(Received February 22, 1995; accepted September 19, 1995)

Abstract—The specificity of the chemical composition of the leaf surface of four *Senecio* species was studied in order to understand the host selection of *Tyria jacobaeae*, a monophagous moth that has *Senecio jacobaea* as its principal host plant. Pyrrolizidine alkaloids characteristic for *Senecio* species were not detected in water and sulfuric acid extracts of the leaf surface of *Senecio jacobaea*. Water extracts of the leaf surfaces of *S. jacobaea*, *S. vulgaris*, *S. viscosus*, and *S. sylvaticus* contained low concentrations of free amino acids. The proportions of these amino acids were very different from those inside the leaf tissues. In a discriminant analysis, the four species could be completely separated on the basis of the relative proportions of amino acids on the leaf surface.

Key Words—Amino acids, leaf surface, chemotaxonomy, phylloplane, pyrrolizidine alkaloids, *Senecio jacobaea*, *Senecio sylvaticus*, *Senecio viscosus*, *Senecio vulgaris*, *Tyria jacobaeae*.

INTRODUCTION

Host-plant recognition by phytophagous insects cannot usually be explained by the presence or absence of a single stimulus, but rather by a combination of many stimuli (Fox and Lalonde, 1993; Renwick and Chew, 1994). The chemical

subset of these stimuli or "chemical search image" plays an important role in host plant recognition (Städler, 1986). For ovipositing insects that do not contact the inner tissues of the plant, but test only the leaf surface, recognition and selection could be determined by small quantities of many types of chemical substances that come from the inner tissues and that are present on the plant surface; for example, free amino acids, organic acids, sugars, secondary metabolites, vitamins, minerals, and growth regulators (Tukey, 1971; Fokkema, 1981; Städler, 1986; Derridj et al., 1989, 1992, 1996; Fiala et al., 1990; Städler and Roessingh, 1990; Jackson et al., 1991; Roessingh et al., 1992). These substances, especially secondary metabolites, could give species-specific information to a phytophagous insect. Many secondary metabolites, however, are large molecules that do not diffuse through membranes and cell walls easily, and thus are not likely to be present on the leaf surface. Primary metabolites, on the contrary, are probably present on the leaf surface of all plants (Tukey, 1971).

Recent developments in chemotaxonomy show that plants can be discriminated on the basis of their internal proportions of primary substances. Laatsch et al. (1993) could separate families of fungi on the basis of their proportions of protein amino acids, and Yeoh et al. (1984) described species-specific amino acid proportions in leguminous plants. It has already been shown that proportions of free amino acids in the phylloplane of maize and sunflower are very stable and specific (Derridj et al., 1989). It is tempting to suggest, therefore, that primary metabolites play a role in interspecific host-plant recognition of phytophagous insects. In this paper we examine this subject by studying the uniqueness of proportions of free amino acids on the leaf surface of *Senecio jacobaea* L., the primary host plant of the monophagous moth *Tyria jacobaeae* L. (Lepidoptera, Arctiidae), by comparing them to the proportions on the leaf surface of *S. vulgaris*, a less preferred host, and *S. viscosus* and *S. sylvaticus*, two nonhosts.

The *Senecio–Tyria* system was chosen for three reasons. Firstly, the microbehavior of females clearly shows that chemical factors playing a role in oviposition must be present on the leaf surface. The females continuously touch the leaf surface with their antennae and most of them (but not all) drum on the leaf with their back tarsae. These tarsae do not contain spines that could penetrate through the cuticle, but contain a large number of contact chemoreceptors. Secondly, we think that the characteristic pyrrolizidine alkaloids (PAs) of *Senecio* species do not play a direct role in oviposition. Neither oviposition nor larval performance seems to be influenced by the concentrations of PAs in the leaf tissues of *S. jacobaea* (van der Meijden et al., 1989; Soldaat and Vrieling, 1992; Vrieling et al., 1991). However, the few food plants known for *Tyria* all contain PAs, indicating that PAs or PA-related factors are present on the leaf surface, where the only contact between female and plant takes place. Such related factors could be the amino acids arginine or ornithine, which are pre-

cursors of PAs. The third reason to study the *Senecio–Tyria* system is that oviposition preference is positively related to the concentration of organic nitrogen in the plant tissues (van der Meijden et al., 1989). Amino acids on the leaf surface are the most likely cue to assess organic nitrogen concentrations inside the plant.

To examine the hypothesis that primary metabolites may be concerned in the host specificity of *Tyria jacobaeae*, we first had to study the presence of pyrrolizidine alkaloids on the leaf surface and to investigate whether it is possible to discriminate between different *Senecio* species on the basis of the amino acids on their leaf surfaces.

METHODS AND MATERIALS

Seeds of *S. jacobaea* came from plants in the sand dunes of Meijendel (near the Hague, the Netherlands), seeds of *S. vulgaris* were collected in an experimental field of the INRA at Versailles and seeds of *S. sylvaticus* and *S. viscosus* were supplied by the National School of Horticultural Science (ENSH) at Versailles. The seedlings of each species were placed in 11 pots, filled with a 1 : 1 mixture of perlite and compost and cultivated in a greenhouse. The pots were saturated with nutrient solution for 5 min three times a day. The conditions in the greenhouse were: ambient photoperiod and light, relative humidity 70% ± 10%, maximum daytime temperature 25°C and minimum nightime temperature 15°C. Leaf samples for analysis were cut in the middle of the day in order to minimize variation between replicates due to circadian rhythms in the plants. Leaf area in all experiments was determined using a photoplanimeter.

Amino Acids on Leaf Surface

Experiment 1. In this experiment the four plant species were grown and analyzed successively through the year. *S. jacobaea* was analyzed in November 1992. Four replicates were performed; each replicate consisted of three plants of which two leaves were washed. *S. vulgaris* was analyzed in May 1993; three replicates were performed, each consisting of three plants of which three leaves were washed. *S. viscosus* was analyzed in March 1993; three replicates were performed, each replicate consisting of three plants of which two leaves were washed. *S. sylvaticus* was analyzed in May 1993; again, three replicates were performed, each consisting of one plant of which two leaves were washed, because of the limited number of suitable plants. The number of genotypes per replicate was therefore 3, 3, 3, and 1 for the four species, respectively. As *S. jacobaea* is a biennial plant species, the cultivation of flowering plants takes several months. Therefore, we used middle-aged leaves of rosette plants, while for the other three annual species, leaves halfway up the flowering stem were

used. All plants were 2–3 months old when sampled. All the phenological stages mentioned can be found in the field when oviposition of *T. jacobaeae* takes place.

Experiment 2. In this experiment the four species were analyzed simultaneously. The growing conditions and the growth stages of the plants at the time of sampling were the same as the first experiment. The experiment was performed in November 1993 on three successive days. On each day we sampled and sprayed four leaves of one plant for three species and eight leaves for *S. vulgaris*, which has smaller leaves than the other three species. In this experiment each replicate consisted of one genotype.

Leaf Washing

Amino Acids. Leaves were cut from the plants and weighed. The petioles were packed in aluminum foil to prevent contamination of the leaf surface by the leaking of substances from the inner tissues. Then the leaves were sprayed with 20–25 ml of ultrapure water during 25–30 sec, following the technique described by Fiala et al. (1990). The upper surface and the lower surface of the leaves were sprayed separately. After filtration through a 0.45-μm Millipore filter and evaporation, the leaf washings were stored at $-80°C$. In the second experiment the washings of both sides of the leaves were collected together in order to enlarge the quantities of substances in each sample.

Alkaloids on Leaf Surface of Senecio jacobaea. Leaves of 3-month-old rosette plants of *S. jacobaea* were dipped vertically for 30 sec in a narrow plastic container filled with 600 ml solvent. The youngest and oldest leaves of a plant were not used. During dipping the leaves were held by the cut petioles, which prevented contamination of the solvent with substances from the inner leaf tissues. The leaves were lightly agitated up and down. The following solvents were used: (1) water to which 10% ethanol was added to increase contact between the water and the leaf surface, (2) 0.005 M H_2SO_4; (3) 0.05 M H_2SO_4; and (4) 0.5 M H_2SO_4. Sulfuric acid was added because pyrrolizidine alkaloids solve easily in acid solutions. A total of 60 leaves was dipped in each solution (six plants, 10 leaves per plant). This experiment was repeated on three successive days, which brought the total number of analyzed leaves to: 3 (replicates) $\times$ 4 (solutions) $\times$ 6 (plants) $\times$ 10 (leaves) = 720 leaves. The solutions were filtered through a 0.45-μm Millipore filter, and stored at $-30°C$. Methanol was added to prevent the solutions from freezing.

Amino Acids Inside Leaf Tissues

For *S. jacobaea* only, we determined the concentrations of free amino acids inside the leaves in the first experiment. After spraying, the leaves were frozen in liquid nitrogen, freeze-dried, ground, and stored dry until chemical analysis.

Chemical Analyses

Amino Acids. Free amino acids were determined using a Biotronik LC 5001 analyzer (physiological program run with lithium buffers, detection at 570 and 440 nm after postcolumn derivatization with Ninhydrin) and the PE Nelson 2100 software.

Pyrrolizidine Alkaloids. The solutions were macerated for 2 hr with excess zinc powder to reduce N-oxides and filtered over a Büchner funnel supplied with a paper filter and made alkaline (pH > 10) with 0.5 ml 25% ammonium hydroxide. Then the solutions were passed through an Extrelut column (Merck) and after 20 min the PAs were recovered with 2× 15 ml dichloromethane (van Dam et al., 1993). After evaporation of the dichloromethane, the residue was redissolved in 5.0 ml methanol. The presence of PAs was determined spectrophotometrically in duplicate by a color reaction (Mattocks, 1967). Monocrotaline (Sigma, 99% purity) was used as a reference.

RESULTS

Amino Acids on Leaf Surface of Four Senecio *Species*

All protein amino acids (less cysteine) and also ornithine and GABA were present on the leaf surface of all four plant species (Table 1) in very low, but for insects detectable concentrations (Table 2). The concentrations of cysteine were too low to be accurately detected. Unknown peaks of Ninhydrin-positive compounds were found in the chromatograms of all species, but none of these compounds was specific for a species. The total concentrations of amino acids varied significantly between the four species and between the two experiments (Table 2). The significant interaction between species and experiment is caused by *S. sylvaticus*, which had relatively low concentrations in the first and high concentrations in the second experiment as compared to the other three species. For the rest, the same order in the total concentration of amino acids was found in both experiments, with *S. vulgaris* having by far the highest concentrations (Table 2). No significant differences were found in a pairwise *t* test between the concentrations on the upper and lower sides of the leaves of *S. jacobaea* in the first experiment (upper side: 2254 ± 570 nmol/m^2 (SE); lower side: 2183 ± 410 nmol/m^2; $N = 4$ pairs).

The proportions of free amino acids found on the leaf surface were roughly similar both between species and between experiments within a species (Table 1), except for some amino acids (especially glutamine, proline, ornithine, and arginine). For the proportions of each amino acid, we performed a two-way ANOVA, with experiment and species as factors. The significance level of 5% was corrected for the number of analyses performed (21), using the sequential

[a]Results are given in μmol/m^2 for all replicates, and results of a two-way analysis of variance on the data.

Bonferroni test (Rice, 1989). The proportions of proline, ornithine, and tryptophan were significantly different between the experiments. Only the proportions of proline, glycine, and GABA differed significantly between the four species, but the interaction between species and experiments was also significant. The proportions of all other amino acids on the leaf surface did not vary significantly between the experiments and between the four species. Consequently, it was impossible to discriminate between the four species on the basis of the proportions of a single amino acid. We therefore compared the four species with a discriminant function analysis. This analysis was performed with all data of the two experiments in order to increase the number of observations. All data were arcsine-root transformed. Methionine and tryptophan were left out of the analysis because their concentrations were too low. As the proportions of amino acids are not independent, we also left the most abundant amino acid (serine) out of the analysis, which diminishes this statistical problem. The discrimination between the species was perfect: either using the concentrations or the proportions of amino acids, we could ascribe 100% of the observations to the correct species (Figure 1). The amino acids that clearly discriminated between the four species were histidine on the first discriminant function; aspartine, threonine, glutamine, and glutamic acid on the second function, and GABA,

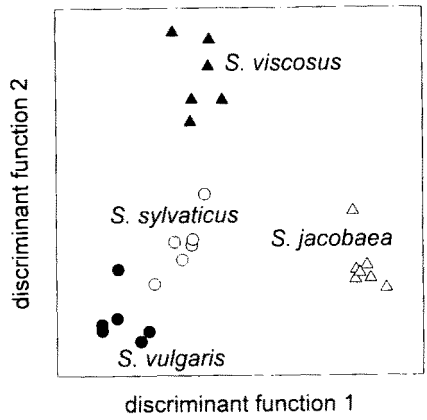

FIG. 1. Discrimination of four *Senecio* species on the basis of their proportions of amino acids on the leaf surface. Plot of all observations on the first two discriminant functions. The first and second discriminant functions contain 77.2 and 15.9 of the variation, respectively.

proline, alanine, phenylalanine, glycine, and tyrosine on the third function. In a discriminant function analysis using just these 11 amino acids, all observations were also classified correctly.

Amino Acids in Leaf Tissues of S. jacobaea

The mean total concentration of amino acids inside the leaf tissues of *S. jacobaea* in the four replicates of experiment 1 was 2.61 ± 0.11 mmol/m^2. The proportions of individual amino acids were very stable, as indicated by the small standard errors (Table 1). For some amino acids these proportions were very different from their proportions on the leaf surface. Inside the leaves, the dominant acids were serine, glutamic acid, aspartic acid, glutamine, and alanine, but the latter three were much less abundant on the leaf surface. Other amino acids, such as glycine, showed very low proportions inside the leaves but high proportions on the leaf surface. The correlation between the proportions of amino acids inside the leaf tissues and their proportions on the leaf surface, averaged over the four replicates (between the first two columns in Table 2), was consequently low: $r = 0.542$ ($N = 21$, $P = 0.03$).

Alkaloids on Leaf Surface of S. jacobaea

No alkaloids could be detected in any washing of the leaf surface of *S. jacobaea*. Taking into account the sensitivity of the alkaloid analysis, this means that if alkaloids were present on the leaf surface, their concentrations

were below 60 nmol/m^2. A second analysis on a large quantity of two of the samples showed that in these samples the concentrations of alkaloids, if present, must have been below 10.5 and 7.2 nmol/m^2, respectively. This, may still be above the detection limit of insects, however.

DISCUSSION

Our results show that the composition of free amino acids on the leaf surface of the four *Senecio* species is species-specific. It is generally believed that many phytophagous insects can perceive amino acids (Blaney and Simmonds, 1990; Schoonhoven and Blom, 1988). It is reasonable to suggest that such common substances that are so closely related to the nutritional value of a plant can be perceived by females seeking food plants for their larvae. This is supported by the results of another study, in which we found a behavioral response of ovipositing *Ostrinia nubilalis* to primary metabolites on the leaf surface of leek and maize (Derridj et al., 1996). The next important step in our investigation will be to determine responses of *Tyria jacobaeae* to amino acids and leaf surface washings, both sensorially and behaviorally.

The remarkable differences between the proportions of amino acids inside the leaf tissues and those on the leaf surface may reflect the selective passage of amino acids through the cuticle, caused by the physical and chemical properties of both the amino acids and the cuticle. As the composition and, thus, the physical and chemical properties of the cuticle and its intra- and epicuticular waxes varies between plant species (Jeffree, 1986; Espelie et al., 1991), it may be expected that the concentration of chemicals on the leaf surface also varies from species to species, as we show here. It must be stated, however, that passage through the cuticle can only be studied *in vivo* by comparing the proportions on the leaf surface to those in the apoplast. Passage through this free space (the cell wall volume between adjacent cells) is obligatory for amino acids to reach the leaf surface. The amino acid composition of the leaf apoplast is probably quite different from that which we determined for the whole leaf.

Many factors may change the concentrations of free amino acids on the leaf surface where they are directly exposed to the environment. Rain, dew, and fog may leach the amino acids from the leaf (Tukey, 1971), but also epiphytic microorganisms may modify the biochemical composition of the leaf surface (Schreiber and Schönherr, 1992), in particular with respect to amino acids (Martin et al., 1993). We know nothing at present about the mechanisms by which the proportions of free amino acids on the leaf surface are stabilized.

As the passage through the cuticle is probably passive, it is unlikely that large molecules like pyrrolizidine alkaloids (molecular weight 300–400) can leave the inner tissues, which explains why we did not find them on the leaf

surface of *S. jacobaea*. Although in some plant species alkaloids were found on the leaf surface (Tukey, 1971), they are probably usually stored in the vacuoles, as found by Ehmke et al. (1988) in *S. vulgaris*. In that case, the way for *Tyria* to detect alkaloid-containing plants could be by detecting the presence of smaller precursors, such as, amino acids or polyamines on the leaf surface. Such indirect assessment of secondary metabolites may be common among phytophagous insects and complicates investigation of the substances responsible for host recognition.

We do have preliminary information that the proportions of organic acids on the leaf surface of the *Senecio* species studied here are also more or less species-specific. The same may be true for numerous other substances that are present on the leaf surface after leaking through the cuticle from the inner tissues. Together, all these substances may constitute a distinctive chemical image of the plant, enabling phytophagous insects to select between different plant species. Secondary chemicals are just a part of this mixture, which may explain why it is so difficult to find a single secondary chemical that explains host specificity of an insect (Jermy, 1993; Renwick and Chew, 1994). To conclude: "Errors of judgement . . . are only avoidable by a careful examination and comparison of many types of characters" (Hegnauer, 1986), and the problem of recognizing a plant species may be the same for phytophagous insects and chemotaxonomists.

Acknowledgments—Special thanks to Dr. R. Wesselingh and Dr. P. Robert for supplying seeds, M. Provot for the amino acids analyses, and H. de Vos for alkaloid analyses. We thank Dr. R. Dean, Prof. Dr. E. van der Meijden, Dr. S.J. Milton, and Dr. K. Vrieling for valuable comments on the manuscript.

(Received March 13, 1995; accepted August 20, 1995)

Abstract—We compared the behavior of two subspecies of *Podarcis hispanica* lizards in cages that had been chemically marked by a saurophagous snake, the viper *Vipera latastei*. One of the subspecies (*P.h. atrata*) has experienced a relaxation from predation pressure by this viper, as snakes were eradicated from the island it inhabits over 100 years ago. Nevertheless, individuals from *P.h. atrata* responded to the snake's chemicals similarly to individuals from a population of *P.h. hispanica*, currently sympatric with *V. latastei*. Lizards exhibited more stress-indicating behaviors (foot shakes, tail vibrations, sudden starts), became less mobile, and tongue-flicked more while moving in a snake-inhabited terrarium than when in a clean, unfamiliar terrarium.

Key Words—Antipredator behavior, chemoreception, lizards, Lacertidae, Reptilia, predation, relaxation, snakes.

INTRODUCTION

Predation is an important selective force that can shape the morphological, behavioral, and life-history characteristics of prey animals. Studies on a variety of species [e.g., spiders (Riechert and Hedrick, 1990), fish (Magurran and Seghers, 1990; Gelowitz et al., 1993), salamanders (Dowdy and Brodie, 1989; Ducey and Brodie, 1991), snakes (Sweet, 1985), and mammals (Owings and Coss, 1977)] have demonstrated that geographical variation in predation pressure is reflected in parallel variation in antipredator behavior of prey animals; prey animals from predator-free or -poor habitats fail to recognize predators in staged

encounters (Magurran, 1986; Magurran and Seghers, 1990; Gelowitz et al., 1993; Mathis and Smith, 1992) or show inappropriate responses to predator stimuli (Breden et al., 1987; Dowdey and Brodie, 1989; Herzog and Schwartz, 1990; Riechert and Hedrick, 1990). These intraspecific differences in antipredator behavior may arise from differential experience within the lifetime of an individual (Magurran, 1989; Olla and Davis, 1989; Jaervi and Uglem, 1993), from natural selection acting upon genetic variation (Huntingford, 1982; Breden et al., 1987; Riechert and Hedrick, 1990), or from a combination of both (Giles and Huntingford, 1984; Magurran, 1990).

In this paper, we compare the ability of two subspecies of the lacertid lizard *Podarcis hispanica* to detect chemicals from the saurophagous snake *Vipera latastei*. Predator recognition is a necessary first step of adequate antipredator behavior. The vomeronasal system of reptiles offers good opportunity to study the ability to recognize predatory cues, without the need to actually confront the animals with the predator itself. Reptiles have been shown to react to chemicals left behind by predators with an increased rate of tongue extrusions (Chiszar et al., 1978; Thoen et al., 1986; Van Damme et al., 1990, 1995). The intensified movements of the forked tongue probably facilitate delivery of chemical substances to the ducts leading to Jacobson's organ (Parsons, 1970). Tongue-flick rate can therefore be used as a quantitative bioassay of interest in a variety of stimuli, including food and predator chemical cues.

One of the lizard subspecies under study, *P.h. atrata*, is endemic to the Mediterranean archipelago of the Columbretes Islands (Castellón, Spain). A large population of *Vipera latastei* inhabited the main island of this archipelago but was completely eradicated when a lighthouse was constructed by the end of the 19th century. In spite of several herpetological expeditions, not a single live snake was observed after 1886 (Castilla et al., 1987). The other subspecies, *P.h. hispanica*, lives on the nearby mainland of Spain (ca. 50 km away) and is still sympatric with *V. latastei*. Our objective was to test whether the recent relaxation of the predation pressure in *P.h. atrata* has resulted in the loss of the ability to recognize viper chemicals. If *P.h. atrata* still reacts to the snake chemicals, this strongly suggests that the chemosensory recognition of predator cues is genetically based, since none of the individuals has ever been in contact with snake predators. Alternatively, lizards may respond to chemicals that the viper has in common with other predators now present on the island. If *P.h. atrata* fails to recognise the stimuli, recognition is either based on experience and/or has been lost in the island population.

METHODS AND MATERIALS

Typically, *Podarcis hispanica* is a small [snout-vent length 40–60 mm], slender, flattened wall lizard living on rocks, stony slopes, walls, and other

habitats dominated by vertical elements. Like most other lacertids, *P. hispanica* has an active-searching foraging mode, a predominantly arthropod-based diet, and a diurnal activity pattern. It should be noted, however, that the species exhibits substantial variation in body dimensions and habitat preferences throughout its distributional range in Iberia and northwest Africa (Salvador, 1986). The population of *P.h. hispanica* sampled here has the typical characteristics described above. These lizards lived on garden walls and in a small park and were almost exclusively seen on stony substrates elevated more than 0.5 m above ground. Adult SVL ranged between 40 and 55 mm ($\bar{X}$ = 46.9 mm; SD = 3.7 mm; N = 27). The subspecies *P. hispanica atrata*, from Columbretes Islands, is aberrant in its large adult body size (range 52–71 mm; $\bar{X}$ = 60.5 mm; SD = 4.2 mm; N = 44). Although lizards from this population climb regularly, they are most frequently seen on flat, horizontal surfaces, often at ground level.

Vipera latastei is a rather small (adult SVL 50–60 cm), stocky snake from the Iberian Peninsula and northwest Africa. It prefers sunny, stony, and slightly vegetated slopes and open deciduous forest. The snake feeds on rodents, lizards, and bird nestlings, killing its prey by injecting neurotoxic and hemorraghic venom (Gruber, 1989).

We caught 10 adult *Podarcis hispanica atrata* (four males and six females) on the bigger island of the Columbretes archipelago (Columbrete Grande) and 10 *P.h. hispanica* (six males and four females) from the nearby mainland (Castellón, Spain) and transported them to the laboratory in Antwerp, Belgium. Lizards were housed in five large terraria and daily were given ample amounts of food (crickets and mealworms) and water. Two 150-W spotlights suspended above both extremes of each terrarium provided light and heat for 10 hr/day. Individuals from both populations were kept apart. A male viper (*Vipera latastei*, SVL 45 cm) was obtained from the province of Burgos (Spain) and was kept in a cage located in a separate room. We took care that none of the lizards was in visual or chemical contact with this viper outside experimentation.

We followed the experimental procedure outlined in Thoen et al. (1986) and Van Damme et al. (1990) to assess the lizards' responses to snake chemical cues. We introduced each individual lizard successively into two small terraria. These terraria were identical in dimensions (25 × 25 cm), substrate (sand, mosses, and stones), illumination, and heating (provided by a 150-W spotlight suspended 22 cm above the substrate). One of the cages (hereafter referred to as the viper situation) had previously been inhabited by the viper. After the snake had resided in the cage for at least 12 hr, we removed it and replaced it by a lizard. The other test terrarium was free from any viper chemicals; we used it to monitor lizard behavior in an unfamiliar but predator-free situation. The order in which a lizard was tested in the control and the viper situation was decided by chance. Since *P. hispanica* is known to react to chemicals left behind

on the substrate by conspecifics (Gómez et al., 1993), we changed the sand and vegetation and rinsed the stones from the testboxes after each experiment.

We observed the lizards' behavior from behind a one-way mirror. Observations started about 10 sec after transfer of the lizard to the test box and lasted 15 min. We distinguished the following behavioral acts and locomotor patterns. (1) Tongue-flick: the lizard extrudes and rapidly retracts its tongue, regardless of whether the tongue touches the substrate or is "waved" in the air. (2) Walk: continuous, relatively fast forward movement. This is the locomotor type typically observed in unrestrained lizards. (3) Slow motion: very slow movement accompanied by jerky or waving movements of the forelimbs. (4) Stand up: the lizard stands in an upright position against the glass wall of the terrarium and performs scratching movements with the forelegs. (5) No move: the lizard stands still, its ventrum resting on the substrate; this pattern can be accompanied by movements of head, tail or forelimbs. (6) Bask: the lizard rests under the light bulb with the ribs spread laterally; one or more feet are often tilted upwards. (7) Start: sudden jump, most often followed by a quick, short run. (8) Foot shake: the raised forelimbs are alternately and rapidly moved up and down. (9) Tail vibration: the entire tail, or its posterior portion, is moved rapidly from side to side.

We used a BASIC program run on a personal computer to record the lizards' behavior. The program assigns a key to each of the behavioral acts distinguished and checks every second which key on the computer keyboard is being pressed by the observer. At the end of an observation period, the program lists for every second the behavior performed by the lizard, the number of tongue flicks, starts, foot shakes, and tail vibrations.

We used 2×2 factorial repeated measures analysis of variance on the total duration or frequency of behavioral acts to test for differences between treatments (viper/control) and populations. Lizards clearly extruded their tongues more frequently while moving than when basking or resting. Therefore, if we want to use tongue-flick frequency as a bioassay for predator recognition, we have to correct for the amount of time the lizard spent moving. We did this by introducing the total duration of walk and slow motion as a covariate into the analysis of variance.

Lizard activity typically consists of alternating mobile (foraging, exploration) bouts and stationary periods (basking, resting). We suspected that the length and frequency of these bouts might differ between treatments and/or populations. There is a practical difficulty in delimiting a locomotion bout, because lizards in general do not move in a continuous way, but now and then pause for a couple of seconds before resuming their itinerary. We used an algorithm described by Sibly et al. (1990) to distinguish between these short stops within a locomotion bout and "real" stationary periods. In this method, two regression models (a one-process model and a two-process model) are fitted

to a $\log_e$ frequency distribution of gap lengths. A gap is every interval between two successive movements. The one-process model assumes that all events are generated by a single Poisson process, and thus that behavior cannot be split into bouts. The two-process model considers events to be generated by one of two random Poisson processes, a fast process operating within bouts and a slow process generating new bouts. In our case, the two-process model clearly fitted better to the data than the one-process model. We derived a bout-criterion interval (Slater and Lester, 1982) of 28 sec, which means that gaps between real locomotory bouts must at least be this long. If the interval is shorter than 28 sec, the gap is considered as a short pause within a movement. Using this criterion, we calculated for each observational period the average locomotory bout length and frequency, the length of the interval between bouts, and the number and frequency of pauses within locomotion bouts. These new behavioral parameters were compared between treatments and populations using repeated-measures analysis of variance. Since the number of pauses is clearly dependent on the time spent moving, we corrected for this by introducing total bout duration (mean bout length × frequency) as a covariate into the analysis. All statistical analyses were performed with the SPSS/PC+ statistical package (Norusis, 1990).

RESULTS AND DISCUSSION

Lizards of both populations reacted to the former presence of *Vipera latastei* in the test terrarium by an increased number of starts, foot shakes, and tail vibrations (Table 1). These behaviors are typically displayed by lizards in conflict situations, during encounters with conspecifics (Verbeek, 1972), potential prey, or predators (Nuyten and Van Wezel, 1984; Thoen et al., 1986; Van Damme et al., 1990, 1995). Since the presence or absence of predator chemicals constitutes the only difference between our two test situations, we assume that the increase in these stress-indicative behaviors in the viper situation represents a shift in motivational status towards enhanced awareness and possibly fear.

We found significant treatment × population interaction effects for the number of foot shakes and tail vibrations. This suggests that although lizards from both populations respond to viper chemicals, the predator-sympatric *P. hispanica hispanica* reacted more vigorously than the predator-allopatric *P. hispanica atrata*. This differentiation was, however, not evident in the other stress-indicative behavioral components (the number of tongue-flicks and starts).

In contrast to *Lacerta vivipara* (Thoen et al., 1986; Van Damme et al., 1990, 1995), *Podarcis hispanica* did not tongue-flick more in the viper situation than in the control situation. This finding is deceptive, however, because tongue-flick frequency is clearly higher during locomotion, and lizards moved significantly less in the viper situation than in the control situation. After correction

TABLE 1. BEHAVIOR OF LIZARDS FROM POPULATIONS ALLOPATRIC (COLUMBRETES) AND SYMPATRIC (CASTELLÓN) WITH *Vipera latastei*[a]

[a]Lizards were observed in a terrarium that had been previously inhabited by a snake (viper) and in an unfamiliar, but clean, terrarium (control). Presented are the number or duration (seconds) of behavioral acts observed during 15-min observation periods. Values are means (±SD, $N = 10$ for both populations). The last three columns give the P values for the effects of population, treatment, and the interaction between population and treatment, as derived from repeated-measures analysis of variance.

for the amount of time spent moving (walk + slow motion), lizards of both populations extruded their tongues more often in the viper situation than in the control terrarium (Figure 1, $F = 8.38$, $df = 1$ and 17, $P = 0.01$). This finding suggests that lizards perceive chemical clues indicating the presence of the viper and that these stimuli invoke an enhanced utilization of the chemoreceptive apparatus.

We found no population or treatment × population interaction effects for the corrected tongue-flick frequency (both $P > 0.2$). We conclude that the ability to detect viper chemicals must be genetically based in *P.h. atrata*, since none of the lizards from this subspecies had any experience with predatory snakes before. Furthermore, 100 years of relaxed predation pressure have not resulted in the loss of the ability for chemoreceptive recognition. Alternatively, lizards may respond to chemicals that the viper has in common with other predators present in its habitat. Little is known regarding the degree of specificity of responses by the lizard to such chemicals. In the case of *P.h. atrata*, however, this alternative explanation seems unlikely, since the Columbretes Islands are

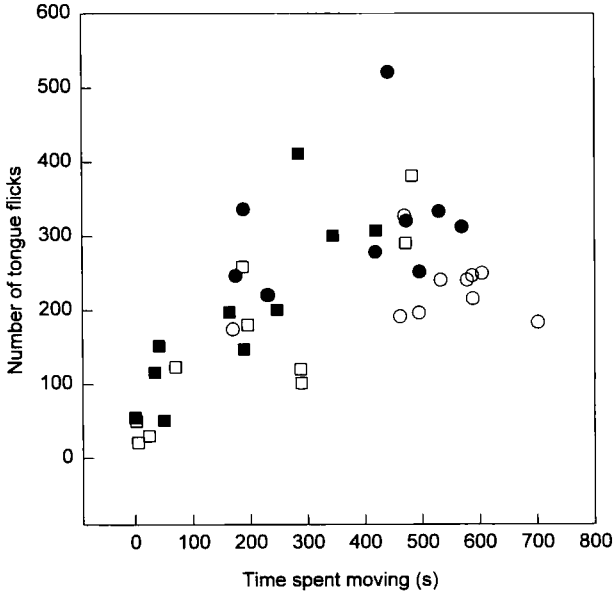

FIG. 1. Number of tongue flicks performed by the lizard *Podarcis hispanica* as a function of the time spent moving. Lizards were observed for 15 min in terraria previously inhabited by a viper (filled symbols) and in unfamiliar but clean terraria (open symbols). Circles represent individual lizards from a predator-allopatric population (*P.h. atrata*), and squares refer to lizards from a predator-sympatric population (*P.h. hispanica*).

currently nearly devoid of potential predators. There are no snakes or mammals and no typical saurophagous birds such as corvids or shrikes (Castilla et al., 1987), leaving only two species of gulls (*Larus cachinnans michahellis* and *Larus audouinnii*) as potential predators of lizards. These gulls primarily predate or scavenge on fish and marine invertebrates (Cramp, 1983), but it is not impossible that they occasionally attack a lizard.

Locomotion patterns differed between populations and treatments. In the control situation, *P.h. atrata* showed a much higher tendency to explore the cage than *P.h. hispanica* and thus obtained higher mobility scores (Table 1). This difference in mobility between populations was largely due to the longer mean duration of locomotion bouts performed by the island subspecies (Table 1). Although we cannot present quantitative data to support this, the observed differences in locomotory activity seem to persist outside our experimental situations. Both in the field and in their home cages in the laboratory, individuals of *P.h. atrata* can be seen moving about far more often than their conspecifics from the mainland. Although it is tempting to ascribe this difference to the higher predation risk on the mainland, many other factors involved in the cost-benefit balance of locomotory activity (e.g., body dimensions, prey density, social context, etc.) may also be involved.

Locomotion in *P. hispanica* is not smooth and continuous, but consists of a pattern of bursts of movement alternating with pauses. Although seemingly widespread among lizard species (see Avery et al., 1987, and references therein), the exact ecological significance and/or the physiological basis of this jerky motion pattern remains obscure. In our experiments, the number of pauses per unit time traveled and the mean duration of pauses did not differ between species or treatments. Therefore, we have no reasons to suppose that the frequent stops are a part of the antipredator behavior of *P. hispanica*.

We conclude that the lizard *P. hispanica* is capable of detecting the former presence of a predatory snake, the viper *V. latastei*, presumably through chemosensory perception of chemicals left behind on the substrate. The ability is still present in individuals from a population that has experienced relaxation from predation by snakes during the past 100 years. In *P.h. atrata*, the response to the viper's former presence may constitute another example of a "ghost of predation past" (Peckarsky and Penton, 1988; cf. Connell, 1980) or may reflect responses to chemicals common to a range of predatory species. Assuming that the ability to detect predator chemicals is genetically based, it may not be surprising that it has survived in the viper-free population. The rate at which vestigial characters disappear from a population is likely to be a negative function of the costs of expressing the character, and we cannot think of any substantial costs involved in this case. It would be interesting to study predator recognition abilities in populations that are liberated from specific predators for longer periods of time.

(Received March 27, 1995; accepted August 22, 1995)

Abstract—The intertidal pulmonate limpet *Trimusculus reticulatus*, which is found in caves or crevices along the California coast, was previously reported to contain two novel diterpenoids, 6β-isovaleroxylabda-8,13-dien-7α,15-diol (**1**) and 2α,7α-diacetoxy-6β-isovaleroxylabda-8,13-dien-15-ol (**2**). Dissection of the animals prior to extraction revealed that the diterpenoids were concentrated in the mantle, foot, and mucus, but not in the viscera. The presence of *T. reticulatus* or its mucus was toxic to veliger larvae of the sabellariid reef-building tube worm *Phragmatopoma californica*. The major diterpenoid **1** was responsible for the observed larvicidal activity. Protection against overgrowth by settling invertebrate larvae is important for the survival of this sessile filter-feeding pulmonate. A related pulmonate, *T. conica*, which was found in similar intertidal habitats in New Zealand, contained 6β-acetoxy-7α-isovaleroxylabda-8,13-dien-15-oic acid (**3**) and 1β,7β,12β,18-tetraacetoxycholest-5-en-3β-ol (**4**). The diterpene **3** was also localized in the foot, mantle, and mucus of *T. conica* but was not larvicidal to *P. californica*.

Key Words—*Trimusculus reticulatus*, *Trimusculus conica*, pulmonate, limpet, sessile, filter feeding, mucus, secondary metabolite, diterpene, steroid, *Phragmatopoma californica*, larvicidal.

INTRODUCTION

The intertidal pulmonate limpets of the family Trimusculidae are unusual in both their habitat and behavior. The air-breathing trimusculids, which lack a gill and

instead have a modified mantle cavity that serves as a lung, live on exposed rocky coastlines and are found only in narrow crevices and deep caves where they hang inverted and tightly clustered in large colonies (Walsby et al., 1973). The adults are essentially sessile, and fertilization is internal in these hermaphrodites. The eggs are brooded under the shell on each side of the foot and, after direct development, the young emerge from the eggs as crawling slugs (Haven, 1973). Unlike most intertidal limpets, which feed by grazing on thinly encrusting microalgae, trimusculids filter feed by producing a mucous net that traps suspended phytoplankton from the surging tide. The limpet uses its oral lobes to inspect the mucous net frequently for the presence of food and then the mucus and trapped particles are ingested (Walsby et al., 1973). An abundance of subepithelial glands on the mantle and sides of the foot produce the copious milky white mucus, which has been suggested to be repugnatorial (Yonge, 1958). Mucus collected from *T. reticulatus*, which occurs on the California coast, was shown to repel the predatory seastars *Pisaster ochraceus* and *P. giganteus* (Rice, 1985).

Due to their unique lifestyle, the trimusculids live with unusual constraints. They are essentially sessile and do not exhibit the common flight response that most limpets display when in the presence of a seastar. Additionally, their method of collecting food by filter feeding necessitates that they be undisturbed by other encrusting invertebrates that could occupy this space in the intertidal zone. Our earlier report of relatively large quantities of diol **1** and diacetate **2** (Figure 1) isolated from *Trimusculus reticulatus* and its mucus (Manker and Faulkner, 1987) raised questions concerning the possible role the chemicals may play in fulfilling the unusual ecological needs for these pulmonate limpets.

Many marine molluscs have been shown to contain secondary metabolites, and there have been numerous studies investigating the role of these compounds. The dorid nudibranchs are a shell-less order of gastropods that have been shown, in some cases, to sequester secondary metabolites from their specialized sponge diet. These animals have few predators despite their lack of a shell or other means of physical defense. In addition, many are brightly colored, and this has often been thought to have an aposematic function. Several studies have been carried out to determine the ecological role of storage of sponge metabolites in nudibranchs (Thompson et al., 1982; Hagadone et al., 1979; Castiello et al., 1980; reviewed by Faulkner, 1992), and these cases support the hypothesis that the compounds are used as a chemical defense to deter predation. A correlation between the lack of a shell and alternative defense mechanisms has been suggested by Faulkner and Ghiselin (1983). In addition, a number of molluscs bearing shells have also been shown to contain unusual secondary metabolites. The shell-bearing archeaogastropod limpet *Collisella limatula* was found to contain a defensive triterpene, limatulone **5** (Figure 1) (Albizati et al., 1985). Pawlik et al. (1986) reported that intertidal fish and crabs rejected pieces of the foot of

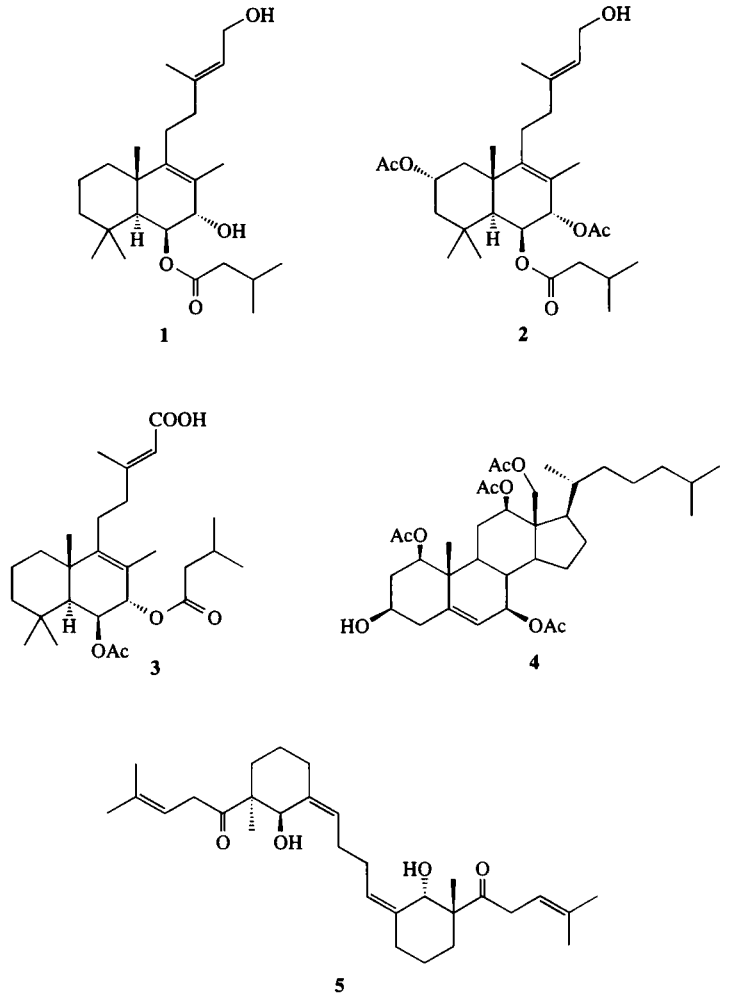

FIG. 1. Structures of compounds **1** and **2** found in *Trimusculus reticulatus*, compounds **3** and **4** found in *T. conica*, and compound **5** from *Collisella limatula*.

C. limatula but consumed foot tissue of other gastropods that occur in the same area. Food pellets treated with natural concentrations of limatulone caused regurgitation in the intertidal fish *Gibbonsia elegans*, a known limpet predator. Pulmonate limpets of the family Siphonaridae, which are closely related to the trimusculids, contain a plethora of secondary metabolites. However, a role for these compounds has not been established (Manker, 1986).

Considering the unusual habitat (Haddock, 1989) and life-style of the trimusculids, competition for space may be a high priority. One of the most important resources in the intertidal zone is space, for which competition is often intense. Many intertidal invertebrates have planktonic larvae that settle on a suitable substrate before metamorphosis into the juvenile form. A plausible strategy for these sessile, intertidal limpets might be to produce chemicals that are toxic to settling larvae in order to keep the area around them free of other invertebrates. This antifouling function has been invoked for sponges that often contain antimicrobial metabolites and that need to keep their surfaces clean to be efficient filter feeders (Thompson et al., 1985). However, fouling would be just as important in the intertidal community. To date, no relevant research has been done on the pulmonates in this area.

In this paper, we report the results of investigations into the distribution and role of secondary metabolites from trimusculid limpets.

METHODS AND MATERIALS

General. ^{1}H NMR spectra were recorded on 360 MHz Nicolet or Bruker WP-200 SY spectrometers. ^{13}C NMR spectra were run at 50 MHz on the Bruker WP-200 SY spectrometer. High-resolution mass spectra were obtained from the Regional Mass Spectrometry Facility at U.C. Riverside. High-performance liquid chromatography separations were carried out using a Waters model 6000A solvent delivery system monitored by a Waters model 440 absorbance detector and a Waters model R401 refractive index detector. All solvents used were either HPLC grade or distilled in glass prior to use.

Collection and Extraction of Trimusculus reticulatus. The animals (N = 115) were collected intertidally from crevices between boulders on San Nicholas Island, California. Mucus produced by the specimens was separated and lyophilized, then extracted with ether. Whole animals were lyophilized and extracted sequentially with hexane, dichloromethane, and ethyl acetate. The dichloromethane extract was separated by HPLC on silica, using 9:9:2 hexane–ethyl acetate–isopropanol as eluant, followed by HPLC using 45% hexane in ethyl acetate as eluant to obtain 6β-isovaleroxylabda-8,13-dien-7α,15-diol (**1,** 201 mg) and 2α,7α-diacetoxy-6β-isovaleroxylabda-8,13-dien-15-9-ol (**2,** 4 mg). The extracted mucus was purified in the same manner to obtain the pure diol (**1,** 9 mg, 78 μg/animal).

Dissection of T. reticulatus. Seven individuals of *T. reticulatus* were lyophilized and then dissected to separate the foot, mantle, viscera, and shell. The dissected components were separately soaked in acetone for 12 hr, after which time the acetone was decanted and evaporated to dryness. The crude organic extracts of each component were analyzed by ^{1}H NMR spectroscopy. Each crude organic extract was further purified by HPLC to obtain individual compounds.

Collection and Extraction of Trimusculus conica. The animals (N = 123) were collected intertidally from cracks between boulders at Anawhata Cove on the North Island of New Zealand. The animals were stored in acetone for one week, and then the solvent was decanted and evaporated to obtain an aqueous suspension. The aqueous phase was extracted with ethyl acetate (4 × 50 ml), and the extracts were combined, dried over anhydrous sodium sulfate, and evaporated to obtain a brown oil (405 mg). The crude extract was purified by flash chromatography on silica using 1:1 hexane–ethyl acetate as eluant. The fractions containing the UV active material were combined and applied to a 1000-μm preparative silica gel TLC plate and developed in 2:3 hexane–ethyl acetate. The UV active band was removed from the silica gel plate, and the silica was extracted with ethyl acetate to yield 6β-acetoxy-7α-isovaleroxylabda-8,13-dien-15-oic acid (**3,** 75 mg) (Figure 1). A second less polar UV active band was also removed and extracted to obtain a yellow oil (21 mg). The oil was purified by HPLC on partisil using 3:7 hexane-ethyl acetate as eluant to obtain 1β,7β,12β,18-tetraacetoxycholest-5-en-3β-ol (**4,** 12 mg).

Dissection of T. conica. Thirty-three specimens of *T. conica* were lyophilized and then dissected to separate the foot, mantle, viscera, and shell. The dissected components were separately soaked in acetone for 12 hr, after which time the acetone was decanted and evaporated to dryness. Each crude organic extract was analyzed by ^{1}H NMR spectroscopy and then subjected to HPLC to obtain pure compounds.

Seastar Response to T. reticulatus. One individual of *T. reticulatus* was placed in an aquarium containing one *Astrometis* sp., and the response was recorded for 30 min (three trials). In control experiments, the response of *Astrometis* sp. to the presence of *Colisella limatula* or *C. scabra* was recorded in a similar manner. In a separate experiment, mucus was collected from one individual of *T. reticulatus* or *C. limatula* by molesting the animals with a cotton swab until no further mucus production was observed. Each mucus-containing cotton swab was presented to the tip of the arm of an *Astrometis* sp. and the response recorded (three trials).

Fish Feeding Deterrence. Pure compounds were dissolved in ether or acetone and injected into freeze-dried krill pellets (*Euphausia* sp., San Francisco Bay Brand Ocean Plankton, 4–6 mg each) to reach a concentration of 100 μg compound/mg krill. Pellets were then dried under nitrogen. Control pellets were treated with solvent alone. Experimental and control pellets were paired and randomly fed to fish (*Thallasoma lunare*). The responses were recorded as eaten or, if the pellet was regurgitated three or more times, as rejected. The assay was repeated twice for each compound. The known repugnatorial compound limatulone (Pawlik et al., 1986) was used as a positive control.

Inhibition of Larval Settlement. Planktotrophic larvae of *Phragmatopoma californica* were reared at 20°C on a 1 : 1 mixture of *Phaeodactylum tricornutum* and *Monochrysis lutheri* under the same conditions described previously by Pawlik (1986). After 20–30 days, 10 larvae were transferred to 100-mm-diameter Petri dishes filled with 10 ml of 1-μm-filtered seawater. Each dish contained 1 g of Ottawa sand (20–30 mesh, Fisher Scientific), which had been treated in one of four ways: (1) control—100 μl ether; (2) settling inducer—100 μg palmitoleic acid in 100 μl ether; (3) settling deterrent—a known quantity of a pure compound in 100 μl of ether; or (4) larval toxicity—100 μg palmitoleic acid and a known quantity of a pure compound in 100 μl ether. After 24 hr, larvae were scored as swimming (not metamorphosed, no loss of provisional setae or

rotation of larval tentacles), metamorphosed (attachment, loss of provisional setae, rotation of larval tentacles or tube building), or dead.

For experiments with *Trimusculus reticulatus*, a whole limpet was placed in a Petri dish with 1 g of sand and 10 ml of filtered seawater. *Collisella* sp. were used as controls. In another treatment, mucus collected from one specimen of *T. reticulatus* was spread onto 1 g of sand and subsequently freeze-dried. Ten larvae were added and after 24 hr, larvae were scored as swimming, metamorphosed, or dead. Three replicates were carried out for each experiment.

RESULTS

Chemical Studies of T. conica. Investigation of the organic extract of this species resulted in the isolation of two novel compounds. 6β-Acetoxy-7α-isovaleroxylabda-8,13-dien-15-oic acid (**3**), $[\alpha]_D = +64.1$, was isolated as a colorless oil. The molecular formula, $C_{27}H_{42}O_6$, was deduced from ^{13}C DEPT experiments and from a fragment ion peak in the mass spectrum, $m/z = 445.2962$ $(M\text{-}OH)^+$. Comparison of ^1H and ^{13}C spectral data indicated that acid **3** was closely related to the diol **1** previously isolated from *T. reticulatus*. The differences in structure were deduced from the following data. The presence of the α,β-unsaturated acid in **3** is supported by the ^{13}C NMR signals at δ 172.0, 114.9, and 162.6, an IR stretch at 1640 cm^{-1}, and ^1H NMR signals at δ 5.74 (br s, 1H) and 2.22 (s, 3H). Treatment of **3** with diazomethane gave the expected methyl ester. Resolution enhancement of two broad signals at δ 4.99 (br s, 1H) and 5.33 (br s, 1H) in the ^1H NMR spectrum revealed a mutually coupled doublet and triplet, respectively ($J_{6,7} = 1.5$ Hz), similar to the signals assigned to H-6 and H-7 in diol **1.** The downfield shift of H-7 (δ 4.99 in **3** compared to 3.67 in diol **1** along with the appearance of a methyl singlet at δ 2.05 suggested esterification of the alcohol at C-7 by acetate. However, a long-range 2-D carbon–hydrogen correlation experiment revealed that the isovalerate ester was attached at C-7 and the acetate ester was at C-6, which was not the expected substitution pattern. This experiment showed that the ester carbonyl signal at δ 169.6 was coupled to both the acetate methyl signal at δ 2.05 and the methine signal at 5.33 (t, 1H, $J = 1.5$ Hz, H-6), while the ester carbonyl signal at δ 171.8 was coupled to the isovalerate α-methylene signal at 2.25 and the methine signal at 4.99 (d, 1H, $J = 1.5$ Hz, H-7). All other data are consistent with the proposed structure for 6β-acetoxy-7α-isovaleroxylabda-8,13-dien-15-oic acid (**3**).

The minor component of the organic extract was the sterol tetraacetate **4,** which was isolated as an oil, $[\alpha]_D = +29.7$. The molecular formula, $C_{35}H_{54}O_9$, was established by EI-MS [$m/z = 601.3740$, $(M\text{-}OH)^+$]. The ^1H NMR spectrum displayed signals at δ 0.86 (d, 3H, H-26), 0.87 (d, 3H, H-27), 0.92 (d, 3H, H-21), and 1.09 (s, 3H), representing four of the five methyl groups expected

for a cholestane sterol, the missing signal being that of the C-18 methyl group that is normally at δ 0.6 (s, 3H). Four methyl signals at δ 2.03 (3H), 2.04 (6H), and 2.10 (3H) indicated that four acetate groups were present. The presence of mutually coupled signals at δ 4.27 (d, 1H, J = 12.4 Hz) and 4.38 (d, 1H, J = 12.4 Hz) suggested that the C-18 methyl group was replaced by a $-CH_2OAc$ group. A signal at δ 4.68 (dd, 1H, J = 11.2, 5.1 Hz) was coupled to signals at 1.90 (m, 1H, H-11α) and 1.56 (m, 1H, H-11β), and the latter signal was in turn coupled to a signal at 1.40 (m, 1H, H-9), indicating the presence of an equatorial acetate group at C-12. The H-7 signal at δ 5.14 (br dd, 1H, J = 8.7, 2 Hz), was coupled to both the H-8 (J = 8.7 Hz) and the H-6 (J = 2 Hz) signals and also, through homoallylic coupling, to a proton signal at 2.05 (H-4α). The olefinic proton signal at δ 5.39 (br s, 1H, H-6) also showed allylic coupling to H-4α. The small coupling constant between H-6 and H-7 is consistent with an allylic, axial acetoxy group as described by Fattorusso *et al.* (1985). The signal at δ 3.27 (tt, 1H, J = 12, 4 Hz) is characteristic of the H-3 proton in a 3β-hydroxy sterol. The proton signal at δ 3.27 was coupled to a signal at 2.15 (H-2), which was in turn coupled to the remaining downfield signal at 5.21 (br d, 1H, J = 11 Hz, H-1), which required a 1β-acetoxy group. The remaining data were consistent with the structure of 1β,7β,12β,18-tetraacetoxycholest-5-en-3β-ol (**4**).

Localization of Metabolites. Diol **1**, the major secondary metabolite of *T. reticulatus*, was found only in the extracts of the foot and mantle, while the viscera contained none of the compound. The mucus produced by *T. reticulatus* when placed in a bag during collection also contained diol **1**, but the amount of mucus produced in this manner is less than would have been obtained by deliberately molesting the animals. Diterpene **3** and sterol **4** were found only in extracts of the foot and mantle of *T. conica*, but no mucus was collected from *T. conica*. The distribution of these metabolites is shown in Table 1.

TABLE 1. DISTRIBUTION OF DIOL **1** IN TISSUES (N = 7) AND MUCUS (N = 115) OF *T. reticulatus* AND OF ACID **3** AND STEROL **4** IN TISSUES OF *T. conica* (N = 33)

	Diol **1**	Acid **3**	Sterol **4**
Foot	260 μg/animal	100 μg/animal	+[a]
Mantle	4.0 mg/animal	400 μg/animal	+
Viscera	0	0	–
Shell	0	0	–
Mucus	78 μg/animal		

[a]Visible by thin-layer chromatography; –, not visible by thin-layer chromatography.

Seastar Response to T. reticulatus. When the seastar *Astrometis* sp. encountered the limpet *T. reticulatus*, the seastar retracted its arm by curling it up and backwards to avoid further contact. The seastar then changed direction to avoid further contact. When *Collisella limulata* or *C. scabra* were encountered, the seastar did not retract its arm but proceeded to crawl over the limpets. The cotton swab containing the mucus of *T. reticulatus* caused a similar arm-curling avoidance response to that caused by the whole animal. The cotton swabs containing mucus from *C. limulata* were not avoided and were crawled over.

Fish Feeding Deterrence. All krill pellets treated with diterpenoids **1** and **2** from *T. reticulatus* were readily eaten by the wrasse, *Thallasoma lunare*; these compounds did not appear to inhibit fish feeding. However, when the krill pellets

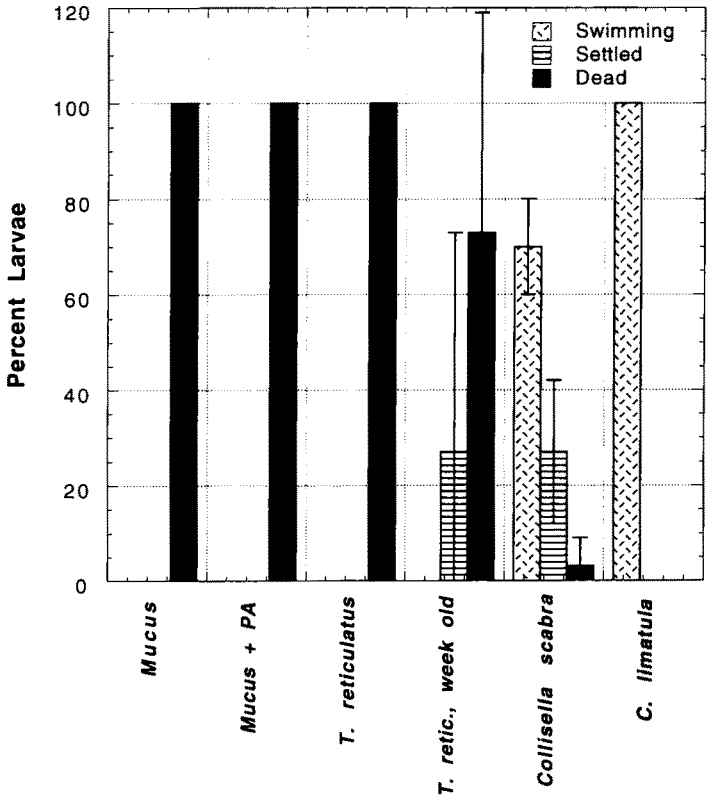

FIG. 2. The effect of *Colisella limatula, C. scabra, Trimusculus reticulatus*, mucus of *T. reticulatus*, mucus + palmitoleic acid (PA), and "aged" (1 week) *T. reticulatus* on *Phragmatopoma californica* larvae ($N = 30$).

were treated with limatulone (**5**), a known feeding inhibitor, the pellets were tasted and rejected by the wrasse.

Inhibition of Larval Settlement. The presence of a live individual of *T. reticulatus* was toxic to *Phragmatopoma californica* larvae. The presence of dried mucus collected from one individual limpet also caused 100% larval mortality. If the pulmonate limpet was kept in captivity for one week before carrying out the experiment, some of the effect was lost. The presence of the sympatric limpets *Collisella scabra* and *C. limatula* had no effect on the larvae. These results are summarized in Figure 2. The purified metabolite **1** from *T. reticulatus* had the same effect on the larvae as did the presence of the limpet or its mucus. At concentrations of 100 μg/treatment or greater, diol **1** caused 100% mortality (Figure 3). The effect was observed to drop off at 50 μg/treatment. However, when palmitoleic acid was added to the treatment and the larvae were induced to settle, 50% settled abnormally (Figure 4). Ether (100 μl) was used as a negative control, and when applied, 100% of the larvae remained swimming.

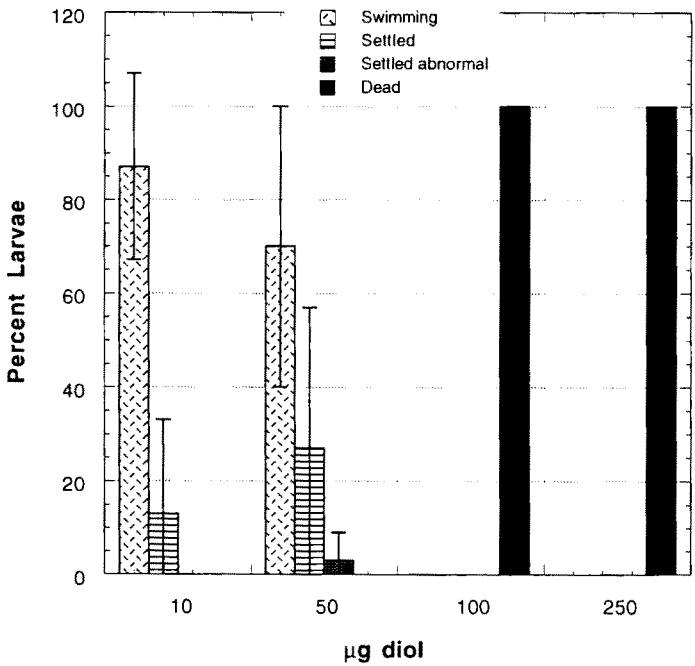

FIG. 3. The effect of diol **1** (micrograms per gram of sand) on *Phragmatopoma californica* larvae (N = 30).

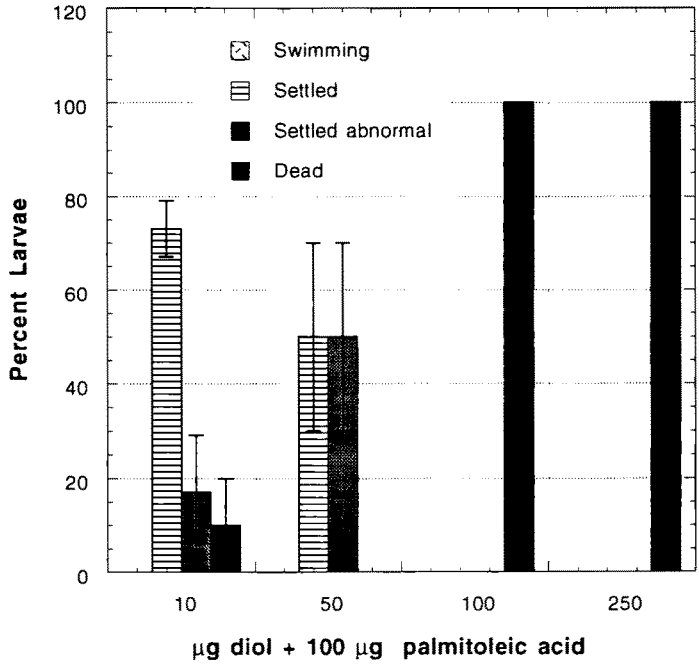

FIG. 4. The effect of diol **1** (micrograms per gram of sand) and palmitoleic acid (100 µg/g of sand) on *Phragmatopoma californica* larvae ($N = 30$).

When 100 µg of palmitoleic acid was used alone, 100% of the larvae settled normally. Acid **3** from *T. conica* did not cause larval mortality. However, it did appear to have some effect on settling, and at 100 µg/treatment, acid **3** caused 50% of the larvae to settle abnormally.

DISCUSSION

A careful investigation of the localization of the secondary metabolites of *T. reticulatus* revealed that the diterpenes were heavily concentrated in the mantle, foot, and mucus of the limpet. Neither the viscera nor the shell contained any of the chemicals. Another species of trimusculid, *T. conica* from New Zealand, was also collected to determine whether it contained similar compounds. The pulmonate limpets from New Zealand contained only one diterpene, the acid **3**, which was very closely related to those found in the California species, together with the sterol **4**. Similarly, the diterpene **3** and **4** were found

to be present only in extracts of the foot, mantle, and mucus. The localization of the diterpenes in the most exposed areas of the limpet suggests that they are deployed externally, probably in the mucus.

The compounds were screened in a number of bioassays to test their effectiveness as either defensive chemicals or antifouling agents. We observed the mucus of *T. reticulatus* to be repugnant to the sympatric seastar *Astrometis* sp., (cf. Rice, 1985), but diol **1** alone did not elicit the same response in the echinoderm. Insufficient quantities of diacetate **2** prevented similar tests. This may be due to the lack of an adequate carrier to mimic a mucus for presentation of diol **1** to the seastar. It is also feasible that more than one component is necessary in the mucus to repel seastars. The secondary metabolites did not inhibit feeding in the tropical rainbow wrasse, *Thallasoma lunare*. However, diterpene **1** was found to be highly toxic to veliger larvae of the sabellarid tube worm *Phragmatopoma californica*, which forms large reefs in the intertidal zone in proximity to colonies of *T. reticulatus*. The limpet, its mucus, or diol **1** at natural concentrations was also extremely larvicidal, while the prosobranch limpets caused no effect. In those experiments in which a settling factor, palmitoleic acid, was added and the *P. californica* larvae were induced to settle onto sand containing the diterpene, abnormal settlement was observed. This manifested itself in a failure to metamorphose, which included an inability to shed provisional setae or not rotating the larval tentacles anteriorly. Thus, a mucus secretion containing diterpene **1** would be very effective in preventing settling of a potential competitor. The lack of toxicity observed when using an individual *T. reticulatus* that had been starved for one week suggests that the concentration of secondary metabolites may have decreased to below the threshold required for efficacy and that dietary intake may be required for the production of diol **1.**

A second species, *T. conica*, which occurs in New Zealand, was found to contain diterpene **3,** which was closely related to the diterpenes found in *T. reticulatus*. Dissection and analysis showed similar localization of metabolites in the foot, mantle, and mucus. However, acid **3** was not effective against veliger larvae of the California tube worm. This lack of activity might be expected since *T. conica* has coevolved with different intertidal competitors in New Zealand.

CONCLUSION

The sessile nature of *T. reticulatus* and the fact that it filter feeds would make it particularly important for the limpet to keep the area around it free from fouling organisms. *P. californica* occurs in the same habitat and tidal range as *T. reticulatus*. The results show that natural concentrations of mucus or the presence of a live trimusculid limpet kills the larvae of *P. californica*. However,

in the presence of *Collisella scabra* or *C. limatula*, larvae of *P. californica* were not adversely affected. Clearly, the mucus of *T. reticulatus* is larvicidal to *P. californica*. The same activity is elicited by diol **1** purified from the mucus or whole animal, and it seems most likely that this compound is the larvicidal principle in the mucus. This may be an important strategy to the sessile, filter-feeding members of the genus *Trimusculus* that must keep their shells and the area around them free from other intertidal invertebrates in order to survive.

(Received February 22, 1995; accepted August 23, 1995)

Abstract—The long-chain carboxylic acids identified in the sternal gland secretion of *Polistes dominulus* and *P. sulcifer* females were tested individually on three species of ants, *Crematogaster scutellaris*, *Formica cunicularia*, and *Lasius* sp., in order to verify if they have a repellent effect. The unsaturated acids (palmitoleic, linoleic, and oleic) act as repellents of all three ant species, while the saturated acids (lauric, myristic, palmitic, and stearic) have no effect. The mixture reproducing the secretion of the sternal glands of *P. dominulus* maintained its repellency for at least four days.

Key Words—Vespidae, Polistinae, *Polistes*, sternal glands, nest defense, ant repellents, allomones, unsaturated carboxylic acids.

INTRODUCTION

Several studies have shown that ants, especially in tropical and subtropical areas, exert high predatory pressure on the nests of social wasps, preying on their immature brood (Jeanne, 1975, 1979; Yamane, 1996). As active defense is less effective when only a few wasps constitute the colony, chemical defense against

ants is used by many species. In at least some species of Stenogastrinae, the Dufour's gland secretion, consisting of a gelatinous substance, is used as a storage substrate for the larval food as well as a barrier against ants (Turillazzi, 1991, 1994). In females of the independently nest-founding Polistinae, the gland cells of the last gastral sternites secrete ant repellent substances (see Downing, 1991; Jeanne, 1996). By rubbing the abdomen on it, females apply these substances to the pedicel, which suspends the nest from the substrate and constitutes the only access to the nest for pedestrian predators. Recently, the production of ant-repellent secretions by gastral sternal glands has also been reported for two species belonging to the subfamily Vespinae (Martin, 1992).

Bioassays on several species of ants have been carried out using nest pedicels (Jeanne, 1970; Hermann and Dirks, 1974; Post and Jeanne, 1981; Turillazzi and Ugolini, 1979; Martin, 1992), glass capillaries or small wooden sticks stroked along the last abdominal sternites (Jeanne, 1970; Turillazzi and Ugolini, 1979; Post and Jeanne, 1981; Kojima, 1983; Martin, 1992), and solvent-extracted sternal glands (Keeping, 1990; Kojima, 1992). All the bioassays have shown that the sternal gland secretion and the substances coating the pedicel have a repellent effect on ants. Turillazzi and Ugolini (1979) and Kojima (1983) report that in *Polistes* and *Ropalidia*, respectively, the secretion loses activity a short time after the application, while Martin (1992) found that the repellent action lasts for several hours in *Vespa*.

From the sixth sternite glands of *Polistes fuscatus*, Post et al. (1984) isolated two components active against ants. One of these was identified as methyl hexadecanoate (methyl palmitate). Bioassays using methyl palmitate and some related methyl esters (methyl myristate, methyl linoleate, methyl linolenate, and methyl stearate) on several ants species (Post et al., 1984; Henderson and Jeanne, 1989) and on flies (Henderson et al., 1991) showed that only methyl myristate and methyl palmitate had a repellent effect, the former being more active than the latter. Also in these trials, the repellent effect lasted only for some hours.

More recently, hexadecanoic (palmitic) and octadecenoic (oleic) acid have been identified in the sixth sternite glands of *P. annularis* workers (Espelie and Hermann, 1990). The same compounds, together with other carboxylic acids (dodecanoic or lauric, tetradecanoic or myristic, hexadecenoic or palmitoleic, octadecadienoic or linoleic, and octadecanoic or stearic acid), have been found by Dani et al. (1995) in the fifth and sixth sternite glands of *P. dominulus*. *P. sulcifer*, a social parasite of *P. dominulus* (see Turillazzi, 1992; Cervo and Dani, 1996) has been shown to have most of the same fatty acids (palmitoleic, palmitic, oleic, and stearic) in its sternal glands also (Dani et al., 1995).

In the present research, bioassays have been performed in order to test if the acids found in the *P. dominulus* and *P. sulcifer* gastral sternite glands have an effect in repelling ants.

METHODS AND MATERIALS

Ant Species

The experiments were conducted in the laboratory at the Dipartimento di Biologia Animale e Genetica of Florence University. Most of the bioassays were carried out on *Crematogaster scutellaris*, but tests were also done on *Formica cunicularia* and a *Lasius* species. Turillazzi and Ugolini (1979) observed *Lasius* sp. and *Crematogaster* sp. invading nests of European *Polistes*, while Dani and Cervo (personal observation) have found nests invaded by *Formica* sp. *Crematogaster scutellaris* foragers were captured with an aspirator in the garden of the department and quickly used for the experiments. *Formica cunicularia* and *Lasius* sp. workers were collected in the Appennines near Pesaro (together with some immature brood coming from their nests) and used for the experiments the day after collection.

Experimental Apparatus

In all the experiments we used an experimental apparatus of the type employed by Turillazzi and Ugolini (1979). In each trial, about 40 ants were placed on an inverted Petri dish (9.5 cm in diameter), placed in the center of a bigger Petri dish (15 cm in diameter) containing water. A bridge was constructed with glass rods to permit the ants to escape from their water-surrounded dish. It consisted of a large glass rod (30 mm long and 2 mm in diameter), connected via a Y junction to two narrow glass rods (80 mm long and 1 mm in diameter). The end of the larger rod was put on the smaller Petri dish while the other two rods were placed on the border of the bigger Petri dish. Ants arriving at the Y junction had to make a decision to continue on one or the other branch to escape confinement. In each trial, before placing the bridge, one of the two smaller rods (experimental branch), near its junction with the main stem, was treated with a hexane solution containing synthetic carboxylic acids (the solvent was allowed to evaporate) while the other tube (control branch) was treated only with the same quantity of hexane. If the solution had a repellent effect, at the branching point, the ants tended to follow the control branch. Each trial lasted 20 min, unless all the ants crossed the branches in a shorter time. During the trial, the position of the experimental and control rods was alternated about every 5 min. If ants were walking on the rods, we waited until they had reached the end of the rods before alternating them. Four trials were made for each kind of experiment.

The results (i.e., the number of ants crossing the experimental and the control rods) of the four trials of each experiment were tested with the χ^2 homogeneity test. When the probability given by the test was not significant,

the data were cumulated and compared, using the G test, with a two-class uniform distribution (50%–50%), to find if a significantly different number of ants chose one of the two routes. When the probability given by the homogeneity test was significant, the G test was done for each single trial.

For graphic representation, we report the index of repellency of each acid as the percentage of ants that crossed the control route with respect to the total number of ants crossing both routes.

Experiments

Control Experiments. Prior to the experiments, nine control trials in which neither branch was treated were carried out on *Crematogaster scutellaris* to verify that the ants walked indiscriminantly on the two branches of the experimental device.

Effect of Each Acid. Oleic acid is the main component found in the sternal gland secretion of *P. dominulus*; the sixth sternite glands of one worker contained about 2.5 μg of this compound (Dani et al., 1995). In experiments on *Crematogaster scutellaris*, we tested separately lauric (dodecanoic), myristic (tetradecanoic), palmitoleic [(Z)-9-hexadecenoic], palmitic (hexadecanoic), linoleic [(Z,Z)-9,12-octadecadienoic], oleic [(Z)-9-octadecenoic], and stearic (octadecanoic) acid, by applying to the experimental branch 2.5, 25, or 250 μg of one of these acids diluted in 2μl of hexane (from solutions previously prepared), except that stearic and palmitic acid at 250 μg were each dissolved in 4 μl of hexane because of the limited solubility of these acids in hexane. Only the 250-μg quantity was tested on *Formica cunicularia* and on *Lasius* sp.

Duration of Repellent Effect. The sixth sternal glands of one *P. dominulus* worker contained, on average, the acids in the following percentages (Dani et al., 1995): lauric acid, 2.9% (195 ng); myristic acid, 5.9% (393 ng); palmitoleic acid, 4.1% (271 ng); palmitic acid, 21.4% (1410 ng) linoleic acid, 21.3% (1405 ng); oleic acid, 38.3% (2523 ng); and stearic acid, 5.9% (390 ng). A solution of pure acids, mixed in these proportions was tested on *Crematogaster scutellaris* by applying 2 μl of hexane containing the equivalent of the sixth sternite glands of 10 workers. The effect of this solution was tested at 0, 24, 48, and 96 hr after application to the rods.

RESULTS

Control Experiments. The control experiments showed that the device was balanced. In fact, although it was not possible to cumulate the data of the nine trials (homogeneity test; $\chi^2 = 6.58$, $P < 0.05$), in none of them did we find that significantly more ants preferred one of the two branches.

Effect of Each Acid. We report the average percentage (of the four trials) of *Crematogaster scutellaris* foragers that chose the control branch at the Y junction, using 2.5, 25, or 250 μg of each acid in Figure 1.

At 2.5 μg, palmitoleic, linoleic, and oleic acids had a highly repellent effect. It was not possible to cumulate the results of the four trials for palmitoleic acid (homogeneity test; $\chi^2 = 8.76$, $P < 0.01$), but in all of them significantly more than 50% of the ants crossed the control branch (Trial 1, $G = 21.26$, $P < 0.001$; Trial 2, $G = 33.00$, $P < 0.001$; Trial 3, $G = 39.57$, $P < 0.001$; Trial 4, $G = 6.70$, $P < 0.01$). The data of the other two unsaturated acids were cumulated ($\chi^2 = 3.12$, NS for linoleic acid; $\chi^2 = 1.65$, NS for oleic acid); in both the experiments significantly more ants followed the control branch ($G = 20.90$, $P < 0.001$ for linoleic acid; $G = 18.60$, $P < 0.001$ for oleic acid). No repellent effect was found for lauric, myristic, palmitic, and stearic acids.

At the 25-μg quantity, no ants at all crossed the rods to which linoleic acid ($\chi^2 = 0.01$, NS; $G = 250.93$, $P < 0.001$) or oleic acid ($\chi^2 = 0.21$, NS; $G = 141.42$, $P < 0.001$) had been applied, and only very few crossed the rods treated with palmitoleic acid ($\chi^2 = 0.31$, NS; $G = 215.19$, $P < 0.001$). No repellent effect was shown by lauric, myristic, palmitic, and stearic acids.

Because at 25 μg linoleic and oleic acids repelled all the ants (100%), we did not test these substances in the 250-μg experiments. In the trials with 250 μg, only very few ants chose the path with palmitoleic acid ($\chi^2 = 0.09$, NS; $G = 200.30$, $P < 0.001$), and no repellent effect was found for lauric, myristic, palmitic, and stearic acids.

Similar results were obtained in the experiments with *Formica cunicularia* (Figure 2) and with *Lasius* sp. (Figure 3) using 250 μg of acid. No *Formica cunicularia* ants used the branch treated with palmitoleic acid ($\chi^2 = 0.042$, NS; $G = 94.17$, $P < 0.001$). Only very few used that treated with oleic ($\chi^2 = 0.25$, NS; $G = 148.47$, $P < 0.001$) or linoleic acids ($\chi^2 = 0.12$, NS; $G = 158.20$, $P < 0.001$), and no repellent effect was shown by lauric, myristic, palmitic, and stearic acids.

Only a few *Lasius* sp. crossed the path treated with palmitoleic, linoleic, and oleic acids (respectively: $\chi^2 = 0.12$, NS; $G = 136.55$, $P < 0.001$; $\chi^2 = 0.08$, NS; $G = 148.02$, $P < 0.001$; $\chi^2 = 0.72$, NS; $G = 121.37$, $P < 0.001$), while lauric, myristic, palmitic, and stearic acids had no repellent effect.

In the case of *Crematogaster scutellaris*, we compared the results obtained in the experiments with the three different amounts of each acid. No differences in the repellent effect of the saturated acids were found between the 2.5- and 25-μg and between the 25-μg and 250-μg experiments. For linoleic and oleic acids, it was found that 25 μg of each substance had a greater repellent effect than 2.5 μg (respectively: $G = 87.92$, $P < 0.001$; $G = 65.11$, $P < 0.001$).

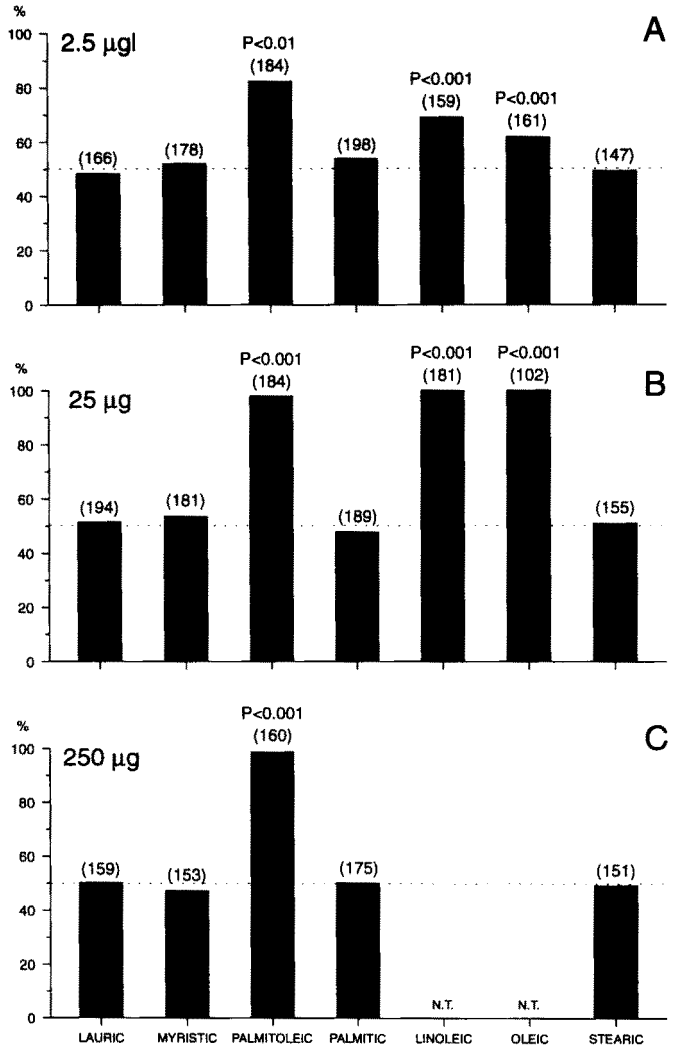

FIG. 1. Histograms showing the average percentage of *Crematogaster scutellaris* workers crossing the control branch with respect to the total number of ants crossing both control and experimental branches in the four trials using 2.5 µg (A), 25 µg (B), or 250 µg (C) of each acid. The total number of ants that crossed the experimental and the control branches in the four trials is given in parentheses. When the number of ants crossing the two branches significantly differs from a two-class uniform distribution (50%–50%) the result of the *G* test is given over that bar. Since in the 25-µg experiments linoleic and oleic acids repelled all the ants, these acids were not tested in the 250-µg experiments (N.T.).

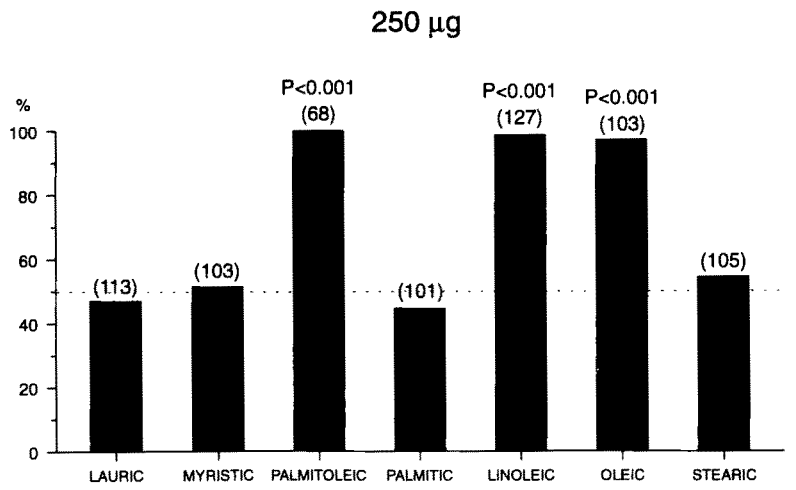

FIG. 2. Histogram showing the average percentage of *Formica cunicularia* workers crossing the control branch with respect to the total number of ants crossing both control and experimental branches in the four trials done using 250 μg of each acid. The total number of ants that crossed the experimental and the control branches in the four trials is given in parentheses. When the number of ants crossing the two branches significantly differs from a two-class uniform distribution (50%–50%) the result of the G test is given over that bar.

In three of the four trials with 2.5 μg (the result cannot be cumulated, see above), palmitoleic acid had less repellent effect than in the 25-μg experiment (Trial 1, $G = 13.13$, $P < 0.001$; Trial 2, $G = 38.63$, $P < 0.001$; Trial 3, $G = 4.06$, $P < 0.05$), while for the fourth trial no differences were found.

We conclude that the unsaturated acids (palmitoleic, linoleic, and oleic) have a strongly repellent effect on ants of the three species, while the saturated acids (lauric, myristic, palmitic, and stearic) have no effect, even if applied in a large amount. Ants reaching the surface covered with the unsaturated acids usually retreated and spent considerable time cleaning their antennae. Despite the fact that the applied surface seemed to be tacky and ants seemed to have difficulty walking on it, they did not become trapped by it.

The results obtained for each acid in the 2.5-μg experiments on *Crematogaster scutellaris* were compared. No statistical differences were found between the effects of the saturated acids. Comparing the effect of the unsaturated acids, we found no statistical differences between oleic and linoleic acid, while in three trials, palmitoleic acid was more repellent than oleic and linoleic ($G = 4.04$, $P < 0.05$; $G = 10.41$, $P < 0.01$; $G = 15.28$, $P < 0.001$ for the comparison between linoleic and palmitoleic acid; and $G = 5.32$, $P < 0.05$; $G = 12.35$,

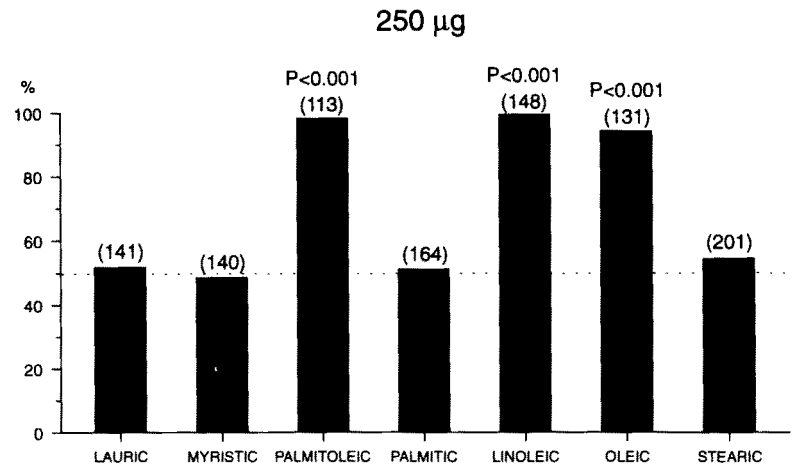

FIG. 3. Histogram showing the average percentage of the *Lasius* sp. workers crossing the control branch with respect to the total number of ants crossing both control and experimental branches in the four trials done using 250 µg of each acids. The total number of ants that crossed the experimental and the control branches in the four trials is given in parentheses. When the number of ants crossing the two branches significantly differs from a two-class uniform distribution (50%—50%) the result of the G test is given over that bar.

$P < 0.001$; $G = 17.47$, $P < 0.001$ for the comparison between oleic and palmitoleic acid). We found a statistical difference every time we compared the effect of a saturated acid with that of linoleic acid ($G = 12.31$, $P < 0.001$, for lauric acid; $G = 8.64$, $P < 0.01$, for myristic acid; $G = 6.18$, $P < 0.02$, for palmitic acid; $G = 10.60$, $P < 0.01$ for stearic acid), and similarly with oleic acid ($G = 10.33$, $P < 0.01$, for lauric acid; $G = 6.86$, $P < 0.01$, for myristic acid; $G = 4.58$, $P < 0.05$, for palmitic acid; and $G = 8.74$, $P < 0.01$, for stearic acid). Indeed, we found a statistical difference ($0.05 < P < 0.001$) any time we compared the results of the four trials with palmitoleic acid with those of the experiments with the saturated acid, with the exception of one comparison between a trial of palmitoleic and palmitic acid.

In the 25-µg experiments on *Cremastogaster scutellaris*, there were no statistical differences between the effects of the saturated acids; while for the unsaturated ones we found that linoleic acid was more repellent than palmitoleic ($G = 5.54$, $P < 0.02$). We found statistical differences in any comparison between saturated and unsaturated acids (G test, $P < 0.001$ for the 12 comparisons).

In the 250-µg experiments on *Cremastogaster scutellaris*, no differences

TABLE 1. DURATION OF REPELLENCY EFFECT ON *Crematogaster scutellaris* WORKERS OF A SOLUTION OF SYNTHETIC ACIDS REPRODUCING PROPORTIONS OF ACIDS IN STERNAL GLAND SECRETION OF 10 *Polistes dominulus* WORKERS[a]

	Time (hr) after application			
	0	24	48	96
Average percent repellency ± SD (Total number of ants crossing control and experimental branches)	78.5 ± 0.09 (107)	82 ± 0.08 (107)	86 ± 0.04 (133)	86.5 ± 0.08 (135)

[a]Each experiment consisted of four trials. The mean percentage (with the standard deviation) of ants crossing the control branch with respect to the total number crossing both experimental and control branches (in parantheses) is reported.

were found between the effects of the saturated acids. As oleic and linoleic acid were not tested at this amount (see above), comparisons between unsaturated acids were not done. Finally, palmitoleic acid was more repellent than any saturated acids (G test, $P < 0.001$ for the four comparisons).

The 250-μg experiments on *Formica cunicularia* and on *Lasius* sp. revealed no statistical differences between the saturated acids. For *F. cunicularia* we also found no differences between the unsaturated acids, while for *Lasius* we found that the linoleic acid is more active than oleic ($G = 0.63$, $P < 0.01$). For both species we always found a highly significant difference any time we compared the effect of an unsaturated with that of a saturated acid (G test, $P < 0.001$ for the 12 comparisons).

Duration of Repellent Effect. The repellency of the mixture (applied as a 10-worker equivalent) did not change much with time (Table 1). It initially increased a little (but not significantly) and then remained constant for at least four days after application.

DISCUSSION AND CONCLUSIONS

All the results indicate that the unsaturated carboxylic acids found in the fifth and sixth sternite glands of *P. dominulus* and *P. sulcifer* have an ant repellent effect, while the saturated acids are not repellent at all. The unsaturated carboxylic acids have a repellent effect even if tested in amounts similar to that contained in the sternal glands of just one female.

The saturated and unsaturated long-chain carboxylic acids differ in their physical and chemical properties. Physically, the saturated acids are solids and

the unsaturated acids are liquids at room temperature. Chemically, the unsaturated acids possess a reactive double bond and react with atmospheric oxygen. We do not think the physical state of the unsaturated acids is the cause of their repellency, and no oily surface is observable on the nest pedicel.

Myristoleic, palmitoleic, oleic, and linoleic acids appear in ants dead for several hours (Blum, 1970), and they induce necrophoric behavior in ants belonging to the genera *Pogonomyrmex*, *Solenopsis*, and *Myrmecia* (Wilson et al., 1958; Blum, 1970; Haskins and Haskins, 1974; Gordon, 1983). Oleic acid occurs in the eggs of the beetle *Gastrophysa cyanea*, where it acts as a feeding deterrent against several species of ants (Howard et al., 1982). Fatty acids from the cornicles of aphids have a repellent effect on *Monomorium* workers (Phelan, personal communication in Howard et al., 1982). Howard et al. (1982) suggested that the use of fatty acids as ant repellents is a widespread phenomenon among insects, and our results seem to support this hypothesis.

Turillazzi and Ugolini (1979) and Kojima (1983) found that the repellent effect of the sternal gland secretion is not long lasting, suggesting that the frequent gastral rubbing performed by females on the pedicel is related to the rapid loss of repellency of the secretion. Similar experiments by Post et al. (1984) and Henderson and Jeanne (1989) using the methyl esters of some of the acids we tested in this research showed repellent action for only methyl myristate and methyl palmitate, but it was very limited.

Besides the production of allomones, an involvement of the sternal glands of *Polistes* wasps in communication between nestmates has also been supposed (West-Eberhard, 1982; Downing and Jeanne, 1983). For the social parasite *P. sulcifer* it has been suggested that the sternal glands are involved in the chemical control of the host colony (Turillazzi et al., 1990). Further studies are necessary to verify if carboxylic acids may have some role in communication between nestmates.

Acknowledgments—This research was supported with funds from the Italian MURST (60% and 40%). We wish to thank Dr. D.A. Grasso for help in identification of ant species and Prof. R. Pepino of the Dipartimento di Chimica Organica of the University of Florence.

(Received February 28, 1995; accepted August 23, 1995)

Abstract—Foliage from the pepper tree, *Schinus molle* L., is traditionally used in Ethiopia to "repel" house flies, *Musca domestica* L. The volatile extracts of pepper tree leaves were shown to have repellent and feeding-deterrent activity against house flies in a two-choice laboratory bioassay. High-performance liquid chromatographic fractionation of steam-distilled volatiles from leaves, monitored by laboratory bioassays, demonstrated that bioactivity is associated with two compounds, *cis*-menth-2-en-1-ol and *trans*-piperitol. The absolute configuration of the latter was established as (1*S*,6*S*)-piperitol by comparison of acetyl lactate derivatives. Racemic compounds were synthesized from piperitone, and bioassays with house flies indicated *trans*-piperitol to be the most active house fly repellent.

Key Words—Pepper tree, *Schinus molle*, house fly, *Musca domestica*, *cis*-menth-2-en-1-ol, *trans*-piperitol, repellent, feeding deterrent.

INTRODUCTION

The pepper tree, *Schinus molle* L. (California or Australian pepper tree, Peruvian or American mastic tree) (Anacardiaceae), is native to the Peruvian Andes (Heywood, 1982) and is widely grown in tropical and subtropical countries (Zeven,

*To whom correspondence should be addressed.

0098-0331/96/0100-0049$09.50/0 © 1996 Plenum Publishing Corporation

1982). The tree grows 6–10 m high with a 60 to 90-cm-diameter trunk. The foliage consists of 12 to 20-cm-long, pinnate, feathery, green leaves. The flowers are yellow–white and develop into red fruits (drupes) (Graf, 1981).

Foliage of the pepper tree is reported to be a traditional source of repellents for house flies, *Musca domestica* L., in Ethiopia and some rural people drape branches and leaves over their heads to repel house flies. Pepper tree leaves are spread on eating tables, and occasionally in slaughter houses and meat-processing areas. A number of investigators have identified several chemical constituents of pepper tree volatiles (Aziz-Ur-Rahman et al., 1974; Bernhard et al., 1983; Delvalle et al., 1987; Dominguez et al., 1971; Hashim et al., 1980; Navarrete et al., 1989; Talenti et al., 1989), none of which has been reported as a repellent for house flies.

On the basis of Ethiopian tradition, our objective was to investigate the hypothesis that volatile chemical house fly repellents are present in the pepper tree. The hypothesis was strengthened by the results of preliminary field bioassays (conducted by K.N.S., J.H.B., and T.A.), which showed that chopped leaves and berries of pepper trees, and crude ethanolic extracts thereof, were repellent to house flies in Ethiopia. This paper reports the laboratory bioassay, isolation, and identification of candidate house fly repellents from pepper tree leaves (Wimalaratne, 1993).

METHODS AND MATERIALS

Preparation of Pepper Tree Extracts

Fresh pepper tree leaves were obtained from 1 to 2-year-old trees grown in a greenhouse at Simon Fraser University, British Columbia, Canada. Shoots with matured leaves were separated intact from the trees, and were stored in sealed polyethylene bags at −20°C. Pepper tree leaves (400 g) were blended with distilled water (1500 ml) until a pulp was formed. Leaf volatiles were extracted into pentane from the macerated pulp using a modified Likens-Nickerson simultaneous distillation–solvent extraction drive (Flath and Forrey, 1977) over a period of 6 hr. The pentane extract was dried over anhydrous Na_2SO_4 and filtered. The filtrate was concentrated by distillation of the pentane through a Dufton column, and the residual solvents were removed by aspiration with nitrogen.

Bioassay

A two-choice laboratory bioassay was developed in which wooden cages (16 × 16 × 13 cm) were used as bioassay chambers. The back wall of each cage was a fine plastic screen and the front wall was a transparent Plexiglas

sheet with central hole (2 cm diam.), through which insects were released into the cage and which was then closed with a cork. The plastic sheet could also be raised, providing a means to place baits and water vials in the cage and to remove dead flies. A water vial with a cotton wick was kept inside the cage to maintain high relative humidity and to provide drinking water for the flies.

Two glass cover slips (2.2 × 2.2 cm) served as bait stations. Prior to bioassays the center of each cover slip was treated with a 50-μl drop of sucrose solution (sucrose–water 1 : 1 w/v); heating to dryness at 60–70°C in an oven left a sugar coating on the glass. Newly emerged adult house flies were obtained from the insectary at Simon Fraser University, British Columbia, Canada. For each bioassay replicate, 20 laboratory-reared, randomly selected flies (mixed sex and age) were released into a cage and held without food for 1 hr. One bait station was treated with the test stimulus (25 μl), and the other with solvent (25 μl). After evaporation of the solvent, the bait stations were placed 10 cm apart on the floor of the cage. The number of sustained fly contacts ≥ 10 sec on both bait stations were counted for 6 min. The proboscis was usually extended on such contacts. Each treatment was assayed with five groups of 20 flies each at room temperature and humidity. Bioactive constituents characteristically induced flies that made contact with the treated substrate to depart immediately (repellency), but if contact was sustained, extension of the proboscis and feeding was sometimes also repressed (deterrency) (Nordlund, 1981). Because the former response predominated, for convenience we refer to the combined effect as repellency.

Bioassay experiments were conducted to test the activity of steam-distilled volatile extracts, fractions, and two synthetic candidate repellents, *cis*-menth-2-en-1-ol **(I)** and *trans*-piperitol **(II)** (Figure 1). Known weights of racemic samples of **I** and **II** diluted in distilled hexane were assayed on house flies. Three series of experimental samples were prepared with **I** and **II** individually and a 1 : 1 w/w mixture of **I** and **II.** Dose–response experiments were conducted to determine the minimum quantity of each compound separately, and in combination, required to elicit significant repellency.

Percent responses (pooled data for the five groups of flies) to experimental stimuli were compared to those to crude extract stimuli by a z test ($\alpha = 0.05$) (Zar, 1984).

Isolation and Identification of Repellents

Gas–liquid chromatographic (GC) analysis was performed on a Hewlett-Packard 5880A gas chromatograph equipped with a DB-1 fused-silica capillary column. Matching retention times for isolated active components and authentic samples were performed on a Hewlett-Packard 5890A gas chromatograph using both DB-1 and DB-23 fused-silica capillary columns.

Fractionation of the steam-distilled volatile extract of pepper tree leaves was performed on a Waters LC625 high-performance liquid chromatograph (HPLC) at 1 ml/min with a Waters 486 variable wavelength UV–visible detector system set at 280 nm.

Electron impact ionization mass spectra (MS) were obtained on a Hewlett-Packard 5985B GC-mass spectrometer. NMR spectra of synthesized compounds were recorded with a Bruker 400 MHz instrument after D_2O exchange and chemical shifts were reported in parts per million (ppm). Infrared (IR) spectra were obtained on neat samples (NaCl plates) with a Perkin Elmer 1600 FTIR instrument.

Fractionation of Repellent Extracts

The crude extract of pepper tree leaves was fractionated by HPLC on a Nova pak silica column in a nonlinear step-gradient program to give seven fractions (5 ml each, ether–hexane: 1% at 5 min, 5% from 5 to 10 min, 10% from 10 to 15 min, 15% from 15 to 20 min, 20% from 20 to 25 min, 30% from 25 to 30 min, 100% from 30 to 35 min). Fractions to be subjected to GC analysis were concentrated by evaporation under a stream of nitrogen with ice cooling and were bioassayed on house flies. The behaviorally active fourth fraction obtained with 15% ether–hexane was refractionated by HPLC on a reverse-phase Nova pak C_{18} column (10 fractions, 1 ml each, water–acetonitrile: 15% isocratic for 10 min). Fractions were extracted into pentane, analyzed by GC, and bioassayed. The behaviorally active fourth fraction was refractionated by HPLC on a Nova pak CN-HP column (20 fractions, 0.5 ml each, λ-220 nm, 0.5 ml/min, ether–hexane: 1% at 2 min, 1% to 11% from 2 to 20 min). Fractions were analyzed by GC and bioassayed.

Microscale Analysis

Authentic samples of (1*R*,2*S*,5*R*)-(−)-menthol, (1*S*,2*R*,5*R*)-(+)-isomenthol, and (1*S*,2*R*,5*S*)-(+)-menthol were obtained from Aldrich Chem. Co., Milwaukee, Wisconsin.

Acetylation. The partially concentrated final active fraction was treated with an excess of acetic anhydride (0.3 ml), pyridine (0.3 ml), and 4-dimethylaminopyridine (~5 mg) and stirred overnight at room temperature. The reaction was quenched by adding water and the mixture extracted into hexane (4 × 0.5 ml). The hexane extract was washed successively with 10% HCl (5 × 0.5 ml), water (2 × 0.5 ml), saturated NaCl (0.5 ml), and dried over anhydrous Na_2SO_4, filtered, and concentrated. Product identity was confirmed by matching GC retention times with standards on DB-1 and DB-23 columns of different polarity and GC-MS fragmentation patterns.

Hydrogenation. Hydrogenation of the final active fraction was carried out in a thick-walled Reacti-vial (1 ml) equipped with a tight-fitting Teflon-lined septum. A mixture of the hexane–ether solution of the behaviorally active sample and 10% palladium on carbon (~2 mg) was pressurized with hydrogen and stirred for 1 hr. The product was filtered through glass wool and concentrated. Identification of the products was made by matching GC retention times with standards and GC-MS fragmentation patterns.

Hydrogenation of acetylated products of behaviorally active fractions and acetyl lactyl derivatives of synthetic *trans*-piperitol **(II)** [*trans*-3-methyl-6-(1-methylethyl)-2-cyclohexene-1-ol] were conducted according to the same procedure.

Oxidation. To the sample in dichloromethane (0.4 ml) a small amount of pyridinium chlorochromate (PCC, ~50 mg) was added and stirred for 2 hr at room temperature (Corey and Suggs, 1975). The mixture was diluted with anhydrous ether (0.25 ml), filtered through Florisil and concentrated.

Chiral Determination Using Acetyl S-Lactyl Chloride. Preparation of acetyl lactyl chloride (AclacCl) reagent and derivatization of compound **II** in the concentrated final behaviorally active fraction and synthetic standards were carried out as reported by Slessor et al. (1985). Separation of prepared acetyl lactyl derivatives of *trans*-piperitol was performed by HPLC using a Nova pak silica column (λ-220 nm, 5% ether/hexane isocratic).

Synthesis of cis- *and* trans-*Piperitol* ***(II)***

Piperitone (ICN, Inc., Costa Mesa, California) was reduced with $LiAlH_4$ to provide a mixture of *cis*- and *trans*-piperitol (Wheeler and Chung, 1969). The crude product was separated by column chromatography (Alumina, Fisher, 80–200 mesh) with pentane, ether, and methanol. The ratio of *cis* and *trans* unsaturated alcohols was 33 : 67, and the former eluted with pentane–ether (1 : 1), whereas the latter eluted with ether–methanol (6 : 4).

The first eluted *cis*-alcohol showed 99% purity by GC and exhibited the following spectra: IR (film) 3373, 2927, 2869, 2724, 1673, 1473, 1448, 1383, 1233, 1159, 1129, 1046, 1022, 956, 902, 847, 802 cm^{-1}; *m/e* (relative intensity); 154(M^+, 4), 139(28.5), 121(2.5), 112(9), 111(8), 97(5), 95(5), 94(3), 93(13), 92(2.5), 91(9), 85(7), 84(100), 83(35), 81(6), 79(9), 77(11), 71(9), 69(9), 67(5), 65(4), 56(10), 55(13.5), 53(6), 51(3), 43(13). ^1H NMR ($CDCl_3$) ppm 0.955 (3H, $-CH_3$, d, J = 6.5 Hz), 0.995 (3H, $-CH_3$, d, J = 6.5 Hz), 1.31 (1H, m), 1.6–1.8 (2H, m), 1.69 [3H, $-CH = C(C\underline{H}_3)-$, s] 1.9–2.1 (3H, m), 4.12 [1H, $-C(OH)\underline{H}-$, m], 5.63 (1H, $=C\underline{H}-$, m).

The *trans*-alcohol **(II)** was 99% pure by GC and exhibited the following spectra: IR (film) 3318, 2930, 2871, 2724, 2341, 1676, 1466, 1434, 1384, 1297, 1232, 1158, 1049, 1027, 985, 899, 840 cm^{-1}; *m/e* (relative intensity);

154(M^+, 8.6), 139(39), 136(11), 121(9.5), 112(10), 111(11.6), 97(7), 95(7), 94(6.5), 93(42), 92(10), 91(33), 85(6), 84(100), 83(43), 81(8), 79(16.5), 78(6), 77(34), 71(11.5), 69(12), 67(8), 65(10.6), 56(12), 55(17.4), 53(10), 51(7), 43(22.4). ^{1}H NMR ($CDCl_3$) ppm 0.84 (3H, $-C\underline{H}_3$, d, J = 7 Hz), 0.96 (3H, $-C\underline{H}_3$, d, J = 7 Hz), 1.24 (1H, m), 1.6–1.75 (2H, m), 1.67 [3H, $=C(C\underline{H}_3)-$, s) 1.9–2.05 (3H, m), 4.01 [1H, $-C(OH)\underline{H}-$, d, J = 7.5 Hz), 5.38 (1H, $=C\underline{H}-$, m).

Synthesis of cis-*Menth-2-en-1-ol* ***(I)***

The resulting *cis*-piperitol was converted to compound I by acid catalyzed rearrangement as reported for amitinol (Francke et al., 1980). A solution of 0.5% BF_3 in CH_2Cl_2 (150 ml) at −78°C was added, with stirring, to a solution of *cis*-piperitol (0.5 g, 0.003 mol) (obtained from the previous experiment) in CH_2Cl_2 (5 ml). The mixture was stirred for 2 hr at about −40°C. The reaction was monitored by GC every 15 min. The reaction was quenched with water (100 ml), and the organic layer was separated. The aqueous layer was extracted with CH_2Cl_2 (2 × 25 ml). The CH_2Cl_2 extract was washed with water (4 × 25 ml), saturated $NaHCO_3$ (25 ml), and saturated NaCl (25 ml), and dried over anhydrous Na_2SO_4. The solvent was partially removed on a rotary evaporator.

The mixture was treated with excess acetic anhydride (20 ml) and pyridine (15 ml) and was stirred overnight at room temperature. The reaction was quenched with water (50 ml) and the mixture extracted with hexane (4 × 25 ml). The hexane extract was washed with water (6 × 25 ml), and saturated NaCl and dried over anhydrous Na_2SO_4. The solution was filtered, evaporated and chromatographed on a silica gel column with hexane–ether (8:2), yielding 0.13 g of product with 99% purity by GC. This product exhibited the following spectra: IR (film) 3353, 2959, 2871, 1744, 1726, 1643, 1464, 1384, 1368, 1230, 1206, 1170, 1122, 1105, 1084, 1063, 1012, 996, 968, 944, 906, 863, 818, 807, 734 cm^{-1}; *m/e* (relative intensity); 154(M^+, 6.4), 139(39), 136(17.5), 121(30), 111(38), 107(8), 97(13), 96(12), 95(25), 94(45), 93(65), 92(17), 91(29), 86(6), 84(33), 83(33), 82(7), 81(44.5), 80(9.5), 79(64), 78(8), 77(37), 71(65), 70(7), 69(55), 68(8), 67(27), 66(6.5), 65(14), 58(12), 57(6), 55(31), 53(11.5), 51(7), 45(5), 43(100). ^{1}H NMR ($CDCl_3$) ppm 0.89 (3H, $-C\underline{H}_3$, d, J = 7 Hz), 0.91 (3H, $-C\underline{H}_3$, d, J = 7 Hz), 1.27 [3H, $-C(OH)C\underline{H}_3-$, s), 1.35–1.55 (2H, m), 1.65 (2H, m), 1.85 (2H, m), 5.65 (2H, m).

RESULTS AND DISCUSSION

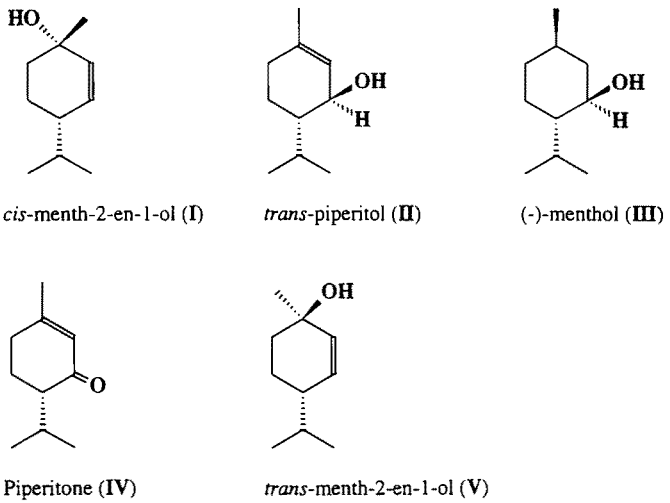
Maximal activity in 6-min bioassays was obtained with 0.3 mg of steam-distilled oils. Only fraction 14 of the final HPLC fractionation was behaviorally active on house flies and its GC trace showed two major compounds, **I** and **II**

(Figure 1) (3.81 and 4.91 min, respectively, DB-1 column, 30 m × 0.25 mm ID, 2 min at 80°C, 10°C/min to 210°C). Compounds **I** and **II** were present in 0.2% and 0.03% in the steam-distilled oils of pepper tree as determined by GC.

Compounds **I** and **II** had been observed in all fractions exhibiting repellent activity but in different ratios throughout the fractionations, suggestive of compound lability and interconversion.

Identification of I and II. The MS spectra of compounds **I** and **II** indicated the molecular weight of both compounds as 154, corresponding to a molecular composition of $C_{10}H_{18}O$ with two degrees of unsaturation. The fragmentation patterns in both spectra indicated the loss of a methyl (*m/e* 139) and water (*m/e* 121), indicating the presence of both methyl and hydroxyl functionalities. Analysis of the acetylated product of the behaviorally active fraction by GC indicated two major detector responses, one at a retention time identical to compound **I** and another with a retention time (6.70 min) later than compound **II.** The mass spectrum of the early retention compound was identical to that of compound **I,** indicating that compound **I** had not been acetylated and was suggestive of a tertiary alcohol, whereas the acetylation of compound **II** was suggestive of the presence of a primary or secondary alcohol.

Hydrogenation of the biologically active fraction showed three major GC peaks (3.98, 4.45, and 4.66 min), all of which were different from the **I** and **II.** Only the earliest-eluting peak was identical to that obtained from hydrogenation of the acetylated fraction, indicating that it was derived from the unace-



cis-menth-2-en-1-ol (I) *trans*-piperitol (II) (-)-menthol (III)

Piperitone (IV) *trans*-menth-2-en-1-ol (V)

FIG. 1. Structures of compounds **I** and **II** isolated from pepper trees, and related compounds.

tylated tertiary alcohol, **I.** The presence of only one hydrogenated product from **I** seemed to infer a disubstituted ring double bond, which would not lead to stereoisomers on reduction. The secondary alcohol, **II,** on the other hand, generated two stereoisomers, indicating the presence of a trisubstituted double bond. One of the products of the hydrogenation of **II** gave GC retention (4.45 min) and MS data identical to menthol (**III,** Figure 1), providing a ring size and substitution pattern for **II.** Oxidation of **I** and **II** produced a single product whose GC retention times (5.39 min) and MS fragmentation pattern was identical to piperitone (**IV,** Figure 1). The secondary alcohol **(II)** present in the behaviorally active fraction must therefore be *trans*-piperitol.

The hydroxyl group of piperitol migrates between the C-1 and C-3 positions in acidic media (Clark et al., 1977), suggesting either *cis* or *trans*-menth-2-en-1-ol as the structure of the tertiary alcohol **I.** Synthetic *cis*-menth-2-en-1-ol and *trans*-piperitol showed identical GC retention characteristics on two different column phases (DB-1 and DB-23) and gave identical MS fragmentation patterns to the two behaviorally active alcohols **I** and **II.**

Determination of Chirality of trans-Piperitol from Pepper Trees. The acetyl-lactated product of synthetic *trans*-piperitol (**VII, XII,** Figure 2) showed two signals in the gas chromatogram. Hydrogentation of HPLC separated diastereomers (**VIII, XIII,** Figure 2) each generated two compounds (**IX** and **X, XIV** and **XV,** Figure 2) with distinct GC retention times (DB-1 column, 30 m × 0.25 mm ID, 145°C isothermal, 5.10, 5.25, 5.19, and 5.31 min for **IX, X, XIV,** and **XV,** respectively) and appropriate MS fragmentation patterns. GC retention times and MS fragmentation of the products **IX, XIV,** and **XV** corresponded to those of the acetyl lactates of authentic samples of (1*R*,2*S*,5*R*)-(−)-menthol **(XVI),** (1*S*,2*R*,5*S*)-(+)-menthol **(XVII),** and (1*S*,2*R*,5*R*)-(+)-isomenthol **(XVIII),** respectively, indicating that compounds **XIII** and **VIII** were the acetyl lactates of (1*R*,6*R*)-piperitol and (1*S*,6*S*)-piperitol. Derivatization of the final behaviorally active fraction produced a single product that was identical in GC retention time and MS fragmentation to that of compound **VIII.** Hydrogenation of **VIII,** derived from the natural compound **II,** produced two products identical with those of compounds **IX** and **X,** respectively. These results established the structure of compound **II** to be (1*S*,6*S*)-piperitol.

Bioassay of Synthetic Compounds. Synthetic compounds *cis*-menth-2-en-1-ol **(I)** and *trans*-piperitol **(II)** had both repellent and feeding deterrent effects on house flies, eliciting maximum response at doses of 1 and 0.1 mg, respectively (Table 1). The latter repressed both sustained contacts and extension of the probosis for the full 6-min test period, whereas the former induced such a maximal response for only 4 min at the 0.1-mg dose. Thus, *trans*-piperitol appears to be the major repellent in steam-distilled volatile extracts of pepper tree leaves.

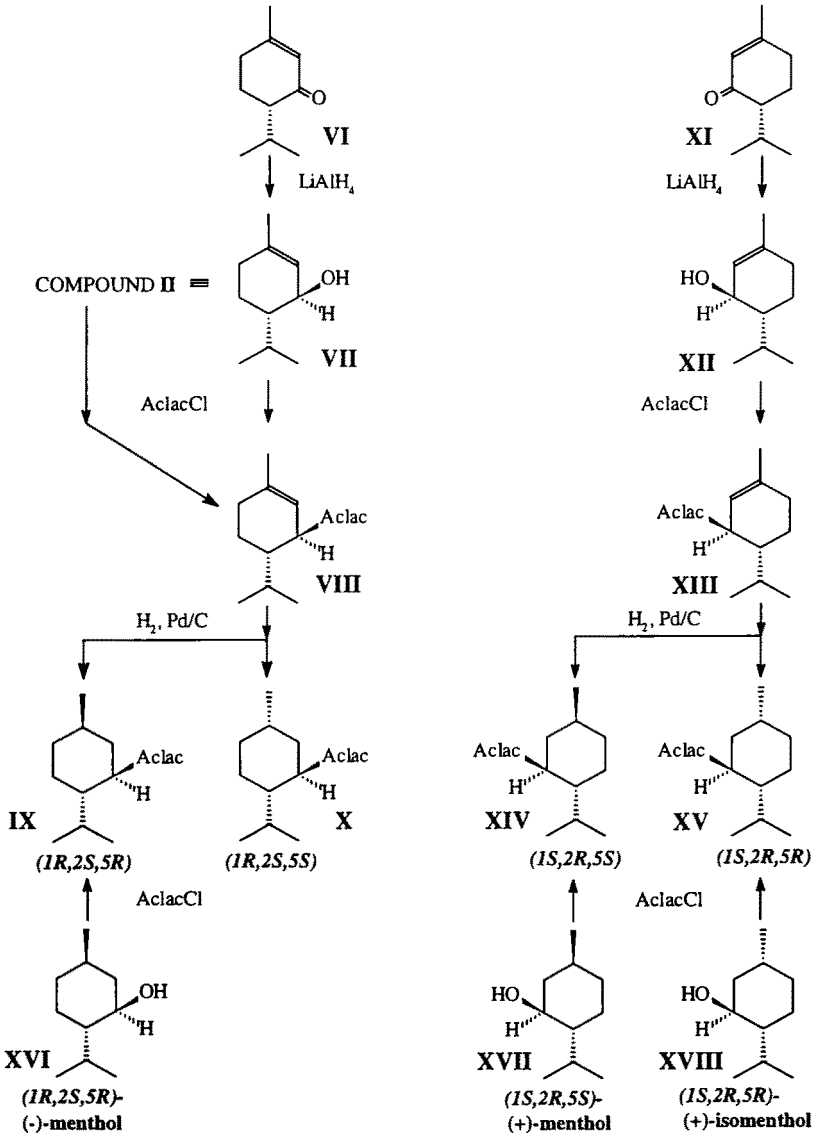


FIG. 2. Determination of chirality of compound **II**.

TABLE 1. RESPONSE OF HOUSE FLIES TO SUGAR-COATED SOLVENT CONTROL STATIONS IN TWO-CHOICE LABORATORY BIOASSAYS[a]

Dose (mg/25 μl)	Percent of total sustained contacts on solvent control station[b]			
	Crude pepper tree oil	Compound **I**	Compound **II**	1 : 1 ratio mixture of **I** and **II**
0.001	—	62***	60***	60***
0.01	—	78**	66***	83**
0.05	—	—	—	100
0.1	—	93	100	100
0.8	100	—	—	—
1	—	100	100	—

[a]One of the sugar-coated experimental stations was treated with various doses of crude pepper tree oil or synthetic compounds **I** (*cis*-menth-2-en-1-ol), **II** (*trans*-piperitol) and 1 : 1 ratio mixture of **I** and **II**.

[b]Significant differences (*z* test) from those to the crude pepper tree oil indicated by $^{**}P < 0.01$ or $^{***}P < 0.001$.

A higher response was observed for the binary mixture of the alcohols than for the individual compounds, eliciting maximum response to 0.05-mg doses, and complete repellency for 4 min to 0.01-mg doses. Volatility and evaporation of the pure alcohols is the likely cause of the decline in activity observed at low concentrations in comparison to extracts that contain many other components acting in a "keeper" role.

Practical Implications. The bioactivity of **I** and **II** suggests that they could be the basis for the folkloric use of cut pepper tree leaves and branches to repel house flies in Ethiopia. However, their volatility and hence short-lived activity in pure form indicates that they would need to be prepared in a very well-controlled, slow-release formulations to have any practical utility. It has recently been found that a powder made from green pepper tree berries can protect bean seeds, *Phaseolus vulgaris* L., for at least three months from infestation by bruchid beetles (T. Abate, unpublished results). This finding suggests that **I** and **II** released at slow rates from the green seed powder could have repellent properties for insects other than house flies. Alternatively, there may be additional volatile or nonvolatile components in pepper tree berries that have potential practical use as insect repellents.

(Received June 15, 1995; accepted August 24, 1995)

Abstract—We examined the effects of inhibitors of the octadecanoid pathway (*n*-propyl gallate, acetosalicylic acid, salicylhydroxamic acid, methyl salicylate, and antipyrine) on wound- and jasmonate-induced nicotine accumulation and compared the nicotine-inducing ability of exogeneous additions of linolenic acid (18:3) and its methyl ester, linoleic acid (18:2), abscisic acid, traumatic acid, and methyl dihydrojasmonate to the nicotine-inducing ability of exogenous additions of methyl jasmonate (MJ). The first four of these inhibitors significantly reduced wound-induced nicotine accumulation when applied in a lanolin paste to wounded tissues immediately after wounding at concentrations of 89–90 μg/plant. When methyl salicylate and propyl gallate were mixed individually with MJ, neither inhibited MJ-induced nicotine synthesis, which suggests that the inhibitors block jasmonate synthesis or release from stored pools and not its effects. Linolenic acid or its methyl ester applied to undamaged plants or damaged plants (to either damaged or undamaged leaves) or to the roots of hydroponically growing plants did not induce nicotine accumulation or increase nicotine accumulation above levels found in damaged plants. Similarly, traumatic acid, linoleic acid, and abscisic acid did not induce nicotine accumulations. Methyl dihydrojasmonate, which is biosynthetically derived from linoleic acid, had 12–56% of the nicotine-inducing acitivity of MJ when added to the roots of hydroponically grown plants. The signal transduction pathway mediating wound-induced nicotine production therefore shares many features of the pathway eliciting wound-induced proteinase inhibitor production but differs in not being regulated at the lipase step in jasmonic acid production and not being responsive to abscisic acid.

Key Words—Induced defense, *Nicotiana sylvestris*, nicotine, methyl jasmonate, linolenic acid, abscisic acid, methyl dihydrojasmonate.

INTRODUCTION

Nicotiana sylvestris is an annual that accumulates nicotine at 0.1–1% leaf dry mass in undamaged plants, but after real or simulated folivory, nicotine concentrations in remaining leaves increase dramatically to attain concentrations (1–4%) that are sufficient to protect induced tissues from nicotine-adapted insect herbivores in laboratory feeding trials (Baldwin, 1988a–c, 1989, 1991). The induced increase in whole-plant nicotine pools is thought to result primarily from increases in *de novo* synthesis. Leaf damage results in threefold increases in the rates of *de novo* nicotine synthesis as determined with ^{15}N pulse-chase techniques (Baldwin et al., 1994b). Diverse experiments indicate that nicotine is synthesized largely in the roots and transported to the shoot in the xylem stream. For example, when the roots and shoots of nicotine- and non-nicotine-producing species are grafted together in different combinations, only the combinations with nicotine-producing roots accumulate nicotine in substantial quantities (Dawson, 1942; Baldwin, 1991). Leaf damage dramatically increases the amount of nicotine exported from the roots in the xylem stream of tobacco plants (Baldwin, 1989; Baldwin et al., 1993). Induced increases in nicotine accumulation are inhibited in plants whose stems have been steam girdled below the leaf damage (Baldwin, 1989). Last, the distribution of nicotine's biosynthetic enzymes is consistent with nicotine synthesis in roots. Wagner et al. (1986) and Feth et al. (1986) determined that putrescine *N*-methyltransferase (PMT) was the key regulatory enzyme in nicotine biosynthesis, that roots had higher PMT activity than shoots, and that PMT activity was stimulated by damage to the shoot (Mizusaki et al., 1973; Saunders and Bush, 1979; Wagner et al., 1986). The sequence of the PMT gene from *N. tobaccum* has recently been determined: the mRNA coding for the PMT is found only in root tissues and the amount of mRNA increases after damage to the shoot (Hibi et al., 1994).

This large separation between the site of nicotine synthesis and the site of herbivore attack requires a long-distance signal transduction pathway, and some advances have been made in understanding this signal transduction pathway. The damage cue is a positive cue and correlates with the amount of damage a plant receives (Baldwin, 1989; Baldwin and Schmelz, 1994). The fact that it can be blocked by steam girdling the stem of a plant below the site of damage suggests that it is phloem-borne: steam kills the phloem but leaves the xylem intact. The damage signal is relatively slow-moving, taking more than 1 hr to leave a damaged leaf. This makes an electrical damage signal unlikely (Baldwin et al., 1994a). Because the *de novo* rates of nicotine synthesis increase 10 hr after leaf damage (Baldwin et al. 1994a,b), the signal that effects these changes in root nicotine metabolism must travel from damaged leaves to the roots within this time period. Jasmonic acid (JA) is intimately involved in the signal transduction cascade, because leaf damage rapidly (<0.5 hr) increases shoot JA

pools and, more slowly (<2 hr), root JA pools. JA levels subsequently decay to levels found in undamaged plants within 24 hr and 10 hr for shoots and roots, respectively. Moreover, additions of JA to roots as its methyl ester, MJ, increase *de novo* nicotine synthesis from $^{15}NO_3$ in a manner similar to that induced by leaf damage; and additions of MJ to the shoots mimic both the timing of changes in pool size induced by damage and the magnitude of increased nicotine synthesis. It is not yet known if the wound-induced JA in the shoot is directly transported to the roots or if some other indirect signal pathway is involved. In tomato, the octadecapeptide, systemin, stimulates the wound-induced increase in proteinase inhibitors (PIs) by increasing the pools of JA (Farmer et al., 1994). A similar transduction pathway may be also be responsible for wound-induced nicotine production. Hence, the working model for the long-distance signal transduction cascade is that wounding increases the shoot pool of jasmonates, which, either directly through transport or indirectly through a systemin-like signal, increases the jasmonate pool in the roots; these, in turn, stimulate root nicotine synthesis and increase whole-plant nicotine pools (Figure 1).

The signal transduction pathways responsible for inducing PIs in tomato and potato and of benzo[*c*]phenanthridine alkaloids in tissue culture are better understood than the wound-induced production of nicotine in tobacco in four important regards. First, in the PI system, the addition of mammalian cyclooxygenase (COX) and lypoxygenase (LOX) inhibitors to wounded tissues, which are thought to inhibit lypoxygenases or hydroperoxide dehydrases in the biosynthesis of JA from linolenic acid (LA), inhibit induced PI production and inhibit the wound-induced increase in jasmoantes (Peña-Cortés et al., 1993, 1995). Moreover, the addition of diethyldithiocarbamic acid (DIECA), which reduces 13-hydroperoxylinolenic acid to the hydroxylinolenic acid and thereby scavenges substrates from the jasmonate biosynthetic pathway, inhibits both the wound- and systemin-induced increase in PIs (Farmer et al., 1994). These results demonstrate that jasmonate synthesis from LA to the production of 12-oxophytodienoic acid (Figure 1) is a necessary requirement for wound-induced PI production. Second, in the PI system (Farmer and Ryan, 1992), as well as in other jasmonate-induced responses, such as the tendril-coiling response of *Bryonia dioica* (Falkenstein et al., 1991), the induced responses appear to be regulated at the lipase step in the biosynthesis of jasmonates because the addition of exogenous LA to plants induces the responses. Third, the common plant hormone, abscisic acid (ABA) activates the wound-induced production of PI II in tomato and potato (Hildmann et al., 1992; Peña-Cortés et al., 1995). Fourth, a second lipid cascade starting with linoleic acid via 15, 16-dihydro-12-oxophytodienoic acid to 9,10-dihydrojasmonic acid (dhJA) is also active in the induction of the enzymes in the benzo[*c*]phenanthridine alkaloid biosynthetic pathway in tissue culture (Blechert et al., 1995). In these well-described model systems, wounding, signal production, and response occur in the same tissues. Without

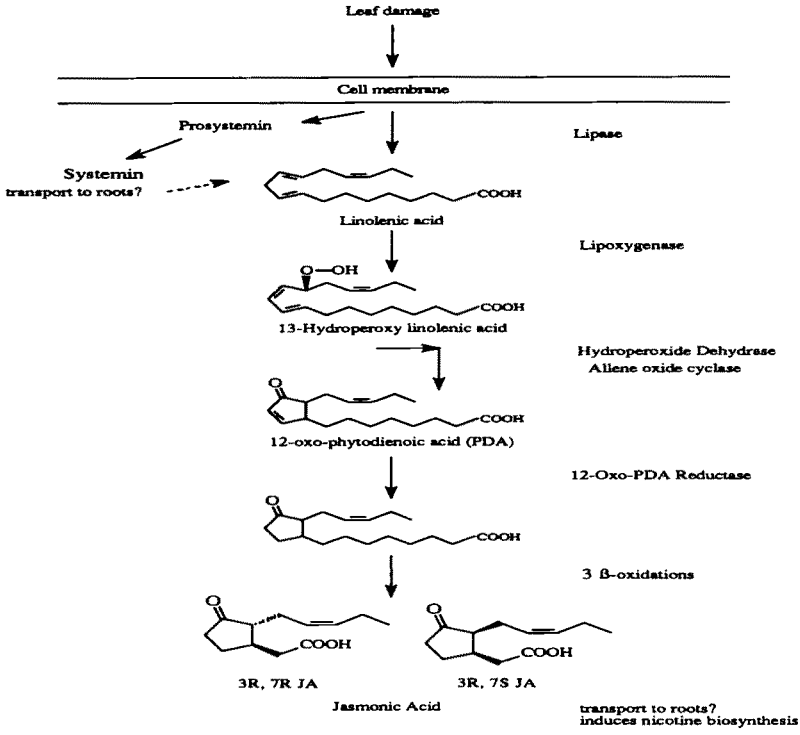

FIG. 1. Biosynthesis of jasmonic acid (JA). For the nicotine system, we have established that leaf damage increases endogenous pools of JA first in the shoots and 2 hr later in the roots (Baldwin et al., 1994a). The stereoconfiguration of carbon-3 and -7 of the induced JA pool remains unresolved; the two naturally occurring isomers are depicted. Exogeneous addition of methyl jasmonate to leaves mimics both the wound-induced changes in JA in the root and shoot and the changes in nicotine pools.

a large spatial separation between the sites of damage and the wound-induced responses, local and systemic transduction pathways are difficult to untangle.

Here we explore these four aspects of the signal transduction pathway mediating wound-induced nicotine production. Specifically, we report experiments that examine the effect of: (1) mammalian LOX and COX inhibitors on wound- and jasmonate-induced nicotine accumulation; and (2) exogenous additions of LA and its methyl ester (Me-LA), linoleic acid, ABA, traumatic acid, and methyl dihydrojasmonate (dhMJ) on induced nicotine accumulation. We examine the effect of traumatic acid, because it is a derivative of 13-hydroperoxy

linolenic acid, which, to our knowledge, has not been examined in any wound-induced defense response. Traumatic acid is known to stimulate leaf abscission in cotton (Strong and Kruitwagen, 1967) but has largely been ignored in the recent surge of interest in the function of octadecanoid metabolites (Farmer, 1994).

METHODS AND MATERIALS

Chemicals. MJ and dhMJ were obtained from Bedoukian Research (Danbury, Connecticut). We determined by GC-MS analysis that MJ was close to the thermodynamic equilibrium for the epimers of MJ (Mueller and Brodschelm, 1994): 90.1% 1*R*,2*R* MJ and 8.3% 1*R*,2*S* MJ. The dhMJ contained 98.14% 1*R*,2*R* dhMJ and 1.86% 1*R*,2*S* dhMJ and did not contain detectable quantities of MJ. All plant nutrients and other chemicals used were purchased from Sigma Chemical Co. (St. Louis, Missouri); oxygen-sensitive compounds were stored under nitrogen at −20°C.

Plant Growth. We report the results of eight experiments. The plants used in each experiment were grown in hydroponic culture with the following protocol: *Nicotiana sylvestris* Spegazzini and Comes seeds were germinated and grown in Cornell mix A (Boodley and Sheldrake, 1977) for 15–20 days, after which they were transferred to 40-liter hydroponic boxes containing a complete nutrient solution [0.292g/liter Peter's Hydro-sol (W.R. Grace, Inc., Fogelsville, Pennsylvania), 0.193g/liter $CaNO_3$, and 70m/liter of a nitrogen-free nutrient solution (described in Ohnmeiss and Baldwin, 1994)] for three to four days. To reduce between-plant genetic variance, we used seeds that were full sibs. Plants were transferred to individual opaque 1-liter containers with the nitrogen-free nutrient solution that was supplemented with KNO_3 to produce a 2.0 mM solution. Solutions in the 1-liter containers were maintained at 900–1000 ml with additions of the no-nitrogen nutrient solution. All plants were grown in a glasshouse with supplemental lighting from 400-W sodium-vapor lamps for 16 hr/day, which provided a minimum PAR of 220 μmol photons m^{-2} s^{-1}. After 8–12 days of growth in the individual containers, plants were weighed. Plants with the most similar masses and morphologies were assigned to treatment groups of five plants each, sorted according to wet mass, and assigned to treatment groups by consecutive random divisions (as described in Ohnmeiss and Baldwin, 1994). This consecutive random allocation of plants produced groups with plant wet mass means that were not significantly different on day 0, the start of each experiment. Plants were randomly assigned to positions on the glasshouse bench independently of their treatment. The nitrogen-free nutrient solution of each individual plant chamber was supplemented with KNO_3 to produce a 0.5 mM solution on day 0, and all plants were harvested on day 5,

the time when maximum damage-induced nicotine production had occurred after a single damage event (Baldwin et al., 1994b).

Leaf Damage. Reproducible amounts of leaf damage were produced by rolling a pattern-tracing wheel (Dritz Spartanburg, South Carolina) across two leaves at phylotactically adjacent positions 3 and 4 (with the apical leaf designated as position 1). Each leaf received eight rows of evenly distributed tracing-wheel damage on each side of the mid-rib over a 4-cm length of the lamina in the middle of the lamina. On average, tracing-wheel damage resulted in 4.5 1-mm^2 punctures/cm of leaf and killed the cells in the puncture zone. Punctures were produced by crushing leaf tissue between the blunt spokes of the tracing wheel and a plastic card, and resulted in minimal vasculature damage and undetectable leaf dry mass loss or reductions in biomass gain (Ohnmeiss and Baldwin, 1994; Baldwin and Schmelz, 1994). In all experiments in which leaves were treated with compounds in a lanolin paste, lanolin was spread on all plants in the area to be damaged and the tracing wheel was rolled over the area treated with lanolin.

Application of Chemicals to Plants. Chemicals were applied to plants in either lanolin pastes on leaves or in aqueous solutions applied in the hydroponic growth medium. Lanolin pastes were applied to the adaxial surface of leaves occupying positions 3 and 4 from the apical leaf. The lanolin (0.093 $\pm$ 0.001 g/plant) was spread with a plastic applicator in a thin layer spanning the middle 4 cm of the lamina and was divided equally between the two leaf positions. Control untreated plants and damaged plants had the same leaf positions treated with the same amount of pure lanolin. Lanolin pastes, containing precisely quantified amounts of the chemicals to be added to plants, were prepared less than 2 hr before their application. They were prepared by liquefying lanolin in a warm (50°C) water bath, adding the chemical, stirring vigorously, and weighing (on wax paper) aliquots to be added to each plant. The amount of chemicals added to each plant is presented (micrograms) in the figure captions.

Whole-Plant Nicotine Concentrations. On day 5 of each experiment, plants were separated into roots and shoots, frozen in liquid nitrogen, lyophilized, weighed (to 0.1 mg), and ground to a fine powder (850 μm mesh) in a Wiley mill (Thomas Scientific, Swedesboro, New Jersey). Nicotine analysis was modified from Baldwin (1988c) to obtain whole-plant nicotine measures. A weighed portion (approximately 50 mg) of lyophilized and homogenized plant was extracted for three days in 10.0 ml of aqueous alkaloid extraction solution (40% methanol, 0.1% HCl). Nicotine contents of these extracts were determined by HPLC with external standard curves run with each experiment. Whole-plant nicotine concentrations were calculated from biomass values and whole-plant nicotine pools.

Statistical Analysis. Nicotine concentrations were arcsine-transformed before statistical analysis. One-way ANOVAs with treatments as main effects

were performed for biomass and nicotine concentration parameters, and contrasts among treatment groups were constructed from the one-way ANOVAs. All data analyses were performed with the MGLH module of the SYSTAT statistical package (Evanston, Illinois).

RESULTS

Effects of Inhibitors. Three inhibitors (ibuprofin, mefenamic acid, and DIECA applied at 90, 98, and 93 μg/plant, respectively) killed cells in the leaf five days after the lanolin paste containing these compounds were applied. The damage caused by these inhibitors likely overwhelmed any effect the inhibitors might have had on the mechanical wounding of the leaf, and these treatments were dropped from the analysis. Five inhibitors (Figure 2) caused no visible damage to the leaves on which they were applied, and undamaged plants treated with the same amounts of each inhibitor had nicotine concentrations not different from plants treated only with pure lanolin ($F_{1,24} = 0.234$). Wounded plants treated with pure lanolin had nicotine concentrations significantly higher than unwounded plants treated with pure lanolin ($F_{1,28} = 8.34$; $P < 0.0074$) and

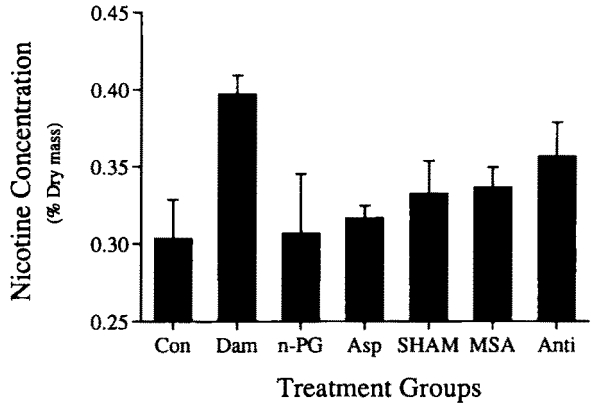

FIG. 2. Mean (±SEM) whole-plant nicotine concentrations of undamaged plants with leaves treated with pure lanolin (Con) and plants damaged with a tracing wheel where the damaged areas of the leaves were thinly coated with either pure lanolin (Dam) or lanolin containing 89–91 μg/plant of the following mammalian LOX and COX inhibitors: *n*-propyl gallate (*n*-PG); acetosalicylic acid (Asp); salicylhydroxamic acid (SHAM); methyl salicylate (MSA); and antipyrine (Anti). Plants were harvested for alkaloid analysis five days after treatment applications.

wounded plants treated with 89–90 μg/plant of either propyl gallate (*n*-PG), aspirin, SHAM, or methyl salicylate (MSA) ($F_{1,28} = 8.10$; $P < 0.0082$). Wounded plants treated with the latter four inhibitors had nicotine concentrations not significantly different from unwounded plants ($F_{1,28} = 0.651$; $P < 0.426$). Wounded plants treated with 91 μg/plant of antipyrine had nicotine concentrations not sigificantly different from wounded plants ($F_{1,28} = 1.44$; $P < 0.239$).

In a second experiment (Figure 3), the ability of two inhibitors (*n*-PG and MSA) to inhibit both wound- and MJ-induced responses were examined. Again, wounding significantly increased nicotine concentrations above unwounded controls ($F_{1,28} = 12.06$; $P < 0.0001$), and the two inhibitors applied at 90 μg/plant significantly suppressed the wound-induced nicotine accumulation ($F_{1,28} = 4.42$; $P < 0.002$). Unwounded plants treated with 90 μg/plant of MJ mixed with an equal amount of either MSA or *n*-PG had nicotine concentrations not

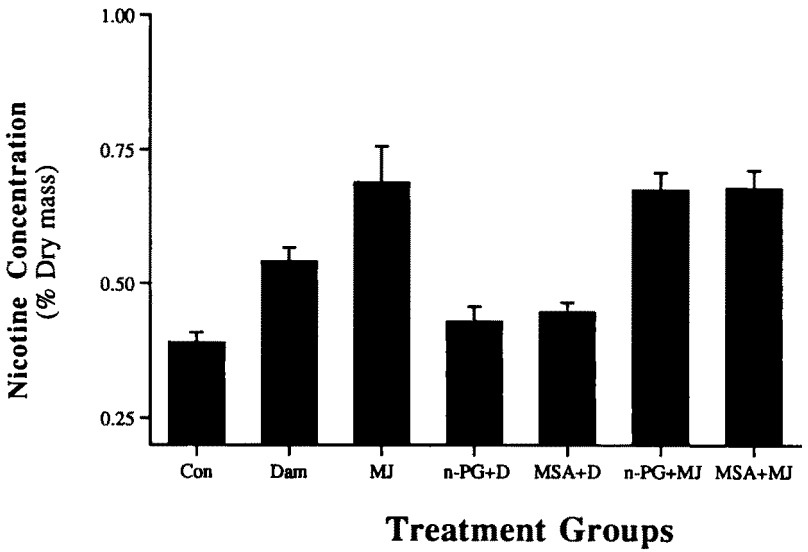

FIG. 3. Mean (±SEM) whole-plant nicotine concentrations of undamaged plants with leaves treated with pure lanolin (Con), lanolin containing 90 μg/plant of *n*-propyl gallate and 90 μg/plant of methyl jasmonate (*n*-PG + MJ), or 90 μg/plant of methyl salicylate and 90 μg/plant of methyl jasmonate (MSA + MJ). Plants also were damaged with a tracing wheel and the damaged areas of the leaves were thinly coated with either pure lanolin (Dam), lanolin containing 90 μg/plant of *n*-propyl gallate (*n*-PG + D), or methyl salicylate (MSA + D). Plants were harvested for alkaloid analysis five days after treatment applications.

significantly different from those treated with MJ alone ($F_{1,28} = 0.019$ and 0.037, respectively). These results demonstrate that putative LOX or hydroperoxide dehydrase inhibitors can quantitatively suppress a wound-induced response but do not suppress MJ-induced increases in nicotine at the applied concentrations.

Effects of Fatty Acids, Abscisic Acid and Traumatic Acid. Abscisic acid (ABA), MJ, and JA were applied to unwounded plants at 186 μg/plant (Figure 4A). This was the highest concentration of ABA that did not significantly inhibit growth five days after application as determined from a preliminary experiment. JA, MJ, and wounding significantly increased nicotine concentrations above unwounded controls ($F_{1,26} = 5.03$–7.84; $P < 0.0034$). The nicotine concentration of plants treated with ABA did not differ from controls ($F_{1,26} = 0.19$).

The nicotine concentration of unwounded plants treated with 90, 900, and 2300 μg/plant LA (Figure 4B and D) or with 915 μg/plant of the methyl ester of LA (Me-LA; Figure 4B) applied to their leaves did not differ significantly ($F_{1,20} = 0.0223$ and $F_{1,12} = 1.85$) from control plants treated only with lanolin. Similarly, wounded plants with LA applied to phylotactically adjacent unwounded leaves at position 5 had nicotine concentrations (Figure 4C) not significantly different from wounded controls ($F_{1,24} = 1.02$). Wounded plants treated with LA directly to the wounds (Figure 4B) had nicotine concentrations lower than wounded controls ($F_{1,24} = 5.35$; $P = 0.029$) but higher than unwounded controls ($F_{1,24} = 4.58$). Plants treated with traumatic acid at 300 μg/plant or linoleic acid at 2300 μg/plant (Figure 4D) had nicotine concentrations not sigificantly different from control plants ($F_{1,28} = 0.21$). Nicotine production was therefore not induced by the addition of fatty acids, ABA, or traumatic acid to leaves in lanolin pastes in a manner comparable to nicotine inductions resulting from the addition of MJ or JA in lanolin pastes. Experiments with the addition of LA in DMSO, detergents, or directly without a carrier to leaves caused substantial amounts of cell death at the site of application and therefore could not be used.

To test the hypothesis that failure of LA to induce nicotine synthesis might be because it is not transported from sites of wounding in the shoot to sites of nicotine synthesis in the roots, we added Me-LA to the roots of hydroponically growing plants. Additions of Me-LA at 10, 100, or 200 μg/plant did not affect plant growth or nicotine concentrations (Figure 5: $F_{1,60} < 0.14$). The addition of LA to the roots at 10 μg/plant inhibited growth in a preliminary test and therefore the free fatty acid could not be used.

MJ and dhMJ Comparison. MJ was found to be significantly more active in inducing plants than dhMJ at all concentrations tested (Figure 5). At 10 μg/plant dhMJ was 12.5% as active as MJ; at 50 μg/plant, 33.6%; at 100 μg/plant, 42.2%; and at 200 μg/plant, 56.4% as active.

Treatment Groups

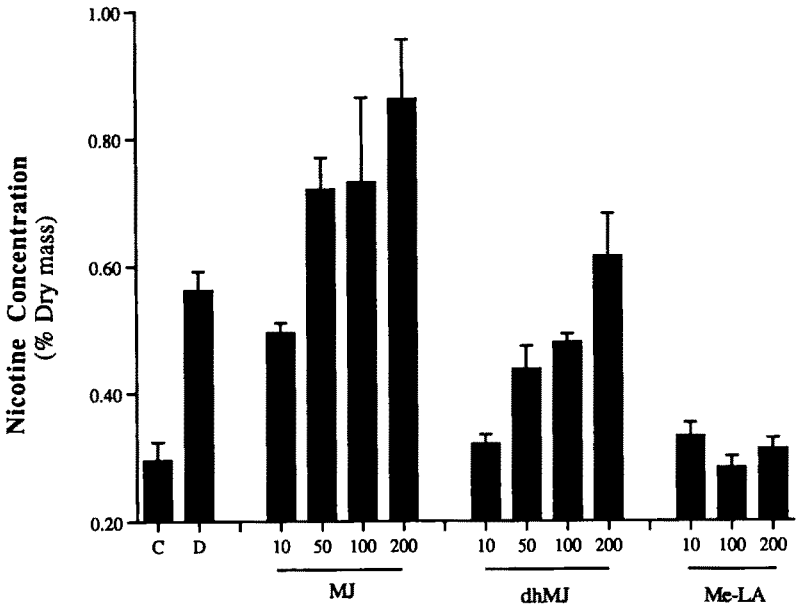

FIG. 5. Mean (±SEM) whole-plant nicotine concentrations of undamaged plants (C), plants damaged with a tracing wheel (D), and undamaged plants that had 10, 50, 100, or 200 μg/plant of methyl jasmonate (MJ) or methyl dihydrojasmonate (dhMJ) or 10, 100, or 200 μg/plant of linolenic acid methyl ester (Me-LA) added to the hydroponic solution of each plant. Plants were harvested for alkaloid analysis five days after treatment applications.

FIG. 4. Mean (+SEM) whole-plant nicotine concentrations of undamaged plants with leaves treated with pure lanolin (Con); plants damaged with a tracing wheel where the damaged leaf areas were thinly coated with either pure lanolin (Dam) or lanolin containing 90 μg/plant of linolenic acid (LA 90 + D); and undamaged plants each treated with lanolin containing 186 μg of jasmonic acid (JA-186), 186, 90, or 45 μg of methyl jasmonate (MJ-186, MJ-90, MJ-45), 186 μg of abscisic acid (ABA-186), 90, 900, or 2300 μg of linolenic acid (LA-90, LA-900, LA-2300), 915 μg of linoleic acid methyl ester (MeLA-915), 2300 μg of linoleic acid (LE-2300), or 300 μg of traumatic acid (TA-300). For all of the above treatments, damage and lanolin applications were performed on leaves in positions 3 and 4 from the apical leaf. For treatments in panel C labeled "LA on Different Leaf," leaf position 4 was damaged and lanolin containing either 90 μg (LA 90 + D) or 900 μg (LA 900 + D) of linolenic acid was applied to the leaf in position 3 of each plant. Plants were harvested for alkaloid analysis five days after treatment applications.

DISCUSSION

Mammalian LOX and COX inhibitors inhibit the wound-induced accumulation of nicotine when applied to the wound site but are not able to inhibit MJ-induced accumulations (Figures 2 and 3). These results are consistent with the requirement of wound-induced jasmonate synthesis for nicotine induction and suggest that the inhibitors function by inhibiting steps upstream of JA synthesis in the octadecanoid pathway. These results are similar to those found in the PI system (Peña-Cortés et al., 1993, 1995) but should be interpreted cautiously. The effect of inhibitors on jasmonate pools in damaged leaves and on their transport to the roots needs to be examined before we can conclude that wound-induced jasmonate synthesis is a necessary step in the pathway leading to wound-induced nicotine production.

While the results of the inhibitor experiments highlight similarities between the induced-nicotine and -PI systems, the results of the fatty acid addition experiments (Figures 4 and 5) demonstrate that the signal cascade activating induced nicotine production differs subtly from that responsible for the induction of PIs in two regards. First, the plant hormone, ABA, which induces PI II genes (Hildmann et al., 1992), does not induce nicotine production in concentrations (300 μg/plant) 10 times that required to induce nicotine production with MJ or JA (Baldwin et al., 1994a) (Figure 5). Second, the exogenous addition of LA, the 18:3 fatty acid precursor of JA (Figure 1), or its methyl ester to leaves does not induce nicotine production, as it clearly does in the PI system (Farmer and Ryan, 1992) or in the tendril-coiling response of *Bryonia* (Falkenstein et al., 1991). One way to reconcile the differences in effects of LA on the different systems is that in the PI system, PIs are produced in the shoot and adding LA may increase local JA production and local PI synthesis. In the nicotine system—where the response occurs primarily in the distal tissues, namely the roots—adding LA may indeed induce JA synthesis locally. If JA is not transported to the roots, however, it would not affect nicotine synthesis. This possible reconciliation was clearly falsified by the addition of the fatty acid to the roots (Figure 5), where it was found to be inactive. We found that the addition of LA at high concentrations in lanolin pastes or detergents caused extensive cell death at the application site, and it is possible that the activity of LA in some tests may be due to "wounding." More plausible is the possibility that in the PI system, inducible JA synthesis is regulated at the lipase step and at some point later in the pathway in the nicotine system.

The results presented here also demonstrate that dhMJ, the product of the parallel octadecanoid pathway starting from the related 18:2 fatty acid, linoleic acid, was active in inducing nicotine synthesis, but only 12–56% as active as MJ in inducing nicotine synthesis. dhMJ is also less active than MJ in inducing the enzymes of the benzo[*c*]phenanthridine alkaloid biosynthetic pathway

(Blechert et al., 1995). Since the supply of MJ and dhMJ used in these experiment differed slightly in the ratio of their respective 1*R*,2*R* and 1*R*,2*S* epimers, the possibility exists that the difference in activities is due to the difference in epimers. We find this possibility unlikely because we have found no difference in the nicotine-inducing activity of the two naturally occurring epimers of JA (Figure 1) under experimental conditions similar to those reported here (Zhang and Baldwin, unpublished results). Since the exogeneous addition of linoleic acid, like the addition of LA, also failed to induce nicotine accumulations (Figure 4D), it appears that the pathway leading to dhJA synthesis is also regulated after the lipase step. This conclusion is contingent on the demonstration that dhJA pools are induced by damage.

The octadecanoid pathway in plants, like the prostaglandin pathway in animals, elicits a diverse suite of responses, many of which relate to wounding and microbial attack. The fact that the plant pathway can be inhibited by LOX and COX inhibitors used by humans to suppress the pain and inflammation mediated by prostaglandins in response to wounding may prove to be an important tool for chemical ecologists interested in the functional significance of induced responses.

Abstract—The bolas spider, *Mastophora hutchinsoni*, attracts adult males of four species of nocturnally active Lepidoptera through aggressive chemical mimicry of those species' sex pheromones. Here we report the identification of the sex pheromone of one prey species, the smoky tetanolita (*Tetanolita mynesalis*). In sex pheromone gland extracts, only two peaks stimulated an electrophysiological response as measured by a coupled gas chromatography–electroantennographic detection analysis. These two peaks had retention times identical to (3*Z*,6*Z*,9*Z*)-heneicosatriene (3*Z*,6*Z*,9*Z*-21:H) and (3*Z*,9*Z*)-*cis*-6,7-epoxy-heneicosadiene (3*Z*,9*Z*-*cis*-6,7-epoxy-21:H), respectively, and mass spectra identical to these two compounds. It was determined that 0.23 ± 0.16 and 0.56 ± 0.26 ng of 3*Z*,6*Z*,9*Z*-21:H and 3*Z*,9*Z*-*cis*-6,7-epoxy-21:H, respectively, were present in pheromone gland extracts from individual females. A 1:1 blend of 3*Z*,6*Z*,9*Z*-21:H and 3*Z*,9*Z*-6*S*,7*R*-epoxy-21:H was an effective attractant for adult males from feral populations. Blend ratios of these two components from 2:1 to 1:2 were equally effective as attractants. Greater deviation from the optimal blends resulted in diminished trap catches. The enantiomer 3*Z*,9*Z*-6*R*,7*S*-epoxy-21:H not only was not effective in attracting males, its presence in the effective blend shut down trap catches. These results indicate that the pheromone blend consists of 3*Z*,6*Z*,9*Z*-21:H and 3*Z*,9*Z*-6*S*,7*R*-epoxy-21:H. This is the first report of a hydrocarbon/epoxide pheromone for a prey species of this bolas spider. Sex attractants or pheromones for the other three prey species are composed of aldehydes or acetates.

Key Words—Chemical mimicry, pheromone, *Mastophora hutchinsoni*, bolas spider, *Tetanolita mynesalis*, 3*Z*,6*Z*,9*Z*-heneicosatriene, 3*Z*,9*Z*-6*S*,7*R*-epoxyheneicosadiene.

INTRODUCTION

Late-stadia and adult females of bolas spiders in the genus *Mastophora* hunt by aggressive chemical mimicry of the sex pheromones of their lepidopterous prey (Eberhard, 1977; Stowe et al., 1987; Yeargan, 1988, 1994). Only adult males of a limited subset of available prey species are attracted to volatile chemicals emitted by these spiders (Stowe, 1988; Yeargan, 1994). The bolas spider, *Mastophora hutchinsoni* Gertsch, has been found to capture only four species of nocturnally active Lepidoptera, including three noctuid moths—the smoky tetanolita, *Tetanolita mynesalis* (Walker), the bristly cutworm, *Lacinipolia renigera* (Stephens), and the bronzed cutworm, *Nephelodes minians* Guenée—and one pyralid moth, the bluegrass webworm, *Parapediasia teterrella* (Zincken) (Yeargan, 1988). Sex pheromones or attractants for the latter three species have been shown to be unsaturated long-chain aliphatic acetates or aldehydes (Clark and Haynes, 1990; Haynes, 1990; Underhill et al., 1977). There are no known attractants or pheromone components for *T. mynesalis*. However, this species belongs to the Herminiinae, a subfamily of Noctuidae within which monoepoxide derivatives of triene or diene hydrocarbons have been shown to be attractants for several species (Wong et al., 1985; Millar et al., 1991). This information concerning the known sex pheromones and attractants for three of the prey species, and phylogenetic inferences regarding potential attractants for one of the most frequently captured prey species, *T. mynesalis*, suggested that this bolas spider may be capable of producing a biosynthetically diverse set of allomones. The objective of the research described herein was to identify the female-produced sex attractant pheromone of *T. mynesalis*, thus providing additional indirect evidence that addresses this hypothesis.

METHODS AND MATERIALS

Insects. Adult *T. mynesalis* were collected at blacklight traps in suburban backyards in Lexington and Richmond, Kentucky, during June–August 1994. Captured adults were transferred to 473-ml paper cartons with nylon screen lids. Eggs were removed from the inner surface of the carton and transferred to a 10-cm-diam. × 1.5-cm Petri dish containing a damp 7.5-cm piece of filter paper. Hatched larvae were transferred to plastic containers (15 cm diam. × 7.5 cm) lined with moist paper towels containing a mulch consisting primarily

of white oak, *Quercus alba* L., leaves that had fallen to the ground the previous autumn. Covell (1984) indicated the larval food for *T. mynesalis* was probably dead leaves. With this suggestion as our starting point, we selected white oak leaves as the larval food when these leaves proved to be adequate to rear *T. mynesalis* to the adult stage. Larvae were reared under laboratory conditions, without any effort to control light or temperature cycles. After pupation, male and female pupae were separated by sex based on external genital characteristics (Mosher, 1969). Pupae were kept in Petri dishes with moist filter paper. On emergence, adults were transferred to 473-ml paper cartons. Pupae and adults were held in an environmental chamber with a 16L:8D light cycle and temperature cycle of 25°C:18°C.

Chemicals. The *n*-pentadecane and *n*-tricosane used as internal standards were obtained from Alltech (Deerfield, Illinois). Z9-14:Ac and Z11-16:Al, which were used in standard solutions for GC-EAD, were obtained from the Institute of Pesticide Research (Wageningen, The Netherlands) and Scentry (Buckeye, Arizona), respectively. 3*Z*,9*Z*-6*S*,7*R*-Epoxy-21:H (94.15% enantiomeric purity, or 88.3% enantiomeric excess) and 3*Z*,9*Z*-6*R*,7*S*-epoxy-21:H (94.10% enantiomeric purity, or 88.2% enantiomeric excess) were synthesized previously (Millar and Underhill, 1986). 3*Z*,6*Z*-9*Z*-21:H was 96.4% pure and was synthesized as described by Underhill et al. (1983).

Extraction of Pheromone Glands. When females were 2–5 days old (primarily 3–4 days old), they were removed from the environmental chamber at midscotophase. Gentle pressure was applied to the abdomen of each female until the ovipositor and the associated pheromone gland emerged. The ovipositor and gland were removed with a pair of fine dissecting scissors, and placed into a 100-μl conical-bottom vial containing 20 μl of methylene chloride. For pooled extracts, several glands were extracted per vial. For analyses intended to document variation in pheromone content among individuals, only one gland was extracted per vial. Each vial was either analyzed immediately or sealed and stored at −80°C until needed. Before analysis, a vial was removed from the freezer and allowed to warm to room temperature. For the study of individual variation, 10 μl of an internal standard solution containing 1 ng/μl of *n*-pentadecane (15:H) and *n*-tricosane (23:H) were added to each vial. Previously it was determined that these internal standards would not coelute with components of the gland extracts. The volume of the solution was reduced under N_2 to 1 to 2 μl before injection.

Chemical and Electrophysiological Analysis. The GC-electroantennographic detection system was similar to that described by Struble and Arn (1984) and Leal et al. (1992). A DB-5 column (30 m × 0.25 mm ID, J&W Scientific Folsom, California) was installed in a Hewlett-Packard 5890 Series II GC. Injections were splitless. The effluent from the column was split at a 1:1 ratio between a flame ionization detector (FID) and a electroantennographic detector

(EAD). The oven temperature was held at 80°C for 2 min and then increased to 260°C at a rate of 20°C/min. Just prior to the split, a makeup gas (nitrogen) flow rate of 120 ml/min was introduced via a VSIS-5 T connector (Scientific Glass Engineering, Austin, Texas). The effluent flowed out of this T connector through a 5-cm section of deactivated column (0.53 mm), which was inserted into a deactivated Universal Y Press-Tight connector (Resteck, Bellefonte, Pennsylvania). A 10-cm section of deactivated column was used to make a connection of one branch of the Y to the FID. An identical section of column connected the other branch of the Y through a separate heated zone into the side of a modified glass condenser. Air flowed through the system at 1 liter/min and was humidified by bubbling through water before it entered the condensor. Chilled water circulated through the outer jacket of the condenser, cooling the humidified air to 22°C. This air flowed over the end of the GC column and delivered the GC effluent to the antennal preparation, which was 5 cm downstream from the end of the GC column.

The antennal preparation was similar to that of Leal et al. (1992) with the following exceptions. The base of the moth's excised head was placed into a drop of Pringle's saline (Pringle, 1938). The terminal segment of one antenna was removed, and the cut tip placed into a separate drop of saline. Silver–silver chloride electrodes were placed into each drop of saline and connected through a Grass P16 high-impedance probe to a Grass P16 amplifier (Quincy, Massachusetts). Baseline drift was controlled by the passive high-pass filter (capacitor = 10,000 μF, resistor = 130 Ω) described by Struble and Arn (1984). The amplified EAD and FID signals were sent to a Dataq model DI-420 Signal Conditioning Module (Akron, Ohio). Both signals were recorded and analyzed using Dataq MCA-CODAS software (Akron, Ohio).

A Hewlett-Packard 5890 Series II gas chromatograph equipped with either a DB-5 or a DB-WAX column (both columns 30 m × 0.25 mm ID, J&W Scientific, Folsom, California), linked with a Hewlett-Packard 5972 mass selective detector (MSD), was used for analysis of gland extracts. GC operating conditions for both columns were the same with an initial oven temperature of 50°C for 2 min, increasing to 240°C at a rate of 10°C/min. The flow rate of helium through the column was maintained at 1 ml/min. The MSD was set to scan from 40 to 400 amu, to obtain electron impact (70 eV) spectra.

Field Tests. For the first field exp riment, the quantity of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21:H applied to a red rubber septum (A.H. Thomas, Swedesboro, New Jersey) that had previously been extracted two times in hexane was kept constant at 100 μg and the quantity of 3*Z*,6*Z*,9*Z*-21:H was varied to yield 1:1, 4:1, and 10:1 blend ratios of this epoxide relative to the hydrocarbon. Fifty microliters of one of these three blends in hexane or hexane only was loaded onto a septum. Each rubber septum was hung by a paper clip from inside the top of a Pherocon IC trap (Trécé, Salinas, California). These traps were suspended from

limbs of trees so that the trap opening was approximately 1.8 m above the ground, which corresponds to a normal height at which the bolas spider *M. hutchinsoni* has been observed to catch male *T. mynesalis*. Traps were separated by at least 5 m. The assignment of a particular treatment to one of these trap positions was determined at random. The positions of treatments were rerandomized after each trapping period (one or two nights). A priori we had decided not to include any blocks of the experiment in which no males were caught in any of the four treatments (unsuccessful replications). A total of 13 successful replications were conducted between 23 and 28 September 1994 at the University of Kentucky's South Farm ($N = 2$), Coldstream Farm ($N = 2$), Spindletop Farm ($N = 2$), a suburban backyard in Lexington, Kentucky (backyard site 1) ($N = 2$), and suburban backyard in Richmond, Kentucky (backyard site 2) ($N = 5$). After each trapping period, sticky bottoms of the traps were returned to the laboratory and the numbers of male *T. mynesalis* were counted. A Kruskal-Wallis nonparametric anlaysis of variance was performed for this and subsequent experiments (Statistix 4.0, St. Paul Minnesota). This statistical approach was necessary because often control traps (and for some experiments other treatments) caught no moths; thus the homogeneity of variance assumption of the more powerful standard parametric analysis of variance was violated (with or without transformation). Means were separated with an experimentwise error rate set at $\alpha = 0.05$.

In a second field experiment, the following blend ratios of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H, 3*Z*,6*Z*,9*Z*-21 : H, and 3*Z*,9*Z*-6*R*,7*S*-epoxy-21 : H were tested: (a) 0 : 0 : 1, (b) 0 : 1 : 1, (c) 1 : 1 : 1, (d) 1 : 1 : 0, and (e) 1 : 0 : 0. The quantity of each compound when it was part of the blend to be applied to a rubber septum was kept at 100 μg. Control septa were loaded with hexane only. Because a methodological experiment conducted after our first experiment indicated that traps set at heights of about 30 cm were more effective in capturing male *T. mynesalis* than those set at 1.8 m (Haynes and Yeargan, unpublished data), we conducted this second and all subsequent tests at the lower height. Other details of this experiment were similar to our first experiment except that a trapping period was two or three nights. A total of eight successful replications were conducted between 3 and 12 October 1994 at the University of Kentucky's South Farm ($N = 2$), Spindletop Farm ($N = 2$), backyard site 1 ($N = 2$), and backyard site 2 ($N = 2$).

In the third field experiment, the following blend ratios of 3*Z*,9*Z*,-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9-*Z*-21 : H were evaluated: (a) 1 : 1, (b) 1 : 4, (c) 1 : 10, and (d) 0 : 1. The quantity of 3*Z*,6*Z*,9*Z*-21 : H applied to a rubber septum was kept at 100 μg, and the quantity of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H was varied (100, 25, 10, and 0 μg). Control septa were loaded with hexane only. Other details of this experiment were similar to our second experiment, except that the Spindletop site was dropped because of the apparent low population density of

T. mynesalis found there, and one additional location was added at both the South Farm and Richmond (backyard site 2) sites. A total of 14 successful replications were conducted between 12 and 19 October 1994 at the University of Kentucky's South Farm ($N = 6$), backyard site 1 ($N = 2$), and backyard site 2 ($N = 6$).

In the last field experiment, the following blend ratios of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H were evaluated: (a) 2 : 1, (b) 1 : 1, and (c) 1 : 2. The total quantity of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H plus 3*Z*,6*Z*,9*Z*-21 : H applied to a rubber septum was kept constant at 200 μg. Thus, for example, the 2 : 1 blend ratio consisted of 133 μg 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H plus 67 μg 3*Z*,6*Z*,9*Z*-21 : H. An additional septum was loaded with hexane only. Other details of this experiment were similar to our third experiment. A total of 14 successful replications were conducted between 19 and 26 October 1994 at the University of Kentucky's South Farm ($N = 6$), backyard site 1 ($N = 2$), and backyard site 2 ($N = 6$).

Voucher specimens of male *T. mynesalis* trapped with a 1 : 1 blend of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H, and males reared from eggs laid by females caught in a black light trap have been deposited in the University of Kentucky, Department of Entomology, Collection.

RESULTS AND DISCUSSION

Chemical and Electrophysiological Analysis. The GC-EAD analysis indicated there were two compounds present in gland extracts of individual female *T. mynesalis* that stimulated male *T. mynesalis* antennae (Figure 1A). The EAD activity was observed at 12.00 and 13.20 min (DB-5), but there were no prominent FID peaks at these retention times. Other peaks were present in the gland extracts, but these did not stimulate an EAD response. The retention times of the straight-chain hydrocarbon standards 20 : H, 21 : H, 22 : H, and 23 : H were 11.52, 12.11, 12.77 and 13.52 min, respectively. Because monoepoxide derivatives of triene hydrocarbons have been shown to be attractants for several species in the same subfamily (Wong et al., 1985), we evaluated standard solutions of 17- to 21-carbon triene (3*Z*,6*Z*,9*Z*-17–21 : H) and 17- to 22-carbon monoepoxide derivatives (6*Z*,9*Z*-*cis*-3,4-epoxy-17 to 22 : H; 3*Z*,9*Z*-*cis*-6,7-epoxy-17 to 22 : H; and 3*Z*,6*Z*-*cis*-9,10-epoxy-17 to 22 : H). The 21-carbon hydrocarbon and epoxides gave the closest retention time matches to the EAD active compounds. Synthetic 3*Z*,6*Z*,9*Z*-21 : H and 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H had retention times identical to the EAD active compounds (12.00 and 13.20 min, respectively) and stimulated strong EAD responses (Figure 1B). Other compounds (e.g., aldehydes and acetates) that have been determined to be pheromone components or sex attractants for other prey species of *M. hutchinsoni* did not stimulate EAD activity in male *T. mynesalis* antennae (Figure 1B).

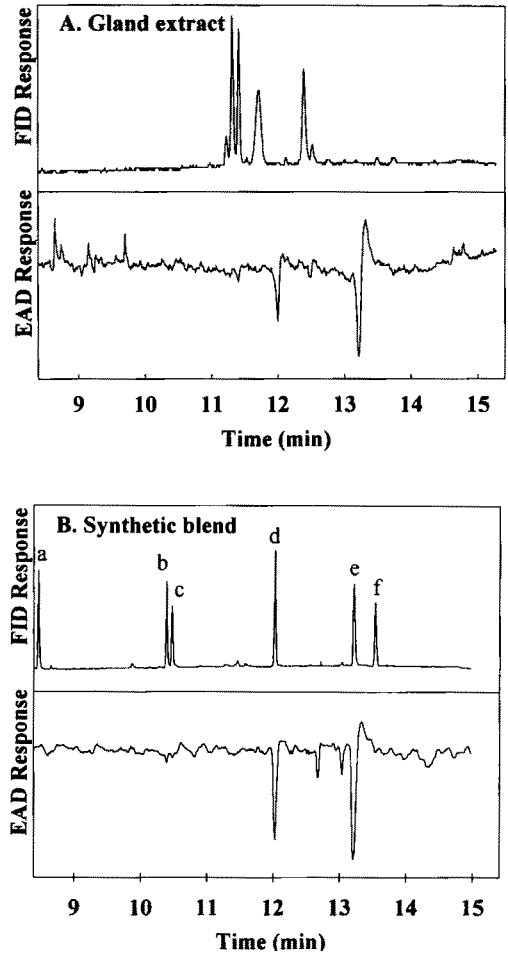

FIG. 1. (A) GC-EAD analysis of the pheromone gland extract of one female *T. mynesalis*. The top trace shows the response of the flame ionization detector (FID). The bottom trace shows the electroantennogram (EAD) response. Peaks of EAD activity were seen at retention times (R_t) of 12.00 and 13.20 min (B). A synthetic blend consisting of 0.5 ng (a) 15:H (R_t = 8.45), (b) *Z*9-14:Ac (R_t = 10.37), (c) *Z*11-16:Al (R_t = 10.45), (d) 3*Z*,6*Z*,9*Z*-21:H (R_t = 12.00), (e) 3*Z*,9*Z*-6*S*,7*R*-epoxy-21:H (R_t = 13.20), and (f) 23:H (R_t = 13.52) was analyzed by GC-EAD. The top trace shows the response of the FID. EAD responses (bottom trace) were seen at R_t of 12.00 and 13.20 min.

GC-MSD analysis of the pheromone extract using the DB-5 column indicated that two minor compounds present in individual gland extracts corresponded exactly in retention times and mass spectra with those of synthetic 3*Z*,6*Z*,9*Z*-21 : H (20.09 min) and 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H (21.66 min). From pooled extracts (5 or 10 female equivalents), the first peak and 3*Z*,6*Z*,9*Z*-21 : H were characterized by prominent ions at *m/z* 55, 67, 79, and 108, as well as less abundant ions at 234 and 290 (the molecular ion for 3*Z*,6*Z*,9*Z*-21 : H). The less abundant ions were reliably detected only in pooled extracts, while the prominent ions were consistently found in individual and pooled extracts. The diagnostic ions (Underhill et al., 1983) at *m/z* 55 ($CH_3CH_2CH{=}CH^+$) and 108 [$CH_3CH_2(CH{=}CH)_3H^+$], located the first of the three double bonds at C-3, and indicated that all three double bonds are clustered at one end of the structure. A further diagnostic ion at *m/z* 234 [$CH_3(CH_2)_{10}(CH{=}CH)_3H^+$] located a second double bond at C-9 (Underhill et al., 1983). On the basis of exact matches in retention times and spectra, and on the reasonable assumption that conjugation of the third double bond with either one of the other two would significantly change the retention time, the triene was tentatively assigned the 3*Z*,6*Z*,9*Z*-21 : H structure. Further evidence for this structure was provided by exact retention time matches of the insect-produced compound with a synthetic standard on a different GC column (DB-WAX).

The second EAD-active peak had a retention time identical to synthetic 3*Z*,9*Z*-*cis*-6,7-epoxy-21 : H on two columns (DB-5 and DB-WAX). Its mass spectrum exactly matched that of a synthetic standard of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and data reported in the literature (Millar and Underhill, 1986). In particular, the mass spectrum was characterized by prominent ions at *m/z* 55, 67, 83, 95, and 111, as well as less abundant ions at 223, 277, and 306 (the molecular ion for 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H). The prominent ion at *m/z* 111 is diagnostic for a structure of this type with the epoxide in the 6,7 position (cleavage of C–C bond adjacent to the epoxide; Tóth et al., 1992). However, the enantiomer 3*Z*,9*Z*-6*R*,7*S*-epoxy-21 : H cannot be distinguished from 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H by retention time or mass spectra.

In individual gland extracts of five females analyzed by GC-MS on the DB-5 column, the quantity of 3*Z*,6*Z*,9*Z*-21 : H ranged from 0.12 to 0.51 ng with a mean of 0.23 ± 0.16 ng/gland. The quantity of 3*Z*,9*Z*-*cis*-6,7-epoxy-21 : H ranged from 0.30 to 0.86 ng with a mean of 0.56 ± 0.26 ng. The range in blend ratios of 3*Z*,9*Z*-*cis*-6,7-epoxy-21 : H to 3*Z*,6*Z*,9*Z*-21 : H was 1.59 : 1 to 3.28 : 1 (blend ratio defined as the quantity of the epoxide divided by the quantity of the triene hydrocarbon) with a mean of 2.66 ± 0.68 : 1. Results were similar for independent analyses of five glands conducted on a DB-WAX column. The quantity of 3*Z*,6*Z*,9*Z*-21 : H ranged from 0.19 to 0.65 ng with a mean of 0.36 ± 0.17 ng/gland. The quantity of 3*Z*,9*Z*-*cis*-6,7-epoxy-21 : H ranged from 0.39 to 1.11 ng, with a mean of 0.71 ± 0.32 ng. The range in blend ratios of 3*Z*,9*Z*-

cis-6,7-epoxy-21 : H to 3*Z*,6*Z*,9*Z*-21 : H was 1.31 : 1 to 3.01 : 1, with a mean of 2.12 ± 0.77 : 1.

Field Tests. Following a preliminary field test in which traps baited with 100 μg of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H caught four male *T. mynesalis*, and the enantiomer 3*Z*,9*Z*-6*R*,7*S*-epoxy-21 : H caught no males, we opted to focus the first full field experiment on varying blend ratios of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H. In this experiment, the 1 : 1 blend of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H was the most attractive blend for trapping male *T. mynesalis* (Figure 2). Traps baited with this blend caught significantly more male *T. mynesalis* than control traps [Kruskal-Wallis statistic (H) = 17.73, $P < 0.001$, experimentwise error rate set at $\alpha = 0.05$ for mean comparisons]. The mean numbers of males caught in traps baited with the 4 : 1 and 10 : 1 blends of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H were intermediate between and not significantly different from the numbers caught in control traps (zero) and the 1 : 1 blend, using this conservative statistical test.

In the second field experiment, traps baited with a 1 : 1 blend of 3*Z*,9*Z*,6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H caught the largest number of

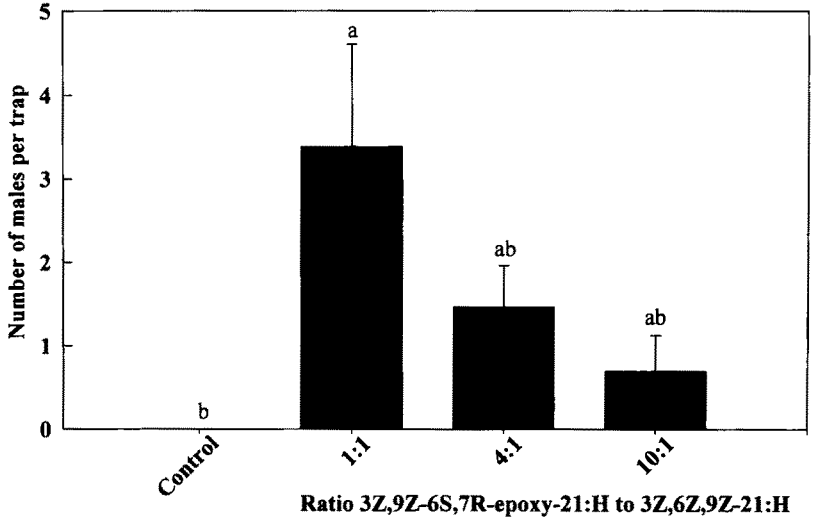

FIG. 2. Captures of male *T. mynesalis* moths in traps baited with blend ratios of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H, or a hexane-treated control. The quantity of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H was kept constant at 100 μg. Bars represent standard errors. Numbers are the mean number of males caught per trap per trapping interval (see Methods and Materials). Means that do not share a letter in common are significantly different (experimentwise error rate $\alpha = 0.05$, Kruskal-Wallis nonparametric analysis of variance).

males and significantly more than all other treatments except for traps baited with 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H alone (Figure 3) ($H = 32.42$, $P < 0.0001$). The enantiomer, 3*Z*,9*Z*-6*R*,7*S*-epoxy-21 : H was ineffective in attracting males to traps either by itself or as part of a 1 : 1 blend with 3*Z*,6*Z*,9*Z*-21 : H. Addition of this enantiomer to the otherwise effective attractant of a 1 : 1 blend of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H shut down the response to the lure.

In the third field experiment, traps baited with 3*Z*,6*Z*,9*Z*-21 : H alone or a 1 : 10 blend of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H were significantly less effective in catching male *T. mynesalis* than traps baited with the 1 : 1 blend ratio (Figure 4) ($H = 45.39$, $P < 0.0001$). The hydrocarbon by itself and the 1 : 10 blend of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H were no more effective than control traps in capturing males in traps.

In the fourth trapping experiment, we focused on a narrower range of blend ratios of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H. The number of males caught in traps baited with blend ratios of 2 : 1, 1 : 1, and 1 : 2 of 3*Z*,9*Z*-6*S*,7*R*-

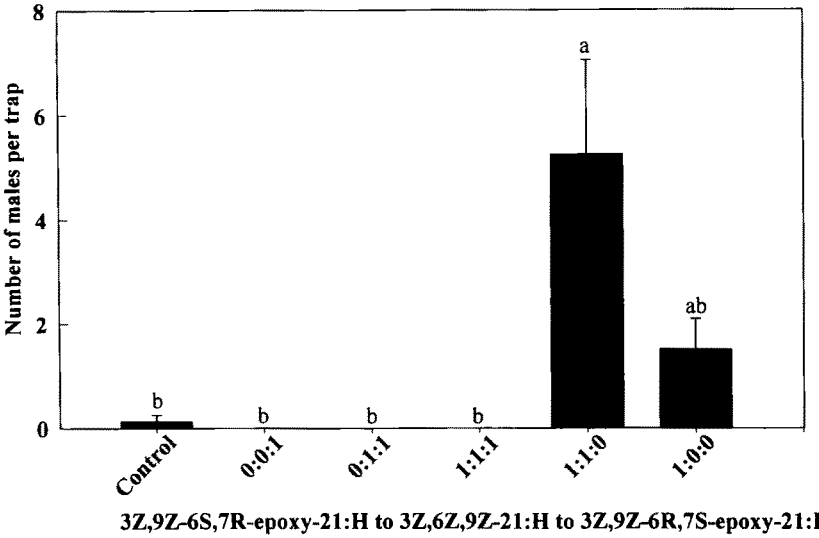

FIG. 3. Captures of male *T. mynesalis* moths in traps baited with blend ratios of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H, 3*Z*,6*Z*,9*Z*-21 : H, and 3*Z*,9*Z*-6*R*,7*S*-epoxy-21 : H, or a hexane-treated control. The quantity of each compound was kept at 100 μg. Bars represent standard errors. Numbers are the mean number of males caught per trap per trapping interval (see Methods and Materials). Means that do not share a letter in common are significantly different (experimentwise error rate $\alpha = 0.05$, Kruskal-Wallis nonparametric analysis of variance).

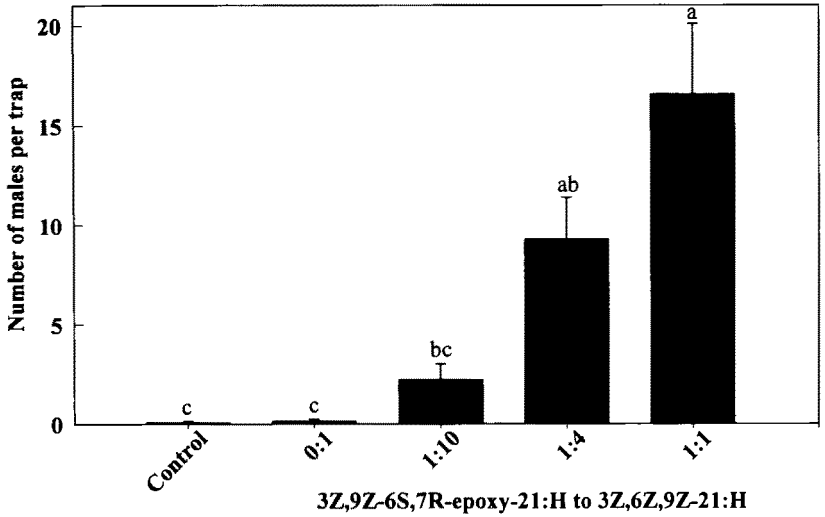

FIG. 4. Captures of male *T. mynesalis* moths in traps baited with blend ratios of 3Z,9Z-6*S*,7*R*-epoxy-21 : H and 3Z,6Z,9Z-21 : H, or a hexane-treated control. The quantity of 3Z,6Z,9Z-21 : H was kept constant at 100 μg. Bars represent standard errors. Numbers are the mean number of males caught per trap per trapping interval (see Methods and Materials). Means that do not share a letter in common are significantly different (experimentwise error rate $\alpha = 0.05$, Kruskal-Wallis nonparametric analysis of variance).

epoxy-21 : H and 3Z,6Z,9Z-21 : H were not significantly different from each other, but each of these blend ratios was significantly more attractive than hexane alone (Figure 5) ($H = 29.59$, $P < 0.0001$).

Blend ratios from 2 : 1 to 1 : 2 of 3Z,9Z-6*S*,7*R*-epoxy-21 : H and 3Z,6Z,9Z-21 : H were effective in capturing male *T. mynesalis* in sticky traps. The range of blend ratios of 3Z,9Z-*cis*-6,7-epoxy-21 : H to 3Z,6Z,9Z-21 : H found in pheromone gland extracts (1.31 : 1 to 3.28 : 1) overlapped this range. The chromatographic techniques we employed did not allow us to distinguish between the enantiomers 3Z,9Z-6*S*,7*R*-epoxy-21 : H and 3Z,9Z-6*R*,7*S*-epoxy-21 : H, and to date, there is no reported analytical chemistry method for distinguishing these two enantiomers at nanogram levels. However, the results from the second field test indicate that 100 μg of 3Z,9Z-6*R*,7*S*-epoxy-21 : H is not effective in attracting males when presented with 100 μg of 3Z,6Z,9Z-21 : H. In addition, the presence of 100 μg of 3Z,6Z,9Z-6*R*,7*S*-epoxy-21 : H within an otherwise effective 1 : 1 blend of 3Z,9Z-6*S*,7*R*-epoxy-21 : H and 3Z,6Z,9Z-21 : H (100 μg each) prevented captures of any males, and thus at this level 3Z,9Z-6*R*,7*S*-epoxy-21 : H is a behavioral antagonist. The enantiomeric purity of the synthetic 3Z,9Z-

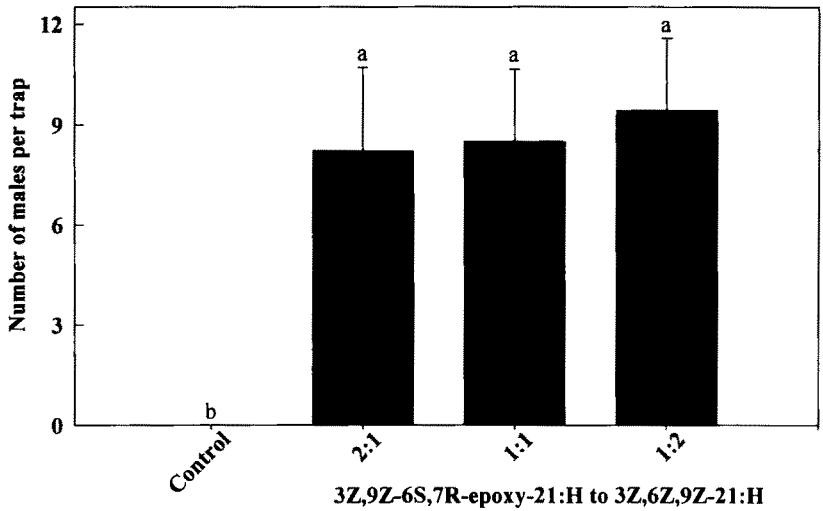

FIG. 5. Captures of male *T. mynesalis* moths in traps baited with blend ratios of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H, or a hexane-treated control. The total quantity of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H plus 3*Z*,6*Z*,9*Z*-21 : H applied to a rubber septum was kept constant at 200 μg. Bars represent standard errors. Numbers are the mean number of males caught per trap per trapping interval (see Methods and Materials). Means that do not share a letter in common are significantly different (experimentwise error rate α = 0.05, Kruskal-Wallis nonparametric analysis of variance).

6*S*,7*R*-epoxy-21 : H was approximately 94% (Millar et al., 1986). This leaves open the possibility that even this 6% level of 3*Z*,9*Z*-6*R*,7*S*-epoxy-21 : H within 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H had a negative (or possibly a positive) impact on captures of males. This cannot be tested until material of higher enantiomeric purity is available.

The identification of a blend of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21 : H and 3*Z*,6*Z*,9*Z*-21 : H as a sex pheromone for *T. mynesalis* is the first such identification for a species in the Herminiinae subfamily of the Noctuidae (Arn et al., 1992). However, in field trials, monoepoxide dienes or trienes (19–21 carbons) have been reported to be sex attractants for other Herminiinae, including *Bleptina caradrinalis* Guenée, *Idia aemula* (Hübner), *I. americalis* (Guenée), and *Palthis angulalis* (Hübner) (Wong et al., 1985; Millar et al., 1991).

Every pheromone blend that has been identified to date for prey species of bolas spiders is composed of unsaturated straight-chain aliphatic aldehydes, alcohols, or acetates (see Yeargan, 1994; Arn et al., 1992). No diene or triene hydrocarbons or their monoepoxide derivatives have been discovered to be sex attractants for any of these prey species. Four noctuid prey species (three species

belonging to Catocalinae and one to Herminiinae) of *M. bisaccata* and two prey species (Geometridae: Larentiinae) of *M. phrynosoma*, however, are closely related to species that have been attracted to specific diene or triene hydrocarbons or monoepoxide derivatives in field screening tests of these compounds. This taxonomic relationship suggests it is very likely that the pheromone blends of a subset of the prey species of these two bolas spiders will be hydrocarbons or epoxides, as is the case for *M. hutchinsoni*.

Prior to the present study, sex attractants or pheromones were known for three of the four species of moths that are captured by *M. hutchinsoni*. Previously, Haynes (1990) determined that female bristly cutworm moths, *Lacinipolia renigera* (Noctuidae: Hadeninae), emit *Z*9–14:Ac and *Z,E*-9,12–14:Ac (3.8% of *Z*9–14:Ac) and that synthetic blends of these two components are attractive to males. Males of the bronzed cutworm, *Nephelodes minians* (Noctuidae: Hadeninae), are attracted to *Z*11–16:Al (Underhill et al., 1977). An optimized attractant for male bluegrass webworms, *Parapediasia teterrella* (Pyralidae: Crambinae), consists of a 20:1 blend of *Z*11–16:Al and *Z*9–16:Al (Clark and Haynes, 1990). Yeargan (1988) found that *T. mynesalis* (52.6%) and *L. renigera* (40.0%) accounted for the vast majority of the 460 moths caught by *M. hutchinsoni* in a two-year study. Thus, the two most frequently captured prey use pheromones that are composed of different classes of chemicals.

The identification of a blend of 3*Z*,9*Z*-6*S*,7*R*-epoxy-21:H and 3*Z*,6*Z*,9*Z*-21:H as a sex pheromone for *T. mynesalis* suggests that female *M. hutchinsoni* may be capable of synthesizing a diverse set of allomones, including both straight-chain aliphatic acetates and aldehydes and triene hydrocarbons and monoepoxide derivatives. Stowe (1988) discussed the evolution of chemical mimicry in plants and animals, including the case of bolas spiders and moths. At the time of his review, no prey species of bolas spiders had been shown to use diene or triene hydrocarbons or their monoepoxide derivatives in their sex pheromones, but the phylogenetic relationships of some prey to species for which these pheromones or attractants had been found suggested that these compounds were likely candidates to be pheromone components of certain prey. Stowe (1988) offered several possible explanations of how bolas spiders might capture moth species that use chemically diverse pheromone components; given the results of our current study, three alternative hypotheses seem most plausible to explain this diversity. First, there may be variation in the attractants produced among individual bolas spiders, resulting in specialization by individual spiders but yielding a more diverse assemblage of prey at the population level. Second, the blend produced by an individual spider might change over time. Last, each spider might produce a consistent single blend of compounds, if individual components do not interfere with attraction of the other species of prey.

Yeargan (1988) found definitive evidence that precludes the possibility of interindividual variation in *M. hutchinsoni* leading to extreme specialization of

individual spiders on a single prey species. He found that the majority of spiders (56.3%) that caught two or more prey items on a single night also caught two or more species of prey. In fact, some individual spiders caught all four of the known prey species over the course of his study.

It is possible that a spider changes the attractant blend it produces over the course of the scotophase, because the two principal prey of *M. hutchinsoni* are captured at different times of night. *L. renigera* is captured before 10:30 PM, while *T. mynesalis* is captured after 11:00 PM, except on very cool nights (Yeargan, 1988). Preliminary evidence suggests that temporal variation may occur in the composition of the blend emitted by *M. cornigera*, the only species of bolas spider for which allomonal components have been identified from the spider itself (Stowe et al., 1987).

An alternative to temporal variation in the allomonal blend produced by *M. hutchinsoni* is that the spider, while hunting, may produce a relatively constant blend of the attractants for the two principal prey species. This would be possible if the chemical constituents do not interfere with the effectiveness of either attractant. The GC-EAD results (Figure 1) indicate that the male *T. mynesalis*'s antenna does not show a measurable EAD response to Z9–14 : Ac (the major pheromone component of *L. renigera*) or Z11–16 : Al (the major sex attractant component for *P. teterrella*). Thus, it is possible that these heterospecific pheromone blends are not even detected by *T. mynesalis*.

Either the second hypothesis (temporal variation) or the third hypothesis (consistent, compatible blend) could account for the ability of *M. hutchinsoni* to capture moths that use chemically diverse pheromones. We plan to investigate this chemical mimicry system to ascertain which hypothesis is correct.

Acknowledgments—Walter Leal provided helpful advice concerning the setup of the GC-EAD. F.W. Knapp and P.A. Weston kindly reviewed an earlier draft of the manuscript. This work was supported in part by State and Federal Hatch funds to the Kentucky Agricultural Experiment Station (paper no. 95-08-062).

(Received April 7, 1995; accepted August 29, 1995)

Abstract—Two potato genotypes resistant to the Colorado potato beetle (CPB) and three susceptible genotypes were used to investigate the role of total foliar polyphenol oxidase (PPO) on the performance of CPB larvae in long-term feeding assays. A significant positive correlation was found between larval mortality and PPO content in potato foliage. Moreover, a significant negative correlation was also observed between PPO content and larval weight, fecundity, and relative larval growth rate. These results suggest a significant role of PPO in conferring potato resistance to the Colorado potato beetle at least in those clones where the PPO levels were above a certain threshold.

Key Words—*Leptinotarsa decemlineata*, Colorado potato beetle, polyphenol oxidase, PPO, *Solanum berthaultii*, glandular trichomes, plant resistance.

INTRODUCTION

The high reproductive capacity of the Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say), its genetic plasticity that allows adaptation to a wide range of environments, and its notorious ability to develop resistance to synthetic

insecticides (Forgash, 1985) have combined to make this insect the major limiting factor in potato production in the northeastern and Atlantic regions of the United States and a serious problem in Europe (Gauthier et al., 1981; Ferro, 1985). The increasing public concern about environmental problems associated with synthetic insecticides is currently stimulating research directed toward the development of new potato cultivars with resistance to CPB.

Early reports associated the insect resistance of wild potato species with foliar glycoalkaloids (Schreiber, 1957; Pierzchalski and Werner, 1958; and see Tingey 1984 for a review). Most subsequent studies on the response of CPB adults and larvae to specific glycoalkaloids suggest feeding inhibition as the primary resistance mechanism (Sinden et al., 1988).

Another important mechanism of insect resistance in wild potatoes involves the mechanical and chemical properties of their glandular trichomes. Type A and B glandular trichomes of *Solanum berthaultii* Hawkes confer resistance to a number of important insect pests of potato (Gibson, 1971; Tingey and Gibson, 1978; Tingey and Laubengayer, 1986; Tingey, 1991). Most of the work on type A trichomes of *S. berthaultii* has focused on entrapment and immobilization of small arthropods by polymerized trichome exudate (Ryan et al., 1983). Type A trichomes also contain a component that acts as a feeding deterrent to adult CPB (Yencho et al., 1994). The acyl sucroses secreted by type B trichomes enhance entrapment of small arthropods by type A exudate (Gregory et al., 1986); antifeedant activity against aphids and the Colorado potato beetle has also been suggested (Pelletier and Smilowitz, 1990).

Polyphenol oxidase (PPO) is an ubiquitous class of enzymes produced by vascular plants. The type A glandular trichomes of *S. berthaultii* contain a unique PPO with a molecular weight of 59 kDa (Kowalski et al., 1992). Felton et al. (1989) have suggested that PPO-generated quinones might confer post-ingestive insect resistance by reducing the digestibility, palatability, and nutritive value of plant tissue to herbivores. The study reported here was undertaken to indirectly test that hypothesis by comparing performance of CBP larvae on potato clones with differing levels of foliar PPO and differing field resistance to the Colorado potato beetle.

METHODS AND MATERIALS

Plants. Plants of the CPB-susceptible *S. tuberosum* cv. Superior, and the field resistant *S. tuberosum* × *S. berthaultii* hybrid, NYL 235-4 (Plaisted et al., 1992) were grown from disease-free certified seed tubers. Plants of the resistant wild species, *S. berthaultii* (PI 473334), were grown from seeds obtained from the USDA Potato Introduction Station, Sturgeon Bay, Wisconsin. Plants of the

field-susceptible (W.M.T., personal communication) *S. tuberosum* × *S. berthaultii* hybrids N133-67 and N133-93 were grown from nodal cuttings obtained from field-grown plants. All of the genotypes except cv. Superior bear type A glandular trichomes on their foliage. None of these genotypes bear acyl sugar-producing type B glandular trichomes. Plants were grown in 35-cm plastic pots using a peat–perlite soil mix (Pro-Mix B) containing fertilizer (Osmocote 14-14-14 at 2.3 kg/m^3). All plants were grown in a greenhouse at temperatures ranging from 20 to 26°C and relative humidity fluctuating between 90 and 60% in synchrony with temperature. Natural light was supplemented with metal halide illumination of 3600 μE/m^2/sec at plant level to provide a photoperiod of 16 : 8 hr (light–dark). Plants were fertilized weekly with Peters soluble fertilizer (20 : 10 : 20; N-P-K). Plants were about four weeks from emergence or transplanting when used for experimental purposes.

Insects. Eggs of *L. decemlineata* were obtained from a colony reared on *S. tuberosum* cv. Atlantic in greenhouse environmental conditions identical to those described above. This colony is renewed annually with wild adults collected from potato fields in Freeville, New York. Larvae used in experiments came from eggs held in a growth chamber at 26°C and 16 : 8 hr light–dark photoperiod and collected within 24 hr of eclosion.

Foliar glycoalkaloids. Fifty grams of foliage of each clone was collected, frozen, lyophilized, and sent to S.L. Sinden (Vegetable Research Laboratory, USDA, ARS, Beltsville, Maryland) for determination of specific glycoalkaloid content.

Foliar PPO Activity. One leaf immediately below the one to be used for larval confinement was removed and its terminal leaflet was used to estimate total PPO content. Polyclonal antibodies raised against the 59-kDa PPO of *S. berthaultii* trichomes were used to measure PPO content following the method of Kowalski et al. (1992).

Feeding Assays. Larval performance on the selected potato genotypes was determined by confining 10 neonate larvae on the fourth node leaf using a Velcro-sealed 17-cm × 30-cm sleeve cage, made with polyester No See Um insect screening (BaLarval Isom Hercules Corp., Providence, Rhode Island). Six cages were placed on each genotype; plants were held in a greenhouse under the previously described environmental conditions and arranged in a completely randomized block design. Larval mortality and developmental stage were determined at two-day intervals. Larvae were weighed when they began to show borrowing behavior, as evidenced by a change to more yellow color, using a CAHN model DTL 7500 balance. After weight determinations, they were transferred to 500-ml clear plastic cups containing moist soil for pupation. Date of adult emergence was recorded, adults were sexed, and then confined on potato genotypes as described previously. Three pairs of adults were placed in each

cage; cages were replicated three times on each potato genotype. Fecundity was estimated by measuring egg production per female at two-day intervals over an eight-day period following the onset of oviposition. Relative growth rate (RGR) was calculated by ln (wt gain)/days (Felton et al., 1992b).

Amino Acid Analysis of Feces. To evaluate possible antinutritive effects of PPO upon larvae, through chemical degradation of essential amino acids, feces were collected from larvae reared from egg hatch to L4 on each of the potato genotypes as follows: 24 L4 were starved for 9 hr prior to being placed back, as cohorts of six, on leaves at the fourth node of each clone, and confined similarly as above. Thereafter, larvae were fed on each one of those genotypes for 16 hr. Then, all larvae were removed and individually placed into a six-well tissue culture plate (3.5 cm diameter, flat bottom), where they were allowed to defecate for 3 hr after which the feces were immediately frozen at −80°C. Larvae were then transferred to clean plates in the same fashion and allowed to defecate for another 3 hr. One leaflet of each leaf allocated for feeding was removed for determination of its amino acid content using an automated amino acid analyzer at the Cornell Plant Science Center.

Data Analysis. All data were analyzed by one-way analysis of variance (ANOVA). Treatment means were compared by Student-Newman-Keuls or Duncan new multiple-range procedures. Simple regression analysis was made using SUPERANOVA (Abacus Concepts, Inc., Berkeley, California). The P value corresponds to a slope of 0, R is the coefficient of correlation.

RESULTS

Foliar PPO Activity. Foliage of PI 473334 had the highest levels of PPO followed by NYL235-4, N133-67, N133-93, and Superior in decreasing order. Significant differences ($P < 0.05$) were found between PI 473334 and NYL 235-4 and between them and all the other clones. No significant differences were found among the other clones (Table 1).

Foliar Glycoalkaloids. Foliage of the CPB-susceptible cultivar Superior was characterized by the presence of solanine (0.8 mg/g dry weight) and chaconine (1.4 mg/g dry weight) at the highest levels observed for any of the genotypes; no glycoalkaloids were detected in foliage of PI 437334. The same four glycoalkaloids (solamargine, solasonine, solanine, chaconine) were detected in foliage of all *S. tuberosum* × *S. berthaultii* hybrids at levels ranging from 0.5–2.0 mg/g dry weight for solamargine, 0.20–1.23 mg/g dry weight for solasonine, 0.14–0.80 mg/g dry weight for solanine and 0.4–1.4 mg/g dry weight for chaconine. Among the hybrids, levels of solanine and chaconine, two gly-

[a] Values are mean ± SE ($N = 6$). Mean ± SE with the same letter within each category are not significantly different from each other ($P < 0.05$, Newman-Keuls test).

[b] Values are mean ± SE (from an initial $N = 60$; six cohorts of 10). Values with the same letter within each category are not significantly different from each other ($P < 0.05$, Newman-Keuls test).

coalkaloids reported to affect feeding behavior or metabolism of CPB larvae at high concentrations, were particularly low.

Fecal Amino Acid Content. No significant differences were observed in fecal content of the nucleophilic amino acids cysteine, methionine, tryptophan, and lysine from larvae fed on the different potato genotypes (data not shown).

Feeding Assays. Larval mortality was very high (27.0–37.0%) and significantly different from the control ($P < 0.05$) in all clones with high PPO levels, as well as in N133-67, even though the latter clone had PPO contents similar to the control (cv. Superior) and N133-93. A significant positive correlation ($r = 0.49$, $P < 0.01$; $y = 1.43 + 1.36x$) was found between total PPO levels in the potato leaves and CPB larval mortality (Figure 1a). Conversely, larval weight was similar for all clones regardless of the PPO levels except for *S. berthaultii* PI 473334, where larval weight was significantly ($P < 0.05$) reduced. However, a highly significant negative correlation ($r = -0.53$, $P < 0.01$; $y = 180.4 - 30.4x$) was observed between larval weight and PPO (Figure 1b). Likewise, the larval development (number of days to pupation) was the same for all cases except PI 473334, where a two-day delay was observed (Table 1).

The number of eggs per female was significantly reduced ($P < 0.05$) on all clones with high PPO levels relative to cv. Superior. Although there were no differences in the number of egg masses per female, the number of eggs per mass was significantly different between PI 473334 and the clones with low

NYL 235-4	0.944 ± 0.02 b	611.78 ± 12.2 a	14.150 ± 0.2 a	37.530 ± 2.7 ab
PI 473334	1.689 ± 0.06 c	535.13 ± 31.9 a	15.233 ± 0.4 a	33.123 ± 2.0 a

[a] Values are mean ± SE ($N = 6$). Mean ± SE with the same letter within each category are not significantly different from each other ($P < 0.05$, Newman-Keuls test).

[b] Values are mean ± SE ($N = 5$ replicates of four couples for Superior, $N = 4$ for NYL 235-4, and $N = 3$ for N133-93 and PI473334. Values for N133-67 are missing due to less than three replicates available). Mean ± SE with the same letter within each category are not significantly different from each other ($P < 0.05$, Duncan's new multiple-range test).

PPO activity (Table 2). A significant negative correlation ($r = 0.57$, $P < 0.01$; $y = 677.7 - 82.2x$) was found between the number of eggs per female and PPO activity (Figure 2a). Total PPO in foliage was strongly negatively correlated ($r = 0.8$, $P < 0.001$; $y = 0.45 - 0.05x$) with relative growth rate (RGR) of larvae (Figure 2b). No differences were found in the sex ratio regardless of PPO contents among clones.

DISCUSSION

Our study on prolonged ingestion of potato foliage by CPB (from neonate to pupation), suggests that PPO has a negative effect on CPB. We have shown a differential effect of several potato genotypes on the performance of Colorado potato beetle. Several potato allelochemicals, such as the leptine glycoalkaloids, have been implicated in resistance to this beetle (Sinden et al., 1991). However, other glycoalkaloids, e.g., solasonine and solamargine have no effect on its feeding behavior or metabolism, at biologically relevant levels (Gregory et al., 1981; Tingey and Sinden, 1982). Furthermore, these two glycoalkaloids also occur in *S. rostratum*, one of the Colorado potato beetles' original wild hosts (Schreiber, 1968). These facts along with the low concentrations of solasonine and solamargine in our plants suggests that these compounds did not play a role in the results obtained here.

For *S. berthaultii* (highest PPO levels), larval mortality was very high (37.0%), larval development was extended two days, and there was a significant

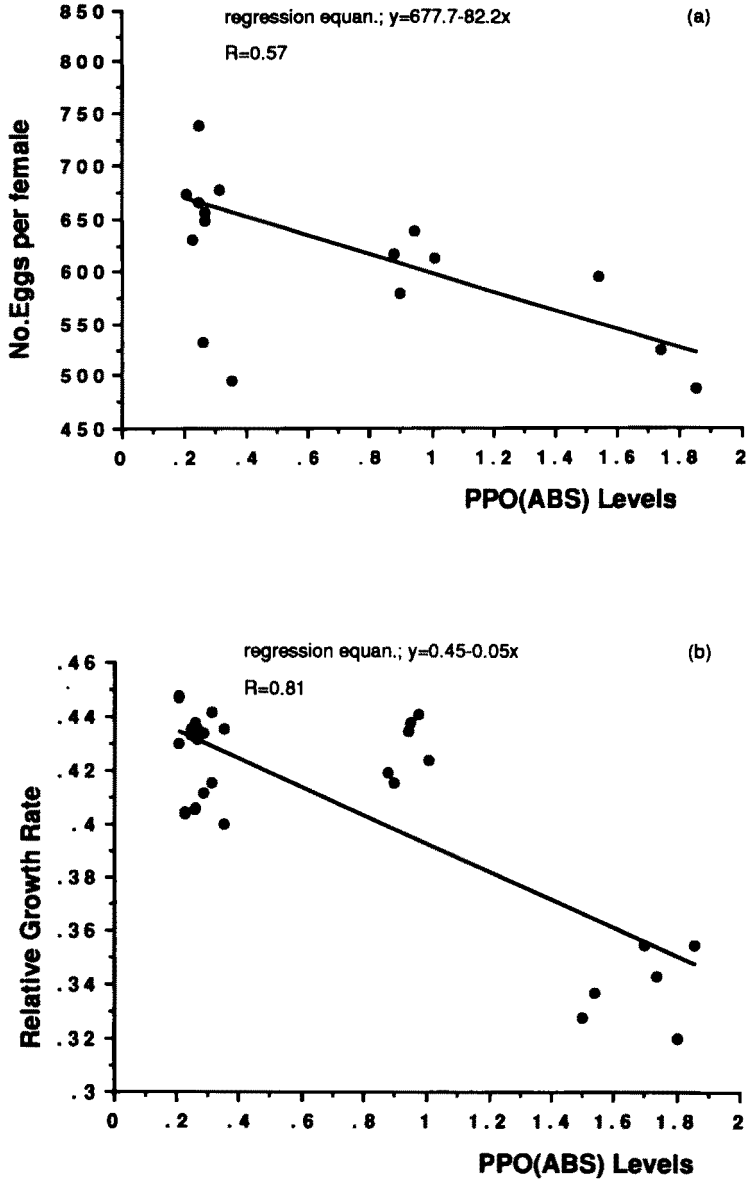

FIG. 2. Relationship between the PPO levels and (a) fecundity and (b) the relative larval growth rate of CPB.

reduction ($P < 0.05$) in late fourth-instar (L4) weight when compared to cv. Superior (Table 1). Not all of these effects are likely to be associated strictly with PPO content. For example, N133-67 has about the same PPO level as that of Superior and N133-93, but larval mortality was in the range of the genotypes with three-fold and five-fold greater PPO levels. However, the data strongly suggest an association between total PPO levels and CPB larval performance, statistically supported by a significant positive correlation between PPO and larval mortality (Figure 1a). Moreover, a negative correlation was found between foliar PPO levels and L4 weight, fecundity, and the relative growth rate (Figures 1b and 2). These data suggest that PPO plays a role in resistance to CPB larvae, at least in those clones where the PPO content is above a certain threshold.

