acrostichoides*, *Dictyota dichotoma*, *Homoeostrichus sinclarii*, *Zonaria diesingiana*), Ectocarpales (*Endarachne binghamiae*), and Fucales (*Sargassum vestitum*, *S. linearifolium*, *Phyllospora comosa*, *Cystophora moniliformis*). For each species, six individual algal plants were collected in summer (February and March) in New South Wales, Australia.

In New Zealand, nine species of brown algae were assayed by the Prussian

blue and Folin-Denis techniques for comparison of relative sensitivity to interferences. These included *Carpophyllum flexuosum*, *C. maschalocarpum*, *C. angustifolia*, *C. plumosum*, *Ecklonia radiata*, *Sargassum sinclarii*, *Xiphophora chondrophylla*, *Lessonia variegata*, and *Cystophora torulosa*. Five individuals from each species were collected and analyzed in summer and autumn at the University of Auckland, Leigh Marine Laboratories, New Zealand.

Assessment of Interferences

Phenolic levels in plant tissue may be overestimated if nonphenolic compounds in algal extracts react with assay reagents, e.g., ascorbic acid or peptides in the Folin-Denis assay (Ragan and Glombitza, 1986). While the DMBA assay was developed in order to avoid such interferences, this assay may not be suitable for all studies. Thus, the problem of interferences was further addressed in two ways.

PVPP Treatments. Polyvinylpolypyrrolidone (PVPP) is a polymer that can remove tannins and phlorotannins from acidic aqueous solution (Loomis and Bataille, 1966; Yates and Peckol, 1993). Thus, one way of assessing the levels of interferences in an algal extract is to measure total phenolics in the extract with the Folin-Denis or Prussian blue procedure before and after treatment with PVPP (e.g., Yates and Peckol, 1993). Any color yield in a Folin-Denis assay after treatment with PVPP should be due to nonphlorotannins, such as proteins or ascorbic acid (or free phloroglucinol, which adheres poorly or not at all to PVPP), and in theory an interference-free measure of phlorotannins could then be obtained by subtraction. Extracts treated with PVPP should not yield any color in the DMBA assay, since DMBA reacts specifically with phlorotannins.

We compared phenolic levels in untreated samples and PVPP-treated samples using both the DMBA and Folin-Denis assays. These experiments give us information about both the efficacy of PVPP in removing phlorotannins from solution and the amounts of nonphlorotannin interferences in our fresh algal extracts. Because both Yates and Peckol (1993) and Targett et al. (1995) note that PVPP is effective in a slightly acidic environment, the pH of the methanol extracts of algae was adjusted if necessary by the addition of 10 μl of acetic acid to a pH of ≈ 4. Both fresh extracts and pure phlorotannins were treated with 20 mg PVPP/ml solution (Kellem et al., 1992; Yates and Peckol, 1993). The mixtures were shaken overnight at 4°C, centrifuged, and the supernatants assayed for phenolic level.

"Phenolic" Analyses of Red and Green Algae. A second way of assessing likely levels of interfering compounds in brown algae is to assay species of red and green algae, which lack phlorotannins (Ragan and Glombitza, 1986). Color obtained in such assays should be due only to interferences such as ascorbic acid, polypeptides, or, in the case of some red algae, simple phenols (Phillips

and Towers, 1982). This method assumes that the levels of these interferences, such as ascorbic acid or proteins, are not substantially different in red and green versus brown algae. In our view this assumption would be strengthened by looking at a taxonomically wide range of species. Thus we measured total phenolics in extracts of 12 species of red algae (seven from California, five from New Zealand) and five species of green algae (three from California, two from New Zealand) in the Folin-Denis and Prussian blue assays. The California algae tested were *Prionotus lanceolata*, *Endocladia muricata* (Order Cryptonemiales), *Halosaccion glandiforme* (Rhodymeniales), *Iridaea flaccida*, *Mastocarpus papillata* (Gigartinales), *Porphyra* sp. (Bangiales), *Rhodomela larix* (Ceramiales), *Chaetomorpha* sp., *Cladophora* sp. (Cladophorales), and *Ulva* sp. (Ulvales); New Zealand algae tested were *Vidalia colensoi* (Ceramiales), *Gigartina circiuta*, *Melanthalia abscissa* (Gigartinales), *Prilonia* sp. (Nemalionales), *Pterocladia lucida* (Gelidiales): *Ulva* sp. (Ulvales), and *Codium fragile* (Siphonales). Sample size was five individuals from each species in all cases. Extraction procedures followed those described above for brown algae.

Although the chemistry of the DMBA reaction should preclude any color formation with red and green algae (unless phlorotannins are present), we assayed a selection of red and green algae (which are known to contain secondary metabolites) with DMBA. We extracted and assayed the following seaweeds: *Laurencia rigida*, *Delisea pulchra*, *Caulerpa scalpeliformis*, and *Codium fragile*. Four species that lack known secondary chemistry were also tested (the red algae *Soliera* sp., *Amphiroa* sp., *Corallina* sp., and the green alga *Ulva lactuca*).

RESULTS

Reaction between Phlorotannins and 2,4-Dimethoxybenzaldehyde (DMBA)

Preliminary characterization of the reaction of *Ecklonia radiata* and *Carpophyllum maschalocarpum* phlorotannins with DMBA in glacial acetic acid showed that formation of the colored adduct was both time- and temperature-dependent (Figure 1). A reaction time of 1 hr was selected since at that time absorbance was relatively stable; slight variations in reaction time did not cause large changes in absorbance. Adequate sensitivity was obtained even at room temperature, but we chose to use slightly elevated temperatures (30°C) to ensure good temperature control despite seasonal fluctuations in room temperature. Higher temperatures gave increased sensitivity, but also increased problems with degradation of DMBA and with acetic acid fumes during the reaction. Based on these results, phlorotannins were routinely allowed to react with the DMBA for exactly 60 min at 30°C before determinations were made. The λ_{max} for the colored product of the reaction is 510 nm so spectrophotometric measurements were made at that wavelength.

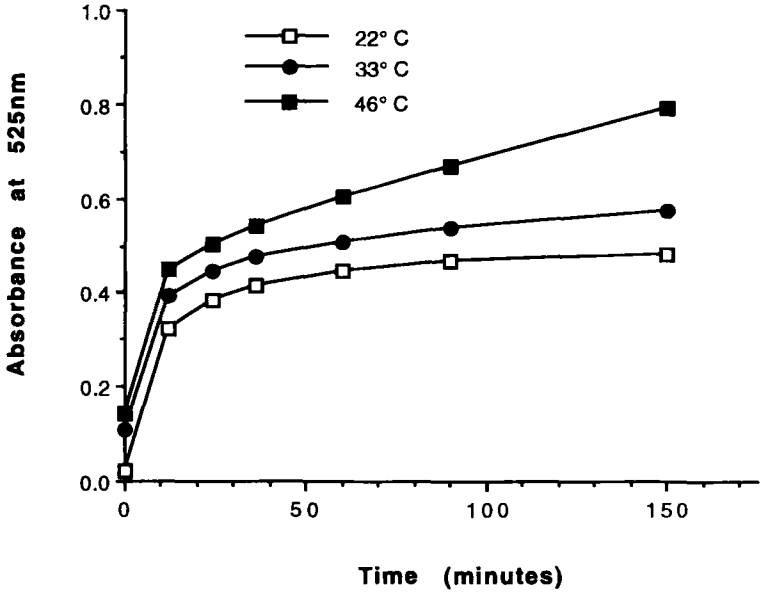

FIG. 1. Kinetics of the reaction between 20 μg of *Carpophyllum maschalocarpum* phlorotannins and 2,4-dimethoxybenzldehyde at three temperatures.

The relationship between mass of phlorotannin and color yield in the DMBA assay for six purified phlorotannin fractions and phloroglucinol is shown in Table 1. The relationship was linear to at least 40 μg, with r^2 values >0.975 for all phlorotannins and phloroglucinol. The limit of detection was approximately 5 μg. The spectra of the reaction products of several different algal phlorotannins with DMBA were similar, indicating that the adduct formed between DMBA and various phlorotannins was the same. Phloroglucinol, the monomer unit of phlorotannins, forms a peak at 510 nm after an initial peak (within the first minute) at 565 nm, which later is masked by the peak at 510 nm. This is probably due to slight differences in the chemistry of phloroglucinol from phlorotannins; e.g., phloroglucinol lacks the aryl and ether linkages of the polymeric phlorotannins (K. Barrow, personal communication).

The DMBA assay is based on chemistry similar to the vanillin assay (Ribéreau-Gayon, 1972). In the vanillin assay, the use of acidified glacial acetic acid as a solvent increases color yield, simplifies the reaction kinetics, and stabilizes the colored product of the reaction between the aldehyde and phenolic (Butler et al., 1982). Furthermore we found that glacial acetic acid is an excellent solvent for phlorotannin/protein precipitates (Stern et al., in press). We suggest

TABLE 1. REGRESSION EQUATIONS FOR ABSORBANCE AS A FUNCTION OF MASS OF PHLOROTANNINS IN THREE DIFFERENT PHENOLIC ASSAYS[a]

Algae	Folin-Denis	Prussian blue	DMBA	$R_{DMBA/FD}$
Phloroglucinol	$y = 0.00290x - 0.0335$	$y = 0.111x + 0.0793$	$y = 0.0620x + 0.053$	1
Agarum cribrosum (L)	$y = 0.00223x - 0.015$	$y = 0.122x + 0.10416$	$y = 0.0140x - 0.020$	0.293
Ecklonia radiata (L)	$y = 0.0020x - 0.017$	$y = 0.0898x + 0.0804$	$y = 0.0190x - 0.006$	0.444
Dictyoneurum californicum (L)	$y = 0.0017x - 0.016$	$y = 0.0920x + 0.0144$	$y = 0.0110x - 0.005$	0.302
Fucus vesiculosus (F)	$y = 0.00256x - 0.007$	not done	$y = 0.0197x + 0.009$	0.360
Carpophyllum maschalocarpum (F)	$y = 0.0013x - 0.013$	$y = 0.0822x + 0.0804$	$y = 0.00640x + 0.002$	0.230
Sargassum vestitum (F)	$y = 0.00083x - 0.087$	not done	$y = 0.00540x - 0.003$	0.304
Overall regression	$y = 0.00207x - 0.0134$	not done	$y = 0.0134x - 0.004$	not done

[a] Equations are in the form: Absorbance = m (μg phenolics) + absorbance. $N = 3$ for each extract at each mass; four masses assayed. The range of masses used were 0–400 μg for the Folin-Denis and Prussian Blue assays, 0–40 μg for the DMBA assay. All r^2 values are >0.975. The overall regression was calculated from data for all compounds. F = Order Fucales, L = Laminariales (kelps). $R_{DMBA/FD} = (m_{DMBA}/m_{PG})/(m_{FD}/m_{PG})$, where m = the slope for standard curves of a given phlorotannin or phloroglucinol (PG); this ratio has been suggested to provide information about molecular weight (Ragan and Glombitza 1986).

the use of a fume cupboard, covered waterbath, and cuvettes with stoppers when using this solvent.

It has previously been reported that small amounts of methanol inhibit the reaction between vanillin and phenolics (Butler et al., 1982). Similarly, we found that as little as 4% methanol, water, or dimethylformamide in the reaction reduced the color yield in the DMBA reaction. When using methanolic or aqueous extracts of plant material, controls must be included to account for this variation. Quantification of brown algal phlorotannins in aqueous methanol extracts (e.g., such as those used here) does not suffer significantly from this decrease in color yield as only very small volumes of extract are required for use in the assay (see Methods and Materials).

Comparisons among Assays Using "Purified" Phlorotannin Fractions and Phloroglucinol

There was considerable variability in the reactivity of different purified phlorotannins within the three assays performed, as indicated in Table 1 by the variation in slopes of the regressions for absorbance versus the mass of each phlorotannin. In general, variation in the reactivity of different phlorotannins was least in the Prussian blue assay, with slopes varying between 0.0822 and 0.111 (including phloroglucinol). Variability in reactivity was greatest in the DMBA assay with slopes varying between 0.005 and 0.02 for the six phlorotannins tested (Table 1, excluding phloroglucinol). The reactivity of phloroglucinol (PG) with DMBA is very high, relative to phlorotannins, with the slope of the standard curve for phloroglucinol in the DMBA assay 3–11 times greater than for the phlorotannin regressions. In comparison, the slope for phloroglucinol in the Folin-Denis assay was 1–3 times higher than slopes for the phlorotannins.

For a given polyphenolic (p), the ratio of color yield in a vanillin assay (V) to a Folin-Denis assay (FD), relative to phloroglucinol (PG) (i.e., $(m_{Vp}/m_{VPG})/(m_{FDp}/m_{FDPG})$ where m is the slope for a given phlorotannin standard curve), may provide information about phlorotannin molecular weight (Ragan and Glombitza, 1986). This is based on the idea that polymerization of phloroglucinol is generally via ether linkages, decreasing Folin-Denis reactive sites (and thus color yield), while vanillin and DMBA color yield is a function of available positions on a benzene ring between meta-oxygen substitutions (Ribéreau-Gayon, 1972). Such positions would not be consumed if polymerization is via ether linkages, and therefore color yield should be strictly proportional to the number of phloroglucinol molecules present. Thus, with increasing molecular weight, vanillin should yield proportionally more color per unit mass than Folin-Denis. Color yield within an assay for a phlorotannin must be taken as relative to color yield for phloroglucinol to account for between-assay differences in extinction coefficients.

Because of the similarity in the chemistry of the vanillin–phlorotannin and DMBA–phlorotannin reaction, we might expect a similar trend for the ratio between DMBA absorbance and vanillin absorbance (vanillin is 3-methoxy-4-hydroxy benzaldehyde). Comparison of these ratios in Table 1 indicates a high ratio for the monomer phloroglucinol, as expected, and the next highest ratios are for the relatively small polymers from *Ecklonia radiata* (van Altena and Steinberg, 1992). However, the polymers from *Fucus vesiculosus*, which span a large size range (Ragan 1985; Ragan and Glombitza, 1986), also yield a high value, suggesting that the ratio of DMBA to FD does not consistently provide easily interpretable information about the molecular weight of phlorotannins (see Discussion, below).

There was some similarity in the response of pure phlorotannins from taxonomically related algae in these assays (Table 1). For example, in the DMBA assay, slopes of the regression lines for the three kelps (Order Laminariales) varied between 0.01 and 0.02 (Table 1). Phlorotannins from the confamilial species *Sargassum vestitum* and *Carpophyllum maschalocarpum* (Order Fucales, family Sargassaceae), had lower slopes: 0.0054 and 0.0064, respectively. A similar grouping was observed in the Folin-Denis assay. However, absorbance of phlorotannins from the fucoid *Fucus vesiculosus* (family Fucaceae) was more similar to that of the kelps in both assays.

Assays of Fresh Algae

The effect of the choice of standard for the determinations of phenolic levels in crude extracts from 11 species of Australian brown algae is shown in Table 2. Phlorotannin levels were measured in the Folin-Denis and the DMBA assay based on three standards: (1) phloroglucinol, the typical standard used in such studies; (2) the overall regression for each assay (Table 1); and (3) purified phlorotannin fractions from *Sargassum vestitum* and *Ecklonia radiata*. The choice of a standard curve substantially affected the measured estimates of phenolic content for most species. For example, estimated levels of phenolics in the DMBA assay for *Sargassum vestitum* varied between 1.8% dry wt (phloroglucinol reference) and 24.6% dry wt (*S. vestitum* phlorotannin reference), depending on the reference used. Similarly, the Folin-Denis assay resulted in estimates varying from 6.1% dry wt (phloroglucinol reference) to 23.1% dry wt (phlorotannin reference) for *Sargassum vestitum*.

Effects of PVPP

Polyvinylpolypyrrolidone (PVPP) failed to completely remove phlorotannins from all fresh algal extracts except those of *Ecklonia radiata*. Extracts of most algae showed significant color formation (up to 40% of original absorbance) in the DMBA assay after treatment with PVPP (Figure 2).

TABLE 2. PHLOROTANNIN CONTENT (PERCENT DRY WEIGHT) OF 11 SPECIES OF ALGAE USING THREE DIFFERENT STANDARDS FOR FOLIN-DENIS AND DMBA ASSAYS[a]

[a] Er = *Ecklonia radiata*, Sv = *Sargassum vestitum*, Sl = *S. linearifolium*, Sg = *S. globulariaefolium*, Cm = *Cystophora moniliformis*, Pc = *Phyllospora comosa*, Dm = *Dilophus marginatus*, Da = *Dictyopteris acrostichoides*, Dd = *Dictyota dichotoma*, Hs = *Homoeostrichus sincalarii*, Zd = *Zonaria diesingiana* Eb = *Endarachne binghamiae*; L = Laminariales, F = Fucales, E = Ectocarpales, D = Dictyotales. Data are means and standard deviations for $N = 6$ samples for all species except *E. radiata* ($N = 9$). Note that negative values reflect the high y intercept for phloroglucinol relative to absorbances for phlorotannins. An asterisk indicates an alga with a high phloroglucinol content, suggesting a phloroglucinol reference is appropriate. Overall regression reference from Table 1.

PVPP also failed to completely remove from solution purified phlorotannins extracted from *Carpophyllum maschalocarpum*, *Fucus vesiculosus*, *E. radiata*, and *S. vestitum* (Figure 2). The difference in the efficacy of PVPP in removing *E. radiata* phlorotannins from fresh extracts versus "pure" fractions is unexplained, although this may be due to qualitative differences in specific polymers present in the two samples.

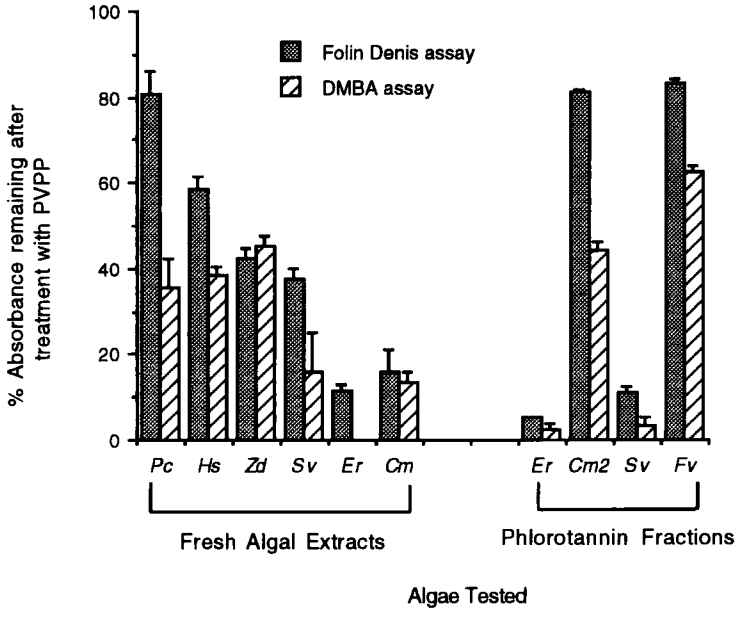

FIG. 2. Percent of initial absorbance remaining after treatment of fresh extracts and purified algal phlorotannins with PVPP. If PVPP is effective at removing phlorotannins, absorbance in the DMBA assay should be zero. (*Pc* = *Phyllospora comosa*, *Hs* = *Homoeostrichus sinclarii*, *Zd* = *Zonaria diesingiana*, *Er* = *Ecklonia radiata*, *Cm* = *Cystophora moniliformis*, Cm_2 = *Carpophyllum maschalocarpum*, *Sv* = *Sargassum vestitum*, *Fv* = *Fucus vesiculosus*).

Sensitivity of Prussian Blue Assay to Interferences

If the Prussian blue assay is less sensitive to interfering compounds than the Folin-Denis assay, then the slope of the line relating estimates of phenolic levels from the two assays should be significantly less than one. For phenolic levels in nine species of New Zealand brown algae, measured in two seasons, the regression had a slope of 0.983 with 95% confidence limits of 0.825 and 1.14 (Figure 3). Thus the Prussian blue assay does not differ significantly from the Folin-Denis assay in sensitivity to interfering compounds present in algal extracts.

Phenolic Levels in Red and Green Algae

Levels of reactive substances (nonphlorotannins) measured by the Folin-Denis and Prussian blue assays for red and green algae from California were mostly $<0.6\%$ by dry wt (Folin-Denis overall mean = 0.50%, Prussian blue

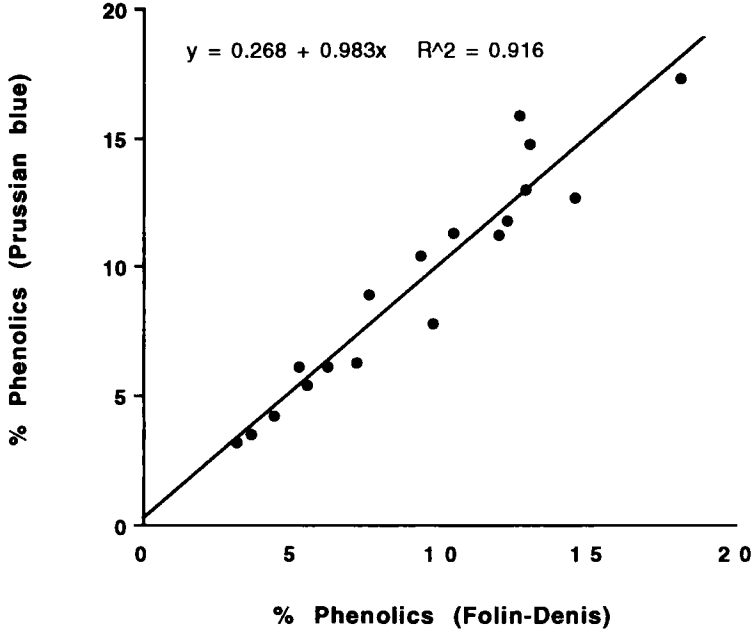

FIG. 3. Phenolic content of nine species of New Zealand algae for summer and autumn measured via the Prussian blue versus the Folin-Denis assay. Regression analysis of mean phenolic levels in each assay ($N = 5$) for each species is highly significant ($P < 0.0001$) with slope = 0.983. The slope is not significantly different from 1 (see text). Species of algae used were *Carpophyllum flexuosum*, *C. maschalocarpum*, *C. angustifolia*, *C. plumosum*, *Ecklonia radiata*, *Sargassum sinclarii*, *Xiphophora chondrophylla*, *Lessonia variegata*, and *Cystophora torulosa*.

overall mean = −0.22%). Higher levels (mean of ≈ 1%) were observed in one species, *Rhodomela larix*; however, this species contains halogenated phenolic monomers at up to 1.2–3.8% dry wt (Phillips and Towers, 1982), which should react in these assays.

Five of the seven New Zealand red and green species assayed also contained relatively low levels of reactive substances. Two species, *Vidalia colensoi* and *Melanthalia abscissa*, had substantially higher levels of reactive substances in both assays (Table 3). The overall average of reactive substances from 17 red and green algal species was 0.50% (Folin-Denis) and 0.09% (Prussian blue). In contrast to the data in Figure 3, this suggests that the Prussian blue assay may be less sensitive to nonphlorotannin interferences than the Folin-Denis assay. However, the large negative values for some species in the Prussian blue

TABLE 3. PERCENT DRY WEIGHT OF PHENOLIC SUBSTANCES IN RED AND GREEN ALGAE FROM CALIFORNIA AND NEW ZEALAND AS MEASURED BY FOLIN-DENIS AND PRUSSIAN BLUE ASSAYS (N = 5 IN ALL CASES)

(which contribute to the lower overall mean) are not easily explained and cast some doubt on the utility of this assay for algae. A paired t test across all species from California and New Zealand, using species means as individual replicates, indicates that the Prussian blue values are in fact significantly less (P = 0.0396, df = 16).

As predicted from the chemistry of the DMBA–phlorotannin reaction (Ribéreau-Gayon, 1972), analysis of aqueous methanolic extracts of eight species of red and green algae in the DMBA assay (five of which contain nonpolar metabolites such as terpenoids or acetogenins) yielded essentially no "phenolics" (all samples <0.05% dry wt "phenolics"). Moreover, the λ_{max} of these extracts was often shifted higher than 510 nm (e.g., 580 nm for *Laurenica*

rigida). This suggests that although nonpolar compounds may react in the DMBA assay, color production of such reactions will be slight, and will not interfere with estimation of phlorotannin levels.

DISCUSSION

The new DMBA assay described here has a number of advantages over previously used methods for the analysis of phlorotannins. First, because it is specific to 1,3- and 1,3,5-phenolics, it is insensitive to interferences, measuring only phlorotannins. Second, it is inexpensive and rapid. Third, the DMBA assay was specifically designed to investigate the interaction of phlorotannins with other macromolecules. Thus, this assay can be used to quantitatively measure phlorotannin precipitation by protein (Stern et al., in press), thereby linking together previously disparate methodologies.

The chemical basis for the reaction between aromatic aldehydes such as vanillin (or DMBA), with activated phenolics, such as phloroglucinol, is an electrophilic attack by the aldehyde and must be carried out in a strongly acidic solution (Ribéreau-Gayon, 1972). The product of the reaction is a colored adduct and the intensity of the color is dependent in part on the structure of the aldehyde (Butler et al., 1982). Although vanillin does react with phlorotannins, we took advantage of the increased color yield obtained with DMBA.

The DMBA method can also be easily adapted for determining phlorotannins in plant extracts, gut contents, or other biological samples. Preliminary work in vivo has demonstrated that staining with DMBA can indicate the presence of phlorotannins in the digestive tract of herbivorous marine gastropods and echinoderms (Stern, unpublished data).

One disadvantage of the DMBA assay is that the variation in reactivity of different phlorotannin fractions is somewhat greater than that for the Folin-Denis assay and Prussian blue assay (although fewer phlorotannin fractions were examined for this assay). This variation in reactivity within a given assay presumably reflects differences in the chemical structures of different phlorotannins (Ragan and Glombitza, 1986). Thus the choice of a reference compound becomes particularly important for the DMBA assay, because comparing samples to different standards can result in substantial variation in the estimation of phenolic levels (Table 2).

In an effort to eliminate this problem by finding a commercially available standard, we compared published data on the reactivity of vanillin from a variety of phloroglucinol structural analogs. Information about molar extinction coefficients for these potential reference compounds (e.g., catechin, epicatechin, phloretin, resorcinol, and butein) (Goldstein and Swain, 1963) suggests that they are inappropriate for the DMBA assay.

In some instances, knowledge of the phenolic constituents present in a

particular species can also obviously assist in the appropriate choice of a reference compound. For example, *H. sinclarii* contains substantial amounts of phloroglucinol (determined by thin layer chromatography, unpublished data), as do many species of *Zonaria* (Amico et al., 1981; Blackman et al., 1988; Gerwick and Fenical, 1982) and therefore phloroglucinol would be an appropriate reference for such species. For most algal species neither phloroglucinol nor catechin were suitable as references for DMBA because DMBA responds too strongly to these substances relative to other phlorotannins and therefore significantly underestimates the mass of the phlorotannin measured.

One potential disadvantage of DMBA is that, like vanillin, it can form chromophores with some nonpolar metabolites (under different conditions from this assay and absorbing at different wavelengths than 510 nm) that may interfere with quantitative determinations of phlorotannins in algal extracts (R. de Nys, personal communication). However, all five red and green algae tested with DMBA known to contain nonpolar secondary metabolites yielded negligible values ($<0.05\%$ dry wt) and thus such metabolites are unlikely to pose a problem.

Like DMBA, the Prussian blue and Folin-Denis tests respond differently to different phlorotannins, but with less marked variation. This differential variation is due to differences in chromophore formation. In the Folin-Denis assay oxidation of phenols is coupled with the reduction of phosphomolybdic and phosphotungstic acids to stable chromophores (Ragan and Glombitza, 1986). Thus, although the reaction does not incorporate the phenols into the colored product, it is stoichiometrically dependent on the number of free hydroxyl groups (Ragan and Glombitza, 1986). Aldehydes such as vanillin and DMBA react with the aromatic compound at positions between meta-substituted hydroxyl groups to yield a colored product (Ribéreau-Gayon, 1972).

Ragan and Glombitza (1986) stated that the ratio of color formation between vanillin (and, thus, by implication the vanillin analog DMBA) and Folin-Denis, relative to phloroglucinol, is indicative of phlorotannin molecular weight, with higher ratios indicating lower molecular weights. Our data do not support this for the DMBA assay, as the highest values for this ratio (other than for the monomer phloroglucinol; Table 1) were observed for the low-molecular-weight polymers (MW $\approx 10^4$) from *Ecklonia radiata* (van Altena and Steinberg, 1992) and the high molecular weight polymers from *Fucus vesiculosus*. More generally, the usefulness of obtaining molecular weight information by comparing vanillin- or DMBA-type reactions with Folin-Denis may be limited since: (1) vanillin and DMBA may react preferentially with terminal groups on the molecule, as is the case for terrestrial tannins (Butler et al., 1982); (2) variation in ether and aryl linkages alter reactivity in an unpredictable manner if the structure is unknown; (3) phlorotannins extracted from seaweeds probably span a range of molecular weights; and (4) chromophore production in Folin-Denis is due to

both the number of oxidizable groups as well as their redox potential (which depends on the surrounding molecular environment).

This lack of a consistent relationship between DMBA–FD ratios and molecular weight is unfortunate because molecular weight may explain some of the variation in responses of marine herbivores to phlorotannins. In particular, Boettcher and Targett (1992) showed that variation in the molecular weight of different phlorotannin fractions from *Lobophora variegata* and *Ascophyllum nodosum* significantly affected assimilation efficiencies in the marine herbivorous fish *Xiphister mucosa*, with high-molecular-weight phlorotannin fractions the most inhibitory. In contrast to these results, Steinberg and van Altena (1992; their Figure 7a) and van Altena and Steinberg (1992) found no clear evidence for a relationship between feeding deterrence and phlorotannin molecular weight. Not surprisingly, the importance of molecular weight in the phlorotannin–herbivore interaction is likely to depend on the herbivore and phlorotannins in question and the kind of response examined (e.g., feeding deterrence versus physiological measures, etc.).

The data presented here for the DMBA assay indicate that it is the method of choice for studies of variation in phlorotannin levels in a single species or a group of closely related species. In such a case a purified phlorotannin fraction should be extracted from the algae and used as a standard. This will eliminate difficulties due to differences between the reactivity of the standard and that of the samples.

The appropriate method for broad comparisons among many species from different taxa (Steinberg 1989, Targett et al., 1992) is less clear. The problems associated with using different reference compounds were readily evident for the three colorimetric assays examined in this study. Because a single appropriate reference compound is not readily available for the DMBA assay we recommend that an overall regression consisting of many phlorotannin standard curves may be used as a reference (Tables 1, 2). This seems to minimize the error in estimating phenolic levels across many species and taxa (especially when compared to using phloroglucinol as a standard).

The major advantage of the DMBA assay is that it does not measure nonphenolic interferences, as do the Folin-Denis or Prussian blue assays. Based on our analyses of red and green algae, and assuming that levels of nonphenolic interferences are similar in red, green, and brown algae, levels of interferences are likely to account for 0–1.5% by dry weight (mean $\simeq$ 0.5%) of the phenolic levels measured using these assays. This is somewhat higher than the estimate of nonphenolic materials in *Fucus gardneri* measured by Van Alstyne (1995) using the Folin-Ciocalteau assay, but is still probably an acceptable level of error for assays of phenolic-rich algae, which can have levels of phenolics exceeding 10% by dry weight. Estimates of phenolic levels in more phenolic-poor species may be significantly affected by such levels of interferences, how-

ever. Although levels of reactive nonphenolic substances in *F. gardneri* (Van Alstyne, 1995) were low, the Folin-Ciocalteu assay does not resolve the problem of interferences for brown algae in general. It does have an advantage over the Folin-Denis assay in that it does not suffer from precipitate formation and thus can be used with small sample volumes. The DMBA assay also only uses small volumes of samples and reagents.

Measurement of phenolic levels using the Folin-Denis assay before and after mixing the extract with PVPP does not solve the problem of interferences. Although PVPP has been used in Folin assays to correct estimates of phenolic levels for interferences (e.g., Yates and Peckol, 1993), we found that PVPP failed to remove all phlorotannins from solution, and thus this method can significantly underestimate the levels of phlorotannins in an extract. Van Alstyne (1995) also questioned the utility of PVPP in these assays, although Targett et al. (1995) demonstrated reliable removal of phlorotannins after determining optimal conditions. However, optimal conditions are likely to vary for each phlorotannin–PVPP interaction.

Our data reflect on the accuracy of previously reported algal phenolic levels in one final respect. That is, using phloroglucinol as a reference compound in the Folin-Denis or DMBA assays significantly underestimated the phlorotannin content of most species assayed, relative to using an overall regression standard or purified phlorotannin fractions (Table 1). These differences undoubtedly reflect differences in the chemistry between phloroglucinol and phlorotannins and emphasize the need to continue to improve techniques for specifically quantifying phlorotannins.

(Received October 26, 1995; accepted March 4, 1996)

Abstract—The volatile compounds emitted by leaves of four crabapple cultivars susceptible to damage by Japanese beetles and four relatively resistant cultivars were examined. Twelve compounds, mostly terpene hydrocarbons, were identified from intact leaves. The terpenes (*E*)-β-ocimene, caryophyllene, germacrene D and (*E,E*)-α-farnesene occurred in significantly higher levels in susceptible cultivars, whereas resistant cultivars produced greater amounts of (*E*)-4,8-dimethyl 1,3,7-nonatriene and linalool. The relative attractiveness of the cultivars as determined in a pitfall bioassay, however, was not related to their susceptibility to the Japanese beetle as previously determined by defoliation sustained in the field. The attractiveness of individual cultivars was found to be positively correlated with linalool as a percent of the total volatile blend emitted by leaves. This study and previous work suggest that variation in susceptibility of crabapple cultivars to defoliation by Japanese beetles is not due to the attractiveness of the individual cultivars but rather to nonvolatile components of susceptibility and/or resistance. A scenario for host location by the Japanese beetle is presented.

Key Words—*Popillia japonica*, Coleoptera, Scarabaeidae, crabapple, *Malus* spp., semiochemical, linalool, attractant.

INTRODUCTION

The Japanese beetle, *Popillia japonica* Newman (Coleoptera: Scarabaeidae), is an introduced pest that feeds upon nearly 300 species of plants in a wide variety of unrelated taxa. Among these, many members of the Rosaceae are especially vulnerable to attack, with apple, cherry, and rose being examples of highly favored hosts (Fleming, 1972).

Olfaction plays a major role in host location by the Japanese beetle (Ahmad, 1982). Many volatile compounds have been shown to be attractive, with the most effective known lure being a 3:7:3 combination of geraniol, phenethyl propionate, and eugenol (Ladd and McGovern, 1980). Smith (1924) and Smith and Hadley (1926), citing the early literature, reported that essential oils attractive to the Japanese beetle all contained geraniol in varying amounts. Similarly, Langford et al. (1943) found that essential oils from apple and peach fruit, rose flowers, and sassafras leaves were attractive to the Japanese beetle and that all contained benzaldehyde, citral, eugenol, geraniol, and linalool in various combinations. The volatile compounds produced by Japanese beetle host plants have not been examined, however, using modern isolation procedures and analytical techniques.

In addition to a role in host location, volatile compounds may also play a key part in host acceptance via olfactory and/or gustatory stimulation (Fleming, 1972; Ahmad, 1982). Evidence to support this view includes the observation that removal of a beetle's antennae drastically reduced feeding rates in leaf-disk feeding assays (Ahmad, 1982). Furthermore, it was found that by applying a solution of eugenol in glycerine to *Ginkgo biloba* leaves, a plant not normally susceptible to Japanese beetles, feeding rates were greatly stimulated (Major and Tietz, 1962).

Recently, Spicer et al. (1995) reported marked differences in susceptibility of 42 crabapple cultivars (*Malus* spp.) to the Japanese beetle. Defoliation ranged from nearly 100% to less than 10% for cultivars grown at the same site. Subsequently, a number of physical and chemical variables of crabapple leaves were examined in an attempt to determine the factors involved in Japanese beetle discrimination between different cultivars (Potter and Spicer, unpublished results). Leaves of preferred cultivars generally contained higher levels of nitrogen and sugars and lower amounts of tannins (ANOVA, orthogonal contrasts, $P < 0.001$). Still, a large proportion of the variation in the beetle's feeding patterns could not be explained by these factors.

Because volatile compounds have been assumed to play an important part in host location and acceptance by *P. japonica* (Fleming, 1972; Ahmad, 1982), we examined the volatile compounds emitted by intact leaves of crabapple cultivars that differ in susceptibility to Japanese beetles. We also compared the relative attractiveness of the cultivars in order to determine if olfaction plays a

role in Japanese beetle discrimination between intact foliage of preferred and non-preferred hosts.

METHODS AND MATERIALS

Insects and Plants. Japanese beetles were captured in the field using traps baited with commercial food-type lures (a 3:7:3 ratio of geraniol, phenethyl propionate, and eugenol) (Trécé Inc., Garwood, New Jersey). Six-year-old crabapple trees were maintained in nursery plots at the University of Kentucky's South Farm in Lexington, Kentucky. The four relatively resistant cultivars examined were Baccata Jackii, David, Harvest Gold, and Jewelberry. In a two-year field study of a separate plot with very high beetle populations, these sustained average defoliation levels of 12.2, 31.1, 17.8, and 10.4%, respectively (Spicer et al., 1995). The four susceptible cultivars were Dolgo, Radiant, Red Splendor, and Royalty. These sustained average defoliation levels of 79.4, 100, 97.5, and 92.8%, respectively (Spicer et al., 1995). Plots used in the present experiments had low to moderate beetle populations.

Volatile Compound Collection and Identification. Leaves used for volatile collections were collected from trees from mid-May through early June, prior to the beginning of beetle flight in mid-June. Between 8:00 and 9:00 AM EST, about 10 g of leaves (detached at the base of the petiole) were collected from one tree of each crabapple cultivar. The leaves were placed in a push–pull volatile collection apparatus that had eight chambers for samples and which has been described elsewhere (Loughrin et al., 1995). During the 4-hr collection period, airflow was maintained through the vacuum side of the apparatus at a rate of 250 ml/min, resulting in adsorption of volatile compounds on Super Q absorbent traps (50 mg; Alltech Associates, Deerfield, Illinois).

At the end of the collection period, the traps were removed and compounds were eluted with 180 μl of an 80:20 mixture of hexane–CH_2Cl_2. Cumene (1000 ng) was added as an internal standard and compounds were quantified by 3.0-μl injections onto a gas chromatograph operated with a 60-sec splitless delay and equipped with a 60-m × 0.32-mm Supelcowax 10 column (polyethylene glycol; Supelco Inc., Bellefonte Pennsylvania). GC operating conditions were as follows: oven temperature 60°C for 1 min then programmmed at 2°C/min; injector 220°C; flame ionization detector 240°C; He carrier linear flow velocity 21 cm/sec. Leaf collections and volatile trapping were replicated five times using different trees, and levels of individual compounds were contrasted between susceptible and resistant cultivars by orthogonal comparisons (Sokal and Rohlf, 1981).

Gas chromatography–mass spectroscopy (GC-MS) was performed on a Hewlett-Packard mass ion detector operated in electron impact mode and inter-

faced to a GC equipped with a 30-m × 0.25-mm HP-5 column (5% phenyl, 95% dimethylsiloxane; Hewlett-Packard Co., Palo Alto, California) run as follows: oven temperature 60°C for 1 min and then programmed at 2°C/min to 220°C; injector 220°C; He carrier linear flow velocity 21 cm/sec. Compound identification was performed by computer library searches and retention-time matches of the natural plant products with authentic standards on the Supelcowax 10 column and a 30-m × 0.32-mm AT-5 column (5% phenyl, 95% dimethylsiloxane, Alltech Associates) operated as described for GC-MS analyses. Authentic samples of volatile compounds were obtained from commercial sources except for (*E*)-4,8-dimethyl 1,3,7-nonatriene, which was donated by J. H. Tumlinson (USDA, Gainesville, Florida), and (*E*,*E*)-α-farnesene and germacrene D, which were isolated from the hydrocarbon fraction of ylang-ylang oil (Gaydou et al., 1986).

Pitfall Bioassays. Leaves were collected from the plots during the early stages of beetle flight to minimize the effects of feeding damage. Attraction of Japanese beetles to intact leaves of susceptible and resistant crabapple cultivars was measured in a pitfall bioassay system (Loughrin et al., 1995), which consisted of eight 50-ml Erlenmeyer flasks in plastic trays with lids (32 × 26 cm, 10 cm deep). The trays were filled with dry sand until level with the mouths of the flasks. About 1 g of leaves of a given cultivar was placed in an individual flask and resistant or susceptible cultivar choices were alternated in the trays in a 4 × 2 matrix. Arrangements for all eight cultivars were randomized for each replicate while maintaining a resistant–susceptible cultivar order.

Thirty female beetles were placed lengthwise down the middle of the trays and allowed to choose between the various flasks. Assays were run at room temperature using overhead fluorescent lighting and were allowed to proceed for 3 hr or until 25 beetles had been captured. The assays were replicated 10 times, and the number of beetles responding to each cultivar was analyzed by Friedman's two-way nonparametric analysis of variance (Hollander and Wolfe, 1973).

RESULTS AND DISCUSSION

The identity and yields of volatile compounds obtained from the crabapple cultivars are presented in Table 1. Ten compounds were identified on the basis of mass spectra and retention-time matches with those of authentic samples on the carbowax and AT-5 columns. In addition, (*Z*)-β-farnesene and (*Z*,*E*)-α-farnesene were tentatively identified on the basis of mass spectroscopy, as no authentic samples of these compounds were available to us.

Yields of identified volatiles ranged from about 150 ng g fresh weight for the cultivar Red Splendor to over 1800 ng/g for Royalty. Both of these are

susceptible cultivars. The differences in total yields from the various crabapple cultivars were largely due to variation in the levels of terpene hydrocarbons. For instance, yields of the sesquiterpene (*E*,*E*)-α-farnesene varied from about 13 ng/g for the cultivar Dolgo to over 750 ng/g for Royalty. Similar variations in yield from the various cultivars were noted for the monoterpene (*E*)-β-ocimene and the methylene sesquiterpene (*E*)-4,8-dimethyl 1,3,7-nonatriene.

The relatively high yield of terpene hydrocarbons emitted by crabapple leaves and the marked variation in their yields between the various cultivars within and between resistance groupings is of interest. A number of these terpenes have been shown to be insect attractants. For instance, (*E*,*E*)-α-farnesene is an attractant and oviposition stimulant for the codling moth (*Laspeyresia pomonella*), a serious pest of apples in the Unites States (Sutherland et al., 1977). (*E*,*E*)-α-Farnesene is also a component of the volatile blend emitted by calling male Mediterranean fruit flies (Heath et al., 1994). Caryophyllene has been determined by electroantennogram studies to be attractive to the damson-hop aphid, *Phorodon humuli* (Campbell et al., 1993).

When the yields of volatile compounds from crabapple leaves were grouped according to susceptibility or resistance of the various cultivars to the Japanese beetle (Table 2), a number of significant differences were noted. Specifically, the terpenes caryophyllene, germacrene D, and (*E*,*E*)-α-farnesene occurred in significantly higher levels in susceptible cultivars while (*E*)-4,8-dimethyl 1,3,7-nonatriene and linalool occurred in significantly higher amounts in resistant cultivars ($\alpha = 0.05$, ANOVA, orthogonal contrasts).

To determine if the differences in volatile emission from leaves of the different crabapple cultivars were related to their relative attractiveness to Japanese beetles, we conducted pitfall bioassays in which the beetles were allowed to choose between equal weights of leaves (Table 3). We also wished to determine if beetles discriminate between the various cultivars based on their relative susceptibility to feeding damage. The various cultivars differed significantly in attractiveness to Japanese beetles (Friedman statistic = 15.4; $\alpha = 0.012$, χ^2 approximation). The relative rankings of the cultivars, however, were not related to their degree of susceptibility to damage by Japanese beetles ($r = 0.579$, $P = 0.135$). Of the four most attractive cultivars, three were previously shown to be highly resistant to defoliation in the field (Spicer et al., 1995). Thus our results suggest that susceptibility or resistance of particular crabapple cultivars to damage by Japanese beetles is not necessarily correlated with the relative attractiveness of intact leaves. Rather, variation in resistance may be affected more by differences in nonvolatile biochemical components affecting palatability of leaves (Spicer et al., 1995) or differences in feeding-induced volatiles (Loughrin et al., 1995).

To further explore what compounds or combinations of compounds were

most closely correlated with relative attractiveness of the crabapple cultivars to Japanese beetles, we conducted correlation analyses on the cultivar rankings obtained from the Friedman test with absolute amounts of individual compounds from each cultivar and their relative percentage of the total identified volatile blend from each cultivar. There was no relationship between the absolute levels of individual compounds and the relative attractiveness of the cultivars in the pitfall bioassays. However, relative attractiveness was significantly correlated with linalool as a percent of the total identified blend ($r = 0.833$, $P = 0.01$, Table 4). There was also a trend for attractiveness to be correlated with (*E*)-4,8-dimethyl 1,3,7-nonatriene as a percent of the identified blend ($r = 0.652$, $P = 0.08$). Correlation between relative attractiveness and the combined percent of the total blend for both of these compounds was also significant ($r = 0.841$, $P = 0.046$).

Geraniol has been widely reported as a volatile constituent of Japanese beetle host plants (Smith, 1924; Smith and Hadley, 1926; Langford et al., 1943; Fleming, 1972). Linalool, however, readily undergoes acid-catalyzed rearrangement to geraniol (Bauer and Garbe, 1985). It is likely, therefore, that geraniol was an artifact caused by steam distillation.

The Japanese beetle is known to be attracted to a number of common and widely distributed plant aroma constituents such as linalool (Schwartz and Hamilton, 1968). It has been suggested that a generalist herbivore such as *P. japonica* should be attracted to a variety of compounds present in plant aromas and

nonspecific blends containing these compounds (Lance, 1983). More specialized herbivores such as the Colorado potato beetle [*Leptinotarsa decemlineata* (Say)], in contrast, would be attracted to a blend of compounds in a more definite ratio (May and Ahmad, 1983; Bernays and Chapman, 1994). It should be noted, however, that specialist herbivores often exhibit attraction to single test compounds of either common or restricted occurrence (Finch and Skinner, 1982; Košťál, 1992). The present study supports the hypothesis for generalist herbivores in that linalool seems to be more important in Japanese beetle attraction than any of the other compounds identified from crabapple leaves. The overall character of the blend, however, may be more important in determining attractiveness to the Japanese beetle than the presence of specific compounds in the blend. Of the compounds we identified from crabapple leaves, only linalool may be described as floral. The Japanese beetle is highly attracted to flowers (Fleming, 1972), and so volatile blends in which floral fragrance compounds comprise relatively high proportions of the total blend should presumably be highly attractive.

Recently, we demonstrated how the volatile compounds induced from crabapple leaves by overnight feeding damage by either Japanese beetles or fall webworms (*Hyphantria cunea* Drury) attracted Japanese beetles (Loughrin et al., 1995). In pitfall bioassays, leaves damaged by overnight feeding were significantly more attractive than undamaged leaves. Artificially damaged leaves or leaves freshly damaged by Japanese beetles, in contrast, were not significantly more attractive than undamaged leaves. The blends of volatile compounds induced by overnight insect feeding damage were distinctly floral in character, which may explain their attractiveness to Japanese beetles.

Results from the present study and that of Loughrin et al. (1995) suggest the following scenario for host location and acceptance by *P. japonica*: Beetles that emerge early in the season respond to odors from a wide variety of plants that differ in characteristics such as the levels of feeding stimulants (e.g., sugars) and the levels of defensive compounds, such as alkaloids and/or tannins. If a beetle locates and samples an acceptable host, feeding is stimulated and this induces volatile release from the damaged leaves. If the host is unacceptable, then the beetle would continue investigating other plant odors until an acceptable host is found. Later-emerging beetles then could exploit the induced volatile blends as a more efficient means of host location. This sequence of events may help to explain the aggregative behavior of Japanese beetles, which has previously been suggested to be the result of a beetle-produced aggregation pheromone (Iwabuchi and Takahashi, 1983).

In summary, we have demonstrated variation in the attractiveness of crabapple cultivars to the Japanese beetle. The attractiveness of individual cultivars was most closely correlated with the relative proportion of linalool in the overall blend of aroma compounds emitted by leaves. While the beetles exhibited

differential attraction to intact leaves of different crabapple cultivars, this was not related to variation in susceptibility to defoliation by Japanese beetles in the field. Volatile compounds could still be important factors in determining the amount of defoliation by Japanese beetles in that the blend of volatile compounds induced by feeding damage (Loughrin et al., 1995) may vary in attractiveness among crabapple cultivars. Future research may resolve whether feeding-induced volatile compounds play a role in discrimination among plant cultivars or plant species.

(Received October 30, 1995; accepted March 4, 1996)

Abstract—Secretions of the dorsal gland of free-ranging adult male and female collared peccaries (*Tayassu tajacu*) were analyzed by gas chromatography–mass spectrometry. Both sexes contain (2*E*,6*E*,10*E*)-geranylgeraniol; squalene (all *E* isomer); and the following isomers of springene, a diterpene homolog of β-farnesene: (3*E*,6*E*,10*E*)-α-springene, (3*Z*,6*E*,10*E*)-α-springene, and (6*E*,10*E*)-β-springene. A diterpene alcohol and an additional isomer each of squalene and springene also were observed. Straight- and branched-chain esters abound in the secretions of females, but they were not detected in males.

Key Words—Dorsal gland, collared peccary, *Tayassu tajacu*, geranylgeraniol, springene, squalene, straight-chain esters, branched-chain esters.

INTRODUCTION

All peccaries, *Tayassu* spp. (Tayassuidae), possess a large skin gland, called the dorsal gland, that opens at a nipple-like papilla on the midline of the rump (Sowls, 1984). This gland, unique to the Tayassuidae, contains both sebaceous (holocrine) and sudoriferous (apocrine) secretory tissues that empty from common sacs into a single lumen (Werner et al., 1952; Epling, 1956). Peccaries

typically rub the secretions of the dorsal gland onto conspecifics, branches, and other objects; they also may forcibly eject glandular fluids into the environment as a stream.

A number of functions have been hypothesized for dorsal gland secretions, including territorial scent-marking (Schweinsburg and Sowls, 1972; Sowls, 1984), herd recognition and cohesion (Schweinsburg and Sowls, 1972; Byers, 1985), alarm signaling (Neal, 1959), and predator repulsion (Epling, 1956). The observation that male collared peccaries (*T. tajacu*) nuzzle and lick the dorsal gland of females before copulating has prompted some authors to suggest that the glandular exudates convey reproductive information (Hannon et al., 1991).

Little is known of the composition of dorsal gland secretions. Radioimmunoassays of secretions from female *T. tajacu* suggest the presence of progesterone, the highest concentrations of which were observed in pregnant individuals (Hellgren, 1984). The strong odor often noted for these secretions is consistent with the emission of volatile compounds, but none has previously been characterized.

We report here the results of an analysis by gas chromatography–mass spectrometry (GC-MS) of the volatile components of the dorsal gland secretions of free-ranging adult male and female *T. tajacu*. Our study indicates the dorsal gland as a new vertebrate source of springene, a diterpene homologue of β-farnesene (Burger et al., 1978, 1981), and it reveals sex differences in secretion composition.

METHODS AND MATERIALS

Adult *T. tajacu* were obtained during February 1994 from a hunting station at the Chaparral Wildlife Management Area in the Rio Grande Plains region in Dimmit and LaSalle counties, Texas, U.S.A. Secretions were obtained within 5 hr of sacrifice by exposing the naked area of skin overlying the gland (Figure 1), placing the mouth of a glass vial over the papillary duct opening, and manually compressing the body of the gland. Secretions from six males were pooled in two vials, each containing samples from three individuals. Secretions from eight females were pooled in two vials; one vial contained samples from six individuals, the other contained samples from two individuals. Several milliliters of hexane were added to each vial, whereupon a light brown supernatant appeared. The vials were sealed with polyethylene-lined caps, transported on dry ice, and stored at $-20°C$.

Samples of secretions were diluted with hexane containing dihexyl sulfide as an internal standard for the retention index. Samples (1 μl) of the resulting solutions were analyzed on a Hewlett-Packard 5890 gas chromatograph with a polydimethylsiloxane column (25 m $\times$ 0.32 mm ID, 0.5-μm film thickness)

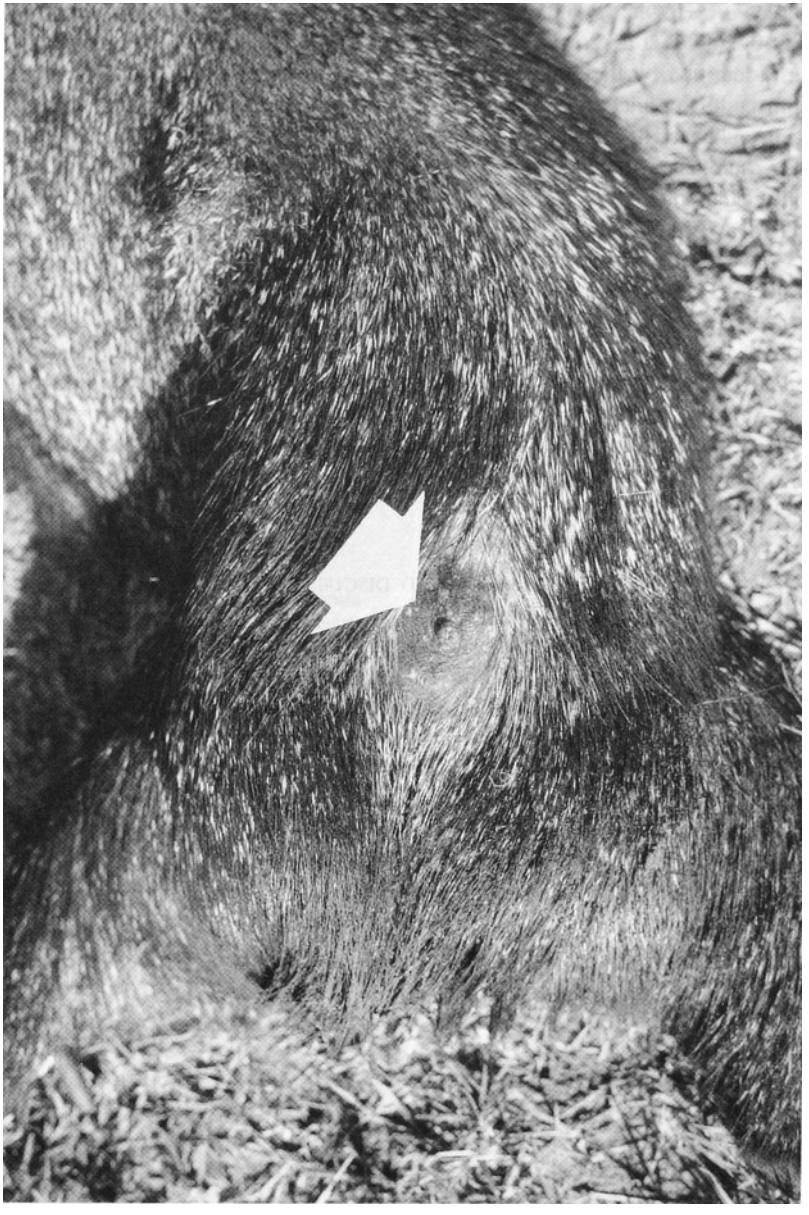

FIG. 1. Posterodorsal view of a *T. tajacu* showing (arrow) naked area of rump with centrally located papillary duct opening of dorsal gland.

coupled to a Hewlett-Packard 5970 mass spectrometer. The temperature program was 40–240°C at 4°C/min, and finally held at 240°C for 20 min. Compounds were identified by their mass spectra. The identities of most compounds were confirmed by coinjection of secretion extracts with authentic compounds, resulting in enhanced GC peaks. Geometric isomerism was defined by GC elution order established for the compounds and their homologs after authentication by ^{13}C nuclear magnetic spectroscopy (Burger et al., 1978; Picket and Griffiths, 1980; Dawson et al., 1982).

Two isomers of springene (α and β) indicated in the secretions were synthesized as described by Burger et al. (1981). Most esters observed were synthesized by refluxing a toluene solution of equimolar proportions of the appropriate carboxylic acid and alcohol in the presence of a strongly acidic ion exchange resin, Amberlyst 15 (Aldrich, Gillingham, U.K.), under automatic water separation until the production of water was complete. Authentic standards of (2*E*,6*E*,10*E*)-geranylgeraniol (Tocris Cookson, Bristol, U.K.) and (6*E*,10*E*,14*E*,18*E*)-squalene (all *E* isomer) (Aldrich, Gillingham, U.K.) were obtained commercially.

RESULTS AND DISCUSSION

Our analysis of the dorsal gland secretions of *T. tajacu* indicates that both males and females contain (2*E*,6*E*,10*E*)-geranylgeraniol and squalene (all *E* isomer) (Table 1); both samples of each sex gave similar results for these and other components. Two compounds, one eluting before squalene (all *E* isomer), the other immediately after, were partially identified. The first of these compounds, characterized as a diterpene alcohol, displayed the following *m/z* (%) values, but no molecular ion: 229 (3), 186 (6), 161 (8), 135 (10), 123 (8), 121 (13), 119 (8), 109 (8), 107 (18), 105 (10), 95 (6), 93 (29), 81 (42), 69 (100), 43 (55), 41 (55). The second compound, characterized as an isomer of squalene, displayed the following *m/z* (%) values: 410 (M^+, 6), 355 (8), 347 (18), 321 (8), 272 (10), 257 (12), 229 (18), 215 (10), 203 (34), 189 (42), 187 (32), 173 (53), 161 (58), 147 (12), 135 (24), 123 (13), 121 (18), 119 (13), 109 (13), 107 (24), 105 (10), 95 (18), 93 (35), 81 (47), 69 (100), 57 (42), 55 (29), 43 (26), 41 (61).

The following isomers of springene, each of which was identified by a molecular ion *m/z* = 272 and a characteristic fragmentation pattern (NIST Standard Reference Data Base, 1990), also were observed in both sexes: (3*E*,6*E*,10*E*)-3,7,11,15-tetramethylhexadeca-1,3,6,10,14-pentaene [(3*E*,6*E*,10*E*)-α-springene]; (3*Z*,6*E*,10*E*)-3,7,11,15-tetramethylhexadeca-1,3,6,10,14-pentaene [(3*Z*,6*E*,10*E*)-α-springene]; and (6*E*,10*E*)-7,11,15-trimethyl-3-methylenehexadeca-1,6,10,14-tetraene [(6*E*,10*E*)-β-springene] (Table

1). The mass spectrum of a fourth springene isomer displayed the following *m/z* (%) values: 272 (M^+, 2), 236 (6), 192 (5), 159 (8), 132 (47), 123 (32), 97 (32), 95 (34), 83 (47), 81 (40), 69 (61), 67 (42), 55 (95), 43 (63), 41 (100). These values are consistent with (4*E*,6*E*,10*E*)-3,7,11,15-tetramethylhexadeca-1,4,6,10,14-pentaene, an isomer not previously reported from nature, although additional spectral data are needed to confirm this structure.

Isomers of springene are known from a variety of natural sources, including a plant (Uegaki et al., 1980), insects (Billen et al., 1988; Fukushima et al., 1990), a crocodilian (Avery et al., 1989), and another mammal, the springbok antelope (*Antidorcas marsupialis*, Bovidae) (Burger et al., 1978, 1981). In the springbok antelope, (3*E*,6*E*,10*E*)-α-springene, (3*Z*,6*E*,10*E*)-α-springene, and β-springene are the volatile products of a skin gland also called the dorsal gland; this organ also is situated on the midline of the dorsum and is hypothesized to release alarm pheromones (Burger et al., 1981). The dorsal gland of the spring-

bok antelope and that of peccaries are not homologous, and we surmise that the abilities of these ungulates to biosynthesize springene isomers evolved independently.

Both pooled samples of secretions from female *T. tajacu* contained high concentrations of the following esters: tetradecyl hexanoate, tetradecyl octanoate, pentadecyl 5-methylheptanoate, pentadecyl octanoate, hexadecyl hexanoate, hexadecyl 4-methylpentanoate, hexadecyl 6-methylheptanoate, hexadecyl octanoate, heptadecyl 4-methylheptanoate, hexadecyl 8-methylnonanoate, hexadecyl decanoate, and hexadecyl dodecanaote (Figure 2). The mass spectra of these compounds display a base peak, $RCO_2H_2^+$, resulting from a double hydrogen transfer. Esters were not detected in either of the two pooled samples of males.

Straight- and branched-chain esters are known from the skin gland secretions of a variety of mammals (see Albone, 1984). In the beaver (*Castor fiber*, Castoridae), esters have been observed in the anal gland secretions of males but not females (Grønneberg and Lie, 1984), the reverse situation from the one

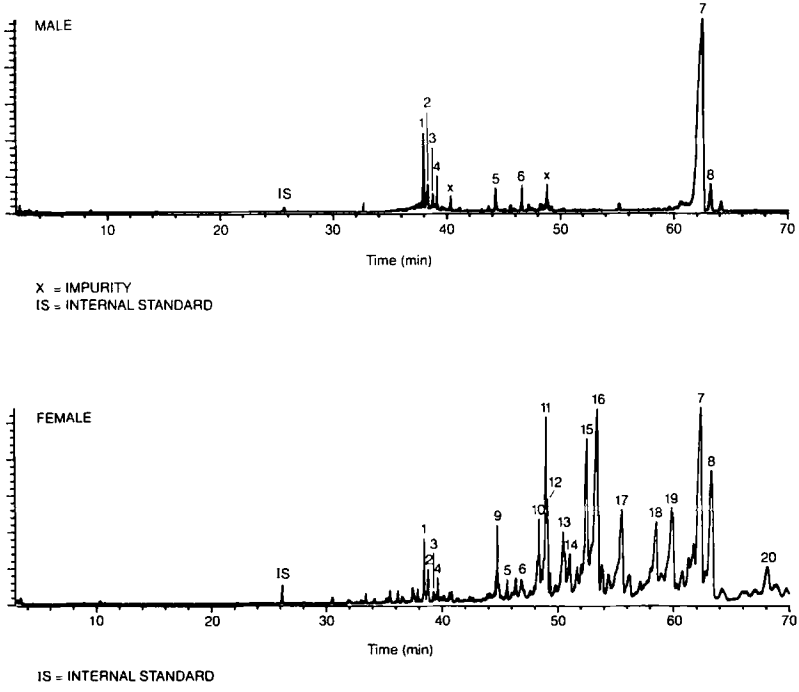

FIG. 2. Chromatograms of dorsal gland secretions of three male and of two female *T. tajacu*. Peak numbers correspond to compounds listed in Table 1.

observed for the secretions of *T. tajacu*. The significance of sex differences in the dorsal gland products of *T. tajacu* is unclear. It is worth noting that the secretory activities of this gland also differ according to sex; sebaceous tissues are better developed in males, while sudoriferous tissues are better developed in females (Hannon et al., 1991). Further investigations are needed to relate these histological observations to the chemistry of the secretions and to the function(s) of the gland.

STRUCTURE–ACTIVITY RELATIONSHIP OBSERVATIONS FOR THE BAGWORM MOTH PHEROMONE

J. D. WARTHEN,* J. A. KLUN, and E. D. DEVILBISS

United States Department of Agriculture, Agricultural Research Service
Insect Chemical Ecology Laboratory, BARC-W
Beltsville, Maryland 20705

(Received October 2, 1995; accepted March 6, 1996)

Abstract—Structure-activity relationship (SAR) observations were made for the bagworm moth pheromone, (*R*)-2-pentyl decanoate, and a series of analogs with modifications in the alcohol portion of the molecule. Observed attractiveness of these analogs was related to molecular structure and their physical attributes using computational chemistry. Electrostatic potential and Van der Waals (VdW) electrostatic coded surface three-dimensional (3D) maps of the molecular mechanics (MM) minimized lowest energy conformation of the pheromone show that size, shape, charge distribution, and chirality of the molecule are related to attractiveness.

Key Words—SAR, Psychidae, *Thyridopteryx ephemeraeformis*, bagworm moth, sex pheromone, (*R*)-2-pentyl decanoate, Chem-X, molecular modeling.

INTRODUCTION

The bagworm, *Thyridopteryx ephemeraeformis* (Haworth), defoliates ornamentals and trees throughout the Southeast and lower Midwest of the United States (Jones and Parks, 1928). The adult male moth, which flies during the day, is attracted to the adult wormlike female in her pupal case within a silk bag (Neal, 1982) via the female's sex pheromone on her thoracic hairs, which she places at the bottom of the bag until she mates (Leonhardt et al., 1983). After insemination, the female oviposits; the eggs overwinter, and larvae emerge to feed in the spring.

The sex pheromone of the female bagworm moth is (*R*)-2-pentyl decanoate

(**1a**) (Figure 1); the antipode (**1b**) is biologically inactive and only acts as a diluent in a racemic mixture (Leonhardt et al., 1983; Klun et al., 1986). The same *R* enantiomeric compound was identified as a sex pheromone in the bagworm, *Oiketicus kirbyi* (Guilding); however, in *O. kirbyi*, the *S* enantiomer inhibited the response of the *R* enantiomer (Rhainds et al., 1994).

To gain information about the structure-activity relationship (SAR) of this chiral pheromone, we report research on the pheromone and a series of analogs based on field studies and computer molecular modeling.

METHODS AND MATERIALS

The bagworm moth pheromone and its analogs (Figure 1) were synthesized via classical esterification procedures (Schwarz and Klun, 1986) with decanoic acid and the following alcohols (Aldrich Chemical Co., Inc., Milwaukee, Wisconsin): (*R*)-2-pentanol, (*S*)-2-pentanol, (±)-2-hexanol, (*R*)-2-hexanol, (*S*)-2-hexanol; 2-methyl-2-pentanol, (±)-3-methyl-2-pentanol, and (±)-4-methyl-2-pentanol. 2,4-Dimethyl-2-pentanol (Wiley Organics, Inc., Coshocton, Ohio) was also used.

(±)-2,3,4-Trimethyl-2-pentanol was synthesized beginning with 3-methylbutanoic acid (isovaleric acid, Aldrich), which was converted to 2,3-dimethylbutanoic acid via butyl lithium in tetrahydrofuran and diisopropylamine to obtain the lithium derivative. The lithium derivative was then treated with methyl iodide and hexamethylphosphoramide (Pfeffer and Silbert, 1970), for an 81.9% yield after distillation at 100°C and 25 torr. The acid chloride formed (Vogel, 1978, p. 498) via thionyl chloride was then converted to the methyl ester with methanol for a 57.8% yield after distillation at 125°C and 760 torr. The desired product was obtained from the methyl ester utilizing methyl magnesium iodide (Vogel, 1978, p. 371).

To determine the purity of the samples, GLC analyses of the analogs (Table 1) were performed on a Shimadzu GC-14A gas chromatograph (GC) equipped with a capillary injector system, a flame ionization detector, and a CR501 data

processor. A Hewlett-Packard 12-m × 0.20-mm-ID dimethylsilicone (DMS) fused silica capillary column was used for the analyses with the following conditions: injector port 200°C; detector 225°C; DMS column, 30°C for 2 min, then programmed at 5°C/min to 180°C and held for 5 min. Total run time was 37 min. A split ratio of 1:50 was used with a helium flow of 1 cm^3/min plus 33 cm^3/min makeup helium. Esters were dissolved in *n*-hexane to make 0.1% solutions, and 1 μl of the solutions was injected for GLC analyses. GC-MS analyses of the analogs (Table 1) were performed on a Finnigan MAT INCOS 50 GC-MS equipped with a Varian 3400 gas chromatograph. The GC component was equipped with a 60-m × 0.25-mm-ID DB-1 capillary column (J&W Scientific) for analyses of the analogs of the female bagworm sex pheromone. The column was held at 100°C for 1 min, then programmed at 20°C/min to 280°C. Analogs were dissolved in *n*-hexane to make 0.01% solutions, and 1 μl of the solutions was injected for GC-MS analyses.

The bagworm female sex pheromone and its analogs were tested for attractiveness for adult males in the field (Table 2). The tests were conducted using Pherocon 1C sticky traps (Trécé, Salinas, California). All traps were baited with rubber stoppers (Thomas Scientific, Catalog no. 1780-J07, Swedesboro, New Jersey) that had been treated with a 60–100 μg/μl methylene chloride solution of compound. In test 1 (Table 2), stoppers were each treated with 1 mg of

compound; in test 2 (Table 2), stoppers were each treated with 5 mg of compound. Each treated stopper was hung on a paper clip at the center of the trap above its sticky surface. Traps were suspended 1.5 m from the ground and 30 m apart on a chain link fence that surrounded the Beltsville Agricultural Research Center. A randomized complete block design with three replicates and replication over time was used in each test. A blank trap served as the control in both tests. Male captures in the traps were recorded daily or every two days. Freshly treated stoppers were placed in the traps after three to five days in test 1; in test 2, stoppers charged with 5 mg compound were left in the traps throughout the 15 days of the test.

The female bagworm moth pheromone and its analogs were constructed via the computer molecular modeling program, Chem-X (January 1993 VAX version, Chemical Design Ltd, Oxford, England). Lowest-energy conformations were determined using molecular mechanics (Burkert and Allinger, 1982; Clark, 1985) with modified force-field parameters (including Gasteiger charges). Electrostatic potential (Figure 2) and Van der Waals (VdW) electrostatic coded surface three-dimensional (3D) (Figure 3) maps of the bagworm moth pheromone (**1a**) were also constructed.

RESULTS AND DISCUSSION

Previous field tests showed that the *S* enantiomer (**1b**) of the levorotatory bagworm moth pheromone, (*R*)-2-pentyl decanoate (**1a**) (Figure 1, Table 1), is inactive and does not inhibit the attractiveness of the *R* enantiomer (Leonhardt et al., 1983; Klun et al., 1986).

To study the SAR of the pheromone (**1a**), modifications were made in the alcohol portion of the molecule. The alcohol chain was extended by one carbon via synthesis of (±)-1-hexyl decanoate (**2a, 2b**). This racemate was ~20% as active (test 1, Table 2) as the pheromone; the levorotatory *R* (**2a**) enantiomer of this analog was ~35% as active as the pheromone, and the *S* (**2b**) enantiomer was inactive. To confirm the latter findings, test 2 was conducted; the levorotatory *R* enantiomer (**2a**) was 17% as active as the pheromone, and the *S* (**2b**) enantiomer was inactive. In both tests, the levorotatory *R* enatiomer (**2a**) was about twice as active as the racemate (**2a, 2b**). This indicated that the inactive *S* enantiomer was not inhibitory to the *R* enantiomer (**2a**).

Other structural changes to the pheromone molecule were also considered, which contributed to the SAR study. A carbon was added to the pheromone at the 2-pentyl position to give 2-(2-methyl)pentyl decanoate (**3**), which was essentially inactive in field traps. A carbon was added to the pheromone at the 3-pentyl position to give (±)-2-(3-methyl)pentyl decanoate (**4a–4d**), which was inactive. Similarly, a carbon was added to the pheromone at the 4-pentyl position

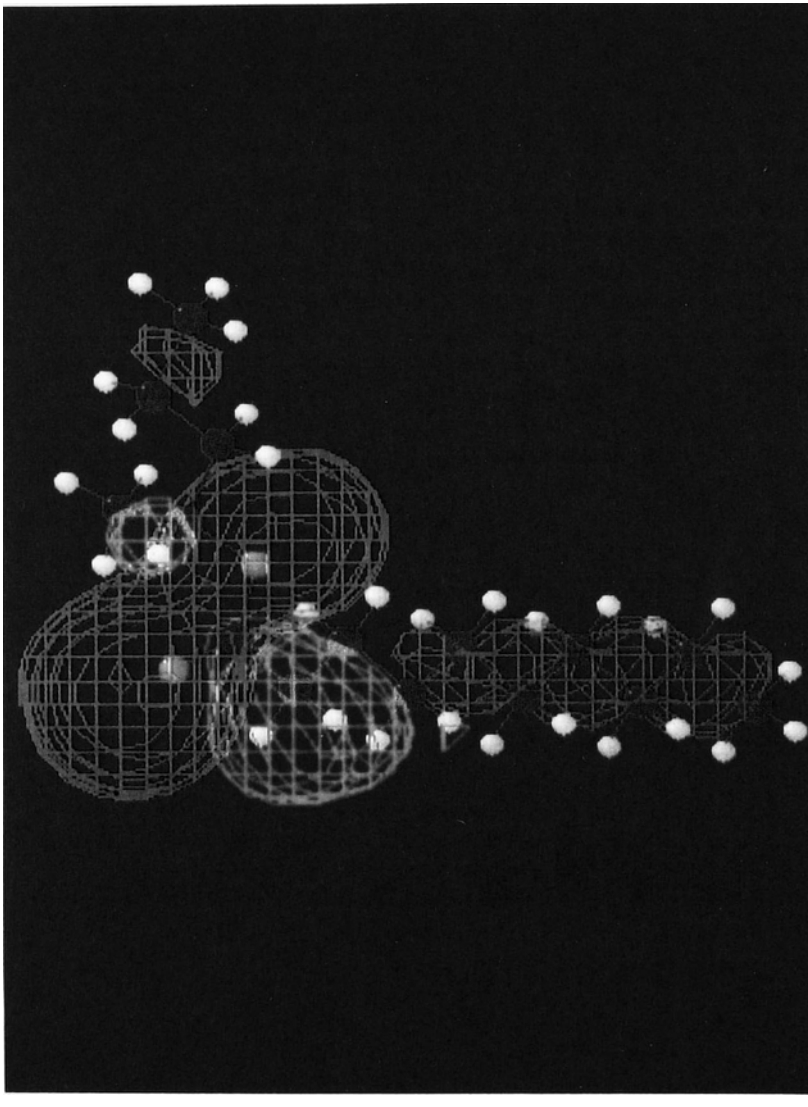

FIG. 2. Electrostatic potential 3D map of bagworm moth pheromone (**1a**). Standard contours: cyano, < -10.0 kcal; red, > 10.0 kcal; significance = 20; grid density = 2.5 contours/Å.

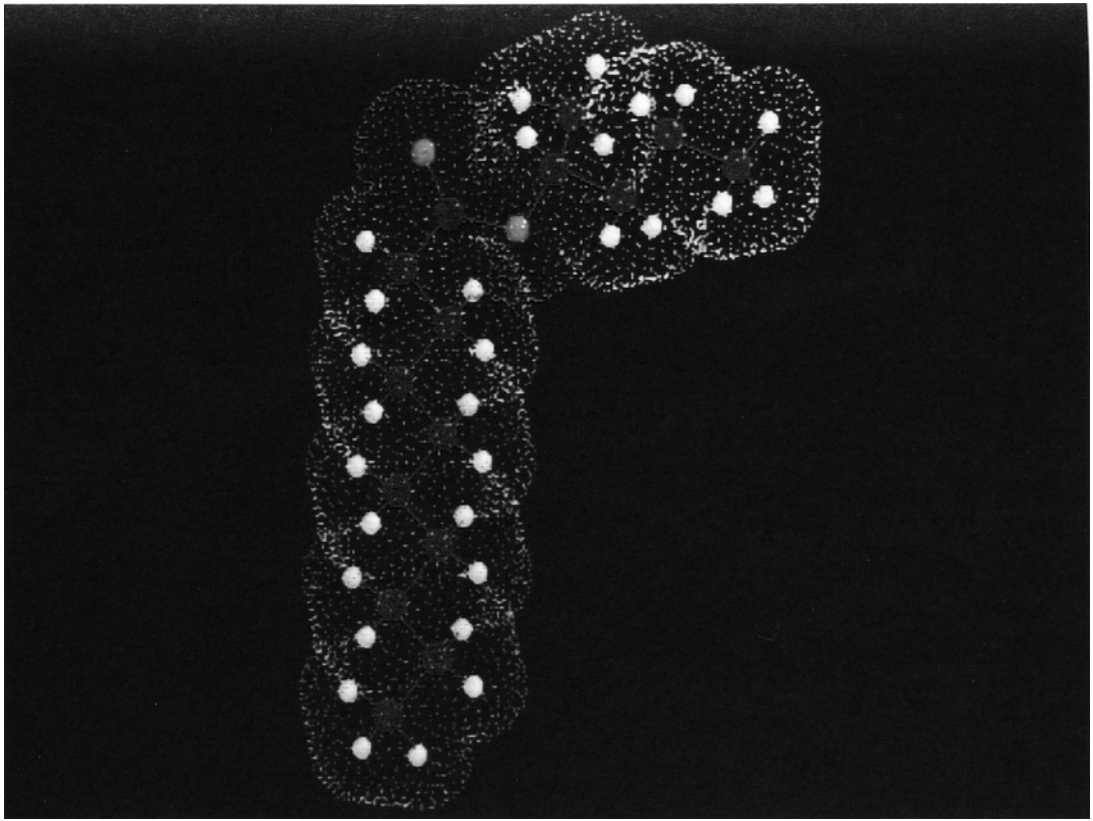

FIG. 3. VdW electrostatic coded surface 3D map of bagworm moth pheromone (**1a**). Standard contours: cyano, < -20.0 kcal; green, < -10.0 kcal; white, < 10.0 kcal; yellow, < 20.0 kcal; red, > 20.0 kcal; significance = 0.95; grid density = 2.5 contours/Å.

to give (±)-2-(4-methyl)pentyl decanoate (**5a, 5b**), which was also inactive; two carbons were added to the basic pheromone structure to give 2-(2,4-dimethy)pentyl decanoate (**6**), which was inactive. Finally, three carbons were added to the basic pheromone structure to give (±)-2-(2,3,4-trimethyl)pentyl decanoate (**7a, 7b**) which was also inactive.

The GLC purity (Table 1) of the analogs was 92+% except for (*R*)-2-hexyl decanoate (**2a**) and (±)-2-(2,3,4-trimethyl)pentyl decanoate (**7a, 7b**), which were 82.6 and 72.2%, respectively. The two diastereoisomers of (±)-2-(3-methyl)pentyl decanoate (**4a–d**) were resolved on the 12-m × 0.20-mm-ID column, but not on the 60-m × 0.25-mm-ID column with the conditions used. All analogs had a parent ion in the GC-MS, except for **2a, 3,** and **6,** which had $M^+ - 15$ ions.

The electrostatic potential map (Figure 2) of the pheromone (MM energy = −1.2071 kcal/mol), (*R*)-2-pentyl decanoate (**1a**), shows partially charged positive areas on the hydrogen at the (*R*)-2 position and on the hydrogens at the α-position of the decanoate chain. There is also a partially charged negative area around the two O atoms because of the electronegativity of these atoms. This could indicate that not only is the chiral steric effect of the (*R*)-2-CH_3 necessary for attractancy, but so is the partially charged positive (*R*)-2-H in relation to the partially charged negative oxygens with adjacent partially charged positive α-hydrogens on the decanoate chain. The volumes of the cyano (< −10 kcal electrostatic potential) and red contours (> 10 kcal electrostatic potential) are 67.8989 $Å^3$ and 17.9873 $Å^3$, respectively; the surface areas of the cyano and red contours are 97.4782 $Å^2$ and 30.7097 $Å^2$, respectively.

The VdW electrostatic coded surface 3D map (Figure 3) of the pheromone gives an indication of the size (volume = 216.47 $Å^3$), surface shape (area = 230.312 $Å^2$), and electrostatic charge distribution that is required for biological activity.

The antipode (**1b**) of the pheromone and **2b** are inactive because they appear right-handed instead of left-handed, with electrostatic potentials on the (*S*)-2-H and the α-hydrogens of the decanoate that are reversed in relation to the potential on the oxygens. In **1a** and **1b,** the energy minimized structure is L-shaped (Figure 3). Chirality determines whether the front or back surface of the L shape contains the electropositive 1-H proton. The large difference in their activity suggests only one surface (i.e., front) is active. Compound **2a** has the correct chirality for activity, but is tempered in activity by steric effects corresponding to extra molecular volume and surface area of a terminal methyl. Analogs that are achiral at position-2 (**3, 6,** and **7a, 7b**) lack the (*R*)-2-H to give the appropriate electrostatic potential distribution. The remaining compounds (**4a–d** and **5a, 5b**) have an (*R*)-2-H in the racemate, but the added substituents cause an increase in the molecular volume and surface area that could exceed the requirements. The volatilities of compounds (Tables 1 and 2)

would be expected to be quite similar except for **7a** and **7b**, with a retention time of 2.6–3.9 min greater than the other compounds.

No modifications were attempted on the acid portion of the pheromone for this study.

CONCLUSIONS

Modifications in the alcohol portion of the levorotatory bagworm moth pheromone, (*R*)-2-pentyl decanoate (**1a**), revealed that the chirality at the 2-pentyl position is absolutely essential for attractiveness since the *S* antipode (**1b**) is not attractive. It was also determined that the most stable conformation is L-shaped. Lengthening the alcohol with a terminal carbon reduced attractiveness by 65–83% as long as the correct chirality (**2a**) was maintained. Steric effects from the addition of a carbon at the 2 (**3**), 3 (**4a–d**), or 4 positions (**5a, 5b**); two carbons at the 2 and 4 positions (**6**); or three carbons at the 2, 3, and 4 positions (**7a, 7b**) of the pheromone resulted in no attractiveness. The bagworm moth allows very few changes in the alcohol portion of the pheromone if attractancy is to be maintained. The dumbbell shape of the electrostatic partial negative charge of the oxygen atoms in relation to the electrostatic partial positive charge of the chiral (*R*)-2-H and the electrostatic partial positive charge of the α-hydrogens on the decanoate chain point toward the importance of the front surface of the L-shaped (**1a**) enantiomer. Size and shape linked to this chiral surface contribute to its attractiveness for bagworm moths.

Acknowledgments—We thank Meyer Schwarz, USDA Collaborator, for the synthesis of compounds used in this study.

(Received August 3, 1995; accepted March 10, 1996)

Abstract—Lignans from *Virola sebifera* Aubl., *Virola* sp., and *Otoba parvifolia* (Mkfg.) A. Gentry (Myristicaceae) inhibited the in vitro growth of the fungus cultivated by leaf-cutting ants of the species *Atta sexdens rubropilosa* Forel (Hymenoptera: Formicidae). A comparison of activity among the lignans was obtained.

Key Words—Lignans, leaf-cutting ants, antifungal compounds, *Virola sebifera*, *Otoba parvifolia*, *Atta sexdens rubropilosa*.

INTRODUCTION

Leaf-cutting ants belonging to the genera *Atta* and *Acromyrmex* are widely distributed in the New World and have been considered to be among the most destructive herbivores in this area (Weber, 1972). In natural ecosystems, ants show a preference for some plant species that are constantly defoliated, while others are not attacked even though abundant and close to their nests (Cherrett, 1968; Hubbel and Wiemer, 1983; Littledyke and Cherrett, 1975; Rockwood, 1976).

*To whom correspondence should be addressed.

0098-0331/96/0700-1325$09.50/0 © 1996 Plenum Publishing Corporation

Attraction or repellency of different plants for ants may be influenced by physical and chemical properties of leaves, such as thorns, hardness of the epidermis, hairs, moisture level, nutritional quality, and secondary metabolites (Hubbell and Wiemer, 1983; Hubbell et al., 1984). Chemical defense of plants is generally associated with toxicity to herbivores of secondary metabolites such as alkaloids and terpenoids. (Harborne, 1994). There is some experimental evidence that secondary metabolites may be harmful to leaf-cutting ants and their symbiotic fungus (Howard et al., 1988). In Brazil the native species *Virola sebifera* Aubl. (Myristicaceae) seems not to be cut by leaf-cutting ants in the natural environment. In a preference assay, Bueno et al. (1989) showed that their leaves were not chosen, thus confirming that this plant is not used as a forage source by these ants.

Fernandes et al. (1988) showed that leaves of *V. sebifera* have lignans of both the furofuran and dibenzylbutyrolactone groups. Lignans largely occur in plants, and more than 500 compounds of this class are already known. Lignans are known for their antitumoral, antimitotic, and antiviral activities (MacRae and Towers, 1984).

We have recently (Pagnocca et al., 1990) reported the activity of sesame (*Sesamum indicum*) extracts on the growth of the symbiotic fungus cultivated by leaf-cutting ants of the species *Atta sexdens rubropilosa* Forel (Hymenoptera: Formicidae). During our continuing work on the isolation of bioactive natural products we have found that lignans can also inhibit the growth of the symbiotic fungus of the leaf-cutting ants *A. sexdens rubropilosa*. Lignans are known to be present in sesame oil. The possibility that they might also be found in the leaves of *S. indicum* prompted us to check some lignans isolated from other plants for activity against the symbiotic fungus of *A. sexdens rubropilosa*.

METHODS AND MATERIALS

Plant Extracts and Lignans Source. Extracts were prepared from leaves of *V. sebifera* Aubl. (Figure 1: **1, 2, 5, 6**), *Virola* sp. (**3, 7, 8**), and fruits of *O. parvifolia* (Mkfg.) A. Gentry (**4**) (Myristicaceae). Fernandes et al. (1988) and Ferreira et al. (1989) isolated some of the lignans used in the experiments, and others (lignans **3, 7,** and **8** from *Virola* sp.) were isolated by H. F. Paulino Fo. (unpublished data).

Microorganism. The fungus was isolated from a laboratory nest of the leaf-cutting ant *A. sexdens rubropilosa* Forel by streaking the spongelike mycelial material (fungal garden) in Petri dishes containing Sabouraud agar supplemented with 200 mg/liter of chloramphenicol and the pH adjusted to 4.0 with 1 N HCl. The nest was maintained in the laboratory with green leaves, mostly of *Eucalyptus alba*. The fungus showed typical characteristics of the ant fungus *Leucocoprinus gongylophorus*, syn. *Rozites gongylophora* Möller (Heim, 1957).

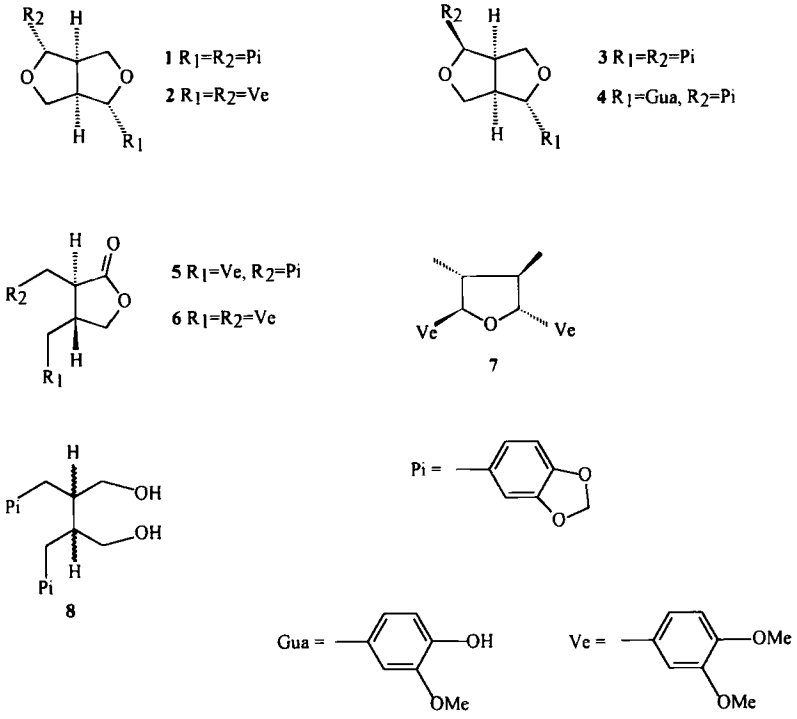

FIG. 1. Structures of the lignans tested. Substitutions in the basic lignan structure include the piperonyl rings (Pi), the guaiacyl group (Gua), and the veratryl group (Ve).

Culture Medium, Inoculum, and Growth Evaluation. The following culture medium (grams per liter) was used for both the assays and maintenance of the culture: glucose, 10.0; sodium chloride, 5.0; Bacto-peptone, 5.0; malt extract, 10.0; and agar, 15.0. The medium (9 ml) was distributed in test tubes (180 × 18 mm) and 1.0 ml of each lignan (10 × concentrate) was added in order to get a final concentration as follows: **1** = 70 μg/ml; **2** = 160 μg/ml; **3, 4, 5, 7, 8** = 200 μg/ml; and **6** = 210 μg/ml. Solutions of concentrated lignans were prepared by adding about 20.0 ml of solvent (dichloromethane) to crystals of pure lignans, and the concentration (10×) reached was a consequence of their yield after the purification procedure. Before addition to the culture medium, the volume was adjusted to give a final concentration near 200 μg/ml except for lignan **1,** which was shown to be active in a lower concentration (Pagnocca et al., 1987). To the controls (10 test tubes) was added 1.0 ml of dichloromethane. The complete medium was autoclaved for 10 min at 120°C. To check if a possible remaining amount of solvent could inhibit fungal development, a

second control was used with water instead of dichloromethane. The mycelium present in six stock culture tubes about 30 days old was transferred aseptically to an all-glass tissue grinder (250 × 25 mm) containing a small amount of peptone solution (0.1 w/v) and gently fragmented. Then, it was diluted with about 100 ml of sterile saline, and 1.0 ml (corresponding to 5.3 ± 1.0 mg of dry weight) was added to tubes containing slanted medium. The tubes were shaken to provide a good distribution of mycelial fragments on the agar slant and incubated in an oven at 25 ± 1°C for 30–35 days. The assays were run with 10 test tubes and repeated twice. After the period of incubation, the fungal growth was estimated macroscopically on the basis of mycelial surface and density and the relative growth was registered and expressed in percentage.

RESULTS AND DISCUSSION

Our previous experience showed that during autoclaving the organic solvent used was evaporated and did not inhibit the fungal development. The same was observed in the current assay.

Lignans varied in their inhibitory effect on the development of the symbiotic fungus from *A. sexdens rubropilosa*. Lignans **3** and **8** did not inhibit fungal growth at 200 μg/ml (Table 1). Lignan **4** (philygenol) from *O. parvifolia* and lignan **5** from *V. sebifera* both inhibited fungal development only slightly at a concentration of 200 μg/ml. Fungal growth was inhibited about 40% by lignan **2** (eudesmin) at a concentration of 160 μg/ml and 60% by lignan **6** from *V. sebifera* at 210 μg/ml. Complete inhibition of fungal development was obtained from lignan **7** (epigalgravin) and **1** (sesamin) at concentrations of 200 μg/ml and 70 μg/ml, respectively (Table 1).

Sesamin is found in different plants (Budowski, 1964) and has been shown

Table 1. INHIBITORY EFFECT OF LIGNANS ON FUNGUS GROWTH

Lignan	Final concentration (μg/ml)	Maximum fungus growth after (30–35 days) (%)
Sesamin (**1**)	70	<20
Eudesmin (**2**)	160	60
Episesamin (**3**)	200	100
Philygenol (**4**)	200	80
Lignan (**5**)	200	80
Lignan (**6**)	210	40
Epigalgavrin (**7**)	200	<20
Lignan (**8**)	200	100

to be a more potent inhibitor of fungal growth than other lignans. Lignan **6** (dibenzylbutyrolactone) also showed good inhibition activity and is an abundant constituent of *V. sebifera* (Fernandes et al., 1988). Furthermore, lignans **6** and **7** showed activities in tubulin binding and antitumor assays together with podophyllotoxin (Kelleher, 1978). Lignans **7** (tetrahydrofuran) and **6** (dibenzylbutyrolactone), and even lignan **2** (furofuran), in spite of inhibiting the fungal growth at a lower concentration than the first two (**1, 7**), had antifungal activity independent of chemical structural type.

Sesamin (**1,** furofuran) has two piperonyl rings (*cis*) linked to the furofuran central ring, while episesamin (**3**) presents the piperonyl rings *trans*. This difference in the stereochemistry maybe responsible for the lack of antifungal activity of episesamin. Eudesmin (**2,** furofuran) presents two veratryl rings (*cis*), and the presence of this group instead of piperonyl, as in sesamin, may lower antifungal activity. Lignan **4** (philygenol) shows one guaiacyl and one piperonyl ring and had weak activity in spite of the rings being *trans*, as in episesamin. This suggests that the guaiacyl group may have more influence than the piperonyl group on antifungal activity. This hypothesis will be tested in future studies when a lignan with two guaiacyl rings will be compared with sesamin. When the dibenzylbutyrolactone lignans **5** and **6** were compared, it was observed that the replacement of one veratryl group by a piperonyl group reduced antifungal activity by about 50%.

Of all components tested, sesamin was the most potent in the inhibition of fungus growth. The presence of lignans in the *V. sebifera* could be the main reason why leaf-cutting ants do not cut their leaves.

(Received July 11, 1995; accepted March 11, 1996)

Abstract—A two-choice laboratory behavioral bioassay was used to demonstrate that dichloromethane elicits the dose-dependent attraction of second-instar western and southern corn rootworms. Preliminary data suggest that second-instar banded cucumber beetles are also attracted to dichloromethane. An eluotropic series of 10 materials, including distilled water, ethanol, methanol, acetone, ethyl dichloroacetate, dichloromethane, diethyl ether, benzene, hexadecane, and hexane, was tested for attraction of western corn rootworm larvae. Dichloromethane was the only one attractive at all doses tested, and orthogonal comparisons revealed a quadratic trend (convex) for responses of larvae to increasing dose. Benzene and hexadecane also attracted larvae, but significantly fewer than dichloromethane, and only at three doses and one dose, respectively. Orthogonal comparisons revealed no linear or quadratic trend for responses of larvae to increasing doses of either compound. Dichloromethane is the first organic compound demonstrated to attract western corn rootworm larvae in the absence of carbon dioxide. Carbon dioxide has previously been reported to attract western corn rootworm larvae either independently or when combined with other organic compounds, and the sensitivity of our bioassay was tested by demonstrating the dose-dependent attraction of western corn rootworm larvae to carbonated water as a carbon dioxide source. We have also demonstrated the attraction of southern corn rootworm larvae to carbon dioxide and propose that carbon dioxide and dichloromethane behave analogously when they interact with chemoreceptor sites on larvae.

Key Words—*Diabrotica virgifera virgifera*, *Diabrotica undecimpunctata howardi*, *Diabrotica balteata*, Coleoptera, Chrysomelidae, semiochemical, structure-activity, host-finding, carbon dioxide, corn, soybeans.

INTRODUCTION

Several *Diabrotica* species with varying host ranges are associated with corn, cucurbits, or soybeans. The western corn rootworm (WCR), *Diabrotica virgifera virgifera*, (Coleoptera: Chrysomelidae) is the most economically important insect in the United States; requiring more than one billion dollars annually for the reduction of damage caused when its larvae feed on the roots of corn plants (Metcalf and Metcalf, 1993). WCR larvae can survive on the roots of other grasses, completing their immature development on at least 14 species of graminaceous plants and producing fertile adults on at least five species (Branson and Ortman, 1967, 1970). Branson and Ortman (1970) concluded that the larvae are probably oligophagous and that their host range is limited to certain species of the Poaceae, but that corn is still the most favorable host for larval development. The southern corn rootworm (SCR), *Diabrotica undecimpunctata howardi* is also considered a pest of corn, but has a broader host range and has been collected from more than 200 common weeds, grasses, and cultivated crops, including soybeans (Metcalf and Metcalf, 1993). Like the SCR, the banded cucumber beetle (BCB), *Diabrotica balteata* (Coleoptera: Chrysomelidae), also has a broad range and has traditionally been considered a defoliator of cucurbits, but in the past several decades it has developed into an important pest of soybeans in the gulf states (Metcalf and Metcalf, 1993).

Several compounds associated with corn facilitate host-finding by WCR larvae, but none have been reported for SCR or BCB larvae. Carbon dioxide is released from corn roots (Harris and van Bavel, 1957; Massimino et al., 1980) and has previously been demonstrated to attract first-instar WCR (Strnad et al., 1986). Extracts of germinating corn seedlings have been demonstrated to augment attraction of either first- or second-instar WCR to a source of carbon dioxide in laboratory bioassays (Strnad et al., 1986; Strnad and Bergman, 1987; Hibbard and Bjostad, 1988, 1990). Some organic compounds in these extracts have been identified and demonstrated to influence larval behavior in laboratory bioassays with carbon dioxide. Bjostad and Hibbard (1992) reported the combination of 6-methoxy-2-benzoxazolinone (MBOA) and carbon dioxide as a cue for larval host recognition in laboratory bioassays. Field experiments have also supported the role of MBOA as a host recognition cue for larvae (Hibbard et al., 1995). Hibbard et al. (1994) reported that each of three fatty acids that were isolated from corn, including stearic acid, oleic acid, and linoleic acid, when combined with carbon dioxide, served as host recognition cues for larvae in laboratory bioassays.

While developing new bioassay approaches for the isolation of more behaviorally active compounds from corn, we observed the attraction of second-instar larvae to dichloromethane. We then initiated the systematic evaluation of WCR behavioral responses to 10 different materials that comprise a wide range of

polarities. We evaluated the sensitivity of our bioassay by testing the responses of WCR larvae to carbonated water as a carbon dioxide source. The dose-dependent attraction of SCR larvae to carbon dioxide and to dichloromethane was also considered. Attraction of BCB larvae to dichloromethane was tested as well.

METHODS AND MATERIALS

WCR, SCR, and BCB Larvae. Second-instars of WCR and SCR, between 5 and 7 days old and 4–7 mm long, were used for all our experiments. WCR larvae were obtained from the colony in our laboratory that was established and maintained using methods described by Jackson (1986) with modifications by Hibbard and Bjostad (1988). The original source of our WCR was a nondiapausing strain obtained in June 1986 from the USDA-ARS laboratory in Brookings, South Dakota. The colony has been supplemented frequently since then with eggs from French Ag. Research Inc. (R.R. 2, Box 294, Lamberton, Minnesota 56152). SCR larvae (a nondiapausing strain reared on germinating corn seeds) were obtained from French Ag. Research Inc., and bioassays with them began on the day of their receipt. BCB larvae (reared on germinating wheat seeds) between 3 and 5 days old and 3–6 mm long were obtained from Michael Jackson (USDA-ARS, U.S. Veg. Lab., 2875 Savannah Hwy., Charleston, South Carolina 29414) and were used on the day of their receipt.

Bioassay Apparatus. Each bioassay apparatus contained an arena, a stand for the arena, and dispensers for the volatile compounds (Figure 1). Arenas of the two-choice bioassay were constructed from a single 90-mm × 15-mm disposable, polystyrene Petri dish (Becton Dickinson and Company, 2 Bridgewater Lane, Lincoln Park, New Jersey 07035). Two round holes (11 mm diameter) were made in the bottom of the dish, 65 mm opposite from one another, using a brass tube attached to a soldering iron. Filter papers (qualitative, number 4, 90 mm diameter, Whatman International Ltd., Maidstone, England) were cut to a diameter of 86 mm. Two round holes (11 mm diameter) were cut opposite one another in the filter papers with a gasket punch (Snap On Tools Corp., Kenosha, Wisconsin 53140). The filter paper was used to cover the bottom of the Petri dish, with the holes aligned. Stands for the arenas were constructed from 10.5-cm × 15.7-cm pieces of heavy paper (110 lb, Dixon Paper Co., 3900 Lima St., Denver, Colorado 80239). When finished, the two arms of each stand were 45 mm high. Two 4-ml glass shell vials (Baxter Healthcare Corp., Scientific Products Div., McGaw Park, Illinois 60085-6787) were uncapped and placed on the stand, and their open tops were flush with the top of each arm on the stand. An arena was set on the stand such that the two holes in the bottom of it were aligned with the openings in the tops of the two shell vials. Larvae

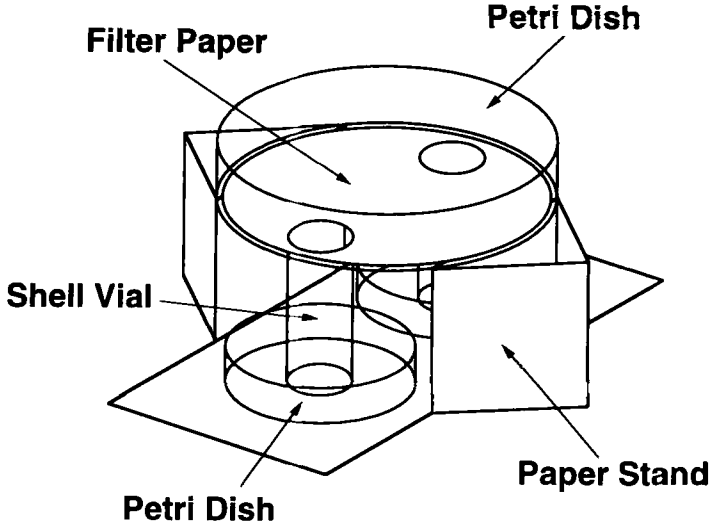

FIG. 1. Schematic of the two-choice bioassay apparatus and its five components, including three Petri dishes, two shell vials, filter paper lining, and a paper stand.

could still escape from between the arena and the dispensers, so each shell vial was set in a moat constructed from the bottom of a 60-mm × 15-mm-diameter Petri dish filled with water to capture them.

Compounds Tested. Dichloromethane, diethyl ether, acetone, hexane, and hexadecane were purchased from Mallinckrodt Specialty Chemicals (Swingey Ridge Rd., Chesterfield, Missouri 63017-1077). The diethyl ether was distilled over lithium aluminum hydride (LAH) to ensure dryness. Carbonated water (Canada Dry, Cadbury Beverages Inc., Stamford, Connecticut 06905-0800) served as a carbon dioxide source. Ethyl dichloroacetate was obtained from Pfaltz and Bauer Chemical Company (P.O. Box 5205, Flushing, New York 11352). Ethanol and benzene were obtained from Fisher Scientific (Fair Lawn, New Jersey 07410). Methanol was obtained from Alltech Associates, Inc. (Applied Science Labs, 2051 Waukegan Road, Deerfield, Illinois 60015).

Two-Choice Bioassay with Organic Solvents. Ten larvae were used in each replication. Larvae were taken randomly from our colony and transferred with a small, moist, camel-hair paint brush to the inside of a polystyrene cap from a 4-ml shell vial. Caps containing the larvae were kept on a moist paper towel to prevent the larvae from desiccating. The filter paper inside an arena was moistened with distilled water, and the excess was blotted away with a clean paper towel. The cap and the larvae were then placed into the center of the

arena and inverted. The cap was used to cover and contain the larvae there until commencement of the bioassay.

A 10-μl glass, fixed-needle syringe (Alltech Associate) was used to introduce 0.5, 1.0, 2.0, or 4.0 mg of distilled water, ethanol, methanol, acetone, ethyl dichloroacetate, dichloromethane, diethyl ether, benzene, hexadecane or hexane into the 4-ml glass shell vial on one side of the arena. The other dispenser remained empty. Both shell vial dispensers were positioned beneath the arena, the cap containing the larvae was removed, and the lid was placed over the petri dish arena. The duration of each bioassay was 30 min. When a replication was completed, the number of larvae in the bottom of the two dispensers and in the moat around them was recorded. WCR, SCR, and BCB larvae were used only once for testing, and each arena and dispenser was used only once. Temperature during the bioassays was between 23 and 27°C.

Two-Choice Bioassay with Carbonated Water. Carbonated water, used to test attraction of WCR larvae to different doses of carbon dioxide, was diluted and brought to a total volume of 200 μl with distilled water. Distilled water was introduced to the dispenser first with a 1-ml glass, fixed-needle syringe (Alltech Associates), and then the appropriate amount of carbonated water was added gently, also with a 1-ml glass, fixed-needle syringe (partial degassing of the carbonated water produced a headspace inside the syringe, and this headspace was not added). Ratios of carbonated water to distilled water used for our experiments were 0, 1:7, 1:3, 1:1, and undiluted carbonated water. For controls in our two choice tests, dispensers opposite the carbon dioxide treatments were filled with 200 μl distilled water. To assure a stable release of carbon dioxide and to prevent any effects from immediate out-gassing, 5 min were allowed to elapse between introduction of carbonated water to a dispenser and commencement of a bioassay. When both shell vials were prepared, behavioral bioassays were conducted as described above, except that 30 larvae were used for each replication and each bioassay was allowed to proceed for 10 minutes.

Statistical Analyses. Data were analyzed with SAS (SAS Institute Inc., SAS Circle, P.O. Box 8000, Cary, North Carolina 27512-8000). A t test was performed to identify any differences existing between the number of larvae attracted to the treatment dispenser and the control dispenser for each dose of all experiments. For the eluotropic series of compounds, ANOVA was conducted using differences between the number of larvae recovered from the treatment and control dispensers. Duncan's multiple range test was used to compare responses of WCR larvae to the compounds in the eluotropic series for each dose that yielded an ANOVA with a significant P value (0.05). Orthogonal comparisons of larval responses to increasing doses of each compound in the eluotropic series were made, identifying any linear or quadratic trends that may exist.

RESULTS

WCR Larvae. WCR larvae were attracted to carbon dioxide released from carbonated water (Figure 2). Carbon dioxide from the tested doses of carbonated water attracted significantly more WCR larvae after 10 min than controls of distilled water. Even the lowest concentration of carbonated water tested (12.5%) was significantly attractive. When WCR larvae were presented a choice of distilled water on both sides of the bioassay, they were recovered in equal numbers from both dispensers at its conclusion.

All doses of dichloromethane tested, including 0.5, 1.0, 2.0, and 4.0 mg, attracted second-instar WCR in our behavioral bioassay (Figure 3). A significantly greater number of WCR larvae were recovered from dispensers of dichloromethane than from empty dispensers. Orthogonal comparison of larval responses to increasing doses of dichloromethane revealed a quadratic (convex) trend. A significantly greater number of WCR larvae were recovered from dispensers of two benzene doses (0.5 and 2.0 mg) (Figure 3), but orthogonal comparison revealed no significant trend in larval responses to the doses tested. A significantly greater number of WCR larvae were also recovered from dispensers of one hexane dose (1.0 mg) (Figure 3), but orthogonal comparison revealed no significant trend in larval responses to the doses tested of that compound either. Although no significant attraction of larvae to any dose of methanol was observed, orthogonal comparison of larval responses to the tested doses revealed a significant (positive) linear trend. No significant attraction of WCR larvae to other solvents in the eluotropic series was observed (Figure 3), nor did orthogonal comparison reveal any significant trends in attraction of larvae to their increasing dose. Ethyl dichloroacetate was significantly repellent at all doses tested, which was expected because of its noxious qualities, and diethyl ether was repellent at three doses (0.5, 2.0, and 4.0 mg).

Multiple range tests revealed significant differences in the numbers of larvae attracted to each of the four doses among compounds in the eluotropic series.

FIG. 2. Behavioral responses of western corn rootworm (WCR) larvae *Diabrotica virgifera virgifera* to carbonated water (H_2O) as a carbon dioxide source. Each point on a line represents the average number of 30 larvae introduced to the center of the arena that were recovered from either of the two dispensers for n replications. Bars represent standard error values. (A) 100% carbonated H_2O = 200 μl of carbonated water introduced to the dispenser on the treatment side of the two-choice bioassay. (B) 50% carbonated H_2O = 100 μl of carbonated water + 100 μl of distilled water introduced to the dispenser on the treatment side. (C) 25% carbonated H_2O = 50 μl of carbonated water + 150 μl of distilled water introduced to the dispenser on the treatment side. (D) 12.5% carbonated H_2O = 25 μl of carbonated water + 175 μl of distilled water introduced to the dispenser on the treatment side. (E) Distilled H_2O = 200 μl of distilled water.

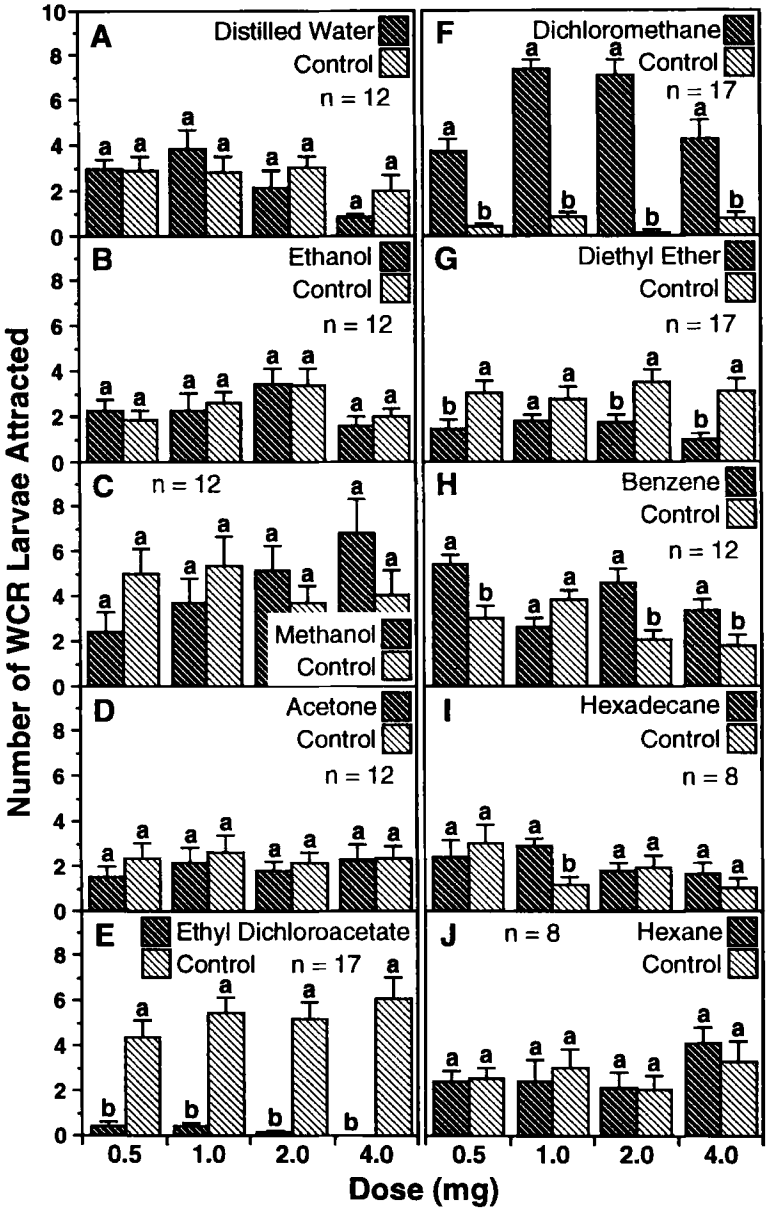

FIG. 3. Behavioral responses of western corn rootworm (WCR) larvae *Diabrotica virgifera virgifera* to an eluotropic series of compounds, including (A) distilled water, (B) ethanol, (C) methanol, (D) acetone, (E) ethyl dichloroacetate, (F) dichloromethane, (G) diethyl ether, (H) benzene, (I) hexadecane, and (J) hexane (0.5, 1.0, 2.0, and 4.0 mg); n = number of replications for each experiment. Bars on columns represent standard error values. Average responses to control and treatment sides within a dose denoted by the same letter are not significantly different ($P = 0.05$).