Recently, Felton et al. (1992a) reported that polyphenol oxidases are unlikely to have significant antinutritive effects on the Colorado potato beetle. However, their data were based on a short-term feeding experiment using fourth-instar CPB larvae, and total foliar PPO was not considered. In contrast, our data were obtained from a much longer feeding study, possibly leading to a cumulative effect. In fact, nearly 75% of the larvae died during the second and third instars on those clones with high PPO activity. Similarly, field resistance of NYL 235-4 is expressed by high mortality during the first and second instars (Plaisted et al., 1992).

Lowest mortality (about 9%) was observed during the fourth instar. This may partially explain why we did not find significant differences in the essential nucleophilic amino acids cysteine, methionine, tryptophan, and lysine in the feces of late fourth-instar CPB larvae. This result is in agreement with Felton et al. (1992a), who suggested that the mildly acidic midgut of CPB larvae would impede the covalent conjugation of amino acids with the electrophilic quinones, thus preventing the loss of essential amino acids. Nevertheless, the high mortality observed in the second and third-instar CPB suggests that other physiological and/or biochemical properties of the PPO–digestive system are implicated. In fact, PPO has the potential to confer resistance because its end products, O-quinones, might alkylate foliar protein, leading to reduced digestibility and nutritive value, as reported for other insect species (Felton et al., 1989; Duffey and Felton, 1991). Glandular trichome PPO (foliar PPO in our conditions) is one component of an interacting system of several chemical and physical characteristics that result in the expression of insect resistance (Kowalski et al., 1990). This work is a first step in unraveling the complex of biochemical mechanisms that underlay the ecological interactions between trichome A-mediated resistance of *S. berthaultii* and the Colorado potato beetle. Future studies need to address the effects of PPO on feeding and physiology of CPB, particularly now that transgenic plants with different levels of PPO can be obtained.

Acknowledgments—We thank Robert L. Plaisted for supplying the germplasm used in these studies and Nancy T. Eannetta for technical assistance. This research was supported by grants from the International Potato Center and by Hatch Project NYC 139416.

(Received January 13, 1995; accepted August 28, 1995)

Abstract—The main component of the sex pheromone of the caddisfly *Hesperophylax occidentalis* (Banks) (Trichoptera: Limnephilidae) was identified as 6-methylnonan-3-one (enantiomeric composition has not yet been determined). Extracts of adult females elicited strong electroantennogram (EAG) responses from adult male antennae, but elicited significantly smaller EAG responses from adult female antennae. Extracts of adult males did not elicit appreciable EAG responses from antennae of either sex. Racemic 6-methylnonan-3-one was synthesized and elicited EAG responses from male antennae as strong as those obtained with female extracts. In field tests with baited sticky traps near lakes and streams, traps baited with synthetic racemic 6-methylnonan-3-one caught significantly more males than control traps. Female adults contained approximately 1 μg of 6-methylnonan-3-one per individual. Related ketones and alcohols of other chain lengths were also tentatively identified, being present in tiny amounts in female extracts. Extraction of different body parts showed that 6-methylnonan-3-one occurs only in a region near the intersegmental membrane between the fourth and fifth abdominal sternites of the female (no discrete glands were observed). Extracts of males did not contain 6-methylnonan-3-one, nor did pupae of either sex.

Key Words—Electroantennogram, EAG, caddisfly, Trichoptera, Limnephilidae, pheromone, attractant, semiochemical, infochemical, mating, sex, volatiles.

INTRODUCTION

Scent production in caddisflies was first discussed by naturalists near the end of the last century (Müller, 1888; Cummings, 1914; Elteringham, 1919; Mosely, 1919, 1922, 1923), and it was suggested that these chemical secretions and similar ones from Microlepidoptera may serve a role in defense against predation (Kimmins, 1956; Kristensen, 1972). The possible role of volatile compounds in mating communication in the Trichoptera was not considered until relatively recently (Kelner-Pillault, 1975; Wood and Resh, 1984; Resh and Wood, 1985; Resh et al., 1987), despite the fact that sex pheromones have been characterized for more than a thousand insect species (Mayer and McLaughlin, 1991), distributed among nine orders (Orthoptera, Homoptera, Hemiptera, Lepidoptera, Coleoptera, Mecoptera, Neuroptera, Hymenoptera, and Diptera). The majority of the sex pheromones so far identified are for species in the Lepidoptera (Mayer and McLaughlin, 1991). The first chemical identifications of sex pheromones in the Trichoptera (Hydropsychidae and Rhyacophilidae) were reported only recently (Valeur et al., 1990; Löfstedt et al., 1994).

The first report of sex pheromone communication in the Trichoptera was for the sericostomatid *Gumaga griseola* (McLachlan) and *Gumaga nigricula* (McLachlan) (Wood and Resh, 1984). Field experiments showed that males are attracted to caged females and to female extracts (Wood and Resh, 1984; Resh et al., 1987). A female-produced sex pheromone has been found in *Rhyacophila nubila* (Zetterstedt) (Rhyacophilidae), and males were attracted to sticky traps baited with females only during the early hours of the night (Solem, 1985). Other researchers have also demonstrated sex pheromone communication in caddisflies, including the Glossosomatidae (Resh et al., 1987), Limnephilidae (Kelner-Pillault, 1975; Resh and Wood, 1985), Philopotamidae (Wood and Resh, 1984), Helicopsychidae (Resh et al., 1984), and Molannidae (Solem and Petersson, 1987), by conducting field tests with live females or with extracts from different female parts. Field trapping experiments with extracts of specific body sections from adult female *Gumaga nigricula* (Sericostomatidae), *Gumaga griseola* (Sericostomatidae), and *Dicosmoecus gilvipes* (Hagen) (Limnephilidae) have implicated the fifth abdominal sternite in pheromone release (Resh and Wood, 1985). Mating communication in *Mystacides azurea* L. (Leptoceridae) and *Athripsodes cinereus* Curtis (Leptoceridae) apparently does not involve sex pheromones, and visual cues seem to be more important (Petersson and Solem, 1987).

Hesperophylax occidentalis (Banks) is a univoltine species common in temporary streams at high elevations or latitudes (Anderson, 1976). Eggs are laid in a single mass just below the water's surface (Parker and Wiggins, 1985), and adults emerge from April to October, typically with peaks in May and June. The life history and ecology of *Hesperophylax occidentalis* have been described

(Martinson and Ward 1982). The present study on *Hesperophylax occidentalis* is the first chemical identification of a sex pheromone for a species in the family Limnephilidae.

METHODS AND MATERIALS

Insects. Pupae were found attached by silk strands to the undersides of rocks. They were collected at two locations. In Colorado, pupae were collected from late May to late July from the upper streambed of Hewlett Gulch in Roosevelt National Forest (approximately 20 miles west of Fort Collins, Colorado). In Wyoming, pupae were collected from the edge of Glacier Lakes in Medicine Bow National Forest throughout August. Pupae were placed in an insulated plastic picnic cooler (4-liter capacity, Rubbermaid, Gott Corp., Winfield, Kansas) and covered with water from the stream or lake from which they were collected. A battery-powered air pump (ordinarily used to keep fishing bait alive; B&M Air Pump, West Point, Mississippi 39773) provides constant aeration to the pupae through an airstone. Adults often began emerging from the pupae within an hour after collection, and emergence continued for several weeks after return to the laboratory. Continuous aeration of pupae with an aquarium pump was maintained after return to the laboratory from a field site. Twigs were placed at one end of the container (protruding from the water) to allow adults an emergence site.

For one experiment (comparison of male and female electroantennogram responses to extracts of both sexes), adults were collected from Endovalley Campground at Rocky Mountain National Park, Colorado, in September, under the auspices of a permit issued to P.A. Opler. Adults were attracted to a white sheet (2 × 2 m) laid on the ground, with a mercury vapor lamp (140 W, Electripak, Box 30489, Memphis, Tennessee 38130-0489) in the center, powered by a gasoline-powered generator (Honda model EX1000). Adults were placed in Ziploc freezer bags (4-liter size, DowBrands L.P., Indianapolis, Indiana) and stored in a refrigerator (5°C).

Extracts. Extracts were made by placing different body parts of males and females in 1 ml of dichloromethane in a 4-ml glass vial with a Teflon-lined cap for 1 hr. Body parts were separated by using fine forceps to tear between tergites. Preliminary experiments demonstrated that male antennae respond electrophysiologically to extracts of female abdomens and that ventrum extracts were more active than tergum extracts.

The site of pheromone storage was determined by cutting the ventrum into pieces with a razor blade and extracting each piece separately with dichloromethane. Cuts were made transversely through the center of each sternite, so as to include the intersegmental membrane between successive sternites.

Gas–Liquid Chromatography. To obtain purified material for identification, a dichloromethane extract of 25 female ventra was separated into fractions with a packed OV-101 column (3 mm × 3 m, glass) with temperature programming from 60°C to 250°C at 10°C/min (1 min delay) on a Hewlett-Packard 5890 gas–liquid chromatograph (GLC). Each fraction was collected for 1 min in a 20-cm Pasteur pipet (10 cm of this was a glass capillary), with the tip of the pipet inserted into a Teflon fitting attached to the jet at the end of the GLC. Compounds were recovered from the pipet by attaching a rubber bulb to the pipet and drawing distilled dichloromethane up and down in the capillary portion of the pipet several times. Capillary gas–liquid chromatography with flame ionization detection was conducted with two columns, a nonpolar RSL-150 column (0.25 mm × 25 m, Applied Science) and a polar Supelcowax column (0.25 mm × 25 m, Applied Science).

Mass Spectrometry. Electron ionization–mass spectrometry (GC-EI-MS) was conducted with a HP 5790 mass spectrometer interfaced with a HP 5890 gas chromatograph, using a methyl silicone capillary column in splitless mode (0.25 mm × 25 m, Applied Science) with temperature programming from 60°C to 250°C at 10°C/min (1 min delay). Chemical ionization–mass spectrometry (GC-CI-MS) was conducted similarly, with ammonia as the reagent gas. A computer data base of electron ionization mass spectra (approximately 15,000 compounds) from the National Bureau of Standards was available on the HP 5790 mass spectrometer.

Lithium Aluminum Hydride Reaction. Preliminary evidence from EI-MS indicated that the main pheromone component was a 3-ketone. A larger amount of this main pheromone component was purified by GLC and then derivatized with lithium aluminum hydride (LAH) to prepare the corresponding alcohol for further characterization. The purified main component from GLC collection was placed in 0.5 ml diethyl ether in a 4-ml glass vial with a Teflon-lined cap, and 20 mg LAH was added with a microspatula (Fieser and Fieser, 1960). For destruction of excess LAH, 3 ml of ether was shaken with water in a separate vial, and this "wet" ether solution was added dropwise to the LAH reaction of the main pheromone component. The small amount of water in the "wet" ether destroyed excess LAH with a minimum of fizzing. When no further reaction was observed upon dropwise addition of "wet" ether, the ether solution was washed three times with water and filtered through a small piece of a Kimwipe (disposable cellulose wiper, Kimberly-Clark Corp., Neenah, Wisconsin 54956) in a glass Pasteur pipet. The solvent was removed by evaporation with a nitrogen stream, and 0.5 ml of dichloromethane was added to redissolve the product. The product was analyzed by GC-EI-MS.

Triphenylphosphine Dibromide Reaction. The alkyl bromide analog of the main pheromone component was prepared with triphenylphosphine dibromide (Wiley et al., 1964). Triphenylphosphine dibromide was prepared by adding

bromine dropwise with shaking to a solution of triphenylphosphine (50 mg) in dichloromethane (1 ml) until a yellow color persisted, then adding more triphenylphosphine until the solution lost the yellow tint. The LAH product of the main pheromone component (in dichloromethane solution) was added to the triphenylphosphine dibromide solution and shaken gently for 1 min. Evaporation with a nitrogen stream was used to remove nearly all the solvent, and hexane (1 ml) was added to precipitate unreacted triphenylphosphine dibromide. The solution was filtered through a small piece of a Kimwipe in a glass Pasteur pipet, solvent was removed by evaporation with a nitrogen stream, and hexane (1 ml) was added. This solution was applied to the top of a small chromatograph column made from a Pasteur pipet half-filled with a slurry of Florisil in hexane. Elution of the alkyl bromide was carried out with 4 ml of hexane, leaving behind any unreacted alcohol. The product was analyzed by GC-EI-MS.

Sodium Borohydride Reaction. The hydrocarbon skeleton was prepared from the alkyl bromide derivative of the main pheromone component by using sodium borohydride in dimethyl sulfoxide (DMSO), as described by Hutchins et al. (1969). Solvent was removed from a solution of the alkyl bromide derivative of the main pheromone component by evaporation with a nitrogen stream, and 0.5 ml of DMSO was added. Sodium borohydride (20 mg) was added with a microspatula, the vial was capped (with a Teflon-lined cap), and the vial was placed in an oven (85°C) for 18 hr. The vial was cooled, hexane (1 ml) was added, and the hexane solution was washed three times with water. The hydrocarbon skeleton was analyzed by GC-EI-MS.

Synthesis of Main Pheromone Component. Synthesis of racemic 6-methylnonan-3-one was carried out in three steps. Racemic 4-methylheptan-1-ol (Wiley Organics, Coshocton, Ohio) was oxidized by constant stirring (24 hr) with pyridinium dichromate (PDC, Aldrich Chem. Co., Milwaukee, Wisconsin) in dichloromethane to form 4-methylheptanal (Corey and Schmidt, 1979). Particulate material was removed by centrifugation after the reaction was complete. The aldehyde was purified by elution through a column of Florisil with a 1 : 1 mixture of dichloromethane and diethyl ether. Racemic 6-methylnonan-3-ol was prepared by adding ethylmagnesium bromide (3 *M* solution in diethyl ether; Aldrich Chem. Co.) to 4-methyl-heptanal under nitrogen (Fieser and Fieser, 1967). Unreacted ethylmagnesium bromide was destroyed by adding a water-saturated solution of diethyl ether, and particulate material was removed by centrifugation. Racemic 6-methylnonan-3-one was prepared from 6-methylnonan-3-ol by constant stirring (24 hr) with PDC in dichloromethane (Corey and Schmidt, 1979) and was purified by elution from Florisil with a 1 : 1 mixture of dichloromethane and diethyl ether.

Electroantennograms. Electroantennogram (EAG) tests were conducted as described by Bjostad (1988). An antenna was plucked from the head with fine forceps, cut at the distal end, and suspended between the tips of the electrodes,

made from glass Pasteur pipet containing 0.15 M KCl saline solution with Ag–AgCl wires in contact with the saline solution. The signal from the antenna was amplified (5000×, FET amplifier) and processed with an analog-to-digital converter for recording with a microcomputer. Antennae used for EAG tests were taken from insects within a few days of adult emergence (typically two to three days).

Field Trapping. Trécé 1C wing traps (Pest Management Supply, Inc., Hadley, Massachusetts) were used to test synthetic pheromone lures. This trap type has previously been used to trap Trichoptera (Resh and Wood, 1985; Resh et al., 1987). Lures were prepared by placing dichloromethane solutions of racemic 6-methylnonan-3-one in the large ends of rubber serum stoppers (Aldrich Chem. Co.) and allowing the solvent to evaporate in a chemical fume hood.

Traps were tested along the lakesides of Glacier Lakes in Medicine Bow National Forest, Wyoming, in July, August, and September (*H. occidentalis* pupae were found in abundance just offshore). A lure was placed in the center of each trap, and the trap was placed in a tree approximately 1 m above the ground. Sex pheromone release takes place at low light intensity in other caddisfly species (Benz, 1975; Solem, 1985; Resh et al., 1987), and traps were accordingly set out a few hours before dark. It has been previously demonstrated with other caddisfly species that lures are attractive for several days (Resh et al., 1987), and lures were replaced every three to seven days in the present study. Placement of traps can have a substantial influence on the relative numbers of adults captured (Cardé and Elkinton, 1984). Males of other caddisfly species have been observed to patrol bushes along the banks of rivers, presumably in search of females (Solem, 1984, 1985). Traps for *H. occidentalis* were placed about 10 m apart in vegetation on the banks of both the lake and stream approximately 1 m from the ground, similar to methods used by Resh et al. (1987).

Adult caddisflies were removed from traps, and sex was determined by examining the genitalia (Parker and Wiggins, 1985). Species and sex of specimens were determined by Dr. Boris Kondratieff (Colorado State University, Fort Collins, Colorado) and by David Ruiter (Environmental Protection Agency, Denver, Colorado). Female abdomens were brown and had a noticeable odor (to the human nose), and abdomens of males were pale green and odorless.

Statistical Analyses. Data were analyzed by one-way analyses of variance. Differences among means were determined by Newman-Keuls multiple-range test (Winer, 1971).

RESULTS

In EAG tests, male antennae responded strongly to extracts of female abdomens, and female antennae responded significantly less (Figure 1). Extracts of

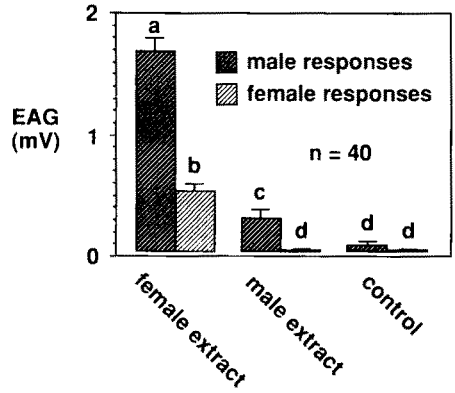

FIG. 1. Male and female responses to male and female extracts; n = total number of responses to each treatment recorded from eight males and 10 females. Bars on each column indicate standard error. Treatments denoted by the same letter are not significantly different with Newman-Keuls multiple-range test ($P = 0.05$).

male abdomens produced weak EAG activity with both male and female antennae. Males and females for this experiment were collected from a mercury vapor lamp and carried to the laboratory in Ziploc bags.

Capillary GLC-FID of a female abdominal extract on a methyl silicone column showed one major peak and a number of smaller peaks (Figure 2). A single area of EAG activity from male antennae was observed among gas chromatographic fractions (methyl silicone, packed column) that were collected from

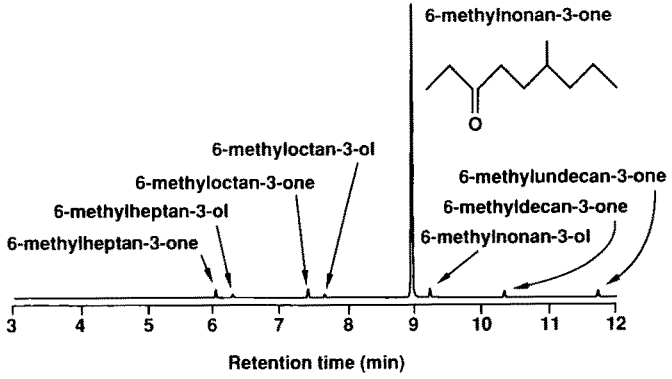

FIG. 2. Capillary gas–liquid chromatogram (methyl silicone) of *Hesperophylax occidentalis* female abdominal extract.

a female extract. The most EAG-active fraction (6–8 min) contained essentially all of the major peak observed previously by capillary GLC (Figure 2). EAG activity in subsequent fractions was apparently due to slight tailing of this compound (above the EAG threshold of the male antennae).

EI-GC-MS analysis of the major peak in female extracts indicated an apparent mass of 156 (Figure 3A). Probability-based matching with a National Bureau of Standards computer data base of mass spectra suggested that the compound was an alkan-3-one. The retention time of this major peak was 7.05 min, shorter than the retention time of synthetic decan-3-one (7.63 min) and longer than the retention time of synthetic nonan-3-one (5.78 min). This suggested that the compound was a methyl-branched nonan-3-one. CI-GC-MS analysis (with ammonia as the reagent gas) of the major peak in female extracts indicated a base peak of 174 (M+18), corroborating the mass of the compound as 156 (Figure 3B).

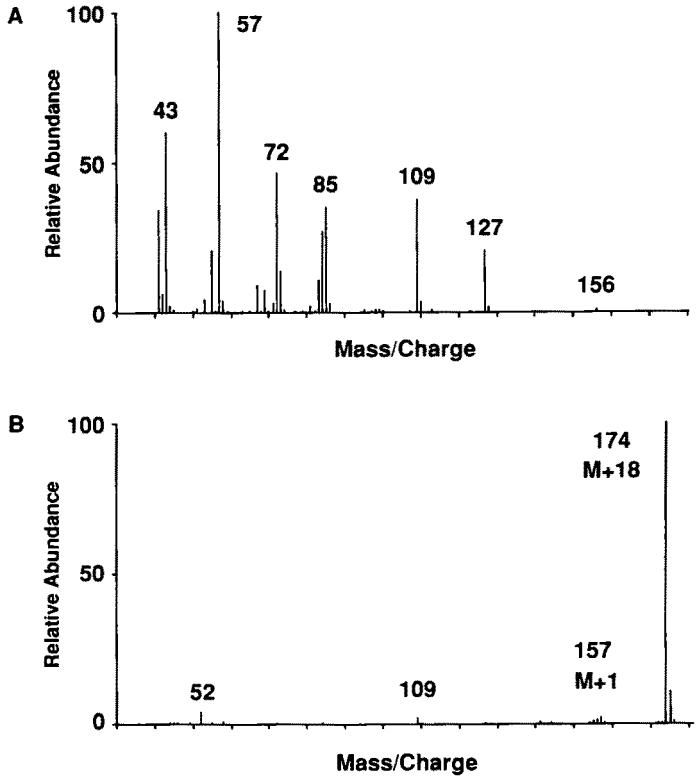

FIG. 3. (A) Electron ionization mass spectrum and (B) chemical ionization mass spectrum of 6-methylnonan-3-one extracted from a female *Hesperophylax occidentalis*.

The hydrocarbon skeleton was prepared from the main pheromone component in order to determine the position of the methyl branch. The mass spectra of all monomethyl nonanes are in the literature and differ appreciably from one another (Stenhagen et al., 1974). Derivatization of the main pheromone component with LAH produced a compound with a slightly later retention time (7.20 min). EI-GC-MS analysis of this compound indicated a mass of 158 (consistent with a monomethyl-nonanol), and probability-based matching with a National Bureau of Standards mass spectral data base suggested that the compound was an alkan-3-ol. Derivatization of this alcohol with triphenylphosphine dibromide produced a compound with a later retention time (8.49 min), and EI-MS of this compound was consistent with a monomethyl bromononane. The hydrocarbon skeleton (retention time 4.22 min) was prepared from the monomethyl bromononane with sodium borohydride in DMSO, and EI-MS indicated that this compound was 4-methyl-nonane, with diagnostic peaks at *m/z* 142 (M+, 4%), 57 (100%), 43 (80%), 41 (44%), 70 (38%), 71 (36%), 98 (26%), and 99 (10%). Nonanes with methyl branches at other positions have substantially different mass spectra (Stenhagen et al., 1974).

Two structural possibilities existed at this point. The derivative 4-methylnonane would be generated as a hydrocarbon skeleton from either 6-methylnonan-3-one or 4-methylnonan-3-one. To distinguish between these possibilities, the fragments in the EI mass spectrum of the parent pheromone component were considered in detail (Figure 4). The parent pheromone component was initially identified as 6-methylnonan-3-one on the basis of diagnostic fragments at *m/z* 72 and *m/z* 84 (4-methylnonan-3-one would be expected to have diagnostic fragments at *m/z* 70 and *m/z* 86). Synthetic 6-methylnonan-3-one (racemic) prepared in our laboratory had a retention time (7.05 min) and EI mass spectrum that were identical to those for the isolated main pheromone component from females. GC-EI-MS of related compounds was conducted for comparison, including 7-methylnonan-3-one (retention time 7.07 min) and 2-methylnonan-3-one (retention time 6.82 min), and both compounds had mass spectra easily distinguishable from that of 6-methylnonan-3-one.

Gas chromatographic analysis of extracts of separate pieces of the female ventrum indicated that 6-methylnonan-3-one occurs selectively in the region between the midpoints of the fourth and fifth abdominal sternites (the pieces were obtained by cutting transversely through the midpoint of each sternite, so as to include the intersegmental membrane between successive sternites). No discrete glands were observed, however. Approximately 1 μg of 6-methylnonan-3-one was found per female. Other compounds were also found in small amounts in female extracts, and these were tentatively identified on the basis of mass spectra and relative retention times as 6-methyl-alkan-3-ones, including 6-methylheptan-3-one [retention time 3.61 min, with diagnostic peaks at *m/z* 99 (8%), 86 (50%), 71 (75%), 57 (100%), and 43 (78%)], 6-methyloctan-3-one [retention time 5.56 min, with diagnostic peaks at *m/z* 113 (20%), 95 (49%), 85 (18%),

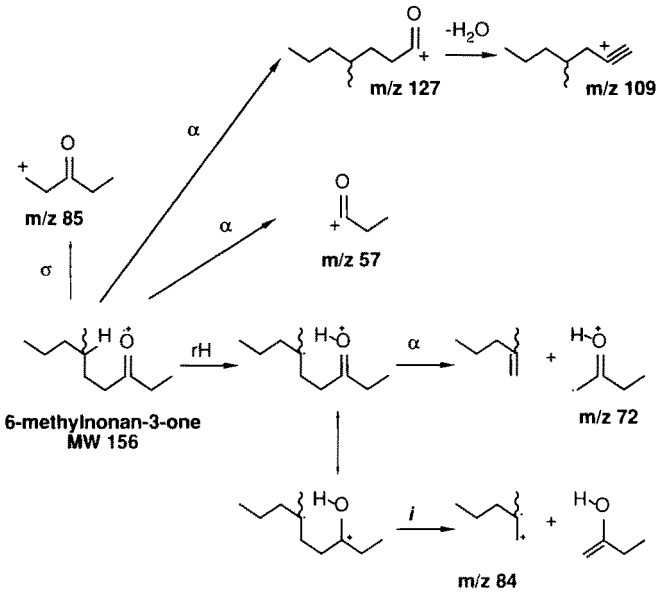

FIG. 4. Proposed fragmentation pattern for electron-ionization mass spectrum of 6-methylnonan-3-one.

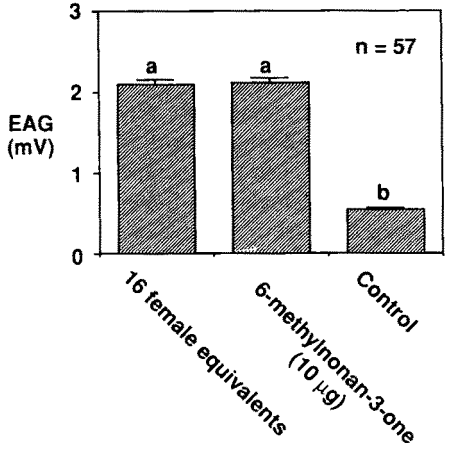

FIG. 5. Male *Hesperophylax occidentalis* EAG responses; n = total number of recorded responses to each treatment. Bars on each column indicate standard error. Treatments denoted by the same letter are not significantly different by Newman-Keuls multiple-range test ($P = 0.05$).

72 (48%), 57 (100%), and 43 (77%)], 6-methyldecan-3-one [retention time 8.50 min, with diagnostic peaks at *m/z* 141 (17%), 123 (6%), 98 (20%), 85 (24%), 72 (48%), 57 (100%), and 43 (52%)], and 6-methylundecan-3-one [retention time 9.95 min, with diagnostic peaks at *m/z* 155 (14%), 137 (7%), 112 (18%), 72 (49%), 57 (100%), and 43 (63%)]. Small amounts of the corresponding alcohols were also tentatively identified for some of these compounds, including 6-methylheptan-3-ol [retention time 4.25 min, with diagnostic peaks at *m/z* 101 (9%), 83 (16%), 59 (100%), and 41 (38%)], 6-methyloctan-3-ol [retention time 5.85 min, with diagnostic peaks at *m/z* 115 (22%), 97 (74%), 69 (39%), 59 (64%), 55 (100%), and 41 (60%)], and 6-methylnonan-3-ol [retention time 7.20 min, with diagnostic peaks at *m/z* 129 (23%), 111 (29%), 69 (100%), 59 (96%), 55 (43%), and 41 (53%)]. A small amount of indole [retention time 11.95 min, with diagnostic peaks at *m/z* 151 (100%), 124 (13%), 116 (23%), and 89 (41%)] was observed in some extracts, but not in others.

To verify that the main pheromone component is 6-methylnonan-3-one, EAG responses of male antennae to synthetic 6-methylnonan-3-one (racemic) and to extracts of female abdomens containing a comparable amount of the main pheromone component were compared (Figure 5). Responses of male antennae were equal for 16 female equivalents and for 10 μg of 6-methylnonan-3-one (racemic).

Traps baited with racemic 6-methylnonan-3-one caught almost exclusively male *H. occidentalis*, and the males were selectively attracted to the 100-μg lures, with higher and lower amounts attracting significantly fewer males (Figure 6A). A small number of females were also trapped, but the numbers of females caught in traps baited with 6-methylnonan-3-one were not significantly different from the number caught in control traps (Figure 6B).

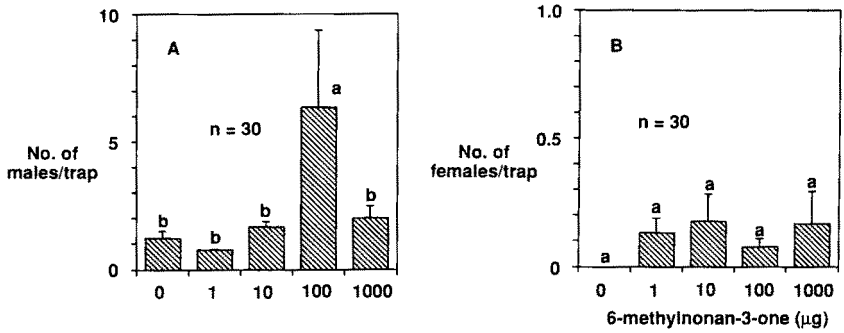

FIG. 6. (A) Males and (B) females caught in traps baited with different amounts of synthetic, racemic 6-methylnonan-3-one; n = number of times adults were counted. Bars on each column indicate standard error. Treatments denoted by the same letter are not significantly different by Newman-Keuls multiple-range test (P = 0.05).

DISCUSSION

The main sex pheromone component of *Hesperophylax occidentalis* is 6-methylnonan-3-one. This is apparently the first report of this compound as a natural product. We have not yet determined the enantiomeric composition of the 6-methylnonan-3-one from female *Hesperophylax occidentalis* (this presumably will be quite difficult to determine for a methyl group with no other functional groups nearby). Smaller amounts of several structurally related compounds were also tentatively identified in extracts of pheromone glands, including 6-methylheptan-3-one, 6-methyloctan-3-one, 6-methyldecan-3-one, 6-methylundecan-3-one, 6-methylheptan-3-ol, 6-methyloctan-3-ol, and 6-methylnonan-3-ol. Synthetic 6-methylnonan-3-one (racemic) prepared in our laboratory was active in EAG tests and also in field trapping tests with male *H. occidentalis*. Further EAG tests with analogs of 6-methylnonan-3-one have been conducted, including chain-length analogs, keto-position analogs, and methyl-group-position analogs (Jewett, 1993). Small EAG responses from male antennae were observed in response to male abdomen extract (Figure 1), but this may simply be due to slight contamination of the extracted males with volatile compounds from females during transport from the field to the laboratory.

Males were selectively caught in traps containing 100 μg of synthetic 6-methylnonan-3-one. Small numbers of females were also trapped, but the numbers of females caught in traps baited with different doses of 6-methylnonan-3-one were not significantly different from one another nor from the number caught in control traps (Figure 6B). This implies that males were indeed attracted to the synthetic pheromone, not to the small numbers of females that were incidentally caught in some of the traps (in fact, qualitatively it was observed that the smallest number of females was caught in traps containing the 100-μg lures).

The first chemical identifications of pheromones shown formally to be involved in sexual communication have recently been reported (Valeur et al., 1990; Löfstedt et al., 1994) for two caddisfly species, *Rhyacophila fasciata* (Hagen) (Rhyacophilidae) and *Hydropsyche angustipennis* (Curtis) (Hydropsychidae), and possible pheromone components (no behavioral data reported) have been observed in *Rhyacophila nubila* (Zetterstedt) (Rhyacophilidae) (Löfstedt et al., 1994). In both *Rhyacophila* species, sexual communication appears to involve a traditional sex pheromone, with females attracting males. *R. nubila* females produce approximately equal amounts of heptan-2-ol, heptan-2-one, and nonan-2-one, and they produce a smaller amount of nonan-2-ol (although considerable variability was observed, with some extracts predominating in heptan-2-one). *R. fasciata* females produce mainly heptan-2-ol, with smaller amounts of heptan-2-one, nonan-2-one, and nonan-2-ol. Appropriate blends of the syn-

thetic compounds were shown to be attractive to males of *Rhyacophila fasciata*. Ansteeg and Dettner (1991) previously identified heptan-2-ol from females of *R. nubila*, but they did not test this compound for attraction. Males of both these *Rhyacophila* species (Ansteeg and Dettner, 1991; Löfstedt et al., 1994) produce acetophenone, hexanoic acid, and octanoic acid (the possible role of these compounds in sexual communication has not been tested). Females of a third rhyacophilid species, *Rhyacophila fuscula* (Walker), have been shown (Duffield, 1981) to produce nonan-2-ol (similarly, the possible role of this compound in sexual communication has not been tested).

Sexual communication in *Hydropsyche angustipennis* appears to be more complex (Valeur et al., 1990; Löfstedt et al., 1994). Females produce nonan-2-one (the only compound that was electrophysiologically active for male antennae), but males produce a blend of seven compounds (all of which were electrophysiologically active for male antennae) that included heptan-2-one, octan-2-one, nonan-2-one, decan-2-one, undecan-2-one, nonan-2-ol, and (*Z*)-6-nonen-2-one. This blend of male-produced compounds [(*Z*)-6-nonen-2-one was omitted from the blend] attracted both males and females to traps, suggesting that it may act as an aggregation pheromone, not as a traditional sex pheromone. Males and females of *Hydropsyche siltalai* produce the same compounds as the respective sex of *Hydropsyche angustipennis* (Löfstedt et al., 1994).

Mating communication in *Hesperophylax occidentalis* appears to involve a traditional sex pheromone that is produced by females and that attracts males. Female extracts elicited strong electrophysiological activity from male antennae, but not from female antennae, and male extracts did not elicit strong electrophysiological activity from antennae of either sex. The electrophysiologically active compound in female extracts was 6-methylnonan-3-one, and this compound attracted males but not females. This implies that mating communication in *H. occidentalis* is similar to that observed for the *Rhyacophila* species studied by Löfstedt et al. (1994) and does not resemble the system of mating communication observed in *Hydropsyche angustipennis* (Löfstedt et al., 1994).

Although chemical identifications of sex pheromones have not been reported for the Limnephilidae prior to the present study on *H. occidentalis*, a blend of defensive compounds (active against ants) has been chemically identified from the fifth abdominal sternite for both male and female *Pycnopsyche scabripennis* (Limnephilidae), including *p*-cresol, indole, and skatole (Duffield et al., 1977). Similarly, a defensive role was ascribed to compounds found in the fifth abdominal sternites of two other caddisfly species, *Polycentropus flavomaculatus* (Pictet) and *Phryganea grandis* L., on the basis of irritability reactions in larvae of *Calliphora vomitoria* (Ansteeg and Dettner, 1991). *Polycentropus flavomaculatus* (Polycentropodidae) males produce 2-methylbutanoic acid, and both sexes produce several hydroxymethylacetophenones that have not yet been fully characterized (Ansteeg and Dettner, 1991). Female *Phryganea grandis* produce a

blend of pentan-1-ol, octan-1-ol, and 3-methylheptan-2-one, and 2-phenylethanol (Ansteeg and Dettner, 1991).

In our preliminary observations during the present study, we did not observe discrete pheromone glands in the female abdomen. However, we found, by gas chromatographic analysis, that the region between the midpoints of the fourth and fifth sternites in *H. occidentalis* females was the only part of the ventrum that contained the main sex pheromone component 6-methylnonan-3-one. A paired exocrine gland associated with the fourth and fifth abdominal sternites has been identified as the source of pheromonal secretions in *Hydropsyche angustipennis*, *Rhyacophila nubila*, and *R. fasciata* (Löfstedt et al., 1994). There have been reports of pheromone release by Trichoptera from both the fourth and fifth sternites (Resh and Wood, 1985; Solem, 1985; Resh et al., 1987; Wagner and Rosovsky, 1991; Löfstedt et al., 1994). Most female ditrysian Lepidoptera studied have pheromone glands in the region between abdominal segments eight and nine (Götz, 1951; Jefferson et al., 1968; Percy and Weatherston, 1971; Percy-Cunningham and MacDonald, 1987) that may be homologous (Wagner and Rosovsky, 1991) to exocrine glands observed on the eighth and ninth abdominal segments of several Trichoptera (Nielsen, 1980). The postures of pheromone-releasing Lithocolletinae (Tineiodea) and *Niditinea* suggest that the site of pheromone release is also from terminal abdominal segments (Wagner and Rosovsky, 1991). In contrast to higher Lepidoptera, the female genitalia of these species appear to be involved in pheromone release. Although pheromones have not been identified from preditrysian Lepidoptera, sternal glands and globular reservoirs associated with the fifth abdominal sternite have been described for the Micropterigidae (Philpott, 1925; Kristensen, 1984), Heterobathmiidae (Kristensen and Nielsen, 1979), Neopseustidae (Davis, 1975), and Eriocraniidae (Davis, 1978). Wagner and Rosovsky (1991) surmised from these observations that female pheromone-releasing tissues or glands have evolved independently at least five times in the Amphiesmenoptera from structures on the thorax and abdomen.

The active compounds released by many species of Lepidoptera are straight-chain aliphatic molecules (12–18 carbon atoms) with a single functional group (alcohol, aldehyde, epoxide, ketone, etc.) and one or more double bonds (Arn et al., 1986; Tamaki, 1988; Mayer and McLaughlin, 1991). Recently, small (7–9 carbon atoms) secondary alcohols and ketones have been identified from some species of Lepidoptera (Tóth et al., 1995; Zhu et al., 1995). These compounds are similar in structure to the ones that have been implicated in pheromone communication in *H. occidentalis* (present study) and other caddisfly species (Löfstedt et al., 1994). This structural similarity appears to reflect the close phylogenetic relationship of the Trichoptera and Lepidoptera and may represent a symplesiomorphy for these sister groups, as suggested by Zhu et al. (1995).

Resh and Wood (1985) suggested that understanding chemical communication in the Trichoptera may provide insights into their systematic and ecological relationships. The Trichoptera are one of the largest and most successful groups of aquatic insects (Wiggins and Mackay, 1978), with approximately 1340 Nearctic species for which the adult systematics have been well established (Duffield, 1981; Wiggins, 1988). The Trichoptera and the Lepidoptera constitute a monophyletic group, the superorder Amphiesmenoptera, which is among the most highly corroborated ordinal clusterings in the Insecta (Hennig, 1953; Kristensen, 1981a, b, 1984; Nielsen, 1989). Similarities in morphology (Ross, 1955; Carpenter, 1992), embryology (Kobayashi and Ando, 1988), and pupation (Weaver, 1984; Wiggins and Wichard, 1989; Wiggins, 1992) have been found to support a strong phylogenetic relationship between the two orders. The time of reproductive activity is also similar for the Trichoptera and for the Lepidoptera. Adults of many caddisfly species are reproductively active following eclosion at either dusk or dawn (Davis, 1934; Solem, 1986; Peckarsky et al., 1990), and their activity is dependent on light intensity, but not temperature (Benz, 1975). Similarly, flight activity in early Lepidoptera (such as the Hepialidae) is dependent on light intensity (Madge, 1954; Martyn, 1960; Barton Browne, et al. 1969; Van Gerwen et al., 1972; Hardy, 1973; Mikkola, 1974; Mallet, 1984; Wagner, 1985). In trichopteran families such as the Lepidostomatidae and the Sericostomatidae, the basal segments of the male antennae are enlarged and distorted (Wiggins, 1984). This is suggestive of the sexual dimorphism associated with sex pheromone reception in male saturniid moths (Boeckh, 1967; Lerner et al., 1990), in which the larger male antennae are important for long-distance pheromone reception (Steinbrecht, 1987).

Acknowledgments—Funding for this project was provided by Colorado Agricultural Experiment Station project number 622, and by a grant to D.K. Jewett from the American Museum of Natural History Theodore Roosevelt Memorial Fund. Statistical assistance was provided by J. Zumbrunnen, Statistics Department, Colorado State University. Collection of adults in Rocky Mountain National Park was made possible by a permit issued to P.A. Opler. We thank M. Harris, W. Painter, M.A. Lee, E.J. Bernklau, and E.M. Abou-Fakhr for field assistance.

(Received January 13, 1995; accepted August 28, 1995)

Abstract—Electroantennogram (EAG) analyses of *Hesperophylax occidentalis* male and female antennae were used to generate dose-response curves for synthetic, racemic 6-methylnonan-3-one and to demonstrate the chemical specificity of male antennal olfactory cells. Male antennae responded to 6-methylnonan-3-one, the main female pheromone component. Females also demonstrated a response to 6-methylnonan-3-one, but a smaller one than males. The chemical specificity of male antennal receptors was determined by comparing EAG activity of synthetic, racemic 6-methylnonan-3-one and a series of structural analogs. The three structural parameters considered, including keto position, chain length, and methyl-group position, were demonstrated to contribute significantly to the reception of synthetic, racemic 6-methylnonan-3-one by male antennae. For straight-chain nonanones with keto groups at different positions, nonan-3-one elicited the greatest EAG responses from male antennae. For straight-chain alkan-3-ones with different chain lengths, the EAG responses of male antennae to nonan-3-one and decan-3-one were the same, but greater than those to other chain lengths. For methyl-branched nonan-3-ones, 6-methylnonan-3-one elicited greater EAG responses from antennae than analogs with the methyl group at another position.

Key Words—Caddisfly, limnephilid, aquatic insect, adults, EAG, attractant, antennae, analogs, chemical specificity, receptors.

INTRODUCTION

Mayer and McLaughlin (1991) listed over 1300 insect species for which the sex pheromones or other attractants have been reported. These species comprise 10 orders, including the Trichoptera (Jewett, 1993; Löfstedt et al., 1994; Bjostad et al., 1995), Orthoptera, Homoptera, Hemiptera, Lepidoptera, Coleoptera, Mecoptera, Neuroptera, Hymenoptera, and Diptera (Mayer and McLaughlin, 1991). Despite its pervasiveness, the use of sex pheromones by members of the Trichoptera and other aquatic insects has received little attention until recently.

Wood and Resh (1984) first demonstrated chemically mediated sexual communication in the Trichoptera by trapping *Gumaga griseola* males with live, caged females and whole-body extracts. Chemical extracts of specific body sections from adult *G. nigricula*, *G. griseola*, and *Dicosmoecus gilvipes* females have also been used in field trapping (Resh and Wood, 1985). These experiments indicated that the fifth abdominal sternite of females contains the sex pheromone. Similar methods were employed to demonstrate sex pheromone use by the rhyacophilid, *Rhyacophila nubila* (Solem, 1985).

The identification of sex pheromones has been reported for several caddisfly species, including *Hesperophylax occidentalis* (Jewett, 1993; Bjostad et al., 1995), *Hydropsyche angustipennis* and *R. fasciata* (Löfstedt et al., 1994). *H. occidentalis* females produce a blend of compounds to which males demonstrate both an electrophysiological response in the laboratory and a behavioral response in the field (Jewett, 1993; Bjostad et al., 1995). Previous electroantennogram (EAG) experiments demonstrated that *H. occidentalis* males respond to extracts of the membrane between the fourth and fifth sternites in *H. occidentalis* females, but not to the sternites themselves. The pheromone blend was shown to include indole, 6-methylundecan-3-ol, 6-methylnonan-3-ol, 6-methylnonan-3-one, 6-methyloctan-3-ol, 6-methyloctan-3-one, 6-methylheptan-3-ol, and 6-methylheptan-3-one. Of these compounds, 6-methylnonan-3-one is present in greatest abundance and elicits the strongest EAG response from male antennae (Jewett, 1993; Bjostad et al., 1995).

The electroantennogram (EAG) has been a tool frequently used to study antennal receptor function for sex pheromones of moths and other insects. EAG response is assumed to be the summation of bioelectrical potentials generated by many olfactory receptor cells responding to odor stimulants (Nagai, 1984). The amplitude of the receptor potential of most insects is influenced not only by stimulus intensity, but by the chemical structure of the stimulus. The intersexual exchange of information by insects often transpires via molecules that differ only by their functional groups (Bestmann et al., 1987). Although receptor neurons are generally most active when exposed to the genuine pheromone, individual neurons may be excited by higher doses of a related analog. Male antennal neurons of many lepidopterans are generally receptive to pheromones

released by conspecific females or females belonging to closely related sympatric species (Priesner, 1979).

Interactions between pheromone molecules and their receptors have been investigated by analyzing the responses of identified receptor neurons to a homologous series of compounds (Boeckh, 1967; Kafka, 1970, 1974; Liljefors et al., 1985; Priesner et al., 1977; Schwarz et al., 1989; Vareschi, 1971; Dumpert, 1972; Kafka and Neuwirth, 1975). The literature is replete with structure–activity studies for lepidopteran, hymenopteran, orthopteran, isopteran, dipteran, and coleopteran pheromones (Prestwich, 1987). Analogs have been classified by chain length, functional group, regiochemicals with relocated double bonds, or carbonyls, diastereoisomers, and enantiomers (Prestwich, 1987).

The chemical specificity of *H. occidentalis* male antennae for 6-methylnonan-3-one was evaluated by comparing its EAG activity with that of several analogs. The analogs tested were different from 6-methylnonan-3-one either in keto position, chain length, or methyl-group position.

METHODS AND MATERIALS

Collection of Pupae and Preparation of Adults. Pupae were obtained during the summer and early autumn of 1990 and 1991 from a small stream in Hewlett Gulch, a tributary of the Poudre River (Larimer County, Colorado), or from the westernmost lake at Glacier Lakes approximately 5 km northwest of Centennial, Wyoming. Pupae in larval cases attached to the undersides of rocks by a silk thread were removed and placed into insulated coolers (4-liter capacity; Rubbermaid, Gott Corp., Winfield, Kansas) containing ambient water. Sufficient aeration was provided by battery-powered aquarium pumps (B&M Air Pump, West Point, Mississippi 39773) similar to those used by fishermen to maitain live bait. Pupae were returned to the laboratory where preparations were made for their eclosion.

Adult females frequently emerged several days later than males, but overlapping was observed. Behavioral studies suggest that caddisfly adults may be reproductively active following eclosion at either dusk or dawn (Williams and Feltmate, 1992). To prevent copulation and its consequent effects upon female production of or male response to pheromone that has been observed in some insects (McNeil, 1991), adults were removed from their styrofoam emergence containers immediately after eclosion and separated by sex.

The sexes of *H. occidentalis* adults were determined using their genital characteristics, abdominal color, and/or odor. Under a 25× low-power microscope, claspers that males use during copulation are visible. Parker and Wiggins (1986) present excellent illustrations of male and female genitalia. Abdomens of males were usually a pale green, while females could be identified by their

drab brown color. This characteristic is subject to geographical variation (Parker and Wiggins, 1985). Finally, the odor of compounds (to the human nose) secreted from a female's abdomen was very distinct, while the male displayed no detectable odor. Voucher specimens were deposited in the C.P. Gillette Museum of Arthropod Biodiveristy at Colorado State University, Fort Collins, Colorado 80523.

Synthetic Compounds. Octan-3-one, nonan-3-one, decan-3-one, and nonan-2-one were purchased from Aldrich Chemical Company, Inc. (1001 St. Paul Avenue, Milwaukee, Wisconsin 53233) (Figure 1). Nonan-4-one and 2-methylnonan-3-one were purchased from Wiley Organics (1245 6th St., Coshocton, Ohio 43812) (Figure 1). Dr. Louis Hegedus (Chemistry Department, Colorado State University) provided the nonan-5-one (Figure 1).

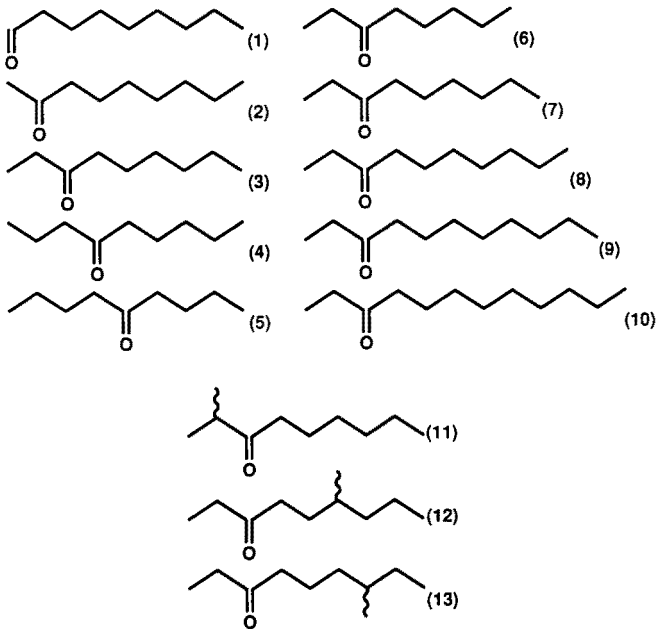

FIG. 1. Synthetic compounds used to characterize the specificity of male *Hesperophylax occidentalis* antennae. Squiggly lines represent a methyl group of undetermined stereochemistry; (1) nonanal, (2) nonan-2-one, (3) nonan-3-one, (4) nonan-4-one, (5) nonan-5-one, (6) octan-3-one, (7) nonan-3-one, (8) decan-3-one, (9) undecan-3-one, (10) dodecan-3-one, (11) 2-methylnonan-3-one, (12) 6-methylnonan-3-one, and (13) 7-methyl nonan-3-one.

The optical nature of the main sex pheromone component, 6-methylnonan-3-one, in *H. occidentalis* females is presently unknown. Many lepidopteran pheromones are optically active (Mayer and McLaughlin, 1991), which suggests a role for stereospecificity in the pheromone blend of *H. occidentalis* females. However, we did not have access to different optical isomers of 6-methylnonan-3-one, and only racemic mixtures were tested.

The racemic compounds 6-methylnonan-3-one, and 7-methylnonan-3-one (Figure 1) were synthesized from the racemic starting compounds 4-methylheptan-1-ol and 5-methylheptan-1-ol (Wiley Organics), respectively. Dodecan-3-one, and undecan-3-one were synthesized from decan-1-ol (Aldrich Chemical Company, Inc.), and nonan-1-ol (Aldrich Chemical Company, Inc.), respectively. Syntheses were completed by oxidizing 4-methylheptan-1-ol, 5-methylheptanol, decanol, and nonanol with pyridinium dichromate (PDC) (Corey and Schmidt, 1979) in $MeCl_2$ to form the corresponding aldehydes. A Grignard reaction with ethyl magnesium bromide (EtMgBr) in diethyl ether (Et_2O) was then performed to generate the secondary alcohols (Fieser and Fiesser, 1967). Reaction with EtMgBr was followed by another oxidation by PDC to generate the ketones. Final purification of the ketones was accomplished by their elution through a Florisil column with an equimolar mixture of $MeCl_2$ and Et_2O.

Synthesis of the racemic compounds 6-methylnonan-3-one, 7-methylnonan-3-one, dodecan-3-one, and undecan-3-one was modified from Corey and Schmidt (1979) and Fieser and Fieser (1967). The PDC reaction proceeded for 24 hr instead of 1 hr, with stirring provided by a 5-mm metal-impregnated glass rod. The remaining solid material was centrifuged to a small pellet at the bottom of the vial, and the final product in solution was transferred with a pipet to a clean vial.

Workup of the Grignard reaction was also modified. Excess EtMgBr was destroyed by adding to the reaction medium a water-saturated Et_2O solution. Destruction of excess EtMgBr was complete when water was no longer observed to react with it. The remaining white solid material was centrifuged to a pellet, and the Et_2O solution was pipetted to a clean vial, where it was extracted several times with distilled water. The final product was passed through a column of Florisil packed with Et_2O.

Treatment Preparations. Dose–response curves for males and females were obtained with five amounts of 6-methylnonan-3-one in $MeCl_2$: 0.1, 1.0, 10.0, 100, and 1000 μg, and a blank of 100 μl $MeCl_2$ that was evaporated to apparent dryness before testing.

In studies using synthetic analogs with different chain lengths, different keto positions, or different methyl-group positions, units of 200 μg were tested. All experiments included comparisons with 200 μg of synthetic, racemic 6-methylnonan-3-one as a positive control, and a blank of 100 μl $MeCl_2$ that

was evaporated to apparent dryness before testing. Preliminary experiments indicated that 200-μg doses elicited the maximum EAG response possible for each compound (for example, see Figure 2 below), which would tend to minimize differences in EAG responses due to differences in volatility among the compounds tested.

EAG Procedure. Because their life has not been observed to exceed five days under laboratory conditions, expedient use of the adult caddisflies was important. One antenna held at the base was plucked from the head with a pair of fine forceps. To increase exposed surface area and facilitate measurement of any depolarization, a 0.5-cm tip of the antenna was removed with a pair of thread trimmers and discarded. The remainder of the antenna was placed between two glass pipets filled with 0.15 M potassium chloride solution serving as electrodes. A few minutes were frequently required before testing to permit equilibration of the antenna and the KCl solution. Treatments were applied to separate 1×3-cm strips of filter paper from which the $MeCl_2$ was permitted to evaporate. The filter paper was folded lengthwise, slipped into a Pasteur pipet, and used immediately before active compounds could volatilize. Treatments were tested in random order. A 5.0-ml glass syringe was used to expel 0.5 ml air through the Pasteur pipet and across the antenna. A drop in potential across an antenna was enhanced by a $5000\times$ amplifier interfaced with a Commodore 64 computer (Commodore Business Machines, Wayne, Pennsylvania), and displayed graphically on a monitor (Bjostad and Roelofs, 1980; Bjostad, 1988). Fatigue was minimal throughout the duration of testing each antenna, as indicated by the small variation in responses to compounds tested.

Statistical Analyses. Data obtained from the electroantennograms were analyzed with SAS (SAS Institute Inc., SAS Circle, Box 8000, Cary, North Carolina 27512-8000). Experiments in which ANOVA yielded significant P values (0.05) were subjected to a comparison of total EAG activity with Newman-Keuls multiple-range test.

RESULTS

Both male and female antennae produced significant EAG responses to synthetic, racemic 6-methylnonan-3-one (Figure 2). The EAG responses of males to synthetic, racemic 6-methylnonan-3-one were greater than the EAG responses of females. Electrophysiological responses of both male and female antennae were directly proportional to the amount of synthetic, racemic 6-methylnonan-3-one applied to them (Figure 2). The amount of 6-methylnonan-3-one required to elicit a response from male antennae was four orders of magnitude less than that required for females; 1000 μg of 6-methylnonan-3-one was required to elicit a response from female antennae significantly greater than that elicited by a

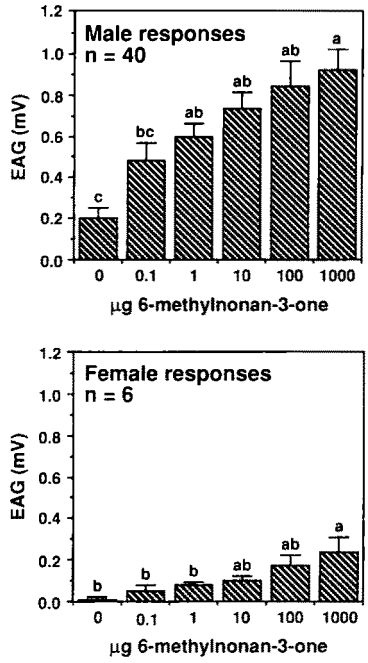

FIG. 2. Synthetic, racemic 6-methylnonan-3-one dose–response curves for *Hesperophylax occidentalis* males and females; n = number of responses to each treatment recorded from three male and three female antennae. Bars on columns represent standard errors. Treatments denoted by the same letter are not significantly different by Newman-Keuls multiple-range test ($P = 0.05$).

control of evaporated $MeCl_2$. The lowest dose of 6-methylnonan-3-one tested was 0.1 μg, and it elicited a significantly greater response from male antennae than the control.

Results of the EAG experiments were consistent with our prediction of chemical specificity for reception of 6-methylnonan-3-one by male antennal olfactory cells and support the importance of all structural parameters used. The responses elicited from male antennae waned with analogs whose structure deviated increasingly from that of the main pheromone component, 6-methylnonan-3-one. When considering the effect of different keto positions, there were also significant differences in the EAG activity elicited by analogs of 6-methylnonan-3-one (Figure 3). Multiple-range tests indicated that a significant difference exists between nonan-3-one and all other treatments, but no statistically significant differences exist among nonan-2-one, nonan-4-one, and nonan-5-one.

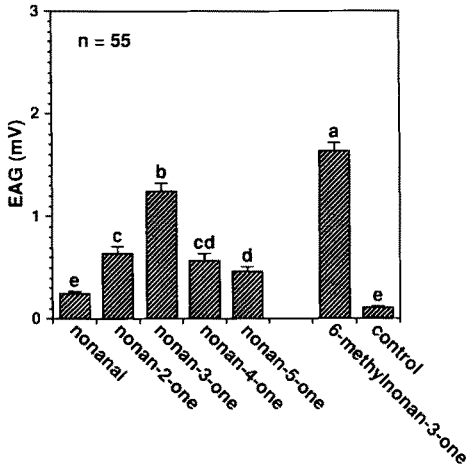

FIG. 3. *Hesperophylax occidentalis* male EAG responses to nonanones with varying keto positions (200 μg of each); n = number of responses to each treatment recorded from 11 male antennae. Bars on columns represent standard errors. Treatments denoted by the same letter are not significantly different by Newman-Keuls multiple-range test (P = 0.05).

Significant differences were obtained between nonan-5-one and nonanal and between nonanal and the control of evaporated $MeCl_2$. Responses elicited by 6-methylnonan-3-one were significantly different from all other treatments.

When considering the effect of different chain lengths, a significant difference among EAG activity elicited by analogs of 6-methylnonan-3-one was observed (Figure 4). EAG responses of male antennae to nonan-3-one and decan-3-one were equally strong. These two compounds elicited significantly higher responses than octan-3-one, which elicited significantly higher responses than undecan-3-one. Undecan-3-one elicited significantly higher responses than dodecan-3-one. No significant difference was observed between EAG responses to dodecan-3-one and the control of evaporated $MeCl_2$. The average response elicited from male antennae by 6-methylnonan-3-one in that experiment was significantly greater than all other treatments.

Significant differences were observed among the EAG activity of 6-methylnonan-3-one analogs differing in methyl-group position (Figure 5). Responses by male antennae to methyl-group position analogs were smaller than those of synthetic 6-methylnonan-3-one. Furthermore, the magnitude of the EAG responses was inversely related to the distance of the methyl group from the sixth carbon. 7-Methylnonan-3-one elicited a significantly larger response than

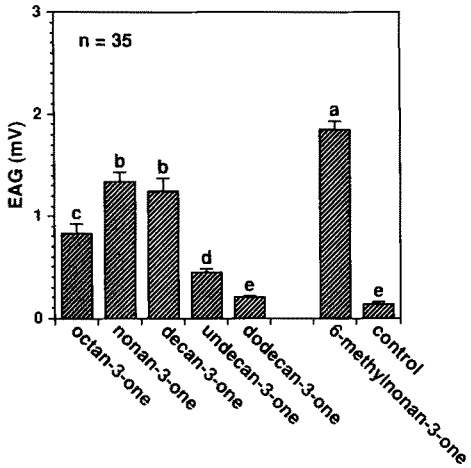

FIG. 4. *Hesperophylax occidentalis* male EAG responses to alkan-3-ones of varying length (200 μg of each); n = number of responses to each treatment recorded from 11 male antennae. Bars on columns represent standard errors. Treatments denoted by the same letter are not significantly different by Newman-Keuls multiple-range test (P = 0.05).

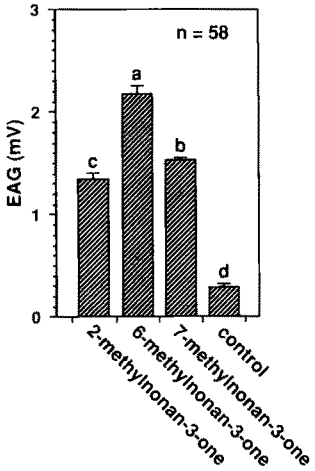

FIG. 5. *Hesperophylax occidentalis* male EAG responses to varying methyl-substituted nonan-3-ones (200 μg of each); n = number of responses to each treatment recorded from 12 male antennae. Bars on columns represent standard errors. Treatments denoted by the same letter are not significantly different by Newman-Keuls multiple-range test (P = 0.05).

2-methylnonan-3-one. Other commercially available methyl-branched alkanones were also tested as indicators of antennal specificity for the main pheromone component. 7-Methylnonan-3-one and 2-methylnonan-3-one elicited significantly larger EAG responses than 5-methyloctan-3-one. 5-Methyloctan-3-one elicited a response significantly higher than that elicited from 4-methylheptan-3-one. The activity elicited by 4-methylheptan-3-one was not significantly different from the control. The average male EAG response elicited by synthetic 6-methylnonan-3-one was significantly greater than that from all other treatments.

DISCUSSION

Results of our EAG experiments were consistent with previous observations that females produce compounds to which males have a highly selective response. Small structural changes in the molecule 6-methylnonan-3-one caused appreciable reductions in the receptor potentials of *H. occidentalis* male antennae. These reductions in receptor potential demonstrate that the olfactory cells of male antennae are selective for 6-methylnonan-3-one. The structural parameters demonstrated to be responsible for this selectivity are keto position, chain length, and methyl-group position. The consequences of selectivity by olfactory cells are illustrated by our experiment comparing the electrophysiological activity of chain length analogs. EAG responses of male antennae to nonan-3-one and to decan-3-one were the same, consistent with our expectation that the putative receptor for 6-methylnonan-3-one is specialized for a compact molecule that is sterically intermediate between nonan-3-one and decan-3-one.

Previous work has demonstrated that similar structural alterations in pheromone components significantly reduce EAG activity, indicating that receptors on insect antennae characteristically have limited flexibility. For sex pheromones of moths, it has been demonstrated that chain length, double-bond position, double-bond configuration, and terminal functional groups (typically alcohol, aldehyde, or acetate) all influence the magnitude of EAG responses (Roelofs, 1984). Structure–activity studies with analogs of (*E*,*Z*)-2,13-octadecadien-1-yl acetate, a main pheromone component of the currant clearwing moth, *Synanthedon tipuliformis*, indicate that hydrophobic, steric, and electronic effects of chain terminal groups are important physical parameters responsible for biological activity of the compound (Hoskovec et al., 1993).

Chain length of sex pheromone analogs was an important determinant of EAG activity in our work with *H. occidentalis* and has been considered elsewhere. Electrophysiological recordings from single receptor cells were obtained from antennae of *Agrotis segetum* in response to chain-length analogs of the main sex pheromone component (*Z*)-5-decan-1-yl acetate, and strong reductions

in elicited potentials were observed with chain lengths other than 10 carbon atoms (Liljefors et al., 1985). Single-sensillum studies indicated that the terminal methyl group and the acetate group of (*Z*)-5-decenyl acetate interact with highly complementary sites in the receptor cavity (Bengtsson et al., 1990). Furthermore, the magnitude of responses decreased with the elimination of methylene units.

With respect to alkyl substituents, Jönsson et al. (1991a, 1993) found that methyl groups placed at different locations in (*Z*)-5-decenyl acetate resulted in a significant reduction of EAG response. Methyl-substituted analogs of the pheromone for the turnip moth were synthesized and used to study the degree of steric complementarity between the acetate-substituted alkyl chain of the pheromone component and its receptor (Jönsson et al., 1991a,b). Fescemeyer and Hanson (1990) introduced either a cyclopropyl or *tert*-butyl group at the terminal portion of (*Z*)-11-tetradecen-1-ol acetate, the main pheromone component of the European corn borer moth *Ostrinia nubilalis*, and they found that EAG responses of males were either significantly higher or lower than responses to the main pheromone component itself, depending on the genetic strain tested.

We have not yet determined the enantiomeric blend of 6-methylnonan-3-one that is involved in pheromone communication in *H. occidentalis*. The EAG technique can play an important role in determining relative antennal response activity among optical isomers that cannot be characterized with minute quantities of natural material (Roelofs, 1984). EAG studies demonstrated that the highest responses occurred selectively with the correct enantiomer of 4-methylheptan-3-ol, the trail pheromone of the ant *Leptogenys diminuta* (Kern and Bestmann, 1993). Studies with the American cockroach *Periplaneta americana* indicated that EAG responses were higher with the correct enantiomer of periplanone-A than with an optically active analog (Okada et al., 1990). *R* and *S* enantiomers of methyl-substituted compounds elicited different EAG responses from male *Agrotis segetum* for some methyl-group positions, but not all (Jönsson et al., 1993). EAGs were used to provide insight into the enantiomeric blend of the aggregation pheromone used by both *Pissodes strobi* and *P. nemorensis* (Hibbard and Webster, 1993). In that study, responses of *P. nemorensis* antennae to (1*R*,2*S*)-grandisal were significantly higher than to (1*S*,2*R*)-grandisal. EAG analyses demonstrated that the 9*S*,10*R* enantiomer of (*Z*,*Z*)-3,6-*cis*-9,10-epoxyheneicosadiene elicits a male antennal response two to three times greater than the 9*R*,10*S* enantiomer from *Hyphantria cunea* and *Estigmene acrea* (Hill et al., 1982).

Kentaro et al., (1991) studied the EAG responses of cockroaches to periplanone and four groups of analogs. The analogs were those containing a germacrene skeleton, those without the *exo*-methylene and isopropyl groups on the 10-membered ring, compounds similar to periplanone, but with altered chain length, and the four candidates of periplanone-A (P-A) including Hauptmann's

P-A, Macdonald's P-A, Persoon's P-A, and its epimer. Hauptmann's P-A elicited the strongest responses of the four analogs, suggesting that it is a natural P-A produced by female cockroaches.

EAGs provide useful information on the specificity of insect olfactory receptors, but recordings from individual olfactory cells are necessary for a detailed understanding of the perception of odor molecules by insects (Wadhams, 1984). For example, in a comparison of EAG responses and single sensillum responses of the sugar beet moth (*Scrobipalpa ocellatella*), Renou et al. (1980) found that the responses to a series of pheromone analogs were almost identical, but the single sensillum recordings showed that responses from two cell types contributed to the EAG profile. Similar specificity of single cells for one compound (or a small set) has been found in other species as well. Single-unit recordings from sex pheromone antennal receptors in the moth *Antheraea polyphemus* indicated that one antennal receptor type responds to the acetate pheromone component, but not to the aldehyde component, and a second antennal receptor responds selectively to the aldehyde component (Bestmann et al., 1987). Single-sensillum recordings from *Yponomeuta rorellus* males revealed two types of cells in most sensilla (Löfstedt et al., 1990). A large spike amplitude cell was stimulated by tetradecyl acetate and the unsaturated analogs (*E*)-11-, (*E*)-6-, and (*E*)-12-tetradecenyl acetate, and to a lesser extent by the (*Z*)-11, (*Z*)-6, and (*Z*)-12 isomers. A cell with medium spike amplitude was stimulated by (*Z*)-9-tetradecenyl, and (*Z*)-11-hexadecenyl acetate. Some sensilla contained a third cell firing with a small spike amplitude, which was activated by (*Z*)-11-tetradecenol.

The dose–response curve in the present study generated from electrophysiological recordings from females with synthetic, racemic 6-methylnonan-3-one supports previously observed female response to female-produced compounds (Jewett, 1993; Bjostad et al., 1995). The response appears to be genuine, and similar scenarios have been observed in lepidopteran species such as *Choristoneura fumiferana* (Birch, 1977; Light and Birch, 1979), and *Trichoplusia ni* (Palaniswamy and Seabrook, 1978). The behavioral significance of *H. occidentalis* females responding to their own sex pheromone has not been determined.

Acknowledgments—We thank the Theodore Roosevelt Memorial Fund of the American Museum of Natural History, and the Colorado Agricultural Experiment Station for funding this project. B.C. Kondratieff, D. Ruiter, B. Painter, and M. Harris were helpful in locating *Hesperophylax occidentalis* populations and confirming the identification and sex of individuals used in experiments. L. Hegedus provided us with nonan-5-one. Discussions with T.O. Holtzer, R. Vogt, and W. Meyer yielded many insights into the behavioral phenomena discussed in this paper. J. Zumbrunnen, M. Carter, and B.E. Hibbard were consulted for regarding statistical analyses. M.A. Lee, E. Abou-Fakhr, and E.J. Bernklau assisted in the field, collecting pupae from which adults were reared.

(Received November 4, 1994, accepted September 5, 1995)

Abstract—The globemallow, *Sphaeralcea emoryi* Torrey, a plant native to Arizona was evaluated as a source of feeding or oviposition deterrents to the boll weevil, *Anthonomus grandis* Boheman. Feeding and oviposition responses of reproductive weevils to the flower buds and artificial diets spiked with dry powder or extracts of the globemallow buds were determined. Boll weevils were deterred from feeding and ovipositing in the flower buds unless the calyxes were removed. Male and virgin female weevils were discouraged from feeding as much as gravid weevils. Secondary chemicals in the flower buds served primarily as feeding deterrents but also prevented oviposition. The concentration of these chemicals was highest in the calyxes of the buds, and potent deterrent activity could be extracted from the calyxes with methanol. Boll weevils were able to perceive the deterrents by contact chemosensory organs on the antennae, maxillary palps and labial palps.

Key Words—*Anthonomous grandis* Boheman, boll weevil, *Sphaeralcea emoryi* Torrey, globemallow, feeding deterrent, oviposition deterrent, chemical ecology.

INTRODUCTION

The boll weevil, *Anthonomus grandis* Boheman, develops successfully only on plants of the family Malvaceae including *Gossypium hirsutum* L and *Cienfue-*

gosia drummondii (Gray) in the United States. Globemallows *Sphaeralcea* spp., perennial shrubs native to Arizona, are recognized as alternate feeding hosts for overwintering weevils (Stoner, 1968) and Cross et al. (1975) reported that, like *Hibiscus* and *Pseudabutilon*, *Sphaeralcea* spp. may serve as marginal hosts for boll weevil. Efforts to discover natural products that might be used to manipulate boll weevil behavior have been focused on the defensive mechanisms of several nonhost plants and alternate host plants (Miles et al., 1987, 1990). Maxwell et al. (1965) and Parrot et al. (1966) found that feeding and oviposition by the boll weevil was reduced on the flower buds of *Hibiscus syiacus* L., an alternate host. This finding led to the identification of unsaturated fatty acids and their methyl esters in the calyxes of the hibiscus that acted as feeding deterrents (Bird et al., 1987).

Significantly less feeding and oviposition by the boll weevil in cotton squares treated with an aqueous extract of a globemallow, *S. emoryi* Torrey were reported (Palumbo et al., 1990), suggesting that flower buds of this plant possess some chemical defensive agent(s) limiting weevil attack and that any factors influencing selection of a feeding site or of feeding behavior must also influence oviposition, i.e., oviposition follows only where feeding is successful.

Our studies investigated whether the buds of *S. emoryi* contain feeding and/or oviposition deterrents for the weevils, and if so how they perceive such deterrent stimuli.

METHODS AND MATERIALS

Insects. Boll weevils were obtained from the USDA Boll Weevil Research Laboratory at Mississippi State, Mississippi. They were reared on artificial diet pellets (0.8 cm diam. × 2 cm long made of Coax powder) coated with a 1:1 mixture of beeswax and household paraffin (Vanderzant and Davich, 1961; Gast, 1965), under a 16L:8D photoperiod at 25 ± 1°C. Coax is a proprietary feeding stimulant from Buckeye Oil Seed Prod. Co., Fort Worth Texas 76110 and is used to increase acceptability of insect diets.

Plant and Plant Extracts. Flower buds of a globemallow, *Sphaeralcea emoryi* Torrey were collected in Tucson, Arizona, during May 1990 and 1991. They were dried at 60°C, finely chopped in a Waring blender, and stored at −5°C. Some of the flower buds were dissected into three parts consisting of caylx, petals, and anthers, and dried as above. Fresh flower buds were stored at 4°C. Dry powder of whole flower buds was sequentially extracted with 500 ml each of *n*-hexane, acetone, methanol, and distilled water. The organic solvent extracts were concentrated under reduced pressure to near dryness, and the water extract was filtered through Celite 454 prior to lyophilization. Methanol extracts of the dried powders of the calyxes, petals, and anthers were also prepared.

Physical and Chemical Blocking Sensory Organs. Weevils were anesthetized on an ice bed and their antennal, tarsal, and/or mouthpart sensory organs were surgically or chemically blocked. In surgical operations, antennae, maxillary palps, or labial palps were ablated with a finely tapered forceps. Chemical blocking of sensilla on the tarsi or mouthparts was performed under a binocular microscope by contacting these organs for 20 sec with 6 N HCl containing a drop of Triton X-100 in a microcapillary.

Bioassays. One evaluation of boll weevil response to globemallow was carried out with a two-choice test in a 9-cm Petri dish in which a pair of test materials (treatment and control) were placed in parallel in the center. One set of the test material was composed of intact flower buds and flower buds with the calyxes removed. In another set of choice tests, diet pellets were made by substituting the dry powders of calyx, petals, or anthers for the 75% of Coax powder in the basic diet. These were then compared with the basic diet pellets as control. The organic solvent and water extracts of whole flower buds or methanol extracts of each flower organ of the globemallow were applied topically and spread evenly over the surface of basic diet pellets before bioassay. The control basic diet pellets were treated with the solvent alone prior to testing.

Ten reproductive-age weevils of each sex were placed in a dish and given a choice among five intact buds and five buds from which the calyxes had been removed. Observations were carried out at 30-min intervals during 3.5 hr with five replicates. The number of weevils on the flower buds and the number of feeding on the buds was recorded. Artificial diet pellets (treated and untreated) were also placed in parallel in the center of the dishes and exposed to 10 pairs of reproductive weevils for 20 hr. Male and virgin female weevils were also examined separately in the same bioassay. After 0.5, 1.0, 1.5, 2.0, and 20.0 hr, the number of weevils on each diet pellet was counted, and the total number of weevils at each of the five test periods was recorded, but weevils mounting other weevils feeding or ovipositing were subtracted from the data. At the end of the assay (after 20.0 hr) all weevils were removed from the test arena, and the number of feeding and oviposition punctures was counted and the number of eggs in each diet pellet was counted under a binocular microscope after removing the wax coating. A discrimination index (DI) was calculated for the three criteria of each test material according to the formula: $DI = C/(C + T)$, where C and T were the number of weevils, punctures, or eggs on the control diet (basic diet) pellets and test diet pellets, respectively. Thus, significantly higher DI values than 0.5 meant that weevils were able to discriminate treated diet pellets from untreated (control) ones, indicating high deterrency of treated ones.

Another type of bioassay employed was an olfactometer. The Plexiglas olfactometer (Figure 1) consisted of a round main chamber (9 cm diam. × 7 cm in high) and two side tubular arenas (1.0 cm diam. × 10 cm long) connected

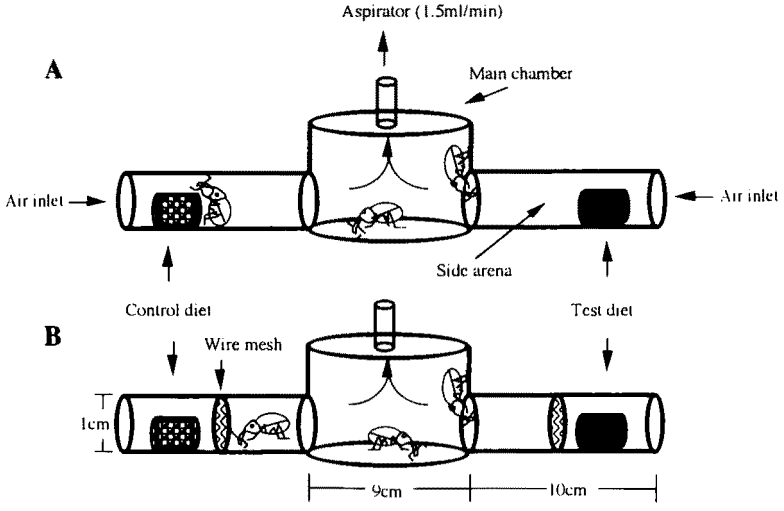

FIG. 1. Diagrams of olfactometers for evaluating behavioral responses of the boll weevil to flower bud extracts of globemallow, *Sphaelarcea emoryi*, in an artificial diet.

with each 40-cm-long glass tube as an air inlet. The two air inlets contained a cotton plug and an activated charcoal filter to purify the ambient air. Ventilation of the chambers (1.5 liters/min) was performed by aspirating air from the center of the lid of the main chamber. Test materials were placed in the side arenas 5 cm from the inner openings. In this bioassay, weevils were allowed access by two different ways to test materials in the side arena. The weevils were, in the first one, able to contact the test material directly (A in Figure 1), and in the second one, a small wire screen was placed just in front of the source of stimuli to prevent the weevils from contacting it (B in Figure 1). The responses of 10 starved weevils per test were observed every 10 min for 1 hr with five replicates, and the number of weevils in each side arena was counted.

All tests were conducted under the same conditions as for adult rearing, and all data were subjected to statistical analysis by χ^2 test.

RESULTS AND DISCUSSION

Feeding and Oviposition Responses to Flower Buds and Plant Extracts. Initial observations were made to detect the ability of boll weevils to feed and/or oviposit on *S. emoryi* flower buds. When the weevils were allowed to choose between the flower buds with and without calyxes in the two-choice test, most

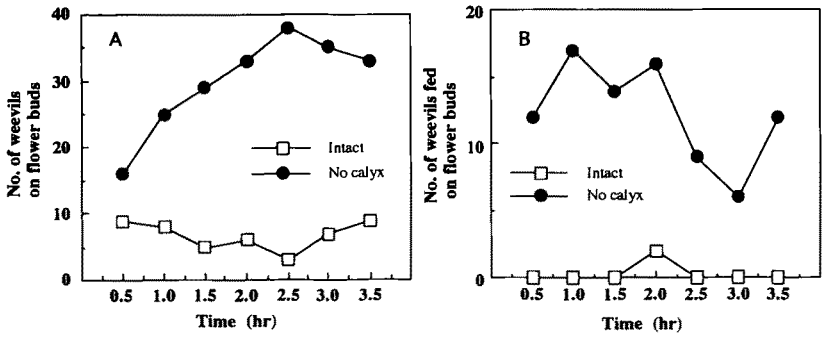

FIG. 2. Comparative responses of boll weevils on globemallow flower buds with and without the calyxes in a two-choice test. (A) Number of weevils on flower buds with calyx (open square) and without calyx (filled circle); (B) number of weevils fed on the flower buds with calyx (open square) and without calyx (filled circle).

were found on the flower buds with calyxes removed, while the number of weevils on intact buds never increased throughout the whole test (Figure 2A). In addition, boll weevils on the two types of flower buds revealed distinctly different behavioral responses. Weevils initiated feeding (puncturing) when they were on the buds with the calyxes removed, but not on the buds with calyxes (Figure 2B). The calyxes of *S. emoryi* were conspicuously pubescent with trichomes. Trichomes on plant surfaces are considered a defensive component of plants against herbivorous insects (Chapman, 1977; Stipanovic, 1983; Southwood, 1986). Trichomes often contain deterrent, repellent, or sticky compounds and can act as an entangling barrier. Palumbo et al. (1990) also observed preferential feeding by boll weevils on pollen through the smooth corolla over the pubescent calyx of *S. emoryi*, and they suggested that the trichomes on the calyx might physically deter females from oviposition.

In the absence of the calyxes (perianth), the developing flower buds of *Hibiscus syriacus*, L. were more acceptable to boll weevils (Parrot et al., 1966; Everett and Earle, 1964) and interference with feeding or oviposition by the calyxes of alternate hosts was effective only at the prebloom stage of the flower buds (Everett and Ray, 1964). We also used normal buds that were completely enveloped in calyxes as intact buds for the bioassays, but some buds partly exposed their petals after the end of the assays, and these were accepted for feeding by the boll weevils.

As shown in Figure 3 a large discrimination index (DI) for the number of weevils, punctures, and eggs was found when the methanol extract of calyxes was applied to the diet pellet surface, and significant deterrent potency to the

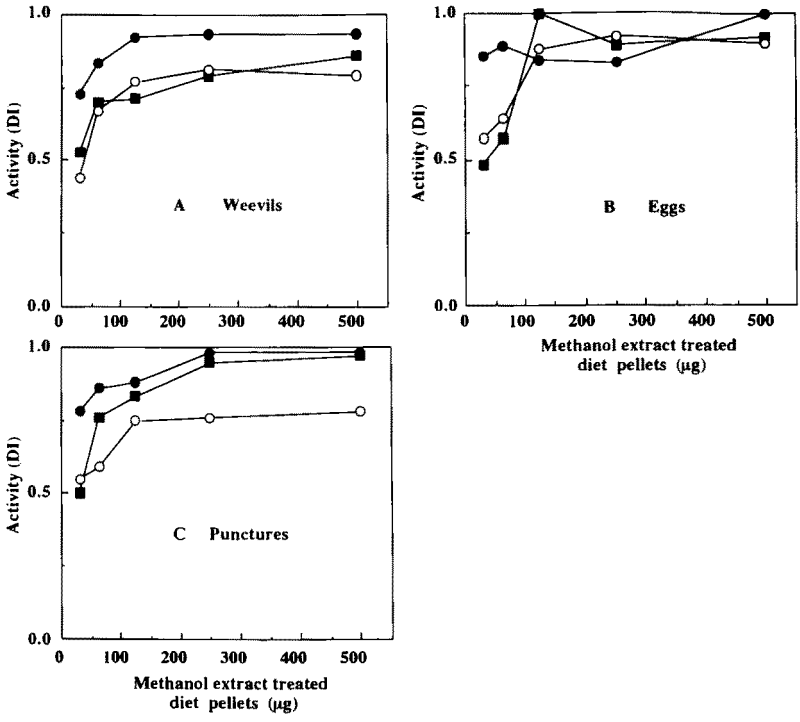

FIG. 3. Globemallow extract deterrent activities evaluated by three criteria: number of weevils (A), eggs (B), and punctures (C) by boll weevil. Methanol extracts of globemallow flower buds were applied on wax coating of artificial diet pellets. Solid square: anther; open circle: petal; solid circle: calyx, $DI = C(C + T)$, C: control; T: test, see text.

weevils was observed even at a dosage of 31.3 μg/pellet. At this dosage, however, methanol extracts of petals and anthers had no deterrent activity, although some deterrency of those extracts occurred at higher dosages. These results suggest the presence of some chemical agent(s) functioning as feeding and/or oviposition deterrents against boll weevils in the calyxes of *S. emoryi* flower buds. The surface of the diet pellets treated with the active calyx extract was slightly sticky compared to those treated with inactive extracts, and it seemed possible that boll weevil feeding or oviposition might have been disturbed by changes in the microtexture of diet pellets. Therefore, a similar preference test was undertaken on artificial diets to which dry powder of flower bud organs was added. When calyx powder or whole bud powder was incorporated into the diet

pellets, the weevils refused to feed or oviposit in these diet pellets, but not in diet pellets containing petal powder or another powder (Figure 4). Under these conditions, the texture of all of the diet pellets was identical. Accordingly, we believe that these studies confirm the presence of chemical deterrents against feeding and/or oviposition by boll weevils in the flower buds of *S. emoryi*. It seems a reasonable defensive strategy for *S. emoryi* to concentrate a deterrent in the calyxes of flower buds, since they constitute the outermost covering of the buds, and constitute an unavoidable barrier when boll weevils attempt to feed or oviposit on the flower buds.

The methanol extract of intact fresh buds at dosages of 500 to 50 μg/pellet evidenced potent deterrent activity to the weevils, while hexane and water extracts were inactive even at 500 μg/pellet (Table 1), demonstrating that methanol was the most effective solvent for extracting the deterrents from the flower buds and that the active component(s) are fairly polar compound(s). It is noteworthy that Palumbo et al. (1990) observed deterrent activity in aqueous extracts of the flower buds of *S. emoryi*, and a feeding deterrent in the calyxes of rose of Sharon, *H. syriacus* L. was water soluble and thermolabile (Maxwell et al., 1965). Several polar unsaturated fatty acids and their esters served as feeding deterrents for weevils in hibiscus (Bird et al. 1987). Clearly, alternative hosts

of the boll weevil deploy a wide spectrum of defensive feeding deterrents to limit weevil herbivory and reproduction.

Function of Deterrent Agent of Globemallow. When males and virgin females were exposed separately to diet pellets treated with 100 or 500 μg/pellet of the flower bud methanol extract, they completely refused treated ones, yielding large DI values for the presence of weevils and for punctures on the pellets (Table 2). These facts indicated that feeding (puncturing) behavior itself might be affected independently of oviposition because males and virgin females do not lay eggs. In addition, we found no instance where oviposition alone by

gravid boll weevils was prevented by plant materials or extracts tested in this study. A typical sequence of oviposition behavior by boll weevils consists of six essential behavioral steps including feeding (puncturing), and normal oviposition never occurs on a substrate without feeding (Everett and Ray, 1964). The feeding punctures also serve as the entry point for oviposition. When feeding (puncturing) is negated by a deterrent agent from *S. emoryi*, oviposition was never elicted from females. Therefore, our results clearly demonstrate that a deterrent(s) in the flower buds of *S. emoryi* must act primarily on feeding by the weevils and also serve as a chemical cue preventing oviposition.

Chemosensory Mechanisms of Deterrent Perception. In a preliminary assay, untreated diet pellets (basic diet) and controls (empty) were offered to reproductive pairs of boll weevils in the olfactometer. When allowed to directly access the diet pellets, the starved weevils quickly found the basic diet pellet and accumulated on it. On the other hand, when they were prevented from contacting the diet pellet by a small wire mesh placed in front of the diet pellet, they frequently moved about randomly and went in and out of both side arenas (Figure 5). These results indicate that the weevils must ultimately recognize their feeding and oviposition substrates by contact cues rather than by olfaction. Similar responses by the weevils were observed in the second bioassay, where treated and untreated diet pellets were used as sources of stimuli. When weevils were prevented from contacting the diet pellets, they continued moving in and

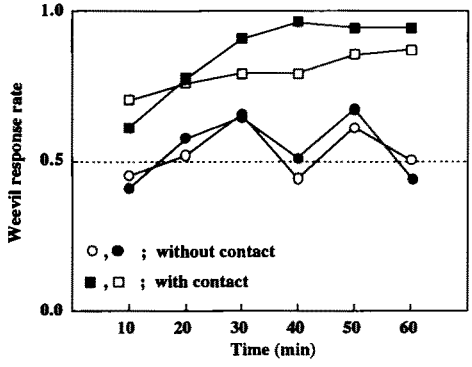

FIG. 5. Discrimination between an artificial diet coated with methanol extract of globemallow flower buds and untreated diet by boll weevils in an olfactometer. Open circle: untreated diet (test) vs. empty arm (control); solid circle: treated diet (test) vs. untreated diet (control); open square: untreated diet (test) vs. empty arm (control); solid square: treated diet (test) vs. untreated diet (control); weevil response is the number of weevils in control side/(number of weevils in control side + number of weevils in test side). Without contact: weevils tested in olfactometer B; with contact: weevils tested in olfactometer A.

out of the side arenas. When they were allowed to contact both diet pellets, they easily discovered and aggregated on the untreated diet pellet. The results of these two olfactometer tests indicate that the flower bud of *S. emoryi* may possess contact deterrent agents but no olfactory repellents.

In the final series of experiments, the sensory basis of deterrent perception was examined by observing modifications in feeding or oviposition behavior induced by selective sensory organ inactivation including those on the antennae, tarsi, and mouthparts. Data are summarized in Table 3. Antennectomy (treatment 1 in Table 3) as well as inactivation of tarsal sensory organs (treatment 2) resulted in DI values near 1, indicating that those treatments were less effective in modifying discrimination between treated and untreated diet pellets. Inactivation of sensilla on the mouthparts with HCl (treatment 3) and palpectomy of the maxillary and labial palps (treatments 4–6) were also unsuccessful in disrupting discrimination behaviors. However, binary blocking (treatments 7–9) by antennectomy and palpectomy resulted in very small DI values, indicating failure of the weevils to discriminate against deterrents. A tertiary blocking (treatment 10) by antennectomy, palpectomy, and tarsal inactivation with HCl was also effective in blocking discrimination, but binary blocking (treatment 11) by

inactivating only receptors on the palps and tarsi did not block discrimination. These results suggest that when sensory input from certain organs is blocked, other sensory organs may be able to compensate and allow detection of the deterrents(s).

The weevils were still able to discriminate between the treated and untreated diet pellets when a double coating of paraffin–beeswax was applied to diet pellets in which the inner layer was treated with methanol extract of *S. emoryi* flower buds and the outer layer was untreated (treatment 12). The number of punctures on the outer wax layer was not different from the number on the untreated diet pellets (control), but the number of punctures on the inner wax layer treated with flower bud extract was significantly less than the number of control diets. Under these test conditions, the weevils could make contact with the deterrent agents on the surface of the inner way layer only with mouthparts or ovipositor chemoreceptors, but not with antennal and tarsal chemoreceptors.

In the Coleoptera a variety of sensory organs seem to be involved in host discrimination, although certain ones appear to assume a more dominant or pivotal role. Maxillary palps were shown to be the most important sensory organs affecting egg laying by bean weevils, *Acanthoscelides obtecutus* (Say) (Pouzat, 1970; Szentesi 1976), whereas in Mexican bean beetles, *Epilachna varivestis* Mulsant, antennal and maxillary palp chemosensilla were most responsible for discriminating between susceptible and resistant hosts (Fisher and Kogan, 1976). Our observations of the behavioral responses of boll weevils revealed that they ordinarily contact the surfaces of the test diet pellets with their antennae or mouthparts prior to tarsal contact. Therefore, contact sensory organs on the antennae or mouthparts seems to be important in detecting deterrent agents in the flower buds of the globemallow, *S. emoryi*.

PHYTOTOXICITY OF SESQUITERPENE LACTONE PARTHENIN ON AQUATIC WEEDS[1]

D. K. PANDEY

Physiology Section, National Research Centre for Weed Science (I.C.A.R.) Adhartal, Jabalpur (M.P.)-482 004, India

(Received October 28, 1995; accepted September 6, 1995)

Abstract—The sesquiterpene lactone parthenin, one of the major toxins in an obnoxious weed, parthenium (*Parthenium hysterophorus* L.), was toxic at 50 ppm to the floating aquatic weeds pistia (*Pistia stratiotes* L.) and lemna (*Lemna pausicostata* Hegelm.) and at 100 ppm to water hyacinth (*Eichhornia crassipes* Mart Solmns.), salvinia (*Salvinia molesta* Mitchell), azolla (*Azolla nilotica* Decne.), and spirodella (*Spirodella polyrhiza* L. Schleid). The lethal dose for the submerged weeds najas (*Najas graminea* Del.), ceratophyllun (*Ceratophyllum demersun* L.), and hydrilla (*Hydrilla verticillata* L. f. Royle) was 25 ppm. The submerged aquatic weeds were more sensitive to parthenin. Water hyacinth was used as a representative for studying the phytotoxicity of parthenin on aquatic weeds. Inhibition of water hyacinth by parthenin was associated with decline in water use, root dysfunction, excessive leakage of solutes from roots indicative of massive damage to cellular membranes, loss of dehydrogenase activity in the roots, and loss of chlorophyll in the leaves. Plant death occurred in a period of one to two weeks. Parthenin phytotoxicity is gradually lost in an aquatic environment as a lethal dose became nonlethal in about 30 days under outdoor conditions. Possible buildup of a toxin concentration may affect population dynamics and a shift in the aquatic weed flora in the immediate area of parthenium stands. Accumulation of the toxin in an aquatic environment, however, at a level sufficient to produce such changes in a natural ecosystem as a consequence of rain washing parthenium plants and leaching of toxin from their residue appears to be unlikely.

Key Words—Aquatic weeds, parthenin, biomass, membrane integrity, dehydrogenase activity, chlorophyll, water use.

INTRODUCTION

Parthenium (*Parthenium hysterophorus* L.) is an obnoxious terrestrial weed of worldwide distribution posing serious threats to agriculture, human health, and environment. The weed is well known for its toxic substances. Among the toxic substances are the sesquiterpene lactones parthenin and traces of coronopilin and compounds belonging to phenolic and organic acid classes (Towers et al., 1977; Kanchan and Jayachandra, 1980). The biological activities of sesquiterpene lactones were reviewed by Picman (1986), and the role of terpinoids in allelopathy was discussed by Fisher et al. (1994). Parthenium plants inhibit other plants in their surroundings through inhibitors released from the aerial and underground parts directly and/or from their residue in the soil. Parthenium leaves and inflorescence have been reported to have the maximum quantity of parthenin, followed by the stem and roots (Kanchan and Jayachandra, 1980). This distribution of parthenin coincides with the inhibitory activity of residues of these plant parts (Pandey et al., 1993a,b; Pandey, 1994a,b).

Parthenium residues are relatively more toxic to nine aquatic weeks than to wheat, the test crop species (Pandey et al., 1993a), and to paddy seedling growth (Pandey, 1994b). The present investigation was undertaken to study phytotoxicity of parthenin on nine aquatic weeds to evaluate its possible herbicidal activity on aquatic weeds and to ascertain the implications of parthenin toxicity on population dynamics and shifts in weed flora in a natural aquatic ecosystem.

METHODS AND MATERIALS

Aquatic Weeds. The weeds used in the experiments included the floating weeds water hyacinth (*Eichhornia crassipes* Mart Solmns.), salvinia (*Salvinia molesta* Mitchell), pistia (*Pistia stratiotes* L.), azolla (*Azolla nilotica* Decne.), spirodella (*Spirodella polyrhiza* L. Schleid), and lemna (*Lemna pausiocostata* Hegelm.); and the submerged weeds hydrilla (*Hydrilla verticillata* L. f. Royle), ceratophyllum (*Ceratophyllum demersum* L.), and najas (*Najas gramineae* Del.). All were maintained in the culture medium described earlier (Pandey 1994a).

Isolation and Purification of Parthenin. Parthenin was isolated and purified by the method described by Picman et al. (1980) with modifications (P.V. Subbarao, personal communication, 1992) detailed earlier (Pandey, 1994a). Parthenium leaves were harvested, washed quickly, and blot dried. They were further dried at 70°C for 48 hr. The dried leaves were refluxed with methanol in a Soxhlet apparatus for 12 hr, and parthenin was isolated and purified as previously described (Pandey, 1994a).

Effect of Parthenin on Aquatic Weeds. Parthenin was dissolved in 0.20–0.40 ml of ethanol, distilled water was added to 500 ml, and the final volume made to 1 liter with a nutrient medium (Jain et al., 1989) to prepare solutions of 25, 50, and 100 ppm parthenin. The small quantity of ethanol (maximum final concentration = 0.04%) used for dissolving the toxin did not affect growth of the aquatic weeds, as determined from preliminary results using ethanol at 0.01–4.00%, v/v, in the nutrient medium for culture of the nine aquatic weeds. Final ethanol concentrations that did not inhibit growth of the weeds were 0.10% for azolla and lemna, 2% for najas and hydrilla, 3% for water hyacinth, and 4% (the highest concentration tried) for ceratophyllum, pistia, spirodella, and salvinia. None of the weeds was killed even at 4% ethanol. Plants growing in half-strength nutrient medium served as controls. Ceratophyllum, hydrilla, and najas were grown with and under the stand of floating spirodella and lemna (as direct sunlight was inhibitory to these submerged weeds) in 1-liter beakers with their side walls covered with black paper. Biomass was monitored, and the volume of solutions in the beakers was kept constant by replenishing evapotranspiratory loss twice daily with distilled water.

Physiological Effects of Parthenin Toxicity on Water Hyacinth. Selected physiological effects were studied on water hyacinth plants grown in parthenin solutions. The effect of parthenin on water use by water hyacinth over a brief period was measured by placing preweighed plants in 1 liter of aqueous medium containing 50 or 100 ppm parthenin in half strength nutrient medium (Jain et al., 1989). Plants similarly kept in the medium without parthenin served as controls. Containers of water were also kept for measuring evaporative loss from the free open surface. The plants were removed, weighed, and the volume of aqueous medium was measured at each observation. Then the volume of the medium or water was replenished to 1 liter, and the plants were replaced. The quantity of water absorbed by the plants was calculated by measuring the evaporative loss.

Effect of parthenin on solute leakage from roots of the water hyacinth plants was measured by the procedure of Pandey (1994a). An optical density (OD) of 0.01 at 264 nm (corresponding to UV-absorbing materials such as amino acids, nucleotides, and polypeptides) was considered as one unit of UV-absorbing substances and was expressed on a per gram root (fresh weight) basis.

For total dehydrogenase activity determination, about 0.5 g roots were soaked in 5 ml of 1% (w/v), 2,3,5-triphenyl tetrazolium chloride in darkness at 30°C ± 1°C for 4 hr. The formazan produced was extracted and its absorbance determined at 520 nm (Pandey, 1994a). An enzyme unit was defined as an optical density change of 0.01 OD at 520 nm, and activity was expressed on a per gram root (fresh weight) basis.

Chlorophyll *a* and *b* and total chlorophyll were determined on freshly sampled leaf discs (about 5 cm^2). The discs were weighed and ground in a mortar

with a small quantity of acid-washed silica sand in 25 ml of 80% (v/v) acetone (Pandey et al., 1993a). Absorbance of the final extract was measured at 645, 652, and 663 nm, and chlorophyll *a* and *b* and total chlorophyll, respectively, were calculated considering equal area equal weight by the method of Arnon (1949).

Persistence of Parthenin Phytotoxicity. Pistia was used to assess the persistence of parthenin phytotoxicity, as it was one of the most sensitive species among the floating weeds. Parthenin (50 mg) was dissolved in a small quantity of ethanol and made up to one half the total volume with water and the remaining half with the nutrient medium for a final volume of 1 liter. Preweighed pistia plants were placed in the 50 ppm parthenin solution and incubated for 0, 10, 20, 30, and 40 days under outdoor conditions. Biomass was monitored, and the experiments were conducted under outdoor conditions. All experiments and determinations were repeated at least three times. A completely randomized design was used. The data were subjected to an analysis of variance and when significant *F* values were found, the least significant difference (LSD) was used to separate means.

RESULTS AND DISCUSSION

Results of the effect of parthenin on different aquatic weeds are shown in Figure 1. In controls, all aquatic weeds increased their biomass. Lethal doses of parthenin for different aquatic weeds were 50 ppm for pistia and lemna; 100 ppm for water hyacinth, salvinia, azolla, and spirodella; and 25 ppm each for submerged aquatic weeds ceratophyllum, hydrilla, and najas. The concentrations just below the lethal level reduced biomass in all cases, except in salvinia, in which biomass continued to increase. Higher concentrations of parthenin usually

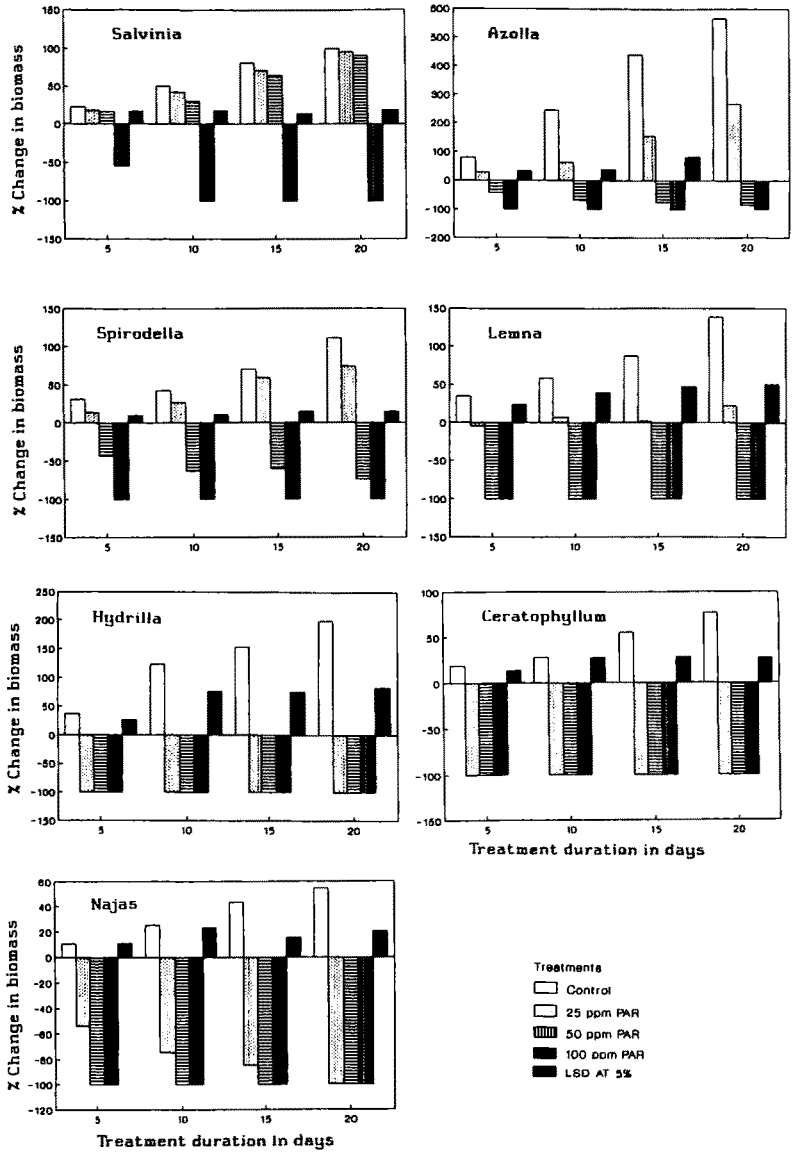

FIG. 1. Continued.

killed plants quicker. Submerged aquatic weeds appear to be more sensitive to parthenin. Parthenin was not inhibitory to water hyacinth at 25 ppm, nor to salvinia even at 50 ppm, although initially short-lived desiccation of frond margins occurred. Parthenin was inhibitory at 25 ppm to pistia > lemna > azolla > spirodella. At 10 ppm the toxin was still inhibitory to the submerged aquatic weeds (data not shown). At the lethal dose, the time required to kill the weeds was about five days for pistia, azolla, lemna, spirodella, hydrilla, and ceratophyllum; 10 days for water hyacinth and salvinia; and 20 days for najas.

The symptoms of parthenin toxicity were drying from leaf or frond margins that gradually progressed towards the growing point, dull green color, flaccid texture, wilting, yellowing, desiccation, and drying of above-water plant parts. The roots showed gradual loss of turgidity, massive fragmentation, and were shed into the medium. These changes consequently resulted in death and decay of the treated plants. Submerged weeds developed flaccid texture, dull green color, and finally fragmentation of plant and plant parts following death and decay.

Parthenin reduced water use by the water hyacinth plants (Figure 2). This was apparent as early as two days after initiation of the treatment. The reduction in water use in treated plants was drastic by six to seven days. The massive increase in solute leakage from the roots of water hyacinth plants grown at the lethal dose of parthenin for two, four, and eight days (Figure 3a) indicated damage to cellular membranes that resulted in loss of cellular structures and

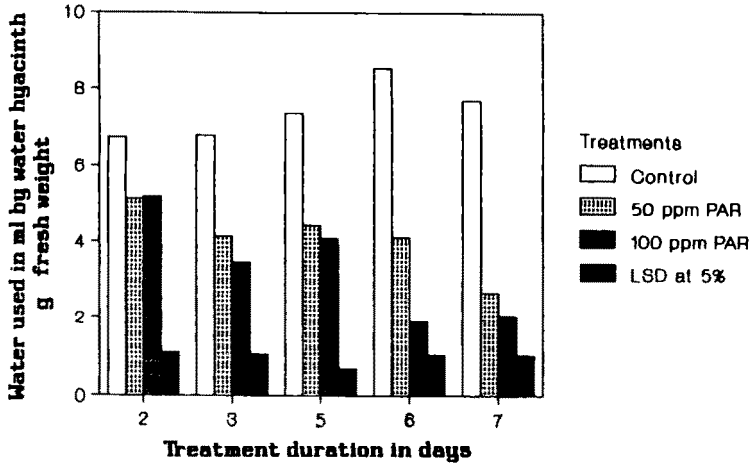

FIG. 2. Effect of parthenin (PAR) on water use by water hyacinth. Values are means of three replications.

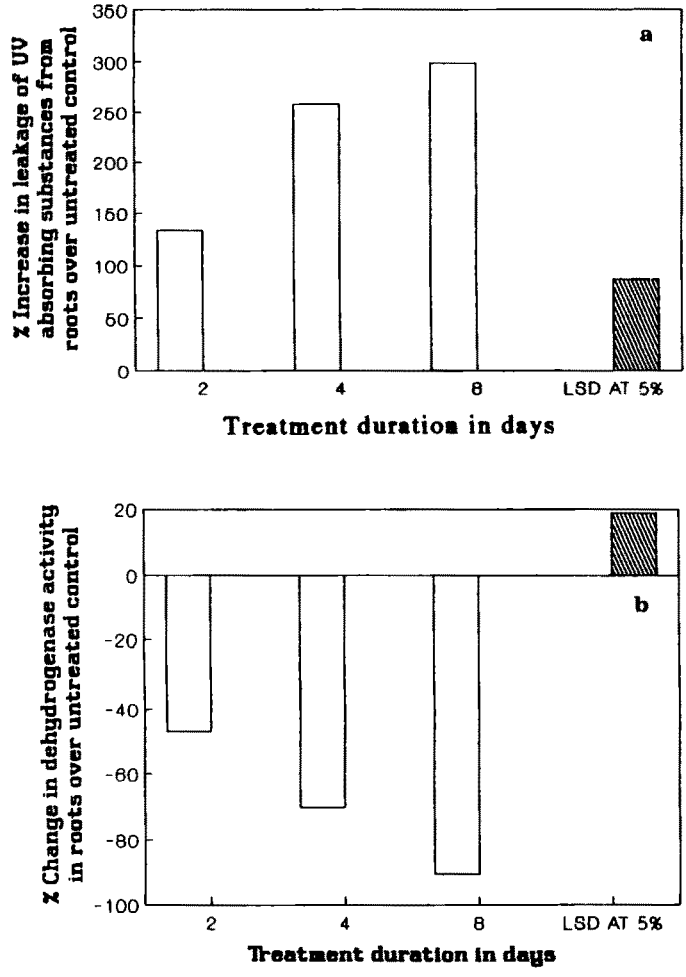

FIG. 3. Effect of lethal dose of parthenin (100 ppm) on (a) leakage of UV-absorbing substance from the roots of water hyacinth and (b) on total dehydrogenase activity in roots of water hyacinth. Values are means of three replications.

constituents. Total dehydrogenase activity in the roots of water hyacinth allowed to grow in 100 ppm parthenin (lethal dose) solution declined rapidly (Figure 3b). Enzyme activity declined by about 50% in two days. Parthenin at the lethal dose markedly reduced chlorophyll *a* and *b* and total chlorophyll contents in water hyacinth leaves (Figure 4).

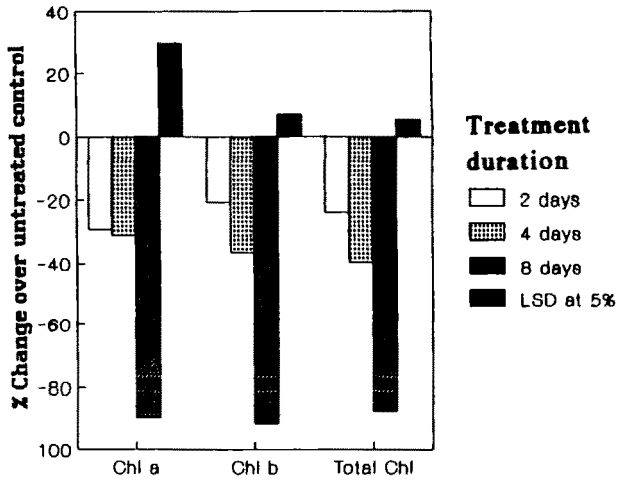

FIG. 4. Effect of lethal dose of parthenin (100 ppm) on chlorophyll *a* (Chl a), chlorophyll *b* (Chl b), and total chlorophyll (Total chl) contents in leaves of water hyacinth. Values are means of three replications.

Parthenin phytotoxicity dissipated rapidly, and a lethal dose for pistia became nonlethal under outdoor conditions in about 30 days, although the medium continued to be inhibitory. After 40 days of incubation of a lethal dose under outdoor conditions, the medium was inhibitory initially for pistia plants, but they recovered and subsequently grew well with an increase in biomass over the beginning value (Figure 5).

Parthenin appears to be a potent phytotoxin in an aquatic environment and might play a decisive role in determining population dynamics and shifts in weed flora in natural ecosystems if it reached concentrations of 25–100 ppm. Submerged weeds appear to be relatively more sensitive to the toxin, and among the floating weeds, pistia was the most sensitive followed by lemna, with all others showing similar sensitivity.

Sesquiterpene lactones have been reported to be phytotoxic. They react with -SH groups of cysteine, glutathione, and many proteins, modifying the original properties of the amino acids and proteins (Picman, 1986). Some are novel uncouplers of oxidative phosphorylation (Chefurka, 1978). The mode of action of parthenin on the weeds in this study is unknown, but a variety of toxic actions, including some of those previously reported, may have combined to cause the stalled growth and development of the weeds in this study. Parthenin reduced water use by water hyacinths and caused desiccation of the above-water plant parts consequent to root dysfunction and death. Massive damage to cellular

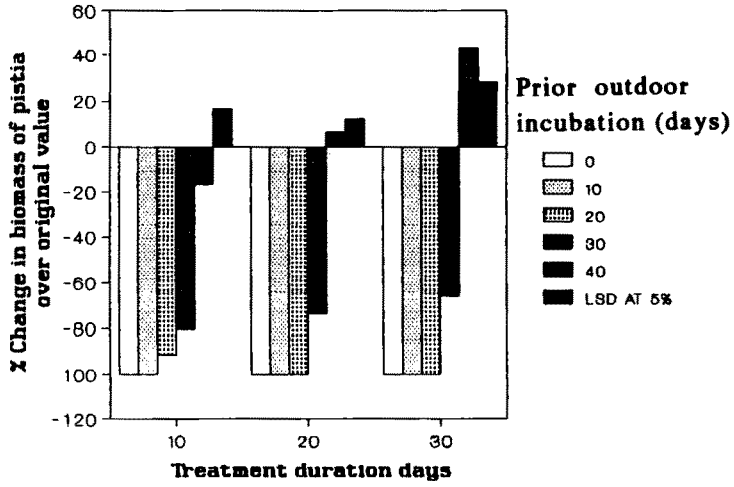

FIG. 5. Persistence of phytotoxicity of parthenin (50 ppm, original lethal dose) under outdoor conditions. Pistia plants were placed in solutions of parthenin (originally 50 ppm) that had been incubated outdoors for 0, 10, 20, 30, and 40 days, and then incubation continued for number of days indicated in the abscissa. Values are means of three replications.

membrane integrity was shown by excessive leakage of solutes from the roots of the treated plants, loss of dehydrogenase activity in roots, and loss of chlorophyll content in the leaves. These effects suggest that parthenin phytotoxicity may be mediated by affecting macromolecules such as proteins, lipids, and nucleic acids. The physiological effects of parthenin in the present study resemble those found earlier with parthenium plant residue on water hyacinth and salvinia (Pandey et al., 1993a; Pandey, 1994a).

Parthenium phytotoxicity dissipated relatively rapidly in about a month under outdoor conditions and was similar to that observed previously (Pandey et al., 1993b; Pandey 1994b). The high level of parthenin in the leaves and flowers largely determines the inhibitory activity of the residue. In a natural ecosystem, build up of concentration of parthenin to a toxic threshold concentration in the area immediately surrounding a parthenium stand may affect population dynamics and shifts in aquatic weed flora, with submerged weeds the first to be affected. Due to the rapid dissipation of parthenin, however, the accumulation and persistence of parthenin in an aquatic environment at a concentration sufficient to produce such changes in natural ecosystems some distance from a parthenium stand appears to be unlikely.

OVIPOSITION RESPONSE OF *Lobesia botrana* FEMALES TO LONG-CHAIN FREE FATTY ACIDS AND ESTERS FROM ITS EGGS

BRUNO GABEL[1] and DENIS THIÉRY*

Laboratoire de Neurobiologie Comparée des Invertébrés
INRA-CNRS (URA 1190), BP 23
91440 Bures sur Yvette, France

(Received March 13, 1995; accepted September 6, 1995)

Abstract—Avoidance of occupied ovisposition sites supposes that females perceive information related to their own progeny. Fatty acids identified from egg extracts have been reevaluated using a different extraction method, and we have investigated the dose-dependent oviposition response of European grape vine moths (*Lobesia botrana*) to myristic acid, palmitic acid, palmitoleic acid, stearic acid, oleic acid, linoleic acid, methyl palmitate, methyl oleate, and ethyl palmitate; all except ethyl palmitate have been identified from eggs of *L. botrana*. A methylene dichloride extract of eggs from *L. botrana* revealed the presence of saturated free fatty acids (myristic, palmitic, and stearic) and unsaturated acids (palmitoleic, oleic, linoleic, and linolenic) in amounts ranging from 3.9 ng/egg equivalent for myristic acid to 30 ng/egg equivalent for palmitic and oleic acids. The extract also contained traces of methyl palmitate and methyl stearate. The greatest avoidance indexes were observed in response to palmitic, palmitoleic, and oleic acids. All the other compounds tested caused weaker responses. A reduction in the number of eggs laid was observed when moths were exposed to each of the esters applied at 0.3 μg per application spot. Reduction in eggs laid was also observed at a 10-fold higher dose of oleic acid. The present results confirm that general and simple molecules can be involved in the regulation of oviposition site selection and that they may participate in chemical marking of the eggs.

Key Words—Behavior, *Lobesia botrana*, oviposition, insect, Tortricid, Lepidoptera, fatty acids.

INTRODUCTION

When females oviposit on nonoccupied plants, but fail to oviposit on similar plants that are already occupied, it may mean that females perceive the occurrence of either eggs, larvae, possible marking of the oviposition site, or plant chemicals induced by larval feeding. Intraspecific avoidance of eggs or larvae exists in several insect species (Anderson, 1986; Roitberg and Prokopy, 1987), and it is assumed that recognition of conspecific individuals would limit competition within species and ensure an optimal share of a resource. It has been suggested that accumulation of individuals in an exhaustible resource may affect the fitness of species (Peters and Barbosa, 1977; Prokopy 1981). Some species probably accrue advantage by avoiding conspecific competitors, but more generally, one may assume that avoiding any potential competitor would be advantageous. A possible way to prevent larval competition, regardless of species, would be for females to respond to general chemical markers. These might be nonspecific chemicals produced by eggs or larvae.

Gas chromatographic analyses of egg extracts revealed the occurrence of common fatty acids (FA) with 14–18 carbons and esters of these fatty acids in several Lepidoptera species (Thiéry and Le Quéré, 1991; Thiéry et al., 1992). Blends of those chemicals deterred oviposition in the tortricid moth *Lobesia botrana*, the European grapevine moth (EGVM) (Thiéry et al., 1992). An identical behavioral response has been reported in three other tortricids: the codling moth (*Cydia pomonella*), the Oriental fruit moth (*Cydia molesta*), and the grape berry moth (*Eupoecilia ambiguella*) Thiéry and Gabel, 1993; Gabel and Thiéry, 1994; Thiéry et al., 1995). In codling moth eggs of different ages, almost constant ratios between FAs, but with important variation in absolute amounts, suggest the hypothesis that FAs may provide some temporal information related to fruit colonization (Thiéry et al., 1995). Oviposition deterrence against *C. pomonella*, *L. botrana*, and *E. ambiguella* was also observed on fruits baited with synthetic blends of fatty acids and esters both in the laboratory and field experiments (Gabel and Thiéry, 1994; Thiéry et al., 1995; and unpublished data). In anticipation of field application, one objective of this study was to verify our previous identification of chemicals extracted from the eggs by washing them in methylene dichloride. Another objective was to focus on the biological activity of the more stable linear fatty acids produced by the eggs, i.e., the saturated ones or those with a single double bond. We also examined the dose-dependent behavioral responses of EGVM females to each of six fatty acids and three esters previously identified from the eggs. The functional perception of fatty acids and esters is discussed in relation to the chemical ecology of several species.

METHODS AND MATERIALS

Insects and Bioassay. Experiments were conducted on 2-day-old *L. botrana* mated females exposed to artificial oviposition substrates (smooth cardboard). Insects (strain from Station Federale de Recherches Agronomiques, Nyon, Switzerland) were reared on semiartificial diet, and adults were maintained after emergence at 23 ± 0.5°C and 85 ± 5% relative humidity during the 16 hr of photophase and at 20 ± 0.5°C and 75 ± 5% relative humidity during the 8 hr of scotophase.

The oviposition assays were conducted with 3 to 4-day-old females grouped by two or three (without males) during one night in Plexiglas tubes (6.5 cm ID, 13.6 cm length) containing a piece of cardboard (10.7 × 13.6 cm) positioned inside the tube at the upper part. Females were isolated the night following exposure in small glass tubes in order to check whether they had started to oviposit. Those that did not oviposit were discarded. Each cardboard provided a dual choice between a 36-cm^2 treated area consisting of 32 equidistant 5-μl application spots each 1.1 cm in diameter, with centers 2.1 cm apart, and a 3× larger non untreated area of 109 cm^2 (Gabel and Thiéry, 1992). An avoidance index (*AI*) was calculated from the numbers of eggs laid on nontreated (*A*) and treated areas (*B*), corrected for the equivalent areas available for oviposition, according to the formula $AI(\%) = [(A - 3B)/(A + 3B)] \times 100$. No avoidance would give a value of 0%, while the *AI* value for maximum avoidance would be 100%. Myristic acid ($C_{14:0}$), palmitic acid ($C_{16:0}$), palmitoleic acid ($C_{16:1}$, *Z*9), oleic acid ($C_{18:1}$, *Z*9), stearic acid ($C_{18:0}$), linoleic acid ($C_{18:2}$, *Z*9–*Z*12), methyl palmitate ($meC_{16:0}$), ethyl palmitate ($etC_{16:0}$), and methyl oleate ($meC_{18:1}$) were obtained from Sigma and were >99% pure. All were tested at doses of 0.3, 1.5, and 3 μg applied in a spot. Palmitic, palmitoleic, and oleic acids also were tested at 0.06 μg/spot. Compounds were diluted according to the dose required in a mixture of acetone–distilled water (5:5) except for stearic acid (acetone–water, 8:2). Doses are given as micrograms per application spot. Their effect was compared to a control (Cs) of acetone–water (5:5) and to paraffin oil (Cw), 3 μg/spot, in acetone–water (5:5). Acetone (purity for GC-MS) and paraffin oil (purity >99%) were from Prolabo.

Chemical Analysis of Egg Extract. Females 2–3 days old were allowed to oviposit on clean glass slides during two nights, until a harvest of ca. 10,500 eggs was obtained. Eggs attached to the glass slides were then extracted for 1 hr in purified methylene dichloride and, after removal of scales by filtration through milipore GW, 0.22 μm, the extract was concentrated under a stream of pure nitrogen. Analysis of the extract was performed by gas chromatography (GC) with no prior treatment except filtration described above and by GC-MS. The GC contained an HP Ultra 1 column (0.20 mm ID × 25 m) and a flame

ionization detector. The temperature program started at 60°C with a 2 min isothermal, and then was linearly increased by 5°C/min to 240°C with a 10-min isothermal at the end. The mass spectrometer was a HP 5971 A mass selective detector with positive 70-eV ionization. Spectra were compared to the MS data bank and to spectra obtained from pure standards. The amount of fatty acids and esters are expressed in nanograms per egg equivalent.

Statistics. In each treatment 12–21 replicates were performed, involving 26–60 females according to treatments. Avoidance indices and numbers of eggs laid were compared between treatments by using the nonparametric Mann-Whitney U test (Siegel, 1956). The null hypothesis that two groups have the same distribution was rejected if $P < 0.01$.

RESULTS

Chemical Analysis of Egg Extract. The GC-MS analysis of the egg extract revealed seven fatty acids, which represented the major constituents. The free acids myristic, palmitic, stearic, palmitoleic, oleic, linoleic, and linolenic acids were present in amounts ranging from 3.9 ng/egg equivalent for myristic acid to 30 ng/egg equivalent for palmitic and oleic acids. Traces of methyl palmitate and methyl stearate were detected but not quantified (Table 1).

Oviposition Preferences. The control solvent (Cs) had no effect on oviposition site selection by EGVM females. The mean avoidance index (AI) in grouped females was 2 ± 2% and was similar in range to that obtained in previous experiments with females grouped by 10 (Gabel and Thiéry, 1992), by five, and by isolated females (Thiéry and Gabel, 1993). Paraffin oil (Cw), which was applied in order to test the perception by females of waxy surfaces, had no effect on the oviposition site selection ($AI = 0 \pm 3\%$, $Z = -2.3$, NS). With Cs and Cw the highest value of *AI* was 7%.

The avoidance response to each of the six fatty acids tested increased with the dose (Figure 1). Palmitic ($C_{16:0}$), palmitoleic ($C_{16:1}$), and oleic ($C_{18:1}$) acids at 0.06 μg/spot were the most effective acids, and they provoked avoidance in the range of 20%. The avoidance response to $C_{16:0}$ and $C_{16:1}$ acids increased at 0.3 μg/spot ($C_{16:0}$; $Z = -3.31$, $P = 0.001$; $C_{16:1}$; $Z = -4.55$, $P = 0.0001$), and the maximum response to $C_{16:1}$ was obtained at 0.3 μg/spot. The highest dose tested (3 μg/spot) of $C_{16:0}$ acid gave an *AI* of 71 ± 18%. The dose-response to $C_{18:1}$ acid paralleled that of $C_{16:0}$, and the avoidance index at only one dose (0.3 μg/spot) was statistically different between the two acids (Figure 1). The difference in the avoidance index for $C_{16:0}$ and $C_{18:1}$ acids at 3 μg/spot was not significant ($Z = -1.12$, NS). $C_{16:0}$ acid induced avoidance indices higher than 80% in seven of 21 replicates, but a similar avoidance index

TABLE 1. IDENTIFICATION OF FATTY ACIDS IN METHYLENE DICHLORIDE EXTRACT OF *L. botrana* EGGS[a]

		Extraction solvent	
		Methylene dichloride	Methanol[a]
Myristic acid	$C_{14:0}$	3.91	0.26
Palmitic acid	$C_{16:0}$	30.0	1.37
Palmitoleic acid	(Z9)-$C_{16:1}$	12.5	n.f.[b]
Stearic acid	$C_{18:0}$	14.0	0.18
Oleic acid	(Z9)-$C_{18:1}$	32.5	n.f.
Linoleic acid	(Z9,Z12)-$C_{18:2}$	21.0	n.f.
Linolenic acid	(Z9,Z12,Z15)-$C_{18:3}$	15.7	n.f.
Methyl palmitate	me$C_{16:0}$	trace	1.37
Methyl palmitoleate	me(Z9)-$C_{16:1}$	trace	0.08

[b] n.f. = not found

was obtained in only two of 21 replicates with $C_{16:1}$ acid and in three of 19 replicates with $C_{18:1}$ acid.

Myristic ($C_{14:0}$), linoleic ($C_{18:2}$), and stearic ($C_{18:0}$) acids provoked little avoidance (range 6 ± 5% to 11 ± 9%) at 0.3 μg/spot, but mean indices were still different from those induced by the controls Cs or Cw (smaller difference: $Z = -3.18$, $P = 0.001$). As dose of 3 μg/spot of each of these three acids was necessary to obtain a range of avoidance similar to that induced by 0.06 μg/spot of $C_{16:0}$, $C_{16:1}$, or $C_{18:1}$ (bigger difference, $Z = -0.15$, NS).

In order to determine if esterification affected the response of moths, we tested esters of the two most effective free acids, palmitic and oleic. Methyl palmitate (me$C_{16:0}$), ethyl palmitate (et$C_{16:0}$), and methyl oleate (me$C_{18:1}$) produced very similar avoidance responses, characterized by bell-shaped dose-response curves. The dose of 1.5 μg/spot was most avoided, compared to the two other doses (smaller difference, $Z = -2.93$, $P = 0.003$).

One way to illustrate the avoidance response to each FA is to take into

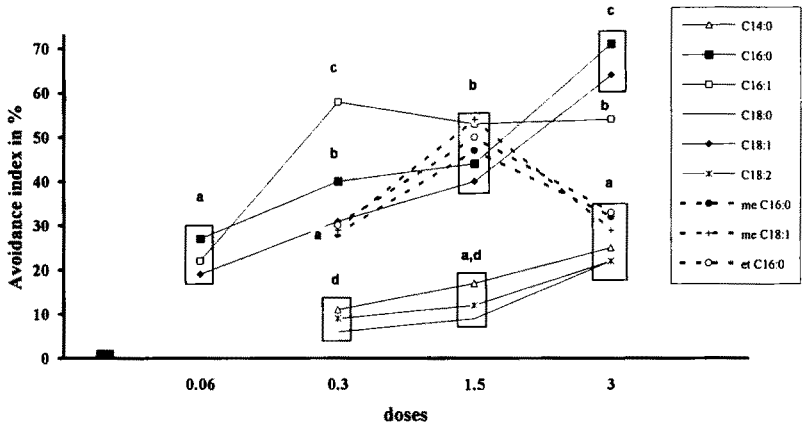

FIG. 1. Oviposition site preferences of *L. botrana* females exposed to six fatty acids and three esters. Values represent an avoidance index (AI) varying from 0% (no avoidance) to 100% (maximum avoidance). Doses are expressed as picograms/spot of application; 0.06 pg of $C_{16:0}$ is equivalent to two eggs of *L. botrana*. Black vertical bar represents AI obtained in response to the solvent alone (Cs). Values inside a frame are not statistically different at $P < 0.01$.

account its amount per egg (Table 2) and to estimate an expected number of eggs per application spot that would be necessary to produce given levels of avoidance if eggs produced a single compound. For example, 10 eggs producing only $C_{16:0}$, or between 5 and 25 producing $C_{16:1}$, would provoke an avoidance

TABLE 2. ESTIMATION OF NUMBER OF EGG EQUIVALENTS FOR EACH FATTY ACID NECESSARY TO RELEASE DIFFERENT PERCENTAGES OF AVOIDANCE (AI)

	AI (%)				
	25	40	50	60	70
$C_{14:0}$	750	no[a]			
$C_{16:0}$	<2	10	50	50–100	100
$C_{16:1}$	5	5–25	5–25	5–25	no
$C_{18:0}$	>210	no			
$C_{18:1}$	2–10	45	45–90	90	no
$C_{18:2}$	200	no			

[a]no = AI not obtained.

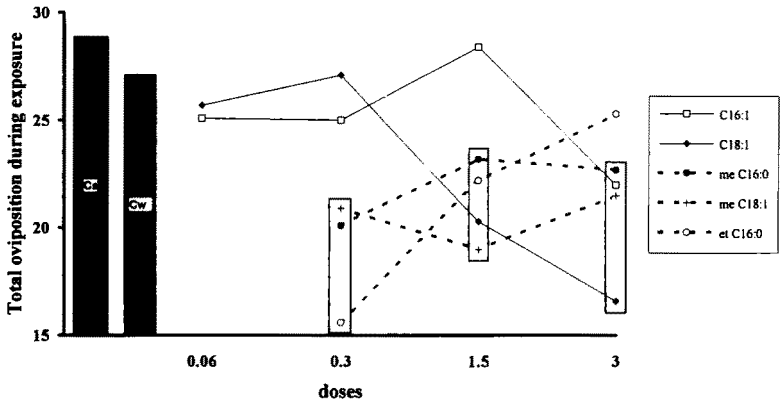

FIG. 2. Effect of the exposure to fatty acids or esters on the number of eggs laid by *L. botrana* on the whole substrate; only compounds that influenced egg laying (compared to Cs) are represented. Doses are expressed as micrograms per spot of application. Black vertical bar represents the number of eggs when exposed to the application phase and the striped bar when exposed to paraffin oil. Values inside frames are statistically different from controls (Cs and Cw) at $P < 0.05$.

index of 40%. Nearly 45 eggs producing only $C_{18:1}$ would be necessary to produce identical avoidance (Table 2).

Egg Production during Exposure. The number of eggs laid per female in Cs controls (29 ± 8.8 eggs) was very close to that obtained in Cw controls (27 ± 6.9 eggs) ($Z = -0.68$, NS). These numbers were slightly lower than the 39 ± 5.1 to 43 ± 15.6 eggs previously observed (Thiéry and Gabel, 1993), probably because of strain differences. The three esters and $C_{18:1}$ reduced the number of eggs significantly per female compared with Cs (Figure 2). The strongest reductions were obtained, respectively, with 0.3 μg/spot of $etC_{16:0}$ (15.6 ± 4.6 eggs, $Z = -3.43$, $P = 0.0006$), or $meC_{16:0}$ (18.9 ± 10 eggs, $Z = -2.86$, $P = 0.004$), and 3 μg/spot of $C_{18:1}$ (16.6 ± 12 eggs, $Z = -3.33$, $P = 0.0009$). These three values were not statistically different from each other. There was a marginal increase due to $C_{16:0}$ at each dose tested, but none was statistically different from the control (bigger difference, $Z = -1.39$, NS).

In anticipation of application of fatty acids in vineyards, we have considered the number of eggs laid per female on treated surfaces. In this we combined the avoidance response and the regulation of the number of eggs laid (Figure 3). The lowest numbers of eggs were laid on areas treated with $C_{18:1}$ at 3 μg/spot (1.1 ± 1.1 egg). About two eggs were laid on treated areas either baited with $meC_{18:1}$ at 1.5 μg/spot (1.8 ± 1.7), $C_{16:0}$ at 3 μg/spot (2.1 ± 1.8), and $C_{16:1}$ at 0.3 μg/spot (2.2 ± 1.7) (Figure 3). Ethyl palmitate, which was not found in

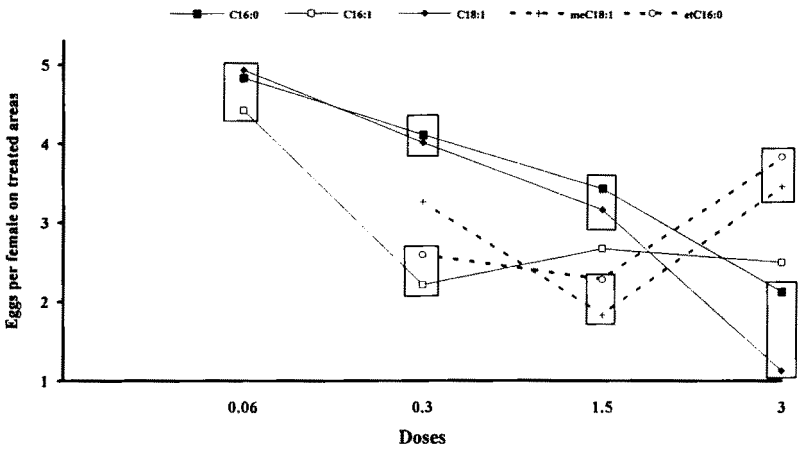

FIG. 3. Mean numbers of egg laid by *Lobesia botrana* on the treated areas (1/3 of the total area). We only considered the chemicals that reduced this amount up to ca. 2 eggs at one of the tested doses: palmitic acid ($C_{16:0}$), palmitoleic acid ($C_{16:1}$) and oleic acid ($C_{18:1}$), methyl oleate ($meC_{18:1}$) and ethyl palmitate ($etC_{16:0}$). Controls: Cs (6.8 $\pm$ 1.8 eggs) and Cw (7 $\pm$ 2.1 eggs) are note represented. Doses are expressed as micrograms per spot of application. Values inside a frame are not statistically different at $P < 0.01$.

the egg extract, also induced a low number of eggs (2.3 $\pm$ 1.1 eggs) at 1.5 μg/spot (Figure 3), but in none of these tests with esters were the numbers of eggs different ($C_{18:1}$, 3 μg, versus $C_{16:1}$, 0.3 μg: $Z = -1.27$, NS).

DISCUSSION

We have identified several fatty acids in addition to those previously reported in the eggs of *L. botrana*. We question the quantity of methyl esters previously identified. By extracting eggs in methylene dichloride, we harvested >20 times the amounts of each free fatty acid than reported previously with methanol as solvent (Thiéry et al., 1992) and only traces of two esters. We suggest that free fatty acids were underevaluated and that esters were overevaluated in our previous work due to esterification by the extraction solvent, methanol. Esterification could be obtained experimentally by dissolving FAs in cold methanol, and this will be detailed elsewhere (Farkas et al., unpublished data). The present analysis of an extract of *L. botrana* eggs revealed similar constituents as in *C. pomonella* eggs, but with different concentrations and ratios (Thiéry et al., 1995). However, occurrence of methyl esters both in methylene dichloride and ethyl ether extracts of *C. pomonella* eggs suggests that fatty acid esters are

probably produced in low amounts by eggs (Thiéry et al., 1995). The present identification is consistent with that for other tortricids such as *C. pomonella* (Thiéry et al., 1995), *Cydia molesta* and *Eupoecifia ambiguella* (P. Farkas, B. Gabel, and D. Thiéry, unpublished data).

We now propose that at least three fatty acids (palmitic, palmitoleic, and oleic) may participate in the regulation of the oviposition site selection by EGVM. In addition, two esters (methyl oleate and methyl palmitate) reduced the number of eggs laid. Ethyl palmitate was not detected in the eggs, but it reduced the number of eggs laid. The highest avoidance indices obtained with the saturated C_{16} and the monounsaturated C_{18} suggest that *L. botrana* females perceive and react to both chain length and chain unsaturations, with saturated stearic and diunsaturated linoleic acids evoking weaker responses than oleic acid. We previously reported avoidance and also reduction in the number of eggs laid by *L. botrana* in response to a blend of three fatty acids and six methyl esters of fatty acids in which palmitic acid and methyl oleate were the two major compounds (Thiéry et al., 1992; Thiéry and Gabel, 1993). Avoidance indices between 55% (Thiéry et al., 1992) and 64% (Thiéry and Gabel, 1993) were obtained using ca. 30 ng/spot of palmitic acid blended with other molecules, while 60 ng/spot of pure palmitic acid was necessary to obtain an avoidance index of only 30%. Even if palmitic, palmitoleic, and oleic acids explain most of the avoidance observed, we suspect that other fatty acids and methyl esters can synergize this effect. We also reported that a blend of three acids and six esters reduced the number of eggs laid by EGVM females (Thiéry and Gabel, 1993) and by CM females (Gabel and Thiéry, 1994). Long-chain free FAs and esters are probably commonly produced by eggs or larvae of several species; these compounds have already been found in eggs from several Lepidoptera (see references above), and larval cuticles of honeybees (Trouiller, 1993). Several works report the effect of fatty acids on egg or larval parasites. Rickli et al. (1992) demonstrated by using a servosphere apparatus that a distant source of palmitic acid improved the orientation of the bee mite *Varroa jacobsoni*. The generalist parasitoid of Lepidoptera eggs, *Trichograma brassica*, raises its locomotor activity in response to a distant source of oleic acid (Frenoy et al., 1992). These observations support the hypothesis that long-chain free fatty acids and derivatives may be involved in the perception of young instars.

Palmitoleic, oleic, and linoleic acids also deter oviposition in the mosquito *Culex quinquefasciatus* (Hwang et al., 1984), but saturated acids were not assayed in their work. The decision to oviposit or not often results from the balance between oviposition stimulants and deterrents (Renwick, 1989). In that respect chemical cues involved in the dispersion or aggregation of progeny may interact with those produced by the plant that stimulate oviposition. EGVM avoid oviposition in response to fatty acids produced by its eggs and also typically oviposit on berries that are suspected to bear lower amounts of palmitic

acid compared to grape leaves. Whether females perceive contrasts between chemical backgrounds, such as fatty acids produced by plant surfaces, or especially high amounts of fatty acids and esters corresponding to eggs needs further study.

One purpose of this work was to focus on the most oviposition deterring chemicals that can potentially be applied in the field, i.e., that are inexpensive and stable compounds. Therefore, we disregarded linolenic acid with three double bonds as too unstable. Palmitic acid and oleic acid are good candidates to explain the avoidance induced by the egg extract. Their greater stability and efficacy may make them good candidates for further field applications. The two esters are poor candidates because the number of eggs laid on treated areas increased with the dose. A definitive selection of active chemicals that could be applied in vineyards should, however, take into consideration their physical properties and their behavior under field conditions, which were not assayed in this work.

Acknowledgments—We are indebted to Dr. Pavel Farkas, Food Research Institute at Bratislava, Slovakia, who performed the GC-MS analyses. We greatly appreciate the help of Martine Rhyn, Station Federale de Recherches Agronomiques, Nyon, Switzerland, for supplying EGVM chrysalids and of Dr. Lamya Moulay for experimental assistance. We thank Dr. Luc Legal (CNRS, Orsay) for comments on the manuscript. This project was supported by HiRA-DRIV.

Abstract—Feeding tests with loggerhead shrikes (*Lanius ludovicianus*) showed this bird to accept *Utetheisa ornatrix*, a moth (Arctiidae) protected by pyrrolizidine alkaloids, but to avoid *Lytta polita*, a beetle (Meloidae) containing cantharidin.

Key Words—Arctiidae, Meloidae, *Utetheisa ornatrix*, *Lytta polita*, pyrrolizidine alkaloids, cantharidin, feeding aversion.

INTRODUCTION

The moth *Utetheisa ornatrix* (family Arctiidae) and the beetle *Lytta polita* (family Meloidae) are both chemically protected, the former by pyrrolizidine alkaloids (PAs) sequestered from the larval food plant (Eisner and Meinwald, 1995), the latter by cantharidin, produced by the beetle itself (McCormick and Carrel, 1987). We recently undertook some feeding tests with loggerhead shrikes (*Lanius ludovicianus*, family Laniidae), in the expectation that the birds would reject both these insects, but found that they spurned *L. polita* only, and fed readily

on *U. ornatrix*. We here present the results of these tests and discuss their implications.

METHODS AND MATERIALS

The tests were conducted in June 1993 on the grounds of the Archbold Biological Station, Lake Placid, Highlands County, Florida, where loggerhead shrikes and both species of insect coexist naturally.

Loggerhead shrikes are sit-and-wait predators whose diet comprises mostly arthropods (Yosef and Grub, 1993), including a wide range of Lepidoptera. Like other shrikes, they commonly impale prey on sharp objects prior to consumption. Yosef and Whitman (1992) found loggerhead shrikes to impale chemically noxious prey for periods of up to three days (e.g., the lubber grasshopper, *Romalea guttata*; the danaid butterfly, *Danaus gilippus*; the southern narrow-mouthed toad, *Gastrophyne carolinensis*) and argued that such preingestive exposure of prey could provide time for spontaneous chemical breakdown of deterrent substances contained therein. However, shrikes do not invariably impale their prey. Loggerhead shrikes, for instance, at our Florida study site, were repeatedly noted in the field to capture beetles and moths and to ingest these outright (Yosef, unpublished).

U. ornatrix contain PAs at all stages of development. PAs sequestered by the larvae are retained throughout metamorphosis and eventually are transmitted in part to the eggs. Eggs, larvae, and adults are protected against arthropod predators as a result (Eisner and Meinwald, 1995). Whether PAs protect *U. ornatrix* also against vertebrate predators had not been established.

U. ornatrix can be raised in the laboratory to be either PA-containing or PA-free. The latter moths are obtained by raising larvae on a semisynthetic, pinto bean-based diet (PB diet) devoid of PA (Miller et al., 1976). PA-containing moths are obtained by raising larvae on CS diet, consisting of a blend of PB diet and seeds from one of the normal food plants (*Crotalaria spectabilis*) of *U. ornatrix* (Bogner and Eisner, 1991). The principal PA in the seeds of this plant is monocrotaline. Adult *U. ornatrix* raised on CS diet contain over 0.5 mg monocrotaline (Bogner and Eisner, 1991), an amount commensurate with the level of PA present in field-collected *U. ornatrix* (field-collected moths from our Florida site contain primarily usaramine, the principal PA in *Crotalaria mucronata*, the dominant *U. ornatrix* food plant in the area; usaramine and monocrotaline are closely similar chemically) (Conner et al., 1990; Eisner, unpublished).

U. ornatrix commonly respond to disturbance by emitting a froth from the neck region (Figure 1). The fluid, which consists mostly of blood, contains PA in both field-collected and CS-diet-raised individuals (Eisner, unpublished).

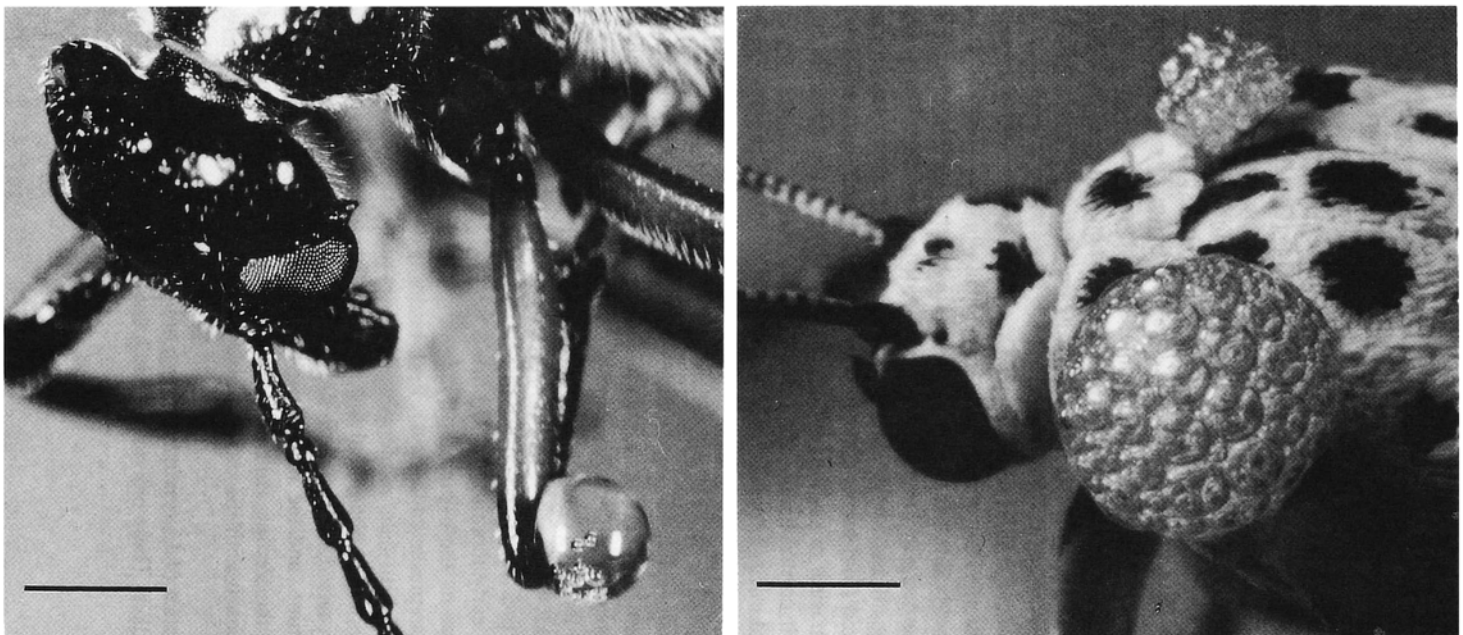

FIG. 1. *Lytta polita* (left) and *Utetheisa ornatrix* (right) responding to disturbance by emitting, respectively, a droplet of blood from a knee joint (reflex bleeding) and froth from the neck region. Bars = 2 mm (left) and 1 mm (right).

U. ornatrix, unlike moths generally, take readily to the wing in the daytime. The moth is distinctly aposematic, being white and pink with black and yellowish markings. It is therefore exposed and discernible to diurnal predators.

L. polita shows the general characteristic of Meloidae of reflex bleeding from the femorotibial joints when disturbed (Figure 1) (Carrel and Eisner, 1974). As is true for Meloidae generally, the emitted fluid contains cantharidin. Actual levels of cantharidin in the blood of *L. polita* are in the range of 10^{-1}–10^{-2} M (J. Carrel, unpublished); whole *L. polita* may contain as much as 0.4 mg cantharidin (McCormick and Carrel, 1987). *L. polita* are evenly greyish brown in coloration. While lacking the gaudy coloration characteristic of aposematic insects, they are nonetheless visually conspicuous when resting on their preferred feeding site, the male cones of slash pine (*Pinus elliottii*), from which they derive pollen (Carrel et al., 1990).

Ten loggerhead shrikes were trapped (Yosef and Lohrer, 1992) for purposes of experimentation. They were placed individually in 3-m^3 screened cages, to which they quickly adapted. Each cage bore a central upright post (1.3 m), outfitted with barbed wire around the top to provide for prey impalement. Opaque plastic sheeting affixed to the sides of the cages ensured that the birds were visually insulated from one another. Following experimentation, all birds were released at their sites of capture and were noted in the days thereafter to have returned to their normal haunts and behaviors (foraging, brooding).

Insects and mice (*Mus musculus*) that we fed to shrikes in our experiments (including to free-ranging shrikes) had all been killed shortly beforehand by freezing.

For the first days following capture, the birds were offered only innocuous prey (mice, plus various insects known or suspected to be chemically undefended). The prey were offered in deep plastic trays (12-cm-high sides, opaque plastic), which the birds came to associate with food presentation by the second day (they quickly approached the trays to investigate their holdings as soon as the trays were presented). To ensure that the birds were hungry, feedings were initiated in the early morning (07:00 hr).

Subsequent to these preliminary feedings, tests were carried out with *U. ornatrix* (also presented in trays). Each bird was offered a total of six moths, comprising one pair (male and female; the sexes are easily told apart by structural differences of the abdominal tip) of each of the three categories: PB-diet-raised, CS-diet-raised, field-collected. The moths were offered a pair of each category at a time, and the fate of each item was noted. Forty minutes after termination of the feeding sequence, each bird was offered a mouse, to check whether experience with the moths had in some fashion affected their feeding behavior.

A separate set of *U. ornatrix* presentations was done with five free-ranging loggerhead shrikes. These individuals had habituated to R.Y., who could readily

attract them to prey offered on the palm of the hand. Each of these birds was also offered six *U. ornatrix* (a male and female of each of the three categories) presented one at a time on the hand in varying order, in a single feeding session. Twenty minutes after presentation of the last moth, each bird was manually given a mouse. The tests with free-ranging shrikes were carried out at the same time as those with the caged specimens; there was therefore certainty that the two sets of birds comprised different individuals.

The experiments with *L. polita* were carried out with the trapped shrikes only and involved presentation (for a period of 6–7 hr) of mixed assortments of insect prey. These experiments were initiated some days following the tests with *U. ornatrix* and extended for four consecutive days. Observation during the daily experimental period was continuous for the first hour, and then intermittent at intervals of 2–3 hr. On day 1, each bird was given a tray bearing 20 mealworms (larvae of *Tenebrio molitor* beetles; family Tenebrionidae), plus a number of mice. On day 2, a tray was offered bearing 20 mealworms, plus 20 *Loxa flavicollis* (a stink bug, family Pentatomidae) and 20 dung beetles (*Dycenetus morato*, family Scarabaeidae). On day 3, the tray was loaded as on day 2, but contained an additional 20 longhorned beetles (*Monochamus* spp., family Cerambycidae). On day 4, the assortment equaled that of the previous day, but included an added five *L. polita*. An effort was made to keep the arrangement of insects on the trays variable.

Shrikes characteristically regurgitate residual stomach contents in the form of discrete pellets, which they void at intervals following ingestion. We found such pellets to be disgorged by our cages shrikes, and collected these pellets from the cage floors on the days of experimentation and on the following mornings prior to renewed feeding. The pellets were individually checked under the stereomicroscope for undigested remains (bones, fur, insect parts).

RESULTS

The *U. ornatrix* were all eaten, both by the caged and free-ranging shrikes. The caged birds took the moths individually in relatively quick succession (within a span of 14 min or less) and showed no hesitation in seizing or swallowing the moths. There were also no ill effects noticed in the 40 min period following the testing sequence. All birds avidly ate the individual mice that were offered to them at the end of that interval.

The free-ranging shrikes also failed to show any reluctance vis-à-vis the moth offerings. They came to the hand quickly to take each moth, and unhesitatingly ate the mouse later offered.

Scrutiny of the pellets from the caged shrikes revealed no remnants (except scales) of *U. ornatrix* (only bones and fur from the mice).

TABLE 1. NUMBER OF INSECT PREY EATEN BY TEN LOGGERHEAD SHRIKES ON DAYS 3 AND 4 OF 4-DAY EXPERIMENT[a]

Prey species	Number eaten ($X \pm$ SEM)	
	Day 3	Day 4
Mealworm, *Tenebrio molitor*	18.6 ± 0.6	18.4 ± 0.6
Pentatomid bug, *Loxa flavicollis*	18.8 ± 0.5	18.9 ± 0.4
Dung beetle, *Dycenetus morator*	18.5 ± 0.5	19.6 ± 0.2
Cerambycid beetle, *Monochamus* sp.	18.7 ± 0.4	19.7 ± 0.2
Meloid beetle, *Lytta polita*		none touched

[a]Each shrike was given 20 of each insect on each day, except of *L. polita*, which were offered, 5 per shrike, on day 4 only.

The four-day test sequence culminating in the *L. polita* presentations revealed, first, that loggerhead shrikes are voracious insectivores. The birds ate virtually all insects offered, which on days 3 and 4 amounted to nearly 80 items (Table 1). Consumption rate for these two days was calculated to average 15 ± 1.9 (SD) insects/shrike/hr. However, rate of insect intake was not constant, since the birds paused at intervals during the feeding sessions for relatively lengthy periods prior to ejection of individual gastric pellets (during the first hour of prey presentation, we timed such pauses to be in the range of 27–48 min). A total of 56 pellets were produced by the shrikes during the four days of experimentation. Examination of these pellets revealed ample skeletal parts from the beetles and pentatomids. None of these insects was regurgitated intact with the pellets.

The salient finding from the four-day test was that the *L. polita* offered on day 4 were all ignored. In not a single instance was one of these beetles noted to be taken in the bill by a bird. The rejections were all effected on the basis of noncontact assessment.

The feeding behavior of the shrikes in the four-day test was quite consistent. Typically, birds hopped into the tray and remained in it for 3 sec or less as they chose and consumed an individual insect. Two of the birds differed somewhat from the others in that they tended first to drop the prey on the ground beside the tray and to retreat briefly to a perch, before returning to the item to eat it. In not a single instance in our tests with caged shrikes was an insect impaled on the barbed wire of the pole. Mice were always impaled by the shrikes, to facilitate the butchering process.

DISCUSSION

U. ornatrix and *L. polita* were evidently treated very differently by our shrikes. The birds ate all 90 *U. ornatrix* offered, without hesitation and without betraying ill-effects. We are reluctant to conclude, however, that loggerhead shrikes fail to taste PAs or that they are fully tolerant of the chemicals. PAs are strongly toxic to vertebrates (hepato-, pneumo-, and nucleotoxic), and the toxicity is sometimes of delayed onset (Mattocks, 1972; Hartman, 1991). A more lengthy series of *U. ornatrix* feedings (our birds ate only four PA-laden moths, all on the same day, and may have received no more than 2–3 mg PA each) might thus well have had deleterious effects on the birds and led these eventually to discriminate against the moths on the basis of taste or sight. We were reluctant to expose the shrikes to potential risk by feeding them *U. ornatrix* in greater numbers. Shrikes are on the decline worldwide, a fate they are not escaping in Florida (Yosef et al., 1993). One point worth noting is that loggerhead shrikes do appear to consume *U. ornatrix*, at least at times, in nature. We have noted occasional specimens of the moth impaled at actual prey caches of the birds in Florida (Yosef, unpublished).

The fact that no trace (except scales) of *U. ornatrix* could be found in the pellets is not surprising, since the moth is soft-bodied and devoid of the sort of jagged, potentially abrasive parts that are usually regurgitated by shrikes with their pellets. We therefore assume all our *U. ornatrix* to have been passed without residue into the intestine of the birds.

The dead *U. ornatrix* used in our tests were obviously not able to emit froth. While this might have somewhat reduced their state of defendedness, the froth is not the only means by which *U. ornatrix* externalize their PA. The entire integument of the moth, including the wing surfaces and perhaps even the scales, is laden with PA (Eisner, unpublished). The PA in the moths should therefore have been detectable to the shrikes.

One should not assume, from our results with shrikes, that *U. ornatrix* is generally acceptable to avian predators. Preliminary data obtained by one of us (T.E.) with free-ranging scrub jays (*Aphelocoma coerulescens*; family Corvidae), indicate that these birds tend to reject the *U. ornatrix*, both on sight and after tasting. Moreover, scrub jays showed these tendencies vis-à-vis both PA-laden and PA-free (that is, PB-diet-raised) moths, indicating that compounds other than PAs may also contribute to the defense of *U. ornatrix*. It is doubtful, however, that scrub jays are major natural enemies of *U. ornatrix*, since the birds tend not to forage in the habitats frequentated by the moth.

Data on the deterrent potential of PAs to vertebrates are scant. Our findings with shrikes do not rule out the possibility that PAs might be deterrent to other birds, or for that matter to nonavian vertebrates, on account of either bitterness

or toxicity. Interestingly, PAs appear not to be effective as taste deterrents to mice (Glendinning et al., 1990).

Whether the avoidance of *L. polita* by our shrikes was a reflection of innate aversion or of discrimination based on direct experience with the beetles remains unknown. Either way, one is tempted to attribute the defendedness of the beetle to the one deterrent compound, cantharidin, that it is known to contain, but such attribution should be advanced with caution. Cantharidin is a potent feeding deterrent to insects (Carrel and Eisner, 1974) and is highly toxic to some vertebrates (Kaiser and Michl, 1958), but its actual effect on birds has yet to be properly assessed. Again, because of the potential risk to the shrikes, we were reluctant to subject our birds to feeding experiments with cantharidin itself. Interestingly, some birds are able to tolerate cantharidin ingestion (Carrel, 1971). In our judgment, one cannot rule out the possibility that compounds other than cantharidin also play a role in bird aversion to Meloidae.

Meloid beetles constitute a diverse group at our Florida site. They range broadly in size and color pattern (*L. polita* is the largest; many species are colorful) and most lead a relatively exposed adult existence. It would be interesting to know whether loggerhead shrikes discriminate against them all. We have never seen meloid beetles among the insects impaled at loggerhead shrike caches (Yosef, unpublished).

A point of interest concerns the evident acceptability of the *Loxa flavicollis* that we offered. When live, these insects, like other Pentatomidae, would have been able to spray a carbonyl compound-laden secretion (Blum, 1981) when attacked. While these insects might well have been treated differently had they been given live to our birds, the shrike must in all likelihood have gotten "a taste" of the exocrines, since remnants of the chemicals must have been present in the glands of the corpses.

The fact that the pellets produced by our shrike contained cuticular remains only when hard-bodied insects were fed (*L. flavicollis* and the various beetles), but none when a soft-bodied insect such as *U. ornatrix* was fed, indicates that pellet analysis can yield at best only partial information about dietary intake in shrikes. Pellet analyses undertaken in conjunction with studies of shrike population declines, and intended to reveal the causes of such declines, should therefore be interpreted with caution.

Acknowledgments—We thank Mark Deyrup for help during our study and for identification of some of the insects. Fred E. Lohrer provided input on an early version of the manuscript. Support was provided in part by grant AI-02908 from NIH.

INFLUENCE OF SNAIL FECES AND MUCUS ON OVIPOSITION AND LARVAL BEHAVIOR OF *Pherbellia cinerella* (DIPTERA: SCIOMYZIDAE)

JAMES B. COUPLAND

(Received May 1, 1995; accepted September 27, 1995)

Abstract—Larvae of the sciomyzid fly *Pherbellia cinerella* are voracious predators of terrestrial helicid snails. Eggs are deposited in areas where snails occur and larvae hunt actively for their prey. Snail feces and mucus were tested to determine if they had any kairomone or stimulatory effects on *P. cinerella*. Adult flies oviposited more frequently on substrates containing fresh snail feces than on substrates containing snail mucus or water (control). However, mucus and feces both stimulated increased search behaviour in first instar larvae. These results are discussed in relation to snail biology, and the potential for augmentation of these flies in areas affected by pest snails.

Key Words—Oviposition stimulant, kairomone, searching behaviour, Sciomyzidae, snails, Mollusca, biological control.

INTRODUCTION

The family Sciomyzidae are parasitoids and predators of both terrestrial and aquatic snails. Since Berg (1953, 1966) drew attention to the malacophagous nature of sciomyzids and their potential as biological control agents of medically important snails, intensive study has been carried out on their biology (see review in Berg and Knutson, 1978). Attempts at using these flies as biological control agents have been aimed at the control of aquatic or semiaquatic vector snails. In Hawaii, *Sepedon macropus* Walker was released for the control of *Lymnea ollula* Gould and *Pseudosuccinea columella* Say, intermediate hosts of *Fasciola gigantica* Cobbold, a liver fluke of cattle (Chock et al., 1961). Recently, an attempt has been made to augment populations of *Sepedon scapularis* Adams

0098-0331/96/0200-0183$09.50/0 © 1996 Plenum Publishing Corporation

for the control of intermediate hosts of schistosomiasis in South Africa (Maharaj et al., 1992).

Although there have been no releases of sciomyzids for the control of pest and vector terrestrial mollusks, their potential use was discussed by Berg and Knutson (1978). Knutson et al. (1970) examined the biosystematics and potential of *Salticella fasciata* Meigen as a biocontrol agent of pest helicid snails and concluded that it may have good potential due to its host specificity. Recently, the effectiveness and potential of *S. fasciata* as a biological control agent of the helicid pests *Theba pisana* Müller and *Cermuella virgata* da Costa was reexamined by Coupland et al. (1994), who concluded that the species was an inappropriate biocontrol agent due to its inability to kill the pest target snails. However, another sciomyzid, *Pherbellia cinerella* Fallén, is known to be a predator of helicid snails, but its potential as a biological control agent has never been tested.

Most Diptera oviposit on or near their food source. Some Sciomyzidae, such as *S. fasciata*, lay their eggs directly on the host snail at the umbilicus (Knutson et al., 1970). In other species, such as *P. cinerella*, eggs are laid on the ground and first-instar larvae actively search for prey snails. Host-produced chemicals that stimulate both increased oviposition and search behavior have been documented for several dipteran predators and parasites of Lepidoptera and earthworms (Morris and Pivnick, 1991; Nettles and Burke, 1975). Snail mucus is known to induce trail following in several insect predators of snails such as the Lampyridae (Schwalb, 1961). In addition, several species of snails use mucus in homing, food finding (especially carnivorous snails), and courtship behavior (Cook, 1992). Snail feces have been implicated in interference competition between *T. pisana* and *C. virgata*. As part of a general study on the biology of *P. cinerella* and its suitability as a biological control agent of pest helicid snails, this paper reports on the oviposition and first-instar larval responses of *P. cinerella* to feces and mucus of the snail *C. virgata*.

METHODS AND MATERIALS

Rearing Procedure. A laboratory culture of *P. cinerella* was established using eggs of field-collected females (Viols le Fort, Herault, France). Flies were placed in male–female pairs in clear plastic rearing cages (16 × 14 × 14 cm) with moistened filter paper (to maintain humidity) and a stick for perching. Flies were fed a mixture of honey, brewer's yeast, and skim-milk powder and kept at 20°C under natural light conditions. Eggs were collected from rearing cages, placed on moist filter paper, and kept in Petri dishes at 21°C. After hatching, larvae were maintained with excess *C. virgata* (approx. 5 mm in diameter).

Effect of Feces and Mucus on Oviposition. The effect of feces and mucus on the selection of oviposition site by female flies was tested using a three-

choice assay. Mated first-generation females (F_1) were introduced singly into rearing cages that contained a choice of three substrates—moist peat with feces, moist peat with snail mucus, and as a control moist peat with water—placed in small Petri dishes (5 cm diam.) on the bottom of the cage. Fresh feces from several snails (*C. virgata*) reared on carrot and oatmeal were collected from snail-rearing boxes. Approximately 0.5 g of feces was mixed thoroughly with 20 g of sterilized peat moistened with sterilized deionized water. Snail mucus was collected (approx. 5 ml) from several snails stressed by pressing on their foot with a small needle. This mucus was mixed with sterilized deionized water and the mixture was then used to moisten 20 g of peat. The control was peat moistened with the sterilized deionized water. The experiment was replicated 12 times with different flies. The eggs of *P. cinerella* laid within each dish were counted daily, fresh substrate was added, and the Petri dishes containing each substrate were replaced in random positions. The experiment continued two weeks.

Larval Behavior Experiments. First-instar larvae of *P. cinerella* crawl actively in search of host snails. During this period they often step and tap their head on the soil surface from side to side. The frequency of this tapping behavior per unit time was used to determine if feces and mucus had a stimulatory effect on search behavior. Experiments were conducted in Petri dish arenas (15 cm diam.) on filter paper. Larva were introduced and allowed to acclimatize for 1 hr on moist filter paper, after which a 10-cm-diameter disk of filter paper impregnated with either a deionized water and snail feces mixture (20 ml and 0.5 g), a deionized water and snail mucus mixture (20:5 ml ratio), or just deionized water was introduced. Care was taken not to cover the larva with the introduced disks. Introductions were done when the larva was at the side of the Petri dish. Preliminary observations indicated no behavioral differences when larvae were in different areas within the dish. Five minutes before introduction of the test disk the number of larval head taps per 5 mins was counted. When the larvae crawled on to the test disk, the number of head taps was again recorded for a period of 5 mins. This procedure was replicated 20 times for each test disk using a different larva each time. The difference between the number of taps before and during and treatment was then recorded.

Statistical Analysis. The total number of eggs laid on each substrate and the differences in number of larval taps for each treatment were compared using Kruskal-Wallis ANOVA.

RESULTS AND DISCUSSION

P. cinerella laid more eggs on the substrate that contained feces than on the substrates containing either mucus or deionized water (control) (Figure 1). The latter two were not significantly different. Larval head tapping increased in

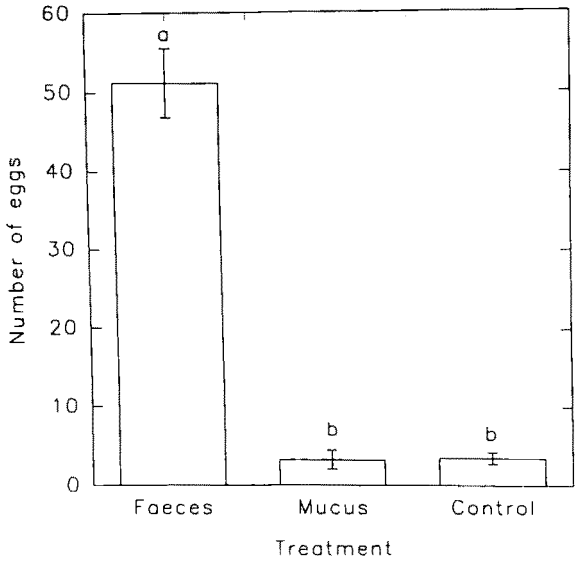

FIG. 1. Mean (±SE) number of eggs laid on each of the treatment substrates over 14 days from 12 replicates. Bars with the same letter are not significantly different, Kruskal-Wallis ANOVA, $P < 0.05$.

the presence of both feces and snail mucus, which did not significantly differ (Figure 2). The behavior of larvae presented with the deionized water (control) disks did not significantly differ from the pretreatment behavior.

While *Pherbellia cinerella* will oviposit in the absence of snail feces, as shown in this study, their presence increases the likelihood of oviposition. This is the first demonstration of a snail-produced kairomone in a snail-sciomyzid interaction. The use of only snail feces as an oviposition kairomone is an interesting result. While mucus is known to elicit a response from invertebrate predators of snails (Schwalb, 1961) and other snails (Cook, 1992), feces have never been implicated as eliciting a response. Fecal matter was shown to reduce activity in coexisting helicid snails and has been proposed as a mechanism for interspecific competition through negative effects from its ingestion. In herbivorous insects, host plant volatiles in the feces are known to act as kairomones for both their parasites (Takabayashi and Takahashi, 1989) and predators (Wyatt et al., 1993). However, since *C. virgata* is primarily a detrivore, no specific secondary plant compound would be consistently associated with its feces. One possibility may be that the kairomone is produced by gut microorganisms. These have recently been implicated in kairomone production in the leek moth (*Acrolepiopsis assectella* Zeller). In another helicid snail, *Helix pomatia* L, the bacterial

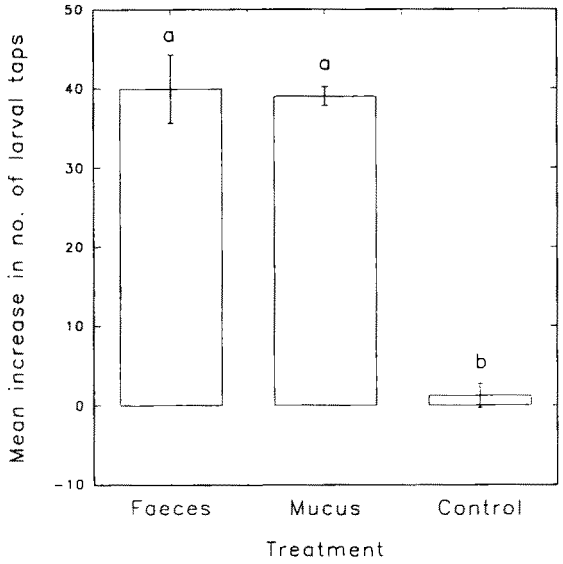

FIG. 2. Mean (±SE) increase in number of larval head taps when presented with different treatment filter paper disks. Bars with the same letter are not significantly different. Kruskal-Wallis ANOVA, $P < 0.05$.

flora were found to be the same among individuals, especially in relation to the chitinase-producing bacteria (Florkin and Lozet, 1949). It may be that the gut flora of individual *C. virgata* are also similar in species composition.

A possible reason for a predator using a fecal kairomone may be that many terrestrial mollusks, including slugs, tend to return to the same resting spot during periods of inactivity (i.e., during the day) (Cook, 1979; Lorvelec, 1990). At these resting sites, snails tend to defecate before forming a resting epiphragm (Coupland unpublished data). Therefore the presence of feces would be a good indicator that snails were in proximity. In contrast, mucus, widely spread during the previous evening of foraging, would indicate only that snails are present, with no clue as to their proximity. In contrast to *P. cinerella*, the earthworm predatory fly, *Coenesia tigrina* Fallen is stimulated to extend its ovipositor by earthworm mucus, but tests were not conducted on earthworm casts (Morris and Pivnick, 1991). Since earthworms are mainly subterranean, with only periodic activity at the surface when producing soil casts, mucus would seem to be as good as indicator of earthworm presence as their casts. However, casts have been found to be highly variable in their composition, especially with respect to microorganisms (Parle, 1963), possibly making it more difficult for a suitable component to be utilized as a kairomone.

While snail mucus had no effect on the oviposition behavior of *P. cinerella*, it stimulated increased searching (head tapping) behavior in first instars. Feces had a similar effect, although this may be due to contamination as feces are inevitably contaminated with some mucus. Snail mucus is also used by other invertebrate snail predators, notably *Lampyris* spp. (glow-worms), that follow mucus trails. Glow-worm larvae are so sensitive to mucus that they can distinguish between mucus secreted at the head and tail end of a snail by its chemical composition. *Lampyris* spp. use this information to inject poison into the anterior end of the snail, paralyzing it more quickly (Schwalb, 1961).

Pherbellia cinerella is a very common pasture-inhabiting fly that attacks and kills a wide range of snail species (Coupland and Baker, 1995). In most pastures in the south of France there are two to seven snail species that coexist, all of which are attacked by *P. cinerella*. Furthermore, many of these species are pests of both pasture and crops in Australia and in regions of the Mediterranean (Baker, 1986). If a kairomone could be identified and manufactured, it may be possible to use it to augment or direct populations of adult *P. cinerella* in or to areas where such snails are a problem.

Abstract—Synthetic sex pheromone of the pea moth *Cydia nigricana*, (*E*,*E*)-8,10-dodecadien-1-yl acetate (*E*8,*E*10-12 : Ac), was applied in a 3-ha pea field at a rate of 17 g/ha, in two different dispenser formulations. Aerial concentrations within pea canopy, as determined by a field electroantennogram (EAG) apparatus, were 2 and 3 ng/m^3 in the two dispenser treatments. The validity of the EAG measurements was corroborated by sampling of field air, followed by gas chromatographic quantification of *E*8,*E*10-12 : Ac. Males were attracted to fresh dispensers releasing *E*8,*E*10-12 : Ac plus less than 2% of the antagonistic *E*, *Z*; *Z*, *E*; and *Z*, *Z* isomers. Two days after placement, the proportion of these isomers had increased to 6%. Males were then no longer attracted to the dispensers, but were observed to fly out of the treated field. Male attraction to calling females was almost entirely suppressed, and attraction to traps baited with synthetic pheromone was significantly reduced. Larval infestation in the pheromone-treated field was 2%, compared to 36% in a control field.

Key Words—Sex pheromone, (*E*,*E*)-8,10-dodecadien-1-ol acetate, antagonist, inhibitor, mating disruption, behavioral observations, field EAG, *Cydia nigricana*, Tortricidae, Lepidoptera

INTRODUCTION

The potential of a blend of sex pheromone (*E*,*E*)-8,10-dodecadien-1-yl acetate (*E*8,*E*10-12 : Ac) and the antagonistic isomers *E*,*Z*-, *Z*,*E*-, and *Z*8,*Z*10-12 : Ac (Witzgall et al., 1993) for mating disruption of the pea moth, *Cydia nigricana* F., has recently been demonstrated. After isomerization of initially pure *E*8,*E*10-12 : Ac in the dispensers, *C. nigricana* males were repelled from a 0.6-ha pea field, and male attraction to traps baited with *E*8,*E*10-12 : Ac was suppressed during the test period of 35 days (Bengtsson et al., 1994). However, larval infestation in the treated field was not significantly different from the adjacent control field. For the present study, a larger and isolated field site has been chosen to minimize immigration of mated females.

Although males were no longer seen in the treated field a few days after dispenser placement (Bengtsson et al., 1994), short-range attraction of males to females within the canopy might have been overlooked. It therefore remained to be determined whether traps with synthetic *E*8,*E*10-12 : Ac on rubber septa were indeed suitable to monitor disruption of sexual communication in *C. nigricana*. Although traps and septa were exchanged regularly, they may have been less attractive than females, due to isomerization of *E*8,*E*10-12 : Ac (Witzgall et al., 1993). During the present study, we have observed male attraction to calling females, and a propheromone compound, releasing pure *E*,*E* isomer (Streinz et al., 1993).

The measurement of the dispersal and aerial concentrations of mating disruptant chemicals within the crop is fundamental to the optimization of dispenser load and placement and the comparison of different experiments. A portable electroantennogram (EAG) apparatus, using the male antenna as sensor, allows direct detection of ambient pheromone (Sauer et al., 1992). For determination of absolute concentrations in field air, the antennal response was correlated with stimulus concentrations in syringes (Bengtsson et al., 1994). To substantiate this calibration, we have now concurrently determined aerial pheromone concentrations by field EAG and by gas chromatographic analysis of air samples (Caro et al., 1978, 1979).

METHODS AND MATERIALS

Chemicals and Dispensers. *E*8,*E*10-12 : Ac was formulated in puzzlepiece configuration trilaminate dispensers (Hercon Environmental Co., Emigsville,

Pennsylvania) and in polyethylene tube dispensers (rope dispensers) (Shin-Etsu Chemical Co., Tokyo), at 50 mg *E*8,*E*10–12:Ac/dispenser. Isomeric purity of *E*8,*E*10–12:Ac before formulation was 99.6% and 99.1%; chemical purity was 99.7% and 99.7% by capillary gas chromatography (GC). Rope dispensers from the same batch had been used in a preceding study (Bengtsson et al., 1994).

For field trapping (see below), we used HPLC-purified *E*8,*E*10–12:Ac (99.8% isomeric purity by GC) and a propheromone compound, tricarbonyl [(8,9,10,11-η)-8,10-dodecadien-1-yl acetate] iron, releasing isomerically pure E8,E10–12:Ac (Streinz et al., 1993).

Gas Chromatography. GC analyses were done on Hewlett Packard 5890 instruments with flame ionization detection, on a DB-Wax, and on a DB-1 column (J&W Scientific, Folsom, California) 30 m × 0.25 mm ID. The temperature was programmed from 60°C at 10°/min to 100°C, 1.5°/min to 150°C, and 20°/min to 230°C.

Measurement of Release Rates. Release of Δ8, Δ10–12:Ac from the dispensers, rubber septa, and propheromone filter papers was measured in 250-ml round-bottom flasks in a static atmosphere. The dispensers were suspended for 2 hr, and the atmospheric concentration in these flasks was saturated after >5 hr (see Bengtsson et al., 1994). Dispensers were collected from the field nine times, 0–71 days after application, and were stored at −20°C until analysis. Rubber septa and propheromone papers were aged in the laboratory at 25°C.

Release of *E*8,*E*10–12:Ac from individual *C. nigricana* females was measured during the first 30 min of calling. A constant airstream (100 ml/min) passed over the female in a cylindrical holding chamber (1.5 × 3 cm long), into glass capillary tubes (0.1 × 12 cm long) (Witzgall and Frérot, 1989). The capillaries were eluted with 5 μl of redistilled heptane.

Field Facilities and Dispenser Placement. The test field (60 × 500 m) at Veberöd (Skåne, Sweden, 1993) was 8 km from the nearest pea field. The long dimension was perpendicular to the main wind direction; the downwind side was bordered by trees and shrubs, and the upwind side was adjacent to vegetable cultures and open meadows. In 1992, 3 ha of peas had been grown at 200 m upwind; this field had been infested with pea moths (Table 1). The test field and a control field (4 ha at Höör, 30 km from Veberöd), were sown with green peas, *Pisum sativum* L., of the variety Capella.

The test field was partitioned into a grid of adjacent 10- × 10-m squares. Dispensers were attached to top shoots of pea plants on the flagged corners and on the middle of the sides of each square, on June 12, 1993, several days before the first peas were flowering. Dispenser density was 8 per "unit square"; overall density was 333 dispensers/ha (16.5 g *E*8,*E*10–12:Ac/ha). A total of 880 laminate dispensers was placed on 60 × 440 m and 120 rope dispensers on 60 × 60 m. In addition, eight laminate or eight rope dispensers were placed in two single 100-m^2 squares within the control field.

TABLE 1. MATING DISRUPTION OF *C. nigricana* IN 3-HA PEA FIELD (VEBERÖD, 1993)[a]

	Dispenser material

[a] Pea moth, *Cydia nigricana*, F. (Lep., Tortricidae); on green peas, *Pisum sativum* L. Sex pheromone: *E*8,*E*10-12:Ac (Greenway, 1984; Witzgall et al., 1993). Release: calling female, 3.1 ± 1.4 ng/hr; rubber septum (100 μg; 3 days), 18.0 ± 5.7 ng/hr; propheromone (3 mg; 1–21 days), 311 ± 38 ng/hr.
[b] Days after dispenser placement; measurement in static atmosphere.

Field Electroantennogram Recordings. The field EAG apparatus (Sauer et al., 1992) was operated according to Bengtsson et al. (1994). For measurements of ambient pheromone, air was drawn at 42 ml/sec through a glass chamber containing the antenna holder. The airstream was filtered with active charcoal for recordings of the resting potential of the antenna. The EAG response from antennae of *C. nigricana* males (1 day old) was normalized to 2-ml pulses from a syringe holding a red rubber septum with 10 μg *E*8,*E*10–12 : Ac to obtain "relative EAG amplitudes." Data were sampled at 18.2 Hz and peak heights were averaged off-line for the first 2 sec of each recording.

Each recording included three pulses of synthetic pheromone before and after each of three measurements of field air, during a period of ca. 15 min. Recordings were made at two locations in the control field (Höör) and at six locations within the test field, at $\geq$15 m downwind from the field border (Veberöd), 21–36 days after dispenser application. The apparatus was placed in the middle of 100-m^2 squares (see above) and air was drawn from 10–20 cm below canopy top.

Relative EAG amplitudes to pulses from syringes holding filter papers with synthetic *E*8,*E*10–12 : Ac had been correlated with the concentrations of *E*8,*E*10–12 : Ac in these syringes (see Bengtsson et al., 1994). Using this correlation, we calculated concentrations of *E*8,*E*10–12 : Ac in field air from the EAG amplitudes.

Air Sampling. Air from the test field was drawn by a suction pump (Brey GmbH, Memmingen, Germany) at 17 liters/min during 4 hr through a Tenax filter to adsorb ambient *E*8,*E*10–12 : Ac. The flow rate was regulated with a flowmeter (Kytölä Instruments, Muurame, Finland). The filter inlet was held at 10–20 cm below the pea canopy top. Sampling was done simultaneously with the EAG recordings at three locations in the test and control field.

The filters were glass tubes (0.5 $\times$ 4.5 cm) containing 50 mg of Tenax (ca. 0.5 cm deep), held by plugs of glass wool. They were extracted ca. 1 hr after sampling with 0.5 ml of diethyl ether (Prolabo, Paris) containing 12 : Ac as internal standard. The solvent evaporated from glass vials with an elongated tip (0.25 $\times$ 3.5 cm long) at room temperature to ca. 10 μl, 6 μl of which was injected on a DB-1 column. The remaining solvent volume was measured by a syringe and was injected on a DB-Wax column.

The outlet from the DB-1 column was split between a flame ionization (FID) and an electroantennogram detector (EAD) (Arn et al., 1975), using a male antenna of *C. splendana* for detection of *E*8,*E*10–12 : Ac (Witzgall et al., unpublished data). For quantification, area counts at the retention times of *E*8,*E*10–12 : Ac were averaged from runs on the DB-1 and the DB-Wax columns. Data were corrected for a recovery efficiency of 47%, which was determined by applying *E*8,*E*10–12 : Ac to the filters and drawing air at 17 liters/min during 4 hr.

Field Trapping. Tetra traps (Arn et al., 1979) were baited with 100 μg *E*8,*E*10–12 : Ac (99.8% isomeric purity) on red rubber septa (Thomas Scientific) or 3 mg of propheromone (tricarbonyl [(8,9,10,11-η)-8,10-dodecadien-1-yl acetate] iron) on 2.5-cm^2 filter papers (see above). Propheromone sources release isomerically pure *E*8,*E*10–12 : Ac (Streinz et al., 1993) and were not replaced during the study. Since *E*8,*E*10–12 : Ac isomerizes rapidly on rubber septa (Davis et al., 1984; Witzgall et al., 1993), traps and septa were replaced every three to five days.

Three trap pairs (*E*8,*E*10–12 : Ac and propheromone, spaced at 10 m, perpendicular to the main wind direction) were placed in both treatments within the test field and in the control pea field at >5 m from the border, on an area of 60 × 60 m. In the test field, traps were placed in the center of 100-m^2 squares, surrounded by eight dispensers (see above).

Behavioral Observations. Last instars of *C. nigricana* were field-collected at Höör in 1992 and were overwintered under field conditions. Ten females, or 10 females plus 12 males, were transferred on the day of emergence to transparent PVC cylinders (12 × 20 cm) with a white polyethylene mesh covering both openings and supplied with sucrose solution. In the test field, cages with females, cages with females and males (at 1 m distance from each other and 2–4 days old), and propheromone traps without sticky bottoms were installed in the centers of 100-m^2 unit squares at 5–7 m distance from the surrounding dispensers.

Nine to 37 days after dispenser application, insect cages and propheromone traps were observed simultaneously by two people during the diel flight period of *C. nigricana* between 4 and 9 PM. Observations in the field treatments and in the control field were done on consecutive days. The protocol included the number of upwind flights over at least 1 m distance to traps or females, followed by landing. Repeated short-range flights and landings were not recorded, and males reorienting to the female cage from several meters' distance were not distinguished from newly arriving males. The duration of female calling (abdomen lifted from support, pheromone gland visibly protruded) and matings in the cages with naive females and wild males (during three consecutive days) was recorded at 15-min intervals.

Larval Counts. The larval density in pea fields at Veberöd and Höör was monitored in 1992 (Bengtsson et al., 1994) and 1993. During August 1993, after the flight period of *C. nigricana*, squares of 1 m^2 in the test field (N = 24) and the control field (N = 20) were chosen at random and all pea pods were checked for larval damage.

RESULTS AND DISCUSSION

The principal parameters of this second mating disruption trial against pea moth, *C. nigricana*, are summarized in Table 1.

Release Rates of Disruptant Chemicals and Pheromone

Release from Dispensers. The release of *E*8,*E*10–12:Ac from the rope dispensers was 17.5 ± 5.2 μg/dispenser/hr ($N = 3$) on the first day and was then rather uniform between 2 and 71 days after placement (6.5 ± 1.7 μg/dispenser/hr; $N = 21$) (see also Bengtsson et al., 1994). The trilaminate dispensers emitted 4.3 ± 1.3 μg/hr ($N = 3$) on the first day, 3.3 ± 0.9 μg/hr between days 2 and 6 ($N = 9$), and leveled off to 0.2 ± 0.2 μg/hr between days 26 and 34 ($N = 15$) (see also Table 1). The release rates were measured in a static atmosphere and are expected to be higher in the field.

Isomeric purity of *E*8,*E*10–12:Ac was >99% before formulation. Fresh rope and trilaminate dispensers released 1.7% and 2.1% of the other isomers, *E*,*Z*-, *Z*,*E*-, and *Z*8,*Z*10–12:Ac. In the rope dispensers, the isomer proportion increased within two days to 6.4 ± 1.2% ($N = 3$) and was quite consistent over the following 69 days (8.8 ± 2.1%; $N = 21$). By comparison, in the trilaminates, the isomer proportion steadily increased from 5.6 ± 2.3% on day 2 ($N = 3$) to 34.2 ± 5.9% on day 71 ($N = 3$) (see also Table 1).

Pheromone Release from Females and Trap Baits. Female pea moths produce pure *E*8,*E*10–12:Ac. The other isomers are strong attraction antagonists (Witzgall et al., 1993). The mean release rate of *E*8,*E*10–12:Ac from individual females during the first 30 min of calling was 3.1 ± 1.4 ng/female/hr ($N = 4$). The release rate of *E*8,*E*10–12:Ac from propheromone sources was 311 ± 38 ng/hr during the first 21 days, 65 ± 48 ng/hr on day 29, and 22.5 ± 10 ng/hr on day 36 ($N = 3$). Other isomers were not detected. Traps with rubber septa were exchanged every three to five days, and the release from 3-day-old rubber septa was 18.0 ± 5.7 ng/hr ($N = 3$) (Table 1).

Dispersal and Aerial Concentrations of Disruptant Chemicals

Field EAG Recordings. Of the test pea field, 2.6 ha were treated with laminate dispensers and 0.4 ha with rope dispensers for comparison with a prior study (Bengtsson et al., 1994). EAG recordings at three locations within each treatment 21 days after dispenser placement indicated a homogenous distribution of disruptant chemical within the pea canopy. The average relative EAG amplitudes were 0.33 ± 0.09 ($N = 9$) in the laminate dispenser section and 0.54 ± 0.12 ($N = 9$) in the rope dispenser section. EAG recordings were then repeated at one location within each treatment at 26, 31, and 36 days after dispenser placement. The relative EAG amplitudes were consistently higher among rope dispensers (0.58 ± 0.18; $N = 27$) compared to laminate dispensers (0.31 ± 0.12; $N = 27$).

In the control pea field, two 100-m^2 plots were treated with eight trilaminate or eight rope dispensers. The relative EAG amplitudes in the centers of these isolated plots did not differ significantly from amplitudes recorded in the field treatments with the two dispenser types (Figure 1, A and B).

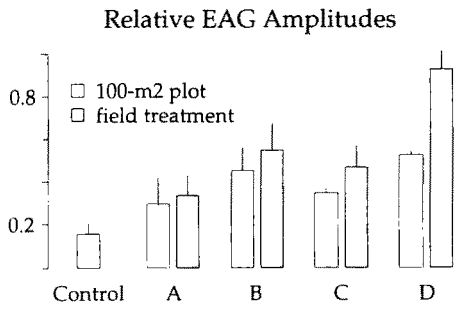

FIG. 1. Male *C. nigricana* field EAG response within pea canopy, in the center of single 100-m^2 plots in control fields (open bars) and in field treatments (shaded bars). All recordings were done in the middle of the field, except for one recording at the wind-protected border of a field treatment (D; shaded bar). A: trilaminate dispensers at 8 dispensers/100 m^2; B and C: rope dispensers at 8 dispensers/100 m^2; D: rope dispensers at 12 dispensers/100 m^2. A and B: this study. C and D: data from Bengtsson et al. (1994).

In the prior study by Bengtsson et al. (1994), the EAG apparatus was set in the center of 10- × 10-m unit squares, surrounded by 8 dispensers/100 m^2 in the field middle, and by 12 dispensers/100 m^2 close to the field border. The EAG amplitudes in the middle of this field treatment were not significantly different from a single eight-dispenser plot within the untreated control field (Figure 1, C). However, the border of the treated field was protected from wind by dense bushes, and at 5 m from the border relative EAG-amplitudes were almost twice as high as in a single 12-dispenser-plot in the open control field (Figure 1, D).

Dispersal of Disruptant Chemicals. The comparison of recordings in isolated plots and in field treatments shows that wind transport of disruptant chemical is limited within the canopy and that ambient concentrations result from a continuous release from proximate dispensers. Losses of disruptant chemical are due to adsorption on foliage and soil (Hensson, 1977; Wall et al., 1981; Bengtsson et al., 1994; Karg et al., 1994). Losses are also due to turbulent winds at the canopy surface, and the antennal signal above the pea canopy showed much stronger fluctuations than within the canopy (Bengtsson et al., 1994).

Caro et al. (1980) measured the vertical distribution of (Z)-9-tetradecen-1-ol formate by air sampling in a corn field. Little vertical mixing of disruptant within the canopy coincided with lower wind speeds, whereas rapid dilution occurred at the canopy top due to higher wind shear. The field EAG apparatus allows sensitive detection of ambient pheromone at a high temporal resolution,

but only a simultaneous input of wind vector data will allow detailed investigations of the dispersal of disruptant chemicals (Koch et al., 1992).

The impact of foliage on the distribution of disruptant chemicals and the success of mating disruption is exemplified by trials with the European grape berry moth, *Eupoecilia ambiguella*, in which reliable control was achieved during the second flight period when the vines were in leaf (Vogt et al., 1993). The presence of vine foliage results in a more homogenous distribution and higher concentrations of pheromone (Karg et al., 1990; Karg and Sauer, 1993). Compared to vineyards or orchards the canopy of pea fields is much denser. This favors maintenance of aerial disruptant concentrations and facilitates the simulation of field treatments in small experimental plots within untreated pea fields (Figure 1).

Aerial Concentrations of Disruptant Chemicals. An essential requirement for pheromone concentration measurements based on EAG recordings is the low response of *C. nigricana* male antennae to nonpheromonal volatiles in pea fields (Bengtsson et al., 1994). By comparison, *Cydia pomonella* and *Epiphyas postvittana* strongly respond to the background odor in orchards (Suckling et al., 1994; Rumbo et al., 1995).

A correlation of *E*8,*E*10–12:Ac stimulus concentrations and EAG amplitudes was used to calculate aerial concentrations from the field EAG recordings (Bengtsson et al., 1994). The average concentration of *E*8,*E*10–12:Ac at 21–36 days after dispenser placement was 1.6 ± 1.2 ng/m^3 (N = 36) in the laminate dispenser treatment and 2.7 ± 1.9 ng/m^3 (N = 36) in the rope dispenser treatment (Table 1). The male antenna also responds to the nonpheromonal isomers *E*,*Z* (55%), *Z*,*E* (27%), and *Z*,*Z* (35%) relative to *E*,*E*, respectively (Bengtsson et al., 1994).

The concentration of *E*8,*E*10–12:Ac in the rope dispenser treatment, obtained by sampling ca. 4 m^3 of field air on Tenax filters, was 1.3 ± 0.5 ng *E*8,*E*10–12:Ac/m^3 (N = 3). This compares well to the results from EAG recordings (Table 1). Aerial *E*8,*E*10–12:Ac concentrations among the laminate dispensers were below the quantitative limit of approx. 1 ng/m^3 (N = 4). Samples of 2 m^3 air from the rope dispenser treatment did not contain detectable amounts of *E*8,*E*10–12:Ac (N = 2). Identity of *E*8,*E*10–12:Ac in the air samples was confirmed by GC/EAD.

Air from pea fields did not contain volatile compounds interfering with *E*8,*E*10–12:Ac on the DB-1 and the DB-Wax columns. Air samples from forests or orchards may contain more nonpheromonal volatile compounds and in larger amounts. Methods to identify and quantify pheromones from more polluted air samples, including clean-up and derivatization procedures, have been developed by Caro et al. (1978, 1979) and Wiesner et al. (1980). For chemical quantification, ambient pheromone must be collected from several cubic meters of air during several hours. Data on time-averaged concentrations are available only

after sample work-up in the laboratory. In contrast, the field EAG apparatus directly visualizes the antennal response to ambient pheromone.

Behavioral Observations

Observations in Untreated Fields. During late afternoons, with the first noticeable decrease in light intensity, males were observed to fly above the pea canopy, frequently changing direction. Visual and olfactory cues from the host plant may contribute to the guidance of these flights, which were apparently not oriented upwind. Such flight activity in the vicinity of food plants is commonly observed in tortricid species (Bradley et al., 1979) and is clearly different from the much slower, anemotactic flight in the proximity of pheromone sources.

Males were attracted to synthetic pheromone during ca. 1 hr prior to the onset of female calling. Cages with females were unattractive at this time (Figure 2). A few minutes before the first female in the cage assumed the typical calling position, the first males were already landing and wing-fanning on the cages. Visibly calling females were more attractive than traps with propheromone sources (Figure 2). Cages with calling females, kept in an air-tight container outside the field, attracted the first male within 1.1 ± 0.4 min ($N = 3$) after they had been placed in the pea field.

We conclude from our observations in the control field that most males are already on their wings when they perceive a calling female. *C. nigricana* females are likely to be mated as soon as they start to release pheromone, and mating success should be highest for males that quickly arrive at the female from a short distance. Male upwind orientation flights over 50 m or more, although readily induced by sources of synthetic pheromone (Wall and Perry, 1980, 1987), would only occur at low population densities.

Observations in Pheromone-Treated Field. During the day after dispenser placement, male moths were attracted to rope dispensers and frequently landed and wing-fanned on surrounding pea plants. Males were observed to spend several minutes searching within one 100-m^2 plot and were also attracted to traps with synthetic pheromone, but only from distances of < 1 m (see also Bengtsson et al., 1994).

After formation of 6% of the antagonistic isomers *E,Z*-, *Z,E*-, and *Z*8,*Z*10-12:Ac, two days after dispenser placement (see above), male attraction to dispensers or prolonged searching within the canopy no longer occurred. Instead, orientation flights were directed towards the traps, sometimes over several meters. Males leaving the traps often flew rapidly downwind and out of the pea field, at least 1 m above the canopy. Males arriving from the outside were repelled at the field border.

Compared to the control field, only few males were observed and attraction to traps was significantly reduced (Figure 2). According to larval counts and

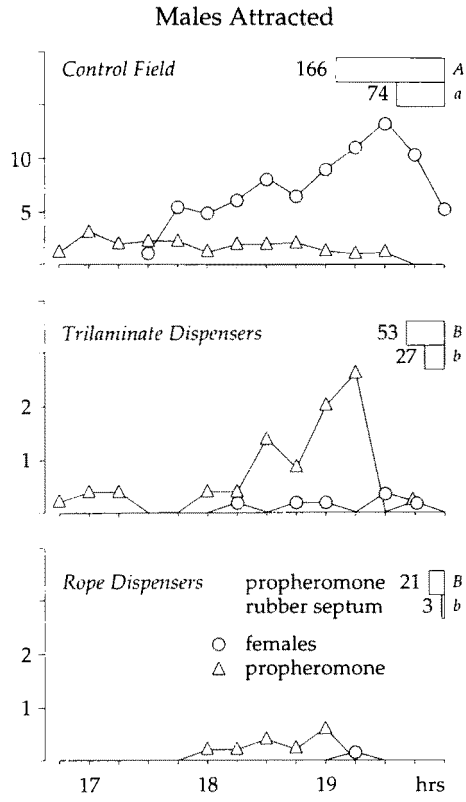

FIG. 2. Observations of *C. nigricana* male attraction to calling females and propheromone sources (circles, triangles) and trap catch (bars) with propheromone sources and *E*8,*E*10–12:Ac on a rubber septum. Average number of males per 15 min per day attracted, in the untreated control field at Höör (three flight periods) and in the trilaminate and rope dispenser treatments in the test field at Veberöd (five flight periods, each), 9–37 days after dispenser placement. The number of males observed in the control field was significantly different from both treatments (Wilcoxon test; $P = 0.05$). Total trap catch of *C. nigricana* males (bars) with 100 μg *E*8,*E*10–12:Ac on a rubber septum or 3 mg propheromone on filter paper, 0–65 days after dispenser placement ($N = 3$; Tukey test; $P = 0.05$).

trapping experiments during the past two years, population densities were similar at Höör (control) and Veberöd (treatment) (Table 1).

In a previous test (Bengtsson et al., 1994), males were not observed at all within the treated field after isomerization of *E*8,*E*10–12:Ac. This was probably

due to higher pheromone concentrations (see below), but the field was also surrounded by dense bushes. At the present study site at Veberöd, males may have traveled downwind 200 m over open farmland from the site of emergence (previous year's pea field) into the treated field.

Male Attraction to Calling Females and Synthetic Pheromone in Relation to Aerial Disruptant Concentrations. Male attraction in the two treatments correlated with pheromone release rate from the attractant source and the background level of disruptant (Table 1, Figure 2). The propheromone traps attracted more males than traps baited with rubber septa or cages with females. Fewer males responded in the rope dispenser than to the trilaminate dispenser section.

At 330 dispensers/ha, the overall release rate was 45 and 14 mg *E*8,*E*10–12 : Ac/ha/day in the rope dispenser and trilaminate dispenser treatments, respectively, 10–34 days after dispenser placement. Aerial concentrations according to EAG measurements were 3 and 2 ng/m^3 (Table 1). During the previous trial (Bengtsson et al., 1994), in which 600 rope dispensers/ha were used (releasing 82 mg *E*8,*E*10–12 : Ac/ha/day, 20 days after dispenser placement), aerial pheromone concentrations ranged from 2 to 7 ng/m^3, and trap catch was completely shut down with 100 μg *E*8,*E*10–12 : Ac on rubber septa.

In the disruption field, calling females were less attractive than propheromone sources. During five calling periods a total of one and six males was attracted to cages with calling females in the rope and laminate dispenser treatments (Figure 2). At aerial concentrations of a few nanograms of Δ8,Δ10–12 : Ac (Table 1), the males remaining in the test field apparently no longer perceived the female signal. Concentrations of ≥ 1.4 ng/m^3 of gossyplure in cotton fields prevented trap catches of *Pectinophora gossypiella* (Flint et al., 1990).

The elevated release rate from propheromone sources (Table 1) may explain the superior attractancy of calling females in the control field (Figure 2). However, a synergistic effect of minor gland components cannot be excluded. These did not increase trap catch when added to *E*8,*E*10–12 : Ac in the female-produced ratios, but an antagonistic effect of *E*9–12 : Ac at 100% addition hints at a behavioral role of this compound (Witzgall et al., 1993).

Female Calling and Mating in Field Cages. Sexual communication over a few centimeters' distance was not disrupted; the mean frequency of matings in cages with females and males was 31% per day in the control (N = 50 females; over three days), and, in the two treatments, 25% (N = 60) and 27% (N = 60). Female calling behavior was unchanged. The average duration of female calling was 51 $\pm$ 29 min (N = 50) in the control field, 61 $\pm$ 27 min (N = 60) among the laminate dispensers, and 58 $\pm$ 36 min (N = 60) among the rope dispensers. Peak calling occurred at 18.45 hr in the control and at 19.00 hr in both treatments. However, it remains to be determined whether ambient pher-

omone modifies premating dispersal of females. Shortly before onset of calling, a high locomotory activity was observed among the caged females, both in the treated and untreated field.

Larval Counts

The test field at Veberöd was isolated from other pea fields. Larval attack was significantly reduced (1.8 ± 0.8%; 6.0 ± 3.2 larvae/m^2) compared to a field at the same site in 1992 (34.1 ± 8.4%; 52 ± 12.8 larvae/m^2) and the control field at Höör (36.2 ± 16.3%; 48 ± 13.0 larvae/m^2). A high density of parasitoids may enhance the efficacy of species-specific control by mating disruption in the following season.

CONCLUSION

The attraction of male pea moths, *C. nigricana*, to calling conspecific females was almost completely eliminated by air permeation with *E*8,*E*10–12 : Ac and its geometric isomers. An off-blend of sex pheromone and attraction antagonists is thus effective in suppressing sexual communication in *C. nigricana*. The significant reduction of larval infestation suggests that the pea moth can be controlled by mating disruption without the use of insecticides.

According to the field EAG recordings, aerial concentrations of at least 2 ng/m^3 of Δ8,Δ10–12 : Ac are required to ensure disruption of mating. At a concentration of 1.6 ± 1.2 ng/m^3 among the trilaminate dispensers, a significant number of males were attracted to traps baited with 100 μg *E*8,*E*10–12 : Ac, and a few males even responded to cages with calling females. In a previous study, trap catch was entirely suppressed with concentrations ranging from 2 to 7 ng/m^3 (Bengtsson et al., 1994). These aerial concentrations were computed from field EAG recordings and can only be considered as estimates, even though their validity is supported by sampling of field air followed by chemical analysis. Furthermore, the EAG data correspond with behavioral observations and trap catch data at different dispenser densities and release rates.

Immediately after placement of the fresh dispensers that were emitting rather pure *E*8,*E*10–12 : Ac, males frequently landed and wingfanned on dispensers and surrounding pea plants. Plumes emanating from traps may have been camouflaged by ambient *E*8,*E*10–12 : Ac, as males were attracted only from a short distance. Thereafter, isomerization of *E*8,*E*10–12 : Ac to *E*,*Z*-, *Z*,*E*-, and *Z*8,*Z*10–12 : Ac had a strong antagonistic effect on male searching within the field. In contrast to a previous trial (Bengtsson et al., 1994), some males remained in the field and were attracted to traps, probably because of lower disruptant concentrations. These males oriented over at least several meters' distance to

sources of *E*8,*E*10–12 : Ac, against a background blend of Δ8,Δ10–12 : Ac. The higher proportional release of the antagonistic isomers by trilaminate dispensers compared to the rope dispensers may have accounted for a satisfactory reduction of larval attack, despite lower release rates.

The time lag between the onset of male responsiveness to pheromone and the onset of female calling may be decisive for mating disruption of *C. nigricana* by Δ8,Δ10–12 : Ac. Males were repelled from the treated field as early as at the beginning of their diel flight period, up to 1 hr before females started to release pheromone. Manipulation of male behaviors during this premating flight activity should be most efficacious when using repellents, rather than attractants. This is particularly important in nonpermanent crops. Peas are sown in different fields every year, precluding moth emergence within the crop. As shown by matings in cages with males and females, it is impossible to impair matings at nanogram aerial concentrations of disruptant if the males are close enough to calling females.

Mating disruption is effective in the grape berry moth *Eupoecilia ambiguella*. Dispenser formulations contain the main pheromone component, *Z*9–12 : Ac, and a few percent of the antagonistic *E* isomer (Arn et al., 1986; Vogt et al., 1993). Mating disruption of the other European grape berry moth, *Lobesia botrana*, by its main pheromone component *E*7,*Z*9–12 : Ac (Arn et al., 1988) is less reliable. This may be due to male attraction to vineyards treated with this compound (see Arn and Louis, 1996), rather than the use of an incomplete pheromone blend.

(Received December 22, 1994; accepted October 9, 1995)

Abstract—A procedure for headspace sampling and long-term storage of organic volatiles coupled with gas chromatographic-mass spectrometric (GC-MS) analysis was used to study the volatile chemosignals in a biological secretion prior to bioassay. The approach involved collecting the volatiles in evacuated canisters from an apparatus in which 1 ml of secretion was dispersed for headspace sampling. These canisters, stainless steel, 850 ml, and 100% internally electropolished, have been demonstrated to store volatile compounds, in chemically stable form, for several weeks. The GC-MS analyses provided the quantitation and identification of compounds from C_3 through C_{14} at concentrations as low as 0.10 parts per billion volume. The approach was used to study chemosignals of musth temporal gland secretions (TGS) from a male Asian elephant (*Elephas maximus*). Fresh TGS material loses its biological activity within 1 hr. TGS material stored at −20°C usually looses its activity within 30 days. The usefulness of this method for long-term storage of the volatile chemosignals was demonstrated by the retention of biologically active TGS headspace compounds, as determined through bioassays, stored in these canisters for one year.

Key Words—Chemosignal, pheromone, Asian elephant, *Elephas maximus*, temporal gland secretion, musth, avoiding reactions, headspace analysis, 2-hexanone, 3-pentanone, 1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane.

INTRODUCTION

Temporal gland secretion (TGS) during the condition of musth in the male Asian elephant has been described by Eisenberg et al. (1971), Jainudeen et al. (1972), and Rasmussen et al. (1984, 1990). Chemosignals in TGS produce avoidance reactions in conspecific females (Molamure, 1969; Perrin, 1995; Rasmussen, personal communication). The avoidance reaction by female Asian elephants to fresh TGS is an instantaneous and rapid backing away, involving both trunk and body movements (Perrin, 1995). Our previous evidence indicates that only freshly collected TGS elicits the avoidance reaction in the females. Frozen (−20°C) TGS material and fresh, nonrefrigerated TGS more than 1 hr old does not elicit this response. Olfaction is the primary chemosensory system utilized by the females to detect these compounds (Perrin, 1995). Thus, we hypothesized that the TGS avoidance compounds were volatile and ephemeral. To study these volatile chemosignals, we developed an in situ study approach to collect and store compounds in TGS headspace samples from fresh material for subsequent analyses and bioassay. This study is the first to investigate biologically active compounds from temporal gland secretions of elephants that appear to elicit deterrence.

METHODS AND MATERIALS

Collection of Temporal Gland Secretion. The secretion to be studied, temporal gland secretion (TGS), was obtained in the following manner. Twenty-one samples of 5–7 ml volume of fresh TGS were collected from a 28-year-old male Asian elephant during an entire musth cycle (three months) at the Metro Washington Park Zoo, Portland, Oregon. For collection, the animal was loaded into a squeeze chute (a hydraulic operated restrainer) in the mid-morning and several TGS samples were collected per week throughout the three-month study period. A beaker was placed under the temporal gland (mid-cheek region), and the gland was gently pressed several times causing secretion to flow into the beaker. Immediately after collection, 3 ml of the freshly collected TGS was set aside for bioassay, and 1 ml was placed in the sample collection apparatus for a headspace sample.

Sample Collection Apparatus and Headspace Sampling Procedure. The TGS headspace sampling apparatus (Figure 1) contained two 850-ml stainless steel (Type 304) canisters and a 400-ml glass jar with an air-tight lid perforated with two Swagelok bulkhead O-ring fittings for a gas tight seal. The canisters were 100% internally electropolished by the Summa process (Winberry et al., 1990a) and were fitted with ultraclean Nupro SS-4H4 bellow-stem valves. Electropolishing renders the internal stainless steel surface less reactive by forming an enriched chrome oxide layer so that compounds do not readily adhere or

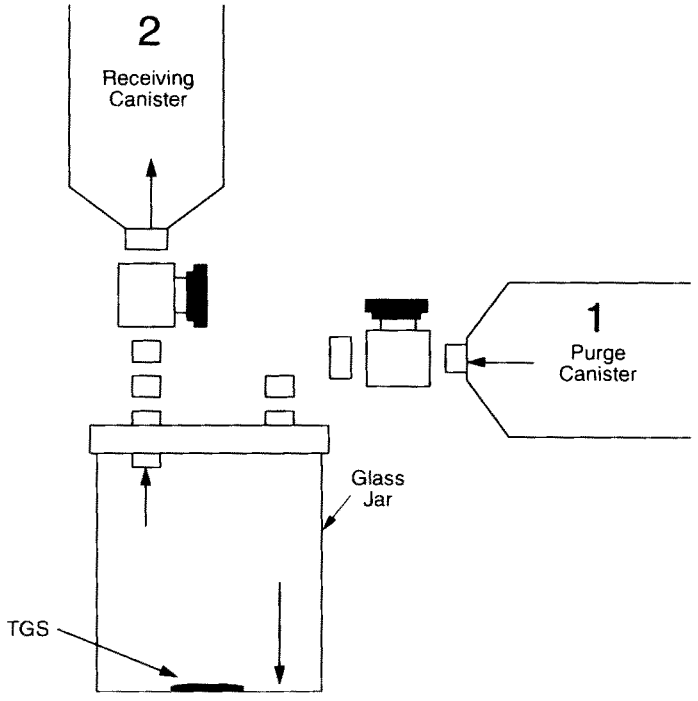

FIG. 1. Diagram of sample collection apparatus showing the positions of the purge canister (canister 1) and the receiving (sample) canister (canister 2). The arrows indicate the directions of airflow.

react to this surface. This improves the recovery of compounds for subsequent chromatographic analyses and bioassay.

The two canisters of the sampling apparatus were the purge canister and the receiving or sampling canister. The purge canister was filled to 30 psig with "zero" air (manufactured air of very high purity) and was connected to the jar at one of the Swagelok fittings, the flushing port, via a 12-in. × 0.25-in. OD piece of Teflon tubing. From this fitting, a glass tube, 0.25-in. OD, extended to within an inch of the bottom of the jar. Although compounds from the ambient air will inevitably show up in the chromatographic analyses due to the sensitivity of the analytical procedure, purging the system with zero air reduces the concentration of these background compounds to insignificant levels. The receiving canister was evacuated to 30 in. Hg vacuum for sample collection and storage and was connected to the other fitting on the jar. This fitting, which is the headspace sampling port, was flush with the inside of the lid, i.e., it did not

extend into the jar, so that the headspace sample was drawn from the top of the jar.

The headspace sampling procedure is described as follows. With the lid removed, 1 ml of fresh TGS, taken directly from the elephant, was placed in the jar. The lid was immediately replaced and fastened. The purge canister was securely fastened to the flushing port, and the receiving canister was connected loosely (finger tight) to the headspace sampling port. The valve of the purge canister was opened, allowing zero air to flow down the glass tube to the bottom of the jar, over the TGS material, and returning to exit at the headspace port. This resulted in a flush to remove any residual air contaminants. The valve of the purge canister was then closed, the connection between the receiving canister and the headspace port was securely tightened, and the TGS compounds were allowed to equilibrate with the headspace. At 10 min, a TGS headspace sample was drawn into the evacuated canister when the valve of this canister was opened.

Upon removal from the jar, the receiving canisters were pressurized with helium to 30 psig to facilitate chromatographic analyses and improve long-term storage. All canister samples were analyzed by a gas chromatograph (GC) that used a flame ionization detector (FID) within one month of collection and then stored for one year at room temperature. The jar, lid, and fittings of the apparatus were washed, rinsed with deionized water, and baked in a high temperature over before reuse. The Teflon tubing of the apparatus was purged with zero air for 5 min, at an elevated temperature (100°C), before reuse.

GC-FID Analysis of Polar Compounds in Dry and Moist Canisters. Although electropolished, the internal walls of the stainless steel canisters still have some degree of adsorption. Compounds, especially polar compounds, will bind to this surface, leading to poor recovery of the sample compounds from the canisters during the chromatographic procedures and bioassays. A moist internal environment greatly improves the recovery of the compounds withdrawn from the canisters. The hypothesized mechanism is that moisture will preferentially bind to the reactive sites on the stainless steel surface, permitting the polar compounds to be much less adsorbed on the internal walls. TGS fluid has a high water content. The water in the TGS very quickly saturated the headspace in the sample jar of the apparatus and would ultimately adhere to the internal stainless steel walls of the sample canisters. Thus, optimum recovery of the TGS headspace compounds during chromatographic analyses was expected. However, we did perform an experiment to demonstrate the necessity of a moist internal canister environment for recovery of polar compounds from a calibration standard prepared in dry nitrogen. This would also be important for the preparation of synthetic mixtures for bioassay.

The procedure for this experiment was as follows. Six canisters, initially under high vacuum, were utilized. Three canisters were injected with 0.5 ml of deionized water and the other three were not. All six cans were subsequently

filled with a polar compound standard in the low parts per billion volume (ppbv) range containing acetone, 2-propanol, 2-butanone, and 1-butanol (this was a National Institute of Standards and Technology standard gas mixture). Each canister was pressurized with helium to 60 psig and the headspace volatiles were analyzed by GC-FID within a 24-hr period. A mean and standard deviation of the peak area response for each compound was determined from multiple analyses.

GC-FID and GC-MS Systems. The gas chromatograph used for this study was a Hewlett Packard 5790A with a flame ionization detector. The column used was a DB-1, 0.32 mm ID × 60 m × 1.0-μm film thickness, polymethyl silicone-coated capillary column (J&W Scientific, Inc.). The FID output was processed via a Hewlett Packard 3392A integrator. The sample introduction system employed a Carle six-port valve in line with a U-tube cryogenic trap (0.125-in. OD × 9-in.) containing 60/80 mesh glass beads. The GC oven was temperature programmed from −60°C to 200°C at 4°C/min, with a 5-min initial hold at −60°C.

More specific analyses were obtained with a gas chromatographic–mass spectrometric (GC-MS) system. This system consisted of a Hewlett Packard 5890A GC and a 5970B Hewlett Packard mass spectrometer. The GC used a DB-1, 0.25 mm ID × 60 m × 1.0-μm film thickness, polymethyl silicone-coated capillary column (J&W Scientific, Inc.). The temperature program and sample introduction procedure was identical to that used in the GC system above. The mass spectrometer was programmed for a mass ion scan of 33–300. This allowed for identification of compounds from C_3 through C_{14} down to levels as low as 0.10 ppbv concentration. Compounds were identified using a NBS 75 K Hewlett Packard MS Chem Station library search and were manually rechecked with NIST/EPA/NIH Mass Spectral Data Base Version 4.01.

Bioassay of Fresh Temporal Gland Secretion. The bioassay of fresh TGS consisted of controlled airflow (zero air) passing over the TGS exiting through a 4-in. opening in the wall of a 20 × 40-ft. room containing four female Asian elephants. The observer had a safe and inconspicuous position with an unobstructed view of all animals via an elevated platform. When an elephant placed her trunk on or near the hole in the wall, airflow over the TGS material was initiated and avoidance reactions were monitored for that animal. A sample was only considered biologically active if at least one animal exhibited instantaneous retreat subsequent to exposure to the air flowing over the fresh TGS. The study time (20 min) was considered complete when all animals were exposed once to the TGS sample. A total of 21 bioassays with fresh TGS were conducted.

GC-MS Analyses of Temporal Gland Secretion Headspace Canister Samples. At the end of a one-year storage period, the behaviorally characterized TGS headspace canister samples (21) were divided into two groups. The bioactive samples (10) were in one group, and the inactive samples (11) were in the other group. The total nonmethane organic carbon (TNMOC) in these samples

was determined using the US Environmental Protection Agency (EPA) Compendium TO12 method (Winberry et al., 1990b). This was done to determine the total concentration of the analytes so that the optimum amount of sample could be loaded on the column for GC-MS analyses. The results of the EPA TO12 analyses indicated that there was not enough material in the canisters for both GC-MS analyses and subsequent bioassays. To increase the amount of material for GC-MS analyses and bioassays, the bioactive canister samples were cryogenically transferred (pooled) into a single 850-ml canister, and the inactive canister samples were pooled into another 850-ml canister. Another TNMOC analysis was conducted on both of these pooled samples, and it determined that there was an adequate quantity of material for both GC-MS analyses and subsequent bioassays. Four micrograms of the pooled active and the pooled inactive TGS headspace samples were each separately analyzed by GC-MS.

Bioassay of Pooled Temporal Gland Secretion Headspace Material. The pooled active and inactive TGS headspace material was bioassayed. Because of the limited amount of material, the original bioassay procedure was modified. We connected a purge-tee assembly, which included a 0–60 psig gauge and a toggle valve, to the canisters and manually placed the canisters under the trunk orifices of the same four female elephants utilized in the initial bioassays. A brief purge of the sample was administered, approximately 400 ml, to the opening of their trunks by depressing the toggle valve lever. A canister of zero air was the control. One bioassay per animal was performed due to the limited availability of sample. These bioassays had a total duration of 5 min.

Preparation of Synthetic Compounds for Bioassay. Ten compounds (purity = 99.8% or higher) that were identified in TGS were bioassayed among three female Asian elephants at the Metro Washington Park Zoo, Portland, Oregon, in 16 bioassay tests. The known compounds were prepared by injecting them into the 850-ml canisters. These canisters were preinjected with 0.50 ml deionized water to ensure that the compounds would not adsorb onto the walls of the canisters. The canisters were then filled with zero air to 30 psig. The compounds were bioassayed at concentrations of approximately 1 parts per million volume (ppmv). Purge-tees were connected to the canisters, and the contents of the canisters were vented to the end of the elephant's trunk. Approximately 400 ml of sample was released per test and responses for each animal were monitored.

Control Samples. Control blanks were run on the headspace of the TGS apparatus. The results demonstrated that contamination from this possible source was minimal. One contaminant, dichloromethane, did show up in these control blanks. Dichloromethane is routinely utilized for organic extractions in our laboratory. The TGS apparatus is stored in our laboratory where high levels of dichloromethane in the lab air probably got into and adhered to the apparatus.

RESULTS

Bioassay of Fresh Temporal Gland Secretion. The bioassays of the 21 fresh TGS samples established that 11 were biologically active, i.e., elicited avoidance reactions, and 10 were inactive (Table 1). During these bioassays, there was individual variation in response to the TGS samples among the four females. Among the 11 samples categorized as bioactive, two females (elephants B and C) responded to nearly all of these samples, one female (elephant A) responded to one sample, and one animal (elephant D) did not respond to any of the samples.

Bioassay of Pooled and Stored Temporal Gland Secretion. The results of the bioassay tests with the pooled TGS headspace material stored for one year were as follows. In all of the bioassay tests performed, no animals responded to the inactive TGS material. Likewise, the zero air control samples elicited no responses. In contrast, three of the four animals displayed an avoidance reaction to the pooled bioactive TGS headspace material (Table 2). The animal that did not avoid the pooled bioactive TGS sample (elephant A) was generally nonresponsive to freshly collected TGS samples, as mentioned above.

GC-FID Analysis of Polar Compound Standards in Dry and Moist Canisters. Four compounds—acetone, 2-propanol, 2-butanone, and 1-butanol—were tested for recovery from moist and dry canisters. The percent recovery of these

compounds in the dry canisters was considerably reduced (27% to 93%) in comparison to the percent recovery demonstrated in the moist canisters (Table 3). In addition, in the moist canisters, the standard deviations of the mean recovery of compounds were smaller relative to the standard deviations of the mean recovery of compounds in dry canisters (Table 3). The smaller standard deviations indicate that moisture inside the canisters increases the reproducibility of recovery of compounds during repeated GC-FID analyses.

GC-MS Analysis of Pooled and Stored Temporal Gland Secretion. The results of the GC-MS analyses of the pooled headspace material stored for one year were as follows: The compositions of the pooled TGS samples, as deter-

mined by GC-MS, were similar to the compositions of the single TGS samples measured at the time of collection (one year earlier) by GC-FID. Forty-three compounds, ranging from 44 da to 142 da molecular weight, were identified by GC-MS in the biologically active pooled TGS sample (Perrin, 1995). Using GC-FID standards that were calibrated against NIST/SRM of propane and benzene, it was determined that these compounds ranged in concentrations from 2 ppbv to 6 ppmv. Most of the compounds identified were relatively simple ketones, aldehydes, and alcohols. Most of the compounds had a 95% or higher match with the library. Because of the relatively simple nature of the compounds and the accurate retention times, it was not necessary to confirm their identity using known materials. In addition to the 43 compounds identified in TGS, 24 compounds were identified in the background ambient air and are listed in Table 4. These compounds commonly occur in the atmosphere and were generally in concentrations of less than 1 ppbv.

By comparisons of the GC-MS and GC-FID chromatograms, it was established that 10 of the compounds identified in the pooled bioactive TGS sample were present in all 11 single bioactive samples and were not present in any of the 10 inactive samples. These compounds are listed in Table 5 and are shown in the GC-MS chromatogram in Figure 2. The compounds consisted

of eight ketones, one alcohol, and one terpene (1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane, commonly known as frontalin). The identification of frontalin was confirmed by GC-MS with a frontalin standard (Figure 3).

Bioassay of Synthetic Compounds Identified in Temporal Gland Secretion. The 10 synthetic compounds that were bioassayed included four compounds that were present only in active TGS (Table 6). Among these four compounds, two compounds, 2-hexanone and 3-pentanone, elicited avoidance reactions in the females. All of the other compounds, including the zero air controls, did not elicit any avoidance reactions during 16 bioassay tests with three female Asian elephants.

DISCUSSION

This is the first study to demonstrate avoidance by female Asian elephants to conspecific male musth temporal gland secretions in a series of controlled experiments. This is also the first study where a biologically active component of temporal gland secretion was collected and stored in the gas phase. Our approach resulted in the identification of at least two possible avoidance chemosignals in TGS. This was possible in part because of the use of a methodology that allowed the stored volatiles to retain biological activity for bioassay.

The retention of biological activity upon long-term storage in the canisters was verified in that three of four elephants avoided the stored bioactive TGS sample when presented with it. The fact that the sample did not elicit avoidance in one of the females (elephant A) may have been related to her dominant

position. For example, in previous studies, females of subordinate rank responded to a natural component of TGS, cyclohexanone, more frequently than dominant females (Perrin and Rasmussen, 1994; Perrin, 1995).

Additional factors that may affect responses to TGS include estrous status and experience with a bull or sexual maturation (Perrin, 1995). The youngest female (elephant D) did not respond to any fresh TGS samples in the first set of bioassays tests. However, one year later she exhibited avoidance to the stored sample. In the year that elapsed between presentations of the two types of TGS samples, this young female had several exposures to a bull in musth for the first

time. Thus, avoidance to TGS may be a complex learned behavior that is related to dominance, sexual maturation, experience with a male elephant, and perhaps other factors.

The collection and storage of the TGS headspace volatiles allowed us to characterize possible avoidance compounds. We hypothesized that one or more of the 10 compounds present only in the bioactive TGS elicited avoidance. This hypothesis was supported by the results of initial bioassays with single synthetic compounds demonstrating that 2-hexanone and 3-pentanone elicited avoidance. Although 4-methyl-2-pentanone and 2-pentanone did not elicit avoidance reactions when bioassayed as singlets, it is possible that they may augment avoidance elicitation in combination with other compounds.

Two possible bioactive compounds and an unusual terpene, frontalin, were

identified in TGS. It was surprising to find frontalin in male Asian elephant temporal gland secretion because it had not previously been identified in a mammalian secretion. Interestingly, this terpene, a bicyclic ketal, is a well-established aggregation pheromone in bark beetles (Kinzer et al., 1969; Lindgren, 1992). Although frontalin has not yet been bioassayed, it may be involved in avoidance elicitation either as a single compound or in combination with other compounds. In addition, this compound may provide insight into unusual biosynthetic pathways of compounds in TGS.

This study was possible because: (1) a sampling method was developed to collect the headspace volatiles from temporal gland secretion material immediately after it was obtained; (2) the bioassay procedure provided reliable behavioral information allowing discrimination between bioactive and nonbioactive TGS; (3) the internal electropolished surface in the Summa canisters provided sufficient inertness to allow labile compounds in the volatile chemosignal to be stable for up to one year before bioassay; (4) the volume of the canisters allowed for sufficient amounts of headspace sample to be collected for both analyses and bioassay of the TGS material; and (5) the importance of moisture inside the canisters for optimum recovery of compounds for analyses and bioassay also was verified in this experiment.

The points stated above highlight the characteristics and advantages of this new method. Because of the general similarities among most mammalian secretions, e.g., high water content and complex chemical compositions, we suggest that this method would be applicable to the study of chemosignals from a variety of mammalian secretions.

Acknowledgments—We thank the Metro Washington Park Zoo, Mrs. Sherry Sheng, Director, Mr. Dennis Pate, Curator, Dr. Jill Mellen, Conservation Research Coordinator, and Dr. Michael Schmidt, Chief Veterinarian, for permission to carry out these studies. We thank Mr. Roger Henneous, Mr. Jay Haight, Mr. James Sanford, and Mr. Charlie Rutkowski for obtaining the temporal gland secretion samples. We also thank Mr. Robert Dalluge, Mr. Robert Watkins, Mr. Donald Stearns, Mr. Kurt Walker, and Mr. James Mohan for their technical assistance. DAILY RHYTHMS OF METABOLIC RATES: ROLE OF CHEMICAL SIGNALS IN COEXISTENCE OF SPINY MICE OF THE GENUS *Acomys*

ABRAHAM HAIM* AND SASSON FLUXMAN

Department of Biology
University of Haifa at Oranim
Tivon 36006, Israel

(Received April 24, 1995; accepted October 9, 1995)

Abstract—The common spiny mouse *Acomys cahirinus* and the golden spiny mouse *A. russatus* coexist in the extreme arid and hot parts of the Arava Rift Valley in Israel. The coexistence of these two species is through exclusion of *A. russatus* from nocturnal activity by *A. cahirinus*, which is nocturnal. An attempt was made to study the daily activity rhythm response of *A. russatus* to chemical signals released by *A. cahirinus*, in order to understand the mechanism of segregation. For this purpose oxygen consumption, $\dot{V}O_2$, was studied in individuals of *A. russatus* kept alone in a metabolic chamber in a constant ambient temperature of 32°C under two photoperiod regimes: 12L:12D, and constant darkness (D:D). After three days of $\dot{V}O_2$ recording under these conditions, chemical signals released from *A. cahirinus* were passed through the metabolic chamber. This treatment caused a shift in the activity rhythm only of *A. russatus* kept at 12L:12D, while a decrease in $\dot{V}O_2$ rates of *A. russatus* was noted in both groups. These results suggest that chemical signals released by *A. cahirinus* may play a role in shifting *A. russatus* toward its diurnal activity.

Key Words—Arid rodents, circadian rhythm, chemical signals, coexistence, metabolic rates, phase shift, oxygen consumption.

INTRODUCTION

The spiny mice of the genus *Acomys* are common murids inhabiting the arid parts of Israel. Two species, the common spiny mouse, *A. cahirinus*, and the

*To whom correspondence should be addressed.

golden spiny mouse, *A. russatus*, are sympatric and coexist in the same rocky habitat. Although the golden spiny mouse is limited in its distribution to the most extreme hot and dry parts of the Rift Valley and in wadis running into it, the common spiny mouse is distributed in the steppe regions of the Negev highlands and even in the Mediterranean mesic parts of the country (Harrison and Bates, 1991).

In the rocky habitats of the Rift Valley, where both species are sympatric, it was discovered that their coexistence is possible due to competitive exclusion of *A. russatus* from nocturnal activity by *A. cahirinus* (Shkolnik, 1966, 1971). The removal of *A. cahirinus* from the habitat caused a change in the activity pattern of *A. russatus*, which became nocturnal (Shkolnik, 1971). Shkolnik (1966) and Shkolnik and Borut (1969) suggested that certain characteristics of *A. russatus*, such as low metabolic rate, a high lower critical temperature, and a concentrated urine, enable it to cope with an extreme hot and arid environment as a diurnal species.

In recent observations in our laboratory (Rubal et al., 1992) it was determined that when kept alone in a cage under laboratory conditions, *A. russatus* exhibits the activity pattern of a nocturnal rodent. An open question on the relations between these two sympatric species is the mechanisms used by *A. cahirinus* to exclude *A. russatus* from nocturnal activity.

The social response of rodents to chemical signals and its ecological significance has been studied in many species (Stoddart, 1980; Rozenfeld *et al.*, 1987). Phase response curves for social entrainment were reported by Mrosovsky (1988) for the golden hamster *Mesocricetus auratus*. In his opinion social interactions and other disturbances can be mediated through an oscillator phased by general arousal.

This study investigated the phase response of *A. russatus* to chemical signals released by the urine and feces of *A. cahirinus* to assess the mechanism for the competitive exclusion of *A. russatus* from nocturnal activity by *A. cahirinus*.

METHODS AND MATERIALS

Measurements were carried out on six individuals of *A. russatus* kept under a photoperiod regime of 12L:12D and six under free running rhythm (FRR) conditions with a constant dim red light. These individuals were obtained from our breeding colony, in which the ancestors were brought from the Dead Sea area, where both species coexist.

Activity was monitored by the daily rhythms of oxygen consumption, ($\dot{V}O_2$), which was measured by using an open flow system (Depocas and Hart, 1957; Hill, 1972). A flow of 600 ml/min of air dried by silica gel (TamRod)

was used. VO_2 was monitored from air leaving the metabolic chamber by an applied Electrochemistry S-A3 oxygen analyzer. The results were recorded continuously on a Tek-dyn 712 recorder.

The tested individual was kept in a metabolic chamber with a volume of 2.5 liters. The metabolic chamber was kept inside a Forma growth chamber with controlled temperature and photoperiod. The mice were kept at an ambient temperature (T_a) of 32°C, which is the lower critical point of *A. russatus* (Haim and Borut, 1981) and with a photoperiod of 12L : 12D or under constant darkness (FRR).

Rat pellets and carrots were offered at the beginning of each session of measurements and each session lasted for six days. The daily rhythms of $\dot{V}O_2$ were recorded for three days. After this period, a column containing feces and filter paper saturated with urine of *A. cahirinus* was connected to the system just before the flowmeter, and $\dot{V}O_2$ measurements continued for another three days. The urine and feces were added 2–3 hr after the lights went on and were changed daily after 24 hr.

$\dot{V}O_2$ was calculated for every hour of measurement, and all results were corrected to STPD. All $\dot{V}O_2$ patterns were analyzed by the fit cosinor model (Minors and Waterhouse, 1989). A paired *t* test was used in order to establish statistical differences between the results obtained for the mice before and after exposure to the chemical signals.

RESULTS

Reproducible rhythms of $\dot{V}O_2$ were recorded in all measured golden spiny mice. In such mice, the best-fit *tau* analysis revealed a major significant daily rhythm of 24 hr.

Before exposure to chemical signals from *A. cahirinus*, individuals of *A. russatus* kept under a photoperiod regime of 12L : 12D displayed a nocturnal activity pattern. After exposure to chemical signals in urine and feces of *A. cahirinus*, the *A. russatus* mice showed an advance of 3 hr in their activity. Oxygen consumption in mice exposed to the chemical signals showed a tendency to increase as early as 10:30–12:00 hr, while in those not exposed to the chemical signals, the increase began at 13:30–14:00 hr. A significant ($P < 0.001$) advance was noted also in the acrophase (the peak of oxygen consumption). When the *A. russatus* mice were exposed to the chemical signals, the acrophase of oxygen consumption was shifted to 21:40 ± 00:12, while before exposure it was at 00:25 ± 00:11 (Figure 1). Moreover, $\dot{V}O_2$ during maximal activity was about 20% lower in *A. russatus* exposed to chemical signals of *A. cahirinus*.

A. russatus kept under FRR conditions did not respond to the chemical signals of *A. cahirinus* by a phase shift. The addition of the chemical signals

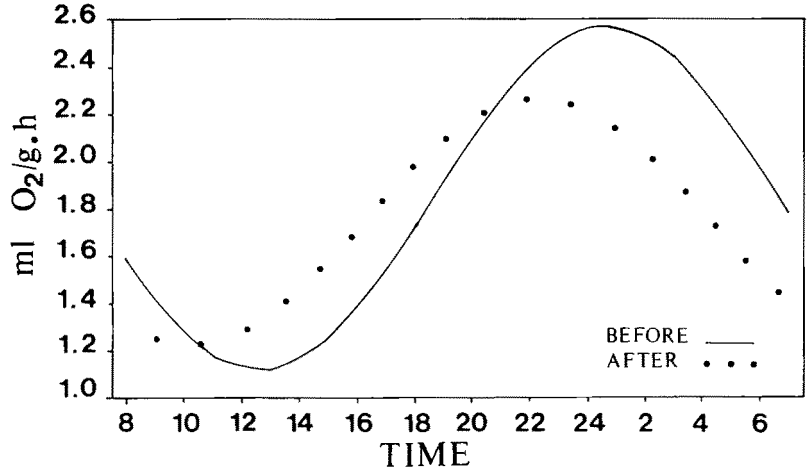

FIG. 1. A cosinor graph describing the average daily rhythm of oxygen consumption ($\dot{V}O_2$) ml O_2/g/hr measured in *Acomys russatus*, kept under a photoperiod regime of 12L : 12D. The solid line describes the rhythm before the addition of the chemical signal released by *A. cahirinus*. The dotted line describes the rhythm after the addition of the chemical signal.

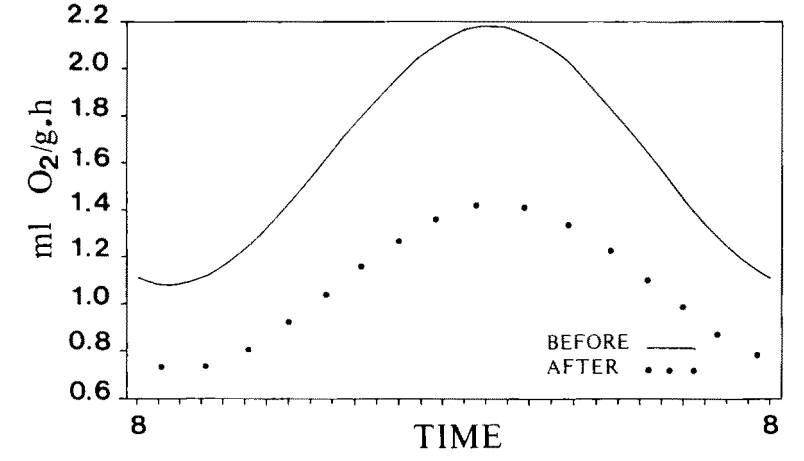

FIG. 2. A cosinor graph describing the average rhythm of oxygen consumption ($\dot{V}O_2$) ml O_2/g/hr measured in *Acomys russatus*, kept under free running conditions. The solid line describes the rhythm before the addition of the chemical signal released by *A. Cahirinus*. The dotted line describes the rhythm after the addition of the chemical signal.

caused a change in their pattern of activity, and several peaks occurred during the activity period, which did not fit the cosinor curve. However, the maximal $\dot{V}O_2$ value (amplitude) of 2.21 $\pm$ 0.2 ml O_2/g/hr was significantly ($P < 0.001$) higher in mice kept alone than in the same mice after exposure to chemical signals of *A. cahirinus*, whereupon the value was only 1.41 $\pm$ 0.3 ml O_2/g/hr (Figure 2). The difference in the maximal values during activity was about 60% and during the resting period only 30%.

DISCUSSION

The desert environment is characterized by low precipitation, which is highly variable and infrequent, with a large unpredictable component. Water is the most important controlling factor for most of the biological processes occurring in such ecosystems (Noy-Meir, 1973). The Arava Rift Valley is a part of the Great Palaearctic deserts, and, apart from its aridity, it is also a very hot desert. To maintain water balance, small mammals inhabiting such arid environments are nocturnal. As such they escape the heat of the day. One of the best-studied examples is the kangaroo rat, *Dipodomys merriami* (Schmidt-Nielsen, 1964).

However, an exception to this behavioral pattern is displayed by the golden spiny mouse, *A. russatus*, a diurnal murid. The diurnal activity of this species results from exclusion by the common spiny mouse *A. cahirinus* (Shkolnik, 1971). The "competitive exclusion principle" formulated by Gause (1934) makes it clear that two species of the same genus cannot occupy identical niches. Furthermore they displace each other, so that one species can take possession of a peculiar mode of life or kind of food, which gives it an advantage over its competitor. The coexistence of these two *Acomys* species is an outstanding example of such relations. Removal of *A. cahirinus* from the common habitat caused a shift in the activity pattern of *A. russatus*, which became nocturnal (Shkolnik, 1971).

Endotherms generally possess a long-term stable mean body temperature with a circadian (24 hr) variation (Aschoff, 1982; Kenagy and Vleck, 1982; Haim and Levi, 1990). The circadian rhythm of body temperature is regulated by a combination of heat production and heat dissipation. In the pouched mouse, *Saccostaomus campestris*, the daily rhythm of $\dot{V}O_2$ is the major metabolic and thermoregulatory rhythm (Haim *et al.*, 1989).

The results of our study reveal that when *A. russatus* is kept alone in the metabolic chamber under a 12L : 12D photoperiod regime or even in free running rhythm (FRR) conditions, it shows a pattern of $\dot{V}O_2$ characteristic of a nocturnal rodent. This result is consistent with those of Shkolnik (1971) from a field study in which *A. cahirinus* was removed from the common habitat and *A. russatus* under such conditions became nocturnal.

Our results also demonstrate that under both photoperiod acclimation conditions, *A. russatus* responded to chemical signals released by *A. cahirinus* by decreasing the $\dot{V}O_2$ values. These results suggest that in the presence of odors released by *A. cahirinus*, *A. russatus* decreases its activity. This behavioral pattern should be further studied.

The addition of chemical signals from *A. cahirinus* caused a shift in the activity of *A. russatus* kept under a 12L:12D photoperiod regime. By contrast, individuals kept under FRR conditions did not respond by a shift of activity. These results suggest that the endogenous oscillator of *A. russatus* is entrained by photoperiod, and under such conditions it may also entrain its daily rhythm of activity by chemical signals released by *A. cahirinus*. In the absence of photoperiodic cues, the oscillator will not respond to the chemical signals released from *A. cahirinus* with a shift in activity.

Acknowledgments—We thank Mr. H. Kosik for his help in maintenance of the animals. We also thank Dr. Joy Hoffman, Dr. Lee C. Drickamer, and anonymous referee for their helpful remarks on the manuscript. This study was partly supported by a BSF grant.

(Received June 27, 1995; accepted October 9, 1995)

Abstract—Thin-layer chromatography was used to study neutral lipids in snail-conditioned water (SCW) from *Biomphalaria glabrata* snails. A major lipid fraction in SCW at 2 and 4 hr after snail incubation contained free fatty acids. Fatty acids released per snail per milliliter of water when 10 snails were incubated in 5 ml of deionized water for 4 or 2 hr was 2.4 ± 0.4 μg/ml and 0.9 ± 0.1 μg/ml (mean ± SE), respectively. The amount released at 4 hr was significantly greater than at 2 hr. Snails also released free sterols, a sterol ester–hydrocarbon fraction, methyl esters, and other unidentified lipid fractions into the water. The potential of these neutral lipids to serve as chemoattractants for larval trematodes or snails remains to be determined.

Key Words—Snail-conditioned water (SCW), neutral lipids, free fatty acids, *Biomphalaria glabrata*, TLC, densitometry.

INTRODUCTION

The medically important planorbid snail, *Biomphalaria glabrata*, releases substances into water that attract larval parasites or conspecific snails (Chernin, 1970; Marcopoulos and Fried, 1994). Water containing these substances has been referred to by numerous workers as snail-conditioned water (SCW). SCW contains numerous substances released by the snail from the mouth, anus, nephridiopore, genital openings, body surface, and other structures including nitrogenous wastes, fecal matter, gametes, mucus, and other substances. To

date, most studies have examined SCW in its entirety, mainly to determine its role as a chemoattractant for larval trematodes or for cohort species of snails.

Except for a recent study by Haas et al. (1995) on SCW from *Lymnaea stagnalis* snails, qualitative and quantitative analyses of the chemicals in SCW are not available. The purpose of this study was to determine the composition of neutral lipids released into deionized water by *B. glabrata* and to quantify by densitometric TLC the major free fatty acid fraction.

METHODS AND MATERIALS

Sample Preparation. Stock cultures of *B. glabrata* were maintained in the laboratory on a mixed diet of boiled leaf lettuce and Tetramin tropical fish food (Tetra Werka, Melle, Germany) (Duncan et al., 1987). To obtain SCW, 10 snails with shell diameters of 7–10 mm were placed in 10-ml beakers containing 5.0 ml of Milli-Q purified water (Millipore Co., Bedford, Maine) for either 2 or 4 hr. Aliquots of 1 ml were removed by pipet from the beaker at 2 or 4 hr and placed in vials. This procedure was repeated 12 times to get eight samples at 2 hr and four samples at 4 hr. Lipids were extracted from each sample with 2.0 ml of chloroform–methanol (2 : 1). The upper aqueous fraction was removed with a pipet and discarded. The lower lipid fraction was evaporated to dryness using a stream of nitrogen gas, and the residue was immediately reconstituted with 100 μl of chloroform–methanol (2 : 1).

HPTLC of Lipids. TLC analysis was performed using Whatman LHP-KDF high-performance preadsorbent silica gel plates (Clifton, New Jersey). Each plate was 10 × 20 cm and contained 19 individual lanes. The standard used to analyze the sample lipids was the neutral lipid standard 18-4A, which contains 0.2 μg/μl each of cholesterol, oleic acid, triolein, methyl oleate, and cholesteryl oleate (Matreya, Pleasant Gap, Pennsylvania).

Various aliquots (1, 2, 4, 8, and 16 μl) of the standard and reconstituted SCW extract were spotted on the preadsorbent area of the TLC plate using a 25-μl Drummond digital microdispenser. The plate was dried with a hair dryer and placed in a paper-lined, glass Camag Twin-Trough HPTLC chamber containing the mobile phase petroleum ether–diethyl ether–acetic acid (80 : 20 : 2). The plate was allowed to develop until the solvent front reached 7.5 cm past the preadsorbent-silica gel interface. Plates were air dried, and the lipids were detected as blue spots on a yellow background after spraying with 5% ethanolic phosphomolybdic acid (PMA) and heating for 15 min at 115°C. Qualitative identification of sample zones was based on migration comparisons with the zones in the lipid standards.

The free fatty acids were quantified by scanning with a Shimadzu CS 930 densitometer operated in single-beam, reflectance mode at a wavelength of 700 nm. The oleic acid standard zones were scanned, and calibration curves relating

scan area and weight spotted were generated from a Quattro 5.0 linear regression program. The single free fatty acid sample zone that had a visual intensity closest to that of the middle standard was measured by scanning, and the weight of free fatty acids for that zone was determined by interpolating from the calibration curve. The amount of free fatty acid in the 1-ml aliquot of SCW was calculated from the following equation: μg free fatty acid in 1 ml SCW = $(W \times R)/S$, where W is the interpolated weight of the free fatty acid in the sample zone, R = 100 μl (the sample reconstitution volume), and S is the volume of sample spotted. The amount of free fatty acid in the original 5 ml of SCW was obtained by multiplying the value obtained by 5.

RESULTS

Based on 12 trials, a major lipid component of SCW for both 2- and 4-hr samples was determined by TLC analysis to be free fatty acid (R_f = 0.43). Figures 1 and 2 show chromatograms of 2- and 4-hr SCW extract, respectively. A sterol ester–hydrocarbon fraction (R_f = 0.84) and a methyl ester-like fraction (R_f = 0.73) were also present but were not further characterized. Trace amounts of free sterol (R_f = 0.29) were also apparent, particularly at 4 hr (not clearly shown in the figures). In Figure 2, a small amount of an undetermined band (R_f

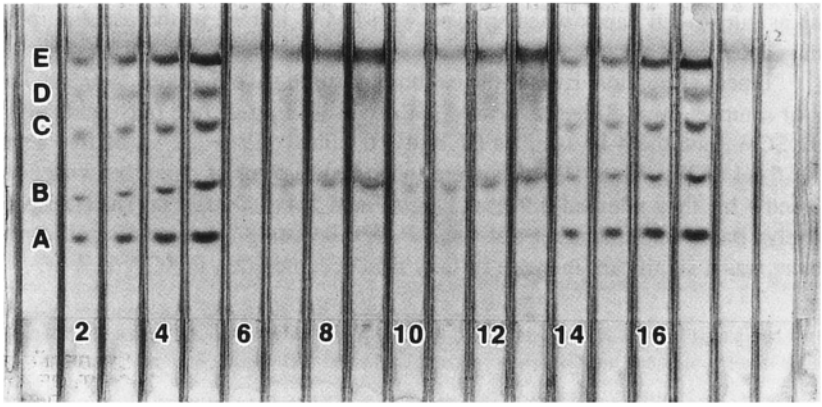

FIG. 1. Photograph of a chromatogram showing 1, 2, 4, and 8 μl of standard 18-4A in lanes 2–5 and in lanes 14–17. Lanes 6–9 contain 2, 4, 8, and 16 μl of extract, respectively, of a sample of water conditioned with *Biomphalaria glabrata* for 2 hr. Lanes 10–13 contain 2, 4, 8, and 16 μl of extract, respectively, of a second sample of water conditioned for 2 hr. Lane 18 contains 8 μl of an extract of deionized water. Abbreviations: A, free sterols; B, free fatty acids; C, triacylglycerols; D, methyl esters; E, sterol esters.

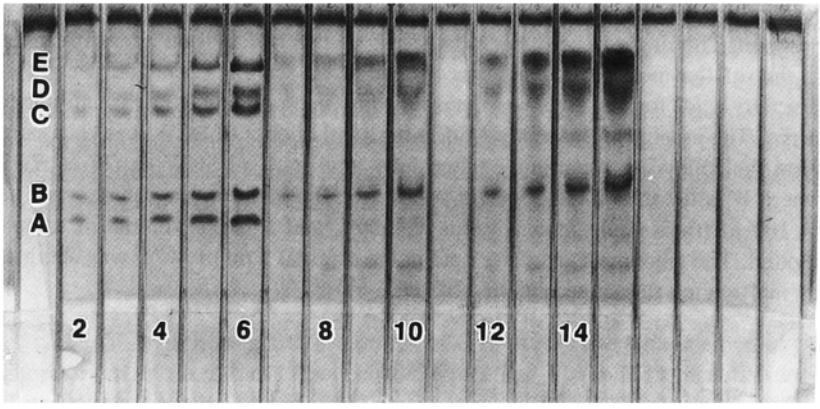

FIG 2. Photograph of a chromatogram showing 1, 2, 4, 8, and 16 μl of standard 18-4A in lanes 2–6. Lanes 7–10 contain 2, 4, 8, and 16 μl of extract, respectively, of a sample of water conditioned with *Biomphalaria glabrata* for 4 hr. Lanes 12–15 contain 2, 4, 8, and 16 μl of extract, respectively, of a second sample of water conditioned for 4 hr. Lane 16 contains 8 μl of an extract of deionized water. Abbreviations: A, free sterols; B, free fatty acids; C, triacylglycerols; D, methyl esters; E, sterol esters.

= 0.59) appeared between the free fatty acid and triacylglycerol (R_f = 0.63) fractions. There were unidentified lipids (R_f = 0.17; R_f = 0.26) that showed up as purple–red bands when sprayed with PMA, instead of the usual purple–blue color.

Linear regression data for the calibration curve gave R values > 0.98. The 2-hr samples (N = 8) had a mean ± SE of 46 ± 3 μg of free fatty acids per 5 ml SCW, and the 4-hr samples (N = 4) contained 119 ± 22 μg of free acids per 5 ml SCW. When 10 snails were incubated in 5 ml of deionized water for 2 and 4 hr, they released 0.9 ± 0.1 μg/ml and 2.4 ± 0.4 μg/ml/snail, respectively. Based on Student's t test (with $P < 0.05$ being considered significant), there was a significant increase in fatty acid accumulation in SCW at 4 hr.

DISCUSSION

Fried and Sherma (1990) reviewed the salient literature on the lipid composition of *B. glabrata* and the medical significance of this snail as a vector of the human blood fluke, *Schistosoma mansoni*.

This study provides quantitative data for the first time on free fatty acids released into water conditioned by *B. glabrata*. Information obtained from this study may be useful in designing a bioassay to test free fatty acids as potential chemoattractants for larval trematodes or snails.

The petroleum ether–diethyl ether–acetic acid (80:20:2) solvent system was suitable for TLC densitometric analyses of the free fatty acid fraction. However, it was not suitable for quantifying other neutral lipids, e.g., the sterol ester–hydrocarbon fraction or the methyl ester-like fraction that appeared as significant components in SCW. Another solvent system, e.g., *n*-hexane–petroleum ether–ethyl ether–acetic acid (50:20:5:1), as described by Smith et al. (1995), may be suitable for further characterization and possible quantitative analysis of these fast-moving zones.

The purple–red zones that appeared following detection of the neutral lipids with PMA could not be identified. In the more than 15 years of experience with PMA as a detection method, two of the authors (B.F. and J.S.) have not seen this reaction on silica gel plates sprayed with PMA.

The accumulation of chemicals in *B. glabrata* SCW will depend on the snail strain, age, diet, and amount of time the snail has spent in the water. In practice, SCW is collected in different ways, over various time periods. For instance, Roberts et al. (1979) collected SCW by maintaining *B. glabrata* snails in distilled water (2 snails/ml) for 5 hr, whereas Marcopoulos and Fried (1994) maintained this snail in chemically defined artificial spring water for 4 hr (1 snail/200 μl). The length of time used to collect SCW was a factor in quantifying neutral lipid components in this work, and about three times the amount of free fatty acids was present at 4 hr compared to 2 hr. Because workers collect SCW at different times (anywhere from 2 to 24 hr after snails are placed in water), the time of sample collection must be considered an important variable when identifying and quantifying components in SCW.

Abstract—Odors produced in the human female axillae are of both biological and commercial importance. Several studies have suggested that extracts from female underarm secretions can alter the length and timing of the female menstrual cycle. In addition, more than 1.6 billion dollars are spent annually on products to eliminate or mask the axillary odors. Our recent studies have determined that the characteristic axillary odors in males consist of C_6–C_{11}, saturated, unsaturated and branched acids, with (*E*)-3-methyl-2-hexenoic acid (3M2H) being the major compound in this mixture. The 3M2H appears to be carried to the skin surface bound to two proteins in the axillary secretions. Data reported here show that the same mixture of odorous compounds is found in female axillary secretions, with several minor qualitative differences. Separation of the female apocrine secretions into aqueous and organic soluble fractions demonstrated that 3M2H, and several other members of the acids in the characteristic odor, are released by hydrolysis with base. Electrophoretic separation of the proteins found in the aqueous phase of female apocrine secretions revealed a pattern identical to that seen in males. The qualitative similarity of the acidic constituents making up the characteristic axillary odors of both females and males as well as the proteins present in the aqueous phase suggest a similar origin for axillary odors in both sexes.

Key Words—Axillary odors, human females, 3-methyl-2-hexenoic acid, androstenol.

INTRODUCTION

Odors produced in the human axillae are of both biological and commercial importance. For example, studies performed in several laboratories have suggested that extracts made from human axillary secretions can alter the length and timing of the human menstrual cycle (Russell et al., 1980; Preti et al., 1986; Cutler et al.; 1986; Stern and McClintock, 1993). In addition, in the United States alone, more than 1.6 billion dollars are spent annually on products to eliminate, mask, or prevent the formation of axillary odors (Ramirez, 1990).

Prior to our studies, investigators examining the nature of axillary odors emphasized the steroid biochemistry occurring in the underarm (Labows, 1988; Gower and Ruparelia, 1993). Radioimmunoassay and gas chromatography–mass spectrometry techniques have been used to identify and trace the origins of volatile, odoriferous steroids in the underarm, such as 5α-androst-16-en-3α-ol (androstenol) and 5α-androst-16-en-3-one (androstenone). The musky, urine-like odors were thought to resemble the odor produced in the axillae (Gower et al., 1994). However, recent studies that employed organoleptic evaluation of gas chromatographic eluants and other analytical techniques, particularly GC-MS, to examine the axillary odor from a combined group of males found that the characteristic odors consist of C_6–C_{11}, saturated, branched, and unsaturated acids, with (*E*)-3-methyl-2-hexenoic acid (*E*-3M2H) being the major component of this mixture (Zeng et al., 1991). The *Z* isomer is also present at about 1/10 the level of the *E* isomer. In terms of relative abundance, these acids, particularly *E*- and *Z*-3M2H are present in far greater quantity than those odoriferous steroids within the acid fraction of the combined male samples; the neutral and basic compounds in these male extracts had little to no odor (Zeng et al., 1991, 1992). Both *E*-3M2H and *Z*-3M2H, as well as a number of other axillary odor components, appear to be carried to the axillary skin surface bound to water-soluble proteins found in apocrine secretions (Zeng et al., 1992; Spielman et al., 1995).

Female axillary secretions and odors have been examined organoleptically and microbiologically (Leyden et al., 1981). These studies suggest that males and females with the same axillary microflora will produce qualitatively similar axillary odors. A greater number of males appear to have the *Corynebacteria* as axillary residents; these bacteria are associated with the strongest axillary odors (Leyden et al., 1981). However, psychophysical studies suggest that the assignment of gender based upon axillary odor is most likely done by intensity and not by overt qualitative differences (Russell, 1976; Doty, 1981).

Studies have examined the volatile steroids present in the female axillary

extracts and made quantitative comparisons in the levels of these to males (Gower et al., 1985; Preti et al., 1987). Our earlier investigation of axillary extracts also suggested that at least one volatile steroid, androstenol, appears to be present in greater concentration during the follicular phase of the menstrual cycle than at any other time (Preti et al., 1987). However, no analyses of secretions from the female axillae have been done to determine whether females contain the same array of acidic compounds in their characteristic odor components. Results of analyses described below demonstrate that both males and females are very similar, although some qualitative distinctions are present.

METHODS AND MATERIALS

Subjects and Collection of Axillary Secretions. Six healthy female donors (ages 24–34; mean = 28.70) were employed to collect the axillary secretions used in this study. The axillae of each subject was sampled to determine its bacterial microflora prior to secretion collection (Leyden et al., 1981). Each subject was found to have lipophilic diphtheroids as normal axillary residents. The latter have been associated with the production of the stronger axillary odors (Leyden et al., 1981). Secretions were collected using 4-in. × 4-in. cotton pads worn in the axillae three times a week as in our previous studies (Preti et al., 1986; Zeng et al., 1991). Briefly, this protocol requires subjects to go without the use of deodorants, antiperspirants, deodorant soaps, or colognes in the axillae. They may wash once a day, only in the morning, with a nonfragranced soap (Ivory) during the collection protocol.

Preparation of Axillary Secretion Extract. A total of 24 pads were extracted to yield the axillary extract. Four pads from each subject were chosen. Extracts were prepared by extracting 12 pads at a time (two per subject) with double-distilled ethanol, as previously described (Cutler et al., 1986; Preti et al., 1987). After removal of the ethanol, pads were subsequently soaked with a mixture of 85:15 chloroform–methanol (15 ml/pad) for 1 hr and then squeezed. (Nanograde solvents were from Mallinkrodt, St. Louis, Missouri; these solvents contain few or no impurities by GC-MS analysis when 100–200 ml is concentrated to ≤ 50 μl.) The two 12-pad extracts yielded 300 ml and 310 ml total volumes, respectively. The two extracts were combined; 1 ml of saturated $NaHCO_3$ was added to this volume, and the extract was concentrated under vacuum to dryness. A 1.5-ml aliquot of doubly distilled water was employed to wash the flask and dissolve all dried solids. This aqueous solution was transferred to a 12-ml conical centrifuge tube in order to isolate the acidic compounds from the bases and neutral components.

Isolation of Acidic Components from Axillary Extract. The aqueous solution was extracted with 1.5 ml of Nanograde chloroform (Mallinkrodt) by vigorous

vortexing for 10 sec. The resulting two layers were separated by centrifugation in a clinical (IEF) centrifuge at top speed for 5 min. The bottom layer, containing the basic and neutral components, was transferred to a 10-ml vial by using a thinly drawn pipet. Two subsequent 1.5-ml aliquots of $CHCl_3$ were used to extract the aqueous layer, and the $CHCl_3$ layers were combined for 4.5 ml total. Fractionation of the basic and neutral compounds was done as described previously (Zeng et al., 1991), and the fractions were stored at $-10°C$ until they were concentrated and analyzed.

The aqueous layer remaining in the centrifuge tube was acidified by single drop additions of 2 N HCl until a pH of 2 was achieved. The mixture was extracted with $CHCl_3$ (1.5 ml $\times$ 2). The $CHCl_3$ layer was separated by centrifugation (as described above) and concentrated to 20 μl prior to analysis by GC-MS.

Gas Chromatography–Mass Spectrometry (GC-MS) Analysis. A Finnigan 4510 GS-MS data system equipped with a split/splitless injector, a fused silica capillary column, and with capabilities for operation in both electron impact and chemical ionization modes was used for analyses. The columns employed were a 30-m $\times$ 0.32-mm-ID fused silica column with a 1.0-μm coating of Stabilwax (cross-bonded polyethylene glycol, Restek Inc., Bellefonte, Pennsylvania), or a 30-m $\times$ 0.32-mm-ID fused silica RTX-1 column with a 1.0-μm coating of cross-bonded methylsilicon (Restek Inc.).

The analysis conditions for the Stabilwax column were as follows: 60°C, 4 min, then 3°/min to 220°C; hold at 220°C for 1 hr. Analyses performed with the RTX-1 column used the following conditions: 60°C for 4 min, then 4°/min to 300°C; hold at 300°C for 20 min.

The mass spectrometer was interfaced with a Nova 4X computer that utilized the Super Incos software for data acquisition, analysis, and quantitation. The mass range employed during these analyses was typically m/z 40–400, with one scan per second. A typical run included 3600 scans. The data system also includes the NBS library of 42,000 compounds.

As in our previous studies (Zeng et al., 1991, 1992; Spielman et al., 1995), identifications were based on comparison of unknown spectra with those from synthetic or commercial standards. In addition, the relative chromatographic retention times of unknown and known standards were compared with a mixture of fatty acids ethyl esters (van den Dool and Kratz, 1963).

Collection of Apocrine Secretions. Four of the six female subjects who donated axillary secretions collected on pads agreed to donate apocrine secretions. The axillae was prepared for sampling and apocrine secretions stimulated by an intradermal injection of 1:10,000 adrenalin (in physiologic saline) as in our previous reports (Labows et al., 1979b; Zeng et al., 1992). The amount of secretion collected varied greatly with the individual subject (≤ 10 μl).

Separation of Apocrine Secretions in Aqueous and Organic Soluble Fractions. The apocrine secretions collected from each subject were combined by washing the vials with a total of 300 μl of doubly distilled water. Each of the collection vials was then washed with 400 μl of Nanograde chloroform. The chloroform and aqueous layers were combined and vigorously shaken for 10–15 sec. The mixture was centrifuged in a clinical (IEC) centrifuge for 5 min at top speed to form two layers. The bottom chloroform layer was removed in a thinly drawn pipet.

The remaining aqueous layer was extracted two more times with chloroform (2 × 400 μl) and subsequently separated by the same procedure as above. This procedure gave a volume of 1.2 ml of the chloroform solution and 300 μl of aqueous apocrine solution. Aliquots of 10 μl of the aqueous phase and 10 μl of the chloroform layer were analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). This is described below.

Hydrolysis of Apocrine Secretion Aqueous Phase. The aqueous apocrine solution was refluxed for 20 min with 1 ml, 5% aqueous sodium hydroxide under a stream of nitrogen. The mixture was allowed to cool to room temperature and acidified with 2 N HCl to pH 2. A slight axillary-like odor developed in the reaction mixture upon acidification. The acidified mixture was extracted with 3 × 150 μl chloroform. The combined chloroform extracts were concentrated to approximately 5 μl for organoleptic evaluation and GC-MS analysis.

Hydrolysis of Apocrine Secretion Organic Phase. The chloroform extract was concentrated to approximately 100 μl and refluxed for 20 min with 5% NaOH in 2 ml of a 1 : 1 solution of methanol–water under a stream of nitrogen; the same conditions were also used for the aqueous-phase hydrolysis. After removal of the solvent, the reaction mixture was acidified with 2 N HCl of a pH of 2; no odor was detected. This acidic solution was extracted with chloroform (3 × 0.5 ml) and concentrated to approximately 5 μl for organoleptic and GC-MS analyses.

Organoleptic Evaluation of Axillary Extracts and Hydrolyzed Apocrine Secretion Samples. Organoleptic evaluation was performed by a panel of three or four judges in a manner similar to that used previously for evaluation of chromatographic eluants (Zeng et al., 1991). Judges were presented in a blind manner with either fractions of axillary extracts or the acidified, hydrolyzed aqueous or organic portions of apocrine secretion and asked which had an odor that most resembled the axillary odor. A small (2- to 5-μl) aliquot of concentrated axillary extract on a filter-paper strip (in a sealed vial) was on hand for reference if requested by a judge.

SDS-PAGE of Apocrine Secretion Aqueous and Organic Soluble Fractions. SDS-PAGE was done according to Laemmli (1970). The stacking gel was 5% acrylamide and the separating gel was 15%. Samples (10 μl) of each fraction

were dried down to approximately 5 μl, then mixed with 5 μl of sample buffer containing 2% SDS, 5% β-mercaptoethanol, 10% glycerol, 0.001% bromophenol blue, and 50 mM Tris HCl at pH 6.8 (Laemmli, 1970). After electrophoresis, the gels were stained with Coomassie blue.

RESULTS

Organoleptic evaluation of the concentrated neutral, base, and acidic components from the pad extract demonstrated that the acidic portion of the extract contained the characteristic axillary odor and most resembled the entire concentrated extract, a result analogous to that found with male samples (Zeng et al., 1991). Consequently, analyses by GC-MS were performed on the components in the acidic fraction. All the pads used in the extracts were collected during the presumed ovulatory portion of the menstrual cycle ($\pm$3 days of presumed ovulatory day) as judged by the subjects' basal body temperature charts and cycle length.

Figure 1 shows the reconstructed ion chromatogram (RIC) resulting from the analyses of the acidic components using the Stabilwax column. The part of the chromatogram shown in Figure 1 (bottom) is the area in which the C_6–C_{11} acids elute; these compounds have been shown to constitute the characteristic axillary odor in males. Both the identity of the lettered components and their presence in male extracts are listed in Table 1.

The top part of Figure 1 shows a mass chromatogram of m/z 60. This ion is formed by McLafferty rearrangement and is generally the most intense ion in the mass spectrum of aliphatic acids (with an available γ-hydrogen and unsubstituted α carbon) (Budzikiewicz et al., 1967). The large, regularly spaced maxima for peaks showing m/z 60 in Figure 1 suggest the presence of a series of *n*-aliphatic acids. Interpretation of the mass spectra of these chromatographic peaks when considered together with their relative retention times (ethyl ester units) (van den Dool and Kratz, 1963) led to the conclusion that these compounds were *n*-organic acids: hexanoic (peak A) through undecanoic acid (peak Gg).

The identity of all the peaks labeled in Figure 1 are shown in Table 1. This table also indicates which of these compounds were also found in the characteristic axillary odors from males (Zeng et al., 1991). Figure 2 shows the bottom portion of Figure 1 and the same portion of the chromatogram from the previously published combined male sample (Zeng et al., 1991) to show the relative differences between the male and female samples. Peak L in the bottom portion of Figure 2 is *E*-3M2H, and peak K in the top part of this figure is *E*-3M2H (male sample). Peaks H and G, bottom and top, respectively, are the *Z* isomer. Although *E*-3M2H was the major component in the combined male sample, this

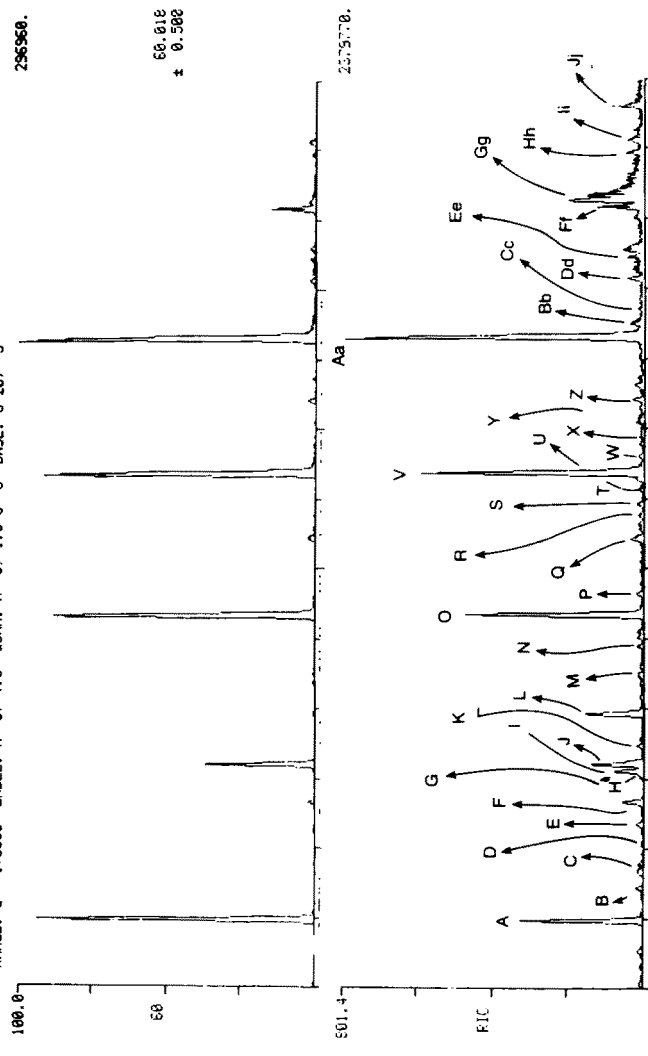

FIG. 1. The top part of the figure shows a plot of m/z 60 (mass chromatogram) in the area where the characteristic axillary odors elute. This ion is prominent in the mass spectra of aliphatic acids with an unsubstituted α-carbon and available γ-hydrogen as discussed in the text. This ion is the base ion for many normal-chain acids. The identity of the labeled peaks in the reconstructed ion chromatogram (bottom portion of the figure) may be found in Table 1, together with their relative retention tiumes.

TABLE 1. COMPOUNDS IDENTIFIED IN COMBINED FEMALE (F) AXILLARY EXTRACTS IN COMPARISON TO MALES

Peak	Compound	Molecular weight (kDa)	Retention time (ethyl ester units)	Present in combined female (F) male (M) extract
A	*n*-Hexanoic acid[G]	116	12.20	F/M
B	2-Methylhexanoic acid[G]	130	12.39*	F/M
C	3-Methylhexanoic acid[G]	130	12.55*	F/M
D	(*E*)-3-Methyl-2-pentenoic acid	**114**	**12.60***	**F only**
E	Dimethylsulfone[G] ($C_2H_6SO_2$)	94	12.63	F/M
F	γ-C_8-Lactone[G]	142	12.79	F/M
G	4-Ethylpentanoic acid[G]	130	12.97*	F/M
H	(*Z*)-3-Methyl-2-hexenoic acid[G]	128	13.10*	F/M
I	2-Ethylhexanoic acid	144	13.13	F/M
J	*n*-Heptanoic acid[G]	130	13.22*	F/M
K	2-Methylheptanoic acid[G]	144	13.36*	F/M
L	(*E*)-3-Methyl-2-hexenoic acid[G]	128	13.50*	F/M
M	Phenol	94	13.65	F/M
N	γ-C_9-Lactone[G]	156	13.91	F/M
O	*n*-Octanoic acid[G]	144	14.28*	F/M
P	2-Methyloctanoic acid[G]	158	14.41	F/M
Q	4-Ethylheptanoic acid[G]	158	14.81*	F/M
R	7-Octenoic acid[G]	142	14.95*	F/M
S	2-Piperidone[G]	**99**	**14.55***	**F only**
T	γ-C_{10}-Lactone[G]	170	15.01	F/M
U	*n*-Tetradecanol[G]	214	15.21	F/M
V	*n*-Nonanoic acid[G]	158	15.28	F/M
W	2-Methylnonanoic acid[G]	172	15.38	F/M
X	(*E*)-3-methyl-2-octenoic acid[G]	**156**	**15.45***	**F only**
Y	4-Ethyloctanoic acid[G] ("goat acid")	172	15.64*	F/M
Z	Unsaturated C_9 acid[T]	156	16.04*	F/M
Aa	*n*-Decanoic acid[G]	172	16.28	F/M
Bb	2-Methyldecanoic acid[T,G]	186	16.36	F/M
Cc	Unsaturated C_{10} acid[T]	170	16.46*	F/M
Dd	4-Ethylnonanoic acid[T,G]	186	16.69*	F/M
Ee	9-Decenoic acid[G]	170	16.90*	F/M
Ff	*n*-Hexadecanol	242	17.24	F/M
Gg	*n*-Undecanoic acid[G]	186	17.29	F/M
Hh	4-Ethyldecanoic acid[T,G]	200	17.66	F/M
Ii	10-Undecenoic acid[G]	184	17.76*	F/M
Jj	Benzoic acid[T]	122		

"The following symbols are used in this table: T = tentatively assigned by mass spectral data; G = correspondence of mass spectrum and relative chromatographic retention times with commercially available or synthetic sample. *Compounds judged to be important contributors to axillary odor, from data reported in male samples (Zeng et al., 1991).

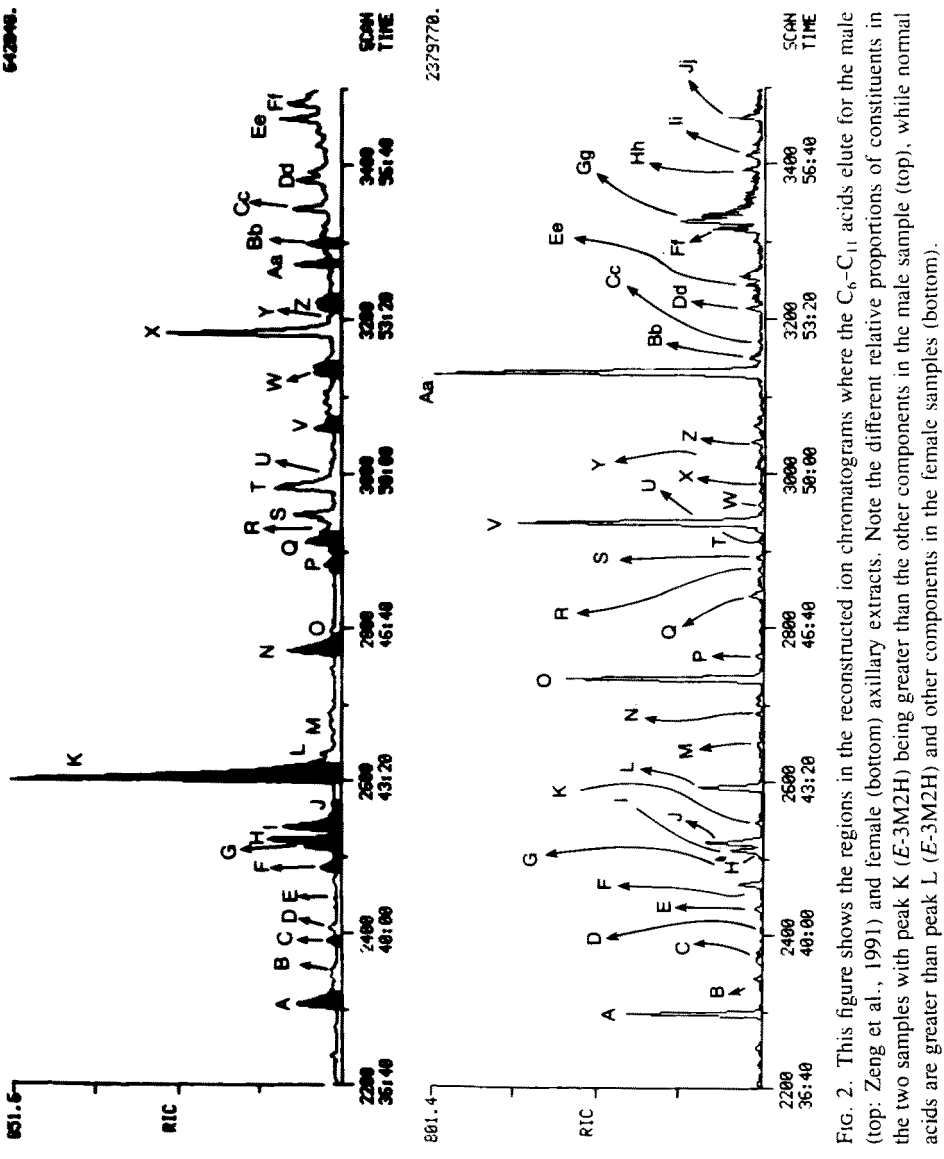

FIG. 2. This figure shows the regions in the reconstructed ion chromatograms where the C_6–C_{11} acids elute for the male (top: Zeng et al., 1991) and female (bottom) axillary extracts. Note the different relative proportions of constituents in the two samples with peak K (*E*-3M2H) being greater than the other components in the male sample (top), while normal acids are greater than peak L (*E*-3M2H) and other components in the female samples (bottom).

is not the case in the combined female sample. In the latter, the *n*-aliphatic acids are present in greater quantity than *E*-3M2H.

Comparison of injections of known amounts of 3M2H suggests ~150 ng/μl of *E*-3M2H is present in the female extract, while the male extract contained ~357 ng/μl of *E*-3M2H. In addition, the *E* to *Z* ratio in the combined female sample is 16:1, indicating a greater relative amount of the *E* vs. *Z* isomer in the female sample than previously reported in males, in which the ratio was 10:1 (Zeng et al., 1991).

The same series of γ-lactones reported in the combined male samples is present in the combined female sample. Although only C_8–C_{10}, γ-lactones are listed in Table 1, several lower members of the homologous series were also found eluting prior to the components in the area of the characteristic odor components.

Several other compounds whose structures were reported in male samples, and which are present here, included 7-octenoic acid (peak R) and two higher homologs (peaks Ee and Ii); goat acid (4-ethyl-octanoic acid, peak Y) and several homologs (peaks G, Q, Dd, and Hh); and 2-methylhexanoic acid (peak B) as well as four higher homologs (peaks K, P, W and Bb). Peak C was found to be 3-methyl-hexanoic acid.

Several subtle, qualitative differences between the male and female samples were seen, as noted in Table 1. Two homologs of the (*E*)-3-methyl-2-hexenoic acid are present in the female sample: 3-methyl-2-pentenoic (3M2P) and 3-methyl-2-octenoic (3M2O) acids. The relative retention times of both the lower and higher homologs matched with those of the synthetic *E* isomers we had in our possession (Zeng et al., 1992). The mass spectrum and relative retention time of peak S corresponded to 2-piperidone, a six-membered lactam.

To determine whether the aqueous soluble molecules from the apocrine secretions of females could be treated with base to yield 3M2H (Zeng et al., 1992), these secretions were separated into water-soluble and organic-soluble compounds as in our previous study (Zeng et al., 1992). Ten microliters of each fraction was saved for electrophoretic separation of putative proteins in each phase using SDS–polyacrylamide gels (Zeng et al., 1992). The rest of the aqueous and organic phases were treated with 5% NaOH to effect hydrolysis, and the acid components liberated by this procedure were isolated as in our previous study on male apocrine secretions (Zeng et al., 1992).

The reconstructed ion chromatograms (RICs) from the analyses of the aqueous and organic phase hydrolysates are shown in Figure 3A and B, respectively. Identity and/or data concerning the labeled peaks are shown in Table 2. Far greater amounts of *E* and *Z*-3M2H are seen in the hydrolysate of the aqueous phase than in the hydrolyzate of the organic phase molecules as indicated in Table 3. In addition, both the ratio of *E* to *Z* isomers in the aqueous hydrolyzate (~11.5:1) and the differences between the amount of *E* isomers in the aqueous

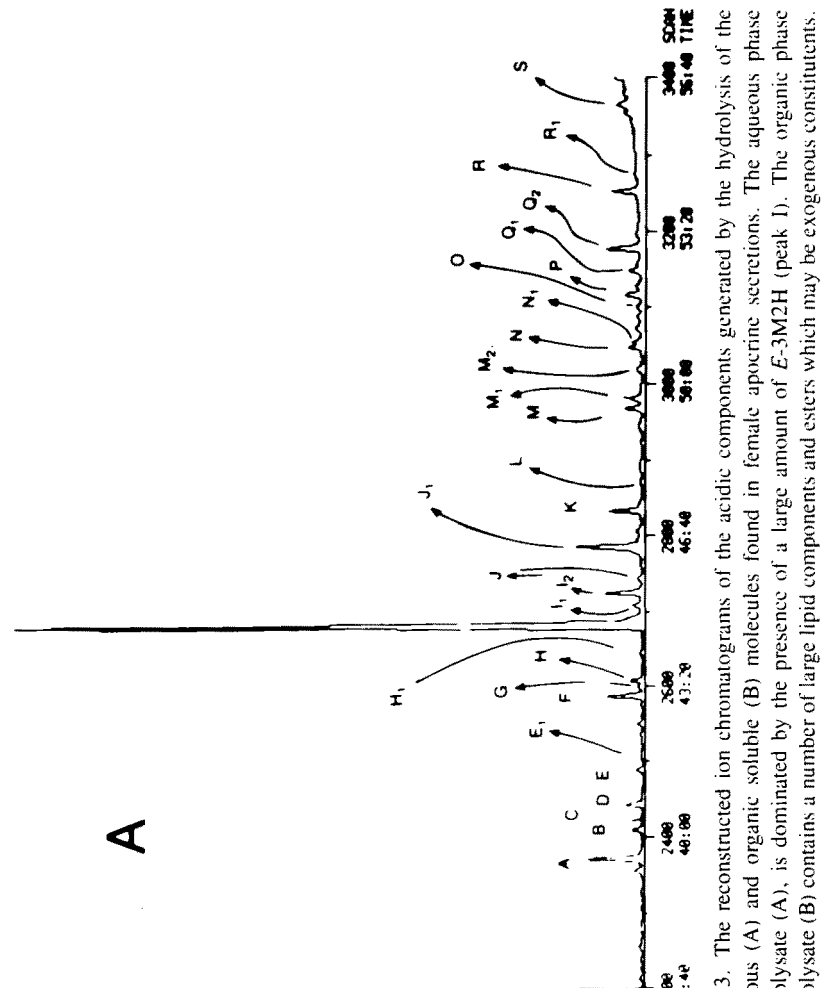

FIG. 3. The reconstructed ion chromatograms of the acidic components generated by the hydrolysis of the aqueous (A) and organic soluble (B) molecules found in female apocrine secretions. The aqueous phase hydrolysate (A), is dominated by the presence of a large amount of *E*-3M2H (peak I). The organic phase hydrolysate (B) contains a number of large lipid components and esters which may be exogenous constituents.

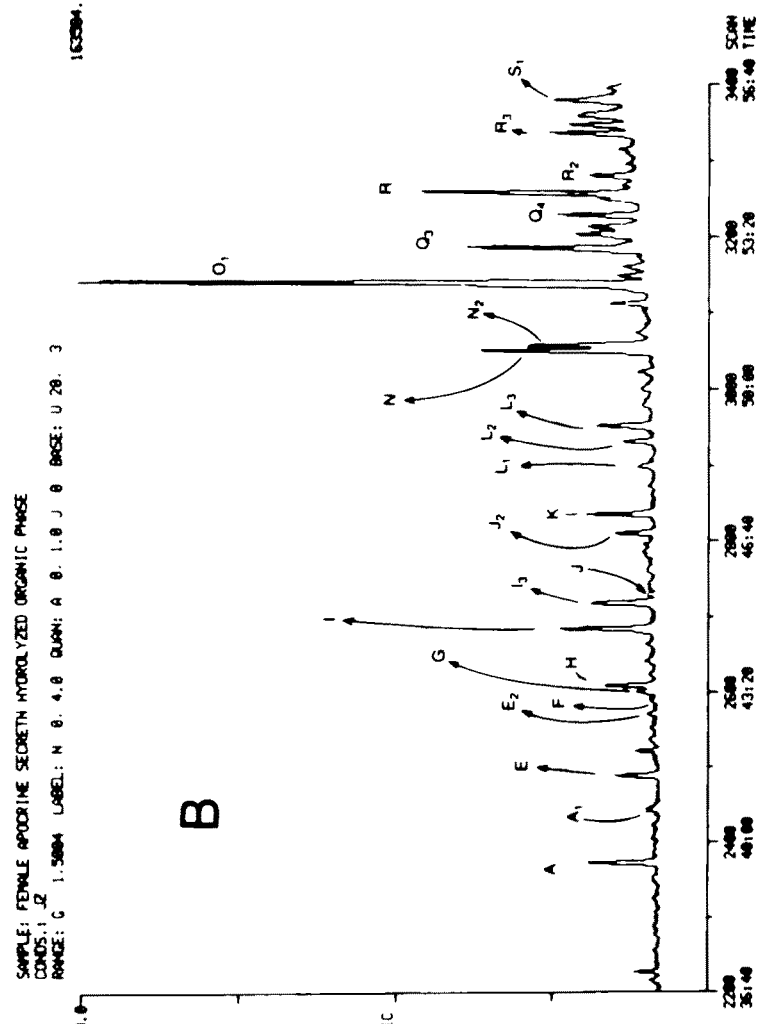

FIG. 3. Continued.

TABLE 2. COMPOUNDS IDENTIFIED IN HYDROLYZED FEMALE APOCRINE SECRETION: AQUEOUS PHASE MOLECULES OR ORGANIC PHASE MOLECULES[a]

Peak	Compound	Molecular Weight (kDa)	Found in aqueous phase (a) or organic phase (o) hydrolysate
A	*n*-Hexanoic acid[G]	116	a/o
A_1	Benzyl alcohol	108	o
B	Unknown[b]		a
C	2-Methylhexanoic acid[G]	130	a
D	Unknown[c] plus (*E*)-3-methyl-2-pentenoic acid[G]	114	a a
E	δ-Lactone[T,d]		a/o
E_1	Dimethylsulfone[G]	94	a
E_2	δ-Lactone[T,d]		o
F	(*Z*)-3-Methyl-2-hexenoic acid[G]	128	a/o
G	2-Ethyl-hexanoic acid[G]	144	a/o
H	*n*-Heptanoic acid[G]	130	a/o
H_1	2-Hexenoic acid[T,e]	114	a
I	(*E*)-3-Methyl-2-hexenoic acid[G]	128	a/o

[a]The following symbols are used in this table: T = tentatively assigned from mass spectral data; G = correspondence of mass spectrum and relative chromatographic retention times with commercially available or synthetic standards.

[b]Unknown seen only in aqueous phase hydrolysate: *m/z* (relative intensity) 45(20), 49(100), 51(31), 63(37), 77(2), 82(11), 84(4), 97(4), 112(42), 114(16): Chlorine containing?

[c]Unknown seen only in aqueous phase hydrolysate: *m/z* (rel. intensity) 41(45), 43(28), 55(100), 56(10), 56(10), 57(7), 59(10), 61(12), 69(38), 71(43), 81(12), 87(12), 97(41), 103(5), 105(4), 114(16), 115(12), 148(5): Sulfur containing?

[d]Proposed δ-lactones, seen only in organic phase, suggested by large ion an *m/z* 99 but few other ions suggestive of structure.

[e]Proposed 2-hexenoic acid, seen only in aqueous phase hydrolysate: *m/z* (rel. intensity) 41(48), 42(52), 43(22), 45(34), 55(35), 57(10), 60(11), 68(22), 71(8), 73(100), 74(12), 99(22), 114M$^+$(10).

[f]C_7 unsaturated branched acid, only in aqueous phase: *m/z* (rel. intensity) 41(90), 43(20), 45(10), 53(11), 55(54), 60(5), 67(35), 68(20), 69(100), 71(52), 82(22), 83(28), 85(6), 87(5), 95(6), 100(3), 113(10), 128(57). Isomeric with 3M2H?

[g]C_7 unsaturated branched acid, only in aqueous phase: *m/z* (rel. intensity) 41(82), 42(18), 43(30), 55(45), 57(12), 60(13), 67(30), 68(25), 69(100), 71(41), 82(42), 83(35), 95(8), 100(5), 113(12), 128(15). Isomeric with 3M2H?

[h]C_7 unsaturated branched acid, only in aqueous phase: *m/z* (rel. intensity) 41(30), 43(50), 55(11), 57(21), 71(100), 72(9), 73(4), 85(7), 100(1), 128(1).

[i]Aliphatic alcohol, only in organic phase hydrolysate: relative retention time suggests a C_{13} alcohol.

[j]Proposed cyclohexane carboxylic acid, seen only in the organic phase hydrolysate: *m/z* (rel. intensity) 41(55), 42(9), 43(11), 55(100), 56(29), 68(12), 69(29), 73(83), 83(50), 87(3), 99(9), 100(2), 110(4), 128(17).

[k]C_8 unsaturated acid, seen only in the aqueous phase: *m/z* (rel. intensity) 41(51), 43(37), 53(11), 55(100), 56(11), 57(11), 67(25), 68(10), 69(55), 71(19), 81(15), 82(62), 83(33), 96(18), 111(3), 124(9), 142(20). Isomeric with 7-octenoic acid?

[l]C_8 unsaturated acid, seen in the aqueous phase: *m/z* (rel. intensity) 41(71), 42(15), 43(54), 45(20), 54(16), 55(69), 56(33), 57(28), 67(28), 68(8), 69(18), 71(18), 73(9), 82(49), 83(21), 84(2), 85(100), 87(15), 96(16), 100(13), 111(2), 113(5), 124(19), 128(6), 142(1).

[m]C_9 unsaturated acid, seen in the aqueous phase: *m/z* (rel. intensity) 41(92), 42(25), 43(65), 45(31), 55(97), 57(29), 67(25), 68(35), 69(100), 71(32), 81(48), 83(38), 85(21), 96(65), 97(15), 114(42), 120(12), 138(1), 156(23).

[n]C_9 unsaturated acid, seen only in the aqueous phase. Mass spectrum reported previously (Zeng et al., 1992).

[o]Long-chain alcohol only in the organic phase, relative retention time suggests a C_{15} alcohol.

[p]C_{10} unsaturated acid, seen only in the aqueous phase: *m/z* (rel. intensity) 41(20), 43(100), 45(12), 55(20), 56(28), 57(6), 68(7), 69(13), 81(6), 96(5), 110(8), 114(10), 128(4), 152(3), 170(5).

TABLE 3. AMOUNTS OF 3-METHYL-2-HEXENOIC ACID LIBERATED FROM FEMALE APOCRINE SECRETION BY NaOH HYDROLYSIS

	Amount (ng/μl)	
	E isomer	*Z* isomer
Aqueous phase	244.7	21.2
Organic phase	1.4	0.01

phase (>200×) vs. the organic phase were almost identical to the ratios found in comparable male samples (Zeng et al., 1992).

As may be further observed in Figure 3A and Table 2, many of the same components seen in the combined female pad extract are apparently liberated by the hydrolysis procedure, albeit at different relative proportions than those in the male samples (Zeng et al., 1992). The organic soluble molecules contain many compounds that are lipophilic in nature, such as long-chain methyl esters and alcohols (peaks O_1, Q_3, Q_4, R_2, R_3, S_1) and may have been present in the apocrine secretions and extracted into the chloroform. A number of these compounds have been previously identified as compounds of exogenous origin in axillary area (Labows et al., 1979c).

Although 3M2H and normal C_6–C_{11} acids are present, their levels are far lower in the organic hydrolysate than in the aqueous phase hydrolysate (see Table 3). Further, the hydrolysate from the aqueous soluble molecules contain traces of *E*-3-methyl-2-pentenoic and *E*-3-methyl-2-octenoic acids (3M2O) as well as 7-octenoic acid. A number of the compounds found only in the aqueous phase appear to be acids whose molecular weights and mass spectral fragmentation patterns suggest that they are isomeric with 7-octenoic acid (M), 3M2H (I), and 3M2O (O): isomers of M are M_1 an M_2; isomers of 3M2H are I_1, I_2, and J_1; and isomers of O are Q_1 and Q_2. Further, the mass spectrum of Q_2 appears to be similar to that of an unknown C_9-unsaturated acid discussed in our previous studies on males (Zeng et al., 1991, 1992).

Other interesting compounds are the 2-hexenoic acid (tentatively identified from its mass spectrum) and peaks B and D found in aqueous phase hydrolyzate. The fragmentation of the latter two (see Table 2) suggest that they may be chlorine- (peak B) or sulfur-containing (D) compounds.

The results of the electrophoretic separation shown in Figure 4 were analogous to that found in males. The figure showing the gel on which the male apocrine secretion proteins were separated (lanes 2 and 3) [shown previously in Zeng et al. (1992)] was placed side-by-side with the female samples for com-

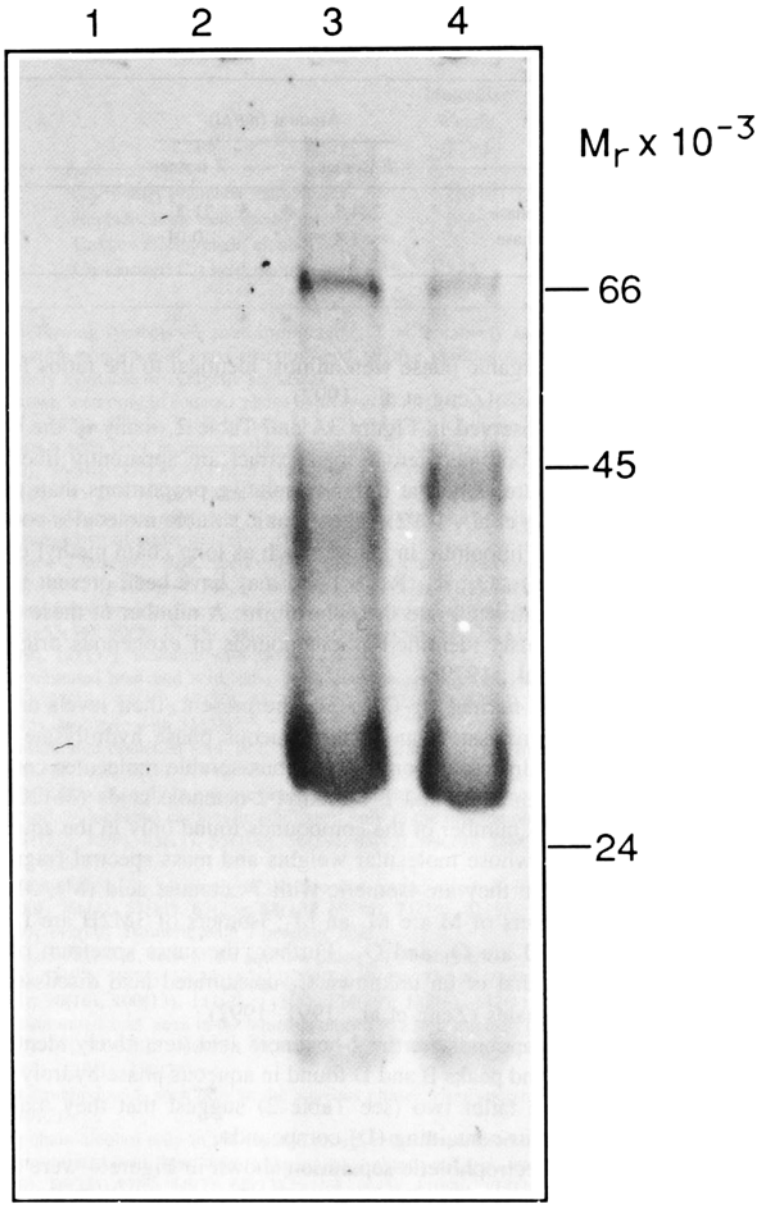

FIG. 4. The SDS-PAGE profile of the unhydrolyzed organic (lanes 1 and 2) and aqueous phases (lanes 3 and 4) from female (lanes 1 and 4, respectively) and male (lanes 2 and 3, respectively) apocrine secretions. The aqueous phase of both sexes display very similar profiles. Molecular weight markers were used to generate the scale to the right.

parison (lanes 1 and 4). The aqueous phase from female apocrine samples appears rich in proteins (lane 4), while the organic phase demonstrated no staining indicative of protein constituents (lane 1). The major protein bands in the aqueous phase are found at 26, 45, and 66 kDa. In male apocrine secretions, the proteins found at apparent molecular masses of 26 kDa and 45 kDa have been shown to carry 3M2H to the skin surface (Spielman et al., 1995).

The acid fraction of the combined pad extract as well as the apocrine secretion aqueous and organic phase hydolysates were examined for the presence of volatile steroids and/or steroid sulfates by GC-MS using a previously developed analysis protocole on a bonded methyl silicon column (Zeng et al., 1992; Preti et al., 1987). The combined pad extract and the aqueous phase hydrolysate contained androstenol (5α-androst-16-en-3α-ol) but no detectable amounts of androstenone (5α-androst-16-en-3-one). Neither of these volatile steroids was seen in the organic phase hydrolysate. The approximate levels of androstenol (i.e., when compared to injection of standards) were 3.5 ng/μl for the acid fraction from the combined pad extract and 0.81 ng/μl for the hydrolyzate from the aqueous soluble molecules from female apocrine secretions. Each of the samples analyzed contained detectable amounts (no quantitation attempted) of 17-oxo-5-androsten-3α-yl sulfate (dehydroepiandrosterone sulfate) and 17-oxo-5α-androstan-3α-yl sulfate (androsterone sulfate); these two sulfates were detected as their pyrolysis products (Labows et al., 1979b; Preti et al., 1987). In addition, each of the three samples contained the free steroids androsterone and dehydroepiandrosterone.

DISCUSSION

The results of our study demonstrate that men and women with similar axillary microflora are qualitatively similar in the array of volatiles produced. The characteristic axillary odor in the combined female axillary pads resides with the acidic compounds; the neutral/basic compounds possess little or no odor. The major components in both sexes were the same, the normal C_6–C_{11} acids and *E*-3M2H; however, as noted above, the relative proportions are reversed in the females' sample vs. the males'; in the latter, the *E*-3M2H was present in larger amounts than any of the normal C_6–C_{11} acids. The female sample also had a different ratio of *E*:*Z* isomers for 3M2H in the pad extracts; males have a 10:1 ratio, while a 16:1 ratio was seen in the female pad extract.

The combined pad extracts from both males and females did not employ internal standardization; therefore, the amounts of 3M2H and androstenol noted in the results are estimated, post-hoc, from comparison with injections of known amounts of standard compounds in the GC-MS system. The recovery of 3M2H and androstenol during extraction in combined pad samples is estimated to be 59% and 67%, respectively (Zeng et al., 1991; Preti et al., 1987).

Some subtle differences between males and females were noted in the constituents found in the combined pad extract acid fraction. For example, the female sample contained traces of *E*-3M2H and *Z*-3M2O and 2-piperidone. The latter compound is a six-membered ring lactam and is most likely not present as such in the pads, but may arise from a thermally induced cyclization of the compound δ-amino pentanoic acid (in the injector of the GC). We cannot explain why this compound was not seen in males.

In our previous study with the acid fraction from the combined male pad extract, we only determined that androstenol and androstenone were present via mass spectrometric evidence and retention times (Zeng et al., 1991). A re-examination of these data and comparison to standard injections of these steroids analyzed near the time frame this sample was run suggests that both compounds were present at an estimated level of ~0.5 ng/μl of extract. Consequently, the acid fraction from the combined female pad extract appears to have more androstenol than the acid fractions of the combined male pad extract; however, the female sample had no detectable amount of androstenone. It is likely that most of these steroidal molecules are extracted into the neutral components.

The female pads used in this study came from the presumed ovulatory portion of the menstrual cycle of each subject. Consequently, the relative proportions of the various components discussed here may differ in other parts of the menstrual cycle. Further, it is not known whether one donor contributed more than others to the levels of 3M2H, C_6–C_{11} acids, androstenol, and other compounds. This remains to be determined by the analyses of daily axillary samples from individual donors.

In contast to the female pad extract, the dominant component in the acids liberated from the aqueous soluble molecules was 3M2H, not normal C_6–C_{11} acids. This may reflect the individual contributions of one or more donors and/or possibly the time in the menstrual cycle. Because of the individual variability in the amount of apocrine secretion that could be collected, it was not possible to pool apocrine secretions from distinct times in the menstrual cycle; the results above represent the hydrolysis of a pooled sample from donors at different times in the menstrual cycle.

Another factor that may influence the relative proportions of compounds is the formation from axillary bacteria vs. liberation of these compounds by NaOH. The bacteria may add their own array of metabolites to the odor as it "matures" under the arm or release components from the apocrine secretions in a far different manner than does a base hydrolysis (Zeng et al., 1992).

The γ-lactones listed in Table 1 are minute components, as seen in Figure 1. They are most likely due to the metabolic action of lipophilic yeasts such as *Pityrosporum* species. We postulate this origin for γ-lactones, as we did for similar compounds in male axillary samples. These organisms are found in areas of human skin that contain large numbers of sebaceous glands, such as the

axillae and scalp (Leyden et al., 1991; Labows et al., 1979a). *Pityrosporum ovale* species isolated from the scalp have been shown to produce γ-lactones in the presence of human sebum; these lactones have a pleasant odor (Labows et al., 1979a).

Unlike the base-hydrolyzed male aporcine phase (Zeng et al., 1992), the comparable female samples studied here yielded androstenol after hydolysis. Whether this means that androstenol is secreted bound to a different, base-labile precursor or that there is more of the same precursor present in females than males and therefore has a greater probability of interacting with base and liberating the free steroid is not known.

Small amounts of C_6–C_{11} normal-chain acids and 3M2H were present in the organic phase hydolysate. This suggests that their precursors may have been present in minute quantity in the organic phase (slight solubility) because the separation of apocrine secretions into two phases may not be totally complete. Another possibility is that the volatile compounds were present at low levels (below olfactory threshold) in the apocrine secretion (Labows et al., 1979b; Gower and Ruparelia, 1993) prior to hydrolysis. As may be seen in Table 2, there are a number of lipophilic compounds (long-chain alcohols and δ-lactones) that were most likely present in the secretion at the times of collection (perhaps in the hair follicle near the skin surface) and partitioned in the organic phase and/or were formed during the hydrolysis reaction. Some compounds present in the organic phase, as noted above, such as methyl esters, may be present as artifacts from past use of cosmetic products (Labows et al., 1979c); however, we cannot explain why these esters remain after a base hydrolysis, except that the hydrolytic conditions may not have been harsh enough for total ester conversion to their respective acids.

The qualitative similarity in the bouquet of volatile organic acids that make up the characteristic female and male axillary odors suggest a similar origin and mechanism for odor production in males and females. In addition, experiments reported here, which utilized female apocrine secretions, demonstrate that: (1) the characteristic axillary odors can be released from the aqueous soluble molecules while only traces of 3M2H are present in the organic soluble molecules, (2) approximately 200× more 3M2H is liberated by hydrolysis of the aqueous phase molecules than the organic phase molecules, and (3) the electrophoretic profile of proteins in the aqueous soluble molecules from female and male apocrine secretion is qualitatively similar. Consequently, the water-soluble components of apocrine secretions carry 3M2H and other components of the characteristic axillary odor to the surface where they are liberated by the resident, axillary microflora, particularly the lipophilic diphtheroids. Since similar arrays of proteins are present in the female and male apocrine secretion aqueous phase, we may assume that individual proteins at 26 kDa and 45 kDa carry 3M2H out to skin surface, as has been found for males (Spielman et al., 1995). Further

support for this comes from preliminary immunohistochemical data, which reveal these two proteins in the apocrine glands of females and males (Spielman et al., 1994).

Acknowledgments—The authors wish to thank Ms. Mary Yardley and Mr. John Chicchi of K.G.L./Ivy Laboratories for recruiting subjects for apocrine secretion collection as well as aiding Dr. Leyden with the procedure. We also thank Ms. Donna Ayres and Mrs. Linda Robinson for preparing the manuscript. (Received May 2, 1995; accepted October 11, 1995)

Abstract—A major component of female contact sex pheromone of the yellow-spotted longicorn beetle, *Psacothea hilaris* (Pascoe), was isolated from the elytra and identified as (*Z*)-21-methyl-8-pentatriacontene. The synthetic compound released the typical mating behavior including holding, mounting, and abdominal bending in males, although its activity was considerably lower than the extract of female elytra when treated on a gelatin capsule as an artificial female model.

Key Words—Cuticular hydrocarbon, contact pheromone, sex pheromone, mating behavior, Coleoptera, Cerambycidae, *Psacothea hilaris*, (*Z*)-21-methyl-8-pentatriacontene.

INTRODUCTION

The importance of contact sex pheromone(s) in mating behavior of the yellow-spotted longicorn beetle, *Psacothea hilaris* (Pascoe) was demonstrated through analysis of the mating sequence (Fukaya and Honda, 1992). Adults were

observed to mate promiscuously when they encountered potential mates while wandering or resting on host trees, including the mulberry, *Morus bombycis* (Yokoi, 1990; Iba, 1993). Typically, a male dashes toward a female, and immediately after antennal contact with her holds her body with his forelegs and mounts on her back. The male then adjusts his body axis to hers and tries to make parameral contact, which is necessary for successful copulation (Fukaya and Honda, 1992). This succession of events in the mating behavior of males is released by a contact pheromone on the female body surface (Fukaya and Honda, 1992). The sex pheromone consists of at least two components with different functions. One component is distributed mainly on female prothorax and induces dashing toward a female immediately after antennal contact to her. The other component, on her whole body, releases a series of mating behaviors from holding to abdominal bending (Fukaya and Honda, 1995). The present report deals with the chemical identification of the major component of the contact sex pheromone from female elytra, which releases male mating behaviors from holding to abdominal bending.

METHODS AND MATERIALS

Insects. The *Psacothea hilaris* beetles used for the bioassay were the progeny of beetles collected from the mulberry gardens in Ibaraki and Gunma prefectures in 1992 and 1993. The larvae and adults were individually reared on an artificial diet for silkworms (wet type Silkmate 2S, Nihon Nosan Kogyo Co. Ltd.) at 25°C and under a 15L:9D photoperiod regime (Fukaya and Honda, 1992). For the bioassay, reproductively mature males were selected from 14- to 60-day-old nonmated individuals by checking their response to intact females.

Bioassay. Pheromonal activity was evaluated according to the methods previously described by Fukaya and Honda (1992). A gelatin capsule (24 mm length, 8 mm diam., Japan Pharmacopoeia No. 00) was fixed on a filter paper disc (9 cm diam., Toyo No. 2) and coated with the test solution. After evaporation of the solvent, a treated capsule (or an intact female) was exposed to a male beetle, and the male response was observed for 5 min after encounter with the capsule (or female). Typical responses to the elytra extracts included holding the capsule, mounting the capsule, and abdominal bending (copulatory attempt) toward the capsule (Figure 6 below). Abdominal bending, the final step before copulation, was taken as a positive mating response in this study. Assays were conducted using 50 males within 3 hr before the beginning of scotophase under 25°C, 60% relative humidity, and ca. 300 lx.

Extraction. Extracts were obtained from the elytra of the females that were collected in mulberry fields in Gunma and Tochigi prefectures in 1993 and 1994. The elytra were removed from 180 females and dipped in 200 ml of ether for

24 hr. Extracts were filtered, dried over anhydrous Na_2SO_4, concentrated under reduced pressure, and the residue was dissolved with hexane. The extract solution was kept in a glass tube below −20°C until use.

Chromatography. The extract of elytra was chromatographed on 10 g of silica gel (Wakogel C-200, 200 mesh, Wako Pure Chemical Industries Ltd.) and eluted successively with hexane, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, and 90% diethyl ether in hexane; and diethyl ether (150 ml each). Active fractions were further fractionated by column chromatography on 1.5 g of silica gel impregnated with 10% $AgNO_3$ (200 mesh, Aldrich Chemical Company, Inc.). The column was washed successively with 20 ml each of hexane and 0.5%, 1%, 2%, and 5% ether in hexane.

Gas Chromatography (GC). GC analyses were conducted on a Hewlett-Packard (HP) 5890II gas chromatograph equipped with a cool on-column capillary injector and a flame ionization detector (FID). A fused silica capillary column (HP-1, 12 m × 0.2 mm ID, 0.33-μm film thickness; HP) was used for analyses. Injector temperature was programmed to equal the oven temperature plus 3°C. Injections were made at an initial oven temperature of 50°C. After 1 min the temperature program was started (20°C/min to 150°C and then 5°C/min to 310°C) and held at the final temperature for 20 min. Helium was used as the carrier gas.

Preparative Gas Chromatography. A large-diameter capillary column (HP-1, 5 m × 0.53 mm ID, 2.65-μm film thickness; HP) was connected to the cool on-column injector. The GC column effluent (30 ml/min) was split at the outlet end of the column to the transfer tube and the FID at a ratio of 5:1. The compounds eluted from the transfer tube were collected with a glass capillary (1 mm ID × 12.7 cm) at room temperature. Helium was used as the carrier gas.

Gas Chromatograph–Mass Spectrometer (GC–MS). GC–MS analyses were conducted with a JEOL SX-102A double-focusing magnetic sector mass spectrometer in the EI mode (70 eV, 170°C), which was interfaced with an HP5890II GC. The GC contained a 30-m × 0.25-mm-ID DB-1 capillary column (J&W) with a cool on-column injector. Injections were made at an initial oven temperature of 50°C. After 1 min the oven temperature was increased at 20°C/min to 120°C, and then at 5°C/min to 310°C, and held at the final temperature for 20 min.

Proton Nuclear Magnetic Resonance (PMR). PMR analyses were conducted with a JEOL model JMN-Eclipse 500-MHz Fourier-transform NMR spectrometer system. Data points (16,000) were collected with a 5.6-μsec pulse.

Microchemical Reactions. Microozonolysis was conducted according to Beroza and Bierl (1967). Oxygen containing ozone was blown into ca. 10 μl of hexane solution of the sample below −50°C through a glass capillary tube for 2 min. For GC–MS analysis of carbonyl products, 0.5 μl of the solution was

immediately injected. The remaining products were treated with a few milligrams of $NaBH_4$ in ca. 10 μl of ethanol for 17 hr at ca. 60°C to reduce compounds to the corresponding alcohol compounds. The alcohol products were purified with a short Florisil column (6% aqueous; 200 mg in a Pasteur pipet). The alcohol compounds were then treated with 25 μl of methanesulfonyl chloride in 25 μl of dimethylformamide in a small sealed glass tube filled with N_2 and kept for 16 hr at 65°C according to the procedure of Evans et al. (1968). The reaction mixture was then directly poured onto a short column containing 200 mg of Florisil (6% aqueous). The chloride derivatives were eluted with 1 ml of hexane.

Chemicals. The authentic compounds, (*Z*)-21-methyl-8-pentatriacontene (*Z*8-21Me-35:Hy) and its *E* isomer (*E*8-21Me-35:Hy), were synthesized as racemic mixtures. The procedure will be published elsewhere. As standard compounds for GC analyses, straight carbon-chain hydrocarbons were used; they were purchased from Sigma Chemical Co.

RESULTS

The crude extracts of female elytra [180 female equivalent (FE)] were fractionated with silica gel column chromatography. In the bioassay, the fractions eluted with hexane and 10% ether in hexane released the abdominal bending (AB) response to males as potent as the crude extract at 1 FE/capsule. The 90% ether in hexane fractions showed weak activity. The hexane fraction was further fractionated by column chromatography on 1.5 g of $AgNO_3$-impregnated silica gel. Activity was found in the fraction eluted with 0.5% ether in hexane.

When the 0.5% ether in hexane fraction was injected into the GC, one large peak, which accounted for ca. 60% of the total peak area, and several minor peaks were observed (Figure 1). Therefore, this 0.5% fraction was injected into the preparative GC and two fractions were obtained: one contained only one major peak (major fraction) and the other several minor peaks (minor fraction). Activity was observed only when the major fraction was applied on a gelatin capsule (Figure 2). In separate experiments, the average amount of major component was estimated to be 53.5 $\pm$ 27.8 μg/female (mean $\pm$ SD, $N = 7$) and for the minor components 32.3 $\pm$ 11.6 μg ($N = 7$).

The major fraction was injected into the GC–MS system (Figure 3). The EI mass spectra of the major compound gave an evident molecular ion at *m/z* 504, which indicated that this compound was a monounsaturated 36-carbon hydrocarbon. In separate GC analyses, however, retention values of the major compound, tetratriacontane, and hexatriacontane were 33.88 min, 32.64 min, and 34.89 min, respectively, which suggested that the major compound has an alkyl branch.

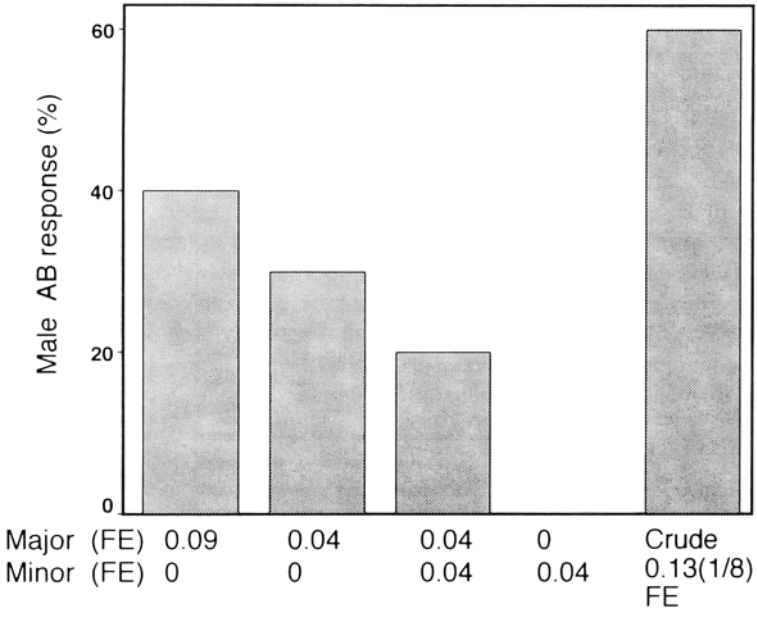

FIG. 2. Pheromonal activities of major and minor fractions from preparative GC and crude extract. Major fraction: 1 FE = 53.5 μg, minor fraction: 1 FE = 32.3 μg.

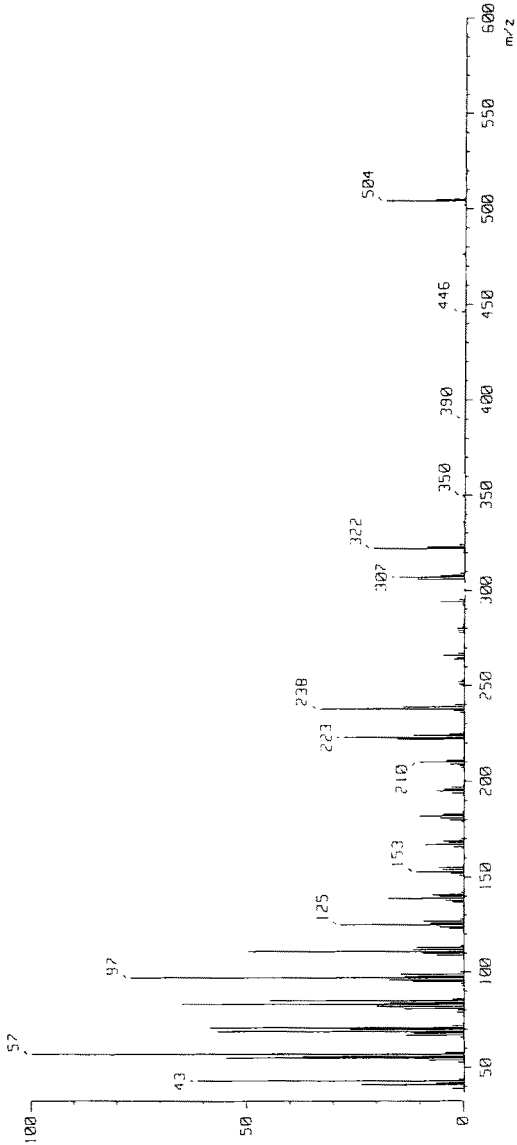

FIG. 3. EI mass spectrum of the major compound from preparative GC of 0.5% ether in hexane fraction.

Two large peaks and two small peaks were observed when ozonolysis products of the major fraction were injected into the GC–MS system. The large ones were octanal, whose mass spectrum and retention value were identical to those of authentic compound, and C_{28}-aldehyde, which was expected to contain an alkyl branch in the molecule. Minor products were decanal and C_{26}-aldehyde. These data indicated that the major and minor compounds in the major fraction have a double bond at the 8 and 10 positions, respectively.

To determine the position of the alkyl branch, the ozonolysis products were derivatized to chloride compounds. Mass spectrum of the major chloride derivative is shown in Figure 4. The molecular ion was evident at *m/z* 428 (intensity 1.32), which was accompanied by an M + 2 ion at *m/z* 430 (0.46). Diagnostic ions, which were generated by cleavage at the carbon branch, were observed at *m/z* 225 (48.16) and *m/z* 231 (29.01). The latter ion was accompanied by an M + 2 ion at *m/z* 233 (9.42), which indicated these ions contained one chlorine atom. The major chloride derivative was therefore considered to be 1-chloro-13-methylheptadocosane. This product, and the fact that octanal was detected as one of the major products of the ozonolysis reaction, indicate that the original major compound should be 21-methyl-8-pentatriacontene.

As minor derivatives, 1-chloro-11-methylpentadocosane and 1-chloro-13-methylpentadocosane were found. Based on similar interpretation, these two compounds indicated that the original parent molecules should be 21-methyl-10-pentatriacontene and 23-methyl-10-pentatriacontene, whose contents were 8.2% and 12.0% of the major compound, respectively.

The PMR spectrum (Figure 5) of ca. 5 mg of the 0.5% fraction indicated the presence of a monoolefin system. The signals of two olefin protons and four methylene protons neighboring the double bond were observed at 5.346 ppm and 2.012 ppm, respectively. These signals were also apparent in the PMR spectrum (800 scans) of ca. 5 μg of the major fraction collected from the preparative GC. In the NMR spectra of authentic *E* and *Z* isomers, chemical shifts (δ) for olefin protons were observed at 5.383 ppm and 5.349 ppm, respectively, and those for the methylene protons neighboring to the double bond were at 1.964 and 2.014 ppm, respectively. Thus, the geometric configuration was determined to be *Z*, and the pheromone component is (*Z*)-21-methyl-8-pentatriacontene (*Z*8–21Me–35 : Hy).

For evaluation of behavioral activity, synthetic Z8–21Me–35 : Hy was applied onto a gelatin capsule and male response was observed (Table 1). The synthetic compound elicited no dash behavior and released AB behavior for 62% of males at 107 μg/capsule (2 FE/capsule) (Figure 6). The female elytra extract elicited 94% of male AB at 1 FE/capsule, although the synthetic compound did not release the dash behavior to males. Therefore, the major sex pheromone component on the female elytra was identified as Z8–21Me–35 : Hy.

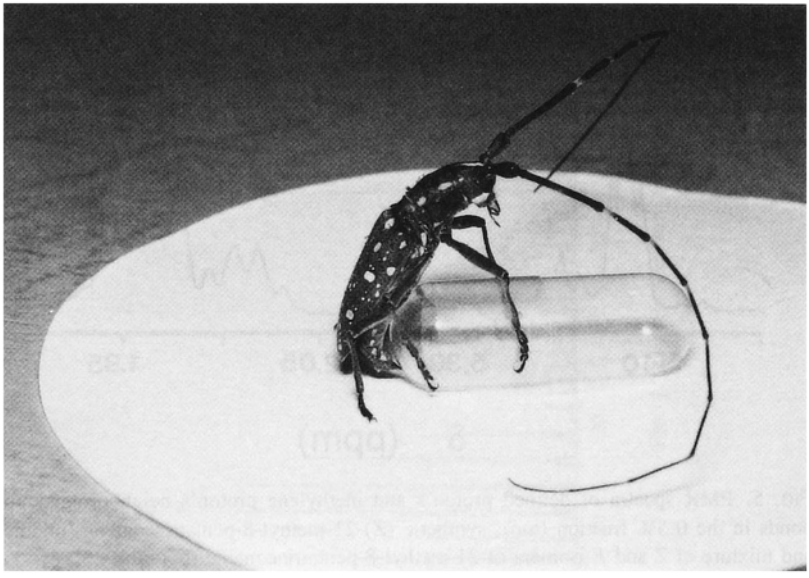

FIG. 6. Male abdominal bending response to a gelatin capsule covered with synthetic (Z)-21-methyl-8-pentatriacontene.

DISCUSSION

In the present study, we successfully identified one of the pheromone components from the female elytra as (Z)-21-methyl-8-pentatriacontene (Z8–21Me–35 : Hy). This compound released typical mating behavior in males from holding to abdominal bending. This is the first identification of a contact pheromone component of the female in cerambycids. Pheromones of several cerambycids were found to be perceived by contact or only at close range (Kuboki, et al., 1985, Wang et al., 1991, Fauziah et al., 1992), but none has been chemically identified. Kim et al. (1993) found hydrocarbon compounds in the female sex pheromone fraction of *Semanotus japonicus*. In cerambycids, sex attractants were also identified from a male (Iwabuchi, 1982, Sakai et al., 1984) and a female (Leal et al., 1994).

The activity of Z8–21Me-35 : Hy was, however, considerably lower than that of female extract (Table 1). In the present experiment, weak activity was eluted with 90% ether in hexane after the elution of major activity from silica gel column chromatography.

The synthetic Z8–21Me–35 : Hy released holding to abdominal bending behavior but not dash behavior. In a previous paper, at least two pheromone components with different functions were demonstrated: one induces dash behavior and the other elicits holding and abdominal bending (Fukaya and Honda, 1995). The major component, which showed the latter activity, was identified in the present study, but the identification of the compound(s) responsible for dash behavior remains to be conducted.

Acknowledgments—We thank Mr. I. Senbongi and Ms. A. Nishimura of Gunma Pref. Agricultural Research Institute, and Dr. M. Sakakibara, Dr. Y. Hirai and Mr. M. Watanabe of the National Institute of Sericultural and Entomological Science for help with insect collection, and Ms. A. Komatsuzaki, and Ms. K. Aoki and Ms. A. Sakairi for assistance with insect rearing. Thanks are also due to Dr. T. Nakashima and Dr. H. Kato of the Forestry and Forest Products Research Institute, Japan, for help with NMR analyses of the samples.

(Received December 3, 1994; accepted October 12, 1995)

Abstract—Octadecanal (18:Ald), (*E*)-11-octadecenal (*E*11-18:Ald), (*E*)-14-octadecenal (*E*14-18:Ald) and (*E*,*E*)-11,14-octadecadienal (*E*11,*E*14-18:Ald) were isolated and identified as major components from the pheromone glands of the tea cluster caterpillar, *Andraca bipunctata*, in Taiwan by analyzing the mass spectra of gland components and their DMDS adducts. GC retention times and mass spectra of the components were in agreement with those of authentic synthetic compounds. The average amount of 18:Ald, *E*11-18:Ald, *E*14-18:Ald and *E*11,*E*14-18:Ald per female gland (1 to 3 days old) was 121 ± 76, 50 ± 20, 187 ± 75, and 237 ± 110 ng, respectively, in a ratio of 20:8:31:41. Synthetic *E*11,*E*14-18:Ald caught more males than each of the other three components or blank control in field trapping tests. *E*11,*E*14-18:Ald is reported as an insect sex pheromone for the first time. Male antenna responded to *E*11,*E*14-18:Ald strongly in an EAG analysis. Furthermore, 4 hr after the injection of PBAN (pheromone biosynthetic activating neuropeptide) into decapitated female moths (2 days old), the percentage of the *E*11,*E*14-C18 Ald in the gland extract increased from 0% to 75.5%, which was also significantly more than that of unligated and uninjected control at 55.1%. All these data indicated that *E*11,*E*14-18:Ald is the sex pheromone of the *Andraca bipunctata* in Taiwan.

Key Words—Decapitated female moth, octadecanal, (*E*)-11-octadecenal, (*E*)-14-octadecenal, (*E*,*E*)-11,14-octadecadienal.

INTRODUCTION

The tea cluster caterpillar, *Andraca bipunctata*, distributed mostly in Sumatra, Java, India, southern China and Taiwan, causes severe damage to tea plants, often resulting in abandoning of whole tea plantations. Current method of controlling this pest with pesticides is ineffective (Banerjee, 1982; Tseng, 1994). In previous work, we demonstrated that the use of the female sex pheromone of the smaller tea tortrix moth, *Adoxophyes* sp., for monitoring population and mating disruption was very successful in tea plantations in Taiwan (Kou et al., 1990; Kou and Chow, 1991; Tsai and Chow, 1992). It is contemplated that the same strategy may be applicable to the control of the tea cluster caterpillar. The sex pheromone of the tea cluster caterpillar, *Andraca bipunctata*, however, has not been described. To facilitate possible future utilization, we characterized and identified the chemical constituents of the sex pheromone gland of the tea cluster caterpillar by analyzing the mass spectra of components in the glandular extracts and their DMDS adducts. The double-bond configuration was determined by comparing the natural products with authentic synthetic compounds on several GC columns. The effectiveness of each of the synthetic compounds was tested by the EAG method. Synthetic compounds or their mixtures were used to catch males in field-trapping tests. Results showed that *E*11,*E*14-18:Ald, or mixtures that contained *E*11,*E*14-18:Ald effectively caught more males than the blank control under field conditions. We concluded that (*E*,*E*)-11,14-octadecadienal is the sex attractant of *A. bipunctata* in Taiwan.

Previously sex pheromone has been identified for only two species in the family Bombycidae, *Bombyx mori* (Linnaeus) and *B. mandarina* Moore (Butenandt et al., 1959; Kuwahara and Yen, 1979; Mayer and McLaughlin, 1991). Both species use (*E*,*Z*)-10,12-hexadecadien-1-ol (bombykol) as the principal component of their sex pheromone. To our knowledge, this is the third member of Bombycidae whose pheromone has been identified. It is also the first identification of (*E*,*E*)-11,14-octadecadienal as an insect sex pheromone.

METHODS AND MATERIALS

Insects. The experimental colonies were set up with pupae supplied by the Taiwan Tea Experiment Station, Hsinchu, Taiwan. Hatched larvae were reared on fresh tea leaves. Male and female pupae were held in separate rooms at 20°C under a 14L:10D regime.

Preparation of Pheromone Gland Extracts. Ovipositors from 1- to 3-day-old virgin females were excised 2 hr into the scotophase and immersed in 10 μl hexane per gland for 2 min. The extracts were stored at 4°C until bioassay and structure analysis (Kou and Chow, 1991).

Derivatization. Dimethyldisulfide (DMDS) derivatives of monounsaturated and diunsaturated compounds were prepared as described previously (Buser et al., 1983; Vincenti et al., 1987).

Chemical Analysis. Gas Chromatography (GC) of the extract was performed on a Varian 3700 GC equipped with a flame ionization detector. Three different capillary columns were used: a 30-m × 0.25-mm-ID fused silica capillary column of DB-Wax phase, a 30-m × 0.25-mm fused silica capillary column of DB-23 phase, and a 30-m × 0.25-mm fused silica capillary column of DB-225 phase. Chromatographic conditions included nitrogen carrier at 0.5 kg/cm^2, isothermal column temperature at 200°C for the DB-Wax column; a temperature program from 100°C to 250°C at 5°C/min for the DB-23 column, and a program from 100°C to 220°C at 4°C/min for the DB-225 column.

Gas chromatographic–mass spectrometric (GC-MS) analysis was conducted using a Finnigan MAT Incos 50 spectrometer. Samples were introduced through a 30-m × 0.25-mm DB-23 capillary column programmed from 80° to 250°C at 5°C/min and held at 250°C for 5 min. Helium was used as the carrier gas. For the analysis of the DMDS adducts of the unsaturated compounds a 30-m × 0.25-mm DB-5 capillary column was used and the temperature was programmed from 150°C to 320°C at 1°C/min. Electron impact (EI) mass spectra were collected at 70 eV with the separator at 250°C and the source at 180°C.

Chemical Synthesis: (*E*)-11-Octadecenol was obtained from NU-Chek-Prep. Inc. Elysian, Minnesota. (*E*)-2-Hexenol, (*Z*)-2-hexenol, 1-pentyne, and 1-octyne were purchased from Tokyo Chemical Industry Co. Pyridinium dichromate (PDC), 10-bromodecanol, and 11-bromoundecanol were obtained from Aldrich Chemical Company, Inc. (Milwaukee, Wisconsin). 7-Dodecynol was purchased from Lancaster Synthesis Ltd. (Lancashire, United Kingdom). Octadecanol and dimethyl disulfide were obtained from Merck Chemical Company.

Octadecanal and (*E*)-11-octadecenal were prepared from octadecanol and (*E*)-11-octadecenol, respectively, using PDC as an oxidizing reagent according to Corey and Schmidt (1979). (*Z*)-11-Octadecenal, (*Z*)-14-octadecenal, (*E*)-14-octadecenal, (*E,E*)-11,14-octadecadienal, and (*Z,E*)-11,14-octadecadienal were synthesized according to the procedures outlined in Figure 3 below. (*E*)-2-Bromohexene was prepared from (*E*)-2-hexenol by reacting with HBr vapor. For the synthesis of (*Z,Z*)-11,14-octadecadienal, the same strategy was used in the preparation of (*Z,E*)- and (*E,E*)-octadecadienal, except that (*Z*)-2-hexenol was used as starting material.

Pheromone Titer Determination. The extracts were prepared as described above and subsequently analyzed with the external standard method of quantitative analysis. Pheromone biosynthesis activating neuropeptide (PBAN), a 33-amino acid peptide, was obtained from Dr. A. Raina (USDA INHL, Bldg 306, Barc-East, Beltsville, Maryland 20705) as a gift. For PBAN analysis, virgin female moths were ligated between the head and thorax and decapitated. Forty-

eight hours after decapitation, 5 pmol of PBAN was injected into the abdomen, and 4 hr later the sex pheromone gland was excised and extracted with hexane. Saline was injected into the abdomen of controls. The extract was stored at 4°C for later analysis. Quantitative analysis was performed by the external standard method as before.

EAG Analysis. Chemicals of different dosage were loaded in a 5-ml glass syringe and puffed over an antennae. The EAG response from the chemicals was compared to the response of the antennae to an air blank. Each chemical was tested using EAG with at least six different antennae. The EAG response was preamplified (100× or 1000×) and recorded with a V1000 video, 4035 digital storage oscilloscope and ES1000 recorder (Gould Co. Ltd.) (Yang et al., 1992).

Field Testing. Field testing of the synthetic chemical formulation was carried out first for released males in a tea plantation in Taiwan Tea Experiment Station, Puehsin, Hsinchu, Taiwan, during November 1994, and subsequently in a local open tea plantation near Academia Sinica for wild males in April and May 1995. Synthetic chemicals were used separately and as a mixture. A total of 0.1 mg synthetic compounds was dissolved in hexane and loaded in plastic tubes, 5 cm × 1 mm ID. The plastic tube was suspended on the inside at the top of a wing-shaped sticky trap (Kou et al., 1992). Blank traps and traps baited with two female extracts were used for comparison. Traps were placed 10 m apart and 1.5 m above ground. For the capture of released males, a total of 120 laboratory-reared 1- to 3-day-old unmated males were released. Each trap was checked every afternoon for eight days. For the wild male field tests, traps were checked every week.

RESULTS AND DISCUSSION

Chemical Analysis. GC analysis showed a total of four major peaks, labeled A–D, in the chromatogram of a gland extract (Figure 1). Component A, with a molecular weight of 268, had the same mass spectrum as octadecanal (Table 1). Components B and C, both having a molecular weight of 266, had virtually identical mass spectra, with only a slight difference in relative intensities. The mass fragmentation patterns suggested isomeric monounsaturated octadecenals. Component D had a molecular weight of 264, and the mass spectral fragmentation pattern suggested an octadecadienal.

Synthetic octadecanal matched component A from gland extract in retention times on three GC columns and by mass spectrometry (Table 2), and we concluded that component A is octadecanal (Figure 1). The double-bond position of the monounsaturated aldehydes, components B and C, were inferred by the DMDS derivatization method, which was previously used for the determination

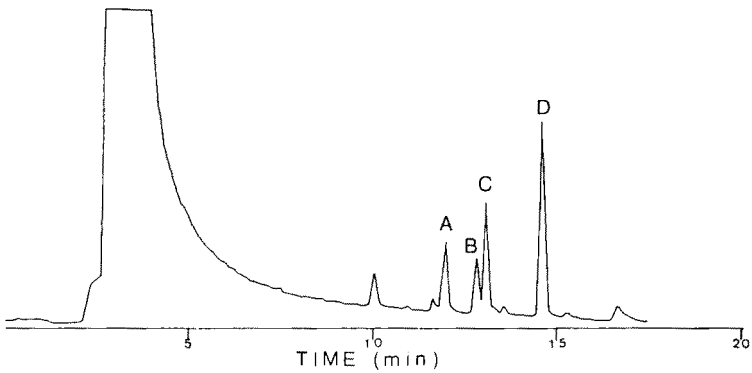

FIG. 1. Gas chromatogram of female sex pheromone gland crude extract. The gas chromatography was performed on a 30-m × 0.25-mm DB-Wax column and the oven temperature was isothermal at 200°C.

of the double-bond position in monounsaturated acetates (Buser et al., 1983). DMDS adducts of the aldehydes were prepared, and the relevant mass spectral data are shown in Table 3. The mass spectrum of the DMDS derivative of component B showed a molecular ion at *m/z* 360 and two intense ions at *m/z* 145 and 215, presumably arising from a cleavage between the vicinal thiomethyl groups. Two possible aldehydes could yield the observed ions. The parent compound may be 11-octadecenal and the ion at *m/z* 145 could represent $CH_3-(CH_2)_5-CH=S^+CH_3$, which arises from the distal end of the molecule, whereas the ion *m/z* 215 would represent the functional-group-bearing end of the molecule (Figure 2A). Alternatively, the parent compound may be 6-octadecenal, with the ion at *m/z* 215 representing $CH_3-(CH_2)_{10}-CH=S^+CH_3$, arising from the distal end of the molecule, and the ion *m/z* 145 representing the functional-group-bearing end of the molecule. In order to distinguish between 11- and 6-octadecenal, the compounds in the gland extract were reduced to alcohols by $LiAlH_4$ and then derivatized to the DMDS adduct. The mass spectrum of the DMDS adduct of the alcohol of component B (Table 3) showed that the major fragments are at *m/z* 217 and 145, and we concluded that the component B is 11-octadecenal. The DMDS adduct of 6-octadecenol would give major fragments at *m/z* 147 and 215. Both (*E*)-11- and (*Z*)-11-octadecenal

[a]The ranges of abundance are due to the presence of chromatographically separated DMDS adduct isomers with slight differences in their mass spectra.

(Figure 3A) were synthesized and retention times on the DB-23 column were compared (Table 2). (*E*)-11-Octadecenal cochromatographed with component B of the gland extract, so it was concluded that component B is (*E*)-11-octadecenal.

Similar analysis of the mass spectrum of the DMDS derivative of component C (Table 3) revealed that the parent compound might be 14-octadecenal or 3-octadecenal (Figure 2B). Component C was reduced to the alcohol by $LiAlH_4$, as above, and the DMDS adduct of the corresponding alcohol was prepared and analyzed by GC-MS. The mass spectrum (Table 3) showed that the major fragments were at *m/z* 259 and 103, suggesting that the component C is 14-octadecenal, since the DMDS adduct of 3-octadecenol will give major fragments at *m/z* 105 and 257. Both *E* and *Z* isomers of 14-octadecenal were synthesized (Figure 3B) and compared with compound C on different GC columns (Table 2). The results indicated that (*E*)-14-octadecenal cochromatographed with component C of the gland extract and component C was identified as (*E*)-14-octadecenal.

The diunsaturated octadecadienal was derivatized according to the procedure described by Vincenti et al. (1987). GC-MS analysis of the DMDS adduct showed fragments at *m/z* 215 and 103 (Table 3). From this fragmentation pattern, component D in the gland extract could be 11,14-octadecadienal or 3,6-octadecadienal (Figure 2C). Component D in the gland extract was reduced to an alcohol by $LiAlH_4$ and derivatized to its DMDS adduct. GC-MS analysis of

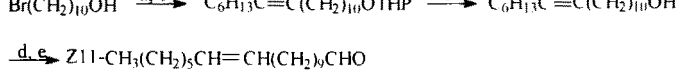
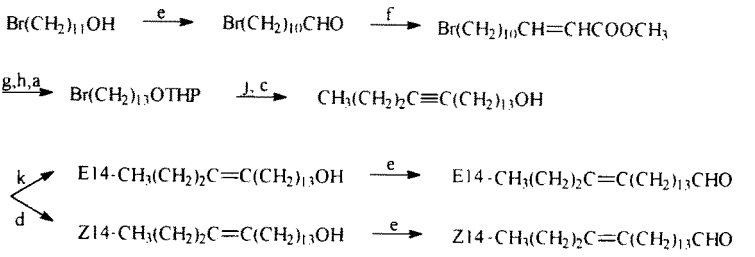
(A) Preparation of (Z)-11-octadecenal



(B) Preparation of (E)- and (Z)-14-octadecenal



(C) Preparation of (E,E)- and (Z,E)-11,14-octadecadienal

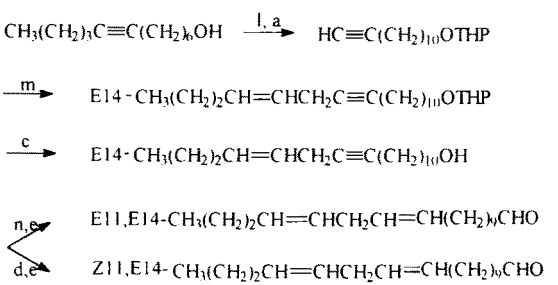


FIG. 3. Preparation of (*Z*)-11-octadecenal, (*E*)-14-octadecenal, (*Z*)-14-octadecenal, (*E,E*)-11,14-octadecadienal, and (*Z,E*)-11,14-octadecadienal. Reagents: (a) dihydropyrane/*p*-TSA (*p*-toluenesulfonic acid); (b) 1-octyne/*n*-BuLi (Schwarz and Waters, 1972); (c) MeOH/*p*-TSA; (d) H_2/Pd/$BaSO_4$; (e) PDC (pyridinium dichromate); (f) Wittig reaction, $Ph_3P{=}CHCO_2CH_3/CH_2Cl_2$; (g) H_2/Pd; (h) DIBAL (diisobutylaluminum hydride) (Yoon and Gyoung, 1985); (j) pentyne/*n*-BuLi (Schwarz and Waters, 1972); (k) $LiAlH_4$/diglyme (diethyleneglycol dimethyl ether) (Rossi and Carpita, 1977); (l) potassium 3-aminopropylamide (KAPA) (Brown and Yamashita, 1976); (m) (*E*)-2-bromohexene/*n*-BuLi (Schwarz and Waters, 1972); (n) Na/NH_3 (Schwarz and Waters, 1972). *Abbreviation:* THP, 2-tetrahydropyranyl.

the adduct showed a molecular weight of 392 and fragments at *m/z* 217 and 103 (Table 3). These results indicated that the alcohol was 11,14-octadecadienol, since 3,6-octadecadienol would give major fragments at *m/z* 215 and 105. Thus, it was concluded that component D in the gland extract was 11,14-octadecadienal. The four geometric isomers of 11,14-octadecadienal, i.e., (*E*,*E*)-, (*Z*,*E*)-, (*Z*,*Z*)-, and (*Z*,*E*)-11,14-octadecadienal, were synthesized and their retention times on GC were compared with that of the component D (Table 2). Cochromatography of (*E*,*E*)-11,14-octadecadienal with the natural product showed agreement on different columns. Thus, component D in the sex pheromone gland extract was identified as (*E*,*E*)-11,14-octadecadienal.

Pheromone Titer Determination and PBAN Stimulation Tests. Recently, Raina et al. (1989) reported that pheromone biosynthesis activating neuropeptide (PBAN) regulates pheromone production in some female insects. We found that the amount of the four components was zero if the adult female moth of the tea cluster caterpillar was decapitated and saline was injected into the abdomen (Table 4). In contrast, if PBAN was injected instead of saline into the neck-ligated and decapitated moth, the four components we have identified were found in the gland extract, and the percentage of *E*11,*E*14-18:Ald in the gland extract was as high as 75.5%. This indicated that all four compounds were probably related to pheromone production. The fact that the percentage content of *E*11,*E*14-18:Ald in the gland extract of the PBAN treated females was more than that of normal virgin females (55.1%) suggests that *E*11,*E*14-18:Ald is the sex pheromone of *Andraca bipunctata*.

EAG Analysis. The EAG analysis of octadecanal, (*E*)-11-octadecenal, (*E*)-14-octadecenal, and (*E*,*E*)-11,14-octadecadienal of different dosage showed that the antennae of the male strongly responded to (*E*,*E*)-11,14-octadecadienal and only slightly to the other three components (Figure 4). The EAG response of each component was measured only at doses of 200 and 300 ng since the response induced by 200 or 300 ng of synthetic chemicals was comparable to

[a]The lure dispenser was a plastic tube.

that of one female equivalent. The EAG results provided support for (*E*,*E*)-11,14-octadecadienal as the sex pheromone of the insect.

Field Trapping of Released Males. The results of field trapping of released males with mixtures of the synthetic compounds in a ratio of 20:8:31:41 and virgin-female extract are shown in Table 5. A total of 120 males were released and only 13 were caught. The reason for the poor recapture of males in this experiment was probably due to the low winter temperature when the trapping took place.

Field Trapping of Wild Males. The results of field trapping of wild males with each of the synthetic compounds and mixtures of the synthetic compounds are shown in Tables 6 and 7. The results in Table 6 showed that component D (*E*11,*E*14–18:Ald) alone, two-component treatments (A + D, B + D, C + D), and mixtures of four synthetic compounds (mixed in the same ratio as in the virgin female extract) caught more males than treatments without component D. The numbers of moths caught by the different treatments were not significantly different as long as component D was present. Table 7 shows the comparison of the number of males caught by three-component and four-component treatments. Although the adult season was almost over in May, and only a few male moths were caught in this test, the results also showed no difference between the three-component treatments and four-component treatments. The fact that the number of males captured by *E*11,*E*14–18:Ald alone and by mixtures of two, three, or four components were not significantly different from each other support EAG data and PBAN results, and we conclude that *E*11,*E*14–18:Ald is the attractive component of the sex pheromone gland of *Andraca bipunctata*. Although a single pheromonal component is rare in insect literature, it is not unprecedented. For example, female gypsy moths use only (7*R*,8*S*)-*cis*-7,8-epoxy-12-methyloctadecane to attract males. To see if there is any synergetic effect of the other components found in the gland extract, more extensive field tests will be conducted in the near future.

From our results of PBAN stimulation, EAG analysis, and field trapping tests, we tentatively conclude that the sex pheromone of *Andraca bipunctata* is *E*11,*E*14–18:Ald. If the additional three components in the gland extract do not have any function in male attraction, the reason they are present may be that they are precursors in the biosynthesis of (*E*,*E*)-11,14-octadecadienal. The moth may synthesize *E*11,*E*14–18:Ald from 18:Ald via *E*11–18:Ald or via *E*14–18:Ald in the pheromone gland. The Δ11 desaturase enzyme identified from some Lepidoptera may produce *E*11–18:Ald from the saturated 18:Ald (Roelofs and Wolf, 1988). A Δ14 desaturase is also reported to be involved in the biosynthesis of pheromone in the Asian corn borer (Zhao et al. 1990). Thus the sex pheromone *E*11,*E*14–18:Ald reported here could be produced by catalytic activities of the Δ11 and Δ14 desaturases in its biosynthetic pathway as reported in other insects.

(Received July 11, 1995; accepted October 13, 1995)

Abstract—A sequence of reactions is presented for inverting the configurations of both epoxide carbons in 1,2-disubstituted epoxides. As examples, (+)-disparlure was converted to its enantiomer, (−)-disparlure, and *exo-endo* conversion of a cyclohexene oxide was demonstrated.

Key Words—Enantiomer, chirality, pheromone, disparlure.

INTRODUCTION

(+)-Disparlure **1** [(7*R*,8*S*)-2-methyl-7,8-epoxyoctadecane] (Figure 1), the sex pheromone of the gypsy moth, *Lymantria dispar* L., (Bierl et al., 1970) is a chiral biomolecule whose performance in trapping experiments has been found to be very sensitive to the presence of even small amounts of the (−) enantiomer (Plimmer et al., 1977). We recently developed an analytical procedure for determining the chirality of **1** that involved conversion, with two inversions of configuration, to *N*-(α-methylbenzyl)aziridines (Oliver and Waters, 1995). This procedure involved epoxide opening with α-methylbenzylamine (stereoselective with inversion, but not regioselective), mesylation of the OH, and intramolecular displacement of the mesylate (stereoselective with inversion). It occurred to us that a similar sequence, but using an appropriate oxygen nucleophile, ought to be applicable to an epoxide–epoxide enantiomeric conversion that would complement the formal *cis–trans* inversions of disparlure developed in our labora-

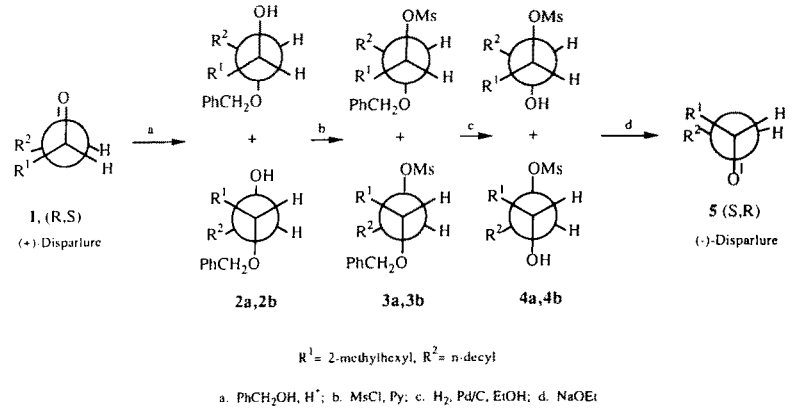

FIG. 1. Conversion of (+)-disparlure to (−)-disparlure.

tories a number of years ago (Sonnet and Oliver, 1976a,b). Here we report the application of epoxide inversion to the synthesis of (−)-disparlure and an unrelated epoxide of semiochemical interest.

METHODS AND MATERIALS

Gas chromatography was performed on Shimadzu 9A and 14A instruments, equipped with 15-m DB-5 and 60-m SPB 608 capillary columns, respectively. The former was generally used for following the progress of reactions and flash chromatography, whereas the latter, operated isothermally at 240°C, was employed for disparlure chirality analyses (Oliver and Waters, 1995) and also for attempted separations of positional isomers derived from epoxide opening of disparlure (e.g., **2a, 2b** and **3a, 3b**). ^{1}H NMR spectra were obtained with a General Electric QE-300 spectrometer on deuteriochloroform or deuteriobenzene solutions. Mass spectra were recorded on a Finnigan model 4510 GC-MS. (Mention of a proprietary product or company does not imply endorsement by the U.S. Department of Agriculture.)

Inversion of (+)-Disparlure to (−)-Disparlure. A mixture of (+)-disparlure (170 mg), benzyl alcohol (466 mg), and 2 Nafion beads (Aldrich, ca. 10 mg) was allowed to stand at room temperature for four days, then was thoroughly partitioned between pentane and water. Flash chromatography (2.5% then 5% EtOAc in cyclohexane) provided separation from rearrangement products and gave 155 mg (66%) of a mixture of regioisomeric benzyloxy alcohols **2a** and **2b.** [No GC separation of the ketonic rearrangement products was realized;

chemical ionization mass spectrometry confirmed molecular weight 282 (isomeric to **1**); the electron impact spectrum contained the four expected acyl ions for 2-methyloctadecan-7-one and 2-methyloctadecan-8-one (*m/z* 127, 141, 169, 183) but the predicted McClafferty rearrangement ions (*m/z* 142, 156, 184, 198) although visible, were too weak to be very diagnostic: m/z(%), 183 (13), 169 (16), 127 (10), 123 (10), 109 (23), 96 (14), 95 (19), 85 (18), 83 (15), 82 (100), 71 (57), 67 (11), 59 (13), 58 (39), 57 (73), 55 (34). Its infrared spectrum (neat, 1712 cm^{-1}) indicated ketone(s), as did the lack of a deshielded signal in the ^1H NMR spectrum indicative of an aldehyde.] The entire sample of **2a** and **2b** in pyridine (2 ml) was treated with methanesulfonyl chloride (100 μl) in a nitrogen atmosphere, and the solution was allowed to stand overnight at room temperature. It was then partitioned between cold, dilute HCl and pentane, and the pentane was rinsed with water and with aqueous sodium carbonate. Removal of solvent provided 203 mg of **3a** + **3b** as a clear oil that was not purified (TLC yielded a single spot, R_f = 0.43, 5% EtOAc/toluene), but was hydrogenated (1 atm, 10% Pd on charcoal) in absolute ethanol—see below. No gas chromatographic resolution was achieved between regioisomers **2a, 2b,** or **3a, 3b,** and detailed characterization was not attempted. Mass and ^1H NMR spectra were recorded on mixtures of the isomers: Mass spectrum **2a** + **2b** (GS introduction; mol wt 390 confirmed by chemical ionization with both methane and ammonia reagent gases) electron ionization m/z (%) 390 (0.03, M^+), 127 (6), 92 (14), 91 (100), 83 (5), 69 (10), 57 (6), 55 (7). Mass spectrum of **3a** + **3b** (probe introduction): m/z (%), 468 (0.1, M^+), 127 (6), 111 (8), 107 (10), 97 (9), 92 (7), 91 (100), 83 (10), 69 (17), 57 (10), 55 (10).

Following hydrogenation of **3a, 3b,** filtration and evaporation of solvent gave 111 mg of **4a** + **4b** as a glassy residue. Addition of methanol (2 ml) followed by 0.25 ml of 2.9 M sodium methoxide in methanol resulted in the almost immediate precipitation of a white solid. After 1.75 hr the solvent was concentrated, and the residue was partitioned between water and pentane. Flash chromatography of the pentane-soluble product (hexane followed by 2.5% and finally 5% ethyl acetate in hexanes) gave 67 mg of (−)-disparlure **5** indistinguishable from the starting material except for its chirality (Oliver and Waters, 1995—see text). Mass spectrum of **5** (e. i., m/z (%)]: 282, M^+ (0.2), 183 (8), 111 (17), 110 (17), 109 (10), 97 (42), 95 (17), 85 (9), 84 (11), 83 (27), 82 (58), 71 (17), 70 (22), 71 (17), 70 (22), 69 (100), 67 (25), 57 (38), 56 (39), 55 (64).

Opening of Ethyl-trans-4-Methyl-7-oxabicyclo[4.1.0]heptane-3-cis-Carboxylate **6.** A mixture of **6** (racemic, 7.36 g), benzyl alcohol (30 ml), and Nafion (0.5 g) was allowed to stand at room temperature for 12 days (this reaction could also be conducted at elevated temperatures if desired). The product was partitioned between pentane and water, and then, after evaporation of

the pentane, between cyclohexane and water. Alternatively, the bulk of the excess benzyl alcohol could be removed by distillation *in vacuo* prior to partitioning. Removal of solvent gave 9.87 g of a clear oil that contained **8** plus its positional isomer and very little benzyl alcohol. Mass spectrum of **8:** m/z (%), 168 (8), 155 (8), 137 (6), 111 (13), 109 (10), 94 (12), 92 (15), 91 (100), 85 (8), 83 (6), 81 (20), 71 (14), 65 (10), 55 (9).

Benzyloxymesylate **9.** The preceding sample, dissolved in a mixture of pyridine (15 ml) and dichloromethane (30 ml), was stirred and cooled in a nitrogen atmosphere while a solution of methanesulfonyl chloride (3.5 ml) in dichloromethane (10 ml) was added dropwise. After 2.5 hr at 0°C the ice bath was removed, and after an additional hour 0.5 ml of methanesulfonyl choride was added slowly. After stirring at room temperature one more hour, ice was added and the mixture was partitioned between water and ether–hexane (1 : 1). The solution was rinsed with water, twice with 2 N HCl, again with water, and finally with 1 M Na_2CO_3. The solution was dried and concentrated, and the residue (12 g) was passed through a short silica gel column with 10% followed by 20% ethyl acetate in hexanes. Evaporation of solvent gave 10.46 g (84%) of **9** plus its regioisomeric benzyloxy mesylate. A sample of the major isomer **9** was isolated by flash chromatography (ca. 20% ethyl acetate in hexanes). Mass spectrum of **9:** m/z (%), 370 (1, M^+), 168 (17), 122 (6), 95 (6), 94 (38), 92 (8), 91 (100), 81 (7), 65 (6). ^1H NMR of **9** ($CDCl_3$) 0.94 (d, J = 6.6, 6-Me), 1.24 (t, J = 7.2, $C\underline{H}_3CH_2$), 1.73 (m, H-$5_{a,b}$), 1.96 (m, H-2), ca. 2.05 (m, H-6), 2.40 (dt, J = 5.4 and 10.2 H-1), 2.98 (s, $C\underline{H}_3SO_3$), 3.79 (app. d, H-3), 4.15 (q, J = 7.2, $CH_3C\underline{H}_2$), 4.55 (d, J = 11.7, $PhC\underline{H}_2$), 4.62 (d, J = 11.7, $PhC\underline{H}_2$), 4.84 (app. d, J = 3.0, H-4), 7.34 (phenyl).

Hydrogenolysis. A solution of 1.47 g of **9** in absolute ethanol (20 ml) plus 0.17 g 10% Pd on C was hydrogenated at one atmosphere. No reaction occurred, and eventually the mixture was filtered and the catalyst was replaced with ca. 0.2 g of PtO_2. Three drops of conc. HCl were added, but no hydrogenation occurred until the solution was again filtered and the catalyst replaced with 0.25 g of fresh PtO_2. After two more hours, GC indicated the disappearance of **9** and the appearance of two products, **10** and **11,** with the **10** predominating by about 2 : 1. The mixture was filtered through Celite, and the filtrate was treated with 2 ml of 3 N NaOEt in ethanol. After 0.5 hr the mixture was partitioned between aqueous ammonium chloride and 8 : 2 hexane–ethyl acetate. Removal of solvent gave 0.63 g of an oil that was flash chromatographed (10%, 20%, and 30% EtOAc in hexanes) to give 277 mg of epoxide **7** and 215 mg of cyclohexanemethanol derivative **11.** The epoxide **7** was identical to **7** produced along with **6** upon epoxidation of the corresponding olefin. Epoxide **7:** m/z (%) 184 (0.7, M^+), 139 (32), 138 (10), 114 (14), 112 (12), 111 (34), 110 (100), 101 (21), 95 (24), 93 (53), 91 (10), 86 (10), 85 (14), 84 (34), 83 (24), 82 (15),

81 (41), 79 (13), 77 (11), 73 (18), 72 (19), 71 (10), 70 (25), 69 (25), 68 (13), 67 (33), 56 (13), 55 (71), 53 (15). ^{1}H NMR ($CDCl_3$) 0.84 (d, J = 6, 6-Me), 1.25 (t, J = 7.2, $C\underline{H}_3CH_2O$), 1.52 (m, H-$5_{a,b}$), 1.66 (m, H-6), 2.01 (m, H-$2_{a,b}$), 2.13 (m, H-$5_{b,a}$), 2.23 (m, H-1), 2.27 (m, H-$2_{a,b}$), 3.14 (app. t, H-4), 3.22 (br s, H-3), 4.13 (dq, J = 1.2 and 6.9, $CH_3C\underline{H}_2O$). Compound **11** was identified by its mass and NMR spectra: m/z (%) 331 (6), 207 (10), 185 (45), 183 (30), 155 9260, 139 (12), 138 (8), 137 (22), 111 (55), 109 (11), 97 (62), 96 (13), 95 (16), 94 (17), 93 (25), 81 (22), 79 (17), 65 (11), 63 (13), 55 (100), ^{1}H NMR ($CDCl_3$) 0.92 (d, J = 6.6, 6-Me), 1.27 (t, J = 6.9, $C\underline{H}_3CH_2$), 1.65 (m, H-$5_{a,b}$), 1.85 (m, H-$5_{a,b}$), 1.92 (m, H-2), 2.32 (dt, J = 4.8 and 10.2, H-1), 3.04 (s, CH_3SO_2), 3.24 (dd, J = 6.6 and 9.0) and 3.31 (dd, J = 6.6 and 8.7), $C\underline{H}_2$-cyclohexyl, 3.62 (br d, H-3), 4.15 (q, J = 7.2, $CH_3C\underline{H}_2O$) 4.81 (br, H-4).

*Confirmation of Cyclohexanemethanol Derivative **11**.* A solution of **6** (166 mg) and pyridinium *p*-toluenesulfonate (23 mg) in cyclohexanemethanol (1 ml) was heated as 110°C under nitrogen ca. 20 hr. Part of the cyclohexanemethanol was removed in vacuo, and the residue was thoroughly partitioned between pentane and water. To about 90% of the crude product was added benzene (2 ml), pyridine (0.5 ml), and methanesulfonyl chloride (0.5 ml). After 3 hr at room temperature the mixture was partitioned between water and ether–hexane (1 : 1). The organic phase was rinsed with dilute HCl, with water, and with aqueous Na_2CO_3, and then dried and concentrated. Flash chromatography (20–25% EtOAc–hexane gave a total of 90 mg of **11**, part of which was crystallized from hexane, mp 60–61. This material was identical to **11** isolated from the above reaction.

RESULTS AND DISCUSSION

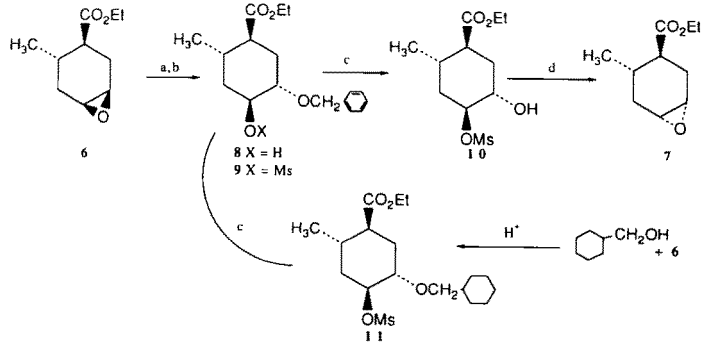
We had noted (Oliver and Waters, 1995) that disparlure (**1**) was very resistant to ring opening under nonacidic conditions, but that anhydrous neutral alumina (Posner and Rogers, 1977) satisfactorily catalyzed ring opening with α-methylbenzylamine at 145°C. Under similar conditions (sealed tube), alumina catalyzed epoxide opening with benzyl alcohol. Rearrangement (the rearrangement of **1** is assumed to proceed more or less equally to two regioisomeric ketones, but like other regioisomers in the disparlure series, no gas chromatographic resolution was achieved—see Methods and Materials) competed with opening, but the products were readily separated by flash chromatography and **2a, 2b** were isolated in 34% yield. Other catalysts were also investigated: a trace of sulfuric acid quickly catalyzed rapid opening of **1** in benzyl alcohol at room temperature, but considerable self-condensation of benzyl alcohol also

occurred [product(s) not investigated] Nafion-catalyzed opening (Olah et al., 1981) with benzyl alcohol as solvent was slow (four to seven days at room temperature for complete reaction), but epoxide rearrangement was minimized ($\leq 15\%$), and **2a, 2b** were obtained in 66% yield after chromatography. Pyridinium toluenesulfonate seemed quite similar to Nafion as a catalyst, although a systematic comparison was not made.

Mesylation of regioisomers **2a, 2b** proceeded without incident, as did hydrogenolysis (EtOH, Pd on C, 1 atm) of the benzyloxymesylates **3a, 3b.** Treatment of the resulting hydroxymesylates **4a, 4b** with sodium ethoxide resulted in rapid conversion to expoxide **5** (7*S*,8*R*), indistinguishable from **1** by gas chromatography or mass spectrometry. The yield of **5,** after flash chromatography, from **3a, 3b** was 81% (Figure 1).

For successful conversion of **1** to **5,** both the epoxide opening and closing reactions have to occur with inversion. If one of the two were to occur with retention, the result would be *trans*-disparlure (7*R*,8*R*) or (7*S*,8*S*). *trans*-Disparlure is separable from **1** and **5** by GC or even column chromatography, and, in fact, ca. 0.6% of the *trans* epoxide was detectable (by GC) in at least one conversion of **1** to **5.** The starting material for this sequence had been 97.3% **1** and 2.7% **5,** and the product analyzed for 2.2% **1** and 97.8% **5.** It is uncertain whether this 0.5% difference is outside of experimental error, but in any event, the stereoefficiency was very high.

Another example of epoxide inversion involved **6** and **7** (Figure 2). These had long ago been found to be attractive to Mediterranean fruit flies (Valega and Beroza, 1967), but only a mixture of *exo* and *endo* epoxides is available upon epoxidation of *trans*-6-methyl-3-cyclohexenecarboxylic acid or its esters. In contrast, the *exo*-epoxide **6** is readily available via an iodolactone (see, for



a. $PhCH_2OH$, H^+; b. CH_3SO_2Cl, Py; c. H_2, Pt, EtOH; d. NaOEt

FIG. 2. The *exo-endo* epoxide inversion.

example, Ogliaruso and Wolfe, 1993), but comparison of the attractiveness of pure **6** and the mixture of **6** and **7** suggested that the activity lay with the latter (R.T. Cunningham and J.W. Avery, unpublished results). Epoxide **6** (in this case racemic) was less subject to rearrangement than disparlure, and ring opening could conveniently be carried out at 100–110°C with either pyridinium toluenesulfonate or Nafion in benzyl alcohol. In this case the opening was somewhat regioselective, and after treatment of the crude product with methanesulfonyl chloride, mesylate **9** could be isolated as a solid. Benzyloxymesylate **9** was more resistant to hydrogenation than **3a, 3b.** No reaction was observed with palladium on carbon in ethanol (1 atm), whereas addition of a trace of HCl and replacement of the catalyst with platinum oxide permitted a very slow reduction to occur (in some cases requiring two or more days to reach completion at one atmosphere). The major product was evidently the expected alcohol **10,** since treatment of the ethanol solution with sodium ethoxide rapidly gave the desired epoxide **7.** No isomers of **7** were detected, although a minor product was observed from the conversion of **9** to **7.** After isolation by flash chromatography, it was identified by mass spectrometry and NMR spectroscopy as the cyclohexylmethyl ether **11,** i.e., the product of aromatic ring reduction instead of hydrogenolysis. Platinum-catalyzed ring saturation of benzyl ethers, although generally unanticipated, is not without precedent (see Rylander, 1979). The structure of **11** was confirmed by opening **6** with cyclohexanemethanol instead of with benzyl alcohol, then treating the ether–alcohol with methanesulfonyl chloride.

In summary, a straightforward procedure for the inversion of certain 1,2-disubstituted epoxides is reported. Although asymmetric epoxidation procedures can often be applied to either enantiomer, particularly of acyclic epoxides, many cyclic epoxides, naturally occurring epoxides, or epoxides prepared by microbial- or enzyme-mediated sequences, may be more available as one enantiomer than the other (Besse et al., 1994), and the current method may prove useful in such cases. We have not investigated inversions of trisubstituted epoxides, anticipating that epoxide rearrangements as well as difficulties with tertiary mesylates could present competing pathways. Unsaturated substrates subject to catalytic hydrogenation would present another limitation of the sequence described, but alternative oxygen nucleophiles convertible to OH by other means, such as *p*-methoxyphenol (Corey and Link, 1992), or masked OH nucleophiles (Fleming, 1988) might also find application. Ironically, an initial objective of the project was to invert the configuration of (+)-diethylepoxyfumarate. We were unable to effect ring opening of that epoxide with benzyl alcohol under a variety of acidic or alkaline conditions; only very slow (over several weeks) transesterification occurred under the conditions described above for the opening of **1** or **7,** and the corresponding dibenzyl ester (examined separately) failed to react at all.

Acknowledgments—We are grateful to Dr. P.E. Sonnet for his suggestion of inverting the stereochemistry of the epoxyfumarates and for supplying both the diethyl and dibenzyl esters. We thank Dr. James Avery for a sample of epoxide **6** and for a mixture of **6** and **7.**

Abstract—The parasitic dwarf mistletoe *Arceuthobium vaginatum* attacks *Pinus ponderosa* as its primary host and *P. contorta* as an occasional host. Within ponderosa pine stands there is also differential parasitism among individual trees. We compared biochemical features of phloem and xylem oleoresin between infected individuals of the two pine species ($N = 15$ for each species) and also between infected ($N = 30$) and nearby uninfected ($N = 30$) ponderosa pine conspecifics. There were significant differences in chemical features, both at the interspecific (*P. ponderosa* vs. *P. contorta*) and intraspecific (*P. ponderosa*) levels. Discriminant function analysis based on chemical features of phloem correctly classified all trees used in the analysis as either *P. ponderosa* or *P. contorta*, and 95% of all ponderosa pine trees as either parasitized or nonparasitized. Monoterpene composition of oleoresin was distinct between species, and differences between parasitized and nonparasitized *P. ponderosa* were also significant. Many of the observed chemical differences are probably constitutive, although levels of nonstructural carbohydrates and α-pinene may change in response to dwarf mistletoe infection. Biochemical differences at the intraspecific level were distinct from interspecific differences. Patterns of differential attack can have genetic consequences upon both the parasite and its hosts, and, in the process, may contribute to the evolution of host races of the parasite and to the evolution of host resistance within ponderosa pine.

INTRODUCTION

The differential utilization of hosts by parasites is often affected by chemical features of the host phenotype. When parasites are animals, they may move about the landscape sampling different potential hosts and make active choices about which individual hosts to attack. Host choice can be based in part on nutritive value or chemical repellency of individual hosts, or some combination of both (e.g., Denno and McClure, 1983; Fritz and Simms, 1992; Snyder, 1992). When parasites are plants (or microbes) and are dispersed passively by seeds or spores, patterns of attack do not involve such active choices. Nonetheless, patterns of attack by passively dispersed parasites may also be mediated by specific features of host chemistry, since parasites may be differentially successful (e.g., germination, survival, reproduction) on hosts with different phenotypes (Scharpf et al., 1992; Linhart et al., 1994). Variability of chemical features of hosts is often poorly known and needs to be documented in detail to gain a better understanding of host–parasite interactions.

To investigate the potential role of host chemistry in these interactions, we examined patterns of attack by the dwarf mistletoe *Arceuthobium vaginatum* subsp. *cryptopodum* (Viscaceae) and chemical characteristics of its known and potential hosts. The chemical features we examined are known to be associated with patterns of use by a variety of herbivores and parasites of these trees (Snyder, 1992, 1993; Snyder and Linhart, 1994; Linhart et al., 1994). *Arceuthobium vaginatum* resides in the Rocky Mountains and the southwestern United States. Its primary host species is ponderosa pine (*Pinus ponderosa* subsp. *scopulorum*), but it utilizes lodgepole pine (*P. contorta*) as an occasional host (Hawksworth and Wiens, 1972). Within forest stands, the distribution of dwarf mistletoes is usually patchy (Scharpf and Parmeter, 1978; Hawksworth and Johnson, 1989), but even in stands where it is very dense, certain trees can be heavily infected, while nearby trees often are free from parasitism (Linhart, 1989; Linhart et al., 1995). These observations suggest that there may be differences in biochemical features of host and nonhost trees. Such differences may be important to dwarf mistletoe establishment and survival after seeds germinate and send "sinkers" into the phloem and xylem of potential hosts, since dwarf mistletoes obtain all of their water and elemental nutrients and the majority of their carbohydrate resources from host trees. Once established, dwarf mistletoe individuals can live up to several years on their hosts. They show differential mortality (Scharpf et al., 1992) when introduced experimentally onto host trees

known to be resistant or susceptible, suggesting that biochemical characteristics of hosts may affect dwarf mistletoe survivorship.

In order to determine whether host biochemistry is associated with patterns of attack and establishment by dwarf mistletoe, we compared the biochemical features of phloem and of xylem oleoresin between infected individuals of ponderosa and lodgepole pines. We also compared these same chemical features between infected ponderosa pines and nearby ponderosa pine individuals free from infection. We asked the following specific questions:

1. At the interspecific level, what biochemical features of phloem and xylem oleoresin differentiate infected trees of the primary host (*P. ponderosa*) and occasional host (*P. contorta*) of *A. vaginatum*?

2. At the intraspecific level, is attack by *A. vaginatum* associated with particular biochemical features of individual *P. ponderosa* trees?

3. To what extent do interspecific and intraspecific differences in host characteristics correspond? That is, in ponderosa pine, do parasitized trees differ from nonparasitized trees in the same ways that ponderosa pine, the primary host, differs from lodgepole pine, the occasional host?

METHODS AND MATERIALS

Locations and Sample Sizes. We used two study sites in the southern Rocky Mountains, one for intraspecific comparisons, another for interspecific comparisons. Trees for the intraspecific comparisons ($N = 15$ pairs) occupied a stand of ca. 5 ha of ponderosa pine at 2182 m elevation on Bald Mountain, 6.1 km west of Boulder, Colorado. For these comparisons, we designated pairs of trees (i.e., 30 heavily parasitized and 30 trees with no visible symptoms of dwarf mistletoe infection) that were matched for size (within 10% of each other in height and diameter), that were near each other, and subject to similar soil type, aspect, and solar exposure. The trees designated for sampling in the interspecific comparison were intermixed in a stand of ca. 3 ha at 2591 m elevation in the Roosevelt National Forest 2 km north of Nederland, Colorado, and included both infected and noninfected trees of both species. The stand consisted of a relatively dense mixture of both host species. Neither site was characterized by significant heterogeneity of soils or parent materials.

Collection and Processing. For all trees, two live branches 1–3 cm in diameter that showed no visible symptoms of dwarf mistletoe infection were collected from separate locations within the tree crown using an extendable rope-pull tree pruner. Branches were brought to the laboratory and stored at 5°C until processing (<48 hr). Phloem was peeled from twigs with a drawknife and scalpel, air-dried, and pulverized to a fine powder in a steel, motorized grinder. All samples were analyzed for percentage of total nonstructural carbohydrates

using a phenol–sulfuric acid colorimetric method that determines percent total nonstructural carbohydrate expressed as percent glucose equivalents (Hodge and Hofreiter, 1962). Concentrations of aluminum, boron, calcium, cadmium, copper, iron, manganese, magnesium, nitrogen, phosphorus, potassium, silicon, sodium, titanium, and zinc were determined using an inductively coupled plasma spectrometer as described in Snyder (1992).

Oleoresin flow rates were measured for intraspecific comparisons only. Rates were determined by tapping the xylem of trees according to methods modified slightly from those of Smith (1977) as detailed by Snyder (1992). Within each site, all trees were tapped within a 3-hr period on the same day because flow rates can vary with ambient temperature (Smith, 1977). Xylem oleoresin collected from individual trees was analyzed subsequently by gas–liquid chromatography for percentage composition of nine monoterpenes found in measurable quantity (α-pinene, β-phellandrene, β-pinene, camphene, 3-carene, limonene, myrcene, γ-terpinene, and terpinolene). Handling and analysis of oleoresin samples were performed according to methods modified slightly from Smith (1977) as detailed in Snyder (1992).

RESULTS

Chemical characteristics of phloem differed significantly between ponderosa and lodgepole pines (Table 1). Eleven of 15 elements showed significant differences, and 13 of 15 elements were found at higher concentrations in phloem of lodgepole pine than in phloem of ponderosa pine. Monoterpene characteristics of oleoresin also differed markedly, with ponderosa pine containing variable levels of nine monoterpenes that were found in measurable amounts (α-pinene, β-phellandrene, β-pinene, camphene, 3-carene, limonene, myrcene, γ-terpinene, and terpinolene), and lodgepole pine characterized by measurable quantities of only β-phellandrene (Table 1). Discriminant function analysis based on chemical characteristics of phloem correctly classified 100% of trees as either *P. ponderosa* or *P. contorta*; levels of boron and zinc contributed most to the discriminant function.

At the intraspecific level, there were significant differences in phloem characteristics between ponderosa pines infected with dwarf mistletoe and those free from infection (Table 2). Seven of 15 elements showed differences significant at the 0.05 level. Discriminant fucntion analysis based on chemical features of phloem correctly classified 95% of the trees (57 of 60) used in the analysis as parasitized or nonparasitized. Relative concentrations of boron, magnesium, and manganese (Table 2) contributed most to the discriminant function. At the intraspecific level, discriminant function analysis based on xylem oleoresin characteristics (monoterpene composition and flow rate) correctly classified 62% of

ponderosa. Approximately half the elements in phloem show the same trend at the intra- and interspecific levels (Tables 1 and 2). β-Phellandrene, the only monoterpene found in measurable quantity in xylem oleoresin of *P. contorta*, was not found in significantly different percentage compositions in parasitized and nonparasitized *P. ponderosa*.

DISCUSSION

When dwarf mistletoes disperse their seeds in multiple directions, the propagules can land on many potential hosts. The random component of dispersal may be overcome by differential mortality on various hosts, as evidenced by variable densities of infection even on adjacent trees. Our results indicate that adjacent trees, whether they are the same or different species, often have very different biochemical features and that some of these features can be associated with the presence or absence of dwarf mistletoe colonies. Discriminant function analysis based on phloem chemistry correctly classified 100% of the trees used in the interspecific analysis as either *P. ponderosa* (primary host) or *P. contorta* (occasional host). These findings might be expected when comparing biochemical features of different species. However, our intraspecific comparisons of parasitized and nonparasitized trees showed that differences in biochemical features separated them with nearly the same level of discrimination as in the interspecific comparisons: discriminant function analysis based solely on phloem chemistry correctly classified 57 of the 60 trees (95%) as either parasitized or nonparasitized. This high level of discrimination suggests that host biochemistry may be at least partly responsible for the patchy distribution of the dwarf mistletoe *A. vaginatum* within populations of its primary host, *P. ponderosa*.

In order for host biochemistry to be an important determinant of dwarf mistletoe establishment, the differences we have documented between host and nonhost trees must exist prior to dwarf mistletoe attack; that is, they must be constitutive. An alternative is that these differences have somehow been induced by infection, perhaps representing defensive responses or other parasite-induced chemical/physiological interactions. We believe that most of the differences are, in fact, constitutive and reflect a genetically based biochemical heterogeneity. There is very strong evidence from ponderosa pine (Smith, 1977), other pine species (Squillace, 1971), and many other plants (e.g., Vernet et al., 1986) that there is a well-defined genetic basis for oleoresin monoterpene composition and flow rate; indeed the production of specific monoterpenes is controlled by single loci in the species referred to. There is also strong evidence that elemental accumulation in various plant tissues, including phloem, has a hereditary basis; this is also true both for conifers (e.g., MacLean and El Kassaby, 1986) and other plants (e.g., Roy, 1982; Clark, 1983). The demonstrated hereditary bases of phenotypic biochemical variability in ponderosa pine, even in the absence of dwarf mistletoe involvement (e.g., Smith, 1977; Snyder, 1992; Snyder and Linhart, 1994; Linhart et al., 1995), indicate that these stands consist of highly variable trees, i.e., comprise a highly heterogeneous substrate upon which dwarf mistletoes can potentially germinate and survive.

An alternative explanation to the chemical differences between host and

nonhost trees is that they are induced by dwarf mistletoe attack. This explanation may be relevant for at least three specific features of these trees: levels of carbohydrates and of α-pinene and the oleoresin flow rate. Dwarf mistletoes are known to secrete hormones that can lead to the accumulation of carbohydrates near the site of infection (Livingston et al., 1984). Therefore the higher levels of nonstructural carbohydrates we detected in parasitized trees may reflect this phenomenon, although we were careful to collect phloem well away from visibly infected sites and only from branches that showed no visible signs of infection. Levels of α-pinene and other monoterpenes may sometimes increase following attacks by insects such as *Dendroctonus* bark beetles (Lieutier et al., 1989) and in response to mechanical wounding (Marpeau et al., 1989). Oleoresin flow rate is known to have a strong hereditary component, but there is also evidence that trees stressed either by drought or parasitic attacks can have reduced rates of flow (Scharpf and Parmeter, 1978; Smith, 1977).

A potential complication in comparing characteristics of parasitized and nonparasitized trees is that apparently uninfected trees may have dwarf mistletoe endophytic growth with no external evidence of infection. However, in such trees infection is clearly in remission or at very low levels and has little impact upon tree health. Further, we attempted to minimize any potential complications from undetected endophytic growth by comparing trees that had no visible sign of infection with carefully matched trees that supported large numbers (20 to several hundred) of dwarf mistletoe individuals.

In summary, we are aware of the possibility that induction and other ecological factors such as soil heterogeneity may provide a partial explanation for some of the observed differences. However, we believe most of the differences we see are constitutive for the following reasons: (1) in pines, including ponderosa pine, monoterpene induction is responsible for only a small fraction of the documented heterogeneity (Squillace, 1971; Smith, 1977); (2) the trees we sampled grew within small areas, with relatively homogeneous soil and exposure characteristics; and (3) it appears unlikely that pines undergo simultaneously significant selective accumulation (e.g., B, Mg, Tn) and elimination (e.g., Al, Cu, Mn) of individual elements in response to parasite attacks. We are presently engaged in further tests of the possible importance of induction. The most definitive experiments involve experimental infection of trees with the parasite, and testing of tree biochemistry prior to and at intervals following infection.

Differences in biochemical characteristics of the primary (*P. ponderosa*) and secondary (*P. contorta*) host species do not correspond to differences between host and nonhost ponderosa pine. The two host species are biosystematically quite different, belonging to different subsections of the genus (Critchfield and Little, 1966). These differences are associated with differences in biochemical composition: lodgepole pine phloem contains markedly higher

levels of many elements than ponderosa pines growing intermixed with them, suggesting some fundamental differences in uptake/processing of elements, while nonstructural carbohydrate levels are remarkably similar. In addition, the almost uniform oleoresin monoterpene profiles of lodgepole pines contrast sharply with the tree-to-tree heterogeneity of ponderosa pine. Parasitized ponderosa pines, compared with nonparasitized conspecifics, had higher concentrations of some elements and monoterpenes and lower concentrations of others. It is hardly surprising, then, that intra- and interspecific comparisons do not match. These results point out that the heterogeneity of the potential environment for *A. vaginatum* is very great, and contributes to the complex selection pressures facing these organisms.

The patterns of differential establishment and host utilization we describe may have several important genetic consequences. At the interspecific level, the marked chemical differences in phloem and xylem oleoresin between ponderosa and lodgepole pines provide the opportunity for genetic differentiation between dwarf mistletoe subpopulations that parasitize these two host species. We have evidence for such differentiation at the Nederland site and at another site in Colorado where *A. vaginatum* parasitizes both lodgepole and ponderosa pine (Linhart et al., 1994). There is evidence that host race formation can occur in other dwarf mistletoe species although it may not necessarily occur under conditions of sympatry (e.g., Nickrent and Stell, 1990).

At the intraspecific level, the dwarf mistletoe *A. vaginatum* can create significant selective pressures upon ponderosa pine populations. This parasite is by far the most damaging disease agent of ponderosa pine in the southwestern United States. It routinely reduces the growth and reproductive output of its host trees by 50% or more compared with uninfected trees and often kills its hosts in the long run (Hawksworth and Wiens, 1972; Scharpf and Parmeter, 1978; Linhart and Snyder, in preparation). This reduction in host fitness, coupled with evidence that there is a strong hereditary basis for elemental accumulation (MacLean and El Kassaby, 1986) and oleoresin composition (Squillace, 1971; Smith, 1977) in various conifers, suggests a possible mechanism for the evolution of host resistance to this parasite in ponderosa pine. Such resistance to *Arceuthobium* has indeed been reported in both ponderosa and the related Jeffrey pine (*P. jeffreyi*) (e.g., Roth, 1974; Scharpf et al., 1992).

In conclusion, (1) biochemical features of both phloem and xylem oleoresin differ significantly between the primary and occasional host of *A. vaginatum*. This may provide the opportunity for genetic differentiation between dwarf mistletoe subpopulations that parasitize different host species. (2) Significant biochemical differences between parasitized and non-parasitized ponderosa pines may be partly responsible for the patchy distribution of attack by *A. vaginatum* within populations of its primary host. (3) The lack of congruence between these

intra- and interspecific chemical differences underscores the complex nature of selection pressures facing *A. vaginatum*.

Acknowledgments—We thank the late F. Hawksworth, and A. Benedict, R. Reynolds, W. Shepperd, and C. Southwick for stimulating discussion on dwarf mistletoe ecology and chemical mediation of parasite-host interactions; and J. Phelps, A. Premoli, P. Gibson, and B. Snyder for assistance in the field. Two anonymous reviewers provided constructive criticisms of an earlier version of the manuscript. The work was supported by the National Science Foundation (BSR 8918478 and DEB 9120065).

(Received March 20, 1995; accepted October 15, 1995)

Abstract—Female *Cotesia flavipes* Cameron and *Cotesia sesamiae* (Cameron) were attracted to odors in a Y-tube olfactometer from uninfested maize (*Zea mays* L.), sorghum [*Sorghum bicolor* (L.)], and napier grass (*Pennisetum purpureum* Schumach). In dual choice tests, *Cotesia flavipes* showed a preference for maize over sorghum, while maize and napier grass were equally attractive. In contrast, *Cotesia sesamiae* preferred volatiles from sorghum and napier grass over those from maize. The two parasitoids were significantly more attracted to maize infested with the stemborers, *Chilo partellus* (Swinhoe), *Chilo orichalcociliellus* Strand, *Sesamia calamistis* Hampson, and *Busseola fusca* (Fuller), than uninfested maize. In dual choice tests, *Cotesia flavipes* and *Cotesia sesamiae* were unable to discriminate between odors from plants infested by the different species of stemborers.

Key Words—Host location, host habitat location, *Cotesia flavipes*, *Cotesia sesamiae*, Hymenoptera, Braconidae, cereals, parasitoid, stemborers, Lepidoptera, Pyralidae, Noctuidae, Y-tube olfactometer.

INTRODUCTION

Classical biological control has been used as a strategy for suppressing populations of introduced lepidopteran pests in the tropics. The success of classical biological agents has been attributed in part to the high searching efficiency of the natural enemy for its host (Waage, 1990). The ability of a natural enemy to locate a suitable host in a complex environment is critical to its successful establishment in a new environment (Nordlund et al., 1988). The host selection process is divided into three steps: host habitat location, host location, and host acceptance (Vinson, 1976). Allelochemicals are known to play an important role in this process. Chemicals emitted by plants influence the searching behavior of parasitoids (Nordlund et al., 1988; Lewis and Martin, 1990; Vet and Dicke, 1992; Dicke, 1994; Godfray, 1994). In addition, females of many insect parasitoids may rely on host and host-related chemicals (e.g., from frass) in their search for hosts (Vinson, 1976; Weseloh, 1981; Arthur, 1981; Vet and Dicke, 1992). However, host-produced chemicals often play a much less important role in long-distance searching by parasitoids than do plant-produced chemicals (Turlings et al., 1991a,b; Vet and Dicket, 1992; Steinberg et al., 1993; Geervliet et al., 1994; Potting et al., 1995a).

Chilo partellus (Swinhoe) (Pyralidae) is one of the major lepidopterous stemborer pests of cereal crops in Kenya (Overholt et al., 1994a). This pest was introduced into Africa sometime in the early 1930s (Tams, 1932). Indigenous natural enemies, including the larval parasitoid, *Cotesia sesamiae* (Cameron), are not able to maintain the pest population density at a level acceptable to farmers (Oloo, 1989; Overholt et al., 1994a). *Cotesia flavipes* Cameron, which has been used successfully in classical biological control of gramineous stemborers in other parts of the world (Overholt et al., 1994b), was introduced into Kenya from Pakistan in an attempt to reduce the severity of the stemborer problem.

Chilo partellus is found in cultivated gramineous plants together with indigenous stemborer species, which include *Chilo orichalcociliellus* Strand (Pyralidae), *Busseola fusca* (Fuller), and *Sesamia calamistis* Hampson (Noctuidae). The same complex of stemborer species is also found on wild grasses (Mathez, 1972; Seshu Reddy, 1989; Harris, 1990). Little is known about the foraging behavior of *Cotesia flavipes* and *Cotesia sesamiae* in the system comprising the stemborers and plants mentioned above. It was reported that *Cotesia flavipes* cannot discriminate between maize infested with *Chilo partellus* and maize infested with *B. fusca* (Potting et al., 1993). However, *Cotesia flavipes* showed a preference for maize stems with feeding *Chilo partellus* larvae over artificially damaged maize, larvae alone, host frass, or uninfested maize (Potting et al. 1995a). It is not known whether this parasitoid is attracted to the different

gramineous plants (which are the food of its hosts, e.g., maize, sorghum, napier grass) occurring in the area of release, the coast of Kenya. It is also not known whether *Cotesia flavipes* has a preference for any of these host plants either uninfested or infested by larvae of different stemborer species (*Chilo orichalcociliellus, Chilo partellus, S. calamistis*) occurring in that area. No information is available on the host selection process of the closely related indigenous parasitoid, *Cotesia sesamiae*. The extent of overlap in the niches of the two *Cotesia* species also is not known. The aim of this study was, therefore, to investigate the response of *Cotesia flavipes* and *Cotesia sesamiae* to volatiles from uninfested maize, sorghum and napier grass and the response of both parasitoids to volatiles from different stemborer–plant complexes that are likely to be found in the area of release.

METHODS AND MATERIALS

Parasitoids

A colony of *Cotesia flavipes* was started in 1991 from material collected from *Chilo partellus* at Rawalpindi, Pakistan, by the International Institute of Biological Control (IIBC). The *Cotesia sesamiae* colony was also started in 1991 with material collected from *Chilo partellus* in the coastal zone of Kenya. *Cotesia flavipes* and *Cotesia sesamiae* were reared on *Chilo partellus* and *S. calamistis* larvae, respectively, according to the method described by Overholt (1993). *Chilo partellus* and *S. calamistis* are among the respective natural hosts of *Cotesia flavipes* and *Cotesia sesamiae*. After parasitization, stemborers were maintained on artificial diet (Ochieng et al., 1985; Onyango and Ochieng'-Odero, 1994) at 25°C, 65–70% relative humidity, and 12L:12D photoperiod. Parasitoid cocoons were collected in glass vials and kept in a clean Perspex cage until emergence of adults. Adult parasitoids were provided a 20% honey–water solution as diet. One-day-old, mated, naive female parasitoids were used in all experiments.

Stemborers

Chilo partellus, S. calamistis, and *Chilo orichalcociliellus* were collected from maize fields near the Kenyan coast. A colony of *B. fusca* was initiated with larvae and pupae collected from maize in western Kenya. Larvae of *Chilo* spp. were reared on an artificial diet developed by Ochieng et al. (1985). The noctuids, *B. fusca* and *S. calamistis*, were reared on media described by Onyango and Ochieng'-Odero (1994). Prior to any experiment, stemborer larvae were removed from artificial diet and fed on fresh maize stems for 48 hr.

Plants

Maize (*Zea mays* L., hybrid 5-11) and sorghum [*Sorghum bicolor* (L.), Serena cultivar], were grown in 20-liter plastic buckets in a nursery at the International Centre of Insect Physiology and Ecology (ICIPE). Potted plants were kept under large field cages (2 × 2 × 2 m), which were covered with fine mesh (400 μm) netting to protect them from insect attack. Additional maize plants were grown in the field. Napier grass (*Pennisetum purpureum* Schumach.) was collected from farmers' fields near Nairobi.

Behavior Assays

The Y-tube olfactometer used in this study has been described by Steinberg et al. (1992). The odor sources were placed in two Perspex chambers (30 × 30 × 120 cm) sufficiently large to accommodate whole plants (2–3 months old) (Figure 1). One of the square ends of the chamber was left open. For the system

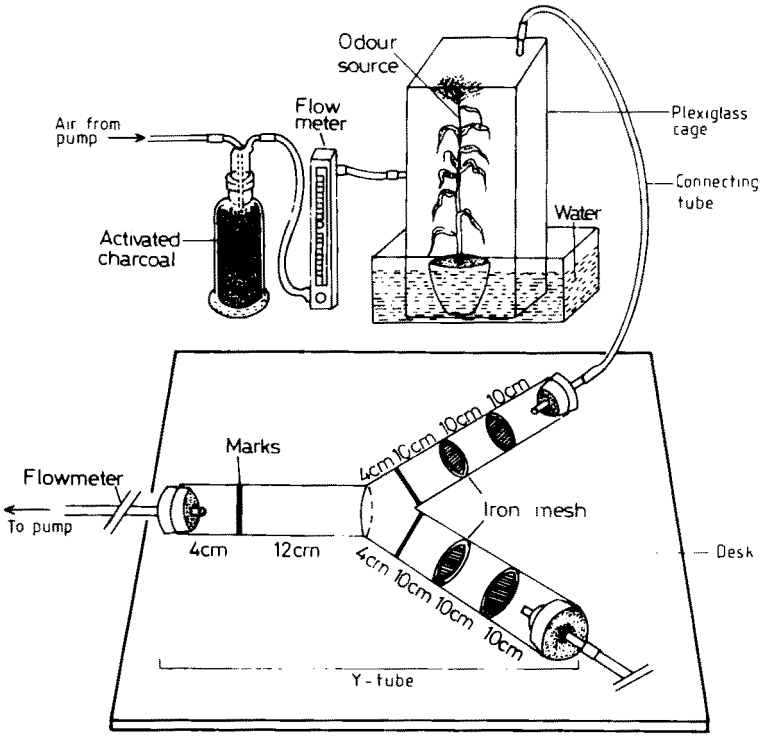

FIG. 1. A schematic diagram of the Y-tube olfactometer.

to be airtight, the open end of each box was placed over the test material, which stood in water held in a plastic basin. The open end was submerged 15 cm below the meniscus. The two chambers were connected to the arms of the Y-tube with Tygon tubing from the top of the chambers. An inlet, through which clean air entered the chamber, was drilled 30 cm from the bottom of the chamber on one side. One vacuum pump (Cole-Parmer Air-Cadet) drew and pushed air through the closed system. Air was pushed through an activated charcoal filter into the two chambers and drawn into the Y-shaped glass tubing of the olfactometer. The airflow was set at 2.5 liters/min for each arm. Parasitoids were released individually in the stem of the Y-tube and allowed 5 min to choose one of the arms. When a parasitoid remained more than 15 sec beyond the finishing line (4 cm past the intersection), it was recorded as a choice. The connections of the odor source chambers to the arms of the olfactometer were reversed after testing five insects to rule out the effect of asymmetrical bias in the olfactometer or its surroundings. A cream-white curtain was used to separate the experimental area from the surroundings. Tests were conducted at 23–26°C, 65–75% relative humidity, and light intensity of 350–450 lux. All tests were replicated at least three times with 20 parasitoids per replicate. Data were analyzed using the log likelihood ratio test (G test) for goodness of fit (Sokal and Rohif, 1981).

Response to Volatiles from Uninfested Plants. Uninfested maize, sorghum, and napier grass plants 8–10 weeks old were used in the experiments. All plant species were tested in single and dual choice experiments in the Y-tube olfactometer.

A first series of experiments was conducted to determine the attractiveness of odors from uninfested plants. Maize, napier grass, and sorghum were tested in single choice experiments. Individual parasitoids were given a choice between odor from potted maize and air drawn over a pot with soil only, odors from potted sorghum plant and air drawn over a pot with soil only, and finally odor from napier grass cut above the soil level and air drawn over an empty chamber.

A second series of tests was conducted to determine the parasitoid's preference for odors from different uninfested plant species. Plants were placed in chambers connected to both arms of the olfactometer. An approximately similar biomass of plants was used for each arm. Attractiveness of volatiles from potted maize was compared with attractiveness of volatiles from potted sorghum, and odors from maize plants from the field excised above soil level were compared with that of napier grass treated the same way. Field materials were checked for damage before each test and dissected after a test to establish it was uninfested.

Response to Volatiles from Plants Infested by Different Stemborer Species. In the Y-tube olfactometer, parasitoids were given a choice between odors from plants infested with different stemborer species [plant–herbivore complex (PHC)]

and uninfested plants. The following PHC combinations were tested against the control (uninfested plants): (1) maize plants infested with *Chilo partellus*, (2) maize plants infested with *Chilo orichalcociliellus*, and (3) maize plants infested with *S. calamistis*. Potted maize plants were infested with two fourth instars by boring two holes in the maize stem (1 cm deep) with a 4-mm cork borer and placing one larva in each hole. Larvae were allowed to feed overnight, and tests were conducted 18–20 hr after infestation. Holes were also made in control plants, but no larvae were introduced. Plants were transferred into the chambers connected to the Y-tube in the pot in which they were grown 30 min before observations were made (to allow time for volatiles to be released in the chamber). Only plants grown in pots were used in this test. In a few cases potted plants that were too tall to enter the test chamber were excised and tested. Plants in both arms were treated in the same manner (cut at the base or kept in pots).

A second series of tests was conducted to determine the parasitoids' preference between plants infested by different stemborer species. The following combinations were tested: (1) maize infested with *Chilo partellus* larvae versus maize infested into *Chilo orichalocociliellus* larvae, (2) maize infested with *Chilo partellus* larvae versus maize infested with *S. calamistis* larvae, and (3) maize infested with *Chilo partellus* larvae versus maize infested with *B. fusca* larvae [only *Cotesia sesamiae* was used for the test with *B. fusca; Cotesia flavipes'* response having already been studied by Potting et al. (1993)].

A third series of tests was conducted to determine the response of parasitoids depending on the number of stemborer larvae feeding of the plant. The following number/species combinations of stemborers per plant were compared: (1) two *Chilo partellus* versus 10 *S. calamistis*, (2) five *Chilo partellus* versus five *S. calamistis*, (3) 10 *Chilo partellus* versus two *S. calamistis*, and (4) two *B. fusca* versus ten *Chilo partellus* larvae.

RESULTS

Response to Volatiles from Uninfested Plants. Cotesia flavipes and *Cotesia sesamiae* were more attracted to odors from gramineous plants (maize, sorghum, napier grass), the habitat of their host, than to the control, clean air (Figure 2). *Cotesia flavipes* did not exhibit a preference between maize and napier grass (Figure 3). However, maize was preferred over sorghum by *Cotesia flavipes*, whereas *Cotesia sesamiae* preferred sorghum over maize (Figure 3). The preferences of the two parasitoids significantly differed (contingency table, $\chi^2 = 16.71$, $df = 1$; $p < 0.001$); *Cotesia sesamiae* also preferred napier grass over maize (Figure 3).

Response to Maize Plants Infested by Different Stemborer Species. Parasitoids of both species preferred odors from maize plants infested with two larvae

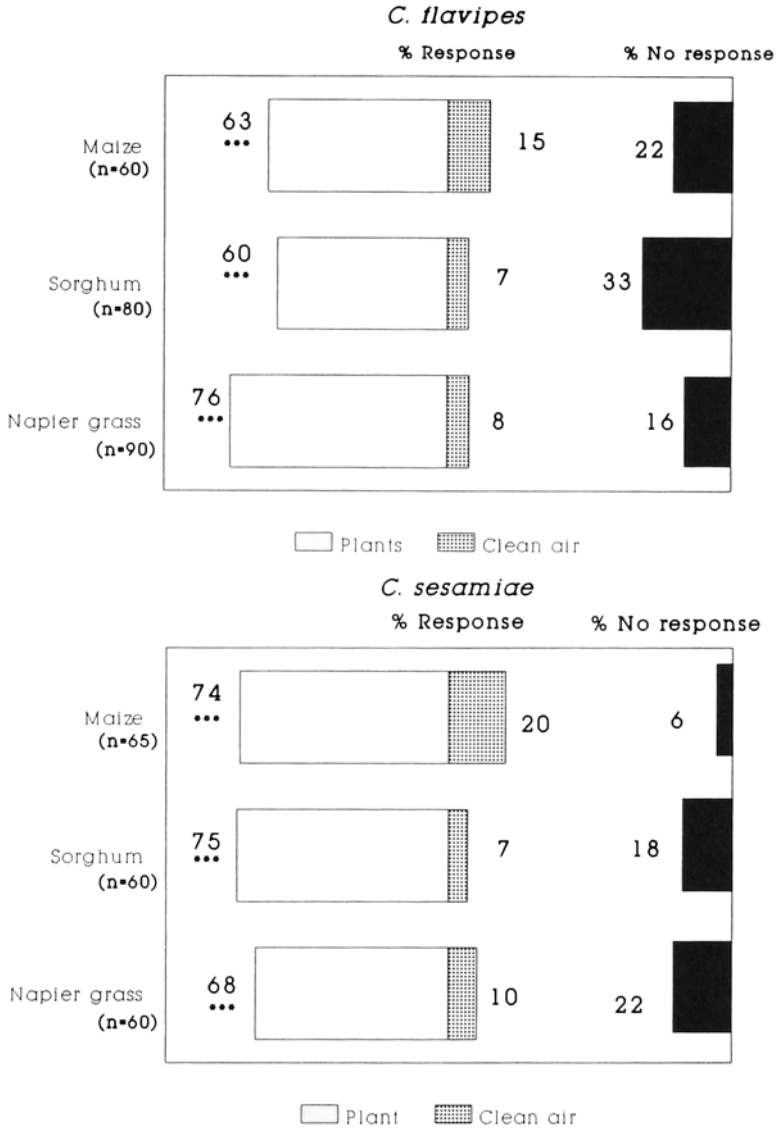

FIG. 2. Response of naive *Cotesia flavipes* and *Cotesia sesamiae* to odors from uninfested plants versus clean air in a Y-tube olfactometer. N = number of replicates. Numbers next to the bars indicate the percentages of parasitoids that made a choice for one of the two odor sources or did not make a choice at all. The three percentages add up to 100%. Asterisks indicate significant differences within the choice test: $*P < 0.05$, $**P < 0.01$; $***P < 0.001$, ns = not significant, G-test for goodness of fit.

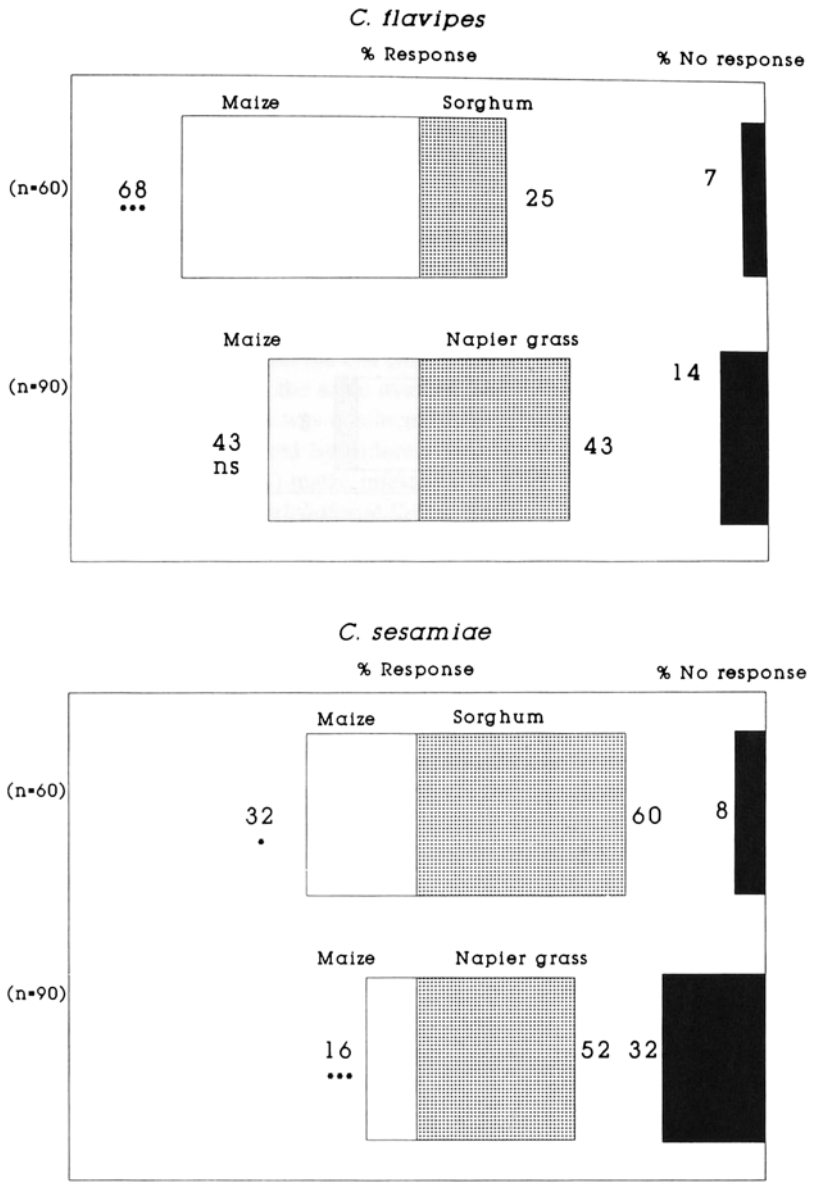

FIG. 3. Response of naive *Cotesia flavipes* and *Cotesia sesamiae* to odors from uninfested plants in two-choice tests in the Y-tube olfactometer. For other explanations see legend of Figure 1.

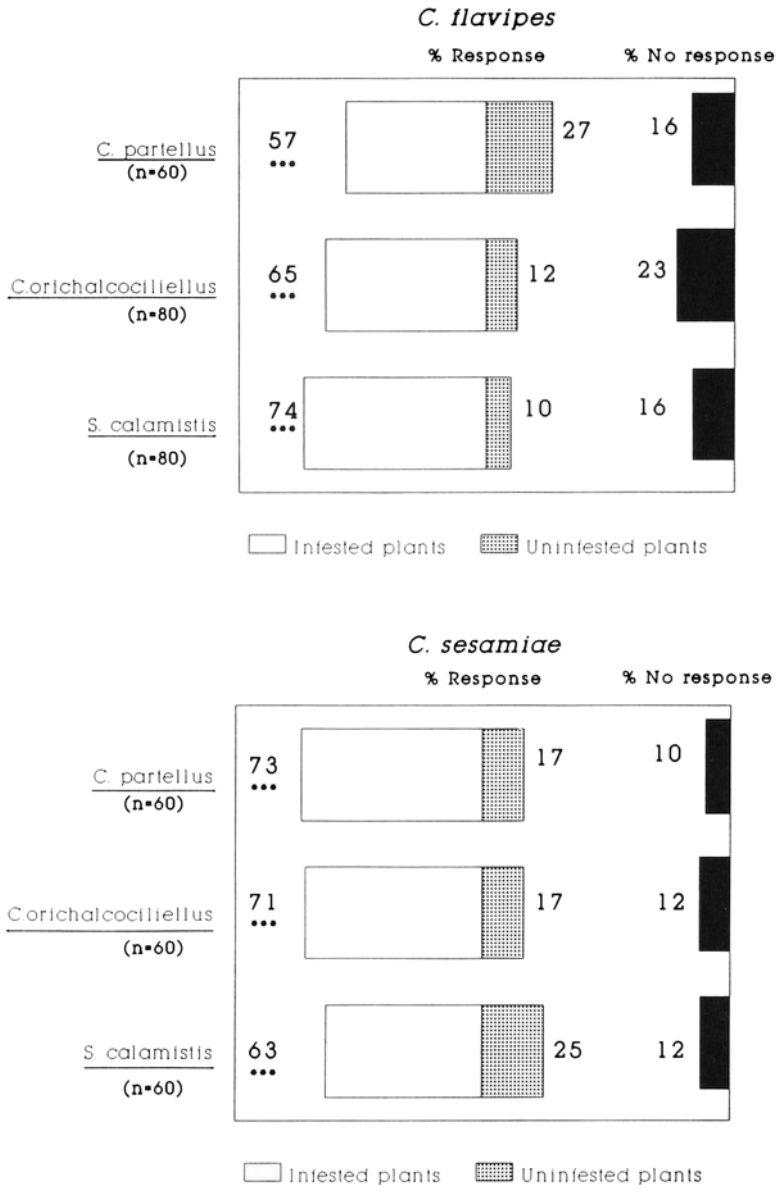

FIG. 4. Response of naive *Cotesia flavipes* and *Cotesia sesamiae* to odors from maize plants infested with different stemborer species versus uninfested maize plants in a Y-tube olfactometer. For other explanations see legend of Figure 1.

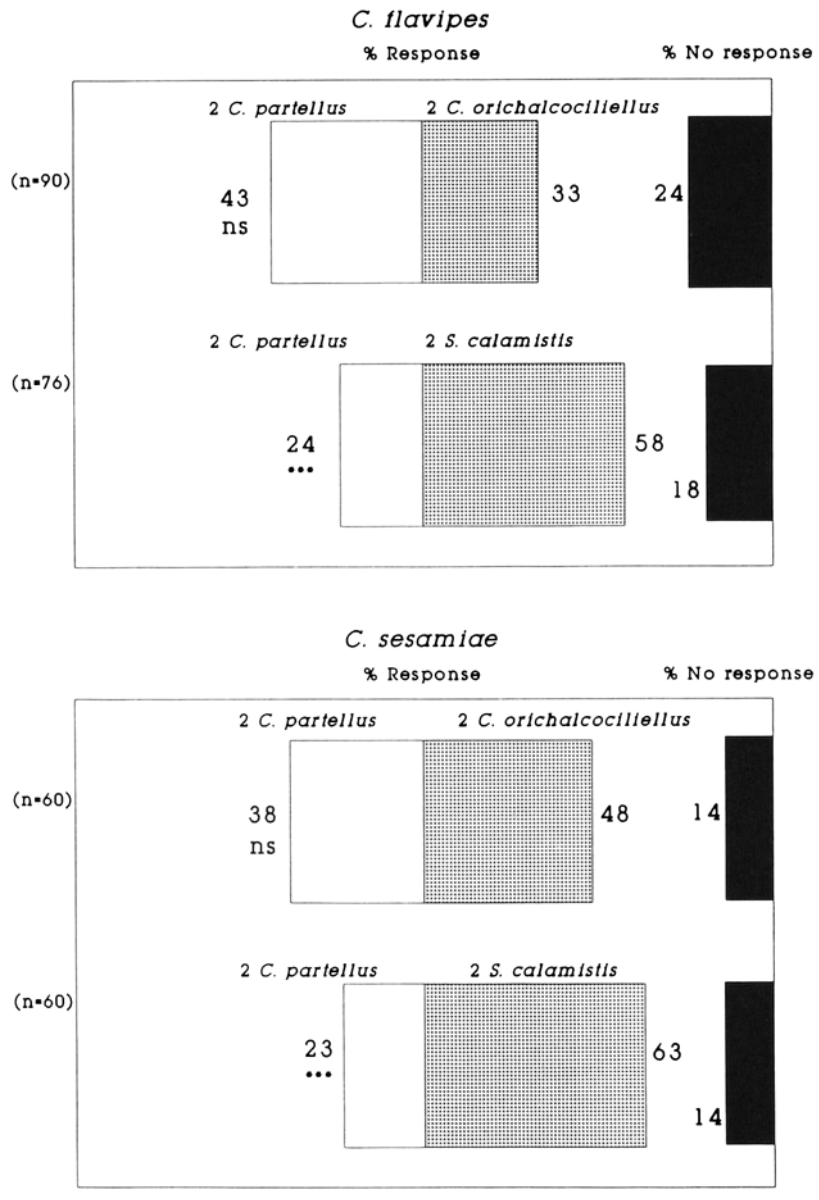

FIG. 5. Response of naive *Cotesia flavipes* and *Cotesia sesamiae* in the Y-tube olfactometer to odors from maize plants infested with two stemborer larvae per plant, in two-choice tests. For other explanations see legend of Figure 1.

of *Chilo partellus*, *S. calamistis*, or *Chilo orichalcociliellus*, per plant, over odors from uninfested maize plants (Figure 4).

When maize plants infested with two larvae of one of two species were offered in dual choice situations, both parasitoid species preferred odors of plants infested by *S. calamistis* over those infested with *Chilo partellus*. Neither parasitoid species discriminated between maize plants infested with two *Chilo partellus* larvae and maize plants infested with two *Chilo orichalcociliellus* larvae (Figure 5).

Several other combinations were tested with *Chilo partellus* and *S. calamistis* as herbivores. When maize plants infested by two larvae of one species were offered versus plants infested by 10 larvae of the other, *Cotesia flavipes* preferred odors from maize plants infested with 10 larvae in both cases. When odors from plants infested with five *Chilo partellus* larvae were offered versus odors from plants infested with five *S. calamistis* larvae, *Cotesia flavipes* females did not discriminate (Figure 6).

Cotesia sesamiae preferred odors from maize plants infested with two larvae of *B. fusca* over odors from uninfested maize. This parasitoid also preferred

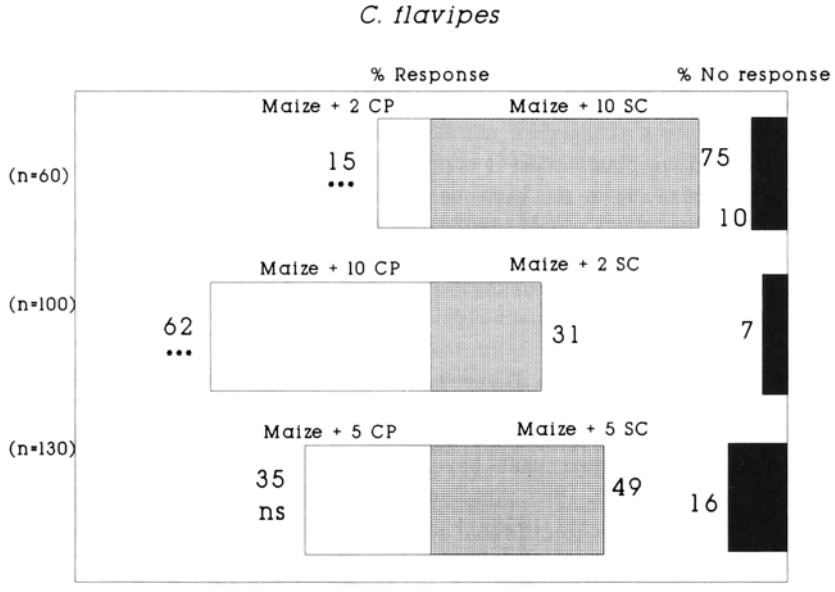

FIG. 6. Response of naive Cotesia flavipes in the Y-tube olfactometer to odors from maize plants infested with larvae of *Chilo partellus* (CP) or *Sesamia calamistis* (SC) at different densities. For othr explanations see legend of Figure 1.

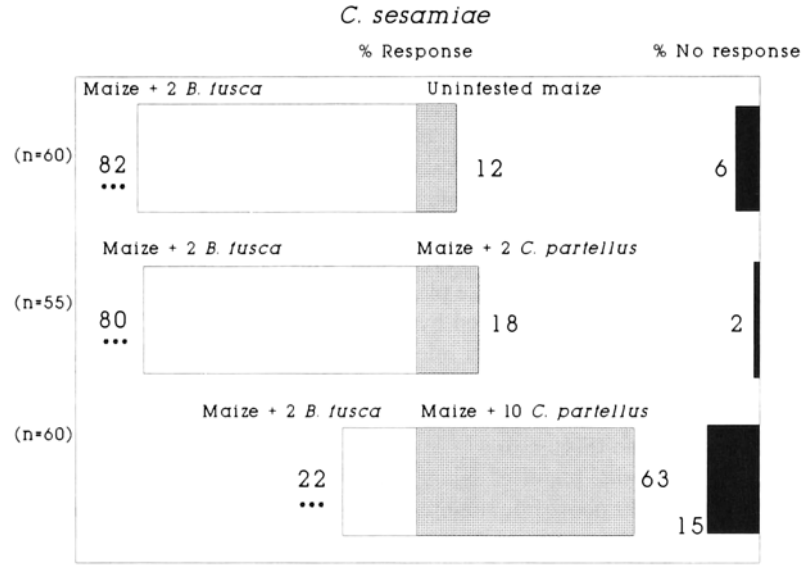

FIG. 7. Response by naive *Cotesia sesamiae* in the Y-tube olfactometer to odors from uninfested maize plants and maize plants infested with larvae of *B. fusca* and plants infested with larvae of *Chilo partellus* or *B. fusca* at different densities. For other explanations see legend of Figure 1.

odors from maize plants infested with *B. fusca* over odors from those infested with *Chilo partellus* at the same density (two larvae per plant) (Figure 7). However, when plants where infested with 10 *Chilo partellus* larvae and two *B. fusca* larvae, *Cotesia sesamiae* showed preference for odors emanating from plant infested with *Chilo partellus* (Figure 7).