At the 0.5-mg dose, both dichloromethane and benzene were attractive and were not significantly different from one another. At the 1.0-mg dose, dichloromethane and hexadecane were the only compounds attractive to larvae, but dichloromethane was significantly more attractive than hexadecane. At the 2.0-mg dose, dichloromethane and benzene were the only compounds attractive to larvae, but dichloromethane was significantly more attractive than benzene. At the 4.0-mg dose, dichloromethane and benzene were the only compounds attractive to larvae, and they were not significantly different from one another.

SCR Larvae. SCR larvae were attracted to carbon dioxide released from carbonated water. When presented with a choice of 500 μl carbonated water and 500 μl distilled water, significantly more SCR larvae were attracted to carbonated water. With 17 replications, an average of 5.55 ± 0.68 larvae were recovered from in and around dispensers of carbon dioxide, while only 0.45 ± 0.15 larvae were recovered from in and around dispensers of distilled water. SCR larvae were also attracted to dichloromethane (Figure 4). Significantly more

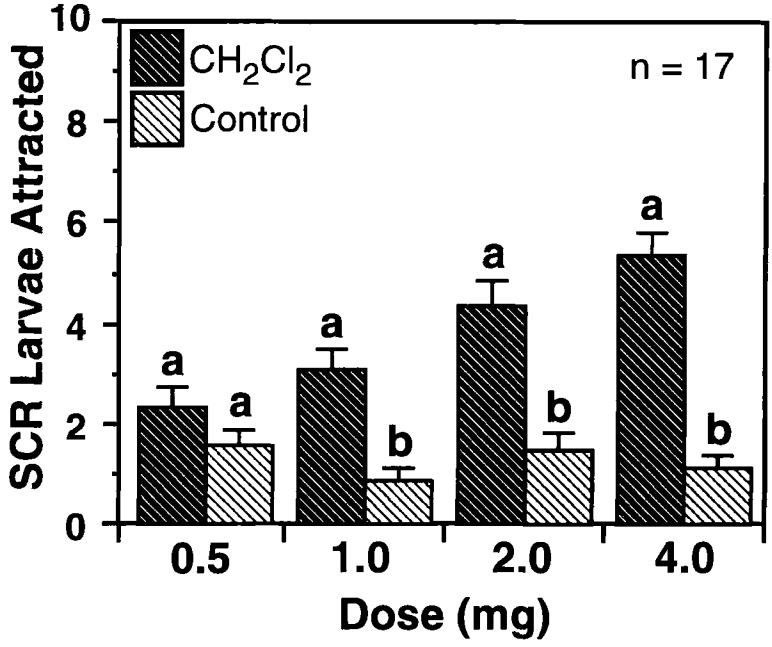

FIG. 4. Behavioral responses of southern corn rootworm (SCR) larvae *Diabrotica undecimpunctata howardi* to dichloromethane (CH_2Cl_2) (0.5, 1.0, 2.0, and 4.0 mg). There were 17 replications. Bars on columns represent standard error values. Average responses to control and treatment sides within a dose denoted by the same letter are not significantly different ($P = 0.05$).

SCR larvae were recovered from in and around dispensers of 1.0, 2.0, and 4.0 mg dichloromethane than from controls. The lowest dose of dichloromethane tested (0.5 mg) was not significantly attractive. Orthogonal comparison of SCR larval responses to increasing doses of dichloromethane revealed a significant (positive) linear trend.

BCB Larvae. BCB larvae were attracted to a 2.0-mg dose of dichloromethane. After eight replications in which BCB larvae were presented a choice of 2.0 mg dichloromethane and an empty dispenser, significantly more larvae were recovered from in and around dispensers of dichloromethane (4.13 ± 0.44) than from in and around empty dispensers (0.88 ± 0.23).

DISCUSSION

WCR larvae were attracted to carbonated water used as a carbon dioxide source, an observation consistent with that of Strnad et al. (1986). Dichloromethane also attracted second-instar WCR in our behavioral bioassay at all doses tested. These experiments represent the first time an organic compound has been demonstrated to attract WCR larvae in the absence of carbon dioxide. Dichloromethane also attracted second-instar SCR larvae for all but the lowest dose tested (0.5 mg) and elicited the attraction of BCB larvae at the only dose tested (2.0 mg). We also found that SCR larvae were attracted to carbonated water, which is the first report that carbon dioxide is an attractant for this species. The rationale for attraction of diabroticite larvae by carbon dioxide is its release from the roots of corn, a principal host (Massimino et al., 1980).

The selective attraction of WCR larvae to dichloromethane, but not to other organic solvents, may be a consequence of the mechanistic details of carbon dioxide reception by the insect. We suggest that carbon dioxide is oxidized to bicarbonate in the antennal hemolymph, and that bicarbonate is the form that is actually received by chemoreceptors in the dendrites. We further propose that dichloromethane mimics bicarbonate as it interacts with these chemoreceptors, and thereby results in larval attraction. As illustrated in Figure 5, the chlorine atoms of dichloromethane resemble the oxygen atoms of bicarbonate in size and electronegativity, and the bond angles between the heteroatoms are also similar.

Of the compounds in our eluotropic series, dichloromethane was the only one attractive at all doses tested. Most other solvents tested were neither attractive nor repellent, suggesting that the attraction to dichloromethane is not merely a response to organic solvents in general. These results also suggest that the general polarity of a compound is not an important component of its interaction with receptor sites on larvae, but that specific structural parameters are.

Many invertebrates of agricultural and medical importance, including the two diabroticite larvae discussed in this manuscript, cerambycid larvae (Meeking

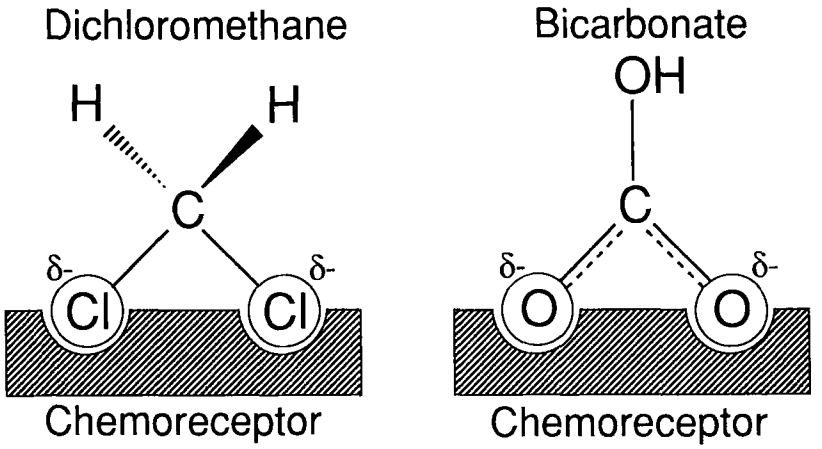

FIG. 5. Schematic of the model depicting mimicry between carbon dioxide (as bicarbonate) and dichloromethane at a molecular level in the context of receptor-semiochemical interaction.

et al., 1974), corn earworm larvae (Rasch and Rembold, 1994), mosquitos (Kellogg, 1970), tse tse flies (Bogner, 1992), stable flies (Warnes and Finlayson, 1986), tropical bont ticks (Steullet and Guerin, 1992; Perritt et al., 1993), and plant parasitic nematodes (Prot, 1980), are attracted by carbon dioxide. Furthermore, WCR, SCR, and BCB larvae are attracted by dichloromethane, which suggests that chemical mimicry of these compounds and other analogs may be common among invertebrates that use carbon dioxide for host-finding. If a relationship between carbon dioxide and dichloromethane is confirmed, new synthetic analogs may be available for use to enhance agricultural production or to reduce the incidence of invertebrate-spread diseases. Presently, because of the potential affect dichloromethane may have on the behavior of many invertebrates that use carbon dioxide for host-finding, behavioral results obtained after using it to extract, isolate, and identify semiochemicals should be regarded critically.

Its migratory habits have rendered attempts to manage the adult stage of the WCR unsuccessful, so management strategies have concerned the larvae (Levine and Oloumi-Sadeghi, 1991). Protection of corn roots has relied primarily upon soil insecticides (Suguiyama and Carlson, 1985), but the need for an alternative management strategy has been expressed because of concerns for resistance, the environment, and the potential for extended diapause (Stoewen, 1989). In response to this need, semiochemicals have been included as part of integrated pest management programs (Bjostad et al., 1993), and the goal of developing more convenient formulations with an increased range of activity

has inspired researchers to consider synthetic analogs of semiochemicals (Briggs et al., 1986).

Halogenated analogs of semiochemicals are behaviorally active for other insect species. (*E*8,*E*10)-dodecadien-1-ol (codlemone) is the main sex pheromone component of the codling moth, *Cydia pomonella*, and halogenated analogs were tested for field activity with the expectation that they may be more effective than the native form (Lucas et al., 1994). F(10,11)-codlemone and Cl-codlemone were more attractive to male codling moths than codlemone itself. A series of mono-, di-, and trihalogenated methyl-substituted analogs of (*E*8,*E*10)-dodecadien-1-yl acetate, a sex attractant for the alfalfa moth, *Cydia medicaginis*, were less active than the original acetate (Svatos et al., 1990). Many structure–activity studies with semiochemicals have considered the replacement of hydrogen atoms on moth pheromones with fluorine atoms (Camps et al., 1984; McLean et al., 1989; Prestwich et al., 1986; Bengtsson et al., 1990; Linn et al., 1992). Analogs of this nature were still active, but insects usually required a longer recovery time. Other structure–activity studies have considered optically active analogs (Suzuki et al., 1984; Li et al., 1986), and methyl-substituted frontalins (Payne et al., 1988).

Semiochemicals could facilitate management of the WCR in many ways. Use of baits with insecticides could reduce the amount of insecticides applied to manage populations of WCR larvae in the field. Soil insecticides do not necessarily control populations of larvae, but instead protect root systems from injury by confining damage to peripheral roots or ones outside the protected band [Felsot et al. as cited in Levine and Oloumi-Sadeghi (1991)]. Current application procedures of corn growers appear to be compatible with semiochemical techniques for enhancing the efficiency of insecticides (Hibbard et al., 1994). WCR soil insecticides are typically formulated on clay, sand, or gypsum carrier granules (Levine and Oloumi-Sadeghi, 1991), and semiochemicals could be formulated with them to develop an attracticide. Semiochemicals may encourage feeding of WCR larvae on artificial diets to facilitate screening of insecticides and improve laboratory rearing techniques (Sven Strnad, American Cyanamid, Box 400, Princeton, NJ 08540-0400, personal communication). Use of artificial diets has already improved rearing of the SCR in colonies and facilitated screening of insecticides (Marrone et al., 1985).

Acknowledgments—We thank the Colorado Agricultural Experiment Station for partial funding of this project. W. Painter, T. O. Holtzer, R. Vogt, D. Brigham, and G. Orr provided many insights into the understanding of semiochemical–receptor interactions at the molecular level. J. Zum-Brunnen, P. Chapman, K. Bondari, and B. E. Hibbard were consulted for statistical analyses. L. French was a reliable and consistent source of SCR larvae and information regarding their biology, M. Jackson supplied us with BCB larvae. Corn seed for maintaining laboratory culture of WCR was provided by G. D. Lawrance (Pioneer Hi-Bred International Inc.).

(Received April 28, 1994; accepted March 13, 1996)

Abstract—Membrane feeding studies were conducted to determine the effects of raw juices and chemical extracts of leaves of aphid-resistant (ICV-12) and aphid-susceptible (ICV-1) cultivars of cowpea [*Vigna unguiculata* L. (Walp.)], on the survival, growth, and reproduction of cowpea aphid *Aphis craccivora* Koch. Life table and demographic statistics of the cohort population and subsequent generations were estimated. Compared to ICV-1, the leaf juices and chemical extracts of ICV-12 exhibited significant ($P \leq 0.05$) adverse effects on aphid survival, growth, and reproduction. Raw leaf juice and ethyl acetate extract of ICV-12 in both water and sucrose significantly ($P \leq 0.05$) limited aphid performance. The adverse long-term effects were often more extreme than those resulting from a diet of distilled water alone. Methanol extract of ICV-12 showed an intermediate level of adverse effects on aphids, being generally less than that of ethyl acetate but greater than that of hexane. Compared to the other ICV-12 extracts, the hexane extracts in water or sucrose media did not significantly affect the aphid performance. Overall, it was determined that antibiosis was a governing modality of aphid-resistance in ICV-

12. Postingestive intoxication was caused by foliage components of seedling plants of that cultivar.

Key Words—Net reproduction rate, postingestive intoxication, membrane feeding, ethyl acetate extract, sucrose, ICV-12, antibiosis, aphid performance *Vigna unguiculata*, *Aphis craccivora*, cowpea resistance, cowpea aphid.

INTRODUCTION

Effects of certain phytochemicals and different cowpea cultivars on aspects of the biology of the cowpea aphid, *Aphis craccivora* Koch have been well studied (Mansour et al., 1982; Lattanzio et al., 1990). Extensive research using electronic feeding monitoring has been conducted on aphid feeding behavior on different crops and cultivars of the same crop (McLean and Kinsey, 1964; Nielson and Don, 1974; Brown and Holbrook, 1976; van Helden and Tjallingii, 1993; Prado and Tjallingii, 1994), and on plant extracts and other artificial diets (Tjallingii, 1985; Annan, 1992). However, the effects of plant extracts on aphid reproduction and population dynamics have not been well-documented.

Cowpea *Vigna unguiculata* (L.) Walp., is an important crop throughout the tropics, due to its nutritional and agronomic value (Singh and Rachie, 1985). *Aphis craccivora* is the most serious insect pest of the cowpeas worldwide (Singh et al., 1978). It attacks and damages all parts and growth stages of the plant. Genetic studies and selections of aphid-resistant cowpea germplasm have been extensively studied (Bata et al., 1987; Ombakho et al., 1987; Pathak, 1988), but identification of the specific mechanisms of aphid resistance in cowpeas is not well understood.

The cowpea cultivars selected for these studies were the aphid-susceptible cv. ICV-1 and the aphid-resistant cv. ICV-12, both of which were registered and released by International Center of Insect Physiology and Ecology (ICIPE) in Kenya (Pathak and Olela, 1986). ICV-1 was a single-plant selection developed from landraces of eastern Kenya, whereas ICV-12 was obtained from ICV-1 by point mutation of a chromosome using gamma irradiation. Both cultivars have similar morphological habits and phenological traits, but differ mainly in their resistance or susceptibility to *Aphis craccivora*. Aphid resistance in ICV-12 is highly expressed in seedling plants (Pathak, 1988; Annan, 1992).

This study was conducted as part of an overall research effort to characterize the mechanisms of the observed field resistance of ICV-12 against *Aphis craccivora*. Previous studies using electrical penetration graphs from aphid feeding behavior on seedling plants and leaf extracts of ICV-12 suggested that antixenosis is a governing mechanism of aphid resistance in that cultivar (Annan, 1992). Other studies with plants and excised plant parts of that cultivar indicated

that seedling plants of ICV-12 expressed high levels of antibiosis against the reproductive performance and population dynamics of the *A. craccivora* (Annan, 1992; Givovich et al., 1988; Firempong, 1988).

The main objective of this work was to evaluate the role of chemical extracts from ICV-12 seedling foliage in modulating the antibiosis resistance in that cultivar, using the aphid-susceptible ICV-1 cultivar as a standard check. Horizontal life tables (Southwood, 1978) were used to analyze the aphid performance and demographic statistics on the two crop cultivars.

METHODS AND MATERIALS

Laboratory and greenhouse studies in this work were conducted at the ICIPE-Mbita Point Field Station in Western Kenya. There were four blocks corresponding to the timing of experiments, namely: May to June 1990, August to September 1990, November to December 1990, and February to March 1991.

Experimental Design and Test Conditions. The test was set up in a randomized complete block design, with six replications of each treatment in each block. Experiments were conducted in the laboratory at 26 ± 0.5°C, 40–80% relative humidity, and supplied by an overhead bank of 40-W Tezla Z Daylight fluorescent lamps (Tezla, Czech Republic). Aphids used were the progenies of a colony obtained with a few field-collected individuals that were maintained in the greenhouse on plants of a susceptible cowpea cultivar VITA-7 at 25 ± 2°C, 40–90% relative humidity and a 14L:10D photo period. Fresh plants were added to the colony every three days, to maintain colony vigor.

Raw leaf juices and solvent extracts from aphid-resistant ICV-12 and aphid-susceptible ICV-1 cultivars were used to study the expression of cowpea resistance to *A. craccivora* in terms of the effects on aphid reproductive performance. Plant extracts dissolved in either water or in 0.5 M sucrose solution were compared to a double control system consisting of sucrose solution only, on which there is high aphid feeding and survival, and to plain water, on which aphid feeding and survival is low.

In order to ascertain that the three solvents used in the extractions were not toxic to the aphid, a 100-μl titer of each solvent was homogenized in plain water or sucrose solution and tested on aphids. The experiment was repeated five times. It was first done before tests with plant extracts and was repeated as a set of control treatments in all four tests with plant extract tests.

Overall there were 16 treatments: eight plant extracts consisting of hexane extracts, ethyl acetate extracts, methanol extracts, and raw leaf juices of each ICV-12 and ICV-1; and eight control treatments consisting of distilled water only or 0.5 M sucrose solution or either solution with 100 μl aliquots of the respective solvents added.

Leaf Sample Collection and Extraction Method. Field grown plants were used in the studies. Foliage of 2-week-old seedling plants of cv. ICV-12 and cv. ICV-1 were harvested. Samples were carefully handled to maintain plant integrity. Prior to extraction, leaf samples were frozen in a portable ice chest.

Extraction of leaf samples was started within 30 min after harvesting. Sequential extractions of leaves were made with hexane, ethyl acetate, and methanol, in order of increasing solvent polarity. Extracts were obtained by soaking 50 g fresh foliage in 150 ml of each solvent for 24 hr. All extractions were done at room temperature. After extraction with each solvent, leaves were air-dried at room temperature to remove solvent residues. Leaf fresh weights were recorded before extraction and after extraction with each solvent. Percent fresh weights of leaf matter extracted in the different solvents were calculated.

After each extraction, solvent residues in the extracts were evaporated with a Büchi model RE-111 Rotavapor Evaporator (American Scientific, McGaw Park, Illinois). Then the extracted matter was redissolved in 100 ml of the same solvent to obtain the stock solution used for each test. Prior to bioassay, 100 μl of an extract were homogenized in 1 ml of water for ca. 10 min using a hand-operated Fischer Sonic Dismembrator Portable Homogenizer (Fischer Scientific, Pittsburgh, Pennsylvania).

Membrane Feeding Bioassay. Cylindrical plastic vials (7 cm long $\times$ 3 cm diam.), with a small hole (1 cm diam.) cut at the top end and the bottom end sealed, were used as test units. Each vial consisted of two 3.5-cm-long cylindrical plastic drums joined in the middle with a 32-mesh/mm^2 No-See-Um organdy screen. Two holes (0.5 $\times$ 0.5 cm) were cut on opposite sides of the bottom drum of the vials beneath the organdy screen to improve ventilation, and vials were covered with black muslin tape to exclude light.

During the membrane feeding tests, homogenates were dispensed into feeding membrane sachets made of sterilized finely stretched 2-cm $\times$ 2-cm pieces of Parafilm M (American National Can, Greenwich, Connecticut) and placed over the hole at the top of the test vial. Five apterous adult aphids of similar age were placed on the organdy screen and provided feeding access to parafilm sachets with the test solutions. Vials were placed in small cups half-filled with water to exclude ants. Each vial comprised a treatment replicate. Determination of aphid stylet penetration of sachets during feeding was made with a Wild light microscope (50–60 Hz) (Wild Co., Heerbrugg, Switzerland).

Data Collection, Parameters, and Analyses. Daily observations of aphids were made, and new nymphs or dead individuals were counted and removed. Data were recorded for each vial until all cohort individuals died. In a few cases, vials were discarded due to leakage of sachets, causing mortality and colony collapse. Specific data used to estimate aphid life table statistics included: survival to adult stage (l_x), net rate of reproduction (R_O), intrinsic rate of natural increase (r_m), and number of generations. Data analyses were performed using

ANOVA (SAS Institute, 1988). Data on the percentage of surviving aphids covered a wide range of values. Therefore, those data were subjected to arcsin transformations (Snedecor and Cochran, 1980). Significant differences in treatment effects of similar extracts of ICV-12 and ICV-1 or the different extracts of each cultivar were determined using 95% confidence intervals and orthogonal contrasts.

RESULTS

Calculations of mean percent fresh leaf weights of ICV-12 that was extracted in the various solvents were: 33% weight in hexane, 21% in ethyl acetate, and 16% in methanol, with 30% being the unextracted leaf matter; for ICV-1 there was 31% weight in hexane, 16% in ethyl acetate, 12% in methanol, and 41% remaining in the residue after extractions. Initial inspection of the aphid life table data indicated similar trends in distribution. Thus, there was no significant effect of blocking or time of experimentation, and the raw data for all four experiments were pooled and analyzed.

At the 95% CI, there were no significant differences in the aphid population parameters on plain water only compared to when the respective solvents were mixed with water. Similarly, there were no significant differences between aphid performance on plain water diet and 0.5 M sucrose diet plus solvents (Table 1). However, specific orthogonal contrasts indicated that all aphid life table param-

TABLE 1. SUMMARY OF COWPEA APHID LIFE TABLE DATA[a]

Diet	Survival l_x[b]	Intrinsic rate of increase, r_m	Net reproduction rate, R_0	Generations (N)
Water	0.43 ± 0.001	0.22 ± 0.001	8.5 ± 1.02	1.2 ± 0.05
Water + hexane	0.61 ± 0.18	0.25 ± 0.05	6.5 ± 1.72	0.9 ± 0.12
Water + ethyl acetate	0.38 ± 0.07	0.31 ± 0.12	6.8 ± 0.92	1.0 ± 0.11

[a] Based on diet treatments of distilled water or 0.5 M sucrose solution only, and where 100 μl of hexane or ethyl acetate or methanol are added to either medium (means ± 95% CI).

[b] Proportion of cohort individuals surviving to adult stage to reproduce; arcsin transformed data (N = 30)

eters estimated were significantly reduced ($F_{1,60} = 4.03$, $P \leq 0.05$) on plain water diet compared to the sucrose diet. Those two treatments were used as the control checks in comparing effects of the various leaf extracts of the two cultivars.

ANOVA revealed that in comparison with the respective controls of water or sucrose diets, there were significant effects of ICV-12 extracts on aphid survival to the adult stage for both extracts in water ($F_{8,207} = 27.04$, $P < 0.001$) and extracts in sucrose ($F_{8,211} = 43.56$, $P < 0.001$) (Figure 1). Furthermore, there was a decreased number of generations for extracts in sucrose ($F_{8,211} = 10.98$, $P < 0.001$) (Figure 2).

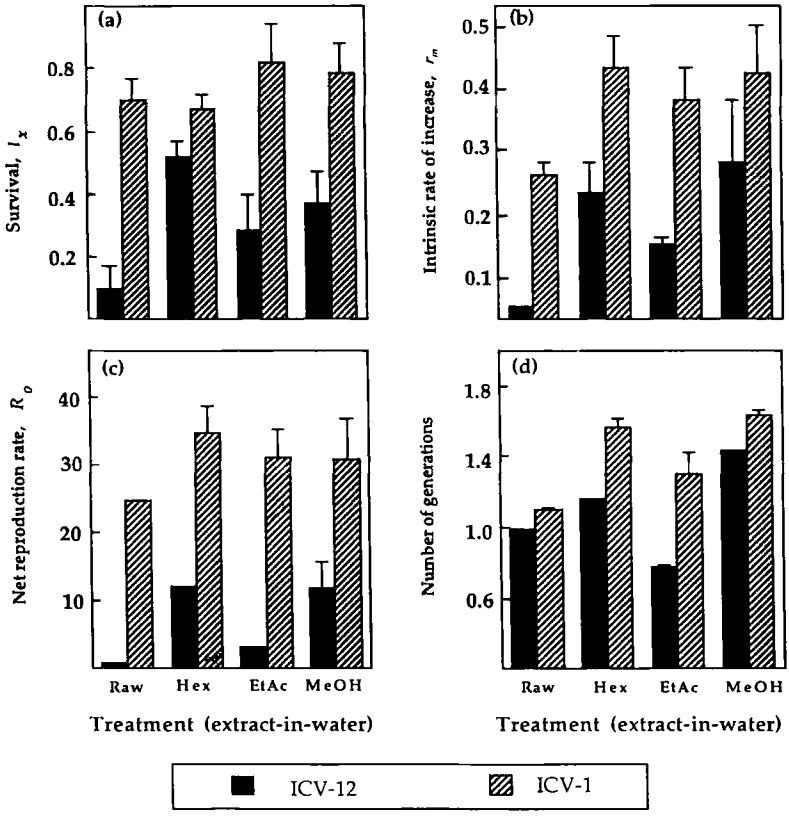

FIG. 1. Interactions between cowpea cultivar and treatments of leaf extracts in water, on cowpea aphid life table parameters: (a) survival l_x, (b) intrinsic rate of increase r_m, (c) net reproduction rate R_O, and (d) number of generations, (means ± 95% CI; $N = 24$).

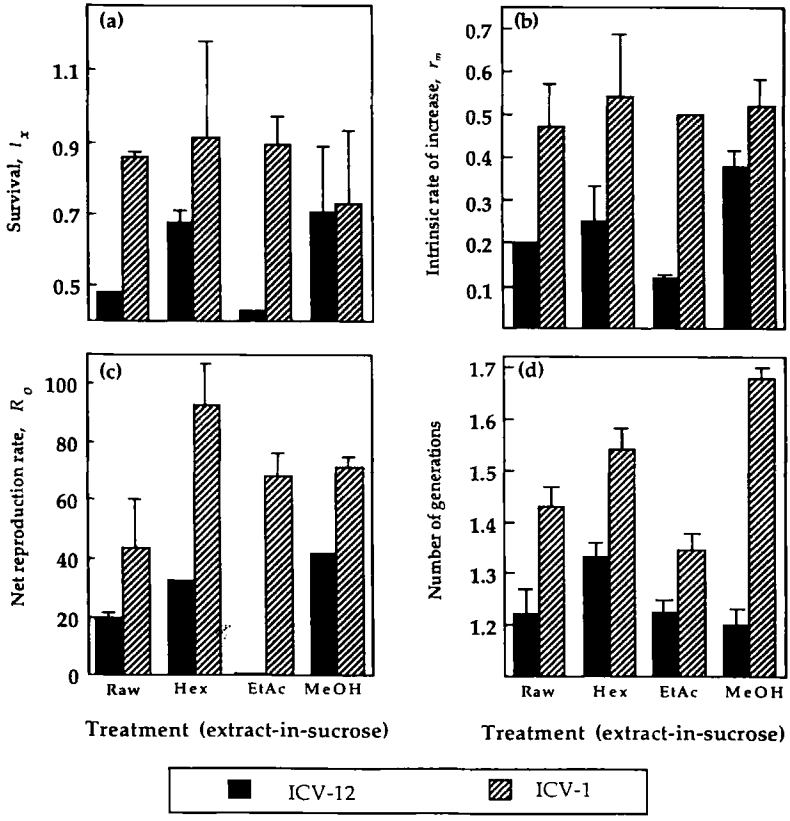

FIG. 2. Interactions between cowpea cultivar and treatments of leaf extracts in sucrose, on cowpea aphid life table parameters: (a) survival l_x, (b) intrinsic rate of increase r_m, (c) net reproduction rate R_O, and (d) number of generations; (means ± 95% CI; N = 24).

Compared to similar extracts of ICV-1 foliage, the ethyl acetate extract and raw juice of ICV-12 significantly impaired all life table parameters of cowpea aphid. Compared to the ICV-1 methanol extracts, the same fractions of ICV-12 had variable activity. ICV-12 methanol extract in water significantly limited aphid survival and net reproductive rate (Figure 1), while the same extract in sucrose reduced the intrinsic rate of increase and net reproduction rate (Figure 2). For ICV-12, the ethyl acetate extract and raw leaf juice in both water and sucrose media generally reduced cowpea aphid performance to a greater extent than did the hexane and methanol extracts. The exceptions were in water, where activity of the ethyl acetate extract was not significantly different

from the methanol extract activity for aphid survival to adult stage, and in sucrose, where the raw leaf juice activity did not significantly differ from the hexane extract for intrinsic rate of increase. Furthermore, activity of both ethyl acetate extract and raw leaf juice of ICV-12 in sucrose were not significantly different from the methanol extract for the number of generations.

Thus, the long-term adverse effects of ICV-12 extracts on aphid reproduction and growth performance were greater than those of ICV-1. The levels of reduction in aphid performance by both the ethyl acetate extract and raw leaf juice of ICV-12 were not mitigated in sucrose medium, but in the cases of net reproduction rate and number of generations produced, the effects were even more severe.

DISCUSSION

Cowpea aphid survival, growth, and reproductive biology were adversely affected by ethyl acetate extracts and raw leaf juices of the aphid-resistant ICV-12 cultivar, indicating the presence of unidentified chemical resistance factors in the foliage of that cultivar. Antibiosis activity of the ethyl acetate fraction was pronounced and was not reduced in the sucrose medium. This suggested the possibility of feeding deterrence activity in that fraction. However, using electrical penetration graphs of *A. craccivora* feeding behavior, Annan (1992) determined that individual aphids readily fed on ICV-12 leaf extracts, suggesting that the resistance factor would also most likely act as a postingestive intoxicant. Hence, the author concluded that the observed field aphid resistance in the ICV-12 cultivar was governed by both antixenosis and antibiosis. This assertion corroborated the findings of Givovich et al. (1988) and Firempong (1988) with *A. craccivora* feeding on the same cowpea cultivar. Similar studies and findings of resistance to other aphids species in various crop cultivars also have been well-documented (Niassy et al., 1987; van Helden and Tjallingii, 1993; Tjallingii, 1985; van Helden, 1995).

In comparison to other solvents, ethyl acetate extracts contain many phenolics and other secondary compounds, whereas methanol extracts contain mainly glycosides and other sugar derivatives. Hexane extracts contain mainly nonpolar materials such as leaf waxes, fatty acids, and cholorophyll (J. A. A. Renwick, personal communication). The possible involvement of flavonoids, phenols, and coumarins from the ICV-12 ethyl acetate extract in impairment of cowpea aphid performance is consistent with previous reports on that cultivar and other resistant cowpea cultivars by MacFoy and Dabrowski (1984), Lattanzio et al. (1990), and Mansour et al. (1982). While we did not determine the exact components of the ethyl acetate extracts, the high activity of that fraction, coupled with the findings in those previous studies on the chemical composition of similar extracts from cowpeas, suggested the involvement of phenolics in the aphid resistance

of ICV-12. None of the fractions of ICV-1 extract produced any significant impairment of aphid performance in either water or sucrose medium, nor did any of the various ICV-1 extracts differ from each other.

Although the sucrose diet was used as a control treatment to ensure maximal aphid feeding, continual rearing of aphid generations on it was not possible, perhaps because the diet lacked other nutrients that are essential for optimal survival, growth, and reproduction of aphids. When compared to bioassays on intact plants and excised plant parts reported elsewhere (Annan, 1992), there were sharp declines in net reproduction rate and intrinsic rate of increase of aphids. This can be partially attributed to the lack of other essential nutrients in the sucrose diet. Nevertheless, since sucrose diet provided better nutrition and thus enhanced aphid performance than just plain water in earlier tests (Table 1), it was a suitable medium for the plant extracts.

Leaf waxes were implicated in aphid resistance in barley (Tsumuki et al., 1989). However, due to the lack of activity of the hexane extract, which should have extracted leaf waxes, chlorophyll, and fatty acids, and since the ethyl acetate extracts that produced deleterious effects on aphid performance would not contain waxes and other leaf surface materials, we suggest that those factors probably do not contribute to aphid resistance in ICV-12. Similarly, we would argue that glycosides and other factors extracted in the methanol extracts also do not contribute significantly to aphid resistance in that cultivar.

Seedling foliage of both varieties is already extensively used for human consumption and in livestock feeds in East Africa and other tropical regions. The seedling leaf factors that were extracted in the ethyl acetate fraction and that were involved in ICV-12 impairment of *A. craccivora* performance could therefore have specific aphicidal properties, but little or no toxic effects to humans or livestock. However, both size and the relative amounts of leaf material ingested are likely to be potential factors in toxicity.

(Received September 7, 1995; accepted March 22, 1996)

Abstract—The involvement of the glucoalkaloid strictosidine in antimicrobial and antifeedant activity in *Catharanthus roseus* leaves was investigated. Strictosidine and its deglucosylation product, specifically formed by the enzyme strictosidine glucosidase, were shown to be active against several microorganisms. In contrast, neither the intact glucoside, nor the aglycone product(s) was found to exhibit antifeedant activity against *Spodoptera exigua* larvae, as was found for intact *C. roseus* leaves and leaf extracts. Besides alkaloids further downstream in the biosynthesis pathway, a more apolar, yet unidentified compound may be involved in this activity.

Key Words—Antifeedant, fungi, bacteria, *Spodoptera exigua*, *Catharanthus roseus*, *Fusarium solani*, *Fusarium oxysporum*, *Trichoderma viride*, *Cladosporium cucumerinum*, *Phytophthora infestans*, strictosidine, strictosidine glucosidase, indole alkaloids.

INTRODUCTION

Madagascar periwinkle *Catharanthus roseus* (L.) G. Don (Apocynaceae) is a plant of pharmaceutical interest since it produces a number of important sec-

[3]Current address: Division of Pharmacognosy, Uppsala University, Box 579, S-75123 Uppsala, Sweden.

ondary metabolites used in medicine. For example, the dimeric alkaloids vinblastine and vincristine are invaluable in the treatment of acute lymphatic leukemia (DeConti and Creasey, 1975; Neuss and Neuss, 1990).

The reason why the plant produces these compounds is still unclear. It has been suggested that these chemicals function as defenses against herbivores. Indeed, antifeedant activity against polyphagous *Spodoptera* larvae has been reported for *C. roseus* extracts (Chockalingam et al., 1989), and for the alkaloids vinblastine and catharanthine (Meisner et al., 1981). The reported induction of biosynthesis of these indole alkaloids in *C. roseus* after moderate wounding (Frischknecht et al., 1987) supports such a defense mechanism. Alkaloids from *C. roseus* have also been reported to show antimicrobial activity. For example, ajmalicine, catharanthine, and vindoline appeared to inhibit bacterial and fungal growth (Hernandez, 1979). These compounds may therefore be multifunctional in their biological role. However, it is not evident whether the antifeedant and antimicrobial effects of *C. roseus* extracts are solely caused by the mentioned alkaloids; more compounds might be involved in this activity.

In this paper, the involvement of strictosidine (**1**; Figure 1) in the chemical defensive system of *C. roseus* was studied. This glucoalkaloid is considered to

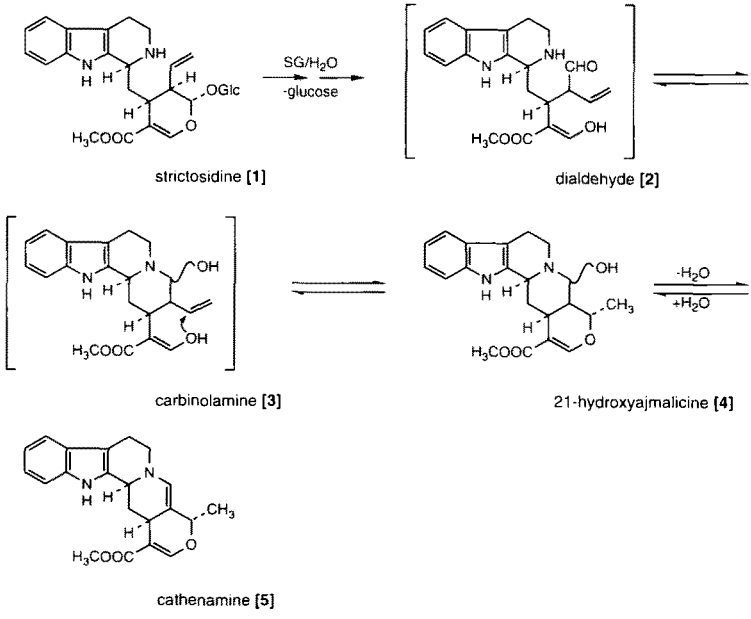

FIG. 1. Scheme showing the conversion of strictosidine and subsequent steps in *C. roseus*.

be the general precursor of all monoterpene indole alkaloids (Stöckigt and Zenk, 1977). It is formed by condensation of secologanin with tryptamine in a reaction catalyzed by the enzyme strictosidine synthase (SSS; EC 4.3.3.2). It has been shown that this reaction takes place inside the cell vacuole (McKnight et al., 1991). The occurrence of strictosidine itself can be confirmed in extracts of the plant (particularly in young leaves), suggesting the existence of a vacuolar pool. The converting enzyme, strictosidine glucosidase (SG; EC 3.2.1.105), is suspected to be located on the outside of the vacuolar membrane (Stevens et al., 1993). In this way, the substrate can be deglucosylated only if this barrier is overcome, either when transported over the vacuolar membrane or when the membrane is actually damaged.

The hypothesis we tested is that the strictosidine pool inside the cell vacuole serves in a "trigger mechanism" in which cell damage leads to strictosidine deglucosylation, resulting in the formation of compound(s) with antimicrobial and/or antifeedant activity. Concentration of SG on the vacuolar membrane guarantees a high turnover rate of the substrate. Strictosidine deglucosylation leads, via a number of reactive intermediates (Stöckigt et al., 1978), to 21-hydroxyajmalicine (**4**; see Figure 1) (Stevens, 1994).

A similar trigger mechanism has been reported for *Tulipa* (Beijersbergen and Lemmers, 1972), and for oat (*Avena sativa*) leaves. In the latter, vacuolar glucosides were shown to be involved in a mechanism in which deglucosylation by a specific tonoplast avenacosidase yields aglycones with a strong antifungal activity (Kesselmeier and Urban, 1983; Grünweller and Kesselmeier, 1985). In our paper, the involvement of strictosidine and SG in the antifeedant activity of *C. roseus* leaves was investigated. For comparison, the activity of constitutive compounds further downstream in the indole alkaloid biosynthetic pathway was investigated by using *C. roseus* leaf extracts. As test organisms, larvae of beet army worm, *Spodoptera exigua* (Noctuidae), were used since species of this genus are generally polyphagous; they have proven to be useful for judging antifeedant activity of alkaloids (Meisner et al., 1981; Chockalingam et al., 1989).

Antimicrobial activity of strictosidine and its turnover products was investigated by in vitro incubation of several species of plant fungi and bacteria in different concentrations of strictosidine (both with and without SG).

METHODS AND MATERIALS

Chemicals were from Merck, except for *p*-methylhydroxybenzoate, ascorbic acid, tryptamine hydrochloride, and secologanine (Aldrich), and vancomycine (Duchefa, Haarlem, The Netherlands). Organic solvents were distilled prior to use. The secologanin obtained was further purified over a silica gel column

by using a stepwise acetone gradient (0–50%) in ethyl acetate. Strictosidine was synthesized by condensation of secologanin with tryptamine catalyzed by purified strictosidine synthase from *C. roseus*, immobilized on a column of CNBr-activated Sepharose (Pharmacia) (Pfitzner and Zenk, 1982).

C. roseus plants were grown in a greenhouse at 20°C and 70% humidity, in a 16-hr/8-hr day–night regime. Ten plants were used to prepare a leaf extract by grinding 11.8 g of freshly picked leaves in 200 ml of methanol–HCl 0.02 M (1:1, v/v), using an Ultra-Turrax. A part of this extract was lyophilized. This dry extract was used to prepare different concentrations of extract in methanol for testing. Alkaloids were determined in the extract by HPLC with photodiode array detection (van der Heijden et al., 1987). A linear gradient of acetonitrile (15–50%) was the eluent. Quantification of strictosidine was made from an external standard. Catharanthine, vindoline, and anhydrovinblastine were quantified from absorbances at their respective UV maxima, using molar absorption coefficients reported in the literature (Hesse, 1964, 1968).

The SG used was partially purified from *C. roseus* cell cultures (Luijendijk, unpublished data). SG activity was determined using the HPLC assay described by Stevens et al. (1993). SG stability was tested by incubating a part of the enzyme solution at 25°C for 24 hr. Regularly a sample was taken and frozen at −80°C. The collected samples were then assayed for SG activity.

Test Organisms. Larvae of *Spodoptera exigua* (Lepidoptera: Noctuidae) were reared on an artificial diet consisting of maize grains (224 g), brewer's yeast (60 g), wheat germ (56 g), agar (40 g), ascorbic acid (9.6 g), benzoic acid (2.4 g), methyl-*p*-hydroxybenzoate (2 g), and vancomycin (50 mg), prepared in 1360 ml of water. Larvae were kept at 23°C and 70% relative humidity in a controlled 16-hr/8-hr day–night regime. Larvae were used when they reached the L4 stage (approx. 10 days after hatching), in order to assure good feeding and accurate weight measurement. The larvae were offered leaves of winter purslane (miner's lettuce), *Claytonia perfoliata* Willd., a vegetable not known to produce alkaloids, that had been treated with different amounts of test substances. This vegetable was chosen because of its suitability as food for *Spodoptera* larvae and its relatively flat leaves, facilitating quantification of herbivory by leaf area measurements. Single larvae were starved for 3 hr, weighed, and transferred to separate Petri dishes containing one test leaf per dish together with a moistened piece of filter paper. The *C. perfoliata* leaves were treated with 100 μl of test solution (Figure 2) and dried at room temperature to allow evaporation of the solvent (methanol) before feeding the leaves to the larvae. In the control series E and F, leaves were treated with solvent only. For each concentration of test substance, 10 Petri dishes were used. For determination of antifeedant activity, larval weight increase and leaf area decrease after 24 hr and 48 hr were measured. For the measurement of leaf areas, a video-operated

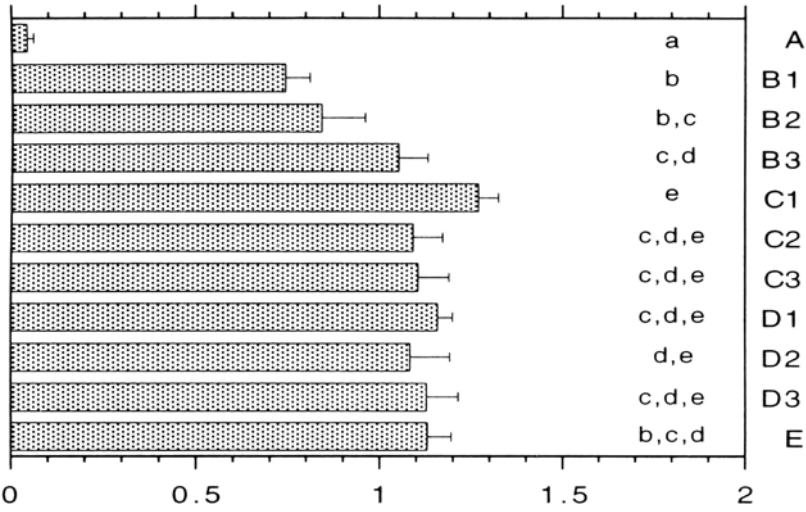

FIG. 2. Preference indices for *Spodoptera exigua* feeding for 48 hr on leaves ($N = 10$ per series) treated with the following test substances:

Series	Foliage	Test Solution
A	*Catharanthus roseus*	none
B1	*Claytonia perfoliata*	*C. roseus* leaf extract (5× conc)
B2	*Claytonia perfoliata*	*C. roseus* leaf extract (undiluted)
B3	*Claytonia perfoliata*	*C. roseus* leaf extract (5× diluted)
C1	*Claytonia perfoliata*	200 μg strictosidine
C2	*Claytonia perfoliata*	40 μg strictosidine
C3	*Claytonia perfoliata*	4 μg strictosidine
D1	*Claytonia perfoliata*	as C1, with 100 μl SG sol. (0.13 nKat) applied to the other side of the leaf
D2	*Claytonia perfoliata*	as C2, with 100 μl SG sol. (0.13 nKat) applied to the other side of the leaf
D3	*Claytonia perfoliata*	as C3, with 100 μl SG sol. (0.13 nKat) applied to the other side of the leaf
E	*Claytonia perfoliata*	100 μl SG solution (0.13 nKat)

Error bars indicate the standard errors per group. The lowercase letters a, b, c, d, e indicate the categories in which the test series could be grouped according to a multiple range analysis.

planimeter was used. After 48 hr, the larvae were frozen in liquid nitrogen and extracted with methanol by homogenization with a glass rod.

In a different set-up, analogous to that described by Kubo (1991), larvae were offered a choice of pieces of artificial diet prepared with *C. roseus* extracts.

For this purpose the original methanol–hydrochloric acid extract was freeze-dried and redissolved in (A) 0.1 M NaOH or (B) 0.1 M HCl, and extracted using dichloromethane. The antifeedant effects of these extracts and of the aqueous layers after extraction were compared with those of the original methanol–hydrochloric acid extract, a leaf extract prepared with petroleum ether (boiling range 60–80°C), and a control without additions.

Test media were prepared in small portions by adding the extract to one of the constituents of the artificial medium and subsequent evaporation of the solvent, before preparation of the medium.

A total of 49 larvae (seven per plate) was offered the choice between seven disks (diameter 8 mm) of these diet media. Four times during 24 hr (after 1, 5, 12, and 24 hr), the diet preference of the larvae was assessed by counting larvae on the different disks.

For the antifungal activity tests, *Fusarium solani*, *Fusarium oxysporum*, and *Trichoderma viride*, originally isolated from fruits (Department of Phytopathology, Wageningen), and *Cladosporium cucumerinum* (CBS 177.54) were grown on potato dextrose agar. *Phytophthora infestans*, originally isolated from potato (Department of Phytopathology, Wageningen), was grown on rye agar. The bacterial strains *Escherichia coli* (ATCC 8739) and *Bacillus subtilis* (ATCC 6633) were maintained in CASO broth. All media mentioned were obtained from Merck.

All dilutions and inoculations were carried out under sterile conditions. Fungal tests were performed in 24-well or 96-well microtiter plates with 250 μl or 50 μl of potato dextrose agar, respectively. Per well, approx. 600 sporangia (in 50 μl) were added to the 24-well plates, and approx. 150 sporangia (in 25 μl) to the 96-well plates. Germination was allowed for 6 hr at 25°C, after which 100 μl of test solution was added to each well (50 μl for the 96-well plates). Test solutions were prepared in 50 mM potassium phosphate buffer (pH 6.0) (15 mM phosphate, with 20 mM sodium chloride for *Phytophthora infestans*), and sterilized by filtration through 0.2-μm cellulose acetate filters (Schleicher & Schüll). Buffer exchange of the SG preparations was performed by gel filtration over Sephadex G-25 (PD-10 columns, Pharmacia). For most species, a concentration range of 0.003–25 mM of strictosidine was tested in duplicate (nine concentrations, four wells per concentration) and compared to a similar range of strictosidine concentrations in the presence of SG (75 pKat, 1 Kat defined as the enzyme activity converting 1 mole of strictosidine per second, at 30°C). As controls, similar tests were done using preincubated strictosidine–SG mixtures, SG solution alone, and inactivated SG solution to exclude the possibility of the enzymes solution itself being active on microbial growth. Control of inhibition was done with nystatin (1 mg/ml).

Comparative incubations were done with ajmalicine and yohimbine. It was necessary to use a solubilizing agent for ajmalicine; Tween 80 in a concentration of 0.25% was found to solubilize the compound sufficiently without itself having

any influence on fungal growth. The preparations were sterilized by autoclaving for 20 min (121°C, 1 bar overpressure). Ajmalicine proved to be stable during this procedure. All incubations were done in the dark at 25°C until good growth was obtained in the control wells (usually after 72 hr). Growth was judged visually before and after staining the mycelia with lactophenol cotton blue. Minimum inhibitory concentration values were determined from the lowest concentrations in the wells not showing fungal growth. For more detailed investigation a Nikon binocular microscope was used.

Tests with bacteria were carried out using liquid media (CASO broth) in glass test tubes. In a total volume of 260 μl (125 μl CASO, 100 μl strictosidine in aqueous solution, 25 μl = 75 pKat SG solution, 10 μl inoculum), bacteria were incubated in the presence of a range of strictosidine concentrations (0.05–0.5 mM). For each concentration tested, three tubes were used. After 16 hr of incubation at 37°C, growth was determined by the turbidity of the solutions.

RESULTS AND DISCUSSION

Alkaloid contents found in fresh *C. roseus* leaves are summarized in Table 1. Noteworthy is the relative low content of strictosidine compared to the compounds further downstream in the biosynthetic pathway. This is in accordance with earlier results, which showed that strictosidine in indole alkaloid-producing plants is mainly formed in the young leaves, while later products are predominantly found in older leaves (Aerts et al., 1991; Naaranlahti et al., 1991). SG activity of the tested solution was found not to be affected by incubation at 25°C, since no activity loss was observed, even after 24 hr. Therefore, it was concluded that the enzyme was stable enough to be used in the tests for biological activity.

Antifeedant Tests. Figure 2 shows the preference indices (PI) derived from the antifeedant tests after 48 hr, in which $PI = 2T/(C + T)$. In this formula,

TABLE 1. CONTENT OF SOME INDOLE ALKALOIDS IN MATURE AND YOUNG *C. roseus* LEAVES[a]

	Mature leaves		Young leaves	
	μmol/g FW	μg/g FW	μmol/g FW	μg/g FW
Strictosidine	0.12 ± 0.06	63 ± 29	0.50 ± 0.06	260 ± 30
Catharanthine	0.79 ± 0.10	260 ± 30	2.32 ± 0.12	780 ± 40
Vindoline	0.45 ± 0.05	200 ± 20	n.d.	n.d.
Anhydrovinblastine	1.03 ± 0.07	820 ± 60	n.d.	n.d.

[a]Averages (and standard deviations) are given for three extractions of 40 leaves each. (n.d. = not determined)

C is the leaf area eaten in the control, and T is the area eaten from the test leaves. Thus, a PI = 0 implies a strong deterrent activity of the test substance, PI = 1 no preference, and PI = 2 a strong rejection of the control or preference for the test substance (Kogan and Fischer, 1991). The data were normally distributed in each group. No toxic effects of the applied test solutions were suspected, since only two of the larvae died during the experiment.

A one-way analysis of variance (ANOVA) of the PI values demonstrated significant differences in the antifeedant activity between the tested groups ($\phi = 11$, $F = 19.24$, $P < 0.0001$). To test which groups differed from each other, a multiple-range analysis was used to distinguish between homogeneous groups (Figure 2). Group A (*C. roseus* leaves) was significantly different from all other groups, and group B1 (the highest concentration of *C. roseus* leaf extract) was different from all others but group B2. The average activity in the leaf extract preparations (B1, 2, and 3) seemed to follow the applied concentration. The activity of these *C. roseus* leaf constituents was accentuated by the fact that the highest applied amount of leaf extract (B1) accounted for the contents of only 10% of an average *C. roseus* leaf, as calculated from the leaf area.

The results presented here confirmed the presence of antifeedant compounds in *C. roseus* leaves, since the acidic methanol extract already showed a significant activity. The involvement of strictosidine, however, seems to be unlikely. Both the series with strictosidine solution applied alone and the ones with strictosidine and SG combined showed no significant antifeedant activity, even though the highest concentrations (C1 and D1) were more than an order of magnitude higher than the concentrations in vivo in old leaves, and three times higher than in young leaves. The proposed trigger mechanism, in which the active compound is only formed by enzymatic conversion after plant damage, is therefore not likely to be an important factor in the plant's defense against this insect herbivore. A chemical turnover of the aglycone product during the test procedure cannot be excluded, but is unlikely since cathenamine is reported to be stable and precipitates on formation (Stevens, 1994). There is the possibility that the tested compounds might show effects towards other insect species less polyphagous than the *Spodoptera* species tested here.

No strictosidine could be retrieved from the larvae fed with strictosidine and SG combined, so an inactivation of SG by the feeding larvae or by the plant material is not likely. Strictosidine itself was probably not affected by nonspecific decomposition since significant amounts could be retrieved by methanol extraction of the larvae fed with leaves treated with strictosidine alone (results not shown). Apparently the larvae were not harmed by this compound, which was retrieved in concentrations up to 30 μg/g body weight.

Experiments in which the test extracts were incorporated in the rearing medium of the *Spodoptera* larvae showed that the active compounds in the methanol–hydrochloric acid extract were largely present in the alkaline dichloromethane preparation made from this extract, indicating an alkaloidal nature.

However, the other fractions obtained from this preparation were not preferred by the larvae either; the untreated preparation was significantly favored (Kruskal-Wallis test, $P < 0.05$). Not only the MeOH–HCl extract showed a pronounced antifeedant activity, but so did a petroleum ether leaf preparation (Figure 3). Since alkaloids are too polar to be extracted with petroleum ether, the involvement of other active compounds is suspected. This suggests the presence of antifeedant compounds of a very apolar nature, which might therefore be present in the wax layer of the leaves, thus presenting a chemical barrier against herbivores. The findings that *C. roseus* leaves were mostly left untouched by the tested larvae and the antixenotic (as opposed to antibiotic) nature of the components support this hypothesis. Alkaloids are predominantly found deeper down in the *C. roseus* mesophyll since idioblasts were found to contain a significantly higher alkaloid concentration (Mersey and Cutler, 1986), making these products less likely to be responsible for this result. Further research into the apolar fraction may give more clarity in this respect.

Antimicrobial Tests. After 72 hr of incubation, the higher concentrations of tested substances showed clear growth inhibition. Growth was normal in the controls. Any influence by the enzyme preparation itself, or by the buffer used,

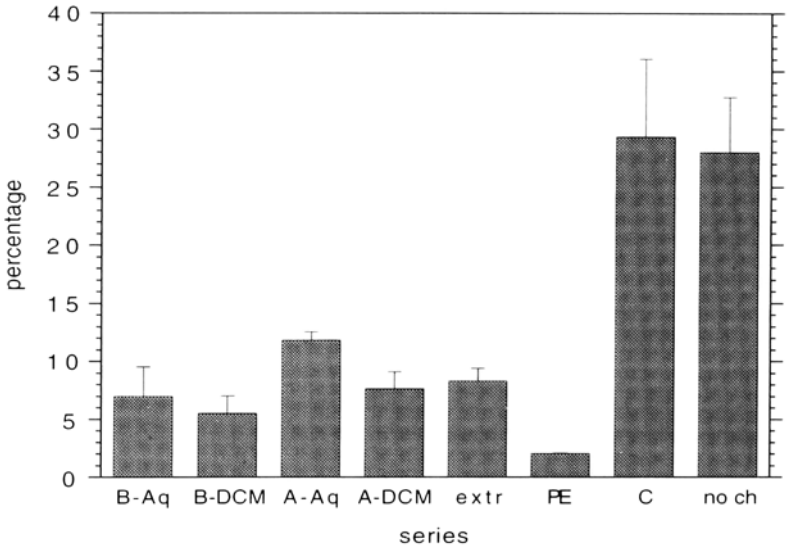

FIG. 3. Percentage of *Spodoptera exigua* larvae present on seven pieces of feeding media prepared with different *C. roseus* extracts. Average values and standard errors are shown for four time points during 24 hr. B-Aq = basic aqueous fraction after DCM extraction, B-DCM = basic DCM extract, A-Aq = acidic aqueous fraction after DCM extraction, A-DCM = acidic DCM extract, extr = original acidic MeOH leaf extract, PE = petroleum ether leaf extract, C = control, no ch = no choice.

TABLE 2. MINIMUM INHIBITORY CONCENTRATION OF STRICTOSIDINE AND STRICTOSIDINE IN COMBINATION WITH STRICTOSIDINE GLUCOSIDASE (SG) TO SEVERAL FUNGAL SPECIES

Species	Strictosidine (mM)	SG/strictosidine (mM)
Fusarium solani	25	0.33
Fusarium oxysporum	25	0.33
Trichoderma viride	10	1
Cladosporium cucumerinum	>1	0.33
Phytophthora infestans	<0.008	<0.008

could thus be excluded. In all cases fungal growth was inhibited in the presence of nystatin. From Table 2 a clear difference can be seen in the minimum inhibitory concentration (MIC) values of strictosidine compared to those of strictosidine that was converted by SG. For several species, the MIC value of strictosidine/SG was around 0.33 mM. Only *Phytophthora infestans* showed a different pattern; even the slightest addition of strictosidine inhibited development, suggesting a strong antifungal activity of strictosidine against this phytopathogen. On the other hand, this activity may not necessarily be specific, since *Phytophthora infestans* has been reported to be very susceptible to differences in culture conditions (Woloshuk et al., 1991).

Microscopic study of the fungal material in the other species present in concentrations just below the MIC value showed that hyphae were thinner and showed no or only very few divisions, as compared to those in controls. This might suggest an action on the developing hypha membrane or cell wall, causing a lethal lysis. No sporangicidal effects by the tested substances could be determined.

Comparison of incubations of strictosidine with SG in situ, or with SG before addition to the developing fungi (thus allowing a complete turnover of strictosidine to 21-hydroxyajmalicine), showed marked differences; this suggests this product to be the active compound. However, it is possible that an equilibrium exists in the rearrangements of the aglycone after SG-mediated hydrolysis, providing a sufficient concentration in situ of one of the intermediates for expression of its antifungal activity.

Although the MIC value of 0.33 mM (180 μg/ml) may not be as low as those for some other antifungally active alkaloids, e.g., cryptopleurine (0.3 μM; Al-Shamma et al., 1982), it may indicate an antifungal function in vivo, since strictosidine concentrations in young *C. roseus* leaves of 260 μg/g fresh weight and SG levels of 750 pKat/g were found. In contrast, older *C. roseus* leaves were found to contain significantly lower levels of both strictosidine and SG. The young leaves, vulnerable during their development, may very well be using these high levels of strictosidine as a protective mechanism.

For comparison, similar assays were performed using two other corynan-

thean type alkaloids, yohimbine and ajmalicine, as test substances. No influence on fungal growth was observed in the concentration range used (0.008–0.83 mM). This is an indication that the antimicrobial activity found in the strictosidine/SG assays is not related to the general structure of the corynanthean type of indole alkaloids but is more specifically caused by 21-hydroxyajmalicine (**4**) or cathenamine (**5**) formed after strictosidine deglucosylation.

Bacterial assays showed growth inhibition of *B. subtilis* for concentrations over 0.1 mM strictosidine in the presence of SG, while strictosidine alone did not show any effect. *E. coli* was only inhibited at the highest concentration tested (0.5 mM strictosidine, with SG), again with no effect in incubations with strictosidine alone. It thus represented a similar situation to that described in most antifungal tests. Therefore, an antimicrobial compound seems to be involved that is formed only after deglucosylation of strictosidine.

CONCLUSIONS

Strictosidine, and especially its aglycone product, were shown to possess antifungal activity in vitro. The compounds may therefore be involved in an antimicrobial defense system in indole alkaloid-producing plants. In particular, the turnover product, after deglucosylation by SG, shows activity at physiological concentrations. The subcellular separation of strictosidine formation and conversion (by SG) in *C. roseus* may serve a trigger mechanism against such infections. On the other hand, this defensive system does not seem to be involved in the antifeedant activity *C. roseus* leaves show against *Spodoptera exigua* larvae. In addition to an acidic methanol extract, a petroleum ether extract of *C. roseus* leaves also showed antifeedant activity, suggesting an apolar nature of some active compound(s). The indole alkaloids present in the leaves of *C. roseus*, reported in previous studies to show antifeedant potential, may therefore not be the only compounds responsible for the in vivo activity.

(Received October 27, 1995; accepted March 27, 1996)

Abstract—This study considered how host plant allelochemicals may contribute to defense against insects and fungi that jointly colonize the subcortical tissues of trees, the relative roles of constitutive and inducible chemistry in these defenses, and how the actions of two different feeding guilds might be interrelated. Our model consisted of the coniferous tree *Pinus resinosa*, the root- and lower stem-colonizing beetles *Hylastes porculus* and *Dendroctonus valens*, and their associated fungi *Leptographium procerum* and *L. terebrantis*, and the stem-colonizing bark beetle *Ips pini* and its associated fungus *Ophiostoma ips*. In a novel bioassay, extracts from reaction tissue elicted by wound inoculation with *L. terebrantis* were more repellent to beetles than were similar extracts from constitutive or mechanically wounded tissue. The effect on beetle behavior was more pronounced in nonpolar extracts, which contain mostly monoterpenes, than in polar extracts, which contain mostly phenolics. Synthetic monoterpenes at concentrations present in the various tissues exerted similar effects and were likewise repellent in dose–response experiments. Growth of *L. procerum* and *L. terebrantis* was inhibited by polar extracts from constitutive and reaction tissue. Inhibition was higher in wounded than control tissue, but the inhibition response did not vary with the type of wounding. Synthetic monoterpenes strongly inhibited spore germination and mycelial growth of both fungi. Colonization of red pine roots by *Leptographium* spp. altered the subsequent effects of extracts of stem phloem tissue on *I. pini*. These effects varied with host condition. Beetles preferred extracts from constitutive stem phloem tissue of healthy trees to that of root-diseased trees. However, extracts from reaction tissues of healthy trees were more repellent

to *I. pini* than were the reaction tissues of root-diseased trees. The implications of these results to plant defense against insect-fungal complexes and interactions among different feeding guilds are discussed.

Key Words—Insect-fungal interactions, host selection, plant stress, forest decline, monoterpenes, phenolics, bark beetles, *Ophiostoma ips*, *Ips pini*, *Dendroctonus valens*, *Hylastes porculus*, *Leptographium procerum*, *Leptographium terebrantis*, *Pinus resinosa*.

INTRODUCTION

Plant parasitic insects and plant pathogenic microorganisms are confronted with similar defensive mechanisms when invading potential host plants (Schultz, 1983; Krischik et al., 1991; Hammerschmidt, 1993); yet the chemical ecology of plant defense against these organisms has largely been studied separately. Recent discussions of plant defense theory emphasized the need for integrated studies on plant-insect-microbial interactions (e.g., Barbosa et al., 1991; Schowalter and Filip, 1993). Bark beetle (Coleoptera: Scolytidae)-ophiostomatoid fungi complexes that colonize living conifers provide a valuable system for comparing host plant defenses against herbivory and disease. Most bark beetle species vector only a few, or at most several, ophiostomatoid wood-colonizing fungi. These insect-fungal symbioses may initially be mutually advantageous in overcoming host tree resistance (Berryman, 1972; Hemingway et al., 1977; Raffa and Berryman, 1983a; Berryman et al., 1985; Whitney, 1982), but fungi may reduce beetle success during subsequent development (Barras, 1970; Bridges and Perry, 1985; Fox et al., 1983).

The physiology and chemistry of conifer constitutive and induced defenses against attack by phloem-invading complexes have received significant attention. Constitutive defenses include tough outer bark, several classes of allelochemicals, and elaborate networks of resin ducts or glands. Attacks by invading bark beetles elicit localized host responses including rapid formation of resinous lesions around the attack sites (Berryman, 1972; Raffa and Smalley, 1995). In instances of successful tree defense, the beetle and its associated microbes are contained within these lesions. When the tree is unsuccessful, the beetle and microbes colonize and kill host tissue. In these cases, host defensive reactions are only barely apparent and appear to have been exhausted by the rapid arrival of numerous beetle-fungal units mediated by aggregation pheromones (Raffa and Berryman, 1983a,b).

Two classes of allelochemicals, monoterpenes and phenolics, are particularly abundant in conifer subcortical tissue and increase in concentration in response to invasion of living phloem (Jorgensen, 1961; Shain, 1967; Russell and Berryman, 1976; Raffa and Berryman, 1982, 1983b; Hain et al., 1983;

Cook and Hain, 1986; Faeth, 1986; Lorio, 1986; Miller et al., 1986; Paine et al., 1987; Lewinsohn et al., 1991; Herms and Mattson, 1992; Klepzig et al., 1995b). Hence, these compounds have been proposed as important components of chemical defense. Evidence in support of this hypothesis includes observations that monoterpenes can inhibit mycelial growth of beetle-vectored fungi and repel or kill bark beetles under some conditions (Smith, 1963; Cobb et al., 1968; Shrimpton and Whitney, 1968; DeGroot, 1972; Coyne and Lott, 1976; Bordasch and Berryman, 1977; Raffa et al., 1985; Bridges, 1987; Delorme and Lieutier, 1990; Paine and Hanlon, 1994). However, we know little about how host defenses may affect beetle and fungal establishment during the early and most critical phases of this interaction. In particular, integrated studies on how host chemistry affects fungal propagule germination and beetle host-selection behavior are lacking.

We have utilized an insect–fungal complex associated with a forest decline disease to investigate chemical defenses in a coniferous host plant (Klepzig et al., 1991, 1995a,b). This complex includes root-infesting (*Hylastes porculus* Erichson) and stem-infesting (*Dendroctonus valens* LeConte) bark beetles (Scolytidae) that vector two ophiostomatoid fungi, *Leptographium terebrantis* Barras and Perry and *L. procerum* (Kendrick) Wingfield, to red pine (Klepzig et al., 1995a). Colonization by this complex is not lethal to mature red pine. The pine engraver, *Ips pini* (Say) (Scolytidae), colonizes the stem above ground, vectors the fungus *Ophiostoma ips* (Rumb.) Nannf., and ultimately kills declining trees (Klepzig et al., 1991).

In this study we sought to determine the role of monoterpenes and phenolics in the constitutive and inducible defenses of red pine against two insect–fungal complexes from different feeding guilds and examine the effects of previous activity by one feeding guild on subsequent plant-defense reactions against another.

METHODS AND MATERIALS

Two sets of experiments were conducted. The first series evaluated the effects of constitutive and induced allelochemicals on subcortical beetles and their associated fungi. Healthy, mature red pines were wound-inoculated with *L. terebrantis* to simulate natural attacks. Phloem tissue was collected from these inoculations at one and three weeks after inoculation to determine if the host reaction changed with time since inoculation. Extracts from constitutive (unwounded) and reaction (wound-inoculated) phloem tissue were tested in insect behavioral, fungal germination, and fungal growth assays. The monoterpene and phenolic compositions of these extracts were previously reported in Klepzig et al. (1995b). The bioassays were also conducted using defined concentrations

of synthetic monoterpenes that simulated the composition of host constitutive and reaction tissue. The tests with synthetic monoterpenes included both individual compounds and combinations, as recent work demonstrates the importance of synergistic interactions in some systems (e.g., Berenbaum et al., 1989).

A second set of experiments considered how colonization by a member of a root-colonizing guild (*L. terebrantis*, the fungal associate of *H. porculus*) affected host plant interactions with a member of a stem-colonizing guild (*I. pini*). Our previous research demonstrated an association between colonization by *I. pini* and prior root infection with *Leptographium* spp. (Raffa and Klepzig, 1996). In the current set of experiments, the effects of extracts from healthy and root-diseased trees on behavior of stem-colonizing beetles were compared.

Insect and Fungal Culture

Adult *H. porculus* and *D. valens* were collected from red pine plantations and held at 7°C until use. Adult *I. pini* were obtained from a laboratory colony reared in red pine logs using previously described methods (Raffa and Smalley, 1995). Refrigerated slant cultures of *L. terebrantis* (isolate K9013, from an adult *D. valens*, and isolate LT23, from a *Pinus resinosa* Ait. root) and *L. procerum* [isolate LP5, obtained from an adult *Hylobius radicis* Buchanan (Curculionidae)] were transferred to plates of potato dextrose agar (PDA) and allowed to grow for 10–14 days at 24°C.

Host Treatment and Extraction

Healthy, mature red pines were wound-inoculated (Wright, 1933) to the phloem–xylem interface with a 12-mm disk of PDA colonized by *L. terebrantis*, mechanically wounded with a sterile 12-mm cork borer, or left unwounded (constitutive). Reaction lesions were sampled at one or three weeks after inoculation. In the wounding and inoculation treatments, the xylem and phloem tissues containing the resinous reaction lesion were removed with a chisel and transported to the laboratory on Dry Ice. Samples of constitutive tissues of similar size were removed from a randomly chosen site at the same height on the stem, but were otherwise treated the same as wounded and inoculated tissues. The phloem was separated from the xylem and weighed. The phloem was chopped into small ($< 1 \times 1$ mm) pieces and extracted for 24 hr at 25°C, in either polar or nonpolar solvents. Polar solvents were used to extract phenolics. In 1986, tissue samples were extracted in 10 ml of 50% methanol for 24 hr at 25°C. In 1993, tissue samples were extracted in 10 ml of 70% acetone for 24 hr at 25°C. Extracts were filtered through medium-porosity filter paper and stored at −30°C in sealed vials. Constitutive and reaction tissues were extracted in 10 ml of pentane for 24 hr at 25°C to extract monoterpenes. Extracts were

filtered through medium-porosity filter paper and stored at −30°C in sealed vials.

Effects of Induced and Constitutive Allelochemicals on Beetle Host Selection Behavior

Polar extracts (primarily phenolics), nonpolar extracts (primarily monoterpenes), or synthetic pure monoterpenes (Klepzig et al., 1995b) were incorporated into artificial media.

Polar Extracts. A host selection medium was developed to elicit tunneling and feeding behaviors. Melted 1.5% PDA (500 ml) was combined with 80 g of ground, freeze-dried, autoclaved, constitutive red pine phloem from healthy unwounded mature trees. A strip of plastic transparency film was sealed with melted paraffin wax across the middle of a half-section of a two-compartment I-plate Petri dish (Fisher Scientific, Pittsburgh, Pennsylvania). Test extracts were added directly to the two quarter-sections of the Petri plate. A 0.5-ml aliquot of one extract was added to one section of the assay medium, and 0.5 ml of a different extract was added to the other section, such that the resulting concentrations within the medium were similar to those found in an equivalent weight of red pine phloem. Molten host selection medium (15 ml) was mixed thoroughly with the extracts on each side and allowed to solidify, after which the plastic divider was removed. This assay was used to compare the biological acitivity of polar extracts from unwounded phloem tissue and reaction phloem tissue that had been wound-inoculated with *L. terebrantis* and sampled after three weeks on the tunneling behavior of *D. valens*, *H. porculus*, and *I. pini*. Polar extracts from mechanically wounded tissue were not available for use in these assays.

Nonpolar Extracts. A modified medium was prepared from freeze-dried, ground red pine phloem, water, and Bacto-agar (Difco, Detroit, Michigan) 2:0.002:1 (phloem–water–agar). Approximately 1.5 g of medium was pressed into a 5-mm layer within one of the half-sections of a two-compartment I-plate Petri dish, allowed to dry, and divided into two quarter-sections with a razor blade. Nonpolar extracts from constitutive, mechanically wounded, or inoculated trees were concentrated from 2.0 to 0.5 ml under nitrogen. Subsamples (0.25 ml) of these extracts were added to one or the other quarter-section of medium. The pentane was evaporated under nitrogen, and the razor blade divider was removed.

This assay was used to compare the biological activity of nonpolar extracts from unwounded phloem tissue, phloem tissue that had been mechanically wounded and sampled after three weeks, and phloem tissue that had been wound-inoculated with *L. terebrantis* and sampled after one or three weeks. Preliminary assays of the effects of these extracts on *H. porculus* and *I. pini* tunneling

behavior (Klepzig, 1994) revealed no significant differences between extracts of 1-week-old and 3-week-old inoculations. In addition, these two types of extracts were not found to differ significantly in monoterpene composition (Klepzig et al., 1995b). Due to this, and to the availability of extracts, extracts from 3-week-old inoculations were compared to extracts from constitutive phloem, and extracts from 1-week-old inoculations were compared to extracts from 3-week-old mechanical wounds. *D. valens* was only sporadically available during this time period and was excluded from further assays. However, because *H. porculus* was readily available from the field, and a laboratory colony of *I. pini* was readily available during this time period, these two species were used in this assay.

In all of the above assays, a semicircular piece of plastic transparency film was placed on top of the medium and sealed in place with molten paraffin wax. A hole (2–3 mm in diameter) was drilled through the midpoint of the half-section divider, and 4 mm into the medium. The plate was tilted and either one female *D. valens* or *H. porculus*, or one male *I. pini* (the host-selecting sex, respectively) was introduced into the hole. The hole was sealed behind the insect with cotton and transparent tape. The beetle could then enter either of the two quadrants and move freely between them. The lid of each dish was replaced and sealed with Parafilm. All assay chambers were incubated in a dark growth chamber at 24°C and examined daily for three to five days. Each beetle's path was traced, and the distance tunneled was recorded daily. The location of the beetle was also recorded for each assay dish. For purposes of this assay, the beetle was considered to have made no choice between the two extract types if any part of its body lay along the midline separating the two sections of medium. If, at the time of measurement, the beetle was entirely within one of the two sections, it was recorded as being located on that side for that day. For this reason, the percentages of time on either side of the assay chamber often did not add up to 100%. The total amount of tunneling and the percentage of time located in each side were analyzed by ANOVA (Abacus Concepts, 1989). Where significant treatment effects were observed, the means were compared using the protected least squares means procedure.

Synthetic Monoterpenes. Two-way choice assays were used to compare the effects of concentrations of α-pinene, camphene, β-pinene, 3-carene, myrcene, and limonene equivalent to those found in unwounded, mechanically wounded, and wound-inoculated mature red pine phloem (Klepzig et al., 1995b) on tunneling by *I. pini*. *I. pini* was used because of availability from a laboratory colony and also because of its pivotal role as a final mortality agent in red pine decline disease (Klepzig et al., 1991).

The monoterpenes tested comprise approximately 99% of the monoterpene fraction of red pine phloem (Raffa and Smalley, 1995). We calculated the amount

of each monoterpene necessary (milligrams per gram of medium) to simulate the concentrations (milligrams per gram phloem) found in constitutive, mechanically wounded, and wound-inoculated phloem tissues (Klepzig et al., 1995b). Each section of medium (3.65 g) meant to simulate constitutive phloem received only 0.004 ml of α-pinene. All the other major monoterpenes occurred at levels too low to incorporate effectively into the medium. Each section of host selection medium meant to simulate mechanically wounded phloem sampled after three weeks received 0.066 ml α-pinene, 0.022 ml β-pinene, 0.002 ml 3-carene, and no camphene, myrcene, or limonene. Each section of host selection medium meant to simulate *L. terebrantis* wound-inoculated phloem sampled after three weeks received 0.168 ml α-pinene, 0.001 ml camphene, 0.068 ml β-pinene, 0.005 ml 3-carene, 0.001 ml myrcene, and 0.002 ml limonene. The effects of α-pinene and β-pinene on tunneling by *I. pini* were also compared to each other in two-way choice assays using the concentrations of these compounds described above.

The effects of increasing concentrations of α-pinene and β-pinene on *I. pini* feeding were examined in no-choice assays. In one series of assays, beetles were introduced into host selection medium containing 3.4, 6.8, 17.1, 34.3, 171.6, or 343.2 mg α-pinene/g of medium. A separate series of assays was conducted using the same range of concentrations of β-pinene. Mean amounts of tunneling were measured and analyzed as described above.

Effects of Induced and Constitutive Allelochemistry on Fungal Germination and Growth

The effects of host allelochemicals on fungal growth and germination were determined by exposing spores and/or mycelia to polar host extracts and/or synthetic monoterpenes.

Fungal Propagule Germination. The effects of monoterpenes on fungal germination were determined using the synthetic monoterpenes described above. Molten PDA (0.05 ml) was dispensed into the wells of sterile Falcon 96-well tissue culture plates (Becton Dickinson Labware, Lincoln Park, New Jersey), and allowed to solidify. Spore suspensions (200,000 spores/ml) were prepared from actively growing colonies of *L. terebrantis* or *L. procerum* and dispensed in 0.005-ml aliquots into each well. Sterile glass fiber filter paper disks (0.7 cm diameter) were placed so that they fit snugly in the top of each well but did not touch the agar surface 0.5 cm below. Each of the common red pine monoterpenes was assayed at saturated concentrations (200 μl applied to each filter paper disk) against both fungi. Varying concentrations of α-pinene and β-pinene were also tested. A total of 12 assay wells were tested per fungus–monoterpene combination. Plates were incubated, with lids in place, at 20°C in darkness. Mean percentages of germination were calculated for each fungus–monoterpene com-

bination, and compared using the protected least squares means procedure in ANOVA (Abacus Concepts, 1989).

Fungal Growth. Polar extracts from phloem of mature red pine trees (N = 25) that had been left unwounded, aseptically mechanically wounded, or wound-inoculated with actively growing *L. terebrantis* were incorporated into PDA. The crude extracts were first partitioned in chloroform, and the residue was dissolved in 40 μl of a 1 : 1 acetone–water mixture. Molten PDA (1 ml) was dispensed into the vial, the vial was capped and agitated, set horizontally until the agar solidified, and uncapped to allow the acetone to evaporate. A 2-mm-diameter disk of actively growing *L. terebrantis* (isolated LT23) mycelia on PDA was placed face down on the surface of the medium. The vials were capped and incubated at 24°C in the dark. Mean linear growth (millimeters) at three days was calculated. Means were compared using Duncan's multiple range test in the general linear models procedure in SAS (SAS Institute, 1982).

Nonpolar extracts could not be incorporated effectively into molten PDA. Therefore, mycelia of *L. terebrantis* and *L. procerum* were expoed to atmospheres saturated with pure synthetic monoterpenes found to be most prevalent in red pine—α-pinene, camphene, β-pinene, 3-carene, myrcene, limonene, and γ-terpinene (Klepzig et al., 1995b; Raffa and Smalley, 1995). Each assay chamber consisted of a sterile 90- × 15-mm plastic Petri plate (Fisher Scientific, Pittsburgh, Pennsylvania) containing PDA. Each monoterpene (200 μl) was dispensed directly onto a filter paper disk (0.45 cm diameter) fastened to the plate lid with paraffin wax. A disk (0.5 cm diameter) of either *L. terebrantis* (isolate K9013) or *L. procerum* (isolate LP5) mycelia on PDA was placed face down in the center of the assay plate. The lid was sealed into place with Parafilm, and assay chambers were incubated inverted at 20°C in darkness. Chambers with sterile filter paper fastened to their lids served as controls. This experiment was replicated 10 times for each fungus–monoterpene combination (control and myrcene treatments were replicated 20 times). Mean colony diameters at five days were calculated and compared using the protected least squares means procedure in ANOVA (Abacus Concepts, 1989).

Effect of Root Disease on Bark Beetle Host Selection Behavior

We extracted phloem tissue from mature, field-grown red pine to examine the effects of root infection with *Leptographium* on defense against insects and fungi. Test trees were in a 25-year-old red pine plantation in Sauk County, Wisconsin. We had previously determined the levels of infection with *Leptographium* spp. in these trees, relative to their distance from the decline epicenter, by examining and culturing from excavated roots (Klepzig et al., 1991). Inoculations, sampling, and chemical extractions were conducted as described above for trees estimated to have high and low levels of root infection, based on prior

excavations. Monoterpene extracts from constitutive and reaction tissue from these trees, as well as synthetic monoterpenes at concentrations found within these tissues, were incorporated into medium and applied in two-way choice host selection assays with *H. porculus* and *I. pini* as described above.

RESULTS

Effects of Constitutive and Induced Allelochemistry on Host Selection Behavior of Subcortical Insects

Polar Extracts. The relative effects of polar extracts of constitutive versus induced-reaction tissue on beetle tunneling varied between species (Table 1A).

[a]Media amended with extracts from mature red pine trees that were left unwounded (constitutive), mechanically wounded, or wound-inoculated with *L. terebrantis* and sampled three weeks after inoculation, except*, sampled one week after inoculation. Mean (standard error) tunneling and percent of assay period spent on each side in two-way choice assays. Duration of assays = 5 days. $N = 20$ for all comparisons.

D. valens tunneled further and remained for longer periods in extracts of constitutive than reaction tissue. The distances tunneled by *H. porculus* in medium containing extracts of constitutive and reaction tissue did not significantly differ. However, they remained on the side of the assay chamber containing constitutive extracts for a longer period. *Ips pini* showed no significant preferences between polar extracts of constitutive and reaction tissue.

Nonpolar Extracts. Host condition significantly affected tunneling by *H. porculus* and *I. pini* in nonpolar extracts from red pine. In two-way choice assays, *H. porculus* tunneled over six times as far, and spent nearly five times as much time, in extracts from constitutive than reaction tissue (Table 1B). These beetles exhibited no significant preference between extracts from constitutive and mechanically wounded tissue.

In choice assays involving nonpolar extracts of constitutive and reaction tissue, *I. pini* exhibited preferences similar to those of *H. porculus* (Table 1B). *Ips pini* spent over three times as much time within the side of the assay chamber containing extracts from constitutive tissue than in extracts from reaction tissue. However, the distances tunneled by beetles in these extracts did not significantly differ. *Ips pini* did not exhibit clear preferences between extracts from constitutive versus mechanically wounded tissue.

Synthetic Monoterpenes. Synthetic monoterpenes significantly affected *I. pini* behavior. *Ips pini* tunneled nearly three times more, and spent over four times more time, within the side of the assay chamber containing medium amended with the concentration of α-pinene found in constitutive tissue than in reaction tissue (Table 2). *Ips pini* also tunneled over five times farther, and spent over twice as much time within medium amended with the concentration of α-pinene found in mechanically wounded tissue than in the concentration found in reaction tissue. However, *I. pini* did not exhibit significant preferences between α-pinene concentrations found in constitutive versus mechanically wounded tissue.

In two-way choice assays, *I. pini* exhibited no significant preference between medium amended with the concentrations of β-pinene found in constitutive versus reaction tissue or between concentrations found in mechanically wounded versus reaction tissue (Table 2). *Ips pini* did tunnel over twice as much within medium containing the concentrations of β-pinene found in mechanically wounded as in concentrations found in constitutive tissue.

In no-choice assays, monoterpene concentration significantly affected beetle behavior. *Ips pini* tunneled over five times more in medium containing the lowest concentration of α-pinene tested (3.4 mg/g, only slightly lower than the concentration found in constitutive red pine phloem) than in medium containing the highest concentration of α-pinene tested (343.2 mg/g, only slightly higher than the concentration found in wound inoculated red pine phloem) (Figure 1A). A linear equation described the effects of α-pinene on *I. pini* feeding: $y = -0.004x$

[a] Mean (standard error) tunneling and percent of assay period spent on each side in two-way choice assays. Media amended with pure monoterpenes at concentrations similar to those found in nonpolar extracts of mature red pine trees which were left unwounded (constitutive), mechanically wounded, or, wound-inoculated with *L. terebrantis* and sampled three weeks after inoculation. Duration of assay = 4 days. All = α-pinene, camphene, β-pinene, 3-carene, myrcene, and limonene combined.

+ 1.717; $r^2 = 0.974$; where y is the distance tunneled by the beetle, and x is the α-pinene concentration in the media. Likewise, *I. pini* tunneled over eight times more in medium containing the lowest concentration of β-pinene tested (3.4 mg/g, over 30 times higher than the concentration found in constitutive red pine phloem) than in medium containing the highest concentration of β-pinene tested (343.2 mg/g, nearly three times higher than the concentration found in wound inoculated red pine phloem) (Figure 1B). A linear equation described the effects of β-pinene on *I. pini* feeding: $y = -0.004z + 1.323$; $r^2 = 0.903$; where y is the distance tunneled by the beetle, and z is the β-pinene concentration in the media.

Effects of Induced and Constitutive Allelochemistry on Fungal Germination and Growth

Germination of both *L. terebrantis* and *L. procerum* was reduced by increasing concentrations of both α-pinene and β-pinene (Figure 2). At most doses tested, β-pinene was more inhibitory to both fungi than α-pinene. The

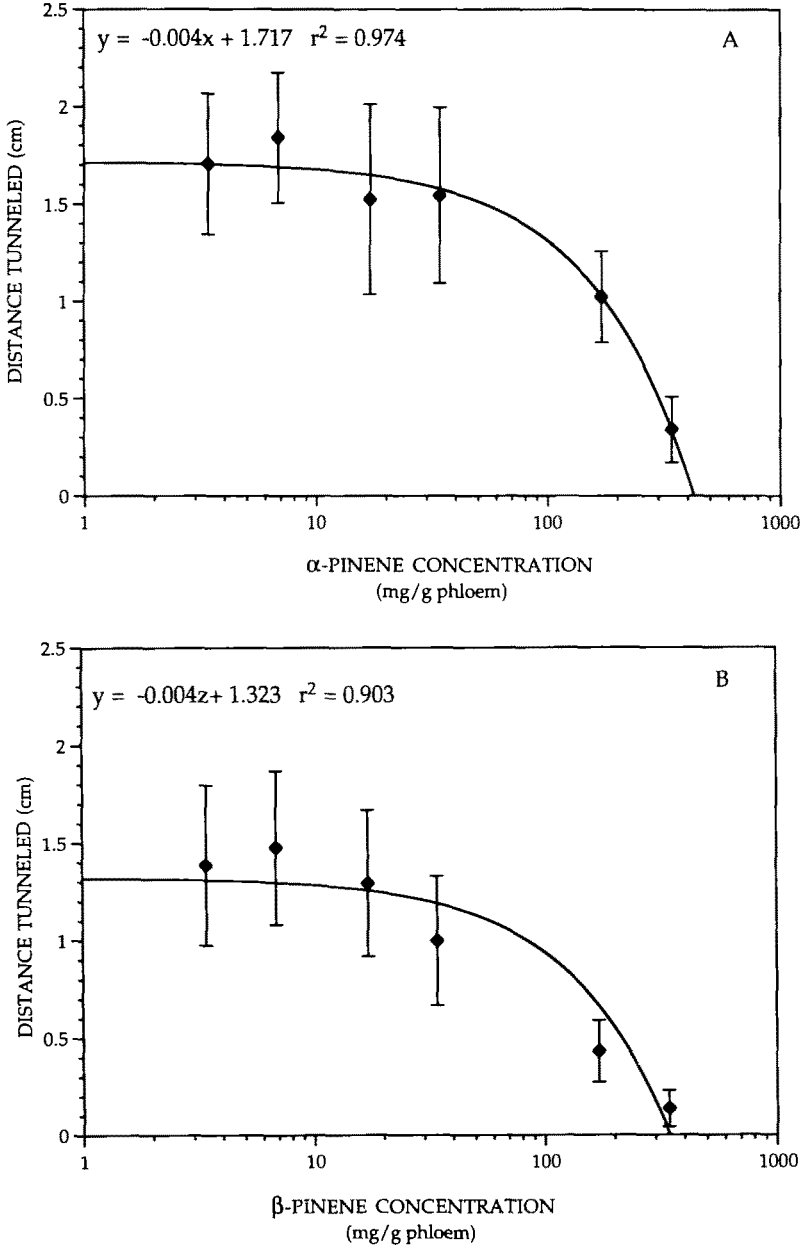

FIG. 1. Effects of synthetic monoterpenes on *I. pini* tunneling (mean ± SE). No-choice assay for two days in phloem-based medium amended with (A) α-pinene, $df = 20$, F 2.93, $P < 0.0001$, or (B) β-pinene, $df = 10$, $F = 2.15$, $P < 0.02$.

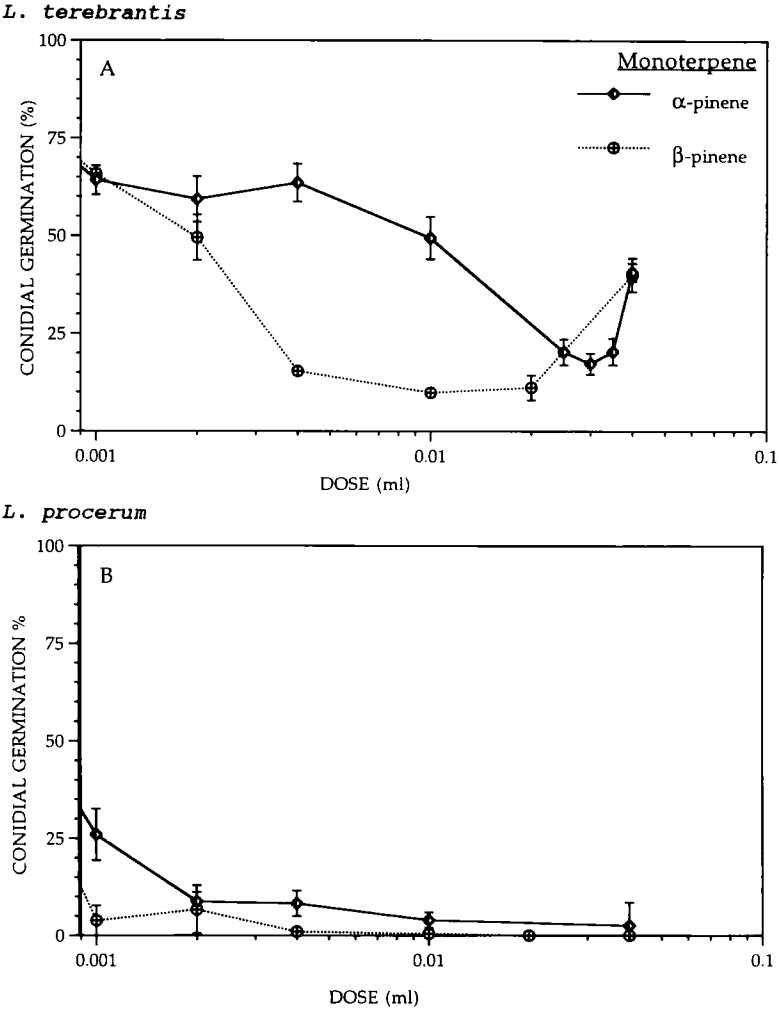

FIG. 2. Effects of α-pinene and β-pinene on germination (mean ± SE) of *L. terebrantis* and *L. procerum* conidia. Fungus by monoterpene interaction: $df = 24$, $F = 93.9$, $P < 0.0001$. Mean percent germination (and standard error) of fungi not exposed to monoterpenes: *L. terebrantis* = 98.0 (0.6) and *L. procerum* = 89.9 (2.3).

highest concentrations of both α-pinene and β-pinene, however, resulted in less inhibition of *L. terebrantis* germination than did intermediate concentrations. No such reduction in inhibitory activity at high concentrations was observed with *L. procerum*.

Polar Extracts. Polar extracts from both constitutive and reaction tissue reduced fungal growth (Figure 3). Extracts from constitutive tissue inhibited mycelial growth of *L. terebrantis* by approximately 15% relative to the control. Extracts of reaction tissue that had been mechanically wounded, inoculated with killed *L. terebrantis*, or inoculated with living *L. terebrantis* inhibited growth equally. Growth was approximately 44% lower on media containing these extracts than on media containing no additives. Medium amended with acetone alone did not differ in inhibitory activity from unamended medium.

Synthetic Monoterpenes. Mycelial growth of *L. terebrantis* was significantly inhibited by vapors of pure α-pinene, camphene, β-pinene, limonene,

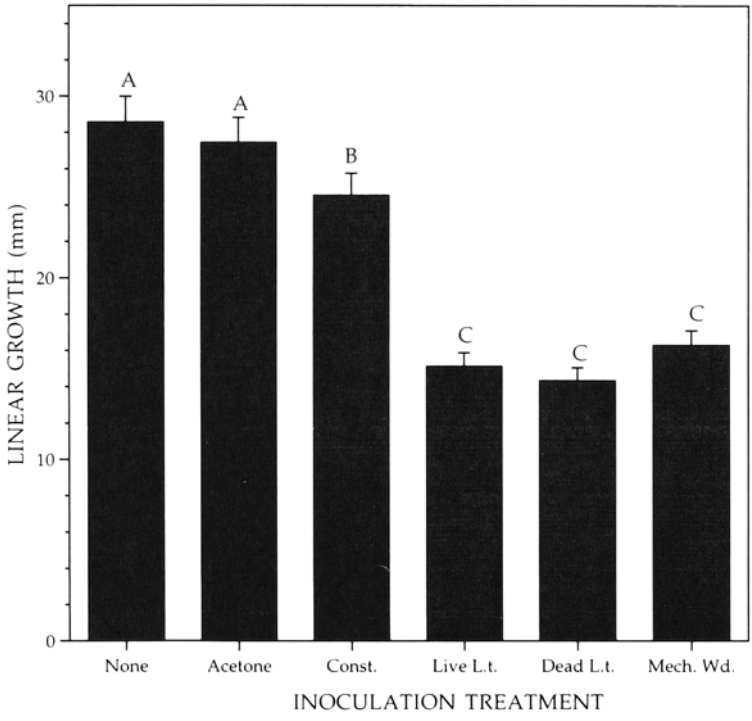

FIG. 3. Effect of acetone–methanol extracts on linear growth (mean ± SE) of *L. terebrantis*. Means followed by different letters are significantly different at $P < 0.05$ by Duncan's multiple range test. Controls: potato dextrose agar (PDA) only (None); PDA + acetone (Acetone). Sources of extracts: constitutive stem tissue (Const.); stem tissue one week after inoculation with viable *L. terebrantis* (Live L.t.); stem tissue 1 week after inoculation with nonviable *L. terebrantis* (Dead L.t.) stem tissue one week after mechanical wounding (Mech. Wd.). $df = 5$, $F = 63.79$, $P < 0.0001$.

TABLE 3. EFFECTS OF PURE MONOTERPENES ON GROWTH AND GERMINATION OF FUNGI[a]

	Mean linear growth (cm)		Mean conidial germination (%)	
Monoterpene	*L. terebrantis*	*L. procerum*	*L. terebrantis*	*L. procerum*
α-Pinene	2.71 (0.04) d	1.25 (0.02) b	40.7 (2.3) e	27.9 (3.0) e
Camphene	2.20 (0.00) e	0.02 (0.01) c	45.9 (2.6) ce	46.6 (3.5) d
β-Pinene	2.61 (0.05) d	1.19 (0.01) b	58.8 (2.5) bd	25.3 (5.2) e
3-Carene	3.34 (0.02) ab	1.35 (0.02) ab	52.7 (2.3) bc	49.7 (4.4) d
Myrcene	3.36 (0.07) ab	1.29 (0.04) ab	60.7 (3.0) ad	68.2 (2.7) c
Limonene	3.26 (0.10) c	1.24 (0.06) ab	76.2 (2.2) a	74.9 (2.5) b
γ-Terpinene	1.60 (0.03) f	0.96 (0.99) c	68.4 (3.2) a	23.2 (2.1) e
Control	3.52 (0.16) a	1.33 (0.02) a	98.0 (0.6) a	89.8 (2.3) a

[a]Mean (standard error) linear growth (cm) of mycelia and mean (standard error) germination (%) of conidia exposed to saturated atmospheres of pure monoterpenes found in red pine reaction tissue and to no monoterpenes (control). Linear growth measured at five day's exposure. Percent germination measured at 1 day of exposure. Means within a column followed by different letters are significantly different at $P < 0.05$ as determined by protected least squares means procedure.

and γ-terpinene (Table 3). Growth of *L. procerum* was significantly inhibited by α-pinene, camphene, β-pinene, and γ-terpinene. The greatest inhibition against both fungi was exerted by camphene and γ-terpinene, which are only trace components in red pine. Among the major components of host monoterpenes, α-pinene and β-pinene were the most inhibitory.

Saturated atmospheres of the predominant monoterpenes in red pine also reduced spore germination of both *L. terebrantis* and *L. procerum* (Table 3). All monoterpenes significantly inhibited germination of *L. procerum* relative to the control. Germination by *L. terebrantis* was significantly inhibited by α-pinene, camphene, β-pinene, and 3-carene. α-Pinene and camphene were the most potent inhibitors of *L. terebrantis*, inhibiting germination by 59% and 53%, respectively. γ-Terpinene, α-pinene, and β-pinene were the most potent inhibitors of *L. procerum*, inhibiting germination by 74%, 69%, and 72%, respectively.

Effect of Root Disease on Bark Beetle Host Selection Behavior

Nonpolar extracts from stem phloem of trees with high and low levels of root infection differentially affected the behavior of *I. pini* and *H. porculus*. In two-way choice assays, *H. porculus* showed no significant preferences between nonpolar extracts from healthy versus root diseased trees (Table 4A). This was true regardless of whether the extracts came from constitutive or reaction tissue.

Ips pini tunneled over four times more, and spent nearly three times more

TABLE 4. EFFECT OF NONPOLAR PHLOEM EXTRACTS AND SYNTHETIC MONOTERPENES FROM HEALTHY AND ROOT-DISEASED RED PINES ON HOST SELECTION BEHAVIORS BY *H. porculus* and *I. pini*[a]

[a]Mean (standard error) tunneling and percent of assay period spent on each side in two-way choice assay. A: Nonpolar extracts of healthy vs. root-diseased mature red pine trees that were unwounded (constitutive) or wound-inoculated with *L. terebrantis* and sampled three weeks after inoculation; B: Media amended with concentrations of pure monoterpenes similar to concentrations found in extracts of healthy and root-diseased mature red pine trees that were wound inoculated with *L. terebrantis* and sampled three weeks after inoculation. Duration of assay = 3 days. $N = 20$ for all comparisons.

time, within extracts of constitutive tissue from healthy trees than in extracts from trees with high levels of root infection. However, this pattern was reversed when tree defensive capacity was challenged by wound inoculation with *L. terebrantis*. *Ips pini* tunneled over twice as much, and spent over three times more time, within extracts of reaction tissue from trees with high than low levels of root infection (Table 4A).

Synthetic pure monterpenes incorporated into media at concentrations equivalent to those found in reaction tissue from trees with high and low levels of root infection did not significantly affect *I. pini* behavior (Table 4B).

DISCUSSION

These experiments demonstrate the ability of allelochemically based defenses in red pine to affect both insect and fungal parasites. In this system, the early stages of combined parasitic invasion can apparently be interrupted by host

chemical defenses. Beetles and fungi invading red pine are only slightly (or not at all) inhibited by the levels of polar compounds (phenolics) and nonpolar compounds (monoterpenes) present in the constitutive tissue that they first encounter. However, as the beetles tunnel into subcortical tissue, they elicit an induced response from the host (Cheniclet et al., 1988; Miller et al., 1986; Berryman, 1988; Raffa and Smalley, 1995). The resulting elevated concentrations of phenolics and monoterpenes can significantly inhibit the germination of fungal spores or inhibit subsequent hyphal development. Continued insect tunneling and fungal development elicit further host reactions, which are usually sufficient to repel the attack in vigorous, healthy trees.

The effects of particular components of the induced host response vary with the type and species of invading parasite. In this system, phenolics appear to affect fungi to a greater degree than insects but are only moderately inhibitory to both. Conversely, monoterpenes in red pine are highly active in inhibition of both insects and fungi. Based on the results with synthetic monoterpenes, these compounds can partially, but not fully, explain beetle preferences for various host extracts.

H. porculus and *I. pini* both tended to prefer constitutive to induced reaction tissue, at least as indicated by beetle location. However, only *I. pini* discriminated between reaction tissues elicited in response to mechanical wounds versus fungal inoculations. Likewise, only *I. pini* discriminated between extracts from healthy versus diseased trees. These results suggest that *I. pini* is more discriminating than *H. porculus* with regard to monoterpene concentrations and that responses to induced reactions are an essential component of *I. pini*'s overall host selection process. These preferences may relate to host selection behavior by *I. pini* in the field. That is, *I. pini* males must discriminate between vigorous hosts capable of mounting an effective defense and stressed hosts that might be more suitable for colonization and subsequent brood production. *I. pini* preferred extracts from constitutive tissue from healthy trees to extracts from similar tissue from diseased trees. However, monoterpene concentrations were very low in constitutive tissues (Klepzig et al., 1995b), and this may merely represent a stimulatory effect of low concentrations of monoterpenes on *I. pini* tunneling. In reaction tissue resulting from wound inoculation with *L. terebrantis*, this preference was reversed. Soon after *I. pini* enters red pine, it inoculates its associated fungus, *O. ips*, into the phloem and initiates a rapid induced response (Raffa and Smalley, 1988). This is the type of tissue with which *I. pini* is most likely confronted as it begins the process of gallery construction that may lead to pheromone production and subsequent mass attack by other *I. pini*. Thus, the ability of a tree to mount an effective induced response may be as important, or more important, than its constitutive allelochemical composition. We currently know very little about the biology and behavior of *H. porculus*, so results with this root-feeding species are more difficult to interpret (Klepzig, 1994).

The closely related fungi studied here also differed in their sensitivities to host extracts. The germination and growth of *L. procerum* were strongly inhibited by saturated atmospheres of monoterpenes. The germination and growth of *L. terebrantis* were also inhibited by monoterpenes, but to a lesser extent. The biological significance, if any, of the decreased levels of inhibition of germination of *L. terebrantis* conidia by the highest concentrations of α- and β-pinene is unclear. These higher doses may be artificially high and/or the decreased level of inhibition at these doses may be an artifact of the assay chamber design. The differences between the two fungi in allelochemical tolerance, however, may relate to life history traits of these two fungi. *L. procerum* is only weakly virulent in red pine and most other conifers. *L. terebrantis*, the more allelochemically tolerant species, may be among the most virulent of the bark beetle-associated fungi (Harrington, 1993). In two growth-chamber studies *L. terebrantis*, but not *L. procerum*, was able to kill red pine seedlings (Klepzig, 1994). Although this pattern does not demonstrate a definite link between allelochemical tolerance and virulence in these plant parasites, it is consistent with this hypothesis and argues for further work on this aspect of conifer–scolytid–fungal interactions.

Biotic and abiotic stresses can impair the defense mechanisms described above. Trees whose roots have been extensively colonized by parasitic organisms are less able to produce reaction tissue that is inhibitory to *I. pini*. These behavioral reactions correspond to reduced levels of induced allelochemical accumulation, following *I. pini–O. ips* attack in root-infected trees (Klepzig et al., 1995b). Thus, successful colonization by the root-colonizing beetle *H. porculus* and its associated fungus *L. terebrantis* appears to predispose red pine to subsequent attack and colonization by the main stem-colonizing beetle *I. pini* and its associated fungus *O. ips*. Tree mortality data are consistent with this proposed mechanism (Klepzig et al., 1991; Raffa and Klepzig, 1996). Abiotically stressed trees can also be more susceptible to infection by these facultatively pathogenic fungi (Klepzig, 1994). As with most infection, the stem subcortical tissue of light-limited trees showed altered patterns of allelochemical induction in response to simulated attack (Klepzig et al., 1995b). Both of these examples of increased susceptibility in relation to biotic and abiotic stress can be at least partially explained by changes in the carbon-based defensive chemistry. That is, the observed chemical changes are consistent with physiological changes associated with impaired host abilities to compete for resources. For example, diseased roots and shaded needles are less able to capture water and nutrients, and sunlight, respectively.

The relationships among trees physiology and plant parasites described here have implications for the ecology and management of forest ecosystems. In particular, they suggest a probable sequence for the multiple species interactions involved in a decline disease affecting red pine (Klepzig et al., 1991). The most

frequent and most severe examples of this decline typically occur in trees growing off site, often on poor soils, and under potentially resource-limiting conditions. The resulting chronic stresses may represent predisposing factors as defined by Manion (1991). Likewise, some short-term stresses that can serve as inciting factors in this decline have been identified. These include reduced light availability, root disease, lightning strike, and/or root damage due to temperature or moisture extremes. However, the exact identity, relative incidence, and overall importance of various inciting factors in red pine decline disease remain unclear. Contributing factors appear to include a complex of subcortical root- and stem-infesting insects and their associated fungi partially described here (Klepzig et al., 1991). Induced defensive reactions to attack by this multispecies complex appear to be compromised by both the predisposing and contributing factors. This may allow increasingly successful attacks by root insects and fatal attacks by *I. pini–O. ips* complexes (Klepzig et al., 1991). This hypothetical framework has also led to suggested strategies for managing red pine decline disease, including severing root grafts in advance of the spread of the root-infecting fungi and planting trees in mixed-species blocks.

(Received October 30, 1995; accepted March 31, 1996)

Abstract—Response of adults of the West Indian sugarcane weevil, *Metamasius hemipterus sericeus*, to various semiochemical treatments and physical trap designs was studied in southern Florida in field-grown banana and Canary Island date palms. Ethyl acetate released alone at 860–1007 mg/day was as effective for the capture of *M. h. sericeus* as a combination of ethyl acetate (844–919 mg/day), ethyl propionate (348–362 mg/day), and ethyl butyrate (117–137 mg/day) and in one trial was more effective than fermenting sugarcane (250 g), ethyl propionate alone (353–384 mg/day), ethyl butyrate alone (123–174 mg/day), or no treatment. Ethyl acetate released alone at 675–683 mg/day was as attractive as 250 g of fermenting sugarcane or the racemic blend of the male-produced aggregation pheromones [(±)-5-methyl-nonan-4-ol and (±)-2-methyl-heptan-4-ol (8:1 ratio) "metalure"] at 3 mg/day. Weevil counts increased with binary combinations of ethyl acetate, sugarcane, and/or metalure over these treatments alone and the ternary combination was two to three times more effective than any of the binary treatments. Attraction to ethyl acetate released alone at 777 mg/day with metalure was greater than to the hydrolysis products of ethyl acetate (ethanol and/or acetic acid each released at about 6–8 mg/day) with metalure. Weevil counts from traps baited with 250 g of sugarcane and metalure increased with increasing dose of ethyl

acetate to about 400 mg/day and then appeared to plateau. Ethyl acetate (about 700 mg/day) and metalure increased weevil counts in traps with increasing amounts of sugarcane (0–2 kg). Molasses (45 g) + water (158 ml) substitutes for sugarcane were about as effective for capturing *M. h. sericeus* as 250 g of fermenting sugarcane [all treatments with ethyl acetate (847 mg/day) and metalure]. Early experiments used a lethal pitfall trap. We demonstrated that several alternative trap designs were more effective than the lethal pitfall trap for capturing weevils. Color and height (on ground vs. 1 m on pole) did not affect trap efficacy when baited with the ternary combination of ethyl acetate (672–825 mg/day), sugarcane (250 g), and metalure.

Key Words—Aggregation pheromones, attraction, banana, Canary Island date palm, ethyl acetate, kairomones, monitoring, *Phoenix canariensis*, West Indian sugarcane weevil, sugarcane, trapping.

INTRODUCTION

The West Indian sugarcane weevil, *Metamasius hemipterus sericeus* (Olivier), is an important pest of palms, sugarcane, pineapple, and bananas in the West Indies, Mexico, and Central and South America (Giblin-Davis et al., 1994b; Vaurie, 1966). Adult females lay eggs in cracks or damaged areas of the host plant or in the petioles or crown shaft of certain species of healthy palms. The larvae bore and feed in the host tissue, causing extensive physical damage that can lead to the death of the host (Giblin-Davis et al., 1994b). This weevil first became established in Dade County, Florida in about 1984 (Woodruff and Baranowski, 1985) and has recently become established in Broward and Palm Beach counties (Giblin-Davis et al., 1994b).

The container and field-grown ornamental palm industry in Florida is valued at more than $50 million per year. Current Florida Department of Plant Industry regulations stipulate that palm nurseries with *M. h. sericeus* must be quarantined and sprayed with insecticides until the weevils are no longer detectable in plants for sale or distribution. There is an urgent need for an effective, optimized, semiochemical-based lethal trap for monitoring and mass-trapping of *M. h. sericeus* in Florida.

Male-produced aggregation pheromones (4-methyl-nonan-5-ol and 2-methyl-heptan-4-ol) have been identified for *M. h. sericeus* (Perez et al., unpublished data; Rochat et al., 1993). Furthermore, early fermentation products from sugarcane and other plant tissues are very attractive to *M. h. sericeus* (Giblin-Davis et al., 1994b). Several kairomones (ethyl acetate, ethyl butyrate, and ethyl propionate) have been identified for *M. h. sericeus* from fermenting host tissue (Perez et al., unpublished data). We previously developed a lethal pitfall trap that can be baited with sugarcane or other fermenting fruit or palm tissues (Giblin-Davis et al., 1994b) and with identified kairomones or male-

produced aggregation pheromones. The purpose of this study was to further optimize the bait, design, height of placement, and color for a safe, lethal, semiochemical-based trap.

METHODS AND MATERIALS

Field Attraction to Synthetic Host Kairomones Compared with Sugarcane

Trap. A semiochemical-based lethal pitfall trap for *M. h. sericeus* (Giblin-Davis et al., 1994b) was used for field experiments comparing the attraction of the kairomones, ethyl acetate, ethyl propionate, or ethyl butyrate versus chopped sugarcane, *Saccharum officinarum* L. (250 g of 2- to 5-cm-long stem pieces). Each trap consisted of two translucent white, high-density polyethylene (HDPE) plastic tapered containers (Fisher Scientific Co., Pittsburgh, Pennsylvania), one 4.9 liter and the other 0.9 liter in size. Soapy water in the bottom of the larger container acted as the lethal agent. Two drainage holes in the sides, 6 cm from the bottom, allowed for rain overflow. The smaller container had a screened lid (8.5-cm screened opening), to retain the sugarcane and prevent weevils from interacting with it when inverted, and was suspended with a vinyl-coated wire inside the larger container. Each assembled trap was buried to within about 2.5 cm of the trap opening in the shade of a mature banana plant.

Kairomone Release. Two devices were used for the release of synthesized host kairomones: (1) 1 ml of a test chemical in a 2-ml Gold Brand ampule (Wheaton, Millville, New Jersey) (designated AMP) with a 4-mm-diam. opening, and (2) 4 or 8 ml of test chemical in a 14.8-ml glass vial (OD × H = 21 × 70 mm) without a top (11.4-mm-diam. opening) (4NT) (Giblin-Davis et al., 1994a). Release devices were placed in a 120-ml HDPE specimen container (Fisher Scientific) suspended from inside of the 0.9 liter test stimulus container by wires. The amount of each test semiochemical released was gravimetrically quantified at the end of each trapping period, and a mean daily release rate was calculated. The actual release rates would have varied during the day with changing temperature and relative humidity.

Low-Release Rate Experiment. Ethyl acetate (Fisher Scientific), ethyl propionate (Aldrich Chemical Co., Milwaukee, Wisconsin), or ethyl butyrate (Kodak Chemical Co., Rochester, New York), all ≥99% pure, were released individually using the AMP device and compared with a ternary combination of individually released chemicals, ethyl acetate released alone using the 4NT device, and 250 g of sugarcane. Both of the following experiments were conducted in a 15.5-ha, 2-year-old banana plantation, located near Homestead, Dade County, Florida. Two five-replicate experiments were done during February 3–9 and February 10–16, 1993. Treatments were rerandomized after the first trial.

Experimental Design and Analysis. All of the following experiments were designed and analyzed as follows, unless otherwise stated. Treatments were about 20 m apart in a randomized complete block design separated by ≥20 m. Total numbers of adult male and female *M. h. sericeus* collected per trap for each trapping period were used for analysis. Counts were $(x + 0.5)^{0.5}$ transformed and the proportion of females (female/female + male) were arcsine-transformed to make the variances independent of the means and a Statistical Analysis System general linear models procedure (SAS Institute, 1985) for unbalanced analysis of variance (ANOVA) was used. Untransformed means are presented. Significant differences ($P \leq 0.05$) among treatment means were separated using the least-square-difference (LSD) method (SAS Institute, 1985).

High-Release Rate Experiment. Ethyl acetate, ethyl propionate, and ethyl butyrate were released individually using the 4NT device and compared with a ternary combination of all three chemicals released individually, and a treatment of 250 g of sugarcane. Two five-replicate experiments were done during February 17–22 and February 24–March 1, 1993. Treatments were rerandomized after the first trial.

Field Attraction to Ethyl Acetate or Ethyl Acetate Hydrolysis Products, Sugarcane or Sugarcane Substitutes, and/or Metalure

Trap. Experiments were discontinued in the banana plantation because the bananas were removed and replaced with another crop. All subsequent field testing was done in a 1-ha field nursery of 6-year-old Canary Island date palms, *Phoenix canariensis* Hortorum ex Chabaud, interplanted with 6-year-old Sabal palms, *Sabal palmetto* (Walter) in Broward County, Florida. The *P. canariensis* palms were heavily infested with *M. h. sericeus*. Prelminary testing with the lethal pitfall trap at this site was hampered due to a large population of raccoons that disturbed the traps. Studies with marked dead weevils suggested that the raccoons were eating them. Preliminary field tests showed that duct-taping the lethal pitfall trap to a green metal fencepost with the trap opening at a 1-m height, between palm trees, stopped tampering by raccoons and appeared to have no effect on trap efficacy. Subsequent field experiments used this trap design and placement, unless otherwise stated (Figure 1A).

Metalure and Kairomone Release. Racemic 4-methyl-nonan-5-ol and 2-methyl-heptan-4-ol were synthesized (>95% purity) and released in an 8:1 ratio (metalure) from hermetically sealed polyethylene envelopes (total release rate 3 mg/day at 25°C) for all experiments using metalure in this paper. Metalure was released from outside the inner bucket of the lethal bucket trap. Ethyl acetate (8 ml) was released from a 14.8-ml glass vial (OD × H = 21 × 70 mm) with a screw top with a 4-mm-diam. hole (4DH) that was placed in a wired 25.9-ml polystyrene vial that hung outside the inner bucket (Giblin-Davis et al., 1994a).

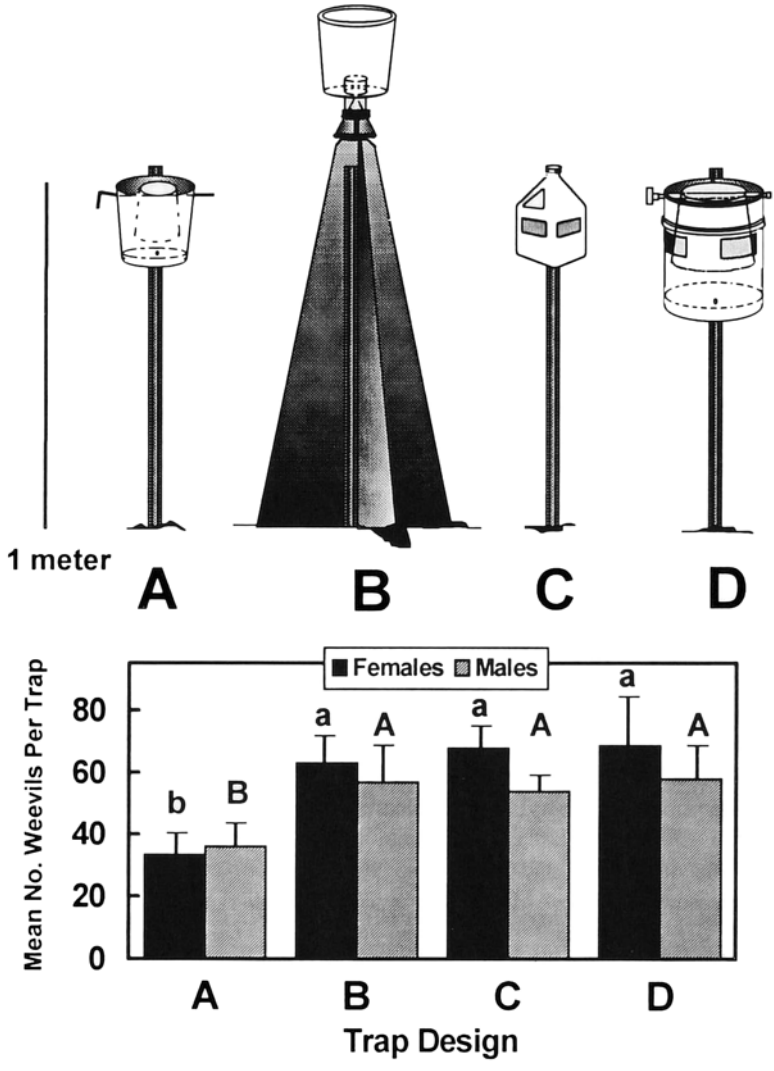

FIG. 1. Comparison of counts of *Metamasius hemipterus sericeus* females and males (mean ± SE) from different lethal trap designs in a Canary Island date palm planting in Broward County, Florida (March 3–7, 1995). Traps were baited with 250 g of sugarcane (treated to runoff with carbaryl at 1.11 ml a.i./liter of water), ethyl acetate (672 mg/day), and metalure [(±)-5-methyl-nonan-4-ol and (±)-2-methyl-heptan-4-ol, 8:1 ratio, total release rate of 3 mg/day] (7 replicates). (A) Lethal pitfall trap mounted on a pole; (B) modified Tedder's trap; (C) milk container trap on pole; and (D) 19-liter black bucket trap on pole shown with 4.9 liter stimulus container. Means followed by the same upper- or lowercase letter are not significantly different (least significant difference, $P \leq 0.05$). Count data were $(x + 0.5)^{0.5}$ transformed prior to analysis; untransformed means are presented.

Experiment 1: Individual, Binary, and Ternary Combinations. Two experiments, with treatments being replicated three and five times each during February 10–14 and February 14–18, 1995, respectively, were conducted to assess how ethyl acetate (released at 400–800 mg/day) would affect trap efficacy in all possible single, binary, and ternary combinations with 250 g of sugarcane and/or metalure. There were a total of seven treatments. The first three involved the release of metalure alone, 250 g of sugarcane alone, or ethyl acetate released alone from the 4DH device. The three possible binary combinations and one ternary combination of the above-mentioned individual treatments were also used. Treatments were rerandomized after the first trial.

Experiment 2: Field Attraction to Ethyl Acetate or its Hydrolysis Products. A five-replicate experiment was conducted during March 7–13, 1995, to determine if hydrolysis products of ethyl acetate (ethanol and/or acetic acid) were attractive to *M. h. sericeus* when released at rates similar to what is produced (6–8 mg/day) in ethyl acetate released from the 4DH release device (400–800 mg/day) (Oehlschlager et al., unpublished observation). Trap design was as previously described (Figure 1A). The five treatments were: no treatment, ethyl acetate released from the 4DH device, ethanol hermetically sealed in polyethylene envelopes and released at 6–8 mg/day at 25°C, acetic acid released at 6–8 mg/day at 25°C, and a combination of separately delivered ethanol and acetic acid (both released at 6–8 mg/day at 25°C). No sugarcane was used in this experiment, and all treatments received metalure.

Experiment 3: Ethyl Acetate Dose–Response with Sugarcane (250 g) and Metalure. A seven-replicate experiment was conducted during February 22–27, 1995, to determine how ethyl acetate release rates affected the efficacy of a trap baited with 250 g of sugarcane and metalure. The four treatments used were combinations of metalure and 250 g of sugarcane with no ethyl acetate, or ethyl acetate released from the AMP, 4DH, or 25 ml of ethyl acetate in a 40.7-ml glass vial (OD × H = 28 × 108 mm) without a top (17.8-mm-diam. opening) (11NT) (Giblin-Davis et al., 1994a). All buckets received a 120-ml HDPE specimen container for holding the ethyl acetate release devices, and it was suspended outside the inner bucket as previously described.

Experiment 4: Sugarcane Dose–Response with Ethyl Acetate (4DH device; 400–800 mg/day) and Metalure. A seven-replicate experiment was conducted during March 13–17, 1995, to determine how different amounts of sugarcane (0–250 g) affected the efficacy of a trap baited with ethyl acetate (4DH device) and metalure. The four treatments were combinations of metalure and ethyl acetate released from the 4DH device with no sugarcane, or 50, 100, or 250 g of sugarcane.

Another seven-replicate experiment was conducted during March 22–27, 1995, to determine if an increased amount of sugarcane (250 g, 500 g, or 2 kg) would affect trap efficacy of the ternary semiochemical combination (ethyl ace-

tate, sugarcane, and metalure). The trap design was modified to accommodate a larger amount of sugarcane (2 kg) as described in the trap optimization design section that follows (Figure 1D) except that a 4.9-liter HDPE container was used instead of the 0.9-liter container. The three treatments were combinations of metalure and ethyl acetate released from the 4DH device with 250 g, 500 g, or 2 kg of sugarcane.

Experiment 5: Sugarcane Substitutes. A five-replicate experiment was conducted during June 7–12, 1995, to evaluate molasses-based substitutes for sugarcane in black 19-liter bucket traps on green fenceposts as described (Figure 1D). All traps received metalure and ethyl acetate (4DH release device). The five treatments were no sugarcane, 250 g of sugarcane, a 36 × 43-cm cotton terry towel (Stout Industries) treated with 45 g of molasses (Grandma's "unsulphured" "mild flavor" Mott's U.S.A., Stamford, Connecticut), 45 g of molasses and 158 ml of tap water, or 45 g of molasses, 158 ml of tap water, and 0.15 g of Fleischman's active dry yeast (Specialty Brands, San Francisco, California).

Optimization of Trap Design, Placement, and Color Using Sugarcane (250 g), Ethyl Acetate (4DH Release Device), and Metalure as Bait

Design. Four trap designs were field-tested in a seven-replicate experiment during March 3–7, 1995, with metalure, ethyl acetate (4DH release device in the 29-ml polystyrene vial), and 250 g of sugarcane that was treated to runoff with Sevin liquid [21.3% carbaryl; 1-naphthyl *N*-methyl-carbamate (1.11 ml a.i./liter water)] (Figure 1A–D). The insecticide was used on all sugarcane to make the treatments semiochemically equal and to make designs 1B and 1C lethal to weevils that entered these traps. The designs follow: (A) A lethal pitfall trap (see above) that was duct-taped to a green metal fencepost that stood 1 m high (same as experiment 1). (B) A Tedder's (Tedder, unpublished data) modified boll weevil trap (Great Lakes IPM, Vestaburg, Michigan), that opened into a translucent white, 4.9-liter, HDPE stimulus container (where the sugarcane was placed) and was set on top of a 1.25-m-tall black triangular plastic base anchored to the soil with a green fencepost. The hole in the screen funnel of the boll weevil trap was expanded to a diameter of 8 mm and the metalure and the ethyl acetate were released from the outside of the stimulus container. (C) A clean 3.78-liter HDPE milk container, with three 4 × 10-cm openings cut 12 cm from the bottom, was attached to a green metal fencepost with duct tape. Pesticide-treated sugarcane was placed inside the container, and the metalure and ethyl acetate were hung from the outside. (D) A 19-liter black HDPE plastic bucket (United States Plastics Corp., Lima, Ohio) with three 4 × 13-cm openings spaced 10 cm apart and 21 cm from the bottom was attached to a green metal fence post with an elastic cord and duct tape. A translucent white,

0.9-liter, HDPE stimulus container with a fine screened lid was inverted and suspended 2 cm from the opening of the bucket with a PVC crossbar capped with a PVC cap and tee. Drainage holes were 5 cm from the bottom of the 19-liter bucket and a detergent solution was used to kill the weevils entering the trap (Giblin-Davis et al., 1994a).

Height. The lethal trap (see Figure 1D) was field-tested with metalure, ethyl acetate (4DH release device), and 250 g of sugarcane (no pesticide) on the ground versus mounted at 1-m height on a green metal fencepost. The ground-mounted trap was the same as the pole mounted trap except that it was anchored to the ground with metal posts driven through the PVC tees (see trap 1A of Giblin-Davis et al., 1994a). The experimental design and analysis were as previously described except that a *t* test was used for testing significance. The 10-replicate experiment was conducted during March 27–31, 1995.

Color. The ground-mounted 19-liter bucket trap (see Height section) baited with metalure, ethyl acetate (4DH release device), and 250 g of sugarcane (no pesticide) was used to assess the effects of bucket color on trap efficacy. There were two experiments. The first five-replicate experiment used black, white, and gray buckets (United States Plastics) and was conducted during April 21–25, 1995. The second five-replicate experiment used black, red, green, yellow, and blue buckets (United States Plastics) and was conducted during May 8–11, 1995.

RESULTS AND DISCUSSION

Field Attraction to Synthetic Host Kairomones Compared with Sugarcane

Low-Release Rate Experiment. There were no significant differences between any of the treatments using the lethal pitfall trap in the banana field for the capture of *M. h. sericeus* in either time replicate of this experiment (F = 1.09 and 1.87; df = 6, 4 and 6, 4; P = 0.3980 and 0.1281 for time replicates 1 and 2, respectively).

High-Release Rate Experiment. Ethyl acetate released alone at (mean release rates for time replicate 1;2) 860;1007 mg/day from lethal pitfall traps in banana fields was as effective for the capture of *M. h. sericeus* as a combination of ethyl acetate (833;919 mg/day), ethyl propionate (348;362 mg/day), and ethyl butyrate (117;137 mg/day) and in time replicate 2 was more effective than fermenting sugarcane (250 g), ethyl propionate alone (353;384 mg/day), ethyl butyrate alone (123;174 mg/day), or no treatment (Figure 2). The proportion of females per trap was about 68–70% for the different treatments for both time replicates. In general, electrophysiologically active host kairomones (ethyl acetate and, to a lesser degree, ethyl propionate) were as attractive as fermenting sugarcane when released alone or in a ternary combination with ethyl butyrate

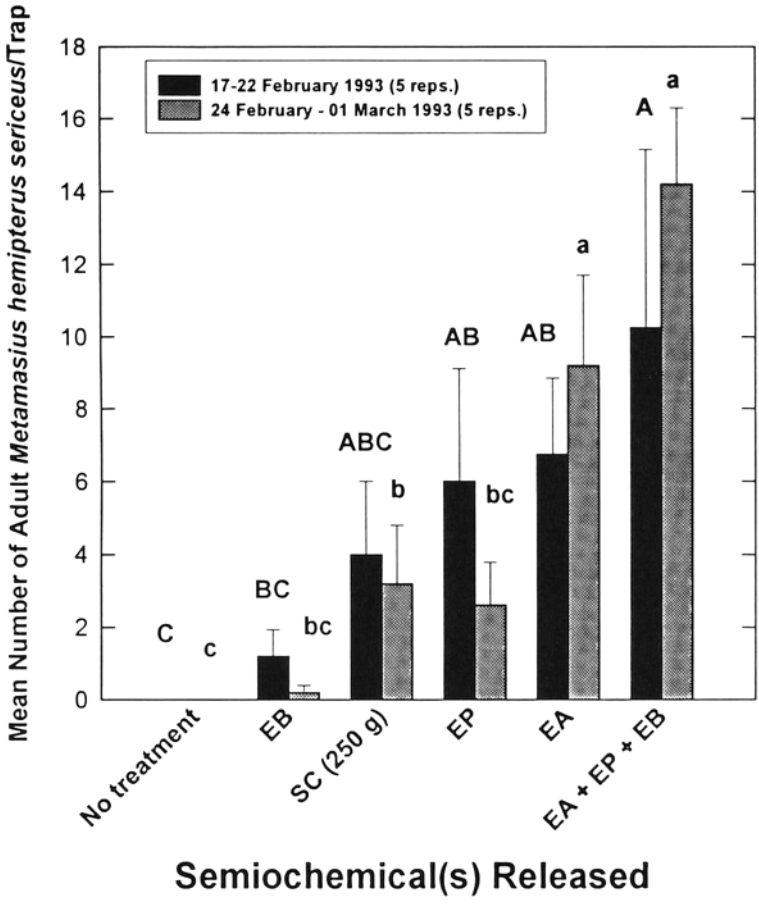

FIG. 2. Comparison of counts of *Metamasius hemipterus sericeus* adults (mean ± SE) from lethal pitfall traps in a banana planting in Dade County, Florida. Traps were baited with 250 g of sugarcane (SC); ethyl acetate alone (EA, mean release rates for time replicates 1;2) at 844;919 mg/day; ethyl propionate alone (EP) at 353;384 mg/day; ethyl butyrate alone (EB) at 123;174 mg/day; a ternary combination of EA, EP, and EB released individually at 860;1007, 348;362, and 117;137 mg/day; and no-treatment control. Means followed by the same upper- or lowercase letter are not significantly different (least significant difference, $P \leq 0.05$). Count data were $(x + 0.5)^{0.5}$ transformed prior to analysis; untransformed means are presented.

at the rates tested (Figure 2). One explanation for the lack of improvement in trap counts with the ternary treatment of ethyl acetate, ethyl propionate, and ethyl butyrate compared with the individual releases of these molecules (Figure 2) is that they may be stimulating the same receptors. The results from this experiment differ from what was observed for the palmetto weevil, *Rhynchophorus cruentatus* (F.), where ethyl acetate synergized attraction of the synthesized male-produced aggregation pheromone [(±)-5-methyl-octan-4-ol; cruentol] but was not attractive by itself at different doses (Giblin-Davis et al., 1994a). These results (Figure 2) prompted us to do experiments 1–5 to help optimize a semiochemical bait for *M. h. sericeus* in the field.

Field Attraction to Ethyl Acetate or Ethyl Acetate Hydrolysis Products, Sugarcane or Sugarcane Substitutes, and/or Metalure

Experiment 1: Individual, Binary, and Ternary Combinations. Ethyl acetate released alone from the 4DH device was as effective for capture of both sexes of *M. h. sericeus* in trap design A in the Canary Island date palm grove as 250 g of fermenting sugarcane, but more effective than metalure (F = 19.88 and 48.64; df = 6, 2 and 6, 4; P = 0.0001 and 0.0001 for time replicates 1 and 2, respectively). Weevil counts increased with all three binary combinations of ethyl acetate, sugarcane, and/or metalure compared with these semiochemical treatments alone. For males, binary combinations with ethyl acetate (ethyl acetate + metalure or ethyl acetate + sugarcane) were more effective than sugarcane + metalure (Figure 3). The ternary combination increased trap efficacy two to three times over any of the binary treatments for both time replicates (Figure 3). There was no difference in the release rates of ethyl acetate from the different treatments for either time replicate; mean release rates were 683 and 675 mg/day for time replicates 1 and 2, respectively (F = 3.28 and 0.75; df = 3, 2 and 3, 4; P = 0.1005 and 0.5446). There also was no difference in the proportion of females per trap for the different treatments for time replicate 1 (41%) (F = 2.50; df = 6, 2; P = 0.0892). There were differences in the proportion of females per trap in time replicate 2 (F = 10.37; df = 6, 4; P = 0.0001). Comparisons between time replicates 1 and 2 showed no consistent trends between the proportion of females and treatment suggesting that these differences may not be real.

These results are similar to the work of Jaffé et al. (1993), who reported that ethyl acetate (release rate undetermined) increased capture of *Rhynchophorus palmarum* (L.) in lethal and nonlethal traps baited with sugarcane and its major aggregation pheromone [2(*E*)-6-methyl-2-hepten-4-ol; rhynchophorol]. That sugarcane contributed to the attraction of ethyl acetate in binary or ternary combinations with metalure suggests that there are other kairomones to be identified from fermenting sugarcane. Research with different species of palm and

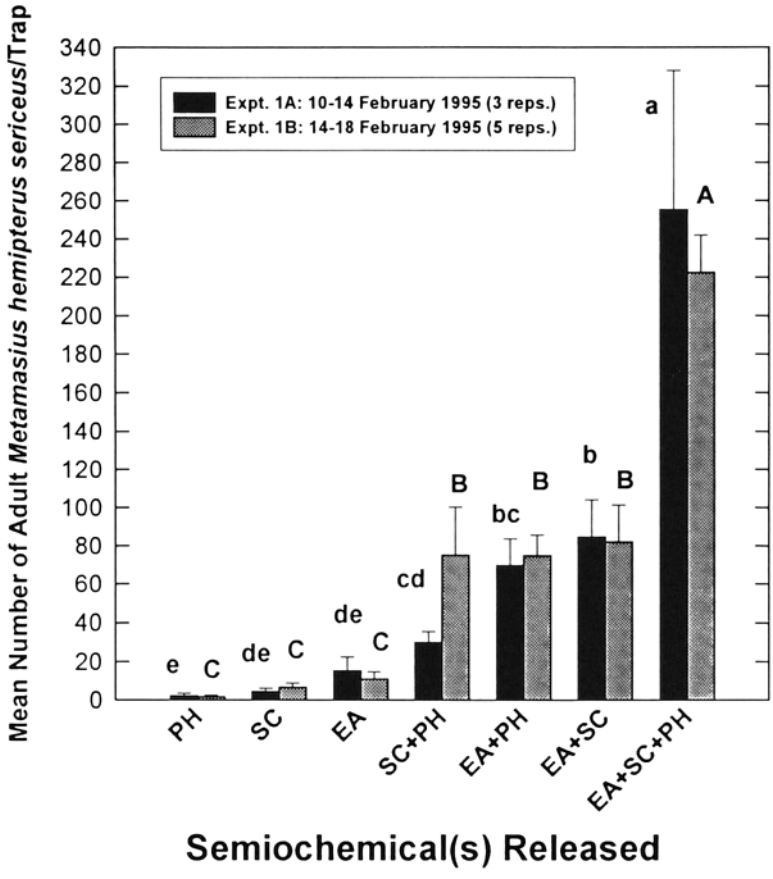

FIG. 3. Comparison of counts of *Metamasius hemipterus sericeus* adults (mean ± SE) from lethal trap design A in a Canary Island date palm planting in Broward County, Florida. Traps were baited with 250 g of sugarcane (SC), ethyl acetate (EA, mean release rate for time replicates 1;2) (683;675 mg/day), or metalure (PH) [(±)-5-methyl-nonan-4-ol and (±)-2-methyl-heptan-4-ol, 8:1 ratio, total release rate of 3 mg/day] in all individual, binary, and ternary combinations. Means followed by the same upper- or lowercase letter are not significantly different (least significant difference, $P \leq 0.05$). Count data were $(x + 0.5)^{0.5}$ transformed prior to analysis; untransformed means are presented.

sugarcane weevils in the subfamily Rhynchophorinae suggests that in addition to ethyl acetate, ethyl propionate, and ethyl butyrate, there are probably other classes of unidentified host kairomones that may be shared by these insects (Giblin-Davis et al., 1994a; Gries et al., 1994; Jaffé et al., 1993).

Experiment 2: Field Attraction to Ethyl Acetate or its Hydrolysis Products. Total counts from traps (design A) baited with ethyl acetate (4DH device; 777 ± 39 mg/day) and metalure were greater than traps baited with ethyl acetate hydrolysis products (ethanol and/or acetic acid) and metalure or metalure alone ($F = 30.88$; $df = 4, 4$; $P = 0.0001$) (Figure 4). There was no difference in the proportion of females per trap (50%) for the different treatments ($F = 0.97$; $df = 4, 4$; $P = 0.4840$).

We estimated that under the conditions of this study with ethyl acetate released from the 4DH device that the hydrolysis products, ethanol and acetic acid, would each be released at about 6–8 mg/day (Oehlschlager et al., unpublished data). This experiment (Figure 4) demonstrates that ethanol and/or acetic acid when released at these rates with metalure were not any more attractive than metalure alone. Thus, only ethyl acetate appears to increase trap efficacy.

Experiment 3: Ethyl Acetate Dose-Response with Sugarcane (250 g) and Metalure. Release of ethyl acetate increased efficacy of the semiochemical-based trap (design A) baited with 250 g of sugarcane and metalure in a dose-dependent manner for both males and females of *M. h. sericeus* ($F = 10.93$ and 24.13; $df = 3, 6$ and $3, 6$; $P = 0.0003$ and 0.0001 for females and males, respectively) (Figure 5). Weevil counts increased sharply with up to 400 mg/day of ethyl acetate, then appeared to level off through 1663 mg/day (Figure 5). There was no difference in the proportion of females per trap for the different treatments (44%) ($F = 1.24$; $df = 3, 6$; $P = 0.3258$).

Thus, ethyl acetate, which may be available in nature at much lower concentrations than 400–1600 mg/day (Samarajeewa et al., 1981), is not repellent to *M. h. sericeus* at up to 1663 mg/day. Samarajeewa et al. (1981) showed that the ethyl acetate concentration of arrack, a palm wine distillate, varied between 14 and 3353 mg/liter. Because arrack is a distillation product of palm wine (toddy), the actual concentrations of ethyl acetate in the naturally fermented palm sap would be about three- to seven-fold diluted (i.e., 2–280 mg/liter). Thus, the actual available ethyl acetate to the environment from 250 g of fermenting sugarcane would be contingent upon the microbes present and probably be in the range of 0–30 mg/day. reported that ethyl acetate, ethyl propionate, or ethyl butyrate released alone at about 20–30 mg/day did not synergize attraction of *M. h. sericeus* to metalure at the same level as fermenting sugarcane in Costa Rica. Our work in Florida demonstrates that ethyl acetate released from the 4DH device, which released between 400 and 900 mg/day, depending upon temperature, significantly added to the attraction of metalure or sugarcane in a binary trap or metalure and sugarcane in a ternary trap (Figure 3). Because ethyl acetate is not repellent at the high rates of 400–1600 mg/day in the field (Figure 5), it may increase the effective range of a trap, improve short-range resolution for trap location, or function somehow as a more effective arrestant for *M. h. sericeus* in or near traps. Although ethyl acetate release rates of 400–1600 mg/

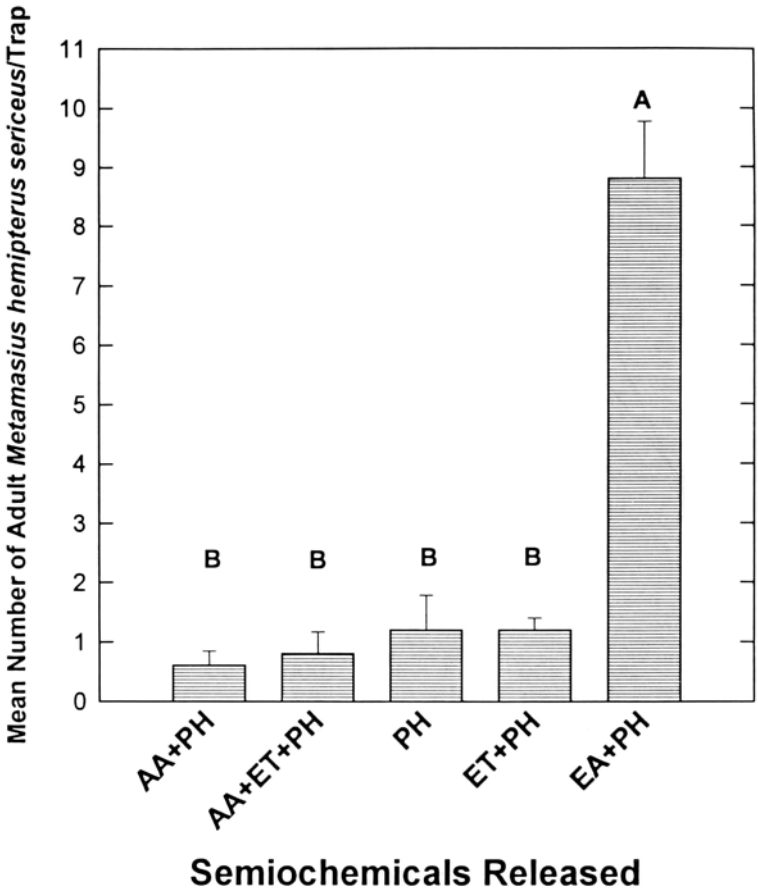

FIG. 4. Comparison of counts of *Metamasius hemipterus sericeus* adults (mean ± SE) from lethal trap design A in a Canary Island date palm planting in Broward County, Florida (March 7–13, 1995, five replicates). Traps were baited with metalure (PH) [(±)-5-methyl-nonan-4-ol and (±)-2-methyl-heptan-4-ol, 8:1 ratio, total release ratio of 3 mg/day] alone, or with ethyl acetate (EA) (777 mg/day), acetic acid (AA) (6–8 mg/day), ethanol (ET) (6–8 mg/day), or AA and ET. Means followed by the same uppercase letter are not significantly different (least significant difference, $P \leq 0.05$). Count data were $(x + 0.5)^{0.5}$ transformed prior to analysis; untransformed means are presented.

day may seem high relative to 250 g of sugarcane, these rates may not be that high relative to the local levels produced in heavily rat- or wind-damaged sugarcane fields or in large damaged palm trees. In addition, Jaffé et al. (1993) suggested that ethyl acetate is perceived by males of *R. palmarum* and stimulates

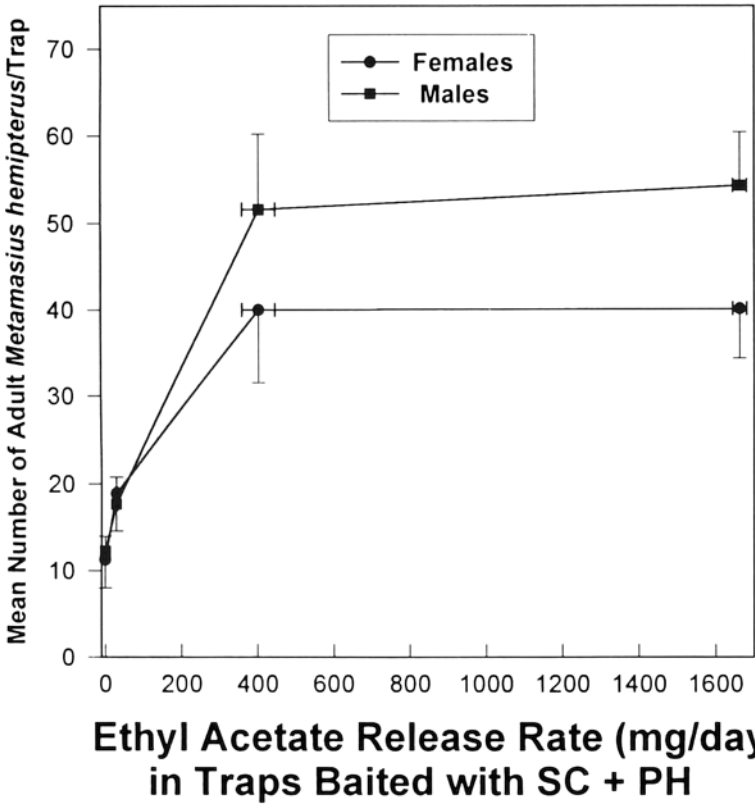

FIG. 5. Plot of counts of *Metamasius hemipterus sericeus* females and males (mean ± SE) from lethal trap design A in a Canary Island date palm planting in Broward County, Florida (February 22–27, 1995) (seven replicates). Traps were baited with 250 g of sugarcane (SC) and metalure (PH) [(±)-5-methyl-nonan-4-ol and (±)-2-methyl-heptan-4-ol, 8:1 ratio, total release rate of 3 mg/day], with different release rates of ethyl acetate (0, 29, 403, 1663 mg/day).

them to produce their aggregation pheromones. If this is true for *M. h. sericeus*, then live weevils in the vicinity of a trap baited with high levels of ethyl acetate might produce more pheromone than weevils in the vicinity of traps with little or no ethyl acetate. Recent work with metalure release rates and *M. h. sericeus* field attraction (Oehlschlager et al., unpublished data) suggests that a 10-fold increase in metalure with sugarcane results in a doubling of trap counts in Costa Rica. However, this modest increase in trap efficacy does not outweigh the increased cost of the metalure. Thus, some of the effect of ethyl acetate may be

due to stimulation of weevils to produce aggregation pheromones prior to entry into the trap.

Experiment 4: Sugarcane Dose–Response with Ethyl Acetate (4DH device; 400–800 mg/day) and Metalure. Regarding 0–250 g sugarcane, male and female counts from traps (design A) baited with ethyl acetate, metalure, and 250 g of sugarcane were greater than traps baited with ethyl acetate, metalure, and 100, 50, or 0 g of sugarcane ($F = 39.83$ and 17.60; $df = 3, 6$ and 3, 6; $P = 0.0001$ and 0.0001 for females and males, respectively) (Figure 6). There was no difference in the release rates of ethyl acetate from the different treatments; mean ethyl acetate release rate was 509 mg/day ($F = 0.63$; $df = 3, 6$; $P = 0.6074$). There also was no difference in the proportion of females per trap (38%) for the different treatments ($F = 0.37$; $df = 3, 6$; $P = 0.7764$). This experiment demonstrates that 250 g of sugarcane provides enough of an increase in trap counts to justify the time and expense of using it over lesser amounts.

Regarding 250–2000 g sugarcane, female counts from traps (design D) baited with ethyl acetate, metalure, and 2 kg of sugarcane were greater than counts from traps baited with ethyl acetate, metalure, and 500 or 250 g of sugarcane, which were equal to each other ($F = 23.80$ and 7.24; $df = 2, 6$ and 2, 6; $P = 0.0001$ and 0.0087 for females and males, respectively) (Figure 7). Male counts from traps baited with ethyl acetate, metalure, and 2 kg of sugarcane were greater than counts from traps baited with ethyl acetate, metalure, and 250 g of sugarcane; male counts from traps with 500 g of sugarcane were intermediate to traps baited with 250 or 2 kg of sugarcane (Figure 7). There was no difference in the release rates of ethyl acetate from the different treatments; mean ethyl acetate release rate was 652 mg/day ($F = 0.89$; $df = 2, 6$; $P = 0.4389$). There also was no difference in the proportion of females per trap for the different treatments (42%) ($F = 1.06$; $df = 2, 6$; $P = 0.3761$). Ethyl acetate was released in this experiment within the range of its highest effective dose (400–1600 mg/day), and larger amounts of sugarcane continued to increase trap counts of *M. h. sericeus*. This supports the hypothesis that other class(es) of kairomones still need to be identified from fermenting host tissue. The added number of weevils captured due to the increase of sugarcane per trap from 250 g to 2 kg probably does not justify the added cost.

Experiment 5: Sugarcane Substitutes. Male counts from traps (design D) baited with ethyl acetate, metalure, and 250 g of sugarcane were equal to counts from traps baited with ethyl acetate, metalure, and a cotton terry towel soaked with molasses and water (with or without yeast) (Figure 8). Male counts from traps baited with ethyl acetate, metalure, and molasses (with no water) were intermediate to counts from traps baited with ethyl acetate, metalure, and molasses and water (with or without yeast) and to counts from traps baited with ethyl acetate and metalure only, but lower than counts from traps baited with ethyl acetate, metalure, and sugarcane ($F = 5.82$; $df = 4, 4$; $P = 0.0043$) (Figure

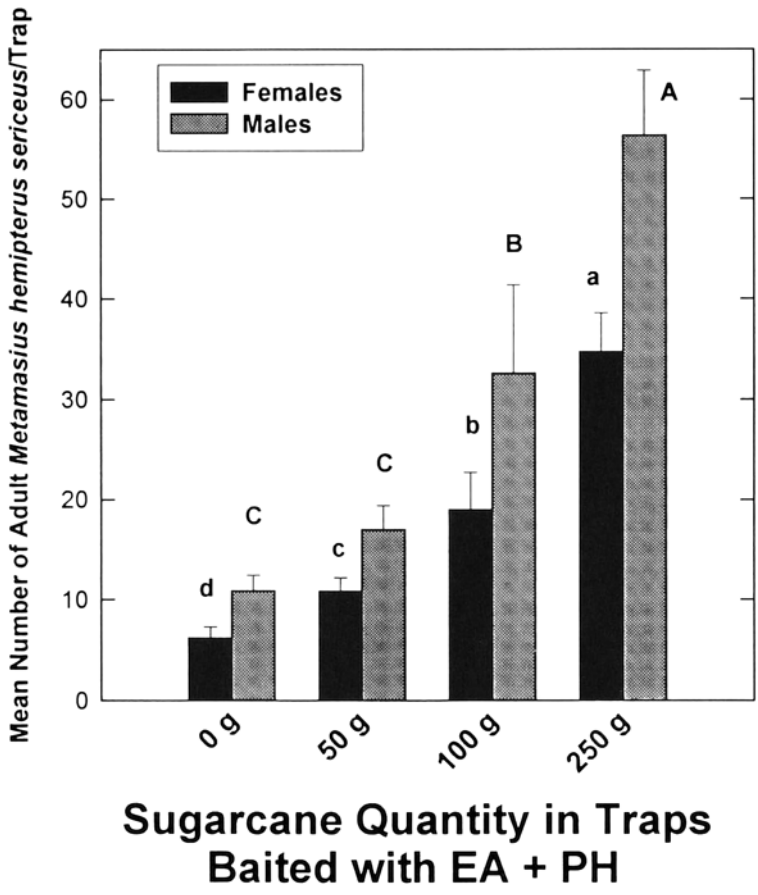

FIG. 6. Comparison of counts of *Metamasius hemipterus sericeus* females and males (mean ± SE) from lethal trap design A in a Canary Island date palm planting in Broward County, Florida (March 13–17, 1995) (seven replicates). Traps were baited with ethyl acetate (EA) (509 mg/day) and metalure (PH) [(±)-5-methyl-nonan-4-ol and (±)-2-methyl-heptan-4-ol, 8:1 ratio, total release rate of 3 mg/day], with different amounts of sugarcane (0, 50, 100, or 250 g). Means followed by the same upper- or lowercase letter are not significantly different (least significant difference, $P \leq 0.05$). Count data were $(x + 0.5)^{0.5}$ transformed prior to analysis; untransformed means are presented.

8). Female counts showed similar trends to the males ($F = 7.10$; $df = 4, 4$; $P = 0.0017$) (Figure 8). The molasses treatment without water smelled more like molasses than both the molasses and water treatments that had a fermented smell. The pH of the fluid from the towels of both molasses and water treatments (with and without yeast) were similar, at about 2.3, after five days in the field. The

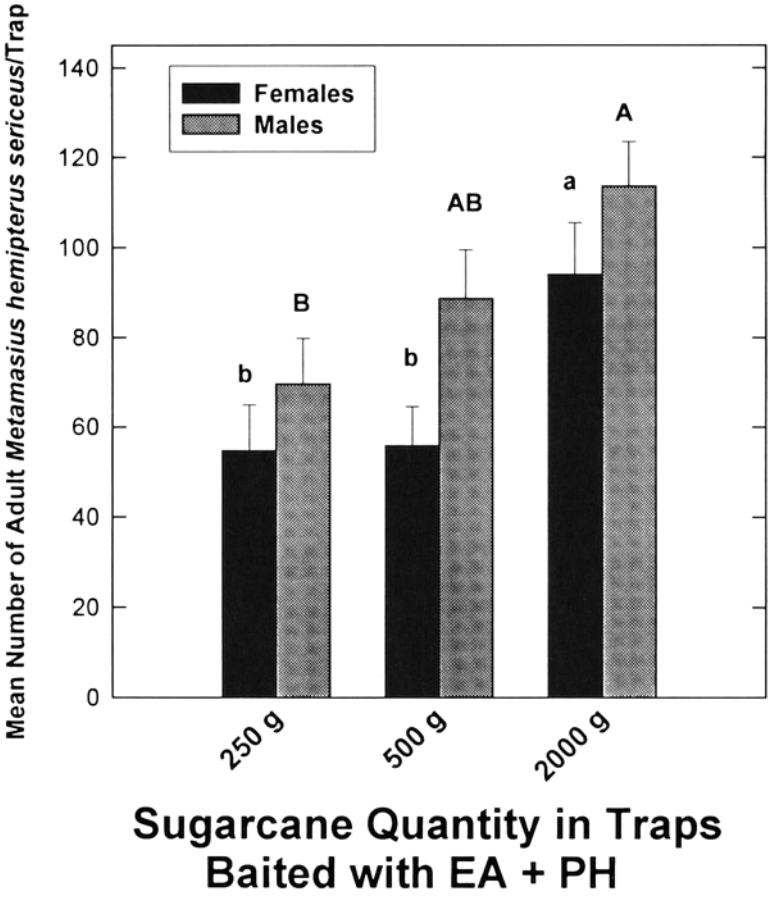

FIG. 7. Comparison of counts of *Metamasius hemipterus sericeus* females and males (mean ± SE) from lethal trap design D (modified with a 4.9-liter stimulus container) in a Canary Island date plam planting in Broward County, Florida (March 22–27, 1995) (seven replicates). Traps were baited with ethyl acetate (EA) (652 mg/day) and metalure (PH) [(±)-5-methyl-nonan-4-ol and (±)-2-methyl-heptan-4-ol, 8:1 ratio, total release rate of 3 mg/day], with different amounts of sugarcane (250, 500, and 2000 g). Means followed by the same upper- or lowercase letter are not significantly different (least significant difference, $P \leq 0.05$). Count data were $(x + 0.5)^{0.5}$ transformed prior to analysis; untransformed means are presented.

treatment with yeast smelled more yeasty than any of the other treatments. There was no difference in the release rates of ethyl acetate from the different treatments; total mean ethyl acetate release rate was 847 mg/day ($F = 0.47$; $df = 4, 4$; $P = 0.7586$). There was no difference in the proportion of females per

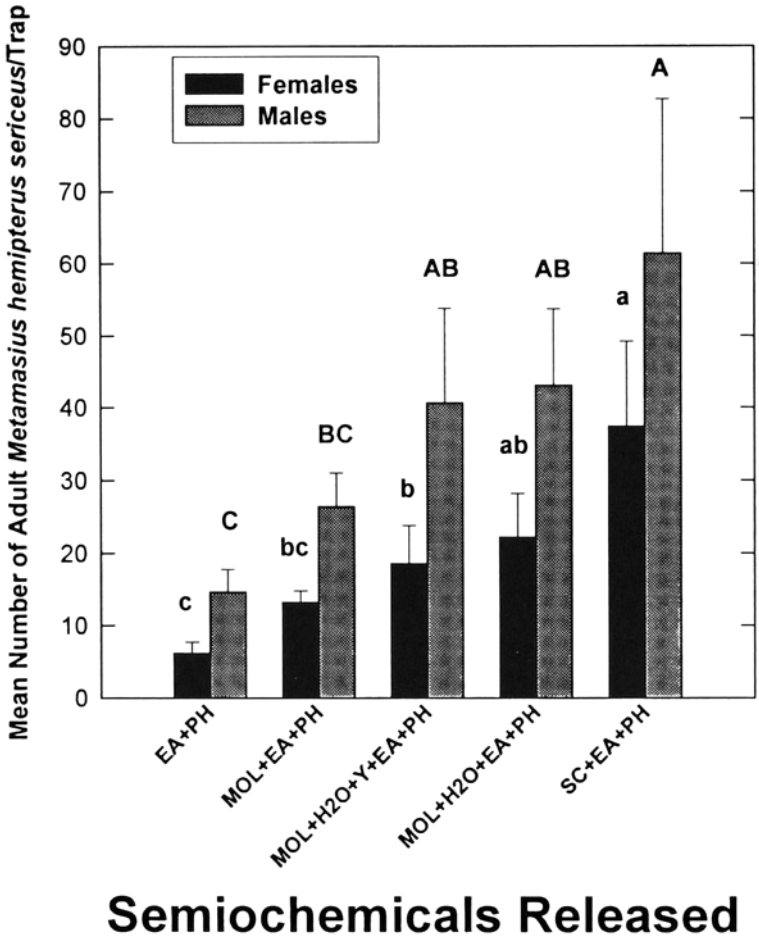

FIG. 8. Comparison of counts of *Metamasius hemipterus sericeus* females and males (mean ± SE) from lethal trap design D in a Canary Island date palm planting in Broward County, Florida (five replicates). Traps were baited with ethyl acetate (EA) (847 mg/day) and metalure (PH) [(±)-5-methyl-nonan-4-ol and (±)-2-methyl-heptan-4-ol, 8:1 ratio, total release rate of 3 mg/day] only, or with 250 g of sugarcane (SC), a cotton towel with 45 g of molasses (MOL), MOL and 158 ml of tap water (H_2O), or MOL + H_2O and 0.15 g of Fleischman's yeast (Y). Means followed by the same upper- or lowercase letter are not significantly different (least significant difference, $P \leq 0.05$). Count data were $(x + 0.5)^{0.5}$ transformed prior to analysis; untransformed means are presented.

trap for the different treatments (34%) ($F = 0.58$; $df = 4, 4$; $P = 0.6815$). The results from our experiment corroborate work by Arango and Rizo (1977), where a yeast, water, and molasses mixture that was applied to sugarcane bagasse in single open-ended bamboo cylinder traps with pesticide was shown to be attractive to *M. hemipterus* in Colombia. The data also show that water is necessary for fermentation of molasses to produce kairomones for *M. h. sericeus*.

Fermenting sugarcane and pineapple work equally as well for attracting *M. h. sericeus* (Giblin-Davis et al., 1994b). However, these materials can be expensive or unavailable in parts of Florida. In addition, storing cut sugarcane for trapping can attract unwanted weevils into an area. This experiment (Figure 8) shows that molasses and water can be used as an inexpensive and easily obtained substitute for sugarcane or pineapple for future work with semiochemical-based trapping of *M. h. sericeus*.

Optimization of Trap Design, Placement, and Color Using Sugarcane (250 g), Ethyl Acetate (4DH Release Device), and Metalure as Bait

Design. Counts from trap designs B–D baited with the ternary semiochemical combination [ethyl acetate (4DH device), sugarcane (250 g), and metalure] were equal and greater than counts from trap design A ($F = 4.58$ and 1.39; $df = 3, 6$ and 3, 6; $P = 0.0159$ and 0.2813 for females and males, respectively) (Figure 1). There was no difference in the release rates of ethyl acetate from the different trap designs: mean release rate of 672 mg/day ($F = 0.65$; $df = 3, 6$; $P = 0.5936$). There was no difference in the proportion of females per trap (55%) for the different trap designs ($F = 0.63$; $df = 3, 6$; $P = 0.6032$).

It is not clear why trap A performed less effectively than traps B–D. Traps B–D have more surface area for landing and crawling than design A. Trap B had the greatest surface area and connection to the soil. Trap C is similar in design to the trap used in Costa Rica for *M. h. sericeus* (Perez et al., 1995) and *R. palmarum* (Oehlschlager et al., 1993), except that it was not hung on palms at chest height, allowing the palm to function as a landing and walking platform. *Rhynchophorus palmarum* required trap contact with the ground or palm trunk for significant trap efficacy (Oehlschlager et al., 1993). The relatively small *M. h. sericeus* is more agile in flight than the larger species of *Rhynchophorus* and therefore may not require a large landing surface or connection to the soil. However, differences in the amount of suitable landing surface area between trap A and traps B–D may account for the lower trap efficacy in trap A.

Height. Weevil counts from trap design D baited with the ternary semiochemical combination [ethyl acetate (4DH release device), sugarcane (250 g), and metalure] at 1 m on a pole and on the ground were equal ($T = -1.56$ and -1.48; $df = 18$ and 18; $P = 0.1353$ and 0.1574 for females and males,

respectively). Traps on the ground caught 76 ± 10 females and 118 ± 17 males compared with 57 ± 7 females and 86 ± 12 males at 1 m. This suggests, as observed for *R. palmarum* (Oehlschlager et al., 1993), that traps with greater connection to possible landing areas may work a little better. However, because *M. h. sericeus* appears to be more agile in flight than *R. palmarum*, it can still enter a trap even when it is suspended in the air on a pole. There was no significant difference in the release rates of ethyl acetate from the different trap designs: mean release rate of 758 mg/day ($T = -0.22$; $df = 18$; $P = 0.8211$). There was no difference in the proportion of females per trap (40%) for the different trap heights ($T = 0.07$; $df = 18$; $P = 0.9455$). We have had problems with the ground-mounted trap (design D) in subsequent work because raccoons learned how to get into them and eat the weevils. This has not yet occurred with the pole mounted trap design D.

Color. Weevil counts from black, white, and gray ground-mounted traps (design D) that were baited with the ternary semiochemical combination [ethyl acetate (4DH device), sugarcane (250 g), and metalure] were equal ($F = 1.09$ and 1.48; $df = 2, 4$ and 2, 4; $P = 0.3813$ and 0.2846 for females and males, respectively). Black, white, and gray traps caught 43 ± 11, 32 ± 11, and 28 ± 5 females and 45 ± 11, 32 ± 11, and 38 ± 10 males, respectively. There was no difference in the release rates of ethyl acetate from the different trap colors: mean release of rate 796 mg/day ($F = 1.47$; $df = 2, 4$; $P = 0.2851$). There was no difference in the proportion of females per trap (48%) for the different trap designs ($F = 0.37$; $df = 2, 4$; $P = 0.7037$).

Weevil counts from black, blue, green, red, and yellow ground-mounted traps (design D) that were baited with the ternary semiochemical combination [ethyl acetate (4DH device), sugarcane (250 g), and metalure] were equal ($F = 1.24$ and 0.12; $df = 4, 4$ and 4, 4; $P = 0.3352$ and 0.9742 for females and males, respectively). Black, blue, green, red, and yellow traps caught 28 ± 4, 18 ± 5, 21 ± 5, 25 ± 6, and 18 ± 4 females and 40 ± 4, 42 ± 4, 45 ± 7, 44 ± 6, and 44 ± 19 males, respectively. There was no difference in the release rates of ethyl acetate from the different trap colors: mean release rate of 825 mg/day ($F = 2.10$; $df = 4, 4$; $P = 0.1282$). There was no difference in the proportion of females per trap (33%) for the different trap colors ($F = 2.44$; $df = 4, 4$; $P = 0.0894$). Similarly, Oehlschlager et al. (1993) reported for *R. palmarum* that there was no difference in semiochemical-based trap efficacy with different trap colors.

CONCLUSIONS

Our study demonstrates that in banana and palm plantings in Florida, the kairomone ethyl acetate was as effective at 500–1000 mg/day as 250 g of fer-

menting sugarcane alone for capturing *M. h. sericeus*. This led to a study of the effects of ethyl acetate, metalure, and/or 250 g of sugarcane alone or in binary or ternary combinations on trap counts of *M. h. sericeus*. Each of these semiochemicals or semiochemical sources were additive or synergistic. It was ethyl acetate and not its hydrolysis products (ethanol and acetic acid) that were attractive to *M. h. sericeus*. Ethyl acetate increased attraction to traps baited with sugarcane and metalure in a dose-responsive manner with the most attraction occurring between 400 and 1600 mg/day. Increases in the amounts of fermenting sugarcane in traps baited with ethyl acetate and metalure resulted in increases in trap efficacy. So far, the most cost-effective semiochemical-based bait is a ternary combination of sugarcane (250 g), ethyl acetate (400–800 mg/day), and metalure (3 mg/day). Molasses (45 g) and water (158 ml) can be used as a substitute for 250 g of sugercane in situations where sugarcane is not available or is too expensive. Physical trap designs were studied, and it appears that traps with greater surface area work better. Trap placement (on ground vs. 1 m high) and color of trap body do not appear to affect trap efficacy.

Acknowledgments—We thank Lilliana M. Gonzalez, Carlos M. Chinchilla, Regine Gries, Gerhard Gries, Harold D. Pierce, Jr., Anthony McCall, Mickey Stanaland, Rita E. Duncan, Barbara J. Center, Z. Alegria, and F. G. Bilz for their suggestions and technical assistance, and Bill Howard and Omelio Sosa for critically reviewing the manuscript. We are grateful to E. Suarez and P. Naranjo of Homestead, Florida, and Peter Gardener of Continental Citrus, Broward County, Florida, for allowing us to do field attractancy tests on their respective properties. The research was supported in part by U.S. Department of Agriculture Special Grant in Tropical and Subtropical Agriculture, CRSR-95-34135-1763, to R. M. G.-D. and J. E. P., and by the Dade and Broward county chapters and the state organization of the Florida Nursery Growers Association (FNGA). LIPID COMPOUNDS IN SECRETIONS OF FISHING BAT, *Noctilio leporinus* (CHIROPTERA: NOCTILIONIDAE)

ANNE P. BROOKE* and DENICE M. DECKER

Graduate Program in Ethology
University of Tennessee
Knoxville, Tennessee 37996

(Received November 13, 1995; accepted April 1, 1996)

Abstract—The distinctive odor of *Noctilio leporinus* arises from oily secretions found beneath the wings in the subaxillary region. Analysis of secretions by gas chromatography–mass spectrometry identified 372 lipid compounds. Differences in number and chemical composition of glycolipids suggest that secretions of males from the same roost are more similar to each other than to other males or females. Differences in number and chemical composition of nonpolar lipids indicate that secretions of males are more similar to each other than to females. Since secretions differ between sexes, information on sexual identity and reproductive condition may be communicated. Individually unique lipid compositions further suggest that bats may be recognizable by their odor within the roost and while flying.

Key Words—Bats, scent marking, lipids.

INTRODUCTION

Bats (Order Chiroptera), like other mammals, produce an assortment of scents that are used in intraspecific communication (Schmidt, 1985). Although distinctive odors are common in many bat species, the function of most of these scents is poorly known. Individual identification from olfactory signals has been suggested by research on groups of little brown bats (*Myotis lucifigus*) (Thomas et al., 1979) and for individual vampire bats (*Desmodus rotundus*) (Schmidt and Manske, 1973). Mother Mexican free-tailed bats (*Tadarida brasiliensis*) use olfaction to help distinguish their young in densely packed nursery creches that

contain tens of thousands of similarly aged young (McCracken and Gustin, 1991).

A few instances are known of bats using secretions to mark territories. Harem boundaries are delineated by male gray-headed flying foxes (*Pteropus poliocephalus*) (Nelson, 1965) and insular fruit bats (*P. tonganus*) (Grant and Banack, 1995) by rubbing secretions from neck and shoulder glands against tree branches. Both male and female Samoan flying foxes (*P. samoensis*) mark vegetation within foraging areas with secretions from neck glands (Brooke, personal observation).

Bats also use secretions to mark conspecifics. Dominant male velvet free-tailed bats (*Molossus molossus*) mark both females and subordinate males with musky smelling secretions from their throat glands (Schmidt, 1985). Displaying male sac-winged bats, *Saccopteryx bilineata*, shake their wings at females and rival males dispensing secretions from wing pockets (Bradbury and Emmons, 1974).

Increases in secretions corresponding with seasonal mating have been found in male gray-headed flying foxes, *P. poliocephalus* (Ratcliff, 1932; Herreid, 1960; Nelson, 1965), velvet free-tailed bats, *M. molossus* (Schmidt, 1985), and Mexican free-tailed bats, *T. brasiliensis* (Davis et al., 1962), suggesting that scent production is a secondary sexual signal. In addition, sexually dimorphic chest glands are present in the Phyllostomidae (Valdivieso and Tamsitt, 1964) and Molossidae (Werner and Lay, 1963).

The fishing bat, *Noctilio leporinus*, has a particularly strong and distinctive odor. Goodwin (1928) identified flying *N. leporinus* on nights too dark to make visual observations on the basis of their distinctive musky odor. This smell has been attributed to their fish-eating diet (Gudger, 1945; Goodwin and Greenhall, 1961) or, alternatively, to the rank odor from the inguinal glands (Ruschi, 1951; Studier and Lavoie, 1984). Two different smells present are produced in different places: the skin and hair of the subaxial area beneath the wings of both males and females is covered by varying amounts of an oily yellow fluid that had a strong, musky-sweet odor, and second in males there is a rank or bitter scent that comes from the inguinal pockets found on either side of the testes.

Subaxial secretions have been reported only in one other bat species, the smaller *N. albiventris* (Dunn, 1934). In both *N. albiventris* and *N. leporinus* the musky-sweet odor is stronger and more noticeable in males than in females (Goodwin, 1928; Dunn, 1934; Gudger, 1945). The odor is persistent: people who have handled bats of either species reported that the distinctive odor remains on their hands for several days, despite removal efforts (Dunn, 1934; Goodwin, 1928). No obvious gland can be found in the subaxial region of either species (Dunn, 1934; Brooke, personal observation).

Noctilio leoprinus has a polygynous social organization where discrete groups of 3–10 females cluster together with a single harem male in the roost

(Brooke, 1994). Many groups may utilize the same hollow tree or rock crevice, but each group exclusively uses a specific area within the roost. Female groups may remain together in the same location for several years regardless of turnover in harem males, who may retain their tenure for two or more reproductive seasons. Bachelor males roost alone or in small groups separate from females.

Female bats marked themselves with the subaxial secretions of other females in the same group (Brooke, 1994). "Head rubs" occurred when a female pressed her head beneath the wing of another and rotated her head from side to side, thereby transferring the scent of the other bat. Females also rubbed their foreheads or chins against the foreheads of other females in their group. Females did not rub against either the subaxial area of resident males or the males' head. Female bats routinely "visited" different groups within the roost (Brooke, 1994). When a visitor first entered the group of roosting bats, her head and wings were thoroughly smelled by the groups. Conversely, group members did not elicit any interest when entering their group.

In this paper we investigate whether the scent of *N. leporinus* differs between adult males and females. Bats were captured to measure the amount of secretions and collect a sample for analysis. Secretions were collected and analyzed to determine differences in the chemical compounds between individuals, within social groups, and among different roosts. We compare lipids of adult males and females and of individuals from different roosts. Bats of known sex and social status were followed while foraging and when entering and exiting a night roost to detect odor in flight.

METHODS AND MATERIALS

This study was conducted on the island of Culebra, 40 km east of Puerto Rico. Culebra is approximately 11 km × 3 km at its longest and widest points, respectively (for a complete description of the study site see Brooke, 1994).

Bats were captured in mist nets while exiting or returning to their day roost. Relative age, adult or juvenile (less than 1 year old) was determined by tooth wear and fused epiphysial joints (Brooke, 1994). The area covered by subaxial secretions was measured in square millimeters with a ruler.

Samples of subaxial secretions from 12 individuals (five males and seven females) from three different roosts were collected on sterile swabs, sealed in glass containers, and frozen. Secretions were extracted by a modified Bligh-Dyer solvent system (While et al., 1979) by D. Decker. Samples were analyzed for lipid composition following methods described for extraction, lipid isolation, gas chromatography, and mass spectrometry in Decker et al. (1992). The nonpolar lipid sample from one female was lost.

To determine how the lipid components of secretions varied among indi-

viduals, sexes, and different roosts, the presence and quantities (in picomoles) of each lipid compound were compared using an unweighted paired-group cluster analysis using arithmetic averages (UPGMA) using the NTSYS computer program (Rohlf, 1987).

To establish differences between males and females in flight, we followed two harem males and 23 females by radio telemetry (Brooke, 1994). On 10 occasions when bats flew within 5 m of us, we noted whether the distinctive smell was evident. Behavioral observations were made inside a building used as a night roost by up to 30 bats during May 1989. Whenever bats entered the building and flew from the roost we noted whether we could detect the musky odor. Sex of bats was established when each roosted.

RESULTS

The area covered by subaxial secretions was determined in 199 bats. The area covered by secretions in adults varied among individuals and between the sexes. There were no visible secretions on 43 juvenile bats examined. Of the 80 adult females examined, 59 individuals (73%) had no visible subaxillary secretions, 11 (14%) had only trace amounts visible, and 10 (12%) had 15–100 mm^2 covered by secretions. None of the 59 females without secretions had the sweet odor typical of males, while the 21 females with visible secretions carried the odor. Of the 76 adult males examined, 22 individuals (29%) had no visible secretions, while 54 (71%) had up to 200 mm^2 covered by secretions. Only males with secretions carried the distinct odor.

A total of 372 lipid compounds was identified in the secretions of 13 individuals: 52 glycolipids (Table 1), 196 nonpolar lipids (Table 2), and 124 phospholipids. Males and females shared 45 glycolipid compounds, 95 nonpolar compounds, and 13 phospholipid compounds. Males had an additional five glycolipid compounds, 55 nonpolar lipid compounds, and 13 phospholipid compounds not shared with females. Females had two glycolipid compounds, 46 nonpolar lipid compounds and 40 phospholipid compounds not shared with males. Three glycolipid compounds (12, 26, and 40) were found in large quantities in both sexes (Table 1).

The UPGMA showed differences by sex and roost affiliation in glycolipid (Figure 1) and nonpolar lipid fractions (Figure 2). Since there was no apparent separation of individuals by either sex or roost affilitation by phospholipids, we have not reported further on these samples. There was no clear separation by sex within the glycolipid analysis. Harem males from the same roost (two individuals from roost 1 and two individuals from roost 3) were more similar to each other than to any other individual (Figure 1). Glycolipid results from a third male, however, were closer to females than to any of the other males.

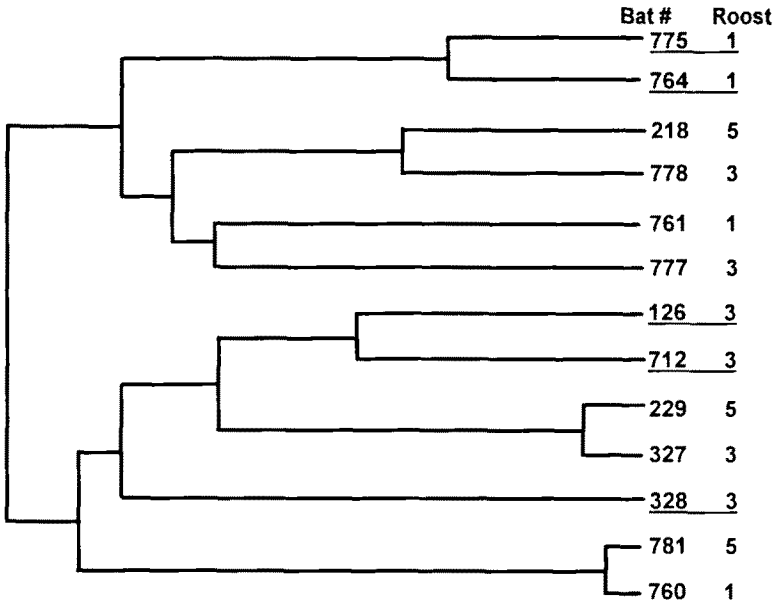

FIG. 1. UPGMA cluster analysis of the relationships among glycolipid compounds found in the subaxial secretions of 13 *Noctilio leporinus* from Culebra, Puerto Rico. Males underlined.

Although two pairs of males from the same roost grouped together, females were not grouped by roost affiliation (Figure 1). After separation of lipids during analysis, the distinctive smell of secretions was present only in glycolipids.

In the nonpolar lipid analysis, five males were more similar to each other than to females in the concentrations and numbers of compounds (Figure 2). There was no clear separation of males from different roosts. Two females from the same roost were more similar to each other than to any other individual.

The odor of harem males was very noticeable to human observers as bats foraged for insects over fields at night. On six occasions when radio-tagged male bats flew within 5 m of our position, the musky scent was obvious. Arrivals and departures of resident males at the night roost were also evident from odor alone ($N = 7$). Conversely, females were not identifiable by their odor when foraging close to our position ($N = 4$) or when flying within the night roost ($N = 9$).

DISCUSSION

Subaxial secretions were a mixture of glycolipids, nonpolar lipids, and phospholipids that varied among individuals in composition, concentration, and

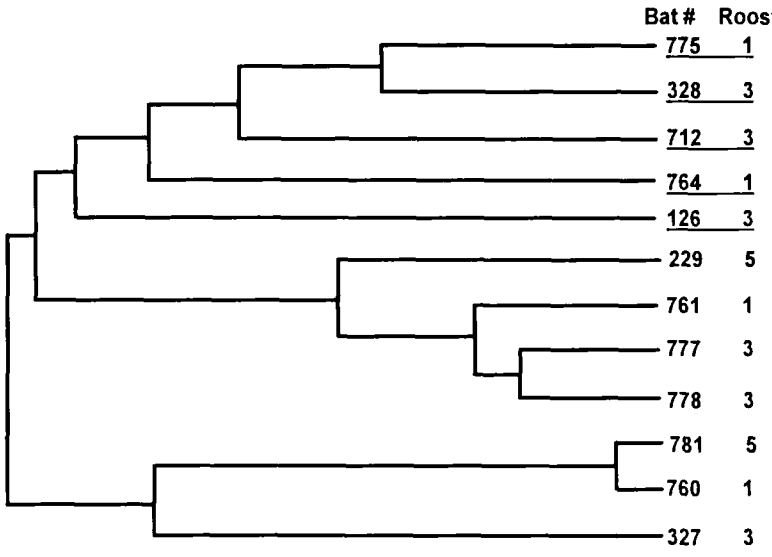

FIG. 2. UPGMA cluster analysis of the relationships among nonpolar lipid compounds found in the subaxial secretions of 12 *Noctilio leporinus* from Culebra, Puerto Rico. Males underlined.

the number of compounds. A number of compounds were present only in males or females, suggesting that scents may be sex-specific (Tables 1 and 2). Further evidence of dimorphic scent comes from the similarity of nonpolar lipid compounds in the five males. Production of chemicals in scent glands has been linked with an individual's hormonal status (Ebling, 1977). As with secondary sexual characteristics of other mammals, the strong scent of males' subaxial secretions may advertise social status.

The individually unique chemical cocktail of subaxial secretions suggests that odor profiles differ among *N. leporinus*. Differences in type and quantity of chemicals in subaxial secretions may form the basis for individual recognition by olfaction. Individual *N. leporinus* smelled the head and wings of conspecifics when they first met, both in day and night roosts. This interest in individual smell suggests that scent plays a role in individual identification. Whether *N. leporinus* is able to distinguish among conspecifics by scent was not tested in this study and remains to be answered.

The smaller amount of subaxial secretions in most females compared to males may be a result of behavioral removal of secretions by head rubs. When female *N. leporinus* rub their heads together, secretions are probably transferred between individuals. Through this scent transfer, the mixture of individual scents may develop a group olfactory identity.

The similarity in both concentration and specificity of glycolipids between males from the same roost suggests that these individuals may develop comparable odor profiles, possibly as a result of frequent interactions. The presence of nonpolar lipids in males distinguished them from females but showed no apparent within-roost or within-group distinctiveness. As phospholipids are both odorless and tasteless to humans and, presumably, to other mammals, they may not contribute to a communicative scent. Consequently, lack of differences among bats of different sex and roost affiliation is not surprising.

Mammalian scent-marking behavior is recognized to play a role in signaling social status (Brown, 1979). Many terrestrial mammals, such as hyenas, badgers, and wolves, regularly mark territorial boundaries with chemical signals (Macdonald, 1985). Female little brown bats may mark trees, possibly to aid orientation between foraging areas and roost when young are first learning to fly (Buchler, 1980). *Noctilio leporinus* were not observed using subaxial secretions to scent mark; however, the strong odor of harem males is broadcast when the bat flies. Odor trails left by these males may serve to advertise foraging territories and arrivals at night roosts. Schnitzler et al. (1994) reported that a male *N. leporinus* they watched defending a foraging territory from other bats was accompanied by a strong wave of odor. Similarly, the sweet odor of two other neotropical bat species, *Tonatia bidens* and *Mimon crenulatum*, may also function in social behavior, as the males' secretions can be detected as a bat flies nearby (Brooke, personal observation).

If male *N. leporinus* use odor trails to advertise their presence, other individuals might be able to detect small amounts of the scent. The sensitivity of bats to intraspecific odors is unknown, but the sensitivity of some bats to fruit odors has been examined. The short-tailed fruit bat (*Carollia perspicillata*) is able to locate fruit exclusively by olfaction (Laska and Schmidt, 1986). When tested for sensitivity to fruit odors (esters, alcohols, and carbon acids), short-tailed fruit bats were able to detect from 3.6×10^{15} to 2.7×10^{10} molecules/cm^3 (Laska, 1990). In comparison, moths that orient toward the source of an airborne chemical plume can detect 10^3–10^6 molecules/cm^3 (Dusenbery, 1992). Bats may be able to detect airborne odor trails, but the morphological variation in the number of olfactory receptor cells and amount of olfactory muscosa suggest that bat species differ greatly in olfactory ability (Schmidt, 1985).

We have described the chemical constituents of subaxial secretions, but how the the secretions are important to *N. leporinus* remains unknown. Do bats distinguish the odors of other individuals? Do female groups have a distinct group odor? Future experimental work should be considered with captive populations where diet can be both controlled and manipulated, reproductive status monitored, and subaxial secretions sampled repeatedly from the same individual over time.

Acknowledgments—We wish to thank M. Barnaby, A. Green, J. Howe, G. F. McCracken, D. Ridley, D. Simard, and T. Tallavast for assistance in the field. The staff of the Caribbean office of the United States National Wildlife Refuge and the United States Fish and Wildlife Service generously aided with logistical problems. G. McCracken, G. Gittleman, A. Green, and two anonymous reviewers offered helpful comments on the manuscript. Financial support for this research was provided to A. Brooke by a National Institute of Health Predoctoral traineeship to the University of Tennessee, the Theodore Roosevelt Fund of the American Museum of Natural History, the American Society of Mammalogists, the Animal Behavior Society, and the University of Tennessee Ethology Program.

(Received December 7, 1995; accepted April 2, 1996)

Abstract—GC profiles of the airborne volatiles produced by adult males and females of the rice bug, *L. chinensis* showed no qualitative chemical dimorphism. However, GC-EAD experiments showed that eight of the compounds elicited strong responses in male and female antennae. Ruling out alarm pheromone and compounds that were not found in the whole-body extracts of the bugs, four compounds remained to be tested as possible attractants. In field experiments, the whole mixture or tertiary blends were not attractive; however, males were strongly attracted to a 5:1 mixture of 2-(*E*)-octenyl acetate and octanol. The attractancy of the binary mixture was decreased by the addition of 3-(*Z*)-octenyl actetate. Although the binary lure specifically attracted males, there was no evidence that it triggered any response of sexual behavior in males.

Key Words—Heteroptera, Alydidae, GC-EAD, 2-(*E*)-octenyl acetate, octanol, 2-(*E*)-octenal, 2-(*E*)-octenol, octyl acetate, 3-(*Z*)-octenyl acetate, rice bug, *Leptocorisa chinensis*

INTRODUCTION

There are some 35,000 species of Heteroptera worldwide, yet sexual pheromones are fully known only for a few species. The diverse nature of the group

*To whom correspondence should be addressed.

0098-0331/96/0800-1429$09.50/0 © 1996 Plenum Publishing Corporation

itself has hindered progress, and the copious defensive secretions from metathoracic glands found in most true bugs can contaminate sex pheromone samples (Aldrich, 1995). In order to alleviate the problem derived from their overwhelming chemical fortification, we have used gas chromatography coupled with an electroantennographic detector (GC-EAD) to study chemical communication in the bean bug, *Riptortus clavatus*. This technique allowed us not only to separate defensive substances from semiochemicals but, more importantly, to isolate an alarm pheromone (Leal and Kadosawa, 1992) from other attractants. Further studies led to the identification of male-specific multifunctional semiochemicals that play the double role of attractant pheromone for adults as well as aggregation pheromone that enables second instars to find the host food plant (Leal et al., 1995). This prompted us to investigate chemical communication of other species of the same family (Alydidae). In that connection, the rice bug, *Leptocorisa chinensis* (Dallas), *kumoherikamemushi* in Japanese, is an interesting case study because it is an economically important pest in Japan, China, and other South East Asian countries for which alternative methods of control are badly neeeded. Surprisingly, we found that males and females of the rice bug produce various semiochemicals that are sensed by both sexes, two of them being attractive only to males.

METHODS AND MATERIALS

Analytical Procedures. Gas chromatography (GC) was carried out with a Hewlett-Packard 5890 II Plus instrument equipped with a split/splitless injector, electronic pressure control, a flame ionization detector, and an HP 3365 Series II Chemstation. High-resolution GC analyses were performed with polar and nonpolar capillary columns: HP-Innowax and HP-5MS (30 m × 0.25 mm × 0.25 μm; Hewlett-Packard), respectively. These columns were operated at 70°C for 1 min, increased to 230°C at a rate of 10°C/min, and held at this temperature for 10 min. Low-resolution mass spectrometry (MS) was carried out with an HP 5890 II Plus gas chromatograph linked to a mass selective detector MSD 5972 (Hewlett-Packard). Chromatographic resolution was achieved on a HP-Innowax column operated under the same conditions as described above. MS were also obtained on an Hewlett-Packard gas chromatograph electron ionization detector GCD Series, equipped with an HP-5MS capillary column that was operated at 50°C for 1 min, increased to 150°C at a rate of 5°C/min, held at this temperature for 1 min, increased to 230°C at a rate of 10°C/min, and finally held at this temperature for 10 min.

Gas Chromatography with Electroantennographic Detector (GC-EAD). The responses of *L. chinensis* antennae were recorded with a GC-EAD system (Struble and Arn, 1984). An HP 5890 Series II Plus Gas chromatograph was modified

to have the effluent from the capillary column split between EAD and FID (3:1 ratio). Bug antennae were placed in a previously described acrylic stage (Leal et al., 1992) which was set inside the glass transfer line (2 cm away from the GC outlet) and connected with gold wires to an amplifier (gain 5). The signal was filtered through a passive filter (cutoff frequency 0.12 Hz) and fed into an A/D 35900E interface (Hewlett-Packard). Simultaneous acquisitions of FID and EAD signals were obtained with the above chemstation.

Extracts. For the collection of airborne volatiles, field-collected adult bugs, separated into male and female groups, were anesthetized with CO_2 to minimize the release of defensive secretion and transferred to an all-glass aeration apparatus. The aeration apparatus contained a piece of wet cotton and an ear of foxtailgrass, *Setaria viridis* (Gramineae). The chamber was placed inside an incubator maintained at 25°C and a 16L:8D photoperiod. Volatile compounds were trapped on a Super Q (Alltech, Deerfield, Illinois) column. The trapped compounds were eluted by washing the column with hexane and the extract was concentrated to 0.1 insect equivalent/μl. Whole-body extracts were obtained by immersing at least three individuals in hexane for 3 min.

Chemicals. 2-(*E*)-Octenyl acetate and 3-(*Z*)-octenyl acetate were prepared by the reaction of the respective alcohols with acetyl chloride in dichloromethane. Octyl acetate, 2-(*E*)-octenol, and octanol were purchased from Tokyo Chemical Industry Co. Ltd.

Traps and Field Tests. Newly developed sticky traps (20 × 20 cm) were made of waterproof paper coated on both sides with adhesive polybutadiene. Field experiments were conducted in a rice field inside Ibaraki Research Center in the summer of 1995. Chemicals (1 mg) were incorporated in plastic pellets (4–5 mm in diameter) made of polyethylene-vinyl acetate. Ten pellets were loaded on the sticky plate traps, and tests were run with the traps distributed around a rice field with three replicates. Traps were placed at 25 cm above the ground with an intertrap distance of 10 m. Capture data were collected daily for at least three consecutive days; these data were transformed to log $(x+1)$ before difference among means were tested for significance by ANOVA with the JMP Software, Version 2 (Anonymous, 1989). Treatments followed by the same letters are not significantly different at the 5% level in the Tukey-Kramer honestly significant difference test.

RESULTS AND DISCUSSION

The GC-EAD profile of the airborne volatiles collected from *L. chinensis* females showed the occurrence of at least eight peaks that were EAD-active (Figure 1). The same EAD responses were obtained with male or female antennae as the sensing element.

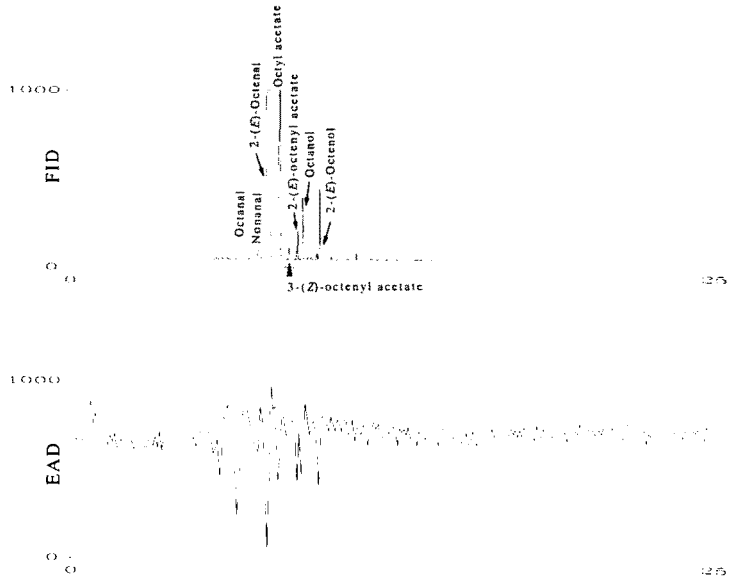

FIG. 1. Parallel FID and EAD chromatograms obtained from airborne volatile of *L. chinensis* females during the scotophase (0.1 female equivalent) and separated on an HP-Innowax column. The EAD profile using a female antenna as the sensing element (in the figure) was identical to the profile obtained with male antenna (not shown).

Interestingly, these EAD-active peaks were detected in the extracts from males as well as from females not only in the scotophase (Figure 2), but also in the photophase. The FID profiles showed only quantitative differences. There was no qualitative difference in the whole-body extracts of males and females.

The EAD-active peaks were identified by their mass spectra, followed by comparison with authentic compounds that gave the same retention times as the natural products on both polar and nonpolar columns. Because the bugs released abundant amounts of 2-(*E*)-octenal when disturbed, this compound was considered to be part of the alarm pheromone system. In fact, 2-(*E*)-octenal has been previously identified as an alarm pheromone of other hemipterans (Blum, 1985). Toxicity and repellency tests also showed that 2-(*E*)-octenal is part of the defensive secretion of the rice bug, *L. oratorius* Fabricius (Gunawardena and Bandumathie, 1993). Octanal and nonanal were ruled out as part of an attractant pheromone since these compounds were not found in the whole-body extracts.

Four compounds remained to be tested as possible attractants for the adult bugs: octyl acetate (OAc), 2-(*E*)-octenyl acetate (2EOAc), octanol (OL), and

FIG. 2. GC profiles of the airborne volatiles of (A) female and (B) male *L. chinensis* collected during 6 hr of the scotophase.

2-(*E*)-octenol (2EOL). The activity of these compounds was tested in the field by utilizing the ratio typically found in the airborne extracts; the ratio of 2EOAc, OAc, 2EOL, and OL was 10:5:2:2. This is not the ratio of the sample shown in Figure 1. Preliminary experiments showed that captures in traps baited either with a full mixture or with tertiary mixtures were not significantly different from catches in control traps.

Finally, the attractants were identified by testing binary combinations of the four compounds. These experiments revealed that a mixture of 2EOAc and OL was very attractive to males (Figure 3).

Catches in traps baited with 2EOAc and 2EOL, albeit small, were also significantly higher than captures in control traps. Further experiments involving only two treatments confirmed that males were attracted significantly more to the 2EOAc + OL lure than to the 2EOAc + 2EOL; the latter also captured significantly more bugs than control traps (Figure 4). The results were clear-cut because there was no catches at all in control traps throughout these experiments. In the preliminary tests, however, bugs were captured in control traps, probably due to the effect of weeds in the vicinity of the traps. This interference was completely eliminated by cleaning the rice field before the next series of experiments.

It was found that both male and female *L. chinensis* also produce 3-(*Z*)-octenyl acetate (3ZOAc), although EAD response to this compound was very

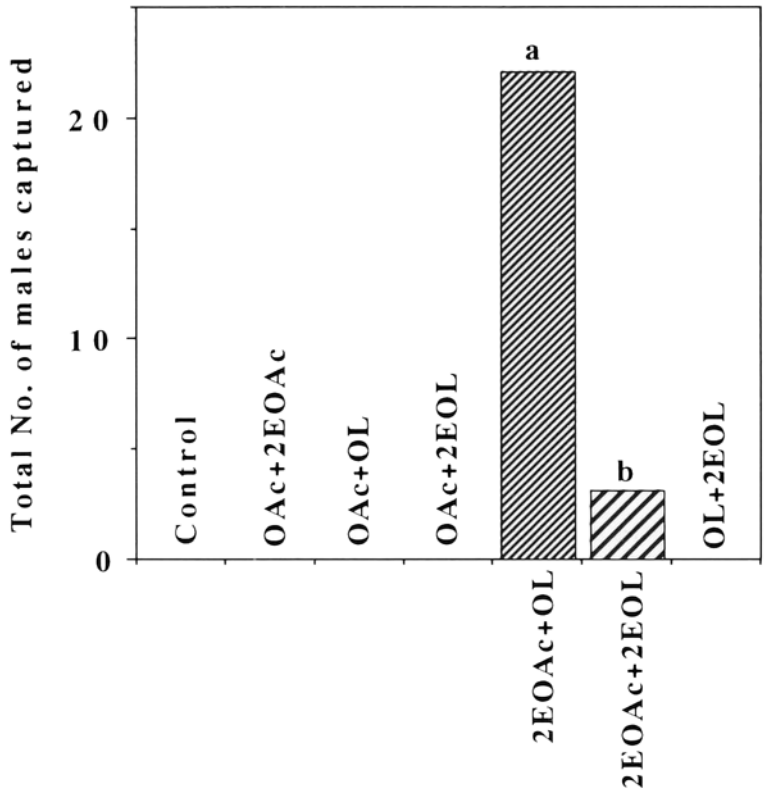

FIG. 3. Catches of *L. chinensis* males in sticky traps baited with binary combinations of the four possible attractants.

weak. Field tests showed that this compound decreased the captures of male rice bug in traps baited with the attractant mixture, 2EOAc + OL (Figure 5). Whether 3-(*Z*)-octenyl acetate is a part of the alarm pheromone system of the rice bug or a behavioral antagonist is yet to be clarified. Furthermore, 2EOL seems to have negative effects on the catches, but further experiments must be carried out to determine the role of this semiochemical in the chemical communication of the rice bug.

Sex pheromones have traditionally been considered by researchers to be those compounds that are emitted by individuals of one sex and that cause attraction of members of the opposite sex, resulting in the location of the emitter, and subsequently, mating (Baker, 1989). Contrary to many other families, sex pheromones of hemipterans are largely produced by males. It is worth noting that in alydids, the metathoracic scent glands are sometimes sexually dimorphic,

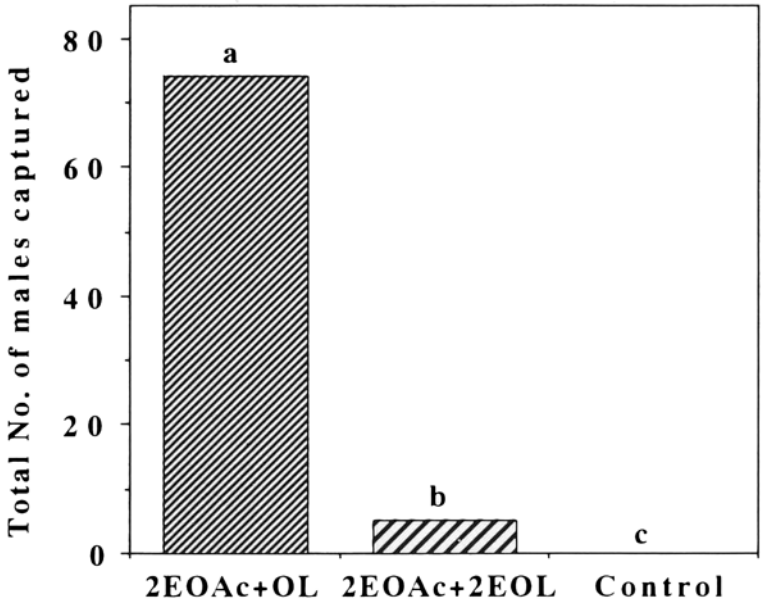

FIG. 4. Captures of males of the rice bug in sticky traps baited with 2-(*E*)-octenyl acetate plus octanol and 2-(*E*)-octenyl acetate plus 2-(*E*)-octenol.

and the dimorphisms are expressed chemically (Aldrich et al., 1993). Recently, we found that males of the bean bug *Riptortus clavatus* release semiochemicals that attract both males and females (Leal et al., 1995). Interestingly, the case of the rice bug is just the opposite, i.e., only males are attracted to semiochemicals that are produced and released by both males and females. Although female antennae of *L. chinensis* can "smell" the male attractants (and the other semiochemicals tested), they do not elicit any attraction for females. Throughout the whole series of experiments, only four females were captured, although insect samples collected in the same field had a sex ratio nearly 1 : 1.

In conclusion, 2EOAc and OL are produced by both male and female of *L. chinensis* and attract only males of the same species. Field experiments showed that a 5 : 1 mixture is very attractive, but the optimum ratio of the attractants is yet to be determined.

For this attractant pheromone we avoided using the term sex pheromone (Tamaki, 1985) because, despite the fact that the chemicals are "secreted by an organism to the outside and cause a specific reaction in a receiving organism of the same species" (Nordlund, 1981), there is no evidence that these semiochemicals trigger any sexual behavior in males other than attraction. Future

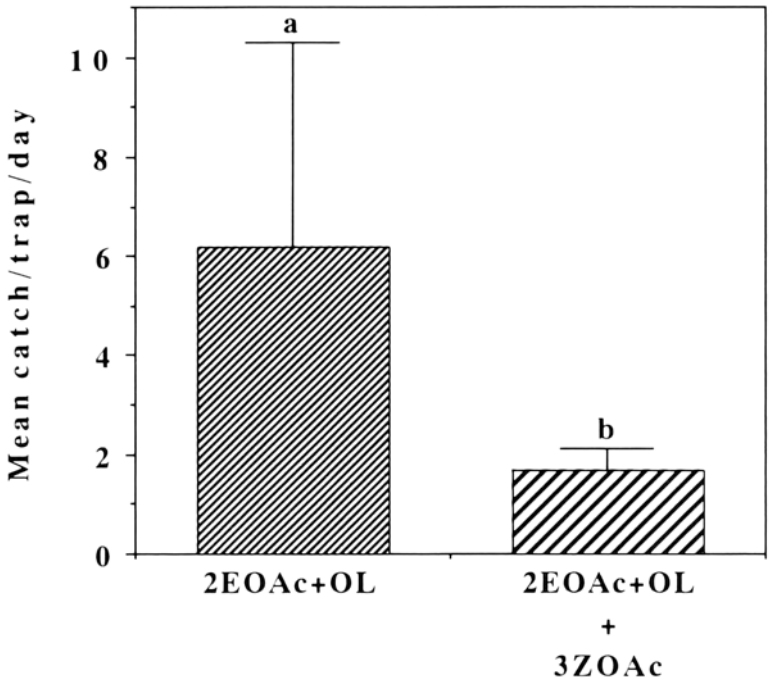

FIG. 5. Captures in traps baited with a 2-(*E*)-octenyl acetate + octanol (5 : 1) and the binary mixture plus 3-(*Z*)-octenyl acetate (5 : 1 : 1).

detailed behavioral studies will be carried out to test the possibility that these semiochemicals are involved in lek formation.

Throughout this paper we used the term semiochemicals (Nordlund and Lewis, 1976) for all EAD-active compounds because the compounds are released and sensed by the same species, and they are likely to be involved in chemical interactions between the rice bugs. Further studies are needed to clarify their specific role in the chemical ecology of this species.

Acknowledgments—This work was supported in part by a special coordination fund for promoting science and technology (SCF) in the basic research core system by the Science and Technology Agency, Japan, granted to W.S.L. Partial financial support of Japan Tobacco Co. is greatly appreciated. MSD was on loan from Fuji Flavor Co. Ltd. Kazumi Yoneyama and Shigeo Tada helped with field experiments and volatile collections. We wish to thank Dr. Kiyomitsu Ito, Hokkaido National Agricultural Experiment Station, for suggesting that we investigate chemical communication in the rice bug as well as for his critical review of a draft version of the manuscript. The manuscript has been critically read also by Klaus Jaffé (Universidad Simon Bolivar) and Pierre Escoubas (SUMBOR).

INTERSPECIFIC ADVANTAGE RESULTS IN INTRASPECIFIC DISADVANTAGE: CHEMICAL PROTECTION VERSUS CANNIBALISM IN *Utetheisa ornatrix* (LEPIDOPTERA: ARCTIIDAE)

FRANZ X. BOGNER

Institut für die Didaktik der Biologie
Fakultät der Biologie, Ludwig-Maximilians-Universität
Barbarastr. 16/V, D-80797 Munich, Germany

(Received September 25, 1995; accepted April 4, 1996)

Abstract—This study suggests that alkaloid deficiency in *Utetheisa* (Lepidoptera: Arctiidae) is a main cause of cannibalism; moreover, cannibalism can be predicted on the basis of alkaloid deficiency and of systemic alkaloid accumulation. This chemical plays a central role in the life of this species, because, first, it provides acquired chemical protection from potential predators, and, second, it determines mating success (as the alkaloid is an essential precursor of the male pheromone). Consequently, losers in the larval sequestering of alkaloids, which would result in a lack of chemical protection and in decreased mating success, tend to target conspecific winners, which are normally substantially protected against a variety of predators; by cannibalizing those accumulated alkaloid sources the losers tend to become the winners of cannibalistic encounters while making up their shortfall of these chemicals. What is a presumptive advantage in selection under high predation pressures and/or high alkaloid availabilities could become a disadvantage under high conspecific population densities and shortages of alkaloid supplies for larval uptake. Cannibalism may be expected to have general ecological importance in the evolutionary play of *Utetheisa* and may contribute to a balanced regulation of the acquired alkaloid contents in these arctiid populations.

Key Words—Larval cannibalism, pyrrolizidine alkaloid, chemical protection, population density, *Utetheisa ornatrix*.

INTRODUCTION

Larval cannibalism is a well-known major mortality factor and for that reason could be a basic regulatory factor of populations in some species (Stinner et al.,

0098-0331/96/0800-1439$09.50/0 © 1996 Plenum Publishing Corporation

1977; reviews by Fox, 1975a; Polis, 1981 and references therein). In such a function cannibalism could lower population densities to levels where resource limitation is merely a minor cause of mortality (e.g., Polis, 1980). Other factors promoting cannibalism were identified, such as food availability or quality (e.g., Banerjee and Mahapatra, 1987), developmental stages (e.g., Polis, 1981), and physical conditions including parasitization (Dindo, 1990). However, most reports about cannibalism are anecdotal and are often passing remarks within other studies dealing with problems of laboratory cultures and/or of parameters such as size, age, molting stages and/or gender.

Larvae of *Utetheisa ornatrix* (Lepidoptera: Arctiidae), the subjects of this study, feed on plants of the genus *Crotalaria* (family Leguminosae), long known to contain pyrrolizidine alkaloids (PAs). The larvae preferentially eat the seeds that have the highest concentrations of the alkaloids within the plant (Eisner and Meinwald, 1987 and references therein). Unlike most other larvae, *Utetheisa* tolerate these alkaloids. Moreover, they sequester those chemicals systemically and retain them through metamorphosis into the adult stage. However, the retained alkaloid supply may vary drastically in adult moths depending on larval access to *Crotalaria* seeds. Individual moths reared outdoors on seed-bearing *Crotalaria spectabilis* contained 701 $\pm$ 59 (mean $\pm$ SEM) μg monocrotaline, while the ones reared on immature (seedless) *Crotalaria spectabilis* contained only 98 $\pm$ 10 μg (Conner *et al.*, 1990). Natural variation and the sometimes substantially reduced quantities of PAs in *Utetheisa* could result from short supplies of *Crotalaria* seeds, competition within high population densities of *Utetheisa* for available seeds, interspecific competition with *Etiella zinckenella*, a pyralid moth that is also able to feed on that plant, or from combinations of these. A sufficient systemic chemical load is essential for chemical protection and also essential in synthesizing the male pheromone, a significant attractant for successful mating (Eisner and Meinwald, 1987).

One might imagine that *Utetheisa* larvae are unlikely to become cannibals due to their chemical protection by alkaloids (Eisner and Meinwald, 1987). However, larval *Utetheisa* that are deficient in alkaloids could make up their shortfall by turning to pupal or egg cannibalism (Bogner and Eisner, 1991, 1992). This specific alkaloid-biased cannibalism was shown to be primarily a consequence of an alkaloid deficiency rather than hunger. Specifically, it was shown that larvae acquire alkaloids by feeding on conspecific pupae or eggs that are not deficient in this alkaloid. However, this kind of cannibalism is either rare, because larvae normally pupate away from their food plants, or inefficient, in terms of alkaloid uptake. For example, the alkaloid contents of eggs are at microgram levels, magnitudes lower than necessary for successful use. In that context, larval cannibalism would be more likely in nature and could be a sufficient way of making up alkaloid. Therefore, a series of larval cannibalism experiments was undertaken in order to determine if larvae are predisposed to

be cannibalistic when they are PA-deficient and to test an hypothesized existence of chemically biased conspecific foraging, i.e., if larvae display a high preference for PA-containing larvae when given a choice.

METHODS AND MATERIALS

Experimental Animals

The *Utetheisa* were from a laboratory culture, established with stock taken near Lake Placid, Highlands County, Florida. Voucher specimens are on deposit (Lot 1154) in the Cornell insect collection. The moths were reared on two diets: (1) PB diet, a semisynthetic diet (c.f. Miller et al., 1976) based on pinto beans and devoid of PAs (shown by a minus sign in the following text), and (2) CS diet, identical to PB diet, but with 10% (by weight) of its pinto bean content replaced by ripe *Crotalaria spectabilis* seeds (shown by a plus sign). *Crotalaria spectabilis*, one of the principal foodplants of *Utetheisa* in the southeastern United States, contains the PA, monocrotaline, mostly in its seeds (Johnson et al., 1985). It is known that the CS diet is an appropriate substitute for the natural foodplant. Individuals raised on that diet contain 782 $\pm$ 141 (SEM) μg monocrotaline/moth (N = 4) (J. Kopecky, cited in Bogner and Eisner, 1992).

Basic Experimental Protocol

For the experiments, the caterpillars were transferred directly from the laboratory colony (no starvation times) to test containers (85 mm diameter, 35 mm height) with a bottom filter paper (diameter = 75 mm). The containers provided no food, but a small wet cotton ball supplied humidity. For the singular tests, first, third, or fifth instars (see below) were placed in the containers kept at a constant 23°C for the duration of the experiment time in a temperature-controlled room with 16L:8D photoperiod.

Utetheisa caterpillars show no external genitalic sex differences. However, randomly dissected samples showed equal distributions of sexes. Each larva, taken at least one day after the last molt, participated in only one test. First counts of survivors were made after 24 hr, followed by further successive 24-hr counts. No replacements were made for cannibalized larvae. It was not possible for the larvae to crawl out of the container during the experiment. In the case of the fifth instars, the tests were interrupted when the first pupation within a cage took place, which is the reason for lower numbers in fourth experimental day in test series 2 and 3.

The design of the experiments was aimed at unveiling any type of larval cannibalism in *Utetheisa*. Population densities or different body sizes were examined to look for potential clues of cannibalism (Semlitsch and West, 1988). Alkaloid dependency was hypothesized as the main cause of cannibalism.

Experimental Rationale

Test Series 1: Varying Density Parameters. The first experimental series was designed to evaluate potential density and/or alkaloid dependencies in larval cannibalism of *Utetheisa*. Roughly same-sized third instars of the same intermolting periods (middle size, 12–15 mm) were used. The experiment involved placing 5, 10, 15, or 20 larvae per cage, and included 15 replicates within each density. Only (+)-alkaloid or (−)-alkaloid-grown were grouped together in each test series. In each case the survival rate was scored every 24 hr during the following seven days.

Test Series 2: Size Dependency (Control Design for Test Series 3). Similar to the experimental design of the previous test series, the second experiment focused on potential cannibalism caused by differential larval body size and was a control for the later test series 3. Sets of second instars (small-size, 6–8 mm) or fifth instars (large size, 24–27 mm) were caged, and survival rates were monitored during three consecutive starvation days. The experimental time was limited by pupation after four days of the large caterpillars. In each test, 10 same-sized caterpillars, either (+)- or (−)-grown, shared containers. Each test was replicated 15 times.

Test Series 3: Asymmetric Encounters of Different PA-Content. In the third experiment body size and alkaloid content were brought into the design as additional parameters. Although the experimental larvae were not labelled according to their alkaloid content, due to the different body sizes, the alkaloid content of the subjects could be assured: (+)- and (−)-grown larvae could be distinguished by body sizes only when they had been placed together in a common cage. In each case, 10 caterpillars, for instance, five large (+) and five small (−) etc., shared containers during four sequential starvation days, covering all combinations of size (large/small) and alkaloid content (-laden/-deficient). The purpose of this test was to disentangle size and alkaloid dependencies in asymmetric-sized conspecific clashes. Each test was replicated 25 times.

Field Observation

The study sites for the field observation were patches of *Crotalaria mucronata* at the Archbold Biological Station or at the Agro-Ecology Research Station, both in Highlands County, Florida. The plants were of all ages, many of them mature and with seed pods at all developmental stages, but they were only moderately infested with *Utetheisa*. During field observation periods, this low population density was indicated by only a few larvae per plant, although intact seed pods were in ample supply. However, many larvae could be present within the seeds and therefore not (or only barely) visible in heavy infestations and consequently dozens of *Utetheisa* larvae may be present on single plants (Eisner,

personal communication). Most of the plants were inspected at irregular intervals.

Statistical Protocol

For testing the significance of the analysis of variance within the density experiments (Figure 1), a MANOVA test of between-subjects affects was undertaken. In Table 1 statistical differences of the linear effect of day 0 to day 8 are presented. Repeated measures using orthogonal polynomial transformations were performed. Only the linear trend differed significantly from zero when tested by a classical t test. However, since the typical data for this test are raw data values, here the differences between values are tested. In the case of the cross-cannibalism experiments (Figure 3 below), for the between-group comparisons, median comparisons were performed using Mann-Whitney U-Wilcoxon's rank sum W test by computing a linear trend calculation (Table 2). Details of these

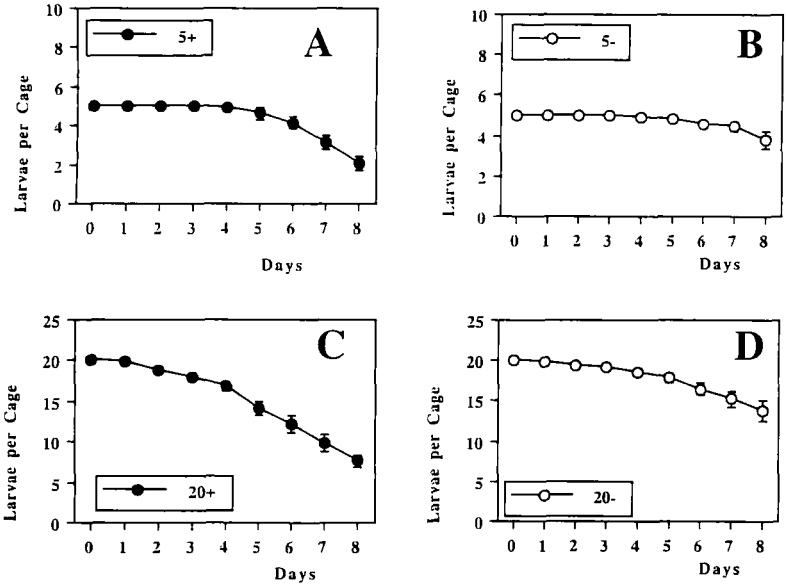

FIG. 1. Survival rate of same-sized third-instar *Utetheisa* caterpillars caged in numbers of 5 and 20 per container: one design with (+), the other with (−) specimens [(−) means alkaloid-deficient, (+) alkaloid-laden]. The results of identical experiments with 10 and 15 caterpillars per cage are displayed in Table 1. No food was presented during the eight-day periods (values are means, bars are ± SEM). Each experiment had 15 replicates.

tests are given in Siegel (1956). All computations were performed using the statistical package SPSS for Windows (see Norusis, 1993a,b).

RESULTS

Experiment 1: Rate of Cannibalism and Density Between Caterpillars with Identical Alkaloid Content. Even high population densities caused no severe intraspecific feeding in middle-sized caterpillars after the first starvation day (Figure 1, Table 1), but, as expected, survival rates were dependent on popu-

lation densities. Not surprisingly, the more crowded a cage, the more cannibalism occurred. However, hunger should not depend on density since no food was provided in any of the cages, but larvae may simply feed in part on larvae dead from starvation (although this has never been observed). Nevertheless, the survival rates were high in comparison to other studies (Semlitsch and West, 1988; see Discussion), even after long starvation periods. However, the mortality was significantly dependent on the systemic PA content of the caterpillars, because death rates in alkaloid-containing larvae were twice as high, even in less crowded situations, as in alkaloid-deficient caterpillars (Figure 1B–D). However, on the basis of this experimental design alone, the possibility still exists that the mortality rates of (−) and (+) larvae differ (see below).

Experiment 2: Cannibalism Rate and Larval Body Size. Middle-sized caterpillars, caged as 10 per container, displayed almost no cannibalism within the first three days, i.e., it was identical to the situation of five caged caterpillars in Figure 1 (A and B). This was also true, given the same population densities, in the case of small-sized and large-sized larvae during the tested period. Therefore, body size did not seem to play any considerable role in cannibalism when (+) and (−) caterpillars could not encounter each other (Figure 2A–D).

Experiment 3: Cannibalism of Different-Sized Caterpillars with Different Alkaloid Content. Caged middle-sized caterpillars showed an alkaloid-dependent probability of being cannibalized when the starvation period lasted long enough (Figure 1); in these tests the encounters were of equal body size and of equal alkaloid content. The observed cannibalism rate was also low when large or small caterpillars shared the same container (Figure 2). When physical advantage was taken into account, the cannibalism rate was highest in the case where small alkaloid-laden caterpillars shared the cage with large alkaloid-deficient caterpillars (Figure 3D). The same design, but the reversed constellation (small alkaloid-deficient and large alkaloid-laden) revealed cannibalism, too, but at substantially lower rates (Figure 3C). Both controls, that is, larvae of both sizes containing equal alkaloid backgrounds also revealed lower mortality rates (Figure 3A,B). The small-sized "haves" apparently faced a considerably greater risk from large-sized "have-nots" (Figure 3D, Table 2). Large caterpillars might be better in defending themselves as well as more prone to attacking when in need of the alkaloid.

Field Observation. Cannibalism was only rarely observed in a field population of *Utetheisa*, although causal observations become relevant at this point. Caterpillars often pierce holes in the *Crotalaria* pods and crawl into the pods until they are completely hidden. During the time when the invasion takes place, the caterpillars may poorly oppose an attack while presenting a vulnerable abdomen towards the attacker. In two observed cases, the incumbent caterpillar could not turn around quickly enough within the pod (or retreat out of the gnawed pod) and could not resist the attack, and thus was cannibalized. The (successful)

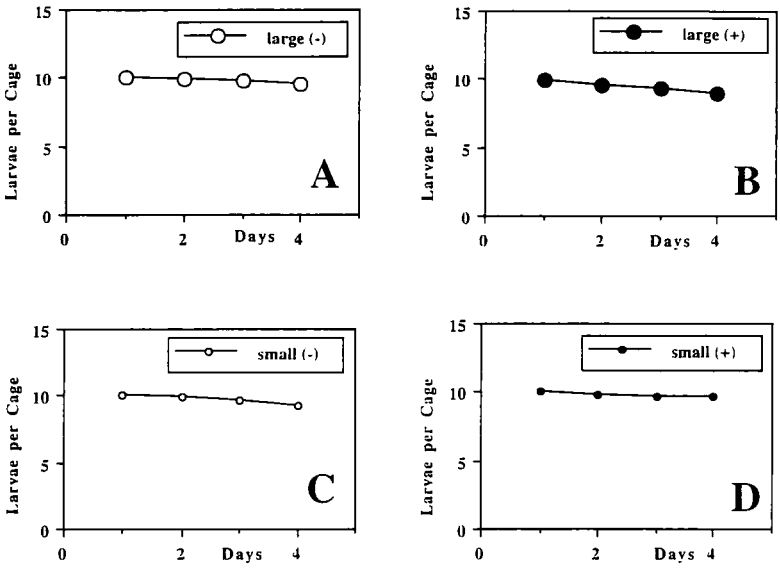

FIG. 2. Survival rate of 10 *Utetheisa* larvae per cage [large means fifth instar, small means second instar; (−) is alkaloid-deficient, (+) is alkaloid-laden]; 15 replicates were undertaken (in the case of the fourth day, due to pupation $N < 15$). Values are means (SEM not shown).

challenger ate the leaking hemolymph and cannibalized the caterpillar. Cuticular residues found within the pods may point to cannibalism, too.

DISCUSSION

The most important implication of the experiments presented is the demonstration of the likelihood that an alkaloid is the driving force for cannibalism in *Utetheisa* caterpillars. Intraspecific mortality seems to be caused basically by the deficiency and availability of the alkaloid rather than by other parameters alone, such as exaggerated population densities or starvation. Under the simple choice conditions of the present laboratory tests, *Utetheisa* larvae may opt to forage upon conspecific larvae that are alkaloid-laden. Although there is a decrease in the larval numbers due to starvation, alkaloid content is shown to be linked to susceptibility to cannibalism. The chemically protected caterpillars of *Utetheisa* are less likely to survive than their alkaloid-deficient conspecifics.

Although it is still unclear how the caterpillars identify the alkaloid within conspecifics and how they could sense which conspecifics carry alkaloids, the

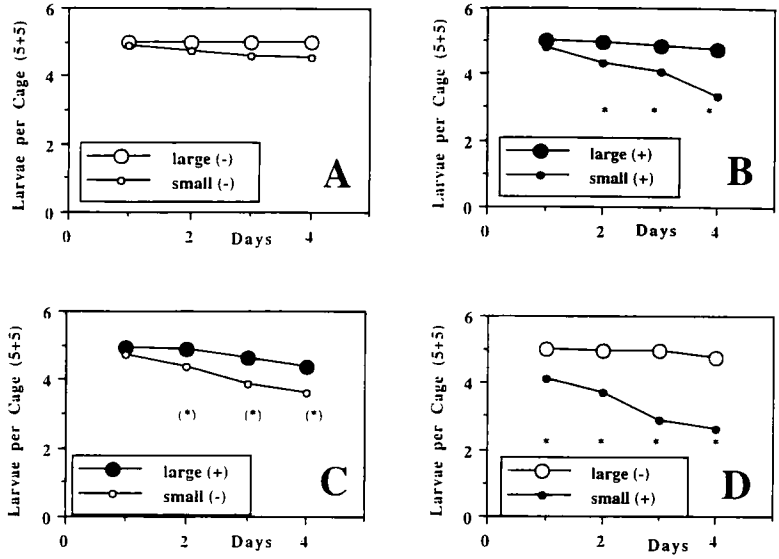

FIG. 3. Survival of five large (fifth instar) and five small (second instar) caterpillars, caged in the same containers. The design allowed recognizing of larval alkaloid contents without artificial markings. No food was presented during the experimental period. Each experiment had 25 replicates (in the case of the fourth day, due to pupation $N < 25$). Values are means; z-values: * ≤ 0.001, (*) ≤ 0.01).

experiments presented identify the systemic alkaloid content as the major cause of being cannibalized. This is in line with previous work (Bogner and Eisner, 1991, 1992). Chemical analyses indicate that in *Utetheisa* larvae, one single cannibalistic act is sufficient to provide the cannibals' drug requirement (see also, Bogner and Eisner, 1991, 1992).