DISCUSSION

Plant odors play an important role in communication in tritrophic systems. Volatiles from uninfested plants have been found to be long-range attractants for parasitoids (Vinson, 1985; Nordlund et al., 1988; Whitman, 1988; Williams et al., 1988; Lewis et al., 1990). For example, *Campoletis sonorensis* (Cameron) is attracted to uninfested food plants of its hosts (Elzen et al., 1983). *Macrocentrus grandii* Goidanich, a larval parasitoid of the European corn borer, *Ostrinia nubilalis* (Hübner), is also attracted to several plant species including its host's food, uninfested maize (Ding et al., 1989). In the present study, *Cotesia flavipes* and *Cotesia sesamiae* were strongly attracted to odors emanating

from several gramineous plants (maize, sorghum, and a wild host, napier grass), which are host plants of stemborers. In all single-choice tests, the gramineous plant was selected over the control, regardless of the plant species. *Cotesia flavipes* showed a preference for maize over sorghum in the dual choice experiments. This parasitoid was imported from Pakistan, where it was collected from *Chilo partellus* in maize fields. This preference may, therefore, be a reflection of a genetic adaptation to searching in maize. In contrast, the indigenous parasitoid *Cotesia sesamiae* was more attracted to sorghum odors, and this may have been due to a genetic adaptation as well: there has been a long history shared by *Cotesia sesamiae* and sorghum, which has its center of origin in Africa (Doggett, 1988). Except for a few records showing *Cotesia flavipes* attacking *Diacrisia obliqua* Walker and *Porthesia scintillans* Walker, feeding on castor in India (Muthukrishnan and Senthamizhselvan, 1987; Senthamizhselvan and Muthukrishnan, 1989), *Cotesia flavipes* and *Cotesia sesamiae* have been collected only from noctuid and pyralid hosts feeding on gramineous plants (Polaszek and Walker, 1991). This specificity suggests that plants provide important cues to the searching parasitoids. Similarly, it was reported that taxonomically unrelated hosts feeding on the same species of plants frequently shared the same parasitoids (Picard and Rabaud, 1914) and that the amount of parasitism suffered by a polyphagous host species may often depend on the food plant attacked (Vinson, 1981, 1985; Nordlund et al., 1988).

Cotesia flavipes and *Cotesia sesamiae* preferred odors from infested plants over odors from uninfested plants, indicating that both parasitoids were able to identify plants attacked by their hosts. Similar findings have been reported in several tritrophic systems [see Vet and Dicke (1992) for a review]. Dicke et al. (1990a,b) reported that Lima bean and cucumber plants infested with two spotted spider mites, *Tetranychus urticae* Koch, emitted a blend of volatiles that attracted the predatory mites *Phytoseiulus persimilis* Athias-Henriot. Turlings et al. (1990a,b; 1991a,b) found that maize plants damaged by the beet armyworm [*Spodoptera exigua* (Hübner)] emitted volatile chemicals that were attractive to the parasitoid *Cotesia marginiventris* (Cresson).

Odors from maize plants infested with two *S. calamistis* were more attractive to *Cotesia flavipes* and *Cotesia sesamiae* than odors from maize plants infested with a similar number of *Chilo partellus* larvae. *Sesamia calamistis* is a larger stemborer and feeds more voraciously than *Chilo partellus*, thereby inflicting greater injury to the plant and producing greater quantities of frass. The quantities of volatiles emitted may be proportional to the amount of plant injury, and that could explain the greater attraction to plants infested with *S. calamistis*. This hypothesis is supported by the fact that a larger number of hosts on a plant increased attractiveness (Figure 6). Similar observations were made when *Cotesia sesamiae* was exposed to odors from plants infested with *B. fusca*, also a large stemborer, and *Chilo partellus* (Figure 7). In a related study, Potting

et al. (1993) found that odors from maize plants infested with two larvae of *B. fusca* were more attractive to *Cotesia flavipes* than odors from maize plants infested with two larvae of the smaller *Chilo partellus*. These results strongly suggest that the two parasitoids are not able to discriminate between maize plants infested by the four herbivore species under study and that they both seem to use a similar set of stimuli to locate their hosts. In contrast, *Cotesia marginiventris*, which is a generalist parasitoid of numerous species of leaf-feeding insects on a wide range of plants, is able to distinguish between odors of two different plants fed on by the same host and also between two different host species feeding on the same plant species (Turlings et al., 1989). Different herbivore species may cause a differential release of plant compounds that can be detected by parasitoids after experience (Turlings et al., 1990a). For *Cotesia flavipes*, however, learning has not been detected (Potting et al., unpublished data), possibly because the insects live for only 2–3 days (Moutia and Courtois, 1952; Gifford and Mann, 1967; Kajita and Drake, 1969; Potting et al., 1995b). Because of their short life-span, females of *Cotesia flavipes* may search primarily within the habitat where they emerge and may have adapted to attacking all lepidopterous stemborers occurring in that habitat.

Cotesia flavipes was released in the coastal area of Kenya in 1993. The primary target of this biological control program was the introduced stemborer *Chilo partellus*. However, two other stemborer species, *S. calamistis* and *Chilo orichalcociliellus*, occur in the same ecosystem. During the two cropping seasons (long rains, April–June; short rains, October–December), all three stemborer species coexist in maize fields (Overholt et al., 1994a) and in wild grasses (J.C. Mbapila, unpublished data). In periods between cropping seasons, some stemborers estivate in maize stubbles, while others remain actively feeding in wild grasses, including napier grass, in the proximity of cultivated areas (J.C. Mbapila, unpublished data). The results of this study suggest that *Cotesia flavipes* may be able to search and attack all three stemborer species in cultivated and wild grasses during the cropping seasons and in wild grasses during periods between cropping seasons. Moreover, when maize and sorghum are grown in proximity, our results suggest that *Cotesia flavipes* may exhibit a greater propensity for searching in maize.

Cotesia flavipes and *Cotesia sesamiae* are attracted to odors from the same host habitats, which suggests that the niches of the two parasitoids overlap and competition for hosts is likely to occur. However, due to the differences observed in host-plant preference and host suitability (Ngi-Song et al., 1995), both parasitoids may persist in the same region.

APPLE FOLIAGE ENHANCES MATING DISRUPTION OF LIGHT-BROWN APPLE MOTH

D.M. SUCKLING,* G. KARG, and S.J. BRADLEY

HortResearch, P.O. Box 51 Lincoln
Canterbury, New Zealand

(Received April 14, 1995; accepted October 15, 1995)

Abstract—Uptake and release of pheromone and behavioral inhibitor of *Epiphyas postvittanna* by apple leaves was tested using field electroantennograms (EAG), trap catches to synthetic lures and virgin females, and chemical analysis. Trap catches in single apple trees ($N = 3$) were monitored for six cycles of six days' duration, using delta traps baited with synthetic pheromone. Polyethylene dispensers (0, 1, 10 per tree) releasing pheromone and inhibitor were present for only the first three days of each cycle. Application of 10 dispensers per tree resulted in complete disruption of trapping, which continued for one day after dispensers were removed. Over the three nights following the removal of the dispensers (days 4–6), trap catch was 0, 10, and 15% of the control catch. In contrast, the presence of only one dispenser per tree led to 0–20% of control catches, but on the three nights following dispenser removal catches were 35, 40, and 80% of the control catch. Field EAGs indicated significantly higher relative pheromone concentrations in the trees with 10 dispensers present, compared to trees with single dispensers, but removal of dispensers produced no detectable treatment effect compared to the control trees one day after dispenser removal. In a second experiment, releases of marked male moths into apple orchard plots following the removal of polyethylene dispensers (1 hr earlier that day) resulted in significantly lower catches in traps baited with virgin females in blocks that had been treated, compared to controls. Recovery of pheromone by solvent washing of leaves loaded with 50 μg of the main component of the sex pheromone (1.26 $\mu g/cm^2$) was low (2.5%). Leaves held in a pheromone-saturated atmosphere were loaded with 0.045 ± 0.007 μg pheromone/cm^2. Analysis of apple leaves taken from a pheromone-treated tree at different distances from the pheromone dispenser showed a decay of the pheromone load per square centimeter with increasing distance from the dispenser, as previously indicated by EAG.

Key Words—*Epiphyas postvittana*, Tortricidae, mating disruption, pheromone, apple leaves, adsorption, release rate, electroantennogram, EAG, light-brown apple moth.

INTRODUCTION

Adsorption and release of insect sex pheromone has been recorded from several plants (Wall et al., 1981; Noldus et al., 1991; Karg et al., 1990, 1994; Sivinski et al. 1994). Wall et al. (1981) and Wall and Perry (1983) showed the possible behavioral importance of this phenomenon in male pea moth (*Cydia nigricana* F.), which precisely located the previous position of a pheromone trap after its removal. Pea leaves functioned as a secondary source of pheromone and release rates were sufficient for male moths to orient to the vacated position of the odor source. The adsorption and release of pheromone by foliage of brassicas more recently has been described by Noldus et al. (1991). Their aim was to investigate the possible role of plants to bridge the gap between the time of calling of females and the searching behavior of parasitoids. Their experiments showed that plants adsorbed the female sex pheromone and released it over an extended period of time. In addition, they showed that male *Mamestra brassicae* L. was attracted to Brussels sprouts (*Brassica oleraceae* L.) releasing the female sex pheromone.

The impact and potential importance of adsorption and release of pheromone by plants on the temporal and spatial distribution of pheromone in mating disruption has long been neglected. However, experiments by Karg et al. (1990) and Karg and Sauer (1992) showed the importance of grape vines for the pheromone concentration achieved in a vineyard treated with pheromone for mating disruption of the European grapevine moth *Lobesia botrana* Hb. In areas with fully developed vegetation, the pheromone concentration was more than 100-fold higher than the same location without foliage in spring or in a defoliated vineyard nearby (Karg and Sauer, 1992, 1995). In addition, the plant canopy affects the structure of the odor plume, with pheromone more evenly distributed in vineyards with a dense plant canopy. The EAG signal shows more intermittency without vegetation. We reported greater variance of EAG signals recorded above grass, compared to adjacent apple tree rows (Suckling et al., 1994). Bengtsson et al. (1994) also showed that pheromone concentrations were lower above a pea canopy and the EAG signal fluctuated more above than within the canopy, although the signal variance was not examined in detail.

Measurements of the adsorption and release of the pheromone of *Epiphyas postvittanna* (Walker) showed the effect of apple leaves in more detail (Karg et al., 1994). Pheromone released from apple leaves was still detected 24 hr after exposure of the leaves to pheromone. Traps baited with leaves exposed to pheromone caught significant numbers of males for three nights after treatment. EAG

measurements along a transect through a pheromone-treated orchard showed significant differences in the EAG response and therefore in the mean pheromone concentration, with increased concentrations closer to the trees in which the dispensers were present. These results were interpreted as showing that leaves could affect the atmospheric pheromone concentration and its temporal distribution and could thereby enhance the success of mating disruption.

In this study, we hypothesized that the release of pheromone from foliage would be sufficient to disrupt male behavior. Experiments were carried out in order to examine the impact of pheromone adsorption and release on apple trees. In addition, the adsorption by apple leaves of the pheromone and inhibitor of *E. postvittanna* was quantified by chemical analysis.

METHODS AND MATERIALS

Insects. Male and female *E. postvittana* were obtained as pupae from a colony in Auckland, New Zealand. The pupae were then kept at 20°C until eclosion, and kept at 12°C for one to two days before use.

Pheromones. Dispensers containing 54.9 mg (*E*)-11-tetradecen-1-yl acetate (*E*11-14:OAc), 2.5 mg of (*E*,*E*)-9,11-tetradecan-dien-1-yl acetate (*E*9,*E*11-14:OAc), 19.7 mg (*Z*)-11-tetradecen-1-yl acetate (*Z*11-14:OAc) as well as 16.8 mg of other substances such as stabilizers, were obtained from Shin-Etsu Chemicals Co., Tokyo. This blend has the disadvantage that *Z*11-14:OAc inhibits trap catch when presented with the pheromone (Rumbo et al., 1993). However, this blend has been used very successfully in a great number of mating disruption trials (Suckling and Shaw, 1991, 1995; Suckling et al., 1990a, 1994) and was therefore tested in these experiments.

Traps. Standard delta traps (Suckling and Shaw, 1990) with sticky bases, baited with rubber septa containing 100 μg of *E*11-14:OAc and 5 μg of *E*9,*E*11-14:OAc (Bellas et al., 1983) were used. Traps were checked daily and sticky bases changed every 10 days. To avoid contamination, separate traps were used for controls when dispensers were present, and after dispenser removal, for both dispenser treatments. In the second field experiment, these traps were baited with virgin female moths held in gauze canisters (Suckling et al., 1990b).

Electroantennogram Apparatus. The electroantennogram (EAG) apparatus and measuring procedure used in these experiments are described in Karg et al. (1994) and Suckling et al. (1994) in full. Briefly, the insect antenna was held between wells containing Ringer solution and silver–silver chloride electrodes. The antenna holder was placed inside a glass chamber, protecting the antenna from ambient air, with a steady airstream (ca. 2.5 liters/min) through the chamber transporting odors or charcoal-filtered air to the antenna. The signal was amplified, filtered, and stored on a computer. For calibration purposes, a 15-ml

volume of air was blown by a second pump across a rubber septum and into the main airstream. The rubber septum (Arthur H. Thomas, Philadelphia, Pennsylvania) was loaded with 105 μg of the true pheromone blend as used in the delta traps. Three measurements of antennal responses were averaged and normalized to the responses to three calibration pulses in charcoal-filtered air, giving one reading of relative EAG amplitude. Normalizing was defined as $EAG_{ambient\ air}/EAG_{calibration}$. Normalization was necessary because of differences in antennal sensitivity to pheromone, as well as changes over time in the same antenna. Nine EAG readings were made for each day of each treatment. The normalized EAG values for the control sites were subtracted from those taken at treated sites. This value is defined as the differential EAG amplitude.

Field Experiment 1. The trial site was a mixed cultivar orchard block (5 m between rows, 5 m within row tree spacing), at the Lincoln University Biological Husbandry Unit. This site was chosen due to its spray-free status and a history of high *E. postvittana* catches during past seasons. Three trees in each block (three blocks) were chosen with similar foliage cover, with at least one guard tree between experimental trees. Each tree had three trap sites marked approximately equidistant around the periphery (radius of ca. 1.5 m) at ca. 1.6 m height. Trees were untreated (control) or treated with either one dispenser in the center of the center-leader tree, or one dispenser placed at each of 10 sites (one in the center of the tree and three between each trap site, around the tree periphery). Dispensers were removed after three days. Trap catch was recorded for this period and for the following three days. After this period, the treatments were cycled among the same trees, in the following manner: after three days without dispensers, the trees that had been treated with the one dispenser treatment became the controls, the trees with 10 dispensers received the treatment with one dispenser, and the controls received the 10 dispenser treatment. To minimize effects of the daily variation of moth flight, treatment of each block was staggered one day and each block was used for six cycles. EAG recordings were taken at the trap positions (as described above), after removal of the traps.

Field Experiment 2. The effect of disruption from pheromone and inhibitor released from foliage alone was also examined in the following manner. Dispensers ($N = 36$) as above were placed into orchard plots ($N = 4$, 22.5 $\times$ 22.5 m), consisting of six rows of trees, with 12 trees per row for two days. Comparable blocks ($N = 4$) 60 m away were untreated. Nine delta traps, each baited with three virgin female moths held in a gauze container (Suckling et al., 1990b), were put into a 3 $\times$ 3 array (9-m sides), at 1.5 m height, in order to maximize moth catch in each plot. Traps were placed in alternate trees from those that had contained dispensers in the central three rows (one guard row on one side, and two guard rows on the other). Male moths were anesthetized with CO_2 and marked with felt tip pens (Suckling et al., 1990b). After two days in place,

dispensers were removed from the orchard at 4 PM. At 5 PM, 52–125 marked males were released among four sites in the middle two rows between traps. Moths were released onto a plastic tray, and those incapable of flight were subtracted from the total. Trap catch of wild and marked moths was recorded the next day. This procedure was repeated four times, in a different pairs of treated and control blocks on each night.

GC and GC-EAD. A Hewlett Packard model HP 5830 A gas chromatograph with a DB-Wax capillary column (30 m × 0.25 mm) and a flame ionization detector (FID) was used for chemical analysis. After 3 min at 80°C, the temperature was increased at 10°C/min. up to 230°C. The carrier gas was hydrogen at 140 kPa. A 1 : 1 split separated the outlet of the column between the FID and the electroantennogram detector (EAD). The EAD signal was amplified and filtered according to standard procedure (Hansson et al., 1989) and printed with a chart recorder at a chart speed of 33 mm/sec. The FID signal was recorded with a HP 18850 A GC-Terminal integrator.

Experiments were carried out in order to identify the GC peaks representing pheromone and inhibitor *E*11–14:OAc and *Z*11–14:OAc, respectively, and *n*-decan-1-ol (11:OH) (which elicits no EAD response). These compounds were independently injected in order to measure their respective retention times. For the analysis of the leaf extracts, 6 μl of the solvent extract was injected. All GC-EAD experiments were repeated at least three times. The low quantity of diene present in dispensers prevented its inclusion in these experiments, due to difficulties in obtaining reproducible results near the detection threshold.

Topical Application of Pheromone onto Leaves. Five micrograms of *E*11–14:OAc (50 μl *n*-heptane containing 100 ng/μl *E*11–14:OAc) was applied to 15 leaves (of similar age and an approximate size of 40 cm^2), and left for 30 min to be adsorbed by leaf waxes, before being put into a polyethylene bag. The same number of untreated control leaves were in a second plastic bag. After 14 hr, the apple leaves were taken out of each plastic bag and washed in 50 ml solvent (25 ml redistilled *n*-heptane and 25 ml redistilled *n*-hextane) for 14 hr on an orbital shaker at 150 rotations/min. The extract was then filtered twice using analytical filter paper (Munktells, Sweden, type 1002). As an internal standard, 5 μl 11:OH was added to the extract. The volume of the extract was reduced to 10 ml under nitrogen, and 6 μl of the extract was injected into the GC for both GC and GC-EAD analysis.

Pheromone Loading of Leaves at Saturation. Three small branches with six to seven apple leaves were taken from an untreated orchard, the cut stems placed in a vial containing water, and the branches taken to the laboratory. There each branch was placed in a 20-liter plastic bag each containing a small fan generating an intermittent airstream at 0.25 m/sec (cycling on and off every 30 min) for 14 hr. The plastic bags were sealed for separation from the outer

environment. In the first plastic bag, four aged dispensers with an average liquid length of 148 mm were attached to a metal frame inside the sealed plastic bag. The mean release rate of each dispenser, estimated by liquid length (Bradley et al., 1995), was 23.7 μg per hour. It was ensured that there was no physical contact between the dispensers and apple leaves. The same number of untreated control leaves was placed in a second plastic bag. After 14 hr, the apple leaves were taken out of each plastic bag and treated as above.

Pheromone Loading of Leaves Taken from Treated Fields. Ten aged pheromone dispensers with a mean liquid length of 146 mm were applied to 10 mature apple trees on May 18, 1994, at one per tree. After 39 days, leaves at different distances from the dispensers were picked and treated as described above. Leaves were taken at approximately 0.04 m, 0.3–0.4 m, and 0.9–1 m away from a central dispensers. As a control, 15 leaves were taken from an untreated orchard. Leaves were washed and the pheromone extracted as above.

Calculation of Amount of Pheromone Uptake by Leaves. The size of all leaves used in these experiments was measured. Leaves of similar size and age were used as far as possible, and the amount of pheromone per square centimeter of leaf area was calculated by dividing the calculated amount of pheromone by the sum of the leaf areas. The amount of pheromone taken up by the leaves was calculated using the internal standard (50 μg 11:OH) as follows: amount of pheromone = $(\text{area}_{\text{pheromone}} \times 50\ \mu\text{g})/\text{area}_{\text{internal standard}}$.

Statistical Analysis. In the first field experiment, the catches of moths in traps were tested for fit to the normal distribution and found to be skewed. Catches were then compared between treatments using analysis of variance and *t* tests of the log transformed total from three traps per tree and back-transformed for presentation (by anti-logs). Catches were pooled from each tree to avoid pseudoreplication (Hurlbert, 1984). The three blocks and six repetitions through time provided 18 replicates. In the second field experiment, trap catches in all nine traps per plot were again pooled because traps in each plot were not true replicates. Recapture rates were compared between treatment and control plots using Fisher's exact test (Zar, 1984), and catches of wild moths were compared by *t* test after log transformation. The analysis was performed using individual nights as replicates. EAG values were normally distributed and were compared untransformed using analysis of variance and *t* tests.

RESULTS

Field Experiment 1, Trap Catches. No moths were caught in trees treated with 10 dispensers while the dispensers were present (Table 1). The catch was also significantly suppressed for three days after removal of the dispensers, compared to the controls ($t = 2.36$, 16 *df*, $P < 0.05$). Trap catch for the three

nights after dispenser removal was 0, 10, and 15% of the control catch (Figure 1). Trees treated with a single dispenser also had suppressed trap catch during the presence of dispensers. Single moths were caught on two occasions, compared to 25 moths in the controls, so that catch in this treatment averaged 4% of catches in control trees. After removal of the single dispenser, trap catch subsequently increased over the following nights to 33, 40, and 80% of the control catch (Figure 1), with no significant difference from control catches (Table 1).

Field Experiment 2. Moth catches were significantly reduced in blocks that had been treated with pheromone up to 1 hr before moth releases (Table 2). The mean level of recapture in the control was 28% (SEM 2.5%), with 10.3% (2.1%) recapture in the previously pheromone-treated plots. Hence, the pretreatment of foliage with pheromone resulted in a reduction to 37% of the catches from that in the untreated plots. This level was very similar to the result on the first night of dispenser removal in the previous experiment (35%, Figure 1). Catch of wild moths was also reduced to 35% in previously treated [mean of 6.3 (SEM1.5)], compared to control plots [mean of 17.5 (SEM 5.1)] ($t = -2.43$, $df = 6$, $P = 0.05$).

Field Experiment 1, EAG Measurements. Differential EAG measurements at the periphery of the trees (after the removal of traps) reflected the presence

of high concentrations of atmospheric pheromone with one or 10 dispensers in the trees (Figure 2), although readings in the treated trees were only significantly higher than the control trees on the second day ($P < 0.05$). EAG values declined after removal of the dispensers, with no differences from control levels after 24 hr. The comparatively insensitive field EAG response in this species is due to

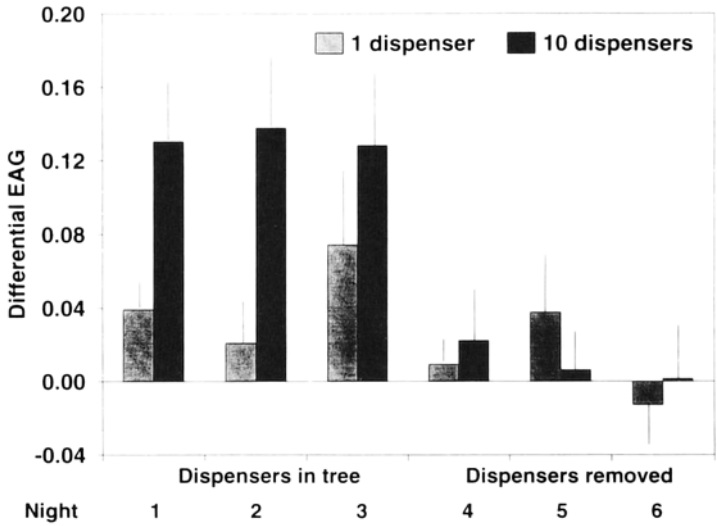

FIG. 2. Differential electroantennogram amplitudes recorded in trees during the presence or after removal, of one or 10 polyethylene dispensers containing pheromone and inhibitor. Bars show the standard error.

the high background response to environmental odors (Karg et al., 1994; Suckling et al., 1994; Rumbo et al., 1995).

GC-EAD Analysis. GC analysis of the extract of the untreated leaves did not show a GC peak with a retention time corresponding to those measured for *E*11-14:OAc or Z11-14:OAc (Figure 3). There was also no antennal response from the male. *E*11-14:OAc as well as Z11-14:OAc were present in the extract of saturated leaves as well as in the extracts of the leaves taken from the field

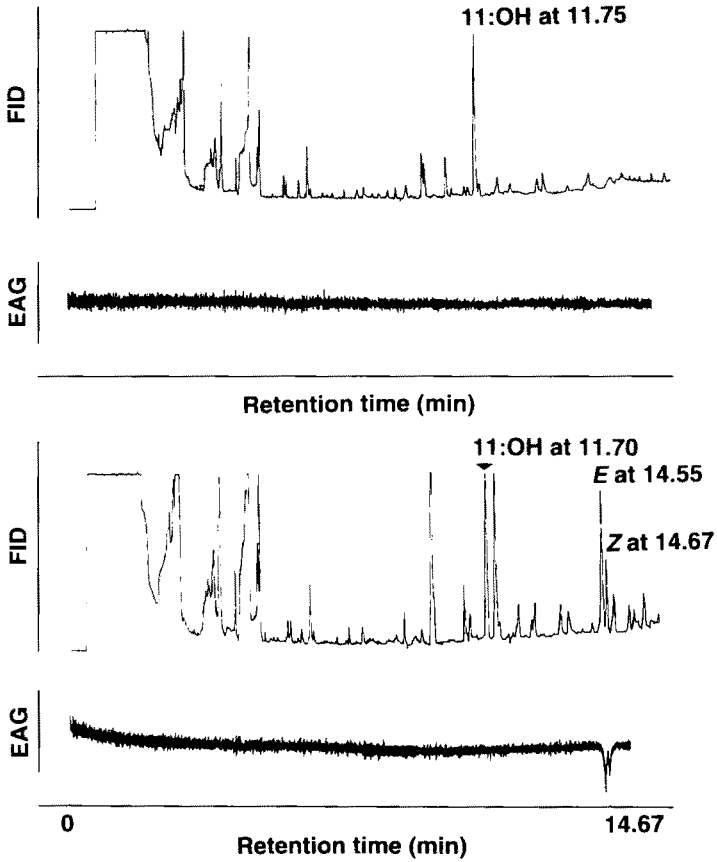

FIG. 3. Gas chromatogram and coupled electroantennogram (EAG) recordings of antenna of male *E. postvittana*. The upper traces show a chromatogram from a untreated leaf and the corresponding EAG recording. The lower traces show the chromatogram of pheromone saturated leaves and the corresponding EAG recording. Pheromone and inhibitor peaks are indicated by arrows.

at different distances from the dispenser. A typical GC-EAD recording for leaves exposed to the dispensers is shown in Figure 3. Antennal response was elicited by *E*11–14:OAc and Z11–14:OAc (as reported by Bellas et al., 1983).

Chemical Analysis of Extracts From Treated Leaves. GC analyses detected that 0.032 ± 0.004 μg of *E*11–14:OAc/cm^2 leaf area could be recovered from topically treated leaves averaging 39.6 cm^2. Hence 1.26 μg of *E*11–14:OAc/cm^2 of leaf area had an aquisition rate of 2.54%. No pheromone was found on untreated leaves.

Chemical Analysis of Extracts from Saturated Leaves. The chemical analysis detected 0.045 ± 0.007 μg of *E*11–14:OAc and 0.019 ± 0.002 μg of Z11–14:OAc (average leaf area of 49.8 cm^2) taken from a bag containing the four dispensers (Table 3). This is a 1:0.42 ratio of *E* to *Z* in the leaves from a saturated environment, compared to a 1:0.42 ratio in dispensers, indicating no error in the ratio of the two components and, therefore, more precision in these data than was evident from the standard errors. Comparison with the results from the treated leaves suggests that ca. 1.66 μg/cm^2 of *E*11–14:OAc was loaded in the saturated air. No pheromone was found on untreated leaves.

Leaves Taken from a Pheromone-Treated Orchard. Analysis of the leaves taken from the field at different distances from the pheromone dispensers showed the highest load on leaves taken close to the dispensers. At 4 cm from the source of pheromone, leaves contained an estimated 0.014 ± 0.009 μg of *E*11–14:OAc and 0.004 ± 0.004 μg of Z11–14:OAc. The *E*:*Z* ratio was 1:0.26, compared to a ratio of 1:0.43 at 30 cm, and 1:0.39 at 95 cm from the dispenser. This comparison implies less precision in the data for the point nearest the pheromone dispenser, which is corroborated by the larger error bars (Figure 4).

The amounts of detectable pheromone and inhibitor decreased linearly with the square root of the distance from the dispenser, so that almost no pheromone was detectable in foliage about 1 m from the source (Figure 4). The change in concentration of *E*11–14:OAc = 0.0169 − 0.0016*x* (where *x* = square root of

TABLE 3. LOAD OF *E*11–14:OAc AND Z11–14:OAc (PHEROMONE AND INHIBITOR) ON LEAVES TOPICALLY DOSED WITH *E*11–14:OAc OR FROM A SATURATED ENVIRONMENT WITH A 70:30 RATIO

Treatment	Mean load of (μg/cm^2) *E*11–14:OAc	Standard deviation	Mean load of (μg/cm^2) Z11–14:OAc	Standard deviation
Topically dosed	0.032	0.004	NA	
Saturated	0.045	0.007	0.019	0.002

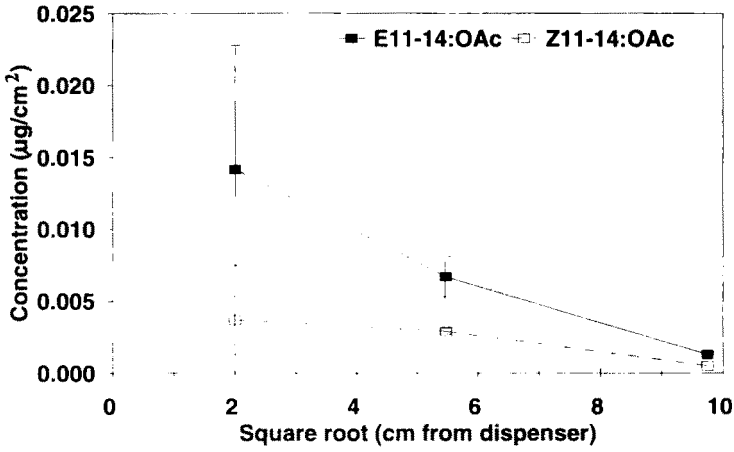

FIG. 4. Decay of the pheromone and inhibitor load on apple leaves with square root of distance from a dispenser.

distance from dispenser in centimeters, $r^2 = 0.61$, $df = 8$, $P < 0.05$). The change in concentration of Z11-14:OAc = $0.0048 - 0.0004x$ (where x = square root of distance from dispenser in centimeters, $r^2 = 0.34$, $df = 8$, $0.10 < P < 0.05$). Leaves taken only 4 cm from a dispenser were far below saturation with either E11-14:OAc and Z11-14:OAc. The estimate of proportion of saturation of these leaves compared to those kept in a saturated bag varied from 0.2 (Z11-14:OAc) to 0.3 (E11-14:OAc).

DISCUSSION

Trap Catches. Several possible explanations for the initial reduction in trap catch after removal of the dispensers can be identified. First, the pheromone and inhibitor released from the apple leaves may have masked the pheromone plume released from the traps, decreasing their attractiveness. Although this species discriminates spacially separated pheromone and inhibitor sources (Rumbo et al., 1993), the pheromone component being released from the foliage may have masked the more directional plume of pheromone from the rubber septa in the traps, reducing the peak-to-mean ratio (Murlis et al., 1992). Second, adaptation and habituation of the sensory system of insects in the vicinity of the trees that had previously held dispensers could have been caused by the background of pheromone released from the leaves, reducing male responsiveness to pheromone released by traps. In addition, male responsiveness could be reduced to inadequate stimulation with pheromone. The leaves in the treated

trees would continuously release pheromone, thereby generating a comparatively stable pheromone background. This type of pheromone cloud arrests the upwind flight of male moths approaching a pheromone source (Kennedy et al., 1981), because intermittent pheromone stimulation is required for sustained upwind flight (Baker et al., 1985). However, decreased trap catches over one to two days cannot be explained by those phenomena alone.

Recovery of preexposed males from habituation may be quite rapid, on the order of minutes (Rumbo and Vickers, unpublished data) or perhaps hours (Bartell and Lawrence, 1973), although this is likely to be dose-dependent. Given the extent of moth movement and the physical layout of the trees in small blocks, it seems very unlikely that most or all moths in the vicinity of the treated trees would be disrupted for three days after removal of dispensers. There was no evidence that catch in the controls was affected by the presence of the dispensers in nearby trees.

However, the suppression of catch indicates that leaves released enough pheromone in the first night after dispenser removal to affect male orientation in single trees. This effect may be substantially more influential in orchards without the large untreated areas that characterize the field site used in the first experiment here. This effect was further tested using larger plots in the second experiment, where release of moths not previously exposed to pheromone ensured that the only source of pheromone and inhibitor affecting catch to female-baited traps was from the foliage. In this case, the effect was significant for each test. The results from wild moths also closely corroborated the first experiment.

EAG Measurements. The EAG was capable of detecting a significantly higher atmospheric pheromone level when 10 dispensers were present in each tree, compared to the presence of single dispensers or no dispensers. However, traps more effectively displayed a difference in efficacy of disruption between treatments. The sensitivity of the EAG readings was insufficient to detect any effect from the pheromone treatment on the day after the removal of the 10 dispensers. Higher mean EAG values in the treatments with 10 dispensers present were mainly due to detection of intermittent peaks arriving from nearby dispensers, rather than a noticably raised background, and this effect is evident in the higher standard errors of EAGs recorded in trees with 10 compared to one dispenser.

Chemical Analysis. Our experiments confirm that the major pheromone component and inhibitor of *E. postvittana*, *E*11-14:OAc and *Z*11-14:OAc, are taken up and released by apple leaves. Hrdý et al. (1990) used GC-EAD to confirm the uptake of pheromone by stonefruit tree foliage, using Oriental fruit moth (*Cydia molesta* Busck). Uptake is presumably due to the similarity of the chemical attributes (lipophilicity) of the pheromone and the waxes (Jeffree, 1986; Baker, 1982).

The velocity and direction of the process could be determined by the pher-

omone gradient, the volume of the wax, as well as the wind speed and pheromone concentration of surrounding air. the small proportion of pheromone recovered from the leaves can be explained partly by this shift of the equilibrium towards the airborne pheromone with increased release of the phermone into the surrounding air, compared to the uptake, that takes place simultaneously. Adsorption of pheromone onto the glass walls remains a technical problem for the technique used, as it decreases the amount of pheromone recovered. The low proportion of pheromone recovered from leaves harvested from the field, compared with the saturated environment, was likely to be due to the lower ambient concentration.

Airborne pheromone of *E. postvittana* released from polyethylene dispensers is taken up within seconds by apple leaves (Karg et al., 1994). The decline in pheromone load with distance corroborates the EAG measurements of Karg et al. (1994), where the EAG response to pheromone from leaves was inversely related to the square root of distance from a central pheromone source. Unlike the first experiment, where the pheromone was directly applied to the waxes covering the leaves, the pheromone had to be taken up from the surrounding orchard air. The amount of pheromone taken up depends on the airborne pheromone concentration and on the partition constant of the pheromone into the leaf-waxes. Factors limiting the uptake include atmospheric pheromone concentration, length of time of exposure to pheromone in moving air in the field, and amount and chemical constitution of leaf waxes. The amount and composition vary with leaf age and season, and different varieties may have different waxes (Fernandes et al., 1964). In our experiment, the quantity of *Z*11–14:OAc released from dispensers and detected from foliage was small, accounting for the lower level of significance compared to *E*11–14:OAc.

A static model of pheromone concentrations in orchards, based on diffusion gradient alone, would suggest that concentrations taken up and released by foliage near dispensers are high, with isoconcentration spheres in foliage centered on dispensers. Karg et al. (1994) used EAG readings from leaf transects to show that this model was basically correct. Concentrations of pheromone in the air among foliage would therefore be predicted to have a three-dimensional distribution centered on major (dispenser) and minor point sources (leaves), with rapidly diminishing average concentrations away from the major sources. Instantaneous atmospheric concentrations would also be affected directly by filamentous plumes from dispensers, as well as the more numerous but less concentrated pheromone plumes emitted from foliage. The arrival of odor plumes, or "bursts" with high pheromone concentrations (Murlis and Jones, 1981; Murlis, 1986; Murlis et al., 1992) from these point sources would give much higher instantaneous pheromone concentrations.

Wall et al. (1981) placed wheat leaves near the open ends of pheromone traps containing rubber septa loaded with 10 mg pheromone (*E*8,*E*10–12:OAc),

and used GC and GC-EAD techniques to confirm behavioral observations that the foliage was releasing pheromone. Adsorption and release of pheromone can play an important role in mate-finding, as reported by Noldus et al. (1991) for another moth and by Sivinski et al. (1994) for fruit flies. In the context of mating disruption, the pheromone released from foliage will also assist adaptation and habituation of males by providing a background level of pheromone and lowering the signal-to-noise ratio. This ratio is recognized as necessary for sustained upwind flight (Willis and Baker, 1984), so any reduction in it may lead to a reduction in take-off and subsequent behaviors and consequently mate finding. In our experiments, the pheromone and inhibitor release rates from leaves were sufficient to lead to a reduction in trap catch after removal of the pheromone dispensers for one to two nights.

The results of this study corroborate the findings of earlier studies on pheromone adsorption and release from plants. Crop foliage is likely to be of great importance for the success of mating disruption by increasing the likelihood of unstructured pheromone clouds with reduced variance in concentration and temporal distribution. Apple leaves can function both spatially and temporally as pheromone buffering systems by reducing wind speed, as well as acting as a source for secondary release of pheromone. In our view, uptake and release of pheromone from plant waxes at many point sources (= leaves) generate a background concentration supporting disruption. The relative importance to disruption of leaf-released pheromone and pheromone released directly from dispensers is still uncertain, but these experiments indicate that the role of crop foliage in mating disruption should not be overlooked.

Acknowledgments—We thank Dr. Arne Sauer (University of Kaiserslautern) for providing and adapting computer software, the New Zealand Lottery Grants Board for funding of an oscilloscope, and the New Zealand Foundation of Research, Science and Technology for funding the research program. We thank Drs. Eric Rumbo and Richard Vickers (CSIRO) for access to unpublished data on habituation in oriental fruit moth.

(Received May 8, 1995; accepted October 15, 1995)

Abstract—Trapping tsetse flies belonging to the *palpalis* group still relies totally upon luring by visual cues even though odor-baited trapping is used effectively against the *morsitans*-group species. Forty-three percent of the antennal olfactory cells of *Glossina f. fuscipes*, a member of the *palpalis* group, respond to 1-octen-3-ol. For this species we report a structure–activity relationship between 1-octen-3-ol analogs, in which carbon chain length and the configuration of the hydroxyl and π-bond moieties are varied, and biological activity. Although the optimum chain length for all cells sensitive to 1-octen-3-ol is eight and most cells give lower responses when the hydroxyl function is omitted, there is a clear division into two groups. One group is diverse and represents cells that appear indifferent to the presence or position of the π bond; many will respond to such disparate structures as acetone and 3-methylphenol as well as to 1-octen-3-ol. In the other group, the structural requirements for the stimulus are more stringent; the cells appear to be specifically tuned to 1-octen-3-ol. Their thresholds are three orders of magnitude lower than those of the former group. The existence of two clusters points to a functional division in the olfactory sense. We suggest that the latter low-threshold group is involved in host detection from a distance while the former diverse group is involved in host discrimination at close range. Trap harvests with 1-octen-3-ol as a bait may have been disappointing because the appropriate mixture for generating a landing response on the traps is still lacking.

Key Words—Tsetse, *Glossina f. fuscipes*, host location, olfaction, structure-activity relationship, electrophysiology, 1-octen-3-ol.

INTRODUCTION

The thirty-one species of tsetse flies (*Glossina* spp.) have been classified by morphology and habitat into three groups: the *morsitans*, *palpalis*, and *fusca* tsetse (cf. Jordan, 1977). All feed exclusively on blood, which they take from mammals, birds, or reptiles (Weitz, 1963). Although host odors lure flies of the *morsitans* group (e.g., Hargrove and Vale, 1978; Owaga, 1984; Torr, 1989; Vale, 1974), the *palpalis* group "gives the impression that it detects its hosts by sight rather than smell" (ex., Laveissière et al., 1990). Indeed, trapping of the *palpalis*-group flies now still relies entirely on providing visual cues (see Cuisance et al., 1991; Gouteux and Sinda, 1990; Gouteux and Le Gall, 1992; and Ogwal et al., 1992 for recent examples).

Chemical baits that attract the *morsitans*-group tsetse include 1-octen-3-ol (Hall et al., 1984), a blend of phenols (Hassanali et al., 1986; Owaga et al., 1988; Vale et al., 1988), and acetone (Vale and Hall, 1985). These are sensed by the antennae. Screening spike responses of olfactory cells to the array of attractants shows that in the *morsitans*-group species *G. m. morsitans*, 40% of the olfactory cells respond to 1-octen-3-ol, 18% to the phenols, and 10% to acetone. A similar survey of the receptors in the *palpalis*-group species *G. f. fuscipes* gives a surprising result: the percentages are 43 for 1-octen-3-ol, 18 for the phenols, and 9 for acetone. Moreover, the sensitivity of the receptors for these odors appears to be the same in the two species (Den Otter and Van der Goes van Naters, 1992; Van der Goes van Naters, unpublished). Thus, electrophysiological experiments suggest that the organization of the olfactory sense in the two is similar even though field trials with odors indicate that the *morsitans*- and *palpalis*-group tsetse behave quite differently.

Clearly, our understanding of the sensory basis of host location in the *palpalis*-group tsetse is still limited. Reexamination of the odor spectra of the antennal olfactory receptors, of which cells responsive to 1-octen-3-ol constitute the largest set, is needed. Our objective in this structure–activity relationship (SAR) study on octenol-derived chemicals is to characterize the specificity of olfactory receptors in *G. f. fuscipes* and to theorize on their role in host location.

METHODS AND MATERIALS

Insects. Pupae of *G. fuscipes fuscipes* Newstead 1910 were obtained from the colony of the Département d'Elevage et de Médecine Vétérinaire (CIRAD-EMVT) in Montpellier, France. The pupae were kept individually in glass vials until emergence of the flies, whereupon these were grouped in cages by sex and age. Pupae and flies were kept in a 12L:12D photoperiod at 25°C and 75%

relative humidity. Flies were fed off rabbits' ears on alternate days beginning the day after emergence.

Electrophysiology. Recording of action potentials was accomplished as described by Den Otter and Van der Goes van Naters (1992). A fly was tested when between 4 and 15 days old; it was fed the previous day. Cells at two sites on the antennae of each fly were tested, one on the medial funicular face and the other on the lateral face. A current of air, issuing from a 7-mm-ID tube at 2 m/sec, was directed at the head of the fly. The tube was provided with an opening through which test compounds were injected.

Test Compounds. Test chemicals used included 1-octen-3-ol and structurally related compounds in three sets of experiments (Table 1). These chemicals vary in carbon chain length and in the positions/presence of the π bond and hydroxyl moieties. Additionally, acetone and 3-methylphenol were tested. Purity according to specification was >98% and chiral substances were racemics unless otherwise indicated. All were purchased from Fluka (Buchs, Switzerland) except for the three isomers 2-, 3-, and 5-octen-1-ol (Johnson Matthey, Karlsruhe, Germany), 1-hexen-3-ol (Aldrich, Milwaukee, Wisconsin), and 1-nonen-3-ol (ICN, Cleveland, Ohio). These chemicals are liquids at room temperature and pressure (RTP: 298K, 1 atm). Saturated vapor concentrations at RTP, as determined by weight loss over 24 hr of samples in glass-stoppered 1-liter flasks, are given in Table 1.

Three log step dilutions in air were prepared by transferring appropriate amounts of the saturated vapors of the chemicals in 1.2-liter glass serum bottles fitted with screw caps and rubber seals. Saturation of the atmosphere in a "mother" bottle was achieved and maintained throughout the study by addition of 2 ml of a chemical. The three dilutions from these were remade at the beginning of each day; two dilution series of bottles for each substance were alternated. Thus a bottle used on one day was left standing uncapped the next, the cap and seal being placed on its twin. This allowed the uncapped bottle to cleanse of odor while the rubber seal, after a number of exchanges, had absorbed what it could and was no longer a biasing factor on the concentration of a dilution.

Test chemicals were drawn from the bottles through the rubber seals into plastic syringes (Omnifix 5 ml) immediately before presentation. Syringes were equilibrated with the bottle atmosphere by pumping the plunger 10 times prior to taking a sample. Not more than 10 syringe fills were taken from a bottle per day. A syringe was mounted on a spring-powered device and 1.5 ml of its contents was injected in 0.1 sec into the airstream directed at the head of the fly.

Vapors of acetone and 3-methylphenol were not taken from bottles but were dispensed from filter papers placed inside syringes. Syringes with acetone

	1-octene		7.6×10^{-4} M
	3-octanol		7.5×10^{-6} M

[a]The parent compound 1-octen-3-ol was the reference chemical in each experiment.
[b]At RTP: 298K, 1 atm.

contained 10 mg of the chemical; those with 3-methylphenol were charged with 5 mg.

Experimental Procedure. Cells on the antennae were screened for response to a stimulus of saturated 1-octen-3-ol vapor. When a cell sensitive to 1-octen-

3-ol was located, the test chemicals were drawn from the bottles and injected in ascending concentration. The order in which substances were presented was varied. We observed intervals of 30 sec between presentations to allow the cells to return to baseline activity. After all concentrations of each substance in an experiment had been presented, the odor spectra were further characterized with acetone and 3-methylphenol.

Analysis of Data. Recordings were transferred from tape to paper for analysis. The magnitude of response was calculated from the maximum number of action potentials in a space of 0.1 sec after injection of the stimulus, the non-stimulated activity prior to presentation of the odor being similarly measured and subtracted. This figure was multiplied by 10 to obtain spikes per second as the unit of response.

To characterize the odor spectra of the olfactory receptors, multidimensional graphs were envisaged with each axis representing the response to a different substance relative to that on stimulation with 1-octen-3-ol. Here we present graphs with two dimensions only, as more are difficult to visualize. Cells with similar spectra form clusters.

As a supplement to this common-sense visual approach for grouping cells, several types of multivariate statistical analyses were considered, including hierarchical cluster analysis, factor analysis, and multidimensional scaling. Bieber and Smith (1986) note that for cluster and factor analysis "the popularity of these intuitive procedures is rooted in the absence of sound statistical theory concerning the appropriateness of the final solution." Multidimensional scaling has the characteristic that the meaning of the dimensions that reveal the underlying structure in the data is abstract. We have opted for the first of the three (hierarchical cluster analysis from SPSS/PC$^+$ with average linkage over Euclidean distances) and base our choice of cluster solution on a scree procedure.

The different clusters that emerged from the analyses were considered separately, and the average responses of the constituent cells are plotted in dose-response curves. Points in the curves are connected by line segments; sigmoid or other curve fitting did not appear feasible in our graphs due to the limited number of concentrations per substance. This has a drawback: statistical analysis of the dose-response curves is not possible without a function to fit to the data because the concentrations used are different for each chemical. Therefore conclusions are based on the most salient features of the data only.

RESULTS

The results comprise a data set of 183 cells recorded from 41 female flies and 52 males. Responses to four concentrations of 1-octen-3-ol did not differ between the sexes (ANOVA, $P = 0.84$); hence the data are pooled. The three experiments (Table 1) are treated separately.

Effect of Chain Length. The relative effectiveness of the six homologs of 1-octen-3-ol is the same for all 28 cells tested, as is reflected by the graph in Figure 1a. Figure 1a shows a single cluster in a plot with the relative responses to 1-hepten-3-ol and 1-nonen-3-ol on the axes. This is true also in graphs with

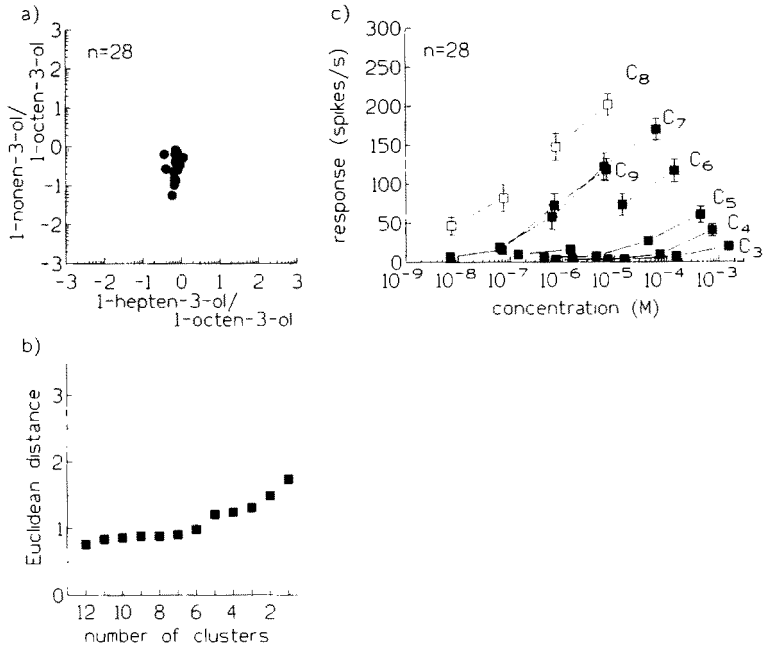

FIG. 1. (a) Spike responses of cells on stimulation with 1-hepten-3-ol (abscissa) and 1-nonen-3-ol (ordinate) relative to the responses on stimulation with the parent compound 1-octen-3-ol. Each data point represents one cell. The plotted values are proportions, have no units, and are averages over four concentrations. Axes are numbered with exponents and extend from 10^{-3} to 10^{3}. Stimuli to be graphed on the axes were selected to maximize clustering of cells. The data points are seen as a single cluster. (b) Scree diagram for the last 12 agglomeration stages in the hierarchical cluster analysis on the 28 cells. Dimensions in the analysis are the relative responses to the six homologs of 1-octen-3-ol as in (a). The ordinate gives the distance over which the two nearest clusters are combined to create the number of clusters given on the abscissa. Each successive stage fuses two clusters that are further apart. The rise is steady and the distances are small as compared with Figure 2b. We choose the one-cluster solution. (c) Dose–response curves for 1-octen-3-ol (C_8) and its homologs. The abscissa is the molar concentration of the stimulus; the ordinate gives the average spike responses with SEM of the cells in the cluster of (a).

any other combination of the homologs represented (not shown). When cells are grouped by hierarchical cluster analysis, the Euclidean distances over successive stages of the agglomeration process show a steady increase (Figure 1b): we allow clustering to progress to its end. In the sample, five cells responded to acetone, three to 3-methylphenol, four to both, and 16 to neither.

Figure 1c shows the average responses to the saturated vapors and three log step dilutions of each homolog. Note that the curves are staggered on the abscissa: the saturated vapor pressures decrease with increasing chain length (Table 1). The C_7 and C_9 curves overlap. A chain length of eight carbon atoms is clearly optimal in the range of homologs tested.

Effect of Relative Positions π-Bond and OH Moieties. When the relative responses to 2-octen-1-ol and 3-octen-1-ol are represented on the axes, two diffuse clusters are apparent (Figure 2a: arbitrarily designated P and Q). These represent 19 and 32 cells, respectively. The scree procedure confirms that a two-cluster solution is appropriate (Figure 2b).

Recordings from the cells in cluster P always showed two spike amplitudes, which suggests that they are collocated with a second type of cell (Figure 4). Further investigation proved the latter responds to 3-methylphenol only and not to any of the other substances tested. Cluster P cells themselves are unresponsive to either acetone or 3-methylphenol. The dose-response curves show that the cells are very discriminating to deviation of the positions of the π-bond and hydroxyl moieties (Figure 2c). The 1-3 configuration is the only adequate structure.

Of the cells in cluster Q, 8 responded to acetone, 2 to 3-methylphenol, 10 to both, and 12 to neither. The curve of 1-octen-3-ol (Figure 2d) lies somewhat below the other three. This suggests that positioning of the hydroxyl group on carbon 1, instead of on carbon 3, may enhance the response. A closer look at Figure 2a seems to bear this out. The points in the cluster are spread over a 45° diagonal relative to the two axes: the variation in the cluster is largely due to the OH-group position rather than to the position of the π bond. Although cells in the left range of cluster Q appear to be indifferent to the OH position (relative responses are around $10^0 = 1$), there is a continuum up to cells that respond 10 times more strongly on stimulation with 2- or 3-octen-1-ol than with 1-octen-3-ol. The cells seem indifferent to the position of the π bond (Figure 2d).

Due to a procedural error, the lowest point in each curve was lost.

Effect of Omission of π Bond or OH. Cluster formation is less pronounced in this experiment (Figure 3a). Several cells are detached from two rather dense agglomerations. This is reflected in the scree diagram by a less salient elbow point (Figure 3b) than is shown in Figure 2b. For ease of interpretation, we chose a two-cluster solution. These are again assigned letters P and Q (38 and 66 cells, respectively).

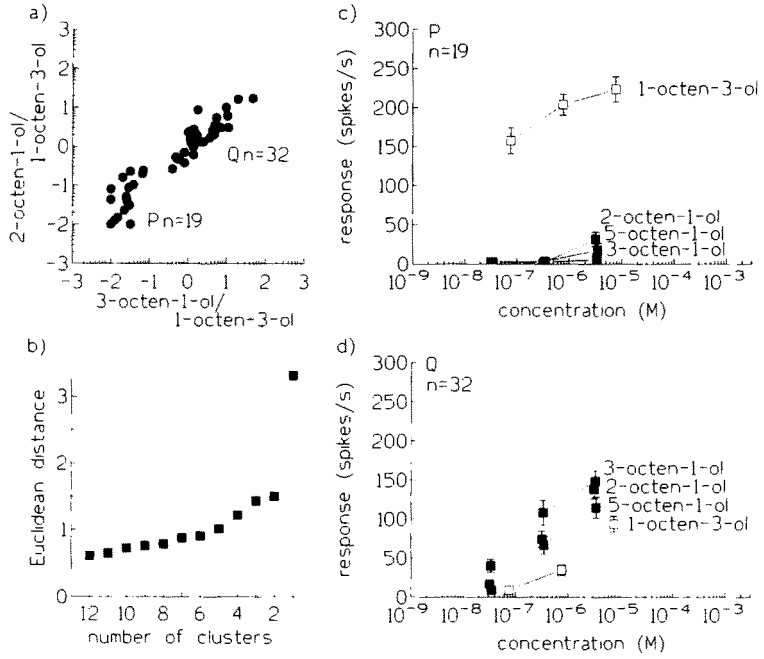

FIG. 2. (a) Spike responses of cells on stimulation with 3-octen-1-ol (abscissa) and 2-octen-1-ol (ordinate) relative to the responses on stimulation with 1-octen-3-ol. See Figure 1a for details. The two clusters are marked P and Q. (b) Scree diagram for the hierarchical cluster analysis by relative response to 2-, 3-, and 5-octen-1-ol. See Figure 1b for details. A salient elbow in the steady rise of Euclidean distances at the two cluster solution suggests agglomeration should be terminated there. (c) Dose–response curves for the cluster P cells in (a). Abscissa: molar concentration of the stimulus; ordinate: average spike responses with SEM. (d) Dose–response curves for the cluster Q cells in (a). Abscissa: molar concentration of the stimulus; ordinate: average spike responses with SEM.

Recordings of cells in cluster P display the characteristics described in Figure 4. The curves in Figure 3c show that 1-octen-3-ol is clearly the most stimulating followed by 3-octanol and 1-octene. Octane gives little or no response.

Cluster Q has a wider spread. In this cluster, 16 cells responded to acetone, 8 to 3-methylphenol, 17 to both, and 25 to neither. The curves for octane and 1-octene overlap, as do the pair for 3-octanol and 1-octen-3-ol (Figure 3d). The latter are clearly more stimulatory on average. However, the averages in Figure 3d mask the extremes. Thus, for a number of cells of the cluster (those on the

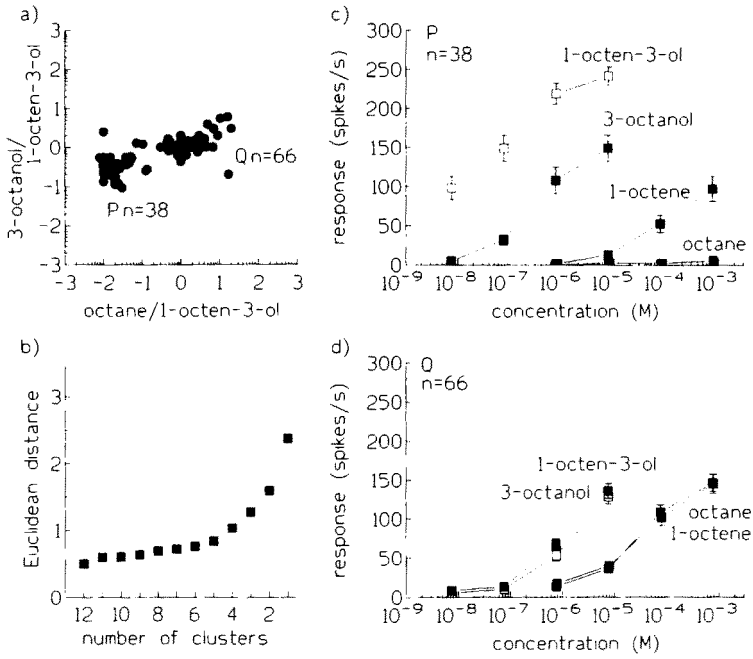

FIG. 3. (a) Spike responses of cells on stimulation with octane (abscissa) and 3-octanol (ordinate) relative to the responses on stimulation with 1-octen-3-ol. See Figure 1a for details. For ease of interpretation, five outliers are disregarded to give two clusters, P and Q. (b) Scree diagram for the hierarchical cluster analysis by relative response to octane, 1-octene, and 3-octanol. See Figure 1a for details. We choose the two-cluster solution. (c) Dose-response curves for cluster P cells in (a). Abscissa: molar concentration of the stimulus; ordinate: average spike responses with SEM. (d) Dose-response curves for cluster Q cells in (a). Abscissa: molar concentration of the stimulus; ordinate: average spike responses with SEM.

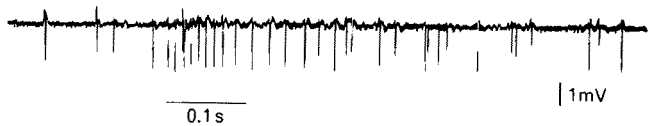

FIG. 4. Response of a cluster P cell (large-amplitude spikes) to a low stimulus intensity of 1-octen-3-ol (0.1-sec duration). Cluster P cells continue firing at an elevated rate beyond stimulus duration. They are insensitive to acetone and 3-methylphenol. Collocated always is a phenol-sensitive cell with similar temporal characteristics (small-amplitude spikes).

right-hand side in Figure 3a), the responses to octane and 1-octene are 10 times those to 1-octen-3-ol.

DISCUSSION

The sample of 183 cells is a motley conglomeration. An underlying order can, however, be made apparent even though our tools are crude. The grouping of cells here is not an expression of our human inclination to classify but is a real feature of the data set. The existence of clusters in the population of cells responsive to 1-octen-3-ol points to a functional division in the olfactory sense.

Clustering proves that the population of olfactory cells works with more than one type of receptor molecule. The wide spread of data points within the clusters—especially for clusters Q in Figures 2a and 3a—suggests that even within a subset of the population there are different types. This may extend to the cell membrane, as was shown for the sugar cells of the fleshfly (Shimada et al., 1974). Until we are sure that a membrane harbors but one type of receptor site, we cannot model sites from SAR studies on a cellular level. The most we can do is indicate which moieties in an odor molecule play a role in the odor-membrane interactions.

Clustering also shows the importance of testing the olfactory cells individually. Antennal differentiation necessitates that reception of odors be studied at the sensory level, by single-cell recording if possible. Perception of odors is reflected by the flies' responses in wind tunnels and field trials. Other behavioral assays may give valuable data as well, although they can be difficult to interpret. Saini et al. (1989) reported an SAR study on 1-octen-3-ol in which they assessed the relative perception of odors by counting the number of flies that raise their antennae to a stimulus. They concluded that the chemoreceptors involved may not be very specific and commented on features of the receptor sites. The differences between our results may be a contrast in species—their work is on *G. m. morsitans*—but more likely reflect differing methodologies.

Whether or not cells form disjunct groups in Figures 1a, 2a, and 3a seems to be dependent on the type of chemicals tested. While all cells respond in similar fashion to the homologous series 1-propen-3-ol through 1-nonen-3-ol, they are differentially sensitive to the other 1-octen-3-ol derivatives.

Clusters P in experiments 2 and 3 (Figures 2a and 3a) appear to correspond: cells of both have the characteristics outlined in Figure 4. From this it follows that clusters Q in experiments 2 and 3 (Figures 2a and 3a) must also be identical. That the two clusters P each represent the same proportion of the total, approximately 37% (experiment 2: $19/51 \approx 37.3\%$; experiment 3: $38/104 \approx 36.5\%$), supports this.

The thresholds of cluster Q cells for 1-octen-3-ol are on average between

10^{-8} and 10^{-7} M (Figures 2d and 3d). The position or presence of a π bond in the molecules appears to be of no consequence. The hydroxyl group is important (Figure 3d: the curve for 3-octanol intercepts the abscissa > 1 log unit lower than the octane curve), and the effect of its position on the spike responses varies between nil and a 10-fold factor for the substances tested (Figure 2a). On average, molecules appear more stimulatory with an OH on carbon 1 than on carbon 3 (Figure 2d).

For cluster P cells the structural requirements for a good stimulant appear to be more stringent than for the cluster Q cells. Both the presence of the π-bond and hydroxyl moieties as well as their position in the molecule are important (experiments 2 and 3: Figures 2c and 3c). None of the tested compounds meet the requirements as well as 1-octen-3-ol. Extrapolating the dose–response curves for 1-octen-3-ol in Figures 2c and 3c to the abscissa gives an average threshold concentration of 10^{-12} to 10^{-10} M.

According to the latest data now available (Torr et al., personal communication), an ox exhales 0–0.119 mg 1-octen-3-ol/hr with an average of 0.014 mg/hr. Presupposing a ventilation rate of approximately 5000 liters/hr (Spector, 1956) and with a relative molecular mass of 128.22 g/mol for 1-octen-3-ol, its concentration in cattle breath is 2×10^{-11} M [0.014×10^{-3}/(128.22 × 5000) g/mol/hr/(hr/g/liter)]. Downwind, the odor spreads into a larger volume, although the rate of diffusion is difficult to estimate.

Despite the decline in concentration downwind of an ox, we suggest that cluster P cells are sufficiently sensitive to 1-octen-3-ol to aid in host detection. Furthermore, threshold concentrations between 10^{-12} and 10^{-10} M will be overestimates if the fly applies a more sensitive method of decoding its afferent signals than we have used in our analyses of the recordings. It is clear, however, that the cells will be functioning at the lower limit of their dynamic range. The cells appear to be specifically tuned to 1-octen-3-ol; no structural alteration tested augmented the response nor did structurally unrelated chemicals prove effective.

The function of the cluster Q cells remains open due to their high thresholds. Many of these cells respond to structurally unrelated compounds as well as to 1-octen-3-ol and its derivatives. Either the prime stimulant is not among these or chemicals in mixtures may act synergistically on a cell. The latter possibility is now being investigated.

With dissimilar but overlapping odor spectra, the cluster Q cells could be involved in discriminating the odor mixtures from different hosts (across fiber pattern coding; cf. Erickson, 1963, 1982). We suggest the cluster P cells aid in host detection from a distance while the cluster Q cells are involved in host recognition at close range.

Contrary to the results of the trapping experiments in the field, our electrophysiological experiments indicate 1-octen-3-ol may be a powerful attractant for *G. f. fuscipes*. Sutcliffe (1987) notes that disparate odors mediate successive

stages in the distance orientation of biting flies to their hosts. The odors that attract tsetse appear to be different from those that cause the flies to alight for feeding (Saini et al., 1993). We suggest that although the *palpalis*-group tsetse should be attracted by 1-octen-3-ol in field tests, the trap harvests thus far may have been disappointing because the mixture required for an alighting response has not yet been developed.

Acknowledgments—We are very grateful to Dr. D. Cuisance of the CIRAD-EMVT: he was so kind to again provide us with an ample supply of tsetse. We also would like to acknowledge Dr. D.G. Stavenga, who proofread the manuscript, and Dr. H. van der Wel for discussions. We thank the anonymous referees for their constructive critique. The study was financially supported by the Dutch Foundation for the Life Sciences (NWO-SLW, grant 811-425-083).

(Received May 15, 1995; accepted October 16, 1995)

Abstract--Production of 4-methyl-5-nonanol, and 4-methyl-5-nonanone by two sympatric Asian palm weevils, *Rhynchophorus ferrugineus* (Oliv.) and *R. vulneratus* (Panz.) suggested that enantiospecificity of either compound could impart species specificity of pheromone communication. Weevil-produced, racemic 4-methyl-5-nonanol and 4-methyl-5-nonanone and their stereoselectively synthesized optical isomers were subjected to gas chromatographic-electroantennographic detection (GC-EAD) and GC-mass spectrometry (MS) on a chiral Cyclodex-B column. Only the *S,S* stereoisomer of 4-methyl-5-nonanol was EAD active and was produced by both *R. ferrugineus* and *R. vulneratus*. Production and EAD activity of (*S*)-4-methyl-5-nonanone exceeded that of its antipode in both weevils. In field experiments in Java, (4*S*, 5*S*)-4-methyl-5-nonanol and the stereoisomeric mixture were equally attractive. The 4*R*,5*R* stereoisomer was inactive. The corresponding ketone enantiomers neither enhanced nor reduced attraction to (4*S*,5*S*)-4-methyl-5-nonanol. Lack of apparent differences between *R. ferrugineus* and *R. vulneratus* pheromones suggests that synonomy of both weevils should be considered unless other pre- or postzygotic reproductive isolating mechanisms are disclosed in future studies.

Key Words—Coleoptera, Curculionidae, *Rhynchophorus*, aggregation pheromone, pheromone chirality, 4-methyl-5-nonanol and 4-methyl-5-nonanone, Asian palm weevils.

INTRODUCTION

Pheromone specificity contributes to habitat and resource partitioning among competing species in the Coleoptera. Only rarely has intraspecific attraction and interspecific interruption of response been attributed to enantiospecific production of more than one aggregation pheromone. (+)-Ipsdienol and (−)-ipsenol produced by *Ips paraconfusus* (Lanier) interrupt the aggregation of sympatric *I. pini* (Say) (Birch et al., 1977, 1980; Light and Birch, 1979). *Trogoderma granarium* (Everts) uses the (*R*)-(−)-enantiomers of (*Z*)- and (*E*)-trogodermal in a 92:8 ratio, while beetles of three other *Trogoderma* spp. respond to the (*R*)-(−)-enantiomers of either (*E*)- or (*Z*)-trogodermal. Ratios of both geometrical and optical isomers of brevicomin determine response and pheromonal specificity of sympatric *Dryocoetes confusus* (Swaine) and *D. affaber* (Mannerheim) (Camacho et al., 1993).

Rhynchophorus palm weevils produce single isomers of chiral alcohols as aggregation pheromones (Rochat et al., 1991, 1993a,b; Oehlschlager et al., 1992, 1995; Gries et al., 1993; Hallett et al., 1993a,b; Zagatti et al., 1993; Weissling et al., 1994; Perez et al., 1994). 4-Methyl-5-nonanol (ferrugineol, **1**, Figure 1) is a male-produced aggregation pheromone of the two Asian palm weevils, *R. ferrugineus* (Oliv.) and *R. vulneratus* (Panz.) (Hallett et al., 1993a,b). 4-Methyl-5-nonanone (ferrugineone, **2**) is produced and elicits anten-

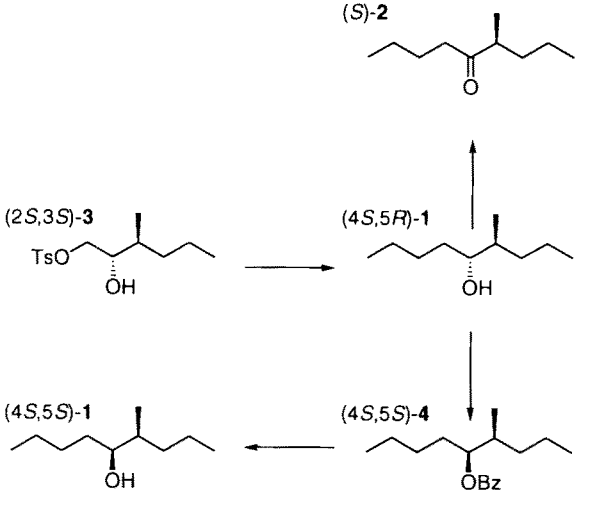

FIG. 1. Scheme for the synthesis of optical isomers of ferrugineol (**1**) and ferrugineone (**2**).

nal responses by both palm weevils, but seemed to have behavioral activity only in *R. ferrugineus* (Hallett et al. 1993a). Lack of pronounced differences in response to isomeric **1** and **2** suggested that pheromone chirality may impart species specificity of semiochemical communication. However, Perez et al. (1993) and Mori et al. (1993) demonstrated that both *R. ferrugineus* and *R. vulneratus* produce (*S,S*)-**1**, leading us to hypothesize that enantiospecific production of and response to **2** contributes to species isolation. We report the syntheses, as well as electrophysiological and behavioral activity of optical isomers of **1** and **2** in *R. ferrugineus* and *R. vulneratus*.

METHODS AND MATERIALS

Laboratory Analysis

Male and female *R. ferrugineus* and *R. vulneratus* were collected at Bojongkalong, West Java. Porapak Q-captured **1** and **2** from both weevils (Pierce et al., 1981; Hallett et al., 1993a) were subjected to gas chromatographic–electroantennographic detection (GC-EAD) (Arn et al., 1975; Perez et al., 1994) (Hewlett Packard 5890A) and GC-mass spectrometry (MS) (Hewlett Packard 5985 B) on a fused silica, cyclodex-B-coated column (30 m × 0.25 mm ID, J&W Scientific, Folsom, California), which separates optical isomers of both **1** and **2** with baseline resolution. Chemical ionization (CI, isobutane) GC-MS analyses were conducted in both full-scan and selected-ion-monitoring mode (SIM). A full-scan mass spectrum of synthetic **1** and **2** was obtained to select diagnostic ions. For GC-MS CI-SIM, synthetic **1** and **2**, hexane and concentrated weevil-produced pheromone were injected in split mode and analyzed by scanning for diagnostic ions.

Instruments and General Procedures

Nuclear magnetic resonance (NMR) spectroscopy was conducted on a Bruker AMX-400 spectrometer at 400.13 and 100.62 MHz for ^{1}H and ^{13}C-NMR spectra, respectively. ^{1}H chemical shifts are reported relative to TMS and ^{13}C chemical shifts are referenced to $CDCl_3$. Gas chromatographic analyses were performed on Hewlett-Packard 5880A and 5890 instruments equipped with flame ionization detectors and fused silica, DB-1 coated columns (15 m × 0.25 mm ID; 0.25 mm film, J&W Scientific). Elemental analyses were performed using a Carbo Erba model-1106 Elemental Analyzer. Diethyl ether (Et_2O) and benzene were freshly distilled from sodium-benzophenone-ketyl and activated 4 Å molecular sieves, respectively. Chemicals obtained from commercial sources were used without further purification unless otherwise indicated. All moisture- and air-sensitive reactions were conducted under argon. Column chromatography

refers to flash chromatography using Silica Gel 60 (230–400 mesh, E. Merck, Darmstadt, Germany). Thin layer chromatography (TLC) was conducted on aluminum-backed plates precoated with Merck Silica Gel 60F-254 as the adsorbent and visualized by treatment with an acidic solution of 1% $Ce(SO_4)_2$ and 1.5% molybdic acid followed by gentle heating.

The stereoisomers of **1** and **2** were synthesized according to a method modified from Perez et al. (1994). Oxidation of (4*S*,5*R*)-**1** and (4*R*,5*S*)-**1** were performed using the procedure of Brown et al. (1971).

(4S,5R)-5-Methyl-nonan-5-ol [(4S,5R)-1]. This compound was prepared by the alkylation of (2*S*,3*S*)-3-methyl-1-tosyloxyhexan-2-ol (**3**) according to the procedure of Perez et al. (1994). Enantiomer (4*S*,5*R*)-**1** was obtained as a colorless liqud. bp 75–78°C at 18 mm Hg; ^1H ($CDCl_3$): δ 0.88 (3 H, d, J = 8 Hz), 0.90 (6H, m) 1.34 (12H, m), 3.44 (1 H, m); ^{13}C ($CDCl_3$): δ 76.07, 38.55, 34.12, 33.09, 28.32, 22.78, 20.40, 15.24, 14.33, 14.04; Cl-MS *m/z* (relative intensity): 140 (100) (M^+-H_2O); Anal. calcd. for $C_{10}H_{22}O$: C, 75.87; H, 14.02; found: C, 76.10; H, 13.98 (4*R*,5*S*)-**1**: bp 80–83°C at 22 mm Hg; 2.62 g, 83% yield, 95% ee; Anal. Calcd. for $C_{10}H_{22}O$: C, 75.87; H, 14.02; found: 75.62; H, 13.97.

[(4S,5S)-4-Methyl-5-nonyl]benzoate [(4S,5S)-4]. Triphenylphosphine (7.87 g, 30 mmol), benzoic acid (3.66 g, 30 mmol), and (4*S*,5*R*)-**1** (2.39 g, 15 mmol) in 100 ml of dry benzene were stirred for 10 min at −10°C before diisopropyl azodicarboxylate (6.07 g, 5.9 ml, 30 mmol) (Aldrich Chemical Co., Milwaukee, Wisconsin) was added via syringe. After stirring overnight at room temperature, pentane was added, resulting in the formation of a white precipitate. The reaction mixture was filtered through a Florisil pad and concentrated in vacuo. Purification by column chromatography (9 : 1, pentane–ether as eluant), and by TLC using the same solvent system (R_f = 0.61) afforded (4*S*,5*S*)-**4** (2.46 g, 63% yield) as a pale yellow liquid: ^1H ($CDCl_3$): δ 0.90 (6H, m), 1.0 (3H, d, J = 8.9 Hz), (1.20 (2H, m), 1.36 (5H, m), 1.51 (1H, m), 1.60 (1H, m), 1,70 (1H, m), 1.98 (1H, m), 5.10 (1H, m), 7.48 (2H, ddd, J = 7.5, 1 Hz), 7.55 (1H, ddd, J = 7.5, 1Hz), 7.56 (2H, dd, J = 7.5 1Hz); ^{13}C ($CDCl_3$): δ 166.33, 132.59, 130.97, 129.54, 128.27, 125.48, 77.94, 36.19, 35.41, 31.23, 27.95, 22.62, 20.31, 14.41, 14.02, 13.92; Cl-MS *m/z* (relative intensity): 262 (2), 140 (M^+-C_6H_5-CO, 100)]; Anal. calcd. for $C_{17}H_{26}O_2$: C, 77.81; H, 9.99; found: C, 77.71; H, 10.17. (4*R*,5*R*)-**4**: 3.06 g, 73% yield; Anal. calcd. for $C_{17}H_{26}O_2$: C, 77.81; H, 9.99; found: C, 77.76; H, 9.90.

(4S,5S)-4-Methyl-5-nonanol [(4S,5S)-1]. Saponification of (4*S*,5*S*)-**4** (Perez et al., 1994) yielded (4*S*,5*S*)-**1** (1.20 g, 81% yield, 98% ee) as a colorless liquid: bp 72–74°C at 17 mm Hg; $[\alpha]_D^{20}$ = −25.5° (c = 1.765, Et_2O); ^1H ($CDCl_3$): δ 0.86 (2H, d, J = 8Hz), 0.90 (6H, m), 1.18 (2H, m), 1.34 (11H, m), 3.48 (1H, m); ^{13}C ($CDCl_3$): δ 75.19, 37.91, 35.64, 34.19, 28.45, 22.75, 20.43, 14.27, 14.00, 13.50; Anal. calcd. for $C_{10}H_{22}O$: C, 75.87; H, 14.02;

found: C, 76.01; H, 13.90. (4*R*,5*R*)-**1**: bp 65–68°C at 10 mm Hg; $[\alpha]_D^{20}$ = +26.6° (c = 1.895, Et_2O); 1.59 g, 85% yield, 98% ee; Anal. calcd. for $C_{10}H_{22}O$: C, 75.87; H, 14.02; found: C, 76.00; H, 13.99.

(S)-4-Methyl-5-nonanone [(S)-2)]. Oxidation of (4*S*,5*S*)-**1** (Brown et al., 1971) yielded (*S*)-**2,** bp 48–50°C at 20 mm Hg; $[\alpha]_D^{20}$ = +16.3° (c = 2.220, Et_2O); (2.34 g, 83% yield, 95% ee). IR (neat) 2959, 2874, 1713, 1460, 1409, 1378, 1124, 1046, 989 cm^{-1}; ^1H ($CDCl_3$): δ 0.90 (6H, m), 1.04 (3H, d, *J* = 8Hz), 1.29 (5H, m), 1.55 (2H, m), 1.60 (1H, m), 2.42 (2H, ddd, *J* = 8, 4Hz), 2.52 (1H, m); ^{13}C ($CDCl_3$): δ 214.94, 46.12, 40.84, 35.23, 25.86, 22.32, 20.49, 16.32, 14.09, 14.02; Anal. calcd. for $C_{10}H_{20}O$: C, 76.85; H, 12.91; found: C, 76.75; H, 12.86. (*R*)-**2:** bp 42–45°C at 10 mm Hg; $[\alpha]_D^{20}$ = −13.4° (c = 2.390, Et_2O); 2.40 g, 95% yield, 95% ee; Anal. calcd. for $C_{10}H_{22}O$: C, 76.85; H, 12.91; found: C, 77.03; H, 13.11.

Optical purities of (4*S*,5*R*)-**1** (96%), (4*R*,5*S*)-**1** (95%), (4*S*,5*S*)-**1** (98%), (4*R*,5*R*)-**1** (98%), (4*S*)-**2** (95%), and (4*R*)-**2** (95%) were determined by GC analyses on a Cyclodex-B column. Racemic **1** and **2** were synthesized as previously described (Hallett et al., 1993a).

Field Experiments

Response of *R. ferrugineus* and *R. vulneratus* to chiral isomers of **1** and **2** were investigated in coconut plantations at the Coconut Research Station, Pakuwon, West Java (August–December 1993, July and November–December 1994). Bucket traps (Oehlschlager et al., 1993a) were attached at 2 m height or at the base of coconut palms in randomized complete blocks. There are no significant differences in trap effectiveness for these two trap placements (Oehlschlager et al., 1993b; R.H. Hallett, unpublished data). Minimum intertrap and interblock distances were 16 and 45 m, respectively. All traps contained 1 kg of freshly cut coconut stem (approx. 5 × 5 × 20 cm) treated with a 0.3% a.i. solution of Basudin 60 EC (diazinon, Ciba-Geigy) to retain captured weevils.

Compounds **1** and **2** were released from 1-mm-ID capillary tubes (0.1 mg/day at 25°C) opened 1 cm above the liquid meniscus and placed inside 400 μl Eppendorf tubes. Eppendorf tubes had four 3-mm-diameter holes 1 cm below the top and were suspended 3–4 cm below the trap lid.

An experiment with four treatments and 20 replicates (August 16–30, 1993) tested attraction of both *R. ferrugineus* and *R. vulneratus* to coconut tissue alone or in combination with stereoisomeric **1** (0.4 mg/day at 25°C), (*S*,*S*)- or (*R*,*R*)-**1** (0.1 mg/day at 25°C). A second experiment with four treatments and 20 replicates (November 29–December 4, and December 7–15, 1993) tested attraction of both *R. ferrugineus* and *R. vulneratus* to coconut stem alone or in combination with racemic (0.4 mg/day at 25°C), (*S*)-, or (*R*)-**2** (0.2 mg/day at 25°C). A final experiment (four treatments, 19 replicates) (July 9–21, and

November 21–December 6, 1994) tested attraction of both *R. ferrugineus* and *R. vulneratus* to (*S*,*S*)-**1** (1 mg/day at 25°C) plus coconut stem alone or in combination with either racemic (0.2 mg/day at 25°C), (*S*)- or (*R*)-**2** (0.1 mg/day at 25°C), approximating the natural 10:1 ratio (Hallett et al., 1993a).

Statistical Analysis

Despite transformation by $\log(x + 1)$, data for all field experiments were not normally distributed and were therefore subjected to analysis by χ^2 tests ($\alpha = 0.05$) for species and treatment differences (Zar, 1984).

RESULTS AND DISCUSSION

Stereoisomers of **1** were produced according to rules used for preparation of structurally related pheromones of *R. phoenicis* and *R. cruentatus* (Figure 1) (Perez et al., 1994). Sharpless epoxidation of (*E*)-2-hexen-1-ol proceeded with high enantioselectivity unlike that of the *Z* isomer (Perez et al., 1994). Enantiomeric epoxides were stereo- and regiospecifically cleaved with trimethylaluminum and tosylated to produce (2*S*,3*S*)-3-methyl-1-tosyloxyhexan-2-ol [(2*S*,3*S*)-**3**] and its antipode. These derivatives were alkylated via cuprate (Grignard) displacement of the tosylate (Fouquet and Schlosser, 1974) to produce (4*S*,5*R*)-**1** (*anti*) and its antipode. The hydroxyl-bearing carbons of both stereoisomers were inverted through Mitsunobu chemistry to produce (4*S*,5*S*)-**1** and its antipode in high optical purity (95–98% ee).

Ketone (*R*)-**2** has previously been prepared in excellent optical purity (98% ee) using 1-amino-2-methoxymethylpyrrolidine as a chiral auxiliary (Enders et al., 1984). Although both enantiomers of the chiral auxiliary are available, this method requires stoichiometric amounts of these expensive reagents. Since the stereoisomers of **1** were obtained with very high enantiomeric excess, we investigated oxidation to the corresponding ketone (Figure 1). Jones' oxidation of alcohols possessing chiral α-carbons proceeds without loss of optical activity if conducted in a two-phase system ($Et_2O:H_2O$) (Brown et al., 1971). Applying Brown's procedure, (4*S*,5*R*)-**1** and its antipode yielded (*S*)-**2** and (*R*)-**2**, respectively, in high chemical yield and optical purity. Synthesis of ketones (*S*)-**2** and (*R*)-**2** in 30–35% overall yield (95% ee) based on 2-hexen-1-ol is comparable to the 44% overall yield (Enders et al., 1984) obtained in the previous four-step synthesis of (*S*)-**2**.

Gas chromatographic analysis of weevil-produced and synthetic (stereoisomeric) **1** on a SP-1000 column revealed that both *R. ferrugineus* and *R. vulneratus* produced the *syn* diastereoisomer (Perez et al., 1993, 1994). Further GC-EAD and GC-MS-SIM analyses on a Cyclodex-B column disclosed that

both palm weevils produce and antennally respond only to (4*S*,5*S*)-**1** (Figures 2 and 3). Production of (4*S*,5*S*)-**1** as an aggregation pheromone for these two species confirms previous results (Perez et al., 1993; Mori et al., 1993); (4*S*,5*S*)-**1** has also been reported as an aggregation pheromone for *R. bilineatus* (Montr.) in Papua New Guinea (Oehlschlager et al., 1995).

In field experiments, (±)-**1** or (4*S*,5*S*)-**1**, but not (4*R*,5*R*)-**1**, significantly enhanced attraction of both *R. ferrugineus* and *R. vulneratus* to traps baited with coconut stem tissue (Figure 4). No significant differences in attraction were found between the two species ($\chi^2 = 0.467$, $df = 3$, $P > 0.90$). As reported

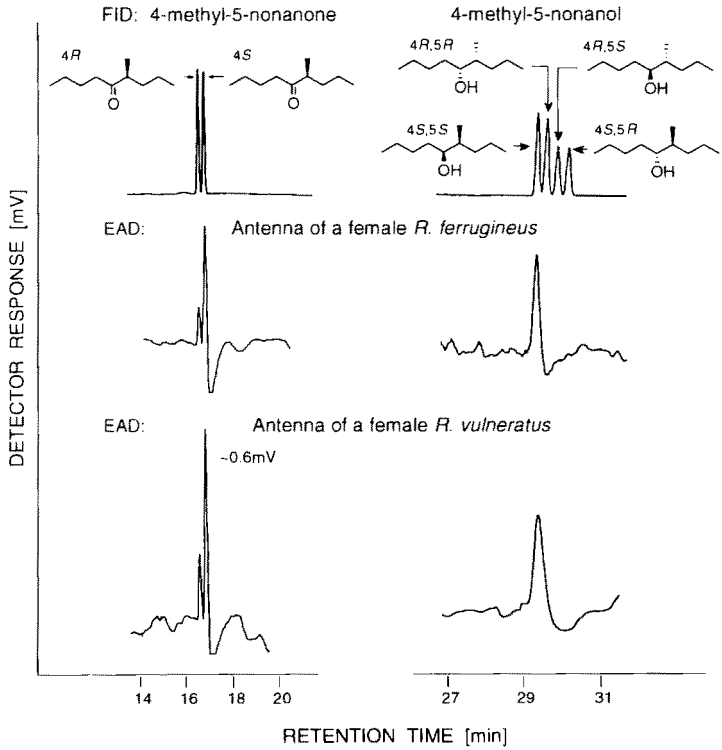

FIG. 2. Representative GC-EAD recordings of female *R. Ferrugineus* and *R. vulneratus* antenna responding to stereoisomers of 4-methyl-5-nonanone (**2**) and 4-methyl-5-nonanol (**1**) (Hewlett Packard 5890A; Cyclodex-B column; 100°C isothermal; split injector; linear flow velocity of carrier gas: 35 cm sec^{1}; injector temperature: 220°C). Different weevil antennae and chart speeds of 0.5 and 1.0 cm/min were used for the analyses of **2** and **1**, respectively.

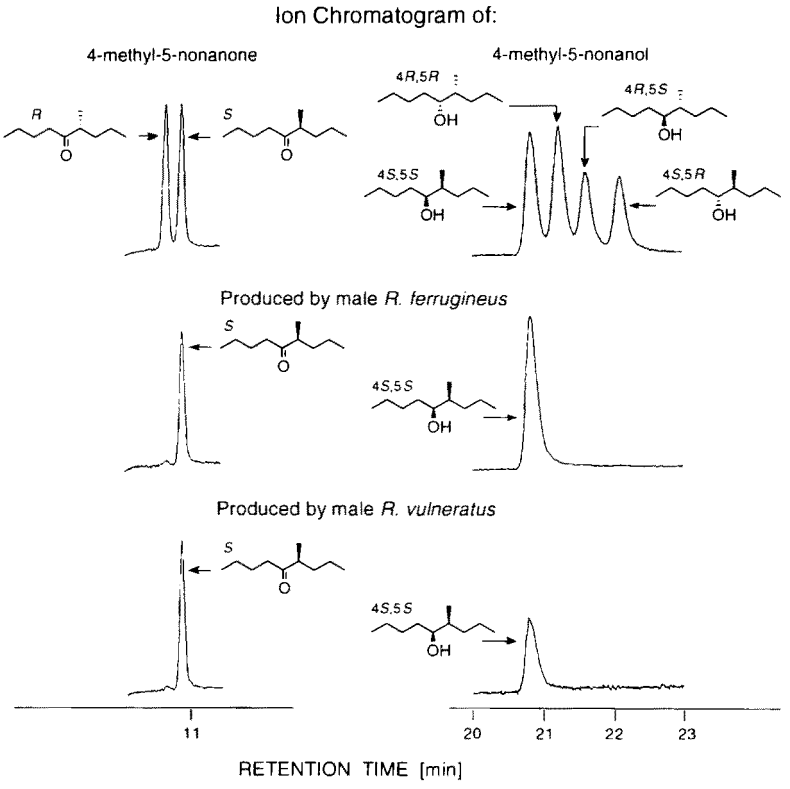

FIG. 3. Selected ion *m/z* 157 and *m/z* 141 chromatograms (Hewlett Packard 5985B GC-MS) of stereoisomeric and weevil-produced 4-methyl-5-nonanone (**2**) and 4-methyl-5-nonanol (**1**). *m/z* 157 and *m/z* 141 were, respectively, the parent ions of the full-scan mass spectra in CI mode of **2** [$(M^+ + H)$ 157] and **1** [$(M^+ + H)$ 159, $(M^+ - H_2O)$ 141] (column and chromatographic conditions as in Figure 2). Relative abundance of **2** and **1** in these ion chromatograms do not represent natural ratios.

in other Rhynchophorinae, nonnatural stereoisomers of the aggregation pheromone neither enhanced nor reduced attraction to the natural isomer (Oehlschlager et al., 1992, 1995; Perez et al., 1993, 1994).

Because (4*S*,5*S*)-**1** is an aggregation pheromone in both *R. ferrugineus* and *R. vulneratus*, we hypothesized that enantiospecific production of and response to **2** may impart species specificity of pheromone communication. However, GC-EAD and GC- MS-SIM analyses on a Cyclodex-B column of weevil-produced **2**, synthetic (±)-**2**, and each of the two enantiomers indicated that both

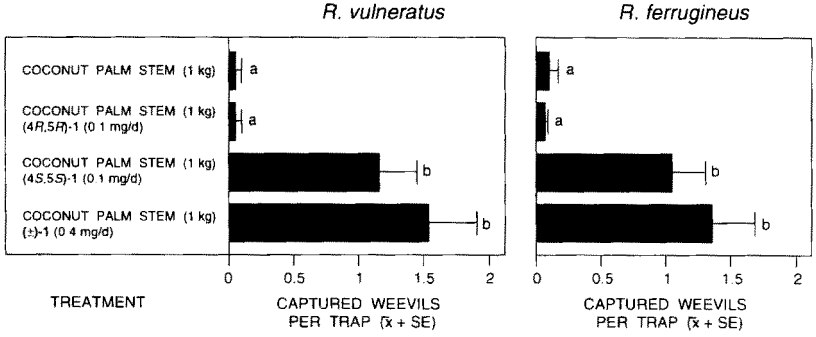

FIG. 4. Mean captures of *R. ferrugineus* (χ^2 = 41.157, *df* = 3, $P < 0.01$) and *R. vulneratus* (χ^2 = 36.987, *df* = 3, $P < 0.01$) in bucket traps baited with stereoisomers of 4-methyl-5-nonanol (**1**) and coconut stem tissue (Coconut Research Station, Pakuwon, West Java) August 16–30 1993; $N = 20$). Means followed by the same letter are not significantly different (χ^2 test, $\alpha < 0.05$).

R. vulneratus and *R. ferrugineus* produce and antennally respond more strongly to (*S*)-**2** than to (*R*)-**2** (Figures 2 and 3). Field experiments at Balitka, West Java, using coconut stem alone or in combination with (±)-**2**, (*S*)-**2**, or (*R*)-**2** (data not shown), indicated no significant differences between treatments for *R. ferrugineus* (χ^2 = 3.60, *df* = 3, $P > 0.25$) and *R. vulneratus* (χ^2 = 4.259, *df* = 3, $P > 0.20$) and no significant differences in attraction between the two species (χ^2 = 0.154, *df* = 3, $P > 0.95$). Furthermore, comparison of capture rates of traps baited with coconut stem tissue and (4*S*,5*S*)-**1** plus either (±)-**2**, (*S*)-**2**, or (*R*)-**2** at the natural 10:1 ratio of **1**:**2** did not indicate any behavioral activity of (±)-**2** or its enantiomers (Figure 5). No significant differences were found between the two species (χ^2 = 1.699, *df* = 3, $P > 0.50$) or between the two time periods (*R. ferrugineus:* χ^2 = 6.350, *df* = 3, $P > 0.05$; *R vulneratus:* χ^2 = 3.206, *df* = 3, $P > 0.25$) in which the experiment was conducted.

Although **2** is antennally active in both species, the result of four experiments did not disclose behavioral activity for either species in Indonesia or for *R. ferrugineus* in the United Arab Emirates (Figure 5) (Hallett et al., 1993a,b). Furthermore, in our field experiment in Java, **2** did not have significant behavioral activity in either weevil and did not impart specificity of pheromone communication. Throughout their wide geographic distribution, populations of *R. ferrugineus* and/or *R. vulneratus* may exist that respond to **2**.

Although *R. ferrugineus* and *R. vulneratus* are distinguished primarily by differences in dorsal coloration (Wattanapongsiri, 1966), there are color inter-

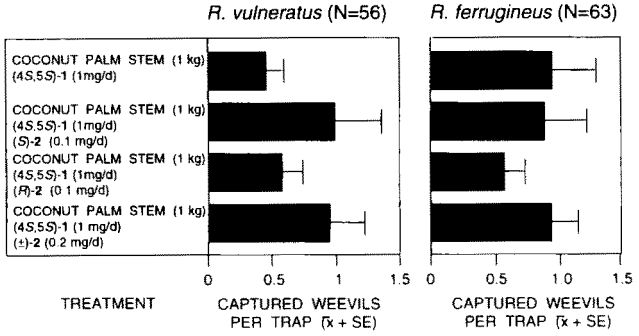

FIG. 5. Mean captures of *R. ferrugineus* and *R. vulneratus* in bucket traps baited with coconut stem tissue, (4*S*,5*S*)-4-methyl-5-nonanol (**1**), and isomers of 4-methyl-5-nonanone (**2**) (Coconut Research Station, Pakuwon, West Java, July 9–21 and November 21–December 6, 1994; $N = 19$. Data pooled for two time periods.). Means are not significantly different (χ^2 test, $\alpha = 0.05$).

morphs between the two species (Hallett et al., 1993a). Moreover, they are sympatric with similar food preferences (Wattanapongsiri, 1966), and in captivity exhibit interspecific copulation. In the scolytid genus *Ips*, closely related species are cross-attractive, but unlike *R. ferrugineus* and *R. vulneratus* maintain reproductive isolation through allopatric or parapatric distributions (Lanier and Wood, 1975). Failing the demonstration of other pre- or postzygotic reproductive isolating mechanisms, such as nonviability of progeny, *R. ferrugineus* and *R. vulneratus* should be synonymized.

(Received May 26, 1995; accepted October 26, 1995)

Abstract—Artificially damaged cotyledons of subterranean clover (*Trifolium subterraneum* L.) released several volatile metabolites, including 1-octen-3-one, arising from lipid peroxidation. The amount of 1-octen-3-one produced was negatively correlated with feeding damage caused by the red-legged earth mite (*Halotydeus destructor*) in nine out of 10 resistant and susceptible *T. subterraneum* varieties tested. The EC_{50} of this compound in deterring mites from feeding in a membrane bioassay was 50 ppm. Cotyledon toughness was also involved in resistance. The resistant variety, S3615D, which has the lowest toughness value among the resistant varieties, produced the highest amount of 1-octen-3-one recovered from the headspace in 1 hr. Artificially damaged cotyledons of both susceptible Dalkeith and resistant DGI007, growing in shade, showed lower toughness, but had enhanced production of C_8 volatile compounds and were avoided by mites during a 3-hr feeding test. When both 1-octen-3-one content and cotyledon toughness value were taken as cofactors in resistance, the resultant multiplication value yielded a more significantly negative correlation with mite feeding damage scores within the 10 varieties than either factor alone. We conclude that 1-octen-3-one has a role in resistance of subclover cotyledon to the mite.

Key Words—Subterranean clover, *Trifolium subterraneum*, cotyledons, red-legged earth mite, *Halotydeus destructor*, deterrence, 1-octen-3-one, volatiles, host resistance, antixenosis.

INTRODUCTION

The red-legged earth mite, *Halotydeus destructor* (Tucker) (Acarina: Penthaleidae) causes an estimated annual loss of $200 million in production from pastures in southern Australia. Subterranean clover (subclover), *Trifolium subterraneum* L., suffers serious damage from feeding by the mites, especially at the seedling stage. As a consequence, cotyledons and even whole seedlings can be destroyed by mites. Screening for resistant varieties at the seedling stage has therefore become a priority in the control of this pest and a number of resistant varieties have been selected (Gillespie, 1994).

Cotyledons of the resistant varieties show antixenotic properties, with less mites feeding on them and being less damaged than susceptible varieties (Jiang and Ridsdill-Smith, unpublished data). Physical toughness of the cotyledons, regarded as a possible defense against the mite, is negatively correlated with mite feeding damage in at least 16 varieties of subclover (Jiang and Ridsdill-Smith, unpublished data). An exception is the resistant variety S3615D, in which the toughness value is as low as susceptible varieties, suggesting the likelihood that other resistance mechanisms are involved.

Cotyledons of the resistant varieties are not completely immune to mite feeding (Gillespie, 1993; Ridsdill-Smith and Gillespie, 1993). Behavioral observations reveal that mites visit cotyledons of resistant varieties initially in choice tests and some feeding occurs on such cotyledons in nonchoice tests. Silver patches, caused by feeding damage, are visible on cotyledons of resistant as well as susceptible varieties within several minutes (unpublished), although they are limited to small areas for the former varieties. Electron microscopy studies have shown that feeding damage is largely a result of a mechanical process, with mite chelicerae making penetration holes in epidermal cells (Ridsdill-Smith et al., 1996). These observations led us to hypothesize that "antifeedant" properties are not detected until the mite penetrates and damages the cotyledons. Since a mite sucks the content from single cells and penetrates cells quickly, any plant response to cell damage would need to be produced rapidly to have an effect on a feeding mite. The release of volatile compounds can occur within seconds following damage to plant tissue, and such a process could play a significant role in determining resistance. It is possible to investigate the volatile compounds with artificially damaged cotyledons, since Dicke and Sabelis (1992) have demonstrated that artificially damaged Lima bean leaves produce virtually all the same volatile compounds induced by spider mite feeding damage.

We have shown that volatiles from artificially damaged cotyledons are strongly deterrent and/or repellent to the mite at certain concentrations when tested in a membrane sachet bioassay (Jiang et al., unpublished data). The volatile compounds collected from a resistant variety are more deterrent than those from a susceptible variety (Jiang et al., unpublished data). In this paper,

we present evidence that the volatile compound, 1-octen-3-one, was involved in resistance. Bioassay results indicated that the compound was deterrent to the mite in a concentration-dependent manner. Furthermore, in an experiment designed to find effects on mite feeding of cotyledons growing in the shade, it was found, unexpectedly, that although the cotyledons had significantly lower toughness, the mites did not feed on shaded cotyledons and production of 1-octen-3-one was increased in shaded cotyledons.

METHODS AND MATERIALS

Plant Material. Seeds of four susceptible and six resistant subclover varieties were sown in pots (each 12 cm diameter) with standardized sand–loam soil as described by Ridsdill-Smith and Gillespie (1993). For each test, two susceptible and two resistant varieties were grown under the same glasshouse conditions. Seedlings were harvested and processed on the same day for collection of volatile compounds, 12 or 13 days after seed sowing. To study the effects of toughness and volatiles of cotyledons growing in the shade on feeding of mites, seedlings in five pots of each variety (Dalkeith, susceptible; DGI007, resistant) were covered with a cardboard box with four openings of 5 × 5 cm in the middle of the side walls, allowing in dim light to the plants. As controls, seedlings in five other pots were not covered. Cotyledons were used at 12 or 13 days after seed sowing.

Mites. Red-legged earth mites were collected from the field, near Perth, in winter. They were age-graded after collection and only young adult mites were used for bioassays. Before the bioassay, mites were starved for 2 hr in a humid vial.

Chemicals. 1-Octen-3-ol and 2-(*E*)-hexenal were purchased from Aldrich and Sigma Chemical Company, respectively. 1-Octen-3-one was prepared by oxidation of 1-octen-3-ol with pyridinium chlorochromate.

Headspace Collection of Volatile Compounds from Artificially Damaged Cotyledons. A stream of air filtered through granulated charcoal (about 50 g) was drawn into a separating funnel (8 cm diameter) that contained the plant tissues. The air carrying the volatile compounds was passed into a trap made of 50 mg powdered charcoal in a Pasteur pipet. The airflow was controlled by the water pump (about 500 ml/min). Trapping was generally conducted for 1 hr only, unless specified otherwise. For quantitative comparison among 10 varieties, 2.4 g of cotyledon tissues of each variety were used. To determine the 1-octen-3-one content after collection for different times (1 and 6 hr), 7.8 g of cotyledon tissues were used for each variety. To test cotyledons grown in the shade, 3.5 g of tissues were used. Detached cotyledons were frozen in liquid nitrogen and ground (damaged) in a mortar. The powdered tissues were trans-

ferred, with a filter paper, into a round funnel (8 cm diameter), in which another filter paper (Whatman No. 1), cut netlike, was set at the bottom to hold the powder. The tissue was deposited on the walls of the funnel by turning it around. By this time, the tissue had thawed and collection of the volatile compounds was started. To compare different varieties, 5 or 10 μl of hexanol was added as an internal standard. The charcoal traps were stored at −20°C.

Gas Chromatography (GC). The volatile compounds were desorbed with 1 ml of dichloromethane. The compounds collected were analyzed by GC, using a Hewlett-Packard 5790A instrument equipped with a fused silica BP 1 column (0.25-μm film thickness, 0.22 mm ID × 25 m) and an FID detector with hydrogen as the carrier gas (1.5 ml/min). Temperature was programmed from 40°C for 5 min and then to 290°C at 20°C/min. For each sample, at least two chromatograms were recorded.

Gas Chromatography–Mass Spectrometry (GC-MS). Volatile compounds were analyzed using a Hewlett-Packard 5986 GC-MS (EI, 70 eV). The compounds were identified by comparison of their mass spectra and retention time, singly and in admixture, with those of authentic compounds.

Air Oxidation of 1-Octen-3-ol. 1-Octen-3-ol (1 μl; 98% purity) was treated under the same conditions as described for damaged cotyledon tissues. In another test, 1 ml of 0.05% (v/v) aqueous 1-octen-3-ol solution was added onto the frozen powders of ground cotyledon tissues of a resistant variety (DGI007) and the volatiles were collected as for other treatments.

Membrane Feeding Test. The bioassay of the volatile compounds was conducted by using membrane sachets as described in Jiang et al. (unpublished data). Briefly, compounds were added to pure Tween 80. A solution of glucose in distilled water was added to achieve a final concentration of 5% Tween 80 and 1% glucose. To measure the EC_{50} for deterrence, a range of concentrations of a compound were tested. The aqueous solution used as feeding medium was sandwiched between two layers of parafilm membranes stretched over a plastic ring (2 cm diameter). In the two-choice tests, a sachet with the test compound was a treatment, whereas the other contained only Tween 80 and glucose and served as a control. Two membrane sachets were set into the surface of a sand–loam soil close to each other in a tissue culture cup (5.7 cm diameter). Twenty mites were released onto the soil, and mite numbers were counted every 20 min for the first hour and then every 30 min afterwards for a further 2 hr. There were 10 replicates for each treatment. The averages from seven observations for each replicate were used to calculate the mean and standard errors, which were compared with a t test for statistical significance in a choice test. Mite counts provide a relative estimate of feeding (Jiang and Ridsdill-Smith, unpublished data) based on the formula [(numbers of mites on control − numbers of mites on treatment)/both mite numbers added)] × 100. Mite selection between the treatment and control membranes was expressed as deterrence of the test

compound (indicated by a positive value) or as preference for the test compound (indicated by a negative value).

Scores of Mite Feeding Damage to Cotyledons over Two Weeks. Seedlings in pots with multivariety choices were exposed to mites for two weeks (Gillespie, 1993). Mite feeding damage to seedlings was scored for each variety from more than two experiments with a 1–10 rating system (1 = 10% feeding damage and 100% = death of seedlings). Damage scores collected by Gillespie from different varieties were used in this study to calculate regression between the resistance and amounts of volatile compounds.

Cotyledon Choice Feeding Test. The choice feeding methods are described in Jiang and Ridsdill-Smith (unpublished data). The cotyledons were cut and two were placed close to each other on the sand–loam in a small Petri dish (5 dm diameter). Cotyledons from the same or a different variety (Dalkeith, susceptible; and DGI007, resistant) were compared for effects of shaded cotyledons on mites. Numbers of mites feeding on cotyledons were counted every 20 min in the first hour and then every 30 min afterwards for 2 hrs. There were 10 replicates for each choice test. Numbers of mites counted from the seven observations during 3 hr were averaged and used to calculate mean, standard error, and statistical significance (t test). Mite preference for a cotyledon was calculated with the above formula.

Toughness Test of Cotyledons. Toughness of cotyledons from varieties (Dalkeith, susceptible; and DGI007, resistant) growing in shade or light was measured with a pipet-balance penetrometer (Jiang and Ridsdill-Smith, unpublished data). Four penetrations were made for each cotyledon, on both sides of the main vein away from the base, with 10 replicate cotyledons for each treatment.

Combined Effects of Toughness and Volatiles. Based on the results obtained in this work for 1-octen-3-one and the results collected by Jiang and Ridsdill-Smith (unpublished data) for toughness, it was assumed that both 1-octen-3-one and toughness contributed to the resistance in cotyledons. It is unknown whether both factors are of equal importance in resistance, but values of both for a variety were multiplied to produce an index. Regressions were made between the index and damage scores for the different varieties.

RESULTS

Identification of Compounds Present in Headspace Collection. No qualitative difference in the volatile compounds produced was found among the varieties examined (Figure 1). Of the five major compounds, three, 2-(E)-hexenal, 1-octen-3-one, and 1-octen-3-ol, have been identified. Comparison of their mass spectrometric and chromatographic properties with those of authentic samples

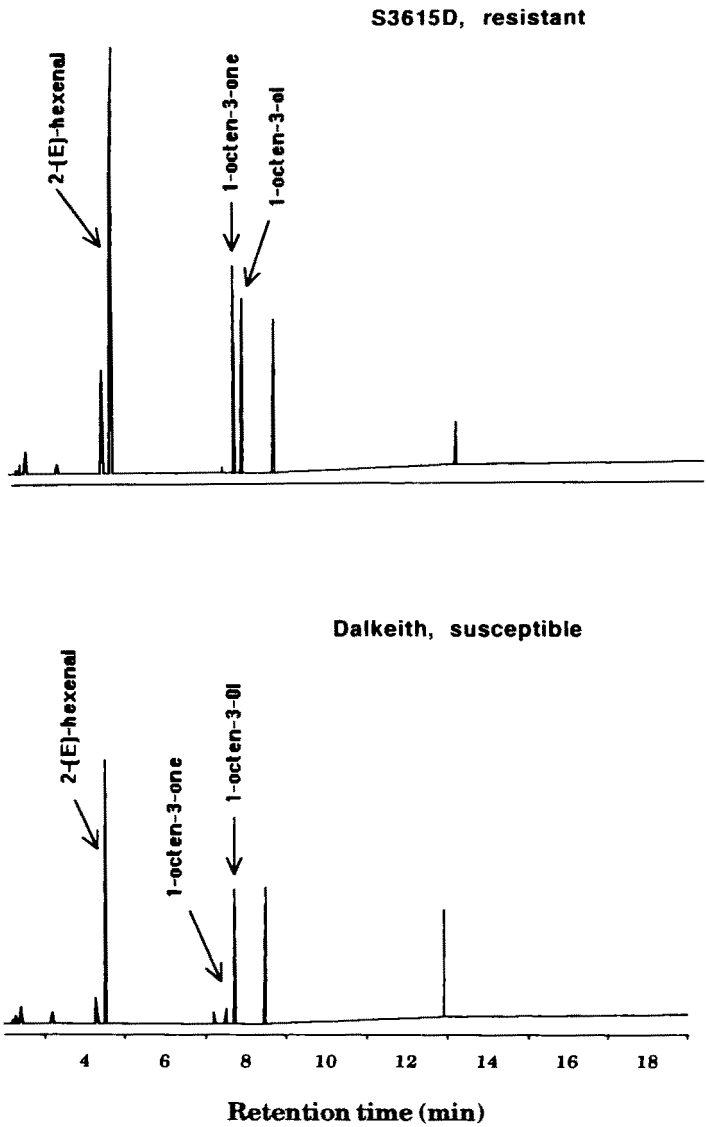

FIG. 1. Gas chromatograms of headspace volatile compounds collected from damaged cotyledons of subclover. Varieties shown here were S3615D (resistant) and Dalkeith (susceptible). Positions of 2-(*E*)-hexenal, 1-octen-3-ol, and 1-octen-3-one are indicated. Some volatile compounds are unidentified.

established their identity. Not more than 0.5% 1-octen-3-one was detected from the headspaces of either 1-octen-3-ol or combined 1-octen-3-ol and ground DGI007 cotyledon tissues, indicating negligible air oxidation of this metabolite.

Quantitation of Volatile Compounds and Correlation with Mite Feeding Damage. The relative amounts of the three compounds collected from 10 varieties over a 1-hr period are presented in Table 1. There was variation of the compounds between varieties, but only 1-octen-3-one was consistently higher in resistant than in susceptible varieties, with one exception (82S47.16.2). There is a significant negative correlation ($R^2 = 0.713$) between the levels of 1-octen-3-one produced and scores of mite feeding damage within a two-week testing period.

Collection of 1-octen-3-one over 6 hr yielded a higher amount than in 1 hr in all three varieties (Figure 2). The estimated amount of 1-octen-3-one collected within 1 hr from the damaged cotyledons was about 5 ppm in the susceptible varieties, whereas in resistant varieties it was about 15 ppm (19 ppm in S3615D). The amount of 1-octen-3-ol collected was generally higher than that of 1-octen-3-one and varied from 2 ppm (variety 82S47.16.2) to 28 ppm (variety S3617D). 2-(*E*)-Hexenal also varied from 11 ppm (variety Dalkeith) to 30 ppm (variety DGI007).

Antifeeding Activity of 1-Octen-3-one with Membrane Feeding Tests. At high concentrations, all three volatile compounds, 1-octen-3-one, 1-octen-3-ol,

TABLE 1. VOLATILE COMPOUNDS RELATIVE TO *n*-HEXANOL IN HEADSPACE OF ARTIFICIALLY DAMAGED COTYLEDONS (2.4 g) OF SUBCLOVER VARIETIES[a]

Varieties	Character	Compound (mean ± SE)		
		1-Octen-3-one	1-Octen-3-ol	2-(*E*)-Hexenal
Dalkeith	Susceptible	0.13 ± 0.001	0.44 ± 0.001	0.47 ± 0.026
Denmark	Susceptible	0.11 ± 0.001	0.21 ± 0.001	2.84 ± 0.010

S3615D	Resistant	0.48 ± 0.005	0.65 ± 0.002	2.69 ± 0.005

[a]Collection of compounds was completed at 1 hr. The internal standard was 10 μl *n*-hexanol ($n = 2$).

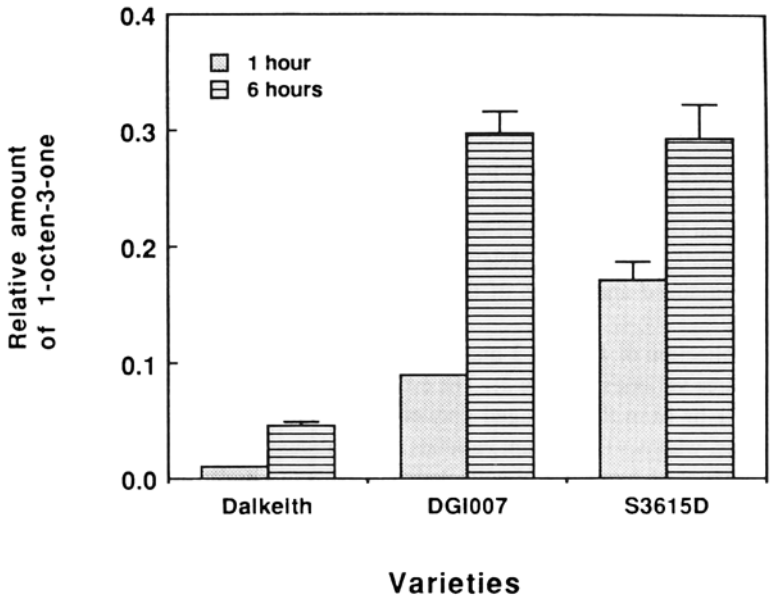

FIG. 2. Relative amounts of 1-octen-3-one collected for 1 and 6 hr from the headspace of damaged cotyledons of three subclover varieties, Dalkeith (susceptible), DGI007 (resistant), and S3615D (resistant).

and 2-(*E*)-hexenal, exhibited antifeeding activity towards mites in the membrane feeding test. This is illustrated for 1-octen-3-one (Figure 3). The EC_{50} for deterrent activity was 50 ppm for 1-octen-3-one, 55 ppm for 2-(*E*)-hexenal, and 285 ppm for 1-octen-3-ol. For 1-octen-3-one and 2-(*E*)-hexenal, all mites were repelled from feeding on both treatment and control membrane sachets with concentrations of 1000 ppm and higher. At low concentration (about 1 ppm), 1-octen-3-one and 2-(*E*)-hexenal were attractive to the mites in the three hour test.

Correlation of 1-Octen-3-one Content and Toughness in Relation to Mite Feeding Damage. Most resistant varieties tested not only produce high amounts of 1-octen-3-one but also have high toughness values (Jiang and Ridsdill-Smith, unpublished data), although 1-octen-3-one is low for variety 82S47.16.2 and toughness for variety S3615D (Figure 4). Multiplication between 1-octen-3-one content and the toughness value for each variety yields an index that was negatively correlated with mite feeding damage scores. The R^2 value (0.873) obtained was higher than that (0.713) in the correlation between 1-octen-3-one

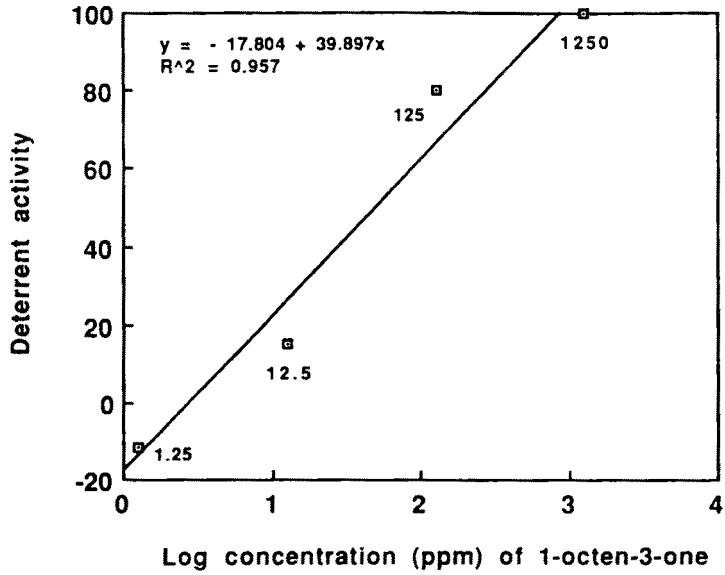

FIG. 3. Responses of the red-legged earth mite to 1-octen-3-one tested at four concentrations (1.25, 12.5, 125, and 1250 ppm) in a membrane bioassay. Note attractiveness of the compound at 1.25 ppm.

alone and damage score and that (0.752) in the correlation between toughness and damage score.

Shading Effect on Mite Feeding and Volatile Content. Cotyledons of both Dalkeith (susceptible) and DGI007 (resistant) grown under shading were smaller than nonshaded cotyledons, but they were green. The shaded cotyledons of both varieties were completely avoided by mites in choice feeding tests during 3 hr (Table 2). Nonshaded cotyledons of DGI007 were more acceptable than shaded Dalkeith cotyledons. Toughness test indicated that shaded cotyledons of both varieties had significantly lower toughness values ($P < 0.01$) than the nonshaded counterparts: with Dalkeith (susceptible), toughness was 59.1 $\pm$ 0.93 for nonshaded and 43.9 $\pm$ 0.46 for shaded cotyledons; with DGI007 (resistant), this was 81.8 $\pm$ 1.04 for nonshaded and 52.4 $\pm$ 1.15 for shaded cotyledons. However, analyses of volatile compounds showed that C_8 volatile compounds, especially 1-octen-3-one, increased by more than 50%, whereas 2-(*E*)-hexenal decreased 9% in both varieties with shading (Table 3).

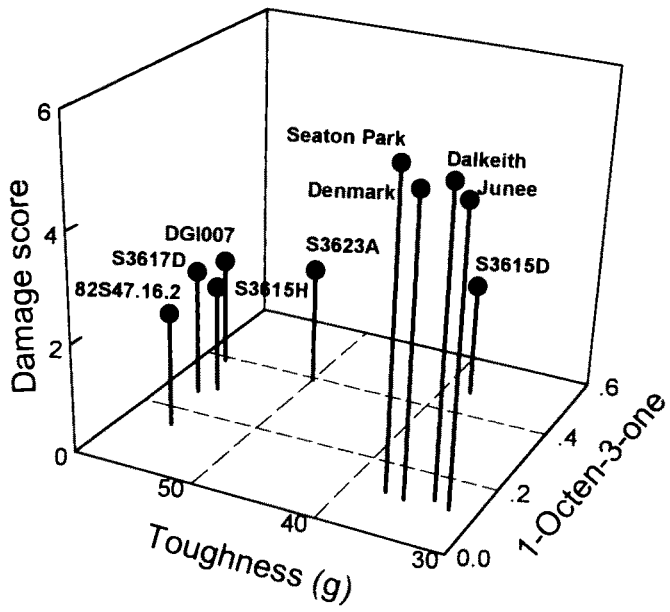

FIG. 4. Three-dimensional relationships between mite feeding damage scores, relative amount of 1-octen-3-one, and toughness value of the same 10 varieties of subclover. Note the four susceptible varieties are grouped as having both the lowest content of 1-octen-3-one and toughness values, whereas the resistant varieties are scattered around with either high 1-octen-3-one content or toughness values or both.

DISCUSSION

There is no visible difference in surface structure between subclover cotyledons of resistant and susceptible varieties. The cotyledons do not possess trichomes (Ridsdill-Smith et al., 1995), which are important chemical and physical barriers against spider mites in many other plant species. Furthermore, no antifeedant activity was found in nonvolatile extracts from resistant varieties, in comparison to susceptible varieties.

Higher amounts of 1-octen-3-one are produced in most resistant than in susceptible varieties, in particular the S-lines, which originate from Sicily, Italy. The significant correlation between 1-octen-3-one produced and resistance and its concentration-dependent deterrent activity strongly suggest that it could be responsible, at least in part, for the deterrent activity of the variety S3615D, which has low cotyledon toughness, as well as in other varieties with high cotyledon toughness such as DGI007. The concentration of 1-octen-3-one occur-

Non-shaded	0.26 ± 0.005	1.11 ± 0.006	3.36 ± 0.010
Shaded	0.49 ± 0.005	1.17 ± 0.001	3.05 ± 0.010

[a]The difference between shaded and nonshaded cotyledons is significant within the same variety using the t test ($P < 0.05$). An internal standard of 5 μl n-hexanol was used in quantification ($N = 2$).

ring in the resistant variety S3615D (19 ppm, collected within 1 hr) is within the range of concentrations for which mite deterrence is observed. With the susceptible variety Dalkeith, we were able to demonstrate production of 2-(*E*)-hexenal, 1-octen-3-ol, and 1-octen-3-one from cotyledons damaged by red-legged earth mites feeding activity (unpublished). Thus, the volatile compounds pro-

duced by artificially damaged cotyledons are representative of those produced by cotyledons after mite feeding.

The two- to threefold increase in 1-octen-3-one collected with time suggests that the compound is produced in a time-dependent manner and/or that collection within 1 hr underestimates the amount of compounds. Because the mites readily distinguish between cotyledons of resistant and susceptible varieties within 1 hr, it is reasonable to correlate mite resistance with the compounds collected within 1 hr. Terpenoids do not appear to be present in detectable amounts. We have shown that this is not due to the trapping system employed, since terpenes from damaged *Eucalyptus* leaves were trapped effectively using the same technique (unpublished). Dicke and Sabelis (1992) also found no production of terpenes in artificially damaged Lima bean leaves.

The striking negative effect of shade-grown cotyledons on mite feeding behavior and on the relative proportions of the volatile compounds are consistent with the results above. Shade-grown cotyledons have much lower toughness than nonshaded ones, but mites apparently do not like gathering and feeding on them. Although other changes, such as morphology and content of sugar, in these cotyledons could also affect mite feeding behavior, production of C_8 compounds (1-octen-3-one and 1-octen-3-ol) in both shade-grown susceptible and resistant varieties increased considerably. This could explain, at least in part, the reduced acceptance of the cotyledons by mites. The DGI007 variety is highly resistant to the red-legged earth mite (Gillespie, personal communication), and it appears that both high toughness value and high 1-octen-3-one production contribute to this resistance. However, the experiments with shade-grown cotyledons tend to suggest that the role of 1-octen-3-one in resistance is more important than toughness.

2-(*E*)-Hexenal has been shown to arise from the unsaturated fatty acid, linolenic acid (Hatanaka, 1993; Vick and Zimmerman, 1987). This is present in greater amounts in green leaves, particularly in the membranes of chloroplasts, than in nongreen and dark-grown leaf tissues (Harwood, 1980). On the other hand, the C_8 volatile compounds originate from linoleic acid (Mau et al., 1994), which is produced in greater amounts in dark-grown leaves than in green leaves and more in white than in the green parts in *Chlorophytum* (Harwood, 1980).

The above observations further support the correlation between 1-octen-3-one and mite resistance and help to rationalize the lack of correlation between levels of 2-(*E*)-hexenal and mite resistance. We presume that 2-(*E*)-hexenal collected from artificially damaged cotyledons is produced by the green palisade and spongy mesophyll cells that are not the major feeding sites of the mite. However, C_8 volatile compounds are probably produced, for the most part, in the nongreen epidermal cells. If this is true, the C_8 compounds should have a

much higher local concentration than is revealed from headspace trapping experiments.

Hildebrand et al. (1986) have observed enhanced lipid peroxidation and lipoxygenase activity in soybean leaves infested with spider mites. The authors suggest that the metabolite hexenal played a role in the induced resistance of soybean to spider mite (Kasu et al., 1994). We are not in a position to judge whether or not hexenal could also be involved in resistance because our measurements were for the whole cotyledon tissue, rather than for those specific tissues subjected to feeding mites.

In conclusion, the results strongly suggest that wound-induced C_8 compound, 1-octen-3-one, plays a significant role in the deterrence of cotyledons of some resistant subclover varieties to the red-legged earth mites. The combined effects of the compound and physical toughness confer more resistance to a variety than either factor alone. In the future, we need to establish whether or not other chemical compounds, e.g., those specifically induced by mite feeding, are also involved in the antixenotic resistance of subclover cotyledons to the redlegged earth mite.

Acknowledgments—Bioassay and toughness measurement of cotyledons were performed by J. D'Arcy-Evans. T. Picen helped in preparation of mites in some experiments. We thank D.J. Gillespie for providing seeds of subclover varieties and unpublished data on screening.

ANAL GLAND SECRETION OF EUROPEAN MOLE: VOLATILE CONSTITUENTS AND SIGNIFICANCE IN TERRITORIAL MAINTENANCE

CHANTAL KHAZANEHDARI, ALAN J. BUGLASS, and JOHN S. WATERHOUSE*

(Received June 6, 1995; accepted October 16, 1995)

Abstract—The chemical composition of the volatile components of the anal gland secretion of mature and immature moles of both sexes was examined by gas chromatography and mass spectrometry. The compounds in the secretion of adult males appear to vary little throughout the year and are similar to those from the adult female outside the breeding season. The secretions are dominated by C_5–C_{10} carboxylic acids. Female glands regress as they enter proestrus, accompanied by profound changes in the chemical composition of the secretion with early disappearance of the carboxylic acids. In juvenile moles, the compostion of the secretion changes as the animal matures, with carboxylic acids becoming dominant only as the animal reaches maturity. Anal gland secretion probably plays an important role in territorial maintenance.

Key Words—Moles, *Talpa europaea*, anal glands, scent marking, territoriality, semiochemical, proestrus, carboxylic acids.

INTRODUCTION

For most of the year the European mole (*Talpa europaea*) lives a solitary life in its own subterranean tunnel system and actively avoids contact with other members of its own species. The home ranges of females or of a male and a female may, however, overlap, and lengths of tunnel may be used in common. Moles in overlapping territories are aware of each other's existence and move-

ments, and they will organize their daily routine so as to avoid each other (Stone and Gorman, 1985; Gorman and Stone, 1990). The only time of the year when moles purposefully meet is during the mating season, when male moles will migrate into female territories in order to mate (Godfrey and Crowcroft, 1960). Studies by Gorman and Stone (1990) have suggested that the mole's efficient territorial maintenance is controlled at least in part by chemical signals produced by the secretion of specialized glands in the inguinal region of both sexes. These glands have been termed "preputial glands" by some workers (Racey, 1978; Stone and Gorman, 1985; Gorman and Stone, 1989, 1990), but we have recently shown that they are in fact anal glands (Clevedon Brown et al., 1994).

We present results here that support the hypothesis that the secretion from the anal glands plays a central role in the territorial maintenance of the mole. Our evidence is based on studies on variations in glandular mass and the chemical composition of the volatile components of the glandular secretion throughout the year.

METHODS AND MATERIALS

Moles used for both the anatomical and chemical studies were caught in lethal traps in Cambridgeshire and adjacent parts of Norfolk by a professional mole catcher (DRE Pest Control, Swavesey, Cambridgeshire). The carcasses were frozen immediately on collection for transport to the laboratory, where they remained frozen at −20°C until dissection. Anal glands were separated from extraglandular material and weighed. The glandular secretion was released by crushing the gland, and the volatile components therein were trapped on an activated charcoal disc using a Gorb dynamic headspace apparatus as previously described (Buglass et al., 1990). The volatiles were eluted from the disc with 8 μl of dichloromethane containing dihexyl sulfide (115 ng/μl as internal standard), and 1 μl of the resulting solution injected into a Hewlett-Packard 5890 gas chromatograph equipped with a polydimethylsiloxane column (length, 15 m; ID, 0.25 mm) and connected to a Hewlett-Packard 5970 mass spectrometer detector. The temperature program was 35–240°C at a rate of 4°C/min with a final hold at 240°C for 45 min. Compounds were identified from their mass spectra and also, in most cases, by comparison of retention times with those of authentic compounds (see Table 1 below).

Male moles in breeding condition were distinguished from nonbreeding males by the great increase in size of the testes and epididymus. Proestrus in the female was characterized by the presence of the vaginal opening, the increase in length and breadth of the reproductive tract resulting from growth and thickening of its wall, and vascularization of the uterine cornua (Harrison Matthews, 1935). We observed an increase in length of the uterovaginal canal to around

40–45% of body length during proestrus, as opposed to a normal value of less than 20%, in line with the findings of Harrison Matthews (1935). As estrus itself lasts for only about 30 hr in the mole (Godfrey and Crowcroft, 1960), no attempt was made to distinguish between the proestrous and the estrous female.

RESULTS AND DISCUSSION

In East Anglia the mating season for moles occurs early in the year. Females approach estrus as early as January. The gestation period is four weeks and lactation follows for a further four weeks (Deanesly, 1966; Godfrey and Crowcroft, 1960; Harrison Matthews, 1935); hence by February or March, females are likely to be pregnant or to be lactating. Additionally, we have observed a low incidence of second proestrus and presumably estrus in September.

Preliminary results from our study of the changes in anal gland size during the year showed that the glands of males and females behave differently (Buglass et al., 1995). Male glands increase in weight during the breeding season, reaching a maximum value at the peak of the breeding season in February and March. This change is probably due to vascular development resulting from a surge in testosterone, which in the shrew serves to increase vascularity of sebaceous tissue (Pearson, 1946). The increase in size and weight of the gland is associated with a deepening of its color to dark red. In contrast, female glands undergo a reduction in size as the female enters estrus in January or February. In the majority of 14 females that were collected in January, the glands had regressed to such a degree that they were invisible to the naked eye. Female glands enlarge as the breeding period ends, but the average value drops sharply in May before climbing again during summer and fall. We explain this effect by the inclusion of juveniles in the catch from May onwards. The glands of juveniles are flaccid and less developed than those of the mature mole, and it is not until August or September that glands of moles born in that year become indistinguishable from those of mature animals. The results of an extension of this study, involving a greater number of moles, are shown in Figure 1. These results are in full agreement with our earlier findings.

Samples of anal gland secretion from a total of 130 moles were analyzed by gas chromatography and mass spectrometry. For adult moles, chromatograms were obtained from secretion collection in each month of the year. A typical chromatogram from a nonbreeding male, a breeding male, a juvenile male, a nonbreeding female, a proestrous female, a pregnant female, a lactating female, a female approaching second estrus, and a juvenile female are shown in Figure 2A–I, respectively. Compounds are identified in Table 1.

With the exception of the proestrous female, C_5–C_{10} carboxylic acids, both straight and branched chain, form a significant component of the secretions of

TABLE 1. COMPOUNDS IDENTIFIED IN ANAL GLAND SECRETION OF MOLE
(Numbers in parentheses match those in Fig. 2.)

Carboxylic acids
- Butanoic acid (10)[a]
- 2-Methylbutanoic acid (18)
- Pentanoic acid (28)[a]
- Heptanoic acid (33)[a]
- Octanoic acid (39)[a]
- Nonanoic acid (44)[a]
- 6-Methylnonanoic acid (47)
- Undecanoic acid (53)[a]
- 3-Methylbutanoic acid (14)[a]
- 4-Methylpentanoic acid (25)[a]
- Hexanoic acid (30)[a]
- 7-Octenoic acid (36)
- 2-Methylhexanoic acid (40)
- 8-Nonenoic acid (45)[a]
- Decanoic acid (51)[a]
- Dodecanoic acid (54)[a]

Esters
- Methyl 2-ethylpropenoate (15)
- Ethyl decanoate (48)[a]
- Methyl decanoate (42)

Aldehydes
- Pentanal (5)
- Heptanal (20)[a]
- Nonanal (34)[a]
- Hexanal (8)[a]
- Octanal (47)[a]

Ketones
- 3-Hydroxybutan-2-one (1)
- Heptan-2-one (19)[a]
- Nonan-2-one (32)

Ketones Continued
- Tridecan-7-one (46)
- 5-Methylhexan-2-one (13)[a]
- 11-Dodecen-2-one (29)
- Undecan-2-one (41)
- Pentadecan-8-one (52)

Alcohols
- Pentan-2-ol (2)
- Pentan-1-ol (6)[a]
- Hexan-2-ol (9)[a]
- 3-Methylpentan-1-ol (12)[a]
- Hexan-1-ol (17)[a]
- 3-Methylhexan-1-ol (22)
- Heptan-1-ol (24)[a]
- Octan-1-ol (31)[a]
- *cis*(?)-3-Nonen-1-ol (37)
- Decan-1-ol (43)[a]
- 2-Undecen-1-ol (50)
- 3-Methylbutan-1-ol (4)[a]
- 3-Methylbut-2-en-1-ol (7)
- 4-Methylpentan-1-ol (11)[a]
- 5-Methylhexan-2-ol (16)
- Heptan-2-ol (21)
- *cis*-3-Hepten-1-ol (23)[a]
- *cis*(?)-3-Octen-1-ol (26)
- 1-Octen-3-ol (35)[a]
- Nonan-1-ol (38)[a]
- 3-Decen-1-ol (49)

Sulfide
- Dimethyl disulfide (3)

[a]Compounds whose identities were confirmed by comparison of retention times with those of the authentic compounds.

adult moles. Bacterial activity has been shown to be responsible for volatile carboxylic acids in the anal sacs of the lion (Albone et al., 1974), the red fox (Albone et al., 1974; Ware and Gosden, 1980), and the beaver (Svendsen and Jollick, 1978) and in the inguinal pouch of the rabbit (Merritt et al., 1982), but we have shown (Buglass et al., 1995) that no bacteria are present in the anal gland of the mole, and so carboxylic acids are formed by metabolic processes within the cells of the animal.

Bearing in mind that the samples came from different animals, the chromatograms in Figure 2A and B show remarkable similarity in the profile and composition of the volatile components of the anal gland secretion of the male

in the nonbreeding and the breeding seasons. The secretions are characterized by relatively high concentrations of carboxylic acids. The secretion from the nonbreeding female (Figure 2D) is also clearly similar in composition to that of the male, showing large carboxylic acid peaks. This corroborates the other male-like characteristics of the nonbreeding female, such as her external genitalia. As the female approaches estrus, however, there are profound changes in the composition of the anal gland secretion (Figure 2E), which occur together with the recession of the glands (Figure 1). The carboxylic acids disappear relatively early in the process and, as a consequence, alcohols become the main components for the period during which the glands are still secreting. The pattern in the female secretion is repeated in the rare occurrence of second estrus in September (Figure 2H), but in this case the carboxylic acids had not entirely disappeared at the time the animal was trapped. The characteristic male-like composition of the female secretion is quickly reestablished after estrus, as is shown in the secretion of the pregnant and lactating female (Figure 2F and G, respectively), both of which have significant carboxylic acid peaks.

The seasonal changes in the size of the female anal gland and in the composition of its secretion occur concurrently with profound changes in the ovary. The ovary contains two distinct glandular masses: an ovarian part and an interstitial gland, and these features vary in relative size and activity during the year. Outside the breeding season the interstitial gland is far larger than the ovarian part; but during the breeding season the ovarian part enlarges as the interstitial part atrophies, and for a short period the ovarian part is the larger of the two glandular masses (Harrison Matthews, 1935). The enlargement of the ovarian part occurs during the period in which the anal glands regress. After parturition the interstitial gland begins to return to its dominant state as the ovarian part atrophies. The interstitial gland is considered to be homologous to the male testis and to produce male hormones that suppress the normal female characteristics outside the breeding season (Harrison Matthews, 1935). The return to dominance of the interstitial tissue after parturition coincides with the reappearance of the male-like composition of the female anal gland secretion.

Our results provide further evidence for the role of the anal gland secretion in territorial maintenance. Outside the breeding season, when both sexes deter conspecifics from entering their tunnel systems, the glandular secretions of both sexes are clearly similar in their volatile compositions, which suggests that they produce a common chemical "keep out" signal. For female moles this signal is interrupted only in the breeding season with regression of the anal glands, often to the point of invisibility (Figure 1). It is at this time that a male is able to approach the female and mate. The change in composition of the secretion that accompanies the regression of the gland may produce a chemical signal that alerts a neighboring male mole to the approach of sexual receptiveness in the female, and complete cessation of the secretary activity as regression of the

glands is completed may serve to fine tune the mating period; however, a note of caution is required here, for the amount of secretion produced by the regressing glands is very small. It may simply be that males are no longer deterred from entering the female tunnels owing to the switching off of a keep-out signal; moreover, our results do not preclude the attraction of males by odors from other sources in the receptive female. The rapid reappearance of the male-like composition of the female secretion after estrus is consistent with the need for the female to protect her tunnel systems during pregnancy, and particularly during lactation, in order to ensure the young's survival.

The analytical data suggest that carboxylic acids play a significant semiochemical role. A set of identical carboxylic acids form the dominant component in the secretion of adult males and anestrous females; it is these carboxylic acids that disappear in the secretion of the proestrous female; they are rapidly reestablished during pregnancy and lactation. The development in the composition of the secretion of juveniles is also instructive. Our analysis showed that the composition of the secretion of both sexes at the same stage of maturity was very similar and that the composition of the secretion changes as the animal develops and its anal glands increase in size and secretory ability. Figure 2C and 2I illustrate this trend. In the young male caught in May (Figure 2C), carboxylic acids are only very minor components, and the profile is similar to those of the proestrous females (Figures 2E and 2H). Figure 2I shows the chromatogram from a juvenile female caught in late July. This animal was more mature than the juvenile male, although her reproductive tract was still not fully developed. The animal would be nearing the dispersal phase when she would need to set up a territory and mark it as her own. The carboxylic acids in the secretion have now become significant components at this stage in the mole's development.

Acknowledgments—We wish to thank David Ellington and Ian Smythe of DRE Pest Control, Swavesey, Cambridgeshire, for catching and supplying moles. We also thank Anglia Polytechnic University for financial support.

(Received December 2, 1994; accepted September 29, 1995)

Abstract—The effect of cacalol and extracts (water and petroleum ether) derived from the roots of *Psacalium decompositum* (Asteraceae) on the germination and radicle growth of two plants, *Amaranthus hypochondriacus* (Amaranthaceae) and *Echinochloa crusgalli* (Poaceae), and on the radial growth of four phytopathogenic fungi is described. The activity of two cacalol derivatives (methyl cacalol and cacalol acetate) was also investigated. Germination of *A. hypochondriacus* was inhibited by almost all the treatments. The extracts and cacalol produced a significant inhibition of radicle growth of *A. hypochondriacus* and *E. crusgalli*. Cacalol acetate showed a specific inhibition on *E. crusgalli*, and methyl cacalol significantly inhibited the growth of *A. hypochondriacus*. In general, antifungal activity depended upon the target fungi and the concentration of each treatment. Cacalol had also effects on the morphology and coloration of the fungal mycelium. The bioactivity shown by the extracts of *Psacalium decompositum* on the tested seeds and fungi is mainly due to their content in cacalol.

Key Words—*Psacalium decompositum*, Asteraceae, sesquiterpene, cacalol, phytotoxicity, fungitoxicity, phytopathogenic fungi, *Amaranthus hypochondriacus*, Amaranthaceae, *Echinochloa crusgalli*, Poaceae.

INTRODUCTION

Psacalium decompositum (A. Gray) H. Rob. & Brettell (Asteraceae), locally called matarique or maturin, is a shrub widely distributed in the northern part of Mexico. With three other species of the same genus—*P. peltatum*, *P. sinuatum*, and *Psacalium* sp., and the species *Acourtia thurberi*—all of which belong to the Asteraceae family and are native of Mexico and southern North America, *P. decompositum* is part of a medicinal plant complex widely used in this area. All species of the complex share similar names and root characteristics, and all are used as remedies for the same illnesses. The infusion of the roots of *P. decompositum*, the most valued plant of the group, has a pungent odor and a bitter hot taste; it is used for the treatment of rheumatism, colds, stomach ache, back pains, jaundice, malaria, diabetes, and snake bites. It is also employed as a tonic and diuretic agent (Linares and Bye, 1987).

Romo and Joseph-Nathan (1964) isolated from the roots of *P. decompositum* two crystalline sesquiterpenes named cacalol (Figure 1a) and cacalone. These compounds were the first representatives of a new class of molecules possessing the unusual tetrahydronaphthofuran structure, not previously known to occur in nature (Figure 1a). Cacalol derivatives were also isolated from *Senecio* species and from *Roldana heterogama* (Pippen, 1968; Bohlmann and Zdero, 1978; Bohlmann and Bapuji, 1982; Bohlmann et al., 1990).

Terpenoids, the largest group of plant chemicals (15,000–20,000) with a common biosynthetic origin, possess enormous potential for mediating ecological interactions (Langenheim, 1994). Plant terpenoids may produce effects on seeds and soil microbiota through volatilization, leaching from plants, or decomposition of plant debris. These interactions can significantly affect community and ecosystem properties (Harper, 1977; Duke, 1991). The allelopathic and phytotoxic properties of plant terpenoids, particularly sesquiterpene lactones, have received special attention in numerous publications and reviews (Amo and

FIG. 1. Chemical structures of cacalol (1a), cacalol acetate (1b), and methyl cacalol (1c).

Anaya, 1978; Picman, 1986; Fischer, 1991; Macías et al., 1992; Fischer et al., 1994). Earlier treatments of phytotoxic and possible allelopathic actions of secondary plant metabolites including terpenoids were presented in several books by Rice (1984), Thompson (1985), Putnam and Tang (1986), Waller (1987), and Harborne (1988).

Lotina-Hennsen et al. (1991) found that cacalol inhibited ATP synthesis, proton uptake, and electron transport (basal, phosphorylating, and uncoupled) from water to methylviologen. Cacalol and its derivatives act as electron transport inhibitors at the oxygen evolution level. Taking these results as a basis, Lotina-Hennsen et al. (1991) suggested that cacalol probably behaves as an allelochemic agent, interfering with the metabolism of other organisms. In addition, Jiménez-Estrada et al. (1992) found that the organic extracts of the roots, cacalol, and some of its derivatives had antimicrobial activity against *Candida albicans*, *Cryptococcus neoformans*, *Staphylococcus aureus*, and *Streptococcus pyogenes*.

These previous studies clearly show that secondary metabolites from the roots of this plant possess biological activity. Therefore, as part of a project devoted to the search of bioactive metabolites from Mexican plants of medicinal or ecological importance and with potential agrochemical applications, we studied the effect of some extracts of the roots of *P. decompositum*, as well as cacalol and some of its derivatives on the germination and growth of two species of plants and four species of phytopathogenic fungi.

METHODS AND MATERIALS

General Bioassay Procedures

Bioassays with Seeds. The roots of *Psacalium decompositum* were obtained in October 1992, at the Sonora Market, the biggest medicinal plant market of Mexico City. The whole dry roots were soaked for 4 hr in distilled water (1 g/100 ml). The water extract was filtered, and the osmotic pressure was measured in a freezing-point osmometer in order to avoid the effect of this factor on germination and growth (Anaya and Rovalo, 1976). Osmotic pressures of 15–20 mosm/liter were recorded, well below the level of 150 mosm/liter observed to delay germination (Leather and Einhellig, 1985). Bioassay experiments were designed to measure the effect of the water extract (1%) and petroleum ether extract of the roots of *P. decompositum*, and of cacalol, methyl cacalol, and cacalol acetate (50, 100, and 200 μg/ml—because of the limiting available amounts of the compounds) on the radicle growth of *Amaranthus hypochondriacus* (Amaranthaceae) and *Echinochloa crusgalli* (Poaceae).

A completely randomized block design with four repetitions × treatment

for each target species was used. Ten seeds of each species were sown on Whatman No. 4 qualitative filter paper in 5-cm Petri dishes. Distilled water (1.5 ml) was added in each dish. The dishes were incubated in darkness at 27°C. The radicle length was measured after 24 hr in the case of *A. hypochondriacus*, and 48 hr in the case of *E. crusgalli*. The data were analyzed by ANOVA.

Bioassay with Phytopathogenic Fungi. Four target species were chosen: *Helminthosporium* sp., *Fusarium oxysporum*, *Alternaria* sp., and *Pythium* sp. The bioassays were carried out by incubating in 10-cm Petri dishes a fungal bud on a potato–dextrose–agar (PDA) sterile medium, to which the water extract of *P. decompositum* (1%) or the petroleum ether extract or the pure compounds (5, 50, and 500 μg/ml) were added. Buds 5 mm in diameter were obtained from pure 8-day-old fungal cultures. The sown fungi were incubated in darkness at 27°C. A randomized complete block design with three replications was utilized. The effect of compounds was determined by measuring the radial growth of the mycelium. Two perpendicular measurements of colony diameter were taken, and the mean value was obtained. The measurements were made at three and eight days. The data were analyzed by ANOVA.

CHEMICAL PROCEDURES

Isolation of Cacalol

Five hundred grams of dry roots of *P. decompositum* were extracted three times with 1 liter of petroleum ether (PE). The extract was evaporated under reduced pressure to dryness, yielding 45 g of a red residue with a characteristic odor. Ten grams of this residue was chromatographed through an alumina column (400 g). Elution was accomplished with PE and with PE–AcOEt (9.8–0.2). From several of these column fractions, crude cacalol was obtained as a yellow crystalline product. Cacalol was purified by recrystallization from PE and PE-pentane to yield 350 mg of pure compound **1a** (Figure 1), as prisms mp 92–94°, negative $FeCl_3$ test $[\alpha] + 10°$, λ_{max} 218, 256, 264, and 286 nm; ϵ 30,400, 10,500, 10,000, 1840; ν max 3550 (hydroxyl group), weak bands at 1635 and 1602 cm^{-1}. ^1H NMR δ ppm: 1.2 (d, 3H, C-12), 2.3 (d, 3H, C-10), 2.5 (s, 3H, C-11), 5.0 broad (1H, OH), 7.2 (1H, C-2), 2.9 (q, 1H, C-5), 1.8 (m, 4H, C-6 and C-7), and 3.2 (m, 2H, C-8). Found: C, 78.23; O, 14.17. Calc for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88; O, 13.89%. MS, M^+ 230. Fragments *m/z* 215, 200, and 187 (Jiménez-Estrada et al., 1992).

Cacalol Acetate. Acetylation of 40 g of the brown–red oil from the PE extract was made by adding acetic anhydride and pyridine in the usual way (1 hr on a steam bath). This procedure produced 33 g of a red oil, which was chromatographed in a column with bentonite (tonsil) as the adsorbent and PE

as the eluent; pale yellow crystals (19%) of cacalol acetate (Figure 1b) were obtained. mp = 98° and R_f = 0.72 (8:2 petroleum ether–ethyl acetate).

Methyl Cacalol. Cacalol (800 mg) was dissolved in methanol (20 ml) and treated with an ethereal solution of diazomethane (prepared from 3 g of *N*-nitrosomethylurea). After 24 hr the excess diazomethane was eliminated with acetic acid and the solution evaporated to dryness. After an alumina column chromatography (PE), the oily residue (730 mg) produced yellow crystals identified with IR, NMR and MS as methyl cacalol (Figure 1c) (Jiménez-Estrada et al., 1992).

RESULTS AND DISCUSSION

Bioassays with Seeds. The two target species, *A. hypochondriacus* and *E. crusgalli* were chosen because of their experimental convenience (their seeds are small and have a high and quick germination) and represent the two major groups of angiosperm, monocotyledons and dicotyledons. Most phytotoxic compounds and herbicides show a selective activity on these two groups of plants. On the other hand, *A. hypochondriacus* belongs to a family with some remarkable weeds such as *A. dubius*, *A. retroflexus*, *A. spinosus*, and *A. hybridus*. Two cultivated amaranths, *A. hypochondriacus* (sin *A. leucocarpus*) and *A. cruentus*, are considered as pseudocereals with great nutritional content (particularly proteins) and had a great economic importance in pre-Hispanic agriculture in the Valley of Mexico (Ritchie, 1979; Amo et al., 1988). These two cultivated species can easily escape into the wild and become important weeds in different field crops (Anaya et al., 1987). *E. crusgalli* is a weed grass with a wide geographic distribution and is considered as one of the main weeds in a number of crops (Duke, 1985).

The effects of the different treatments from *P. decompositum* on the germination and radicle growth of the two target species are shown in Table 1. Although there is natural variation in the germination of the test seeds, particularly *E. crusgalli*, it is clear that germination of *A. hypochondriacus* was affected by all the treatments, notably by the water extract and cacalol. On the other hand, germination of *E. crusgalli* was affected only by cacalol at 200 μg/ml.

The water and petroleum ether extracts and cacalol produced a significant inhibition of the radicle growth of both species tested. The IC_{50} values for the petroleum ether extract and cacalol on *A. hypochondriacus* were 143.58 and 102.73 μg/ml, respectively. In the case of *E. crusgalli* the IC_{50} values were 218.43 and 266.43 μg/ml, respectively.

Lotina-Henssen et al. (1991) suggested that the —OH group of cacalol is an important structural feature for the inhibition of oxygen evolution in photosynthesis. Therefore, in order to investigate whether the free hydroxyl group of

"$P < 0.05$.

cacalol has any influence on the activities we have observed, we synthesized two derivatives of greater liposolubility than cacalol: cacalol acetate (Figure 1b), and methyl cacalol (Figure 1c). Cacalol acetate significantly inhibited the radicle growth of *E. crusgalli* but did not affect growth of *A. hypochondriacus*. On the other hand, the inhibitory effect of methyl cacalol on *E. crusgalli* was observed only at 200 μg/ml. When acting on *E. crusgalli*, methyl cacalol was less potent than cacalol and cacalol acetate in inhibiting radicle growth. To a lesser degree and independently of concentration, methyl cacalol inhibited the growth of *A. hypochondriacus*.

These results clearly indicated that substitution of the free hydroxyl group in cacalol did not enhance the inhibition of radicle growth in *A. hypochondriacus* and *E. crusgalli*, but resulted in a more selective activity. It is possible that cacalol acetate, because of its ester properties, could be biotransformed to cacalol by enzymatic action inside the seeds of *E. crusgalli*. On the other hand, *A.*

hypochondriacus may be unable to make this biotransformation, so cacalol acetate remains as such inside its seeds, causing no effect on them. Methyl cacalol acts in an analogous, but less potent fashion than cacalol acetate.

Bioassays with Phytopathogenic Fungi. The four phytopathogenic species chosen for these bioassays have economic importance. They produce different common diseases in plants, especially cultivated ones, affecting leaves, stems, flowers, fruits, and tubers (Agrios, 1991).

The effects of the water extract from the roots of *P. decompositum* on the radial growth of the phytopathogenic fungi are shown in Figure 2. There was a specific effect of the water extract on each fungus species. A significant stimulant effect of the water extract on the growth of *Alternaria* at three days of growth was found. Conversely, this treatment exerted a significant inhibitory effect on the growth of *Pythium* and *Fusarium*. At eight days a significant inhibition was observed for *Pythium* and *Helminthosporium*, and at that time, no stimulant effect on the other fungi was observed. This inhibition could prove to be useful in plant protection (El-Zik and Frisbie, 1985).

The same phenomenon was observed in the bioassays with the petroleum ether extract, cacalol, and its derivatives. Their effects on radial growth of fungi at three and eight days of growth are shown in Table 2. At 500 μg/ml, the petroleum extract showed greater inhibition than the other treatments. At this concentration, this extract strongly inhibited the growth of *Pythium* after three

and eight days of growth. At a lower concentration (5 μg/ml), this extract produced a significant stimulant effect on the growth of *Pythium* after three days of growth. A similar effect of the petroleum ether extract was observed on the growth of the other species of fungi. The fungitoxic effect of the petroleum ether extract at 500 μg/ml was stronger than the effect observed with the other treatments at the same concentration, probably due to a synergistic effect of the chemicals in the mixture where cacalol is the major compound.

After three days of growth cacalol significantly inhibited the radial growth of *Pythium* at the three concentrations tested (Table 2). At this time, the inhibitory effect of cacalol increased when the concentration was changed from 50 to 500 μg/ml. At eight days of growth, the inhibitory effect of cacalol at 500 μg/ml on the growth of *Pythium* is still significant, but its effect at this time is totally the opposite at 5 and 50 μg/ml. Cacalol produced a significant inhibition on the growth of *Alternaria* and *Fusarium* after three and eight days of growth at 50 and 500 μg/ml. To a lesser degree, cacalol has an inhibitory effect on *Helminthosporium* only at 500 μg/ml.

Methyl cacalol (Figure 1c) showed no inhibitory effect on the growth of *Pythium* at any time (Table 2) but produced a significant stimulation on the growth of *Pythium* at 5 and 50 μg/ml after three and eight days of growth. *Alternaria* was the most sensitive species to the effect of methyl cacalol. It was significantly inhibited by this compound at the three concentrations tested, particularly after eight days of growth. Methyl cacalol had no effect on the growth of *Fusarium* and inhibited *Helminthosporium* only at 50 μg/ml.

Cacalol acetate (Figure 1b) was the least active compound. It had no effect on the growth of *Pythium*; however, it slightly inhibited *Alternaria* and *Fusarium* at 500 μg/ml after three and eight days of growth. The effect of cacalol acetate on *Helminthosporium* depended on concentration; it was stimulatory at 5 and 50 μg/ml and slightly inhibitory at 500 μg/ml.

In general, the fungitoxic activity of all treatments used in the bioassays was concentration-dependent, a fact usually observed with some allelochemicals and other growth regulators. Many secondary metabolites have a stimulatory effect at low concentrations and an inhibitory one at higher concentration (Einhellig, 1985). Results of our bioassays with fungi confirm this fact. *Pythium* was the most sensitive species to the fungitoxic effect of these treatments. On the other hand, it is probable that all these fungi could metabolize the four treatments tested at the lower concentrations and use them as a carbon source (Griffin, 1994). Our interest was focused on the effect of the different treatments on the growth of the mycelium, but probably more relevant than this was the effect of cacalol on the morphology and structure of the mycelium of the target fungi, which changed both their appearance and color in the presence of the compound. It is possible that this sesquiterpene modifies some aspects of the metabolism and reproduction of these particular microorganisms. Overall we can conclude that the bioactivity exhibited by the extracts of the roots of *Psacalium decompositum* on the tested seeds and fungi is mainly due to their cacalol content.

It is important to point out the potential ecological role of the allelochemicals produced by the roots of *Psacalium decompositum* and other related plants. We have not done any field studies yet. However, further research under natural conditions is in progress in order to determine whether water can leach the mixture of allelochemicals from the roots of this species, and if the released mixture has an effect on other plants and microorganisms in the environment. If cacalol and other related secondary metabolites are effectively released in sufficient amounts to the environment, they could have an ecological effect on other receptor organisms, particularly on rhizosphere microorganisms and surrounding plants. Other related species such as *Senecio* spp., *Roldana heterogama*, *Psacalium peltatum*, and *P. sinuatum* are known to synthesize cacalol derivatives. Therefore, it would be important to study the allelochemical role of these secondary metabolites.

Increasing global concern about the indiscriminate use of, overdependence on, and hazards of synthetic pesticides has prompted exploration of natural plant products as alternatives for plant protection since they could be expected to be comparatively safe. Surprisingly, while much emphasis has been given to the integration of various strategies of pest control, little effort appears to have been made to develop multipurpose natural pesticides capable of controlling more than one agricultural pest (Rizvi and Rizvi, 1992). The present study points out the potential of allelochemicals from the roots of *P. decompositum* as natural selective herbicides and fungicides. We are well aware that traditional ethnobotanical knowledge, so rich in Mexico, has frequently led to the discovery of bioactive compounds. Thus, we will continue to explore Mexican biodiversity to expose the great chemical diversity and ethnobiological richness (Anaya et al., 1995).

Acknowledgments—This study was sponsored by project IN203394 of DGAPA-UNAM and project 1179-N9202 of CONACYT. We thank Dr. Rachel Mata for all her valuable comments, Frida Soria, MS, for the review of the manuscript, and Francisco Hernández, MS, for his help.

(Received March 1, 1995; accepted October 29, 1995)

Abstract—Chloroform extracts from a culture broth of the biocontrol fungus *Sporothrix flocculosa* were separated by thin-layer chromatography (TLC). Compounds with antifungal activity were revealed with the *Cladosporium cucumerinum* bioassay on TLC plates and were isolated by using silica gel column, preparative TLC, and reverse-phase high-performance liquid chromatography (RP-HPLC). They were identified by standard methods of nuclear magnetic resonance (NMR), gas chromatography (GC), mass spectrometry (MS), and infrared spectrum (IR). In addition to an active molecule previously described, two new fatty acids with antibiotic activity were characterized, 9-heptadecenoic acid and 6-methyl-9-heptadecenoic acid, the latter displaying the strongest activity among all three active molecules. This high number of active metabolites produced by *S. flocculosa* would explain its rapid and strong activity as a biocontrol agent of powdery mildews. In this context, screening of *S. flocculosa* isolates for increased production of these molecules should help in selection of candidates with superior biocontrol properties.

Key Words—*Sporothrix flocculosa*, antibiotics, fatty acids, biocontrol.

INTRODUCTION

Sporothrix flocculosa (Traquair, Shaw & Jarvis) has been reported in numerous studies as a potential antagonist against powdery mildew fungi (Jarvis et al., 1989; Hajlaoui and Bélanger, 1991, 1993; Bélanger et al., 1994). Practical exploitation of *S. flocculosa* as a biocontrol agent presupposes a thorough knowl-

edge of its mode of action. Only through an understanding of the mechanisms of activity of *S. flocculosa*, will it be possible to achieve consistency of efficacy and selection of superior strains. To this end, cytochemical studies of the interaction between *S. flocculosa* and *Sphaerotheca pannosa* var. *rosae* have revealed that disintegration of host cytoplasm occurred in the absence of hyphal penetration, suggesting the involvement of extracellular diffusible molecules (Hajlaoui et al., 1992). In addition, it was shown that *S. flocculosa* produced antimicrobial compounds active against several microorganisms such as *Fusarium oxysporum*, *Botrytis cinerea*, *Trichoderma viride*, and *Bacillus subtilis* (Hajlaoui et al., 1994; Choudhury et al., 1994). Recently, two aliphatic molecules (4-methyl-7,11-heptadecadienoic acid and 4-methyl-7,11-heptadecadienal), were isolated from liquid cultures of *S. flocculosa* and *S. rugulosa*, with the former compound displaying antimicrobial activity (Choudhury et al., 1994). It thus appears evident that antibiosis is the main mode of action by which *S. flocculosa* exerts its biocontrol activity. However, it is still unclear whether this activity is mediated by one or several molecules, and if the latter, whether those molecules can be isolated and characterized. In this context the objectives of the present study were twofold: (1) to screen extracellular metabolites produced by *S. flocculosa* for potential antifungal activity, and (2) to purify and characterize active molecules.

METHODS AND MATERIALS

Fungal Culture. Single-spore isolates of *Sporothrix flocculosa* were obtained by reisolating the fungus from rose leaves that were submitted to weekly applications of a fungal suspension initiated from an isolate of *S. flocculosa* graciously provided by Dr. W. R. Jarvis, Agriculture and Agri-food Canada (Harrow, Ontario, Canada). Stock cultures of the isolates were maintained at 4°C on yeast–malt–peptone–dextrose agar (YMPDA) containing yeast extract (3 g/liter), malt extract (3 g/liter), peptone (5 g/liter), dextrose (10 g/liter), and bacto-agar (15 g/liter). Erlenmeyer flasks (500 ml) each containing 100 ml YMPD broth were inoculated with 10^6 conidia/ml of *S. flocculosa*. The fungus was grown in still culture at 26°C in the dark for 28 days.

Cladosporium cucumerinum Ellis and Arth was obtained from Biosystematics Research Centre (Ottawa, Ontario, Canada) and was maintained on potato dextrose agar (PDA) at 25°C.

Screening of Molecules with Antifungal Activity. The liquid medium was separated from the biomass through a filter paper (Whatman No. 1) and the mycelium discarded. The filtrates were further extracted with chloroform ($CHCl_3$). The organic fraction was dehydrated with Na_2SO_4 and dried under vacuum. The residue was redissolved in chloroform.

Thin-layer chromatography (TLC) of the culture filtrate extracts was carried out on silica gel plates (Merck 60 F 254, 0.1 mm thick, 10 × 5 cm). The extracts were deposited as spots of 80 μl, and after drying, the chromatograms were developed in ethyl acetate–hexane (1 : 4, v/v). The spots were viewed under ultraviolet radiation at 254 nm and 366 nm. To localize zones of antifungal activity, silica gel plates were seeded with a sporal suspension of *Cladosporium cucumerinum* as described by Homans and Fuchs (1970). Because of the dark pigmentation of spores and mycelium of this fungus, zones of antifungal activity can be readily identified as white spots, each one representing zones where spore germination is inhibited.

Purification Procedures. The chloroform extracts from the filtrates were applied to a silica gel column (Silica Gel; 230–400 mesh, Baker Analyzed reagent) and flash-chromatographed by successive elution with 100% hexane (200 ml); 150 ml each of 1%, 5%, 8%, and 15% of diethyl ether in hexane; 250 ml of 100% diethyl ether; and 100% of methanol. For each eluted fraction, assessment of antifungal activity was carried out with the TLC bioassay as described above. The active fractions were purified with a combination of preparative TLC and high-performance liquid chromatography (HPLC). Preparative TLC was performed with Silica Gel 60 G (0.30 mm thick). Chloroform concentrates from the active fractions were spotted in a line along the bottom of the plate and developed in ethyl acetate–hexane (1 : 4, v/v). The bands corresponding to active spots were scraped off the plates, and the active molecules were extracted from silica gel with chloroform. These chloroform extracts were separated by HPLC with C_{18} reverse-phase columns (Millipore-Waters, 8 × 10 cm). Elution was performed with methanol–water–acetonitrile in gradient mode at a flow rate of 1.0 ml/min. Absorbance of the effluent was monitored by a photodiode array scanning between 220 and 400 nm.

Identification of Active Fractions. FT-IR spectra of the fractions were obtained on a Bruker FT-IR instrument. All NMR spectroscopy (^1H, ^{13}C, 2D, Hector) were recorded in deuterated chloroform ($CDCl_3$) with tetramethylsilane (TMS) as an internal standard using a Bruker 300 MHz. GC-MS data were recorded with a Hewlett Packard (HP) 5890 series II gas chromatograph coupled with MS HP mass selective detector 5972. Precise location of double bonds was obtained by ozonolysis using O_3/HCO_2H according to the method described by Frans et al. (1965). The position of methyl branching was confirmed by using acylpyrrolidines according to Andersson and Holtman (1975).

RESULTS AND DISCUSSION

On silica gel thin-layer chromatograms, chloroform extracts were separated into several spots as visualized under ultraviolet radiation at 254 and 366 nm.

Spraying of a sporal suspension of *C. cucumerinum* revealed only one major active spot in the chloroform extract with an approximate R_f value of 0.8 (Figure 1). However, when the active spot was viewed under low (254 nm) and high ultraviolet (366 nm) radiation, further bands were observed, indicating the presence of several molecules at this spot.

Fractionation of the chloroform extract by column chromatography and preparative TLC followed by reverse-phase HPLC revealed three active compounds on TLC based on the bioassay with *C. cucumerinum* (Figure 2). The physicochemical analysis (^{1}H NMR, ^{13}C NMR, IR, GC-MS) of these compounds revealed two new active fatty acids: 6-methyl-9-heptadecenoic acid ($C_{18}H_{34}O_2$) (Figure 3a) and 9-heptadecenoic acid ($C_{17}H_{32}O_2$) (Figure 3b) and another active compound corresponding to 4-methyl-7,11-heptadecadienoic acid previously isolated and characterized by Choudhury et al. (1994). Based on our bioassays, the 6-methyl-9-heptadecenoic acid appeared to display the highest antifungal activity among the three isolated compounds (Figure 2).

FIG. 1. Fungitoxicity of chloroform extracts from *Sporothrix flocculosa* culture filtrates on thin layer chromatograms (TLC). Eighty microliters were spotted on a silica gel TLC plate and developed with ethyl acetate–hexane (1:4, v/v). After drying, the plate was sprayed with a conidial suspension of *Cladosporium cucumerinum* and incubated at room temperature. After 48 hr of incubation, one major zone of inhibition was revealed with R_f value of approximately 0.8.

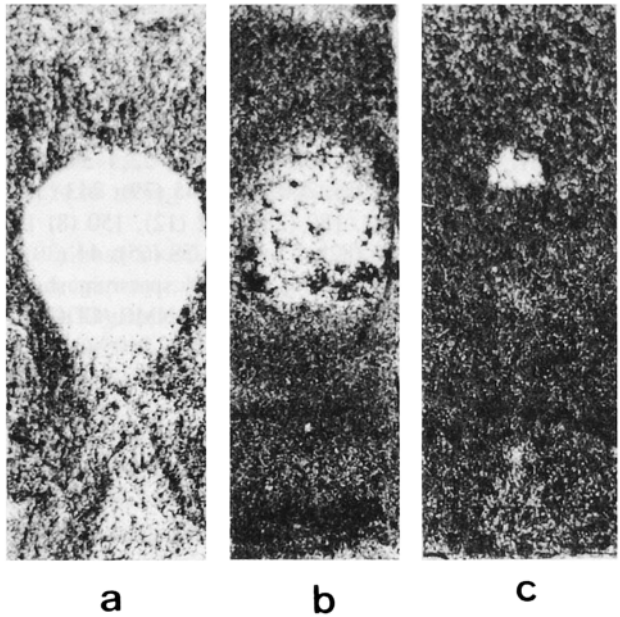

FIG. 2. Fungitoxicity of fatty acids from *Sporothrix flocculosa* culture filtrates on thin layer chromatograms (TLC). After purification with silica gel column, preparative TLC, and HPLC, aliquots (120 μl) from (a) 6-methyl-9-heptadecenoic acid, (b) 4-methyl-7,11-heptadecadienoic acid, and (c) 9-heptadecenoic acid were spotted on silica gel TLC and developed with ethyl acetate–hexane (1:4; v/v). After drying, the plates were sprayed with a conidial suspension of *Cladosporium cucumerinum* and incubated for 48 hr at room temperature.

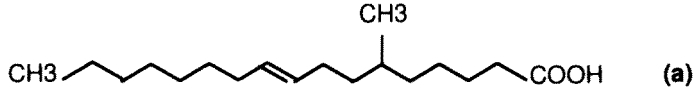

FIG. 3. Structure of the new fatty acid antibiotics: (a) 6-methyl-9-heptadecenoic acid and (b) 9-heptadecenoic acid.

The 6-methyl-9-heptadecenoic acid (Figure 3b) infrared spectrum exhibited strong absorption at 3350, 2680, 1720, 1660, 1420 cm^{-1}. ^1H NMR ($CDCl_3$, 300 MHz) was: $\underline{\delta}$ppm 10.80 (s, 1H), 5.35 (m, 2H), 2.30 (t, 2H), 2.18 (m, 4H), 1.95–2.0 (m, 18H), 0.89 (d, 3H), 0.83 (d, 3H). Cosy NMR (C-H coupling) ($CDCl_3$, 300 MHz) was: δppm 180.2 (s, COOH), 130 (d, CH=CH), 129.56 (d, CH=CH), 45.3 (q, CH_3), 38.3 (s, CH), 22.4–34.0 (t, $12CH_2$), 13.90 (q, CH_3). El-MS: *m/z*: 282 (92), 260 (58), 245 (39), 243 (35), 232 (2), 220 (3), 201 (8), 199 (10), 192 (4), 180 (28), 162 (12), 150 (8) 136 (4) 122 (47) 111 (48), 93 (50), 83 (25), 73 (82), 71 (100), 58 (65), 41 (30).

The 9-heptadecenoic acid (Figure 3b) infrared spectrum showed strong absorption at 3400, 2700, 1710, 1650, 1420 cm^{-1}. ^1H NMR ($CDCl_3$, 300 MHz) was: δppm; 10.85 (s, 1H), 5.38 (m, 2H), 2.30 (t, 2H), 2.05 (m, 4H), 1.6 (m, 2H), 1.2 (m, 18H), 0.85 (t, 3H). Cosy NMR (couplage C—H) ($CDCl_3$, 300 MHz) was: δppm 180.26 (s, COOH), 129.85 (d, CH=CH), 129.56 (d, CH=CH), 22.5–33.9 (t, $13CH_2$), 13.91 (q, CH_3). El-MS: *m/z* 268 (85), 246 (70), 219 (35), 219 (3), 194 (5), 152 (4), 138 (5), 111 (25), 83 (32), 55 (92), 41 (82), 28 (25).

The number of double bonds was confirmed by catalytic hydrogenation using Pt/H_2 and by ^1H and ^{13}C NMR based on integration of ethynilic protons, which indicated the presence of one double bond in both compounds. Ozonolysis of 6-methyl-9-heptadecenoic acid gave a mixture of a monoacid that was identified as octanoic acid by comparison of its analytical data (^1H and ^{13}C NMR) with a commercial product (Aldrich, Milwaukee, Wisconsin), and a decadioic acid branch for which the number of carbons was determined by ^{13}C NMR. Ozonolysis of 9-heptadecenoic acid gave a mixture of two compounds that were identified as octanoic and azelaic acids by comparison of their analytical data with commercial products (Aldrich). These analytical and transformation techniques indicated the presence of a unique double bond between carbons 9 and 10 in the two compounds described. The saturated pyrrolidide derivative of 6-methyl-9-heptadecenoic acid showed a minimum between the fragment $[M\text{-}C_{11}H_{23}]^+$ (molecular ion 182) and the fragment $[M\text{-}C_{13}H_{27}]^+$ (molecular ion 154). This minimum had a molecular ion of 168 corresponding to the fragment $[M\text{-}C_{10}H_{21}]^+$ minus $[CH\text{—}CH_3]$, which confirmed the position of the methyl branch on carbon 6.

It was thus possible to isolate and purify three active compounds from the culture filtrates of *S. flocculosa*, two of which are reported for the first time. In a previous study, Choudhury et al. (1994) had isolated and identified two molecules with antimicrobial activity from *S. flocculosa* and *S. rugulosa*. They were both observed here, but the 4-methyl-7,11-heptadecadienal, which rapidly oxidizes into 4-methyl-7,11-heptadecadienoic acid could only be detected in trace amounts because of its instability at room conditions. The latter compound (4-methyl-7,11-heptadecadienoic acid) was determined to be active to varying

degrees against a number of fungi based on an agar diffusion assay (Choudhury et al., 1994). However, reliability of this bioassay may be variable with apolar compounds such as fatty acids, which do not diffuse readily in agar. In addition, such an assay is not amenable to rapid screening. By a more discriminating bioassay directly on TLC, it was possible to identify two additional fatty acids with antibiotic activity, 9-heptadecenoic acid and 6-methyl-9-heptadecenoic acid, which appear to be more active than 4-methyl-7,11-heptadecenoic acid (Figure 3).

Previous ultrastructural studies had shown that cellular alterations caused in the target fungi were similar to those caused by the organism (Hajlaoui et al., 1992, 1994; Hajlaoui and Bélanger, 1993). Indeed, treatment of target fungi with the fungus or with extracts from its culture filtrates induced similar reactions, such as plasmalemma retraction and the leakage of cytoplasmic content, indicating an alteration of physiological properties of the cytoplasmic membrane (Hajlaoui et al., 1994). However, the molecular mechanism of action of fatty acids with antimicrobial activity has been little studied. It has been suggested that the fluidity of the cell membrane can be disturbed maximally by lipophilic compounds of particular chain lengths, unsaturation, or with particular hydrophilic functional groups (Kabara et al., 1977; Ko et al., 1994). In addition, alteration of the fluidity of the cell membrane by fatty acids was shown to be responsible for the inhibition of some membranous proteins such as α-mannosyl transferase (Watson and Rose, 1980), valyl-tRNA synthetase (Black, 1985) or (1,3)-β-glucan synthase (Ko et al., 1994).

The antimicrobial activity of certain fatty acids has been demonstrated in several studies (Bayliss, 1936; Nieman, 1954; Conley and Kabara, 1973; Kabara et al., 1972, 1977). For instance, some saturated and unsaturated fatty acids inhibited some bacteria such as *Pseudomonas aeruginisa*, *Streptococcus* (group A), and *Staphyloccocus aureus;* yeast fungi such as *Candida albicans* and *Saccharomyces cerevisiae* (Conley and Kabara, 1973, Kabara et al., 1972, 1977); and algae (Ikawa et al., 1984). These studies also reported on structure–function relationships and showed that the optimum antimicrobial activity for even-carbon-numbered aliphatic acids was found in C_{12} saturated fatty acids and C_{18} mono- and diunsaturated fatty acids (Bayliss, 1936; Nieman, 1964; Conley and Kabara, 1973). In addition, it was emphasized that *cis* unsaturated isomers were active while the *trans* isomers were always less active or inactive when compared to the more common unsaturation form (Kabara, 1987).

From an ecological point of view, our findings of antibiotic production by *S. flocculosa* are consequent with its description as an epiphyte. In fact, it is known that this biocontrol agent has a restricted ecological niche in the phylloplan (Traquair et al., 1988), and it would appear plausible that it is protected by antibiotics since it is neither a good competitor nor a parasite (Hajlaoui et al., 1992). In addition to the new antibiotics reported here and the one previously

described by Choudhury et al. (1994), other rare and unusual molecules have been isolated from the organism, the roles of which are still unknown (Choudhury et al., 1995).

The role of antifungal molecules in disease suppression has been shown to be of considerable importance, and the screening of mycelial culture from some biological control agents has led to the discovery of a great number of metabolites with antimicrobial activity (Fravel, 1988). It is evident from this work that *Sporothrix flocculosa*, a biocontrol agent against powdery mildew fungi, produces several antibiotics that account for its rapid and strong activity on target fungi, as demonstrated previously (Jarvis et al., 1989; Hajlaoui and Bélanger, 1991, 1993; Hajlaoui et al., 1994). In this context, screening of *S. flocculosa* isolates for increased production of these molecules should help in selection of strains with superior biocontrol properties.

Abstract—Field tests comparing the ability of codlemone, (*E*,*E*)-8,10-dodecadien-1-ol, and isomers of codlemone to disrupt pheromonal communication of codling moth were carried out. In a pear orchard, four nonisomerizing, gray septa dispensers were placed in the upper canopy of each tree containing a trap baited with 10 virgin female codling moths. The dispensers were at trap height and 70 cm from the edge of each trap. Trap catches of released male codling moths in three test areas were compared simultaneously when trees in each of the test areas contained unbaited dispensers, dispensers with 1 mg of codlemone containing 1% isomers, and dispensers with 1 mg of a test communication disruptant. When the test disruptant was an equilibrium mixture of codlemone and its isomers (61% codlemone, 39% isomers), the percent communication disruption was 86.8% compared to 68.7% for codlemone ($P < 0.001$). When the disruptant was (*E*,*Z*)-8,10-dodecadien-1-ol (94% *EZ*, 3% *EE*), the percentage disruption was 86.4% compared to 62.7% for codlemone ($P < 0.002$). These results show that the previously reported superior disruptant potency (relative to codlemone) of compositions containing codlemone with a high percentage of isomers was not a result of the proximity of the dispensers to the traps. The percent disruption of compositions of codlemone with 10 and 20% isomers was also determined. A plot of percentage disruption versus logarithm of percentage of nonpheromone isomers in the mixture from 1% to 97% gave a straight line with $R^2 = 0.93$.

Key Words—Codling moth, *Cydia pomonella*, sex pheromone, codlemone, (*E*,*E*)-8,10-dodecadien-1-ol, sex pheromone isomers, 8,10-dodecadien-1-ol isomers, (*E*,*Z*)-8,10-dodecadien-1-ol, mating disruption, communication disruption.

INTRODUCTION

Previously, we reported (McDonough et al., 1994) that the (*E*,*Z*)-8,10- and (*Z*,*E*)-8,10- isomers of codlemone, (*E*,*E*)-8,10-dodecadien-1-ol, and the equilibrium mixture of isomers of codlemone (61% *EE*, 20% *EZ*, 14% *ZE*, and 5% *ZZ*) were more potent communication disruptants than codlemone itself. These results were unexpected, because the sex pheromone of the codling moth is the single component, (*E*,*E*)-8,10-dodecadien-1-ol (Roelofs et al., 1971; McDonough et al., 1995), and based on reports of other insects, it was expected that the natural pheromone would be a more potent communication disruptant than nonpheromone compounds.

In earlier studies of a nonpheromone communication disruptant of *Trichoplusia ni* (cabbage looper), Tumlinson et al. (1972) reported inhibition of trap catch when the disruptant was mixed with the pheromone at levels as low as 0.1% of the pheromone. Subsequently, Kaae et al. (1974) and McLaughlin et al. (1974) tested the inhibitor in widely spaced evaporators. When the amount of the inhibitor was as high as 10 times the amount of pheromone that elicited 84% communication disruption, no disruption was obtained. McLaughlin et al. (1974) proposed that the inhibitor was perceived by a sensory neuron separate from that for the pheromone and that the insect could resolve the inhibitor and the pheromone signal, and then, through a more central integrative process, become habituated to the inhibitor while remaining responsive to the pheromone. More recently, the proposal of McLaughlin et al. (1974) gained support from the studies of Liu and Haynes (1992, 1993) on the cabbage looper and Rumbo et al. (1993) on the light-brown apple moth.

It is not known if the isomers of the codling moth pheromone are detected by sensory neurons separate from those for the pheromone. If they are, and the proposal of McLaughlin et al. (1974) were applicable to the codling moth, then a possible reason for our different results (McDonough et al., 1994) was that the disruptant dispensers were too close to the pheromone source (about 10 cm from the trap edge). Part of the isomer concentration may have mixed thoroughly enough with the much lower concentration of pheromone emitted by the females that the mixture was perceived as one (Liu and Haynes, 1992). Furthermore, if false trail following is an important mechanism for communication disruption, then the pheromone might gain in relative effectiveness as the distance between the traps and the disruptants were increased. For these reasons, this study was undertaken to retest the isomers with a distance of 70 cm between the disruptants

and the edge of the female baited traps, and if the previous results were confirmed, to determine the disruptant potency over a range of isomer concentrations.

METHODS AND MATERIALS

Chemicals. (*E*,*E*)-8,10-Dodecadien-1-ol (Bedoukian Research Inc., Danbury, Connecticut) was recrystallized from pentane and was 99.0% isomerically pure by capillary gas chromatography. (*E*,*Z*)-8,10-Dodecadien-1-ol (94% *EZ*, 3% *EE*, 1% *ZE*, 2% *ZZ*) was synthesized by the method of McDonough and Smithhisler (1989) for the synthesis of (*E*,*Z*)-10,12-tetradecadien-1-ol except that 1,8-octanediol was used in place of 1,10-decanediol. The equilibrium mixture of isomers of 8,10-dodecadien-1-ol was prepared as previously reported (McDonough et al., 1993). The isomeric content was 61% *EE*, 20% *EZ*, 14% *ZE*, and 5% *ZZ*. The compositions containing 10% and 20% isomers were prepared by mixing the appropriate quantities of the compositions containing 1% and 39% isomers.

Disruptant Dispensers. Gray elastomeric septa (size 1F, formulation #1888, The West Co., Lionville, Pennsylvania) were used to dispense disruptant compositions because they minimize isomerization of conjugated dienes (Brown and McDonough, 1986). The dose was 1 mg/septum for all compositions. Each composition was added to the cup of the dispenser in 200 μl of dichloromethane.

Traps. The trap was a modified Pherocon 1 (Trécé Corp., Salinas, California), and was identical to that previously described and pictured (McDonough et al., 1994) except that the wires for holding the disruptant dispensers were deleted. Each trap was baited with 10 females in wire cages.

Insects. Pupae were obtained from a laboratory colony reared on artificial diet (Howell, 1972; Toba and Howell, 1991). Individual pupae were placed in 15 × 50-mm vials and maintained at 20°C and 68% relative humidity on a 10:14-hr dark–light cycle. After emergence, the adults in their vials were sexed under a magnifying glass. In all experiments, both male and female codling moths were used two to four days after eclosion.

Field Test Area. A commercial pear orchard was used for the tests (Figure 1). The intrarow distance between adjacent trees was 6.1 m and the separation between rows was 6.1 m. Males were released in the stipple-designated trees of Figure 1. Each stipple-designated tree was surrounded by four black-designated trees, each of which contained a trap baited with 10 female codling moths. There were six groups of these trees (Figure 1) and two groups were used for each test composition. The foliar dimensions of the trees were about 4.6 m high and about 5.8 m in diameter. To facilitate placement and removal of the traps, a 1.9-cm-OD steel pipe was driven into the ground next to each tree trunk. The

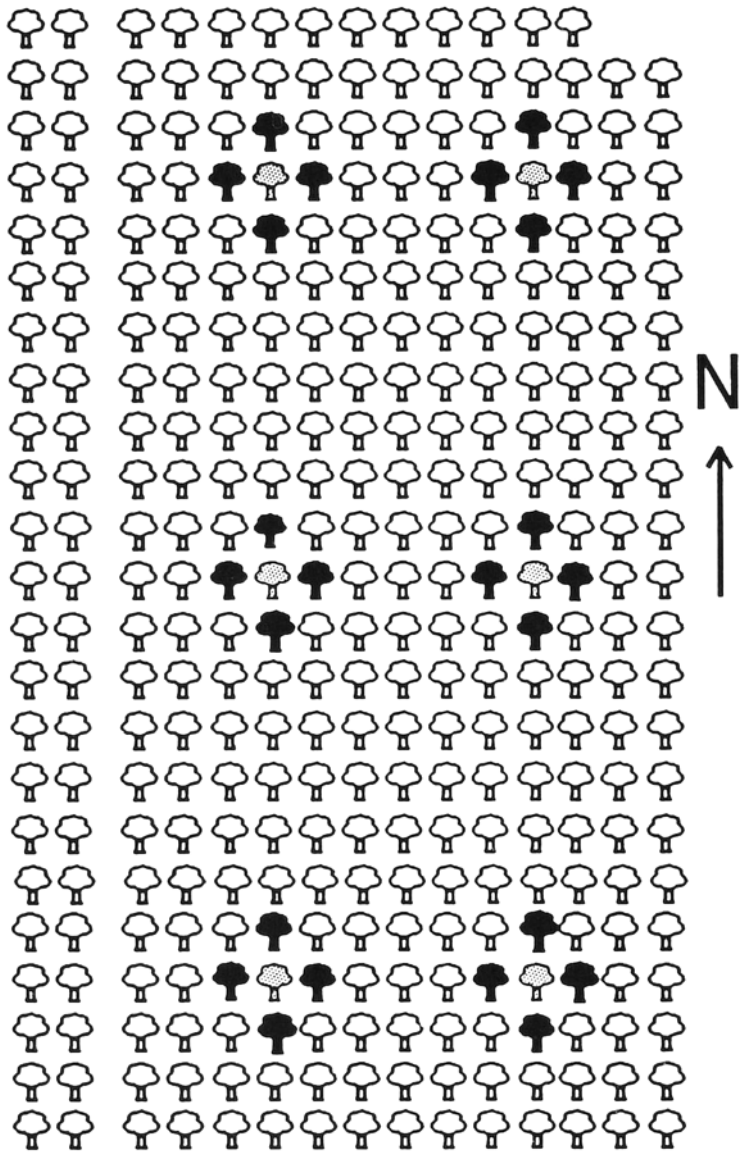

Fig. 1. Map of the section of the pear orchard used for communication disruption tests. Males were released in the stipple-designated trees. Female baited traps and disruptant dispensers were placed in the black-designated trees.

steel pipe extended to a height of about 4 m. A metal shelf bracket was attached to the top of the pipe by means of a steel hose clamp. A wire hook was attached to the trap and one to the shelf bracket, and the trap was hooked to the shelf bracket hook by a wire hook on the end of a long pole. The traps were placed at a height of about 3.5 m. There were four disruptant dispensers on each tree containing a female-baited trap. The dispensers were wired to a limb in the four cardinal directions at trap height, 80 cm from the center of the trap and about 70 cm from the edge of the trap.

Test Protocol. The test data of each week consisted of the sum of two three-day test periods: Tuesday–Thursday and Friday–Sunday. Since a commercial orchard was used, feral populations of male codling moths were expected to be low and unevenly distributed. Therefore, dyed males were released to provide sufficient numbers and even distribution. The dyes were nontoxic (Moffitt and Albano, 1972) and were from Day-Glo Color Corp., NALCO Chemical Co., Cleveland, Ohio. Male and female moths were put out on Tuesdays and Fridays at midday and were removed when trap catches were counted at approximately the same time on Fridays and Mondays. Males and females in their vials were chilled in a refrigerator to facilitate their transfer. Ten females were placed in each of the 24 15-mesh aluminum wire cages (240 females/release or 480 females/week), and 30 males were placed in each of four cylindrical cartons [8.5 cm diameter × 9 cm high, internally coated with a dye (Moffitt and Albano, 1972)] at each release tree (720 males/release or 1440 males/week). The males were held in their cartons for an hour. Then the cartons were placed in galvanized wire screen holders (2-mesh and 11 cm diameter × 13 cm high) with a galvanized wire-screen lid to prevent bird predation, and the lids of the cartons were removed. The cartons were placed at a height of about 1.5 m. On the days when traps were removed, the number of males remaining in the cartons and the number of dead females in the cages were counted. In these tests, insect mortality was always low. For the season, 4.3% of the caged females were dead when the traps were removed from the trees, and 2.3% of the males failed to leave their cartons. The recapture rate in the control was usually 40–60%, with a high of about 70%. When the recapture rate was below 30%, the experiment was repeated. Feral males were rarely caught, and then only one or two per test, and were not included in the counts. Each east-west couplet of tree groups (Figure 1) (one male release tree and four trees with female baited traps per group) was used for a different test composition: the control "composition" was always blank, another was always codlemone, and the third was the isomeric mixture being evaluated. After each week the positions of the test compositions were changed, so that after three weeks each composition had occupied each position for one week. Each complete test required three weeks. The isomeric disruptant mixtures in the four tests were as follows: (1) the equilibrium mixture

of codlemone and isomers (39%), (2) codlemone and isomers (20%), (3) codlemone and isomers (10%), and (4) (*E,Z*)-8,10-dodecadien-1-ol (94% *EZ*, 3% *EE*, 2% *ZZ*, 1% *ZE*).

Calculations and Statistical Analysis. The percent disruption was calculated by determining the catch in a test area as a percent of the catch in the control area and subtracting that value from 100. Because different colored males were used for each test area, the data could be analyzed either in terms of total catch or catch of the males of the color for that area. The two analyses yielded equivalent results, and the results reported are for total catch. Data were analyzed with the Statistical Analysis System (SAS) general linear models procedure (SAS Institute, 1985) to test for differences between codlemone (1% isomers) and one of the test materials.

Linear Regression of Percentage Disruption Versus Logarithm of Percentage of Nonpheromone Isomers. For this calculation the four values for percentage disruption by codlemone (1% isomers) were averaged. The values for the other four compositions were normalized to this average value. The values plotted were 1, 10, 20, 39, and 97% nonpheromone isomers. The 97% value was obtained from (*E,Z*)-8,10-dodecadien-1-ol, which had different proportions of the nonpheromone isomers than the other four compositions. This was justified because in our previous study (McDonough et al., 1994), the *EZ* and *ZE* isomers elicited equal percentages of disruption.

RESULTS AND DISCUSSION

The results of the four major tests are summarized in Table 1. In test 1 the equilibrium mixture of isomers of 8,10-dodecadien-1-ol (39% non-*EE* isomers) gave a higher percentage of communication disruption than codlemone (1% non-*EE* isomers) and the difference was highly significant ($P < 0.001$). In test 2 (*E,Z*)-8,10-dodecadien-1-ol gave a higher percentage of communication disruption than codlemone, and again the difference was highly significant ($P < 0.002$). These tests support our earlier report (McDonough et al., 1994) and establish that the superiority of the isomers as communication disruptants was not dependent on the proximity of the disruptants to the calling females, as previously described.

In the case of the pea moth (*Cydia nigricana*), superior disruption of communication was also found when isomers of the pheromone, (*E,E*)-8,10-dodecadien-1-ol acetate, formed (Bengtsson et al., 1994). The authors reported that males moved out of the field as the isomers formed. When mixed with the pheromone as an attractant, the isomers of the pea moth pheromone were potent inhibitors (Witzgall et al., 1993), whereas, when the isomers of the codling moth pheromone were mixed with the pheromone as an attractant, the inhibitory

TABLE 1. COMPARISON OF PERCENT COMMUNICATION DISRUPTION OF CODLEMONE (*E,E*)-8,10-DODECADIEN-1-OL (99%; 1% ISOMERS) WITH FOUR OTHER COMPOSITIONS HAVING HIGHER ISOMER CONTENT

Test	Composition	Mean % disruption (± SEM)	*P*
1	Codlemone (99%; 1% isomers)	68.70 ± 13.01	<0.001
	Codlemone (61%; 39% isomers)	86.75 ± 2.2	
2	Codlemone (99%; 1% isomers)	62.65 ± 6.03	<0.002
	(*E,Z*)-8,10-dodecadien-1-ol (94%; 3% codlemone; 2% *ZZ*, 1% *ZE*)	86.43 ± 2.72	
3	Codlemone (99%; 1% isomers)	62.13 ± 7.41	<0.011
	Codlemone (80%; 20% isomers)	82.92 ± 4.42	
4	Codlemone (99%; 1 isomers)	57.40 ± 19.90	<0.175
	Codlemone (90%; 10% isomers)	68.63 ± 4.71	

effect was moderate and the mixture was still significantly attractive (McDonough et al., 1993; Roelofs et al., 1972). These differences indicate that the disruption mechanisms of the isomers are not necessarily the same for these two species.

Recently, Mayer and Doolittle (1994) reported synthetic sex pheromone analogs that synergized responses of the sex pheromone olfactory specialist neurons of the main sex pheromone components of male cabbage looper (*Trichoplusia ni*) and corn earworm (*Helicoverpa zea*) moths. The synergism in the electrophysiological studies was corroborated by behavioral tests of upwind anemotactic responses in flight tunnel tests. It may be that the isomers of the codling moth sex pheromone also exert their inhibitory effect by interaction with the sex pheromone olfactory specialist neuron. Then the codling moth would not be able to resolve the inhibitor signal from the pheromone signal, even when there was a spatial difference between the pheromone and the inhibitor. In contrast, as pointed out earlier, the ability of the cabbage looper to locate a pheromone source was not disrupted when the pheromone inhibitor was separated from the pheromone, and in that case the inhibitor was perceived by a sensory neuron separate from that for the pheromone (McLaughlin et al., 1974).

Tests 3 and 4 in Table 1 show the percentage of communication disruption for the blends containing 10 and 20% isomers. Again both compositions elicited higher percentages of communication disruption than did codlemone, and the results were highly significant for the 20% composition ($P < 0.011$), but less so for the 10% composition ($P < 0.175$) as might be expected for the lower isomer percentage.

Although the total doses of test disruptants were constant in the four tests,

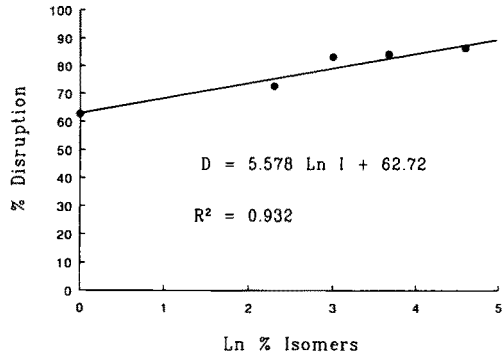

FIG. 2. Relationship between percent communication disruption and natural logarithm of the percentage of nonpheromone isomers from 1 to 97% isomers.

the doses of pheromone and of the isomers in the mixtures varied. Previously we found that a plot of logarithm of dose versus percentage of disruption gave good straight lines for both codlemone and the equilibrium mixture of isomers (McDonough et al., 1994). Therefore, their combination with varying proportions of pheromone and isomers was also expected to give a straight line. A plot of the logarithm of the percentage of isomers versus the percentage of disruption is shown in Figure 2. The correlation, $R^2 = 0.932$, indicates the relationship is linear.

Because of factors such as multiple mating of males, the percentages of communication disruption, as measured by trap catch, may not correlate quantitatively with the percentages of mating disruption. Nevertheless, disruption of communication is the mechanism by which mating disruption is achieved. Because the degree of communication disruption of the isomeric compositions was determined relative to codlemone, it is reasonable to expect that these relative differences will carry over to mating disruption, and therefore the isomers should have practical value in control programs.

Acknowledgments—We thank the Washington State Tree Fruit Research Commission for a grant to partially support this work, Dave Allan for providing the pear orchard for these tests, Tina Johnson and Tyson Miller for technical assistance, and Dr. Gary Richardson, Agricultural Research Service, Fort Collins, Colorado, for advice on statistical analysis of the data.

(Received June 5, 1995; accepted November 2, 1995)

Abstract—The effects of organic solvent extracts from perennial ryegrass (*Lolium perenne* L. cv. Friend), orchardgrass (*Dactylis glomerata* L. cv. Akimidori) and *Lolium* × *Festuca* hybrid on the hay consumption of goats were measured by simple two-choice feeding assays. Orchardgrass hay treated with methanol extracts (resuspended in water) of perennial ryegrass showed an increased intake by goats compared to untreated hay ($P < 0.01$). The palatability of hay tended to be slightly decreased by spraying it with pentane extract of perennial ryegrass and orchardgrass. Furthermore, extracts of hybrid with pentane inhibited goats from feeding ($P < 0.05$). Methanol extract stimulated hay consumption whereas the pentane extracts did not change or reduce intake.

Key Words—Goat, herbage, organic solvent extracts, feeding stimulants, perennial ryegrass, orchardgrass, hybrid.

INTRODUCTION

Secondary chemicals in food plants are thought to stimulate plant selection in domestic and wild herbivores through olfactory and gustatory senses (Müller-Schwarze, 1991). Arnold (1966) demonstrated that the two senses contributed to the selection of plants by using sensory-impaired sheep. Many researchers have reported on plant chemicals that deter wild and domestic herbivores from feeding on plants (Schwartz et al., 1980; Elliott and Loudon, 1987; Sunnerheim-Sjöberg, 1992; Estell et al., 1994).

However, there is very little information about the presence of stimulative

*To whom correspondence should be addressed.

0098-0331/96/0300-0425$09.50/0 © 1996 Plenum Publishing Corporation

chemicals and odors in plants and their effects on domestic herbivores, although use of feeding stimulants to increase intake and improve productivity is promising. Limited information on stimulants, including glucose, butyric acid, and sodium glutamate, was obtained by assaying chemicals already known to be present in herbaceous plants (Arnold et al., 1980; Grovum and Chapman, 1988; Gherardi and Black, 1991). In order to accumulate more information about stimulants, it is necessary to investigate extracts of herbage and their fractions for palatability to domestic herbivores and to then identify specific stimulants.

Organic solvent extracts from palatable and widely used herbage was examined for potential effects on herbage consumption by goats. The extractions were conducted with two organic solvents with different polarities. Behavioral choice-test bioassays using goats were used to test the biological activity of extracts.

METHODS AND MATERIALS

Animals and Management. Six castrated male Siba goats (2–3 years old and weighing 35–55 kg) were used in the experiments. Except during experimental periods, they were maintained on pasture from about 10:00 to 16:00 hr and then fed a small amount of concentrate (main ingredients: barley and soybean) to lure them into their barns each evening. Water, orchardgrass hay, and mineral blocks were provided *ad libitum* in the barn. During experimental periods animals were individually housed and fed in 2-m^2 pens. Throughout the experimental periods, water and mineral blocks were available *ad libitum* and each animal was fed 200 g of hay from 17:00 to 09:00 hr. The hay, which was second cutting orchardgrass in the vegetative growth stage obtained in July 1994 from the National Grassland Research Institute, was chopped in a chaff cutter to about 1.5-cm lengths. The prepared hay also was used in the two-choice tests. Before the experiments, the goats were allowed five days to become adjusted to experimental conditions.

Organic Solvent Extraction. Perennial ryegrass, orchardgrass, and hybrid grass in the vegetative growth stage were collected from grasslands in October 1994, and then cut to about 1-cm lengths with scissors. The cut leaves (260 g) were added to 500 ml of *n*-pentane and blended with a mixer at 10,000 rpm for 5 min while being cooled in an ice bath. The solution was filtered, concentrated to 100 ml in a draft chamber, and then stored at −20°C.

Methanol extract of perennial ryegrass was obtained as described above and stored at −20°C. Preliminary experiments demonstrated that methanol alone inhibited feeding by goats immediately after spraying it on hay. Therefore, 200 ml of distilled water was added to the methanol extract, methanol was removed with a rotary evaporator at 60°C for about 1 hr under vacuum, and the aqueous portion was stored at −40°C. Before the bioassays, the aqueous solution was

adjusted to 100 ml with distilled water. The pentane and methanol solvents used in these experiments were of analytical reagent grade.

Two-Choice Test. Tests were conducted using pentane extracts from perennial ryegrass, orchardgrass, hybrid grass and methanol extracts from perennial ryegrass over a four-day period. Each pen contained two troughs placed 50 cm apart, with one containing 600 g of the hay cut into 1.5-cm lengths and sprayed with 50 ml of a methanolic aqueous extract solution (130 g equivalent of perennial ryegrass). The other trough contained control hay sprayed with 50 ml of distilled water. The prepared fodders were fed to goats immediately. The amount of intake from each trough over a 2-hr period was measured for each goat. The methanolic aqueous extract tests were repeated twice from about 10:00 to 12:00 hr and from 14:00 to 16:00 hr on the same day with the exception of the positions of the troughs (left vs. right), which were switched each time. The significance of differences between the total intake volumes over the 4-hr period was examined via Student's paired t test. Each of the three pentane extracts was tested in the same manner, with pentane used as a control. The troughs were cleaned before any new treatments were sprayed to ensure that no residual substances remained.

RESULTS AND DISCUSSION

It is known that livestock preference for different plant species, plant varieties, and plants at different stages of growth is variable (Garner, 1963; Bryant et al., 1976; Evans and Potter, 1984; Colebrook et al., 1990). However, it is unclear whether chemical constituents are responsible for these differences. This study was designed to extract feeding stimulants from herbage given to domestic herbivores. Arnold et al. (1980) and Gherardi and Black (1991) reported that a bioassay using hay treated and untreated with chemical compounds was suitable to evaluate the effects on feeding by sheep. Their methods were adopted in these experiments, but modified to use organic solvent extracts from herbage with goats as the experimental animals. This choice test enabled us to assess the effects of specific extracts on forage preference with other factors affecting herbage preference excluded (i.e., physical factors, insoluble chemicals etc.).

Because herbage odor is thought to play an important role in stimulating livestock feeding (Müller-Schwarze, 1991), the herbages were first extracted with pentane, which should extract most of the volatile chemicals in the herbage (Blanch et al., 1991). However, pentane extracts of perennial ryegrass and orchardgrass did not stimulate hay consumption by goats, rather it tended to deter intake. The hybrid extract significantly inhibited feeding by goats (Figure 1).

These results suggested that chemicals extracted by pentane inhibited feed-

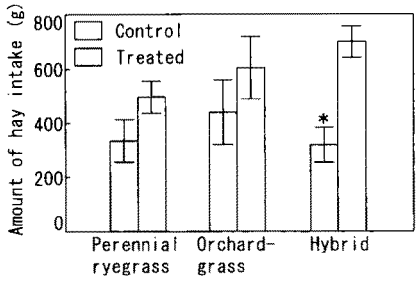

FIG. 1. Effect of *n*-pentane extracts from three types of herbage on hay intake by goats ($N = 6$) in two-choice tests. Asterisk and vertical bars denote significance ($P < 0.05$) and standard errors, respectively.

ing by goats. However, pentane extracts included not only volatile chemicals but also nonvolatile compounds that may deter consumption. Furthermore, pentane extracts may not reproduce the exact odor of the herbage due to the incomplete quantitative extraction and/or release of the volatile chemicals contained in the herbage. When hay was sprayed with pentane extracts, it lost its natural odor due to a blending with the odors from the pentane extracts. Goats might perceive sprayed hay as unfamiliar food with an odor different from that of hay or herbage. Some authors reported herbivores were unwilling to eat a food with which they were not familiar (Arnold and Maller, 1977; Hutson and van Mourik, 1981; Chapple et al., 1987; Burritt and Provenza, 1991). Therefore, the low preference goats have for hay sprayed with pentane extracts may be due to a lack of familiarity with the chemicals added to the hay from the extracts rather than to a congenital dislike of the chemicals in the extracts. Based on results obtained in these experiments, we concluded that no specific volatile chemicals with an intensely stimulative activity were present in the pentane extracts.

Aqueous solutions obtained from methanol extracts increased hay intake by goats even though the goats were unfamiliar with hay sprayed with the extract, suggesting that the extract contained strongly stimulative chemicals (Figure 2). The methanol extract likely contained more polar chemicals than the pentane extract. Because most of the methanol was removed from the extract before it was sprayed on hay, the solution probably contained less volatile chemicals than the pentane extract. Therefore, it seems that gustatory chemical substances that were detected by goats stimulated food intake more than odors. However, during this process chemicals in the methanol extracts may also be modified by heating, and it is possible that modified chemicals not present in perennial ryegrass are stimulants. Glucose, monosodium glutamate, and butyric acid were reported to stimulate drinking and feeding behavior of cattle and sheep

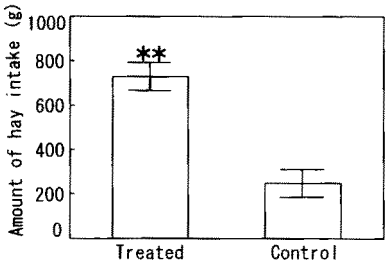

FIG. 2. Effect of methanol extract from perennial ryegrass on hay intake by goats (N = 6) in two-choice tests. Asterisks and vertical bars denote significance ($P < 0.01$) and standard errors.

(Arnold et al., 1980; Grovum and Chapman, 1988; Gherardi and Black, 1991). These substances would likely be extracted with methanol from plant tissues. Thus, the presence of these compounds might partially explain the stimulative effect of the methanol extract, but other chemical stimulants may also be present.

This study was a preliminary one aimed at elucidating what kinds of chemical constituents in herbage are responsible for preferences among domestic herbivores. Isolation and identification of the active compound(s) in the methanol extract of perennial ryegrass is currently under way. As for the pentane extracts, it will first be necessary to test the activity at higher extract concentrations than those used in these experiments because the weight of forage for extraction in this study may be too low to permit goats to detect palatable chemicals in the pentane extract. Furthermore, we should determine whether the presence of unpalatable chemicals in the extracts or unfamiliarity with the hay sprayed with them plays an important role in the low preference of goats for pentane extracts.

Acknowledgments—We would like to thank Dr. K. Okamoto and Prof. M. Shiyomi for their helpful suggestions and Mr. M. Igarashi, Mr. K. Satou, and Mr. Y. Yagisawa for the technical assistance. This work was supported in part by a Grant-in-Aid (Bio Cosmos Program) from the Ministry of Agriculture, Forestry and Fisheries. (BCP 95-II-A-2)

(Received February 28, 1995; accepted November 3, 1995)

Abstract—The fifth abdominal segment of female *Eriocrania semipurpurella* (Stephens) and *E. sangii* (Wood) contains a pair of exocrine glands. Hexane extracts of this segment were prepared from both species and analyzed by gas chromatography with simultaneous flame ionization and electroantennographic detection (EAD). For both species, the EAD active peaks were identified as nonan-2-one, (*Z*)-6-nonen-2-one, and (*Z*)-6-nonen-2-ol by means of mass spectrometry and comparison of retention indices with those of synthetic standards. Enantiomeric separation of chiral alcohols from the female extracts was achieved by gas chromatographic analysis on a cyclodextrin column. In *E. semipurpurella*, a mixture of (2*S*,6*Z*)-nonen-2-ol and (2*R*,6*Z*)-nonen-2-ol

(2 : 1) was found, whereas in *E. sangii* (2*S*,6*Z*)-nonen-2-ol was the predominant enantiomer and only traces of the *R* enantiomer were indicated by the antennal response. In field tests, a blend of the three compounds was not attractive to conspecific males. A subtractive assay showed that the alcohol in various enantiomeric mixtures was the only attractive compound, whereas addition of (*Z*)-6-nonen-2-one to the alcohol completely inhibited the attraction of both species. A trapping experiment including a wide range of ratios between the *R* and *S* enantiomers showed that baits containing 95–100% of the *S* enantiomer were attractive to male *E. sangii*, whereas males of *E. semipurpurella* were attracted to all tested ratios of the enantiomers. However, the response profiles of male *E. semipurpurella* differed between populations from southern Sweden, south Finland, and the Kola Peninsula in Russia. In south Sweden males were maximally attracted to a racemic mixture of the alcohols. At the Kola Peninsula *E. semipurpurella* was attracted to baits containing 95–100% of the *R* enantiomer. In south Finland all tested ratios between 0 and 100% *R* enantiomer trapped *E. semipurpurella*, but the trap catches appeared to be bimodally distributed with peaks around 15 and 70% *R* enantiomer. The trapping results suggest the existence of pheromone races or sibling species among the specimens identified as *E. semipurpurella*.

Key Words—*Eriocrania semipurpurella*, *Eriocrania sangii*, Eriocraniidae, Lepidoptera, sex pheromone, GC-EAD, chiral gas chromatography, mass spectrometry, synthesis, field trapping, nonan-2-one, (*Z*)-6-nonen-2-one, (2*S*,6*Z*)-nonen-2-ol, (2*R*,6*Z*)-nonen-2-ol.

INTRODUCTION

Sex pheromones identified from the higher moths, the so-called Ditrysia, are remarkably similar in chemical structure. The pheromone components identified from more than 400 species of higher Lepidoptera generally consist of aliphatic fatty acid derivatives with 10–20 carbon atoms in the carbon skeleton (Arn et al., 1992). Recent studies on *Eriocrania cicatricella* (Zhu et al., 1995) and *Stigmella malella* (Tóth et al., 1995) showed that these nonditrysian moths possess pheromones that differ in chemical structure from those of ditrysian Lepidoptera, but are very similar to pheromones of caddisflies with respect to both chemistry and site of pheromone production (Löfstedt et al., 1994; Zhu et al., 1995). However, data on pheromones of the first evolutionary lineages of the order Lepidoptera are still very scanty, and more identifications of pheromones from species in such lineages are needed for understanding the evolution of the lepidopteran pheromone communication systems.

The present study of two eriocraniid moths was aimed at the identification of the pheromones of two closely related species, *E. semipurpurella* (Stephens) and *E. sangii* (Wood). The study was promoted by a forthcoming taxonomic revision of the family Eriocraniidae (O. Karsholt, personal communication), which shows a large morphological variation in the two species and reveals

problems in their identification. Additionally, these species recently became the target objects for a study of leaf-miner responses to aerial emissions of nickel–copper smelters (Koricheva and Haukioja, 1992; Kozlov and Haukioja, 1993), which created an urgent need for synthetic blends to monitor their population densities.

METHODS AND MATERIALS

Insects. Moths of *E. semipurpurella* and *E. sangii* were collected as adults from young birch forests on May 1–6, 1992 (Turku, Finland), April 21–30, 1993, and April 24–28, 1994 (Lund, Sweden). Adults were sexed immediately after capture, kept in plastic vials containing moist filter paper, and transported to the laboratory in Lund for electrophysiological tests and chemical analyses.

Since identification of these species sometimes is problematic, it should be mentioned that the key character we used to discriminate the two species was the form of the terminal segment of the long, folded maxillary palp; specimens with a pointed apex of this segment were attributed to *E. semipurpurella*, whereas the presence of a clear bifurcation indicated *E. sangii* (O. Karsholt, personal communication).

Preparation of Extracts. Extracts of the fifth abdominal segment from adult females were used for gas chromatography with electroantennographic detection (GC-EAD). The insects were anesthetized by cooling them to −20°C before dissection. The dissected segment of an individual female was extracted for at least 30 min in a pointed tube containing 20 μl redistilled hexane. These extracts were subsequently used for both electrophysiological tests and chemical identification.

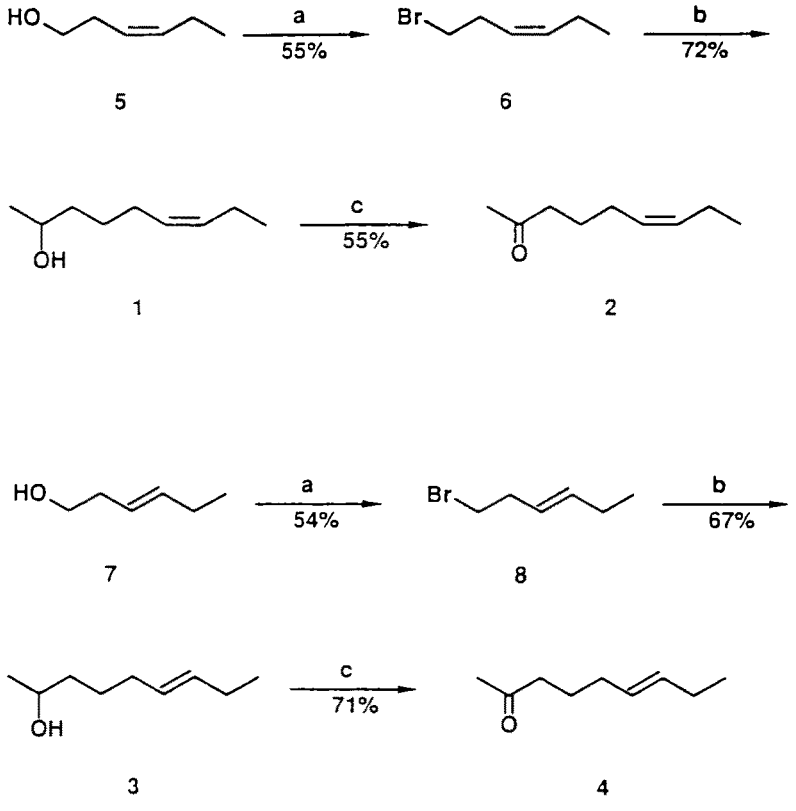
Chemical Analyses. To examine male antennal sensitivity to extracts of females of the two species, the tip of the male antenna was cut off and the antenna was mounted between two pipet electrodes containing Beadle-Ephrussi Ringer, and grounded via an Ag–AgCl wire. The tip electrode was connected to a high-impedance DC amplifier with automatic baseline drift compensation. GC-EAD analyses of extracts of female fifth abdominal segments of the two species were conducted on a Hewlett Packard 5830 GC equipped with either of two different columns, a DB-WAX column (30 m × 0.25 mm ID, J & W Scientific, Folsom, California) or a cyclodextrin column (25 m × 0.25 mm ID) coated with a mixture of 6-*O*-methyl-2,3-di-*O*-pentyl-γ-cyclodextrin and OV-1701 in a ratio of 1:4 (Prof. W. A. König, Institute of Organic Chemistry, University of Hamburg, Hamburg, Germany). An effluent split allowed simultaneous flame ionization (FID) and electroantennographic detection (EAD) of the separated pheromone components. Hydrogen was used as carrier gas, and the effluent split ratio was approximately 1:1. Samples were injected splitless.

The split valve was opened 1 min after injection. The injector temperature was kept at 250°C and the column temperature was maintained at 40°C for 3 min following the injection on the DB-WAX column and then linearly increased to 230°C at a rate of 5°C/min. When using the cyclodextrin column, the injector temperature was kept at 150°C and the column temperature was maintained at 60°C for 3 min following the injection and then linearly increased to 160°C at a rate of 5°C/min. The outlet for the EAD was placed in a purified humidified airstream flowing over the antennal preparation at a speed of 0.5 m/sec. Either 5 μl of extracts containing 5–10 female equivalents or 5 μl of an individual female abdominal segment extract were injected into the columns for the analyses. Gas chromatographic analyses of the geometric isomers were performed using a fused-silica capillary column (50 m × 0.32 mm ID) coated with Free Fatty Acid Phase (FFAP), programmed from 60 to 220°C at a rate of 5°C/min.

Mass spectra of EAD active compounds were recorded first on a Hewlett Packard 5970 GC-MSD equipped with a DB-WAX column, programmed from 40 to 230°C at a rate of 5°C/min and, second, with a double-focusing instrument (VG 70-250 SE; Vacuum Generators, Manchester, England) at 70 eV by using a fused-silica capillary (50 m × 0.32 mm ID) coated with FFAP, programmed from 60 to 220°C at a rate of 5°C/min. Microhydrogenation of natural products was carried out according to Huwyler (1973). Enantiomeric separation was achieved using a cyclodextrin column operated under the following conditions: 12 min at 60°C, then linearly increased to 120°C at a rate of 3°C/min. NMR spectra (400.1 MHz for ^{1}H and 100.6 for ^{13}C) of synthetic samples were run on a Bruker AMX 400; δ TMS = 0, δ $CDCl_3$ = 7.26 (s = singlet, bs = broad singlet, d = doublet, t = triplet, qu = quintet, m = multiplet, dtt = doublet of a triplet of a triplet, dbq = doublet of a broad quartet, dbqu = doublet of a broad quintet); attribution of ^{13}C signals was made according to DEPT spectroscopy (CH_3 and CH = +; CH_2 = −; quart C = 0).

Chemical Syntheses. Our straightforward syntheses of the target compounds are shown in Scheme 1. Commercially available 3-hexen-1-ols were converted into the corresponding bromides according to Wijnberg et al. (1981). Grignard reaction with epoxypropane (Johnston and Slessor, 1979) afforded 6-nonen-2-ols, which were subsequently oxidized to the ketones following the method of Herscovici et al. (1982). Optically active (*Z*)-6-nonen-2-ols were produced from (*Z*)-3-hexen-1-ol and optically active epoxypropanes.

(Z)-1-Bromo-3-hexene (6). A solution of 16.0 g bromine (0.11 mol) in 20 ml dichloromethane was added at −10°C to a stirred solution of 26.2 g (0.11 mol) of triphenylphosphane in 120 ml dichloromethane. Subsequently at the same temperature, 10.0 g (0.10 mol) of commercially available (*Z*)-3-hexen-1-ol (Aldrich) dissolved in 40 ml dichloromethane was added dropwise. After 30 min the mixture was poured on 500 ml water, the organic layer was separated,



a) PPh_3Br_2/ CH_2Cl_2 ; b) 1.Mg,CuI/ THF 2.methyloxirane ;
c) PDC, MS4 Å

SCHEME 1.

and the aqueous phase was extracted twice with 500 ml of dichloromethane. The combined organic phase was washed twice with saturated sodium bicarbonate, dried over magnesium sulfate, and concentrated under reduced pressure. The crude product was distilled in vacuo yielding 9.0 g (55%) of **6**, bp_{12}: 60–61°C.

^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 5.59 (dtt, 1H, J = 10.8 Hz, J = 7.2 Hz, J = 1.5 Hz), 5.37 (dtt, 1H, J = 10.8 Hz, J = 7.2 Hz, J = 1.5 Hz), 3.37

(t, 2H, $J_{1,2}$ = 7.2 Hz, H-1), 2.62 (dbq, 2H, $J_{2,3}$ = 7.2 Hz, $J_{2,4}$ = 1.5 Hz, H-2), 2.06 dbqu, 2H, $J_{5,4}$ = $J_{5,6}$ = 7.2 Hz, H-5), 0.98 (t, 3H, $J_{6,5}$ = 7.6 Hz, H-6). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 134.75 (+), 125.20 (+), 32.85 (−), 30.75 (−), 20.74 (−), 14.16 (+). MS; *m/z*, 39 (50), 41 (100), 53 (16), 55 (94), 67 (31), 69 (13), 82 (14), 83 (50), 162 (11, M^+), 164 (11, M^+).

rac.(Z)-6-Nonen-2-ol (1). From 2.5 g (15.3 mmol) of **6,** dissolved in 25 ml tetrahydrofurane and 0.38 g (15.6 mmol) magnesium turnings, a Grignard reagent was prepared. After addition of 0.24 g (1.3 mmol) copper(I) iodide, the mixture was stirred for 15 min at room temperature. Subsequently, after cooling to −20°C, 0.72 g (12.4 mmol) rac. methyl oxirane (Merck) was added under stirring. After slowly warming up to room temperature, 20 ml saturated aqueous ammonium chloride was added and the mixture was extracted three times with portions of 50 ml of ether. The combined organic extracts were washed with brine, dried with magnesium sulfate, and concentrated under reduced pressure. The crude product was distilled in vacuo to yield 1.57 g (72%) of **1,** bp_{12}: 90°C.

^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 5.28–5.42 (m, 2H, H-6,7), 3.76–3.84 (m, 1H, H-2), 2.00–2.08 (m, 4H, H-5,8), 1.58 (bs, 1H, OH), 1.40–1.51 (m, 4H, H-3,4), 1.19 (t, 3H, $J_{1,2}$ = 6.4 Hz, H-1), 0.96 (t, 3H, $J_{9,8}$ = 7.6 Hz, H-9). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 131.99 (+), 128.84 (+), 68.05 (+, C2), 38.47 (−), 26.59 (−), 25.47 (−), 23.09 (+, C1), 20.12 (−, C8), 13.94 (+, C9). MS is shown in Figure 2B below.

(2R,6Z)-Nonen-2-ol. The synthesis was essentially the same as for rac. **1.** Commercially available (Aldrich) (*R*)-methyloxirane (0.72 g, 12.4 mmol) yielded 1.1 g (62%) of (2*R*)-**1**; $[\alpha]^{22}$ = −7.9 (c = 4.1 CH_2Cl_2).

(2S,6Z)-Nonen-2-ol. The synthesis was essentially the same as for rac. **1.** Commercially available (Aldrich) (*S*)-methyloxirane (0.72 g, 12.4 mmol) yielded 1.2 g (68%) of (2*R*)-**1**; $[\alpha]^{22}$ = +7.9 (c = 3.3 CH_2Cl_2).

(Z)-6-Nonen-2-one (2). To a solution of 1.0 g (7.0 mmol) of **1** in 45 ml dichloromethane, 2.67 g (7.1 mmol) pyridinium dichromate and 2 g pulverized molecular sieve (4 Å) were added. After vigorous stirring for 4 hr, the mixture was filtered over 20 g silica (Merck 60, 200–240 mesh). The silica was washed with 150 ml of diethyl ether, and the organic solution was concentrated. The residue was chromatographed on 20 g silica (Merck 60, 200–240 mesh, using pentane–diethylether 20:1 as the eluent), yielding 550 mg (55%) of **2.**

^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 5.40 (dtt, 1H, $J_{6,7}$ = 10.8 Hz, $J_{6,5}$ = 7.0 Hz, $J_{6,8}$ = 1.5 Hz, H-6), 5.28 (dtt, 1H, $J_{7,8}$ = 7.0 Hz, $J_{7,5}$ = 1.5 Hz, H-7), 2.43 (t, 2H, $J_{3,4}$ = 7.4 Hz, H-3), 2.13 (s, 3H, H-1), 1.98–2.08 (m, 4H, H-5,8), 1.64 (qu, 2H, $J_{4,5}$ = $J_{4,3}$ = 7.4 Hz, H-4), 0.96 (t, 3H, $J_{9,8}$ = 7.6 Hz, H-9). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 209.04 (o, C2), 132.67 (+), 128.04 (+), 43.05 (−, C3), 29.90 (+, C1), 26.39 (−), 23.39 (−), 23.74 (−), 20.53 (−), 14.32 (+, C9). The mass spectrum is shown in Figure 2A below.

(E)-1-Bromo-3-hexene (8). Starting from 10.0 g (0.10 mol) of commercially available (*E*)-3-hexen-1-ol (**7**), the synthesis was essentially the same as for **6,** yielding 8.8 g (54%) of **8;** bp_{12}: 62–63°C.

^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 5.54 (dtt, 1H, J = 14.8 Hz, J = 6.2 Hz, J = 1.3 Hz), 5.39 (dtt, 1H, J = 14.8 Hz, J = 6.6 Hz, $J_{5,3}$ = 1.5 Hz), 3.37 (t, 2H, $J_{1,2}$ = 7.2 Hz, H-1), 2.54 (m, 2H, H-2), 2.03 (m, 2H, H-5), 0.98 (t, 3H, $J_{6,5}$ = 7.6 Hz, H-6). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 135.84 (+), 125.45 (+), 36.06 (−), 32.90 (−), 25.56 (−), 13.64 (+). MS; *m/z*, 39 (47), 41 (100), 53 (15), 55 (95), 63 (16), 67 (31), 69 (16), 82 (16), 83 (62), 162 (13, M^+), 164 (13, M^+).

rac. (E)-6-Nonen-2-ol (3). In a reaction carried out analogously to the synthesis of rac. **1,** 2.5 g (15.3 mmol) of **8** and 0.72 g (12.4 mmol) methyloxirane yielded 1.4 g (67%) of **3;** bp_{12}: 90°C.

^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 5.35–5.50 (m, 2H, H-6,7), 3.75–3.83 (m, 1H, H-2), 1.96–2.03 (m, 4H, H-5,8), 1.35–1.50 (m, 5H, H-3, 4, OH), 1.09 (t, 3H, $J_{1,2}$ = 6.2 Hz, H-1), 0.96 (t, 3H, $J_{9,8}$ = 7.4 Hz, H-9). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 132.49 (+), 128.88 (+), 68.08 (+, C2), 38.83 (−), 32.48 (−), 25.76 (−), 25.59 (−) 23.50 (+, C1), 13.97 (+, C9). MS; *m/z*, 39 (30), 41 (65), 43 (35), 45 (55), 53 (10), 55 (28), 58 (14), 67 (100), 68 (18), 71 (36), 81 (13), 82 (59), 95 (15), 109 (4), 113 (1), 124 (1), 127 (1), 142 (4, M^+).

(E)-6-Nonen-2-one (4). The synthesis was essentially the same as for **2,** 350 mg (2.5 mmol) of **3** yielded 250 mg (72%) of **4.**

Field Tests. Field trapping was conducted in young birch forests in the surroundings of Lund (Sweden), Turku (Finland), and Kirovsk (Russia) in 1993 and 1994. Synthetic blends were prepared in hexane. Red rubber septa (Arthur H. Thomas Co. Catalog No. 1780-J07) were used as dispensers, and the traps used were Lund II sticky traps (Anderbrant et al., 1989). All traps were hung on the branches of young birch trees 1–2 m above the ground and checked every day. Within a replicate (N = 5–10), traps were spaced at least 5 m apart, and trap positions within a series were randomized at each sampling time to minimize the effects of habitat heterogeneities. Subtractive assays were first carried out in Kirovsk, June 11–15, 1993, to determine the attractivity to males of blends

containing compounds identified from the female pheromone gland extracts. In 1994 different ratios of (2*S*,6*Z*)- and (2*R*,6*Z*)-nonen-2-ol were tested in all three places. Finally, dose–response experiments with (2*S*,6*Z*)-nonen-2-ol were performed in Lund and Turku, whereas different doses of a 3 : 1 mixture of (2*S*,6*Z*)- and (2*R*,6*Z*)-nonen-2-ol were tested in Turku only.

RESULTS

GC-EAD of Female Extracts and Chemical Identification

Eriocrania sangii. GC-EAD analysis of the extracts from female fifth abdominal segment on a DB-WAX column indicated that three compounds elicited strong responses from a conspecific male antenna (Figure 1). The mass spectra of these three GC-EAD active compounds suggested two methylketones as indicated by the fragment *m/z* 58 and a methylcarbinol showing the characteristic *m/z* 45. Comparison of mass spectral data (McLafferty and Stauffer, 1989) and gas chromatographic retention time proved the minor ketone to be nonan-2-one (C_9-2-one). The mass spectrum of the major ketone shown in Figure 2A was known to us from earlier work (Francke et al., 1979; Vanderwel et

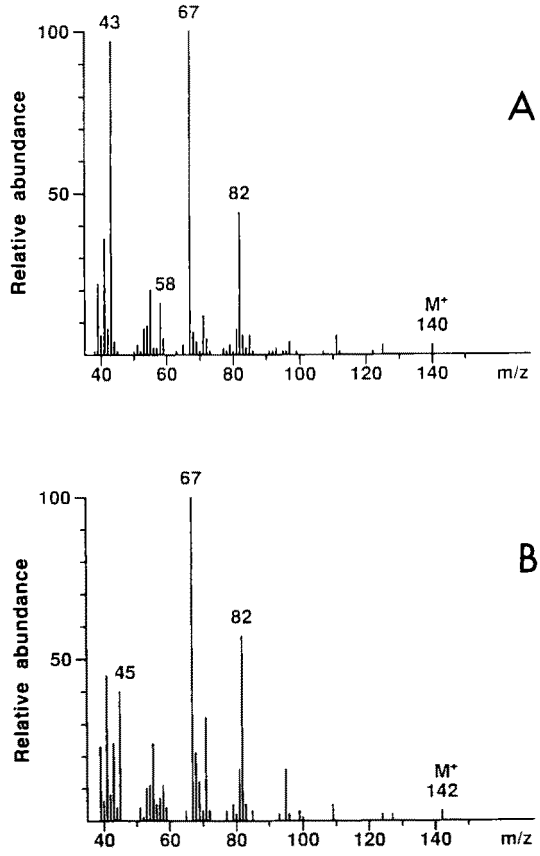

FIG. 2. Mass spectrum of (Z)-6-nonen-2-one (A) and (Z)-6-nonen-2-ol (B) found in female gland extracts of *Eriocrania sangii*.

al., 1992). The compound was clearly shown to be 6-nonen-2-one by the molecular ion at *m/z* 140 and a McLafferty rearrangement producing *m/z* 58 and an intense signal at *m/z* 82, which upon loss of a methyl group gave rise to the formation of the base peak of the spectrum at *m/z* 67. Upon gas chromatography, the double bond was shown to have *Z* geometry since the synthetic (Z)-6-nonen-2-one (Z6-C_9-2-one), which produced the same mass spectrum, coeluted with the natural compound, while the *E* isomer eluted earlier (Figure 3A). The third EAD active compound produced nonan-2-ol upon microhydrogenation (Huwyler, 1973). With intense signals at *m/z* 82 and *m/z* 67, its mass spectrum (Figure

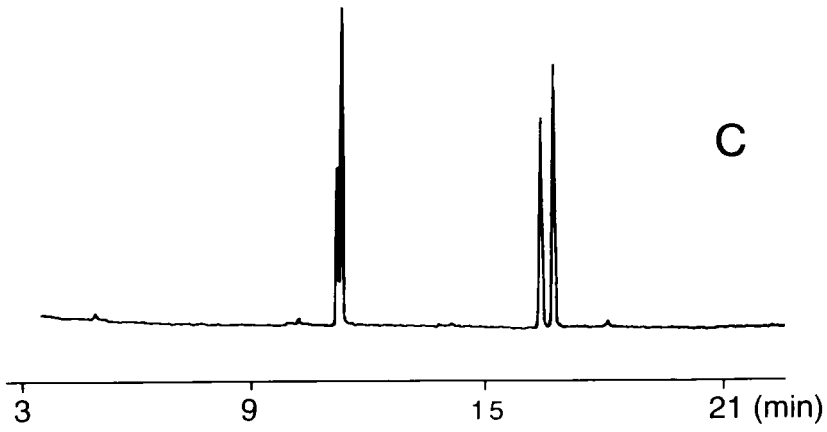

FIG. 3. Continued.

2B) was strikingly similar to that of 6-nonen-2-one, but its molecular mass of *m/z* 142 suggested a nonen-2-ol. Assuming close structural and biogenetic relations between this compound and (*Z*)-6-nonen-2-one, it was tentatively assigned to be (*Z*)-6-nonen-2-ol (Z6-C_9-2-ol). A synthetic sample produced the same mass spectrum as the natural compound and coeluted upon gas chromatography (Figure 3B), while the *E* isomer appeared earlier (Figure 3C). As shown with the synthetic samples, the enantiomers of Z6-C_9-2-ol could be gas chromatographically well separated using a modified cyclodextrin as the stationary phase (Figure 4A). The earlier eluting *S* enantiomer coeluted with the natural product (Figure 4C). We could not exclude the presence of a very small amount of the *R* enantiomer. However, as shown by GC-MS, the minor peak eluting shortly after (*S*)-Z6-C_9-2-ol (Figure 4C) does not represent the *R* enantiomer. Further GC-EAD analyses of female extracts on a cyclodextrin column and using a conspecific male antennae as the detector showed that the *S* enantiomer was found predominantly in the female extract. However, a tiny amount of *R* enantiomer was detected in the extract based on evidence that a compound with the same retention time as the synthetic *R* enantiomer elicited a small, but significant antennal response (Figure 5). The EAD active compounds in the female extract could thus be identified as C_9-2-one, Z6-C_9-2-one, and (*S*)-Z6-C_9-2-ol.

E. semipurpurella. Three compounds with the same retention indices as those found in *E. sangii* elicited strong responses from male antennae in GC-EAD analyses of female extracts on a DB-WAX column (Figure 6). Mass spectra of these three compounds were also the same as those described in *E.*

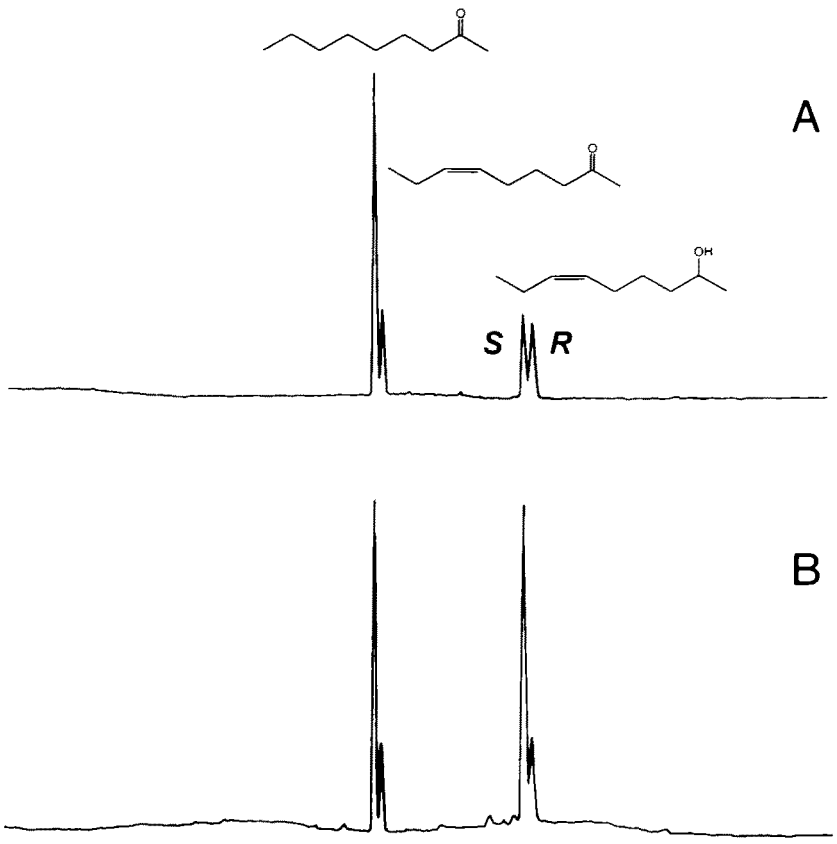

FIG. 4. Gas chromatographic separation of (A) 2-nonanone, (Z)-6-nonen-2-one, and (Z)-6-nonen-2-ols; (B) sample A + (2*S*,6*Z*)-nonen-2-ol; (C) female extracts of *Eriocrania sangii;* (D) sample A + sample C on a cyclodextrin column.

sangii. However, gas chromatography on a chiral cyclodextrin column showed that both *S* and *R* enantiomers of the alcohol, in a relative ratio of 2:1, were found from the analyses of individual female extract (Figure 7). GC-EAD analysis of a synthetic mixture containing the two enantiomers in a relative ratio of 1:0.9 showed that male antennae responded to both enantiomers (Figure 8). The EAD active compounds in the extracts could thus be identified to be C_9-2-one, Z6-C_9-2-one, (*S*)-Z6-C_9-2-ol, and (*R*)-Z6-C_9-2-ol.

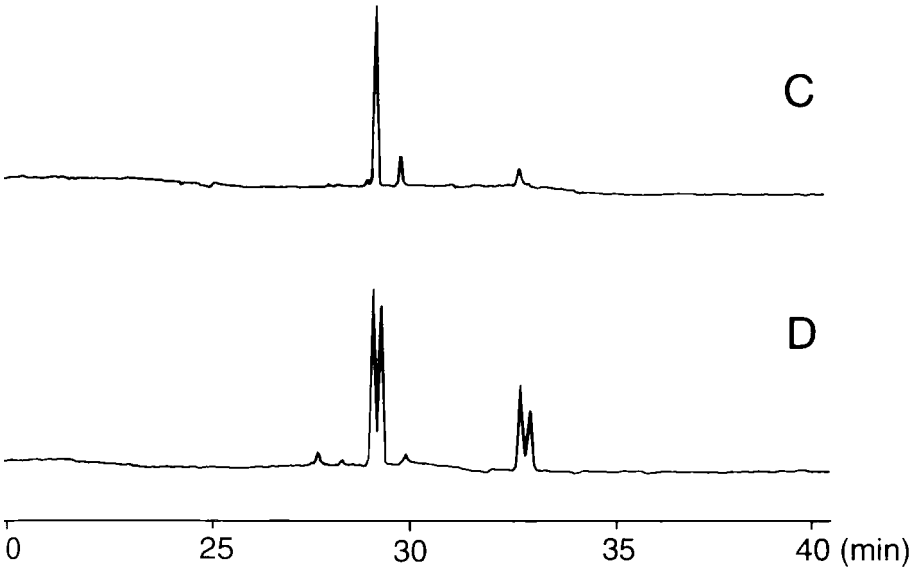

FIG. 4. Continued.

Field Tests. The three synthetic compounds in two different ratios were not attractive to males of either species (Table 1). However, subtraction of the major compound, Z6-C_9-2-one, increased the bait attraction to males of *E. sangii* significantly. The highest number of trapped males was observed when the bait contained pure (*S*)-Z6-C_9-2-ol only. Thus, we concluded that (*S*)-Z6-C_9-2-ol was the only behaviorally attractive sex pheromone component for *E. sangii* males. Males of *E. semipurpurella* were also attracted to the baits containing (*S*)-Z6-C_9-2-ol, but the catch number was extremely low compared to numbers of male *E. sangii* caught in the traps.

The importance of the enantiomeric composition of the alcohol was elucidated in the field tests with different ratios of (*S*)- and (*R*)-Z6-C_9-2-ol (Figure 9). The traps with baits containing pure *S* enantiomer of Z6-C_9-2-ol and its mixture with 5% of the *R* enantiomer were attractive to males of *E. sangii* in all three regions. The bait completely lost its attractivity to males of *E. sangii* by adding more than 20% of the *R* enantiomer in the blend. However, presence of the *R* enantiomer seemed obligatory to attract males of *E. semipurpurella*, and the attractive ratios of chiral alcohols differed in three locations. In southern Sweden a racemic mixture of the two alcohols was the only bait attracting

significant numbers of *E. semipurpurella*. In the northwest of Russia baits with pure *R* enantiomer or its mixture with 5% of *S* enantiomer caught the largest number of *E. semipurpurella* males. The intermediate situation was discovered in southern Finland, where all examined ratios of (*S*)- and (*R*)-Z6-C_9-2-ol caught a number of male *E. semipurpurella*, but lures containing 50–80% of (*R*)-Z6-C_9-2-ol were more attractive than other tested ratios.

[a] Means followed by the same letter within series A and B, respectively, are not significantly different according to a Kruskal-Wallis analysis of variance followed by pairwise comparisons using the Fligner-Policello robust Mann-Whitney U test ($P < 0.05$), $N = 5$.
[b] Ratios of the three pheromone candidates are the same as those found in the female extracts of *E. semipurpurella*.
[c] Ratios of the three pheromone candidates are the same as those found in the female extracts of *E. sangii*.

A mixture of the (*S*)- and (*R*)-Z6-C_9-2-ol in a ratio of 3 : 1 and the pure *S* enantiomer were also tested in different doses (Table 2). The higher doses (10–1000 μg) of the pure *S* enantiomer caught the largest number of males *E. sangii*. Males of *E. semipurpurella* were trapped in Finland only, and the 1000-μg dose of the enantiomeric mixture was the most attractive.

DISCUSSION

The present investigation of *Eriocrania semipurpurella* and *E. sangii* confirms that the chemical structures of sex pheromones in a primitive lineage of Lepidoptera are different from those in the ditrysian moths. The two species

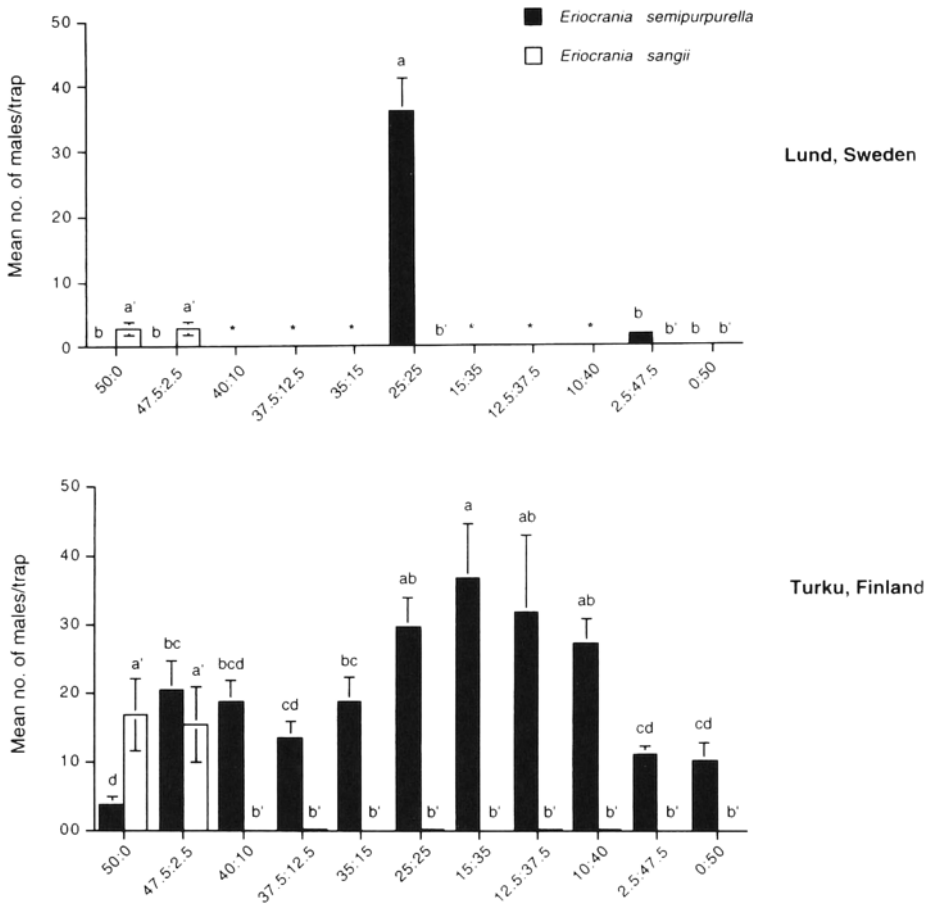

FIG. 9. Geographical variation in mean number of male moths (±SE) trapped with baits containing different enantiomeric ratios of (2*R*,6*Z*)- and (2*S*,6*Z*)-nonen-2-ol, as observed in field tests conducted at three locations in 1994. Bars accompanied by the same letters represent means that are not statistically different according to a Kruskal-Wallis analysis of variance followed by pairwise comparisons using the Fligner-Policello Mann-Whitney U test ($P < 0.05$), $N = 5$. Blends indicated with an asterisk were not tested.

investigated, as well as *E. cicatricella* studied earlier (Zhu et al., 1995), produce short-chain ketones and alcohols as pheromone components that are similar to sex pheromone components earlier found in Trichoptera (Löfstedt et al., 1994).

The alcohols found in *E. semipurpurella* and *E. sangii* are likely to be the reduction products of corresponding methylketones. The antagonistic behavioral

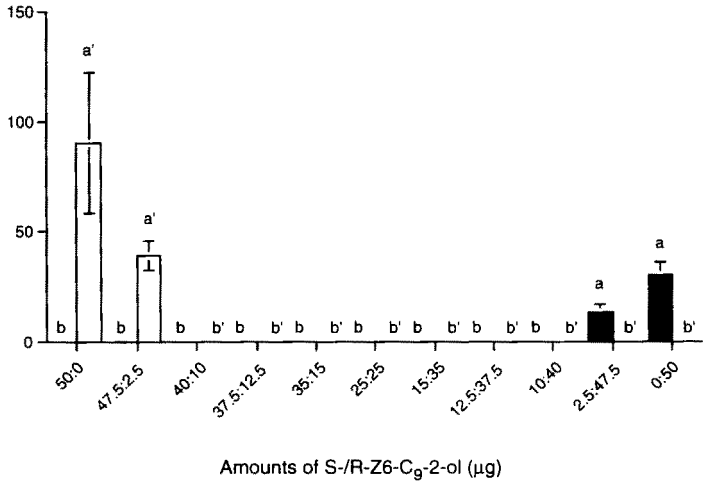

FIG. 9. Continued.

activity of Z6-C_9-2-one when tested in mixtures with the alcohols strongly suggests that the ketones are precursors of the alcohols and that they are not released by calling females under natural conditions. Methyl ketones are widespread gland constituents among Hymenoptera (Blum, 1981), and Z6-C_9-2-one together with *exo*-brevicomin (Silverstein et al., 1968) has been identified as a male-specific component in the ash bark beetle, *Leperisinus varius* (Francke et al., 1979). Francke (1981) postulated a biogenetic relationship between these two compounds and regarded the unsaturated ketone as a precursor of brevicomin, since enzymatic epoxidation of the ketone followed by ring closure would directly yield brevicomin (see also Kohnle et al., 1992). This route was recently confirmed by Vanderwel et al. (1992) in an *in vivo* experiment in the mountain pine beetle, *Dendroctonus ponderosae*, based on evidence that the beetles transform labeled Z6-C_9-2-one into *exo*-brevicomin. Interestingly, secondary alcohols such as 2-tridecanol and 2-pentadecanol with the *S* configuration were identified from the defensive secretion of larvae of two notodontid caterpillars (Attygalle et al., 1993). In addition, (2*S*)-alkan-2-ols were found to be components of the sex pheromone of queens of the stingless bee, *Scaptotrigona postica* (Engels et al., 1990).

The fact that closely related species of insects commonly use similar pheromone components may seem to limit their use in species-specific communication. However, the signal may be specific not only because of compounds involved in a given blend, but also due to the ratio between pheromone components, including the enantiomeric composition of optically active components.

[a]Means within each column in each experiment followed by the same letter are not significantly different according to a Kruskal-Wallis analysis of variance followed by pairwise comparisons using the Fligner-Policello robust Mann-Whitney U test ($P < 0.05$), $N = 5$.

Chirality plays a very important role in the specificity of many pheromones, and often one enantiomer gives a positive biological response while the other enantiomer acts as an inhibitor. In the present study males of *E. sangii* were attracted by the baits containing pure *S* enantiomer or a mixture with less than 5% of *R* enantiomer. The attractivity was decreased significantly after addition of more than 5% of the *R* enantiomer. Females of *E. sangii* produce mainly the *S* enantiomer as their pheromone, while female extracts of *E. semipurpurella* contain both *R* and *S* enantiomers. The pheromone of *E. cicatricella*, another species in the same genus, was identified as (2*R*,4*Z*)-hepten-2-ol. No males of *E. cicatricella*, but a large number of *E. sparrmannella*, were caught in traps baited with (2*S*,4*Z*)-hepten-2-ol (Zhu et al., 1995).

Enantiospecific activity has been well documented in several other species of Lepidoptera. (3*Z*,9*Z*-6*S*,7*R*)-epoxy-nonadecadiene is used as a sex pheromone

component by *Erannis defoliaria*. However, the addition of its 6*R*,7*S* antipode significantly decreases male catches in the field. In contrast, this compound is very attractive to males of another geometrid moth, *Colotois pennaria* (Szöcs et al., 1993). The sex pheromone of the gypsy moth, *Lymantria dispar*, was identified as (*Z*)-7,8-epoxy-2-methyloctadecane (Bierl et al., 1970). Studies using (7*R*,8*S*)-(+) and (7*S*,8*R*)-(−) enantiomers and the racemic mixture indicated that males only respond to the (+) enantiomer and are inhibited by very small amounts of (−)-disparlure (Cardé et al., 1977). Hansen (1984) reported that females of the nun moth, *L. monacha*, produced a 90:10 blend of (−)- and (+)-disparlure, and male moths responded to both of the enantiomers but were mostly attracted to the mixture (Klimetzek et al., 1976; Vité et al., 1976).

E. semipurpurella and *E. sangii* are difficult to distinguish morphologically, even when the male genitalia are investigated (Heath, 1976). Recently, however, the form of the terminal segment of the maxillary palp was demonstrated as a reliable external character to distinguish between *E. semipurpurella* (pointed apex) and *E. sangii* (forked apex). The difference in female pheromone composition and in male pheromone response among the two forms correlated to this morphological difference, which supports the notation that *E. semipurpurella* and *E. sangii* are two different species, although closely related to each other.

Geographical differences in responses to pheromones have earlier been reported in both Lepidoptera and Coleoptera. Behaviorally significant variation in pheromone composition has been shown among populations of the turnip moth, *Agrotis segetum* (Arn et al., 1983; Löfstedt et al., 1986; Tóth et al., 1992). The largest difference in attraction of males appeared between populations north and south of the Sahara Desert. Pure (*Z*)-5-decenyl acetate is not attractive to males in most of the European populations investigated but is very attractive to males in two South African populations. This male behavioral difference corresponds to significant differences in female pheromone production between European and African populations (Wu, Cottrell, Hansson, and Löfstedt, unpublished results). Both inter- and intrapopulational variation of ipsdienol configuration have been noted in the pine engraver, *Ips pini*. Populations of *I. pini* in Idaho (Plummer et al., 1976) and California produce primarily (−)-ipsdienol and also preferentially respond to this component, while the New York population specifically produces and responds to a 65:35 mixture of (+)-:(−)-ipsdienol (Lanier et al., 1980). The different pheromone response profiles among males of *E. semipurpurella* at three locations in northern Europe is another example of geographic pheromone variation with respect to enantiomeric composition of the pheromone. Males from Lund, in the south of Sweden and from Turku, in the south of Finland, respond to different mixtures of (*R*)- and (*S*)-*Z*6-C_9-2-ol, whereas males from the population in Kirovsk, northwest Russia, are specifically attracted to the pure *R* enantiomer. The *R* enantiomer does not

attract any males in Lund, whereas in Turku some males were found in the traps baited with this compound, albeit in significantly lower numbers compared to traps baited with the mixtures. Female extracts of *E. semipurpurella* collected in Lund were found to contain mixtures of *R* and *S* enantiomers in a ratio of 1:2. We were not able to collect females from Kirovsk for pheromone analysis, but based on the field-trapping tests we expect females from this area to produce mainly the *R* enantiomer.

Foster et al. (1987) analyzed pheromone production and response among some geographical populations of New Zealand tortricids and discovered several sibling species within the genera *Ctenopseustis* and *Planotortrix*. The differences in response profiles among geographical populations of *E. semipurpurella* and the apparent bimodal distribution of trap catches among baits with different enantiomeric composition in Finland suggest that we are actually dealing with a complex of sibling species. This possibility will be investigated by pheromone analysis and morphological investigations of *E. semipurpurella* from more places in Sweden, Finland, and Russia.

(Received December 7, 1994; accepted November 7, 1995)

Abstract—Lectins have been used to locate and ascribe a function to sensory organs of nematodes. We had two objectives: (1) to determine the location of carbohydrate exudates on the surface of three species of entomopathogenic nematodes with different foraging strategies and (2) to evaluate the importance of carbohydrates in host finding and recognition. *Steinernema carpocapsae* finds hosts by ambushing, and most individuals respond poorly to host cues. No specific areas of lectin binding were recorded for this species. Wheat germ agglutinin bound specifically to the anterior region of *Heterorhabditis bacteriophora* and to the anterior and posterior of *S. glaseri*. These two nematode species are cruise foragers and are highly responsive to host cues. The behavioral effects of lectins varied. None of the species' responses to volatile host cues was affected. *S. carpocapsae*'s rate of attachment during ambushing was increased by treatment with WGA, and this effect was negated by treatment with a competing sugar (*N*-acetylglucosamine). The infectivity of *S. glaseri* in an assay that required movement through 5 cm of sand to find the host was significantly decreased by treatment with WGA.

Key Words—Entomopathogenic nematodes, behavior, foraging, lectins, insects, biological control, ecology.

INTRODUCTION

Most parasitic nematodes find and assess hosts via chemical cues. Information on host quality and location is detected by chemosensilla, primarily the anteriorly located amphids (Ward, 1978), situated in body pores filled with glycoprotein exudates (Aumann, 1993). Behavioral responses to host cues or food resources have been described in detail for plant-parasitic (Pline and Dusenbery, 1987; Grundler et al., 1991), insect-parasitic (Gaugler et al., 1980; Lewis et al., 1992, 1993; Khlibsuwan et al., 1992), and free-living nematodes (Grewal and Wright, 1991; Andrew and Nicholas, 1976). The location and role of nematode sensory organs and their associated glycoprotein exudates have been shown by scanning electron micrography (Forrest et al., 1988; Bird and Bird, 1991) and studied indirectly by labeling with lectins (Zuckerman, 1983; Bone and Bottjer, 1985; Jansson and Nordbring-Hertz, 1984; Jansson, 1993).

Studies using lectins to inhibit behavioral responses of nematodes have elucidated many aspects of their sensory capabilities. Lectins are proteins or glycoproteins that show a specific affinity for a particular sugar residue, and they sometimes inhibit behavioral responses to cues from chemicals that bind to sensilla-produced glycoproteins. Comparative studies of closely related nematode species with different sensory requirements, however, are lacking. Here we use lectins to label the carbohydrate exudates and to determine their role in the infection process for three species of entomopathogenic nematodes with different foraging strategies.

Entomopathogenic nematodes are lethal parasites of insects. The infective stage finds a suitable host and penetrates the hemocoel through natural openings. After penetration, the nematodes release symbiotic bacteria in the genus *Xenorhabdus* (for steinernematids) or *Photorhabdus* (for heterorhabditids). The host is killed within 48 hr by a combination of septicemia, bacteria-produced toxins (Akhurst and Boemare, 1990), and nematode-produced toxins (Burman, 1984). Developing nematodes consume the bacteria and degrading host tissue, produce two to three generations inside the host cadaver, and produce infective juveniles 7–10 days after the initial infection.

Infective stage juvenile entomopathogenic nematodes depend upon chemical cues to find and assess hosts. The importance of different types of cues varies, depending upon the nematode's foraging strategy (Lewis et al., 1995). Cruise foraging nematodes rely on volatile cues for long-range host location and on contact cues for short-range information (Lewis et al., 1992, 1993). *Heterorhabditis bacteriophora* and *Steinernema glaseri* have many characteristics of cruise foragers. At the other end of the foraging continuum is *Steinernema carpocapsae*, which primarily ambushes hosts by nictation, a behavior in which nematodes lift the anterior 95% of their body from the substrate to facilitate attachment to passing hosts (Campbell and Gaugler, 1993). Attachment to hosts

does not appear to depend upon any behavioral response to host chemicals on the nematode's part. *Steinernema carpocapsae* is relatively unresponsive to volatile long-range host cues (Lewis et al., 1993). The difference in the importance of chemical cues to host finding among these species suggests that the level of involvement of sensory organs and their exudates varies during host finding.

We had two aims: (1) to determine the location of carbohydrate exudates on the surface of these three species of entomopathogenic nematodes and (2) to measure the degree of involvement (if any) of these carbohydrates in host finding and recognition.

METHODS AND MATERIALS

Nematode Culture. Nematodes were reared in last-instar *Galleria mellonella* after the method of Dutky et al. (1964) at ambient room temperature (21–23°C). Infective-stage juveniles were harvested from white traps (Woodring and Kaya, 1988), after which nematodes were stored at ambient temperature for one to four weeks before testing. Approximately 24 hr before treatment with lectins, all nematodes were desheathed by concentrating them on a membrane filter and allowing them to crawl into distilled water, where they were trapped.

Lectin Treatment. Desheathed infective juveniles of each nematode species were washed three times in phosphate buffer saline (PBS), pH 7.4, and then incubated for 30 min at room temperature with wheat germ agglutinin (WGA) for most behavioral assays and binding location experiments. Soybean agglutinin (SBA) and Osage orange agglutinin (MPA) were additional test lectins in the *S. carpocapsae* attachment assays (see below). Lectins conjugated with fluorescein (FITC) or rhodamine isothiocyanate (TRITC) were obtained from Sigma (St. Louis, Missouri) or EY Labs (San Mateo, California) and used at concentrations of 100 μg lectin/ml in PBS. The treated infective juveniles were washed three times in PBS following the incubation period. Live nematodes with fluorescent-conjugated WGA were then mounted under cover slips on glass microscope slides and examined by incident fluorescence microscopy with excitation and emission filters specific to FITC or TRITC. Control nematodes were incubated with WGA and 0.1 M *N*-acetylglucosamine simultaneously, and examined similarly.

Behavioral Assays. Infective juvenile nematodes were treated as described above for all lectin bioassays. Because of the varied foraging behaviors of these nematode species, four types of bioassays were performed to determine the effects of lectin binding on nematode behavior. Two of the assays measured attraction to host-produced volatiles on an agar substrate and two measured a combination of host finding and establishment of an infection in a host in either a three-dimensional sand matrix or on a two-dimensional surface. Each assay

described below was designed to demonstrate treatment effects on nematodes with particular foraging strategies, so not all assays were performed with all nematode species.

Attraction of nematodes to host volatiles was measured with an agar/plate assay developed by Andrew and Nicholas (1976) to test for attraction to bacteria, later modified by Lewis et al. (1993). Briefly, we tracked infective juveniles' attraction to volatiles in quartered 100-mm Petri dishes filled with 2% agar and marked with concentric rings at 1-cm intervals. At the edge of one quarter were two *G. mellonella* larvae housed in a 1-ml pipet tip suspended approximately 0.5 cm above the agar. The opposite quarter served as the control direction. Nematodes in each section of the two opposite quadrants were counted at 5, 10, and 20 min after inoculation for *S. glaseri* and *S. carpocapsae* or 5, 10, and 30 min for *H. bacteriophora*. An index was calculated to yield the average movement in centimeters towards the host per individual infective juvenile (Lewis et al., 1993).

The quadrant plate assay was used in two ways. First, the attraction of *H. bacteriophora*, *S. glaseri*, and *S. carpocapsae* to *G. mellonella* volatiles was measured with and without lectin treatment. *Steinernema carpocapsae* has been shown to respond poorly to host volatiles (Lewis et al., 1993). However, when cues were offered in natural order, first contact followed by volatiles, *S. carpocapsae* were attracted strongly to host volatiles (Lewis et al., 1995). For the second quadrant plate assay, we collected desheathed *S. carpocapsae* on a membrane filter and wiped about 1000 individuals onto the cuticle of a *G. mellonella* larva with a probe. After 30 min, the nematodes were washed from the insect cuticle with distilled water and then treated as described above for 30 min with WGA or a PBS control. Nematodes were then inoculated into the assay chamber, and their attraction to hosts was assessed. These tests were repeated four times. All data from the quadrant plate bioassay were analyzed with multiple variate analysis for repeated measures (MANOVA; SAS, 1987).

To test the effect of lectin binding on ambushing efficiency, we used a chamber designed to allow nictation and attachment of *S. carpocapsae* to mobile hosts (Campbell and Gaugler, 1993). Petri plates (100 mm) with filter papers moistened with 250 μl deionized water served as the chamber. We sprinkled sand (particle size > 1 μm) on the filter paper to provide a substrate upon which the nematodes could nictate. After treatment with lectins or control solutions, nematodes (either 500 or 1000 individuals) were released into the chamber. Thirty minutes later, one *G. mellonella* was released into the chamber. After a 30-min exposure to nematodes, the insects were removed, the nematodes were washed into separate dishes, and the insect larvae were held for 24 hr and dissected. Nematodes either washed from the insect cuticle or dissected from the hemocoel were counted as successful. Four lectin treatments were tested for

their affect on *S. carpocapsae* attachment to hosts: (1) nematodes exposed to one of three lectins (WGA, SBA, MPA) and a control for 30 min; (2) nematodes exposed to WGA for 15, 30, or 60 min; (3) nematodes exposed to heated (denatured) WGA vs. non-heated WGA; and (4) combinations of hosts and nematodes treated for 30 min with WGA.

We used a sand column assay to determine the effects of lectin (WGA only) binding on the ability of *S. glaseri* to find and infect hosts. The control treatment was nematodes incubated with PBS only. Cylindrical plastic containers (5 cm diam) were filled with 5 cm of moist sand. At the bottom of the column was one *G. mellonella* last instar. Approximately 1000 infective juveniles in water were applied to the top of the column. Sixteen hours later the insects were removed from the assay chamber, washed with water and held two days for dissection. The nematodes washed from the cuticle were counted immediately. After two days of incubation at 25°C, the insects were dissected and all nematodes inside were counted. Data are reported as the percent of the original inoculum that located the insect, including nematodes washed from the cuticle and those that penetrated into the hemocoel.

Unless otherwise specified, all data were analyzed by analysis of variance, and means were separated with the Student-Newman-Keuls test at $\alpha = 0.05$ (SAS, 1987). Percent data were transformed by arcsin (X) before analysis. All means are presented as mean $\pm$ SEM.

RESULTS

Location of Glycoconjugate Exudates. WGA bound specifically to the anterior end of the cruise foraging species *S. glaseri* (Figure 1A) and *H. bacteriophora* (Figure 1B) and generally to the cuticle of the ambush foraging species *S. carpocapsae* (Figure 1C). Most behavioral assays, with the exception of attachment of *S. carpocapsae*, were conducted with WGA only. In all cases, when nematodes were incubated with the lectin plus the competing carbohydrate, no lectin binding occurred.

Behavioral Assays. Lectin binding had various effects on *S. carpocapsae* host-finding behavior, depending on the lectin used and the assay in which the effect was tested. The rate of attachment to mobile hosts in a nictation arena was increased (nearly doubled) by nematode exposure to SBA and WGA when compared to the control, but no such increase was caused by MPA (Figure 2). All subsequent tests were performed with WGA only. WGA affected *S. carpocapsae* attachment differently when the nematodes, the host, or both were treated. Treatment of *G. mellonella* with lectin significantly decreased the rate of attachment by *S. carpocapsae*, whether or not the nematodes were treated

with the lectin (Figure 3). The effect of WGA on *S. carpocapsae* attachment to hosts was nullified when the lectin was denatured by heating.

There was no effect of lectin treatment on nematode response to host volatiles for any of the species tested (Figures 4A–C). *Steinernema glaseri* and *H. bacteriophora* continued to be strongly attracted to host volatiles regardless of WGA treatment, whereas *S. carpocapsae* was not attracted before or after lectin exposure. We also tested the attraction of *S. carpocapsae* to volatiles after contact with host cuticle, but again the level of attraction remained unchanged regardless of lectin treatment (Figure 4D).

When challenged with finding and parasitizing a host in a sand column assay, WGA treatment significantly decreased *G. mellonella* parasitization by *S. glaseri*. Control nematodes found hosts at a rate of 24.8 ± 1.65%, whereas only 13 ± 2.6% of WGA-treated nematodes found the host.

DISCUSSION

The location of the binding sites of WGA corresponded with what we predicted on the basis of nematode foraging strategy. Cruise foragers (*S. glaseri* and *H. bacteriophora*) are responsive to host cues, and the areas of their sensory

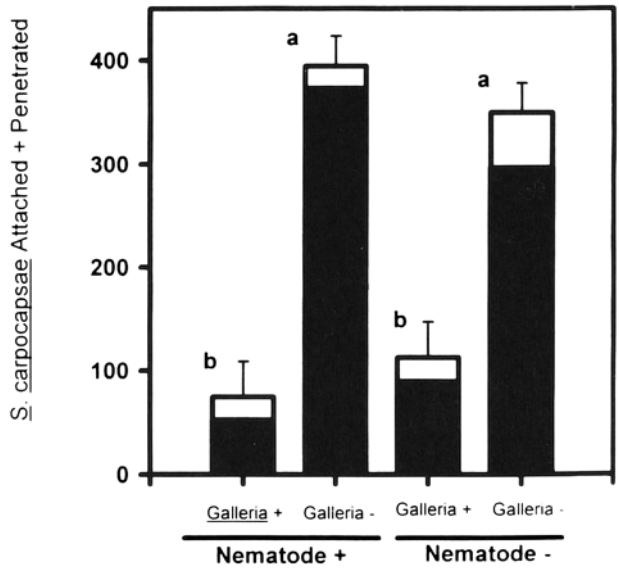

FIG. 3. Effect of wheat-germ agglutinin (WGA) treatment of nematodes, *G. mellonella*, or both on attachment of *S. carpocapsae* to hosts. Galleria +: insects treated with WGA. Galleria −: insects treated with PBS (phosphate buffered saline control). Nematode +: nematodes treated with WGA. Nematode −: nematodes treated with PBS. organs were labeled with the lectin. Nematode sensory organs produce carbohydrates that are associated with chemotaxis (Zuckerman, 1983). *Steinernema carpocapsae*, an ambush forager, was relatively unresponsive to host cues when they were offered singly (Lewis et al., 1992; 1993), and WGA did not bind to their sensory organs. Species differences in the location of lectin binding sites are not uncommon among nematodes. Bone and Bottjer (1985) compared the location of binding of *Lens culinaris* agglutinin to three gastrointestinal parasite sexual stages and found that all body regions showed binding in *Trichostrongylus colubriformis* and *Haemonchus contortus*, but the head and tail regions of *Nippostrongylus brasiliensis* did not show binding. The differences we have found may be related to the responses to host cues of the nematodes tested.

Effects of lectin binding on the host-finding ability of nematodes have been inconsistent. The first report of lectins mediating nematode chemotaxis was that treatment of *Panagrellus redivivus* with limulin decreased nematodes' response to the nematophagous fungus *Drechmeria coniospora* by binding to sialic acid

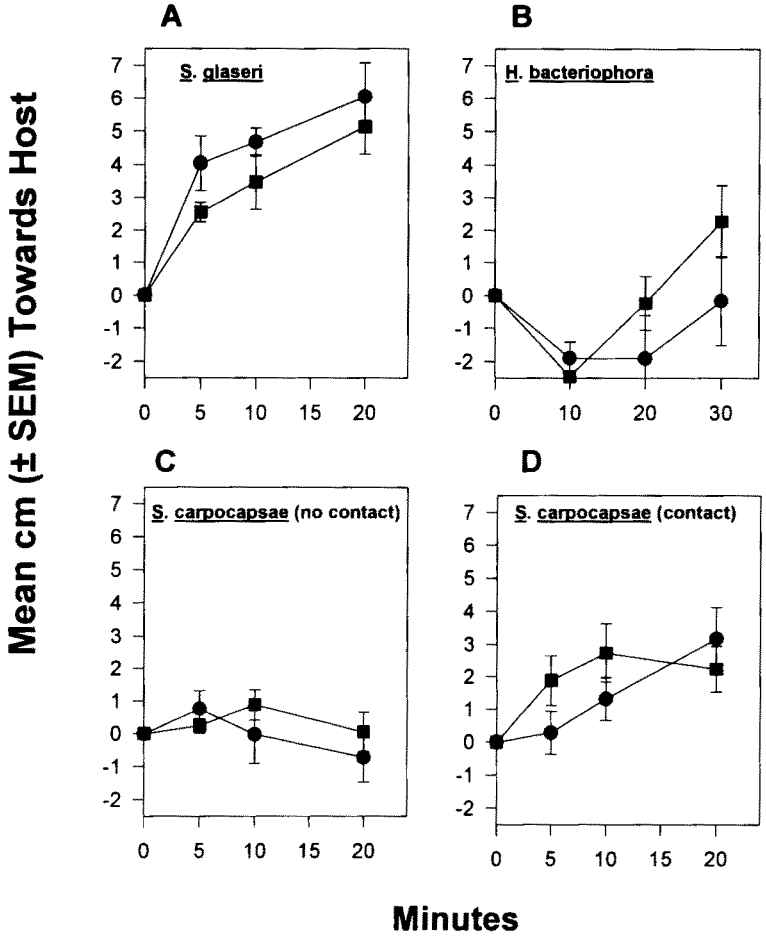

FIG. 4. Effect of wheat germ agglutinin (WGA) treatment of nematodes on movement toward *G. mellonella* volatile cues. (A) *S. glaseri*, (B) *H. bacteriophora*, (C) *S. carpocapsae*, (D) *S. carpocapsae* after exposure to host cuticle. ●, WGA treatment; ■, phosphate-buffered control treatment.

(Jansson and Nordbing-Hertz, 1984). Inhibition of nematode responses to attractants have also been documented for *C. elegans* to *E. coli* filtrates (Jeyaprakash et al., 1985) and male *T. colubriformis* to conspecific female sex pheromone (Bone and Bottjer, 1985). Kerwin et al. (1990) also found that incubation of *Romanomermis culicivorax* with Con A and lentil lectins significantly reduced

nematode attachment to *Anopheles freeborni*. Conversely, lectins have had negligible effects on chemotaxis by *Heterodera schachtii* males in response to female sex pheromone (Aumann et al., 1990) or by *S. carpocapsae* to host plasma (Khlibsuwan et al., 1992). We likewise found that WGA binding had no effect on the response of entomopathogenic nematode infective juveniles to host-produced volatiles on an agar substrate. However, other lectins may yield different results.

Surprisingly, the attachment rate of *S. carpocapsae* infective juveniles was increased by treatment with some lectins. Attachment to passing hosts by this species is primarily passive, so the mechanism for the increase is more likely physical than behavioral. When *G. mellonella* larvae were treated with WGA, attachment of *S. carpocapsae* to the host was significantly decreased from that of the control. This same lectin interfered with the recognition response of *R. culicivorax* to *An. freeborni* when the host was treated with WGA. The decreased attachment to *G. mellonella* suggests lack of recognition on the part of the parasite due to masking by WGA of a specific carbohydrate associated with insect cuticle.

The binding pattern of WGA suggests that nematodes with cruise foraging strategies rely more upon sensory reception of host cues during host location than ambushing nematodes. However, lectin binding to the glycoconjugates associated with their sensory organs had no apparent effect on the response to host cues. Lectins may, however, block behavioral steps leading to parasitization other than host finding in which host volatiles are not involved. Host recognition, in which presumably larger molecules associated with the insect cuticle convey the necessary information, may be affected. Further studies are underway to test the effect of other lectins on host recognition behavior of entomopathogenic nematodes.

Lewis et al. (1993) suggested that species differences in entomopathogenic nematodes' responses to host cues could be explained by the nematodes' foraging strategies. Ambushing parasites would experience little selection pressure to maintain sensitivity to remote cues because they rely upon host movement for host location. We found no specific binding of lectins to the sensory organs of ambushing nematodes, whereas cruising nematodes' amphidial regions were bound by the same lectins. Specific differences in the location of WGA binding sites among nematode species with different foraging strategies may illustrate underlying mechanisms of behavioral differences.

(Received April 17, 1995; accepted August 25, 1995)

Abstract—Fathead minnows (*Pimephales promelas*) are able to detect conspecific alarm pheromone in the feces of northern pike (*Esox lucius*) and have been shown to avoid areas labeled with the feces of pike that were fed minnows. The minnows did not avoid areas labeled with the feces of pike that were fed swordtails (*Xiphophorous helleri*), which lack ostariophysan alarm pheromone. In laboratory experiments, pike fed a diet of minnows localized their defecation away from their foraging area. It has been suggested that in doing so, pike may remove chemical cues that label their foraging area as dangerous to prey species. As yet there has been no conclusive evidence to support this hypothesis. In this experiment, we test the effects of different predator diets on localized defecation by pike. Pike were fed minnows, swordtails, or mice (*Mus musculus*). Swordtails and mice lack ostariophysan alarm pheromones. Area use and location of feces were recorded. Pike fed minnows spent significantly more time in the home area (i.e., area of the test tank where they were fed) and defecated significantly more often in the opposite end of the tank. Pike fed swordtails also exhibited a significant preference for the home area in area use, while those fed mice showed no such preference. When fed either swordtails or mice, there was no significant difference between the proportion of time spent and proportion of feces in each area of the test tank. These data suggest that pike localize their defecation only when consuming prey items containing alarm pheromone. The current findings support the hypothesis that pike localize their defecation to remove chemical cues from the foraging area of the home range in order to avoid chemically labeling their foraging area as dangerous to prey.

Key Words—Fathead minnow, *Pimephales promelas*, northern pike, *Esox lucius*, localized defecation, predator labelling, alarm substance.

INTRODUCTION

Fathead minnows (*Pimephales promelas*) possess epidermal club cells, which, when mechanically damaged, release an alarm pheromone [alarm substance (AS) or Schreckstoff (Smith, 1986, 1992)]. Mechanical damage typically occurs when a minnow is attacked or captured by a predator. When detected by conspecifics, AS elicits a stereotypic fright response, characterized by a variety of antipredator behavior patterns (Heczko and Seghers, 1981; Lawrence and Smith, 1989; Krause, 1993; Mathis and Smith, 1993a). Mathis et al. (1995) have demonstrated that predatory northern pike (*Esox lucius*) are attracted to minnow alarm pheromone.

Mathis and Smith (1993a,b) have recently demonstrated that fathead minnows that had never encountered a pike responded with antipredator behavior to chemical stimuli (water containing urine, feces, mucus that had housed a pike) from pike if the pike had recently consumed minnows, but not swordtails (*Xiphophorus helleri*) or breeding male minnows. Swordtails lack ostariophysan alarm pheromones (Mathis and Smith, 1993a,b), and breeding male fathead minnows lose their alarm substance cells during the spawning season (Smith, 1973, 1976). Brown et al. (1995a,b) have demonstrated that AS is contained in feces of a predatory pike and that minnows that have never encountered a pike will avoid areas labeled with feces of pike that have been fed minnows but do not avoid feces of pike fed swordtails.

Brown et al. (1995a) showed that pike fed fathead minnows localize their defecation away from their foraging area. They suggested that pike may do so in order to remove chemical cues that could label their foraging territory as dangerous to prey fish. As yet, there has been no conclusive evidence to support this hypothesis. In the current study, we examine the effects of different diets on localized defecation by pike. We predict that if pike are localizing their defecation to remove possible chemical cues from their foraging range, then pike fed a diet which lacks AS should not show localized defecation.

METHODS AND MATERIALS

Test Fish. Northern pike were collected with seine nets from Van Patten's Creek in south central Saskatchewan. Pike were transported to the lab and held in 60-liter holding tanks at approximately 16°C, under a 14 : 10 light–dark cycle. Prior to the experiments, pike were fed one or two fathead minnows once every four days.

Fathead minnows were taken from Pike Lake, an oxbow lake of the South Saskatchewan River near Saskatoon, Saskatchewan. Minnows were held in 300-liter artificial stream channels under a 14 : 10 light–dark cycle. Minnows were

fed daily with commercial fish food. Swordtails (maintained on same diet as minnows) and frozen neonatal mice (*Mus musculus*) were obtained commercially. Swordtails were used as a fish prey because they lack ostariophysan alarm pheromone (Mathis and Smith, 1993a). It is unlikely that swordtails possess any form of alarm pheromone, as two additional species of *Xiphophorus* (*X. maculatus* and *X. variatus*) have been shown to lack alarm pheromones (Pfieffer, 1977). Mice were chosen as a representative terrestrial prey because they are taken opportunistically by inshore pike (Lawler, 1965; Scott and Crossman, 1973) and lack ostariophysan alarm pheromone. Mice possess disturbance chemical alarm signals, which are released in urine and/or feces when disturbed (Rottman and Snowdon, 1972). These cues are likely not present in our trials, since the mice were dead when fed to the pike. In addition, under natural conditions, mice would be swimming near the surface, while feces would be restricted to the substratum. Mice were thawed in water prior to use.

Test Tanks. Three, identical 500-liter glass aquaria (183 cm long × 49 cm wide × 56 cm high) were used as test tanks. The test tanks were not filtered, and there was no appreciable flow. A single airstone was suspended near the back wall of the tank, halfway down the length of the tank. We divided each tank into seven compartments, as in Brown et al. (1995a), by drawing gridlines on the exterior of the tank. The first compartment was 38 cm wide, and each of the remaining six compartments were 24 cm wide. The first compartment was designated as the home area and contained rocks and artificial plants that extended to within 15 cm of the water surface. In addition, opaque plastic covers were placed over the home range to provide shade. The floor of the entire tank was covered with silica sand to a depth of 4 cm. Water temperature in the testing tanks was maintained at approximately 18°C. Test tanks were illuminated with overhead fluorescent lights and maintained on a 14:10 light–dark cycle.

Experimental Protocol. Trials lasted one week, and each trial consisted of five days of acclimation and two days of testing (days 6 and 7). An individual pike was placed in the test tank on the morning of day 1. During days 1–5, we fed each pike one of the following diets: fathead minnow, swordtail, or mouse. For each condition, pike were fed one food item daily (mean ± 1 SD = 1.45 ± 0.21, 1.82 ± 0.32, and 1.71 ± 0.27 ml, minnow, swordtail, and mouse, respectively, measured by volumetric displacement in water). Prior to feeding, minnows and swordtails were killed by a blow to the head. Each food item was injected with approximately 0.5 ml of ultraviolet fluorescent dye (Tracer Glo). Since pike do not readily accept dead prey (Huntingford, 1984), prey items were suspended on the end of a fine-gauge stainless steel wire. The use of the wire allowed us to manipulate the prey item and induce the pike to strike. In the case of minnow or swordtail diets, the wire was placed at the base of the caudal peduncle. In the case of the mouse diet, the wire was placed through a fold of

skin near the hind legs. This allowed us to pull the wire free without disturbing the pike. Prey were always presented in the home area.

At the end of day 5, all feces were removed from the test tank with a siphon. On day 6, we began recording two measures: (1) proportion of time the pike spent in each area of the tank (area use), and (2) the location of feces. We quantified area use by recording the location of each pike once every 10 sec for a 10-min observation period once each hour for eight consecutive hours on days 6 and 7. Observations began at approximately 08:00 hr each day.

The location of feces was quantified after the final area use observation on days 6 and 7. We recorded (and removed with a siphon) the number of fecal pellets in each compartment of the test tank. Fecal pellets within 1 cm of each other were recorded as a single pellet. After recording the location of feces on day 7, we removed the pike and carefully drained the tank so as not to disturb the substrate. A UV light was used to check for any fecal pellets that may have partially dissolved or been covered with sand. We recorded the presence of fluorescent dye as a fecal pellet, using the same criterion as above.

A total of nine pike (mean $\pm$ SD = 18.21 $\pm$ 2.61 cm) were used in the experiment. Each pike was tested once in each diet condition. The order of trials was random, and pike were tested once every three weeks. Individual pike were tested in different tanks for each of the three diet conditions. No qualitative differences were observed in the acceptability of each of the three prey types.

Statistical Analysis. We employed a one-way analysis of variance (ANOVA; Sokal and Rohlf, 1981) to determine if there was a significant difference in the amount of time spent or the number of fecal pellets in each of the seven areas of the test tank. We compared the percent of time versus the percent of total feces in each area of the tank using paired t tests, corrected for increasing alpha using a modified Bonferronni procedure (Keppel 1982).

RESULTS

Pike fed minnows and pike fed swordtails spent a significantly greater proportion of time in the home area end of the test tank ($F_{6,56} = 13.22$, $P < 0.0001$ minnow diet, $F_{6,56} = 3.90$, $P < 0.003$ swordtail diet; Figure 1). Pike fed mouse did not localize their time in any section of the test tank ($F_{6,56} = 1.21$, $P = 0.30$; Figure 1). In the minnow diet trials, pike defecated significantly more often in the opposite end of the test tank ($F_{6,56} = 54.30$, $P < 0.0001$; Figure 1). Pike fed swordtails defecated significantly more often in or near the home area ($F_{6,56} = 3.90$, $P < 0.003$; Figure 1). In the trials of pike fed mouse, there was no significant difference in the number of fecal pellets in any of the seven areas of the test tank ($F_{6,56} = 1.21$, $P = 0.32$; Figure 1).

When pike were fed minnows, there was a significantly greater proportion of time spent in the home area and the two adjacent areas compared to the

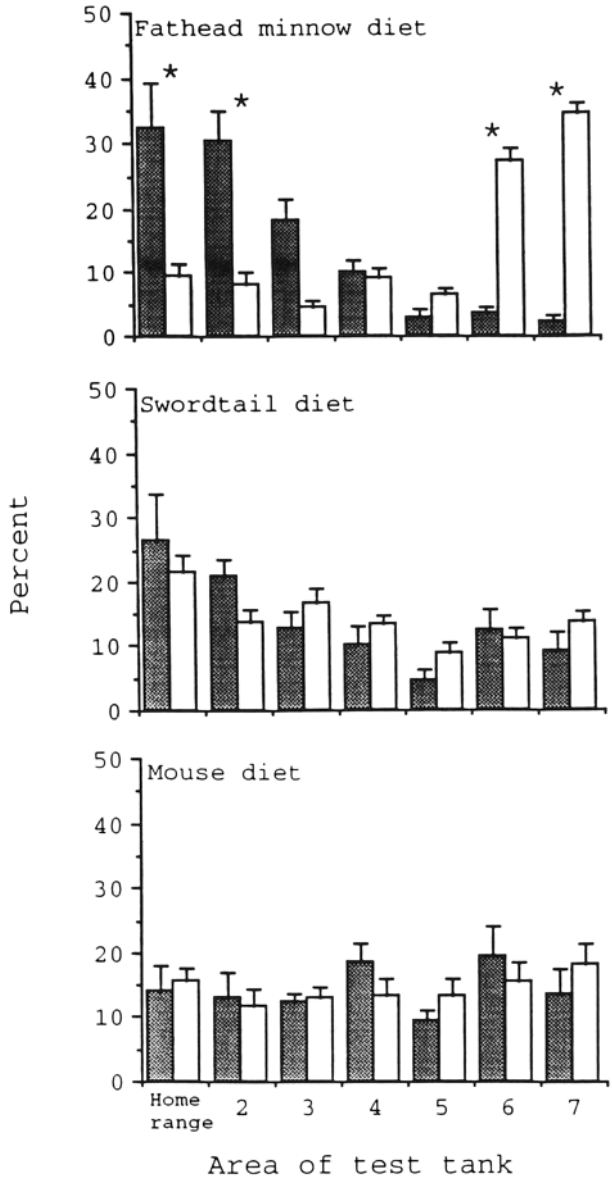

FIG. 1. Mean (±SE) percent time spent (closed bars) and percent total feces (open bars) in each area of the test tank for each of the three diet conditions. An asterisk denotes significant difference ($P < 0.05$) for comparison between percent time and percent feces in each area of the test tank. See text for details.

percent of total feces ($P < 0.05$, Figure 1). Conversely, there was a significantly greater proportion of feces compared to the percent of time in areas 6 and 7 of the test tank (Figure 1) when fed minnows. In both the swordtail and mouse diet conditions, there was no significant difference in the percent time vs. percent feces in any area of the test tank (Figure 1).

DISCUSSION

The results of the current study clearly demonstrate an effect of diet on localized defecation by northern pike. When fed a diet of fathead minnows, pike localized their defecation away from the home or foraging area, confirming the results of Brown et al. (1995a). When fed a diet of either swordtails or mice, which lack alarm pheromones, there was no difference between the percent of time spent and percent of total feces in each area of the test tank, indicating that the pike did not localize their defecation when fed these diets. These results support the hypothesis that pike localize defecation in order to avoid chemically labeling their foraging area as dangerous to potential prey.

There exist alternate hypotheses that may explain the observed localized defecation in pike. In particular, pike may localize defecation for sanitary reasons. By defecating away from the home or foraging range, pike may decrease the likelihood of pathogen or parasite infection. Such a system has been shown for a variety of avian and mammalian species (Poole, 1985). While the current data cannot refute the antipathogen/parasite hypothesis, we observed localized defecation only in response to the minnow diet. Our data do support the hypothesis that pike localized defecation to remove chemical cues from their foraging territory. In addition, these hypotheses are not mutually exclusive and could both serve as selection pressures for localized defecation behavior in pike.

These data demonstrate an effect of diet on the foraging patterns of pike. In both the minnow and swordtail diet conditions, pike spent a significantly greater proportion of time in the home end of the test tank, while in the mouse diet condition, pike did not exhibit such a preference. Since pike are primarily ambush predators (Hobson 1979; Chapman and MacKay, 1984; Savino and Stein, 1989), it would benefit a pike to remain under the cover of vegetation and wait for suitable prey to come within its attack range. Conversely, terrestrial prey items, such as mice, would be swimming near the surface. Hence, when fed a mouse diet, it would benefit the pike to remain in open water. These differences in foraging strategy would account for the lack of localized area use observed in the mouse diet condition, even though the pike were fed in the same manner regardless of diet condition.

These results also indicate a more general phenomenon, whereby the foraging strategy of predators is affected by diet. By altering the foraging strategy

to match the most abundant prey type, the pike would maximize its probability of future foraging success. As a result, if pike have experienced terrestrial prey in open water and are subsequently fed terrestrial prey, then we would predict that they should not show a preference for area of the test tank containing vegetation.

There are a variety of mechanisms by which the presence of alarm pheromone in the home or foraging area could decrease a pike's foraging efficiency. Initially, Brown et al. (1995a) demonstrated that the alarm pheromone is present in the pike's feces. The presence of feces containing minnow alarm pheromone has been shown to decrease area use by minnows (Brown et al., 1995b). This would serve to decrease the pike's foraging efficiency by deterring prey fish from entering the pike's foraging area.

Chivers and Smith (1995a) have shown that fathead minnows are able to learn the identity of risky habitats when the chemical cues of a particular microhabitat are paired with AS. If AS in pike feces were present in the pike's foraging range, then the minnows may learn to avoid the risky area. Alternatively, the minnows may be more vigilant when in the area and therefore less likely to be captured (Mathis and Smith, 1993c; Chivers and Smith, 1995a). Given that minnows can culturally transmit recognition of dangerous habitats (Chivers and Smith, 1995b), the effects may extend to other minnows.

Cross-species reactions to alarm pheromones have been identified in a variety of species (e.g., Smith, 1982; Smith et al., 1991; Mathis and Smith, 1993d; Chivers and Smith, 1994; Wisenden et al., 1994, 1995; Chivers et al., 1995a,b). Prey species typically avoid areas containing heterospecific alarm pheromones of members of their prey guild (i.e., those species with which they share predators). The presence of minnow alarm pheromone in the pike's foraging range would likely also decrease area use by other species, such as brook sticklebacks (Mathis and Smith, 1993d), that recognize and respond to minnow AS. By defecating away from their foraging range, pike can increase the likelihood of future predation events in that location not only on minnows, but on other species of the prey guild as well.

Minnow alarm pheromone has been shown to attract pike (Mathis et al., 1995). A pike that is attracted to AS (i.e., a secondary predator) could interfere with a primary predator that has captured a minnow. The secondary pike could compete for the prey item directly, or it could attack the primary predator as a prey item. Avoidance of secondary predator interference could account for the observed localized defecation. By removing minnow alarm pheromone from their foraging range, pike could decrease the possibility of attracting secondary predators.

In summary, the data presented in the current study demonstrate an effect of diet on the localized defecation of northern pike. Localized defecation was observed when pike had consumed minnows, but not when pike had been fed

swordtails or mice. These data thus support the hypothesis that pike localized their defecation in order to avoid chemically labeling their foraging area with the alarm pheromone of their prey.

(Received May 12, 1995; accepted November 7, 1995)

Abstract—Nagilactones isolated from *Podocarpus nagi* (Thunb.) Zoll. et Moritz. are known by their physiological activities as a plant growth inhibitor or antiherbivory substance. As the first step in clarifying the nagilactone dynamics in a forest canopy, the seasonal variations in nagilactone contents in leaves and mass of nagilactones accumulated in the canopy were examined at Mt. Mikasa, Nara City, central Japan. Nagilactone content in mature leaves dropped sharply in May, when new leaves flushed. The nagilactone content of new leaves was far greater than that of mature leaves, implying a translocation of nagilactones from old leaves to new leaves. The total mass of nagilactones in the canopy was 3.9 kg/ha.

Key Words—*Podocarpus nagi*, nagilactone, deer, antiherbivory, forest canopy.

INTRODUCTION

Nagilactone isolated from *Podocarpus nagi* (Thunb.) Zoll. et Moritz. (Ohwi, 1965) by Hayashi et al. (1968, 1972) has six structural isomers. Its physiological activities as a plant growth inhibitor are well known as described elsewhere (Hayashi and Sakan, 1974; Hayashi et al., 1975, 1979; Ishikawa, 1971; Suganuma, 1975). A mixture of nagilactone and other chemicals, such as epicatechin, may reduce the original inhibitory activity of nagilactone (Kubo et al., 1985). Furthermore, nagilactone is an antiherbivory chemical for animals, such as insects and deer (Hayashi and Sakan, 1974), and has antitumor activity for

*To whom correspondence should be addressed.

sarcoma (Hayashi et al., 1979). However, the effects of nagilactone on plant growth and sustainment of *P. nagi* populations in a natural forest still remain obscure, although the negative effects of nagilactone on trees other than *P. nagi* in the forest have been suggested by ecological studies (Koshimizu, 1943; Suganuma, 1975; Tamai, 1989). As the first step in clarifying the nagilactone dynamics, in situ, the present study dealt with seasonal change of nagilactone concentrations in leaves.

METHODS AND MATERIALS

Study Forest. Our study was carried out in a *Podocarpus nagi* forest, on a western slope of a low hill, Mt. Mikasa, 294 m alt., 40 ha area, 34 N latitude, and 135 E longitude, in Nara City, central Japan (Figure 1). The forest is part of a forest of the Kasuga Shinto Shrine, which was established in the fifth century. In this forest, two forest types have been identified. One is the *P. nagi* forest and the other is a warm-temperate evergreen rain forest with oak and laurel dominants. The latter is the original vegetation around Mt. Mikasa

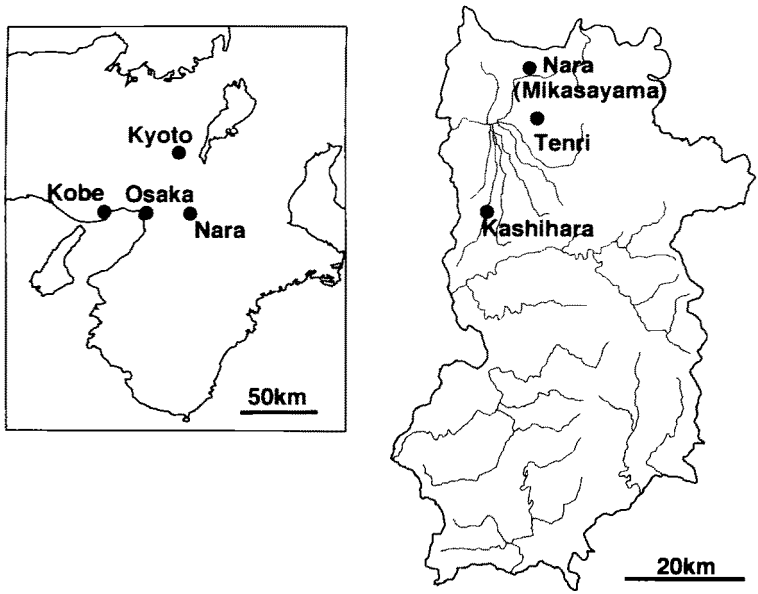

FIG. 1. Map of the Kansai area and Nara Prefecture, showing study site, Mt. Mikasa, in the northern Nara Prefecture.

(Suganuma, 1975; Miyawaki, 1984) and is tentatively designated the mixed oak–laurel forest.

The *P. nagi* forest is believed to be derived from a few pairs of female and male trees transplanted to this site from another Shinto shrine, since *P. nagi* is dioecious and has never been recorded in native vegetation around Nara City (Koshimizu, 1943; Suganuma and Kawai, 1978). The *P. nagi* forest dominates the original mixed oak–laurel forest through competition between *P. nagi* and other trees. The forest has been protected without any human manipulation of the vegetation.

Deer Protected by Kasuga Shinto Shrine. Deer, *Cervus nippon,* have also been protected by the Kasuga Shinto Shrine, since they were believed to be holy animals by the Shinto followers. According to the Society of Deer Conservation, Nara (1994), the population density of deer might be rather constant, about 1000 head in an area around the forest, although it may have decreased in socially unstable eras, such as war time. Recent records of the deer population suggested a rather stable population density after a recovery from a disaster at the time of the Second World War (Figure 2). The deer feed freely in and out of the forest and have been influential in the structure and composition of the forest (Suganuma, 1975; Shimoda et al., 1994).

Climate Conditions. The climatic data recorded from 1961 to 1990 at the Nara Meteorological Station (104 m alt.) about 2.5 km northwest of our study forest at Mt. Mikasa indicates a rather mild climate at the study site. Mean annual temperature was 14.4°C with a range of mean monthly temperatures of −0.7°C (January) to 22.2°C (August). Mean annual precipitation was 1355 mm, with a mean monthly rainfall range of 40.4 mm (December) to 212.3 mm (June). Frost was common in winter, but snow was seldom over 10 cm.

Study Plot and Forest Inventory. A research plot of 30 × 30 m was established on a hill slope dominated by *P. nagi* at Mt. Mikasa in May 1991. The

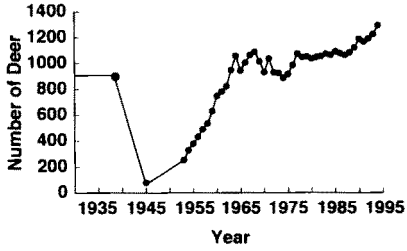

FIG. 2. Population density of deer protected by the Kasuga Shinto Shrine. Data were supplied by the Society of Deer Conservation, Nara. The population density decreased during World War II.

plot was selected so as to represent a mature phase of the forest growth cycle (Whitmore, 1984). The plot was subdivided into 7.5 × 7.5-m quadrants following conventional procedures for a forest inventory. In each quadrant, all trees and woody climbers 1.0 cm and more in stem diameter at breast height (DBH, 1.3 m above the ground) were individually labeled, mapped, identified, and measured (Figure 3).

Leaf Biomass. Leaf biomass in the study plot was estimated by summing up the leaf mass of individual trees by using the allometry method (Ogawa, 1977). Various dimensions and partial biomasses of trees were calculated from DBH (D, centimeters) by allometric equations for estimating individual tree leaf mass. The calculated quantities were tree height H (meters), stem dry weight $W(S)$ (kilograms), branch dry weight $W(B)$ (kilograms), and leaf dry weight $W(L)$ (kilograms) per tree. We adopted the following allometric equations proposed by Wang (1993):

$$1/H = 1/(1.41D) + 1/31.34$$

$$W(S) = 0.0394\ (D^2H)^{0.9187} + 0.120$$

$$W(B) = 0.140\ [W(S)]^{1.031}$$

$$W(L) = 0.173\ [W(B)]^{0.699}$$

Various trees, such as oaks, laurels, etc., were recognized in lower forest layers. To estimate the leaf biomass of flowering trees other than podocarps, we used the following allometric relations (Ogawa and Saito, 1965):

$$1/H = 1/(2.12D) + 1/10.4$$

$$W(S) = 0.0396\ (D^2H)^{0.9326}$$

$$W(B) = 0.0602\ (D^2H)^{1.027}$$

$$1/W(L) = 21.6/[W(S) + W(B)] + 0.02$$

Among these allometric equations for flowering trees, the relation between tree height, H, and stem diameter, D, were obtained by the forest inventory in this study. The other allometric equations were obtained by cutting sample trees (Ogawa and Saito, 1965).

Green Leaf Sampling. Green podocarp leaves were sampled monthly from October 1991 to October 1992 for chemical analysis of nagilactone contents in living leaves. A large female tree (27.8 cm DBH and 20.1 m tree height) was selected for the sampling around the plot for the forest inventory (Figure 3). The sample leaves were grown in sun, sclerophyllous, fully matured, and 2 years old. New leaves were separately sampled on June 22 to compare their nagilactone contents with those of mature leaves.

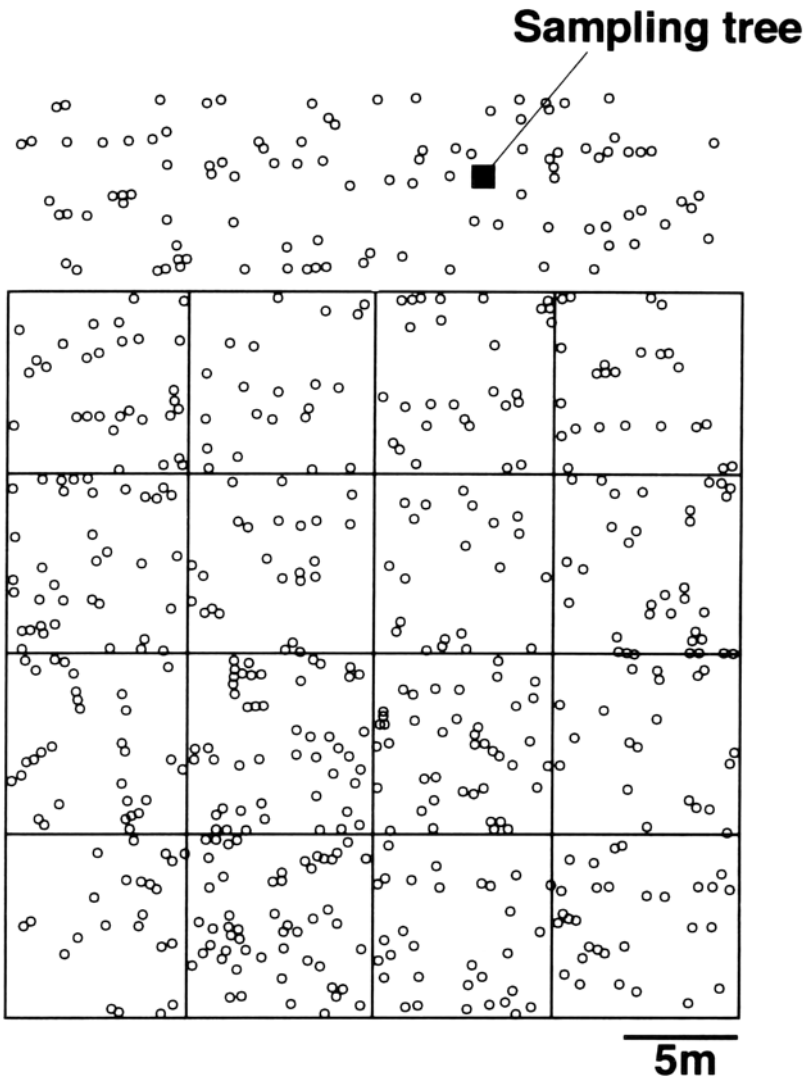

FIG. 3. Map showing positions of individual podocarp trees in the study plot. Circles indicate tree positions; the solid square represents the position of a sample tree for the determination of leaf nagilactone contents.

Nagilactone. Six structural isomers of nagilactones have been identified by Hayashi (1973), as already described. They are nagilactones A ($C_{19}H_{24}O_6$), B ($C_{19}H_{24}O_9$), C ($C_{19}H_{24}O_8$), D ($C_{18}H_{20}O_8$), E ($C_{19}H_{24}O_6$), and F ($C_{19}H_{24}O_4$) (see Figure 4). Furthermore, they are characterized by different melting points, 305, 258–261, 290, 265–266, 295, and 225–226°C, respectively (Hayashi, 1973; Singh et al., 1979). Among these isomers, nagilactones A, B, C, and D are contained in leaves, while nagilactones E and F are found in the roots (Hayashi, 1973). Pure nagilactones were supplied by Hayashi for standard materials in this study.

Extraction of Nagilactone from Leaves. Podocarp leaves were first crushed in a blender for easy extraction of nagilactones. Crushed leaves were kept in pure methanol in glass bottles for two weeks. A mixture of various substances extracted from leaves with methanol was vacuum-filtered through a Buchner funnel using Advantec No. 5A filter paper. The filtered aqueous fraction was evaporated at 40°C, to remove methanol. The evaporated fraction was successively partitioned with hexane, dichloromethane, and ethyl acetate. These three organic fractions were dehydrated with anhydrous magnesium sulfate, filtered through a Buchner funnel, evaporated in a rotary evaporator to dryness at 40°C, and the solid residue weighed. The three crude solids were kept in a refrigerator at −30°C.

HPLC Analysis. A crude solid was dissolved with methanol for HPLC analysis. If the weight of the solid was 1.0 mg, 1.0 ml methanol was used for

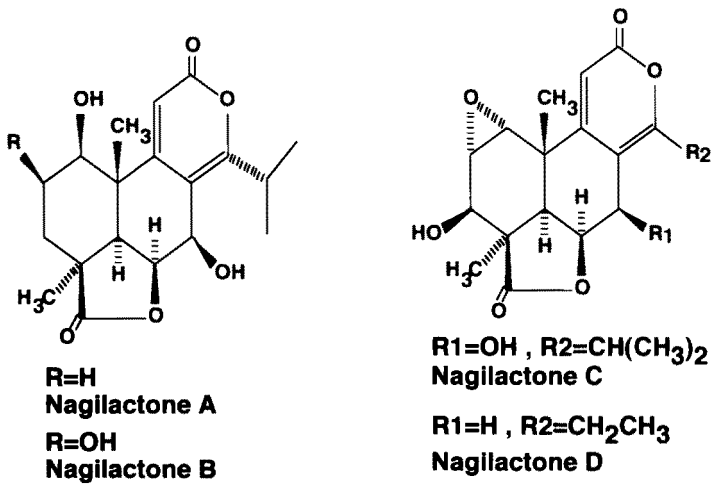

FIG. 4. Chemical structure of nagilactones.

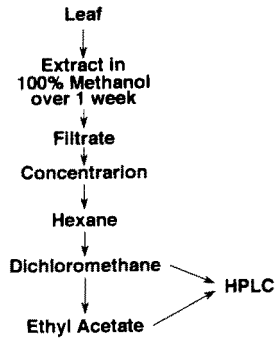

FIG. 5. Summary of procedures for fractionation of nagilactones.

solvent. The mixture of nagilactones dissolved in methanol was separated into respective nagilactones by a Waters HPLC apparatus on a Shiseido Capcell Pak C18 cartridge column (S-5 μl 4.6 $\times$ 250 mm), employing water–acetone–methanol (7:2:1). Nagilactones A, C, and D were found, while the other nagilactones were not observed in samples. Nagilactone B was rarely reported in leaves, and nagilactones E and F were mainly contained in root bark (Hayashi and Sakan, 1974). Separated nagilactones A, C, and D were quantified by a Waters variable-wavelength UV spectrophotometer at 300 nm wavelength (Figure 5).

RESULTS

Stand Structure. In addition to 137 podocarp trees, only three flowering tree species were observed in our 30 $\times$ 30-m research plot. These were *Neolitsea aciculata* (88 individuals), *Pieris japonica* (three individuals), and *Symplocos prunifolia* (one individual). The former two species have unpalatable leaves, which contain toxic secondary metabolites, such as dodecanoic acid in *N. aciculata* (Glasby, 1991) and asebotoxins in *P. japonica* (Glasby, 1991), and are seldom eaten by deer or other animals. The latter species, *S. prunifolia,* seemed to be an escape from, or remnant of, the original vegetation, mixed-oak-laurel forest, which covers the entire 250 ha at the Kasugayama hill about 500 m to the east of the study plot. *S. prunifolia* is a common pioneer tree whose seeds are dispersed by small birds in the mixed oak–laurel forest. In the forest at Kasugayama, about 500 m east of our study plot, 20 or 30 tree species are easily recognizable in a small area (Fujii, 1991), such as in the 30 $\times$ 30 m plot demarcation in this study. Thus, the species diversity of the study forest was the lowest among the natural forest vegetations at lower altitudes in Japan,

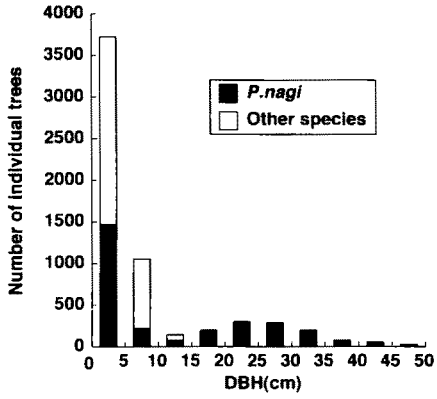

FIG. 6. Frequency distribution of DBHs of individual trees in the study plot.

suggesting strong effects of toxic secondary metabolites of plants on stand architecture.

The frequency distribution of DBHs of individual trees within the plot (Figure 6) represents high densities of smaller podocarp and *N. aciculata* trees, respectively, suggesting continuous germination, good seedling growth, and perpetual self-maintenance of the two species. It is noteworthy that *N. aciculata* does not grow larger than podocarps, but they formed the dense second story beneath the first story of podocarps. Thus, the study forest looked like a pure stand of podocarps in its physiognomy.

Leaf Biomass. The leaf mass of individual trees in the stand was calculated by the allometry method already described. The results are summarized in Figure 7, which represents the frequency distribution of the leaf mass of individual trees in the stand. Leaf biomass estimates were 10.2 ton/ha and 0.5 ton/ha for podocarps and the other three species, respectively. The total leaf biomass of 10.7 ton/ha resembled leaf biomass in broad-leaved evergreen rain forests in Japan, and the shape of podocarp leaves is similar to that of broad-leaved evergreen trees. These values are necessary for calculating the total amount of nagilactones accumulated in the forest canopy, as described later.

Nagilactone Calibration Lines. The retention times of nagilactones A, C, and D on HPLC were 10.6, 7.6, and 13.0 min, respectively. Denoting the height of a peak at each retention time by h (in centimeters), the calibration lines for three nagilactone contents in samples were approximated by: $C(A) = 0.0638h$, ($r^2 = 0.99$), $C(C) = 0.0564h$, ($r^2 = 0.99$), and $C(D) = 0.0921h$, ($r^2 = 0.99$), where $C(A)$, $C(C)$, and $C(D)$ stand for the concentrations of three nagilactones A, C, and D, respectively.

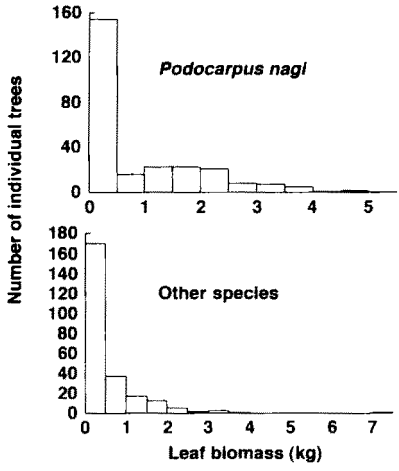

FIG. 7. Frequency distribution of individual leaf mass in dry weight within the study plot.

Nagilactone in Leaves. Nagilactone content in mature green leaves was quantified by HPLC techniques and calibration lines. Nagilactone content was expressed as the amount of nagilactone per unit leaf dry weight, and biomass was expressed by the unit of dry weight. Nagilactone C was the highest in concentration among the three isomers throughout a year (Figure 8). Nagilactones A and D were not detected in some samples. Their concentrations apparently fluctuated seasonally (Figure 8). The total nagilactone concentration per unit leaf dry weight increased in the winter season from December to March. The highest peak of 777.2 μg/g in nagilactone concentration in March sharply dropped to 83.6 μg/g in May (Figure 8). This sudden drop in nagilactone concentration in old leaves corresponded to a high concentration of 972.2 μg/g (sum of nagilactones A, C, and D) in new leaves sampled in June 1992. The concentration in new leaves was far greater than that (472.5 μg/g) in mature leaves sampled in June 1992.

The mass of nagilactones accumulated in canopy leaves is easily computed by multiplying the leaf biomass (10.2 ton/ha) of podocarps by nagilactone contents per unit leaf weight. For purposes of computation, a mean nagilactone content per year was estimated to be 2.91×10^{-5} g/g for nagilactone A, 2.94×10^{-4} g/g for nagilactone C, and 6.10×10^{-5} g/g for nagilactone D. The nagilactone mass values thus calculated were 296.8 g/ha, 2,998.8 g/ha, and 622.2 g/ha for nagilactones A, C, and D, respectively. The total of these values was 3,917.8 g/ha.

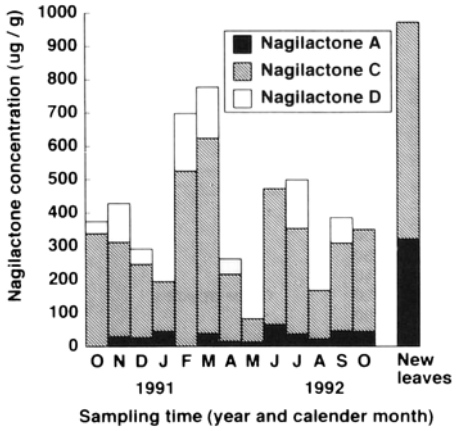

FIG. 8. Seasonal change in nagilactone content in leaves. A large nagilactone content in new leaves, 972.2 μg/g, was recorded in June 1992.

DISCUSSION

The dominance of *P. nagi* in our study forest is clear, since 95% of canopy leaves consisted of podocarp leaves in terms of leaf biomass. The mono-dominance of podocarps in forest stands is rare in Japan, as described below.

Trees of the genus *Podocarpus* are subcosmopolitan conifers, which are distributed mostly in the Southern Hemisphere but extend into the Northern Hemisphere crossing a tropical life zone (Willis, 1973). Among 100 species of the genus *Podocarpus*, two species and one variety are recognizable in Japan, which demarcates the northern latitudinal boundary in the natural geographical range of podocarp trees. Two of the Japanese podocarps, (*P. nagi* Thunb, and *P. macrophyllus* Siebold) are tall and native to Japan, while the other (*P. macrophyllus* var. Maki Siebold) is a dwarf and was introduced from China (Kitamura and Murata, 1979). The former two are mostly found as scattered individuals and their tree density is low, intermingled with various trees in the mixed oak–laurel forests. The two podocarps are generally rare in original Japanese forests (Suganuma, 1975), and the dense growth of *P. nagi* in our study site at Mt. Mikasa is unusual.

According to legend some *P. nagi* were transplanted in the forest with oak–laurel dominants by a Shinto follower to soothe the Shinto spirits over 1000 years ago (e.g., Koshimizu, 1943). If that is true, the podocarp forest at our study site offers a typical example of ecological invasion. Japanese botanists

and ecologists have suggested the following hypotheses, reviewed by Koshimizu (1943) and Suganuma (1975) to account for the dense growth of *P. nagi* at Mt. Mikasa: (1) an appropriate sex ratio of transplanted founders, (2) good soil conditions for podocarp growth at Mt. Mikasa, (3) the high shade tolerance of podocarp seedlings, (4) inhibitory effects of nagilactone on the growth of other plants, and (5) the unpalatability of podocarp leaves resulting in the escape from feeding pressures of herbivores, such as deer protected by the Shinto Shrine. The fourth suggestion stresses the importance of the allelopathy of podocarps, and the last hypothesis is related to the biological activity of nagilactone as an antiherbivory substance. The results of the present study are related to the last hypothesis.

The total nagilactone contents in mature leaves changed from month to month and their annual mean was 3.84×10^{-4} g/g (Figure 8). By multiplying this value and the weight of a single leaf, 0.17 g in dry weight, we get the mean mass of the total nagilactone, 6.53×10^{-5} g, contained in a leaf. If this quantity of nagilactone could dissolve in leaf water, 0.184 g per leaf on average, its liquid concentration per leaf would be equivalent to 1×10^{-3} mol/liter in terms of the largest molecular weight of nagilactone C. This concentration may be enough to inhibit plant growth, since the nagilactone concentrations for 50% growth inhibition for *Avena* coleoptiles were much less than 10^{-4} mol/liter (Hayashi and Sakan, 1973). A nagilactone concentration of 1×10^{-3} mol/liter may be available for defense against insects and vertebrates. Grazing scars were not found on living leaves and dead leaves in our experience. Repeated feeding tests of podocarp leaves to deer showed that deer never eat podocarp leaves.

The seasonal change in nagilactone concentrations in leaves suggested the possibility of translocation of nagilactone from old leaves to new leaves. Alternatively, new leaves might actively produce nagilactone. To confirm the translocation of nagilactone in terms of production ecology, the daily changes in photosynthesis, leaf respiration, growth, and nagilactone content of new leaves must be measured simultaneously. The high concentration of nagilactone in new leaves may protect them from herbivores.

The poor species composition of the podocarp forest, consisting of a few poisonous trees, suggested an important role of deer browsing in the maintenance of the forest. This fact coincided well with the biological activity of nagilactone, such as a growth inhibitor or antiherbivory measure and supported the aforementioned last hypothesis.

The total mass of nagilactones accumulated in canopy leaves was 3.9 kg/ha, and this provides a basis for evaluating the flow of nagilactone in a forest ecosystem through litter fall and throughfall. Nagilactone in leaves was 3.84×10^{-4} g/g annual mean content and probably worked effectively against the feeding pressure by animals.

Acknowledgments—Our profound thanks are due to the Kasuga Shinto Shrine for their generous approval in conducting research in their forest. We are very grateful to Dr. Yuji Hayashi, Emeritus Professor at Osaka City University, for his kind offer of pure nagilactones and his helpful suggestions during the study. We owe much to Drs. Makoto Taniguchi, Hideo Iio, Takashi Tokoroyama, Mamoru Kanzaki, and Kyoji Yoda at Osaka City University for their attentive support. We are also very grateful to anonymous reviewers in rewriting our original manuscript.

(Received June 5, 1995; accepted November 7, 1995)

Abstract—Leaf beetles of the species *Trirhabda geminata* are specialized herbivores that are able to feed on the chemically well-protected foliage of the desert sunflower *Encelia farinosa*, which contains the insecticidal chromene derivative encecalin. Chemical analysis of the beetles and their fecal excretions indicated that encecalin is present only in the alimentary canal and is not absorbed across the gut membrane, as previously shown for other herbivorous insects (e.g., the Egyptian armyworm, *Spodoptera littoralis*) that are susceptible to this chromene derivative. Further differences between *T. geminata* and nonadapted insects were observed with regard to the metabolism of encecalin. Whereas the encecalin-resistent leaf beetles metabolize encecalin mainly to encecalol by reduction of the acetyl group, susceptible insects, such as larvae of *S. littoralis*, metabolize encecalin mainly by epoxidation of the 3,4 double bond, which creates a powerful alkylating agent and is responsible for the toxicity of encecalin. Reductive rather than oxidative metabolism of encecalin therefore seems important for the resistance of *T. geminata* against the chemical defense of their host plant *E. farinosa*.

Key Words—*Trirhabda geminata*, Chrysomelidae, *Encelia farinosa*, Asteraceae, chromenes, benzofurans, chemical defense, plant–insect interactions.

INTRODUCTION

Chromene derivatives (e.g., **1,** Figure 1) and the structurally related benzofurans (e.g. **8,** Figure 1) occur frequently in species of the Asteraceae (Proksch and Rodriguez, 1983; Proksch and Kunze, 1995). In species of the desert sunflower *Encelia* Adans. (Asteraceae) chromenes are detected in all plant parts analyzed, including roots, stems, leaves, and flowering heads. The highest concentrations (on a dry weight basis) of these natural products, however, are usually found in soft and vulnerable tissues such as young expanding leaves or in flowering heads (Proksch and Rodriguez, 1984), where up to 250 μmol chromenes/g dry wt may be present (Kunze et al., 1995). These valuable and important plant parts are thought to be chemically defended by chromenes such as encecalin (**1,** Figure 1) against herbivorous insects (Kunze et al., 1995). The insecticidal activity of encecalin and of related naturally occurring chromenes has, in fact, been demonstrated repeatedly. Insects that proved susceptible to encecalin or related compounds included the migratory grasshopper, *Melanoplus sanguinipes* (Isman et al., 1986); the variegated cutworm, *Peridroma saucia* (Isman et al., 1987b); and the Egyptian armyworm, *Spodoptera littoralis* (Srivastava and Proksch, 1991).

In spite of the potent insecticidal activity of encecalin and several of its derivatives, larvae and adults of the leaf-feeding herbivore, *Trirhabda geminata* Horn (Chrysomelidae), are able to feed exclusively on *E. farinosa* and constitute the primary insect herbivore on this species (Hogue, 1970). Whereas the tolerance of these beetles towards the defensive chemistry of *E. farinosa* has been amply demonstrated in the past (Wisdom, 1985), neither the fate of encecalin when incorporated by the beetles, nor possible reasons for the remarkable resistance of *T. geminata* towards this chromene have ever been investigated before. In the present study we have analyzed the tissue distribution and metabolism of incorporated encecalin in adults of *T. geminata.* Evidence provided from this study suggests that the tolerance of *T. geminata* towards encecalin is due to the rapid excretion of this chromene from the gut as well as to the insect metabolism of encecalin, which is mainly converted into the more polar encecalol (**4**) instead of the corresponding epoxide (**6,** Figure 1), as previously observed for susceptible insects (Randriaminahy et al., 1992; Kunze, 1995).

METHODS AND MATERIALS

Beetles and Plant Material. Eggs and adults of *Trirhabda geminata* and live plant samples of *Encelia farinosa* were collected at Box Spring Mountain, Riverside, California, U.S.A., in April and May 1994. The beetles were main-

FIG. 1. Structures of compounds **1–11.**

tained in the laboratory at room temperature (ca. 25°C) and allowed to feed freely on *Encelia farinosa* for 8 hr prior to their use in experiments.

Experimental Design. Groups of 20 beetles were starved for 0, 3, 6, 12, and 24 hr on wet tissue paper; the nonstarved control group consisted of 32 individuals. Hemolymph was collected from five beetles of each group and immediately dissolved in acetone. Frass and eggs were collected and freeze dried. Freeze-dried beetles and leaf samples were ground and extracted three times for 24 hr with acetone and shaking. The solvent was evaporated under vacuum, and the residue was dissolved in a known amount of methanol and filtered prior to HPLC and GC-MS analyses. Frass and eggs were ground and extracted once with acetone and filtered prior to HPLC and GC-MS analyses. The acetone solution of the hemolymph was filtered and analyzed by HPLC.

Sample Analysis. The HPLC system was from Knauer (Berlin, Germany) and equipped with a multi-wavelength detector (Knauer). Samples were injected on a Eurospher 100-C18 column (Knauer) (125 × 4 mm, 5-μm pore size) and separated using a linear binary gradient consisting of solvent A (H_2O, adjusted with orthophosphoric acid to pH 2) and solvent B (methanol) (from 100% A to 100% B in 45 min followed by an isocratic segment at 100% B for 15 min). Flow was at 1 ml/min, with detection at 254 nm. Encecalin, euparin, and methyleuparin were quantified using the external standard method. Encecalin and euparin were isolated from *Encelia* as described previously and were identified by their ^1H NMR and mass spectra (Proksch and Rodriguez, 1982).

The GC-MS system was a Carlo Erba Mega 5160 gas chromatograph equipped with a quartz column (30 m × 0.32 mm; DB-1, J&W Scientific, Folsom CA), which was directly coupled to a quadruple mass spectrometer (Finnigan MAT 4515). Conditions: injector 250°C, temperature program 150–300°C at 6°C/min, split ratio 1:20, carrier gas He at 0.5 bar.

RESULTS

HPLC analysis of leaves from *E. farinosa* infested with *T. geminata* revealed the presence of the chromenes encecalin (**1**) and encecalol (**4**) as major hydroxyacetophenone derivatives, followed by comparatively small amounts of the chromenes demethylencecalin (**2**) and demethoxyencecalin (**3**) and the benzofurans euparin (**8**) and methyleuparin (**9**) (Figure 1, Table 1). The sesquiterpene lactone, farinosin, previously reported from *E. farinosa* (Geissman and Mukherjee, 1968), was only detected as a trace constituent in the analyzed samples of *E. farinosa*. Compounds were identified based on their MS data and retention times as well as by comparison with authentic standards isolated earlier (Isman et al., 1987a; Proksch et al., 1987; Randriaminahy et al., 1992).

Beetles collected from the leaves (t = 0 hr, Table 1) showed the same

pattern of chromenes as present in *E. farinosa*. From the benzofurans of *E. farinosa* only euparin (**8**) was detected in *T. geminata*, suggesting that the beetles had transformed methyleuparin (**9**) into euparin (**8**) by demethylation. Hemolymph obtained from the beetles, however, was free of any chromene or benzofuran derivatives (Table 1), indicating that the ingested hydroxyacetophenone derivatives were apparently not absorbed across the gut membranes but remained largely in the alimentary canal.

Fecal pellets produced by *T. geminata* while feeding on leaves of *E. farinosa* (t = 0 hr, Table 1) were found to contain encecalin (**1**), demethylencecalin (**2**), demethoxyencecalin (**3**), encecalol (**4**), and euparin (**8**), as well as an additional chromene metabolite that was identified as 2-hydroxymethylencecalol (**5**) based on its mass spectral data (Proksch et al., 1987).

The relative amounts of encecalol (**4**) compared to the parent compound encecalin (**1**) were significantly higher in beetles as well as in fecal pellets of *T. geminata* when compared to leaves of *E. farinosa* (Table 1). Whereas the relative proportions of encecalin (**1**) and encecalol (**4**) amounted to 59% and 21% in leaves, the ratio shifted to 56%:39% in the beetles (t = 0 hr) and even to 25%:61% in the feces (t = 0 hr), indicating that reduction of the acetyl substituent was the major step in the metabolic fate of encecalin (**1**) when ingested by *T. geminata*.

Beetles that had been starved for 3 hr were found to be almost completely free of extractable chromene derivatives, whereas the fecal pellets produced during starvation contained encecalol (**4**) as the major chromene (76% of all identified hydroxyacetophenone derivatives) (Table 1). Encecalin (**1**) and the 2-hydroxymethylderivative of encecalol (**5**) were present as minor constituents (Table 1). Compared to the chromenes present in fecal pellets collected at t = 0 hr (Table 1) the relative amount of encecalol (**4**) had further increased during starvation at the expense of the parent compound encecalin (**1**). Two antraquinones (**10** and **11**) detected in *T. germinata* are apparently biogenetic products of the beetles since no anthraquinone derivatives were found in *E. farinosa*.

DISCUSSION

Chrysomelid beetles *T. geminata* are oligophagous herbivores that are well adapted to feeding on their host plant *E. farinosa* (Wisdom, 1985; Paine et al., 1993), in spite of its noxious natural products such as encecalin (**1**), which is well known for its insecticidal activity (Isman and Proksch, 1985; Srivastava and Proksch, 1991). The resistance of *T. geminata* towards encecalin is apparently closely correlated to the fate of this chromene when ingested by the beetles. HPLC analysis of hemolymph samples from beetles feeding on *E. farinosa* indicated that encecalin (**1**) or other hydroxyacetophenones are not absorbed from the gut (Table 1) but are largely confined to the alimentary canal (Table 1). Furthermore, ingested chromenes are rapidly cleared from the gut via the feces. Beetles that had been starved for only 3 hr were almost completely devoid of any detectable chromene derivatives (Table 1). In comparison, larvae of the generalist herbivore *Spodoptera littoralis* (Noctuidae), which are susceptible to the detrimental effects of chromenes, were previously shown to absorb encecalin (**1**) from the gut when feeding on artificial diet spiked with sublethal amounts of encecalin (Randriaminahy, 1992). When transferred to an encecalin-free diet, larvae of *S. littoralis* took more than 24 hr to completely excrete previously ingested encecalin (Randriaminahy et al., 1992; Randriaminahy, 1992).

Further difference between *T. geminata* and larvae of *S. littoralis* were observed with regard to metabolism of ingested encecalin. Whereas encecalol (**4**) was identified as major metabolite of encecalin in *T. geminata* (Table 1) the 3,4-*trans*-diol (**7**) was the predominating metabolite of encecalin (**1**) detected in feces of *S. littoralis* (Randriaminahy et al., 1992; Kunze, 1995). Encecalol as well as the 3,4-diol (**7**) are more polar and significantly less toxic than their parent compound and can be regarded as detoxification products of encecalin (Isman et al., 1987b). However, the diol (**7**) formed by larvae of *S. littoralis* originates from the unstable and cytotoxic 3,4-epoxide (**6**). Metabolism of ingested encecalin by larval mixed function oxidases (MFOs) is, in fact, req-

uisite for the toxicity of encecalin to larvae of *S. littoralis* since simultaneous treatment of larvae with encecalin and the powerful MFO inhibitor tetcyclasis was shown to increase larval survival significantly when compared to larvae treated with encecalin alone (Kunze, 1995). Thus, in larvae of *S. littoralis* encecalin is apparently subject to suicide metabolism similar to that of pyrrolizidine alkaloids in mammalian liver cells (Röder, 1984), whereas the resistant *T. geminata* beetles metabolize encecalin primarily by reduction of the acetyl group and apparently not by epoxidation of the 3,4-double bond as judged from the recovered metabolites.

(Received July 31, 1995; accepted November 7, 1995)

Abstract—Ammonium acetate was more attractive than other ammonium salts to Mexican fruit flies (*Anastrepha ludens*) in an orchard test. We hypothesized that acetic acid enhanced the attractiveness of ammonia in the orchard test and that acetic acid may similarly enhance attractiveness of AMPu, an attractant consisting of a mixture of ammonium bicarbonate or ammonium carbonate, methylamine HCl, and putrescine. In laboratory experiments, acetic acid was attractive to flies deprived of either yeast hydrolysate or both sugar and yeast hydrolysate but not to flies fed both sugar and yeast hydrolysate. AMPu/acetic acid combinations were more attractive than AMPu alone to flies deprived of both sugar and yeast hydrolysate but not to flies fed sugar, regardless of yeast hydrolysate deprivation status. Acetic acid is the first attractant found that has become more attractive with both sugar and protein deprivation in studies with *A. ludens*. It is also the first that has enhanced the attractiveness of another attractant type. In orchard tests, yellow sticky panels baited with either AMPu or 17 mg of acetic acid were at least six times more attractive than unbaited panels. However, panels baited with both acetic acid (17–68 mg) and AMPu were less attractive than AMPu alone. These results differed from the laboratory data in which combinations were never less attractive than AMPu alone.

Key Words—Attractants, Mexican fruit fly, Diptera, Tephritidae, *Anastrepha ludens*, ammonia, methylamine, putrescine, acetic acid.

INTRODUCTION

Ammonia has been used as a trap bait for Tephritidae since at least the 1920s (Ripley and Hepburn, 1929; Jarvis, 1931), predating even protein baits (McPhail, 1939; Steiner, 1952). Numerous ammonium salts have been used as sources of ammonia: ammonium sulfate (Prokopy and Economopoulos, 1975); ammonium bicarbonate (Haniotakis and Vassiliou-Waite, 1987); ammonium phosphate (monobasic) (Stavrakis, 1970); ammonium phosphate (dibasic), ammonium carbonate, ammonium oleate, and ammonium chloride (Gothilf and Levin, 1989); and ammonium acetate [Hodson (1943), Reissig (1974) and Prokopy (1975) with *Rhagoletis pomonella* Walsh; Burditt et al. (1983) with *Anastrepha suspensa* (Loew); Hedstrom and Jimenez (1988) with *A. obliqua* Macquart and *A. striata* Schiner; Gothilf and Levin (1989) and Heath et al. (1995) with *Ceratitis capitata* Wiedemann]. The great number of investigations using ammonium acetate as a fruit fly attractant testifies to its superior attractiveness relative to other ammonium salts.

Results of the above studies suggest that acetic acid, the form in which acetate volatilizes from solution, is the key to the superior attractiveness of ammonium acetate. Acetic acid has been reported attractive to *C. capitata* (Keiser et al., 1976) and to *Anastrepha ludens* Loew (Robacker and Flath, 1995). As discussed above, ammonia has long been acknowledged as an attractant for fruit flies. Therefore, we hypothesized that attractiveness of ammonium acetate probably was due to combined attractiveness of ammonia and acetic acid.

Robacker and Warfield (1993) described a three-component attractant (AMPu) for *A. ludens* that also utilizes ammonia as an attractive principal. AMPu consists of a mixture of ammonium bicarbonate or ammonium carbonate, methylamine HCl, and putrescine. AMPu was developed following the approach used by Wakabayashi and Cunningham (1991) to develop an attractant for *Bactrocera cucurbitae* Coquillett. The overall attractiveness of AMPu has been shown to be the result of additive effects of the three components.

In agreement with the above results, other studies in our laboratory have shown that combinations of attractive components within systems [for example, within the pheromone system (Robacker, 1988)] were more attractive than individual components to *A. ludens*. Conversely, combinations of chemicals from different systems (for example, pheromone with fruit odor) were either no more attractive or less attractive than the more attractive of the two systems (Robacker and Garcia, 1990). If ammonium acetate actually is more attractive than other ammonium salts, then we were interested in learning if AMPu/acetic acid combinations would also be more attractive than AMPu alone.

In addition to studies of component additivity on overall attractiveness, our laboratory has actively studied the effects of physiological state on responses of fruit flies to attractants in *A. ludens*. Most relevant to the current problem, effects

of hunger on attraction of flies to bacterial odor have been studied (Robacker and Garcia, 1993; Robacker and Moreno, 1995). Because bacterial odor contains acetic acid (Robacker and Flath, 1995), we wondered if hunger of flies would affect their attraction to acetic acid in the same way as to bacterial odor. The functional-group dissimilarity of acetic acid compared with the ammonia/amino compounds that comprise most of the attractive volatiles of bacterial odor suggested that acetic acid and bacterial odor would elicit different hunger-mediated responses.

The purposes of the current research were twofold: to determine the effects of sugar and protein hunger on attractiveness of acetic acid and AMPu to *A. ludens*, and to investigate interactions of acetic acid and AMPu with respect to their attractiveness, including effects of hunger on the interactions. The research was conducted as a series of three experimental paradigms. The first was a field test to verify that ammonium acetate was in fact more attractive than other ammonium salts to *A. ludens*. Next, we conducted laboratory experiments to determine effects of sugar and protein hunger on attraction of flies to AMPu, acetic acid, and their combination. Finally, field tests of AMPu, acetic acid, and their combination were conducted.

METHODS AND MATERIALS

Insects. A. ludens used in most experiments were from a culture that originated from mangoes collected in Morelos, Mexico, in 1953. Flies used in the orchard test of ammonium salts were from a culture that originated from yellow chapote fruit, a native host of the fly, collected in Nuevo Leon, Mexico, in 1987. Both cultures had been maintained on a laboratory diet since establishment. Flies used in orchard tests were irradiated with 70–84.7 Gy ^{137}Cs one to two days before adult eclosion for release into the orchard, to comply with quarantine laws for releasing *A. ludens*. Flies used in laboratory bioassays were not irradiated. Mixed-sex groups of 150–200 flies were kept in 0.5-liter cardboard cartons with screen tops until used in tests. Laboratory conditions for holding flies were 20–25°C, 50–70% relative humidity, and photophase from 06:30 to 19:30 hr provided by fluorescent lights.

Chemicals. AMPu originally was developed as an aqueous solution of ammonium bicarbonate, methylamine HCl, and putrescine in a 10:10:1 ratio (Robacker and Warfield, 1993). More recently, ammonium carbonate was substituted for ammonium bicarbonate because of its greater solubility in water, keeping the molar ratios of ammonia, methylamine, and putrescine the same as in the original AMPu (Robacker, 1995). Ammonium bicarbonate, methylamine HCl, and putrescine were obtained from Sigma Chemical Co. (St. Louis, Missouri), ammonium carbonate from Aldrich Chemical Co., Inc. (Milwaukee,

Wisconsin), and glacial acetic acid from Mallinckrodt Specialty Chemicals Co. (Paris, Kentucky). All chemicals were at least 98% pure.

Orchard Tests of Ammonium Salts (Experiment 1). A mixed citrus orchard located near the laboratory in Weslaco, Texas, was used for all field experiments. The orchard contained several varieties of orange, lemon, grapefruit and tangerine trees of varying ages. A section of the orchard containing Rio Red grapefruit (*Citrus paradisi* MacFadyen) was used for this experiment. Six treatments were tested in a 6 × 6 Latin-square design. Treatments were: 1% ammonium acetate; 5% ammonium phosphate (monobasic); 2.5% ammonium lactate; 2.5% ammonium sulfate; 2.5% ammonium citrate (dibasic); and 10% NuLure (Miller Chemical and Fertilizer Corp., Hanover, Pennsylvania) with 3% borax, a standard protein-hydrolysate bait for fruit flies. These concentrations of ammonium salts were more attractive than others tested in preliminary laboratory tests.

Treatments were prepared in deionized water. All except NuLure contained 0.01% Triton X-100 (Rohm and Haas Co., Philadelphia, Pennsylvania) as a surfactant. Treatments were tested in plastic McPhail-type traps, 200 ml of each per trap. Traps were hung one to a tree, 1–2 m aboveground, on the northeast sides of trees. Traps were placed in alternate trees within rows, and in alternate rows within the orchard. Positions of treatments were randomized within rows and columns. Flies were released into the orchard when 3–4 days old during the evening of the day before a test. Flies were fed a 6% sucrose solution up until the time of release. Approximately 5000 flies were distributed equally among the 36 test trees. Traps were placed in the orchard during the morning and removed for fly counts and cleaning two days later. The experiment was not repeated.

Laboratory Bioassays (Experiments 2–4). Three experiments were conducted to assess effects of sugar and protein hunger on attractiveness of AMPu, acetic acid, and their combination using cage-top bioassays. Attractiveness of acetic acid to Mexican fruit flies fed sugar but not protein was established in earlier work (Robacker and Flath, 1995). Of four quantities tested, 10 μg of acetic acid was the most attractive. Therefore, this quantity was used in the current research. AMPu was also tested at quantities of chemicals that were most attractive in previous work (Robacker and Warfield, 1993): ammonium bicarbonate, 10 μg; methylamine HCl, 10 μg; and putrescine, 1 μg. Both acetic acid and AMPu were prepared in water. The pH of the AMPu solution was adjusted to 8.8 with NaOH, a pH that was highly attractive in previous work (Robacker and Warfield, 1993). Test quantities of both acetic acid and AMPu were administered to flies in 10 μl of the aqueous solutions.

In the first laboratory experiment (experiment 2), flies fed ad libitum from eclosion on standard adult-fly diet, a mixture of sucrose (sugar from local grocery store) and enzymatic yeast hydrolysate (U.S. Biochemical Corp., Cleveland, Ohio). Additional sugar cubes were provided so that flies could regulate

the amount of carbohydrate and protein they received. In experiment 3, flies fed ad libitum on sugar cubes only. Experiment 4 was conducted like experiment 3 except sugar cubes were removed 48 hr before bioassays. Flies in all three experiments had access to water at all times.

Bioassays were conducted by placing four filter paper triangles (3 cm/side), one containing acetic acid, one with AMPu, one with acetic acid and AMPu, and one with water (10 μl), near the corners on the top of an insect cage (30 cm/side, aluminum-screened). For the papers containing both acetic acid and AMPu, the 10-μl quantities of each were loaded as separate spots so that non-volatile acetate salts did not form on the papers. Five counts of flies were made, at 1-min intervals, at each of the four treatments in their initial positions on the four corners of the cage-top. Then new papers with new loadings of the same four treatments were placed on the cage-top but rotated by 90° into new positions for five more counts, and so on, until all four treatments occupied each of the four positions for five counts. Totals of the 20 counts at each treatment were calculated, and these totals were used in statistical analyses. The filter papers were raised 5 mm above the cage top using plastic rings to ensure that olfaction and not contact chemoreception was solely responsible for the response of the flies.

One carton of 180–200 flies was used in each bioassay cage. Flies were tested when 5–9 days old. Tests were conducted between 10:00 and 14:00 hr under a combination of fluorescent and natural light. Sixteen replications of experiment 2, 14 replications of experiment 3, and 12 replications of experiment 4 were conducted.

Orchard Tests of AMPu and Acetic Acid (Experiments 5 and 6). One row of Ruby Red grapefruit (*C. paradisi*) and one row of Dancy tangerine (*C. reticulata* Blanco) were chosen for tests. Two linear blocks of eight consecutive trees each were used in each row, for a total of four blocks in the orchard.

AMPu and acetic acid were formulated into agar (Bacto Agar, Difco Laboratories, Detroit, Michigan) in 1.9-ml polypropylene microcentrifuge tubes (A. Daigger & Company, Inc., Wheeling, Illinois). Both the AMPu/agar tubes and the acetic acid/agar tubes were prepared by mixing hot agar solution with aqueous AMPu or acetic acid solutions in the microcentrifuge tubes to a volume of 1.7 ml. Final agar concentration was 1% in both AMPu and acetic acid tubes. AMPu concentrations in agar tubes were 60 mg/ml ammonium carbonate, 100 mg/ml methylamine HCl, and 10 mg/ml putrescine. Final pH of the AMPu tubes was 8.5–8.8. Acetic acid tubes were prepared at 10 concentrations of acetic acid, five of which were tested in experiment 5 and five in experiment 6. Different concentrations of acetic acid were tested in an attempt to test a range that included concentrations that were too low to have any effect up to concentrations that were so high as to be repellent. Concentrations tested in experiment 5 were 2.5, 5.0, 10, 20, and 40 mg/ml. Concentrations tested in experiment 6 were

0.06, 0.12, 0.25, 0.50, and 1.0 mg/ml. Experiment 6 used lower acetic acid concentrations because results of experiment 5 indicated that concentrations may have been too high.

Eight treatments were tested in each block. Experiment 5 treatments consisted of unbaited, AMPu, and acetic acid at 10 mg/ml and five combinations of the single concentration of AMPu and one of the five higher concentrations of acetic acid (2.5–40 mg/ml). Experiment 6 treatments consisted of unbaited, AMPu, and acetic acid at 0.25 mg/ml and five combinations of AMPu with one of the five lower concentrations of acetic acid (0.06–1.0 mg/ml). AMPu tubes and acetic acid tubes were fastened with their caps open to the tops of yellow panel traps (13 × 18 cm) (Robacker, 1992). For traps containing combinations of AMPu and acetic acid tubes, the two tubes were placed on opposite sides of the trap. Traps were coated with Tangle-Trap (Tanglefoot Company, Grand Rapids, Michigan) and were hung one to a tree, north of center, at 1–2 m height.

Flies were released into the test orchard when 4–14 days old during the late afternoon of the day before a test. Flies were fed sucrose and water until the time of release. Approximately 2000 flies were distributed equally among the 32 test trees in the four blocks. Traps were placed in the orchard during the morning and removed for fly counts and cleaning on the following morning. Traps were reused after removing flies and applying Tangle-Trap as necessary. Positions of treatments within each block were randomized for the first replication of each experiment. Positions of treatments in consecutive replications were not randomized but were moved sequentially within each block. Ten replications of experiment 5 and eight replications of experiment 6 were conducted.

Statistical Analyses. The field test of ammonium salts (experiment 1) was analyzed by analysis of variance (ANOVA) for a Latin-square design. Count data were analyzed after transformation to natural logarithms. Treatment means were compared by Fisher's protected least significant difference (LSD) method. These analyses and those described below were conducted using SuperANOVA (Abacus Concepts, 1989).

Two-way ANOVA was conducted for the three laboratory experiments (experiments 2–4) to separate effects of replication (each bioassay) and test chemical or chemical combination. Data used in ANOVAs were total counts at each treatment or water control for each bioassay resulting in counts of 16, 14, and 12 for experiments 2, 3, and 4, respectively. Means separations were by Fisher's protected LSD.

Separate one-way ANOVAs were conducted for males, females, and males plus females for each of the two field experiments of AMPu/acetic acid (experiments 5 and 6). Counts from traps were converted to proportions, then transformed by arcsin of the square root before ANOVAs were conducted. For example, the proportion of males captured in a particular trap on a particular

day was calculated as the number of males in that trap divided by the number of males captured in all traps in the block containing that trap on that day. Proportions were used to eliminate the high variability in capture rates from day to day because tests were conducted over two seasons. Means separations were by Fisher's protected LSD.

Sex ratios of flies captured by the lures were compared for experiments 5 and 6. Totals of females and males captured on each trap date by each lure type were used to calculate the proportion of females captured by each lure type per day. Data were analyzed by one-way ANOVA without transformation.

RESULTS

Orchard Tests of Ammonium Salts (Experiment 1). Ammonium acetate captured significantly more flies than the other ammonium salts (Figure 1). Only NuLure was comparable in attractiveness. A total of 1077 flies were captured in this experiment.

Laboratory Bioassays (Experiments 2–4). Acetic acid was no more attractive than water to flies fed both sugar and yeast hydrolysate until the time of testing (experiment 2) (Figure 2). Acetic acid was significantly more attractive than water to flies fed sugar but not protein (experiment 3) and to flies that were hungry for both sugar and protein (experiment 4). AMPu was significantly more attractive than both water and acetic acid to flies of all hunger-status groups.

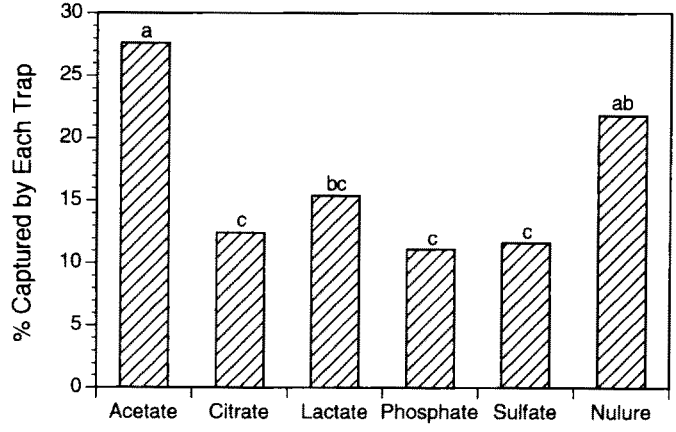

FIG. 1. Captures of *A. ludens* in McPhail-type traps containing solutions of various ammonium salts or NuLure (experiment 1), expressed as mean percentages of the total flies captured by the six treatments. Bars with the same letter are not significantly different by Fisher's protected LSD ($P < 0.05$).

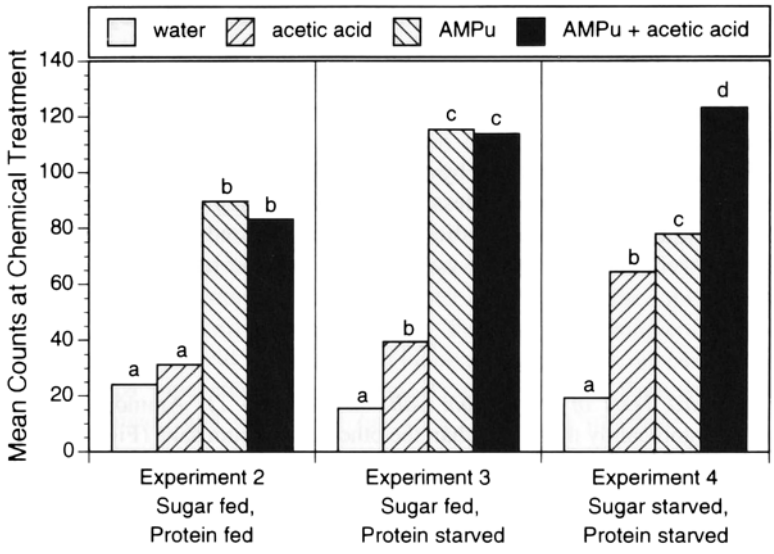

FIG. 2. Mean counts of *A. ludens* of three hunger states at filter papers containing water, acetic acid, AMPu, or an AMPu/acetic acid combination in cage-top bioassays. Within each experiment, bars with the same letter are not significantly different by Fisher's protected LSD ($P < 0.05$).

The combination of acetic acid and AMPu was more attractive than AMPu alone to flies hungry for both sugar and protein, but not to the other hunger-status groups of flies.

Orchard Tests of AMPu and Acetic Acid (Experiments 5 and 6). Experiment 5 showed that yellow panel traps baited with 17 mg (10 mg/ml × 1.7 ml) of acetic acid were considerably more attractive than unbaited yellow panel traps (Figure 3). AMPu-baited traps were not significantly more attractive than acetic acid-baited traps. Traps baited with combinations of acetic acid ranging in concentration from 2.5 to 40 mg/ml and AMPu were generally less attractive than traps baited with AMPu alone. The combinations were significantly less attractive than AMPu alone at the three highest concentrations of acetic acid. A total of 930 flies were captured in this experiment, summed over all treatments and replications.

In experiment 6, AMPu traps captured six times as many flies as unbaited traps, about the same as in experiment 5. The ANOVA was highly significant ($F = 16.2$; $df = 7,248$; $P < 0.0001$). Traps baited with 0.4 mg (0.25 mg/ml × 1.7 ml) of acetic acid were not significantly more attractive than unbaited

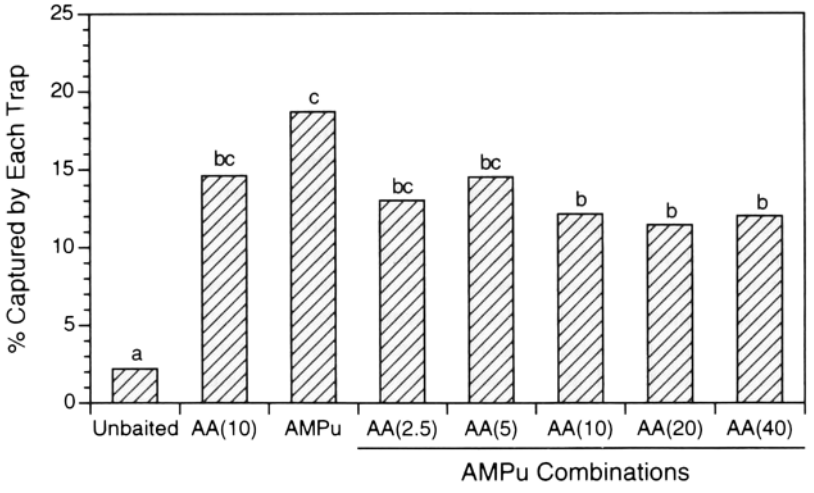

FIG. 3. Captures of *A. ludens* on sticky panel traps baited with nothing (unbaited), 17 mg of acetic acid [AA(10) = 10 mg/ml × 1.7 ml], AMPu, or combinations of AMPu with five amounts of acetic acid (experiment 5), expressed as mean percentages of the total flies captured by the eight treatments. Bars with the same letter are not significantly different by Fisher's protected LSD ($P < 0.05$).

traps by Fisher's protected LSD at the 5% level. Traps baited with combinations of acetic acid ranging in concentration from 0.06 to 1 mg/ml and AMPu also were not significantly different from traps baited with AMPu alone by LSD ($P < 0.05$). A total of 1640 flies were captured in this experiment, summed over all treatments and replications.

Most of the trap/lure combinations captured more females than males. The percentage of males and females in released flies was not recorded so it was not possible to determine if the various lures captured females or males in significantly different proportions than were present in the orchard. However, Robacker and Warfield (1993) showed that AMPu was approximately equally attractive to males and females.

We did compare the attractiveness to males vs females of the various lures relative to each other. In experiment 5, percentages of females captured by the various lures were unbaited, 52.4%; acetic acid, 49.6%; AMPu, 61.4%; and all AMPu/acetic acid combinations, 65.4%. In experiment 6, percentages of females captured by the lures were unbaited, 54.5%; acetic acid, 60.7%; AMPu, 57.6%; and all AMPu/acetic acid combinations, 59.5%. ANOVAs of proportions of females captured by traps per test day showed no significant differences among the lures.

DISCUSSION

Ammonium Acetate. The great attractiveness of ammonium acetate compared to the other ammonium salts suggests that acetic acid plays a role in attractiveness of ammonium acetate. The results of the experiments in which acetic acid was combined with AMPu proved that acetic acid affected overall attractiveness of these combinations. Based on the experiments with AMPu, it is more prudent to argue that acetic acid affected attractiveness of ammonium acetate than to argue otherwise. We cannot argue with certainty that acetic acid was the primary reason that ammonium acetate was more attractive than the other ammonium salts tested in this work because no attempt was made to equalize emissions of ammonia from the various preparations. However, each compound was tested at a concentration that ensured optimum performance based on preliminary testing.

Effects of Hunger on Attractiveness. The attractiveness of AMPu, acetic acid, and AMPu/acetic acid combinations was shown to be affected by the hunger status of flies. AMPu was attractive to flies of all hunger states. Although results of the experiments could not be compared statistically with each other, it appeared that AMPu was most attractive to flies hungry for protein (experiment 3) and least attractive to flies hungry for sugar (experiment 4). Previously, Robacker and Garcia (1993) demonstrated that bacterial odor was not attractive to *A. ludens* that were hungry for sugar, and Robacker and Moreno (1995) demonstrated that bacterial odor was most attractive to flies hungry for protein. The similar result found here for AMPu is not surprising due to the similarity of attractive principals in AMPu and bacterial odor (Robacker et al., 1993; Robacker and Flath, 1995).

Data for acetic acid revealed a very different relationship between hunger and attractiveness compared with AMPu. Acetic acid became more attractive as hunger for either sugar or protein increased. This relationship is also different from that of CEH, a three-component attractant (1,8-cineole, ethyl hexanoate, and hexanol) developed from odor of fermented host fruit (Robacker et al., 1990b). Like acetic acid, attractiveness of CEH increased with sugar deprivation of flies (Robacker, 1991). However, protein deprivation had little effect on attractiveness of CEH. Acetic acid is the first chemical studied that became more attractive to *A. ludens* deprived of either sugar or protein. With these data as a base, acetic acid does not fit into either the sugar-hunger or protein-hunger attractant systems described by Robacker (1991).

The greater attractiveness of the AMPu/acetic acid combination relative to either attractant alone when flies were starved for both sugar and protein is also unique among attractants studied to date in *A. ludens.* It is the first time that a combination of two attractants containing such different chemical moieties, and which operate somewhat differently with respect to effects of hunger, was more

attractive than one or the other of the two attractants alone. However, this result only occurred when flies were hungry for sugar and may occur in the field only at times when natural sources of carbohydrate are scarce.

Orchard Tests of AMPu/Acetic Acid Combinations. Combinations of AMPu with acetic acid were either less attractive or no more attractive than AMPu alone in field tests. This result cannot be attributed to acetic acid acting as a repellent. Acetic acid was attractive when tested alone, as discussed above. The field data resemble the laboratory data in that AMPu was the most attractive lure, acetic acid generally was more attractive than blanks, and the AMPu/acetic acid combinations were generally not more attractive than AMPu alone. In other ways, however, these results resemble neither laboratory experiments 2 and 3, in which acetic acid was much less attractive than AMPu and AMPu/acetic acid combinations, nor laboratory experiment 4, in which the AMPu/acetic acid combination was significantly more attractive than AMPu. The reason for these differences between the laboratory and field tests is unknown. Previous research indicated that irradiation attenuated attraction of *A. ludens* both to odor of fermented host fruit (Robacker et al., 1990a) and to bacterial odor (Robacker and Garcia, 1993) by similar amounts. What effects irradiation of flies used in field tests in this work may have had on relative attraction to acetic acid, AMPu, and their combinations cannot be predicted.

Diminution of attractiveness when attractants were combined has been reported before in *A. ludens.* Robacker and Garcia (1990) reported that the combination of attractive odor of fermented chapote fruit and male-produced pheromone was much less attractive to sexually mature virgin females than was pheromone alone. That work also showed that the combination was less attractive than chapote odor alone to sexually immature females. Robacker (1991) showed that a combination of CEH and bacterial odor was less attractive than CEH alone to 2- to 3-day-old flies that had not been fed as adults. In *B. oleae* (Gmelin), combinations of pheromone and proteinaceous feeding attractants were also found to be less attractive than the proteinaceous attractants alone (Haniotakis and Skyrianos, 1981; Zervas, 1989) or pheromone alone (Haniotakis and Vassiliou-Waite, 1987).

Zervas (1989) overcame the repellency problem of the pheromone/yeast hydrolysate combination by moving the pheromone dispenser 0.5–1 m away from the trap. This trapping system resulted in an increase in the capture of *B. oleae* compared to either bait alone. In the current study with *A. ludens,* putting AMPu vials and acetic acid vials on opposite sides of the panel traps did not result in an increase in the number of flies captured compared with AMPu alone. No attempt was made to duplicate Zervas' (1989) results by moving the AMPu and acetic acid lures 0.5–1 m apart.

As discussed above, Zervas (1989) successfully increased captures of *B. oleae* by combining two different types of attractants. In addition, Landolt et

al. (1992) demonstrated that a combination of pheromone from *Toxotrypana curvicauda* Gerstaecker with host-fruit odor was more attractive to females than either pheromone or host-fruit odor alone. Even more relevant to the current work, MacCollom et al. (1992, 1994) found that a combination of bacterial cells with apple volatiles was more attractive than either alone to *R. pomonella* in an apple orchard. These results indicate that it should be possible to develop more powerful attractants for at least some species of Tephritidae by combining different types of attractants. However, no evidence has been found to suggest that combining various types of attractants for the Mexican fruit fly, including AMPu with acetic acid, as shown in this paper, will enhance capture of the flies beyond captures by AMPu or other nitrogenous types of attractants alone.

Acknowledgments—I thank Pravait Kaochoung (Office of Atomic Energy for Peace, Bangkhen, Bangkok, Thailand) and Maura Rodriguez and Cyndi Rodriguez for technical assistance; Sammy Ingle for insects; and A. W. Guenthner (USDA-APHIS, Mission, Texas) for irradiation of pupae. Use of a product brand in this work does not constitute an endorsement by the USDA.

(Received January 10, 1995; accepted November 8, 1995)

Abstract—Hexane extracts of leaves of 307 accessions from 73 host plant species of *Helicoverpa zea* were analyzed by gas chromatography (GC) and used for *H. zea* oviposition and neonate larvae orientation bioassays. The gas chromatographic (GC) retention times of compounds statistically associated with behavioral activity were identified by correlation of GC peak area with oviposition and larval orientation preferences. Although taxonomically diverse in their origin, compounds for study were purified from extracts of species of the genus *Lycopersicon*, due to their relative abundance. The structures of eight long-chain alkanes associated with oviposition preference were assigned by mass spectrometry, and the structures of five similarly associated organic acids and a terpenoid alkene were identified by ^{1}H and ^{13}C nuclear magnetic resonance spectroscopy. The structures of a number of other phytochemicals from the plant leaves were identified for comparative purposes, including a previously unknown terpene, 7-epizingiberene. Bioassays were performed on the isolated acids and on the alkane wax fractions of several *Lycopersicon* species, and significant differences were found in oviposition stimulation for both classes of compounds. Of the hundreds of compounds found in the extracts, none were observed to act as oviposition deterrents. The results of these bioassays may be useful in explaining the broad host range of *H. zea*, as well as the process and evolution of host plant selection for oviposition.

Key Words—Oviposition, kairomone, *Helicoverpa zea*, corn earworm, *Lycopersicon*, *Nicotiana*, host-plant selection, insect chemoreception, Lepidoptera, Noctuidae.

INTRODUCTION

The larvae of *Helicoverpa zea* are a major agricultural pest in the United States and Central and South America, with damage and control costs for *H. zea* and *H. virescens*, a related pest, estimated to be one billion dollars each year. Their host plants include a variety of economically important crops such as corn, tomatoes, cotton, tobacco, and soybeans (Johnson et al., 1986). Traditionally, *H. zea* has been controlled primarily through the repeated application of pesticides, but ecological and economic costs of pesticides and the possibility of insecticide-resistant strains of *H. zea* have led to an increased interest in other pest management strategies. Some of these strategies depend on research in *H. zea* semiochemicals, with the eventual goal of modifying growers' cultural practices or genetically manipulating host species to produce naturally resistant plants.

One focus of research has been insect pheromones. Pheromones have been used with varying degrees of success to bait field traps to monitor *H. zea* pest populations (Leonard et al., 1989; Raulston et al., 1990). A second focus involves research in plant/insect semiochemicals (kairomones and allomones), as well as plant-produced mimics of insect hormones. Because the larvae are the agricultural pests, one reasonable approach to control of *H. zea* involves identifying oviposition stimulants. This could lead to a number of insect control strategies, including improved monitoring of female *H. zea* populations in the field, possible disruption of egg-laying behavior, and cultivation of host species that do not produce the stimulants so that the moths would no longer recognize crop plants as hosts for oviposition.

Although many stimuli are involved in lepidopteran oviposition behavior, chemical stimulation is considered the major factor (Städler, 1986), with visual and mechanical stimuli also playing roles. In their study of the attraction of *H. subflexa* to plant extracts, Tingle et al. (1989) noted that the flight of mated females (but not males or virgin females) was particularly directed toward extracts of leaves of *Physalis* and that the total positive response to plume trails of leaf extract, including anemotaxis, contact, and landing, was greater than 80%. Thus, identification and manipulation of the leaf chemical components may allow for potential manipulation of oviposition behavior.

A number of natural and synthetic oviposition stimulants for *H. zea* and related pests have been identified. Jones et al. (1970) discovered that the triester triacetyl glycerol, a component of some pen inks, stimulated significant levels of oviposition activity. Jones et al. (1973) tested 141 compounds structurally related to triacetyl glycerol, including esters and halogenated esters, and found that 26 of them stimulated oviposition in lab tests, but none showed any activity in field tests. Wiseman (1989) found that chemicals from corn silk stimulated oviposition of *H. zea*. Mitchell et al. (1990) tested methanol and methylene chloride leaf washes from ground cherry (*Physalis angulata*), and the *H. zea*

host plants tobacco (NC 2326), *Desmodium tortuosum*, and cotton (*Gossypium hirsutum*) for oviposition activity with *H. zea*, *H. subflexa*, and *H. virescens*. They found that while *H. subflexa* was stimulated by groundcherry and *H. virescens* by tobacco, *H. zea* was not influenced by any of the extracts.

Previous work in our labs has centered on β-bergamotenoic acid, and the structurally similar α-bergamotenoic and α-santalenoic acids, compounds exuded from trichomes on the leaf surface of *Lycopersicon hirsutum* (Coates et al., 1988; Juvik et al., 1988). β-Bergamotenoic acid in particular was found to stimulate oviposition activity in *H. zea*. A number of bicyclic and acyclic analogs of β-bergamotenoic acid were synthesized and tested for oviposition activity. The acid functionality was essential for oviposition stimulation, since none of the alkene, ester, or acetate analogs of β-bergamotenoic acid had activity (Douglass et al., 1993).

Part of the problem associated with identifying kairomones for *H. zea* is the diversity of its host range and of the chemical constituents present among many host-plant species. A single accession of a host species may have more than 70 different compounds in its leaf surface extracts (Juvik, unpublished data). The goal of the present work was to implicate, by statistical correlation of gas chromatographic and oviposition bioassay data, larval attractants and oviposition stimulants for *H. zea* from a broad range of its host plants. Structural determinations and *H. zea* oviposition bioassays were then performed on putative kairomonal compounds isolated from the leaves of the plant family Solanaceae, primarily from species of *Nicotiana* and *Lycopersicon*.

METHODS AND MATERIALS

Plant Material and Extracts

Seeds of wild and cultivated *Lycopersicon* species were obtained from Dr. C. M. Rick, Tomato Genetics Stock Center, Department of Vegetable Crops, University of California, Davis, and from Dr. J. McFerson, Germplasm Resources Unit, United States Department of Agriculture (USDA), Geneva, New York; seeds of wild and cultivated *Capsicum* species were obtained from Dr. P. W. Bosland, Department of Agronomy and Horticulture, New Mexico State University, Las Cruces, New Mexico; seeds of wild *Gossypium* species were obtained from Dr. A. E. Percival, Cotton and Grain Crops Research Unit, USDA, College Station, Texas; seeds of tobacco and *Nicotiana* species were obtained from Dr. D. M. Jackson, Tobacco Research Laboratory, USDA, Oxford, North Carolina. All other seeds were purchased locally.

During the summers of 1988 and 1989, accessions from 73 species (Table 1) of plants known to host *H. zea* (Kogan, 1986) were grown in the greenhouses at the University of Illinois, Urbana-Champaign, and then transplanted into the

[a]Oviposition values are the number of *H. zea* eggs on a disk treated with the hexane wash of the accession listed, divided by the mean number of eggs on two adjacent untreated disks.

field plots at the Agricultural Experiment Station South Farm. Leaves from each of the accessions were harvested two to three months later and transported to the laboratory. Leaf tissue (100 g) was placed in a canning jar with 400 ml of hexane and gently shaken for 30 min at room temperature. The extract was filtered through 24-cm Whatman No. 4 qualitative filter paper, and the extraction procedure was repeated using 100 ml of hexane. The extracts were combined

and concentrated to the equivalent of 0.5 g of leaf tissue per milliliter of hexane and stored in a −20°C freezer for subsequent analysis.

Accession Oviposition and Larval Orientation Bioassays

Gravid female moths of *H. zea* were obtained from our laboratory colony. Arenas for oviposition studies were used as described by Juvik et al. (1988). Hexane extracts for the various accessions were tested by placing 0.5 ml of hexane extract from each accession on 4.25-cm Whatman No. 1 filter paper disks and then allowing the hexane to evaporate. A control disk treated only with hexane, eight disks individually treated with extracts from eight accessions, and nine untreated disks were placed into arenas with 15 gravid female moths. Each treated and the control disk had two untreated disks adjacent to it. One of the nine treatments in each arena was the leaf extract from *Lycopersicon hirsutum* accession, LA 1777, which had been previously shown to stimulate *H. zea* oviposition (Juvik et al., 1988). Since it was known that similar concentrations of LA 1777 extract were highly attractive to the moths, it was used as a positive control, so that moth activity could be standardized over arenas and over days. In order to improve moth viability, a Petri dish containing sterile cotton infused with a 10% (v/v) honey in water solution was placed in the center of the bottom of each arena. The moths were allowed to oviposit for three days, with egg counts taken after each 24-hr period. Moth oviposition preference values were calculated by recording the number of eggs oviposited on the treated filter paper disks divided by the mean number of eggs on the two adjacent untreated disks. There were three replicates of each arena, with the positions of the treated disks for each arena randomized with respect to the other treated disks within that arena.

Larval bioassays were conducted by removing the eggs (including those on the filter paper disks) from the sides of the arenas used to determine moth oviposition preference values. These eggs were often damaged, and so were not used for the subsequent bioassay; however, enough eggs remained on the lid of the arena to provide an adequate hatch of larvae for the assays. There were approximately 5000 larvae per assay. Each of the treated disks was then resaturated with another 0.25 ml of extract of the same accession, allowed to dry, and returned to the arena. The eggs were allowed to hatch over a three-day period, and the number of the neonate larvae on each disk was counted at the end of each 24-hr period, at which point the larvae would be returned to the bottom of the arena by inducing anesthesia with a stream of CO_2. Larval orientation preference was calculated by dividing the number of larvae on each treated disk by the mean number of larvae on the two adjacent untreated disks. Larval bioassays were conducted only on the 226 accessions grown in 1988.

Statistics

The 1988 and 1989 GC data were tabulated by entering the retention times (corrected for drift by comparison with internal standard retention times) and peak area values for all peaks with areas more than or equal to a concentration of 0.005 mg 2-dodecanone/ml. Peak area values were standardized by dividing the actual integrated area by the integrated area of the 2-dodecanone internal standard, added just before GC analysis. Because many of the chemicals were present in a number of the extracts, the data entry procedure generated a matrix with retention times along one axis (as chemical identifiers), plant accession number along the second axis, and standardized peak areas for the individual chemicals as elements. For the 226 plant accessions in 1988, there were 310 chemicals identified by different GC retention times, with no one accession having more than 80 chemicals. For the 97 plant accessions in 1989, there were 171 chemicals recorded.

The oviposition bioassay data were entered as oviposition preference values, as calculated above. These values were standardized by dividing the oviposition preference value for a given accession by the oviposition preference value for LA 1777 for that arena minus the oviposition preference value for the hexane control for that arena, as shown in the following equation:

$$\text{Oviposition preference} = \frac{\text{Accession value}}{\text{LA 1777 value}} - \text{Control value}$$

Values for each of the three replicates were entered, for each of the three days of observation, for each accession. Larval bioassay data were entered as larval orientation preferences as defined above. They were standardized by dividing the larval orientation values for each accession by the larval orientation value for the hexane control disks. The number of larvae on LA 1777 was not used as an additional high standardization technique because we had no prior evidence that LA 1777 was attractive to *H. zea* larvae. As with the oviposition data, values for each of the three replicates were recorded for each of the three days of observation, for each accession.

Two-way analyses of variance (SPSS-X, 1990) of accession extracts, days, and their interaction were used to determine whether the replicates or the day of observation had a significant effect on standardized larval orientations or moth oviposition preferences. Because there were no significant main effects of replicates, day of oviposition, or their interaction, means were taken of the standardized values of oviposition and larva preference over the three days and three replicates.

For each year, correlations (SPSS-X, 1990) between oviposition preference values for each accession and standardized peak area of each chemical (as identified by GC retention time) in each accession were run to examine the variation

in oviposition preference values with the variation in standardized peak area. Only accessions with detectable amounts of a particular component were included in the regression for that component. For the 1988 standardized oviposition values, GC data from 16 chemicals that either individually accounted for a high proportion of total variability in the linear model ($R^2 > 0.40$) or had correlation coefficients whose P values were less than 0.05 were put into a subset. For the 1989 oviposition, 18 compounds fulfilled the above requirements, and their GC data were put into a subset. No negative correlations between compound concentrations and oviposition preference values were observed in these experiments.

Similarly, correlations (SPSS-X, 1990) between the larval preference values and the standardized peak area of each chemical in each accession were run to examine the variation in larval preference values with the variation in standardized peak area. For the larval orientation values, GC data from 17 chemicals that either accounted for a high amount of total variability in the linear model ($R^2 > 0.40$) or had a significant ($P < 0.05$) correlation with larval orientation were put into a subset.

Forward selection multiple regression (SPSS-X, 1990) was run on the data subsets to determine, for each year of oviposition and larvae preferences, which of the chemicals in each subset accounted for most of the total variability in activity. For 1988 standardized oviposition preference values, seven chemicals significantly increased the R^2 value of the regression equation ($P < 0.03$); for the larval standardized preference values, six chemicals significantly increased the R^2 value of the regression equation ($P < 0.002$); for 1989 standardized oviposition values, five chemicals significantly increased the R^2 value for the regression equation and were chosen for further analysis. In each of these three cases, the additional chemicals in the subsets had significantly greater P values, and so were not chosen for further investigation. GC-MS as described below was performed on the 18 putative kairomonal compounds (see Table 2 below) to determine their molecular weights and empirical formulas.

Chemical Analyses

Gas chromatography (GC) was performed on a Hewlett-Packard model 5790 gas chromatograph with a HP 7671A autosampler, a Hewlett-Packard Ultra Performance 12.5-m cross-linked methyl silicone capillary column (0.2 mm ID, with a 0.33-μ 100% dimethylpolysiloxane liquid phase) and a flame ionization detector. The carrier gas was helium; the split ratio was 100:1. The oven temperature was held at 90°C for 1 min, then raised by 10°C/min to 170°C, then 15°C/min to 320°C, and held at 320°C for 5 min. The injector was set at 325°C and the detector was maintained at 327°C. Internal standards (0.6 mg/

ml) of 2-dodecanone (Pfaltz and Bauer) and squalene (Aldrich) were used to standardize retention times by adjustment of retention times with internal standard retention time drift and peak integration values by comparison with internal standard GC peak integration. 2-Dodecanone was chosen as an internal standard because it elutes early in the GC run, separately from any naturally occurring compounds and is analogous to the 2-tridecanone and 2-undecanone found in *L. hirsutum* f. *glabratum* (Weston, 1989); squalene was chosen as an additional standard because it elutes much later in the run, separately from any of the naturally occurring compounds and so could be used for the standardization of compounds eluting at the end of the runs. Since a new column was used on the 1989 extracts, the chromatographic data from the two years were kept separate to avoid any possible misclassification of compound retention times.

Gas chromatography–mass spectrometry (GC-MS) was done in the Mass Spectrometry Laboratory of the School of Chemical Sciences at the University of Illinois. A Hewlett-Packard model 5890 GC was used, with the same column as described earlier. The runs were done as splitless injections, with helium as the carrier gas, under various oven conditions. A typical splitless run would be held at 35°C for 30 sec, then raised at 50°C/min to 90°C, then 10°C/min to 170°C, then 15°C/min to 320°C. The mass spectrometer used was a Fisons VG Analytical 70-VSE, with combined chemical ionization–electron impact ionization (CI-EI) capability, and a VG/OPUS data system. When samples were run in the ACE mode (alternating CI-EI mode, with 0.3 sec between scans), the ionization gas used was methane. For EI scans, the electron energy was 70 eV. High-resolution GC-MS was also performed on the same Fisons VG 70-VSE spectrometer. Electron ionization MS was used to observe fragmentation patterns, chemical ionization MS was used to confirm the molecular ions, and high-resolution MS was used to determine empirical formulas for the biologically active compounds. Fragmentation patterns of mass spectra were interpreted as discussed below.

Proton and carbon-13 nuclear magnetic resonance spectroscopy (^1H and ^{13}C NMR) were performed on a Varian XL200 NMR (200 MHz for ^1H) or on a Varian Unity 400 NMR (400 MHz for ^1H), as indicated. NMR chemical shifts were referenced to that for the deuterated solvent ($CDCl_3$ unless otherwise specified).

Flash chromatography was performed as described by Still (1978) using Merck 0.04 to 0.063-mm silica gel or Merck silica gel impregnated with 10% or 15% (w/w) silver nitrate. Thin-layer chromatographic (TLC) analysis was performed with glass plates precoated with 0.25 mm of silica gel F-254 with fluorescent indicator, manufactured by Merck. TLC plates for argentation chromatography were obtained from Alltech Associates, Inc. Plates were 20 × 20 cm, 250 μm thick, and coated with either 10% or 15% (w/w) silver nitrate–

silica gel. Plates were visualized by spraying with 5% phosphomolybdic acid in 95% ethanol and heating.

Reactions were carried out under a nitrogen atmosphere unless specified otherwise. All reagents and solvents were reagent grade and used without further purification unless specified otherwise. Hexanes were distilled prior to use. Ethereal diazomethane was produced from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (Diazald) in ether with potassium hydroxide in ethanol following the procedure described by Black (1983).

Identification of Alkane Waxes

The structures of the alkane waxes were determined by gas chromatography in conjunction with mass spectrometry (GC-MS) and by the use of standardized retention times, or Kovats indices (Kovats, 1965). The use of these indices, in conjunction with the carbon number as judged by GC-MS, was used to determine whether the particular alkane was branched or unbranched, and the extent of branching present. A similar technique relying on Kovats's work was used to show that the alkanes were members of homologous series. Because members of homologous series will elute from an isothermal GC run so that the logarithms of their retention times are proportional to the numbers of carbons in the molecules, a plot of the logarithm of isothermal retention time versus the carbon number will result in straight lines (Hutchins and Martin, 1968).

Interpretation of mass spectral fragmentation patterns according to rules described by Pomonis et al. (1980) and Nelson et al. (1980, 1984) was used to determine the number and position of methyl branches and whether a chromatographic peak represented a single component or a mixture of coeluting alkanes. Authentic samples of the *n*-alkanes pentacosane, hexacosane, heptacosane, octacosane, dotriacontane, and tritriacontane were obtained from Sigma Chemical Company, (St. Louis, Missouri) and were used to corroborate GC retention times, mass spectral fragmentation patterns, and the line generated from plotting the logarithms of the isothermal GC retention time versus carbon number for the natural *n*-alkanes. The Kovats indices of the authentic alkanes were the same as those for the natural alkanes, and they agreed with those in the literature (Pomonis and Hakk, 1984). Literature values for the Kovats indices of the 2- and 3-methyl alkanes showed these alkanes to be homologous with 2- and 3-methyl alkanes for which Kovats indices were available in the literature (Pomonis et al., 1980, 1989). GC coinjection of the authentic *n*-alkanes also helped corroborate the identification of the methyl branched alkanes, since it is known that the order of elution for alkane structural isomers is 2-methyl-, 3-methyl-, *n*-alkanes (Nelson, 1977). In all cases, comparison with the authentic samples confirmed the structural assignments given.

Chemical Identification

The structures of all the compounds used in these experiments except the fatty acids (7, 10, 13-hexadecatrienoic, palmitic, and linolenic acids) and the long-chain alkanes are shown in Figure 1.

Chemicals implicated as biologically active include: 2-methyldotriacontane

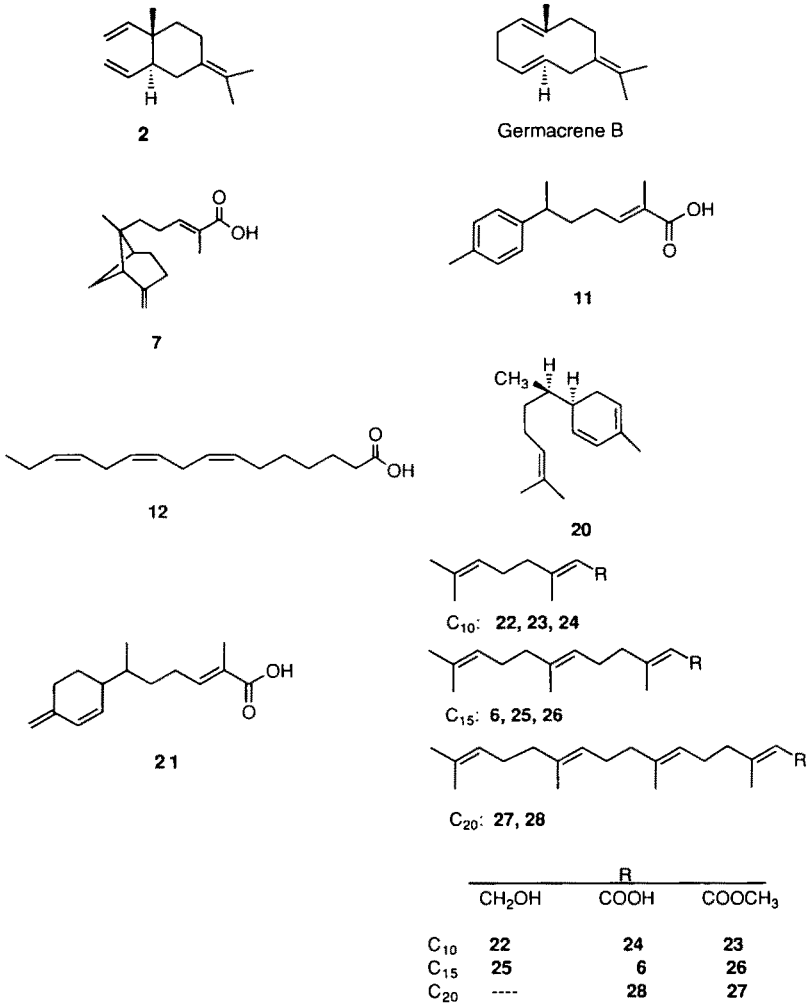

FIG. 1. *Helicoverpa zea* kairomones from Solanaceae species.

(**1**), 3-methylhentriacontane (**3**), *n*-dotriacontane (**4**), 2-methyltriacontane (**5**), 2-methyloctacosane (**9**), *n*-pentacosane (**10**), 3-methylnonacosane (**14**), 2-methylnonacosane (**16**). Wax fractions were separated from the rest of the neutral fraction by flash chromatography on silica gel, as described by Still (1978). The structure of these alkane waxes, as well as several others without apparent biological activity, were determined by the mass spectral methods discussed above. The MS for **1** is consistent with that in Gülz (1968); that for **3** is consistent with the data given in Brown et al. (1990); that for **5** is consistent with data in Pomonis (1989); those for **9** and **14** are consistent with spectra in Coudron and Nelson (1978). Alkanes **4** and **10** were identified by GC-MS comparisons (coelution and MS) with authentic standards (Sigma).

Germacrene B. This sesquiterpene was isolated from the neutral fraction of the hexane extract of *Lycopersicon hirsutum* LA 1557. The hexane extract was washed with aqueous 10% Na_2CO_3 to remove organic acids. Flash chromatography of the neutral fraction on 15% (w/w) silver nitrate silica gel with pure hexane as eluant provided a clear oil, GC analysis of which (at an injector temperature of 210°C) gave only one peak at 8.58 min. The ^1H NMR (400 MHz) spectrum of this oil in C_6D_6 (to avoid acid-catalyzed cyclization) provided a spectrum identical to that in the literature (Clark et al., 1987). ^{13}C NMR analysis gave the following resonances (100 MHz, C_6D_6): 14.26, 16.35, 20.47, 20.80, 22.70, 26.14, 32.87, 34.41, 39.25, 126.82, 127.88, 128.12, 128.42, 128.50, 131.55. GC reanalysis of this oil from LA 1557 with an injector temperature of 325°C, the temperature used for the GC analysis that provided the data for the statistical tests, showed peaks at 7.09 min (33%) and at 8.58 min (67%, germacrene B) with HR-MS obs. 204.1858, calc. for $C_{15}H_{24}$, 204.1878. In the original chromatograms of all the accessions, the occurrence and relative amounts of the chemicals with these two retention times was highly correlated ($R = 0.94$), as they would be if the two compounds were biochemically related or if one were a degradation product of the other. Unfortunately, our regression analysis implicated the earlier retention time, 7.09 min, which we believe to be that for γ-elemene (**2**), the Cope rearrangement product of germacrene B, as that of the biologically active product. This compound has previously been identified by MS and infrared spectroscopy from hexane washes of *Lycopersicon hirsutum* (Weston et al., 1989). We have not yet isolated γ-elemene (**2**) or germacrene B in quantities sufficient for bioassay.

(+)-(E)-endo-β-Bergamotenoic acid (7). The sesquiterpene acid was isolated from the hexane wash of the leaves of *Lycopersicon hirsutum* accession LA 1557 by means of base extraction, esterification, chromatographic fractionation, and saponification as described in Coates et al. (1988).

Palmitic Acid (18). This fatty acid, with HR-MS obs. 256.2411, calc. for $C_{16}H_{32}O_2$, 256.2402, was identified from *Lycopersicon hirsutum* f. *glabratum*

accession PI 126449 by computerized searching of a mass spectrum library, and the identity was confirmed by GC coinjection with an authentic sample (Aldrich) and comparison of its mass spectrum with that from the authentic sample. Samples used for bioassay were from Aldrich (99% purity).

(E,E)-*Farnesoic acid (6).* This compound was isolated by base extraction of the hexane wash from *Lycopersicon hirsutum* f. *glabratum* accession PI 199381, esterification with diazomethane, and subsequent chromatographic fractionation on silica gel and then 20% (w/w) silver nitrate–silica gel to obtain 167 mg of methyl farnesoate (83% purity by GC). HR-MS obs. 236.1771, calc. for $C_{15}H_{24}O_2$, 236.1776. The ^1H NMR shifts of the methyl ester compare closely with those in Kulkarni et al. (1987). The preliminary identification was confirmed by synthesis of methyl farnesoate from farnesol by Corey's method (Corey et al., 1968a,b) and GC coinjection and comparison of ^1H and ^{13}C NMR resonances of the synthesized sample and the methyl ester of **6.** ^{13}C NMR of the methyl ester gave the following shifts (100 MHz, $CDCl_3$): 15.89, 17.56, 18.70, 25.56, 25.83, 26.55, 39.56, 40.83, 50.63, 115.12, 122.75, 124.12, 131.25, 136.02, 160.04, 167.11. Saponification of 45 mg of the ester in 1 ml of absolute ethanol with 0.75 ml of aqueous 2 M KOH gave 20 mg of farnesoic acid (76% total acid purity by GC, with 64% 2*E*,6*E* isomer and 12% 2*Z*,6*E* isomer) for bioassay.

(R)-*2-Methyl-6-(4-methylphenyl)-2-heptanoic Acid (Curcumenoic Acid, 11).* This sesquiterpene acid (HR-MS obs. 232.1461, calc. for $C_{15}H_{20}O_2$, 232.1463) was isolated as its methyl ester from base extraction of the hexane wash of *Lycopersicon hirsutum* f. *glabratum* accession PI 199381. Esterification with diazomethane and subsequent chromatographic fractionation first on silica gel and then on 15% (w/w) silver nitrate–silica kgel gave 51 mg of the methyl ester of **11** (95% purity by GC). Saponification of 26 mg of the methyl ester (95% purity) by the method described above for **6** provided 18 mg of **11** (91% total acid purity, with 83% 2*E* isomer and 8% 2*Z* isomer, and an additional 5% of unreacted acid methyl ester). ^1H NMR of the methyl ester (400 MHz, $CDCl_3$): δ 1.23 (d, J = 7 Hz, 3 H), 1.69 (dt, J = 7.5, 1.8 Hz, 2H), 1.72 (d, J = 0.8 Hz, 3H), 2.04 (q, J = 3.1 Hz, 2H), 2.31 (s, 3H), 2.66 (sextet, J = 7.0 Hz, 1H), 3.71 (s, 3H), 6.73 (dt, J = 7.3 Hz, 1H), 7.08 (m, 4H). ^{13}C NMR (100 MHz, $CDCl_3$): 12.32, 20.96, 22.54, 26.79, 36.92, 39.07, 51.63, 126.80 (two overlapping peaks), 127.42, 129.04 (two overlapping peaks), 135.44, 142.46, 143.63, 168.65. The ^1H NMR data for the ester compare closely to those for (±)-methyl curcumenoate in Alexander and Rao (1968). Stereochemistry was determined by optical rotation (Breeden and Coates, 1994).

(Z,Z,Z)*Hexadeca-7,10,13-trienoic Acid (12).* This acid (HR-MS obs. 250.1932, calc. for $C_{16}H_{26}O_2$, 250.1933) was isolated as a mixture of its methyl ester with the methyl ester of linolenic acid. Base extraction of the hexane wash

of *Lycopersicon hirsutum* f. *glabratum* accession PI 199381, esterification with diazomethane, and subsequent flash chromatographic fractionation on silica gel and then on 15% (w/w) silver nitrate–silica gel afforded an oil that was 25% of the methyl ester of **12** and 75% of the methyl ester of linolenic acid (**19**), whose identification is discussed below. Further flash chromatography provided no further separation of the two compounds. The MS for **12** proved to be analogous to that for authentic linolenic acid (Sigma), with similar patterns of fragmentation and base peaks, except the mass peaks for **12** were consistently 28 atomic mass units fewer than those for linolenic acid. The ^{1}H NMR spectrum of the mixture of acid esters is identical to that for 96% pure linolenic acid methyl ester in location of shifts, peak size, and peak shape. ^{1}H NMR spectral values agree well with those predicted by the rules given in Frost and Barzilay (1971) and rule out *trans* or conjugated double bonds.

Some compounds were not implicated by the regression analysis as biologically active.

Linolenic Acid (19). This fatty acid, MS molecular weight 278, was identified by GC coinjection with authentic sample (Sigma). MS for the authentic sample and the sample from *Lycopersicon hirsutum* accession LA 1557 were identical. Samples used for bioassay were from Sigma (98% purity). ^{1}H NMR spectral values agree well with those predicted by the rules given in Frost and Barzilay (1971).

7-Epizingiberene (20). This sesquiterpene hydrocarbon (HR-MS obs. 204.1872, calc. for $C_{15}H_{24}$, 204.1878) has not been previously reported in the literature in this stereochemical form. It was isolated by flash chromatography of the neutral fraction of the *Lycopersicon hirsutum* f. *glabratum* accession PI 199381 hexane leaf wash. The regression analysis did not implicate it as stimulating oviposition. A full account of its isolation and identification is available in Breeden and Coates (1994).

Kairomone Oviposition Bioassays

Oviposition assays were conducted as described above, except that hexane solutions of the putative kairomones (concentrations of these solutions are described below) were used instead of crude plant extracts. The amounts of the kairomones to be tested were determined by comparison of their GC peak areas with that for β-bergamotenoic acid. For each of the naturally occurring compounds, the concentration on the leaf surface was determined by comparison of the area under the GC peak for that compound with that for β-bergamotenoic acid, for which a standardized amount per square centimeter of leaf area had already been determined (0.48 mg/cm^2) (Douglass et al., 1993). Compounds that were not isolated from the plants were applied on an equimolar basis (2.1

$\mu M/cm^2$) with the naturally occurring concentration of β-bergamotenoic acid (**7**).

Bioassay 1 tested straight-chain acids having chain length of 6 and between 8 and 18 carbons and was conducted to ascertain the relationship between the size of the acid molecule and moth oviposition chemoreceptor. The amounts tested were equimolar to **7** and were 4.31 mg/disk for octanoic acid, 4.72 mg/disk for nonanoic acid, 5.14 mg/disk for decanoic acid, 5.56 mg/disk for undecanoic acid, 5.98 mg/disk for dodecanoic acid, 6.40 mg/disk for tridecanoic acid, 6.82 mg/disk for tetradecanoic acid, 7.24 mg/disk for pentadecanoic acid, 7.65 mg/disk for hexadecanoic acid, and 8.49 mg/disk for octadecanoic acid.

Bioassay 2 tested the moths' response to the alkane wax fractions from several *Lycopersicon* accessions, in order to address the role of these compounds in *H. zea* oviposition. The amount (milligrams per square centimeter) of alkanes naturally occurring on the leaves was calculated, and because these concentrations were low, twice this amount was applied to the disks for bioassay. The alkane fractions were separated from the rest of the neutral fraction of each accession and suspended in hexane. For LA 1374, this was 0.30 mg/disk of total alkane fraction; for LA 1557, 3.96 mg/disk; for PI 126449, 3.47 mg/disk; for PI 365906, 2.85 mg/disk; for PI 365907, 0.75 mg/disk; for PI 365908, 0.66 mg/disk; for PI 390514, 0.58 mg/disk; and for PI 199381, 0.54 mg/disk.

Bioassay 3 tested the organic acid kairomones whose GC retention times had been implicated as biologically active. For this bioassay, the naturally occurring concentrations of each acid on the leaf surface (milligrams per square centimeter) were determined by comparison of the standardized GC peak area for that acid with the standardized GC peak area for β-bergamotenoic acid, whose leaf surface concentration was known. These amounts were then multiplied by the size of the disk, and then corrected for purity (as determined by GC). This amounted to 0.214 mg/disk for **12,** 1.46 mg/disk for **11,** 2.78 mg/disk for **6,** 0.12 mg/disk for **18,** 7.0 mg/disk for **7,** and 1.43 mg/disk for **19.** Because **12** was not chromatographically separable from **19,** a mixture of 75% **19** and 25% **12** was used, with the applied concentration of **12** being 0.214 mg/disk.

RESULTS

Accession Oviposition and Larval Orientation. GC data were compared with oviposition and larval preferences in order to show that the compounds played a role in stimulating oviposition and in larval preference. Analysis of variance revealed highly significant differences among the extracts for oviposition stimulation ($F = 5.40$, $P < 0.0001$ for 1988; $F = 7.71$, $P < 0.0001$ for

1989) and larval orientation preference ($F = 4.89$, $P < 0.0001$). The range of oviposition values for accessions from each of the species assayed is listed in Table 1. A complete list of these values for all accessions and chromatographic peak data is available upon written request to the corresponding author. The wide range of responses to the extracts suggested that certain plant species may be preferred over others in part because of their leaf surface constituents. These results indicated that extracts from members of the *Lycopersicon* and *Nicotiana* species had the greatest oviposition stimulation, that *Glycine max* had a strong stimulatory effect, and that other species, such as those of the genus *Gossypium*, had some stimulatory effect. This is in agreement with the work of Johnson et al. (1986), who reported a decreasing order of preference with corn > tobacco > soybeans > cotton for *H. zea* oviposition. In particular, wild tomato species had a strong stimulatory effect with six of the top 12 highest extract oviposition preference values.

Identification of Kairomones. Putative kairomones were implicated by the initial correlations, and then multiple regression was performed on a subset of the data, in order to select compounds for chemical isolation, purification, and identification. Table 2 lists the compounds suggested as biologically active, as well as the empirical formulas for those compounds, the number of accessions that had a compound with the same retention time, and the R^2 and P values for the correlations between standardized peak area of each putatively active component and oviposition or larval orientation values. The empirical formulas indicated that all the stimulatory compounds fell into the following chemical classes in order of their GC retention times: sesquiterpene hydrocarbons (**2**), sesquiterpene acids (**6, 7, 11**), fatty acids (**12, 18**), and long-chain alkanes (**1, 3, 4, 5, 9, 10, 14, 16**). Four of the compounds (**8, 13, 15, 17**) were not present in sufficient quantities to allow us to perform GC-MS on them, so no chemical data are available and they are listed as unknowns.

Simple correlations of moth oviposition preferences with larval orientation for 156 of the accessions planted in 1988 gave no correlation ($r = -0.09$, $P = 0.27$), which suggested that the compounds that stimulate oviposition for the moths did not influence orientation by the larvae. This may have been due to the reduced importance of chemoreception for larval feeding selection or, more likely, the fact that the larval chemoreceptors are sensitive to compounds found inside the leaf rather than those found only on the surface. An evolutionary scenario that might explain this is that the moths' chemoreceptors have been selected so as to be sensitive to compounds on the leaf surface that alert the moth to the presence of healthy, robust host plants on which to oviposit. In contrast, larval chemoreceptors more likely have evolved to be sensitive to compounds encountered during feeding.

Previous studies help to provide support for our results since the statistical analysis picked out compound **7**, which we know to be β-bergamotenoic acid

TABLE 2. EMPIRICAL FORMULAS, ABUNDANCE, AND STATISTICAL SIGNIFICANCE OF BIOLOGICAL ACTIVITY OF *Helicoverpa zea* MOTH AND LARVAL KAIROMONES

Biological activity[a]	Compound number	Compound name	Empirical formula	Number of accessions[b]	Simple regression	
					R^2 value	P value
Moth oviposition 1988	1	2-Methyldotriacontane	$C_{33}H_{68}$	66	0.1551	0.0008

[a] Biological activity indicates the type of activity with which the compound was associated. Because the GC retention times for 1988 and 1989 were incompatible, statistical correlations were run separately for each year.

[b] The number of accessions listed is the number of accessions that had a GC peak at the retention time for that compound, out of 226 total accessions tested in 1988 and 96 accessions tested in 1989.

(Coates et al., 1988; Juvik et al., 1988), from the 310 compounds present in the accessions tested in 1988. That this stimulatory compound, present in only eight accessions, was implicated as active by the regression analysis validates this procedure. All of the compounds implicated by our regressions as having biological activity were later observed in their isolated forms to confer *H. zea* oviposition stimulation. Other compounds not quantitatively associated with oviposition preference in our observations (e.g., palmitic and linolenic acids, **18** and **19**; see Table 4 below) were inactive when later isolated and bioassayed.

The empirical formulas of the compounds associated with biological activity suggested that only five of the 18 chemicals so implicated are organic acids. The acids may have played a more specialized role in stimulating oviposition than previously reported. Most of the active compounds were saturated long chain alkanes. Eight of the 18 compounds contributing to the R^2 value for 1988 oviposition equations were alkanes. The differences in structure and electron densities between long-chain alkanes and organic acids further suggested that at least two different sets of receptors that mediate oviposition response may exist in *H. zea*, since the shape and electronic properties of these two classes would likely produce distinct interactions with the receptors (Moncrieff, 1967). The empirical formula of the remaining compound suggests that it is a sesquiterpene alkene. This may represent a third chemical class of oviposition stimulants for *H. zea*.

TABLE 3. *Helicoverpa zea* OVIPOSITION PREFERENCES FOR ALKANE WAX FRACTIONS FROM *Lycopersicon hirsutum* ACCESSIONS

Accession name	Amount applied (mg)[a]	Oviposition preference[b]
Hexane control	0.0	0.965a
Lycopersicon hirsutum, LA 1374	0.30	1.002a

Lycopersicon hirsutum, LA 1557	3.96	2.408d

[a]The amount applied is twice the naturally occurring concentration.

[b]Oviposition preferences were calculated by dividing the number of eggs on the disk on a given day by the mean number of eggs on two adjacent untreated disks and are reported as means over three days and four replications. Means followed by dissimilar letters are significantly different at $P = 0.05$ using Fisher's protected LSD test.

The results of bioassay 2 are given in Table 3 and indicated significant ($P < 0.05$) differences among oviposition preferences for the alkane wax fractions of the accessions listed. These differences may be explained largely as a function of overall alkane concentration, because regression of the summed peak areas of the alkanes against the oviposition preference values for each accession yielded an r value of 0.86, with $P = 0.001$. Six alkanes of the 13 analyzed by multiple regression were identified as significantly contributing to the model R^2 value, and these accounted for 100% of the variation in the model. When these vari-

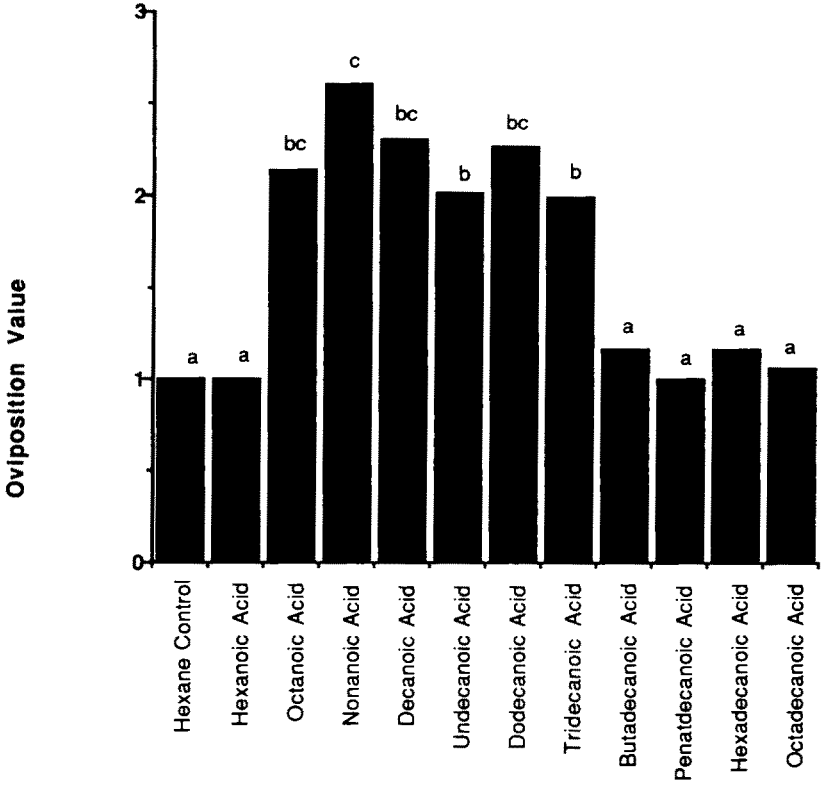

FIG. 2. *Helicoverpa zea* preference values, as a function of chain length of aliphatic organic acids. Acids were applied in equimolar amounts. Oviposition preference values were calculated by dividing the number of eggs on a treated disk by the mean number of eggs on two adjacent untreated disks and are reported as means over two days and four replicates. Dissimilar letters indicate significant differences between means, using Fisher's protected LSD test ($P = 0.05$).

ables were removed and multiple regression was rerun on the remaining waxes, the remaining seven variables still accounted for 90% of the total variation. This suggested that the moths do not discriminate between individual alkanes and that most or all of the alkanes stimulated oviposition to some extent. Moth perception of the waxes may be a response to the physical texture of the epicuticular surface elicited by tarsal mechanoreceptors in contrast to chemical reception.

The results of the aliphatic acid oviposition bioassay (bioassay 1), presented in Figure 2, showed significant ($P < 0.05$) differences among the acids tested. Only acids with greater than seven and fewer than 14 carbons significantly stimulated oviposition. Douglas et al. (1993) also reported that heptanoic and octanoic acids significantly stimulated *H. zea* oviposition while hexanoate did not. This is in agreement with the hypothesis that the shape of the molecule determined the ability of the kairomone to bind to the receptor, as those beyond a certain length did not stimulate oviposition, nor did those with fewer than seven carbons. It further helped to confirm our suggestion that the moth responded more to the acid side chain of β-bergamotenoic acid than to the bicyclic ring (Douglass et al., 1993).

The results of bioassay 3 of six naturally occurring acids, of which four had been implicated as stimulating oviposition (**12, 11, 7, 6**), are given in Table 4. All four of the acids that had been implicated as stimulating oviposition were significantly active. Neither linolenic (**19**) nor palmitic acid (**18**), which were present in many of the extracts analyzed, but not implicated as active by regression analyses, was found to stimulate oviposition. These results again validated

TABLE 4. *Helicoverpa zea* OVIPOSITION PREFERENCES FOR KAIROMONAL ACIDS ISOLATED FROM *Solanaceae* SPECIES

Compound name	Compound number	Amount applied (mg)	Oviposition preference[a]
Hexane control	—	0.0	0.972a
Palmitic acid	18	0.12	1.092a
Linolenic acid	19	1.43	2.030ab
Hexadecatrienoic acid	12	0.214	2.590bc
Curcumenoic acid	11	1.46	3.205c
β-Bergamotenoic acid	7	7.00	9.788d
Farnesoic acid	6	2.78	12.802d

[a]Oviposition preferences were calculated by dividing the number of eggs on the disk on a given day by the mean of the number of eggs on the two adjacent untreated disks and are reported as means over three days and four replications. Means followed by dissimilar letters are significantly different at $P = 0.01$ using Fisher's protected LSD test.

the regression procedure for correctly implicating compounds that contribute to oviposition stimulation, since compounds that were present in only a very few accessions, like farnesoic acid (**6,** four accessions), and curcumenoic acid (**11,** 11 accessions), were implicated. The statistical technique also implicated stimulatory compounds that were present in only very small quantities, such as 7,10,13-hexadecatrienoic acid, which was found in 82% of the accessions tested in 1989, but accounted for (on average) only 2.0% of the total peak area from the chromatograms of the extracts.

DISCUSSION

None of the compounds in the extracts was observed to be associated with reduced oviposition. This lack of moth repellents/oviposition deterrents from any of the tested accessions suggests that *H. zea*'s perception of host-plant chemical cues only elicit positive ovipositional responses. This is in keeping with the species' polyphagous nature and reproductive strategy. It would also allow for ovipositional "mistakes" that would diversify *H. zea*'s host range, provide the opportunity to adapt to agricultural monocultures, and potentially result in subspeciation.

That kairomones and allomones influence insect behavior is well established in the literature (Juniper and Southwood, 1986; Rosenthal and Berenbaum, 1991), and evidence suggests that these chemicals influence behavior through their interaction with specifically shaped protein-based chemoreceptors (Moncrieff, 1967; Evershed, 1988). A molecule of the appropriate size and shape with charge densities in the appropriate orientation will interact with the chemoreceptor and elicit a neurochemical response, whereas other molecules will not. Slight modification of the molecular structure of a stimulant may abolish its biological activity entirely, as in the case of *Bactrocera dorsalis* (Metcalf et al., 1979, 1981, 1983). Stimulation of feeding by *B. dorsalis* was reported by Metcalf et al. (1981) to be associated with hydrophobicity and the location of electron rich areas in various compounds that they synthesized and bioassayed.

Douglass et al. (1993) tested various bicyclic and acyclic analogs of β-bergamotenoic acid on *H. zea* oviposition preference. They proposed that the hydrogen bonding between the $-$OH functionality of the carboxylic acid group and the chemoreceptor plays a crucial role in biological activity, because while cyclic and acyclic acids stimulated oviposition, esters, alkenes, and acetates did not. They also found that modifying β-bergamotenoic acid by reducing the side-chain double bond (thereby allowing free rotation of the acid group) increased the oviposition response as well.

Straight-chain acids have been reported to be ubiquitous (Kolattukudy,

1969; Tulloch, 1976), and the oviposition activity of these acids may help to explain the evolutionary significance of the relationship between *H. zea* and β-bergamotenoic acid. Because β-bergamotenoic acid is so rare (present in only eight accessions), it seems odd that it would be a primary stimulant for a moth with as wide a host range as *H. zea*. If, however, as Douglass et al. suggest, the stimulatory power of this rare acid developed as a coincidence of the stimulatory power of the much more common aliphatic acids, then the evolutionary picture is clearer.

If the compounds identified in this paper as long-chain alkane waxes play a role in oviposition stimulation, this may help explain the polyphagy of *H. zea*, as these compounds are ubiquitous (Kolattukudy et al., 1976). Epicuticular waxes have been shown to stimulate oviposition in several insect species (See review by Eigenbrode and Espelie, 1995). These compounds serve the plant by performing such functions as water repellency and retention, frost resistance, transpiration regulation, etc. (Tulloch, 1976; Jeffree, 1986). Alkane waxes would be ideal host indicators for phytophagous insects, because compounds as important as these to the plants' biology would likely not be selected against in the course of evolution, regardless of their kairomonal properties for host species. Thus, the cycle of selection and adaptation described by Ehrlich and Raven (1964), in which the evolutionary advantage and opportunity for speciation switch from the insect to host species and back again, would be circumvented because of the advantage conferred by the alkanes regardless of their stimulatory role in *H. zea* oviposition.

Alkane waxes serve a number of roles in the ecology of *H. zea*. In addition to the biological functions mentioned above, Hendry et al. (1976) reported that four *n*-alkanes, which serve as kairomones for the *H. zea* parasite *Trichogramma evanescens*, constituted the major portion of the surface lipids of *Zea mays*, a host plant for *H. zea*. The incorporation of alkanes endogenous to plants into the cuticular lipids of insects feeding on the plants has been demonstrated (Espelie and Bernays, 1989; Blomquist and Jackson, 1973). If the alkanes from *Zea mays* are incorporated directly into *H. zea* from the plant source, rather than synthesized de novo or chemically modified after consumption, then, while they serve as kairomones for *T. evanescens*, they may also serve as allomones for the plant by attracting parasites of *H. zea*. Together, these reports suggest that alkanes may play a more significant role in the ecology of *H. zea* than might have been anticipated for such seemingly structurally simple compounds.

The activity of these alkanes is likely an adaptive response by the moth to plant leaf chemistry. The alkanes may serve as a nonspecific cue for living plants. The next step in *H. zea* host differentiation could then have been the evolution of moth perception of compounds with the acid moiety. The stimulatory power of these acids may represent an evolutionary event associated with

the speciation of *H. zea*, since oviposition by *H. virescens*, a sibling species, is stimulated by the long-chain alkanes but not by the acid compounds (Juvik, unpublished data). The structural dissimilarities between these two classes of compounds suggest that at least two distinct reception systems (one possibly mechanical and the other chemical) stimulate oviposition behavior in *H. zea*. The evolution of the acid chemoreceptor and its influence on host plant selection may have been associated with the phylogenetic divergence of *H. zea* and *H. virescens*.

Similarly, the results of the acid bioassays may help to explain *H. zea*'s polyphagy. Although the terpene acids are taxonomically restricted in the plant kingdom, the data indicate that the acid functionality of more common aliphatic acids (Kolattukudy et al., 1976) may also serve as stimulants. While the data in Tables 2 and 4 and in Figure 2 indicate that acids of the proper chain length stimulate oviposition, other functional groups [such as the side-chain methyl groups and sites of unsaturation in farnesoic acid (**6**)] also play a role. This sesquiterpene acid (**6**), even though present at only one third the molar concentration of β-bergamotenoic acid, was more stimulatory for *H. zea* oviposition activity. We propose that the active acids are stimulating the same receptor system, with the differences explicable on the basis of other functionalities among the molecules. The role of these other functionalities is also made evident by the slight stimulatory activity of 7,10,13-hexadecatrienoic acid, which has a chain length of 16 carbons and stimulated activity, while the saturated C_{16} palmitic acid did not. It is not clear from these assays whether this increased activity is attributable to the ability of the electron densities in the unsaturated acids to interact with chemoreceptors or to the fact that the *cis* double bonds in 7,10,13-hexadecatrienoic acid shorten the total length of the molecule such that it is more structurally compatible with the receptor. Molecular modeling could be used to determine whether the sites of unsaturation significantly shorten the molecule.

The sesquiterpene acids are also implicated in other ecological relationships. β-Bergamotenoic acid (**7**) has been implicated as an allelopathic compound, inhibiting seed germination and root formation in a number of different species, including Grand Rapids lettuce, purslane, wild mustard, and cultivated tomato (Bish et al., 1993). Thus, while this acid stimulates *H. zea* oviposition, it is evolutionarily advantageous in its allelopathic abilities. Similarly, curcumenoic acid (**11**), β-bergamotenoic acid (**7**), farnesoic acid (**6**), and γ-elemene (**2**), which strongly stimulate *H. zea* to oviposit, have also been reported as deterrents to the spider mite (*Tetranychus urtichae*), a pest of tomatoes (St. Pyrek et al., 1991; Weston et al., 1989; Guo et al., 1993). In addition, St. Pyrek and Snyder have shown that 2,3-dihydrofarnesoic acid and zingiberenoic acid confer resistance to *T. urtichae* (Snyder et al., 1993), and we have tenta-

tively identified both from the extract of *L. hirsutum* f. *glabratum* PI 199381 by MS and HR-MS. The allomonal properties of these compounds may also provide an evolutionary explanation for the production of these acids.

The identification and confirmation of the biological activity of these compounds may be useful both in pest management programs and more broadly in chemical ecology. As detailed in Metcalf (1985), there are a number of pest-control strategies that are connected with identification of kairomonal allelochemicals, including trapping for the purposes of population monitoring, removal trapping, and behavior disruption, as has been done for *Dacus cucurbitae* (Metcalf, 1985). Similarly, genetic manipulation could be used in the case of some of the sesquiterpenoic compounds, if not the alkanes, to produce plants without these cues and to induce antixenosis. Conversely, the cues could be bred into commercially less valuable crops for the purposes of providing a decoy to lure *H. zea* away from the protected crops, as has been successfully done by using *Curcubita ecuadorensis* as a trap for *Diabrotica speciosa* (Metcalf, 1985). These examples suggest that environmentally friendly agricultural practices that arise from ecological research may be viable on the scale needed for commercial production.

Acknowledgments—The authors thank Nancy Juvik for her assistance with the insect bioassays. C. S. Elmore and M. A. Klobus for their assistance with the ^{1}H and ^{13}C NMR spectra, R. Milberg of the University of Illinois Mass Spectrometry Lab for his assistance with the mass spectrometry, and Mike Woods and the staff of the Social Sciences Quantitative Laboratory for their assistance with the statistical procedures. This research was funded in part with a grant from the National Institutes of Health (GM 13956 to R. M. C.), Illinois Agricultural Experiment Station Hatch Project 65-0348 (J. A. J.), and a Fellowship grant from the Program for the Study of Cultural Values and Ethics, at the University of Illinois (to D. C. B.).

(Received July 25, 1994; accepted November 9, 1995)

Abstract—*Diglyphus isaea* Walker is a larval ectoparasitoid used in biological pest control against the American serpentine leaf miner *Liriomyza trifolii* Burgess. We studied the parasitoid's host searching behavior, using olfactometric methods. Our data show that the parasitoids locate host larvae (a leaf-mining dipteran) on the basis of volatile signals released by the plant-host complex. Female *D. isaea* are strongly attracted to the odors arising from damaged bean plants, whereas they show practically no response to intact plants. The results of our chemical analyses showed that about 15 components were present, two of which, *cis*-3-hexen-1-ol and 4-hydroxy-4-methyl-2-pentanone, were present in significantly larger quantities in the leaf extracts from mined or damaged bean plants than in those from healthy plants. The damage inflicted by the host larvae on these plants triggers the release of larger amounts of these substances, which probably lead the parasites to their hosts. The compounds thus act as synomones.

Key Words—Parasites, volatile signals, synomone, host detection, Hymenoptera, Eulophidae, *Diglyphus isaea*.

INTRODUCTION

Chemical signals play an important role in the interactions between plants, phytophagous insects, and the latter's natural enemies. When searching for their hosts, numerous entomophagous parasitoids rely on volatile chemical stimuli

*To whom correspondence should be addressed.

arising from their host's natural habitat (Vinson, 1975, 1981; Weseloh, 1981; Van Alphen and Vet, 1986). Once the host's habitat has been located, the parasitoids have to find the hosts themselves. For this to be possible, the parasitoids have to be able to detect their hosts from a distance and to orient their movements in response to stimuli produced or induced by the host larvae or by their activity on the plant (Weseloh, 1981). The natural enemies of several phytophagous insects are strongly attracted by volatile compounds released by the host plants when they are damaged (Drost et al., 1988; Dicke et al., 1990; Turlings et al., 1990, 1991). The components of the plant–host complex may originate from either the plant, the host insect, or from the latter's feces or saliva (Vinson, 1976; Kennedy, 1984; Mudd et al., 1984; Takabayashi and Takahashi, 1989).

In order to understand insect behavior involving chemical communications, it is necessary to determine the nature of the signals arising from the insect's natural environment, that play an important role in their intra- and interspecies relationships. Chemical signals are known to play a role in *Dacnusa sibirica* (Dicke and Minkenberg, 1991) and in *Opius dissitus* (Petitt et al., 1992). In the present study, we analyzed the chemical stimuli used by the entomophagous parasitoid, *Diglyphus isaea* Walker (family Eulophidae). *D. isaea* is used in biological control of agromyzid leaf miners in greenhouses (Lyon, 1986; Nedstam et al., 1987; Van Lenteren and Woets, 1988). The ectoparasitoid uses several leaf miners as its hosts, especially *Liriomyza trifolii*, a pest that inflicts considerable damage on greenhouse vegetable and flower crops. Female parasitoids oviposit in the last larval stages of *L. trifolii* (Minkenberg and Van Lenteren, 1987).