The alkaloid content of *Crotalaria* provides the plant with considerable chemical protection. Among other attributes, the chemicals are extremely potent toxins in mammals (Mattson, 1980). Therefore, species such as *Utetheisa*, which can use as a food plant plants that other herbivore species avoid due to chemical load, might be less likely limited by food scarcity than other plant-eating caterpillars. Less interspecific competition towards food resources could result in less intraspecific larval competition. Laboratory experiments with *Utetheisa* reveal little cannibalism within the experimental time compared to other studies (Semlitsch and West, 1988). Although we do not know about relevancies of the latter experiment for *Utetheisa*, and although the *Utetheisa* population could peak at high densities (see Materials and Methods, Field Observations), cannibalism in *Utetheisa* could be less necessary to reduce oversized populations

before, for instance, mass starvation occurred (Fox, 1975b). However, in very high population densities, where heightened feeding activity results in more frequent confrontations, more harmful intraspecific interactions take place, resulting in higher cannibalism rates and consequently contributing to lower densities (Breden and Chippendale, 1989).

Intraspecific larval confrontation often has resulted in cannibalism, especially when encounters occurred between asymmetric sizes of larvae. Smaller conspecifics were more frequently eaten than larger ones (Polis, 1981; Semlitsch and West, 1988). This is also true in the case of *Utetheisa*, but only under certain circumstances, such as the larger counterparts being in need of alkaloid. The greatest probability of becoming cannibalized was observed when small alkaloid-laden caterpillars were encountered by large alkaloid-deficient ones. The parameter of small body size could not be the sole determinant of becoming a cannibalized victim, but the body content of alkaloid appears to be the reason for being predisposed to being a cannibal or a victim.

A persistent weakness of most studies on larval cannibalism has been the evaluation of cannibalism in natural populations. The present study does not compensate for this insufficiency. However, in the case of *Utetheisa* there may be much (invisible) cannibalism within the pods. If a caterpillar is hidden within pods and another one tries to invade the pod, a cannibalistic encounter would be almost inescapable, especially when a potential invader faces the (vulnerable) abdomen of the incumbent that has not completed its invasion into a pod. Variations of larval alkaloid content in nature could result from the host plants containing alkaloids in varying amounts, from insufficient access to the seeds (see above), or from both.

Although chemical protection by alkaloid load is only one facet of the chemical ecology of the animal, it could be argued that potential predators use the aposematic coloration of *Utetheisa* as an avoidance cue. They may not be able to assess the chemical load of individual caterpillars via volatile principles as the adult *Utetheisa* can (Bogner et al., 1992). This would bring automimicry into play since the systemic alkaloid content varies. Besides chemical protection the alkaloid also plays a central role as a basic chemical for the biosynthesis of the male pheromone, hydroxydanaidal. Just as the male transfers a spermatophore, the female transfers the alkaloid load into the eggs (Dussourd et al., 1988), providing essential protection for this vulnerable life stage. Given the importance of the alkaloids in the life of *Utetheisa*, caterpillars might cannibalize alkaloid-laden conspecifics for their own source when in need.

Beyond the fitness of *Utetheisa* caterpillars in terms of chemical protection and mating success (Eisner and Meinwald, 1987), it could be argued, although without any labeling evidence for this assertion, that the alkaloid also could be a major source of nitrogen. Such energy transfer has been discussed in related studies (Mattson, 1980; Banerjee and Mahapatra, 1987). Extended starvation

stress causes an increasing cannibalism rate in *Utetheisa*, which was substantially lower than the rate in other species (Semlitsch and West, 1988). Conspecific caterpillars are potential competitors while feeding on potentially limited food resources. Finally, in *Utetheisa*, the alkaloids function as phagostimulants, as was shown in previous studies (Bogner and Eisner, 1991, 1992). The alkaloids, therefore, could function as an essential cue for caterpillars to direct attacks preferentially on larvae that are PA-laden. This should be even more important when caterpillars can move between plants, since in such cases even more substantial differences between the caterpillars could be expected. However, the cannibalistic threat could result in behavior whereby *Utetheisa* caterpillars initially try to avoid each other and disperse as far as foodplant availabilities permit and offer alternatives.

CONCLUSION

The alkaloidal variance in field specimens could reflect not only availability and foraging of alkaloidal resources, but could also reflect a balancing of: (1) a cannibalism threat, (2) chemical protection, and/or (3) male fitness (in terms of the male pheromone production). The observed alkaloid amount gained during larval life could play a crucial rule. Winners in sequestering alkaloids are well protected against predators, whereas losers are not; therefore, the more alkaloid the better should be expected as the rule. Chemical protection could be replaced by automimicry (for less-protected larvae), and it could also increase cannibalism. Even when all *Utetheisa* advertise chemical protection by aposematic coloration, within the natural environment probably only the larval conspecifics are able to detect the truth in its favorable focusing on the winner. Therefore, given the importance of alkaloids in the life of *Utetheisa*, good chemical protection could be a good investment only when predation pressures are high and alkaloid availabilities are abundant. It could be a bad investment when population densities of *Utetheisa* are high and alkaloid availabilities are scarce. In that context, the general rule, the more sequestering the better, would be inapplicable, especially when the best available alkaloid sources might be conspecifics. In the latter situation, the loser would be in less danger of being cannibalized, whereas the winner would be the preferential target and victim of this intraspecific interaction. Within sexual selection (in terms of alkaloid sequestering and endowment), the balancing of the chemical load should, therefore, be the optimal evolutionary guideline.

Questions raised in Bogner and Eisner (1992) are still to be answered. Are there times when it is beneficial for *Utetheisa* to be alkaloid-deficient, such as when the threat from cannibalism outweighs that from predation? This could occur when foodplant seeds are scarce, population densities are high, and intra-

specifics would be the most concentrated alkaloid sources. There is still a lack of field data supporting the laboratory phenomenon that usurpation of alkaloids by cannibalism provides the balance of the chemical in *Utetheisa*. The laboratory data presented here should be a reliable basis to disentangle another thread of the complex chemical ecology network of *Utetheisa*.

Acknowledgments—The laboratory experiments were done at the Section of Neurobiology and Behavior, Cornell University, Ithaca. Therefore, I am greatly indebted to T. Eisner for valuable facilities and also for productive and beneficial discussion. Additionally, I am very grateful to D. Murchan and M. Wiseman as well as two unknown referees for constructive discussions. I appreciate the chemical analysis data from J. Kopecky, assistance from K. Amerman, T. Dillon, G. Scoles, and P. Bogner; and space and facilities from the staff of the Archbold Biological Station. The study was supported by the Deutsche Forschungsgemeinschaft (DFG).

INSECT ANTIFEEDANT AND GROWTH-REGULATING ACTIVITIES OF SALANNIN AND OTHER C-SECO LIMONOIDS FROM NEEM OIL IN RELATION TO AZADIRACHTIN

T. R. GOVINDACHARI,* N. S. NARASIMHAN, G. SURESH, P. D. PARTHO and GEETHA GOPALAKRISHNAN

Centre for Agrochemical Research, SPIC Science Foundation, 110, Mount Road, Madras 600 032, INDIA.

(Received October 3, 1995; accepted April 16, 1996)

Abstract—The antifeedant and insect growth-regulating activities of salannin, nimbin, and 6-deacetylnimbin, in comparison with azadirachtin-A, have been studied against *Spodoptera litura*, *Pericallia ricini*, and *Oxya fuscovittata*. Salannin deterred feeding, delayed molt by increasing larval duration, caused larval and pupal mortalities, and decreased pupal weights in the two lepidopterans. Salannin also caused molt delays and nymphal mortalities in *Oxya fuscovittata*. The role of salannin and other compounds in conferring bioactivity, along with azadirachtin-A, to neem oil/neem seed extracts is emphasized.

Key Words—Antifeedant activity, insect growth-regulating activity, salannin, nimbin, 6-deacetylnimbin, azadirachtin-A.

INTRODUCTION

Neem oil and neem seed kernel extracts from *Azadirachta indica* A. Juss (Meliaceae) have been used in India since ancient times for the protection of plants from insect attack. The wisdom of this traditional practice was validated by the isolation, by Butterworth and Morgan (1968), of azadirachtin, which was stated to be a feeding deterrent against the desert locust at a concentration of 40 μg/liter. This remarkable observation aroused the interest of chemists and biologists all over the world during the past two decades, and as a result more than 100

*To whom correspondence should be addressed.

compounds have been isolated from all parts of the tree (Siddiqui et al., 1989; Devkumar and Sukh Dev, 1993; Kraus, 1995). Azadirachtin has been shown to be a potent antifeedant at 10–100 ppm and an ecdysis inhibitor at 1–10 ppm (Warthen, 1989; Govindachari, 1992; Champagne et al., 1992; Hansen et al., 1994; Schmutterer, 1995) in over 200 species of insects. Since neem seeds and neem oil are readily available, there is every promise that formulations based on them will be useful for pest control without harmful effects to the ecosystem. Indeed, a large number of formulations have been produced and marketed during the past few years, which have been standardized in terms of azadirachtin content.

A recent study (Govindachari et al., 1995a) reported the isolation of the major triterpenoids in neem oil by preparative high-performance liquid chromatography and quantified their abundance by analytical HPLC. Salannin (1.4%), nimbin (0.5%), deacetylnimbin (0.4%), azadiradione (0.2%) and epoxyazadiradione (0.13%) are the major constituents in neem oil, while azadirachtin-A was present to the extent of only 0.03%. Interestingly, neem oil contains other azadirachtins, such as azadirachtins-B, -D, -H, and -I, which together constitute, on a conservative estimate, at least 0.2% of the oil. These azadirachtins possess the same order of activity as azadirachtin-A (Govindachari et al., 1994). Neem kernel extracts also contain all these compounds and azadirachtin-A alone is present, on average, at ca. 0.3%.

It is generally believed that the bioactivity of neem preparations is due to the azadirachtin content in them. According to Isman et al. (1990) "even though other limonoids from neem and related meliaceae have demonstrated bioactivity against insects, none of these are within two orders of magnitude as active as azadirachtin and thus their contribution to bioactivity of neem oils may be largely discounted."

There are only a few entomological studies on the constituents of neem other than azadirachtin-A. Salannin, for instance, has been shown to be an antifeedant, as active as azadirachtin-A against *Epilachna varivestis* (Schwinger et al., 1984, Kraus et al., 1987) and more active against *Pieris brassicae* (Luo Lin-er et al., 1995). However, it had no insect growth regulatory (IGR) activity (Rembold, 1989, Simmonds et al., 1990). Azadiradione and epoxy azadiradione are feeding deterrents to a lesser extent than azadirachtin-A (Govindachari et al., 1995b). It may be noted that the major limonoids, except azadirachtin-A, have been tested for bioactivity, especially for IGR activity, only against a few insect species. While azadirachtin content in neem oil correlated well with behavior-disrupting and growth-regulating activity of *Peridroma saucia* (Isman et al., 1990), no such correlation was found with neem kernel extracts from different sources against *Epilachna varivestis* and *Aedes aegyptii* (Ermel et al., 1984). Subsequently, Ermel et al. (1987), based on 66 neem kernel extracts, claimed strong correlation of EC_{50} values of all samples with absolute amounts

of azadirachtin. However, they have indicated that "because of the lack of sufficient data, this finding is statistically significant only for the Benin extract, but an obvious tendency existed with other extracts".

The present study was undertaken to assess the relative contribution of these major limonoids, viz., salannin, nimbin, deacetylnimbin, and also azadirachtin-A (Fig. 1) (for comparison) in terms of insect antifeedant and growth regulating activities.

METHODS AND MATERIALS

Salannin, deacetylnimbin, nimbin, and azadirachtin-A were isolated by a direct preparative HPLC method, their purities confirmed by analytical HPLC (Govindachari et al., 1995a), and their identities established by comparison with authentic samples (NMR and mass spectral data).

The test insects, *Spodoptera litura* and *Pericallia ricini*, were reared on the leaves of *Ricinus communis*. *Oxya fuscovitatta* was reared on the leaves of *Coix lachryma*. A dual-choice bioassay was performed (Govindachari et al., 1995b). For *S. litura* and *P. ricini*, circular disks (180 cm^2) were cut from the

leaves of *R. communis*, with the median vein as the marker between the two equal halves. One milliliter of acetone alone or the test compound in acetone (at 50, 10, 5, and 1 $\mu g/cm^2$ area of leaf) was spread with the help of a fine pipet on the right half (90 cm^2 treated), leaving the left half untreated. For each compound and concentration, five replicates were used. After air-drying, each leaf disk was placed inside separate Petri dishes and five freshly molted third instars (from the same egg batch, approximately similar in weight and size) were placed at the center of the leaf. After 24 hr, the insects were removed and the uneaten area in the treated half was measured using a ΔT area measurement meter. For *O. fuscovittata*, leaf strips (60 × 4 cm) were cut with the median vein acting as a marker between two equal halves and assayed as indicated above. Percent feeding index (PFI) was calculated (c.f. Luco et al., 1994) using the formula

$$\text{PFI} = \frac{\text{area fed in treated}}{\text{area fed in treated} + \text{area fed in solvent control}} \times 100$$

where treated is the area treated with the solution of compound in 1 ml acetone and solvent control is the area treated with 1 ml acetone.

For the insect growth regulation study, leaf disks (180 cm^2 of *R. communis* leaves for *S. litura* and *P. ricini* and 240 cm^2 of *C. lachryma* leaves for *O. fuscuvittata*) were spread with 2 ml of a solution of the test compound in acetone, to have 0.5 μg of test compound/cm^2 leaf area. Leaves treated with acetone alone were kept as control. The leaves were air-dried and placed in separate Petri dishes. Five replicates were maintained for each compound. Five freshly emerged third instars of *S. litura/P. ricini* were introduced into each Petri dish and forced to feed until they molted into the next instar. From the fourth instar, the larvae were provided with normal diet (*R. communis* leaves) until the end of the experiment. In the case of *O. fuscovittata*, five fifth instar females were introduced into the cage along with the treated *C. lachryma* leaves and the nymphs were fed till they molted to the adults. Durations of *S. litura* and *P. ricini* instars, mortality of larvae, numbers of pupae, and pupal weights were recorded. For *O. fuscovittata*, nymphal duration and mortality were recorded. The data were subjected to one-way ANOVA and Student Neumann-Keul means were presented.

RESULTS

Among the insects tested, *Oxya fuscovittata* was the most sensitive in terms of antifeedancy to all four compounds, even at concentrations of 1–10 $\mu g/cm^2$ leaf area, while *Spodoptera litura* was the least sensitive. As an antifeedant, azadirachtin was the most effective compound followed by salannin, nimbin,

and deacetylnimbin in order of decreasing activity. Azadirachtin was twice as active as salannin against *S. litura* and *Pericallia ricini*; salannin, nimbin, and azadirachtin were equally active against *O. fuscovittata* (Table 1).

The insect growth-regulatory activities of the above four compounds were assessed in terms of larval duration, pupal duration, larval and pupal mortalities, and pupal weights. A significant increase in larval durations was noted in *S. litura* and *P. ricini* when fed on each of the four compounds (Table 2). The effect was pronounced in the fifth instars of *S. litura* and the third and fourth instars of *P. ricini*. No significant differences were found among salannin, nimbin, and deacetylnimbin, clearly indicating equal effectiveness in increasing the larval durations of *S. litura* and *P. ricini*. A marginal, but significant, increase in pupal duration was noted in *P. ricini* when fed on all four limonoids, while no such change was noticed with *S. litura*. In the case of *O. fuscovittata*, azadirachtin and salannin significantly increased duration of the fifth instars (Table 3).

Larval mortality was comparatively higher in azadirachtin-fed *S. litura* and *P. ricini*, while pupal mortality was as high in salannin- and nimbin-fed individuals as in azadirachtin-fed individuals (Table 2). In the case of *O. fuscovit-*

TABLE 3. DEVELOPMENTAL DURATION OF FINAL INSTAR OF *Oxya fuscovittata* FED ON SOME C-SECO LIMONOIDS[a]

Compound	Duration of development (days)	Mortality (%)
Control	6.2(0.55)a	1
Azadirachtin-A	8.4(0.46)b	20
Salannin	8.0(0.25)c	16.6
Nimbin	7.8(0.42)c	6.6
6-deacetyl nimbin	7.9(0.50)c	6.6

[a]Experiment initiated with 30 individuals (six replicates with five individuals each). Values presented are Student-Newmann-Keul means; values in parentheses indicate ± SD; concentration of compounds used = 0.5 $\mu g/cm^2$ area of *Coix lachryma* leaf.

tata, fifth instar mortality was much higher in azadirachtin- and salannin-fed individuals as compared to that observed for nimbin- and deacetylnimbin-fed individuals (Table 3). Significant reduction of pupal weight was characteristic of azadirachtin-fed individuals. Salannin, although less effective, brought about significant pupal weight reductions compared to nimbin, deacetyl nimbin, and the control.

DISCUSSION

In our bioassay experiments salannin, nimbin, and deacetylnimbin were half as active as azadirachtin as antifeedants. However, in growth-regulatory activity against *S. litura*, *P. ricini*, and *O. fuscovittata*, salannin is comparable to azadirachtin-A. Thus, salannin deters feeding, delays molt by increasing larval duration, causes larval and pupal mortality, decreases pupal weights in *S. litura* and *P. ricini*, and causes molt delay and nymphal mortalities in *O. fuscovitatta*. It was reported that salannin had no growth regulatory activity against *E. varivestis* (Rembold, 1989), *Spodoptera frugiperda*, *Spodoptera littoralis* (Simmonds et al., 1990), and *Heliothis virescens* (Simmonds et al., 1990, Klocke, 1987). In the present communication, salannin has been shown to be an effective insect growth regulator against some insects. Therefore, the absence of IGR activity of salannin against certain insects cannot be generalized for all insect species. In our bioassay experiments, nimbin and deacetylnimbin do not show any appreciable growth-regulating activity against *S. litura*, *P. ricini*, and *O. fuscovittata*.

Salannin, which has good antifeedant and growth-regulating activity, is present in neem oil in at least three to four times the concentration of azadi-

rachtin. Nimbin, deacetylnimbin, azadiradione, and epoxy azadiradione, although less active than azadirachtin, are also present in considerable quantities (Govindachari et al., 1995a). Therefore, while azadirachtin is undoubtedly a remarkable antifeedant and growth-regulating compound, the role of other limonoids (especially salannin) in the bioactivity of formulations should not be ignored or underestimated. Further experiments are in progress for the study of antifeedant and growth-regulating activities of salannin and other major terpenoids in neem against other insect pests.

(Received June 5, 1995; accepted April 7, 1996)

Abstract—The behavioral responses by the nematode *Caenorhabditis elegans* to 12 organic compounds was explored using tethered nematode and computer tracking methods. Results indicate that the nematode is attracted to acetone, diethyl ether, isoamyl acetate, isoamyl alcohol, 2,4-pentanedione, and *n*-propanol. No responses were detected to acetaldehyde, acetylcholine, ethanol, formaldehyde, i-propanol, and valerate. Isoamyl acetate and acetone were found to be the most potent attractants eliciting minimal responses at concentrations near 10^{-10} M. The geometry and charge distribution of a single hypothetical receptor that would interact with all the compounds that elicited a response and none of the compounds that failed to elicit a response is explored.

Key Words—Acetone, active site, chemoreceptor, chemosensitivity, isoamyl acetate, metabolite, nematode, threshold, *Caenorhabditis elegans*.

INTRODUCTION

The ability of organisms to detect chemicals has been explored in numerous studies. These studies have indicated remarkable chemosensitivity in some cases. The lowest threshold for chemosensation of a compound in the liquid phase was demonstrated by spermatozoa of the alga *Scytosyphon lomentaria*, which exhibited chemotaxis to conspecific sex pheromone concentrations as low as 6×10^{-13} M (Maier and Muller, 1986). The lowest threshold for chemosen-

sation of compounds in the vapor phase may occur in lepidoperans. For example, the Indian meal moth, *interpunctella* (Mankin et al., 1980), exhibited chemotaxis to pheromone vapor phase concentrations as low as 2×10^4 molecules/cm^3. These thresholds are close to the limits of what is physically possible (Dusenbery, 1992a).

Further understanding of the mechanisms and functions of threshold chemosensation would be facilitated by studying an organism in which genetic chemosensory mutations can be isolated. These studies could probably be accomplished with the nematode *Caenorhabditis elegans*, which is now probably the most thoroughly characterized animal (Wood, et al., 1988). *C. elegans* is a soil nematode that is approximately 1 mm long, around 90 μm in diameter, and eats bacteria.

Although chemoreception has been studied in *C. elegans* for over 20 years (Dusenbery, 1973, 1974, Ward, 1973), none of the identified stimuli have been effective at concentrations sufficiently low to suggest a high specificity of binding to a receptor (Dusenbery, 1980b). The very high degree of potency (chemotaxis at 6×10^{-9} M) reported for chemotaxis of the nematode *Panagrellus redivivus* to amyl acetate (Balan, 1985) prompted us to look at the responses of *C. elegans* to related chemicals. More recently, a wide variety of polar organic molecules has been found to be effective in *C. elegans* chemotaxis (Bargmann et al., 1993), but threshold concentrations were not reported. Here we report on threshold determinations for several of these chemicals.

METHODS AND MATERIALS

Two different methods were utilized to determine the threshold for chemosensation by *C. elegans*. The first involved holding the nematode by its tail and pumping test solutions past it while recording its behavior with an oscillograph (Dusenbery, 1980a). These studies are referred to as "tethered nematode studies." In the second method, air containing a test compound was blown over the nematodes whose movements were tracked by a computer using a television camera for data input (Dusenbery, 1985, 1992b). These studies are referred to as "computer tracking studies." In order to verify behavioral analysis for isoamyl acetate, attraction studies were performed that involved comparing the number of nematodes that migrated towards the stimulant with the number that failed to do so on an agar surface.

All experiments were performed with young adult nematodes. The nematodes were obtained by transferring, three days prior to experimentation, approximately 500 N2 dauers (nematode larvae) to a bacterial lawn of *E. coli* (strain OP50) grown on NGM agar (Brenner, 1974).

A common problem in chemotaxis assays is false-positive results due to

contamination or ambient physical stimuli such as temperature (Pline et al., 1988). Consequently, protocols to guard against these problems were employed.

Tethered Nematode Studies. These experiments were used to test the *C. elegans* response to isoamyl acetate and acetylcholine. Concentrations tested and number of runs performed are presented in Table 1. Each experiment was initiated by placing one nematode on a testing platform on the observation stage of a microscope (Dusenbery, 1980a). The nematode was captured by its tail utilizing vacuum applied through a micropipet. Then it was moved into the testing chamber and situated so that its image fell on a series of photocells. The signal from the photocells was amplified and sent to an oscillograph to provide a graphical record of the nematode's movement.

Control runs were performed by filling the two syringe pumps with N-100 buffer [5.84 g NaCl, 0.50 g K_2HPO_4, and 3.00 g KH_2PO_4 added to 1.0 liter dH_2O (deionized water)] and alternately pumping the buffer from the two pumps past the nematode for 90-sec periods. One pump was designated the stimulus pump and the other as the control pump. One cycle was considered to consist of flow from the stimulus pump for 90 sec followed by flow from the control pump for 90 sec. Ten such cycles constituted a run. Two control runs were performed followed by two test runs. Test runs were performed in the same manner as control runs except that the stimulant pump contained N-100 buffer plus a known amount of test compound.

C. elegans exhibits several characteristic behavioral patterns that were utilized for determining chemosensation. The nematode usually moves forward via backward waves that are backwardly propagated undulations of the body (Croll, 1975). Forms of avoidance behavior include forward waves, body kinks, and coiling. Forward waves are referred to as a reversal bout if several come in succession.

Nematode behavior during a run was analyzed by counting the periods of avoidance behavior and noting which pump was actuated when each occurred, and whether a test run or a control run was being performed. Data for test runs were normalized by dividing the number of avoidance behavior periods when each pump was on during each test run by the number of periods of avoidance behavior displayed during the two control runs when the same pump was on. For each test run, a response value (R) was calculated such that $R = 1.0 - 2.0\ [A_s/(A_s + A_c)]$ where A_s is the normalized number of periods of avoidance behavior displayed when the stimulus pump was on, and A_c is the normalized number of periods of avoidance behavior displayed when the control pump was on. Possible values for R are between -1.0 and 1.0.

Computer Tracking Studies. These studies were used to confirm the nematode's response to isoamyl acetate and to detect possible responses to the rest of the compounds tested except acetylcholine (see Table 1). A suspension of nematodes was obtained by washing nematodes from the bacterial lawn on which

TABLE 1. RESPONSES AND STATISTICS[a]

[a]Concentrations are given in moles per liter. The number of positive runs over the number of negative runs are listed for each concentration tested of a given compound. Responses considered to represent threshold are **in bold.** Statistical analysis applies to threshold responses. Compounds designated with double asterisks (**) represent tethered nematode studies while the rest of the compounds were studied via computer tracking studies.

they were grown. Bacteria were removed by allowing the nematodes to settle out of solution and siphoning off the supernatant. The nematodes were then washed with N-50 buffer (2.92 g NaCl, 0.50 g K_2HPO_4, and 3.00 g KH_2PO_4 added to 1.0 liter dH_2O), and the procedure was repeated until the concentration of bacteria was considered negligible. The nematodes were then transferred to glass plates on which tracking agar (0.09 g NaCl and 0.30 g Bacto Agar added to 30 ml dH_2O) had been poured in a thin layer covering roughly 50 cm^2. The nematodes were allowed to acclimate to their new environment for about half an hour before experiments were started.

Experiments were initiated by transferring the plates that contained the nematodes to the stage under the camera. The stage was designed in such a manner that when the glass plate was placed on it, a chamber was formed through which air could be passed (Pline and Dusenbery, 1987). The air that passed through the chamber and over the nematodes was first equilibrated with a solution in one of two sparging bottles. During control runs, both sparging bottles contained dH_2O. For test runs, one bottle contained dH_2O while the other contained dH_2O plus a known amount of test compound.

During a run, the computer kept track of the rate of movement of nematodes, with 50–100 nematodes usually being monitored. As in the tethered nematode studies, each run consisted of a series of cycles and in each cycle nematodes were exposed first to air from one bottle for 50 sec followed by air from the other bottle for 50 sec. Six cycles constituted one run, with the first cycle being treated as an acclimation cycle (no data collected).

The data set from each run was the rate of locomotion of the nematodes averaged over the five cycles. Average rates of locomotion were displayed in 5-sec intervals, yielding a representation of the average rate of locomotion as a function of time. Data from test runs were normalized by dividing rates of locomotion by the average rate of locomotion during corresponding time intervals in the two control runs. Next, the average normalized rate of locomotion during each half cycle was calculated by summing the ten 5-sec intervals and dividing by 10. The value (R) of the response of the nematodes to the stimulant was then calculated as $R = 2.0\ [L_s/(L_s + L_C)] - 1.0$ where L_s is the average normalized rate of locomotion during the stimulus half cycle, and L_c is the average normalized rate of locomotion during the control half cycle.

Attraction Studies. These experiments were performed with isoamyl acetate in order to verify that the behavioral patterns explored above represent nematode attraction to this compound. Attraction assays were performed as follows. First, plain agar was poured into 10-cm-diameter Petri plates. After the agar cooled, 2-cm-long sections of 50 μl micropipets were filled with dH_2O or with a nearly saturated solution of isoamyl acetate in dH_2O. The micropipet segments were placed at opposite sides of the Petri plate, and a drop of N-50 buffer containing around 100 nematodes was placed at the center of the Petri plate. The nematodes

were allowed to migrate for 15 min. Nematodes found within 0.5 cm of a given micropipet segment were counted.

Vapor Phase Concentrations. The mole fraction (y) of isoamyl acetate in the vapor phase that flowed over the nematodes during computer tracking studies was estimated for $y = x\gamma p_A/\phi P_s$ where x is the liquid phase mole fraction of isoamyl acetate; γ is 3830, the activity coefficient of isoamyl acetate that was calculated via UNIFAC (Fredenslund et al., 1975); p_A is 4 mm Hg, the partial pressure of isoamyl acetate at experimental temperature; ϕ is 1.0, the fugacity coefficient of isoamyl acetate; and p_s is the pressure of the system, taken to be one atmosphere. The number of molecules of isoamyl acetate per cubic centimeter (n) was estimated as $n = (yP_s/ZRT)\ (6.023 \times 10^{23})/1000$, where all variables are as above and Z is the compressibility factor, R is the gas constant, T is the experimental temperature, 6.023×10^{23} is Avogadro's number, and 1000 converts from molecules per liter to molecules per cubic centimeter.

Statistical Analysis. Student's one-tailed t test and binomial probability were utilized to verify significant results. The 95% confidence intervals and minimum values of α (α_{min}), which yielded 95% confidence levels, were calculated with Student's one-tailed t test. Values of $\alpha_{min} \leq 0.05$ were taken to indicate significant results. Binomial probability was based upon an assumed probability of getting a positive result being equal to 50% in the absence of an induced response. Binomial probabilities less than ≤ 0.05 were again taken to indicate significant results.

RESULTS

The results of experiments with isoamyl acetate are shown in Figure 1 (tethered nematode studies) and Figure 2 (computer tracking studies). Figure 1 indicates that the nematodes demonstrated a minimal response when the concentration of isoamyl acetate reached 10^{-10} M (theoretically 9×10^{-11} M). This low threshold was confirmed via computer tracking studies as shown in Figure 2. Figure 3 shows that the nematodes probably also demonstrated a minimal response to acetone at an acetone concentration of 10^{-10} M (theoretically 8×10^{-11} M). Table I indicates the statistical significance of these results.

Table I also shows that the results indicate chemosensation of diethyl ether, 2,4-pentanedione, n-propanol, and probably isoamyl alcohol. It should be noted that actual threshold for chemosensation of these compounds may be lower than indicated. Responses were not detected to acetaldehyde, acetylcholine, ethanol, formaldehyde, i-propanol, and valeric acid.

Attraction studies (eight repetitions) showed an average of 86 (± 6.0 SD) nematodes around the micropipet that contained isoamyl acetate for every 22

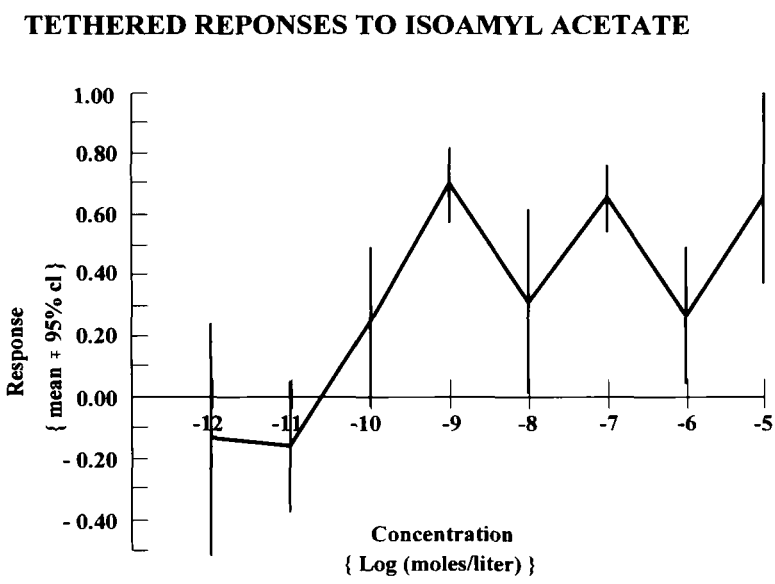

FIG. 1. The response demonstrated by *C. elegans* upon exposure to isoamyl acetate during tethered nematode studies. The data indicate that threshold response occurs at an isoamyl acetate concentration around 9×10^{-11} M. In this and the following figures vertical bars indicate the 95% confidence intervals according to Student's one-tailed *t* test.

(±9.5 SD) nematodes found around the micropipet that contained dH_2O only. The relatively high number of nematodes found around the latter micropipet was due to nematodes becoming entrapped in the meniscus formed by water at the interface between the micropipet and the agar surface. These results indicate that the behavioral response demonstrated by *C. elegans* to isoamyl acetate is an attractive response.

DISCUSSION

Caenorhabditis elegans demonstrated a remarkable response to both acetone and isoamyl acetate, which interestingly, has a pleasant aroma to humans and is known as pear or banana oil (Merck Index, 1968, p. 578). Isoamyl acetate was tested because Balan (1985) found amyl acetate to be a very potent stimulant of the nematode *P. redivivus*. The experiments performed with *C. elegans* indicated that isoamyl acetate elicited a response at a concentration of around 10^{-10} M (theoretically 9×10^{-11} M), while the experiments performed by

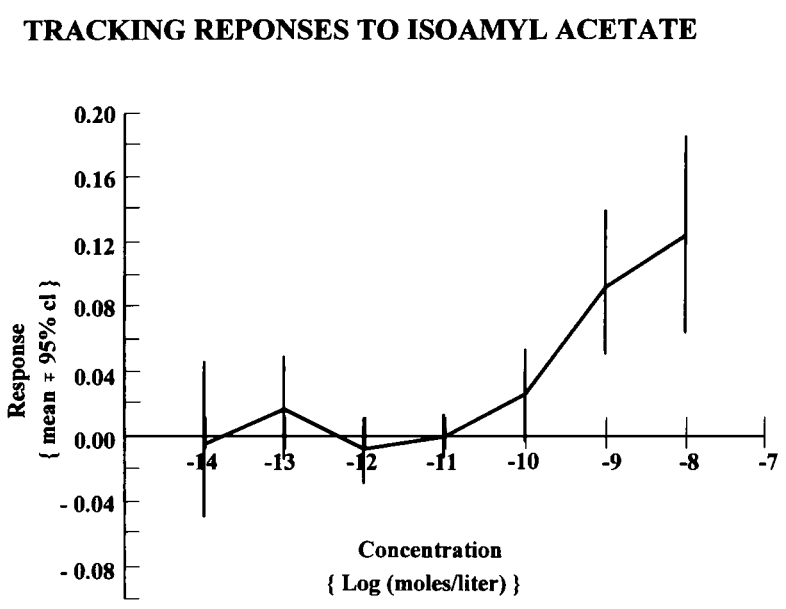

FIG. 2. The response demonstrated by the nematodes upon exposure to isoamyl acetate during computer tracking studies. The graph shows that data for computer tracking studies also indicated that the nematodes can respond to an isoamyl acetate concentration around 9×10^{-11} M.

Balan indicated that threshold response occurred at a concentration of 10^{-8} M (theoretically 6×10^{-9} M).

The difference in observed thresholds may depend more on the techniques used than on an inherent difference in the sensitivity of the two species. The experimental procedures employed in determining the threshold for *C. elegans* allowed free movement of the nematodes, while Balan's methods required that the nematodes accumulate in and under agar plugs containing the stimulant. The free movement of *C. elegans* in a liquid would allow for a higher rate of transfer of the stimulant to the sensilla than would occur when nematodes accumulated in agar plugs where the diffusivity of the solute would be lower and increased transfer due to convective currents would be absent. There is also a possibility of decreased availability of the solute due to absorption by the agar matrix, and it is possible that in Balan's experiments the nematodes were required to sense the stimulant at lower concentrations between the agar plugs.

Estimation of the vapor-phase concentration of isoamyl acetate at threshold indicated that it was around 10^9 molecules per cubic centimeter (theoretically

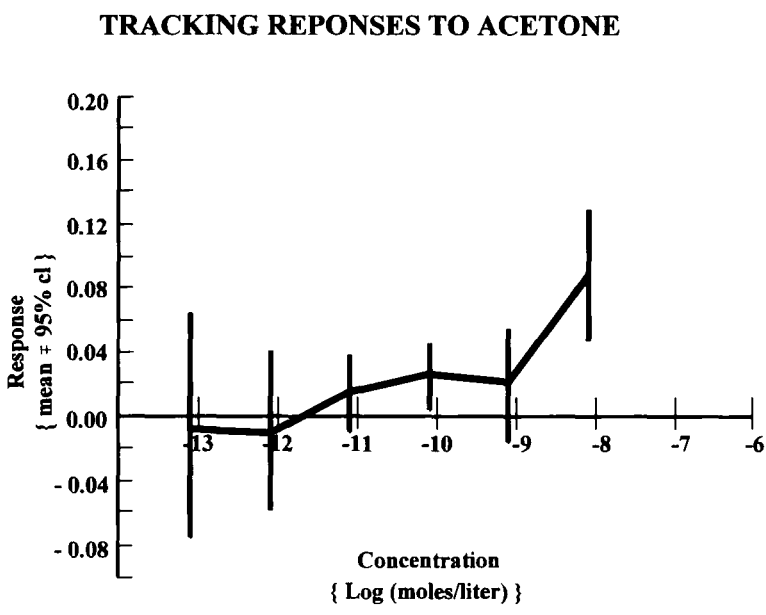

FIG. 3. The response profile demonstrated by *C. elegans* upon exposure to acetone during computer tracking studies. The graph shows that the nematodes may be sensing acetone concentrations as low as 8×10^{-11} M.

8×10^8 molecules/cm^3). This value is much higher than that found for the Indian meal moth *Plodia interpunctella*, which exhibited responses at a threshold concentration of 2×10^4 molecules/cm^3 (Mankin et al., 1980). This apparent difference in chemosensitivity probably results from differences in the size of the chemosensory organs (Dusenbery, 1992b).

It is interesting to consider why *C. elegans* would be so sensitive to isoamyl acetate when it is not a common bacterial metabolite. One possible explanation may be found in the fact that isoamyl acetate is commonly found in fruit (Gallander, 1974). It is plasuible that decaying fruit (the process of which would release isoamyl acetate into the local environment) represents a rich source of bacteria upon which the nematode feeds and also provides an important environment for the reproduction of *C. elegans* (Dusenbery, 1980b). This possibility is supported by two facts. First, *C. elegans* is a species specialized for the rapid exploitation of temporary resources due to its self-fertilization and rapid growth. Second, *C. elegans* is not found in general surveys of soil nematodes but appears in baits of decomposing vegetable matter (Dusenbery, 1980b).

Another interesting observation lies in the fact that short-chain acids, alco-

hols, and ketones (especially acetone) are common bacterial products under anaerobic conditions and that even though the macroscopic environment may be aerobic, the microscopic environment of a bacterial colony can be anaerobic, inducing the production of these products. The possibility that isoamyl acetate interacts with the same receptor that detects acetone was postulated when an experiment indicated that the nematodes responded to isoamyl acetate, isoamyl alcohol, and acetone, but not to valeric acid. These results indicate that, if these compounds were interacting with the same chemoreceptor, its active site would be composed of two hydrophobic regions on opposite sides of an electropositive crevice, which is 2–3 Å across. Actuation of the receptor would occur via simultaneous hydrophobic interactions between the two hydrophobic regions of the active site and hydrophobic regions of the stimulatory molecule. The electropositive crevice may act to help properly orient the stimulatory molecule. It may also assist in the actuation of the receptor if it consists of more than one properly oriented electropositive amino acid residues (i.e., electrorepulsion would become electroattraction in the presence of an electronegative oxygen atom). This hypothetical description and operation of the active site would explain the nematodes' attraction to appropriate polar organic molecules. This hypothesis was tested by predicting that diethyl ether, 2,4-pentanedione, and *n*-propanol would elicit a response from the nematodes and that the remainder of the compounds tested would not. Experimental results conformed with the prediction.

Several lines of experimental evidence indicate that the above mechanism of receptor actuation is correct and that all of the molecules that elicited a response from the nematodes are interacting with the same receptor. Support for the prediction that the active site operates via hydrophobic interactions can be gleaned from observing that the response to isoamyl acetate, which is a highly hydrophobic molecule, is stronger at any given concentration than is the response to acetone, which has low hydrophobicity (R = 0.091, 0.124, 0.181 for isoamyl acetate and R = 0.020, 0.087, 0.081 for acetone at 10^{-9} M, 10^{-8} M, 10^{-7} M, respectively). This result would be expected if the molecule operated via hydrophobic interactions. The postulate that both hydrophobic regions of the active site must simultaneously interact with hydrophobic regions of the stimulatory molecule is supported by observing that all of the molecules that elicited a response from the nematodes are capable of doing so, as shown in Figure 4, and that none of the compounds that failed to elicit a response from the nematodes would be able to do so, as shown in Figure 5. The possibility that all of the molecules that elicited a response from the nematodes are interacting with the same receptor is supported by comparing thresholds elicited in Table 1 with how easily a given molecule would be able to activate the receptor, as shown in Figure 4. If these molecules were interacting with separate receptors, each of which was adapted to detect a specific molecule, one would expect thresholds to be more or less uniform since interactions between each receptor and its

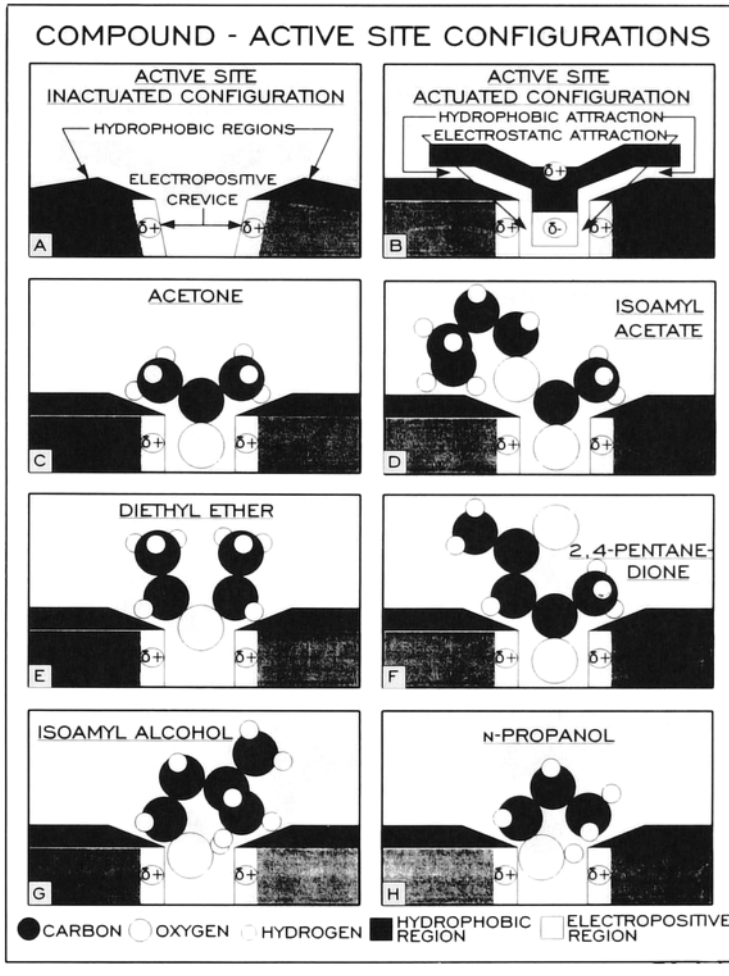

FIG. 4. A chemoreceptor whose active site was composed of two hydrophobic regions that were opposed to each other by 180° around an electropositive crevice 2–3 Å across would be able to interact with all of the molecules eliciting a response from the nematodes in an appropriate manner (i.e., simultaneous interaction between hydrophobic regions of the ligand and hydrophobic regions of the active site). These interactions would produce a conformational change in the receptor resulting in its activation.

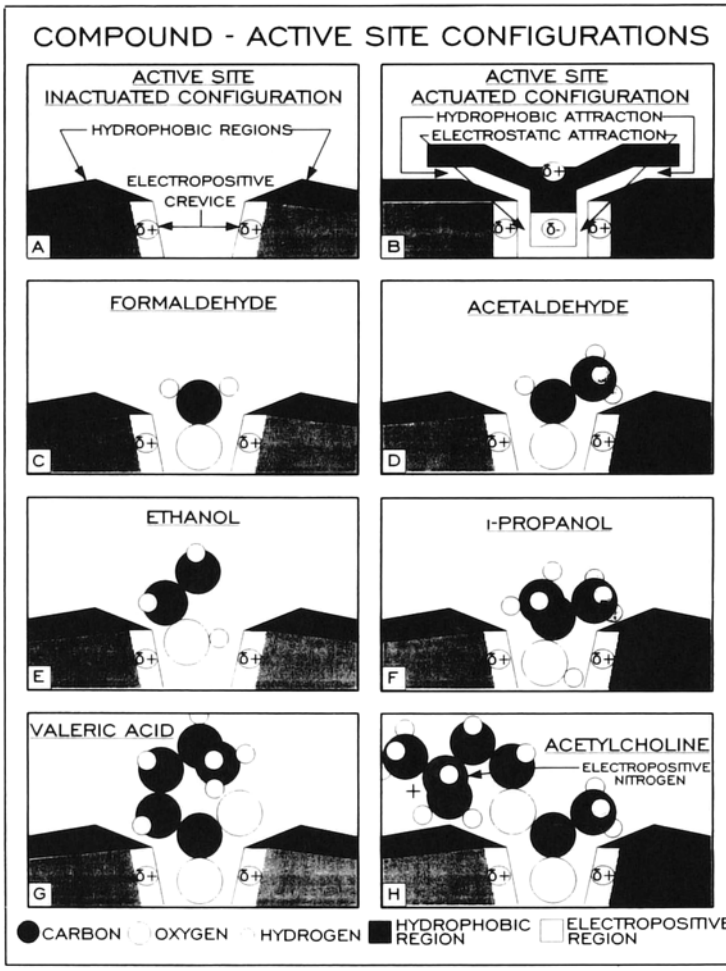

FIG. 5. All of the compounds that failed to elicit a response from the nematodes would be incapable of simultaneously interacting with both hydrophobic regions of the active site. Steric constraints and hydrophilic considerations prevent these interactions for i-propanol, valeric acid, and acetylcholine, respectively.

ligand should be highly proficient. However, what the above comparison indicates is that molecules that structurally have two hydrophobic groups opposed to each other around an oxygen atom, and therefore most easily interact with the active site, have the lowest thresholds. Molecules that must assume a restricted configuration in order to interact have higher thresholds, and the greater

the restriction on the configuration, the higher the threshold. This result conforms with the molecules interacting with the same active site. Further exploration of the nature of this chemoreceptor via additional testing, model building, and possibly amino acid sequencing would indeed be an interesting project.

(Received November 30, 1994; accepted April 9, 1996)

Abstract—The principal volatile component (99+%) of the sex pheromone glands of *Lutzomyia longipalpis* from Lapinha, Brazil, has been isolated and characterized as a novel homosesquiterpene with the specific structure proposed as 9-methylgermacrene-B, (*E*,*E*)-8-(1-methylethylidenyl)-1,5,10-trimethyl-1,5-cyclodecadiene.

Key Words—Sex pheromone, tergal gland, *Lutzomyia longipalpis*, gas chromatography, mass spectrometry, high-performance liquid chromatography, nuclear magnetic resonance, homosesquiterpene, 9-methylgermacrene-B.

INTRODUCTION

The sandfly, *Lutzomyia longipalpis* (Lutz & Neiva) (Diptera: Psychodidae) is the vector of the protozoan parasite *Leishmania chagasi* (Cunha & Chagas) (Kinetoplastida: Trypanosomatidae), the causative agent of visceral leishmaniasis (VL) in the New World.

Male *L. longipalpis* release a sex pheromone from glands that appear as pale patches on the third or alternatively the third and fourth tergites of the

*To whom correspondence should be addressed.

abdomen (Lane et al., 1985). Studies on the morphology of these glands have shown that they are highly vacuolated from four days after emergence onwards (Boufana, 1990). Hexane extracts from the glands placed on filter paper disks attracted females (Ward et al., 1989) from distances of up to 60 cm (Morton and Ward, 1989). Hamilton et al. (1994) showed that in a population of sandflies collected in Jacobina, Brazil, the principal volatile component (90+%) of the tergal gland extract was responsible for sex pheromonal activity. The single component composition of the pheromone was supported by Dougherty et al. (1994), who showed that only one type of olfactory cell in the ascoid sensilla on the female antenna was stimulated by the sex pheromone gland extract.

L. longipalpis is known to exist as a species complex. Coupled gas chromatography–mass spectrometry (GC-MS) of pheromone gland extracts (Lane et al., 1985; Phillips et al., 1986) showed that there were two populations of *L. longipalpis* producing single compounds. One population produced a compound with a molecular weight of 218, whereas the other population produced a compound with a molecular weight of 272. These molecular weights and the fragmentation patterns suggested the components were homosesquiterpene ($C_{16}H_{26}$) and diterpene ($C_{20}H_{32}$) hydrocarbons. The former showed similarity to the homofarnesene isolated from the Dufour's gland of *Myrmica rubra* (Attygalle and Morgan, 1982).

GC analysis of pheromone gland extracts prepared from *L. longipalpis* from a wide geographic range in South America indicated that there could be up to six different populations of this sandfly (Hamilton and Ward, 1991). These populations fall within the two chemically distinct classes suggested by Lane et al. (1985) and Phillips et al. (1986) and represent sibling species.

The objective of this current work was to characterize structurally the major compound in the pheromone of *L. longipalpis* from Lapinha, Brazil.

METHODS AND MATERIALS

Sandflies. Sandflies were obtained from Gruta da Lapinha, Minas Gerais, Brazil (19.34S, 43.58W). They were colonized according to the method of Modi and Tesh (1983) at a temperature of 26°C, 98% relative humidity, and a 12:12LD photoperiod. Pheromone extract was prepared as described previously (Hamilton et al., 1994) from 4 to 5 day-old adult males. Samples were stored at −70°C in sealed glass ampoules prior to analysis.

For NMR analysis approximately 8000 males were collected in light traps suspended from the roof of a cave during eight nights at Gruta da Lapinha. Samples extracted in pesticide-grade hexane were stored at −70°C until transport to the UK in a 3DS dry shipper liquid nitrogen container. Extract was

filtered through glass wool, and solvent was reduced under N_2 to 1 male equivalent (ME)/μl prior to further analysis.

Column Chromatography. Column chromatography was performed on a silica gel microcolumn prepared by placing BioSil-A (20–44 μm) (BioRad, Hemel Hempstead, England) silica gel (0.25 g) in a Pasteur pipette. The column was precleaned by eluting sequentially with hexane (10 ml) (pesticide grade, BDH, Poole, England) followed by diethyl ether (10 ml) (chromatography grade, BDH). The sample was eluted in three column volumes of hexane.

High-Pressure Liquid Chromatography (HPLC). HPLC analysis was performed with a Waters HPLC system: 600E multisolvent pump and gradient controller, U6K injector, and 991 photodiode array detector (Waters, Watford, England). Analyses were carried out on two C18 analytical columns (3.9 × 300 mm) (Waters Resolve) in series with a C18 precolumn (Waters Resolve), heated to 30°C. The mobile phase was acetonitrile–isopropanol 70:30 at 1 ml/min. Standards used for calibration and monitoring of separations were (−)-β-caryophyllene and caryophyllene oxide (Aldrich, Gillingham, England) (1 μg/μl). Fractions for further GC, GC-MS, and NMR analysis were collected manually in 10 ml acid cleaned beakers. The nonpolar gland extract was recovered from the relatively polar mobile phase by a liquid–liquid partition (hexane–H_2O). For NMR studies deuterated cyclohexane (C_6D_{12}) was used as the organic phase in the liquid:liquid separation.

Gas Chromatography (GC). GC analyses were carried out using a J&W DB-1 capillary column (Alltech, Carnforth, England) (30 m × 0.32 mm ID, 0.25 μm phase thickness) in a Shimadzu model 15-A gas chromatograph (Shimadzu Corp, Kyoto, Japan) linked to a Shimadzu CR-5A data-pac integrator. Injection of extract was via a Grob split/splitless injector in the splitless mode (0.6 min sampling time) at 180°C. Carrier gas was helium at 1 ml/min. The GC was temperature programmed with an initial 2 min at 45°C, then a rise of 15°C/min to a final isothermal period at 310°C. Detector (FID) temperature was set at 310°C.

Preparative Gas Chromatography. Preparative GC was carried out using a HP1 megabore capillary column (Hewlett Packard, Stockport, England) (10 m × 0.53 mm ID, 2.65 μm phase thickness) in a Pye Series 105 gas chromatograph (Pye Ltd., Cambridge, England). Carrier gas was helium at 1 ml/min. The GC was temperature programmed with an initial 2 min at 45°C, then a rise of 15°C min to a final isothermal period at 310°C. Injector temperature was set at 180°C, and detector (FID) temperature was set at 310°C. For the collection of injected material, a column split of 99:1 was used. The majority of the effluent passed through a heated outlet and was collected in a precleaned (heated) capillary tube (100 mm × 2.0 mm). Collected material was eluted from the capillary tube for NMR analysis in deuterated chloroform.

Gas Chromatography–Mass Spectrometry (GC-MS). Coupled GC-MS was performed on a Hewlett-Packard 5880A GC with an HP-1 capillary column (50 m × 0.32 mm ID, 0.25 μm film thickness) directly coupled to a VG 70-250 MS (electron impact, 70 eV, 250°C). Sample was introduced via a cold (30°C) on-column injector. The GC was temperature programmed with an initial 5 min at 30°C, then a rise of 5°C min to a final isothermal period at 250°C. GC-MS studies were performed on crude extract from dissected glands, hexane fractions from a BioSil-A column, as well as on reduction, epoxidation, and rearrangement products.

Gas Chromatography–Infrared–Mass Spectrometry (GC-IR-MS). Further analysis was carried out using a Hewlett Packard 5890 II+ Gas Chromatograph coupled to a Hewlett Packard 5972A benchtop mass spectrometer (electron impact, 70 eV, 165°C). A Hewlett Packard 5965B Fourier transform infrared detector was placed in series between the GC and MS. Injection of the sample was via a splitless injector (110°C) (sampling time 0.7 min). Chromatographic analysis was on a HP-5 capillary column (3 m × 0.32 mm ID, 0.52 μm film thickness), IRD was connected to the MS via a capillary transfer line (1.2 m × 0.10 mm ID, 0.17 μm film thickness). Carrier gas was helium at 2 ml/min. Injector temperature was set at 120°C. The GC was temperature programmed with an initial 2 min at 45°C, then a rise of 20°C/min to a final isothermal period at 150°C. IR data were obtained with flow cell and transfer line temperatures set at 130°C.

IR and MS spectra for standards were obtained with a DB Wax capillary column (30 m × 0.25 mm ID, 0.25 μm film thickness). Carrier gas was helium set at 1.5 ml/min with the injector set at 120°C. The GC was temperature programmed with an initial 50°C, then a rise of 10°C/min to a final isothermal period at 250°C. IR data were obtained with flow cell and transfer line temperatures set at 150°C.

Nuclear Magnetic Resonance (NMR). NMR spectra were recorded in deuteriochloroform ($CDCl_3$) or deuteriocyclohexane (C_6D_{12}) solution using tetramethylsilane as the internal standard. Proton NMR spectra (^1H NMR) were recorded at 400 MHz on a Jeol JNM-GX400 with Fourier transform facility. Carbon-^{13}NMR spectra (^{13}C NMR) were similarly recorded at 100 MHz.

Hydrogeneration. Ten male equivalents of *L. longipalpis* extract (10 μl) were placed in a small reaction vessel prepared from a Pasteur pipet. Palladium black (20 μg) (Aldrich Chem. Co.) catalytic reducing agent was added and the mixture was shaken. Hydrogen was bubbled through the solution for 2 min.

Expoxidation. Dimethyldioxirane (DMD) reagent was prepared as described by Adam et al. (1987). *L. longipalpis* extract (100 ME, 100 μl) was eluted from a Florisil (350 mg) pipette column in hexane (2 ml). The volume was reduced

under N_2 to 100 μl and the fraction then placed in a 1-ml vial and reagent (40 μl) added. The reaction was allowed to proceed for 24 hr before analysis by GC and GC-MS.

Rearrangement with Silicic Acid. Using a technique described by Nishino et al. (1977), 100 ME of HPLC purified extract (100 μl) was placed in a glass vial with silicic acid (100 μg). The preparation was sealed and stored at 37°C for 12 hr before GC-MS analysis.

Thermal Rearrangement. HPLC extract (100 ME, 100 μl) was heated to 180°C under N_2 and the products analyzed by GC-MS and NMR.

Standards. Germacrene-B was synthesized according to the method of Brown et al. (1967) and was also obtained from the hydrocarbon fraction of the peel of Key limes (*Citrus aurantifolia* Swingle) (Clark et al., 1987). Germacrene-D was similarly obtained from tansy (*Tanacetum vulgare* L.). Germacrone was obtained from rocksfoot cranesbill (*Germanium macrorhyzum* L.) (Ognjanoff et al., 1957; Herout et al., 1959).

Synthesis of Hexahydro-9-methylgermacrene (9-Methylgermacrane). Germacrone was treated with lithium diisopropylamide as base in dimethoxyethane and iodomethane in 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (DMPU) to give (±)-9-methylgermacrone, *m/z* 232(M^+, 12), 135(100), ^{1}H-NMR ($CDCl_3$) 1.21(d, 3H, J = 7) 1.41(s, 3H), 1.47(s, 3H), 1.69(s, 3H), 1.77(s, 3H), 2.0–2.5(complex, 4H), 2.87(m, 2H), 3.57(q, 1H, J = 7), 4.63(m, 1H), 5.05(m, 1H), ^{13}C NMR 11.1, 13.3, 15.7, 19.8, 22.3, 23.6, 29.7, 37.7, 57.7, 125.7, 130.0, 130.5, 132.2, 134.7, 138.4, 210.4. Purification was achieved on a Florisil column in a solvent gradient from hexane (100%) to hexane–diethyl ether (80:20) and crystallization from chilled methanol (mp 51°C). Hydrogenation was effected by Adams catalyst in acetic acid under hydrogen at room temperature and pressure to give hexahydro-9-methylgermacrone (as a mixture of stereo-isomers), *m/z* 238(M^+, 12), 55(100). A loss of olefinic proton and carbon absorbencies indicated complete hydrogenation. Conversion of the ketone to the corresponding methylene was achieved via reduction to the hexahydro-9-methylgermacrol (new absorbencies at 3.75 ppm in ^{1}H NMR and in the 75–78 ppm region in ^{13}C NMR, consistent with alcohol function) with lithium aluminum hydride in diethyl ether. Treatment with methanesulfonyl chloride gave elimination products, showing olefin absorbencies at 4.75–4.85 ppm in ^{1}H NMR and 129–140 ppm in ^{13}C NMR, comprising a mixture of the tetrahydro-9-methylgermacrenes. These olefins were hydrogenated with 5% palladium on charcoal in ethanol under a hydrogen atmosphere at ambient temperature and pressure to give hexahydro-9-methylgermacrene (9-methylgermacrane). On GC-MS a cluster of four peaks was observed that gave very similar spectra. Loss of olefinic absorbencies in the IR spectra indicated complete hydrogenation.

RESULTS

GC. GC analysis of extract prepared from dissected pheromone glands gave the typical chromatogram seen in Figure 1A. Two dominant peaks at 11.6 (*a*) (37%) and 12.3 (*b*) (63%) min were seen. By comparison the retention times (R_t) of pentadecane and hexadecane were 11.5 and 12.2 min, respectively. Peak *b* had a conspicuous leading edge, while the presence of other small peaks between 10 and 16 min indicated the presence of other material in trace amounts.

HPLC. HPLC analysis of pheromone gland extract produced the typical chromatogram seen in Figure 1B. The chromatogram was dominated by a single peak (*c*) at 10.7 min (λ_{max} = 203.4 nm) (99%). Caryophyllene (λ_{max} = 208.2 nm) and caryophyllene oxide (λ_{max} = 209.5 nm) had R_t of 7.16 and 10.3 min, respectively. The large peak (10.4–11.2 min) was collected as was eluent from before (8–10.4 min) and after (11.2–13.0 min) the main peak. GC analysis of these fractions indicated that the large HPLC peak (*c*) gave rise to the main GC peaks *a* and *b* at 11.6 and 12.3 min in the same approximate proportion as the crude extract (33–66%). Tests on the caryophyllene standard indicated that preparative HPLC and subsequent back extraction into hexane was between 60 and 90% efficient.

GC-MS. The recovered large HPLC peak (*c*) was injected via cold on-column injector, and one homogeneous but symmetrically diffuse peak was obtained. The mass spectrum of this material is given in Figure 2. On reduction this material gave a cluster of several isomers separating into four peaks with similar spectra. The major peak was compound *d*, *m/z* 224(M^+, 8), 181(7), 125(32), 111(53), 97(85), 83(86), 69(100), 57(97), 55(100), 43(65). Epoxidation of the natural material gave compound *e*, *m/z* 266(M^+, 1), 248(2), 123(28), 109(33), 95(45), 85(32), 84(31), 83(32), 69(55), 55(65), 43(100). Two silicic acid rearrangement products were seen, compound *f*, *m/z* 218(M^+, 99), 175(72), 203(66), 105(62), 95(62), 119(60), 95(60), 133(55), 81(39), 67(35), 55(52), 43(28), and compound *g*, *m/z* 218(M^+, 74), 175(100), 133(43), 122(52), 107(70), 95(85), 81(52), 55(58), 67(38). The heat-treated parent compound (*c*) gave three products eluting as sharp peaks. The first of these (*h*), unlike the parent compound, gave a sharp peak that eluted (R_t = 38.7 min) before the parent compound (R_t = 40.3 min), *m/z* 218(M^+, 10), 203(15), 175(16), 161(10), 147(13), 135(50), 121(100), 107(60), 93(76), 79(31), 67(50), 55(33), 41(62). Two closely eluting compounds (*j* and *k*) were seen at R_t = 41.7 min, *m/z* 218(M^+, 85), 203(31), 189(8), 175(78), 161(19), 133(68), 119(67), 105(65), 95(72), 55(60), 41(100), and at R_t = 42.0 min, *m/z* 218(M^+, 60), 203(36), 189(14), 175(93), 149(37), 122(55), 107(88), 95(89), 81(54), 67(46), 55(55), 41(100).

GC-IR-MS. Infrared spectra for the putative pheromone from *L. longipalpis*

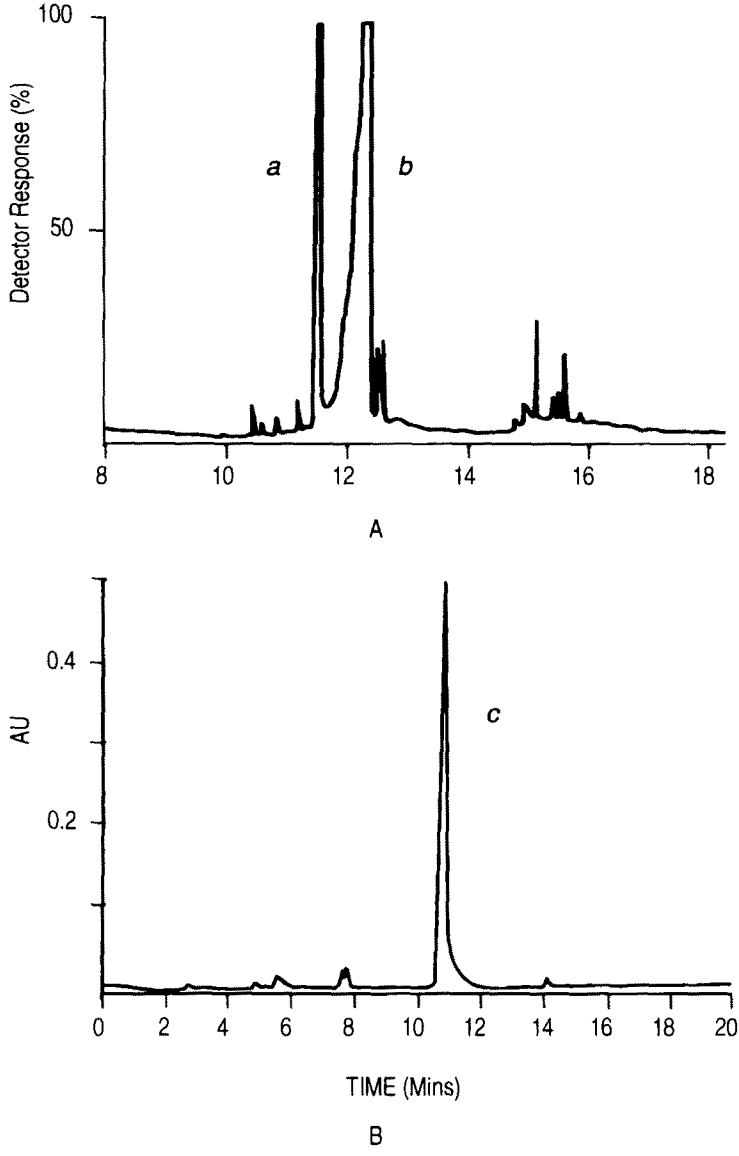

FIG. 1. GC (A) and HPLC (B) trace of hexane extract of dissected sex pheromone gland of male *L. longipalpis*.

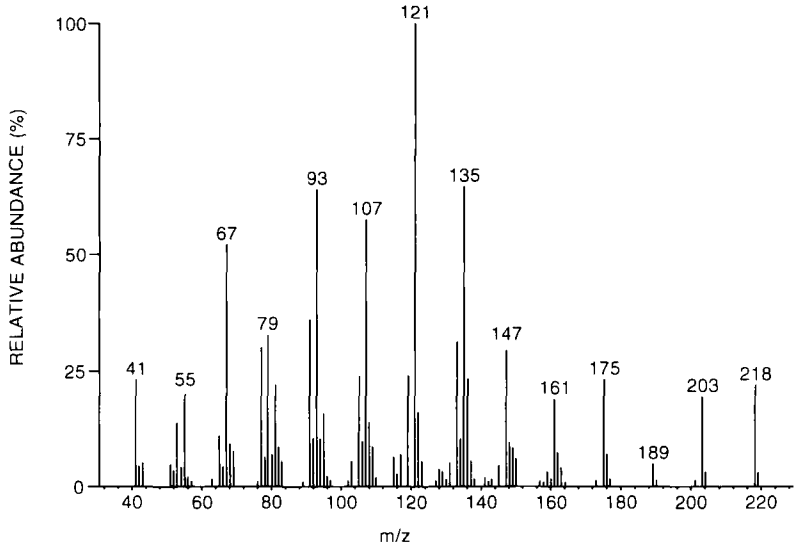

FIG. 2. Mass spectrum (cold on-column GC-MS) of main component *c*, of extract of sex pheromone gland of male *L. longipalpis*.

Lapinha and the reduced product are given in Figure 3A and B. Peaks at 2362 and 2336 cm^{-1} are due to CO_2.

NMR. For untreated putative pheromone from *L. longipalpis* (*c*): ^1H NMR (C_6D_{12}) 0.94(d, 3H, J = 7), 2.98(d, 1H, J = 14), 4.30(d, 1H, J = 11), 4.62(d, 1H, J = 11). Solvent impurities obscured the highfield region between 1.2 and 1.6 ppm. ^1H NMR ($CDCl_3$) 0.96(d, 3H, J = 7), 1.36(s, 3H), 1.46(s, 3H), 1.61(s, 3H), 1.63(s, 3H), 1.8–2.3(complex, 8H), 2.98(d, 1H, J = 14), 4.30(d, 1H, J = 11), 4.62(d, 1H, J = 11).

For preparative GC thermolysis products from pheromone gland extract: ^1H NMR ($CDCl_3$). The major component showed singlet absorbencies at 4.52 and 4.77 ppm and a singlet absorbency at 5.36 ppm. The minor component had absorbencies at 4.60(s, 1H), 4.85(s, 1H), 4.86(d, 1H, J = 16), 4.98(d, 1H, J = 10), 5.56(dd, 1H, J = 16, 10).

For thermal rearrangement of 9-methylgermacrone: ^1H NMR ($CDCl_3$). The olefin region showed absorbencies at 4.72(s, 1H), 4.87(d, 1H, J = 17), 4.91(s, 1H), 5.04(d, 1H, J = 11), 5.66(dd, 1H, J = 17, 11).

DISCUSSION

HPLC analysis and elution from a Florisil column by hexane suggested a hydrocarbon structure for the putative sex pheromone. The single peak (*c*)

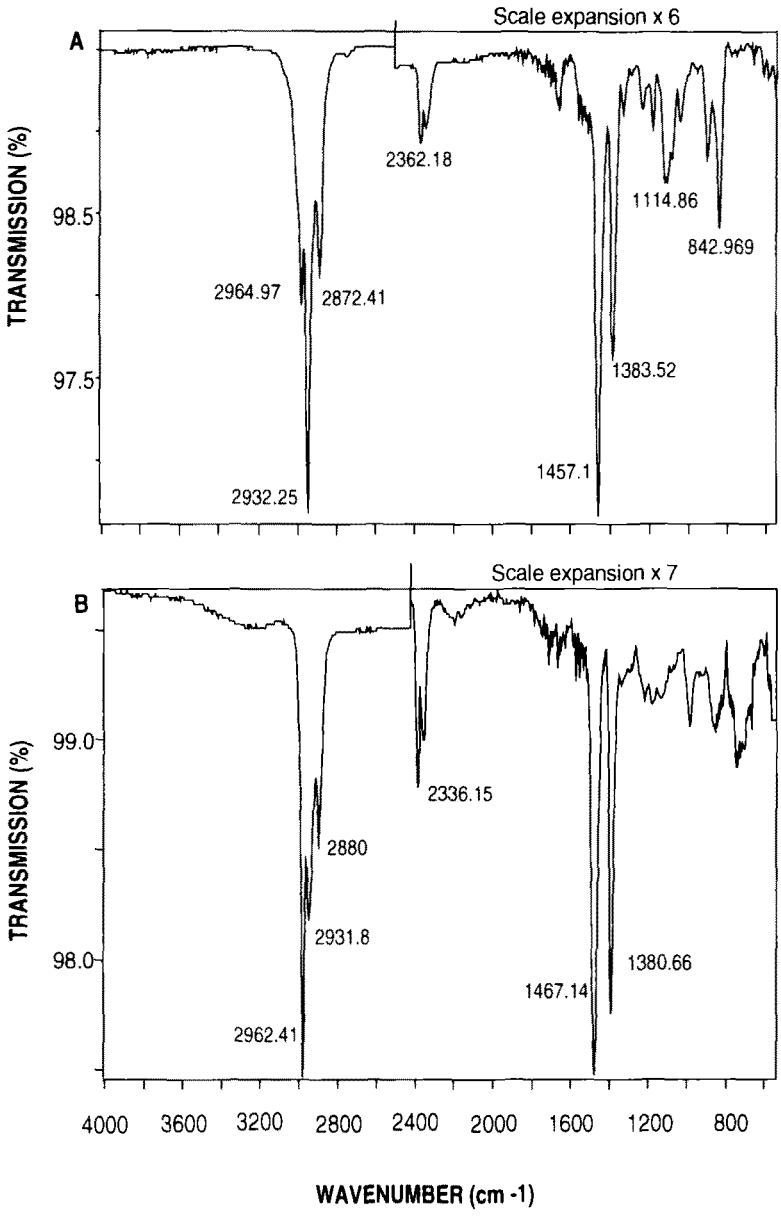

FIG. 3. Infrared spectra of (A) the main component *c* and (B) reduced main component *d* of extract of sex pheromone gland of male *L. longipalpis*.

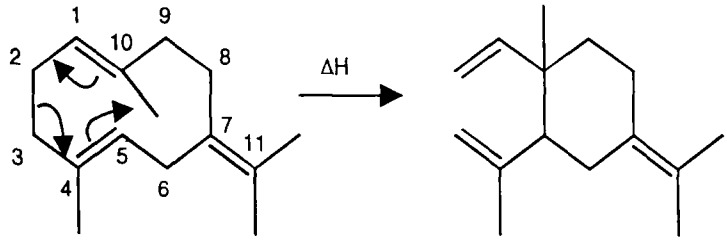
obtained by HPLC was at variance with the two major components (*a* and *b*) suggested by GC. However, use of the cold on-column injector (30°C) gave only one peak that was symmetrically diffuse, also corresponding to *c*. These observations suggested thermal rearrangement taking place in the heated injector and during chromatography. The EI mass spectrum suggested a molecular weight of 218, which was confirmed by CI-MS. Reduction and epoxidation gave products (*d* and *e*) with molecular weights higher by 6 amu (224, M^+) and 48 amu (266, M^+), respectively, confirming the presence of three double bonds.

The EI mass spectrum for the putative sex pheromone has the ions *m/z* 175, 203, and 218 (M^+), each 14 amu higher than for ions of corresponding intensity in the spectrum of germacrene-B (I), a plant component previously known as germacratriene (Allen and Rogers, 1967; Hartley and Fawcett, 1969), i.e., 161, 189, 204 (M^+) (NIST, 1990), and showing strong similarities at lower *m/z* values. In addition the IR spectrum of *c* had similar features to that of germacrene-B (Clark et al., 1987). The mass spectrum of the putative sex pheromone was substantially different from those for the other germacrenes, A and D. This suggested a structure for this compound related to germacrene-B but with an extra methylene placed so as not to disrupt the main features of fragmentation during mass spectrometry.

Thermolytic rearrangement of a compound similar to that of germacrene-B (I), would explain why several peaks were obtained when the gland extract was analyzed on a GC with a heated injector. By comparison, when a cold on-column injector was used, a single peak was obtained that appeared diffuse through decomposition on the column during development of the chromatogram. Thermal rearrangement on heating at 180°C gave three main products with the earliest eluting peak (*h*) having a mass spectrum closely similar to that of the parent compound *c* but suggesting a structure similar to that for the elemene, elixene (II), which could arise from the thermal rearrangement of germacrene-B

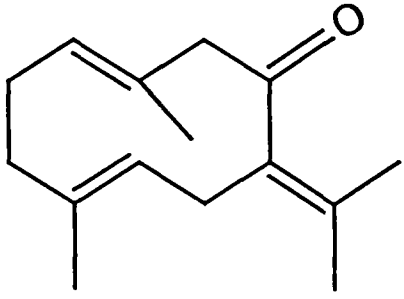


(I) (II)

(I) via a sigmatropic Cope rearrangement (Jones and Sutherland, 1968; Yoshihara et al., 1969; Weinheimer et al., 1970). The compounds eluting later, *j* and

k, appeared to be products of further cyclization of the germacrene-B ring structure. Germacrenes are also acid labile, and treatment with silicic acid gave two main products *f* and *g*, which had spectra with intense molecular ions suggesting bicyclic products that are known to result from rearrangement of germacrenes catalyzed by protonation (Hartley and Fawcett, 1969; Weinheimer et al., 1970).

The ^{1}H NMR (in $CDCl_3$) spectrum for *c* was similar to that for germacrene-B (Clark et al., 1987, Allen and Rogers, 1967). There also were similarities with the spectrum of germacrone (III). The most striking feature of the



(III)

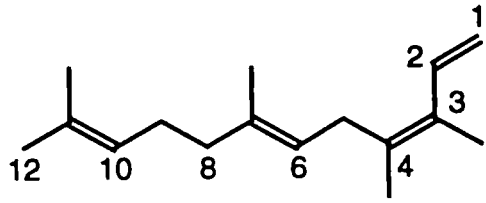
proton NMR spectrum of the putative sex pheromone (*c*) was the high field position of the olefinic protons at 4.62 and 4.30 ppm. These absorbances, as with germacrene-B (Clark et al., 1987), are very broadened doublets. The broadening is due to the transannular effects that hinder normal relaxation of the molecule in the NMR experiment and the appearance as only doublets arises through the *J* value being almost zero for one of the adjacent methylene protons.

^{1}H NMR (in $CDCl_3$) of the compounds obtained by preparative GC of the sex pheromone gland extract revealed the presence of two components arising from *c* by thermal rearrangement during GC. The major component (R_t = 12.3 min) had singlet olefinic absorbencies at 4.52, 4.77, and 5.36 ppm. The minor component (R_t = 11.6 min) was significant in that it had absorbencies at 4.60 and 4.85 ppm and absorbencies characteristic of an isolated vinyl group at 4.86(d, 1H, J = 16), 4.98(d, 1H, J = 10) and 5.56(dd, 1H, J = 16, 10). These NMR data supported a structure similar to elemene (II).

The position of the additional methylene on the sesquiterpene skeleton was suggested by a process of elimination and by taking into account biosynthetic considerations. The four allylic methyl groups analogous, and with similar NMR shift values, to those present in germacrene-B and germacrone, were at 1.36, 1.46, 1.61, and 1.63 ppm as singlets for *c*, demonstrating that the extra methylene was not substituted into a methyl of the germacrene-B structure. Indeed, the methylene comprised an extra methyl at 0.96 ppm and was as a doublet, *J*

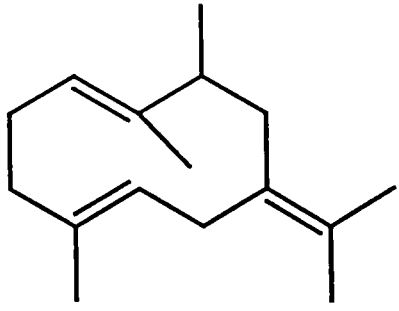
= 7, suggesting substitution at a ring methylene of the germacrene-B structure. Such substitution at carbon 6 could be eliminated as the absorbances at δ = 2.25 and 2.98 pm are correlated in the H-H COSY experiment. The possibility of substitution at carbon positions 2 or 3 was discounted because the elemene, corresponding to elixane (II) from the heat-treated putative sex pheromone, displayed five olefinic proton absorbances, whereas any substitution here would reduce the olefinic absorbencies to four.

Homosesquiterpenes, where encountered so far, fall into three biosynthetic classes, those arising from: (1) oxidative clevage products of diterpenoids (Gäbler et al., 1991); (2) juvenoids, i.e., with methylene substitution into the methyl positions; and (3) homofarnesenes with the methylene substitution at carbon 4, e.g., (*Z,E*)-α-homofarnesene (IV) (Ritter et al., 1977; Vander Meer, 1983,



(IV)

1986; Attygalle and Morgan, 1982, Jackson and Morgan, 1993). The first two are eliminated by spectroscopic properties already discussed. Biosynthetic class (3) would suggest substitution at carbon 3 in germacrene-B but has been discounted. However, position 9 in germacrene-B, i.e., position 8 in the homofarnesene (IV), would be biosynthetically analogous. This position is therefore favored over carbon position 8 for the pheromone component. The putative sex pheromone *c* structure is therefore proposed as 9-methylgermacrene-B, systematically named (*E,E*)-8-(1-methyl ethylidenyl)-1,5,10-trimethyl-1,5-cyclo decadiene (V).



(V)

Although germacrene-A comprises the alarm pheromone for the spotted alfalfa aphid, *Therioaphis maculata* (Nishino et al., 1977), and germacrene-D is a plant-derived sex stimulant for male American cockroach, *Periplaneta americana* (Tahara et al., 1975), neither germacrene-B or any homogermacrenes have been reported from insects.

Approaches were made to the synthesis of 9-methylgermacrene-B from 9-methylgermacrone, numbered here as for structure I, by the approach successfully used for germacrene-B by Brown et al. (1967). However, in the key step of the reaction pathway, lithium–ammonia reduction of 8-acetoxy-9-methylgermacrol yielded only the corresponding alcohol (unpublished). Nonetheless a degree of confirmation by synthesis was achieved when 9-methylgermacrone was reduced and deoxygenated to give a product that had the same MS and very similar IR to the hydrogenation product from the pheromone, i.e., compound *c*, and that gave peak enhancement on GC by coinjection.

There are four asymmetric carbons in hexahydro-9-methylgermacrene, i.e., 9-methylgermacrane, creating eight potentially separable diastereoisomeric pairs of enantiomers, but only four main peaks were resolved on GC. All of the natural product peaks were enhanced by coinjection of synthetic product and the spectra for the four peaks were similar within and between the two samples. Hexahydro-9-methylgermacrene gave a similar pattern of fragmentation to germacrane (NIST, 1990), with the higher mass ions differing by 14 amu.

Attempts are being made to confirm this proposed structure by synthesis and the absolute stereochemistry at carbon 10 will be determined. The characterization of the pheromones for two other populations of *L. longipalpis* is in progress.

Acknowledgments—We would like to thank Dr. A. L. Falcao, Centro de Pesquisas Rene Rachou, F.I.O.C.R.U.Z., Belo Horizonte, Minas Gerais, Brazil, for providing facilities for the collection of the sandflies; Professor R. D. Ward, who made the field collection of 8000 sandflies for NMR analysis; and Mr. M. J. Dougherty who helped with the HPLC purification of crude extract also for NMR analysis. In addition, we would like to thank Ms. Pauline Ambrose for maintaining the sandfly colony at the Liverpool School of Tropical Medicine. This work was carried out with the financial support of the Wellcome Trust, London. IACR-Rothamsted receives grant-aided support from the Biological and Biotechnology Sciences Research Council of the United Kingdom.

Abstract—Heather (*Calluna vulgaris*), a common dietary component of many mammalian herbivores, contains a broad range of tannin phenolics, flavonoids, and simple phenolic compounds. These may lead to a number of negative effects on herbivores as a result of toxicity or digestive inhibition. We assessed the effect of some simple phenolic compounds from heather on rumen microbial activity using the *in vitro* consecutive batch culture technique. The compounds tested were orcinol, quinol, and arbutin, a glucoside of quinol. At a concentration of 10 mM, both orcinol and quinol depressed production of gas and volatile fatty acids (VFAs). Orcinol and, to a lesser extent, quinol also reduced digestion of the substrate. In contrast to these negative effects on rumen microbial fermentation, arbutin stimulated both gas and VFA production, probably due to the presence of the fermentable sugar moiety. The presence of arbutin also resulted in different concentrations and proportions of VFAs compared to the presence of orcinol and quinol. Since many simple phenolic compounds are found in plants in the form of glycosides, the negative digestive effects of the phenolic moieties may be accompanied by the positive effect of the sugar moiety, which is liberated in the gastrointestinal tract on hydrolysis by glycosidase enzymes. This study suggests that when phenolics are present as glycosides, they do not necessarily adversely affect digestion by herbivores.

Key Words—Heather, *Calluna vulgaris*, sheep, secondary compounds, phenolic, rumen, microorganisms, activity.

INTRODUCTION

Plant secondary compounds are involved in complex interactions between plants and their biotic environment (Bell, 1981) and may be produced by plants to deter feeding by herbivores (Freeland and Janzen, 1974; Rhoades and Cates, 1976; Rosenthal and Janzen, 1979). One of the largest and most widespread groups of plant secondary compounds are the phenolics (Harborne, 1991), which sometimes are consumed in large quantities by herbivores, particularly those that utilize lignified or woody plants as part of their diet (McArthur et al., 1991). Their effects may be beneficial, although in large quantities they are considered to have a negative impact because they are either toxic or reduce digestibility (Scheline, 1991; Kumar and Singh, 1984), or both (Foley and McArthur, 1994). Many mammalian herbivores, including ruminants, utilize microbial fermentation to digest food substrates, producing volatile fatty acids (VFAs) from carbohydrates (Van Soest, 1983). In this study we investigate both positive and negative effects of some specific non-tannin phenolics using a batch culture technique that simulates a rumen-like fermentation in the laboratory.

Phenolic compounds may have a negative effect on digestion in a number of ways. Firstly, certain phenolic compounds, particularly tannins, have the ability to interact with proteins and carbohydrates, thus reducing the digestibility of these components of the diet (Hagerman et al., 1992; Barry and Duncan, 1984). They may also interact with digestive enzymes and reduce their activity (Makkar et al., 1988). Phenolic compounds can also affect digestion through their toxic effect on rumen miroorganisms (Akin, 1982). A number of previous *in vitro* studies have shown that phenolic acids that are associated with the carbohydrates of cell walls have an inhibitory effect on rumen microorganisms. The effects observed include (1) reduced bacterial growth rate (Akin, 1982; Borneman et al., 1986; Chesson et al., 1982; Hartley and Akin, 1989), (2) reduced colonization of plant material (Akin and Rigsby, 1985; Varel and Jung, 1986), leading to (3) reduction of digestibility of cellulose and hemicellulose (Akin, 1982; Akin and Rigsby, 1985; Borneman et al., 1986; Varel and Jung, 1986).

Heather (*Calluna vulgaris*) is a woody perennial plant found in many areas of the northern hemisphere and is a particularly dominant species in the European oceanic heathlands (Bunce and Barr, 1988). Many herbivores such as mountain hares (*Lepus timidus*) (Iason and Waterman, 1988), red grouse (*Lagopus lagopus scoticus*) (Savory, 1978), red deer (*Cervus elaphus*) (Gordon, 1989), and sheep (Milner and Gwynne, 1974) depend on heather as an important part of their diet, particularly during the winter when other food sources are scarce. Heather contains a large proportion of phenolic secondary compounds (Iason et al., 1993), including many non-tannin phenolics that may be present as simple phenolics or as phenolic glycosides (Harborne and Williams, 1969; Jalal et al.,

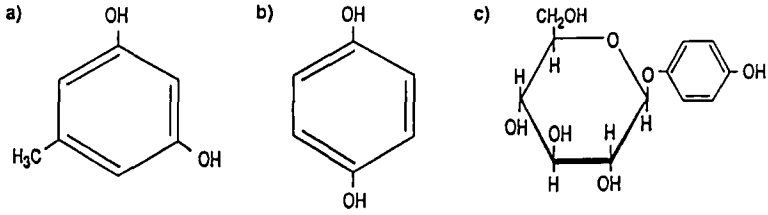

FIG. 1. The structure of: (a) orcinol, (b) quinol, and (c) arbutin.

1982). The aim of this study was to measure the effect of some of these compounds on rumen microbial digestion *in vitro*. The compounds tested were orcinol, quinol, and arbutin, the D-glucoside of quinol (Figure 1). Orcinol was chosen as it is present in *Calluna* shoots (Martin et al., 1983). Quinol is also present in *Calluna* shoots, in the form of its glucoside, arbutin (Martin et al., 1983; Jalal et al., 1982). On ingestion by ruminant herbivores, phenolic glycosides are readily hydrolyzed in the rumen by glycosidase enzymes (Scheline, 1991), allowing the phenolic and sugar moieties to act independently. Therefore, it may be hypothesized that any negative effects on rumen microorganisms by a phenolic compound ingested in the form of a glycoside may be accompanied by the sugar moiety providing a readily fermentable substrate. Inclusion of both quinol and arbutin in this study permits quantification of these effects.

METHODS AND MATERIALS

The *in vitro* system used in this study was the consecutive batch culture technique of Theodorou et al. (1984, 1987), which reproduces a rumen-like fermentation in the laboratory with the microbial population being maintained in the growing phase. Rumen microbial activity was assessed by gas production, volatile fatty acid (VFA) production, and percentage dry matter (DM) loss of substrate.

One hundred milligrams of dried timothy hay (*Phleum pratense*), milled to pass a 1-mm sieve, was weighed into 48 glass culture tubes (16 × 125 mm Hungate tubes, Bellco Glass Inc., Vineland, New Jersey). The tubes were arranged as two replicate series of six tubes for each of the four treatments—orcinol, quinol, arbutin (Figure 1), or control, to which no phenolic was added. The phenolic compounds were dissolved in methanol (99%) at concentrations such that additions of 0.5 ml to the hay gave the equivalent of a 10 mM solution of phenolic compounds once the methanol had been evaporated and the culture medium (9 ml) and the rumen inoculum (2 ml) had been added. The control tubes were treated with 0.5 ml of methanol, which was evaporated to dryness

under a gentle stream of air as for the phenolic treatments. Rumen liquor was collected by aspiration from a rumen-fistulated sheep fed a diet of hay and grass pellets. The rumen liquor was filtered through two layers of muslin and stored under carbon dioxide before inoculation of the tubes. At the start of the experiment, 2 ml of rumen liquor and 9 ml of anaerobic culture medium (Hungate and Stack, 1982) were inoculated into the first tubes of each series. The tubes were sealed by septum stoppers retained by screw caps; the contents of the tubes were then mixed and incubated at 38°C for 48 hr. Consecutive batch culture was achieved by transferring 2 ml of inoculum from these tubes every 48 hr into the subsequent fresh tubes in the series, containing 9 ml of Hungate and Stack culture medium plus the appropriately treated hay substrate. This was continued over a period of 12 days in which there were five transfers on days 2, 4, 6, 8, and 10. Anaerobiosis was maintained throughout by conducting all procedures under a continuous flow of oxygen-free carbon dioxide.

After each 48-hr incubation, measurements of gas production, dry matter loss, and VFA concentration were made. Gas production was measured by piercing the rubber septum in the top of the tubes with a 2-ml glass syringe and measuring the displacement of the plunger. Following incubations, the tubes were centrifuged for 8 min at 12,000 rpm. The residue left in the tubes was washed twice with distilled water before being freeze-dried and weighed to determine percentage dry matter loss. The supernatant was stored at −20°C prior to analysis for VFA concentration. To 1 ml of the supernatant, 0.25 ml of internal standard (20 mM solution of 2-ethylbutyric acid in 20% H_3PO_4) was added. Gas–liquid chromatography (GLC) analysis for VFAs was carried out on a Pye Unicam PU 4500 gas chromatography (GC) with a glass column length of 1.5 m and diameter 4 mm), packed with SP-1200 (Supelco). A sample of 0.2–0.4 μl was injected into the column at an initial injector temperature of 150°C. Helium was the carrier gas, with a flow rate of 35 ml/min and oven temperature of 140°C. Detection was by flame ionization and calibration was carried out using a mixture of VFAs (C2–C5) in approximately the same proportions and concentrations as found in the rumen samples.

Statistical analysis was carried out using the GENSTAT 5 statistical package (Lawes Agricultural Trust, Release 3.1). Because of the sequential nature of the transfers of inoculum, there was a strong possibility of carryover effects between days of measurement within each series of tubes. The statistical analysis hence examined the effects of treatments and days in a two-way factorial analysis of variance, which was blocked within days, which in turn was blocked within series of tubes. Specific comparisons were made using the LSD test (Snedecor and Cochran, 1982). Although all data are presented, the statistical analysis was conducted after omitting the results from day 2 since the composition of this first set of tubes incubated was different to subsequent batches as it contained

fresh rumen liquor. All quoted standard errors of difference (SED) derive from analyses on these restricted data.

RESULTS

The presence of phenolic compounds had a significant ($F = 9.93$, $df = 3, 15$, $P < 0.001$) effect on gas production (Figure 2a). Mean gas production in the presence of orcinol (3.62 cm^3, SE 0.095) and quinol (3.44 cm^3, SE 0.226) was significantly lower ($P < 0.05$, LSD test) than the control treatment (4.25 cm^3, SE 0.120). In the tubes containing arbutin there was no overall significant effect on microbial gas production (4.75 cm^3, SE 0.299) compared to the control treatment, but gas production was significantly greater than the quinol treatment ($P < 0.05$, LSD test).

Dry matter (DM) loss of grass hay during continuous batch culture varied significantly between phenolic treatments ($F = 23.87$, $df = 3, 15$, $P < 0.001$; Figure 2b). The mean DM loss was significantly lower ($P < 0.01$, LSD test) in the presence of arbutin (16.4%, SE 1.18) and orcinol (20.5%, SE 0.72) compared to the control treatment (22.9%, SE 0.70). The addition of quinol had no significant effect on DM loss (21.2% SE 0.92) compared to the controls ($P < 0.1$). The DM loss was significantly lower in the arbutin treatment than the quinol treatment ($P < 0.001$).

There was a significant effect ($F = 80.02$, $df = 3, 15$, $P < 0.001$) of phenolic compounds on total VFA concentration (Figure 2c). Total VFA concentration was significantly higher ($P < 0.01$, LSD test) in the presence of arbutin (54.8 mmol/liter, SE 1.02) compared to the control (39.6 mmol/liter, SE 1.01). In contrast, the presence of both orcinol and quinol resulted in significantly lower total VFA concentrations compared with controls (orcinol: 30.2 mmol/liter, SE 0.96, $P < 0.01$, LSD test; quinol: 34.9 mmol/liter, SE 1.90, $P < 0.05$, LSD test). This suggests that arbutin was stimulating VFA production and orcinol and quinol were suppressing it. There were no significant phenolic treatment × day interaction effects on gas production, dry matter loss, or VFA concentration, indicating that any effects of phenolic treatment were consistent across days.

Table 1 shows the effects of phenolic compounds on acetate, propionate, and butyrate concentration. There was a significant effect of treatments on mean concentrations of acetate ($F = 18.90$, $df = 3, 15$, $P < 0.001$), propionate ($F = 116.24$, $df = 3, 15$, $P < 0.001$) and butyrate ($F = 84.91$, $df = 3, 15$, $P < 0.001$). The presence of arbutin led to a higher acetate concentration than controls ($P < 0.05$, LSD test), whereas orcinol and quinol resulted in lower acetate concentrations than the controls ($P < 0.05$, LSD test). As with acetate

Day

concentration, the presence of arbutin resulted in a higher propionate concentration, whereas orcinol and quinol decreased the propionate concentration compared to controls (all comparisons: $P < 0.001$, LSD test). In contrast, all three phenolics, orcinol, quinol, and arbutin, resulted in a significantly higher mean butyrate concentration in comparison to the control ($P < 0.001$, LSD test). There was a significant effect of days on the concentration of butyrate ($F = 12.02$, $df = 4, 4$, $P < 0.05$), although no consistent trends were apparent (Table 1).

Incorporation of data from day 2 into the analyses led to significant ($P < 0.05$) main effects of day on all variables, thus confirming the magnitude of this methodological effect.

DISCUSSION

This study was conducted to determine whether simple phenolic compounds found in heather had an adverse effect on rumen microbial activity. Such adverse effects on microbial activity would result in reduced digestibility of the plant material and reduced supply of energy to the animal.

The presence of orcinol at a concentration of 10 mM resulted in a reduction in microbial gas production, percentage DM loss, and total VFA concentration, suggesting a toxic effect on rumen microorganisms. The nutritional significance of this reduction in the digestibility of plant material is the lower microbial production of VFAs, the fermentation products that are a major energy source for ruminants and other herbivores utilizing microbial fermentation (Van Soest, 1983). Gas production and total VFA concentrations were reduced in the presence of quinol but percentage DM loss was unaffected. The presence of arbutin, which is a glucoside of quinol, resulted in a significant reduction in percentage DM loss. This is likely to result from the release of glucose from the glucoside, as glucose has been shown to cause catabolite repression of cellulolysis by some rumen microorganisms (Morrison et al., 1990). Thus it appears that the microorganisms utilized the glucose derived from arbutin as a fermentation substrate, resulting in reduced utilization of the hay, but permitting increased total VFA and/or gas production. The arbutin added to the tubes was equivalent to the addition of 0.11 mmol of both glucose and quinol, in the form of the glucoside.

FIG. 2. The effect of additions of the phenolics orcinol (—□—), quinol (---●---), and arbutin (—○—), and solvent-only controls (--■--), on (a) gas production, (b) dry matter disappearance, and (c) volatile fatty acid (VFA) concentration in consecutive batch culture. SED shown is for comparisons of phenolic treatments within days. Unlike letters denote significant differences ($P < 0.05$, LSD test) between means pooled across days 4–12 (see text).

	SED_p	1.053	SED_w:	12.352	SED_p:	0.768	SED_w:	1.717	SED_p:	0.222	SED_w:	0.496

[a] SED_p: standard error of difference for comparisons between means of phenolic treatments pooled across days; SED_w: standard error of difference between phenolic treatments within days. Values followed by different letters indicate significant differences ($P < 0.05$, LSD test) between means pooled across days 4–12 (see text).

Assuming that microbial fermentation of 3 mol of glucose yields 4 mol of gas (Van Soest, 1983), and 1 mol of gas occupies 24.5 liters at 25°C, then complete fermentation of the glucose would have yielded 3.58 ml of gas at 25°C. The difference in gas production between the arbutin (quinol glucoside) and the quinol-only treatment was 1.30 ml. This is less than the expected maximum amount of 3.58 ml that could have been formed from the additional hexose, suggesting either incomplete hydrolysis of the arbutin by glycosidases, incomplete fermentation of the liberated glucose, or glucose-induced catabolite repression of cellulolysis, leading to fewer hexose intermediates.

The concentrations of phenolic compounds used in this experiment would be higher than the overall concentration of those individual phenolic compounds found in rumen fluid (Jung et al., 1983), although the amounts added are probably not dissimilar to the total concentration of the non-tannin phenolic compounds, about 1% of the substrate dry matter, that would be found in *Calluna* (Jalal et al., 1982). However, it has been suggested that rumen microorganisms *in vivo* would encounter effectively higher levels of phenolic compounds in the microenvironment within the cell matrix as they act on the surfaces of the plant material near the site of release of the phenolics (Chesson et al., 1982; Borneman et al., 1986). Previous studies demonstrated differential effects of the phenolics on the components of the microbial population (Hungate, 1966); particular species of bacteria (Chesson et al., 1982) or taxonomic groups of microorganisms such as the fungi (Akin and Rigsby, 1985) may not be equally susceptible to the effects of specific phenolics. This factor may have led to the differences in the observed concentrations and proportions of VFAs produced in the presence of the different phenolics; fermentation in the presence of arbutin produced contrasting patterns of VFAs compared to orcinol and quinol, which depressed acetate and propionate concentrations relative to controls but stimulated butyrate production. The general stimulation of VFA production by arbutin was consistent with an overall stimulatory effect due to its glucose component (Van Soest, 1983).

Calluna is rich in both tannin and non-tannin phenolics (Iason et al., 1993; Jalal et al., 1982). Tannin phenolics are one of the factors affecting digestibility and, hence, intake and diet selection by ruminants (Robbins et al., 1987; McArthur et al., 1993). This study has shown that simple phenolic compounds of heather—orcinol and quinol—also have negative effects on *in vitro* digestion by rumen microorganisms and are thus also likely to influence feeding ecology. However, the presence of these compounds in plants, mainly as glycosides (Jalal et al., 1982), means that on ingestion by ruminants, their negative digestive effects would be reduced or offset by the positive effects of the sugar unit that is liberated and used as a fermentation substrate. Although this effect may reduce the influence of the phenolic glycosides on digestibility, even small residual

changes in digestibility can have large population consequences for ruminants (White, 1983). The non-tannin phenolics, including orcinol and quinol, have also been hypothesized to affect intake and diet selection by deer via toxic effects following absorption (McArthur et al., 1993; Iason and Murray, 1996). However, toxic effects of specific compounds appear not to be a prerequisite for deterrency to a specialist insect herbivore (Bernays, 1990).

Acknowledgments—We thank Sylvia Duncan for technical assistance; Alan Duncan, Bob Mayes, John Milne, John Speakman, and two anonymous referees for helpful comments or discussion; and David Elston of Biological Statistics Scotland for statistical advice. The research was funded by the Scottish Office Agriculture and Fisheries Department.

(Received February 21, 1995; accepted April 10, 1996)

Abstract—Pheromone compounds so far identified from most geometrid moths consist of all-*Z* diene, triene, or tetraene hydrocarbons with chain lengths of C_{17} to C_{21}, and their monoepoxide derivatives biosynthesized from linoleic and linolenic acids. The present study reports the occurrence of olefinic acetates as sex pheromones in three species of Geometridae. (*Z*,*Z*)-9,11-tetradecadienyl acetate and (*Z*,*Z*)-7,9-dodecadienyl acetate found in female gland extracts of *Idaea aversata* elicited significant responses from conspecific male antennae in gas chromatography with electroantennographic detection (GC-EAD). In extracts of *I. straminata*, (*Z*,*E*)-7,9-dodecadienyl acetate, (*E*,*Z*)-7,9-dodecadienyl acetate, and (*Z*,*Z*)-7,9-dodecadienyl acetate were found, and the synthetic compounds elicited strong responses from conspecific male antennae. In the third species, *I. biselata*, only (*Z*,*Z*)-7,9-dodecadienyl acetate was found in the female extracts, and this compound elicited a strong EAD

response from the conspecific male antenna. The identities of the pheromone components in *I. aversata* and *I. straminata* were further confirmed according to their characteristic ions after GC-MS analyses. Single sensillum recordings from *I. aversata* showed two types of pheromone-detecting sensilla present on the male antenna. One type contained two receptor neurons, one of which was specifically tuned to (*Z*,*Z*)-9,11-tetradecadienyl acetate, the other to (*Z*,*E*)-9,11-tetradecadienyl acetate. A second type contained one neuron responding to (*Z*,*Z*)-7,9-dodecadienyl acetate. The two types were clearly different also with respect to external morphology, the former being considerably longer and having a larger base diameter. Also in *I. straminata* two physiological types of sensilla could be distinguished. One type contained two neurons, one of which responded to (*Z*,*Z*)-7,9-dodecadienyl acetate, the other to (*Z*,*E*)-9,11-tetradecadienyl acetate. The second type contained one neuron, responding to (*Z*,*Z*)-7,9-dodecadienyl acetate. No correlation between external morphology and physiological response of the investigated sensilla was observed in *I. straminata*. In field tests, a two-component blend containing (*Z*,*Z*)-9,11-tetradecadienyl acetate and (*Z*,*Z*)-7,9-dodecadienyl acetate in a ratio of 10 : 1 was attractive to males of *I. aversata*. This two-component blend was also attractive to males of *I. straminata*, but in a ratio of 1 : 1. High numbers of male *I. biselata* were caught in traps baited with (*Z*,*Z*)-7,9-dodecadienyl acetate alone. The incorporation of deuterium labels into pheromone components after topical application of deuterium-labeled palmitic acid confirmed that the pheromone components of *I. aversata* could be synthesized from this precursor, as has been previously observed for acetate pheromone components of many other moth species. Our results suggest that an evolutionary reversal back to the production of palmitic acid-derived pheromone components has occurred within the geometrid subfamily Sterrhinae.

Key Words—Sex pheromone, *Idaea aversata*, *Idaea straminata*, *Idaea biselata*, (*Z*,*Z*)-9,11-tetradecadienyl acetate, (*Z*,*Z*)-7,9-dodecadienyl acetate, (*Z*,*E*)-7,9-dodecadienyl acetate, Lepidoptera, Geometridae, electroantennography, single cell recording, biosynthesis, phylogeny, evolution.

INTRODUCTION

The majority of pheromones of higher Lepidoptera consist of unsaturated acetates, alcohols, or aldehydes, and the carbon skeletons of these pheromone components can be biosynthetically derived from palmitic acid (hexadecanoic acid) or stearic acid (octadecanoic acid) by a combination of chain-shortening, desaturation, reduction, and acetylation reactions (Bjostad et al., 1987). A less common type of moth pheromone component includes unsaturated hydrocarbons and their epoxides, which can be derived from linoleic and linolenic acid (Rule and Roelofs, 1989). Such pheromone components occur mainly within the superfamilies Noctuoidea and Geometroidea (Arn et al., 1992). In Geometridae, sex pheromones have been identified for around 28 species, and sex attractants have been reported for an additional 55 species (Arn et al., 1992 and references therein). In most of these reports, sex pheromones and sex attractants were

all-*Z* diene, triene, or tetraene hydrocarbons with chain lengths from C_{17} to C_{21} and/or their corresponding monoepoxides. Three hemlock loopers utilize branched hydrocarbons as their pheromones (Gries et al., 1991, 1993a,b), and a few reports indicate that olefinic acetates and aldehydes can also be used as pheromones or attractants in some species of Geometridae, but only within the subfamily Sterrhinae. For example, (*E*,*Z*)-7,9-dodecadienyl acetate (*E*7,*Z*9–12:OAc) was reported to be attractive to males of *Idaea biselata* (Biwer et al., 1975), and compounds such as (*E*,*Z*)-7,9-dodecadienal (*E*7,*Z*9–12:Ald) and (*Z*)-7-dodecenyl acetate (*Z*7–12:OAc) have also been shown to be attractive for males of this species (E. Priesner personal communication and Ando et al., 1987). *Z*7–12:OAc, *E*7,*Z*9–12:OAc, and (*E*,*Z*)-7,9-dodecadienol (*E*7,*Z*9–12:OH) were reported as attractants for males of *I. imbecilla*, *I. rubraria*, and *I. trisetata*, respectively (Szöcs et al., 1987; Ando et al., 1977, 1987).

The type of sex pheromone components used in moths may be of taxonomic significance at the genus, subfamily, and family levels, and pheromone characteristics may be used for phylogenetic analysis of different taxa (Roelofs and Brown, 1982; Löfstedt et al., 1991; Löfstedt and Kozlov, 1996). The possibility that acetates are used as pheromone components in one geometrid subfamily, whereas other subfamilies appear to use branched hydrocarbons or unsaturated hydrocarbons and/or their corresponding epoxides as pheromone components, is intriguing and deserves to be studied in more detail. In the present study we confirm the occurrence of acetates as sex pheromone components in three geometrid moths, *I. aversata* (L., 1758), *I. straminata* (Borkhausen, 1794), and *I. biselata* (Hufnagel, 1767). Active components were detected by gas chromatography with electroantennographic detection (GC-EAD) and identified by gas chromatography and gas chromatography–mass spectrometry. The activity of synthetic pheromone components was confirmed by single sensillum recordings on male antennae and by field trapping.

METHODS AND MATERIALS

Insects. Female adults of all three investigated species were collected at various sites in southern and south-central Sweden. Laboratory cultures were established from eggs laid by these collected insects. The larvae were reared on withered moist leaves from a number of plant species, predominantly willows (*Salix* spp.). The cultures were kept under a 16 L:18 D photoperiod at a temperature of 22°C and a relative humidity of 60%. Sex was determined at the pupal stage, and the emerging adults were kept individually in small cups under the same environmental conditions as the larvae.

Pheromone Gland Extraction. Females of all species started calling 3–4 h after darkness on the second day after emergence. The pheromone glands of calling females were excised and extracted for 30 min in redistilled hexane.

Electrophysiological and Chemical Analyses. For electroantennographic (EAG) recordings, excised male antennae were placed with the base in a capillary electrode filled with Beadle-Ephrussi Ringer, and grounded via an Ag–AgCl wire. The distal tip of the antenna was cut, and the exposed surface was placed in contact with a second electrode, similar to the indifferent electrode. The tip electrode was connected to a high-impedance DC amplifier with automatic baseline drift compensation.

Single sensillum recordings were performed utilizing the tip-cutting technique. Either excised male antennae or intact insects were used. Excised antennae were placed with the base in a capillary electrode as described above. Intact insects were restrained in holders cut from plastic disposable pipet tips, and the head and antennae were fixed in position with dental wax. A thin tungsten wire serving as ground electrode was inserted into the abdomen. Olfactory sensilla were cut by means of two glass knives, and a recording electrode was placed in contact with the cut surface of the sensillum. The recording electrode was a glass pipet with a tip diameter of about 4 μm, filled with Beadle-Ephrussi Ringer. The recording electrode was connected to a high-impedance AC amplifier via an Ag–AgCl wire. The recorded data was analyzed on a Macintosh computer with a Maclab analog/digital interface (M. C. Macknight, Analog Digital Instruments).

In both EAG and single sensillum experiments, the antenna was continuously flushed with charcoal-filtered and moistened air (0.5 m/sec) delivered through a glass tube (8 mm ID) ending 10 mm in front of the preparation. Stimulus cartridges consisted of Pasteur pipets containing a piece of filter paper (7 × 15 mm) on which the stimulus had been applied. In the dose–response tests, serial dilutions (10^{-2}–10^{2} μg in decadic steps) of the compounds dissolved in 10 μl of hexane were applied. Air (2 ml) was passed over the filter paper in the stimulus cartridge during 0.5 sec and injected into the airstream 150 mm upstream of the antenna.

A Hewlett Packard 5830 gas chromatograph (GC) equipped with a DB-wax column (30 m × 0.25 mm ID, J & W Scientific, Folsom, California) and an effluent split, allowed simultaneous flame ionization (FID) and electroantennographic detection (EAD) of the separated pheromone components. Hydrogen was used as carrier gas, and the effluent split ratio was approximately 1 : 1. Samples were injected in splitless mode. The injector temperature was 250°C and the split valve was opened 1 min after injection. The column temperature was maintained at 80°C for 3 min following the injection and then linearly increased to 230°C at 10°C/min. The outlet for the EAD was placed in a purified airstream flowing over the antennal preparation at a speed of 0.5 m/sec. Either female pheromone gland extracts or synthetic standard were injected into the column for the analysis. GC retention times of EAD-active components were converted to equivalent chain lengths (ECLs) relative to the retention times of

homologous, straight-chain acetates (7–22:OAc). The electrophysiological methods were identical to those described above.

Individual female pheromone gland extracts were also analyzed on a Hewlett-Packard 5880 GC equipped with the same column and under the same operating conditions as described above.

Mass spectrometry with electron impact ionization (70 eV) was performed on a HP 5970B GC-MS system equipped with a 59970B computer system, and interfaced with a HP 5890 GC. Gas chromatographic conditions for analyses were the same as those described above.

Biosynthesis Experiment. [16,16,16-$^2H_3$]hexadecanoic acid (D_3-16:COOH) (Larodan Fine Chemicals, Malmö, Sweden) dissolved in DMSO (4 μg/0.2 μl) was applied topically to the pheromone glands of 2- to 3-day-old female *I. aversata* with a 10-μl syringe. After 1 hr incubation, the pheromone glands were dissected and extracted for 30 min in 6 μl redistilled hexane containing 1 ng Z8–13:OAc as an internal standard. Deuterium-label incorporation from different precursors into pheromone components was determined by GC-MS in the selected ion monitoring mode. An acquisition program was designed in which diagnostic ions (DI) of unlabeled and D_3-labeled (DI+3) pheromone acetates were monitored simultaneously and the selected ions were changed at the appropriate time during the separation based on the retention times of the synthetic standards. This allowed selective detection of each of the pheromone components and their respective D_3-labeled analogs. Thus, *m/z* 164.20 and 167.20 were chosen for detection of unlabeled and deuterium-labeled Δ-7,9–12:OAc, respectively, whereas Δ-9,11–14:OAc was monitored by *m/z* 192.20 and 195.20.

Field-Trapping Tests. Field tests were conducted in the Hågadal and Nåsten regions of Uppsala in south-central Sweden from the end of June to the beginning of August in 1992 and 1993. Synthetic blends were prepared in hexane. Red rubber septa (Arthur H. Thomas Co. Catalog No. 1780-J07) were used as dispensers, and the traps used were delta traps. Traps were placed in woodland habitats, where all the species under investigation occur, and were hung on the tree twigs or placed in low bushes approximately 1 m above the ground. Within a replicate ($N = 5$), the traps were set at least 2 m apart. The traps were checked and the captured males removed once a week, and trap positions within a series were randomized to minimize the effects of habitat heterogenities. In a first experiment, from June 26 to August 1, 1992, 14 different blends of pheromone components were tested at 50 μg loading on the dispenser (details in Table 1). In a second field test from July 4 to August 21, 1993, different doses and ratios of those pheromone components that had been most attractive in the field test of 1992 were tested.

Chemicals. Z9,E11–14:OAc was prepared as described by Hall et al. (1975). The product was further purified by flash column chromatography on silica gel in 2% diethyl ether in hexane to remove any traces of the corresponding

alcohol and contained 1.2% *E*9,*E*11-14:OAc after Kugelrohr distillation (100°C/0.02 mm).

*Z*9,*Z*11-14:OAc was prepared by Wittig reaction of propyl (triphenylphosphonium) bromide with potassium *t*-butoxide in tetrahydrofuran and the tetrahydropyranyl ether of (*Z*)-11-hydroxy-2-undecenal. The latter was prepared by coupling of propargyl alcohol with the tetrahydropyranyl ether of 8-bromooctan-1-ol using lithium amide in liquid ammonia, hydrogenation of the resulting acetylenic alcohol over Lindlar catalyst in ethanol at 0°C, and oxidation of the allylic alcohol with activated manganese dioxide in toluene. The aldehyde was used without further purification and gave 9,11-14:OAc isomers *ZE*:*EZ*:*ZZ*:*EE* in 6:7:87:<0.5 ratio after removal of the tetrahydropyran protecting group with *p*-toluenesulfonic acid in methanol and acetylation with acetic anhydride in pyridine. This material was further purified by liquid chromatography on silica gel impregnated with 10% silver nitrate eluted with a

gradient of diethyl ether in hexane to give a product containing *ZE*:*EZ*:*ZZ*:*EE* isomers of 9,11-14:OAc in 2.3:0.8:96.9: <0.5 ratio after Kugelrohr distillation (120°C/0.02 mm).

*Z*7,*Z*9-12:OAc was prepared by reduction of (*Z*)-9-dodecen-7-ynyl acetate (Brückner et al., 1988) with activated zinc in methanol–water (1:1) (Boland et al., 1987). At best, only 72% conversion was achieved even after 6 days at room temperature. The product, which was separated from unreacted starting material by liquid chromatography on silica gel, eluted with 5% diethyl ether in hexane to give material containing *ZE*:*EZ*:*ZZ*:*EE* isomers of 7,9-12:OAc in 0.7:0.6:98.7: <0.1 ratio after Kugelrohr distillation (90°C/0.03 mm).

(*Z*)-9-Dodecen-7-ynyl acetate was isomerized in sunlight with a catalytic quantity of iodine in hexane solution to give a mixture of the *E* and *Z* isomer in 61:39 ratio. This mixture was reduced with activated zinc as above and the resulting mixture of *Z*7,*E*9-12:OAc and *Z*7,*Z*9-12:OAc was separated by chromatography on a silver ion exchange column eluted with methanol at atmospheric pressure (cf. Houx et al., 1974). Fractions containing the *Z*7,*E*9-12:OAc only were combined to give material containing less than 0.3% of any other isomers after Kugelrohr distillation (86°C/0.01 mm).

GC analyses of the different isomers of these two conjugated acetates were conducted on a polar CP Wax 52CB column (25 m × 0.32 mm ID; Chrompack UK), helium carrier gas at 0.5 kg/cm^{-2}, oven temperature 70°C for 2 min, then programmed at 20°C/min to 120°C and then at 4°C/min to 230°C. The order of eluted synthetic compounds was *ZE*-, *EZ*-, *ZZ*-, *EE*-7,9-12:OAc and 9,11-14:OAc, respectively.

Scanning Electron Microscopy. To examine the possible correlation between the external morphology of the pheromone-sensitive sensilla and their response specificity, antennae of *I. aversata* and *I. straminata* were fixed in 70% ethanol and subsequently dehydrated in absolute ethanol, critical point-dried, mounted with epoxy glue on specimen holders, and coated with gold/palladium (Polaron E5500 high resolution sputter) before examination in a Jeol JSM-T330 scanning electron microscope, operated at 15 kV.

RESULTS

Chemical Analyses. In *Idaea aversata*, analysis of female pheromone gland extracts by GC-EAD showed that two compounds elicited strong responses from a conspecific male antenna (Figure 1B). ECLs of the two active peaks were 1390 and 1596, respectively. By comparison of these retention indices to those of synthetic compounds, these two compounds were tentatively identified as (*Z*,*Z*)-7,9-dodecadienyl acetate (*Z*7,*Z*9-12:OAc) and (*Z*,*Z*)-9,11-tetradeca-

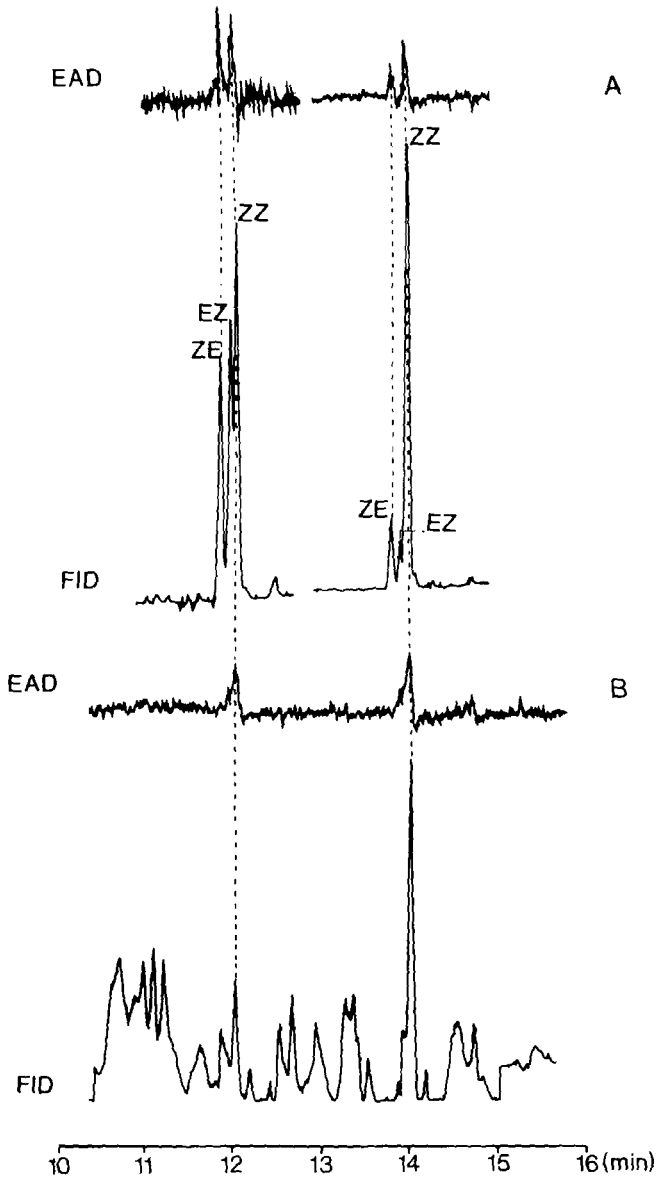

FIG. 1. GC-EAD analyses using antennae of male *Idaea aversata*. (A) Responses to the mixture of *Z*7,*E*9-, *E*7,*Z*9-, and *Z*7,*Z*9-12:OAc and the mixture of *Z*9,*E*11-*E*9,*Z*11-, and *Z*9,*Z*11-14:OAc, respectively. (B) Responses to female gland extracts.

dienyl acetate (Z9,Z11-14:OAc). Coupled GC-MS analysis of the same extracts supported the assignment of chemical structures to these two active compounds. The mass spectrum of the first eluting compound included ions at *m/z* 224 (M) and *m/z* 164 (M − 60), typical of a dodecadienyl acetate with conjugated double bonds. The spectrum of the second active peak included ions at *m/z* 252 (M) and *m/z* 192 (M − 60), indicating a tetradecadienyl acetate with conjugated double bonds. In separate GC-EAD analyses of synthetic standards, a mixture of Z7,E9-, E7,Z9-, and Z7,Z9-12:OAc produced responses to the *ZE* and *ZZ* isomers, while Z9,Z11-14:OAc containing small amounts of Z9,E11- and E9,Z11-14:OAc produced responses to the former two compounds (Figure 1A).

In *I. straminata*, combined GC-MS analyses of female pheromone gland extracts confirmed the occurrence of Z7,Z9- as well as Z7,E9- and E7,Z9-12:OAc in the females. A peak with the retention time of synthetic Z9,Z11-14:OAc was found in several gas chromatographic analyses of female extracts. When mixtures of the geometric isomers of 7,9-12:OAc and 9,11-14:OAc were tested in the GC-EAD experiments, the dodecadienyl acetates were more active than the tetradecadienyl acetates, with the Z7,Z9-12:OAc being the most active stimulus (Figure 2).

In *I. biselata*, only one active peak was found when female extracts were analyzed by GC-EAD with a conspecific male antenna as a detector (Figure 3B). The retention time of the active compound corresponded to that of synthetic Z7,Z9-12:OAc. Analysis of a synthetic sample confirmed the activity of Z7,Z9-12:OAc (Figure 3A).

Male Antennal Morphology. In *I. aversata*, sensilla trichodea of two clearly different size classes were present, as is evident from Figure 4. A large type (type I) measured ca. 70 μm in length with a diameter at the base of 3 μm. A smaller type (type II) was approximately 50 μm long and measured 2 μm at the base. The type I sensilla were much more prominent, being almost perpendicular to the antennal surface. Intermediates between the two categories were rare. In *I. straminata* the sensilla also showed a variation in size, but the differences were less pronounced.

Electrophysiology. The biological activity of the synthetic pheromone compounds was tested by EAG in all three species while single sensillum recordings were performed in two species. EAG data (Figure 5) showed that antennae of male *I. aversata* responded strongly to Z9,E11-14:OAc, Z9,Z11-14:OAc, and Z7,Z9-12:OAc. Significant responses were obtained when the male antennae of *I. straminata* and *I. biselata* were stimulated by each of the four isomers of 7,9-12:OAc. Antennae of *I. straminata* responded also to Z9,Z11-14:OAc and those of *I. biselata* showed some response to all four isomers of 9,11-14:OAc. The strongest response from male antennae of both species was elicted by Z7,Z9-12:OAc.

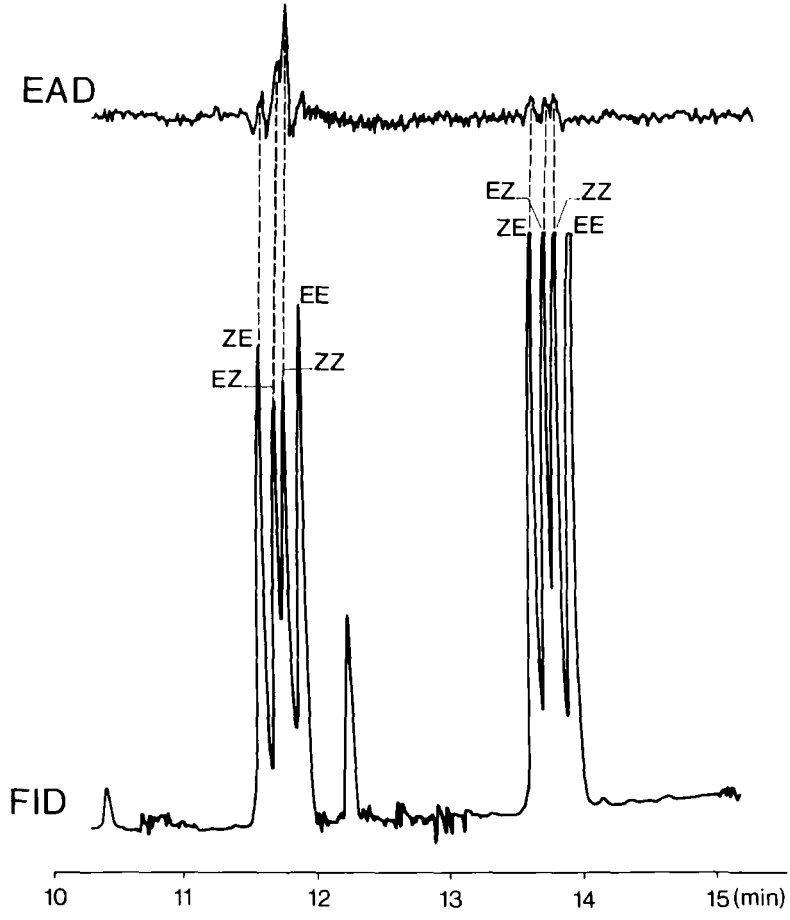

FIG. 2. GC-EAD analysis displaying male *Idaea straminata* antennal response to the mixture of four isomers of 7,9-12:OAc and four isomers of 9,11-14:OAc.

Single sensillum recordings were conducted on sensilla trichodea present on the male antennae of *I. aversata* and *I. straminata*. Recordings were made from 35 sensilla of males of *I. aversata*. All these sensilla displayed one or two receptor neurons responding to pheromone compounds. Two physiological types could be distinguished. Type I ($N = 30$) contained two neurons. One, characterized by a large action potential (spike) amplitude (neuron A), responded to *Z*9,*E*11-14:OAc, and the other, characterized by a smaller spike amplitude (neuron B) responded to *Z*9,*Z*11-14:OAc. Type II ($N = 5$) contained only one

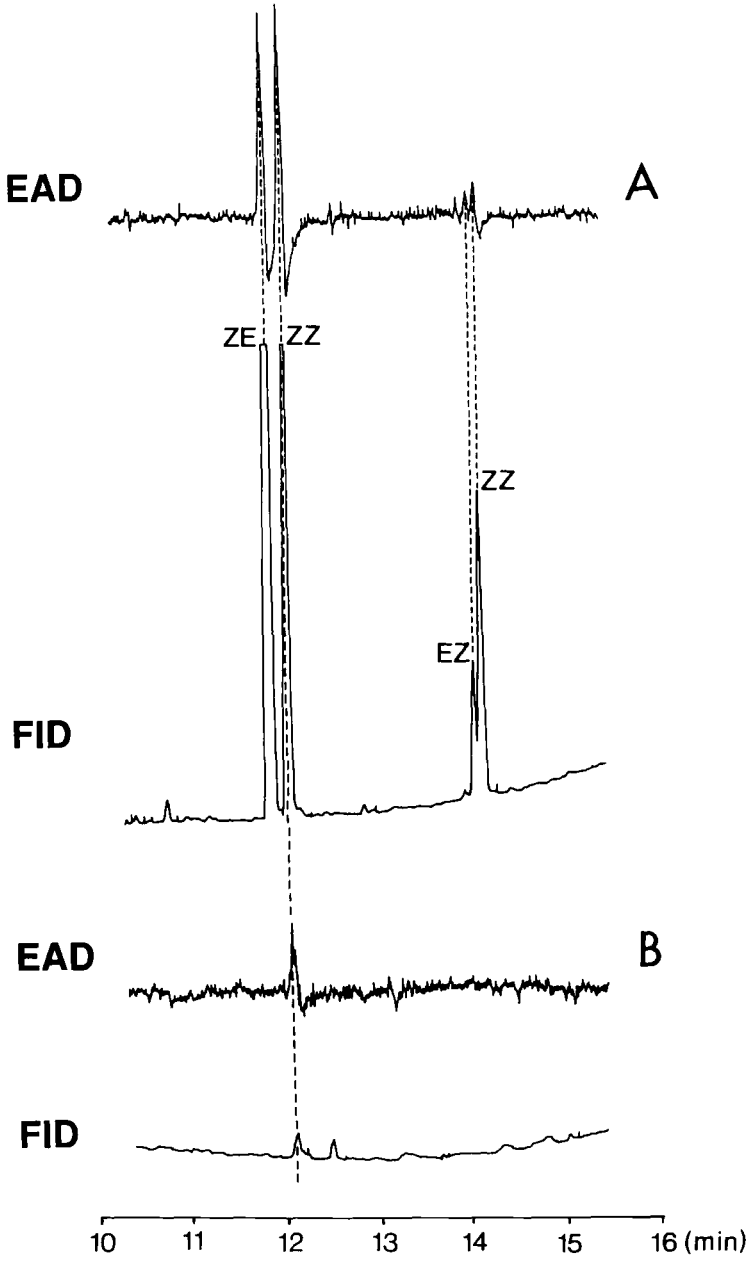

FIG. 3. GC-EAD analyses using antennae of male *Idaea biselata*. (A) Responses to the mixture of *Z*7,*E*9- and *Z*7,*Z*9–12 : OAc and *E*9,*Z*11- and *Z*9,*Z*11–14 : OAc. (B) Responses to female gland extracts.

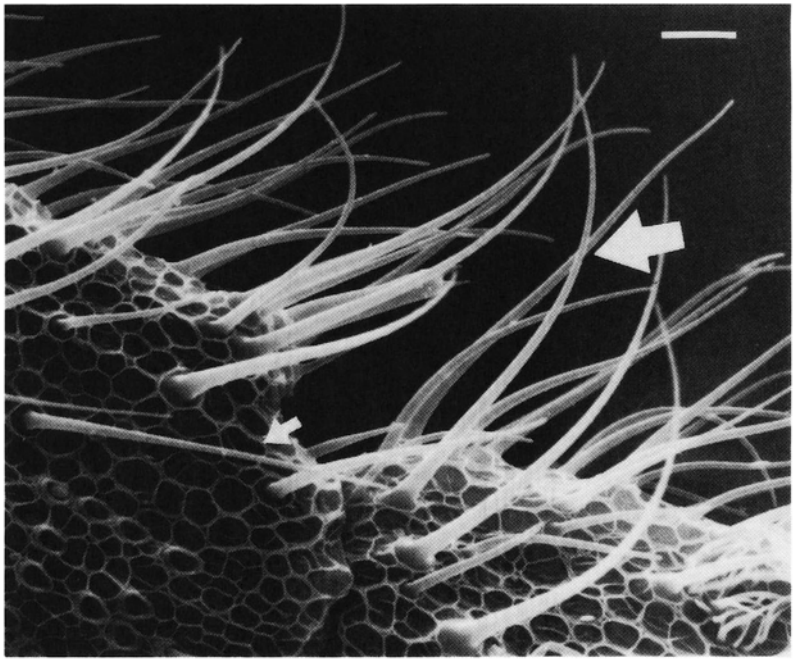

FIG. 4. The surface of male antennal segments of *Idaea aversata*, showing sensilla trichodea type I (large arrow) and type II (small arrow). Scale bar = 10 μm.

physiologically active neuron, which was specifically tuned to Z7,Z9–12:OAc. Representative recordings from these three cell types are shown in Figure 6a–c. The spike amplitudes of the two receptor neurons present in sensillum type I were quite similar, and only a thorough, computer-aided investigation of the recordings yielded an unambiguous identification (Figure 6b, inset). Type I sensilla were found among the long morphological type, while type II sensilla were found among the shorter. Dose–response tests showed that all three receptor neuron types responded to their respective key stimulus with equal sensitivity (Figure 7a–c).

In *I. straminata*, two physiologically different types of sensilla could also be distinguished. Type I (N = 17) contained two neurons, one of which responded with a large spike amplitude (neuron A) to Z7,Z9–12:OAc, and one characterized by a smaller spike amplitude responding to Z9,E11–14:OAc (neuron B). Type II (N = 13) contained one activated neuron, responding to Z7,Z9–12:OAc. Recordings from all three receptor neuron types are shown in Figure 8a–c. No correlation between external morphology and physiological specificity was established in this species. In dose–response tests, the two Z7–Z9–12:OAc

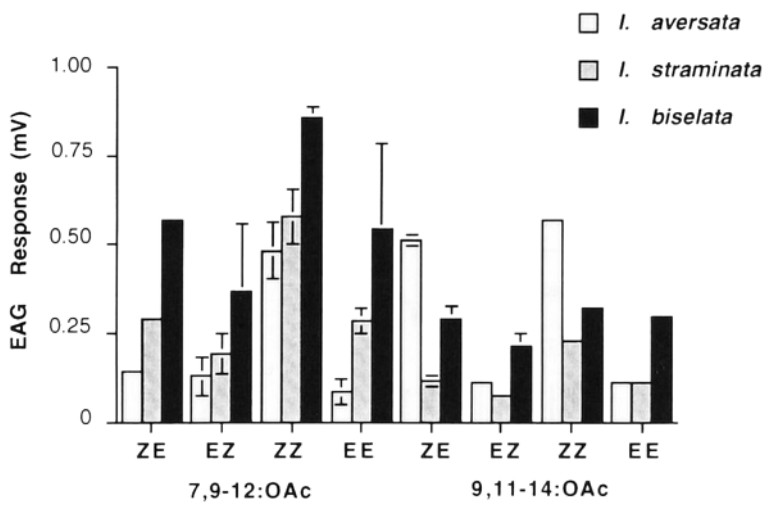

FIG. 5. EAG responses of males of *Idaea aversata*, *I. straminata*, and *I. biselata* to synthetic compounds. The blank response (air) was subtracted from each actual response. Vertical bars indicate the standard error of the mean. $N = 2$–3.

receptor neurons responded with equal sensitivity (Figure 7d). However, the *Z*9,*E*11–14:OAc receptor showed a significantly lower response.

Biosynthesis Experiments. When D_3-16:COOH was applied to the glands of *I. aversata*, there was significant incorporation into both pheromone compounds, *Z*7,*Z*9–12:OAc and *Z*9,*Z*11–14:OAc, as shown by selected ion monitoring. The D_3 analog eluted approx. 0.05 min before the unlabeled components (Löfstedt et al., 1986).

Field Tests. The results of the first field trapping test including 14 different blends of the potential pheromone compounds (Table 1), showed that males of *I. aversata* were attracted by baits containing two compounds, *Z*9,*Z*11–14:OAc and *Z*7,*Z*9–12:OAc in a ratio of 10:1, but the attraction of males was significantly increased when *E*9,*Z*11–14:OAc was included in the blend. Males of *I. straminata* were also attracted to the two component blend active to *I. aversata*, but with the compounds present in a different ratio (1:1). Such baits also trapped males of *I. emarginata*, and high captures of males of this species were obtained by adding 5 μg of *Z*7,*E*9–12:OAc to the two-component mixture. High numbers of male *I. biselata* were attracted to the bait containing only *Z*7,*Z*9–12:OAc, and adding any of the other isomers of either 9,11–14:OAc or 7,9–12:OAc reduced attractiveness significantly.

When a mixture of the two compounds *Z*9,*Z*11–14:OAc and *Z*7,*Z*9–

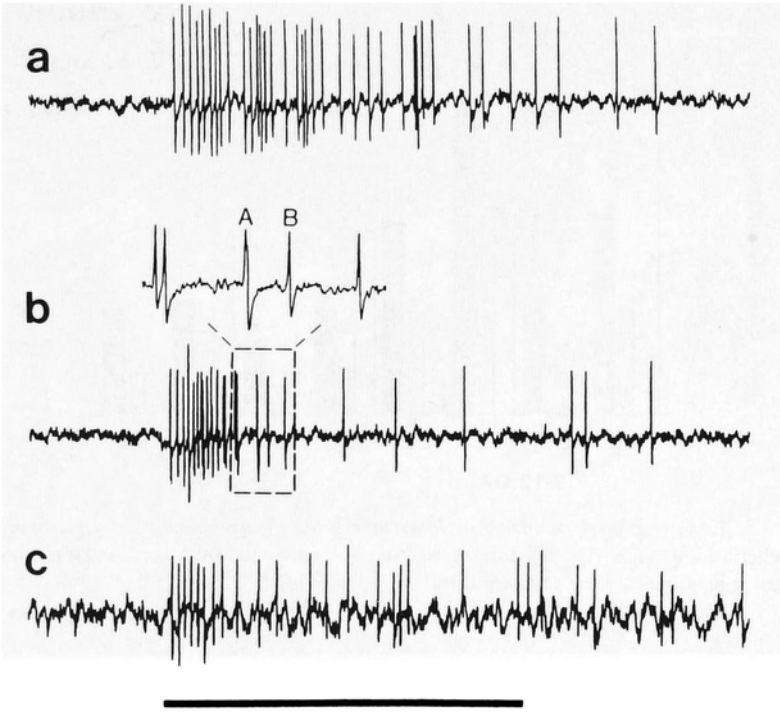

FIG. 6. Physiological responses recorded from receptor neurons present in sensilla trichodea on the male *Idaea aversata* antenna. (a) Response of the large-spike-producing neuron in the type I sensillum trichodeum to Z9,E11-14:OAc. (b) Response of the small-spike-producing neuron, present in the same sensillum type, to Z9,Z11-14:OAc. Inset shows the amplitude difference between the two receptor neurons present in sensillum trichodeum type I. (c) Response of the only receptor neuron firing in the type II sensillum trichodeum to Z7,Z9-12:OAc. Horizontal line under the records indicate duration of stimulation.

12:OAc in different ratios was tested again, the catches were low but the results confirmed those of the previous year (Table 2).

The dose-response test of Z7,Z9-12:OAc showed that *I. biselata* males responded in high numbers to baits with doses in the range of 5-500 μg. Reducing the loading further to 0.5 μg gave significantly lower catches (Table 3). No males of *I. emarginata* were trapped by baits containing 100 μg of Z7,E9-12:OAc. The attraction of males of *I. biselata* to 100 μg of Z7,Z9-12:OAc was not significantly affected by the addition of 10 μg Z7,E9-12:OAc (Table 3).

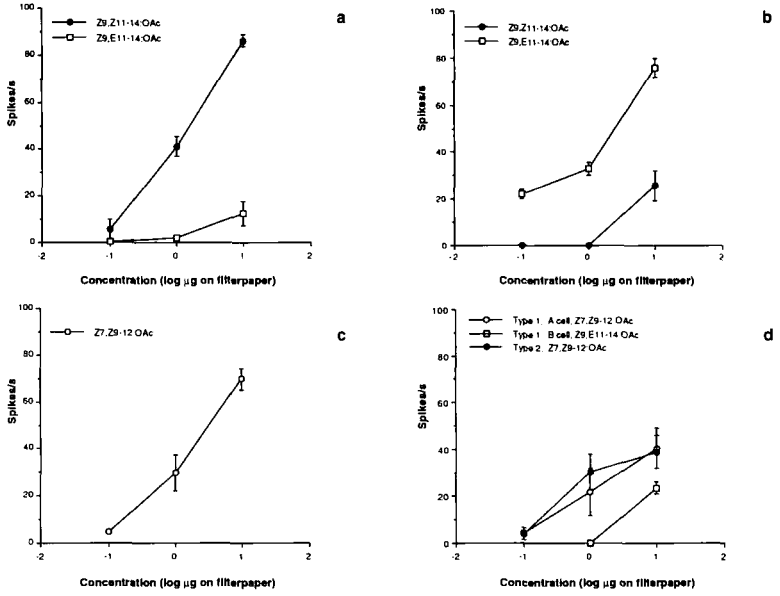

FIG. 7. Dose-response relationships for the different types of receptor neurons in *Idaea aversata* (a–c), and *I. straminata* (d). (a) *I. aversata* sensillum type I: responses of A cell to Z9,Z11-14:OAc and Z9,*E*11-14:OAc. (b) *I. aversata* sensillum type I: responses of the B cell to Z9,Z11-14:OAc and Z9,*E*11-14:OAc. (c) *I. aversata* sensillum type II: response of the single activated receptor neuron to Z7,Z9-12:OAc. (d) *I. straminata* sensillum type I and II: responses to Z7,Z9-12:OAc and Z9,Z11-14:OAc.

DISCUSSION

Our chemical analyses, electrophysiological assays, and field tests support the identification of tetradecadienyl and dodecadienyl acetates as pheromone components in the genus *Idaea*. Thus we were able to confirm previous reports on such similar compounds acting as sex attractants for certain geometrid moths (cf. Arn et al., 1992). Conjugated tetradecadienyl and dodecadienyl acetates, alcohols, and aldehydes have earlier been reported as sex pheromone components in a number of species belonging to the Pyralidae, Tortricidae, and Noctuidae families (Arn et al., 1992).

Relatively small numbers of insects were available for this work, and the identifications are by no means complete. In *I. aversata*, Z7,Z9-12:OAc and Z9,Z11-14:OAc, were identified in extracts of female glands by their GC retention times and mass spectra, and these components caused strong EAG responses in GC-EAD analyses of the female extract. In the field test, a 1:10 mixture of

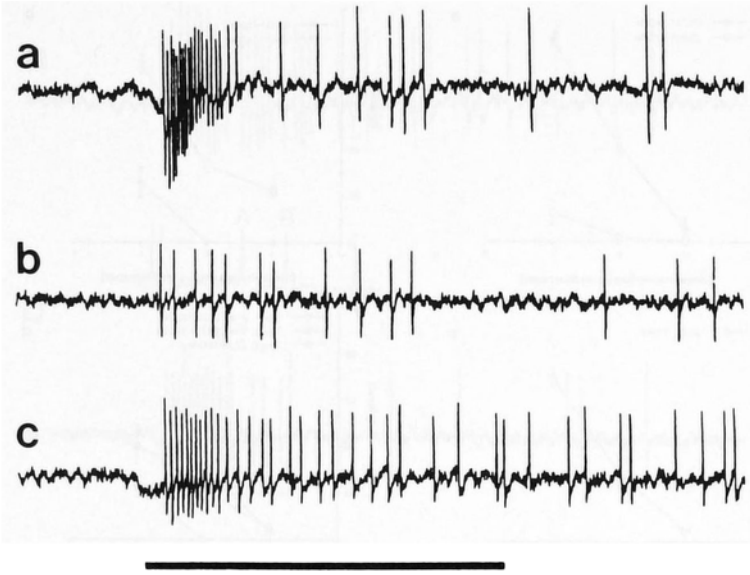

FIG. 8. Physiological responses recorded from receptor neurons present in sensilla trichodea on the male *Idaea straminata* antenna. (a) Response of the large-spike-producing neuron in the type I sensillum trichodeum when stimulated with Z9,E11-14:OAc. (b) Response of the small-spike-producing receptor neuron, present in the same sensillum type, to Z7,Z9-12:OAc. (c) A strong response was elicited by the same compound in the neuron present in the sensillum type II. Horizontal line under the records indicate duration of stimulation.

[a]Catch numbers followed by the same letter are not significantly different according to a Kruskal-Wallis analysis of variance followed by pairwise comparisons using the Fligner-Policello robust Mann-Whitney U test ($P > 0.05$), $N = 5$.

these two compounds was attractive to male moths, and their attractiveness seemed to be increased by addition of *E*9,*Z*11–14:OAc. For *I. straminata*, the presence of *Z*7,*Z*9–12:OAc in female pheromone gland extracts was confirmed by GC-MS, and a peak at the retention time of *Z*9,*Z*11–14:OAc was observed in GC analyses. *Z*7,*Z*9–12:OAc was the most active of the isomers of 7,9–12:OAc and 9,11–14:OAc in GC-EAD analyses, and in field tests a 1:1 mixture of *Z*7,*Z*9–12:OAc and *Z*9,*Z*11–14:OAc attracted male moths. Biwer et al. (1975) and Szöcs et al. (1987) reported that males of *I. biselata* are attracted to *E*7,*Z*9–12:OAc and according to E. Priesner (personal communication referred to in Arn et al. 1992), *Z*7–12:OAc is also attractive to this species. In the present study, GC-EAD analyses showed that both *Z*7,*E*9–12:OAc and *Z*7,*Z*9–12:OAc elicited strong male antennal responses, but only the latter compound was identified from female extracts. *Z*7,*Z*9–12:OAc alone attracted a high number of male moths in the field, and no increase of male catches was observed after addition of *Z*7,*E*9–12:OAc. Since *E*7,*Z*9–12:OAc was not found in female extracts of *I. biselata*, this compound was not tested in our field tests.

The overall catches of male *I. aversata* and *I. straminata* were rather low, although the chemical analyses and electrophysiological data from EAG, GC-EAD, and single sensillum recordings of both species were mutually corroborating. The low catches could be due to the poor weather during the period of field tests, especially in 1993. Missing minor components, suboptimal ratios between pheromone components, or the presence of minor impurities in the synthetic blends with antagonistic effects on male attraction may more likely have contributed to the observed low attraction, since we observed quite a few males flying around the traps. Compounds with conjugated double bonds are

known to isomerize on the rubber septa used as pheromone dispensers (Brown and McDonough, 1986). The composition of the blends released from the septa may, after a short time, deviate significantly from what was applied to the septa.

Among eight synthetic compounds tested, the suggested major pheromone components elicited the highest EAG responses in all three species assayed. The responses of male sensilla trichodea to the female sex pheromone in Lepidoptera are well known, but the single sensillum recordings reported in the present paper are the first published on geometrid male responses to female sex pheromone components such as Z9,Z11-14:OAc,Z7,Z9-12:OAc, etc. A response pattern often encountered in various moth orders was found (Den Otter, 1977; Hansen, 1984; Priesner et al., 1984; Hansson et al., 1987, 1990): a large spike amplitude cell responding to the main pheromone component in the female pheromone gland extracts and a small spike amplitude cell responding to the minor component. The B neuron in type I sensilla of male antenna of *I. aversata* has a smaller spike amplitude responding to Z9,*E*11-14:OAc, which acts as a behavioral antagonist as demonstrated in the field bioassay. Z9,*E*11-14:OAc has not been found in pheromone gland extracts of female *I. straminata*, but the presence of a receptor specific for this compound in males suggests that its behavioral activity should be further investigated.

The use of sex pheromones and sex attractants for taxonomic and phylogenetic analysis should be carried out with caution since considerable diversity exists in the placement of functional group, double-bond positions, and chain lengths of pheromone components among species of the same genus (Renou et al., 1988). Roelofs and Bjostad (1984) have postulated that the elucidation of pheromone biosynthesis is a more useful criterion than comparison of the pheromone components themselves for determining evolutionary relationship. The sex pheromones used by the great majority of lepidopteran species so far investigated consist of unsaturated straight-chain aliphatic acetates, aldehydes, or alcohols with chain lengths of 12–18 carbons. Previous research on the biosynthesis of these pheromone components has shown that they are typically synthesized de novo from acetyl-CoA and malonyl-CoA in the pheromone glands, which produce palmitic or stearic acid via the fatty acid cycle. These acids in turn serve as precursors for a number of different acyl intermediates that can be generated by various combinations of desaturation and chain shortening (Bjostad et al., 1987). Δ11-Desaturation seems to account for the largest number of unsaturated pheromone components, and this type of pheromone component is widely distributed among ditrysian moths (Löfstedt, 1991). In females of *Spodoptera littoralis*, the sex pheromone component Z9,*E*11-14:OAc is synthesized by chain-shortening of palmitic acid to tetradecanoic acid, which, by action of a *E*11 desaturase and subsequently a Z9 desaturase, is converted into (*Z*,*E*)-9,11-tetradecadienoate (Martinez et al., 1991). Reduction and acetylation of this

compound finally leads to formation of the tetradecadienyl acetate. The incorporation of deuterium-label into pheromone acetates after applying D_3-palmitic acid onto the pheromone gland of *I. aversata* shows that palmitic acid can serve as a precursor for pheromone biosynthesis in this species. However, further experiments are needed to clarify whether or not the pheromone biosynthesis of *Idaea* species involves the same pathway as that found in *S. littoralis*.

The biosynthesis of hydrocarbon pheromone components, such as those used by most species of geometrids, has only been investigated in the arctiid moth, *Phragmatobia fuliginosa* (Rule and Roelofs, 1989). Its pheromone component, (Z,Z,Z)-3,6,9-heneicosatriene is derived from chain elongation of linolenic acid to docosatrienoic acid, presumably followed by decarboxylation. Thus, biochemical evidence suggests that two very different biosynthetic pathways are used for the production of the two major compound classes used as pheromone components in Geometridae, of which the less common pathway is similar to the route employed in most other ditrysian moths.

The higher classification (phylogeny) of Geometridae is poorly resolved. Among the commonly recognized subfamilies Archiearinae, Oenochrominae (s.str.), Geometrinae, Ennominae, Larentiinae, and Sterrhinae, it is quite likely that at least the latter is polyphyletic (M. Scoble, personal communication). There is no reason to view "Sterrhinae," including *Idaea*, as the sister group to the rest of the Geometridae. The subfamily that has often been considered as the most primitive within Geometridae is the Archiearinae. Where larvae are known, the prolegs are all present (although somewhat reduced), which is unlike the typical, and characteristic, geometrid situation. However, this view is not based on any particularly detailed analysis, and Archiearinae may eventually be shown to belong within the Ennominae (M. Scoble, personal communication). There are less than a dozen species of Archierinae in the world and nothing is known on the composition of their pheromones. Ennominae include about half of the species of Geometridae. Oenochrominae are polyphyletic; true Oenochrominae are probably confined to the Australian region, and this group may, as with Archiearinae, eventually be subsumed into the Ennominae. Again the association of Geometrinae with Ennominae may be close. So the picture may be one group of Archiearinae, Oenochrominae (s.str.), Geometrinae, Ennominae; another group including the Larentiinae; and a few independent groups from the "Sterrhinae." To these groupings can be added various genera from the Oenochrominae (s.l). The phylogenetic situation is clearly involved and unresolved (M. Scoble, personal communication).

According to the relationships between the chemical structures of identified sex pheromones or sex attractants reported and the taxonomic position of species in Geometridae, Szöcs et al. (1991) drew a distribution pattern showing that methylene-interrupted polyenic hydrocarbons and their oxygenated derivatives

are predominant in Oenochrominae, Larentiinae, and Ennominae, and olefinic acetates and derivatives are used by species in Sterrinae and Geometrinae. The limited information on pheromones of Geometridae currently available can obviously not be used to resolve the phylogeny of the family. However, it is interesting to discuss the possible ancestral state of pheromones in geometrids as this could shed some light on how pheromone communication systems may change in evolutionary time. Minet (1991) suggested that the superfamily Geometroidea should include: Geometridae, Sematuridae, and Uraniidae. Pheromones of Sematuridae and Uranidae are not known. He identified Drepanoidea (i.e., Drepanidae and Epicopeiidae) as the sister group to Geometroidea. All sex attractants reported from Drepanidae are similar to the pheromones identified from *Idaea* (Arn et al., 1992). Thus, it appears likely that the common ancestor of Geometroidea and Drepanoidea possessed the ability to produce unsaturated acetate pheromone components from palmitic acid, and this type of pheromone most likely belongs to the groundplan of all ditrysian moths (Löfstedt and Kozlov, 1996). In general it is more likely that the presence of a complex apomorphic (derived) character in many entities (species, genera, families, etc.) is the result of common heritage rather than independent evolution, as parallel/convergent evolution would depend on similar functional selection pressure operating on all the taxa under consideration. Thus, we propose that the multistep biosynthetic machinery required to produce pheromone components derived from linoleic/linolenic acids has evolved once in the evolution of Macrolepidoptera, but the production of the actual pheromone components has been subsequently and repeatedly turned on and off in the evolution of certain taxa within Geometroidea (and Noctuoidea, where such compounds occur in several families such as Noctuidae, Arctiidae, and Lymantriidae). This hypothesis would be supported if the production of "the other type of pheromone component" could be induced in "nonproducing taxa" by the artificial administration of critical "missing" precursors. Finally, identification of pheromones from certain key groups among Macrolepidoptera, as well as better resolved phylogenies based on all relevant characters, are critical to allow a rigorous reconstruction of pheromone evolution in higher Lepidoptera. With respect to geometrids, the presumed primitive geometrid subfamily Archiearinae and the sister groups of Geometridae (Sematuridae and Uraniidae), for which information on pheromone composition is scanty or missing, deserve special attention.

Acknowledgments—We thank A. Fohrman for assistance with insect rearing; L. Holmberg for field assistance; and Drs. M. Scoble, J. Dugdale, and J. Byers for helpful discussions. We also thank Dr. E. Buschmann (BASF) for a gift of (Z)-9-dodecen-7-yl acetate and Dr. R. Robinson (NRI) for assistance with synthesis. This study was financially supported by the Swedish research councils (NFR and SJFR) and the Bank of Sweden Tercentenary Foundation. N. Ryrholm is grateful to the Foundation for Zoological Research at Uppsala University for supporting the field tests.

THE IMPORTANCE OF SEQUESTERED IRIDOID GLYCOSIDES AS A DEFENSE AGAINST AN ANT PREDATOR

LEE A. DYER,[1,2,*] and M. DEANE BOWERS[2]

(Received April 24, 1995; accepted April 10, 1996)

Abstract—We reared larvae of *Junonia coenia* Hubner (Nymphalidae) on artificial diets with trace concentrations of iridoid glycosides and on leaf diets with higher concentrations of iridoid glycosides. We offered these caterpillars to predacious ants and observed the effects of the following on predation: diet (artificial vs. leaf), site (ant colonies in dry vs. wet areas), instar (early vs. late), and time (changes in predation over five days). Diet and site were consistently significant predictors of the ants' propensities to reject prey and the caterpillars' abilities to escape predation. Leaf-diet caterpillars escaped more frequently than artificial-diet caterpillars, and ants from dry sites were more likely to reject prey than ants from wet sites. The percentage of iridoid glycosides found in individual caterpillars was also a good predictor of the probability of rejection by predators and prey escape. Caterpillars with higher levels of iridoids were more likely to be rejected and to escape, suggesting that sequestered iridoid glycosides are a defense against predaceous ants.

Key Words—Predation, iridoid glycosides, *Junonia coenia*, *Formica planipiles*, *Plantago lanceolata*, specialist herbivore, larval defenses, unpalatability, sequestration.

INTRODUCTION

Several recent studies have shown that some specialist insect herbivores are better protected than generalists against invertebrate predators (Bernays and Cor-

*To whom correspondence should be addressed.

nelius, 1989; Bernays, 1988; Stamp, 1992; Dyer and Floyd, 1993). However, it is still unknown what mechanisms are responsible for this difference. One possibility is that some specialist insects sequester plant secondary compounds that may be used as a defense (Duffey, 1980; Brower, 1984; Bowers, 1991; Dyer, 1995). Although some generalist insects can sequester plant secondary compounds (e.g., arctiids, Rothschild, 1977; Rothschild, et al., 1979), and not all specialists can sequester such compounds (Bowers, 1992), this ability may be critical in protecting many specialists against natural enemies.

The efficacy of such chemical defenses may be affected by several factors. Certain predators, for example, exhibit intraspecific phenological (Hagen et al., 1976) or spatial (Dyer and Floyd, 1993) variation in their responses to various defenses. Furthermore, other prey characteristics, such as developmental rate or body size, could either augment or weaken chemical defenses. It is important to consider confounding factors such as these when testing the overall effectiveness of a chemical defense.

In this study we examined the importance of iridoid glycosides in the larval diet of the buckeye, *Junonia coenia* Hubner (Nymphalidae), as a deterrent to the ant, *Formica rufa planipiles* Creighton (Formicidae). We also examined the effects on predation of prey developmental stage, previous predator exposure to prey, and predator habitat type.

The iridoids, aucubin and catalpol, are sequestered by buckeye caterpillars (Bowers and Collinge, 1992), presumably for defense against predators (Stamp, 1992; De la Fuente et al., 1994). These caterpillars are specialists and regularly feed on narrow-leaved plantain (*Plantago lanceolata* L.: Plantaginaceae) (Bowers, 1984) and on members of three other families of plants that contain iridoid glycosides (Bowers, 1991). Iridoid glycosides are terpene-derived compounds that are synthesized in plants by the mevalonic acid pathway (Bowers, 1991). These compounds generally are noxious to herbivores (Bowers, 1991) and are used as defenses by herbivores against predators (Nishida and Fukami, 1989). Narrow-leaved plantain contains the iridoids aucubin and catalpol (Duff et al., 1965; Bobbitt and Segebarth, 1969).

Formica planipiles is sympatric with *J. coenia* in northern California, and Dyer has observed *F. rufa*-group species preying on buckeye caterpillars. *Formica rufa*-group species can be voracious predators on a variety of prey (Skinner and Whittaker, 1981; Cherix and Bourne, 1980); one colony, for example, can harvest over 21,000 arthropod larvae in a single day (Hölldobler and Wilson, 1990).

We asked the following questions about the interactions between *F. rufa* and buckeye caterpillars that have sequestered variable levels of iridoid glycosides: (1) Are buckeye caterpillars that have sequestered high concentrations of aucubin and catalpol better protected against ant predation than caterpillars that have sequestered low concentrations of aucubin and catalpol? (2) Do buckeye

caterpillars become more unpalatable to ants as they reach later developmental stages (because of increased levels of sequestered compounds)? (3) Do ants learn to avoid unpalatable buckeye caterpillars over short periods of time? (4) Do colonies of ants with different resource availabilities show different responses to the Buckeye caterpillars?

METHODS AND MATERIALS

Three field experiments were conducted in August 1992 at the Sierra Nevada Aquatic Research Laboratory (SNARL), which is situated at 37°36'N 118°51'W in the Great Basin Desert at the base of the eastern Sierra Nevada. We used two sites at SNARL; one site was on the upper third of a glacial moraine, about 0.25 km south of SNARL, and the second site was along Convict Creek, which is at the base of the moraine and runs through SNARL. We used ants from eight colonies of *F. planipiles* as predators; for each site, we used four colonies within 50 m of each other. Before choosing colonies, we examined them to estimate subjectively the mound size (above ground volume of nest materials) and foraging activity (number of ants leaving and returning to the nest) and tried to select colonies with approximately the same sizes and foraging rates.

Larvae from eggs laid by female buckeyes were collected from Buck Meadows, California (about 80 km west of SNARL). The ants were an appropriate species of predator for these experiments because they co-occur with buckeyes in many sites near SNARL (including the Buck Meadows site). However, we used the SNARL colonies because they were naive to the prey (the host plants do not occur at SNARL), thus their reactions to caterpillars with variable amounts of iridoids would not be affected by previous encounters. Caterpillars in instars 2 and 3 were classified as early-instar caterpillars, while those in instars 4 and 5 were classified as late-instar caterpillars.

Larvae were reared on two different diets: a leaf diet consisting of fresh, new *P. lanceolata* leaves, which contain 4–8% dry weight aucubin and catalpol (Bowers and Stamp, 1993), and an artificial diet containing only trace quantities (less than 1% dry weight) of *P. lanceolata*. The plantain leaves used in the artificial diet were of all ages, including ages with lower levels of iridoid glycosides (see Bowers and Stamp, 1993). Thus the iridoid glycoside concentration of the artificial diet was approximately 1/100th that of the leaves fed to larvae, and probably even lower. The *P. lanceolata* leaves were collected from Buck Meadows, California. The artificial diet was based on a recipe by Nijhout (unpublished data) and included the following for one 53-g batch (dry weight): 2.5 g Wesson salts, 6.3 g sucrose, 16.3 g wheat germ, 8.3 g casein, 5 g yeast, 1.7 g cellulose, 340 mg cholesterol, 300 mg methyl paraben, 2 g Vanderzandt vitamin mix, 500 mg ascorbic acid, 500 mg aureomycin, 330 mg sorbic acid,

5 g dried and powdered *P. lanceolata* leaves, 4 g agar, 1 ml linseed oil, and 227 ml water.

An additional 50 caterpillars were reared on artificial or leaf diets (25 on each diet) to determine mean iridoid glycoside concentrations for caterpillars reared on these different diets. For these caterpillars, and for caterpillars used in experiment 3, iridoid glycoside content was determined using gas chromatography of the trimethyl silylated derivatives of the iridoids (Gardner and Stermitz, 1988; Bowers and Collinge, 1992). Caterpillars were starved for 24 hr, lyophilized, and ground to a fine powder for analysis.

Experiment 1. Individual buckeye caterpillars were offered to six of the eight *F. planipiles* colonies by placing them along main foraging trails and within 5 m of the colony entrance. This method was not utilized to mimic natural encounters between ants and caterpillars, but to maximize predator–prey interactions in order to test the efficacy of iridoids against the ants, which was the major goal of this study. However, the design was not entirely artificial. Foraging *F. planipiles* can encounter buckeyes on the ground along and near the foraging trails, because caterpillars often move along the ground to access new host plants and often are found on lower leaves (personal observations).

The experimental design was a full factorial, repeated over five successive days, with site (three creek colonies vs. three moraine colonies), diet (artificial vs. leaf), and instar (early vs. late) as main effects. Each cell in the experimental design contained three replicates, which were spatially (different foraging trails) or temporally (different times of day) separated. Each colony therefore received 12 caterpillars per day: three early-instar artificial-diet caterpillars, three late-instar artificial-diet caterpillars, three early-instar leaf-diet caterpillars, and three late-instar leaf-diet caterpillars.

The experiments were conducted between 06:00 and 19:30 hr, but were usually restricted to hours of greatest ant activity (07:00–10:00 and 15:00–18:00). The first colony visited each day was selected randomly, followed by a predetermined visitation sequence among the colonies. The caterpillars were offered to ant colonies by selecting them haphazardly from prepacked and marked containers; each container had the diet, colony, and instar marked. Caterpillars from different diet treatments were matched for similar size and mass. Two caterpillars (on two different foraging trails) were given to each colony per visit.

Each offering, lasting at least 5 min, began when an ant encountered a caterpillar. We recorded the following response variables: number of rejections, number of ants touching the caterpillar at the end of each minute, and whether the caterpillar escaped or was eaten. A rejection consisted of an individual ant approaching, touching, and permanently leaving a caterpillar. It was obvious when the ant was leaving the caterpillar for recruitment (rather than rejecting it), because it would walk in growing circles which always brought it back to the prey. In these cases, the individual would eventually return with other ants.

If at least one ant was already touching a caterpillar, no further rejections (i.e., another ant encountering and leaving the caterpillar) were counted. Caterpillars "escaped" when they were rejected by at least five ants or when they were not eaten within the 5-min time period. The rejection and escape variables are different because caterpillars that avoided being eaten for 5 min were not always touched and rejected by the ants. The number of caterpillars completely rejected was therefore not equal to the number of caterpillars that escaped because a caterpillar that was never touched (and therefore escaped predation) was counted as a missing value for the rejection response variable. This distinction between the two variables is important because some caterpillars were completely ignored by the ants and therefore could never be considered rejected (even though they may have escaped predation). If a caterpillar moved too far from the foraging trail before the 5 min was over, it was returned to the trail. By 5 min it usually was obvious if the ants were going to take the caterpillar back to the nest.

Rejections were pooled into three categories: no rejections, some rejections (less than five), and completely rejected (five or more); this pooling was based on preliminary studies with the ants and previous work with other species of ants (Dyer and Floyd, 1993; Dyer, 1995, unpublished data). The rejection categories and the escape response variable were dependent variables in logit models (see Christensen, 1990), which is the most appropriate method for testing associations between categorical dependent and independent variables (Feinberg, 1970; Christensen, 1990). These models allowed us to test both the main effects and interactions of the variables diet, site, day, and instar on ant response.

To test the effects of the independent variables on recruitment, the number of ants visiting a given caterpillar every minute was the dependent variable in a repeated measures analysis of variance, with time as the repeated measure and diet, site, and instar as fixed effects. To test the effects of the independent variables on possible changes in recruitment due to learning over a longer period of time, the numbers of ants visiting every minute were totaled over the 5-min period. This total was used as a dependent variable in a repeated measures analysis of variance, with day as a repeated measure and diet, site, and instar as fixed effects. All means for numbers of ants visiting are reported $\pm$ 1 SE.

Experiment 2. Because it is possible that buckeyes might be protected by automimicry (sensu Brower, 1984), we compared predation by naive ants that were offered caterpillars reared on both diets with that of naive ants that were only offered caterpillars reared on artificial diets. Caterpillars were offered to two of the eight colonies (neither of which was used for experiment 1) during a separate five-day period. The methods used were the same as those in experiment 1, with the exception of the diet treatment; the two colonies (one creek and one moraine colony) received only caterpillars reared on artificial diets. We used chi-square contingency tables to compare predation on artificial-diet caterpillars from colonies fed caterpillars reared on both diets (data from the six

colonies in experiment 1) with that from colonies fed only artificial-diet caterpillars.

Experiment 3. To examine correlations between iridoid glycoside concentrations and ant responses, we conducted a third experiment in which the caterpillars were retained for iridoid glycoside analyses. This experiment was conducted after the experiments described above were completed and was identical in design to the five-day experiments with the following exceptions: the experiment was conducted over a two-day period, only the three colonies at the creek site were used, only fifth-instar larvae were used, and the caterpillars were taken from ants before they were dragged into the nests. Caterpillars were allowed to recover for 24 hr after the experiment and were fed their original diets during this time; this recovery period permitted caterpillars to regain iridoids lost in secreted hemolymph or regurgitant. To clear the gut, the caterpillars then were starved for another 24 hr and lyophilized.

To test for correlations between levels of iridoids and ant response, the rejection categories and the escape response variable were dependent variables in logistic regressions (see Christensen, 1990) with percent aucubin and percent catalpol as predictors. The number of replicates was too small to examine relationships between iridoids and number of ants visiting the caterpillars.

RESULTS

Caterpillars reared on leaf diets had significantly higher concentrations (percentage dry weight) of iridoid [leaf-diet aucubin mean = 4.53%, artificial-diet aucubin mean = 0.36%, unequal variances $t_{(39.3)} = -7.74$, $P < 0.001$; leaf-diet catalpol mean = 3.42%, artificial-diet catalpol mean = 0.12%, unequal variances $t_{(40)} = -8.78$, $P < 0.001$]. Late-instar caterpillars had significantly higher percentages of aucubin than early instars, but there were no significant differences between instar categories in the concentrations of catalpol [late-instar aucubin mean = 3.03%, early-instar aucubin mean = 1.31%, unequal variances $t_{(23.5)} = -2.41$, $P = 0.024$; late-instar catalpol mean = 2.19%, early-instar catalpol mean = 1.08%, $t_{(67)} = -1.34$, $P = 0.184$].

Experiment 1. A total of 360 caterpillars were offered to three creek colonies and three moraine colonies. Day was never a significant predictor of the dependent variables, so it was excluded from subsequent models to keep cell sizes large enough for meaningful comparisons (see Christensen, 1990). Diet [$\chi^2_{(1)} = 25.97$, $P < 0.001$] and site [$\chi^2_{(1)} = 22.69$, $P < 0.001$] were significant predictors of the escape variable, while instar was not [likelihood ratio for unsaturated logit model: $\chi^2_{(8)} = 12.88$, $P = 0.116$]. Leaf-diet caterpillars were much more likely to escape than were artificial-diet caterpillars (Figure 1), and creek colonies were much more likely to eat caterpillars than were moraine colonies (Figure 2). None of the higher order interactions were significant.

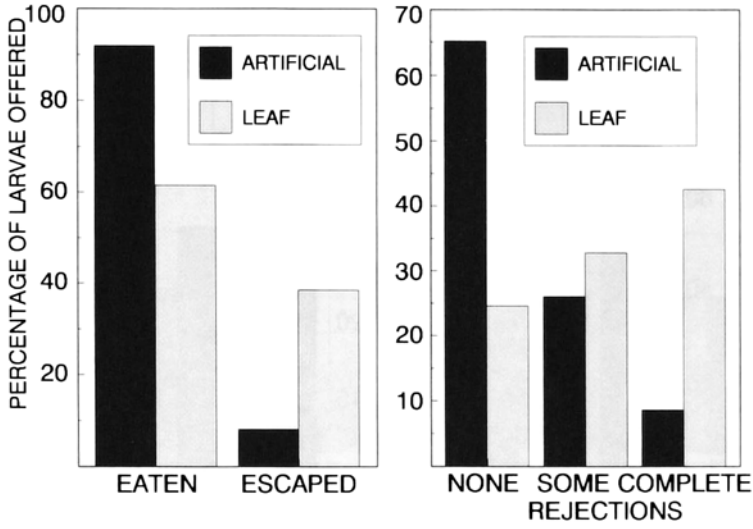

FIG. 1. The association between larval diet and predation response variables. "Leaf" refers to caterpillars reared on *Plantago lanceolata*, while "artificial" refers to caterpillars reared on an artificial diet with trace quantities of *P. lanceolata*. The *y* axes represent percentages of all larvae ($N = 360$), with specific diets that received the predator response indicated on the *x* axis. For example, 91% of the artificial-diet caterpillars offered to the ants were eaten. The predator responses on the *x* axis were categorical dependent variables in logit models.

Diet [$\chi^2_{(2)} = 44.44$, $P < 0.001$] and site [$\chi^2_{(2)} = 10.27$, $P = 0.006$] were also significant predictors of rejection, while instar was not [likelihood ratio for unsaturated logit model: $\chi^2_{(12)} = 12.64$, $P = 0.396$]. Leaf-diet caterpillars were more likely to be rejected than artificial-diet caterpillars (Figure 1), and moraine colonies were more likely to reject caterpillars than were creek colonies (Figure 2). None of the higher order interactions were significant.

The number of ants visiting a caterpillar increased significantly over time [Wilks' lambda $F_{(4,343)} = 32.39$, $P < 0.001$]. There were, however, significant time × diet [Wilks' lambda $F_{(4,343)} = 10.98$, $P < 0.001$] and time × site [Wilks' lambda $F_{(4,343)} = 6.20$, $P < 0.001$] interactions; the number of ants visiting a caterpillar increased significantly more over time for artificial-diet caterpillars than for leaf-diet caterpillars, and the number of ants visiting a caterpillar increased significantly more over time for creek colonies than for moraine colonies (Figure 3). For the between-subjects effects (which are hypotheses tests with the dependent variable equal to the total number of ants over the five time categories), there was a significant three-way interaction between diet, site, and instar [$F_{(1,346)} = 4.40$, $P = 0.037$], indicating that total

FIG. 2. The association between predator habitat type and predation response variables. "Moraine" refers to ant colonies located on a glacial moraine, while "creek" refers to colonies located adjacent to a creek below the moraine. The *y* axes represent percentages of all larvae ($N = 360$) offered to predators from specific habitats ($N = 6$ ant colonies) that received the predator response indicated on the *x* axis. For example, 40% of the caterpillars offered to ant colonies on the glacial moraine were never rejected. The predator responses on the *x* axis were categorical dependent variables in logit models.

ant visits (for the 5-min time period) depended on specific combinations of diet, colony, and instar. Late-instar, leaf-diet caterpillars offered to moraine colonies had the fewest ants visiting (7.0 ± 0.8), while late-instar, artificial-diet caterpillars offered to creek colonies had the most ants visiting (19.9 ± 0.9).

The total number of ants visiting caterpillars (for the 5-min time period) did not change between days [$F_{(4,340)} = 0.47$, $P = 0.760$]. There were significant diet [$F_{(1,340)} = 86.02$, $P < 0.001$], site [$F_{(1,340)} = 18.47$, $P < 0.001$], and instar [$F_{(1,340)} = 4.11$, $P = 0.044$] effects; total number of ants visiting was greatest for artificial diet caterpillars (16.9 ± 0.7), creek colonies (15.2 ± 0.7), and late instars (14.5 ± 0.6).

Experiment 2. A total of 60 caterpillars reared on artificial diets were offered to one creek colony and one moraine colony. The contingency table for rejections of artificial-diet caterpillars offered to colonies that received only artificial-diet caterpillars and colonies that received both artificial-diet and leaf-diet caterpillars revealed no significant association between colony type and level of rejection [$\chi^2_{(2)} = 4.009$, $P = 0.135$]. There was, however, a significant rela-

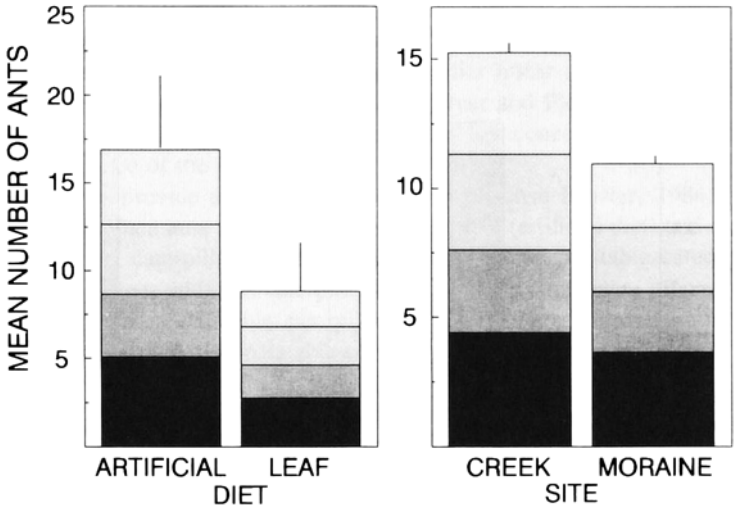

FIG. 3. The effects of larval diet and predator habitat site on ant recruitment. The *y* axes represent mean number of ants visiting caterpillars reared on specific diets and mean number of ants from specific sites visiting caterpillars. The number of ants for each minute is stacked upon the previous minute. The standard error bars are for the numbers of ants totaled over the 5 min.

tionship between colony type and level of escape [$\chi^2_{(1)} = 6.187$, $P = 0.013$). Artificial-diet caterpillars offered to colonies that received only artificial-diet caterpillars never escaped, while 9% of the artificial-diet caterpillars escaped at colonies that received caterpillars reared on both diets.

Experiment 3. We offered a total of 68 caterpillars to three ant colonies at the creek site. Percent aucubin was a significant predictor of escape [$\chi^2_{(1)} = 9.99$, $P = 0.002$] and rejection [$\chi^2_{(2)} = 14.84$, $P < 0.001$]. Likewise, percent catalpol was a significant predictor of escape [$\chi^2_{(1)} = 7.31$, $P = 0.007$] and rejection [$\chi^2_{(2)} = 14.66$, $P < 0.001$], indicating that iridoid glycoside concentration of larvae influenced predator response to these larvae. Caterpillars that escaped and were completely rejected had much higher iridoid concentrations than caterpillars that were eaten and had no rejections (Figure 4).

DISCUSSION

The results of the present study indicate that diet is an important component of the suite of defenses found in the specialist caterpillar, *J. coenia*. Larvae reared on leaves of *P. lanceolata*, which contain aucubin and catalpol (4–8%

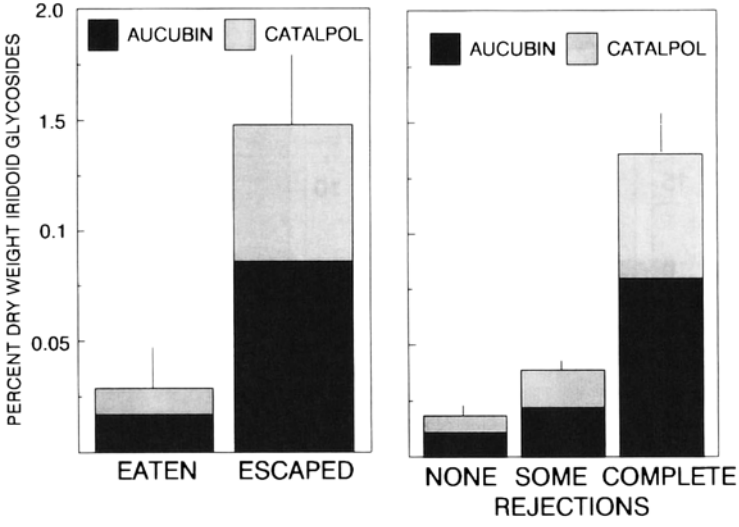

FIG. 4. The effects of iridoid glycoside concentrations (percent dry weight of aucubin and catalpol) on predation response variables. The *y* axes represent mean percent iridoids sequestered by caterpillars that received the predator response indicated on the *x* axis. For example, the mean percent dry weight of aucubin sequestered by caterpillars that escaped was 0.085%. The standard error bars are for total iridoids. The predator responses on the *x* axis were categorical dependent variables in logit models.

dry weight), are better protected against a voracious predator than larvae reared on an artificial diet with less than 0.4% dry weight iridoid glycosides. Sequestered iridoids seem to be the main component of the leaf-diet caterpillars' enhanced defenses. While it is true that iridoid concentrations are not the only differences between the two diets (i.e., one diet is plant material, the other is an agar-based gel), chemistry was the only obvious difference between the caterpillars reared on these different diets. For example, one might expect that the size and behavior of caterpillars would vary depending on their diet, but the caterpillars offered to the ants were matched for size and there were no apparent differences in their activity levels. Furthermore, the concentrations of iridoids found in caterpillars on both diets were good predictors of whether or not those caterpillars escaped predation or whether or not they were rejected by individual ants.

The fact that instar number was never a significant predictor of prey escape or predator rejection suggests that the low percentages of iridoid glycosides found in early instars are as effective as the higher percentages (especially for aucubin) found in later instars in deterring predation by ants. These chemicals,

therefore, seem to act as "qualitative" defenses against predators—high concentrations are not necessary for effective deterrence. Furthermore, certain invertebrate predators usually prefer smaller and earlier instar caterpillars as prey, including those that are chemically defended (Dyer and Floyd, 1993; also see Reavey 1993), so the protection of early instars by low concentrations of iridoids is further evidence of the efficacy of this defense.

Our results provide evidence of automimicry (sensu Brower, 1984) in *J. coenia* larvae. When ants were offered both palatable (artificial diet) and unpalatable (leaf diet) caterpillars of the same species, some palatable caterpillars were able to escape, while no caterpillars escaped when ants were offered only palatable caterpillars. Palatable caterpillars therefore were afforded some protection by the presence of unpalatable conspecifics. This is a rather weak example of automimicry, since most (>90%) of the palatable caterpillars were eaten by ants that had also been offered unpalatable caterpillars; additionally, there was no significant association between colony type and the level of rejection for palatable caterpillars. The difference in results between escape and rejection response variables may indicate that ants were *ignoring* or *avoiding* all caterpillars (regardless of diet) because they have received unpalatable buckeyes. Such avoidance would allow caterpillars to *escape*, as opposed to being examined and *rejected* by ants; as a result, the numbers of rejections for the palatable caterpillars offered to the same colonies would be lower (because they were simply ignored).

Despite the effectiveness of iridoids as a qualitative defense against *F. planipiles*, some leaf-diet caterpillars and caterpillars with high iridoids were still eaten by ants. In addition, *F. planipiles* showed no short-term ability to learn to avoid buckeye caterpillars, despite the fact that other species of predaceous ants are often able to learn prey avoidance quickly (Dejean, 1988; Bowers and Larin, 1989). The weak example of automimicry discussed above illustrates the ants' abilities to retain some sort of information within a 12-hr period, but there were no day-to-day changes in the colonies' responses to unpalatable caterpillars over a period of five days. This inability to retain information has the potential effect of minimizing selective pressures exerted by these and similar predators on distasteful prey, since there is not a consistent advantage provided by unpalatability. Aposematism, for example, is not likely to evolve in organisms exposed mostly to predators lacking the ability to learn or remember. Nevertheless, the presence of this chemical defense does provide a significant selective advantage over caterpillars that have not sequestered iridoids.

Ants from certain colonies were less likely to reject buckeyes. The creek colonies, which have high prey resources (mostly creek invertebrates; Dyer, *personal observations*), were more voracious: they recruited more, rejected fewer caterpillars, and the caterpillars were less likely to escape from these colonies. In contrast, the moraine colonies, which spend most of their time tending ho-

mopterans (Dyer, *personal observations*; McIver and Loomis, 1993) were much less interested in buckeyes as prey. This type of intraspecific variation is important to consider when conducting assays with predators or when examining the selective pressures exerted by specific predators. If our study had included only moraine colonies, a result such as iridoid sequestering caterpillars being no better defended than nonsequestering caterpillars might only reflect the fact that these particular colonies were not interested in preying on buckeyes. However, because there were no significant diet × colony interactions in the present study, the intraspecific variation in levels of predation by ants did not indicate that predators with fewer available prey were more likely than those with abundant prey to attack unpalatable prey, a pattern one might expect if prey abundance is an important selective pressure on prey choice.

In conclusion, we have demonstrated the defensive utility of a secondary compound sequestered by a specialist herbivore, and this contributes to a better understanding of how specialist herbivores protect themselves against invertebrate predators. We have also demonstrated intraspecific variation in prey preferences of an invertebrate predator, and such variation should be considered in the increasing numbers of studies on the natural enemies of insect herbivores.

Acknowledgments—This research was supported by a University of Colorado Fellowship to L.A.D., a Dean's Small Grant Award to L.A.D., and NSF grant BSR-8905895 to M.D.B. We thank Dan Dawson for the use of a laboratory at SNARL. Mark Camara collected many of the adult buckeyes and much of the plantain used in these experiments. Jim McIver pointed out and identified the colonies of *Formica rufa planipiles*. An earlier version of this manuscript benefited from the critical comments of Mark Camara and four anonymous reviewers.

(Received November 6, 1995; accepted April 10, 1996)

Abstract—Experiments were conducted in southern New South Wales to evaluate the potential of mass-trapping using synthetic aggregation pheromones and a coattractant as a control option for *Carpophilus* spp. in stone fruit orchards. A cordon of 54 pipe and 54 funnel traps (one trap of each type per perimeter tree) baited with pheromones of *C. mutilatus* and *C. davidsoni* and coattractant (fermenting bread dough) was maintained around an apricot orchard for three weeks prior to harvest. The incidence of *Carpophilus* spp. in ripe fruit in the center of the orchard was significantly reduced compared to a nearby orchard or the perimeter trees containing traps. A cordon of 16 water-filled Magnet funnel traps baited with pheromones of *C. mutilatus* and *C. davidsoni* and coattractant was placed around a 9 × 9 block of trees in a peach orchard (single traps on alternate perimeter trees). This trapping regime significantly reduced infestation of fruit baits by *Carpophilus* spp. in the center tree over a period of six weeks compared to fruit baits in trap trees and distant (100 m) control trees. However, cordons of eight pheromone traps within 1 m of single trees or a single trap adjacent to a tree increased *Carpophilus* spp. infestation of fruit baits by up to 7.5 × compared to trees without pheromone traps. Mass-trapping based on perimeter positioning of pheromone

traps (at a yet to be determined distance from protected trees) appears to show potential as a control strategy for *Carpophilus* spp. in stone fruit orchards during fruit ripening and harvest but traps too close to trees must be avoided. Development of a strategy for population suppression is discussed with respect to trap type, efficacy, positioning, and density; pheromone and coattractant delivery systems; and orchard sanitation.

Key Words—*Carpophilus mutilatus*, *Carpophilus davidsoni*, *Carpophilus hemipterus*, Coleoptera, Nitidulidae, aggregation pheromones, mass-trapping, stone fruit, population suppression.

INTRODUCTION

Three species of nitidulid beetles in the genus *Carpophilus* [*C. hemipterus* (L.), *C. mutilatus* Erichson, *C. davidsoni* Dobson] are major pests of ripening stone fruit in southern Australia (James et al., 1994, 1995). The recent identification and synthesis of aggregation pheromones for these species (Bartelt et al., 1990a, 1993; Bartelt and James, 1994) and demonstration of field activity (Bartelt et al., 1992, 1994a,b; James et al., 1994), has highlighted the potential of these semiochemicals for nitidulid management in stone fruit orchards.

Aggregation pheromones of *C. hemipterus*, *C. mutilatus*, and *C. davidsoni* are branched unsaturated hydrocarbons and are synergized by food volatiles such as those from fermenting bread dough or decomposing fruit (Bartelt et al., 1992; James et al., 1993). Wind-oriented pipe traps (Dowd et al., 1992) baited with rubber septa impregnated with 500 μg of synthetic pheromone and fermenting bread dough are highly effective in trapping large numbers of beetles. Bartelt et al. (1994b) reported trap catches of up to 63,500 *C. mutilatus* per trap per week in a California date garden and up to 20,179 *C. davidsoni* were trapped in a single trap in one week in a peach orchard in southern Australia (James, unpublished observation). Even larger numbers of beetles are caught in traps using higher doses of pheromone. Pheromone (5000 μg) generally increases trap catches of *C. hemipterus* and *C. mutilatus* by 5–8 × compared to traps using 500 μg of pheromone (Bartelt et al., 1994a; James et al., 1994). Finally, James et al. (1996) showed that pheromone-baited, water-based funnel traps were about five times more effective than wind-oriented traps in capturing *Carpophilus* spp. Clearly, synthetic pheromones in combination with a host-related coattractant have the potential to be an important weapon for managing *Carpophilus* spp. populations in stone fruit orchards. They could be used as the basis of a sensitive monitoring system (to better time chemical sprays) or for mass-trapping beetles to suppress orchard populations below damaging levels. Mass-trapping as a control option for *Carpophilus* spp. was first suggested by Warner (1960, 1961), who reported a reduction in infestation levels in figs through the use of traps containing fermenting figs as a bait.

Here, we report the results from a series of field experiments aimed at identifying and evaluating a strategy using synthetic pheromones for suppression of *Carpophilus* spp. populations in stone fruit orchards.

METHODS AND MATERIALS

Synthetic Pheromones

Pheromones for *C. hemipterus*, *C. mutilatus*, and *C. davidsoni* were used in these experiments. The pheromone for *C. hemipterus* consisted of a 100:31:11:8 blend of (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene, (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-undecatetraene, (2*E*,4*E*,6*E*,8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-decatetraene, and (2*E*,4*E*,6*E*,8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-undecatetraene, respectively (Bartelt et al., 1992). The pheromone for *C. mutilatus* consisted of a 100:7 blend of (3*E*,5*E*,7*E*)-5-ethyl-7-methyl-3,5,7-undecatriene and (3*E*,5*E*,7*E*)-6-ethyl-4-methyl-3,5,7-decatriene (Bartelt et al., 1993). The pheromone for *C. davidsoni* consisted of a 100:9:31:160 blend of (2*E*,4*E*,6*E*)-5-ethyl-3-methyl-2,4,6-nonatriene, (3*E*,5*E*,7*E*)-6-ethyl-4-methyl-3,5,7-decatriene, (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-undecatetraene, and (2*E*,4*E*,6*E*,8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-undecatetraene (Bartelt and James, 1994). The synthetic pheromones were purified only by distillation and open column chromatography on silica gel. These procedures did not remove the small amounts of *Z* isomers produced in the syntheses (Bartelt et al., 1990b), but there is no evidence that these (presently unavoidable) impurities are detrimental to pheromonal activity (Bartelt et al., 1992). Pheromones were appropriately diluted with hexane and stored in a freezer until needed. Concentrations of components were determined by gas chromatography on diluted aliquots (instrumentation as described by Bartelt et al., 1990a). Pheromone solutions were applied to rubber septa (11 × 20 mm, red rubber, Aldrich Chemical Co., Milwaukee, Wisconsin) followed by 300 μl of methylene chloride. Once the liquid had soaked into the septa, they were aired in a fume hood for 1-hr and stored in a freezer in tightly closed bottles until needed.

Septa used in suppression traps were prepared with 5000 μg each of *C. mutilatus* and *C. davidsoni* pheromone per septum. Prior monitoring indicated *C. hemipterus* was uncommon, therefore, it was not included in the suppression trials. Septa used in monitoring traps were loaded with 5000 μg each of pheromones for the three species.

Traps and Coattractant Baits

Suppression experiments were conducted using either the wind-oriented pipe trap of Dowd et al. (1992), a simple funnel trap (Faulder funnel) designed as part of this research (James et al., 1996), or the commercially available

Magnet funnel trap (Agrisense, Pontypridd, Glamorgan, UK). The pipe trap has been used in most of the pheromone studies previously conducted by the authors (e.g., Bartelt et al., 1994a; James et al., 1994). Traps were constructed from white PVC piping and assembled in the form of a T. Beetles entered the trap through a cone-shaped piece of screen in one horizontal branch and ended up in a plastic 140-ml gauze-bottomed plastic bottle attached to the bottom of the trunk pipe. The trap design incorporates a fin that enables orientation with the wind so that the trap entrance is always accessible to beetles approaching the trap from downwind. No killing agent was used, and screen barriers prevented beetles from contacting the bait, which is in the other horizontal branch.

The Faulder funnel trap was constructed from a 12-cm length (11 cm diameter) of white PVC piping with red plastic funnels fitted at either end; the top funnel had its base inside the pipe and that of the lower funnel was directed downward. The base of the top funnel (4 cm diameter) was covered with nitidulid-proof gauze except for a central opening. The bottom funnel screwed onto the pipe via a flange and led into a 140-ml solid-bottomed collecting bottle half-filled with water. The Magnet funnel trap is a simple funnel design primarily used for trapping moths. James et al. (1996) showed this trap, when used with water to a depth of 2–4 cm, to be highly effective for *Carpophilus* spp., trapping 3–7× as many beetles as dry pipe or funnel traps.

Fermenting whole wheat bread dough was used as the pheromone synergist (coattractant) (approximately 10 ml/trap) held in a 20-ml glass tube with a gauze lid. The coattractant and pheromone septum were placed in the bait compartment of the pipe trap, taped to the inside of the Faulder funnel pipe or taped to the inside of the downward projecting funnel of the Magnet™ funnel trap. In the orchard-scale suppression experiment, all traps were suspended from tree branches at about 1.5 m above the ground. Traps were serviced weekly, beetles collected, and dough replaced. Pheromone septa were replaced fortnightly. *Carpophilus* spp. collected in suppression traps were counted in the laboratory, while those trapped in population-monitoring traps and collected from fruit were also identified to species using Dobson (1954, 1964).

Experimental Design and Sites

An orchard-scale suppression experiment was conducted in a commercial orchard followed by a series of smaller, within-orchard experiments at another site aimed at suppressing *Carpophilus* spp. populations on single trees. Both sites were located near Leeton in the Murrumbidgee Irrigation Area of southern New South Wales.

Suppression of Carpophilus *spp. in a Commercial Apricot Orchard*

This experiment was conducted in a 1-ha apricot (cv Trevatt) orchard containing 187 trees (10 × 20 rows) with 5-m spacing. Three pipe traps were

placed in the center of the block (10 m apart and 30 m from perimeter) in early spring (September 28, 1994) to monitor *Carpophilus* spp. activity Suppression traps (one pipe trap and one Faulder funnel trap) were placed in each perimeter tree ($N = 54$) on December 7, 1994, when *Carpophilus* spp. populations began to increase dramatically. Traps were hung on opposite outside edges of canopies and were aimed at intercepting incoming beetles in addition to luring beetles already within the orchard. Harvesting commenced on December 27, and trapping terminated on January 4. The orchard was bordered on two sides by citrus but no ripe fruit or obvious *Carpophilus* spp. population was present. Three methods were used to assess *Carpophilus* spp. populations inside and outside the orchard.

Fruit Examination. Damaged (split or bird-pecked) ripe hanging fruit and fallen fruit were collected on December 29 and examined individually for *Carpophilus* spp. Samples were collected randomly, either from the center (i.e., >20 m from perimeter trees) of the experiment block (fallen fruit: $N = 30$) or taken from central or perimeter trees ($N = 40$ ripe fruit/area). Ripe and fallen fruit were also sampled from the center of an apricot orchard 1 km from the experiment orchard.

Fruit Baits. Three trays of ripe, punctured apricots (20/tray) were placed randomly in the center of the block (1 m above the ground in tree crotches) on December 23 and 30. Trays were retrieved after five days and examined in the laboratory for beetles. On December 23 this procedure was replicated in the nearby orchard. On December 30 three fruit bait trays were placed in citrus trees adjacent (15 m) to the experiment orchard.

Pipe (monitoring) Traps. Beetle catches from the center of the block were collected prior to and during the experiment.

Suppression of Carpophilus *spp. in Single Peach Trees*

Four separate experiments were conducted using pheromone and fermenting bread dough-baited Magnet funnel traps to protect provisioned ripe fruit in single peach trees from *Carpophilus* spp. All experiments were conducted consecutively during January–March 1995 in an unsprayed orchard with no naturally occurring ripe fruit.

Experiment A. The aim of this experiment was to protect provisioned, overripe fruit from *Carpophilus* spp. by placing a cordon of pheromone traps around the tree. Two pairs of trees forming the four corners of a square were selected in the center of the block. Two trees were "treated" with pheromones (diagonally opposite) and the other two were untreated controls. Trees were separated from each other by at least 10 m. Eight steel posts were erected around each of the treatment trees with an interpost distance of 1.5 m. A Magnet funnel trap filled with water to a depth of 3–4 cm was attached to the top of each post at a height of about 1.5 m. The distance from traps to tree canopy was approx-

imately 1 m. All trees were baited with three plastic containers (1 liter) with drainage holes, each containing four overripe, punctured apricots. The containers were tied to branches and well separated within the tree canopy. After five days beetles were removed from the traps and fruit baits and counted in the laboratory. Beetles in the fruit baits were also identified to species.

Experiment B. In this experiment, the effect of trap height on protecting fruit from beetle attack was investigated. A cordon of eight traps was positioned at two heights: 2.5 m above ground level (approximately at upper canopy height) and at ground level. Two overripe peaches, each with a single puncture, were used in each fruit bait and the experiment ran for three days. An additional two distant (100 m) control trees were used in this and the following two experiments.

Experiment C. In this experiment one trap on a single post was used to protect fruit baits on trees, rather than a trap cordon. Overripe apricot fruits with a single puncture were used in the baits and the experiment ran for three days.

Experiment D. The strategy in this experiment was to protect fruit baits from *Carpophilus* spp. on a single tree using a cordon of pheromone traps positioned 20–30 m away. A 9 × 9 block (50 × 40 m) of trees within the orchard was selected and traps ($N = 16$) placed in alternate trees around the perimeter of this block. The protected tree was in the exact center of the block. Three fruit baits (each containing two overripe, single punctured peaches) were placed in the protected tree and each of the four corner trap trees. Baits were also placed in two tree (controls) 100 m either side of the cordoned block. The experiment ran for six weeks with weekly servicing of traps (replacement of dough and pheromone), collection of beetles from traps and fruit baits, and replacement of fruit in bait containers.

Two pipe traps were also placed in this orchard away from the experiment area throughout the single tree experiments, to monitor *Carpophilus* spp. incidence.

Data were transformed to the log $(x + 1)$ scale or arcsin-transformed (proportions) and subjected to analysis of variance and least significant difference procedures.

RESULTS

Suppression of Carpophilus *spp. in a Commercial Orchard*

A total of 22,669 beetles was caught in the suppression traps during this experiment, with significantly greater numbers captured in the Faulder funnel traps ($P < 0.05$) (Table 1). The number of beetles trapped in the central monitoring traps fell significantly after the suppression traps were installed. However, trappings did not decline further during the experiment and were comparable

to those recorded in the suppression pipe traps (n.b., monitoring traps contained pheromones for *C. davidsoni*, *C. mutilatus*, and *C. hemipterus*).

Damaged, ripe fruit sampled from the center of the orchard on December 29 had a very low level of beetle infestation. In contrast, virtually all fruit sampled from perimeter trees (containing suppression traps), contained beetles (Table 2). This was also the case for ripe, damaged fruit sampled from the nearby orchard. *C. davidsoni* was the only species present in ripe fruit. There was little difference in overall numbers of beetles in fallen fruit or fruit bait samples taken from the experiment orchard, the nearby orchard or the adjacent citrus block (Tables 2 and 3). However, the ratio of *C. davidsoni* plus *C. mutilatus* (the species targeted by the suppression traps) to *C. hemipterus* in baits and fallen fruit was reduced within the experiment orchard (22–50%) compared to adjacent citrus (69%) and the nearby orchard (62–81%) (Tables 2 and 3). *C. davidsoni* and *C. mutilatus* also dominated captures in the monitoring traps (89–98%) (Table 1).

Suppression of Carpophilus *spp. Populations in Single Trees*

Experiment A. The eight trap cordons surrounding the two pheromone-protected trees caught 1767 and 1445 beetles, respectively. Significantly greater numbers of beetles were found in the trap tree fruit baits than in the untreated tree baits ($P < 0.05$) (Table 4).

Experiment B. Trap cordons at a height of 2.5 m around each tree captured totals of 892 and 758 beetles, respectively. Fruit baits in these trees collected a mean of 45 beetles/bait which was 3.5× greater than the nearby untreated trees and 7.5× greater than the distant untreated trees (Table 4). Trap cordons set at ground level around each tree captured 536 and 452 beetles, respectively. Fruit baits in these trees collected a mean of 87 beetles/bait, which was similar to the levels in the nearby untreated trees but almost four times the number of beetles in distant untreated trees (Table 4).

Experiment C. The single traps adjacent to each tree captured 20 and 30 beetles, but fruit baits in these trees contained a mean of 45 beetles/bait, significantly greater than beetle numbers in control tree baits (Table 4).

Experiment D. The 16-trap cordon significantly suppressed beetle numbers in fruit baits on the center tree in all weeks compared to numbers in fruit baits on trap and control trees ($P < 0.05$) (Table 5). The species targeted by the suppression traps (*C. davidsoni* and *C. mutilatus*) comprised the majority of beetles found in fruit baits on the center and trap trees in all weeks. *C. hemipterus* was significantly more abundant than *C. davidsoni*/*C. mutilatus* in con-

trol tree fruit baits in three of the six weeks but overall there was no significant difference in their relative abundance ($P > 0.05$).

The *Carpophilus* population in this orchard, as determined by the monitoring traps, was dominated by *C. davidsoni* and *C. mutilatus* with these species accounting for 60% and 26%, respectively, of beetles trapped during the single tree experiments.

DISCUSSION

Synthetic aggregation pheromones of *Carpophilus* spp. have enormous potential for monitoring the populations of these pests. In Australian stone fruit production, the use of pheromones prior to harvest should allow growers to monitor the presence and population build up of *Carpophilus* spp., enabling precise judgement for the need and optimal timing of insecticide treatments. The potential for using synthetic pheromones for control of *Carpophilus* has remained largely unexplored; this study is the first to investigate mass-trapping based on pheromones as a control option for *Carpophilus* spp. The data obtained from this series of experiments suggest that the prospects are good for development of pheromone-based mass-trapping as a management strategy for orchard suppression of *Carpophilus* spp. By testing various ways of using pheromones and/or traps to mass-trap beetles and protect fruit, we have highlighted strengths and weaknesses that can be targeted in future research.

Pheromone trapping studies over a number of seasons have shown *Carpophilus* spp. in all major stone fruit growing regions of southern Australia are most abundant during spring. These populations decline naturally (probably due to shortage of breeding sites, e.g., ripe fruit) to a fairly low level in late spring/early summer (late November–early December) (James et al., 1993, 1994, 1995). Mass-trapping as a control strategy is therefore most appropriately timed to begin after the natural decline has occurred and before populations begin increasing again, fueled by the increasing seasonal availability of ripening fruit. Mass-trapping of the large spring populations of *C. mutilatus* that can occur in California date gardens, as suggested by Bartelt et al. (1994b), may be appropriate because of the continuous availability of host resources, which prevents a marked population decline.

In the commercial orchard experiment mass-trapping in perimeter trees for three weeks before harvest appeared to have some impact on *Carpophilus* spp. populations. Numbers of beetles caught in the center of the orchard fell after mass-trapping started and damaged, ripe fruit in the center of the orchard at harvest were largely beetle-free. This contrasted with fruit in perimeter (trap) trees and fruit in the nearby orchard, which were heavily infested with beetles. In experiment D beetle populations in fruit baits on a central tree in a small

block cordoned by 16 funnel traps were also suppressed in comparison to populations in fruit baits on the trap trees and distant control trees. While mass-trapping in a perimeter zone appears to reduce beetle populations within a block, large populations occur near the traps. In experiments A–C beetle numbers in fruit baits on trees cordoned by eight traps were up to 7.5× greater than those on trees not surrounded by pheromone traps. Height of the traps did not appear to influence this response. Clearly, not all beetles attracted to pheromones emanating from traps are actually trapped. Once drawn to the vicinity of a pheromone trap they can be diverted to nearby ripe fruit. The positioning of pheromone traps is therefore an important consideration for both mass-trapping and monitoring *Carpophilus* spp. Further studies are needed to determine the extent of the potential damage zone around pheromone traps. Stone fruit orchards in the MIA are often bordered by citrus or grapevines and suppression traps could be positioned in the perimeter zones of these crops, which are not affected by *Carpophilus* spp.

Although very small numbers of beetles were observed in ripe fruit in the center of the commercial orchard compared to the perimeter and the nearby orchard, this was not the case in samples of fallen fruit and the fruit baits. Total numbers of beetles in fallen fruit or fruit baits were comparable in the experiment orchard, the nearby orchard, and adjacent citrus. However, *C. hemipterus* dominated beetle populations in fallen fruit and fruit baits in the experiment orchard, but *C. davidsoni* dominated elsewhere. This suggests that *C. davidsoni* was suppressed within the orchard allowing the nontargeted *C. hemipterus* (only pheromones of *C. davidsoni* and *C. mutilatus* were used in suppression traps) to infest fruit at a higher rate. *C. hemipterus* attracted to the orchard by ripening fruit were not intercepted by the suppression traps, as the other two species were, and therefore became the dominant species within the orchard. Although some cross-attraction does occur with *Carpophilus* spp. pheromones, the pheromones of *C. davidsoni* and *C. mutilatus* are poor attractants for *C. hemipterus* (Bartelt et al., 1994b; Bartelt and James, 1994). Season-long pheromone trapping of *Carpophilus* spp. (using pheromones of all three species) in three other stone fruit orchards in the MIA during 1994/95 confirmed *C. davidsoni* was the dominant species (total captures of *C. davidsoni* 72%, *C. mutilatus* 26%, *C. hemipterus* 2%) (James unpublished data). Similar results, contrary to those obtained from fruit samples were obtained from the monitoring traps in the center of the orchard. Pipe traps baited with pheromone and dough attract *Carpophilus* spp. from distances of up to 350 m (James, unpublished data). Thus, beetles caught in the orchard monitoring traps may have reflected the *Carpophilus* spp. population over a wider area than just the pheromone-treated orchard. Significant differences in species ratio also occurred in fruit baits from pheromone-treated and untreated trees in the single tree experiments in 1995.

In the small block experiment (D), beetle numbers in fruit baits on the

protected tree were always very small but invariably dominated by *C. davidsoni* and/or *C. mutilatus*. These were individuals that presumably had leaked through the suppression trap cordon (baited with *C. davidsoni* and *C. mutilatus* pheromones). The large numbers of beetles in fruit baits on the trap trees were dominated by *C. davidsoni* and *C. mutilatus*, but on the distant control trees *C. hemipterus* was sometimes dominant. *C. hemipterus* presumably did not invade the protected block as it did in the commercial orchard because the ripening fruit stimulus was insufficient (the only ripe fruit within the protected block were in the three fruit baits on the central tree). The alteration of species ratio in the small block experiment was indicative of suppression traps drawing the *C. davidsoni* and *C. mutilatus* populations away from the rest of the block, leaving *C. hemipterus* as the dominant species.

A number of parameters were used in these experiments to determine the effect of mass trapping on *Carpophilus* spp. populations (total counts and relative incidence of *Carpophilus* spp. in suppression traps, monitoring traps, and samples of ripe and fallen fruit and fruit baits). As discussed above, the long-range attraction of pheromone-baited monitoring traps prevents these from giving an accurate indication of *Carpophilus* spp. numbers in the immediate trap vicinity. The use of coattractant only (fermenting bread dough) in these traps, reducing their long-distance attraction, should give better results. Beetle damage to hanging ripe fruit is likely to be the best criterion for judging the suppressive effect of mass trapping on *Carpophilus* spp. populations, as this defines their economic importance. Observations indicate that small populations of *Carpophilus* spp. can occur in stone fruit orchards (utilizing fallen fruit as hosts) without causing economic damage to fruit on the trees (James, unpublished observations).

Success in suppressing *Carpophilus* spp. populations will depend on the efficacy of the traps used. James et al. (1996) showed water-based funnel traps to be the most effective in capturing large numbers of beetles. The number of traps necessary for suppressing beetle populations in a given area must also be determined. Data from current studies on the range and efficiency of *Carpophilus* spp. pheromone traps should indicate optimal trap spacing and density. Other aspects that require further research include development of improved delivery systems for the pheromones and the coattractant. Pheromone-impregnated rubber septa only work at maximum efficiency for about a week (Bartelt et al. 1994a) and full activity over a longer period is clearly desirable. A longer lasting and possibly more effective synthetic coattractant would also improve the practical aspects of mass trapping. It is possible that a lower quantity of pheromone (500 μg instead of 5000 μg) might improve trapping efficiency, increasing the proportion of beetles entering maps and minimizing the numbers of untrapped beetles attracted to the trap vicinity.

Pheromone-based mass trapping is unlikely to totally remove *Carpophilus* spp. populations from orchards. However, in combination with other measures,

such as the removal of fallen fruit and limiting the impact of nearby *Carpophilus* spp. populations through sanitation or spraying, mass trapping has the potential to assist in effective integrated control of these increasing pests of Australian stone fruit.

Acknowledgments—We thank Beverley Vogele, Richard Faulder, Merv Graham, and Trudy Wallace for expert technical assistance in this study. We particularly thank Richard Faulder for constructing the Faulder funnel and pipe traps. We also thank F. Franco, M. Nardi, M. Pirrotina and other cooperative fruit growers for allowing us to conduct experiments and take fruit samples from their orchards. The Australian Horticultural Research and Development Corporation, Canned Fruits Industry Council of Australia, Suncentre Horticultural Development Association, and Cropcare Ltd. are thanked for their financial support of this research.

(Received December 15, 1995; accepted April 10, 1996)

Abstract—The pheromone system of the scarab beetle *H. consanguinea*, an agricultural pest native to India, was investigated by extracting abdominal glands of females with dichloromethane and ether and analyzing them by GC-MS. Indoor bioassays with the natural product separated on a silica gel column showed that males responded to the hexane–ether (80:20) fraction by displaying a clear sexual behavior. Although the indoor bioassay-oriented approach did not lead to the identification of the active compound(s), field tests of candidate chemicals—anisole, indole, and phenol—showed that beetles responded strongly to anisole. Males and females were captured in anisole-baited traps in a ratio close to 1:1. Nearly the same sex ratio was also observed in beetles captured over the time during the flight activity of the beetles in the field. Because no clear evolutionary basis exists for why competing females are attracted to the semiochemical, it was simply referred to as a "female-released pheromone."

Key Words—Coleoptera, Scarabaeidae, anisole, indole, phenol, aggregation behavior.

INTRODUCTION

Although we cannot rule out the existence of signals that arise *de novo*, perhaps most insect signals are postulated to have arisen from characteristics originally having other functions (Otte, 1974). For the evolution of chemical signals, either the compound or the sensory apparatus to detect these compounds may have preceded the evolution of functional communication. Thus, pheromones may have originated from hormones, plant allelochemicals, cuticular constituents, the insect's own defensive compounds, metabolic waste products, or some combination of these or other factors. The original functions of the chemicals may or may not be eventually lost. In the origin of chemical communication, there are several examples that seem to fit this secondary function hypothesis (reviewed in Haynes and Potter, 1995).

Recent studies on the chemical ecology of scarab beetles have led to the identification of sex pheromones of various species in the subfamilies Melolonthinae and Rutelinae (Leal, 1996). Interestingly, most of the chemicals utilized by the more advanced group (Rutelinae) are likely to be fatty acid derivatives, whereas the more primitive group (Melolonthinae) utilizes ubiquitous compounds per se or as an immediate precursor. Based on the facts that the sex pheromones of melolonthines are largely produced in huge amounts (Leal et al., 1993), enantiomeric purity is not critical (Matsuyama et al., 1994), and since most of them have antimicrobial activity (Leal and Kurata, 1994), it was suggested by Leal (1996) that these semiochemicals may have evolved from a primary defensive role.

Some melolonthine species, notably *Holotrichia* and *Phyllophaga* species, emerge at dusk and aggregate in a small time window. Females of *H. parallela*, for example, display a calling behavior only for ca. 15 min (Leal et al., 1993). It is conceivable that this behavior could also have advantages other than mate finding, such as minimizing the effect of a predator. In such cases, selection could favor nonspecific pheromones that would attract both sexes equally. We now report that a female-released pheromone of *H. consanguinea*, an economically important pest in India, is responsible for the aggregation of male and female beetles.

METHODS AND MATERIALS

Analytical Procedures. Gas chromatography (GC) was carried out on a Hewlett-Packard 5890 II Plus instrument equipped with a split/splitless injector, electronic pressure control, a flame ionization detector, and an HP 3365 Series II Chemstation. High-resolution GC analyses were performed with polar and nonpolar capillary columns: HP-Innowax and HP-5MS (30 m × 0.25 mm ×

0.25 μm; Hewlett-Packard), respectively. These columns were operated at 50°C for 1 min, increased to 180°C at a rate of 4°C/min, held at this temperature for 1 min, increased again to 230°C at a rate of 10°C/min, and finally held at this temperature for 20 min. Low-resolution mass spectrometry (MS) was carried out either with an HP 5890 II Plus gas chromatograph linked to a mass selective detector MSD 5972 (Hewlett-Packard) or on an Hewlett-Packard gas chromatograph electron ionization detector GCD series. Chromatographic resolution was achieved on HP-5MS and HP-Innowax columns operated under the same conditions for GC.

Extracts. A kit containing all the materials necessary for the extractions of pheromone glands was shipped to India, where the pheromone was collected. Specially prepared solvents were used, a small portion being kept as a blank. Abdominal tips of calling females were excised with forceps, cleaned, and then washed with either dichloromethane or ether. Extracts of 10–20 females were transferred to ampules, flame-sealed, and shipped to Japan.

Isolation of Pheromone. In Japan, the extracts were analyzed by GC and GC-MS. An extract of 80 females equivalents (FE) was fractionated on a silica gel column (Wako C-200) by successively eluting with hexane–ether mixtures in the following order: 100:0, 95:5, 90:10, 80:20, 50:50, and 0:100. All the fractions were concentrated to 0.5 FE, and two thirds of each fraction was sent back to India for bioassay, whereas the remainder was used for chemical analysis.

Indoor Bioassay. The arena consisted of 75 × 60 × 60-cm wire gauge cages, containing a layer of moist soil (8 cm thick) on the bottom. Males collected in the field, when they were about to copulate, were released in each cage (45 per cage) one day before the bioassay. Fractions were transferred from the ampule to a filter paper that was placed inside the arena. Behavioral responses were observed from 19:00 to 21:30 hr.

Field Experiments. Evaluation of the candidate pheromones was conducted at the fields of the Agricultural Research Station, Durgapura-Jaipur, Rajasthan in the summers of 1994 and 1995. Funnel traps (Japan Tobacco, Inc., Tokyo), were baited with synthetic lures incorporated into plastic pellets (4–5 mm in diameter) made of polyethylene–vinyl acetate. These pellets were placed inside pellet holders (Fuji Flavor Co., Tokyo) and set 2 cm above the trap lip. Traps were positioned with the pheromone dispenser at 2.5 m above the ground. The candidate lures were replicated ($N = 2$) in randomized blocks with an intertrap distance of 10 m. Capture data were collected daily for at least three consecutive days and, after inspection, the traps were rerandomized. Capture data were transformed to log $(x + 1)$ before differences among means were tested for significance by ANOVA with JMP Software, Version 2 (Anonymous, 1989). Treatments followed by the same letters are not significantly different at the 5% level in the Tukey-Kramer honestly significant difference test.

RESULTS AND DISCUSSION

GC and GC-MS analyses of the crude extract from abdominal glands of *H. consanguinea* females gave a very clean profile (Figure 1). Some of the peaks appeared also in the solvent when it was concentrated to the same extent

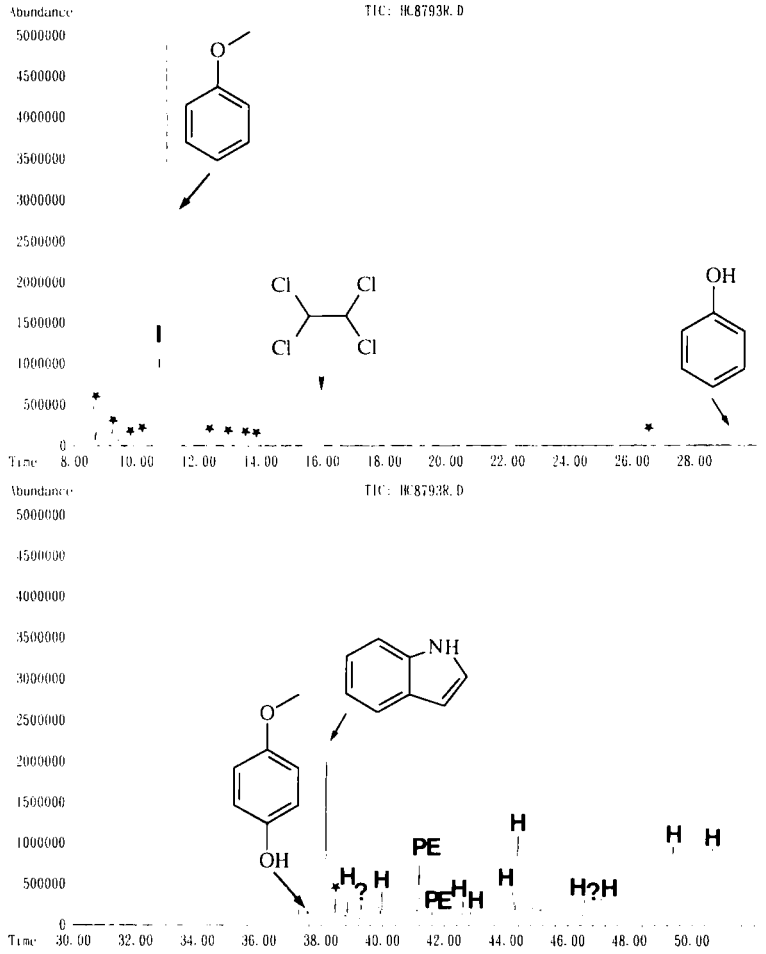

FIG. 1. Reconstructed total ion monitor profile of a crude extract sample from abdominal glands of *H. consanguinea* separated on a polar capillary column, HP-Innowax. The peaks labeled with an asterisk are due to solvent impurities. Cuticular hydrocarbons and phthalate esters are labeled with H and PE, respectively.

as the samples. One peak (I) was considered to be an impurity because it was observed only in one of 12 samples analyzed. Apart from the hydrocarbons, probably of cuticular origin, and phthalate esters, there were only a few relevant peaks. These were identified as methoxybenzene (anisole), 1,1,2,2-tetrachloroethane (an impurity from dichloromethane), phenol, 4-methoxyphenol, and indole.

Indoor bioassays revealed that the hexane–ether (80:20) fraction was very active. Males responded by attempting to take flight, orienting towards the pheromone source, aggregating on the source, and trying to copulate with each other. However, it was not possible to implement the bioassay for all the fractions under the same conditions. This was due to the fact that *H. consanguinea* is active for a very short period of time. Responses of one group to a certain fraction could not be compared to the responses of other individuals to a different fraction. This difficulty is intrinsic to the behavior of *Holotrichia* and *Phyllophaga* species. In order to overcome this barrier, bioassays to identify the active compound(s) in the pheromone system of *H. parallela* have been conducted in the field (Leal et al., 1992). This required a reasonable amount of sample and ultimately the full mixture could be identified only by assaying synthetic candidate compounds (Leal et al., 1993).

Because the indoor bioassay-oriented strategy could not lead unambiguously to the active compound(s) in a short period of time, we changed our strategy and assayed the insect response to candidate compounds in the field. The two major compounds found in the gland extracts, anisole and indole (Figure 1), were considered as possible attractants, notwithstanding the fact that indole is normally found in feces of scarab beetle males and females (Leal, unpublished data). Since phenol has been previously identified as a sex pheromone of another melolonthine species, *Costelytra zealandica* (Henzell and Lowe, 1970), it was also tested.

Field experiments showed that all the lures containing anisole were very attractive (Figure 2), whereas traps baited with indole and phenol (either alone or combined) did not capture significantly more beetles than control traps. Traps baited with caged virgin females did not capture significantly more than control traps, but this might be due to the fact that females of *Holotrichia* species hardly call when they are confined in a narrow cage (Leal, personal observation). Catches in traps baited at 3, 4.5, and 6 m were not significantly different.

Interestingly, the male-to-female ratio of the beetles captured was very close to 1:1. It has been previously observed that traps baited with synthetic sex pheromone of the Oriental beetle (and other species) also catch females (Leal et al., 1994). Nevertheless, the 1:1 ratio is very unusual. Recently, we have tested a previous hypothesis that males of the Oriental beetles caught in the traps released a semiochemical that would attract females. Traps baited with 30 males failed to attract any females in the field (Leal, unpublished data). On

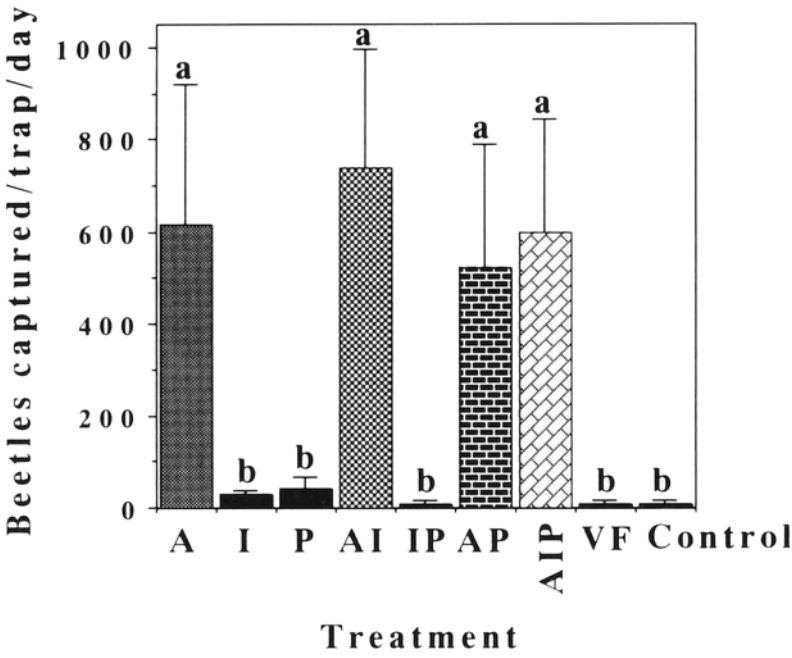

FIG. 2. Capture data of *H. consanguinea* in traps baited with candidate pheromones (A, anisole; I, indole; P, phenol), a combination of these compounds, virgin females (VF), and control traps.

the other hand, we also have evidence that female *Anomala octiescostata* can detect their own sex pheromone (Leal, unpublished data).

Recently, male-released pheromones have been identified from two scarab species in the subfamily Dynastinae, namely, *Oryctes monoceros* (Gries et al., 1994) and *O. rhinoceros* (Hallet et al., 1995). Because of male and female attraction to the semiochemicals, they were referred to as "aggregation" pheromones. However, there was evidence that chemical communication in *H. rhinoceros* involves a female-released sex pheromone in addition to the aggregation pheromone (Hallet et al., 1995).

In order to determine whether the male and female responses in *H. consanguinea* would be different during the calling period, we collected the capture data for both sexes at intervals of 5–10 min. Throughout the period of mating activity, the average ratio of three traps separated by 10 m was very close to 1 : 1 (Figure 3). Because the normal ratio in the field is also 1 : 1, we concluded that both males and females respond equally to the female-released compound.

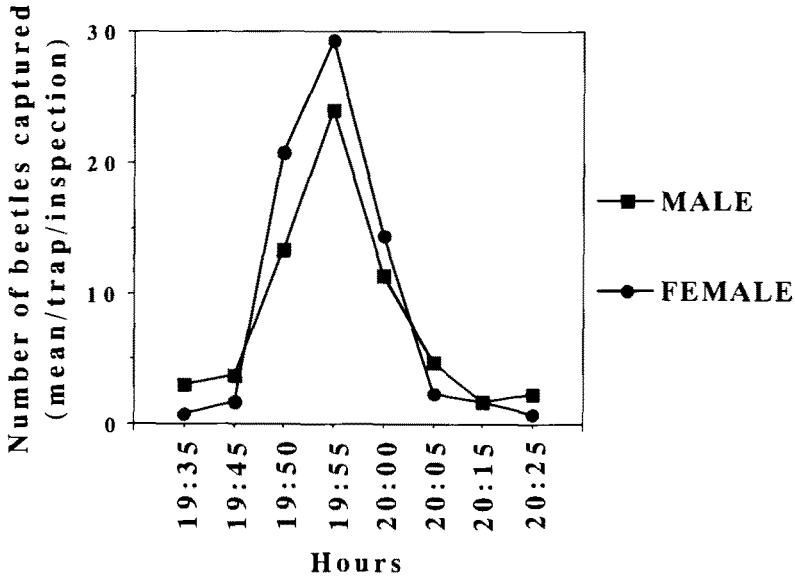

FIG. 3. Male and female responses of *H. consanguinea* as revealed by trap catches during the flight activity of July 12, 1995, in Durgapura. Throughout the period the male-to-female ratio was close to 1 : 1.