More specifically, the aim of the study was to investigate whether *D. isaea* uses volatile chemicals to locate its hosts, and if so, to determine which of the chemical signals emitted by the plants, the agromyzid larva, and larval secretions (saliva, feces) influence the behavior of the parasitoids.

METHODS AND MATERIALS

Insects. The parasitoids used in these experiments were from a permanent rearing station set up by the INRA at Antibes, using the "alternate open field rearing and caged ovipositing" method (Lyon, 1976).

Plants. Bean plants (*Phaseolus vulgaris*) were grown in a nursery garden and were harvested at the cotyledon stage.

Behavioral Analyses. Behavioral observations were conducted with 2-day-old female *D. isaea* in their rearing cages (50 × 50 × 60 cm). For each experiment, two bean plants, each in its own pot, were provided; one plant contained only two healthy leaves and the other, two leaves mined by stage 2

(L2) larvae. Five female parasitoids were used in each test and 15 replications were conducted. Parasitoid visits to each of the two kinds of leaves were counted during a period of 20 min. Tests were carried out at 25°C and 50% relative humidity.

The Olfactometer. The linear olfactometer was a combination between the olfactometer designed by Leconte and Thibout (1981) and that described by Zagatti (1985). It was 30 cm in length, 2 cm in diameter, and was divided into compartments numbered 0–5 through which pure (control) air and air containing the odor to be tested were pushed alternately for 4 min. The device was placed between two neon-shelving (upper tube: 60 W, lower tube: 2 × 60 W). The parasitoids were classified as weakly attracted, moderately attracted, or strongly attracted depending on where they were located in the olfactometer. Five 2-day-old mated female parasitoids were placed in compartment 0 at the beginning of each test. All the tests were carried out at 25°C with 50% relative humidity. Circulating air (10 cm/sec) was filtered through an active charcoal disk and then through a tube containing fibreglass wool.

The odor streams were delivered as follows: for each test, 2 μl of the extract was placed on a 2-cm^2 filter paper dish and when the solvent had completely evaporated, the filter paper was placed in the olfactometer and swept by a stream of humidified air. The control airstreams were passed over a similar Whatman paper filter treated only with solvent.

Linear Olfactometer Data Processing. The number of females in each compartment was recorded every 30 sec, and 16 replications were conducted. These data were used to calculate the relative attraction indices as described by Zagatti (1985).

$$\frac{\sum_{i=0}^{5} in_{it} - \sum_{i=0}^{5} in_{i0}}{\sum_{i=0}^{5} (5 - i)n_{i0}} \times 100$$

where i is the number of compartments in the olfactometer (from 0 to 5), n_{it} is the number of insects in the compartment i at time t, and n_{i0} is the number of insects in the compartment i at $t = 0$. The results were analyzed statistically with the Mann-Whitney test.

Collecting and Analyzing Volatile Substances. A cold-trapping method was used to collect the odors arising from healthy beans, beans infested by stage two larvae, and beans that had been mechanically damaged by cutting the leaves with a razor blade. A steady flow (500 ml/min) of purified air was circulated through a closed 2-liters experimental chamber containing 25 leaves during 20 min. The molecules emitted were trapped on the walls of a capillary tube (10 cm × 0.2 mm) that was embedded in dry ice at −80°C. The trapped odors

were eluted with 300 ml of dichloromethane. The extract was then concentrated to obtain 50 μl and used in behavioral tests in the olfactometer and for chemical analyses. Samples were analyzed with a gas chromatograph, a Delsi 330 apparatus, equipped with a flame ionization detector and a Supelcowax 10 polar capillary column (30 m $\times$ 0.32 mm, 0.25-μm film thickness). The split/splitless injector was kept in the splitless mode for 15 sec after the injection. The carrier gas was helium at a pressure of 1 bar. The temperature program was isothermal at 30°C for 10 min and then increased in 5°C/min steps to 220°C. The data were captured and processed by a Chromatopac C-R4AX Shimadzu integrator. The results were quantified by introducing a solution containing two internal standards: 375 ng of *n*-dodecane and 400 ng of octanol.

Leaf extracts were obtained by soaking about 50 previously weighed leaves in 200 ml of dichloromethane for 24 hr. The extract was then filtered and concentrated in a nitrogen atmosphere. GC analyses confirmed that these samples contained the same substances as those obtained with the air-entrainment trapping method, but in higher concentrations. For identification of components, it was decided, therefore, to soak the leaves and to use gas chromatography coupled to mass spectrometry (GC-MS). The equipment consisted of a Hewlett-Packard 5890 Series II GC equipped with a single Supelcowax 10 polar column (30 m $\times$ 0.32 mm, with 0.25-μm film thickness), connected to a Hewlett-Packard 5989A MS Engine (EI, 70 eV). The apparatus was controlled by an MS Chemsystem HPUX multitask data processor using the Unix system. Helium at a pressure of 2 bars was used as the carrier gas. The GC oven temperature was maintained at 30°C for 5 min before being increased in 5°C/min steps to 210°C, and maintained for 10 min. The temperature was 240°C at the source, 250°C at the interface, and 100°C at the quadrupole. The masses were swept at 35–300 mass units at a rate of one scan per second. A standard range of *n*-alkanes from *n*-C_{12} to *n*-C_{20} was coinjected, and comparisons with the Wiley 138 library of reference spectra aided in identification of the main compounds present.

RESULTS

Behavioral Data. In the experimental cage, *D. isaea* made more frequent visits (Table 1) to mined leaves (43 visits) than to intact leaves (15 visits, $Z = 1.3 \times 10^{-4}$, $P < 0.001$). The parasitoid therefore appeared capable of distinguishing between the two categories of leaves. The mined leaves had yellowish tunnels that were clearly visible at the surface, each containing one larva. It is possible that the parasitoids located the mines through visual cues. In any case, the results of this test show that *D. isaea* are able to distinguish between healthy leaves and those containing a host larva.

TABLE 1. BEHAVIOR OF *Diglyphus isaea* RELEASED IN CAGE CONTAINING UNDAMAGED AND DAMAGED BEANS[a]

	Number of visits/20 min trial
Mined leaves	4 1 3 3 3 3 1 2 2 2 3 4 4 4 4 =43
Healthy leaves	1 2 0 1 0 2 1 1 1 0 1 3 1 0 1 =15

[a]The results from 15 replications were compared using the Mann-Whitney test. ($Z = -3.82$; $P < 0.001$).

The results of the linear olfactometer tests on female parasitoids exposed to trapped odors of healthy plant leaves are given in Figure 1. During the first 3 min, the females reacted very little to the trapped volatile substances originating from a healthy bean plant. The relative attraction indices (RAI) were low (5.6, 6.9, 7.4, 9.9, 9.5). Female parasitoids nevertheless showed a characteristic behavior in which they positioned themselves facing the oncoming flow of odor-

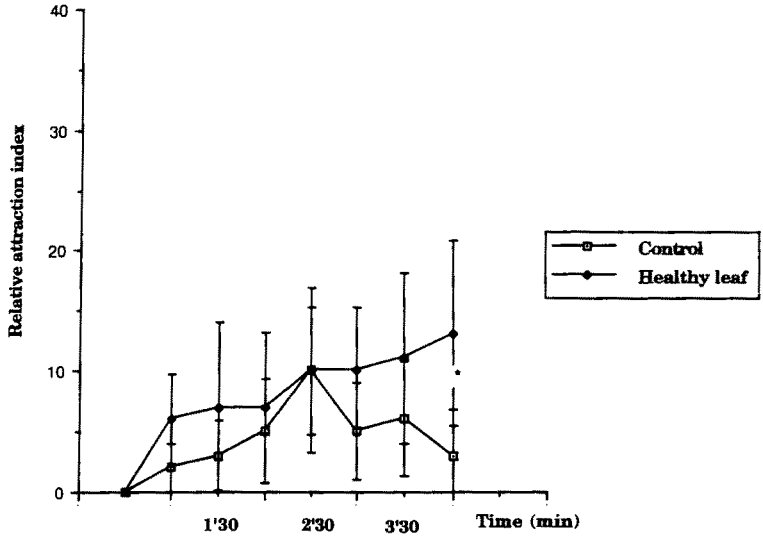

FIG. 1. Bioassay of healthy bean plant leaves and the control (pure air) stimulus for attraction of parasitoid females. There were 16 replications involving five females in each replication. Statistical analysis: Mann-Whitney test, $*P < 0.05$.

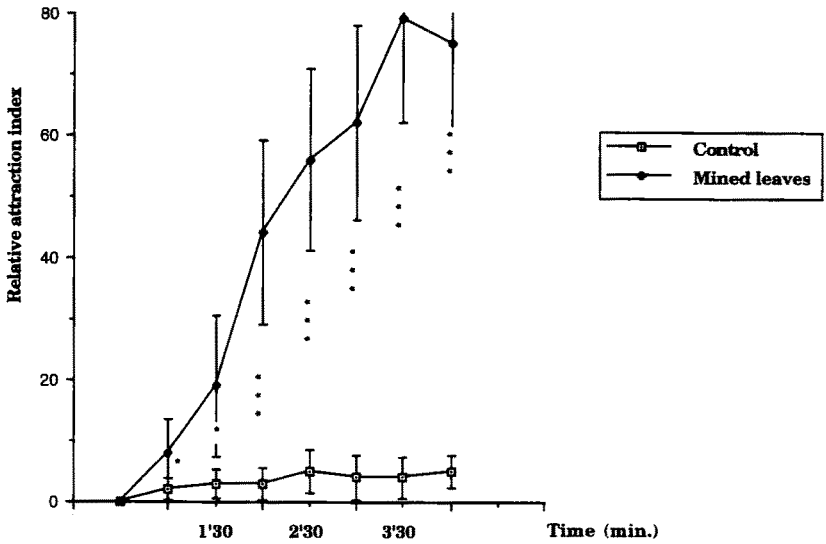

FIG. 2. Movement of five parasitoid females (16 replications) towards extracts of mined bean plant leaves compared with the control stimulus (pure air). Statistical analysis: Mann-Whitney test, $*P < 0.05$; $***P < 0.001$.

impregnated air with their antennae extended, and then made a series of antennal movements before advancing against the airstream. A significant difference was found to exist 4 min after the beginning of the experiments ($t + 4$ min) between the RAI indices obtained with impregnated and pure air at the 5% significance level ($Z = 0.25$) (RAI = 13.4 vs. RAI = 3.1 under control conditions).

In response to the airstream carrying trapped volatile substances extracted from bean plants infested with stage 2 larvae, female parasitoids oriented much more quickly towards the oncoming airstream (Figure 2). The RAI increased much more quickly, from 7.6 after 1 min to 61.7 after 3 min, and reached 75.5 by the last minute of observation. Females actively worked their way up against the odor-laden stream of air, frequently contracting their abdomen. This behavior is typical of females moving towards a mined area. As early as 1 min after the beginning of the test, the differences between the control test and the tests with extracts were significant at the 5% threshold level ($Z = 0.014$), and shortly afterwards, they became significant at the 1% level ($Z = 1.8 \times 10^{-6}$ at the fourth minute of the test).

Figure 3 gives the comparative data on movements of the female parasitoid towards healthy versus mined bean plants. These females also responded to the airstream carrying the trapped odor of mechanically damaged leaves (Figure 4).

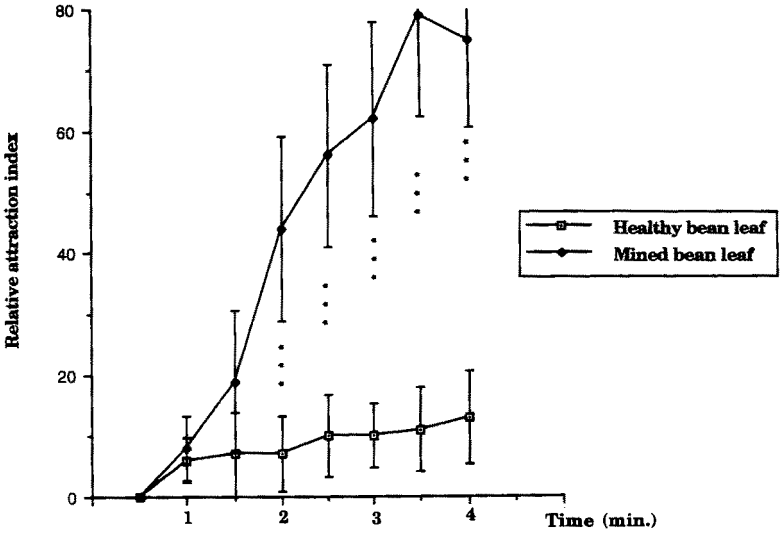

FIG. 3. Movement of parasitoid females (5 females, 16 replications) towards extracts of healthy bean leaves compared with mined bean leaves. Statistical analysis: Mann-Whitney test, $***P < 0.001$.

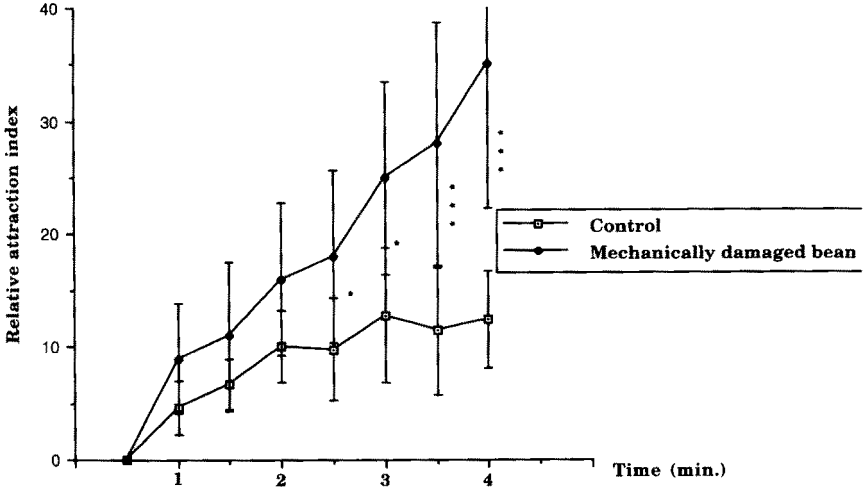

FIG. 4. Attraction of parasitoid females (5 females, 16 replications) by extracts of mechanically slashed bean plant leaves compared with the control stimulus (pure air). Statistical analysis: Mann-Whitney test, $*P < 0.05$; $***P < 0.001$.

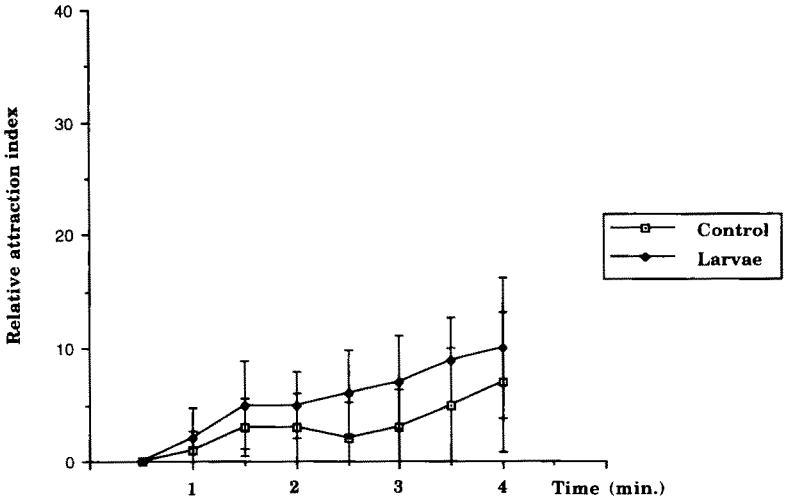

FIG. 5. Movement of parasitoid females (5 females, 16 replications) towards leaf miner larvae previously fed with bean plant leaves. Statistical analysis: Mann-Whitney test, not significant.

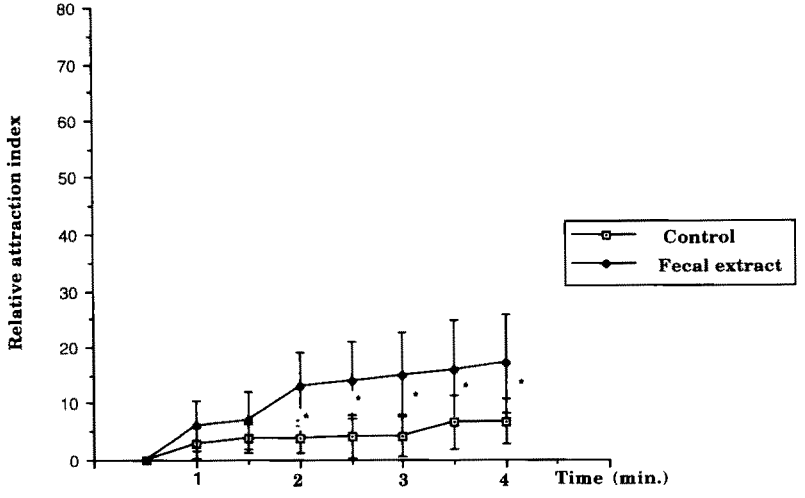

FIG. 6. Movement of parasitoid females (5 females, 16 replications) towards fecal extracts of leaf miner larvae compared with the control stimulus (pure air). Statistical analysis: Mann-Whitney test, $*P < 0.05$.

The attraction indices increased by 8.8 at $t + 1$ min, and reached 34.7 at $t + 4$ min. In comparison with pure air conditions, the RAI differed significantly at the 5% threshold ($Z = 0.025$) at $t + 3$ min, and then at the 1% threshold ($Z = 7.76 \times 10^{-3}$ at $t + 3.5$ minutes, $Z = 2.24 \times 10^{-3}$ at $t + 4$ min). Here the parasitoids' behavior was fairly similar to that observed with mined leaves.

The movements of *D. isaea* females towards stage 2 *Liriomyza trifolii* larvae did not differ from those elicited by control air (Figure 5). The relative attraction indices followed the same pattern in both cases, ranging between 2.2 and 10 with odor-impregnated air and between 1 and 7.2 with pure air ($Z = 0.82$ at $t + 1$ min and $Z = 0.5$ at $t + 5$ min). These data show that the host larvae alone exerted no attraction for the parasitoids.

The odor of the feces of leafminer larvae was attractive to the parasitoid females (Figure 6). The RAI reached 16.8 within $t + 4$ min, as compared with 6.7 in pure air ($Z = 0.06$). The differences observed between the indices recorded under control conditions and with the fecal odors were significant within 2 min at the 5% threshold level ($Z = 0.19$ at $t + 2$ min, $Z = 0.02$ at $t + 2.5$ min, $Z = 0.17$ at $t + 3$ min).

Chemical Analysis. Representative chromatograms obtained with trapped volatile extracts from healthy, mined, and mechanically damaged bean plant leaves are shown in Figure 7. Fifteen peaks occurred consistently from one test to another. None of these compounds was detected in the blank trapping extracts used as controls.

Figure 8 shows details of a typical reconstructed ion chromatogram obtained with mined leaves that were soaked in dichloromethane. Some of the substances were present only in trace quantities in the healthy leaves (peaks 7, 9, and 10). The composition of all substances present in larger amounts could be clearly determined. Three of the quantified components (peaks 6, 7, and 12) varied with the state of the leaves (whether healthy, mined, or damaged).

Table 2 presents the identity of compounds, the diagnostic ions used as the basis for identification, and the quantities of the three main components. Most of the substances were oxygenated molecules and included primary and tertiary alcohols (1-pentanol, *cis*-3-hexen-1-ol, 3-octanol, 5-octa-5-dien-3-ol), aldehydes (2-butenal, propanal-2-methyl oxime, and 2,4-heptadienal), or ketones (4-hydroxy-4-methyl-2-pentanone, previously identified by Hefetz and Lloyd (1983) in a formicine (ant) anal gland. Some short-chain hydrocarbons were identified also, including *n*-dodecene (peak 3), *n*-tridecane (peak 5), 4,8-dimethyl tetradecane (peak 14), and the monoterpene camphene (peak 2). Table 2 and Figures 7 and 8 show that the volatile profiles of healthy, mined, and damaged plants did not differ qualitatively with the exception of 1-octen-3-ol. This compound was present only in mined leaves at the same retention time as that of 2,4-heptadienal.

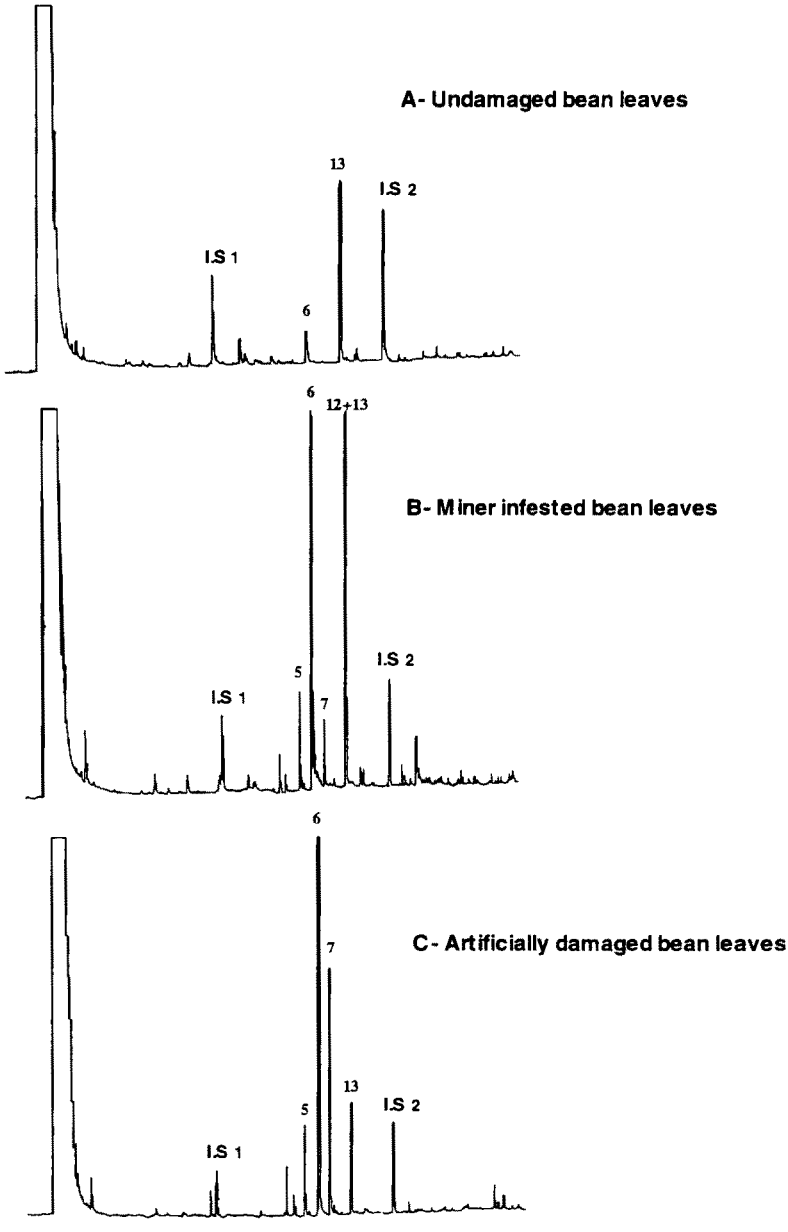

FIG. 7. Gas chromatogram (Supelcowax 10) of volatiles from undamaged bean leaves (A), damaged bean leaves containing feeding *Liriomyza trifolli* larvae (B), and artificially damaged bean leaves (C). Internal standards (IS1: *n*-docosane and IS2: octanol) are shown.

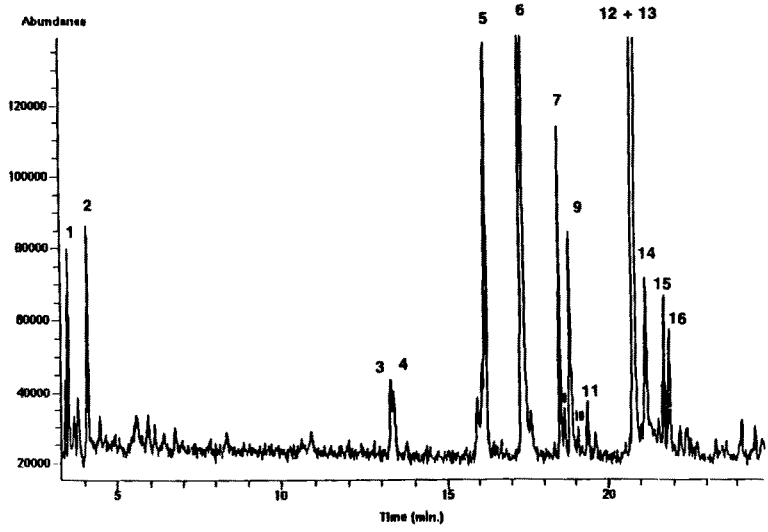

FIG. 8. Total ion chromatogram of damaged beans with numbered peaks: (1) 2-butenal, (2) camphene, (3) *n*-dodecene, (4) 1-pentanol, (5) *n*-tridecane, (6) 4-hydroxy-4-methyl-2-pentanone, (7) *cis*-3-hexen-1-ol, (8) unknown, (9) propanal, 2-methyl oxime, (10) 3-octanol, (11) unknown, (12) 1-octen-3-ol, (13) 2,4-heptadienal, (14) 4,8-dimethyl tetradecane, (15) 5-octa-1,5-dien-3-ol, (16) unknown.

Determinations were conducted on three of the main substances in a dozen samples of soaked healthy, mined, and damaged leaves. The amounts of all three substances increased whenever the leaves had been either attacked by biological agents or by the activity of the larvae or artificially damaged. Alcohols such as *cis*-3-hexen-1-ol (peak 7), which could not be quantified in the healthy leaves because it was present at such low levels, increased to as much as 600 ng/g of leaf matter in mined leaves and up to 700 ng/g in artificially damaged leaves. Likewise, 1-octen-3-ol (peak 12), which was not detected in the healthy leaves, reached the level of 1200 ng/g in mined leaves. 1-Octen-3-ol was not detected in extracts from damaged leaves. Lastly, 4-hydroxy-4-methyl-2-pentanone (peak 6) was extracted from the healthy leaves at about 350 ng/g, but it increased to as much as 6800 ng/g in mined leaves and 5700 ng/g in damaged leaves.

DISCUSSION

D. isaea are attracted by odor signals emitted by plants and by the host insects living on these plants. The results of our experiments using cold-trapped

TABLE 2. IDENTIFICATION OF VOLATILES BASED ON GC-MS EI IONIZATION

Peak	Compound	Formula	Diagnostic EI-MS ions	MW	Undamaged	Damaged	Artificially damaged
1	2-Butenal	C_4H_6O	39, 41, 56, 70 (M^+)	70	+	+	+
2	Camphene	$C_{10}H_{16}$	79, 93, 121, 136 (M^+)	136	+	+	+

bean plant extracts to attract the parasitoids show that they are able to recognize bean plants on the basis of volatile chemical signals that the plants give off. With the cold-trapping technique used in these experiments, natural conditions are better reconstituted by eliminating heavy, less volatile compounds such as triterpenes and phenols that are removed during the soaking or crushing processes (Wolfender et al., 1993).

Bean plants infested with leafminer larvae release much higher quantities of volatile molecules from the leaves than do healthy, non-mined plants. Larvae feeding on these plants may be responsible for the enhanced production of these substances. In our experiments, *D. isaea* females placed in an olfactometer responded to these chemical signals by moving towards the odor source, and it seem likely that they behave in the same way in natural surroundings. When plants are attacked, they seem to release substances that guide the parasitoids to their hosts.

The molecules we identified here have been previously mentioned in the literature. *cis*-3-Hexen-1-ol, for instance, occurs in more than 25 plant families (Visser et al., 1979) and has been reported from healthy leaves of potato plants (Visser et al., 1979), cowpeas (Whitman and Eller, 1990), several crucifers (Wallbank and Wheatley, 1976), and in strawberry plant leaves (Buttery et al., 1984; Hamilton-Kemp et al., 1988). Saijo and Takeo (1975) established that *cis*-3-hexen-1-ol is produced by green plants when the leaf tissues are damaged.

1-Octen-3-ol has previously been reported from strawberry foliage (Hamilton-Kemp et al., 1988), in the leaves of a shrub endemic to Florida (Jordan et al., 1992), and in corn tassels (Buttery and Ling, 1980). In the present study, this compound was emitted only by mined leaves. The presence of 2,4-heptadienal was observed in both healthy and damaged leaves. It has also been detected in corn (Buttery et al., 1978; Buttery and Ling, 1980).

We also identified some quite rare substances, such as oximes, in the trapped volatiles obtained from mined and artificially damaged bean plant leaves. Oximes have been previously identified in apple leaves attacked by *Tetranichus urticae* (Takabayashi et al., 1991) and in cucumber leaves (Takabayashi et al., 1994).

D. isaea do not use only one pest species as a host, and the question arises as to whether there may exist a common set of molecules used by the parasitoid to detect the mined leaves of any of their potential hosts. In our studies the parasitoid seems to recognize volatiles common to several plants. Guerin et al. (1983) suggested that the recognition of a plant's odor may be based on a synergy between molecules that are common to a whole set of plants, plus some more specific molecules. If true, this hypothesis would explain why *D. isaea* are so effective in attacking several leafminer pests.

Although *D. isaea* responded actively to plant extracts used in our study, it should be remembered that these results were obtained under experimental

conditions. Each odor was presented separately in the olfactometer, whereas in natural surroundings, olfactory stimuli are more complex. In our study the volatile chemical signals emitted by the *D. isaea–L. trifolii–Phaseolus* complex mediated communications between the plants, the plant-eating insects, and the insect-eaters.

Green plants such as tomatoes, potatoes, and bean plants release volatile compounds that give cut leaves a characteristic "green" odor. These volatiles are mainly alcohols with six carbon atoms, such as *cis*-3-hexen-1-ol, *cis*-2-hexen-1-ol, 1-hexanol, and aldehydes such as *trans*-2-hexenal and their derivatives (Visser et al., 1979; Hamilton-Kemp et al., 1988, 1989; Hernandez et al., 1989).

In the present study, the proportions of two of the molecules released by bean plant leaves, *cis*-3-hexen-1-ol and 4-hydroxy-4-methyl-2-pentanone, increased considerably in plant leaves attacked by the agromyzid larvae and in those that had been mechanically lacerated. The release of these compounds, or possibly just one of them, may inform parasitoids that they are in the vicinity of damaged plants, and the plants subsequently benefit from the messages it has sent out.

In the chemical interactions described here, communications seem to occur between the first and third trophic levels. The emitter and the receiver of the chemical messages both benefited from the exchange (Whittaker and Feeny, 1971). Here the term "allomones" does not apply in the strictest sense since the interactions were reciprocal. Nordlund and Lewis (1976) proposed the term synomone, which seems to describe more appropriately the type of signals occurring in our model. Several authors (Whitman, 1988; Dicke and Sabelis, 1988, 1989; Dicke et al., 1990) have explained communication of this kind in terms of the plants calling for help when they are attacked by larvae. Elzen et al. (1983), Nadel and Van Alphen (1987), Dicke and Sabelis (1988), and Turlings et al. (1991) have established that herbivore-damaged plants are more attractive to parasitoids than healthy ones. The idea that plants may have developed a defense mechanism that elicits participation of insect parasitoids seems quite plausible. This hypothesis presupposes that there exists a long-standing association between the plants, the phytophagous insects, and the parasitoids.

Plants may be induced to emit attractants utilized by insect parasitoids by either the host saliva (Turlings et al., 1990), its excretory droppings (Ramachandran et al., 1991), and/or its cocoon (Bekkaoui and Thibout, 1993). In our experiments with the olfactometer, *D. isaea* showed some sensitivity to feces of leafminer larvae feeding on bean plant leaves. We were not able to extract the substance responsible for this attraction.

In locating a host, *D. isaea* wasps have to search for various potential hosts living on different plants growing in diverse habitats. In such a complex chemical

environment, simply searching for a single kairomonal chemical may not suffice for the parasitoid to be able to make the most of all the available resources.

Long-range signals probably will convey only information about the host's habitat, while more short-range semiochemical substances emanating from infested plants or from the host's feces or other secretions will provide more direct and more reliable information about the availability of hosts and the sites where they are to be found. A parasitoid searching for a host probably uses a continuous, dynamic flow of information to locate hosts. Some parasitoids appear to be able to make use of what they have previously experienced and learned in order to take advantage of this complex system of interactions (Vinson et al., 1977; Vet and Groenwold, 1990).

Acknowledgments—We are grateful to the Conseil Regional Provence-Alpes-Côte-d'Azur and Duclos Agrobiotech Society for their financial support. We would like to thank G. Dusticier and E. Tabone for their cooperation, Jessica Blanc for the English translation, and Arlette Poveda for helpful secretarial assistance.

RELATIONSHIPS BETWEEN *Dendroctonus micans* KUG. (COLEOPTERA: SCOLYTIDAE) SURVIVAL AND DEVELOPMENT AND BIOCHEMICAL CHANGES IN NORWAY SPRUCE, *Picea abies* (L.) KARST., PHLOEM CAUSED BY MECHANICAL WOUNDING

ANDREW J. STORER* and MARTIN R. SPEIGHT

Department of Zoology, South Parks Road, Oxford, OX1 3PS, England

(Received March 17, 1995; accepted November 9, 1995)

Abstract—The bark of Norway spruce trees, *Picea abies* (L.) Karst., was wounded to produce areas of bark with differing biochemical characteristics. Adults and larvae of *Dendroctonus micans* Kug. were inserted into these trees at points around the wounds. Larval survival was higher, larval dry weights were higher, and adults were more likely to oviposit at sites around the wound that had higher phloem moisture contents. Larvae showed higher survival and dry weights in phloem with low terpene contents. Adults oviposited in phloem with lower stilbene glucoside contents. Phloem moisture differed at sites around the wound compared with that at a control site away from the wound, and the nitrogen content of entire bark cores was higher above wounds than at control sites away from the wounds. Phloem moisture correlated with the nitrogen content of entire bark. Phloem terpene contents correlated with each other, as did the stilbene contents. Associations between the host exploitation pattern of *D. micans* and the biochemistry of the host phloem are discussed in relation to preselection by adults of sites suitable for larval development.

Key Words—Norway spruce, *Picea abies*, *Dendroctonus micans*, tree defenses, terpenes, stilbene glucosides, phloem biochemistry, host exploitation.

INTRODUCTION

The susceptibility of living host trees to bark beetles has been shown to depend on factors that affect the whole tree, as well as localized areas on those trees.

Tree stress has been artificially induced in many studies (e.g., Vité, 1961; Moeck et al., 1981; Coulson et al., 1986; Miller and Berryman, 1986). Freezing of the tree base of ponderosa pine, *Pinus ponderosa* Laws., caused severe moisture stress, which predisposed them to attack by bark and ambrosia beetles, including *Dendroctonus valens* LeConte, *D. ponderosae* Hopk., and *D. brevicomis* LeConte (Moeck et al., 1981). When loblolly pines, *P. taeda* L. were damaged by artificial lightning strikes, *D. frontalis* Zimm., *D. terebrans* (Oliv.), and several *Ips* spp. were frequently associated with the mortality of the trees (Coulson et al., 1986). Alleviation of tree stress, for example, by reducing the canopy density and improving the nutrition of the trees, has been used to demonstrate reduced predisposition to bark beetle attack (Waring and Pitman, 1983, 1985). Lodgepole pines, *P. contorta* Dougl. significantly increased their resistance to mountain pine beetle, *D. ponderosae*, when canopy density was decreased and nitrogen nutrition improved (Waring and Pitman, 1983).

More localized areas within trees have also been investigated. For example, *D. ponderosae* favored sites around mechanical wounds on *P. contorta* that had a high carbohydrate content (Miller and Berryman, 1986). The development of late instars of *D. frontalis* was slower on bark with a high moisture content, but early instars developed more slowly in bark with a much decreased phloem moisture content (Wagner et al., 1979). Overall brood survival of *D. frontalis* was lower in trees with a high phloem moisture content (Webb and Franklin, 1978).

The defensive compounds found in trees are important in tree resistance to bark beetles. Monoterpene vapors vary in their toxicity to *D. brevicomis*. For example, limonene vapor, an important constituent of the resinous defenses of *P. ponderosa*, caused high levels of mortality to adult *D. brevicomis* (Smith, 1965). Contact of the fir engraver, *Scolytus ventralis* LeConte, with cortical resin blisters or canals in white fir, *Abies concolor* (Gord. & Glend.) Lindl. ex Hildebr., resulted in failure to produce egg galleries (Ferrell, 1983). Other defensive compounds found in conifers, such as the stilbene glucosides, which act as antifungal substances in spruce trees (Woodward and Pearce, 1988), may have activity against insects.

The great spruce bark beetle, *D. micans* Kug., is a pest of spruce, *Picea* spp., and other conifers in Europe (Grégoire, 1988). In the United Kingdom, infestations of this insect occur most frequently on Norway spruce, *Picea abies* (L.) Karst., and Sitka spruce, *P. sitchensis* (Bong.) Carr. (King and Fielding, 1989). Outbreaks of *D. micans* have been positively correlated to periods of prolonged drought and negatively correlated to stand density (Shavliashvili and Zharkov, 1985). Due to considerable variation in these types of observations, opposite effects have been demonstrated in other studies. For example, Granet and Perrot (1977) observed a positive relationship between attack and stand density.

In contrast with many other bark beetle species, *D. micans* larvae feed *en masse* throughout their development. Mass attack of trees by adults does not occur, and mating among siblings occurs in their brood chamber. No association with plant pathogenic fungi has been demonstrated (King and Fielding, 1989; Grégoire, 1984; Lieutier, 1993). Adults initiate attack on trees that appear to be healthy, and host defenses are tolerated or overcome on a localized basis. The success of attack is not related to the induced defense reaction of the host (Lieutier et al., 1992). Within a spruce stand, some trees may not be attacked despite multiple *D. micans* attacks on neighboring trees (Bevan and King, 1983). In addition, individual trees may have a number of aborted attacks on them, as well as some successful attacks (Bevan and King, 1983). These patterns of attack may be a result of between- and within-tree variation in the suitability of hosts for successful attack by *D. micans*. Physical and biochemical differences in host trees may be important in explaining these phenomena.

The experiments reported here aimed to produce a range of chemical and physical bark characteristics by mechanical wounding of trees. The null hypotheses tested were that variation in bark characteristics between trees, or as a result of tree wounding, would have no effect on oviposition by *D. micans* and/or the survival and development of *D. micans* larvae.

METHODS AND MATERIALS

Tree Wounding. Bark strips, 5 mm wide, were removed from trees to produce a standard pattern of wounding modified from the patterns used by Miller and Berryman (1986) (Figure 1). The phloem was completely severed along these strips by using a razorblade knife. The six sites at which beetles were inserted around the wound varied in the degree to which vertical and horizontal movement of materials into or away from the site was possible through the phloem. Wounds of this pattern were made on trees that had a minimum diameter at breast height (DBH) of 18 cm three weeks prior to the insertion of beetles. Wounds were made on an area of bark away from branch nodes, and at 1.7 m above the ground. It was hypothesized that the biochemical characteristics and moisture content of the phloem would vary around the wound site and that these could be correlated to oviposition by *D. micans* and the development and survival of larvae. Site 2 was on the opposite side of the tree to the wound, and was regarded as a control site for comparisons with other locations around the wound.

Insertion of Larval D. micans *into Wounded Trees.* Ten trees were selected from a pool of Norway spruce trees that were wounded on June 30, 1988, at Frostle Wood, Shropshire, England. Second and third instars of *D. micans* reared in the laboratory on Norway spruce logs were allocated at random to 60

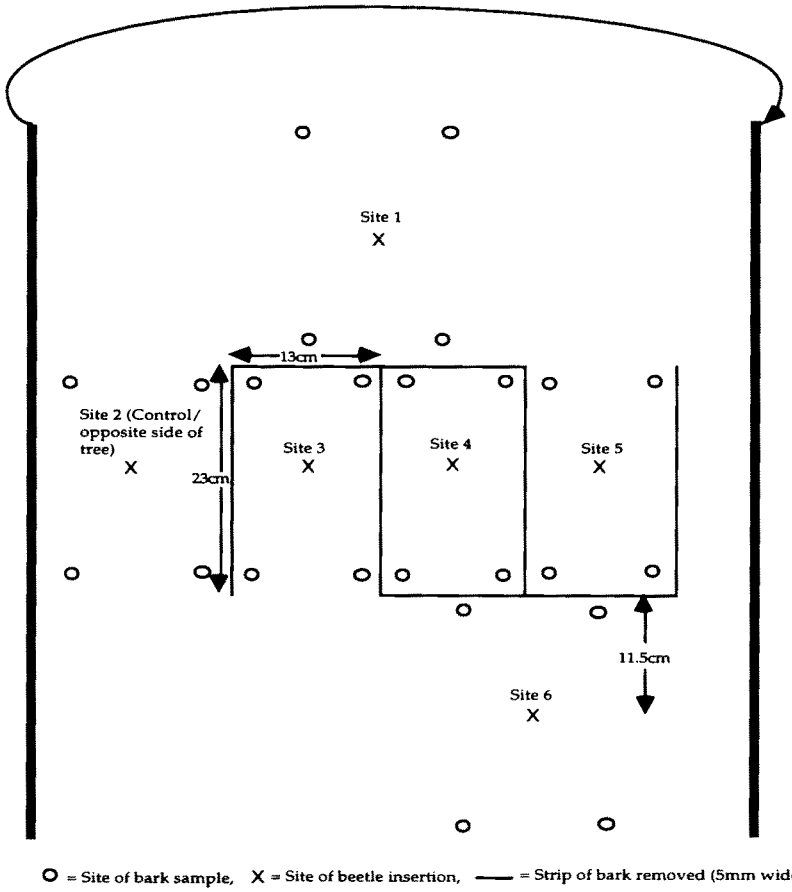

FIG. 1. The standard wounding pattern used in experiments to manipulate biochemical characteristics and moisture content of phloem on Norway spruce trees.

broods of 10 larvae each. After determining the mean fresh weight of the larvae in each brood, six broods were inserted into each of the wounded trees three weeks after the wounding had been carried out. An inverted v-shaped cut was made into the bark at the insertion point, and the living phloem was removed to leave a triangular flap of dead outer bark. The larvae were carefully placed (to prevent crushing) behind the flap of bark and secured by stapling brown wax paper over the insertion point.

Two bark samples, selected at random from the four bark sampling sites

around each of the six insertion points (Figure 1), were taken two weeks after insertion of the larvae. These samples were used to assess the percentage moisture, and the terpene content of the phloem. Two weeks after bark sampling, all larval broods were excavated from the trees, and the larvae were placed in compartmentalized boxes at 4°C for two days to empty their guts. They were then dried in an oven, and weighed to determine their dry weight.

Correlation coefficients were calculated to investigate the relationships between survival and mean dry weight of larvae at the end of the experiment and the biochemical characteristics of the phloem (Sokal and Rohlf, 1981). The dependence of larval survival on the position of the brood in relation to the wound was determined with χ^2 tests (Zar, 1984), and differences in larval dry weight at the sites around the wounds were tested by analysis of variance (Sokal and Rohlf, 1981). In the χ^2 tests and analysis of variance, five contrasts were carried out between the control site (site 2) and each of the other sites around the wound (Zar, 1984).

Insertion of Adult D. micans *into Wounded Trees.* Individual adults of *D. micans* were inserted at the six sites around the wound on each of 10 trees selected at random from the pool of trees wounded on June 30, 1988. The beetles were selected from a population of 100 brood adults that were fully tanned and assumed to be ready to emerge and attack host trees. They were collected from an infested tree at Wyre forest, Wales, and were assumed to be female based on their large size (Robinson et al., 1984). Determination of sex by morphological characteristics (Robinson et al., 1984) was not carried out due to the risk of injury to the limited number of beetles available. Insertions were made three weeks after wounding by removing a 9.8-mm-diameter bark and phloem disk from the insertion point, placing the beetle in the hole produced in the bark, and confining it with a plastic cap secured with a pin.

Three bark samples, selected at random from the four bark sampling sites around each of the six insertion points (Figure 1), were taken two weeks after insertion of the adults. These were used to determine the percentage moisture, terpene and stilbene glucoside content of the phloem, and the percent nitrogen content of the bark. The terpene and stilbene glucoside contents of the phloem were assessed for five of the 10 trees, and the other characteristics were assessed for all of the trees. Four weeks after beetle insertion, galleries were excavated. The presence of a brood chamber and eggs was recorded as a successful insertion (Lieutier et al., 1992). In all cases where oviposition had not occurred, the adult had exited the tree.

A t test was used to determine differences in bark characteristics between sites where insertions were successful and where they were not. The dependence of oviposition on the site around the wound was determined by a χ^2 test. Separate χ^2 tests compared the control site with each of the other sites (Zar, 1984).

Assessment of Bark Characteristics. Bark samples were collected from beyond the limit of any visible darkening of the phloem in response to the wounding (up to 2 cm from the cut edge of the bark), by removing a core of bark with a cork borer (9.8 mm ID). With the exception of the bark cores for nitrogen determination, the outer bark was removed from the phloem tissue.

Percentage Moisture Content. Phloem cores were placed in air-tight plastic vials of known weight in a cool box, and weighed to determine fresh weight. Phloem cores were then dried in an oven at 80°C for 48 hr and reweighed. The percentage moisture content of the phloem was then calculated. The term moisture content was preferred over water content, because during the drying process volatiles in the phloem, such as terpenes, as well as water were evaporated.

Terpene Content. Gas chromatography (GC) was used to detect and quantify terpenes in the phloem core (von Rudloff, 1969). Each phloem core was placed in a glass screw-top vial with 3 ml of methanol. The weight of the vial and methanol was known, and reweighing with the phloem core permitted determination of the phloem fresh weight. The samples were placed on Dry Ice in the field, and then stored at −20°C. After three days the methanol was poured into another glass vial and replaced with a fresh 3-ml wash of methanol. After three more days the two wash samples were pooled, producing 6 ml of phloem extract. All phloem washes were kept at −20°C during the production and storage of the phloem extracts. Since the phloem cores were small (9.8 mm diameter), they were not cut up to improve extraction.

Samples (2 μl) were analyzed with a Carlo Erba Fractovap 4130 gas chromatograph equipped with an LT programmer and a Varian Series 8000 autosampler. An OV-1 fused silica capillary column (25 m × 0.32 mm ID, film thickness 0.5 μm, stationary phase polydimethylsiloxane) was used. Air and hydrogen flows to the flame ionization detector were 500 ml/min and 10 ml/min, respectively. The carrier gas was helium at a flow of 3 ml/min. The injector and detector temperatures were 200°C and 250°C, respectively. The column temperature was 50°C for the first 2 min, and then was increased at 4°C/min to a final temperature of 170°C. Separated chemical constituents were recorded as absolute amounts (microliters per milliliter) and identified by comparison with known pure terpene standards. The quantities were converted into microliters per gram of phloem fresh weight.

Stilbene Glucoside Content. The two major stilbene glucosides in spruce bark are astringin (5,3′,4′-trihydroxystilbene-3-β-D-glucoside) and isorhapontin (5,4′-dihydroxy-3′-methoxystilbene-3-β-D-glucoside), and techniques for their quantification have been developed (Woodward and Pearce, 1988).

Aliquots (20 μl) of the extract prepared for terpene determination were separated by reverse-phase high pressure liquid chromatography (HPLC (Novapak C-18 Radial-Pak cartridge column, 10 cm × 8 mm ID) by using a solvent system of water containing 10 mg/liter EDTA (solvent A), and methanol alcohol

(MeOH) (solvent B). An elution gradient was used with an initial solvent ratio of 3:1 (A:B), with a linear change to a ratio of 13:7 after 3 min, and finally changing to a ratio of 3:7 in a concave curve (Waters 600 gradient controller, curve 8) at 15 min. This increased linearly to 100% B at 17 min, and was maintained at this composition for a further 5 min before returning to the initial solvent composition (via 100% A) over a total cycle (including equilibration at the initial conditions) of 40 min. A flow rate of 1.5 ml/min was used, and detection was by UV absorbance at 325 nm. A C-18 precolumn cartridge (μ-Bond-a-pak) was used to protect the column. Stilbene glucosides were quantified on a peak area basis against an external, purified isorhapontin standard. Astringin was estimated by using a conversion factor based on the molar extinction coefficients of these two compounds, taken as 4.37 for astringin and 4.35 for isorhapontin (Toscano Underwood and Pearce, 1991). Stilbene contents were expressed as milligrams per gram of fresh phloem weight.

Nitrogen Content. Bark cores, with outer bark attached, were placed in plastic capsules of known weight on Dry Ice. After reweighing the capsules to establish the weight of the bark pieces, samples were stored at $-20°C$. The total nitrogen content of 50-mg bark samples was assessed by digestion of the organic nitrogen by the Kjeldahl procedure (Allen, 1974), and the resulting ammonia was measured by colorimetric techniques (Havilah et al., 1977). The absorbance of the ammonia–salicylate complex was read at 660 nm in a Technicon Autoanalyzer II. Results were calculated as percentage nitrogen by comparison with standard solutions.

Variation in Bark Characteristics Around Standard Pattern of Wounding. Analyses of variance were used to compare the bark characteristics around the standard wound. Five contrasts were carried out between the control site (site 2) and each of the other sites around the wound.

RESULTS

Effects of Bark Characteristics on Larval Development. The mean fresh weight of larvae at the start of the experiment did not correlate with the mean dry weight of larvae at the end of the experiment ($r = 0.00$, 51 *df*, $P > 0.05$) or with the number of larvae recovered at the end of the experiment ($r = 0.06$, 58 *df*, $P > 0.05$). Hence the outcome of the experiment was not related to the weights of the larvae at the start of the experiment. Correlation coefficients showed that larvae achieved greater mean final dry weights and had greater chances of survival in phloem with a high moisture content and low α-pinene, β-pinene and δ-3-carene content (Table 1). There was no significant correlation between levels of β-phellandrene and larval survival and final dry weight.

Effects of Bark Characteristics on Success of Adult Insertions. Higher adult

success rates occurred in the phloem at insertion sites with higher moisture contents ($P < 0.05$) and lower levels of astringin ($P < 0.05$) and total stilbenes ($P < 0.05$) (Table 2). There were no significant differences in the levels of isorhapontin, and therefore the significantly lower levels of total stilbenes at sites where oviposition occurred may be a reflection of the lower astringin levels at these sites.

Relationships Between Adult Success and Larval Development, and Standard Wounding Pattern. Adults were less likely to oviposit at sites 1, 3 and 5

Total nitrogen content of bark (%)	0.55a ± 0.035	0.57a ± 0.028

[a] Values in same row followed by different letters are significantly different (*t* test, $P < 0.05$).

TABLE 3. RELATIONSHIPS AMONG OVIPOSITION BY ADULT *D. micans*, SURVIVAL, MEAN DRY WEIGHT OF *D. micans* LARVAE, AND STANDARD WOUNDING PATTERN[a]

	Site					
	1	2	3	4	5	6
Adults						
Proportion laying eggs (N = 10)	0.3	0.8	0.1	0.6	0.2	0.5
Probability of difference from control (site 2)	*		**	NS	**	NS
Larvae						
Proportion surviving (N = 100)	0.66	0.53	0.48	0.48	0.49	0.6
Probability of difference from control (site 2)	NS		NS	NS	NS	NS
Mean final dry weight (mg)	2.88	2.43	2.05	3.79	2.06	3.05
Standard error	0.42	0.44	0.42	0.42	0.44	0.40
Probability of difference from control (site 2)	NS		NS	**	NS	*

[a] Probabilities are from χ^2 tests and analysis of variance. NS = $P > 0.05$, * = $P < 0.05$, and ** = $P < 0.01$. In each case, differences between the trees in the experiment are significant ($P < 0.01$). Standard errors of mean final dry weights of larvae are calculated from the residual mean square in the analysis (Zar, 1984).

than at the control, but were as likely to oviposit at sites 4 and 6 ($P < 0.05$) (Table 3). There was no difference in larval survival at the insertion points close to the wounds (sites 1, 3, 4, 5, and 6) compared with the control (site 2), but mean larval dry weights were higher at sites 4 and 6 than at the control ($P < 0.05$), and no different from the control at sites 1,3 and 5. In each case, variation between trees was significant (adults: $\chi^2 = 14.0$, 9 *df*, $P < 0.01$; larval survival: $\chi^2 = 62.2$, 9 *df*, $P < 0.01$; mean larval dry weight: $F = 4.01$, 9, 39 *df*, $P < 0.01$).

Variation of Bark Characteristics Around Standard Wounding Pattern. Phloem moisture contents were lower at sites 1, 3, 5 ($P < 0.01$) and 6 ($P < 0.05$) than at control site 2, and higher at site 4 ($P < 0.05$) (Table 4). Total nitrogen content of the bark was significantly higher at site 1 than at control site 2 ($P < 0.05$), but there were no significant differences between other sites and control site 2 (Table 4). All of the bark parameters considered differed between trees in the study ($P < 0.05$).

Relationships Between Bark Characteristics. Isorhapontin levels correlated positively with the levels of astringin, and the levels of each of these stilbenes correlated negatively with the moisture content of the phloem (Table 5). Four of the six correlations between the terpenes were significantly positive, and

nitrogen content of the whole bark correlated positively with the moisture content of the phloem.

DISCUSSION

The response of trees to wounding was variable, but variation in bark characteristics between the trees was significant in all cases. Therefore, while larvae or adults may be more successful at sites with certain phloem characteristics, the effect of tree wounding may not produce consistent variations in bark characteristics in relation to the wound. As a result, certain sites around the wound on one tree may be suitable for *D. micans*, but a corresponding site on a different tree may be unsuitable.

Larval survival and mean dry weight were inversely correlated with the levels of three monoterpenes (α-pinene, β-pinene and δ-3-carene) in the phloem and positively correlated with phloem moisture content. Larval survival and mean dry weight differed among the trees in the study. No consistent differences in terpene contents were evident at the different sites around the wounds, but phloem moisture content was higher at site 4 than the control and lower at the other sites than the control. The higher moisture content of the phloem at site 4 may therefore explain the higher larval weights attained at these sites. Although site 6 had a significantly lower moisture content in the phloem than the control site, larvae still attained greater mean final dry weights than at control site 2. It appears that other factors may be important at site 6 or that the other bark characteristics that were assessed were too variable to produce significant differences between site 6 and the control.

Adult *D. micans* were more likely to oviposit at sites with higher moisture contents and lower astringin and total stilbene contents in the phloem. Oviposition was less likely to occur at sites 1, 3, and 5 than at the control site, and each of these sites had lower phloem moisture contents than the control. Site 6 also had a lower phloem moisture content than the control, and site 4 had a higher phloem moisture content than control site 2; adults were as likely to oviposit at these sites as they were at the control site. Oviposition varied among trees, as did all of the phloem characteristics assessed.

The sites at which larvae achieved greater mean dry weights (sites 4 and 6) corresponded with the sites where adults were as likely to oviposit as they were at the control site. Conversely, at sites 3 and 5, larvae did not attain greater mean final weights than at control site 2, and oviposition was lower at these two sites than at the control site. Hence, adults appear to select oviposition sites suitable for larval development.

Moisture and nitrogen content were positively correlated, as they are in other plant tissues, and both are important in insect nutrition (Scriber and Slan-

sky, 1981). Oviposition and larval weight were higher in phloem with a higher moisture content. However, in *D. frontalis* lower phloem moisture favored larval survival and development (Webb and Franklin 1978), up to a point where excessive phloem drying had occurred (Wagner et al., 1979). This result may reflect the suitability of phloem conditions for the growth of microorganisms (Franklin, 1970; Barras, 1970, 1973). No plant pathogenic fungi appear to be associated with *D. micans* (Lieutier, 1993), and hence larvae are not more successful at sites favoring fungal development. Since the nitrogen content of the bark was positively related to the percent moisture content of the phloem, larval success may be due to a higher nitrogen content in the bark (including the phloem), although nitrogen contents were not assessed in the experiment with larvae.

Higher terpene contents in the phloem resulted in reduced larval survival and reduced larval dry weight. Vapors of the major terpene components of spruce resin are not toxic to adult *D. micans*, and topical applications to larvae never resulted in greater than 30% mortality (Everaerts et al., 1988). However, the toxicity of terpene vapors to larvae and the contact toxicity of terpenes to adults are not known. Adult *D. micans* survive immersion in resin during host attack, so the contact toxicity of terpenes would appear to be low. The effect of resin crystallization rate on adults and larvae is also not known, although adults that have died in resin are rarely found in nature (Bevan and King, 1983).

Stilbenes are among the phenolic compounds implicated in antimicrobial biochemical defense in conifers. In spruce these compounds are present constitutively in the phloem as glucosides (Woodward and Pearce, 1988). Many bark beetle species have fungal associates (Whitney, 1982) and may therefore select trees with lower levels of stilbenes in the phloem. Adult *D. micans* were less likely to oviposit in phloem with higher astringin and total stilbene contents. Stilbene levels and moisture content of the bark were negatively correlated so it is impossible to determine whether the success of adult insertions was due to high moisture contents of the phloem or lower stilbene contents. Higher moisture contents favor larval development, but the effect of stilbene glucosides on larval development has not been considered. The presence of a fungal symbiont during the evolution of this species may be indicated by the fact that adult *D. micans* are less likely to oviposit in areas of bark with higher astringen and total stilbene contents. Furthermore, larvae may develop better in bark with lower stilbene glucoside levels, but further work is necessary to determine the effects of stilbene glucosides on *D. micans* larvae.

Host selection by *D. micans* may be determined in part by the suitability of the substrate for larval development. Hence, sites are favored with a higher moisture content in the phloem, which is positively correlated to the nitrogen content of the complete bark. If high quantities of monoterpenes are transported to the site, larval mortality may increase, with a subsequent reduction in larval weight. The packing of frass by adults around the eggs may act as a sponge for

the terpenes produced by the host tree. Hence, in broods resulting from natural adult attack, the importance of terpene content of the phloem to the larvae may be reduced. Adults may also select sites on trees with lower stilbene contents, even though fungi that would be expected to be sensitive to these compounds are apparently absent.

Acknowledgments—We are grateful to David Wainhouse, David L. Wood, and Pierluigi Bonello for their valuable discussions and reviews of this manuscript; and to Ray B. Pearce, Linda Lockhart, and John Castle for discussions and assistance with biochemical analyses. Funding for this work was provided by the Natural Environment Research Council and the U. K. Forestry Authority.

GROWTH AND PHYSIOLOGICAL RESPONSES OF BLACK SPRUCE (*Picea mariana*) TO SITES DOMINATED BY *Ledum groenlandicum*

INDERJIT and A. U. MALLIK

Department of Biology, Lakehead University
Thunder Bay, Ontario, Canada P7B 5E1

(Received August 7, 1995; accepted November 9, 1995)

Abstract—Growth and physiological parameters of black spruce planted eight years previously were compared at sites with and without *Ledum groenlandicum* to quantify the adverse effects on black spruce in *Ledum* sites. Tree height, crown diameter, and dry weights of stems, branches, and needles of black spruce were significantly less at the *Ledum*-dominated sites. Annual stem height, basal diameter, growth ring width, and cumulative wood volume of black spruce were significantly reduced in the *Ledum* sites compared to those of the non-*Ledum* sites. Yearly growth of black spruce in the first seven years after planting was more affected in the *Ledum* site than the eighth year's growth. Foliar nutrient analysis of black spruce in the *Ledum* site showed an overall imbalance in nutrient accumulation. Black spruce growing in the *Ledum* site had higher foliar concentrations of Al, Ca, Fe, Ni, and S and lower concentrations of N and Si than those growing in the non-*Ledum* site. Black spruce growing in the *Ledum* site also had a higher foliar phenolic content. Preliminary experiments suggest that *Ledum* has the potential to leach water-soluble phenolics to its immediate organic soil.

Key Words—*Ledum groenlandicum*, black spruce, nutrient imbalances, allelopathy, phenolics, growth check.

INTRODUCTION

Ledum groenlandicum (hereafter referred to as *Ledum*), commonly called Labrador tea, is a perennial ericaceous understorey shrub in boreal forests (Soper and Heimburger, 1985). Its distribution in Ontario ranges from Lake Ontario through Hudson Bay, and from Ottawa and the St. Lawrence Valley through Lake-of-the-Woods. *Ledum* is common in *Sphagnum* bogs and in moderately wet soils

0098-0331/96/0300-0575$09.50/0 © 1996 Plenum Publishing Corporation

with thick humus layers. The plant regenerates well vegetatively following light fires that remove the aboveground component of the plant and the surface litter (Viereck, 1983).

LaBarron (1948) reported that *Ledum* could interfere with early growth of black spruce (*Picea mariana*). However, no data are available on growth and physiological damage of black spruce due to *Ledum*. Robert Bolton (personal communication) reported that approximately 100,000 ha of new plantations of black spruce of Abitibi-Price Limit, a paper factory, in the Iroquois Falls area alone experienced noticeable growth inhibition due to *Ledum*. Symptoms of black spruce growth inhibition in *Ledum*-dominated sites are similar to "growth check," a phenomenon observed in other conifers such as Sitka spruce (*Picea sitchensis*) inhibition due to *Calluna vulgaris* (Gimingham, 1972), western hemlock (*Thuja heterophylla*), red cedar (*T. plicata*) inhibition due to *Gaultheria shallon* (Weetman et al., 1990), and black spruce growth inhibition in the presence of *Kalmia angustifolia* (Mallik, 1994).

In boreal forests, black spruce is one of the most desirable tree species because of its superior fiber quality. Poor growth of planted black spruce in *Ledum* sites affects its overall productivity. Optimum plant growth is dependent upon a balance of nutrients in the leaves (Shear et al., 1948; Comerford and Fisher, 1984), and any imbalance in foliar nutrients may cause adverse effects on growth. In view of this, the growth and physiological responses of black spruce growing with and without *Ledum* were quantified. The objectives of the present study were to study the adverse effects on growth of black spruce growing in *Ledum*-dominated sites and to investigate if black spruce growing in *Ledum*-dominated sites have altered foliar chemistry.

METHODS AND MATERIALS

Study Site and Sampling. The study was conducted in a young black spruce stand of approximately 1 ha located beside Little Abitibi Road, Highway 67, in the Abitibi-Price forest area, Iroquois Falls (lat. 48°46'N; long. 80°41'). The area was planted with paper plug container-stock black spruce eight years previously. One half of this area, about 50 m south of the highway, was infested with *Ledum groenlandicum* with 50–80% cover and had a thick carpet of mosses (70–90% cover), mainly *Pleurozium schreberi, Dicranum* spp., and some *Sphagnum*. Other associated vascular plants were *Epilobium* spp., *Aster* spp., *Solidago* spp., *Viola* spp., *Carex* spp., *Vaccinium angustifolium*, and *V. myrtilloides*, each having less than 10% cover. The site had thick organic matter with undecomposed *Ledum* litter on top. The contiguous half of this area further away from the highway did not have *Ledum* as a component of the vegetation.

This site was relatively drier, with a thinner (ca. 30%) organic layer compared to the adjacent *Ledum* site. Mineral soil of the site was light-colored and clayey loam (for detailed soil classification, see Sims et al., 1989).

Ten planted black spruce trees were selected randomly from each site (with and without *Ledum*). The planted trees were identified by the presence of paper plugs at their stem bases. The trees were cut, numbered, and brought back to the laboratory for growth and foliar chemical analysis.

Growth Characteristics. Data on height and crown diameter of each tree from *Ledum* and non-*Ledum* sites were recorded. Oven-dry weights of stem, branches, and needles were recorded at 60°C until constant weight was achieved. All analyses were made in triplicate.

Chemical Analysis. Black spruce needles were analyzed for a number of nutrient: Al, As, B, Ba, Ca, Cd, Cu, Fe, Hg, K, Mg, Mn, Na, Ni, P, S, Se, Sr, Ti, N, and Zn. Only needles were analyzed for elements, as leaf habit was suggested to be a major determinant of growth and nutrient use by forest species (Chapin and Tryon, 1983). Moreover, foliar nutrient analysis generally reflects soil nutrient conditions, even with different species compared at two sites (van den Driessche, 1970; Garten, 1976; Chapin and Tryon, 1983).

Needles from each of the trees from *Ledum* and non-*Ledum* sites were oven-dried at 70°C for 6 hr. After digestion with HNO_3, all elements except N were analyzed with an inductively coupled plasma analyzer (Jarrell-Ash ICAP 9000). Needle N was determined colorimetrically following Allen (1989). Percent ash was determined by burning the samples in a muffle furnace at 550°C for 5 hr.

To determine if the black spruce trees growing in the *Ledum* site were under some physiological stress and had high phenolic content, total foliar phenolic content was determined by Folin-Ciocalteau reagent following Swain and Hillis (1959).

Annual Growth. LaBarron (1948) reported that *Ledum* affected black spruce growth in its early phase of the life cycle and that eventually the tree may overcome the adverse effects of *Ledum*. Therefore, to determine whether early phases of black spruce growth were more sensitive to *Ledum*, year-wise data on shoot height and diameter of black spruce were collected. The width of each year's growth ring was determined by taking cross sections of stem at 0–10 cm above ground. The annual volume increase was calculated by the equation:

$$V = \frac{\pi D^2}{4} \times h \times 0.333 \qquad (1)$$

where V is the volume of the wood, D is the cumulative diameter, and h is the cumulative height of each tree.

Total Phenolic Content of Ledum*-Amended Organic Soils.* To determine if *Ledum* has the potential to leach water-soluble phenolics to the environment, organic soils previously not associated with *Ledum* were amended with *Ledum* leaves. Organic soil (15 g) was amended with 2.5, 5, and 10 g of air-dried *Ledum* leaves, and kept for 72 hr. These amended soils were identified as AS1, AS2, and AS3, respectively. Organic soils previously not associated with *Ledum* were used as controls. Total phenolic content of the control soil and amended soils (AS1–AS3) was determined following Swain and Hillis (1959).

RESULTS

Growth of black spruce trees was significantly inhibited in the *Ledum* site (Table 1). Tree height, crown diameter, and dry weights of stem, branches, and needles of black spruce were all significantly ($P < 0.001$) lower in the *Ledum* site compared to the non-*Ledum* site (Table 1). Annual growth of stem height and wood volume of black spruce were significantly ($P < 0.001$) higher in the non-*Ledum* site than the *Ledum* site (Figures 1 and 2). Growth of black spruce in the *Ledum* site was reduced for seven years following planting. However, in the eighth year a significant increase in stem height was observed compared to the previous years. Similarly, the difference in stem base diameter of black spruce between *Ledum* and non-*Ledum* sites was reduced in the eighth year. For example, compared to an 82% reduction in base diameter of black spruce in the *Ledum* site during the first year after planting, only a 38.6% reduction was recorded in the eighth year. Reduction in stem diameter of black spruce in the *Ledum* site relative to the non-*Ledum* site was 78%, 78%, 65%, 77%, 74%, and 66% in the second, third, fourth, fifth, sixth, and seventh years, respectively. Annual ring width of black spruce from the *Ledum* site was significantly

TABLE 1. BIOTIC CHARACTERISTICS OF 8-YEAR-OLD BLACK SPRUCE WITH AND WITHOUT *Ledum groenlandicum*[a]

Biotic characteristics	Non-*Ledum* site	*Ledum* site
Shoot height (cm)	196.77 ± 20.31	75.32 ± 16.12*
Crown diameter (cm)	72.18 ± 10.37	32.30 ± 14.44*
Dry weight of stem (g)	670.14 ± 294.55	24.23 ± 12.85*
Dry weight of branches (g)	532.89 ± 185.11	28.39 ± 15.83*
Dry weight of needles (g)	807.86 ± 212	42.77 ± 15.83*

[a]Data are average of ten tree samplings. The asterisk denotes that values are significantly different at the level of $P < 0.001$.

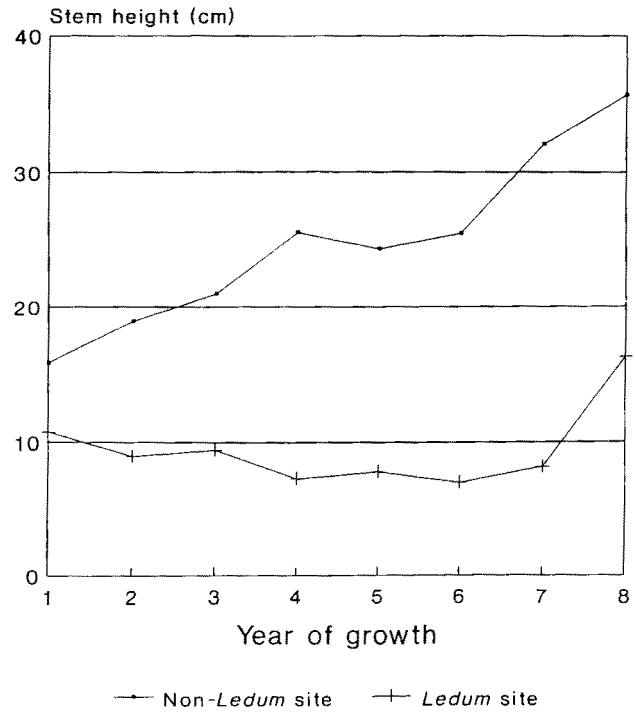

FIG. 1. Annual stem height of black spruce growing in non-*Ledum* and *Ledum* sites. Data are average of 10 tree samplings. Values are significantly different at the level of $P < 0.001$.

($P < 0.005$) less than that of the non-*Ledum* site (Table 2). There was a significant decline in volume of wood produced by black spruce growing in the *Ledum* site (Figure 2). Compared to the non-*Ledum* site, black spruce in the *Ledum* site suffered a 92.73% decline in volume of wood over the eight years.

Of the 21 nutrient elements analyzed, foliar concentrations of Al, Ca, Fe, Ni, N, and Si were significantly different. Concentrations of Al, S ($P < 0.005$), Ca, Fe, and Ni ($P < 0.05$) were significantly higher in needles of black spruce grown in the *Ledum* site. On the other hand, foliar N ($P < 0.05$) and Si ($P < 0.005$) concentrations were significantly lower in black spruce grown in the *Ledum* site compared to the non-*Ledum* site (Table 3). Needles of black spruce grown in the *Ledum* site also had higher total phenolic content compared to that of the non-*Ledum* site (Table 3).

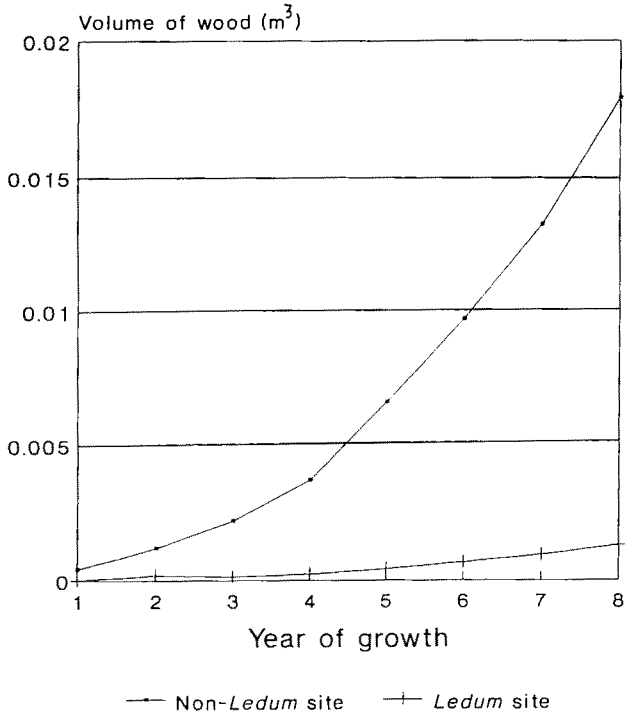

FIG. 2. Cumulative wood volume of black spruce growing in non-*Ledum* and *Ledum* sites. Data are average of 10 tree samplings. Values are significantly different at the level of $P < 0.001$.

Total phenolic content of soils amended with *Ledum* leaves (AS1–AS3) was significantly higher ($P < 0.005$) compared to unamended (control) soil (Table 4).

DISCUSSION

The present study unequivocally demonstrates a significant growth reduction and foliar nutrient imbalance in black spruce growing in the *Ledum* site compared to those growing in the non-*Ledum* site (Tables 1–3). Low foliar concentrations of N and Si and high foliar concentrations of Al, Ca, Fe, Ni, and S were observed in black spruce growing in the *Ledum* site compared to that of the non-*Ledum* site (Table 3). Optimum tree growth may be impaired due to nutrient imbalances (Comerford and Fisher, 1984). Reduced foliar N of

black spruce growing in the *Ledum* site may be the cause of its poor growth because N deficiency can directly affect plant growth (Stone and Will, 1965). Munson and Timmer (1989a,b) suggested that seedling growth and productivity of conifers following outplanting depend on N uptake and accumulation. Interference with N accumulation and growth was evident from the results of this study, as black spruce of the non-*Ledum* site had better growth and a higher N concentration compared to those in the *Ledum* site (Tables 1 and 3). Lavender (1970) found lower foliar N in suppressed Douglas fir trees than in dominant trees. van Dijk and Roelofs (1988) reported that imbalances in N with K, Mg, and P were correlated with arginine accumulation. A lower P/N ratio was observed in black spruce growing in the non-*Ledum* site (2.984) than in trees growing in the *Ledum* site (4.798). A high P/N ratio could result in higher foliar concentrations of Al, Ca, Fe, Ni, and S in black spruce growing in the *Ledum* site (Chapin and Tryon, 1983; Ericsson et al., 1993; Penning de Varies, 1975). Various studies showed that, compared to dominant trees, nondominant trees had higher tissue nutrient concentrations (Wright and Will, 1958; Madgwick, 1964; van den Driessche, 1974). Although experimental evidence of this relationship in black spruce requires further studies, the present study showed that black spruce growing in the *Ledum* site suffers from nutrient imbalances, and that may be a reason for, or a result of, its poor growth.

Ca is an important nutrient in a forest ecosystem because of its large accumulations in forest trees (Alban et al., 1978). In the present study significantly higher concentrations of Ca were recorded in needles of black spruce growing in the *Ledum* site than in needles of trees in the non-*Ledum* site (Table 3). Rennie (1955) found that in *Calluna*-associated soils removal of soil Ca by *Pinus sylvestris* resulted in reduced tree growth. Thus, higher foliar Ca in black spruce from the *Ledum* site may contribute to the observed growth reduction.

The *Ledum* site was different from the non-*Ledum* site in that it had higher

contents of phenolics, organic matter, acidity, moisture, and the presence of *Sphagnum*. Occurrence of *Ledum* with *Sphagnum* moss has been reported by others (Soper and Heimburger, 1985; Baldwin and Sims, 1989). High total phenolic content in organic soils amended with *Ledum* (Table 4), indicate that *Ledum* has the potential to leach water-soluble phenolics to its immediate environment. Furthermore, because of its evergreen nature, *Ledum* accumulates large amounts of organic matter, mainly leaf litter and fine roots, as does *Kalmia angustifolia* (Damman, 1971). It thus contributes substantial phenolics to the soil environment (Patrick, 1971; Rice, 1984). The high organic layer build-up results in more soil moisture content (Brady, 1990), which helps in leaching water-soluble phenolics from living *Ledum* leaves or its litter. High acidity in *Ledum* sites (Sims et al., 1989) could be due to a higher phenolic content of *Ledum* soils and the presence of *Sphagnum* moss.

Total phenolic content was higher in needles of black spruce growing in the *Ledum* site than in needles of trees in the non-*Ledum* site (Table 3). This may be due to the higher uptake of phenolics from the *Ledum* soils (Rice, 1984) or due to synthesis of more phenolics by black spruce in response to physiological stress created in the *Ledum* site (Inderjit and Dakshini, 1992; Rice, 1984; Tang et al., 1995). Phenolics have the potential to create nutrient imbalances in susceptible plants growing in the vicinity of donor plants (Einhellig, 1995; Inderjit and Dakshini, 1992; Rice, 1984). Whether the observed changes in foliar chemistry of black spruce growing in *Ledum* sites, were due to phenolics contributed by *Ledum* needs further experimentation.

The sensitivity of a plant to allelopathic compounds may be related to its age. If the susceptible plant survives until the sensitive age is crossed, it can generally overcome the adverse effects of allelopathy. In the present study, shoot height of black spruce was strongly affected in the *Ledum* site during the first seven years, but in the eighth year black spruce in the *Ledum* site showed better growth compared to the earlier years. However, even if black spruce could overcome the growth inhibition eventually, it has lost a significant part of its initial seven years of growth. This is a serious loss from the forest productivity point of view. Planting older black spruce seedlings in *Ledum* sites may minimize the adverse effects of *Ledum* sites.

In nature many factors interact both simultaneously and sequentially, and their relationships are constantly changing. There exist many collinearities such as humus increase, soil temperature decline, soil temperature increase, and phenolic content increase (Inderjit and Dakshini, 1995). The present study in no way demonstrates the allelopathic interference of *Ledum* with the growth and physiological parameters of black spruce. This study only quantifies the damage to growth and physiological variables of black spruce growing in *Ledum*-dominated sites. Preliminary data on soil chemistry indicate that allelopathy may be one of the mechanisms for these growth differences observed. The most likely

explanations for the observed growth reductions could be: (1) soil differences that could be mediated by allelopathic compounds (e.g., effects on nitrogen cycle, or phenolics could stimulate microbial activity which depletes soil nitrogen), (2) competition by *Ledum*, (3) allelopathic compounds that affect spruce-mycorrhizae symbiosis adversely, and (4) phenolics that may have direct effects on plant growth. Our future investigations will pursue the mechanism for the observed growth differences of black spruce at sites with and without *Ledum*, particularly the role of allelopathic compounds.

Acknowledgments—We thank Mr. Robert Bolton of Abitibi-Price, Iroquois Falls, for his help in sampling black spruce and Dr. A. D. Macdonald for reviewing the manuscript prior to submission.

(Received May 15, 1995; accepted November 13, 1995)

Abstract—Twenty-nine free and glucosylated dihydrophenanthrenes and tetrahydropyrenes isolated from *Juncus effusus* have been tested against the unicellular green alga *Selenastrum capricornutum*. The free compounds showed a strong inhibitory activity, while the glucosides were inactive or had a slight stimulating effect on growth. Tetrahydropyrene **33**, obtained by hydrolysis of the natural β-glucosides **29** and **30** or by hemisynthesis from **1**, is the most active compound, causing 90% inhibition of the growth at 2.5×10^{-5} M concentration. Synthetic α-glucosides **28**, **31**, and **32** showed comparable activity to those of **29** and **30**.

Key Words—*Juncus effusus*, dihydrophenanthrenes, tetrahydropyrenes, algicides, *Selenastrum capricornutum*.

INTRODUCTION

It is well known that excessive algal growth can have detrimental effects on both indigenous organisms and potential human uses of aquatic ecosystems (Lembi et al., 1988). Algae can cause poisoning of fish and livestock (Steidinger and Baden, 1984; Carmichael, 1986), as well as damage irrigation canals, drainage ditches, and other man-made structures (Hansen et al., 1984).

The need for algicides not harmful to the environment prompted us, several years ago, to screen natural substances isolated from aquatic macrophytes that

*To whom correspondence should be addressed.

could give useful results in the control of algal growth. Although some sterols and fatty acids toxic to algae have been found (Aliotta et al., 1990; Pinto et al., 1995), phenolic compounds have given more promising results. These chemicals are among the most frequently identified allelochemicals from higher plants and are also toxic to various microorganisms (Elliot and Cheng, 1985). Phenolic compounds active against microalgae have been isolated from aquatic and wetland plants such as *Acorus gramineus, Pistia stratiotes, Myriophyllum verticillatum,* and *Arum italicum* (Aliotta et al., 1995).

Recently, it has been shown that dihydrophenanthrenes, uncommon phenolic compounds isolated from the wetland plant, *Juncus effusus,* have a strong toxic action on microorganisms such as *Agrobacterium tumefaciens* and on small invertebrates such as *Artemia salina* (Della Greca et al., 1993). The toxicity of these aromatic compounds to algae is still unknown. In this paper we report the biological effects of a series of free and glucosylated dihydrophenanthrenes, isolated from *Juncus effusus,* on the unicellular green alga *Selenastrum capricornutum.*

METHODS AND MATERIALS

Plant Collection and Extraction. Plants of *Juncus effusus* were collected during spring and summer 1991 near Naples. A voucher specimen is on deposit at the Botanical Garden of Naples. The plants were dried at room temperature and sequentially extracted with ethyl ether (Et_2O) and methanol (MeOH). The extracts were frozen and stored at −20°C until used.

General Experimental Procedures. NMR spectra were recorded at 400 MHz for ^1H and 100 MHz for ^{13}C on a Bruker AC 400 spectrometer in $CDCl_3$ or acetone-d_6 solutions for dihydrophenanthrenes and pyrenes and in DMSO-d_6 solutions for the glycosyl derivatives. One-bond and long-range H-C COSY experiments were performed with the XHCORR microprogram using delays corresponding to $J_{C,H}$ = 160 Hz and 8 Hz, respectively. EI and FAB mass spectra were obtained with a Kratos MS 80 and a VG ZAB 2SE, respectively. IR spectra were determined in $CHCl_3$ solutions on a FT-IR Perkin-Elmer 1740 spectrometer. DCCC was run with a mixture of $CHCl_3$, MeOH, and H_2O (13:7:4 for **19, 20, 23–26,** and **29;** 26:14:5 for **27** and **30;** and 13:7:2 for **21** and **22**); the polar upper layer was used as the mobile phase. Reverse-phase HPLC was performed using LiChrosorb RP18 columns [MeOH–H_2O (9:1) for **5, 12,** and **14;** MeOH–H_2O (4:1) for **1** and **6;** MeOH–H_2O (3:1) for **2, 15,** and **18**], LiChrosorb RP8 columns [MeOH–H_2O (1:1) for **19, 20, 23–26** and **29;** MeOH–H_2O (2:3) for **21** and **22;** MeOH–H_2O (3:7) for **30**], and a LiChrosorb NH_2 column [CH_3CN–H_2O (4:1) for **27**].

Ethyl Ether Extract Fractionation. The Et_2O extract (125 g) was separated by conventional procedures into an acidic (34 g) and a neutral fraction (85 g). The neutral fraction was chromatographed on silica gel and the fractions eluted with hexane–Et_2O (9:1). Preparative TLC (hexane–benzene, 2:3) gave pure juncunol (**3**) (66 mg) (Sarkar et al., 1988). Elution with hexane–Et_2O (17:3) gave **11,** purified by preparative TLC (hexane–AcOEt, 13:7) (4 mg): IR: ν_{max} 3340 and 1603 cm^{-1}; EI-MS: *m/z* 266 $[M]^+$ (96%), 251 $[M - Me]^+$ (100), 236 $[M - 2\ Me]^+$ (52), 165 (84), 149 (39). Elution with hexane–Et_2O (4:1) gave a mixture of **7** and **8,** which were separated by preparative TLC (benzene–Et_2O, 9:1). Pure **7** had (18 mg) IR: ν_{max} 3480, 1612, and 1260 cm^{-1}; EI-MS: *m/z* 280 $[M]^+$ (76%), 265 (100), 250 (53), 237 (42). Pure **8** had (16 mg) IR: ν_{max} 3475, 1614, and 1257 cm^{-1}; EI-MS: *m/z* 280 (78%), 265 (100), 250 (44), 237 (51).

The acidic fraction was chromatographed on HCl-washed silica gel. The fractions eluted with hexane–Et_2O (17:3) were chromatographed on silica gel to give **4, 5, 12, 14,** and **16.** Compound **4** (250 mg) eluted with benzene–Et_2O (3:17) had IR: ν_{max} 3350 and 1605 cm^{-1}; EI-MS: *m/z* 266 (96%), 251 (100), 236 (45), 165 (80), 149 (50). Compound **16** eluted with benzene–Et_2O (1:19) was purified by preparative TLC (benzene–Et_2O, 17:3) (5 mg); it had IR: ν_{max} 3460, 1620, and 1140 cm^{-1}; EI-MS: *m/z* 298 (100%), 283 (80), 255 (43). The mixture of **5, 12,** and **14,** eluted with benzene–Et_2O (1:19), was resolved by preparative reverse-phase HPLC to give juncunone (**12,** 18 mg) (Miles et al., 1981), **14** (16 mg), and **5** (125 mg). Compound **14** had IR: ν_{max}: 3340, 1705, and 1620 cm^{-1}; EI-MS: *m/z* 268 (100%), 239 (51). **5** had IR: ν_{max} 3340 and 1610 cm^{-1}; EI-MS: *m/z* 266 (90%), 251 (100), 236 (40), 165 (80). The fractions eluted with hexane–Et_2O (4:1), after chromatography on silica gel (hexane–Me_2CO, 7:3) and reverse-phase HPLC, gave juncusol (**1,** 16 mg) (Shima et al., 1991) and **6** (130 mg). Compound **6** had IR: ν_{max} 3130 and 1605 cm^{-1}; EI-MS: *m/z* 266 (85%), 251 (100), 236 (70). The fractions eluted with benzene–Et_2O (7:3) were chromatographed on silica gel. Benzene–Et_2O (19:1) gave effusol (**2,** 64 mg) (Shima et al., 1991), purified by reverse-phase HPLC, and **13** (13 mg), purified by preparative TLC [hexane–acetone (Me_2CO), 7:3]. Compound **13** had IR: ν_{max} 3350, 1705, 1620, and 1603 cm^{-1}; EI-MS: *m/z* 282 (70%), 267 (100), 253 (45). Benzene–Et_2O (4:1) gave a mixture of **18** and **15** and a mixture of **9** and **10.** The first mixture was resolved by reverse-phase HPLC to give micrandol B (**18,** 7 mg) (De Alvarenga and Gottlieb, 1974) and **15** (40 mg). Compound **15** had IR: ν_{max} 3340 and 1605 cm^{-1}; EI-MS: *m/z* 284 (100%), 266 (68). The latter mixture was separated by preparative TLC (benzene–Et_2O–AcOH, 60:31:1) to give **9** (8 mg): IR: ν_{max} 3520, 1690, and 1610 cm^{-1}; EI-MS: *m/z* 280 (100%), 273 (65), 235 (55) and **10** (10 mg): IR: ν_{max} 3500, 1685, and 1620 cm^{-1}; EI-MS: *m/z* 280 (100%), 273 (72), 235 (41). The

fractions eluted with hexane–Et_2O (3:2) gave, after preparative TLC (benzene–Et_2O, 1:3), **17** (22 mg): IR: ν_{max} 3350 and 1610 cm^{-1}; EI-MS: *m/z* 284 (100%), 266 (75).

Methanol Extract Fractionation. The MeOH extract (350 g), after removal of the solvent, was partitioned between ethyl acetate and water. The organic layer was chromatographed on silica gel and the fractions eluted with $CHCl_3$–MeOH (9:1) were chromatographed on Sephadex LH-20 (MeOH–H_2O, 1:1). DCCC and HPLC of fractions 85–116 gave pure **19** (6 mg): FAB-MS: *m/z* 428; **20** (12 mg): FAB-MS: *m/z* 428; and **29** (15 mg): FAB-MS: *m/z* 428. DCCC chromatography and HPLC chromatography of fractions 130–143 gave pure **23** (10 mg): FAB-MS: *m/z* 446; **24** (8 mg): FAB-MS: *m/z* 432; **25** (11 mg): FAB-MS: *m/z* 432; and **26** (6 mg): FAB-MS: *m/z* 432. The aqueous layer was chromatographed on Amberlite X-AD2 and the MeOH fraction was chromatographed on Sephadex LH-20 (MeOH–H_2O, 1:3). Subsequent DCCC and HPLC processes gave pure **21** (11 mg): FAB-MS: *m/z* 590; **22** (14 mg): FAB-MS: *m/z* 590; **27** (11 mg): FAB-MS: *m/z* 608; and **30** (8 mg): FAB-MS: *m/z* 590.

Synthesis of Compounds 28, 31, 32, and 33. Pure 2,7-dihydroxy-1,6-dimethyl-5-vinyl-9,10-dihydrophenanthrene (**1**, 400 mg) was dissolved in EtOH (10 ml) and 2 N NaOH (20 ml) and Me_2SO_4 (4 ml) were added. After 18 hr with magnetic stirring the reaction mixture was extracted with ethyl ether and the crude methoxy derivative of **1** (**1m**) was purified by preparative TLC (hexane–benzene, 1:1). A solution of the methoxy derivative **1m** (240 mg) in benzene (200 ml) was irradiated with a 450-W Hanovia lamp equipped with a Pyrex filter sleeve for 1.5 hr under N_2. After removal of the solvent, the reaction mixture was chromatographed by preparative TLC (hexane–benzene, 1:1) to give pure 2,7-dimethoxy-1,6-dimethyl-9,10,12,13-tetrahydropyrene (**33m**) (200 mg): ^1H NMR: δ ($CDCl_3$) 6.65 (s, H-3 and H-8), 2.86 (s, H-9, H-10, H-12 and H-13), 2.22 (s, H-11 and H-14), 3.88 (s, OMe); ^{13}C NMR: δ 121.5 (C-1 and C-6), 156.2 (C-2 and C-7), 107.8 (C-3 and C-8), 132.6 (C-4 and C-8a), 134.8 (C-5 and C-1a), 28.9 (C-9 and C-13), 25.1 (C-10 and C-12), 11.2 (C-11 and C-14), 124.1 (C-4a and C-5a), 55.7 (OMe).

A solution of BBr_3 (1 M) in CH_2Cl_2 (300 μl) was added to a solution of pure **33m** (180 mg) in dry CH_2Cl_2 (9 ml) at −70°C under N_2. After 4 hr at 0°C with magnetic stirring, H_2O (6 drops) and sat'd. aq. $NaHCO_3$ (6 ml) were added and the mixture was extracted with EtOAc to give crude 2,7-dihydroxy-1,6-dimethyl-9,10,12,13-tetrahydropyrene **33** (170 mg), which was purified by preparative TLC (benzene–Et_2O, 7:3), and had ^1H NMR: δ 6.53 (s, H-3 and H-8), 2.64 (s, H-9, H-10, H-12, and H-13), 2.07 (s, H-11 and H-14); ^{13}C NMR: δ 118.7 (C-1 and C-6), 153.3 (C-2 and C-7), 111.7 (C-3 and C-8), 131.7 (C-4 and C-8a), 134.0 (C-5 and C-1a), 28.1 (C-9 and C-13), 24.6 (C-10 and C-12), 11.2 (C-11 and C-14), 122.6 (C-4a and C-5a).

Tetrahydropyrene (**33,** 135 mg, 0.5 mmol) in dry CH_3CN (10 ml) was treated with $Hg(CN)_2$ (1.5 mmol) and acetobromo-α-D-glucose (1 mmol). After 24 hr at room temperature the mixture was diluted with $CHCl_3$ and filtered. The filtrate was chromatographed on silica gel to give crude peracetates of **28** (hexane–EtOAc, 7:3, 31 mg) and **29** (hexane–EtOAc, 3:2, 65 mg) and a mixture of peracetates of **30, 31,** and **32** (hexane–EtOAc, 1:1, 60 mg). The peracetates of **28** and **29** were heated 30 min with refluxing ethanolic KOH (5%) and the glucosides **28** and **29** were extracted with *n*-BuOH and purified by HPLC. Compound **28** (22 mg) had ^{1}H NMR: δ (CD_3OD) 6.95 (s, H-3), 6.51 (s, H-8), 5.48 (d, J = 2.8 Hz, G-1), 2.75 (s, H-9, H-10, H-12, H-13), 2.25 (s, H-11), 2.14 (s, H-14).

The mixture of peracetates was resolved by preparative TLC (benzene–Et_2O, 3:2), and the pure compounds were hydrolyzed with ethanolic KOH (5%) to give **30** (8 mg), **31** (13 mg), and **32** (9 mg). Compound **31** had ^{1}H NMR: δ (CD_3OD) 6.92 (s, H-3), 6.97 (s, H-8), 5.50 (d, J = 2.8 Hz, G-1β), 4.88 (overlapped G-1α), 2.78 (s, H-9, H-10, H-12, H-13), 2.24 (s, H-11), 2.26 (s, H-14). Compound **32** had ^{1}H NMR: δ (CD_3OD) 6.97 (s, H-3 and H-8), 5.51 (d, J = 2.8 Hz, G-1), 2.78 (s, H-9, H-10, H-12, H-13), 2.26 (s, H-11 and H-14).

Bioassay. The strain UTEX 1648 *Selenastrum capricornutum* was maintained on Bold basal medium (BBM) (Nichols, 1973) solidified with agar 1.5% in continuous light at 23°C. Fresh axenic cultures for the experiments were grown in 100-ml cylinders on the same culture medium. For the growth tests the phenanthrenes **1–18** and **33** were dissolved in acetone, compounds **21, 22, 27,** and **30–32** in water, and the remaining compounds in DMSO. Each solution (20 μl) was added to the test tubes containing 6 ml of inoculated medium, to give final concentrations of 10^{-4}, 7.5×10^{-5}, 5×10^{-5}, 2.5×10^{-5}, and 10^{-5} M. Blanks containing only acetone, DMSO, or water in BBM, respectively, were also tested. The test tubes were incubated at 23°C on a shaking apparatus previously described (Aliotta et al., 1991). The total irradiation of 150 μE/sec m^2 was provided by daylight fluorescent lamps (Philips TLD 30 w/55) from below the apparatus. The photoperiod was 16 hr light–8 hr dark. Growth of cultures was followed daily either by measuring the absorbance increase at 550 nm with a Bausch & Lomb Spectronic 20 colorimeter or by counting the cell numbers with a Thoma blood-counting chamber. The cell numbers of the initial inocula ranged from 10^6 to 1.5×10^6/ml, corresponding to 0.05–0.06 units of absorbance. Growth experiments were carried out in triplicate. According to the two types of growth inhibition observed (reduced growth rate for compounds **1, 2,** and **4–32** and increased lag phase for **3** and **33**), the growth rates or the lag phases were calculated. To test statistical significance of results, one-way ANOVA was performed at $\alpha = 0.05$. For each

compound, a comparison among means was performed using Student-Newman-Keuls test (SNK), at $\alpha = 0.05$. The SPSS statistical package was used.

The index of inhibition for compounds **1, 2,** and **4–32** was calculated as: $(1 - X_a/Y_a) \times 100$ (Blankley, 1973), where X_a is the growth rate of the alga in the presence of the compound tested, and Y_a is the growth rate of the control. The inhibition for compounds **3** and **33** was calculated as: $(1 - X_b/Y_b) \times 100$ (Blankley, 1973), where X_b is the lag phase of the alga in the presence of the compounds tested, and Y_b is the lag phase of the control.

RESULTS AND DISCUSSION

The structures of the compounds tested in this study are shown in Figure 1. Plants of *J. effusus* were air-dried and extracted with ethyl ether and methanol sequentially. The crude extracts were assayed for their biological effects on *S. capricornutum,* one of the organisms recommended for the standard algal assay procedure developed for aquatic systems (Pipe and Shubert, 1984). Both extracts were effective in inhibiting algal growth. The ethyl ether extract was separated into an acidic and a neutral fraction and sequential bioassay-oriented chromatographic processes (CC, TLC, and HPLC) of these fractions gave dihydrophenanthrenes **1–18,** which were mainly identified on the basis of their ^{13}C NMR (Tables 1 and 2) and ^{1}H NMR data (Tables 3 and 4) (Della Greca et al., 1992, 1993). The bioassay-oriented chromatographic processes (CC, DCCC, and HPLC) of the methanolic extract gave 11 glycosides, which were identified as dihydrophenanthrene glucosides **19–27** and tetrahydropyrene glucosides **29** and **30** on the basis of their spectroscopic features (Tables 2, 4, and 5) (Della Greca et al., 1995a–c).

The natural compounds **1-27, 29,** and **30** and the correlated hemisynthetic tetrahydropyrenes **28, 31–33** were assayed in broth against *S. capricornutum.* Two types of inhibition were observed. Compounds **1, 2,** and **4–32** caused a decrease of the growth rate during the exponential phase of growth, while in the experiments with **3** and **33** an increase of the lag phase, with lengthening dependent on the initial concentration of the compounds, was observed. The activity was calculated as percentage of inhibition or stimulation caused by compounds at five different concentrations (Tables 6 and 7).

All the free dihydrophenanthrenes inhibited algal growth. Compounds **1, 4, 6, 12, 15,** and **16** were lethal to the alga at 10^{-4} M, the highest concentration used, and 13 compounds (**1, 4, 7–13** and **15–18**) caused 15–30% inhibition at 10^{-5} M, the lowest concentration tested.

A comparison among compounds **1, 2,** and **5,** which had identical patterns of substituents at C-1, C-2, C-5, and C-7, showed that the presence of the

[d]The couplings (Hz) are reported in parentheses.

methyl group in the C ring enhanced the activity. Compound **1** with the methyl at C-6 was more active than compound **5** with the same substituent at C-8.

Less important is the presence of the polar hydroxyl group in the C ring. Compound **3,** which lacks this group, and compound **8,** which has a methoxyl group, exhibited high activity. The isomeric compounds **1, 4, 5, 6,** and **11** as well as the isomeric carboxylic acids **9** and **10** and the isomeric carbinols **15** and **17** had rather similar activity showing that the relative positions of substituents is unimportant.

The presence of a substituent at C-5 seems to be important for biological activity. Compound **18,** which has a hydrogen at this position, is less active than compounds **4, 12, 15,** and **16.** The activity of aldehyde **14** is not comparable because of its instability in the bioassay conditions.

Glucosylated dihydrophenanthrenes **19–27** did not inhibit the algal growth and compounds **26** and **27** had a slight stimulating effect. These results are in

[a]Recorded in CD_3OD. [b]The couplings (Hz) are reported in parentheses.

agreement with the well-known detoxification process of phenolic compounds in plants occurring by glucosylation (Harborne, 1977).

Among tetrahydropyrenes, a similar pattern of inhibition was observed. Unnatural tetrahydropyrene **33,** obtained by hemisynthesis from **1,** was the most active compound tested, causing 90% inhibition of growth at 2.5×10^{-5} M. Glucosylation of the hydroxyl groups as in **28–32** drastically reduced the biological activity, and the activities of the natural β-glucosyl derivatives **29** and **30** were comparable to those of the synthetic α-derivatives **28, 31,** and **32.**

Although the reduction of nutrient efflux in the environment remains the most effective method for the control of the algal growth, mainly in the case of filamentous algae (Canale and Auer, 1982; Lembi et al., 1988), the use of algicides could be important in those sites where nutrient reduction is not readily

applicable, such as irrigation and drainage channels that collect water from crops.

On the other hand, the search for new compounds toxic to algae has not been very successful. According to Milne and Callow (1985), there is a conflict between the need for a powerful, selective algicide and the requirement of using a safe and harmless compound. At the present time only a few algicides are effective in the control of algal growth in fresh water. Anderson and Dechoretz

(1984) indicated six active ingredients currently used in the United States for algal control: copper sulfate, simazine, endothall, acrolein, diquat, and chlorine. Copper sulfate is less toxic and a more commonly utilized algicide; it can be used in water for fishing, aquaculture, irrigation, and swimming, although its harmful effects on aquatic fauna preclude its use in large-scale treatments in natural environments (Andrews, 1986). On the other hand, this salt can have little effect on the algal population to be controlled when a dense growth occurs, especially if organic chelators are present in water (McKnight, 1981). Moreover, Elder and Horne (1978) pointed out that alkaline pH and high organic carbon levels in the water may detoxify the copper ions, so that it may actually stimulate growth.

There is evidence that certain phenolic compounds are selectively toxic to algae. Recently, a study carried out on 22 compounds that mimic natural phenylpropanoids revealed that some of these substances have a selective antialgal activity (Della Greca et al., 1995d). The differential resistance to phenylpropanoid seems to reflect ultrastructural and physiological differences within algae. A previous study provides evidence that the ultrastructure of the cell wall in green algae influences the toxic action of α-asarone. In fact, when a trilaminar cell wall with a sporopollenin layer was present, as in strain C202.7a *Ankistrodesmus braunii*, the toxic effect of α-asarone was very reduced (Pollio et al., 1993).

Previous results have indicated that the action of phenanthrenes also can be selective. Dihydrophenanthrenes **1–18** have been tested for their cytotoxic activity against brine shrimp, *Artemia salina* (Della Greca et al., 1993). It is noteworthy that some of these compounds, such as **12** and **13**, were strongly active against *S. capricornutum* and ineffective against *A. salina* at the same concentrations. Further investigations are in progress to ascertain whether dihydrophenanthrenes and tetrahydropyrenes are able to selectively control the growth of different algal strains.

(Received March 21, 1995; accepted September 4, 1995)

Abstract—The composition of the five-component honey bee queen mandibular gland pheromone (QMP) of mated European honey bee queens was compared to those of virgin and drone-laying (i.e., laying only haploid unfertilized eggs that develop into males), European queens and Africanized mated queens. QMP of mated European queens showed significantly greater quantities of individual components than all queen types compared, except for a significantly greater quantity of 9-hydroxy-(*E*)-2-decenoic acid (9-HDA) found in Africanized queens. Glands of European drone-laying queens contained quantities intermediate between virgin and mated queens, reflecting their intermediate reproductive state and age. QMP ontogeny shifts from a high proportion of 9-keto-(*E*)-2-decenoic acid (ODA) in young unmated queens to roughly equal proportions of ODA and 9-HDA in mated queens. A biosynthetic shift occurs after mating that results in a greater proportion of 9-HDA, methyl *p*-hydroxybenzoate (HOB), and 4-hydroxy-3-methoxyphenylethanol (HVA) production, accompanied by a decreased proportion of ODA. Africanized QMP proportions of ODA and 9-HDA were significantly different from European queens. A quantitative definition of a "queen equivalent" of QMP is proposed for the various queen types, and a standard queen equivalent for mated European honeybee queen mandibular gland pheromone is adopted as 200 μg ODA, 80 μg 9-HDA, 20 μg HOB, and 2 μg HVA.

Key Words—*Apis mellifera*, honey bee, queen mandibular gland pheromone, Africanized honey bee.

INTRODUCTION

One of the most interesting aspects of honey bee biology is the variability found within and between races of *Apis mellifera*. Bees vary in behavioral, morphological, and physiological characteristics. Much of the worldwide success of this species is attributed to the variation among colony members providing adaptive advantages in different habitats (Seeley, 1985; Winston, 1987, 1992). A great deal is known about the phenotypic and genotypic variability among worker bees within colonies, but the variability among queen honey bees is not as widely studied. Here we present a detailed characterization and comparison of inter- and intraracial variation of queen mandibular gland pheromone.

Queen mandibular gland pheromone (QMP) is a blend of the three abundant aliphatic acids, 9-keto-(*E*)-2-decenoic acid (ODA), and 9-hydroxy-(*E*)-2-decenoic acid (9-HDA), present as two optical isomers [*R*-(−) and *S*-(+)], and two aromatic compounds; methyl *p*-hydroxybenzoate (HOB), and 4-hydroxy-3-methoxyphenylethanol (HVA) (Slessor et al., 1988). As a primer pheromone, QMP has been shown to delay swarming (Winston et al., 1991), suppress queen rearing (Pettis et al., 1995; Winston et al., 1989, 1990), inhibit worker juvenile hormone (JH) biosynthesis in the laboratory (Gast, 1967; Hildebrandt and Kaatz, 1990; Kaatz et al., 1992), and regulate foraging age of adult worker bees and suppress JH titers in colonies (Pankiw et al., unpubl. data). QMP also has some releaser pheromone functions, including retinue formation around the queen (Slessor et al., 1988; Kaminski et al., 1990), attraction of workers to swarms (Winston et al., 1989), stimulation of pollen foraging (Higo et al., 1992), calming of queenless workers (Naumann et al., 1990), and attraction of foragers to crops (Currie et al., 1992a,b).

In this study we extracted QMP from the glands of various European and Africanized queen types and compared the quantities and ratios of individual components. The ontogenetic development of the QMP signal also is presented, and a definition of one queen equivalent is proposed that reflects racial and reproductive differences, while allowing for the natural variation found among individuals.

The only previous descriptions of the five-component blend of QMP in *Apis mellifera* L. have been done by Slessor et al. (1988, 1990). The study presented here analyzes a greater number and range of queen types and permits a more complete description of QMP in *Apis mellifera*. The queen types examined here include European mated, virgin, and drone-laying queens, representing various female honey bee reproductive types, and mated Africanized queens. Africanized bees are derived from South African bees accidentally released in

South America. The rapid expansion of Africanized honey bees throughout South and Central America can be attributed to their propensity to higher swarming rates with smaller swarm sizes (Winston et al., 1983). Since QMP is important to colony cohesion and plays a role in the timing of swarming both in European and Africanized honey bees (Pettis et al., 1994; Winston et al., 1991), QMP difference may influence differences in swarming behavior between these races.

METHODS AND MATERIALS

Queen Collection and Mandibular Gland Component Analysis

Queens were immediately placed on Dry Ice upon collection, then into labeled Eppendorf tubes, and stored at −70°C prior to dissection, except where stated otherwise. Mandibular glands were extirpated, then extracted in 2 × 50 μl of methanol containing 10-undecenoic acid (0.22 mg/ml) as an internal standard. Two-microliter aliquots of the extracts were derivatized with BSTFA (Slessor et al., 1990), diluted with hexane and analyzed by splitless capillary gas chromatography on an HP5890 gas chromatograph equipped with a flame ionization detector (FID), and a 30-m DB-1 fused-silica capillary column. The FID was calibrated with standards of known concentration, and these FID responses were used to calculate the amount of each component in the mandibular gland extracts.

European Mated Queens. Mandibular gland extract data from 125 1- and 2-year-old mated queens of Simon Fraser University stock most similar to *Apis mellifera ligustica* were combined to establish a baseline mated queen mandibular gland component profile. Data from 10 queens have not been reported previously, and the remainder are from Slessor et al. (1990), Pankiw et al. (1994), and Pettis et al. (1995).

Virgin Queens. Ten virgin queens of Simon Fraser University stock most similar to *Apis mellifera ligustica* were reared until 2 weeks old and then collected in July and August 1992. Mandibular gland component analysis results from these queens were combined from seven queens from Slessor et al. (1990) for a total of 17 queens.

European Drone-Laying Queens. Twenty-two queens of mixed stock most similar to *Apis mellifera ligustica* were narcotized two times with CO_2 seven days after emergence and instrumentally inseminated with insect saline solution to induce haploid male egg laying. They then were collected from five-frame nucleus colonies at 8 weeks of age on August 21 and 22, 1991, as above. Queens were dissected from May 20 to June 6, 1992.

Africanized Mated Queens. Twenty mated Africanized queens were obtained from Mexico in 1992. Morphometric (Daly and Balling, 1978) analysis of the progeny confirmed the racial status of these queens. Queens were transported

on Dry Ice by overnight courier from Mexico and received March 3, 1992. The queens were stored at −70°C prior to dissection from June 22 to 29, 1992.

Proportions and Ratios

To develop an ontological profile of queen mandibular gland components, the results reported in Slessor et al. (1990), Pankiw et al. (1994), Pettis et al. (1995), and this study were combined. Ratios of HDA, HOB, and HVA to ODA were calculated to develop a definitive formula of a QMP queen equivalent.

Statistical Analysis

Analysis for statistical differences between European mated and all other queen types were performed using the one-tailed *t* test Satterthwaite method for unequal variances (Snedecor and Cochran, 1980). Analysis for statistical differences between European mated and all other queen types for proportion and ratio data were by the Kruskal-Wallis test (Conover, 1980). SAS was used for all statistical analyses. The level of significance throughout was at the 0.05 level, unless stated otherwise.

RESULTS

Quantities. Glands of European mated queens contained statistically greater quantities of all QMP components compared to virgin, drone-laying, and Africanized queens (Figure 1), except for a statistically similar quantity of 9-HDA in Africanized and European mated queens (Figure 1).

Proportions and Ratios. Queen mandibular gland biosynthetic capabilities appear to be ontogenetic (Figure 2); an examination of individual QMP component proportions to the total amount of QMP reveals a reproductive shift in the pheromonal "bouquet" (Figure 2). Virgin queen glands contained high proportions of ODA and lower 9-HDA proportions. Drone-laying queen ODA and 9-HDA proportions were intermediate between virgin and mated queens. Mated queen glands contained significantly greater proportions of 9-HDA compared to virgin queens (Figure 2). Africanized queen ODA proportions were significantly lower, and 9-HDA higher, compared to mated European queens.

The aromatic component (HOB and HVA) proportions changed significantly with reproductive status (Figure 2). Virgin and drone-laying queen glands contained significantly lower proportions of the aromatic components. Africanized queen gland aromatic proportions were similar to mated European queens (Figure 2).

The ratios of 9-HDA, HOB, and HVA to ODA in the glands for the various

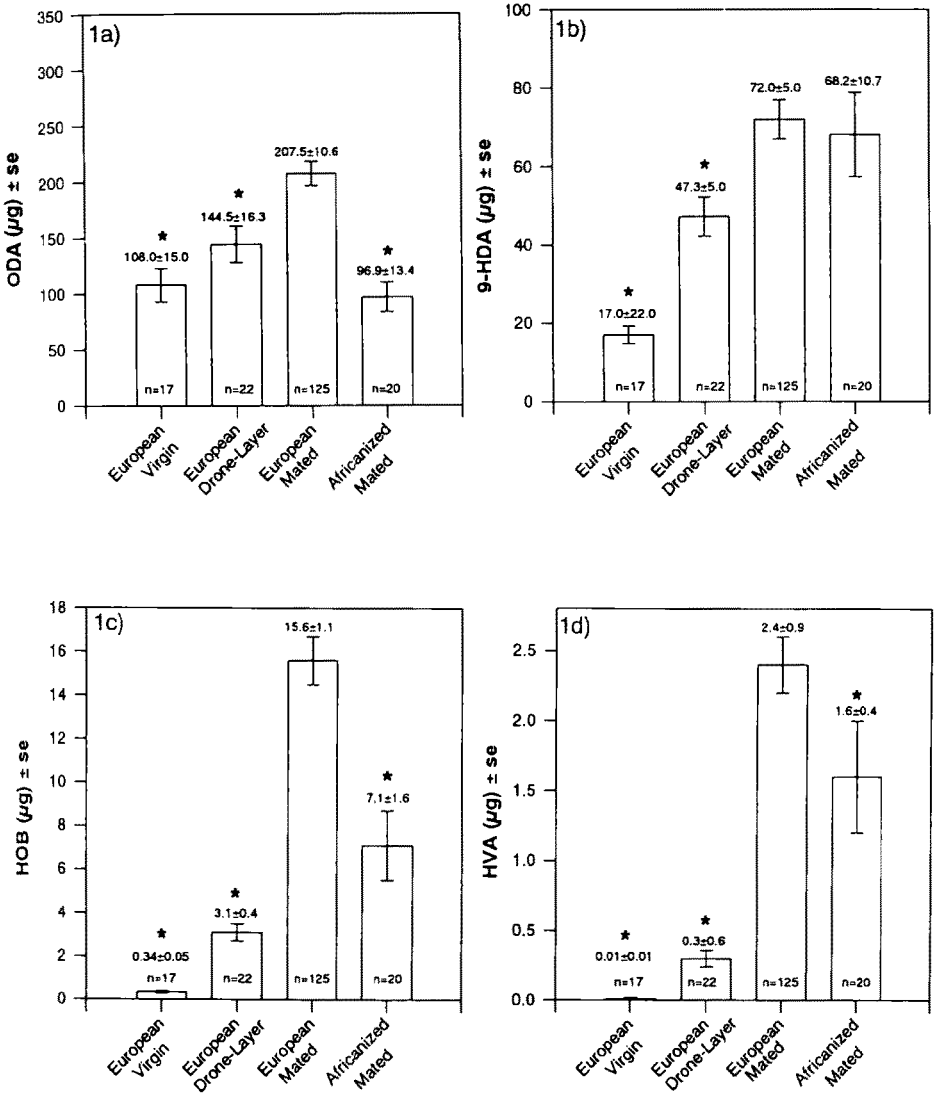

FIG. 1. Whole gland quantities of individual queen mandibular pheromone components. An asterisk above a bar indicates a statistically significant difference from the mated European queen mean at the 0.05 level; (a) ODA, 9-keto-(*E*)-2-decenoic acid; (b) 9-HDA, 9-hydroxy-(*E*)-2-decenoic acid; (c) HOB, methyl *p*-hydroxybenzoate; (d) HVA, 4-hydroxy-3-methoxyphenylethanol.

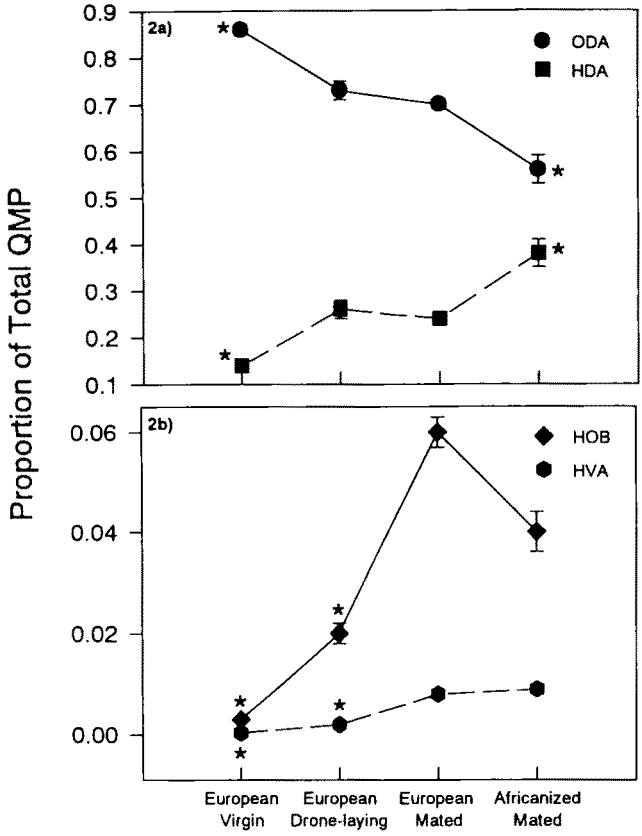

FIG. 2. Ontogenetic and reproductive profile of QMP extracted from glands. An asterisk indicates a statistically significant difference from the mated European queen mean at the 0.05 level. Invisible standard error bars are less than the size of the symbol.

queens are summarized in Table 1. The gland ratio of 9-HDA/ODA was significantly higher in Africanized than European mated queens and significantly lower in the virgin queens. The virgin and drone-laying queen glands contained significantly lower ratios of HOB/ODA, and HVA/ODA compared to the European queens, whereas Africanized queen glands contained similar ratios.

Table 2 demonstrates examples of calculated queen equivalents of glandular QMP based on the mean ODA values from Figure 1a.

Frequency Distributions. Frequency distributions of QMP component quantities of the mated European queens (Figure 3) indicated a wide range of variability in the composition of this pheromone.

TABLE 1. MEAN RATIOS OF QMP COMPONENTS TO ODA FOR VARIOUS QUEEN TYPES

Queen type	Ratios		
	9-HDA/ODA	HOB/ODA	HVA/ODA
European mated	0.40	0.09	0.01
Africanized mated	0.75[a]	0.07	0.02
European drone-laying	0.40	0.03[a]	0.002[a]
European virgin	0.20[a]	0.004[a]	0.0004[a]

[a]Significant ($P < 0.0002$) difference from mated European queen.

TABLE 2. CALCULATED VALUES FOR ONE QUEEN EQUIVALENT OF QMP

Queen type	Queen equivalent QMP components (μg)[a]			
	Mean ODA	Calculated 9-HDA	Calculated HOB	Calculated HVA
European mated	208 (200)	83 (80)	19 (20)	2 (2)
Africanized mated	97 (100)	39 (40)	7 (10)	2 (2)
European drone-layer	145 (145)	58 (60)	4 (5)	0.4 (1)
European virgin	108 (100)	22 (20)	0.8 (1)	0.7 (1)

[a]Values in parentheses are proposed "standard" queen equivalent values.

DISCUSSION

We define one queen equivalent (QE) based on the mean ratios of 9-HDA, HOB, and HVA quantities to ODA for the various queen types (Tables 1 and 2). A standard queen equivalent for the mated European queens, derived by rounding off from values in Table 2 is: 200 μg ODA, 80 μg 9-HDA, 20 μg HOB, and 2 μg HVA. Proportions of the total amount of QMP also may be used to achieve similar queen equivalent values. The primary purpose for proposing a queen equivalent definition is to reflect racial and reproductive differences, while incorporating the variation found in nature. Previously reported definitions of one queen equivalent used for synthetic formulations were: (1) 150 μg ODA, 55 μg 9-HDA, 13 μg HOB, and 1.5 μg HVA (Slessor et al., 1988), and (2) 250 μg ODA, 150 μg 9-HDA, 20 μg HOB, and 2 μg HVA (Slessor et al., 1990). These two queen equivalent values were formulated based on the most current knowledge of mean queen equivalent QMP component values at the time and fit well within the distributions reported here (Figure 3).

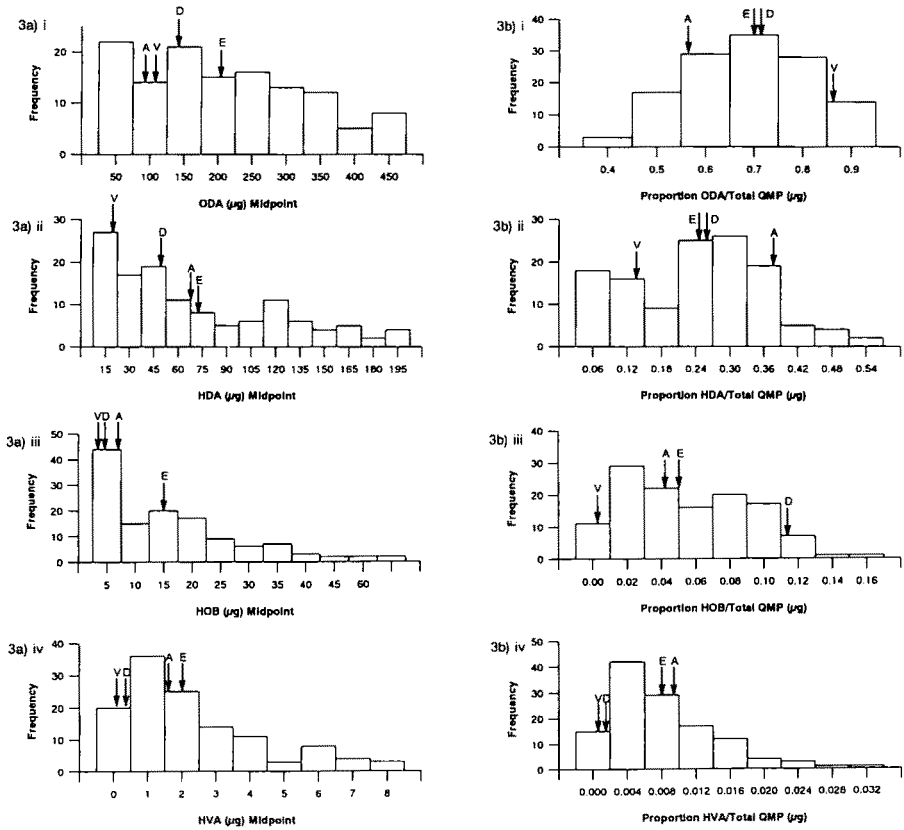

FIG. 3. Frequency distribution histograms of quantity and proportions of QMP components of 125 mated European queens: A = mean, Africanized mated queens; D = mean, European drone-laying queens; E = mean, European mated queens; V = mean, European virgin queens. Midpoint represents the median value of a range, e.g., in Figure 3a)i, a midpoint of 50 µg includes amounts of ODA greater than or equal to 0 µg and less than 75 µg ($0 \leq 50 < 75$).

The first queen equivalent definition was more reflective of mean ratios than the second (Table 1).

The comparisons between European and Africanized mated queens reveal some differences in the quantities and proportions of QMP components in these two honey bee races. However, this trait would not be reliable for classifying individual queens into a race category due to the high variability between individual queens (Figure 3). For all variables, Africanized means fall within high

frequency categories of European means, except perhaps the quantity of 9-HDA. Crewe (1982) reported differences in the proportion of mandibular gland components among *A. m. adansonii*, *A. m. mellifera*, and *A. m. capensis*, but discriminant analysis indicated that gland components were not dependable predictor variables for grouping inbred lines. Methodological differences between previously published African queen mandibular gland component quantities or percentages (Crewe, 1982; Crewe and Velthuis, 1980; Allsopp, 1988) and results reported in this study make comparisons unrealistic, but comparative studies would be of interest in the future.

Queens of either race may head colonies composed of workers of both races (Winston, 1992), and thus it appears that workers will accept racially different queen signals. Further, a European-like synthetic blend of QMP is equally effective at preventing queen rearing in colonies of either European or Africanized bees (Pettis et al., 1994). Nevertheless, the lower total quantity of QMP found in Africanized queens may contribute to the tendency for Africanized colonies to swarm with smaller parent colony sizes. The higher proportion of 9-HDA in Africanized queen glands (Figures 1 and 2) may reflect an adaptation to greater swarming activity in this race, because 9-HDA is an important component for swarm clustering behavior (Winston et al., 1982).

Unmated virgin queens not only produce significantly lower quantities of QMP components, but the proportions of components are significantly different from mated queens (Figures 1 and 2). The older (8 weeks) drone-laying queen glands contained ODA and 9-HDA proportions similar to the European mated queens, but the younger (6–14 days old) virgin queen proportions were significantly different from the mated queens. The older drone-laying queen ODA and 9-HDA proportions may reflect ontogenetic development and enzymatic capabilities of the gland. Conversely, the significantly lower proportions of the aromatic components represent a nonreproductive status (Figure 2) (Slessor et al., 1990). Virgin queens were producing a significantly different signal from the mated queens, suggesting an important biosynthetic change occurs with mating that cannot be explained by age alone, as seen by the intermediate signal produced in drone-laying queens. The essence of the different signals is a combination of quantity and proportion.

The wide variation in the quantity of QMP components suggests a generic signal indicating the individual is a queen, but there are important ontogenetic and reproductive differences in the signal as well. More will need to be known about individual QMP component biological and behavioral influences before any inferences can be made concerning the meaning of total or relative presence of any component in the blend.

(Received April 10, 1995; accepted November 20, 1995)

Abstract—Effects of nitrogen availability on secondary compounds, mycorrhizal infection, and aphid growth of 1-year-old Scots pine (*Pinus sylvestris* L.) seedlings were studied during one growing season. Seedlings were fertilized with nutrient solutions containing low, optimum, and two elevated (2× and 4× optimum) levels of NH_4NO_3. At the end of growing season foliar nitrogen concentration, needle biomass, needle length, water contents of needles, root collar diameter, and number of buds increased with enhanced nitrogen availability. Addition of nitrogen did not have effect on concentrations of monoterpenes in growing needles, but in mature needles significantly decreased concentrations of some individual and total monoterpenes were detected. In growing needles the concentrations of some individual resin acids decreased, and in mature needles concentrations of some individual and total resin acids increased with increased nitrogen fertilization. Higher numbers of resin ducts were found in mature needles with nitrogen fertilization. Nitrogen fertilization decreased total phenolic concentrations in growing and mature needles of the current year, but in needles of the previous year no significant differences occurred. Mycorrhizal infection was highest at medium (optimum and 2× optimum) nitrogen fertilization levels. The relative growth rate (RGR) of grey pine aphid [*Schizolachnus pineti* (F.)] responded positively to the increase in foliar nitrogen content. However, the increase in aphid performance between optimum and the highest fertilization level was slight. This may indicate a deterring effect of resin acids on aphids. The results indicate that carbon/nutrient balance hypothesis fails to predict directly the effects of nitrogen availability on concentrations of carbon-based defensive compounds in mature foliage. Altered nitrogen supply affects allocation to secondary

metabolites differently, depending on the developmental state of the plant and the biosynthesis pathway, cost of synthesis, and storage of compounds.

Key Words—Nitrogen, *Pinus sylvestris*, monoterpenes, resin acids, total phenolics, resin canals, plant–insect interactions, *Schizolachnus pineti*, mycorrhiza.

INTRODUCTION

Scots pine (*Pinus sylvestris* L.) is normally adapted to grow on nutrient-poor sites. An excess of nitrogen increases the growth and changes the phenology of pine seedlings (Will, 1971; Lämsä et al., 1990; Rikala and Huurinainen, 1990; Dewald et al., 1992). Pines produce significant amounts of secondary compounds: phenolic compounds and oleoresin, which mainly contains monoterpenes and resin acids. These substances may have an important role in defense responses against herbivory (Alfaro et al., 1980; Larsson et al., 1986; Schopf, 1986; Elliott and Loudon, 1987; Ross and Berisford, 1990) and pathogen attacks (Flodin and Fries, 1978; Haars et al., 1981; Stenlind and Johansson, 1987; Lieutier et al., 1991; Himejima et al., 1992). Investigations of the interactions between leaf nitrogen and carbon-based chemical defense suggest that both nitrogen and allelochemicals are important factors in determining the nutritional quality of plant tissue for herbivores (Watt et al., 1990), but the response of sucking insects to host plant quality on conifers is poorly known (Waring and Cobb, 1992).

Variations in environmental conditions can modify the quantities of secondary compounds found in plants (Gref and Tenow, 1987; Björkman et al., 1991; Kainulainen et al., 1992; Muzika, 1993). Limited availability of resources, particularly nitrogen, may determine the plant investment in secondary compounds (Bryant et al., 1983; Coley et al., 1985). Bryant et al. (1983) have proposed that the carbon/nutrient balance of individual plants strongly affects their allocation of resources to primary and secondary metabolism. They predicted that increase in availability of nitrogen to plants would increase allocation of carbon to growth, resulting in a corresponding reduction of carbon-based secondary compounds, e.g., terpenes and phenolics. However, changes in terpenoid levels have not conformed to this hypothesis as well as do changes in the levels of other carbon-based compounds, such as phenolic compounds (Bryant et al., 1987; Muzika and Pregitzer, 1992; Muzika, 1993). For example, in pine needles, concentrations of terpenoid compounds increased after nitrogen fertilization (Björkman et al., 1991; McCullough and Kulman, 1991). Terpenoid compounds are synthesized and stored in resin canals, which are specialized anatomical structures. Björkman et al. (1991) suggested that the formation of resin ducts is limited by the low availability of nitrogen.

In mycorrhizal root systems the carbon allocation and nitrogen uptake are closely related (Scheromm et al., 1990; Plassard et al., 1991). Both shortage and surplus of nitrogen are reported to affect adversely ectomycorrhiza development (Marx et al., 1977; Alexander and Fairley, 1983; Väre, 1990; Holopainen and Heinonen-Tanski, 1993). Plants with well-developed ectomycorrhiza were able to allocate more carbon to shoot growth and antiherbivore defense due to better water and nutrient uptake (Gehring and Whitham, 1994). However, carbon/nutrient balance hypothesis (Bryant et al., 1983) does not take into account the changes in nutrient uptake by mycorrhiza and costs of mycorrhiza formation.

The present study measures the responses of secondary compounds, mycorrhiza, and parasite interactions of Scots pine seedlings to different nitrogen availability regimes (low, optimal, and elevated levels). The primary objective was to find out if there is variation in concentrations of secondary compounds during shoot and needle development and if secondary chemical compounds originating from separate metabolic pathways have similar responses to nitrogen availability. A further objective of the study was to detect the possible role of increased nitrogen availability to mycorrhizal symbiosis and phloem-feeding herbivores, because these biotic interactions are often disturbed when the host plant is subjected to increased nitrogen deposition, and they may affect resource allocation patterns in host plant.

METHODS AND MATERIALS

Plant Material and Fertilizer Treatment. Scots pine (*Pinus sylvestris* L.) seedlings (seed origin: Kaskimäki, Toivakka, M29-90-0004, 1 Mk PS-508) were obtained from the forest nursery of Suonenjoki (62°38′N, 27°04′E), central Finland. Seeds were sown in spring in paper pots (PS-508: 124 cm^3) filled with *Sphagnum* peat (Vapo Tree nursery peat; mixture fertilizer 11-11-18 (N-P-K) 1 kg/m^3, dolomite lime 3 kg/m^3, total nitrogen 8 g/m^2). The plants were overwintered in an open field at the Botanical Garden of the University of Kuopio. In the beginning of January, the plants were moved into a greenhouse and kept at a temperature of 5°C for a few days. The seedlings with their peat pot were planted in sand (grain size 0.5–1.2 mm) in 0.5-liter plastic pots (diameter 10.5 cm) with bottom perforations to prevent flooding and kept in a greenhouse at 14°C for one week. After that the plants were grown in a controlled growth chamber simulating the weather conditions of central Finland in June: day/night temperature was 19/12°C, the light/dark cycle 22/2 hr and the maximum light irradiance about 300 μmol photons/m^2 sec.

At the beginning of the period of new shoot growth, the seedlings were arranged into four blocks. One block of seedlings was fertilized with a solution

(50 mg N/liter) that contained the nitrogen and cation nutrition requirement for optimal growth of Scots pine (Ingestad, 1962). Two other blocks were fertilized with nitrogen levels two (100 mg N/liter) and four times (200 mg N/liter) higher than the optimum level. Seedlings were fertilized three times a week and the fourth block of seedlings received the equivalent volume of distilled water (100 ml) at each fertilization time.

Sampling. Eight seedlings of each fertilization level were sampled when the seedlings had received nitrogen equivalent to 0, 9.8, 19.6, and 39.3 g/m^2 (0, 85, 170, and 340 mg N per pot) and needles were still growing. The second sampling was made when the growth of new shoots and needles had ceased with nitrogen concentrations equivalent to 0, 16.7, 33.5, and 67.0 g/m^2 (0, 145, 290, and 580 mg N per pot). Needles and roots of seedlings were collected for secondary chemistry, light microscopy, and mycorrhizal analysis in both samples. Secondary chemistry and light microscopy samples were collected from needles of the current year. Total phenolics were also analyzed from needles of the previous year. Roots were carefully washed and divided into two lots, which were used for mycorrhizal and total phenolic analysis, respectively. In the latter sample, total nitrogen was analyzed from current-year needles of separate seedlings, which had been used in the measurement of the aphid growth rate.

Morphological and Biomass Measurements. At both sampling dates, the height of the seedlings and the water content of the needles of the current and previous years were measured. The fresh weights of current-year shoots were measured from actively growing seedlings in the first sampling. In the latter sampling root collar diameter, needle length, number of buds, and biomass of foliage were measured. Needles and stems for biomass and water content measurements were oven-dried at 60°C for two days and weighed.

Chemical Analysis. Monoterpenes were extracted from fresh needles with *n*-hexane (Kainulainen et al., 1992). Resin acids were extracted from freeze-dried needles following the procedures of Gref and Ericsson (1985). Only abietane and pimarane diterpene resin acids were investigated. Extracts were analyzed using gas chromatography–mass spectrometry (Hewlett Packard GC type 5890, MSD type 5970) using a 25-m-long HP-5 (0.2 mm ID, 0.11 μm film thickness, Hewlett Packard) capillary column as described earlier by Kainulainen et al. (1994).

Total phenolic analysis of current-year needles were made from the same needle powder as resin acids. For total phenolic analysis previous-year needles and roots were oven-dried at 45°C for two days and milled. The samples were stored in a desiccator at 4°C. Needle powder was extracted with 80% (v/v) aqueous acetone (Kainulainen et al., 1993), and total phenolics were analyzed by the Folin-Ciocalteu technique as described by Julkunen-Tiitto (1985). Tannic acid was used as a standard and results expressed as tannic acid equivalents.

Needles for total nitrogen analysis were oven-dried at 60°C for 48 hr and milled. Total nitrogen was analyzed by the standard Kjeldahl technique (Allen, 1989).

Sample Preparation for Light Microscopy. Needle samples were immediately placed in 2% glutaraldehyde in 0.05 M phosphate buffer (pH 7.0). Pieces (about 1 mm) cut from a region 1/3 behind the tip of each needle were prefixed for 20 hr in glutaraldehyde fixative and postfixed in 1% OsO_4 solution for 6 hr at 6°C. After fixation, samples were dehydrated in a graded ethanol series and embedded in Epon LX-112. Blocks were polymerized for one day at 37°C and three days at 60°C. Sections for light microscopy (five replicates) were stained with toluidine blue and studied at magnifications of 100× or 400×. The number and diameter of resin ducts and the cross-sectional area of needles were measured.

Mycorrhizal Infection. The washed root systems of the seedlings that were used for secondary chemistry analysis were stored at −24°C until analyzed. Each root system was positioned over mesh and a total of 1 m of young long roots were randomly sampled. The mycorrhizal root tips were identified under a dissecting microscope after 15 min staining by Ponceau S (Daughtridge et al., 1986). The root systems were highly dominated by one mycorrhizal type—thin-sheathed brown mycorrhizae. Therefore, only the total number of mycorrhizae was counted, and the percentage of rootlets infected by mycorrhizal fungi was used for treatment comparisons.

Aphid Growth. Bioassay with aphids was accomplished on plants that were later used for total nitrogen analysis. Third-instar nymphs of the grey pine aphid [*Schizolachnus pineti* (F.)] reared on pine seedlings receiving optimum fertilization were placed on needles of the current year when the plants had received nitrogen at 0, 16.7, 33.5, and 67.0 g/m^2. The relative growth rate (RGR) was determined by weighing the nymphs before transfer and after three days of feeding on experimental seedlings. The nymphs were weighed individually on a Sartorius Microbalance MP3 (resolution 1 μg). RGR for nymphs was calculated with the formula: $(\ln W_2 - \ln W_1)/t$, where W_2 is final weight, W_1 is initial weight, and t is time in days between the two measurements.

Statistical Analysis. Data were analyzed with one-way analysis of variance and differences between optimal and other nitrogen treatments were compared with orthogonal contrasts (Mize and Schultz, 1985).

RESULTS

Total Nitrogen and Growth. The total nitrogen concentration of needles was significantly increased with higher nitrogen fertilization (Table 1). No sig-

[a]Number of seedlings in parentheses. *F* and *P* values are from one-way analysis of variance. Differences from optimal nitrogen level (16.7 g/m^2) are compared with orthogonal contrasts. NS = not significant.

nificant differences were found in the height of the seedlings, but the appearance of seedlings was quite different among nitrogen fertilization levels. Needles were much longer and relatively easy to detach from the stem at the highest nitrogen fertilization levels compared to lower nitrogen levels. Furthermore, the seedlings with nitrogen fertilization had darker green needles than the seedlings that received only water. The biomass of needles increased linearly with enhanced nitrogen fertilization. The root collar diameter and the number of buds also increased with higher nitrogen availability. The water content of current- and previous-year needles increased with nitrogen fertilization.

Secondary Compounds. The major monoterpenes were α-pinene, 3-carene, camphene, and myrcene, which cumulatively accounted for 75–90% of total monoterpenes. Concentrations of monoterpenes in growing needles were not significantly affected by nitrogen fertilization (Table 2). However, in mature needles concentrations of tricyclene, α-pinene, camphene, myrcene, and total monoterpenes were significantly affected by nitrogen fertilization (Table 3). Concentrations of these monoterpenes were highest at the lowest nitrogen fertilization level.

Of the resin acids studied, abietic acid was the most common. In the growing needles the concentrations of levopimaric, palustric, and neoabietic acids were significantly reduced by enhanced nitrogen fertilization (Table 2). By contrast, in the mature needles the concentrations of isopimaric, palustric, neoabietic, and total resin acids were significantly increased with addition of nitrogen (Table 3).

The total phenolic concentrations of growing and mature needles of the current year were significantly affected by nitrogen fertilization (Tables 2 and 3). In mature needles total phenolic concentration at the lowest nitrogen fertilization level was significantly higher than in the optimum level, but higher fertilization levels did not reduce total phenolic concentrations. Nitrogen availability did not significantly affect the total phenolic concentrations in the previous-year needles.

Total phenolic concentration of roots was not significantly affected by nitrogen fertilization in the first sample (Table 2), but in the second sample concentrations were significantly lower at the 0 g/m^2 level than at the optimum fertilization level (Table 3).

Needle Anatomy. In growing needles the number of resin ducts was significantly higher at the highest nitrogen fertilization level than at the optimal nitrogen fertilization level (Figure 1). By contrast, in mature needles nitrogen fertilization increased the number ($r^2 = 0.287$, $P = 0.018$) and total cross-sectional area ($r^2 = 0.263$, $P = 0.025$) of resin ducts, but did not affect the diameter of resin ducts. There was a significant positive correlation between the cross-sectional area of growing ($r^2 = 0.335$, $P = 0.009$) and mature ($r^2 = 0.472$, $P = 0.001$) needles and nitrogen fertilization level.

[b] β-Pinene and sabinene were not separated from each other on HP-5 column.
[c] Seven samples.

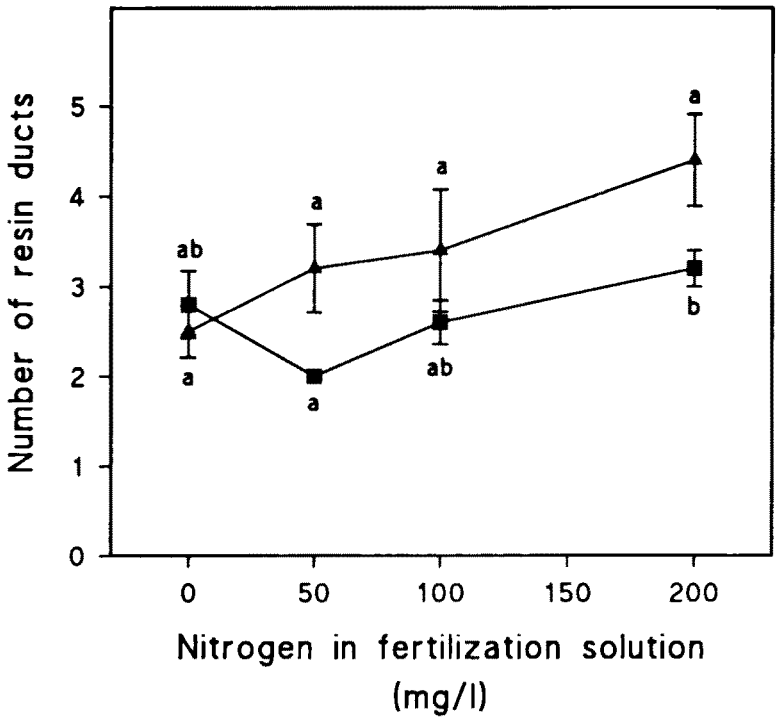

FIG. 1. Number of resin ducts at four different nitrogen fertilization levels in growing (■) and mature (▲) needles. Each value is the mean (±SE) of five samples. Mean values within a same line with the same letter are not significantly different at 0.05 level (Tukey's multiple range test).

Mycorrhizal Infection. Mycorrhizal infection responded similarly to fertilization at both sampling times (Figure 2). Both the lowest and highest nitrogen availabilities resulted in lower mycorrhizal infection levels compared to the medium fertilization levels. At the first sampling, the maximal infection was achieved by higher nitrogen fertilization than in the second sampling. Total phenolic concentration in roots did not correlate with mycorrhizal infection.

Aphid Growth. RGR of *S. pineti* nymphs was significantly ($F_{3,21} = 3.93$, $P = 0.023$) affected by nitrogen fertilization, being significantly lower ($P = 0.013$) at nitrogen fertilization of 0 g/m^2 than at the optimum level (16.7 g/m^2). RGR of nymphs was positively and nonlinearly correlated with foliar nitrogen concentration of pine seedlings (Figure 3). Secondary metabolites were not analyzed from the same seedlings that were used for bioassay. When the ratio of total nitrogen to total resin acids was calculated using treatment means, a

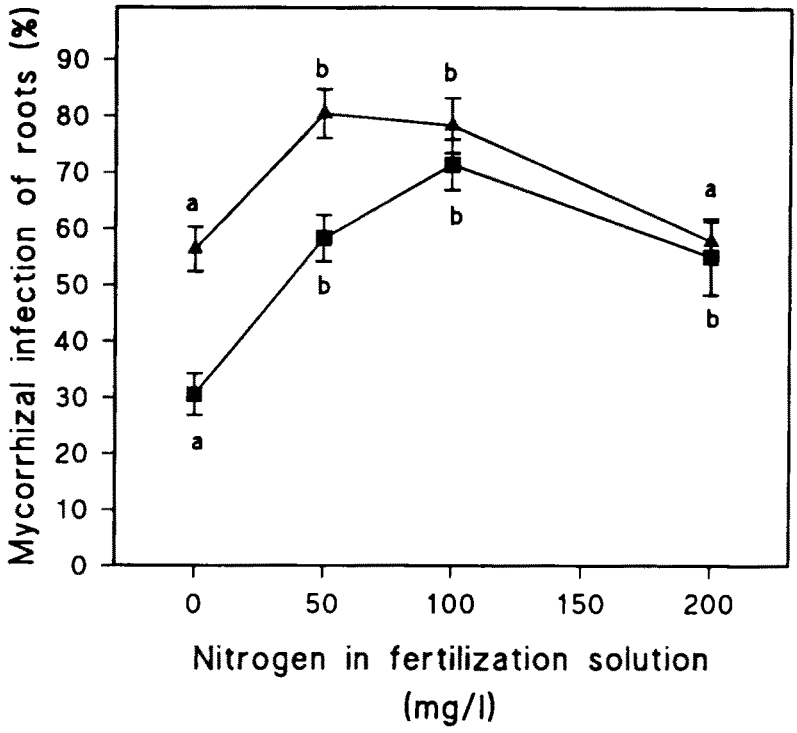

FIG. 2. Mycorrhizal infection of roots at four different nitrogen fertilization levels, in the first sampling when needles were growing (■) and the second sampling when needles were mature (▲). Each value is the mean (±SE) of eight plants. Mean values of the same line with the same letter are not significantly different at 0.05 level (Tukey's multiple range test).

significant linear positive correlation with the mean RGR of *S. pineti* nymphs per treatment was found (Figure 4). Concentrations of total nitrogen, total phenolics, total monoterpenes, and total resin acids and the nitrogen/phenolics and nitrogen/total monoterpenes ratios did not correlate with aphid RGR when treatment means were used in analyses.

DISCUSSION

Plant Growth Responses. The most distinctive growth responses of pine seedlings to increasing nitrogen availability were increases in needle length and

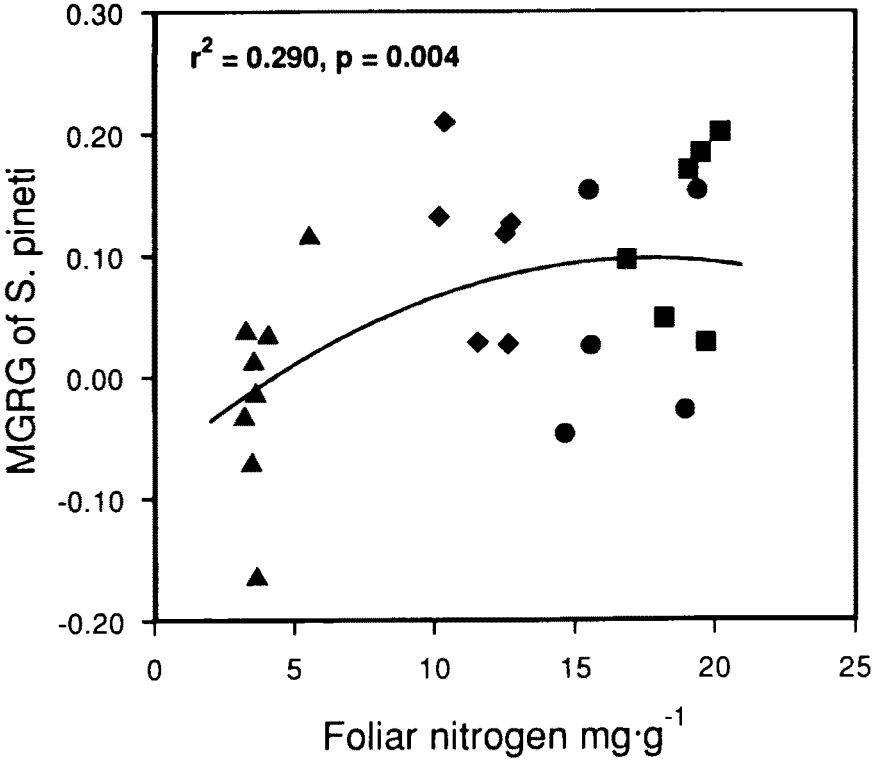

FIG. 3. Relationship between the relative growth rate of nymphs of the grey pine aphid and foliar nitrogen concentration of pine seedlings grown at four different nitrogen fertilization levels: ▲ = 0 g/m², ♦ = 16.7 g/m², ● = 33.5 g/m², and ■ = 67.0 g/m².

foliar biomass. The lack of a height growth response to nitrogen availability is explained by the fixed height growth, which is determined in Scots pine in the previous growing season during bud formation (Lanner, 1976; Kozlowski et al., 1991; Rikala and Huurinainen, 1990; Rikala, 1992). Growth allocation to photosynthesizing needle biomass reflects greater productivity and enhanced competitive ability of seedlings in response to light in a resource-rich environment (e.g., Herms and Mattson, 1992; Van der Werf et al., 1993).

Secondary Chemistry. In the present study concentrations of resin acids in mature needles increased with elevated nitrogen availability, contrary to the carbon/nutrient balance hypothesis (Bryant et al., 1983). By contrast, concentrations of foliar monoterpenes and total phenolics decreased with elevated nitro-

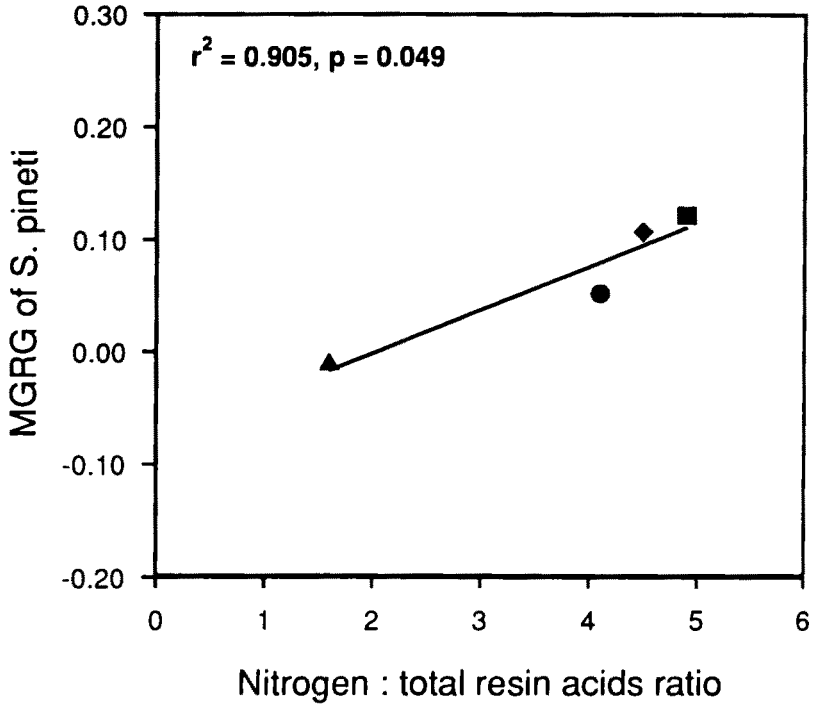

FIG. 4. Relationhip between the relative growth rate of nymphs of the grey pine aphid and foliar nitrogen/total resin acids ratio of pine seedlings grown at four different nitrogen fertilization levels: ▲ = 0 g/m^2, ♦ = 16.7 g/m^2, ● = 33.5 g/m^2, and ■ = 67.0 g/m^2 using treatment means.

gen availability, as expected by the carbon/nutrient balance hypothesis. Björkman et al. (1991) found that nitrogen fertilization resulted in higher levels of resin acids. In woody plants low nutrient availability has been observed to increase (McCullough and Kulman, 1991) or to have no effects (Thorin and Nommik, 1974; Muzika, 1993) on concentrations of monoterpenes, but in terpenoid-bearing herbs low nutrient availability stimulated monoterpene formation (Mihaliak and Lincoln, 1985; Mihaliak et al., 1987). The decreased concentrations of foliage phenolic compounds following nitrogen fertilization agree with earlier studies (Bryant et al., 1987; Muzika and Pregitzer, 1992; Hartley et al., 1995).

Terpenoid compounds, as monoterpenes and resin acids, are formed by the mevalonic acid pathway and phenolic compounds by the shikimic acid pathway. Of the major class of secondary compounds, terpenoids are among the most expensive to produce per gram (Gershenzon, 1994b). The costliest terpenoids

to produce are the ones with the lowest proportions of oxygen, e.g., monoterpenes are more expensive to produce per gram than resin acids (Gershenzon, 1994b). Overall, in Scots pine needles only a minor part of the carbon used in secondary compounds is contained in monoterpenes, while resin acids constitute a significant part of the carbon-based defense (Gref, 1982). In contrast, phenolic compounds are not especially expensive to produce (Gershenzon, 1994b), and they are stored in simple vacuoles. Terpenoid storage in complex secretory structures such as resin ducts in *Pinus* species (Lewinsohn et al., 1991) appears to impose significant costs on plants (Gershenzon, 1994b). The carbon–nutrient balance hypothesis fails to take into account the formation of multicellular storage structures needed for terpenoid synthesis and storage. The formation of these structures requires adequate supplies of nutrients, such as nitrogen, and thus terpenoid accumulation may proceed at only a limited rate under nutrient-poor conditions (Gershenzon, 1994a).

Björkman et al. (1991) observed higher resin acid concentrations in mature needles of fertilized pine seedlings as a result of the increased number and size of resin ducts. Also in the present study, the number of resin ducts and the concentrations of resin acids in mature needles were increased by fertilization. However, in growing needles the number of resin ducts was not correlated with nitrogen fertilization, and the concentrations of resin acids decreased with nitrogen fertilization. This result is consistent with our previous study of 9-week-old Scots pine seedlings, where concentrations of some individual and total resin acids in shoots decreased significantly with increasing nitrogen availability (Holopainen et al., 1995). Tobolski and Zinkel (1982) observed a large fluctuation of some resin acids during maturation of needles. It is possible that, in developing needles, if nitrogen does not strongly limit formation and synthesis of resin ducts, the excess of carbon is synthesized into resin acids. However, in mature needles the anatomy of resin canals is fully developed and the low number and size of resin ducts can limit synthesis and accumulation of resin acids at low nitrogen availability levels.

Both monoterpene (Hiltunen et al., 1975; Yazdani et al., 1982) and resin acid composition are genetically determined (Gref, 1982), but, obviously, environmental conditions can have rather strong effects on the concentrations of some compounds. Nitrogen availability had effects only on the concentration of some individual secondary compounds, while others remained unaffected. This has already been observed in many studies (Muzika et al., 1989; McCullough and Kulman, 1991; Reichardt et al., 1991; Muzika and Pregitzer, 1992; Horner et al., 1993; Muzika, 1993). In the present study concentrations of some individual resin acids—levopimaric, palustric and neoabietic acids—were affected by nitrogen fertilization, which was also seen in our previous study with 9-week-old pine seedlings (Holopainen et al., 1995). It is known that individual enzymes can yield mixtures of secondary compounds, e.g., monoterpenes and

resin acids (Gershenzon, 1994a). Probably some enzymes are more affected by environmental factors than others.

In the present study lower needle biomass was observed in seedlings with high phenolic production. In many studies, nitrogen is negatively correlated with foliage phenol concentrations (Haukioja et al., 1985; Dustin and Cooper-Driver, 1992). It has also been observed that concentrations of phenolic compounds (Ross and Berisford, 1990; Sunnerheim-Sjöberg and Hämäläinen, 1992) are inversely related to tree growth. Phillips and Henshaw (1977) observed that nitrogen inhibits accumulation of phenolics in plant cell culture, which provides evidence of the general inverse relation between nitrogen, enhanced growth, and phenolic production.

We did not find a significant correlation between mycorrhizal infection and total phenolic concentration of roots. Structural studies of roots have shown that during the mycorrhizal development, the penetrating fungus induces the formation of a tannic layer at the uppermost parts of cortex layer (Harley and Smith, 1983; Kottke and Oberwinkler, 1986), and in some other studies roots of mycorrhizal seedlings have contained significantly higher amounts of total soluble phenols than nonmycorrhizal ones (Krupa and Fries, 1971; Chakravarty and Hwang, 1991).

Symbiont and Parasite Interactions. This study indicated that ectomycorrhiza formation is retarded by both very low and high nitrogen availability, as also seen in earlier studies (Väre, 1990; Wallander and Nylund, 1991; Holopainen and Heinonen-Tanski, 1993). At the same time, aphid performance was poor at low nitrogen availability, but did not differ significantly between optimum and high nitrogen availabilities. This suggests that aphid performance is not directly related to the state of ectomycorrhizal infection. However, for some shoot parasites, such as dodder (Sanders et al. 1993), the role of mycorrhizal infection in roots can be crucial.

The interaction between mycorrhizal fungi and foliar-feeding insects is complex and very little is known of the significance of ectomycorrhizae on above-ground herbivores (Jones and Last, 1991; Gehring and Whitham, 1994). On arbuscular mycorrhizal plants aphids exhibit improved growth and reproduction compared to nonmycorrhizal plants (Gange and West, 1994). On trees, free amino acids often determine aphid performance (Kidd et al., 1990). One explanation of the lack of linear aphid growth response between optimum and higher nitrogen availabilities could be the smaller proportion of free amino acids of total nitrogen in seedlings with poor mycorrhizae at the highest nitrogen availability level, because ectomycorrhizal infection could increase the levels of free amino acids in small pine seedlings (Finlay et al., 1988; Näsholm et al., 1991). Well-developed mycorrhizae are known to increase nitrogen uptake significantly by roots (Harley and Smith, 1983), and nitrogen is translocated from the mycorrhizal roots to shoots primarily in the form of amino acids (Finlay et

al., 1988). In addition, increased nitrogen availability per se can change the balance of individual free amino acids in Scots pine seedlings (Gezelius and Näsholm, 1993) that can be harmful for *S. pineti* performance (Kidd et al., 1990).

The growth rates of *S. pineti* nymphs on new needles of nonfertilized pine seedlings was near or below zero, indicating that the needles were poorer food than needles of fertilized seedlings. Low levels of needle nitrogen and moisture or low nitrogen/total resin acid ratio, but with higher levels of total phenolics could explain this. Direct contact with oleoresin has been shown to be a primary factor in insect resistance of trees (Hanover, 1975), but the role of secondary compounds of host plant for aphid growth is poorly known (Pickett et al., 1992). Kidd et al. (1990) found that needles previously fed on by *S. pineti* are poorer food for nymphs than undamaged needles, as they have higher numbers of phenolic compounds, while total phenolics can induce phagostimulation to some stem-feeding aphid species. In field studies (Holopainen et al., 1992) there was no relationship between *S. pineti* population peaks and the foliar levels of monoterpenes and resin acids, suggesting that this aphid avoids penetrating their stylets into resin ducts. However, the present results, indicating a positive correlation in the nitrogen/total resin acids ratio, suggest that resin acids can deter aphid performance.

CONCLUSIONS

The results indicate that nitrogen availability affects allocation of carbon between growth and defense and between different pathways in the synthesis of secondary compounds. Poor nitrogen availability results in accumulation of phenolics but, contrary to the carbon/nutrient balance hypothesis, limits the concentration of carbon-based resin acids that are formed and stored in complicated multicellular structures. Reduced formation of mycorrhizae at high nitrogen fertilization levels decreases the carbon sink in roots and may partly promote carbon allocation to the formation of foliar resin acids. This can lead to decreased or increased resistance against plant parasites depending on the significance of the nitrogen/allelochemicals ratio in specific host–parasite associations. However, only controlled laboratory experiments with different fungal species can verify the actual role of ectomycorrhiza on secondary metabolism of conifers and resistance to insect herbivores.

(Received February 7, 1995; accepted November 26, 1995

Abstract—Chemically mediated host location in the eulophid parasitoid *Aprostocetus hagenowii* (Ratzeburg) was investigated. In Y-tube bioassays 77.6% of female parasitoids responded to a *Periplaneta americana* (L.) ootheca; parasitoids did not respond to air with no volatile stimuli. Frass from adult cockroaches was as attractive as an ootheca. Bioassay of one ootheca equivalent of five lipid fractions (eluted with hexane and 1, 5, 10, and 30% ether in hexane) from silica gel column chromatography indicated that the active component was a hydrocarbon. Further separation and bioassay of oothecal hydrocarbons by $AgNO_3$-impregnated silica gel column chromatography indicated that the biological activity was in one fraction. Gas chromatographic (GC) analysis of this fraction revealed a single peak; this peak was identified by researchers in 1963, 1969, and 1972 as (Z,Z)-6,9-heptacosadiene. Qualitative and quantitative GC analyses of total hydrocarbons from oothecae, frass, and adult females were essentially identical; 6,9-heptacosadiene was the dominant hydrocarbon from each source. The alkadiene was 37 times more abundant in frass than on the ootheca. The volatilization of the alkadiene from oothecae was demonstrated by aeration and trapping on Super Q adsorbent. The current study is the first evidence for biological activ-

ity of (*Z*,*Z*)-6,9-heptacosadiene, a major hydrocarbon component on adult female American cockroaches, on their oothecae, and in their frass.

Key Words—Biological control, cuticular hydrocarbon, attractant, ootheca, 6,9-heptacosadiene, Blattidae, frass, Insecta, *Periplaneta americana*, *Aprostocetus hagenowii*, kairomone.

INTRODUCTION

Kairomone-mediated host location has been well documented. Eggs (Leonard et al., 1987), pupae (Cardé and Lee, 1989), larvae (Vinson et al., 1975), wing scales (Jones et al., 1973; Shu et al., 1990), frass (Jones et al., 1971; Nemoto et al., 1987a,b; Auger et al., 1989; Fukushima et al., 1989), and mandibular gland secretions (Mudd, 1981; Mudd and Corbet, 1982; Mudd et al., 1984) contain compounds that elicit host-finding and host-acceptance behaviors from parasitoids. *Aprostocetus hagenowii* (Ratzeburg), a eulophid parasitoid of oothecae of cockroaches in the family Blattidae, exhibited typical host-recognition behaviors (drumming, tapping, drilling) on glass beads treated with calcium oxalate from colleterial glands and mucopolysaccharides from salivary glands of *Periplaneta americana* (L.) (Vinson and Piper, 1986). *Comperia merceti* (Compere) used the ootheca-fixing cement from the cockroach *Supella longipalpa* as a host-acceptance kairomone (Van Driesche and Hulbert, 1984).

The biology of *A. hagenowii* has been well documented (Roth and Willis, 1954, 1960; Cameron, 1955; Edmunds, 1955; Narasimham, 1984). Its preferred host is an ootheca of *P. americana*, but it will also parasitize oothecae of *P. australasiae* (F.), *P. fuliginosa* (Serville), *P. japonica* Karny, *P. brunnea* Burmeister, *Blatta orientalis* L., *Eurycotis floridana* (Walker), and *E. biolleyi* Rehn. Upon emergence from the ootheca, parasitoid siblings mate and females can immediately oviposit. Developmental time (i.e., oviposition to adult emergence) is approximately 30 days at 30°C; the sex ratio of the resultant clutch is strongly female-biased (86%). The broad host range, fecundity, and life cycle of *A. hagenowii* make it an excellent candidate for the biological control of Blattidae. In this study, we investigated a host-location kairomone for *A. hagenowii* from *P. americana* oothecae.

METHODS AND MATERIALS

Parasitoid. A. hagenowii was colonized in *P. americana* oothecae in the spring of 1993 from 10–20 adult female parasitoids collected at the Swine Research Unit on the University of Florida campus in Gainesville, Florida. A sample of parasitoids was sent to the U.S. National Museum, Washington, D.C., and identified by Dr. M. E. Schauff.

Oothecae were placed individually into 18-ml snap-cap vials (Thornton Plastics, Salt Lake City, Utah) each containing a single 2- or 3-day-old female parasitoid that had emerged from laboratory- and field-stung, sentinel oothecae placed in treehole microhabitats, a primary cockroach harborage in Florida. The vials were stored in plastic boxes (20 × 32 × 10 cm) and held at 27–30°C, in natural light (i.e., by a window) and humidity. Each day the vials containing newly emerged progeny were placed, with snap-caps intact, into a Plexiglas cage (30 × 30 × 30 cm) (Hagenbuch et al., 1988) and held for 24 hr to ensure sibling mating. After 24 hr the snap cap was removed from each vial, allowing parasitoids to mix. Water and food were provided from water and honey–water soaked cotton balls.

A. hagenowii used in this study were 1-day-old (29 ± 11 hr), unfed females that had emerged from three to five laboratory-stung *P. americana* oothecae. The day preceding bioassay parasitoids were released together into a clean Plexiglas cage (Hagenbuch et al., 1988) different from those cages used for parasitoid colony maintenance. The oothecae from which the parasitoids had emerged were removed from the cage to avoid possible habituation to the kairomone.

Oothecae. P. americana oothecae were collected in ootheca production units according to the method of Hagenbuch et al. (1988). Adult cockroaches were obtained as needed from a sewage treatment plant on the University of Florida campus (see Cornwell, 1968, Figure 115). One hundred to 300 mixed-sex adult cockroaches were placed in each tub and provided water from a chick waterer, seven polyvinylchloride harborages (5 cm ID × 12 cm long), and laboratory rat chow (23% crude protein; Purina, #5001, St. Louis, Missouri). Dead cockroaches were replaced, water and food replenished, and oothecae collected weekly.

Olfactometer. A Y-tube olfactometer similar to the one described by Vander Meer et al. (1988) was used in this study. The insect trap was created by a 24/40 ground glass joint. Breathable-quality compressed air was humidified (approximately 75% relative humidity) by passge over 100–200 ml of saturated NaCl solution before being regulated through two flowmeters (65 mm variable area, stainless steel float, 333 ml/min maximum airflow; Cole Parmer, Niles, Illinois) mounted to the inside back wall of a white, wood box (58 cm high × 74 cm wide × 69 cm deep) with an open front and top. The olfactometer was placed on the center floor; a space (3 cm high × 74 cm wide) between the floor and the bottom of the back wall allowed each flowmeter outlet tube to connect to each lateral arm of the olfactometer. All the airflow tubes were corrugated Teflon FEP tubing (Cole Parmer).

A chamber, constructed from the top half of a 50-ml Nalgene bottle (3 cm ID, 1 cm ID at the mouth), was built to allow the unprovoked, natural migration of parasitoids into the common arm of the olfactometer during a bioassay. Into

the bottom of the chamber was a fitted stainless steel screen (150 mesh; Small Parts Company, Miami, Florida) to prevent parasitoids from escaping and to allow the free flow of air from the common arm. Parasitoids were transferred from the Plexiglas holding cage into the chamber through its mouth, which was then fitted to the end of the common arm.

Ootheca and Frass Bioassays. All bioassays were conducted between 09:00 and 17:00 hr at 28–31°C. A single, clean (i.e., without attached detritus), < 10-day-old ootheca was placed distally in a lateral arm of the olfactometer. Ten parasitoids were then placed into the common arm of the olfactometer, and after 10 min the number that (1) moved into the olfactometer trap containing the ootheca, (2) moved into the olfactometer trap containing air only, and (3) failed to enter either trap was recorded. The procedure was repeated but with the ootheca in the other lateral arm of the olfactometer. Thus, a replicate was the response of 20 parasitoids. Each bioassay was conducted with a different cohort of 10 parasitoids. After each bioassay, the olfactometer was disassembled, rinsed with acetone, and fan-dried for 3–5 min. The bioassay was conducted at airflow rates of 30, 60, 120, and 240 ml/min/arm of the Y tube. Finally, the response of parasitoids to air (i.e., no ootheca in either lateral arm) was investigated at the highest airflow rate of 240 ml/min/olfactometer arm.

The bioassay apparatus was used to test 50, 100, and 200 mg samples (N = 2, 3, and 2 replicates, respectively) of 1- to 5-day-old frass from mixed sex adult and large nymphal *P. americana* for its attractiveness to *A. hagenowii*. All frass bioassays were conducted at the highest airflow rate of 240 ml/min/arm.

Isolation of Kairomone from Oothecae. Thirty < 10-day-old oothecae were sequentially immersed in hexane (99.9%; Baxter, Muskegon, Michigan) for 10, 5, 2, and 2 min to remove cuticular lipids. The washes were combined, reduced in volume under a gentle stream of nitrogen and chromatographed on a silica gel column (5 cm) (70–230 mesh; Sigma, St. Louis, Missouri) in a Pasteur pipet. Fractions were collected by gravity elution with sequential 6-ml aliquots of hexane, followed by 1, 5, 10, and 30% anhydrous ether (99.9%; Aldrich, Madison, Wisconsin) in hexane (Carroll, 1961). Each fraction was dried under nitrogen and immediately (< 1 min) reconstituted in hexane to provide one ootheca equivalent (OE) per 10 μl. For each fraction, 1 OE was pipetted onto a paper wick (3 × 14 mm; Northfork, Tumwater, Washington) and bioassayed at the highest airflow rate (240 ml/min/arm); a paper wick control wetted with 10 μl hexane was placed in the opposite lateral arm. A replicate was the response of 20 parasitoids (i.e., 10 parasitoids bioassayed for 1 OE in each lateral arm). Each replicate was expressed as a percentage of the response to an ootheca on the day fractions were bioassayed (i.e., on the same day, the number of parasitoids responding to a fraction divided by the number responding to an ootheca, typically 7–9 of 10).

Cuticular oothecal lipids were removed as described previously, and total hydrocarbons collected by column elution with hexane (Brill and Bertsch, 1985). Total hydrocarbons were then reduced in volume and chromatographed on a column (3 cm) of 10% $AgNO_3$-impregnated silica gel (200+ mesh; Aldrich). Fractions were collected by gravity elution with hexane followed by 2% and 10% ether in hexane (Carlson and Service, 1980). The resulting fractions were passed through a 1-cm column of silica gel and eluted with 2 ml of hexane to remove residual silver ions. Fractions were dried, reconstituted in hexane, and bioassayed.

Collection of Frass and Adult Female Hydrocarbons. Total hydrocarbons from 1- to 5-day-old frass from adult and large nymphal cockroaches and from adult females of unknown age were collected as described previously (Brill and Bertsch, 1985). Frass pellets (200 mg) were immersed in hexane for 24 hr, ground with a glass rod, and rinsed with additional hexane. Thirty adult females were immersed in hexane to remove cuticular lipids. The lipids were reduced in volume by rotoevaporation to 5 ml, and total hydrocarbons were eluted from a silica gel column (1 × 25 cm) with 80 ml hexane.

GC Analysis of Ootheca-, Frass-, and Female-Derived Hydrocarbons. Total hydrocarbons from oothecae, frass, and adult females were analyzed by GC, as were the oothecal hydrocarbon fractions from $AgNO_3$-impregnated silica gel. Additionally, the quantity of 6,9-heptacosadiene was determined for oothecae and frass ($N = 4$ independent total hydrocarbon fractions measured for each) by coinjection of 0.1 μg *n*-hexacosane standard and 0.1 OE of total hydrocarbon or with 0.1 mg equivalent of total hydrocarbon from frass.

Hydrocarbon samples (in 1 or 2 μl hexane) were analyzed with a Tracor gas chromatograph (model 540) equipped with a cool on-column injector, a flame ionization detector (340°C), and hydrogen carrier gas. The capillary column was nonpolar fused silica (DB-1; 30 m × 0.32 mm ID, 0.25-μm film thickness; J & W Scientific, Folsom, California), and the temperature program was 60°C/2 min, 20°C/min to 240°C, held for 0 min, 5°C/min to 320°C, and held for 30 min. Data were recorded with Turbochrom 3 (PE Nelson, Cupertino, California) software with a PE Nelson 900 Series Interface.

Hydrocarbons in this study were identified by chromatogram comparison with published identification of *P. americana* cuticular hydrocarbons (Baker et al., 1963; Beatty and Gilby, 1969; Jackson, 1972), and retention time comparisons with *n*-alkane standards. Baker et al. (1963) and Jackson (1972) identified the alkanes (*n*-pentacosane, 3-methylpentacosane, *n*-heptacosane, and *n*-nonacosane) by their lack of complexing on $AgNO_3$ TLC, response to hydrogenation, inclusion (or not) in a 5 Å molecular sieve, response to bromination, and comparison of GC data from known *n*-alkane standards. 3-Methylpentacosane was further identified by comparison of its mass spectrum with spectra from other cockroach-derived 3-methyl hydrocarbons (3-methyltricosane and 3 meth-

ylheptacosane). Baker et al. (1963), Beatty and Gilby (1969), and Jackson (1972) each identified 6,9-heptacosadiene by its complexing to $AgNO_3$-impregnated silica gel, response to hydrogenation, NMR, IR, UV, and mass spectroscopy. Location of the double bonds was determined by production of both caproic and stearic acids following oxidative cleavage by ozonolysis and potassium-permanganate.

Collection of Volatile 6,9-Heptacosadiene from Oothecae. Compressed air (7.2 liters/hr) was passed through charcoal gravel (#202292, GC hydrocarbon trap grade; Chromatec, Lake Worth, Florida) packed between two, 2-cm-long plugs of highly activated charcoal (Lewcott, Millbury, Massachusetts) in a glass tube (0.6 cm ID). The cleaned air then passed over 175, 1- to 7-day-old oothecae packed into a glass tube (0.6 cm ID). Volatile 6,9-heptacosadiene was collected on 20–30 mg Super Q adsorbent (Alltech, State College, Pennsylvania) held between glass wool plugs and packed into the constriction of a disposable Pasteur pipet attached to the glass tube housing the oothecae. Before volatile collection, the adsorbent was cleaned by elution with 4–5 ml of hexane and dried under a stream of nitrogen. Volatile collections were conducted at 28–30°C. After volatile collection was complete, the adsorbent was eluted with approximately 0.5 ml hexane, concentrated to 0.1 ml, and analyzed by GC-MS. Mass spectral data from volatile 6,9-heptacosadiene was generated on a Perkin-Elmer gas chromatograph (model 8420) interfaced with a Finnigan ion trap. Data were collected and analyzed by INCOS data collection software driven by an IBM-compatible 80286 computer. The capillary column was nonpolar fused silica (DB-1; 30 m × 0.25 mm ID; J & W Scientific). Samples were injected in splitless mode followed, after 30 sec, by a split-purge flow of helium. The helium carrier gas linear flow rate was 25 cm/sec, and the temperature program was 60°C/2 min, followed by 5°C/min to 320°C, and held for 10 min.

RESULTS

Ootheca and Frass Bioassays. A. hagenowii was attracted to volatiles from *P. americana* oothecae and frass. A significantly greater percentage of parasitoids responded to the ootheca at the highest airflow rate than at any of the lower airflow rates (Figure 1). Additionally, at the highest airflow rate parasitoids did not respond when exposed to only air from both lateral arms of the olfactometer; of 100 parasitoids assayed, only one was trapped. *P. americana* frass was also attractive to *A. hagenowii*; 50, 100, and 200 mg of 1- to 5-day-old frass were 97, 124.4, and 96.4% as attractive as an ootheca.

Bioassay of Oothecal Lipids and Hydrocarbons. A. hagenowii was attracted primarily to the hexane fraction (i.e., hydrocarbons) and moderately to the 1%

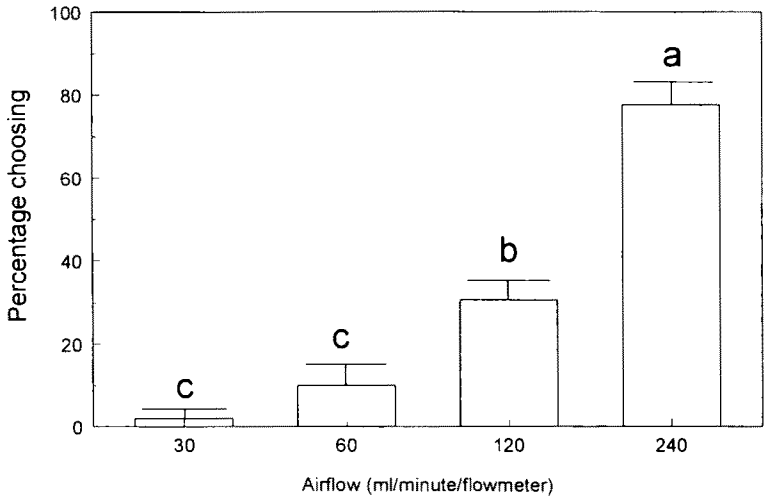

FIG. 1. Ten minute Y-tube bioassay response (mean ± SE, percentage choosing ootheca) of 1-day-old unfed *A. hagenowii* to a < 10-day-old *P. americana* ootheca at each of four airflow rates. $N = 6, 9, 5$, and 5 replicates for the 30, 60, 120, and 240 ml/min/flowmeter airflow rates, respectively. A replicate is the response of 20 insects. Bars topped by different letters are significantly different ($F = 50.4$, $df = 3,45$, $P < 0.0001$) [Tukey's Studentized range test (SAS Institute, 1988)].

ether fraction; fractions eluted with more polar solvent blends were not very attractive (Figure 2A). The hexane and 1% ether fractions were, on average, 77.6 and 19.9%, respectively, as attractive as an ootheca. Bioassay of the hydrocarbon fractions from $AgNO_3$-impregnated silica gel clearly demonstrated that the attractive compound was in the 10% ether fraction (Figure 2B); this fraction was 62.6% as attractive as an ootheca.

GC Analysis of Ootheca-, Frass-, and Female-Derived Hydrocarbons. GC analyses of total hydrocarbon from oothecae, frass, and adult females were qualitatively (Figure 3) and quantitatively (Table 1) very similar; the five dominant peaks constituted 87–96% of the hydrocarbons from each source. The dominant hydrocarbon from each source was 6,9-heptacosadiene (peak 3 in Figure 3). Baker et al. (1963), Beatty and Gilby (1969), and Jackson (1972) had previously found 6,9-heptacosadiene as the major cuticular hydrocarbon on American cockroaches.

GC analysis indicated excellent separation of saturated and unsaturated oothecal hydrocarbons by elution from $AgNO_3$-impregnated silica gel with hex-

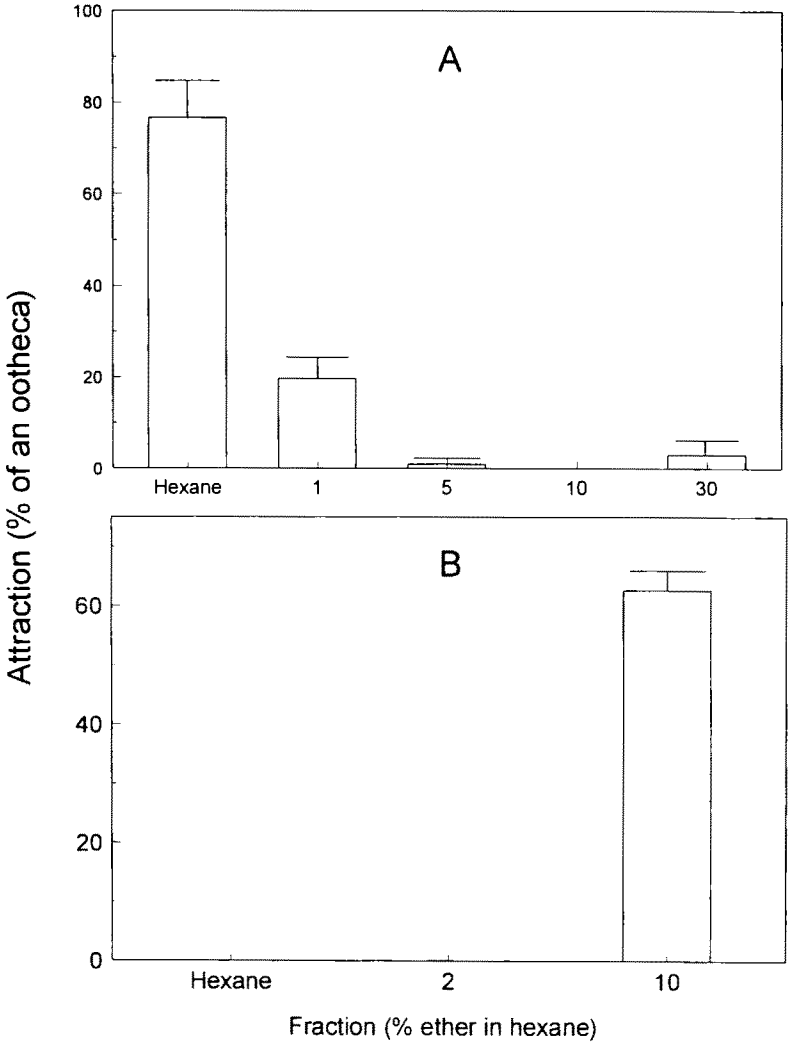

FIG. 2. Attraction (mean percentage of an ootheca ± SE) of 1 OE of (A) cuticular lipids chromatographed on 70–230 mesh silica gel, and (B) cuticular hydrocarbons separated on 10% $AgNO_3$-impregnated silica gel. Attraction is the number of parasitoids responding to a chromatographic fraction divided by the number responding to an ootheca on the same day (i.e., a percentage of the activity of an ootheca). (A) N = 7, 7, 6, 6, and 5 replicates for the hexane, 1, 5, 10, and 30% ether in hexane fractions. (B) N = 6, 6, and 9 replicates for the hexane, 2 and 10% ether in hexane fractions. A replicate is the response of 20 insects.

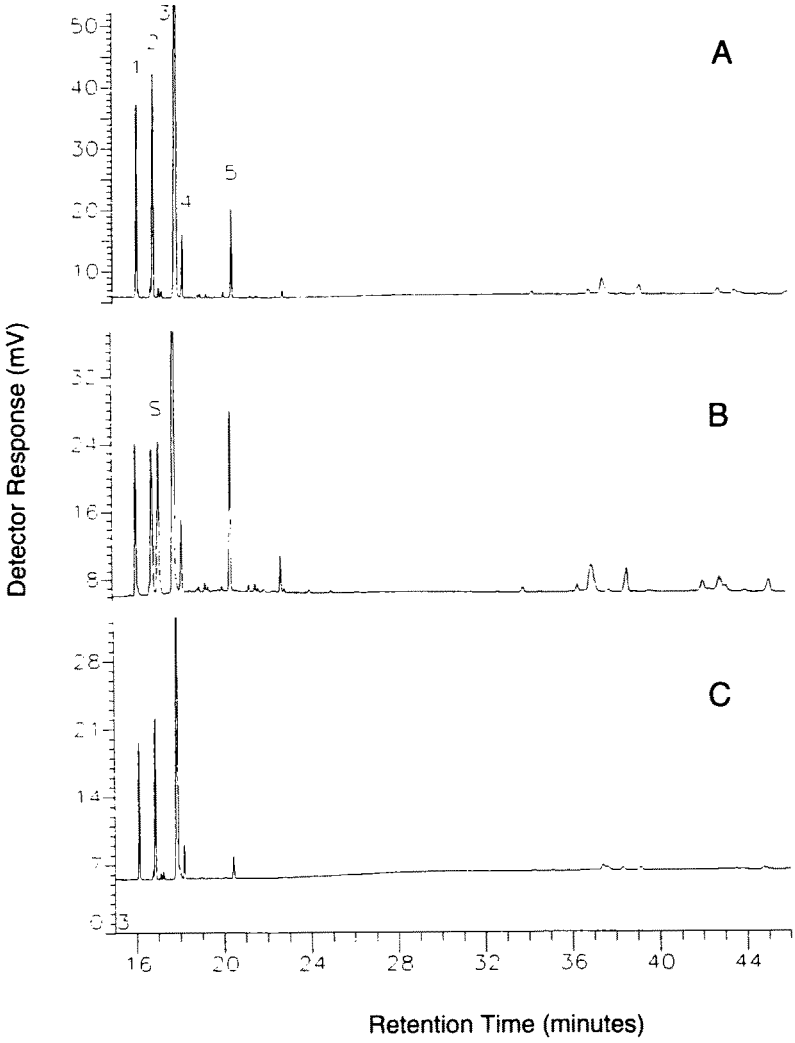

FIG. 3. Gas chromatographic analysis of total hydrocarbons from (A) 1- to 7-day-old *P. americana* oothecae, (B) 1- to 5-day-old frass, and (C) adult females. Hydrocarbon identification after Baker et al. (1963). Peak 1: *n*-pentacosane; 2: 3-methylpentacosane; 3: 6,9-heptacosadiene; 4: *n*-heptacosane; 5: *n*-nonacosane. See Table 1 for corresponding peak area percentages. Peak 3 is off scale to highlight smaller peaks. S is 0.1 μg *n*-hexacosane internal standard. Column: DB-1 (30 m × 0.32 mm ID, 0.25-μm thickness). Temperature program: 60°C/2 min, 20°C/min to 240°C, held for 0 min, 5°C/min to 320°C, and held for 30 min.

TABLE 1. PEAK AREA PERCENTAGE OF HYDROCARBONS FROM *P. americana* OOTHECAE, FRASS, AND ADULT FEMALE

Hydrocarbon source	*N*	% Peak area (mean ± SE)[a]					% of total
		1	2	3	4	5	
Ootheca	5	12.4 ± 0.83	14.7 ± 0.61	60.0 ± 1.04	3.4 ± 0.16	5.5 ± 0.23	96.0 ± 1.71
Frass	4	11.5 ± 1.30	12.9 ± 0.58	45.9 ± 1.10	4.8 ± 0.45	11.9 ± 2.33	87.0 ± 3.45
Female	4	12.9 ± 0.23	15.2 ± 0.18	62.7 ± 0.91	2.9 ± 0.14	3.0 ± 0.06	96.7 ± 0.59

[a] 1 = *n*-pentacosane, 2 = 3-methylpentacosane, 3 = 6,9-heptacosadiene, 4 = *n*-heptacosane, 5 = *n*-nonacosane. Identifications after Baker et al. (1963), Beatty and Gilby (1969), and Jackson (1972).

ane and 2% and 10% ether in hexane (Figure 4). Collectively, Figures 2 and 4 provide strong evidence that the hydrocarbon 6,9-heptacosadiene is the compound responsible for the attraction of *A. hagenowii* to *P. americana* oothecae. This compound was the only one detected in fraction 3 (Figure 4D). There was also a trace amount (2% of total) of diene present in the 2% ether fraction (Figure 4C). The hexane fraction contained only saturated hydrocarbons (Figure 4B).

On a per milligram fresh weight basis, frass contained approximately 37.1 times the amount of 6,9-heptacosadiene as oothecae (surface only). An ootheca extract contained approximately 2.09 ± 0.30 μg 6,9-heptacosadiene, or 0.024 ± 0.003 μg/mg fresh weight (based on an oothecal weight of 87.9 ± 1.29 mg, $N = 9$) and frass contained 0.881 ± 0.10 μg of the alkadiene per milligram fresh weight.

Volatiles. 6,9-Heptacosadiene that volatilized from oothecae was trapped on Super Q (peak 3, Figure 5B). Confirmation of its identity as 6,9-heptacosadiene was determined by several methods. First, via coinjection with alkane standards (*n*-hexacosane and *n*-heptacosane), its Kovats retention index (KI) on a DB-1 column was 2666 (two independent volatile collections); the KI of 6,9-heptacosadiene from *P. americana* oothecae (i.e., Figure 4D) was 2673. In addition, coinjection of oothecal-derived 6,9-heptacosadiene and the volatiles collected from oothecae resulted in elution of a single peak at the retention time of the alkadiene. Finally, the mass spectrum from 6,9-heptacosadiene trapped on Super Q adsorbent was very similar to the spectrum of 6,9-heptacosadiene derived and purified by solvent washing of oothecae; a prominent molecular ion (M^+) of 376 was present in each sample at approximately equal abundance.

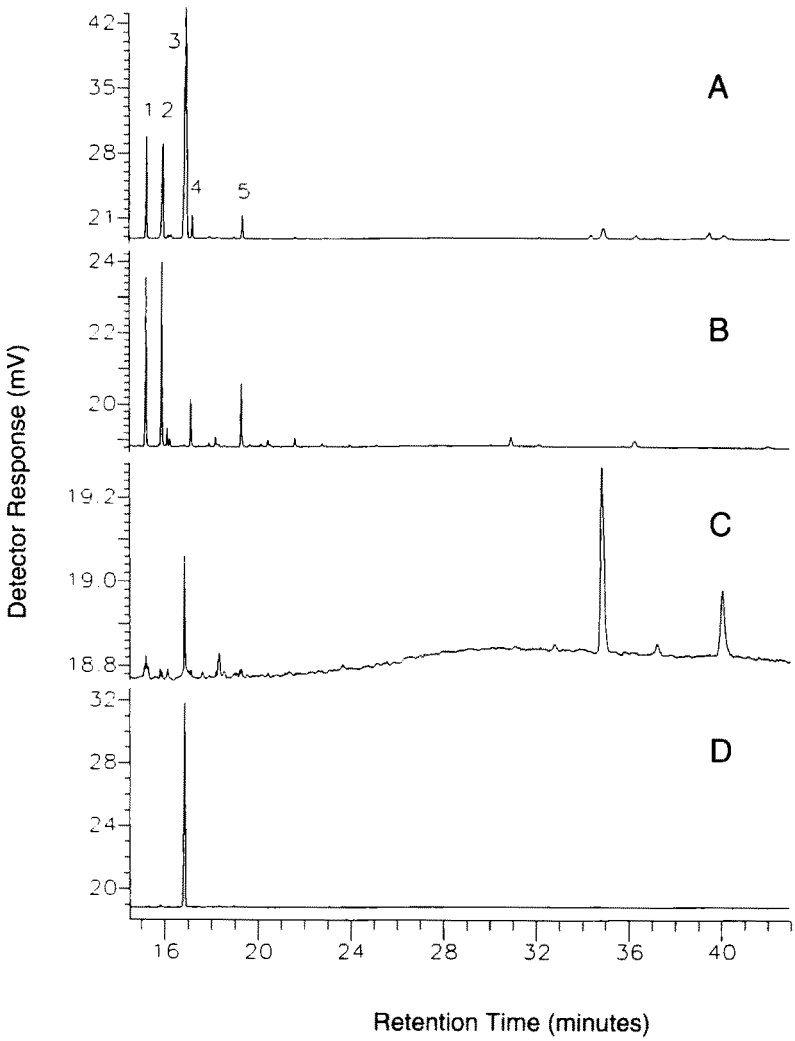

FIG. 4. Gas chromatographic analysis of (A) total hydrocarbons from 1- to 7-day-old *P. americana* oothecae, and oothecal hydrocarbons, which were separated on 10% $AgNO_3$-impregnated silica gel by elution with (B) hexane, (C) 2% ether in hexane, and (D) 10% ether in hexane, with 0.2 OE injected for the hexane, 2%, and 10% ether fractions. Hydrocarbon identification after Baker et al. (1963). Peak 1: *n*-pentacosane; 2: 3-methylpentacosane; 3: 6,9-heptacosadiene; 4: *n*-heptacosane; 5: *n*-nonacosane. The column and conditions are the same as those in Figure 3.

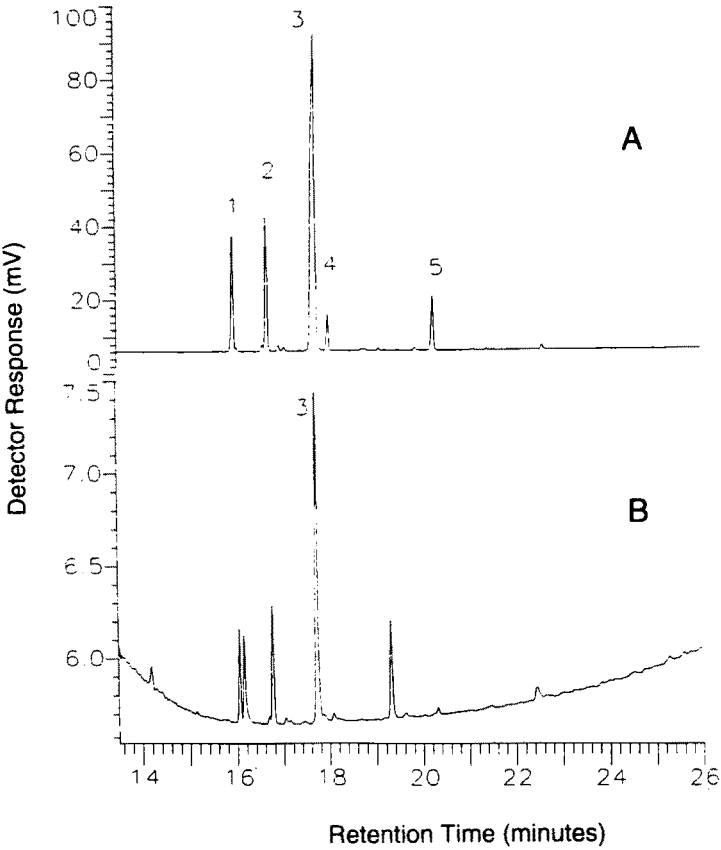

FIG. 5. Gas chromatographic analysis of (A) hydrocarbons from 1- to 7-day-old *P. americana* oothecae, and (B) partial volatiles from < 10-day-old oothecae. Hydrocarbon identification after Baker et al. (1963). Peak 1: *n*-pentacosane; 2: 3-methylpentacosane; 3: 6,9-heptacosadiene; 4: *n*-heptacosane; 5: *n*-nonacosane. The column and conditions are the same as those in Figure 3.

DISCUSSION

The hydrocarbon 6,9-heptacosadiene is used as a short-range kairomone by *A. hagenowii* for locating *P. americana* oothecae. 6,9-Heptacosadiene was identified as a cuticular component in *P. americana* adults (Baker et al., 1963) and is the most abundant lipid constituent of cuticle. Hydrocarbons account for the majority (75–95%) of cuticular lipids in *P. americana* (Gilby and Cox,

1963; Jackson, 1972), and 6,9-heptacosadiene makes up approximately 65–70% of its total hydrocarbon composition. In the present study, total hydrocarbon composition from oothecae, frass, and adult females were qualitatively and quantitatively similar, and paralleled earlier analyses of the hydrocarbon composition of adult *P. americana* (Baker et al., 1963; Beatty and Gilby, 1969; Jackson, 1972).

The current study is the first evidence of biological activity of 6,9-heptacosadiene. Alkadienes with behavioral activity have been found in other insects. For example, 7,11-heptacosadiene, found in the cuticular wax of female *Drosophila melanogaster* (Antony and Jallon, 1982; Antony et al., 1985), has activity in mating bioassays, and 6,9-nonadecadiene is a component of the sex pheromone of several geometrid moth species (Szocs et al., 1984; McDonough et al., 1986). Bartelt et al. (1982) identified a series of 9,19-alkadienes (C_{28}–C_{39}) as the sex pheromone blend of a sawfly, *Pikonema alaskensis*.

The identification of a kairomone in the frass and cuticle of a host was first documented by Jones et al. (1971), who identified 13-methylhentriacontane in the frass, larvae, saliva, and hemolymph of *Heliothis zea* as a host-seeking cue for its parasitoid *Microplitis croceipes*. *P. americana*-infested harborages often contain many kairomone-laden materials such as frass, oothecae, exuviae, and dead cockroaches. The kairomone in these materials may help to maintain a high density of parasitoids in the cockroach breeding area. Lewis et al. (1972) significantly enhanced the parasitism of Lepidoptera eggs by *Trichogramma evanescens* in Petri dishes, greenhouses, and cotton fields by prerelease application of a hexane-soluble host-location kairomone, later identified as *n*-tricosane, from moth scales. Eggs placed in locations treated with the extract suffered higher parasitism than control eggs (i.e., no kairomone). In a later study, Lewis et al. (1975) discovered that broadcast application of *n*-tricosane resulted in increased parasitism of sentinel and wild Lepidoptera eggs by wild and released *Trichogramma* spp. Unlike the inundative release of sex pheromone for mating disruption, large-scale application of a host-seeking stimulant did not confuse the parasitoids; it stimulated host-searching, resulting in increased parasitism.

Acknowledgments—We thank Michelle Hosack for technical assistance, Robert K. Vander Meer for helpful suggestions throughout the study, James L. Nation for use of his mass spectrometer, James B. Hoy and David H. Oi for early reviews, and two anonymous reviewers. This is Florida Agricultural Experiment Station Journal Series Number R-04846.

(Received July 25, 1995; accepted November 26, 1995)

Abstract—*Carneocephala floridana*, an oligophagous leafhopper that inhabits the salt marshes along the coasts of Florida, utilizes *Borrichia frutescens* and *Salicornia virginica* (both herbs) as primary summer hosts, but uses two grasses, *Distichlis spicata* and *Spartina alterniflora*, during the winter. We tested whether the seasonal patterns of abundance and apparent host-switching by *Carneocephala* are related to plant quality. In laboratory experiments, nymphs of *Carneocephala* reared on nonfertilized control plants of the two herbs produced adults that were similar in size to field-collected insects. Only *Carneocephala* raised at the lowest densities on *Spartina* and *Distichlis* from the highest fertilizer treatments produced adults similar in body mass to those reared on nonfertilized *Borrichia* and *Salicornia*. For *Distichlis*, superior quality (high foliar nitrogen) plants were able to mitigate the negative effect of nymphal crowding on adult body mass. However, laboratory fertilization regimes produced an extremely high foliar nitrogen content in the two herbs and the organic acid concentration in the xylem fluid of *Borrichia*, the only host species suitable for xylem fluid extraction, increased 2.5- to 3-fold. Total amino acid concentration in the xylem fluid of fertilized *Borrichia* decreased compared to nonfertilized plants. *Carneocephala* demonstrated reduced feeding efficiencies on high nitrogen *Borrichia*. Our results suggest that *Carneocephala* prefers, and performs better on, plants with high nitrogen content up to a threshold, beyond which high nitrogen levels result in reduced leafhopper feeding rates and assimilation efficiencies.

Key Words—*Carneocephala floridana*, leafhopper, nitrogen content, amino acids, organic acids, insect nutrition, preference, performance.

INTRODUCTION

Laboratory studies have revealed that peak insect performance occurs at nitrogen levels that are well above those found in most host-plant tissues (McNeill and Southwood, 1978; Mattson, 1980). Moreover, the form of host plant nitrogen is crucial to insect performance (Strong et al., 1984; Brodbeck and Strong, 1987). Plant secondary chemicals may have a significant negative effect on host-plant utilization and insect performance, even when total nitrogen or soluble protein are found in high concentrations within the plant's tissues (Feeny, 1970).

Secondary chemicals probably have the greatest impact on folivores because they are housed within the vacuoles or other organelles of the leaf cells (McKey, 1979). As a result, secondary chemicals may mask the direct nutritional values of host tissues on insect performance. Unlike leaf-chewers, xylem-feeders provide an excellent opportunity to study the nutritional effects of amino acid levels on insect preference and performance, while largely eliminating interactions with plant secondary compounds (Brodbeck et al., 1990). Xylem sap is primarily composed of water (typically around 98%) and the majority of organic solutes are amino and organic acids (Mattson, 1980; Andersen and Brodbeck, 1989; Andersen et al., 1989). Although relatively few secondary chemicals are found in the xylem fluid, the concentration of nitrogen-containing compounds is often two to three orders of magnitude lower than those found in the leaf tissues, which are in turn below the levels required for maximum insect performance (Mattson, 1980; Brodbeck et al., 1993).

How then do xylem feeders survive on such a dilute diet? Leafhoppers have developed several adaptations that have enabled them to specialize on xylem fluid. First, they have a highly modified oral cavity (the cibarial pump), which allows them to pull against the negative pressure of the xylem vessels (Backus, 1985). Moreover, they are very efficient feeders. For example, Brodbeck et al. (1993) found that three species of xylophagous leafhoppers had assimilation efficiencies of 99% and 94% for carbon and nitrogen, respectively.

Carneocephala floridana, an oligophagous xylem-feeding leafhopper, is a common inhabitant of salt marshes along Florida's coastal regions (Ball, 1927; Nottingham, 1932; Rossi and Strong, 1990). *Carneocephala* shows distinct seasonal patterns on its four primary hosts, which include two herbs, *Borrichia frutescens* and *Salicornia virginica*, and two grasses, *Spartina alterniflora* and *Distichlis spicata*. In northwest Florida, *Carneocephala* utilizes the herbs as its primary hosts during most of the year, but in the winter when the herbs experience an extensive dieback, the leafhopper switches to the grasses (Rossi, 1991;

Rossi et al., 1994). Although seasonal differences of interspecific host-plant nitrogen content were not good predictors of host choice by *Carneocephala*, temporal abundance of leafhoppers on each plant species was more closely correlated with intraspecific nitrogen content (Rossi, 1991). In both laboratory and field-plot studies, we have found that *Carneocephala* shows a preference for, and performs better on, superior quality (i.e., higher nitrogen) culms of *Spartina* than on low-nitrogen culms (Rossi, 1991; Rossi, and Strong, 1991).

In the present study, we investigated the effect of fertilization on the abundance of *Carneocephala* in field-plot monocultures of *Spartina* and *Borrichia*. In the laboratory, we examined the influence of host-plant nitrogen level and insect crowding on nymphal performance. Lastly, we extracted the xylem fluid from one suitable species, *B. frutescens*, grown under different fertilization regimes, which allowed us to relate specific dietary components to insect performance. Understanding these relationships may help to explain the selective advantages of seasonal shifts in host-plant specificity exhibited by *Carneocephala*.

METHODS AND MATERIALS

Interspecific Host Choice. Simultaneous laboratory choice experiments were performed during the summer and winter to assess interspecific host-plant preference of *Carneocephala* according to the methods of Rossi and Strong (1991). Several hundred small shoots or culms of the four host-plant species were collected and grown in a greenhouse for approximately three months prior to the choice experiments. Plants of similar wet mass were randomly assigned to one of four positions within Plexiglas choice arenas. One day prior to the choice experiments, several hundred female *Carneocephala* were collected from a patch of mixed vegetation, which consisted of the four major hosts, from Goose Creek, Wakulla County, Florida. Ten female leafhoppers were released into each arena, and the number of insects present on each plant was recorded after 24 and 48 hr. After 48 hr, the insects were removed from the arenas, and the total number of eggs laid as well as per capita rate of egg production was calculated for each plant species. The experiment was replicated 10 times. The proportions of leafhoppers on each plant, after 48 hr, were arcsine-square-root transformed and then analyzed using a one-way ANOVA (Sokal and Rohlf, 1969). Differences among host species for total number of eggs and per capita egg production were assessed by a one-way ANOVA on log-transformed egg counts. When appropriate, comparisons among treatments were subjected to Tukey's HSD post-hoc test for separation of means (Petersen, 1985).

Insect Performance. Carneocephala were reared from first instar to adult on differentially fertilized *Borrichia*, *Distichlis*, and *Salicornia* to determine the

relationship among insect survivorship, body mass, and host nitrogen. The fertilizer solutions were identical to those in Rossi and Strong (1991) except nitrogen concentrations, in the form of NH_4NO_3, used in the current study were 0 (control), 60 (low), and 200 (high) mg/liter.

Leafhoppers were maintained in acetate tubes (5.5 cm OD), which completely enclosed the plant and were sealed at the top with organdy cloth. This method allowed the nymphs to choose their own feeding site. Like many species of homopterans, *Carneocephala* nymphs typically feed in small groups. Although the reasons for this behavior in *C. floridana* are unknown, gregarious feeding, often seen in many species of aphids (Mittler, 1957; Dorschner et al., 1987), may produce a sink for plant resources, benefiting the group members, or it may be that there are a limited number of preferred feeding sites on the plant. To assess effects of crowding on leafhopper performance, nymphs were placed in groups of either two or five nymphs per plant. This design enabled us to measure the effects of host-plant nitrogen content (quality) and leafhopper crowding on development time and dry mass at eclosion. The proportion of leafhoppers surviving was arcsine-square-root transformed and the data were analyzed using a two-way ANOVA with plant nitrogen content and leafhopper density as main effects.

Fertilized Field Plots and Laboratory Experiments with Borrichia. Plots of Borrichia were fertilized with NH_4NO_3 at two sites: Kornegay and Southsides at Oyster Bay, Florida, according to the methods described in Rossi et al. (1992). This allowed us to investigate the importance of plant nitrogen on *Carneocephala* host preference under field conditions and compare the results to those from *Spartina* (from Rossi, 1991; Rossi and Strong, 1991). At each site, four 2-m^2 plots were marked at the corners using polyvinylchloride (PVC) stakes. Plots were paired and separated by approximately 1 m. One plot in each pair was randomly assigned to the control treatment and received no fertilizer; the other plot received approximately 530 g/m^2 of fertilizer, broadcast on January 13 and March 8, 1990. Nitrogen as a percentage of total dry mass was determined in duplicate with an elemental analyzer (model 1600, Carlo Erba, HBI, Saddle Brook, New Jersey) using 10 leaves collected from the field plots on May 13, 1991. Leaf samples were placed in plastic bags and kept on Dry Ice until they were returned to the laboratory. Samples were stored at $-60°C$ until analysis. Prior to nitrogen analysis, the samples were freeze-dried for 72 hr and then ground in a Wiley mill (see Rossi and Strong, 1991; Rossi et al., 1992, for full details).

Trends in *Carneocephala* abundance were monitored using standard 3 × 5-in. (7.6 × 12.7-cm) index cards. The cards were held in place on PVC stakes with clips and placed just above the tops of the plants. The cards were painted with a bright Day-Glo yellow paint and wrapped in an acetate sheet that was

coated with Tangle-Trap (The Tanglefoot Co., Grand Rapids, Michigan), and are referred to as yellow sticky traps (YSTs). Traps were changed approximately every two to three weeks for one year beginning in February 1990. Because fertilized plants eventually become larger than control plants, the number of leafhoppers captured on the YSTs in the fertilized plots would be expected to be greater than those captured on the traps in the control plots because fertilized plots contain more biomass and, hence, should support more insects. Therefore, we converted the number of *Carneocephala* captured on the YSTs to a standardized "hopper load." The hopper load was calculated by dividing the number of hoppers on the YST for a given plot by the average leaf area, determined with a leaf area meter (model CI-201, CID, Inc., Moscow, Idaho 83843), of 20 haphazardly-chosen leaves collected from each plot on October 30, 1990. Because leaf area was determined late in the growing season and well after fertilization in the treatment plots when the treatment leaves were much larger than those from control plots (see Rossi et al., 1992 for details), the method was conservative.