Sex pheromones have been considered by researchers to be those compounds that are emitted by individuals of one sex and that cause attraction of members of the opposite sex, resulting in the location of the emitter, and subsequently, mating (Baker, 1989; Tamaki, 1985; for a review of terminology, see also Nordlund, 1981). In that sense, anisole may be considered a sex pheromone because it is emitted by female beetles and males responded by displaying a clear sexual behavior. Males attracted to anisole tried to copulate with any individual (either male or female) in the vicinity. They also fluttered their wings when sitting on the trap lips or on the strings used to hang the traps. However, females were equally attracted to the same compound, and those that were not trapped displayed calling behavior on the traps.

The active compounds could be referred to as aggregation pheromones (sensu Borden, 1985): "substances that are produced by members of either and both sexes that induce members of both sexes to aggregate." It is not clear on an evolutionary basis why competing females are attracted to the female-released semiochemical. Thus, we rather prefer to refer to the semiochemical of *H. consanguinea* as a "female-released pheromone."

It is worth noting that aggregations of both sexes of melolonthines species

have been documented in other species as well. In the case of *H. serrata*, a species also native to India, it has been hypothesized that the chemical cues involved in the aggregation are not likely produced by only one of the two sexes to attract the opposite sex, because, if only females produce the cues to attract males and/or females, then the formation of pure male clumps could not be explained. Similarly, the formation of pure female clumps could not be explained if only males produced the pheromones to attract the males and/or females (Ganeshian and Kumar, 1993). We have no evidence for the formation of clumps of only one sex in *H. consanguinea*.

The adaptive basis of pheromone response by both sexes is not clear. It might not be selected for attracting females because it increases competition for mates. However, if the aggregation has any advantage other than mate finding, selection could be expected to favor the use of a pheromone that is not sex-specific. Due to our meager knowledge of the chemical ecology of this species, the advantage is obscure to us. It is intriguing, however, that such a phenomenon was found in a species that displays calling behavior in a very narrow window. Minimizing the period of calling and having, at the same time, a pheromone that attracts both males and females could be advantageous in escaping from a predator, for example.

These findings seem to shed more light on the secondary function hypothesis for the evolution of sex pheromonal communication in melolonthines (Leal, 1995). More recent findings support the conclusion that melolonthines largely utilize more "primitive" compounds as sex pheromones that may be also involved in other primary functions (Yarden et al., 1996; Leal et al., unpublished data), although one exception has been found. (*R*,*Z*)-7,15-Hexadecadien-4-olide has been identified as a sex pheromone of the Melolonthinae beetle *Heptophylla picea* (Leal et al., 1996).

Additional strong evidence for the secondary function hypothesis for the origin of sex pheromones in scarab beetles is the serendipitous discovery of the attraction of male *Cyclocephala lurida* (Scarabaeidae: Dynastinae) to grubs (Haynes et al., 1992). A recent study has been conducted (during a sabbatical leave of W.S.L. at Cornell University) to test whether the attraction to grubs was mediated by the same chemical(s) used by adults as sex pheromone. GC-EAD analyses of airborne volatiles and whole-body extracts from female beetles and whole-body extracts from grubs revealed that there is a common EAD-active component in the grubs and adult female extracts. That this EAD-active compound was involved in pheromonal communication was corroborated by a GC–behavioral bioassay (GC-BB). Males responded by gathering at the GC outlet soon after the EAD-active peak eluted from the GC, and some males displayed precopulatory behavior (Leal et al., unpublished data). The hypothesis for the ontogeny of the sex pheromone in this species is discussed elsewhere (Haynes and Potter, 1995).

If the chemical has preceded the evolution of functional communication in scarab beetles, it is possible that only later in the evolution a signal becomes sex-specific. *H. consanguinea*, for example, could be on an evolutionary ladder in which the signal is yet to be evolved as a sex-specific chemical cue.

We hope that this speculative hypothesis will stimulate further research on chemical communication of scarab beetles.

(Received December 29, 1995; accepted April 12, 1996)

Abstract—The ability of a range of glucosinolates and other compounds in stimulating oviposition of the cabbage root fly (*Delia radicum*) was determined using a bioassay based on the use of surrogate leaves coated with test compounds. The results show that chemically dissimilar compounds are effective stimulants providing they contain the S=O group. No other part of the glucosinolate molecule was shown to be necessary. It has been shown that compounds other than glucosinolates may be important in the oviposition behavior of *D. radicum*.

Key Words—Oviposition, behavior, Insecta, Diptera, Anthomyiidae, *Delia radicum*, host plant chemicals, glucosinolates, sulfate, structure–activity relationships, bioassay.

INTRODUCTION

In the cabbage root fly, *Delia radicum* (L.) (Diptera, Anthomyiidae), oviposition behavior is associated with host plant location and recognition. The host plants are found mainly within the family Cruciferae and facets of behavior are influenced by host plant chemicals that are largely specific to that family (Hawkes et al., 1978). Before contact with the plant, isothiocyanates induce upwind

*To whom correspondence should be addressed.

orientation and increase flight activity in mated and gravid females (Hawkes and Coaker, 1979). The behavioral outcome is the movement upwind of females in a series of flights. On landing on the host plant, glucosinolates stimulate the first of a series of behavior patterns that result in eggs being laid generally in the soil in the vicinity of the host plant (Tranyier, 1967). Contact with glucosinolates or host plant material is necessary for oviposition, the presence of volatile isothiocyanates being insufficient alone (Nair and McEwen, 1976).

Electrophysiological studies (Roessingh et al., 1992) have shown that tarsal contact chemoreceptors occur in female cabbage root fly that are sensitive to glucosinolates. The biological activity of a range of glucosinolates was investigated using electrophysiological recording and a bioassay based on the use of surrogate leaves coated with test compounds. A significant correlation was found between the overall length of the side chain of the glucosinolate molecule and biological activity. The most stimulating fraction of plant surface extract contained no glucosinolates, and it was concluded that compounds in addition to glucosinolates play an important role in oviposition.

In this paper we report the results of an investigation into the structure–activity relationship of glucosinolates and other related compounds as oviposition stimulants for *D. radicum* using a bioassay method.

METHODS AND MATERIALS

Insects. All experiments and the culture of flies were carried out in a climate controlled room (18 L:6 D-photoperiod, 21 ± 1.5°C and 70 ± 10% relative humidity). A culture was maintained using the method of Finch and Coaker (1969).

For the bioassays, emerging flies were transferred into a separate holding cage every 24 hr and used in experiments when 7–8 days old.

Oviposition Sites. The design of the surrogate leaf structure was adapted from Roessingh and Städler (1990) and Koštál (1993). Each leaf consisted of a circle of white cardboard (9 cm diameter) with vertical folds 1 cm apart. This was slotted into a plastic tube stem (4 cm length, 0.5 cm diameter). The structure was then coated with a uniform layer of paraffin wax (Merck, mp 42–44°C) by a short immersion into warm water with a floating layer (0.6–1 cm) of the molten wax on top. Three leaves were sprayed with 0.6 ml of a 2.5×10^{-5} M solution of sinigrin in 75% aqueous methanol as the standards, three were treated with 0.6 ml of a test solution at a known concentration in 75% aqueous methanol, and the final three were treated with 75% aqueous methanol as the blanks. The model leaves were left to dry for approximately 30 min and then each one was fixed into the center of a Petri dish (9 cm diameter, 1.5 cm deep). Fine sand was placed into the dish around the leaf in which the flies could lay their eggs.

FIG. 1. Layout of surrogate leaf structures on the bioassay cage floor. Test 1 is the control standard of leaves treated with 2.5×10^{-5} M sinigrin solution and test 2 is the compound under test.

The accuracy of the application technique in the preparation of the surrogate leaves was tested by recovery experiments using HPLC (Spinks et al., 1984). Sinigrin was recovered 95% or greater levels from the leaves in four repeat experiments.

Bioassays. Bioassay experiments were performed in screen cages (50 × 50 × 50 cm), on the floor of which were placed nine surrogate leaf structures in a random grid arrangement (Figure 1). Ten female flies, 7–8 days old, and an average weight of 11 mg, were introduced into the cage for 24 hr, after which times the "leaves" were removed and the number of eggs laid on and around each one determined by flotation in water.

Treatment of Results. The best-fit model of the observed data was found to be a cubic equation relating the fly oviposition response to the natural log of the concentration as shown:

$$Y = ax^3 + bx^2 + cx + d$$

where x is $\log_{10}$ concentration (molar), Y is relative stimulation $(T_2 - B)/(T_1 - B)$, with T_1 the total number of eggs laid on the sinigrin control standards (test 1), T_2 the total number of eggs laid on the "leaves" treated with the test compound (test 2), and B the total number of eggs laid on the blanks.

The optimum concentration (C) of a compound required to give maximum relative stimulation (Y_{max}) for each compound was then calculated from the model and used as a measure of biological activity. Compounds were designated as biologically active if egg laying on the treated sites was significantly higher than that on the blanks according to the F test for variance and the appropriate t test. A value of Y greater than 0.01 was obtained as the level indicating significant oviposition stimulation.

Test Compounds and Their Synthesis. All test compounds and the starting materials were purchased from Aldrich UK Ltd. and used as received unless stated otherwise. Potassium salts of three different glucosinolates were used: sinigrin, glucobrassicin, and glucotropaeolin. Sinigrin was purchased from Sigma UK Ltd., and the other two were provided by the Department of Biological

Sciences, University of Plymouth. Desulfosinigrin, sinigrin tetraacetate, acetone sodium bisulfite, *S*-methyl cysteine sulfoxide, and the corresponding sulfone were synthesized as described below.

Desulfosinigrin was obtained by the desulfation of the glucosinolate molecule using the enzyme aryl sulfatase (Sigma UK Ltd.). The enzyme (10 mg) was added to 5 mg of sinigrin dissolved in 50 ml of 0.2 M acetate buffer, pH 5.57. The solution was left overnight at 25°C and the desulfation was considered to be complete since the sample was chromatographically homogeneous following the procedure of Spinks et al. (1984) with no trace of sinigrin present. The reaction solution was bioassayed immediately with an appropriate blank.

Sinigrin tetraacetate was synthesized according to the method of Kjaer and Gmelin (1956). A 10-fold excess of acetic anhydride was used, and the reaction mixture was kept at 50°C for 6 hr. The product had a melting point of 194°C (lit. value 194°C; Benn and Ettlinger, 1965). The material was chromatographically homogeneous as shown by thin-layer chromatography. R_f values of 0.27 and 0.6 were obtained on 60 G silica gel plates for sinigrin and its tetraacetate, respectively, with an *n*-butanol–acetic acid–water (60 : 15 : 25% by volume) solvent system.

The bisulfite addition compound was prepared according to Vogel (1970) and *S*-methyl cysteine sulfoxide according to Greenstein and Winitz (1961). *S*-Methyl cysteine sulfone was synthesised by the oxidation of *S*-methyl cysteine sulfoxide.

RESULTS

Table 1 shows the structures, optimum concentrations (C), and maximum stimulation relative to the 2.5×10^{-5} M sinigrin standard (Y_{max}) for three naturally occurring glucosinolates and two structural modifications of sinigrin. Table 2 shows similar data for 12 other nonglucosinolate compounds tested, plus one mixture.

Figures 2–4 show plots of relative stimulation (Y) versus $\log_{10}$ concentration (x) for all of the compounds tested together with the best-fit curves in each case from which C and Y_{max} can be calculated.

Glucobrassicin (Table 1, compound 1) proved to be the most effective compound in terms of number of eggs laid relative to a standard (Y_{max}). Examination of Tables 1 and 2 together with Figures 2–4 shows that the concentration of a compound (C) required to produce the maximum stimulus (Y_{max}) shows a considerable range (4.29×10^{-4} to 1.16×10^{-6} M). All of the bioactive compounds show a decrease in activity at higher concentrations.

Figure 5 shows a plot of maximum relative stimulation (Y_{max}) against optimum concentration (C) for each compound. With the exception of sinigrin and

DISCUSSION

The naturally occurring glucosinolate molecules can be divided into three structural regions: a side-chain (R), a thioglucose, and a sulfated oxime. Examination of Table 1 shows that variations in R result in modification of activity, demonstrated by sinigrin, glucobrassicin, and glucotropaeolin. Similar findings have been reported by Roessingh et al. (1992) for *D. radicum* and by Simmonds et al. (1994) for *D. floralis*.

Modification of the thioglucose residue of sinigrin by acetylating all of the hydroxyl groups to give sinigrin tetraacetate caused some decrease in activity. The level was well above the threshold of nonstimulus, however. This implies that the glucose residue is not a key structural requirement.

Desulfation of the oxime sulfate group resulted in the formation of desulfated sinigrin, which was devoid of all activity. The sulfate group seems to be an essential structural feature for oviposition—a region that could be identified as an on–off switch for egg laying.

A series of compounds containing the SO_3H group bonded to a variety of other organic residues or functional groups was then examined to test this hypothesis. Table 2, compounds 1–6, shows that all the compounds examined that contained the SO_3H group possessed significant biological activity despite the wide variety of structures attached to the group. Toluene-*p*-sulfonic acid (2) was tested as both a free sulfonic acid and as the potassium salt. There was no difference in the bioassay results, showing that it is not necessary to have the ionized SO_3^- group rather than the parent acid. The most effective compound

in terms of Y_{max} was the simple compound sulfamic acid (5), in which the sulfur atom is bonded directly to an amino-nitrogen atom. Hydroxylamine-*O*-sulfonic acid (4), which contains the three atom system N-O-S present in glucosinolates, was also an effective stimulant.

Attempts to sulfate the oxime group of simple ketones to produce compounds more strictly analogous to glucosinolates were unsuccessful, the reaction producing an amide by a spontaneous Beckmann rearrangement of the desired product. This result was not unexpected.

The results obtained from compounds showing a progressive decrease in the oxidation state of the original SO_3H sulfur atom are given in Table 2, compounds 6–11. From these results it becomes quite clear that the key structural requirement for oviposition stimulus is the presence of an S=O group in a molecule. This group is present in *S*-methyl cysteine sulfoxide (10), which was bioactive. *S*-Methyl cysteine, lacking the S=O group, was devoid of biological activity. Sodium bisulfate (12), in which the S atom is in its maximum oxidation state, also lacked activity.

Städler and Shöni (1990) produced evidence that more than one group of compounds stimulates oviposition. Roessingh et al. (1992) report that compounds additional to glucosinolates play a role in the stimulation of oviposition. The compounds were not identified, however.

S-Methyl cysteine sulfoxide (10) is known to be present in the leaves of a variety of Brassicae, including cabbage at significant levels (Morris and Thompson, 1956; Synge and Wood, 1956). In view of the demonstration of its oviposition-stimulating ability on surrogate leaves, it is possible that it could have the same property in vivo. However there was no synergistic activity between sinigrin and (10) (Table 3), the effect being only additive.

TABLE 3. RESULTS OF SYNERGISM EXPERIMENTS WITH SINIGRIN AND *S*-METHYL CYSTEINE SULFOXIDE

Compounds	Initial concentration (M)	% Used in test mixture	Concentration in test mixture (M)	Expected *Y* (additive)	Actual *Y*

(Received August 14, 1995; accepted April 17, 1996)

Abstract—Substances with antiaphid activity were extracted from the leaf surface of aphid-resistant *N. benthamiana* and purified. Sugar esters and diacyl glycerols were isolated from the chloroform extract, but only diacyl glycerols showed significant activity. However, the major activity was found in the water extract rather than in the chloroform extract. From the water extract calcium chloride was isolated as the most abundant active substance. Only calcium chloride showed significant activity among several calcium salts and chlorides of several metals that are abundant in plants. Calcium contents per unit area of leaf surface of *N. benthamiana* and aphid-resistant *N. gossei* were almost equal to each other and 10–100 times higher than that of aphid-susceptible *N. tabacum*.

Key Words—*Nicotiana benthamiana*, *Myzus persicae*, green peach aphid, *Nicotiana gossei*, calcium chloride, plant resistance to insects.

INTRODUCTION

Aphids damage a wide range of crops not only by feeding on them but also by spreading viruses from one plant to another. Various kinds of pesticide have

*To whom correspondence should be addressed.
[4]Present address: Leaf Tobacco Research Laboratory, Japan Tobacco Inc., Idei 1900, Oyama, Tochigi 323, Japan.

0098-0331/96/0900-1579$09.50/0 © 1996 Plenum Publishing Corporation

been developed to control aphids. However, they are not always able to control aphids since the pests multiply very quickly and often acquire immunity to pesticides. Several plant species are known to resist aphids. Understanding the resistance mechanisms could suggest ways to develop safe and effective pesticides as well as ways to breed new aphid-resistant varieties. *Nicotiana benthamiana* is highly resistant to aphids (Hagimori et al., 1993) and the leaf-eating caterpillar *Spodoptera litura* (Joshi and Sitaramaiah, 1975). Somatic hybrids between *N. benthamiana* and *N. tabacum* have already been produced to introduce aphid resistance into tobacco (Hagimori et al., 1993). In the course of this work, we observed numerous droplets—considered to be trichome exudates—on the leaf surface of *N. benthamiana*. The aphid resistance of *N. benthamiana* leaf explants decreased to the level of *N. tabacum* if the droplets were removed, suggesting that the causative agent of the resistance is present in the droplets. The purpose of the present work is to isolate and identify substances with antiaphid activity present on *N. benthamiana* leaf surfaces. Leaf surface lipids, especially sugar esters, were attributed to be the cause of the aphid resistance of several plant species (Goffreda et al., 1989; Neal et al., 1990; Severson et al., 1992). In *N. benthamiana*, we previously analyzed leaf surface lipids and found novel glycerolipids and glycolipids (Matsuzaki et al., 1992). Therefore, we first examined these lipids for antiaphid activity. We subsequently searched for other active substances in the leaf surface extract of *N. benthamiana*.

METHODS AND MATERIALS

Plant Materials. *Nicotiana benthamiana* Domin., *N. gossei* Domin. (both of which are aphid resistant), and *N. tabacum* L. (which is aphid susceptible) were used in this work. They were grown in a greenhouse and were watered carefully so as not to wet their leaves to avoid washing off leaf surface substances.

Analysis of Leaf Surface Lipids. Leaves of 3-month old plants of *N. benthamiana* were collected. The leaf surface lipids were extracted by dipping the leaves into chloroform for 10 sec. The chloroform-extracted lipids were separated by silica gel column chromatography and high-performance liquid chromatography (HPLC) according to Matsuzaki et al. (1992).

Extraction and Fractionation of Leaf Surface Substances. Leaves of 3-month-old plants of *N. benthamiana* were collected. Leaf surface material was extracted with either chloroform or distilled water by dipping the leaves in the solvent for 20 sec. Both chloroform and water extracts were assayed for antiaphid activity. The water extract was designated WS. A portion of WS was extracted with chloroform twice. The combined chloroform extracts were designated WS1. The residue was dissolved in water and designated WS2. Both

WS1 and WS2 were assayed for antiaphid activity. Diaion HP20 was used to fractionate WS2 by ion exchange chromatography into three fractions, HP1, HP2, and HP3. First, HP1 was obtained by eluting with water, then HP2 and HP3 were eluted successively with 20% ethanol and ethanol, respectively. HP1 was further fractionated by HPLC using the Shodex KS801 column. The solvent used in the HPLC was water, and the flow rate was 1 ml/min. Effluent was scanned with a refractive index photometer. Only one peak was detected. The fraction of the peak was collected and designated P1.

Antiaphid Activity Assay. A colony of green peach aphids, *Myzus persicae* Sulzer, was reared and maintained on tobacco seedlings in a greenhouse at 22°C. Apterous viviparous adults were collected and starved for 4 h before use. Two 96-well microplates for ELISA (Nunc) were used for each assay. In one microplate, one aphid was deposited in each of the 96 wells. In another microplate, either 400 μl of 20% sucrose solution or 400 μl of artificial diet, which contains sucrose, amino acids, vitamins, and minerals (Mittler and Koski, 1974), was placed in each of the 96 wells as food for the aphids, and the microplate was sealed tightly with stretched Parafilm (American National Can, Greenwich, Connecticut). A 20% sucrose solution was used in the assays for the activity of the leaf surface lipids and the activities of the crude extracts, WS, WS1, and WS2. The artificial diet, which is thought to be the more suitable food for aphid, was used in the other assays except for the assay of the toxicity of calcium chloride. In the assay of the toxicity, no aphid food was supplied. The substance to be assayed was dissolved in either methanol or distilled water and spread on the upper surface of the Parafilm at a concentration 100 $\mu g/cm^2$. For the control, either methanol or distilled water was spread on the upper surface of the Parafilm. After the surface dried, one microplate sealed with the Parafilm was placed upside down on top of another one that contained aphids so that the wells of the two microplates faced each other with the Parafilm held between them. The microplate assembly was turned over to make the aphids settle on the Parafilm. Then the assembly was turned over again and incubated at 25°C in darkness for 72 h. Every 24 h we counted the number of aphids that settled on the Parafilm and the number of unsettled living and dead ones.

Identification of P1. X-ray analysis was performed using a JSM-6400 X-ray analyzer equipped with SEM-EDX (JEOL Ltd., Tokyo, Japan). ^{1}H NMR spectra were obtained with a Bruker AC-300 NMR spectrometer. HPLC analysis was performed using an ODS column (YMC pack A321). Water was used as the solvent at a flow rate of 1 ml/min.

Quantitative Analysis of Calcium on Leaf Surface. About 10 g of fresh leaves were collected from each individual. The total area of the leaves was measured by the AAC-400 (Hayashi Denkoh Co., Ltd., Tokyo, Japan) automatic area meter. The leaves were dipped in 300 ml of deionized distilled water for 20 sec. The extract was evaporated in vacuo and residue was dissolved in

25 ml deionized distilled water. The calcium content in the solution was assayed by the ICPA-575 II (Nippon Jarrell-Ash, Uji, Japan) inductively coupled argon plasma atomic emission spectrophotometer.

Detection of Nicotine. Nicotine was detected by silica gel thin-layer chromatography. Two kinds of solvent were used: a 1 : 1 solution of hexane–acetone and a 65 : 25 : 4 solution of chloroform–methanol–water. Spots of nicotine were detected by spraying with Dragendorff's reagent.

RESULTS

Antiaphid Activity of N. benthamiana Leaf Surface Lipids. We obtained 60 g of leaf surface lipids from 10 kg of fresh *N. benthamiana* leaves. The leaf surface lipids were further fractionated to yield 1.2 g of 1,2-diacyl glycerol (1-*O*-acetyl-2-*O*-acylglycerol, DG), 12 g of glucose diester (3,4-di-*O*-acyl-α-D-glucopyranose, GE), 8 g of sucrose triester [6-*O*-acetyl-4-*O*-acyl-α-D-glucopyranosyl-3-(*O*-acyl)-β-D-fructofuranoside, STE], and 0.8 g of sucrose diester [4-*O*-acyl-α-D-glucopyranosyl-(3-*O*-acyl)-β-D-fructofuranoside, SDE]. These substances were assayed for antiaphid activity. Table 1 shows the results observed 48 h after initiation of the assay. GE, STE, and SDE had no effect on the aphids. Only DG showed significant activity of repelling and killing aphids.

Antiaphid Activity of Crude Extracts. Leaf surface substances of *N. benthamiana* were extracted with two kinds of solvents (i.e., water and chloroform). The crude extracts were assayed for antiaphid activity (Table 2). Chloroform

extracts had no effect on the aphids. On the other hand, the water extract showed significant activity. This result demonstrates that major antiaphid substances of *N. benthamiana* are soluble in water and insoluble in chloroform.

Purification and Identification of Active Antiaphid Substances in Water Extracts of N. benthamiana Leaf Surface Substances. The water extract from *N. benthamiana* leaf surface substances was further fractionated to purify the active antiaphid substances. Figure 1 shows the procedure schematically and the yields of each fraction. The antiaphid activity of each fraction was assayed. In the first step, the water extract (WS) was separated into two fractions: WS1 and WS2. We obtained 410 mg WS1 and 5260 mg WS2 from 1.23 kg of fresh leaves. Thin-layer chromatography detected nicotine only in WS1, not in WS2. Table 3 depicts the antiaphid activity of WS, WS1, and WS2. Antiaphid activity in WS was concentrated in WS2, not in WS1. WS2 was further fractionated to obtain three fractions: 3.61 g HP1, 80 mg HP2, and 60 mg HP3. All of these fractions exhibited almost equally robust antiaphid activity (Table 4). HP1, by far the most abundant fraction, was subsequently subjected to HPLC using the Shodex column. Only one peak was detected, and the fraction was collected (P1, 2.86 g). P1 was subjected to further HPLC using an ODS column and, again, only one peak was detected.

Identification of P1. X-ray analysis of P1 showed the existence of calcium and chlorine. ^1H NMR of P1 gave no clear signals except for a broad singlet at 4.4 ppm due to H_2O. These results suggested that P1 was $CaCl_2 \cdot nH_2O$. The retention time of $CaCl_2 \cdot 2H_2O$ was the same as that of P1 in HPLC in both columns mentioned above. The antiaphid activity of $CaCl_2 \cdot 2H_2O$ was compared with that of P1. $CaCl_2 \cdot 2H_2O$ exhibited almost the same activity as P1 (Table 5). From these results, we concluded that P1 was $CaCl_2 \cdot 2H_2O$. The antiaphid

activity of calcium chloride concentration, in the range of 5–1000 $\mu g/cm^2$, was examined. Calcium chloride showed significant activity at more than 50 $\mu g/cm^2$, but the levels of activity did not go up in response to increase in concentration higher than 50 $\mu g/cm^2$ (data not shown).

Antiaphid Activity of Calcium Salts and Chlorides. To clarify which component of $CaCl_2 \cdot 2H_2O$ was responsible for the antiaphid activity, the following calcium salts and chlorides were assayed for the activity (Table 6): $CaCl_2 \cdot 2H_2O$, $Ca(H_2PO_4) \cdot 2H_2O$, $CaSO_4 \cdot 2H_2O$, $CaCO_3$, NaCl, KCl, and $MgCl_2$. Contrary to expectation, only $CaCl_2 \cdot 2H_2O$ showed significant activity. $MgCl_2$ may possess slight activity.

Calcium Content on Leaf Surface of N. benthamiana and Other Nicotiana *Species.* To clarify whether there is a correlation between aphid resistance and calcium content on the leaf surface, *N. benthamiana*, *N. gossei* (which is the most resistant among *Nicotiana*), and susceptible *N. tabacum* were assayed for calcium content on their leaf surface (Table 7). The calcium contents of the two resistant species, *N. benthamiana* and *N. gossei*, were nearly equivalent and were 10–100 times higher than that of susceptible *N. tabacum*.

Toxicity of Calcium Chloride to Aphids. To determine the mode of action of calcium chloride (whether it is a feeding deterrent or a toxic compound), calcium chloride was assayed for antiaphid activity without supplying aphid food. Calcium chloride showed significant activity also in this condition (Table 8).

DISCUSSION

Quite a few plant species are known to be aphid resistant. The mechanism of the resistance has been investigated, and several compounds existing in or

on the surface of the plants were reported to be the cause of the resistance (Pickett et al., 1992; Corcuera, 1993). Sugar esters are among such compounds. Goffreda et al. (1989) attributed the aphid resistance of *Lycopersicon pennellii* to glucose esters of branched-chain carboxylic acids contained in trichome exudates of the plant. Aphid resistance of *Solanum berthaultii* was attributed to the 3′,3,4,6-tetra-*O*-acyl sucroses present in large amounts in the trichome exudates (Neal et al., 1990). In *Nicotiana gossei*, the most resistant species in the genus *Nicotiana*, Severson et al. (1992) reported that two types of glucose ester and two types of sucrose ester isolated from the cuticular extract were toxic to the tobacco aphid and the sweet potato whitefly. In the case of *N. benthamiana*, however, although sugar esters were present on the leaf surface in considerable amounts, they did not show the antiaphid activity.

In *Nicotiana* spp., nicotine alkaloids such as nicotine, nornicotine, anabasine, and *N*-acylnornicotines were attributed to be the cause of the resistance (Thurston et al., 1961; Huesing et al., 1989). In *N. benthamiana*, however, this is unlikely since nicotine was collected in the inactive fraction (WS1).

In this work, diacyl glycerol (DG) and calcium chloride were identifed as the active antiaphid substances present on the leaf surface of *N. benthamiana*. DG is not present on the leaf surface of susceptible *N. tabacum* (Hagimori et al., 1993), supporting the view that DG might be responsible for at least a portion of the resistance of *N. benthamiana* to aphids. However, the somatic hybrids between *N. benthamiana* and *N. tabacum* did not contain DG but were nevertheless almost as resistant to aphids as *N. benthamiana* (Hagimori et al., 1993). Furthermore, major antiaphid activity was in the water extract, not in the chloroform extract (Table 2), while DG is washed out from the leaf surface with chloroform. These results suggest that DG is not the major cause of the resistance.

It is generally agreed that for any plant substance to be regarded as the causative agent of resistance to aphids, it should meet the following criteria: First, the substance should have some antiaphid activity. Second, the concen-

tration of the substance in the part of the plant where the aphids feed should be high enough to cause the effects in artificial diets. Third, there should be a correlation between the concentration of the substances and plant resistance to the aphids (Corcuera, 1993). Our results indicate that calcium chloride meets the first and third criteria, while it does not appear to meet the second. The concentration of calcium on the leaf surface of *N. benthamiana* and *N. gossei* was around 3 $\mu g/cm^2$. This calcium value is equivalent to about 11 μg of $CaCl_2 \cdot 2H_2O$. This is still only one fifth of the minimum effective concentration used in the antiaphid activity assay (50 $\mu g/cm^2$). Although it is not known how the calcium chloride comes to exist on the leaf surface, it is unlikely to reside uniformly on the leaf surface as was the case with the Parafilm membrane used in the assay. It is more likely to be concentrated around the exuding tissues on the leaf, such as the trichomes or stomata, to a level high enough to repulse aphids. Thus, it is possible that the second criterion might also be fulfilled.

Other unidentified active substances were indicated to be in fractions HP2 and HP3. Their activities were comparable to that of calcium chloride at the concentration of 100 $\mu g/cm^2$, but their concentrations on the leaf surface of *N. benthamiana* were much lower than that of calcium chloride.

The antiaphid activity levels were almost the same when concentrations were more than 50 $\mu g/cm^2$. It seemed that the concentration was saturated in this assay.

Therefore we concluded that calcium chloride is the major causative agent of *N. benthamiana* aphid resistance. The fact that not only *N. benthamiana* but also *N. gossei* exhibit high calcium concentrations suggests that this mechanism of aphid resistance might be widespread.

Ma (1972) reported that calcium chloride was a feeding deterrent to *Pieris brassicae*. In our experiment, calcium chloride also showed significant antiaphid activity without supplying aphid food (Table 8). This result suggests that calcium chloride is toxic to aphids rather than a feeding deterrent.

Although there are a few reports on the effects that mineral salts borne by leaves have on aphids (Salas et al., 1990; Corcuera, 1993), this is the first report to our knowledge that shows calcium chloride exuded on the leaf surface is the major cause of the aphid resistance.

Acknowledgments—We would like to thank Mr. K. Ohyoshi for the quantitative analysis of calcium.

RELATIVE IMPORTANCE OF SEMIOCHEMICALS FROM FIRST AND SECOND TROPHIC LEVELS IN HOST FORAGING BEHAVIOR OF *Aphidius ervi*

Y.-J. DU, G. M. POPPY, and W. POWELL*

IACR-Rothamsted
Harpenden, Hertfordshire AL5 2JQ, UK

(Received October 23, 1995; accepted April 18, 1996)

Abstract—The responses of female *Aphidius ervi* to odors from a host food plant (*Vicia faba*), host aphids (*Acyrthosiphon pisum*), nonhost aphids (*Aphis fabae*), and aphid–plant complexes were investigated in a specially designed wind tunnel and a Y-tube olfactometer. In single-target (no-choice) and two-target (dual-choice) experiments, plant volatiles played a crucial role in the host foraging behavior of *A. ervi*. The odor from the *A. pisum*–plant complex elicited the strongest responses by *A. ervi* females, followed by the odor from plants previously damaged by the feeding of *A. pisum*. There was a significantly weaker response to odor from *A. pisum* in the absence of the plant and to undamaged plants. Similarly, mechanically damaged plants and plants infested with the nonhost aphid *A. fabae* did not elicit strong responses. A plant that had been damaged by *A. pisum* and subsequently washed with distilled water was as attractive as an unwashed, previously infested plant. *Aphidius ervi* probably overcomes the reliability–detectability problem by selectively responding to herbivore-induced, volatile, semiochemical cues emitted by the first trophic level and by distinguishing between the volatiles induced by host and nonhost aphids.

Key Words—*Aphidius ervi*, host location, olfaction, plant volatiles, aphid feeding, *Acyrthosiphon pisum*, *Aphis fabae*, wind tunnel, Y-tube olfactometer, tritrophic interactions.

INTRODUCTION

The host foraging behavior of female insect parasitoids has been divided into a series of steps that include habitat orientation, host community location, and

*To whom correspondence should be addressed.

0098-0331/96/0900-1591$09.50/0 © 1996 Plenum Publishing Corporation

host location (Vinson, 1985). Chemical cues play an important role in all of these stages, and such chemicals have been termed infochemicals (Vet and Dicke, 1992). The volatile chemical cues employed by parasitoids during host foraging may originate from the plant upon which the host is feeding, the host itself, other organisms associated with the host, or chemicals released as a result of interactions between the host and its food plant (Lewis and Martin, 1990). The utility of chemical information depends upon its reliability and its detectability (Vet and Dicke, 1992; Steinberg et al., 1993). Information originating directly from the host is the most reliable, but this is often difficult to detect, especially over longer distances, as the infochemicals are usually produced in minute amounts and must be detected against the background of odors in the environment (Vet and Dicke, 1992). On the other hand, plant volatiles are easily detected but have a low reliability as they do not guarantee the host's presence. According to Vet and Dicke (1992), such a dilemma can be overcome by the parasitoid in three ways: (1) by responding to conspicuous cues from stages of the host different from the one which is attacked; (2) by focusing on stimuli associated with interactions between the host and its food plant; and (3) by learning to link easy-to-detect cues with less detectable but reliable cues. There is now strong evidence that some parasitoids of lepidopteran pests, as well as certain predatory mites, use the second approach and respond to host herbivore-induced plant volatiles (Steinberg et al., 1993; Takabayashi et al., 1994; Tumlinson et al., 1993; Turlings et al., 1990, 1991; Vet and Dicke, 1992).

Much less is known about the role of chemical cues in the foraging behavior of aphid parasitoids (Hymenoptera, Braconidae, Aphidiinae) than is known about their role in the foraging behavior of parasitoids attacking lepidopteran hosts. Nevertheless, in several studies using Y-tube olfactometers, host plant volatiles were also important cues for foraging aphid parasitoids (Read et al., 1970; Schuster and Starks, 1974; Powell and Zhang, 1983; Wickremasinghe and van Emden, 1992). In contrast, females of the aphid parasitoid *Aphidius nigripes* did not respond to plant volatiles in the olfactometer but were strongly attracted by odors from host aphids (Bouchard and Cloutier, 1984). Furthermore, flight responses to odors from aphid hosts and uninfested or host-infested plants have been recorded in wind tunnels for *Diaeretiella rapae*, *Aphidius ervi*, and *Lysiphlebus testaceipes* (Scheehan and Shelton, 1989; Guerrieri et al., 1993; Grasswitz and Paine, 1993). Thus, different aphid parasitoid species appear to differ in their responses to chemical cues originating from different trophic levels in the system but, in the case of *A. ervi*, there is recent evidence that aphid-induced plant volatiles are important foraging cues (Guerrieri et al., 1993). In this study we extended these investigations of tritrophic influences on *A. ervi* foraging behavior, testing both nonhost aphid plant complexes and mechanically damaged plants in wind-tunnel bioassays and also developing bioassays involving a choice of two targets.

METHODS AND MATERIALS

A. ervi was reared on colonies of the pea aphid (*Acyrthosiphon pisum*) feeding on broad bean plants (*Vicia faba*). The black bean aphid (*Aphis fabae*) was also reared on *V. faba*. Aphid and parasitoid cultures were maintained in separate environmental chambers operating at 18 ± 1°C, 75 ± 5% relative humidity, and a 18L:6D photoperiod. Prior to their use in experiments, adult female wasps were mated within 24 hr of emergence and kept in cages with access to honey solution (50%) under the same environmental conditions as described above. All parasitoids used in the tests were 2 days old and naive, having had no exposure to either aphids or plants since emergence, and each individual was used only once. Most of the experiments were done using a laboratory culture that was established in 1992 from approximately 20 females reared from *A. pisum* collected in a lucerne crop on Rothamsted farm (British strain). For comparison, some experiments were also done using a culture established in 1992 from approximately 30 females reared from *A. pisum* in lucerne crops in Bulgaria (Bulgarian strain). All experiments were done 8–12 hr after the start of the 18-hr light period of the photoperiodic regime under which the parasitoids were reared.

Wind-Tunnel Experiments

The flight responses of *A. ervi* females to a range of olfactory cues were investigated using a wind tunnel that was specially designed for studying parasitoid flight behavior. This consisted of a rectangular Plexiglas chamber (90 × 30 × 30 cm) through which air was pulled by an electronically operated fan, controlled by a variable voltage regulator. Air entering the flight chamber was purified by passing through a charcoal and glass wool filter, and a laminar flow was obtained by means of a perforated mesh panel that reduced the eddy size and created a uniform airstream. Mesh panels were present at both ends of the tunnel to increase the uniformity of the airstream, essential for obtaining well-defined odor plumes. Titanium chloride and smoke from a candle wick were used to test plume structure with various targets present in the wind tunnel. The wind speed in all experiments was adjusted to 23 ± 2 cm/sec. Exhaust air was vented outside the room so as to avoid contamination of the room with test odors. Light intensity in the wind tunnel was 3600 lux at the insect-releasing site and the lighting was supplied by three U-shaped incandescent lights suspended above the tunnel. Tissue paper was placed between the lights and the tunnel roof to diffuse the light and thus prevent parasitoids from flying directly upwards after release. A black and white striped pattern was placed beneath the tunnel floor to aid visual orientation by flying parasitoids. All plants used in the

experiments were 10 cm high broad bean seedlings (cv. Sutton) with two or three pairs of leaves.

No-Choice Experiments. Single-target (no-choice) experiments were done using the following treatments: (1) host aphids (100–150), *A. pisum*, presented in a glass tube that was open at both ends and placed horizontally in the air-stream, nylon mesh over the ends of the tube prevented aphid escapes. (2) an uninfested plant, (3) a plant infested with 100–150 *A. pisum* 24 hr before testing (plant–host complex), (4) a plant that had previously been infested with 100–150 *A. pisum* but from which the aphids had been removed immediately before use in the bioassay (host damaged plant), (5) an uninfested plant that had been mechanically damaged using a pin to pierce the leaves, 100 pin pricks were administered to the plant immediately before the experiment, and (6) a plant infested with 100–150 *Aphis fabae*, an aphid species that is not a host for *A. ervi*.

Between 50 and 90 parasitoid females were tested individually by releasing them in the odor plume 20 cm downwind from the target, the release distance used by Guerrieri et al. (1993). They were released from a glass cylinder (4.5 cm diameter, 7.3 cm long), open at both ends, which was placed horizontally 10 cm above the tunnel floor and positioned so that the odor plume could pass through. The number of parasitoids taking off from the release site, the number performing direct flights oriented towards the target, and the number landing on the target were recorded. Each female was allowed a maximum of 5 min to respond and given only one opportunity to fly. The mean percentage response per day was calculated for each of the treatments (treatments were randomized so as to eliminate any time variation). Daily mean values were then averaged to give the overall response $\pm$ SE. The proportions responding (showing oriented flight and landing on the target) were subjected to logit transformation to normalize the data and then analyzed using a two-way analysis of variance to test the effect of strain and treatment on the response. Tukey multiple comparison tests were used to compare individual treatment means.

For all treatments, except plants infested with *A. fabae*, two strains of *A. ervi*, one originating in the UK and the other in Bulgaria, were tested and compared. Because both the British and Bulgarian strains of *A. ervi* showed the same patterns of responses in the single-target experiments, only the British strain, which was more readily available, was used in all other experiments.

Screen Experiments. To reduce the possible influence of visual cues on the flight responses, further tests were done in which a fine mesh screen was placed in front of the target, either uninfested plants or the plant–host complex. Responses to screened targets were compared with those to unscreened targets. Three treatments were used: (1) an uninfested *V. faba* plant, (2) a screened, uninfested plant, and (3) a screened plant that was infested with 100–150 *A. pisum*, 24 hr before the experiment.

The experiment was repeated on three separate days and a minimum of 12 parasitoids were tested for each treatment on each day. The proportions responding (showing oriented flight and landing on the target) were subjected to logic transformation to normalize the data and then analyzed using a one-way analysis of variance. Tukey multiple comparison tests were used to compare individual treatment means.

Dual-Choice Experiments. The dual-choice experiments were undertaken to reduce the problem of day-to-day variation in parasitoid responsiveness, without the need for complex randomizations or trying to complete sufficient replications of all no-choice treatments in any one day. Dual-target (choice) experiments were done using the following target combinations: (1) an uninfested plant vs. the plant–host complex, (2) an uninfested plant vs. a host-damaged plant, (3) the plant–host complex vs. a plant infested with the nonhost *A. fabae*, (4) an uninfested plant vs. a plant infested with *A. fabae*, (5) an uninfested plant vs. a mechanically damaged plant, (6) an uninfested plant vs. host aphids (*A. pisum*), (7) the plant–host complex vs. a host-damaged plant, and (8) a host-damaged plant vs. a host-damaged plant that had been washed to remove water-soluble compounds associated with aphid honeydew and exuviae.

All the plant–aphid complexes consisted of a *V. faba* plant that had been infested with 100–150 aphids (either *A. pisum* or *A. fabae*) 24 hr before the experiment. The targets were placed 10 cm apart, and smoke tests showed that they produced separate plumes that began to merge approx. 45 cm downwind. Therefore, the parasitoid release tubes were sited a little over 45 cm downwind from the targets. The number of parasitoids taking off and the number landing on one of the targets were recorded. Each parasitoid was allowed 5 min to respond and between 88 and 110 individuals were used for each experiment. A χ^2 test was used to test whether there was a significant preference between the targets. Only those parasitoids that landed on one of the targets were included in the analysis.

Y-Tube Olfactometer Experiments

A Y-tube olfactometer was also used to investigate the responses of *A. ervi* females when presented with a choice of odors in the absence of any visual cues. A pump was used to pull air through activated charcoal and a molecular sieve so that it was purified of any contaminating odors before passing over the target and entering the Y-tube. The airflow through each of the olfactometer arms was maintained at 800 ml/min. In the experiments parasitoids were given a choice between an undamaged plant and either *A. pisum* aphids or the plant–host complex. Fifty female parasitoids were tested, individually, in each experiment.

The first choice of each parasitoid was noted as well as its final choice after 5 min. If during these 5 min it reached the end of the arm of its choice, this was regarded as a final choice. A χ^2 test was used to determine significant differences between numbers of parasitoids choosing different odor treatments or arms of the olfactometer.

RESULTS

Wind-Tunnel Experiments

No-Choice Experiments. ANOVA analysis showed that both parasitoid strain ($P < 0.05$) and treatment ($P < 0.001$) significantly affected the parasitoid response, but there was no interaction ($P = 0.17$). A greater proportion ($P < 0.05$) of the Bulgarian strain landed on the targets compared with the British strain (Figure 1). For both strains the plant–host complex and the host-damaged plant were equally attractive, and both these targets were significantly more attractive than either the undamaged plant and host aphids ($P < 0.05$). Mechanical damage did not significantly increase the attractiveness of a plant undamaged by aphids, although both undamaged and mechanically damaged plants were more attractive than aphid hosts that had been removed from the plant (Figure 1). The presence of the nonhost aphid *A. fabae* on plants did not significantly increase parasitoid responses, compared with those to undamaged plants, although this treatment was only tested with the British strain of *A. ervi* (Figure 1). These results were unaltered when those parasitoids that exhibited oriented flight but failed to land on the target were included in the analysis.

Screen Experiments. A significantly greater percentage of parasitoids ($P < 0.05$) landed on a screened plant–host complex than on either a screened or unscreened undamaged plant (Figure 2). The responses to screened and unscreened undamaged plants were not statistically different (Figure 2).

Dual-Choice Experiments. In all choice experiments, 88% or more of the parasitoids took off from the release tube and oriented upwind, but the number is not presented as we were interested in the final choice between the targets. There were no significant differences in the percentage landing on the two targets in choices between: the plant–host complex and a host-damaged plant (22.7%:17.0%); a host-damaged plant and a washed host-damaged plant (22.3%:20.2%); an undamaged plant and a plant infested with *A. fabae* (11.8%:17.6%); and an undamaged plant and a mechanically damaged plant (11.6%:8.4%) (Figure 3).

Significantly more parasitoids landed on the plant host complex than on an undamaged plant (35.5%:10.7%; $P < 0.05$) and significantly more landed on a host-damaged plant than on an undamaged plant (20.0%:3.8%; $P < 0.05$) (Figure 3). In the choice test between a plant infested with the host *A. pisum*

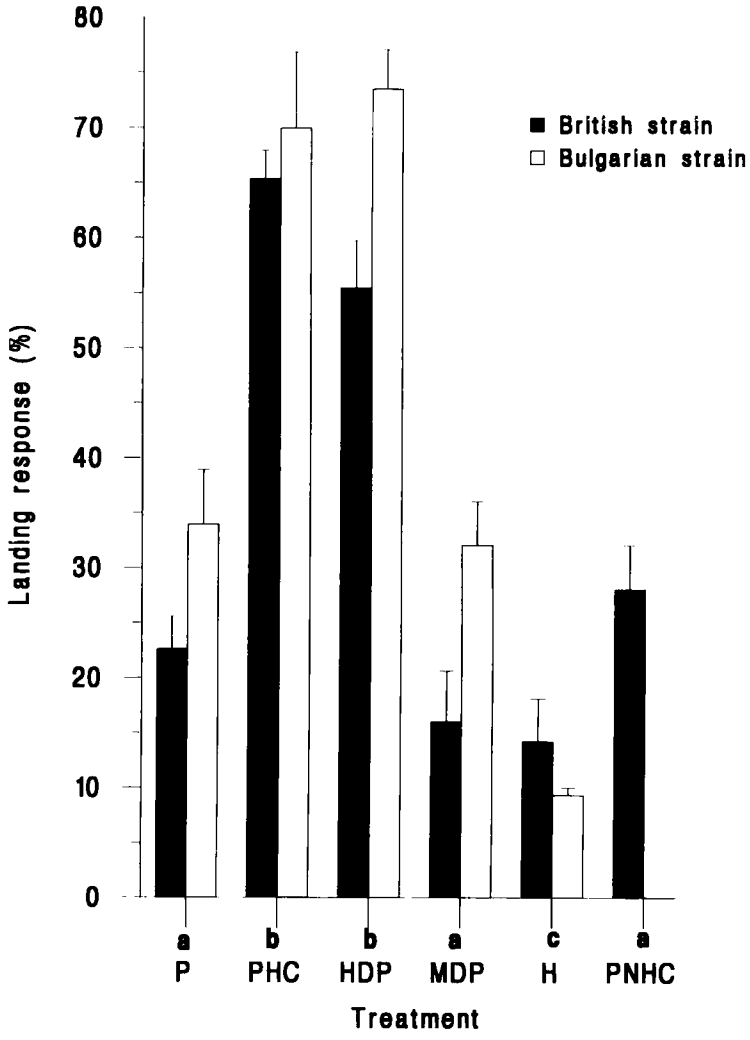

FIG. 1. Percentage of British and Bulgarian strain *Aphidius ervi* females landing on targets in no-choice wind-tunnel experiments. P: undamaged *Vicia faba* plant; PHC: plant-host (*Acyrthosiphon pisum*) complex; HDP: host-damaged plant (aphids removed); MDP: mechanically damaged plant; H: host (*A. pisum*); PNHC: plant-nonhost (*Aphis fabae*) complex. Two-week-old *V. faba* seedlings were used in the experiments. Analysis of variance was performed on the data after a logit transformation. Treatments with different letters beneath were significantly different ($P < 0.05$) based on Tukey multiple comparison tests.

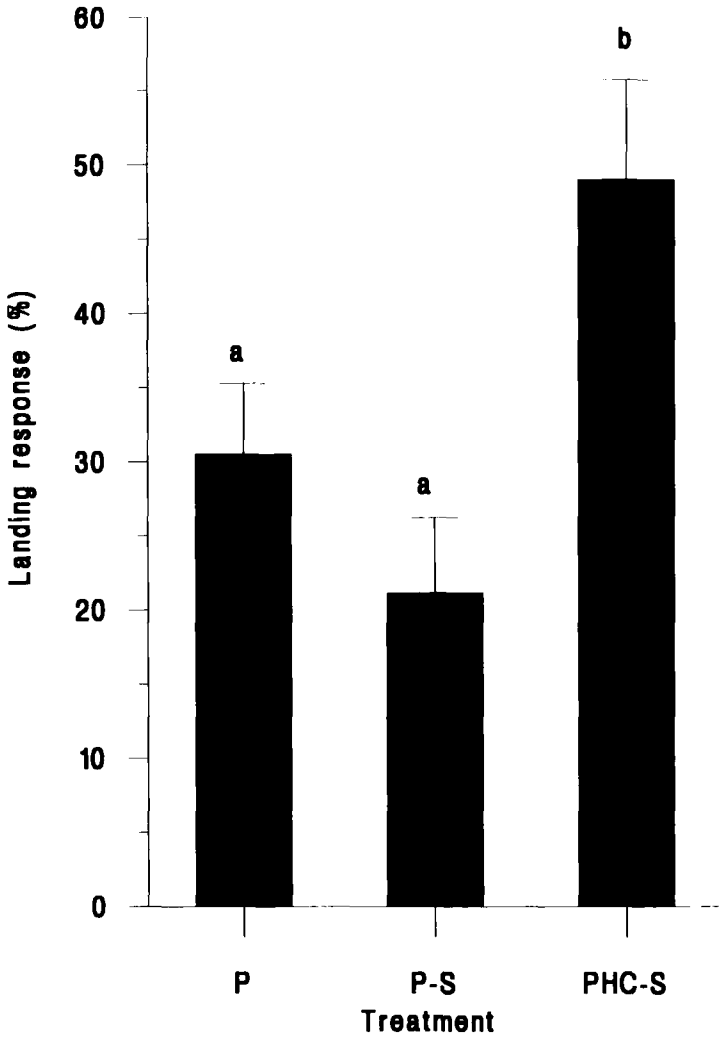

FIG. 2. Percentage of *Aphidius ervi* females landing on undamaged *Vicia faba* plants (P) and on a screen placed in front of either an undamaged plant (P-S) or a plant–host (*Acyrthosiphon pisum* complex, (PHC-S) in no-choice wind-tunnel experiments. Analysis of variance was performed on the data after logit transformation. Treatments with different letters were significantly different ($P < 0.05$) based on Tukey multiple comparison tests.

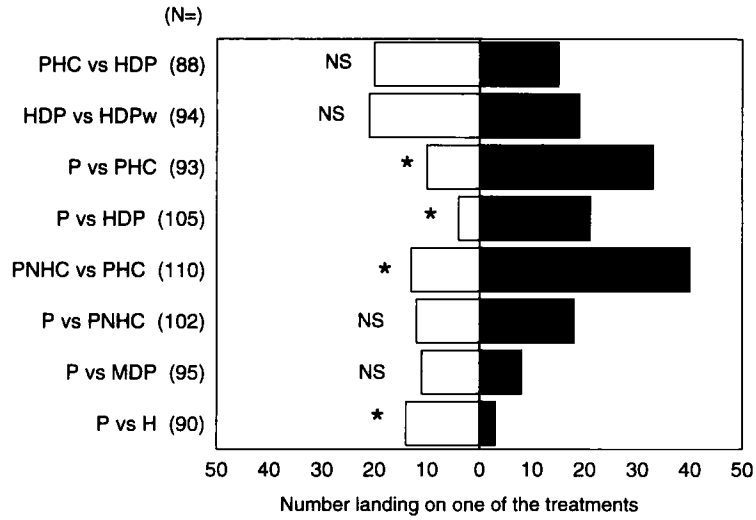

FIG. 3. Percentage of *Aphidius ervi* females landing on each target in dual-choice wind-tunnel experiments. P: undamaged *Vicia faba* plant; PHC: plant–host (*Acyrthosiphon pisum*) complex; HDP: host-damaged plant (aphids removed); HDPw: host-damaged plant (aphids removed) washed with distilled water; MDP: mechanically damaged plant; H: host (*Acyrthosiphon pisum*); PNHC: plant–nonhost (*Aphis fabae*) complex. Two-week-old *V. faba* seedlings were used in the experiments. (*Significant difference between targets, χ^2 test, $P < 0.05$).

and a plant infested with the nonhost aphid *A. fabae*, significantly more parasitoids landed on the former (36.4%:11.8%; $P < 0.05$). Finally, significantly more parasitoids landed on an undamaged plant than on an open-ended tube containing host aphids (15.6%:3.3%; $P < 0.05$).

Y-Tube Olfactometer Experiments

In both experiments [undamaged plant (P) vs. the plant–host complex (PHC) and undamaged plant vs. host (H) aphids] there were no significant differences between the numbers of parasitoids entering each of the two olfactometer arms as a first choice (22 P vs. 26 PHC, $P > 0.05$; 28 P vs. 21 H, $P > 0.05$) (Figure 4). However, significantly more ($P < 0.05$) made a final choice of the plant–host complex (32) than chose the undamaged plant (14) and significantly more ($P < 0.05$) made a final choice of the undamaged plant (31) than chose the host aphids, *A. pisum* (14). Of the 50 parasitoids used in each experiment only two in the first experiment and one in the second failed to enter either

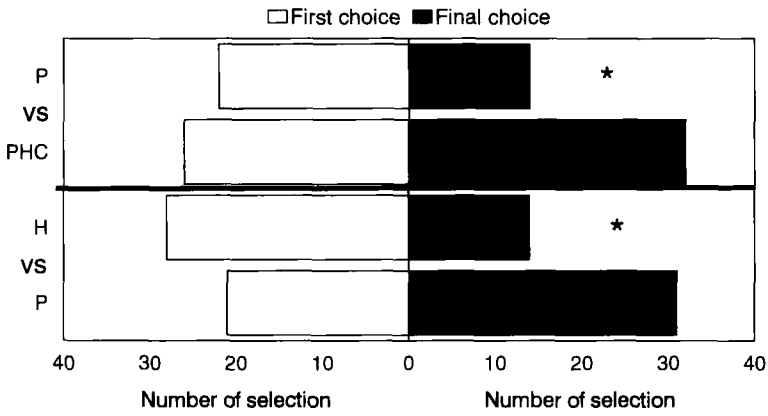

FIG. 4. Responses of *Aphidius ervi* females to undamaged plant *Vicia faba* (P) vs. host aphids (*Acyrthosiphon pisum*) (H) and plant–host (*A. pisum*) complex (PHC) vs. undamaged plant (P) in a Y-tube olfactometer. (*Significant difference between arms in final choices only, χ^2 test, $P < 0.05$).

olfactometer arm, while two in the first and four in the second failed to make a definite final choice after 5 min. Most of the parasitoids either remained in the first arm they entered or changed arms only once.

DISCUSSION

Our results confirm the main conclusions of the study by Guerrieri et al. (1993), that both the *Vicia faba/Acyrthosiphon pisum* plant–host complex and plants damaged by *A. pisum* (but from which the aphids had been removed) are more attractive odor sources than either undamaged plants or aphids alone. The response of parasitoids to odors in the Y-tube olfactometer and the flight responses to screened targets in the wind tunnel indicate that visual cues are not essential, at least in the long-range stages of *A. ervi* foraging behavior. As many parasitoids (almost 50%) orient upwind to odors from the plant–host complex placed behind a screen, it proves that odor alone can elicit oriented upwind flight. Subsequent experiments with the wind tunnel have shown that parasitoids will fly upwind to filter paper targets treated with chemical extracts isolated from the plant–host complex (Du et al., unpublished), emphasizing that the visual cue provided by the plant is not essential for a response. However, visual cues are known to be important in later stages of the host location process of some parasitoids (Michaud and Mackauer, 1995; Wäckers, 1994).

The weak responses observed to undamaged plants and to host aphids in the absence of the plant suggest that chemicals emitted from these sources are not efficient cues for foraging *A. ervi* during host habitat and host location. In fact, the weakness of the flight response to host aphids in a glass tube is emphasized by the fact that some landing (8%) occurred on an empty glass tube. Thus, although aphid-derived volatile cues are very reliable, because they guarantee the presence of the host, they appear to be much less important as *A. ervi* flight orientation cues than are volatiles from the plant–host complex, presumably because they are relatively difficult to detect. In contrast, plant odors are much more detectable but, unless they are linked directly to the presence of the parasitoids' host, are not very reliable beyond the location of appropriate habitats in which to forage. *A. ervi* has overcome this problem by evolving strong responses to plant odors directly associated with host damage and can distinguish from a distance between a plant infested with or recently damaged by host aphids and an undamaged plant. The release of herbivore-induced plant volatiles that act as reliable and detectable host-location cues for parasitoids and predators has previously been demonstrated for several other tritrophic systems (Dicke et al., 1990; Turlings et al., 1990; Whitman and Eller, 1990). The fact that *A. ervi* responded just as strongly to host-damaged plants whether or not the aphids were still present on the plant suggests that aphid-induced volatiles are the main stimuli. This is reinforced by the continued strong response by parasitoids to damaged plants from which aphid honeydew and exuviae have been removed by washing with water. It is still possible, of course, that some aphid-derived, non-water-soluble chemicals remained on the leaf surfaces.

The reliability of the chemical cues produced by aphid-damaged plants would be greatly reduced if the same range of plant volatiles was emitted following all forms of plant damage. Mechanical damage to plants is known to increase their attractiveness to parasitoids in some tritrophic systems (Elzen et al., 1993; Eller et al., 1988a,b; Ding et al., 1989; Turlings et al., 1990; McAuslane et al., 1991; Steinberg et al., 1993). However, mechanical damage to the leaves of *V. faba* plants did not increase their attractiveness to *A. ervi* in our wind-tunnel trials, but this result needs to be treated with caution because the plants were damaged immediately before they were used as targets. Plants may have been tested too quickly for the completion of changes in volatile emissions induced by the damage. There is evidence from other studies that the emission of specific plant volatiles following mechanical damage is intermittent and that the induced changes in emissions can wane very quickly unless the damage is repeated at regular intervals (Tumlinson et al., 1992; Steinberg et al., 1993).

Mechanical damage to plants results in an increased emission of C_6 alcohols, aldehydes, and their esters, the so-called green leaf volatiles (Mattiacci et

al., 1994). Although several parasitoid species are known to be attracted to these green leaf volatiles (Whitman and Eller, 1990), their ratio can be important in determining an insect's perception of the plant (Visser et al., 1979; Visser, 1986). Changes in volatile ratios due to mechanical damage have been reported to confuse the perception of aphids to host plant odors (Nottingham et al., 1991) and similar confusion may also have occurred with *A. ervi*, causing its lack of response to the mechanically damaged target. Further work on this aspect is obviously needed. Nevertheless, it has been shown that some natural enemies do discriminate between the volatiles of a mechanically damaged plant and those of an herbivore-damaged plant (Vet and Dicke, 1992; Turlings et al., 1990; Dicke, 1994).

The specificity, and therefore reliability, of the semiochemical cues emitted by the plant–host complex is emphasized by the fact that *A. ervi* showed the same weak response to plants infested by the nonhost aphid *A. fabae* as it did to undamaged plants. Thus *A. ervi* appears to have overcome the reliability–detectability problem (Vet and Dicke, 1992), by responding to olfactory cues produced by the plant when it is damaged by an appropriate host species. The dual-choice experiments demonstrated that *A. ervi* females could distinguish between plants infested with each of the two aphid species tested, when equal numbers of aphids had been feeding on the plants for the same length of time. However, it is possible that different aphid species stimulate the production of host-induced volatiles by the plant at different rates, which could account for parasitoid choice in the wind-tunnel tests. This is currently being investigated by generating dose–response curves for the two aphid species. Nevertheless, different aphid species may induce different changes in plant volatile emissions, and comparisons of the feeding biology of these two aphids may provide clues to the physiological and biological processes involved in herbivore-induced volatile emission. Air entrainment samples of uninfested bean plants and plants infested with *A. pisum* or *A. fabae* had significantly different chemical compositions (Du et al., unpublished). Previous studies of other tritrophic systems have also produced evidence that herbivore-induced plant synomones may be specific for the herbivore species involved (Dicke, 1988, 1994; Turlings et al., 1990; Takabayashi et al., 1991). In the single-target wind-tunnel experiments it was not possible to complete tests of all targets within one day, and it was observed that the general responsiveness of the parasitoids could vary from day to day. Such variation has been noted in other wind-tunnel studies with parasitoids and may be caused by changes in barometric pressure and, in particular, the direction of those changes during the course of an experiment (Steinberg et al., 1992). However, the results from the choice experiments confirmed the hierarchy of responses deduced from the single-target experiments, even though the target distance in the dual-choice experiments was greater (45 cm) than in the no choice experiments (20 cm). The overall percentage of parasitoids landing

on the plant–host complex and host-damaged plant targets was lower in the choice experiments (Figure 3) than when these targets were presented alone (Figure 1), which may have been partly due to the increased flight distances.

Although the Y-tube olfactometer detects short-range responses to volatile cues by walking parasitoids, whereas the wind tunnel detects long-range flight responses, the results suggest that the same plant-associated semiochemical cues are playing a role in both situations. Previous studies had shown that *A. ervi* females responded to both *A. pisum* and *Vicia faba* leaves in a Y-tube olfactometer when these were tested separately (Powell and Zhang, 1983). The parasitoids were presented with a choice in the present study that demonstrated a preference for the undamaged plant over *A. pisum*. The aphid-derived semiochemical cues may operate most efficiently at close range during the later stages of host location, when visual cues also come into play.

A legitimate criticism of many Y-tube studies is a failure to account for wrong initial decisions made by the insect while searching within the apparatus. This was overcome by recording the final choice of olfactometer arm after a set time period. Many of the parasitoids that made a "wrong" first choice either reversed their decision or failed to make a definite final choice of olfactometer arm. Thus, if the final choice is considered, this type of olfactometer is useful as a fast and efficient initial screen in foraging behaviour studies.

In the tritrophic system involving *V. faba*, *A. pisum*, and *A. ervi*, naive parasitoids overcome the reliability–detectability problem by utilizing cues coming from the plant when the appropriate host aphid has fed upon the plant. Recent work indicates that experienced *A. ervi* females also use the third solution proposed by Vet and Dicke (1992), associative learning, to overcome this problem (Du et al., in prepration). Our data suggest that an active series of physiological and biochemical processes occur within the plant as a result of aphid feeding, leading to quantitative and/or qualitative changes in the volatiles emitted, and that the parasitoid can distinguish between plants infested with host and nonhost aphid species. We are currently investigating how many aphids and for how long (aphid hours) are needed to induce these changes, how long the effects last once the aphids have been removed, and whether there is a systemic release of herbivore-induced plant signals from uninfested parts of the plant.

(Received May 25, 1995; accepted April 23, 1996)

Abstract—Twenty-six compounds have been identified from fresh orange airborne volatiles, the most abundant being limonene and alloaromadendrene. Ethyl- and butylhexanoates were found in middle concentrations, whereas the other compounds occur at low levels. Electroantennograms recorded from *Ceratitis capitata* Wied. (males and females) revealed limonene, butyl hexanoate, dihydrocarvone, and limonene oxide to be most active. In the case of dihydrocarvone, 4-ethyl acetophenone, and carvone, female antennae give greater responses than antennae of males. Limonene oxide was more active for males than females. Total airborne volatiles recovered from oranges elicited high EAGs, with females being more sensitive than males.

Key Words—Oranges, fruit volatiles, odor, *Ceratitis capitata*, Mediterranean fruit fly, Diptera, Tephritidae, olfaction, electroantennogram, electrophysiology.

INTRODUCTION

Ceratitis capitata (Wied.) is a highly polyphagous species capable of adapting itself to a great variety of fruits. In Florida (USA) up to 175 potential host plant species are described including apricots, peaches, nectarines, oranges, cherries, and plums. Females respond to host-plant stimuli such as color, shape, size,

and volatile substances of the fruit, and oviposit by sticking the tip of the ovipositor into the epidermis and laying eggs in small two- to eight-unit packs (Hippe, 1987; Levinson et al., 1987). When the larvae hatch they feed by tunneling through these fruits.

Trimedlure, a synthetic attractant, attracts only males and mimics the sexual pheromone or the lek-forming pheromone (Prokopy and Roitberg, 1984; Shelly et al., 1993). In order to develop new less-polluting detection and control methods, it may be useful to find female-attracting compounds. These could give rise to a great number of applications, since they could be combined with pesticides, sterilizing agents, and entomopathogenic microorganisms in strategically situated traps.

Several papers have been published on plant components, extracts, and essential oils that attract *C. capitata* females and males (Teranishi et al., 1987; Warthen and McInnis, 1989). From the essential oil of *Angelica arcangelica* α-copaene was isolated; it is more attractive to males than trimedlure, although females are not attracted. α-Copaene was later isolated from other essential oils, including that of orange (Fornasiero et al., 1969; Jacobson et al., 1984). Guerin et al. (1983) and Light et al. (1988) found that the antennae of *C. capitata* are more sensitive to compounds with six carbon atoms than to other chain lengths. Dickens et al. (1990) observed an increase in the number of females attracted to traps when green leaf volatiles [especially (*E*)-2-hexenal] were added to the volatiles released by males.

Within this scope, we have identified volatile compounds emitted by oranges (OAV) and studied their EAG activity on antennae of males and females of *C. capitata*.

METHODS AND MATERIALS

Oranges (navel variety) were collected in Buñol (Valencia, Spain) during March (1991–1992). Fruits were introduced into a sealed glass bottle through which a clean airflow (60 ml/min) was passed. The air was cleaned by passing successively through filters of 20% potassium permanganate, charcoal, and Porapak Q. The airflow carried the orange airborne volatiles (OAV) into a stainless steel column (15 × 1 cm) packed with 10 mg porapak Q (Jang et al., 1989). Approximately 10 fruits were placed into the bottle and changed every four days up to a period of 20 days. Volatiles trapped on Porapak Q were extracted by a rinse with 20 ml of dichloromethane followed by pentane in a Soxhlet extractor for 12 hr.

OAV were analyzed by GLC using a Perkin-Elmer Sigma 3B gas chromatograph with a flame ionization detector and Hewlett Packard HP3396A recorder. The analytical column was HP Ultra 1 (methyl silicone gum; 25 m ×

0.2 mm × 0.33-μm film thickness). Chromatography conditions were: initial temperature 50°C; rising 4°C/min to 180°C and then 10°C/min to 280°C; N_2 was the carrier gas at 1.8 ml/min.

In order to identify the minor components, the total extract was fractionated with the same chromatograph to which a 2:8 splitter was coupled at the end of the column to collect fractions. For this purpose an HP-1 column (methyl silicone gum 5 m × 0.53 mm × 2.65-μm film thickness) was used. Conditions were: initial temperature 50°C, 5 min; rising 3°C/min to 120°C and then 10°C/min to 280°C; N_2 was the carrier gas at 6 ml/min. The different fractions were collected in stainless steel capillary tubes having a U-shaped loop immersed in acetone–Dry Ice (25:75) at −70°C, and an end branch placed into a glass tube containing 0.5 ml dichloromethane kept at −70°C. Capillaries were washed with dichloromethane.

Fractions were analyzed by GLC-MS using a Hewlett Packard 5988A quadrupole with electronic impact at 70 eV. The analytical column was HP Ultra 2 (5% phenyl methyl silicon; 25 m × 0.2 mm × 0.33-μm film thickness). Chromatography conditions were: initial temperature 50°C; rising 4°C/min to 180°C and then 10°C/min to 280°C; He was the carrier gas at 1.8 ml/min).

Identification was also verified through calculation of Kovats index numbers and standards provided by Aldrich Chemical Company Inc. (Steinheim, Germany), Sigma Products (Deisenhofen, Germany), Fluka Chemie AG (Buchs, Switzerland), Alfa Products (Karlsruhe, Germany), Extrasynthese (Genay, France), and Merck-Schuchhardt (Darmstadt, Germany); or synthetized in our laboratory.

Activity Assays in EAG. C. capitata was reared at 26 ± 1°C, 70 ± 5% relative humidity and 16L:8D photoperiod. Adults were separated by sex and kept on a diet of sugar, hydrolyzed proteins, and water. Virgin males and females were used five to six days after emergence.

Compounds at six different doses between 10^{-2} and 10^3 μg dissolved in 10 μl of dichloromethane were impregnated on glass fiber filter paper (1 cm^2). The solvent was evaporated, and the paper was introduced into a Pasteur pipet. A flow of 300 ml/min air was passed for 1 sec through the Pasteur pipet and mixed with a 1 liter/min humid airstream at a point 5 cm from the insect's antenna. Dichloromethane (10 μl) was used as a control and 100 μg of hexanol as standard. There were no significant differences between male and female responses to the standard signal (7.8 ± 0.8 mV). The response of each substance was corrected with those of the control (0.5 ± 0.02 mV), and they were given with respect to the standard according to the following formula: {[mV(test) − mV(control)] × 100}/[mV(hexanol) − mV(control)]. Each assay (one substance × six doses) was repeated with five different males and females. Air was passed during a 2-min interval between tests (Light et al., 1988). A silver recording electrode made contact with the third antennal segment, whereas the

silver indifferent electrode was immersed in saline Ringer's solution. The measuring system consists of two nonamplifying buffers, each of them connected to an electrode for signal conditioning, with a low impedance output. Both output systems were connected to an amplifying module; a high-precision DC level fixer and a low-pass filter were used to deal with the contact potentials that were amplified. The signal was recorded by means of a Tektronic TDS 310 oscilloscope coupled with an IBM PC-AT and a Hewlett Packard LaserJet IIP printer.

Statistical data management was carried out by a mixed analysis of variance (ANOVA), which takes into account not only the structure of the experiment (mixture of crossed and hierarchical factors) but also the nature of factors (combination of fixed and random effects) (Kendall and Stuart, 1976; Dixon, 1992). Apart from simple effects, the statistical model evaluates the following interactions: substance–sex, substance–concentration, concentration–sex, and substance–concentration–sex.

RESULTS

Composition of Fresh Orange Airborne Volatiles. Orange volatiles collected on Porapak Q were fractioned into four parts by using semipreparative GLC with a splitter. Figure 1 shows the analytical chromatograms of the four fractions. The compounds were identified by GLC-MS, Kovats index, and in some cases by comparison with authentic standards (Table 1). The most abundant substances were limonene and alloaromadendrene. 1,2-Diethylbenzene, 1,3-diethylbenzene, *n*-butyl *n*-hexanoate, and *n*-hexyl *n*-hexanoate were found at intermediate levels, whereas very small amounts of the other compounds were detected.

Activity Assays. Figure 2 shows EAG responses for 13 identified products at six concentrations tested with both females and males. Table 2 summarizes the ANOVA results and shows a statistical significance for most terms of the model. The significance of the interactions in the product factor also shows that the differences in the EAG responses between compounds depend not only on their load on filter paper but also on the sex of the fly.

The response was greater at the highest doses along the range tested, except for 4-ethyl acetophenone, which yielded a maximum response at 100 μg from female antennae. For other substances, the antennae become saturated at low doses, for example, at 10 μg in the case of carveol and nootkatone (both sexes); at 10 μg and 100 μg for carvone and 4-ethyl acetophenone, respectively (males); and at 100 μg for dihydrocarvone (females). P $\times$ C interaction indicated a difference in the effect of concentration (within the range tested) depending on the product used. The increase in the response with increased concentration was

greatest for limonene, limonene oxide, dihydrocarvone, and caryophyllene oxide, and smallest for 1,3-diethylbenzene and nootkatone. The significance in P × S interaction is due to the high response of limonene oxide in males and dihydrocarvone in females.

FIG. 2. Dose-response curves of EAGs for *C. capitata* females and males at serial dilutions (from 10^{-2} to 10^{3} µg) of substances identified in fresh orange airborne volatiles. Vertical lines show the ± standard error (N = 5). A 100% response approximately corresponds to 8 mV.

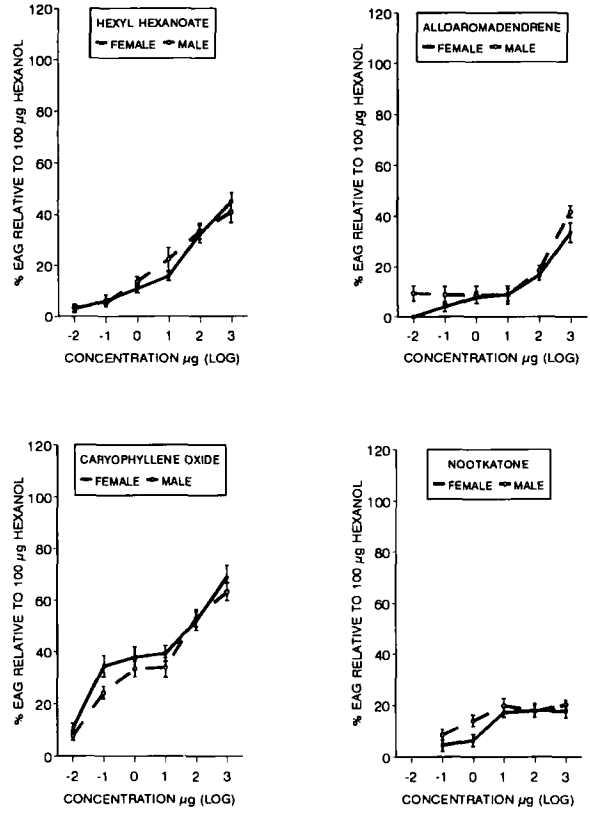

FIG. 2. Continued

Figure 3 shows the responses to each substance at their optimum doses and that of the total extract of OAV at the 1000-µg dose. The most active compound for females was dihydrocarvone, and the response was compared to that obtained for total OAV, followed by limonene, butyl hexanoate, 4-ethyl acetophenone, and caryophyllene oxide. Antennae of females gave a significantly much higher signal than did males ($P < 0.05$) to dihydrocarvone, 4-ethyl acetophenone, carvone, and total OAV. The most active compounds for males were limonene, limonene oxide, dihydrocarvone, butyl hexanoate, and total OAV.

DISCUSSION

Limonene is the most abundant compound in both orange essential oil and in the OAV and is a constituent of the volatiles released by males of *C. capitata* (Jang et al., 1989). Another major compound in OAV is alloaromadendrene, which has not been described in the orange essential oil but is present in that of *Sideritis hirsuta* (Mateo et al., 1983) and others (Connolly and Hill, 1991). Butyl and ethyl hexanoate found in OAV at intermediate levels have been described from orange essential oil.

Some other chemicals found in OAV at very low concentrations (limonene oxide, menta-2,8-dien-1-ol, dihydrocarvone, carveol, carvone, β-copaene, γ-bisabolene, cadinene, caryophyllene oxide, and nootkatone) are minor components in the orange essential oil (McLeod et al., 1988; Sugiswa et al., 1989; Schreier et al., 1977), 1-Isopropyl-4-methylbenzene is a component of the essential oil of *Catasetum* and *Clowesia* (Knudsen et al., 1993), ethyl acetophenone occurs in *Ophrus insectifera* L. y *O. speculum* Link (Knudsen et al., 1993), aromadendrene is found in *Eucaliptus delegatensis* (Connolly and Hill, 1991), cascarilladiene is in present *Guisa aromatica* (Claude-Lafontaine, et al., 1976), glogulol occurs in *Eucaliptus globulus*, sphatulenol is present in *Eucaliptus sphatulata* (Connolly and Hill, 1991), and 1(10)-aristolen-2-one is found in *Aristolochia longa* (De Pascual et al., 1983). Clovene and 2,6-di-t-butyl-1,4-benzoquinone have not been described as components of plant aromas.

1,2-Diethylbenzene and 1,3-diethylbenzene, which occur at intermediate concentrations, may be artifacts of Porapak Q, although they have been described

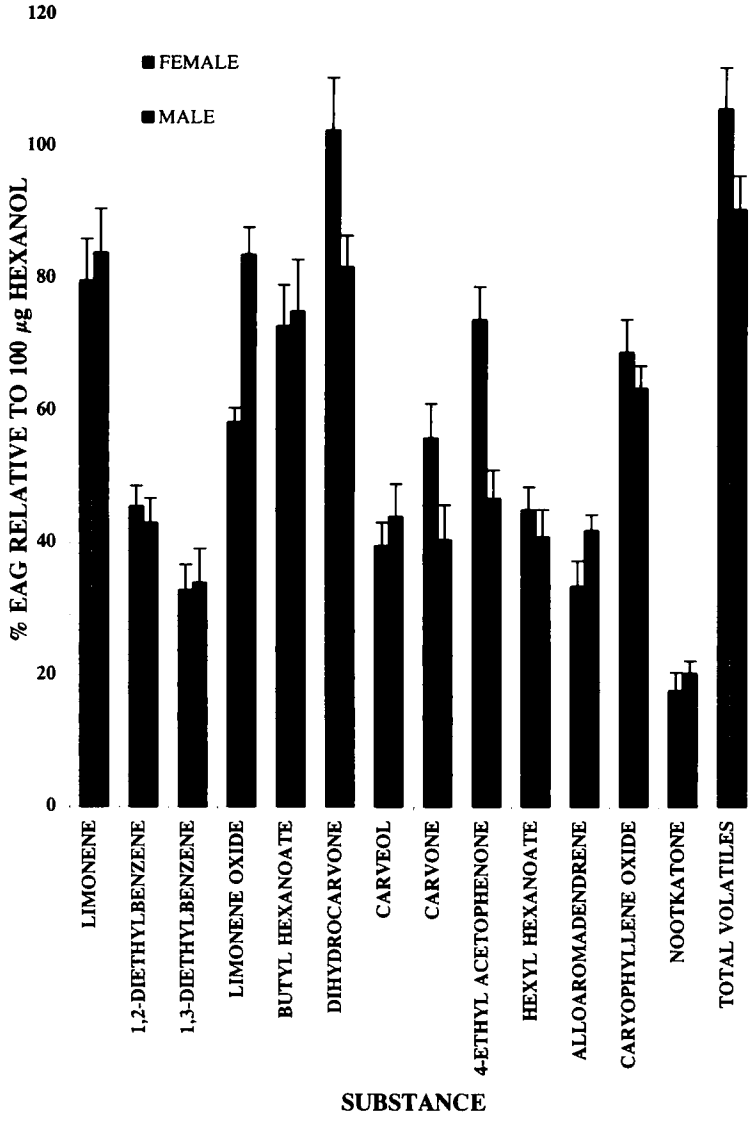

FIG. 3. Mean EAG optimal responses from antennae of *C. capitata* females and males to the compounds identified in fresh orange airborne volatiles. The dose represented is 1000 μg for all compounds, except 4-ethyl acetophenone and carveol in females (100 μg). Vertical lines show the ± standard error ($N = 5$). A 100% response approximately corresponds to 8 mV.

as constituents of the essential oil of *Syringa* (Knudsen et al., 1993). Dihydrocarvone, 4-ethyl acetophenone and carvone produced a much higher response from females than from males. The most active compounds to females were limonene, 4-ethyl acetophenone, butyl hexanoate, dihydrocarvone, and caryophyllene oxide. Jang et al. (1989) found that ethyl acetate, geranyl acetate, (*E*,*E*)-α-farnesene, myrcene, linalyl acetate, ethyl butyrate, nonyl acetate and (*E*)-β-farnesene, all isolated from volatiles released by males, elicited larger EAGs in females than in males. Light et al. (1988) found that females have a higher sensitivity than males for 1-undecanol, (*E*)-2-buten-1-ol, (±)-2-heptanol, (±)-1-octen-3-ol, hexanal, nonyl acetate, decyl acetate, and decanoic acid. The compounds ethyl acetate, methyl octanoate, myrcene, (*Z*)-3-hexen-1-ol, β-felandrene, ethyl butyrate, hexanal, and δ-decalactone identified in the essential oil of nectarines elicited higher responses in females (Light et al., 1992).

The most active compounds in the EAG for both males and females were limonene (one of the most abundant in orange volatiles), butyl hexanoate (intermediate concentration in the volatiles), and dihydrocarvone, limonene oxide, and caryophyllene oxide (low concentrations in the volatiles). There does not seem to be a relationship between the concentration of a compound in the volatiles and the magnitude of the EAG response. This agrees well with the results obtained by Light et al. (1992) in nectarines.

The total OAV elicited larger EAGs, females being more sensitive than males. There were no significant differences between the response to dihydrocarvone and total OAV. Levinson et al. (1990) assayed the essential oil of some fruits by EAG and obtained the highest responses to orange, lemon, and bergamot. Higher signals were obtained in females than in males in all instances.

(Received September 29, 1995; accepted April 23, 1996)

Abstract—Previous research identified the presence of unique semivolatile compounds in alfalfa weevil (*Hypera postica* Gyllenhal) (AW) -resistant *Medicago* accessions. These compounds may impart repellency to AW in alfalfa (*Medicago sativa* L.). The objective of our study was to analyze within- and between-population variation for four of these unique semivolatile compounds across eglandular and glandular-haired *Medicago* accessions. Seven *Medicago* accessions were evaluated under greenhouse conditions in an experiment arranged as randomized complete blocks with four replicates. Volatile compounds were extracted via supercritical fluid extraction and then quantitatively analyzed for levels of 2,7-dimethyl, 2,6-octadienol; *cis*-geraniol; 1,(*E*)-8,(*Z*)-10-tetradecatriene; and 1-hepten-3-ol. Significant difference ($P < 0.05$) among entries were observed for 2,7-dimethyl,2,6-octadienol; *cis*-geraniol; 1, and (*E*)-8,(*Z*)-10-tetradecatriene. These compounds were found only in glandular-haired accessions. There were no significant differences in levels of 1-hepten-3-ol. Our findings demonstrate that the genetic incorporation of 2,7-dimethyl, 2,6-octadienol; *cis*-geraniol; 1, and (*E*)-8,(*Z*)-10-tetradecatriene into cultivated alfalfa will require interspecific crossing. Alfalfa weevil behavioral tests using these compounds must be conducted prior to such crosses in order to ascertain the efficacy of repellency by these compounds.

Key Words—*Medicago* spp., alfalfa, volatiles, grandular hairs, insect repellents, *Hypera postica* Gyllenhal, germplasm.

INTRODUCTION

The Egyptian and western strains of alfalfa weevil (AW) are serious economic pests of alfalfa in the western United States of America (Hsiao, 1993). Because no AW-resistant cultivars exist (Hodgson and Posler, 1986) and economic losses are high (Kennedy et al., 1987), other means have been employed to curb this injurious pest. Early harvest, chemical control, and biological control have all been attempted with only marginal success. (Hsiao, 1993; Danielson et al., 1987b; Keith et al., 1982; Manglitz and Ratcliffe, 1988; Moffett et al., 1986; Anonymous, 1984).

Researchers have identified a number of wild *Medicago* species exhibiting significant AW resistance (Barnes and Ratcliffe, 1969; Johnson et al., 1980a,b; Shade et al., 1975). In some cases, nonpreference was attributed to deterrence caused by erect glandular hairs present on leaves and stems of wild *Medicago* spp. Trichome density has also been suggested, but not correlated, as an agent of repellency (Danielson et al., 1986, 1987a,b; Johnson et al., 1981). Other studies have focused on plant volatile compounds, in addition to trichomes, as contributors to antixenosis (Core et al., 1994; Doss et al., 1989, Doss and Johnson, 1991).

Core et al. (1994) isolated and tentatively identified 97 plant volatile and semivolatile compounds from three wild *Medicago* species and five alfalfa cultivars. Of these 97 compounds, 17 were qualitatively unique to AW-resistant, glandular-haired *Medicago* species. Three of the 17 compounds were observed in relatively high concentrations. If these volatiles compounds are found in high concentrations in glandular-haired *Medicago* species exhibiting alfalfa weevil repellency, they may represent biologically active compounds. Furthermore, if significant variation for these compounds is present in alfalfa cultivars, then it may be possible to increase selectively the emanation of those volatiles exhibiting biological activity. Otherwise, interspecific hybridization and selection will be required to introgress volatiles from the wild species into cultivated types. The objective of our study is to analyze within- and among-population variation in tissue content for four unique semivolatile compounds among eglandular and glandular-haired *Medicago* accessions.

METHODS AND MATERIALS

Four volatile compounds [1-hepten-3-ol (HEPT); *cis*-geraniol (GERA); 2,7-dimethyl,2,6-octadien-1-ol (OCTA); 1,(*E*)-8, (*Z*)-10 tetradecatriene (TETR)], tentatively identified by Core et al. (1994), were analyzed for quantitative variation among seven *Medicago* accessions consisting of five cultivars, Caliverde, Caliverde 65, CUF101, Moapa 69, and CADL, and two germplasm

sources, KS94GH6 (*M. glandulosa* David) (Sorensen et al., 1986) and KS108GH5 (*M. glutinosa* Marshall von Bieberstein) (Sorensen et al., 1985). Accessions were planted in a glasshouse as randomized complete blocks with four replicates. Leaf and stem tissue from five individual plants per accession were sampled from each replicate and subjected to supercritical fluid extraction as described by Henning et al. (1994). Supercritical fluid extraction was utilized due to its proven efficiency in extraction and recovery of volatiles often lost by other procedures such as headspace sampling and Soxhlet extraction (Hawthorne et al., 1988; Henning et. al., 1994). Using this procedure allowed for a more accurate assay of all volatile compounds produced by the plant, both precursor and emitted volatiles.

A Hewlett Packard Series II model 5890 gas chromatograph with flame ionization detection capabilities fitted with an Alltech Associates, Inc. Econocap, 30-m × 0.24-mm-ID capillary column (0.25-μm coating of SE-54) was used for compound separation. Temperature and flow parameters were as follows: carrier (helium) velocity = 21 cm/sec, makeup gas (nitrogen) flow = 30 ml/min, initial oven temperature = 45°C for 5 min, temperature program ramp = 5°C/min, final temperature = 200°C for 5 min. We injected 2 μl of sample using a splitless injection for 1.2 min followed by split purge with a split of 100:1. The inlet temperature was maintained at 215°C, while the detector was set to 250°C.

Quantitative analyses of the four volatile compounds were determined based on their relationship to the peak height of an internal standard (36.5 μg of dodecane), which was added to every sample. An external standard of dodecane was assayed every 10 samples. Peak areas for the four compounds were transformed to represent equivalent micrograms of dodecane. All data are thus reported as microgram equivalents of dodecane per gram of plant material.

The data were analyzed as a split plot where accessions were considered as whole plots and genotypes within accessions as subplots. Replicates and accessions were considered as random effects. Analysis of variance using least-squares procedures (Snedecor and Cochran, 1980) were computed on the data using Statistix v.4.0 analytical software.

RESULTS AND DISCUSSION

We selected HEPT for analysis in this study because in a previous study it was qualitatively the most abundant compound, appearing in all GC chromatograms across all *Medicago* germplasm sources (Core et al., 1994). The other three compounds were chosen because: (1) they were qualitatively observed in a limited sample consisting of three plants representing three different wild *Medicago* species, and (2) their peaks were readily discernible on a GC chro-

matogram. The relative abundance of these threse semivolatile compounds, however, appeared to be far less than the relative abundance for HEPT (Core et al., 1994).

We observed significant differences ($P < 0.05$) between seven germplasms for GERA, OCTA, and TETR (Table 1). Mean separation analysis using Fisher's least significant difference (LSD) (Snedecor and Cochran, 1980) identified KS94GH6 as possessing significantly higher levels ($P < 0.01$) of GERA and OCTA than the other six germplasm sources (Table 2). KS94GH6 possessed

significantly higher levels of TETR than did the alfalfa cultivars with the exception of KS108GH5. Our data indicate that GERA, OCTA, and TETR are not present or are found in extremely low levels in the *M. sativa* cultivars we tested. There were no significant differences among entries for HEPT (Table 1). Levels of HEPT were at 100- to 200-fold higher levels than any of the other three compounds.

Both qualitative and quantitative results indicate that volatile components occur in AW-resistant KS94GH6 and KS108GH5 germplasm, which are either not present, or are present in extremely low levels, in the susceptible alfalfa cultivars examined. These data suggest that attempts to develop alfalfa cultivars possessing high levels of these compounds will require interspecific crosses. Following interspecific crossing, several cycles of selection for increased expression of these compounds must be practiced while selecting against undesirable traits coincorporated with these speculative repellent compounds.

If these compounds were expressed in nontrichome tissue, then the next question is whether or not they are genetically correlated. We did observe a strong phenotypic correlation ($P \leq 0.01$) between GERA and OCTA (Table 3). This phenotypic correlation between GERA and OCTA suggests (but does not prove) a relationship between these two compounds based potentially on biosynthetic pathways. *cis*-geraniol is one of the monoterpenes produced directly from geranyl pyrophosphate (GPP) (Goodwin and Mercer, 1983) and as such may contribute to the production of OCTA, or OCTA may be formed directly from GPP or neryl pyrophosphate, another monoterpene precursor. The compounds TETR and HEPT were not correlated with each other or with either of the two terpenes (GERA and OCTA). This is what would be expected due to the dissimilarities in their respective biosynthesis pathways.

GERA ($C_{10}H_{18}O$) is an isomer of isogeraniol, differing only in the placement of one double bond (Figure 1). Isogeraniol was isolated from AW extracts

and may be a possible pheromone for this insect although its exact function is unknown (Hedin et al., 1988). The other two volatile compounds, OCTA and TETR, may function as secondary plant compounds involved in AW repellency due to their singular presence in glandular-haired repellent species. Behavioral assays will be necessary to determine the attractancy or repellancy of these compounds to alfalfa weevils.

Abstract—Pea (*Acyrthosiphon pisum* Harris) and blue alfalfa aphid (*A. kondoi* Shinji) deterrency in alfalfa (*Medicago sativa* L.) may result from incorporating higher levels of the aphid alarm pheromone, (*E*)-β-farnesene relative to (*E*)-β-caryophyllene. We evaluated five eglandular and two glandular-haired alfalfa accessions for differences in (*E*)-β-farnesene and (*E*)-β-caryophyllene content under glasshouse conditions using supercritical fluid extraction and gas chromatography. In addition, pea and blue alfalfa aphid olfactory behavioral tests were conducted upon *Medicago* species containing different ratios of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene. No differences in (*E*)-β-caryophyllene content were observed among the seven entries (μ = 0.42 ng/g plant material). Significant differences ($P \leq 0.05$) among entries were observed for (*E*)-β-farnesene content, with KS94GH6 exhibiting the highest (1.18 ng/g), and CUF 101 the lowest levels (0.35 ng/g). Elite tetraploid sources possessed significantly lower levels (μ = 0.42 ng/g) of (*E*)-β-farnesene than did wild and cultivated diploid accessions (μ = 0.83 ng/g). Olfactory behavioral tests for both the pea and blue alfalfa aphids demonstrated KS94GH6 repelled aphids while cultivated alfalfa types attracted aphids in each case. Previously demonstrated aphid resistance in diploid KS94GH6 may result from superior (*E*)-β-farnesene levels, but (*E*)-β-farnesene is probably not a factor in cultivated alfalfa resistance. Finally, accession KS94GH6 could act as an excellent germplasm resource for the incorporation of higher (*E*)-β-farnesene levels into cultivated alfalfa.

INTRODUCTION

Pea aphids and blue alfalfa aphids cause significant economic losses in alfalfa. A combination of pesticides and resistant cultivars is currently used to control infestations. Pesticides registered for use on alfalfa have been curtailed due to tighter government regulations and high registration or reregistration costs. Resistance in most alfalfa cultivars is due to antibiosis (Manglitz and Ratcliffe, 1988). In some cases, antibiosis resistance has broken down as strong selection for adapted aphid biotypes has taken place (Nielson et al., 1971). Additional resistance mechanisms should be incorporated into elite germplasms in conjunction with antibiosis to impede the development of resistant aphid biotypes.

Plant resistance due to nonpreference, when coupled with antibiosis, may reduce selection pressure and ultimately prolong plant resistance. Ferguson et al. (1982) described one mechanism in which aphid nonpreference was thought to be due to chemical signals in glandular-haired *Medicago* spp, but the signals responsible for nonpreference were not identified, Gibson and Pickett (1983) identified (*E*)-β-farnesene as the chemical cue for aphid (*Myzus persicae* Sulzer) nonpreference in *Solanum berthaultii* Hawkes. (*E*)-β-Farnesene, a sesquiterpene, is the alarm pheromone for *M. persicae* and is also the alarm pheromone for pea aphids and a number of other economically important aphid species (Nault et al., 1973; Pickett and Griffiths, 1980).

Research by Dawson et al. (1984) suggested that aphid repellency due to the aphid alarm pheromone could be overcome by the presence of sufficient (*E*)-β-caryophyllene, another sesquiterpene found in glandular hairs of *Solanum tuberosum* L.. This group observed that as ratios of (*E*)-β-farnesene to (*E*)-β-caryophyllene were reduced below 3:1, aphids were less likely to be repelled. Ratios greater than 3:1 of (*E*)-β-farnesene to (*E*)-β-caryophyllene resulted in aphid repellency.

Buttery et al. (1982) identified both (*E*)-β-farnesene and (*E*)-β-caryophyllene as minor volatile components of alfalfa foliage. We hypothesize that it might be possible to reduce pea and blue alfalfa aphid feeding preference by increasing the quantities of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene. This alteration may be achieved through interspecific crosses with germplasms known to exhibit aphid repellency. Prior to attempting such crosses, it would be desirable to know: (1) if sufficient levels of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene were present in cultivated alfalfa, or if higher levels might be obtained through introgression from aphid-repellent wild perennial species, and (2) if nascent levels of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene in cultivated

alfalfa and aphid-repellent germplasm are sufficient to repel both blue alfalfa aphids and pea aphids.

METHODS AND MATERIALS

Quantification of Plant Volatiles. Seven plant entries consisting of five alfalfa varities, CUF 101, Caliverde, Caliverde 65, Moapa 69, CADL, and two *Medicago* germplasms, KS94GH6 (Sorensen et al., 1986) and KS108GH5 (Sorensen et al., 1985), were planted in soil beds (mixed, thermic Typic Torripsamments) in a glasshouse at Las Cruces, New Mexico. Glasshouse conditions were: 30°C ± 5°C (day), 25°C ± 5°C (night); and 16L:8D photoperiod. The seven entries were selected based on their levels of resistance or susceptibility to blue alfalfa and pea aphids (Table 1). CADL was chosen based upon its ability to produce fertile offspring from crosses with diploid KS94GH6. The experiment was arranged as a randomized complete block design with four replicates. Sources of variation for the experiment were: individual plants (five plants per entry per replicate), entry (seven entries), and replicates (four replicates). Entry plots were spaced 1 m apart. Plant individuals were considered nested within entries. Entries were considered fixed, while replicates and individual plants within entries were considered as random factors.

Leaf and stem tissue samples were collected and processed according to the procedures reported by Core et al. (1994). Plant volatile compounds were extracted via supercritical fluid extraction (SFE) as described by Henning et al. (1994) using a Hewlett-Packard model 7680A (Avondale, Pennsylvania).

TABLE 1. LEVEL OF RESISTANCE TO BLUE ALFALFA APHIDS (BAA; *Acyrthosiphon kondoi* SHINJI) AND PEA APHIDS (PA; *Acyrthosiphon pisum* HARRIS)[a]

Germplasm	Resistance level[b]	
	BAA	*PA*
CUF101	HR	HR
Moapa 69	NA	S
Caliverde	S	S
Caliverde 65	S	S
CADL	NA	NA
KS108GH5	R	R
KS94GH6	HR	HR

[a] As reported in the Alfalfa Catalog (Townsend et al., 1994).
[b] HR = high resistance (>50% of population is resistant), R = resistant (31–50% of population is resistant), S = susceptible (0–5% of population is resistant, NA = information not reported).

Peak identification and cochromatographic verification of (*E*)-β-farnesene and (*E*)-β-caryophyllene from plant tissues were determined on a gas chromatograph–mass spectrophotometer (GC-MS) (Saturn model, Varian Inc.; Sugarland, Texas) with an ion-trap detector. The GC-MS conditions were the same as those published by Henning et al. (1994). Quantification of (*E*)-β-farnesene and (*E*)-β-caryophyllene content was accomplished with a Hewlett-Packard model 5890 Series II gas chromatograph (GC) with external standards of (*E*)-β-farnesene (20.78 ng/μl), (*E*)-β-caryophyllene (20.78 ng/μl), and docanal (internal standard) at 18.25 ng/μl.

Gas chromatography was carried out with the initial GC oven temperature set at 45°C for 5 min. The oven temperature was then increased 5°C/min to a final temperature of 200°C, resulting in a total run time of 41 min. The GC operating conditions were: injector temperature, 215°C; detector temperature, 250°C; 2 μl splitless injection, split turned on after 1.2 min; helium carrier flow rate, 1 ml/min; nitrogen makeup flow rate, 30 ml/min; hydrogen flow rate, 45 ml/min; and compressed air flow rate, 350 ml/min.

The data were analyzed initially by analysis of variance. Bartlett's test for variance heterogeneity (Snedecor and Cochran, 1980) revealed significant differences among entry variances. As a result, post hoc mean comparisons among germplasms were accomplished through the use of Student's *t* test (Snedecor and Cochran, 1980).

Aphid Behavioral Studies. Pea and blue alfalfa were obtained from R. Barberet and A. Zarrabi (Department of Entomology, Oklahoma State University) and were maintained in two separate growth chambers to ensure purity of lines for testing. Blue alfalfa aphids were maintained under a 16L:8D photoperiod, 20°C, and 50% relative humidity, while pea aphids were maintained under similar conditions, but at 23°C temperature. Aphids were denied food (*Medicago sativa* L. cv CUF 101) for 2 hr prior to testing. This length of time was determined to be optimum for aphid behavioral activity.

The linear track olfactometer used in our study was based upon the design reported by Brewer et al. (1983) and consisted of a transparent Plexiglass Y tube fitted with recepticles designed to hold either 2 g of plant material or moistened filter paper. A purified, humidified airflow of 2.5 liters/min/arm was utilized in all behavioral tests. Aphids were prevented from viewing recepticles containing the test materials by means of black construction paper. Thus, the only means of attraction for aphids consisted of volatile compounds either present (plant material) or absent (moistened filter paper).

Plant materials used in behavioral assays were maintained in the greenhouse under optimum growth conditions. Five entries were bioassayed. Four of the entries were selected from the experimental line COMP88, representing four ratios of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene: i.e., high–high, high–low, low–high, and low–low (Table 2). We used the aphid-resistant germplasm

TABLE 2. AVERAGE CONCENTRATION OF (*E*)-β-FARNESENE AND (*E*)-β-CARYOPHYLLENE AND RATIO BETWEEN COMPOUNDS IN FOUR PREVIOUSLY SELECTED RATIO TYPES OF ALFALFA (*Medicago sativa* L.) AND KS94GH6 (*M. sativa* var. *viscosa*)

Plant type	Concentration (ng/g[a])		Ratio
	(*E*)-β-Farnesene	(*E*)-β-Caryophyllene	
Low-high[b]	0.345	0.533	0.65:1
Low-low	0.260	0.245	1.06:1
High-high	0.490	0.400	1.23:1
High-low	0.505	0.285	1.77:1
KS94GH6	1.180	0.430	2.75:1

[a] Nanograms compound per gram of plant material.
[b] Ratio of (*E*)-β-farnesene to (*E*)-β-caryophyllene.

KS94HG6 (Sorensen et al., 1986) as the fifth entry due to its high level of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene (Table 2). Levels of (*E*)-β-farnesene and (*E*)-β-caryophyllene were determined as reported above.

Tests consisted of introducing 10 aphids into the Y tube, sealing the end, and allowing aphids 30 min for choice of arm. At the end of this time, the number of aphids choosing either the air arm or the plant arm were recorded and then removed. The Y tube was then washed in 95% ethanol, dried, and utilized for the next set of experiments. For blue alphafa aphids, a total of 80 aphids was used for each of the plant entries with the exception that 20 aphids were used for KS94GH6. The same number of aphids were used for pea aphid tests. Student's *t* tests (Snedecor and Cochran, 1980) were utilized to test for differences between entries within aphid species. No tests were run for differences between aphid species.

RESULTS AND DISCUSSION

We observed significant differences among germplasms for (*E*)-β-farnesene concentration levels ($P = 0.005$). The germplasm source, KS94GH6 (*M. glandulosa*) exhibited the highest concentration (1.17 ng/g plant material) of (*E*)-β-farnesene among all entries (Table 3). None of the tetraploid alfalfa cultivars (CUF101, Moapa 69, Caliverde, and Caliverde 65) differed in their content of (*E*)-β-farnesene. There appeared to be a trend ($P \leq 0.05$) with the wild-type or diploid germplasm accessions (KS94GH6, CADL, and KS108GH5) containing significantly higher levels of (*E*)-β-farnesene ($\mu = 0.83$ ng/g) than the tetraploid cultivars ($\mu = 0.42$ ng/g). We also observed significant differences

among germplasm sources for within-population variances (Table 3), with KS94GH6 exhibiting the greatest variation followed by CADL and KS108GH5. Not surprisingly, the cultivated alfalfa entries exhibited the lowest within-population variances.

There were no differences between entries for concentration of (*E*)-β-caryophyllene (Table 4). Mean concentration of (*E*)-β-caryophyllene ranged from

0.35 to 0.50 ng/g plant material. In addition, there were no differences between population variances for this compound (data not shown). These results suggest that selection for decreased concentration of (*E*)-β-caryophyllene may not be possible due to a potential lack of genetic variation in the alfalfa populations we studied.

We observed significant differences in blue alfalfa aphid attraction to the five entries studied for aphid behavior (Figure 1). There was a significant trend towards repellency with increasing ratios of (*E*)-β-farnesene to (*E*)-β-caryophyllene ($y = 97.318 - 21.024 * x$, $P = 0.0102$). KS94GH6, with a ratio of 2.75 : 1 [(*E*)-β-farnesene to (*E*)-β-caryophyllene], which appears to repel aphids as more aphids chose the air arm over the plant arm. Thus, it appears that near-sufficient levels of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene are present in KS94GH6, while insufficient levels of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene were found in cultivated alfalfa types. Thus, KS94GH6 holds promise as a means for introducing higher levels of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene into cultivated alfalfa.

Similar results were observed for behavioral tests using pea aphids, with

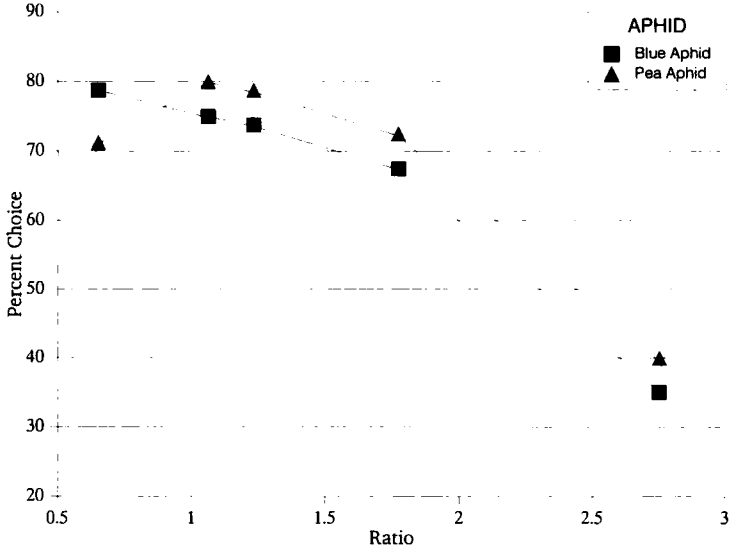

FIG. 1. Relative percentage of blue alfalfa aphid (*Acyrthosiphon kondoi* Shinji) and pea aphid (*Acyrthosiphon pisum* Harris) choosing olfactometer arm with *Medicago* species plant volatiles (*y* axis = aphid choice) as a function of ratio of (*E*)-β-farnesene to (*E*)-β-caryophyllene (*x* axis = ratio).

KS94GH6 repelling pea aphids while all alfalfa entries attracted aphids (Figure 1). The analysis of variance for regression of aphid choice on ratio was not significant ($P = 0.0732$). The most probable cause for this result may be that the aphids from one replication of the alfalfa entry for low–high (0.65 : 1 ratio) inadvertently were tested too soon after feeding, resulting in no choice by all 10 aphids. This reduced the number of potential plant arm choices for the 0.65 : 1 ratio to levels below that of the other three alfalfa types. Nonetheless, all four alfalfa types attracted aphids, while the KS94GH6 repelled aphids.

Sorensen et al. (1986) described KS94GH6 as possessing high resistance to pea and blue alfalfa aphids. Our data indicate that part of this resistance may be due to high concentrations of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene (2.75 : 1). The cultivar CUF101, however, also exhibited high resistance to both pea and blue alfalfa aphids (Townsend et al., 1994), but it possessed significantly lower levels of (*E*)-β-farnesene and exhibited a lower ratio of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene (0.88 : 1) than did KS94GH6. Resistance in CUF101 appears to be due to another mechanism, possibly antibiosis.

One potential method to increase the levels of (*E*)-β-farnesene emitted by plant tissue is to increase the internal concentration of this compound relative to (*E*)-β-caryophyllene. The fact that genetic variation for (*E*)-β-caryophyllene may not be present, coupled with the apparent lack of correlation between (*E*)-β-caryophyllene and (*E*)-β-farnesene concentration, may allow single-trait selection for increased (*E*)-β-farnesene levels, particularly since (*E*)-β-farnesene was present in all *M. sativa* entries. Our results suggest that higher internal (*E*)-β-farnesene levels may be incorporated through genetic integression with KS94GH6 as a donor parent. Some of the problems encountered by such a procedure are requirements for (1) scaling up from a diploid to a tetraploid during the initial cross, and (2) numerous back-crosses to cultivated alfalfa to eliminate undesirable characteristics contributed from KS94GH6.

The ultimate goal in increasing internal (*E*)-β-farnesene levels is to increase the release of this alarm pheromone compound while maintaining low levels of (*E*)-β-caryophyllene. Montgomery and Nault (1978) demonstrated that headspace concentrations (the concentration of compound immediately surrounding the plant) of (*E*)-β-farnesene in excess of 0.1 ng were necessary to repel *Myzus persicae*. The internal plant concentration of (*E*)-β-farnesene in KS94GH6 ranged from 0.00 to 6.14 ng/g (Table 2). Further studies were necessary to determine if these higher values are sufficient to generate threshold headspace values greater than 0.1 ng.

Simply increasing the internal (*E*)-β-farnesene content of alfalfa may not produce the desired repellency, but Dawson et al. (1984) determined that increasing the relative concentration of (*E*)-β-farnesene to (*E*)-β-caryophyllene from 1 : 3 to 10 : 3 significantly increased aphid dispersal of *Lipaphis erysimi* L. and *Phorodon humulis* S. Our behavioral work suggests similar threshold

requirements for both the pea and blue alfalfa aphids. Nevertheless, additional work is required to determine the actual threshold ratios for these two compounds to repel both pea and blue alfalfa aphids. Once this ratio is known, accurate goals can be set regarding the internal levels of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene necessary to condition aphid dispersal.

CONCLUSION

There are no published reports on the presence of genetic variation for (*E*)-β-farnesene in *Medicago* species. Interspecific crosses with accessions such as KS94GH6 are one means of increasing the internal concentration of this compound in alfalfa. Once higher levels of (*E*)-β-farnesene are introduced into an autotetraploid background, repeated cycles of selection for individuals exhibiting superior levels of (*E*)-β-farnesene relative to (*E*)-β-caryophyllene may condition aphid repellency in alfalfa. The genetic incorporation of higher levels of (*E*)-β-farnesene into alfalfa cultivars already possessing antibiosis may help to impede the breakdown of plant resistance to aphids.

(Received August 14, 1995; accepted April 27, 1996)

Abstract—Coupled GC-EAG techniques have been applied to the study of volatiles from the grain weevil, *Sitophilus granarius*, for the first time. The size of EAG response was independent of the sex of the responding insect but was consistently larger to extracts of males than those of females. This difference was reflected in a behavioral preference for the male extracts by mated adults of both sexes tested together and virgin adults of both sexes tested separately. The GC-EAG results provide evidence for two materials that are released specifically by the males. Using circular dichroism, one has been found to be identical stereochemically with the (2*S*,3*R*)-sitophilate reported by others as the aggregation pheromone in a different strain. This enhances the prospects for the development of a single pheromone lure that would be generally applicable whatever the origin of the strain. The small amount of sitophilate found in the males suggests that it is not stored in large amounts. The other material, present in such a small amount that it has yet to be fully characterized, elicits a higher antennal activity than sitophilate and may have a significant role to play in enhancing the trap catch of this economically important pest.

Key Words—*Sitophilus granarius*, grain weevil, Coleoptera, aggregation pheromone, electroantennogram, coupled GC-EAG, behavioral bioassay, circular dichroism.

INTRODUCTION

The grain, or granary, weevil, *Sitophilus granarius* (L.), is a primary storage pest, being able to attack previously undamaged grains. It can infest wheat, barley, maize, various other cereals, and cereal products. Although it is ecologically suited to more temperature climates, it is found all over the world and is spread by trade. Presently, it is one of the most important storage pests in the UK (Prickett, 1988; Prickett and Muggleton, 1991) and causes serious nutrient and economic damage. The development of its immature stages, unseen within grain kernels, means that its presence may go unnoticed until serious damage has been caused and emphasizes the need for improved detection: typically, traps in grain may catch less than 1% of the *S. granarius* present (Cogan and Wakefield, 1994).

Faustini et al. (1982) presented evidence for a male-produced *S. granarius* aggregation pheromone that was attractive to both sexes. This has since been identified as 1-ethylpropyl (2*S*,3*R*)-3-hydroxy-2-methylpentanoate [trivial name (2*S*,3*R*)-sitophilate] (Phillips et al., 1987, 1989). Laboratory tests of its effectiveness in the presence of wheat have been conducted (Plarre, 1994) but there have so far been no examples of its practical application in a trap lure.

To enhance trap catch in practical situations, it is essential to gain a detailed understanding of semiochemicals such as pheromones. Previous work has demonstrated the contribution to such an understanding from the combined study of antennal and behavioral responses of other storage beetles (White and Chambers, 1989; White et al., 1989; Chambers et al., 1990) and the differences in behavioral response to pheromone components shown by different strains of the same species (Chambers et al., 1990).

The aim of the present work was to apply a combined study of antennal and behavioral responses of *S. granarius* to male-produced volatiles to help understand their role in coordinating behavior.

METHODS AND MATERIALS

General. S. granarius (Windsor strain), cultured at an average population density of 500 insects per 50 g wheat grain (CV Avalon) and at 25°C and 70% relative humidity, was used for all experiments. All glassware was washed and then heated at 470°C for 8 hr before use. Solvents were of HPLC grade and, in addition, dichloromethane was eluted through Al_2O_3 (neutral, Brockmann grade 1) and stored in darkness at 10°C.

Collection of Insect Volatiles. Volatiles from individual insects of known age and sex were collected by a method adapted from Phillips et al. (1985). Individual grains from an insect culture were checked for infestation by nuclear

magnetic resonance (Chambers et al., 1984). Infested grains were placed individually in glass tubes (5 × 2.5 cm diameter) coated on the inside near the top with Fluon (an aqueous suspension of polytetrafluoroethylene from Whitford Plastics Ltd., Runcorn, UK). The tubes were stored at 25°C and 70% relative humidity and capped. They were vented for about 5 min three times each week to provide sufficient oxygen.

The sex of newly emerged adults was determined on the basis of their abdominal and rostral characteristics (Halstead, 1963). Each insect was placed in a clean tube with one wheat grain and a filter paper disk (Whatman grade 1, 2 cm diameter). The disks and grains were changed weekly over eight weeks. Each week's disks were pooled for each sex (200 males and 200 females) and extracted with 200 ml dichloromethane for at least 24 hr, giving extracts 1–8M and 1–8F. (Abbreviations for each extract and its origin are given in Table 1.) Similarly, 200 tubes each containing a filter paper disk and an uninfested wheat grain cut transverse to the crease, were maintained under standard conditions for two weeks. Two weekly extracts were made, as above, but were pooled to give extract W.

For a second batch, the volatiles of 210 males (extracts 1′–8′M) and 109 females (extracts 1′–8′F) were collected for eight weeks. In addition, frass was collected from the tubes after eight weeks, and the males were cut at the thorax–elytra junction, bisected to give two body sections for extraction. These were the heads together with prothoraxes, and rest of thoraxes with the abdomens. The separate frass from the males and females and the male body sections were

TABLE 1. IDENTITY OF EXTRACTS

Label	Origin
1–8M, 1–8F	Dichloromethane extract of 200 disks from tubes with males and wheat grains (M) or females and wheat grains (F) for one of eight consecutive weeks (1–8) after emergence
W	Dichloromethane extract of volatiles from 200 uninfested cut wheat grains for two weeks
1′–8′M, 1′–8′F	Repeat of first extraction experiment using 210 males (M) and 109 females (F)
Fr_m, Fr_f	Dichloromethane extract of frass of males (m) or females (f) collected after the repeat extraction experiment
H + P, T + A	Dichloromethane extract of heads and prothoraxes (H + P) or thoraxes and abdomens (T + A) of males used in the repeat extraction experiment
$Mf_{1\text{–}4}$, $Ff_{1\text{–}4}$	Preparative gas chromatography fractions (1–4) of pooled weekly extracts of males (M) or females (F) from the first extract experiment

extracted with 200 ml dichloromethane each, giving extracts Fr_m, Fr_f, H + P, and T + A, respectively. All extracts were reduced to 1 ml by rotary evaporation at 30–35°C (bath) and 16 mm Hg, then stored at −20°C.

Electroantennography. The electroantennogram (EAG) system was similar to that described previously (White et al., 1989). The recording and indifferent electrodes were inserted into the terminal antennal segment and the ventral surface of the head, respectively. Test cartridges consisted of 40 × 4-mm filter paper strips impregnated with the test material and placed inside Pasteur pipets, from which an airstream at 1000 ml/min in 1-sec pulses took volatiles to a delivery tube. The outlet of the delivery tube was aligned along the antennal axis at a distance of approximately 10 mm, which ensured that the whole antenna was within the airstream. To ensure that odors were removed after presentation, an exhaust system was suspended over the preparation. Recordings were made using intact individuals. A total of five male and five female beetles two to six weeks after emergence were tested in each experiment.

To determine whether adult beetles produced any EAG-active volatiles, the EAG responses to the first batch of extracts were studied. Each beetle was presented with 10 μl of 1M–6M and 1F–6F in randomized order. In a further experiment beetles were presented with 10 μl of 2M, 2F, and W volatiles. Results were analyzed by split-plot ANOVA.

In a third EAG experiment, to determine which of (2*S*,3*R*)- and (2*R*,3*S*)-sitophilate produced the greater EAG response, synthetic samples (Mori and Ishikura, 1989) were assayed at 10^{-1} ng to 10^4 ng to give dose–response curves. The EAG activities of the two diastereomers of the closely related racemic 1-ethylpropyl 3-hydroxy-2-methylbutanoate (separated by preparative GC) were recorded at doses from 10^{-1} to 10^3 ng.

Pitfall Bioassays. The level of attraction to extracts was measured using a two-choice pitfall test (White and Birch, 1987). Test insects were conditioned for 24 hr without food and in darkness. Ten insects were introduced into each arena and allowed 1 hr to settle. Test and control stimuli (5 μl) were then applied to 2-cm-diameter filter paper disks supported on wire grids to aid solvent evaporation. Grids were used once only to prevent cross-contamination. The dichloromethane solvent was allowed to evaporate for at least 1 min, the disks were placed in pitfall tubes, and the arenas covered with glass plates. After 1 hr the numbers of insects in the test and control tubes were counted. All tests were set up and run under red light at 25°C and 70% relative humidity during mornings. The insects were tested only once and then discarded.

Two sets of tests were undertaken. In the first, mated adults of both sexes combined, three to five weeks since emergence, were given choices between 2M and dichloromethane, 2F and dichloromethane, W and dichloromethane, or 2M (test) and W (control). In the second set of tests, virgin adults of the separate sexes, 10 weeks ± 1 day after emergence, were given choices between 2M and

dichloromethane or 2F and dichloromethane. Six replicates of each test were conducted using a randomized design.

The results were subjected to binomial logistic analysis, first for the proportion of insects responding (insects found in either pitfall), then for the directional nature of the response by comparing the numbers of insects in the test and control pitfall tubes (Chambers et al., 1990).

Coupled Gas Chromatography–Electroantennogram (GC-EAG) Procedure. Extracts were analyzed using a coupled GC-EAG technique (White and Birch, 1987). Extracts 2M, 2F, and W were analyzed using a 50-m × 0.32-mm-ID OV-1 column (Phase Separations Ltd.) with helium as a carrier gas and an oven temperature held at 50°C for 1 min, then programmed to 220°C at 10°C/min. Injections were made in the splitless mode with the injector at 220°C and the flame ionization detector (FID) at 240°C. The antennal responses of a female were recorded twice to each of 2M and 2F; the responses of three males were recorded in all 12 times to 2M, and five times to each of 2F and W. The same system was later fitted with a 50-m × 0.25-mm-ID CPSil5CB column (Chrompack) to compare a combined male extract (Mf_2, see later for preparative GC method) with the two diastereomers of racemic 1-ethylpropyl 3-hydroxy-2-methylbutanoate and to compare extracts 2′M and 6′M with synthetic (2*S*,3*R*)-sitophilate. Oven temperature programs were varied. The antennal responses of a female were recorded three times for Mf_2 and once for each of a mixture of Mf_2 and each of the diastereomers. The responses of a second female were recorded once for 2′M, three times for 6′M, and once for (2*S*,3*R*)-sitophilate.

Capillary Gas Chromatography (GC). Comparison of extract 2M with (4*R*,5*R*)- and (4*S*,5*R*)-sitophilure [synthesized by Mori and Ebata (1986)] was conducted using a 50-m × 0.25-mm-ID CPSil5CB column (Chrompack) with splitless injection; injector 220°C; FID 280°C; oven 50°C for 1 min then to 220°C at 10°C/min. Extracts Fr_m, Fr_f, H + P, T + A, 1′M–8′M, Mf_3, and synthetic (2*S*,3*R*)-sitophilate were analyzed on a 50-m × 0.25-mm-ID CPSil19CB column (Chrompack) with splitless injection; injector 220°C; FID 280°C; oven 50°C for 1 min then to 220°C at 5°C/min.

Coupled Gas Chromatography–Mass Spectrometry (GC-MS). Extract 2M was analyzed with a Hewlett-Packard 5790 GC coupled to a Jeol JMS-DX300 mass spectrometer. Samples were introduced by splitless injection (injector 230°C) onto a 25-m × 0.22-mm-ID BP-1 column with helium as carrier gas. Oven programs were varied, and column effluent was ionized by electron impact (EI) at 70 eV and chemical ionization (CI) with ammonia. Fractionated pooled weekly extracts Mf_2 and Ff_2 (see later for preparative GC method) were analyzed on the same system using a 50-m × 0.25-mm-ID CPSil5CB column (Chrompack); injector 220°C; oven 50°C for 1 min then to 220°C at 5°C/min. This system, fitted with a 50-m × 0.25-mm-ID CPSil19CB (Chrompack) column, with the injector temperature at 230°C and an oven program from 40°C for 1

min then to 270°C at 10°C/min, was also used to compare a synthetic mixture of all four stereoisomers of 1-ethylpropyl 3-hydroxy-2-methylbutanoate with Mf_2. For these extracts the eluent was ionized solely by electron impact at 70 eV.

Preparative Gas Chromatography. The first batch of extracts was pooled for each sex and fractions collected after elution through a 2-m × 2-mm-ID column of 3% OV-101 on Chromosorb W-HP 100–120 mesh; injector 220°C; thermal conductivity detector 240°C; filament temperature 290°C; filament current 211 mA. Helium was used as carrier gas at 30 ml/min, and the oven was programmed from 50°C to 130°C at 3°C/min then to 220°C at 20°C/min. Four fractions were collected for both male and female extracts (Mf_{1-4} and Ff_{1-4}, respectively) to separate different components which showed EAG activity.

Crude 1-ethylpropyl 3-hydroxy-2-methylbutanoate was purified using the same system with an oven program of 50°C to 120°C at 1°C/min. Two fractions (diastereomers 1 and 2) representing the two enantiomeric pairs were collected.

Circular Dichroism (CD) Spectroscopy. Solutions of synthetic (2*S*,3*R*)- and (2*R*,3*S*)-sitophilate and Mf_3 (containing sitophilate) were analyzed with a Jasco J600 Spectropolarimeter. The synthetic solutions were made up to 2.5×10^{-2} mol/dm^3 in acetonitrile and scans taken from 285 to 185 nm at a 0.05-cm pathlength with a time constant of 4 sec and bandwidth of 2 nm. The extract solution was more dilute at 1.2×10^{-4} mol/dm^3 in acetonitrile and 10 scans taken at a 1-cm pathlength were averaged.

Synthesis of 1-Ethylpropyl 3-hydroxy-2-methylbutanoate. 3-Pentanol (40 ml, 0.37 mol) and pyridine (16.2 ml, 0.2 mol) were mixed in a 250-ml round-bottom flask and 2-bromopropionyl chloride (17 ml, 0.17 mol) was added slowly. The reaction mixture was stirred at 75°C for 4 hr and then filtered into 50 ml water. After shaking, the water was discarded and the organic layer washed successively with three 50-ml aliquots of 1 mol/dm^3 aqueous copper sulfate, 50 ml water, 50 ml 1 mol/dm^3 sodium hydrogen carbonate, and 50 ml brine. After drying over calcium sulfate, the product was distilled and 1-ethylpropyl 2-bromopropionate (0.1 mol, 59% yield) collected at 1 mm Hg between 73.5 and 75.5°C. (60 MHz ^{1}H NMR, $CDCl_3$: ppm relative to TMS, splitting pattern, relative intensity, assignment: 0.9, triplet, 0.40, 2 $-CH_3$; 1.6, quintet, 0.26, 2 $-CH_2-$; 1.7, doublet, 0.21, $-CH_3$; 4.4, quartet, 0.06, CH—Br; 4.8, quintet, 0.06, CH—O—.)

This bromo ester was converted to the required β-hydroxybutyric ester by a Reformatski reaction procedure (Rathke and Lindert, 1970). Zinc powder (unactivated, 3.27 g, 0.05 mol) was put into a 100-ml round-bottom flask which was then flushed with nitrogen and sealed with a rubber septum. Tetrahydrofuran (13 ml), acetaldehyde (2.8 ml, 0.05 mol) and trimethylborate (13 ml) were injected through the septum, and stirring of the mixture commenced. The

1-ethylpropyl 2-bromopropionate (9 ml, 0.04 mol) was injected and the mixture maintained at 40°C. After 4 hr a mixture of glycerol (14 ml) and ammonium hydroxide (pH 13, 14 ml) was added, and after shaking the organic phase was separated. The aqueous layer was extracted with three 15-ml aliquots of diethyl ether, which were added to the organic phase. The combined organic phase was washed with 100 ml brine. Vacuum distillation between 54 and 74°C and 1 mm Hg yielded 0.02 mol unreacted bromo ester and a residue that was not distilled. This residue was shown to be 1-ethylpropyl 3-hydroxy-2-methylbutanoate [MS, EI: 36(27%), 43(45%), 55(65%), 70(25%), 74(100%), 83(15%), 85(7%), 101(85%), 144(5%), 159(4%)] in a yield of 25% (0.01 mol). (60 MHz ^{1}H NMR, $CDCl_3$: ppm relative to TMS, splitting pattern, relative intensity, assignment: 0.9, triplet, 0.29, 2 $-CH_3$; 1.0–1.4, overlapping multiplets, 0.31, $-CH_3$ and $-CH_3$; 1.6, quintet, 0.23, 2 $-CH_2-$; 2.5, multiplet, 0.07, $-CH-CO_2-$; 4.4, multiplet, 0.05, $-C\underline{H}-OH$; 4.8, quintet, 0.05, $-CH-O-$.)

RESULTS

In the EAG analysis of extracts 1–6M and 1–6F, there was no difference between the response of the two sexes ($F = 1$, NS), so the data have been combined (Table 2). There was no consistent increase or decrease in response to the six weekly male or female extracts. Extracts from males produced significantly larger EAG responses than female extracts, in both males and females ($P < 0.001$). In the comparison of extracts 2M, 2F (week 2 having been chosen arbitrarily), and W (Table 3), the response to 2M was significantly greater ($P < 0.001$) than to either 2F or W, and the response to W was significantly greater ($P < 0.05$) than to 2F (t test).

In the first set of pitfall bioassay tests there was no significant difference between the different treatments in activity (the probability of responding to either of the two pitfalls taken together; $\chi^2 = 7.22$, $P > 0.05$). The fitted probability of responding was 0.81 (95% confidence intervals 0.70, 0.88). However, of those insects that did respond, there was a significant difference between the numbers responding to the test pitfall as opposed to the control pitfall ($\chi^2 = 13.86$, $P < 0.005$). The fitted probabilities of responding to the test pitfall are presented in Table 4. Significantly more insects entered the pitfall containing 2M, 2F, and W when these were paired with solvent and the pitfall containing 2M when paired with W. In the second set of pitfall bioassay tests, there was no significant difference between the number of virgin males and females responding to either of the two pitfalls but there were significant differences between the treatments ($\chi^2 = 8.3$, $P < 0.005$). In general, more insects responded in the 2M vs. dichloromethane test than in the 2F vs. dichloromethane

[a]Equal response to the two pitfalls would be represented by a probability of 0.50.

test (Table 5A). The virgin males and females differed in the directional nature of the response (Table 5B). In general, more females responded to the test pitfalls than males, and there was a greater response to 2M than to 2F.

Analysis of extract 2M by GC-EAG showed four areas of EAG activity (Figure 1): component A, retention time (R_t) between 11.89 and 12.11 min; component B R_t 12.91 min; component C R_t 13.15 min; component D R_t 13.91 min. Component A gave the largest EAG response but no identifiable FID signal. The female extract contained only components B and D. Extract W showed no areas of EAG activity by GC-EAG.

GC-MS of extract 2M suggested that component C was aliphatic [MS, EI: 43(39%), 55(34), 59(27), 69(18), 74(100), 85(12), 97(8), 103(24), 115(45),

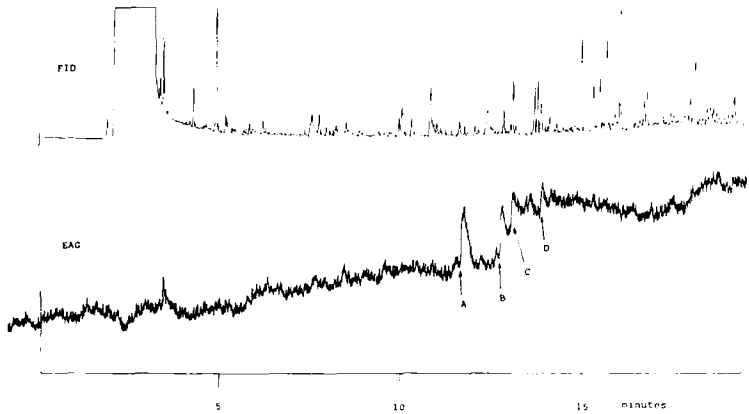

FIG. 1. GC-EAG response from a female *S. granarius* to extract 2M from males showing the position of components A–D.

144(6), 173(3); MS, CI: molecular ion of 202] and MS data were consistent with those of sitophilate (Phillips et al., 1987). Component C was collected in the fractionated pooled weekly extract Mf_3. CD spectral data of natural sitophilate in Mf_3 (λ_{max} = 212 nm, Δe = positive), synthetic (2*S*,3*R*)-sitophilate (λ_{max} = 212 nm, Δe = +0.3), and (2*R*,3*S*)-sitophilate (λ_{max} = 212 nm, Δe = −0.3) suggested that the natural material is the 2*S*,3*R* stereoisomer. In the EAG dose–response tests, there were no significant differences between the responses of the two sexes, so the data have been combined. Figure 2a shows that the 2*S*,3*R* stereoisomer is significantly more active than the 2*R*,3*S* stereoisomer. In the capillary GC comparison, the amount of sitophilate detected increased from none in 1′M to less than 1 μg in each of 2′M and 3′M, and to more than 2.5 μg in each of 4′M to 8′M. No sitophilate was found in Fr_f, but Fr_m contained 7 μg (equivalent to less than 1 μg collected per week). T + A contained 0.6 μg sitophilate whereas none was detected in H + P.

Identification of component A was also attempted because of its high EAG activity and because it was present in only the male extracts. Comparison by capillary GC showed that synthetic (4*R*,5*R*)- and (4*S*,5*R*)-sitophilure (R_t 8.5 and 8.6 min, respectively) eluted before component A in extract 2M (R_t approximately 10 min). GC-MS of extract 2M gave no structural information about component A as there was insufficient material. Preparative GC of the pooled weekly extracts provided more material for analysis. In the region where component A would be expected to elute, GC-MS analysis of male extract Mf_2 showed an unknown [MS, EI, 36(63%), 43(53%), 55(95%), 70(33%), 74(100%), 83(10%), 85(14%), 101(55%), 144(2%), 159(2%); MS, CI: molec-

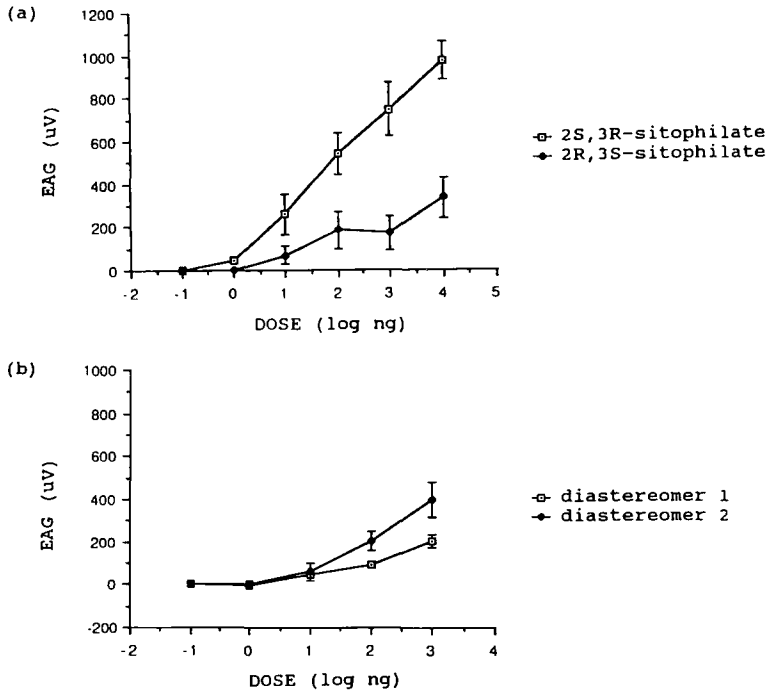

FIG. 2. EAG dose–response curves of ten *S. granarius* adults, five of each sex, to (2*S*,3*R*)- and (2*R*,3*S*)-sitophilate (a), and to diastereomers 1 and 2 of 1-ethylpropyl 3-hydroxy-2-methylbutanoate (b).

ular ion of 188]. This unknown was not found in female extract Ff_2. Comparison with the MS data for sitophilate suggested that the unknown might be 1-ethylpropyl 3-hydroxy-2-methylbutanoate. This compound was synthesized and GC-MS showed that it coeluted with the unknown and the MS data were identical for both.

EAG dose–response curves for diastereomers 1 and 2 of racemic 1-ethylpropyl 3-hydroxy-2-methylbutanoate (Figure 2b) showed low activity for diastereomer 2 and significantly lower activity for diastereomer 1 when compared with EAG response to (2*S*,3*R*)-sitophilate (Figure 2a). GC-EAG analysis of Mf_2 and mixtures of Mf_2 with either diastereomer showed (Table 6A) that diastereomer 2 has a different retention time from component A and that the coelution of diastereomer 1 with component A does not cause a proportional increase in the EAG response to component A. The ratios of the EAG and FID responses in Table 6A show that component A has higher relative EAG activity than either

TABLE 6. RELATIVE EAG AND GC (FID) RESPONSES OF MATERIALS ELUTING IN THE REGION OF VARIOUS COMPONENTS

Injection	R_t (min)	FID signal[a]	EAG signal[a]	EAG/FID ratio	Comments
A. Component A in male extract Mf_2 and diastereomers 1 and 2 of 1-ethylpropyl 2-methyl-3-hydroxybutanoate					
Mf_2	24.4	30	35	1.2	Component A
Mf_2	23.9	30	25	0.8	Component A
Mf_2 + Diast.1	24.2	75	20	0.3	Diast.1 + component A
Mf_2 + Diast.2	24.4	23	25	1.1	Component A
	24.7	93	24	0.3	Diastereomer 2
B. Components A and C in male extracts 2'M and 6'M and synthetic (2*S*,3*R*)-sitophilate					
2'M	24.2	3	6	2.0	Component A
	26.9	25	25	1.0	Component C
6'M	24.2	5	12	2.4	Component A
	26.9	70	26	0.4	Component C
(2*S*,3*R*)-Sitophilate	26.9	40	30	0.8	Sitophilate

[a]Arbitrary units.

of the diastereomers. Thus 1-ethylpropyl 3-hydroxy-2-methylbutanoate is not the highly EAG-active component A. Comparison of 2'M, 6'M, and (2*S*,3*R*)-sitophilate by GC-EAG (Table 6B) confirms that the relative activity of component A is higher than component C and that the activity at component C is associated with sitophilate.

DISCUSSION

There was no difference between the two sexes in the size of EAG response to the volatiles tested, whether they were of synthetic or natural origin. In comparison with other storage pests, the saw-toothed grain beetle, *Oryzaephilus surinamensis*, also shows no sexual differences (White and Chambers, 1989), although the females of two *Cryptolestes* species show larger EAG responses than the males (Chambers et al., 1990). These results may reflect sexual dimorphism in antennal structure of the *Cryptolestes* species. Details of the antennal structure of *Sitophilus granarius* have not yet been established, although some interesting branched sensilla have been observed (D. B. Pinniger, personal communication). Our results with the sitophilate isomers are comparable with those of Levinson et al. (1990) from a different strain of *S. granarius*.

The consistently greater EAG response to the male extracts than the female extracts implies that the release of male-produced EAG-active volatiles remains

essentially constant over the first six weeks after their emergence. The EAG response to female extract 2F was probably smaller than to wheat extract W because by the end of each week, the females had consumed most of the wheat grain. The extracts made in the seventh and eighth weeks were not tested by EAG although they were pooled with the other extracts for fractionation by preparative gas chromatography.

The results of the two-choice pitfall tests were separated into activity (whether the insects respond to either pitfall) and directional nature of the response (whether responders are found in the test or control pitfall) (Chambers et al., 1990) to overcome the inadequacy of the commonly used formula: (test − control)/number tested. This separation showed that with the mated insects the differences in response between treatments arose solely from the different directional effects of the extracts rather than any differences in their ability to stimulate a response. The results demonstrate the behavioral importance of the male-produced volatiles. Although male-produced volatiles from the saw-toothed grain beetle showed no sexual differences in EAG response, marked differences were found in behavioral effects, with a greater response from females than males (White and Chambers, 1989). To investigate whether this might also be the case with *S. granarius*, a second set of behavioral tests was conducted using virgin males and females tested separately. Differences were found, with the females giving a greater directional response than the males, but the differences were not statistically significant.

This is the first time that coupled GC-EAG studies have been reported for *S. granarius* and their usefulness is clearly demonstrated by rapidly locating two volatiles with EAG activity produced only by the males, components A and C, the former not having been reported previously. Further, the fact that the wheat extract showed no specific areas of activity by GC-EAG shows that its EAG activity when presented as a mixture must be due to small contributions from a large number of components. This would appear to be typical of the response of storage pests to food aromas.

Component C has the same gross structure as the sitophilate found in a different strain of *S. granarius* (Phillips et al., 1987). The novel application of circular dichroism confirmed that the strain studied here produces the 2*S*,3*R* isomer of sitophilate, like the strain studied by Phillips et al. (1989). This is reflected in the behavioral effects of the 2*S*,3*R* and 2*R*,3*S* isomers, comparable threshold doses for attractancy being 10 and 100 ng, respectively (McGreevy et al., 1993). Analysis of the frass extracts confirmed that sitophilate production is confined to the males, and the small amount in these extracts relative to those in the extracts of the filter paper disks suggested that its presence in the frass was merely due to some slight absorption on it rather than being its source. The small amount found in the thorax and abdomen extract of the males suggests that sitophilate is not stored in large amounts.

It was thought at first that component A, the other material with EAG activity produced specifically by the males, might be sitophilure, which has been found in trace amounts in extracts of *S. granarius* (Schmuff et al., 1984). (4*S*, 5*R*)-Sitophilure is the trivial name given to (4*S*,5*R*)-5-hydroxy-4-methyl-3-heptanone, the aggregation pheromone of *S. zeamais* and the rice weevil, *Sitophilus oryzae* (Schmuff et al., 1984; Walgenbach et al., 1987). It has been reported that both sexes of *S. granarius* are attracted to volatiles collected from male *S. zeamais* (Walgenbach et al., 1983) and synthetic racemic sitophilure (Phillips et al., 1985), which would imply that there should be some EAG response. However, in the present study no evidence has been found for either diastereomer of sitophilure in the extracts of volatiles from *S. granarius*.

The EAG activity of component A is readily observable, yet its FID response is very small and correct assignment is complicated by the presence of other materials with similar retention times. The discovery of a male-specific material in this region with similar mass spectral characteristics to sitophilate suggested that the identity of component A should be the analogous butanoate. Comparison with synthesized material, however, demonstrated that neither diastereomer has the right EAG characteristics. The butanoate is not an obvious degradation product of the pentanoate, sitophilate, so is unlikely to have been formed during isolation and probably is produced by the males. It may be formed as a secondary metabolite by a similar pathway to sitophilate but from different starting materials. It is nevertheless curious that its GC elution characteristics should be so similar to the still unidentified component A.

It is particularly interesting that component A should have a noticeably higher EAG response per unit FID response than sitophilate. It would be surprising if it did not have some important significance for *S. granarius*. In preliminary tests to compare an extract of males containing 10 ng (2*S*,3*R*)-sitophilate with 10 ng of this sitophilate isomer alone, females responded significantly more ($P < 0.05$) to the former. This confirms the behavioral activity of materials in the extract other than sitophilate. This activity may be sexually specific since males showed no significant difference in this comparison. The generally greater behavioral response of virgin females compared with virgin males to isolates of natural volatiles from *S. granarius*, observed both here and in earlier work (Faustini et al., 1982), contrasts with the observation of almost identical response of the two sexes to synthetic (2*S*,3*R*)-sitophilate (Phillips et al., 1989) and might be explained by the presence of component A in the natural isolates. Laboratory tests with synthetic (2*S*,3*R*)-sitophilate in the presence of wheat have shown that its function is more that of an arrestant than an attractant (Plarre, 1994), which suggests that the function of component A might be complementary to that of the sitophilate in guiding insects to its source. If this is so, then component A would have a valuable role to play in enhancing trap catch.

Acknowledgments—The authors are grateful to the Pesticide Safety Directorate and the Arable Crops Group of the UK Ministry of Agriculture, Fisheries and Food for funding this work. They would like to thank Mrs. J. A. Dendy and Mr. P. B. McGreevy for conducting the behavioral comparison of sitophilate and the equivalent amount of natural extract, Dr. A. F. Drake, Birkbeck College, University of London for recording the circular dichroism spectra, Mr. J. P. G. Wilkins of Central Science Laboratory, Harpenden for conducting the GC-MS analyses and Mr. C. E. Bowman of Process, Maidenhead for advice on the statistical analysis of the pitfall bioassays.

Abstract—The fall armyworm, *Spodoptera frugiperda* (J. E. Smith), (FAW) is a major pest of corn, *Zea mays* L., in the southeastern United States. The damage to pretassel corn is caused by larvae feeding primarily on immature inner whorls. In this study, resistant lines were found to contain more crude fiber in whorls, mostly hemicellulose and cellulose. While hemicellulose, chiefly an arabinoxylan, was higher in resistant (R) lines than in susceptible (S) lines, the distribution of constituent neutral sugars was very similar in the lines. Both lines also contained *p*-coumaric and ferulic acids. These phenolic acids are known to occur both in the free state and in the cell wall as complexes bound by ester linkages to the arabinose moiety of the arabinoxylan. ^{13}C NMR data showed that the intensity of the carbonyl carbon (184 ppm) in resistant hemicellulose was stronger, indicating a greater degree of cross-linking. Thus, resistant hemicellulose is both structurally different from susceptible hemicellulose and present in greater quantities. In two of three laboratory dietary tests, FAW larval weight gains were significantly higher on diets with (S) hemicellulose incorporated at the same level as (R) hemicellulose. Therefore, resistance to the FAW appears to be correlated with both a greater amount and a higher degree of cross-linking of the hemicellulose of (R) lines.

Key Words—Corn, *Zea mays* (L.), fall armyworm, *Spodoptera frugiperda* (J. E. Smith), Lepidoptera, feeding resistance, hemicellulose.

INTRODUCTION

The fall armyworm, *Spodoptera frugiperda* (J. E. Smith), (FAW) is a major pest of corn, *Zea mays* L., in the southeastern United States (Davis et al., 1988a,b). The damage to pretassel corn is caused by larvae feeding primarily on inner whorl leaf tissue. The damage caused by this insect can be extensive; in fact, late-planted corn is sometimes destroyed.

A long-continuing corn breeding program at Mississippi State, Mississippi, has led to the release of eight germplasm lines with leaf-feeding resistance to the FAW and the southwestern corn borer (SWCB), *Diatraea grandiosella* Dyar (Davis et al., 1988a,b). These lines have also shown resistance to the sugarcane borer, *Diatraea saccharalis* (Fab.), the corn earworm, *Heliothis zea* (Boddie), and the European corn borer (ECB), *Ostrinia nubilalis* (Hubner) (Davis et al., 1988b). The resistance appears to be operating by the same mechanisms (antibiosis and nonpreference), suggesting that the same or similar chemical and physical factors may govern the resistance of corn to these insects (Wiseman et al., 1981, 1983; Williams et al., 1985, 1987; Davis et al., 1988a,b).

Two major qualitative factors of resistance in corn to one or several corn insects are 6-MBOA–DIMBOA (Klun and Brindley, 1966) and maysin (Waiss et al., 1979). However, our investigations demonstrated that either these compounds possessed only limited toxicity to the FAW or SWCB or that they were present at minor levels in the corn lines found to have significant resistance to these two insects (Hedin et al., 1984, 1990, 1993). Resistance to a leaf disease in corn was also attributed to lignin by Lyons et al. (1993), but we could only find 1.5% lignin in susceptible corn whorls and 1.6% lignin in resistant whorls (Hedin et al., 1984).

Waxes may also contribute to FAW resistance. The surfaces waxes of FAW-resistant lines were reported to be thicker (Davis et al., 1995). Earlier, Hedin et al., (1993) found the yield of waxes averaged 0.047% and 0.069% from fresh tissue for (S) and (R) lines, respectively. GLC and GLC-MS analyses revealed only minor differences in the composition of the waxes, but 6-MBOA, DIMBOA, and *N-O*-Me-DIMBOA were present in higher concentrations in (R) lines. However, these constituents are known not to be very toxic to the FAW and SWCB (Hedin et al., 1993). Thus, any contribution to resistance by the waxes is probably related to physical attributes that may modify the behavior of the larvae (Yang et al., 1991, 1992).

Because qualitative defenses such as DIMBOA do not appear to contribute significantly to resistance of whorls to the FAW and the SWCB, quantitative defenses by cell wall constituents should be considered. The cell wall of plants has been characterized as consisting of cellulose microfibrils embedded in a lignin–hemicellulosic macromolecule to which acetyl and phenolic acid groups

are bound (Morrison, 1979). Arabinoxylans are the characteristic hemicellulose of cereals (Fry, 1989).

The phenolic constituents of the cell walls of graminaceous plants consist largely of *p*-coumaric and ferulic acids (Hartley and Jones, 1978; Sosulski et al., 1982). These acids are bound to cell wall polysaccharides through ester bonds (Fry, 1986). Based on polysaccharide hydrolase digests of sugar cane and corn cell walls, ferulic acid was shown to be linked to arabinose, which in turn is linked to xylose (Kato and Nevins, 1985). Classen et al. (1990) concluded that cell wall-bound ferulic acid was the only significant factor explaining the variation in kernel damage by larvae and in adult preference for oviposition by some grain storage insects. However, the constituent phenolic acids do not appear to be important because Bergvinson (1993) found that ferulic acid in meridic diets did not cause significant larval mortality of the ECB and that sugar conjugates of ferulic and *p*-coumaric acids extracted from resistant lines were phagostimulants.

In recent years, a laboratory bioassay based on lyophilized corn whorl tissue has been developed and refined to evaluate the leaf-feeding resistance in lines of corn to the FAW, the SWCB, and other corn insects (Williams et al., 1990, 1995; Buckley et al., 1991; Williams and Buckley, 1992; Williams and Davis, 1995). These workers concluded that growth of larvae on diets based on lyophilized leaf tissue was correlated with the average performance of the different lines.

Davis et al. (1995) studied the anatomical characteristics of corn resistant to leaf-feeding by SWCB and FAW. The most striking and consistent difference between resistant and susceptible inbreds was the thickness of the cuticle and the epidermal cell wall. The cell wall complex of resistant inbreds was 1.7× thicker than that of susceptible inbreds. This finding is consistent with our chemical data that showed resistant lines contained higher levels of fiber, including hemicellulose (Hedin et al., 1984, 1990).

This present work concentrated on the hemicelluloses that were found to be higher in resistant lines. They were extracted, purified, chemically defined, and reconstituted in diets.

METHODS AND MATERIALS

Corn Lines and Harvesting. Corn lines used in these studies were developed by the Corn Host Plant Resistance Research Unit at Mississippi State, Mississippi. They were selected for desirable resistance properties to the FAW and grown using normal agronomic practices in the area. Whorls were excised on site from plants in the midwhorl V_{8-10} (Ritchie and Hanway, 1982) stage of

growth, transported to the laboratory where they were frozen at −20°C, and dissected with minimal warming to obtain the inner green–yellow tissue that constitutes the feeding site. This section was then freeze-dried, ground in a Wiley mill (40 mesh), and the powder stored in a freezer until used in a diet, fractionated, or analyzed.

Dietary Evaluations. Larval growth on several experimental diets was compared to that of larvae fed a standard casein–wheat germ diet that had been established by Davis (1989) for the SWCB and FAW. The casein–wheat germ diet contains 17.0% casein and 14.3% wheat germ, with the remainder consisting of agar, alphacel, and other nutritional solids. Because wheat germ contains hemicellulose, it was excluded from the experimental diets and the casein was increased to 22.1% of total solids to provide an equal amount of protein. The hemicellulose and cellulose isolates were included in the diet at 15% of total solids, about half of their content in tissue. This variance was necessary because larger quantities caused diets to be too viscous for successful blending. Two diets, the first containing a mixture of 0.1% *p*-coumaric acid and 0.1% ferulic acid, and the second containing a mixture of 1.0% *p*-coumaric acid and 1.0% ferulic acid, were also included.

The treatments (diets) were arranged in a randomized complete block design with 10 replications. Each treatment was represented by four larvae fed individually in 30-ml plastic cups, each containing approximately 10 ml of diet.

The FAW and SWCB larvae were fed for 10 and 14 days, respectively, before weighing. Their rearing environment was 27.6°C, 50–60% relative humidity, with a 16L:8D photoperiod.

The data were subjected to analysis of variance (ANOVA), and the least significant difference (LSD) tests was used to compare treatment means.

Analytical Procedures. Association of Official Analytical Chemists (AOAC) methods (Horwitz, 1975) were used for the following analyses: total solids (moisture), 14.083; crude fat, 14.019; crude fiber, 14.118; acid detergent fiber, 7.056, 7.057, ash, 14.114; total protein, 2.049 (percent nitrogen × 6.25); nitrogen-free extract (NFE) by difference from 100%. AOAC methods were also used for analysis of acid detergent fiber, 973.18; and lignin (by loss on ignition), 973.18C (Helrich, 1990).

Neutral detergent fiber was determined by the methods of Van Soest and Wine (1967). From these procedures, lignin, cellulose, and hemicellulose were determined directly, and soluble cell wall contents by difference from 100%.

p-Coumaric and ferulic acids were determined by GLC-FID of their silyl derivatives, and their presence was confirmed by GLC-MS. Using the general procedures of Bergvinson (1993), freeze-dried corn whorl (5 g) was first extracted with 50% aqueous ethanol to remove chlorophyll. The residue was extracted in the dark for 4 hr with 2 N aq. NaOH (300 ml). Then the NaOH solution was extracted exhaustively with ethyl acetate. The ethyl acetate solution was dried

with Na_2SO_4 and concentrated to ca. 20 ml from which a 1-ml aliquot was silylated with *N,N*-bis(trimethyl-silyl)acetamide (Pierce Chemical Co., Rockford, Illinois). The analyses were quantitated by comparison with authentic, weighed samples of *p*-coumaric and ferulic acids (Fluka, Ronkonkoma, New York).

Extraction and Analysis of Hemicellulose and Cellulose. The procedures were based on those of Selvendran and Ryden (1990). Typically, 100 g of ground freeze-dried whorl was extracted at boiling by Soxhlet with 50% aqueous ethanol, yielding about 20% solubles including the pigments, lipids, sugars, and salts. The residue from the aqueous ethanol extraction was extracted with 1 N KOH (1:25 w/v) for 24 hr, centrifuged, and the resulting residue was resuspended in water and centrifuged a second time. The supernatants were combined and adjusted to pH 5.0 with glacial acetic acid so that the hemicellulose precipitated. The residues from the centrifugation (chiefly cellulose) and the HOAC precipitate (hemicellulose) were transferred to dialysis tubing and dialyzed with daily changes of deionized water for seven days, after which they were freeze-dried and weighted to determine yield.

Glycosyl compositions (sugars) were determined via hydrolysis with 2 mol/liter trifluoroacetic acid and subsequent preparation and analysis of their alditol acetates according to the methods of Sturgeon (1990).

Solid- and Liquid-State NMR Experiments. The ^{13}C solid-state NMR spectra of freeze-dehydrated whorl powders and their isolated hemicelluloses were recorded at 75.49 MHz on a Bruker AMX-300 spectometer with a Level I Solids Accessory using a 4-mm rotor. The Bruker pulse program cp21ev was used with a prepulse delay of 3 sec and a contact time of 3.0 msec. Each spectrum was obtained using a MAS spinning rate of 7.5 kHz and 6000 scans.

Samples of resistant (Mp 708) and susceptible (SC 229) hemicelluloses were prepared by dissolving 80 mg of each in 2.5 ml of D_2O containing 20% KOH (by volume). All spectra were referenced to internal 2,2-dimethyl-2-silapentane-5-sulfonate (DSS). Isotopically enriched D_2O was purchased from Isotec Inc. (Miamisburg, Ohio), and 2,2-dimethyl-2-silapentane-5-sulfonate was purchased from Cambridge Isotope Company (Woburn, Massachusetts). Both compounds were used without further purification. All NMR experiments were conducted with a Bruker AMX-300 spectrometer. The one-dimensional proton spectra were acquired at a frequency of 300.1355342 MHz using a spectral width of 6024 Hz, with 16K data points yielding a digital resolution of 0.37 Hz/point with a total acquisition time of 1.35 sec/scan. A total of 32 scans (1 sec delay between scans) were acquired and then processed with an exponential multiplication defined by a 1-Hz line broadening. The one-dimensional carbon-13 spectra were acquired at a frequency of 75.4685870 MHz using a spectral width of 19,230 Hz, with 32K data points yielding a digital resolution of 0.6 Hz/point with a total acquisition time of 3.4078 sec/scan. A total of 35,000

scans (1 sec delay between scans) was acquired and then processed with an exponential multiplication defined by a 3-Hz line broadening.

Statistical Methods. Data were combined for analysis of variance or comparison of standard errors of the mean.

RESULTS AND DISCUSSION

The results from attempts to chemically characterize the (S) and (R) whorl powders are summarized in Table 1. Crude fiber was 27% higher on average in the (R) whorls than in the (S) whorls. Proximate analyses of AB 24E (S), SC 229 (S), Mp 704 (R), and Mp 708 (R) gave results similar to those previously reported for several other (S) and (R) lines (Hedin et al., 1984, 1990). Table 1 also shows results for the contents of lignin, cellulose, hemicellulose, and cell wall solubles from determinations based on the use of AOAC neutral and acid detergent fiber procedures. Tissue from (R) plants was 20% higher on average in cellulose and 31% higher in hemicellulose, again similar to our earlier findings (Hedin et al., 1984). Lignin was very low (1.8–2.0%), and not different in (S)

[c] GLC-FID and GLC-MS analysis of silylated isolates.

and (R) whorls. The higher content of cell wall solubles in (S) whorls (35% on average) suggested higher digestibility and availability of nutrients.

To evaluate completeness of the extractions, the isolated hemicellulose and cellulose fractions were analyzed by the crude fiber procedure, which is defined as the loss on ignition of dried residue remaining after digestion of sample with boiling 1.25% H_2SO_4 and 1.25% NaOH (AOAC 14.118). As expected, the hemicellulose was solubilized (0.0–0.7%), whereas the cellulose was retained (58.8–60.4%), thus confirming that the two isolates were different and essentially free of each other; this was important information for the interpretation of subsequent laboratory bioassays.

Free *p*-coumaric and ferulic acids (as extracted with 2 N NaOH) were found to be about equal, respectively, in (S) whorls (0.95–0.97%) and in (R) whorls (1.21–1.34%) (Table 1). They were present in somewhat higher concentrations than reported by Bergvinson (1993). However, alkaline extractable *p*-coumaric and ferulic acids could not be isolated from purified hemicellulose. This is not surprising, since extraction of the hemicellulose from whorls initially had utilized aqueous NaOH, which was subsequently discarded.

To further characterize the hemicellulose, a series of isolates were prepared for determination of their substituent sugars and in sufficient quantities for dietary tests. Initially, sugar analysis via the alditol acetate procedure was performed on the untreated whorls. The recovery of neutral sugars (Table 2) (by summation) was about 21% for two (S) lines and nearly 29% for two (R) lines. Xylose and arabinose, from the hemicellulose, and glucose, chiefly from carbohydrates other than cellulose, were the major sugars. When several replications each of hemicelluloses from an (S) line (SC 229) and an (R) line (Mp 708) were analyzed for neutral sugar content, they were found to be significantly higher in the (R) line (52%) than in the (S) line (37%). However, the proportion of hemicellulosic xylose was not higher in the resistant lines. The approximate ratio of xylose to arabinose in the purified hemicellulose was 9:1, defining whorl hemicellulose as an arabinoxylan. For comparison, a corn cob arabinoxylan (isolated and analyzed by R. B. Hespell, Northern Regional Research Laboratory, USDA-ARS, Peoria, Illinois) gave a somewhat higher recovery of sugars, but the ratio of neutral sugars was fairly similar to corn whorl. A commercial xylan sample (Sigma Chemical Co., St. Louis, Missouri) yielded 64.2% neutral sugars and contained only a small amount of arabinose (Table 2).

The solid-state ^{13}C NMR analyses of the (R) and (S) whorls (Figure 1, Table 3) showed significant differences in the samples, and indicated that the (R) hemicellulose had a greater degree of cross-linking than (S) hemicellulose. The following solid-state ^{13}C NMR peaks were present in both the (R) and (S) samples: 25 (R), 55 (CH_3O), 65 (CH_2O), 75 (CH—O), 103 (anomeric C), 173 (broad carbonyl 1), and 181 (carbonyl 2) ppm. In the (R) sample, the peaks at 181 and 25 ppm were more intense than the corresponding peaks in the (S)

TABLE 2. NEUTRAL SUGARS IN FAW SUSCEPTIBLE AND RESISTANT CORN PLANT INNER WHORL TISSUES AND THEIR HEMICELLULOSE FRACTIONS

Sample[a]	Neutral sugars (%)[b]	Distribution of neutral sugars (%)[c]					
		A	X	M	Ga	Gl	Othe

[a] Analyses performed in duplicate except for hemicellulose and cellulose. Two xylans were isolated and ana lyzed.

[b] Percent neutral sugars in sample. Differences in total from 100% largely attributable to cellulose, which resistant to acid hydrolysis, and to xylan, which on acid hydrolysis yields only about 65% of theoretic value.

[c] Sugars determined by GLC of the alditol acetates (Sturgeon, 1990). A, arabinose; X, xylose; M, mannos Ga, galactose; Gl, glucose.

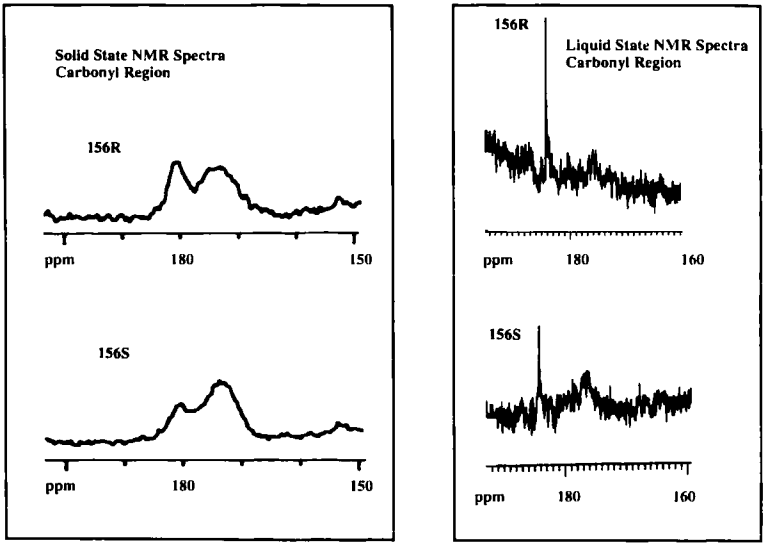

FIG. 1. Solid- and liquid-state ^{13}C NMR spectra of the carbonyl region (150–220 ppm) of SC 229 (156S) and Mp 708 (156 R) purified hemicelluloses.

TABLE 3. LIQUID- AND SOLID-STATE CARBON-13 NMR ASSIGNMENTS FOR RESISTANT (Mp 708) AND SUSCEPTIBLE CORN (SC 229) WHORL HEMICELLULOSES

Peak No.	R (ppm)[a]	S (ppm)[a]	Possible assignment
1	184.00	184.02	Carbonyl, possibly water
2	175.8 br	175.95 br	Carbonyl, possibly carboxylate
3	111.79 w	111.77 w	Possible aromatic or alkene carbon
4	104.70	104.67	α or β isomer of C-1 carbon (ketal linkage)
5	104.28	104.27	α or β isomer of C-1 carbon (ketal linkage)
6	88.80 w	88.68 w	Peaks 6, 7, 8 most likely correspond to carbons
7	82.85 w	82.86 w	contained in the furanose (five membered
8	80.95 w	80.79 w	ring) sugars
9	78.72	78.69	Most of the contributions to peak intensity in
10	76.81	76.75	this region (9-11) correspond to carbons
11	75.65	75.64	contained in the pyranose (six membered ring)
12	75.38	75.34	Sugars with some overlap with the carbons
13	65.80	65.76	contained in the furanose sugars
14	65.53	65.61	
15	25.92 w	25.92 w	Peaks 15 and 16 correspond to alkyl compounds
16	25.75 w	25.75 w	

[a]br = broad singlet; w = resonance which is less than 20% of most intense resonance.

sample, indicating that the (R) sample contained more carbonyl 2 functionalities and more aliphatic carbons than did the (S) sample. Common carbonyl compounds that appear in this region include carboxylic acids, esters, and carboxylate salts (about 5 ppm more deshielded than their corresponding acid). Since the liquid samples were analyzed in NaOH, these two carbonyl peaks can be attributed to an acid carboxyl and/or carboxylate salt because the acid would have been converted into the salt under the basic liquid NMR conditions. The liquid and solid NMR showed the same relative amounts of carbonyl 1 and carbonyl 2 compounds.

In liquid-state ^{13}C NMR studies (Figure 1, Table 3), the carbon-13 spectra of Mp 708 (R) and SC 229 (S) hemicelluloses were complicated by the relatively large molecular weights of the hemicelluloses and by the high pH of samples. The use of 20% KOH, which was necessary to dissolve the compounds, caused line broadening and baseline problems. The one-dimensional carbon-13 spectra are qualitatively very similar, as seen in Table 3, but the quantitative intensities of the carbon resonances for (R) and (S) are much different. As can be seen in Figure 1, the carbonyl resonance at approximately 184 ppm was much stronger in the (R) hemicellulose than it was in the (S) hemicellulose. However, the relative intensity of the broad carbonyl resonances centered at approximately 175.9 ppm was higher in (S) than (R). The intensity of the resonances occurring

between 90 and 80 ppm also seemed to be relatively greater in (S) than in (R). These features clearly differentiated between the two hemicelluloses.

The proton spectra (not presented) of both (R) and (S) gave only broad singlets with no observable couplings, and there were no clear differences between the proton spectra of the two compounds. ^{13}C NMR spectra were also taken on the original whorl powders. However, no differences in carbonyl carbon intensity between the (S) and (R) powders were evident, presumably because the hemicelluloses comprised only a relatively small fraction of the whorl powders.

Table 4 shows the results of five laboratory feeding bioassays, three with the FAW and two with the SWCB for comparison. In two of three bioassay tests, growth of FAW larvae on diets containing (R) hemicellulose was significantly lower than on diets containing equal amounts of the (S) hemicellulose. In the third test, larval weights on diets containing the (S) and (R) hemicelluloses were not statistically different. If it had been dietarily feasible to test the (S) and (R) hemicelluloses at higher levels, reflecting their contents in the whorl, the effect of the (R) hemicellulose may have been greater.

As with the FAW, weight gains of SWCB larvae fed the (R) hemicellulose diet tended to be lower, but not significantly so, than those fed the (S) hemicellulose diet. On the other hand, larval weights were increased significantly on diets containing the (R) cellulose.

TABLE 4. WEIGHTS OF FAW AND SWCB LARVAE FED CASEIN-BASED LABORATORY DIETS CONTAINING 15% CORN WHORL HEMICELLULOSE AND CELLULOSE (milligrams)[a]

	FAW			SWCB	
Diet[b]	Test 1	Test 2	Test 3	Test 1	Test 2
Casein-wheat germ	483.8 a			287.3 a	
Casein-wheat germ plus cellulose	484.7 a	353.6 a	226.6 bc	298.8 a	238.7 a
Casein	199.9 d			126.2 de	94.0 e
Casein plus cellulose	238.2 cd	105.2 d	175.6 c	112.4 e	
Casein plus S whorl hemicellulose	338.2 b	207.8 b	272.8 b	144.3 cd	145.5 cd
Casein plus R whorl hemicellulose	189.1 d	161.5 c	254.6 b	127.1 de	126.6 d
Casein plus S whorl cellulose	254.0 c	180.6 bc	403.7 a	147.7 c	147.4 c
Casein plus R whorl cellulose	363.9 b	176.1 c	281.3 b	201.8 b	183.1 b
LSD 0.05	54	56	21	19	18

[a]Means followed by different letters are significantly ($P = 0.05$) different according to Duncan's multiple range test.

[b]Based on the laboratory diet of Davis (1989). Hemicellulose and cellulose isolated by procedures based on those of Selvendran and Ryden (1990).

Two diets, one containing 0.1% each of *p*-coumaric and ferulic acids, and the other containing 1.0% each of these two phenolic acids added to the control diet were bioassayed in feeding tests with the FAW. The average larval weight at 10 days on diets containing 0.1% each of the phenolic acids was 184.9 mg. At the 1.0% level, the average weight was 127.6 mg. The lower level of this phenolic acid mixture was approximately that which was found by Bergvinson (1993), and the higher level reflected that found by us (Table 1).

Freeze-dried whorl powders have been dispersed in laboratory diets to evaluate FAW resistance (Williams and Buckley, 1992; Williams et al., 1995). The aqueous residue from resistant whorls was associated with poor growth (Williams and Davis, 1995). However, to identify the actual basis of resistance, it is necessary to devise extractive procedures that conserve biological activity upon recombination of fractions. Unfortunately, no entirely satisfactory procedures could be established because extraction at reflux with presumably mild solvents, including water, ethanol, and 50% aqueous ethanol, failed to give extracts that elicited growth upon recombination with the residue. An all-purpose vitamin mixture partially restored activity, but this approach could not be optimized. Aqueous extractions at intermediate temperatures (65–70°C) gave full activity upon recombination with the residue. However, further treatments of the extracts or residues resulted in lost activity, so efforts to use a bioassay based on conserving the activity of whorl powder were abandoned. An alternative strategy was then adopted to isolate fractions or components that differed in concentration in (S) and (R) lines, and then to evaluate their biological activities in laboratory diets.

Hartley et al. (1988) proposed that a portion of the phenolic acids may become bound to hemicellulose through a mechanism in which a four-membered ring is formed from the double bonds of the side chains in either a head-to-tail fashion to form truxillic acids, or in a head-to-head fashion to form truxinic acids. Both phenolics may be attached to arabinose and xylose prior to the phytochemical reaction. The cyclobutane dimers consist of both ferulic and *p*-coumaric acid, and it has been hypothesized that they may constitute a defense against insect attack (Hartley and Ford, 1989; Iiyama et al., 1990; Bergvinson et al., 1994). The levels of these cyclobutane dimers are highest in tissues that intercept sunlight, with leaf blades having the highest levels, followed by sheath and stem tissue (Eraso and Hartley, 1990). Head-to-tail dimers are generally in the greatest abundance (Morrison et al., 1991). The formation of these dimers in full sunlight may explain why maize plants grown in greenhouses are more susceptible to the ECB feeding on leaves, as reported by Guthrie et al. (1986) and Bergvinson et al. (1994).

In summary, more hemicellulose was found in (R) whorls than in (S) whorls. Using standard analytical procedures, (R) lines were also found to contain more crude fiber and cellulose, but less protein and cell wall solubles. NMR

evidence was obtained for a higher level of carbonyl carbon in (R) hemicellulose. In dietary tests, larval weight gains were higher on (S) hemicellulose incorporated in diets at the same level as (R) hemicellulose. These data suggest that the lower weight gains can be attributed to the relative amounts and differences in structure of hemicelluloses.

Acknowledgments—The authors thank Mr. Paul Buckley for performing preliminary insect bioassays, Mrs. Debbie B. Saebo for performing NMR analyses, and Mr. Douglas Dollar for performing GLC sugar analyses.

(Received February 3, 1995; accepted May 1, 1996)

Abstract—Individual differences in flank gland secretions were examined among males of the monogamous shrew *Crocidura russula* during the breeding and nonbreeding seasons. Gas chromatography was used to measure intra- and interindividual variation of flank gland secretions of free-ranging shrews from different populations. The number of compounds detected by gas chromatographic analyses was correlated with body mass, flank gland size, and the presence of blood parasites in individual shrews. Very few compounds were detected from the flank gland area of juvenile males. After they reached sexual maturity, however, the number of compounds detected from the flank gland secretions increased significantly. At the beginning of the reproductive season 48 different compounds were detected from male flank gland secretions. In the middle of the breeding season 70 compounds were detected, while only 11 compounds were detected during the nonbreeding season. Few compounds were common to all males. There were more volatile compounds in the flank gland secretions of males in the beginning of the breeding season than later in the breeding season. Males from the same population had fewer differences in the elution profile of compounds than males from different populations indicating that individuals from a distinct population have similar elution profiles of compounds and that each population has its own type of elution profile. No correlations were found between the number of compounds

detected by gas chromatography for each male and the male's body mass or flank gland size. Blood parasites (trypanosomes, *Trypanosoma crocidurae*) were found in only three of 30 males investigated.

Key Words—*Crocidura russula*, flank gland secretions, gas chromatography, flank gland size, body mass, blood parasites, shrews.

INTRODUCTION

Social communication through the use of odors in small mammals is well known (Eisenberg and Kleiman, 1972; Mykytowycz and Goodrich, 1974; Stoddart, 1976; Brown and Macdonald, 1985). In rodents, the scent glands and their odors play an important role in reproduction, mate selection, parent–offspring interactions, interindividual recognition, and scent marking of territory (see review in Brown, 1985a,b). The secretions of scent glands can be studied with chemical analyses for species, sex, and individual differences (Albone, 1984). Few studies have been carried out on the role of olfaction in the social behavior of shrews and other insectivores, probably because they are difficult to observe in their natural habitat and they are rarely used in the laboratory.

Shrews (Soricidae) have poor visual acuity and are mainly nocturnal, thus olfaction may play a major role in their social communication (Poduschka, 1977; von Holst, 1985; Poduschka and Wemmer, 1986). This conclusion is based on the facts that shrews have a well-developed olfactory system (Sigmund and Sedlacek, 1985) with a prominant vomeronasal organ (Ärnbäck-Christie-Linde, 1914) and numerous cutaneous glands (Niethammer, 1962; Murariu, 1971, 1972, 1973). The largest odoriferous glands are the lateral flank glands present in most shrews of both sexes (Geoffroy-St-Hilaire, 1815). Histological (Johnsen, 1914; Eadie, 1938; Pearson, 1946; Murariu, 1973; Balakrishnan et al., 1986) and physiological studies (Pearson, 1946) especially with castrated shrews (Dryden and Conaway, 1967; Balakrishnan and Alexander, 1976), have shown that the flank glands of shrews are under hormonal control and are generally more developed in males than in females, especially during the breeding season. Cantoni and Rivier (1992) showed a sexual dimorphism in flank gland secretions, with males having numerous compounds in their flank gland secretions revealed by gas chromatography analysis while no compounds were detected from the flank gland area of the females.

Scent-marking behaviors in mammals are very common and provide the means by which social odors can be transmitted over distance and time or directly to conspecifics by partner marking. In shrews the flank gland secretions may be useful during the reproductive season for finding a mate, and partner marking may promote the sexual receptivity of the female by the male (von Holst, 1985). *Suncus murinus* and *Blarina brevicauda* scent mark by rubbing

their flank glands against objects (Tennant et al., 1987; Platt, 1976), and these flank gland marks may be used for territorial defence (Pearson, 1946; Poduschka and Wemmer, 1986).

In shrews (*Suncus murinus* and *Blarina brevicauda*), it has been shown that the postauricular glands, ventral glands, and lateral flank glands are associated with reproduction, with males exposing their postauricular glands to female biting, which promotes the receptivity of the female (Poduschka and Wemmer, 1986). Scent marks of males may also be used for mate selection and mate recognition, as has been shown in rodents (Newman and Tang Halpin, 1988; Tang-Martinez et al., 1993; Johnston and Jernigan, 1994). Cantoni and Rivier (1992) found that few compounds detected by gas chromatography were common to different individual male *C. russula*. This suggests that each male *C. russula* produces a unique odor that could play an important role in mate choice and mate recognition in this monogamous species.

The aim of the present study was to use gas chromatography to analyze individual differences in flank gland secretions among male *C. russula* by measuring intra- and interindividual variations of flank gland secretions of free-ranging shrews coming from different populations during the breeding and nonbreeding season. The number of compounds detected by gas chromatography analysis of the flank gland secretions were correlated with morphological measures (body mass and flank gland size). Blood samples were analyzed for the presence of blood parasites, because the presence of these parasites could affect the physiology of the animal (Sebek, 1978; Milinski and Bakker, 1990; Harvey and Bradbury, 1991). Parasitized male mice are less attractive as mates than healthy males (Kavaliers and Colwell, 1995). These particular parameters were assessed because of their potential role in determining the attractiveness of a male to a potential mate (Cockburn, 1991; Milinski and Parker, 1991; Harvey and Bradbury, 1991).

METHODS AND MATERIALS

Study Animals. Crocidura russula, originally from North Africa, are found in Switzerland only near human habitation. The breeding season of *C. russula*, which is a monogamous shrew (Ricci and Vogel, 1984; Cantoni and Vogel, 1989), is strongly influenced by climatic conditions and altitude (Genoud, 1981). The shrews in this study were all trapped in residential gardens in the neighborhood of Lausanne (altitude 500 m, Vaud, Switzerland). In this region the breeding season generally begins in March and ends in September. *C. russula* have a life-span of 12–18 months (Vogel, 1972) and females have an average of three or four litters per year with a mean of 4.4 pups per litter (Besançon, 1984). At weaning, the juveniles weigh 6–9 g (Besançon, 1984). They grow

rapidly and may become reproductive adults within 42 days of birth when population densities are low (Genoud, 1981; Besançon, 1984). Early the following spring, the individuals that have survived are reproductively active and weigh 10–13 g. In sexually active males and only during the breeding season, the lateral flank glands become enlarged and produce strong odoriferous secretions (Besançon, 1984; Cantoni, 1990). In females, sexual maturity is characterized by evidence of gestation. There is no increase in size or secretion rate of the flank gland in sexually active females (Murariu, 1973; Cantoni and Rivier, 1992).

Collection of Flank Gland Secretions. During the breeding season in 1988 and 1989, 27 adult male, 12 juvenile male, and 17 subadult male *C. russula* were trapped in two gardens in Lausanne. All individuals were trapped in Longworth traps (Penlon, Abingdon, UK). The flank gland secretions of the males were collected as soon as the males were removed from the traps. This was done to prevent the stress of being handled from influencing the scent gland secretions and also to prevent any contamination of the gland areas from our hands. The method used to collect the flank gland secretions was similar to that used by Erlinge et al. (1982) as modified by Cantoni and Rivier (1992). This method consisted of rubbing each flank gland back and forth four times with a piece of filter paper (Whatman 40, 3 × 3 mm) held with tweezers, which were cleaned with 70% alcohol between each individual sample. Two samples were taken from each flank gland and then the four filter papers collected from each individual were extracted and stored in 200 μl dichloromethane ($CHCl_2$) inside a hermetically sealed vial and kept at −30°C until they were analyzed by gas chromatography. When no flank glands were visible, their position was estimating using the method described by Murariu (1973) and the area rubbed with filter paper in the manner described above. After flank gland samples were taken, the shrews were identified, weighed, sexed, marked by toe-clipping and released at the point of capture.

Control samples were regularly taken at the beginning of each new trapping session and consisted of four pieces of clean filter paper dropped directly into 200 μl $CHCl_2$ and stored at −30°C. This was done in order to check for any contamination of the solvent ($CHCl_2$) and/or the filter papers during the study period.

In December 1988, during the nonbreeding season, two old adult males (born in 1987) and nine young adult males (born in the current year) were trapped in the same two gardens and their flank gland secretions were collected using the method described above.

During the breeding season in 1993, 33 adult males were repeatedly trapped in six different gardens. These gardens were far apart (2–20 km) and separated by roads, fences, and other barriers, such that migration of shrews between

these gardens was unlikely. One or two trapping sessions were done in each of the six gardens. Each trapping session lasted 12–48 hr, and each male was trapped one to six times. The flank gland secretions of these 33 males were collected as described previously, and the size of each of the two flank glands from 30 of the 33 males was measured with vernier calipers each time the male was trapped. The shape of the gland is rather oval and the length was taken at the longest point of the gland. The means of all measures of gland length for each male were used for analysis. Blood samples were taken the first time each of the 30 males were trapped. Blood was collected when the individuals were marked by toe clipping or from a small transverse cut at the base of the tail made with a sterilized scalpel and the blood was smeared on glass slides (two slides per male). Finally, each male was weighed. Because traps were baited with meal worms (*Tenebrio molitor*), however, some individuals had a full stomach and some did not, depending on how long they had been in the trap. To avoid this bias, the 30 males were kept in individual cages for 2 hr after their capture without food but with water, and weighed again. The second weight was used for analysis. Males were then released at their point of capture.

Gas Chromatographic Analysis of Flank Gland Secretions. Gas chromatographic analysis of the flank gland secretions was performed according to the procedure of Rivier and Baumann (1976) as modified by Cantoni and Rivier (1992). The vials containing the four filter paper wipes from each animal in 200 μl $CHCl_2$ were each considered as an individual sample. To each sample, 10 μl of standard mixture of the *n*-alkanes [solution of 0.033% (w/w), $C_{14}H_{30}$, $C_{15}H_{32}$, and $C_{16}H_{34}$ in hexane] was added as an internal standard. This solution was chosen because its elution time is very short and does not interfere with the elution time of the compounds contained in the samples. From each sample, 1 μl of solution was injected (250°C) into a gas chromatograph (Hewlett Packard 5790) capillary column (25 m × 0.2 mm) containing a methyl silicone phase (OV-101). The oven temperature was initially at 130°C, held there for 1 min, and then increased 10°C/min to 280°C, and maintained for 10 min (12 PS, pressure at the head of the column). These eluting compounds were detected by a flame ionization detector maintained at 300°C.

Peak retention times and peak areas were measured. The same elution program was used for all analyses, thereby permitting comparison of the number of peaks, area of peak, and peak retention time of the detected substances of the different chromatograms. Peak retention times were rounded up to the first decimal and, when necessary, peak retention time was adjusted as a function of the mean elution time of the three peaks of the internal standard solution. The three peaks (C_{14}, C_{15} and C_{16}) of the internal standard were used to evaluate any minor shifts of the retention time that may occur from one chromatographic analysis to another even if the same analytical conditions are used. Therefore,

these three peaks were useful for the comparative study of the chromatograms in order to identify homologous peaks. No identification of the different compounds detected was undertaken.

Reliability of Flank Gland Secretion Collecting Method. In order to test the reliability of the method for collecting the flank gland secretions in the field, four to six samples of flank gland secretions were taken over a short period of time (from 3 hr to 7 days), from each of four males trapped in the same garden. All samples were analyzed by gas chromatography as described above. The aim of this experiment was to determine whether our method of collecting the flank gland secretions gave repeatable results for each male. In order to test whether the gas chromatograms from repeated samples from the same individuals resulted in the same set of compounds being detected, we used a Mantel test (Mantel, 1967), which is a general method of matrix comparison dealing with two similarity or distance matrices obtained independently and describing the relationships among the same objects. The similarity or distance matrices can be obtained using an appropriate association coefficient from Legendre and Legendre (1979). In our case, the first matrix contained Euclidean distance data, r_{Huben} (Legendre and Legendre, 1979), calculated on the presence or absence of the compounds detected by gas chromatography within the flank gland secretions of the same individual and/or different individuals.

The second matrix was the theoretical matrix that corresponded to our hypothesis that variability in eluting compounds within the same individual is smaller than variability in eluting compounds between different individuals. This matrix had a maximal distance for the comparison of the secretions from two different individuals and a null distance for the comparison of secretions from the same individual. The observed data in the first matrix can then be compared to the second matrix, which represents the data expected. The null hypothesis is that the first matrix is not correlated with the second matrix.

In Mantel's (1967) procedure, correlations are calculated between pairs of matrices and tested by permuting at random the rows and corresponding columns of one matrix 1000 times. After each permutation, the correlation statistic is obtained, producing a set of values of the normalized Mantel statistic, r, obtained under H_0. These values represent the sampling distribution, which is used for the significance test. The "R Package for Multivariate Data Analysis" (P. Legendre and A. Vaudor, University of Montreal) was used for this analysis.

Statistical Analysis of Gas Chromatograms. Compounds in the flank gland secretions of the different males, detected by gas chromatography, were analyzed with correspondence factorial analysis, which is a multivariate analysis similar to principal component analysis and developed by Benzecri (1973). In a principal component analysis, the factors (first, second, . . . , etc. principal components) are the combination of the variables and allow one to project the objects in the space of the variables. In the correspondence factorial analysis the factors are

the linear combination of the variables and the objects and, therefore, allow one to project the objects and the variables together in the same space. In our case, the individuals were considered as the objects and the areas of the detected compounds (peaks), according to their retention time, were considered as the variables. Principal component analysis was used by Natynczuk and Macdonald (1994) to analyze rat haunch odors. By using a correspondence factorial analysis instead of a principal component analysis, we were able to measure and visualize the relationships between the individuals, the peaks, and the individuals and the peaks.

Variability in compounds detected from the flank gland secretions of individuals coming from the same population (same garden) and individuals coming from different populations (separate locations) were tested with the Mantel test using the procedure described above. The first matrix contained Euclidean distance data, r_{Huberl} (Legendre and Legendre, 1979), calculated on the presence or absence of the compounds detected by gas chromatography on the flank gland secretions of individuals from the same or different populations. The second matrix had a maximal distance for comparison of the secretions of individuals from different populations and a null distance for comparison of individuals from the same population. The null hypothesis, H_0, is that the first matrix is not correlated with the second matrix.

Pearson correlations were performed between the total number of detected compounds, body mass, and flank gland size.

Blood Smear Analysis. The blood samples were analyzed for the presence of parasites such as *Plasmodium* or *Trypanosoma*. To perform this analysis, the blood smears on each slide were colored with Giemsa (Kit Colorrapid, Bioreac, Lausanne, Switzerland), and the slides were examined under a microscope (Leitz Laborlux D, magnification 500×) for the presence of parasites.

RESULTS

As a preliminary test of the reliability of the sampling technique, four males were tested and we found that the variability in the compounds of secretions from different individuals (Mantel test: $r_{\text{Huberl}} = 0.516$, $P < 0.05$). This means that all of the eluting compounds detected in the flank gland secretions of one individual are characteristic of that individual and the sampling method used is reproducible. Thus, our sampling of the flank gland secretions is accurate enough to distinguish different males and, therefore, only one sample of the flank gland secretion of each male was collected.

The flank gland secretions of 60 different adult males trapped in the breeding seasons of 1988, 1989, and 1993 were analyzed by gas chromatography. A mean of 54.6 ± 21 peaks were detected per adult male and up to 215 different

compounds were found over all males (Figure 1A). Each male had its own elution profile of compounds (combination of peak retention times and peak areas), and only a few peaks per male were common to all males (see Cantoni and Rivier, 1992). The elution profile of the peaks for the same male were similar in samples taken within a short period of time (several hours to seven days) (compare Figure 2B and C), but the elution profile of peaks for the same

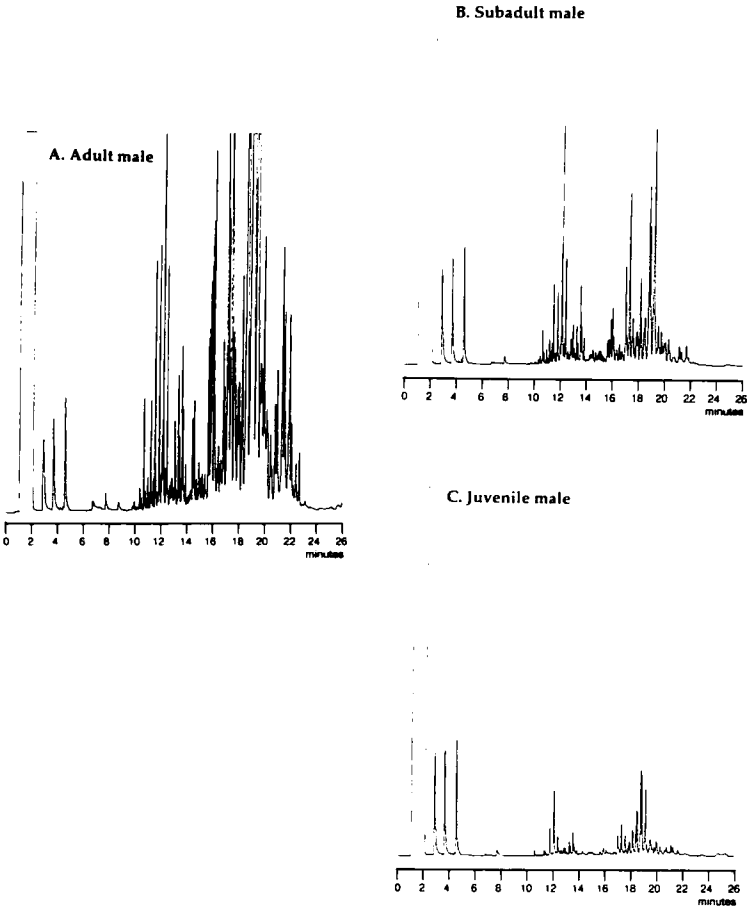

FIG. 1. Typical gas chromatograms obtained for the flank gland secretions of male adult, subadult, and postweaning juvenile *C. russula*. The first peak of each trace is the solvent front and the three following peaks are the internal standard peaks ($C_{14}H_{30}$, $C_{15}H_{32}$, and $C_{16}H_{34}$).

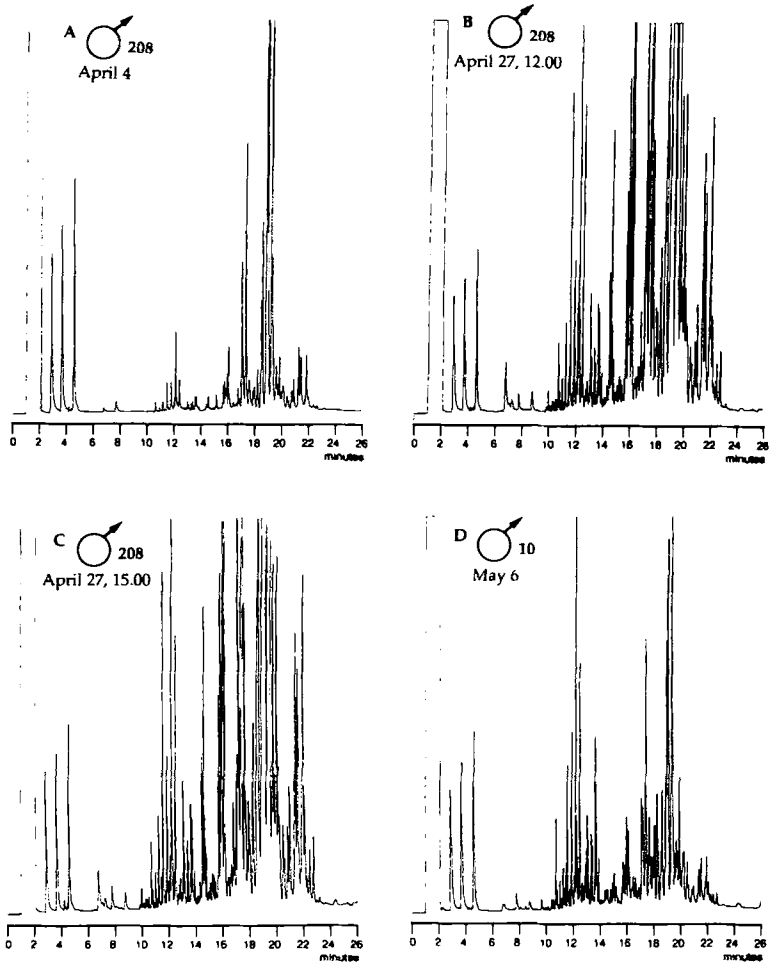

FIG. 2. Examples of gas chromatograms obtained for the flank gland secretions of one adult male (number 208) sampled on (A) April 4, 1993, (B) April 27, 1993 at 12:00 hr, and (C) April 27, 1993 at 15:00 hr. The gas chromatogram obtained from the flank gland secretion of another adult male (number 10) from another garden and sampled on May 6, 1993, is shown in (D). The abscissa represents the elution time (minutes) and the ordinate indicates the detector response. The first peak of each trace is the solvent front and the three following peaks are the internal standard peaks ($C_{14}H_{30}$, $C_{15}H_{32}$, and $C_{16}H_{34}$).

male changed over the breeding season (compare Figure 2A and C). The area of each peak indicates the amount of each chemical in the flank gland secretion. Table 1 shows the retention times for the five largest peaks in each adult male at four sampling periods. Most individuals had a different set of five largest peaks, and only a few of these peaks were common to all individuals in the same sampling period. Therefore, Table 1 indicates many individual differences in the chemicals in the flank gland secretions.

Chromatograms obtained from the flank glands of 17 subadult males trapped in 1988 showed a mean of 52.1 $\pm$ 12 peaks per male (Figure 1B). In general, the peak areas of the compounds detected for these subadult males were smaller than those detected for the adult males (compare Figure 1A and B). These subadults were young males that had yet not reproduced but were almost sexually mature according to Besançon (1984).

The chromatograms of the flank gland secretions of the 12 postweaning juveniles trapped during the breeding season in 1988 showed few compounds (Figure 1C), with a mean of 7.5 $\pm$ 4 peaks per juvenile.

The number of different compounds detected in the flank gland secretions of the adult males changed over the reproductive cycle. At the beginning of the breeding season, in April and May, adult males had, respectively, 48.1 $\pm$ 16 ($N = 27$) and 56.9 $\pm$ 25 ($N = 26$) peaks, and there was a significant increase in the number of peaks between these two months (Wilcoxon signed ranks test: $Z = 1.965$, $P = 0.049$). The number of peaks increased from May until the middle of the breeding season in July (71.0 $\pm$ 8, $N = 7$) peaks but not significantly (Wilcoxon signed ranks test: $Z = -1.572$, $P = 0.116$). During the nonbreeding period (December) only 13.1 $\pm$ 15 ($N = 11$) peaks were observed, which was significantly fewer peaks than in the breeding season (Wilcoxon signed ranks test: from April to December $Z = -2.937$, $P = 0.003$; from May to December $Z = -2.936$, $P = 0.003$; and from July to December $Z = -2.366$, $P = 0.018$). In December the flank gland size decreased, and in most individuals the glands were regressed and not visible. In December the sample was composed of nine young adult males (born in the current year) and two older adult males (born the previous year). Even though the two older males had a longer breeding season than the young ones, they were all in a nonreproductive state.

In 1988, several males were trapped repeatedly during the breeding and nonbreeding seasons, and the variation in the flank gland compounds detected by gas chromatography was analyzed using correspondence factorial analysis (Benzecri, 1973). This analysis allowed us to describe and to visualize associations or separations between variables (peak retention times and peak areas), between objects (individuals), and between variables and objects. These associations or separations are plotted as a function of the three main factors explaining the total variance of the analysis. For the sake of clarity, the results of the analysis were plotted into two figures having the same spatial configuration.

TABLE 1. RETENTION TIMES (RT) OF DIFFERENT COMPOUNDS (PEAKS) FOUND AMONG FIVE LARGEST PEAKS (AREA) OBSERVED IN EACH ADULT MALE AS FUNCTION OF SAMPLING PERIOD IN 1988 AND 1989.[a]

Sampling period (month, year)	Retention times of the five largest peaks																	Individuals (*N*)

[a]The number (*N*) below the retention time indicates in how many individuals the peak was found among the five largest peaks at this period of the year. In December 1988, some individuals had less than five peaks, therefore the sum of the numbers (*N*) below the retention times are not equal to five times the number of individuals (11 in December 1988).

Figure 3 represents the individuals (objects) and Figure 4 the peaks (variables). Furthermore, peaks (Figure 4) were grouped and represented (on the figure only, not in the analysis) with three different symbols according to their elution time. The individuals (Figure 3) and the peaks (Figure 4) were both projected on the planes formed by the first three factors, explaining, respectively, 15%, 10%, and 9% of the total variance of the analysis.

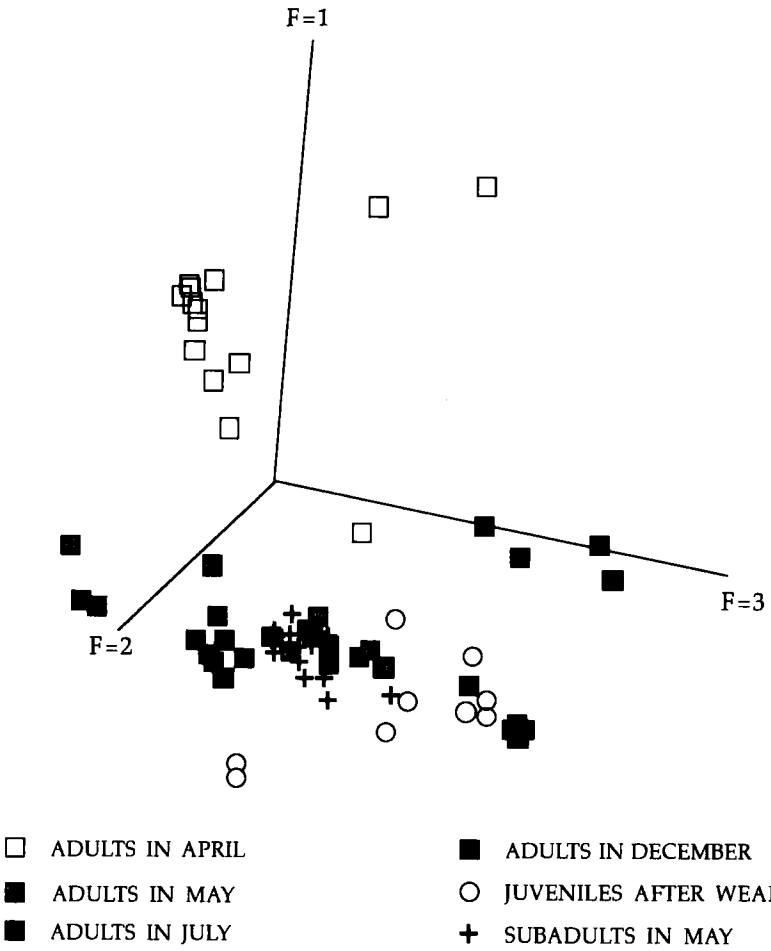

FIG. 3. Projection of the individuals (objects) in the planes formed by the first three factors (F1, F2, and F3) of the correspondence factorial analysis of the flank gland secretions of male *C. russula* during the breeding and nonbreeding season.

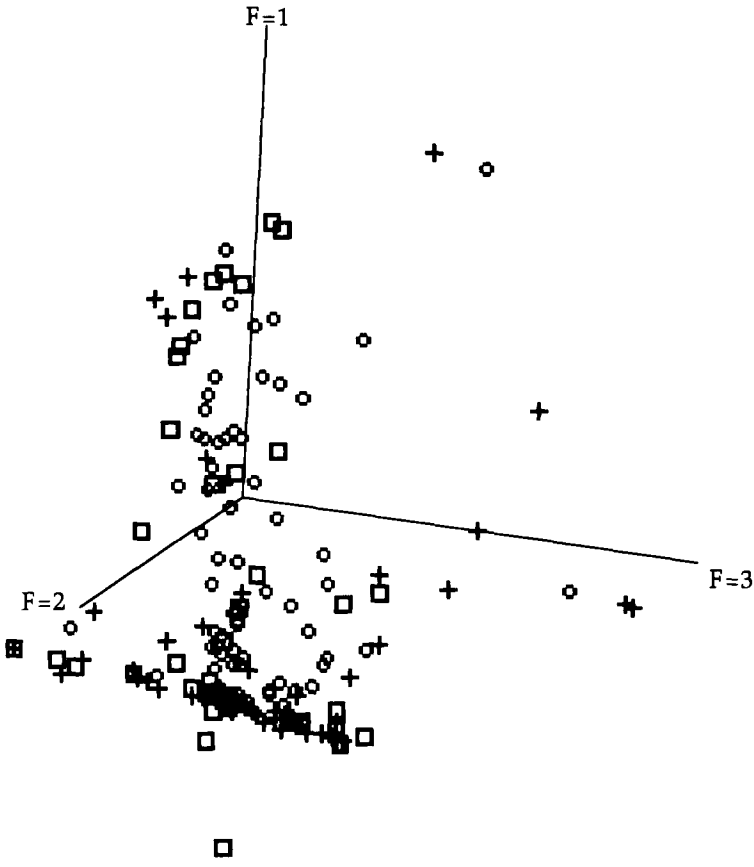

FIG. 4. Projection of the peaks (variables) in the planes formed by the first three factors (F1, F2, and F3) of the correspondence factorial analysis of the flank gland secretions of male *C. russula* during the breeding and nonbreeding season.

This analysis showed that individuals trapped during the same month are grouped together (Figure 3), indicating that they have a similar elution profile of compounds even if they do not have identical peaks. This analysis also showed that individuals trapped during a particular time of the year do not have the same elution profile of compounds as they do when trapped during another

time of the year (adults from April to July as compared to adults in December). This indicates that the flank gland secretions of each individual changed during the year. The postweaning juveniles are grouped between the subadults and the adults trapped in December and May (Figure 3). This is principally due to the fact that juveniles have few compounds detected by gas chromatography, which is also the case for individuals in December. The juveniles also have an elution profile of compounds that is quite similar to that of the individuals trapped in May, a period of the year when these juveniles were also trapped. Subadults and adults trapped in May were grouped together even if adults had generally more compounds than did subadults. Several peaks are linked with certain individuals or groups of individuals (compare Figures 3 and 4), indicating that these compounds are characteristic of these individuals. Associated with the individuals trapped at the beginning of the breeding season (adults trapped in April), we find more volatile compounds (compounds eluting between 2.7 and 17.9 min) than later in the breeding season (adults trapped in May and July), when heavier compounds were detected (Figure 4).

The flank gland secretions of the 33 males from six different populations collected in 1993 were analyzed to detect within- and between-population variability in flank gland secretions. A mean of 5.5 $\pm$ 1.8 individuals per population were sampled. The variability in the compounds detected between individuals and between populations was tested with the Mantel (1967) test. The results showed that the differences in the elution profile of compounds detected are significantly larger between populations than within populations (Mantel test: $r_{\text{Huber}} = 0.499$, $P = 0.04$), indicating that individuals from a distinct population have similar elution profiles of compounds and that each population has its own elution profile (Figure 2A, B, vs. D).

In order to test a possible correlation among the number of peaks, flank gland size, and potential male quality expressed by body mass and by absence of blood parasites, 30 adult males trapped in April and May 1993 were analyzed. There was a mean of 41 (SD = 15) peaks detected by gas chromatography from the flank secretions of these males. These males had an average flank gland length of 9.1 $\pm$ 0.8 mm, and an average body mass of 12.6 $\pm$ 1.2 g. The number of compounds detected in the flank gland secretions of the 30 males was not correlated with body mass ($r = 0.046$, $P = 0.807$) or flank gland size ($r = 0.164$, $P = 0.387$). However, body mass and flank gland size were correlated ($r = 0.391$, $P = 0.033$). These results indicate that the variance in the number of compounds detected between individuals depends on factors other than body mass and flank gland size. Blood parasites (trypanosomes, *Trypanosoma crocidurae*) (Brumpt, 1923) were found in only three males, two of which came from the same population. Due to the existence of blood parasites in only three individuals, no correlation was performed between the number of peaks detected and this physiological parameter.

DISCUSSION

Our results show that the flank gland secretions of male *C. russula* vary with the age and reproductive state of the male. These changes occur over four steps and involve the number and the amount (peak area) of compounds as well as the retention time of the compounds detected. As males grow from juveniles to subadult males, there is a large increase in the number of compounds detected in flank gland secretions (from 7 to 52) and a small change in peak area, as indicated by the height of each peak in Figure 1. During the change from subadult to reproductive adult, there is a small increase in the number of compounds detected (from 52 to 55), and a great increase in the amount (peak area) of the compounds detected (see Figure 1). Thirdly, during the breeding season, there are changes in the elution profile of compounds. At the start of the breeding season, there were more volatile compounds detected than later in the breeding season, where more heavier compounds were detected. Finally, in the nonbreeding season, there was a drop in the number and area of the compounds detected. The juveniles born late in the breeding season generally reached the subadult stage at the end of the breeding season and produced few or no flank gland secretions. During the nonbreeding season the population consisted principally of young adults, subadults, and few older adults, all of which can be considered as sexually mature but in a nonreproductive state. Indeed, Besançon (1984) observed a few cases of reproductive behavior during the nonbreeding season in an especially mild winter. Few compounds were detected from the flank gland secretions collected during the nonbreeding season, and these were similar for all males.

The age-related changes in flank gland secretions are probably related to the increased androgen secretions as these males reached sexual maturity. Indeed, Dryden and Conaway (1967) and Balakrishnan and Alexander (1976) have shown that the flank gland secretions of *Suncus murinus* were under gonadal hormonal control. They demonstrated that castration greatly reduced the production of odoriferous secretions and scent-marking behavior in this species. When these authors gave gonadal hormones in food pellets to castrated *S. murinus*, there was a reactivation of the flank gland secretions and scent marking behavior. At the onset of the reproductive season of *C. russula*, testes mature rapidly (Besançon, 1984), increasing androgen levels, which might be the cause of the development of flank gland secretions characterized by the large increase in detected compounds. The same phenomenon occurs for the postweaning juveniles, born early during the breeding season, which become adults in the same breeding season. Gonadal hormones are also likely to influence the decrease of flank gland secretions, especially when shrews enter their nonbreeding period. Nonbreeding is characterized by a strong regression of the flank glands, which produced no odorous secretions.

Our results also show that differences in the compounds detected in the flank gland secretions of males during the breeding season are significantly smaller among males coming from the same population than they are among males coming from different populations. This finding raises the question of whether the flank gland secretions are related to genetic factors. Favre and Vogel (1992) used DNA fingerprinting to show that populations of *C. russula* are highly inbred. Furthermore, it was noted that breeding dispersal is biased towards females for this species (Favre and Vogel, unpublished data). These different points suggest that the chance of trapping related males (i.e., brothers or cousins) is fairly high within a defined population. This factor could have influenced our results. Nevertheless, the notion that the elution profile of compounds detected in the flank glands of male *C. russula* is genetically based is yet to be shown conclusively. Further experiments involving comparative gas chromatographic analyses of flank gland secretions of related and unrelated individuals need to be performed.

External factors can influence the elution profile of compounds detected in flank gland secretions. Changes in diet can significantly alter the odors from skin glands, urine, and feces (Beauchamp, 1976; Skeen and Thiessen 1977; Schellinck et al., 1992, Brown and Schellinck, 1992, Salamon, 1996). This could explain a part of the change in the flank gland secretions of *C. russula* occurring during the breeding season, which may be correlated with seasonal changes in prey species leading to changes in the shrew's diet. The fact that we have found significantly fewer differences in the compounds detected among males coming from the same population versus males coming from different populations may be due to local variations in invertebrate diversity or other environmental factors that could influence the elution profile of compounds detected.

Bacteria are another external factor that may affect the production of secretions by scent glands (Brown, 1979; Albone, 1984). The external region of the flank glands in shrews is probably colonized by diverse bacteria. During the nonbreeding period, several male and female *C. russula* share a communal nest and rest together in very close contact (Cantoni and Vogel, 1989). During this period, which lasts until the onset of the breeding season, the bacterial fauna of different individuals can be easily mixed. As only a few communal nests are observed per population, the hypothesized existence of local common bacterial fauna could influence the elution profile of compounds detected within a population by gas chromatography and therefore lead to a higher similarity within populations.

We found no correlations among body mass, flank gland size, and the number of peaks detected by gas chromatography in the flank gland secretions of *C. russula*. This indicates that the size of the flank glands and body mass have no direct influence on the number of compounds detected. However, in this analysis we did not take into account the type (retention time) of peaks

detected; only the number of peaks was considered. Perhaps only a few compounds are playing a direct role in the social behavior of shrews. We can not even be sure that the strong musky scent perceived by humans is the main odor component detected by shrews. Further studies of flank gland secretions should not only identify all the compounds by gas chromatography–mass spectrum analysis, but also test them in bioassays in order to understand their function.

We found only three individuals among the 30 we examined that were contaminated with blood parasites. The *Trypanosoma* parasite found has already been described for *C. russula* (Edrissian et al., 1976; Walter and Liebisch, 1980) and for other species of shrew (Sebek, 1978). These three individuals had normal body mass with no apparent signs of poor health. Furthermore, all three were paired with a female. Very little is known regarding the effects of this blood parasite in small mammals. Helminthes, which often heavily infest shrews (Vaucher, 1971), may have a stronger influence on male body conditions.

Our findings show that male *C. russula* produce individually distinct flank gland secretions that undergo several changes during their life-span. Many complex factors are probably involved in the initiation and regulation of these secretions. Several hypotheses on the function of scent glands in shrews have been suggested. Johnsen (1914) and Eadie (1938) suggested that they function as a predator repellent. But why do females, which have the same predators as males, have no active glands? Many shrew species are solitary, thus scent marking of territories was suggested (Pearson, 1946). For the highly territorial *Sorex*, we would expect to find scent gland activity during winter when territoriality is at its maximum (Croin Michielsen, 1966). *Sorex* male flank glands, however, develop only in spring. One of the oldest interpretations of flank gland function (Geoffroy-Saint-Hillaire, 1815) deals with mate localization and male recognition. In the monogamous *C. russula*, females are able to discriminate between the odors produced by the flank glands of their partner and those of other males (Cantoni et al., unpublished data). Finally, according to Rissman (1987, 1989), female sexual receptivity in *Suncus murinus* is enhanced by male-related chemical cues. The different hypotheses are probably all parts of the reality, but flank glands are not the unique source of pheromones in shrews. Other glands, such as the postauricular glands (Dryden and Conaway, 1967), anal and subcaudal glands (Niethammer, 1962), and the ventral gland in *Cryptotis* (Pearson, 1946) certainly contribute, along with urine and feces, to a complex system of chemical signals. Moreover, among Soricidae, there are important differences in social behavior (Cantoni, 1993), reproductive strategies (Genoud and Vogel, 1990), and energetic strategies (Vogel, 1980, Genoud, 1988), suggesting the existence of different roles played by flank gland secretions in different species of shrew.

Acknowledgments—Many thanks to Dr. R. E. Brown for his constructive criticisms and valuable ideas, to N. C. Wathen and H. M. Schellinck for their helpful comments and English corrections on an earlier draft of this paper, and to two anonymous reviewers for their valuable

comments. We also thank Dr. M. Genoud, who provided valuable discussions and ideas throughout the study. We thank the Swiss Tropical Institute (Basel, Switzerland) for the determination of the blood parasite *Trypanosoma crocidurae*.

(Received October 9, 1995; accepted May 1, 1996)

Abstract—Interdigital secretions were collected from eight male white-tailed deer of various ages. Analysis of volatiles was performed by gas chromatography–mass spectrometry with a modified headspace technique. Forty-six volatile compounds were found including alkanes, arenes, aldehydes, ketones, aliphatic acids, esters, pyrroles, furans, and sulfur compounds. Eleven occurred in higher concentrations ($P \leq 0.10$) in dominant ($\geq$3.5-year-old) than in subordinate ($\geq$1.5-year-old) animals. Dominant males typically have higher serum testosterone levels, and fatty acids and esters fluctuate with sebum production, which is under hormonal control. Therefore, these compounds may reflect testosterone levels and act as chemical signals indicating the presence of a dominant male. Interdigital volatiles also may act as generalized scent trail markers.

Key Words—Interdigital gland, *Odocoileus virginianus*, pheromone, scent communication, semiochemical, volatiles, white-tailed deer.

INTRODUCTION

White-tailed deer (*Odocoileus virginianus*) have been the subject of various studies involving scent communication. Deer rely on olfaction and the deposition of various semiochemicals to facilitate communication among conspecifics. These compounds can be carried on the deer or deposited in the environment

in the form of olfactory signposts (Müller-Schwarze, 1972; Moore and Marchinton, 1974; Miller et al., 1987; Marchinton et al., 1990).

Originally described by Quay (1959), the interdigital glands are pockets between the primary digits of both fore- and hind feet. The associated skin is characterized by enlarged sebaceous glands with few apocrine glands. Enlarged erector pili muscles may act to force the glandular material out of the ducts and hair follicles. Quay (1959) reported that the sebaceous glands may enlarge with age, and the exudate may become more pigmented. Similarly, interdigital secretions from Rocky Mountain mule deer (*O. hemionus hemionus*) also become more pigmented with age (Quay and Müller-Schwarze, 1971). Pigmentation change suggests a change in chemical composition.

In reindeer (*Rangifer tarandus tarandus*), Brundin et al. (1978) found that the interdigital secretions contained several short-chain aliphatic acids, and that isovaleric and isobutyric acids elicited a behavioral response. Brundin and Andersson (1979) further found that the interdigital ketones 6-methyl-2-heptanone, 7-methyl-3-octanone, and 7-methyl-1-octen-3-one varied annually with cyclic changes in behavior and physiology.

Atkeson (1983) performed crude extractions on interdigital gland secretions of white-tailed deer and found that they contained butyric and isovaleric acids. He also suspected that acetic, propionic, and isobutyric acids were present, but these identifications were tentative. Because white-tailed deer have been observed tracking other deer and even back-tracking themselves when apparently lost (Nichol, 1938), these glands likely are responsible for leaving an olfactory trail. Few previous efforts have specifically examined the volatiles in white-tailed deer interdigital gland secretions, and those efforts were limited by the accuracy or availability of adequate analytical equipment. Therefore, we investigated the composition of the volatile compounds present in the interdigital glands and evaluated differences in the concentrations of these compounds between dominant and subordinate males.

METHODS AND MATERIALS

Secretions were collected from the interdigital glands of eight male white-tailed deer (1.5–11.5 years old). Deer were housed at the Whitehall Deer Research Facility operated by the University of Georgia's Daniel B. Warnell School of Forest Resources. They were fed a commercial feed (Checkers Pellet, Purina Mills, Inc.) and alfalfa (*Medicago sativa*) ad libitum. This provision of a similar food to all deer tested, along with extremely limited browse, helped to eliminate diet-related differences in semiochemical production. Deer were divided into several groups and placed into 1-ha pens. Does and fawns also were placed in the pens to provide possible olfactory stimuli that would induce the establishment of dominance.

Sampling of behavioral data began in October and ended December 1993. Observation periods were conducted within 2 hr after sunrise or 2 hr before sunset. The all-occurrences method described by Lehner (1979) was used due to the adequate visibility and frequency of behaviors. Matrices were then established according to Lehner (1979) to determine the social ranking of each individual within his group. At the end of the sampling period, the hierarchies were fairly stable, with all immature deer (1.5 years old, $N = 4$) being subordinate and all mature deer (3.5+ years old, $N = 4$) being dominant (Gassett, 1995).

In December 1993, deer were immobilized with a mixture of ketamine hydrochloride and xylazine hydrochloride (Mech et al., 1985). The interdigital glands of the rear foot of each deer were swabbed with medical-grade sterile cotton swabs designed for microbial sampling. Swabs were frozen immediately in glass vials at −60°C. Anesthesia was reversed with yohimbine hydrochloride.

Volatiles were removed from the swabs with a modified headspace technique (Novotny et al., 1974; McConnell et al., 1979). Swabs were placed into a headspace sampling apparatus and subjected to a stream of purified helium gas at a flow rate of 50 ml/min for 30 min at 75°C. Volatiles were passed through a cooled condenser to reduce water mist originating from the sample. Subsequently, the volatiles were trapped onto a 4-mg Tenax GC precolumn. Upon completion of the extraction, the precolumn was placed into a modified injection port of a Hewlett Packard model 5980A GC-MS. Volatiles were desorbed from the precolumn at 200°C and cryogenically retrapped for 15 min to compress the sample at the column inlet. The column used was a fused silica capillary column (Restek RTX 225, 30 m, 250 μm ID) that was provided with a cyanopropyl phase. Column temperature was programmed from 30°C to 190°C at a rate of 2°C/min. Volatile constituents were identified through their mass spectra with electron impact ionization at 70 eV. Peak areas were evaluated by a GC-MS data station. Unused swabs were subjected to the same sampling protocol to assay for background volatiles in the swabs, carrier gas, and headspace apparatus. The few background volatiles present were low enough in concentration that the interdigital assay was unaffected.

Concentrations were normalized by use of a known concentration of internal standard (7-tridecanone). Because of nonnormally distributed data, statistical comparisons of volatile concentrations between dominant and subordinate bucks were performed using a Mann-Whitney U test. Significance was accepted at $\alpha \leq 0.10$.

RESULTS AND DISCUSSION

Headspace sampling and subsequent GC-MS analysis identified 46 volatiles from interdigital secretions. The GC-MS recording shown in Figure 1 is typical of the volatile profile obtained from the analysis. The internal standard

(7-tridecanone), which typically elutes between 55 and 60 min, is not shown on this figure. Representing it on the figure would have compressed the figure further and prevented the differentiation of several important compounds. It should also be noted that the compounds in Figure 1 do not coincide directly with the values in Table 1. Figure 1 is a representative chromatogram of one deer, while the values in Table 1 represent the mean for each group of deer tested. Classes of compounds identified included alkanes, arenes, aldehydes, ketones, aliphatic acids, esters, pyrroles, furans, and sulfur compounds (Table 1).

Concentrations of 11 compounds varied between dominant and subordinate animals. Because all the subordinate deer in this study were 1.5 years old and all dominant animals were ≥ 3.5 years old, we were unable to definitively conclude whether the differences in compounds were age-related or dominance-related. However, since rank typically is related to age, it is likely that both played some part in the variations.

The classes of compounds that differed included ketones, esters, arenes, alkanes, aliphatic acids, and pyrroles. Acetic acid, ethyl-2-methyl butanoate, butanone, methyl salicylate, pyrrole, pentyl butyrate, benzene, a branched

[a] Values represent concentrations relative to the standard (7-tridecanone). Samples were collected at the University of Georgia's Whitehall Deer Research Facility in December 1993.

decane, undecane, styrene, and an unidentified arene all occurred in greater concentrations in dominant than subordinate males ($P \leq 0.10$). Many of these compounds commonly are associated with lipid secretion. Because androgenic hormones affect sebum production, and testosterone levels are generally higher in dominant males, the variation between social classes could indicate that these compounds act as dominance-specific semiochemicals.

The short-chain fatty acids we found may have resulted from microbial hydrolysis of triglyceride ester linkages. Microbes can break triglyceride ester linkages to release fatty acids as by-products. However, the esters we found in the interdigital secretions (Table 1) are similar to those found in the seba of most mammalian species and are not hydrolyzed easily by microbial action (Albone, 1984). Thus, the esters and fatty acids probably differ in their origins, but both groups likely are present as the result of secretions of the sebaceous glands.

The presence of androgens markedly increases sebaceous gland size and sebum production (Albone, 1984). Because androgen levels are higher in dominant male white-tailed deer during the breeding season (Miller et al., 1987), deer with higher androgen levels would be expected to produce larger quantities of interdigital fatty acids and esters. In a behavioral study of reindeer interdigital gland secretions, Müller-Schwarze et al. (1978) found that animals were more attracted to secretions from animals of the same sex, but the male scent elicited stronger behavioral responses. Social or age-related variations in the secretions may give the dominant animals a stronger scent and could act as a signal to females and subordinate males that a dominant male is in the area.

The remaining background volatiles secreted from the interdigital glands are produced at a constant rate and could possibly act to establish trails between bedding, feeding, and shelter areas. These compounds are of a volatility that would allow them to remain in the environment for several hours (or longer in a lipid matrix).

(Received November 6, 1995; accepted May 1, 1996)

Abstract—A synthetic blend of the aggregation pheromone [(3*R*,4*S*,1′*E*)-3,4-bis(1′-butenyl)tetrahydro-2-furanol, linalool, farnesol, and nerolidol] of the spined citrus bug, *Biprorulus bibax*, and the pentatomid defense chemical, (*E*)-2-hexenal, both attracted adult *B. bibax* to individual trees in citrus orchards. Lemon trees containing single glass vials with aggregation pheromone or (*E*)-2-hexenal were colonized by significantly greater numbers of reproductive *B. bibax* than unbaited trees. There was no significant difference between the treatments and bug recruitment was not improved by using both treatments. *B. bibax* did not enter cylinder/funnel traps baited with aggregation pheromone but colonized trees containing the traps. Orange or lemon trees containing aggregation pheromone on orchard perimeters recruited significantly larger populations of emigrating, nonreproductive *B. bibax* during fall than untreated trees. Nonreproductive bugs were not attracted to trees containing (*E*)-2-hexenal. The potential for using these semiochemicals as management tools for *B. bibax* is discussed.

Key Words—Aggregation pheromone, (*E*)-2-hexenal, *B. bibax*, citrus, Pentatomidae.

INTRODUCTION

The spined citrus bug, *Biprorulus bibax* Breddin (Hemiptera: Pentatomidae), is an important pest of citrus in inland southeastern Australia causing internal

*To whom correspondence should be addressed.

staining/drying of fruit and fruit drop (Hely et al., 1982; James, 1994). Recent research on the biology and ecology of this native insect (e.g., James, 1990a–c, 1991; James et al., 1990) led to development and adoption of an integrated management strategy based on monitoring, natural enemy conservation, and judicious use of the insecticide, endosulfan, at a rate harmless to natural enemy survival (James, 1993, 1994). However, endosulfan is likely to be removed from use as a horticultural pesticide in Australia in the near future and an alternative control tactic is required.

Studies on the pheromone biology of *B. bibax* commenced after James and Warren (1989) reported the presence of sexual dimorphism in the dorsal abdominal glands (DAGs) of adult bugs. The enlarged DAGs of male *B. bibax* contain the novel hemiacetal, (3*R*,4*S*,1′*E*)-3,4-bis(1′-butenyl)tetrahydro-2-furanol, linalool, two isomers of farnesol, and nerolidol (Oliver et al., 1992; Mori et al., 1992, 1993). The small DAGs of female *B. bibax* contain only linalool. James et al. (1994), in a shade house bioassay permitting flight, demonstrated significant attraction of postdiapause, prereproductive, and reproductive female *B. bibax* to heptane extracts of male DAGs and a synthetic blend of the male DAG secretion. Mating leks have been observed in *B. bibax* (James, 1989; James and Warren, 1989), indicating both sexes respond to the pheromone, similar to the situation reported for the North American predaceous pentatomid, *Podisus maculiventris* (Say) (Aldrich et al., 1984). Shade house bioassays have also demonstrated attraction of *B. bibax* to (*E*)-2-hexenal (James, unpublished observations), a major component of the defensive secretion of *B. bibax* and many other pentatomid species (MacLeod et al., 1975; Aldrich, 1988). A synthetic pheromone-trapping system would substantially improve the current monitoring system for *B. bibax* (tree searches) and might also have potential as the basis of a control tactic (e.g., mass trapping) to replace the use of endosulfan.

This study provides information on the field response of *B. bibax* to synthetic aggregation pheromone and (*E*)-2-hexenal.