To supplement the performance studies and field experiments with *Borrichia*, we examined the effects of intraspecific host-plant nitrogen in the laboratory using a subset of differentially-fertilized *Borrichia*. *Borrichia* was the only host used in this experiment because it is possible to collect and analyze its xylem fluid, which allowed for measurement of nutrient intake by feeding *Carneocephala* (described in the next section). A single plant of *Borrichia* from each of the three previously described fertilizer treatment groups was randomly assigned a position within the choice arenas (the remaining position was occupied by a sand-filled pot). Ten adult females were released into each arena, analogous to the methods used for the interspecific experiments, and the number of hoppers on each plant was recorded after 24 and 48 hr. The experiment was replicated six times. Because the plants were destructively sampled after 48 hr to search for eggs, the proportion of leafhoppers on each plant was divided by the mass of the plant to produce a hopper load, which provided a more precise measure of leafhopper preference than the hopper load calculated from the field plots.

Chemical Profile of Insect Exudate and Borrichia *Xylem Fluid.* Individual adult female leafhoppers were maintained in small clip cages 2 cm OD × 4 cm long and sealed at both ends with plastic lids. The cages were placed over the stems of *Borrichia*. A 1.5-ml Eppendorf tube was placed through a hole in the bottom lid to collect the exudate (excreta) produced by the insects. Leafhopper feeding rates were determined on plants from each treatment group by measuring the amount of excreta collected in clip cages in a 24-hr period. Excreta was collected using a 25-μl pipet. Because exudate was very dilute, it was necessary to pool the excreta produced from insects feeding on several plants within a

group to provide sufficient quantities for chemical analyses. The exudate was stored at −60°C until analysis.

Xylem fluid was extracted at night, when xylem tensions are typically highest (least negative) (Salisbury and Ross, 1985), from 10- to 20-cm-long shoots of *Borrichia* using a pressure chamber apparatus (Scholander et al., 1965; Andersen et al., 1989). The xylem tissue was exposed by peeling back tissue exterior to the xylem ring. Xylem fluid was extracted by variable pressure ranging from 0.5 to 1.5 MPa for up to 3 min. The fluid was collected with a 5-μl pipet and stored at −60°C until analysis. As with the exudate, it was necessary to pool xylem fluid from several plants within a treatment group to provide sufficient quantities for chemical analyses. Both excreta and xylem fluid were collected during the two weeks of the performance experiments, and thus a replicate was the pooled exudate and xylem fluid for a week ($N = 2$).

Samples of xylem fluid and insect excreta were centrifuged at 12,000*g* for 20 min. The supernatant was collected, filtered through a 0.22-μm mesh, and then split into equal aliquots for amino acid and sugar/organic acid analyses. Samples used for amino acid analysis were hydrolyzed with 6 M HCl at 110°C for 24 hr under a nitrogen atmosphere and then freeze-dried. Samples were derivatized prior to amino acid analysis by adding 100 μl of 2:2:1 ethanol–triethanolamine (TEA)–H_2O, drying under a vacuum, and than adding 20 μl of 7:1:1:1 ethanol–TEA–H_2O–phenylisothiocyanate (PITC) to each sample. The derivatizing mixture was allowed to react for 20 min under a nitrogen atmosphere at 22°C. Samples were dried and reconstituted in a phosphate buffer containing 5 mM sodium phosphate with 6% acetonitrile. Samples and external amino acid standards were quantified with a Waters Associate HPLC gradient system equipped with a Pico Tag column (Heinrickson and Meredith, 1984; Andersen et al., 1989).

Organic acids were analyzed by cation exchange chromatography on a Waters 600 HPLC system (modified from Turkelson and Richards, 1978). Samples in 0.01 N H_2SO_4 buffer were run isocratically through an Ion-300 polymeric cation exchange column at 37°C. Organic acids were monitored at a wavelength of 214 nm. Sugars were quantified by a Waters refractive index detector (model R401).

RESULTS

Interspecific Host Choice: Summer Trials. During the summer, *Carneocephala* showed a strong group preference for the two herbs and a moderate preference for *Spartina* ($F = 6.57$; $df = 3,36$; $P = 0.001$) (Table 1). Although total eggs laid per plant differed significantly among the host plants ($F = 12.01$; $df = 2,27$; $P < 0.001$), per capita egg production was not significantly affected

TABLE 1. PROPORTION OF FEMALES, TOTAL NUMBER OF EGGS, AND PER CAPITA NUMBER OF EGGS/FEMALE LAID BY *Carneocephala floridana* ON ITS MAJOR HOST PLANTS[a]

Host species	Proportion	Total eggs	Per capita no. eggs
Summer			
Borrichia frutescens	0.30 ± 0.04ab	12.2 ± 1.1a	3.0 ± 0.5
Distichlis spicata	0.14 ± 0.04c	0.6 ± 0.2[b]	0.1 ± 0.1[b]
Salicornia virginica	0.36 ± 0.03a	12.5 ± 1.3a	1.7 ± 0.2
Spartina alterniflora	0.20 ± 0.03bc	4.8 ± 1.3b	2.9 ± 0.8
Winter			
Borrichia frutescens	0.39 ± 0.05a	18.1 ± 2.0a	3.4 ± 0.3a
Distichlis spicata	0.34 ± 0.05ac	6.1 ± 1.6b	1.3 ± 0.3c
Salicornia virginica	0.10 ± 0.03b	18.0 ± 1.9a	9.2 ± 0.9b
Spatina alterniflora	0.17 ± 0.04bc	7.3 ± 1.8b	2.8 ± 0.7c

[a] Values are mean ± SE. Means followed by different letters within each column are significantly different at $\alpha = 0.05$.
[b] Eggs laid on this species not used in calculation of ANOVA.

by plant species ($F = 1.79$; $df = 2,27$; $P = 0.19$). Feeding and oviposition on *Distichlis* was low. In fact, so few eggs were laid on *Distichlis* that it had to be dropped from egg analyses. While the total number of eggs laid on the two herbs averaged over 12 eggs/plant, the total laid on *Spartina* averaged only 5 eggs/plant.

Winter Trials. Host-plant species had a significant effect on leafhopper preference in the winter choice experiment ($F = 7.23$; $df = 3,36$; $P = 0.001$). While *Carneocephala* continued to show a strong preference for *Borrichia*, it also settled on *Distichlis* in large numbers (Table 1). Only 10% of the leafhoppers settled on *Salicornia* compared to 36% in the summer. Females continued to lay the majority of their eggs on the herbs ($F = 12.83$; $df = 3,36$; $P < 0.001$). Moreover, per capita egg production was highest on the two herbs ($F = 25.05$; $df = 3,36$; $P < 0.001$), especially on *Salicornia*, which averaged 9.2 eggs/female/day.

Insect Performance. In the laboratory, survivorship of *Carneocephala* from first instar to adult was low on the two fertilized treatments of both herbs (Figures 1 and 2). As a result, these two species (and the species main effect) had to be dropped from the calculation of the ANOVA. Therefore, only data collected using *Distichlis* (Figure 3) were used to analyze the effects of host-plant nitrogen and juvenile crowding on adult body mass of *Carneocephala*.

Nitrogen content had a significant effect on dry adult body mass at eclosion ($F = 9.784$; $df = 2$; $P < 0.001$), but the sexes did not respond equally ($F =$

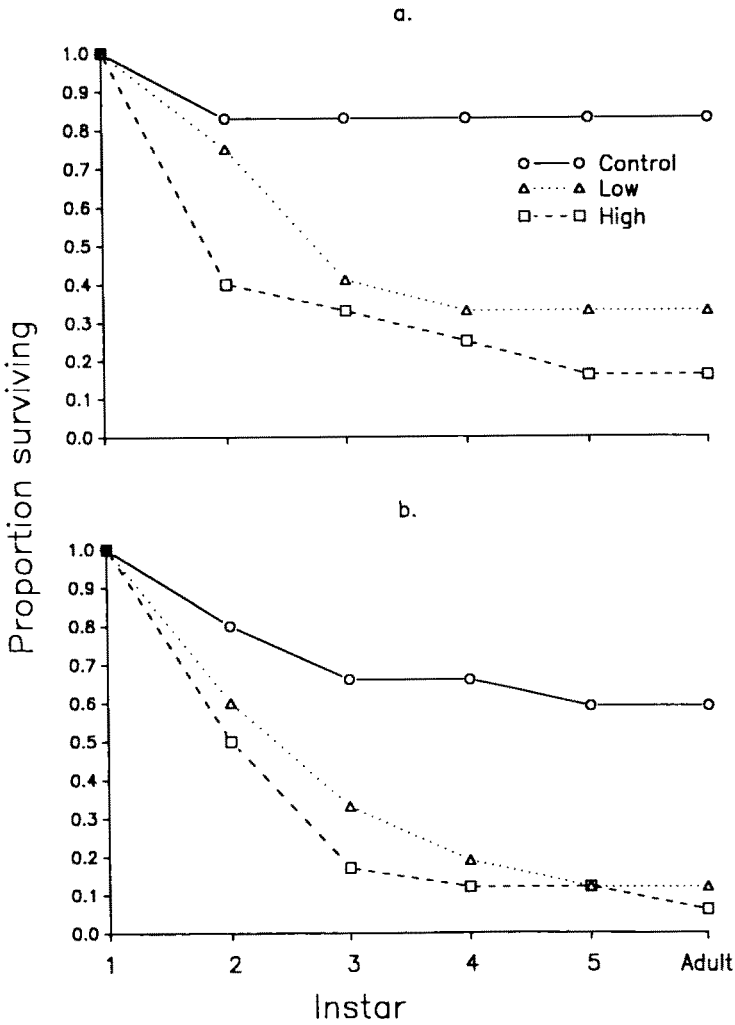

FIG. 1. The proportion of *Carneocephala floridana* surviving from first instar to adult on differentially fertilized *Salicornia virginica* at two densities: (a) 2 nymphs/plant and (b) 5 nymphs/plant.

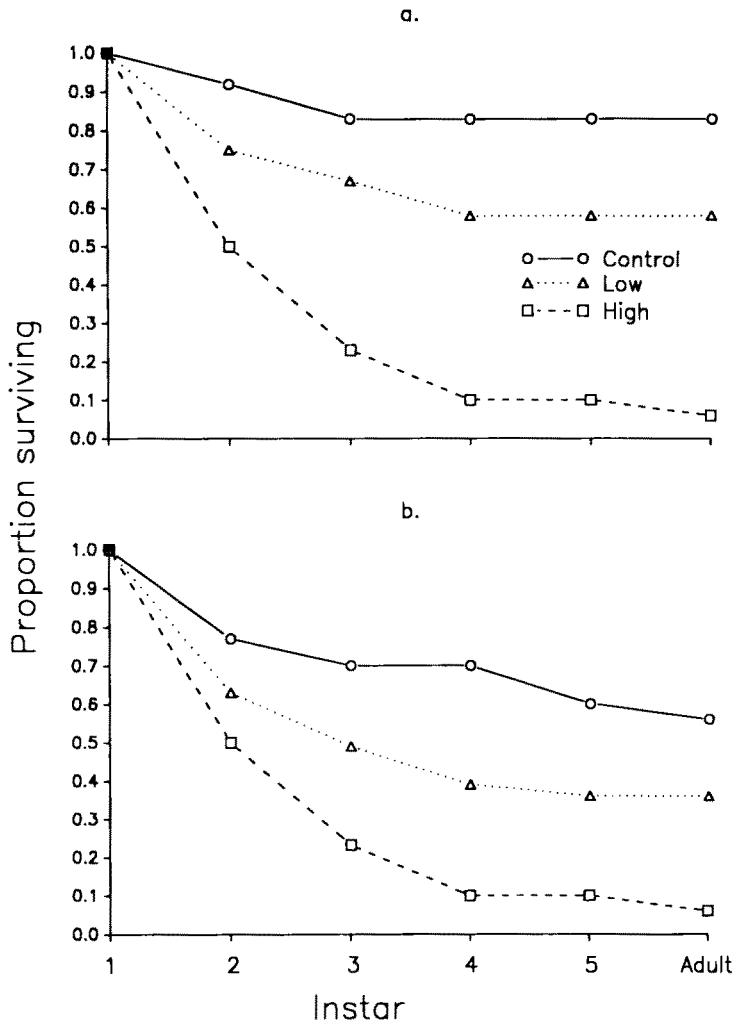

FIG. 2. The proportion of *Carneocephala floridana* surviving from first instar to adult on differentially fertilized *Borrichia frutescens* at two densities: (a) 2 nymphs/plant and (b) 5 nymphs/plant.

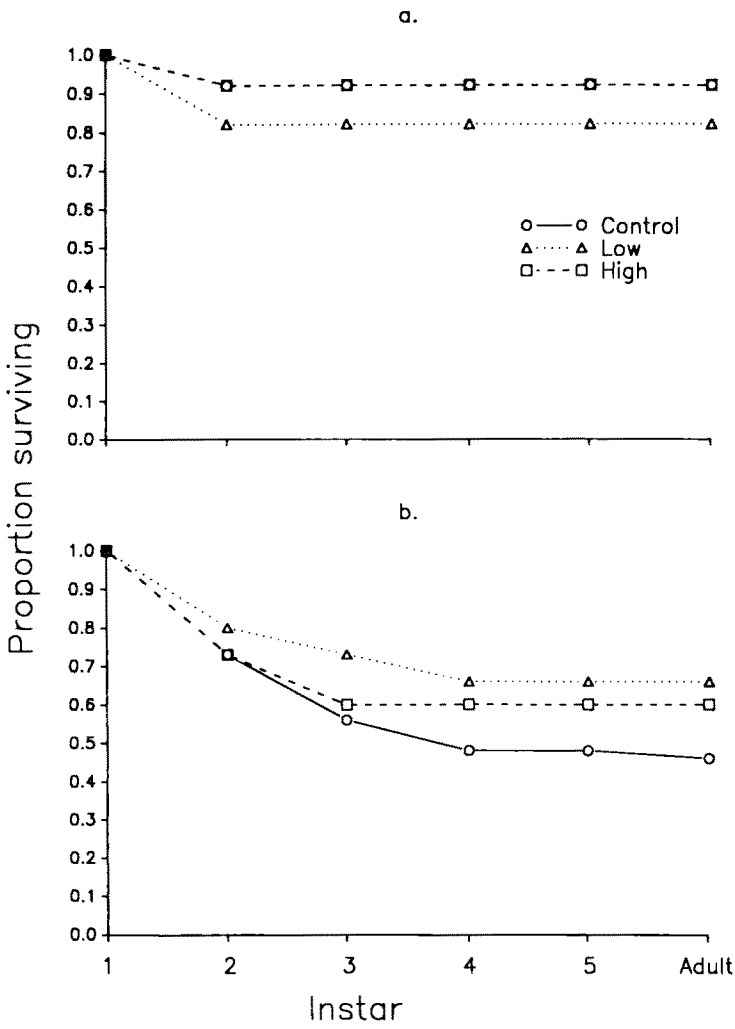

FIG. 3. The proportion of *Carneocephala floridana* surviving from first instar to adult on differentially fertilized *Distichlis spicata* at two densities: (a) 2 nymphs/plant and (b) 5 nymphs/plant.

80.899; $df = 1$; $P < 0.001$). Nymphal density had a highly significant effect on adult body mass ($F = 10.128$; $df = 1$; $P = 0.003$). Leafhoppers reared at 2 nymphs/culm were consistently larger than those reared at 5 nymphs/culm (Figure 4). Although both males and females showed a positive increase in body mass on fertilized plants at low densities, females showed a 77% increase in body mass as plant nitrogen increased from 1.9% to 2.5%, while males only demonstrated an 18% increase. For both males and females, the positive influence of host-plant nitrogen content on body mass was reduced for leafhoppers reared at high density (11 and 21% for males and females, respectively). Development time was not affected by nitrogen level of the host plant or nymphal density.

Fertilized Field Plots and Laboratory Experiments with Borrichia. Fertilization had a significant effect on the percent nitrogen content of *Borrichia* in field plots ($F = 26.52$; $df = 1,2$; $P = 0.04$; see Rossi et al., 1992, for full details). Mean nitrogen content for control and fertilized plots were 1.37 ± 0.010% and 2.95 ± 0.23%, rspectively. Moreover, hopper loads in fertilized plots at both sites were significantly higher than those of controls ($F = 92.243$; $df = 1$; $P = 0.001$). The only other significant effect was that of time ($F = 3.381$; $df = 13$; $P = 0.001$), which reflected seasonal patterns of *Carneocephala*'s abundance (Figure 5).

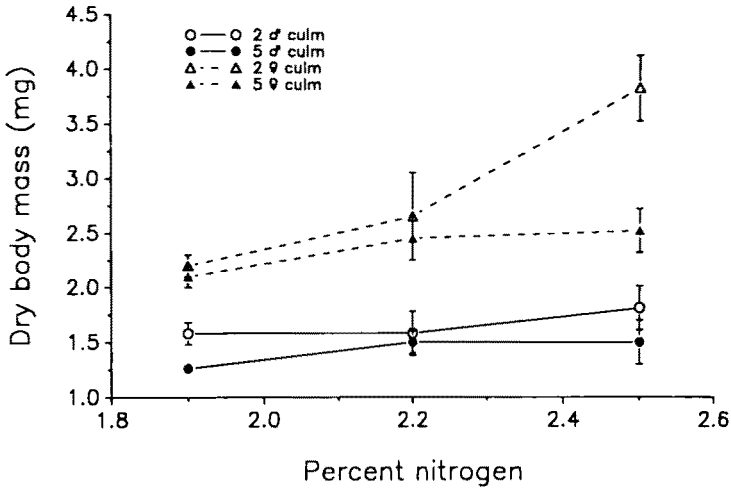

FIG. 4. Mean adult dry body mass of male and female *Carneocephala floridana* reared at two densities on differentially fertilized *Distichlis spicata* having variable nitrogen content. Bars are standard errors.

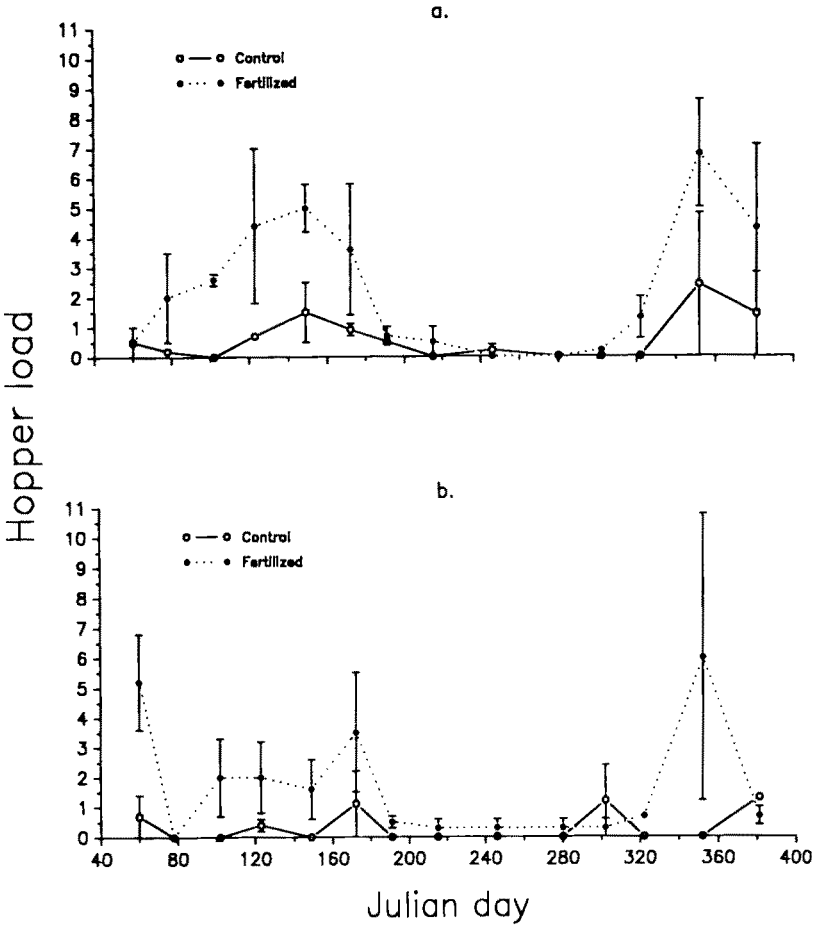

FIG. 5. *Carneocephala floridana* hopper loads (see text) from control and fertilized field plots of *Borrichia frutescens* at two sites: (a) Kornegay and (b) Southsides.

In laboratory trials, fertilization treatment also had an effect on preference of *Carneocephala*. This is evident in the significantly lower hopper loads ($F = 5.64$; $df = 2,14$; $P = 0.02$), and reduced exudate output ($F = 7.13$; $df = 2,42$; $P = 0.002$) on the two fertilized groups of *Borrichia* (Table 2). While the total number of eggs laid was not significantly affected by the application of fertilizer ($F = 2.37$; $df = 2,15$; $P = 0.13$), the per capita rate of egg production was

TABLE 2. EFFECT OF LABORATORY FERTILIZATION REGIMES ON NITROGEN CONTENT OF *Borrichia frutescens* AND PREFERENCE OF *Carneocephala floridana*[a]

Fertilizer treatment	Percent nitrogen	Volume (ml) exudate/24 hr	Hopper load	Total eggs	Per capita eggs

Total	678	5.78	219	31.06	208	22.22

[a] Results are from two pooled samples. All concentrations are given as micromolar. ND = not detectable in xylem fluid < 4 μM and in exudate < 0.25 μM.

altered ($F = 5.28$; $df = 2,15$; $P = 0.02$). Individually, female *Carneocephala* laid fewer eggs on the two fertilized groups.

Chemical Profile of Insect Exudate and Borrichia *Xylem Fluid.* Amino acid concentration of the xylem fluid varied greatly among plants receiving differing levels of nitrogen fertilizer (Table 3). Abundance of *Carneocephala* was higher on nonfertilized control plants, which had amino acid concentrations approximately three times *higher* than those of the fertilized groups, despite the fact that fertilized plants were 2–2.5 times higher in total nitrogen content (see previous section). Moreover, assimilation efficiency of amino acids (i.e., percent organic compounds extracted during feeding) was >99% on control plants; assimilation efficiency dropped to 85 and 89% on low and high fertilized plants, respectively. The amino acid profile of nonfertilized *Borrichia* consisted primarily of asparagine and glutamine. Conversely, proline was especially high in the amino acid profiles of the two fertilized treatments and asparagine and glutamine were low. Although NH_4^+ was not quantified, a large increase in the peak that corresponds to ammonium was observed for fertilized plants compared to nonfertilized control plants.

In contrast to the amino acid profiles, the organic acid concentrations of the xylem fluid of plants from the two fertilized treatments increased threefold over the control plants (Table 4). Tartaric, citric, and malic acids showed the greatest increases with the addition of fertilizer. Feeding efficiencies of organic acids by *Carneocephala* on plants from the three groups were similar; 47, 49, and 41% for control, low, and high treatments, respectively.

TABLE 4. MEAN ORGANIC ACID CONCENTRATIONS IN XYLEM FLUID OF DIFFERENTIALLY FERTILIZED *Borrichia frutescens* AND EXUDATE PRODUCED BY FEEDING *Carneocephala floridana*[a]

Organic acid	Fertilization treatment					
	Control		Low		High

	Control		Low		High	
Sugar	Xylem	Exudate	Xylem	Exudate	Xylem	Exudate
Glucose	129	43	195	36	63	44
Fructose	158	45	220	93	291	42
Sucrose	288	38	126	ND	137	ND
Total	575	126	541	129	591	83

[a]Results are from two pooled samples. All concentrations are given as micromolar. ND = not detectable in xylem fluid < 5 μM and in exudate < 1.25 μM.

Lastly, sugar concentrations, which ranged from 0.5 to 0.6 mM, showed little response to the addition of fertilizer (Table 5). Feeding efficiencies of sugars by *Carneocephala* were 78, 76, and 86% for control, low, and high fertilizer treatments, respectively.

DISCUSSION

While *Borrichia* and *Salicornia* were the preferred hosts for both feeding and oviposition in the summer, this pattern showed dramatic changes during the winter trials. In the winter, *Carneocephala* still showed a strong preference for *Borrichia* as a feeding and ovipositional substrate, but it also exhibited a strong feeding orientation to *Distichlis*, largely at the expense of *Salicornia*. Interestingly, while the feeding preference for *Salicornia* dropped by more than 70% in the winter, this succulent remained a preferred ovipositional host for the leafhopper.

Both *Borrichia* and *Salicornia* experience a substantial dieback during the winter months (Rossi and Strong, 1991; Rossi et al., 1994). The leaves on *Borrichia* generally remain intact until the first hard frost. Dieback for this species appears to be largely temperature mediated since it actively grows throughout the winter in protected sites. In contrast, *Salicornia* gradually loses its green color and turns bright red in the winter, which is the consequence of the breakdown of chlorophyll and the production of anthocyanins on cool days (Salisbury and Ross, 1985). Thus, although *Salicornia* did not die back in the greenhouse during the winter, some chemical changes (apparently controlled by

day length) occurred that may have reduced its palatability to *Carneocephala*. However, the soft succulent stems were still acceptable to the leafhopper during the winter as an ovipositional substrate.

Experiments in which we reared *Carneocephala* nymphs at different densities and on differentially-fertilized *Distichlis* suggest that feeding on high-nitrogen plants moderated the negative effect of juvenile crowding on resultant adult body mass. This pattern of increased adult size was also observed during experiments in which *Carneocephala* were reared on fertilized *Spartina* (Rossi and Strong, 1991). Denno et al. (1986) also found that rearing the planthopper, *Prokelisia marginata*, on high-nitrogen ("superior quality") *Spartina* offset the negative effects of high insect densities on adult body length.

If high-nitrogen plants are generally beneficial to leafhopper growth and suvivorship, why did so few *Carneocephala* survive on fertilized *Borrichia* and *Salicornia*? Moreover, why did *Carneocephala* show less preference for fertilized *Borrichia* as both feeding and ovipositional hosts in laboratory experiments than it did for nonfertilized control plants? These results seem contradictory to field studies in which *Carneocephala* showed significantly higher hopper loads in fertilized plots. This apparent discrepancy can be explained by the fact that *Borrichia* in fertilized field plots had a nitrogen content of only 2.9% (compared to 1.4% for control plants) (Rossi and Strong, 1991), while the low- and high-fertilized groups of *Borrichia* reared in the laboratory produced foliar nitrogen levels of 4.5 and 5.0%, respectively. In addition, the extremely high nitrogen levels in the laboratory plants actually resulted in lower total amino acid concentrations in their xylem fluid. Fertilized lab plants had highly unbalanced amino acid profiles, in which proline became the predominant amino acid constituent (comprising 51 and 38% of the total amino acid concentration for the low- and high-fertilizer plants, respectively, compared to 9% for the nonfertilized plants). Studies using artificial diets have shown that highly unbalanced diets of amino acids may be unusable or even toxic to insects (Reese, 1979; Brodbeck et al., 1990). The high mortality rates and low feeding efficiencies of the leafhoppers reared on fertilized plants in laboratory suggests that one, or both, of these processes may have been operating on *Carneocephala*.

Total organic acid concentrations showed large increases in the two fertilized treatments. Fertilization typically results in increased organic acid concentrations, which serve to counter the increase in positively charged ions (Andersen et al., 1989). This increase in the organic acid titer also may have been responsible for the decrease in the preference of *Carneocephala* for fertilized plants. For example, oxalic acid has been demonstrated to be a feeding deterrent for the brown planthopper (Sōgawa, 1982), and it was the least efficiently assimilated organic compound ingested by three species of xylophagous leafhoppers (Brodbeck et al., 1993).

Increases in host-plant nitrogen, up to a critical level, appear to be correlated with increased preference and performance of *Carneocephala*. However, very high levels of nitrogen uptake by the plant may result in toxic effects to the leafhopper. The unusually high nitrogen contents produced in laboratory plants in the current study are probably well above those naturally encountered in the field. However, our results suggest that small to moderate increases in host nitrogen are detected by, and beneficial to, developing *Carneocephala* (see also Rossi and Strong, 1991). Moreover, the two herbaceous species appear to be superior hosts for *Carneocephala*. For instance, nymphs reared on nonfertilized *Borrichia* and *Salicornia* produced insects that were similar in size to field-collected adults (>3 mg for females and >1.4 mg for males) (Rossi, 1991; Rossi and Strong, 1991). Only insects reared on *Distichlis* at the lowest nymphal densities and highest nitrogen levels produced adults similar to field-collected adults.

Recently, Rossi et al. (1994) reported that plant- and parasitoid-mediated mortality also was significantly lower on the two herbaceous species compared to the two grass species. Selective pressures to avoid natural enemies and utilize plants of superior quality appear to be working together to maintain the apparent hierarchy of hosts in *Carneocephala*'s diet. This study supports the contention that *Borrichia* and *Salicornia* are superior hosts for *Carneocephala* and that this leafhopper should utilize these hosts until they become unavailable through winter dieback or until changes in their chemistry make them unsuitable for growth and development.

STEREOSELECTIVE SYNTHESIS OF DOMINICALURE 1 AND 2: COMPONENTS OF AGGREGATION PHEROMONE FROM MALE LESSER GRAIN BORER *Rhyzopertha dominica* (F.)

J. RAZKIN, P. GIL,* and A. GONZALEZ

Departamento de Química, Universidad Pública de Navarra
Campus Arrosadía, 31006 Pamplona, Spain

(Received June 13, 1995; accepted November 27, 1995)

Abstract—Dominicalure 1 (**9a**) and dominicalure 2 (**9b**), were synthesized by esterification of α,β-unsaturated acids **4a** and **4b** with (*S*)-(+)-2-pentanol (**8**). The key step was the asymmetric reduction of 3-penten-2-one (**5**) to give the chiral intermediate **6**, which, upon diimide reduction, DNB derivatization, recrystallization, and hydrolysis, yielded **8** in 63% ee. Acids **4a** and **4b** were prepared in a simple and efficient three-step synthesis with an overall yield of 54% and 62%, respectively, in stereoisomerically pure form.

Key Words—Pheromone, *Rhyzopertha dominica*, Coleoptera, Bostrichidae, dominicalure, (*S*)-(+)-2-pentanol, asymmetric reduction, (*E*)-2-methyl-2-pentenoic acid, (*E*)-2,4-dimethyl-2-pentenoic acid.

INTRODUCTION

The lesser grain borer, *Rhyzopertha dominica* (F.) (Coleoptera: Bostrichidae), is a worldwide primary pest of stored products. The aggregation pheromone of this beetle was isolated and identified as a mixture of (*S*)-(+)-1-methylbutyl (*E*)-2-methyl-2-pentenoate and (*S*)-(+)-1-methylbutyl (*E*)-2,4-dimethyl-2-pentenoate and named dominicalure 1 and 2, respectively (Williams et al., 1981). Very few syntheses of this pheromone have been reported so far. In one (Williams et al., 1981), glutamic acid was used as a source of chirality giving (*S*)-2-pentanol; the method suffered from low overall yield. In another synthesis (Lin-Yu and Guo-Qiang, 1990), the key step was Sharpless asymmetric epox-

idation, but surprisingly low values of specific rotation of the final compounds were obtained. Recently, syntheses of dominicalure 1 (Rossi et al., 1993) and dominicalure 2 (Rossi et al., 1992) have been described, using commercially available (*S*)-2-pentanol.

We report here a new synthesis of dominicalure 1 and 2.

METHODS AND MATERIALS

Instrumentation

Gas chromatography analyses were conducted in a Shimazu model GC-14B, equipped with a flame ionization detector and a capillary column β-DEX 110 (30 m × 0.25 mm, Supelco Co.); helium was used as the carrier gas at 130 kPa, split 100:1. NMR (^{1}H and ^{13}C) spectra were obtained with a Varian Gemini-200 on $CDCl_3$ solutions. Infrared spectra were recorded on a Nicolet 510M FT-IR. Optical rotations were measured in a JASCO-DIP-370 polarimeter. Elemental analyses were performed in a Carlo Erba EA1108 Analyzer. Ozone gas was generated from a Fischer Ozon Generator 500M apparatus. For column chromatographic separations, SDS silica gel 230–400 mesh was used.

Reagents

Propanal, 97% (Aldrich) (**1a**); 2-methylpropanal, 98% (Aldrich) (**1b**); 1-chloro-2-butene, >95% (Merck); sodium chlorite, 80% (Aldrich); 3-penten-2-one, 65% (Aldrich) (**5**); 3,5-dinitrobenzoyl chloride, >98% (Fluka); and LAH 1.0 M solution in THF (Aldrich) were the reagents used. Optically pure (*S*)-(−)-binaphthol was prepared according to the Kazlauskas (1990) procedure, mp = 208–210°C, $[\alpha]_D^{23} = -33.5°$ (THF, $c = 1.0$).

Synthesis

*(E)-2-Methyl-2-pentenoic acid (**4a**) (Figure 1).* To a solution of saturated aqueous ammonium chloride/THF (50 ml/10 ml) were added 13.58 g (150 mmol) of 1-chloro-2-butene, 4.35 g (75 mmol) of **1a**, and then 10.32 g (150 mmol) of zinc dust. After stirring the grey suspension overnight at room temperature, a white precipitate of inorganic salts appeared. The suspension was filtered through celite and the liquid extracted with ether (3 × 20 ml). The organic layer was dried and concentrated to give 6.86 g of a colorless liquid (**2a**). This was taken up in dry methanol (120 ml), cooled to −78°C, and a stream of ozone was bubbled through the solution for 4 hr. Then 18 g of Me_2S in 20 ml of MeOH was added; after 10 min the reaction mixture was allowed to warm to room temperature, the solvent was removed, and the residue was dissolved in 100 ml of dichloromethane. An aqueous solution of NaOH (180

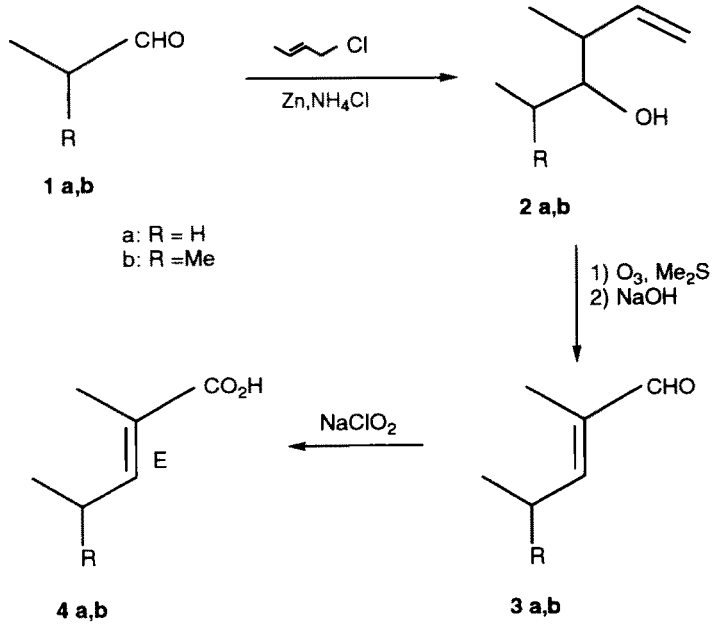

FIG. 1. Synthesis of α,β-unsaturated acids **4a** and **4b**.

ml) was added in small portions and stirring was continued for about 20 min. After extractive work-up, 7 g of a colorless liquid (**3a**) was obtained. Finally, oxidation of aldehyde with sodium chlorite according to Dalcanale and Montanari (1986) afforded 5.8 g of a colorless liquid, which was purified by column chromatography (hexane–ethyl acetate, 5 : 1) to yield 4.62 g of chemically and stereoisomerically pure acid **4a** (54% overall yield from **1a**). IR (neat): 1687 (C=O), 1645 (C=C) cm^{-1}; ^1H NMR: δ 1.02 (t, J = 7.5 Hz, 3H); 1.80 (s, 3H); 2.18 (quintet, J = 7.4 Hz, 2H); 6.87 (tq, J = 7.4 and 1.4 Hz, 1H); 11.70 (br s, 1H); GC: temp. 150°C R_t = 3.65 min (single peak).

(E)-2,4-Dimethyl-2-pentenoic acid (4a) (Figure 1). The procedure described for synthesis of **4a** was used. From 5.4 g of **1b**, 5.9 g of pure acid **4b** (62% overall yield) was obtained. IR (neat): 1687 (C=O), 1645 (C=C) cm^{-1}; ^1H NMR: δ 1.00 (d, J = 6.6 Hz, 6H); 1.81 (s, 3H); 2.57–2.65 (m, 1 H); 6.69 (dq, J = 9.7 and 1.4 Hz, 1H); 11.00 (br s, 1H); GC: temp. 150°C, R_t = 3.70 min (single peak).

(S)-(+)-2-Pentanol 3,5-dinitrobenzoate Ester (7) (Figure 2). A solution of the unsaturated ketone **5** (1.6 g, 18.7 mmol) in THF (15 ml) was added dropwise at −100°C to (*S*)-BINAL-H generated from LAH (56 ml, 56 mmol), ethanol

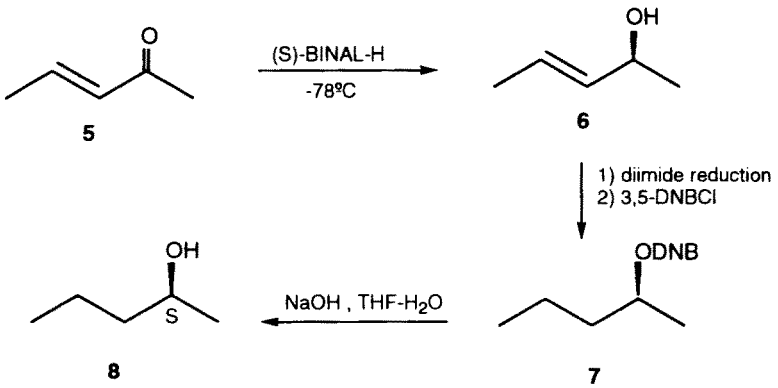

FIG. 2. Synthesis of (*S*)-2-pentanol.

(2 M THF solution, 28.3 ml, 56.6 mmol), and (*S*)-binaphthol (16.2 g, 56.8 mmol). The mixture was stirred for an additional 1 hr at −100°C and then at −78°C for 25 hr. Methanol (3 ml) and water (5 ml) were added, and the mixture was warmed to room temperature. Ether (120 ml) was added, and the solution was stirred for 1 hr and treated with anhydrous magnesium sulfate for 1 hr more. The suspension was filtered through celite, and the filtrate was washed with 1 N HCl (3 × 40 ml) to remove aluminum salts. The organic phase was extracted with 1 N NaOH (3 × 60 ml) and, after neutralization and extractive work-up of the aqueous layer, 13.2 g of (*S*)-binaphthol was recovered. The ethereal phase was concentrated with caution due to the volatility of unsaturated alcohol **6.** For diimide reduction, MeOH (120 ml) was added and then potassium azodicarboxylate (78 g, 400 mmol) and acetic acid (30 ml, 529 mmol) in MeOH (60 ml). After stirring overnight, the yellow color of the solution disappeared. After work-up and careful evaporation of the solvent, the saturated alcohol was converted to its 3,5-dinitrobenzoate derivative by adding dropwise at 0°C a solution of the alcohol in CH_2Cl_2 (20 ml) to a solution of 3,5-dinitrobenzoyl chloride (6.13 g, 26 mmol), DMAP (0.2 g, 1.6 mmol), and Et_3N (7.2 ml, 52 mmol) in CH_2Cl_2 (90 ml). The mixture was stirred at room temperature for 5 hr, and after extractive work-up, 2.9 g of crude **7** was obtained as a brown oil. Purification by column chromatography (hexane–ethyl acetate, 40:1) yielded 2 g of pure **7** as a white solid (43% from **5**). IR (KBr): 1716 (C=O), 1545, 1339 (NO_2) cm^{-1}; ^1H NMR: δ 0.94 (t, J = 7.1 Hz, 3 H); 1.38 (d, J = 6.2 Hz, 3H); 1.45–1.81 (m, 4H); 5.25 (sextet, J = 6.3 Hz, 1H); 9.11–9.19 (m, 3 H); ^{13}C NMR: δ 13.91, 18.76, 20.01, 37.94, 74.27, 122.08, 129.26, 134.42, 148.46, 161.93; $[\alpha]_D^{24}$ = +13.5° (c = 1, $CHCl_3$). Compound **7** (0.7 g) was recrystallized from hexane–ether (20:1) yielding white crystals (0.35 g). Spec-

troscopic data were as above; mp = 85.5–86.5°C; Anal. calc. for $C_{12}H_{14}N_2O_6$: C, 51.06; H, 4.99; N, 9.92; Found: C, 50.84; H, 5.28; N, 9.85; $[\alpha]_D^{24}$ = +20.8° (*c* = 1, $CHCl_3$).

(S)-(+)-2-Pentanol (8) (Figure 2). To a stirred and ice-cooled solution of recrystallized compound **7** (0.35 g) in THF (10 ml) was added dropwise aq. 2 N NaOH (20 ml). After stirring for 5 hr at room temperature followed by extractive work-up, 74 mg (68%) of **8** was obtained (63% ee by GC of its acetate derivative).

Determination of Optical Purity of 8. Alcohol **8** (40 mg) was treated with acetic anhydride (0.5 ml) and pyridine (0.5 ml) and the mixture stirred at room temperature for 4 hr to give the acetate ester. After extractive work-up, the organic phase was analyzed by GC. At 70°C the retention times were 4.88 min [(*S*)-acetate] and 5.54 [(*R*)-acetate].

(S)-(+)-1-Methylbutyl (E)-2-methyl-2-pentenoate (9a) (Figure 3). A solution of compound **4a** (0.08 g, 0.7 mmol) in 5 ml of $CHCl_3$ and thionyl chloride (0.2 ml, 2.6 mmol) was heated to 60°C for 90 min, and the excess thionyl chloride was removed under vacuum. The crude carboxylic acid chloride obtained was treated with a solution of **8** (37 mg, 0.42 mmol) in chloroform (6 ml) and pyridine (0.12 ml, 1.5 mmol) at 50°C for 2 hr and then at room temperature overnight. The mixture was treated with sodium bicarbonate and extracted with ether. The organic phase was washed with brine, dried, and concentrated yielding an oil that was purified by column chromatography using hexane–dichloromethane (5:1) to give **9a** as a colorless liquid with a sweet odor (60 mg, 79%). IR (neat): 1709 (C=O), 1645 (C=C) cm^{-1}; ^1H NMR: δ 0.78 (t, *J* = 7.1 Hz, 3H); 0.91 (t, *J* = 7.5 Hz, 3H); 1.10 (d, *J* = 6.2 Hz, 3H); 1.14–1.65 (m, 4H); 1.68 (s, 3H); 2.05 (quintet, *J* = 7.5 Hz, 2H); 4.82 (sextet, *J* = 6.2 Hz, 1H); 6.58 (tq, *J* = 7.4 and 1.3 Hz, 1H); $[\alpha]_D^{25}$ = +21.5° (*c* = 0.74, ether).

FIG. 3. Preparation of dominicalure 1 and 2 from acids **4a** and **4b**.

(S)-(+)-1-Methylbutyl (E)-2,4-dimethyl-2-pentenoate (9b) (Figure 3). The procedure for preparation of **9a** was used. From 37 mg of **8,** 65 mg (76%) of pure **9b** was obtained. IR (neat): 1709 (C=O), 1645 (C=C) cm^{-1}; ^1H NMR: δ 0.9 (t, J = 7 Hz, 3H); 0.99 (d, J = 6.6 Hz, 6H); 1.21 (d, J = 6.3 Hz, 3H); 1.27–1.63 (m, 4H); 1.80 (d, J = 1.5 Hz, 3H); 2.54–2.63 (m, 1H); 4.90 (sextet, J = 6.5 Hz, 1H); 6.52 (dq, J = 9.6 and 1.4 Hz, 1H); $[\alpha]_D^{25}$ = +21.8° (c = 0.84, ether).

RESULTS AND DISCUSSION

One of the most common methods to obtain α,β-unsaturated esters is the Wittig reaction, or any of its modifications, from which a mixture of *E/Z* isomers is always formed (Wadsworth, 1977). The need for stereoisomerically pure *E* acids **4a** and **4b** required an alternative route. These acids have been prepared in stereoisomerically pure form using stereo-defined organometallic compounds, but requiring a lengthy synthesis with only moderate overall yields (Rossi et al., 1992, 1993).

The first step in the synthesis (Figure 1) was the reaction of the allylic zinc reagent with propanal or 2-methylpropanal to give the alkenes **2** in almost quantitative yield and pure enough for the following steps. This is a well-documented process for C—C bond formation (Yamamoto, 1993). The oxidative cleavage of the alkenyl group was then studied in an attempt to directly obtain the acids **4,** but it proved difficult to dehydrate the β-hydroxyacids. So, under reductive ozonolysis, followed by addition of aqueous NaOH solution, the aldehydes **3** were obtained. Finally, oxidation of the aldehyde group with sodium chlorite (Dalcanale and Montanari, 1986), yielded pure acids **4a** and **4b** in an overall yield from **1a** and **1b,** of 54% and 62%, respectively. Capillary GC analysis and NMR spectroscopy of **4a** and **4b** showed that the corresponding *Z* isomers were undetectable. In the course of this work we found it not worthwhile to isolate and purify intermediates **2** and **3** due to their volatility. Spectral properties of analytical samples of these compounds were consistent with their structures.

The key step was the asymmetric synthesis of (*S*)-(+)-2-pentanol, **8** (Figure 2). The known BINAL-H reduction (Noyori, 1984b) was applied to the alkenyl ketone **5** yielding the chiral intermediate **6,** which was not isolated because of its volatility. The progress of the reaction was followed by GC: temperature 60°C, R_t = 5.10 min for **6;** R_t = 4.57 min for **5.** After diimide reduction of **6,** reaction with 3,5-dinitrobenzoyl chloride gave **7** in 43% yield from commercially available **5** (67% with respect to pure ketone). The advantage of isolating **7** is that upon recrystallization, the optical purity of alcohol **8** can be increased. The specific rotation of dinitrobenzoate **7** was +13.5° prior to recrystallization and +20.8° after recrystallization, which corresponds to an increase

in the enantiomeric excess of alcohol **8** from 41% to 63%. This was determined in each case from GC of its acetate derivative. The reduction of the saturated ketone 2-pentanone with (*R*)-BINAL-H under the same conditions gave (*S*)-2-pentanol **8** in only 16% ee; this is in agreement with Noyori's explanation about the effect of electronic as well as steric factors on the direction and extent of the enantioselective reduction with the BINAL-H reagent (Noyori, 1984a).

Dominicalure 1 and 2, **9a** and **9b** (Figure 3) were prepared from acids **4a** and **4b** by esterification through the corresponding acid chloride **8** and pyridine. An excess of alcohol was employed to obtain racemic dominicalure 1 and 2 as reference compounds because inexpensive 2-pentanol was the reagent. However, for the synthesis of the optically active pheromone **9a** and **9b,** an excess of acids **4a** and **4b** was used with comparative yields. The advantage of this procedure is that it is easier to recover unreacted acids **4a** and **4b** than unreacted alcohol **8,** if necessary. Thus obtained **9a** had a specific rotation $[\alpha]_D^{25} = +21.5°$ ($c = 0.74$, ether) [lit. for natural dominicalure 1: $[\alpha]_D^{25} = +32.1°$ ($c = 0.156$, ether) Williams, 1981]. For **9b:** $[\alpha]_D^{25} = +21.8°$ ($c = 0.84$, ether) [lit. for natural dominicalure 2: $[\alpha]_D^{25} = +32.3°$ ($c = 0.777$, ether), Williams, 1981].

In conclusion a simple and efficient three-step synthesis of the stereoisomerically pure acids **4a** and **4b** was developed, which could be applied to the synthesis of other (*E*)-α,β-unsaturated acids. Although there may be better methods of preparing (*S*)-2-pentanol, Noyori's reduction procedure permits the synthesis of both enantiomers and recovery of optically active binaphthol without any racemization. Furthermore, the isolation of dinitrobenzoate **7** is a means of purification and enantiomeric enhancement of chiral alcohol **8,** an otherwise difficult compound to handle.

(Received March 30, 1995; accepted November 28, 1995)

Abstract—Multiple regression predictive models based on data acquired by near-infrared (NIR) spectrophotometry suggest that stalk surface wax components contribute towards resistance to *Eldana saccharina* Walker in sugarcane. At least 35 sugarcane clones of known resistance were required to calibrate a predictive model that accounted for approximately 54% of the variation in resistance to *Eldana*. Wavelengths chosen in multiple regression models suggest that alcohols and carbonyls are important in the wax contribution. Through the use of wax fractionation and gas chromatography, a high alcohol/aldehyde ratio and shorter carbon chain length appears to be associated with resistance. The use of NIR in the screening of wild germplasm and the early screening of breeding material for resistance, without prior knowledge of the biochemical mechanisms involved, is an exciting prospect. However, cause-and-effect relationships remain to be shown.

INTRODUCTION

The stalk borer *Eldana saccharina* Walker is the major pest of sugarcane (*Saccharum* spp. hybrids) in South Africa (Atkinson et al., 1981). Since 1979 variety resistance to the stalk borer has been a selection criterion in the plant breeding program (Bond, 1988). However, field-based selection is largely restricted to one of five selection sites where borer numbers are relatively high, and the effectiveness of the selection program is further limited by the presence of low levels of the pest during years of high rainfall (Anon., 1984). The development of rapid, laboratory-based techniques, applicable to early selection stages when many clones are present, is desirable.

Newly hatched borer larvae spend about one week on the stalk surface before survivors attempt to bore in. Observed differences in sugarcane resistance to borers might therefore be partly explained by biochemical influences of the stalk surface on larval behavior and survival. Surface wax components have been shown to influence the behavior and survival of insect pests on sorghum and maize, two panicoid species related to sugarcane (Woodhead and Taneja, 1987; Yang et al., 1993). Sorghum and maize waxes also have been shown to vary in their component compositions between varieties (Avato et al., 1990a,b).

The technique of component profiling (metabolic profiling), as applied to insect-plant interactions, usually involves the chromatographic separation and quantification of components in a relevant extract followed by implication of individual components in either resistance or susceptibility (Brennan et al., 1992). This can result in a multiple regression model for the prediction of the proportion of resistance conferred by those components. However, chromatographic techniques do not lend themselves to the rapid screening of large numbers of genotypes required in sugarcane plant breeding selection programs.

Organic components can be more rapidly analyzed in an unseparated mixture by measuring spectral absorbances in the near infrared (NIR) (Osborne and Fern, 1986). Spectra of complex organic materials are composed of overlapping spectra for all of the individual components. Complex NIR data can, if necessary, be effectively analyzed by powerful multivariate chemometric packages for the prediction of components (Martens and Naes, 1984). Frequently, however, stepwise multiple regression is found to be adequate.

Given the solubility of sugarcane wax in NIR transparent carbon tetrachloride, and the ability of NIR to analyze mixtures, we decided to explore this technique as a means to profile unknown sugarcane wax components in relation to known larval survival ratings for the stalk borer. To our knowledge, NIR has never been used to quantify insect resistance in any crop. If this proved possible, NIR technology would greatly expedite sugarcane germplasm development, allowing the early identification of clones with a measure of stalk borer resistance.

The objectives of this study were: (1) to determine whether sugarcane wax NIR data could be correlated with borer resistance, (2) to gain some insight from the NIR data as to the identity of any likely active components, and (3) if successful in predicting borer resistance, to develop a rapid NIR technique for the prediction of wax-based resistance in unclassified clones.

METHODS AND MATERIALS

Wax Preparation for NIR and GC Analyses. Lengths of stalk from the base to the natural breaking point (from a time when 1 m plus of stalk had accumulated) were scraped with razor blades. Five stalks per clone were sampled yielding 100–200 mg of crude wax. Scraped crude wax (100 mg) was dissolved in 10 ml of helium-degassed carbon tetrachloride under nitrogen in an oven at 80°C for 10 min. This was then filtered through glass wool. Samples for GC contained 0.5 mg/ml of tricosane ($C_{23}H_{48}$) as an internal standard.

NIR Feasibility Study—Filter-Based Spectrophotometer. Series of commercial varieties from several seedcane nurseries and of increasing cane age were sampled in an initial feasibility study. A model 400 InfraAlyzer (Technicon Industrial Systems, New York, New York), operating 19 different optical filters with wavelengths from 1445 to 2348 nm, was used to acquire transflectance values as log 1/reflectance (log $1/R$) for wax dissolved in carbon tetrachloride. Samples (180 μl) were placed on a transflectance cell under a glass slide and each was read three times by the InfraAlyzer 400. Resistance ratings based on survival of borer larvae were entered into the accompanying InfraAlyzer calibration software (IACAL) as knowns for each clone. Stepwise linear multiple regression on log $1/R$ filter readings against resistance ratings was performed.

Determination of Resistance Ratings. Cane was grown in buckets for nine months before being stressed through reduced watering followed by inoculation with stalk borer eggs (Nuss and Atkinson, 1983). Assessment of resistance trials for larval survival, larval mass, and percent internodes damaged was made 500 day-degrees (with a developmental threshold of 10°C) after inoculation. Each clone was rated by each of the above measures and an average rating was obtained.

In this paper a rating based on larval survival alone was used, since final larval numbers appear to be decided during the approximate one-week period larvae spend on the stalk surface before stalk entry (K. J. Nuss, personal communication). Survival ratings are expressed as low 1, 2, and 3 (resistant); intermediate 4, 5, and 6; and high 7, 8, and 9 (susceptible), based on comparison with five standard varieties.

Calibration of Scanning NIR Spectrophotometer. An NIRSystems 5000 scanning monochromator (NIRSystems, Silver Spring, Maryland) was used to

acquire transmission spectra (1-cm light path) with near-infrared radiation from 1100 to 2500 nm for waxes from an expanded calibration set of 40 clones including both commercial varieties and unreleased late selection stage clones. Borer larval survival ratings were entered as knowns into the accompanying NIRSystems spectral analysis software (NSAS). Stepwise linear multiple regression was performed on the second derivative of log $1/R$ spectra against survival ratings.

Determination of Wax Load and Composition. Crude scraped waxes were obtained from commercial varieties N20 and N14 at 8 and 12 months of age. Stalk surface area and mass of crude wax were recorded. Dissolved crude waxes were filtered, and after drying, carbon tetrachloride insoluble and soluble fractions were determined gravimetrically. The soluble wax was further fractionated on a silicic acid column eluted with cyclohexane followed by chlorofrom and then chloroform–ethyl acetate (95:5 v/v) and finally ethyl acetate. Fractions were roughly designated as follows: 1, alkanes; 2, esters and aldehydes (carbonyls); 3, alcohols; and 4, acids. Quantities were determined gravimetrically and fractions were analyzed by GC.

Gas Chromatography. An OV-5 30-m × 0.32-mm ID capillary column was used. Approximately 0.4 μl of 10 mg/ml whole wax solutions or fractions thereof were injected without splitting onto a cold column (50°C for 1 min). The column was then heated to 200°C at 10°C/min and held for 1 min. The main separation occurred during the temperature rise at 5°C/min to 310°C. Injector and detector (FID) temperatures were 310°C. The carrier gas was nitrogen at 1.6 ml/min.

RESULTS

Results from an initial feasibility study suggest that chemical differences exist in sugarcane wax that can be correlated with resistance or susceptibility to the stalk borer. Wavelengths chosen for each regression (material from different sites and of different ages) were fairly stable, indicating that the same wax components were implicated (Table 1). In each model, 1982 nm (1940 nm on one occasion) was chosen first as the most highly correlatable single wavelength. As a general trend, it appeared that with increasing cane age the correlation coefficient declined, the y intercept (on the predicted rating axis) increased, and the slope of the regression line decreased.

Results from the feasibility study suggested that progress might be made with an expanded calibration set. Forty clones of known larval survival ratings were sampled at 8 (Figure 1), 10, and 12 months of age for use in conjunction with an NIRSystems 5000 scanning spectrophotometer. The results obtained suggest that variations in wax characteristics might account for around 53.5%

of the variation in larval survival ratings (Table 2). Again, the correlation between predicted and known ratings declined with increasing cane age.

Ideally a calibration set should be large enough that all the variation in the population has been sampled, i.e., the correlation coefficient reaches a plateau and the F statistic retains significance. Figure 2 shows that for an enlarging model, both the correlation coefficient and wavelength selection began to stabilize when more than 30 clones were used in the calibration. Since only 40 clones of known larval survival ratings were available, neither further extension of the calibration set nor a blind validation trial were possible.

Wavelengths in the region of 1940–1945 nm were the most highly correlated individual wavelengths throughout the clone addition exercise. According to spectra–structure correlation charts, such as that of Goddu and Delker (1960),

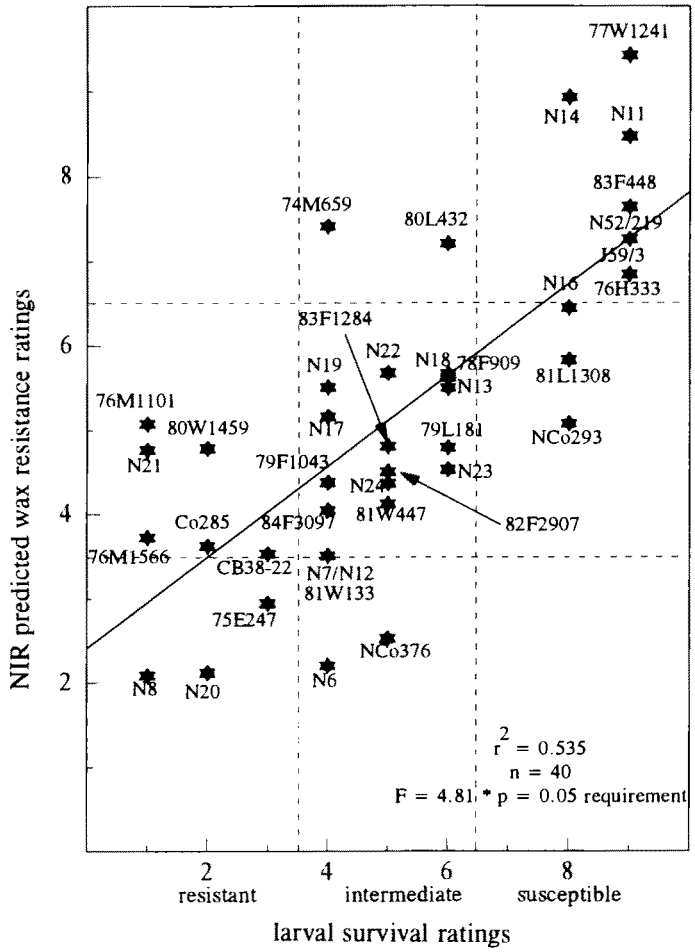

FIG. 1. Relationship between larval survival ratings and NIR wax predicted ratings for 8-month-old cane (40 clones).

wavelengths selected by both the IACAL and NSAS softwares suggest that alcohols and carbonyls might be important in the interaction between sugarcane and the stalk borer. In waxes, 1940–1945 nm might be characteristic of alcohols (−OH) or carbonyls (−C=O). Wavelengths in the region of 2070 nm are also characteristic of alcohols, as well as of hydroperoxides. Hydroperoxides are known to be present in sugarcane wax (Lamberton and Redcliffe, 1960).

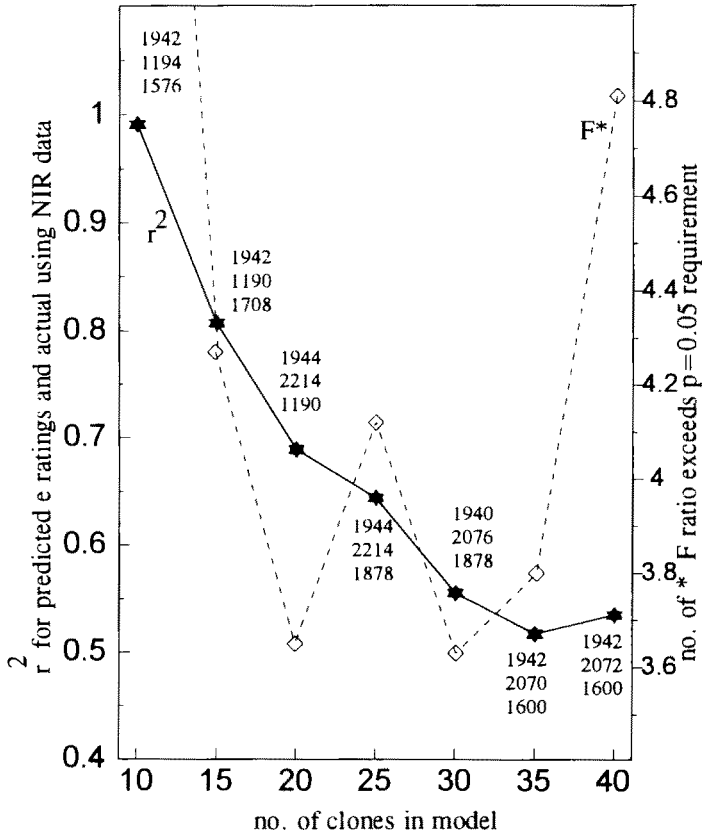

FIG. 2. Number of clones required to sample NIR variation in wax resistance (8-month-old cane).

GC wax chromatograms of resistant N20 and susceptible N14 at 8 months highlight the extremes of GC profile type among commercial varieties (Figure 3). These two varieties also differed greatly in NIR prediction.

Fractionation of wax and analysis by GC revealed that peaks 4, 6, and 8 were in the alcohol fraction while peaks 3, 5, and 7 were in the ester/aldehyde fraction. Peaks 3, 5, and 7 were independently identified by GC–mass spectroscopy (GC-MS) as the C_{26}, C_{28}, and C_{30} aldehydes, respectively, while peak 6 was identified as the C_{28} alcohol. The C_{28} aldehyde and alcohol are known to be components of sugarcane stalk wax (Tulloch, 1976). Due to their frac-

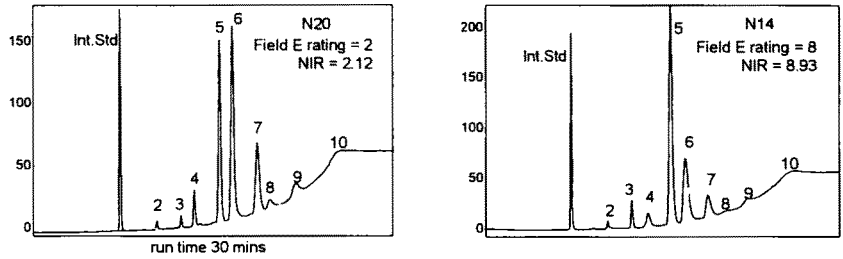

FIG. 3. Gas chromatograms of wax from resistant (N20) and susceptible (N14) commercial clones.

tionation properties, peaks 4 and 8 were considered to be the C_{26} and C_{30} alcohols, although they were not positively identified by GC-MS.

Fractionation of waxes from resistant and susceptible varieties suggests that the alcohol fraction decreases as a proportion of the total with both susceptibility and age. In addition, wax load decreased with age while nonsoluble contaminants (mostly dirt and fungal hyphae) increased (Table 3).

In order to further implicate GC peaks in resistance or susceptibility, peak areas relative to the internal standard were entered into the IACAL software. Using larval survival ratings as knowns, peaks were associated with either resistance (negative coefficients) or susceptibility (positive coefficients). Peaks were similarly associated with 8-month NIR predicted ratings.

TABLE 3. LOAD AND FRACTIONATION OF CRUDE SCRAPED WAX FROM VARIETIES N20 (RESISTANT) AND N14 (SUSCEPTIBLE) AT 8 AND 12 MONTHS OF AGE

Variety and age	Nonsoluble load (mg/100 cm^{-2})	Soluble load (mg/100 cm^{-2}) (% of 8 month total)	Alkane fraction (%)	Carbonyl fraction (%)	Alcohol fraction (%)	Acid fraction (%)	Crude wax in peaks 3–8 (%)[a]
N20 (8 months)	0.5	8.9 (95)	9	43	41	7	29.7

The C_{28} (peak 5) and C_{30} (peak 7) aldehydes were associated with NIR predicted susceptibility and known susceptibility (positive coefficients). The C_{26} aldehyde and alcohol and the C_{28} alcohol were associated with resistance while the C_{30} alcohol appeared to be associated with susceptibility (Table 4). It is therefore possible that the high alcohol/aldehyde ratio and shorter chain length might be involved in resistance to the stalk borer. GC peak models accounted for 31.5% and 62.8% of the variation in known larval survival ratings and NIR predited ratings, respectively (Table 4), while the NIR model for the prediction of larval survival ratings accounts for 53.5%. This suggests that the NIR technique profiles a greater proportion of the total wax than the GC technique. Evidently not all of the dissolved wax emerges from the GC column (Table 3).

The GC profiles of three *S. spontaneum* clones can be compared with those of three *S. officinarum* clones (Figures 4 and 5). These data revealed that *S. spontaneum* was dominated by shorter chain length C_{26} rather than C_{28} aldehydes and alcohols, while *S. officinarum* wax resembled that of hybrids.

DISCUSSION

It is not claimed that the relationships between NIR- and GC-determined wax components and resistance or susceptibility to the stalk borer represent cause and effect. Although considerably more clones are desirable in a calibration set, the 40-clone (8-month) NIR model produced does appear to have predictive

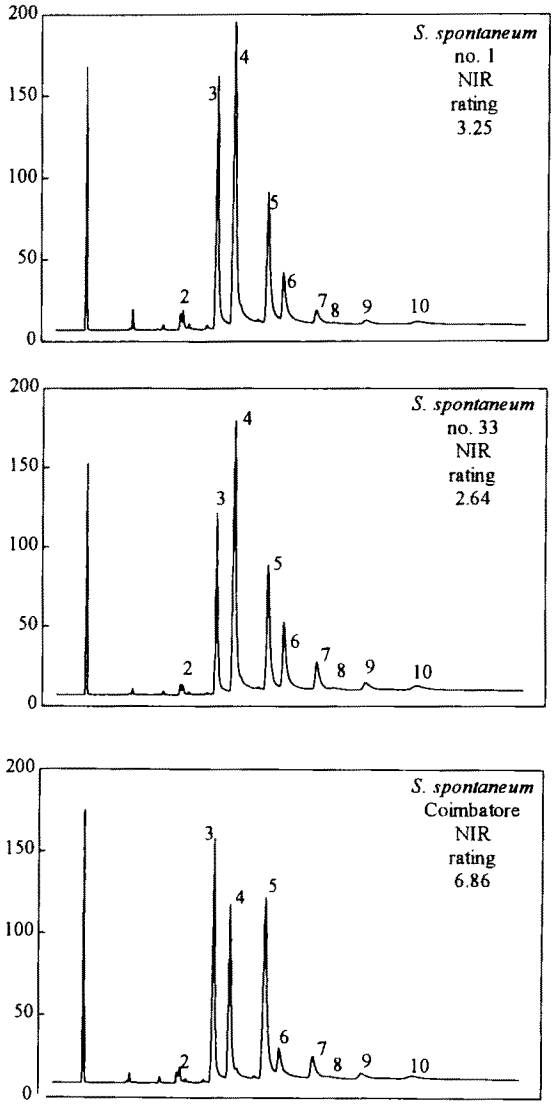

FIG. 4. GC wax profiles for three *S. spontaneum* clones.

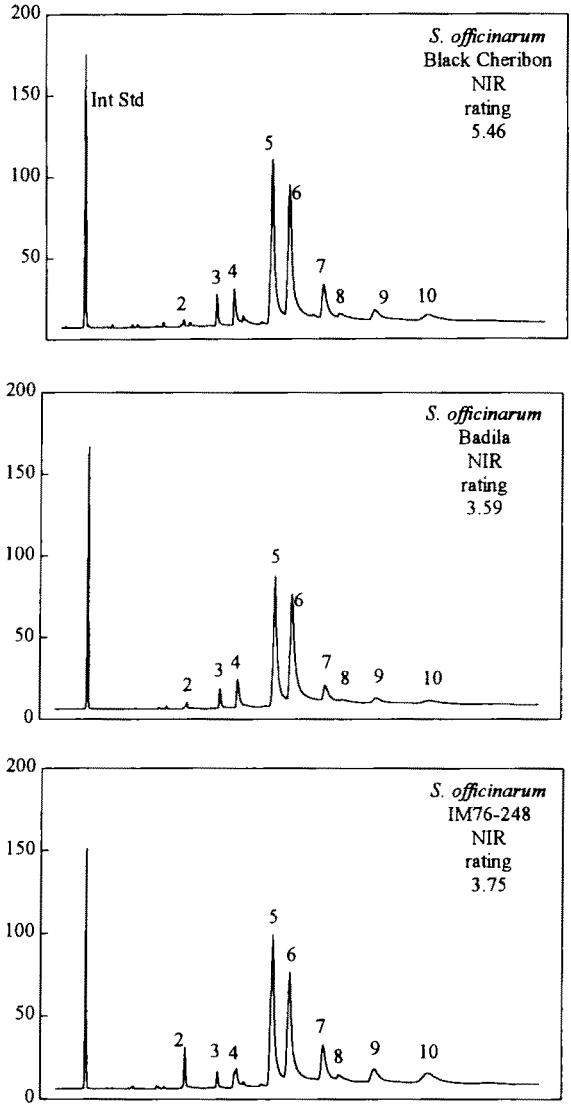

FIG. 5. GC wax profiles for three *S. officinarum* clones.

value. If clones predicted to be susceptible were discarded from a selection program, only 4% of resistant clones would be lost based on a correlation coefficient in the region of 0.53 (Schenk and Westerhaus, 1993). Since variation in wax composition explains 53.5% of variation in larval survival, such clones could be resistant for reasons other than wax composition.

Again based on a correlation coefficient of 0.53, approximately 60% of resistant or susceptible clones should be correctly classified. For susceptible clones in the calibration set, six of nine (66%) were predicted correctly; however, for resistant clones, only 33% were predicted correctly, suggesting a skew (Figure 1). Despite this, no resistant clones were predicted to be susceptible and vice versa.

Decreasing wax load, alcohol content, and NIR model correlation coefficients with increasing cane age all suggest that the wax contribution towards resistance might decline in older cane. Weathering and microbial action are probably the main causes of wax disappearance and degradation (Kolattukudy, 1980). The production of wax alcohols in maize has been shown to decline with increasing plant maturity (Avato et al., 1990b). It is well known that mature cane is more easily infested by the stalk borer than immature cane (Carnegie and Smaill, 1980).

These results suggest that wax alcohols might be associated with resistance while aldehydes appear associated with susceptibility. The indication that shorter chain length is also associated with resistance suggests that additional resistance might be obtained through further introgression of selected *S. spontaneum* germplasm.

S. spontaneum has already played an important role in the development of modern varieties by contributing many desirable characteristics, including disease and drought resistance (Roach, 1984). Modern varieties have a narrow genetic base; however, their genealogies can be traced to two *S. spontaneum* clones (Glagah and Coimbatore) and between 9 and 11 clones of other *Saccharum* species, mostly *S. officinarum* (Arceneaux, 1965). *S. spontaneum* Coimbatore has a susceptible NIR wax prediction and also a more susceptible GC profile when compared with two other unutilized *S. spontaneum* clones. Coimbatore would probably not have been selected for use as an ancestor of modern hybrids if greater resistance to the stalk borer had been the reason for the introgression. Glagah was not available for analysis.

Cause and effect as well as validation of the NIR method remain to be shown. To show cause and effect, experiments designed to demonstrate behavioral or feeding responses to waxes with variant NIR predictions are in progress. To validate the NIR method, sets of unclassified clones are being predicted and their larval survival ratings are being determined by exposure to the insect over several years. These clones can then be added to the calibration set.

NIR offers the potential of a rapid technique for the selection of borer resistant genotypes. Wax scraping is not destructive of clonal seed material and hundreds of clones can be predicted in one day. The use of fiberoptics in conjunction with hand-held NIR instruments for analysis of the stalk surface in situ is a possibility for the future.

Acknowledgments—Special thanks are due to the Plant Breeding and Entomology departments of the South African Sugar Association Experiment Station for the provision of stalk material and larval survival ratings. The GC-MS identification of wax components by R. Osborne of the Department of Chemistry, University of Natal, Durban, South Africa, is also acknowledged.

ROLE OF CUTICULAR HYDROCARBONS OF APHID PARASITOIDS IN THEIR RELATIONSHIP TO APHID-ATTENDING ANTS

(Received February 17, 1995; accepted November 30, 1995)

Abstract—*Lysiphlebus cardui*, the dominant aphidiid parasitoid of the black bean aphid, *Aphis fabae cirsiiacanthoidis* (Afc), on creeping thistle, is able to forage in ant-attended aphid colonies without being attacked by ants. Several behavioral observations and experimental studies led to the hypothesis that *L. cardui* mimics the cuticular hydrocarbon profile of its host aphid. Chemical analysis of the cuticular extracts revealed that both *L. cardui* and Afc exclusively possess saturated hydrocarbons: *n*-alkanes, monomethyl (MMA), dimethyl (DMA), and trimethyl alkanes (TMA). Comparison of the hydrocarbon profiles of parasitoid and aphid showed great qualitative resemblance between parasitoid and host: *L. cardui* possesses almost all host-specific compounds in addition to species-specific hydrocarbons of mainly higher molecular weight ($>C_{30}$). However, there is a lesser quantitative correspondence between parasitoid and host aphid. Furthermore, we analyzed the cuticular hydrocarbon profile of another parasitoid of Afc, *Trioxys angelicae*. This aphidiid species is vigorously attacked and finally killed by honeydew-collecting ants when encountered in aphid colonies. Its cuticular hydrocarbon profile is characterized by the presence of large amounts of (*Z*)-11-alkenes of chain lenghts C_{27}, C_{29}, C_{31}, and C_{33}, in addition to alkanes and presumably trienes. The role of the unsaturated hydrocarbons on *T. angelicae* as recognition cues for aphid-attending ants is discussed.

Key Words—*Aphis fabae cirsiiacanthoidis*, Aphididae, *Lysiphlebus cardui*, *Trioxys angelicae*, Aphidiidae, parasitoids, ant–parasitoid relationship, cuticular hydrocarbons, chemical mimicry.

INTRODUCTION

Cuticular surface lipids serve a variety of physiological and behavioral functions in insects (Blomquist and Dillwith, 1985; Jackson and Blomquist, 1976; Lockey, 1988). In recent years aspects of chemical communication via surface lipids have been increasingly investigated. Cuticular hydrocarbons have been shown to play a role as sex pheromones in numerous insect species (for examples, see review of Blomquist et al., 1993), or as nestmate recognition cues in social insects (see Howard, 1993, and references therein). In addition, they also function in chemical mimicry systems. Numerous insect species that integrate into colonies of social insects possess the same cuticular hydrocarbon profile as their host (see reviews of Stowe, 1988; Dettner and Liepert, 1994).

Chemical mimicry was suggested to be involved in the aphid–ant–parasitoid system of the black bean aphid on creeping thistle, *Aphis fabae cirsiiacanthoidis* Schrank (Afc), the ant species *Lasius niger* L., and the aphidiid wasp *Lysiphlebus cardui* (Marshall) (Völkl and Mackauer, 1993). *L. cardui* was supposed to mimic the cuticular hydrocarbon profile of its host aphid. This assumption was based on the observation that *L. cardui* was able to forage in Afc colonies without being attacked by attending ants. In contrast, a second aphidiid species that parasitizes Afc on thistle, *Trioxys angelicae* (Haliday), is rapidly recognized and vigorously attacked by ants when foraging in aphid colonies (Völkl and Mackauer, 1993). This different ant response depends on the cuticular signature of the parasitoid (Liepert and Dettner, 1993). When hexane-washed dead individuals of *L. cardui* were treated with the hexane extract of *T. angelicae* and offered in attended aphid colonies, the ants rapidly seized the parasitoid and transported it off the plant. In contrast, hexane-washed dead *T. angelicae* with the cuticular hexane extract of *L. cardui* did not induce ant attacks.

The purpose of the present study was to determine the cuticular hydrocarbon profiles of both parasitoids and the host aphid. If chemical mimicry is involved in the case of *L. cardui*, then we expect a resemblance of cuticular hydrocarbon profiles between parasitoid and host that makes it impossible for the ants to discriminate between aphid and *L. cardui*. Furthermore, we were interested in which cuticular components of *T. angelicae* might be responsible for triggering ant aggression.

METHODS AND MATERIALS

Insect Material. Aphids and parasitoids were obtained as described in Liepert and Dettner (1993). Neither parasitoid species had contact with the aphid host or its host plant. For the extraction of the cuticular lipids only female

parasitoids (30–40 individuals of each species) were used because they come into contact with aphid-attending ants when searching for hosts in which to oviposit. Aphids of the first to fourth instar (about 200 individuals) were extracted with hexane as these instars are the preferred hosts for both *L. cardui* and *T. angelicae* (Völkl, 1990).

Chemical Analysis. Cuticular hydrocarbons were recovered by extracting the insects twice in hexane for 60 sec at room temperature. The hexane extracts were combined and the solvent was evaporated under a gentle stream of nitrogen. The cuticular extracts were redissolved in 50 μl of hexane. To separate the hydrocarbon fraction from other lipid classes, the cuticular extract was applied to a column (5 cm $\times$ 0.5 cm ID) of silica gel 60 (70–230 mesh, Merck). Hydrocarbons were eluted with 4 ml hexane. Column chromatography was only applied to the aphid extract, since the gas chromatographic analysis of the cuticular extract of *L. cardui* exclusively yielded hydrocarbons. In the case of *T. angelicae*, insufficient sample was available for column chromatography; therefore, the cuticular lipid profile of the parasitoid is presented.

Gas Chromatography (GC) was carried out on a Carlo Erba GC 6000 Vega Series 2 equipped with a split-splitless injector and a flame ionization detector. A fused silica capillary column (30 m $\times$ 0.32 mm) with a chemically bonded DB-1 stationary phase of 0.10-μm film thickness was used for the analysis. Helium was the carrier gas with a flow rate of 1.5 ml/min. The oven temperature was kept at 180°C for 5 min, increased to 250°C at a rate of 15°C/min, then further increased at 6°C/min to the final temperature of 325°C, which was kept constant for 10 min. For diagnostic purposes an *n*-alkane standard from C_{20} to C_{36} was injected.

GC-MS was performed on a Finnigan MAT 95 connected with a Varian 3700 chromatograph that was equipped with a fused silica capillary column (DB-1, 30 m $\times$ 0.3 mm, FD = 0.25 μm). Helium was used as carrier gas. The oven temperature was programmed from 180°C to 310°C at a rate of 3°C/min. The final temperature was kept constant for 20 min. Mass spectra were obtained at an electron energy of 70 eV.

Substances were identified by their characteristic mass spectral fragmentation patterns and retention times. The mass spectra of some compounds were compared to spectra published in the National Bureau of Standards Mass Spectra Library. The branching positions of methyl-substituted hydrocarbons were determined by the mass ions that were formed by the α-cleavage at the branch point (McCarthy et al., 1968). The localization of double-bond positions in unsaturated lipids was determined by GC-MS analysis of dimethyl disulfide (DMDS) derivatives (Dunkelblum et al., 1985). Double-bond configuration was investigated by GC-FTIR (Bruker analytische Messtechnik GmbH, Karlsruhe, Germany).

RESULTS

Combined GC-MS analysis of the cuticular hydrocarbons of the aphid Afc and the aphidiid species *L. cardui* and *T. angelicae* resulted in the identification of *n*-alkanes, branched alkanes, and unsaturated hydrocarbons (Table 1). The species-specific capillary gas chromatograms obtained from the respective hexane extracts are shown in Figure 1. The numbers given to the peaks in the chromatograms refer to Table 2, where the identification of the signals and the relative mean abundance of each component are summarized.

Normal alkanes dominated in all three species (Table 1). They accounted for almost 70% of the total peak area (TPA) in the aphid Afc and around 50% in the parasitoids. Their chain lengths ranged from C_{23} to C_{35} with the odd-numbered carbon backbone being prevalent (Table 2). Pentacosane (peak 6) was the major component on the aphid and on *T. angelicae*, followed by heptacosane (peak 14) and nonacosane (peak 25) in decreasing quantities; in Afc pentacosane accounted for almost 50% of the TPA. *L. cardui* was characterized by the dominance of *n*-alkanes of higher molecular weight, i.e., nonacosane (peak 25) and hentriacontane (peak 37).

Methyl-substituted components could be found in all three species (Table 1). The parasitoid *T. angelicae* only possessed monomethyl alkanes (MMA) in the range between C_{23} and C_{31}; both terminally branched MMA, i.e., MMA with the methyl group at position 2 and 3, respectively, and internally branched MMA were common on the cuticle of *T. angelicae*. Quantitatively, MMA played a minor role in *T. angelicae* (Table 1). In contrast, Afc and *L. cardui* were characterized by a variety of methyl alkanes. MMA ranged from C_{23} to C_{33} on the aphid and from C_{23} to C_{35} on *L. cardui* (Table 2). This substance

[b] Tr = trace (<0.2% of the total peak area).

class accounted for more than 20% of the TPA in both species (Table 1). Furthermore, polysubstituted methyl alkanes were also present. The chain length distribution ranged from C_{29} to C_{35}. The aphid possessed three dimethyl alkanes (DMA) (peaks 29, 40, and 50) with odd carbon numbers. *L. cardui* was characterized by a broader range of DMA; in addition, on the parasitoid DMA of even carbon numbers (peaks 35, 44, and 54) were detected. The relative mean abundance of the DMA on *L. cardui* was more than 21% of the TPA (Table 1). In the aphid this substance group was of minor importance quantitatively. Relatively small amounts of trimethyl alkanes (TMA) in the chain length range of C_{29}–C_{33} could be detected in the extract of *L. cardui* (peaks 30, 41, and 52). The aphid possessed two hydrocarbon components that eluted at the same retention times as 11,15,19-triMeC$_{31}$ (peak 41) and 11,15,19-triMeC$_{33}$ (peak 52) present in the extract of *L. cardui*, but we could not obtain mass spectra of these peaks. We supposed that Afc also possessed traces of TMA (Table 2).

Large amounts of unsaturated hydrocarbons could be identified in the lipid extract of *T. angelicae* (Table 1). Analysis of the DMDS derivatives and the results from GC-FTIR revealed that this aphidiid species possessed (Z)-11-alkenes of the chain lengths C_{27}, C_{29}, C_{31}, and C_{33} (peaks 13, 24, 36, and 45). Of these, nonacosene (peak 24) and hentriacontene (peak 36) were the prevalent

alkenes. We assume more unsaturated components on *T. angelicae*, namely, the substances with the peak numbers 22, 33, and 43 (Table 2). Their molecular masses were at *m/e* 402, 430, and 458, respectively. Their fragmentation pattern was typical for polyunsaturated hydrocarbons with the diagnostic ion fragments at *m/e* 55, 67, 81, and 95. Moreover, after DMDS derivatization of the extract, these peaks vanished at their characteristic retention times. Therefore, we propose a triene structure with the chain lengths C_{29} (peak 22), C_{31} (peak 33), and C_{33} (peak 43).

In the case of the parasitoid species *T. angelicae*, some polar lipid components could be detected. Two substances in the lower molecular mass range were indicative of methyl docosanol and methyl tetracosanol (in Figure 1 these peaks are marked by an asterisk). The lipid components in the equivalent chain length of more than C_{33} have not been identified so far, but their mass spectra indicated a nonhydrocarbon nature.

Comparison of the cuticular hydrocarbon profiles of Afc and *L. cardui* revealed that the parasitoid possessed almost all hydrocarbons that could be detected on its host aphid (Table 2). *L. cardui* matched 23 of the total of 25 hydrocarbons on Afc. Eight of these matching compounds belonged to the *n*-alkane fraction, whereas the remaining 15 compounds belonged to the methyl-branched alkanes. Especially in the mass range between C_{23} and C_{30}, the hydrocarbon patterns of host and parasitoid were qualitatively very similar. In the higher molecular weight range of more than 30 carbon atoms, *L. cardui* was characterized by the presence of species-specific hydrocarbons. A quantitative comparison showed less resemblance between Afc and *L. cardui*, with differences in relative abundances mainly expressed in the *n*-alkane and DMA fraction (Table 1). The cuticular hydrocarbon profile of *T. angelicae* corresponded to that of its host aphid in only a dozen compounds. The great majority (eight compounds) belonged to the *n*-alkane fraction, while the remaining four compounds were terminally branched MMA (Table 2).

DISCUSSION

Four observations support the hypothesis that the aphidiid wasp *L. cardui* uses chemical mimicry in order to exploit ant-attended Afc colonies. First, ants behave towards the parasitoid in a similar way as towards the aphids when encountered in the colony; *L. cardui* is either totally ignored or only briefly antennated by the ants. Second, different ant species even belonging to different families show the same behavior towards this parasitoid (Völkl and Mackauer, 1993). Third, *L. cardui* females aggregate in cages and attempt to oviposit in conspecifics when aphid hosts are not present (Starý and Völkl, 1988). Such an oviposition attack does not differ from that towards host aphids. The parasitoid

briefly antennates the host, bends its abdomen ventrally between its legs, and pushes its ovipositor towards the body of the host (C. Liepert, personal observation). This phenomenon shows that *L. cardui* possesses "host" signals on its cuticular surface that elicit species-specific oviposition behavior. Fourth, the acceptance of *L. cardui* by aphid-attending ants is based on cuticular surface lipids (Liepert and Dettner, 1993).

In general, for a chemical mimicry system to work, the signal emitted by the mimic must be indistinguishable for the receiver from the model signal (Dettner and Liepert, 1994). In such cases where there is a complex cuticular hydrocarbon pattern involved, it is not possible to specify which compounds and/or whether their relative abundances are important to fool the signal receiver. In the present example the qualitative and/or quantitative resemblance of the hydrocarbon profiles of *L. cardui* and its host aphid Afc are sufficient for the parasitoid to be considered as "aphid" by the ants. This means that the ants only perceive that portion of the complex cuticular hydrocarbon profile of *L. cardui* that corresponds to the substances on the host aphid, while parasitoid-specific compounds do not play a role in the recognition process. Presumably, components of the mass range between C_{23} and C_{30} might be involved in the communication process, because there is a strong qualitative resemblance between parasitoid and host. The *L. cardui*-specific hydrocarbons are characterized by a molecular weight of more than C_{30}. Similar results were obtained from the beetle *Myrmecaphodius excavaticollis*, an inquiline of *Solenopsis* species (Vander Meer and Wojcik, 1982). The beetle only acquires the host-specific hydrocarbons of lower molecular weight. When living in nests of *S. richteri*, *M. excavaticollis* possesses cuticular substances in the range between C_{22} and C_{28}. As an inquiline of the related species *S. invicta*, the host-specific hydrocarbons on the beetle range from C_{27} to C_{29}. In both cases, the beetle also expresses innate components of higher molecular weight (C_{30}–C_{38}).

In addition to the importance of chain length, additional structural characteristics of hydrocarbons are also of major importance in chemical communication systems in insects. Methyl-branched alkanes definitely represent a substance class with great informative value. In general, methyl alkanes have been demonstrated to be physiologically active in several contexts of insect communication (see Howard, 1993). Moreover, they have been shown to be fairly specific, and changing the methyl position by one or two carbon atoms to either side in the chain markedly reduced kairomonal activity in the host–parasite system of *Helicoverpa zea* and *Microplitis croceipes* (Jones et al., 1971). Branched hydrocarbons also play an important role in communication between ants. Bonavita-Cougourdan et al. (1987), studying the ant species *Camponotus vagus*, demonstrated that methyl-branched alkanes can be involved in nestmate recognition processes. Therefore, we suspect that the presence of host-specific

methyl alkanes on the cuticle of *L. cardui* represents a major cue in its mimicry system. In fact, the parasitoid has 15 methyl-branched alkanes in common with the aphid Afc. Although *n*-alkanes also correspond in the cuticular extracts of aphid and parasitoid, we believe that they are of minor importance in the communication process because they are widely distributed components of the cuticular lipid layer of insects (Lockey, 1988).

Quantitative comparison of the cuticular hydrocarbon profiles revealed less resemblance between Afc and *L. cardui*. However, it is still a matter of conjecture whether such quantitative differences between model and mimic are important in chemical mimicry systems. For example, Howard et al. (1990) also reported differences in relative abundances of cuticular hydrocarbons in the mimicry system of the syrphid *Microdon albicomatus* and its host ant *Myrmica incompleta*. Quantitative differences of cuticular hydrocarbons are believed to play a major role in nestmate recognition processes in ants. Bonavita-Cougourdan et al. (1993), in investigations of the functional subcaste discrimination in the ant species *Camponotus vagus*, postulated that the ants are able to discriminate foragers and brood-tenders by means of quantitative differences in their hydrocarbon profiles.

In the present system we cannot rule out that other cuticular compounds, as well as hydrocarbons, may also be important in the chemical mimicry of the parasitoid *L. cardui*. For example, Franks et al. (1990) pointed out that fatty acids should be included in analyses and thought that they might play a more important role than cuticular hydrocarbons in recognition processes. They showed that the cuckoo ant, *Leptothorax kutteri*, possesses similar cuticular hydrocarbon and fatty acid profiles to workers of its host ant species, *L. acervorum*.

The source of the cuticular hydrocarbons of the aphidiid *L. cardui* is still unknown. Generally, the two possibilities are acquisition or biosynthesis of the substances. For both possibilities there are numerous examples known in the literature (see Dettner and Liepert, 1994). Acquisition by grooming and/or rubbing behavior can be excluded, since we analyzed naive parasitoids that had no prior contact with its host aphids. Moreover, grooming behavior towards host aphids has never been reported for *L. cardui* in the literature and has never been observed by us. The aphidiid parasitoid *Paralipsis eikoae*, however, displays rubbing behavior in order to acquire the odor of *L. niger* ants that attend the parasitoid's host aphid colonies. *P. eikoae* has to succeed in mounting an *L. niger* ant and rubbing its legs on the ant's body in order to be accepted by the ants (Takada and Hashimoto, 1985).

The parasitoid species *T. angelicae* possesses a qualitatively very different hydrocarbon profile compared to its host aphid Afc. The most striking feature of *T. angelicae* is the presence of large amounts of unsaturated hydrocarbons on its cuticle (see Table 1), in particular the homologous series of (*Z*)-11-alkenes

of chain lengths C_{27}, C_{29}, C_{31}, and C_{33}. They represented about 45% of the total hydrocarbon fraction. It is very likely that these compounds induce ant attacks against *T. angelicae*. Preliminary bioassays, in which *T. angelicae*-specific amounts of (*Z*)-11-heptacosene and (*Z*)-11-nonacosene were applied to dead hexane-washed parasitoids and then offered in ant-attended Afc colonies, showed that *L. niger* responded very aggressively towards such test objects (Stegen, Liepert, and Dettner, unpublished data). However, we cannot exclude other chemicals produced in exocrine glands of *T. angelicae* that may be responsible for ant aggression. Exocrine gland secretions from parasitoids can have a modifying effect on the behavior of ants. Völkl et al. (1994) demonstrated that the aphid hyperparasitoid *Alloxysta brevis* uses mandibular secretions to overcome ant aggression when searching for hosts in an aphid colony.

The strategy of using chemical mimicry as an integrating mechanism is very effective in the case of the aphidiid wasp *L. cardui*. It can parasitize almost the entire aphid colony without being molested by attending ants (Völkl, 1992). In general, nonaggressive ant–parasitoid interactions seem to be quite common within the genus *Lysiphlebus*. The specialized *L. hirticornis* and the polyphagous *L. fabarum* show the same behavioral pattern of a cryptic performance as *L. cardui* when foraging in ant-attended host colonies (Starý, 1966; Mackauer and Völkl, 1993; C. Liepert, personal observation), and the polyphagous *L. testaceipes* is at least not attacked by *L. niger* (Völkl and Mackauer, 1993). Therefore, further studies and chemical analyses of host aphids and parasitoids have to be undertaken to clarify whether all *Lysiphlebus* species utilize chemical mimicry and whether the polyphagous species are able to adjust their cuticular hydrocarbon profile to that of the respective host aphid.

Acknowledgments—We thank especially Wolfgang Völkl and two anonymous reviewers for helpful comments on an earlier draft of this manuscript. We further gratefully acknowledge the help of Prof. Dr. W. Boland (Bonn, Germany) for identifying the configuration of the alkenes and for supplying authentic substances. The Deutsche Forschungsgemeinschaft provided financial support to K.D. (De 258/6-1).

(Received July 13, 1995; accepted December 1, 1995)

Abstract—The effect of protein and birch bark powder (BBP) content of forage on food consumption and growth of root voles (*Microtus oeconomus*) was studied by feeding young voles with eight different diets for two weeks. Voles ate more when the protein content of forage was moderate (6%) or low (3%), and when BBP was added to the diets, as compared to a high (12%) protein diet without BBP addition. On high and moderate protein diets voles gained weight, whereas on low protein diets they lost weight. Addition of BBP caused reduced growth or weight loss. Consuming a diet with moderate (6%) protein and high BBP (20%) resulted in high mortality (9 of 10 died). These results show that root voles need at least 6% protein for growth and that the effect of birch bark depends on the protein content of the forage.

Key Words—Vole, *Microtus oeconomus*, birch, *Betula pendula*, dietary protein, food consumption, growth, mortality, liver glycogen.

INTRODUCTION

Recent experimental data indicate that plant secondary metabolites and nutrients in the forage influence the consumption of food, growth, and survival of arvicoline (microtine) rodents (Jung and Batzli, 1981; Batzli, 1985; Lindroth et al., 1986). Generalist herbivores usually prefer plant species that simultaneously offer high amounts of nutrients with relatively low levels of secondary com-

0098-0331/96/0400-0709$09.50/0 © 1996 Plenum Publishing Corporation

pounds (Bergeron and Jodoin, 1987; Marquis and Batzli, 1989; Bucyanayandi and Bergeron, 1990).

During winter, root voles and other arvicoline voles gnaw the bark of young deciduous and coniferous trees (Tast, 1966; Buchalczyk et al., 1970; Gebczynska, 1970; Korhonen et al., 1983; Spencer, 1984; Batzli and Henttonen, 1990). Gnawing of the bark of birch (*Betula pendula* Roth) is most obvious in winters when high numbers of voles are present (Hansson, 1986, 1989), probably because more palatable food items are scarce or unavailable (Tast, 1966; Korhonen et al., 1983; Bergeron, 1984). Birch bark is not rich in protein (Palo et al., 1985; Harju and Tahvanainen, 1994), but it contains high amounts of plant secondary compounds, such as phenolics and terpenoids (Tahvanainen et al., 1991). Feeding on forage low in protein and rich in secondary chemicals was recently shown to affect field voles (*Microtus agrestis* L.) adversely (Harju and Tahvanainen, 1994).

Here I report an experiment on the interaction of dietary protein and birch bark powder (BBP) using young root voles as experimental animals. BBP was used as a source of secondary compounds in the experimental diet. Voles were fed for two weeks with eight different diets containing three levels of protein and BBP. The hypotheses tested were: (1) low dietary protein in interaction with birch bark powder reduces growth of animals and increases intake of forage (see Harju and Tahvanainen, 1994), and (2) high dietary protein compensates for the adverse effects of birch bark powder.

METHODS AND MATERIALS

The experimental diets were prepared by adding dried BBP in food pellets. For the preparation of BBP, twigs of the current year's growth of young, winter-dormant silver birch (*Betula pendula* Roth) (up to 2.5 m tall) were collected in November 1988 near Joensuu, in eastern Finland. The resinous twigs (< 10 mm in diameter) were peeled and the bark was dried in a ventilated oven at 48°C for 20 hr. The dried bark was ground and the powder stored frozen (−20°C) until used.

The crude protein concentrations of the food pellets used were 3%, 6%, and 12% (manufacturer: FinnEwos). Eight diets were prepared (Table 1) by mixing ground pellets with water, a small amount of potato flour, and different amounts of birch bark powder (0%, 5% and 20%, w/w). Pellets weighing 20–30 g were dried in a ventilated oven at 48°C for 20 hr.

The voles used were first- to third-generation offspring from a stock of root voles (*Microtus oeconomus* Pallas) maintained at the University of Joensuu. The original population was brought from Pallasjärvi, northern Finland. The parent population received ad libitum commercial pellets for laboratory animals (crude

TABLE 1. PROTEIN AND BBP CONTENT OF DIETS AND MORTALITY OF EXPERIMENTAL ROOT VOLES WITHIN EACH TREATMENT

Treatment	Protein content (%)	BBP content (%, w/w)	Mortality (individuals)
3/0	3	0	0/10
3/5	3	5	0/10
6/0	6	0	1/10
6/5	6	5	4/10
6/20	6	20	9/10
12/0	12	0	1/10
12/5	12	5	0/10
12/20	12	20	4/10

protein content about 20%), water, and slices of potatoes and carrots as fresh food.

Young voles were weaned at the age of 18 days and kept as littermate groups. They received water and commercial pellets ad libitum until the beginning of the experiment. At about 5 weeks of age (range 4–8 weeks) individuals were randomly divided among the experimental groups (Table 1) and started on their respective diets. Each group consisted of 10 individuals. The sex of the voles was not recorded.

During the experiments the voles were housed individually in plastic cages (22 × 27 × 10 cm) with hardwood chip bedding. Fresh water was given every day in a plastic cup inside the cage. The temperature was kept at 18–19°C, and the light cycle was 6L:18D. Both the voles and their food were weighed daily. The experiment lasted for 14 days. At the end of the experiment the voles were anesthesized with ether and killed by dislocating the neck.

The glycogen content of liver tissue, used as an approximate index of nutritional status, was measured by the method described by Lo et al. (1970). A piece of liver tissue weighing about 100 mg was hydrolyzed with 1 ml of 30% KOH (saturated with Na_2SO_4) for 20–30 min in a boiling water bath until a homogenous solution was obtained. Samples were cooled in ice. Glycogen was precipitated from the alkaline digestae by adding 1.2 ml of 95% ethanol. Samples were kept on ice for a further 30 min. After centrifugation (3000 rpm, 25 min) the supernatant was removed and the remaining glycogen precipitate was dissolved in 10 ml of distilled water. Then 0.05 ml of this solution was brought to a sample volume of 1 ml by adding distilled water, and 1 ml of 5% phenol and 5 ml of 96–98% H_2SO_4 were added to the solution. After standing for 10 min, the samples were shaken and placed for 10–20 min in a water bath

(25–30°C). The absorbance was read at 490 nm with Hitachi U-2000 spectrophotometer. All samples were analyzed in duplicate. Results were read from the glycogen standard curve (glycogen stock solution 5 mg/ml distilled water).

Statistical tests were performed with SAS (Freund et al., 1986). The effect of age, initial body mass, and diet on the survival of voles was tested with the LOGISTIC procedure. The food consumption and growth data were tested using the GLM repeated measures procedure for analysis of variance, using type IV sums of squares (Freund et al., 1986), and the liver glycogen data were tested using two-way ANOVA. The two variables were dietary protein content and birch bark powder concentration. Individuals that did not survive through the experimental period were excluded from the analyses.

RESULTS

The more BBP the forage contained, the less likely the root voles were to survive ($\chi^2 = 14.0$, $P < 0.001$) through the experiment (Table 1). Protein as such did not affect survival ($\chi^2 = 0.27$, $P = 0.6067$). The age ($\chi^2 = 1.39$, $P = 0.2393$) or the initial body mass ($\chi^2 = 0.004$, $P = 0.9528$) of nonsurviving voles did not differ significantly from those of the surviving voles.

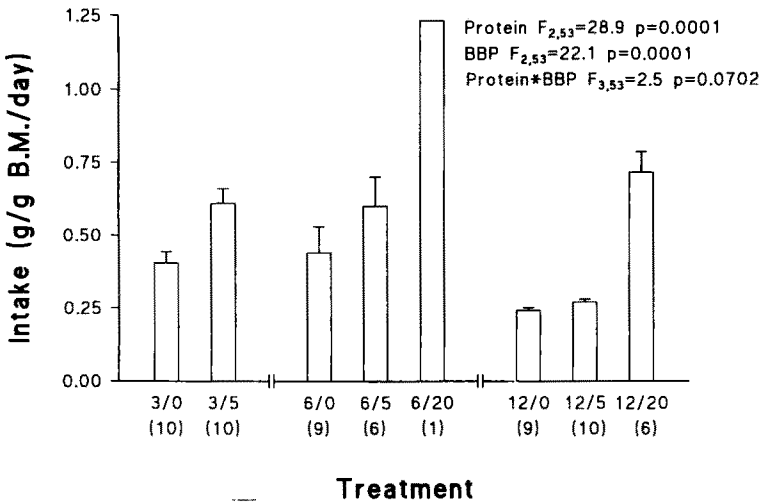

FIG. 1. Mean daily consumption of food by surviving root voles ($X \pm$ SE). Treatments as in Table 1. Number of individuals in parentheses.

Consumption of food was affected significantly (Figure 1) by both the protein level ($F_{2,53} = 28.9$, $P = <0.001$) and BBP concentration of the forage ($F_{2,53} = 22.1$, $P < 0.001$). There was a nearly significant interaction between dietary protein and BBP ($F_{3,53} = 2.5$, $P = 0.0702$). The consumption was lowest on the high (12%) protein diet without BBP. On all protein levels, addition of BBP into the diet increased consumption. The consumption was highest on diets containing 20% BBP. Individual voles within high BBP treatments (groups 6/20 and 12/20), however, responded to the diets in two different ways. The first group had very low intake (average daily intake 0–6 g) and a short survival time (1–2 days, $N = 10$). The other group of animals had very high intake (average daily intake 12–26 g) and longer survival time (4–14 days, $N = 10$) with seven individuals surviving through the experiment.

Growth of voles was affected by both the protein and BBP content of the diet (protein $F_{2,53} = 17.8$, $P < 0.001$; BBP $F_{2,53} = 3.1$, $P = 0.0531$). There was no significant interaction between dietary protein and BBP ($F_{3,53} = 1.1$, $P = 0.3135$). Growth was best on high (12%) protein diets, and a decrease in protein content caused slower growth or loss of weight (Figure 2). Despite

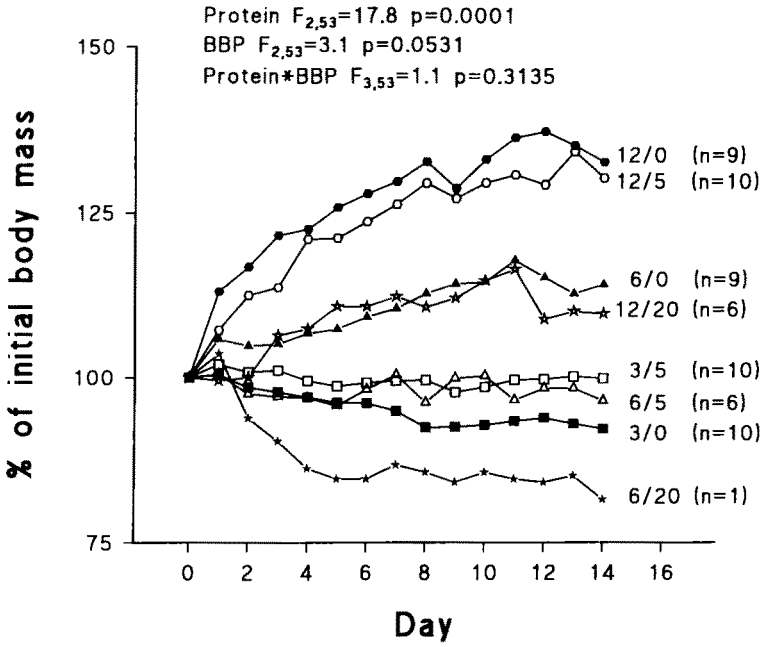

FIG. 2. Mean body mass of surviving root voles, shown as percent of initial body mass, in different treatments. Treatments as in Table 1.

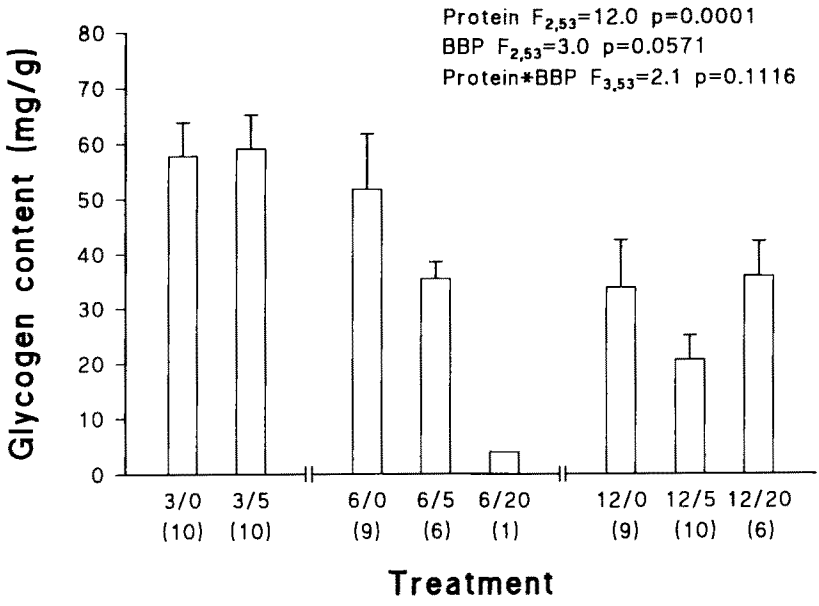

FIG. 3. The mean ($X \pm$ SE) glycogen content of liver tissue of surviving root voles. Treatments as in Table 1. Number of individuals in parentheses.

increased consumption, the voles gained less or even lost weight when BBP was added to the forage, with the exception of groups 3/0 and 3/5. On the diet containing 6% protein and 20% BBP, only one individual survived, losing about 20% of its weight in two weeks.

The glycogen content of the livers (Figure 3) was low on high protein diets as compared with low protein diets ($F_{2,53} = 12.0$, $P < 0.001$). The increase in BBP concentration tended to result in lower glycogen content ($F_{2,53} = 3.0$, $P = 0.0568$) as compared to diets without BBP addition. There was no significant interaction between dietary protein and BBP ($F_{3,53} = 2.1$, $P = 0.1116$).

DISCUSSION

Feeding on diets containing 20% BBP resulted in heavy mortality of experimental voles (Table 1). Poor survival of voles when fed forage containing secondary compounds was reported also by Lindroth and Batzli (1984) and Jung and Batzli (1981). In this experiment the voles that did not survive usually refused to eat or ate only very little, and died within one to two days (six voles

in group 6/20 and four in group 12/20). This suggests that the death of animals was caused by starvation, not by the toxicity of the added BBP. However, in a few cases (three voles in group 6/20) voles ate high amounts and yet died. These voles were probably unable to handle the secondary compounds received from BBP in the forage, and the mortality here was apparently due to the toxic effects of BBP. According to Lindroth and Batzli (1984), meadow voles need at least 8% protein in forage to detoxify phenolic-rich diets. Low protein diets were also reported by Dauterman (1980) and Sipes and Gandolfi (1986) to decrease the ability of animals to metabolize plant toxins.

In the present experiment there was a clear increase in consumption of food when dietary protein content decreased from 12% to 6%. There was no further increase when protein content decreased from 6% to 3%. On the other hand, an increase in consumption was seen also when concentration of BBP was increased. Increased consumption of low-quality food, as seen in this study, was probably due to an effort to meet the nutritional requirements (Batzli and Cole, 1979; Batzli, 1985) in the absence of alternative food. However, whatever the demand for nutrients, food cannot be ingested faster than the gut can process it (Batzli, 1985). At the highest intake rates (groups 6/20 and 12/20), the voles consumed about their own weight of forage per day, which might be the limit set by the gut (Batzli, 1985).

The increase in dietary concentration of BBP, while promoting consumption, significantly decreased the growth of voles. This and low liver glycogen content indicate an increased metabolic cost in processing these diets (Thomas et al., 1988). On low protein diets (with or without BBP) the voles apparently did not gain enough protein for growth, hence they stored glycogen (=energy). On high protein diets, on the other hand, the glycogen in liver was probably used as an energy source for growth. The lower glycogen content when BBP was added to the diets was probably due to the increased need for energy to metabolize the secondary compounds of BBP. The compensatory effect of high dietary protein content has previously been reported for rats also (Glick and Joslyn, 1970). According to Jean and Bergeron (1986), voles seem to tolerate secondary compounds of commonly eaten plants but seem to be adversely affected when nutrients such as proteins are low in the forage.

In conclusion, these results show that the bark of birch twigs is a low quality forage for voles (see also Harju and Tahvanainen, 1994). In general, voles are well adapted to utilizing food high in fiber and low in protein (Batzli, 1985; Hume et al., 1993). However, when secondary compounds are present in high quantity, the performance of voles seems to be dependent on the concentration of dietary protein. Low dietary protein in interaction with BBP reduces the growth of the animals and increases their consumption of food. The results presented here show that a high dietary protein level can compensate for the harmful effects of birch bark powder.

The wintering success of root voles seems to depend on their ability to maintain their body mass (Tast, 1972, 1984), which has been shown to correlate with the quality/quantity of winter forage (Tast, 1984). According to Tast (1972) and Cole and Batzli (1979), the quality of available food can exert a strong influence on the density of herbivores. This leads to the suggestion that utilizing bark of birch or other trees as winter forage may cause serious problems to root voles and may affect the population dynamics during high vole densities.

EFFECT OF BIRCH (*Betula pendula*) BARK AND FOOD PROTEIN LEVEL ON ROOT VOLES (*Microtus oeconomus*): II. DETOXIFICATION CAPACITY

ANU HARJU

Department of Biology
University of Joensuu
P.O. Box 111, FIN-80101 Joensuu, Finland

(Received July 13, 1995; accepted December 1, 1995)

Abstract—The effect of protein and birch bark powder (BBP) content of forage on detoxification capacity of root voles (*Microtus oeconomus*) was studied. Young voles were fed with eight different diets for two weeks. Individuals on low (3%) protein diets had significantly lighter livers and kidneys than those on moderate (6%) or high (12%) protein diets. Birch bark powder addition did not have significant effect on organ weight. Detoxification was significantly induced, apparently due to secondary compounds in BBP. The activity of ethoxyresorufin-*O*-dealkylase (EROD) was high when protein content or BBP concentration in forage was high as compared to low protein diets or diets containing no BBP. Glucuronidation, on the other hand, was not induced by BBP. High BBP content caused serious physiological stress to the voles. The only individuals surviving were those capable of sufficiently allocating energy and protein to detoxification.

Key Words—Voles, *Microtus oeconomus*, birch, *Betula pendula*, dietary protein, detoxification capacity, EROD, glucuronidation.

INTRODUCTION

Mammalian herbivores utilize several physiological mechanisms to overcome the adverse effects of plant secondary compounds (Freeland and Janzen, 1974). One of these mechanisms is a two-phase detoxification system located mainly in the liver (Bidlack and Smith, 1984; Sipes and Gandolfi, 1986). Addition of functional groups (phase I) to the compound provides reactive sites for the conjugative (phase II) reactions (Freeland and Janzen, 1974; Sipes and Gandolfi,

0098-0331/96/0400-0719$09.50/0 © 1996 Plenum Publishing Corporation

1986; Siess et al., 1988). In phase I the relatively nonspecific cytochrome P-450-containing monooxygenases (Sipes and Gandolfi, 1986), such as ethoxyresorufin-*O*-dealkylase (EROD), carry out oxidation, hydroxylation, and reduction. In phase II different transferases conjugate compounds with, e.g., glucuronic acid or inorganic sulfate (Caldwell, 1986). These metabolic alterations produce more hydrophilic, more readily excreted, and generally less toxic compounds as compared with the parent compound(s) (Freeland and Janzen, 1974; Caldwell, 1986; Sipes and Gandolfi, 1986).

The nutritional value of the diet seems to influence the ability of herbivores to detoxify plant secondary compounds (Schwass and Finley, 1985; Sipes and Gandolfi, 1986). Nutritional deficiencies (e.g., lack of protein or minerals) may reduce the activity of oxidative and conjugative enzymes (Schwass and Finley, 1985; Bidlack and Smith, 1984; Bidlack et al., 1986; Sipes and Gandolfi, 1986; but see Sell and Rogler, 1983). Ingestion of plant secondary compounds, on the other hand, can induce these enzymes (Bidlack and Smith, 1984; Chadha and Madyastha, 1984; Sipes and Gandolfi, 1986; Alldrick et al., 1988; Siess et al., 1988; Harju and Tahvanainen, 1994), which allow herbivores to alleviate the harmful effects of those compounds. Detoxification is energetically expensive, and there is a limit to the extent the enzymes can be induced (Freeland and Janzen, 1974; Harborne, 1991). This limit should be dependent on the nutritional quality of the diet.

As a secondary source of food, arvicoline (microtine) voles gnaw the bark of young deciduous trees, such as birch (*Betula* spp.) (Buchalczyk et al., 1970; Korhonen et al., 1983; Batzli and Henttonen, 1990). The bark of birch and other woody species is gnawed especially in winters with high vole densities (Hansson, 1986), probably because more palatable food is scarce (Korhonen et al., 1983; Bergeron, 1984). Consuming birch bark causes voles serious stress and leads to poor growth and survival of animals, although intake of food increases (Harju and Tahvanainen, 1994; Harju, 1996).

Birch bark is poor in protein (Palo et al., 1985) but rich in secondary compounds such as terpenoids and phenolics (Tahvanainen et al., 1991). Both phenolics and terpenoids are shown to be metabolized (phase I) by cytochrome P-450 monooxygenases (Scheline, 1978; Watabe et al., 1980; Gordon et al., 1987; McLean et al., 1993) and conjugated (phase II) with glucuronic acid (Scheline, 1978; McLean et al., 1993). In the present experiment, birch bark powder (BBP) was used as a source of secondary compounds in the diet. This paper reports an experiment on the effect of BBP ingestion and protein content of forage on the detoxification capacity of young root voles (*Microtus oeconomus* Pallas). The hypotheses tested were: (1) secondary compounds in BBP should induce detoxification (Harju and Tahvanainen, 1994), and (2) high dietary protein should improve detoxification.

METHODS AND MATERIALS

Root voles, about 5 weeks old, were fed for two weeks with eight different diets (Table 1). During the feeding voles were housed individually in plastic cages (22 × 27 × 10 cm). Details of the preparation of the diets and the feeding trial are reported in Harju (1996). At the end of the experiment voles were killed by dislocating the neck. Liver and kidneys were removed and weighed, and a piece of liver was stored in liquid nitrogen until used. The substrates and other biochemicals for the chemical assays were manufactured by Sigma Chemical Company.

The microsomal fraction of hepatic tissue was prepared as in Burke and Mayer (1974), with slight modifications. The tissue was homogenized in 0.25 M sucrose (1 g:4 ml). The homogenate was centrifuged at 4°C and 10,000*g* for 20 min, and the resulting supernatant was centrifuged at 4°C and 105,000*g* for 60 min. The microsomal pellets were resuspended in 0.25 M sucrose, 0.05 M Tris buffer, pH 7.4 (HCl), 1 ml corresponding to 1 g of original tissue sample. The microsomal suspensions were stored at −80°C until used. The protein content of microsomes was measured by the method of Lowry et al. (1951), using bovine serum albumin as a standard.

Both enzyme assays were performed at 37°C. The activity of EROD was measured from the microsomes as described in Lubet et al. (1985). The reaction mixture contained 25 μl of microsomal suspension, 1875 μl of Tris HCl buffer (0.1 M, pH 7.8), and 100 μl of 10 μM ethoxyresorufin. The activity was measured at an excitation wavelength of 530 nm and an emission wavelength of 585 nm with a Shimadzu RF-5000 spectrofluorophotometer. The reaction was started by adding 20 μl of 5 mM NADPH. After 3 min, 20 μl of 0.1 mM

TABLE 1. PROTEIN AND BBP CONTENT OF DIETS AND MORTALITY OF EXPERIMENTAL ROOT VOLES WITHIN EACH TREATMENT

Treatment	Protein content (%)	BBP content (%, w/w)	Mortality (individuals)
3/0	3	0	0/10
3/5	3	5	0/10
6/0	6	0	1/10
6/5	6	5	4/10
6/20	6	20	9/10
12/0	12	0	1/10
12/5	12	5	0/10
12/20	12	20	4/10

resorufin was added as an internal standard. The activity was found to be linear over the time period used for the assay. Duplicate determinations of activity were carried out on the same liver extract. Enzyme activity was expressed as nanomoles of substrate hydrolyzed per individual per minute.

With *p*-nitrophenol (*p*-NP) as an aglycone and uridine 5′-diphosphoglucuronic acid (UDPGA) as the glucuronyl donor, UDP-glucuronosyltransferase (UDP-GT) activity of microsomes was measured as described in Hänninen (1968). The reaction mixture of 0.1 ml potassium phosphate buffer (0.5 M, pH 7.0) containing 0.35 mM *p*-NP and 6.89 mM UDPGA, and 0.2 ml of sucrose-diluted microsomes (25 μl of original microsome suspension), was incubated for 20 min. The reaction was stopped by adding 900 μl of cold 3% tricholoroacetic acid. The mixture was centrifuged and the supernatant solution added to 100 μl of 5 M NaOH. The absorbancy was measured immediately at 400 nm with a Hitachi U-2000 spectrophotometer. The activity was found to be linear over the time period used for the assay. Duplicate determinations of activity were carried out on the same liver extract. Enzyme activity was expressed as nanomoles of *p*-NP glucuronylated per individual per minute.

Results were tested with the SAS GLM-procedure for two-way analysis of variance (Freund et al., 1986). The variables were dietary protein content and birch bark powder concentration. The initial body mass of voles was used as a covariate in analyses of liver and kidney mass (Shirley, 1977).

RESULTS

Individuals on low (3%) protein diets had lighter livers and kidneys than voles on other diets (Figure 1, Table 2). Dietary BBP did not have a significant effect on either liver or kidney mass. There was no significant interaction between protein and BBP, despite the different trends seen on moderate (6%) and high (12%) protein diets.

The protein content of hepatic microsomes (Figure 2) was significantly higher on high protein diets than on low protein diets (Table 2). BBP did not have a significant effect on microsomal protein content, and there was no interaction between protein and BBP content of the diet (Table 2).

The capacity of EROD was higher on high protein diets than on low protein diets, and dietary BBP caused a significant increase of capacity (Figure 3, Table 2). The only surviving individual in group 6/20 had the highest EROD capacity. There was also a significant interaction between the protein and BBP content in the diet. Capacity of UDP-GT, on the other hand, was affected only by dietary protein (Figure 4, Table 2). Dietary BBP did not have a significant effect on UDP-GT capacity.

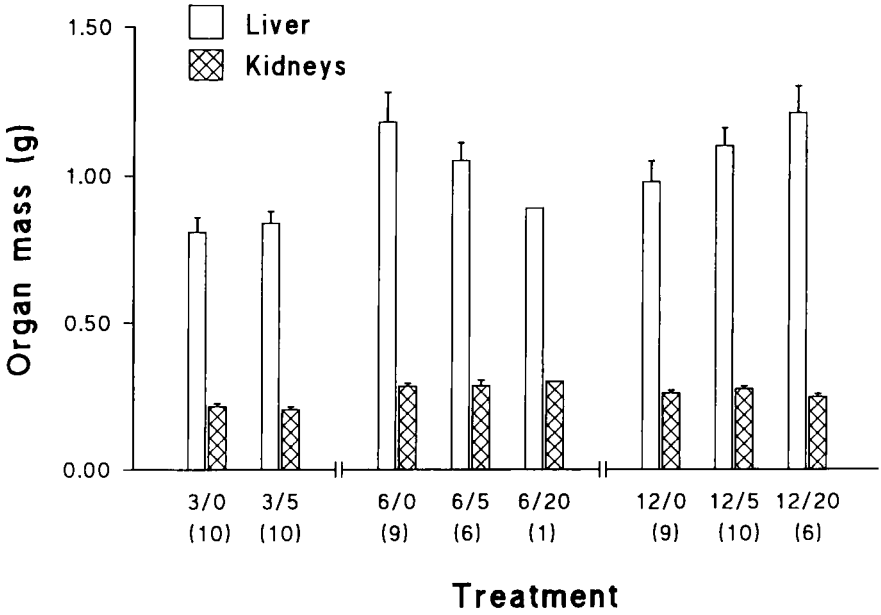

FIG. 1. Mean mass ($X \pm$ SE) of liver and kidneys of surviving root voles. Treatments as in Table 1. Number of individuals in parentheses.

TABLE 2. RESULTS OF TWO-WAY ANOVA FOR EFFECTS OF PROTEIN AND BBP ON MASS OF LIVER AND KIDNEYS, MICROSOMAL PROTEIN, AND MICROSOMAL EROD AND UDP-GT CAPACITY OF ROOT VOLES

	Effect of protein	Effect of BBP	Interaction
Liver mass	$F = 5.60$	$F = 0.14$	$F = 2.42$
	$P = 0.0063$	NS	NS
Kidney mass	$F = 30.92$	$F = 0.20$	$F = 0.77$
	$P = 0.0001$	NS	NS
Microsomal protein	$F = 10.16$	$F = 1.83$	$F = 1.28$
	$P = 0.0002$	NS	NS
EROD capacity	$F = 20.60$	$F = 22.96$	$F = 9.86$
	$P = 0.0001$	$P = 0.0001$	$P = 0.0001$
UDP-GT capacity	$F = 4.61$	$F = 0.68$	$F = 0.17$
	$P = 0.0142$	NS	NS

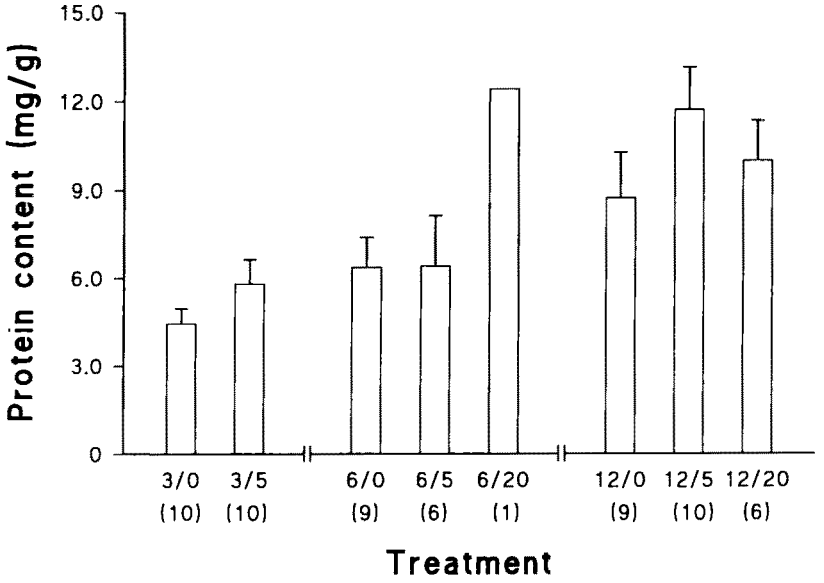

FIG. 2. Mean microsomal protein content (milligrams of protein per gram of liver tissue, $X \pm$ SE) of surviving root voles in different treatments (Table 1). Number of individuals in parentheses.

DISCUSSION

Significant changes in liver or kidney mass due to BBP in the forage were not seen in this study. Recent reports on the effects of plant secondary compounds indicate that increasing the concentration of BBP in the diet might have been expected to result in an enlarged liver to detoxify the secondary compounds and enlarged kidneys to process the resulting wastes (Jung and Batzli, 1981; Bergeron and Jodoin, 1982, 1984; Konarzewski and Diamond, 1994). In this study there might have been a hypertrophy of metabolically active tissue but a concomitant depletion of glycogen (Harju, 1996) and/or fat reserves may have resulted in apparently unchanged liver/kidney mass (Konarzewski and Diamond, 1994).

The lower microsomal protein content on low protein diets suggests that there was a protein deficiency in the liver that limited the capacity of the detoxification system on these diets (Figure 3). Inadequate protein in the diet has been reported to decrease significantly hepatic phase I detoxification activity in rats (Schwass and Finley, 1985; Sipes and Gandolfi, 1986). There was an increase in UDP-GT capacity when dietary protein content increased, suggesting

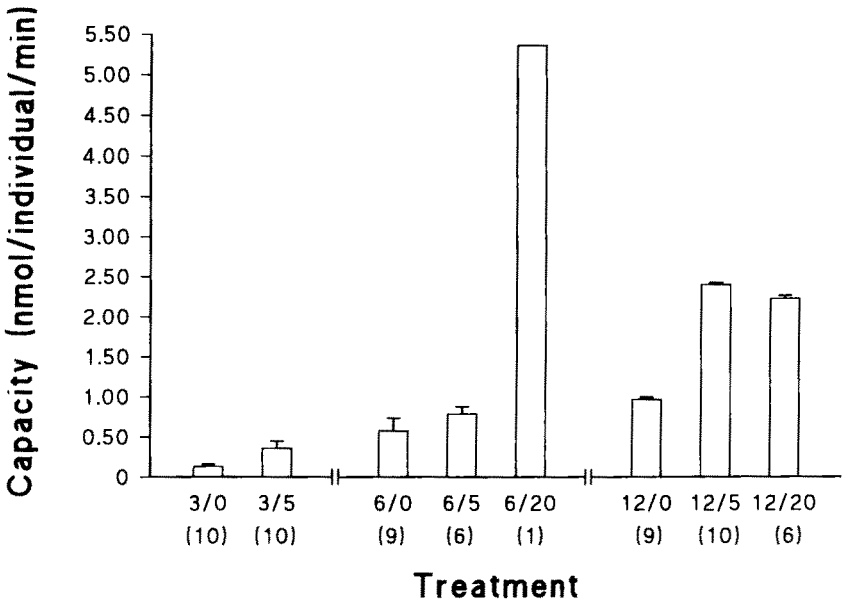

FIG. 3. Mean capacity of EROD (nanomoles of substrate hydrolyzed per individual per minute) of surviving root voles in different treatments (Table 1). Values expressed as mean ± SE. Number of individuals in parentheses.

that UDP-GT activity also would have been protein limited. Dietary BBP, on the other hand, had no significant effect. This is inconsistent with the results showing that glucuronidation activity may increase when availability of dietary protein decreases (Sell and Rogler, 1983) or when animals are exposed to secondary compounds (Siess et al., 1988). The dose of secondary compounds may have not been large enough in this study to induce the phase II reactions. Another alternative is that the compounds produced in phase I were conjugated with another endogenous substrate. Low doses of phenolics, for example, have been shown to conjugate with inorganic sulfate preferentially (Sipes and Gandolfi, 1986).

The detoxification enzymes are induced on the first encounter with xenobiotics such as plant secondary compounds (Harborne, 1991), increasing the capacity of the animal to handle these substances. In this study, a high concentration of BBP in the diet induced phase I detoxification capacity significantly, thus giving partial support to the first hypothesis. Low dietary protein seemed to limit the detoxification capacity, thus supporting the second hypothesis. Individuals capable of inducing detoxification enzymes seem to be less susceptible

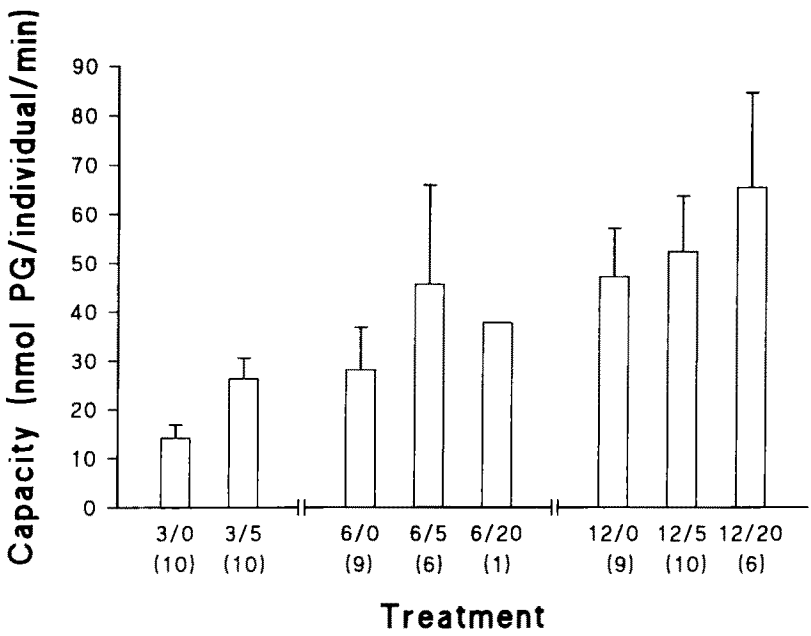

FIG. 4. Mean capacity of UDP-GT (nanomoles of substrate glucuronylated per individual per minute) of surviving root voles in different treatments (Table 1). Values expressed as mean ± SE. Number of individuals in parentheses.

to dietary poisoning (Brattsten et al., 1977). High dietary protein concentration together with induced detoxification enhanced the ability of voles to survive the exposure to BBP containing secondary compounds (see Harju, 1996).

Voles can compensate for a reduction in dietary protein by increasing their intake of food (Harju, 1996). This compensatory feeding causes an increase in consumed BBP (and secondary compounds therein), and thus increases physiological stress. At a certain ratio of protein/BBP concentration the detoxification capacity and physiological tolerance of voles seems to collapse, resulting in high mortality (Harju, 1996). This may happen in times of high population densities when woody plant material containing a low concentration of protein and high amounts of secondary compounds constitutes a high proportion of the diet of voles.

Acknowledgments—The author thanks Jorma Tahvanainen, Heikki Henttonen, Markku Keinänen, and two anonymous reviewers for critical reading of an earlier version of the manuscript and useful suggestions for improvements. This study was a part of the project "Herbivory and the Regulation of Secondary Metabolism of Deciduous Trees" and was supported by the University of Joensuu and the Academy of Finland.

(Received June 26, 1995; accepted December 3, 1995)

Abstract—*Oechalia schellenbergii* is one of the most common predatory insects in Australia and the islands of the South Pacific. Adult males of this predaceous "true bug" collected during March near Gatton, Queensland, Australia, had a pair of enlarged exocrine glands opening underneath their wings that presumably produce an attractant pheromone. The two major components of the secretion are 3-methylenehexyl acetate and 9-hydroxygeranyl diacetate [2,6-dimethyl-2(*E*),6(*E*)-octadien-1,8-diol diacetate].

Key Words—Predator, Hemiptera, Asopinae, stink bug, geraniol, diacetate.

INTRODUCTION

Augmentation of predaceous pentatomids (Pentatomidae: Asopinae) is a promising biological control tactic for vegetable crop pests (Biever and Chauvin,

*To whom correspondence should be addressed.

1992a,b; Hough-Goldstein and Keil, 1991), but large numbers of predators must be available to growers at reasonable cost for this approach to be a viable strategy (Hough-Goldstein and Whalen, 1993). Stink bugs that prey on many different insect species are the most common, wide-ranging asopines (McPherson, 1982). Moreover, these abundant predators are often exceptionally reliant on pheromones to congregate (Aldrich, 1988, 1995), perhaps because volatiles associated with specific prey are too varied to be reliable aggregating cues for generalist predators. The availability of synthetic pheromones for general predators offers a means of managing wild populations of these beneficial insects for improved biological pest control.

In Australia and New Zealand, *Oechalia schellenbergii* (Guérin-Méneville) is an important predator of several larval Lepidoptera (Awan, 1988) and Coleoptera (Edwards and Suckling, 1980). One of us (J. R. A.), while on sabbatical in Australia, had the opportunity to initiate a semiochemical investigation of *O. schellenbergii*. Here we report the identification of the suspected attractant pheromone blend of this general predator, including several compounds heretofore unknown as natural products.

METHODS AND MATERIALS

Laboratory Analysis. Some *Oechalia* adults were reared on locally collected caterpillars from eggs of a female collected in November 1990 at the Maroochy Horticultural Research Station, Nambour, Queensland. Other adult predators used for the study were collected in alfalfa fields near Gatton, Queensland, on March 19, 1991, and April 26, 1994, and were dissected within two days of being caught.

Dorsal abdominal glands were excised from CO_2-anesthetized bugs submerged in tap water, and macerated with forceps in ca. 150 μl of CH_2Cl_2 (glands from 6 and 7 males were pooled per sample). After standing at least overnight, the solution was dried with Na_2SO_4, and transferred to a clean vial prior to analysis. Most samples were analyzed on DB-5 and DB-1 (J&W Scientific, Folsom, California) columns (0.25 μm film, 30 m $\times$ 0.25 mm ID) in a Varian 3500 gas chromatograph (GC) with helium as carrier (50 cm/sec), a temperature program from 50°C for 2 min to 235°C at 15°/min, with a flame ionization detector, and recording data using the Varian GC Star Workstation (Sunnyvale, California) software on a Gateway 2000 386/25 computer (North Sioux City, South Dakota). The GC trace (Figure 1) excludes the solvent peak and normalizes peaks to the most abundant natural product. Electron impact-mass spectra (EI-MS) were obtained using a Hewlett Packard 5971 GC-MS instrument at 70 eV, with a HP-5 (Kennett Square, Pennsylvania) column (0.11 μm film; 25 m $\times$ 0.2 mm ID), programmed from 50°C for 2 min to 250°C at 15°/min.

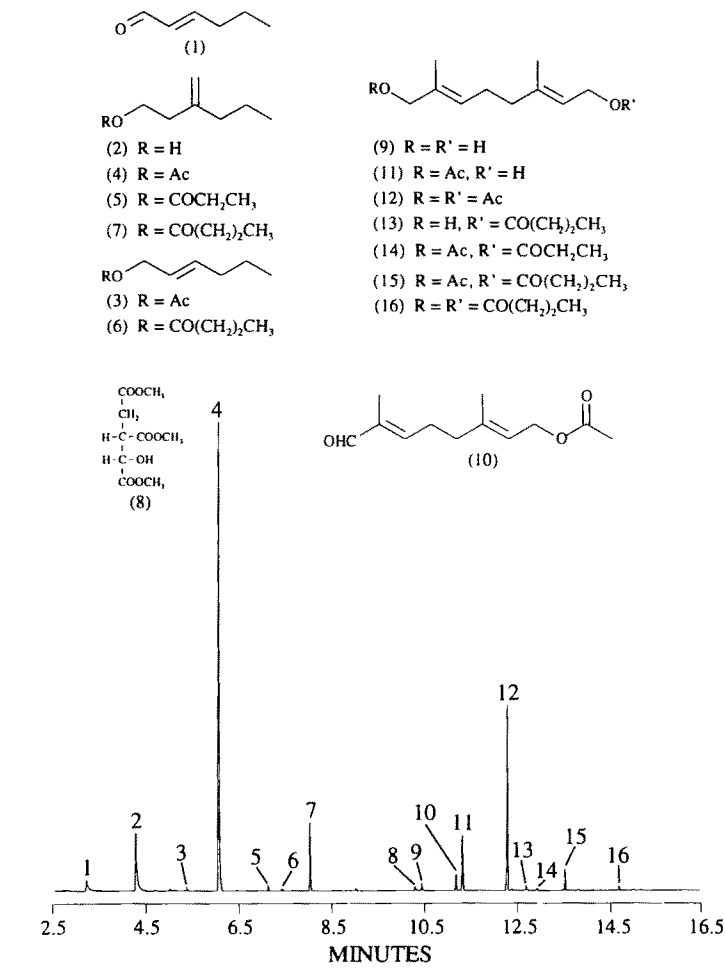

FIG. 1. Gas chromatogram of male *Oechalia schellenbergii* (Heteroptera: Pentatomidae) dorsal abdominal gland secretion.

Chemical ionization-mass spectra (CI-MS) were collected using a Finnigan 4510 GC-MS with an INCOS Data System, a 30-m DB-1 column programmed from 60°C for 2 min to 250°C at 5°/min, and either NH_3 or ND_3 as reagent gas. ^1H NMR spectra were recorded in $CDCl_3$ at 300 MHz on a General Electric QE-300 instrument with TMS as an internal standard. Assignments were made with the COSY technique.

Commercial and Synthetic Standards. All compounds reported in Figure 1, except for **5** and **14,** were verified by mass spectra and by coelution on 30-m DB-5 and/or 60-m DB-1 columns. 3-Methyl-1-hexanol was purchased from Narchem Corp. (Chicago, Illinois), and geranyl acetate was purchased from Givaudan Corp. (Clifton, New Jersey); other standards and reagents were obtained from either Bedoukian Research Inc. (Danbury, Connecticut) or Aldrich Chemical Company (Milwaukee, Wisconsin). The general scheme for preparation of the terpenoid synthetic standards is shown in Figure 2. Sodium borohydride reductions were conducted by adding the aldehyde to a suspension of $NaBH_4$ in absolute ethanol (approximately 0.5 mg $NaBH_4$/mg of aldehyde), stirring at room temperature 1 hr, carefully adding a few drops of acetic acid, and partitioning between pentane and water. Esterifications of primary alcohols were performed by allowing the alcohol to react with an acid chloride or anhydride at room temperature in the presence of pyridine (1–2 hr followed by partitioning into pentane). Saponifications were conducted by KOH in aqueous methanol at room temperature followed by dilution with water and partitioning. Selenium dioxide oxidations were performed as described by Hirata et al. (1981). The trimethylester of isocitric acid was prepared via diazomethane esterification of isocitric acid.

3-Methylenehexan-1-ol (2) and 3-Methylenehexyl Acetate (4). Standards of **2** and **4** were prepared by repeating an ene reaction between 2-methyl-1-pentene

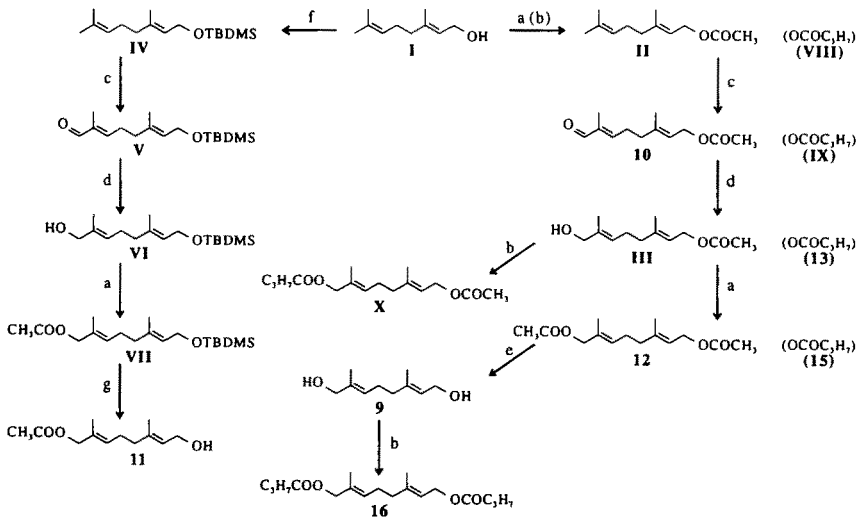

FIG. 2. Scheme for preparation of terpenoid synthetic standards.

and trioxane (Snider et al., 1982). A hexanes solution of dimethylaluminum chloride was used instead of the dichloromethane solution originally described. The three unsaturated alcohols constituted 97% of the products detected by GC (93% yield), and the major (55%), earliest eluting (DB-1 column) isomer was identical by GC coelution and mass spectrometry to the *Oechalia* C_7 alcohol (**2**); EI-MS [*m/z* (%)]: 96 (M − H_2O, 15%), 81 (100), 71 (12), 69 (25), 68 (20), 67 (27), 56 (40), 55 (53), 54 (16), 53 (13), 51 (6), 43 (14), 42 (15), 41 (55), 39 (30); CI-MS (NH_3) [*m/z* (%)]: 166 [M + $(NH_3)_3H$, 7%], 149 [M + $(NH_3)_2H$, 100], 132 (M + NH_4, 45); CI-MS (ND_3) [*m/z* (%)]: 177 [M + $(ND_3)_3D$ − H + D, 18], 157 [M + $(ND_3)_2D$ − H + D, 100], 137 (M + ND_4 − H + D, 25). Acetylation of a portion of the sample gave a mixture of acetates, of which the first eluting by GC (DB-1 column) was identical by retention time and mass spectrometry to **4** (3-methylenehexyl acetate); EI-MS [*m/z* (%)]: 96 (17%), 82 (4), 81 (57), 79 (4), 73 (3), 69 (6), 68 (60), 67 (21), 56 (3), 55 (10), 54 (9), 53 (6), 43 (100), 41 (14), 39 (12); CI-MS (NH_3) [*m/z* (%)]: 330 (2M + NH_4, 5%), 208 [M + $(NH_3)_3H$, 8], 191 [M + $(NH_3)_2H$, 100], 174 (M + NH_4, 57), 157 (M + H, 3). Flash chromatography of the mixture of acetates on silica gel followed by silver nitrate-impregnated silica gel (20% by weight $AgNO_3$) chromatography, eluting successively with 2, 4, and 6% ethyl acetate in cyclohexane, gave about 10 mg of pure **4** (the latest eluting of the three isomers) for ^{1}H NMR spectroscopy; ^{1}H NMR ($CDCl_3$): δ 0.91, t, J = 7.5 Hz, Me6; 1.46, m, two H5; 2.01, t, J = 7.5 Hz, two H4 (partially obscured by Ac Me); 2.04, s, Ac Me; 2.33, t, J = 6.9 Hz, two H2; 4.17, t, J = 6.9 Hz, two H1; 4.49, app. d, J = 10.2 Hz, two H7.

3-Methylenehexyl Propionate (5). EI-MS [*m/z* (%)]: 96 (23%), 82 (7), 81 (66), 79 (3), 69 (8), 68 (93), 67 (26), 57 (100), 55 (19), 54 (13), 53 (9), 43 (13), 41 (18), 39 (9).

3-Methylenehexyl Butyrate (7). Synthetic **7** was derived from **2** by treatment with butyryl chloride; EI-MS [*m/z* (%)]: 96 (24), 82 (5), 81 (73), 79 (3), 72 (3), 71 (60), 69 (8), 68 (100), 67 (20), 55 (20), 54 (9), 53 (5), 43 (49), 42 (6), 41 (27), 39 (13); CI-MS (NH_3) [*m/z* (%)]: 386 (2M + NH_4, 2%), 236 [M + $(NH_3)_3H$, 6], 219 [M + $(NH_3)_2H$, 100], 202 (M + NH_4, 58), 185 (M + H, 4).

2,6-Dimethyl-2(E),6(E)-octadien-1,8-diol (9-Hydroxygeraniol) (9), 8-Oxo-3,7-dimethyl-2(E),6(E)-octadienyl Acetate (10), 2,6-Dimethyl-2(E),6(E)-octadien-1,8-diol Diacetate (12), and 2,6-Dimethyl-2(E),6(E)-octadien-1,8-diol Dibutyrate (16). Geraniol (**I**) was converted to geranyl acetate (**II**), which was then oxidized using selenium dioxide in aqueous dioxane as described for linalool (Hirata et al., 1981), to give the previously known compound (Meinwald and Opheim, 1973), 8-oxo-3,7-dimethyl-2(*E*),6(*E*)-octadienyl acetate (**10**) (Figure 2); EI-MS [*m/z* (%)]: 150 (12%), 135 (9), 121 (10), 107 (5), 95 (3), 93 (6), 91 (3), 85 (16), 84 (40), 82 (9), 68 (4), 67 (8), 65 (3), 55 (11), 53 (7), 43

(100), 41 (12), 39 (10); CI-MS (NH_3) [*m/z* (%)]: 245 [M + $(NH_3)_2H$, 22%], 228 (M + NH_4, 100); ^1H NMR ($CDCl_3$): δ 1.75, broad s, two Me; 2.05, s, Ac Me; 2.24, t, J = 7.5 Hz, two H5; 2.51, dt (app. q), two H4; 4.60, d, J = 6.9 Hz, two H8; 5.39, tq, J = 6.9 and 2.4 Hz, H3; 6.45, tq, J = 6.9 and 2.4 Hz, H7 (H3 and H7 may be reversed); 9.39, s, CHO; literature (Meinwald and Opheim, 1973) (CCl_4): δ 1.75, s, 6H; 1.97, s, 3H; 2.35, m, 4H; 4.55, d, J = 7 Hz, 2H; 5.40, broad t, J = 7 Hz, 1H; 6.42, broad t, J = 6 Hz, 1H; 9.38, s, 1H.

Synthetic **10** was reduced with sodium borohydride to 8-hydroxy-3,7-dimethyl-2(*E*),6(*E*)-octadienyl acetate (**III**). Acetylation of **III** with acetic anhydride gave 2,6-dimethyl-2(*E*),6(*E*)-octadien-1,8-diol diacetate (**12**); EI-MS [*m/z* (%)]: 212 (0.2%), 195 (0.5), 152 (2), 135 (5), 134 (21), 127 (6), 126 (8), 119 (15), 107 (2), 105 (3), 93 (5), 92 (3), 91 (3), 85 (12), 84 (30), 79 (4), 68 (12), 67 (14), 55 (4), 53 (5), 43 (100), 41 (10), 39 (5); CI-MS (NH_3) [*m/z* (%)]: 526 (2M + NH_4, 8%), 289 [M + $(NH_3)_2H$, 15], 272 (M + NH_4, 100); ^1H NMR ($CDCl_3$): δ 1.66, s, Me9; 1.71, s, Me10; 2.06, s, Ac Me; 2.07, s, Ac Me; 4.45, s, two H1; 4.59, d, J = 7.2 Hz, two H8; 5.35, tq, J = 7.1 and 2.1, H7; 5.44, tq, J = 6.9 and 1.2, H3.

Saponification of **12** gave 9-hydroxygeraniol (**9**); EI-MS [*m/z* (%)]: 137 (6%), 134 (4), 121 (11), 119 (7), 115 (7), 109 (8), 107 (6), 95 (10), 94 (12), 93 (9), 84 (38), 83 (13), 81 (14), 71 (17), 69 (15), 68 (61), 67 (32), 57 (20), 55 (25), 53 (18), 43 (100), 41 (57), 39 (21); CI-MS (NH_3) [*m/z* (%)]: 205 [M + $(NH_3)_2H$, 8%], 188 (M + NH_4, 100), 170 (M + NH_4 − H_2O, 6); CI-MS (ND_3) [*m/z* (%)]: 214 [M + $(ND_3)_2D$ − 2H + 2D, 15%], 194 (M + ND_4 − 2H + 2D, 100).

Treatment of **9** with butyryl chloride gave 2,6-dimethyl-2(*E*),6(*E*)-octadien-1,8-diol dibutyrate (**16**), EI-MS [*m/z* (%)]: 155 (3), 154 (5), 135 (7), 134 (19), 119 (16), 107 (3), 106 (3), 93 (6), 92 (4), 84 (8), 79 (3), 71 (100), 68 (9), 67 (9), 55 (4), 53 (3), 43 (41), 41 (12); CI-MS (NH_3) [*m/z* (%)]: 345 (M + $(NH_3)_2H$, 2%], 328 (M + NH_4, 100).

*8-Hydroxy-2,6-dimethyl-2(*E*),6(*E*)-octadienyl Acetate (**11**), 2,6-Dimethyl-2(*E*),6(*E*)-octadien-1,8-diol 1-Butyrate (9-Hydroxygeranyl Butyrate) (**13**), and 2,6-Dimethyl-2(*E*),6(*E*)-octadien-1,8-diol 1-Acetate 8-Butyrate (**15**).* 8-Hydroxy-2,6-dimethyl-2(*E*),6(*E*)-octadienyl acetate (**11**) was prepared from the *t*-butyldimethylsilyl ether of geraniol (**IV**) by a parallel series of reactions consisting of sequential selenium dioxide oxidation (**V**), sodium borohydride reduction (**VI**), esterification with acetic anhydride (**VII**), and desilylation with 1 M tetrabutylammonium fluoride in THF for 1 hr at room temperature; EI-MS of **11** [*m/z* (%)]: 152 (1%), 137 (2), 134 (8), 123 (2), 121 (40), 119 (6), 109 (3), 107 (2), 94 (5), 93 (6), 85 (8), 84 (33), 79 (5), 69 (6), 68 (36), 67 (19), 57 (4), 55 (8), 53 (6), 43 (100), 41 (18), 39 (8); CI-MS (NH_3) [*m/z* (%)]: 247 [M

+ $(NH_3)_2H$, 9%], 230 (M + NH_4, 100); CI-MS (ND_3) [*m/z* (%)]: 255 [M + $(ND_3)_2D$ − H + D, 15%], 235 (M + ND_4 − H + D, 100).

Selenium dioxide oxidation of geranyl butyrate (**VIII**) by the procedure used to prepare **10** (Hirata et al., 1981) gave the 8-butyrate of 8-hydroxy-2,6-dimethyl-2(*E*),6(*E*)-octadienal (**IX**). Sodium borohydride reduction gave 9-hydroxygeranyl butyrate (**13**); EI-MS [*m/z* (%)]: 154 (2%), 152 (2), 137 (4), 135 (3), 134 (14), 123 (4), 121 (9), 119 (10), 109 (4), 107 (4), 95 (8), 94 (11), 93 (10), 84 (44), 81 (7), 79 (8), 71 (100), 69 (11), 68 (52), 67 (22), 57 (6), 55 (11), 53 (7), 43 (84), 41 (31), 39 (10); CI-MS (NH_3) [*m/z* (%)]: 275 [M + $(NH_3)_2H$, 6%], 258 (M + NH_4, 100); (ND_4) *m/z* 283 [M + $(ND_3)_2D$ − H + D, 8%], 263 (M + ND_4 − H + D, 100).

*2,6-Dimethyl-2(E),6(E)-octadien-1,8-diol 1-Acetate 8-Propionate (**14**).* EI-MS [*m/z* (%)]: 209 (0.6%), 152 (2), 141 (3), 140 (5), 135 (7), 134 (25), 127 (4), 126 (5), 119 (20), 105 (4), 93 (5), 92 (2), 85 (10), 84 (28), 81 (2), 69 (11), 67 (15), 57 (100), 55 (5), 53 (6), 43 (72), 41 (8), 39 (5); CI-MS (NH_3) [*m/z* (%)]: 303 [M + $(NH_3)_2H$, 3%], 286 (M + NH_4, 100).

Acetylation of **13** gave 2,6-dimethyl-2(*E*),6(*E*)-octadien-1,8-diol 1-acetate 8-butyrate (**15**); EI-MS [*m/z* (%)]: 223 (0.5%), 195 (0.3), 155 (2), 154 (3), 152 (2), 135 (7), 134 (25), 127 (4), 126 (5), 121 (3), 119 (20), 107 (3), 105 (4), 93 (7), 92 (4), 85 (7), 84 (22), 79 (4), 71 (84), 68 (13), 67 (14), 55 (5), 53 (5), 43 (100), 41 (16), 39 (5); CI-MS (NH_3) [*m/z* (%)]: 317 [M + $(NH_3)_2H$, 3%], 300 (M + NH_4, 100).

RESULTS AND DISCUSSION

Oechalia adults reared from eggs of the female collected in November at the Maroochy Horticultural Research Station, Nambour, Queensland, did not exhibit sexually dimorphic dorsal abdominal glands after two to three weeks in captivity and, similarly, the glands of males collected April 26, 1994, in alfalfa fields near Gatton, Queensland, were not noticeably larger than those of females. However, the dorsal abdominal glands of *O. schellenbergii* males collected March 19, 1991, in alfalfa at the Gatton site were roughly 50 times larger than those of females. Two 150-μl dichloromethane extracts of the enlarged glands from groups of six and seven of these wild adult males provided sufficient material for characterization of the secretion.

Sixteen components were identified and account for 96% of the total detectable components eluting from the column. Mass spectral data for components **1, 3,** and **6** indicated that these compounds were identical to previously known, common exocrine constituents from Heteroptera (Aldrich, 1988), and comparisons to authentic standards verified these structures as (*E*)-2-hexenal, (*E*)-2-

hexenyl acetate, and (*E*)-2-hexenyl butyrate, respectively. The mass spectrum of minor component **8** matched that of the trimethylester of isocitric acid, and coeluted with the synthetic compound. The mass spectra of the remaining components of the secretion were not identical to available published spectra (Hewlett-Packard MS library). CI-MS (NH_3 and ND_3 CI-MS) established that **2, 8, 11,** and **13** possess one exchangeable proton each, **9** contains two exchangeable protons, while the remaining numbered components lack exchangeable protons.

Compound **2** (MW 114) appeared to be an unsaturated alcohol, but eluted prior to (*E*)-2-heptenol, suggesting that **2** is a branched, monounsaturated alcohol. The CI-MS of **4** indicated MW 156, while in the EI-MS there was a base peak at *m/z* 43 plus prominent ions at *m/z* 81 and 96, which were the same as those of **2,** suggesting that **4** may be the acetate ester of **2.** Hydrogenation of a portion of the insect secretion and comparison of the EI-MS of the saturated product of **2** with published spectra of various C-7 alcohols (Baumeister et al., 1991) suggested that it was a primary alcohol with a methyl branch at either the 2 or 3 position. Branching at the 2 position was eliminated as a possible structure feature because comparison of the MS of saturated **2** to the MS of 2-methyl-1-hexanol prepared from 2-methyl-2-(*E*)-hexenoic acid showed they were different. However, a commercial standard of 3-methyl-1-hexanol coeluted with and gave a mass spectrum identical to that of saturated **2.** Likewise, the hydrogenation product of **4** coeluted with and gave a spectrum that was identical to the EI-MS of synthetic 3-methylhexyl acetate.

The position of unsaturation in **2** and **4** was determined by synthesis and NMR analysis of synthetic **4** (see above); synthetic **2** and **4** were identical to the insect-produced materials by mass spectrometry, and coeluted by GC with the respective insect-derived materials. Treatment of **2** with butyryl chloride gave synthetic **7,** which was identical to insect-derived **7.** We infer that **5** is the corresponding propionate, 3-methylenehexyl propionate.

The CI-MS of **12** indicated a MW of 254, and the EI-MS exhibited an exceptionally abundant base peak at *m/z* 43. The greater abundance of the *m/z* 43 ion in the EI-MS of **12** relative to that for **4** suggested the possibility of a diacetate ester of a $C_{10}H_{18}O_2$ diol. This possibility was strengthened by the observation that the EI-MS of **14** and **15** showed less abundant *m/z* 43 ions with the addition of ions at *m/z* 57 and 71, respectively, suggesting that **14** and **15** (MW = 268 and 282, respectively) could be monopropionate and monobutyrate (or monoisobutyrate) homologs of **12.** Earlier discovery of 8-hydroxylinalool from an exocrine secretion of another true bug (Aldrich et al., 1990) raised the prospect that **12** could be the diacetate of 8-hydroxylinalool. Synthetic 8-hydroxylinalyl diacetate [prepared from an earlier diol sample (Aldrich et al., 1990)] eluted before **12** by GC, but the similarity of its EI-MS to that of **12** prompted us to prepare the corresponding diacetate derived from geraniol.

Geranyl acetate was oxidized with SeO_2 to give 8-oxo-3,7-dimethyl-2(*E*),6(*E*)-octadienyl acetate, which proved identical to insect-derived **10.** Synthetic **10** was reduced with sodium borohydride to 8-hydroxy-3,7-dimethyl-2(*E*),6(*E*)-octadienyl acetate (**III**), whose mass spectrum and GC retention time were very similar, but not identical, to those of the insect material (**11**). Acetylation of **III** gave diacetate **12,** which was indistinguishable from the insect-derived **12,** and saponification gave a diol whose properties were identical to those of insect-derived **9.** Treatment of **9** with butyryl chloride gave dibutyrate **16.** These conclusions suggested that the correct monoacetate should be the geranyl diol acetylated at the opposite terminus. Consistent with this conclusion, **11** was synthesized (see above) and was found to be identical to the insect-produced material.

Similarly, treatment of monoacetate **III** with butyryl chloride gave monoacetate, monobutyrate **X** whose retention times and mass spectra were very similar, but not identical, to those of the natural monoacetate, monobutyrate, indicating **15** as the correct isomer. Selenium dioxide oxidation of geranyl butyrate gave the 8-butyrate of 8-hydroxy-2,6-dimethyl-2(*E*),6(*E*)-octadienal (**IX**). Sodium borohydride reduction gave monobutyrate **13,** identical to insect-derived material, and acetylation gave the monoacetate, monobutyrate **15,** which was identical to insect-derived **15.** By analogy, we infer that the insect-produced monoacetate, monopropionate isomer is 2,6-dimethyl-2(*E*),6(*E*)-octadien-1,8-diol 1-acetate 8-propionate (**14**).

In summary, adult *Oechalia schellenbergii* males have dorsal abdominal glands that are much larger than those of females, at least during part of their life cycle, and these glands are homologous to those of other predatory bugs whose male-specific secretions have proven to be attractant pheromones (Aldrich, 1988, 1995). Thus, it is likely that the secretion from the enlarged glands of *Oechalia* males also serves as a pheromone.

Acknowledgments—We thank Ms. Dawn Harrison for chemical ionization mass spectrometry, Ms. Sini Panicker for assistance with syntheses, Ms. Jennifer Graf for help with chemical analyses, and Dr. Dennis Voden for assistance with nomenclature. Mention of a commercial product does not necessarily constitute endorsement by the U.S. Department of Agriculture.

(Received May 30, 1995; accepted December 4, 1995)

Abstract—Using electron impact and chemical ionization mass spectrometry with methane and nitric oxide as reactant gases in conjunction with mass spectral analysis of the dimethyl disulfide derivatives of unsaturated constituents, 51 compounds have been identified in addition to the compounds previously found in the preorbital secretion of the grysbok *Raphicerus melanotis*. The compounds identified are saturated, monounsaturated, and diunsaturated alcohols and formates, saturated and monounsaturated aldehydes, saturated carboxylic acids, γ- and δ-lactones, alkyl methyl sulfides, and β-hydroxyalkyl acetates. All of these compounds have unbranched structures. The constituent previously incorrectly identified as (Z)-5-tetradecen-1-ol, was found to consist of the coeluting (Z)-7- and (Z)-8-tetradecenols.

Key Words—*Raphicerus melanotis*, mammalian semiochemicals, mammalian pheromones, exocrine secretion, preorbital secretion, double bond localization, mass spectrometry.

INTRODUCTION

The Cape grysbok, *Raphicerus melanotis*, is a small, squat antelope characterized by rufous brown upperparts abundantly flecked with white hairs and underparts with a lighter brown color. The incidence of white hairs diminishes down the sides and legs. The tail is short and the grey–brown ears are proportionately large with white hairs on the inside. The average shoulder height is about 54 cm and the average mass is about 10 kg. Only rams have short, smooth, slightly

back-angled horns with an average length of about 8 cm (Stuart and Stuart, 1990). The rufous brown upperparts flecked with white distinguish it from the steenbok, as do the brown underparts. The Cape grysbok is similar to Sharp's grysbok, *Raphicerus sharpei*, in appearance, but their distribution ranges do not overlap (Stuart and Stuart, 1990).

The distribution of the grysbok is restricted to a narrow belt along the southwestern and southern Cape coast and adjacent interior of South Africa. An inhabitant of relatively thick scrub–bush, it is almost entirely restricted to the "fynbos" vegetation of the Cape. It is mainly a nocturnal animal but is active in the early morning and late afternoon if not disturbed, or on overcast and cool days. Grysbok are usually single except when mating or when ewes are tending lambs. Although lambs may be dropped at any time of the year, most are born from September to December. A single lamb is born after a gestation period of approximately 180 days. The grysbok is considered to be a nuisance in vineyards as it grazes on the young grapes and terminal buds.

The grysbok belongs to the order Artiodactyla, the family Bovidae and the subfamily Antilopinae. Members of this subfamily, also known as dwarf antelope, vary considerably in appearance and habitat. The pygmy antelope, *Neotragus batesi*, for instance, inhabits the dense forests of Central Africa, whereas the oribi, *Ourebia ourebi*, is found on open grass plains near water. The klipspringer, *Oreotragus oreotragus*, prefers mountainous territory and the dik-dik, *Madoqua kirkii*, is found in arid bushveld regions. The only similarities between members of this subfamily are their size and their well-developed exocrine glands, especially the preorbital glands, which are used for territorial marking (Macdonald, 1984). Territoriality is important to these animals as it is essential for them to have the necessary knowledge regarding food supplies in their environment and to eliminate any competition with regard to their food supply. Feeding is an important factor because their metabolic processes are rapid as a result of their small body size. Consequently, in relation to their body size, they need more nutritious food than larger animals (Macdonald, 1984). As the grysbok is found in areas with dense vegetation, olfactory communication is expected to be an important means of communication. Both sexes possess active preorbital glands, the secretions of which consist of a black aqueous emulsion of organic compounds. Grysbok rams are solitary and territorial and mark territories with the preorbital secretion (Novellie et al., 1984). Although no qualitative and only small, probably insignificant, differences were found between the male and female secretions (Le Roux, 1980), marking activity is only rarely observed in females.

In a previous study (Le Roux, 1980; Burger et al., 1981a) 34 of the constituents of the preorbital secretion of the grysbok were identified. Due to the uninformative mass spectra of long-chain, unbranched compounds, only a limited number of these constituents were identified solely by means of mass spec-

trometry. Some of the major representative constituents were therefore isolated for NMR analysis using preparative gas chromatography. This entailed the collection of 1000 gland equivalents of the secretion from five animals over many months. In spite of an enormous investment in time, only 18 constituents of the secretion were isolated in sufficient quantities for ^{1}H NMR analysis. Of five of these constituents ^{13}C NMR spectra could be obtained. The position of the double bonds in some of these compounds was determined by microozonolysis. The *Z* configuration was assigned to unsaturated compounds on the available ^{1}H and ^{13}C NMR data.

The availability of more efficient capillary columns, and new methods for the determination of the position of double bonds in long-chain compounds, led to the decision to reinvestigate the preorbital secretion of the grysbok. In this communication we report the confirmation of the structures of 27 of the compounds identified in the previous investigation and the identification of another 51 constituents of the secretion.

METHODS AND MATERIALS

General. All Pyrex glassware used in the handling of biological material and extracts, as well as in the preparation of reference compounds, was heated to 500°C in an annealing oven to remove any traces of organic material. Dichloromethane (Merck, Residue Analysis Grade) was analyzed gas chromatographically and found to be pure enough for extraction purposes when used in small quantities. Syringes, stainless-steel needles, etc., were cleaned by rinsing with this solvent.

Analytical Methods. Gas chromatographic (GC) analyses were carried out with Carlo Erba 4200 and 5300 gas chromatographs equipped with flame ionization detectors, Grob split-splitless injectors, and glass columns coated by the Laboratory for Ecological Chemistry with a 0.25-mm film of the apolar stationary phases, PS-089-OH, a silanol-terminated, 95%-dimethyl–5%-diphenylsiloxane copolymer, and OV-1701-OH. Helium was used as carrier gas at a linear velocity of 28.6 cm/sec at 40°C. The flame ionization detector was operated at 280°C and the injector was normally used at 220°C. In analyses of material dissolved in dichloromethane, the samples were injected in the split mode, and the volatiles entering the column were thermally focused at ca. 30°C, and subsequently analyzed using a temperature program of 2°C/min from 40°C to 260°C (hold). In analyses in which solventless sample introduction was used, cryotrapping with Dry Ice was employed. Quantification was done with Barspec software and a 386 personal computer.

Electron impact (EI) mass spectra were recorded at 70 eV on a Carlo Erba QMD 1000 gas chromatograph–mass spectrometer (GC-MS system), using the

columns and conditions described above. The QMD 1000 consists of a Carlo Erba 5300 gas chromatograph with a line-of-sight interface to a VG Analytical Trio 1 quadrupole mass spectrometer. An interface temperature of 250°C was used. The ion source temperature was set at 200°C and the pressure in the source housing was ca. 2×10^{-5} torr at a column temperature of 40°C, decreasing to ca. 1×10^{-5} torr towards the end of the temperature program.

Chemical ionization (CI) mass spectra were obtained with methane and nitric oxide as reactant gases. With methane as reactant gas, spectra were recorded at 75 eV and a source temperature of 150°C. The flow of methane into the ion volume of the source was regulated with a fine metering valve to obtain equally abundant *m/z* 17 and 29 plasma ions. With NO as reactant gas, an iridium filament coated with thorium oxide was used. Spectra were recorded at 75 eV and a source temperature of ca. 80°C. The source pressure was adjusted to obtain a maximum abundance of the *m/z* 60 plasma ion. With isobutane as reactant gas, optimal tuning was reached by adjusting the source pressure to produce the *m/z* 39, 43, and 57 plasma ions in a ratio of 1:4:6. All three reactant gases required a source housing pressure of ca. 8×10^{-5} torr for optimal tuning.

Sample Collection and Preparation. Preorbital secretion was collected with a tubular PTFE scoop from animals kept in pens (10 × 10 m) at the Tygerberg Zoo. The scoop, with an inside diameter of 5 mm, was furnished with a PTFE plunger with which the collected material could be ejected into a 300-μl or 1-ml Reacti-Vial.

The organic volatiles were extracted from the secretion by stirring collected material with dichloromethane (ca. 100 μl) using a thin (0.5 mm) glass rod to produce a homogeneous suspension that was centrifuged at 2000–3000 rpm for about 15 min to separate solid material, the dichloromethane extract, and a small quantity of water and mucus. The dichloromethane extract was removed from underneath the supernatant water and mucus layer with a 100-μl syringe, transferred to a Reacti-Vial, and stored at −30°C. Most extracts could be used without subsequent evaporation of the solvent. If more concentrated solutions were required, the solvent was removed in a slow stream of purified (activated charcoal) nitrogen.

Dimethyl disulfide (DMDS) derivatization of the organic material extracted from the secretion was carried out according to the method described by Vincenti et al. (1987). A 10-μl aliquot of a dichloromethane extract of the preorbital secretion was concentrated in a 1-ml Reacti-Vial using a slow stream of purified nitrogen, the residual material dissolved in dimethyl disulfide (50 μl), and treated with a solution of iodine (300 μg) in carbon disulfide (50 μl). The Reacti-Vial was sealed using a PTFE-faced rubber septum and the reaction mixture left at 60°C for 40 hr in the oven of a gas chromatograph. The reaction was quenched with aqueous sodium thiosulfate solution (5%). The organic and aqueous layers

were separated by centrifuging for a few minutes at 2000 rpm after which the organic layer was transferred to another Reacti-Vial. The solution was concentrated to 5 μl for GC-MS analysis.

Reference Compounds. Some of the compounds identified in the preorbital secretion of the grysbok are commercially available, while others were available from previous research projects in this series. The following compounds were synthesized during the present investigation.

Heptadecanyl formate was synthesized by the uncatalyzed reaction of 1-heptadecanol (50 mg) with an excess of absolute formic acid (100 μl). The reaction mixture was heated overnight at 80°C in a Reacti-Vial, after which the excess formic acid was removed in vacuo to give pure (GC) heptadecan-1-yl formate. ^{13}C: δ ($CDCl_3$) 161.18 (s, C-1'), 64.14 (t, C-1), 31.95 (t, C-15), 29.21–29.71 (11C, t, C-4–C-14), 28.54 (t, C-2), 25.84 (t, C-3), 22.71 (t, C-16), 14.12 (q, C-17).

Octadecan-4-olide was synthesized by the Mn(III) acetate-catalyzed free radical coupling of hexadec-1-ene and acetic acid (Heiba et al., 1983). $KMnO_4$ (1.09 g; 7 mmol) was added to a stirred solution of Mn(II) acetate (7.07 g; 29 mmol) in acetic acid (40 ml). After an initial increase in the temperature, the reaction mixture was allowed to cool to 90°C. The temperature increased on slow addition of acetic anhydride (10 ml) and the reaction mixture was again allowed to cool to 90°C, after which hexadec-1-ene (5.01 g; 23 mmol) was added to the mixture. This was immediately followed by the addition of anhydrous sodium acetate (16.7 g, 204 mmol). The reaction mixture was refluxed for 2 hr, diluted with a large volume of water (120 ml), the γ-lactone extracted with benzene, and the extract dried on anhydrous Na_2SO_4. Removal of the solvent and bulb-to-bulb distillation gave the pure (GC) octadecan-4-olide (4.95 g, 78%), bp 235°C/0.015 torr (air bath temperature). ^{13}C: δ ($CDCl_3$) 177.24 (s, C-1), 81.06 (d, C-4), 35.64 (t, C-2), 31.97 (t, C-16), 29.40–29.74 (10C, t, C-6–C-15), 28.04 (t, C-3), 25.27 (t, C-5), 22.72 (t, C-17), 14.12 (q, C-18).

Hexadecan-5-olide was synthesized by oxymercuration of tridec-1-ene, followed by free radical coupling of the product with acrylonitrile, and hydrolysis of the resulting 5-hydroxyhexadecane-1-nitrile according to the method of Giese et al. (1984). Mercury(II) acetate (4.35 g; 13.6 mmol) and tridec-1-ene (2.49 g; 13.6 mmol) were added to a solution of THF (35 ml) in water (15 ml), and the reaction mixture was stirred for 1 hr. Acrylonitrile (2.16 g; 40.7 mmol), sodium hydroxide solution (2 M, 15 ml), and sodium borohydride (1.03 g; 27.2 mmol) dissolved in sodium hydroxide solution (2 M, 55 ml) were added to the reaction mixture, which was stirred for a further 30 min. The organic material was extracted with dichloromethane. Removal of the solvent gave the crude hydroxynitrile, which was saponified by refluxing it with sodium hydroxide (2 M, 40 ml) for 4 hr. Unsaponified material was extracted with ether, after which the water layer was acidified with sulfuric acid (2 M) and the δ-lactone extracted

with ether, the ether extract dried on anhydrous Na_2SO_4, and the solvent removed in vacuo. Bulb-to-bulb distillation gave the required hexadecan-5-olide (2.36 g, 68%), bp 175°C/0.02 torr (air bath temperature). ^{13}C: δ ($CDCl_3$) 171.97(s, C-1), 80.61(d, C-5), 35.88(t, C-2), 31.94(t, C-14), 29.37–29.69(8C, t, C-6–C-13), 27.83(t, C-4), 24.96(t, C-6), 22.70(t, C-15), 18.53(t, C-3), 14.11(q, C-16).

RESULTS AND DISCUSSION

A typical total ion chromatogram of an extract of the preorbital secretion is shown in Figure 1. Tentative identification of a number of the volatile organic constituents was based on a comparison of their mass spectra with those in NBS and Wiley mass spectra libraries. Further structural information on many of the volatile constituents of the secretion was furnished by their chemical ionization mass spectra obtained with methane and nitric oxide as reactant gases. Information on the position of the double bond(s) in some of the unsaturated constituents was obtained from their CI(NO) mass spectra (Malosse and Einhorn, 1990) and the EI mass spectra of their dimethyl disulfide derivatives (Buser et al., 1983; Carlson et al., 1989; Vincenti et al., 1987).

The most salient aspects of the identification of most of the compound types present in preorbital secretions based on their EI, CI(CH_4) and CI(NO) spectra have been discussed in considerable detail in the previous communication in this series (Mo et al., 1995) and will not be repeated here. However, since mass spectral information on long-chain compounds is not readily available, the relevant information for some of the constituents identified in the secretion, is given in Tables 1 to 6. The diagnostic ions in the EI mass spectra of the DMDS derivatives of the mono- and diunsaturated compounds that were used to determine the position of the double bonds in these compounds, are summarized in Tables 7 and 8.

In contrast to the preorbital secretion of the oribi, which contains compounds having a finite chain length (Mo et al., 1995), the preorbital secretion of the grysbok appears to contain large concentrations of compounds having chain lengths beyond those identified in the present investigation. These compounds have very low vapor pressures and, if the frequency of territorial marking in the grysbok is taken into account, it seems unlikely that these long-chain compounds could be essential ingredients of the territorial marking pheromone of the animal. They may, however, constitute a controlled-release medium for the more volatile constituents of the secretion. A consequence of the presence of these long-chain compounds in the secretion is that capillary columns coated with highly polar and thermally less stable stationary phases such as Carbowax,

could not be employed in GC and GC-MS analyses, as these phases cannot survive repeated high-temperature conditioning. Limited use was made of capillary columns coated with OV-1701-OH, but the apolar PS-089-OH column produced the best results, although some of the isomeric alkenols were found to coelute from this column. Fortunately the DMDS derivatives of these compounds were separated on the apolar column and could therefore be unequivocally identified.

Probably because it has a relatively large ion volume, the CI ion source of the QMD 1000 mass spectrometer gives poor CI spectra with a build-up of the baseline towards the end of the total ion chromatogram. It was nevertheless possible to obtain useful information from the CI(CH_4) spectra of some of the more volatile constituents of the secretion. The use of NO as CI reactant gas deserves mention. The CI(NO) mass spectra furnish information from which the molecular mass of a compound, in many cases the compound type, and the position of the double bond in monounsaturated compounds can be derived (Hunt et al., 1982). Due to the previously noted problems with the CI source, ions furnishing information on the position of the double bond in unsaturated compounds could be detected only in the spectra of compounds that were present in relatively high concentrations and/or were well separated from the other constituents of the secretion. The results obtained in these analyses nevertheless illustrated the potential of NO as CI reactant gas.

Only two saturated and one unsaturated aldehyde are present in low concentrations in the preorbital secretion of the grysbok, whereas the oribi's secretion contains several saturated, monounsaturated, and diunsaturated aldehydes. The possibility was considered that this difference could be the result of autoxidation of the aldehydes taking place much more readily in the open preorbital cavity of the grysbok than in the deeper preorbital structure of the oribi. However, since neither the secretion of the oribi nor that of the grysbok contains detectable amounts of carboxylic acids and aldehydes having the same chain lengths, this does not seem to be a tenable hypothesis.

The EI mass spectra of components 43, 52, 61, 69, and 81 all have a base peak of high relative abundance at m/z 85. These compounds were identified as pentadecan-4-olide, hexadecan-4-olide, heptadecan-4-olide, octadecan-4-olide, and icosan-4-olide, respectively using, among others, data obtained from their CI mass spectra.

In addition to these compounds having a base peak at m/z 85 in their EI mass spectra, the preorbital secretion contains component 54 with an equally abundant base peak at m/z 99 in its EI mass spectrum. Taking the unbranched structures of the other constituents of the preorbital secretion into consideration, the possibility that this component could be an alkan-5-olide or δ-lactone, was considered. The molecular ion is not observed in its EI mass spectrum, but the CI(CH_4) mass spectrum affords conclusive evidence that the compound has a

molecular mass of 254. The pair of peaks at *m/z* 70 and 71, possibly formed by the loss of, respectively, CHO and CO from the ion at *m/z* 99, are typical for δ-lactones of this type. Final confirmation that this component is hexadecan-5-olide was furnished by retention-time comparison with an authentic synthetic sample of the compound.

The preorbital secretion of the grysbok contains two constituents, 57 and 73, each having ions at *m/z* 48, 61, 75, and 103 in the lower mass range and two ions of high abundance differing by 15 mass units in the high mass range of their EI mass spectra. Information afforded by the CI(CH_4) mass spectra of the two compounds indicates that the ions at *m/z* 286 and 314 in their EI mass spectra are their respective molecular ions. Properties such as the molecular mass of the compounds, the facile loss of a methyl radical, the stability of the molecular ions, etc., suggest these compounds to be alkyl methyl sulfides. Taking component 57 as an example, the formation of some of the sulfur-containing ions in its spectrum can be formulated as shown in Scheme 1.

Components 57 and 73 were identified as heptadecyl methyl and methyl nonadecyl sulfides, respectively. It is interesting that reasonably abundant M^+, $(M-H)^+$, $(M-2H)^+$, $(M-3H)^+$, and $(M-SCH_3)^+$ ions are present in the CI(CH_4) spectra of both compounds. The $(M-SCH_3)^+$ ions, present in these mass spectra, are not observed in their EI spectra, possibly because the resulting primary carbocations undergo rapid fragmentation under EI conditions.

In certain respects the EI mass spectra of components 75 and 84 are similar to those of several hydroxyesters present in the dorsal secretion of the springbok, *Antidorcas marsupialis* (Le Roux, 1980; Burger et al., 1981b), and the interdigital secretion of the bontebok, *Damaliscus dorcas dorcas* (Nell, 1992). The hypothesis that these two components could possibly be similar hydroxyesters is supported by their EI and CI(CH_4) mass spectra. The high-resolution EI spectra of the hydroxyesters found in the dorsal secretion of the springbok (Le Roux, 1980) provided evidence supporting the formation of some of the diagnostically significant ions in the mass spectrum of, for example, 2-hydroxyicosan-1-yl acetate 84 (Figure 2) as shown in Scheme 2.

It is clear that the hydroxy group cannot be present in either the carboxyl function of the molecule or on the α-carbon atom of the alcohol residue of the molecule. Its presence on the β-carbon atom is confirmed by the ion at *m/z* 103. The formation of the prominent ion at *m/z* 74 in its mass spectrum can be rationalized in terms of the expulsion of a molecule of formaldehyde, followed by a McLafferty rearrangement (Scheme 3).

It can be accepted that the ions at *m/z* 357 and 355 in the CI(CH_4) mass spectrum of this compound (Figure 3) are generated by M+H and M−H processes, respectively, and that the ions at *m/z* 297 and 295 are formed by the expulsion of acetic acid from these respective ions. The unbranched structure

of the alcohol residue of the molecule was confirmed by coinjection of an extract of the secretion with a synthetic sample of 2-hydroxyicosan-1-yl acetate synthesized in an Al_2O_3-catalyzed reaction of 1,2-epoxyicosane and acetic acid (Greyling, 1992). Component 75 was identified along similar lines as 2-hydroxyoctadecan-1-yl acetate.

Six γ-lactones, a δ-lactone, and the two hydroxyesters are the only chiral compounds identified in the preorbital secretion of the grysbok. The structure of the preorbital cavity is not so favorable for the survival of bacteria as that of the interdigital cavity of the bontebok and blesbok, but several bacteria, e.g., *Escherichia coli*, have been identified in the preorbital secretion of the grysbok (Ruppel, 1984). Lactones were found to be produced by the bacteria in the interdigital cavity in the bontebok and blesbok (Nell, 1992), and it is therefore possible that similar processes could be responsible for the presence of some of the constituents of the preorbital secretion of the grysbok. Regardless of whether these chiral constituents are synthesized in the gland or by bacteria, they are expected to be optically active. The determination of the absolute configuration of these compounds was not undertaken in the present study, however.

The double bonds in all of the unsaturated constituents of the secretion were assumed to possess *Z* configuration. In a previous study (Le Roux, 1980) representative examples of the various unsaturated compound types were isolated in quantities large enough to allow the recording of their ^{13}C NMR spectra. The presence in these spectra of a resonance at ca. 27.2 ppm, which can be ascribed to the allylic carbon atoms, was taken as unambiguous evidence that the double bonds in these compounds have the *Z* configuration, as the resonance of allylic carbon atoms in compounds with *E* configuration appears at ca. 32.5 ppm (Breit-

maier et al., 1979; Wenkert et al., 1976). Careful comparison of retention times and of retention time increments confirmed this assumption. In this regard it is noteworthy that in the chemical characterization of the preorbital secretion of the oribi, *Ourebia ourebi*, in which more reference compounds were available, all the unsaturated constituents were found to possess the *Z* configuration (Mo et al., 1995). Both the oribi and the grysbok belong to the tribe Neotragini.

The compounds identified in the preorbital secretion of the grysbok are listed in Table 9, together with compounds identified in the previous study (Le Roux, 1980; Burger et al., 1981a) and information on the analytical methods employed.

Unfortunately, a number of compounds still remained unidentified, mainly due to the lack of structurally significant information in their mass spectra and to the poor quality of the CI total ion current chromatogram. As the whole secretion was subjected to DMDS derivatization for the determination of the position of double bonds in the unsaturated constituents, the DMDS derivatives of the minor constituents could in some cases not be found in the total ion current chromatogram of the derivatized material, probably because the derivatives coeluted with certain constituents of the secretion. The unidentified constituents are also listed in Table 9 with mass spectral data, including the molecular ion or the ion at highest mass in a mass spectrum. The minor constituents, formic acid, hexanal, 2-heptanone, 2-octanone, 2-nonanone, and nonanoic acid, identified in the previous study of the preorbital secretion of the grysbok, are not visible in the total ion chromatogram depicted in Figure 1 and are not included in Table 9. In the previous study the coeluting alcohols (Z)-6-tridecen-1-ol and (Z)-7-tridecen-1-ol were incorrectly identified as (Z)-4-tridecen-1-ol.

PRESERVATION OF SALICACEAE LEAVES FOR PHYTOCHEMICAL ANALYSES: FURTHER ASSESSMENT

RICHARD L. LINDROTH* and PATRICK A. KOSS

Department of Entomology
University of Wisconsin
Madison, Wisconsin 53706

(Received June 9, 1995; accepted December 4, 1995)

Abstract—The chemistry of the plant family Salicaceae has been of interest to researchers as diverse as chemical ecologists, chemosystematists, and paper chemists. Continuing the debate on proper methods for preservation of plant material prior to analysis, vacuum-drying was recently advocated, because freeze-drying may cause degradation of phenolic glycosides. This study was conducted to clarify the consequences of freeze-drying for foliar secondary chemicals and to evaluate the consequences of vacuum-drying for primary compounds (protein and carbohydrates). Leaves of quaking aspen (*Populus tremuloides*) were flash-frozen in liquid nitrogen and freeze-dried or vacuum-dried at room temperature. We then analyzed samples for levels of salicortin and tremulacin (phenolic glycosides), condensed tannins, nitrogen, soluble protein, sugars, and starch. Freeze-drying did not alter the concentrations of phenolic glycosides or tannins, relative to vacuum-drying. Freeze-drying did cause a small and inexplicable decline in nitrogen and soluble protein. Vacuum-drying, however, reduced starch concentrations by 38%. We suggest that the vacuum-drying method be used in studies in which carbohydrates are of no interest. For studies measuring carbohydrates, however, freeze-drying is a better alternative, and should effect no changes in levels of secondary compounds if samples are not allowed to thaw during the drying process.

Key Words—Carbohydrates, leaf preservation, phenolic glycosides, *Populus*, protein, Salicaceae, salicortin, tannins, tremulacin.

INTRODUCTION

Members of the plant family Salicaceae have played prominent roles in research on chemosystematics (Steele and Ronald, 1973; Julkunen-Tiitto, 1986) and

*To whom correspondence should be addressed.

chemical ecology, including interactions with insects (Lindroth et al., 1988; Bryant et al., 1987), mammals (Basey et al., 1990; Reichardt et al., 1990), birds (Jakubas, 1989), fungi (Kruger and Manion, 1994), and multiple trophic levels (Pasteels et al., 1983; Smiley et al., 1985). These studies have emphasized secondary compounds, most notably condensed tannins and a variety of phenolic glycosides (Palo, 1984; Julkunen-Tiitto, 1986; Bryant et al., 1987; Lindroth et al., 1987a). Moreover, because the secondary chemistry of members of the Salicaceae exhibits substantial phenotypic and genotypic variation, these species have been the subject of studies on induced chemical defenses (Clausen et al., 1989), resource availability (Larsson et al., 1986; Bryant et al., 1987) and genotype by environment interactions (Price et al., 1989; Julkunen-Tiitto et al., 1993).

Given the importance of secondary compounds of the Salicaceae for understanding diverse ecological and evolutionary interactions, proper methods for preservation of foliar material prior to chemical analysis are of utmost importance. They have also been the subject of debate. Low-temperature oven-drying was formerly widely used for processing of leaf and bark tissues. Lindroth and Pajutee (1987) documented hydrolytic degradation and interconversion of phenolic glycosides in aspen (*Populus tremuloides*) samples subjected to oven-drying or slow freezing (−20°C) followed by freeze-drying, and advocated processing of fresh leaf material. We later found that flash-freezing of leaf tissue followed by freeze-drying did not alter phenolic glycoside concentrations (Lindroth et al., 1993) and adopted this method for large-scale studies that precluded collection and analysis of leaf tissues on the same day. Julkunen-Tiitto and Tahvanainen (1989) showed that air-drying of *Salix* tissues effected no qualitative changes and only minor quantitative changes in phenolic glycoside compositions, but did not measure responses of tannins. Most recently, Orians (1995) reported that freeze-drying and air-drying reduced levels of phenolic glycosides and condensed tannins, respectively, in *Salix* leaves. He suggested vacuum-drying of fresh leaves as the method of choice for researchers interested in concentrations of both types of secondary compounds.

Vacuum-drying of fresh material provides obvious, practical advantages over previous methods that relied on flash-freezing of tissues in liquid nitrogen prior to freeze-drying, but this new approach also raises some questions: (1) Are results from earlier work on freeze-dried tissues valid? (2) Does vacuum-drying without flash-freezing cause changes in levels of other plant chemicals routinely measured in phytochemically oriented studies? Here we report that when properly executed, flash-freezing followed by freeze-drying does not alter levels of phenolic glycosides or tannins. This method also helps to preserve concentrations of carbohydrates, although levels of protein may be marginally affected.

METHODS AND MATERIALS

Leaf Material. Leaves were collected from a single aspen tree (containing intermediate levels of phenolic glycosides and condensed tannins) in the University of Wisconsin Arboretum in early September 1994. Approximately 70 g of fully expanded, mature leaves were clipped at the petiole and transported to the laboratory on ice. Leaves were then mixed together and divided into twelve 5-g aliquots. For the vacuum-drying treatment, six aliquots were placed directly into a Virtis freeze-dryer and dried at room temperature for four days. For the freeze-drying treatment, six aliquots were flash-frozen in liquid nitrogen, then placed into a precooled (−25°C) drying chamber of another Virtis freeze-dryer, and dried at low temperature for four days. Following drying, leaves were ground (40-mesh) and stored at −20°C until analyzed.

Chemical Analyses. Leaf material was analyzed for the major carbon-based secondary compounds (phenolic glycosides and condensed tannins) as well as for primary compounds of recognized importance in plant–insect interactions. The latter included Kjeldahl nitrogen (as an index of total protein), soluble protein, hexoses, sucrose, and starch. With the exception of the nitrogen assay, all our chemical assays relied on solvent extraction; data presented represent the extractable portion occurring in aspen leaf tissue.

Quaking aspen produces a suite of four phenolic glycosides, of which salicortin and tremulacin constitute >90% by mass (Lindroth et al., 1987b). We measured concentrations of these two compounds by high-performance thin-layer chromatography (HPTLC). We extracted 25 mg of tissue in 1 ml methanol for 15 min, with sonication. Duplicate 1-μl aliquots of the extracts were then applied to HPTLC plates (Silica gel 60, 10 × 20 cm); purified salicortin and tremulacin standards were applied similarly. Plates were developed in 6:1:1 methylene chloride–methanol–tetrahydrofuran, then scanned (274 nm) in a Camag TLC Scanner II. Chromatograms were analyzed using Camag TLC evaluation software (CATS 3.11). Chromatograms were also visually inspected for the presence of salicin, which typically occurs in aspen tissues near the limit of detection with our standard HPTLC technique.

We measured condensed tannin concentrations by a modification of the method of Porter et al. (1986). Leaf material (50 mg) was extracted (4 × 1 ml, 4°C, 30 min with sonication) with 70% acetone (containing 10 mM ascorbic acid as antioxidant). For hydrolysis, duplicate samples were immersed in boiling water for 50 min. Condensed tannins purified from aspen leaves (method of Hagerman and Butler, 1980) served as a standard.

For Kjeldahl nitrogen determinations, 25-mg quantities of leaf tissue were digested according to the procedure of Parkinson and Allen (1975). We quantified nitrogen contents of the digests in duplicate samples by a micro-Nessler-

ization technique (Lang, 1958), using glycine–*p*-toluene–sulfonic acid (5.665% N) as a standard. We also measured soluble protein, using a modification of the procedure of Jones et al. (1989). Samples of 25 mg were extracted in 0.1 N NaOH (containing 0.05% sodium dodecyl sulfate to prevent precipitation of protein). Extracts were analyzed in duplicate and bovine serum albumin served as the protein standard.

Carbohydrate concentrations were measured by the method of Schoeneberger et al. (1995). This procedure provides for separate quantification of hexoses (glucose and fructose), sucrose, and starch in 25-mg samples. Fructose, sucrose, and starch are enzymatically converted to glucose, which is then quantified indirectly via reduction of NADP to NADPH.

RESULTS AND DISCUSSION

Concentrations of secondary compounds in aspen leaves were not affected by the method of leaf preservation (Figure 1). Our results for phenolic glycosides differ from those of Orians (1995), who found that freeze-drying reduced concentrations of salicortin by 45–73% in *Salix* leaves. Orians used a freeze-dryer without temperature control of the drying chamber and acknowledged that some thawing of leaf tissue after flash-freezing may have contributed to the loss of salicortin (and 2′-cinnamoyl salicortin). Moreover, Orians detected substantial increases in levels of salicin in freeze-dried samples, whereas we detected none. Salicin is formed upon hydrolytic degradation of salicortin and tremulacin, as is likely to occur during thawing of frozen leaf tissue. Thus the reductions in phenolic glycoside concentrations reported by Orians were likely due to thawing of leaf tissue, not freeze-drying per se. These results emphasize the importance of maintaining samples in the frozen state when freeze-drying is used for sample preservation. Our results for condensed tannins agree with those reported by Orians (1995), who also found that freeze-drying did not alter concentrations.

To our surprise, freeze-drying altered foliar protein levels, although only minimally. Concentrations of total nitrogen and soluble protein declined by 7 and 10%, respectively, in freeze-dried tissues. Because flash-freezing and freeze-drying should be benign with respect to protein concentrations, the reasons for the apparent decline are unknown.

Carbohydrate concentrations are likely to be susceptible to leaf preservation methods, as starch may be labile under conditions that fail to inhibit activity of the starch-degrading enzyme α-amylase. Such appears to be the case for vacuum-dried leaves. Although overall starch levels were low in our late-season leaves, concentrations declined 38% in vacuum- versus freeze-dried samples. As expected, the reduction in percent leaf dry mass for starch was reflected by a corresponding increase in percent leaf dry mass for hexoses (glucose), although

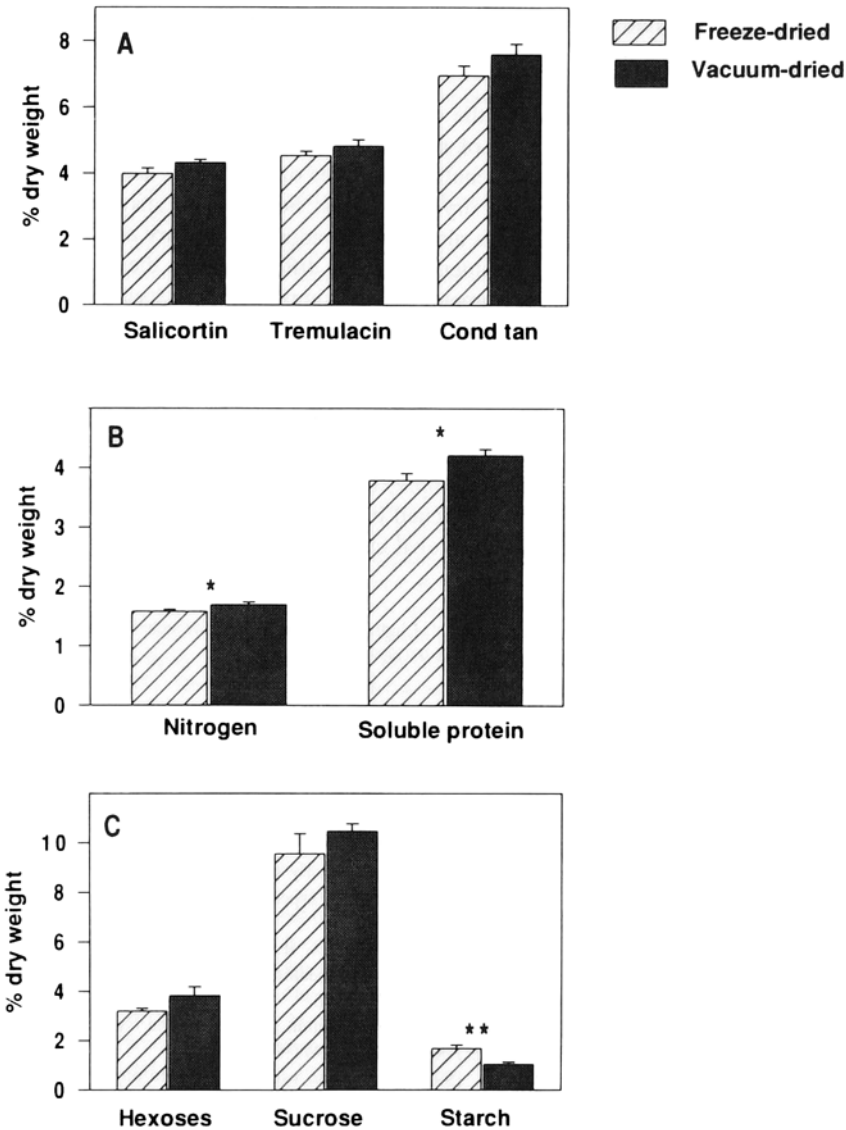

FIG. 1. Effects of preservation method on phytochemical composition of quaking aspen leaves: (A) Secondary compounds (cond tan = condensed tannins); (B) nitrogen and protein; (C) carbohydrates. Vertical lines indicate 1 SE. Means compared by t tests (*$0.01 < P < 0.05$; **$0.001 < P < 0.01$). P values for all nonsignificant comparisons were > 0.10.

the increase was not statistically significant. Our results suggest that freeze-drying is preferable to vacuum-drying for studies in which leaf carbohydrates are of interest.

In conclusion, the answer to the question of whether results from earlier work on the secondary chemistry of aspen are valid is "yes"; freeze-drying does not alter concentrations of phenolic glycosides or condensed tannins when samples remain frozen during the drying process. Second, the answer to the question of whether drying methods alter concentrations of primary compounds is also "yes", although the constituents affected differ between the two preservation methods tested. We recommend that the simple vacuum-drying method advocated by Orians (1995) be used for studies in which carbohydrate concentrations are not of interest. For example, because gypsy moth performance is related to aspen phenolic glycosides but not to carbohydrates (Hemming and Lindroth, 1995), our future studies will use the vacuum-drying method. We also recommend, however, that freeze-drying be used for studies in which leaf carbohydrates are of interest. For example, because starch concentrations may approach 10% leaf dry weight in enriched carbon dioxide environments (Lindroth et al., 1993, 1995), our future global change research will use the freeze-drying method.

(Received June 27, 1995; accepted December 4, 1995)

Abstract—The importance of learning for sibling odor preference in juvenile Arctic char was analyzed in the present study. Fish were reared in the following eight conditions: (1) communally with siblings for 15 months; (2) communally with siblings for 17 months; (3) in isolation since fertilization; (4) in isolation since fertilization and exposed to sibling scent during the whole rearing period; (5) in isolation since fertilization and exposed to sibling scent from time of free swimming; (6) in isolation since fertilization and exposed to sibling scent during the whole rearing period, except two months without scent until testing; (7) in isolation since fertilization and exposed to sibling scent from time of free swimming, except two months without scent until testing; and (8) communally with siblings followed by a two-month isolation until testing. Char were followed individually in a Y-maze (fluviarium test) with a video-computer-based image analysis system for 12 hr. Sibling-scented water was supplied to one lateral half of the test area and water from nonsiblings on the opposite half. Isolated individuals without any preexposure to siblings showed no significant preference. Test fish reared with siblings and those that had been reared in isolation but exposed to sibling scent until testing preferred water conditioned by their own siblings. Isolated fish that had been exposed to sibling scent since fertilization, or since free swimming, followed by a two-month period with only pure water, showed no significant preference. Char isolated for two months after being communally reared preferred water scented by siblings. The results demonstrated that behavioral discrimination between siblings and nonsibling odors occurred after total isolation (isolated both from siblings and sibling odors) only in individuals that had been communally reared. This may suggest that social interactions are important for learning and long-term memory of sibling odors in Arctic char.

Key Words—Arctic char, attraction, fish, fluviarium, kinship, odor, salmonids, *Salvelinus alpinus*, siblings.

INTRODUCTION

Behavioral discrimination of siblings or close relatives has been demonstrated in social organisms of various taxonomic groups (reviews: Holmes and Sherman, 1983; Blaustein and O'Hara, 1986; Fletcher and Michener, 1987; Waldman, 1987, 1988). Such behavior has been proposed to be part of a kin recognition or discrimination mechanism. It has been suggested that the ability to discriminate kin may increase an individual's inclusive fitness (its own and close relatives' reproductive success) and decrease the risk of inbreeding (Hamilton, 1964).

Four mechanisms have previously been proposed for kin recognition (Blaustein, 1983; Holmes and Sherman, 1983), (1) spatial distribution—relatives are distributed predictably in space; (2) familiarity or previous association, i.e., recall of features learned during previous social interactions with a special group of kin; (3) phenotypic matching—an individual learns the phenotypes of relatives or itself, and relationships with other individuals are determined by comparing the learned phenotype with that of an unfamiliar conspecific; and (4) both the phenotype and its recognition have genetic bases and no learning is involved. This division into four mechanisms has recently been revised by some authors. Waldman (1988, 1991) divided kin recognition mechanisms into two categories: indirect (item 1 above) and direct (items 2–4 above) recognition. He suggested that direct recognition is composed of a series of events. Individuals expose labels, which are perceived by a second individual, and due to the fit of these labels to a template (innate or acquired) recognition occurs, which, in an appropriate social context, may lead to behavioral discrimination. It is the behavioral response that tells the observer that recognition and discrimination has occurred.

In fish, very little is known about the ability to distinguish between individuals or groups with different degrees of relationship. Most studies have been concerned with the ability of salmonids to use olfaction for kinship discrimination (Olsén, 1992). In salmonids sibling discrimination by chemical cues has, up to now, been demonstrated in three species, i.e., coho salmon, *Oncorhynchus kisutch*, Arctic char, *Salvelinus alpinus*, and rainbow trout, *Oncorhychus mykiss* (Quinn and Busack, 1985; Quinn and Hara, 1986; Olsén, 1989; Winberg and Olsén, 1992; Brown et al., 1993). Test fishes preferred water scented by unfamiliar siblings over unfamiliar nonsiblings. These studies indicated that the olfactory cues acting as intraspecific attractants are genetically determined. The results also suggest that odor traits from siblings are learned and then used as templates against which unfamiliar traits are compared.

Winberg and Olsén (1992) demonstrated that individual Arctic char kept in isolation since fertilization showed no preference when given a choice between two water currents scented by siblings and nonsiblings. The results indicated that juvenile Arctic char either learn the odor quality of siblings but not their

own smell, or they do not use the information (i.e., no self-matching). The study also indicated that the olfactory features are learned at an early age, because fish that were placed with siblings for 50–62 days after 15 months in isolation still showed no preference. In the present study we try to analyze the impact of isolation and communal rearing for sibling odor preference in juvenile Arctic char. Isolated fish were exposed to sibling-scented water either from the time of fertilization or from free swimming until testing. In some other isolated individuals, sibling odors was removed for two months before testing. Moreover, char were placed in isolation for two months after they had been reared communally since fertilization. The results suggest that communal rearing is important for permanent learning of sibling odors in Arctic char.

METHODS AND MATERIALS

Fish. Two full-sibling families were created by using two pairs of Arctic char at the Kälarne hatchery of the Swedish National Board of Fisheries. The parents were offspring of individuals caught in Lake Hornavan, Lapland, Sweden. Egg lots from these two pairs, family A and family B, were transported to the Department of Limnology, Uppsala University, within 12 hr of fertilization at the hatchery.

Most eggs from family A (ca. 300) were placed together and supported for communal rearing (called rearing regimes 1a and 1b in Figure 1) and hereafter referred to as test groups 1a and 1b. These eggs from family A and the fertilized eggs from family B (ca. 300) (B fish were only used as odor donors in fluviarium tests, not as test fish) were placed in two separate troughs (41 cm long, 69 cm wide, and 12.5 cm deep) supplied with 800 ml/min of aerated tap water. These two families were later transferred to a fiberglass holding tank (500 liters), supplied with 1200 ml/min of aerated tap water.

Twenty-five fertilized eggs from family A were placed individually in a trough with separate compartments (58 × 58 × 45 mm deep). Each compartment had its own water supply and outlet and was supplied with 40 ml/min of aerated Uppsala tap water (oxygen at least 80% of saturation). Eleven of the fish were reared in total isolation (i.e., only supply of tap water) up to testing (rearing regime 2). When fish became free swimming (four months after fertilization), the supply of sibling-scented water was started to the remaining 14 (rearing regimes 4a and 4b). Fish supported to rearing regime 4a were exposed to sibling odors up to testing as group 4a. At 15–16 months after fertilization, the supply of sibling odors was stopped to seven fish, giving rearing regime 4b (group 4b), and the group was tested two months later (median 56 days; range 52–60).