METHODS AND MATERIALS

Five experiments to evaluate the field response of adult *B. bibax* to a synthetic blend of aggregation pheromone and (*E*)-2-hexenal were conducted in four mature commercial citrus orchards in the Yanco-Narrandera district of southern New South Wales during February–May (late summer–late fall) 1995. The aggregation pheromone was formulated to approximate the composition of male DAG extracts and extracts of volatiles from live males (hemiacetal 46%, linalool 40%, farnesol 13%, nerolidol 1%) (James et al., 1994). The racemate of (3*R*,4*S*,1′*E*)-3,4-bis(1′-butenyl)tetrahydro-2-furanol was synthesized in Japan (Mori et al., 1992) and shipped to Australia. The other components of the

pheromone were obtained from Sigma-Aldrich Pty. Ltd. (Castle Hill, New South Wales). All components (hemiacetal 46 mg, linalool 40 mg, farnesol 13 mg, nerolidol 1 mg) were blended in 3 ml of heptane in 5-ml glass vials and stored in a freezer until used (within 48 hr of preparation). Uncapped vials were taped to interior (shaded) tree branches or placed in traps and replaced weekly. Approximately 10 mg of pheromone per vial was released daily.

(*E*)-2-Hexenal was obtained from Sigma-Aldrich and used in uncapped glass vials (300 mg/vial) taped to tree branches. Release rates were approximately 100–200 mg/day (according to weather conditions). Vials were replaced daily due to the rapid oxidation of (*E*)-2-hexenal on exposure to air/light.

Experiment 1. This was conducted in a 1.5-ha lemon [*Citrus limon* (L.) Burm. f.] (var. Eureka) orchard at Cudgel near Narrandera, New South Wales, from February 14 to March 3 to investigate the effect of (*E*)-2-hexenal on reproductive adult *B. bibax*. Twenty trees, evenly distributed throughout the block, were selected and assigned as treatment ($N = 10$) or nontreatment ($N = 10$). All of the treatment trees were in the bottom half of the block and the nontreatment trees in the top half. A minimum distance of 10 m separated each tree marked by colored tape. On February 14, a pretreatment count of adult *B. bibax* on all marked trees was conducted with approximately 2–3 min spent scanning fruit and foliage on the outside of the tree canopy, without disturbing the bugs. Subsequent counts in all experiments were conducted by the same observer in the same way. Treatment trees were baited with a single vial of (*E*)-2-hexenal. Posttreatment counts were conducted on 13 of the following 20 days.

Experiment 2. Conducted during March 6–17, in the same orchard as experiment 1, this experiment looked at the individual effects and combined effect of (*E*)-2-hexenal and aggregation pheromone on recruitment of reproductive adult *B. bibax* to individual trees. The same trees were used as in experiment 1 with five control trees in one top quarter of the block assigned to an aggregation pheromone + (*E*)-2-hexenal treatment (one vial of each per tree), while the other five remained as untreated controls. In the bottom half of the block, five trees remained as (*E*)-2-hexenal-treated while the other five were assigned to aggregation pheromone only treatment. Pretreatment counts were conducted on March 6, prior to commencement of baiting. Posttreatment counts were conducted on nine of the 11 days following initiation of treatments.

Experiment 3. This experiment was conducted during March 17–23, in the first row of oranges [*Citrus sinensis* (L.) Osbeck] (var. Valencia), adjacent to the lemon orchard used in the previous experiments, to determine whether reproductive adult *B. bibax* would enter cylinder/funnel traps baited with aggregation pheromone. Cylinder/funnel traps were constructed from Perspex cylinders (27 × 15 cm) with two holes (4 cm diam.) on opposite sides. Each hole was covered by an inwardly projecting screen funnel. A single trap was used in each tree

and hung from an interior (shaded) branch approximately 1.5 m above ground level. Three traps were baited with aggregation pheromone (vial taped to interior surface of the trap) and placed in trees adjacent to the section of the lemon orchard used as an untreated area in earlier experiments. Three unbaited traps were placed in trees adjacent to the aggregation pheromone-treated area of experiment 2. No bugs were found in any of the six trees prior to baiting. Posttreatment counts of adult *B. bibax* in traps or on the trees in which the traps were hung were conducted on the final three days of the six-day period following treatment.

Experiment 4. The experiment was conducted during April 4–May 29, in a different commercial lemon orchard (2 ha) near Narrandera, to determine the effect of aggregation pheromone and (*E*)-2-hexenal on recruitment of nonreproductive adult *B. bibax* to individual trees for overwintering. In late March–early April adult *B. bibax* enter reproductive dormancy (James, 1991) and usually leave lemon orchards to overwinter in large aggregations (50–500 individuals per tree) in adjacent nonlemon citrus, usually oranges (James, 1989, 1990a,b; James et al., 1990). This experiment commenced prior to development of overwintering aggregations and ran during the period when most colonization of overwintering sites occurred. A large population of reproductive *B. bibax* (40–60 adults found in an hour's search on March 24) occurred in this lemon orchard prior to commencement of the experiment. The orchard was bordered on three sides by oranges, the first row of which harbored large numbers of overwintering *B. bibax* in previous seasons (James, unpublished observations). Nine orange trees (three on each side of the lemon orchard) were selected, marked, and assigned (three replicates) as aggregation pheromone, (*E*)-2-hexenal, or no treatment. Both treatments and the control were represented on the three sides of the lemon orchard and a minimum distance of 20 m separated treatment and control trees. No bugs were present in any of the nine trees prior to treatments, which began on April 4. Posttreatment counts were conducted on 26 of the 55 days following initiation of treatments.

Experiment 5. These tests were conducted in parallel with experiment 4 in a 0.25-ha lemon orchard and a nearby (20 m) orange orchard (0.5 ha) at the Yanco Agricultural Institute, again to determine the effect of aggregation pheromone and (*E*)-2-hexenal on recruitment of nonreproductive *B. bibax* to individual trees for overwintering. *B. bibax* was not present in either of these orchards, so 1000 nonreproductive adult *B. bibax* collected from district orchards were released into the center of the lemon block on April 3. Treatment of three trees in the outside row on two sides of the block with either aggregation pheromone, (*E*)-2-hexenal, or no treatment commenced on April 4. The six trees were separated by at least 7 m and contained no bugs prior to treatment. Six trees in the two outside rows of the nearby orange block were treated in the same way. Posttreatment counts were conducted in both blocks on 26 of the 55

days following initiation of treatments. Although most *B. bibax* overwinter on nonlemon citrus, individuals can overwinter successfully on lemon (James et al., 1990).

All data were transformed to the log $(X + 1)$ scale and subjected to analysis of variance and least significant difference procedures.

RESULTS

Experiment 1. Numbers of adult reproductive *B. bibax* on trees treated with (*E*)-2-hexenal were significantly greater (mean: 2.5 ± 0.2 bugs/tree/day) than on untreated trees (1.3 ± 0.1) ($P < 0.05$). Significantly greater numbers of bugs occurred on the treated trees on all occasions except pretreatment, the day following first treatment, and on February 20 and 22 ($P < 0.05$) (Figure 1).

Experiment 2. Numbers of adult reproductive *B. bibax* on trees treated with (*E*)-2-hexenal, aggregation pheromone, or (*E*)-2-hexenal + aggregation pheromone were significantly greater (means: 6.5 ± 0.6, 8.2 ± 1.2, and 7.7 ± 1.6 bugs/tree/day, respectively) than on untreated trees (1.9 ± 0.4) ($P < 0.05$). There was no significant difference between the three experimental treatments ($P > 0.05$). Significantly greater numbers of bugs occurred on the trees treated with aggregation pheromone and aggregation pheromone + (*E*)-2-hexenal than on untreated trees on all occasions except pretreatment and the day following

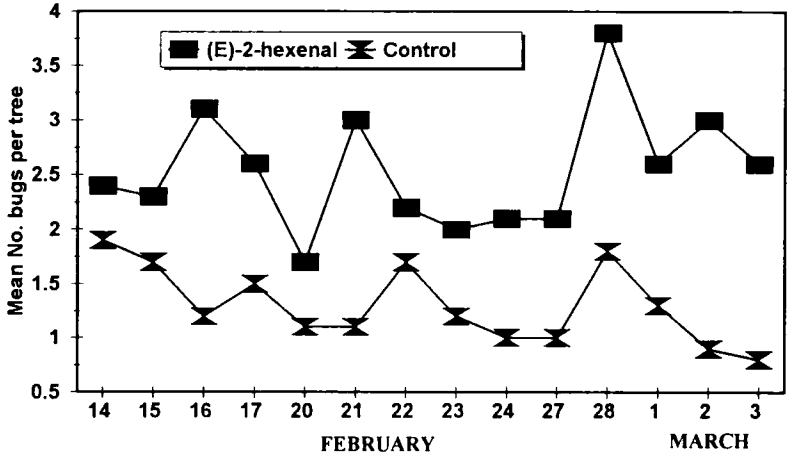

FIG. 1. Abundance of reproductive adult *B. bibax* on lemon trees treated with (*E*)-2-hexenal compared to untreated trees (control). Treatment commenced on February 14 after pretreatment counts. Significantly greater numbers of bugs occurred on treated trees on all posttreatment dates except February 15, 20, and 22 ($P < 0.05$).

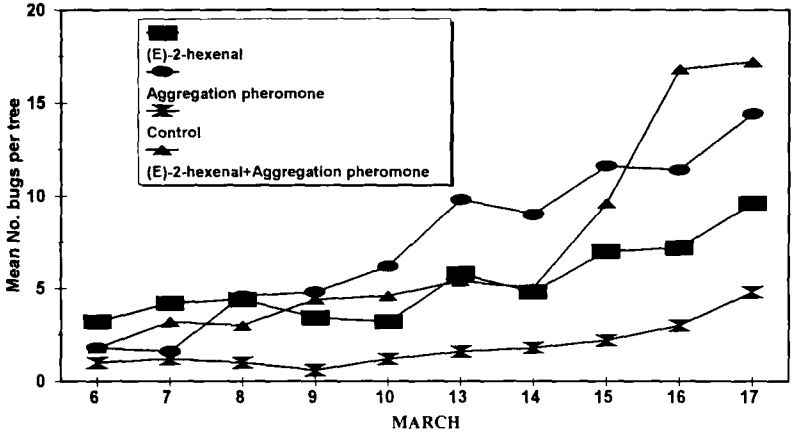

FIG. 2. Abundance of reproductive adult *B. bibax* on lemon trees treated with (*E*)-2-hexenal, aggregation pheromone, and (*E*)-2-hexenal + aggregation pheromone compared to untreated trees (control). Treatments commenced on March 6, after pretreatment counts. Significantly greater numbers of bugs occurred on trees treated with aggregation pheromone or aggregation pheromone + (*E*)-2-hexenal than on untreated trees on all posttreatment dates ($P < 0.05$). Significantly greater numbers of bugs occurred on (*E*)-2-hexenal treated trees on all posttreatment dates except March 10, 14, and 17 ($P < 0.05$).

first treatment ($P < 0.05$) (Figure 2). Significantly greater numbers of bugs were found on (*E*)-2-hexenal-treated trees than on untreated trees on all but three occasions (March 10, 14, 17) ($P < 0.05$).

Experiment 3. No bugs were trapped but significantly greater numbers occurred on aggregation pheromone-treated trees (27 ± 5/bugs/tree) than on untreated trees (4.3 ± 0.7) ($P < 0.05$). From no bugs pretreatment, treated trees recruited 22–54 bugs per tree within five days, while untreated trees gained 1–6 per tree (Figure 3).

Experiment 4. Aggregation pheromone-treated trees recruited significantly greater numbers of nonreproductive *B. bibax* (69 ± 5.4 bugs/tree/day) than either (*E*)-2-hexenal-treated (1.2 ± 0.2) or untreated trees (3.9 ± 0.6) ($P < 0.05$). There was no significant difference between (*E*)-2-hexenal-treated and untreated trees ($P > 0.05$). Up to 168 bugs were counted on individual aggregation pheromone-treated trees during May while (*E*)-2-hexenal-treated and untreated trees harbored a maximum of 10 and 21 bugs per tree, respectively. Significant recruitment to the pheromone-treated trees commenced around mid-April and continued for about four weeks (Figure 4).

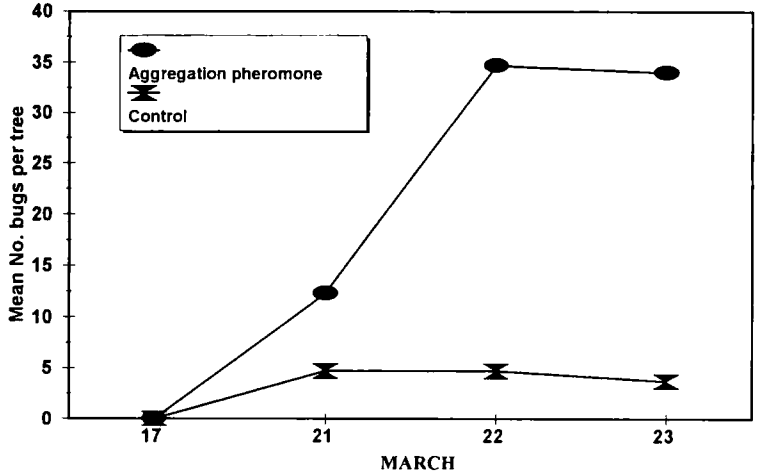

FIG. 3. Abundance of reproductive adult *B. bibax* on orange trees containing cylinder/funnel traps baited on March 17 with aggregation pheromone and on trees without traps (control). Significantly greater numbers of bugs occurred on trees with traps on all post-treatment dates ($P < 0.05$).

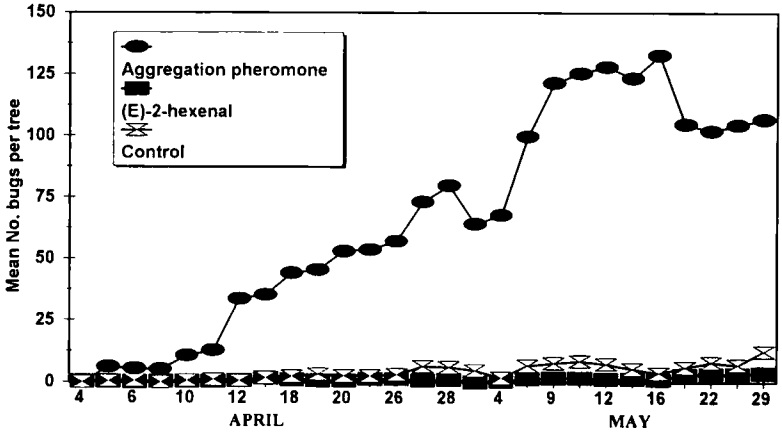

FIG. 4. The effect of aggregation pheromone and (*E*)-2-hexenal on fall colonization of orange trees on the perimeter of a lemon orchard by non-reproductive adult *B. bibax* seeking overwintering sites.

Experiment 5. Aggregation pheromone-treated trees recruited significantly greater numbers of nonreproductive *B. bibax* in the lemon block (5.1 ± 0.6 bugs/tree/day) and orange block (1.5 ± 0.3) than either (*E*)-2-hexenal-treated trees (lemon: 0.04 ± 0.03; orange: 0.06 ± 0.03) or untreated trees (lemon: 0.02 ± 0.02; orange: nil) ($P < 0.05$). No significant difference occurred between (*E*)-2-hexenal-treated and untreated trees in either block ($P > 0.05$). Recruitment to pheromone-treated trees, particularly in the lemon block, followed a similar pattern to that observed in experiment 4 with maximum numbers of bugs in mid-May (Figure 5).

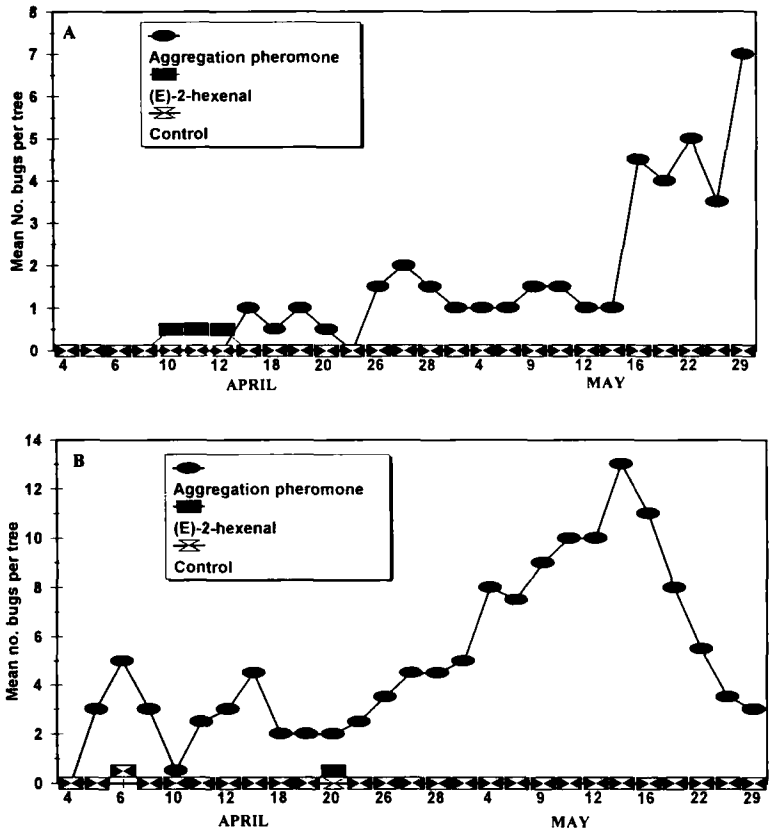

FIG. 5. The effect of aggregation pheromone and (*E*)-2-hexenal on fall colonization of orange (A) and lemon (B) trees by nonreproductive *B. bibax* seeking overwintering sites.

DISCUSSION

This study demonstrates synthetic aggregation pheromone to be a potent attractant for reproductive and nonreproductive *B. bibax* in the field. In addition, it provides field evidence for (*E*)-2-hexenal, a major component of stink bug defense chemistry, as an attractant for *B. bibax* in its own right.

Synthetic aggregation pheromone released from single glass vials at a rate of approximately 10 mg/day significantly increased the colonization of citrus trees by reproductive and nonreproductive *B. bibax*. Although no accurate counts were made, males and females occurred on treated trees in similar numbers. In earlier studies (James et al., 1994), reproductive and prereproductive female *B. bibax* were significantly attracted to synthetic aggregation pheromone in shade house experiments, although nonreproductive females collected from fall populations were not. The impressive recruitment of *B. bibax* to pheromone-treated trees on the periphery of colonized blocks during fall (particularly in experiment 4) was a convincing demonstration of the potency of aggregation pheromone to diapausing individuals, and the disparity between shade house and field results is difficult to explain. The pheromone-producing DAGs of diapausing male *B. bibax* are smaller than those of reproductive males but larger than those of teneral males (James and Warren, 1989), indicating a role for aggregation pheromone in the formation and maintenance of overwintering colonies (James, 1990a). The colonies of *B. bibax* in pheromone-treated trees often formed dense clusters like naturally occurring overwintering aggregations (James, 1990a), although populations were undoubtedly underestimated because bugs within canopies were not counted.

Although *B. bibax* were readily attracted to trees containing pheromone, they did not enter pheromone-baited cylinder/funnel traps. Pheromone traps of a similar design have successfully trapped smaller pentatomids (e.g., Aldrich et al., 1984), and it is possible that the less agile flight of the relatively large and heavy *B. bibax* (James et al., 1990) prevented direct location of trap entry holes. The relatively high release rate of pheromone (and therefore high content in air around the tree) may have inhibited further searching by bugs for a source point after alighting on the tree. This was supported by occasional observations on trees adjacent to pheromone-treated trees that invariably indicated bug populations almost as large as on the pheromone-treated tree. The possibility that a lower rate of pheromone release might overcome this problem should be investigated.

Trees treated with (*E*)-2-hexenal developed populations of reproductive *B. bibax* two to three times larger than those of untreated trees. In experiment 2, where the effect of aggregation pheromone and (*E*)-2-hexenal were compared, there was no difference in bug response to these treatments. However, unlike

aggregation pheromone, there was no response to (*E*)-2-hexenal by nonreproductive *B. bibax*.

The most notable function of (*E*)-2-hexenal in pentatomid and, indeed, heteropteran biology, is as a major component of defensive secretions active against invertebrate predators such as ants (Aldrich, 1988). It also acts as an alarm pheromone, alerting conspecifics to danger and stimulating dispersal (Ishiwatari, 1974, 1976; Lockwood and Story, 1987). However, Ishiwatari (1976) showed (*E*)-2-hexenal was bifunctional in its effect on first-instar nymphs of *Eurydema rugosa* Motschulsky; large quantities (>0.05% in water) caused dispersal while smaller quantities enhanced aggregation of the nymphs. Lockwood and Story (1985) demonstrated a similar bifunctionality for *n*-tridecane, another important component of pentatomid defensive secretions, in first instars of *Nezara viridula* (L.). Interestingly, (*E*)-2-hexenal is an important component of the aggregation pheromones of some predatory pentatomids in the genus *Podisus* (Aldrich, 1995). However, the current study is the first to demonstrate field attraction of an adult pentatomid to (*E*)-2-hexenal alone. Point sources dispensing 100–200 mg of (*E*)-2-hexenal per day produced an atmospheric concentration that clearly encouraged tree colonization by reproductive adult *B. bibax*. In contrast, close-range exposure of adult *B. bibax* to (*E*)-2-hexenal in the laboratory induces dispersal behavior (James, unpublished observations), as it does with many other pentatomids (e.g., Lockwood and Story, 1987). These observations support Ishiwatari's (1976) conclusions on dose-determined bifunctionality of (*E*)-2-hexenal for first-instar nymphs of *E. rugosa*. Aldrich (1995) suggested that the major hemiacetal of the aggregation pheromone of *B. bibax* may be formed by enzymatic dimerization of 2-hexenal, "extending an ancient biosynthetic pathway." If this is the case, then (*E*)-2-hexenal may be the ancestral aggregation pheromone for *B. bibax*, which evolved into the distinctive hemiacetal-dominated pheromone that presumably has major functional advantages (e.g., lower volatility, slower degradation, increased efficacy over long distances). (*E*)-2-Hexenal is an ancient compound; small amounts occur as a volatile in most green leaves (leaf aldehyde). *B. bibax* also may use (*E*)-2-hexenal as a cue to locate host plants and/or to synergize the response to pheromone.

Synthetic aggregation pheromone and (*E*)-2-hexenal clearly deserve further study as potential tools for use in orchard management of *B. bibax*. The aggregation pheromone is an effective attractant for reproductive and nonreproductive adults, and further research should concentrate on developing pheromone-based management strategies. For example, the pheromone could be used to divert/congregate bugs in selected areas for targeted chemical control. Pheromone-based trapping of *B. bibax* either for monitoring or control should be investigated further. Traps that require minimal navigational skills for entry by *B. bibax* (e.g., upward-facing funnel or water-pan traps) and lower pheromone release

rates should be tested. Despite improvements to synthesis of the hemiacetal component of the aggregation pheromone (Mori et al., 1993), it is still relatively difficult and expensive to produce. While (*E*)-2-hexenal requires a lot more field evaluation to determine its merits and potential use relative to that of the aggregation pheromone (its noneffect on nonreproductive bugs is a drawback), it does have the advantage of being readily available. The problems of rapid degradation and high volatility should be resolvable by using antioxidants and slow-release devices.

AVOIDANCE RESPONSE OF A TERRESTRIAL SALAMANDER (*Ambystoma macrodactylum*) TO CHEMICAL ALARM CUES

DOUGLAS P. CHIVERS,* JOSEPH M. KIESECKER, MICHAEL T. ANDERSON, ERICA L. WILDY, and ANDREW R. BLAUSTEIN

Department of Zoology, Oregon State University

(Received December 22, 1995; accepted May 2, 1996)

Abstract—Organisms from a wide variety of taxonomic groups possess chemical alarm cues that are important in mediating predator avoidance. However, little is known about the presence of such alarm cues in most amphibians, and in particular terrestrial salamanders. In this study we tested whether adult long-toed salamanders (*Ambystoma macrodactylum*) showed an avoidance response to stimuli from injured conspecifics. Avoidance of stimuli from injured conspecifics could represent avoidance of a chemical alarm cue or, alternatively, avoidance of a territorial pheromone or conspecific predator odor. Consequently, we also tested whether salamanders avoided stimuli from noninjured conspecifics. Salamanders avoided stimuli from injured but not from noninjured conspecifics. Therefore, we concluded that the response to injured conspecifics represents avoidance of a chemical alarm cue and not avoidance of a territorial pheromone or predator cue. This is the first clear demonstration of chemical alarm signaling by a terrestrial amphibian and the first report of chemical alarm signaling in an ambystomatid salamander. By avoiding an area containing stimuli from injured conspecifics, long-toed salamanders may lower their risk of predation by avoiding areas where predators are foraging.

Key Words—Alarm pheromone, chemical signaling, predator avoidance, long-toed salamanders, *Ambystoma macrodactylum*.

INTRODUCTION

A wide variety of taxa have been shown to detect and respond to chemical alarm signals (alarm pheromones) released by conspecifics. Such signals can be released by the sender either before or after a predator captures the prey (e.g., Smith, 1992; Wisenden et al., 1995a,b). Signals that are released upon mechanical damage to the sender (known as damage-release alarm signals) should act as reliable indicators of predation risk in that they indicate that a conspecific in the immediate vicinity was recently attacked or captured by a predator. By avoiding areas where predators have recently captured a conspecific, prey should be able to lower their probability of being captured.

Damage-release chemical alarm signals have been documented in various taxa (insects: Sih, 1986; Chivers et al., 1996; gastropods: Snyder, 1967; Appleton and Palmer, 1988; echinoderms: Parker and Schulman, 1986; Lawrence, 1991; sea anemones: Howe and Sheikh, 1975; crayfish; Hazlett, 1994; fishes: Smith, 1992; amphibians: see below). Except for fish, there is relatively little information on the distribution of alarm pheromones among the vertebrates. For example, few studies have been conducted on amphibian alarm pheromones. Eible-Eibesfeldt (1949), Hrbacek (1950), and Kulzer (1954) described an alarm response to stimuli from injured conspecifics in common toad (*Bufo bufo*) tadpoles. In laboratory experiments, tadpoles exposed to conspecific stimuli typically swam to the bottom or to the side of the tank opposite from where the pheromone was introduced. In field experiments, tadpoles avoided alarm pheromones by swimming into deeper water. Pfeiffer (1966) tested nine species of larval anurans in five different families. He found responses in two species of bufonid tadpoles (*Bufo bufo* and *B. calamita*), and speculated that alarm pheromones may be restricted to the family Bufonidae. Alarm pheromones are also known from another bufonid, the western toad (*Bufo boreas*) (Hews and Blaustein, 1985; Hews, 1988). Recent studies have shown that alarm pheromones may also be found in larval ranid frogs, including Cascades frog tadpoles (*Rana cascadae*) (Hews and Blaustein, 1985, but see Hokit and Blaustein, 1996) and red-legged frog tadpoles (*Rana aurora*) (Wilson and Lefcort, 1993).

Only two studies have investigated the possibility of chemical alarm signals in salamanders. Lutterschmidt et al. (1994) showed that adult plethodontids, *Desmognathus ochrophaeus*, avoid skin extracts from conspecifics and congeners, *D. brinleyorum*. This may represent an avoidance response to chemical alarm cues. However, this response may also represent avoidance of territorial pheromones or predator odors. Other plethodontid salamanders have been shown to avoid territorial pheromones and odors of predatory plethodontids (e.g., Jaeger, 1986; Roudebush and Taylor, 1987). In another experiment that tested for the presence of alarm signals in salamanders, Marvin and Hutchison (1995)

demonstrated that two species of adult semiaquatic newts (fire-bellied newts, *Cynops pyrrhogaster* and red-spotted newts, *Notophthalmus viridescens*) avoided the area of a test chamber containing moistened paper towel that was saturated with skin extracts from conspecifics. Since adult newts are not territorial and are not preyed upon by other newts or salamanders, Marvin and Hutchison (1995) concluded that the avoidance response represented avoidance of a chemical alarm cue.

In this study we investigated the avoidance response of the terrestrial form of the long-toed salamander (*Ambystoma macrodactylum*) to stimuli from injured conspecifics. Although adult long-toed salamanders are not known to be territorial or to prey on conspecifics, we also tested the salamanders for an avoidance response to chemical stimuli from noninjured conspecifics. An avoidance response to stimuli from noninjured conspecifics may indicate avoidance of territorial pheromones or conspecific predator odors and would complicate our interpretation of an avoidance response to stimuli from injured conspecifics. However, if adult long-toed salamanders are shown to avoid chemical cues from injured conspecifics but not from noninjured conspecifics, our study would be the first to clearly show chemical alarm signaling by a terrestrial amphibian.

METHODS AND MATERIALS

Collection and Maintenance. In November 1995, we collected adult long-toed salamanders on or beside a 200-m section of Oakville road, located approximately 8 km east of Corvallis, Benton County, Oregon. Each salamander was maintained individually in a Petri dish (150 mm diameter × 25 mm deep) that contained a moistened paper towel. The salamanders were maintained on a 14L:10D photoperiod at approximately 16°C and were periodically fed with crickets. The salamanders were not fed for three days prior to testing.

Experimental Protocol. We tested the avoidance response of individual salamanders to three different stimuli: (1) chemical stimuli from injured conspecifics, (2) chemical stimuli from noninjured conspecifics, and (3) a combination of chemical stimuli from both injured and noninjured conspecifics. Testing the response of salamanders to a combination of stimuli from injured + noninjured conspecifics was done in order to allow us to speculate on the strength of an avoidance response to either injured or noninjured stimuli. To prepare the injured conspecific stimulus we killed six animals by decapitation and removed their viscera, spinal column, and legs. The remaining tissue (approximately 12.0 g, which contained mostly skin, but also some muscle tissue) was ground with a mortar and pestle, combined with 200 ml of dechlorinated tap water and filtered through a fine mesh net. We used 5 ml of injured conspecific stimulus per trial.

This solution was used within 15 min of preparation. For a source of chemical stimuli from noninjured conspecifics, we used moistened paper towels that had housed a single conspecific for 48 hr.

For each trial we lined half of a rectangular plastic container (32 × 18 × 8 cm) with a paper towel that was moistened with dechlorinated tap water (control side). The treatment side of the containers was lined with paper towel that contained stimuli from injured conspecifics, stimuli from noninjured conspecifics, or a combination of both. The two paper towel substrates in each container were separated by approximately 2 cm to reduce diffusion of chemicals between the sides. After the appropriate stimuli were added to each side of the test containers, we used a spray bottle containing dechlorinated tap water to saturate the paper towels. This ensured that any observed avoidance of the control or stimulus sides could not be attributed to differences in moisture level between the sides.

At the start of each trial, we introduced a single test salamander into the center of the container. Every 3 min for 2 hr we recorded whether the test salamander was located on the control or treatment side of the container. If the salamanders were positioned across the middle of the containers, we used the position of the salamanders' snout to assign location. To control for the possibility of a bias in the salamanders' orientation in the room, we rotated the containers 180° every half hour during the experiment.

Twenty different salamanders were tested in each of the three treatments for a total of 60 tests in this experiment. Individual salamanders were never used in more than one test. We size-matched the salamanders for tests in the three treatments. The snout–vent length of salamanders was 45.0 ± 7.9 mm (mean ± SD). For each trial we summed the number of times each salamander was located on the treatment side of the container out of a possible 40 observations (one observation every 3 min for 120 min = 40 observations). For each of the three treatments, we used a binomial test (Siegel and Castellan, 1988) to compare the number of trials in which the salamanders spent less than 50% of their time on the stimulus side.

RESULTS

In trials using stimuli from noninjured conspecifics, there was no difference in the number of trials in which test salamanders chose the control side over the stimulus side of the testing chamber (Table 1, Figure 1). However, in both the injured conspecific and injured + noninjured conspecific treatments, the test salamanders showed a significant avoidance of the treatment side of the containers (Table 1, Figure 1).

TABLE 1. NUMBER OF TRIALS IN WHICH TEST SALAMANDERS CHOSE STIMULUS AND CONTROL SIDES OF EXPERIMENTAL CONTAINERS[a]

Treatment	Trials (N) where test animals spent majority of time		P
	Stimulus side	Control side	
Noninjured	12	8	0.504
Noninjured + injured	5	15	0.042
Injured	3	17	0.002

[a]See text for details, P values are based on two-tailed binomial tests.

DISCUSSION

The results of our study show that adult long-toed salamanders avoid chemical stimuli from injured conspecifics. Given that salamanders did not avoid stimuli from noninjured conspecifics, the avoidance response to injured conspecific stimuli cannot be interpreted as an avoidance response to territorial pheromones or predator odors. As a result, we conclude that the avoidance response of the salamanders to injured conspecifics represents avoidance of a chemical alarm cue. This is the first clear demonstration of chemical alarm signaling in a terrestrial amphibian and the first report of chemical alarm signaling in an ambystomatid salamander.

We found that salamanders exposed to stimuli from injured conspecifics spent more time on the control (dechlorinated water) side of the testing chamber than salamanders exposed to stimuli from injured + noninjured conspecifics. The intermediate response of salamanders to the combined stimuli from injured + noninjured conspecifics, in relation to either the noninjured or injured treatments alone, indicates that the salamanders may have a conflicting response to the combined stimuli. In the combined treatment, the presence of noninjured stimuli appeared to have weakened the intensity of the avoidance response to the injured conspecific stimuli. Nevertheless, salamanders still exhibited a significant avoidance of alarm cues in the combined stimulus treatment.

We do not know the identity of the chemical(s) that act as the alarm cue in long-toed salamanders. Nevertheless, the cue is likely contained in the skin (and/or possibly muscle tissue) as these were the tissues we used to prepare the injured conspecific stimulus. Kulzer (1954) suggested that bufotoxin, a predator deterrent contained in the skin of bufonid tadpoles, may serve as the alarm cue for bufonid tadpoles. In his study, bufotoxin (bufodienolides) and γ-bufotoxin

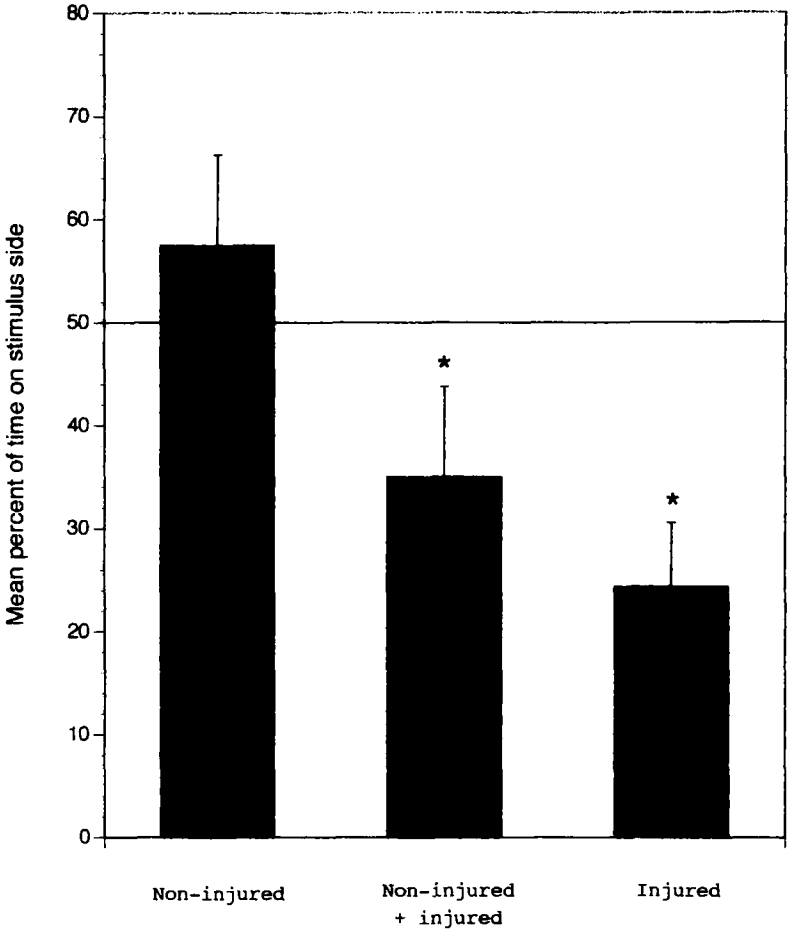

FIG. 1. Mean (+ SE) percentage of time test salamanders spent on the stimulus side of the experimental containers. Means and SE are used to illustrate trends in the data only. The data were analyzed with two-tailed binomial tests. *Significant difference at $P < 0.05$.

were as effective as chemical stimuli from injured tadpoles in eliciting alarm responses in toad tadpoles. Lutterschmidt et al. (1994) suggested that pseudotritontoxin (PTTX), a toxin contained in plethodontid salamanders, may function as the alarm cue in *Desmognathus ochrophaeus*. Ambystomatid salamanders are

known to possess toxins in their skin (e.g., Brodie and Gibson, 1969; Mason et al., 1982). As in other amphibians, these chemicals may also serve a dual function as both predator deterrents and alarm cues.

The behavioral response we quantified was avoidance of the alarm cue. This is a common response of a variety of prey to the presence of alarm cues (e.g., Lutterschmidt et al., 1994; Chivers and Smith, 1994). By avoiding an area where a predator has recently captured a conspecific, the prey should be able to lower their risk of predation by avoiding the predator's foraging microhabitat. Under natural conditions, multiple exposures of prey to alarm cues in specific microhabitats may facilitate recognition of the area as dangerous. It is unknown whether such an effect occurs in amphibians. However, some prey fishes are able to learn the identity of dangerous microhabitats based on the presence of alarm cues (Chivers and Smith, 1995; Wisenden et al., 1995a).

(Received September 15, 1995; accepted May 4, 1996)

Abstract—The behavior of the desert locust, *Schistocerca gregaria* (Forskål) (Orthoptera: Acrididae), is adjusted rapidly to population density and is a phase characteristic. We used discriminant analysis to quantify the extent of phase transition from the solitary to the gregarious phase and accurately classify the phase status on the basis of two decisive behavioral parameters: nymphal activity and social interaction. Fecal extracts, examined by olfactometry, attract solitarious nymphs but do not contribute to behavioral phase transition. Neither do visual stimuli alone. Short-range olfaction of airborne volatiles slightly affects behavioral phase transition. Antennectomy abolishes density response. Cuticular lipid extract, containing presumptive contact pheromones, does not attract nymphs, but does significantly affect behavioral phase transition.

Key Words—*Schistocerca gregaria*, desert locust, phase transition, behavior, cuticular lipids, contact pheromones, olfactometry, discriminant analysis.

INTRODUCTION

Locusts are in essence polymorphic grasshoppers whose morphology and behavior are affected by population density. Isolated solitary individuals are cryptically colored, tend to avoid contact, and are more subdued in activity. At high population density, gregarious chromatic forms dominate. The term "phase tran-

*To whom correspondence should be addressed.

sition" is used here to designate the transformation from the solitary to the gregarious phase.

In the field, dense populations evolve as a consequence of a variety of environmental and biotic factors (Rainey, 1962). Among these, seasonal winds leads to the convergence of scattered adult locusts (Rainey, 1989), while restricted local vegetation attracts and encourages the congregation of locust nymphs or adults (Kennedy, 1939). Aggregation of solitary desert locusts occurs in the field at favorable oviposition sites (Roffey and Popov, 1968). Finally, precipitation and increased quality and quantity of vegetation together promote the development of large populations, initially maintained as cohesive bands of hoppers and later as adult swarms (Uvarov, 1966, 1977).

Polymorphic changes occur gradually over several molts. In contrast, the behavioral response to changes in population density is rapid, sometimes within hours (Ellis, 1962, 1963; Gillett, 1988; Roessingh and Simpson, 1994). In broad terms, two behavioral characteristics are dominant features of phase-related behavior. Gregarious locusts are more active than are solitary locusts, and they also interact socially, whereas solitary locust do not (Uvarov, 1966).

Locusts communicate chemically in the process of phase transition. It is well known that the polymorphic and behavioral response of solitary locusts occurs when gregarious locusts are present in their vicinity (Gillett, 1968). There has been some uncertainty concerning the direct role of locust-derived volatile aggregation factors, loosely termed gregarization pheromones (Nolte, 1970, Gillett and Phillips, 1977) in phase transition. Aggregation pheromones, species-specific stimuli for convergence of both sexes, together with nonspecific attractants, contribute to an increase in population density. Cohesion pheromones maintain aggregation (Fuzeau-Braesch et al., 1988). Definitive locust phase transition implies more than aggregation and cohesion. Distinctive behavioral characteristics are expressed (Uvarov, 1966, Roessingh et al., 1993), followed much later by polymorphic changes.

In order to rapidly differentiate between these different pheromone functions, we have devised a quantitative bioassay for evaluating phase-related behavior and have concurrently measured attractancy of different locust-derived compounds by olfactometry. The contributions of the different parameters characterizing phase transition were integrated by discriminant analysis and a discriminant function was derived that defines a relative phase index. Progressive phase transition was evaluated by aligning the behavioral response to various effectors on a sliding scale, relative to the behavior of the solitary nymphs versus the behavior of nymphs from a crowded culture. Comparison of these different behavioral responses to different locust-derived compounds—attractancy on the one hand and phase-related behavior (activity and social interaction) on the other hand—indicates that aggregation and phase behavior are induced by different factors.

METHODS AND MATERIALS

Insects

The culture of the desert locust, *Schistocerca gregaria* (Forskål), used in these experiments was established from individuals field-collected in Niger in 1991. Cultures of nymphs were maintained under crowded conditions (designated gregarious) at a controlled temperature of 28 ± 2°C within the cages, under constant illumination and density of >200 locusts per cage (50 × 50 × 60 cm). They were fed fresh grass supplemented with flaked oats. First-generation nymphs were reared in isolation (designated solitary) from the middle of the second instar in small aluminum rearing cages (20 × 20 × 10 cm), partitioned by aluminum into four chambers. They were fed fresh wheat sprouts and flaked oats and kept in a temperature controlled room (28 ± 2°C), separate from the stock culture. All behavioral assays were performed with developmentally synchronized mid-fourth-instar first-generation isolated nymphs three days after the L_3 to L_4 molt.

Behavioral Assays

Ten gregarious nymphs, chosen at random from the crowded culture, or 10 solitary nymphs, were placed together in a 45-cm-diameter circular arena and videotaped for 15 min. The first 5 min were found to be necessary for adaptation of the nymphs to their unfamiliar surrounding, during which time their behavior was erratic. Behavior is stable for at least 30 min thereafter (Heifetz, unpublished). The second 5-min interval was therefore assessed for six behavioral parameters, as follows:

Social Interactions. Four parameters of the positional relations of the 10 nymphs in the arena were measured by examining three time frames with a Panasonic AG7355 video recorder. The first frame was taken 5 min after the adaptation period and the next two at 1 min and 2 min thereafter.

An associative index (AI) was calculated from the following formula:

$$AI = \sum_{i=1}^{10} \frac{n_i}{10}$$

where n_i signifies the number of nymphs positioned within one body length of the reference nymph i (each nymph in its turn).

For the number of groups, a group is defined as two or more nymphs located within one body length from one another.

The number of nymphs within the groups was determined.

For the distribution of nymphs, the distances separating each of the 10 nymphs in the arena from the other nymphs were measured from three individual

frames of the video recording, as detailed above. Analysis was performed on a Power Macintosh 7100/66AV (equipped with an LG-3 Scientific Frame Grabber, Scion Corp., Frederick, Maryland) using the public domain NIH Image program, ppc 1.56 (written by Wayne Rasband at the U.S. National Institutes of Health and available from the Internet by anonymous ftp from zippy.nimh.nih.gov or on floppy disk from NTIS, 5285 Port Royal Rd., Springfield, Virginia 22161, part number PB93-504868). The log variance from the average distance was calculated.

Activity. Two activity-related parameters of the 10 nymphs were measured during the 2 min following the first video frame examined for the associative index: The activity level (AL) is the mean amount of time spent in movement by each of the individual 10 nymphs in the arena. The relative rate of movement was measured by capturing 120 consecutive frames from the video cassette at 1-sec intervals and substracting one frame from another. Movement was analyzed by the NIH Image program, ppc 1.56 (see above) and expressed as the area of body displacement of the 10 nymphs per second.

Discriminant Analysis

Discriminant analysis (Dillon and Goldstein, 1984) of the behavioral parameters was performed (SAS, 1992) in order to determine the phase affiliation of the experimentally manipulated nymphs. Discriminant analysis categorizes individuals to one of K distinct groups on the basis of the values of interrelated normal variables ($X_1, \ldots, X_p$). A linear combination ($Y = a_1X_1 + \cdots + a_pX_p$) of the normal variables is sought, using data for individuals of known affiliation, which exhibits maximal differences between groups, relative to differences within groups. In this present case, a discriminant function Y was then derived to determine the phase index of individuals for which values of $x_1, \ldots, x_p$ are available but whose group affiliation is unknown.

The classification of nymphal behavior is presented as a phase index on a sliding scale, calculated from a discriminant function. Negative values are classified as solitary and positive values are classified as gregarious. The discriminant function is calculated from the distinctive behavior of nymphs conditioned to either isolation or crowding. Percentage phase prediction indicates the degree to which the replicate bioassays conform to the predicted phase category (i.e., the average phase index may position the behavior on the solitary side of the threshold of discrimination, while a certain percentage of the replicates are individually categorized by the discriminant function as gregarious, and vice versa).

Evaluation of Isolated Sensory Stimuli.

Nymphs of the gregarious stock culture were isolated from the second instar and kept in individual chambers of a small aluminum cage (20 × 20 × 10 cm),

partitioned into four separate chambers by either aluminum, glass, or wire screening until mid-fourth instar. A fourth group consisted of four nymphs reared together from the second instar in a cage of similar dimensions but with no partitions. The discriminant function was derived from the behavior of the group of four nymphs and that of the solitary nymphs.

Collection of Airborne Volatiles

This was adapted from Yarden and Shani (1994). Volatiles were collected at different times in 3-hr intervals from groups of 60 fourth instar nymphs placed in a 3-liter flask connected to an all-glass system (see Figure 1) and subjected to a continuous flow (15–19 ml/min) of compressed clean dry air (Maxima, Ramat Gan Israel) and further purified by passing through a trap of silica blue (Merck Co., Darmstadt, Germany) and Porapak Q (Millipore Co., Millford, Massachusetts) filters. The outlet tube from the flask led into a trap of hexane cooled in ice and acetone. The hexane solutions were later reduced in volume by a gentle flow of N_2 gas and used for the behavioral assays.

Synthetic Phenol Derivatives

Several candidate compounds previously identified in air collected from locust colonies (Fuzeau-Braesch et al., 1988) were purchased from Sigma and individually dissolved in chloroform.

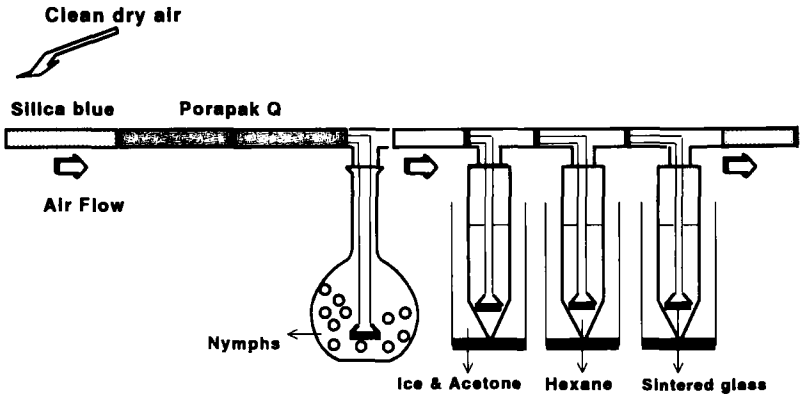

FIG. 1. Diagram of extraction apparatus for collection of airborne volatiles from crowded fourth instar nymphs of the desert locust. Groups of 60 nymphs were placed in a 3-liter glass flask and volatiles were entrained in a stream of clean air and captured in a series of cold traps.

Cuticular Surface Extracts

Groups of 50 nymphs were taken from the crowded culture, immersed in 150–200 ml of dichloromethane and gently shaken for 10 min. The extracts were collected and reduced in volume.

Fecal Extracts

Cages of crowded nymphs were cleaned of feces every 5 hr, and the collected material weighed and stored at −20°C until extracted with dichloromethane, as above. The dichlorometane extracts were reduced in volume in a rotary vacuum evaporation system (Rotavapor-R, Büchi, Switzerland).

Treatment of Solitary Nymphs

Nymphal volatiles were applied to Whatman No. 1 filter paper disks that were impregnated with paraffin oil to attenuate the rate of release. Cuticular extracts, feces extracts, or synthetic phenol derivatives were applied to 10 × 15-cm polyethylene screens as solutions in organic solvents. The solvents were evaporated and one disk or screen placed in each chamber. Solitarious nymphs were exposed to treated or control screens (pure solvent only applied) for 5 hr. Ten exposed nymphs of each treatment were then placed together in the arena and their behavior assayed.

Olfactometry

A Y-shaped glass olfactometer system was designed with an inner diameter of 2.5 cm. The outlet tube was 20 cm in length and each of the two arms were 18 cm in length. These dimensions are sufficient for a locust nymph to move through comfortably. The connections of the glass Y-shaped olfactometer to other components of the system were with S-40 ground glass connectors. Each arm led to a glass trap and from there to a flask. One flask contained a test preparation, and the other remained empty. The olfactometer was attached at its outlet to a vacuum pump (ABM, Germany) and a constant flow rate of 60 ml/min was maintained and monitored. A second flowmeter was attached with Tygon tubing via a cylinder of activated charcoal to the inlet of each flask in order to equalize the airflow rate through the control and test flasks. Individual nymphs were released at the beginning of the outlet tube and monitored as they moved against the airflow into either of the two arms of the olfactometer, after which they fell into the trap. Extracts of nymphal cuticle, feces, and airborne volatiles were assayed separately, and their attraction for single solitarious nymphs was assessed.

RESULTS

Solitary and Gregarious Behavior

Six parameters were evaluated for their contribution to the discrimination between gregarious and solitary nymphs. They were all found to be significantly affected by rearing density (Table 1) with univariate t tests. Correlation analysis and stepwise discriminant analysis (SAS 1992) detected various degrees of correlation between the different variables. The most striking differences were observed between activity levels and associative indices: Gregarious nymphs are almost three times as active as solitary nymphs ($P < 0.0001$), and the associative index of gregarious nymphs is about double that of solitary nymphs ($P < 0.0003$). These two parameters were chosen by stepwise discriminant analysis as sufficient for discriminating between the two phases, and the discriminant function was derived from them only.

Effect of Density

Behavior was evaluated by placing nymphs together in groups of 2–10 from the second until mid-fourth instar. Phase transition is considerably shifted in groups of three nymphs together and crosses the threshold for discrimination of gregarious phase in groups of five nymphs (Figure 2). Crowding 10 nymphs together induces even more marked gregarious behavior, although less than that elicited with highly crowded nymphs from the standard culture. In addition to the shift in phase index, which approaches and then crosses over the threshold for discrimination of gregarious behavior, the percentage of nymphs classified as gregarious increases.

TABLE 1. PARAMETERS OF ACTIVITY AND SOCIAL INTERACTIONS DESCRIPTIVE OF GREGARIOUS AND SOLITARY DESERT LOCUST FOURTH-INSTAR BEHAVIOR[a]

	Activity level[b]	Associative index	Groups (N)[c]	Nymphs (per group)	Rate of movement[d]	Distribution[e]
Solitary	24.15 ± 3.3	0.3 ± 0.05	1.08 ± 0.1	2.13 ± 0.2	3.20 ± 0.8	2.10 ± 0.03
Gregarious	69.52 ± 3.4	0.77 ± 0.09	1.93 ± 0.1	2.93 ± 0.2	6.05 ± 0.4	2.23 ± 0.02

[a] Average of 10 replicates ± SEM.
[b] Number of seconds spent in activity during 2 min.
[c] Individual nymphs are regarded as associated in a group if they are within one body-length of any other nymph.
[d] Area of body displacement during 2 min.
[e] Log variance of distribution of the 10 individual nymphs within the arena.

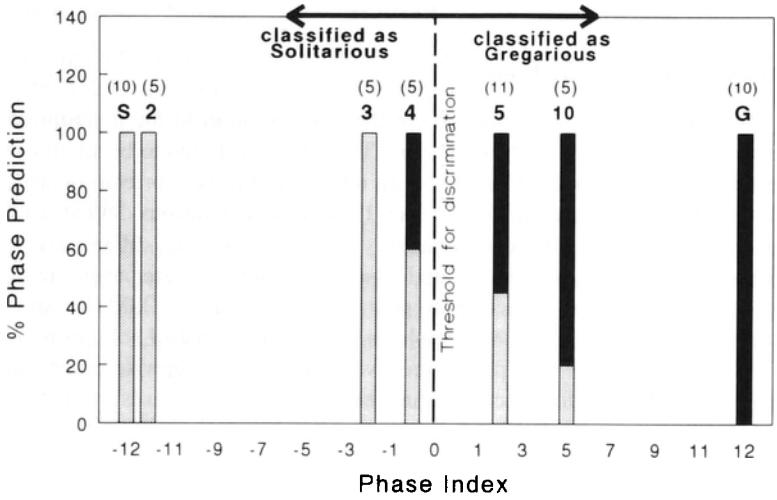

FIG. 2. Phase indices (PI) of desert locust nymphs reared at different densities in chambers measuring 10 × 10 × 10 cm from second to mid-fourth instar. The bold letters and numerals above the bars indicate density: **S** = 1 nymph per chamber (solitarious), **2–10** = number of nymphs per chamber; **G** = nymphs from standard culture (200 per large cage). ▬ = percentage gregarious behavior; ▬ = percentage solitary behavior. Numbers in parentheses are numbers of replicate experiments at each density. PI was calculated from data of solitary and high-density standard culture nymphs (PI = 0.45 AL + 9.14 AI − 25.78).

Asymetrical Plasticity of Phase Behavior

Newly eclosed fourth instars from the crowded culture were isolated for three days and their behavior assayed. When regrouped 10 together, reversal to gregarious behavior was evident after 6 hr, and behavior completely reverted to gregarious behavior after the nymphs were regrouped for 24 hr. The change of gregarious to solitary nymphal behavior is less rapid than the converse. When newly eclosed fourth instar nymphs were kept at a density of 10 per cage for three days and then isolated, only partial behavioral changes were evident 24 hr later when 45% of the groups were still behaving gregariously (Figure 3).

On the basis of the effects of density and time, an exposure time of 5 hr of solitary nymphs to various chemical affectors was routinely chosen, and the discriminant functions were calculated according to the nymphal equivalents of compounds assessed in separate experiments.

A variety of components—visual recognition at short-range, sensillar chemoreception, and/or tactile mechanoreception—are presumably involved in the

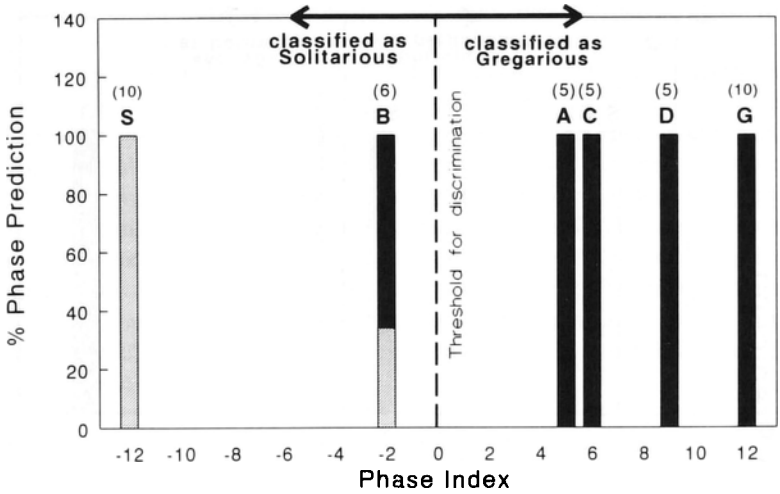

FIG. 3. Phase indices of desert locust nymphs of standard culture isolated for three days and then regrouped for 6 hr (**C**) or 24 hr (**D**) or distributed at a density of 10 nymphs per chamber for three days, and then separated for 6 hr (**A**) or 24 hr (**B**). **S** = solitary; **G** = 10 nymphs crowded for 4 days.) ■ = percentage gregarious behavior; ■ = percentage solitarious behavior. Numbers in parentheses are numbers of replicate experiments of each treatment. PI was calculated from data of solitarious nymphs and of the density of 10 nymphs (PI = 0.44 AL + 25.91 AI − 30.12).

induction of phase transition. We evaluated the relative contribution of these different stimuli to the process of phase transition by assaying each component separately.

Effect of Sensory Stimuli on Phase Transition. Solitary nymphs were obtained by rearing them individually in aluminum-partitioned cages, thereby isolating them from all interactive stimuli. Visual stimuli alone do not shift the phase index towards gregariousness: this was demonstrated by replacing the aluminum partitions with glass, thus depriving them of olfactory and tactile stimuli. When separated by wire screening only (i.e., deprived of tactile stimuli but exposed to olfactory and to somewhat restricted visual stimuli, 33% behaved gregariously (Figure 4a).

Antennal chemoreceptive sensilla are the main sensors for olfactory stimuli (Blaney and Simmonds, 1990). In order to evaluate whether phase transition occurs in the absence of antennae, the behavioral response of antennectomized crowded nymphs was examined.

Antennal Sensory Perception. Gregarious nymphs were operated on when in the fourth instar and kept together for an additional 24 hr after surgery. In

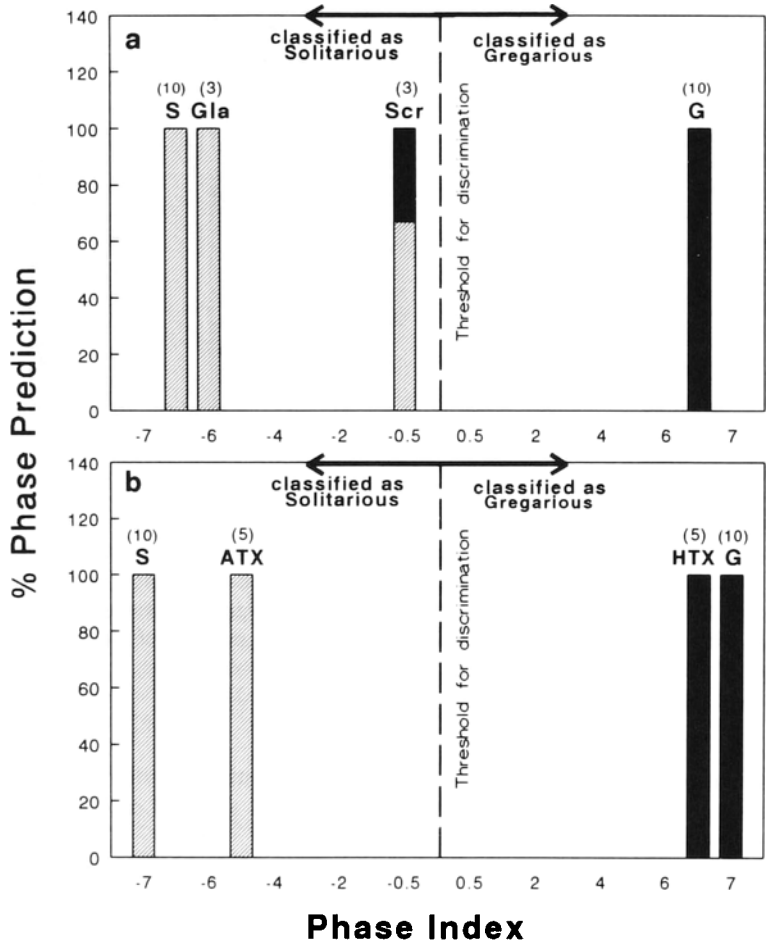

FIG. 4. Phase indices of (a) effects of visual, olfactory, and contact stimuli on phase transition. Nymphs were reared from second to mid-fourth instar in chambers separated by partition. **S** = aluminum partition (solitarious); **Gla** = glass partition; **Scr** = wire screen partition; **G** = group of four nymphs together with no partition. PI was calculated from data of solitary nymphs and of the density of four nymphs in a 20 × 20 × 10 cm cage (PI = 0.28 AL + 11.13 AI − 15.93). (b) Effects of antennectomy (**ATX**) or hind-tarsal amputation (**HTX**) of mid-fourth-instar nymphs from the standard culture, kept together in groups of four for an additional 24 hr. PI was calculated from data of solitary nymphs and of the density of four nymphs in a 10 × 10 × 10 cm cage. ▬ = percentage gregarious behavior; ▬ = percentage solitarious behavior. Numbers in parentheses are number of replicates. (PI = 0.36 AL + 17.32 AI − 21.23.)

the absence of sensory input from the antennae, the crowded nymphs were behaviorally solitary, and neither tactile interactions nor vision was able to maintain gregarious behavior (Figure 4b). Hind tarsal amputation was performed on separate groups as a control surgical procedure, but the surgery was unable to depress the interactive stimuli maintaining gregariousness. The solitary behavior did not result from a reaction to surgery, but rather from sensory deprivation.

Experiments were designed to identify the character of the presumptive chemical stimuli essential for behavioral phase transition. Different experimental treatments were performed with material applied at doses adjusted to different nymphal equivalents. A nymphal equivalent was defined as the amount of material derived from one nymph. Standardization of the phase index was achieved by deriving different discriminant functions from the behavioral data of specific nymphal densities.

Effect of Locust-Derived Compounds on Induction of Gregarious Phase Behavior.

Exposure of solitarious nymphs for 5 hr to extracts of nymphal cuticle (5 nymphal equivalents) strongly shifted the phase index, and 60% of the groups behaved gregariously in the behavioral test (Figure 5a). Exposure to airborne nymphal volatiles (10 nymphal equivalents) had a slight effect on phase index (Figure 5b), while extract of nymphal feces (4 g/ml, or 50 nymphal equivalents) had none (Figure 5c).

Airborne phenol derivatives such as guaiacol and veratrole (Fuzeau-Braesch et al., 1988) are present in fecal extracts (Torto et al., 1994; Obeng-Ofori et al., 1994). Individual and combined effects of phenols on nymphal behavior was next assessed.

Behavioral Response to Phenol Derivatives

Solitary nymphs were exposed for 5 hr to 5 mmol guaiacol, veratrole, or both veratrole and guaiacol together. These two compounds, particularly guaiacol, slightly affected activity levels (data not shown). We tend to attribute this slight increase in activity to nonspecific sensory stimulation of nymphal chemoreceptors. Associative indices were not significantly affected by treatment with these odorants either separately or together (data not shown). When subject to discriminant analysis, veratrole or guaiacol alone, or both together, did not affect phase index (Figure 6).

Cuticle extracts markedly shifted the phase index of exposed solitary nymphs toward the gregarious state. They might conceivably have been acting indirectly as attractants, leading to aggregation, whereas other short-range factors might thereafter induce gregarious phase behavior. Attraction was therefore next examined in an olfactometer.

PI was calculated from data of solitary and gregarious nymphs. Numbers in parentheses are number of replicates. (PI = 0.45 AL + 9.14 AI − 25.78.)

Olfactometry

No significant attraction of solitary nymphs to cuticular extracts was observed in olfactory assays under conditions where no contact could occur between the extracts and the test nymphs (Figure 7). In contrast, orientation in the olfactometer of female and male nymphs to extracts of nymphal feces was two-fold higher than nonspecific movement into a flow of clean air (χ^2 = 12.73 and 18.57, respectively; $P < 0.001$).

FIG. 5. DISCUSSION

Locust phase behavior is a rapid response to changes in population density. The relative importance of the various behavioral phase characteristics and the degree of their expression at different population densities have not been sufficiently evaluated. A quantitative bioassay of sufficient sensitivity to measure partial phase transition was designed and evaluated by discriminant analysis (Dillon and Goldstein, 1984). Stepwise discriminant analysis independently chose and limited observations and measurements of behavior to those essential for describing the phase status of locust nymphs that had been exposed to various treatments. Activity levels and associative indices were found to be essential and sufficient to attributing the experimental group of locusts to either of the two phases. The merit of discriminant analysis is that it can assist in critically evaluating partial effects and quantifying the intensity of response on a sliding scale of phase index.

Density-related behavioral response is not an all-or-nothing event, and moderate crowding elicits intermediate behavior (Uvarov, 1966). In the experimental design used in these present experiments, a marked shift in behavior at a density of three nymphs was observed, while the behavior at a density of five nymphs was unequivocally classified as gregarious. Gregarious behavior of 10 nymphs crowded together was even more pronounced but still distinguishable in intensity from that of nymphs of the standard locust colony. The intensity of response is density-dependent.

The duration of exposure to the different densities or treatments affects the intensity of phase shift as well. Six hours were required for nymphs reared in isolation to behave gregariously when placed 10 together, and after 24 hr of regrouping they were classified as markedly gregarious. However, 6 hr of isolation only slightly shifted the phase index of gregarious nymphs towards solitary behavior, while 24 hr of isolation were required for them to cross the threshold to solitary behavior. After being separated for four days during the fourth instar, the phase index approaches that of solitarious nymphs. These results are consistent with previous reports that transition to gregarious behavior can occur within 0.5–4 hr of crowding, whereas transition from crowded to solitary nymphal behavior is much slower (Ellis, 1962, 1963; Gillett, 1988; Roessingh and Simpson, 1994).

Visual, olfactory, and tactile stimuli are reported to be essential for gregarious phase induction (Gillett, 1968). We reexamined individual roles and found that visual stimuli did not induce behavioral phase transition, while olfaction (presumably antennal) shifted the phase index considerably. This is corroborated by the observation that when gregarious nymphs were antennectomized and kept together (thus with lack of antennal chemoreception but maintenance

of visual stimuli), solitary behavior was induced. Hind-tarsal amputation did not elicit this response. We conclude that lacking antennal chemoreception, gregarious behavior cannot be maintained even under crowded conditions. This complements observations of chromatic changes in desert locust nymphs after antennectomy (Mordue, 1977), interpreted as due to reduction in sensory input, and to behavior indicative of the solitary phase in crowded nymphs after antennectomy, but not after tarsal amputation (Gillett, 1983).

Various volatile degradation products of plant-derived lignin from fecal extracts have been studied in the context of locust gregarization. One of these, 5-ethyl guaiacol, was reported to reduce the rate of melanin loss by isolated nymphs (Nolte, 1963) and to affect chiasma frequency (Nolte, 1967), but its bioactivity and the validity of its identification were subsequently questioned (Dearn, 1974; Fuzeau-Braesch *et al.*, 1988). We found that fecal extracts did attract individual solitary nymphs, but that gregarious phase behavior was not induced. These results are in accord with previous reports demonstrating that group formation is not promoted by chronic exposure of isolated nymphs to feces or fecal extracts (Gillett, 1983).

The attractant effects of phenol, guaiacol, and other odorants from culture cages derived directly from the locust and presumably also from the feces have been previously examined with locust nymphs and adults (Fuzeau-Braesch et al., 1988). In our experiments, we did not find any effect of guaiacol and veratrole, or both together, on phase transition, nor did total airborne volatiles attract solitary nymphs. However, airborne volatiles did shift phase behavior somewhat.

The most consistent effects on behavioral phase index were elicited by cuticular components. Cuticular components did not attract solitary nymphs, and this is in contrast to previous studies that had suggested that cuticular components were involved in mutual attraction between locusts (Norris, 1963, 1964). Presumably, complete phase transition is induced by a variety of stimuli together. Each might also be expected to elicit only a partial response when acting alone. The shift in the phase index was somewhat less than when nymphs were in contact, but this might also have been due to the marginal concentration applied.

All of these results lead to the conclusion that a fundamental difference exists between attraction (i.e., effect of fecal extracts) and phase-related behavior (i.e., effect of cuticular extracts). Fecal extracts strongly attracted fourth instar nymphs but did not affect the phase index, while the cuticular extract did not attract at all, but did shift behavioral phase.

We find that these controlled laboratory bioassays relate closely to events occurring in the field, where a series of sequential events presumably induces the gregarious phase. Wind convergence, aggregation on available vegetation, and particularly sexual attraction, and attraction to limited oviposition sites bring solitary adults together. Initial aggregation may be enhanced by feces-derived

attractant compounds. Visual stimuli are not necessarily essential for these initial events but could later contribute to recognition of the gregarious phase and cohesion of hopper bands. It is the mutual contact of nymphs, aggregated by environmental factors or locust-derived chemicals, that finally leads to the induction of behavioral phase transition, presumably mediated by cuticular contact pheromones.

Abstract—Electroantennograms (EAGs) from field-collected *Hyles lineata* moths were recorded in response to 10 individual floral volatiles identified from *Clarkia breweri* (Onagraceae), to 22 scent compounds produced by other moth-pollinated flowers and to eight ubiquitous "green leaf volatiles." Females' EAGs were generally 1.5- to 2-fold greater than those observed for male moths. Female : male EAG rank orders were significantly correlated, but marked differences in order were observed for some compounds (e.g., benzyl alcohol, cinnamic aldehyde, geraniol, and linalool). Linalool, benzyl acetate, methyl salicylate, and pyranoid linalool oxide elicited the largest EAG responses (−1.2 to −0.8 mV) among scent compounds from *C. breweri*. EAG responses were significantly lower for monoterpenes as a pooled compound class than for aromatic esters, alcohols and aldehydes, fatty acid derivatives, N-bearing compounds and oxygenated terpenoids. EAG responses to structurally related scent compounds were not significantly different in most

cases. Both male and female *H. lineata* were sensitive to most *C. breweri* scent compounds at 10^{-2} to 10^{-4} $\mu g/\mu l$ doses, and rank order in potency varied with the dose/concentration tested. *H. lineata's* olfactory sensitivity to diverse volatile compounds across a range of doses/concentrations suggests that a broad array of volatiles could function as floral attractants for foraging hawkmoths.

Key Words—Aromatics, EAG, floral attraction, floral scent, green leaf volatiles, hawkmoths, monoterpenes, nitrogen-bearing compounds, olfaction, semiochemicals, *Hyles lineata*.

INTRODUCTION

The white-lined sphinx moth, *Hyles lineata* L. (Sphingidae: Lepidoptera), is the most widely distributed hawkmoth species in the world; it is present throughout the Americas (subsp. *lineata*), across Europe, Asia, and Africa (subsp. *livornica*) and in Australia (subsp. *livonicoides*; Rothschild and Jordan, 1903; von Knoll, 1925; Hodges, 1971). *H. lineata* moths are avid flower visitors, foraging for nectar at dusk and early evening in most localities (Clements and Long, 1923; Gregory, 1963, 1964; Kislev et al., 1972; Hodges, 1995). Due to its general abundance and broad distribution, *H. lineata* is probably the most important hawkmoth pollinator throughout much of North America (Cruden, 1970; Stockhouse, 1973; Chase and Raven, 1975; Miller, 1978, 1981). The broad acceptance of flower types by *H. lineata* throughout its distribution suggests either that it is attracted to a wide variety of floral scent compounds (or blends thereof) or that it relies on cues other than floral scent (i.e. visual cues) during foraging. One way to test these possibilities is to study the physiological and behavioral responses of *H. lineata* to the scent compounds of the flowers that it visits.

H. lineata moths visit a broad spectrum of plant species bearing flowers of diverse morphological classes (von Knoll, 1925; Fleming, 1970; Kislev et al., 1972). Grant (1983, 1985) cited *H. lineata* as a visitor to flowers of 41 native plant species from 13 angiosperm families in North America. However, hawkmoths are observed to be effective pollinators of a subset of these plants, those with tubular or trumpet-shaped flowers in which the nectar tubes or spurs are as long as or longer than the extended proboscides of the moth. This geometrical relationship increases the probability of head/body contact with floral sex organs, leading to removal and deposit of pollen (Gregory, 1964; Miller, 1978; Grant, 1983; Dafni et al., 1987; Nilsson, 1988; Hodges, 1995; Raguso, 1995). Many hawkmoth pollinated flowers often are pale in coloration, open during the evening, produce copious amounts of nectar, and emit a strong, sweet aroma. This combination of floral traits has evolved repeatedly in most major angiosperm families worldwide and defines the "hawkmoth-pollination syndrome" (Baker,

1961; van der Pijl, 1961; Gregory, 1963; Faegri and van der Pijl, 1979; Miller, 1981; Grant, 1983).

In western North America, *H. lineata* pollinates a number of plant species with pale, tubular, scented flowers, especially within the genera *Aquilegia* (Ranunculaceae), *Mirabilis* (Nyctaginaceae), and *Oenothera* (Onagraceae; reviewed by Grant, 1983, 1985). One plant species typical of this assemblage is *Clarkia breweri* (Gray [Greene]: Onagraceae). *H. lineata* and other hawkmoths are important pollinators of *C. breweri* in the central Coast Range Mountains of California (Raguso, 1995). Genetic and morphological data suggest a recent origin of *C. breweri* from scentless, bee-pollinated ancestors (Lewis and Lewis, 1955; MacSwain et al., 1973; Gottlieb and Weeden, 1979; Raven, 1979). Moth pollination and strong floral scent emission are not observed in any other *Clarkia* species, and are thought to represent a derived condition in the genus (MacSwain et al., 1973; Raven, 1979; Raguso and Pichersky, 1995). The currently accepted model of hawkmoth foraging behavior proposes that floral scent functions as a sign stimulus that "turns on" or releases anemotactic searching flight behavior, followed by visual close-range orientation to flowers (Baerends, 1950; Brantjes, 1973, 1978). Following this model, we propose that floral scent has evolved in *C. breweri* as an adaptive trait modified through selective pressure by hawkmoth pollinators, including *H. lineata* (Raguso and Pichersky, 1995). For this hypothesis to be valid, hawkmoths must be olfactorily sensitive to the array of *C. breweri's* floral scent compounds and able to detect them at concentrations low enough to serve as cues for flower location from a distance.

We tested the olfactory sensitivity of *H. lineata* moths by measuring their electroantennogram (EAG) responses to the floral scent compounds of *C. breweri*. EAGs have been used to assess the olfactory sensitivities of agriculturally important moth species in response to host plant volatiles (Grant, 1971; Adler and Jacobson, 1972; Tichenor and Seigler, 1980; Gabel et al., 1992; Light et al., 1993; Zhu et al., 1993) and to sex pheromones (Schweitzer et al., 1976; Reed et al., 1987). Little is known, however, about the breadth of hawkmoths' olfactory responses to floral volatiles from different chemical structural classes, or to plant vegetative volatiles in general. The purpose of our study was to characterize, through EAG recordings, the peripheral olfactory responses of *Hyles lineata* moths to 40 scent compounds, including ten floral volatiles from *Clarkia breweri*, 22 floral volatiles identified from other moth-pollinated plants and eight "green leaf volatiles" (GLVs) typical of vegetation.

We used EAG response data to address the following questions.

(1) Do *H. lineata* moths respond differently to diverse chemical classes of plant volatiles?

(2) Can *H. lineata* moths distinguish between structurally similar scent compounds bearing slightly different functional groups?

(3) Can *H. lineata* moths detect floral scent compounds at low doses?

Selective differences in olfactory response to specific compounds or structural classes of compounds might predispose *H. lineata* to respond to certain olfactory stimuli through induction of flight orientation and feeding or ovipositional behaviors. By testing *H. lineata's* responses to volatile compounds from different structural classes (terpenoids, aromatics, fatty acid derivatives, and nitrogen-bearing compounds), we can begin to characterize the potential role of olfaction in the foraging behavior of a widespread hawkmoth species.

METHODS AND MATERIALS

Insects

Adult *H. lineata* moths were collected at UV light traps from September 17 to October 4, 1993 in Tucson, Pima Co., AZ and transported live via overnight courier to Albany, CA. Upon arrival, moths were fed a 10% sucrose solution and held in a 1 m^3 screen cage within the laboratory (25°C, 12 L:12 D). Moths had free access to sucrose solution feeding stations, and were fed manually once daily.

Test Compound Justification

Appendix 1 lists the 40 scent compounds tested, their purities, supply sources, and rationale for inclusion in this study. We measured EAG responses to ten of the 12 principal volatiles identified from the floral headspace of *C. breweri*, constituting 97.9% of total volatile emissions analyzed via GC-MS (Raguso and Pichersky, 1995). *C. breweri* floral volatiles fell into two chemical classes, aromatics and oxygenated monoterpenoids, and included benzyl acetate, linalool, and methyl salicylate, three of the most prevalent floral scent components in hawkmoth-pollinated flowers (Brantjes, 1978; Kaiser, 1993; Knudsen and Tollsten, 1993).

We tested 22 additional floral volatiles from diverse chemical classes, including aromatics, fatty-acid derivatives, monoterpenes, nitrogen-containing compounds, and a sesquiterpene alcohol. Test compounds in this grouping were chosen for one of three reasons; (1) they frequently occur as floral scent constituents in many other hawkmoth-pollinated flowers (e.g., amyl salicylate, farnesol, geraniol, indole; Morgan and Lyon, 1928; Kaiser 1991, 1993; Knudsen and Tollsten, 1993), (2) they stimulate upwind flight in another family of flower-visiting moths, the Noctuidae (e.g., phenylacetaldehyde, 2-phenylethanol; Jacobson et al., 1976; Haynes et al., 1991; Heath et al., 1992), or (3) they share a common carbon skeleton with one of the above compounds, but differ by one functional group (e.g., methyl anthranylate, methyl-2-methoxybenzoate). Inclusion of these compounds allowed us to determine (1) the chemical breadth

of *H. lineata's* olfactory "vocabulary," (2) whether these moths can detect flowers that are attractive to noctuid moths, and (3) whether they can distinguish between similar odorants bearing subtle chemical differences.

We analyzed EAG responses to eight green leaf volatiles (GLVs). These C_6 and C_8 aliphatic alcohols, aldehydes, and acetates are ubiquitous in plant vegetation and provide strong structural contrast to the aromatic and terpenoid floral volatiles. Female *H. lineata* may respond behaviorally to GLVs during hostplant orientation and oviposition. In addition, these compounds are known to synergize male responses to female sex pheromone in noctuid moths (*Helicoverpa zea*, *Heliothis virescens*; Dickens et al., 1993; Light et al., 1993), and may be important to male sphingids as well.

Olfactory Stimuli

Test compounds were dissolved in HPLC-grade hexane to form 10% volumetric solutions. Compounds poorly soluble in hexane, such as indole and vanillin, were dissolved by weight in diethyl ether. One ul of each solution (approx. 100 ug of test odorant) was pipetted onto filter paper strips, which were allowed to evaporate for ca. 30 sec, then inserted into Pasteur pipettes and stored at 5°C until used. Each test cartridge was loaded 20 min prior to its presentation to the moth's antennae.

EAG Technique

EAG deflections were recorded and measured on a Tektronix 5113 storage oscilloscope as described by Light et al. (1988). Silver-chloride electrodes were prepared in drawn glass capillary tubes, and were electrolytically balanced (Raynauld and Laviolette, 1987). Living moths were mounted on a plexiglass block with a central trough molded with soft paraffin to fit the contours of the moth's ventrum. The terminal five segments of the right antenna (out of 58–61 total segments) were excised and the recording electrode was inserted into the antennal cavity, while the ground electrode was inserted into the head at the base of the antenna. The antenna was bathed continuously by a stream of charcoal-filtered, humidified air at a flow rate of one L/min. A "puff" of test compound was delivered onto the antenna when a three-way solenoid valve was activated, diverting air through the test cartridge for a 1 sec stimulation interval. Each compound stimulation was followed by a minimum 60 sec purge period of filtered air to ensure recovery of antennal receptors.

For each compound tested, EAGs were recorded from five male and seven female *H. lineata* moths. In addition, EAG responses to serial dilutions of eight floral volatiles from *C. breweri* (ranging in dose from ca. 10^{-4} to 10^{2} μg/μl per filter paper) were recorded from three males and six females. "Control" stimuli (1 μl of hexane solvent per filter paper) and "standard" stimuli (1 μl of 1%

linalool in hexane per filter paper) were interspersed about every fifth compound or dose tested. The order of compound presentation was randomized for each individual moth. Experiments ranged from 65–110 min in length; standard stimulus EAG data were plotted vs. time, and no consistent patterns were observed. All experiments involved the testing of single compounds; no blends were used.

Treatment of EAG Data

EAG responses (−mV) to test compounds were adjusted to compensate for solvent and/or mechanoreceptive artifacts by subtracting the accompanying "control" stimulation, yielding "corrected −mV" (see Reed et al., 1987; Gabel et al., 1992). EAG data also were expressed as percent responses of the standard stimulant (linalool, a compound of medium MW and volatility), hereafter written "% of standard" (see Light et al., 1992a, 1992b; van Loon et al., 1992). Due to differences in volatility between the 40 stimulant compounds (MW and boiling point data, Appendix 1), we utilized the standard stimulus as a reference point for comparing EAG responses to different stimulant compounds. Thus, "% of standard" EAG data were used in male-female rank order comparisons and all comparisons involving different chemical classes, isomers and functional groups.

EAG Data Analyses and Statistical Tests

Mean EAG responses (% of standard) to all 40 stimulant compounds (at 10% concentration) were ranked 1–40 in descending order of magnitude for both sexes. We compared male and female EAG rank orders using Spearman's Rank Correlation Coefficient (Sokol and Rohlf, 1981), with which we tested the null hypothesis of no correlation (Rho = 0) between male and female scent compound ranks. If a calculated sample product-moment correlation coefficient (R_s) was found to exceed the upper 95% confidence interval, we rejected the hypothesis of no correlation between male and female EAG rank orders.

We attempted to identify variation in EAGs associated with sex and/or differences between and within chemical classes of olfactory stimulants. EAG data (% of standard) were square-root transformed to compensate for unequal variances and were analyzed using Repeated Measures ANOVA models (Systat 5.2.1; 1992). First, we grouped floral scent and vegetative compounds by chemical class (monoterpenes, oxygenated terpenoids, aromatic esters, aromatic alcohols and aldehydes, fatty acid derivatives, and nitrogen-bearing compounds) and derived a mean response value for each chemical class by averaging the mean EAGs for the individual member compounds. These derived data were analyzed for significant differences related to sex, chemical class, and sex x class interactions using Repeated Measures ANOVA. If significant variation were asso-

ciated with chemical class, specific pairs of stimulant classes were then compared in three *a priori* contrasts: monoterpenes vs. oxygenated terpenoids, aromatic esters vs. aromatic alcohols and aldehydes, and all terpenoids vs. all aromatics. Contrasts were examined by computing Scheffé contrast intervals around the differences between the two compared means (Rothman and Ericson, 1987). We rejected the null hypothesis of equal means if the computed Scheffé intervals did not contain the number zero.

Second, we examined each chemical class separately for potential variation due to differences in structure or functional group, using Repeated Measures ANOVA and tracking sex, compound and sex x compound interactions as factors. These analyses were performed using square root transformed mean EAG data for each compound within chemical classes. For GLVs and aromatic compounds, we performed some follow-up comparisons of mean EAGs for select groups of related compounds using Student's *t*-tests adjusted for multiple comparisons with the sequential Bonferroni method described by Rice (1989), testing null hypotheses of no statistical differences between means. Male and female data were pooled for *t*-tests, because there were no significant ANOVA terms associated with sex (see below). For aromatics, we performed a second series of ANOVA on groups of compounds conforming to the following four classes: benzoic acid methyl esters, *ortho*-hydroxyl-benzoic esters (salicylates), benzaldehydes and phenylpropanoids. Follow-up tests focused on two groups of compounds sharing a common carbon skeleton but differing by functional group or carbon chain length.

We analyzed dose-response EAG data (% of standard) with respect to three specific parameters: threshold dose, maximum EAG response and slope of the dynamic response phase (see Light et al., 1992b). Threshold dose represents the lowest dose at which a stimulant evokes a mean EAG response distinguishable from responses to controls. The dynamic response phase describes the stimulus dose interval during which the greatest change or increase in EAG responsiveness (i.e., slope) is observed.

Antennal Morphological Data

We performed a number of morphological measurements on male and female *H. lineata* moths to determine whether sexual dimorphism in body size is reflected in antennal morphology. We measured dry body mass and forewing length (base to apex; a good surrogate for body size, see Haber and Frankie, 1989) of all experimental moths, and compared these measures using one-tailed Student's *t*-tests, with a null hypothesis of female moths not being significantly larger than males. Then, we measured the mass, length, diameter, and number of segments (annuli) of the left antenna of each moth. Antennal diameter was measured under a dissecting microscope (50X) using a glass slide calibrated to

0.1 mm; all other measurements were made with a ruler calibrated to 1.0 mm. Dry body and antennal masses were measured using a Mettler AE 100 analytical balance calibrated to 0.0001 g. Antennal measurements were adjusted for differences between male and female body size and compared using ANCOVA (Systat 5.2). The ANCOVA model considered antennal mass, diameter, length, and segment number as separate dependent variables, with sex as a treatment and dry body mass and forewing length as covariates.

RESULTS

General Antennal Responsiveness

The mean −mV responses of *H. lineata* male (mean ± SE: −0.18 ± 0.02 mV) and female (−0.24 ± 0.03 mV) antennae to hexane solvent "control" stimulations did not differ significantly ($t = 1.521$, $P = 0.08$), but the responses were generally larger and more variable for females than for males. Similarly, males' (−0.22 ± 0.04 mV) and females' (−0.30 ± 0.07 mV) EAG responses to the 1% linalool standard stimulus did not differ significantly, although neither sex's responses were uniform. All test compounds elicited measurable EAGs that were greater than those for hexane controls in male and female moths.

Responses to Clarkia breweri Floral Volatiles

Each of the 10 *C. breweri* floral volatiles elicited measurable EAG responses, but the largest EAGs in both sexes (females > −0.8 mV; males > −0.45 mV) were observed in response to benzyl acetate, methyl salicylate and linalool (Figure 1A). Female EAGs were larger than those of males for all of the *C. breweri* compounds, nearly two-fold larger in the cases of eugenol, methyl salicylate and pyranoid linalool oxide (Figure 1A). Benzyl benzoate elicited EAGs from both sexes that were similar in magnitude to those for eugenol and methylisoeugenol, but benzyl benzoate should be regarded as the most potent stimulant of the three, due to its large size (MW 212) and low volatility (b.p. 323°C; see Appendix 1). Male and female EAG responses to methylisoeugenol, vanillin, and veratraldehyde were the lowest among this group of compounds, less than or equal in magnitude to those for the standard stimulus.

Responses to Other Floral Volatiles

Mean male and female EAG responses to the 22 additional floral scent compounds ranged in magnitude from very high (e.g., 2-methyl-butyraldoxime, < −0.8 mV; Figure 1B) to barely detectable (e.g., myrcene, ≤ −0.15 mV). Female EAGs were greater than those of males for all compounds except *allo-*

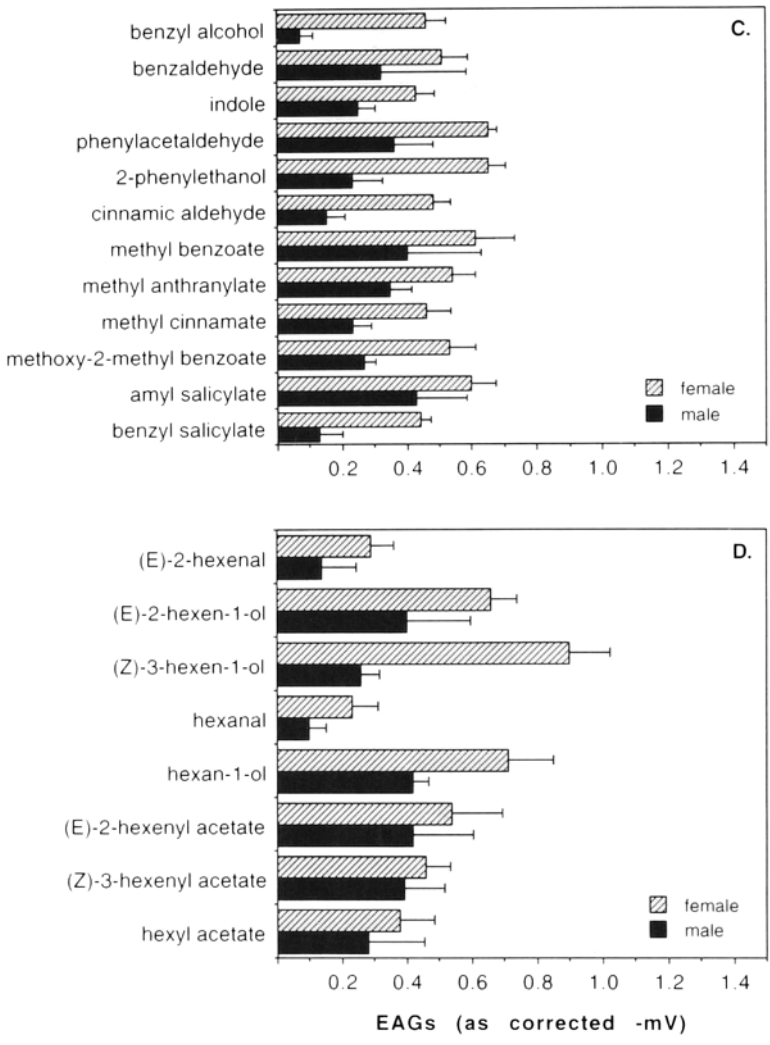

FIG. 1. Continued.

ocimene, especially so in the cases of benzyl alcohol, cinnamic aldehyde, and geraniol (Figures 1B, C). When *H. lineata* EAG magnitudes are scaled to differences in relative volatility, as related to molecular weight and boiling point (Appendix 1), stimulant compounds such as 2-methyl-butyraldoxime (MW 102) and farnesol (MW 222) are comparable in potency, while large compounds (MW

> 200) evoking strong EAG responses, such as amyl salicylate and (*Z*)-jasmone (Figures 1B, C), must be considered among the most highly potent antennal stimulants tested.

Responses to Green Leaf Volatiles (GLVs)

EAG responses to aliphatic alcohols and acetates were moderate to large in magnitude (> -0.4 mV) in both males and females, but EAG responses to the aldehydes hexanal and (E)-2-hexenal were relatively small (Figure 1D). Females' and males' EAG responses to most compounds were similar in magnitude (Figure 1D). The rank order of GLV response potency was: C_6 alcohols $\geq$ C_8 acetates $\geq$ C_6 aldehydes.

Rank Orders of EAG Responses

The rank orders of male and female EAG responsiveness (% of standard) to stimulant compounds at ca. 100 ug dosage are given in Table 1. Male and female ranks were significantly correlated (Spearman's Rank Correlation Coefficient = 0.715, $P < 0.001$), but marked differences in rank were observed for a number of the compounds, particularly within the top ten ranks (see Table 1). Because female EAGs were greater than those of males for most compounds, some differences in rank order were due to high male responsiveness to compounds that were relatively poor female stimulants (e.g., amyl salicylate, *allo*-ocimene, (*E*)-2- and (*Z*)-3-hexenyl acetate, hexyl acetate, linalool; see Table 1). The remaining differences in rank order were attributable to lower male responsiveness to compounds that were strong olfactory stimulants to females (e.g., benzyl alcohol, geraniol, (*Z*)-3-hexen-1-ol, pyranoid linalool oxide, 2-phenylethanol).

Chemical Class Comparisons

When EAG responses to the individual compounds were combined as pooled, averaged and derived indexes for structural chemical classes (Figure 2, Table 2), variation between these classes was significant ($P < 0.001$, Repeated Measures ANOVA). However, the effects of sex and sex x class interactions were not significant (see Table 2A). Monoterpenes elicited the smallest mean EAG magnitudes as a pooled compound class, and these responses were significantly smaller than those elicited by oxygenated terpenoids (Scheffé interval contrast, see Table 2B). However, grand mean EAG responses to aromatic esters were not significantly larger than those to aromatic alcohols and aldehydes, nor were mean responses to aromatic volatiles as a whole statistically separable from those to all grouped terpenoids (Table 2B).

TABLE 1. RANK ORDERS OF *Hyles lineata* EAG RESPONSES TO SCENT COMPOUNDS, EXPRESSED AS % OF STANDARD: FEMALES VS. MALES

Chemical class compound	Female rank	Male rank
Aromatics

(*E*)-*beta*-ocimene	36	35

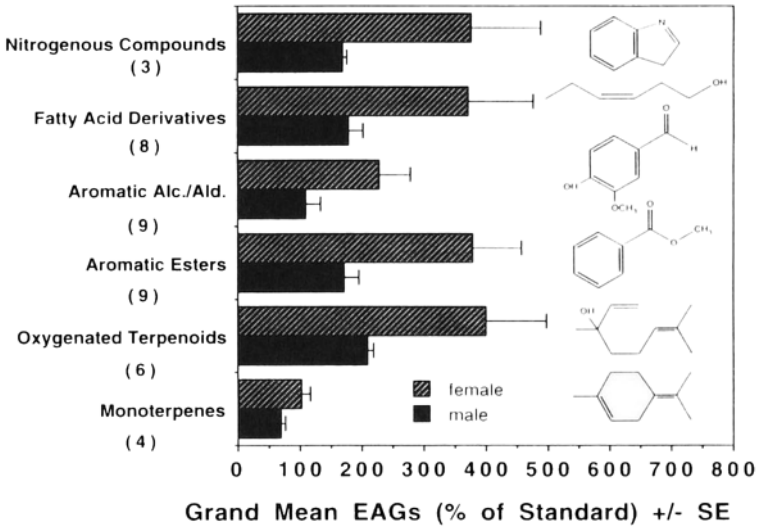

FIG. 2. Summary of *Hyles lineata* moths' EAG responsiveness to different chemical classes, as derived from pooling and averaging the mean EAG responses to each individual test compound belonging to a given chemical class (see Appendix 1). Relative responses are expressed as % of response to standard stimulus (1% v/v linalool in hexane). Number of compounds pooled for each chemical class is given in parentheses. Representative chemical structures are given for each class.

Variation Within Chemical Classes

Significant levels of variation were identified within the aromatic ester, aromatic aldehyde/alcohol, aliphatic GLV, monoterpene, and oxygenated terpene chemical classes (Repeated Measures ANOVA, Table 3). The effects of sex and sex x compound interactions were not found to be significant within most compound classes, with the exception of monoterpenes. This result is most likely due to the small number of compounds in this group (four) and especially strong sex differences in response to limonene (Figure 1B). Among aromatic sub-classes, significant compound-level variance was detected for the salicylates and benzoic acid methyl esters, but not for the benzaldehyde- and phenylpropanoid-related compounds (Table 4).

Follow-up tests of GLV compounds included comparisons of mean EAG responses to compounds varying in the chain position and configuration of C=C double bounds (e.g., (*Z*)-3-hexen-1-ol vs. (*E*)-2-hexen-1-ol) and to C_6 and C_8 GLV compounds sharing the same basic carbon skeleton but differing in degree of saturation, such as hexanal and (*E*)-2-hexenal (Student's *t*-tests, $P \leq 0.005$

B. *A Priori* Scheffé Contrasts

Comparison	Grand means (transformed)	Scheffé[a] interval
Monoterpenes vs oxyg. terpenoids	9.33 17.54	8.17 ± 3.17
Aromatic esters vs arom. aldehydes and alcohols	16.74 13.03	3.70 ± 3.71
Aromatics vs terpenoids	14.89 13.46	1.43 ± 2.63

[a]Null hypothesis of equal means is rejected if Scheffé interval does not contain the number zero.

for multiple comparisons; Table 5A). None of the five comparisons presented in Table 5A resulted in significantly different mean EAG responses.

Although we observed significant variation in EAG responses to aromatic esters (ANOVA, $P = 0.02$, Table 4), individual differences between methyl benzoate and its *ortho*-substituted derivatives were not statistically significant in pairwise *t*-test comparisons (Table 5B). We did not perform other possible pairwise comparisons within this subclass. We also observed significant variation in EAG responses among salicylates (ANOVA, $P < 0.001$, Table 4). EAG responses to methyl salicylate (with a methyl ester) were significantly greater than those to the larger benzyl salicylate (with a benzyl ester), but not significantly different from those for amyl salicylate (Table 5B).

Dose Responses to Clarkia breweri Volatiles

Dose-response EAG curves for male and female responses to test compounds were similar in shape but varied in their threshold, slope, and maximum -mV response (Table 6). Threshold doses for both sexes were on the order of 10^{-4} $\mu g/\mu l$ for linalool, pyranoid linalool oxide, and methyl salicylate (also

ima for both sexes were observed for benzyl acetate, linalool, and methyl salicylate. These compounds evoked the steepest slopes of EAG response curves over the broadest dynamic response ranges (10^{-1} to 10^{2} $\mu g/\mu l$ concentrations; Table 6).

Male and female EAG rank orders for eight *C. breweri* compounds at doses from 10^{2} down to 10^{-4} $\mu g/\mu l$ are listed in Table 7. Mean rank orders over all doses were comparable to those listed for doses of 10% (Table 1), with some inconsistencies resulting from different threshold doses among stimulants (e.g., furanoid linalool oxides). Compounds such as linalool and methyl salicylate were consistently strong antennal stimulants throughout the range of doses tested. Benzyl acetate was a relatively poor stimulant at dosages below 10^{-2} $\mu g/\mu l$, while pyranoid linalool oxide was a relatively strong antennal stimulant at doses below 10^{0} $\mu g/\mu l$.

methylisoeugenol	1.44	A.	< -3	92	35	10^{-1}–10^{1}
		B.	< -3	62	21	10^{-1}–10^{1}

[a]Percent of floral headspace composition, 24 hr scent collection over Tenax TA/charcoal, GC-MS analysis: Raguso and Pichersky, 1995. Vanillin and veratraldehyde were not used in dose-response experiments.
[b]Dosage of compound in hexane solution ($\mu g/\mu l$) as applied to filter papers in odor delivery cartridges.

Morphological Measurements

Female *H. lineata* moths were significantly larger than males, both in terms of dry body mass ($P = 0.007$) and forewing length ($P = 0.002$; one-tailed *t*-test, Table 8A). However, this inequality in body size was not reflected in antennal morphology. After scaling for body size differences using ANCOVA, female and male antennal diameter, antennal mass, and antennal segment number were not significantly different, but male antennae were significantly longer than those of females, relative to body size ($P = 0.014$, Table 8b).

DISCUSSION

Sexual Dimorphism and Rank Order

Antennae of adult male and female *H. lineata* responded in a sensitive and dynamic manner to the presentation of chemically diverse olfactory stimulants.

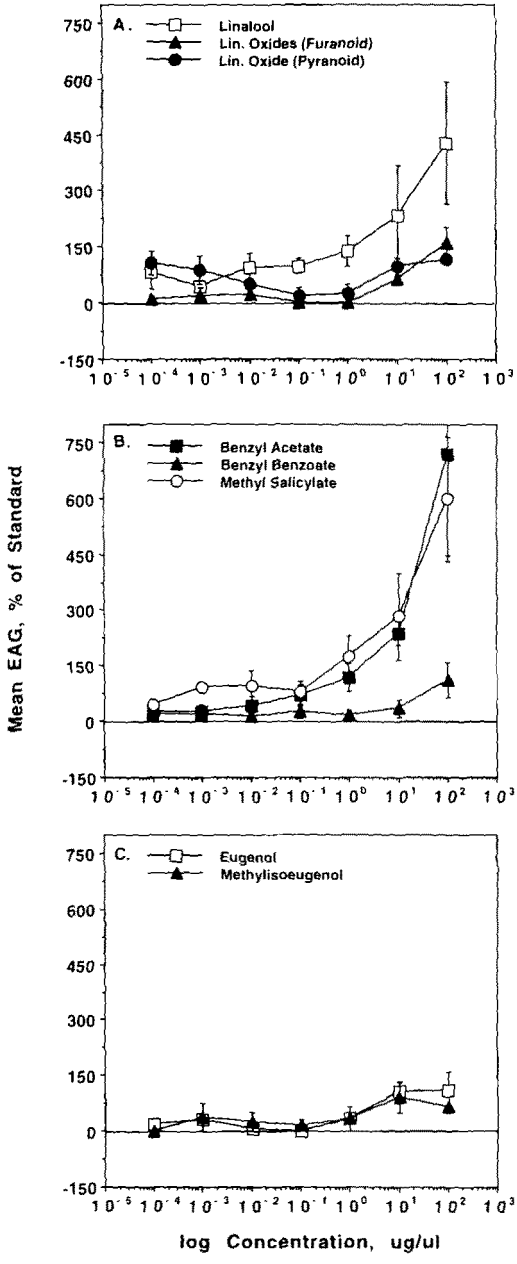

FIG. 3. Dose-response curves of female (A–C) and male (D–F) *H. lineata*, showing EAG responses to *C. breweri* floral volatiles at different v/v concentrations (as applied to filter paper wicks), expressed as mean % of standard ± SE vs log μg/μl.

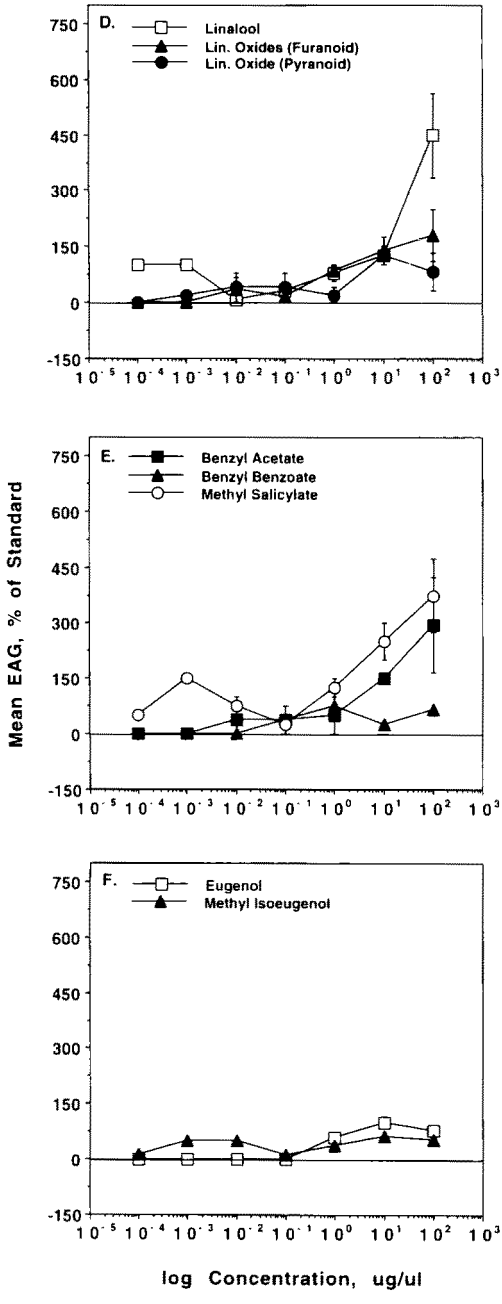

FIG. 3. Continued.

TABLE 7. RANK ORDERS OF EAG RESPONSES (% OF STANDARD) TO DIFFERENT CONCENTRATIONS OF *Clarkia breweri* FLORAL SCENT COMPOUNDS[a]

Stimulatory compound	Log concentration ($\mu g/\mu l$) per filter paper														$\bar{X}$	
	10^{2}		10^{1}		10^{0}		10^{-1}		10^{-2}		10^{-3}		10^{-4}			
	M	F	M	F	M	F	M	F	M	F	M	F	M	F	M	F
benzyl acetate	3	1	2	2	6	3	2	3	4	4	-	6	-	4	3	3
benzyl benzoate	7	6	8	8	4	7	3	4	-	6	-	-	-	-	6	7
eugenol	6	7	6	4	5	5	8	-	-	-	-	-	-	-	8	5
linalool	1	3	4	3	3	2	4	1	6	2	2	3	1	2	2	2
linalool oxides (furanoid)	4	4	3	7	2	8	6	-	5	-	-	-	-	-	4	8
linalool oxide (pyranoid)	5	5	5	5	8	6	1	5	3	3	4	2	-	1	5	4
methylisoeugenol	8	8	7	6	7	4	7	6	2	5	3	4	-	-	7	6
methyl salicylate	2	2	1	1	1	1	5	2	1	1	1	1	2	3	1	1

Note: Dashes indicate that compound could not be ranked at that dosage because it was below the threshold of detection.

[a] M = male (N = 3), F = female (N = 6).

Female EAGs were greater than those of males for most compounds, sometimes dramatically so (Figures 1A–D), yet sex was not a significant factor in most Repeated Measures ANOVA between and within chemical classes (Tables 2–4). The female-biased disparity in EAG responses to our experimental volatiles was not a scaling artifact due to the overall larger body size of females, because female antennae were actually smaller than those of males relative to body size (Table 8). However, variation within sexes was large in general (see error bars, Figures 1A-D), probably due to the sample sizes and differences in the moths' ages and experiences in the wild; thus, sex was not a significant factor in most of our ANOVA tests. Male and female EAG rank orders were significantly correlated (Table 1), and the shapes, thresholds, and slopes of the dose/response curves for the *Clarkia breweri* floral volatiles were fundamentally the same for both sexes, with responses of females being slightly larger in magnitude (Figures 3A–F, Tables 6, 7). These results suggest that male and female antennae are endowed with homologous types of olfactory receptors tuned to a wide range of "floral" and "vegetative" odorants. The few EAG rank order discrepancies observed among males and females (e.g., higher male responses to *allo*-ocimene; higher female responses to geraniol) may reflect (1) specific sex-related quantitative differences in antennal receptor neuron populations, (2) qualitative differences in olfactory physiology, or (3) altered EAG receptivities resulting from adult moth experiences prior to capture in the wild

TABLE 8. COMPARISON OF MALE AND FEMALE *H. lineata* BODY SIZE AND ANTENNAL MORPHOLOGY[a]

A. Sexual dimorphism in body size (one-tailed Student's *t* test)

Category (units)	Mean measurement (± SE)			
	Males	Females	*t*	*P*
Dry body mass (g)	0.250 (± 0.019)	0.340 (± 0.021)	3.14	**0.007**
Forewing length (mm)	32.3 (± 0.9)	37.4 (± 1.0)	3.76	**0.002**

B. Comparison of antennal morphological measurements using ANCOVA

Treatment	SS	*df*	MS	*F*	*P*	Adjusted Measures	
						sex	LSM ± SE
1. Antennal diameter (mm)							
Sex	0.007	1	0.007	2.226	0.170	female	0.75 ± 0.03
Dry mass	0.000	1	0.000	0.083	0.780	male	0.82 ± 0.03
Forewing	0.000	1	0.000	0.015	0.905		
Error	0.028	9	0.003				
2. Segment number							
Sex	10.378	1	10.378	0.307	0.593	female	60.72 ± 2.79
Dry mass	13.788	1	13.788	0.408	0.539	male	58.00 ± 3.11
Forewing	1.490	1	1.490	0.044	0.808		
Error	304.256	9	33.806				
3. Antennal dry mass (g)							
Sex	0.005	1	0.005	2.896	0.123	female	0.0013 ± 0.0002
Dry mass	0.002	1	0.002	1.094	0.323	male	0.0018 ± 0.0002
Forewing	0.000	1	0.000	0.139	0.718		
Error	0.015	9	0.002				
4. Antennal length (mm)							
Sex	3.031	1	3.031	9.326	**0.014**	female	12.24 ± 0.27
Dry mass	1.475	1	1.475	4.538	0.062	male	13.72 ± 0.30
Forewing	0.383	1	0.383	1.179	0.306		
Error	2.925	9	0.325				

Note: Numbers in bold face are statistically significant at $P \leq 0.05$. Sample sizes: females, N = 7; males, N = 6.

[a] Abbreviations: ANCOVA = analysis of covariance, SS = sum of squares, *df* = degrees of freedom, MS = mean square, LSM = least squares mean, SE = standard error.

(see Vet et al., 1990; De Jong and Pham-Delegue, 1991). We have no data bearing on this question at present.

Previous observations of sex-bias in pheromone response (Schweitzer et al., 1976; Reed et al., 1987; Christensen et al., 1989), floral visitation (Kislev et al., 1972; Knudsen and Tollsten, 1993) and host plant orientation and ovi-

position (Yamamoto et al., 1969; Tichenor and Seigler, 1980) in *Manduca sexta* (L.) and other hawkmoth species suggest that complex sexual dimorphism might exist for scent compound receptors in the antennae of nectar-feeding hawkmoths. For example, while both sexes of *M. sexta* visit flowers, females respond to solanaceous host plant volatiles during oviposition behavior (Tichenor and Seigler, 1980), while males respond to female sex pheromone (Schweitzer et al., 1976; Hildebrand et al., 1992), detected by the specific *sensilla trichoidea* receptors that physically and numerically dominate their antennae (up to 69% of all receptors per antennal segment; Lee and Strausfeld, 1990). Thus, greater female EAG magnitudes in *H. lineata* might reflect either larger populations of antennal receptors tuned to plant volatiles (see Mayer et al. 1984), or greater chemosensory efficiency in females, either due to the reduced size of trichoid *sensilla* on their antennae (Lee and Strausfeld, 1990) or to differences in aerodynamic flow of scent-laden air over the differently shaped antennae (M. Willis, pers. comm.). Kislev et al. (1972) suggest that male-bias in floral visitation by *H. lineata* in Israel is due to differences in male and female responses to certain floral scent compounds. Our results, however, support Knudsen and Tollsten's (1993) contention that this bias is not explainable by innate differences in peripheral olfactory reception of floral volatiles. If anything, female *H. lineata* antennae appear to be slightly more receptive to most floral scent compounds than are those of males.

EAG Responses and Chemical Classes