Another 25 eggs from family A were individually placed in a similar trough

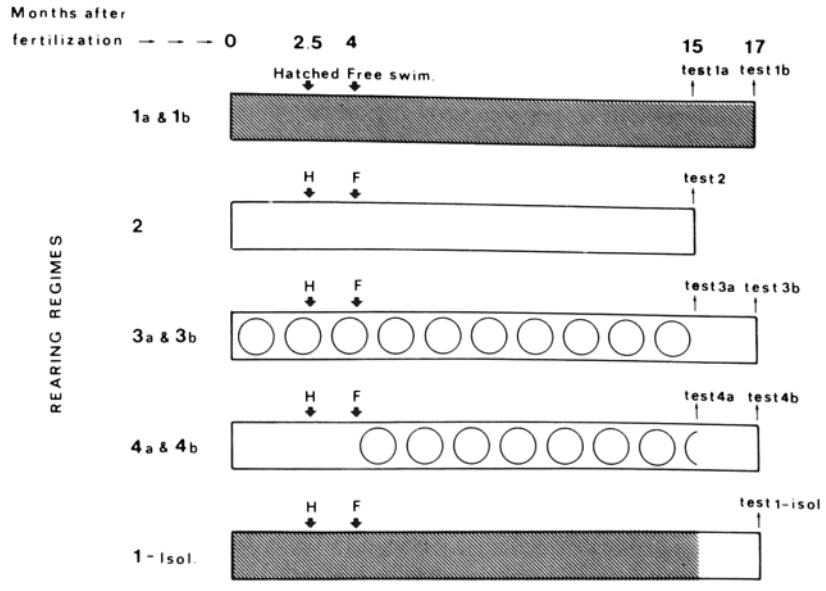

FIG. 1. Diagram of the different rearing regimes giving rise to eight different groups tested in the fluviarium. Two groups of 1b were tested, but for all other groups only one group of each rearing regime was used. Each individual was tested only once. Hatched bar or hatched part of a bar indicates fish kept together with siblings; open bar or open part of a bar indicates isolated fish without any contact with sibling odor; circles in an open bar indicate sibling-scented water was supplied to isolated fish. "Free swim." indicates time when fish had filled their swim bladder and were free swimming.

with separate compartments. These compartments were supplied with 20 ml/min of aerated tap water and 20 ml/min of sibling-scented water taken from the trough containing the 300 family A eggs and later fry. These eggs gave test groups 3a and 3b (rearing regimes 3a and 3b in Figure 1). Fish supported to rearing regime 3a were exposed to sibling odors up to the day of testing. At 15–16 months after fertilization, the supply of sibling odors was stopped to seven fish, giving rearing regime 3b and, the group was tested two months later as group 3b (median 56 days; range 52–60).

At the same time that the supply of sibling odor was terminated to the fish of groups 3b and 4b, 14 fish from the communal holding tank were individually isolated for about two months (median 56 days; range 50–60) in compartments equivalent to the others but only supplied with tap water (40 ml/min). This rearing regime is called 1-isol (Figure 1) and the group tested is referred to as group 1-isol.

The fish hatched in early January (2.5 months after fertilization), and in March the fish isolated since fertilization were transferred to equivalent troughs with larger compartments (polyethylene beakers), but still supplied with the same water qualities at the same flow rate.

The fish were fed 1–2% of their body fresh weight per day (Astra-EWOS F139H). The automatic light/dark regimen reflected conditions at latitude 51°N, with the length of the light/dark periods being automatically adjusted to take seasonal variations into account.

Testing Apparatus. One individual at the time was tested in the standard fluviarium (Höglund, 1961) according to the procedure described by Olsén and Höglund (1985) and Olsén (1986, 1989). Each fish was tested only once. The fish was placed in the test area at least 30 min before the initial test period. Equal amounts of water (340–360 ml/min) from each aquarium (Aq 1 and Aq 2, Figure 2 in Olsén, 1989) were pumped through silicone tubes to opposite lateral halves of the fluviarium. Every 90 min for 720 min the supply was switched automatically from one side to the other. Between tests, both aquaria and the test area in the fluviarium were brushed with 95% ethanol and water. Ethanol and water were also pumped through the tubes and electromagnetic valves.

Two 20-W halogen lamps equipped with a red glass filter (RG 780, Melles Grio), with no transmission of wavelengths shorter than 750 nm (and out of range of the visual system of salmonid fish; Bone et al., 1995), were used as the light source for the video camera. This infrared light was reflected by a glass mirror and a sheet of aluminum foil through a plate of opalescent white glass situated immediately below the bottom of the test area. On the video monitor this arrangement gave a light background, without reflections, against which the fish was readily detected.

The video camera (4.8 mm lens) was placed in the plywood hood, 33 cm above the test area. The camera was connected to a monitor and a computer in an adjacent room.

The position of the fish was recorded once every 2 sec by means of a video-computer-based image analysis system. This system has previously been described for studies of fish behavior, locomotor activity measurements (Winberg et al., 1993), and preference/avoidance responses to chemical substances (Bjerselius et al., 1995). These authors have described the hardware used in the present study. The software used in this image analysis system consisted of the program EthoVision (Noldus Information Technology bv, Wageningen, The Netherlands).

In this system, the data acquisition procedure was based on the following algorithm. A picture of the empty test area was digitized. Thereafter, a picture of the test area with the fish was made. These two pictures were subtracted from each other, leaving the image of the fish and the noise. The noise was filtered

by a threshold filter, followed by transformation to a binary image. Irrelevant objects (e.g., feces) were deleted by testing objects against a criterium of size. In the present study the computer calculated the number of observations in each lateral half of the test area for each 30 min period of the trial.

Procedure. Each fish was only tested once in the fluviarium, but odor donors may have been used more than once in different situations. Each test started at 18:00 hr and ended at 06:00 hr the next morning in order to avoid ordinary working hours in the lab. All tests were run in darkness. Fish from the different rearing conditions were tested for their preference when given a simultaneous choice between water scented by siblings and nonsiblings, respectively. In a control test, unscented water from the two donor aquaria was added to opposite lateral halves of the fluviarium.

Experiment 1. All tests were performed between February 15 and March 31. Fish reared in isolation with a supply of only water (group 2 from rearing regime 2) or a supply of sibling-scented water (groups 3a and 4a), and fish reared together with siblings (group 1a) were tested. Fish of the different groups weighed the same (mean $\pm$ SD: 6.6 $\pm$ 2.4 g; $N = 33$). Twenty char were placed as odor donors in each aquaria. The weights of the odor donors were matched just before they were placed in the donor aquaria so that the difference in total weight between the donor groups was always less than 10%. The water temperature increased during the testing period from 8.3 to 12.1°C.

Experiment 2. All tests were performed between May 1 and July 1. The supply of sibling-scented water to isolated fish was removed (rearing regimes 3b and 4b). Moreover, the effect of isolation later in life was tested by transferring individual fish from communal aquaria to separate compartments, giving rearing regime 1-isol. The fish were reared under these conditions for ca. 2 months (median 56 days, range 52–60) after which they were tested as group 1-isol for their preference when given a simultaneous choice between water scented by siblings and nonsiblings, as described above. Two groups of fish reared with siblings (group 1b) were also tested. The mean weight of all test fish used was 10.7 $\pm$ 3.9 g ($N = 32$). There were 15 odor donors in each donor aquarium. An increase in size of the fish justified the use of fewer odor donors than in experiment 1. The water temperature range was 12.0–14.0°C.

Data Analysis. A fish's preference for either water quality was determined on the basis of the number of observations in each. A reaction value (Rv) for a test was calculated as stated in Olsén (1986) from the following equation:

$$Rv = [(N_1 - N_2)/(N_1 + N_2)] \times 100$$

where N_1 and N_2 represent the number of observations in each half of the test area supplied with water from donor aquaria 1 and 2, respectively. Siblings and nonsiblings were always placed in donor aquaria 1 and 2, respectively. Thus, an attraction towards sibling-scented water is indicated by a positive Rv. The

number of observations ($N_1 + N_2$) in each test was 14,400 (8 × 1800). (For further details see Olsén and Höglund, 1985; Olsén, 1986.)

The arithmetic means of reaction values from identical tests are designed *MRv*. Confidence limits (CL) of *MRv*s were calculated using *t* statistics. The reaction was said to deviate from an indifferent reaction, i.e., from *MRv* = 0, if *MRv* ± 95% CL did not include *MRv* = 0. Kruskal-Wallis analysis was used as an initial test to reveal differences between groups within an experiment. When the Kruskal-Wallis analysis indicated differences between groups, the Mann-Whitney U test (two-tailed) was used to compare the reaction of two groups (Siegel, 1956).

RESULTS

Control Tests. The test fishes did not prefer either water current of unscented water from the two donor aquaria being added to opposite lateral halves of the fluviarium, i.e., the total reaction did not deviate from *MRv* = 0 (*MRv* ± 95% CL: −2.9 ± 5.0) (Figure 2).

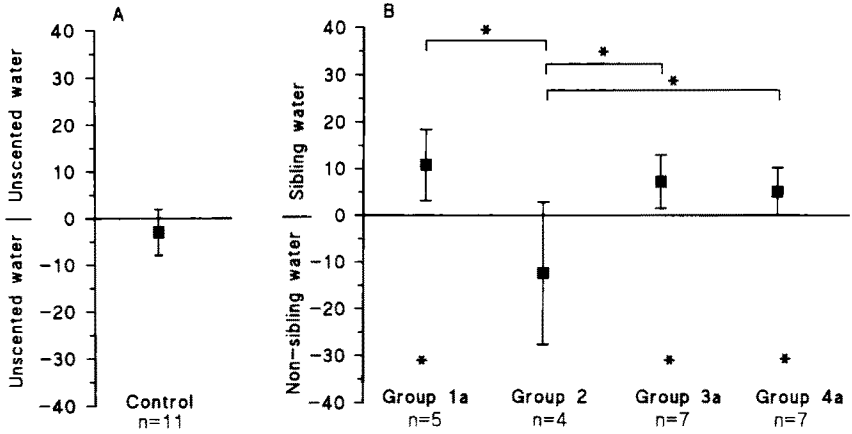

FIG. 2. Reaction of one char at a time during simultaneous choice between two types of water in the fluviarium. (A) Unscented water supplied to both sides, (B) water scented by siblings to the test fish and nonsiblings supplied to opposite sides. Reactions are given as mean reaction values, *MRv* ± 95% CL, for each group (for description of groups see Figure 1 and the text). The reaction shown by a group was said to deviate from an indifferent reaction, i.e., from *MRv* = 0, if *MRv* ± 95% CL did not include *MRv* = 0. Number of fish tested is indicated below each group. A significant difference between groups is denoted by asterisks and a significant difference from the control by asterisks in connection to group affiliation (Mann-Whitney U test). $*P < 0.05$.

Experiment 1. The reactions of char from groups 1a, 3a, and 4a were significantly different from the results of the control test (Figure 2). Kruskal-Wallis analysis revealed that there were differences in reactions between groups 1a, 2, 3a, and 4a ($H = 8.62$, $df = 3$, $0.02 < P < 0.05$).

Char raised communally with siblings (group 1a) preferred water scented by siblings to water scented by nonsiblings (*MRv* ± 95% CL: +10.8 ± 7.6) (Figure 2). Individuals reared in isolation without any supply of sibling-scented water (group 2) showed no preference for sibling- or nonsibling-scented water (*MRv* ± 95% CL: −12.4 ± 15.2) (Figure 2). However, fish that were raised in isolation in compartments provided with sibling-scented water (group 3a) preferred water scented by siblings to water scented by nonsiblings (*MRv* ± 95% CL: +7.2 ± 5.7) (Figure 2). Char that were reared in such compartments but with a supply of siblings odor from free swimming fish (group 4a) exhibited an attraction that approached significance (*MRv* ± 95% CL: +5.1 ± 5.1) (Figure 2).

Individuals raised in isolation in compartments supplied with sibling-scented water since fertilization (group 3a) did not differ from fish that were exposed to sibling odors since they were free swimming (group 4a, Figure 2). However, fish raised with siblings (group 1a) as well as fish raised in separate compartments supplied with sibling odor, either during the whole rearing period (group 3a) or since start of free swimming (group 4a), differed significantly ($P = 0.016$, $P = 0.042$ and $P = 0.024$, respectively) from the char that had been raised in isolation without any supply of sibling-scented water (group 2).

Experiment 2. The reaction of group 1 char (two different groups of 1b in Figures 3 and 4) and group 1-isol (Figure 4) were significantly different from the controls. Kruskal-Wallis analysis revealed differences in reaction between groups 1b, 3b, and 4b ($H = 8.51$, $df = 2$, $0.01 < P < 0.02$) (Figure 3). There was a significant difference in reaction between groups 1b and 4b (Figure 3).

Fish that had been reared in separate compartments supplied with sibling-scented water during the entire rearing period and those that had been reared in such compartments with a supply of sibling odors since they were free swimming showed no significant preference for water scented by siblings after being deprived of the experience of sibling-scented water for two months (*MRv* ± 95% CL for group 3b: +2.2 ± 7.9; and for group 4b: −2.0 ± 4.8) (Figure 3).

No difference in reaction was observed between the fish that remained in the trough with siblings (group 1b) and the fish that previously had been reared in this group but were removed to separate compartments two months prior to testing (group 1-isol) (Figure 4). Both groups showed attraction to sibling-scented water (*MRv* ± 95% CL for group 1b: +10.0 ± 7.6; and for group 1-isol: +12.0 ± 6.7).

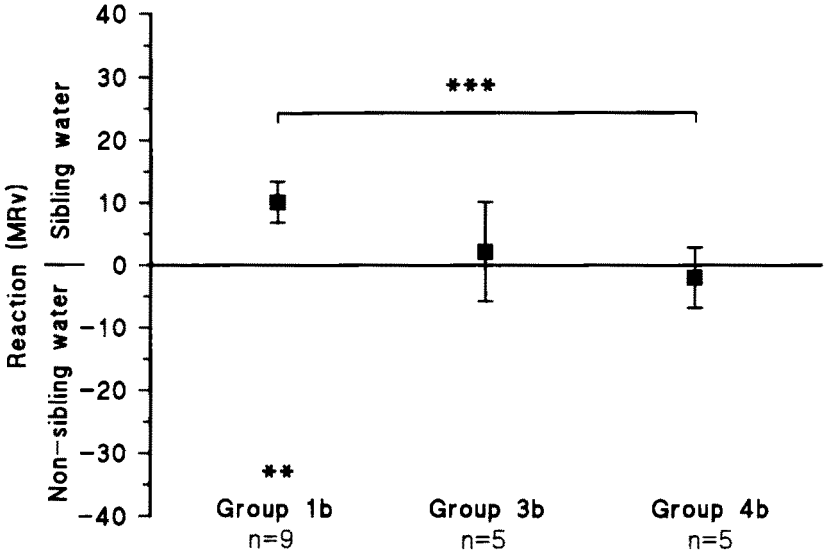

FIG. 3. Reaction of one char at a time during simultaneous choice between water scented by siblings to the test fish and nonsiblings in the fluviarium. Isolated fish preexposed to sibling-scented water were reared for two months without a supply of odors (groups 3b and 4b). For a description of groups see Figure 1 and the text. Reactions are given as described in Figure 2. The number of fish tested is indicated below each group. A significant difference between groups is denoted by asterisks and a significant difference from the control by asterisks in connection to group affiliation (Mann-Whitney U test). $^{**}P < 0.01$; $^{***}P < 0.001$.

DISCUSSION

The present study suggests that communal rearing and social interactions were important for young Arctic char to remember sibling specific odors, at least in the sibling group studied. Individuals only preexposed to water scented by siblings since fertilization or since they were free swimming, but without social contact, lost their ability or motivation to discriminate between sibling and nonsibling odors after termination of the exposure. The results support our previous study in which we suggested that social interactions during the first period after hatching are important for development of sibling recognition in Arctic char (Winberg and Olsén, 1992). We do not know how long the char retain their memory of the odors of their siblings, but salmonids do have the capacity of long-term olfactory memory as, for example, the spawning migration to the home river after one to three years in the sea (Brannon, 1972; Hasler and

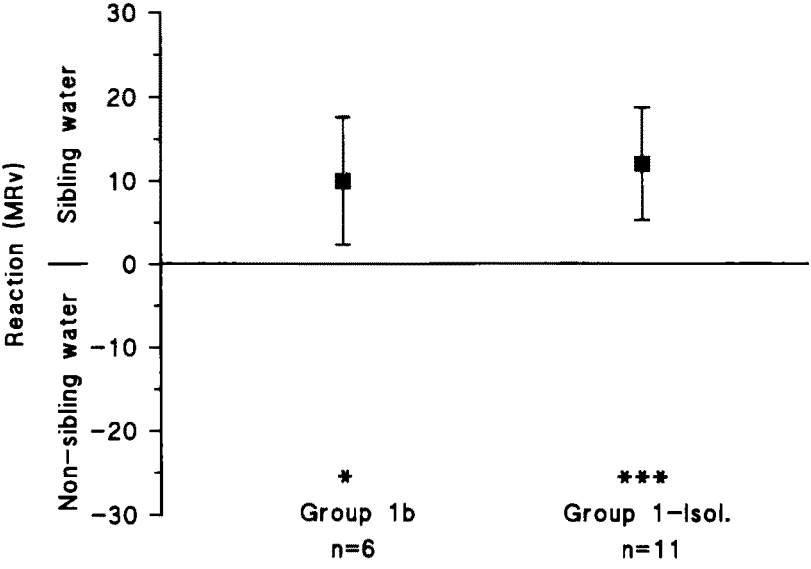

FIG. 4. Reaction of one char at a time during simultaneous choice between water scented by siblings to the test fish and nonsiblings in the fluviarium. Individuals were taken from sibling group A and reared in isolation for two months without a supply of sibling odors (group 1-isol). Test group 1b was not composed of the same fish as in group 1b of Figure 3. For description of groups see Figure 1 and the text. Reactions are given as described in Figure 2. The number of fish tested is indicated below each group. A significant difference between groups is denoted by asterisks and a significant difference from the control by asterisks in connection to group affiliation (Mann-Whitney U test). $*P < 0.05$; $***P < 0.001$.

Scholz 1983; Dodson, 1988). Odors from kin may be an important part of the home river bouquet (Nordeng, 1971; Stabell, 1984; Olsén, 1986).

In tadpoles of some species, learning of sibling odors may take place before hatching (Waldman, 1981; Blaustein and Waldman, 1992; Hepper and Waldman, 1992). In these species individuals isolated as eggs were also able to discriminate between odors of siblings and nonsiblings, an ability that seams to have an important maternal component (Blaustein and O'Hara, 1982). In contrast to our observations with juvenile Arctic char, Van Havre and Fitzgerald (1988) observed that juvenile sticklebacks could discriminate between sibling- and nonsibling-scented water even though the test fish had been isolated since the egg stage. Differences in the mechanisms behind sibling discrimination may reflect differences in natural history traits (O'Hara and Blaustein, 1988).

Grafen (1990) and Barnard (1990) proposed that most studies indicating the existence of kin discrimination fail to demonstrate true kin discrimination, but possibly only species recognition. Previous experiments have demonstrated that juvenile Arctic char are attracted to odors from conspecifics, but not to three other salmonid species (Höglund and Åstrand, 1973; Höglund et al., 1975). They are, in addition, able to discriminate between their own population and another sympatric population (Olsén, 1986) and also between odors from their own unfamiliar siblings and another sibling group from the same population (Olsén, 1989; Winberg and Olsén, 1992). These results give support to the view that juvenile Arctic char are not only able to recognize their own species odor ("pheromone," Karlsson and Luscher, 1959), but also intraspecific variation in odors, which may be a basis for kin recognition.

There are some experiments suggesting that intraspecific odors of salmonids are involved in nepotism (Brown and Brown, 1993a,b). Whether this is due to "true kin recognition" (Grafen, 1990), familiarity, or imprinting to genetically determined intraspecific odors (Winberg and Olsén, 1992), the result may be the same. Recent results with Atlantic salmon, rainbow trout (Brown and Brown, 1993a,b), and brown trout (Olsén, Järvi and Löv, accepted manuscript) have revealed that the aggressiveness in groups of siblings is significantly less than in mixed groups with both siblings and nonsiblings. The authors suggested that kin-biased behavior increased an individual's inclusive fitness, which, according to Hamilton (1964), includes the survival and reproductive success of an individual and its close relatives. Results from Brown and Brown (1993a,b) supported this hypothesis. The authors also observed that the territories were smaller and the growth rate better in pure sibling groups. Brown and Brown (1993a,b) suggested that these benefits of kin-biased behavior may increase the probability of survival.

The sibling group of Arctic char followed in the present study belongs to a lacustrine population with the entire life cycle in Lake Hornavan, Swedish Lapland. Individuals of Arctic char are, at least in lakes, thought to remain together in schools (Aass, 1970; Klemetsen and Grotnes, 1980). Thus kin-biased behavior should not be connected to territorial behavior, as suggested in young specimens of the above-mentioned three salmonid species. If, however, schools of Arctic char are composed of siblings, altruistic behavior towards kin and cooperation within the group may increase an individual's inclusive fitness (cf., Hamilton, 1964). Young individuals of lacustrine Arctic char, including the present population studied, may, however, show high degrees of aggressiveness in small experimental groups (Winberg et al., 1991, 1992), indicating that there is a high degree of plasticity in their occurrence and behavior. Changes in behavior within a group from schooling to agonistic or the reverse may reflect the local distribution of food and predator risk, as has been suggested for juvenile

chum salmon (*Oncorhynchus keta*) (Ryer and Olla, 1991). Fish presented with a defensible source of food abandon schooling and instead fight for access to the source. Kin-biased behavior with positive effects on the individual's inclusive fitness may still work, although schooling is abandoned in favor to territorial defense. The aggressiveness in pure sibling groups of juvenile Lake Hornavan char was significantly lower than in groups of mixed relationship (Olsén and Järvi, unpublished data).

The selfish herd theory proposed by Hamilton (1971) suggests that individuals in a school act in a selfish way to decrease the risk of predation. It may, however, be possible that individuals in schools of kin act in a cooperative way, not observed in groups of unrelated individuals, that increases the members' chances to avoid being eaten by predators (Waldman, 1991). We still do not know, however, if char and other fish species prefer to school with related individuals, as has been demonstrated for tadpoles of some species (Waldman, 1991). The possible preference of juvenile Arctic char to school with kin has to be examined before an analysis of the significance of kinship among school members in relation to predation and survival in general can be tested.

Present knowledge of the behavioral ecology of different local populations or stocks of Arctic char, especially during the first year of life, is scarce and further investigation is needed (Johnson, 1980; Noakes, 1980). We do not know if the present results with the sibling group tested are representative of the population. The high plasticity in behavior within the species is further stressed by the observation that significant population differences in aggressiveness (Olsén and Karlsson, 1990) and foraging behavior (Skúlason et al., 1993) are present during the same experimental conditions.

In summary, communal rearing, which included social interactions, was probably obligatory for long-term memory of sibling-specific odors in the group used in the present study. Social interactions may be obligatory for sibling discrimination in juvenile Arctic char in general. The functions of and mechanisms behind sibling recognition ability and behavioral discrimination in Arctic char have to be investigated further in the context of a plastic species with diverse behavior at individual and local population levels.

Acknowledgments—This study was supported by the Swedish Council for Forestry and Agricultural Research and the Helge Axelson Johnson foundation.

(Received September 11, 1995; accepted December 4, 1995)

Abstract—The sex attractant of *Scrobipalpuloides absoluta* females is a 90:10 mixture of (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate and (3*E*,8*Z*)-3,8-tetradecadien-1-yl acetate. Tetradecadienyl acetates bearing 8*Z*,11*Z*; 3*E*,8*Z*; and 3*E*,11*Z* double bonds were synthesized by stereospecific procedures; the mass spectral and gas chromatographic properties of the 3*E*,8*Z* isomer were found to be congruent with those of the tetradecadienyl acetate from *S. absoluta*. In wind tunnel bioassays, a 10:1 mixture of synthetic (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate and (3*E*,8*Z*)-3,8-tetradecadien-1-yl acetate was highly attractive to *S. absoluta* males. Interestingly, the presence of (8*Z*,11*Z*)-8,11-tetradecadien-1-yl acetate (10%) inhibited the response to (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate completely.

Key Words—Lepidoptera, Gelechiidae, *Scrobipalpuloides absoluta*, tomato, pest, pheromone.

INTRODUCTION

We found recently that the female sex pheromone of *Scrobipalpuloides absoluta* (Lepidoptera: Gelechiidae), a devastating tomato pest in South America, consists of two components. The major component, which represents about 90% of the volatile material found in the sex gland of calling females, was identified as (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate (**1**, Figure 1) (Attygalle et al., 1995; 1996). The minor constituent (10%), was characterized partially by GC-MS as a tetradecadienyl acetate. However, the minute amount of natural material available precluded a full structural assignment by conventional methods.

In order to identify the diene acetate, we decided to synthesize the three possible dienes (**2–4**, Figure 1) with double-bond positions and configurations corresponding to those of the major pheromone component, (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate, and to compare the properties of the synthetic samples with those of the natural material. Results of these experiments, and subsequent bioassays, established the pheromone as a mixture of (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate (**1**) and (3*E*,8*Z*)-3,8-tetradecadien-1-yl acetate (**3**).

METHODS AND MATERIALS

NMR spectra were recorded on a Unity-200 (^{1}H, 200 MHz, Varian), a Unity-400 (^{1}H NMR, 400 MHz; ^{13}C NMR, 100.6 MHz, Varian), and a Unity-

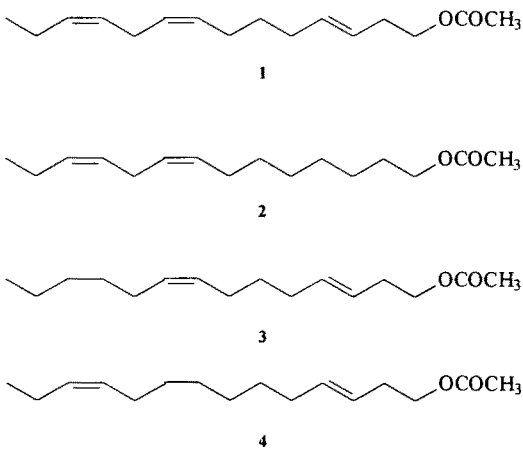

FIG. 1. Structures of compounds **1–4.**

500 instrument (^{1}H NMR, 500 MHz; ^{13}C NMR, 125.7 MHz, Varian) as $CDCl_3$ solutions at room temperature. Chemical shifts, given in parts per million, are expressed as δ values measured from the residual $CHCl_3$ signal (7.26 ppm). Vapor-phase infrared spectra were recorded using a Hewlett-Packard (HP) 5965A IRD coupled to a HP 5890 GC. Electron impact (70 eV) spectra were obtained using a HP 5890 GC coupled to an ion trap detector (ITD 800, Finnigan) or a mass selective detector (HP 5970 MSD). Fast atom bombardment (FAB, in a glycerin matrix) mass spectra were obtained using a ZAB-Q (VG) instrument. For GC analysis a Supelco fused-silica capillary column (30 m × 0.25 mm) coated with SE-54 (0.25 μm) fitted in a HP 5890 GC equipped with a flame-ionization (FID) detector was used. Synthetic samples (hexane, ca. 1 mg/ml) were injected in split mode using a temperature program of 60°C for 4 min, 10°C/min to 270°C, and held for 20 min. Column chromatography was run on silica gel (Merck, H 60) and reactions were monitored by TLC on Baker-flex Silica gel IB2-F plates (J. T. Baker) and on Silufol TLC plates (Kavalier, Sázava, Czech Republic). Silver-nitrate column chromatography was done on silica gel impregnated with $AgNO_3$ (20% of $AgNO_3$ on silica gel Merck H 60).

Biological Material

Pheromone extracts were prepared as described previously (Attygalle et al., 1996).

Chemicals

Butyllithium (1.6 M and 2.5 M solutions in hexane), 1-(tetrahydropyran-2-yloxy)-3-butyne [2-(3-butynyloxy)tetrahydro-2*H*-pyran], $LiAlH_4$, $NaBH_4$, borane–methylsulfide complex, $Cu(I)Br \cdot Me_2S$ complex, and *p*-toluenesulfonyl chloride were from Aldrich Chemical Co. (Milwaukee, Wisconsin), and bromine, ethylenediamine, nickel(II) acetate, and triphenylphosphine from Fluka Chemical Co. (Ronkonkoma, New York); they were used as purchased. 1-(Tetrahydropyran-2-yloxy)-4-pentyne (**5**) (Robertson, 1960) and 1-bromo-6-(tetrahydropyran-2-yloxy)-hexane (**20**) (Kang et al., 1985; Miyashita et al., 1977) were prepared according to published procedures. 1,3-Dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (DMPU, Aldrich Chemicals) was dried over molecular sieves.

(8Z,11Z)-8,11-Tetradecadienyl Acetate (2)

This compound was synthesized according to Scheme 1. Compounds **5–9** were synthesized according to procedures described previously for the synthesis of (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate (**1**) (Attygalle et al., 1995; 1996).

Magnesium turnings (30 mg, 1.28 mmol) were warmed, stirred for 1 hr under dry argon, and covered with dry THF (100 μl). Ten drops of a solution of (4Z,7Z)-1-bromo-4,7-decadiene (**9**) (200 mg, 0.925 mmol) in dry THF (3 ml) were added, and the mixture was brought to reflux. After the reaction started, the remainder of the bromide solution was added dropwise at 0°C over a period of 1.5 hr, and the mixture was stirred for 2 hr at room temperature.

Dry THF (3 ml) was treated with trimethylsilyl iodide (260 mg, 185 μl, 1.30 mmol) at room temperature and stirred for 15 min to form 4-trimethylsilyloxy iodide (**11**) (Jung and Lyster, 1977). The reaction mixture was treated with a solution of $CuCN \cdot (LiCl)_2$ in THF (1 M, 100 μl), cooled to −40°C, and the solution of Grignard reagent **10** described in the preceding paragraph was then added over a period of 30 min (Tamura and Kochi, 1971; Lipshutz et al., 1984). The mixture was stirred at −40 to −20°C for 1 hr, followed by an additional 1 hr at room temperature. The reaction was quenched with NH_4Cl solution and ammonia mixture (2 : 1 v/v), and the product was extracted with hexane–ether (1 : 1) mixture (R_f = 0.60, 19 : 1 hexane–ethyl acetate, v/v). The crude product was dissolved in THF (6 ml), and deprotected with tetrabutylammonium fluoride solution in THF (1 M, 2 ml). The alcohol formed was acetylated with Ac_2O–pyridine mixture (1 : 10 v/v). Flash chromatographic purification afforded (8Z,11Z)-8,11-tetradecadien-1-yl acetate **2** (80 mg) in 34% yield based on the starting bromide **9.**

^{1}H NMR (400 MHz) δ: 5.36 (m, 4H, CH=CH-8, 9, 11, 12), 4.05 (t, J = 6.7, 7.0 Hz, 2H, CH_2-1), 2.77 (dd, J = 6.4, 6.4 Hz, 2H, =CH-CH_2-CH=), 2.06 (m, 4H, CH_2-7, 13), 2.04 (s, 3H, -$COCH_3$), 1.60 (tt, J = 7.3, 7.3, 7.6, 7.6 Hz, 2H, CH_2-6), 1.4-1.2 (m, 8H, CH_2-2, -3, -4, -5) 0.97 (t, J = 7.3, 7.6 Hz, 3H, CH_3-14). ^{13}C NMR (100.6 MHz) δ: 171.2 (C=O), 131.7 (=CH-12), 130.0 (=CH-11), 128.0 (=CH-9), 127.3 (=CH-8), 64.6 (CH_2-1), 29.5 (CH_2-2), 29.1 (CH_2-3, 4), 28.6 (CH_2-5), 27.2 (CH_2-6), 25.9 (CH_2-7), 25.5 (CH_2-10), 21.0 (CH_3C=O), 20.5 (CH_2-13), 14.3 (CH_3). (3E,8Z)-3,8-Tetradecadienyl Acetate (3)

1-(Tetrahydropyran-2-yloxy)-4-decyne (13). A solution of 1-(tetrahydropyran-2-yloxy)-4-pentyne (**5**) (0.66 g, 3.90 mmol) in THF (3 ml) was metallated with n-butyllithium solution (2.5 M) in hexane (1.87 ml, 1.2 eq.), and a solution of n-pentyl bromide (0.725 ml, 1.5 eq.) in DMPU (2 ml) was added. This procedure gave 0.54 g (58% yield) of compound **13.**

^{1}H NMR (200 MHz) δ: 4.60 (m, 1H, CH-2′), 3.65 (m, 4H, CH_2-1, 6′),

2.26 (tt, J = 7.0, 7.0, 2.0, 2.0 Hz, 2H, CH_2-3), 2.13 (tt, J = 7.0, 7.0, 2.5, 2.5 Hz, 2H, CH_2-6), 1.77 (tt, J = 6.8, 6.8, 7.0, 7.0 Hz, 2H, CH_2-2), 1.33 (m, 6H, CH_2-7, 8, 9), 1.52 (m, 6H, CH_2-3′, 4′, 5′), 0.89 (t, J = 7.0 Hz, 3H, CH_3). MS [FAB, m/z(%)] 237 ($M^+ - 1$), 85 (100). IR (CCl_4, cm^{-1}) 2229, 1322, 1331, 1201, 1138, 1121, 1034.

*(4Z)-1-(Tetrahydropyran-2-yloxy)-4-decene (**14**).* 1-(Tetrahydropyran-2-yloxy)-4-decyne (**13**) (0.5 g, 2.1 mmol) was hydrogenated in ethanol (20 ml) over *P*2-Ni, formed from nickel acetate (75 mg) deactivated with ethylenediamine (0.2 ml) for 4 hr (Brown and Ahuja, 1973). After chromatography on silica gel, the product (**14**) (0.43 g) was obtained in 85% yield. GC (R_t): starting material **13,** 22.18 min, 0.4%; desired product **14,** 21.59 min, 97.9%; the 4*E* isomer of **14,** 21.75 min, 1.7%.

^{1}H NMR (200 MHz) δ: 5.37 (m, 2H, CH=CH-4, 5), 4.58 (m, 1H, CH-2′), 3.60 (m, 4H, CH_2-1, 6′); 2.12 (m, 2H, CH_2-6); 2.04 (m, 2H, CH_2-3); 1.16 (tt, 2H, J = 6.8, 6.8, 7.0, 7.0 Hz, CH_2-2); 1.4–1.9 (m, 6H, CH_2-3′, 4′, 5′); 1.29 (m, 6H, CH_2-7, 8, 9); 0.88 (t, 3H, J = 7.0 Hz, CH_3). IR (CCl_4, cm^{-1}) 3007, 1653, 1201, 1138, 1120, 1034. MS [FAB, m/z (%)] 239 ($M^+ - 1$), 85 (100).

*(4Z)-1-Bromodec-4-ene (**15**).* To an ice-cool solution of triphenylphosphine (0.72 g, 2.74 mmol) and bromine (0.41 g, 2.6 mmol) in CH_2Cl_2, a solution of (4*Z*)-1-(tetrahydropyran-2-yloxy)-4-decene (**14**) in CH_2Cl_2 (0.41 g, 1.71 mmol) was added dropwise (Bestmann and Gunawardena, 1992). The usual work-up (Attygalle et al., 1996) gave the product **15** in 90% yield (0.33 g).

^{1}H NMR (200 MHz) δ: 5.42 (dtt, J = 11.0, 7.0, 7.0, 1.0, 1.0 Hz, 2H, CH=CH-4, 5), 3.41 (t, J = 6.6, 6.6 Hz, 2H, CH_2-1), 2.20 (dt, J = 7.0, 7.0, 7.0 Hz, 2H, CH_2-3), 2.04 (dt, J = 6.5, 6.5, 6.5 Hz, 2H, CH_2-6), 1.91 (tt, J = 6.5, 6.5, 6.5 Hz, 2H, CH_2-2), 1.30 (m, 6H, CH_2-7, 8, 9), 0.89 (t, J = 7.0 Hz, 3H, CH_3). MS [EI MSD, m/z (%)] 220 (M^+, 8), 218 (M^+, 8), 164 (12), 162 (12), 150 (23), 148 (23), 135 (8), 109 (12), 97 (44), 95 (14), 83 (55), 82 (14), 81 (37), 79 (15), 70 (21), 69 (100), 67 (39), 56 (29), 55 (93), 54 (20), 43 (21), 42 (20), 41 (92), 39 (30). IR (CCl_4, cm^{-1}) 3008 (*cis* CH=CH), 1246 (RCH_2CH_2Br), 649, 566 (C-Br).

*(8Z)-1-(Tetrahydropyran-2-yloxy)-8-tetradecen-3-yne (**16**).* 1-(Tetrahydropyran-2-yloxy)-3-butyne (0.30 g, 1.94 mmol) was metallated at 0°C with *n*-butyllithium (2.0 M) hexane solution (1.0 ml, 1.0 eq.). The lithium acetylide that formed was alkylated with the bromide **15** (0.20 g, 0.92 mmol), using 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidine (DMPU) as the base. This reaction afforded 214 mg of a mixture containing the desired product **16,** 1-(tetrahydropyran-2-yloxy)-3-butyne (one of the starting materials; 29%), and a nonpolar impurity identified as (8*Z*)-1,8-tetradecadien-4-yne (**19**) (28%). The impurities were removed from compound **16** (52% yield based on **15**) by repeated column chromatography.

^{1}H NMR (200 MHz) (**16**) δ: 5.35 (dtt, J = 11.0, 7.0, 7.0, 1.0, 1.0 Hz, 2H, CH=CH-8, 9), 4.64 (m, 1H, CH-2′), 3.58 (m, 4H, CH_2-1, 6′), 2.46 (tt, J = 7.5, 7.5, 2.5, 2.5 Hz, 2H, CH_2-2), 2.14 (tt, J = 7.0, 7.0, 2.5, 2.5 Hz, 2H, CH_2-5), 2.10 (m, 2H, CH_2-7), 2.04 (dt, J = 6.5, 6.5, 7.0 Hz, CH_2-10), 1.29 (m, 6H, CH_2-11, 12, 13), 1.9–1.4 (m, 8H, CH_2-6, 3′, 4′, 5′), 0.89 (t, J = 7.0 Hz, 3H, CH_3). MS [EI MSD, m/z (%)] (**16**) 133 (12), 107 (10), 85 (100), 67 (15), 55 (8). MS [FAB, m/z] 293.2 (M^+). IR (CCl_4, cm^{-1}) (**16**) 3007 (*cis*-CH=CH), 2232 (acetylenic), 1403, 1201, 1184, 1137, 1122, 1034 (CH_n—O—).

^{1}H NMR (200 MHz) [(8*Z*)-1,8-tetradecadien-3-yne(**19**)] δ: 5.78 (ddt, J = 22.5, 10.5, 2.2, 2.2 Hz, 1H, =CH-2), 5.54 (dd, J = 22.5, 2.7 Hz, 1H, $=CH_2$-1a), 5.36 (dd, J = 10.5, 2.2 MHz, 1H, CH_2-1b), 5.36 (dtt, J = 11.0, 7.0, 7.0, 1.0, 1.0 Hz, 2H, CH=CH-8, 9), 2.31 (dt, J = 2.1, 7.3, 7.3 Hz, 2H, CH_2-5), 2.15 (dt, J = 7.0, 7.3, 7.3 Hz, 2H, CH_2-10), 2.03 (dt, J = 6.4, 6.4, 6.7 Hz, 2H, CH_2-7), 1.59 (tt, J = 7.0, 7.0, 8.0, 8.0 Hz, 2H, CH_2-6), 1.30 (m, 6H, CH_2-11, 12, 13), 0.89 (t, J = 7.0 Hz, 3H, CH_3). ^{13}C NMR ($CDCl_3$) (**19**) δ: 131.1 (=CH-9), 126.4 (=CH-8), 125.5 ($=CH_2$-1), 117.6 (=CH-2), 90.9 (≡C-4), 79.5 (≡C-3), 31.5 (CH_2-12), 29.4 (CH_2-10), 28.7 (CH_2-7), 27.2 (CH_2-11), 26.3 (CH_2-6), 22.6 (CH_2-5), 18.8 (CH_2-13), 14.1 (CH_3-14). MS [EI MSD, m/z (%)] (**19**) 161 (M^+ −29, 5), 133 (35), 119 (25), 105 (50), 91 (100), 79 (35), 67 (30), 41 (50). Wind-Tunnel Experiments

Synthetic samples of test compounds were applied as pentane solutions to rubber septa (cleaned by washing with CH_2Cl_2 for 20 hr in a Soxhlet apparatus), which were used as baits in the wind tunnel. The attractivity of baits loaded with either 100 ng of (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate (**1**), or each individual diene acetate (100 ng, **2–4**), or mixtures of 100 ng of **1** with 10 ng

of each diene acetate **2, 3,** and **4** were compared to that of three calling virgin females (1 to 4 days old) in a cage. The control baits were treated with 100 μl of hexane. The wind tunnel (3.8 × 0.50 m) was operated at a flux speed of 30 cm/sec. The landing platform was 1 m away from the "takeoff" platform. For each experiment, three males (1 to 3 days old) were placed on the takeoff platform and their behavioral responses were observed for 5 min. The test was repeated 10 times for each test sample.

RESULTS AND DISCUSSION

In order to characterize the minor component of the *S. absoluta* pheromone, the dienes **2, 3,** and **4** were synthesized. (8*Z*,11*Z*)-8,11-Tetradecadienyl acetate (**2**) was synthesized according to the reaction shown in Scheme 1.

Intermediates **5–9** were synthesized according to procedures described previously for the synthesis of (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate (**1**) (Attygalle et al., 1996). 1-Iodo-4-trimethylsilyloxybutane (**11**) was prepared in situ from iodotrimethylsilane and an excess of tetrahydrofuran and allowed to react under Cu(I) catalysis with the Grignard reagent **10,** which was prepared freshly from the bromide **9.** The TMS ether (**12**) obtained in this way was deprotected with a THF solution of tetrabutylammonium fluoride and acetylated

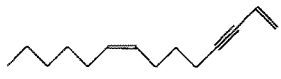
to give the desired dienyl acetate **2** in 34% yield based on the starting bromide **9.**

(3*E*,8*Z*)-3,8-Tetradecadienyl acetate (**3**) was synthesized according to the reaction shown in Scheme 2. This synthesis also employed procedures similar to those used for the synthesis of (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate (**1**), the major pheromone component (Attygalle et al., 1996). An alkylation of the lithiated 1-(tetrahydropyran-2-yloxy)-4-pentyne (**5**) in THF with *n*-pentyl bromide, using 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (DMPU) as the base, gave the THP protected alcohol **13.** The reduction of the triple bond in **13** to a *Z* double bond was accomplished by using P2 nickel catalyst (Brown and Ahuja, 1973). The reaction proceeded with high stereoselectivity (98.3% *Z* isomer). Subsequently, using 1.5 eq of $PPh_3 \cdot Br_2$ (Bestmann and Gunawardena, 1992), the tetrahydropyranyl protected hydroxyl group in **14** was replaced by a bromine atom. A coupling of the lithiated 1-(tetrahydropyran-2-yloxy)-3-butyne with the above-prepared bromide **15,** using DMPU as the base, gave the desired THP protected alkeneynol **16.** However, this reaction also produced a nonpolar impurity, which showed a similar R_f value but a different GC retention time compared to those of the starting bromide **15.** This by-product was removed from the bromide **15** by repeated silica gel chromatography. Based on spectral data, this impurity was identified as (*Z*)-1,8-tetradecadien-3-yne (19, Figure 2).



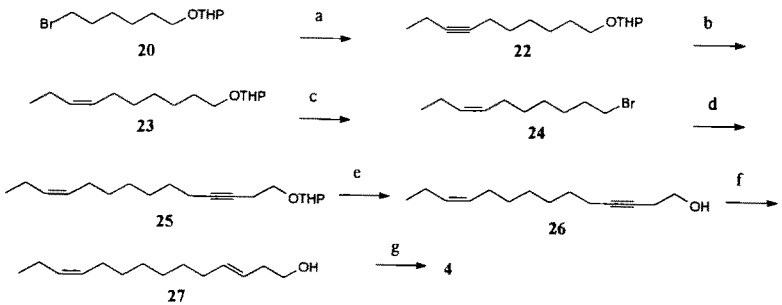
19

FIG. 2. Structure of compound **19.**

This by-product might be expected from a base-catalyzed elimination of the homopropargylic tetrahydropyranyl group. Although this process, to the best of our knowledge, has not been described previously, we have observed other instances in which THP protected 3-alkyn-1-ols give unsaturated impurities even under acidic conditions (TsOH/MeOH also gives rise to the hydrocarbon by-product **19**). In any case, the tetrahydropyranyl protecting group in **16** could be successfully removed, using a Dowex ion-exchange resin in MeOH at room temperature. The product, alcohol **17**, was reduced stereospecifically to dienol **18** with $LiAlH_4$ in diglyme (Rossi and Carpita, 1977). Finally, the reaction mixture containing the dienol **18** was acetylated with Ac_2O/pyridine to give the desired dienyl acetate **3**. Chromatography on a silver-nitrate impregnated silica gel column gave the final product, (3*E*,8*Z*)-3,8-tetradecadien-1-yl acetate **3**, in 97% purity and 17% overall yield (based on lithiated 1-(tetrahydopyran-2-yloxy)-4-pentyne) (Scheme 2).

For the synthesis of (3*E*,11*Z*)-3,11-tetradecadien-1-yl acetate (**4**), we used a procedure similar to that used for the preparation of (3*E*,8*Z*)-3,8-tetradecadien-1-yl acetate (**3**) (Scheme 2). Starting from 1-butynyllithium (**21**) and 1-bromo-6-(tetrahydropyran-2-yloxy)-hexane (**20**), we prepared (3*E*,11*Z*)-3,11-tetradecadien-1-yl acetate in 15% overall yield and in 96% stereoisomeric purity (Scheme 3).

The ion-trap electron-ionization mass spectra of dienes **2**, **3**, and **4** were recorded and compared with those obtained under similar conditions a few months earlier from *S. absoluta* females. Although spectra recorded at different times, even under similar conditions, tend to differ slightly, a comparison of relative intensities within each cluster of *m/z* values provides a more reliable way of asserting whether two spectra represent the same compound or not. An application of this procedure to the spectra presented in Figure 3 disclosed that the



SCHEME 3. (a) Li—≡—/(**21**), DMPU, 0°C; (b) P-2 Ni/H_2; (c) PPh_3/Br_2 1.5 eq, CH_2Cl_2, 0°C; (d) Li—≡—OTHP, DMPU/THF 0°C; (e) Dowex/MeOH; (f) $LiAlH_4$/diglyme, 120–140°C; (g) Ac_2O/pyridine.

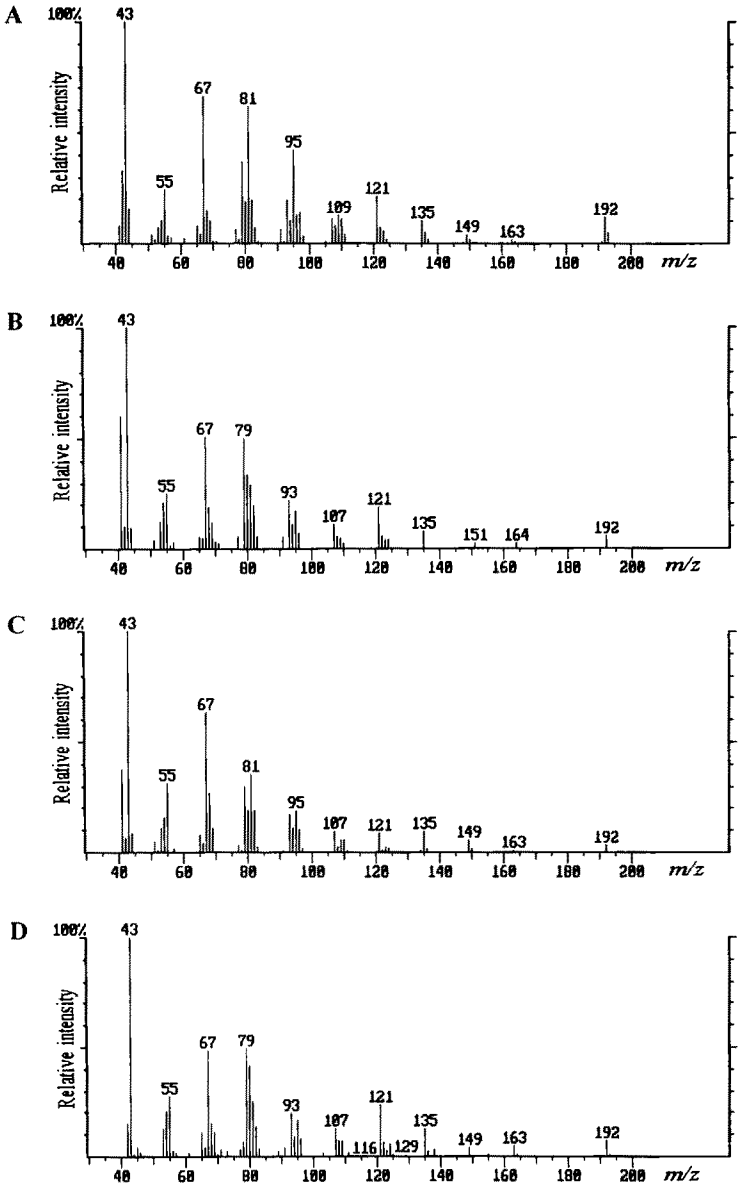


FIG. 3. Ion-trap electron-impact mass spectra of (8*Z*,11*Z*)-8,11-tetradecadien-1-yl acetate (A), (3*E*,8*Z*)-3,8-tetradecadien-1-yl acetate (B), (3*E*,11*Z*)-3,11-tetradecadien-1-yl acetate (C), and the diene acetate from *S. absoluta* (D).

spectrum of synthetic (3*E*,8*Z*)-3,8-tetradecadien-1-yl acetate (**3**) is congruent with that of the natural product. The relative intensities of peaks centered near *m/z* 79 and 91 were particularly useful for characterization of each isomer.

Behavioral activity released by the three synthetic dienes (**2–4**), and by (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate (**1**) was studied in a wind-tunnel bioassay. The diene acetates, although they released some wing-fanning behavior, were essentially inactive, since none of the test insects landed at the source (Figure 4). On the other hand, (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate, the major component of the pheromone, is active by itself, as observed in our previous experiments (Attygalle et al., 1995; 1996). Under the test conditions used in the present study, 53% of test males (N = 30) landed at the source baited only with the triene acetate, while three calling females could induce

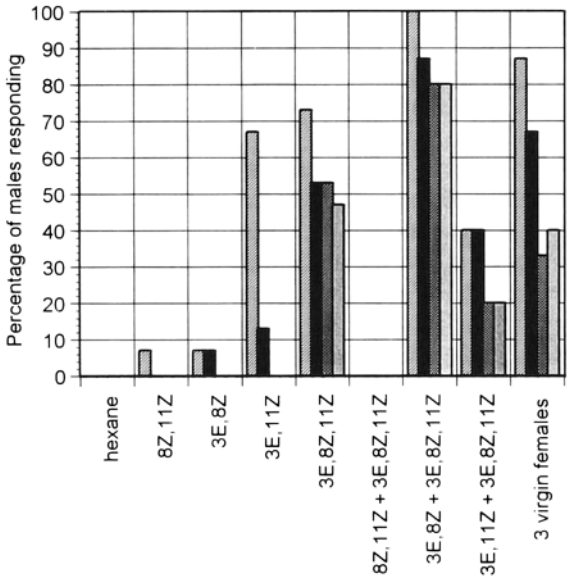

FIG. 4. Percentage of male moths responding in a wind-tunnel behavioral bioassay. Hatched, black, cross-hatched, and stippled bars represent wing fanning, oriented flight, landing at the source, and courtship behavior, respectively. Behavior of 30 males was observed for each test stimulus. Hexane (100 μl) and three calling females were used as control stimuli. Samples of (8*Z*,11*Z*)-, (3*E*,8*Z*)-, and (3*E*,11*Z*)-tetradecadien-1-yl acetate, and (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate were tested individually at the 100-ng level. Binary mixtures contained 10 ng of a diene acetate (**2–4**) and 100 ng of the triene acetate (**1**).

only 33% of the test males to behave similarly. However, the activity released by the binary mixture made of (3*E*,8*Z*)-3,8-tetradecadien-1-yl acetate (**3**) and (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrien-1-yl acetate (**1**) was significantly better (chi-square analysis, $P < 0.001$) than that of the triene acetate alone (Figure 4). This mixture induced 80% of the males to land at the source and show courtship behavior. Interestingly, the activity of the triene acetate is inhibited dramatically by the presence of (8*Z*,11*Z*)-8,11-tetradecadien-1-yl acetate (**2**). The potency of (8*Z*,11*Z*)-8,11-tetradecadien-1-yl acetate as an inhibitor is unequivocal; a binary mixture (10:1 of **1** and **2**) completely failed even to release wing-fanning behavior.

Over 400 compounds have been characterized as constituents of lepidopteran female sex pheromones (Arn et al., 1992; Mayer and McLaughlin, 1991). However, acetates **1** and **3** of *S. absoluta* have not been identified from any other insect. Although our two-component synthetic mixture was more attractive to *S. absoluta* males than the triene acetate alone, it was clear that *S. absoluta* is far less sensitive to the absence of the minor component than most other Lepidoptera that are characteristically highly sensitive to small qualitative or even quantitative changes in the composition of pheromone blends. As we gather more and more data on the composition of lepidopteran pheromones, it will be interesting to see whether moths using structurally less complicated chemicals as pheromones, such as (*Z*)-11-tetradecenyl acetate (a simple ester shared by many species of Lepidoptera as a component of pheromone blends), are more sensitive to qualitative and quantitative variations in composition than are those using less common, more "information-rich" structures.

(Received April 3 1995; accepted: December 5 1995)

Abstract—The goal of this investigation was to determine the effects of allelochemicals on plant respiration that thereby may be responsible for their role in growth inhibition. We have tested the effects of juglone, quercetin, cinnamic acid, and α-pinene on respiration rates, and electron partitioning through the cytochrome and alternative respiratory pathways, by measuring on-line oxygen consumption and oxygen isotope fractionation in soybean cotyledon tissue. Cinnamic acid and α-pinene decreased the oxygen consumption rate and increased the relative partitioning of electron transport to the alternative pathway. Possible biochemical mechanisms of these effects are discussed.

Key Words—Allelopathy, alternative oxidase, α-pinene, cinnamic acid, juglone, on-line ^{18}O fractionation, quercetin, respiration, soybean.

INTRODUCTION

There remains considerable controversy as to the ecological relevance of allelopathy, and not all ecologists accept the concept as a significant competitive factor in plant communities (Harper, 1977; Harborne, 1993; Peñuelas, 1993).

We aimed to determine the possible effects of allelochemicals on plant energy metabolism and consequently their role in growth inhibition. We have tested the effect of some typical, widely occurring allelochemicals from different

*To whom correspondence should be addressed.

0098-0331/96/0400-0801$09.50/0 © 1996 Plenum Publishing Corporation

chemical families (the quinone juglone, the flavonoid quercetin, the phenolic cinnamic acid, and the terpenoid α-pinene) on soybean cotyledon respiration rates and on partitioning through cytochrome and alternative respiratory pathways. We studied the respiratory response of soybean cotyledons, these being one of the most widely used vegetable materials in plant respiration studies. We avoided problems associated with the traditional use of inhibitors such as SHAM or KCN by using on-line fractionation against ^{18}O, which is substantially greater by the alternative oxidase than by cytochrome oxidase (Guy et al., 1989; Robinson et al., 1992).

METHODS AND MATERIALS

We conducted on-line measurements of oxygen consumption and oxygen isotope fractionation (Δ) during dark respiration by soybean cotyledons. Immediately before recording the measurements, 30 soybean cotyledons in darkness were bathed for 30 min in $CaCl_2$ aqueous solutions with 10 mM of each of the tested allelochemicals (quercetin, juglone, and cinnamic acid from Sigma Chemical Co.) except for α-pinene (also from Sigma Chemical Co.), which was kept in an open beaker volatilizing inside the gas-tight syringe chamber we used to measure respiration.

Full details of the equipment and methods for these on-line measurements are described in Robinson et al. (1992). In these experiments we introduced the following modifications and improvements. Thirty soybean cotyledons inside a gas-tight 50-ml chamber were allowed to respire. At regular time intervals, gas samples of 100 μl were withdrawn and injected directly into helium flow to a GC-MS, after stripping water and CO_2. For all the measurements the room temperature was 25°C. The fractionation factor (D) was calculated as the slope of the linear regression of $\ln(R/R_0)$ versus $-\ln f$ through the origin (Guy et al., 1989), where f is the fraction of the original O_2 in the reaction chamber, and R_0 and R are the isotope ratios ($^{18}O/^{16}O$) of the initial and subsequent samples (for all the measured relationships r^2 was larger than 0.99). The fractionation Δ was calculated from D using the equation $\Delta = D/(1 - D)$. These experiments consisted of 8–12 oxygen measurements and were replicated three to six times for each of the allelochemicals studied.

RESULTS AND DISCUSSION

Cinnamic acid and α-pinene (the smaller molecules tested, and therefore the ones more likely to penetrate live tissues) decreased the oxygen consumption rate, while quercetin and juglone had no significant effect (Table 1). These results agree with data suggesting perturbations of mitochondrial and chloroplast

TABLE 1. OXYGEN CONSUMPTION RATES, OXYGEN ISOTOPE DISCRIMINATION Δ, AND PARTITIONING OF RESPIRATORY PATHWAYS IN SOYBEAN COTYLEDONS[a]

	Control	Quercetin	Juglone	α-Pinene	Cinnamic
Respiration (μmol O_2 uptake/g dw/hr)	88.63 ± 6.65	112.68 ± 13.3	85.92 ± 15.96	62.91 ± 3.99[b]	57.59 ± 2.66[b]
Discrimination against ^{18}O (‰)	24.3 ± 0.12	23.7 ± 0.16	23.4 ± 0.15	25.2 ± 0.25[b]	26.8 ± 0.36[b]
Alternative pathway flux (μmol O_2 uptake/g dw/hr)	37.74 ± 2.7	34.93 ± 4.3	28.78 ± 4.7	29.81 ± 1.9	35.53 ± 2.3
Cytochrome pathway flux (μmol O_2 uptake/g dw/hr)	50.89 ± 4.2	77.75 ± 9.2	57.14 ± 8.2	33.1 ± 2.4[b]	22.06 ± 1.1[b]

[a]Cotyledons were bathed for 30 minutes (in darkness) in $CaCl_2$ aqueous solutions with 10 mM of each one of the allelochemicals tested, except α-pinene, which was kept in an open beaker volatilizing inside the gas-tight chamber where we measured respiration. Data of three to six experiments per treatment (8–12 oxygen measurements were conducted in each experiment).

[b]Significantly different from the control at 0.05 probability level according to Student's *t* test for two paired groups.

functions linked to plant growth reductions observed in classical allelopathy experiments (Pellesier, 1993; Hejl et al., 1993; see references in Einhellig, 1995). However, they do not agree with the general hierarchy of allelopathic activity: quinones > flavonoids > phenolic acids (Einhellig, 1995).

The fractionation (Δ) ranged between 31‰ when KCN was used to inhibit the cytochrome pathway and 20‰ when SHAM was used to inhibit alternative oxidase. The Δ of 24.3‰ in control treatments was increased to 26.8‰ by cinnamic acid treatment (Figure 1), indicating an increased percentage of respiratory flux to the alternative pathway from 39 to 62%. The relative partitioning of electron transport to the alternative oxidase pathway was also increased (higher Δ) by α-pinene (Table 1), but was not significantly changed by quercetin or juglone (Table 1). However, none of these allelochemicals changed the absolute electron flux through the alternative pathway (Table 1). Thus, the inhibition of respiration occurred in the cytochrome pathway and possibly in glycolysis; otherwise the redox state of the ubiquinone pool would have increased and enhanced the flux through alternative pathway. The effects on respiration could be secondary through other cell functions, such as, for example, ion uptake, which are energy demanding. Further work on isolated mitochondria is necessary to clarify the situation.

The studies conducted here dealt with responses of isolated allelochemicals,

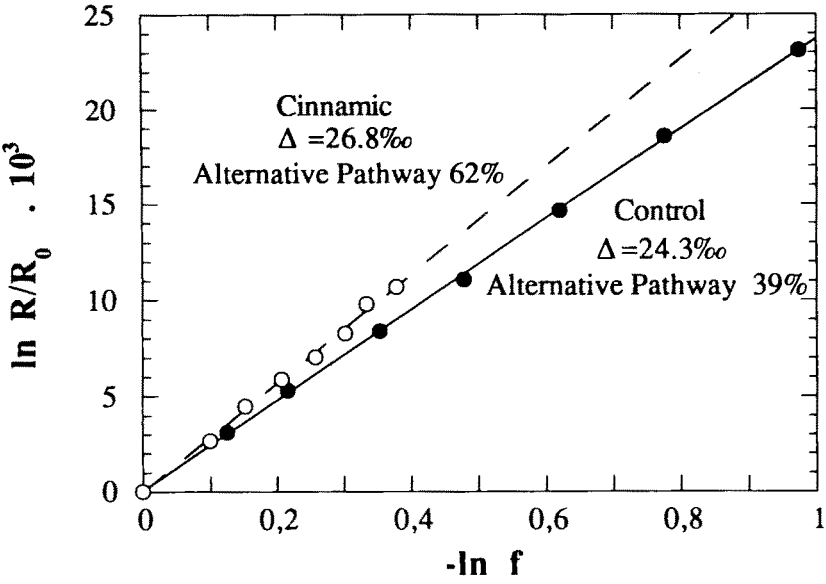

FIG. 1. Example of on-line measurements of oxygen consumption and oxygen isotope fractionation, Δ, during dark respiration by soybean cotyledons. The fraction of the original O_2 in the reaction chamber is f, and R_0 and R are the isotope ratios ($^{18}O/^{16}O$) of the initial and subsequent samples ($r^2 > 0.99$ for all the measured relationships between $\ln R/R_0$ and $-\ln f$). The Δ ranged between 31‰ when KNC was used to inhibit the cytochrome pathway and 20‰ when SHAM was used to inhibit alternative oxidase. Therefore, partitioning to the alternative pathway was calculated as $(\Delta - 20)/(31 - 20)$. These measurements were replicated three to six times for each of the allelochemicals studied (results in Table 1).

and in the short-term, of the order of 1 hr. Of course, such an approach is far from the extreme chemical complexity of the soil and air environment, and additional studies are required to determine how and at what concentrations these substances become actual allelochemicals. Nevertheless, the method used here provides an indication that these allelochemicals alter normal oxygen uptake and may influence significant competitive effects on neighboring plants.

(Received August 11, 1995; accepted December 5, 1995)

Abstract—On potted nonfruiting host trees in outdoor field cages, we evaluated attraction of released mature laboratory-cultured or wild-origin Mediterranean fruit flies (medflies) to odor of freshly picked fruit of host and nonhost plants. Odor of ripe intact or crushed coffee fruit (the presumed ancestral host of medflies) was significantly more attractive than odor of ripe intact or crushed fruit of five lower-ranking hosts and three nonhosts. Odor of crushed coffee fruit was significantly more attractive than odor of intact coffee fruit. Odor of ripe or near-ripe coffee fruit was significantly more attractive than odor of unripe coffee fruit. Immature females (without eggs) were significantly more attracted to odor of a proteinaceous food lure than to odor of ripe coffee fruit, whereas the reverse was true for mature females carrying a high egg load. In some trials, males proved as discriminating as females in favor of coffee fruit odor, but in several other trials males were less discriminating than females. Response patterns of mature laboratory-cultured females were similar to those of mature wild-origin females. In a field of coffee plants, attraction of natural-population females was significantly greater to odor of ripe coffee fruit than to water but was not greater than attraction to odor of proteinaceous food. Findings are discussed in relation to potential use of synthetic volatiles of coffee or other host fruit in traps for monitoring or controlling medflies.

Key Words—Attractants, odor, host fruit, coffee fruit, *Ceratitis capitata*.

INTRODUCTION

Numerous kinds of insects are known to be attracted to odor of their host plants. Most examples involve monophagous or oligophagous species, but in a few cases, polyphagous insects also have exhibited attraction to host plant odor (examples given in Bernays and Chapman, 1994). In tephritid flies, adult attraction to the odor of host fruit in favorable condition for oviposition has been demonstrated in the monophagous papaya fruit fly, *Toxotrypana curvicauda* Gerstaecker (Landolt et al., 1992), the monophagous olive fruit fly, *Bactrocera oleae* (Gmelin) (Scarpati et al., 1993), the oligophagous apple maggot fly, *Rhagoletis pomonella* (Walsh) (Prokopy et al., 1973; Averill et al., 1988), the polyphagous oriental fruit fly, *Bactrocera dorsalis* Hendel (Jang and Light, 1991), the polyphagous Queensland fruit fly, *Bactrocera tryoni* (Froggatt) (Eisemann and Rice, 1992), and the polyphagous Caribbean fruit fly, *Anastrepha suspensa* (Loew) (Nigg et al., 1994).

The Mediterranean fruit fly (medfly), *Ceratitis capitata* (Wiedemann), is a highly polyphagous tephritid that oviposits and develops in more than 300 species of fruits and vegetables (Liquido et al., 1991). To date most studies of medfly reaction to plant odor have involved measuring electroantennogram responses to a spectrum of plant volatiles, including several volatile constituents of host fruit and foliage (e.g., Guerin et al., 1983; Light et al., 1988, 1992). Regarding behavioral responses of medflies to plant odor, Levinson et al. (1990) presented laboratory-cage evidence suggesting lack of medfly attraction to odor of oranges, *Citrus sinesis* (a principal host), but in field cage tests, Katsoyannos et al. (1995) have shown that both sexes of medflies are in fact attracted to odor of oranges. Using an outdoor olfactometer, Keiser et al. (1975) demonstrated significantly greater captures of medflies in traps baited with solvent extracts of various structures of a wide variety of plants (nearly all of which were nonhosts) compared with captures in unbaited traps. Finally, under field conditions, Guerin et al. (1983) found that medflies were attracted to traps baited with heptanal, a constituent of the fruit of several medfly host plants.

Here, in tests conducted in a patch of nonfruiting host trees in an outdoor field cage, we asked whether medflies were more attracted to odor of the fruit of coffee, *Coffea arabica* (the presumed ancestral host of medflies in Africa (Vargas et al., 1995)), than to odor of lower-ranking host fruit and nonhost fruit. We also asked whether both sexes were equal in discrimination among fruit odors of the various types tested, whether crushed fruit was more attractive than intact fruit, whether ripe fruit was more attractive than unripe fruit, whether attraction to host fruit odor was greater or lesser than that to food odor among flies of differing physiological states, and whether response patterns of wild-origin medflies differed from those of laboratory-cultured medflies. Finally, we

asked whether natural-population medflies in the field exhibited a level of response to host fruit odor similar to that of medflies in the field cage.

METHODS AND MATERIALS

Medflies used in field cage tests originated either from a laboratory colony in culture for 10 generations at the USDA Tropical Fruit and Vegetable Research Laboratory in Honolulu or from natural-population larvae that infested field-collected coffee fruit. Unless indicated otherwise, from eclosion until tested 7–10 days afterward (for lab-cultured flies) or 14–18 days afterward (for wild-origin flies), both sexes were held together in 30- × 30- × 30-cm screened cages supplied with protein (enzymatic yeast hydrolysate), sucrose, and water but not fruit under laboratory conditions of about 25°C, 50% relative humidity, and 13 hr natural daylength.

Besides coffee, fruit used in field cage trials included five species that we considered to be low-ranking host fruit because in a 36-year survey in Hawaii (Liquido et al., 1990), only 1–9% of collected batches proved to be infested by medfly larvae (compared with 65% of collected coffee fruit batches found to be infested). These low-ranking host fruit included: guava, *Psidium guajava*; banana, *Musca paradisiaca*; tangerine, *Citrus reticulata*; papaya, *Carica papaya*; and avocado, *Persea americana*. We also evaluated three species of fruit that we considered to be nonhosts of medfly because none of the batches collected by Liquido et al. (1990) were found to be infested by medfly. These included: squash, *Cucurbita maxima*; macadamia nut, *Macadamia integrifolia*; and lipstick plant, *Bixa orellana*. All fruit were picked fresh from fruiting plants and placed immediately at 3°C until testing, which occurred 4–96 hr after picking. Unless stated otherwise, only fruit that we considered to be ripe and in optimum condition for potential medfly oviposition were picked and tested. Two hours before testing, fruit were rinsed with water, allowed to dry, and warmed to 25°C.

The first series of field cage experiments involved assessing attractiveness of odor of intact fruit of each type. In these and all other experiments, fruit of a single type was placed in a cylindrical clear-plastic container (11 × 13 cm) whose side and bottom was covered with aluminum foil to obscure visibility of fruit within. All but the 1-cm periphery of the clear-plastic lid consisted of nylon netting that effectively obscured visibility of fruit but permitted air flow. The number of fruit placed in each container was adjusted so that a total of ~ 140 cm^2 of fruit surface area was exposed to air. With coffee, this was equivalent to 30 fruit that filled to capacity the floor of the container. In cases where the surface area of a single intact fruit exceeded ~ 140 cm^2, excess area was tightly

enveloped in aluminum foil to prevent odor escape. The second series of field cage experiments involved assessing attractiveness of the odor of 5 g per container of freshly crushed skin and flesh of fruit of each type. Succeeding field cage experiments involved primarily the evaluation of medfly response to the odor of various conditions of coffee fruit or Nulure (Miller Chemical Co., Hanover, Pennsylvania), a proteinaceous food-type attractant. We formulated Nulure according to Wakabayashi and Cunningham (1991): 9% Nulure, 5% sodium borate, and 86% water. We used an amount that covered the floor of the container.

All field-cage trials were carried out from 09:00–16:00 hr in a cylindrical, 3-m-tall × 3-m-diam., clear nylon-screen enclosure placed outdoors on the grounds of the USDA Tropical Fruit and Vegetable Research Laboratory in Honolulu. The top of the enclosure was covered with a partly opaque tarpaulin to exclude direct sunlight and rainfall. Flow of wind through the cage was regulated to 0–3 km/hr by using an adjustable, clear-plastic wind barrier at the upwind side of the cage wall. The cage contained four potted nonfruiting guava trees grouped near the center of the cage to form a continuous canopy (120 cm tall × 220 cm diam.). Before use, the foliage and stems of each tree were rinsed thoroughly with water.

At each of four positions within the canopy, we hung a single container of test substance. The positions were about 90 cm apart along the circumference of an imaginary circle about 20 cm inward from the periphery of the upper part of the canopy. For each replicate of each experiment, about 25 flies of each sex were released as a group at the lower center of the canopy. We assumed (but did not document) a 50:50 sex ratio of released flies. Flies that arrived on the screened area of the lid of a container within the 5-min period allotted each replicate were considered as responding to odor of the contents, were sexed, and were removed by an aspirator. Treatment positions were randomized for the first replicate. Treatments were rotated clockwise within the canopy after each replicate until each treatment occupied each position once, requiring a total of about 25 min to complete a set of four replicates. For the next set of four replicates, we used a fresh batch of fruit. Most nonresponding flies had flown to the cage wall by the end of a replicate. To shorten time and hence minimize changes in the state of fruit over the course of testing, we adopted a 5-min test period rather than a longer test period and we did not collect and remove nonresponding flies until the end of an experiment. A separate batch of flies was used for each experiment. During experiments, temperature within the tree canopy ranged from 24 to 31°C.

The field test was conducted in a plantation of coffee plants on Kauai (Vargas et al., 1995) which, at the time of testing in March 1995, had recently been harvested. Very few fruit remained. A container of test substance was

inserted into a hole in the center of a 25- × 25-cm piece of horizontal brown cardboard in such a way that the screened lid of the container protruded about 3 cm above the Tangletrap-coated upper surface of the cardboard. Such traps were suspended 10 m apart from the branches of coffee plants. After 1 hr, captured natural-population medflies were counted and removed, the test fruit was replaced with freshly prepared batches, and the containers were moved to new positions.

Data were analyzed by two-way analysis of variance (ANOVA). Treatment means were compared using the least significant difference test criterion (0.05 level). For ANOVA, the 16 replicates per treatment per experiment were grouped into four sets of four replicates each. For each treatment, the value of a single set of four replicates consisted of the number of flies arriving on the screen of a container for all four positions of that treatment combined. We reasoned that grouping the data into sets of replicates for ANOVA was the most valid approach to minimizing varying effects of treatment position within the tree canopy on fly response to replicates within a set.

RESULTS

Field Cage Tests. In four experiments involving intact fruits, the odor of ripe coffee fruit was significantly more attractive to mature (egg-bearing) laboratory-cultured females than was the odor of five kinds of ripe low-ranking host fruit (guava, tangerine, papaya, banana, and avocado) or the odor of three kinds of ripe nonhost fruit (squash, macadamia nut, and lipstick plant) (Table 1). Except for papaya and avocado, the odor of low-ranking hosts was more attractive than water. Except for macadamia nut, the odor of nonhosts was not more attractive than water. In these four experiments, significantly more males were attracted to coffee odor than to the odor of tangerine, papaya, banana, or avocado (but not guava) (Table 1). Among low-ranking hosts, only the odor of banana attracted significantly more males than water. Except for lipstick plant, the odor of nonhosts was no more attractive to males than was water.

In four similarly designed experiments that involved comparing the response of mature laboratory-cultured medflies to the odor of crushed ripe fruit, again significantly more females were attracted to coffee odor than to the odor of any low-ranking host fruit or nonhost fruit (Table 1). Again, except for papaya and avocado, the odor of low-ranking hosts was more attractive than water, and, except for macadamia nut, the odor of nonhosts was no more attractive than water. In these four experiments, significantly more males were attracted to coffee odor than to the odor of papaya and avocado (but not guava, banana, or tangerine) (Table 1). Among low-ranking hosts, the odor of banana and tangerine (but not papaya, guava and avocado) attracted significantly more males

[a]Sixteen replicates per treatment. Values in each column in each experiment followed by the same letter are not significantly different at the 0.05 level according to least significant difference tests.

than water. Except for lipstick plant, the odor of nonhosts was no more attractive to males than water.

Each sex of mature laboratory-cultured medflies was significantly more attracted to the odor of 30 ripe crushed coffee fruit than to the odor of 30 ripe intact coffee fruit (Table 2). The odor of 30 ripe (dark red) and 30 near-ripe (orange-red) intact coffee fruit was no different in attractiveness to either sex of laboratory-cultured medfly; each was significantly more attractive to each sex than the odor of 30 unripe (green) intact coffee fruit, which proved to be no more attractive than water (Table 2).

One-day-old, laboratory-cultured, protein-fed females were significantly more attracted to the odor of Nulure than to the odor of 30 intact ripe coffee fruit, which was no more attractive than water or an empty container (Table 3). Three-day-old, laboratory-cultured, protein-fed females (having immature eggs only) responded similarly to 1-day-old females, except that coffee odor was now significantly more attractive than water or an empty container. In contrast, 10-day-old, laboratory-cultured, protein-fed females (having a large complement of mature eggs) were significantly more attracted to coffee odor than to Nulure, which was no more attractive than water or an empty container. Ten-day-old, laboratory-cultured, protein-deprived females (that had received only sucrose since eclosion) responded similarly to 3-day-old protein-fed females. The response pattern of 1-day-old and 10-day-old protein-fed males was the same as that of equivalent-type females, but 3-day-old protein-fed males and 10-day-old protein-deprived males did not discriminate among treatments (Table 3).

Coffee	1.6a	0.2b
Nulure	2.3a	2.7a
Water	0.2b	0.6b

[a] Same as footnote of Table 1 except 12 replicates per treatment.

When compared for attraction to the odor of equivalent surface areas of intact coffee fruit, intact guava fruit, Nulure, and water, mature, protein-fed, wild-origin and laboratory-cultured females responded similarly: they showed significantly greater attraction to coffee odor than to the odor of the other three treatments, among which there were no significant differences (Table 4). The same pattern held true for laboratory-cultured males but not for wild-origin males, which did not discriminate among treatment types (Table 4).

Field Test. Natural-population females in a coffee plantation were significantly more attracted to the odor of Nulure and 30 near-ripe crushed coffee fruit (no significant difference between these) than water (Table 5). Natural-population males were significantly more attracted to the odor of Nulure than to the odor of coffee fruit, which was no more attractive than water (Table 5).

DISCUSSION

Our findings show that mature laboratory-cultured medfly females were attracted to the odor of near-ripe and ripe coffee fruit (particularly recently crushed fruit), but not to the odor of unripe coffee fruit. Female response was weaker to the odor of tested types of lower-ranking host fruit and generally lacking to the odor of tested types of nonhost fruit, irrespective of whether such fruit were intact or crushed. Laboratory-cultured females carrying no mature eggs proved to be more attracted to the odor of proteinaceous food (Nulure) than to the odor of ripe intact coffee fruit, but the reverse was true for mature, egg-bearing females. When directly compared, response patterns of mature wild-origin females proved similar to those of mature laboratory-cultured females. Natural-population females were found to be attracted to odor of both Nulure and coffee fruit.

This is the first published study to show that the odor of fresh-picked coffee

fruit, the presumed ancestral host of medflies, is more attractive to medflies than fruit odor of lower ranking host and nonhost plants. To our knowledge, there exist three other studies that have examined the potential attractiveness of coffee plant odor to medflies. First, Keiser et al. (1975) found significant attraction of medfly females and males to ether extracts of coffee bark and stems, but they did not make extracts of coffee fruit. Such extracts proved more attractive than extracts of foliage, bark, or stems of most nonhosts tested, but odor of some nonhosts (e.g., *Diospyros discolor*, *Kallstroemia maxima*) proved more attractive than coffee odor. Second, Vargas and Chang (1991) found that harvest of eggs from oviposition bottles that contained a hot water extract of canned coffee grounds was significantly greater than that from bottles that contained orange, guava, or papaya juice. Third, Lance, Jang, and McInnis (unpublished data) have recent evidence that somewhat parallels the findings of our study: crushed ripe coffee fruit is attractive to both sexes of medflies under laboratory wind-tunnel as well as field conditions. Further research is needed to determine whether the odor of coffee fruit is more or less attractive than the odor of coffee foliage, stems, or woody tissue.

Our finding that the odor of near-ripe and ripe coffee fruit is much more attractive to medflies than the odor of unripe coffee fruit is consistent with the finding of Vargas et al. (1995) that oviposition by natural-population medflies in commercial plantations was dramatically (30 to 70-fold) greater in ripe than unripe coffee fruit. Similarly, Carle et al. (1987) showed that the odor of host fruit of *R. pomonella* was much more attractive to the flies when fruit was ripe than unripe. Furthermore, Jang and Light (1991) found that odor of host fruit of *B. dorsalis* increased in attractiveness to the flies with increasing ripeness of fruit. Together, these findings suggest that future study of the identity of volatile components of coffee plants attractive to medflies should be focused on plants whose fruit are near-ripe or ripe.

We were not surprised that the odor of freshly crushed coffee fruit was more attractive to medflies than the odor of intact coffee fruit. First, one would expect that a greater amount of volatile chemicals is released from recently wounded plant tissue than intact plant tissue (Finch, 1980). Second, Papaj et al. (1989, 1992) demonstrated that medfly females in search of egg-laying sites can respond positively and quickly to recent natural or artificial punctures in host fruit. Exploitation of fresh punctures as potential oviposition sites may be adaptive when females are limited in time available to drill punctures in fruit or when fruit are resistant to puncturing (Papaj et al., 1992), particularly in habitats where predators of ovipositing females are abundant (Papaj et al., 1989). Selection may have given rise to a high level of medfly sensitivity to the odor of host fruit released from fresh punctures (magnified here in the form of freshly crushed host fruit).

Our finding that female medflies were in several instances more responsive to coffee fruit odor than were male medflies parallels the finding of Keiser et al. (1975) that females were somewhat more attracted than males to the odor of coffee stems and bark. In addition, both Levinson et al. (1990) and Light et al. (1992) describe several instances of greater antennal receptor sensitivity of female than male medflies to host fruit volatiles. The biological basis of more frequently detected positive responses of medfly females than males to host odor is uncertain, but it could reside in a strong influence upon females of host odor as indicative of host plants or individual host fruit that are potentially favorable egg-laying sites, whereas host odor might have only a weak influence upon males as indicative of potentially favorable mating sites. Mating in medflies apparently occurs in the vicinity of host plants but is not always restricted to host plants (Hendrichs and Hendrichs, 1990).

The physiological state of an insect and the structure of the resource environment may have important effects on the order in which an insect prioritizes its visits to essential types of resources, such as feeding and egg-laying sites. Precisely how hunger and egg load interact in shaping resource foraging behavior has received considerable attention in insects such as *Blatella* cockroaches, *Phormia* and *Lucilia* blowflies, *Musca* face flies, *Glossina* tsetse flies, and several species of mosqitoes that have distinct ovarian cycles in which response to food stimuli and feeding gradually decline as a developing batch of oocytes approaches maturity (reviewed in Barton Browne, 1993). In tephritid flies, there is strong evidence indicating that *B. tryoni* and *R. pomonella* females denied access to protein and lacking fully developed eggs are more attracted to proteinaceous food than to egg-laying sites, whereas the opposite is true for females provided with protein and carrying moderate to large egg loads (Prokopy et al., 1991, 1995). Our findings here with laboratory-caged medflies whose age and diet prior to testing in field cages were carefully defined are consistent with the pattern exhibited by *B. tryoni* and *R. pomonella*. Unfortunately, we had no knowledge of fly age or feeding history in our study of natural-population medflies in the coffee field. We can only speculate that for whatever reason, those captured were roughly equally divided between females seeking proteinaceous food and females seeking egg-laying sites.

Together, the results of this study have implications for the design of traps used to monitor or control medflies. For example, current traps for medfly females rely solely upon proteinaceous food-type stimuli such as Nulure as attractants (Millar, 1995). If the environment in which food-type traps are placed has abundant natural food, such as honeydew or bird droppings (Nishida, 1980; Prokopy et al., 1992), or if females are not hungry for protein, then food-type traps may be comparatively ineffective in luring medflies. Synthetic host fruit odor could be a valuable complement to food odor in that it could attract females

seeking oviposition sites rather than food. Traps baited with synthetic fruit odor alone have proven very effective in monitoring *R. pomonella* flies in apple orchards (Agnello et al., 1990), while traps baited with a combination of synthetic food and synthetic fruit odor have provided good to excellent commercial control of *R. pomonella* (Prokopy et al., 1994). As pointed out by Millar (1995), competition from fruit odor emitted by host plants themselves and prior experience of natural-population females would have to be considered when developing strategies for deploying medfly traps baited with synthetic fruit odor. Before an intensive effort is made to identify and synthesize host volatiles attractive to female medflies, however, further study is needed to pinpoint which coffee plant structures and which phenological stages of coffee plant development do in fact emit the most attractive odor. Moreover, further study is needed to determine if the odor of coffee plants is more attractive than the odor of other high-ranking host plants of medfly. Finally, research is needed to assess whether a combination of host fruit odor and proteinaceous food odor is more attractive to natural-population medflies than either type of odor alone.

Acknowledgments—We are grateful to Dale Kanehisa for assistance in collecting wild-origin medflies and maintaining medflies in lab cages, to Clifford Lee and Chris Albrecht for collecting fresh host and nonhost fruit, to J. J. Duan for assistance in the field test, and to J. J. Duan, E. Harris, E. Jang, D. McInnis, J. Millar, T. Phillips and T. Shelly for helpful criticism of an earlier version of the manuscript.

BEHAVIORAL RESPONSE OF FEMALE *Helicoverpa (Heliothis) armigera* HB. (LEPIDOPTERA: NOCTUIDAE) MOTHS TO SYNTHETIC PIGEONPEA (*Cajanus cajan* L.) KAIROMONE

ELKE HARTLIEB and HEINZ REMBOLD*

Max-Planck-Institut für Biochemie
D-82152 Martinsried, Germany

(Received December 27, 1994; accepted December 6, 1995)

Abstract—Female *H. armigera* moths are highly attracted by a steam distillate from pigeonpea plants, one of their main hosts. A mixture of six compounds, all sesquiterpenes (β-caryophyllene, α-humulene, α-guajene, α-muurolene, γ-muurolene, and α-bulnesene), mixed in the proportions as found in the steam distillate, elicited the same behavioral responses (oriented upwind flights and contacts with the odor source) as the steam distillate. Only α-bulnesene was attractive by itself, but still less than the whole mixture. In addition, the sesquiterpene mixture acts as an oviposition stimulant. Both behavioral responses, orientation and oviposition, are concentration dependent. Electrophysiological recordings from female and male antennae (EAG) showed the same qualitative and quantitative responses to each of the compounds of the sesquiterpene mixture. The EAG responses to the original steam distillate were higher and similar to chickpea kairomonal components, which were also tested. The pigeonpea sesquiterpene mixture and its individual components elicited weak EAG responses only. The response of the male antenna to female-produced pheromone components was in the same range as the pigeonpea steam distillate.

Key Words—Attractant, *Cajanus cajan*, EAG, *Helicoverpa armigera*, kairomone, Lepidoptera, Noctuidae, oviposition stimulant, pheromone, pigeonpea, sesquiterpene, β-caryophyllene, α-humulene, α-guajene, α-muurolene, γ-muurolene, α-bulnesene.

INTRODUCTION

Chemical stimuli from plants play an important role in insect–plant interactions. In the order Lepidoptera, to which some of the most harmful noctuid agricultural pests belong, much work has been done on the effect of plant volatiles that act as ovipositional stimulants or deterrents (Renwick, 1989; Renwick and Chew, 1994). Little is known, however, about long-range perceptible host-plant signals. Use and manipulation of semiochemicals are important components of an integrated pest management strategy (Rembold and Schroth, 1993).

The noctuid podborer, *Helicoverpa armigera* (Hb.) (Lepidoptera: Noctuidae), is highly polyphagous, like its near relatives, *H. zea*, *H. punctigera*, and *Heliothis virescens*. For two species, *H. virescens* and *H. zea*, it was demonstrated that extracts from their host plants were ovipositional stimulants (Jackson et al., 1986; Mitchell and Heath, 1987; Mitchell et al., 1990; Tingle et al., 1990). *H. armigera* females are significantly attracted by a mixture of four compounds identified in the headspace of chickpea (*Cicer arietinum*) seed powder, three of which are monoterpenes (Rembold et al., 1991). Carbon dioxide has recently been identified as another potent semiochemical for *H. armigera* larvae (Rasch and Rembold, 1994).

Another economically important host plant of *H. armigera* is the pigeonpea, *Cajanus cajan*. Individual eggs are laid scattered on buds, flowers, and leaves. Preliminary studies with headspace volatiles emanating from the seedlings of two pigeonpea varieties of different susceptibility to *H. armigera* attack demonstrated a clear preference of the ovipositing moth for the more susceptible pigeonpea variety; the volatile attractants were identified in the hexane soluble fraction containing mono- and sesquiterpenoids (Rembold and Tober, 1985). We found by application of an olfactometer bioassay (Rembold et al., 1989) that the pigeonpea steam distillate, as well as a synthetic mixture of six pure compounds, were highly attractive to *H. armigera* larvae. The six pigeonpea kairomonal components are sesquiterpenes.

In the present study, we demonstrate the important role of the pigeonpea steam distillate components and of a synthetic kairomone composed of a mixture of six pure components for orientational and ovipositional behavior of female *H. armigera*. In addition, we correlate the behavioral responses of the moth to these plant volatiles with an electrophysiological analysis of the perception of the synthetic kairomone and its individual components.

METHODS AND MATERIALS

Insects. A culture of *H. armigera* was maintained in the laboratory at 26–28°C under a light–dark photoperiod of 16:8 hr. The larvae were reared on a

chickpea semiartificial diet as described by Singh and Rembold (1988). Pupae were separated by sex and kept in plastic boxes until eclosion. For mating the 2-day-old adults (six males and five females) were transferred into a mating cage for two days. During the fifth to sixth night after eclosion, those females that had started laying eggs were tested in the wind tunnel.

Test Materials Sampling of the essential oil from the steam distillate of pigeonpea leaves has been described already (Rembold and Tober, 1985). For tests 500 μl of the concentrated pigeonpea steam distillate (500 mg/ml) were diluted 1:500 in *n*-hexane. A synthetic mixture of six biologically active sesquiterpenes, all present in the team distillate, was prepared as a stock solution (Table 1) in *n*-hexane. Rubber septa (7 mm LD, 500-μl volume, Sigma) were used for dispensing the substances. Each septum was filled with 500 μl of test solution and inserted into the test chamber after evaporation of the solvent at room temperature. Septa baited with 500 μl *n*-hexane were used for controls. For tests with pure α-bulnesene and α-humulene, concentrations five times higher than in the synthetic mixture were used. The synthetic kairomone was also tested by controlled release from a glass capillary. Ten microliters of the test solution were pipetted into a glass vial (4 ml, Zinser) equipped with a short microcapillary (1 mm ID, 5 or 15 mm length) in the grid. This glass vial was placed in a three-necked, round-bottomed flask through which air was passed (19 ml/min). This flask was connected by Teflon tube with the test chamber through a stopper mounted in the middle of the upper glass wall (orientation assay). Empty glass vials were used for controls.

[d] Statistical significance calculated in the χ^2 test after Sokal and Rohlf (1981) and Precht (1982).

Bioassays. Pigeonpea volatiles were assayed for behavioral activity in a wind tunnel similar to that described by Rembold et al. (1991). The flight tunnel was 60 × 20 × 20 cm, with glass walls on the sides and wire screens at the ends. The room was illuminated with dark red light from two electric bulbs (40 W, M7, Phillips) kept 30 cm above the flight tunnel. The wind velocity was 10 cm/sec, and the temperature was held between 22 and 24°C. All tests were conducted within the first 3 hr after lights off, the time of the main activity of the females.

Orientation Assay. One baited septum was placed in the middle of the test tunnel, 5 cm below the top and covered with black paper. For each test, two 5- to 6-day-old egg-laying females were released into the downwind end of the wind tunnel and observed for 45 min. The following behavioral reactions were counted for each individual female: (1) oriented approaches to the source of odor and antennal contact; (2) tarsal contacts with the baited septum; and (3) circles flown around the odor source.

To quantify the attractiveness of a test substance, an attractivity quotient (AQ) was employed, which was calculated from the total number of positive responses per minute of active flight. The bioassay was statistically evaluated by application of the Wilcoxon, Mann-Whitney ranked test (U test) (Sachs, 1972).

Ovipositional Assay. This was designed as a two-choice test; air (10 cm/sec flow rate) entered the test chamber from both ends and was sucked out in the middle of the test chamber with a fan. Only the sesquiterpene mixture was tested, with *n*-hexane being released at the control end. The baited septa were placed behind the wire screens outside the two ends of the test chamber. In this way direct contact with the test solution was excluded and only olfactory perception and orientation were possible. Two 5- to 6-day-old females were placed in the test chamber. The eggs laid on each wire net were counted after 4 hr and a preference value (PV) was calculated as follows:

$$PV = \frac{\text{eggs on kairomone side} - \text{eggs on control side}}{\text{eggs on kairomone side} + \text{eggs on control side}}$$

The synthetic mixture was applied in three concentrations of 500 μl each, i.e., the stock solution without dilution and as 1:25 and 1:50 dilutions in *n*-hexane. For statistical evaluation, the χ^2-test (Sachs, 1972) was used.

Electrophysiological Methods. Electrophysiological recordings from isolated male and female antennae were performed according to standard methods (Schneider, 1957). In addition to the steam distillate and the six sesquiterpenes, three terpenes (Δ-3-carene, α-pinene, and myrcene) and one alcohol (pentan-1-ol) were tested. The mixture of the latter four compounds is attractive as a chickpea kairomone for *H. armigera* females (Rembold et al., 1991). The two

species-specific sex pheromone components, (Z)-11-hexadecenal (Z11–16:Al) and (Z)-9-hexadecenal (Z9–16:Al), were also tested.

The pure compounds were tested in two dilutions (1:10 and 1:100, in paraffin oil), the steam distillate in seven dilutions ($1:10–1:10^7$, in paraffin oil), and the pheromone compounds in six ($1:10–1:10^6$, in *n*-heptane). Fifty microliters of the solutions were applied on a piece of filter paper (1 × 4 cm), which was inserted into a glass syringe. An airstream of 1-sec duration (airspeed 1 m/sec) was blown over the filter paper. The responses from all the stimuli and doses were standardized to the response of 50 μl of (*E*)-2-hexenal in $1:10^2$ paraffin oil dilution, which was set equal to 1. Each substance was tested with five female and five male antennae.

Calculation of Evaporation Rates. The evaporation rate of all the compounds used for electrophysiological recordings was measured by using headspace adsorption on Tenax GC (Chrompack, Mühlheim) with subsequent gas chromatographic analysis. Fifty microliters of the test substance (each compound diluted $1:10^{21}$ in paraffin oil) was pipetted on filter paper (1 × 4 cm) and placed in a glass syringe (15 cm long, 0.8 cm ID). Air was blown over the filter paper at 50 ml/min for 2 sec, and the evaporated material adsorbed on Tenax GC. The quantity of each component collected on Tenax GC was determined by thermal desorption of the Tenax in a DANI 6200 HR gas chromatograph. This was equipped with a modified flame ionization detector (FID) for splitless injections and was used with a 25-mm × 0.31-mm-ID WCOT fused silica column, helium carrier gas (20 ml/min) and a temperature program of 4°C/min rising from 0°C to 150°C. The method of thermal desorption of compounds from Tenax has been described by Nitz et al. (1984) and Rembold et al. (1989).

RESULTS

Orientation Bioassay. Females exposed to a septum baited with the pigeonpea steam distillate demonstrated two to three times more approaches and tarsal contacts than when offered a control septum (Figure 1). The differences in behavior are statistically significant ($\alpha = 0.01$, Wilcoxon, Mann-Whitney U test; Sachs, 1972). Like the original steam distillate, the synthetic mixture was highly attractive to the females. The frequency of approaches to the synthetic kairomone (1.2 approaches/min) was significantly higher than to the control (0.67 approaches/min) (Figure 2). In contrast to the results from the steam distillate, the number of tarsal contacts showed no clear difference between the synthetic kairomone and the control septum.

Are the two compounds with highest activity or are all six components of the synthetic pigeonpea kairomone mixture (Table 1) equally responsible for its attractivity? The synthetic kairomone was compared with mixtures that were

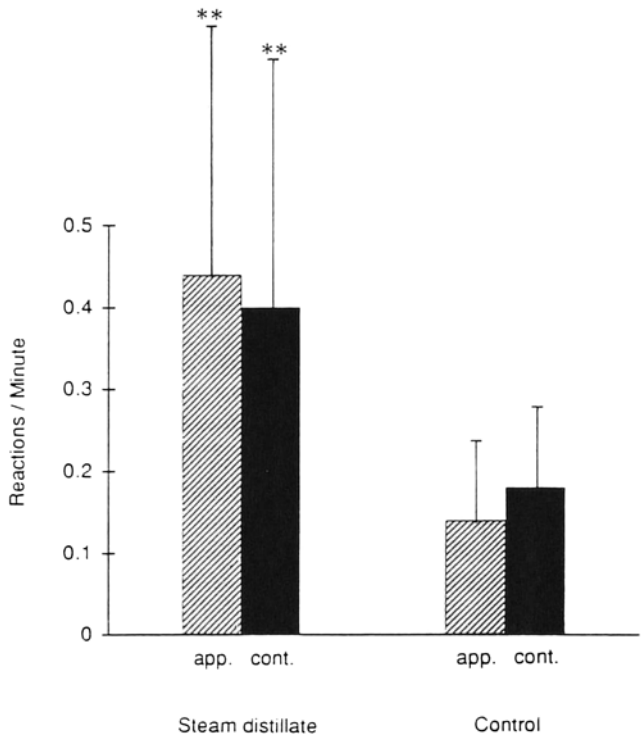

FIG. 1. Behavioral reaction of *H. armigera* females to a pigeonpea steam distillate (N = 10) and to the control (N = 6). Frequency of direct approaches (app.) to the odor source and tarsal contacts (cont.) per minute. **Statistically significant from control at α = 0.01. The bars indicate $\pm$SD.

deficient in the components of highest activity, i.e., α-bulnesene or α-humulene. These two compounds were also tested separately as pure substances. Figure 3 (for α-bulnesene) and Figure 4 (for α-humulene) summarize the results. In the absence of α-bulnesene or α-humulene, the synthetic kairomone lost its activity; the behavioral responses were similar to the control. With pure α-bulnesene the positive responses increased and their number was significantly different from the control (Figure 3). Similar to the synthetic kairomone, the females showed more approaches and antennal contacts (0.95/min) but not more tarsal contacts (0.52/min) to the α-bulnesene-baited septum than to the control (0.67 approaches/

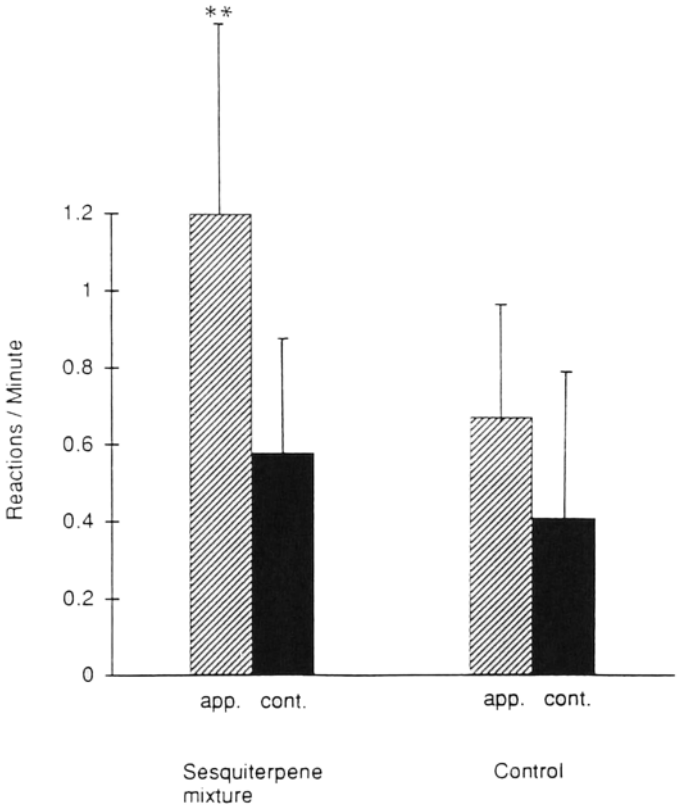

FIG. 2. Behavioral reaction of *H. armigera* females to the sesquiterpene mixture (N = 25) and to the control (N = 38). Frequency of direct approaches (app.) to the odor source and tarsal contacts (cont.) per minute. **Statistically significant from the control at α = 0.01. The bars indicate $\pm$SD.

min, 0.41 tarsal contacts/min). The significance level for the difference in approaches is only $\alpha = 0.05$, which means that α-bulnesene is less active than the whole mixture (significance level $\alpha = 0.01$).

Quite different from α-bulnesene are the responses to the pure α-humulene. There were no additional approaches to this odor source as compared to the control, but the number of tarsal contacts at 0.68/min was significantly higher than to the control at 0.41/min ($\alpha = 0.05$) (Figure 4). Bioassays with a combination of α-bulnesene and α-humulene showed no synergistic effects and no

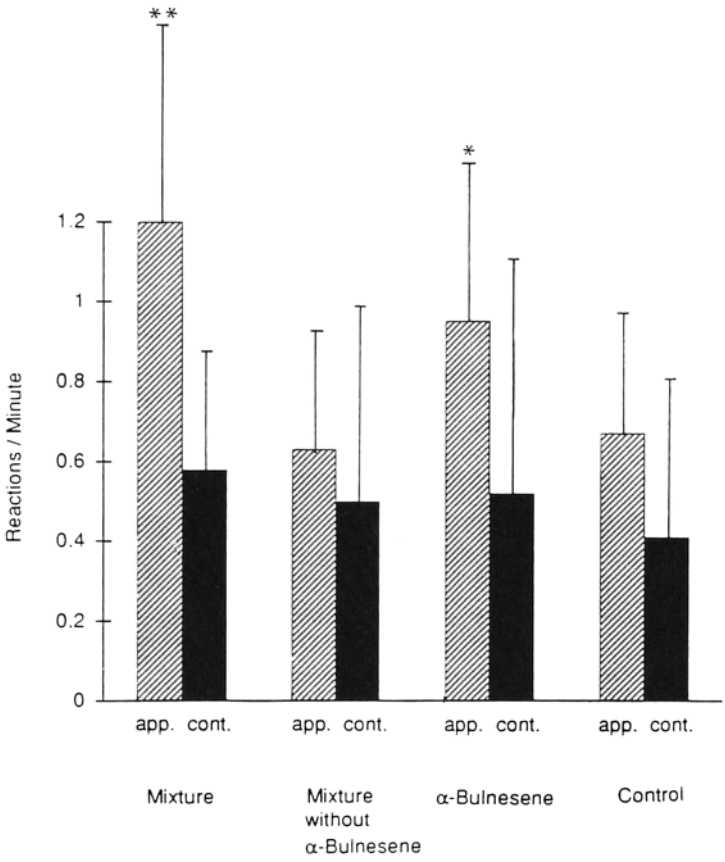

FIG. 3. Frequency of behavioral reactions per minute of *H. armigera* females to the sesquiterpene mixture ($N = 25$), to the mixture without α-bulnesene ($N = 10$), to pure α-bulnesene ($N = 10$), and to the control ($N = 38$); app.: direct approaches to the odor source, cont.: tarsal contacts with the odor source. *Statistically significant from the control at $\alpha = 0.05$; **statistically significant from the control at $\alpha = 0.01$. The bars indicate $\pm$SD.

increase of behavioral responses as compared with the individual substances (Figure 4). A comparison of the attractivity quotients (AQ, total number of positive responses to the test substance per minute flight time) of all the tested odors gives the following sequence of activity. The synthetic kairomone, i.e.,

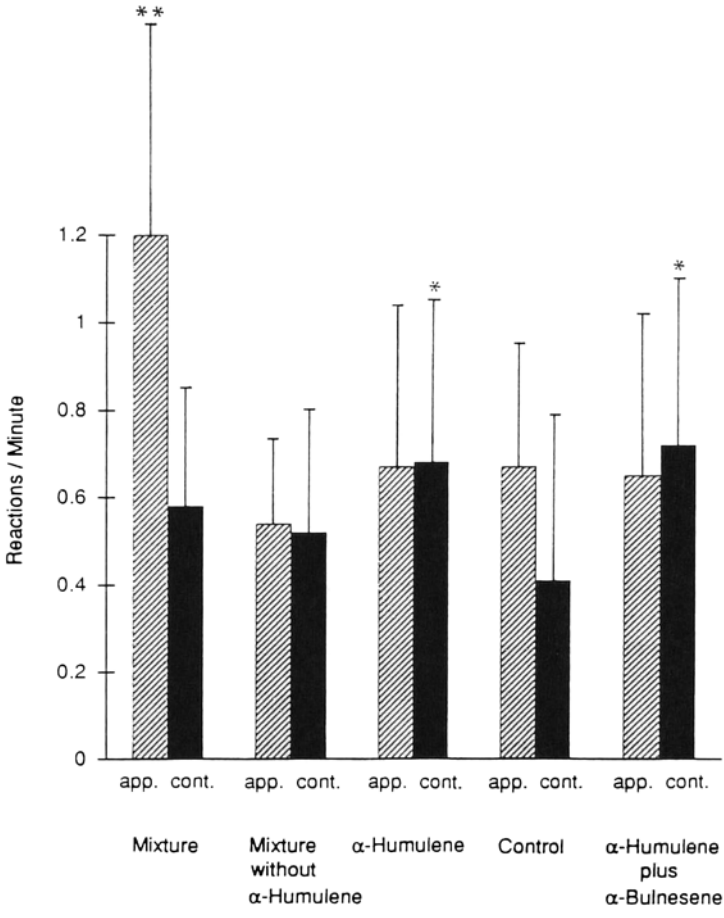

FIG. 4. Behavioral responses of *H. armigera* females to the sesquiterpene mixture (N = 25), to the mixture without α-humulene (N = 12), to pure α-humulene (N = 12), to the control (N = 38), and to the mixture of α-humulene plus α-bulnesene (N = 7). Frequency of direct approaches (app.) to the odor source and tarsal contacts (cont.) with the odor source per minute. *Statistically significant from the control at α = 0.05; **statistically significant from the control at α = 0.01. The bars indicate $\pm$SD.

the whole sesquiterpene mixture (AQ = 1.84) > α-bulnesene (AQ = 1.54) > α-bulnesene plus α-humulene (AQ = 1.5) > α-humulene (AQ = 1.41).

Attraction to the synthetic mixture was concentration dependent. If tested in two relative concentrations (one- and threefold higher) using the capillary method, only the lower concentration was attractive. Females responded to the lower concentration with significantly more approaches per minute (1.24 approaches/min) than to the control (0.47 approaches/min). The number of tarsal contacts was not changed (Figure 5). With the threefold higher concentration

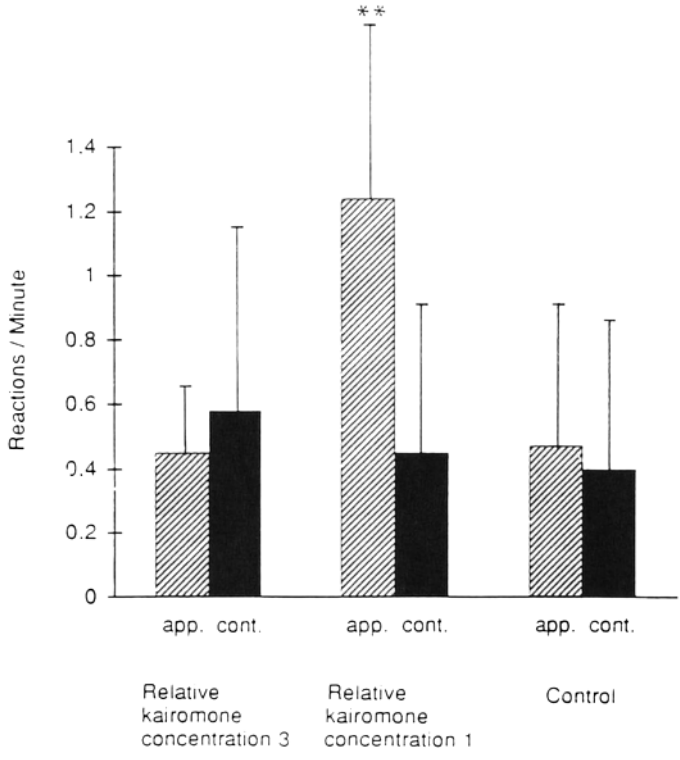

FIG. 5. Behavioral reactions of *H. armigera* females to two different concentrations (relative concentration 1 and relative concentration 3) of the sesquiterpene mixture (N = 8 each) and to the control (N = 16); app.: direct approaches to the odor source, cont.: tarsal contacts with the odor source. **Statistically significant from the control at α = 0.01. TABLE 2. OVIPOSITION TEST WITH THREE DIFFERENT CONCENTRATIONS OF KAIROMONE MIXTURE OF SESQUITERPENES

Kairomone solution	(*N*) Females	Number of eggs			PV (%)[a]	Significance
		Kairomone	Control	Total		
1:50	10	483	263	746	+29.4	0.01
1:25	10	263	315	578	−8.8	NS
1	10	288	435	723	−20.3	0.01

[a]PV = preference value. For calculation see Methods and Materials.

(5 min capillary length) the behavioral responses were not different from the control (Figure 5).

Ovipositional Behavior. The ovipositional assay was designed as a choice test. The influence of the synthetic kairomone on oviposition behavior was concentration dependent (Table 2). Females significantly preferred ($\alpha = 0.01$, χ^2 test) the control side over the stock solution of the sequiterpenes for egg laying [preference value (PV) = −20.3%]. The side with the synthetic sesquiterpene mixture (kairomone) in a 1:50 dilution was preferred (PV = 29.4%), significant at $\alpha = 0.01$. The 1:25 dilution had no effect on the ovipositional behavior since eggs were laid on both sides in nearly the same number (PV = −8.8%).

Electroantennogram. With the plant volatiles, both sexes showed the same electroantennogram responses, but only the male antennae responded to the two individual sex pheromone components (Figure 6A and B). The steam distillate gave a sigmoidal dose–response curve. The distillate elicited much higher electroantennogram responses than its individual compounds or the pheromones at the same concentration. Even at the highest concentration tested (1:10), no saturation in the responses was observed.

Among the individual chemical components, only pentan-1-ol and the three monoterpenes (Δ-3-carene, α-pinene, and myrcene) gave strong EAG responses (Figure 6A and B). The six sesquiterpenes in the 1:10 dilution gave poor activity, and in the 1:100 dilution they produced almost no EAG activity.

The differences between the responses to the individual compounds may have their origin in their different vapor pressures. Quantification of the amount of substance released from the filter paper in 1 sec revealed that the evaporation of pentan-1-ol was twofold higher than that of the three terpenes. The evaporation rate of the terpenes was 20- to 50-fold higher than that of the sesquiterpenes (Figure 7).

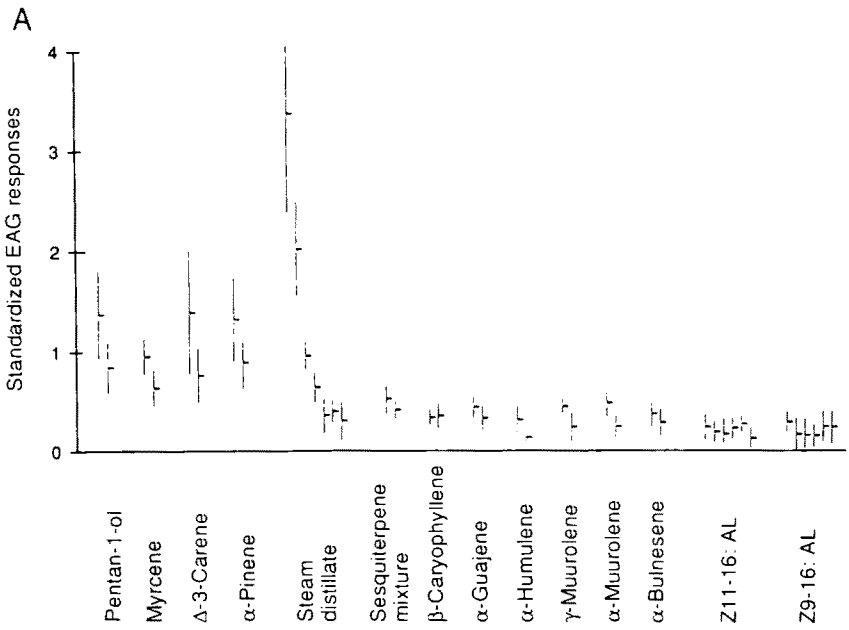

FIG. 6. EAG responses from female (A) and male (B) *H. armigera* antennae, stimulated with different plant volatiles and species-specific pheromone components. Plant volatiles at 1 : 10 and 1 : 100, pigeonpea steam distillate at $1:10–1:10^7$, pheromone components at $1:10–1:10^6$. All responses are standardized based on the response to TRANS-1-hexenal (1 : 100), which is set equal to 1. The bars indicate ±SD.

DISCUSSION

Orientation. Ovipositing *H. armigera* females are strongly attracted by volatiles from a pigeonpea steam distillate, which stimulates two behavioral reactions important for host finding. These are orientation to the odor source from a distance and landing. Several sesquiterpenes were chemically identified in the steam distillate. A mixture of the six sesquiterpenes with the highest attractivity for *H. armigera* first instars (Rembold et al., 1989) was prepared in the same proportion as in the steam distillate and had the same effect on the orientation behavior as the original steam distillate. In contrast to the steam distillate, however, the synthetic mixture of sesquiterpenes did not increase the landing rate of the females compared with the control, indicating that landing might be elicited by several other components. At least some of the six compounds have a synergistic effect, since removal of an individual component (α-

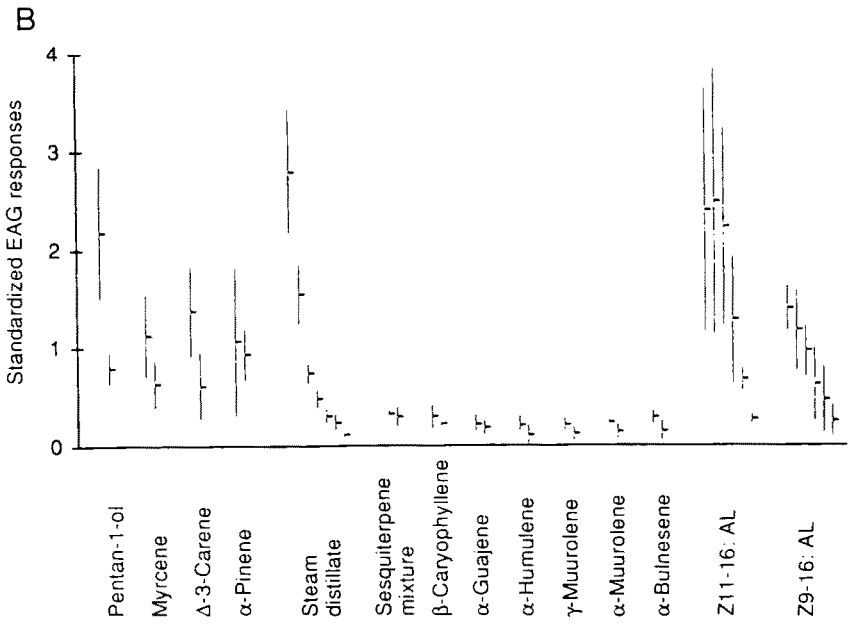

FIG. 6. Continued.

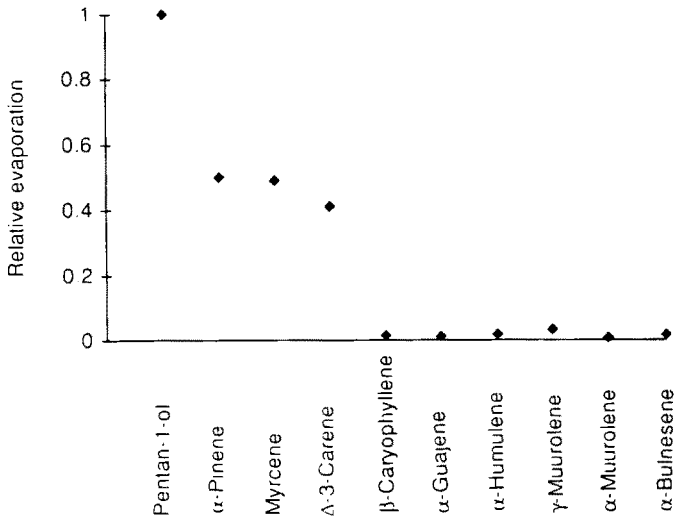

FIG. 7. Relative evaporation of compounds used for the EAG. The release rate of the most volatile compound, pentan-1-ol, is set equal to 1.

bulnesene or α-humulene) resulted in loss of attractivity. α-Bulnesene is the dominant one, as demonstrated by tests with individual compounds in which pure α-bulnesene elicited significantly more approaches than the control, but less than the whole mixture.

Combinations of semiochemicals often are more attractive than individual compounds. Similar results are obtained with the apple maggot fly, *Rhagoletis pomonella* (seven substances; Fein et al., 1982); the carrot fly, *Psila rose* (two substances; Guerin et al., 1983), the beetle *Anthonomus grandis* (five substances; Minyard et al., 1969); and *H. armigera* (four substances; Rembold et al., 1989, 1991). Synergistic effects are not only typical for attractants but have also been found for oviposition-deterring compounds. In *Spodoptera littoralis*, for example, 15 compounds are necessary to elicit a strong deterring effect (Anderson et al., 1993), and in *Ostrinia nubilalis* a mixture of at least five compounds is essential (Thiéry and Le Quere, 1991).

α-Humulene and α-bulnesene stimulate different behavioral responses. α-Bulnesene mainly increased approaches to the odor source, indicating a substance influencing the orientation over long distances, while α-humulene acted at short-distance and positively affected the landing rate. This effect of α-humulene was not visible in the whole mixture and seems to be masked there. With the tse-tse fly, Saini (1980) also found that single compounds and their combinations influenced steps of the searching behavior in different ways.

It is known from preliminary studies that larvae of *H. armigera* are significantly attracted by the sesquiterpene mixture and less strongly by pure α-bulnesene (Rembold et al., in preparation). The same correlation was shown by Rembold et al. (1989, 1991), who found that a mixture of four compounds (three monoterpenes and pentan-1-ol) present in chickpea seed powder was attractive selectively for mated *H. armigera* females (much less for the nonlaying females and not attractive for males) and larvae. Similar olfactory orientation is also known for *Laspeyresia pomonella* larvae and adults in that both stages are attracted to α-farnesene (Sutherland and Hutchins, 1978; Wearing and Hutchins, 1973).

Oviposition. Bioassays demonstrate that the sesquiterpene mixture, in 1 : 50 dilution, stimulates egg laying. The oviposition-stimulating activity of the synthetic mixture is concentration dependent. With increasing concentration, it acts as an oviposition deterrent. Huang et al. (1993) showed, for two *Pieris* species, that their differences in behavioral response to the same substances depended to a large extent on the concentration of the stimuli presented. Similar examples of oviposition stimulants are α-farnesene for the codling moth, *Laspeyresia pomonella* (Wearing and Hutchins, 1973), an ether extract of the host plant for *Papilio demoleus* (Saxena and Goyal, 1978), and dipropyl disulfide for the onion fly, *Delia antiqua* (Harris and Miller, 1988).

Our data suggest that oviposition and orientation are elicited by different optimum stimulus concentrations. The same kairomone concentration that attracts *H. armigera* females is active as an oviposition deterrent, whereas a lower kairomone concentration stimulates egg laying. This selective response reveals that each plant-released stimulus concentration has to be determined experimentally for behavioral response.

Sesquiterpenes have rarely been found as insect attractants or ovipositional stimulants, whereas aliphatic short-chain alcohols and monoterpenes are more common semiochemicals (Smith, 1986; Metcalf, 1988; Renwick and Chew, 1994). Some sesquiterpenes (α-muurolene, γ-muurolene, β-caryophyllene) found in the bark of moribund elm trees (Millar et al., 1986) are attractive to the elm bark beetle, *Scolytus multistriatus*. α-Humulene, α-bulnesene, and β-caryophyllene have been identified in cotton plants (Minyard et al., 1969; Elzen et al., 1985), another host plant of *H. armigera*.

Electroantennograms. Electrophysiological recordings suggest that *H. armigera* females and males respond to plant volatiles in the same way. The steam distillate elicited the strongest EAG responses from antennae of both sexes, while the pheromone components elicited EAG activity only from the male antennae. This finding is consistent with studies with *Agrotis segetum* (Hansson et al., 1989), *Yponomeuta* (Van der Pers, 1981; Van der Pers et al., 1980), and *Pieris rapae* (Topazzini et al., 1990), where females and males responded similarly to plant odor stimuli.

Among the individual compounds, pentan-1-ol and the three monoterpenes gave high EAG responses, and only weak responses were found for the sesquiterpenes. Although the monoterpenes plus pentan-1-ol mixture and the sesquiterpenes mixture are attractive for *H. armigera* females, only the former kairomone mixture gives a clear correlation between EAG responses and behavioral results. There are several examples of semiochemicals that elicit low or no EAG responses (Tichenor and Seigler, 1980; Anderson et al., 1993). A possible explanation may be different component concentrations near the antennae related to the different volatility of alcohols, monoterpenes, and sesquiterpenes. The rate of evaporation of monoterpenes and sesquiterpenes for example, differs by a factor of 20–50. A similar effect was found with single-cell recordings from *Spodoptera littoralis* with aldehydes and terpenes, in which nonanal elicited several times higher EAG responses than the terpenes eugenol and nerolidol in the same doses (Anderson et al., 1993).

An alternative explanation may be that there are fewer receptors for sesquiterpenes on the antenna than for monoterpenes and alcohols. Electrophysiological studies on sex pheromone perception have shown that some components are perceived by a low number of receptor neurons only and therefore give no or very low EAG responses (Löfstedt et al., 1982).

Acknowledgments—We thank Dr. Rienäcker, Max-Planck-Institut für Kohleforschung, Mühlheim, Germany, for providing some of the test compounds. We also thank Prof. K. E. Kaissling, Max-Planck-Institut für Verhaltensphysiologie, Seewiesen, Germany, for hospitality and advice in electrophysiological recordings and Dr. Ch. Rasch, Max-Planck-Institut für Biochemie, Martinsried, Germany, for assistance in electrophysiological recordings. This study was financially supported in part by a project from GTZ, Eschborn, Germany.

(Received July 25, 1994; accepted December 7, 1995)

Abstract—We measured the heart rate (HR) and oxygen consumption ($\dot{V}_{O_2}$) of wapiti (*Cervus elaphus canadensis*) before, during, and after presentation of biologically irrelevant odors (pentane, thiophene, and a perfume), artificial predator odors (an ether extract of cougar feces, and PDT, a compound found in mustelid anal gland secretion), stale predator odors (dog feces and urine and fox urine, kept at ambient temperature for a few weeks), and fresh predator odors (wolf, coyote, and cougar feces and the odor of a dead coyote, kept frozen between collection and test). Overall, responses to odors were small compared to other stressful stimuli. Individual variability was high among scents and among wapiti, but two of the fresh predator odors (cougar and wolf feces) produced larger HR and $\dot{V}_{O_2}$ responses than the other scents and were more often successful at producing responses. As a group, fresh predator odors produced larger tachycardias and elicited a larger number of significant HR responses than biologically irrelevant novel odors, although the two classes of odors did not differ in their effect on $\dot{V}_{O_2}$. Although several other studies have shown that ungulates have reduced feeding levels when their food is scented with predator odors, it is not clear if this is due to reduced palatability

or antipredator behavior. This study is the first demonstration that a wild ungulate species reacted more strongly to predator odors than to other odors in a nonfeeding situation.

Key Words—Predator odor, detection, wapiti, elk, heart rate, oxygen consumption, metabolic rate, *Cervis elaphus canadensis*.

INTRODUCTION

The study of predator detection is similar to the study of intraspecific communication in that it requires that the human observer detect a response (or a change in the probability of subsequent behavior) in the receiver of a signal. Responses may include a change in overt activity, such as fleeing, alarm calling, mobbing, or other antipredator behaviors, or can be more subtle, such as a change in foraging level (Sullivan et al., 1985a,b), activity level (Gorman, 1984), habitat selection (Lima and Dill, 1990), or prey survival (Hirsch and Bolles, 1980). Studying the use of chemical cues in predator detection offers the additional challenge, compared with studying visual and acoustic cues, that the signal itself can be difficult to detect by human observers. As a result, there is a paucity of field studies reporting the detection of predators via chemical cues.

Laboratory studies have shown that prey can detect predator odors. Among aquatic organisms, many amphibian larvae and fish avoid waters containing the scent of predatory fish or display antipredator behaviors or a reduced activity level in such waters (Petranka et al., 1987; Martel and Dill, 1993; Stauffer and Semlitsch, 1993), although no nonpredator novel odor was used in these studies. Reactions to predator odors have been demonstrated in the laboratory for many terrestrial species as well. Rats (*Rattus norvegicus*), probably the best-studied mammal, freeze when subjected to the odor of a cat (*Felis domestica*) (Griffith, 1920, cited in Weldon, 1990). Courtney et al. (1968) have shown that this is not a reaction to the novelty of the stimulus: cat odor increased the time it took a trained thirsty rat to run a gangway to a water bottle, while a novel odor (commercial deodorant) had no such effect. Rats also show behavioral reactions typical of fear, as well as increased corticosterone levels (a sign of stress), in response to the odor of fox (*Vulpes vulpes*) feces or of extracts from fox feces (Vernet-Maury, 1980; Vernet-Maury et al., 1984). Geckos (*Coleonyx variegatus*) usually reacted to a 60-sec presentation of a cotton swab rubbed on the sides of a gecko-eating snake with the tail display, which is used almost exclusively during encounters with potential predators, or with flight. Distilled water and a commercial cologne (nonpredator control odor), on the other hand, elicited no tail display or flight. Furthermore, the scent of an arthropod-eating snake resulted in flight on only 30% of presentations. This showed not only that geckos

react to the predator smell, but that they can identify the source of the chemicals as predator (Dial, 1990).

For most other mammalian prey species, however, evidence for predator detection by chemical cues is not as clear. Many laboratory and field studies have shown that herbivores feed less on food items that have been contaminated with predator odors than they do on clean food items (Müller-Schwarze, 1972; Melchiors and Leslie, 1984; Sullivan et al., 1985a,b, 1990a; Sullivan and Crump, 1986; Abbott et al., 1990; Pfister et al., 1990; Robinson, 1990; Merkens et al., 1991; Swihart et al., 1991; Epple et al., 1993).

Although they constitute the ultimate test if an odor is to be used as a repellent, studies of feeding levels are not entirely satisfactory in assessing whether or not responses are due to an association with predators. Dial (1990) stressed the importance of using predator-specific, defensive aspects of behavior as a bioassay to demonstrate that an association with a predator is made. Reduced feeding levels do not demonstrate an association with predators and could be due to neophobia or reduced palatability. In most studies, nonpredator novel odors were also presented, and these reduced feeding for a short while only or not at all, whereas predator odors were effective much longer, especially if they were replenished periodically or if more sophisticated releasing devices were used to slow down evaporation (Sullivan et al., 1985a,b, 1990a; Sullivan and Crump, 1986; Swihart et al., 1991; Epple et al., 1993), thereby ensuring that the responses were not simply due to neophobia. It is more difficult, however, to dismiss the possibility that reduced palatability caused the reduced feeding levels. This possibility is greatest when odors are applied directly on food items, as in Melchiors and Leslie (1984) and in some of the trials of Sullivan et al. (1985b), Abbott et al. (1990), and Swihart et al. (1991). Indeed, reduced palatability could explain why some nonpredator odors did reduce feeding for lengthy periods (e.g., Shumake, 1977; Melchiors and Leslie, 1984; Sullivan et al., 1985b; Conover, 1987; Swihart and Conover, 1990).

Even when odors were presented in various types of containers located close to the food, instead of applied on the food, smell could have reduced the palatability of food (Moulton, 1967; Garcia and Rusiniak, 1980). Indirect evidence for this is provided by the fact that some nonpredator odors were effective in reducing feeding levels even when not released on the food (see, for instance, Abbott et al., 1990; Pfister et al., 1990; Swihart and Conover, 1990). Abbott et al. (1990) found that nonpredator unpleasant odors were less effective than predator odors, but it is difficult to assess what is unpleasant to other species, and some doubts remain regarding an association of predator odors with predators in feeding experiments. This interpretational difficulty can be avoided by not using feeding level as the dependent variable.

Many studies compared trapping success between clean traps and traps contaminated with predator odors (Stoddart, 1980; Dickman and Doncaster,

1984; Gorman, 1984; Robinson, 1990). It should be noted that even in these studies, rodents were attracted to traps with bait, so it cannot be excluded that a reduction of palatability instead of an association with predators caused a reduction in the capture rate of predator-scented traps. Gorman (1984), however, complemented his field study with laboratory experiments that showed, in a non-feeding situation, some rodent species avoided areas with stoat (*Mustela erminea*) scent, and reduced their activity level when surrounded by stoat scent. Other workers showed avoidance by prey species of areas associated with predator odors (Courtney et al., 1968; Pfister et al., 1990; Sullivan et al., 1990b).

To date, only a few species of wild ungulates have been studied for their responsiveness to predator odors and always with the feeding level paradigm. As part of a larger study of the effect of alertness on the relationship between heart rate (HR) and metabolic rate (estimated by rate of oxygen consumption, $\dot{V}_{O_2}$), we had the opportunity to study the effect of predator odors on HR and $\dot{V}_{O_2}$ of wapiti. HR telemetry can be a more sensitive technique than behavioral observation alone to study the reaction of animals to stimuli in their environment, because HR responses are sometimes detected in the absence of overt behavioral responses (Thompson et al., 1968a; Roshchevskii et al., 1976; MacArthur et al., 1979, 1982; Ball and Amlaner, 1980; Ferns et al., 1980; Zimmer, 1982; Geist et al., 1985; Diehl and Helb, 1986). In fact, HR telemetry has already been used to assess the ability of some sounds and objects to repel birds (Thompson et al., 1968a,b; Stout and Schwab, 1980), or of wolf (*Canis lupus*) howls to frighten white-tailed deer (*Odocoileus virginianus*) fawns (Moen et al., 1978). HR has been used a few times to assess whether or not animals reacted to odors, and even to assess which volatiles caused the responses (Wenzel and Sieck, 1972; Hesterman et al., 1976; Goodrich et al., 1978, 1981, 1986, 1990). This technique has already been used to test the effect of predator odors. Rattlesnakes (*Crotalus viridis, C. atrox, C. ruber,* and *C. scutulatus*) increased their HR when exposed to predator odors (Cowles and Phelan, 1958). However, the odor of fox scats did not change the HR of young red deer (*Cervus elaphus*) calves significantly or consistently (Espmark and Langvatn, 1985). It is unclear why the latter study did not reveal a HR response, considering that many acoustic and visual stimuli were effective. Possibly red deer calves are more sensitive to these classes of stimuli than to chemical stimuli. It is clear, however, that HR is ideally suited as a sensitive and easily quantifiable measure of the response of prey animals to predator odors. Moreover, interpretational problems due to possible effects of altered palatability would be avoided if HR changes to predator odors were recorded in a nonfeeding situation.

$\dot{V}_{O_2}$ has very rarely been used to detect responses to stimuli. Floyd (1987) found that visual, acoustic, and tactile stimuli increased both HR and $\dot{V}_{O_2}$ of caribou (*Rangifer tarandus*), and Moritz and Bürgin (1987) found that alarm

pheromones increased $\dot{V}_{CO_2}$ of wasps and bees, which means that $\dot{V}_{O_2}$ also increased. There are reasons to predict that $\dot{V}_{O_2}$ should be less responsive than HR to environmental stimuli: it has been shown that during psychological challenges (such as mental arithmetic, video games, the stress of flying an aircraft, etc.), humans show HR increases that are far larger than what would be expected from the concomitant $\dot{V}_{O_2}$ increases (Blix et al., 1974; Turner and Carroll, 1985; Allen et al., 1986; Sherwood et al., 1986). Yet, stimuli often increased $\dot{V}_{O_2}$ in these studies, and the question of the energetic cost of the reaction of prey to predator odors warrants including $\dot{V}_{O_2}$ in this study.

The objectives of this study were to determine if novel and predator odors evoked HR and $\dot{V}_{O_2}$ responses in captive wapiti in a nonfeeding context, and if predator odors were more effective than novel, biologically irrelevant odors at evoking changes in HR and $\dot{V}_{O_2}$. Furthermore, even though our data are not ideally suited for this task, we investigate if habituation took place.

METHODS AND MATERIALS

Study Site and Study Animals

This study was conducted at the Ministik Wildlife Research Station, 48 km southeast of Edmonton, Alberta, Canada. The station is at the southern fringe of the boreal mixed-wood forest (Renecker, 1987) and occupies an area of about 265 ha, although the wapiti herd is restricted to various pens totaling about 65 ha. The herd contained 25 mature hinds, 13 yearlings and 12 stags in the spring of 1989, when this study was conducted (May 1–June 11). Wapiti grazed on native vegetation but were supplemented with hay and alfalfa–barley pellets, especially during winter. Wild coyotes (*Canis latrans*) are the only predator present in the study area. Six captive female wapiti 6–12 years old, hereafter referred to as Bell, Black, Blue, Ebony, Jasmin, and Teen, were trained to wear a harness-mounted heart-rate transmitter and to stand quietly in a stall while wearing a face mask. The first three were very tame, whereas the remaining animals were habituated to humans.

Measurement of Heart Rate

Heart rate was obtained via radiotelemetry, using an external ECG transmitter stitched to a nylon harness (Johnson et al., 1980; Chabot et al., 1990). Two patterns of lead position allowed ECG recording with good signal-to-noise ratio: both leads on the sternum, about 15 cm apart, or one lead on the sternum and the other on the side of the neck. Instrumentation was routinely performed in 10 min while the animal was standing in a stall. A three-element directional

receiving antenna fed the signal to a receiver (AVM LA-12). The ECG signal was stored on one channel of a stereo tape recorder (Sony TC-158SD or Sony TC-D5) while a verbal description of behavior was stored on the other channel. In the laboratory, the ECG signal was played back into a custom-built decoder/peak detector hooked to a Macintosh Plus microcomputer (Chabot, 1992). Time between R waves (heart period) was measured with millisecond accuracy using a program written in Pascal and timing routines from Rensink (1990). To eliminate errors from the data, beats that lasted less than 65% or more than 17% of the previous beat were flagged. Flagged beats were located, compared to the playback signal, and corrected if necessary. Beats that were unrecoverable were deleted. After correction or removal of erroneous beats, the heart periods were averaged over 1-min intervals, and then transformed into beats per minute (bpm), as prescribed by Chabot et al. (1991).

Measurement of Oxygen Consumption

A continuous-flow indirect calorimetry system, described in detail elsewhere (Chabot, 1992), was used to assess $\dot{V}_{O_2}$ (liters per minute). Fresh outdoor air was allowed into the mask by three large inlets (2.5 cm ID) fitted with plastic hoses about 80 cm long to prevent exhaled air from being lost during forceful expirations. Airflow through the face mask, corrected to standard temperature (0°C) and pressure (101.32 kPa), dry (STPD) (Withers, 1977), was fairly constant (about 480 liters/min) and was measured about every 5 min. Depletion of oxygen in the airstream was measured every 2 sec with a paramagnetic oxygen analyzer (Servomex model 750-b). $\dot{V}_{O_2}$ was calculated using equation 3a of Withers (1977), correcting the flow out of the mask for vapor pressure using wet- and dry-bulb temperatures. Respiratory quotient (*RQ*) was assumed to be 0.87, except for two tests that took place when the subject was fasted for 18 and 37 hr, respectively. *RQ* was assumed to be 0.775 and 0.75 for these two tests (Chabot, 1992). $\dot{V}_{O_2}$ readings were adjusted for the 13-sec lag between a change in oxygen concentration taking place in the mask and its detection by the oxygen analyzer. To eliminate some of the variability due to breathing patterns, the readings of $\dot{V}_{O_2}$ taken every 2 sec were first subjected to a 29-point moving average, and then averaged every minute.

Odors

Feces of cougar (*Felis concolor*) and wolf were collected at the Calgary Zoo on May 15, 1989. Coyote feces were collected in the study area on May 4, 1989. The feces of these three species were collected within 12 hr of being deposited and kept frozen until needed. In addition, a coyote, killed in late April 1989, was kept frozen until it was used in tests on June 3 and 4, 1989. Lastly,

a few "aged" predator odors were collected at a local fox ranch: dog (*Canis familiaris*) urine and feces kept at ambient temperature for many weeks and red fox urine collected overnight on May 28, 1989. These three compounds were kept at ambient temperature until used in tests.

Two artificial predator odors were tested for possible management applications as ungulate repellents. E1 was the ether extract of cougar feces, whereas PDT (3-propyl-1,2-dithiolane), a compound found in anal gland secretions of stoat, wolverine and other mustelids, was synthesized in the laboratory. Both compounds were used undiluted. Three novel scents that are biologically irrelevant, that is, not normally found in the animal's habitat and not related to intra- or interspecific communication, were also tested: pentane, thiophene, and a perfume (Eau de toilette Cléa, 85% vol. 95 N, Yves Rocher 408).

Testing Procedure

Testing of the control and predator odors was performed in a metabolic stall, about 1 m wide, 3 m long, and 2 m high, located outdoors. Subjects already equipped with HR transmitters were fitted with a halter and tied to vertical rails that allowed them to stand or bed, and then equipped with a face mask. A small vacuum pump (Gast 0531-102B-347) brought air from the odor-releasing device to the mask via a small (5-mm-ID) inlet. A two-way brass valve, located between the pump and the odor-releasing device, allowed bypassing the odor-releasing device. All tubing was Teflon to minimize contamination. The distance of about 5 m between the odor-releasing device and the mask resulted in a delay of less than 1 sec between the beginning of a test and the arrival of the scent in the mask.

Two models of odor-releasing devices were used. A two-piece glass cartridge (1 cm ID and 15 cm long) with a Teflon cock at each end (Figure 1) was used with liquid compounds. To prevent contamination, compounds were applied to a piece of filter paper (5 × 30 mm) using a precision pipet and inserted into a 4-cm section of glass tubing. The latter was sealed at both ends with Parafilm until it was inserted into the odor-releasing device, about 1 min before a trial was due to start. The cocks remained closed until 10 sec before testing. To begin a test, the two-way valve was switched from outdoor air to the odor-releasing device for 1 min. At the end of each test the valve was switched back to outdoor air, the stimulus was removed from the cartridge, and the latter flushed with compressed air for about 1 min.

A larger version of the same system (5 cm ID, 40.4 cm long), made of acrylic, was used for fecal samples. Predator feces were mixed with enough distilled water to form a slurry, and the slurry was put directly into the testing device. Whole feces preparations were reused for one to three animals within 3 hr and sometimes used on the next day for a second presentation with the same

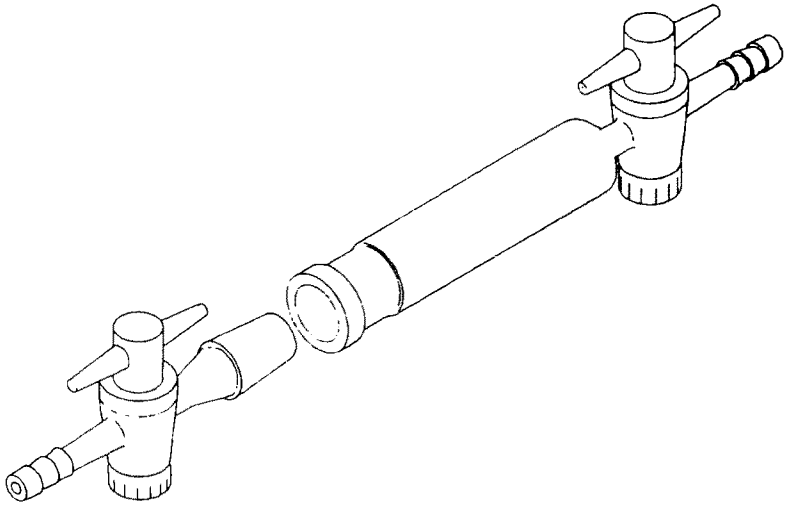

FIG. 1. Odor-releasing device.

animals. The device was washed thoroughly between tests. For the tests involving the dead coyote, the carcass was laid outdoors in the shade, out of view of the subject. No cartridge was used but the pump was connected to a piece of Tygon tubing which picked up air in the animal's fur.

Recording sessions lasted 15–60 min, during which one to six stimuli were applied. Animals were never used in more than two sessions per day. Stimuli were the test odors listed above, a variety of sound playbacks, approaches by a human being, as well as controls with no odor but with the normal toggling of the event recorder's switch at the beginning and end of the 1-min test duration, in case the subjects could hear it. Only the results of control and odor tests are presented here. Attempts were made to obtain 1–2 min of baseline with little or no physical activity before each test, and there was always ≥ 3 min between stimuli. It was impractical to have all test stimuli available at all times for a completely randomized design, but presentation order was random within sessions. There is no information available on wapiti olfaction that would allow the control of perceived stimulus strength across odors; therefore, different concentrations of each odor were attributed quasirandomly across subjects (Table 1). The higher concentrations were easily detected by a human wearing the mask.

Habituation was studied only incidentally: 19 stimulus–animal combinations were tested twice (Tables 1 and 2). On average, time between tests was

80.1 hr (SD = 94.9), with 13 cases tested 10.1–25.2 hr apart, and six cases tested 140.2–266.8 hr apart. Because there was some indication that habituation did occur between trials, only the first presentation of a stimulus to each subject was used to test the effectiveness of the odors.

Statistical Analysis

Assessing Effectiveness of Each Stimulus. HR and $\dot{V}_{O_2}$ were measured before (min −1), during (min 0), and after (min 1) stimulus presentation. Small sample sizes ($N \leq 6$) made it difficult to test the assumptions of univariate or multivariate repeated-measures ANOVA; therefore we used two paired-sample t tests (Zar, 1984) for each dependent variable: one to test for an increase in HR or $\dot{V}_{O_2}$ between min −1 and min 0, and another to test for an increase between min −1 and min 1. Because increases were predicted, one-tailed tests were used. These two comparisons were nonorthogonal, so a level $\alpha = 0.05$ of type I error was maintained by requiring each comparison to be significant at $1 - (1 - \alpha)^{0.5} = 0.025$ (Šidák's multiplicative inequality; Kirk, 1982, p. 110). In the Results section, figures show means with 95% confidence intervals. The one-tailed t test described here is closely approximated by looking for 95% confidence intervals that do not include 0.

A second method of measuring the effectiveness of the odors at increasing HR or $\dot{V}_{O_2}$ was also devised. We computed two new variables, ΔHR and $\Delta\dot{V}_{O_2}$, which are the difference scores between consecutive minutes of recording (MacArthur et al., 1979). The distribution of these two variables for calm animals was assessed using data for the same six animals standing or bedded, and at least 3 min after a change of activity or presentation of a stimulus. For ΔHR, pairwise Kolmogorov-Smirnov tests showed that the distributions were not statistically different for Bell, Black, and Blue, and for Ebony, Jasmin, and Teen. Thus ΔHRs were pooled in two groups. Neither group was normally distributed (Lillifors' test, $P < 0.001$), and both were leptokurtotic (Table 3). Therefore, critically high values ($P = 0.05$, one-tailed) were calculated empirically by ranking ΔHRs for each group in decreasing order and taking the fifth percentile ΔHR. For Bell, Black, and Blue, HR increases of 2.4 bpm or more between subsequent minutes of recording occurred less than 5% of the time when they were calm. For Ebony, Jasmin, and Teen, this number is 3.77 bpm. The same procedure was followed for $\Delta\dot{V}_{O_2}$, except that the distribution of this variable across all six animals was similar enough to pool the data. The distribution of $\Delta\dot{V}_{O_2}$ was normal (Table 3), and increases in $\dot{V}_{O_2}$ of 0.2857 liter/min or more occurred less than 5% of the time.

The effectiveness of a stimulus at increasing HR or $\dot{V}_{O_2}$ was assessed by taking the number of effective and ineffective stimulus presentations, according to the criteria of Table 3, and converting to a probability with the binomial test ($P = 0.05$, $q = 0.95$). This technique, only available for min 0 (i.e., during

TABLE 3. DECRIPTIVE STATISTICS, TEST OF NORMALITY, AND EMPIRICAL CRITICAL VALUES FOR ΔHR AND $\Delta \dot{V}_{O_2}$

ΔHR	Ebony, Teen, Jasmin	640	−9.762	11.799	−0.263	2.472	0.108	2.283	0.062	0.000	3.768
$\Delta \dot{V}_{O_2}$	all six	1560	−0.559	0.712	0.001	0.172	0.084	0.335	0.021	0.122	0.286

stimulus), is less affected by individual differences in responsiveness and by HR or $\dot{V}_{O_2}$ variability than the paired-sample t test, and took advantage of large samples for the distribution of these two variables in calm animals. The t test, however, is more appropriate to detect small but consistent changes in HR or $\dot{V}_{O_2}$ due to the test stimuli and is the only method to detect significant changes in HR or $\dot{V}_{O_2}$ in the minute following stimulus presentation.

Comparing Odor Groups.

There were too many different stimuli relative to the number of subjects for a statistical comparison of the effectiveness of stimuli among each other. Instead we combined the odors into four classes: biologically irrelevant (pentane, perfume, thiophene), artificial (El and PDT), stale predator odors (fox urine, dog urine and feces), and fresh predator odors (cougar, coyote, and wolf feces; dead coyote). In a first test, each odor presentation was scored 1 if it was effective at increasing HR, and 0 otherwise. The scores of the odor groups were then compared using Fisher's exact tests. The same analysis was repeated with $\dot{V}_{O_2}$. A repeated-measures ANOVA was also performed on ΔHR and $\Delta\dot{V}_{O_2}$ for each animal, averaged across the odors of each class. Odor class (four levels) was the within-subject factor. Using the criteria of Potvin et al. (1990), we selected the univariate test corrected with Huynh-Feldt's ϵ.

Effect of Environmental and Physiological Variables. Pooling data from all subjects and odors, stepwise multiple regression (Pedhazur, 1982) with α-to-enter and α-to-remove set to 0.015 (Wilkinson, 1989) was used to test if the size of responses (ΔHR or $\Delta\dot{V}_{O_2}$) was affected by date, time of day, baseline HR, order of presentation within trial, an index of agitation, weight, number of days pregnant, number of days lactating, and ambient temperature.

Stimulus Intensity. For each odor, the effect of stimulus intensity on HR or $\dot{V}_{O_2}$ responses was assessed by calculating Spearman rank correlation coefficients between quantity used and ΔHR and $\Delta\dot{V}_{O_2}$ (Zar, 1984).

Habituation. To test for habituation, ΔHR at min 0 for the first and second presentation of an odor to an animal were compared with paired-sample t tests (one-tailed), combining all odors and animals. The same method was used with $\Delta\dot{V}_{O_2}$. In addition, the number of effective trials upon first and second presentation was compared using Fisher's exact test (one-tailed).

Contingency tables were calculated in SAS (SAS Institute, 1989), t tests in SuperAnova (Abacus Concepts, 1989), and the remaining statistical tests were done with Systat 5.0 (Wilkinson, 1989).

RESULTS

Only cougar feces, wolf feces, and dog urine increased HR significantly during stimulus presentation [paired-sample t test, P (one-tailed) < 0.025; Table

[a]Values in boldface type indicate significant increases in HR.

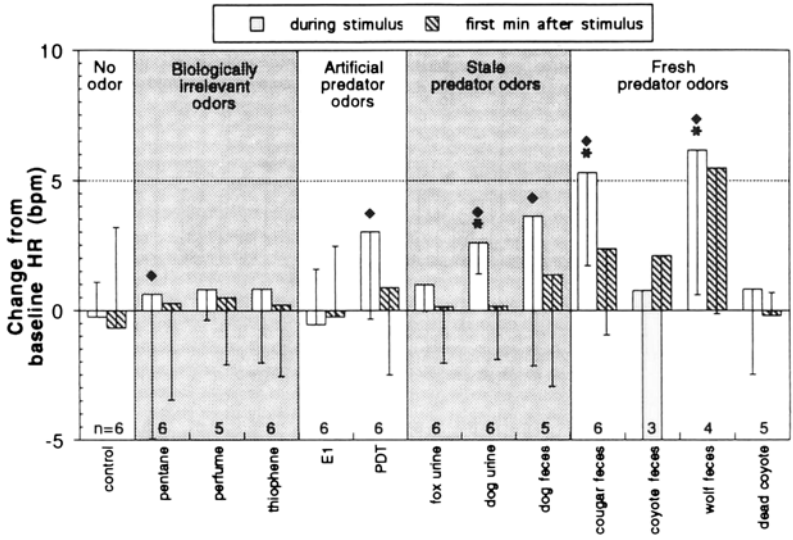

FIG. 2. Change in heart rate, with 95% confidence interval, produced by the test stimuli. Odors found significant with paired-sample t tests are marked with an asterisk, while those found significant with the binomial tests are marked with a diamond. Sample size for each odor is indicated at the bottom of the figure.

4 and Figure 2), although tachycardia was nearly significant for PDT and fox urine ($0.026 \leq P \leq 0.035$). HR during the first minute after stimulus did not differ from baseline HR, although tachycardia was nearly significant with wolf feces ($P = 0.027$; Table 4). All odors found significant with a paired-sample t test were also significant with the binomial test (Table 4), but three more odors, pentane, PDT, and dog feces, were effective when analyzed with the binomial test (Table 4).

$\dot{V}_{O_2}$ during stimulus presentations did not differ from baseline according to paired-sample t tests, but with binomial tests, six odors were found effective at increasing $\dot{V}_{O_2}$: pentane, cougar, dog and wolf feces, dog urine, and the dead coyote (Figure 3, Table 5). $\dot{V}_{O_2}$ during the first minute after exposure to cougar and wolf feces was significantly elevated relative to the prestimulus level (Figure 3, Table 5).

HR responses were not affected by the environmental variables measured (date, time of day, baseline HR, order of presentation within trial, index of agitation, weight, number of days pregnant, number of days lactating, ambient temperature), as the stepwise regression resulted in no variable being entered.

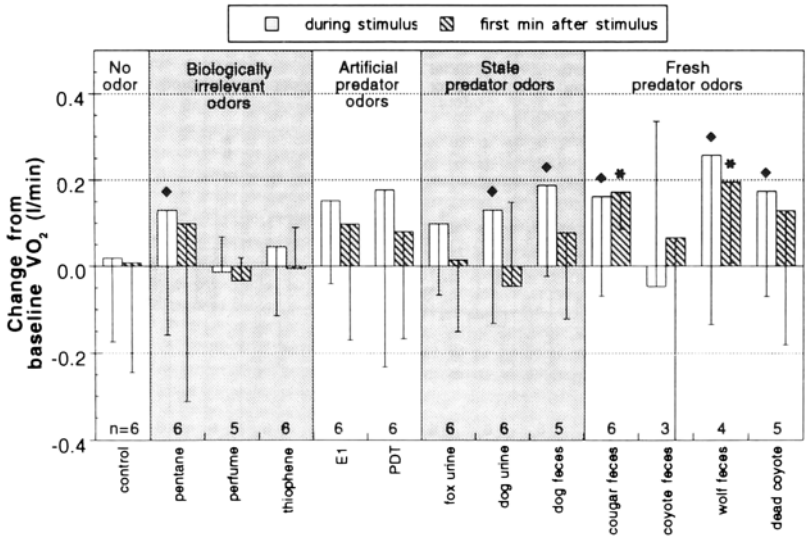

FIG. 3. Change in oxygen consumption, with 95% confidence interval, produced by the test stimuli. Odors found significant with paired-sample *t* tests are marked with an asterisk, while those found significant with the binomial tests are marked with a diamond. Sample size for each odor is indicated at the bottom of the figure.

However, agitation during stimulus presentation resulted in larger $\Delta\dot{V}_{O_2}$:

$$\Delta\dot{V}_{O_2} = 0.066 + 0.024 \text{ Agit } (R^2 = 0.111, P = 0.005)$$

where Agit is an index of agitation ranging from 0 to 15 (mean = 1.8, SD = 2.8).

With the quantities used, there was no evidence that odor strength affected the size of the response. Spearman rank correlation coefficients between quantity used and either ΔHR or $\Delta\dot{V}_{O_2}$ were not significant, although these negative results are likely due to the very small sample sizes.

There was some evidence for habituation. For those animal–stimulus combinations that were tested twice, HR and $\dot{V}_{O_2}$ responses were smaller on the second testing than the first, both during the stimulus presentation and during the following minute. However, this decline was significant only for HR [paired-sample *t*-test (one-tailed), $P = 0.014$ (min 0) and 0.042 (min 1); Table 6]. There was also a reduction in the number of presentations resulting in significant tachycardias (6 of 19 trials vs. 3 of 19 trials) or significant $\dot{V}_{O_2}$ increases (5 of 19 trials vs. 1 of 19 trials; Table 6), but this was not significant [Fisher's exact

[a]Odors were deemed effective when they produced changes in HR or $\dot{V}_{O_2}$ meeting the criteria of Table 3. Mean change in HR or $\dot{V}_{O_2}$ were based on all stimuli ($N = 19$). Means were compared with a paired-sample *t* test (one-tailed).

test, $P = 0.22$ (HR) and 0.09 ($\dot{V}_{O_2}$)]. There were three cases of reversal: for Blue with E1, tachycardia was significant on the second but not the first presentation, whereas for Jasmin with dog urine and Black with PDT, a significant $\Delta\dot{V}_{O_2}$ was found on the second but not the first presentation. Interestingly these three cases all had ≥ 140 hr between tests.

Our data show large individual variability in response rate. Figure 4 compares the frequency of significant tachycardia (using the criteria of Table 3) each animal produced in response to the four classes of odors (the no-odor controls were excluded from this analysis). One animal (Blue) never responded, while another (Bell) responded to at least half of the stimulus presentations in all four stimulus classes. The other animals fell in between these two extremes. Overall (i.e., pooling all odor classes), the six hinds differed significantly in their response rate ($\chi^2 = 11.3$, $P = 0.046$). Individual variability was likewise high with $\dot{V}_{O_2}$, although the difference was not significant ($\chi^2 = 7.5$, $P = 0.189$). Again Blue did not respond to any stimulus (Figure 5). No animal had significant responses in all four odor categories, and some hinds responded to stimuli that did not affect other animals.

Artificial odors affected the fewest animals: two hinds for HR (Figure 4), and a single subject for $\dot{V}_{O_2}$ (Figure 5). Biologically irrelevant odors affected three animals on both dependent variables. Three hinds had HR responses to stale predator odors, whereas four hinds showed $\dot{V}_{O_2}$ responses to these odors. Fresh predator odors had a more general effect, producing HR and $\dot{V}_{O_2}$ reactions in all animals but Blue, even if individual response rates were not higher than for other categories for which an animal also responded. On average, the six hinds responded to 50% of the fresh predator odors with significant tachycardia,

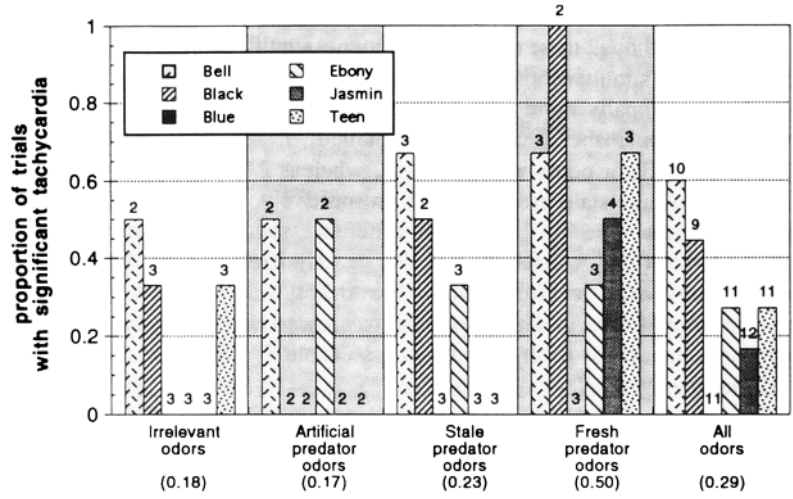

FIG. 4. Rate HR responses of each animal for the four odor categories and for all odors combined. Sample sizes are given above each bar, and the mean percentage of response is given at the bottom.

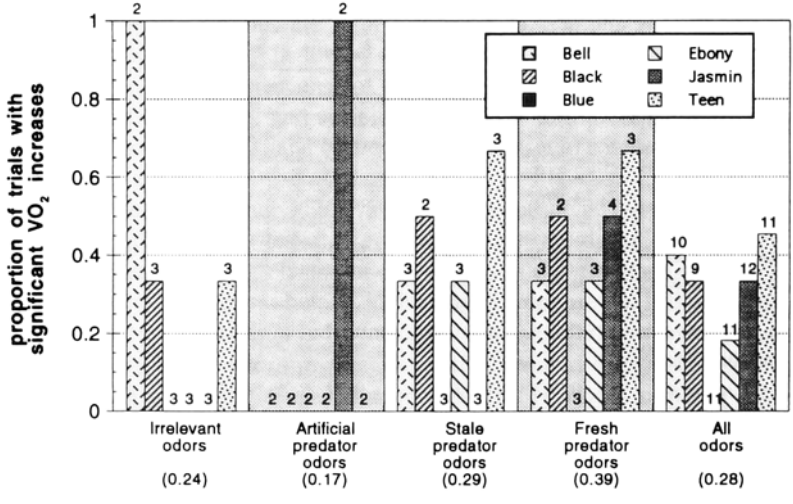

FIG. 5. Rate of V_{O_2} responses of each animal for the four odor categories and for all odors combined. Sample sizes are given above each bar. Sample sizes are given above each bar, and the mean percentage of response is given at the bottom.

but only to 18, 17, and 24% of the irrelevant, artificial, and stale predator odors, respectively. Although these differences were not significant when all four classes were compared simultaneously ($G^2_{[3]} = 5.89$, $P = 0.18$), fresh predator odors elicited proportionally more effective tachycardias than the biologically irrelevant novel odors [Fisher's exact test (one-tailed), $P = 0.047$]. With $\dot{V}_{O_2}$, 39% of the fresh predator odors were effective, whereas 24, 17, and 28% of irrelevant, artificial, and stale predator odors, respectively, had an effect. However, these differences were not statistically different, whether all four odor classes were compared ($G^2_{[3]} = 2.03$, $P = 0.57$), or only irrelevant and fresh predator odors [Fisher's exact test (one-tailed), $P = 0.27$].

The average size of HR responses was lowest for biologically irrelevant smells and highest for fresh predator odors (Table 7). We were unable to discriminate among the four odor classes ($F_{(3,15)} = 2.24$, $P_{\text{H-F adjusted}} = 0.13$). However, fresh predator odors produced larger tachycardias than biologically irrelevant novel odors ($t = 2.26$, $P_{\text{H-F adjusted}} = 0.037$). The size of $\dot{V}_{O_2}$ responses did not differ between odor classes, whether all classes were compared or just

TABLE 7. AVERAGE SIZE OF HEART RATE AND $\dot{V}_{O_2}$ RESPONSES IN FOUR ODOR CLASSES[a]

[a] $\dot{V}_{O_2}$ responses for the minute following scent presentations are also compared because $\dot{V}_{O_2}$ was sometimes significantly elevated then. All responses for each subject were averaged within odor classes, then these averages were themselves averaged across animals.

irrelevant odors and fresh predator odors. The same was true for $\dot{V}_{O_2}$ in the minute following stimulus (Table 7).

DISCUSSION AND CONCLUSIONS

HR and $\dot{V}_{O_2}$ Responses to Odors

Averaging both HR and $\dot{V}_{O_2}$ over 1 min reduced the sensitivity of the analysis. Sometimes a smell induced a few rapid heartbeats near the beginning of a test, but yielded a nonsignificant ΔHR. Such transient HR changes, while indicating that the subject has detected the stimulus, are likely unimportant energetically. Changes in HR or $\dot{V}_{O_2}$ large enough to affect 1-min averages constitute better evidence of increased alertness beyond detection of the stimulus, such as one would expect if associations were made with predators. Other advantages of using 1-min averages were the elimination of much natural variability in the data, and a more even comparison between both dependent variables, which follow different time courses.

The kind of individual variability observed here is not unusual (see for instance, Wenzel and Sieck, 1972). Blue did not respond to any chemical stimulus (although she did respond to some of the other stimuli; Chabot, 1992). She was the dominant female in the herd, and she was an extremely tame and calm animal. Black, and to a lesser degree Bell, were also very calm animals, so calmness alone does not explain why Blue did not respond to any stimulus. Other possible explanations are prior history of the various animals, because exposure to an odor early in life in association with a pleasant or unpleasant experience can affect the response of test animals to the same compound alone in later life (Doty, 1986), and social status, which can affect both HR (Cherkovich and Tatoyan, 1973) and corticosterone levels and could also affect reactivity to mild stimuli.

One effect of the individual variability we observed was to reduce the sensitivity of the paired *t* tests: a few responses in the opposite direction can prevent the detection of a change in HR or $\dot{V}_{O_2}$ in the group of subjects. The alternative binomial test was helpful in this context because it relied on assessing the effectiveness of each trial independently, with no interference from ineffective trials. Overall, 70 odor presentations with six wapiti elicited 18 significant ΔHRs, and 18 significant $\Delta\dot{V}_{O_2}$. Moreover, in 10 cases both variables showed a significant change simultaneously. Two of the odors, cougar and wolf feces, had a stronger effect than the others: mean HR changes were significant and were highest among the 12 odors tested. Cougar and wolf feces were also the only two smells that produced a significant change in mean $\dot{V}_{O_2}$, although this was recorded in the first minute after stimulus instead of during the stimulus. These same two scents also produced the highest proportion of effective trials

(Table 3): with cougar feces, five of six animals showed significant tachycardia, while three of six showed significant increases in $\dot{V}_{O_2}$. Wolf feces affected three of four animals for HR, and two of four animals for $\dot{V}_{O_2}$. Finally, these were the only two odors that were found effective for both dependent variables with both statistical tests (paired-samples *t* test and binomial test). That wapiti responded to wolf and cougar feces with increases in both HR and $\dot{V}_{O_2}$ in a nonforaging context is the first clear demonstration that wild ungulates react to predator odors for reasons other than reduced food palatability.

The other odors appeared less effective than wolf and cougar feces. Two stale predator odors, dog feces and urine, elicited a significant number of HR and $\dot{V}_{O_2}$ responses but affected fewer animals than wolf and cougar feces, and dog urine was found to increase HR significantly by the *t* test (Figure 2). Pentane produced significant increases in both HR and $\dot{V}_{O_2}$ for Bell and Black, the only biologically irrelevant odor to affect both variables in the same subjects. It also increased Teen's $\dot{V}_{O_2}$. Two other smells were effective but with only one of the two dependent variables: the smell of a dead coyote increased $\dot{V}_{O_2}$ in two of six animals, which was significant, whereas PDT, found in anal gland secretions of many mustelids, elicited significant tachycardia in two animals (Bell and Ebony), and increased $\dot{V}_{O_2}$ in another animal (Jasmin). This single $\dot{V}_{O_2}$ response did not lead to a significant binomial test.

Some of these differences could be due to differences in stimulus intensity, which we were unable to equate for the various odors because of the lack of knowledge of wapiti chemoreception. Furthermore, odors in concentrations that differ markedly from those encountered by the animals under natural conditions could release false physiological as well as behavioral reactions (Goodrich et al., 1981) Predator odors were usually presented in large quantities, but irrelevant and artificial predator odors were highly concentrated. The best we could do was to ensure that all odors were detectable in the mask by the observer, at least at the highest intensity for each odor.

Although a statistical comparison of the effectiveness of each odor was impossible due to the large number of odors relative to the number of subjects, we were able to show that the four general classes of odors (biologically irrelevant odors, artificial predator odors, stale predator odors, and fresh predator odors) did not differ in either the size of HR and $\dot{V}_{O_2}$ responses they produced or in the proportion of effective trials they elicited. Possibly, a larger number of subjects would have allowed discrimination among these groups, at least for HR. However, two of these odor groups, the artificial predator odors and the stale predator odors, were used in an attempt to find as many effective stimuli as possible in order to study the relationship between HR and $\dot{V}_{O_2}$ in alert wapiti, which was the main objective of the larger study. They were not necessarily well suited to demonstrate whether or not prey react to predator odors. The extract of cougar feces produced no detectable effect, whereas whole cougar

feces were very effective. It is not clear if this is due to a difference in odor intensity (see above) or to the absence of effective volatiles in E1. As for PDT, it is a synthetic compound that has proven effective with many small prey species, but it is from a carnivore that poses no threat to wapiti. Similarly, the stale predator odors probably lost essential volatiles (Dixon et al., 1987).

Thus, we felt justified to conduct another comparison, restricted to biologically irrelevant novel odors and fresh predator odors, to assess if the reaction to predator odors was merely due to novelty. Fresh predator odors produced a higher proportion of significant tachycardias, and on average, larger tachycardias, than the novel odors, although there was no difference between these two classes in terms of their effect on $\dot{V}_{O_2}$. Even though fresh predator odors were more effective as a group, some of these odors were ineffective. In the case of coyote feces, which were collected fresh in the study area a few weeks before being used in trials, this was especially surprising, coyotes being a potential predator of wapiti calves in this area. This lack of response could be due to the fact that we were able to conduct only three trials with this stimulus, one of them being with Blue, who did not react to any smell. In addition, the quantity used was less than that of the other trials involving predator feces (Table 2). The other fresh predator odor, the dead coyote, may not have been representative of the smell of a live coyote.

Predator Odors in Assessing Predation Risk

The increases observed in HR (2.85–10.23 bpm) or $\dot{V}_{O_2}$ (0.29–0.93 liters/min) of wapiti in response to predator odors were very mild. By comparison, 1-min exposures to fawn distress calls or close proximity to human beings frequently resulted in HR increases of 25–50 bpm, and $\dot{V}_{O_2}$ increases of 0.5–1.7 liters/min (Chabot, 1992). It has been shown that the size of HR responses is indicative of perceived danger and the level of stress induced in animals (Tatoyan and Cherkovich, 1972; MacArthur et al., 1979, 1982; Ball and Amlaner, 1980; Harlow et al., 1987a,b). The small HR responses to odors we observed in this study indicate low arousal levels. This suggests that the subjects were aware of the stimulus but did not consider it an immediate threat, perhaps because coytes were the only natural predator in the study area or because the odors were considered irrelevant in the experimental context (Albone et al., 1986). Even though rats and geckos have shown typical antipredator behavior when exposed to predator odors (Vernet-Maury, 1980; Vernet-Maury et al., 1984; Dial, 1990; Weldon, 1990), there is no evidence that ungulates react that strongly to predator odors alone. Pfister et al. (1990), for instance, reported that with sheep (*Ovis aries*) and cattle (*Bos taurus*), predator odors in feed bins did not reduce the number of approaches or head entries in the bins, but resulted in animals spending less time in proximity of predator-contaminated bias. Müller-

Schwarze (1972) and Sullivan et al. (1985b) also noted that black-tailed deer (*Odocoileus hemionus columbianus*) closely investigated predator odors instead of immediately moving away.

Such findings and the small HR responses obtained here are more compatible with the hypothesis that prey species, as part of their antipredator strategy, assess the risk of predator encounters in various parts of their habitat, and information about predator density can be obtained from predator feces or urine (Lima and Dill, 1990). Such assessment could then be used to make decisions about where and when to feed. The work of Sullivan et al. (1990b) with gophers and of Pfister et al. (1990) with sheep and cattle are most relevant here, because they demonstrate that some prey indeed avoid areas because of predator odors or spend less time and feed less in areas contaminated with predator odors. For bighorn sheep, HR increased as distance to a road decreased, when sheep traveled in timber where visibility was reduced, and when distance to escape terrain increased, suggesting that they perceive risk levels associated with their location or their own behavior. Many other species have been shown to alter their behavior according to perceived predation risk (for a review, see Lima and Dill, 1990).

In this context, care should be taken when making interspecific comparisons. Not all species can make use of predator feces and urine to assess predation risk. Species that normally live where predator density is high probably find such cues of limited value, because they would lead to a large number of false alarms or to the avoidance of large proportions of available habitat. When predators are abundant and the habitat is open, other cues should be used. Walther (1984, pp. 366–367) has observed that African ungulates pay little attention to the many predators around them, so proximity to predators does not always elicit fear or even avoidance. Prey may even be able to discriminate hungry from satiated predators, as demonstrated in guppies (Licht, 1989). For other species, detection avoidance is more important than evasion from predators. For example, in the absence of cover, Townsend's voles (*Microtus townsendii*) preferred to feed on the side of their enclosure without repellents, but when cover was present, voles preferred to feed on the side with cover, regardless of whether or not repellents were present (Merkens et al., 1991).

On the other hand, chemical cues associated with the close proximity of a predator should have effects similar to the sighting of a predator at close range or to the alarm signals of conspecifics. Bighorn sheep show large tachycardias upon sighting dogs or coyotes (MacArthur et al., 1979). While we have no measure of HR when wapiti located a coyote, the study animals were extremely aggressive every time they sighted dogs, and wapiti are known to mob coyotes (Geist, 1982). Thus it is surprising that the body odor of a coyote had no effect on the HR of the five wapiti exposed to it, although it did result in increased oxygen consumption in two of them. Only one coyote was available as a test stimulus. It had been dead for over a month and kept in a freezer containing

other wildlife carcasses, so it may not have been representative of the odor of a live coyote. Additional experiments with live predators, controlling for the kind of information the prey could use (odor, sounds, sight, alone and in combination) and, depending on prey species, with alarm calls or alarm pheromones, would be useful.

Habituation

When the same odor was presented to a wapiti a second time, on average it resulted in a smaller ΔHR and $\Delta\dot{V}_{O_2}$, although the latter did not decrease significantly. Fewer trials were effective on second presentation, but again, this was not significant. Our results suggest that habituation can take place even for biologically relevant stimuli in the absence of feedback. Thompson et al. (1968a) and Espmark and Langvatn (1985) made similar observations with starlings and red deer calves. We had some indication that longer delays might not cause habituation: three of 19 cases had stronger responses on second trial than on the original trial, and all three had delays $\geq$ 173 hr. However, one case was significant on first presentation but not on a second test 215 hr later. Sample sizes were very small for repeated trials, and there was one confounding variable: most of the trials that were effective on the first presentation but not on the second presentation used whole feces. For many of these we reused the same odor sample approximately 24 hr later. Dixon et al. (1987) have shown that new compounds are formed when feces are allowed to age even for a few hours. Therefore, new experiments are required to clarify the question of habituation. Stimulus intensity and quality should be the same on all repeated trials, and a greater range of delays between trials should be used.

HR Telemetry in Future Research on Predator Odors

It was unanticipated that some odors would increase $\dot{V}_{O_2}$ but not HR, and that overall, $\dot{V}_{O_2}$ would be as sensitive a measure of response to predator odors as HR. Many studies showed stronger HR than $\dot{V}_{O_2}$ responses to various stimuli in humans (Blix et al., 1974; Turner and Carroll, 1985; Allen et al., 1986; Sherwood et al., 1986), but this contradiction may be more apparent than real: those studies emphasized that humans react to alertness with exaggerated tachycardias relative to concomitant metabolic demand. However, $\dot{V}_{O_2}$ increased too, but this was not tested statistically. Yet our results confirm that the two variables do not always vary in unison, a difficulty if HR is to be used as an index of $\dot{V}_{O_2}$ (Floyd, 1987). Again, this is partly an artifact: Chabot (1992) has shown that there is a good relationship between ΔHR and $\Delta\dot{V}_{O_2}$ when wapiti hinds became alert, but with small HR and $\dot{V}_{O_2}$ responses, like those found in this study, variability around the regression line can result in apparent disagreement between the two variables.

Even if it proved sensitive here, it is unlikely that $\dot{V}_{O_2}$ will become a widely used index of reaction to stimuli, since it is more difficult to measure in a natural context. Albone et al. (1986) have stressed that mammals do not generally respond to chemical stimuli in isolation, but integrate them with other stimuli. Similarly, Merkens et al. (1991) demonstrated the importance of context for the reaction of mammals to predator odors. The ease with which responses to predator odors can be detected with HR telemetry should make it easier to study the reaction of free-ranging animals to predator odors, be they naturally occurring or provided by experimenters.

Because many researchers used a reduction in feeding levels to demonstrate a reaction to predator odors, it would be relevant to measure the HR responses to predator odors in at least one species that is known to reduce its feeding levels when exposed to predator odors. This should allow the comparison of the two methods and perhaps demonstrate that reduced palatability was not the explanation for reduced feeding levels. Such an experiment should compare HR responses to predator odors, to malodorant nonpredator odors, and to substances known to reduce palatability of food and be conducted both in foraging and nonforaging situations.

Acknowledgments—Financial support was provided by grants from the Natural Sciences and Engineering Research Council of Canada and by the Foundation for North American Wild Sheep to Dr. V. Geist and by a Thesis Research Grant from the University of Calgary to the first author. We thank Mr. F. Wu (Department of Biological Sciences, University of Calgary) for building the decoder/peak detector used to analyze the ECG signal. We are most grateful to Lawrence Harder, Max Bayer, and Nigel Waters for very useful statistical consultation and to the Calgary Zoo and Mr. Mike Hanson for collecting many of the fecal samples. We also wish to thank P. K. Anderson, R. H. Hudson, V. Geist, J.-M. Renaud, and T. Toth for reviewing an early draft of this manuscript.

ATOMIC MODEL OF THE RECOGNITION SITE OF THE AMERICAN COCKROACH PHEROMONE RECEPTOR

M. B. BYKHOVSKAIA* and B. S. ZHOROV

Sechenov Institute of Evolutionary Physiology and Biochemistry
Russian Academy of Sciences
44 Torez Pr., 194223 St. Petersburg, Russia

(Received March 17, 1995; accepted December 1, 1995)

Abstract—All the minimum-energy conformations (MECs) of two sex pheromones of the American cockroach, *Periplaneta americana*, and their 11 structural analogs (seven agonists, two antagonists, and two inactive compounds) were calculated using the molecular mechanics method. The MECs of the analogs were compared with the most populated MECs of the pheromones. The MECs most common in all the ligands were assumed to represent the bioactive conformations. An atomic model complementary to the bioactive conformation of one of the pheromones, periplanone B, was constructed. The model incorporates five groups capable of forming H bonds with oxygen atoms of the ligands and a set of hydrogen atoms contributing to nonbonded interactions with the ligands. Using this model, the energies of ligand–receptor complexes were calculated. For a group of mimics, the activities predicted from the calculated energies of ligand-receptor interactions were in reasonable agreement with the experimentally observed activities. The sites of the receptor model essential for the receptor activation were specified.

Key Words—Periplanone B, molecular mechanics, pheromone antagonists, pheromone agonists, bioactive conformation.

INTRODUCTION

Pheromone receptors are membrane proteins that belong to the superfamily of G-protein-coupled receptors (Buck and Axel, 1991). As the three-dimensional

structure of the receptors remains unknown, it is the analysis of structure–activity and conformation–activity relationships of the ligands that may clarify their structural peculiarities important for ligand-receptor recognition.

Periplanone A (PA) and periplanone B (PB) (Figure 1) are the most active components of the sex pheromone of the American cockroach. In the male antennae, there are two types of receptor cells (A and B) sensitive to the sex pheromone (Sass, 1983). Recordings of the single sensilla impulse activity (Hartmann, 1988) demonstrated that the A cells are activated by PA only, while the B cells may be activated by either PA or PB.

Several studies of the structure–activity relationships of periplanone analogs have been published (see Figure 1 and Table 1). According to the behavioral experiments, seven analogs (III–IX) are mimics, compounds X and XI are antagonists, and compounds XII and XIII are inactive. Antagonist XI inhibited activity of PA, while antagonist X inhibited activity of both PA and PB. All the

[a]The activity of agonists is the threshold dose causing the impulse electrical response of receptor cell A or B or the behavioral reaction of a male. The activity of antagonists is the dose inhibiting the behavioral reaction of a male when mixed with 2×10^{-4} μg of periplanone A or B.

mimics and antagonist XI evoked a significant electrical response in the male antenna. In single-sensilla recordings (Hartmann, 1988), the mimic VI, germacrene D (GD), exhibited stronger activity at the A cells than at the B cells. Thus, although the above compounds are similar in chemical structure (see Figure 1), they demonstrate essentially different biological activity. To explain this, an analysis of three-dimensional structures of the ligands is desirable.

Three-dimensional structures of compounds I–III were determined by X-ray analysis (Mori et al., 1990b). However, each compound is flexible and exists as a mixture of different conformers. If these conformers are close in energy, all of them would be noticeably populated. In such a case, the biologically active conformation of a ligand would not necessarily correspond to the crystalline one. Shimazaki et al. (1991, 1992) calculated minimum-energy conformations (MECs) of the compounds II, IV–VI, and VIII by the molecular mechanics and quantum chemistry methods, suggesting the low-energy MECs to represent the bioactive conformations. Most of the mimics shown in Table 1

exhibit activity essentially lower than that of the natural pheromones. The low activity of the mimics may be due to a low population (high energy) of their bioactive conformation. Therefore, the high-energy MECs should also be considered as candidates for the bioactive conformations.

In the present study, the theoretical conformational analyses of PA, PB, and their analogs have been carried out. The bioactive MEC of PB was determined and a monoatomic shell surrounding it was constructed to represent a model of the PB receptor recognition site. The energy of ligand–receptor interaction calculated for a series of PB analoges was found to correlate with their activity. The preliminary results of this study have been published (Bykhovskaya and Zhorov, 1993).

METHODS AND MATERIALS

Since compounds I–V and VIII–XIII were obtained by stereoselective synthesis (see references in Table 1), the absolute configuration of their chiral atoms is definite. The absolute configuration of atom C-3 in the active isomer of compound VII remains unknown. Therefore both 3*R* and 3*S* enantiomers of compound VII were considered.

All the MECs were calculated by energy minimization in the space of torsion and valence angles (Zhorov, 1993). The latest version of the ZMM program package for molecular mechanics calculations (Zhorov, 1981, 1982) was used. Atomic charges were calculated by the CNDO/2 method. Dielectric constant $\epsilon = 4$ was used for the calculations of electrostatic energy as recommended by Lipkind et al. (1970) for nonpolar surrounding. The hydrogen bonds were calculated using Morse potential with the minimal energy 2 kcal/mol and the optimal distances 1.8 and 2.1 Å for NH. . .O and NH. . .C_{sp2} bonds, respectively (the latter was taken into account for GD (VI) only). Initial loop-closed geometries for the 10-membered rings were generated both systematically (Go and Scheraga, 1970) and randomly.

RESULTS AND DISCUSSION

Conformational Analysis

The 10-membered ring of PB has seven MECs with energy within 3 kcal/mol of the global minimum (Figure 2, Table 2). The global minimum (MEC 1) corresponds to the structure found in X-ray study (Adams, 1979). MEC 2 has an energy of 0.1 kcal/mol above the global minimum. Interestingly, this MEC was not found in the molecular mechanics study of PB by Shimazaki et al. (1992).

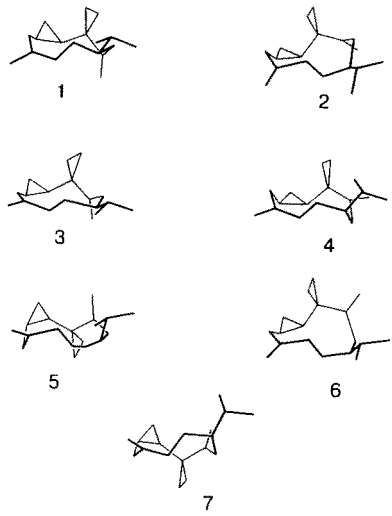

FIG. 2. MECs of PB with the energy within 3 kcal/mol of the global minimum. All the MECs are shown from the side of isopropyl and terminal methylene groups. MECs are numbered as in Tables 2–4.

[a] MEC numbers correspond to those shown in Figure 2. The orientation of isopropyl group is the same for all the compounds: both methyl groups are in *trans* position relative to bonds C-6–C-5 and C-6–C-7 (Figure 1).

[b] From Shimazaki et al. (1992).

Bioactive Conformations

The bioactive MECs of all the active ligands were assumed to have similar torsional angles of the 10-membered ring and similar disposition of the proton acceptor atoms. The selection of the bioactive MECs has been done in two stages. At the first stage, we compared the seven lowest-energy MECs of PB with all the MECs of 12 PB analogs to select the MECs with similar torsional angles. The 10-membered rings of two compounds were regarded to have a similar spatial structure if the root mean square deviation of their endocyclic torsions was less than 45° and the maximum deviation was less than 90°. Six MECs of PB turned out to have similar MECs in the analogs (Table 3). Thus the global minima of compounds I–V and XI–XIII were similar to MEC 1 of PB. The global minima of compounds VI, *R*-VII, IX, and X were similar to MEC 4 of PB. The global minimum of compound VIII was similar to MEC 2 of PB. Only MEC 3 of PB with an energy 0.8 kcal/mol above the global minimum did not have matches for the other active ligands. Therefore, the MEC 3 was excluded from the list of the candidates for the bioactive conformation.

At the second stage, we selected the MECs with similar spatial dispositions

of the proton acceptor atoms in PB and active analogs. The MECs with the similar torsional angles were superimposed by bringing together isopropyl and terminal methylene groups (Figure 3). Two given proton acceptor atoms of two given ligands were assumed to form an H bond with the same H-N group of the receptor if (1) van der Waals spheres of the atoms overlapped (the centers of the atoms were separated by less than the sum of their van der Waals radii) and (2) the overlapping atoms were not shielded from each other by interposing atoms, i.e., some part of the space common for both spheres did not overlap with any other atoms of the superimposed ligands (Figure 3).

The calculated distances between proton acceptor atoms of the superimposed ligands are given in Table 4. It shows that in MEC 2, compounds VII and X have an oxygen atom separated from the nearest oxygen of the superimposed PB by more than 2.8 Å (van der Waals diameter of the oxygen atom). In MECs 4–7, at least one mimic has a proton acceptor atom shielded by interposing atoms from any oxygen atom of the superimposed PB. Therefore, these MECs were not considered as the candidates for the bioactive conformations. Since MEC 3 was excluded at the first stage of the selection, MEC 1 remained the only candidate for the bioactive conformation. This MEC was used as a template to construct the model of the receptor.

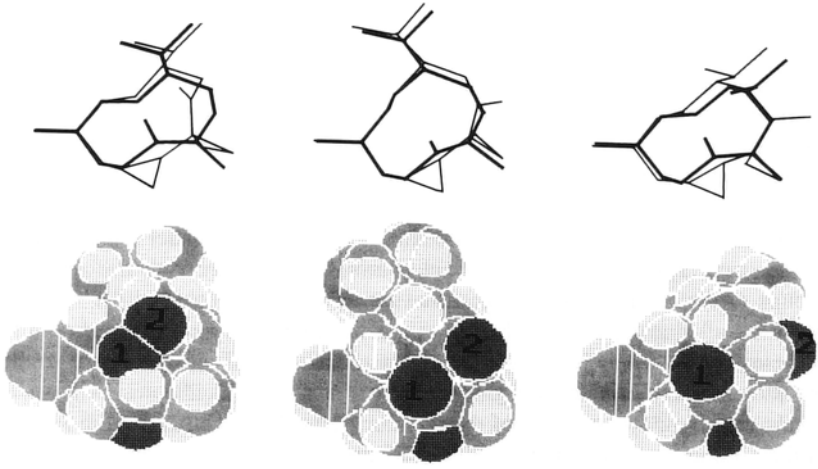

FIG. 3. Wire-frame (top) and space-filling (bottom) models of PB superimposed with compound (*R*-VII). Atom O-4 of PB is denoted by 1; oxygen atom of *R*-VII is denoted by 2. In MEC 1 (left) atoms 1 and 2 overlap (have similar spatial position). In MEC 2 (middle), the distance between atoms 1 and 2 is larger than the sum of their van der Waals radii. In MEC 3 (right) atoms 1 and 2 are separated by carbon and hydrogen atoms. the structures were visualized using the DTMM package (Oxford Electronic Publishing).

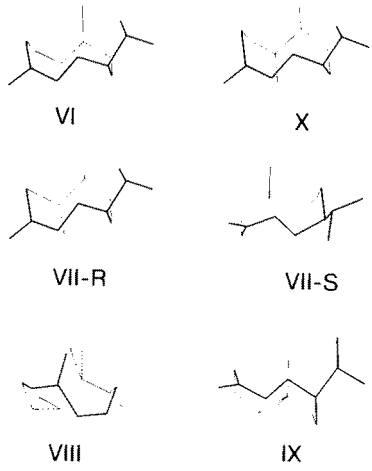

FIG. 4. The lowest-energy MECs (global minima) of compounds (VI–X). All the MECs are shown from the side of isopropyl and terminal methylene groups. The global minimum of the compound (*S*-VII) is not similar to any of the seven lowest-energy MECs of PB but it is symmetric to MEC 4.

The Receptor Model. The pheromone receptor recognition site was modeled as a monoatomic shell surrounding the bioactive conformation of periplanone B. It was constructed using the approach of Zhorov and Govyrin (1984). The shell comprises atoms and groups assumed to be involved in hydrophobic interactions and H bonds with the ligands. The surface of the receptor involved in hydrophobic interactions with the ligands should incorporate hydrogen atoms of alkyl groups and (or) aromatic residues. Since the ligands under consideration do not have aromatic groups (probable partners to interact with the aromatic groups of the receptor), we suggest that the hydrophobic areas of the receptor comprise alkyl groups only. Therefore, a set of hydrogen atoms was chosen to represent the hydrophobic areas of the recognition site. Hydrogen atoms of the receptor hydroxyl and amide groups would be natural candidates to form H bonds with the oxygen atoms of the ligands. These hydrogen atoms are similar in their ability to form H bonds. Since NH groups are common for both protein backbone and side chains (in some residues), we have chosen these groups to represent the proton donors of the receptor. Thus, the receptor model was suggested to incorporate neutral hydrogen atoms to interact with the hydrophobic groups of the ligands and NH groups to form H bonds with the ligands.

The partial charges of $-0.2e$ and $+0.1e$ (e is the proton charge) were assigned respectively for the nitrogen and hydrogen atoms of the receptor amide

[a]The dash means that the pair of atoms was separated by one or several interposing atoms of the ligand (see text and Figure 3, right).
[b]The number of an oxygen atom corresponds to the number of the carbon atom the oxygen is bound to (Figure 1).
[c]The midpoint of the bond C-2=C-3 represents the location of the proton acceptor in GD.

groups. An NH group of the receptor was placed against each lone pair (LP) of PB, the atoms N-H. . .LP-O forming a straight line with the distance LP. . .H equal to 1.8 Å. If two NH groups of the receptor overlapped, they were replaced by a single one positioned between them. The positions and the orientations of the receptor NH groups were then optimized by energy minimization with PB kept rigid within the shell.

A "cup" of seven uncharged hydrogen atoms of the receptor shell was placed against each hydrogen atom of the isopropyl, terminal methylene, and epoxy groups of PB, the distance between any pair of the eight hydrogen atoms being 2.4 Å (van der Waals diameter of the hydrogen atom). One atom of the cup was positioned at the extension of a given C-H bond of PB, six others being in the plane normal to the given C-H bond. All hydrogen atoms of the receptor separated from any atom of PB or from any polar group of the shell or from a couple of uncharged hydrogen atoms of the shell by less than the sum of the corresponding van der Waals radii were removed. Then each couple of the uncharged atoms of the shell separated by less than 2.4 Å was replaced by a single atom positioned exactly between them. The model thus constructed incor-

porated five NH groups forming six H bonds with oxygen atoms of PB (one NH group turned out to form a bifurcate H bond with two oxygen atoms of PB) and 26 hydrogen atoms surrounding the isopropyl, terminal methylene, and epoxy groups of PB (Figure 5).

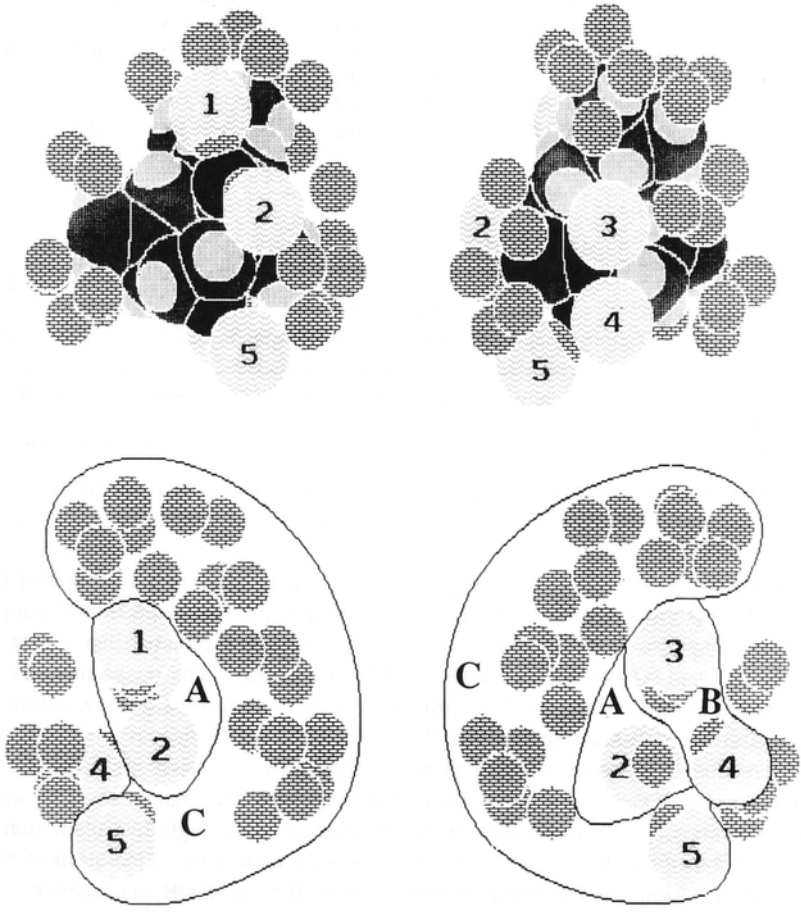

FIG. 5. The space-filled model of PB receptor (bottom) and its complex with PB (top) viewed from the opposite sides. PB oxygens, receptor hydrogens, and receptor nitrogens are outlined with dark, brick, and wave patterns, respectively. Receptor NH groups are number 1 through 5. The solid lines (bottom) separate receptor sites A, B, and C. Site A incorporates NH groups 1 and 2; site B, NH groups 3 and 4; site C, 21 hydrogen atom and NH group 5.

Ligand–Receptor Interactions. Using the constructed atomic model of PB receptor, we predicted the energy of the receptor interaction with different ligands. The bioactive MEC of each periplanone analog was superimposed with PB bioactive MEC inside the shell. Then PB was removed and the ligand conformation and orientation were optimized by energy minimization within the rigid receptor. The obtained energy of receptor–ligand complex (E_{rlc}) represented the sum of receptor–ligand interactions (E_{rli}) and intramolecular interactions of the ligand in the bioactive conformation E_{lbc}):

$$E_{rlc} = E_{rli} + E_{lbc}$$

With reference to the ligands' global minimum (E_{lgl}), the energy of the receptor–ligand complex (ΔE_{rlc}) and the energy of the ligand bioactive conformation (ΔE_{lbc}) were calculated as:

$$\Delta E_{rlc} = E_{rlc} - E_{lgl}$$

$$\Delta E_{lbc} = E_{lbc} - E_{lgl}$$

The activity of the jth ligand relative to that of PB was predicted to be

$$AP^j = \exp\left[-(\Delta E^j_{rlc} - \Delta E^{PB}_{rlc})/RT\right]$$

where R is the universal gas constant and T is temperature. The predicted relative activities were compared with the experimental ones

$$AE^j = TD^{PB}/TD^j$$

where TD^j and TD^{PB} are threshold doses of the jth ligand and PB, respectively.

The results (Table 5) demonstrate a reasonable correlation between the predicted and experimental activities for mimics I, IV, V, VI, and VIII. The experimental activities of mimics III, VII, and IX are greater than the predicted ones. A possible explanation is that these mimics cause the behavioral reaction of the cockroach via activating the A receptor. Calculations demonstrate that only the R isomer of compound VII should be active. This prediction may be tested experimentally.

According to the calculations, compound XIII should be more active than compounds VI, VII, and IX, whereas experiments show compound XIII to be inactive. This may be explained in view of the hypothesis that a pheromone receptor is activated when several of its functional sites interact simultaneously with a ligand (Kafka and Neuwirth, 1975, Kikuchi and Ogura, 1976). We subdivided the receptor model into three functional sites (Figure 5): site A, incorporating NH groups 1 and 2 (they H bond to atom O-4 of PB); site B, incorporating NH groups 3 and 4 (the NH group 3 H bonds to atom O-3 of PB and the NH group 4 forms a bifurcate H bond with O-1 and O-3 of PB); site C, incorporating NH group 5 (it H bonds to atom O-1 of PB); and 21 hydrogen

[a] ΔE_{lbc} is the energy of the ligand bioactive conformation above the global minimum; E_{rli} is the energy of interactions of the ligand's bioactive conformation with the receptor model; ΔE_{rlc} is the energy of ligand-receptor complex relative to the ligand's global minimum; AP is the predicted activity of the ligand relative to PB; AE is the experimental activity of the ligand relative to PB (see text).

atoms (they interact with alkyl fragments of the ligands, in particular, with the terminal methylene and isopropyl groups of PB). We assume that to activate the B receptor, a ligand should interact with at least two sites: either C and B or C and A.

All the agonists as well as PB atagonist X meet the above requirement (Table 5). Inactive compound XIII lacks the isoproyl, terminal methylene, and spiro epoxy groups, and, hence, cannot interact with the receptor site C. Inactive compound XII and PA-specific antagonist XI interact with site C and, in addition, have oxygen atoms which may H bond to NH groups of the site A. However, the calculated energies of these H bonds were less than 1 kcal/mol, whereas the H-bond energies for all the active compounds were greater than 2.5 kcal/mol. This means that the probability of the compounds XI and XII forming H bonds with the receptor site A is 10 times less than that for the active compounds.

In experiments by Nishino et al. (1989), compound IX evoked an electrical response by the male antenna competing only with PA, whereas the available

quantity of compound X was not enough for electrophysiological experiments. Our model predicts compound X to be the PB agonist, while experiments show it to be a PB antagonist. A possible reason is the compound X blocks the cockroach behavioral reaction through nonpheromone receptor cells. This prediction may be tested in electrophysiological experiments.

Thus, the proposed model of the PB receptor predicts the energy of ligand–receptor interactions, in agreement with the experimental activity for those five agonists that interact with receptor sites B and C (Figure 5). The agonists that interact with sites A and C have experimental activities higher than the predicted ones (Table 5). One of the agonists, germacrene D (VI), is known to activate PA receptor. The others may also activate the PA receptor. The simultaneous interaction of a ligand with sites B and C or A and C is suggested to be necessary for PB receptor activation. Inactive compounds XI and XII, which are similar in structure to active compounds VII and X, as well as inactive compound XIII, which is similar to active compounds I and VIII, do not satisfy this requirement.

CONCLUSION

In this work, we have carried out conformational analysis of a series of periplanone B and its 12 analogs. Using a set of energetic and geometric criteria, we determined the bioactive conformation of the ligands of the periplanone B receptor. The bioactive conformation of the most active ligand, periplanone B, was used as a template to construct an atomic model of the receptor recognition site. The atomic model enabled us to calculate energies of ligand–receptor interactions and, hence, to predict activities of the ligands. A reasonable agreement between the predicted and experimental activities was demonstrated for the majority of the mimics. The exception was found in three mimics whose activities in behavioral experiments were higher than those predicted. A possible explanation of the exception is the interaction of the three compounds not only with the periplanone B receptor but also with the periplanone A receptor (another pheromone receptor in the male sensilla). Distinct functional sites in the receptor model have been specified, suggesting that simultaneous interaction of a ligand with at least two functional sites is necessary to activate the receptor. Inactivity of three close structural analogs of periplanone B was explained by their inability to interest simultaneously with two sites of the receptor.

Abstract—Planktivorous fish release a cue of an unknown chemical nature into the water that induces diel vertical migration in *Daphnia* as predator avoidance response. We used a bioassay to obtain information about the chemical nature of the kairomone. We present a method to enrich the cue from holding water of fish by sorbent extraction. The kairomone exuded by *Leucaspius delineatus* can be characterized as a nonolefinic low-molecular-weight anion of intermediate lipophilicity. The presence of amino groups in the molecule can be excluded, whereas hydroxy groups are essential for activity. Separation by HPLC yielded only one active fraction. The kairomones released by *Carassius carassius* and *Rutilus rutilus* showed the same chemical characteristics, suggesting that the kairomones from different species of fish, sensed by *Daphia*, are very similar, if not identical.

Key Words—Behavior, chemical communication, Cladocera, *Daphnia*, diel vertical migration, kairomone, predator avoidance, zooplankton.

INTRODUCTION

The phenomenon of diel vertical migration (DVM) is a common behavior both in marine and in freshwater zooplankton. During the day, the zooplankton stay in the deep layer of the water column and reappear at the surface during the

night. According to the predator-avoidance hypothesis, this behavior reduces the risk of daytime predation by visually orienting predators, mostly fish (Zaret and Suffern, 1976; Lampert, 1989). It has been shown that DVM can be induced by predator-borne chemical cues in a number of zooplankton species (Dodson, 1988; Neill, 1990; Dawidowicz et al., 1990). *Daphnia* (Cladocera), the most important grazer of phytoplankton in temperate lakes, is among the species that respond to fish-exuded kairomones (Dodson, 1988).

The benefit of DVM behavior, reduced predation risk, is traded off with metabolic costs due to low temperature and food levels during the daytime stay in the hypolimnion (Dawidowicz and Loose, 1992). As the abundance of planktivorous fish in the pelagic zone fluctuates during both the course of one season and between seasons, a link between the strength of DVM and the actual risk of predation should be highly adaptive (Pijanowska, 1993). A tightly coupled response of zooplankton towards increasing and decreasing abundance of planktivorous fish has indeed been observed both in the field (Ringelberg et al., 1991) and experimentally (Bollens and Frost, 1991; Loose, 1993; Loose and Dawidowicz, 1994).

The kairomone represents this link between the presence of fish and the behavior of *Daphnia*, and thus its reliability is crucial in order to avoid maladaptive behavior in *Daphnia* (Fagen, 1987). An important feature of the kairomone's reliability is its behavior in the water, which is determined by its chemical nature. Recently, a bioassay has been described that allowed a first characterization of the kairomone released by *Leucaspius delineatus* (Loose et al., 1993). The cue was characterized as low molecular weight, water-soluble, and stable over broad ranges of temperature and pH. Here we present further chemical characterization of the kairomone of *L. delineatus* and a method to enrich the cue from holding water of fish. Both aspects are an important step towards the identification of the kairomone. The kairomones from three cyprinid fish species are compared chemically and by HPLC.

METHOD AND MATERIALS

Bioassay. The characterization of the kairomone was performed by using a bioassay based upon the DVM behavior of small cohorts of *Daphnia*. The standardized experimental design has been shown to be a reliable indicator for the assessment of the kairomone (Loose et al., 1993). A clone of *Daphnia magna* was used as test animals. It was isolated from Grosser Binnensee (northern Germany), where it coexists with fish (Lampert, 1991). Five 4-day-old animals were used per treatment. They were incubated in Perspex tubes (1 m length, 200 ml volume) and placed in a water bath with a defined temperature stratification (20°C at the top, 10°C at the bottom). The tubes were illuminated

from the top (16:8 hr day–night cycle), and *Scenedesmus acutus* was added as food (2 mg C/liter initial concentration). For further details see Loose et al. (1993). The mean day depth of the animals on the third day of incubation was taken as the measure of activity. Mean depths deeper than 60 cm (animals in the cold hypolimnion) indicated the presence of kairomone, whereas a mean depth above 30 cm indicated the absence of the cue.

Production and Enrichment of Kairomone. Artificial medium (Tollrian, 1993) was used for control treatments. Water containing the kairomone was prepared as follows: two to eight adult fish of three different cyprinid fish species (*Leucaspius delineatus*, *Carassius carassius*, *Rutilus rutilus*), were fed with frozen chironomids once a week and kept for 24 hr in 8 liters of artificial medium. Then the water was filtered through a 0.45-μm filter. Filtered holding water was diluted 1:10 with artificial medium prior to biotest (fish water). Twenty milliliters of fish holding water were used for further treatment and eventually diluted with artificial medium prior to biotesting. For the no-fish treatments (control), we used artificial medium, which was processed in a similar way as the holding water of fish.

The kairomone was enriched from holding water by solid-phase extraction (SPE). We tested the efficiency of nonpolar C18, C8, and phenyl-SPE cartridges (500 mg, Analytichem Int.) for the enrichment of the kairomone from holding water of fish. The cartridges were preconditioned with methanol and ultrapure water, 10 ml each, prior to adding the sample. The pH of the sample was adjusted to 7.0 with 2 M HCl. Methanol was added to achieve a 1% concentration, and the resultant solution was passed through the cartridge. The loaded cartridge was washed with 5 ml of ultrapure water prior to elution of the isolate with 10 ml of methanol. Both the eluate and the eluent were evaporated to dryness in order to remove organic solvents, and the residue was resuspended in artificial medium and tested for biological activity.

Chemical Characterization of Kairomone. Polar sorbents, strong and weak anion-exchange cartridges (SAX and DEA-silica bonded sorbents), and strong cation-exchange cartridges (PRS) were washed with 5 ml of ultrapure water. Then C18-SPE-enriched kairomone from 20 ml of holding water was resuspended in 20 ml ultrapure water; the pH was adjusted to 7.5, 5.5, or 2.5 with 0.1 M HCl; and the sample was passed through the ion exchanger. The eluate was collected. For elution of ionically bound compounds, 10 ml of a NaCl solution (0.5 M and 1 M) were applied to the ion-exchange cartridge. Both eluate and eluent were diluted to a volume of 50 ml with ultrapure water and neutralized with 0.1 M HCl, or 0.1 M NaOH, respectively. Salts and contaminants, possibly toxic to *Daphnia*, were subsequently removed by reextracting the kairomone with C18-SPE.

We used base-catalyzed acetylation similar to Watts and Kekwick (1974). An aliquot of C18-SPE-enriched kairomone was gently evaporated to dryness.

Then 800 μl of dried pyridine and 200 μl of acetic anhydride were added and allowed to react for 6 hr at 60°C. The reaction was stopped by evaporation to dryness under nitrogen. The sample was resuspended in 1 ml of methanol, diluted with ultrapure water to a volume of 100 ml, and extracted by C18-SPE using the eluent for the bioassay. In order to make sure that the kairomone was inactivated but not destroyed by acetylation, reversibility of the derivatization was checked by alkaline saponification. The acetylated cue was evaporated to dryness, resuspended in 1 ml of 1 M NaOH, and incubated for 45 min at 80°C. Then the solution was diluted with ultrapure water to a volume of 50 ml, neutralized, and salts were removed by reextraction of the kairomone by C18-SPE, using the eluent (methanol) for the biotest.

Derivatization of primary amino groups was performed according to Münster et al. (1992). First 50 mg of *o*-phthaldialdehyde (OPA) were dissolved in 400 μl methanol, then 3 ml of borate buffer, pH 9.2 (Merck), and 50 μl of mercaptoethanol were added, and the reagent was stored for two days at 4°C. C18-SPE enriched kairomone from 20 ml holding water was evaporated to dryness and resuspended in 100 μl of the above-mentioned borate buffer. Fifty microliters of the reagent were added and allowed to react for 10 min. Subsequently, the sample was diluted to a volume of 50 ml with ultrapure water, neutralized, and ions were removed by reextraction of the kairomone by C18-SPE. In a different approach the dried sample was resuspended in 1 ml of 25 mM $NaHCO_3$/NaOH buffer, pH 9.0, and 30 μl of a fluorescamine solution (10 mg/100 μl acetone) were added (Parejko and Dodson, 1990). The mixture was allowed to react for 15 min prior to reextaction by C18-SPE.

For derivatization of primary and secondary amino groups according to Carpino and Grace (1972), kairomone enriched from 20 ml holding water by C18-SPE was resuspended in 180 μl of 0.13 M borate buffer, and 30 μl of a solution of 10 nmol 9-fluorenylmethyl-chloroformate (FMOC)/μl acetonitrile were added. After mixing for 2 min, the solution was diluted to a volume of 50 ml with ultrapure water, neutralized, and subjected to C18-SPE.
